Abstract: Bader's theory of atoms in molecules is used to rationalize the gas-phase reactivity of tetraphosphacubane vs. H^+, Li^+, Na^+, and Be^{2+}. For this purpose we have used MP2 densities obtained at the 6-31G(d,p) level. The characteristics of the C—P bonds of tetraphosphacubane are discussed. The Laplacian of its electron charge density shows that both phosphorus and carbon atoms are active centers for electrophilic substitutions. This is consistent with the fact that both phosphorus and carbon protonated species are minima of the potential energy surface. The strong charge redistribution associated with carbon protonation explains the enhanced stability of the carbon protonated species with respect to the phosphorus protonated one. The Laplacian field also shows the existence of a cavity inside the cage surrounded by high electronic density that can stabilize a cation of the appropriate size. Our results confirm that Li^+ and Be^{2+} fulfil this requirement and the corresponding complexes, where the cation is located inside the cage, are minima of the corresponding potential energy surface. Na^+ is far too large and a similar structure is a saddle point of the potential energy surface.

Key words: atoms-in-molecules theory, tetraphosphacubane, reactivity, cationization.

Résumé : On a utilisé la théorie de Bader des atomes dans les molécules pour rationaliser la réactivité en phase gazeuse du tétraphosphacubane vs. H^+, Li^+, Na^+ et Be^{2+}. À cette fin, on a utilisé les densités MP2 obtenues au niveau 6-31G(d,p). On discute des caractéristiques des liaisons C—P du tétraphosphacubane. La laplacien de sa densité de charge électronique montre que les atomes tant de carbone que de phosphore sont des centres actifs pour les substitutions électrophiles. Ceci est en accord avec le fait que les espèces protonées, tant phosphorées que carbonées, correspondent à des minima de la surface de l'énergie potentielle. La forte redistribution de charge associée à la protonation du carbone explique la stabilité accrue des espèces protonées carbonées par rapport aux espèces protonées phosphorées. Le champ du laplacien démontre aussi l'existence d'une cavité à l'intérieur de la cage, entourée par une densité électronique élevée qui peut stabiliser un cation d'une taille appropriée. Nos résultats confirment que le Li^+ et le Be^{2+} remplissent ces conditions et les complexes correspondants, dans lesquels le cation se trouve à l'intérieur de la cage, sont des minima des surfaces d'énergie potentielles correspondantes. Le Na^+ est beaucoup trop gros et une structure semblable est un col sur la surface d'énergie potentielle.

Mots clés : théorie des atomes dans les molécules, tétraphosphacubane, réactivité, cationisation.

Introduction

The reactivity of tetraphosphacubane is of particular interest since, in principle, it might be affected by its likely high strain energy. In fact, tetraphosphacubane can be considered as the result of substituting the carbon atoms in alternative corners of cubane, which has a very high strain energy (1–4) although it is thermally stable, by phosphorus atoms. On the other hand, all efforts to synthesize 1,3,5,7-tetraazacubane have failed, probably because the presence of four nitrogen atoms in alternative corners of the cube would imply a significant increase of the strain energy, which as mentioned above is already very high (ca. 165 kcal/mol) for cubane. On the contrary, the tetra-*tert*-butyl substituted derivative of 1,3,5,7-tetraphosphacubane was recently synthesized by M. Regitz and co-workers (5), which is probably an indication that substitution of carbon by phosphorus leads to a certain alleviation of the strain of the system. Since tetraphosphacubane is a quite novel species, we have considered it of interest to investigate its intrinsic reactivity, i.e., its reactivity toward some monocations in the absence of any interaction with the solvent. Along this line, we have studied (6), very recently, the protonation of the tetra-*tert*-butyl substituted derivative of 1,3,5,7-tetraphosphacubane in the gas phase. This *in concert* experimental and theoretical study (6) showed tetraphosphacubane to be an unexpectedly strong carbon base. In this paper we shall try to illustrate that the atoms-in-molecules theory of Bader (7) provides useful information either to rationalize the behaviour of tetraphosphacubane with respect to different closed-shell cations, namely, H^+, Li^+, Na^+, and Be^{2+}, or to describe the charge redistributions that take place upon cationization. We shall have the opportunity to illustrate, once more, that Bader's theory is a very versatile tool for characterizing ion–molecule interactions (8–14) and, in particular, to investigate bond acti-

vations produced by protonation (9) or metal cation association in the gas phase (10–14). Although, as mentioned above, only the 1,3,5,7-tetra-*tert*-butyltetraphosphacubane has been synthesized, we shall limit our theoretical treatment to the unsubstituted parent compound for the sake of economy.

Computational details

The geometries of the complexes of tetraphosphacubane (**1**) with Li^+, Na^+, and Be^{2+} were optimized at the HF/6-31G(d,p) level. The corresponding vibrational frequencies were evaluated by means of analytical second-derivative techniques, in order to classify the stationary points of the potential energy surfaces as minima or saddle points and to evaluate the corresponding zero point vibrational energies (ZPE), which were scaled by the empirical factor 0.893. These geometries were then refined at the MP2/6-31G(d,p) level to account for electron correlation effects. The MP2 densities so obtained were then used for the corresponding Bader's topological analysis. The MP2/6-31G(d,p) optimized geometries of tetraphosphacubane (**1**) and those of the corresponding phosphorus and carbon protonated species, namely, **1PH**$^+$ and **1CH**$^+$, were taken from ref. 6. The binding energies were evaluated at the MP2/6-31G(d,p) level after including the corresponding ZPE corrections.

These standard ab initio calculations were carried out by using the Gaussian-90 (15) and Gaussian-92 (16) series of programs.

The bonding of the neutral species as well as that of the different cations included in this study was investigated by means of a topological analysis of the electronic charge density, ρ, and its Laplacian, $\nabla^2\rho$. As has been shown by Bader et al. (17–19), $\nabla^2\rho$ identifies regions of space where the electronic charge is locally depleted ($\nabla^2\rho > 0$) or built up ($\nabla^2\rho < 0$). We have also located the relevant bond critical points (bcp), i.e., points where the electronic charge density is minimum along the bond path and maximum in the other two directions, because the values of ρ and $\nabla^2\rho$ at these points offer quantitative information on the strength and nature of the bonding. Furthermore, the values of the negative curvatures (λ_1, λ_2) allow us to define the ellipticity of the bond as $\varepsilon = 1 - \lambda_1/\lambda_2$. This topological analysis was carried out by using the AIMPAC series of programs.[2]

The numbering of atoms used throughout this paper is given in Fig. 1. For the sake of consistency we are assuming that phosphorus association takes place systematically at P1. It should be mentioned that all the cations investigated were found to be symmetric with respect to the P1P2C6C5 plane. This also applies to carbon-attached species provided that association takes place at C5.

Results and discussion

Neutral tetraphosphacubane

The MP2/6-31G(d,p) optimized structure of tetraphosphacubane (r_{P-C} = 1.895 Å, CPC = 83.7°, PCP = 96.0°) agrees reasonably well with the X-ray crystal structure of tetra-*tert*-butyltetraphosphacubane (1) (r_{P-C} = 1. 881 Å, CPC = 85.6°, PCP = 94.4°), the differences being likely due to both the effects of the *t*-Bu substituents and the crystal packing. Topological analysis of its charge density reveals the existence of a significant ring strain since the bond path angles are significantly larger than the geometrical ones, in particular, those about phosphorus atoms (see Table 1). This seems to be in agreement with its high ring strain energy, which according to the recent estimations of Bachrach and Perriot (4) is ca. 63 kcal/mol. It is also interesting that the charge densities at the P—C bond critical points (see Table 2) are very close to those

reported in ref. 20 for typical P—C single bonds. As was found for phosphaalkenes (20), the ellipticity of the P—C linkages is small but not zero, indicating that there is some axial distortion of density, due to a certain delocalization of the charge into the corresponding four-membered ring.

In Fig. 2*a* we present the Laplacian of the charge density evaluated in the diagonal plane that bisects the cube. The existence is apparent of nonbonded charge concentrations close to the phosphorus atoms, which are associated with phosphorus lone pairs, but also in the vicinity of the carbon atoms. These regions correspond to sites most susceptible to electrophilic attack (8). This is in agreement with previous findings (6) that indicate that both phosphorus and carbon protonated species are stable cations. Furthermore, as we shall discuss in forthcoming sections, the strong charge redistribution that takes place upon protonation at the carbon atom will be responsible for the enhanced stability of the carbon protonated species (6). There is another interesting feature in Fig. 2*a* which is worth noticing: the existence of a cavity inside the cage, with negligibly small electron charge density, but surrounded by the electronic clouds associated with the P—C linkages. In Fig. 2*b* we present an alternative view of this cavity by showing the Laplacian of the charge density in a plane that contains three of the phosphorus atoms of the system. As we shall discuss later, this cavity may accommodate a cation of the appropriate size leading to a body-centered metal cation complex.

Protonated species

The bonding characteristics of phosphorus and carbon protonated species are summarized in Tables 1 and 2. Several points should be singled out for comment. As has been discussed in ref. 9, in protonation processes there is a large charge transfer from the basic center to the incoming proton. This implies an enhancement of the electronegativity of the basic center, which tries to recover part of this charge by polarizing or depleting, depending on the electronegativity of the other atoms bonded to it, the other bonds in which it participates. If the basic center is the most electronegative one it will depopulate the bond, which accordingly will become longer and weaker. If, on the contrary, the basic center is not the most electronegative one it would only polarize the bonding charge toward it, with the result that the charge density at the bonding

[b]Values within parentheses correspond to the bonding between the metal cation and the carbon atom.

region would increase and the bond would become reinforced. The second case exists when protonation takes place at the phosphorus atom of tetraphosphacubane. Hence, the charge densities at the P1—C5, P1—C7, and P1—C8 bond critical points increase (see Table 2) and the corresponding bond lengths become shorter than in the neutral (1.802 vs. 1.895 Å). The aforementioned polarization effect implies a decrease in the valence charge density about C5, C7, and C8. These atoms recover part of this charge by depopulating the other C—P linkages in which they participate (C7—P2, C5—P3, C8—P4) (see Table 2), which accordingly become slightly longer (1.934 Å) than in the neutral. The remaining linkages of the system are not significantly affected (see Table 2 and Fig. 3*a*).

The enhancement of the electronegativity of P1 upon protonation is necessarily reflected in an increase of the *s* character of the hybrids involved in the P—C linkages. As a consequence, the bond angles about P1 increase significantly (see Table 2). This implies that the protonated phosphorus moves closer to the centre of the cage, and the P1-C7-P2 and P1-C8-P2 bond angles must decrease accordingly (see Table 2). The angles about the other phosphorus and carbon atoms do not change significantly. It must be observed, however, that in the **1PH$^+$** species the bond path angles are still significantly greater than the geometrical ones, indicating that the phosphorus protonated species retains much of the strain present in the neutral.

When protonation takes place at carbon, the situation is completely different. The basic center (C5) is now the most electronegative one and it recovers part of the charge transferred to the incoming proton by depopulating the C5—P1 bond. This effect is clearly seen by comparing Figs. 2*a* and 3*b*, which present the Laplacian of the charge density evaluated in the diagonal plane that bisects the cube, for the neutral and the carbon protonated species, respectively. This comparison shows that the charge depletion at the P1—C5 bonding region is so large that the bond breaks apart, the P1—C5 distance being 3.2 Å (6). This bond fission alleviates significantly the strain of the system, which is reflected in a dramatic increase of the P3-C7-P1 and C5-P3-C7 bond angles (see Table 1). As a consequence, the carbon protonated species becomes about 10 kcal/mol more stable than the phosphorus protonated one (6). The P1—C5 bond fission also implies hybridization changes at both centers that are particularly important at P1, which becomes dicoordinated while C5 maintains its tetraco-

Fig. 2. Laplacian of the charge density of tetraphosphacubane in (*a*) a diagonal plane bisecting the cube; (*b*) a plane that contains three phosphorus atoms. Positive values of $\nabla^2\rho$ are denoted by solid lines and negative values by broken lines. Contour values, in au, are ±0.05, ±0.25, ±0.50, ±0.75, and ±0.95. The arrows indicate nonbonded charge concentrations most susceptible to electrophilic attack.

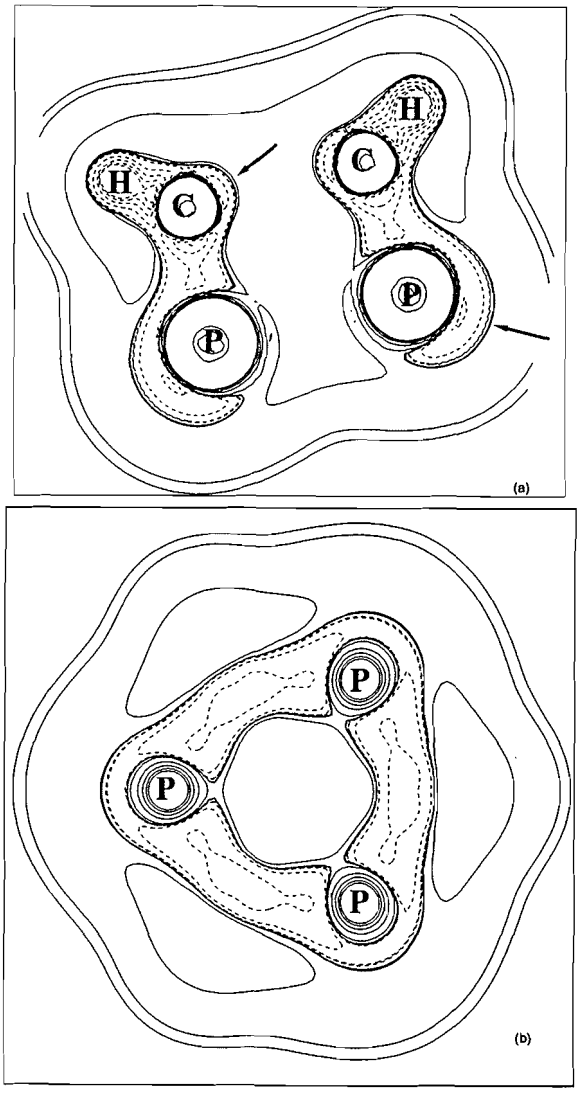

Fig. 3. Laplacian of the charge density in a diagonal plane bisecting the cube for (*a*) phosphorus-protonated tetraphosphacubane; (*b*) carbon-protonated tetraphosphacubane. Same conventions as in Fig. 2.

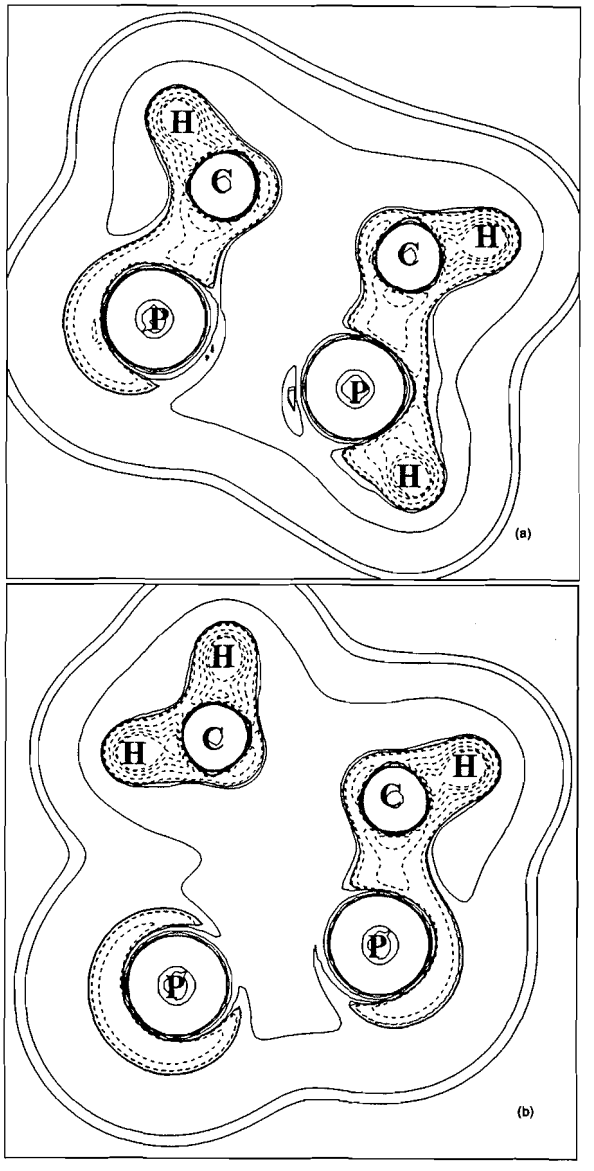


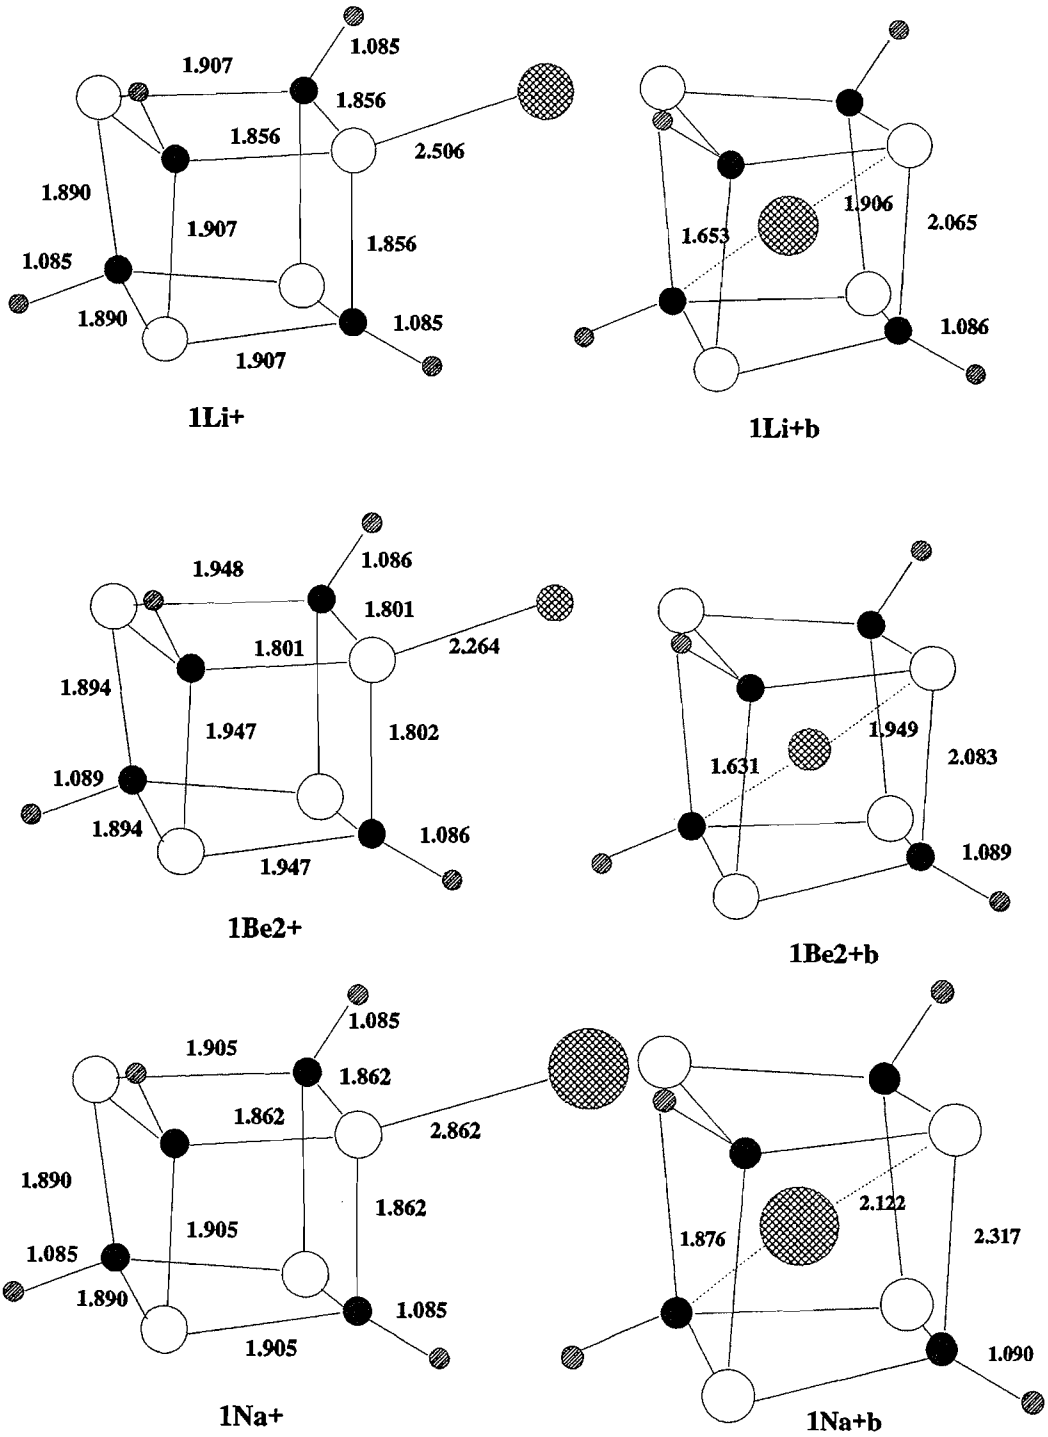
ordination. The consequence is a sizeable strengthening of the P1—C7 and P1—C8 linkages and a parallel weakening of the P3—C7 and P4—C8 bonds (see Table 2).

It is worth noting that the protonated species in which the proton is located at the centre of the cage is not a minimum but a saddle point of the potential energy surface. This is not an unexpected result since is well known that proton attachment is followed by the formation of a covalent linkage, which is strongly favoured when the interaction involves nonbonded charge concentrations such as those exhibited by phosphorus and carbon atoms. Since nonbonded charge concentrations are not found in the charge density that surrounds the centre of the cube cavity, the imaginary vibrational frequencies try to displace the proton outside the cage, in order to favour the interaction with the aforementioned charge concentrations.

Metal cation complexes

The MP2/6-31G(d,p) optimized structures of complexes of tetraphosphacubane with Li^+, Be^{2+}, and Na^+ are shown schematically in Fig. 4. We shall first discuss the alkali metal cation complexes. It can be seen that when the metal cations are located outside the cage only the phosphorus attached complexes, namely, **1Li**$^+$, **1Na**$^+$, are stable. This is consistent with the fact that the molecular electrostatic potential of tetraphosphacubane shows attractive regions only at the phosphorus lone pairs (21), if one takes into account that the interactions of alkali cations with neutral compounds are essentially electrostatic. The Laplacian of the charge density for **1Li**$^+$ (see Fig. 5*a*) and the bonding characteristics of this complex confirm this picture. The charge density at the P—Li^+ bond critical point is small and the Laplacian positive as in typical

Fig. 4. MP2/6-31G(d,p) optimized structures for tetraphosphacubane–X (X = Li^+, Na^+, Be^{2+}) complexes. Bond lengths in Å. The bond angles are given in Table 1. Same conventions as in Fig. 1.



closed-shell interactions. Something similar applies to the **1Na**$^+$ complex. The smaller charge density at the P—Na bond critical point is consistent with a Na^+ binding energy (20.4 kcal/mol) smaller than that found for Li^+ complexes (29.3 kcal/mol). The situation is completely different when the attacking ion is Be^{2+}. As illustrated in Fig. 5*b*, the attachment of Be^{2+} to phosphorus involves charge transfer toward the metal dication that is reflected in a negative value of the Laplacian of the charge density in the P—Be bonding region. The most important consequence is that while the charge redistribution of the neutral upon Li^+ or Na^+ association is small, that found upon Be^{2+} association is quantitatively similar to that found upon protonation (see Tables 1 and 2). It must be observed, however, that the distortions of the bond angles are

Fig. 5. Laplacian of the charge density in a diagonal plane bisecting the cube for (*a*) the **1Li$^+$** complex; (*b*) the **1Be^{2+}** complex. Same conventions as in Fig. 2.

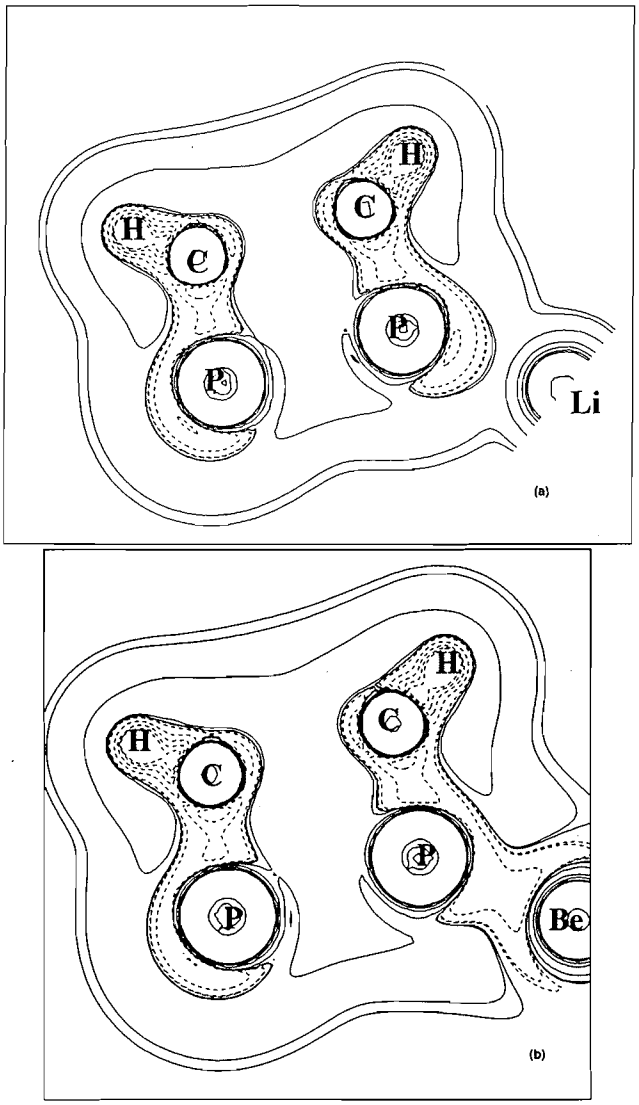


Fig. 6. Laplacian of the charge density in a diagonal plane bisecting the cube for (*a*) the **1Li$^+$b** complex; (*b*) the **1Be^{2+}b** complex. Same conventions as in Fig. 2.

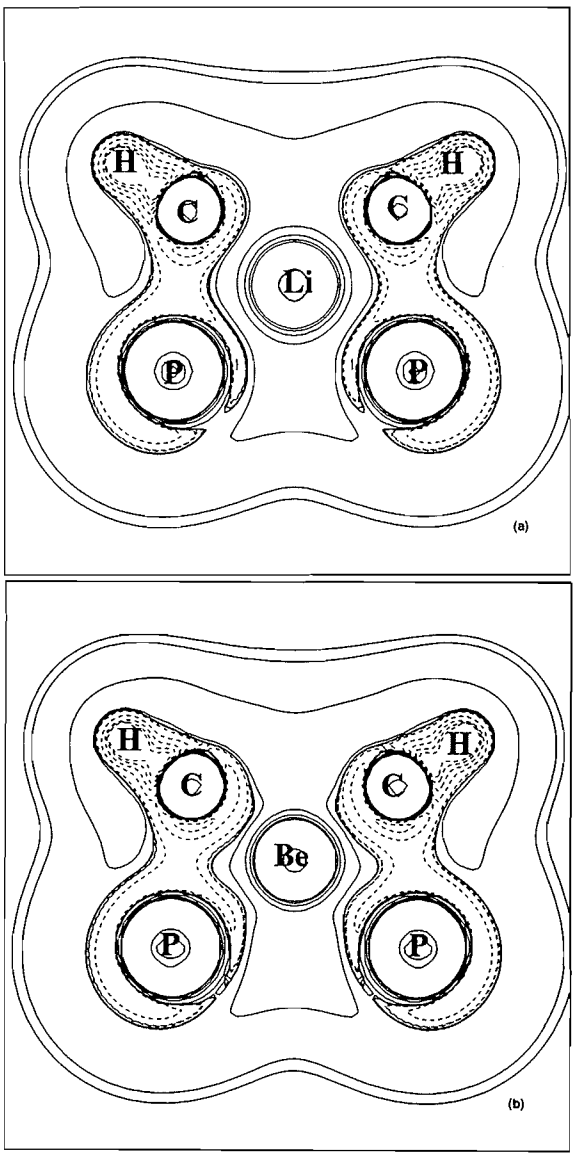
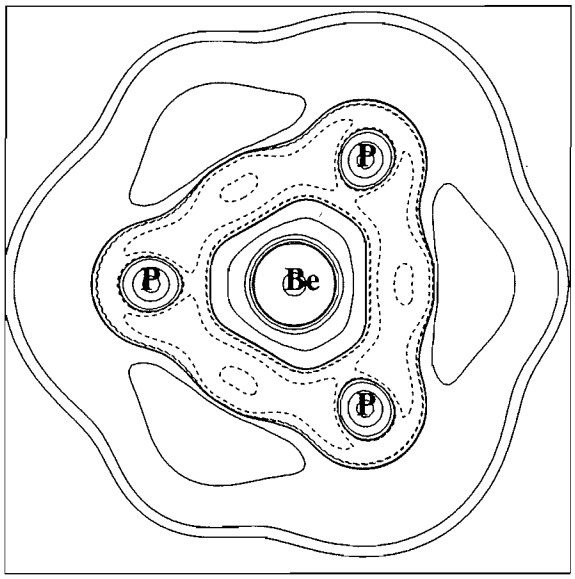


larger for Be^{2+} association than for proton attachment (see Table 1). This is easily understood if one takes into account that in both **1PH$^+$** and **1Be^{2+}** there is a large charge transfer from the neutral to the cation, which reduces significantly the positive charge of the latter. However, while in the **1PH$^+$** species the net positive charge at the proton is rather small (about +0.1), in **1Be^{2+}** the net positive charge at the Be atom is still quite high (about +0.9). This high positive charge is then responsible for an enhancement of the hybridization changes at the basic center, which becomes strongly polarized toward the metal. These effects are mirrored in a significantly large Be^{2+} binding energy (208.5 kcal/mol).

Similarly to what was found upon protonation, Be^{2+} also yields more stable carbon-attached complexes than the phosphorus-attached species **1Be^{2+}**. However, Be^{2+} association implies stronger structural reorganizations than those mentioned above for protonation and, for the sake of conciseness, will not be discussed here.

One of the most significant results of our theoretical survey is that species **1Li$^+$b** and **1Be^{2+}b**, where Li^+ and Be^{2+} are located at the center of the cage cavity, are minima of the potential energy surface, while this was not the case for H^+. As discussed above, this would be expected on the grounds of the different nature of the ion–molecule interactions when the ion is Li^+ or H^+. Since for Li^+ these interactions are essentially electrostatic, the Coulombic attraction between the metal cation and the electronic cloud that surrounds the cavity (see Fig. 6*a*) stabilizes the system. This is confirmed by the existence of bond critical points between Li^+ and the carbon and the phosphorus atoms of the cage (see Table 2). However, since Li^+ is

Fig. 7. Laplacian of the charge density of the **1Be^{2+}b** complex in a plane containing three phosphorus atoms. Same conventions as in Fig. 2.



not a point charge, there is a certain repulsive interaction between its $1s^2$ shell of electrons and the electronic charge density around the cavity that leads to an enlargement of the cage. The obvious consequence, as shown in Table 2, is that the charge density at the P—C bond critical points considerably decreases and the P—C linkages become weaker than in the neutral. From the energetic point of view the destabilization of the P—C bonds is not counterbalanced by the attractive interaction between the cation and the charge around the cavity and the formation of species **1Li$^+$b** becomes endothermic with respect to tetraphosphacubane + Li^+.

Since the ionic radius of Na^+ is significantly greater than that of Li^+, the increase of the cage size in **1Na$^+$b** is dramatic (see Fig. 4). As illustrated in Table 1, the P—C bonds become strongly depopulated and the tetraphosphacubane system strongly destabilized. As a consequence the **1Na$^+$b** species is not a minimum of the potential energy surface.

There are significant differences between the **1Li$^+$b** and **1Be^{2+}b** species that are apparent when comparing the Laplacian fields of both complexes (see Figs. 6*a* and 6*b*), and which are due to the strong polarizations caused by Be^{2+}. As shown in Fig. 6*b*, this is reflected in a migration of electronic charge density from the P—C bonding regions into the interior of the cage. As a consequence the charge density at the P—C bond critical points decreases and the bonds become longer, but at the same time the accumulation of electronic charge around the cavity favours a stabilizing interaction with the metal cation. The result is that the **1Be^{2+}b** species is a minimum of the potential energy surface about 172 kcal/mol more stable than tetraphosphacubane + Be^{2+}. It is worth noting that the polarization caused by Be^{2+} is clearly anisotropic as reflected by the deformation undergone by the cavity (See Fig. 7). Actually the distances between the metal cation and the phosphorus atoms in **1Be^{2+}b** are greater than those found for **1Li$^+$b**, while the contrary holds for the metal cation – carbon distances (see Fig. 4). This is so because, as illustrated in Fig. 1*a*, the charge concentrations around the phosphorus atoms point to the outside the cage, while those around the carbon atoms are closer to the center of the cage, favouring interactions with the metal cation.

Conclusions

We have analyzed the reactivity of tetraphosphacubane by using the theory of atoms in molecules. The characteristics of the C—P bonds of tetraphosphacubane are very similar to single P—C bonds in phosphaalkenes. The differences between bond path angles and geometrical bond angles clearly show that the system presents a non-negligible ring strain. The Laplacian of its electron charge density shows that both phosphorus and carbon atoms are active centers for electrophilic substitutions. This is consistent with the fact that both phosphorus and carbon protonated species are minima of the potential energy surface. The strong charge redistribution associated with carbon protonation results in the fission of one of the P—C bonds in which the protonated carbon atom participates. The consequence of this is a significant alleviation of the strain of the system that results in an enhanced stability of carbon protonated species with respect to phosphorus protonated forms. A similar behaviour is found as far as Be^{2+} association is concerned, although charge polarizations are greater than those found upon protonation. An inspection of the electron charge density and its Laplacian indicates that upon either H^+ or Be^{2+} association there is a strong charge transfer from the neutral to the incoming ion. However, in the latter case the net positive charge of Be atom in the complex is still very high (close to unity) and therefore this center still significantly polarizes the rest of the molecule.

The Laplacian field of neutral tetraphosphacubane also shows the existence of a cavity inside the cage surrounded by high electronic density that can stabilize a cation of the appropriate size. Our results confirm that Li^+ and Be^{2+} fulfil this requirement, and the corresponding complexes, where the cation is located at the center of the cage, are minima of the corresponding potential energy surface. Na^+ is far too large and a similar structure is a saddle point of the potential energy surface. The strong polarization caused by Be^{2+} is high enough to considerably stabilize this structure with respect to the isolated systems. For Li^+ this is not the case and the formation of the body-centered complex is endothermic with respect to tetraphosphacubane + Li^+.

An ab initio study on the insertion reactions of CH ($X^2\Pi$) with NH_3, H_2O, and HF

Zhi-Xiang Wang, Ruo-Zhuang Liu, Ming-Bao Huang, and Zhonghua Yu

Abstract: The mechanisms of the reactions of CH ($X^2\Pi$) with NH_3, H_2O, and HF have been studied by means of ab initio molecular orbital calculations incorporating electron correlation with Møller–Plesset perturbation theory up to the second order. For each of the three CH reactions, the insertion path has been found in the potential energy surface; in the calculated insertion path there exists an intermediate complex prior to the transition state that has a lower energy than the reactants. Energetic results indicate that insertion paths are favourable channels for these CH reactions, which is in line with proposals based on kinetic experiments.

Key words: CH radical, ammonia, water, hydrogen fluoride, reaction mechanism.

Résumé : On a étudié les mécanismes des réactions du CH ($X^2\Pi$) avec le NH_3, le H_2O et le HF en faisant appel à des calculs d'orbitales moléculaires ab initio incorporant une corrélation d'électrons avec la théorie de Møller–Plesset jusqu'au deuxième ordre. Pour chacune des trois réactions du CH, on a trouvé la réaction d'insertion dans chacune des surfaces d'énergie potentielle; de plus, dans chaque voie d'insertion calculée, il existe un complexe intermédiaire antérieur à l'état de transition qui possède une énergie inférieure à celle des réactifs. Les résultats énergétiques indiquent que les voies d'insertion sont des canaux favorables pour ces réactions des CH; ceci est en accord avec les propositions basées sur des expériences cinétiques.

Mots clés : CH radical, NH_3, H_2O, HF, mécanisme des réactions.

[Traduit par la rédaction]

Introduction

Methylidyne (CH) is known to be one of the most reactive of all free radicals (1), and is important in combustion and planetary atmospheric chemistry. The reactions of the CH radical with numerous small molecules have been studied by kinetic experiments (1). However, reported theoretical studies on the CH reactions are very few. To our knowledge, reactions of CH with H_2 (2), C_2H_4 (3), CH_4 (4), and N_2 (5) have been theoretically studied. The CH + H_2 reaction was studied by several theoretical groups (2) and it is well known that accurate ab initio calculations predicted the non-least-motion path to be much more favourable than the least-motion path for the CH ($X^2\Pi$) + H_2 insertion reaction. The theoretical study of Gosavi et al. (3) for the CH ($X^2\Pi$) + C_2H_4 reaction indicated that, in agreement with experiment, the energy barrier for the addition reaction was zero if an asymmetric non-least-motion path was followed. The theoretical study of Yu et al. (4) for the CH + CH_4 reaction predicted a complicated and unexpected mechanism. The CH + N_2 reaction was also studied by several theoretical groups (5) and the predicted mechanisms seem to be very complicated. These studies all show unexpected situations and complexities in the reaction paths.

We have been interested in the reactions of CH ($X^2\Pi$) with the XH_n molecules (X = C, N, O, and F with n = 4, 3, 2, and 1, respectively). For these CH reactions, two mechanistic paths (channels) could be assumed: (*i*) the insertion reaction path, methylidyne insertion (with its C-atom) into one X—H bond of the molecule, leading to CH_2XH_{n-1}; and (*ii*) the abstraction reaction path, leading to CH_2 + XH_{n-1}. Experimental studies (6–8) have suggested that the insertion reaction path is the dominant channel for these CH reactions (no reported experimental study on the CH + HF reaction) because of the weak endothermicity of the abstraction reaction. In 1993, two of us investigated the CH + CH_4 reaction by ab initio molecular orbital (UHF) calculations (4), and the results indicated that, for this CH reaction, the assumed insertion path did not seem to exist and the most favorable channel was an abstraction – addition reaction path, which was not in line with that proposed by experiment (6).

We studied the mechanisms of the CH reactions with NH_3, H_2O, and HF by ab initio molecular orbital calculations incorporating electron correlation with unrestricted Møller–Plesset perturbation theory up to second order (UMP2) (9). In the present paper, we report our UMP2 studies on the mechanisms of the three CH reactions, and also discuss the mechanism of the CH reaction with CH_4.

The important goals of the present study were: (*i*) to find the insertion reaction paths in the CH + XH_n (X = N, O, and F) potential energy surfaces, and (*ii*) to then show that the insertion paths are energetically favorable (dominant).

Calculations details

The UMP2 calculations were carried out with the GAUSSIAN 86 (10) suite of programs using extended 3-21G (11) and polarized 6-31G** (12) basis sets. All the stationary points along the reaction paths were scanned in the geometry optimization calculations with analytic gradient methods at both the UMP2/3-21G and UMP2/6-31G** levels. They were characterized as minima (intermediate complexes) or saddle points (transition states) by means of frequency analysis calculations at the UMP2/3-21G level. In searching the stationary points, geometry optimizations at the UHF level with the 6-31G* basis (12) were also performed. The UMP2/6-31G** optimized geometries and energies are used throughout the text unless otherwise noted.

Results and discussion

1. Insertion reaction paths

The solid-line parts of the potential energy curves shown in (*a*), (*b*), and (*c*) of Fig. 1 represent the UMP2/6-31G** insertion reaction paths of the CH reactions with NH_3, H_2O, and HF, respectively. The insertion products (H_2C–XH_{n-1}) are denoted as 4a, 4b, and 4c, and the transition states of the insertion paths as 3a, 3b, and 3c, respectively. The species 2a, 2b, and 2c represent the intermediate complexes (HC–XH_n) appearing in the insertion paths of the three CH reactions, respectively. The energies of *n*a, *n*b, *n*c (n = 2, 3, and 4) relative to the respective reactants (1a, 1b, and 1c) are given in Fig. 1, and the geometrical parameters of these nine species are given in Fig. 2, together with the UMP2/3-21G and UHF/6-31G* parameters. The insertion paths of these three CH reactions were also found in the UMP2/3-21G potential energy surface. The skeletons of the UMP2/3-21G potential energy curve describing the reaction paths (insertion reactions and subsequent reaction steps) are similar to the UMP2/6-31G** curves shown in Fig. 1.

We examined the geometry evolution of the systems along the insertion paths of the CH reactions with NH_3 and H_2O, for which we looked at the geometries at the stationary points and also those at certain points in between. The UMP2/3-21G geometry optimization calculations were performed at six *Z*-values (the *Z*-parameter, fixed in the optimization, is the distance between the C-atom and the center of the attacked X—H bond) corresponding to the points I, J (2a or 2b), K, L (3a or 3b), M, and N (4a or 4b) on the curves (see Fig. 1). The triangles, shown in Fig. 3(*a*), are the main parts of the six optimized geometries for the CH + NH_3 system, and those shown in Fig. 3(*b*) are for the CH + H_2O system. It is shown in Fig. 3 that, as the *Z*-value decreases, the X—H distance becomes longer and the X—C and C—H distances become shorter, finally leading to the breaking of the X—H bond and simultaneous formation of the X—C and C—H bonds. For all three reaction systems studied, the UMP2/3-21G IRC (intrinsic reaction coordinate) calculations were performed starting at the transition states (3a, 3b, and 3c). In each case, the system, following the calculated IRC, goes downhill to the intermediate complex (2a, 2b, or 2c) in the negative direction of the IRC, and to the insertion product (4a, 4b, or 4c) in the positive direction, which further confirms that the intermediate complex exists prior to the transition state in the path of the insertion reaction for each of the three CH reactions. In 1987, Yates et al. (13) found, in the HF and MPn potential energy surfaces of the CH_2–NH_3 and CH_2–OH_2 systems, two species that could be considered as intermediate complexes in the insertion reactions of $CH_2(^1A_1)$ with NH_3 and H_2O, respectively. In 1991, Sudhakar and Lammertsma (14) reported their theoretical (HF and MPn) studies on singlet nitrene insertion into H_2O and HF, and they found the complexes HN–OH_2 and HN–FH in the insertion reaction paths. These previous studies support our predictions of the existence of intermediate complexes in the insertion paths.

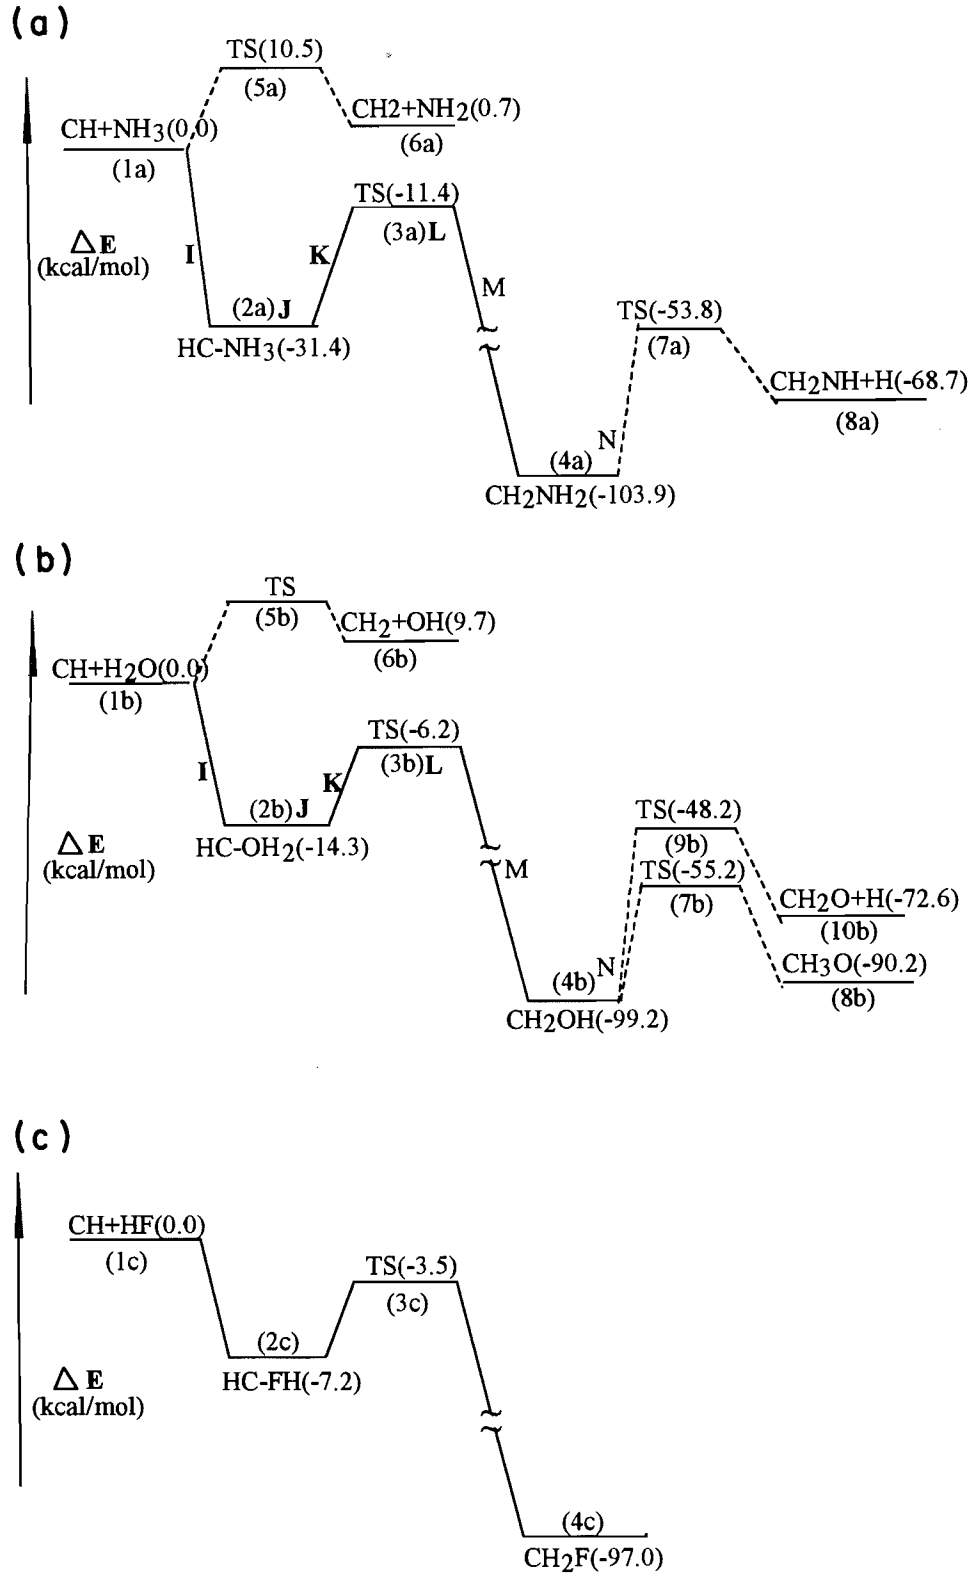
The energetic results for the insertion reaction paths are given in Table 1. Insertion products 4a, 4b, and 4c are predicted to be –103.9, –99.2, and –97.0 kcal/mol more stable than reactants 1a, 1b, and 1c, respectively. The value of –99.2 kcal/mol is reasonably comparable with the available experimental value of –86.2 kcal/mol (8) for the heat of the CH + H_2O reaction. Transition states 3a and 3b are predicted to be 11.4 and 6.2 kcal/mol lower in energy than the respective reactants 1a and 1b, which is line with the experimental facts that the CH + NH_3 and CH + H_2O reactions both have (small) negative activation energies (7, 8). The transition state 3c also has a lower energy than the reactants 1c. The UMP2/6-31G** energetic results definitely indicate that the insertion paths represent the favourable reaction channel for these three CH reactions (see below). The energetic results including the zero-point energy corrections are also given in Table 1, and the changes in the relative energies are small and, as expected, have no effect on the above conclusion for the mechanisms of the reactions.

The energies and geometric parameters, calculated at the UMP2/3-21G and UHF/6-31G* levels, for *n*a, *n*b, and *n*c (n = 2–4) are given in Table 1 and Fig. 2, respectively. The UHF/3-21G and UMP2/6-31G* calculations were also performed for some of the stationary points. The UMP2 calculations with the 3-21G and 6-31G* basis sets predict negative relative energies for the insertion transition states 3a, 3b, and 3c, as with the 6-31G** basis. Due to correlation effects, the UHF energies for these transition states were very high, leading to positive relative energies. As shown in Fig. 2, the UHF/6-31G* values for the C—X distances in 2b and 2c are unreasonably large. Transition state 3c was not found int he UHF/6-31G* calculations.

The intermediate complexes

Intermediate complexes 2a, 2b, and 2c are predicted to be 31.4, 14.3, and 7.2 kcal/mol more stable than reactants 1a, 1b, and 1c, and to be 20.0, 8.1, and 3.7 kcal/mol lower in energy than insertion transition states 3a, 3b, and 3c, respectively (Table 1). Sudhakar and Lammertsma (14) investigated the interactions in the complexes HN–OH_2 and HN–FH, and they were considered as donor–acceptor complexes. In the structures of 2a, 2b, and 2c (Fig. 2), the relatively long C—X distances imply that the three species are only complexes; and the near-orthogonal HCX angles and the orientations of the XH bonds imply that a carbon *p*-orbital is directed at the lone pair (or one of the lone pairs) on the X-atom. The CH radical has two carbon *p*-orbitals perpendicular to its H—C bond, one being singly occupied (SOMO) and the other empty. We found that the SOMO in each of the complexes is just a carbon *p*-orbital perpendicular to the HCX plane, which indicates that there is no interaction between the SOMO of CH and the

Fig. 1. A schematic diagram of the potential energy curves of CH($X^2\Pi$) reactions with NH_3 (*a*), H_2O (*b*), and HF (*c*). The solid-line parts of the curves represent the insertion reactions. The values in parentheses are the UMP2/6-31G** relative energies in kcal/mol.



orbital with lone-pair electrons on the X-atom and that the empty carbon *p*-orbital is only directed at the lone-pair orbital. The interaction between the empty *p*-orbital and the lone-pair orbital causes the lone-pair donation to the empty *p*-orbital, which stabilizes complexes 2a, 2b, and 2c. The binding energies of 2a, 2b, and 2c toward the respective reactants are 31.4,

14.3, and 7.2 kcal/mol, respectively, and the decreasing order could be rationalized by the fact that the higher the electronegativity of the X-atom, the more difficult it is to donate its lone-pair electrons. Due to the basis set superposition errors, the stability of these intermediate complexes is probably somewhat overestimated.

The CH + CH_4 reaction

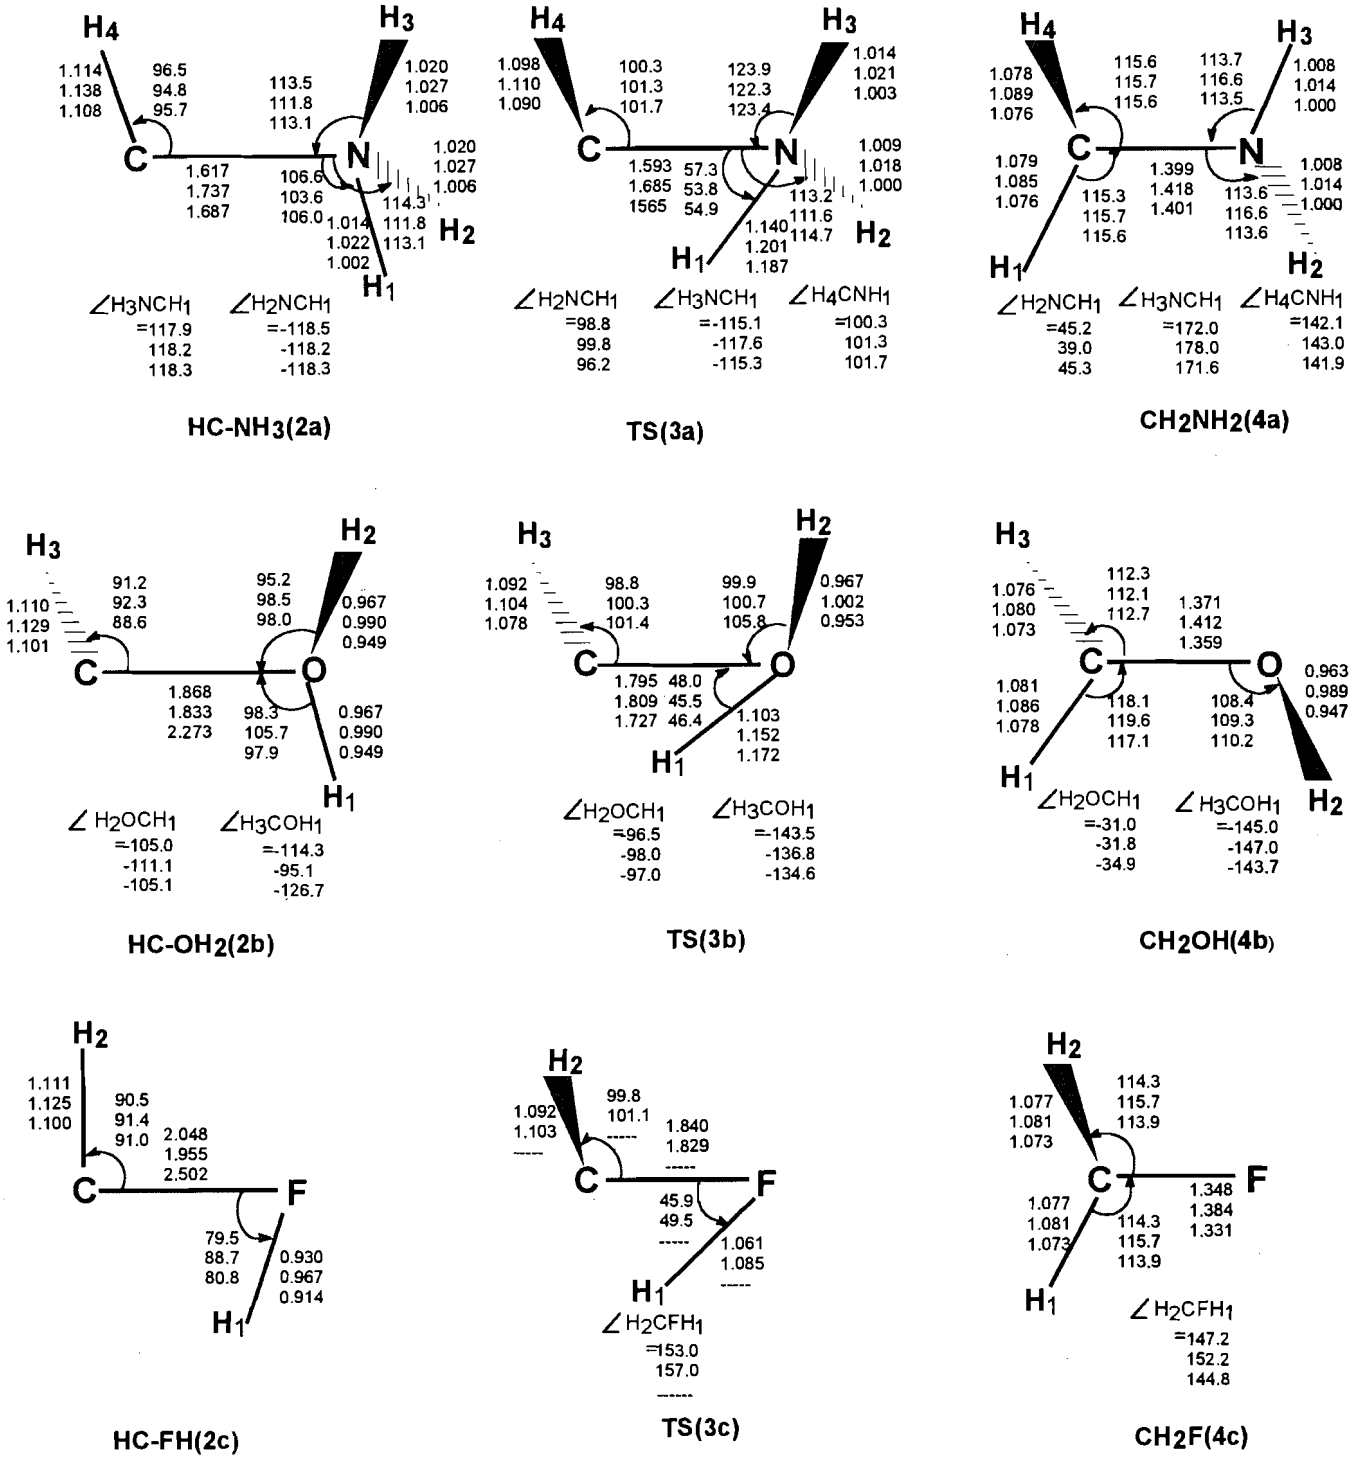
As mentioned above, the insertion path for the CH + CH_4 reaction was not found in the previous theoretical study (4), where the UHF method was used and C_s symmetry was assumed for the system. In the present study, we reinvestigated the CH + CH_4 reaction at the UMP2/3-21G level with no symmetry constraint for the system. We tried many ways of approach for the insertion, but we found no species like 2a or 3a and did not find the assumed insertion path. We claim that the complex (HC–XH_n) does not exist for the CH + CH_4 system because there is no lone pair on CH_4. If the insertion path for the CH + CH_4 reaction indeed exists, the path would have a completely different feature from the insertion paths for the CH reactions with NH_3, H_2O, and HF.

Subsequent reaction steps

In (*a*) and (*b*) of Fig. 1, the broken-line sections, starting at 4a and 4b, of the potential energy curves describe the reaction steps subsequent to the insertion reactions of CH with NH_3 and H_2O, respectively. The energetic results for the reaction steps studied are given in Table 1, and the geometrical parameters of the transition states and the products for these reaction steps are given in Fig. 4.

The reaction step subsequent to the insertion reaction of CH with NH_3 is the dissociation of an H-atom from the N-center of 4a via transition state 7a (Fig. 1). The products 8a (CH_2NH + H) are predicted to be 35.2 kcal/mol less stable than 4a, and the calculated energy barrier is 50.1 kcal/mol. However, the energies of 7a and 8a are still much lower than the energy of the reactants 1a. The energy difference between 8a and 1a of −68.7 kcal/mol is comparable with the experi-

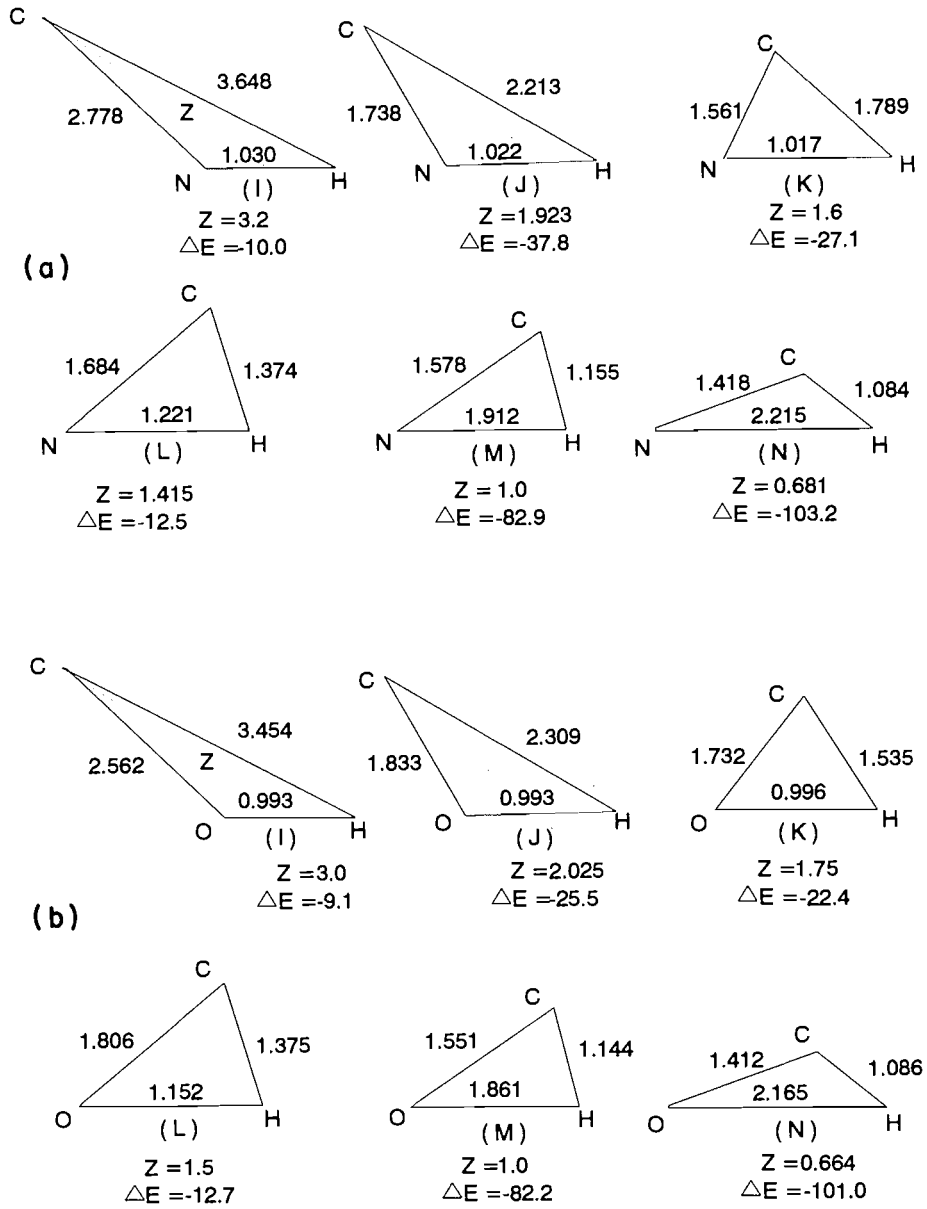
Fig. 2. Optimized structures of the intermediate complexes (2), transition states (3), and products (4) for CH ($X^2\Pi$) insertion reactions with NH_3 (*a*), H_2O (*b*), and HF (*c*). The upper values are the UMP2/6-31G** geometric parameters, and the mid and lower values are the UMP2/6-31G** and UHF/6-31G* ones, respectively. Bond lengths are given in Å and angles in degrees.



mental value of –53.0 kcal/mol for the heat of the CH + NH_3 reaction (7).

Two channels, as the reactions subsequent to the insertion reaction of CH with H_2O, were studied (Fig. 1). One channel represents the dissociation of the H-atom from the O-center of 4b via transition state 9b, leading to products 10b (CH_2O + H), and other represents hydrogen migration from the O-center to the C-center of 4b via a transition state 7b, leading to product 8b (CH_3O (C_s, $^2A'$)). The energetic results (Table 1) indicate that 7b, 8b, 9b, and 10b all have much lower energies than 1b,

Fig. 3. Structures of ΔCXH (X = N (*a*) and O (*b*)) abstracted from the UMP2/3-21G geometries of the CH + XH_n systems optimized at fixed *Z*-values corresponding to the points I, J, K. L, M, and N in (*a*) and (*b*) of Fig. 1. The parameter *Z* is the distance between the C-atom and the center of the XH distances. Distances are given in Å and the UMP2/3-21G energies (Δ*E*) relative to the reactants in kcal/mol.



and that the migration reaction is more favorable than the decomposition reaction, which is in agreement with experiment (8). The species 4b, 7b, 8b, 9b, and 10b and related reactions (rearrangements and decompositions) were previously studied by many groups (15–18) at various levels of theory. For this portion of the potential energy surface, the energetic and geometrical results of the present study are comparable with those reported in the previous studies. In the theoretical study of Saebø et al. (15) for the rearrangement of CH_3O to CH_2OH, the geometries of 4b, 7b, 8b, 9b, and 10b were optimized at the UHF levels and the UMP3/6-31G** energies were calculated at the UHF/6-31G** geometries. For the relative energies of 7b, 8b, 9b, and 10b (to 4b) our (UMP2/6-31G** + ZPE) values are close to their respective (UMP3/6-31G**//UHF/6-31G** + ZPE) values, and their optimized geometries are close (or identical) to our respective UHF/6-31G* geometries. In the theoretical study of Walch (16), accurate CASSCF calculations with a large basis set were performed for 7b and 8b. Our (UMP2/6-31G** + ZPE) relative energy value for 7b to 8b is 31.1 kcal/mol, which is comparable with the CASSCF value of 30.1 kcal/mol (16). Our UMP2/6-31G** values for the C—O bonds in the structures of 7b and 8b (Fig. 4) are about 0.03 Å smaller than the CASSCF values (16), and our value of 1.228 Å for the C—H (the migrating one) distance in the structure of 7b (TS) (Fig. 4) is 0.047 Å smaller than the CASSCF value (16). However, the UMP2/6-

Fig. 4. Optimized structures of the transition states (7a, 7b, and 9b) and products (CH_2NH, CH_2O,and CH_3O) for the reaction steps subsequent to the insertion of CH with NH_3 and H_2O. TS(9b)

CH_2O

31G** values for the other geometrical parameters in the structures of 7b and 8b are quite close to the respective CASSCF values. In the theoretical study of Bauschlicher et al. (17), the relative energy of 8b to 4b was predicted to be 7.0 kcal/mol, which is closer to the experimental value of 5.5 kcal/mol (8) than our UMP2/6-31G** + ZPE value of 9.7 kcal/mol.

The spin contaminations in the wave functions of the intermediates and transition states, appearing along the paths of the three insertion reactions including the subsequent steps, are small and thus the UHF and UMP2 calculations are valid from the methodological point of view.

2. Abstraction reaction paths

Based on the results reported above, it could already be concluded that the CH reactions with NH_3, H_2O, and HF all have their feasible insertion paths that are strongly exothermic and have transition states with negative relative energies. However, we still calculated the abstraction paths of the CH reactions with NH_3 and H_2O, and the calculated paths are represented by the broken-line curves starting at 1a and 1b shown in (*a*) and (*b*) of Fig. 1, respectively. The abstraction products ($XH_{n-1} + CH_2$ (X^3B_1)) are denoted as 6a and 6b, and the transition states as 5a and 5b, respectively. At the UMP2/6-31G** level (Table 1), the abstraction products are predicted to be slightly less stable than the respective reactants, which is in agreement with experiment (7, 8). The calculated energy differences between the products and the reactants are small values of 0.7 and 9.7 kcal/mol, respectively, which are both about 7.0 kcal/mol smaller than the respective experimental values (7, 8) for the heats of the two abstraction reactions. Calculations at higher levels would lead to better quantitative agreements. The UHF/6-31G* and UMP2/6-31G relative energies for 6a and 6b (Table 1) have the wrong signs. Transition state 5a is predicted to be 10.5 kcal/mol higher in energy than 1a. Transition state 5b was found only in the UHF/6-31G* calculations. Spin contaminations in the wave functions of 5a and 5b are large ($\langle s^2 \rangle \approx 1.35$). This is probably because these doublet transition states are connected with products consisting of a triplet and a doublet species.

Summary

For CH ($X^2\Pi$) reactions with NH_3, H_2O, and HF, insertion reaction paths have been found in the potential energy surfaces. In the insertion path calculated for each of these CH reactions there exists an intermediate complex prior to the transition state. The energetic results indicate that these insertion reactions are all strongly exothermic and all have transition states with negative energies relative to the respective reactants. The present study supports the proposal of the experimental workers (7, 8) that the insertion path is the dominant channel for CH reactions with NH_3 and H_2O.

Calculation of static molecular properties in the framework of the unitary group based coupled cluster approach

Josef Paldus and Xiangzhu Li

Abstract: The recently developed and implemented state selective, fully spin-adapted coupled cluster (CC) method that employs a single, yet effectively multiconfigurational, spin-free reference and the formalism of the unitary group approach (UGA) to the many-electron correlation problem, has been employed to calculate static electric properties of various open-shell (OS) systems using the finite field (FF) technique. Starting with the lithium atom, the method was applied at the first-order interacting space single and double excitation level (CCSD(is)) to several first- and second-row hydrides having OS ground state, namely to the CH, NH, OH, SiH, PH, and SH radicals. In the case of NH we also considered three OS excited states. In all cases the dipole moment and polarizability were determined using a high quality basis set and compared with the experiment, whenever available, as well as with various configuration interaction results and other theoretical results that are available from the literature. The agreement of our CCSD(is) values with experiment is very satisfactory except for the $^3\Sigma^-$ ground state of the NH radical, where the experimentally determined dipole moment is too small. No experimental data are available for the corresponding polarizabilities. It is also shown that the FF technique is not suitable for calculations of higher order static properties, such as the hyperpolarizability β and γ tensors. For this reason we formulate the linear response version of our UGA-based CCSD approach and discuss the aspects of its future implementation.

Key words: static molecular properties, dipole moments, polarizabilities, free radicals, unitary group based coupled cluster method, linear response theory, finite field technique.

Résumé : On a utilisé la méthode des «coupled cluster» («CC») complètement adaptée aux spin et sélective des états, développée et mise en place récemment, qui n'utilise qu'une référence sans spin, mais qui est malgré tout effectivement multiconfigurationnelle, ainsi que le formalisme de groups unitaires («UGA») au problème de la corrélation de plusieurs électrons pour calculer les propriétés statiques de divers systèmes en couches ouvertes («OS») en utilisant la technique du champ fini («FF»). En commençant avec l'atome de lithium, on a appliqué cette méthode au premier niveau d'interaction de l'espace des configurations singulièrement et doublement excitées (CCSD(is)) pour plusieurs hydrures des deux premières couches possédant un état fondamental OS, soit les radicaux CH, NH, OH, SiH, PS et SH. Dans le cas du NH, on a aussi considéré trois états excités OS. Dans tous les cas, on a déterminé le moment dipolaire et la polarisabilité en utilisant un ensemble de base de bonne quantité et, dans tous les cas où cela était possible, on les a comparés avec les données expérimentales ainsi qu'avec les divers résultats d'interactions de configuration et d'autres résultats théoriques disponibles dans la littérature. L'accord entre nos valeurs de CCSD(is) et les valeurs expérimentales est satisfaisant, à l'exception de ceux pour l'état fondamental $^3\Sigma^-$ du radical NH pour lequel la valeur expérimentale est trop faible. Il n'y a pas de données expérimentales disponibles pour les polarisabilités correspondantes. Il a été démontré que la technique «FF» n'est pas appropriée pour les calculs des propriétés statiques d'ordre supérieur, tels que les tenseurs d'hyperpolarisabilité β et γ. C'est la raison pour laquelle on formule la version de la réponse linéaire à notre approche «CCSD» qui repose sur l'approche «UGA» et on discute les aspects de sa réalisation pratique dans l'avenir.

Mots clés : propriétés moléculaires statiques, moments dipolaires, polarisabilités, radicaux libres, groupe unitaire basé sur la méthode des agrégats couplés, théorie de la réponse linéaire, technique du champ fini.

1. Introduction

An ab initio determination of static and dynamic molecular properties is very useful in a wide range of both theoretical and practical applications. This is particularly the case for nonlinear optical properties that are closely related with various hyperpolarizabilities (see, for example, ref. 1), but also for molecular electric and magnetic multipole moments that play an important role in diverse spectroscopic studies (2) as well as in the determination of long-range components of intermolecular interaction potentials (3). Very recently, for example, molecular polarizabilities were employed to rationalize an alignment and trapping of molecules in intense laser fields, enabling one to enhance dynamical resolution of collisional or spectroscopic experiments (4). While in the past most of the quantum chemical methodology and computations concentrated on the determination of molecular energetics and structure, more recent developments often focus on property determination as well.

In the framework of the coupled clustered (CC) methodology (5, 6) which proved to be very successful in computations of correlated electronic energies, particularly for nondegenerate closed shell (CS) ground states (6), as well as the closely related many-body perturbation theory (MBPT) (7), a number of different approaches have been exploited for this purpose. These include direct evaluation of expectation values of the operator characterizing the given property (5*b*, 8), variational and bivariational approaches (9), a stationary Lagrangian technique (10), a linear response (LR) theory (6*b*, 11) and related approaches (12, 13), as well as methods using a uniform finite field (FF) or a field generated by a set of strategically placed point charges (14). The direct evaluation of expectation values leads to a nonterminating series expansion (5*b*) that is rather cumbersome to handle (8) and could lead to serious convergency problems in quasidegenerate cases when the magnitude of some cluster amplitudes can be appreciable (cf., however, ref. 8*d*). Similar problems also plague some stationary response methods (9). The last methods (i.e., uniform FF or point charge generated field methods) are easiest to implement, since they can directly employ the existing codes for the electronic energy calculations. However, the FF methods have their limitations when considering higher order properties, as we shall indicate later on. These problems can be circumvented by employing suitable multipolar fields of point changes (14*a*–*e*), as first proposed by McLean and Yoshimine (15) and extensively used even in other than CC approaches (see, e.g., ref. 16).

One of the most appealing approaches of great generality is undoubtedly the LR theory, which can handle not only static properties of various orders, but also the dynamic or frequency-dependent ones. This approach, first outlined in the context of the CC method by Monkhorst (11*a*), requires only a single calculation of the correlation energy and cluster amplitudes for each geometry followed by the solution of a recursive set of linear equations for higher and higher order properties. A recent implementation of this approach in our laboratory (17), within the context of CS orthogonally spin-adapted CCSD (CC method restricted to singly and doubly excited cluster components) formalism (18), enabled very promising applications when computing higher order properties.[3] Even for the second hyperpolarizability tensor we were able to generate the entire property surface,[3] which is required when considering rovibrational effects and computing rovibrationally averaged property values for individual rotational and vibrational states (19).

While considerable progress is being made for CS systems, as we just outlined, the computation of properties (even of static ones) for open shell (OS) molecular systems with more than three electrons is sorely lacking (8*g*, 13*d*–*f*, 20). The principal reason for this state of affairs is the lack of suitable OS CC methodology. Although the proper multireference CC approaches of either the valence universal or state universal types have been formulated, and several of their variants even implemented (for an overview, see refs. 6 and 21), their complexity and the cognate practical difficulties associated with intruder state problem, multiplicity of solutions, or symmetry breaking make their implementation limited even when considering molecular energetics. As far as we are aware, the only properly spin-adapted multireference CC property calculation, using the state universal approach, was recently carried out in our laboratory for the lowest singlet state of methylene (20). Otherwise, most CC approaches to OS systems exploit the simple single reference CCSD approach based on the unrestricted Hartree–Fock (UHF) reference. This very simple and straightforward approach does indeed often provide very useful results in spite of its inherent limitations and conceptual drawbacks (see e.g. ref. 22). Even when the UHF reference is heavily spin contaminated, the spin impurity of the resulting CC wave function is usually greatly reduced (23) and the computed energies are little affected. However, when calculating other properties, the residual spin contamination can play a significant role. For example, even small spin impurities can cause a significant error in calculated vibrational frequencies, since the magnitude of this error is a function of the derivative of the mean value of the total spin $\langle S^2 \rangle$ with respect to the molecular geometry (24). In any case, the choice of a suitable UHF solution as a reference is not unambiguous, since for a certain range of geometries several UHF solutions may exist, and the energetically lowest one may not correspond to the ground state potential energy curve (22). Most importantly, however, the UHF-based CC method is restricted to high-spin states and cannot be used to describe the important case of low-spin, OS singlet states. Similar problems are, of course, encountered in other post-Hartree–Fock approaches that employ the UHF reference, such as the finite order MBPT method (25).

In view of the challenge of handling the OS systems using the CC methodology, we have recently introduced (26) and implemented (27) a single reference, yet effectively multi-configurational, CC approach exploiting a spin-free formalism of the so-called unitary group approach (UGA) (28), or Clifford algebra UGA (CAUGA) (29) and bonded tableau approach (30) to the many-electron correlation problem. Our existing experience (22, 31, 32) indicates a great practical usefulness of this formalism in the handling of many OS sys-

[3] A.E. Kondo, P. Piecuch, and J. Paldus. J. Chem. Phys. In press.

tems, particularly the high-spin doublet and triplet states as well as low-spin OS singlets (involving two OS orbitals). It is thus desirable to explore the potentialities of this formalism in property calculations as well. Although our ultimate goal is to formulate and implement the UGA-based CC version of the LR method, we will first investigate the performance of the UGA-CCSD approximation using the FF technique. For this reason we investigate several static properties for a few first- and second-row hydrides in their OS ground states using the UGA-CCSD FF method. In addition, we also consider the ground state of Li and several excited states of the NH radical, where experimental information concerning the dipole moment is available. These results will not only attest to the reliability of the UGA-based CCSD method for property calculations, but also provide the much needed benchmark values for the testing of various versions of the LR approach based on this method that we intend to develop in the future.

In the next section we thus briefly outline the UGA-based CCSD method employed and its implementation. In Sect. 3 we apply this method, using the FF approach, to a few OS species and compare the calculated property values with the available experimental ones as well as with other computations. The LR approach within the context of UGA-CC formalism is then outlined and discussed in Sect. 4.

2. UGA-based CC method

The single reference CC methods rely on the cluster expansion of the exact wave function $|\Psi\rangle$,

$$[1] \qquad |\Psi\rangle = e^T|\Phi\rangle,$$

where $|\Phi\rangle$ designates an independent particle model reference configuration, represented by a single antisymmetrized product of spin orbitals, and T is the cluster operator, which can be expressed as a linear combination of a suitable set $\{G_I\}$ of excitation operators G_I,

$$[2] \qquad T = \sum_I t_I G_I$$

with t_I labelling the corresponding cluster amplitudes. The excitation operators G_I may then be conveniently represented as products of unitary group generators (33).

In contrast to the standard single reference CC approach, when $|\Phi\rangle$ is represented by an independent particle model (usually Hartree–Fock) single determinantal configuration wave function, the UGA-based formalism employs a spin-free reference representing in general a multi-configurational state. This reference state can be labeled by a Gel'fand, Weyl, or Paldus tableau (28), or by a two-box CAUGA or bonded tableau (29, 30). In the CS case, the resulting approach can be shown to be equivalent to the standard (orthogonally) spin-adapted CC formalism (26). However, in OS cases, the spin-free CC Ansatz [1] is unique to the UGA-CC theory and is not equivalent to some spin-adapted version of molecular spin orbital-based Ansätze.

Adopting thus the spin-free Ansatz [1], we can formally proceed as in the standard single reference case, except that we can no longer exploit the diagrammatic techniques (6, 7*a*, 34) but have to rely solely on the algebraic formalism. Nonetheless, rather than exploiting the second quantization formalism, we can employ directly the unitary group approach (28–30). Starting from the time-independent, spin-free form of the Schrödinger equation for the electronic Hamiltonian H,

$$[3] \qquad H|\Psi\rangle = E|\Psi\rangle$$

and exploiting the cluster expansion [1], we obtain after premultiplying with the inverse operator $\exp(-T)$ the basic equation

$$[4] \qquad e^{-T}He^T|\Phi\rangle = E|\Phi\rangle$$

The projection onto the reference state $|\Phi\rangle$ yields the standard expression for the energy, namely

$$[5] \qquad E = \langle e^{-T}He^T\rangle = \langle H\rangle + \langle [H, T]\rangle + \tfrac{1}{2}\langle [[H, T], T]\rangle + \cdots$$

and the projection on the excited configurations $G_I|\Phi\rangle$ gives the energy-independent CC equations

$$[6] \qquad \langle G_I^\dagger e^{-T}He^T\rangle = 0$$

where $\langle X\rangle$ designates the reference state mean value of an operator X

$$[7] \qquad \langle X\rangle := \langle\Phi|X|\Phi\rangle$$

and $[X, Y]$ the commutator of X and Y,

$$[8] \qquad [X, Y] = XY - YX$$

In contrast to the standard CS case, where the energy expression involves at most bilinear terms in monoexcited cluster amplitudes and only linear terms in biexcited amplitudes, the general OS case may contain even quartic terms thanks to the presence of partially occupied valence or active orbitals in the reference $|\Phi\rangle$. Thus, for the correlation energy $\Delta E \equiv E - \langle H\rangle$ we obtain (26, 27)

$$[9] \qquad \Delta E = \sum_I e_I^{(1)} t_I + \sum_{IJ} e_{IJ}^{(2)} t_I t_J + \sum_{IJK} e_{IJK}^{(3)} t_I t_J t_K + \sum_{IJKL} e_{IJKL}^{(4)} t_I t_J t_K t_L$$

where the general coefficient has the form

$$[10] \qquad e_{IJ\cdots M}^{(n)} = \frac{1}{n!}\langle [\cdots [[H, G_I], G_J], \cdots G_M]\rangle = \frac{1}{n!}\langle HG_IG_J\cdots G_M\rangle$$

The last equality is implied by the fact that

$$[11] \qquad G_I^\dagger|\Phi\rangle = 0$$

since the excitation operators G_I always annihilate at least one core orbital or create at least one virtual orbital.

The corresponding CC equations [6], determining the cluster amplitudes t_I, can involve up to eight commutators and have the general form

$$[12] \qquad \langle G_I^\dagger e^{-T} H e^T \rangle = a_I + \sum_J b_{IJ} t_J + \sum_{J \le K} c_{IJK} t_J t_K + \cdots = 0$$

The absolute, linear, and bilinear coefficients are then given by the following expressions

$$[13] \qquad a_I = \langle G_I^\dagger H \rangle$$

$$[14] \qquad b_{IJ} = \langle G_I^\dagger [H, G_J] \rangle = \langle G_I^\dagger H G_J \rangle - \langle G_I^\dagger G_J H \rangle$$

and

$$[15] \qquad c_{IJK} = [2(1+\delta_{JK})]^{-1} \langle G_I^\dagger ([[H, G_J], G_K] + [[H, G_K], G_J]) \rangle$$

Defining

$$[16] \qquad \tilde{c}_{IJK} = \langle G_I^\dagger H G_J G_K \rangle + \langle G_I^\dagger G_J G_K H \rangle - 2\langle G_I^\dagger G_J H G_K \rangle$$

we can write

$$[17] \qquad c_{IJJ} = \tfrac{1}{2} \tilde{c}_{IJJ}$$

and

$$[18] \qquad c_{IJK} = \tfrac{1}{2}(\tilde{c}_{IJK} + \tilde{c}_{IKJ}), \qquad (K \neq J)$$

The terms involving higher order commutators can be similarly handled. However, in our implementation of the UGA-CCSD approach, which we briefly describe below, we consider at most bilinear terms in CC equations [12], while considering all the terms when evaluating the energy, eq. [9]. Note, however, that the quartic energy term involves only semi-internal monoexcitations and the cubic term at least a pair of such monoexcitations. Similarly, the n-commutator term in CC equations [12] must involve at least $\max\{(2n-8), 0\}$ semi-internal monoexcitations, the remaining amplitudes being either semi-internal biexcitations or all-external monoexcitations. The possible types of nonlinear terms appearing in CCSD equations [12] that arise from n-commutator terms of eq. [6] and involve n excitation operators G_I and n corresponding cluster amplitudes t_I, $2 \le n \le 8$, are listed in Table 1. These n-linear terms are characterized by the number of semi-internal and all-external mono- and bi-excited cluster amplitudes involved. Clearly, we can safely neglect most of the higher than bilinear terms, since they primarily involve semi-internal monoexcitations, or high orders of other terms corresponding to high-order MBPT contributions. In the present version of our codes, at most bilinear terms ($n < 3$) are considered.

Numerous applications carried out so far, and their comparison with the exact full configuration interaction (FCI) results or highly precise data, justify the truncation scheme employed and described above (22, 27, 31, 32). However, it would be worthwhile to explore the role of certain higher order terms in greater detail, particularly for highly stretched geometries. In this work, we shall restrict our attention to geometries that are close to the equilibrium one.

[a]Each n-linear contribution originating from an n-commutator term comprising n excitation operators and cluster amplitudes is labelled by a quadruple of integers (n_1, n_2, n_3, n_4), $n = n_1 + n_2 + n_3 + n_4$, whose components n_i indicate the number of all-external biexcitations (n_1), semi-internal biexcitations (n_2), all-external monoexcitations (n_3), and semi-internal monoexcitations (n_4) involved.

To select a suitable set of excitation operators, we exploit the group chain

$$[19] \qquad U(n_c + n_v + n_a) \supset U(n_c) \times U(n_v) \times U(n_a)$$

where n_c, n_v, and n_a designate the number of core, virtual, and active orbitals, respectively. Recall that the core and virtual orbitals are, respectively, doubly occupied and unoccupied in the reference, while the active orbitals are singly occupied. In this way, the invariance of our formalism with respect to separate unitary transformations within each orbital group (ie., core, active, and virtual) is assured.

In actual applications we truncate the cluster operator expansion [2] at the biexcited level. However, since some of the excitation operators G_I also involve active (or valence) orbitals, which are only partially occupied in the reference $|\Phi\rangle$, we should also include in our set of singly (S) and doubly (D) excited configurations so-called pseudo-single and pseudo-double ones, which involve up to four UGA orbital generators

(in the triplet case; otherwise at most three orbital generators). However, higher than rank two biexcitations usually play a rather unimportant role, at least for near equilibrium geometries. We have in fact examined two distinct approximations (32*b*), namely, the full single and double (SD) excitation space approximation [CCSD(f)], involving all S and D as well as pseudo-single and pseudo-double excitations (the latter represented by rank 3 or rank 4 excitation operators), and the so-called (first-order) interacting space (is) approximation [CCSD(is)], restricting our set of excitation operators to the first-order interacting space, represented by at most rank 2 operators. It turns out that in the vicinity of equilibrium geometries these two approximations differ very little (usually by a few microhartrees) but, even for significantly stretched geometries, this difference does not exceed a few millihartrees (32*b*). Thus, unless we wish to explore the structures with highly stretched bonds (where the method may fail to converge anyway if $|\Phi\rangle$ no longer represents a suitable zero order approximation), the CCSD(is) approximation is adequate.

The explicit form of the excitation operators G_I for the three important cases, namely the high-spin doublet and triplet states (involving one and two OS orbitals, respectively) and the low-spin OS singlet case (involving two OS orbitals) may be found in ref. 27 (for the high-spin cases, see also ref. 26*c*). These operators represent irreducible tensor operators adapted to the chain [19] and generate orthonormal states. Since we have to distinguish a considerable number of these operators (up to 30 in the most involved triplet case), the derivation of the explicit expressions for various coefficients appearing in our CC equations [12] and in the expression for the energy, eq. [9], is very laborious. To facilitate this derivation and to avoid possible errors, we have designed a set of codes that carry out this procedure automatically. This software is described in greater detail in ref. 27, and it generates the FORTRAN codes that set up and solve the UGA-CCSD equations and evaluate the corresponding energy. These codes were carefully tested by duplicating the algebraic derivations by hand in the doublet and OS singlet cases, as well as by careful numerical studies (27).

3. Static property calculations using the UGA-CCSD FF method

To test the capability of our UGA-based CCSD method, as implemented in our codes (27), to provide reliable values of at least low-order static properties for OS systems, we employ the FF approach and examine a few test examples involving states of different multiplicity. These results will also serve us as benchmark values when implementing and testing various versions of the LR approach, which we briefly outline in Sect. 4.

Systems examined and computational details

The systems that we examine in this work comprise the lithium atom (Li), first-row diatomic hydrides methylidene (CH), imidogen, or nitrene (NH) and hydroxyl (OH) radicals, and the second-row hydrides silylidine (SiH), phosphinidene (PH), and sulfhydryl or mercapto (SH) radicals. All of these systems have an OS ground state that is amenable to our UGA-based CC approach. The ground state equilibrium bond lengths were taken from ref. 35 (see Tables 3 and 5). In addition to the ground states of the above-mentioned systems, we also examine three degenerate excited states of NH, namely the states $a^1\Delta$, $A^3\Pi$, and $c^1\Pi$ whose experimental electric dipole moments are known (36). The experimental bond lengths for these excited states were taken from ref. 35 (see Table 6).

Computations of molecular properties generally require large high-quality basis sets, preferably designed specifically for this purpose. We have chosen two different types of basis sets for our investigations. The first type is represented by the POL1 basis sets of Sadlej (37), which are medium-sized polarized basis sets that are specifically tailored for the high-level correlated calculations of molecular electrostatic properties. For the first-row atoms (C, N, and O), this is a [5*s*3*p*2*d*] basis set, for the second-row atoms (Si, P, S) a [7*s*5*p*2*d*] set, and for hydrogen a [3*s*2*p*] set. Basis sets of the second type, which we employed for the first-row hydrides, are due to Widmark et al. (38). In contrast to the property-oriented POL1 bases, these are high-quality, all-purpose basis sets consisting of atomic natural orbitals (ANO) obtained from correlated atomic calculations, as first advocated by Almlöf and Taylor (39). Experience shows that the ANO basis sets can efficiently account for the molecular many-electron correlation effects. The ANO basis set that is relevant for the first-row hydrides is of the [6*s*5*p*3*d*2*f*/4*s*3*p*2*d*] quality.

For the ground states we always employed the ROHF solution as a reference, while for the excited states of NH, the ground state ROHF orbitals were used. In all cases we rely on Cartesian Gaussian functions, thus using 6 *d* and 10 *f* components. In all our OS CCSD calculations we employ the first-order interacting space approximation (40), as already noted in Sect. 2. For the sake of comparison, we also carried out various limited CI computations, in particular CISD(is) (CI interacting space singles and doubles), CISD$^+$, and CISDT$^+$, using the GAMESS system of programs (41).[4] In all post-HF calculations, only valence electrons were correlated (with the exception of the Li atom, in which case all three electrons were correlated). The ROHF calculations were also carried out using the GAMESS program package.

Properties considered

To calculate static electric properties, such as dipole moments, or dipole polarizabilities or hyperpolarizabilities, we employ the finite field (FF) method (42). The energy change ΔE when the system is submerged in a homogeneous electric field $\boldsymbol{F} \equiv (F_x, F_y, F_z)$ can be written as

$$[20] \quad \Delta E \equiv E(\boldsymbol{F}) - E(\boldsymbol{0}) = -\mu_i F_i - (1/2!)\alpha_{ij}F_iF_j - (1/3!)\beta_{ijk}F_iF_jF_k - (1/4!)\gamma_{ijkl}F_iF_jF_kF_l - \cdots$$

where the summation over repeated indices is implied, $E(\boldsymbol{0})$

[4] The CI program for high-spin multiplicity generates some extra CSFs of higher excitation order. Hence various CI approaches will be referred to as CISD$^+$, CISDT$^+$, etc.

designates the energy with no field present, and $F_i (i = x, y, z)$ are the field components. For linear diatomic hydrides in a uniform electric field along the molecular axis (chosen to be the z-axis, $\boldsymbol{F} = (0, 0, F)$), the above expression [20] simplifies to

$$[21] \quad \Delta E = -\mu F - (1/2)\alpha_{zz}F^2 - (1/6)\beta_{zzz}F^3 - (1/24)\gamma_{zzzz}F^4 - \cdots$$

Thus, once we know the functional dependence of E or ΔE on F, the dipole moment μ, the parallel polarizability component $\alpha \equiv \alpha_{zz}$, etc., can be evaluated as, respectively, the first, second, etc., derivative of the energy with respect to the applied field. While there is only one dipole moment component for linear molecules, the number of independent components of the polarizability tensor deserves a comment. Besides the diagonal (or axial) components, the mixed ones, such as α_{xz}, also generally represent useful quantities. Moreover, for degenerate OS states, such as Π or Δ states, one has to distinguish between different perpendicular diagonal components, namely $\alpha_{xx}(\Pi_x) = \alpha_{yy}(\Pi_y)$ and $\alpha_{xx}(\Pi_y) = \alpha_{yy}(\Pi_x)$, while only one such component exists for nondegenerate Σ states. For the sake of simplicity, we examine in this paper only the most important parallel polarizability component $\alpha \equiv \alpha_{\parallel} \equiv \alpha_{zz}$. A complete investigation of other polarizability components will be presented elsewhere.

When considering a very weak field F, we can truncate expansion [21] at the quadratic term. Within such an approximation, we can then evaluate μ and α if we know the energy for at least two different field strengths, in addition to the zero field energy in case of α. Thus, choosing the fields $F_z = \pm F$, the μ and α are given by

$$[22] \quad \mu = [\Delta E(-F) - \Delta E(F)]/2F = [E(-F) - E(F)]/2F$$

$$-\alpha = [\Delta E(-F) + \Delta E(F)]/F^2 = [E(-F) + E(F) - 2E(0)]/F^2$$

In the case of hydrides, we have chosen the field strength to be $F = \pm 0.002$ au. Using fields of this magnitude, the μ and α obtained from formulas [22], which rely on the smallest number of calculations for different fields, turned out to be almost identical with values that were obtained when using the information for four or more nonzero fields. It should also be noted that for $F = \pm 0.002$ au, we require that our energies are precise to at least 4×10^{-8} au if we wish to compute α with an error not exceeding 10^{-2} au. Thus, in all our calculations, the energies were converged to within 10^{-8} au or better. We must also mention that the dipole moment of a hydride XH is defined in such a way that H is in the positive direction assuming that X is located at the origin.

As we pointed out earlier, a very important characteristic of the UGA-based CC method is its ability to handle the low-spin, OS singlet states, which are inaccessible to the standard UHF-based CC or MBPT approaches. For this reason, we have chosen two excited OS singlet states of NH, namely the $c^1\Pi$ and $a^1\Delta$ states, in order to illustrate this feature of our UGA-CCSD approach. We wish to point out that while both the $^1\Pi_x$ and $^1\Pi_y$ components of the $^1\Pi$ state are OS singlets, only the xy component of the $^1\Delta$ state is an OS singlet state.

Of course, only one component of the $^1\Pi$ state needs to be considered in our case.

Results and discussion

We start by considering a simple atomic system, the lithium atom. This enables us to easily obtain the full configuration interaction (FCI) results (that are equivalent to CISDT in this case, since we deal with a three-electron system), representing the exact solution within the N-electron subspace generated by the chosen set of atomic orbitals (AOs), even when employing fairly large basis sets. The computed total energy and dipole polarizability obtained with various methods and the atomic natural orbital (ANO) basis $[6s5p3d2f]$ (38) are compared with the experimental values in Table 2. It is noteworthy that the uncorrelated SCF values of the polarizability (α = 170.1 au) is much closer to the FCI result (α = 165.1 au) than is the limited CISD(is) result (α = 118.2 au). CISD(is) should represent a very good approximation is this case, since the system allows, at most, triexcitations. In fact, the CISD(is) approach recovers almost the entire correlation energy (99.896%) in this case, yet gives a significantly lower polarizability than does even the uncorrelated SCF approximation. Interestingly enough, our UGA-CCSD(is) approach, which improves the total energy relative to the CISD(is) approach by only one microhartree (thus yielding 99.900% of the correlation energy), gives practically the exact value for the polarizability (α = 165.1 au), which is also very close to the experimental value (43). This is a clear indication of the fact that the CCSD(is) wave function is much better than the CISD(is) one, even though both methods employ the same set of excitation operators. Of course, due to the nonlinearity of the CC Ansatz, the effective excited state manifold is much larger in the CCSD(is) case.

For the sake of comparison, we also include in Table 2 the results of two recent theoretical studies of the Li atom. The first employs the fourth-order MBPT and the standard UHF-based CCSD(T) methods with a very large basis set (44), while the second one relies on the combined configuration interaction and Hylleraas methods (45). It is very encouraging that the CCSD(is) polarizability is very close to the result provided by these extensive calculations, all of these

falling within the experimental limits. A comparison with the most recent estimate of the total energy (46) indicates, however, that the fairly large ANO basis set has not yet reached the basis set limit, since our FCI and CCSD(is) energies are about 17 mhartree short of the "experimental" limit. Of course, from the methodological viewpoint, the agreement of the CCSD(is) quantities with the FCI results is most relevant.

The computation of the hyperpolarizability, particularly when using the FF method, is considerably more challenging. Our attempt to determine $\gamma \equiv \gamma_{zzzz}$ using the FF approach was in fact unsuccessful. For example, relying on FCI energies,[5] we get $\gamma = 6.2 \times 10^4$ au using the fields $F = \pm 0.002$ and ± 0.004 au, but only $\gamma = 2.1 \times 10^4$ au with smaller fields $F = \pm 0.001$ and ± 0.002 au. Employing yet smaller fields ($\pm 5 \times 10^{-4}$ and $\pm 10^3$ au) gives $\gamma = 4 \times 10^3$ au. The same unstable behaviour is found when employing CCSD energies. In fact, our recent exploration of mathematical and numerical properties of expansions like [21], using the linear response based CCSD approaches, seems to indicate a fundamental problem of the FF approach when considering higher order properties.[6]

We next considered the first-row diatomic hydrides having a doublet or triplet ground state. The total energies, dipole moments, and polarizabilities obtained with both the POL1 and ANO basis sets at the experimental geometries (35) using various methods are summarized in Table 3, and compared with the available experimental values (47–52) in the case of dipole moments. These results enable us to draw a number of interesting conclusions concerning the role of the correlation effects, the use of relaxed (R) vs. nonrelaxed (N) orbitals, and the size of the basis set employed.

The correlation effects may change the computed dipole moments by about 0.1–0.2 D, causing about 10–15% error, which is hardly acceptable when striving for high-quality dipole moments. The same holds for polarizabilities. The computed dipole moments monotonically decrease with the increasing amount of correlation that is accounted for via higher and higher order of excitations. For the POL1 basis, the largest limited single reference CI that we were able to carry out on our Silicon Graphics (Challenge L) minicomputer is CISDT$^+$ (41). In all cases, the CCSD(is) results are very close to the CISDT$^+$ ones. As might be expected with the CC approach (see, for example, ref. 20), the orbital relaxation effects are not significant, amounting to 0.002, 0.005, and 0.012 D for CH, NH, and OH, respectively. The same holds for polarizabilities, where the changes due to the orbital relaxation are in the range of 0.11 to 0.18 au.

While the dipole moments monotonically decrease with the increasing order of excitations that are included in CI calculations, the polarizabilities change in a less regular manner. The SCF α values are first lowered when the correlation due to the singles and doubles is introduced via CISD(is), only to be subsequently increased when the triple excitations are accounted for, as in the CISDT$^+$ method. Thus, generally, we observe the following order of polarizabilities.

$$[23] \qquad \alpha[\text{CISD(is)}] < \alpha(\text{SCF}) < \alpha(\text{CSDT}^+) \approx \alpha[\text{CCSD(is)}]$$

[5] We used the GAMESS package (41) to compute the FCI energies.

so that the uncorrelated SCF value is always closer to the exact result than is the CISD(is) value. Again, the CCSD(is) polarizabilities are very close to the CISDT$^+$ values, as was the case for dipole moments. We should emphasize here, however, that the CISDT$^+$ method employs a much larger excited state manifold than does CCSD(is). In cases considered here, the dimensions of the CISDT$^+$ spaces are in fact more than 10 times larger than those of the corresponding CCSD(is) or CISD(is) problems. Clearly, the CCSD(is) procedure represents the optimal choice when computing dipole moments as well as polarizabilities.

The choice of a suitable basis set is clearly very crucial

Table 4. Optimized bond length R_e (in Å), vibrational frequency ω_e (in cm^{-1}), dipole moment μ (in D), and polarizability α (in au) at the optimized geometries for the ground state of CH($X\ ^2\Pi$), NH($X\ ^3\Sigma^-$), and OH ($X\ ^2\Pi$), obtained with various basis sets.

when computing electric properties. Both basis sets employed by us, i.e., POL1 and ANO, are sufficiently large and flexible to provide meaningful results for a comparison with experiment. In general, the uncorrelated results are much less sensitive to the basis set choice than are highly correlated ones. Thus, the difference between the computed dipole moments when using the POL1 and ANO basis sets is only about 5×10^{-3} D at the SCF level, but almost an order of magnitude larger at the correlated level (0.05, 0.04, and 0.02 D for CH, NH, and OH, respectively). A similar observation can be made for the polarizability.

The results of Table 3 were obtained for the experimental geometries. To find out how much these differ from the theoretical values for the basis sets employed, we also present in Table 4 the computed equilibrium geometries and harmonic vibrational frequencies, as well as the corresponding dipole moments and polarizabilities. In this case, only the CCSD(is) results with the ANO basis set are shown. For a comparison, we also included the geometries and harmonic frequencies obtained with the 6-31G* basis set,[7] and for the CH ground state also with the POL1 basis set. The latter result clearly indicates that the POL1 basis set, which is specifically tailored for the electrostatic property calculations, is not suited for the structure and energetics determinations. Indeed, the CCSD/POL1 geometry is inferior even to the CCSD/6-31G* geometry (differing from the experimental value by 0.03 and 0.01 Å, respectively) and, similarly, for the corresponding harmonic frequencies (87 and 33 cm^{-1}, respectively). The CCSD/POL1 equilibrium bond length being too large implies a too small dipole moment. Introducing the core correlation (although this is not recommended for the POL1 basis), the equilibrium bond length shrinks a little to 1.149 Å. Clearly, with this property-dedicated basis set it is best to employ the experimental geometry. For this reason, we performed the geometry optimization for the NH and OH ground states only with the ANO basis set (Table 4).

The CCSD/ANO geometries for the CH, NH, and OH ground states, shown in Table 4, agree well with experiment (being, respectively, 0.0017, 0.0018, and 0.0025 Å shorter than the experimental values) and represent a significant improvement over the CCSD/6-31G* values, which are longer by 0.011–0.013 Å. The computed CCSD/ANO harmonic frequencies are also in good agreement with experiment (the differences being 13, 35, and 45 cm^{-1}). Since the optimized bond lengths are close to the experimental ones, the dipole moments and polarizabilities obtained for these theoretical geometries differ very little from those based on experimental geometries (cf. Tables 3 and 4).

The computed CH dipole moment (1.413 D) falls within the experimental error bounds (1.46 ± 0.06 D) (47). The dipole moment in the electronic and vibrational ground state of OH was measured by several groups (48–51). The most recently determined rotationally resolved values, obtained with the molecular beam electric resonance technique by Peterson et al. (51), are μ = 1.6549 D for $\Omega = J = 1/2$ and μ = 1.65520 D for $\Omega = J = 3/2$ (we report them as 1.655 D in our tables). Our CCSD/ANO result of μ = 1.649 D agrees well with these results. In view of the availability of these precise, rotationally resolved experimental results, it will be interesting to obtain the corresponding rovibrationally corrected values, as we did for other systems (19*b*).

The least satisfactory agreement between the CCSD/ANO and experimental (52) dipole moments is found for the NH $^3\Sigma^-$ ground state (1.536 vs. 1.38 ± 0.07 D, respectively). In fact, all ab initio calculations that we are aware of (cf. Table

7) report $\mu \geq 1.5$ D. This fact, as well as the senescence of the experimental result, suggest that it would be worthwhile to reexamine the latter.

We next considered the second-row hydrides SiH, PH, and SH in their ground electronic states, using only the POL1 basis set. The results are summarized in Table 5 and exhibit behaviour similar to that of the first-row hydrides. Thus, the computed dipole moments monotonically decrease with the increasing order of excitations included in CI calculations and the CCSD(is) results are again close to the CISDT$^+$ ones, namely,

$$[24] \quad \mu(\text{SCF}) > \mu[\text{CISD(is)}] > \mu[\text{CISD}^+] > \mu[\text{CISDT}^+] \approx \mu[\text{CCSD(is)}]$$

This decrease in the dipole moment value with the increasing correlation is most pronounced in smaller systems, namely in the SiH case, where the SCF value is about three times as large as the CISDT$^+$ result that we employ as our benchmark. For other systems, the differences between the SCF and CISDT$^+$ dipole moments are not so startling and usually do not exceed 30% (see Tables 3 and 5). This was to be expected, since the smaller the dipole moment, the more critical is the electronic charge distribution and thus the correlation effects.

The behaviour of the computed polarizabilities is also similar to that found for the first-row hydrides. The CISD(is) polarizabilities are thus smaller than either the SCF and CISDT$^+$ ones, and the CCSD(is) method rectifies the shortcomings of the CISD(is) method and yields very close results as found with the computationally demanding CISDT$^+$ method. We also note that the effect of orbital relaxation is again very small when using the CCSD(is) approach.

To our knowledge, there are no experimental data available for the dipole moments in the SiH and PH ground states. For SH, two values have been published: μ = 0.62 D by Carrington et al. (56) and μ = 0.758 D by Meerts and Dymanus (57). Our CCSD(is) value of μ = 0.774 D is closer to the latter, more recent, experimental result. Unfortunately, no experimental information is available concerning the polarizabilities, either for the first- or for the second-row hydrides considered.

Finally, we compute the dipole moment and polarizability for the three degenerate excited states of NH using the POL1 basis set and the experimental equilibrium geometry (Table 6). We have seen above that the orbital relaxation played an insignificant role when we examined the ground states of first- and second-row hydrides. It is thus interesting to examine the performance of our UGA-CCSD methods for excited states, while using the nonrelaxed ground state orbitals. Such orbitals, being neither variationally reoptimized for the excited state considered, nor for the applied perturbing electric field, are clearly as far removed from the "ideal" ones as one can get. It is thus very gratifying to see that our CCSD(is) method, employing the ground state, nonrelaxed orbitals, yields reasonably good dipole moments and polar-

Table 7. Comparison of dipole moments (in D) of first- and second-row diatomic hydrides, obtained by various theoretical methods, with experiment.

izabilities (see Table 6), as a comparison with the CISDT+ results or with the experimental values (for the dipole moments) indicates. The fact that we can use nonrelaxed ground state orbitals for the computation of excited state properties is of considerable practical significance, not only for reasons of economy, but also because of the difficulties that one encounters when trying to converge the SCF orbitals for the excited states to a sufficiently high accuracy.

In concluding this section, let us compare our UGA-CCSD(is) dipole moments for the first- and second-row hydrides considered with those obtained by other methods that account for correlation effects in a different way (see Table 7). These methods include the single reference CI, multi- reference CI, coupled electron pair approximation (CEPA) or its variants, coupled pair functional (CPF), and effective valence Hamiltonian (H_v) methods. The latter represents essentially a version of a quasidegenerate MBPT. The results obtained with these various methods for the dipole moment of CH (refs. 58–60), NH (58, 61–64), OH (58, 65–68), SiH (58, 69–72), PH (58, 72, 73), and SH (58, 72, 74) in their ground electronic states are summarized in Table 7 together with our UGA-CCSD(is) results. Al the results for CH are within the experimental error bounds, the CCSD(is) value being the smallest of them all. Likewise, all results for OH are in good agreement with the very accurate experimental value (51) (a rather high value obtained with the H_v method is most likely due to a relatively small basis set employed). Our CCSD value differs by only 0.005 D and belongs amongst the most accurate theoretical results. For SH, all ab initio dipole moments favor the measurements of Meerts and Dymanus (57). Unfortunately, no experimental data are available for the remaining second-row hydrides, SiH and PH. The theoretical results for SiH range between 0.077 and 0.160 D, a rather large spread, although most seem to favor the narrower range between 0.09 and 0.12 D. Similarly, the values for PH range from 0.403 to 0.481 D.

Finally, let us discuss the results for the ground state of NH, where we find a rather serious disagreement between the theoretical and experimental data. As the results assembled in Table 7 indicate, and as already mentioned above, all ab initio dipole moments are in this case larger than 1.5 D. Thus, all these results fall well beyond the reported experimental error bounds of 1.38 ± 0.07 D (52). Clearly, the rovibrational averaging can lower the purely electronic values given in Table 7. Such an averaging was carried out for the MRCI dipole moment and amounted to 0.03 D (63). This decreased the MR CI electronic value of 1.511 D to 1.48 D (for the vibrationless v = 0 level), which is still too large. Clearly, the existing discrepancy between the computed and measured dipole moment of the NH ground state is of concern and should be clarified.

4. LR approach with UGA-CC formalism

We now outline the LR method within the framework of the UGA-based CC approach. The LR method based on the standard CC approach, as first outlined by Monkhorst (11*a*) and Dalgaard and Monkhorst (11*b*), was recently explicitly formulated (17) in the context of the orthogonally spin-adapted CCSD method (18) and fully implemented and tested in our CC codes (17, 19). The most recent version is capable of providing reliable values even for high-order static proper-

ties, such as the second hyperpolarizability, over the whole range of molecular geometries for which the standard CS CCSD approach is applicable, in contrast to the FF methods, which become particularly troublesome for large internuclear separations (footnote 3). Moreover, the LR formalism can be generalized to handle dynamic properties.

We will essentially follow the development as outlined in ref. 17. However, we can no longer use the diagrammatic technique (34) to obtain the required explicit expressions and will have to rely on an algebraic formalism. We must also account for the fact that in the OS case the excitation operators G_I no longer commute. Finally, since our UGA-based CC formalism can handle rather general OS situations, we also do not employ the normal product form of the Hamiltonian.

Starting with the unperturbed problem [3], we consider the perturbed Hamiltonian

$$[25] \qquad H(\lambda) = H + \lambda W$$

where the perturbation W represents the property we are interested in. We thus look for the solution of the corresponding Schrödinger equation

$$[26] \qquad H(\lambda)|\Psi(\lambda)\rangle = E(\lambda)|\Psi(\lambda)\rangle$$

assuming the following general cluster ansatz for $|\Psi(\lambda)\rangle$,

$$[27] \qquad |\Psi(\lambda)\rangle = e^{T(\lambda)}|\Phi\rangle$$

with

$$[28] \qquad T(\lambda) = \sum_I t_I(\lambda) G_I$$

We further assume a power series expansion for the relevant quantities in terms of the perturbation parameter λ, namely,

$$[29] \qquad E(\lambda) = \sum_{i=0}^{\infty} E^{(i)} \lambda^i$$

and

$$[30] \qquad T(\lambda) = \sum_{i=0}^{\infty} T^{(i)} \lambda^i$$

or, equivalently,

$$[31] \qquad t_I(\lambda) = \sum_{i=0}^{\infty} t_I^{(i)} \lambda^i$$

Clearly, the unperturbed problem of Sect. 2 results for $\lambda = 0$ and is characterized by the energy $E^{(0)} \equiv E(0)$ and cluster amplitudes $t_I^{(0)} \equiv t_I(0)$. We also note that in contrast to the CS case (17), when the cluster operators $T^{(i)}$ representing various orders in perturbation expansion [30] commute, in general OS situations we have that $[G_I, G_J] \neq 0$, unless at least one excitation operator is all-external, i.e., does not involve active or valence orbitals. Consequently, we cannot express the wave operator $\exp(T(\lambda))$ as a product of exponential factors, $\exp T^{(i)}$, as we did in the CS case (cf. eq. [30] of ref. 17). Nonetheless, since we employ a single spin-free configuration state $|\Phi\rangle$ as a reference, we can still benefit from the property [11].

Proceeding then as in the unperturbed case, we arrive at the general equation of type [4] or, equivalently

$$[32] \qquad \{H(\lambda) + [H(\lambda), T(\lambda)] + \tfrac{1}{2}[[H(\lambda), T(\lambda)], T(\lambda)] + \cdots\}|\Phi\rangle = E(\lambda)|\Phi\rangle$$

Expanding in powers of λ, we see immediately that the absolute term, resulting for $\lambda = 0$, recovers the unperturbed CC problem of Sect. 2. We can thus assume the zero-order quantities $E^{(0)}$ and $t_I^{(0)}$ to be known. The LR equations then result from the linear terms in λ. For the energy increment $E^{(1)}$, giving the desired expectation value of the considered property $\langle\Psi(0)|W|\Psi(0)\rangle/\langle\Psi(0)|\Psi(0)\rangle = E^{(1)}$, we thus find

$$[33] \qquad E(1) = \langle W\rangle + \sum_{i\geq 1}\langle\{H, T\}_i^{(1)} + \{W, T\}_i^{(0)}\rangle$$

where we introduced the symbol for the symmetrized sum of the kth order commutator terms

$$[34] \qquad \{X, T\}_k^{(i)} = (k!)^{-1} \times \sum_{i_1+i_2+\cdots+i_k=i} [\cdots[[X, T^{(i_1)}], T^{(i_2)}], \cdots, T^{(i_k)}]$$

For example,

$$[35] \qquad \{H, T\}_3^{(1)} = \tfrac{1}{6}([[[H, T^{(0)}], T^{(0)}], T^{(1)}] + [[[H, T^{(0)}], T^{(1)}], T^{(0)}] + [[[H, T^{(1)}], T^{(0)}], T^{(0)}])$$

while

$$[36] \qquad \{H, T\}_1^{(1)} = [H, T^{(1)}]$$

and

$$[37] \qquad \{W, T\}_1^{(0)} = [W, T^{(0)}]$$

Similarly, the corresponding LR CC equations determining the $t_I^{(1)}$ amplitudes have the form

$$[38] \qquad \left\langle G_I^{\dagger}\left[W + \sum_{i\geq 1}(\{H, T\}_i^{(1)} + \{W, T\}_i^{(0)})\right]\right\rangle = 0$$

In view of eq. [11], we can write again for the property value

$$[39] \qquad E^{(1)} = \langle W\rangle + \langle WT^{(0)}\rangle + \tfrac{1}{2}\langle WT^{(0)}T^{(0)}\rangle + \langle HT^{(1)}\rangle + \tfrac{1}{2}\langle H(T^{(0)}T^{(1)} + T^{(1)}T^{(0)})\rangle + \cdots + \frac{1}{24}\langle H[(T^{(0)})^3T^{(1)} + (T^{(0)})^2T^{(1)}T^{(0)} + \cdots + T^{(1)}(T^{(0)})^3]\rangle$$

assuming that W is a one-electron operator.

In CC equations [38], which are linear in the unknown cluster amplitudes $t_I^{(1)}$, we can again have up to eight commutators for the H-containing terms and six for the terms involving W. Again, these high-order terms can only involve semi-internal monoexcitations. Assuming that we employ an ROHF reference (restricted OS HF), the monoexcited $t_I^{(0)}$ amplitudes should be small, and thus the high-order terms

involving their products should be negligible. We recall that a similar situation arises in the zero-order (unperturbed) level of approximation, where the consideration of at most bilinear terms in CCSD equations provides very good results. It will thus be necessary to find out to which extent this feature extends to the LR methods.

Considering various terms in LR CC equations [38] we see again that the linear and bilinear terms (in mixed zero- and first-order amplitudes) can be handled in the same way as the zero-order amplitude terms in the unperturbed case. For example, considering bilinear terms involving the Hamiltonian we find that

$$
\begin{aligned}
[40] \qquad \langle G_I^\dagger \{H, T\}_2^{(1)}\rangle &= \tfrac{1}{2}\langle G_I^\dagger([[H, T^{(0)}], T^{(1)}] \\
&\quad + [[H, T^{(1)}], T^{(0)}])\rangle \\
&= \tfrac{1}{2}\langle G_I^\dagger \{H(T^{(0)}T^{(1)} + T^{(1)}T^{(0)}) \\
&\quad + (T^{(0)}T^{(1)} + T^{(1)}T^{(0)})H \\
&\quad - 2(T^{(0)}HT^{(1)} + T^{(1)}HT^{(0)})\}\rangle \\
&= \tfrac{1}{2}\sum_{J,K} t_J^{(0)} t_K^{(1)} \langle G_I^\dagger \{H(G_J G_K + G_K G_J) \\
&\quad + (G_J G_K + G_K G_J)H - 2(G_J H G_K \\
&\quad + G_K H G_J)\}\rangle \\
&= \sum_{J\le K} (t_J^{(0)} t_K^{(1)} + t_K^{(0)} t_J^{(1)}) c_{IJK}
\end{aligned}
$$

where c_{IJK} are again defined by eqs. [16]–[18]. Thus, for up to bilinear terms the existing codes generating the required coefficients in both CC equations [40] and in the energy expression [39] can be directly exploited. Of course, when evaluating the corresponding terms involving W, we must employ the corresponding one-electron integrals $\langle\mu|w|\nu\rangle$.

The role of higher than bilinear terms in CC equations (although always linear in $t_I^{(1)}$ amplitudes) must also be addressed. Hopefully, most of these higher order terms will turn out to be of little importance, similarly to the unperturbed case.

Solvent isotope effects as a probe of general catalysis and solvation in phosphoryl transfer

Clinton D. Bryan, K. Barbara Schowen, and Richard L. Schowen

Abstract: Phosphoryl transfer to methanol from tris(*p*-nitrophenyl) phosphate (PNNN), methyl bis(*p*-nitrophenyl) phosphate (PMNN), and dimethyl *p*-nitrophenyl phosphate (PMMN) exhibits general base catalysis by acetate ion but no detectable catalysis by acetic acid. For PNNN, acetate catalysis produces normal solvent isotope effects k_{ROH}/k_{ROD} of 1.68 ± 0.01 at high ionic strength (0.475) and 1.77 ± 0.04 at low ionic strength (0.048). A linear proton inventory indicates most simply that the isotope effect arises from a one-proton catalytic bridge in the transition state, although this model cannot strongly be distinguished from a generalized solvation effect. Reactions of methoxide ions produce slight inverse isotope effects k_{ROD}/k_{ROH} of 1.1–1.2, far smaller than the inverse effect of about 2.5 expected for complete and uncompensated desolvation of the reactant-state methoxide ion. The transition state is thus stabilized by substantial interaction with the solvent. The proton inventory for the least reactive substrate PMMN (relative rate constant 1) is suggestive of transition-state stabilization by a combination of one-proton catalytic bridge(s) and distributed sites, while the proton inventory for the most reactive substrate PNNN (relative rate constant 1388) suggests only generalized transition-state solvation (many distributed sites); the proton inventory for PMNN, a substrate of intermediate reactivity (relative rate constant 60), suggests an intermediate situation. The data are consistent with a model in which transition states with exterior concentrations of charge favor stabilization of the charge by isotope-fractionating one-proton bridges, while transition states with distributed charge favor stabilization of the charge by many distributed sites.

Key words: phosphoryl transfer, proton inventories, solvent isotope effects.

Résumé : Le transfert d'un phosphoryle à du méthanol à partir du phosphate de tris(*p*-nitrophényle) (PNNN), du phosphate de méthyle et de bis(*p*-nitrophényle) (PMNN) et du phosphate de diméthyle et de *p*-nitrophényle (PMMN) est sujet à de la catalyse générale des bases, par l'ion acétate, mais sans catalyse détectable par l'acide acétique. Pour le PNNN, la catalyse par l'acétate conduit à des effets isotopiques du solvant qui sont normaux, k_{ROH}/k_{ROD} de 1,68 ± 0,01 à force ionique élevée (0,475) et de 1,77 ± 0,04 à une force ionique plus faible (0,048). Un inventaire linéaire des protons indique de la façon la plus simple que l'effet isotopique découle d'un pont catalytique à un hydrogène dans l'état de transition, même s'il n'est pas facile de distinguer ce modèle d'un effet généralisé de solvatation. Les réactions des ions méthanolates conduisent à de légers effets isotopiques inverses, k_{ROD}/k_{ROH} de 1,1 à 1,2, beaucoup plus faible que l'effet inverse d'environ 2,5 attendu pour une désolvatation complète et non compensée de l'ion méthylate dans l'état de réactif. L'état de transition est donc stabilisé par une interaction importante avec le solvant. L'inventaire de proton pour le substrat le moins réactif, PMMN (constante relative de vitesse de 1), suggère qu'il y a stabilisation de l'état de transition par une combinaison de pont(s) catalytique(s) à un proton et de sites distribués alors que l'inventaire de proton pour le substrat le plus réactif (PNNN, constante de vitesse relative de 1388) ne suggère qu'une solvatation généralisée de l'état de transition (plusieurs sites distribués); l'inventaire de proton pour le PMNN, un substrat de réactivité intermédiaire (constante de vitesse relative de 60), suggère l'existence d'une situation intermédiaire. Les données sont en accord avec un modèle dans lequel les états de transition avec des concentrations extérieures de charge favorisent une stabilisation de la charge par des ponts à un hydrogène provoquant un fractionnement de l'isotope alors que les états de transition comportant un distribution de la charge favorisent une stabilisation de la charge par les divers sites distribués.

Mots clés : transfert de phosphoryle, inventaires de protons, effets isotopiques du solvant.

Introduction

A vital scientific contribution of Professor Richard Bader was made already in his doctoral research with C. Gardner Swain, at the Massachusetts Institute of Technology. Building upon their panoramic critique of preceding studies in reaction kinetics and mechanism, the chemistry and physics of isotopes, and the spectroscopy and thermodynamics of solutions, Bader, Swain, and Edward R. Thornton produced a deeply detailed and complete theory of isotopic solvent effects and of reaction rates in mixtures of isotopic solvents (1–4). Two of us (K.B.S. and R.L.S.) count ourselves among those "present at the Creation" (or shortly thereafter) and have been profoundly influenced by these and others of Richard Bader's contributions throughout a period now approaching 40 years. It is with a spirit of gratitude that we present this paper describing a current application of isotopic solvent effects to the issue of the *Canadian Journal of Chemistry* celebrating the scientific contributions of Richard Frederick William Bader.

Displacement at phosphorus at the phosphate level of oxidation is of particular importance in biochemistry, where it dominates bioenergetics, the formation and decomposition of the genetic materials DNA and RNA, the regulation of protein properties accompanying transmembrane signal transduction, and many other vital processes. In mechanistic chemistry, the understanding of the mechanism of the reaction remains a subject of vigorous investigation and debate. A comprehensive background on all aspects of this broad subject may be derived from the magisterial review of Thatcher and Kluger (5).

Solvent isotope effects provide an entry to the examination of two aspects of phosphoryl-transfer mechanistic chemistry: (*i*) the role of general acid–base catalysis (where the catalytic proton bridge may be expected to generate an isotope effect), and (*ii*) the desolvation or solvation of centers that lose or develop solvation sites of sufficient basicity to produce hydrogen-isotope fractionation.

Biochemical phosphoryl transfer reactions are sometimes hydrolytic, as in the dephosphorylation of phosphoproteins, but they often involve transfer from phosphoryl donors to non-water nucleophiles: examples include the formation of 2′,3′ cyclic phosphoryl derivatives in the cleavage of RNA by ribonucleases, the formation of phosphoryl serine and tyrosine residues in regulatory events, and the self-splicing of RNA molecules. In these cases, alcoholysis reactions at phosphate centers are occurring either intramolecularly or within catalyst–substrate complexes.

We report here some transition-state structural and energetic features of the phosphate alcoholysis reactions illustrated in Fig. 1. These reactions bear some relationship to the ribonuclease reaction just described, although the systems studied here are artificially activated by use of *p*-nitrophenoxy leaving groups in place of the alkoxy leaving groups present in the natural systems.

Results

General-base catalysis of the methanolysis of PNNN and PMNN

The rate of methanolysis of tris(*p*-nitrophenyl) phosphate (PNNN) was examined (as described in the Experimental section) in methanolic acetate buffers as a function of both buffer ratio and total buffer concentration. Figure 2 shows plots of observed rate constants vs. total buffer concentration at five different buffer ratios (the data are given in Table S1 of the supplementary material[3]). It is not visually obvious but the dependences show a slight upward curvature, probably resulting from a specific salt effect that accompanies replacement of sodium acetate by sodium bromide; thus small negative intercepts with large errors are calculated, as reported in Table S2.[3] When the intercepts were constrained to be zero as in Fig. 2, little change in the mean values of the second-order rate constants resulted and the rate constants thus calculated were used subsequently.

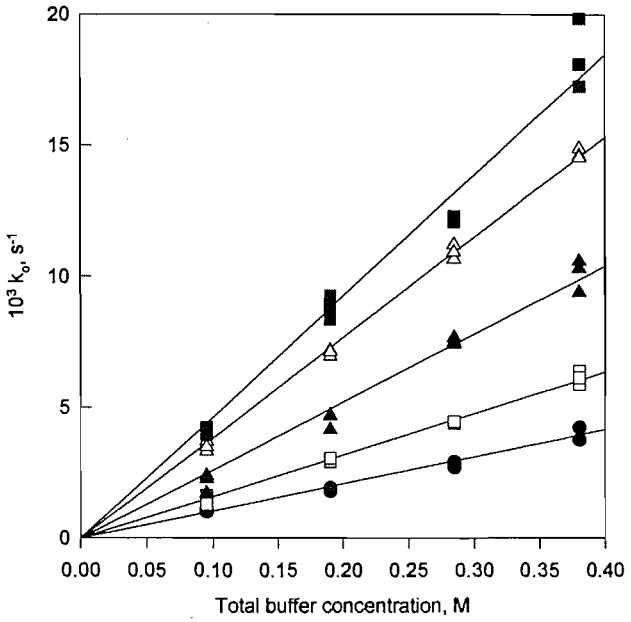
A plot (Fig. 3) of the buffer catalysis constant vs. fraction of base in the buffer shows catalysis to arise only from acetate ion. In these buffers, the reaction is therefore general-base cat-

Fig. 1. The reaction with methanol of the three substrates studied in this work.

$$OP(OAr)(OR^1)(OR^2) + CH_3OH \rightarrow OP(OCH_3)(OR^1)(OR^2) + ArOH$$

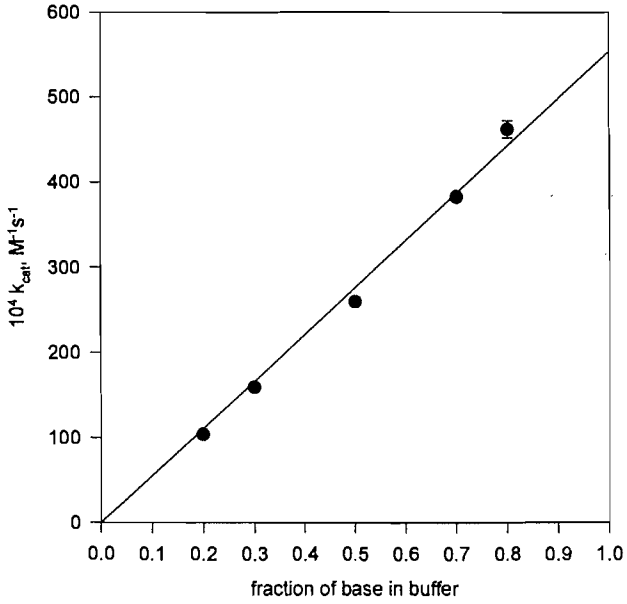
Ar = *p*-nitrophenyl
PNNN: $R^1 = R^2 = Ar$
PMNN: $R^1 = Ar$, $R^2 = CH_3$
PMMN: $R^1 = R^2 = CH_3$

Fig. 2. Observed first-order rate constants for the methanolysis of PNNN as a function of total buffer concentration in acetic acid–sodium acetate buffers at 25.0°C and ionic strength of 0.475 adjusted with sodium bromide. The mole fraction of sodium acetate in the buffer is 0.2 (bottom curve, filled circles), 0.3 (open squares), 0.5 (filled triangles), 0.7 (open triangles), 0.8 (filled squares).



[3] Sets of original data are deposited with the National Research Council of Canada and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Fig. 3. Second-order rate constants for acetate – acetic acid buffer catalysis (slopes of the lines in Fig. 2) as a function of the mole fraction of acetate base in the buffer. The data indicate that acetate and not acetic acid is the catalytic component of the buffer.



alyzed and not general-acid catalyzed. The value of the second-order rate constant for acetate ion general catalysis is $(5.54 \pm 0.11) \times 10^{-2}\ M^{-1}\ s^{-1}$.

A brief examination was made of the buffer catalysis of the methanolysis of dimethyl *p*-nitrophenyl phosphate (PMMN) by a 1:1 buffer of acetic acid and sodium acetate at total buffer concentrations of 0.5, 0.7, and 0.95 M without added salt (Table S3[3]). Assuming acetate ion to be the sole catalyst, its second-order rate constant is $(2.25 \pm 0.22) \times 10^{-4}\ M^{-1}\ s^{-1}$.

Solvent isotope effect and proton inventory for the acetate-catalyzed methanolysis of PNNN

The rate constants for general-base catalysis by acetate ion of the methanolysis of PNNN in CH_3OH, CH_3OD, and binary mixtures of the isotopic solvents were obtained from the observed first-order rate constants in 1:1 buffers of acetic acid and sodium acetate. It was assumed that, as in CH_3OH, acetate was the sole catalyst in the deuterated solvents (otherwise an infinite inverse isotope effect for acetic acid catalysis would be required). The first-order rate constants are presented in Table S4[3] (for an ionic strength of 0.475 maintained by added sodium bromide) and in Table S5[3] (for an ionic strength of 0.048 maintained by added sodium nitrate). The acetate ion catalytic constants are given in Tables 1 and 2.

Solvent isotope effects and proton inventories for the methoxide ion promoted methanolysis of PNNN, PMNN, and PMMN

In Tables S6, S7, and S8 of the supplementary material[3] are given first-order rate constants for methoxide ion promoted methanolyses of PNNN, PMNN, and PMMN in CH_3OH, CH_3OD, and binary mixtures of the isotopic solvents. In a manner reminiscent of the behavior in acetate buffers described above, the plots of first-order rate constants against sodium methoxide concentration exhibited a small upward curvature so that when the data were fitted to a straight line, small but definite negative intercepts with large errors were calculated. A reasonable explanation is a specific salt effect resulting from the replacement of bromide ion by methoxide ion. When the intercepts were constrained to be zero, only modest effects on the calculated second-order rate constants resulted. Values obtained in this way were therefore employed in subsequent considerations. The results of these calculations are presented for the reactions of PNNN, PMNN, and PMMN, respectively, in Tables 3, 4, and 5.

Discussion

Transition-state stabilization in general-base catalyzed methanolysis of *p*-nitrophenyl phosphate esters

General base catalysis of these reactions by acetate ion can in principle occur in any of the following catalytic modes:
(*i*) *nucleophilic mode*, in which the acetate ion displaces *p*-nitrophenoxide ion to form a rapidly solvolyzed acetyl phosphate intermediate;
(*ii*) *protolytic mode*, in which a transition state for attack by

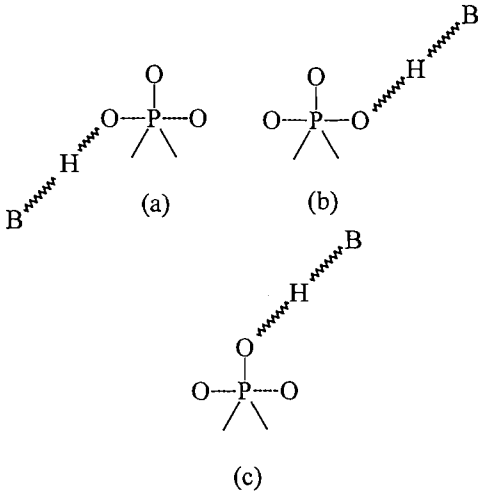
Fig. 4. Three forms of transition-state stabilization for protolytic general-base catalysis of nucleophilic displacement at phosphate-phosphorus. Note that all structures are isomeric and thus kinetically indistinguishable. (*a*) Proton bridging from an attacking nucleophile ROH to a general base B (class n or "classical general-base" catalysis). (*b*) Proton bridging from the conjugate acid of the general base B to the departing leaving-group ArO^- (class e or "specific-base general-acid" catalysis). This is often thought to be probable only if leaving-group departure is occurring in the rate-limiting transition state, as in a concerted displacement reaction. (*c*) Proton bridging from the conjugate acid of the general base B to the P═O oxygen (another form of class e or "specific-base general-acid" catalysis). This is often thought to be probable only if leaving-group departure is not occurring in the rate-limiting transition state, as in formation of a trigonal-bipyramidal adduct.



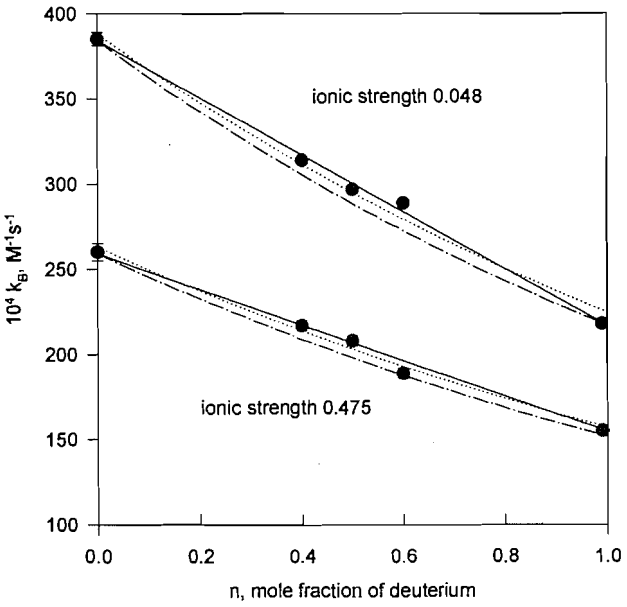
methanol is stabilized through a protonic bridge between an acetate anion and a nucleophilic center in the remainder of the transition state; a protolytic transition state may have several isomeric structures, illustrated in Fig. 4 (for nomenclature, see ref. 6):

(*a*) *protolytic mode class n* (Fig. 4*a*), in which acetate ion accepts a proton bridge from a nucleophilically attacking methanol molecule (often called "classical general-base catalysis");

(*b*) *protolytic mode class e* (Fig. 4*b*,*c*), in which acetic acid donates a proton bridge to a center in the transition state for methoxide ion nucleophilic attack at phosphorus, the most likely acceptor sites being the P═O oxygen or the *p*-nitrophenoxide oxygen (the former more likely if a trigonal-bipyramidyl intermediate is forming, the latter more likely if the displacement reaction is concerted).

The nucleophilic mode is expected to produce only small isotope effects (see below for expected magnitudes) from generalized solvation changes between reactants and transition state, while the various protolytic modes are expected to generate larger isotope effects from the proton in the bridging site of the transition state. In principle, this protonic bridge may be formed of a proton that is "in flight," undergoing transfer in a manner coupled in the reaction coordinate to other bonding changes in the transition state, or it may be stabilizing the transition state through a relatively strong kind of hydrogen bond-

Fig. 5. Proton inventories for the acetate ion general-base catalyzed methanolysis of PNNN at ionic strengths 0.048 (maintained with sodium nitrate) and 0.475 (maintained with sodium bromide). The solid circles represent the experimental data from Tables 1 and 2; where error bars are not visible, they lie within the space of the symbol. The data are buffer catalysis constants at fraction of base 0.5. The solid curves are linear and correspond to one-proton catalysis and to linear least-squares best fits of the data ($10^4 k_B$ (M^{-1} s^{-1}) = (384 ± 3) [1 − n + n(0.565 ± 0.012)] for the upper curve; $10^4 k_B$ (M^{-1} s^{-1}) = (259 ± 3) [1 − n + n(0.585 ± 0.002)] for the lower curve). The dotted curves are exponential and are least-squares fits with no constraints ($10^4 k_B$ (M^{-1} s^{-1}) = (388 ± 7) (0.579 ± 0.020)^n for the upper curve; $10^4 k_B$ (M^{-1} s^{-1}) = (263 ± 4) (0.597 ± 0.019)^n for the lower curve. The dash-dot curves are exponential representations with the rate constant in methanol-h and the isotope effect constrained to the values obtained in the linear best fit.



ing but not participating in the reaction-coordinate motion. The "in flight" proton bridge might be expected to generate larger, and the hydrogen-bonding proton bridge smaller isotope effects (for the question of whether the proton in general acid–base protolytic catalysis need be considered "in flight," see refs. 7–9).

The isotope effects observed in this work for acetate ion catalysis of the methanolysis of PNNN are 1.77 ± 0.04 (low ionic strength) and 1.68 ± 0.01 (high ionic strength). These would generally be regarded as indicative of protolytic catalysis rather than nucleophilic catalysis, although prudence suggests that they be seen as borderline cases. However, if the isotope effects derive completely from a one-proton protolytic bridge, they should generate a linear *proton inventory* (10–14), i.e., plot of rate constant vs. mole fraction of deuterium in mixtures of methanol-*h* and methanol-*d*. If, on the other hand, the isotope effects arise from generalized solvation changes, they should give an exponential proton inventory. This treatment assumes that the relatively weakly basic acetate ion produces negligible isotope fractionation so that the entire solvent isotope effect derives from transition-state sites.

Figure 5 shows the data compared with linear and exponential models. The solid curves describe the linear, protolytic model and are obviously consistent with the data at both ionic strengths. The dotted curves represent unconstrained exponential fits to the data, and are equally consistent with the data at both ionic strengths. Thus, the proton-inventory data do not rigorously distinguish protolytic from nucleophilic catalysis. However, the dash-dot lines provide a suggestive indication that protolytic catalysis may be at work. In these exponential, generalized-solvation models, the rate constants in methanol-*h* and methanol-*d* have been constrained to the values from the linear fit, which are closer to the measurements at the low and high limits of deuteration. These models clearly make a poorer fit to the data than the linear models. We therefore conclude that the more probable mode of catalysis is protolytic but that contributions from nucleophilic catalysis or another generalized-solvation model cannot be rigorously excluded. The protolytic catalysis model may apply as well to the observation of Bel'skii et al. (15) that triethanolamine catalysis of the ethanolysis of diphenyl *p*-nitrophenyl phosphate produces a solvent isotope effect of 2.

The data show that any one-proton bridge that is present is producing an isotope effect no larger than the observed isotope effect of 1.7–1.8: the observed isotope effect is not the resultant of a much larger effect from the proton bridge, partly cancelled by inverse solvent isotope-effect contributions arising from "tightly bound" sites in the solvation sphere of the transition state. An isotope effect from a one-proton catalytic bridge can be as small as 1.7–1.8 in at least two ways: (*a*) the proton may be "in flight" but very asymmetrically disposed between donor and acceptor atoms (16); (*b*) the proton may be in a stable potential with a structure that generates some isotope fractionation, such as the kind of hydrogen bond observed by Kreevoy and Liang (17), a suggestion originally made by Eliason and Kreevoy (18) and others (19) and lately revived under the rubric of "low-barrier hydrogen bonds (20)." Our data cannot distinguish these concepts, although we favor the latter hypothesis for reasons earlier presented (9). *We conclude from these data that a major part of the isotope effect of 1.7–1.8 is associated with a one-proton catalytic bridge in the transition state, with possible contributions from generalized solvation changes.*

Transition-state stabilization in methoxide ion promoted methanolysis of *p*-nitrophenyl phosphate esters

The simplest view of methoxide ion promoted methanolysis of PNNN, PMNN, and PMMN is that methoxide ion is bonding to P in the transition state, with its charge appearing chiefly (*a*) on the oxygen of the P═O group if a hypervalent adduct is forming (such an adduct should expel the ArO leaving group quite rapidly, so formation of the adduct should be the rate-limiting step), or (*b*) on the oxygen of the ArO leaving group (perhaps also on the oxygen of the P═O) if a concerted displacement is occurring. Methanol molecules could be interacting at any of these sites to stabilize the negative charge. On one model, the individual interactions might be quite numerous, weak, and generate only small isotope fractionation at each site; we refer to this model as a "solvation only" model. On the other hand, methoxide ion may be playing the same role in transition-state stabilization that is played by acetate ion in the buffer-catalyzed reaction: there may be transition-

state stabilization (at any of the three sites in Fig. 4) by means of a one-proton bridge. We call this model a "proton-bridge plus solvation model," since more diffuse solvation may also be occurring.

Methoxide ion itself is triply solvated by methanol molecules that generate substantial isotope fractionation (21–24). Each site has a deuterium fractionation factor (10–14) of 0.74 (expressing the deuterium preference relative to an average site in the bulk methanol solvent, so that protium is preferred in the three solvating sites by a factor of 1/0.74 = 1.35). Kresge's formulation (25) can be used to express this reactant-state contribution and the transition-state contribution to the partial solvent isotope effect k_n/k_0. Here k_n is the rate constant in a mixed isotopic solvent with mole fraction n of CH_3OD; k_0 is then the rate constant in methanol-h (n = 0). The result is shown in eq. [1] and eq. [2], where TSC means "transition-state contribution" and RSC means "reactant-state contribution."

$$[1] \quad k_n/k_0 = \text{TSC/RSC} = \text{TSC}/(1 - n + n[0.74])^3$$

$$[2] \quad k_0\,(\text{TSC}) = k_n\,(1 - n + n[0.74])^3$$

A plot of the right-hand side of eq. [2] vs. n can then be used to explore the number of isotope-fractionating sites and the size of the associated isotope effects in the transition states for the methoxide ion promoted methanolysis of PNNN, PMNN, and PMMN. Such plots are shown in Figs. 6, 7, and 8, respectively.

First it should be noted that the observed isotope effects are only slightly inverse for all three substrates, while complete liberation of the three methanol molecules solvating the reactant-state methoxide ion with no compensating effects in the transition state would have produced an inverse solvent isotope effect of $(1/0.74)^3 = 2.47$. Therefore, in all three cases, the transition state includes one or more strongly isotope-fractionating sites that prefer protium over deuterium.

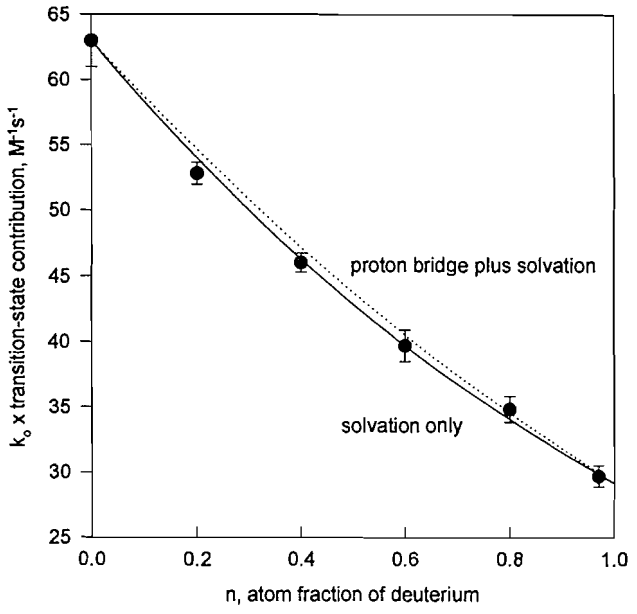
Two plausible, limiting models may readily be generated for such interactions, as described above. On a "solvation only" model, there could be large numbers of sites each generating a quite small amount of isotope fractionation. This model will generate (10–14) an exponential dependence on n (eq. [3], where k_1 is the rate constant in CH_3OD). On a "proton bridge plus solvation" model, one site could be generating isotope fractionation analogous to that in the acetate-catalysis transition state, while the remaining sites could be numerous and diffuse. This situation corresponds to eq. [4], where we have arbitrarily taken the one-proton bridge to generate an isotope effect of 1.5.

$$[3] \quad k_n\,[1 - n + n(0.74)]^3 = k_0\,(k_1/k_0)^n$$

$$[4] \quad k_n\,[1 - n + n(0.74)]^3 = k_0\,[1 - n + n/(1.5)](1.5\,k_1/k_0)^n$$

In Figs. 6, 7, and 8, the "solvation only" model of eq. [3] is plotted as the solid curve and the "proton bridge plus solvation" model of eq. [4] as a dotted curve. Clearly the data lie very close to the predictions of both models, which are only slightly different, so no reliable distinction is possible. On the other hand, a suggestive trend can be noted by comparing the results in the three figures. For the most reactive substrate

Fig. 6. Proton inventory of the transition-state contribution to the solvent isotope effects for methoxide-promoted methanolysis of PNNN, $k_M[1 - n + n(0.74)]^3$. The solid curve is exponential and corresponds to the least-squares best fit to the data, $k_M = 63(0.463 \pm 0.006)^n$. It represents a model in which the entire transition-state contribution to the solvent isotope effect is ascribed to generalized solvation effects. The dotted curve is a plot of the equation, $k_M = 63\,[1 - n + (n/1.5)](0.70)^n$, corresponding to a model that ascribes an isotope effect of 1.5 to a one-proton catalytic bridge analogous to that for acetate catalysis and the remainder of the isotope effect to generalized solvation effects.



PNNN (Fig. 6), the experimental points for the most part lie on or below the curve for "solvation only." For the least reactive substrate, PMMN (Fig. 8), the experimental points lie a good deal closer to the "proton bridge plus solvation" model. For the substrate of intermediate reactivity, PMNN (Fig. 7), the experimental points lie between the curves for the two models.

We interpret these results as consistent with a relationship between *charge concentration* and *one-proton catalytic bridging*. For the least reactive substrate PMMN, where the negative charge is least stabilized by and least dispersed over the non-reacting phosphorus ligands and is thus most concentrated on the three sites (Fig. 4) at which one-proton catalytic bridging is expected, the data lie closest to a model that includes a one-proton bridge. For the most reactive substrate PNNN, where the non-reacting ligands can most effectively disperse the charge, the data lie closest to a model in which the solvating interactions are distributed over many sites, with little isotope fractionation at any single site. The choice of 1.5 as the value of the isotope effect for the one-proton bridge, although arbitrary, is reasonable. Values greater than 1.5 force the dotted curve toward linearity and a poorer fit to the data; values less than 1.5 force the curve down toward that of the pure solvation model.

For the most reactive substrate PNNN, a comparison can be made between the methoxide ion promoted reaction and the acetate ion catalyzed reaction. The methoxide ion reaction

Fig. 7. Proton inventory of the transition-state contribution to the solvent isotope effects for methoxide-promoted methanolysis of PMNN, $k_M[1 - n + n(0.74)]^3$. The solid curve is exponential and corresponds to the least-squares best fit to the data, $k_M = 2.71(0.513 \pm 0.005)^n$. It represents a model in which the entire transition-state contribution to the solvent isotope effect is ascribed to generalized solvation effects. The dotted curve is a plot of the equation, $k_M = 2.71\ [1 - n + (n/1.5)](0.77)^n$, corresponding to a model that ascribes an isotope effect of 1.5 to a one-proton catalytic bridge analogous to that for acetate catalysis and the remainder of the isotope effect to generalized solvation effects.

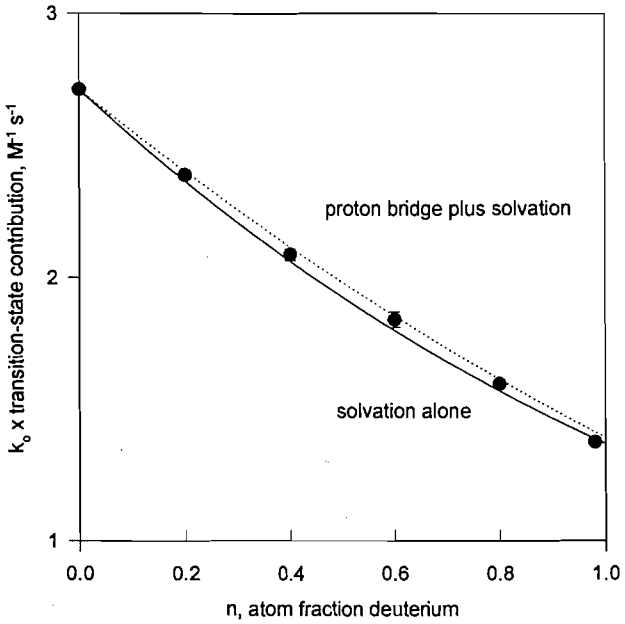


Fig. 8. Proton inventory of the transition-state contribution to the solvent isotope effects for methoxide-promoted methanolysis of PMMN, $100k_M[1 - n + n(0.74)]^3$. The solid curve is exponential and corresponds to the least-squares best fit to the data, $100k_M = 4.54(0.502 \pm 0.005)^n$. It represents a model in which the entire transition-state contribution to the solvent isotope effect is ascribed to generalized solvation effects. The dotted curve is a plot of the equation, $100k_M = 4.54\ [1 - n + n/(1.5)](0.75)^n$, corresponding to a model that ascribes an isotope effect of 1.5 to a one-proton catalytic bridge analogous to that for acetate catalysis and the remainder of the isotope effect to generalized solvation effects.

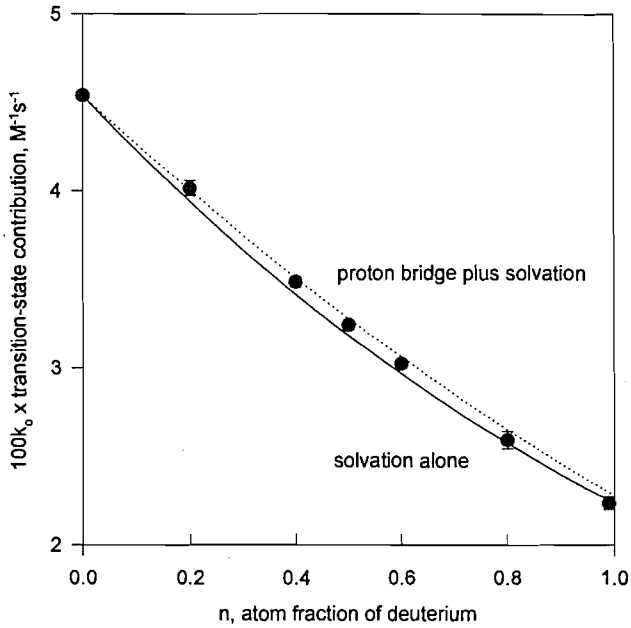

obeys a "solvation only" model, suggesting that methoxide ion attacks as a nucleophile rather than serving as a protolytic general-base catalyst for attack of one of its solvating methanol molecules. Acetate ion, on the other hand, we suggest to serve as a protolytic catalyst for attack of one of its solvating methanol molecules rather than to attack directly as a nucleophile. Thus our suggestion holds that between the strong nucleophile methoxide ion (direct attack, "solvation only") and the weak nucleophile acetate ion (one-proton catalysis of methanol attack), the mechanism changes from nucleophilic catalysis (strong nucleophile) to protolytic catalysis (weak nucleophile). This in turn implies that the protolytic mechanism is less sensitive to nucleophile basicity (smaller Brönsted ß) than the nucleophilic mechanism, and that the nucleophile therefore bears a larger part of the overall unit negative charge in the protolytic than in the nucleophilic transition state. While we have no direct evidence on the point, such a situation appears entirely possible.

We conclude from these data that proton-bridge stabilization of transition states, as in protolytic general acid–base catalysis, tends to be associated with concentrations of charge, probably on the exterior periphery of the transition state, while stabilization through generalized or distributed solvation interactions, relatively numerous and with small isotope fractionation at individual sites, tends to occur in transition states with dispersed charge.

Experimental section

Materials

Anhydrous sodium nitrate (Merck), sodium bromide (Fisher Scientific), and sodium acetate (Fisher Scientific) were stored in a vacuum oven for no less than 2 days at 120–150°C before use; glacial acetic acid (Fisher Scientific) was used as obtained. Methanol (Fisher Scientific and MCB Reagents), acetonitrile (MCB Reagents), and dichloromethane were distilled through a 48 cm Vigreux column after storage over 4A molecular sieves for no less than 2 days. Methanol-*d* (Aldrich Gold Label) was used as obtained. Tris(*p*-nitrophenyl) phosphate (Sigma; PNNN) was used as obtained.

Methyl bis(*p*-nitrophenyl) phosphate (PMNN) and dimethyl *p*-nitrophenyl phosphate (PMMN) were prepared according to Hamilton et al. (26). To PNNN in dichloromethane was added 0.1 M methoxide solution, slowly (1 drop in 10 s) with vigorous stirring, as reaction progress was monitored by TLC. When PNNN was no longer observed, the solution was immediately extracted five times with 10% aqueous potassium carbonate solution and stored 24 h over sodium sulfate. PMNN was recrystallized from 5:12 chloroform – carbon tetrachloride solution (mp 140.5–141.5°C (lit. (26) mp 141–143°C)). Methoxide addition 10-fold faster, followed by extraction with water and 1% sodium carbonate, drying, and evaporation of the dichloromethane, produced a yellow oil. PMMN was

obtained by vacuum distillation through a short-path apparatus (bp 152°C at 0.54 Torr (lit. (27) bp 151°C at 0.51 Torr)). (1 Torr = 133.3 Pa.)

Extinction coefficients

Extinction coefficients were determined in methanol for each component of the reaction mixtures monitored, and in methanolic acetate buffers and sodium methoxide solutions for some materials. The values are given in Table S9 of the supplementary material.[3]

Kinetics procedure

The solvolysis kinetics were determined spectrophotometrically using a personal-computer-interfaced Perkin–Elmer 555 recording spectrophotometer. Temperature was controlled at 25.0°C using a thermostatted cell holder. Buffer or sodium methoxide solutions (950 μL) were thermally equilibrated in a 1.0 cm cuvet for no less than 3 minutes. To initiate reaction, 50 μL of a stock solution of substrate (in acetonitrile) was injected with a pipetter or syringe. The reaction was monitored at 315 nm (acetate buffers) or 388 nm (sodium methoxide solutions), and the data collected by a computer program package developed by the Instrumentation Design Laboratory of the University of Kansas.

Solutions

Acetate buffers were prepared by dilution of weighed samples of the components with appropriate volumes of methanol. Appropriate volumes of these stock solutions were mixed to prepare buffer solutions of desired acid–base ratio. Volumes of stock solutions of sodium nitrate or sodium bromide were added to maintain the desired ionic strength. Sodium methoxide solutions (about 0.1 M) were prepared by weighing sodium under cyclohexane, then washing the metal with methanol, and dissolving it in degassed absolute methanol (Dry Ice – acetone bath). Solutions were standardized against dried potassium biphthalate or against 2-phenylquinoline-4-carboxylic acid (cinchophen) in dimethylformamide–benzene with exclusion of moisture and carbon dioxide. Substrate stock solutions were prepared by weight in dried distilled acetonitrile.

Treatment of data

The generation of *p*-nitrophenol in a solution initially containing only PNNN deviates slightly from an exponential time course because the product PMNN also generates *p*-nitrophenol and PMMN, which in turn generates *p*-nitrophenol. A similar deviation is seen in reactions of PMNN. In principle, the system can be described as a sequence of three irreversible reactions. However, PNNN is around 25 times more reactive than PMNN, which is about 60 times more reactive than PMMN. Thus the absorbance change associated with reactions of PNNN and PMNN can be described as a first-order process with a small zero-order correction (eq. [5]):

$$[5] \quad [\mathrm{ArOH}]_t = [\mathrm{R}]_0(1 - e^{-kt} + at)$$

Here R refers to either PNNN or PMNN, k is the rate constant for reaction of R, and a is the rate constant for reaction of the product formed from R (i.e., PMNN or PMMN, respectively). Least-squares fitting of the data to eq. [5] gives good values of k and values of a that are not inconsistent with the values obtained from the corresponding first-order reaction but which were not used further.

Orthogonal effective atomic orbitals in the topological theory of atoms

I. Mayer

Abstract: A simple formalism has been developed permitting us to extract, from the molecular wave functions, the *effective orthogonal atomic orbitals* characterizing the actual state of the atom in the molecule within the framework of Bader's topological theory of atoms. This may give important conceptual connections between the SCF wave functions obtained in the large-scale ab initio calculations, or even at the Hartree–Fock limit, and the traditional atomic orbital picture. The method is based on some partial orthogonality properties of the non-orthogonal localized molecular orbitals constructed by requiring a maximal weight in the given atomic domain, or in another selected molecular fragment. (The use of such localized orbitals may also be of independent interest.)

Key words: effective atomic orbitals, atomic orbitals from molecular wave functions, non-orthogonal localized orbitals, topological theory of atoms, Bader's theory of atoms in molecules.

Résumé : On a mis au point un formalisme simple qui permet d'extraire, à partir des fonctions d'ondes moléculaires, les *orbitales atomiques orthogonales effectives* qui caractérisent l'état réel de l'atome dans la molécule dans le cadre de la théorie topologique des atomes de Bader. Cette possibilité peut conduire à des relations conceptuelles importantes entre les fonctions d'onde en champ autocohérent obtenues lors de calcules ab initio à grande échelle, ou même dans les limites de Hartree–Fock, et les représentations traditionnelles des orbitales atomiques. La méthode est basée sur quelques propriétés d'orthogonalité partielle des orbitales moléculaires localisées, mais non orthogonales, construites en imposant une hauteur maximale dans un domaine atome donné ou dans un autre fragment moléculaire choisi. (L'utilisation de telles orbitales localisées peut aussi avoir un intérêt par lui-même.)

Mots clés : orbitales atomiques effectives; orbitales atomiques dérivés de fonctions d'ondes moléculaires; orbitales moléculaires localisées, non orthogonales; théorie atomique topologique; théorie de Bader des atomes dans les molécules.

[Traduit par la rédaction]

1. Introduction

The atomic orbital concept is of central importance in our understanding of the basic properties of molecules. The notion that atoms enter molecules with their $1s$, $2s$, $2p$, etc. orbitals (or their hybrids) is so fundamental that its importance can hardly be overestimated: our general picture about the electronic (and also geometrical, etc.) structure of molecular systems is mainly based on this qualitative, but extremely fruitful, application of quantum mechanics. However, as the computational schemes of quantum chemistry developed, it became more and more difficult to find direct links between the results of large-scale ab initio calculations and traditional atomic orbital (AO) concepts. Energetic considerations became paramount, often hiding the atomic nature of the chemical problems.

Bader's topological theory of atoms (see ref. 1) represented a very important step towards establishing a firm theoretical basis for the chemist's view on molecules as consisting of *atoms*, which is something additional to the picture of molecules representing merely assemblies of electrons and nuclei. The aim of the present paper is to show that in the framework of Bader's theory one can also regain the traditional AO description by an *a posteriori* analysis of the large-basis ab initio SCF results (or even the wave functions corresponding to the Hartree–Fock limit) producing the *effective* — distorted but still orthogonal — atomic orbitals by which the atom in question participates in formation of the molecular orbitals. To do this, we shall develop a non-orthogonal localized orbital analysis using an "extrinsic" localization criterion: maximizing the weight of each localized molecular orbital (LMO) within the selected part of the space. The orthogonal AOs are then obtained by applying the results to the special case of individual atomic domains and utilizing some partial orthogonality properties of the non-orthogonal LMOs introduced. This permits introduction of the concept of effective AOs within the molecule in a *basis-independent* manner. The present approach represents a generalization of the recent one (2) involving Mulliken's population analysis.[2] Numerical applications of the latter showed full agreement with the traditional AO picture: for all "ordinary" compounds

Received July 28, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

[2] The analogy is, however, somewhat different from that seen (3) in the case of bond order and valence indices.

one obtains as many molecular orbitals appreciably localized on the given atom as are contained in the classical "minimal basis" for that atom (2). One may also expect similar results in the framework of Bader's theory.

It should be noted that by selecting fragments consisting of two (or more, if necessary) adjacent atomic domains, the present formalism permits one to obtain localized bonding orbitals, etc. as well, which may also be of independent interest. However, it must be stressed once again, that — contrary to more customary localization schemes performing *unitary* transformation of the canonical MO — we do not require the different LMOs to be orthogonal to each other. In fact, the single Slater-determinant SCF wave function is invariant (up to an insignificant constant factor) with respect to any *nonsingular* linear transformations among the occupied orbitals, not only to the unitary ones, and the conservation of orbital orthogonality is only a matter of convenience but not that of essence. At the same time the use of non-orthogonal LMOs permits distinguishing between delocalization effects of "physical" and "mathematical" type (4) — the former correspond to the actual interactions in the system studied, while the latter are simply due to the orthogonality requirement and give rise to so-called orthogonality tails in the LMOs, reducing the degree to which a given LMO is localized on the corresponding molecular fragment.

2. Equations for determining the localized orbitals

We start with considering a general (non-singular but not necessarily unitary) transformation of the occupied molecular orbitals, permitting each LMO φ_i^l to be maximally localized in the respective molecular domain X_i, selected for it. If we introduce the notation $\langle\varphi|\psi\rangle_{X_i}$ for the integration restricted to the volume Ω_i of the domain X_i,

$$[1] \qquad \langle\varphi|\psi\rangle_{X_i} = \int_{\Omega_i} \varphi^*(\boldsymbol{r})\psi(\boldsymbol{r})\mathrm{d}v$$

then the relative weight of the localized orbital φ_i^l in the domain X_i is given by

$$[2] \qquad M_i = \frac{\langle\varphi_i^l|\varphi_i^l\rangle_{X_i}}{\langle\varphi_i^l|\varphi_i^l\rangle}$$

Because there is no restriction concerning the unitary character of the localization transformation, each LMO can be determined independently, so we may require the fulfillment of the condition

$$[3] \qquad \delta M_i = 0$$

for each orbital separately.

The localized orbitals φ_i^l are obtained from the canonical orbitals φ_i^c by a linear transformation characterized by the transformation matrix $\boldsymbol{A}$:

$$[4] \qquad \varphi_i^l = \sum_{j=i}^{n} A_{ji}\varphi_j^c$$

n being the number of the occupied orbitals. The only restriction is $\det(\boldsymbol{A}) \neq 0$. If we define the ith column of matrix $\boldsymbol{A}$ as an n-dimensional vector $\boldsymbol{a}^i$ (its elements are $a_j^i = A_{ji}$), a trivial derivation gives (in matrix notations)

$$[5] \qquad M_i = \frac{\boldsymbol{a}^{i\dagger}\boldsymbol{Q}^i\boldsymbol{a}^i}{\boldsymbol{a}^{i\dagger}\boldsymbol{a}^i}$$

where the elements of the n by n matrix $\boldsymbol{Q}^i$ are defined as

$$[6] \qquad Q_{jk}^i = \langle\varphi_j^c|\varphi_k^c\rangle_{X_i}$$

and orthonormalization of the canonical orbitals φ_i^c has been utilized. From eq. [5] one obtains, in a standard manner, that the requirement $\delta M_i = 0$ is equivalent to the Hermitian n by n matrix eigenvalue equation

$$[7] \qquad \sum_{j=1}^{n} Q_{kj}^i a_j^i = M_i a_k^i$$

for determining the coefficients $A_{ki} = a_k^i$ to be substituted into eq. [4].

3. Analogy with the LMOs derived from Mulliken's population analysis and alternative forms of the equations

In practical calculations one uses the finite basis expansion

$$[8] \qquad \varphi_j^c = \sum_{\mu=1}^{m} c_{j,\mu}^c \chi_\mu$$

for the canonical orbitals, where the $c_{j,\mu}^c$ are the LCAO coefficients and χ_μ is the μth basis orbital, and searches the localized orbitals φ_i^l in a similar form:

$$[9] \qquad \varphi_i^l = \sum_{\mu=1}^{m} c_{i,\mu}^l \chi_\mu$$

In light of the above derivations, the relationship between the LCAO coefficients of the localized and canonical orbitals can be given as

$$[10] \qquad c_{i,\mu}^l = \sum_{j=1}^{n} a_j^i c_{j,\mu}^c$$

or, in matrix form,

$$[11] \qquad \boldsymbol{c}_i^l = \sum_{j=1}^{n} a_j^i \boldsymbol{c}_j^c$$

where $\boldsymbol{c}_i^l$ and $\boldsymbol{c}_j^c$ are the m-dimensional vectors formed from the LCAO coefficients of orbitals φ_i^l and φ_j^c, respectively.

Substituting the expansion [8] into the definition (eq. [6]) of the matrix elements Q_{jk}^i, one gets

$$[12] \qquad Q_{jk}^i = \sum_{\mu,\nu} c_{j,\mu}^{c*} S_{\mu\nu}^i c_{k,\nu}^c$$

where the elements of the matrix $\boldsymbol{S}^i$ are obtained by integrating the products of the basis functions in the volume of domain $\boldsymbol{X}_i$ only:

[13] $$S^i_{\mu\nu} = \langle\chi_\mu|\chi_\nu\rangle_{X_i} = \int_{\Omega_i} \chi^*_\mu(\boldsymbol{r})\chi_\nu(\boldsymbol{r})\mathrm{d}v$$

Equation [12] very much resembles a similar quantity that appeared (2) in the case when non-orthogonal LMOs were required to have a maximal *net* Mulliken's population on the fragment selected (the so-called Magnasco–Perico localization criterion (5)). However, in that case the restriction was related not to the volume of integration but to the summation indices:

[14] $$Q^{i(M-P)}_{jk} = \sum_{\mu,\nu\in X_i} c^{c*}_{j,\mu} S_{\mu\nu} c^{c}_{k,\nu}$$

where the notation $\mu, \nu \in X_i$ indicates that the sum should be taken over the basis orbitals assigned to fragment X_i. The two definitions would lead to the same result in the limiting case when each basis orbital differs appreciably from zero only within its "own" atomic domain. In practice, however, one can expect some deviation between the matrices $\boldsymbol{Q}^i$ calculated by using these two definitions, because there is no direct counterpart of Mulliken's overlap population in the topological theory of atoms.

The analogy between the two approaches is very straightforward; one has only to observe that in the framework of Mulliken's population analysis (i.e., if the Magnasco–Perico criterion is used), the matrix $\boldsymbol{L}^i\boldsymbol{S}\boldsymbol{L}^i$ is a perfect analogue of matrix $\boldsymbol{S}^i$ above. Here $\boldsymbol{L}^i$ is the "cut-off" matrix (2): its block corresponding to the basis functions of fragment X_i is a unit matrix and all other elements are zero:

[15] $$L^i_{\mu\nu} = \begin{cases} \delta_{\mu\nu} & \text{if } \mu, \nu \in X_i; \\ 0 & \text{otherwise} \end{cases}$$

This means that a number of considerations described in ref. 2 can be adapted to our present case simply by replacing the matrix product $\boldsymbol{L}^i\boldsymbol{S}\boldsymbol{L}^i$ by matrix $\boldsymbol{S}^i$ defined above.[3] Therefore, we need not repeat in detail some of the derivations but may refer to those in ref. 2.

We introduce again the usual LCAO "density matrix"[4] $\boldsymbol{P}$:

[16] $$\boldsymbol{P} = \sum_{j=1}^{n} \boldsymbol{c}^c_j \boldsymbol{c}^{c\dagger}_j$$

and consider the variational problem $\delta M_i = 0$ with respect to the variations $\delta\boldsymbol{c}^l_i$ of the LMO coefficient vector $\boldsymbol{c}^l_i$. The variations $\delta\boldsymbol{c}^l_i$ are not quite arbitrary, because the orbital φ^l_i should remain in the subspace of occupied orbitals even after the variation is performed. Therefore, the most general *permitted* variation of vector $\boldsymbol{c}^l_i$ has the form of a projection (2): $\delta\boldsymbol{c}^l_i = \eta\boldsymbol{PSd}$, where $\boldsymbol{d}$, is an arbitrary m-dimensional vector and η is a variational parameter tending to zero. Then, repeating the derivations in ref. 2 we arrive at the alternative form of equations as

[17] $$\boldsymbol{PS}^i\boldsymbol{c}^l_i = M_i\boldsymbol{PSc}^l_i$$

or, because $\boldsymbol{c}^l_i = \boldsymbol{PSc}^l_i$ (the localized orbitals φ^l_i lie completely in the subspace of occupied orbitals):

[18] $$\boldsymbol{PS}^i\boldsymbol{c}^l_i = M_i\boldsymbol{c}^l_i$$

This is an eigenvalue equation for the non-Hermitian matrix $\boldsymbol{PS}^i$, which can be transformed to the generalized eigenvalue equation of a Hermitian matrix by utilizing once again the relationship $\boldsymbol{c}^l_i = \boldsymbol{PSc}^l_i$, and multiplying the equation by matrix $\boldsymbol{S}$:

[19] $$\boldsymbol{SPS}^i\boldsymbol{PSc}^l_i = M_i\boldsymbol{Sc}^l_i$$

Similarly to the case discussed in ref. 2, eqs. [17], [18], and [19] are equivalent to each other and to eq. [7] for all solutions corresponding to non-zero eigenvalues $M_i \neq 0$.

4. Partial orthogonality properties: definition of orthogonal atomic hybrids in a molecule

The non-orthogonal localized orbitals determined by the scheme discussed above have the following partial orthogonality properties analogous to those in ref. 2.

1. The localized orbitals corresponding to *the same* fragment (atomic domain) X_i are automatically orthogonal to one another in the case of different localization criteria (eigenvalues) M_i. (In the case of degenerate eigenvalues they can be chosen to be orthogonal.)

[20] $$\langle\varphi^{l(j)}_i|\varphi^{l(k)}_i\rangle = \sum_l a^{i(j)*}_l a^{i(k)}_l = \sum_{\mu,\nu} c^{l(j)}_{i,\mu} S_{\mu\nu} c^{l(k)}_{i,\nu} = \delta_{jk}$$

Here the additional indices j and k are introduced in order to distinguish between the different solutions of eqs [7], or [17]–[19], corresponding to *the same* fragment (domain) X_i. The orthogonality, eq. [20], follows from the fact that the localized orbitals can be obtained from the canonical ones by solving the Hermitian eigenvalue equation [7].

2. In the case of different eigenvalues M_i, the localized orbitals corresponding to the same fragment have also orthogonal "truncations" within the fragment X_i. This means that defining the functions

[21] $$\psi^{(j)}_i(\boldsymbol{r}) = \begin{cases} \varphi^{l(j)}_i(\boldsymbol{r}) & \text{if } \boldsymbol{r} \in \Omega_i; \\ 0 & \text{otherwise} \end{cases}$$

one has

[22] $$\langle\psi^{(j)}_i|\psi^{(k)}_i\rangle \equiv \langle\varphi^{l(j)}_i|\varphi^{l(k)}_i\rangle_{X_i} = M^{(j)}_i\delta_{jk}$$

Proof: The integral $\langle\varphi^{l(j)}_i|\varphi^{l(k)}_i\rangle_{X_i}$ can be transformed as

[23] $$\begin{aligned}\langle\varphi^{l(j)}_i|\varphi^{l(k)}_i\rangle_{X_i} &= \left\langle \sum_{p=1}^{n} a^{i(j)}_p\varphi^c_p \middle| \sum_{q=1}^{n} a^{i(k)}_q\varphi^c_q \right\rangle_{X_i} \\ &= \sum_{p,q=1}^{n} a^{i(j)*}_p \langle\varphi^c_p|\varphi^c_q\rangle_{X_i} a^{i(k)}_q \\ &= \sum_{p,q=1}^{n} a^{i(j)*}_p Q^i_{pq} a^{i(k)}_q\end{aligned}$$

[3] This cannot of course, be applied directly to the formulae in which the non-orthogonal LMOs are expressed as linear combinations of some columns of matrix $\boldsymbol{P}$.

[4] This nomenclature is not quite fortunate, as the true LCAO representation of the first-order density matrix in the case of an overlapping basis is matrix $\boldsymbol{PS}$, rather than simply $\boldsymbol{P}$ (6). This means, for instance, that $\boldsymbol{PS}$ is the matrix of projection on the subspace of the occupied orbitals.

Utilizing the fact that, according to eq. [7], $\boldsymbol{a}^{i(j)}$ and $\boldsymbol{a}^{i(k)}$ are *orthonormalized* eigenvectors of the Hermitian matrix $\boldsymbol{Q}^i$:

$$\sum_{q=1}^{n} Q^i_{pq} a^{i(k)}_q = M^{(k)}_i a^{i(k)}_p$$

we have

$$[24] \qquad \langle \varphi^{|(j)}_i | \varphi^{|(k)}_i \rangle_{X_i} = M^{(k)}_i \sum_{p=1}^{n} a^{i(j)*}_p a^{i(k)}_p = M^{(k)}_i \delta_{jk}$$

Q.E.D.

The "truncated" orbitals $\psi^{(j)}_i$ can be, therefore, considered as orthogonal atomic hybrids characterizing the atom within the molecule; it might be reasonable to renormalize them by multiplying by the factor $(M^{(j)}_i)^{-1/2}$. A detailed study of orbitals with significant M_i values on individual atoms can provide useful information about the electronic state and *chemical* nature of a given atom in a given molecule. Even if a large basis set is used, the number of hybrids with non-negligible M_i values is expected to remain small;[5] the orbitals and M_i values should quickly converge to their Hartree–Fock limits. (We stress once again in this connection the *basis-independent* nature of the basic definition, eq. [7], expressed solely in terms of the *canonical* molecular orbitals.)

3. As the atomic hybrids $\psi^{(j)}_i$ and $\psi^{(k)}_l$ corresponding to different domains (atoms) X_i and X_l differ from zero in *disjunct* parts of the 3-dimensional space, these orbitals are also automatically orthogonal to each other. This means that *the overlap effects are absorbed in the distortions of the individual hybrids*, so the latter should differ considerably from those in the free atoms.[6] At the same time, this additional orthogonality may permit us to have a new look at the classical VB, etc. theories in which all the orbitals were considered orthogonal, and to get a better understanding of their unquestionable success in qualitative explanation of different chemical phenomena.

[5] As noted in the Introduction, if the criterion based on Mulliken's population analysis was used, there were as many hybrids with non-negligible M_i values on each atom as the number of orbitals in the conventional minimal basis set of that atom (2).

[6] It may be also of considerable interest to select fragment X_i as the *union* of atomic domains for chemically bonded atoms; then bonding orbitals of the respective chemical bonds can also be explicitly studied.

5. Conclusions

This paper was not intended to solve the quantum mechanical problems of the topological theory of atoms, but only to extract some additional, chemically meaningful, information from such solutions, assumed to be already accomplished. Accordingly, we have derived equations permitting us to determine non-orthogonal localized molecular orbitals having a maximal weight in the given atomic domain, or in another selected molecular fragment. (The approach is analogous to a recent one in which the localization criterion was defined as the maximal net Mulliken's population on the fragment in question.) These non-orthogonal localized orbitals have some interesting partial orthogonality properties: the orbitals corresponding to the same fragment and their *truncations* to the given fragment are mutually orthogonal. This permits one to define, in the framework of Bader's topological theory of atoms, the *effective* — distorted but still orthogonal — atomic orbitals by which the atom in question participates in formation of the molecular orbitals. The orbitals determined in this manner may give important conceptual connections between the SCF wave functions obtained in the large-scale ab initio calculations, or even at the Hartree–Fock limit, and the traditional atomic orbital picture.

Electrostatic properties of ammonium fluoride and deuterated ice-I_h

C.G. van Beek, J. Overeem, J.R. Ruble, and B.M. Craven

Abstract: New single crystal X-ray diffraction data have been collected at reduced temperature (120 K) and high resolution ($\sin\theta/\lambda \leq 1.34$ Å^{-1}) for ammonium fluoride and for heavy ice-I_h (D_2O) in order to determine the detailed electron density distribution in these structures. The crystals are isostructural. Ammonium fluoride, NH_4F, is hexagonal with space group $P6_3mc$, $a = 4.4365(3)$, $c = 7.1672(5)$ Å, $Z = 2$. Ice-I_h, D_2O, is hexagonal with space group $P6_3/mmc$, $a = 4.4950(5)$, $c = 7.3170(10)$ Å, $Z = 4$. The X-ray data were collected with Nb-filtered Mo$K\alpha$ radiation ($\lambda = 0.7093$ Å). Refinements with Stewart's rigid pseudoatom model gave $R(F^2) = 0.016$ for 292 reflections for NH_4F and $R(F^2) = 0.023$ for 296 reflections for ice-I_h. Hydrogen nuclear positions and mean-square displacements were taken from previous neutron diffraction studies. The structures each contain two crystallographically distinct H(D) atoms, namely, those with N-H or O-D directed along the c-axis and those that are directed tetrahedrally with respect to c. For NH_4F, maps of the total electron density, the total electrostatic potential, and the values of the Laplacian at the bond critical points show that the bonding interactions involving both kinds of H atom are the same within experimental error. Similar results are obtained for ice-I_h, although there are complications and limitations owing to the disorder in the structure. Nevertheless, the pseudoatom model enables the electron density distribution to be determined for an ordered water molecule isolated from the crystal structure. The estimated molecular dipole moment for water in ice-I_h is 2.1 debye.

Key words: electron density, bond critical points, hydrogen bonding, water dipole moment.

Résumé : Opérant à température réduite (120 K) et utilisant une haute résolution ($\sin\theta/\lambda \leq 1{,}34$ Å^{-1}), on a recueilli de nouvelles données de diffraction des rayons X concernant le fluorure d'ammonium et la glace lourde-I_h (D_2O) dans le but de déterminer la distribution détaillée de la densité électronique dans ces structures. Les cristaux sont isostructuraux. Le fluorure d'ammonium, NH_4F, est hexagonal, groupe d'espace $P6_3mc$, avec $a = 4{,}4365(3)$, et $c = 7{,}1672(5)$ Å, $Z = 2$. La glace lourde-I_h (D_2O) est hexagonale, groupe d'espace $P6_3/mmc$, avec $a = 4{,}4950(5)$ et $c = 7{,}3170(10)$ Å, $Z = 4$. Les données de rayons X ont été obtenues à l'aide d'un rayonnement Mo$K\alpha$ filtré par du Nb ($\lambda = 0{,}7093$ Å). Les affinements à l'aide du modèle du pseudoatome rigide de Stewart a conduit à une valeur de $R(F^2) = 0{,}016$ pour 292 réflexions pour NH_4F et de $R(F^2) = 0{,}023$ pour 296 réflexions pour la glace-I_h. On a utilisé les positions des noyaux hydrogènes ainsi que les déplacements quadratiques moyens qui avaient été obtenus lors d'études de diffractions de neutrons antérieures. Les structures contiennent chacune deux atomes H(D) cristallographiquement distincts, à savoir ceux du N-H ou du O-D qui sont orientés le long de l'axe c et ceux qui sont orientés tétraédriquement par rapport à c. Pour le NH_4F, les cartes de la densité électronique totale, du potentiel électrostatique total et les valeurs du laplacien aux points critique de liaison montrent que les interactions de liaison impliquant chacun des types d'atome H sont les mêmes aux erreurs expérimentales près. Des résultats semblables ont été obtenus pour la glace-I_h, même s'il y a des complications et des limitations résultant du désordre dans la structure. Malgré tout, le modèle du pseudoatome lourd permet de déterminer la distribution de la densité électronique dans des molécules d'eau isolées de la structure du cristal. Le moment dipolaire moléculaire évalué pour l'eau dans l'eau I_h est de 2,1 debye.

Mots clés : densité électronique, points critique de liaison, liaison hydrogène, moment dipolaire de l'eau.

[Traduit par la rédaction]

Introduction

The crystal structure of ordinary ice, designated ice-I_h, has been the subject of many experimental and theoretical studies (1). Ammonium fluoride has been subject to far fewer studies although it has special interest since it is isostructural with ice-I_h (Fig. 1) and it is the only substance known to form solid solutions with ice-I_h. The two substances also form the crystal complexes $NH_4F{\cdot}H_2O$ and $(NH_4F)_4{\cdot}H_2O$ (2).

In 1927, Zachariasen (3) determined the arrangement of the N/F framework in ammonium fluoride, using X-ray diffraction. The structure is hexagonal in the polar space group $P6_3mc$, with each N and F atom at the center of a tetrahedron, as in the wurtzite configuration. The hydrogen positions in ammonium fluoride were determined by Adrian and Feil (4) using both X-ray and neutron diffraction. The arrangement of the oxygen atoms in ice-I_h was first determined by Barnes (5) in 1929, using X-ray diffraction. The O atoms replace N and F

in the NH_4F structure, giving rise to the centrosymmetric space group $P6_3/mmc$. The arrangement of the hydrogen atoms in ice-I_h was determined in 1953 by Owston (6) and then more precisely by Peterson and Levy (7) who carried out a neutron diffraction study on deuterated ice-I_h. These studies confirmed the disordered half-hydrogen model proposed by Pauling (8). In this model, each hydrogen atom is statistically distributed over two equilibrium positions between O···O nearest neighbors. More recent careful diffraction studies of ice-I_h have been carried out by Goto, Hondo, and Mae using X-rays (9) and by Kuhs and Lehmann using neutrons (1). Additional disorder in ice-I_h has been proposed. Chidambaram (10) invoked additional disorder of the H atoms so that the hydrogen bonds would be bent and the H-O-H bond angles would be smaller and similar to the value in the vapor phase. Kuhs and Lehmann (1) proposed disorder for the O atoms to explain the O—H bond length in ice-I_h being longer (0.02–0.05 Å) than values obtained from molecular orbital calculations and spectroscopic data.

A consideration of geometrical aspects brings out the similarities in the structures of ammonium fluoride and ice-I_h. Both are based on a wurtzite-type structure with a tetrahedral configuration of hydrogen bonds about each heavy atom center. Our study draws attention to important chemical differences that are based on the charge density distribution in these structures.

Ammonium fluoride, experimental

A crystal selected from a commercial sample obtained from J. T. Baker Chemical Co. was mounted on a glass fiber with the *c*-axis close to the φ-axis of the Enraf–Nonius CAD-4 diffractometer. To minimize ice formation on the crystal, the diffractometer was placed in a sealed box with a constant supply of dry air into the box. The crystal was kept at a nominal temperature of 120 K in a stream of nitrogen gas. Throughout the data collection the temperature was monitored (± 1 K) using a thermocouple located about 8 mm upstream from the crystal. X-ray data were collected using niobium-filtered Mo$K\alpha$ radiation (λ = 0.7093 Å). Unit cell dimensions (see Abstract) were obtained from a least-squares fit of $\sin^2\theta_{hkl}$ for 25 reflections measured at four symmetry equivalent positions. Bragg intensities were measured using ω/2θ scans for all reflections with $\sin\theta/\lambda \leq 1.34$ Å^{-1} in an octant of reciprocal space (*h* and *k* from 0 to 11, *l* from 0 to 19). The intensities of three monitor reflections were measured every 6000 s of the data collection. Integrated intensities were obtained from the scan profiles using the method of Lehmann and Larsen (11) and the data processing computer programs of Blessing (12). The integrated intensities were internally scaled by factors ranging from 0.979 to 1.007 that were obtained from the observed variations of the monitor reflections during the course of the data collection. A total of 1084 reflections were collected. Averaging gave 513 independent reflections with an internal agreement factor, R_{int} (F_o^2) = 0.019.

Ammonium fluoride, structure refinement

The electronic charge density distribution in the crystal structure was determined by full-matrix least-squares refinement based on the rigid pseudoatom model of Stewart (13). X-ray scattering factors for the pseudoatom *K*-shells of N and F^- were assumed to be those of Hartree–Fock isolated atoms (14). Scattering factors for the spherical component of the *L*-shell of N and F^- were constructed from a linear combination of Slater-type Roothaan–Hartree–Fock atomic wave functions (15). For these spherical valence shells, a variable radial contraction parameter, κ, was introduced (16). Pseudoatom higher multipole terms, as well as the radial scattering factor for H, were assigned a single Slater-type radial function. These functions had a fixed standard value (17) for the radial exponent (α = 7.37 Å^{-1} for N and α = 4.69 Å^{-1} for H). No

higher multipoles were introduced for F^-.[3] The initial nuclear positions and mean-square displacements for the least-squares refinement were taken from the previous neutron study (4). As in previous studies, the origin for the unit cell was defined by placing F at ($\frac{1}{3}$, $\frac{2}{3}$, 0). For H, positional and mean-square displacement parameters were not refined.

The refinement was carried out with the computer program POP (19). The function $\Sigma w\Delta^2$ was minimized, where $\Delta = |F_o^2| - |F_c^2|$, and $w = 1/\sigma^2(F_o^2)$ with $\sigma^2(F_o^2) = \sigma_{cs}^2 + (0.02F_o^2)^2$, where σ_{cs}^2 is the variance due to counting statistics. The structure model involved a total of 20 variables, consisting of the overall scale factor applied to the *K*-shell scattering, κ(F), κ(N), positional and anisotropic mean square displacement parameters for F and N, monopole population parameters for F, N, and H, and for N (but not F) all symmetry-allowed higher multipole population parameters up to octapoles and for H up to dipoles. There was also an isotropic extinction parameter *g* assuming a type II crystal with Lorentzian mosaicity (20). Initially the refinement included all 513 independent reflections, but many of the reflections at high resolution were insignificant in terms of their standard deviations. Reflections having sin θ/λ > 1.00 Å^{-1} and with intensity less then 3σ were omitted and the refinement was then completed with the remaining 292 reflections. Convergence was obtained with $R_w(F^2) = 0.041$, $R(F^2) = 0.016$, and goodness-of-fit = 1.00.[4] The final value $g = 0.29(8)\ 10^4$ rad^{-1} indicated that extinction effects were not serious. The largest correction for a Bragg intensity was a decrease of 6%. The final values for the pseudoatom parameters are given in Table 1*a*. The corresponding atomic distances and angles are in Table 2*a*. During the refinement there were no constraints on the monopole populations p_v; that is, on the number of valence electrons for each pseudoatom. After the refinement, $\Sigma p_v = 15.8(3)$ valence shell electrons, as compared with 16 for a neutral unit cell. The population parameters in Table 1*a* have been scaled to give a neutral unit cell. Both κ(F) and κ(N) are slightly greater than 1.0, indicating a slight contraction of the valence electron density as compared with an isolated Hartree–Fock atom.

Ice-I_h, experimental

The experimental procedures for ice-I_h were very similar to those used for ammonium fluoride. A single crystal of heavy ice-I_h was grown from a sample containing about 89% D_2O.[5] The crystal, having length 0.4 mm and diameter 0.5 mm, was grown with repeated zone melting and freezing in a glass capillary bathed in a stream of cold nitrogen gas. The capillary was already mounted on the diffractometer. Throughout the data collection the crystal was kept at a nominal temperature 120(1)K. Unit cell dimensions (see Abstract) were determined using Mo *K*α radiation in the same way as for ammonium fluoride. Intensity data were collected for all reflections having sin θ/λ ≤ 1.34 Å^{-1} in the hemisphere of reciprocal space with $0 \le h \le 12$, $-12 \le k \le 12$, and $-19 \le l \le 19$. The integrated intensities were internally scaled by factors ranging from 0.975 to 1.018 that were derived from the observed variations in the intensities of the monitor reflections throughout the data collection. An absorption correction (μ = 0.0991 mm^{-1}) was applied (21) that gave correction factors from 1.038 to 1.043. A total of 2358 reflections were collected. Averaging gave 550 independent reflections with an internal agreement factor of $R_{int}(F_o^2) = 0.037$.

Ice-I_h, structure refinement

The refinement procedure was very similar to that used for ammonium fluoride. After an initial refinement using all reflections, those having sin θ/λ > 1.00 Å^{-1} and with intensity less than 3σ were omitted and the refinement was completed with the remaining 296. X-ray atomic scattering factors were derived as described above (14, 15). The higher multipole terms for O were assigned a fixed standard value for the radial exponent of α = 8.50 Å^{-1} (17). The O atoms were assumed to be ordered while half-H atoms were assumed to be disordered according to the Pauling model (8). The initial nuclear positions and mean square displacements were the values for D_2O obtained from neutron diffraction by Kuhs and Lehmann (1). The structure model involved 21 variables consisting of the overall scale factor applied to the *K*-shell scattering, positional and mean-square displacement parameters for O, together with all symmetry-allowed third- and fourth-order displacement parameters as defined in the Gram–Charlier formalism, and all symmetry-allowed multipole parameters up to octapoles for O and up to dipoles for H. A κ-parameter for O was included initially but later was excluded since the value was not significantly different from unity. An isotropic extinction parameter was introduced assuming a type II crystal with Lorentzian mosaicity (20), but extinction was found to be only marginally significant ($\rho = 0.14(8) \times 10^{-3}$ mm). Convergence was obtained with $R_w(F^2) = 0.045$, $R(F^2) = 0.023$, and goodness-of-fit = 1.08. The final values for the structure parameters are in Table 1*b*. The anharmonic third- and fourth-order displacements for O are not listed since all final values were within 1.5σ of zero except $C^{333} = -1.9(8) \times 10^{-9}$ Å^3. After the refinement, the total number of electrons in the asymmetric unit of the structure consisted of the two O-atom *K*-shell electrons, together with the number of valence shell electrons given by the unconstrained sum $p_v(O) + 0.5p_v(D1) + 1.5p_v(D2) = 8.25(11)$. Thus the total number of *K*- and *L*-shell electrons is close to the value 10 that is required for a neutral unit cell. There is further discussion below concerning the atomic charges on the O and H atoms when disorder is taken into account. The population parameters listed in Table 1*b*, have been scaled to give 8 valence shell electrons in the asymmetric unit. Final atomic distances and angles are in Table 2*b*.

Discussion

For an idealized hexagonal packing of equal spheres, the unit cell axial ratio *c*/*a* = 1.6330. The observed ratio is 1.6155 for

[3] In polar space groups, such as $P6_3mc$, instability can be introduced in the least-squares structure refinement owing to strong correlations between electron population parameters for certain pairs of odd-order multipole terms (18). For ammonium fluoride, this problem is avoided by assuming F^- to be spherical.

[4] $R(F^2) = \Sigma|\Delta|/\Sigma|F^2|$, $R_w(F^2) = [\Sigma w\Delta^2/\Sigma(wF^2)^2]^{1/2}$, goodness-of-fit = $[\Sigma w\Delta^2/(m_{obs}-n_{param})]^{1/2}$; where $\Delta = |F_{obs}|^2 - |F_{calc}|^2$.

[5] The composition is estimated by comparison with results of a neutron diffraction study of barbituric acid dihydrate in which the same D_2O sample was used for deuteration. This is unpublished work, which we carried out in collaboration with Dr W.T. Klooster.

Table 1. Pseudoatom parameters. Atoms in the asymmetric unit conform to those used in previous work (1, 4, 7). Positional parameters x, y, z are fractional coordinates in the unit cell. Mean-square displacement parameters U^{ij} are given in Å^2 units and correspond to the expression $T = 2\pi^2\sum_{ij}h_ih_ja^{*i}a^{*j}U^{ij}$. Values without estimated standard deviations (in parentheses) are symmetry constrained. Electron population parameters p_v, d_1, etc., correspond to normalized multipole terms as described by Epstein, Ruble, and Craven (22) and are referred to the crystal cartesian axes a, b^*, c. Multipole terms not listed have zero value.

(*a*) Ammonium fluoride. Nuclear positions and mean-square displacements for H1 and H2 are taken from the neutron diffraction study by Adrian and Feil (4). Valence shell radial contraction parameters have values κ(F) = 1.036(6) and κ(N) = 1.015(14).

ammonium fluoride, indicating a slight deviation from ideality. Consequently, there must be slight departures from a regular tetrahedral configuration of hydrogen bonds. For ice-I_h the axial ratio is 1.6278, close to the ideal value. From Table 2, it can be seen that the two crystallographically independent heavier atom hydrogen-bonding distances in each structure are the same within experimental error (N···F, 2.7071(2) and 2.7076(7) Å; O···O, 2.755(5) and 2.748(2) Å). However, pairs of angles F···N···F and O···O···O, which in a regular tetrahedral arrangement would be 109.47°, are observed to be 108.89(2)° and 110.06(1)° in ammonium fluoride and 109.20(14)° and 109.75(7)° in ice-I_h. Thus, in ammonium fluoride, the distortion from ideality is realized as differences in hydrogen bond angles rather than distances.

The bond distances and angles presently obtained for ammonium fluoride and ice-I_h (Table 2) are similar to those previously reported (1, 4, 7). They will not be discussed further except to point out that the values are uncorrected for the effects of atomic mean-square displacements. For ice-I_h these effects might arise from the static disorder of O and H as well as the atomic thermal vibrations (1, 10). In carrying out the charge density analysis, we assume Stewart's rigid pseudoatom model (13), in which the charge distribution is carried rigidly on the pseudoatom nuclei. The model does not require a distinction between static and dynamic nuclear displacements.

In ammonium fluoride, the monopole population (p_v) of the fluoride is 7.75(10) instead of 8 for a true ion. Thus, according to the pseudoatom model, the crystal structure is ionic with the anion and cation carrying net charges of $\pm 0.75e$.

In ice-I_h the D-atom disorder gives rise to uncertainty in the experimental value for the net charge on a particular water molecule. The disorder allows six possible water molecule configurations about each O-atom site because there are six ways to choose two corners from a tetrahedron. Presumably these configurations occur with equal probability. Three molecules are of the type D1-O-D2 and three are of the type D2-O-D2′. Taking values of p_v from Table 2*b*, the net valence shell charges are $\Sigma p_v = 7.96(11)$ for the first type of molecule and 8.03(11) for the second. Within experimental error, these charges are the same as the value 8 required for a neutral molecule. However, this calculation neglects the possibility that the O atom may have a different value for p_v in the two kinds of water molecule. It is only the average that is constrained to the experimental value of 6.25. We consider that any real difference in the two kinds of water molecules will be very small and therefore, in the following, we assume that the water molecules are all electrically neutral and are chemically identical.

We assume an isolated averaged water molecule with *2mm* point symmetry that is referred to a Cartesian axial system with x along the twofold axis and z normal to the molecular plane. With this system and using the nomenclature of Epstein, Ruble, and Craven (22), the only higher multipole terms for the O atom that are symmetry allowed are d_1, q_1, q_5, o_1, and o_5. The molecule is then rotated in six different ways into the cartesian axial system a, b^*, c as used in the crystal structure refinement. Each rotation is made to correspond with one of the six configurations for water molecules that share a common O-atom site. After each rotation, the population parameter for a multipole term with respect to the crystal axes is given as a linear combination of values for all multipoles of the same order when referred to the molecular axes (23). After summing the results of these rotations, giving them all equal weight, a set of linear equations is obtained that can be solved to obtain the electron population parameters for the isolated molecule in terms of the experimental values for the disordered structure (Table 1*b*). In this way it is shown that, for the O atom, d_1, q_1, and q_5 are small and can be set to zero while the octapole terms have values $o_1 = -3.2$ and $o_5 = -0.8$. These multipole populations, together with average values for the H-atom coordinates and population parameters (Table 1*c*), were used to derive electrostatic properties for an ordered water molecule extracted from the ice-I_h crystal structure. Following the procedure of Stewart (24), we obtain a molecular dipole moment for water in ice-I_h (2.1 debye) that is in good agree-

Table 3. Bond critical point data for ammonium fluoride. Fractional coordinates (x, y, z) are given for the (3, −1) bond critical points. The standard deviations are isotropic estimates (Å units) of the position of the bond critical points. The electron density at the bond critical point $\rho(r)$ is in units e Å^{-3} and the Laplacian of the electron density at the bond critical point $\nabla^2\rho(r)$, which is the trace of the Hessian matrix, is in units e Å^{-5}. The principal values of the Hessian matrix are λ_1, λ_2, and λ_3.

ment with the values 2.3(3) debye obtained for the water molecule in cytosine monohydrate (25) and 1.83 debye obtained for water vapor using microwave spectroscopy (26).

Figure 2 shows the total charge density in the crystal structures of ammonium fluoride and ice-I_h with all atoms stationary. In ice-I_h, the charge density is for an averaged unit cell using the half-hydrogen model. In both structures, regardless of the H-atom disorder in ice-I_h, it can be seen that the total density around the crystallographically distinct H1 (or D1) and H2 or (D2) is remarkably similar. The total density in ammonium fluoride has been analysed further by determining the positions of the bond critical points (Table 3). As pointed out by Bader and Essén (27), these are the (3, −1) critical points that occur in the total density $\rho(r)$, at the saddle point along the bond path between pairs of nuclei. Table 3 also lists the Laplacian of the total density at the bond critical points. The Laplacian can be written as $\nabla^2\rho(r) = \lambda_1 + \lambda_2 + \lambda_3$, where λ_i are the three principal values of the curvature of $\rho(r)$ in order of decreasing magnitude. Because of the saddle point, λ_1 is positive while λ_2 and λ_3 are negative. In ammonium fluoride, each H atom is associated with two bond critical points, one in the covalent N—H bond and the other in the H···F hydrogen bond. In each covalent bond, the Laplacian is negative, corresponding to a local concentration of charge, while in each hydrogen bond the Laplacian is positive, corresponding to a local depletion. The difference in sign is an indication of the difference between a covalent and an ionic or closed-shell interaction. It can be seen from Table 3 that at the (3, −1) critical points associated with the two different H atoms in ammonium fluoride, the respective values of $\rho(r)$, $\nabla^2\rho(r)$, and λ_i are the same within experimental error. These values are also similar to those obtained for the N—H bond in the crystal structure of 1-methyluracil (28).

Because of the disorder of the D atoms, analysis of the critical points in the crystal structure of ice-I_h would not be meaningful. However, using the parameters from Table 1*c*, we have mapped $\rho(r)$ for the average water molecule isolated from ice-I_h and have located the (3, −1) critical point in the O—D bond. The critical point is 0.75 Å from the O atom. At the critical point, $\rho(r) = 2.55$ e Å^{-3}, $\nabla^2\rho(r) = -31$ e Å^{-5}, $\lambda_1 = 45$ e Å^{-5} and $\lambda_2 = \lambda_3 = -38$ e Å^{-5}.

The total electrostatic potential in the crystal structure of

Fig. 3. The electrostatic potential in the crystal structure of ammonium fluoride. The section is the same as in Fig. 2*a*. Contours are at intervals 0.07 e $Å^{-1}$ beginning at -1.30 e $Å^{-1}$. Dashed contours are used for regions of electronegativity. (*a*) The total electrostatic potential. (*b*) The total electrostatic potential after the removal of the contribution of one fluoride ion (center, bottom).

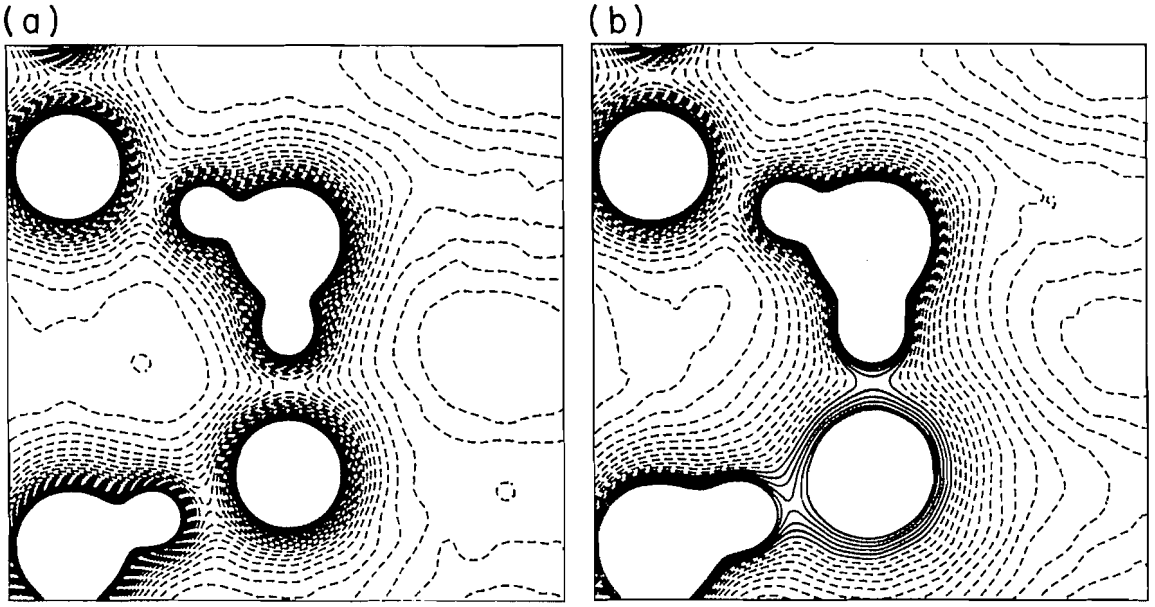

Fig. 4. The electrostatic potential of an averaged water molecule isolated from the crystal structure of ice-I_h. Contours are at intervals 0.05 e $Å^{-1}$ with broken contours representing the region of electronegativity. (*a*) The potential in the molecular plane. (*b*) The potential in the plane normal to the molecular plane and containing the D-O-D bisector. The O—D bonds project towards the bottom of the page.

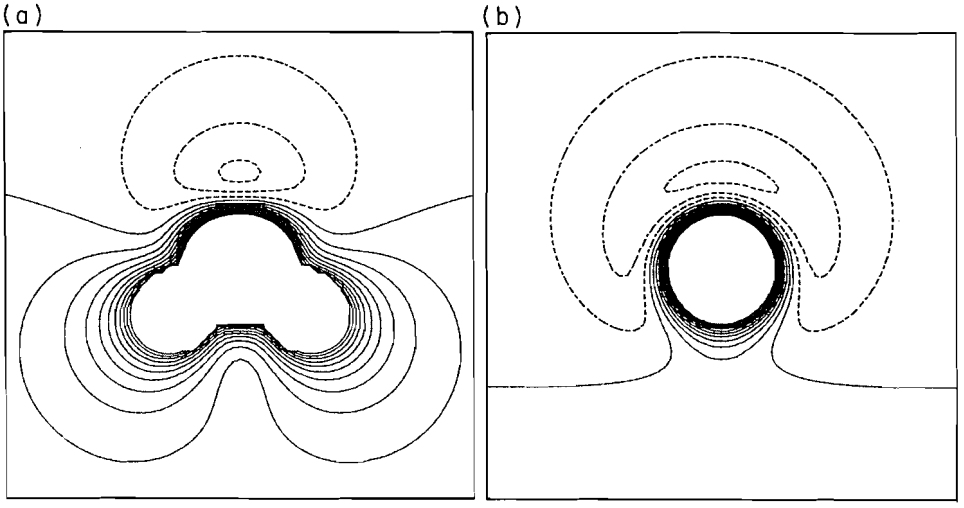

ammonium fluoride (Fig. 3) has been obtained using the procedure described by Stewart (29). The contribution to the potential at short range around each atom center is derived from the nucleus acting as a point charge and from the wave function for the neutral spherical Hartree-Fock atom (30). The lattice sum for the long-range contribution is obtained by a difference Fourier synthesis with coefficients $\Delta F_H/s_H^2$, where $s_H = \sin \vartheta_{hkl}/\lambda$ and $\Delta F_H = F_{ps} - F_{hf}$ where the subscript *ps* refers to the structure factor for the complete pseudoatom model and *hf* for an assembly of neutral spherical Hartree Fock atoms. The mean inner potential, which corresponds to the Fourier term with $H = 0$, is obtained only approximately because in a polar structure such as ammonium fluoride this term is affected by the nature of the surface charges on the crystal. Thus the total potential is subject to uncertainty in the level of the zero contour.

From Fig. 3*a*, it can be seen that the total potential is electronegative in the cavities between the ions and has bridges that are less electronegative along the hydrogen bonds. In Fig. 3*b*, the potential is shown when a vacancy in the crystal is sim-

ulated by subtracting the contribution of a single fluoride ion. The structure is not permitted to relax around the vacancy. As expected, the vacancy has enhanced electropositivity. There is also a tetrahedral deformation of the potential around the vacancy owing to the electropositivity of the surrounding ammonium ions.

We have not attempted to map the total potential for the ice-I_h structure because of the disorder. However, in Fig. 4*b*, we show the total potential for the average water molecule isolated from ice-I_h. The potential was computed from the pseudoatom parameters in Table 1*c* and from Hartree–Fock wave functions (15) using the procedure described by Stewart and Craven (30). There is an electronegative feature associated with the lone pair region of the O atom. This is a single unresolved minimum (-0.16 e Å^{-1}) that extends on both sides of the molecular plane.

As a subject for further study, we conclude that the pseudoatom model might be useful in calculating the electrostatic properties of hypothetical structures involving icelike structures with ordered water molecules and also for studying the effect that the incorporation of ammonium fluoride might have on inducing order in the ice-I_h structure.

Cyclobutene photochemistry. Adiabatic photochemical ring opening of alkylcyclobutenes

William J. Leigh, J. Alberto Postigo, and K.C. Zheng

Abstract: The photochemistry of the *cis* and *trans* isomers of a series of dimethylbicyclo[*n*.2.0]alk-(*n*+2)-enes (*n* = 2–5) (bicyclic cyclobutene derivatives in which the C=C bond is shared by the two rings) in pentane solution is described. Irradiation of these compounds using monochromatic 193- or 214-nm light sources results in ring opening to yield the corresponding 1,2-bis(1-ethylidene)cycloalkanes (C_4–C_7) in high chemical and quantum yields. In all cases, the reaction proceeds with a high (70–90%) degree of disrotatory stereoselectivity. Quantum yields for direct *cis,trans* photoisomerization of the isomeric *E,E*- and *E,Z*-1,2-bis(1-ethylidene)cycloalkanes have also been determined. The product distributions from irradiation of the cyclobutenes are wavelength dependent, but for 214-nm excitation the isomeric diene distributions obtained from cyclobutene ring opening agree fairly closely with those calculated from the quantum yields for *cis,trans* photoisomerization of the isomeric dienes on the assumption that the process involves purely disrotatory ring opening to yield a single diene isomer in the lowest excited singlet state. The results are consistent with an orbital-symmetry-controlled, adiabatic mechanism for ring opening.

Key words: photochemistry, cyclobutene, electrocyclic, adiabatic, conical intersection, orbital symmetry.

Résumé : On décrit la photochimie des isomères *cis* et *trans* d'une série de diméthylbicyclo[*n*.2.0]alc-(*n*+2)-ènes (*n* = 2–5) (dérivés cyclobutènes bicycliques dans lesquels la liaison C=C est partagée entre deux cycles) en solution dans le pentane. L'irradiation de ces composés utilisant des sources de lumière monochromatique (193 ou 214 nm) provoque une ouverture de cycle qui conduit aux 1,2-bis(1-éthylidène)cycloalcanes (C_4–C_7) correspondants avec des rendements chimiques et quantiques élevés. Dans tous les cas, la réaction se produit avec un degré élevé (70–90%) de stéréosélectivité disrotatoire. On a déterminé les rendements quantiques pour la photoisomérisation *cis/trans* des *E,E*- and *E,Z*-1,2-bis(1-éthylidène)cycloalcanes. Les distributions des produits dérivant de l'irradiation des cyclobutènes dépendent de la longueur d'onde, mais, pour l'excitation à 214 nm, les distributions des dienes isomères obtenues pour l'ouverture de cycle du cyclobutène sont en assez bon accord avec ceux calculés à partir des rendements quantiques pour la photoisomérisation *cis/trans* des dienes isomères en supposant que le processus implique une ouverture de cycle strictement disrotatoire pour conduire à un seul diène isomère dans l'état singulet excité le plus bas. Les résultats sont en accord avec un mécanisme, pour l'ouverture de cycle, qui serait adiabatique et sous contrôle d'une symétrie des orbitales.

Mots clés : photochimie, cyclobutène, électrocyclique, adiabatique, intersection conique, symétrie d'orbitales.

[Traduit par la rédaction]

Introduction

The photochemical ring opening of simple alkylcyclobutenes in solution is known to proceed nonstereoselectively (1–5). While this appears to be quite general, there is increasing evidence to suggest that orbital symmetry factors (which predict that ring opening should proceed with disrotatory stereospecificity (6)) *do* play a role in the reaction. Firstly, isolated examples for which a high degree of disrotatory stereoselectivity is observed have been reported (7–9). Secondly, the UV resonance Raman spectrum of cyclobutene has been proposed to be consistent with initial *disrotatory* rotation of the C_1—C_4 and C_2—C_3 bonds immediately after excitation to the lowest excited singlet state (10) (this interpretation has recently been questioned, however (11)). Finally, we have recently reported a study of (C_3/C_4) substituent effects on the quantum yield for ring opening of 1,2-dimethylcyclobutene (12). This study indicates that *syn*-dimethyl substitution at C_3/C_4 reduces the absolute and relative (to cycloreversion) quantum yields for ring opening in a manner that is consistent with the process involving *initial* excited state disrotation about the C_1—C_4 and C_2—C_3 bonds of the cyclobutene ring. Each of these suggest that the photochemical ring opening of cyclobutene at least begins on the (disrotatory) pathway predicted by orbital symmetry selection rules.

Photopericyclic reactions are conventionally explained in terms of the avoided crossing model of Van der Lugt and Oosterhoff, in which stereospecific product formation results from internal conversion to the ground state surface at an

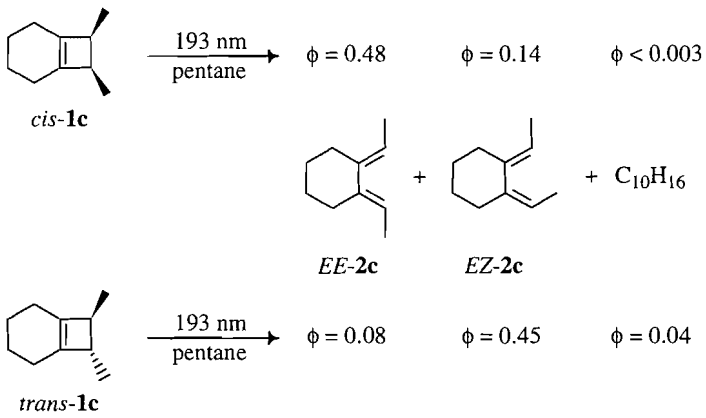
avoided crossing (the pericyclic minimum) between the ground and excited state surfaces for the photochemically allowed (thermally forbidden) pathway (13, 14). This is the mechanistic model that is traditionally employed to explain, for example, why conjugated dienes undergo photochemical ring closure with a high degree of disrotatory stereospecificity (15). If it is valid — and recent theoretical work suggests it is not (16–19) — then the ultimate formation of formally-forbidden diene isomers must be due to some intervening process that competes with internal conversion at the avoided crossing for disrotatory interconversion. The possibilities that have been considered include (1, 9): (*i*) internal conversion to upper vibrational levels of the ground state (before the pericyclic minimum is reached), from which conrotatory ring opening ensues (1, 12); (*ii*) internal conversion to biradicaloid geometries on the diene ground state surface, from which torsional relaxation yields a mixture of isomeric dienes (20); and (*iii*) complete disrotatory ring opening on the excited state surface to yield fully open diene(s) in the first excited singlet state (i.e., adiabatically), followed by decay to the ground state by *cis,trans* isomerization (1, 9, 20). Another, recently suggested possibility is that excited-to-ground state internal conversion occurs via one or more *conical intersections* (geometries where the excited and ground state surfaces are degenerate) (21–23), after which the loss in disrotatory stereochemistry occurs on the ground state surface (17). According to calculations, the approach of the excited molecule to the conical intersection geometry involves rupture of the C_3—C_4 bond (cyclobutene numbering) and substantial twisting about *all three* of the remaining C—C bonds in the cyclobutene/1,3-butadiene framework (17).

Of these, the adiabatic ring-opening mechanism is potentially the easiest to test experimentally. According to this mechanism, a given cyclobutene, appropriately labelled with substituents at C_3 and C_4 in order to track the stereochemistry of the process, will open in purely disrotatory fashion to yield a single (vide infra) diene isomer in the lowest excited singlet state (see Scheme 1). The excited product would then decay to the ground state, yielding *its* characteristic mixture of products. In principle, this characteristic mixture should be the same as that obtained when the diene itself is irradiated directly in solution. Thus, the experimental study of this mechanism would involve comparing isomeric diene distributions obtained from cyclobutene ring opening to distributions calculated from the quantum yields for direct photoisomerization of the corresponding orbital-symmetry-allowed diene isomer. The relevant expression is given by eq. [1], which relates the observed *EE/EZ* diene ratio from ring opening of an appropriate *cis*-disubstituted cyclobutene ($(EE/EZ)_{\text{from CB}}$) to the quantum yields for formation of the *EZ*-diene ($\phi_{EE\rightarrow EZ}$), cyclobutene ($\phi_{EE\rightarrow CB}$), and other products ($\phi_{EE\rightarrow OP}$) from direct irradiation of the *EE*-diene.

The main difficulty with applying this analysis to most of the cyclobutenes that have been studied results from the fact that the photochemistry of aliphatic dienes is conformation-dependent (24–27). Clearly, cyclobutene ring opening would be expected to yield the excited diene in an *s-cis* conformation, so it is the excited state behaviour of the *s-cis* diene conformer that must be known for a reliable analysis of the product distributions obtained from cyclobutene ring opening. Since most acyclic dienes exist preferentially in the *s-trans* conformation in solution at room temperature, they are poor models for the excited state behaviour of dienes under the conditions in which they are (presumably) formed by cyclobutene ring opening; thus, an analysis of this type is meaningless for monocyclic cyclobutenes and their corresponding dienes. A second potential difficulty is that in the case of *cis*-3,4-disubstituted cyclobutenes, there are two stereochemically distinct disrotatory ring-opening modes available, one leading to *E,E*-diene and the other leading to the *Z,Z* isomer. Should ring opening occur by both modes competitively, then an analysis of the type represented in Scheme 1 would clearly not be expected to model the observed diene distribution accurately. Fortunately, however, *Z,Z*-dienes are formed in extremely low yields from irradiation of every *cis*-3,4-disubstituted cyclobutene that has been reported (3, 5), so that this potential difficulty can be safely neglected. Presumably, the preferred formation of the *E,E*- over the *Z,Z*-diene isomer can be attributed to the different steric requirements of the two possible disrotatory ring opening modes (12).

We have recently described our preliminary efforts to test the adiabatic mechanism for photochemical cyclobutene ring opening (9, 28). These studies employed cyclobutene derivatives whose isomeric dienes are *structurally constrained* to exist in the *s-cis* conformation, in order to minimize difficulties associated with the conformational factors noted above. The first study involved a comparison of the diene distributions obtained from ring opening of the isomeric bicyclic cyclobutenes *cis*- and *trans*-**1c** (eq. [2]) with values calculated from the quantum yields for direct photoisomerization of the corresponding isomeric *s-cis* dienes *E,E*- and *E,Z*-**2c** (9). Comparison of the observed diene distributions from irradiation of **1c** with the so-calculated values (see Scheme 1) indicate that the adiabatic mechanism satisfactorily describes the isomeric diene distribution from photochemical ring opening of *cis*-**1c**, but it does not in the case of the *trans* isomer (9).

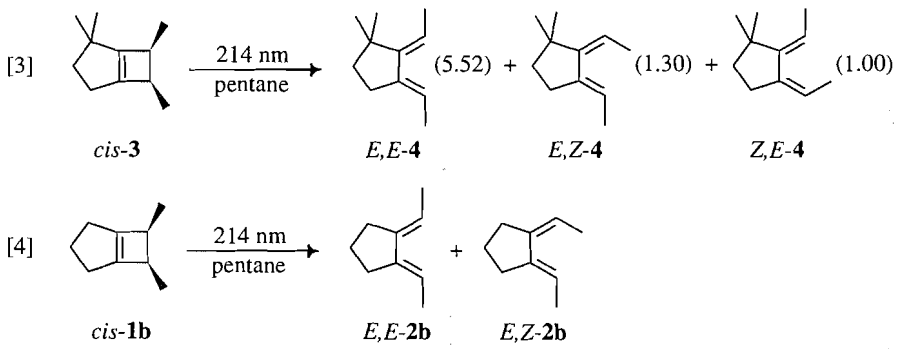
A second, potentially more precise type of comparison employs an asymmetrically substituted *cis*-cyclobutene, whose corresponding (*s-cis*) *E,E*-diene photoisomerizes to yield two *E,Z* isomers in a characteristic ratio (28). This sys-



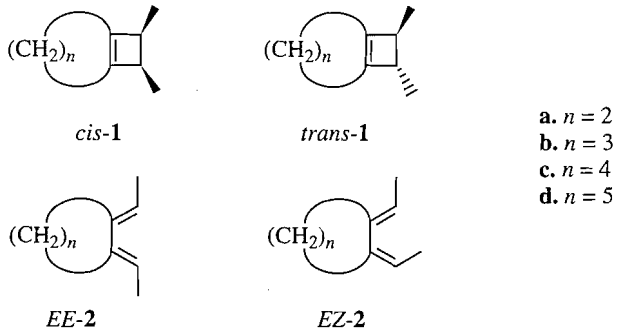
tem has the advantage that quantum yield determinations are unnecessary; the validity of the adiabatic mechanism can be tested by simply comparing product ratios from irradiation of the cyclobutene with those from irradiation of the corresponding allowed diene isomer. The system reported is *cis*-2,2,6,7-tetramethylbicyclo-[3.2.0]hept-1[5]-ene (**3**), whose irradiation (214 nm) in pentane solution yields a mixture of *E,E*-, *E,Z*-, and *Z,E*-1,2-bis(ethylidene)-3,3-dimethylcyclopentane (**4**; see eq. [3]). As predicted by the adiabatic mechanism, the relative yields of *E,Z*- and *Z,E*-**4** obtained from irradiation of **3** (*EZ*/*ZE* = 1.30 ± 0.12) are identical to those obtained in the direct irradiation (254 nm) of *E,E*-**4** (*EZ*/*ZE* = 1.25 ± 0.11) within experimental error. The distribution of allowed and forbidden dienes ([*EE*-**4**]/[*EZ*-**4** + *ZE*-**4**] = 2.4 ± 0.3) is similar to that obtained from irradiation of *cis*-6,7-dimethylbicyclo-[3.2.0]-hept-1[5]-ene (*cis*-**1b**) at the same wavelength ([*EE*-**2b**]/[*EZ*-**2b**] = 2.0 ± 0.3; see eq. [4]), which in turn agrees with the ratio predicted from quantum yields for photoisomerization of *EE*-**2b** (see eq. [1]) within experimental error. This is the best evidence for the validity of the adiabatic ring-opening mechanism that has been obtained to date.

In addition to proceeding cleanly and yielding a predictable mixture of isomeric dienes, the ring opening of these compounds shows the additional unusual feature of proceeding in remarkably high quantum efficiency compared to those of other compounds that have been studied (3, 4, 12). Clearly, some aspect of the unique structures of these molecules is responsible for reducing the rate of nonproductive excited state decay relative to that of ring opening. Three basic differences between the structures of these compounds and simple monocyclic cyclobutenes can be noted: increased ring strain, decreased rotational flexibility of the substituents on the cyclobutene double bond, and decreased central-bond torsional flexibility in the isomeric 1,3-diene products (9). The latter possibility is related to the ability of the system to allow C_1–C_2 torsion during ring opening, which is required according to the conical intersection model for the process (17). Experimental evidence for the importance of such torsional modes in the photochemical ring opening of cyclobutene has been reported by Mathies and co-workers (10).

In the present work, we report the results of a more comprehensive study of the photochemical ring opening of specially

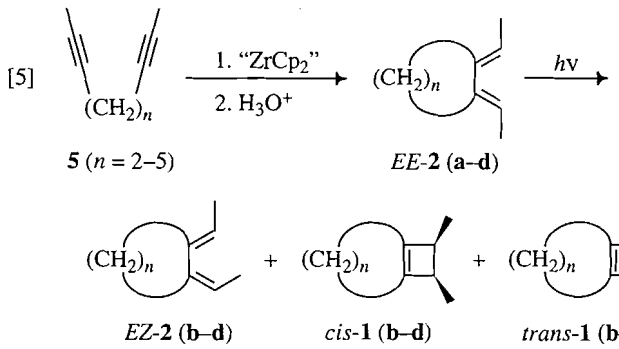


constrained cyclobutene derivatives. Primarily, we wished to attempt to identify the factors that are responsible for the anomalous photobehavior of **1b,c** with respect to ring opening, and to test the adiabatic mechanism for this process in a more detailed and systematic way. We thus report the photochemistry of the series of compounds **1a–d** in hydrocarbon solution with monochromatic 193- and 214-nm light sources. We also report complete details of a study of the photochemistry of the series of isomeric *E,E*- and *E,Z*-1,2-bis-(ethylidene)cycloalkanes **2a–d**. Preliminary results for three members of this series of dienes have been reported previously (9, 29).



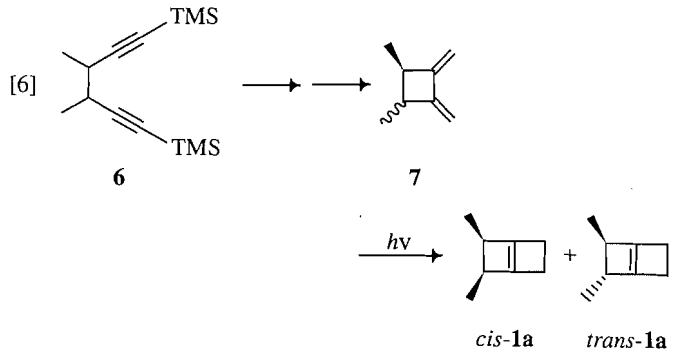
Results

The dienes *E,E*-**2** were prepared by zirconocene-mediated intramolecular coupling of the corresponding dialkynes **5** (n = 2–5; eq. [5]) (30, 31). Exhaustive irradiation of the *E,E*-diene (254 nm) was then carried out to afford isomeric mixtures consisting largely of the *E,E*- and *E,Z*-dienes and the *cis* and *trans*-substituted cyclobutenes, which were separated and purified



by semi-preparative gas chromatography. The irradiation mixtures usually also contained several other minor products; these were all determined to be isomers of **1** and **2** by GC/MS, but were isolated and rigorously identified in only certain cases (see experimental section). The *Z,Z* isomers of **2b–d** were tentatively identified by GC/MS, on the basis of comparisons of retention times and mass spectra (relative to the other components of the mixtures) to *Z,Z*-**2a**, which is a known compound and was isolated and rigorously identified from the exhaustive irradiation of *E,E*-**2a**. Because these compounds were minor components of extremely complex reaction mixtures, however, they were not isolated and rigorously identified.

While the first step in this procedure was successful for the synthesis of all four *E,E*-dienes in the series, the subsequent photoisomerization as a means of generating the desired cyclobutene derivatives was useful only for **2b–d**. In the case of *E,E*-**2a**, direct irradiation led to *cis,trans* photoisomerization and the formation of several minor products whose yields were similar to those of the desired cyclobutene derivatives. Thus, *cis*- and *trans*-**1a** were synthesized by photocyclization of 3,4-dimethyl-1,2-bis-(methylidene)cyclobutane (**7**), which was prepared as a mixture of isomers by zirconocene-mediated cyclization of the dialkyne **6** (eq. [6]) followed by bis-desilylation. This procedure led to excellent chemical yields of the desired cyclobutenes **1a**, which in spite of their rather substantial lability toward polymerization could be separated and purified by semi-preparative GC, and stored under liquid nitrogen until required.



The structures of **1a–d** and **2a–d** were assigned on the basis of their mass, infrared, and high-resolution ^{1}H and (except for **1a**) ^{13}C NMR spectra (see experimental section). The *cis* and *trans* isomers of **1a–d** are readily distinguishable on the basis of ^{1}H and ^{13}C NMR spectroscopy; the present series of compounds exhibit the same spectral regularities with C_3/C_4 stereochemistry as has been reported previously for other systems (20, 32). Ultraviolet absorption spectra of *cis*- and *trans*-**1a–d**, and *E,E*- and *E,Z*-**2a–d**, were recorded in deoxygenated pentane solution at 23°C, and are shown in Figs. 1 and 2, respectively.

Direct irradiation of deoxygenated, ca. 0.02 M pentane solutions of **1b–d** with the pulses from an Ar/F_2 excimer laser (193 nm; 15 ns; 20 mJ; 0.5 Hz repetition rate) resulted in the clean formation of *E,E*- and *E,Z*-**2b–d** as the major products. In the irradiations of the *trans* isomers, minor amounts of the compounds identified (tentatively; vide supra) as *Z,Z*-**2b–d** were also formed, as indicated by comparison of the GC and GC/MS characteristics of the photolysates to those of the crude mixtures from direct irradiation of the *E,Z*-dienes. No other products were observed in yields greater than ca. 3% in any case. Quantum yields for formation of the three products from **1b–d** were determined from the slopes of concentration vs. laser dose plots, using the ring opening of bicyclo[4.2.0]oct-6-ene (**1**) as actinometer for 193-nm irradiations. Representative plots of this type are shown for *cis*- and *trans*-**1d** in Fig. 3.

Irradiation of deoxygenated, ca. 0.02 M pentane solutions of **1a–d** with 214-nm light was carried out using a Zn resonance lamp as the light source. The photolyses of **1b–d** were carried out with vigorous stirring of the solutions, and were monitored over a 0.1–4% conversion range. Relative product yields were calculated from the initial slopes of concentration vs. time plots, examples of which are shown in Fig. 4 for *cis*- and *trans*-**1d**. Quantum yields for ring opening of *cis*- and *trans*-**1a** were determined on unstirred solutions with 214-nm excitation, using the initial slopes of product concentration vs. time plots to determine product yields, and uranyl oxalate actinometry to determine light intensities (12).

Table 1 lists the quantum yield data from irradiation of **1a–d** at 214 nm and **1b–d** at 193 nm. The table also lists *EE*/*EZ* diene ratios from *cis*- and *trans*-**1a–d** and *EE*/*ZZ* diene ratios from *trans*-**1a–c** (the yield of the *Z,Z*-diene from *trans*-**1d** was too low to be determined); these were calculated from the slopes of concentration vs. time plots as described above.

[a]Quantum yields for product formation from *cis*- and *trans*-**1a** were determined using filtered 214-nm excitation and uranyl oxalate actinometry. Those for product formation from **1b–d** were determined using 193-nm excitation and bicyclo[4.2.0]oct-7-ene actinometry.

[b]Calculated from the initial slopes of product concentration versus irradiation dose plots; errors were calculated from the standard deviations of the slopes; *n.d.* = not determined.

[c]*Z,Z*-**2** was not formed in sufficient yield to enable determination of the yield.

A control experiment was performed, in which a deoxygenated pentane solution containing 0.015 M *cis*-**1c** and 0.0011 M 1,3-cyclooctadiene (**8**) was irradiated (193 nm) to ca. 4.5% conversion of the cyclobutene. At these low conversions, isomerization of **8** to *cis,trans*-1,3-cyclooctadiene (the major product of irradiation of **8** (33)) could not be detected in the photolysate within our detection limits (ca. 10^{-6} M). Analogous results were obtained in the irradiation (214 nm) of *cis*- and *trans*-**1d**, employing low concentrations of *E,E*-**2b** as the standard.

As mentioned above, direct irradiation of *E,E*- and *E,Z*-**2a–d** in deoxygenated pentane solution led predominantly to

[e]Quantum yield for formation of *Z,Z*-**2a** from the *E,Z* isomer. No other products are formed, within the limits of our detection method.

cis,trans photoisomerization and the stereospecific formation of *cis*- and *trans*-**1a–d** (from *E,E*- and *E,Z*-**2a–d**, respectively). Other products were also formed in yields of ≤10% in some cases, but these were not rigorously identified. In the cases of *E,Z*-**2b** and **2c**, the most prominent of the minor photoproducts were those tentatively identified as the corresponding *Z,Z*-diene isomers, on the basis of GC/MS and GC retention time comparisons to *Z,Z*-**2a**, which was isolated and rigorously identified (vide supra). Irradiation of *E,Z*-**2d** yielded *E,E*-**2d** and *trans*-**1d** quite cleanly, and a minor product tentatively identifiable as *Z,Z*-**2d** could be detected only after extensive irradiation of the solution. Quantum yields for *cis,trans* photoisomerization and formation of **1a–d** and other minor products were determined in deoxygenated pentane solution (ca. 0.02 M) using potassium ferrioxalate actinometry. Quantum yields for the formation of minor products (*Z,Z*-**2** and all other unidentified products) were estimated in each case by GC (assuming equal response factors to the averages of those of the identified products) at ca. 5% conversion of starting material. Table 2 lists the results of these experiments.

Fig. 3. Product concentration versus laser dose plots for the formation of *E,E* (■) and *E,Z* (◆) **2d** from the photolysis (193 nm) of *cis* (A) and *trans* (B) 8,9-dimethylbicyclo[5.2.0]non-1[7]-ene (**1d**) in deoxygenated pentane solution at 23°C. The laser intensity was not the same in the two experiments.

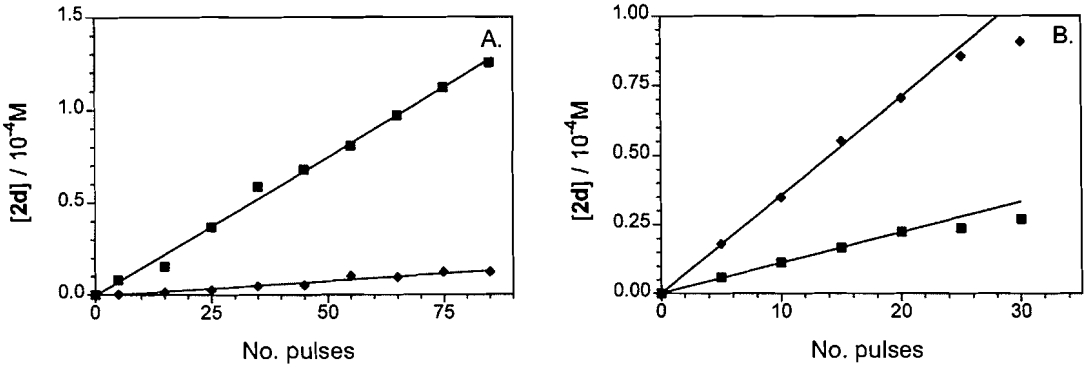

Fig. 4. Product concentration versus irradiation time for the formation of *E,E* (■) and *E,Z* (◆) **2d** from the photolysis (214 nm) of *cis* (A) and *trans* (B) 8,9-dimethylbicyclo[5.2.0]non-1[7]-ene (**1d**) in deoxygenated pentane solution at 23°C.

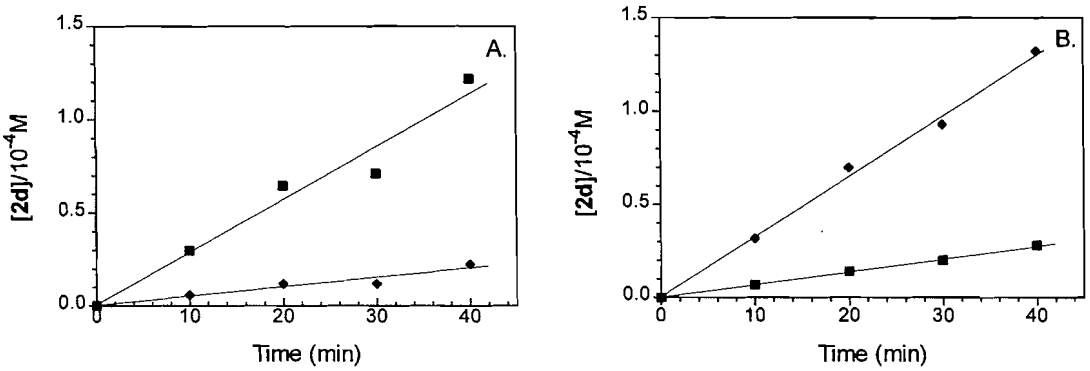

Discussion

The solution-phase UV absorption spectra of the series of bicyclic cyclobutene derivatives **1a–d** (Fig. 1) exhibit interesting trends. We previously reported spectra of several monocyclic alkylcyclobutene derivatives with *cis*- and *trans*-dimethyl substitution at C3/C4, and noted that those of the *cis* isomers are red-shifted with respect to those of the *trans* isomers (32). This was attributed to a stereochemical effect on the relative extinction coefficients of the π,π^* and Rydberg(π,R(3*s*))-like absorption bands. This is particularly noticeable in the gas phase UV spectra of these compounds, where the latter are considerably more intense than in the solution phase spectra. In solution, these absorption bands are sufficiently reduced in intensity that the result is an apparent broadening and red shift in the position of the prominent band in the spectra of the *cis* isomers compared to that in the spectra of the *trans* isomers. Similar differences are observed in the solution phase spectra of *cis*- / *trans*-**1d** and *cis*- / *trans*-**1c**, while the effect is absent altogether in the spectra of *cis*- and *trans*-**1a,b**. We do not understand the origins of the stereochemical effect on the spectra of monocyclic and relatively unstrained bicyclic alkylcyclobutenes such as **1c,d**, but it is interesting to note that the effect is truncated in the more highly strained members of the present series of compounds. It is clear that incorporation of the cyclobutenyl double bond into a second cycloalkyl ring has a significant effect on the UV absorption spectrum of the cyclobutenyl chromophore, to an extent that depends on the size of the ancillary ring.

The UV spectra of the isomeric dienes (Fig. 2) are consistent with an increasing amount of torsional flexibility about the central bond with increasing ancillary ring size throughout the series. For both **2a** and **2b** the long-wavelength bands in the spectra of the *E,E* and *E,Z* isomers are almost perfectly superimposable and exhibit maxima at ~250 nm, consistent with the molecules having planar, *s-cis* conformations that are roughly the same for the *E,E* and *E,Z* isomers. The spectra of the higher members of the series show maxima at shorter wavelengths, consistent with their preferred conformations having twisted *s-cis* geometries. The spectra of *E,E*-**2b** and **2c** are slightly red-shifted, but otherwise similar to those of the parent 1,2-dimethylenecycloalkanes (34).

Direct irradiation of *cis*- and *trans*-**1a–d** leads to ring opening to the isomeric dienes (**2a–d**) with a high degree of disrotatory stereoselectivity in each case (Table 1). None of these compounds undergo formal [2+2]-cycloreversion to any detectable extent, presumably because this process would lead to the formation of the corresponding, highly strained C_4–C_7

[a]Observed diene distributions from irradiation (193 and 214 nm) of *trans*-**1** (see Table 1); calculated from the slopes of concentration vs. time plots for the formation of *EE*-, *EZ*-, and *ZZ*-**2**; *n.d.* = not determined.

[b]Expected *EZ*/*EE*-diene ratios calculated using the quantum yield data in Table 2 and eq. [1] ($(EZ\text{-}\mathbf{2}/EE\text{-}\mathbf{2})_{t\text{-}2,calc}$), and *EE*/*ZZ* diene ratios obtained from direct irradiation of *E,Z*-**2** ($(EE\text{-}\mathbf{2}/ZZ\text{-}\mathbf{2})_{t\text{-}2}$).

[c]*ZZ* isomer was not formed in sufficient yield to enable yield determination.

cycloalkyne (35, 36). Another noteworthy feature of the present results is that *cis*- and *trans*-**1a** undergo ring-opening regiospecifically to yield the various geometric isomers of **2a**. In principle, **1a** has two ring opening modes available: one involving cleavage of the (unsubstituted) C5—C6 bond to yield **7**, and one involving cleavage of the (substituted) C2—C3 bond to yield **2a**. The fact that only the latter occurs in detectable yield is consistent with previous results that indicate that the efficiency of photochemical cyclobutene ring opening depends to some extent on the strength of the cyclobutenyl C3—C4 bond (12, 20).

The possibility that the overall nonstereoselectivity of photochemical ring opening might be explained by a mechanism in which purely disrotatory ring opening occurs adiabatically is suggested by the experimental results of Michl, Yang, and co-workers (37, 38), which demonstrated that direct irradiation of Dewar naphthalene (38) and Dewar anthracene (37) affords the corresponding aromatic hydrocarbons in the lowest excited singlet states. This was evidenced by the observation of the characteristic fluorescence of the aromatic hydrocarbons upon excitation of the corresponding Dewar isomers in solution.

If ring opening of alkylcyclobutenes proceeds in stereospecific, disrotatory fashion to yield a single diene isomer in the lowest excited singlet state, the final distributions of *E,E*- and *E,Z*-diene isomers obtained by irradiation of *cis*- and *trans*-**1a–d** should be determined by the excited state decay characteristics of the initially formed (allowed) diene isomer. These characteristics are given in quantitative form as the ratio of the quantum yields for productive vs. nonproductive decay of the diene (9, 28). Thus, the relevant equation for calculation of the expected distribution of *EE*- and *EZ*-dienes from irradiation of the *cis* cyclobutenes ($(EE/EZ)_{c,calc}$) is given in Scheme 1 (eq. [1]), which assumes that ring opening yields the *E,E*-diene to the exclusion of the other formally allowed product, the *Z,Z* isomer. That this assumption is reasonable follows from the fact that extremely low yields of *Z,Z*-dienes are observed in the photolyses of every *cis*-dimethyl substituted alkylcyclobutene that has yet been reported (3–5). The results of these calculations are listed in Table 3 along with the observed *EE*/*EZ* diene ratios from irradiation of *cis*-**1a–d** with the 193- and 214-nm light sources.

A similar equation can be employed to calculate the expected *EZ*/*EE* diene ratios from irradiation of the *trans* cyclobutenes ($(EZ/EE)_{t,calc}$). In these cases, the *E,Z*-diene is the only formally allowed ring-opening product, so no assumptions regarding the initial excited state product distribution are necessary in order to simplify the calculation. These compounds actually provide additional mechanistic information over that obtainable from the *cis* isomers, in that *two* detectable products are formed upon excited state decay of the *E,Z*-dienes: the *E,E*- and *Z,Z*-diene isomers. The adiabatic ring-opening mechanism would predict that, in these cases, the *EE*/*ZZ* diene distribution from ring opening of a *trans*-3,4-disubstituted cyclobutene should be identical to the *EE*/*ZZ* distribution from direct irradiation of the corresponding *E,Z*-diene (28). Table 4 summarizes the observed *EZ*/*EE* and *EE*/*ZZ* diene ratios from direct irradiation of *trans*-**1a–d**, along

with the expected *EZ/EE* ratios (according to eq. [7]) and the *EE/ZZ* diene ratios obtained in the direct irradiation of *E,Z*-**2a–d**.

As can be seen from inspection of Tables 3 and 4, the degree of agreement between the observed and calculated isomeric diene ratios varies for the two excitation wavelengths. For 214 nm excitation, the calculated and observed *EE/EZ* diene ratios agree within experimental error in seven cases out of eight (i.e., in all cases but *cis*-**1a**). In the cases of the *trans* isomers (**1a–c**), the similarity in the diene distributions from direct irradiation of cyclobutene and *E,Z*-diene extends as well to the *EE/ZZ* diene ratios, although the errors in these ratios are somewhat large due to the fact that the *Z,Z*-dienes are formed in relatively low yields in each case. The *EE/ZZ* ratio could not be determined reliably for *trans*-**1d**, as the yield of the *ZZ*-diene is extremely low in this case; irradiation of *E,Z*-**2d** also yields *Z,Z*-**2d** in unusually low yield, however.

For the most part, the present data support a mechanism in which ring opening occurs in purely disrotatory fashion to *first* yield the allowed diene isomer in the same electronic excited state that is populated upon direct excitation of the particular diene isomer and that is responsible for *cis,trans* isomerization; once formed, the excited diene then relaxes to form its characteristic mixture of products. In fact, this conclusion can be stated in more general terms. *The data support a mechanism in which ring opening occurs on the excited state surface in disrotatory fashion, but decay to the ground state surface(s) for product formation does not occur at the classical avoided crossing for cyclobutene–butadiene interconversion. Rather, it occurs at the same place(s), yielding a similar product distribution, as is(are) involved when the allowed diene isomer is itself excited directly.*

The behaviour of one compound in the series (*cis*-**1a**) is very clearly different from the others, in that its isomeric diene distribution is not modelled accurately by the excited state decay characteristics of the corresponding disrotatory diene (*E,E*-**2a**). We do not believe that the anomalously low disrotatory stereoselectivity observed in this case is due to an experimental artifact resulting from secondary irradiation of the *E,E*-diene. While ruling this out is admittedly more difficult to do in this case because of the shorter wavelength cutoff in the UV absorption spectrum of *cis*-**1a** compared to those in the spectra of **1b–d**, we note that irradiation of *trans*-**1a** (which should be subject to similar problems) leads to very high yields of *E,Z*-**2a** (there is, furthermore, no significant difference in the quantum yields for *cis,trans* photoisomerization of *E,E*- and *E,Z*-**2a** (29)). One possible explanation is that ring opening by the pathway leading to the *Z,Z*-diene isomer is much more important in *cis*-**1a** than in *cis*-**1b–d**; this would lead to a lower *EE/EZ* diene ratio than that predicted from consideration of the quantum yields for photoisomerization of the *E,E*-diene alone, due to isomerization of the *Z,Z*-diene to the *E,Z* isomer. Such behaviour could result from the considerably higher degree of ring strain afforded by the ancillary cyclobutyl ring (compared to that afforded by the ancillary rings in *cis*-**1b–d**), which might outweigh the normally dominant steric effects between the C_3–C_4 methyl groups and reduce the discrimination between the two possible disrotatory ring-opening modes. This explanation seems unlikely, however, given the sheer magnitude of the difference between the calculated and observed *EE/EZ* ratios for this compound (a simple calculation reveals that the yield of *E,Z*-**2a** formed by the *Z,Z*-diene route would have to be four times greater than that formed by the *E,E*-diene route, in order to account for the difference between the observed and calculated *EE/EZ* diene ratios). Besides, one would also expect that the observable yield of the *Z,Z*-diene should be significant if this were true, and such is not the case.

There is an intriguing wavelength dependence observed in the diene distributions throughout the two series of compounds **1b–d**, as is clear from inspection of Tables 3 and 4. With 214-nm excitation, the observed *EE/EZ* diene distributions very closely match those expected on the basis of the adiabatic ring-opening mechanism, as discussed above. On the other hand, the observed ratios for 193-nm excitation clearly deviate from the expected values in some cases, and the data reveal different trends in the variations in the degree of deviation throughout the two series of compounds. For the *cis* compounds, the deviation from expected behaviour increases with ancillary ring size (being largest for **1d**), while it decreases accordingly for the *trans* compounds. In both cases, the deviation occurs in the direction of a *higher* degree of overall disrotatory stereospecificity than the adiabatic mechanism can account for.

Comparison with theoretical models

In terms of the avoided crossing model for excited state pericyclic reactions, the data suggest that in the ring-opening reaction, conversion to the ground state at the avoided crossing does not occur; the excited molecule proceeds instead to the fully open geometry corresponding to the lowest excited singlet state of the symmetry-allowed diene isomer. The excellent agreement between observed and expected diene distributions further suggests that ring opening by the symmetry-forbidden conrotatory pathway does not occur to a significant extent.

This is consistent with the theoretical calculations of Devaquet and co-workers (14) and Morihashi and Kikuchi (39), which suggest that there may be a relatively small barrier between the pericyclic (2^1A_g) minimum for excited singlet state disrotatory ring opening/closure and the lowest Franck–Condon excited singlet (^1B_u) state of *s-cis* 1,3-butadiene (39). The barrier arises as a result of an allowed crossing of the ^1B_u and 2^1A_g states at intermediate geometries for ring closure of the diene. The pericyclic minimum (at which the cyclobutenyl C3—C4 is *partially* broken) occurs on the doubly excited 2^1A_g surface, access to which must involve internal conversion from the initially populated excited state of either cyclobutene (in ring opening) or 1,3-butadiene (in ring closure). Morihashi and Kikuchi determined that the probability of internal conversion from the pericyclic minimum to the ground state, while substantially higher than that on the conrotatory side, is quite low ($\sim 10^{-4}$) (39). Thus, these calculations suggest that full formation of electronically excited *s-cis* diene by disrotatory ring opening could occur competitively with internal conversion to the ground state surface at the pericyclic minimum, providing that such a barrier is small enough.

This model for photopericyclic reactions contains the implicit assumption that product selection in a photochemical reaction occurs *on the excited state surface* after initial relaxation to the favored equilibrium geometry; i.e., that the formation of different products in a photochemical reaction involves motion along different reaction coordinates on the excited

state surface (18). Thus, the formation of *E,Z*-diene by *disrotatory* ring opening of a *cis*-3,4-disubstituted cyclobutene can only result if electronically excited *E,E*-diene is fully formed *prior* to decay to the ground state by *cis,trans* isomerization. The ramifications of these statements are actually easier to understand from the point of view of diene photochemistry: the mixture of products that is normally formed from irradiation of an *s-cis* diene (geometric isomers, cyclobutene, and the *s-trans* conformer in acyclic systems) results from partitioning amongst different *excited state* reaction coordinates, according to the avoided crossing model.

Recent theoretical calculations by Bernardi, Robb, Olivucci and their co-workers suggest a fundamentally different mechanism for such reactions, in which product formation results from evolution along a *single* (preferred) excited state reaction coordinate (21, 23). Decay to the ground state surface then occurs at a single *conical intersection* of the ground and excited state potential energy surfaces to yield a mixture of products that is dictated by the structure of the molecule at the conical intersection, the atomic trajectories that are activated as the excited molecule approaches it, and various barriers that the molecule encounters on the ground state surface as it cascades to stable products. Thus, the formation of *all* the products of direct irradiation of an *s-cis* diene is proposed to be due to funnelling through a single conical intersection of the doubly excited (2^1A_g) and ground (1^1A_g) state potential energy surfaces. At the $2^1A_g/1^1A_g$ conical intersection calculated for *s-cis* butadiene, the molecule is twisted about all three carbon–carbon bonds; the termini (the C1—C2 and C3—C4 bonds in 1,3-butadiene) are twisted in disrotatory fashion, while the central (C2—C3) bond is effectively twisted by ca. 52° as a result of pyramidalization at C2 or C3 (16, 18, 19). One particularly intriguing aspect of this mechanism is the suggestion that torsion about the terminal double bonds of a diene is *accompanied by* torsional motions about the *central* (single) bond. This contrasts expectations based on the avoided crossing model, in which *cis,trans* photoisomerization and disrotatory ring closure are both assumed to involve planarization of the four-carbon framework. We have recently published preliminary experimental evidence that provides tentative support for the importance of central bond torsional motions, and hence for the conical intersection mechanism, in the *cis,trans* photoisomerization of constrained *s-cis* dienes (29).

It seems reasonable to expect that ring opening of cyclobutene should proceed by a pathway that involves internal conversion to the ground state surface at the same conical intersection as is proposed to be involved in the photochemistry of *s-cis* 1,3-butadiene: that which is characterized by disrotatory twisting of the incipient diene double bonds *and* twisting of the central bond. In terms of reaction products, one would expect a distribution that bears a strong resemblance to that obtained from direct excitation of the corresponding diene. In general, an exact match would not be expected if the product distribution depends on the direction of approach to the conical intersection, since this would most reasonably be expected to be different for the cyclobutene and the diene.

The striking similarities in the isomeric diene distributions obtained from cyclobutene ring opening (with 214-nm excitation) and direct diene irradiation, which are observed in all but one of the present series of compounds, may indicate that, in fact, the direction of approach to the conical intersection is *approximately the same* for a given cyclobutene and its corresponding disrotatory diene. This would be the case if ring opening occurs in disrotatory fashion on the ^1B_u surface, after which rapid crossing to the 2^1A_g surface and procession to the $2^1A_g/1^1A_g$ conical intersection occurs by an identical route to that followed when the diene is excited directly.

While there is agreement that the UV resonance Raman spectrum of cyclobutene indicates there to be activation of central (C=C) bond torsional modes within a few tens of femtoseconds after excitation of the molecule (10, 11), our results suggest that large-scale motions of this type are not required for efficient ring opening. If they were, one might expect there to be *some* observable difference in the photobehaviour of **1a–d** as the incipient flexibility of the system changes throughout the series as a function of ancillary ring size. Except for *cis*-**1a**, this does not appear to be the case. There is no variation throughout the series in the degree of agreement between observed and "expected" product distributions (for 214-nm excitation), nor is there any variation in the overall quantum yields for ring opening. Furthermore, the quantum yields for ring opening of **1a–d** are unusually high, compared to monocyclic systems. These considerations suggest that (large-scale) central bond torsion can only be important *after* the ring-opening stage of the reaction (on the excited state surface) is complete.

The conical intersection model is better able to account for the observation of higher disrotatory stereoselectivity with higher excitation energy than is the avoided crossing model; higher energy excitation could provide access to a different pathway for approach of the excited molecule to the conical intersection, one that results in a higher degree of disrotatory stereoselectivity in product formation. An alternate explanation is that the higher excitation energy populates an upper electronic excited state, whose involvement somehow results in a higher degree of disrotatory stereoselectivity. We can provide no reasonable explanation (using either theoretical model) for the difference in the trends in the wavelength dependence of the *cis* and *trans* isomers of this series of compounds.

Summary and conclusions

The isomeric *s-cis* diene distributions obtained from irradiation of alkylcyclobutenes that are structurally constrained at the cyclobutenyl C=C (central) bond are, for the most part, dictated by the excited state decay characteristics of a *single* diene isomer — that which forms by adiabatic ring opening by the disrotatory pathway predicted by orbital symmetry selection rules. Thus, the overall nonstereoselectivity of the reaction is most likely the result of *stereospecific* ring opening to yield an *electronically excited* product. Both the avoided crossing and conical intersection models for photopericyclic reactions can account for the qualitative aspects of the present data, but the latter appears to do so more completely than the former.

Other aspects of the photochemistry of aliphatic dienes are potentially exploitable for further verification of the adiabatic mechanism for excited state cyclobutene ring opening, and to further address the validity of theoretical models for the process. These include photochemical *s-cis* → *s-trans* conformer interconversion (in acyclic systems) and cyclobutene forma-

tion. The former should be detectable using matrix isolation techniques, while the latter could be probed by monitoring photoracemization of an optically active cyclobutene or the interconversion of isomeric cyclobutenes, which are both linked to a single diene isomer via disrotatory ring closure. Experiments of these types are in progress.

Experimental

^{1}H NMR spectra were recorded on Bruker AM300 or AM500 spectrometers, while ^{13}C NMR spectra were recorded at 125.6 MHz on the Bruker AM500; all were recorded in deuteriochloroform (or where noted, carbon tetrachloride) solution and are reported in parts per million downfield from tetramethylsilane. Condensed phase infrared spectra were recorded on a BioRad FTS40 infrared spectrometer as neat samples or in carbon tetrachloride solution (where noted). GC/FTIR analyses were carried out using the same spectrometer, interfaced to a Hewlett–Packard 5890 gas chromatograph via a BioRad GC/C 32 interface and equipped with a DB-17 megabore capillary column (30 m × 0.53 mm; Chromatographic Specialties). Gas chromatographic analyses were carried out using a Hewlett–Packard 5890 gas chromatograph equipped with a flame ionization detector, a Hewlett–Packard 3790 recording integrator, and both conventional heated and cold on-column injectors. A DB-1 microbore capillary column (15 m × 0.2 mm; Chromatographic Specialties, Inc.) was employed in conjunction with the latter, while a DB-1 megabore capillary column (30 m × 0.53 mm; Chromatographic Specialties, Inc.) or a HP-17 megabore capillary column (15 m × 0.53 mm, Hewlett–Packard, Inc.) were used with the conventional injector. GC/MS analyses were performed using a Hewlett–Packard 5890 gas chromatograph equipped with a HP-5971A mass selective detector and a DB-1 microbore capillary column (12 m × 0.2 mm; Chromatographic Specialties, Inc.). Exact masses were determined using a VGH ZABE mass spectrometer, and employed a mass of 12.000 000 for carbon.

Semi-preparative gas chromatographic separations employed a Varian 3300 gas chromatograph equipped with a thermal conductivity detector, a Hewlett–Packard 3390A recording integrator, and one of the following stainless steel columns: (*a*) 20% TCEP on 80/100 Chromosorb PNAW (20 ft × 1/4 in., Chromatographic Specialties, Inc.); (*b*) 20% TCEP on 80/100 Chromosorb PNAW (6 ft × 1/4 in., Chromatographic Specialties); or (*c*) 3.8% UC-W982 on 80/100 Supelcoport (24 ft × 1/4 in., Supelco, Inc.).

Ultraviolet absorption spectra were recorded using a Perkin–Elmer Lambda 9 spectrometer which is interfaced with an IBM PS2 model 30-286 and controlled by software supplied by the manufacturer. The spectrometer sample compartment was continuously flushed with dry nitrogen, and the sample and reference were deoxygenated with a stream of argon prior to recording the spectrum.

Pentane (Baker Photrex), hexanes (Fisher Reagent), *n*-nonane (Matheson, Coleman & Bell), and uranyl sulfate trihydrate (Alfa Ventron) were used as received from the suppliers. Tetrahydrofuran (Caledon Reagent) was dried over calcium hydride and distilled from sodium/benzophenone. Hexamethylphosphoramide, *n*-butyllithium (2.5 M in hexane), zirconocene dichloride, iodomethane, *n*-decane, *cis,cis*-1,3-cyclooctadiene, and 1,8-nonadiyne were used as received from Aldrich Chemical Co. Cerium(IV) sulfate tetrahydrate (Aldrich) was recrystallized three times from distilled water. 1,7-Octadiyne, 1,6-heptadiyne (Wiley Organics), and 1,5-hexadiyne (Lancaster) were purified by alumina column chromatography using hexanes as the eluant. 2,6-Octadiyne, 2,7-nonadiyne, 2,8-decadiyne, and 2,9-undecadiyne were prepared according to the procedure of Negishi et al. (30), and purified by alumina column chromatography (hexanes eluant). Oxalic acid (BDH Reagent) was recrystallized three times from water. Uranyl oxalate was prepared according to the published procedure and recrystallized three times from water (40).

Synthetic photolyses employed a Rayonet photochemical reactor fitted with 12 253.7-nm lamps and a merry-go-round apparatus. Deoxygenated solutions were irradiated in a 30-mL capacity quartz cell.

The (*E,E*)-1,2-bis(ethylidene)cycloalkanes (*E,E*-**2a–d**) were prepared according to the published procedures (30, 31). The *E,Z*- and *Z,Z*- diene isomers and the bicyclic cyclobutenes *cis*- and *trans*-**1b–d** were prepared by 253.7-nm irradiation of deoxygenated 2 M pentane solutions (10.0 mL) of the corresponding *E,E* isomer. For isolation of the dienes, the irradiations were stopped after the photostationary state had been reached; more extensive irradiation times were employed for the synthesis of the cyclobutenes **1b–d**. Following irradiation, the solvent was removed by distillation and the mixtures were passed through an alumina column, eluting with hexane. Following concentration of the solutions by careful distillation, isolation and further purification were achieved by preparative gas chromatography using column (*b*). Analytical and spectroscopic data for these compounds are similar to published data for all three isomers of **2a** (vide infra) (31, 41), *E,E*- and *E,Z*-**2b** (31, 42), *E,E*- and *E,Z*-**2c** (9, 31), and *E,E*-**2d** (31). The following lists complete spectroscopic data for all new or tentatively identified compounds (*Z,Z*-**2b**, *Z,Z*-**2c**, *E,Z*-**2d**, and *Z,Z*-**2d**), as well as previously unpublished data for the others.

(E,E)-1,2-Bis(ethylidene)cyclobutane (E,E-***2a***) (31, 41): IR (gas): 2961 (m), 2929 (m), 2855 (m), 1578 (m), 1561 (s), 1416 (w), 1314 (w), 1068 (s), 1011 (s); ^{1}H NMR, δ: 1.51 (d, J = 6.9 Hz, 6H), 2.49 (br s, 4H), 5.43 (q, J = 6.5 Hz, 2H); ^{13}C NMR, δ: 13.21, 24.99, 111.47, 141.60; MS, *m/z* (*I*): 108 (45), 93 (86), 91 (96), 79 (100), 77 (83), 66 (16), 65 (17), 53 (12), 51 (39), 39 (51), 27 (41).

(E,Z)-1,2-Bis(ethylidene)cyclobutane (E,Z-***2a***) (41): IR (gas): 2962 (m), 2929 (m), 2855 (m), 1470 (s), 1382 (s), 1261 (s), 1097 (s), 1015 (s); ^{1}H NMR, δ: 1.61 (d, 3H, J = 7.0 Hz), 1.72 (d, J = 7.0 Hz, 3H), 2.48 (br s, 4H), 5.11 (cplx q, J = 7.0 Hz, 1H), 5.57 (cplx q, J = 7.0 Hz, 1H); ^{13}C NMR, δ: 13.94, 14.60, 24.98, 26.42, 116.07, 117.29, 140.22, 142.47; MS, *m/z* (*I*): 108 (33), 93 (81), 91 (89), 79 (100), 77 (97), 53 (31), 51 (49), 39 (76), 27 (51).

(Z,Z)-1,2-Bis(ethylidene)cyclobutane (Z,Z-***2a***) (41): IR (gas): 2963 (m), 2928 (m), 2866 (m), 1602 (m), 1448 (w), 1412 (w), 1261 (s), 1097 (s), 1015 (s); ^{1}H NMR, δ: 1.77 (d, J = 7.1 Hz, 6H), 2.41 (br s, 4H), 5.06 (q, J = 7.1 Hz, 2H); MS, *m/z* (*I*): 108 (44), 93 (79), 91 (84),79 (100), 77 (95), 65 (41), 53 (27), 51 (42), 39 (67), 27 (46).

(E,E)-1,2-Bis(ethylidene)cyclopentane (E,E-**2b**) (31, 42): IR (gas): 2961 (m), 2928 (s), 2855 (m), 1678 (m), 1561 (s), 1261 (s), 1101 (m), 1068 (s), 1011 (s); ^{1}H NMR, δ: 1.51 (quintet, 2H), 1.60 (d, J = 7.0 Hz, 6H), 2.23 (t, 4H), 5.21 (m, 2H); ^{13}C NMR, δ (CCl_4): 14.8, 23.8, 30.4, 111.1, 141.1; MS, *m/z* (*I*): 122 (75), 107 (45), 105 (25), 94 (35), 93 (75), 79 (50), 77 (80), 67 (35), 65 (30), 55 (25), 41 (40).

(E,Z)-1,2-Bis(ethylidene)cyclopentane (E,Z-**2b**) (42): IR (gas): 2941 (s), 2872 (m), 1641 (w), 1450 (m), 909 (m); UV (pentane), λ_{max} (ε): 249 nm (9900 M^{-1} cm^{-1}); ^{1}H NMR, δ: 1.61 (quintet, 2H), 1.74 (d, 3H), 1.79 (d, 3H), 2.35 (cplx, 4H), 5.48 (m, 1H), 5,77 (m, 1H); ^{13}C NMR, δ: 15.10, 15.41, 23.78, 31.09, 36.42, 116.06, 120.32, 141.10.

(Z,Z)-1,2-Bis(ethylidene)cyclopentane (Z,Z-**2b**; identification tentative): MS, *m/z* (*I*): 122 (21), 107 (39), 105 (20), 95 (13), 94 (45), 93 (83), 79 (50), 77 (55), 67 (47), 65 (30), 55 (40), 41 (30).

cis-*6,7-Dimethylbicyclo[3.2.0]hept-1(5)-ene* (cis-**1b**) (43): IR (gas): 2965 (s), 2900 (s), 2868 (m), 1459 (w), 1380 (w), 1337 (w), 795 (m); ^{13}C NMR, δ: 14.11, 26.32, 29.81, 38.67, 153.34; MS, *m/z* (*I*): 122 (17), 107 (21), 93 (55), 91 (38), 79 (45), 77 (35), 65 (31), 51 (34), 39 (51).

trans-*6,7-Dimethylbicyclo[3.2.0]hept-1(5)-ene* (trans-**1b**) (43): IR (gas): 2966 (s), 2901 (s), 2865 (m), 1460 (w), 1383 (w), 1331 (w), 790 (m); ^{13}C NMR, δ: 17.50, 26.20, 29.75, 44.62, 152.60; MS, *m/z* (*I*): 122 (25), 107 (20), 93 (61), 91 (43), 79 (44), 77 (37), 65 (33), 51 (41), 39 (45).

(E,E)-1,2-Bis(ethylidene)cyclohexane (E,E-**2c**) (9, 30, 31): IR (gas): 2959 (m), 2939 (s), 2857 (s), 1443 (m), 1375 (w), 1235 (w), 1001 (w), 905 (w), 843 (w), 808 (w); ^{1}H NMR, δ: 1.58 (d, 6H), 1.59 (m, 4H), 2.16 (br s, 4H), 5.26 (q, 2H); ^{13}C NMR, δ: 12.90, 26.29, 27.95, 115.71, 142.03; MS, *m/z* (*I*): 136 (45), 121 (10), 107 (45), 93 (50), 91 (65), 79 (100), 77 (50), 67 (20), 65 (20), 53 (20), 51 (19), 39 (40).

(E,Z)-1,2-Bis(ethylidene)cyclohexane (E,Z-**2c**) (9): IR (neat): 3035 (w), 2935 (s), 2860 (s), 1442 (m), 1375 (w), 1238 (w), 993 (m), 907 (m), 837 (s), 807 (m); ^{1}H NMR, δ: 1.60 (d, 3H), 1.60 (m, 4H), 1.67 (d, 3H), 2.10 (m, 2H), 2.74 (m, 2H), 5.12 (cplx, 2H); ^{13}C NMR, δ (CCl_4): 12.69, 14.11, 27.19, 27.94, 28.66, 37.89, 116.48, 118,85, 137.39, 142.16; MS, *m/z* (*I*): 136 (30), 121 (15), 107 (45), 93 (50), 91 (75), 79 (100), 77 (50), 67 (25), 65 (27), 53 (16), 51 (16), 41 (21), 39 (43).

Exact Mass, calcd. for $C_{11}H_{18}$: 150.1409; found: 150.1418.

trans-*8,9-Dimethylbicyclo[5.2.0]non-1(7)-ene* (trans-**1d**): IR (gas): 2966 (m), 2920 (s), 2866 (m), 1459 (m), 1378 (w), 977 (w), 831 (w), 815 (w); ^{1}H NMR, δ: 1.02 (d, J = 7 Hz, 6H), 1.51 (br s, 4H), 1.58 (cplx m, 4H), 1.95 (cplx m, 4H); ^{13}C NMR, δ: 16.96, 28.53, 29.07, 29.69, 44.11, 146.22; MS, *m/z* (*I*): 150 (33), 135 (17), 121 (39), 107 (42), 105 (22), 93 (99), 91 (77), 81 (25), 79 (100), 77 (61), 67 (39), 65 (25), 55 (16), 53 (25), 39 (52), 27 (29). Exact Mass, calcd. for $C_{11}H_{18}$: 150.1409; found: 150.1409.

The irradiation of *E,Z*-**2b,c** also yielded minor amounts of hydrogen migration products, which were identified as 1-ethyl-2-vinylcyclopentene from *E,Z*-**2b**, and 2-ethyl-3-ethylidenecyclohexene from *E,Z*-**2c**:

1-Ethyl-2-vinylcyclopentene: ^{1}H NMR, δ: 0.98 (t, 3H, J = 7 Hz), 1.80 (t, 2 H), 2.22 (cplx q, 2 H), 2.44 (cplx, 2H), 4.97 (cplx t, 1 H), 5.02 (cplx m, 1 H), 6.65 (dd, 1 H); ^{13}C NMR, δ:

12.87, 21.41, 32.43, 36.26, 112.37, 131.04, 133.31, 144.51; MS, *m/z* (*I*): 122 (20); 107 (23); 93 (60); 91 (64); 79 (100); 77 (53); 65 (17); 51 (15); 39 (27); 27 (17).

2-Ethyl-3-ethylidenecyclohexene: ^{1}H NMR, δ: 1.02 (t, 3H, *J* = 7.2 Hz), 1.63 (br t, 2H), 1.67 (d, 3H, *J* = 6.8 Hz), 2.09 (br m, 2H), 2.14 (cplx q, 2H), 2.26 (br t, 2H), 5.43 (q, 1H); 5.49 (br t, 1 H); ^{13}C NMR, δ: 13.01, 13.41, 22.59, 25.44, 25.52, 25.72, 115.78, 123.04, 135.09, 138.57. MS, *m/z* (*I*): 136 (25); 121 (7); 107 (100); 93 (31); 91 (97); 79 (99); 77 (55); 65 (21); 51 (17); 41 (18); 39 (30).

Preparation of cis- *and* trans-*2,3-dimethylbicyclo[2.2.0]hex-1(4)-ene* (cis- *and* trans-***1a***)

In a flame-dried, 150-mL two-necked flask, fitted with an addition funnel, magnetic stirrer, reflux condenser, and nitrogen inlet, were placed (±)-2,3-butanediol di-*p*-tosylate (19.90 g, 0.05 mol) and tetrahydrofuran (50.0 mL). The system was purged with dry nitrogen and then cooled with an external isopropanol – Dry Ice bath to −78°C, after which a solution of lithium trimethylsilylacetylide (generated from trimethylsilylacetylene (9.82 g, 0.1 mol) and *n*-butyllithium) in tetrahydrofuran (25 mL) was added dropwise over a period of 1 h with vigorous stirring. The resulting solution was stirred for an additional hour at −78°C, allowed to warm to room temperature, and then quenched with ice (20 g) and extracted with pentane (3 × 10 mL). The combined extracts were dried with sodium sulfate, filtered, and the solvent was evaporated to yield a colourless oil that was tentatively identified as 3,4-dimethyl-1,6-bis(trimethylsilyl)-1,5-hexadiyne (4.75 g, 0.019 mol, 38%) on the basis of its ^{1}H NMR and mass spectra: ^{1}H NMR, δ ($CDCl_3$): 0.11 (s, 9H), 1.71 (d, 3H), 5.01 (q, 1H); MS, *m/z* (*I*): 235 (13), 207 (3), 162 (75), 161 (43), 156 (2), 147 (22), 138 (13), 110 (14), 96 (14), 83 (12), 81 (11), 73 (100), 59 (12), 43 (11). The material was used without further purification in the following step.

In a flame-dried, 50-mL two-necked flask fitted with magnetic stirrer, addition funnel, reflux condenser, and gas inlet were placed zirconocene dichloride (2.92 g, 0.01 mol) and tetrahydrofuran (15 mL). The system was purged with dry nitrogen and cooled to −78°C with an external Dry Ice bath. A solution of *n*-butyllithium (0.02 mol) in tetrahydrofuran (5 mL) was added dropwise with stirring over a period of 1 h. After stirring at −78°C for an additional hour, a deoxygenated solution of 3,4-dimethyl-1,6-bis(trimethylsilyl)-1,5-hexadiyne (2.50 g, 0.01 mol) in tetrahydrofuran (5 mL) was added to the reaction mixture by means of a double-headed needle. The resulting solution was stirred at −78°C for an additional 3 h, warmed to room temperature, quenched with ice (20 g), and extracted with pentane (3 × 10 mL). The extracts were combined, the solvent was evaporated, and the residue (1.74 g) was dissolved in dichloromethane (10 mL) and placed in a 25-mL roundbottom flask. Trifluoroacetic acid (3.0 mL) was added and the mixture was stirred for 12 h at room temperature. The resulting brown reaction mixture was quenched with water (10.0 mL) and extracted with pentane (3 × 5 mL). The extracts were combined, dried over sodium sulfate, filtered, carefully distilled to remove the solvent, and finally bulb-to-bulb distilled under vacuum to yield a colourless liquid (0.73 g, 66%) that contained two major isomeric products according to GC/MS analysis. Small (ca. 10 mg) quantities of the two components were isolated by semi-preparative GC (column *c*), and identified as *cis*- and *trans*-3,4-dimethyl-1,2-(bis)-methylenecyclobutane (*cis*- and *trans*-**7**) on the basis of comparison of their ^{1}H NMR spectra to the published data (41).

The remaining portion of the mixture from above was dissolved in pentane (5 mL), placed in a quartz irradiation tube, and sealed with a rubber septum. The solution was deoxygenated with a stream of N_2, and photolysed (253.7 nm) to ca. 70% conversion. GC and GC/MS analysis indicated the formation of two major products, which were isolated and purified by semi-preparative GC (column *a*), and identified as *cis*- and *trans*-**1a** on the basis of their GC retention times, ^{1}H NMR, UV, and mass spectra (see below). As is also known to be the case for the parent compound, bicyclo[2.2.0]hex-1(4)-ene, *cis*- and *trans*-**1a** are relatively unstable compounds, with half-lives of ca. 15 h in pentane solution (1×10^{-2} M) at 25°C. The samples were stored under liquid nitrogen prior to their use in photolysis experiments.

cis-*2,3-Dimethylbicyclo[2.2.0]-hex-1(4)-ene* (cis-***1a***): IR (gas): 2962 (s), 2929 (s), 2872 (m), 2855 (m), 1450 (w), 1381 (w), 1353 (w), 1261 (m), 1101 (m); ^{1}H NMR, δ: 1.60 (d, *J* = 6.5 Hz, 6H), 1.76 (cplx m, 4H), 2.21 (q, *J* = 7.2 Hz, 2H); MS, *m/z* (*I*): 108 (39), 93 (78), 91 (83), 79 (100), 77 (94), 66 (24), 65 (29), 53 (29), 51 (41), 39 (63), 27 (41).

trans-*2,3-Dimethylbicyclo[2.2.0]-hex-1(4)-ene* (trans-***1a***): IR (gas): 2962 (s), 2929 (s), 2872 (w), 2856 (w), 1451 (w), 1261 (m); ^{1}H NMR, δ: 1.60 (d, *J* = 6.5 Hz, 6H), 1.76 (cplx m, 4H), 2.14 (cplx m, 2H); MS, *m/z* (*I*): 108 (40), 93 (96), 91 (96), 79 (95), 77 (100), 66 (23), 65 (27), 53 (33), 51 (44), 39 (64), 27 (42).

Quantitative photolyses employed a Rayonet photochemical reactor fitted with a merry-go-round and two 253.7 nm lamps, a 16-W Phillips 93106E Zn resonance lamp (214 nm) either alone or in conjunction with a 214 nm interference filter (Acton Research Corp. 214-B-ID), or the unfocussed pulses from a Lumonics 510 excimer laser containing Ar/F_2/He mixtures (193 nm, ca. 15 ns, 20 mJ, 0.5 Hz repetition rate). Solutions were contained in 5-mm quartz tubes sealed with rubber septa for 214 nm or 253.7 nm photolyses, or 1 × 2.5-cm round Suprasil UV cells (sealed with rubber septa) for 193 nm photolyses, and were deoxygenated with a stream of dry nitrogen or argon prior to irradiation. *n*-Decane was employed as an internal GC standard in all cases; the VPC detector responses were calibrated using solutions of known concentrations of substrate and standard. The solutions were vigorously stirred with a magnetic stirrer during the photolyses.

Quantum yields for product formation from 253.7 nm irradiation of dienes **2a–d** were carried out by ferrioxalate actinometry (44, 45), using 0.02 M solutions in pentane, and are the averages of triplicate single point determinations taken at conversions of 10% or less.

Quantum yields for product formation from 214-nm irradiation of *cis*- and *trans*-**1a** were carried out on unstirred solutions, using the initial slopes of product concentration vs. time plots to determine product yields, and uranyl oxalate actinometry (40, 44, 46) to determine light intensities.

Quantum yields for product formation from 193-nm irradiation of cyclobutenes **1b–d** were determined using the irradiation of bicyclo[4.2.0]oct-7-ene as the actinometer (1).

Irradiation of substrate and actinometer were followed as a function of light dose between 0.5 and 5% conversion, and quantum yields were determined from the slopes of concentration vs. time plots after correction of the raw data with the corresponding GC response factors.

On the stability of endohedral rare gas fullerenes

Dennis P. Clougherty

Abstract: The stability of $He@C_{60}$ and $Ne@C_{60}$ is discussed in the context of a spherical model where the carbon atoms are smeared out into a uniform shell. The electronic properties of the 60 π-electrons together with those of the central atom are treated in the Thomas–Fermi approximation. Simple electrostatic reasoning elucidates the nature of the radial stability of the complex. A method to include nonspherical corrections is outlined. Possible bonding topologies of the central atom and the C_{60} cage are discussed, as well as the relevance of these topologies to incipient central atom distortions.

Key words: fullerenes, Thomas–Fermi, dopeyball, $He@C_{60}$, $Ne@C_{60}$.

Résumé : On discute de la stabilité des $He@C_{60}$ et $Ne@C_{60}$ dans le contexte d'un modèle sphérique dans lequel les atomes de carbone sont répartis dans une coquille uniforme. On a traité les propriétés électroniques des 60 électrons π avec ceux de l'atome central par l'approximation de Thomas–Fermi. Un raisonnement électrostatique simple permet d'élucider la nature de la stabilité radiale du complexe. On décrit une méthode permettant d'inclure des corrections non sphériques. On discute des topologies de liaison possibles de l'atome central et de la cage C_{60} ainsi que de ces topologies par rapport aux distorsions qui naissent de l'atome central.

Mots clés : fullerènes, Thomas–Fermi, dopeyball, $He@C_{60}$, $Ne@C_{60}$.

[Traduit par la rédaction]

I. Introduction

An interesting consequence of the closed cage structure of C_{60} is that atoms and molecules may be trapped inside, forming endohedral complexes ("dopeyballs"). A variety of such complexes have been produced (1) where the dopant may be a metallic or a rare gas atom/cluster. The electronic structure and mechanical stability of two such endohedral rare gas complexes, $He@C_{60}$ and $Ne@C_{60}$, are considered here.

It has previously been noted (2) that the high symmetry of the C_{60} cage suggests the following geometrical approximation: the one-electron potential of icosahedral symmetry is replaced with its spherical average. Physically, the nuclear charge together with the charge from the core electrons is smeared out into a thin spherical shell of uniform surface charge density and radius R. Such a fictitious molecule — "spherene" — has complete spherical symmetry.

In the case of metallofullerenes such as $Na@C_{60}$, it has been shown (3) that the equilibrium position of the dopant is not at the center of the cage, consequently reducing the symmetry of the complex. For rare gas dopants, however, it was previously asserted (1) that there is no such symmetry reduction. Additionally, previous calculations (4) on $Ne@C_{60}$ indicate that the dopant is stable at the center. Consequently, given the large coordination number of the gas atom and the lack of a distortion from the high symmetry configuration, endohedral rare gas fullerenes seem to be good candidates for the spherical approximation.

The endohedrally doped spherene is treated in the Thomas–Fermi approximation. It is anticipated that the highly delocalized π-electrons of the cage and the closed shell configuration of the gas atom are well suited to such a statistical description. This method of treating high symmetry molecules was originally suggested by March (5).

The cage is parametrized by the radius R and valence electron number N, while the gas atom has nuclear charge Z and an equal number of electrons. The total electron density is calculated using the Thomas–Fermi equations, subject to the shell boundary conditions.

The total energy of the system is calculated for a variety of radii. A stable equilibrium radius is obtained, when the cage self-energy is computed from the system of ionic point charges, rather than from the continuum model. A method of treating nonspherical corrections is outlined. Lastly, possible central atom distortions are discussed in the context of the Bader molecular graphs arising from the electron density.

II. Thomas–Fermi theory of dopeyballs

The nuclear potential from the central atom and the cage atoms can be expanded in a multipole series as

$$[1] \qquad V_n(r) = \sum_{\ell,m} \frac{1}{r^{\ell+1}} \sqrt{\frac{4\pi}{2\ell+1}}\, Q_{\ell m} Y^*_{\ell m}(\Omega)$$

$Q_{\ell m}$ is the 2^ℓ-pole moment, given by

Received October 11, 1995.

[2] $$Q_{\ell m} = eR^{\ell}\sqrt{\frac{4\pi}{2\ell+1}}\sum_i Y_{\ell m}(\Omega_i) + Ze\delta_{\ell 0}$$

where Z is the atomic number of the rare gas atom of interest. From the icosahedral symmetry of the molecule, it has been shown (2) that the first three nonvanishing multipole moments are for ℓ =0, 6, 10. As the occupied one-electron states have an effective $\ell = 5$, it is not necessary to consider $\ell > 10$ multipole terms in first-order perturbation theory.

The spherical approximation consists of retaining only the $\ell = 0$ term in the multipole expansion. The error introduced can be estimated by consideration of the relevant dimensionless parameters

[3] $$\alpha_{\ell m} = \left|\sqrt{\frac{4\pi}{2\ell+1}}\,\frac{Q_{\ell m}}{R^{\ell}Q_{00}}\right|$$

The following values are found as functions of Z: $\alpha_{6,0} = 0.026/(1+Z)$, $\alpha_{6,5} = 0.020/(1+Z)$, $\alpha_{10,0} = 0.021/(1+Z)$, and $\alpha_{10,5} = 0.034/(1+Z)$. As $\alpha_{\ell m} << 1$ for $\ell \leq 10$, it may be concluded that the spherical approximation is justified for such a high symmetry structure, and one-electron splittings under the true icosahedral symmetry can be treated perturbationally.

With spherical symmetry imposed, the endohedral cluster is quasi-atomic in form. The 60 π-electrons of the cage plus the Z electrons of the central atom are now treated in the Thomas–Fermi (TF) approximation where the $Z+N$ electrons see a point charge of Ze at the origin and a uniform shell of charge Ne and radius R. The methodology follows that of March (5).

At temperature $T = 0$, the dimensionless TF equation without exchange is given by

[4] $$\frac{d^2\phi}{dx^2} = \frac{\phi^{3/2}}{x^{1/2}}$$

x is the distance from the center of the shell in units of

[5] $$b = \frac{1}{4}\left[\frac{9\pi^2}{2Z}\right]^{1/3} a_0$$

where a_0 is the Bohr radius of hydrogen. ϕ is related to the potential in the usual way

[6] $$V(r) = \frac{Ze}{r}\,\phi(x)$$

Equation [4] is supplemented with the boundary conditions: $\phi(0) = 1$, and

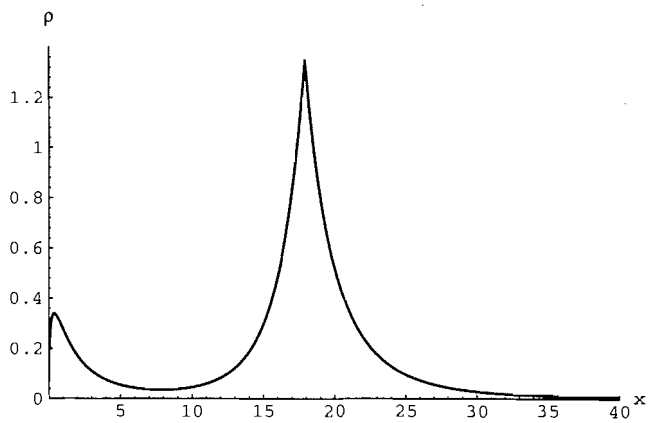
[7] $$\phi'(X^-) - \phi'(X^+) = \frac{N}{ZX}$$

where X is the shell radius in dimensionless units and differentiation is with respect to x. Additionally, ϕ itself is continuous over its domain, and $\phi \rightarrow 0$ as $x \rightarrow \infty$.

III. Numerical results

$\phi(r)$ is found by numerical integration of eq. [4] subject to the above boundary conditions. The charge density $n(r)$ and total electronic energy E_e are subsequently obtained from $\phi(r)$, as

Fig. 1. Radial electron density for Ne@C_{60} (in units of $10/b$) vs. x for $R = 7.36a_0$.



[8] $$n(x) = \frac{Z}{4\pi b^3}\left[\frac{\phi(x)}{x}\right]^{3/2}$$

and

[9] $$E_e = \frac{3Z^2e^2}{7b}\left[\phi'(0) + \frac{4N}{3Z}\,\frac{\phi(X^-)}{X} - \frac{N}{3Z}\,\phi'(X^-) - \left(\frac{N}{Z}\right)^2\frac{1}{X} - \frac{7N}{3Z}\,\frac{1}{X}\right]$$

as was obtained by March. The radial electron density of Ne@C_{60} is given as an example in Fig. 1.

The electronic energy E_e is found for various values of the dimensionless cage radius X in the cases of Z = 2 and 10, corresponding to He@C_{60} and Ne@C_{60}, respectively. As the boundary condition for ϕ at the shell explicitly depends on Z, E_e will not have simple "atomic" scaling with Z ($E_e \sim Z^{7/3}$).

If we add to E_e the electrostatic self-energy of the continuum shell, U, it is found that this total energy $E = E_e + U$ does not have a minimum for finite X, in accord with Teller's no-binding theorem (6) for molecules in TF theory. The continuum shell self-energy is too large and dominates E_e. However, if the self-energy is evaluated as a sum over point ions distributed on the shell surface, an energy minimum at finite shell radius is found. The spherical approximation is abandoned for the purpose of calculating the potential energy for the nuclear configuration.

The self-energy of the nuclear configuration may be written in the form

[10] $$U = \frac{ZNe^2}{bX} + c\,\frac{N^2e^2}{bX}$$

where c is a dimensionless number, computed from the actual equilibrium coordinates of C_{60}. It was previously (2) computed as $c = 0.43101$.

The total energies for He@C_{60} and Ne@C_{60} as a function of the shell radius are displayed in Figs. 2 and 3. The resulting equilibrium radii, R_0, are listed in Table 1, together with the total energies for the equilibrium configuration. Previous results for C_{60} are provided for comparison.

The expansion of the equilibrium cage radius with in-

Z	R	E
0[a]	7.35	−25.313
2	7.41	−32.98
10	7.64	−356.30

[a]Reference 2.

creasing Z is observed, in agreement with a previous restricted Hartree–Fock calculation (4). It should, however, be noted that c is a result of the detailed atomic positions in C_{60}. Certainly, distortions that do not preserve the relative positions of cage ions will give rise to changes in c and, consequently, to changes in R_0. It is also interesting to note that the monotonic increase of R_0 with Z does not follow the "atomic size" scaling relation ($D \sim Z^{-1/3}$).

The shell equilibrium can be understood from electrostatic considerations. At equilibrium, the centrifugal force on the shell resulting from self-interaction is balanced by the centripetal force exerted on the shell by the charge contained inside the shell. The total charge contained inside the shell at equilibrium is $-cNe \approx -25.86e$, and the total number of electrons inside the shell is $(Z+cN)$. Thus we see that endohedral fullerenes whose central atoms have higher Z require more electrons inside the shell to maintain equilibrium.

IV. Beyond spherene

While approximating the discrete cage ions by a uniform spherical shell is a valid approximation with regard to the total energy, it is the corrections to the spherical average that contain all the information regarding the bonding. The spherical approximation reduces the complex to a one-dimensional system. The consequent critical points in the electron density consist of only minima and maxima, and an analysis of the bonding topology requires consideration of the effects of the nuclear multipole moments $\ell > 0$. A method for finding the electron density corrugations of endohedral fullerenes is given below.

To treat these nonspherical contributions, one must return to the general TF equation,

$$[11] \qquad \nabla^2 V = \beta V^{3/2} - 4\pi\rho_+$$

where $\beta = \dfrac{32\pi^2 e^2}{3h^3}(2m)^{3/2}$ and ρ_+ is the (positive) nuclear charge density.

ρ_+ can be expressed as a sum of spherical harmonics,

$$[12] \qquad \rho_+(\boldsymbol{r}) = Ze\delta(\boldsymbol{r}) + \frac{\delta(r-R)}{r^2}\frac{Ne}{4\pi} + \Delta\rho$$

where

$$[13] \qquad \Delta\rho = \frac{\delta(r-R)}{r^2}\sum_{\substack{\ell,m \\ \ell\geq 1}} R^{-\ell}\sqrt{\frac{2\ell+1}{4\pi}}\, Q_{\ell m}\, Y_{\ell m}(\Omega)$$

The potential V is now written as

$$[14] \qquad V(\boldsymbol{r}) = V_0(r) + \zeta(\boldsymbol{r})$$

where V_0 is the spherically averaged solution and ζ results from consideration of the higher order multipole moments. It is assumed that ζ is much smaller than V_0. Thus, eq. [11] leads to a linearized equation for ζ

$$[15] \qquad \nabla^2\zeta = \frac{3}{2}\beta V_0^{1/2}\zeta - 4\pi\Delta\rho$$

Equation [15] is of the form of the single particle Schrödinger equation at zero energy with a central "potential," $\frac{3}{2}\beta V_0^{1/2}$, which is everywhere positive, and a nonhomogeneous boundary term. ζ may be expanded in spherical harmonics inside and outside $r = R$, and the boundary term gives rise to a discontinuity in the radial derivative of ζ. Thus,

$$[16] \qquad \zeta(\boldsymbol{r}) = \sum_{\ell m}\zeta_{\ell m}(r)Y_{\ell m}(\Omega)$$

where $\zeta_{\ell m}$ satisfies the following

$$[17] \qquad \left(\frac{d^2}{dr^2} - \frac{3}{2}\beta V_0^{1/2} - \frac{\ell(\ell+1)}{r^2}\right) r\zeta_{\ell m}(r) = 0$$

and is subject to the following boundary conditions

$$[18] \quad r\zeta_{\ell m} \rightarrow 0, \qquad \text{as } r \rightarrow 0$$

$$[19] \quad r\zeta_{\ell m} \rightarrow 0, \qquad \text{as } r \rightarrow \infty$$

$$[20] \quad \frac{\mathrm{d}}{\mathrm{d}r}(r\zeta_{\ell m})\Big|_{r=R^-}^{R^+} = -R^{-\ell-1}\sqrt{4\pi(2\ell+1)}Q_{\ell m}$$

As the effective "potential" in eq. [17] is positive for all r, only exponential solutions are possible for ζ. Without a discontinuity in the radial derivative, only the trivial solution would satisfy the boundary conditions at the origin and at infinity. Thus, $\zeta_{\ell m}$ is non-zero only when $Q_{\ell m}$ is non-zero. The first nonspherical corrections to the potential and the electron density then are at $\ell = 6$, 10. Not surprisingly, these ℓ values correspond to irreducible representations of the rotation group that contain the trivial representation (A_g) of I_h. It is interesting to note that the centrifugal term in the effective "potential" will reduce the contributions from large ℓ to the density.

V. Structure and bonding

The simplest bonding configuration consistent with the symmetry constraints is that of 60 bonds between the central atom and the carbon atoms in the cage. However, a second possibility was proposed on the basis of an ab initio calculation (4) on Ne@C_{60}. There, it was found that with the Ne atom in the center of the cage, 30 bond paths exist, starting on the Ne atom and terminating on the carbon–carbon double bond points. Is this a stable configuration with respect to central atom displacement?

While the total energy calculations in ref. 4 indicate that Ne is in a stable equilibrium at the center of the cage, unless the bond point at the carbon–carbon double bond is a nonnuclear attractor (8) ("pseudoatom"), it would seem that the bonding topology found in ref. 4 may correspond to that of the metastable state described by Bader (7) as a "conflict structure."

Given that the Na^+ is isoelectronic with Ne, and that Na^+ in $Na^+@C_{60}$ does distort along a fivefold axis, a similiar instability in Ne@C_{60} would seem possible. The possible incompatibility of the molecular graph with the total energy calculations indicates that additional study is warranted, and central atom distortions in rare gas endohedral fullerenes remain as an intriguing possibility.

Local energy and chemical potential equations and the exchange-correlation potential

N.H. March

Abstract: Local energy and chemical potential equations are considered in some detail in relation to low-order density matrices. Some asymptotic properties can be extracted in exact form. The spatial derivative of the chemical potential equation referred to above yields the external force, defined as the (negative of the) gradient of the potential energy of the nuclear framework. This quantity, by utilizing the differential virial theorem, can be expressed as a sum of three terms: (*i*) a Laplacian contribution known explicitly in terms of the ground-state electron density; (*ii*) a kinetic part derivable from the "near-diagonal" behaviour of the first-order density matrix; and (*iii*) a term from electron–electron interactions, that involves the electronic pair correlation function. Following the work of Holas and March, this allows the exchange-correlation potential of density functional theory to be expressed in terms of low-order density matrices. Finally, scaling of electron–electron interactions is briefly considered, as well as the adiabatic connection formula in density functional theory. Such scaling arguments lead to a kinetic correction to the Harbola–Sahni form of the exchange-only potential.

Key words: external force, first-order density matrix, electronic pair function.

Résumé : On considère en détail les équations de l'énergie locale et des potentiels chimiques en relation avec des densités de matrices d'ordre peu élevé. On peut extraire quelques propriétés asymptotiques dans une forme exacte. La dérivé spatiale de l'équation du potential chimique mentionné plus haut fournit le force externe, définie comme la valeur négative du gradient de l'énergie potentielle du squelette nucléaire. Cette quantité, en utilisant le théorème de la différentielle viriale, peut être exprimée sous la forme de la somme de trois termes : (*i*) une contribution d'un laplacien connue explicitement en termes de densité électronique de l'état fondamental; (*ii*) un partie cinétique que l'on peut dériver à partir du comportement «practiquement diagonal» de la matrice de densité du premier ordre et (*iii*) une partie des interactions électron–électron qui implique la fonction de corrélation d'une paire électronique. À la suite du travail de Holas et March, ceci permet d'exprimer le potentiel de corrélation d'échange de la théorie de la densité fonctionnelle en termes de matrices de densité d'ordre peu élevé. Finalement, on considére briévement la possibilité d'échelonner les interactions électron–électron ainsi que la formula de connexion adiabatique dans la théorie de la densité fonctionnelle. De tels arguments d'échelonnage conduisent à une correction cinétique à la forme de Harbola–Sahni du potentiel uniquement d'échange.

Mots clés : force externe, densité du premier ordre, fonction d'une paire électronique.

[Traduit par la rédaction]

1. Introduction

Richard Bader spent a year in Europe around 1980, and half of that period in the Theoretical Chemistry Department in Oxford. I hope we were not too sleepy when Richard arrived: we were certainly wide awake when he left!! For me, that visit and the friendship that built up as a result were very important. We found opportunity to interact, even though Richard was very busy with "Atoms in Molecules" theory (1) and paid many visits to other departments in the U.K. and Europe during his stay. Two things resulted directly from our scientific collaboration: (*i*) a joint contribution in Physics Letters (2) that addressed the question of the relation of the chemical potential μ of density functional theory to the ionization potential I and (*ii*) a short piece in my review (3) on "Topology of Molecular Charge Distributions," a topic I could not have included at that time without his help and advice. These two things have influenced my own thinking a lot and will provide some focal points for the present article in this issue honouring Richard.

Let us start by contrasting the local chemical potential equation, referred to in (*i*) above, with the local energy equation. The first of these equations is the Euler–Lagrange equation of density functional theory (DFT) while the second comes directly from the many-electron Schrödinger equation. In both cases the discussion below will be confined almost exclusively to the ground state, and the second equation referred to above can be viewed as expressing the ground-state energy E of the atom or molecule under consideration as $E = H\Psi/\Psi$, with H the many-electron Hamiltonian. Of course, the N-electron wave function Ψ should be antisymmetrical in the interchange of space plus spin coordinates for any pair of electrons (spin will usually be suppressed below

Received September 27, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

N.H. March.[1] 6, Northcroft Road, Egham, Surrey TW20 ODU, England.

[1] Emeritus Professor, Oxford University, England.

for notational convenience). But whereas the local chemical potential equation can be written formally as

$$[1] \qquad \mu = \text{K.E}|_r + \text{P.E}|_r$$

where the kinetic and potential terms, dependent on a single position vector $\boldsymbol{r}$, are to be defined precisely below; the local energy E above involves N vectors. However, by introducing low-order density matrices, we shall show that considerable reduction of these variables is also again feasible (4, 5).

2. Definitions of density matrices and local energy equation

Let us first define the density matrices in terms of the many-electron wave function (6–8). Then an alternative, and of course equivalent, definition will be given in the language of second quantization and this will be employed to derive the local energy in terms of density matrices.

The second-order density matrix $\gamma_2(\boldsymbol{r}_1,\boldsymbol{r}_2;\boldsymbol{r}'_1,\boldsymbol{r}'_2)$ is defined from the normalized, anti-symmetric N-electron wave function by

$$[2] \qquad \gamma_2(\boldsymbol{r}_1, \boldsymbol{r}_2; \boldsymbol{r}'_1, \boldsymbol{r}'_2) = \frac{N(N-1)}{2} \int \Psi^*(\boldsymbol{r}_1, \boldsymbol{r}_2, \boldsymbol{r}_3 \ldots \boldsymbol{r}_N) \times \Psi(\boldsymbol{r}'_1, \boldsymbol{r}'_2, \boldsymbol{r}_3 \ldots \boldsymbol{r}_N)\mathrm{d}\boldsymbol{r}_3 \ldots \mathrm{d}\boldsymbol{r}_N$$

The other central quantity for the present study is the first-order density matrix $\gamma(\boldsymbol{r}_1,\boldsymbol{r}'_1)$. This is defined by

$$[3] \qquad \gamma(\boldsymbol{r}_1, \boldsymbol{r}'_1) = N \int \Psi^*(\boldsymbol{r}_1, \boldsymbol{r}_2 \ldots \boldsymbol{r}_N) \times \Psi(\boldsymbol{r}'_1, \boldsymbol{r}_2 \ldots \boldsymbol{r}_N)\mathrm{d}\boldsymbol{r}_2 \ldots \mathrm{d}\boldsymbol{r}_N$$

The basic quantity of density functional theory (DFT) — the electron number density $n(\boldsymbol{r})$ — is evidently the diagonal element $\gamma(\boldsymbol{r},\boldsymbol{r})$ of the first-order density matrix. The diagonal element of the second-order matrix is the important electronic pair correlation function $n_2(\boldsymbol{r},\boldsymbol{r}') = \gamma_2(\boldsymbol{r},\boldsymbol{r}';\boldsymbol{r},\boldsymbol{r}')$. For a single determinant ground-state wave function, such as obtains in the Slater–Kohn–Sham reference system or in the Hartree–Fock method, the first-order density matrix is idempotent, i.e., $\gamma^2 = \gamma$. For a fully interacting electronic assembly, this equality is replaced by the inequality $\gamma^2 < \gamma$ reflecting the Pauli Principle requirements.

2.1 Alternative and equivalent definitions: second quantized form

Following Dawson and March (4), we define as an alternative to eqs. [2] and [3] the first- and second-order density matrices in the language of second quantization as ($1 \equiv \boldsymbol{r}_1$ etc):

$$[4] \qquad \gamma(1; 1') = \langle N|\psi^+(1')\psi(1)|N\rangle \equiv \langle\psi^+(1')\psi(1)\rangle$$

and

$$[5] \qquad \gamma_2(1, 2; 1', 2') = \langle N|\psi^+(1')\psi(2')\psi(2)\psi(1)|N\rangle \equiv \langle\psi^+(1')\psi(2')\psi(2)\psi(1)\rangle$$

The three-particle or third-order density matrix constitutes an obvious generalization of the definitions [4] and [5].

Next one defines the time-dependent operator

$$[6] \qquad \psi(1, t) = \mathrm{e}^{iHt/\hbar}\psi(1)\mathrm{e}^{-iHt/\hbar}$$

which obeys the equation of motion

$$[7] \qquad ih\frac{\partial\psi(1, t)}{\partial t} = [\psi(1, t), H]$$

In this eq. [7], H denotes the second quantized Hamiltonian for interacting electrons moving in the external field generated by the nuclear framework. Employing this form of H, together with eq. [7], one is led to the result

$$[8] \qquad i\hbar\frac{\partial\psi(1, t)}{\partial t} = \frac{-\hbar^2}{2m}\nabla_1^2\psi(1, t) + V_n(1)\psi(1, t) + \int u(1-2)\psi^+(2, t)\psi(2, t)\psi(1, t)\mathrm{d}2$$

It can readily be proved that

$$[9] \qquad \gamma(1, t; 1', t) = \langle\psi^+(1', t)\psi(1, t)\rangle$$

is time independent for the Hamiltonian H defined above. Setting therefore its time derivative to zero, and using eq. [8] plus definitions one finds

$$[10] \qquad \frac{-\hbar^2}{2m}(\nabla_1^2 - \nabla_{1'}^2)\gamma(1, 1') + [V_n(1) - V_n(1')]\gamma(1, 1') + \int [u(1-2) - u(1'-2)]\gamma_2(1, 2; 1', 2)\mathrm{d}2 = 0$$

Further use of the quantity

$$[11] \qquad \left[i\hbar\frac{\partial}{\partial t}\langle\psi^+(1', t)\psi(1, t)\rangle\right]_{t=0} \equiv \langle\psi^+(1')\psi(1)H\rangle - \langle\psi^+(1')H\psi(1)\rangle$$

and eq. [8] leads then, after some further manipulation, to the desired result

$$[12] \qquad E\gamma(1:1') = \{\hat{t}_1 + V_n(\mathbf{1})\}\gamma(1:1') + 2\int \mathrm{d}2\{\hat{t}_2 + V_n(\mathbf{2}) + u(12)\}\gamma_2(\mathbf{12}; \mathbf{1'2'}) + 3\int \mathrm{d}\mathbf{2}\,\mathrm{d}\mathbf{3}\,u(\mathbf{23})\gamma_3(\mathbf{123}; 1'23)$$

Here $\hat{t}_i$ denotes simply $-\frac{1}{2}\nabla_i^2$. Next we integrate both sides of eq. [12] over $\mathrm{d}\mathbf{1}$ (after replacing $1'$ by 1)

$$[13] \qquad EN = \int \mathrm{d}\mathbf{1}\{\hat{t}_1 + V_n(\mathbf{1})\}\gamma(\mathbf{1}:1') + 2\int \mathrm{d}\mathbf{1}\,\mathrm{d}\mathbf{2}\{\hat{t}_2 + V_n(\mathbf{2}) + u(12)\}\gamma_2(\mathbf{12}; \mathbf{12'}) + 3\int \mathrm{d}\mathbf{1}\,\mathrm{d}\mathbf{2}\,\mathrm{d}\mathbf{3}\,u(\mathbf{23})\gamma_3(\mathbf{123}; 123)$$

Using reduction properties of density matrices, we can

rewrite eq. [13] as

$$[14]\qquad EN = \left(1+2\frac{N-1}{2}\right)\int \mathrm{d}\mathbf{1}\{\hat{t}_1 + v(1)\}\gamma(\mathbf{1};\mathbf{1}') + \left(2+3\frac{N-2}{3}\right)\int \mathrm{d}\mathbf{1}\,\mathrm{d}\mathbf{2}\,u(\mathbf{12})\gamma_2(\mathbf{12};\mathbf{12})$$

i.e., the well-known expression for the total energy in terms of γ and γ_2.

Having established that eq. [12] leads back to the correct result, eq. [14], for the total energy of the N-electron system, the final step in obtaining the local energy equation paralleling the chemical potential eq. [1] is to put $\mathbf{1}' = 1$ in eq. [12] and to divide both sides by the electron density $n(\boldsymbol{r})$. Then one has the local energy equation, with $t(\boldsymbol{r})$, the kinetic energy density, as (9, 10)

$$[15]\qquad E = \frac{t(\boldsymbol{r})}{n(r)} + V_n(\boldsymbol{r}) + 2\int \mathrm{d}2(\hat{t}_2 + V_n(2) + u(12))\gamma_2(12;12')/n(r) + 3\int \mathrm{d}2\,\mathrm{d}3\,u(23)\gamma_3(123;1'23)/n(r)$$

As already anticipated, this equation now expresses the local energy E, constant throughout the charge cloud of the molecule, as a sum of terms, each of which depends only on a single vector $\boldsymbol{r}$, just as in eq. [1] for μ, but which involve individually density matrices up to, and including, order 3.

One obvious use of eq. [15] would be to test an approximate many-electron wave function of an atom. One would have to integrate the wave function down according to eq. [3], but once the density matrices are known one would want to know how great was the variation with position $\boldsymbol{r}$ of the right-hand side of eq. [15].

Below, however, we shall explore the consequences of eq. [15] in the Hartree–Fock limit.

2.2 Local energy equation: reduction via Hartree–Fock approximation

As Dawson and March (4) emphasized, the Hartree–Fock (HF) approximation introduced into the local energy equation leads to the cancellation of the energy E from that equation. We can then write, in HF theory, with $V_n(\boldsymbol{r})$ the potential energy of the nuclear framework and $V_e(\boldsymbol{r})$ that created electrostatically by the ground-state electron density $n(\boldsymbol{r})$:

$$[16]\qquad t(\boldsymbol{r}) + V_n(\boldsymbol{r})n(\boldsymbol{r}) + V_e(\boldsymbol{r})n(\boldsymbol{r}) - \varepsilon_x(\boldsymbol{r}) = \frac{-\hbar^2}{2m}\int \gamma(\boldsymbol{r},\boldsymbol{r}_2)\nabla^2_{r_2}\gamma(\boldsymbol{r}_2,\boldsymbol{r}) + \int V_n(\boldsymbol{r}_2)\gamma^2(\boldsymbol{r},\boldsymbol{r}_2)\mathrm{d}\boldsymbol{r}_2 - \int u(|\boldsymbol{r}_3-\boldsymbol{r}_2|)\gamma(\boldsymbol{r},\boldsymbol{r}_2)\gamma(\boldsymbol{r}_3,\boldsymbol{r})\mathrm{d}\boldsymbol{r}_2\mathrm{d}\boldsymbol{r}_3 + \int u(|\boldsymbol{r}_3-\boldsymbol{r}_2|)\gamma^2(\boldsymbol{r},\boldsymbol{r}_2)n(\boldsymbol{r}_3)\mathrm{d}\boldsymbol{r}_2\mathrm{d}\boldsymbol{r}_3$$

The left-hand side involves terms that are evidently clear-cut contributions of the form of energy densities; e.g., $t(\boldsymbol{r})$ is the kinetic and $\varepsilon_x(\boldsymbol{r})$ the exchange contribution.

If we now therefore integrate this eq. [16] we find, by making use of the idempotency of the HF first-order density matrix $\gamma(\boldsymbol{r},\boldsymbol{r}_1)$, for the sum of total kinetic plus exchange energies $T+A$:

$$[17]\qquad T + A = \int \gamma(\boldsymbol{r}_2,\boldsymbol{r}_3)\times\left[\frac{-\hbar^2}{2m}\nabla^2_{r_2}\gamma(\boldsymbol{r}_2,\boldsymbol{r}_3) - u(|\boldsymbol{r}_3-\boldsymbol{r}_2|)\right]\mathrm{d}\boldsymbol{r}_2\mathrm{d}\boldsymbol{r}_3$$

One can now drop the integration over $\boldsymbol{r}_3$ to write

$$[18]\qquad t(\boldsymbol{r}) + \varepsilon_x(\boldsymbol{r}) = \int \gamma(\boldsymbol{r}_2,\boldsymbol{r})\times\left[\frac{-\hbar^2}{2m}\nabla^2_{r_2}\gamma(\boldsymbol{r}_2,\boldsymbol{r}) - u(|\boldsymbol{r}-\boldsymbol{r}_2|)\right]\mathrm{d}\boldsymbol{r}_2 + \text{term integrating to zero through all space}$$

This is a somewhat different form from the more conventional expression given by Dawson and March (4).

3. Asymptotic results for exchange and kinetic energies

We shall discuss in this section, motivated by the forms of the local energy equation, and especially eqs. [15] and [18], the asymptotic behaviour far from all nuclei of the kinetic energy density $t(\boldsymbol{r})$ and the exchange energy density $\varepsilon_x(\boldsymbol{r})$. Taking the latter, and working in the Hartree–Fock approximation, one has

$$[19]\qquad A = \int \varepsilon_x(\boldsymbol{r})\mathrm{d}\boldsymbol{r} = -\frac{1}{4}e^2\int\frac{\gamma(\boldsymbol{r},\boldsymbol{r}_1)^2}{|\boldsymbol{r}-\boldsymbol{r}_1|}\mathrm{d}\boldsymbol{r}\,\mathrm{d}\boldsymbol{r}_1$$

The writer, in earlier work (11), defined $\varepsilon_x(\boldsymbol{r})$ by

$$[20]\qquad \varepsilon_x(\boldsymbol{r}) = -\frac{1}{4}e^2\int\frac{\gamma(\boldsymbol{r},\boldsymbol{r}_1)^2}{|\boldsymbol{r}-\boldsymbol{r}_1|}\mathrm{d}\boldsymbol{r}_1$$

which clearly, from eq. [19], integrates to yield the total exchange energy A, as any definition of the exchange energy density must. Furthermore $\varepsilon_x(\boldsymbol{r})$ is always negative at all $\boldsymbol{r}$.

Now we are interested in the asymptotic behaviour of $\varepsilon_x(\boldsymbol{r})$ at large r. As was pointed out in ref. 11, one can, for sufficiently large $\boldsymbol{r}$, inside the integral in eq. [20], neglect $\boldsymbol{r}_1$ relative to $\boldsymbol{r}$. Then using the idempotency of the Hartree–Fock first-order density matrix, we find the asymptotic result

$$[21]\qquad \varepsilon_x(\boldsymbol{r})|_{r\to\infty} = -\frac{1}{2}\frac{e^2}{r}n(\boldsymbol{r})$$

a result that has also been discussed by Umrigar and Gonze (12).

Turning briefly to the kinetic energy density $t(\boldsymbol{r})$, we note that the asymptotic form was determined by Tal and Bader (13), the large r form corresponding to eq. [21] for exchange being

$$[22]\qquad t(\boldsymbol{r}) = In(\boldsymbol{r})$$

where I is the (exact) ionization potential. It is relevant here to add that the limiting form of the kinetic energy density as $\boldsymbol{r}$ tends to zero was discussed by Bader and Beddall (14).

4. Force theorems in relation to local chemical potential equation

For simplicity we start from the one-dimensional case.

4.1 Equation of motion of density matrix: one dimensional without interactions

March and Young (15) gave a treatment of force by starting from the equation of motion of the density matrix. These workers were dealing with one-dimensional motion of N electrons moving independently in a common potential energy $V(x)$. Then, putting the electron–electron interaction $u = 0$ in eq. [10], one is led to the one-dimensional equation of motion:

$$[23] \qquad \frac{\partial^2\gamma(x, x')}{\partial x^2} - \frac{\partial^2\gamma(x, x')}{\partial x'^2} = \frac{2m}{\hbar^2}[V(x) - V(x')]\gamma(x, x')$$

Introducing sum and difference coordinates $\xi = \frac{1}{2}(x+x')$ and $\eta = \frac{1}{2}(x-x')$, eq. [23] becomes

$$[24] \qquad \frac{\partial^2}{\partial\xi\partial\eta}\gamma(\xi, \eta) = \frac{2m}{\hbar^2}[V(\xi+\eta) - V(\xi-\eta)]\gamma(\xi, \eta)$$

Expanding about the diagonal $\eta = 0$, and using the definition of kinetic energy density $t(x)$ already discussed, March and Young obtained the so-called differential form of the virial theorem

$$[25] \qquad \frac{\partial t}{\partial x} = -\frac{1}{2}n(x)\frac{\partial V(x)}{\partial x} + \frac{1}{8}\frac{\partial^3 n}{\partial x^3}$$

They pointed out that by multiplying by x and integrating through the whole of space one recovered the usual virial theorem: of course an integral relation rather than the point-to-point relation, eq. [25].

The recent work of Holas and March (16) has led one to reinterpret this equation [25] as an expression for the force $-\partial V/\partial x$:

$$[26] \qquad -\frac{\partial V}{\partial x} = \frac{2}{n(x)}\frac{\partial t(x)}{\partial x} - \frac{1}{4n(x)}\frac{\partial^3 n(x)}{\partial x^3}$$

This scalar equation for the force $f = -\partial V/\partial x$ is evidently the sum of two parts. One, called f_L for reasons to emerge below, is determined solely by the electron density $n(x)$ as

$$[27] \qquad f_L = -\frac{1}{8n(x)}\frac{\partial^3 n(x)}{\partial x^3}$$

while the other is evidently a kinetic contribution, say f_K. Though formal density functional theory assures us that the kinetic energy density t is indeed also a functional of $n(x)$, that remains unknown at the time of writing. These expressions f_L and f_K will be generalized below to their vector counterparts for interacting electrons in three dimensions.

However, before doing so, it is of interest to provide here some historical background, involving intimately the research of Richard Bader. The derivation of a local form of the quantum-mechanical virial theorem for the general case of a time-dependent system was given by Bader (17). His argument was based on the divergence equations satisfied by the spatial components of the energy–momentum tensor of the Schrödinger field. The result was written in terms of what is now called the quantum stress tensor. This derivation was reviewed and expanded upon by Bader and Nguyen-Dang (18). Bader's own book (1) presents in fact a detailed account of the variational derivation of the atomic statement of the virial theorem and its differential or local form. In the above sources, the integrated and differential statements of the virial theorem are related to the corresponding integrated and local theorems for the Ehrenfest force. These theorems, and corresponding theorems for any observable, are derived from a single fundemental variational principle. Anticipating the following section, we finally note that variational derivations lead naturally to the quantum stress tensor, whereas (see eq. [28] below) the recent paper of Holas and March (16), to be described, works with the related kinetic energy density tensor.

4.2 Differential virial theorem for interacting electrons in three dimensions

We wish to effect the generalization of eq. [25] to interacting electrons. Then, in three dimensions a differential virial theorm represents an exact, local (at space point $\boldsymbol{r}$) relation involving the external potential $v(\boldsymbol{r})$, the e–e interaction potential $u(\boldsymbol{r},\boldsymbol{r}')$, the diagonal elements of the 1st and 2nd order density motion (DMs), $n(\boldsymbol{r})$ and $n_2(\boldsymbol{r},\boldsymbol{r}')$, and the 1st order DM$\gamma(\boldsymbol{r}_1;\boldsymbol{r}_2)$ "close to its diagonal," for a particular system. As Holas and March (16) have shown, it is a very useful tool for establishing various exact relations for a many-electron system. The mentioned dependence on γ may be written in terms of the kinetic energy density tensor, defined as

$$[28] \qquad t_{\alpha\beta}(\boldsymbol{r}; [x]) = \frac{1}{4}\left(\frac{\partial^2}{\partial r'_\alpha \partial r''_\beta} + \frac{\partial^2}{\partial r'_\beta \partial r''_\beta}\right) \times \gamma(\boldsymbol{r}+\boldsymbol{r}'; \boldsymbol{r}+\boldsymbol{r}'')|_{\boldsymbol{r}'=\boldsymbol{r}''=0}$$

This is a real, symmetric tensor, the trace of which is the non-negative kinetic energy density (scalar)

$$[29] \qquad t(\boldsymbol{r}; [\gamma]) = \sum_{\alpha=1}^{3} t_{\alpha\alpha}(\boldsymbol{r}; [\gamma]) \geq 0$$

leading to the global kinetic energy

$$[30] \qquad T = \langle\Psi|\hat{T}|\Psi\rangle = \tilde{T}[\gamma] = \int d^3 r t(\boldsymbol{r}; [\gamma])$$

The differential virial theorem, obtained in refs (16) and (19), has the form

$$[31] \qquad n(\boldsymbol{r})\frac{\partial}{\partial r_\alpha}v(\boldsymbol{r}) + 2\int d^3 r' n_2(\boldsymbol{r}, \boldsymbol{r}')\frac{\partial}{\partial r_\alpha}u(\boldsymbol{r}, \boldsymbol{r}') - \frac{1}{4}\nabla^2\frac{\partial}{\partial r_\alpha}n(\boldsymbol{r}) + 2\sum_\beta \frac{\partial}{\partial r_\beta}t_{\alpha\beta}(\boldsymbol{r}; [\gamma]) = 0$$

No assumptions concerning potentials $u(\boldsymbol{r},\boldsymbol{r}')$ and $v(\boldsymbol{r})$ (like

Coulombic character), except that they lead to bounded solutions Ψ of the Schrödinger equation, were involved in obtaining relation [31]. The density matrices occurring there: $n_2(\boldsymbol{r},\boldsymbol{r}')$, $\gamma(\boldsymbol{r};\boldsymbol{r}')$, and $n(\boldsymbol{r})$ are generated from the normalized Ψ as set out in Sect. 2 above.

It should be mentioned also that no assumption concerning the nature (as GS or excited-state) of the solution Ψ or a degeneracy of its energy level E was invoked in the derivation of eq. [31] by Holas and March (16, 19).

4.3 Force equation for interacting electrons related to local chemical potential equation

The differential virial theorem, eq. [31] can be rewritten following ref. 16 as

$$[32] \qquad \boldsymbol{\nabla}\, v(\boldsymbol{r}) = -\boldsymbol{f}(\boldsymbol{r};\,[u,\,n,\,\gamma,\,n_2])$$

where the following "force" field has been introduced:

$$[33] \qquad \boldsymbol{f}(\boldsymbol{r};\,[u,\,n,\,\gamma,\,n_2]) = \left\{ -\frac{1}{4}\,\boldsymbol{\nabla}\,\nabla^2 n(\boldsymbol{r}) + z(\boldsymbol{r};\,[\gamma]) + 2 \times \int \mathrm{d}^3 r'\, n_2(\boldsymbol{r},\boldsymbol{r}')\,\boldsymbol{\nabla}\, u(\boldsymbol{r},\boldsymbol{r}') \right\} \Big/ n(\boldsymbol{r})$$

with the vector field z having components z_α defined in terms of the kinetic energy density tensor in eq. [28] by

$$[34] \qquad z_\alpha(\boldsymbol{r};\,[\gamma]) = 2 \sum_\beta \frac{\partial}{\partial r_\beta}\, t_{\alpha\beta}(\boldsymbol{r};\,[\gamma])$$

The first term on the right-hand side of eq. [33] involves the Laplacian (L) of the electron density $n(\boldsymbol{r})$. This is then the vector generalization of the scalar f_L introduced in eq. [27]. The term with the vector field z is evidently kinetic, the generalization to vector form of the force f_K discussed in one dimension earlier. That discussion was for independent electrons. Due to the inclusion of electron–electron interaction $u(\boldsymbol{r},\boldsymbol{r}') = e^2/|\boldsymbol{r}-\boldsymbol{r}'|$, there is now a third vectorial contribution to the "total" force $\boldsymbol{f}$ in eq. [32]: namely the electron–electron (ee) $\boldsymbol{f}_{ee}$ given in terms of the electronic pair function $n_2(\boldsymbol{r},\boldsymbol{r}')$ and the interaction u by

$$[35] \qquad \boldsymbol{f}_{ee} = \frac{2}{n(\boldsymbol{r})} \int \mathrm{d}^3 r'\, n_2(\boldsymbol{r},\boldsymbol{r}')\,\boldsymbol{\nabla}\, u(\boldsymbol{r},\boldsymbol{r}')$$

This is the point to relate to the local chemical potential equation, but now in the form

$$[36] \qquad \mu = \frac{\delta F}{\delta n(\boldsymbol{r})} + V_n(\boldsymbol{r})$$

where F is the universal, as yet unknown, functional of $n(\boldsymbol{r})$ introduced by Hohenberg and Kohn (20), with $V_n(\boldsymbol{r})$ the nuclear potential energy only, in contrast to the form in eq. [1]. Differentiating with respect to $\boldsymbol{r}$, and noting again that μ is constant throughout the entire electronic cloud, one recognizes that the force $\boldsymbol{f}$ above has the alternative form

$$[37] \qquad \boldsymbol{f} = \frac{\partial}{\partial \boldsymbol{r}} \left\{ \frac{\delta F}{\delta n(\boldsymbol{r})} \right\}$$

This equation therefore demonstrates that the force $\boldsymbol{f}$ is a functional of the ground-state density, as is to be anticipated, in fact, from the formal theory of Hohenberg and Kohn (20). Unfortunately, of the three terms comprising $\boldsymbol{f}$ above, only f_L is presently known explicitly in terms of the density $n(\boldsymbol{r})$. f_K, the kinetic contribution to the force, involves the "near-diagonal" behaviour of the first-order density matrix $\gamma(\boldsymbol{r},\boldsymbol{r}')$ while evidently, from eq. [35], the electron–electron force term $\boldsymbol{f}_{ee}$ depends on the diagonal element of the second-order density matrix, i.e., the pair function $n_2(\boldsymbol{r},\boldsymbol{r}')$. Nevertheless, it is useful to proceed to extract the exact exchange-correlation potential $V_{xc}(\boldsymbol{r})$ of density functional theory, defined through the third form of chemical potential equation:

$$[38] \qquad \mu = \frac{\delta T_s}{\delta n(\boldsymbol{r})} + V_{\mathrm{Hartree}}(\boldsymbol{r}) + V_{xc}(\boldsymbol{r})$$

Here T_s is the single-particle kinetic energy only, correlation kinetic energy being subsumed into $V_{xc}(\boldsymbol{r})$, which is related to the exchange-correlation energy E_{xc} by the functional derivative relation

$$[39] \qquad V_{xc}(\boldsymbol{r}) = \frac{\delta E_{xc}}{\delta n(\boldsymbol{r})}$$

T_s is customarily calculated via the Slater–Kohn–Sham (SKS) orbitals, which in turn can be utilized to construct, for this reference system, an idempotent density matrix $\gamma_{SKS}(\boldsymbol{r},\boldsymbol{r}')$ already referred to.

5. Exact expression for the exchange-correlation potential

Equation [32] may be viewed as a differential equation for the potential $v(\boldsymbol{r})$. Because $\boldsymbol{f}(\boldsymbol{r}) = -\boldsymbol{\nabla}\, v(\boldsymbol{r})$, the force field $\boldsymbol{f}(\boldsymbol{r})$ is conservative. Therefore, following Holas and March (16) the potential at point $\boldsymbol{r}_0$, say, is the work done in bringing an electron from infinity to $\boldsymbol{r}_0$ against the force field $\boldsymbol{f}(\boldsymbol{r})$:

$$[40] \qquad v(\boldsymbol{r}_0) = -\int_\infty^{\boldsymbol{r}_0} \mathrm{d}\boldsymbol{r} \cdot \boldsymbol{f}(\boldsymbol{r})$$

Since $\boldsymbol{f}(\boldsymbol{r})$ is conservative, the value of the line integral in eq. [40] does not depend on the path of integration chosen. Note that eq. [43] has been written such that $v(\infty) = 0$: a standard choice of gauge for the potential.

By calculating $\boldsymbol{f}$ in the exact fully interacting system and subtracting the same force, but now calculated with exact density matrices in $\boldsymbol{f}$ being replaced by SKS reference density matrices, Holas and March (16) construct $V_{xc}(\boldsymbol{r})$ as a line integral in terms of density matrices. This is a formally exact result, but while it avoids the need for functional differentiation such as is exhibited in eq. [39], to turn it into a density functional theory requires the solution of a difficult many-electron problem. This involves as the first step the relation between the first- and second-order density matrices of a fully interacting electronic assembly. However, a start has already been made on this problem (21–23).

5.1 Exchange-only potential: scaling of electron–electron interactions

Though the exact result above may seem very formal, it was stressed by Holas and March (16) that if the simplest con-

ceivable approximation was then made, namely, to replace all interacting density matrices with their SKS counterparts, then one regained the Harbola–Sahni (24) exchange-only potential. Though their potential is known to be often very accurate, it is nevertheless true that the approximations made in the formally exact line integral result destroy the rigorous path-independence property.

Therefore, very recently, Levy and March (25) generalized the Holas–March (16) work to include the scaling of the electron–electron interactions such that e^2/r_{ij} becomes $\lambda e^2/r_{ij}$. By then taking an appropriate limit of the exact exchange correlation for general λ between 0 and 1, as λ tends to zero, they exhibit the kinetic correction to the Harbola–Sahni result that is required to restore the path independence. Some approximate arguments are given in ref. 25 that throw light on the reasons why this kinetic "correction" is often only a small fraction of the Harbola–Sahni contribution to the exchange-only potential.

5.2 Adiabatic connection formula

In the context of electron–electron scaling, we shall briefly summarize below recent work by Levy et al. (26) on the so-called adiabatic connection formula for the exchange-correlation energy. The formula relates, via integration between 0 and 1 (see eq. [41] below), the potential energy U_{xc} at coupling parameter λ, to the total exchange-correlation energy E_{xc} in eq. [39]. Levy et al. (26) find a linear approximation in λ to become exact in the Thomas–Fermi–Dirac limit of atoms and molecules with large numbers of electrons.

The early references on the idea of an adiabatic connection include those of Harris and Jones (27), Langreth and Perdew (28), Gunnarsson and Lundqvist (29), Levy (30), and Harris (31). Following the route set out, for instance, in the book by Parr and Yang (8), the exchange-correlation energy functional can be written as

$$[41] \qquad E_{xc}[n] = \int_0^1 d\lambda U_{xc}^{\lambda}[n]$$

In this equation, $U_{xc}^{\lambda}[n]$ is defined by

$$[42] \qquad U_{xc}^{\lambda}[n] = \langle \Psi_n^{\lambda} | V_{ee} | \Psi_n^{\lambda} \rangle - J[n]$$

Here $U_{xc}^{\lambda}[n]$ is the potential energy contribution to $E_{xc}[n]$ and $J[n]$ is the Coulomb energy. $\hat{V}_{ee}$ is the electron–electron repulsion operator, and Ψ_n^{λ} is the wave function of a Hamiltonian $\hat{H}_{\lambda}$ that represents a system in which the electron–electron interaction is scaled with λ as discussed already:

$$[43] \qquad \hat{H}_{\lambda} = \hat{T} + \lambda V_{ee} + \sum_i V_{\lambda}(\boldsymbol{r}_i)$$

It also minimizes, for fixed electron density n, the constrained search expression of Levy (32, 33). In the above approach, $n(\boldsymbol{r})$ is to be interpreted as the exact density of the fully interacting ($\lambda = 1$) electronic assembly.

Becke (34) has used the above approach in the context of a two-point integration formula. He writes eq. [41] as (35):

$$[44] \qquad E_{xc}[n] \sim \frac{1}{2}(U_{xc}^0 + U_{xc}^1)$$

where U_{xc}^0 is the exchange energy associated with the SKS reference first-order density matrix while U_{xc}^1 is the potential enery contribution to the exchange-correlation energy of the fully interacting system. This all led Becke to his half-and-half functional, which was the forerunner of his valuable three-parameter functional (36). It is the revival of interest in adiabatic scaling that has led Levy et al. (26) to examine some scaled Hamiltonians in the context of Thomas–Fermi theory and to introduce some new elements into the adiabatic connection approach in SKS theory. For instance, these authors provide a formula that enables use to be made of nonlocal exchange-correlation potential energies, such as those from gradient expansions, for U_{xc}^1 in eq. [44].

6. Discussion and summary

The spatial derivative of the formal chemical potential, eq. [36], yields the external force. By combining this with the differential virial theorem, a force balance equation emerges, the sum of Laplacian, kinetic, and electron–electron force terms appearing. While, in principle, from the theorems of DFT, these are functionals of the ground-state electron density $n(\boldsymbol{r})$, only for the Laplacian contribution is that functional known. However, as Holas and March (16) have shown, the kinetic term is fixed by the "near-diagonal" first-order density matrix. The third, electron–electron interaction term is determined by the diagonal form of the second-order density matrix, i.e., the electronic pair function $n_2(\boldsymbol{r},\boldsymbol{r}')$.

Integrating this equation yields an exchange-correlation potential in the form of a line integral, such as given in eq. [40]. The simplest approximation then leads back to the Harbola–Sahni exchange-only potential, which is, however, known to be path dependent. Levy and March (25) have exhibited, by generalizing the Holas–March result to include the scaling parameter λ, the kinetic correction that, when added to the Harbola–Sahni result, restores the required path independence in the exchange-only potential.

More briefly, the local energy equation has also been discussed and has motivated a discussion of the asymptotic forms of exchange (11) and kinetic energy densities (19) far from nuclei. Finally, new avenues also seem to be opening up in connection with scaling of the strength of the electron–electron interactions, and in particular through adiabatic connection formulae. These involve the potential energy of the exchange-correlation energy, the functional derivative of which was shown by March and Bader (2) to determine the "correction" to the ionization potential I in the chemical potential equation. In the adiabatic connection formulae, one can now use nonlocal exchange correlation potential energies, usually through gradient approximations. Richard Bader was ahead of his time, of course, in recognizing the central role of $\nabla n(\boldsymbol{r})$, and the Laplacian $\nabla^2 n(\boldsymbol{r})$ in problems of molecular electronic structure (1). In the context of the present work, in which density functional theory is approached via density matrices (15, 16), it is highly relevant also to point here to Richard Bader's philosophy regarding the one-electron density matrix. This is summarized in his very recent paper "Chemistry and the Near-Sighted Nature of the One-Electron Density Matrix" (37).

Acknowledgments

The writer is most grateful to Dr A. Holas (Warsaw) for

much fruitful collaboration, and numerous invaluable discussions on the general area embraced by the present paper. My thanks are also due to Professors M. Levy and N.C. Handy for generously involving me in electron–electron interaction scaling theory. The Leverhulme Trust (U.K.) is thanked for financial support. Finally, both referees are to be acknowledged for contributing very helpful and constructive comments on the original manuscript. All their comments are now embodied in the final version.

Topologically partitioned dynamic polarizabilities using the theory of atoms in molecules

Christof Hättig, Georg Jansen, Bernd A. Heß, and János G. Ángyán

Abstract: Frequency-dependent distributed polarizabilities have been determined from time-dependent Hartree–Fock calculations, using the partitioning of the molecular space suggested by Bader's topological theory of atoms in molecules. The basis set dependence of the distributed dynamic polarizabilities is analyzed in terms of the first few Cauchy moments, for the carbon monoxide, water, cyanogen, urea and benzene molecules. Two alternative relocalization schemes have been considered in order to reduce the number of distributed dynamic polarizability parameters. The first one, closely related to the atomic polarizability model of Bader, leads to atomic charge–dipole and dipole–dipole polarizabilities, describing the response of the molecular charge distribution to a uniform external field, in terms of atomic charges and dipoles. The second scheme, similar to that suggested by Stone, retains the fully distributed description of the dynamic charge-flow polarizabilities, while all two-center dipole–dipole and charge–dipole contributions are condensed in one-center dynamic dipole–dipole polarizabilities.

Key words: Bader-partitioning, distributed dynamic polarizabilities, Cauchy-moments, benzene, polarizability of; urea, polarizability of.

Résumé : Faisant appel à des calculs de Hartree–Fock dépendant du temps et utilisant la partition de l'espace moléculaire suggérée par la théorie topologique des atomes dans les molécules de Bader, nous avons déterminé des polarisabilités dynamiques distribuées. L'influence de la base a éte analysé en termes des premiers moments de Cauchy pour les molécules suivantes : monoxyde de carbone, eau, cyanogène, urée et benzène. Afin de réduire le nombre des paramètres de polarisabilité dynamique distribuée, deux méthodes alternatives de relocalisation ont été considérées. La première, qui est fortement apparentée au modèle de polarisabilité atomique de Bader, conduit aux polarisabilités atomiques charge–dipôle et dipôle–dipôle décrivant la réponse de la distribution de charge moléculaire à un champ externe uniforme en termes de charges et de dipôles atomiques. Le deuxième méthode, semblable à celle suggérée par Stone, maintient la description totalement distribuée des polarisabilités dynamique de flux de charges, alors que toutes les contributions dipôle–dipôle et charge–dipôle à deux centres sont réduites à des polarisabilités dynamiques dipôle–dipôle à un centre.

Mots clés : méthode de partition de Bader, polarisabilités dynamiques distribuées, moments de Cauchy, polarisabilité du benzène, polarisabilité de l'urée.

[Traduit par la rédaction]

I. Introduction

Frequency-dependent (dynamic) multipole polarizabilities, which describe the response of a molecular system under the influence of a time-dependent external multipolar field, play an important role in the interpretation of many physical phenomena. They contain information concerning, for example, the refractive index, Rayleigh scattering cross sections, and Raman intensities (1, 2), etc. Dynamic polarizabilities, taken at imaginary frequencies, can be used to calculate long-range dispersion coefficients (3), which are of outstanding importance in the theory of intermolecular interactions. Since dynamic polarizability tensors are difficult to measure experimentally, there is an increasing demand for the reliable theoretical calculation of their components.

The dynamic charge density susceptibility function, $\alpha(\boldsymbol{r},\boldsymbol{r}';\omega)$, describes the linear response of a molecular charge distribution to an arbitrary time-dependent external field (4). The multipole components of a molecular dynamic polarizability tensor, $\alpha_{lm,l'm'}(\omega)$, are related to the dynamic charge density susceptibility function via the following relationship:

$$[1] \qquad \alpha_{lm,l'm'}(\omega) = \int\int \mathrm{d}\boldsymbol{r}\mathrm{d}\boldsymbol{r}' R^0_{lm}(\boldsymbol{r})\alpha(\boldsymbol{r},\boldsymbol{r}';\omega)R^0_{l'm'}(\boldsymbol{r}')$$

Received October 13, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

where $R^0_{lm}(\boldsymbol{r}) = R_{lm}(\boldsymbol{r} - \boldsymbol{R}_0)$ is a regular solid harmonics, taken with respect to the molecular origin $\boldsymbol{R}_0$. Obviously, by taking the above integral over the molecular volume, a certain amount of information about the details of the spatial distribution of response properties is lost. This can be a nuisance, especially in the case of relatively large, extended molecular systems. The difficulty can partially be circumvented by the concept of *distributed* polarizabilities (5), by attributing specific response parameters to atoms and to pairs of atoms (or functional groups) in the molecule. The formal definition of distributed dynamic polarizabilities involves double integration over the volumes Ω_A and Ω_B, corresponding to atoms or functional groups of the molecule:

$$[2] \qquad \alpha^{AB}_{lm,l'm'}(\omega) = \int_{\Omega_A}\int_{\Omega_B} d\boldsymbol{r}d\boldsymbol{r}' R^A_{lm}(\boldsymbol{r})\alpha(\boldsymbol{r},\boldsymbol{r}';\omega)R^B_{l'm'}(\boldsymbol{r}')$$

Once the atomic volumes, Ω_A, are defined, we have, by virtue of eq. [2], an exact partitioning of the total dynamic polarizabilities, eq. [1]. Thus the response of the molecular charge density to an external non-uniform field is described by atomic charges, dipoles (multipoles, $^{ind}Q^A_{lm}$, in general), induced by a set of multipolar field components, $F^B_{l'm'}$, acting at atom B. Accordingly, we can speak of charge–charge (charge-flow) polarizabilities, corresponding to atomic charges induced by the differences in the external potential at different atoms, charge–dipole polarizabilities, describing the atomic charge induced by the external field at different atoms, etc. Charge–multipole polarizabilities satisfy the following sum rule (5):

$$[3] \qquad \sum_A \alpha^{AB}_{00,lm} = 0$$

reflecting the fact that the effect of an external perturbation cannot change the total charge of the system.

The theory of atoms in molecules (AIM) of Bader (6, 7) constitutes an excellent general framework to partition properties of molecular systems into atomic contributions. Atomic regions, Ω_A, surrounded by the atomic surface, $S_A(\boldsymbol{r})$, are defined in an unambiguous manner on the basis of the topological features of the electron density, by the zero-flux condition $\nabla\rho(\boldsymbol{r}) \cdot \boldsymbol{n}(\boldsymbol{r}) = 0$ for $\forall \boldsymbol{r} \in S_A(\boldsymbol{r})$. Application of the principle of stationary action to these atomic regions, in fact open quantum subsystems, leads to a complete quantum mechanical description of their properties. Furthermore, it has been shown (6) that the topological definition of atoms and functional groups (as an assembly of atoms) allows one to maximize the transferability of their properties between various systems.

Application of the topological definition of atoms to partition static (zero-frequency) polarizabilities leads to a consistent set of distributed static polarizability parameters, free of any physically unjustified basis set dependence (8). In fact, distributed polarizability parameters, as obtained by various basis set partitioning schemes, were not stable enough with respect to extension of the basis set: for example, in extended basis sets the charge-flow polarizabilities became extremely large (9). Topologically partitioned polarizabilities do not vary more strongly with the basis set than do the total polarizability components. Furthermore, a recent study on a series of hydrocarbons confirms the transferability of these topologically distributed static polarizabilities (10). Calculation of intermolecular induction energies has shown that the fully distributed description leads to reasonable interaction energies even in those cases where the molecule-centered expansion of electrostatic and induction energies fails completely (11) (e.g., for the cyanogen dimer).

One-center atomic polarizabilities have been investigated recently by Bader and co-workers (12–14) by finite perturbation techniques. In contrast to the fully distributed polarizabilities, which, due to their nonlocal character, are able to describe the charge density response to a non-uniform external field, Bader's atomic polarizabilities

$$[4] \qquad \alpha^{A,mol}_{lm,l'm'}(\omega) = \int_{\Omega_A}\int d\boldsymbol{r}d\boldsymbol{r}' R^A_{lm}(\boldsymbol{r})\alpha(\boldsymbol{r},\boldsymbol{r}';\omega)R^0_{l'm'}(\boldsymbol{r}')$$

give the atomic multipole, $^{ind}Q^A_{lm}$ induced by an external field component $F_{l'm'}$ applied globally to the molecule at its origin. Therefore it is justified to call these quantities "atom–molecule" polarizabilities. For example, the application of a uniform external field F_β gives rise to induced atomic charges and dipoles, which are described by the $\alpha^{A,mol}_{q\beta}$ and $\alpha^{A,mol}_{\alpha\beta}$ charge–dipole and dipole–dipole atom–molecule polarizabilities. To cope with empirical additivity schemes, based on atomic dipole–dipole polarizabilities, the charge–dipole contributions have to be converted to atomic dipole–dipole polarizabilities (13). Unfortunately, there is no unique way to do that; therefore each case should be carefully examined in order to obtain chemically meaningful atomic polarizabilities, as has been done for hydrocarbons (14). Although Bader's atomic polarizabilities are conceptually very helpful in developing additivity and transferability schemes for atomic and group contributions, they are probably less appropriate for the calculation of intermolecular interactions, where molecules are subject to non-uniform external fields.

The present paper extends our earlier study of distributed static polarizabilities (8) to their dynamic counterparts. After a brief overview of the most important working equations, we are going to examine the basis-set sensitivity of topologically partitioned dynamic polarizability components, represented by their Cauchy moments. Since the main goal of our study is to explore the behaviour of the topological partitioning scheme, it has been judged sufficient to calculate Cauchy moments at the simple TDHF (time-dependent Hartree–Fock) level. A simple algorithm, inspired by the scheme proposed by Le Sueuer and Stone (15), is given for partial relocalization of the fully distributed nonlocal Cauchy moments, allowing us to reduce considerably the number of parameters characterizing the dynamic response properties of a molecular system.

II. Method

In full analogy with its molecular counterpart, a distributed dynamic polarizability component for real wave functions, taken at the real frequency, ω, is defined as

$$[5] \qquad \alpha^{AB}_{lm,l'm'}(\omega) = \sum_{n\neq 0} \frac{2(E_n - E_0)\langle 0|\hat{Q}^A_{lm}|n\rangle\langle n|\hat{Q}^B_{l'm'}|0\rangle}{(E_n - E_0)^2 - \omega^2}$$

$$= \sum_{n\neq 0} \frac{f^{AB}_{lm,l'm'}(n)}{(E_n - E_0)^2 - \omega^2}$$

and it can be expanded in a Cauchy power series:

$$[6] \qquad \alpha^{AB}_{lm,l'm'}(\omega) = \sum_{k=0}^{\infty} \omega^{2k} S^{AB}_{lm,l'm'}(-2k-2)$$

where the distributed Cauchy moments (16), $S^{AB}_{lm,l'm'}(k)$, are given by the sum-over-states formula:

$$[7] \qquad S^{AB}_{lm,l'm'}(k) = \sum_{n\neq 0} (E_n - E_0)^k f^{AB}_{lm,l'm'}(n)$$

and $f^{AB}_{lm,l'm'}(n)$ denotes the generalized oscillator strengths of the transition between the ground and the nth electronic state $|n\rangle$, with energy E_n. Static polarizabilities correspond to Cauchy moments of order -2:

$$\alpha^{AB}_{lm,l'm'}(0) = S^{AB}_{lm,l'm'}(-2)$$

In the time-dependent Hartree–Fock approximation the dynamic polarizability components can be obtained by solving the following generalized eigenvalue problem (17):

$$[8] \qquad (\boldsymbol{A}+\boldsymbol{B})C_n = \omega^2_{on}(\boldsymbol{A}-\boldsymbol{B})^{-1}C_n$$

for the TDHF excitation energies, ω_{on} and amplitudes, C_n, which are normalized according to $C_n^T(\boldsymbol{A}-\boldsymbol{B})C_n = 1$. The matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ are defined in terms of occupied i,j and virtual a,b orbitals, as usual:

$$[9] \qquad A_{ia,jb} = (\varepsilon_a - \varepsilon_i)\delta_{ab}\delta_{ij} + 2(ai|jb) - (ab|ij)$$

$$B_{ia,jb} = 2(ai|bj) - (bi|ja)$$

The generalized oscillator strengths are given in this approach by

$$[10] \qquad f^{AB}_{lm,l'm'}(n) = 2\sum_{ia}(i|\hat{Q}^A_{lm}|a)C_{ia,n}\sum_{jb}(j|\hat{Q}^B_{l'm'}|b)C_{jb,n}$$

and they can be used directly to calculate dynamic polarizabilities at a given frequency ω, with the help of expressions [5] and [7], respectively.

The atomic multipole moment operators, $\hat{Q}^A_{lm}$, are defined by their matrix elements:

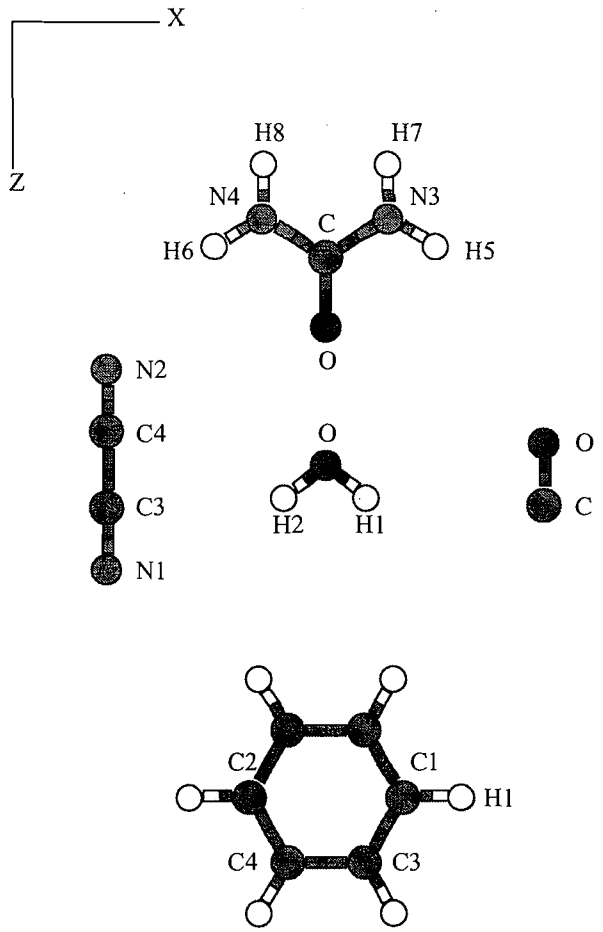
$$[11] \qquad (i|\hat{Q}^A_{lm}|a) = \int_{\Omega_A} d\boldsymbol{r}\phi^*_i(\boldsymbol{r})R^A_{lm}(\boldsymbol{r})\phi_a(\boldsymbol{r})$$

where the volume of integration extends over the atomic basin, limited by a zero-flux surface of the unperturbed molecule.

Total molecular Cauchy moments can be calculated either by replacing the atomic transition integrals in expression [11] by molecular ones, or by reconstituting them from distributed Cauchy moments via translation of the atomic components to the common molecular origin (5).

A series of molecules, carbon monoxide, water, cyanogen, urea, and benzene, has been selected to study the basis-set sensitivity of the frequency-dependent distributed polarizabilities, by examining the behavior of Cauchy moments in five different contracted Gaussian type orbital (CGTO) basis sets.

Fig. 1. Orientation of the molecules in the coordinate frame.



Calculations on CO, H_2O, cyanogen (NCCN), and benzene were done at their experimental gas-phase geometries (18–20). In the case of urea, a planar geometry was used, determined by low-temperature neutron-diffraction measurements (21) of the crystal. The orientation of the molecules is defined in Fig. 1.

Self-consistent field (SCF) calculations were performed with the MOLCAS program (22). We have used the 6-31G** valence double-zeta polarization, the 6-311G(2d,2p) valence triple-zeta double polarization, and the 6-311++G(2d,2p) valence triple-zeta double polarization plus diffuse functions basis sets. The polarization basis set of Sadlej (23), optimized for molecular polarizabilities and electrostatic properties, consists of (6s4p)/[3s2p] and (10s6p4d)/[5s3p2d] contracted sets for H and other atoms, respectively. The largest basis set in our study was derived from that of Widmark et al. (24) by keeping the same exponents. Only the innermost three s- and two p-functions were contracted for the hydrogen atom, resulting in a (8s4p)/[6s3p] CGTO set, and for the other atoms we contracted only the innermost five s-, four p-, and two d-functions, thus yielding (14s9p4d)/[10s6p3d] sets. This basis set contains also the diffuse functions essential for a reliable prediction of polarization properties. Except for the case of 6-31G** basis set, five-component d-functions were always employed.

Table 1. Cauchy moments (in au) calculated with various basis sets, compared to CDOSD, experimental, or theoretical values.

Cauchy moments and dynamic polarizabilities at fixed values of the frequency were calculated with a self-written TDHF program that uses the necessary transformed two-electron integral blocks produced by either a nonstandard link after a closed-shell SCF run of Gaussian 92 (25), or by the MOLCAS-2 suite of programs (22). Our code makes use of eq. [8] and thus inversion of the $(\boldsymbol{A} - \boldsymbol{B})$ matrix is required. This becomes prohibitive for cases with many single excitations. Due to the implementation of Abelian point group symmetries in our code (available when working with MOLCAS), we were able to treat all molecules even with the large [10s6p3d] basis set, except for benzene, where this basis set had to be left out. The occupied/virtual one-electron integral blocks of the distributed moments were generated by a modified version of the Proaim program (26).

III. Results and discussion

The first three molecular Cauchy moments, $S(-2), S(-4)$, and $S(-6)$, which enter in the power series expansion for the dynamic polarizability as calculated by the five basis sets, are listed in Table 1. In the case of CO, H_2O, and C_6H_6 they are compared with the available data obtained by the CDOSD (constrained dipole oscillator strength distribution) method of Meath and co-workers (27–29). Anisotropic static polarizabilities were taken from the experimental data of Murphy (30) for water, and from the theoretical calculations of Sanchez de Merás et al. (31) for urea. In the TDHF calculations on CO and H_2O even the largest-basis results remain significantly smaller than the CDOSD values and the error is enhanced with increasing order of the Cauchy moments. In the case of CO the Sadlej polarization and the [10s6p3d] basis calculations have about −13 and −21% error with respect to the CDOSD results for the mean $S(-4)$ and $S(-6)$ Cauchy moments. The errors are much larger in the case of the water molecule: they are 35 and 55%, respectively. This is in agreement with the observation of Spackman, who underlined the relatively poor quality of the higher Cauchy moments (32), calculated by the TDHF method. Electron correlation, taken into account, for example, by the recently developed time-dependent MP2 (TDMP2) approach, can bring these Cauchy moments into closer agreement with experiment (33, 34). The TDHF results for benzene are in remarkably good agreement with recent CDOSD data. The errors in the mean Cauchy moments of order −2, −4, and −6 are +0.7%, +0.1%, and −3.6% with the 6-311++G(2d,2p) basis set, while they are +1.4%, +3.1%, and +1.5% when using the [5s3p2d] basis set of Sadlej. The good quality of the higher Cauchy moments is probably partly due to the success of the TDHF method in reproducing the first dipole-allowed excitation energy in reasonable agreement with the experiment (6.56 eV calculated vs. 6.9 eV) and partly to the overwhelming importance of the charge-flow contribution to the static *and* dynamic polarizabilities (see below).

The basis set dependence of the higher $S(-4)$ and $S(-6)$ Cauchy moments is similar to that of the static polarizability, $S(-2)$, but the effects are more pronounced. Out-of-plane polarizability components are influenced much more by the quality of the basis set than are the in-plane components. In CO the parallel Cauchy moment components are in reasonable agreement with CDOSD values (below 10%), while the perpendicular ones are in error by 20 and 47%! In the water molecule $S_{yy}(-2)$ varies by a factor of 2.7 between the smallest and the largest basis set, while the higher-order Cauchy moment, $S_{yy}(-6)$, is enhanced by a factor of 5.7. In urea and benzene the approximately twofold enhancement of the out-of-plane static polarizability increases to a 12- and 40-fold enhancement, respectively. The in-plane polarizability components are relatively insensitive to the choice of basis set.

Coming now to the distributed models, selected distributed dipole–dipole Cauchy moment components have been plotted against the basis set quality in Figs. 2 and 3 for the two smallest systems, CO and H_2O. In addition to the static polarizability, $S(-2)$, and the $S(-6)$ Cauchy moment, the $S(0)$ Cauchy moments are also represented in these figures. Zeroth-order Cauchy moments correspond to the high-frequency limit of the multipolar dynamic polarizability components. The $S_{1,1}(0)$ dipolar components, according to the Thomas–Reiche–Kuhn (TRK) sum rule (35), are equal to the total number of electrons in the molecule. For SCF wave functions the TRK sum rule is satisfied in the basis set limit, therefore $S_{\alpha\alpha}(0)$ can be considered as a measure of the basis set completeness in the subspace of dipole excitations.

The general trends observed in the two molecules represented in Figs. 2 and 3 are identical, and they remain the same for the other three molecules, not represented here. Although the TRK sum rule is relatively poorly satisfied for the [5s3p2d] polarization basis set, this basis describes the static polarizability as well as the higher Cauchy moments in very good agreement with the larger [10s6p3d] basis. In fact, this basis set has been optimized by Sadlej to faithfully reproduce molecular polarizabilities, while the description of compact p- and d-orbitals, important for good fulfillment of the TRK sum rule, is less complete. This observation is in agreement with the experience of Mulder and Meath (36), who found that the importance of the core basis set in reproducing various sum rules increases with increasing Cauchy order.

Distributed atom–atom dipole polarizabilities, represented in Fig. 4, vary with the basis set quality in a similar way as the total polarizability components. One could expect that basis set effects would be reflected mostly by distributed dipole–dipole polarizabilities, while charge-flow terms would be reasonably described even by a relatively poor basis set. Distributed static polarizabilities confirm this rule (cf. Fig. 4), but the same is not necessarily true for higher Cauchy moments, i.e., for the frequency dependence of the polarizabilities. The increase in magnitude of the $S(-6)$ charge–charge and charge–dipole Cauchy moments for CO between the 6-311G(2d,2p) and 6-311++G(2d,2p) basis sets in Fig. 4 indicates that diffuse functions are indispensable for their good description.

Analysis of the different kinds of fully distributed terms becomes more and more complicated in larger molecules, due to the increasing number of parameters. Therefore one should envisage some "relocalization" scheme, which simplifies the model but preserves the advantages of the distributed description. As a first step in this direction, we analyzed the various kinds of distributed contributions to the molecular dipole–dipole Cauchy moments.

The molecular dynamic dipole–dipole polarizability, as

Fig. 2. Distributed dipole–dipole Cauchy moments for CO.

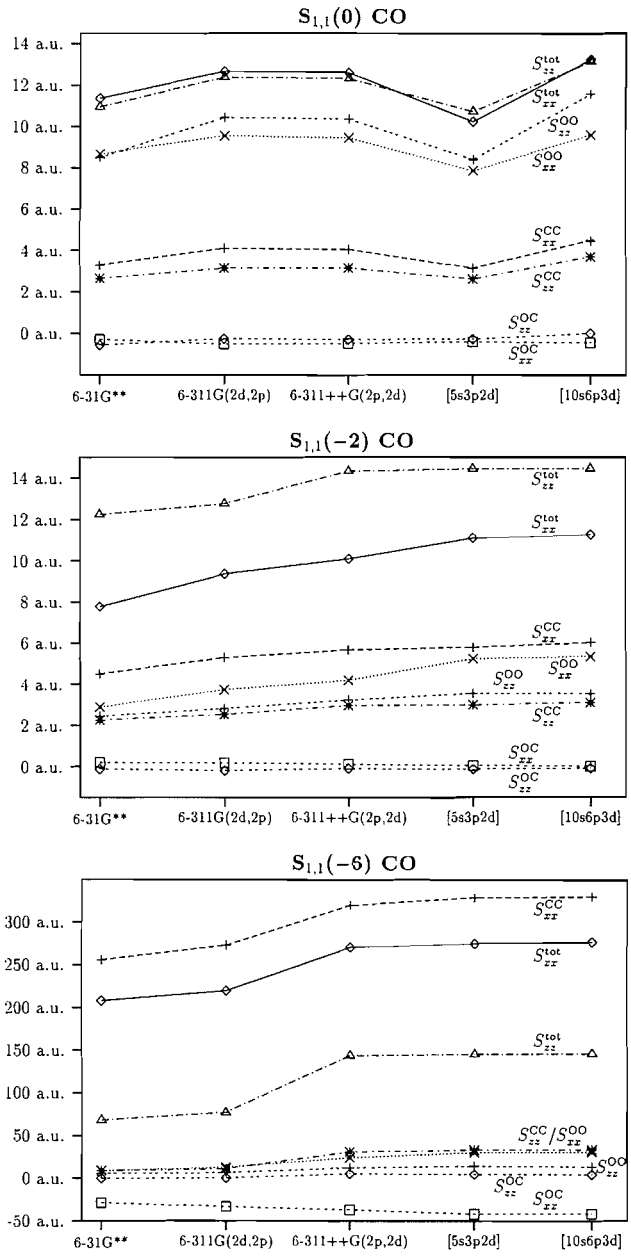

Fig. 3. Distributed dipole–dipole Cauchy moments for H_2O.

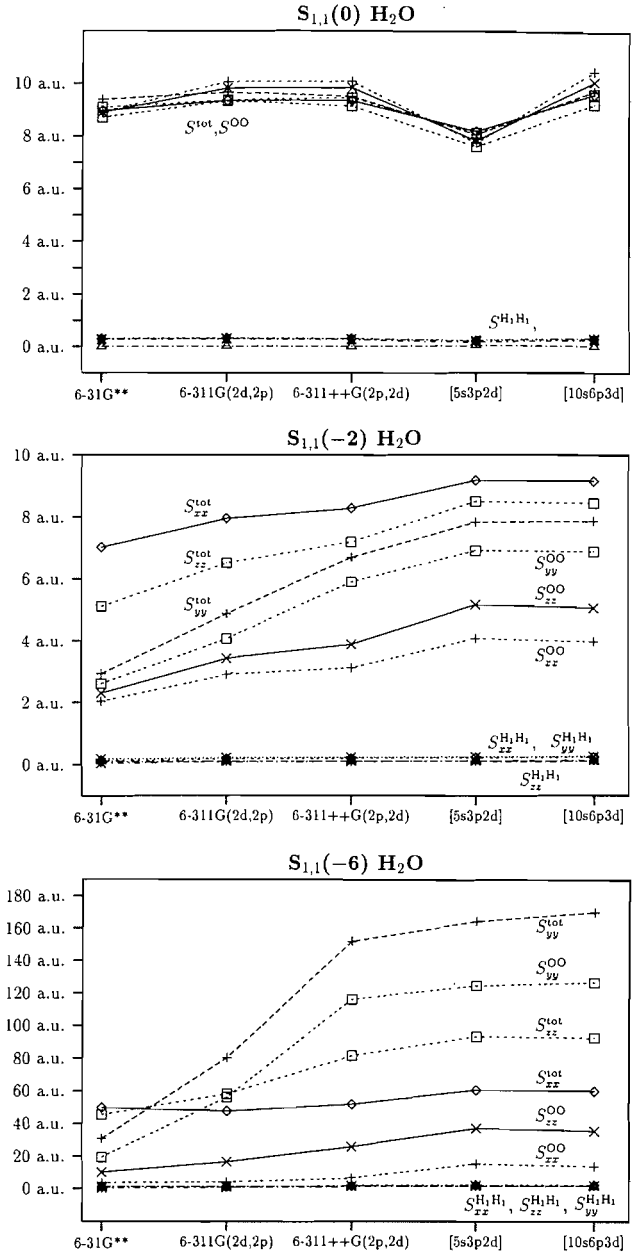


well as the corresponding Cauchy moments, can be broken down into various kinds of distributed components:[2]

$$[12]\qquad \alpha_{\alpha\beta}(\omega) = \alpha_{\alpha\beta}^{[\mu\mu,1-c]}(\omega) + \alpha_{\alpha\beta}^{[\mu\mu,2-c]}(\omega) + \alpha_{\alpha\beta}^{[q\mu]}(\omega) + \alpha_{\alpha\beta}^{[qq]}(\omega)$$

where Greek subscripts $\alpha\beta$ stand for the Cartesian components x, y, z, and the one- and two-center dipole–dipole, the charge–dipole and charge–charge contributions are defined as:

$$[13]\qquad \alpha_{\alpha\beta}^{[\mu\mu,1-c]}(\omega) = \sum_{A} \alpha_{\alpha\beta}^{AA}(\omega)$$

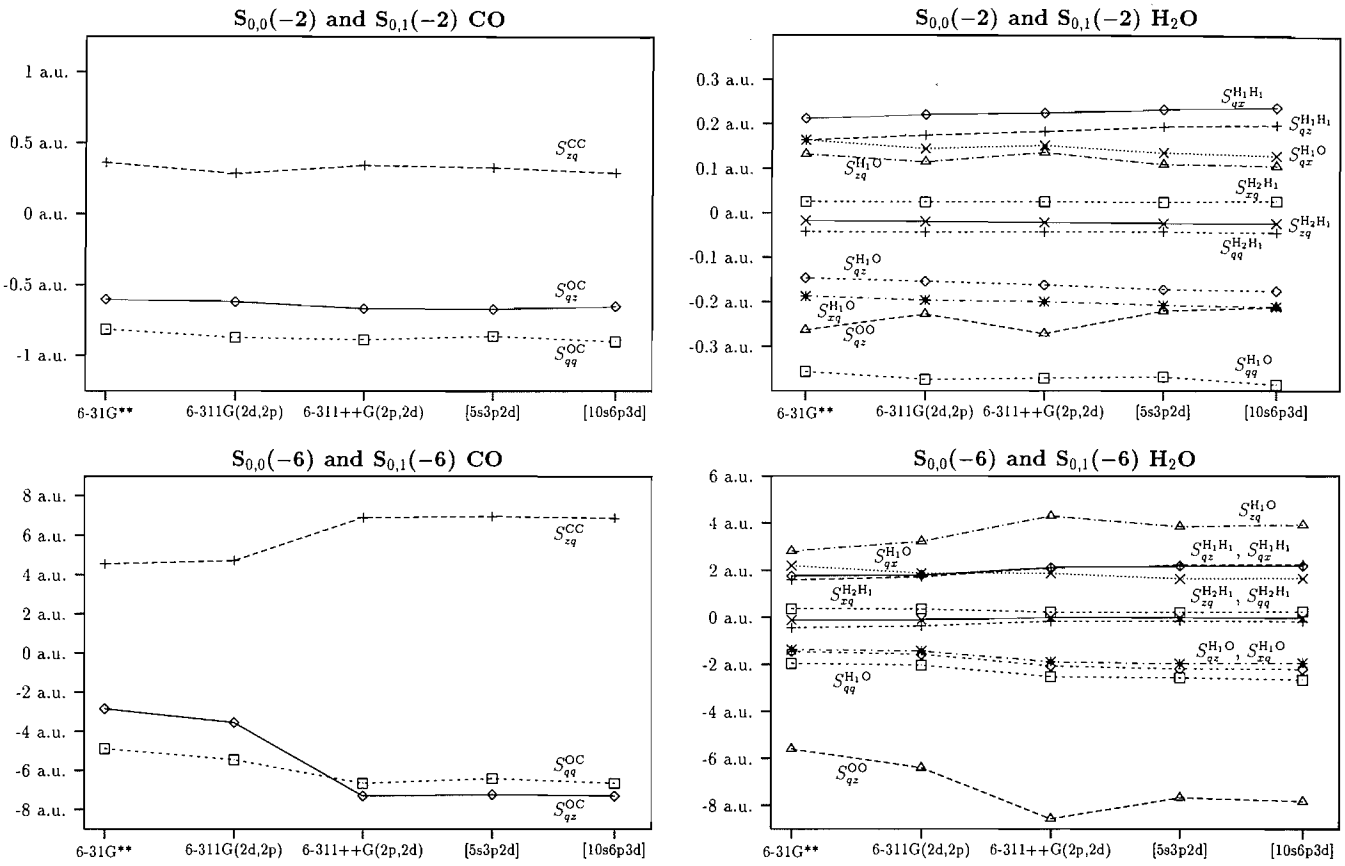
$$[14]\qquad \alpha_{\alpha\beta}^{[\mu\mu,2-c]}(\omega) = \sum_{A} \sum_{B\neq A} \alpha_{\alpha\beta}^{AB}(\omega)$$

$$[15]\qquad \alpha_{\alpha\beta}^{[q\mu]}(\omega) = \sum_{A} \sum_{B} R_{\alpha}^{A} \alpha_{q\beta}^{AB}(\omega) + \alpha_{\alpha q}^{AB}(\omega) R_{\beta}^{B}$$

$$[16]\qquad \alpha_{\alpha\beta}^{[qq]}(\omega) = \sum_{A} \sum_{B} R_{\alpha}^{A} \alpha_{qq}^{AB}(\omega) R_{\beta}^{B}$$

[2] For the sake of simplicity, the formulae in the text are written for the polarizabilities, $\alpha_{\alpha\beta}$, but they are valid *mutatis mutandis* for the corresponding Cauchy moments.

Fig. 4. Distributed charge-flow Cauchy moments for CO and H_2O.



and R_α^A is the α component of the vector from the molecular origin to the Ath atom. Contribution of the different terms depends on the chemical system and on the geometry, as is exemplified by the data for water and benzene molecules in Table 2, calculated with the polarization basis set of Sadlej.

Out-of plane molecular polarizabilities have only one- and two-center dipole–dipole components, since no atomic charge transfer is possible in this direction. The one-center contribution is always considerably larger than the two-center one, although the latter becomes increasingly important for higher order Cauchy moments in all cases. The charge-flow contribution to in-plane polarizabilities is always significant, and it even becomes the most important term for conjugated systems like benzene (and also for cyanogen), where it accounts for 80% of the total in-plane dipole polarizability. The distributed charge–dipole Cauchy moments contribute by 10–30% to the total molecular quantities, and their importance increases for higher orders.

The basis set dependence of distributed components in the larger systems, cyanogen and urea, is illustrated in Figs. 5 and 6, by regrouping all dipole–dipole and charge–dipole contributions in a single term, $S^{[\mu]}(k)$, and denoting the sum of charge–charge contributions by $S^{[q]}(k)$. In the case of the static polarizability, $S(-2)$, the sum of charge–charge terms is quite insensitive to the basis set and, in agreement with the experience obtained by detailed analysis of the smaller systems, the basis set variation of the total Cauchy moments is reflected by the sum of distributed dipole–dipole and charge–dipole Cauchy moments. The situation changes considerably for the contributions to the $S(-6)$ Cauchy moments. Here, the basis set dependence of the charge–charge terms is of comparable importance to that of the dipolar contributions, and diffuse functions are imperatively needed for a good reproduction of charge-flow contributions to higher Cauchy moments as well.

The data discussed above can serve as a starting point in appreciating the advantages or disadvantages of different partial relocalization schemes of distributed polarizabilities and Cauchy moments. Let us consider first the "atom–molecule" polarizabilities. The total molecular dynamic polarizabilities can be reconstituted from dipole–dipole and charge–dipole atom–molecule polarizabilities in the following manner (the argument ω will be omitted for the sake of notational simplicity):

$$[17] \qquad \alpha_{\alpha\beta} = \sum_A (\alpha_{\alpha\beta}^{A,mol} + R_\alpha^A \alpha_{q\beta}^{A,mol})$$

where

$$[18] \qquad \alpha_{\alpha\beta}^{A,mol} = \sum_B \alpha_{\alpha\beta}^{AB} + \alpha_{\alpha q}^{AB} R_\beta^B$$

$$[19] \qquad \alpha_{q\beta}^{A,mol} = \sum_B \alpha_{q\beta}^{AB} + \alpha_{qq}^{AB} R_\beta^B$$

Table 2. Decomposition of total Cauchy moments for water and benzene molecules calculated with the Sadlej [5s3p2d] polarization basis set. Numbers in parentheses indicate the percentage contribution to the total reconstituted Cauchy moment from distributed one- and two-centered dipole–dipole, dipole–charge, and charge–charge contributions.

[a]The number in parentheses below the $S_{\alpha\beta}^{total}$ indicates the percentage error with respect to $S_{\alpha\beta}^{full}$, the Cauchy moment calculated with analytic molecular multipole transition integrals (last column).

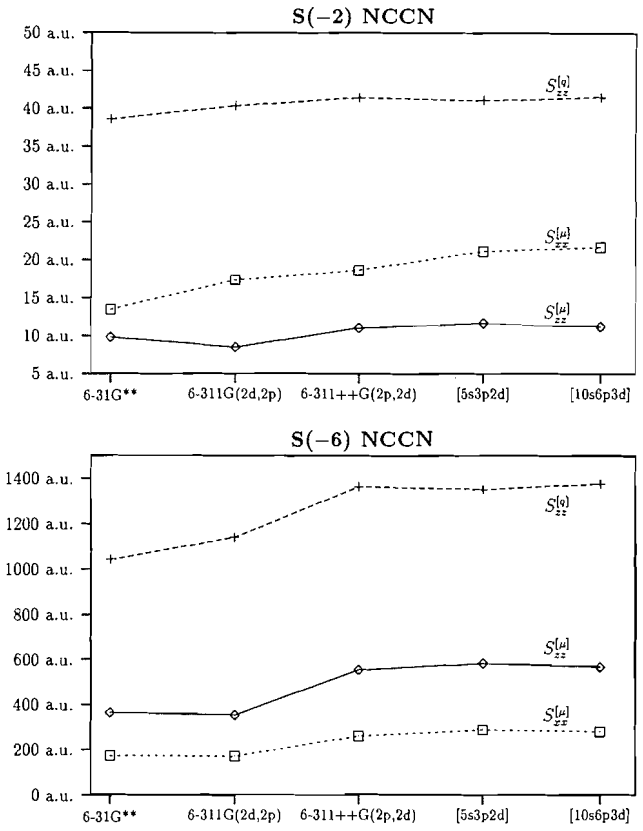
A selected set of significant components of the Cauchy moments $S_{\alpha\beta}^{A,mol}(k)$ as well as of $S_{q\beta}^{A,mol}(k)$ are listed in Table 3. The atom–molecule charge–dipole polarizabilities are relatively large for atoms at the extremities of the molecule, such as the nitrogen in cyanogen, the oxygen in urea, and the hydrogens in benzene. An interesting feature, already remarked by Bader and co-workers in the case of hydrocarbons, is the counter-polarization of "buried" atoms, such as the carbon in cyanogen and in urea: the induced dipole is in the opposite direction with respect to the applied field on the molecule.

A more conventional model, including exclusively atomic dipole–dipole polarizabilities, could be obtained by transforming the charge–dipole terms to atomic dipole–dipole contributions. Taking the molecular center of mass as the molecular origin, a set of atomic polarizabilities can be obtained (cf. the term in parentheses in eq. [17] that can be compared to other models available in the literature. For example, Åstrand et al. proposed a polarizable intermolecular potential for the urea molecule, in which an isotropic polarizability was assigned to each atom (37). A similar model can be constructed from our atom–molecule polarizabilities, using eq. [17]. The mean polarizability of urea, corresponding to the model of Åstrand et al. ($\alpha(C) = 0.0$, $\alpha(O) = 9.62$, $\alpha(N) = 2.63$, $\alpha(H_{cis}) = \alpha(H_{trans}) = 2.14$), is 23.44 au, i.e., practically identical to our 6-31G** result. Taking this basis set, we obtain a model, that is quite similar to theirs: ($\alpha(C) = 0.20$, $\alpha(O) = 6.40$, $\alpha(N) = 3.71$, $\alpha(H_{cis}) = \alpha(H_{trans}) = 2.32$). With the Sadlej polarization basis set, the qualitative features of the model remain unchanged: the polarizability of the carbon is practically zero, and the hydrogen polarizability (coming mainly from induced charge contributions) is about 2.5 au. However, the mean polarizabilities of the O and N atoms are considerably enhanced: they are 9.45 and and 6.21 au, respectively, reflecting the better quality of this basis set.

Atom–molecule polarizabilities have two main drawbacks. First, the external field is supposed to be uniform, which is a considerable restriction for the study of the intermolecular interaction of larger molecules, where a really nonlocal picture would be more appropriate. Second, the charge–dipole parameter cannot be combined in a simple, origin-independent way (the atomic contributions obtained from eq. [17] depend on the choice of the molecular origin) with the atomic dipole–dipole polarizability, except in some special cases.

A closer look at the expression for atom–molecule charge–dipole polarizability shows that only the charge-flow terms are responsible for the impossibility of assigning it to atomic dipole polarizabilities in an origin-independent way. A straightforward solution to this problem, already suggested by Le Sueur and Stone (15), is to keep charge-flow polarizabilities fully distributed, and relocalize only the dipole–dipole and charge–dipole terms, which can be done in a strictly origin-independent way. After a little algebra, using the sum rule, eq. [3], one gets the following expression for the relocalized atomic dipole polarizability:

Fig. 5. Breakdown of the molecular dipole–dipole Cauchy moments to distributed charge–charge ($S^{[q]}_{\alpha\beta}$) and dipole–dipole plus charge–dipole ($S^{[\mu]}_{\alpha\beta}$) contributions ($S^{[q]}_{\alpha\beta} + S^{[\mu]}_{\alpha\beta} = S^{tot}_{\alpha\beta}$) for cyanogen.

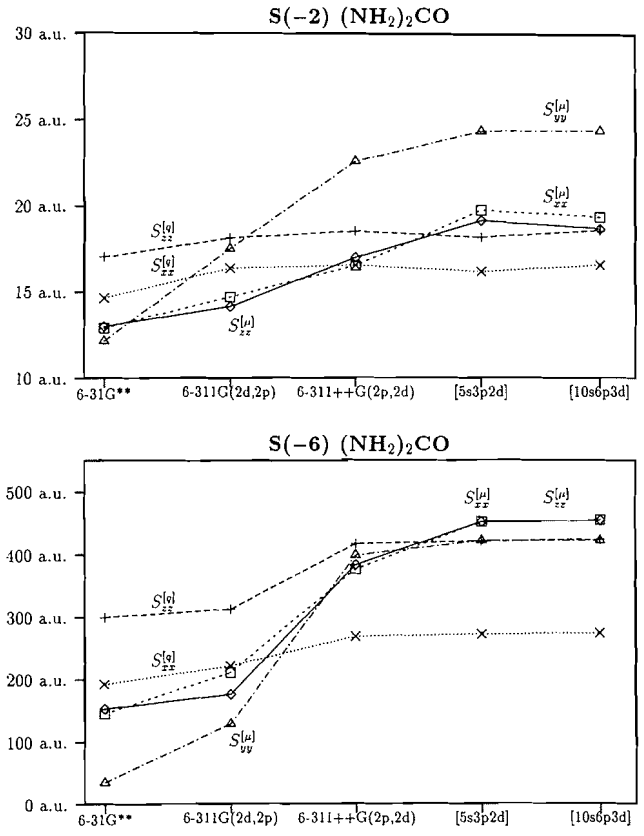


$$[20]\qquad \tilde{\alpha}^{A}_{\alpha\beta} = \frac{1}{2}\sum_{B}(\alpha^{AB}_{\alpha\beta} + \alpha^{BA}_{\alpha\beta}) + r^{AB}_{\alpha}(\alpha^{AB}_{q\beta} - \alpha^{BA}_{q\beta}) + r^{AB}_{\beta}(\alpha^{BA}_{\alpha q} - \alpha^{AB}_{\alpha q})$$

with $\boldsymbol{r}^{AB} = \boldsymbol{R}^{A} - \boldsymbol{R}^{B}$, the vector of interatomic distance. In this scheme all two-center charge–dipole and dipole–dipole terms are distributed in an equal manner between the centers in question. The resulting atomic dipole polarizability tensors are symmetric, unlike the atom–molecule polarizabilities, for which $\alpha^{A,mol}_{\alpha\beta} \neq \alpha^{A,mol}_{\beta\alpha}$. The charge-flow and the relocalized atomic Cauchy moments according to expression [20] are listed in Tables 4 and 5, respectively.

The charge–charge Cauchy moments (Table 4) are expected to be significant mainly between covalently bonded atoms: chemical bonds are natural paths for transferring electrons in a molecule. (A consistent formulation of the covalent bond order using the topological definition of atoms in molecules has been discussed in ref. 38.) The relative magnitude of charge-flow Cauchy moments for pairs of formally nonbonded atoms seems to increase with the order (e.g., N1–C3 compared to N2–C3 in urea, or the *meta* (C1–C4) charge flow in benzene). Several of the examples discussed here (cyanogen, urea, benzene) are conjugated systems, where surprisingly high charge flow may take place between quite distant atoms. For example, the end-to-end N1–N2 charge flow in cyanogen is larger than the charge flow between the first neighbor C3 and C4 atoms. This is already true for $S^{AB}_{qq}(-2)$, and the difference becomes even more important for the moments $S^{AB}_{qq}(-4)$ and $S^{AB}_{qq}(-6)$. Similar trends can be observed for benzene and urea.

Fig. 6. Breakdown of the molecular dipole–dipole Cauchy moments for urea.



Atomic dipole–dipole polarizabilities according to eq. [20] are larger than the corresponding atom–molecule dipole–dipole polarizabilities, since they include the totality of the charge–dipole contributions. Nevertheless, the main qualitative features are similar: negative in-plane polarizabilities for "buried" atoms and relatively small positive out-of-plane components. Hydrogen atoms have consistently small dipole–dipole atomic Cauchy moments ($S(-2)$ usually smaller than 1 au), when connected to the electronegative O and N atoms, but in benzene the component along the C—H bond becomes larger than 2 au. According to these observations a "united atom" description for the XH_n functional groups might be a reasonable model. In the same spirit, the water molecule could be regarded as a single dipole – polarizable oxygen site, bearing about 75% of the total molecular polarizability, and an additional charge transfer contribution between the oxygen and the hydrogen atoms.

IV. Summary and conclusions

We have shown that the atoms-in-molecules theory of Bader constitutes an appropriate framework for partitioning dy-

namic polarizabilities and leads to a physically consistent set of atom–atom parameters describing the nonlocal response of the molecular charge density to a time-dependent external field. The basis set dependence of distributed dynamic polarizabilities has been studied through their first three distributed Cauchy moments, which vary in parallel with the total Cauchy moments when improving the basis set quality.

In the case of static polarizabilities ($S(-2)$ Cauchy moments) the basis set dependence is manifested almost exclusively in the distributed dipole–dipole contributions, and charge-flow terms are quite well described by relatively poor basis sets. Nevertheless, diffuse functions seem to be important for the description of higher order charge–charge Cauchy moments. Static charge–charge polarizabilities between distant pairs of atoms may be quite large in conjugated systems and in all cases the importance of charge-flow Cauchy moments between nonbonded and (or) distant atoms increases with increasing order.

Two alternative schemes have been considered to "relocalize" the fully distributed, nonlocal dynamic polarizabilities. The atom–molecule polarizabilities, closely related to the atomic polarizabilities recently studied by Bader and coworkers, describe induced atomic charges and dipoles of a molecule in a uniform external field. Description of the response in non-uniform fields is possible only by considering higher rank (e.g., charge–quadrupole, dipole–quadrupole, charge–octupole., etc.) atom–molecule polarizabilities, with all the pitfalls of the single-centered Taylor expansion of the external field for spatially extended systems. The other model, which retains all charge-flow terms fully distributed and relocalizes only the charge–dipole contributions, is better suited to the description of molecules in non-uniform fields.

Considering the increasing importance of distant charge-flow contributions with increasing Cauchy order, this second model seems to be more appropriate for the relocalization of distributed dynamic polarizabilities.

The main use of distributed dynamic polarizabilities, which have been characterized in the present study by their various Cauchy moments, is in the field of intermolecular interactions. We have recently developed an efficient computational scheme for obtaining multicentered multipolar dispersion energies. In the case of relatively small molecules, where the dipolar approximation is valid, one can obtain reliable dispersion energies by the CDOSD method (39). Theoretically calculated distributed dynamic polarizabilities allow us to extend the practical utility of the multipolar approximation to larger systems as well. To attain this goal the accuracy of the polarizability calculations has to be improved by

including electron correlation (for example by the TDMP2 method (33)) and the number of independent polarizability components has to be kept at a reasonably low level by the application of appropriate relocalization schemes. Work in these directions is in progress.

Coherent control of electrons in molecules

Andre D. Bandrauk, Hengtai Yu, and Eric E. Aubanel

Abstract: Coherent superposition of electronic states can be achieved by simultaneous laser excitation at different frequencies. As an example, the three-level system is examined in order to demonstrate the possibility of phase control of electron transfer in molecules. Ab initio calculations are used to illustrate the principle in a charge transfer molecule DMBAN, 4-(*N*,*N*-dimethylamino)benzonitrile.

Key words: laser control, charge transfer electrons.

Résumé : On peut effectuer une superposition cohérente d'états électroniques par une excitation simultanée au laser à différentes fréquences. À titre exemple, on a examiné le système à trois niveaux afin de démontrer la possibilité de contrôle de phase du transfert d'électron dans des molécules. On a utilisé des calculs ab initio pour illustrer le principe dans une molécule à transfert de charge, le 4-(*N*,*N*-diméthylamino)benzonitrile (DMABN).

Mots clés : contrôle de laser, électrons de transfert de charge.

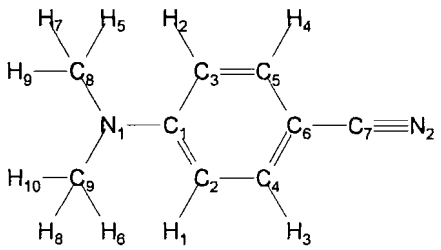
[Traduit par la rédaction]

I. Introduction

Control of photochemical processes has focused on controlling via relative laser beam phases the detailed dynamics of photodissociations of molecules (1–3). There has recently been interest in the possibilities of controlling electrons. Thus high-order harmonic generation in atoms and molecules was shown theoretically to be controllable by superpositions of laser beams of different frequency and phase, as a result of the phase control of electron trajectories upon ionization (4, 5). This numerical demonstration of electron control lead to the highly innovative idea of generating attosecond (subfemtosecond) pulses by using superpositions of elliptically and linearly polarized light in order to control electron recollision with the parent ion (5, 6). Recently we showed that one can control electron transfer, ET, in photodissociating Cl_2 molecules by using a symmetry-breaking excitation scheme with ω and 2ω photons (4–7). Such a scheme has now been demonstrated experimentally to provide a useful means of controlling currents in quantum wells (8), which have strong analogies to molecular systems.

In the present work we investigate the use of optically induced quantum coherence effects, which can be achieved using moderately intense laser fields, well below intensities $I = 10^{13}$ W/cm^2, above which considerable ionization will then occur (9, 10). A well-known coherent effect in atomic quantum optics is the creation of the so-called dark state (11), which is a special dressed superposition state of excited states and is uncoupled from the ground state. We shall focus on the phase dependence of coherent superpositions of the three-level system, called the V-system in atomic physics (12, 13), in order to illustrate the basic principle of **phase-dependent electron transfer**. We then use ab initio calculation of the lowest excited states of a charge transfer (CT) molecular system: DMBAN, 4(*N*,*N*-dimethylamino)benzonitrile, illustrated in Fig. 1. Previous ab initio calculations on this system (14) have shown the existence of ion-pair states in the excited states of this molecule. Thus using electron distributions in DMBAN obtained from ab initio (with CI) calculations we have examined the feasibility of creating laser-induced charge redistributions in order ot control ET, or equivalently CT, in such large molecular systems via the phase of the exciting laser beams. Conditions for such electron control scenarios in large systems are discussed with reference to the ab initio results presented here.

Fig. 1. Coordinate system of DMABN.



II. Phase control in a three-level V system

Previous studies of the coherences induced in a three-level V-system, Fig. 2, have shown the occurrence of dark states that are completely uncoupled from the initial ground states as a consequence of radiative nonlinear coherent properties of such systems during the laser excitation (11–13). We examine here the phase dependence of such systems and explore in the next section their possible application to controlling ET, or equivalently CT, in large molecules.

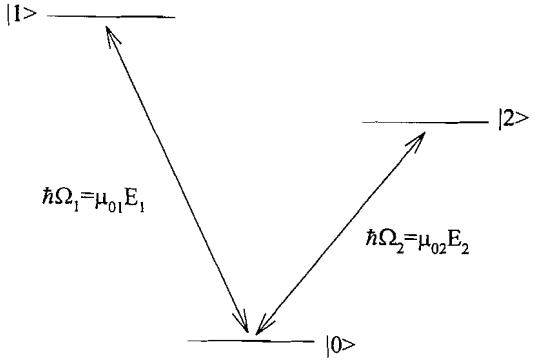
Fig. 2. Resonant three-level V system with appropriate Rabi frequencies Ω, transition moments μ, and laser field amplitudes E.



We limit ourselves here to the resonant case, whereas the nonresonant case (13) will be described in detail elsewhere (15). Figure 2 illustrates the resonant V configuration in which one assumes simultaneous excitation from an initial ground state $|0\rangle$ to two nondegenerate excited states $|1\rangle$ and $|2\rangle$ with Rabi frequencies Ω_1 and Ω_2, where $\hbar\Omega_2 = \mu_{01}E_2$, $\hbar\Omega_2 = \mu_{02}E_2$, μ is the transition moment, and E is the field amplitude. For a real time-dependent field, $E(t) = E\cos(\omega t+\phi) = (E/2)(e^{i(\omega t+\phi)}+e^{-i(\omega t+\phi)})$, in the rotating wave approximation, RWA, one retains only the resonant field $(E/2)(e^{i(\omega t+\phi)}$ contribution. This leads to a time-independent Hamiltonian in the dressed state representation (9, 13),

$$[1] \qquad H = \frac{1}{2}\begin{pmatrix} 0 & \Omega_1 e^{i\phi_1} & \Omega_2 e^{i\phi_2} \\ \Omega_1 e^{-i\phi_1} & 0 & 0 \\ \Omega_2 e^{-i\phi_2} & 0 & 0 \end{pmatrix}$$

where ϕ_1 and ϕ_2 are the phases of the two laser beams E_1 and E_2. Defining an effective three-level Rabi frequency

$$[2] \qquad \Omega = (\Omega_1^2 + \Omega_2^2)^{1/2}$$

one obtains the following three dressed states or eigenmodes of the three-level laser–molecule system (n =photon number),

$$[3] \qquad |\alpha\rangle = 2^{-1/2}\left[|0, n_1, n_2\rangle + \frac{\Omega_1}{\Omega}e^{-i\phi_1}|1, n_1-1, n_2\rangle + \frac{\Omega_2}{\Omega}e^{-i\phi_2}|2, n_1, n_2, -1\rangle\right]$$

$$[4] \qquad E_\alpha = \frac{\hbar\Omega}{2}$$

$$[5] \qquad |\beta\rangle = 2^{-1/2}\left[-|0_1, n_1, n_2\rangle + \frac{\Omega_1}{\Omega}e^{-i\phi_1}|1, n_1-1, n_2\rangle + \frac{\Omega_2}{\Omega}e^{-i\phi_2}|2, n_1, n_2-1\rangle\right]$$

$$[6] \qquad E_\beta = -\frac{\hbar\Omega}{2}$$

$$[7] \qquad |\gamma\rangle = -\frac{\Omega_2}{\Omega}e^{i\phi_2}|1, n_1-1, n_2\rangle + \frac{\Omega_1}{\Omega}e^{i\phi_2}|2, n_1, n_2-1\rangle$$

$$[8] \qquad E_\gamma = 0$$

where $E_{\alpha(\beta,\gamma)}$ are the dressed state energies of the laser–molecule system. We note that the states $|\alpha\rangle$ and $|\beta\rangle$ are Stark shifted by $\pm\hbar(\Omega/2)$, so that the frequency separation between these two dressed states is the effective Rabi frequency Ω defined in eq. [2]. Both states reflect the Rabi-induced superposition of all three electronic states that are phase dependent. The state $|\gamma\rangle$ is the dark state, which remains unshifted and does not contain the initial state $|0\rangle$. Clearly the state $|\gamma\rangle$ will never be populated from the ground state $|0\rangle$ in the V-configuration. As a consequence the total wave function can be written as combinations of $|\alpha\rangle$ and $|\beta\rangle$ only:

$$[9] \qquad |\psi(t)\rangle = 2^{-1/2}(|\alpha\rangle e^{\frac{-i\Omega t}{2}} - |\beta\rangle e^{\frac{i\Omega t}{2}})$$

satisfying the initial condition $|\psi(0)\rangle = |0, n_1, n_2\rangle$, i.e., the ground state. Thus at times $\tau = \pi/\Omega$, one has the superpositions

$$[10] \qquad |\psi(\tau)\rangle = -i2^{-1/2}(|\alpha\rangle + |\beta\rangle)$$

$$= -i\left(\frac{\Omega_1}{\Omega}e^{-i\phi_1}|1, n_1-1, n_2\rangle + \frac{\Omega_2}{\Omega}e^{-i\phi_2}|2, n_1, n_2-1\rangle\right)$$

One observes that at such times, i.e., at $\tau = \pi/\Omega$, the laser-induced coherent state is a pure superposition of the excited state $|1\rangle$ and $|2\rangle$ only, the relative sign of these amplitudes can be controlled by the relative laser phase difference $(\phi_2 - \phi_1)$. To see this more succinctly, we specialize further to the particular case,

$$[11] \qquad \Omega_1 = \Omega_2 = 2^{-1/2}\Omega$$

This can be achieved by varying the laser field amplitudes E_1 and E_2 so that $\mu_{01}E_1 = \mu_{02}E_2$. In this case one recovers the simply transparent result,

$$[12] \qquad |\psi(\tau)\rangle = -i2^{-1/2}(e^{-i\phi_1}|1, n_1-1, n_2\rangle + e^{-i\phi_2}|2, n_1, n_2-1\rangle)$$

Thus if $\phi_1 = \phi_2 = \phi$, one obtains

$$[13] \qquad |\psi^+(\tau)\rangle = -i2^{-1/2}(e^{-i\phi}(|1, n_1-1, n_2\rangle + |2, n_1, n_2-1\rangle)$$

If $\phi_1 = \phi_2 = \pi$, one now has

$$[14] \qquad |\psi^-(\tau)\rangle = -i2^{-1/2}e^{-i\phi}(|1, n_1-1, n_2\rangle - |2, n_1, n_2-1\rangle)$$

We observe that at times $\tau = \pi/\Omega$, one can create new excited state amplitudes that are simple sums or differences of the original excited states. For molecules, this implies that one should be able to prepare simple superpositions of delocalized molecular orbitals and thus create more localized electronic states leading to laser-induced CT.

We designate the states $|\psi^\pm(\tau)\rangle$ as our target states and

Table 1. Optimized geometry of DMABN using 3-21G basis sets.

Bond length (Å)			
C_1—C_2	1.407	C_7—N_2	1.141
C_2—C_4	1.373	C_1—N_1	1.375
C_4—C_6	1.388	C_8—N_1	1.463
C_6—C_7	1.423	C_2—H_1	1.076
C_4—H_3	1.080	C_8—H_5	1.188
Valence angle (degree)			
$C_3C_1C_2$	115.86	$C_1C_2C_4$	121.89
$C_2C_4C_6$	121.31	$C_4C_6C_7$	121.14
$N_1C_1C_2$	122.07	$C_8N_1C_1$	124.35

examine their time evolution from the occupation probability:

$$[15] \qquad P^{\pm}(t) = |\langle\psi^{\pm}(\tau)|\psi(t)\rangle|^2$$

The resulting time-dependent occupation probability of the target states $|\psi^{\pm}(\tau)\rangle$ is readily obtained from eqs. [13]–[15].

$$[16] \qquad P^{\pm}(t) = \tfrac{1}{2}\sin^2\left(\frac{\Omega t}{2}\right)[1 \pm \cos(\phi_2 - \phi_1)]$$

We conclude by observing that in order to obtain complete selectivity of one state or another, i.e., $P^{\pm}(t) = 1$, then: (*i*) the phases of the two lasers must be locked, i.e., $\phi_2 - \phi_1 = 0$ or $= \pi$; (*ii*) the occurrence time of the selectivity is $t_n = (2n+1)\tau = [(2n+1)\pi]/\Omega$. Thus two essential parameters enter into the controllability of the system: the Rabi frequency Ω, which depends on transition moments μ and field E amplitudes, and finally the phase difference ϕ between the two laser beams or pulses. We observe furthermore from eq. [10] that a special feature of the three-level V system is that in the general case the total system oscillates between the ground state $|0\rangle$ and the coherent linear superpositions of $|1\rangle$ and $|2\rangle$ defined by $|(\psi(\tau)\rangle$, eq. [10]. In fact, the general state (eq. [9] can be written as

$$[17] \qquad |\psi(t)\rangle = |0\rangle\cos\left(\frac{\Omega t}{2}\right) - i|\psi(\tau)\rangle\sin\left(\frac{\Omega t}{2}\right)$$

thus showing that at recursion times $t_n = (2n+1)(\pi/\Omega)$, one is indeed in the general coherent state $|\psi(\tau)\rangle$, eq. [10], whereas times $t_m = 2m(\pi/\Omega)$, one is in the ground state, $|0\rangle$. In the next section we examine laser-induced electron density redistributions in a large molecule DMABN based on preparation of the coherent state $|\psi(\tau)\rangle$, eq. [10].

III. AB initio simulations

DMABN is the prototype of CT molecules, in which the formation of a twisted intramolecular charge transfer state is well documented from fluorescence studies. Thus from the red shifts of the fluorescence in polar solvents, it is inferred that the dimethylamino group (see Fig. 1) undergoes a 90° internal rotation with respect to the aromatic ring and an electron is completely transferred from the amino group to the benzonitrile moiety because the conjugation between the amino lone pair and the π orbitals in the aromatic ring is absent (16, 17). The time for such rotation has been estimated to be at least 40 picoseconds (ps) (16).

The static electronic properties of DMABN are calculated here by ab initio methods using the GAMESS program (18). The molecular geometry is reoptimized with split-valence shell 3-21G basis sets (19) using previous results (STO-3G, ref. 14) as a starting point and supposing the molecule has C_s symmetry. The optimized results for the planar geometry are given in Table 1. All energies in the ground state and the first five low-lying excited states are calculated by configuration interaction (CI) methods. MINI4 basis sets (20) are used for all hydrogen and two carbon atoms in the methyl groups, and MINI4+double zeta basis sets (21) are used for all other atoms. There are 39 occupied MOs in DMABN with 78 electrons; 34 orbitals with lower orbital energies were considered as the internal orbitals and the remaining 5 occupied MOs with higher orbital energies and the lowest 5 virtual MOs were included in the CI computations with single and double excitations. The number of symmetry-adapted (C_s) configurations is more than 60 000 for the basis sets mentioned above. The calculated energies are −452.7952, −452.5149, −452.4810, −452.4216, −452.4096, and −452.3958 au for the ground state and the first five low-lying excited states, respectively. This gives the first excitation energy 5.5 eV of state S_1. This value is overestimated by 2.5 eV compared with the experimental excitation energy of ~4 eV (14). The second excited state S_3 can be reached by 8.5 eV from the ground state.

To classify clearly molecular orbital symmetry, so that we can easily simulate ET, DMABN is regarded as C_{2v} symmetry. This way the last three occupied MOs that are used for CI calculations are assigned to symmetries $4b_1(37)$ with mainly character of the N lone pair and triple bond C≡N, $1a_2(38)$ with mainly π character in the aromatic ring, and $5b_1(39)$ of mainly N lone pair character. Similar considerations apply to the lowest two virtual MOs $6b_1(40)$ (lone pair) and $2a_2(41)$ (π character in aromatic ring). It can be seen from an analysis of the coefficients of electronic configuration state functions (CSF) in the CI calculations that the first excited state S_1 is characterized mainly by the two CSF transitions: $5b_1(39) \rightarrow 1a_2(41)$ and $1a_2(38) \rightarrow 6b_1(41)$ in the planar geometry, corresponding to $^1B_2$ symmetry. In fact it is obtained by $n\pi^*$ plus πn^* transitions. The second S_2 and third S_3 excited states are characterized by the three CSF transitions $5b_1(39) \rightarrow 6b_1(41)$ and $4b_1(37) \rightarrow 6b_1(39)$, which correspond to nn^* transitions, and $1a_2(38) \rightarrow 2a_2(41)$, which is a $\pi\pi^*$ transition. Both S_2 and S_3 excited states have the same symmetry $^1A_1$ as does the ground state. Hence they are easily accessible by laser excitation from the ground state. For the sake of convenience, we call these three CSF Φ_A, Φ_B, and Φ_C in the following text.

Now we want to simulate the ET from the N lone pair on the amino group to the triple bond C≡N in the DMABN. Because the first excited state S_1 has different symmetry from the ground state and is formed by the $n\pi^*$ (or πn^*) transition, ideal ET from the amino group to the triple bond can be achieved by considering the exited states S_2 and S_3 only. To construct the coherent state, we assume that the S_2 and S_3 state wave functions Ψ_I and Ψ_{II} can be expressed as a linear combination of the three electronic CSF, Φ_A, Φ_B, and Φ_C:

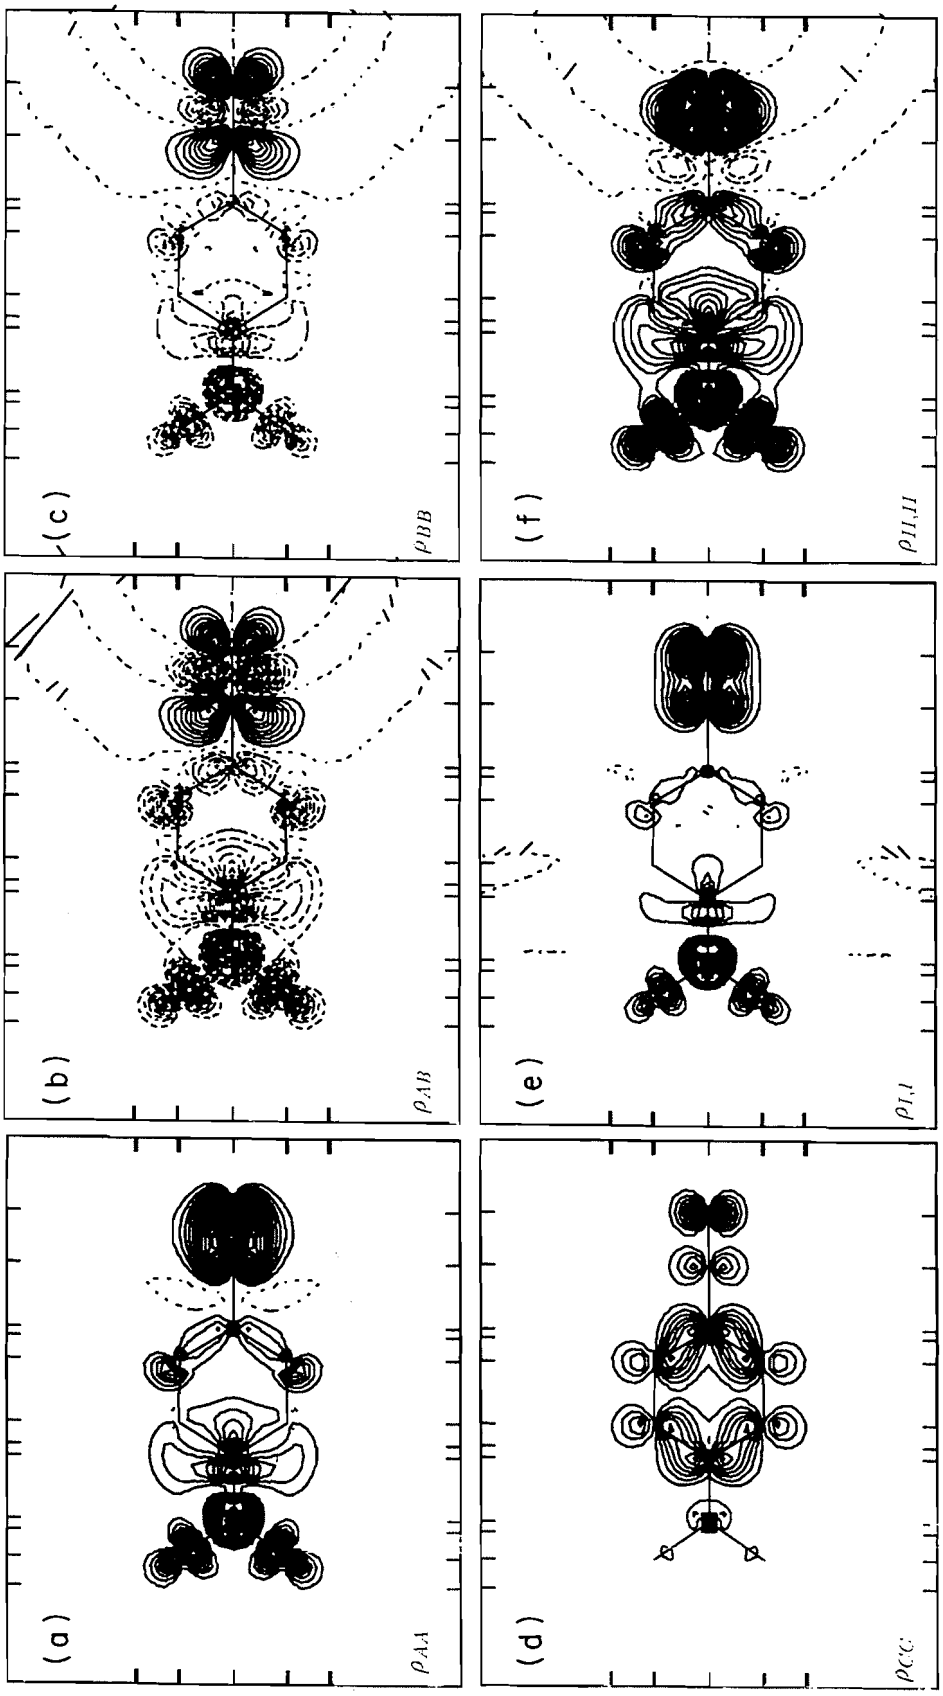


Fig. 3. Density maps of initial wave states: (*a*) ρ_{AA}, (*b*) ρ_{AB}, (*c*) ρ_{BB}, (*d*) ρ_{CC}, (*e*) $\rho_{I,I}$, and (*f*) $\rho_{II,II}$.

[18] $|\Psi_I\rangle = a_1\Phi_A + b_1\Phi_B + c_1\Phi_C$

and

[19] $|\Psi_{II}\rangle = a_2\Phi_A + b_2\Phi_B + c_2\Phi_C$

where a_i, b_i, $c_i (i = 1, 2)$ are the coefficients of CSF in the CI calculations. The calculated values are $a_1 = 0.9635$, $b_1 = 0.1088$, $c_1 = -0.2447$, and $a_2 = -0.4400$, $b_2 = 0.8859$, $c_2 = -0.1467$ after renormalization to eliminate other CSF contributions. Here $|\Psi_I\rangle$ and $|\Psi_{II}\rangle$ correspond to $|1, n_1-1, n2\rangle$ and $|2, n_1, n2_1\rangle$ in eq. [10]. As mentioned above, ET can be controlled by two factors: laser field amplitudes E and the phase difference ϕ between the two laser beams or pulses. According to eq. [10], the coherent state can be written as

[20] $|\Psi_{co}\rangle = C_I e^{-i\phi_1}\Psi_I + C_{II}e^{-i\phi_2}\Psi_{II}$

where C_I and C_{II} are the coefficients related to the laser amplitudes E and ϕ_1, ϕ_2 are the phases of the two laser fields. For simplicity without losing generality, eq. [20] can be rewritten as

[21] $|\Psi_{co}\rangle = \Psi_I + \alpha e^{-i\phi_1}\Psi_I$

where ϕ is the phase difference between the two laser field and α is the coefficient related to the laser amplitude E through RAbi frequency Ω. Putting eqs. [18] and [19] into eq. [21], $|\Psi_{co}\rangle$ becomes

[22] $|\Psi_{co}\rangle = a_1\Phi_A + b_1\Phi_B + c_1\Phi_C + \alpha e^{i\phi}(a_2\Phi_A + b_2\Phi_B + c_2\Phi_C)$

Thus the coherent state density is

[23] $\rho_{co} = \Psi^*_{co}\Psi_{co} = A\rho_{AA} + B\rho_{BB} + C\rho_{CC} + AB\rho_{AB}$

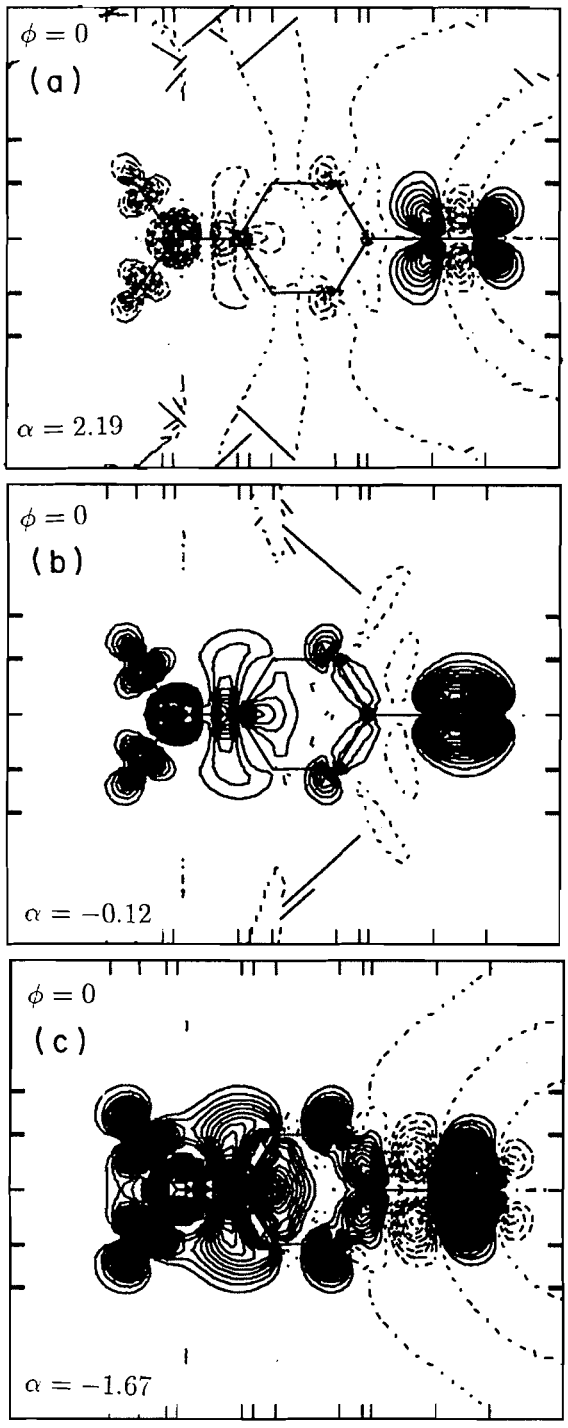
where

[24]
$$A = a_1^2 + (\alpha a_2)^2 + 2\alpha a_1 a_2 \cos(\phi)$$
$$B = b_1^2 + (\alpha b_2)^2 + 2\alpha b_1 b_2 \cos(\phi)$$
$$C = c_1^2 + (\alpha c_2)^2 + 2\alpha c_1 c_2 \cos(\phi)$$
$$AB = 2[a_1 b_1 + \alpha^2 a_2 b_2 + \alpha(a_2 b_1 + a_1 b_2)\cos(\phi)]$$

In deriving eq. [23], we have eliminated $\Phi^*_A\Phi_C$ and $\Phi^*_B\Phi_C$ contributions because they are the transition densities between different symmetries (Φ_C is $\pi\pi^*$ character), which are regarded as zero. The configuration densities are obtained from the wave functions of the excited states S_2 and S_3. Thus we obtain from eqs. [18] and [19] (see also ref. 14):

[25]
$$\rho_{AA} = [b_2^2\rho_{I,I} - 2b_1 b_2\rho_{I,II} + b_1^2\rho_{II,II} - (b_1c_2 - c_1b_2)^2\rho_{CC}]/\text{norm}$$
$$\rho_{BB} = [a_2^2\rho_{I,I} - 2a_1 a_2\rho_{I,II} + a_1^2\rho_{II,II} - (a_1c_2 - c_1a_2)^2\rho_{CC}]/\text{norm}$$
$$\rho_{AB} = -[a_2 b_2\rho_{I,I} - (a_1b_2 + a_2b_1)\rho_{I,II} + a_1b_1\rho_{II,II} - (a_1c_2 - c_1a_2)(b_1c_2 - c_1b_2)\rho_{CC}]/\text{norm}$$

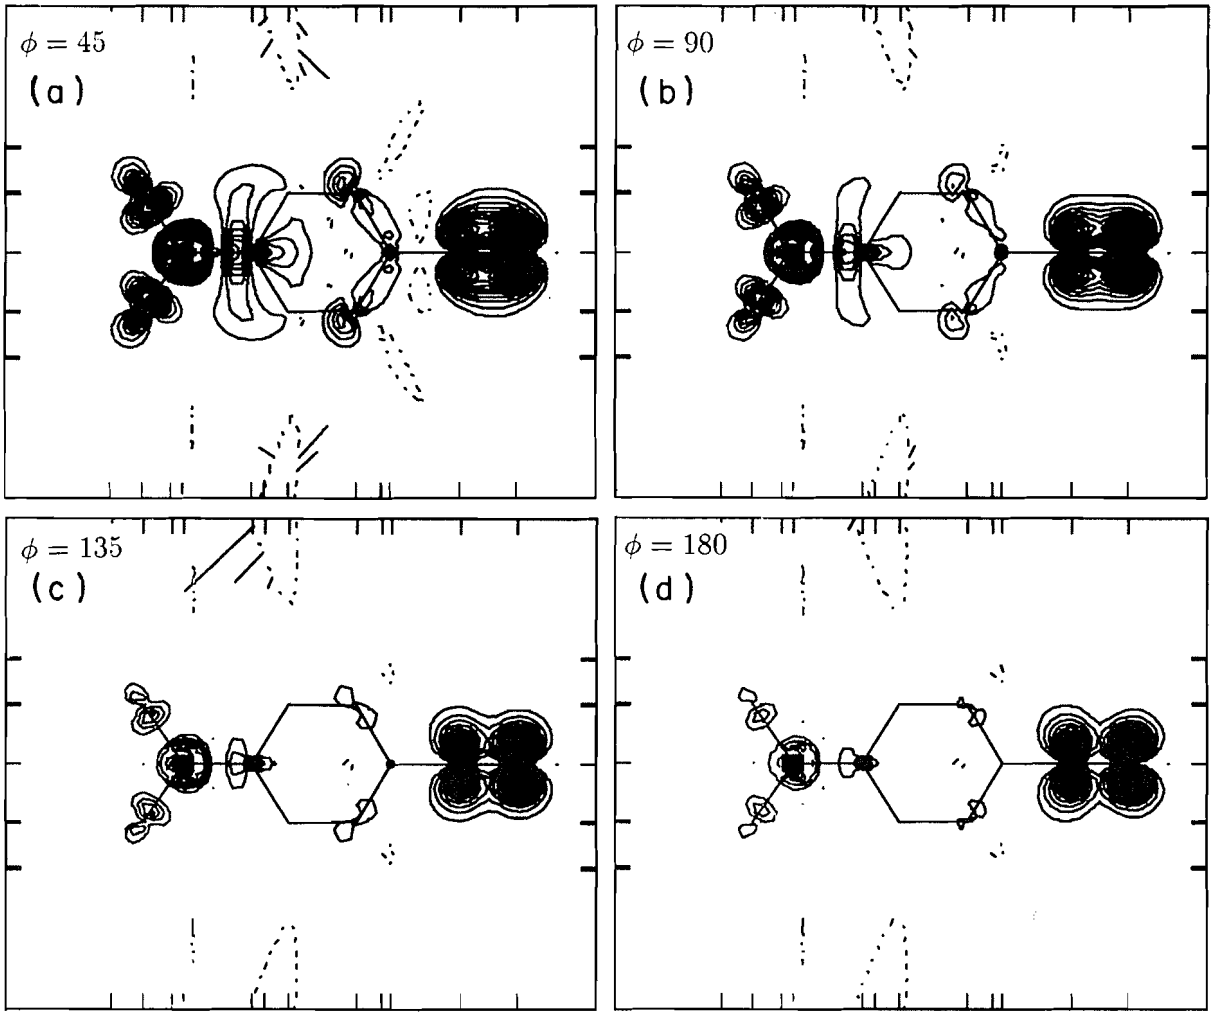
Fig. 4. Density maps obtained by changing α or laser field amplitudes E: (*a*) $\alpha = 2.19$, (*b*) $\alpha = -0.12$ (*c*) $\alpha = -1.67$.



where norm $= (a_1b_2 - b_1a_2)^2$, and $\rho_{I,I}$, $\rho_{I,II}$, and $\rho_{II,II}$ are the densities of S_2 and S_3 and the transition density between these two states, respectively. In deriving eq. [25], ρ_{AC} and ρ_{BC} are considered to be zero as explained above. Putting eq. [25] into eq. [23] we can obtain explicit formula for ρ_{co}, and laser-induced ET can be simulated by changing α and ϕ.

It should be indicated that the excited state S_2 (or S_3) contains 10 active orbitals, 5 occupied and 5 virtual MOs, i.e., 10 electrons are involved in the CI calculations. All

Fig. 5. Density maps obtained by changing the phase difference ϕ at $\alpha = -0.12$ (Fig. 4*b*): (*a*) 45°, (*b*) 90° (*b*) 135° (*d*) 180°.



wave functions we obtain are renormalized and the corresponding density maps are calculated for 10 active electrons. The molecule DMABN is placed in the zx plane and density maps are drawn in the same plane.

The initial state density maps of various wave functions are given in Fig. 3*a–f* for ρ_{AA}, ρ_{AB}, ρ_{BB}, ρ_{CC}, $\rho_{I,I}$, and $\rho_{II,II}$, respectively. It can be seen that the density ρ_{AA} is similar to that of $\rho_{I,I}$, and ρ_{AB} similar to $\rho_{II,II}$, as these reflect the dominant coefficients. For example, Φ_A has the largest coefficient in Ψ_I while on the other hand Φ_B has the largest coefficient in Ψ_{II}. Both represent mainly $nn*$ transitions. ρ_{CC} represents mainly a $\pi\pi^*$ transition as shown in Fig. 3*d*. Transition densities ρ_{AB} between Φ_A and Φ_B are not very large although they are of the same symmetry.

The density maps that correspond to a change in α related to laser amplitudes E are given in Fig. 4*a–c*. When $\alpha = -(a_1/a_2) = 2.19$ and $\phi = 0$, from eqs. [18] and [19], Φ_A is cancelled in Ψ_I and Ψ_{II}. The resulting density map is formed mainly from Φ_B and Φ_C, and is illustrated in Fig. 4*a*. In this case the transferred electrons are concentrated mostly on the triple bond C≡N. We can make Φ_B disappear in Ψ_I and Ψ_{II} by choosing $\alpha = -(b_1/b_2) = -0.12$ with $\phi = 0$. The corresponding map contains mainly Φ_A and Φ_C configurations and is given in Fig. 4*b*. It is similar to ρ_{AA} shown in Fig. 3*a* because Φ_A now plays a principle role in Ψ_I and Ψ_{II}. When we cancel the contribution of configuration state Φ_C with $\alpha - (c_1/c_2) = -1.67$ and $\phi = 0$, the map contains mainly Φ_A and Φ_B. The corresponding map, Fig. 4*c*, shows a strong electron density, mainly concentrated on the N lone pair in the amino group and the triple bond C≡N. This reflects the negative coefficients of Φ_C in Ψ_I and Ψ_{II}. The ET effects shown in Fig. 4 correspond therefore to changes in the laser field amplitude E only through the factor α.

Now we demonstrate the effect of laser phase difference ϕ on ET. The ideal scenario to see how electrons can be transferred from the N lone pair in the amino group to the triple bond C≡N in DMABN involves cancelling the Φ_B state in Ψ_I and Ψ_{II}. Thus when $\phi = 0$, the corresponding map is the same as shown in Fig. 4*b*. The new maps for $\phi = 45°$, 90°, 135° and 180° are given in Fig. 5*a– d*. Comparing Figs. 4*b* and 5, one observes that ET begins to occur at $\phi = 90°$, gradually attaining a maximum at $\phi = 180°$, Fig. 5*d*. In the

latter case, one is essentially changing the sign of α from -0.12 to 0.12, thus enhancing the presence of the Φ_B state function, a nn^* transition.

IV. Conclusions

We have shown that simultaneous laser excitation of different electronic states in CT systems can be used to transfer electrons between different functional groups, e.g., amino to nitrile. This is achieved by varying appropriately configuration state function coefficients through laser amplitudes E. Varying relative phases ϕ of the laser fields will help to enhance ET effects in large molecules. Clearly, as shown from eq. [17], the ET effect only persists during the laser illumination, i.e., at the recursion times $\tau_n = (2n + 1)(\pi/\Omega)$. Since $\Omega(\text{cm}^{-1}) \simeq 10^{-3}I(\text{W/cm}^{-2})\mu$ (au) (9), for a 10 au transition moment μ and intensity $I = 10^8$ W/cm^2, we thus obtain $\Omega \simeq 100$ cm^{-1} and $\tau = \pi/\Omega = 10^{-12}$ s = 1 ps. Considering that DMABN undergoes an internal rotation after 40 ps in order to stabilize the CT state (16, 17), the above calculation shows that laser-induced ET should be feasible with moderate intensity (10^8 W/cm^2) picosecond pulses. Another condition is that the total molecular rotation rate must be smaller than the Rabi frequency Ω. In the present case this condition is satisfied. One should therefore expect molecular alignment along the laser fields (7), since one is exciting both states S_2 and S_3 using transition moments that are parallel to the CT process, i.e., from N to C≡N (see Fig. 1). This will enhance the electron transfer control described in the present work.

V. Acknowledgments

We thank Professor J.D. Goddard for providing GAUSSIAN 92 CI results of DMABN. We thank the Natural Sciences and Engineering Research Council of Canada for support of the present research.

Current-density dependent exchange-correlation functionals

Axel D. Becke

Abstract: Previous models for exchange (Becke and Roussel, Phys. Rev. A: **39**, 3761 (1989)) and for correlation (Becke, J. Chem. Phys. **88**, 1053 (1988)) are, in a simple and natural way, generalized to include explicit dependence on current density $\boldsymbol{J}$. First-principles incorporation of $\boldsymbol{J}$ into exchange-correlation density functionals, as proposed here, is crucial for further progress in the study of magnetic effects in density-functional theory.

Key words: density-functional theory, exchange-correlation functionals, current density.

Résumé : Des modèles antérieures d'éxchange (Becke et Roussel, Phys. Rev. A: **39**, 3761 (1989)) et de corrélation (Becke, J. Chem. Phys. **88**, 1053 (1988)) sont généralisés d'une façon simple et naturelle de façon à inclure la dépendance explicite sur la densité du courant, $\boldsymbol{J}$. Telle que proposée ici, l'incorporation sur la base de principes premiers de $\boldsymbol{J}$ dans les fonctionnelles de la densité de la corrélation d'éxchange est cruciale pour les progrès futurs dans l'étude des effets magnétiques de la théorie de la densité fonctionnelle.

[Traduit par la rédaction]

Introduction

There has been a call in recent density-functional literature for exchange-correlation approximations with explicit dependence on *current* density $\boldsymbol{J}$ as well as the density itself (1, 2). Such functionals are required for proper description of magnetic properties of electronic systems. The formalities of current-density-functional theory have been discussed by Vignale, Rasolt, and Geldart (1). A first-principles derivation of the $\boldsymbol{J}$-dependent exchange-correlation energy in inhomogeneous systems, however, is still lacking. In this note, we present such a derivation.

The various ingredients of this work have, in fact, already been published. Indeed, a related $\boldsymbol{J}$-dependent correlation-only functional may be found in ref. 3. Here, we generate a new, $\boldsymbol{J}$-dependent exchange functional by combining the $\boldsymbol{J}$-dependent exchange-hole curvature formula of Dobson (3, 4) with the hydrogenic exchange-hole model of Becke and Roussel (5). Then, we generate a new correlation functional by generalizing an old correlation model from 1988 (6).

Exchange

The exchange-hole model of Becke and Roussel is based on the following analytic form inspired by the hydrogenic atom (see ref. 5 for details):

$$[1] \qquad \rho_{X\sigma}(\boldsymbol{r}, s) = \frac{a}{16\pi bs}\left[(a|b-s|+1)e^{-a|b-s|} - (a|b+s|+1)e^{-a|b+s|}\right]$$

where $\rho_{X\sigma}$ is the σ-spin exchange charge density, and the arguments $(\boldsymbol{r}, s)$ denote spherical average on a shell of radius s centred on the reference point $\boldsymbol{r}$. This model exchange charge density is always positive definite and properly normalized by construction. Two parameters a and b need to be specified at each reference point. If the leading two terms of the Taylor expansion (around $\boldsymbol{r}$) of the model $\rho_{X\sigma}$ are equated to those of the exact $\rho_{X\sigma}$ at each reference point,

$$[2] \qquad \rho_{X\sigma}(\boldsymbol{r}, s) = \rho_\sigma + Q_\sigma s^2 + \ldots$$

then a parameter-free exchange approximation is obtained. Equating values at $s = 0$ yields the condition

$$[3] \qquad a^3 e^{-ab} = 8\pi\rho_\sigma$$

and equating curvatures Q_σ gives

$$[4] \qquad a^2 b - 2a = 6bQ_\sigma/\rho_\sigma$$

whose solution will be outlined momentarily.

For a system with zero current density, the exact exchange-charge curvature Q_σ is given by (5, 7):

$$[5] \qquad Q_\sigma = \tfrac{1}{6}[\nabla^2\rho_\sigma - 2\tau_\sigma + \tfrac{1}{2}(\nabla\rho_\sigma)^2/\rho_\sigma]$$

where the *kinetic* energy density τ_σ is defined as follows (notice that we do not include a 1/2 factor in the definition):

$$[6] \qquad \tau_\sigma = \sum_k \nabla\psi^*_{k\sigma} \cdot \nabla\psi_{k\sigma}$$

Solution of eqs. [3] and [4] proceeds by introduction of a

new variable $x = ab$; then seeking the (unique) root of the 1D nonlinear equation

$$[7] \qquad \frac{xe^{-2x/3}}{(x-2)} = \tfrac{2}{3}\pi^{2/3}\rho_\sigma^{5/3}/Q_\sigma$$

by an iterative Newton–Raphson scheme (5). Finally, setting

$$[8] \qquad b^3 = \frac{x^3e^{-x}}{8\pi\rho_\sigma}$$

the exchange potential $U_{X\sigma}$ at reference point $\boldsymbol{r}$ is given by

$$[9] \qquad U_{X\sigma} = -(1 - e^{-x} - \tfrac{1}{2}xe^{-x})/b$$

and the total σ-spin exchange energy is

$$[10] \qquad E_{X\sigma} = \frac{1}{2}\int \rho_\sigma U_{X\sigma} d^3\boldsymbol{r}$$

Though not expressible in closed analytical form, this entire procedure is readily automated. We demonstrate in ref. 5 that the resulting exchange energies of atomic systems are significantly better than the LSDA (local spin-density approximation), but not as good as those of the best GGAs (generalized gradient approximation).

The curvature expression of eq. [5] is valid for systems of zero current density only. Dobson has pointed out that the generalization to non-zero currents is simple (3, 4). With the present definition of τ_σ, as given by eq. [6], we find that (see the Appendix)

$$[11] \qquad Q_\sigma = \tfrac{1}{6}[\nabla^2\rho_\sigma - 2\tau_\sigma + \tfrac{1}{2}(\nabla\rho_\sigma)^2/\rho_\sigma + 2\boldsymbol{J}_\sigma^2/\rho_\sigma]$$

where

$$[12] \qquad \boldsymbol{J}_\sigma = -\frac{i}{2}\sum_k [\psi_{k\sigma}^*\nabla\psi_{k\sigma} - \psi_{k\sigma}\nabla\psi_{k\sigma}^*]$$

is the (paramagnetic) σ-spin current density in atomic units. A $\boldsymbol{J}$-dependent extension of the Becke–Roussel exchange approximation is now obvious. Simply replace eq. [5] for Q_σ with eq. [11]. The resulting functional depends explicitly on ρ, $\nabla\rho$, $\nabla^2\rho$, τ, and $\boldsymbol{J}$. It is entirely free of empirical parameters, and its $\boldsymbol{J}$ dependence is incorporated in a first-principles manner.

Correlation

Our dynamical correlation model of ref. 6 (see also ref. 8) yields two correlation functionals: one for opposite-spin pairs,

$$[13] \qquad E_C^{opp} = -0.8\int \rho_\alpha\rho_\beta z_{\alpha\beta}^2\left[1 - \frac{\ln(1+z_{\alpha\beta})}{z_{\alpha\beta}}\right]d^3\boldsymbol{r}$$

and another for parallel-spin pairs,

$$[14] \qquad E_C^{\sigma\sigma} = -0.01\int \rho_\sigma\left\{\tau_\sigma - \frac{1}{4}\frac{(\nabla\rho_\sigma)^2}{\rho_\sigma}\right\} \times z_{\sigma\sigma}^4\left[1 - \frac{2}{z_{\sigma\sigma}}\ln\left(1 + \frac{z_{\sigma\sigma}}{2}\right)\right]d^3\boldsymbol{r}$$

where τ_σ is the same kinetic-energy density as above. Parameters $z_{\alpha\beta}$ and $z_{\sigma\sigma}$ are correlation "lengths" or "ranges" characterizing the sizes of the opposite and parallel-spin dynamical correlation holes, respectively. We approximate these as follows (see ref. 8):

$$[15] \qquad z_{\sigma\sigma'} = |c_{\sigma\sigma'}(U_{X\sigma}^{-1} + U_{X\sigma'}^{-1})|$$

where $U_{X\sigma}$ is the σ-spin exchange potential as in the previous section, and the correlation range constants $c_{\alpha\beta}$ and $c_{\sigma\sigma}$ have values (8)

$$[16] \qquad c_{\alpha\beta} = 0.63, \qquad c_{\sigma\sigma} = 0.88$$

Thus, if the $\boldsymbol{J}$-dependent Q_σ of eq. [11] is used to obtain $U_{X\sigma}$, then a $\boldsymbol{J}$-dependent correlation approximation naturally arises.

Even more importantly, however, the prefactor

$$[17] \qquad \left\{\tau_\sigma - \frac{1}{4}\frac{(\nabla\rho_\sigma)^2}{\rho_\sigma}\right\}$$

in the parallel-spins functional, eq. [14], needs to be modified in the case of non-zero current densities. If the derivation of ref. 6 is repeated using the generalized Q_σ of eq. [11], we obtain the appropriate $\boldsymbol{J}$-dependent extension of the σσ correlation energy:

$$[18] \qquad E_C^{\sigma\sigma} = -0.01\int \rho_\sigma\left\{\tau_\sigma - \frac{1}{4}\frac{(\nabla\rho_\sigma)^2}{\rho_\sigma} - \frac{\boldsymbol{J}_\sigma^2}{\rho_\sigma}\right\} \times z_{\sigma\sigma}^4\left[1 - \frac{2}{z_{\sigma\sigma}}\ln\left(1 + \frac{z_{\sigma\sigma}}{2}\right)\right]d^3\boldsymbol{r}$$

To summarize: the total dynamical correlation energy E_C is the sum

$$[19] \qquad E_C = E_C^{opp} + E_C^{\alpha\alpha} + E_C^{\beta\beta}$$

where E_C^{opp} is given by eq. [13], $E_C^{\alpha\alpha}$ and $E_C^{\beta\beta}$ are given by eq. [18], and the exchange potentials $U_{X\sigma}$ required in eq. [15] are generated from the $\boldsymbol{J}$-dependent Q_σ of eq. [11] via the Becke–Roussel procedure of the previous section.

Conclusions

Exchange and correlation functionals with explicit dependence on current-density $\boldsymbol{J}$ have been developed from first principles by slight modification of existing models (5, 6, 8). No empiricism whatsoever has been employed. Self-consistent computations with the Becke–Roussel functional (5), the foundation of this work, have recently become possible (9). We hope that incorporation of its $\boldsymbol{J}$ dependence, as developed here, will soon follow.

Appendix

Derivation of the exchange-charge curvature Q_σ, as defined in eq. [2], is relatively straightforward. The exchange charge $\rho_{X\sigma}(\boldsymbol{r}_1, \boldsymbol{r}_2)$ is related to the σ-spin orbitals by (see refs. 5 and 7)

$$[A1] \qquad \rho_{X\sigma}(\boldsymbol{r}_1, \boldsymbol{r}_2) = \left| \sum_k \psi^*_{k\sigma}(\boldsymbol{r}_1)\psi_{k\sigma}(\boldsymbol{r}_2) \right|^2 / \rho_\sigma(\boldsymbol{r}_1)$$

where $\boldsymbol{r}_1$ is taken as the reference point and $\boldsymbol{r}_2$ is the variable. Q_σ, the coefficient of the quadratic term in the Taylor expansion of the spherically averaged $\rho_{X\sigma}$ about $\boldsymbol{r}_1$, is equal to (7)

$$[A2] \qquad Q_\sigma(\boldsymbol{r}_1) = \tfrac{1}{6}\nabla^2_{(2)}\rho_{X\sigma}(\boldsymbol{r}_1, \boldsymbol{r}_2)|_{\boldsymbol{r}_2=\boldsymbol{r}_1}$$

with the Laplacian acting on variable $\boldsymbol{r}_2$ only. The indicated manipulations produce eq. [11] relatively easily.

Strongly bound doubly excited states of Be_2

Pablo J. Bruna and James S. Wright

Abstract: The triplet and singlet potential curves of Be_2 generated by single and double excitations from $2\sigma_u$ into $3\sigma_g$ and (or) $1\pi_u$ are studied with a multireference configuration interaction (MRD-CI) method. Relative to $X^1\Sigma_g^+(2\sigma_g^2 2\sigma_u^2)$ with $R_e = 4.72$ bohr and $\omega_e = 258$ cm^{-1} (calculated here), these *antibonding MO* → *bonding MO* excitations lead to average decreases in bond distance (in bohr) of 0.55 ($2\sigma_u \rightarrow 3\sigma_g$), 0.88 ($2\sigma_u \rightarrow 1\pi_u$), 0.93 ($2\sigma_u^2 \rightarrow 3\sigma_g 1\pi_u$), and 1.22 ($2\sigma_u^2 \rightarrow 1\pi_u^2$). The increase in vibrational frequencies ranges from 240 to 600 cm^{-1}. The $3\sigma_g$ MO is found to be less bonding than $1\pi_u$, confirming predictions made by Bader et al. The experimental states $A^1\Pi_u$ and $B^1\Sigma_u^+$ correspond to doubly excited $1^1\Pi_u(2\sigma_u^2 \rightarrow 3\sigma_g 1\pi_u)$ and singly excited $1^1\Sigma_u^+(2\sigma_u \rightarrow 3\sigma_g)$, respectively. The $1^3\Sigma_g^-$ and $1^1\Delta_g$ states, both $2\sigma_u^2 \rightarrow 1\pi_u^2$, preserve their doubly excited structure up to dissociation. Within the Franck–Condon region, $1^3\Pi_u$ changes from bound ($2\sigma_u^2 \rightarrow 3\sigma_g 1\pi_u$) to repulsive (mixed $2\sigma_u \rightarrow 1\pi_g/2\sigma_g \rightarrow 1\pi_u$), thereby creating the unusual situation of a strongly bound potential (short R_e, high ω_e) with an adiabatic dissociation energy near zero. The singlet counterpart $1^1\Pi_u$, however, behaves regularly as its doubly excited character is maintained up to large R(Be—Be).

Key words: ab initio calculations, beryllium dimer, doubly excited states, electronic transitions, potential curves.

Résumé : Faisant appel à une méthode d'interaction de configuration à multiréférences («MRD-CI»), on a étudié les courbes de potentiel triplet et singulet du Be_2 généré par des excitations simple et double de $2\sigma_u$ en $3\sigma_g$ et (ou) $1\pi_u$. Relatives à $X^1\Sigma_g^+(2\sigma_g^2 2\sigma_u^2)$ avec $R_e = 4{,}72$ bohr et $\omega_e = 258$ cm^{-1} (calculé ici), ces excitations d'*OM antiliantes* → *OM liantes* conduisent à des diminutions moyennes des distances de liaisons (en bohr) de 0,55 ($2\sigma_u \rightarrow 3\sigma_g$), 0,88 ($2\sigma_u \rightarrow 1\pi_u$), 0,93 ($2\sigma_u^2 \rightarrow 3\sigma_g 1\pi_u$) et 1,22 ($2\sigma_u^2 \rightarrow 1\pi_u^2$). L'augmentation de fréquences vibrationnelles varient de 240 à 600 cm^{-1}. On a trouvé que les OM $3\sigma_g$ sont moins liantes que les $1\pi_u$, ce qui confirme les prédictions faites par Bader et al. Les états expérimentaux $A^1\Pi_u$ et $B^1\Sigma_u^+$ correspondent respectivement aux états doublement excité $1^1\Pi_u(2\sigma_u^2 \rightarrow 3\sigma_g 1\pi_u)$ et simplement excité $1^1\Sigma_u^+(2\sigma_u \rightarrow 3\sigma_g)$. Les états $1^3\Sigma_g^-$ et $1^1\Delta_g$, qui correspondent tous les deux à $2\sigma_u^2 \rightarrow 1\pi_u^2$, conservent leur structure doublement excitée jusqu'à la dissociation. Dans la région de Franck–Condon, le $1^3\Pi_u$ se change de liée ($2\sigma_u^2 \rightarrow 3\sigma_g 1\pi_u$) à répulsive ($2\sigma_u \rightarrow 1\pi_g/2\sigma_g \rightarrow 1\pi_u$), ce qui crée la situation inhabituelle d'un potentiel fortement lié (valeurs de R_e courte et de ω_e élevée) accompagnée d'une énergie de dissociation adiabatique pratiquement égale à zéro. La contrepartie singulet, $1^1\Pi_u$, se comporte toutefois d'une façon régulière alors que son caractère doublement excité est maintenu jusqu'à une valeur élevée de R(Be—Be).

Mots clés : calculs ab initio, dimère du béryllium, états doublement excités, transitions électroniques, courbes de potentiel.

[Traduit par la rédaction]

1. Introduction

The nature of the bonding in the $X^1\Sigma_g^+(2\sigma_g^2 2\sigma_u^2)$ state of Be_2, formally with a zero bond order, has been the topic of many theoretical studies (1–13). An increase in the net bond order due to mixing with the double excitation $2\sigma_u^2 \rightarrow 3\sigma_g^2$ is responsible for the weakly bound character of the Be_2 ground state (7, 12).

Much less attention has been paid to the equilibrium properties and bonding features of excited states. Bender and Davidson (2) reported several potential curves, without specifying spectroscopic data or electronic configurations. Local spin density (LSD) calculations by Jones (4) analyzed five states ($1^{3,1}\Sigma_u^+$, $1^{3,1}\Pi_g$, $1^3\Sigma_g^-$), while a single-reference (SD)-CI study by Gosavi and Strausz (9) focused on triplets ($1^3\Sigma_u^+$, $1^3\Pi_{g,u}$, $1^3\Sigma_g^-$). These two papers gave partial insight into structures and equilibrium parameters, but the data are not accurate enough for spectroscopic purposes.

Experimentally, two dipole-allowed excited states are known (14), e.g., $A^1\Pi_u$ at 2.66 eV and $B^1\Sigma_u^+$ at 3.44 eV (T_e's). The bonding character of A is stronger than that of B, as pointed out by 3.74 versus 4.16 bohr for R_e, and 686 versus 511 cm^{-1} for ω_e. These values are to be compared with 4.63 bohr and 276 cm^{-1} measured for $X^1\Sigma_g^+$ (14).

Bondybey (14) speculated that $B^1\Sigma_u^+$ and $A^1\Pi_u$ are, respectively, described by the configurations $2\sigma_g^2 2\sigma_u 3\sigma_g$ ($2\sigma_u \rightarrow 3\sigma_g$ with respect to $X^1\Sigma_g^+$) and $2\sigma_g 2\sigma_u^2 1\pi_u$ ($2\sigma_g \rightarrow 1\pi_u$). The relatively tight structure assigned to $B^1\Sigma_u^+$ seems plausible as the $2\sigma_u \rightarrow 3\sigma_g$ excitation increases the bond order. However, it is difficult to justify assigning $2\sigma_g \rightarrow 1\pi_u$ to $A^1\Pi_u$ (with a measured ΔR_e of −0.89 bohr relative to $X^1\Sigma_g^+$) since for this bonding → bonding excitation the bond order remains formally unchanged. Also, it seems unusual for an excitation from the low-lying $2\sigma_g$ MO to lie about 1.0 eV

below that from $2\sigma_u$. Obviously, the $A^1\Pi_u$ assignment needs revision.

Because of the weakly bound character of ground state Be_2, the stability of its doubly excited states is expected to be quite substantial. As shown in various studies from the authors (15–21), particular excited states of X_2 molecules (with 3–8 valence electrons (VEs)) are strongly bound, i.e., they have shorter bond distances and higher vibrational frequencies than in the ground state. (For simplicity, the valence MOs $2\sigma_g$, $2\sigma_u$, $3\sigma_g$, $1\pi_u$, and $1\pi_g$ are hereafter labeled as σ_g, σ_u, σ'_g, π_u, and π_g, respectively.) The so-called strongly bound doubly excited states (SBDES) arise from $\sigma_u^2 \rightarrow (MO)^2$ excitations, with MO^2 corresponding to σ'^2_g, π_u^2, or $\sigma'_g\pi_u$. As the final configurations have *a maximal number of bonding electrons (highest bond order)*, an increase in bond strength upon excitation is understandable. As shown later, the experimental $A^1\Pi_u$ state is in fact an SBDES representative, confirming earlier speculations (22).

This work has been carried out with two goals in mind. First, to follow the changes in bonding for all low-lying excited states of Be_2 generated by single and double excitations from the antibonding σ_u into the bonding σ_g and π_u MOs. Second, to provide reliable potential curves for the interpretation of past and future experimental studies on the electronic spectrum of Be_2.

2. Technical details

The *sp* valence AOs on Be consist of the 10*s*/5*s* and 5*p*/2*p* subsets from Huzinaga (23) and Dunning and Hay (24) optimized for the $^1S_g(s^2)$ and $^3P_u(sp)$ atomic states, respectively. The 5*p* set of primitives given by Dunning (24) is contracted to 311. Additional AOs on Be include one *s* (α = 0.026), one *p* (α = 0.021) and three uncontracted *d* species (α = 0.3, 0.1, and 0.03). Rydberg AOs, with exponents of 0.012 (*s*), 0.01 (*p*), and 0.008 (*d*), are placed at the midpoint of the Be—Be bond. The exponents of the additional AOs have been estimated from the data given in ref. 24, except for the two most compact *d* species whose exponents are taken from ref. 5.

The configuration-interaction calculations are carried out with the MRD-CI method (25). The MOs used for the CI expansions are those corresponding to $1^5\Sigma_u^-(\sigma_g\sigma_u\pi_u^2)$. Exploratory calculations using $X^1\Sigma_g^+(\sigma_g^2\sigma_u^2)$ MOs were more demanding technically, i.e., a large number of reference configurations was needed, and, very often, high-lying states were poorly described ($\Sigma c^2 < 90\%$).

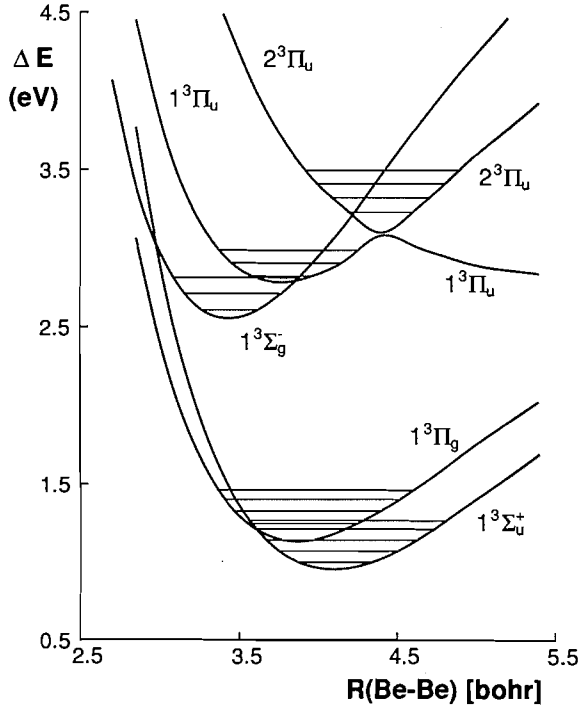
The frozen-core approximation has been used (no excitation from $1\sigma_g^2$ or $1\sigma_u^2$, and the complementary highest lying species discarded), leaving 78 MOs to describe valence correlation. The number of reference configurations ranges from 50 to 60, leading to a total of about 60 000 symmetry-adapted functions (SAFs) on average. Using a configuration selection threshold of 2 microhartree, the diagonalized CI spaces vary from 6000 to 10 000 SAFs. The total and relative energies to be reported correspond to those extrapolated to zero selection threshold and then corrected by the multi-reference analog of the Langhoff–Davidson correction (26).

3. Dissociation channels

The composition and relative energies of the first four dissociation channels are summarized in Table 1. The experimental spacings (27) are reproduced quite well.

Channels II (triplets) and III (singlets), each containing one $s \rightarrow p$ excited atom, give rise to singly excited configurations. Channel IV (quintets, triplets, and singlets), composed of two $s \rightarrow p$ states, is the lowest that generates doubly excited states. Interestingly, the $1^3\Sigma_g^-$ and $^1\Delta_g$ states, both correlating with channel IV, may preserve their doubly excited character over the whole range of bond distances.

Fig. 1. Potential curves of low-lying triplet excited states of Be_2.



4. Excited states

Potential curves are shown in Figs. 1 (triplets) and 2 (singlets), with spectroscopic data being compiled in Tables 2 and 3.

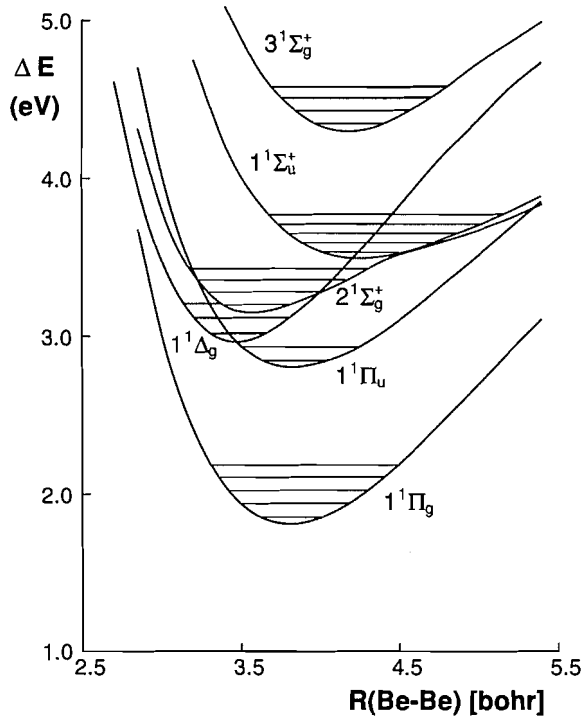
4.1 Triplet states

The first two triplets, $1^3\Sigma_u^+(\sigma_u \rightarrow \sigma'_g)$ and $1^3\Pi_g(\sigma_u \rightarrow \pi_u)$, arise from single excitations. An R_e of 4.09 bohr for $1^3\Sigma_u^+(\sigma_u\sigma'_g)$ versus 3.87 bohr for $1^3\Pi_g(\sigma_u\pi_u)$ indicates that π_u is more bonding than σ'_g. Their mimina lie energetically close (T_e's of 0.90 and 1.08 eV, Table 2).

The next two triplets correspond to the doubly excited states $1^3\Pi_u(\sigma_u^2 \rightarrow \sigma'_g\pi_u)$ at 2.73 eV and $1^3\Sigma_g^-(\sigma_u^2 \rightarrow \pi_u^2)$ at 2.50 eV. Once again, it is noted that σ'_g exhibits weaker bonding than π_u, as pointed out by an R_e of 3.76 bohr for $1^3\Pi_u(\sigma'_g\pi_u)$ versus 3.43 bohr for $1^3\Sigma_g^-(\pi_u^2)$. The bonding features associated with SBDES species are best exemplified by $1^3\Sigma_g^-(\pi_u^2)$, a state having the shortest R_e and highest ω_e (860 cm^{-1}) among all low-lying states of Be_2.

$1^3\Pi_u$ exhibits unusual features (Fig. 1). Specifically, near its minimum, this state is characterized by a well-bound potential (R_e = 3.76 bohr, ω_e= 677 cm^{-1}). However, a T_e value of 2.73 eV, being identical with the location of channel II (Table

Fig. 2. Potential curves of low-lying singlet excited states of Be_2.



1), results in an adiabatic dissociation energy D_e near zero (Table 2). This peculiar behaviour is caused by a crossing near 4.25 bohr with $2^3\Pi_u$, a repulsive state mainly arising from $\sigma_u \rightarrow \pi_g$ at very short R. Past 4.40 bohr, $1^3\Pi_u$ acquires a mixed, singly excited character $\sigma_u \rightarrow \pi_g/\sigma_g \rightarrow \pi_u$, as expected for a state correlating with channel II.

The dissociation barrier of $1^3\Pi_u$ amounts to 0.32 eV, accommodating up to 4 vibrational levels. The existence of this avoided crossing remained unnoticed in earlier studies (2, 4, 9).

Due to that crossing, the structure of $2^3\Pi_u$ complementary changes from $\sigma_u \rightarrow \pi_g$ at short R to $\sigma_u^2 \rightarrow \sigma'_g\pi_u$ at large R. When compared with other states (including the ground state), the mixed singly/doubly excited composition of $2^3\Pi_u$ near equilibrium results in an anomalous relationship between bond distance and vibrational frequency, e.g., large R_e (4.36 bohr) but high ω_e (720 cm^{-1}).

4.2 Singlet states

The lowest singlet excited states correspond to $1^1\Pi_g(\sigma_u \rightarrow \pi_u)$ at T_e = 1.76 eV, and $1^1\Pi_u$ (mainly $\sigma_u^2 \rightarrow \sigma'_g\pi_u$) at 2.76 eV. Since doubly excited $1^1\Pi_u$ has some contribution of the repulsive $\sigma_u \rightarrow \pi_g$ excitation, its potential curve is not as strongly bound as expected. In fact, both $1^1\Pi_g$ and $1^1\Pi_u$ have comparable values of R_e and ω_e (≈3.82 bohr, ≈680 cm^{-1}, Table 3).

Worth noting, the potential curve of doubly excited $1^1\Pi_u$ (Fig. 2) shows a regular behaviour, in contrast to that of $1^3\Pi_u$ having a maximum near 4.25 bohr (Fig. 1).

Slightly above $1^1\Pi_u$ one finds two SBDES, namely, $1^1\Delta_g$ at 2.89 eV and $2^1\Sigma_g^+$ at 3.11 eV. Both arise from the double excitation $\sigma_u^2 \rightarrow \pi_u^2$, like the $1^3\Sigma_g^-$ state. While R_e and ω_e values of 3.49 bohr and 841 cm^{-1} for $1^1\Delta_g$ are as high as for $1^3\Sigma_g^-$, those for $2^1\Sigma_g^+$ indicate a weaker bonding (larger R_e and smaller ω_e, Table 3). This feature is due to contribution of $\sigma_u^2 \rightarrow \sigma'^2_g$ to the $2^1\Sigma_g^+$ wave function — a double excitation increasing the bond strength to a lesser degree than $\sigma_u^2 \rightarrow \pi_u^2$, in line with the observed bonding differences between σ'_g and π_u.

The $3^1\Sigma_g^+$ potential, with T_e = 4.26 eV, interacts with $2^1\Sigma_g^+$ near 4.25 bohr. To some extent, $3^1\Sigma_g^+$ exhibits the same anomalous behaviour as $2^3\Pi_u$, i.e., large bond length (4.17 bohr) but a relatively deep potential (644 cm^{-1}). Such anomalies arise in both cases from avoided crossings between states of the same symmetry.

Since the $2^1\Sigma_g^+$–$3^1\Sigma_g^+$ interaction is not as sharp as that between $1^3\Pi_u$ and $2^3\Pi_u$, none of these singlets develop a potential barrier. The avoided crossing is reflected, however, in a change in the curvature of $2^1\Sigma_g^+$ around 4.25 bohr (Fig. 2). Also worth mentioning is that while the $3^1\Sigma_g^+$ minimum arises from the intersection of two doubly excited states (one strongly bound but the other much less so), the $2^3\Pi_u$ minimum arises from the mixing between singly and doubly excited states (repulsive and bound, respectively).

The $1^1\Sigma_u^+(\sigma_u \rightarrow \sigma'_g)$ state is predicted at T_e = 3.45 eV, in very good agreement with an experimental gas phase value of 3.44 eV (14). An earlier study in inert matrices by Brom et al. (22) reported 0-0 transition energies (in eV) of 3.54 (Ne) and 3.43 eV (Ar). As seen in Fig. 2, the $1^1\Sigma_u^+$ minimum lies close to v' = 5 of the lower lying $2^1\Sigma_g^+$ state, with the possible existence of perturbations.

A $1^3\Sigma_u^+$–$1^1\Sigma_u^+$ splitting of 2.55 eV near equilibrium is almost identical with the energy separation between channels II and III (Table 1), thus explaining why both potential curves run nearly parallel to each other.

5. Comparison with previous studies

Theoretical and experimental results from the literature are summarized in Table 4. There are no data available on $2^3\Pi_u$, $1^1\Delta_g$, and $2,3^1\Sigma_g^+$ for comparison. Changes in R_e and ω_e relative to the ground state are given in Table 5 as ΔR_e and $\Delta\omega_e$.

Only one experimental and two theoretical works have been devoted to the excited states. Data on $1^3\Sigma_u^+$ have also been reported in refs. 2 and 28. Compared with the LSD results (4), this study finds similar values of R_e and ω_e (maximal deviations of 0.07 bohr and 55 cm^{-1}) but higher excitation energies. The discrepancy is quite substantial for $1^1\Sigma_u^+$, with a ΔE of 3.45 versus 1.55 eV (Table 4). On the other hand, the R_e data from a previous SDCI study (9) are similar to ours, but the present transition energies are up to 0.30 eV smaller.

For the $X^1\Sigma_g^+$ ground state, the MRD-CI results for R_e, ω_e, and D_e are in line with prior theoretical estimates, most of them giving bond distances about 0.1 bohr too long and vibrational frequencies ≈ 30 cm^{-1} too small. A recent study by Røeggen and Almlöf (10*b*) reproduces the experimental very closely (Table 4); their work also gives a complete list of earlier theoretical studies.

The present R_e values for $1^1\Pi_u(A^1\Pi_u)$ and $1^1\Sigma_u^+(B^1\Sigma_u^+)$ also overestimate experimental data by about 0.1 bohr. Due to error compensations, however, the measured ΔR_e and $\Delta\omega_e$ are well reproduced (Table 5).

For $1^1\Pi_u(A^1\Pi_u)$, a predicted T_e value of 2.76 eV is about 0.10 eV too high. This state arises from the double excitation

[a]Footnote *a*, Table 2.

$\sigma_u^2 \rightarrow \sigma'_g\pi_u$ rather than $\sigma_g \rightarrow \pi_u$, as proposed by Bondybey (14). Such a doubly excited structure was already suggested in ref. 22.

Vibrationally excited $1^1\Pi_u$ may be perturbed by both $1^1\Delta_g$ and $2^1\Sigma_g^+$ (Fig. 2). Dipole-allowed transitions between these u and g states lie in the near infrared region. In principle, absorption from $1^1\Pi_u$ opens the possibility of spectroscopically studying both (upper) doubly excited states, although both transitions may be of low intensity.

Bondybey speculated that $1^1\Pi_g$ should be the lowest excited singlet of Be_2, which is confirmed by this study. The transition energies $1^1\Pi_u \rightarrow 1^1\Pi_g$ and $1^1\Sigma_u^+ \rightarrow 1^1\Pi_g$ are predicted to be 1.0 and 1.69 eV, respectively. Such small values explain Bondybey's failure in detecting $1^1\Pi_g$ via decay

[a] Relative to the ground state (Table 3).

$1^1\Pi_u \rightarrow 1^1\Pi_g$ or $1^1\Sigma_u^+ \rightarrow 1^1\Pi_g$, as both emission systems lie beyond the spectral range studied by him (from 2 to 3 eV).

Nothing is experimentally known about the triplet states. The near-infrared transition $1^3\Sigma_u^+ \leftrightarrow 1^3\Pi_g$ ($\sigma'_g \leftrightarrow \pi_u$) at 0.18 eV is expected to be rather weak (small ΔE, ΔR_e = 0.22 bohr). Doubly excited $1^3\Sigma_g^-$ cannot be detected in emission as there are no lower lying triplets of the appropiate symmetry. On the other hand, the (weak) infrared absorption band $1^3\Pi_u \leftarrow 1^3\Sigma_g^-$ (ΔE = 0.23 eV, ΔR_e = 0.34 bohr) might have an irregular structure reflecting the $1^3\Pi_u$–$2^3\Pi_u$ crossing, with the possible existence of a continuum due to $1^3\Pi_u$ predissociation.

The absorption transition $1^3\Pi_u \leftarrow 1^3\Pi_g$ (ΔE = 1.65 eV, $\Delta R_e = -0.11$ bohr) may exhibit similarly complex structure. However, this band system has more favorable Franck–Condon factors than does $1^3\Pi_u \leftarrow 1^3\Sigma_g^-$ (cf. Fig. 1).

6. Discussion

Five triplet and six singlet excited states of Be_2, all having

minima below 5 eV, are predicted to be bound. From the eight states generated by channels II and III, only $1^3\Sigma_g^+$(II) is repulsive.

The singly excited states, four in total, arise from $\sigma_u \rightarrow \sigma'_g$ ($1^3\Sigma_u^+$, $1^1\Sigma_u^+$) and $\sigma_u \rightarrow \pi_u$ ($1^3\Pi_g$, $1^1\Pi_g$). Their potential curves have relatively deep minima (Tables 2 and 3). In fact, the lowest lying excited singlet, $1^1\Pi_g$, has a dissociation energy D_e of ca. 3.6 eV, the largest among all states studied. When compared with a D_e of about 0.10 eV for the ground state (Table 4), this represents a tremendous increase in bond strength upon (single) substitution of an antibonding σ_u by a bonding π_u MO.

Interestingly, *seven* excited states (three triplets and four singlets) exhibit a SBDES character $\sigma_u^2 \rightarrow \sigma'^2_g$, $\sigma'_g\pi_u$, or π_u^2 near equilibrium. Their high bond order is reflected by the correspondingly short R_e and high ω_e values. The $1^3\Sigma_g^-(\sigma_u^2 \rightarrow \pi_u^2)$ minimum, for example, occurs at an interatomic distance about 25% shorter than for the ground state; the strong bonding is also manifested by an increase in ω_e of about 300%, and a D_e near 3.0 eV (Table 2).

The stabilities and equilibrium properties of the low-lying excited states of Be_2 are determined by the relative bonding properties of the σ_u, σ'_g, and π_u MOs. As shown in ref. 3, the charge density of σ_u is shifted toward both nuclei, i.e., it is almost zero within the bond, maximal at each Be atom, and still relatively high behind the nuclei. The σ'_g species exhibits a less localized distribution, as the amount of charge density *outside* the bond is practically the same as that *inside* it (see Fig. 2 in ref. 3).

A detailed analysis of orbital forces carried out by Bader et al. (1) for the ground states of N_2, O_2, and F_2 (all having σ_u, σ'_g, and π_u doubly occupied) came to the conclusion that while σ_u is strongly antibonding, σ'_g should be better classified as nonbinding rather than binding. The π_u MO is strongly bonding. The spectroscopic data of the excited states of Be_2 presented in Sect. 5 also indicate that σ'_g is less bonding than π_u.

The triplet–singlet splittings of the excited states $\sigma_u\sigma'_g$, $\sigma_u\pi_u$, and $\sigma'_g\pi_u$ reflect the differences in MO charge distributions. At the monodeterminant level, a splitting is given by twice the value of the corresponding exchange integral, K_{ab}. A small (large) K_{ab} arises when both open-shell MOs *a* and *b* are localized in different (similar) regions of space.

The predicted values (in eV) are 2.55 for $1^{3,1}\Sigma_u^+(\sigma_u\sigma'_g)$, 0.68 for $1^{3,1}\Pi_g(\sigma_u\pi_u)$, and 0.03 for $1^{3,1}\Pi_u(\sigma'_g\pi_u)$. The large $^{3,1}\Sigma_u^+$ splitting results from both σ_u and σ'_g lying in the molecular axis as well as having appreciable density in the same area (outside the bond). A smaller splitting of 0.68 eV for $1^{3,1}\Pi_g(\sigma_u\pi_u)$ is in line with π_u being perpendicular to the bond axis as well as with the significant amount of π_u density around each Be atom, where σ_u is mainly localized. Finally, the quasidegeneracy observed for the $\sigma'_g\pi_u$ states corroborates the fact that, within the bond, σ'_g has much less density than does π_u. Since $1^3\Pi_u$ has some contribution of $\sigma_u \rightarrow \pi_g$, the true $\sigma'_g\pi_u$ splitting might be slightly larger.

Although near equilibrium both states mainly arise from $\sigma'_g\pi_u$, the different behaviour shown by the potential curves of $1^3\Pi_u$ and $1^1\Pi_u$ is striking (Figs. 1 and 2). The reason for this deviation lies in the relative location of their dissociation channels. Specifically, $1^3\Pi_u$ and $1^1\Pi_u$ correlate with channels II ($\approx$ 2.83 eV) and III ($\approx$ 5.28 eV), respectively. Both channels give rise to singly excited states only, whereas the lowest one generating doubly excited states corresponds to channel IV at 5.45 eV (triplets *and* singlets).

Evidently, an asymptotic separation ΔE_a of only 0.17 eV between singly and doubly excited channels (III–IV) makes it possible for $1^1\Pi_u$ to maintain its doubly excited character over a wide R(Be—Be) range. Conversely, a higher asymptotic ΔE_a of 2.72 eV between $1^3\Pi_u$(II) and $2^3\Pi_u$(IV) causes $1^3\Pi_u$ to become singly excited around 4.25 bohr. Another factor for such a mixed composition within the Franck–Condon region is that the $1^3\Pi_u$ minimum lies energetically as high as channel II, so that the crossing of $\sigma_g^2\sigma'_g\pi_u$ with $\sigma_g^2\sigma_u\pi_g$ and $\sigma_g\sigma_u^2\pi_u$ takes place earlier than for $1^1\Pi_u$. As seen in Fig. 1 for $1^3\Pi_u$, the change in structure occurs suddenly; in that area, the interacting configurations are interrelated by the double excitations $\sigma'_g\pi_u \leftrightarrow \sigma_u\pi_g$ and $\sigma_g\sigma'_g \leftrightarrow \sigma_u^2$, respectively.

The states $1^3\Sigma_g^-$ and $1^1\Delta_g$ (both $\sigma_u^2 \rightarrow \pi_u^2$) are peculiar in the sense that they keep a doubly excited character up to large R values. Similar behaviour is shown by other diatomics with less than 4 VEs, e.g., the states $1^4\Sigma_g^-(\sigma_g\pi_u^2)$ of Be_2^+ (21) and $1^3\Sigma_g^-(\pi_u^2)$ of Li_2 (29). In all these cases, the lowest dissociation channel in which *both* atoms are $s \rightarrow p$ excited (a precondition for generating doubly excited states $\sigma^2 \rightarrow \pi_u^2$, with σ = σ_g or σ_u) constitutes, at the same time, *the lowest channel giving rise to* Σ_g^- *states* (channel III in Li_2, VI in Be_2^+, and IV in Be_2). In contrast, for systems with 5 VEs, there always exists a lower lying, singly excited channel that also generates Σ_g^- states. Hence, a SBDES of type $\sigma_u^2 \rightarrow \pi_u^2$ at short R becomes singly excited at large R, as, for example, the $1^4\Sigma_g^-(\sigma_g^2\sigma'_g\pi_u^2)$ state of B_2^+ (16, 17). For 6–8 VE systems, the region in which a given state retains its SBDES character is even more constricted, as previously discussed for B_2 (15–17), C_2^+, and C_2 (15, 18, 19).

Selected Be_2 states may be generated via photodetachment upon the bound states $X^2\Pi_u(\sigma_g^2\sigma_u^2\pi_u)$ and $A^2\Sigma_g^+(\sigma_g^2\sigma_u^2\sigma'_g)$ of Be_2^- (30). For example, the $X^1\Sigma_g^+$ state can be obtained by $\pi_u \rightarrow \infty$ ionization relative to $X^2\Pi_u$, or by $\sigma'_g \rightarrow \infty$ relative to $A^2\Sigma_g^+$. As the ground state of Be_2^- has an R_e about 0.45 bohr shorter than that of Be_2, the photodetachment spectrum $X^1\Sigma_g^+ \leftarrow X^2\Pi_u$ could provide valuable information about higher vibrational levels of Be_2, as well as about the dissociative continuum.

Similarly, $\sigma_u \rightarrow \infty$ ionization from $X^2\Pi_u$ of Be_2^- generates $1^3\Pi_g$ and $1^1\Pi_g$ of Be_2, both states being prevented by the selection rules from combining with the $X^1\Sigma_g^+$ ground state (i.e., difficult to detect spectroscopically). The same ionization process $\sigma_u \rightarrow \infty$ relative to $A^2\Sigma_g^+$ leads to $1^3\Sigma_u^+$ and $1^1\Sigma_u^+$ of Be_2.

7. Summary and conclusions

While no less than *forty-five* theoretical papers have been published about the $X^1\Sigma_g^+$ potential (Table 1 in ref. 10*b*), only *three* have focused on the excited states of Be_2. However, the scope of the data reported in the latter studies is rather limited (see Introduction). To remedy such a situation, in this work all low-lying states of Be_2 generated by single and double excitations, from σ_u into σ'_g and (or) π_u relative to the ground state $X^1\Sigma_g^+$, have been studied with the MRD-CI method and an extended AO basis set.

Seven of the eight states correlating with channels II and III are well bound (Tables 2 and 3); only $1^3\Sigma_g^+$(II) is repulsive.

Doubly excited states arising from channel IV (both atoms $s \rightarrow p$ excited) are particularly stable ($1^3\Sigma_g^-$ and $^1\Delta_g$). In line with predictions made by Bader et al. (1) for heavier first-row diatomics, the $3\sigma_g$ MO of Be_2 is less bonding than $1\pi_u$.

The increase in bond order affected by these *antibonding* → *bonding* excitations is supported by the predicted values for the spectroscopic constants of the excited states, which invariably follow a common trend: short R_e, high ω_e and large D_e (the only exception being doubly excited $1^3\Pi_u$). In detail, the R_e values range from 3.43 ($1^3\Sigma_g^-$) to 4.36 bohr ($2^3\Pi_u$), ω_e from 495 ($1^1\Sigma_u^+$) to 860 cm^{-1} ($1^3\Sigma_g^-$), and D_e from 1.20 ($3^1\Sigma_g^+$) to 3.58 eV ($1^3\Pi_g$). The increase in bonding with respect to $X^1\Sigma_g^+$ is evident, with $R_e = 4.63$ bohr, $\omega_e = 276$ cm^{-1}, and $D_e \approx 0.10$ eV (experimental, ref. 14).

From the 11 excited states of Be_2 lying below 5 eV and having a bound character, only $1^1\Pi_u(A)$ at 2.66 eV and $1^1\Sigma_u^+(B)$ at 3.44 eV have been observed experimentally (14, 22). (N.B.: for all singlet states studied here, dipole-allowed transitions into or from the ground state are therefore currently known.) The T_e values above underline the importance of double excitations for a diatomic with few VEs such as Be_2 — the detected A state (mainly $\sigma_u^2 \rightarrow \sigma'_g\pi_u$) is about 0.8 eV more stable than B (singly excited $\sigma_u \rightarrow \sigma'_g$).

Besides $1^1\Pi_u(A)$ of Be_2 (observed in emission), a few other SBDES cases are also experimentally known, namely $1^3\Sigma_g^-$ ($\sigma_g^2 \rightarrow \pi_u^2$) of Li_2 (29), $2^3\Pi_u(\sigma_u^2 \rightarrow \sigma'_g\pi_u)$ of B_2 (16, 17, 20, 31, 32), $2^2\Sigma_g^+(\sigma_u^2 \rightarrow \pi_u^2)$ of C_2^+, and $E^1\Sigma_g^+(\sigma_u^2 \rightarrow \sigma'^2_g)$ of C_2 (15, 18, 19, 33, 34). These doubly excited states have been detected either indirectly via perturbations ($1^3\Sigma_g^- - 2^3\Pi_g$ in Li_2) or directly via emission or absorption spectroscopy (B_2, C_2^+, C_2).

In Be_2, possible routes for detecting $1^3\Sigma_g^-$, $1^1\Delta_g$, and $2^1\Sigma_g^+$ are provided by the transitions $1^3\Pi_u$–$1^3\Sigma_g^-$ and $1^1\Delta_g$, $2^1\Sigma_g^+$–$1^1\Pi_u$; all these band systems lie in the near infrared. To detect $1^3\Sigma_g^-$ via perturbations with $1^3\Pi_g$ seems difficult since, as seen in Fig. 1, at the $1^3\Sigma_g^-$ minimum the vibrationally excited $1^3\Pi_g$ state lies close to its dissociation continuum.

We hope that the present spectroscopic parameters will serve as a guideline for modeling future experimental studies on those electronic states of Be_2 not yet observed. With the same goal in mind, an analysis of radiative data (Frank–Condon factors, oscillator strengths, radiative lifetimes) for several dipole-allowed transitions, particularly between excited states, is to be reported elsewhere.[2]

Density-functional calculation of core-electron binding energies of glycine conformers

Delano P. Chong

Abstract: Our recent procedure of computing accurate core-electron binding energies (CEBEs) with density-functional theory is applied to glycine conformers in this work. The procedure uses the unrestricted generalized transition-state model and a combined functional of Becke's 1988 exchange with Perdew's 1986 correlation. When a large basis set such as Dunning's correlation-consistent polarized valence quadruple zeta set is used, the average absolute deviation from experiment for the CEBEs of the most stable conformer of glycine is only 0.2 eV, compared with 18 eV for Koopmans' theorem.

Key words: core-electron binding energies, density-functional theory, glycine.

Résumé : Dans ce travail, on a appliqué le procédure que l'on a développée récemment pour calculer avec précision les énergie de liaison des électrons de coeur («CEBE») à l'aide de la théorie de la densité fonctionnelle. La méthode utilise le modèle généralisé et sans restriction de l'état de transition et une fonctionnelle combinée de l'échange de Becke de 1988 avec la corrélation de Perdew de 1986. Quand on utilise un ensemble de base large, comme l'ensemble zêta quadruple, à valence polarisée et en accord avec la corrélation de Dunning, la déviation absolue moyenne des CEBE du conformère le plus stable de la glycine par rapport aux valeurs expérimentales n'est d'environ que de 0,2 eV par comparaison avec les 18 eV pour le théorème de Koopmans.

Mots clés : énergie de liaison des électrons, théorie de la densité fonctionelle, glycine.

[Traduit par la rédaction]

Introduction

Although the gas-phase structure of glycine may be very different from that in the solid (in a zwitterionic form) or in aqueous solutions, it is of great interest and importance in radio astronomy. In the last few years, there have been several studies of the geometry and conformations of glycine (1, 2). The two low-lying conformers, often called conformers **I** and **II**, differ in the nature of the intramolecular hydrogen bond, as shown in Fig. 1. Based on microwave spectroscopy, Godfrey and Brown (1) recently concluded that there is no discrepancy between theory and experiment as far as the structures of conformers **I** and **II** are concerned.

On the other hand, we recently (3, 4) discovered a density-functional (DF) procedure of computing accurate core-electron binding energies (CEBEs) with an average absolute deviation from experiment of about 0.23 eV. The procedure used the unrestricted generalized transition-state (uGTS) model and an exchange-correlation potential labeled as B88-P86, made from Becke's 1988 exchange functional (5) and Perdew's 1986 correlation functional (6). The uGTS model for ionization from orbital k approximates the nonrelativistic ionization energy by

[1] $$I_{nr} = -0.25\ \varepsilon_k(0) - 0.75\ \varepsilon_k(2/3)$$

where $\varepsilon_k(\lambda)$ is the orbital energy when λ electron has been removed from orbital k. Before comparison is made with experimental I_{obs}, relativistic corrections C_{rel} were added to the computed I_{nr} values. A simple estimate of C_{rel} is given (4) by

[2] $$C_{rel} = KI_{nr}^{N}$$

with $K = 2.198 \times 10^{-7}$ and $N = 2.178$, when both I_{nr} and C_{rel} are in eV.

In 1988, Slaughter and Banna (7) reported the CEBE spectrum of glycine vapor. The objective of the present study is to apply our tested procedure to compute the CEBEs of conformers **I** and **II** of gas-phase glycine and to compare the results with the observed X-ray photoelectron spectrum (7).

Preliminary calculations

In most of our studies, we used the deMon DF program (8), which approximates some integrands with auxiliary basis functions. The set of auxiliary basis functions recommended by the authors is (4,4;4,4) for O and (3,1;3,1) for H. The meaning of $(j,k;m,n)$ has been given elsewhere (9, 10). Test calculations with a slightly larger auxiliary set (5,4;5,4) for O and (4,1;4,1) for H showed negligible effects. In contrast, neither Gaussian92 (11) nor CADPAC5 (12) employs fitting functions. Because the evaluation of CEBEs in our uGTS model requires the DF orbital energies, we benchmarked a deMon calculation on H_2O against those using Gaussian92 and CADPAC5.

In all benchmark calculations, we used the experimental geometry of H_2O (13), the local density approximation based

on the Slater exchange term with the correlation function of Vosko, Wilk, and Nusair (14) (SVWN), and the correlation-consistent polarized valence triple-zeta (cc-pVTZ) basis of Dunning and co-workers (15, 16). As in our earlier calculations (3, 4), only *s*-, *p*-, and (six-component) *d*-type basis functions were used. For numerical quadrature in deMon, we used the extra-fine grid, which consists of 32 radial points × 194 angular points per atom. For calculation with Gaussian92 and CADPAC5, we specified 96 radial points × 2048 angular points per atom.

The results of our preliminary calculations are summarized in Table 1, from which several conclusions can be drawn. Both Gaussian92 and CADPAC5 computations have converged as far as numerical quadrature is concerned and there are small numerical errors associated with deMon calculations, possibly due to the lack of *f*-type functions in the auxiliary basis. However, in light of the gain in computing speed, errors of 0.0015 eV in orbital energies and 0.01 debye in dipole moments seem to be tolerable.

Results and discussion

For conformers **I** and **II** of glycine, we used the CCSD/DZP geometry obtained by Hu et al. (2), the correlation-consistent polarized valence quadruple-zeta basis set (cc-pVQZ) of Dunning and co-workers (15, 16), the B88-P86 functional (5, 6)

mentioned above, internal auxiliary basis set of (4,4;4,4) and (3,1;3,1), and an extra-fine grid for numerical integrations. Again, any atomic orbital basis function of *f*-type or higher angular momentum was excluded from our calculations. The relative energy and components of the dipole moment are compared in Table 2. The results obtained by using semi-empirical MO methods HAM/3 (17) and AM1 (18) are also included in Table 2 for comparison. It can be seen that our procedure, which can be labeled B88-P86/cc-pVQZ//CCSD/DZP, leads to results with accuracy comparable to that from CCSD/DZP (2).

Finally, we applied our uGTS model to compute the CEBEs of conformers **I** and **II** of the glycine molecule. The results are summarized in Table 3. Instead of adding the estimated relativistic corrections C_{rel} to the calculated I_{nr} to compare with the observed CEBEs, it is more convenient to subtract C_{rel} from I_{obs} and compare the results with various calculated I_{nr} values. The computed CEBEs for conformer **I** agree better with experiment than those for conformer **II**: every calculated CEBE for conformer **II** deviates more from experiment than the corresponding one for conformer **I** (as are the average and maximum absolute deviations), confirming the conclusion that **I** is the more stable conformer. It can also be seen that we have succeeded in applying our reliable method to compute accurate CEBEs for glycine.

Atoms in molecules from the exact one-electron wave function

Geoffrey Hunter

Abstract: Use of the electron amplitude (i.e., the square root of the electron density) in place of the electron density in Bader's topological theory of atoms in molecules, is shown to lead to identical definitions of bond paths and interatomic surfaces. The concepts of regions of charge concentration and depletion, derived from the Laplacian of the electron density, become the concepts of classically allowed and forbidden regions of space when derived from the Laplacian of the electron amplitude, because the latter is the wave function in the exact Schrödinger equation for (any) one electron in the many-electron molecule. However, the domains of corresponding regions are different, the size and depth of a classically allowed region always being larger than the corresponding region of charge concentration; in some cases there is no region of charge concentration corresponding to a classically allowed region. The surface between the outermost allowed and forbidden regions of space provides a definition of the size and shape of the molecule. This definition of the outermost surface of the electronic charge cloud (the molecular envelope) is exact apart from quantum mechanical tunelling. Hence it is proposed as a basis for molecular graphics; i.e., as the unique, non-arbitrary, and, in principle, exact definition of the size and shape of a molecule.

Key words: electron density, quantum chemistry, molecular graphics.

Résumé : On montre que l'utilisation de l'amplitude électronique (c'est-à-dire la racine carrée de la densité électronique), au lieu de la densité électronique dans la théorie topologique de Bader des atomes dans les molécules, conduit à des définitions identiques pour les chemins de liaison et pour les surfaces interatomiques. Les concepts de régions avec concentration et épuisement de charge sont dérivés du laplacien de la densité électronique; lorsqu'on les dérive du laplacien de l'amplitude électronique, compte tenu du fait que ce dernier est une fonction d'onde dans l'équation exacte de Schrödinger pour tout électron d'une molécule à plusieurs électrons, ils deviennent des concepts de régions de l'espace qui sont classiquement permises et défendues. Les domaines qui correspondent aux régions sont toutefois différents, la taille et la profondeur d'une région classiquement permise étant toujours plus grande que la région correspondante de la concentration de charge; dans quelques cas, il n'existe pas de région de concentration de charge correspondant à une région classiquement permise. La surface entre les régions les plus extérieures permises et les régions de l'espace qui sont interdites fournit une définition de la taille et de la forme de la molécule. Cette défintion de la surface la plus extérieure du nuage de la charge électronique (l'enveloppe moléculaire) est exacte à part de l'effet tunnel de la mécanique quantique. Il est donc proposé comme base pour des graphiques moléculaire, c'est-à-dire comme la définition unique, non arbitraire et, en principe, la définition exacte de la taille et de la forme de la molécule.

Mots clés : densité électronique, chimie quantique, graphiques moléculaires.

[Traduit par la rédaction]

Introduction

The theory of atoms in molecules has been developed by R.F.W. Bader and his associates (1). This theory provides mathematical tools for interpreting the electron density distribution in a molecule in terms of the traditional concepts of chemistry; i.e., in terms of bonds between atoms. The theory provides a precise definition of the bond path[2] between, and the surface separating, a pair of bonded atoms; at the point where the path and the surface intersect the gradient of the electron density is zero.[3] The principal utility of the theory is for the interpretation of electronic wave functions of molecules produced as the results of ab initio calculations.[4]

Received October 2, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

[2] A line (possibly curved but usually straight) between the nuclei of the bonded atoms.

[3] It is a saddle-point, a (3,-1) critical point of the density (ref. 1, p. 19).

[4] Recent advances in X-ray diffraction (keeping the crystal at a very low temperature and analysis of the scattering data in terms of a multipole expansion of the electron density) are now yielding atoms in molecules analyses that are comparable in accuracy with those obtained from ab initio wave functions (2).

In this respect it is a better theory of molecular structure than the valence-bond and molecular orbital theories, because it is applicable to *any* wave function (including correlated wave functions) regardless of any orbital construction or decomposition of the wave function.

The exact one-electron model of molecular structure (3) is an application of the general theory of conditional probability amplitudes in wave mechanics (4). It is closely related to the theory of atoms in molecules, since the exact one-electron wave function is (except for a normalization constant equal to the number of electrons, N) simply equal to the square root of the electron density (ref. 3, eq. (8)):[5]

$$[1] \qquad \rho(r|R) = N\left[\psi(r|R)\right]^2 \qquad \psi(r|R) = +\sqrt{\rho(r|R)/N}$$

in which r represents the three coordinates of a single electron, and R represents all of the nuclear coordinates. For the sake of brevity, and by analogy with the term **electron density**, this exact one-electron wave function (the square-root of the electron density in a many-electron system) will henceforth be referred to as the *electron amplitude*.

The purpose of this article is to discuss the similarities and differences between the models of molecular structure based, respectively, upon the topology of the electron density, and upon the topology of the square root of the electron density. It turns out that the definitions of the bond path and of the interatomic surface are identical for the two models. The important differences between the two models stem from the fact that the square root of the density, $\psi(r|R)$ satisfies a one-electron Schrödinger equation (3):

$$[2] \qquad -\frac{\hbar^2}{2m_e}\nabla^2\psi(r|R) + U(r|R)\psi(r|R) = E(R)\psi(r|R)$$

in which $U(r|R)$ is the effective potential for the motion of the single electron within[6] the many-electron molecule, and $E(R)$ is the total electronic energy.[7] This one-electron Schrödinger equation [2] has been derived in different ways by several different authors (3, 5–7). We used it originally in application to the ground state of the helium atom (8).

2. The exact one-electron model

It is important to realize that the Schrödinger equation satisfied by $\psi(r|R)$ is obtained from the full many-electron, electronic Schrödinger equation of the whole molecule (by the algebra of conditional probability amplitudes) without any approximation whatsoever (4, 9). Thus this Schrödinger equation for the motion of one electron within the many-electron system is, in principle *exact*,[8]. In computational practice the accuracies of the electron amplitude $\psi(r|R)$ and of the potential energy function $U(r|R)$ depend upon the accuracy of the many-electron wave function from which they are computed. Many-electron computations based upon high quality basis sets with allowance for electron correlation will yield correspondingly accurate one-electron wave functions and potentials.

This exact one-electron Schrödinger equation [2] provides an exact dynamical model of the motion of any one electron in the many-electron system. No such dynamical model is known for the electron density itself (9). In particular, the exact one-electron model yields a definition of the surface enclosing the molecule (and of each atom within the molecule) as the turning surface within which the electron would be confined if it were a classical particle.[9] This surface is appropriately called the **molecular envelope**, a name that was coined by Richard Bader *circa* 1985.

3. Critical points of $\rho(r|R)$ and $\psi(r|R)$

The topology of a scalar field such as $\rho(r|R)$ or $\psi(r|R)$ is revealed by the gradient of the field and especially through the critical points where the gradient is zero (ref. 1, Chap. 2).[10] The gradient of a scalar field is, of course, a vector field, and at each point in space the components of the gradient will be 3 independent (say x,y,z) first derivatives of the scalar at the specified point; these components specify both the magnitude of the gradient and its direction, the latter being the direction in which the scalar field is increasing or decreasing most rapidly.

Since $\rho(r|R) = N\left[\psi(r|R)\right]^2$ it follows by the elementary rules of differentiation that:

$$[3] \qquad \nabla\rho(r|R) = 2N\psi(r|R)\nabla\psi(r|R)$$

or

$$\frac{\nabla\rho(r|R)}{\rho(r|R)} = 2\,\frac{\nabla\psi(r|R)}{\psi(r|R)}$$

Note: When plotting the gradient to display its topology our experience has been that the second form of this equation is preferable to the first form; the range of values of $\nabla\rho(r|R)/\rho(r|R)$ is less than that of $\nabla\rho(r|R)$ itself because it is essentially a semi-log plot: $\nabla\rho(r|R)/\rho(r|R) = \nabla\ln[\rho(r|R)]$.

Thus the gradient vector field of $\rho(r|R)$ is equal to the gradient vector field of $\psi(r|R)$ multiplied by the scalar field $2N\psi(r|R)$. Furthermore, multiplication of a vector by a scalar produces another vector in the same direction if the scalar is positive, and in the opposite direction if it is negative, and since the scalar field $\rho(r|R)$ is positive everywhere (as is its positive square root $\psi(r|R)\sqrt{N}$), it follows that the gradient of $\rho(r|R)$ and the gradient of $\psi(r|R)$ *point in the same direction everywhere*; they only differ in magnitude. Specifically the critical points of $\rho(r|R)$ will thus be identical with the critical points of $\psi(r|R)$.

---

[5] The positive square root of $\rho(r|R)$ is chosen since the phase factor of $\psi(r|R)$ is arbitrary.

[6] That is, after averaging over the motion of the other electrons as explained in ref. 3.

[7] All of the quantities are parametrically dependent upon the nuclear coordinates R as is usual in the Born–Oppenheimer approximation.

[8] That is, exact within the framework of the non-relativistic, Born–Oppenheimer approximations commonly used in theoretical chemistry.

[9] That is, in the absence of quantum mechanical tunelling.

[10] The domains where $\nabla\rho(r|R) = 0$ are *points*, because this vector equation is equivalent to the 3 scalar equations: $\partial\rho/\partial x = 0$, $\partial\rho/\partial y = 0$, $\partial\rho/\partial z = 0$, and 3 constraints on a function of 3 variables produces a domain of single points.

The geometrical nature of the critical points is characterized by the signs of the eigenvalues of the Hessian matrix; i.e., the matrix of second derivatives of the original scalar (ref. 1, pp.16–19). Determination of the eigenvalues of the Hessian matrix is equivalent to a transformation to coordinates for which all cross-derivatives of the form $\partial^2\rho(r|R)/\partial x\partial y$ are zero at the critical point being characterized (ref. 1, p. 47).

The **rank** of a critical point is the number of non-zero eigenvalues (1–3) and its **signature** is the sum of the signs of the eigenvalues. Stable critical points[11] are of rank 3 and are of 4 kinds: a maximum or minimum (all 3 eigenvalues negative or positive), and two kinds of saddle (2 eigenvalues negative or positive with the third of opposite sign).

It is not immediately obvious that the Hessian matrix of $\rho(r|R)$ has eigenvalues with the same signs as those of $\psi(r|R)$, because their second derivatives are related, in general, as follows:

$$[4] \qquad \frac{\partial^2\rho(r|R)}{\partial x\partial y} = 2N\left\{\psi(r|R)\frac{\partial^2\psi(r|R)}{\partial x\partial y} + \frac{\partial\psi(r|R)}{\partial x}\frac{\partial\psi(r|R)}{\partial y}\right\}$$

and for a diagonal derivative:

$$[5] \qquad \frac{\partial^2\rho(r|R)}{\partial x^2} = 2N\left\{\psi(r|R)\frac{\partial^2\psi(r|R)}{\partial x^2} + \left(\frac{\partial\psi(r|R)}{\partial x}\right)^2\right\}$$

However, at a critical point, r_c, *all* the first derivatives of $\rho(r_c|R)$ and $\psi(r_c|R)$ are zero (regardless of the orientation of the coordinate axes, x, y, z) , and hence the second terms on the right-hand sides of eqs. [4] and [5] are zero. Hence eq. [4] becomes simply:

$$[6] \qquad \frac{\partial^2\rho(r_c|R)}{\partial x\partial y} = 2N\psi(r_c|R)\frac{\partial^2\psi(r_c|R)}{\partial x\partial y}$$

and thus we see that each second derivative of $\rho(r_c|R)$ is equal to the corresponding derivative of $\psi(r_c|R)$ multiplied by the positive scalar factor $2N\psi(r_c|R)$. Furthermore this scalar factor is *the same* for all 10 second derivatives and hence we conclude that the Hessian matrix of $\rho(r_c|R)$ is equal to the Hessian matrix of $\psi(r_c|R)$ multiplied by this common scalar factor.

Such a common scalar factor will only multiply the eigenvalues of the matrix by the factor, and since the factor is positive everywhere, it follows that the eigenvalues of the Hessian of $\rho(r_c|R)$ have the same signs as those of the Hessian of $\psi(r_c|R)$ at every critical point of $\rho(r_c|R)$ (and of $\psi(r_c|R)$ since they have the same critical points).

In summary: the above analysis leads to the conclusion that the critical points of $\psi(r|R)$ are identical with those of $\rho(r|R)$ in both location (the coordinates r_c) and geometrical nature (i.e., rank and signature).

[11] Stability against small changes to the density distribution is important for characterizing the critical points of a stable molecule, because the ever-present nuclear vibrations cause such changes.

Interpretation

A **trajectory** of the gradient vector field $\nabla\rho(r|R)$ is a (generally curved) line in 3-dimensional space traced out by following the direction of the vector $\nabla\rho(r|R)$ from any given starting point, and from all subsequent points along it (ref. 1, p. 22). Different starting points will usually produce different trajectories, and two different adjacent trajectories will be locally parallel (in the limit as their distance apart tends to zero). Thus by definition two different trajectories cannot meet anywhere except at the critical points of $\rho(r|R)$ where the direction of $\nabla\rho(r|R)$ is undefined. Trajectories thus originate and terminate at critical points of $\rho(r|R)$. Many trajectories originate at infinity where there is a spherical shell throughout which $\nabla\rho(r|R) = 0$, and many trajectories terminate at atomic nuclei, where the direction of $\nabla\rho(r|R)$ is undefined even though its magnitude is finite.

The gradient of the electron amplitude $\nabla\psi(r|R)$ is proportional to the electron's local momentum, $\boldsymbol{p}$, at each point in space:

$$[7] \qquad \boldsymbol{p} = \frac{\hbar}{i}\frac{\nabla\psi(r|R)}{\psi(r|R)}$$

Thus a trajectory of the gradient vector field $\nabla\psi(r|R)$ traces out the path that an electron would follow starting from any given point on the path.[12]

Between every pair of bonded atoms there is a (3,-1) critical point where the electron's momentum is zero so that the direction of its motion at this point is undefined (ref. 1, pp.23–24). The **bond path** between the two atoms consists of two trajectories that originate at this critical point and terminate at the two nuclei; if the electron was at the critical point it would move along one of the trajectories that make up the bond path towards the corresponding nucleus.[13]

The **interatomic surface** is the locus of all trajectories that terminate at the bond critical point; the electron's local momentum has no component perpendicular to this surface. The surface is orthogonal to the bond path at the bond critical point. If the electron were in this surface it would move along a trajectory in the surface until it came to rest at the bond critical point.

The bond critical point is a maximum of $\rho(r|R)$ and $\psi(r|R)$ when approached along any trajectory within the interatomic surface; it is a minimum along the two trajectories that make up the bond path.

4. The Laplacians of $\rho(r|R)$ and $\psi(r|R)$

The Laplacian of $\rho(r|R)$ (or of $\psi(r|R)$) is the divergence of its gradient:

[12] Division by the scalar field does not change the direction of $\nabla\psi(r|R)$. This quasi-physical conclusion is, however, subject to the local momentum, eq. [7], being *imaginary* for real (bound state) wave functions $\psi(r|R)$ because of the factor of i in the quantum mechanical momentum operator.

[13] These descriptions of the electron's motion are not to be taken literally in the sense of classical trajectories; the quantum mechanical uncertainty principle does not allow for the simultaneous specification of the electron's position and momentum. Nevertheless this electron-momentum interpretation of the trajectories has conceptual merit.

$$[8] \qquad \text{div grad}\,\rho = \nabla.\nabla\rho(r|R) = \nabla^2\rho(r|R) = \frac{\partial^2\rho(r|R)}{\partial x^2} + \frac{\partial^2\rho(r|R)}{\partial y^2} + \frac{\partial^2\rho(r|R)}{\partial z^2}$$

It is equivalently the sum of the diagonal elements of the Hessian matrix of $\rho(r|R)$, which[14] is equal to the sum of the eigenvalues of the Hessian matrix. Thus the Laplacian of $\rho(r|R)$ (and of $\psi(r|R)$) is a scalar field whose value is independent of the coordinate system.

As noted above in introducing eq. [4], the Laplacians of $\rho(r|R)$ and $\psi(r|R)$ are not generally simply proportional to each other; this simplicity only pertains at the critical points where the gradients of $\rho(r|R)$ and $\psi(r|R)$ are zero. From eqs. [8] and [5] the relationship between the Laplacians can be expressed by the following equivalent equations:

$$\nabla^2\rho(r|R) = 2N\left\{\psi(r|R)\nabla^2\psi(r|R) + \left[\nabla\psi(r|R)\right]^2\right\}$$

$$[9] \qquad \frac{\nabla^2\rho(r|R)}{\rho(r|R)} = 2\left\{\frac{\nabla^2\psi(r|R)}{\psi(r|R)} + \left[\frac{\nabla\psi(r|R)}{\psi(r|R)}\right]^2\right\}$$

$$\frac{\nabla^2\psi(r|R)}{\psi(r|R)} = \frac{1}{2}\frac{\nabla^2\rho(r|R)}{\rho(r|R)} - \left[\frac{\nabla\rho(r|R)}{2\rho(r|R)}\right]^2$$

where eq. (3) has been used to derive the last of these alternative forms.

The Laplacian of $\psi(r|R)$ is proportional to the local kinetic energy of the electron as is apparent from the Schrödinger equation [2] satisfied by $\psi(r|R)$. Thus in atomic units[15] the expression for the electron's local kinetic energy is:

$$[10] \qquad \text{Kinetic energy} = -\frac{1}{2}\frac{\nabla^2\psi(r|R)}{\psi(r|R)} = -\frac{1}{4}\frac{\nabla^2\rho(r|R)}{\rho(r|R)} + \frac{1}{8}\left[\frac{\nabla\rho(r|R)}{\rho(r|R)}\right]^2$$

which is essentially eq. (15) of ref. 3.[16] It is especially noteworthy that the second term of the right hand-side of this equation (being a quantity squared) always makes a positive contribution to the electron's local kinetic energy. It is this term that produces significant differences between the topologies of the Laplacians of $\psi(r|R)$ and $\rho(r|R)$.

Atomic shell structure

Bader has described the topology of the Laplacian of $\rho(r|R)$ in terms of charge concentration and depletion (ref. 1, p. 252); electronic charge is locally depleted in regions of space where $\nabla^2\rho(r|R) > 0$, and locally concentrated where $\nabla^2\rho(r|R) < 0$.

Calculations based upon this concept were carried out on many atoms by Shi and Boyd (10), and by Sagar et al. (11), and have been summarized by Bader (ref. 1, p. 256). These calculations revealed spherical shells of charge concentration separated by shells of charge depletion and, for elements within the first two periods of the periodic table, the shell structure thus revealed was in one to one correspondence with the shell structure predicted by the Bohr model of the hydrogen atom and the aufbau principle, by which there can be $2n^2$ electrons in each "shell of electrons" ($n = 1, 2, 3, \ldots$),[17] the total number of electrons being equal to the atomic number of the element. The calculations revealed that "at most five shells are seen" (11) based upon the topology of $\rho(r|R)$.

Sagar et al. conducted a parallel study of atomic shell structure based upon the topology of $\nabla^2\psi(r|R) = \nabla^2\sqrt{\rho(r|R)/N}$ (12). They noted that the computed topology of $\nabla^2\psi(r|R)$ was "very similar in nature" to that of $\nabla^2\rho(r|R)$, "the significant difference being that $\nabla^2\psi(r|R)$ displays all seven shells in the heavier elements of the periodic table," whereas (as noted above) $\nabla^2\rho(r|R)$ only displays five shells. This difference is directly attributable to the second (always positive) term on the right-hand side of eq. [10].

In a later study Kohout et al. (13) used relativistic wave functions to compare the atomic shell structures predicted by $\nabla^2\rho(r|R)$, $\nabla^2\sqrt{\rho(r|R)}/\sqrt{\rho(r|R)}$, and $\nabla\rho(r|R)/\rho$. They concluded that there were no topological differences between relativistic and non-relativistic results, and that $\nabla^2\rho(r|R)$ does not resolve the valence shell of heavy atoms, while $\nabla^2\psi(r|R) = \nabla^2\sqrt{\rho(r|R)}$ does show a valence maximum for heavy atoms, but in the case of transition elements this maximum occurs in a (classically forbidden) region of negative kinetic energy.[18] They also concluded that the electron momentum $\nabla\rho(r|R)/\rho$ (eq. [7], equal to $\nabla\psi(r|R)/\psi$ by eq. [3]) describes the complete shell structure in all cases.

In addition to being a better predictor of *atomic* shell structure than $\nabla^2\rho(r|R)$, the Laplacian of $\psi(r|R) = \sqrt{\rho(r|R)/N}$ also displayed a classically allowed outer region in the electron density of the ammonium radical (ref. 3, p. 204) corresponding to this radical's extra electron, whereas the Laplacian of $\rho(r|R)$ computed from the same ab initio wave function did not display a corresponding region of charge concentration.

Interpretation

The computed differences between the topologies of the Laplacians of the electron density, $\rho(r|R)$, and the electron amplitude, $\psi(r|R) = \sqrt{\rho(r|R)/N}$, also reflect their different interpretation. Regions of space where $\nabla^2\psi(r|R) > 0$ correspond to the electron's local kinetic energy being negative

[14] from the properties of matrices.

[15] In which $\hbar = m_e = 1$.

[16] Bader presented this equation in his book (ref. 1, p. 102) in the context of a one-electron atom or molecule.

[17] That is, a separate shell of charge concentration for each principal quantum number, n, occupied in the atom.

[18] This is consistent with the supplementary conclusion of Sagar et al. (12) that: "the outermost zero-extremum is not displayed in the transition elements; i.e., where d-orbital filling is present." That is, the kinetic energy, eq. [10], displays the complete expected shell structure (a shell of positive kinetic energy for each occupied principal quantum number n) for all elements of the periodic table except the transition elements, in which the outermost shell is displayed as a maximum in the kinetic energy but in a classically forbidden (i.e., negative kinetic energy) region.

and hence such a region is a classical forbidden region of space. On the other hand, where $\nabla^2\psi(r|R) < 0$ the electron's local kinetic energy is positive and the region of space is classically allowed.

These classically allowed and forbidden regions of space are separated by surfaces where $\nabla^2\psi(r|R) = 0$.[19] These are the classical turning surfaces of the electron's motion; in classical mechanics the electron's kinetic energy would decrease as it approached such a surface, and it would be zero when it is on the surface. It would then turn around and accelerate into the classically allowed region of space.

5. The molecular envelope

The outermost surface where the electron's kinetic energy is zero is the surface within which it is confined except for quantum mechanical tunnelling; if the electron were a classical particle it would never go outside of this outermost turning surface.[20] Thus this surface is an unequivocal definition of the size and shape of the molecule's cloud of electronic charge surrounding the nuclei. Within the constraints on determinism imposed by the uncertainty principle, it appears to be the best possible unambiguous definition of molecular size and shape, whereas other definitions rely upon arbitrarilly chosen contours such as those having a particular value of the electron density. Furthermore, it is pertinent to recall that the one-electron model, within which this outermost turning surface is defined, is in principle exact.

This non-arbitrary definition of molecular size and shape is appropriately called the **molecular envelope**. In view of its non-arbitrary and in-principle exact nature, it appears to be potentially an excellent basis for molecular graphics. The results already computed and reported for diatomic molecules (3) encourage the further development and application of this well-defined concept of molecular size and shape.

6. Atoms defined as quantum sub-spaces

One of the later developments in Bader's theory of atoms in molecules is the concept that each atomic region of space (delimited by the interatomic surfaces through which the component of the gradient of the density is zero) can be regarded as an independent quantum subsystem, independent of the other subsystems except for the matching boundary conditions at each interatomic surface (ref. 1, Chap. 8).

This concept arises from a consideration of Schwinger's variational derivation of Schrödinger quantum mechanics for which the natural boundary condition (ref. 1, p. 152) at the surface of the sub-space is that the gradient of the wave function, $\nabla\psi(r|R)$, must be tangent to the surface everywhere.[21] This requisite boundary condition for the Schwinger variational principle to be applicable may be regarded as a fundamental definition of an atom as an independent quantum sub-system (ref. 1, p. 402).

It is apparent that the exact one-electron Schrödinger equation [2] is the pertinent Schrödinger equation within each atomic sub-space. Furthermore, it is a reasonable conjecture that the rather erudite mathematics involved in the development of the concept of the atomic sub-spaces[22] may be simplified by regarding the electron amplitude, $\psi(r|R)$, rather than the density, $\rho(r|R)$, as the fundamental amplitude that is being varied according to the principle of least action.

Discussion

The conclusion from the above analysis and discussion, is that basing Bader's atoms in molecules topological analysis of electronic wave functions upon the square root of the electron density (rather than upon the density itself) has merit, and in some respects appears to be superior both conceptually and in terms of computed results. The fundamental reason for this may be that quantum mechanics is a theory of amplitudes rather than one of densities.

It should be noted that in computational practice it is never necessary to actually compute the square root of the density, since the topology of $\psi(r|R)$ is revealed by $\nabla\psi(r|R)/\psi(r|R)$ and $\nabla^2\psi(r|R)/\psi(r|R)$; these topological functions are conveniently computed from the density and its first and second derivatives using eq. [3] and [10].

Thus the proposition that $\psi(r|R)$ is a better basis for the atoms in molecules analysis than $\rho(r|R)$ can be explored with only a very small amount of extra computing and plotting. Indeed efficiency dictates that the computations for $\psi(r|R)$ and $\rho(r|R)$ should be carried out in parallel in the same computer program; very few additional lines of computer code are needed, and the corresponding results can be output and plotted consecutively. This is, in fact, how the results reported in 1986 [3] were obtained — by slightly modifying a computer program in the laboratory of Richard Bader at McMaster University.

In view of the ease with which the above proposition can be explored, it is surely desirable to compute the Laplacians of both $\rho(r|R)$ and $\psi(r|R)$ whenever an atoms in molecules analysis is carried out.

At this juncture many results based upon $\rho(r|R)$ have already been published, whereas very few corresponding results based upon $\psi(r|R)$ have been obtained. The above proposition must, of course, in the spirit of science[23] remain tentative until many comparative computational results have been obtained. The trend already observed in previously

[19] The domains where $\nabla^2\psi(r|R) = 0$ are *surfaces*, because this scalar equation places a single constraint on the function, thus reducing the domain from 3 to 2 dimensions.

[20] At large distances from the nuclei the electron's kinetic energy tends to a negative asymptotic limit equal to minus the ionization energy of the molecule (4, 6). This asymptotic limit is independent of the path by which the electron leaves the molecule, but different paths will have different gradients $\nabla^3\psi/\psi$ that are proportional to the local force necessary to move the electron along the path. Thus ionization will preferentially occur by a path along which the maximum force is minimal.

[21] Equivalently that the scalar product of $\nabla\psi(r|R)$ with a normal to the surface should be zero everywhere.

[22] Defined as being enclosed by the surfaces perpendicular to which $\nabla\rho(r|R) = \nabla\psi(r|R) = 0$.

[23] That is, that ideas are always subject to the scrutiny of experiments, in this case computational experiments.

computed results (3, 12, 13) does, however, encourage the exploration of the proposition in future calculations.

Last but not least, the conceptual basis of using $\psi(r|R) = \sqrt{\rho(r|R)/N}$, based as it is upon the exact one-electron Schrödinger equation [2], offers an exact atoms in molecules analysis firmly based in all the well-established concepts of quantum mechanics as applied in chemistry, without appealing to auxiliary concepts such as charge concentration and depletion.

Acknowledgements

Computations are underway to apply the above analytical methods to molecules, specifically to generate the molecular envelopes of molecules that exhibit hindered rotation or steric hindrance to see if the molecular envelope definition of molecular size and shape is a good predictor of experimental properties. The ultimate objective is to establish an accurate, well-defined basis for molecular graphics. This work is being carried out by A.A. Ahari, with whom discussions about the conceptual aspects contributed to the writing of this article. Similar discussions with Dr. W.T. Chan are also gratefully acknowledged. Financial and logistic support for this work was provided by York University, and by Glenamadda Enterprises, Inc. An incisive review of the original manuscript by an anonymous referee contributed to the completeness and clarity of this article.

Study of NO and CO dissociation on the (100) Cu surface using density functional theory and the topological analysis of the electronic density and its Laplacian

Yosslen Aray and Jesús Rodríguez

Abstract: Molecular orbital ab initio Hartree–Fock, post-Hartree–Fock at the MP2 and QCISD levels, and density functional theory calculations of the dipole moment, the topology of the electronic density, $\rho(r)$, and its Laplacian, $\nabla^2\rho(r)$, for CO and NO molecules are reported. The results obtained confirm that density functional methods provide remarkably good electronic properties and a good description of the topology of $\rho(r)$ and $\nabla^2\rho(r)$. The Becke exchange functional with the correlation functional of Lee, Yang, and Parr was used to calculate the electronic density of the (100) Cu surface. Topological analysis of $\rho(r)$ shows that the crystal graph corresponds to square pyramids between the atoms of the top of the surface and the atoms of the second layer. The topological analysis of $-\nabla^2\rho$ shows that the atomic graph of the Cu surface exhibits one (3,−3) local charge concentration surrounded by four (3,+1) local charge depletion points. Additionally, there is a (3,+3) local depletion in the midpoint between each of four contiguous Cu atoms corresponding to the active site for the adsorption of the (3,−3) local charge concentration on the C atom of the CO or the N atom of the NO molecule. The larger value of the $-\nabla^2\rho$ at the nonbonded charge concentration on the atoms and the geometrical configuration of these critical points favor the interaction of the NO over the CO molecule with the (100) Cu surface. This result is in accord with the known reaction barriers for these molecules.

Key words: density functional theory, Laplacian of the electronic density, (100) Cu surface, carbon monoxide, nitrogen monoxide, molecular graph, atomic graph.

Résumé : Utilisant des calculs d'orbitales moléculaires ab initio de Hartree–Fock, aux niveaux post-Hartree–Fock MP2 et QCISD, et des calculs de la théorie de la densité fonctionnelle, on a évalué les moments dipolaires et la topologie de la densité électronique, $\rho(r)$ et son laplacien, $\nabla^2\rho(r)$, des molécules de CO et de NO. Les résultats obtenus confirment que les méthodes de la densité fonctionnelle conduisent à des propriétés électroniques particulièrement bonnes ainsi qu'à une bonne description de la topologie de $\rho(r)$ et de $\nabla^2\rho(r)$. On a utilisé la fonctionnelle d'échange de Becke avec la corrélation fonctionnelle de Lee, Yang et Parr pour calculer la densité électronique de la surface (100) du Cu. L'analyse topologique de $\rho(r)$ montre que le graphe du cristal correspond à des pyramides carrées entre les atomes au sommet de la surface et les atomes de la deuxième couche. L'analyse topologique de $\nabla^2\rho$ montre que le graphe atomique de la surface du Cu présente une concentration locale de charge (3,−3) entourée par quatre points (3,+1) présentant une déficience de charge. De plus, il y a une déficience locale de charge (3,+3) à la mi-distance entre chacun des quatre atomes de Cu contigus qui correspondent au site actif pour l'adsorption de la concentration locale de charge (3,−3) sur l'atome de carbone du Co ou sur l'atome d'azote de la molécule de NO. La valeur plus élevée du $-\nabla^2\rho$ à la concentration de charges non-liées sur les atomes ainsi que la configuration géométrique à ces points critiques favorisent toutes les deux l'interaction du NO par rapport à celle de la molécule de CO sur la surface (100) du Cu. Ce résultat est en accord avec les barrières connues à la rotation de ces molécules.

Mots clés : théorie de la densité fonctionnelle, laplacien de la densité électronique, surface (100) du Cu, monoxyde de carbone, monoxyde d'azote, graphe moléculaire, graphe atomique.

Introduction

The properties of a molecular charge distribution are summarized in terms of its critical points (CP) (1). These are points where the gradient vector field, $\nabla\rho(\boldsymbol{r})$, vanishes and they are classified by the $\rho(\boldsymbol{r})$ curvatures or three eigenvalues λ_i (i = 1, 2, and 3) of the Hessian matrix ($H_{ij} = \partial^2\rho(\boldsymbol{r})/\partial x_i \partial x_j$). There are, in molecules and crystals, four types of these extremes that, labeled by their rank (number of non-zero eigenvalues) and signature (excess number of positive over negative eigenvalues), are maxima (3,−3), minima (3,+3), and saddles (3,+1) and (3,−1). The (3,−3) points occur generally at the nuclear positions so that each nucleus is a three-dimensional point attractor in the vector field spanned by $\nabla\rho(\boldsymbol{r})$. The region transversed by the gradient paths that terminate at a given attractor is called the basin of the attractor. A (3,−1) CP is found between every pair of neighboring nuclei. It represents both local maxima in two directions and a local minimum in a third and is called a bond critical point. The gradient paths associated with the negative eigenvalues at the (3,−1) point define the zero flux that partitions the molecule or crystal into unique fragments. Therefore, the set of surfaces formed by all (3,−1) points partitions the system into a collection of chemically identifiable regions called atomic basis (2). These are the most transferable pieces one can define in an exhaustive partitioning of the real space (1). The unique pair of trajectories associated with the positive eigenvalue at the (3,−1) CP define a line linking the nuclei along which the charge density is a maximum with respect to any neighboring line. It is called a bond path and its presence provides the necessary and sufficient conditions for the existence of a bond (1). The network of bond paths corresponding to the ground state charge density defines a molecular graph and the structure of a molecule or a crystal. A bond path determines and characterizes all of the atomic interactions in a given system (3, 4) and has proven useful in the analysis of physical properties of insulators, metals, and alloys (3–6).

The reactivity of molecules is reflected in the topology of the Laplacian of the charge density, $\nabla^2\rho(\boldsymbol{r})$ (7–10). The Laplacian of any scalar field such as $\rho(\boldsymbol{r})$ determines where the field is locally concentrated ($\nabla^2\rho(\boldsymbol{r}) < 0$), and locally depleted ($\nabla^2\rho(\boldsymbol{r}) < 0$) (1). The atomic Laplacian (11, 12) exhibits alternating shells of charge concentration and charge depletion equal in number to the number of quantum shells. The outer shell of charge concentrations (VSCC) contains a spherical surface over which $\rho(\boldsymbol{r})$ is maximally concentrated. The distribution of the $\nabla^2\rho(\boldsymbol{r})$ over this surface in the free atom is uniform if one assumes that the nucleus has a negligible electric quadrupole moment. The formation of bonds produces changes in this distribution, and the VSCC of a bound atom exhibits localized concentrations of charge that mimic in number, relative position, and size the pairs of electrons assumed in the Lewis model, topological features that are absent from the relatively simple topology exhibited by the density itself. The structure of the Laplacian for an atom in a molecule (10), called its atomic graph, is most easily visualized in terms of the polyhedron defined by the maxima in $-\nabla^2\rho(\boldsymbol{r})$, a polyhedron whose vertices (V), edges (E), and faces (F) satisfy Euler's formula

$$V - E + F = 2$$

The maxima define the vertices V; the unique pairs of trajectories that originate at (3,−1) critical points and terminate at neighboring vertices define the edges, E; and the (3,+1) critical points define the faces F. The face critical points define the centers of local depletions in the valence-shell charge concentration or VSCC. A Lewis acid–base reaction corresponds to aligning a charge concentration (CC) on the base with a charge depletion (CD) on the acid, that is, by directing a vertex of the atomic graph on the base atom at a face of the polyhedron on the acid. This is a general phenomenon that is observed in many different kinds of interactions (1), examples being the formation of hydrogen bonds (13), the alignment of chlorine molecules in the solid (4), and the adsorption of molecules on surfaces (14–16). The Laplacian of the electronic density provides a physical model that guides one in the determination of the sites of adsorption and the geometry of approach of the substrate relative to the surface site, and predicts whether the interaction will correspond to physi- or chemisorption (14).

Density functional theory (DFT) plays a role of increasing importance in the calculations of ground states of molecules and solids (17–21). The electron correlation, important for many systems such as transition metals, is included in the DFT computational scheme: the Kohn–Sham (KS) equations. Using (18) a nonrigorous approximation to the exchange and correlation energy of an interacting system, KS methodology leads to a scheme analogous to the Hartree method but containing the major part of the effects of exchange and correlation. The resulting KS equations are similar to the Hartree–Fock (HF) equations but do not need multireference representations, which increase the computational requirements and make post-HF methods impractical for large systems.

In this work, the topological analysis of the electron density and its Laplacian, using the charge distribution obtained from DFT calculations, was applied to study the structure of the Cu (100) surface and its reactivity towards CO and NO molecules. These are two examples of interesting catalytic reactions (22). The CO dissociation (23) is important in the production of hydrocarbons from carbon monoxide and hydrogen, components of a synthesis gas. Copper clusters are an important component of DENOX (22), a new class of automotive exhaust catalyst. Comparisons between HF, post-HF, and DFT results are presented.

Methodology

The calculations were carried out with the Gaussian 94 (24) program using the 6-311+G(d,p) (25) basis set. The molecular orbital calculations were performed at HF, Møller–Plesset perturbation (MP2), and quadratic CI (including triple and quadruple terms (QCISD)) levels. In the DFT case, the Becke exchange functional (26) and the correlation functional of Lee, Yang, and Parr (LYP) (27), which includes both local and nonlocal terms (BLYP), and Becke's three-parameter hybrid method with the LYP correlation functional (B3LYP) (28) were used. The topology of $\rho(\boldsymbol{r})$ and $\nabla^2\rho(\boldsymbol{r})$ was analyzed using the Aimpac-94 package.[2]

CO and NO molecules

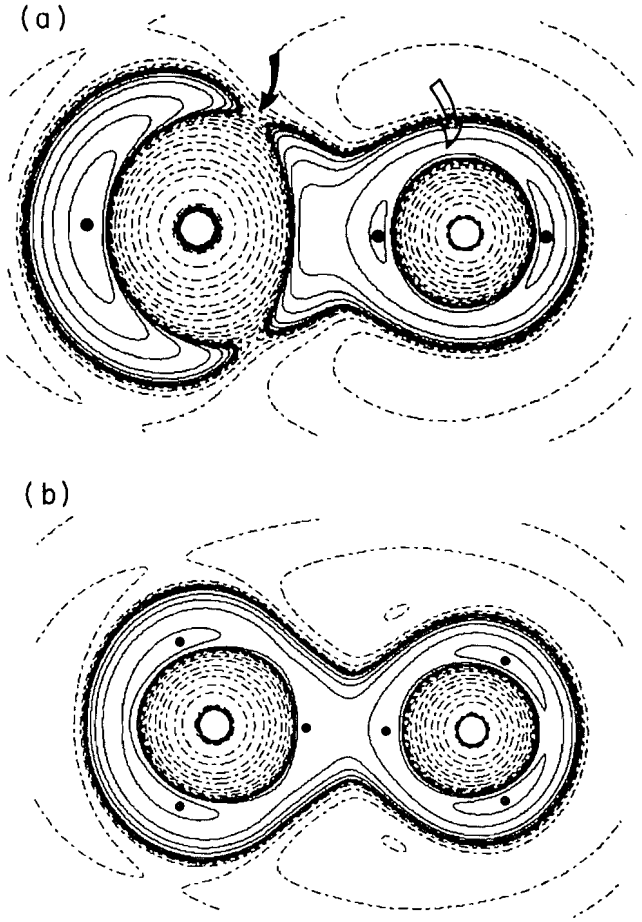
To study the accuracy of the charge density produced by the different methods of calculation, the electric dipole moment, the topological properties of $\rho(r)$, and the local charge concentration in the VSCC for the CO and NO molecules were calculated. The results are reported in Tables 1–3. The molecular geometry in the ground state was optimized in all of the cases. The HF value of the dipole, as it is known, is not correct (29), not only in magnitude but in sign. The experimental dipoles of

CO (30) and NO (30) are 0.12 and 0.15 D in the direction $^{-}C–O^{+}$ and $^{-}N–O^{+}$ while HF results are 0.299 and 0.27, respectively, in the reverse direction $^{+}C–O^{-}$ and $^{+}N–O^{-}$. Inclusion of electronic correlation orients the dipole correctly but the errors are also around 30% in MP2, QCISD, and B3LYP. There is only a small difference between the dipole calculated from the BLYP and the experimental value in both molecules. In spite of these large variations observed in the dipole moments, the topological properties of the electronic density show only small changes (see Table 2). The DFT methods follow the same trend shown by the MO post-HF methods. In general, the curvatures of $\rho(\boldsymbol{r})$ at the critical points reported by the other methods decrease (around 10%) with respect to the HF values. The two negative (λ_1 and λ_2) curvatures measure the degree of contraction of $\rho(\boldsymbol{r})$ perpendicular to the bond towards the critical point while the positive curvature (λ_3) measures the degree of contraction parallel to the bond and away from the critical point towards each of the neighboring nuclei. When the negative curvatures dominate, electronic charge is locally concentrated in the region of the CP, resulting in a sharing of electronic charge by both nuclei forming the bond. These interactions, referred to as shared interactions, are characteristic of the covalent or polar bond and are characterized by large values of $\rho(\boldsymbol{r})$, $\lambda_1/\lambda_3 > 1$, $\nabla^2\rho < 0$ at the CP, and by the large negative value of the potential energy in the internuclear region. If the positive curvature is dominant, the electronic density is concentrated separately in each of the atomic basins and the interaction, referred to as a closed-shell interaction, is dominated by the relatively large positive contributions to the kinetic energy of the system. In this case, ρ is relatively low in value, $\lambda_1/\lambda_3 < 1$, and $\nabla^2\rho > 0$ at the CP. Table 2 shows that in NO there is a shared interaction while in CO there is an intermediate-type interaction characteristic of a polar bond, i.e., ρ is relatively large although $\nabla^2\rho > 0$ and $\lambda_1/\lambda_3 < 1$.

The value of the (3,−3) critical points of the CO and NO molecule are reported in Table 3. Contour maps obtained with the BLYP method are shown in Fig. 1. In CO, the O VSCC distribution shows two local charge concentrations located along the C—O bond direction. One is facing the carbon atom (Vb), while the other is found in the opposite side of the shell forming a nonbonded local charge concentration (Vnb). A ring of degenerate critical points of the (2,0) type in a plane perpendicular to the C–O direction completes the O atomic graph. The carbon atom exhibits only one local charge concentration (Vnb), which is located in the nonbonded region. A torus of charge depletion around the internuclear axis with a ring of degenerate points is found in the C VSCC. We can see in Table 3 that, similar to $\rho(\boldsymbol{r})$, the inclusion of electronic correlation decreases the value of the Laplacian at the critical point. The variations are more pronounced in the carbon nonbonded region (14%) than in the O nonbonded region (10%). The DFT shows again the same trend as the MO post-HF methods.

As is expected from the electronic ground state (π^2) of the NO molecule, the topology of the Laplacian distribution is significantly different from that of the CO molecule (see Fig. 1*b*). The ground state of NO has the open-shell configuration $(1\sigma)^2(2\sigma)^2(3\sigma)^2(4)\sigma^2(5\sigma)^2(1\pi)^4(2\pi)$ so that the extra electron in the 2π molecular orbital, which is mostly located in a plane, destroys the axial symmetry. In NO, both the N and O VSCC show three local maxima, two nonbonded forming an angle of 120° with the bond direction and one located in the bond

Fig. 1. Laplacian distribution for (*a*) carbon monoxide and (*b*) nitrogen monoxide. Solid contours denote negative values of $\nabla^2\rho$, that is, concentrations of electronic charge; broken contours, regions of charge depletion. (3,−3) Critical points or local charge concentrations are denoted by dots. In (*a*), the black arrow points out the torus of charge depletion on the C atom and the white the ring of degenerate points in the O atom.



region. Three (3,−1) critical points lie on the same plane of the (3,−3) forming two faces, one above and the other below the plane, with two (3,+1) capping the atomic graph. In contrast to the CO case, the inclusion of correlation produces larger changes in the bonded region than in the nonbonded region. Most of the variations occur at the b critical point of the N atom which shows around 22% decrease in its value. The previous results and discussion confirm that the DFT methods provide remarkably good values of the electronic properties and a good description of the topology of the electronic density and its Laplacian.

According to Bader's theory (1), the active sites in a molecule are associated with the critical points of $-\nabla^2\rho$ of the VSCC. In a chemical reaction, the V critical point or local charge concentration of some atom in a general base reacts with the F or local charge depletion of the VSCC of another atom in a general acid. The carbon and nitrogen monoxide can act as a base by means of the Vnb of the O or C (N) atoms, respectively. In both molecules the Vnb's of the O atom are characterized by a large radial curvature, μ_3 (489.82 and

Table 4.

Ring	−0.011	0.039	0.041	0.020	0.068
Cage	0.007	0.007	0.021	0.008	0.034

(*b*) Data for critical points in the Laplacian of $\rho(r)$ in the Cu atom on the (100) Cu surface.

Critical points	$-\nabla^2\rho$
One (3,−3) above surface	60.988
One (3,−3) below surface	60.945
Four (3,−3) in surface	61.250
Four (3,−1) above surface	58.604
Four (3,−1) in surface	57.779
Four (3,−1) below surface	57.204
Four (3,+1) above surface	56.992
Four (3,+1) below surface	57.023
One (3,+3) in the middle of each four Cu atoms	+0.022

479.17 at the BLYP level in CO and NO, respectively), which measures the degree of contraction of $\rho(r)$ along the radial direction towards the nuclei, and by much smaller perpendicular curvatures that limit the radial extension ($\mu_1 = \mu_2 = -7.67$ in CO and $\mu_1 = -17.37$ and $\mu_2 = -13.46$ in NO). The μ_3 of the Vnb on the C is 61.33 au and $\mu_1 = \mu_2 = -2.95$ au. Thus, the O atom of CO and NO acts as a hard base while the C acts a soft base. The N of NO with $\mu_3 = 173.42$, $\mu_1 = -9.38$, and $\mu_2 = -4.51$ is a harder base than the C atom of CO. In contrast with CO, in the Laplacian distribution of NO there is no torus of charge depletion in the N density encircling the internuclear axis. This torus provides the region for nucleophilic attack in CO or molecules that contain CO groups. The lack of such a torus in the N atom indicates that a nucleophilic attack is less likely in NO.

The DFT offers simplification in handling the electronic correlation using single-particle density instead of the many determinants considered in the post-HF method (18), so it is relatively easy to study complex systems such as transition metals. In the following section we study an example of one of these complex systems: the (100) Cu surface.

(100) Cu surface

The most stable phase (31) of bulk Cu is cubic fcc and belongs to the *Fm3m* space group with $a = 3.577$ Å. Each atom is linked by bond paths to 12 neighboring atoms. There are no interactions with the second neighbors (6) so the bond path defined by the (3,−1) CPs midway between nearest neighbors forms an octahedron with a cage critical point at the center and eight ring critical points at the faces (Fig. 2*a*). The packing of these polyhedra gives rise to the Cu fcc structure. The lack of translational symmetry in the direction orthogonal to the surface can be dealt with by approximating the semi-infinite crystal by a finite slab of several layers of Cu atoms. It is known (32) that the (100) Cu surface reconstructs only to a small extent, so the surface relaxation effects on the charge distribution are expected to be small. For this reason, a slab of two layers was modeled with a Cu_{13} cluster, illustrated in Fig. 2*b* with the geometrical parameters of the bulk form. Each atom of the surface has eight nearest neighbors and four next-nearest neighbors at distances of 2.529 and 3.577 Å, respectively. The structure, as determined by the gradient vector field map, Fig. 3, is a truncated form of that found for the bulk form with bond paths linking each surface Cu atom to its eight neighbors. The top atoms of the surface form square pyramids with the atoms of the second layer. A contour map of the electron density of the top atoms is shown in Fig. 4. The parameters for the CPs of $\rho(r)$ of one of these pyramids are reported in Table 4. The relatively small values of the density, ρb, and the positive values for $\nabla^2\rho$ are characteristic of closed-shell interactions. Such interactions are dominated by the Pauli principle, which leads to a depletion of electron density in the interatomic surface and hence to low values of ρb. The accompanying separate accumulation of electron density in the basin of each atom results in the value of $\nabla^2\rho$ being dominated by its single positive curvature parallel to the bond path.

The values of the Laplacian at the position of the VSCC critical points for the Cu atoms of the top are given in Table 4. The atomic graph for these atoms has six vertices, two along the axis perpendicular to the surface, one above (L_u) and other below the surface (L_d) and four (L_i with $i = 1, ..., 4$) in the plane along the Cu—Cu bonds. These CPs are linked by 12 edges, 4 between the L_u and L_i, four between L_d and L_i, and four linking the L_i's. Thus, the atomic graph of the Cu atoms is an octahedron with eight faces joining the vertices, four above the surfaces and four below it. There is a (3,+1) CP in the middle of each face. These critical points denote the position where the Laplacian attains its least negative value in the shell described by the atomic graph. In addition to the CPs forming the Cu atomic graph, a Laplacian contour map of the (100) Cu surface shows (see Fig. 5) the presence of a (3,+3) critical point of $-\nabla^2\rho$ in the midpoint of each four Cu atoms. This represents the site of maximum charge depletion on the surface and around the Cu atoms.

Fig. 2. (*a*) Model of the bulk Cu illustrating the crystal graph, an octahedron, corresponding to the fcc structure. (*b*) Diagram of the Cu13, cluster model of a two-layer slab of the (100) surface.

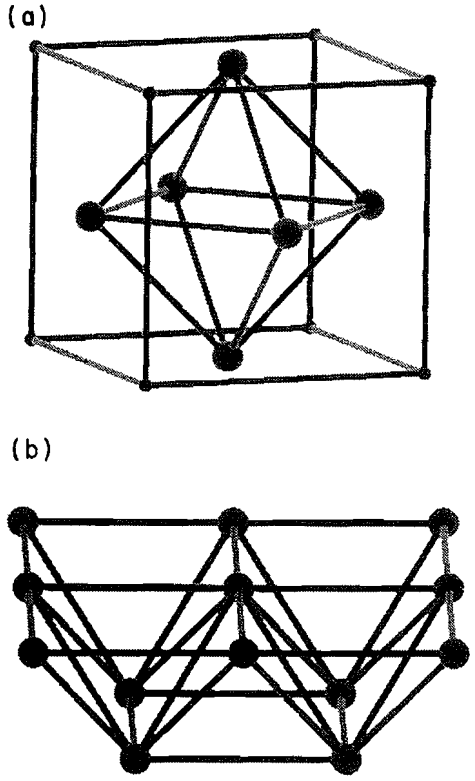

Fig. 3. Trajectories traced out by gradient vectors of the electron density, trajectories of $\nabla\rho$, in the top of the (100) Cu surface. The region of space traversed by trajectories that terminate at a given nucleus where $\rho(r)$ is a local maximum (denoted by open circle) defines the basin of the atom. A unique pair of trajectories originates at each bond critical point (denoted by dots) defining a line of maximum electron density linking bonded nuclei, the bond path. The arrows point out the (3,+1) or ring critical points.

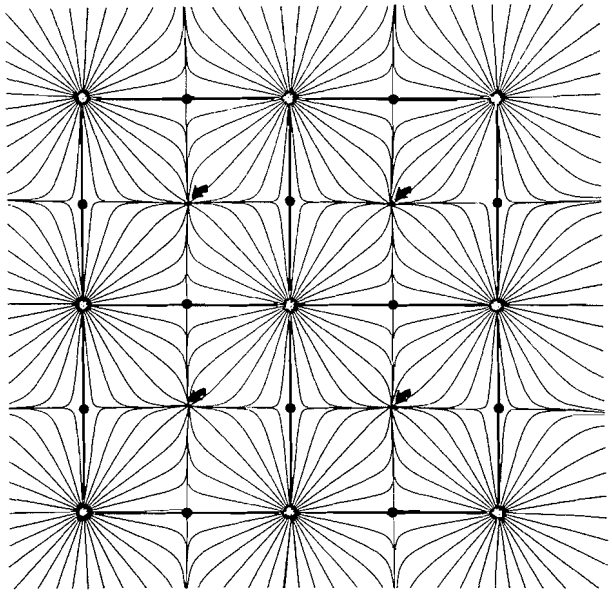

Fig. 4. Contour map of $\rho(r)$ in the top of the (100) Cu surface overlaid with interatomic surfaces, as defined by the gradient vector field in Fig. 3.

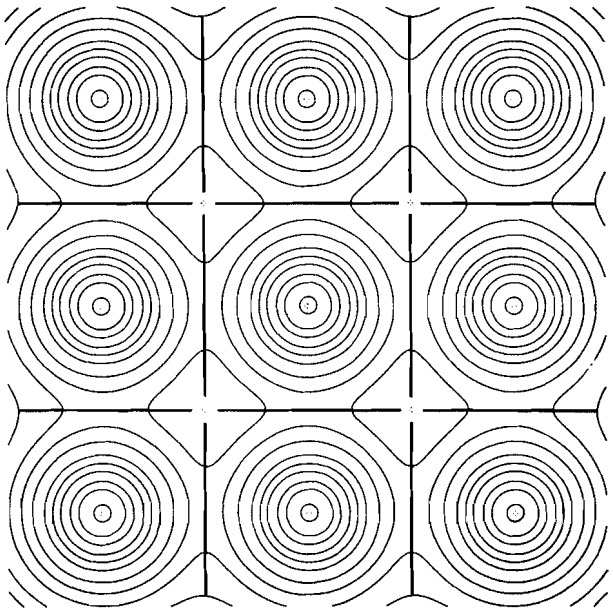
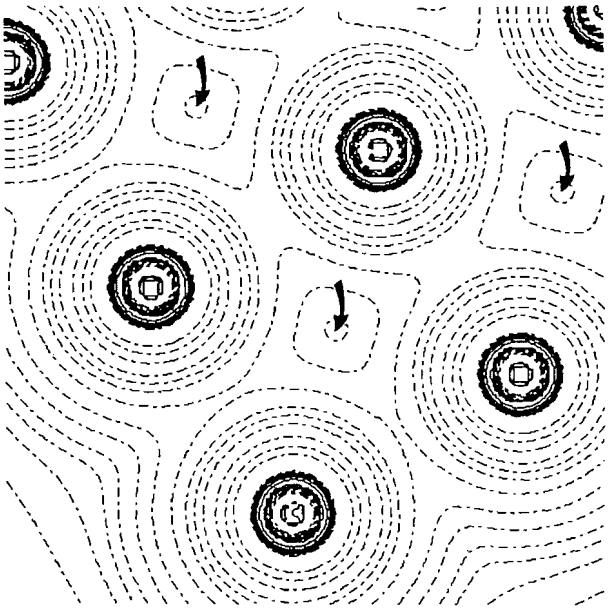


The adsorption pathway of CO and NO on Cu (100) can be anticipated from the topology of $-\nabla^2\rho$. The perpendicular bonding on Cu would require that a CC on the CO molecule interacts with a CC (a repulsive interaction) on the surface, so the CO deviates towards the midpoint of four Cu atoms where the greatest interaction with the faces of the atomic graph above the surface and the (3,+3) CP is reached. Due to the interaction of the CC at the oxygen atom with another nearest CC (3,+3) on the surface and the interaction of the torus of charge depletion on C with CC on the Cu atom, the molecule tilts toward the metal surface and finally the bond will be broken. This suggestion is in accord with recent studies (22) of the transition states of this dissociation for several reaction paths using the same cluster models of the (100) Cu surface. The lateral localization (see Fig. 1*b*) and the larger value of $-\nabla^2\rho$ of the nonbonded CC at the atoms in NO (see Table 4) with respect to those in CO favors the interactions of the NO molecule over those of CO with the (100) Cu surface. This prediction is in agreement with the value of the energy barriers for NO dissociation (30 kcal/mol) and CO dissociation (88 kcal/mol) on the 100 Cu surface (22).

Conclusions

In a variety of calculations for CO and NO molecules it was found that the DFT method using the Becke exchange functional and the correlation functional of Lee, Yang, and Parr (LYP), BLYP, generates more accurate values of the dipole moment than both the post-HF method and Becke's three-parameter hybrid method with the LYP correlation functional, B3LYP. This latter functional yields a result similar to the MP2 and QCISD methods.

Fig. 5. Laplacian distribution of $\nabla^2\rho$ of the (100) Cu surface. Solid contours denote negative values of $\nabla^2\rho$, that is, concentrations of electronic charge; broken contours, regions of charge depletion. The black arrows point out the (3,+3) critical points in the middle of each four Cu atoms.



The values of the topological properties of $\rho(r)$ and $-\nabla^2\rho$ at the critical points for CO and NO molecules follow the same trend shown by the MO post-HF methods. The topology of the $\rho(r)$ and its Laplacian is maintained (same number and type of critical points) but, in general, the inclusion of the electronic correlation decreases (around 10–20%) the value of these quantities with respect to the HF values. These results confirm that the DFT method provides remarkably good electronic properties and a good description of the topology of the electronic density and its Laplacian.

The topology of $-\nabla^2\rho$ not only predicts the active site but also the correct trend for the adsorption and dissociation of CO and NO molecules on the (100) Cu surface. This and earlier work (1, 14–16) demonstrates the potential usefulness of the topology of the Laplacian of the electron density in determining the conditions governing the reactivity of surfaces and in locating the active centers for the adsorption of either Lewis bases or acids.

Delocalized bonding in tetrahedral organo-transition metal clusters: an EHMO study of metal vertex rotations in $Co_2Fe(CO)_9S$, $CpMoCo_2(CO)_8CR$, and in $Cp_2Mo_2(CO)_4(RC{\equiv}CR)$

Krisztina L. Malisza, Lijuan Li, and Michael J. McGlinchey

Abstract: Molecular orbital calculations at the extended Hückel level are used to rationalize the barriers to vertex rotation in the tetrahedral metal cluster complexes $FeCo_2(CO)_9S$, **2**, and $(C_5H_5)MoCo_2(CO)_8CH$, **3**. It is shown that, in accord with experimental observations on **2**, rotation of an $Fe(CO)_3$ fragment through 60° brings about a weakening of the metal–metal bonding interactions within the $FeCo_2$ triangle. In the $MoCo_2$ cluster, **3**, rotation of the $CpMo(CO)_2$ fragment about an axis joining the molybdenum to a central point within the tetrahedron gives rise to three minima in which the cyclopentadienyl ring is oriented *proximal* or *distal* relative to the capping carbynyl moiety, or in the plane of the three metals. The rotation trajectory of the $CpMo(CO)_2$ vertices in $Cp_2Mo_2(CO)_4(HC{\equiv}CH)$, **4**, has been elucidated by means of a Bürgi–Dunitz analysis of the X-ray crystal structures of a series of related clusters in which the $CpMo(CO)_2$ units exhibit a range of orientations. The calculations suggest that the barriers to vertex rotations in **4** are primarily of steric rather than electronic origin.

Key words: metal clusters, vertex rotations, EHMO calculations.

Résumé : On a utilisé des calculs d'orbitales moléculaires au niveau de Hückel étendu pour rationaliser les barrières à la rotation aux sommets des complexes d'agrégats métalliques tétraédriques, $FeCo_2(CO)_8S$, **2**, et $(C_5H_5)MoCo_2(CO)_8CH$, **3**. Il a été démontré que, en accord avec les observations expérimentales sur le composé **2**, la rotation de 60° d'un fragment $Fe(CO)_3$ provoque un affaiblissement des interactions de liaison métal–métal dans le triangle $FeCo_2$. Dans l'agrégat $MoCo_2$, **3**, une rotation du fragment $CpMo(CO)_2$ autour d'un axe reliant le molybdène à un point central à l'intérieur du tétragone conduit à trois minima dans lesquels le noyau cyclopentadiényle prend des orientations *proximale* et *distale* par rapport à la portion carbynyle servant de cap ou une orientation dans le plan des trois métaux. Faisant appel à une analyse de Bürgi–Dunitz des structures cristallines par diffraction des rayons X d'une série d'agrégats apparentés dans lesquels les unités $CpMo(CO)_2$ présentent un ensemble d'orientations, on a élucidé la trajectoire de la rotation des sommets $CpMo(CO)_2$ dans le $Cp_2Mo_2(CO)_4(HC{\equiv}CH)$, **4**. Les calculs suggèrent que l'origine des barrières à la rotation aux sommets dans le composé **4** sont principalement de nature stérique plutôt qu'électronique.

Mots clés : agrégats de métaux, rotations aux sommets, calculs d'OM de Hückel étendues.

Introduction

Molecular orbital calculations at the Extended Hückel level have proven invaluable in gaining an understanding of the structure and reactivity of organo-transition metal clusters. In particular, the fragment approach pioneered by Hoffmann and his colleagues (1, 9) lends itself beautifully to this chemistry since it allows us to take advantage of the picturesque symmetry of these systems. In recent years, we have used these concepts to rationalize the structures of a number of clusters, many of which exhibit stereochemical nonrigidity on the NMR time scale (2–4). Since these simple EHMO methods could be successfully used (5) to account for the fluxional character of five-vertex square-based pyramidal molecules such as **1**, we chose to extend them to encompass the phenomenon of metal vertex rotations in tetrahedral tri- and di-metallic clusters **2** through **4**. We have selected two systems for which reliable experimental data are available: (*a*) the interchange of axial and equatorial carbonyl ligands within the $Fe(CO)_3$ and $Co(CO)_3$ vertices of $FeCo_2(CO)_9S$, **2**, and (*b*) rotation of the $(C_5H_5)Mo(CO)_2$ fragment in $(C_5H_5)MoCo_2(CO)_8CH$, **3**. Moreover, the $(C_5H_5)Mo(CO)_2$ vertex rotation process in dimolybdenum-alkyne clusters, **4**, has been analyzed by means of the Bürgi–Dunitz trajectory technique in which appropriately selected X-ray crystal structures are used to provide a series of "snapshots" of the reaction pathway.

Received November 9, 1995.

This paper is dedicated to our friend and colleague Professor Richard F.W. Bader on the occasion of his 65th birthday. We appreciate his remarkable insight into the nature of chemical interactions.

The bonding within the four vertex atoms in tetrahedral organo-transition metal clusters continues to attract attention. The edge-localized model of $RCCo_3(CO)_9$, **5a**, yields electron counts of 8 and 18, respectively, for the carbon and cobalt atoms. In contrast, the core and valence shell photoelectron spectra of such systems have been rationalized in terms of a carbyne-capped metal triangle, as in **5b** (6). Similarly, a variety of inner-shell spectroscopic measurements have been interpreted by using the latter model (7).

According to Wade's rules (8), a tetrahedral cluster can be regarded either as a *nido*-trigonal bipyramid or as an electron-precise four-vertex system. The barriers toward local rotation of the ML_n vertices provide a probe for the degree of edge-localized bonding. We here present a molecular orbital analysis of the vertex rotations in a series of mixed metal clusters and compare these calculations to the available experimental data.

Results and discussion

$M(CO)_3$ rotation in $FeCo_2(CO)_9S$

As shown in Fig. 1, metal triangles such as $[Co_3(CO)_9]^{3+}$, **6**, or $[Fe_3(CO)_9]$, **7**, give rise to a low-lying set of three filled orbit-

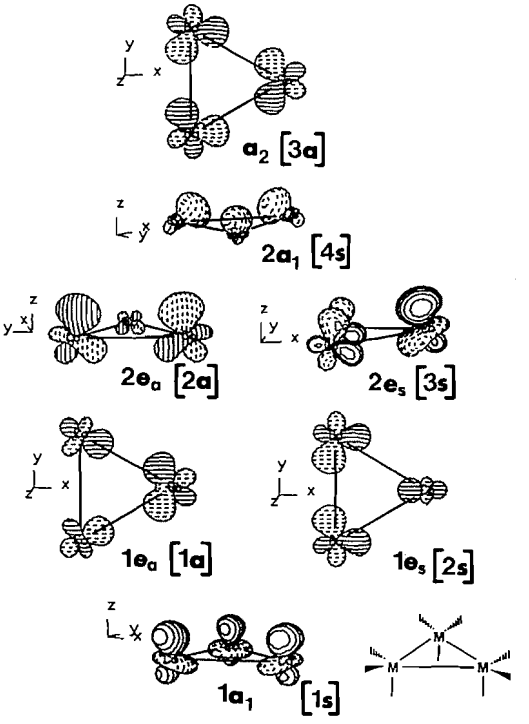
Fig. 1. Frontier orbitals of an $M_3(CO)_9$ fragment. (The symbols in square brackets correspond to the labelling used by Saillard (5) for heterometallic triangles of the type $M_2M'L_9$.)

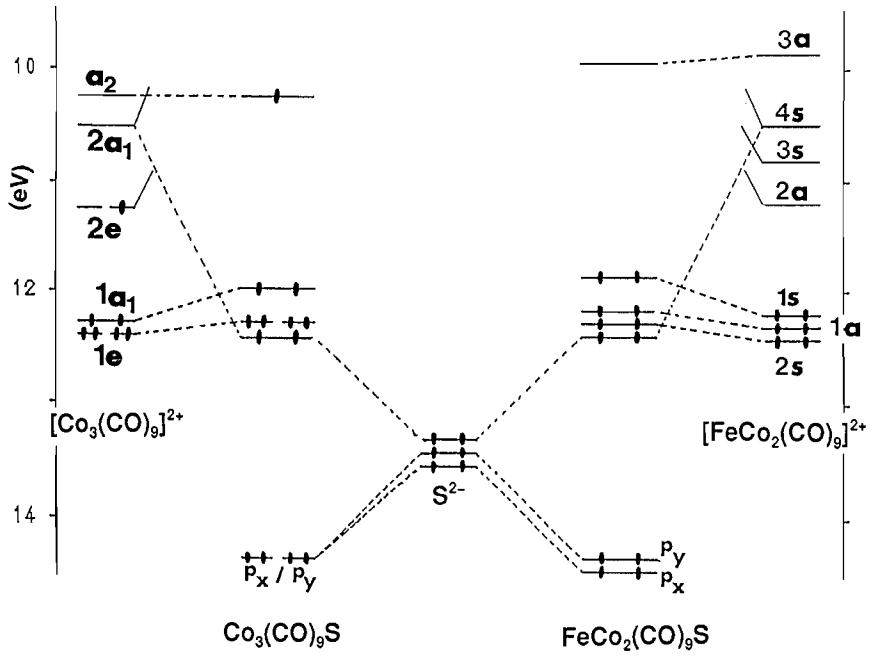


als ($1a_1$ and $1e$) and, at somewhat higher energy, a set of three vacant orbitals ($2a_1$ and $2e$) that serve to accept electron density from capping ligands. There is also an a_2 orbital (made up primarily of out-of-phase d_{xy} orbitals) that is metal–metal antibonding in character. In $Co_3(CO)_9S$, this a_2 orbital does not find a symmetry match with the frontier orbitals of the sulfur cap and is singly occupied in the cluster, as shown in Fig. 2.

Replacement of a $Co(CO)_3$ vertex in the tricobaltnonacarbonyl triangle by a different metal fragment such as $(C_5H_5)Mo(CO)_2$ or $Fe(CO)_3$ lowers the symmetry from C_{3v} to C_s and splits the degeneracies of the $1e$ and $2e$ orbital pairs. Thus the localization of the frontier orbitals on the three metal vertices can change quite markedly. This premise was used previously to rationalize the orientations of alkyne moieties in heterometallic M_3C_2 clusters, **1** (5). (We here follow the notation adopted in Saillard's paper on trimetallic systems (5); the symmetric (s) and antisymmetric (a) labels are used to correlate frontier orbitals in homometallic (M_3L_9) and heterometallic ($M_2M'L_9$) metal triangles.)

Compared to the situation in $[Co_3(CO)_9]^{3+}$, **6**, the localization of the acceptor set of frontier orbitals in the heterometallic fragment $[FeCo_2(CO)_9]^{2+}$, **8**, is much more heavily weighted towards the iron atom than to its cobalt partners. Typically, in the $2e_a$ orbital, which has 22.5% localization on each cobalt in **6**, the distribution in **8** is calculated to be 28% on Fe and only 19% on each cobalt. More importantly, the $3s$ orbital in **8** (which is poised to accept electron density from the p_x orbital of the capping moiety) is now 51% localized on Fe with less than 10% on each cobalt; this is considerably perturbed from that found for the corresponding orbital, $2e_s$, in the tricobalt fragment **6**, which has 42% localization on Co(1)

Fig. 2. Frontier orbital interactions in $Co_3(CO)_9S$ and $FeCo_2(CO)_9S$.



and 13% on each of Co(2) and Co(3). In contrast, the $2e_a$ orbital, which interacts with the p_y donor orbital from the capping sulfur, has only a negligible contribution from Co(1) in **6** (or from Fe in **8**) and so remains almost unchanged. Concomitantly, the filled orbital set arising from the metal triangle is correspondingly more heavily weighted towards the cobalt vertices in **8**.

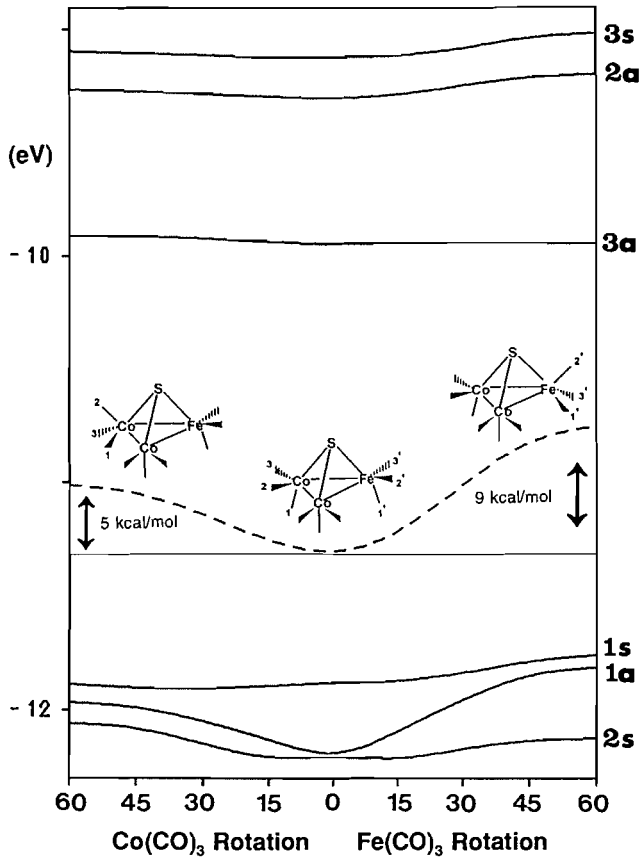
We see in Fig. 2 not merely that the orbital degeneracies present in $Co_3(CO)_9S$ have been lifted in $FeCo_2(CO)_9S$, **2**, but also that the major π-type interactions, viz. sulfur p_x with *3s* and sulfur p_y with *2a*, are now different in magnitude. This enhanced splitting of the bonding components of the metal–sulfur π-interactions may be attributed to the greater contribution of the iron atom to the *3s* acceptor orbital.

To summarize, the interactions of the $1a_1$ and *1e* filled orbital set with p_x, p_y, and p_z, respectively, of sulfur are rather small since the overlaps are poor. The principal differences in bonding between the tricobalt and iron–dicobalt clusters can be traced to the preferential localization of the $2e_s$ orbital of the metal triangle on Fe. In effect, it is not a gross oversimplification to draw a structure **9** in which the sulfur donates an electron pair to iron, which thereby achieves an 18-electron configuration. To the extent that we choose to believe the charge distribution given by the EHMO calculation, we gain some support for a structure such as **9** when we note that the $Fe(CO)_3$ fragment is more negative than each of the $Co(CO)_3$ units by almost 0.5 electrons. This model focusses charge along the sulfur–iron vector and places the metal in a pseudo-octahedral environment. Now, if we allow local rotation of the $Fe(CO)_3$ vertex so as to interchange the axial and equatorial carbonyl ligands, this must proceed via the trigonal-prismatic geometry **10**. (To simplify the problem, and to take maximum advantage of symmetry, the starting molecular geometry for $Co_3(CO)_9S$ (and for $FeCo_2(CO)_9S$) is an idealized version of the crystallographically determined structure (10). Thus, the experimentally observed OC-Co-CO angles differ by only $\approx 2°$ and so we have imposed local C_{3v} symmetry on each $M(CO)_3$ vertex.)

In Fig. 3 we show the result of rotating through 60° either of the $M(CO)_3$ fragments in $FeCo_2(CO)_9S$, **2**, so as to orient the axial ligand *proximal* with respect to the sulfur cap while the two equatorial ligands are now in *distal* positions. It is apparent that the greater barrier must be surmounted when rotating the $Fe(CO)_3$ vertex from the pseudo-octahedral to the trigonal-prismatic geometry. Figure 3 also reveals that this barrier can be traced primarily to the behaviour of the *1a* orbital (corresponding to $1e_a$ in the homometallic clusters), which is destabilized by the rotation process. The remaining orbitals are but little affected since they either lie along the rotation axis or have only a small contribution from the vertex undergoing rotation. In contrast, the component of the *1a* orbital that was originally a d_{xy} orbital on iron is transformed during the rotation into a hybrid with predominant d_{yz} character. One can see from Fig. 4 that this results in a markedly diminished interaction between the iron and the two cobalt atoms; consequently, there is a loss of metal–metal bonding in the plane of the metal triangle. Overall, the EHMO calculations support the idea of a sizeable barrier to $Fe(CO)_3$ rotation (9 kcal mol^{-1}) and a somewhat more modest energetic requirement (5 kcal mol^{-1}) for the $Co(CO)_3$ vertex to spin about its threefold axis.

Experimental data describing the fluxional behavior of $FeCo_2(CO)_9S$, **2**, have been furnished by Aime who showed that the initial ^{13}CO singlet (at +30°C) exhibits a 6:3 splitting at −80°C (11). Clearly, intermetal exchange of the carbonyls has slowed and one sees the six equivalent ligands on cobalt and three bonded to iron. At −100°C the $Fe(CO)_3$ resonance shows a well-resolved 2:1 pattern demonstrating unequivocally that local rotation of the tricarbonyliron fragment has a sufficiently large barrier to slow this process on the NMR time scale. In contrast, the cobalt carbonyl resonance remains a

Fig. 3. Walsh diagram depicting variations in orbital energy levels upon rotation of a $Co(CO)_3$ or an $Fe(CO)_3$ vertex in $FeCo_2(CO)_9S$, **2**. (The broken line represents the change in total electronic energy.)



sharp singlet at all accessible temperatures. These results are in excellent accord with the energy barriers derived from the EHMO calculations.

$(C_5H_5)Mo(CO)_2$ rotation in $(C_5H_5)MoCo_2(CO)_8CR$ clusters

Let us turn now to the question of rotation of the $(C_5H_5)M(CO)_2$ vertex (M = Mo or W) in trimetallic clusters such as $(C_5H_5)MoCo_2(CO)_8CH$, **3**. When the tetrahedral clusters $(C_5H_5)MoCo_2(CO)_8C$-phenyl, **11**, and $(C_5H_5)WCo_2(CO)_8C$-tolyl, **12**, were first synthesized, both Beurich and Vahrenkamp (12) and Stone and co-workers (13) pointed out that there were too many ν_{CO} bands in the infrared spectra to be assigned to a single isomer. Subsequently, Sutin et al. (14) reported that the low-temperature ^{13}C NMR spectrum of $(C_5H_5)MoCo_2(CO)_8C\text{-}CO_2{}^iPr$ revealed the presence of two species that were assigned as those rotamers in which the cyclopentadienyl ring was sited (*i*) below the trimetallic plane, as in **3a**, and (*ii*) above the metal triangle and *proximal* to the carbynyl capping group, as in **3b** (see Fig. 5). The rotational barrier for the interconversion of rotamers **3a** and **3b** is approximately 8.5–9.5 kcal mol^{-1} depending on the nature of the substituents at the carbynyl capping position and within the cyclopentadienyl ring (14). The clusters **11** and **12** reported by Vahrenkamp (12) and by Stone (13) adopt structural type **3a** and, very recently, the latter rotamer, viz. **3b**, has been characterized X-ray crystallographically for the particular case of $(C_5Me_5)MoCo_2(CO)_8C\text{-}CO_2{}^iPr$, **13** (15).

Before attempting to calculate the relative energies of the various rotameric structures on the $(C_5H_5)MoCo_2(CO)_8CH$ hypersurface, one must select a viable rotation axis about which to spin the $(C_5H_5)Mo(CO)_2$ fragment. We were guided in this problem by the powerful concepts developed by Bürgi and Dunitz, who showed that a succession of static X-ray structures can give information about the dynamics of a reaction (16). For decades X-ray crystallography has been recognized as the method *par excellence* for the determination of molecular structures. The Bürgi–Dunitz approach allows us to extract dynamic information by careful scrutiny of a series of related crystal structures. As an example of the beautiful results that have emerged from Dunitz's laboratory, we note that the distribution of crystal structures of more than 60 $(C_6H_5)_3P$-X fragments in many different environments can be related to the "two-ring flip" mechanism by which these chiral propeller-like moieties can undergo racemization (17). These ideas were extended into the organometallic arena by Crabtree and Lavin who showed that carbonyl migration between two metal atoms proceeds via a trajectory in which a linear terminal ligand proceeds through a series of increasingly more bent

Fig. 4. The effect on the *1a* frontier orbital in $FeCo_2(CO)_9S$, **2**, upon rotating the $Fe(CO)_3$ vertex through 60°.

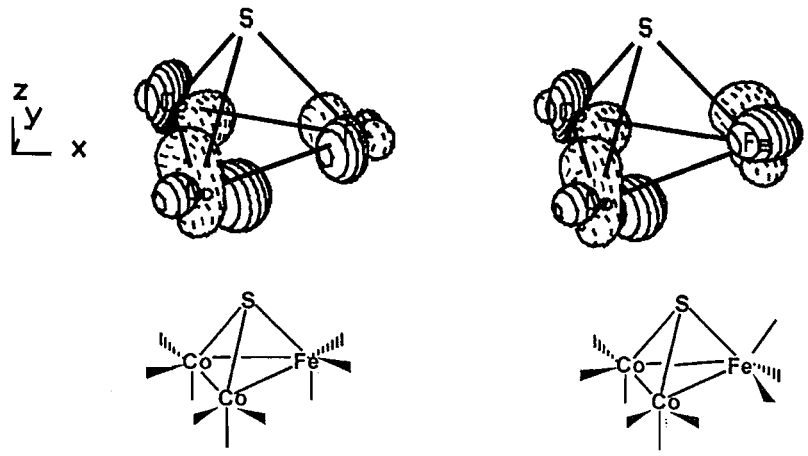


Fig. 5. Rotamers of $CpMo(CO)_2Co_2(CO)_6CR$, **3**; the views are analogous to Newman projections of staggered and eclipsed ethanes.

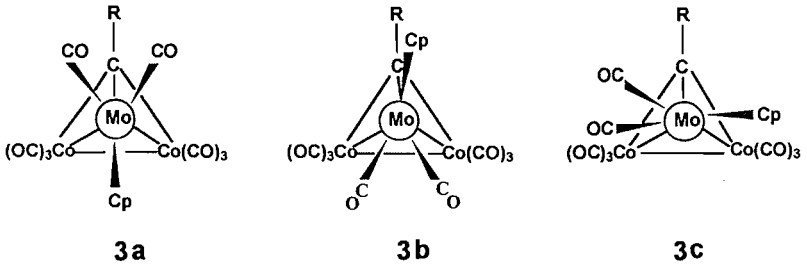

Fig. 6. X-ray crystallographically characterized clusters **12**, **14**, and **15**. Their Newman-type projections correspond to the $CpMoCo_2(CO)_8CR$ rotamers **3a**, **3b**, and **3c**, respectively, as indicated by the labels in square brackets.

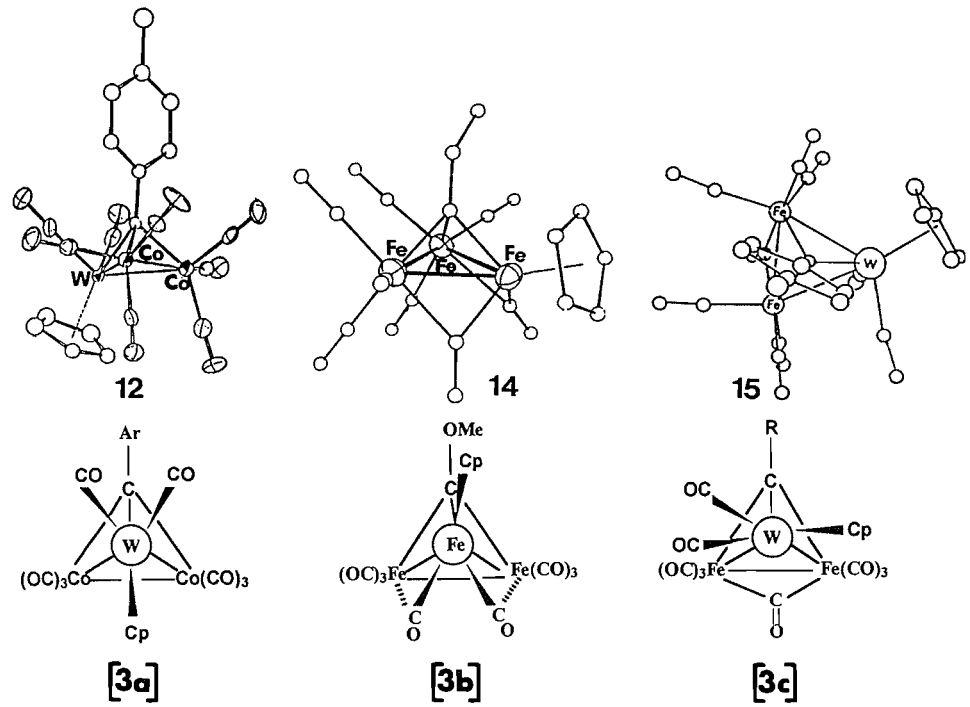

semi-bridging structures to a symmetrically bridging situation (18). Subsequently, this approach was used in an analysis of a series of organometallic derivatives of triphenylsilanol (19). Furthermore, in a study from this laboratory it has been reported that the calculated pathway for antarafacial migration of a CH_2^+ fragment between the molybdenum sites in cation clusters of the type $[Cp_2Mo_2(CO)_4(RC{\equiv}C\text{-}CR_2)]^+$ is paralleled beautifully by the available structural data on such cations (20).

To gain some understanding of the dynamic behavior of the $CpMoCo_2(CO)_8CR$ system, we therefore required several crystal structures in which the $CpM(CO)_2$ unit was oriented differently with respect to the trimetallic plane. As mentioned previously, two essentially identical X-ray structures of type **3a** have been reported (12, 13) and also one of type **3b**. Another molecule closely analogous to **13** is the $(C_5H_5)Fe_3(CO)_8C$-OMe cluster **14** reported by Aitchison and Farrugia (21), and shown in Fig. 6. Finally, we were aware of the structure of the $(C_5H_5)WFe_2(CO)_9C$-tolyl cluster **15** in which the tungsten-to-cyclopentadienyl vector is almost exactly in the plane of the metals, as in **3c** (22). The crucial parameter to note here is the angle made by the $Cp_{centroid}$–metal axis with a line joining this metal to the centre of the cobalt–cobalt (or iron–iron) vector. This angle is 125.5° in **11** and **12**, it becomes 141° in **15**, and opens up to 156°(160°) in **13**(**14**). These values are consonant only with rotation of the $CpM(CO)_2$ fragment about an imaginary line connecting the metal atom to the centre of the cluster.

To be more precise, this imaginary center "**X**" is located as follows: we see from Fig. 7 that, assuming the $CpMo(CO)_2$ vertex executes a simple rotation about the axis defined by the line **X**–Mo, the locus of the centroid of the cyclopentadienyl ring will define a circle. The lowest point "Cp_a" corresponds to structure **3a** for which the angle Cp_a-Mo-**Y** is 125.5° (in **11** and **12**), where "**Y**" is the midpoint of the cobalt–cobalt bond. The highest point "Cp_b" corresponds to structure **3b** for which

Fig. 7. Calculation of the point "**X**" in $CpMo(CO)_2Co_2(CO)_6CH$ (see text).

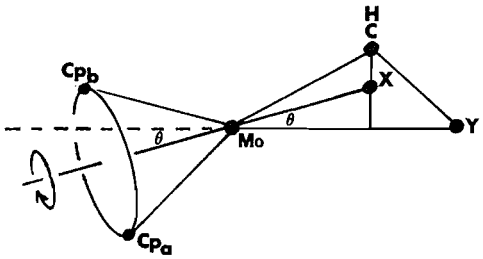

Fig. 8. Frontier orbital interactions in $CpMo(CO)_2Co_2(CO)_6CH$.

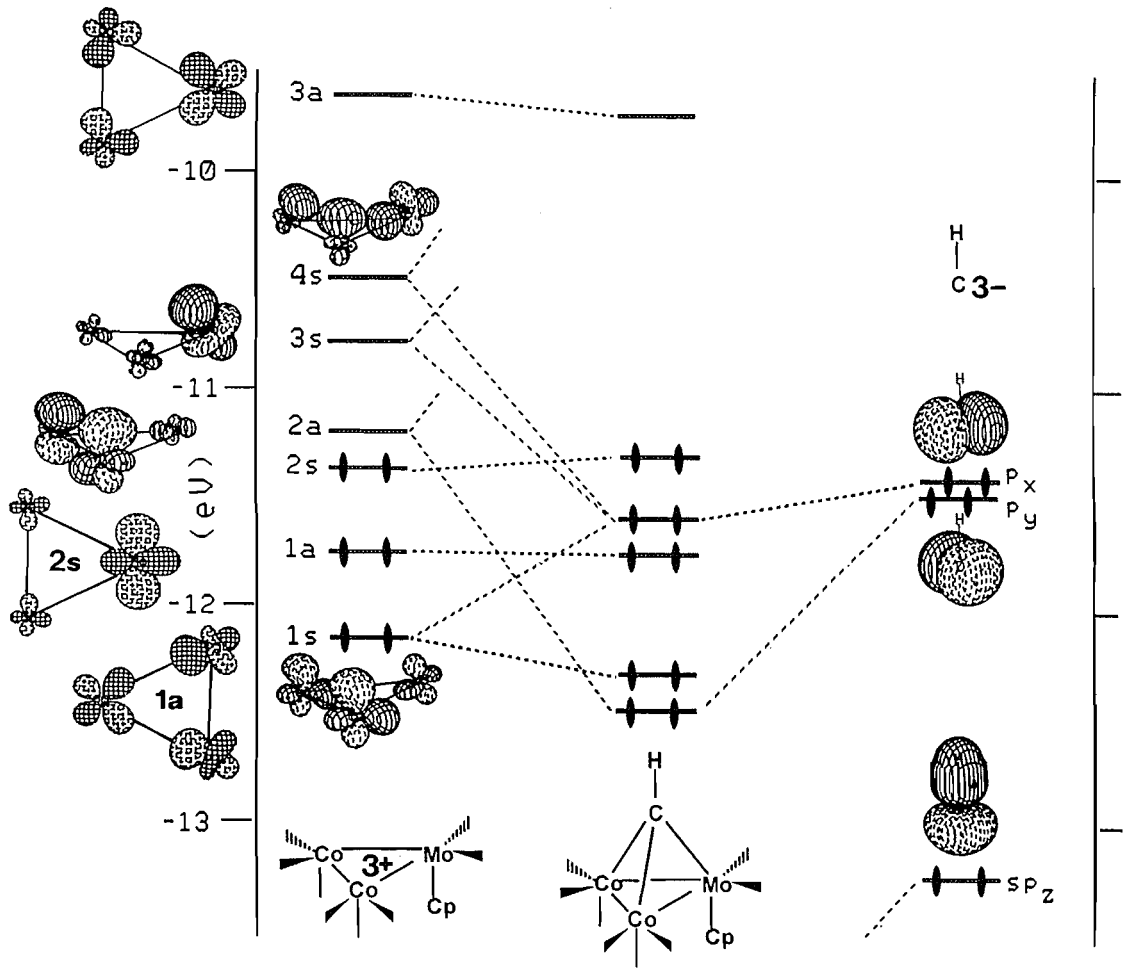


the angle Cp_b-Mo-**Y** is 156° (in **13**). The angle θ in Fig. 7 can thus be evaluated as 15.3°, and so the point **X** can be located vertically below the capping carbon atom.

Such a scenario provides support for the Wade–Mingos delocalized model of cluster bonding (23) rather than one in which there is localized bonding along the edges of the tetrahedron. As a consequence of this analysis, the energies of the rotamers derived by following the trajectory depicted in Fig. 7, i.e., from **3a** to **3b** in Fig. 5, were evaluated by using the EHMO method. The frontier orbitals of the $(C_5H_5)Mo(CO)_2$ moiety have previously been described by Schilling, Hoffmann, and Lichtenberger (24). As with the trimetallic fragments $[Co_3(CO)_9]^{3+}$, **6**, and $[FeCo_2(CO)_9]^{2+}$, **8**, discussed already, the $[(C_5H_5)Mo(CO)_2Co_2(CO)_6]^{3+}$ unit gives rise to a set of three low-lying filled frontier orbitals and also three vacant orbitals (see Fig. 8) that can readily form one σ and two π bonds with the capping carbyne moiety.

A simple rotation of the $(C_5H_5)Mo(CO)_2$ vertex while holding the rest of the molecular geometry constant yields a barrier of more than 40 kcal mol^{-1}; this value arises as a result of unfavorable steric interactions between the cyclopentadienyl and carbonyl ligands on the molybdenum with the carbonyls

attached to cobalt. However, one must recall that, while the barrier to $CpMo(CO)_2$ rotation was sufficiently large that the process becomes slow on the NMR time scale at low temperatures, local rotation of the $Co(CO)_3$ vertices continued unabated. Consequently, the calculations were repeated such that rotation of the $CpMo(CO)_2$ vertex was carried out in 15° increments and the tricarbonylcobalt fragments were each rotated independently so as to give the minimum energy conformation for each point on the curve. At this juncture, the calculated barrier plummeted to 13 kcal mol^{-1}, a value more in line with the experimentally observed barrier of ca. 10 kcal mol^{-1} (14). (It may be relevant to note that Pepermans et al. reported that the perpendicular-to-parallel rotation of the alkyne in $(HC{\equiv}CH)Co_2(CO)_6$ is a forbidden process with a suitably high activation energy barrier. However, when the cobalt carbonyls were allowed to twist concomitant with the alkyne rotation, the barrier was drastically reduced (25).) We reiterate that in the present calculation the $Co(CO)_3$ moieties maintain their local threefold symmetry and all bond lengths are unchanged. Doubtless, if the entire molecular geometry were to be energy minimized at each point of the calculation, one might then reduce this barrier even closer to the experimental value.

These data show that there is a substantial barrier to rotation of the molybdenum vertex and this must be primarily an electronic effect since any potential steric problems can be alleviated via facile rotation of the cobalt carbonyl fragments. Moreover, we note that as the rotation angle of the molybdenum vertex approaches 180°, i.e., towards structure **3b**, it is energetically favorable (to the tune of ≈2 kcal mol^{-1}) to allow the molybdenum carbonyls to become semi-bridging as has been found crystallographically for **13** (15).

In summary, it is evident that there are two strongly favored rotamers of $(C_5H_5)Mo(CO)_2Co_2(CO)_8CH$, both of which possess mirror symmetry: the molybdenum vertex may be oriented with the cyclopentadienyl group below the trimetallic plane, as in **3a**, or above and *proximal* to the carbyne as in **3b**. In the latter case, the molybdenum carbonyls adopt semi-bridging postures and this rotamer is favored when the cyclopentadienyl group is strongly electron donating, as in $(C_5Me_5)Mo(CO)_2Co_2(CO)_6CR$. There is an example of a molecule — the $(C_5H_5)WFe_2(CO)_9C$-tolyl cluster **15** — in which the vertex is rotated through 90°, but the two $Fe(CO)_3$ units are linked by a bridging carbonyl (22). This molecule would be an interesting candidate for a detailed variable-temperature NMR study.

$(C_5H_5)Mo(CO)_2$ rotation in $[(C_5H_5)Mo(CO)_2]_2C_2R_2$ clusters

The NMR fluxionality of alkyne complexes of the type $[(C_5H_5)Mo(CO)_2]_2(RC{\equiv}CR)$ was first investigated by Cotton, who noted that two independent mechanisms were operative (see Fig. 9). The lower energy process involved a pairwise interchange of a terminal carbonyl ligand environment on one molybdenum with a semi-bridging CO on the other metal. The second, and higher energy, process equilibrated the environments of the two cyclopentadienyl groups by a mechanism that must involve some degree of $CpMo(CO)_2$ vertex rotation (26). It is this latter phenomenon that we wish to address.

The dimolybdenum-alkyne clusters originally synthesized by Cotton possess a semi-bridging carbonyl ligand and this structural feature, together with the twisting of the cyclopentadienyl groups, renders the clusters asymmetric.[2] Since that time, many clusters of the type $Cp_2M_2(CO)_4(\boldsymbol{A}{\equiv}\boldsymbol{B})$ have been characterized, where M = Mo or W, and ***A*** and ***B*** are atoms or molecular fragments isolobal (28) with CH. These include systems containing such vertices as P (29), As (30), S^+ (31), O^+ (32), $Co(CO)_3$ (33), $Ir(CO)_3$ (34), etc. In particular, Sullivan and Rheingold have shown that the diarsenic cluster $[(C_5H_5)Mo(CO)_2]_2As_2$, **16**, adopts C_2 symmetry, at least in the solid state (30). Thus the two carbonyl ligands on each molybdenum in **16** are nonequivalent and so, in principle, the barrier to oscillation of the two $(C_5H_5)Mo(CO)_2$ vertices should be measurable by using variable-temperature ^{13}C NMR techniques.

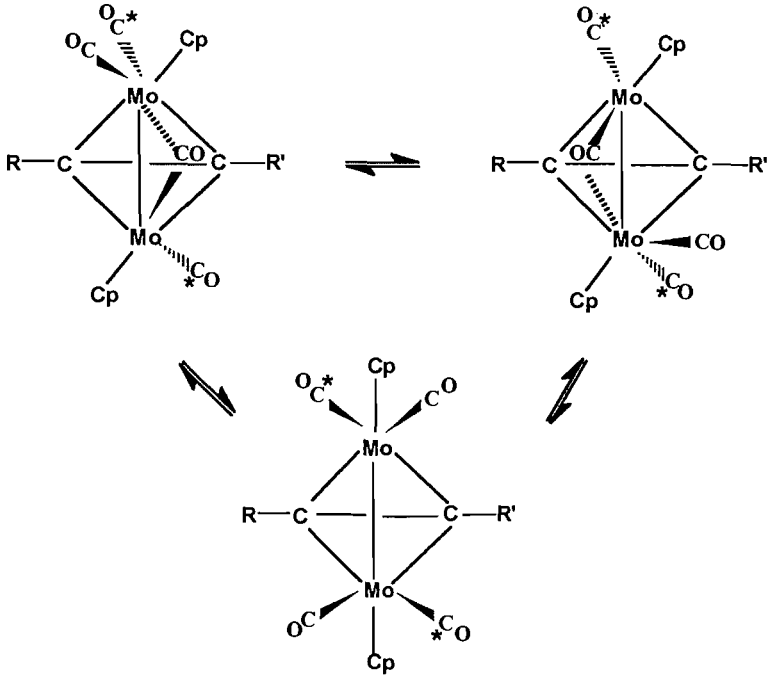
As with the molybdenum–dicobalt tetrahedral clusters discussed above, the $(C_5H_5)Mo(CO)_2$ vertices in $Cp_2M_2(CO)_4(\boldsymbol{A}{\equiv}\boldsymbol{B})$ systems can be considered to oscillate via rotation about a line joining the molybdenum to a point "**X**" within the tetrahedron. This point **X** must be positioned above the midpoint of the Mo–Mo bond along the pseudo-C_2 axis of the molecule; however, establishing its location was a nontrivial exercise and required a Bürgi–Dunitz analysis of the trajectory of the ring-centroid of the cyclopentadienyl fragment. Fortunately, since Cotton's original report (26) of the structure and fluxionality of $[(C_5H_5)Mo(CO)_2]_2(HC{\equiv}CH)$, **4**, there have been more than 20 crystallographically characterized tetrahedral clusters of the general type $Cp_2M_2(CO)_4(\boldsymbol{A}{\equiv}\boldsymbol{B})$, and selected parameters for a number of these clusters are collected in Table 1.

As shown above for $(C_5H_5)MoCo_2(CO)_8CH$ and related trimetallic clusters, the axis of rotation of the $CpMo(CO)_2$ vertex is relatively straightforward to visualize since we have crystallographic data for the two extreme structures **3a** and **3b**, both of which have C_s symmetry. Thus, the **X**–Mo axis about which vertex rotation occurs can be readily defined. Now, for molecules possessing an alkyne bonded transverse to the Mo–Mo vector, we need X-ray crystal structures for which the centroid of the cyclopentadienyl ring lies in the plane defined by the two molybdenum atoms and the midpoint of the C≡C bond. However, the crystallographic data available are all for molecules in which the cyclopentadienyl group has been twisted out of this plane. The problem then becomes one of taking the coordinates of the Cp centroids in the numerous structures of the type $[(C_5H_5)Mo(CO)_2]_2(\boldsymbol{A}{\equiv}\boldsymbol{B})$ and defining the best circle that passes through, or close to, these points.

To this end, the structures of 11 tetrahedral clusters of the type $[(C_5H_5)M(CO)_2]_2(\boldsymbol{A}{\equiv}\boldsymbol{B})$ were selected that closely fit the following criteria: (*a*) the dihedral angle between the M≡M and $\boldsymbol{A}{\equiv}\boldsymbol{B}$ vectors was ≈90°; (*b*) there were no obvious perturbing effects such as the strong bonding interaction of a molybdenum carbonyl with another vertex. This latter criterion eliminated $Cp_2Mo_2(CO)_4Ir_2(CO)_6$ (34). Thus the atomic coordinates for the molecules where $\boldsymbol{A}{\equiv}\boldsymbol{B}$ is

[2] When one of the alkyne substituents is inherently chiral, such as a terpenoid or steroidal group, then the four carbonyl ligands will always yield four ^{13}CO resonances even when all fluxional processes are rapid. At lower temperatures, one sees four ^{13}CO absorptions for each diastereomer. For some recent examples, see ref. 27.

Fig. 9. Fluxional processes that interchange semi-bridging and terminal carbonyl ligands in $Cp_2Mo_2(CO)_4(RC{\equiv}CR')$. Note the pairwise character of the terminal to semi-bridging carbonyl environments.



$RC{\equiv}CR'$, $RC{\equiv}P$, $RC{\equiv}BR'$, $RC{\equiv}Co(CO)_3$, $P{\equiv}P$, $As{\equiv}As$, $O{\equiv}Fe(CO)_3$, or $S{\equiv}Ru(CO)_3$ were entered into the molecular modelling program ALCHEMY[3] and the following parameters were evaluated for both $CpM(CO)_2$ vertices in each molecule: (*i*) the angles $Cp_{centroid}$-M-M and $Cp_{centroid}$-M-C(=O), (*ii*) the torsion angles $Cp_{centroid}$-M-M-$Cp_{centroid}$ and **Q**-**R**-M-$Cp_{centroid}$, where the dummies **Q** and **R** are the midpoints of the ***A***—***B*** and M—M bonds, respectively, as shown in Fig. 10.

As is evident from Table 1, the angles $Cp_{centroid}$-M-C(=O) average 114.3° ± 3.7° for 22 different $CpM(CO)_2$ vertices. This consistency bears witness to the fact that the $(C_5H_5)Mo(CO)_2$ or $(C_5H_5)W(CO)_2$ moiety has a remarkably well-defined geometry and may be regarded as a transferable fragment between clusters, just like the regular functional groups of organic chemistry (35). These molecules were selected as being reasonably representative of tetrahedral clusters in that the dihedral angle between the M–M and ***A***–***B*** vectors was in all cases 90° ± 5°.

In the absence of structurally characterized rotamers in which the $Cp_{centroid}$ lies in the same plane as the two molybdenum (or tungsten) atoms and the bond midpoints **Q** and **R**, it was necessary to extrapolate from the experimentally available data and then estimate a value for θ, i.e., the angle M-M-**X** illustrated in Fig. 10. The original choice of θ = 25° was then refined by use of the molecular modelling program to correlate each M-M-$Cp_{centroid}$ angle and its associated **Q**-**R**-M-$Cp_{centroid}$ torsion angle with the corresponding X-ray derived parameters; that is, the point **X** was located empirically from the crystallographic data, and the best fit is found when θ = 29°.

[3] ALCHEMY: available from Tripos associates, St. Louis, Mo.

It is interesting that the location of the axis of rotation in the dimolybdenum complexes $[(C_5H_5)M(CO)_2]_2$(***A***≡***B***) yields a value of 139° for the angle **X**-Mo-$Cp_{centroid}$. We note that the corresponding angle in the $CpMo(CO)_2Co_2(CO)_6CH$ system is 141°; this again supports the idea of transferability of organometallic vertices between different clusters.

Having established the rotation trajectory for a $CpMo(CO)_2$ vertex, it was possible to carry out EHMO calculations on the rotamers of $[(C_5H_5)M(CO)_2]_2(HC{\equiv}CH)$. We commented previously (27*b*) that racemization of such a cluster can occur either (*a*) by synchronous swivelling of both molybdenum vertices to generate a molecule of C_{2v} symmetry, as in **16** or (*b*) by rotating only one vertex so as to produce a C_s cluster, **17**, in which the cyclopentadienyl rings are oriented in a *syn* manner (see Fig. 11). In the latter case, the other vertex must subsequently swivel to generate the enantiomer of the original molecule. The calculations of the energy barriers for these two processes revealed that (*i*) the most favored rotamer does indeed possess the C_2 geometry found crystallographically for $Cp_2Mo_2(CO)_4As_2$ by Sullivan and Rheingold (30), and (*ii*) the proposed C_{2v} structure **16**, is almost certainly not attainable since it would bring the hydrogens of the cyclopentadienyl groups into direct contact. As Cotton and co-workers have noted (26), these steric constraints are the probable cause of the low symmetry observed even in the parent cluster $Cp_2Mo_2(CO)_4(HC{\equiv}CH)$.

To probe the scenario of independently rotating vertices, EHMO calculations were performed in which one $CpMo(CO)_2$ moiety was maintained at a constant orientation (ϕ) with respect to the alkyne while the other molybdenum vertex was rotated through ω values of 40°–320°. The energy profiles depicted in Fig. 12 reveal minima when the molecule

has either approximate C_2 or C_s symmetry. These calculations yield activation energy barriers of ≈15 kcal mol^{-1}, a value in reasonable accord with the experimental data (36). It is noteworthy that the height of the barrier is *extremely* sensitive to minor geometric perturbations; it is necessary to rotate the cyclopentadienyl ligands about their Cp–Mo axes so as to minimize the steric interactions between these rings at each point of the calculated pathway. Attempts to correlate the rotation barrier of the $CpMo(CO)_2$ vertex with the energy profile of any particular frontier orbital were inconclusive and the process appears to be dominated by steric factors. We reiterate that these calculations use a simple "ball-and-socket" model whereby a rigid $(C_5H_5)Mo(CO)_2$ vertex rotates about a clearly defined axis.

The level of agreement between the idealized trajectory of $CpMo(CO)_2$ rotation and the X-ray crystallographically observed structures is manifest evidence of the power of the Bürgi–Dunitz approach for our understanding of molecular dynamics. According to the basic assumptions of the structure correlation method (16), there should be a concentration of sample points (i.e., crystal structures) in the low-energy regions of three-dimensional space. One may thus identify the transition state as lying in the least densely populated stretch of the reaction path. In the present case, this is the region in which the torsion angle between the Mo–$Cp_{centroid}$ vector and the pseudo-C_2 axis approaches 0° or 180°. Figure 12 shows how the crystallographically determined structures do indeed lie primarily in the low-energy regions of the favored pathway found as a result of the EHMO analysis. Once again, it is an impressive confirmation of the Bürgi–Dunitz concept.

Concluding remarks

It is evident that the barriers to rotation of organometallic vertices in clusters, which can be experimentally determined by using variable-temperature NMR methods, are in some cases rationalizable in terms of the energies and symmetries of their frontier orbitals. In particular, the variations between clusters containing homometallic and heterometallic triangular faces can be traced to the degree of localization of the frontier orbitals on the different metallic vertices. It is also shown that use of the structure correlation technique allows the selection of reasonable pathways for fluxional processes. Vertex rotations in $FeCo_2(CO)_9S$ and in $CpMo(CO)_2Co_2(CO)_6CR$ are controlled primarily by electronic factors, and the electronically favored orientations of the organometallic units correlate with those which have been characterized by X-ray crystallography. In contrast, we have been unable to find an electronic rationale to account satisfactorily for the molecular dynamics of $[(C_5H_5)M(CO)_2]_2(HC{\equiv}CH)$ and related molecules that appear to be dominated by steric effects.

Fig. 11. Proposed mechanism of interconversion of enantiomeric clusters via C_S rather than C_{2v} intermediates.

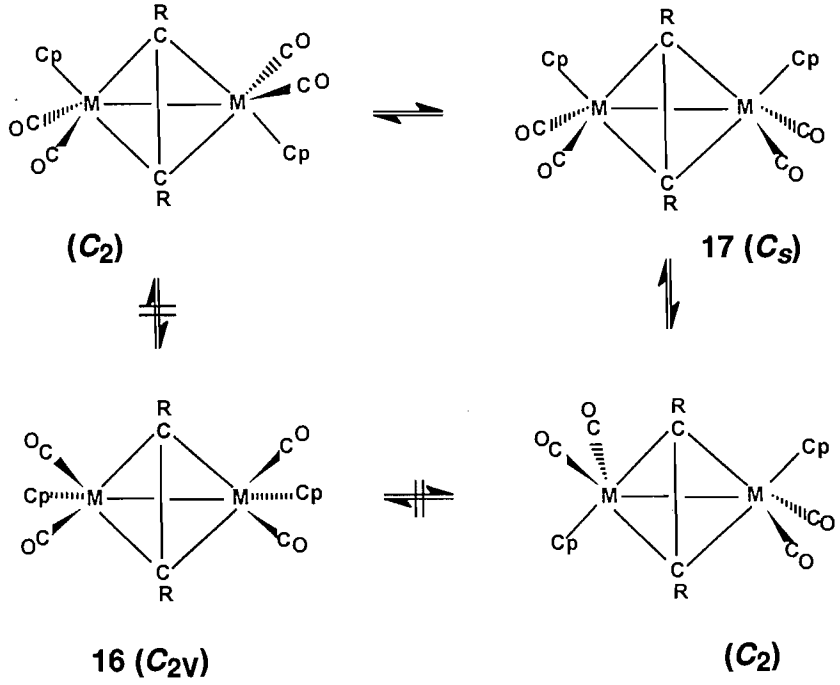

Fig. 12. EHMO-calculated energy profiles corresponding to rotation of only one molybdenum vertex through angle ω while the other $CpMo(CO)_2$ fragment is kept constant, with successive ϕ values ranging from 120° through 145°. The majority of the experimentally observed structures lie in the valleys, and the molecules are numbered as in Table 1.

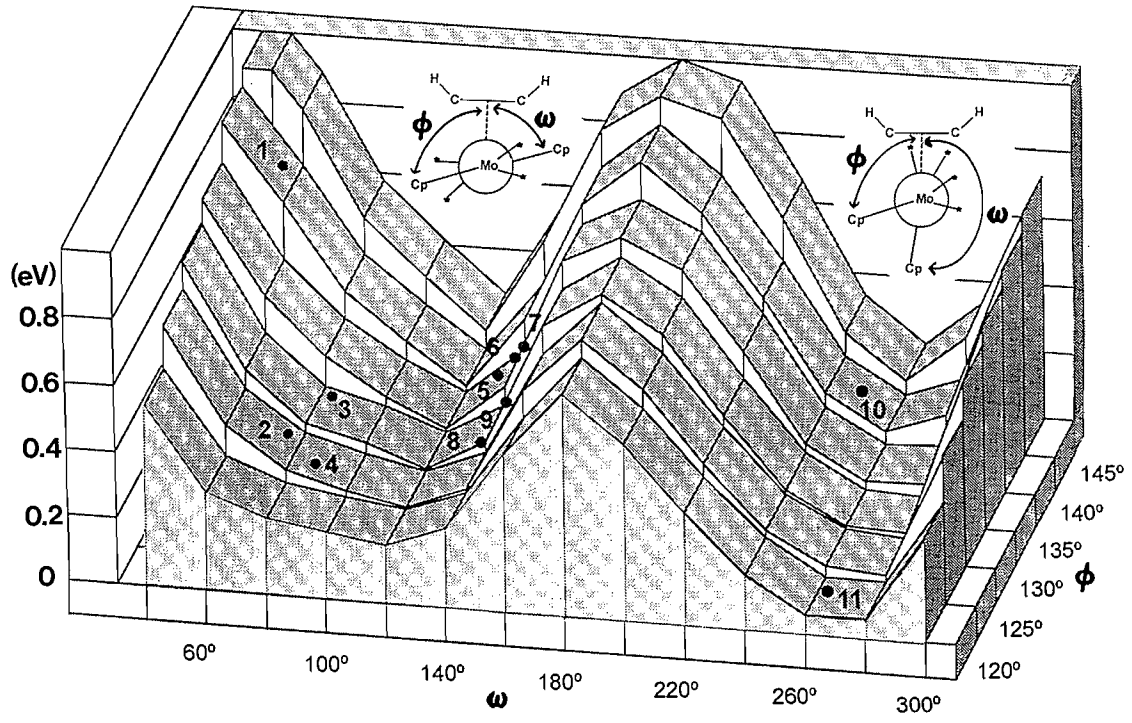

The correlation of X-ray data and fluxional behavior for closely related organometallic clusters could be applied to other situations. An example that could be well worth pursuing is the $RCCo_3(CO)_9$ series of which many have been crystallographically characterized (37). The rotation angles of the $Co(CO)_3$ tripods may tell us whether the intermetallic scram-

bling of the CO ligands over all the metal sites is correlated with rotation of the $Co(CO)_3$ vertices.

Experimental section

Molecular orbital calculations were performed via the extended Hückel method using weighted H_{ij}'s (38); orbital drawings were obtained by use of the program CACAO (39).

On the accuracy of density functional theory for ion–molecule clusters. A case study of PL_n^+ clusters of the first and second row hydrides

Xabier Lopez, Jesus M. Ugalde, Cecilia Sarasola, and Fernando P. Cossio

Abstract: PL_n^+ clusters (n = 1, 2 and L = NH_3, OH_2, FH, PH_3, SH_2, ClH) in both their triplet and singlet states have been characterized by common approximate density functional methods, SVWN, BVWN, BLYP, and B3LYP. The phosphorus–ligand distances (R), dissociation energies (D_0), triplet–singlet gaps (Δ_{t-s}), and several bond properties, such as the electron density ($\rho(r_c)$), the Laplacian ($\nabla^2\rho(r_c)$), and the local energy density $H(r_c)$ at the bond critical point, were compared with those obtained by accurate ab initio molecular orbital theory, namely, second-order Møller–Plesset (MP2) and G2 theory. In general, it is observed that the local spin density approximation (SVWN) yields stronger bonds than ab initio molecular orbital theory. However, addition of gradient corrections to the exchange functional (BVWN) yields ion–molecule bonds that are too weak. Finally, taking account also of gradient corrections to the correlation functional (BLYP) leads to very close agreement with ab initio results. Among these functionals, Becke's hybrid functional, B3LYP, best fit the second-order Møller–Plesset and G2 data, reproducing the qualitative trends observed for the above-mentioned properties of phosphorus clusters, except for $\nabla^2\rho(r_c)$. This fit is particularly good for distances, dissociation energies, and electron densities at the bond critical point, and both methods show similar deviations of the values of binding energies and triplet–singlet gap with respect to the G2 data. Compared with our most accurate ab initio molecular orbital data, namely G2, significant overbinding for the singlets, larger for one-ligand than for two-ligand complexes, and significant overestimation of the triplet–singlet gap for one-ligand complexes is observed for both methods, namely, B3LYP and MP2. The deviations at the second-order Møller–Plesset level of theory are mainly due to the lack of quadratic configuration interaction (QCI) corrections, and this deficiency is also present to some extent in B3LYP. However, for larger clusters these corrections are smaller, therefore the B3LYP functional is expected to lead to accurate descriptions.

Key words: DFT, Bader analysis, G2, ion–molecule complexes, phosphorus.

Résumé : Faisant appel aux méthodes de densités fonctionnelles SVWN, BVWN, BLYP et B3LYP, on a caractérisé les agrégats PL_n^+ (n = 1 et 2 et L = NH_3, OH_2, FH, PH_3, SH_2, et ClH) dans les états tant triplet que singulet. Les distances phosphore coordinat (R), les énergies de dissociation (D_0), les écarts triplet–singlet (Δ_{t-s}) et plusieurs autres propriétés, telles que la densité électronique ($\rho(r_c)$), le laplacien ($\nabla^2\rho(r_c)$) et la densité locale d'énergie $H(r_c)$ au point critique de liaison ont été comparées avec celles obtenues avec de calculs d'orbitales moléculaires ab initio plus précis, à savoir ceux aux niveaux G2 de la théorie et d'autres de Møller–Plesset du deuxiéme ordre (MP2). En général, on a observé que, par comparaison avec les valeurs obtenues par des calculs d'orbitales moléculaires au niveau de la théorie ab initio, celles obtenues par l'approximation de la densité locale de spin (SVWN) conduit à des valeurs plus élevées pour les forces de liaisons. Toutefois, l'addition de corrections de gradients à l'échange fonctionnel (BCWN) conduit à des liaison ion–molécule qui sont trop faibles. Enfin, si l'on essaye aussi de tenir compte des corrections de gradient dans la corrélation fonctionnelle (BLYP), on arrive à de très bons accords avec les calculs ab initio. Parmi ces corrélations fonctionnelles, le fonctionnelle hybride de Becke, B3LYP, est celle qui s'accorde le mieux avec les donnés de Møller–Plesset du deuxième ordre et de G2 en reproduisant les tendances qualitatives observés pour les propriétés mentionnées plus haut pour les agrégats du phosphores, à l'exception du $\nabla^2\rho(r_c)$. Cet accord est particulièrement bon pour les distances, les énergies de dissociation et les densités électroniques au point critique de la liaison et, par rapport aux données G2, les deux méthodes présentent des déviations semblables pour les valeurs des énergies de fixation et pour l'écart triplet–singulet. Si l'on compare nos résultats avec les données les plus précises d'orbitales moléculaires ab initio, soit G2, on note des surfixations importantes pour les singulets qui sont plus importantes avec les complexes à un coordinat que pour ceux à deux coordinats; avec le deux méthodes, soit B3LYP et MP2, on observe aussi une surévaluation importante de l'écart

triplet–singulet pour les complexes à un coordinat. Les déviations au niveau de la théorie de Møller–Plesset du deuxiéme ordre sont principalement dues à un manque de corrections pour l'interaction quadratique de configuration (IQC) et cette déficience se retrouve aussi, jusqu'à un certain point, dans B3LYP. Toutefois, pour les agrégats plus volumineux, ces corrections sont plus petites et on peut s'attendre à ce que la fonctionnelle B3LYP conduise à des descriptions précises.

1. Introduction

The elucidation and characterization of ionic clusters has been the subject of several theoretical and experimental studies over the last decade (1, 2). Because clusters constitute a bridge between the gas and condensed phases, the study of the formation of cluster ions is relevant to an understanding of such phenomena as nucleation, the development of surfaces, catalysis, solvation, acid–base chemistry, combustion, and atmospheric processes. Clusters are also of great theoretical interest, since a variety of bonds can coexist in the same molecular structure. The majority of common interactions inside a molecule fall more or less into three kinds of interaction: ionic, covalent, or van der Waals (the hydrogen bond could be considered as a special case of van der Waals interactions). The ion–molecule bond of an ionic cluster could be due to any of these interactions, and normally a mixture of them is present. Also, transitions between different kinds of interaction can occur as the clusters grow up, i.e., as the number of ligands attached to the ion increases. Thus, covalent bonds are often characteristic of small clusters, while electrostatic interactions dominate for larger clusters. Undoubtedly, this also depends on the nature of both the ligand and the ion. Soft ligands favor covalent interactions over electrostatic ones, while the opposite is found for hard. Also, open-shell ions tend to favor electronic over electrostatic interactions, since empty orbitals of low energy are available. Apart from electrostatic and covalent binding, van der Waals and hydrogen bonds can also be found, especially when the first solvation shell is completed, and new ligands are bound to the ligands on the first solvation shell. Due to these features, much interest has been focused on the determination of bond properties, such as binding energies and distances, as a function of the size of the clusters, the nature of the ligand, and the hardness of ion involved in the cluster structure.

Inclusion of electron correlation (3–6), at least at the MP2 level, is essential to describe the bonds in such systems, and normally the use of a large basis set is necessary to yield accurate binding energies. This makes the computational cost too expensive. This is especially true in the determination of properties that involve large systems, i.e., determination of magic numbers (maximum number of ligands that the ion admits in its first solvation shell) or the effect of the second coordination shell. In these cases, we have to build up large clusters, which means dealing with a large number of electrons. It is a problem for conventional ab initio methods to treat such large systems, at least with a proper degree of accuracy. Density functional theory (7–11) (DFT) can be a promising alternative to these methods. For a wide range of systems DFT has been found to yield properties (geometries, dissociation energies, and frequencies) comparable in quality to the MP2 results (11). Also, it has been established that DFT yields accurate reaction energies for several chemical processes (12–14), when appropriate nonlocal gradient corrections are included. DFT is computationally less demanding than MP2 or other ab initio methods that include electron correlation, especially for large systems. Thus, these systems could in principle be treated within the framework of DFT with large basis sets, extending the range of clusters amenable to study at an assumable computational cost. However, it is not known how DFT works with ionic clusters. Good results have recently been reported for hydrogen bond systems (15–18), hydrated proton clusters (19), proton transfer systems (20), and some ion–molecule complexes (21) when nonlocal gradient corrections are considered. It would be interesting to compare results between highly accurate ab initio calculations and DFT for different ion–molecules, in order to assess the reliability of DFT for such systems.

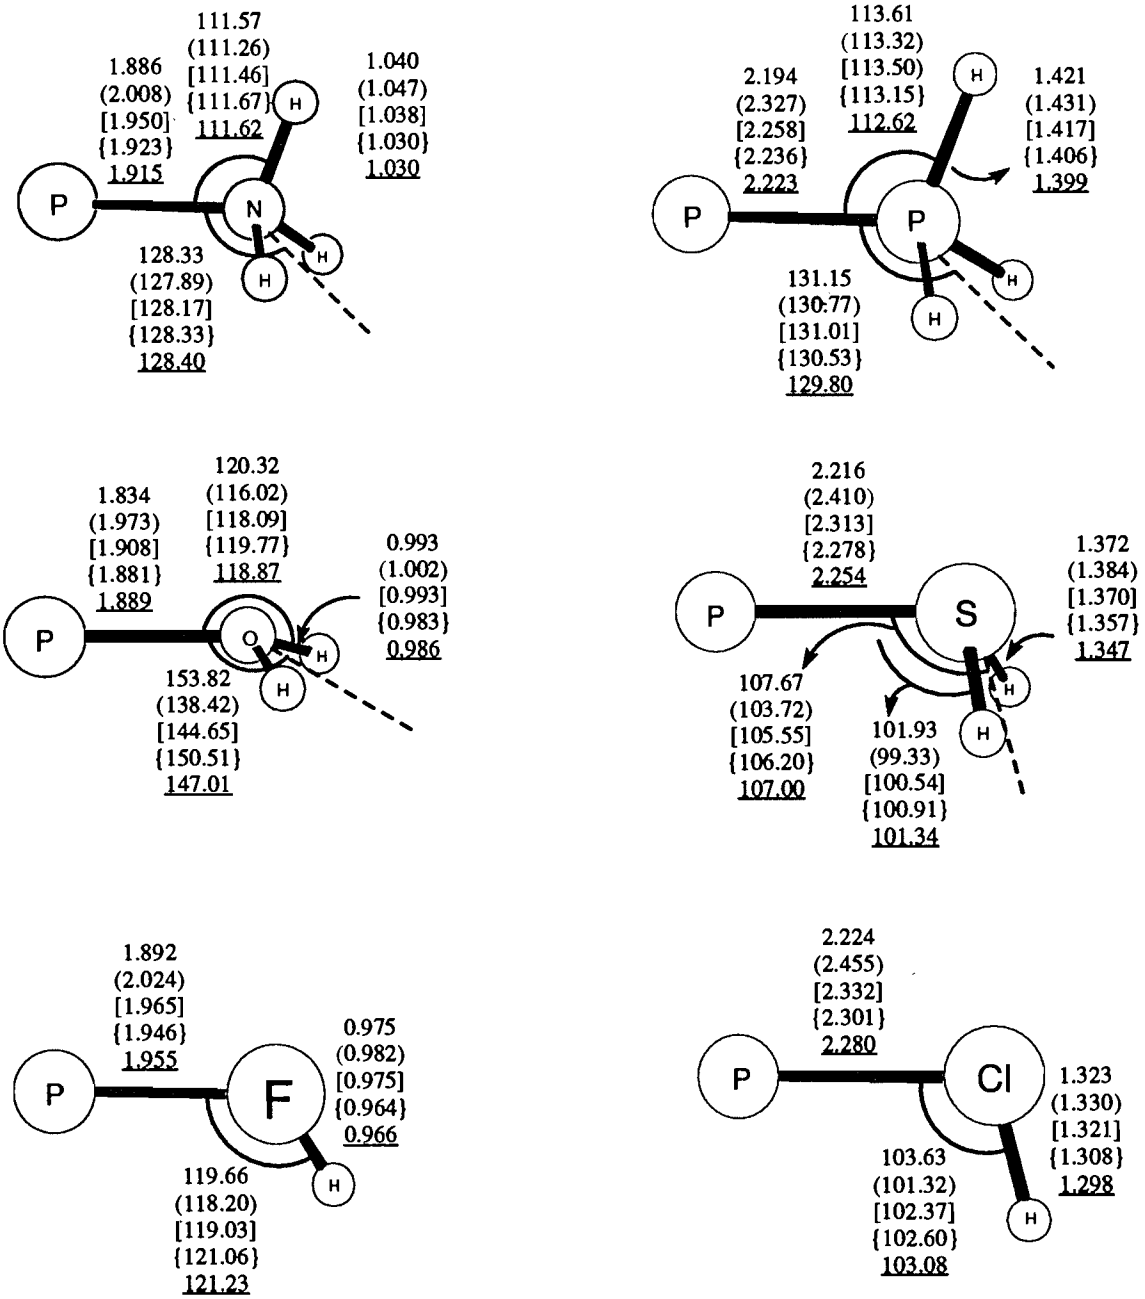
We have tested the quality of DFT methods for the description of ionic clusters, by making a comparative study of the previous (22–24) ab initio characterized PL_n^+ clusters (n = 1, 2; L = NH_3, OH_2, FH, PH_3, SH_2, and ClH), for both their singlet and triplet states. Binding energies, ion–molecule bond distances, and bond properties of the bond critical points were characterized using high accuracy ab initio methods (G1 and G2 methodologies (25–27)). Depending on the spin state of the phosphorus, the hardness of the ligand, and the number of ligands bound to the P^+, different kinds of bond were obtained, from covalent to electrostatic. In this paper, we have recalculated the abovementioned properties, employing four different DFT methods (28–32): SVWN, BVWN, BLYP, and B3LYP. We have considered the local spin density approximation in its SVWN form, and have progressively added nonlocal gradient corrections, firstly, only to the exchange, thus BVWN functional, and then to both exchange and correlation with the BLYP functional. We have also applied the hybrid B3LYP functional, which has been proven to yield accurate results for a wide range of chemical systems.[2] It is the aim of this paper to compare the DFT results with the previous ab initio results, in order to test the reliability of DFT in describing such systems, and the accuracy expected for different types of complexes: singlet and triplet spin states, one- and two-ligand complexes. This will provide us with the necessary information about the quality of DFT and, hopefully, will permit us to treat clusters of higher numbers of ligands in future studies.

2. Methods

All the calculations reported here were carried out using the GAUSSIAN92/DFT (33) suites of programs. In the density

[2] See supplement on DFT in Gaussian 92 manual.

Fig. 1. Geometries of the triplet one-ligand complexes calculated at the SVWN, BVWN (in parentheses), BLYP (in square brackets), B3LYP (in curly brackets), and MP2 (underlined) levels of theory, using the 6-31G(d) basis set. Distances are in Å, and angles in degrees. MP2 values have been taken from ref. 24.



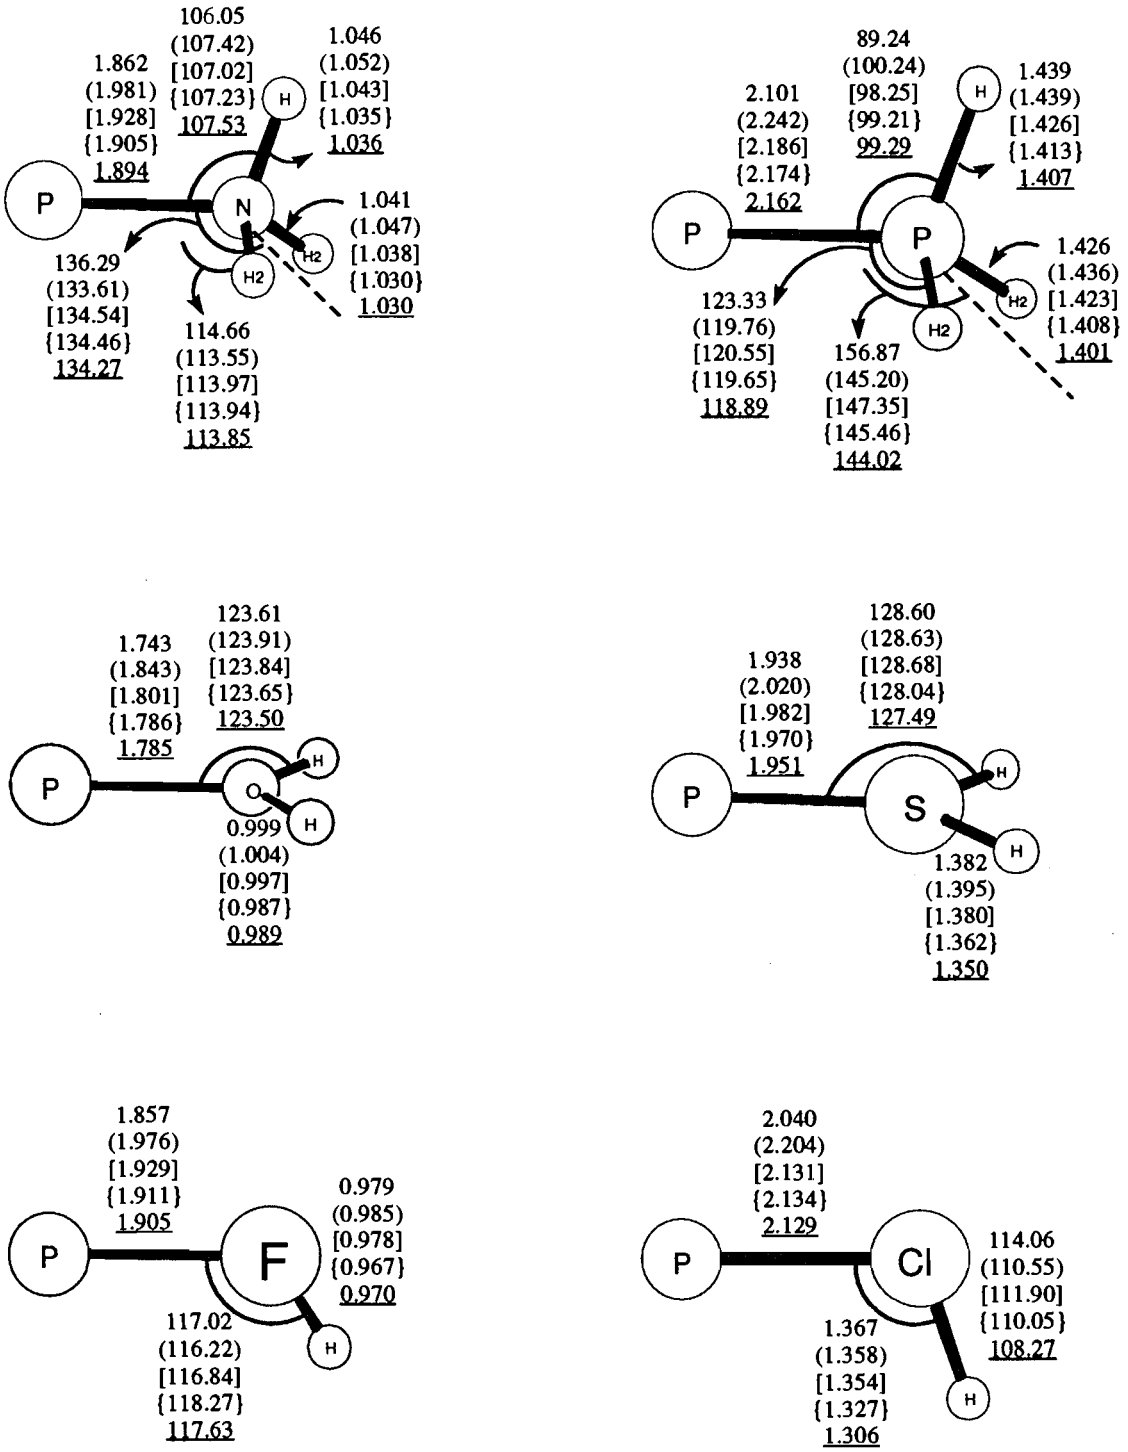
functional theory (DFT) calculations, the Coulombic and the exact exchange integrals were computed analytically and the integrals over the exchange and the correlation functionals were evaluated over numerical grids. Four functionals were employed: (*i*) The SVWN functional, thus, the Slater exchange (28) (local spin density approach, LSDA) and the local correlation of Vosko, Wilk and Nusair (29) (VWN). (*ii*) The BVWN functional, which adds Becke's 1988 exchange functional correction (30). (*iii*) The BLYP functional, which comprises this last Becke's correction plus the gradient-corrected correlation functional of Lee, Yang and Parr (31) (LYP). (*iv*) Finally, we also used the hybrid method consisting of Becke's three-parameter functional (32) in the form

$$[1] \qquad (1-a_0)E_x^{\mathrm{LSDA}}+a_0E_x^{\mathrm{HF}}+a_xE_x^{\mathrm{B88}}+a_cE_c^{\mathrm{LYP}}+(1-a_c)E_c^{\mathrm{VWN}}$$

the values of the parameters being $a_0 = 0.20$, $a_x = 0.72$ and $a_c = 0.81$.

All structures were optimized at the DFT/6-31G(d) level of theory (where DFT is SVWN, BVWN, BLYP, and B3LYP). (For notation of the basis sets see ref. 34.) The optimized geometries, along with the previously obtained MP2 values, can be found in Figs. 1–5. Analytical frequencies at the stationary points were calculated at the DFT/6-31G(d) level of

Distances are in Å, and angles in degrees. MP2 values have been taken from ref. 24.



theory and all of them were found to be positive. At these optimized geometries single-point energy calculations with an extended basis set, 6-311+G(3df,2p), were carried out. We recall that this basis set is the largest one employed in G2 theory (25–27). These energies were corrected by the zero point vibrational energy (ZPVE) corrections, evaluated at the DFT/6-31G(d) level of theory. The total energies calculated in this way were employed to evaluate the dissociation energies (D_0) of the PL_n^+ clusters, which are defined as the energy difference between the ion–molecule complexes and their monomers in the appropriate spin state, thus:

[2] $$(D_0)_{PL_n} = -[(E_{PL_n} - (E_{PL_{n-1}} + E_L))]$$

The calculated binding energies for one- and two-ligand com-

[a]Notice that when triplet is the ground state the gap takes negative values, whereas positive values are obtained when singlet is the ground state.

[b]Values taken from ref. 24.

plexes have been collected in Table 1. These energies have been also used to evaluate the triplet–singlet gap, which is given in Table 2.

The previously obtained MP2 and G2 values for D_0 and Δ_{t-s} have also been reported in Tables 1 and 2, for comparison with DFT. We recall that G2 energy is the result of several additive corrections made to the MP4/6-311G(d,p)//MP2/6-31G(d) base level energy, which accounts for the deficiencies of this energy in the treatment of basis set and electron correlation. One of these corrections, QCI, has also been reported, since, as we shall see below, it accounts for the main differences between MP2 and G2 dissociation energies, and makes a significant contribution to the differences for Δ_{t-s}. These will be found in Table 6. We note that these corrections are calculated as:

[3] $$\Delta E^{QCI} = [QCISD(T)/6\text{–}311G(d,p)] - [MP4/6\text{–}311G(d,p)]$$

We also carried out Bader's topological analysis (35–38) of the electron density ($\rho(\boldsymbol{r})$), for all the DFT methods, using the AIMPAC series of programs (39), based on the DFT/MC-311G(d,p)//DFT/6-31G(d) electron densities. We will focus on the values of various properties at the bond critical points, such as the electron density ($\rho(r_c)$), the Laplacian ($\nabla^2\rho(r_c)$), and the energy density ($H(r_c)$). These values, along with those for MP2, are given in Tables 3, 4, and 5, respectively.

For the comparison between these methods of certain properties, we will consider the mean deviation between them for a given property. These deviations have been calculated by the sum of absolute differences between two given methods over values obtained for all the clusters, divided by the total number of clusters. We will use the following abbreviation to refer to them: ΔX_j^i is the average deviation of "i" method values with respect to "j" method values for a given property X.

3. Results and discussion

3.1 Geometries

Both MP2 and DFT describe structures with intramolecular parameters similar to those of the free molecules, while ion–molecule distances vary greatly depending on the nature of ligand, the number of ligands, and the spin state of phosphorus atom. The DFT structures, irrespective of the functional employed, show the same trends and symmetries as the MP2 ones, the only exception being triplet $P(PH_3)_2^+$ (Fig. 5). In that sense, one-ligand complexes show shorter P—X distances for the singlets than for the triplets, encountering the largest triplet–singlet difference for P—O and P—S bonds within first- and second-row ligands, respectively. Also, changes in the symmetry point group of the complexes on going from triplets to singlets are similar for DFT and MP2. Thus, PXH_3^+ systems change from C_{3v} to C_s and PXH_2^+ from C_s to C_{2v}. It should be noted that in some cases HF and MP2 point groups were in disagreement; for instance, HF predicted as C_{2v} triplet $P(OH_2)^+$ and a C_s singlet $P(SH_2)^+$. Two-ligands complexes, except for triplet $PH_3)_2^+$, show the same tendencies with DFT and MP2 methods. Thus, the two ligands are equivalent for two-ligand complexes, but while linear complexes of large P—X distances are found for triplet complexes, singlets show angular structures with P—X distances much shorter and closer to the values of the one-ligand complexes. It should also be mentioned that the HF method described a situation of unequivalent ligands for triplet $P(NH_3)_2^+$ and triplet $P(SH_2)_2^+$. The exception in this DFT–MP2 agreement is observed for the description of the P—O and P—F bonds of triplet complexes. While MP2 describes a P—F bond larger than the corresponding P—O bond SVWN, BVWN, and BLYP describe the reverse situation. In this case, the only functional in concordance with MP2 is the hybrid B3LYP functional.

Apart from the good qualitative agreement between DFT and MP2 structures, the quantitative agreement is strongly functional dependent. SVWN tends to give longer ion–molecule bonds than MP2. The inclusion of nonlocal gradient corrections to the exchange functional, the BVWN functional, shorten the bonds, but too much compared with MP2,

[a]Values taken from ref. 24.

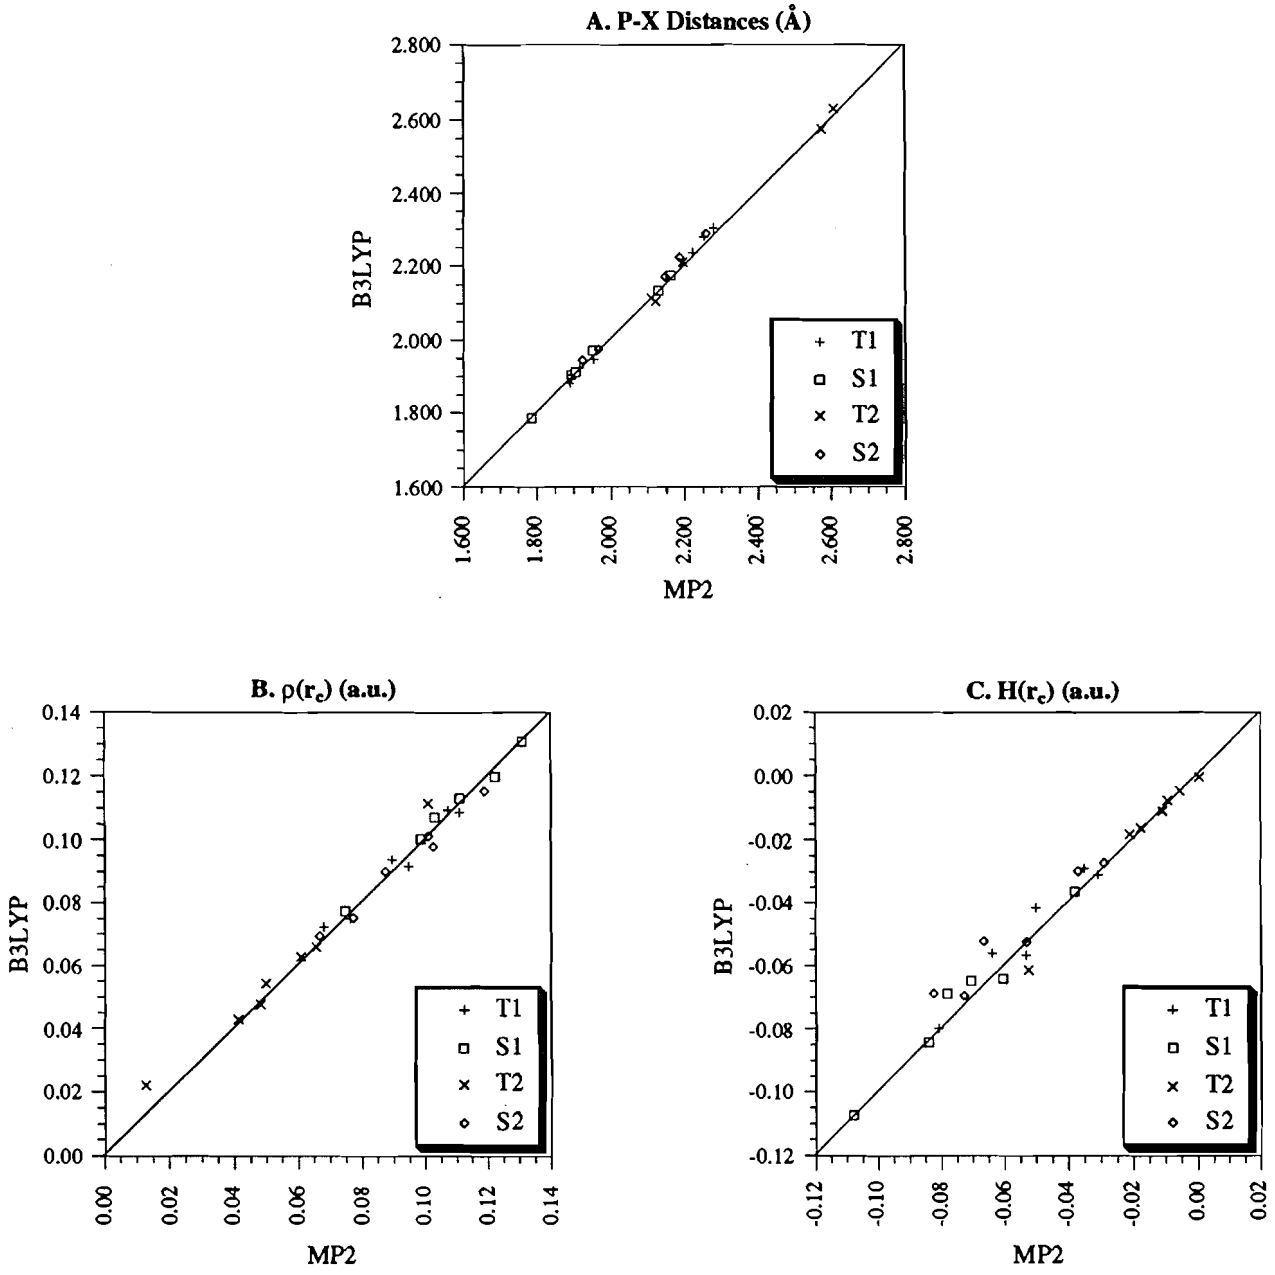
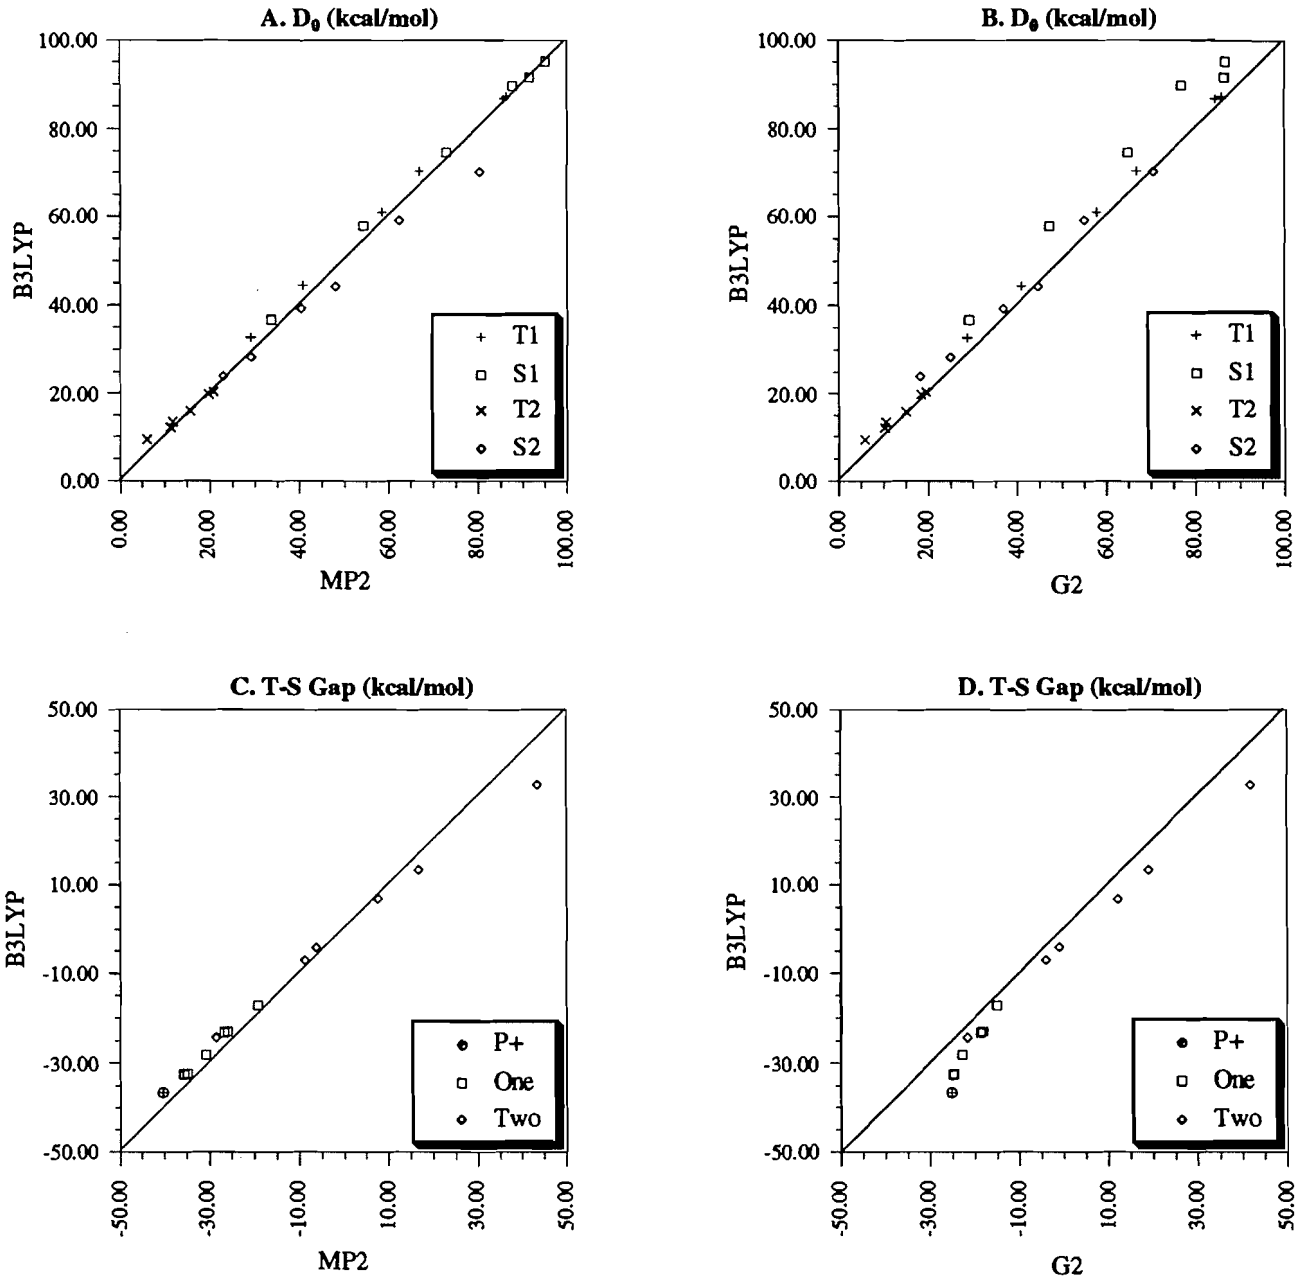
Fig. 6. Plots of the values of P—X distances (*A*), electron density at the P—X bond critical point (*B*), and energy density at the P—X bond critical point (*C*) calculated at B3LYP versus those calculated at MP2. T and S refer to triplet and singlet complexes, respectively, and 1 and 2 to one- and two-ligand complexes. In plot *A*, the data for the anomalous triplet $P(PH_3)_2^+$ have been omitted.



despite the fact that the absolute differences are now diminished. Inclusion of nonlocal gradient corrections to both the exchange and correlation in its BLYP form balances this situation, giving values in quantitative agreement with the MP2 values. The ΔR_{MP2}^{BLYP} is 0.042 Å, without taking into account the anomalous case of triplet $P(PH_3)_2^+$. B3LYP shows a significant improvement of these data and ΔR_{MP2}^{B3} is 0.013 Å. The magnitude of this deviation is maintained quit constant throughout the series, although we are dealing with a great variety of P—X distances and P—X bond types. This can be observed from inspection Figure 6*A*, in which R_{MP2} are plotted versus R_{B3} values. A good fit is obtained for any kind of complex, whether triplet or singlet, or one- or two-ligand complexes. It should also be mentioned that, in general, there is a tendency for the BLYP and B3LYP methods to describe slightly longer bonds than do MP2 methods.

As mentioned, triplet $P(PH_3)_2^+$ constitutes a special case. Its geometries calculated at the different levels of theory can be found in Fig. 5. Contrary to the findings described above, DFT an MP2 describe structures with substantial differences (see Fig. 5). As well, each functional shows different symmetries, except BLYP and B3LYP, which show similar structures. Thus, at the MP2 level of theory (Fig. 5*a*), triplet $P(PH_3)_2^+$ is a linear complex with one ligand strongly bound to the phosphorus, while the other lies at a much greater distance. Instead of that, SVWN describes an angular structure

Fig. 7. The top two charts depicted plots of the dissociation energies calculated at the B3LYP versus those calculated at MP2 (*A*) and G2 levels of theory (*B*). T and S refer to triplet and singlet complexes, respectively, and 1 and 2 to one- and two-ligand complexes. In the bottom two charts, plots of the triplet–singlet gap for B3LYP versus MP2 (*C*) and G2 (*D*) values can be found for phosphorus cation (P^+), one-ligand clusters (One), and two ligand clusters (Two).



with unequivalent ligands (Fig. 5*b*), but the difference in ion–ligand distance has now decreased to a large extent. BVWN methods describe a linear complex, but with both ligands similarly linked to phosphorus (Fig. 5*c*). BLYP and B3LYP structures are angular with an angle close to 100°. However, as in MP2, one ligand is strongly bound to phosphorus, while the other lies at much longer distances, describing a similar kind of complex for the three methods despite the large difference in the PPP angle.

In summary, DFT geometries show excellent agreement with MP2 ones, when the proper nonlocal gradient corrections are used. Our results for B3LYP show similar values to those for MP2. Triplet $P(PH_3)_2^+$ constitutes the only exception, although a similar kind of complex is described by the BLYP, B3LYP, and MP2 methods.

3.2 Dissociation energies

The dissociation energies calculated with the SVWN, BVWN, BLYP, and B3LYP functionals and the MP2 and G2 methods, along with the QCI energy corrections involved in the G2 method can be found in Table 1. Plots of the B3LYP dis-

sociation energies versus their corresponding MP2 and G2 values are shown in Figs. 7*a* and 7*b*, respectively. Inspection of Table 1 reveals that the SVWN dissociation energies are much larger than their corresponding accurate G2 values. Allowing for gradient corrections in the exchange functional only (BVWN functional) weakens the ion–molecule bonds, hence the calculated D_0 values are now lower than those obtained at the G2 level of theory. Nevertheless, when gradient corrections are implemented for both the exchange and electron correlation functionals (BLYP and B3LYP) the dissociation energies show better agreement with G2 values. In particular, it is worth noting that the average deviation of the B3LYP D_0's with respect to those for MP2 is only 2.17 kcal/mol. However, the average deviation of the B3LYP dissociation energies with respect to the G2 ones is worse, $\Delta D_0^{B3}{}_{G2} = 4.30$ kcal/mol, with the general tendency of the B3LYP to overestimate the G2 dissociation energies although this is strongly dependent on the spin multiplicity and the number of ligands of the cluster. Thus, B3LYP D_0's for the triplets and two-ligand complexes are closer to their corresponding G2 values than singlets and one-ligand complexes, respectively. Remarkably, the same observation is also true for the comparison between the MP2 and G2 dissociation energies. This fact points to the QCI energy corrections as the main source of discrepancies between the MP2, and consequently the B3LYP, and the G2 dissociation energies, for the G2 empirical energy corrections cancel exactly between the two terms of the left-hand side of eq. [2]. Indeed, if both the MP2 and B3LYP dissociation energies are added to the QCI energy correction values of the G2 method, we obtain dissociation energies that lie within 1.5 kcal/mol error bar with respect to the G2 values, for both singlet and triplet complexes, irrespective of whether they have one or two ligands. Recall that we have used the largest G2 basis set, namely the 6-11+G(3df,2p), for the calculation of the dissociation energies within the density functional theory. QCI energy corrections to the total energy of the ions studied in this paper are collected in Table 6.

With the previous comments in mind, we will now discuss each kind of complex (one- and two-ligand, triplet and singlet) separately. Both the quantitative agreement and qualitative common patterns among the various methods used to evaluate the dissociation energy will now be analyzed.

3.2.1 Triplet one-ligand complexes

Let us comment first on the agreement between the MP2 and G2 methods. For triplet one-ligand complexes, MP2 and G2 values match each other reasonably well. Even for phosphine, the worst case, the difference is 1.51 kcal/mol, and for any of the other ligands is less than 1 kcal/mol. Hence, ΔD_{G2}^{MP2} is small, namely, 0.58 kcal/mol. Taking into account that G2 has been proven to yield values in accordance with experimental data by 2 kcal/mol for many chemical systems, we can conclude that MP2 seems to describe these systems properly. This good concordance can be easily understood bearing in mind the comments outlined above. Thus, QCI corrections to the D_0's are small (see Table 1), namely, less than 0.5 kcal/mol in all cases, and consequently a good agreement between MP2 and G2 should be expected.

B3LYP fits G2 data worse than does MP2, with ΔD_{G2}^{B3} 3.03 kcal/mol and ΔD_{MP2}^{B3} 2.51 kcal/mol. However, these results should be regarded as reasonably good matching, since discrepancies with respect to G2 values are always maintained below 4 kcal/mol and the same trends are reproduced by B3LYP and G2 methods for the ligand dependency. The deviation with respect to G2 values increases as we move to the right within each row in the periodic table. In that sense, the best agreement is found for XH_3 systems, and the worst for XH. It should also be taken into account that for these complexes BLYP produces results of similar accuracy to B3LYP and that, despite the bad quantitative results of the SVWN and BVWN functionals, they show the same trends for ligand dependency as the other methods.

[a]Values taken from ref. 24.

3.2.2 Singlet one-ligand complexes

As mentioned earlier, the dissociation energies of singlet states do not compare as well with the G2 ones as those of triplets. There is a marked tendency for both MP2 and B3LYP methods to overbind the ion–molecule complexes with respect to the G2 level of theory, hence ΔD_{G2}^{MP2} and ΔD_{G2}^{B3} are significantly larger, namely, 7.41 and 9.03 kcal/mol, respectively, for the singlet one-ligand complexes. The worst fit to G2 data within each row is observed for XH_2 ligands, being even larger than 10 kcal/mol for SH_2 in both methods. Despite this augmented discrepancy, the accord between MP2 and B3LYP remains, leading to a similar value of the ΔD_{MP2}^{B3} as for the triplets, namely, 1.73 kcal/mol. A substantial part of the enhanced deviation between MP2 and G2 data origi-

nates in the augmented QCI corrections, which are now quite important in contrast with the case for triplet states. These corrections, see Table 1, are largest for XH_2 ligands, 6.50 and 7.19 kcal/mol for OH_2 and SH_2, respectively. This discrepancy is also observed for the B3LYP method, leading to similar trends in the G2–B3LYP discrepancies as in MP2.

In spite of these enhanced deviations, both MP2 and B3LYP reproduce the same trends as the G2 method. In this sense, binding energies increase for all ligands when we go from triplets to singlets, decrease as we go to the right through the periodic table, and larger binding energies are found for second-row hydrides than for first-row ones. However, these trends are not always reproduced by the other functionals. For instance, SVWN, BVWN, and BLYP produce larger binding energies for SH_2 than for PH_3, and for some complexes SVWN, BVWN, and BLYP show larger binding energies for the triplets than for the singlets (see Table 2). Discrepancies also appear if we compare the relative strength of the P—X bond of first-row hydrides with that of the analogous second-row ones. B3LYP, MP2, and G2 binding energies for second-row ligands are larger than for the first-row ones, even though the G2 difference is very low for XH_3 ligands. However, this is not always true for SVWN, BVWN, and BLYP functionals. These facts suggest that B3LYP is the only functional that reproduces the trends of the G2 method, despite the significant overbinding mentioned.

The anomalous results obtained for the singlet $P(OH_2)^+$ should also be mentioned. In this case, the largest binding energy among DFT methods is obtained for the B3LYP functional, namely 74.63 kcal/mol, which compares fairly well with that obtained at the MP2 level of theory, 72.89 kcal/mol, but not so well with the 64.84 kcal/mol value of the G2 method. Surprisingly, the best fit to the G2 value is obtained for the SVWN functional, 61.33 kcal/mol.

3.2.3 Triplet two-ligand complexes

At the G2 level of theory, we can observe a large decrease of D_0's when a second ligand is attached to the phosphorus ion in its triplet state. In fact, the lowest D_0's for all ligands are obtained for these complexes. This lowering was related to a marked lowering of covalency, which even changes the bonding character of the covalent bonds, and it was larger as the covalency of the P—X bond increased. This lowering is also reproduced by all functionals and MP2 theory. A fairly good agreement is found between MP2 and G2; differences are always maintained below 1.4 kcal/mol, so ΔD_{G2}^{MP2} is very small, namely 0.94 kcal/mol. This good agreement should be expected since QCI corrections to D_0's are not significant for triplet two-ligand complexes, see Table 1. Apart from the triplet $P(PH_3)_2^+$, B3LYP shows good concordance with MP2 and G2 results, showing a ΔD_{G2}^{MP2} of only 1.81 kcal/mol. The worst fit is observed for the triplet $P(PH_3)_2^+$; a dissociation energy of 5.80 kcal/mol is obtained for G2 whereas B3LYP predicts 9.32 kcal/mol. We recall that B3LYP and MP2 geometries were quite different in this case. Therefore, it should expected that this disagreement would also be present in the D_0. Along with the good B3LYP–MP2–G2 agreement, the trends for the ligand dependencies of the D_0 are equally well reproduced by these three methods.

With respect to the other functionals, it should be mentioned that SVWN and BVWN show discrepancies in the variation of D_0 with the ligand, with respect to G2. For instance, whereas water is bound slightly more strongly to phosphorus than is ammonia, by 1.07 kcal/mol with G2, ammonia is bound more strongly to phosphorus with the SVWN and BVWN functionals, by 0.04 and 0.14 kcal/mol, respectively. For first-row hydrides, the trends are similar to those described before, thus, SVWN D_0's are larger than the G2 values, BVWN smaller, and BLYP, B3LYP, and MP2 lie in between. However, quite surprisingly, for second-row hydrides the best DFT fit to G2 values is obtained with BVWN, in some cases even better than with MP2. Curiously, for triplet $P(PH_3)_2^+$ a similar value to that with G2 is obtained with BVWN, despite the great disagreement between MP2 and BVWN geometries.

3.2.4 Singlet two-ligand complexes

When we add a second ligand to the singlet one-ligand complexes, the lowering of the dissociation energies is not so pronounced as in the triplet states at the G2 level of theory. Exploration of the bonding properties of the electron density reveals that the loss of covalent character is not so pronounced as in the triplet state, so the nature of the covalent bonds remains unchanged. Nevertheless, binding energies were found to be very similar to those of the one-ligand complexes, and the trends in ligand stability were similar to them, in contrast with the behaviour of the triplets. However, this trend is not equally reproduced by the various methods. Once again, B3LYP, MP2, and G2 show similar patterns; thus, D_0 decreases are predicted as we move to the right through the periodic table and larger binding energies are predicted for second-row ligands than for first-row ones. The other functionals, SVWN, BVWN, and BLYP, present some exceptions to these tendencies. As in the singlet one-ligand complexes, OH_2 is the anomalous case of the first-row hydrides, but now by the opposite effect. These three functionals give too large binding energies compared with G2, even the BVWN functional that often gives smaller ones. SH_2 is also poorly reproduced with SVWN and BVWN functionals. Probably, these discrepancies were transferred from the poor results for singlet PXH_2^+ complexes.

With respect to the quantitative agreement, MP2 and G2 show a worse agreement than for the triplets, MP2 tending to overbind the cluster so that ΔD_{G2}^{MP2} is increased to 5.53 kcal/mol. Phosphine is the worst case and the disagreement is close to 10 kcal/mol. However, these differences are sensibly smaller than for the singlet one-ligand complexes and, in contrast, PXH_2^+ complexes now show the best MP2–G2 fit within each row. Here again, the MP2–G2 discrepancies match the trends of the QCI corrections. Thus, QCI corrections represent a more significant contribution for singlets than for triplets, but lower than singlet one-ligand complexes. Also, they are minima for $P(XH_2)_2$ systems within each row.

Again, B3LYP is the functional that best fits G2 values, even better than that of the MP2 method, so ΔD_{G2}^{B3} is now substantially smaller, namely, 2.70 kcal/mol. Its discrepancies with respect to the G2 data follow a similar trend as the MP2 method, except for phosphine, for which good agreement is found between the B3LYP and G2 methods.

3.3 Triplet-singlet gap

The energy difference between high and low spin states of an ion and the relaxation of this triplet–singlet gap, as cluster growths, measures the strength of the ligand field and its dependence upon the nature of the ligands and the size of the cluster. The two lowest spin states of P^+ are the triplet and the singlet, with the singlet lying 25.20 kcal/mol above the triplet at the G2 level of theory. When one ligand is attached to the phosphorus, stabilization of the singlets is observed although it is not strong enough to allow the singlets to become the ground state. This stabilization is mainly due to the ability of the ligands to interact with the empty $3p$ orbital of the singlet phosphorus cation, which lies perpendicular to the bond direction, and this orbital is occupied by one unpaired electron in the triplet ground state.

First, we will briefly discuss the G2 qualitative trends. For one-ligand complexes, the relaxation of the triplet–singlet gap is maximum for the XH_2 systems (6.93 kcal/mol for water and 10.11 kcal/mol for SH_2) because they have an additional lone pair for π donation to the empty $3p$ orbital of P^+. On the other hand, XH_3 ligands, which have a single lone pair, and very hard bases like FH, have triplet–singlet gaps similar to that of the free P^+. Also, it is observed that relaxation of the triplet–singlet gap is larger for second-row hydrides than for the corresponding first-row ones, an indication of the greater capability of the former to delocalize their electronic charge. For two-ligand complexes, the π donation disappears, since now both the formal empty $3p$ orbitals of the singlet P^+ have their own donating ligand, and the relaxation is totally dominated by the σ donation of the ligands. Therefore, for the two-ligand complexes, the relaxation is larger as we go to the left through the periodic table, being large enough for NH_3, PH_3, and SH_2 two-ligand complexes to allow for singlet ground states, by 12.03, 41.81, and 18.87 kcal/mol, respectively, at the G2 level of theory. Also, for the OH_2 complex, the singlet and triplet states are nearly degenerate, the former being above the latter by only 1.03 kcal/mol.

Values of the triplet–singlet gap (Δ_{t-s}) for P^+ and the 12 ion–molecule complexes calculated at the SVWN, BVWN, BLYP, B3LYP, MP2, and G2 levels of theory are given in Table 2. The plots Δ_{t-s}^{B3} versus Δ_{t-s}^{MP2} and Δ_{t-s}^{G2} are shown in Figs. 7*C* and 7*D*, respectively. As evidence in these figures, P^+ and the one-ligand complexes have a worse B3LYP-G2 agreement than the two-ligand complexes, while the B3LYP–MP2 fit is remarkably good. We will now analyze these two cases separately.

For P^+ and one-ligand complexes, DFT and MP2 methods significantly overestimates Δ_{t-s} with respect to G2 values. The MP2 overestimation can be partially understood by considering both empirical corrections to the energy and QCI corrections made in the G2 method. Empirical corrections are different for singlets and for triplets, since they have different numbers of electron pairs (α and β electrons). These empirical corrections suggest a 2.89 kcal/mol stabilization of the singlets with respect to the triplets and it is constant for P^+ and for any cluster. The origin of the QCI corrections to Δ_{t-s} is the enhanced relaxation of the singlets compared with the triplets when these corrections are accomplished. In that way, a method such as MP2, which does not take them into account, tends to understabilize the singlets, overestimating the triplet–singlet gap. Values of Δ_{t-s}^{QCI} can be found in Table 2. Although they do not account for all the overestimation, they are significant for P^+ and one-ligand complexes, Δ_{t-s}^{QCI} are not homogeneously maintained through all the clusters. Within each row, PXH_2 has the lowest Δ_{t-s}^{QCI}, with PXH_3 and PXH showing very similar ones. Besides, Δ_{t-s}^{QCI} are lowered when we go from first-row hydrides to second-row ones. It should be noted that MP2–G2 differences in Δ_{t-s} follow these trends.

As we can see in Fig. 7*C*, B3LYP presents an analogous behaviour. B3LYP tends to give Δ_{t-s} than MP2, rendering results closer to the G2 values. Nevertheless, B3LYP markedly overestimates the Δ_{t-s}, see Fig. 7*D*. The trends in B3LYP–G2 discrepancies are analogous to those of the MP2 method, suggesting here again that B3LYP and MP2 in some way possess similar shortcomings. Despite these failures, the qualitative trends mentioned before are well reproduced by both methods, and we conclude that similar conclusions could be reached from B3LYP, MP2, and G2 data. In general, the other functionals, SVWN, BVWN, and BLYP, do not only tend to overestimate the triplet–singlet gap, but sometimes they do not reproduce the same qualitative trends of the Δ_{t-s}^{G2}. For instance, the poor results for the $P(OH_2)^+$ system should be noted, or the larger triplet–singlet gap obtained for $P(PH_3)^+$ with respect to that of the free P^+.

For two-ligand complexes, we can see that B3LYP and MP2 agreement with G2 improves, see Table 2 and Figs. 7*C* and 7*D*. Recall that QCI corrections to the energy for two-ligand complexes were similar for triplets and for singlets, so that the Δ_{t-s}^{QCI}'s are negligible, as can be seen in Table 2. In this way, a lower MP2–G2 discrepancy is observed. Also, B3LYP shows the best fit to G2 values (Fig. 7*D*), the only exception being $P(PH_3)_2^+$. For his complex, we obtain a value of 32.80 kcal/mol for Δ_{t-s}^{B3}, whereas 43.45 and 41.81 kcal/mol are obtained with the MP2 and G2 methods, respectively. These discrepancies have to be partially attributed to the large differences in the description of triplet $P(PH_3)_2^+$ made by B3LYP and MP2. We recall that triplet $P(PH_3)_2^+$ is almost twice more stable in B3LYP theory than in MP2 or G2, and different geometries were encountered for it using the B3LYP and MP2 methods. Apart from this disagreement, B3LYP and MP2 reproduce properly the qualitative trends in Δ_{t-s}^{G2} mentioned before. The same is not true for the other functionals; for instance, SVWN stabilizes the singlets too much compared to G2, and for $P(OH_2)_2^+$ and $P(ClH_2)_2^+$ we get singlet ground states instead of the triplet predicted by the G2 method. The inclusion of the gradient corrections only to the exchange, the BVWN functional, favors the triplet, and for $P(NH_3)_2^+$ and $P(SH_2)_2^+$ we get a triplet ground state, instead of the G2 singlet. BLYP gives the same ground state as G2 for any ligand but in general shows a worse fit to G2 data than B3LYP.

3.4 Bonding properties: $\rho(r_c)$, $\nabla^2\rho(r_c)$, and $H(r_c)$

Properties of the bond critical points such as the electron density ($\rho(r_c)$), the Laplacian ($\nabla^2\rho(r_c)$), and the energy density ($H(r_c)$) are usually employed for characterization of the binding mechanism in a great variety of systems. A large value of $\rho(r_c)$ with negative values of $\nabla^2\rho(r_c)$ and $H(r_c)$ are typical features of covalent interactions, whereas smaller

$\rho(r_c)$ and positive values of $\nabla^2\rho(r_c)$ and $H(r_c)$ are common to electrostatic interactions. In previous papers, we used these properties to rationalize the bonding of various phosphorus clusters. We found that $\rho(r_c)$ and $H(r_c)$ were useful for these purposes, whereas analysis of $\nabla^2\rho(r)$ could only lead to some inconsistencies. Looking at $\rho(r_c)$ and $H(r_c)$, it was stated that P^+ behaves as a soft acid for one-ligand complexes and prefers to be bound to the softest bases, for which electronic effects are more favored, than to hard ones (FH), for which electrostatics interaction dominates the bond. Larger covalency, which accounts for the enhanced dissociation energies, was characterized for singlets than for triplets, as denoted by the larger $\rho(r_c)$ and more negative $H(r_c)$ found for the former. For two-ligand complexes, great differences were encountered for triplet and singlets. A huge decrease of $\rho(r_c)$ and an absolute value of $H(r_c)$ was observed for the triplets, denoting the large decrease in covalency occurring for these complexes. The loss of covalency was so high that changes in the shape of the Laplacian could be observed for the most covalent systems. This was the origin of the great lowering of the D_0 values mentioned earlier. Singlet two-ligand complexes did not show such pronounced lowering of $\rho(r_c)$ and the $H(r_c)$ in absolute value, denoting that the binding keeps a great deal of its covalent character.

It would be desirable to know how DFT fits these values, and whether or not it provides reliable information, reproducing the trends commented upon above. Values of $\rho(r_c)$, $\nabla^2\rho(r_c)$, and $H(r_c)$ calculated by the SVWN, BVWN, BLYP, B3LYP, and MP2 methods are depicted in Tables 3, 4, and 5, respectively. Also, we have plotted $\rho(r_c)$ and $H(r_c)$ values of B3LYP versus those of MP2, Figs. 6*B* and 6*C*, respectively. From inspection of Tables 3 and 5, it is clear that SVWN tends to assign greater covalency than MP2, whereas the inclusion of non-gradient corrections to the exchange, BVWN functional, removes electron density form the internuclear region, resulting in lower values of $\rho(r_c)$ and less negative values of $H(r_c)$ than those of MP2. This is the origin of the enhanced and lowered bond strength of the SVWN and BVWN methods, respectively. BLYP and B3LYP lead to intermediate values of $\rho(r_c)$ and $H(r_c)$, closer to the MP2 values. Generally, B3LYP shows a better fit to MP2 values than does BLYP. It can be observed from Fig. 6*B* that this fit is very good, resulting in a small $\Delta\rho^{B3}_{MP2}$, namely, 0.0029. According to this good agreement, the qualitative trends in $\rho(r_c)$ are properly reproduced by the B3LYP method, therefore the same conclusions can be drawn from them. $H(r_c)$ shows a bit worse fit (see Fig. 6*C*) with a ΔH^{B3}_{MP2} of 0.0042. The worst cases are the singlet $P(PH_3)_2^+$ and singlet $P(SH_2)_2^+$, showing sensibly lower absolute values than MP2. Despite this worse fit, the qualitative trends in $H(r_c)$ are also reproduced, so that similar conclusions could also be extracted from these data.

On the contrary, B3LYP $\nabla^2\rho(r)$ has a very bad fit; the mean deviation between B3LYP and MP2 data is 0.0217 and, moreover, it is not the functional with a best fit to the MP2 values. SVWN now shows the best fit, with a mean deviation of 0.0189. Its qualitative trends are similar to those shown by MP2 and, in this sense, the same incoherences, which did not allow us to consider the value of $\nabla^2\rho(r)$ as a reliable sole magnitude to characterize the binding mechanism, are observed. Positive values of the Laplacian are encountered for most of the first-row hydride clusters, whereas values of $\rho(r_c)$, $H(r_c)$, and D_0 denote that some covalency is occurring for these bonds.

4. Concluding remarks

Among the functionals studied here, SVWN, BVWN, BLYP, and B3LYP, the B3LYP has been proven to yield the best fit and overall coherence with the MP2 dissociation energies, phosphorus–ligand distances, triplet–singlet energy gap, and local bond properties, such as the electron and the energy densities at the bond critical points. The local spin density approximation, in its SVWN form, tends to describe too strong bonds. The inclusion of nonlocal gradient corrections solely to the exchange weakens the bonds too much, even though lower absolute deviations for various properties with respect to the accurate G2 method are encountered. The inclusion of nonlocal gradient corrections to both exchange and correlation in its BLYP form balances this situation and much better values are obtained for the above-mentioned properties. However, some incoherent results are obtained, especially for systems containing XH_2 ligands, which disagree with the qualitative trends determined at the G2 level of theory. B3LYP improves these results and removes these incoherences, giving a good fit with MP2 data for R and $\rho(r_c)$ and, except for the $P(PH_3)_2^+$ complex, also for D_0 and Δ_{t-s}. This MP2–B3LYP fit is a bit worse for $H(r_c)$, although overall qualitative agreement remains, and it is fairly bad for $\nabla^2\rho(r)$. For the latter property, the lower mean deviation with MP2 is obtained for the SVWN functional.

In general, the deviations of B3LYP and MP2 methods from G2 dissociation energies and the triplet–singlet gap are similar. Thus, while triplets show quite good accord for D_0, significant overbinding, which is larger for one-ligand than for two-ligand complexes, is obtained for the singlets. The overbinding is largest for XH_2 ligands in one-ligand complexes, but smallest for the same ligands in two-ligand complexes. For MP2, the origin of such deviations can be understood as the result of the QCI relaxation. Our results show that B3LYP bears in some way this deficiency of the MP2 method. Also, we could observe an overestimation of the triplet–singlet gap, favoring the former spin state, of both methods, again partially due to the lack of QCI relaxation. QCI corrections can be considered important only when the occupation of the open shell of the singlet phosphorus changes sensibly, adding a new ligand. This is the case for small clusters, when we add one or two ligands. For bigger clusters, we consider that these effects will be negligible and so, taking into account our results, we can conclude that B3LYP is expected to yield accurate characterizations of the bigger clusters.

5. Acknowledgment

This research has been supported by the University of the Basque Country (Euskal Herriko Unibertsitatea), Grant No. UPV 203.215-EB247/95, and by the Basque Provincial Government of Guipuzcoa (Gipuzkoako Foru Aldundia); one of us (X. Lopez) wishes to thank the Basque Government (Eusko Jaurlaritza) for a grant.

Molecular charge density analysis

Juergen Hinze, F. Biegler-Konig, and A.G. Lowe

Abstract: It is proposed to analyse the first-order reduced density matrix of a molecular wave function in terms of the first-order reduced density matrices of different states of the constituent atoms. With this an unambiguous partitioning of the molecular charge distribution in terms of the atomic charge distributions is obtained. Simple practical formulae are derived, such that in many ab initio molecular wave function calculations the analysis proposed can be carried out routinely. The results obtained should be useful for the interpretation of molecular wave functions in terms of their atomic constituents, as well as for the determination of atomic form factors to be used in X-ray molecular structure determination. Some simple examples are given, and the results obtained are compared with those obtained using other methods of analysis.

Key words: charge density, density matrix, goodness-of-fit, correlation coefficient, standard deviation.

Résumé : On s'est proposé d'analyser la matrice de densité réduite du premier ordre d'une fonction d'onde moléculaire en termes de matrices de densité réduite du premier ordre de différents états des atomes qui la constituent. De cette façon, on a pu obtenir une partition non ambiguë de la distribution de la charge moléculaire en termes des distributions des charges atomiques. On en a dérivé des formules pratiques simples telles que, dans plusieurs calculs ab initio de fonctions d'onde moléculaires, l'analyse proposée peut être effectuée d'une façon routinière. Les résultats obtenus devraient être utiles pour l'interprétation des fonctions d'onde moléculaires en termes de leurs constituants atomiques, ainsi que pour la détermination de facteurs f atomiques à être utilisés dans la détermination des structures moléculaires par les rayons X. On donne quelques exemples simples et on compare les résultats avec ceux obtenus en utilisant d'autres méthodes d'analyse.

Mots clés : densité de charge, matrice de densité, facteur d'accord, coefficient de corrélation, déviation standard.

1. Introduction

The analysis of the molecular wave function or the molecular charge density in terms of the corresponding quantities of the constituent atoms has a long history (1–8). The intention is to better understand, on the basis of such an analysis, how much atomic properties predetermine molecular properties and how atomic charges are deformed and modified in the process of molecular formation. In addition, there is the hope of finding criteria for atomic or molecular fragment charge distributions, such that these are transferable and can be used to easily build approximate charge distributions of increasingly larger and more complex molecules. Furthermore, there is the aspiration to derive from the molecular charge distribution information about molecular interactions and reactivity. Foremost in the analysis of the molecular wave function in terms of its atomic contributions ranks the Mulliken population analysis (1) and its variations (9–15) with the aim of achieving a more rational division of the overlap populations. Much insight as well as partial atomic charges can be derived, using these methods; however, they are plagued by the non-uniqueness of the partitioning of the overlap populations. A similar situation obtains in the analysis of the molecular charge density in terms of its atomic contributions (16–22). The use, in these procedures proposed, of spherically averaged atomic "prodensities" makes available significant information; however, it is possible to also determine atomic deformation densities (23, 24). Using these methods requires in general significant extra computational effort, a disadvantage. Also the division of the molecular density into unique atomic regions, being limited by the zero flux surfaces between the atoms (25–30), requires a significant extra computational effort. However, useful chemical insight, which is not always obvious to chemical intuition, has been gained by using this type of analysis of the molecular charge density.

We propose here to analyse the first-order reduced density matrix of the molecule, the diagonal of which is the charge density, in terms of the reduced density matrices of the constituent atoms. We will show that such an analysis is computationally simple in most molecular wave function calculations. The procedure is unique inasmuch as least-squares optimizations are unique, in that they permit a correlation and error analysis of the results obtained. In Sect. 2 we will present a brief definition of the terms used and outline the method proposed. In Sect. 3 we will show the ease with which the required matrix elements can be computed, if a standard basis function method is used to compute the molecular wave function, and in Sect. 4 we will present some

results obtained. In Sect. 5 we will outline the possibility of a correlation and error analysis of the results and consider the possibility of constructing approximate molecular density matrices of complex molecules, using the corresponding atomic or fragment density matrices.

2. Charge density analysis

Rather than analysing the molecular charge density, $\rho_M(\boldsymbol{r})$, directly, as has been suggested in the past (16–21), we propose to analyse the first-order reduced spatial density matrix, $\rho_M(\boldsymbol{r}',\boldsymbol{r})$, which is defined in terms of the molecular wave function, Ψ_M, for an N particle system as (31, 32):

$$[2.1]\quad \rho_M(\boldsymbol{r}',\boldsymbol{r}) = N\int \mathrm{d}s_1 \int \mathrm{d}\tau_2 \cdots \times \int \tau_N [\Psi_M^{\dagger}(\tau_1',\tau_2,\ldots,\tau_N)\Psi_M(\tau_1,\tau_2,\ldots,\tau_N)]_{s_1'\rightarrow s_1}$$

Here the integration is over the spin variable, s_1, of particle one, and the space-spin variables, $\tau_2,\ldots,\tau_N$, of the remaining particles. The molecular charge density is obtained as the diagonal of the density matrix, i.e.,

$$[2.2]\quad \rho_M(\boldsymbol{r}) = \rho_M(\boldsymbol{r}',\boldsymbol{r})_{\boldsymbol{r}'\rightarrow\boldsymbol{r}}$$

The analysis in terms of the density matrix, rather than the charge density, has the advantage of containing more information, in addition to being simpler, as will be seen below. For the analysis we extremalize the functional

$$[2.3]\quad \chi^2 = \int \mathrm{d}\boldsymbol{r}\left|\rho_M(\boldsymbol{r}',\boldsymbol{r}) - \sum_{AI}\rho_{AI}(\boldsymbol{r}',\boldsymbol{r})w_{AI}\right|^2$$

which represents the absolute value square of the difference between the molecular density matrix and the sum of the density matrices of the constituting atoms A in their different states I, weighted with the as yet unknown coefficients w_{AI}. The dependence on the variable $\boldsymbol{r}'$ disappears in eq. [2.3], because the absolute value of the product of two density matrices means

$$[2.4]\quad |\rho_A(\boldsymbol{r}',\boldsymbol{r})\rho_B(\boldsymbol{r}',\boldsymbol{r})| = \int \mathrm{d}\boldsymbol{r}'\rho_A^{\dagger}(\boldsymbol{r}',\boldsymbol{r})\rho_B(\boldsymbol{r}',\boldsymbol{r})$$

Extremalization of χ^2 with respect to the w_{AI}'s yields the linear set of normal equations

$$[2.5]\quad \boldsymbol{Mw} = \boldsymbol{b}$$

for the determination of the elements w_{AI} of the vector $\boldsymbol{w}$.

The matrix elements to be computed are

$$[2.6]\quad M_{BJ,AI} = \int \mathrm{d}\boldsymbol{r}\int \mathrm{d}\boldsymbol{r}'\rho_{BJ}^{\dagger}(\boldsymbol{r}',\boldsymbol{r})\rho_{AI}(\boldsymbol{r}',\boldsymbol{r})$$

and

$$[2.7]\quad b_{BJ} = \int \mathrm{d}\boldsymbol{r}\int \mathrm{d}\boldsymbol{r}'\rho_{BJ}^{\dagger}(\boldsymbol{r}',\boldsymbol{r})\rho_M(\boldsymbol{r}',\boldsymbol{r})$$

With the auxiliary condition of charge conservation, i.e.,

$$[2.8]\quad \sum_{AI}\int \mathrm{d}\boldsymbol{r}\rho_{AI}(\boldsymbol{r})w_{AI} - N = 0$$

introduced with a Lagrange multiplier λ into the functional to be extremalized, the following somewhat modified linear equation is obtained:

$$[2.9]\quad \begin{pmatrix} \boldsymbol{M} & \boldsymbol{N} \\ \boldsymbol{N}^{\dagger} & 0 \end{pmatrix}\begin{pmatrix} \boldsymbol{w} \\ \lambda \end{pmatrix} = \begin{pmatrix} \boldsymbol{b} \\ N \end{pmatrix}$$

Here the coefficient-matrix $\boldsymbol{M}$ is extended by one row and one column by the vector $\boldsymbol{N}$, the elements of which are given as

$$[2.10]\quad N_{BJ} = \int \mathrm{d}\boldsymbol{r}\rho_{BJ}(\boldsymbol{r})$$

i.e., the number of electrons of the atom B in state J; also ions are admissible. The vector with the elements w_{AI} has as the last element λ, the Lagrange multiplier, and the vector with the elements b_{BJ} has as its last element N, the total number of electrons in the molecule.

3. Computation of the matrix elements

For the computation of the matrix elements, eqs. [2.6] and [2.7], it is possible to use highly accurate density matrices for the various states of the constituent atoms. However, the computation becomes particularly simple if the density matrices of the atomic states are determined using the same basis set that is used in the molecular wave function calculation. Represented in such a common basis, the density matrices are

$$[3.1]\quad \rho(\boldsymbol{r}',\boldsymbol{r}) = \sum_{pq}(\boldsymbol{r}'|\chi_p > D_{pq} < \chi_q|\boldsymbol{r})$$

where the D_{pq}'s are the elements of the first-order reduced density matrix in the space spanned by the basis functions. The number of electrons of such a system is then given as

$$[3.2]\quad N = \int \mathrm{d}\boldsymbol{r}\rho(\boldsymbol{r}',\boldsymbol{r})_{\boldsymbol{r}'\rightarrow\boldsymbol{r}} = tr[\boldsymbol{SD}]$$

where $\boldsymbol{S}$ is the overlap matrix with the elements

$$[3.3]\quad S_{pq} = \langle\chi_p|\chi_q\rangle$$

With this the desired matrix elements become

$$[3.4]\quad M_{IJ} = \int \mathrm{d}\boldsymbol{r}'\int \mathrm{d}\boldsymbol{r}\rho_I(\boldsymbol{r},\boldsymbol{r}')\rho_J(\boldsymbol{r}',\boldsymbol{r})$$

$$[3.5]\quad = \sum_{pqrs}\langle\chi_s|\chi_p\rangle D_{I,pq}\langle\chi_q|\chi_r\rangle D_{J,rs}$$

$$[3.6]\quad = tr[\boldsymbol{SD}_I\boldsymbol{SD}_J]$$

Thus they can be obtained using simple matrix multiplication of matrices that are generally available in a standard molecular wave function calculation. With this, the method suggested becomes particularly simple and could be implemented easily in most molecular wave function programs.

4. Results

In Table 1 we present some results obtained, using the method described. These results were computed, using the

Table 1. Weight coefficients w_i for the atomic density matrices calculated by solving eq. [2.9] and partial charges q computed using the w_i's compared with values^M of a Mulliken population analysis and values^H obtained following the method of Hirsfeld (22).

MOLPRO program (33) STO-3G as well as a valence double zeta (VDZ) basis set, in order to have a comparison to the partial charges calculated by Davidson and Chakravorty (22), using Mulliken population analysis (1) and the method of Hirsfeld (18). To be sure, the data presented here are just preliminary and far from being conclusive. They were computed using density matrices of independent Hartree–Fock calculations for the ground states of the molecules and the various states of the atoms. In the case of atomic open-shell configurations, all states arising from these configurations that can couple to the appropriate molecular state are included in the calculation. In Table 1 the result is reported for the configuration in total, in order not to expand the table unduly. This is also the reason that the Mulliken and Hirsfeld values given for comparison are entered in the free spaces in the column headed by q for the partial charge. The partial charges obtained with all methods are reasonable; however, significant differences can be observed. The differences of the results for the two different basis sets can surely be attributed to the inadequacy of the STO-3G basis to yield a reasonable approximation to the true densities; that is particularly apparent in the case of HF. In addition to the partial charges, the method proposed here also yields information on the s- and p-character the atoms use in bond formation. This becomes significant already in the case of LiH, where Li is found to use 30% p-character in its bond to H, and with the P-state of Li in the analysis the partial charge found is reduced by 20%. Even more drastic, as expected, is the situation of BeH. Here the excited P-state of Be is to almost 90% involved in the formation of BeH with a concomitant drastic reduction in the partial charges obtained if this state is included in the analysis. Also in the hydrides of B through F there is a significant though decreasing use of s-character in the bond formation. That the inclusion of F^- in the anal-

ysis of the density of HF (lower right-hand box of Table 1) leads to a significant increase of the resulting partial charges is another finding that could have been anticipated. To assess conclusively the full potential of the method suggested here for the molecular charge density analysis, a much more exhaustive study, including many more molecules and more atomic states and a larger variety of basis set, will be required. This will be presented in the future; however, it is clear from the results presented that their value could be increased if statistical measures can be obtained to determine the significance of the individual contributions to the total molecular density.

5. Quality estimate of calculated data

To gain confidence in the results produced by solving the normal equation we should be able to answer the following questions:

1. How sensitive are the w_{AI} with respect to errors or changes in the density matrix elements?

2. Does the chosen set of atomic density matrices ρ_{AI} supply us with a suitable approximation of the molecular density matrix ρ_M?

3. Does adding a new atomic state AI improve this approximation significantly?

By assuming a normal distribution of the errors we can use statistical methods (34) to obtain numbers that quantify the answers to our questions.

Let us first consider a standard least-squares problem with n data points given and m coefficients to compute. We want to determine an m vector $\boldsymbol{x}$, which minimizes

$$[5.1] \qquad \chi^2 = \|\boldsymbol{b} - \boldsymbol{A} * \boldsymbol{x}\|_2^2 = \sum_{i=1}^{n} \left(b_i - \sum_{i=1}^{m} A_{ij} x_j \right)^2$$

where $\boldsymbol{A}$ is an nxm matrix and $\boldsymbol{b}$ an n vector.

One way of determining $\boldsymbol{x}$ is by solving the normal system of the minimization problem

$$[5.2] \qquad \boldsymbol{M}\boldsymbol{x} = (\boldsymbol{A}^*\boldsymbol{A})\boldsymbol{x} = (\boldsymbol{A}^*\boldsymbol{b})$$

with an $m \times m$ matrix $M = (A^*A)$.

To obtain a measure of the sensitivity of a solution component x_i with respect to errors in the data points we can calculate the variance of x_i:

$$[5.3] \qquad \sigma^2(x_i) = \sum_{j=1}^{n} \left(\frac{\partial x_i}{\partial b_j} \right)^2$$

By substituting

$$[5.4] \qquad x_i = \sum_{j=1}^{m} (M^{-1})_{ij} b_j$$

into eq. [5.3] we obtain for the variance

$$[5.5] \qquad \sigma^2(x_i) = (M^{-1})_{ii}$$

The positive square root of the variance is called the standard deviation of x_i.

To estimate the "goodness-of-fit" of the data to the model we can introduce the correlation coefficient:

$$[5.6] \qquad R^2 = 1 - \frac{\sum_{i=1}^{n} (b_i - \hat{b}_i)^2}{\sum_{i=1}^{n} (b_i - \bar{b})^2}$$

where

$$[5.7] \qquad \hat{\boldsymbol{b}} = \boldsymbol{M}\boldsymbol{x} \qquad \text{and} \qquad \bar{b} = \frac{\sum_{i=1}^{n} b_i}{n}$$

Note that $R^2 = 1$ in the case of a perfect fit (data points are perfectly correlated) and $R^2 = 0$ if no correlation between the data points can be observed.

Returning to the Charge Density Analysis we see that expression [2.3] for χ^2 closely resembles expression [5.1] but with an infinity of data points. The sums over index i therefore change into integrals over $\boldsymbol{r}$.

The definitions of variance and standard deviations of the w_{AI} as the diagonal elements of the inverted normal matrix $\boldsymbol{M}$ are straightforward, see eq. [2.5] or [2.9]:

$$[5.8] \qquad \sigma^2(w_{AI}) = (M^{-1})_{AI,AI}$$

The term in the numerator of eq. [5.6] is equivalent to our χ^2. The mean value in the denominator vanishes in our case (the mean value over the interval $[-\infty, \infty]$ of any square integrable function is zero). Hence the correlation coefficient of eq. [5.6] generalizes to

$$[5.9] \qquad R^2 = 1 - \frac{\int d\boldsymbol{r} \int d\boldsymbol{r}' |\rho_M(\boldsymbol{r}, \boldsymbol{r}') - \sum_{AI} \rho_{AI}(\boldsymbol{r}, \boldsymbol{r}') w_{AI}|^2}{\int d\boldsymbol{r} \int d\boldsymbol{r}' |\rho_M(\boldsymbol{r}, \boldsymbol{r}')|^2}.$$

After defining standard deviations and correlation coefficients for our problem we are able to answer the questions:

1. The standard deviations $\sigma(w_{AI})$ of eq. [5.8] give us a measure for the sensitivity of the calculated data with respect to perturbations in ρ_M and ρ_{AI}.

2. The correlation coefficient R of eq. [5.9] measures the "goodness-of-fit" of our approximation of ρ_M by the weighted sum of atomic densities ρ_{AI}. The closer R is to 1 the better is our fit of ρ_M.

3. By including another atomic state function ρ_{AI} in our approximation we get a modified correlation coefficient R'. The difference $R' - R$ quantifies the progress we made by including an extra w_{AI}.

It is to be expected that, with the inclusion of an increasing number of excited atomic states in the expansion of the molecular density, the coefficient matrix $\boldsymbol{M}$ of eq. [2.5] or its extension in eq. [2.9] will become singular or nearly so. In this case, a singular value decomposition (35) of the coefficient matrix would permit the elimination of redundant linear combinations of the atomic densities, permitting a focus on the remaining significant contributions.

The method suggested is simple and unique; there is no arbitrariness with respect to the division of overlap densities. With the use of atomic ground and excited state densities, specific M_z components along bonds will have to be used for such states; the method will also give information about atomic deformation densities, dependent on the chemical surrounding of an atom. These deformed atomic densities could

then be used to calculate atomic form factors to be used in X-ray molecular structure determinations. The extent to which such deformed atomic densities or also molecular fragment densities can be transferred and used to construct approximate densities of increasingly complex molecules remains to be investigated (36, 37).

Charge density study with the Maximum Entropy Method on model data of silicon. A search for non-nuclear attractors

R.Y. de Vries, W.J. Briels, D. Feil, G. te Velde, and E.J. Baerends

Abstract: In 1990 Sakata and Sato applied the maximum entropy method (MEM) to a set of structure factors measured earlier by Saka and Kato with the Pendellösung method. They found the presence of non-nuclear attractors, i.e., maxima in the density between two bonded atoms. We applied the MEM to a limited set of Fourier data calculated from a known electron density distribution (EDD) of silicon. The EDD of silicon was calculated with the program ADF-BAND. This program performs electronic structure calculations, including periodicity, based on the density functional theory of Hohenberg and Kohn. No non-nuclear attractor between two bonded silicon atoms was observed in this density. Structure factors were calculated from this density and the same set of structure factors that was measured by Saka and Kato was used in the MEM analysis. The EDD obtained with the MEM shows the same non-nuclear attractors that were later obtained by Sakata and Sato. This means that the non-nuclear attractors in silicon are really an artefact of the MEM.

Key words: Maximum Entropy Method, non-nuclear attractors, charge density, X-ray diffraction.

Résumé : Sakata et Sato (1990) ont appliqué la méthode d'entropie maximale (MEM) sur un ensemble de facteurs de structures mesurés par Saka et Kato à l'aide de la méthode Pendellösung. Ils ont trouvé la présence d'attracteurs non nucléaires, c'est-à-dire de maxima dans la densité entre deux atomes liés. On a appliqué la MEM à un ensemble limité de données de Fourier calculés à partir d'une distribution de densité électronique connue (DDE) du silicium. On a calculé la DDE du silicium à l'aide du programme ADF-BAND. Ce programme qui effectue des calculs de structures électroniques, y compris la périodicité, repose sur la théorie de la densité fonctionnelle de Hohenberg et Kohn. Aucun attracteur non nucléaire entre deux atomes de silicium non liés n'a été observé dans cette densité. On a calculé les facteurs de structure à partir de cette densité et, pour l'analyse MEM, on a utilisé l'ensemble de facteurs de structure qui avait été mesuré par Saka et Kato. Les DDE obtenues avec l'analyse MEM montre la présence des mêmes attracteurs non nucléaires que ceux obtenus par Sakata et Sato. On peut en déduire que les attracteurs non nucléaires dans le silicium sont en réalité des artefacts de l'analyse MEM.

Mots clés : méthode d'entropie maximale, attracteurs non nucléaires, densité de charge, diffraction par rayons X.

[Traduit par la rédaction]

1. Introduction

In the study of the electron density distribution (EDD) with the help of X-ray diffraction, experiment yields a set of intensities. In most, if not all, centrosymmetric crystals, structure factors can be derived from these intensities without any ambiguity in the phases. The most common method of extracting the EDD from an incomplete and noisy set of structure factors is to fit the data to a multipole model (e.g., POP (1), MOLLY (2), and LSEXP (3, 4)). The advantages of a multipole fit over a direct Fourier synthesis are that a multipole fit allows one to overcome the series termination effect, to filter out the noise from the data that were measured, and to extract the static density from the thermally smeared density. A drawback to a multipole fit is the fact that bias is introduced, and random errors are traded for systematic errors (5).

In the past few years, the maximum entropy method (MEM) has been used to obtain the EDD from an incomplete and noisy set of structure factors (e.g., Sakata and Sato (6), Sakata et al. (7), and Takata et al. (8)). The MEM is capable of handling the series termination effect by estimating missing data. The MEM selects the EDD that is closest to an a priori EDD or, in its absence, closest to a uniform distribution. It is believed that all the features that show up in the EDD are supported by the data and that the MEM gives least biased results.

It has been pointed out by Jauch (9) that the EDDs produced with the MEM have to be interpreted with great care. Our MEM study on a hypothetical water crystal (10) confirmed these reservations with respect to the method. In particular we showed that the MEM results yield an unrealistic χ^2-distribution. In case the data is very accurate the struc-

Received September 22, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

ture factors are forced to be nearly equal to their measured values and the obtained EDD is independent of the distribution. Therefore, Sakata and Sato (6) did not have similar problems in their MEM study on silicon data since their work was based on highly accurate data. They found a local maximum in the middle of the Si—Si bond. Although this (3, −3) critical point (Bader, ref. 11) was unexpected, no doubt about this non-nuclear attractor was expressed. Recently, a MEM study by Iversen et al. (12) revealed non-nuclear attractors in beryllium. The phenomenon, however, is small and the MEM has not been tested on this level of accuracy by means of model studies. Thus we decided to create a set of structure factors corresponding with a known EDD and to apply the MEM.

To illustrate this we have applied the MEM to data calculated from a known EDD of silicon. This EDD was obtained by means of an electronic structure calculation, including periodicity, with the Amsterdam density functional BAND (ADFBAND) program (13). The results were compared with those obtained by Sakata and Sato (6) who applied the MEM to experimental data on silicon.

2. Method

The maximum entropy principle states that out of all EDDs that satisfy certain constraints one should chose the EDD that maximizes the entropy $\overline{S}$ (because this is the least biased), defined by Jaynes (14) as:

$$[1] \qquad \overline{S} = -\int p(x,y,z) \ln (p(x,y,z)/m(x,y,z))\, dxdydz$$

where

$$[2] \qquad p(x,y,z) = \frac{\rho(x,y,z)}{\int \rho(x,y,z)\, dxdydz}$$

and

$$[3] \qquad m(x,y,z) = m'(x,y,z) \Big/ \int m'(x,y,z)\, dxdydz$$

m' is a prior density for the EDD $\rho(x,y,z)$, i.e., some estimate before the present set of data was used. To calculate the integral in eq. [1] the density is usually represented on a grid ($N_1 \times N_2 \times N_3$), to give:

$$[4] \qquad S = -\sum_{i=1}^{N_1} \sum_{j=1}^{N_2} \sum_{m=1}^{N_3} p_{ijm} \ln (p_{ijm}/m_{ijm})$$

In case the prior density m' is not specified, a uniform distribution is assumed and eq. [4] reduces to

$$[5] \qquad S = -\sum_{i=1}^{N_1} \sum_{j=1}^{N_2} \sum_{m=1}^{N_3} p_{ijm} \ln p_{ijm} + \text{constant}$$

The second term in eq. [5] can be dropped in the maximization process. This is the form we will use since we do not assume any prior information.

The constraints are provided by the experiment and involve the structure factors that were measured. We also constrain the total number of electrons per unit cell to the correct value N:

$$[6] \qquad (V_{cell}/N_1N_2N_3) \sum_{i,j,m} \rho_{ijm} = N$$

The most common way to incorporate the reflections that were measured is by maximizing the entropy subject to

$$[7] \qquad \chi^2 = \sum_{h,k,l} \{[F_{hkl} - D_{hkl}]/\sigma_{hkl}\}^2 = M$$

where D_{hkl} is the measured structure factor, F_{hkl} is the structure factor calculated from the resulting density, σ_{hkl} is the standard deviation of the measurement, and M is the total number of (unique) reflections that were measured. Of course the EDD has to be positive everywhere. This is automatically satisfied since the logarithm of a negative number does not exist.

It has been shown (10) that maximizing the entropy subject to this constraint does not necessarily lead to a proper frequency histogram of reduced differences $(|F_{hkl}| - |D_{hkl}|)/\sigma_{hkl}$ between calculated and observed structure factors. In particular, a few strong low-order structure factors calculated from the EDD obtained by MEM show large deviations (up to 19σ in the model study presented) from the measured values. The value of χ^2 is dominated by these structure factors. This causes the remaining structure factors to be exactly equal to their measured values with disastrous effects on the resulting EDD. The same effect was also observed by Jauch and Palmer (15). The introduction of a weighting scheme as proposed by Feil and co-workers (10) partially solves this problem.

Structure factors can be measured very accurately with the Pendellösung method. In case the error in the measurements is very small the resulting EDD is insensitive to the distribution. The structure factors calculated from the maximum entropy EDD are then forced to have the same value as the measured structure factors. In this case only the series termination effect is dealt with by the MEM.

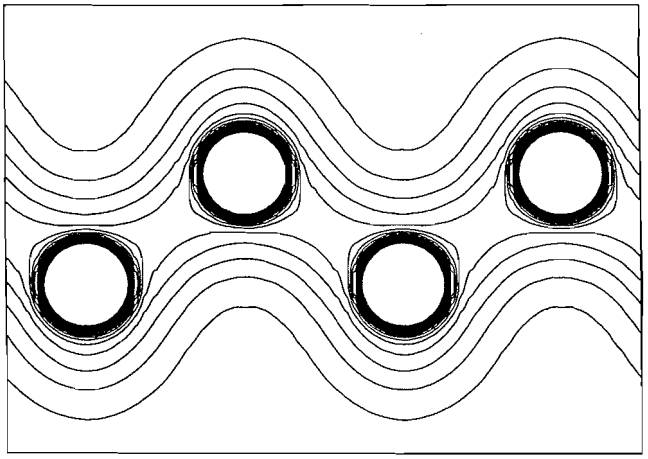
In the present study we focus on the series termination effect. We have calculated structure factors from a known density and want to apply the MEM with $\sigma_{hkl} = 0$. The program that was used to perform the optimization was based on the algorithm that was presented by Skilling and Bryan (16). A detailed description of this algorithm was given by de Vries, Briels, and Feil (10). Since the use of $\sigma = 0$ leads to calculational problems in applying constraint [7] we have chosen the error to be very small ($\sigma_{hkl} = 0.0005$). The iterations were stopped when $\chi^2 = M$ and $\delta < 5 \times 10^{-4}$ where δ is defined as

$$\delta = \frac{1}{2} \left| \frac{\nabla S}{|\nabla S|} - \frac{\nabla \chi^2}{|\nabla \chi^2|} \right|^2$$

3. Calculation of the EDD and the structure factors

The EDD of silicon was calculated with the program ADFBAND (13). This program performs an electronic structure calculation based on density functional theory (17) taking

Fig. 1. Fourier synthesis of the structure factors for which $\sin(\theta)/\lambda < 5.5$ Å^{-1}. The (static) structure factors were calculated with the program ADF-BAND. Thermal motion was introduced with the program FITTER. Contour intervals are at 0.1 e/Å^3.



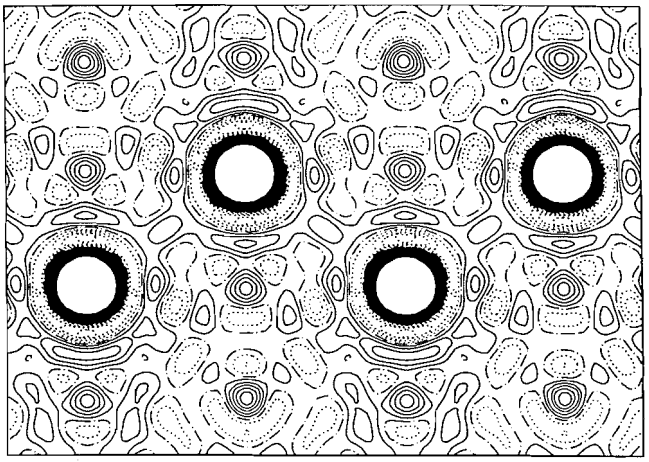
into account the periodicity of the system. For the present purpose it is not important that $\rho(x, y, z)$ be very accurate. It should be a reasonable, but accurately known, density. Once the EDD is known from this calculation, the structure factors can be calculated in a straightforward way by taking the Fourier transformation of the EDD. This will give us the structure factors of the static density. In principle this is very simple. One can calculate the density in the unit cell on a regular, 3-dimensional grid. From this, the structure factors can be calculated using Fast Fourier Transform (FFT) routines. However, the grid that has to be used in this case has to be very dense to make sure that aliasing does not occur in Fourier space. The calculation of the density on all these grid points would simply take too long.

Instead, a different approach is followed that was implemented by Bruning and Feil (18) in the program FITTER. This program contains the following steps:

1. Partition the density according to the stockholder principle (19) to obtain "atomic" densities.
2. Subtract "free" atoms (calculated with the same basis set) from these atomic densities. Since these free atoms are spherically symmetric, their Fourier transform can be easily calculated. The remaining density is referred to as the (atomic) deformation density. It no longer has the problem of "near singularities."
3. Fit the (atomic) deformation densities with suitable functions that can be Fourier transformed analytically.
4. Calculate the Fourier transform of these functions.
5. Add the Fourier transform of the free atoms.
6. Introduce individual atomic thermal motion.
7. Calculate the structure factors by summing the structure factors of all atoms.

In the present study the atomic thermal motion is introduced by multiplying the structure factors with an isotropic temperature factor: $\exp(-B(\sin(\theta)/\lambda)^2$ with $B = 0.4632$ Å^2. This value of B was taken from Spackman (20). Structure factors with $\sin(\theta)/\lambda < 5.5$ Å^{-1} were calculated. A Fourier transform of these structure factors was made to obtain the thermally smeared density, the dynamic density. This is shown in Fig. 1 where the density in the 110 plane of silicon is plotted. Non-nuclear attractors are seen to be absent. We have confirmed this by calculating the electron density along the Si—Si bond: along this line a minimum in the electron density is found. Extension of the set of structure factors by increasing the value of $\sin(\theta)/\lambda$ did not change the EDD. It is easily shown that thermal motion obliterates all information beyond $\sin(\theta)/\lambda = 5.5$ Å^{-1}.

Fig. 2. Fourier synthesis of the same set of structure factors that were measured by Saka and Kato (21). (Structure factors calculated with ADF-BAND and FITTER.) Positive contours are drawn as solid lines, zero contours as dash-dotted lines, and negative contours as dotted lines. The contours are at intervals of 0.8 e/Å^3.



4. Results

A number of MEM calculations was performed using a 64 × 64 × 64 grid to describe the density. The first calculation only involved structure factors with the same h, k, and l values as those measured by Saka and Kato (21). A direct Fourier transformation of these structure factors is shown in Fig. 2. The result of the MEM calculation is shown in Fig. 3. The similarity between the latter density and the density obtained by Sakata and Sato (6), who used experimental data, is striking. To our surprise the same non-nuclear attractors between the silicon atoms appear. However, from Fig. 1, the dynamic density, we know that the midpoint between two bonded atoms is a saddle point.

All structure factors of the dynamic density are known. We can compare them with the values that were "predicted" by the MEM. For a number of structure factors this is shown in Table 1. As can be seen from Table 1, the absolute values of the structure factors predicted by the MEM are, in most cases, smaller than the exact values. Furthermore, the sign of the 622 structure factor is opposite to the sign of the 622 structure factor of the exact density. This is also found when the experimental data are used (comparing the phase of the 622 structure factor with the experimentally determined phase (22)). Sakata and Sato (6) suggested that the 622 structure factor might be affected significantly when the number of pixels is increased. We have done the calculation using a 128 × 128 × 128 grid and found that the value of the 622 reflection hardly changes: $F(622) = -0.0070$.

Fig. 3. The EDD calculated with the MEM from the same structure factors that were used to calculate the EDD of Fig. 2. The contours are at intervals of 0.1 e/Å^3.

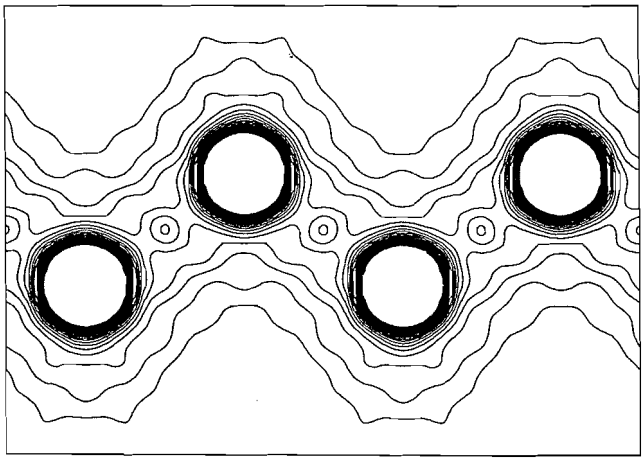


Table 1. The exact values of some structure factors (calculated from the dynamic density) compared with the values that were predicted by the MEM.

9	5	5	−8.4305	−7.9868
10	6	0	11.3806	10.7407

It should be noticed that, although error-free data were used, the contours of the EDD obtained through MEM are still not very smooth. It has been suggested (23) that only a complete sphere of structure factors in reciprocal space should be used in the MEM analysis. This means that the 844 and the 880 structure factors should be omitted from the data set measured by Saka and Kato (21). The result of this calculation is shown in Fig. 4. The contours are indeed much smoother and although it looks like the non-nuclear attractors have disappeared they are still present but do not show on the contour level that was used. One could expect that when all the structure factors (except the forbidden ones) up to the

Fig. 4. The EDD calculated with the MEM from the same structure factors that were used to calculate the EDD of Fig. 2 except for the 844 and the 880 structure factors. The contours are at intervals of 0.1 e/Å^3.

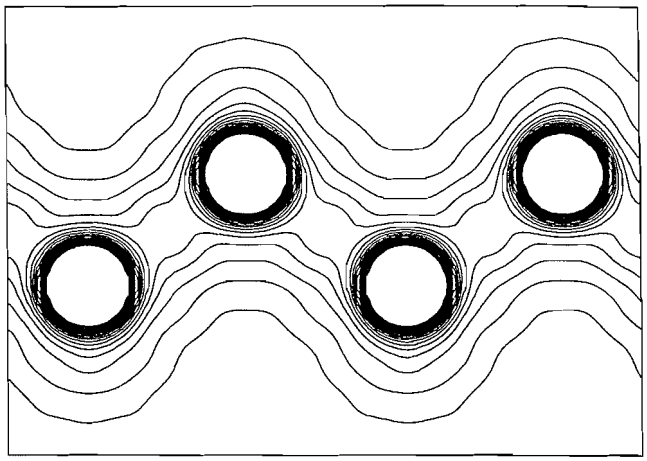

Fig. 5. The EDD calculated with the MEM from all the structure factors up to 880 ($\sin(\theta)/\lambda < 1.05$ Å^{-1}) except the forbidden structure factors. The contours are at intervals of 0.1 e/Å^3.

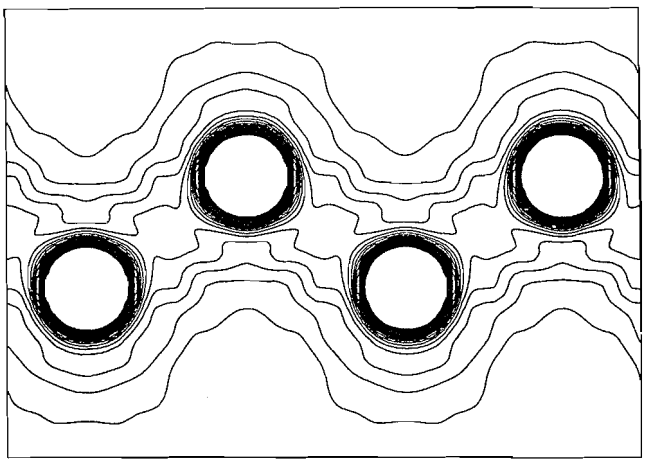

880 reflection (= $\sin(\theta/\lambda) = 1.05$ Å^{-1}, 42 structure factors in total) are used in the MEM analysis, the density should become even smoother. This is shown in Fig. 5. Contrary to expectation, the contours are less smooth than with the MEM optimization shown in Fig. 4. In general, the information of the EDD is not evenly distributed in reciprocal space but occurs in regions of high density. We believe that it is important to include such a high-density region completely in the analysis.

The EDD that is obtained when all the structure factors (except the forbidden ones) for which $\sin(\theta)/\lambda < 1.4$ Å^{-1} (92 structure factors) are included in the optimization is shown in Fig. 6. Figure 7 shows the result when the series cutoff level is extended to the structure factors for which $\sin(\theta)/\lambda <$ 1.7 Å^{-1} (152 structure factors). When we calculate the 222 structure factor from the density that is shown in Fig. 7. we find the value $F(222) = 1.35$. So, although the densities of Fig. 7 and Fig. 1 look very similar, the value of the 222 structure factor is quite different from the exact value.

Fig. 6. The EDD calculated with the MEM from all the structure factors for which $\sin(\theta)/\lambda < 1.4$ Å^{-1} except the forbidden structure factors. The contours are at intervals of 0.1 e/Å^3.

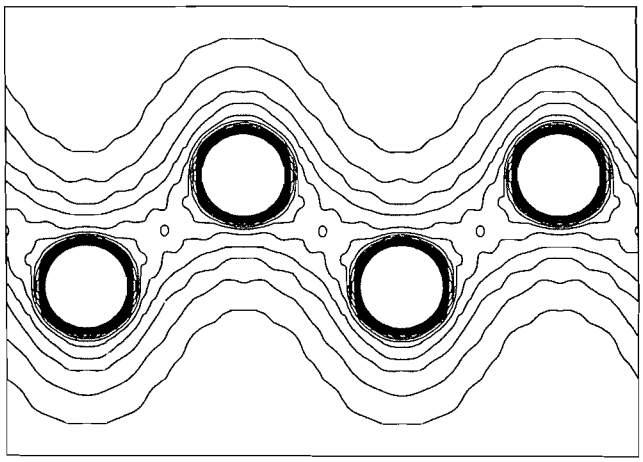

Fig. 7. The EDD calculated with the MEM from all the structure factors for which $\sin(\theta)/\lambda < 1.7$ Å^{-1} except the forbidden structure factors. The contours are at intervals of 0.1 e/Å^3.

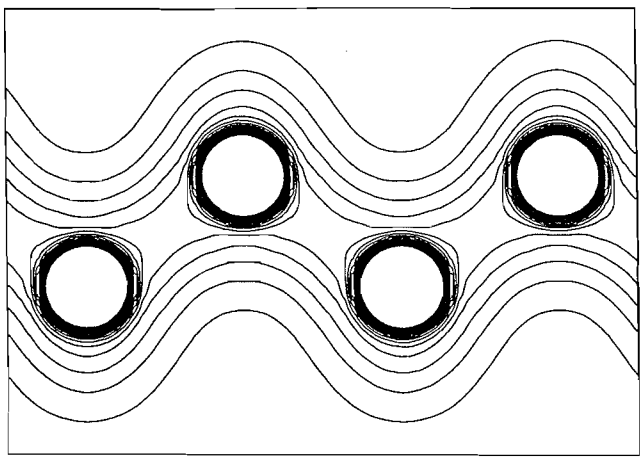

5. Discussion and concluding remarks

The MEM calculation on model data of silicon shows that one has to be very careful when interpreting the EDD obtained by MEM. If we compare both the Fourier synthesis (Fig. 2) of the data and the density obtained by the MEM (Fig. 3) with the original density (Fig. 1) we can say that the MEM deals well with the series termination effect. Minor peaks remain, however, which were not present in the theoretically calculated EDD. In a sense we are the victim of our own success when we interpret the remaining structure as being real physical features. One advantage of the direct Fourier transform of the data is that one will never be tempted to give such an overinterpretation of these little features.

Thus, from remaining maxima obtained by the application of MEM on experimental data one cannot draw conclusions about the presence or absence of non-nuclear attractors in the Si bonds.

The use of a complete sphere in reciprocal space still shows the presence of this non-nuclear attractor but the height of this non-nuclear attractor is much smaller. But a complete sphere is no guarantee that the EDD will be smooth. We have seen that this depends on the range in reciprocal space that is used in the analysis. Increasing the size of the sphere in reciprocal space does not automatically mean that the EDD becomes more smooth.

An interesting option for improving the EDDs obtained by MEM might be the use of prior densities. For instance, by using the sum of "free atoms" as a prior density the method can focus on the deformation density itself.

Acknowledgement

We would like to express our gratitude and admiration to Richard F.W. Bader for the way he taught us the relevance of critical points in charge density analysis.

Topological studies of the charge density of some group 2 metallocenes $M(\eta^5\text{-}C_5H_5)_2$ (M = Mg or Ca)

Ian Bytheway, Paul L.A. Popelier, and Ronald J. Gillespie

Abstract: Ab initio quantum chemical calculations using both the Hartree–Fock and the B3LYP density functional theory methods have been performed for the group 2 metallocenes $M(\eta^5\text{-}C_5H_5)_2$ (M = Mg or Ca). The topology of the calculated charge density (ρ) and its Laplacian ($\nabla^2\rho$) have been analysed using a new critical point search algorithm in order to understand why $Mg(\eta^5\text{-}C_5H_5)_2$ is linear while $Ca(\eta^5\text{-}C_5H_5)_2$ is bent. The Laplacian of the core of the Ca atom in $Ca(\eta^5\text{-}C_5H_5)_2$ is perturbed by the polarizing field of the cyclopentadienyl ligands and the bent geometry is a consequence of the interactions between the distorted core and the ligand atoms. In the case of $Mg(\eta^5\text{-}C_5H_5)_2$, charge concentration maxima in the Mg core occur along the vectors connecting the metal to the centroids of the cyclopentadienyl ligands irrespective of whether or not the molecule is linear, and the preferred geometry is linear as expected. The results of these calculations demonstrate that the geometries of the group 2 metallocenes can be understood in terms of the repulsive interactions between the ligands and between the ligands and the distorted core of the metal atom.

Key words: atoms in molecules, group 2 metallocenes, VSEPR, charge density, Laplacian of ρ.

Résumé : Utilisant les méthodes de Hartree–Fock ainsi que de la théorie de la densité fonctionnelle B3LYP, on a effectué des calculs ab initio de chimie quantique sur des métallocènes du groupe 2, $M(\eta^5\text{-}C_5H_5)_2$ (M = Mg ou Ca). Afin d'essayer de comprendre pourquoi le $Mg(\eta^5\text{-}C_5H_5)_2$ est linéaire alors que le $Ca(\eta^5\text{-}C_5H_5)_2$ est replié, on a analysé la topologie de la densité de charge calculée (ρ) et de son laplacien ($\nabla^2\rho$) en utilisant un nouvel algorithme pour la recherche du point critique. Le laplacien du noyau de l'atome de Ca du $Ca(\eta^5\text{-}C_5H_5)_2$ est perturbé par le champ polarisant des coordinats cyclopentadiényles et sa géométrie repliée est une conséquence des interactions entre le noyau déformé et les atomes du coordinat. Dans le cas du $Mg(\eta^5\text{-}C_5H_5)_2$, la concentration maximale de la charge dans le noyau du Mg se produit le long des vecteurs reliant le métal aux centroïdes des coordinats cyclopentadiényles que la molécule soit linéaire ou pas et on s'attend alors à une géométrie linéaire qui soit privilégiée. Les résultats de ces calculs démontrent qu'il est possible de comprendre les géométries des métallocènes du groupe 2 en termes d'interactions répulsives entre les coordinats et entre les coordinats et le noyau déformé de l'atome de métal.

Mots clés : atomes dans les molécules, métallocènes du groupe 2, VSEPR, densité de charge, laplacien de ρ.

Introduction

The factors governing molecular geometry are important and fundamental to our understanding of chemistry – why do molecules prefer some shapes and not others? In trying to answer this question one is struck by the fact that despite the vast number of different molecules, there exist common geometrical motifs that persist even when the constituent atoms of a molecule are changed. Clearly, rules which allow this vast body of information to be classified are of importance to chemistry as they allow us to understand what is known, and make predictions about what is not.

Perhaps the simplest set of rules that can be used to understand and classify molecular geometries are those of the valence shell electron pair repulsion (VSEPR) model (1–3). The VSEPR model requires that we consider the strength of mutual repulsions between the different types of electron pairs present within the molecule in order to obtain its preferred, or energetically most favourable, geometry. The intuitive nature of the VSEPR model is one of its most useful features, and one that has allowed its application to a wide variety of molecules, ranging from those containing main group atoms (1–3) to those containing transition metals (4, 5). The successes of the VSEPR model should, of course, prompt us to study the model in order to understand why it is often so successful, and, likewise, we should seek the reasons for its failures because uncovering these reasons should lead to a deeper understanding of molecular geometry.

The fundamental postulate of the VSEPR model, that molecular shape is determined by repulsions between bonding and nonbonding pairs of electrons, is explained by the Pauli exclusion principle. Electrons are not, however, really local-

ized to form pairs (6, 7), but this idea remains valid if we consider regions in the valence shell where charge is locally concentrated arising from the localization of the Fermi hole (8, 9). Regions where charge is concentrated, which are revealed by the Laplacian of the charge density ($\nabla^2\rho$) (8–10) have played an important role in understanding the VSEPR model, resulting in it being reformulated in terms of electron-pair domains (2, 3, 11, 12) i.e., the regions in the valence shell where charge is locally concentrated.

For many molecules of the main groups, there is excellent agreement between the expected locations of the electron pairs of the VSEPR model and the locations of maximum charge concentration (8–10). Therefore, the physical basis for the VSEPR model is provided by the Laplacian of the charge density (8, 9) in that preferred molecular geometries may be described in terms of the repulsions between these regions of charge concentration rather than between localized pairs of electrons. For example, the geometries of ClF_3 (**1**) and SF_4 (**2**) are both derived from the trigonal bipyramid, in which the bonding and lone pair electrons of the VSEPR model appear as regions of maximum charge concentration and their preferred geometries explained accordingly (8, 9). This relationship between the VSEPR model and $\nabla^2\rho$ is observed for many main group molecules (9), so that one might then ask what the Laplacian of the charge density reveals for molecules which have geometries not accounted for by the VSEPR model.

One such set of counter-examples to the VSEPR model are the YSF_4 (Y = O, NH, or CH_2) (**3**), which are trigonal bipyramidal as predicted; however, taking into consideration the decreasing electronegativity of the series Y = O, NH, CH_2 it might be expected that both equatorial and axial F-S-F bond angles would decrease. Experimentally, it is found that the equatorial bond angle does decrease (13, 14) as expected but the axial bond angles in fact *increase*. Analysis of $\nabla^2\rho$ for these molecules provides a clear picture of the S—Y bonding region, from which it can be seen that the charge concentrations are elliptical with the major axis in the equatorial plane (15). As Y = O, NH, CH_2 the ellipticity increases, resulting in an increased amount of charge concentrated in the equatorial plane (resulting in decreased equatorial F-S-F bond angles) and a decreased amount of charge concentrated in the axial plane (resulting in increased axial F-S-F bond angles). Thus the observed geometries can be thought of as arising from the repulsions between the different types of bonding charge concentrations as revealed by the Laplacian of the charge density.

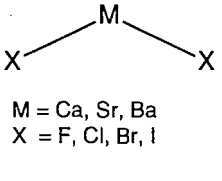
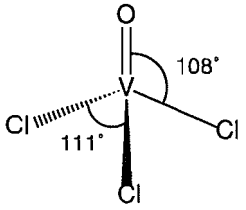
3

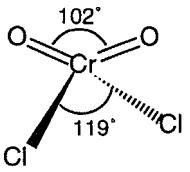
The explanation of these apparent exceptions to the VSEPR model in terms of $\nabla^2\rho$ is encouraging and led to the consideration of others, namely the difluorides of group 2. It has been known for some time that the halides of Ca, Sr, and Ba (**4**) are bent (16, 17) and analysis of $\nabla^2\rho$ for these molecules has shown (18) that this bending is a consequence of distortions of the metal atom by the presence of the fluoride ligands. It is usual to think of the central atoms in these molecules as spherical but, as was suggested some time ago (19), metals may be sufficiently polarizable that their cores are distorted in the presence of some ligands. The importance of considering such distortions of the core charge density of transition metals has been noted previously, for example in explaining the deviation of the bond angles in $VOCl_3$ (20) (**5**) and CrO_2Cl_2 (21) (**6**) from the VSEPR predicted angles. In the case of CaF_2, partial condensation of the core electrons into pairs results in a distorted Ca^{2+} core that contains regions of charge concentration, i.e., it is no longer spherical. Interaction between the ligands and these regions of core charge concentrations (CCC) results in the observed nonlinear geometry for this molecule.



4



5



6

A closely related set of molecules are the metallocenes of group 2, for which gas phase electron diffraction experiments have shown that $MgCp_2$ (22) and $MgCp^*_2$ (23, 24) are linear, while $CaCp^*_2$ (23, 24), $SrCp^*_2$, and $BaCp^*_2$ (25, 26) are all bent. In the solid phase $MgCp_2$ (27) is also linear, while $CaCp_2$ (28), $CaCp^*_2$ (29), and $BaCp^*_2$ (30) are all bent, where Cp = cyclopentadienyl, η^5-C_5H_5 and Cp^* = pentamethyl-cyclopentadienyl, η^5-$C_5(CH_3)_5$. Theoretical studies of the bonding and photoelectron spectra (31–33) have been reported for lanthanide metallocenes and the importance of electron correlation in the description of transition metal metallocenes has also been established (34–36). More recently, ab initio calculations of group 2 and lanthanide metallocenes (37) showed that the bending potential in these molecules is small (<1 kcal

mol^{-1}) and, based on natural population analysis, the preference for nonlinear geometries was ascribed to π-type covalent contributions to the metal–cyclopentadienyl bonding. Recently, molecular mechanics methods have been used to explain the bent nature of these molecules (38, 39) by the introduction of an attractive ligand–ligand potential. We present here the results of ab initio calculations using all-electron basis sets for some group 2 metallocenes (MCp_2 where M = Mg and Ca) and study the distortion of the central metal atom by the cyclopentadienyl ligands in order to understand the preferred nonlinear geometry of these molecules.

Theoretical details

The geometries of the MCp_2 (M = Mg and Ca) were optimized with the imposition of C_s symmetry and with the Cp rings staggered with respect to each other. In addition the M-X vector was fixed normal to the C_5 ring, where X will be used throughout to denote the centroid of the Cp ring. Within this framework, all M—C, C—C, and C—H bond lengths were optimized, as was the X-M-X angle. Calculations were performed at both the Hartree–Fock (HF) and the B3LYP density functional methods using all-electron basis sets. The extended Wachters basis set was used for Ca (40) as this was found to give an adequate description of Ca in previous calculations (18) and the standard 6−311G* basis set was used to describe Mg (41). For C and H the standard 6-31G* was used (41) after preliminary results suggested that the addition of the polarization function to carbon was required in order to obtain a bent equilibrium geometry for $CaCp_2$.

Previous calculations of group 2 dihalides have shown that the inclusion of the effects of electron correlation is required in order to obtain nonlinear geometries. The size of the these metallocenes, coupled with our desire to study the distortion of the metal atom, precluded the use of effective core potentials and Möller–Plesset perturbation theory. To examine the effects of electron correlation, density functional calculations incorporating exchange-correlation functionals, as implemented in the GAUSSIAN92/DFT software package (41), were also performed. The B3LYP functional was chosen because of its successful application to a variety of main group molecules giving results of MP2 (or better) quality (42–44). Additionally, the B3LYP calculations allow for a comparison of total charge densities with those calculated at the HF level.

The wave functions obtained from each of the calculations have been analysed within the context of the theory of "Atoms in Molecules" (AIM), and atomic properties have been calculated using the PROAIM program (45).[2] AIM theory, through the topological analysis of the total charge density (ρ) shows how molecules can be divided naturally into their constituent atoms, while the Laplacian of the charge density ($\nabla^2\rho$) reveals where charge is locally concentrated and depleted. Finding the critical points in these scalar fields that have complicated topologies is both a challenging and cumbersome task unless a robust algorithm can be relied upon. In general, the search for critical points in the Laplacian of the charge density would greatly benefit from such an algorithm as it has a more complex topology than that of the charge density. Unravelling the topology of the charge density for the complexes described here, however, poses serious problems for the conventional algorithm.[3] This is a consequence of the use of the Newton–Raphson (NR) method, which requires excellent starting points in order to be successful. This can be explained by considering that the best step $\boldsymbol{h}$ to get from the current point to the critical point is $\boldsymbol{h} = -\boldsymbol{H}^{-1}\boldsymbol{g}$ where $\boldsymbol{H}$ is the Hessian matrix. This step can be re-expressed in terms of the eigenvectors $\boldsymbol{V}_i$ and eigenvalues b_i of the Hessian (of the scalar field) by

$$[1] \quad \boldsymbol{h} = -\sum_{i=1}^{3} F_i \boldsymbol{V}_i / b_i$$

where $F_i = \boldsymbol{V}_i^T\boldsymbol{g}$ is the projection of the gradient $\boldsymbol{g}$ along the local eigenmode $\boldsymbol{V}_i$.

It has been shown previously (46) that the NR method minimizes along eigenmodes with positive Hessian eigenvalues and maximizes along modes with negative eigenvalues. Suppose we wish to locate a transition state on a surface starting in a region where the Hessian has one negative eigenvalue. In such a region the NR step is appropriate because it does exactly what is required: it maximizes along one mode while minimizing along the others. Thus in general the NR method only successfully locates a critical point provided that it starts in a region where the Hessian has the correct structure. For our purposes, this would mean, for example, that starting in a region where the Hessian has a signature of minus one (corresponding to a bond critical point) we could never find a nearby ring critical point, which has a different signature.

This inadequacy of the NR method has been remedied by using the powerful *eigenvector following method* algorithm (47) and its subsequent refinement (48). Its success has recently been proven convincingly (49) in the context of Atoms in Molecules (AIM). The program MORPHY 1.0 (50), which utilizes the *eigenvector following method*, yielded consistent atomic graphs (i.e., the unique trajectories of the gradient of $\nabla^2\rho$ that link the charge concentration maxima (51)) for all systems studied and was also used to prepare all of the different contour plots presented here. This program searches for critical points in a chainlike manner, i.e., the locations of previously found critical points are used to generate suitable starting points in the search for others. The reduced sensitivity to starting conditions has allowed successful use of MORPHY in the study of $\nabla^2\rho$ (S. Johnson, private communication), nevertheless, the topological studies of $\nabla^2\rho$ of the group 2 metals presented here required a huge computational investment.

Results and discussion

Geometries

Optimized bond lengths and angles for the various calculations of $MgCp_2$ and $CaCp_2$ are given in Table 1 and the optimized geometries are shown in Fig. 1. In general, bond lengths and angles calculated using the two methods agree: compared to the B3LYP method, the HF method predicts slightly longer M—C bond lengths and a larger X-M-X angle. Agreement with experiment is also good and both methods predict a linear $MgCp_2$ molecule, and a bent $CaCp_2$ molecule.

Nonequilibrium geometries were also studied in order to obtain some idea of the bending potential for these molecules. The geometry of $MgCp_2$ was optimized using both the HF and B3LYP methods with the X-Mg-X angle constrained at 150°, and the resultant geometries (Table 1) were 6.8 kcal mol^{-1} (HF) and 6.5 kcal mol^{-1} (B3LYP) higher than at the equilibrium geometries. These results are similar to those obtained previously for HF calculations of $MgCp_2$ (26) from which it was estimated that approximately 3.5 kcal mol^{-1} was required to bend the molecule from 180° to 160°.

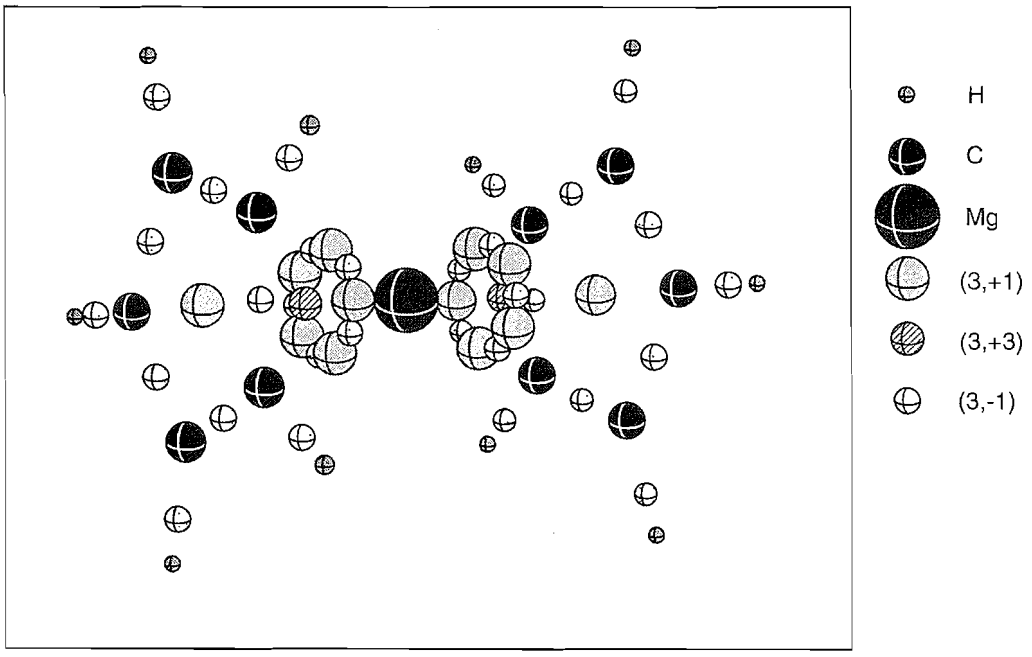
Bending the $CaCp_2$ molecule from the equilibrium X-Ca-X value to 180° requires much less energy, only 0.3 and 1.2 kcal mol^{-1} at the HF and B3LYP levels, respectively. These energies are also consistent with previous calculations (26, 37), where it was found that the location of a bent equilibrium geometry was basis set and method dependent. The use of reasonably sized all-electron basis sets in the calculations given here may be an important factor in obtaining a bent geometry for $CaCp_2$, and indeed the large number of calculations for the group 2 dihalides (52, 53) and previous calculations of metallocenes (34–36) suggests that these systems are very sensitive to the basis sets and calculational methods chosen. Nevertheless, our results support the contention that $CaCp_2$ is bent but very floppy.

In all of the calculations a staggered arrangement of Cp rings was assumed. Experimental results for $CaCp_2$ suggest that this is reasonable (23, 24), however, on the basis of gas phase electron diffraction data it was not possible to assign either a staggered or eclipsed conformation to $MgCp_2$ (22). Although a staggered conformation was used in this work, the HF energy of the eclipsed conformation was found to be only 0.01 kcal mol^{-1} higher in energy than the staggered conformation (i.e., negligible), in agreement with the experimental finding.

Charge density and bonding

The total charge densities of these group 2 metallocenes are expected to have quite complex topologies, comprising: 10 M—C, 10 C—C, and 10 C—H bond critical points; 10 ring critical points belonging to each M and adjacently connected C atoms; a ring critical point in the plane of each cyclopenta-

Fig. 2. The molecular graph for the linear $MgCp_2$ molecule. The complex topology is apparent, with bond (3, −1), ring (3, +1), and cage (3, +3) critical points all in close proximity.



dienyl ligand; and a cage critical point in the region between M and each of the centroids of the cyclopentadienyl rings. All of these critical points are required in order to construct a proper molecular graph that satisfies the Poincaré–Hopf relationship (9) for η^5 coordination of two cyclopentadienyl rings to a metal atom. Initial topological analysis using the Newton–Raphson technique, as implemented by the EXTREME program[3] in the AIMPAC suite of programs, was not successful in the location of the bond and ring critical points between the metal and carbon atoms. The eigenvector following method as implemented in the MORPHY program (49, 50) was successful, however, and the results of the topological analyses are summarized in Table 2. The spatial relationship between the various types of critical points and the atom locations is shown in Fig. 2 for Hartree–Fock optimized $MgCp_2$ molecule; this arrangement of critical points is similar to that found in each of the other total charge density analyses.

The η^5 coordination of the cyclopentadienyl ligands is demonstrated quite clearly by location of bond critical points along all M–C vectors, i.e., bonding occurs between the metal and carbon atoms and *not* between the metal and the centre of the Cp ring. Metal–carbon bond critical points occur at regions of local charge depletion (Table 2) indicative of ionic bonding between these atoms, in accord with that suggested previously (37). Values of ρ and $\nabla^2\rho$ for the different critical points obtained from the HF and B3LYP charge densities are similar; the B3LYP values of ρ at the M—C bond critical points are slightly larger than the analogous HF values, although not significantly so. For $CaCp_2$ the values of ρ at the Ca—C bond critical point are less than was found in $Ca(CH_3)_2$ by approximately 0.015 au (18), indicating that the 10 Ca—C bonds in $CaCp_2$ are not as strong as the two Ca—C bonds in the $Ca(CH_3)_2$ complex. The C—C and C—H nuclei of the cyclopentadienyl ligands are bound via shared interactions, typical of the covalent character expected for these bonds.

Plots of the total charge densities are shown in Fig. 3 for the HF optimized geometries of $MgCp_2$ and $CaCp_2$. For $MgCp_2$ these plots show how the magnesium atom has been distorted from spherical upon complex formation (Fig. 3*a*) and is now more ellipsoidal. The nonspherical shape of the Ca atom is also evident in a similar plot (Fig. 3*b*) while the plot for the Cp ligand in the $MgCp_2$ molecule (Fig. 3*c*) shows quite clearly the atomic boundaries of each atom and the expected ring critical point at the centre of the five-membered ring. Additionally, these plots show how these metallocene molecules may be divided into their constituent atoms.

It is usual to consider the formal charge distribution in these group 2 metallocenes as $M^{2+}(Cp^-)_2$, i.e., analogous with the group 2 dihalides. The AIM atomic charges in these metallocenes were calculated in order to see how much charge may be properly ascribed to the various portions of these MCp_2 molecules, and to see if comparison with the analogous dihalides is indeed warranted. Atomic charges were obtained by integration over the various atomic basins, using the PROMEGA program (45). The charges for $MgCp_2$ indicate a large degree of metal–ligand charge separation, with the Mg atom and Cp ligands having approximate charges of +1.75 and −0.88 respectively (see Table 2). These charges are similar to those obtained previously for MgF_2 (18) and suggest that the ionic model used to describe MgF_2 is applicable to $MgCp_2$. Similarly, charges obtained for the Ca atom and the Cp ligand are of the order of 1.6 and −0.8 respectively, which are similar to the analogous charges obtained previously for CaF_2, CaH_2, and $Ca(CH_3)_2$ (18).

[f]Distance (in au) of the charge concentration maximum from the nucleus.

(X-M-X = 150°) $MgCp_2$ molecule are shown in Fig. 4. The B3LYP charge densities for these $MgCp_2$ molecules yielded similar results to the HF analysis, and these results are given in Table 2. Two (3, −3) critical points in $\nabla^2\rho$ belonging to the core region of the Mg atom were located along the vectors connecting the Mg atom with the center of the Cp ligands. This is shown clearly in Fig. 4*a*, where the locations of the CCC's are shown relative to the Cp ligands. No charge concentration maxima are located along Mg—C bonds, further illustrated in Fig. 4*b*, and the atomic graph of Mg is essentially the same as that found previously for MgF_2 (18).

A plot of $\nabla^2\rho$ for the Cp ligand is given in Fig. 4*c*, which shows clearly the regions of charge concentration along the C—C and C—H bonds. Each carbon atom has three charge concentration maxima, one along each C—C bond and one along the C—H bond. The apparent maxima in the valence shell of the C atoms visible in Figs. 4*a* and 4*b* are a consequence of the plotting plane chosen, and are not (3, −3) critical points in $\nabla^2\rho$.

It is also of interest to see how the atomic graph of Mg changes as the molecule is bent. At an X-M-X angle of 150° it was found that the two CCC's found in the linear molecule (Fig. 4*a*) followed the direction of bending, with one of the maxima now situated along an Mg—C bond (Fig. 4*d*). This behaviour upon bending was also noted for MgF_2, thus the preferred linear geometry in both molecules (i.e., $MgCp_2$ and MgF_2) can be understood in terms of the minimization of both the ligand–ligand and CCC–ligand interactions.

Analysis of $\nabla^2\rho$ for $CaCp_2$

Plots of $\nabla^2\rho$ for the HF optimized $CaCp_2$ molecule are shown in Fig. 5. Figure 5*a* shows the arrangement of the Cp ligands with respect to the regions of charge concentration in the Ca core, and Fig. 5*b* is plotted in this same plane focussing upon the Ca atom. Four charge concentration maxima were located in this core region, two in the region between the bond paths shown in Fig. 5*b*, and two in the same plane, in the long, narrow region apparent in Fig. 5*b*. These latter two charge concentration maxima are very close (≈0.3 au apart) and upon further bending to an X-M-X angle of 148° they coalesce, giving a total of three CCC maxima (see Fig. 6).

To ensure that no charge concentration maxima had been missed, a complete atomic graph was determined, and only the four maxima shown in Fig. 5*b* were located. This arrangement of charge concentration maxima is related to that found for the HF optimized CaF_2 molecule. This relationship is shown schematically in Fig. 6 where the approximate arrangement of the (3, −3) critical points in the Ca core, with respect to the X (i.e., the centroid of the Cp ligands) and F positions in $CaCp_2$ and CaF_2 respectively, is given. This difference in atomic graphs is probably due to the formation of ligand-opposed charge concentrations in CaF_2, resulting in only two maxima, while the expected 10 ligand-opposed charge concentration maxima here collapse into the arrangement found.

At the HF level linear $CaCp_2$ was found to be approximately 0.3 kcal mol^{-1} higher in energy than the bent molecule. This slight preference for the bent geometry may be understood in

Fig. 3. Plots of the total charge density with interatomic surfaces overlaid for the HF optimized $MgCp_2$ and $CaCp_2$ molecules. In these and following plots, bold asterisks; bold, open circles; and filled squares are used to mark the positions of cage (3, +3), ring (3, +1), and bond (3, −1) critical points in ρ, respectively. Bold labels and filled circles are used to label nuclei in the plotting plane, while outlined atom labels and circles are used denote nuclei that are not in the plotting plane. (*a*) In the plane containing four C nuclei and the Mg nucleus. The overlaid interatomic surfaces show the slightly nonspherical shape of the Mg atom. (*b*) A similar plot for $CaCp_2$ shown in the plane containing the Ca atom and a C atom on each Cp ligand. terms of the different distributions of maxima in $\nabla^2\rho$. Figure 7 shows plots of $\nabla^2\rho$ for the linear $CaCp_2$ molecule. The region of core charge concentration is barely visible in Fig. 7*a*, while Fig. 7*b* (plotted in the same plane as Fig. 7*a*) shows the intersection of this plane with the two tori of charge concentration maxima. A plot in the plane of one of these tori of charge concentration is shown in Fig. 7*c*. Five charge concentration maxima were located in this torus and these are staggered with respect to the nearest cyclopentadienyl ring (labelled in Fig. 7*c*). As can be seen in Fig. 7*c*, however, this region of charge

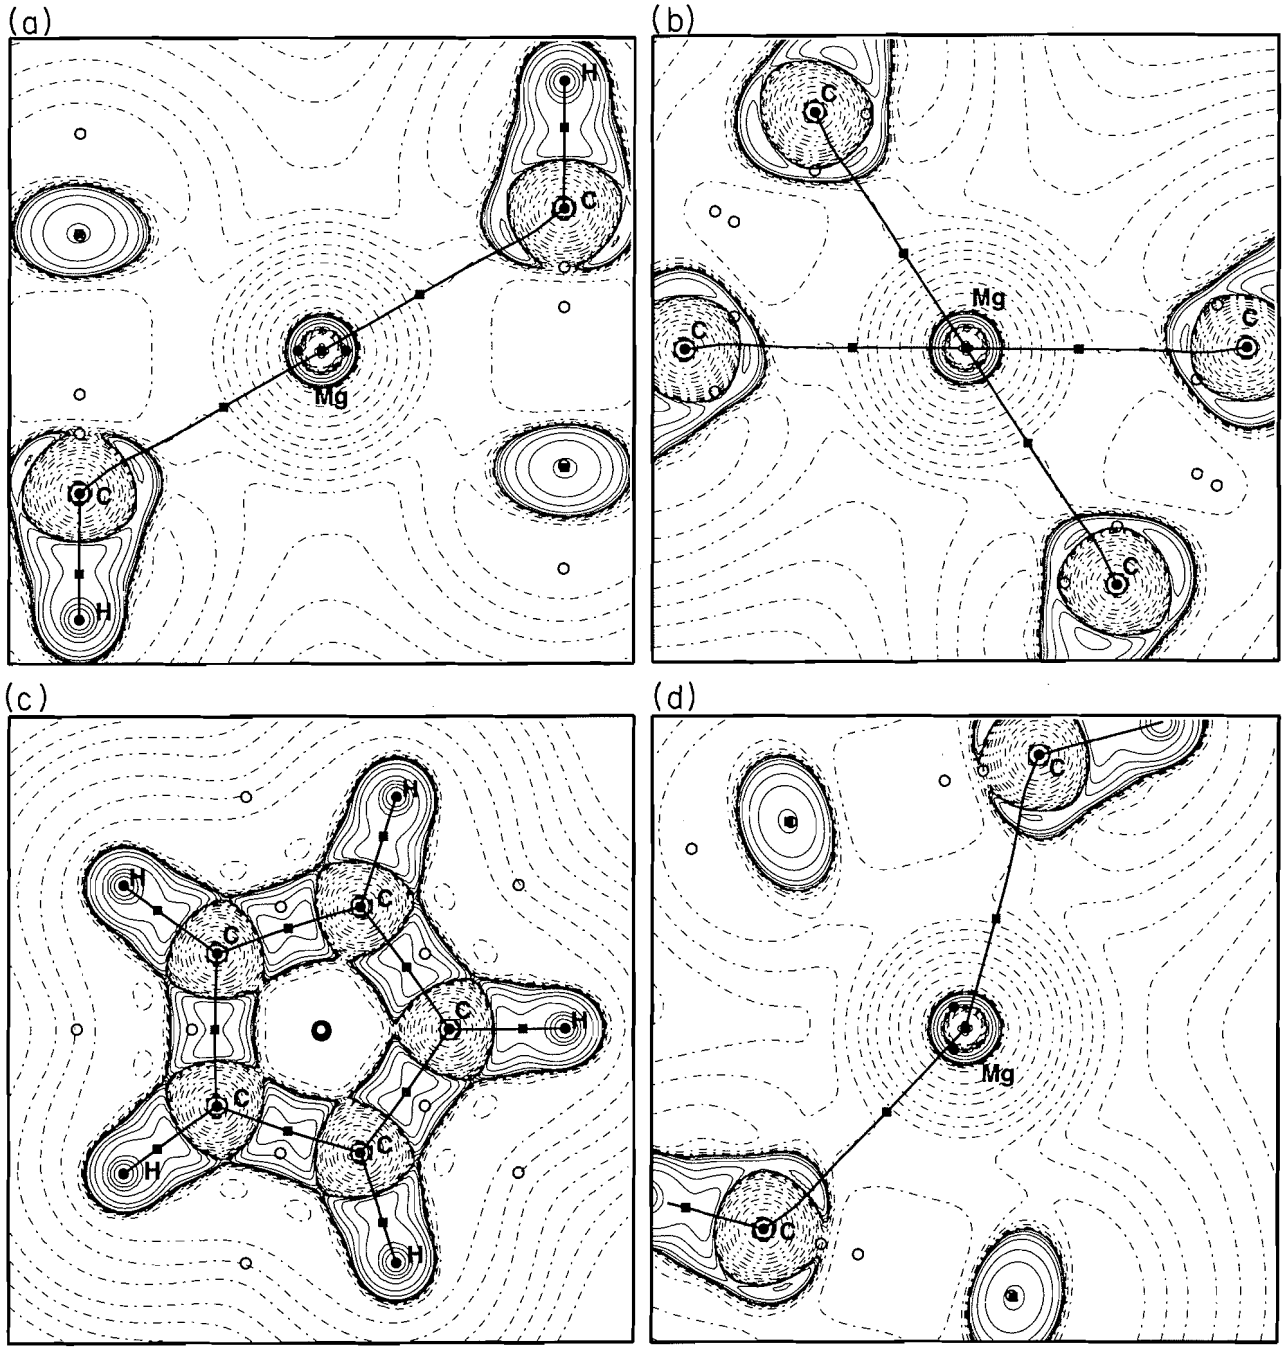
Fig. 4. Plots of the Laplacian of the charge density for the $MgCp_2$ molecule. In this and following plots of $\nabla^2\rho$, regions of charge concentration ($\nabla^2\rho < 0$) are denoted by solid contours and regions of charge depletion ($\nabla^2\rho > 0$) by broken contours. Critical points in ρ are denoted by the same symbols as those used in Fig. 3. (*a*) Linear $MgCp_2$ showing the location of the maxima in $-\nabla^2\rho$ (denoted by the filled circles near the Mg nucleus) in the magnesium core. Note also that the Mg—C bond critical points are in regions of charge depletion. (*b*) $\nabla^2\rho$ plotted in the same plane as that used in Fig. 3*b*. Neither of the magnesium CCC are located in this plane. (*c*) A plot of $\nabla^2\rho$ in the plane of the cyclopentadienyl ligand, showing the covalent C—C and C—H bonds, and the region of charge depletion in the center of the ring. (*d*) A plot of $\nabla^2\rho$ for the bent $MgCp_2$ molecule in the same plane as that shown in (*a*). Note that the CCC are still directed along the Mg–X vector as in the linear molecule.



concentration is better described as a torus as the contour value shown is for a $\nabla^2\rho$ value of 0.395 au while the values at the maxima are only 0.402 au. The resolution of the torus of charge concentration into five maxima is a consequence of the D_{5d} symmetry of the molecule. In contrast to the bent molecule then, there are now regions of charge concentration (i.e., both tori) along all 10 Ca—C bonds in the linear molecule, which results in a less favourable geometry.

Previous studies of ρ and $\nabla^2\rho$ have shown that their topologies remain the same upon inclusion of electron correlation and only small quantitative changes at various critical points were noted (54, 55). With this in mind, the topologies of $\nabla^2\rho$

Fig. 5. Plots of $\nabla^2\rho$ for the HF optimized $CaCp_2$ molecule. (*a*) In the same plane as that used previously in Figs. 4(*a*) and 4(*d*) for $MgCp_2$. The region of charge concentration in the calcium core can be seen, although its topology is not evident. (*b*) In the same plane but focussing upon the calcium core region. Four maxima in $-\nabla^2\rho$ were found in this region, two are well defined by the contour chosen (0.39 au) regions and two in the long, narrow region in the middle left of the plot.

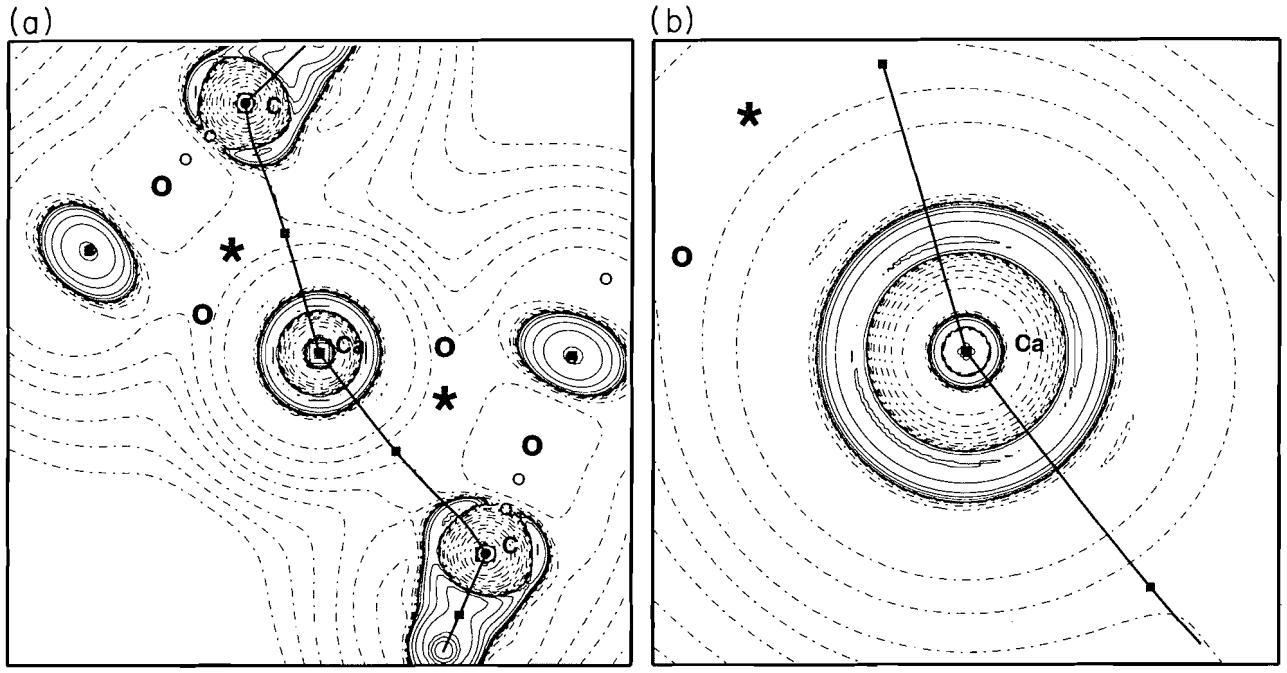


Fig. 6. Schematic representations of the arrangement of charge concentration maxima in the calcium core in both CaF_2 and $CaCp_2$ molecules relative to the fluoride and cyclopentadienyl ligands (X denotes the centroid of the Cp ligand). The approximate positions of charge concentration maxima are denoted by asterisks and are in the plane of the page in all cases except for the B3LYP optimized geometry of $CaCp_2$ (bottom right) in which case + and − symbols denote charge concentration maxima above and below the plane of the page, respectively.

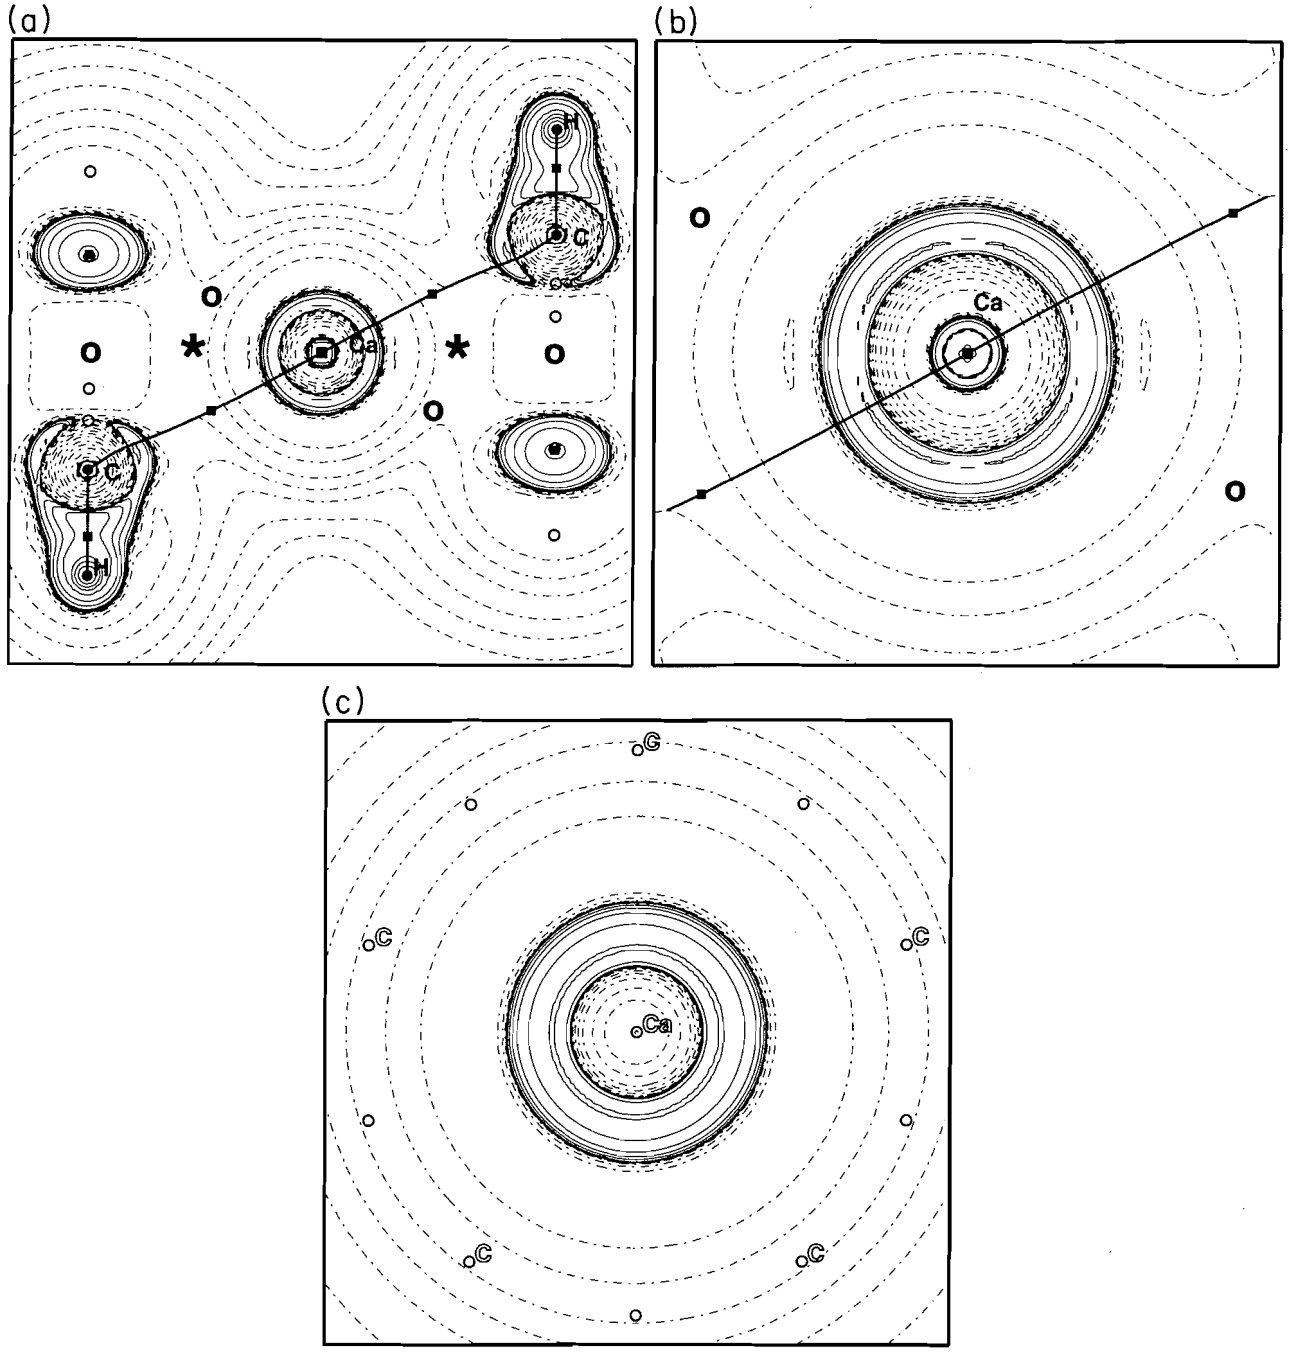
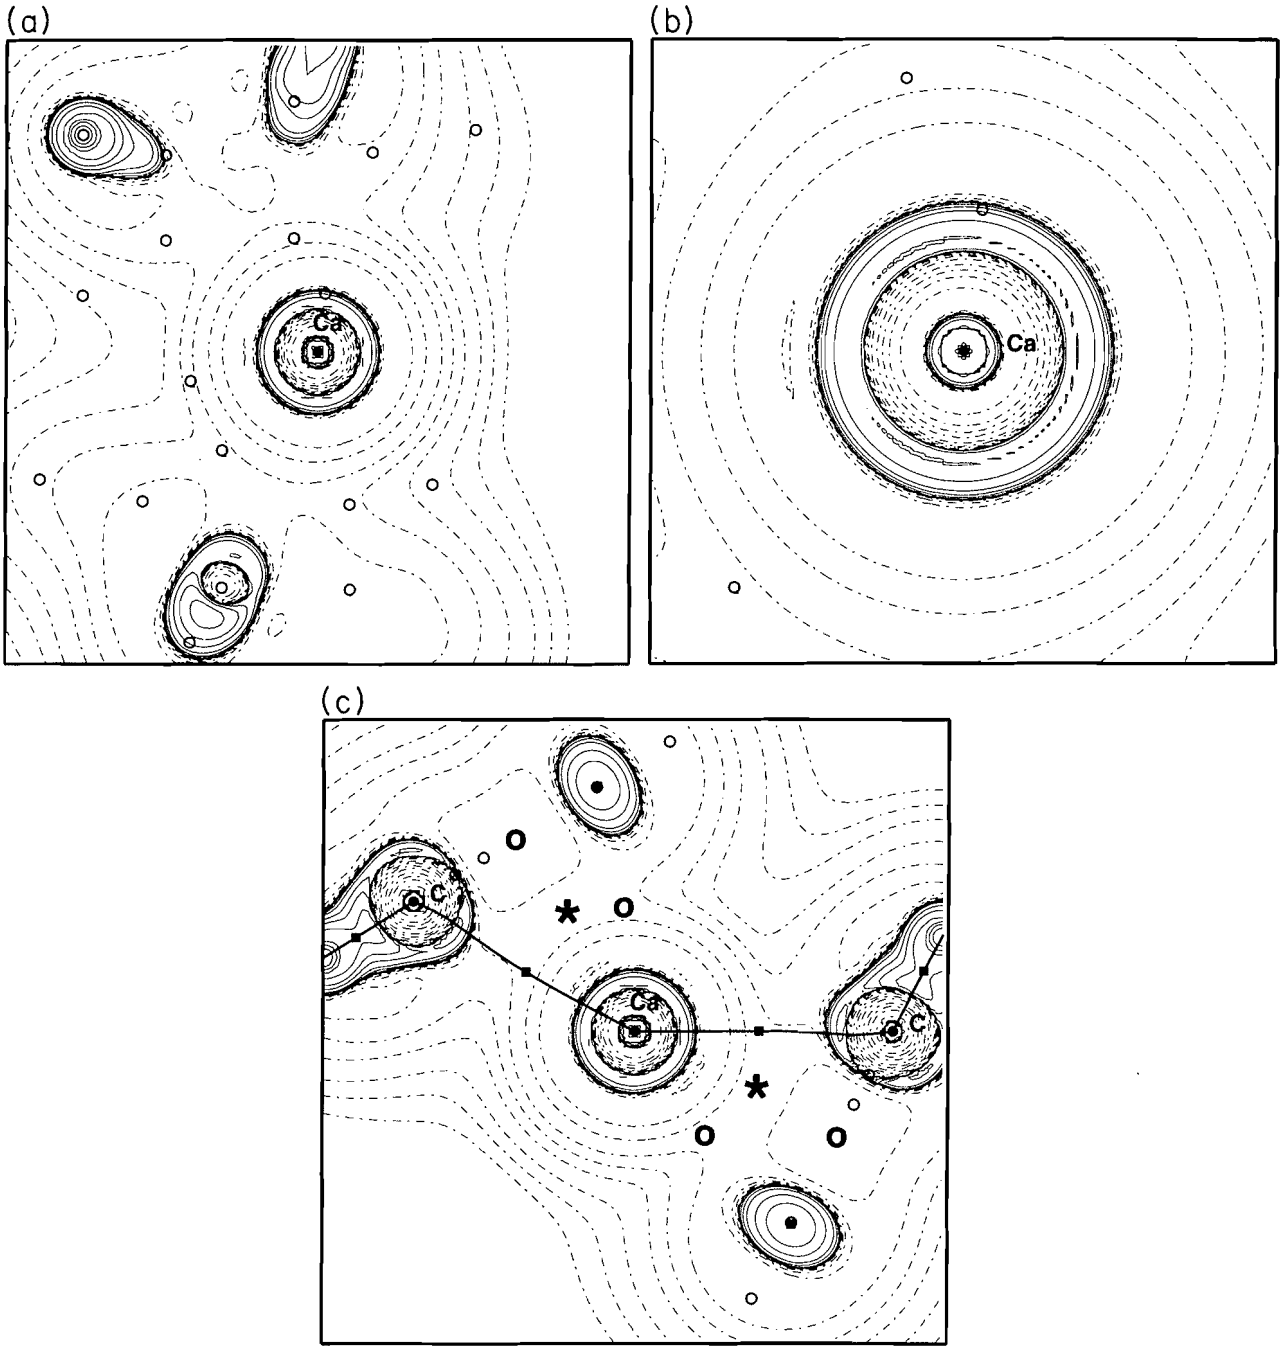
X-M-X = 148°

Fig. 7. Plots of $\nabla^2\rho$ for the linear $CaCp_2$ molecule. (*a*) In the same plane as that used in Fig. 4*a*. (*b*) Focussing on the the calcium core region in this plane. The intersection of this plane with the tori of charge concentration maxima is apparent in this plot. (*c*) Plotted in the plane containing five charge concentration maxima with the C atoms of the nearest Cp ligand labelled. The five maxima are not apparent even though a contour of 0.395 was used and the maxima have values of 0.402 au.



obtained from the B3LYP charge densities were also examined and values of the various (3, −3) charge concentration maxima are given in Table 2. As might be expected, the values of $\nabla^2\rho$ calculated by the two methods are in good agreement with each other, as are the distances from the calcium nucleus to the (3, −3) critical points. There is, however, a small difference in the atomic graphs of Ca given by the two methods. Analysis of the wave function obtained from the B3LYP geometry optimization of $CaCp_2$ revealed a square pyramidal arrangement of charge concentration maxima in the atomic graph of the Ca atom. A summary of the different atomic graphs obtained for the various calculations of $CaCp_2$ are shown in Fig. 6, along with that obtained previously for CaF_2 (18). These diagrams show how the various atomic graphs are related through the joining and splitting of charge concentration maxima.

Fig. 8. Plots of $\nabla^2\rho$ for the B3LYP optimized $CaCp_2$ molecule. (*a*) A view of the molecule plotted in the plane containing three of the calcium CCC maxima. No C or H nuclei are in this plane. (*b*) The calcium core shown in this same plane. The five charge concentration maxima are arranged in the form of a square pyramid, with the apex to the right of the Ca nucleus, and two diametrically opposed maxima shown in the left. (*c*) A plot for this molecule in the plane containing the Ca and two C atoms, i.e., that used in previous plots. $\nabla^2\rho$ in the core region is similar (in gross terms) to that shown in Fig. 5*a*.



A plot of $\nabla^2\rho$ in the plane defined by the apical and two diametrically opposed charge concentrations is shown in Fig. 8*a*, which shows the relationship between the location of the core charge concentration maxima and the cyclopentadienyl ligands — note that no nuclei lie in this plane. Figure 8*b* is a magnification of the Ca core in the same plane as that used in Fig. 8*a*, where the apical charge concentration maximum is to the right of the Ca nucleus. Finally, a plot of $\nabla^2\rho$ in the same plane as that used in Fig. 5*a* is given in Fig. 8*c*, which shows the gross similarity between the HF and B3LYP results.

Results for the B3LYP calculations of the linear $CaCp_2$ molecule are also similar to the HF results, revealing two tori of charge concentration intersecting the Ca—C bond paths. In this case, however, the 10 charge concentration maxima are

eclipsed with respect to the nearest cyclopentadienyl ligand but, as found previously, the values of $-\nabla^2\rho$ are only marginally larger than the surrounding region of charge concentration. Thus a plot of $\nabla^2\rho$ in the plane of the five charge concentrations nearest a Cp ligand obtained from the linear B3LYP wave function is almost indistinguishable from that given in Fig. 7*c*. Although this finding is slightly different than the HF results, the location of critical points is an artifact of the imposed symmetry, and the explanation for the preferred bent geometry is the same.

Conclusions

The work presented here is part of the continuing exploration of the physical basis for the VSEPR model. We have presented charge density analyses for both magnesium and calcium dicyclopentadienes, and have shown that their preferred geometries can be understood using arguments similar to those used to explain the geometries of both MgF_2 and CaF_2 (18). Metallocene formation results in sufficient distortion of the metal atom such that it can no longer be considered spherical, as is usually assumed in the VSEPR model. It is these interactions between the ligands and the distorted core of the metal atom that play an important part in determining the preferred arrangement of the cyclopentadienyl ligands. Thus the preferred geometry is one in which the various types of interactions (i.e., ligand–ligand, CCC–ligand, and CCC–CCC) are minimized, in keeping with the spirit of the VSEPR model.

It is worth noting, however, that the possibility of attractive interactions between the cyclopentadienyl ligands in these group 2 metallocenes has been suggested (38, 39). In these calculations the group 2 metal atom was assumed to be spherical (39) so that the introduction of a Cp–Cp attractive term is then necessary in order to recover the bent nature of these molecules. On the basis of the results presented here it is not possible to dismiss the possibility of such dispersive (attractive) interactions between the Cp ligands in these molecules, although our explanation has the advantage that it is applicable to situations where such ligand–ligand attractions are not expected (e.g., the heavier group 2 dihalides). In terms of a molecular mechanics model, it seems reasonable to suggest that a potential function that mirrors these CCC–ligand repulsions be incorporated in place of the ligand–ligand attractive potential.

The testing ground for these ideas lies in the realm of experiment because, as we have seen, it is the exceptions to the VSEPR model that have prompted further study, and challenged its underlying assumptions. Within the context of this current work, it would be of interest to see how preferred geometries are affected as the size of the coordinated ligands is increased.

A comparative study of the energetics, structures, and mechanisms of the HCN ↔ HNC and LiCN ↔ LiNC isomerizations

V. Sreedhara Rao, Amrendra Vijay, and A.K. Chandra

Abstract: The potential energy surfaces of the HCN ↔ HNC and LiCN ↔ LiNC isomerization processes were determined by ab initio theory using fully optimized triple-zeta double polarization types of basis sets. Both the MP2 corrections and the QCISD level of calculations were performed to correct for the electron correlation. Results show that electron correlation has a considerable influence on the energetics and structures. Analysis of the intramolecular bond rearrangement processes reveals that, in both cases, H (or Li^+) migrates in an almost elliptic path in the plane of the molecule. In HCN ↔ HNC, the migrating hydrogen interacts with the in-plane π,π^* orbitals of CN, leading to a decrease in the C—N bond order. In LiCN ↔ LiNC, Li^+ does not interact with the corresponding π,π^* orbitals of CN.

Key words: potential energy surfaces, intra-molecular bond rearrangement, bond orders, elliptic path, migration of Li^+.

Résumé : On a déterminé les surfaces d'énergie potentielle des processus d'isomérisation HCN ↔ HNC et LiCN ↔ LiNC à l'aide de la théorie ab initio, en faisant appel à des ensembles de base de type double polarisation, triple zêta, totalement optimisés. Dans le but de corriger la corrélation électronique, on a effectué des corrections MP2 ainsi que des calculs au niveau QCISD. Les résultats montrent que la corrélation électronique a une grande influence sur les énergies et les structures. L'analyse des processus de réarrangement intramoléculaire des liaisons révèle que, dans chacun des cas, H (ou Li^+) migre par une voie pratiquement elliptique dans le plan de la molécule. Dans le réarrangement HCN ↔ HNC, l'hydrogène qui migre interagit avec les orbitales $\pi,\pi p^*$ dans le plan CN conduisant à une diminution de l'ordre de la liaison C—N. Dans LiCN ↔ LiNC, Li^+ n'interagit pas avec les orbitales π,π^* correspondantes du CN.

Mots clés : surfaces d'énergie potentielle, réarrangement intramoléculaire d'une liaison, ordres de liaison, voie elliptique, migration du Li^+.

[Traduit par la rédaction]

Introduction

One of the major goals of quantum chemistry is to predict from ab initial calculations the energetics, structures of molecules, and dynamics of chemical reactions. Of many chemically bound molecules, hydrogen cyanide has been studied extensively, both theoretically and experimentally (1–9). Both hydrogen cyanide and its isomer isocyanide are abundant in interstellar clouds (1). The energetics and structures of the HCN ↔ HNC isomerization process have been investigated in several papers by ab initio methods (2–9). Pau and Hehre (10) observed that the heat of reaction of the HCN ↔ HNC isomerization is 60 ± 8 kJ/mol, where HNC is the less stable. Pearson et al. (2) suggested from SCF calculations using double-zeta plus polarization functions that HNC lies 40 kJ/mol above HCN while the configuration interaction yields 61.3 kJ/mol. The barrier heights for this isomerization were estimated at 168.0 and 146.6 kJ/mol by the SCF and CI methods, respectively (2). The latter value of the barrier height was also obtained from the potential energy surface of Murrell et al. (11). Recent calculations at the single and double excitation coupled-cluster (CCSD) and CCSD(T) levels of theory by Lee and Rendell (12) led to a transition state 187 kJ/mol above the HCN isomer, while HNC was predicted to be 61 ± 4 kJ/mol above HCN. All these studies agree that HCN is linear with the H atom bound to carbon and this is borne out by experiment (13). Detailed calculations by Bowman et al. (14*a*) on the HCN ↔ HNC isomerization using a large atomic natural orbital (ANO) 1-particle basis set with the CCSD(T) theory predicts a barrier of 202.3 kJ/mol and an endothermicity of 61.7 kJ/mol measured from HCN. They have fitted the ab initio potential surface with the Morse potential via the nonlinear least-squares method and obtained the vibrational frequencies for the HCN and HNC. Their results are in good agreement, within 10 cm^{-1}, with the experimental frequencies. The further augmentation of g and f functions (14*b*) on heavy (C, N) and light (H) atoms, respectively, to the ANO basis set reveals closer agreement of the fundamental vibrational frequencies with the experimental data.

Extensive studies of the HCN ↔ HNC isomerization have

naturally led to an interest in the LiCN ↔ LiNC isomerization. LiCN is predicted to be linear and to have also an isocyanide structure (15). Besides, the number of valence electron pairs is the same in HCN and LiCN. So the correlation energies of the Li isomers are expected to be close to those of the H isomers. Among the earlier studies of the LiCN ↔ LiNC isomerization, those of Clementi et al. (15) are worth mentioning. They used a Slater-type basis set at the Hartree–Fock level and observed no energy barrier between the LiCN and LiNC linear configurations and that the two molecules have nearly the same energies. Later, Essers et al. (16) performed ab initio SCF calculations using a large polarized Gaussian basis set and observed a small barrier above LiCN for isomerization to LiNC. Experimental studies by Van Vaals et al. (17) via molecular beam microwave spectroscopy confirms the presence of LiNC and its linear structure. Ab initio calculations by von Schleyer et al. (18) predict the presence of another minimum, centered near LiNC, with T-shaped structure. This result has not been confirmed by experiment. Most recent calculations (19) on the LiCN ↔ LiNC isomerization were carried out up to second-order Møller–Plesset perturbation theory, by employing an extended 6-311++G(2d,f) basis set. These results also revealed two linear and one T-shaped structures. The energies of the various structures were found to be very sensitive to electron correlation.

Although ab initio calculations with large basis set including polarization functions are reported, the basis set parameters are not fully optimized. All of the Pople basis sets (20, 21) have larger basis set superposition errors (BSSE) (22) than the Dunning bases (22–24). Therefore the Dunning bases give more accurate energies at the both SCF and CI levels than do the Pople bases. Lee and Rendell (12) used the basis set of triple-zeta double-polarization type (TZ2P) with f functions on hydrogen and g functions on carbon and nitrogen in HCN. Addition of polarization functions generally increases BSSE and optimization of orbital exponents on augmented polarization functions could be tantamount to optimizing BSSE (25). For calculations of LiCN, Makarewicz and Ha (19) used the 6-311++G(2d,f) functions. Grev and Schaefer (26) have studied the 6-311G basis set of Pople and co-workers (27) and observed that this is essentially of the double-zeta quality and should be represented as 63-11G instead of 6-311G. This may be due to collapse of the valence orbitals into the core. The simple comparison of energies calculated with bases of different sizes cannot decide on the quality of the basis set. Rather, the optimum values of the orbital exponents determine the quality of the basis set. The magnitude of the reduced gradient of the energy with respect to the Gaussian exponents

$$|g| = \frac{\sum G_i}{n}$$

where

$$G_i = \frac{\partial E}{\partial \ln \delta_i}$$

and n = number of exponents, has been suggested as a measure of the quality of a basis set by Mezey, Kari, and Csizmadia (28). Recently, Schäfer et al. (29) determined basis sets for several atoms where all the basis set parameters are fully optimized by means of gradient techniques.[2] They noted that Huzinaga's atom-optimized GTO basis sets (30) are, in part, far from being optimized. Even Dunning bases (31) have been found to have large reduced gradients, |g|. Schäfer et al. (29) presented fully optimized basis sets, for several atoms, of relatively small size with least possible loss in accuracy. In this paper we have used their basis sets of the TZ2P type, which are expected to be superior to those created by just contracting atom-optimized GTO sets.

The main purpose of this paper is to determine the energetics, structures, and the minimum energy path for HCN ↔ HNC and LiCN ↔ LiNC isomerizations and to bring out any difference in the mechanisms of these two intramolecular bond-rearrangement processes. Although the energetics of these two processes were studied theoretically earlier, they were reported at different levels of calculation. In this paper, we maintain the same level of calculation for both systems so that a meaningful comparison can be made. We make corrections for electron correlation in our calculations.

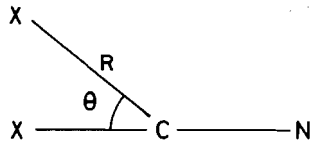
2. Computational methodology

For accurate description of chemical bonding one needs the triple-zeta double-polarization (TZ2P) type of basis set for the SCF calculations. In our calculations, we utilized a triple-zeta basis set in full space augmented with two sets of polarization functions on each atom (TZ2P). The basis set parameters for atomic core and valence orbitals were taken from Schäfer et al. (29). The exponents of the polarization functions were taken from Huzinaga (30) and the values of the polarization functions are α_p(H) = 0.388, 1.141; α_p(Li) = 0.044, 0.161; α_d(C) = 0.288, 1.335; and α_d(N) = 0.412, 1.986. To note the effect of higher polarization functions, we augmented the TZ2P set with one set of d functions on H and Li and one set of f functions on C and N (TZ2P(d,f)). The exponents of the d and f functions were taken from Dunning (31) and the values are α_d(H) = 1.057, α_d(Li) = 0.2, α_f(C) = 0.761, and α_f(N) = 1.093. These basis set parameters were optimized in full space (29). The pure spherical harmonic components of the d and f functions were incorporated in the basis sets. We used the Gaussian 92 (32) series of programs for the restricted Hartree–Fock single configuration calculations using the TZ2P and TZ2P(d,f) basis functions. We then made the correlation corrections using Møller–Plesset perturbation theory by treating the correlation part of the Hamiltonian as a perturbation on the Hartree–Fock and treating the energy expansion at the second order (MP2) (33).

We consider the quadratic configuration interaction with single and double excitations (34). This method, called QCISD, was proposed by Pople et al. (34) and has the features of size consistency. These authors claimed that the results of QCISD calculations deviate from that of CCSD in the fifth order. A more recent report (35) reveals that QCISD and CCSD are correct to the fourth order of perturbation in the space of single, double, and quadruple substitutions

[2] These basis functions were obtained via file transfer protocol from the directory with the internet address "tchibm3.chemie.uni-karlsruhe.de" (internet no. 129.13.107.186) using anonymous login.

Fig. 1. The structural parameters R and θ in the X-CN ↔ X-NC bond rearrangement processes (X = H, Li).



(MP4SDQ). Therefore, the QCISD method may be considered valuable in exploring correlation energies for a wide range of molecules. All the core and valence electrons were considered for electron correlation in both systems.

We consider that, in both the HCN ↔ HNC and LiCN ↔ LiNC isomerization processes, the C—H and C—Li bonds move away from the internuclear axis by the variable angle θ (Fig. 1). Geometry optimizations were carried out analytically at both the SCF and the correlated levels employing Schlegel's technique (36) with an SCF convergence of energy to 10^{-11} au and density to 10^{-9}. At the optimum point, the largest component of the Cartesian gradient vector was less than 10^{-4} hartree/bohr. The first derivatives of the energies were estimated analytically while the force constant matrix elements were evaluated by numerical methods at the QCISD level. The force constant matrix was then diagonalized in mass-scaled Cartesian space to obtain the vibrational frequencies. The saddle point in the isomerization paths was identified by its having only one negative eigenvalue in the force constant matrix.

3. Results and discussion

Energies of HCN, HNC, and the transition state of the HCN ↔ HNC isomerization process obtained at the different levels of calculations are reported in Table 1. Table 2 reports the results of similar calculations for the LiCN ↔ LiNC isomerization. Table 3 gives the optimized structures of the various species observed in the minimum energy paths for the two isomerization processes. The optimized equilibrium structures of HCN, HNC, LiCN, and LiNC are linear. Results show that there is hardly any influence of the additional polarization functions d,f in TZ2P on the energies or the geometrical structures in the HCN ↔ HNC and LiCN ↔ LiNC isomerization processes. On the other hand, electron correlation has a considerable influence on the energetics. Also, at the correlated levels bond lengths are longer than at the SCF level. We observe that the correlation energies in HCN, HNC, LiCN, and LiNC are nearly equal to each other in value. That the correlation energies of the Li isomers are nearly same as those of the H isomers is expected because the number of valence electron pairs is the same. Table 2 shows that at the SCF level LiNC is more stable than LiCN. Clementi et al. (15) also observed that the LiNC structure is more stable than the LiCN structure in the Hartree–Fock model. At the MP2 level of electron correlation, LiCN is more stable than LiNC. This is because the cyanide has a larger correlation energy than isocyanide at the MP2 level. On the other hand, at the QCISD level of calculations LiNC is more stable than LiCN. The linear LiNC equilibrium structure has been confirmed experimentally by molecular beam spectroscopy (17). Our ab initio calculations with corrections for electron correlation reveal three local minima on the potential energy surface of the LiCN ↔ LiNC isomerization. The additional minimum corresponds to a triangular nearly T-shaped structure. Since the energies of the three local minima are very close to each other, the relative stabilities could not be definitely established. Since the energy barrier from this second minimum (T-shaped) to the second transition state is within the error bars of our calculations, no significance is given to the second transition state. Our ab initio calculations with the geometry optimization could not isolate the second transition state between the T-shaped minimum and LiNC. Besides, molecular beam spectroscopy could not detect the T-shaped structure of LiCN. On the other hand, gas phase rotational spectroscopy (37, 38) determined unambiguously the T-shaped structures of NaCN and KCN.

4. HCN ↔ HNC isomerization

Traditional discussions of chemical reaction center on the minimum energy path (MEP), which follows from one minimum over the saddle point to the other minimum. Figure 1 shows the two coordinates R and θ to determine the relative orientations of the migrating atom. In previous papers the C—N bond length was kept fixed during the isomerization process, as it was believed that variation in the C—N bond lengths did not play a crucial role in the reaction. Optimized bond length data in Table 3 reveal that the C—N bond length changes during this isomerization. We select the coordinate θ, which varies monotonically in the course of the reaction, for values of θ varying from 0° to 180°; the optimized values of R are so determined that the energy is minimized. The path of minimum energy is given as a polar graph in Fig. 2*a* where one sees that the path is elliptic but not symmetric about the minor axis. The value of θ at the saddle point is 110°. It should be noted that the value of θ is not very sensitive to the level of calculation. The value of θ obtained by Lee and Rendell for the transition state structure was 104.2°. As the system approaches the transition state, both the C—H and C—N bond lengths increase. The height of the barrier is 187 kJ/mol while the heat of isomerization is 58 kJ/mol at the QCISD level of calculations. Determination of the heat of reaction by Pau and Hehre (10), using ion cyclotron double-resonance spectroscopy, yields 60 kJ/mol, which is in excellent agreement with our QCISD results. The best experimental value of the activation barrier of 145 kJ/mol comes from a semi-empirical potential energy surface of Murrell et al. (11). Lee and Rendell, however, concluded that the PES of Murrell et al. was not accurate in the transition state region and their estimate (12) was 187.3 ± 4.2 kJ/mol. The calculated energy difference between HCN and HNC, where the latter is less stable than the former and there is a large barrier for isomerization from HCN to HNC, explains why HNC was not observed in HCN at room temperature. However, at high temperatures ($T > 900$ K) HNC was observed in equilibrium with HCN (39).

We then consider Mayer's definition of bond order from the standard density matrix (40). The density matrix in the CI calculations is not idempotent and may not give reliable changes in bond order along the minimum energy path (MEP). We consider the density matrix obtained from the single configuration calculations with the MP2 correction using the TZ2P basis functions. In the HCN ↔ HNC isomerization, the C—H bond is broken and an N—H bond is formed. Population analysis shows that the charge on hydrogen is +0.15, so the H—C

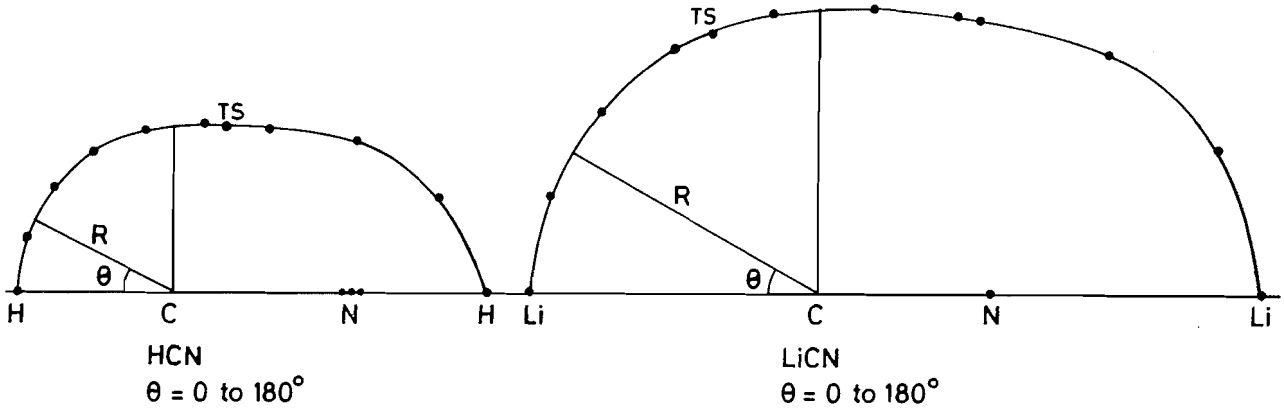
Fig. 2. (*a*) An almost elliptic path for hydrogen migration in the HCN ↔ HNC isomerization. The black dots refer to the changed positions of nitrogen during the rearrangement process. The position of the transition state is indicated by TS. (*b*) An almost elliptic path for Li^+ migration in the LiCN ↔ LiNC isomerization. The position of the transition state is indicated by TS.



bond in HCN is predominantly covalent. Our bond-order calculations reveal that the sum of the C—H and N—H bond orders is nearly constant and close to unity along the MEP. But the C—N bond is not passive during the isomerization process. Figure 3 shows how the C—N bond order (B_{CN}) changes from a nearly triple bond in HCN to a nearly double bond in HNC. Optimization of bond lengths in our ab initio calculations also shows that the CN bond length increases from 1.16 to 1.18 Å in the transition state. When the hydrogen atom migrates in the plane of the molecule, the orbitals of hydrogen interact with the in-plane π and π^* orbitals of CN, as the distance of H from C in the transition state is only 1.18 Å. This leads to a decrease of the C—N bond order and an increase of energy. Thus, the migration of hydrogen from the carbon end to the nitrogen end via the elliptic path (Fig. 2) involves overcoming a large barrier that may arise primarily from the weakening of the C—N bond, as the C—H bond cleavage and the N—H formation may almost annul each other in the reaction path.

5. LiCN ↔ LiNC isomerization

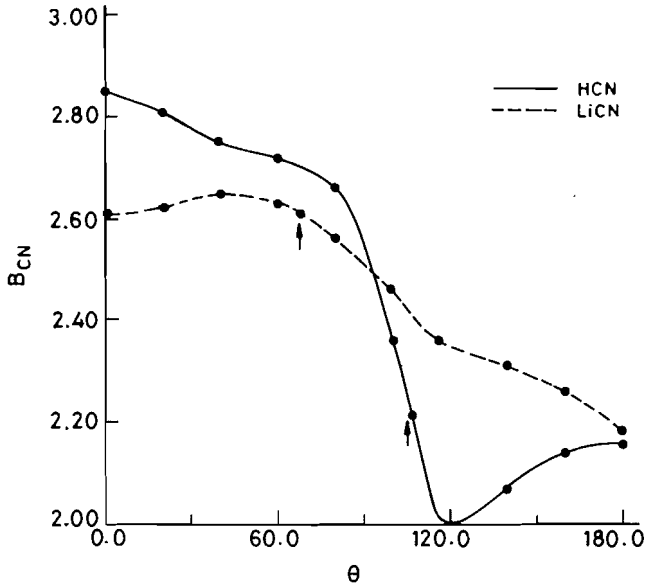
We have now established that the two Li isomers have nearly the same energies. Population analysis of LiCN at the same level as that of HCN reveals that Li has +0.70 charge and therefore the Li—C bond is predominantly ionic. The path of minimum energy for migration of Li^+ from the C-end to the N-end is once again elliptic but not symmetric about the minor axis (shown in Fig. 2*b*). The orbiting of Li^+ around the C—N bond had also been observed earlier by Clementi et al. (15). Since the bond is ionic, the Coulomb force should dominate the bonding. This force is isotropic and the orbiting of Li^+ around the remainder of the molecule involves no, or very little, expenditure of energy, unlike the orbiting of hydrogen in the HCN ↔ HNC isomerization. This is borne out by our observation of a very low barrier of ~10.6 kJ/mol. The value of θ at the saddle point is nearly ~70° in the LiCN ↔ LiNC isomerization. The saddle point is characterized by its having a negative eigenvalue in the force constant matrix. Since a very low barrier exists between the two linear geometries (LiCN and LiNC), the bending of the Li—C bond from the linear structure becomes very easy. Our force constant calculations reveal that the bending force constant in LiCN is lower than that in HCN. Besides, the calculated bending vibration frequencies of the Li—C and H—C bonds in LiCN and HCN are 175 and 756 cm^{-1}, respectively, at the QCISD/TZ2P(d,f) level.

We then consider the bond orders according to Mayer's definition, following the same level of calculations as that the HCN ↔ HNC isomerization. Mayer's definition leads to a small bond order for an ionic bond. The Li—C bond in the equilibrium linear structure of LiCN has a bond order of 0.47, which decreases while that of Li—N increases along the MEP. On the other hand, the C—N bond order remains constant until the transition state is reached and then decreases until LiNC is formed, where the N—C bond is nearly a double bond. The variation of the C—N bond order with θ is shown in Fig. 3. Optimization of bond length shows that the C—N bond length remains constant at 1.18 Å throughout the reaction path while the Li—C bond initially decreases slightly and then increases in LiNC. When Li^+ migrates along an elliptic path in the plane of the molecule, there is hardly any interaction between the orbitals of Li^+ and the in-plane π,π^* orbitals of CN. This is due to the fact that the atomic radius of Li^+ is only 0.19 Å, which is less than the atomic radius of hydrogen (0.30 Å) (41). As well, the H—C distance in the elliptic path during the migration of hydrogen in the HCN ↔ HNC isomerization is smaller than the Li^+—C distance in the LiCN ↔ LiNC isomerization process.

6. Conclusions

We observe that electron correlation has a considerable influence on the energetics and structures in the HCN ↔ HNC and LiCN ↔ LiNC isomerization processes. The correlation energies in HCN, HNC, LiCN, and LiNC are almost the same. In both isomerization processes, H (or Li^+) migrates in an elliptic path in the plane of the molecule. In HCN the C—H bond is predominantly covalent while the Li—C bond in LiCN is predominantly ionic. In the HCN ↔ HNC isomerization, migration of hydrogen involves overcoming a large barrier. The

Fig. 3. The change of the C—N bond order during the HCN ↔ HNC and LiCN ↔ LiNC isomerization processes. The positions of the transition states are indicated by arrows.



origin of the large barrier lies primarily in the interaction of the migrating hydrogen with the in-plane π,π^* orbitals of the C—N bond, which leads to a decrease of the C—N bond order in the transition state. In the LiCN ↔ LiNC isomerization, the Coulomb force dominates the bonding. Since the Coulomb force is isotropic, migration of Li^+ involves very little or negligible barrier. There is hardly any interaction of Li^+ with the in-plane π,π^* orbitals of the C—N bond until the saddle point is reached.

Proton and electron transfers in O•H•O and C•H•O hydrogen-bridged ions: their role in the dissociation chemistry of ionized acetol, $CH_3C(=O)CH_2OH^{\bullet+}$

Paul J.A. Ruttink, Peter C. Burgers, and Johan K. Terlouw

Abstract: Low-energy acetol ions $CH_3C(=O)CH_2OH^{\bullet+}$, **1**, dissociate to $CH_3C(H)OH^+$ and $HC=O^\bullet$ by a double hydrogen transfer (DHT), a common reaction among oxygen-containing radical cations. Recent experimental work has shown that the isotopologue $CH_3C(=O)CH_2OD^{\bullet+}$ specifically loses $HC=O^\bullet$ to produce $CH_3C(D)OH^+$. This finding refutes an earlier postulated attractive mechanism based on the behaviour of **1** in ion–molecule reactions. Using ab initio MO calculations (at the CEPA//RHF/DZP level of theory complemented with valence bond (VB) methods), a low-energy pathway was traced that may explain all of the available experimental observations. It is shown that the unimolecular chemistry of **1** can be understood in terms of two *proton* transfers, taking place in intermediate O•H•O and C•H•O bonded hydrogen-bridged radical cations. The two protons originate from the same moiety and a charge transfer complex is therefore implicated and shown to be involved. These concepts of proton and charge transfer may well be more generally applicable and they do correctly predict the unimolecular chemistry of ionized acetoin, $CH_3C(=O)CH(CH_3)OH^{\bullet+}$ and related α-ketols.

Key words: ab initio calculations, hydrogen-bridged ions.

Résumé : Les ions acétol de basse énergie, $CH_3(C=O)CH_2OH^{\bullet+}$, **1**, se dissocient en $CH_3C(H)OH^+$ et en $HC=O^\bullet$ par un double transfert d'hydrogène (DTH), une réaction courante des cations radicaux contenant de l'oxygène. Des travaux expérimentaux récents ont montré que l'isotopologue, $CH_3(C=O)CH_2OD^{\bullet+}$ perd spécifiquement du $HC=O^\bullet$ pour fournir du $CH_3C(D)OH^+$. Cette observation réfute un mécanisme attrayant proposé antérieurement et qui était basé sur le comportement du composé **1** dans les réactions ion–molécule. Utilisant des calculs d'OM ab initio (au niveau CEPA//RHF/DZP de la théorie avec un complément des méthodes de liaisons de valence), on a pu tracer une voie réactionnelle de basse énergie qui peut expliquer toutes les données expérimentales disponibles. Il a été montré que le chimie unimoléculaire du composé **1** peut se comprendre en termes de deux transferts de *protons* qui se produisent par l'intermédiaire de cations radicaux de liasions hydrogènes pontées O•H•O et C•H•O. Les deux protons ont leur origine dans la même partie de la molécule; il y a donc un complexe de transfert de charge d'impliquer et on l'a démontré. Il est fort possible que ces concepts de transferts de protons et de charges puissent s'appliquer d'une façon générale et ils permettent de prédire correctement la chimie unimoléculaire de l'acétoïne ionisée, $CH_3(C=O)CHCH_3OH^{\bullet+}$ et des α-cétols apparentés.

Mots clés : calculs ab initio, ions de hydrogène-ponté.

Introduction

"The role of physics in chemistry is to predict what can be observed and to provide an understanding of these observations." So begins Professor R.F.W. Bader an influential review article entitled "A quantum chemical theory of molecular structure and its applications" (1). One of the purposes of the present commemorative paper is to show that nowadays state-of-the-art ab initio molecular orbital (MO) calculations can indeed predict experimental observables and that they can indeed lead to a deeper understanding of the underlying phenomena. In this paper we deal with gas-phase ions, that is to say, solitary species free of solvent molecules, which as such are preeminently suited to study by computational methods. Our case concerns the remarkable dissociation behaviour of acetol radical cations, $CH_3C(=O)CH_2OH^{\bullet+}$, and related systems, for which there appear to be (seemingly) conflicting experimental data that we resolve here by computational methods.

Radical cations obtained by electron impact ionization of organic molecules are renowned for their propensity to rearrange prior to dissociation (for selected reviews see ref. 2).

Received October 12, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

This is especially true for those ions that fragment during flight through the mass spectrometer, the so-called metastable ions, which dissociate with rate constants of $10^5 < k < 10^6$ s^{-1} (3). Indeed, it is frequently observed that the decay of such ions, as reflected by their metastable ion (MI) spectra, can be totally different from the fast fragmentations ($k > 10^6$ s^{-1}), which take place in the ion source of the mass spectrometer and give rise to the conventional electron impact (EI) mass spectrum. A case in point is ionized acetol, $CH_3C(=O)CH_2OH^{\bullet+}$: while its EI mass spectrum consists of structure characteristic peaks at *m/z* 43, $CH_3C{\equiv}O^+$ (100%), *m/z* 31, $^+CH_2OH$ (20%), and *m/z* 15, CH_3^+ (10%) arising from fast C—C cleavages, its MI spectrum is dominated by a completely different signal at *m/z* 45, corresponding to $CH_3C(H)OH^+$ (4–7), obviously the result of a rearrangement process involving the loss of HC=O$^\bullet$.

In the context of ionic rearrangements, hydrogen-bridged radical cations, in particular O·H·O bonded ions, are increasingly being proposed as intermediates to rationalize the seemingly unintelligible dissociation behaviour of oxygen-containing radical cations (2). These proposals were inspired by the growing realization (2) both from experiment and theory that O·H·O bonded radical cations can be thermodynamically as stable as the unrearranged reactant ion, making them energetically attractive intermediates. The first indications that such hydrogen-bridged radical cations might well be very stable species were presented by us in this journal more than 10 years ago (8). Based on MI and collision-induced (CID) dissociation characteristics, it was proposed that loss of C_2H_4 from $ROCH_2CH_2CH_2CH_2OH$ (R = H, CH_3) does not produce, via a least-motion extrusion (9), the conventional structure $ROCH_2CH_2OH^{\bullet+}$ but rather a product ion comprised of vinyl alcohol and ROH, $[CH_2{=}CHOH/ROH]^{\bullet+}$, and the possibility was entertained that the observed product ion might be the "proton bound radical-molecule pair" (8) $^\bullet CH_2C(H){=}O\cdots H^+\cdots O(H)R$, whose dissociation characteristics can be rationalized by consideration of the relative proton affinities (PA) of the radical and molecules involved. Subsequent ab initio MO calculations on the $C_2H_6O_2^{\bullet+}$ potential energy surface (PES) (R = H) (8*b*, 10*a*,*b*) revealed that the O·H·O bridged ion is not only thermodynamically by far the most stable isomer (it is 42 kcal/mol more stable than $HOCH_2CH_2OH^{\bullet+}$), but that it is very stable (by ca. 24 kcal/mol) towards dissociation as well. Its most stable structure was found to be $CH_2{=}C(H)O\text{-}H^{\bullet+}\cdots OH_2$, i.e., with the bridging hydrogen more closely connected to the moiety of higher PA. This interesting ion reappeared recently in an ab initio study concerning the enzyme–coenzyme B_{12} catalyzed dehydration of ethylene glycol (10*c*).

Indeed, it is invariably found, from ab initio MO calculations, that such (necessarily asymmetric) O·H·O bridged radical cations can best be described as H-bridged ion–dipole complexes of the type $A\text{–}H^{\bullet+}\cdots B$ (or $A\text{–}H^+\cdots B^\bullet$), where most of the stabilization energy is provided by ion–dipole attractions. Although the hydrogen bridge furnishes additional stabilization, its main function, as we shall see, is to direct the course of isomerization by allowing a relatively facile *proton* transfer.

Recent evidence has suggested that the C·H·O bonded counterparts of the O·H·O bonded species may, despite their elevated enthalpies, be even more important intermediates in the decay of oxygen-containing radical cations (2, 5, 6, 11, 12). A case in point is acetol's fragmentation to $CH_3C(H)OH^+$ and HC=O$^\bullet$, see above, which has been interpreted in terms of O·H·O bonding on the one hand (6) and C·H·O bonding on the other (5).

In their ion cyclotron resonance (ICR) study Pakarinen et al. (6, 7) found compelling evidence from characteristic ion–molecule reactions that ionized acetol rearranges to the O·H·O species $CH_3C{=}O\cdots H\cdots O{=}CH_2^{\bullet+}$, **4**. It was further proposed that ion **4** undergoes a hydrogen shift prior to the loss of HC=O$^\bullet$ as follows:

[1] $CH_3C(=O)CH_2OH^{\bullet+}$ (**1**) $\rightarrow CH_3C{=}O\cdots H\cdots O{=}CH_2^{\bullet+}$ (**4**)

$\rightarrow CH_3C(H){=}O\cdots H\cdots O{=}CH^{\bullet+}$ (**7**)

$\rightarrow CH_3C(H)OH^+ + HC{=}O^\bullet$

George et al. (5) found this mechanism to be incompatible with their isotopic labelling data: they observed from MS/MS/MS experiments that the hydroxyl hydrogen of **1** appears at the carbenium carbon atom of the product ion and not, as expected from eq. [1], at the oxygen atom. These authors proposed a mechanism, supported by ab initio MO calculations, that involves C·H·O bonding:

[2] $CH_3C(=O)CH_2O\mathbf{D}^{\bullet+}$ (**1**) $\rightarrow CH_3C(=O)\text{-}\mathbf{D}\cdots O{=}CH_2^{\bullet+}$ (**5**)

$\rightarrow CH_3C(\mathbf{D}){=}O\cdots H\cdots O{=}CH^{\bullet+}$ (**7**)

$\rightarrow CH_3C(\mathbf{D})OH^+ + HC{=}O^\bullet$

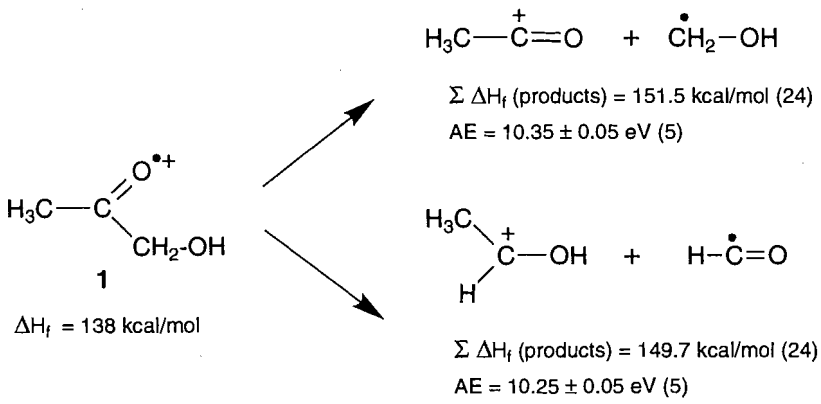
Goaded by these (seemingly) conflicting experimental results, we decided to investigate by state-of-the-art ab initio MO calculations the minimum energy reaction path for the isomerization–dissociation processes of ionized acetol. We note that ionized acetol's decay is an example of a type of reaction that many a radical cation undergoes, namely double hydrogen transfer (DHT) to produce a protonated molecule.

A prototype species that undergoes such a dissociation and has been the subject of a thorough theoretical investigation (13) is ionized ethane-1,2-diol, which dissociates to $CH_3OH_2^+$ and HC=O$^\bullet$. It appears that the isomerization processes involved can be understood in terms of *proton* (14) (as opposed to hydrogen atom) and electron transfers taking place in intermediate hydrogen-bridged ion–dipole complexes. Interestingly, these are the very processes that are known to occur rapidly in hydrogen-bridged radical cations formed by direct ionization of gas phase clusters (15) (these processes also take place rapidly in ion–molecule encounters, see for example ref. 16, and indeed the proposed intermediates in eqs. [1] and [2] can be considered as such ionized "clusters"). Our calculations suggest a reinterpretation of the seemingly conflicting experimental data for ionized acetol, but when this is done there appears excellent agreement.

Theoretical methods

Ab initio calculations were performed using the program sys-

Scheme 1.



tem GAMESS-UK (17) employing RHF and (MR)CI/CEPA methods (18, 19). Dunning's DZP basis (20) was used throughout. ZPVE corrections were calculated on the RHF level and scaled with 0.9 (21). All minima and transition states were checked for the correct number of imaginary frequencies and the transition states were checked for their connections with the relevant minima. Note that inclusion of electronic correlation and ZPVE contributions may affect the relative energies such that a transition state need not even be higher in energy than the minima it connects. This may happen since transition states are more sensitive to correlation effects than minima and the ZPVE also tends to favour transition states.

The (Pople) size consistency correction procedure (22) for the standard HF-SDCI method was not satisfactory for the present system, since $E[CH_3C(H)OH^+ + HCO^\cdot] - E[CH_3C(H)OH^+] - E[HCO^\cdot]$ yielded 5 kcal/mol. We therefore resorted to single-reference open-shell CEPA calculations using our ATMOL/MR-CEPA program (18), which yielded a much smaller size consistency error (< 1 kcal/mol). However, for some intermediates this procedure suffers from an intruder state problem (23), which means that the solution is unstable, because one of the excited configurations becomes dominant in the wave function during the iterative diagonalization process, thereby destroying the ground state character of the wave function. The appearance of the intruder states is caused by the shifts in the diagonal elements of the excitations, which are used to simulate the effects of the higher excitations on the electronic correlation. This effect can be remedied either by using a multi-configuration reference approach or by switching off the diagonal shift for the intruder states. It appears rather difficult to make a balanced selection of reference configurations, i.e., a selection leading to results of uniform accuracy for the whole PES. Therefore we have used the second approach. In all cases the "dangerous" configurations then appear to have small coefficients (<0.15). This yields results that are acceptable as to the size consistency as well as to the stability of the wave function. The results are given in Table 1.

For the acetol radical cation, the RHF calculations indicate that there exist two minima for the acetol radical cation, one with the charge localized on the carboxyl oxygen and one with the charge localized in an accordingly long CC bond, which acts as the reacting configuration for the formation of complexes involving the $CH_3C{=}O$ and CH_2OH units. The first minimum is probably an artefact of the HF calculation, since the correlated results lead to a lower energy for the geometry corresponding to the HF transition state between the HF minima. This is corroborated by an MP2 geometry optimization, which leads to a long CC bond (13).

Results and discussion

Preliminary considerations

Ionized acetol has two dissociation reactions of low energy requirement, see Scheme 1. Both reactions, as evidenced by appearance energy (AE) measurements, take place at their thermochemical thresholds. Although the AE's are not significantly different, the formation of $CH_3C(H)OH^+$ has the expected lower energy requirement, as this is the dominant peak in the MI spectrum, see above. Note that the average kinetic energy release is very small, $T = 7$ meV (5) and this indicates, according to theory (25, 26) and experiment (27), that the excess energy will be correspondingly small, smaller than the uncertainty in the AE measurements (±50 meV); as a consequence, formation of $CH_3C(H)OH^+$ may well dominate the MI spectrum, even if the AE's are the same within experimental error. The small T value also indicates that there is no reverse term and that the final step most likely involves dissociation of an ion–dipole complex (26).

The energy requirement for the rearrangement–dissociation processes (as measured by the difference in AE and ionization energy (IE)) is only 12 kcal/mol (5); that an ion having such a relatively small activation energy should nevertheless dissociate at a slow rate further attests to dissociation of an intermediate ion–dipole complex (28). It is also clear from the above energetic measurements that the leeway in our ab initio calculations is only 12 kcal/mol.

As mentioned above, the ethane-1,2-diol radical cation, $HOCH_2CH_2OH^{\cdot+}$, also undergoes a double hydrogen transfer to produce $CH_3OH_2^+$ and $HC{=}O^\cdot$, and the associated mechanism has been unravelled by high-level ab initio calculations (13). After detailed calculations (see below), we found that the sequence in Scheme 2, which is very similar to that of ionized ethane-1,2-diol, applies to ionized acetol. The corresponding energy diagram is shown in Fig. 1 and the equilibrium and transition structures are shown in Fig. 2.

O/H/O (ion 4) versus C/H/O(ion 5) bonding

First we deal with the mechanistic proposal by Pakarinen et al.

Table 1. Calculated total energies, zero-point vibrational energies ZPVE (kcal/mol), relative energies E_{rel} (kcal/mol), and experimental heats of formation (kcal/mol) of acetol-type $C_3H_6O_2^{\bullet+}$ ions (equilibrium and transition structures) and some dissociation products.

Scheme 2. Proposed reaction mechanism for the loss of $HCO^{\bullet}$ from ionized acetol, **1** (see text for details).

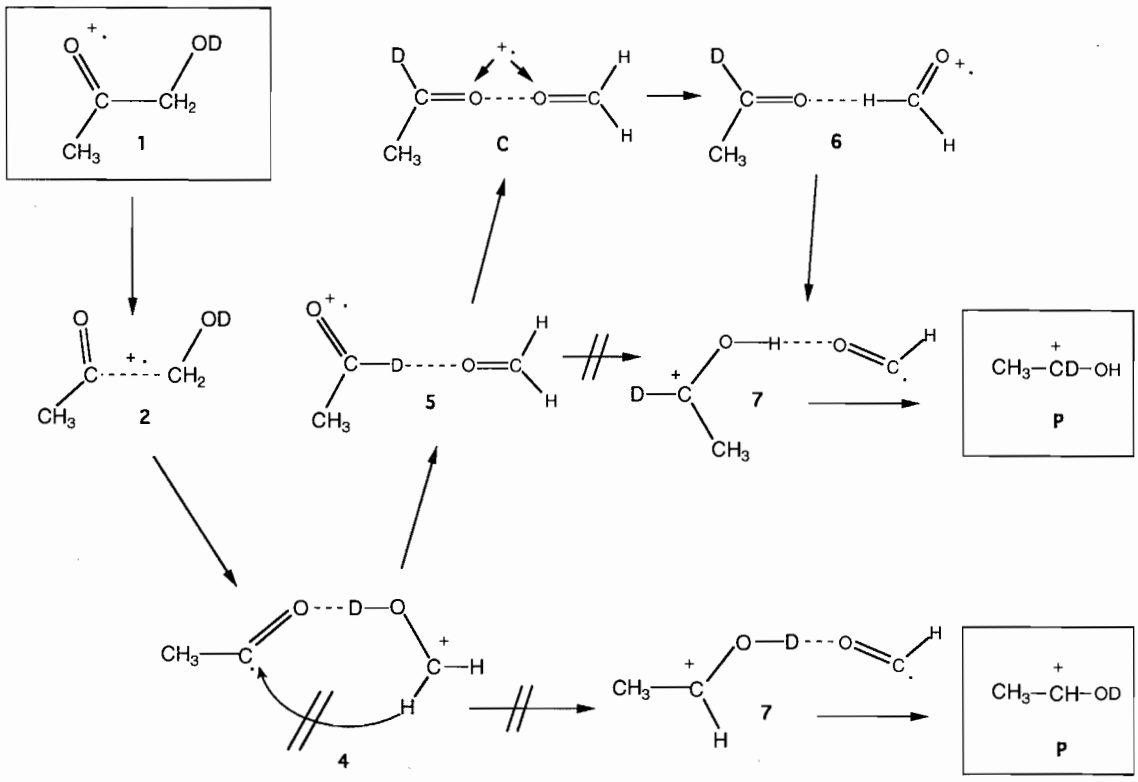

Fig. 1. Theoretical results (CEPA) for the relative energies of the isomers and transition states encountered in the dissociation of acetol radical cations, $CH_3C(=O)CH_2OH^{\bullet+}$. Experimental Appearance Energy of the products as indicated (see text for discussion).

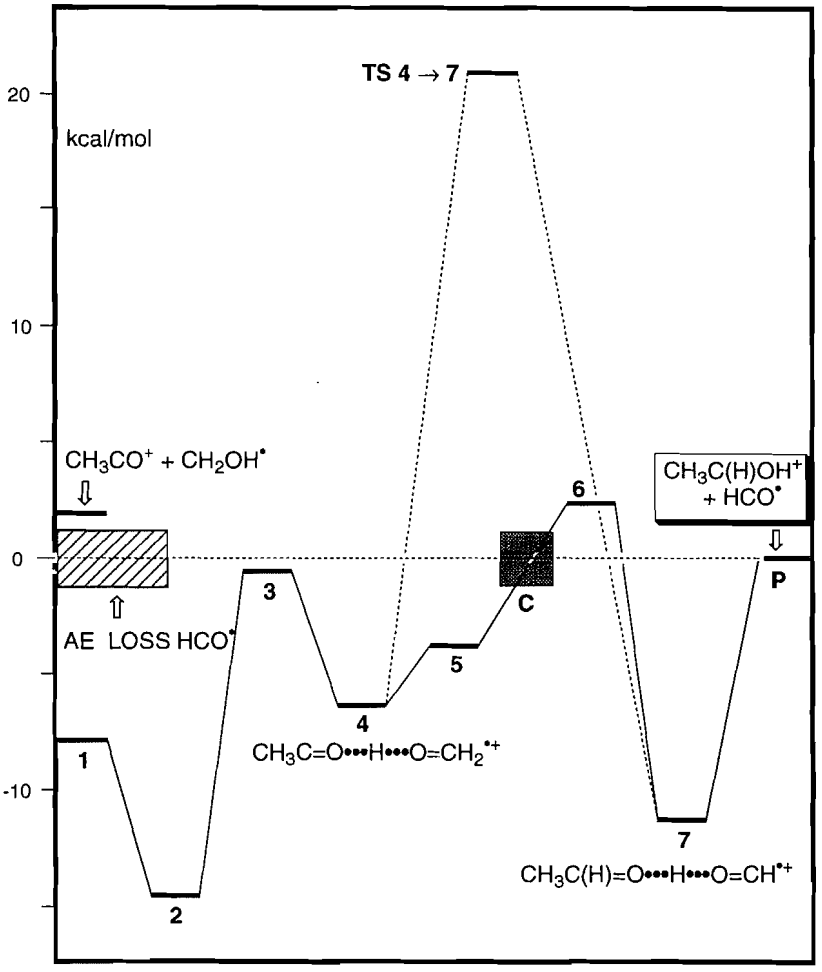

(6). The key intermediate in this proposal is ion **4**, which was proposed to yield the products directly, i.e., **4** → **7**. Our calculations confirm previous computational results (29) that the hydrogen-bridged species **4** is best described as a $^+CH_2OH$ ion interacting through a hydrogen bridge with the acetyl radical dipole, see Fig. 2. Hence this ion is a prime candidate to explain the acetyl *radical* displacement reactions observed for ionized acetol in the ICR experiments of Pakarinen et al. (6). If indeed ion **4** can be generated from **1** below the dissociation limit, then the labelling results of George et al. (5) dictate that **4** does not undergo the hydrogen transfer **4** → **7** depicted in Scheme 2.

According to our calculations, this process indeed has a prohibitively large barrier, see Fig. 1. That this barrier should be large can be understood as follows. As a first step, the bridging deuterium in **4** may be shifted towards the acetyl oxygen atom; since the carbene CH_3-C-OH has a high thermodynamic stability as an ion (30*a*), but not as a neutral (30*b*), this would have to lead to *ionized* CH_3-C-$OD^{\bullet+}$ interacting with the formaldehyde dipole, that is to say, the above deuterium shift would have to be a deuteron, D^+, shift. To produce CH_3-C(H)-OD^+ from the incipient CH_3-$C^{\bullet+}$-OD···O=CH_2 would then require a further hydrogen *atom* shift and there are two reasons why this reaction should have a large barrier. First, this reaction would involve cleavage of a covalent C—H bond in neutral formaldehyde and this requires considerable energy; secondly, to move this H atom to the ionized carbene would require an unfavourable rotation of the formaldehyde dipole.

Alternatively, the above sequence may be reversed, i.e., first one of the C-H hydrogens of the $^+CH_2OD$ ion in **4** is shifted to the acetyl dipole; this would lead to $[CH_3$-C(H)=O···D-O-C-H$]^{\bullet+}$. Again, the incipient carbene, H-C-OD, has a high stability only in its ionized form (31), so that it should bear the charge; hence the above hydrogen shift again would have to be a hydrogen *atom* shift and for the same reason as given above such a shift requires considerable energy, the associated TS (TS **4**→**7**) lying some 20 kcal/mol outside our leeway, see Fig. 1. Thus ion **4** cannot directly lead to the products as shown in eq. [1], in agreement with the experimental findings of George et al. (5).

However, similar arguments can be put forward against the transformation **5** → **7** proposed by George et al. (5). From ion–

Fig. 2. Geometries of the $C_3H_6O_2^{\bullet+}$ isomeric ions and transition states optimized at the RHF/DZP level of theory.

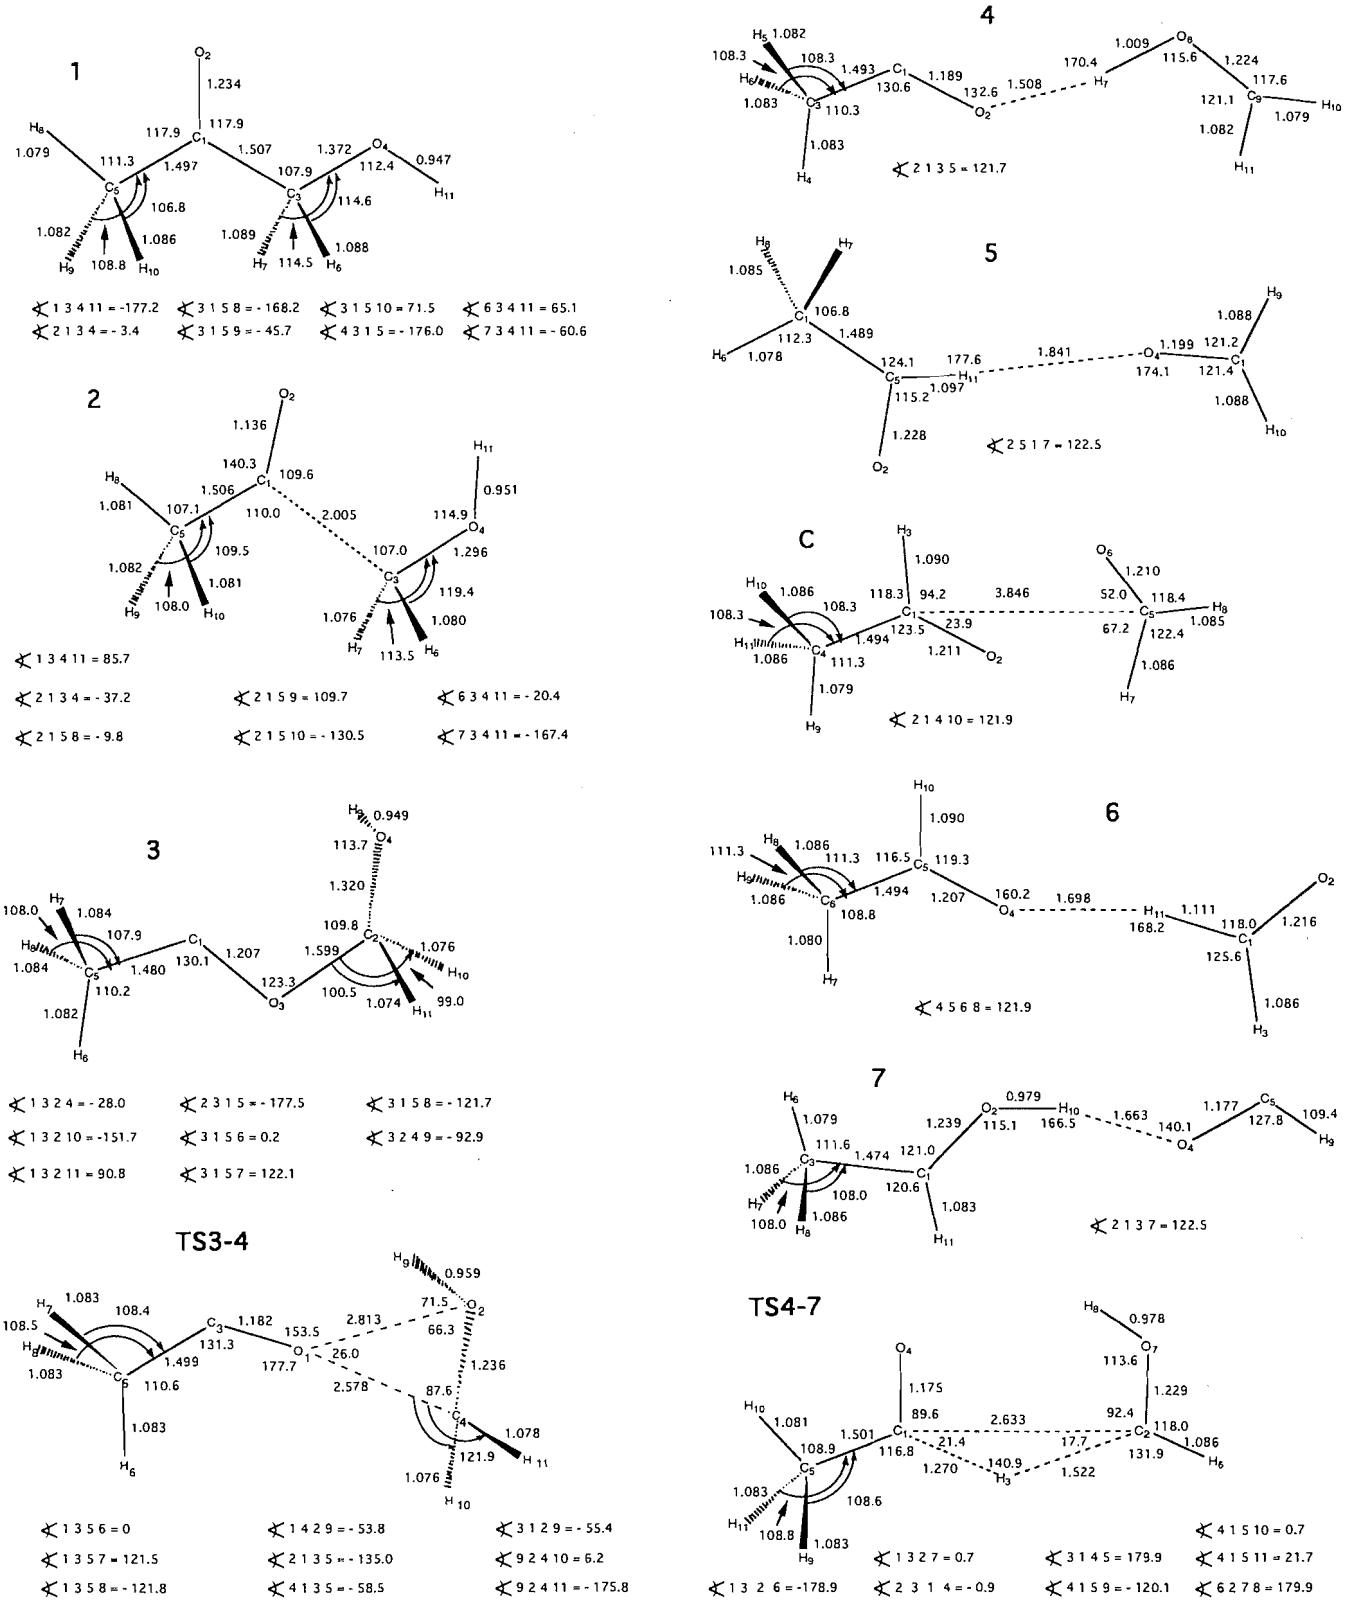

Fig. 3. Proposed isomerization steps involved in the loss of HCO$^{\bullet}$ from ionized acetol, **1**, as visualized by Pluton pictures (see text for details). Orientation: e.g., ion **2**: left-hand side CH_2OH^+, right-hand side $CH_3C{=}O^+$; hydroxyl hydrogen labelled black.

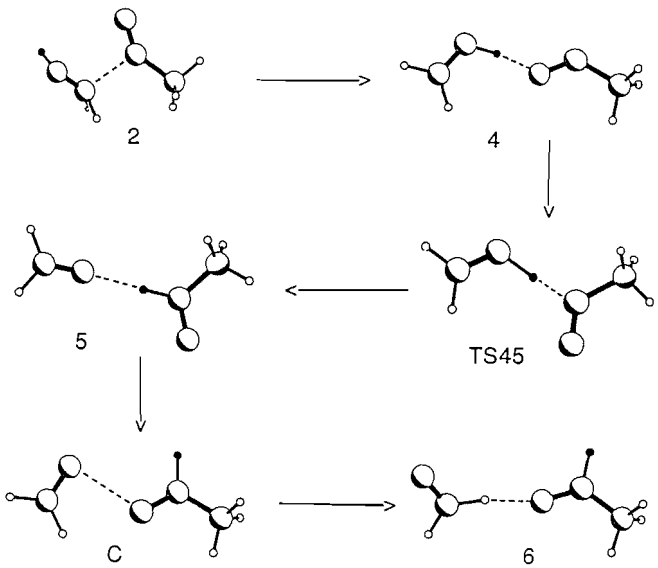

dipole considerations, the charge in **5** must reside on the acetaldehyde moiety, so that the rearrangement **5** → **7** must involve an unfavourable C—H cleavage in neutral formaldehyde, concomitant with a destabilizing rotation of the formaldehyde dipole, and so it is inferred that the transformation **5** → **7** should require considerable energy as well. Note that the above authors did find a low-lying TS (labeled TS**3b**→**5a** in their work) where the formaldehyde group has indeed rotated concomitant with H transfer and which they identified as TS **5**→**7**. However, we have now found that this TS does not connect **7** with **5**, but rather **7** with **6** where the charge is on the formaldehyde group, see Scheme 2.

It therefore appears that neither **4** nor **5** can lead directly to the products at the measured appearance energy and with the observed small kinetic energy release. Nevertheless, there is good experimental evidence that **4** is involved. How then can ion **4** lose HCO$^{\bullet}$?

Rearrangement of ion 4 : $[CH_3\text{-}C{=}O\cdots H\text{-}O{=}CH_2]^{\bullet+}$, 4→5→C→6 (→7)→products

The rearrangement processes of ion **4** leading to the loss of HCO$^{\bullet}$ are visualized as Pluton pictures in Fig. 3. Our calculations indicate that the O/H/O bonded species **4** can rearrange below the dissociation threshold to the C/H/O bonded species **5**. First, the $^+CH_2OH$ moiety undergoes a shuffle along the C=O axis of the acetyl dipole until the configuration TS **4**→**5**, $CH_3\text{-}C(=O)\cdots H\text{-}O{=}CH_2^+$, is reached, which then undergoes a proton transfer to generate **5**. The transition **4**→**5** could be viewed, in principle, as the 1,2-hydrogen shift $CH_3\text{-}C\text{-}OH^{\bullet+} \rightarrow CH_3\text{-}C(H){=}O^{\bullet+}$, catalyzed by the formaldehyde dipole (13, 14). Note, see Table 1, that at the RHF level there is a small barrier for the transition **5**→**4** (10 kcal/mol, including ZPVE contributions). However, with electron correlation (CEPA) this barrier has disappeared, so that the transformation **4**→**5**, which for visualization purposes is depicted as stepwise in Fig. 3, actually occurs smoothly, see energy diagram, Fig. 1. As to the formation of **5**, George et al. (5) found a TS (labelled TS **4a-3b** in that work) that was proposed to connect **2** and **5**. We have found that this TS in actuality connects **4** and **5**, i.e., it is our TS **4**→**5**. So we feel that the sequence **1** → **2** → **4** → **5** presents a more realistic pathway for the formation of **5** than the transformation **2** → **5**.

As mentioned above, the charge in ion **5** is on the acetaldehyde moiety and thus ion **5** cannot yield the desired products directly. We note, however, that in ion **6** the charge is on the formaldehyde group and so **6** can easily donate a proton to the neutral formaldehyde followed by dissociation (**6** → **P**). Ions **5** and **6** can be formed from **5** via the charge transfer complex **C** as follows. We note (see Fig. 1) that ions **5** and **6** have comparable energies. This is so because there is a trade-off between effects arising from the differences in IE's and dipole moments (μ) of acetaldehyde and formaldehyde: the lower IE of acetaldehyde (10.23 eV versus 10.87 eV (32)) favours the charge on the acetaldehyde (ion **5**), whereas the larger dipole moment of acetaldehyde (μ = 2.77 D vs. 2.33 D for fomaldehyde (32)) favours the charge on formaldehyde (ion **6**). Since the acetaldehyde moiety in **5** is charged, it can rotate on the dipole vector of the formaldehyde molecule without loss of too much of the ion–dipole stabilization energy, i.e., only the weak hydrogen bond is sacrificed. That is to say, the relative orientation of the $CH_3CH{=}O$ and $CH_2{=}O$ units is changed (ion–dipole reorientation (33)), such that the dipole vectors of the putative neutral molecules are oriented towards each other. In this situation both choices, i.e., $CH_3\text{-}CH{=}O^{\bullet+}\cdots O{=}CH_2$ and $CH_3\text{-}CH{=}O\cdots O{=}CH_2^{\bullet+}$ will correspond to low-energy situations and such arrangements are acceptable as conformations where the charge transfer may take place easily (**5** → **C** → **6**) (see also the following section on the charge transfer complex).

We can now see why the transition **4** → **5** is necessary to bring about the above charge transfer process. For any charge transfer process $A^{\bullet+}\cdots B \rightarrow A\cdots B^{\bullet+}$ to take place easily, both A and B must represent thermodynamically stable molecules. Now consider ion **4**: this ion could well undergo a shift of the bridging H to generate $CH_3\text{-}C^{\bullet+}\text{-}OH\cdots O{=}CH_2$. This species cannot undergo ion–dipole reorientation and charge transfer along the lines described above, simply because neutral CH_3-C-OH is thermodynamically a high-energy species. This is the reason that the transformation **4** → **5** is necessary.

While we feel that our theoretical calculations (as well as the simple energetic arguments given in the previous section) strongly favour a charge transfer process over the direct dissociation **5** (→ **7**) → **P**, we have no experimental proof of its occurrence, at least not for acetol. However, substituting one of the methylene hydrogen atoms in ionized acetol by $CH_3^{\bullet}$ yields acetoin ions, $CH_3C(=O)CH(CH_3)OH^{\bullet+}$. Ionized acetoin undergoes one unimolecular dissociation to produce $CH_3C(H)OH^+$ (*m/z* 45) + $CH_3C{=}O^{\bullet}$, ostensibly a simple bond cleavage reaction. If the sequence outlined in Scheme 2 also applies to acetoin, i.e., **1**→**4**→**5**→**C**→**6**(→**7**)→**P**, and substituting a methylene hydrogen in **1** by a CH_3 group, then the charge transfer process becomes degenerate, i.e., **5**→**C**→**5**. If such a degenerate process takes place below the dissociation limit, then it is *predicted* (and this prediction, we stress, follows from our ab initio MO calculations) that the labelled pre-

cursor ion $CH_3C(=O^{18})CH(CH_3)OH^{\cdot+}$ should produce $CH_3C(H)OH^+$ (*m/z* 45) and $CH_3C(H)^{18}OH^+$ (*m/z* 47) in a ratio of exactly 1:1. This, as we have recently reported (12) is precisely what is observed experimentally. Equally important are MS/MS/MS experiments (12) on the labelled ion $CH_3C(=O^{18})CH(CH_3)OD^{\cdot+}$. These experiments established that the above acetoin isotopomer generates $CH_3C(D)^{18}OH^+$ (in admixture with CH_3CHOD^+) with the deuterium atom attached to the carbenium carbon atom and not to the oxygen atom, precisely as predicted from our calculations. We therefore feel confident that the acetol radical cation also fragments via a charge transfer complex.

The $[CH_3C(H)=O\cdots O=CH_2]^{\cdot+}$ charge transfer complex: computational aspects

At the end of the reaction sequence a proton transfer from $CH_2=O^{\cdot+}$ to $CH_3C(H)=O$ takes place. The charge localization in the $[CH_3C(H)=O\cdots O=CH_2]^{\cdot+}$ complex will be determined by the relative orientation of the two units. This means that the charge will go to that unit whose dipole moment is directed away from the other unit. Therefore, to create a stable situation for this transfer we have to start with a neutral $CH_3C(H)=O$ and an ionized $CH_2=O$. The dipole of the $CH_3C(H)=O$ is directed toward the charge on the $CH_2=O^{\cdot+}$ unit, ion **6**, which is oriented such that a H-bridge is formed that also stabilizes the complex.

In the intermediate resulting from the first proton transfer, **5**, the charge is located on the $CH_3C(H)=O$ unit, with the dipole of the $CH_2=O$ directed toward the $CH_3C(H)=O^{\cdot+}$. For reasons given above, **5** and **6** have comparable stabilities. However, when we tried to find a transition state for the charge transfer process **5** → **6**, the RHF calculation led to a crossing instead of a saddle point. This situation was also encountered in the dissociation of ethane-1,2-diol (13) (charge transfer between CH_3OH and $CH_2=O$). To find the energetically most favourable geometry for the charge transfer, we optimized the geometry of the transition point within the intersection of the two potential energy surfaces (34). A useful starting geometry for this optimization was obtained by optimizing the complex with the restriction that the -C=O dipole moment vectors are oriented towards each other. This yields the geometry of structure **C**. In this geometry a Valence Bond (VB) calculation (13) was performed involving the two RHF determinants corresponding to the two charge localizations. Since these determinants are degenerate in the transition point, whereas the HF-MO's mutually overlap, the VB calculation will lead to an energy lowering in the neighbourhood of the crossing. As a result the charge transfer process is now described as a continuous process involving an avoided crossing between the two extremes, i.e., structures **5** and **6.** To obtain a final result comparable in accuracy to the results for the other intermediates, we used the Natural Orbitals of the VB function in the final CEPA calculation.

Formation of ion 4, $CH_3C=O\cdots H\cdots O=CH_2^{\cdot+}$, the reaction sequence 1→2→3→4

The calculations by George et al. (5) indicate that, below the dissociation limit, **1** can undergo a 1,4-hydrogen shift to produce the distonic ion $CH_3C^+(OH)CH_2O^{\cdot}$. However, its formation from **1** represents a "cul de sac" isomerization (35) with significant barriers for further rearrangement. This nicely parallels theoretical observations for the distonic ion $H_2O^+CH_2CH_2O^{\cdot}$ generated from ethane-1,2-diol, which too is not the precursor for the O·H·O bonded species.

How then can ion **4** be formed from **1**? Analogous to ethane-1,2-diol, ion **4** could be formed from ion **2**, which is computed to have a long C—C bond (ca. 2 Å) and to lie 6.5 kcal/mol below **1** (this and other results (13) show that in radical cations long bonds can be stronger than short bonds). The C—C bond in ion **2** is a one-electron bond with the charge and radical character both localized in this bond. The possibility therefore exists that the adiabatic Appearance Energy (AE_a) corresponds to **2** and not to **1**. This is the reason, see Fig. 1, that we have anchored the energy levels relative to the products, which are experimentally well known. We note, however, that because of its long C—C bond, the formation of **2** from **1** at the AE_a is not probable kinetically (13).

Starting from ion **2** there is a choice: the lone electron can be transferred to the CH_2OH moiety, and this configuration leads to dissociation to $CH_3C=O^+$ as observed in the conventional mass spectrum, or it can go to the $CH_3C=O$ part. This choice leads to ion **4** as visualized by the Pluton pictures in Fig. 3. Thus after elongation of the C—C bond in **1** to generate **2**, the $^+CH_2OH$ moiety can rotate in the dipole field of the acetyl radical (TS **3** → **4**) to eventually generate **4**, see also Fig. 2. (Along the way the distonic ion **3** is encountered. This ion, which is a minimum at the HF level, has a relatively long O—C bond (ca. 1.6 Å); TS **3** → **4** actually connects **4** with **3** via a torsion motion.) TS **3** → **4** lies close to the experimental energy limit, see Fig. 1.

Thus we have found a low-energy pathway whereby ionized acetol can rearrange to the hydrogen-bridged species **4** via the one-electron bond species **2**. At the same time our results suggest that ion **2** rather than (or in addition to) ion **4** may be responsible for the observed acetyl radical displacement of collisionally cooled ions (6) because, unlike **4**, ion **2** can be spontaneously formed upon ionization, see Fig. 1.

In summary, our calculations lead to the following mechanistic proposal, which is consistent with all of the available experimental data. Upon ionization, acetol relaxes to the one-electron bonded species **2** with a long C—C bond (2 Å). Ion **2** has a choice: the charge can go to the acetyl moiety but then the $\cdot CH_2OH$ dipole is directed away from the charge and is ejected; this leads to $CH_3C=O^+$, *m/z* 43, as observed in the normal mass spectrum. Alternatively, the charge can go to the CH_2-OH unit and now the acetyl dipole has the correct orientation to be attracted by the charge: this choice leads to the O·H·O bonded species **4**, as described above. This species cannot undergo a 1,5-H shift because the necessary orientation of the formaldehyde dipole leads to destabilization. Rather, ions **4** undergo a shuffle (**4** → TS **4** → **5**) and then *proton* transfer to generate the C·H·O bonded species **5**. In ion **5** the charge is on the acetaldehyde moiety. For **5** to undergo a second proton transfer the charge must be moved over to the formaldehyde molecule. This is done via **C**; when the formaldehyde unit has accepted the charge, it can rotate in the acetaldehyde dipole field to produce **6**, which then undergoes *proton* transfer followed by disscociation.

As argued above, the double hydrogen transfer processes that take place in ionized acetol and ethane-1,2-diol can best be viewed as proton (as opposed to hydrogen atom (see for example ref. 36)) transfers and conformations must be sought

to allow such proton transfers. Since the two protons originate from the same moiety a charge transfer complex is implicated; to reach such a complex necessitates C·H·O bonding and this is the reason that the above molecular ions dissociate via C·H·O bonded intermediates, as implicated by experiment.

At the same time, our calculations show that the C·H·O bonded species is most easily formed from the O·H·O bonded ion **4**, rather than directly from **2**, and so a unification of the seemingly conflicting experimental data of Pakarinen et al. (6) (dissociation via O·H·O bonding) and George et al. (5) (fragmentation via C·H·O bonding) is correspondingly manifest: the reactivity experiments (37) of Pakarinen et al. detect **2** and perhaps also **4** (first part of Fig. 1), while the product ion measurements of George et al. detect the higher energy species **5** (second part of Fig. 1). These concepts also offer a mechanistic generalization for the DHT processes observed in related systems including ionized acetoin (12), and methyl glycolate and methyl lactate (11).

Finally we note that ionized acetol is isomeric with ionized methyl acetate, $CH_3C(=O)OCH_3^{\cdot+}$, **8**, and that low-energy ions **8** lose both $CH_3O^{\cdot}$ and $CH_2OH^{\cdot}$ (yielding $CH_3C{\equiv}O^+$) but not $HC{\equiv}O^{\cdot}$. Hence **1** and **8** do not communicate with each other, although ion **4** has been proposed, on the basis of a detailed computational study, to participate as a high-energy transient intermediate in the loss of $CH_2OH^{\cdot}$ from **8** (29). Experimental and computational work to further characterize the behaviour of independently generated ions **4** is in progress.

Topological analysis of the electron localization function applied to delocalized bonds

A. Savin, B. Silvi, and F. Colonna

Abstract: What is a local viewpoint of delocalized bonds? We try to provide an answer to this paradoxical question by investigating representative conjugated organic molecules (namely, allyl cation, *trans*-butadiene, and benzene) together with reference nonconjugated systems (ethylene and propene) by means of topological analysis of the electron localization function ELF. The valence attractors of the ELF gradient field are classified according to their synaptic order (i.e., connections with core attractors). The basin populations $\bar{N}$, (i.e., the integrated density over the attractor basins) and their standard deviation, σ, have been calculated and are discussed. The basin populations and their relative fluctuations, defined as $\lambda = \sigma^2/\bar{N}$, are sensitive criteria of delocalization. In the case of well-localized C—C or C=C bonds, $\lambda \sim 0.4$, whereas for delocalized bonds λ increases to about 0.5. Another criterion of delocalization is provided by the basin hierarchy, which is defined from the reduction of the localization domains. For most systems, delocalization occurs not only for neighboring carbon–carbon disynaptic attractor basins, but also for nearest neighbor disynaptic protonated attractor basins.

Key words: electron localization function, topological analysis, delocalization, population analysis.

Résumé : Y a-t-il un point de vue local des liaisons délocalisées ? Nous essayons de répondre à cette question pour le moins paradoxale en examinant une série de molécules organiques conjuguées et de systèmes non-conjugués de référence à l'aide de l'analyse topologique de la fonction de localisation ELF. Ces systèmes sont d'une part le cation allyl, le *trans*-butadiène et le benzène et, d'autre part l'éthylène et le propène. Les attracteurs de valence du champ gradient de ELF sont classés suivant leur order synaptique (c'est à dire, suivant le nombre de connections qu'ils forment avec les cœurs). La population moyenne par bassin, $\bar{N}$, et son écart-type, σ, ont été calculés et font l'objet d'une discussion. Les populations moyennes par bassin et leurs fluctuations relatives, $\lambda = \sigma^2/\bar{N}$, sont des indicateurs sensibles de la délocalisation. Pour des liaisons C—C ou C=C localisées, $\lambda \sim 0.4$ tandis que pour des liaisons plus délocalisées $\lambda \sim 0.5$. La hiérarchie des bassins, définie à partir de la réduction des domaines de localizations, est un autre critère de délocalisation. Dans la plupart des systèmes la délocalisation affecte non seulement les bassins des attracteurs relatifs au squelette carboné mais également les bassins adjacents d'attracteurs disynaptiques protonés.

Mots clés : fonction de localisation d'électrons, analyse topologique, délocalisation, analyse de population.

1. Introduction

The bonding in conjugated organic systems cannot be represented by a definite Lewis structure and is therefore referred as delocalized. Attempts at understanding such systems on the basis of the Lewis theory of valence have given rise to, for example, chimerical structures such as those proposed by Huggins (1), which were rejected with the advent of quantum chemistry. The valence-bond (VB) and molecular orbital (MO) approaches are at the root of the two basic descriptions of these bonds that can be found in textbooks (2). On the one hand is the resonance concept, in which the true ground state wave function of the system is expressed as a linear combination of wave functions corresponding to definite Lewis structures (3), and on the other hand is the MO description in which the bonding orbitals are delocalized over the whole molecule. As mentioned by Coulson (4): "There is an interesting contrast between the VB and MO descriptions of benzene. Both require complete delocalization, but whereas the VB method introduces it by superposition of Kekulé (and other) structures, in the MO method there is nothing that even remotely resembles a structure. This situation warns us once more against any too literal belief in the reality of our structures." This epistemological difficulty is mostly due to the weakness of interpretative methods that give a physical significance to quantities, such as molecular orbitals or valence-bond structures, appearing as intermediate during the course of approximate procedures of solution of the many-body Schrödinger equation.

The analysis of local functions defined within the exact many-body theory, such as the electron densities and deformation densities, is an alternative interpretative strategy that is more consistent with the interpretative postulates of quantum mechanics. The difficulty is then to find a guideline

Received November 1, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

allowing an objective partition of the molecular space and to make a link with the ideas widespread in the chemistry community. With respect to the delocalization problem, the question of the description provided by such local theories may seem to be paradoxical. In an early version of the loge theory, delocalization in benzene could be accounted for by the presence of "one loge with six delocalized electrons and extending over the carbon cores" (5). This assumption has not been supported by calculations since the numerical complexity of the determination of the boundaries of such a loge is too high to be feasible. The theory of atoms in molecules (6) provides a partition of the molecular space into atomic basins. Though these basins cannot by themselves provide a picture of the delocalization, the definition of bond orders within this framework (7, 8) provides a proper framework for the discussion of the delocalization.

An alternative partition of the molecular space is provided by topological analysis of the electron localization function ELF (9), which yields basins related to the local pairing of electrons. In this paper, we have investigated by this technique the bonding in simple hydrocarbons containing double and single bonds (namely ethylene, propene, allyl cation, *trans*-butadiene, and benzene) in order to compare the local properties in typical localized and delocalized systems.

2. A sketch of the topological analysis of the ELF function

The topological analysis of molecular space has been pioneered for two decades by Richard Bader (6) who investigated the gradient field of the electron density in order to build a rigorous theory of the chemical bond. Gradient field analysis is the mathematically well-established method allowing "access to a rigorous qualitative thinking" (10). In the particular field of the chemical bond, it can help to objectively define the words used to describe molecules on a microscopic scale. In this respect, Bader's definition of the atom within the molecule exemplifies the possibilities of the method. In principle, gradient field analysis can be applied to any well-defined local function. For us, a well-defined local function is a function of the space coordinate $\boldsymbol{r}$, which can be expressed in the framework of an exact many-body theory. Property densities are defined as the integral over the spin coordinate:

$$[1] \qquad \rho_A(\boldsymbol{r}) = \int \hat{A}\rho(\boldsymbol{x};\boldsymbol{x}')_{\boldsymbol{x}'=\boldsymbol{x}}\mathrm{d}\sigma$$

$\hat{A}$ is the Hermitian operator associated with the property, $\rho(\boldsymbol{x},\boldsymbol{x}')$ is the first-order density matrix (11), and $\boldsymbol{x}$ stands for the space and spin coordinates. They are well-defined local functions whereas orbitals, in many-electron systems, have no physical meaning since they appear as mathematical intermediates during the calculation. Functions of densities of property are also local functions. As examples of well-defined local functions we can mention the electron density and derived quantities such as the molecular electrostatic potential. We have recently shown (9) that a similar analysis applied to a localization function such as that of Becke and Edgecombe (12) provides "a clear demarcation between shared-electron interaction, as in covalent and metallic bonding, and unshared-electron interactions, such as in ionic and hydrogen bonded systems" (13).

2.1. The physical significance of ELF

The ELF function proposed by Becke and Edgecombe (12) was originally defined within the framework of Hartree–Fock (approximate) theory as:

$$[2] \qquad \eta(\boldsymbol{r}) = \frac{1}{1+\left(\frac{D_\sigma}{D_\sigma^0}\right)^2}$$

in which D_σ and D_σ^0 represent the curvature of the electron pair density for electrons of identical σ spins (the Fermi hole) for, respectively, the actual system and a homogeneous electron gas with the same density. D_σ is the Laplacian of the conditional probability calculated from a single determinental Hartree–Fock wave function:

$$[3] \qquad D_\sigma = (\nabla_2^2 P_{\mathrm{cond}}^{\sigma\sigma}(1,2))_{1=2} = \sum_{i=1}^{N} |\nabla\varphi_i|^2 - \frac{1}{4}\frac{|\nabla\rho^\sigma(1)|^2}{\rho^\sigma(1)}$$

As mentioned before (14) this expression is formally identical to the difference between the positive definite local kinetic energy of a system of noninteracting fermions $T_s^\sigma[\rho]$ appearing in the Kohn–Sham equations (15) and that appearing in the von Weizsäcker functional (16).

$$[4] \qquad D_\sigma = T_s^\sigma[\rho] - \frac{1}{4}\frac{|\nabla\rho^\sigma(1)|^2}{\rho^\sigma(1)}$$

As pointed out by Tal and Bader (17), the von Weizsäcker functional (16) is a lower bound to the positive definite local kinetic energy that is locally approached at the Hartree–Fock level when a single orbital makes the dominant contribution to the density in the same region of space. The von Weizsäcker functional is also the positive definite local kinetic energy of a system of noninteracting particles of density ρ^σ for which the Pauli repulsion has been switched off. Therefore, D_σ signifies the local excess of kinetic energy due to the Pauli repulsion. The kinetic interpretation of D_σ (14) is very important because it extends the validity of the ELF function to the ground state of real systems for which $T_s^\sigma[\rho]$ can be exactly evaluated within density functional theory. Therefore, for ground state systems ELF gains the status of a well-defined local function. Furthermore, this definition of ELF allows its determination from knowledge of the electron density alone. Thus, instead of considering the Laplacian of the conditional probability, it is more advantageous to consider D_σ in its kinetic interpretation to redefine ELF. For closed-shell systems, $T_s^\alpha[\rho] = T_s^\beta[\rho] = \frac{1}{2}T_s[\rho]$ and $\rho^\alpha(\boldsymbol{r}) = \rho^\beta(\boldsymbol{r}) = \frac{1}{2}\rho(\boldsymbol{r})$, so:

$$[5] \qquad \begin{aligned} D_\sigma &= \frac{1}{2}T_s[\rho] - \frac{1}{8}\frac{|\nabla\rho(1)|^2}{\rho(1)} \\ D_\sigma^0 &= \frac{3}{10}(3\pi^2)^{2/3}\rho^{5/3}(1) \end{aligned}$$

In these expressions, the σ dependence no longer appears on

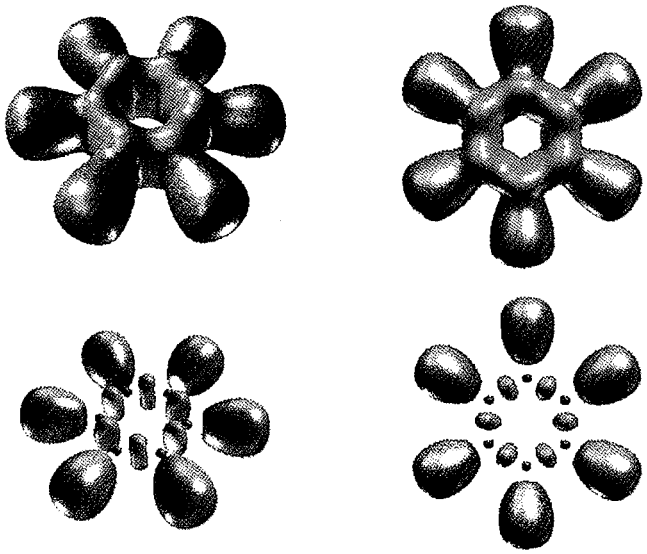

Fig. 3

Plate 1. Fig. 1. Representation of ELF for Li_2 (left) and LiH (right). ELF has been calculated with the density threshold ε set to zero. The value of ELF is given by the color scale. The broken lines correspond to the 10^{-3} e^- bohr^{-3} isodensity contours. **Fig. 2.** $\eta(\boldsymbol{r}) = 0.8$ localization domains of ethylene (top left), propene (bottom left), allyl cation (top right), and *trans*-butadiene (bottom right). The nature of the attractor defining the domain is given by the color code. Magenta: core; green: valence disynaptic; blue: protonated valence disynaptic. **Fig. 3.** The $\eta(\boldsymbol{r}) = 0.5$ and $\eta(\boldsymbol{r}) = 0.8$ localization domains of benzene. Same color code as in Fig. 2.

the right-hand side of the equations and therefore, one may consider D and D^0.[2]

In regions of space where the electron density is very low, the numerical representation of the wave function and of the density is not accurate enough to warrant the reliability of the gradients of local functions. Spurious attractors may appear that are due to computational artefacts such as roundoff errors or to basis set effects. Such troubles arise when D_σ tends to zero faster than $\rho(\boldsymbol{r})$. In practice, one can remove these difficulties by taking an effective ELF written as:

$$[6] \quad \frac{1}{1+\left(\frac{D+\varepsilon}{D^0}\right)^2}$$

ε is chosen such that ELF tends to zero with the density ρ. In actual calculation we use $\varepsilon = 2.87 \times 10^{-5}$. This value constrains ELF to be less than 0.5 for $\rho \leq 10^{-3}$.

ELF is a local measure of the effect of the Pauli repulsion on the kinetic energy density. In the region of space where the Pauli repulsion is weaker than in a uniform electron gas of identical density (we should say, where the local parallel pairing is lower), ELF is close to 1 whereas where the local parallel pairing is higher (and therefore the Pauli repulsion strongly active) ELF is low. For example, in a closed-shell system, though the α and β spin densities are equal everywhere, there are regions of low ELF between high ELF regions.

2.2. The topological analysis of ELF

As ELF is a scalar function, the analysis of its gradient field allows us to locate attractors to which we have given a chemical signification (9). Usually, the attractors of a gradient field[3] are single points as is the case for the gradient field of the density. However, for the ELF function, they can also be circles and spheres if the system belongs to a continuous symmetry group (here, cylindrical and spherical symmetry, respectively). In actual cases, the local symmetry remains very strong and, effectively, circular and spherical attractors can be found in molecules belonging to finite symmetry groups. There are, basically, two types of attractors: core and valence attractors. The attractors are designated according to the presence of a nucleus (except a proton) within their basin. They are either points (K-shell attractors) or spheres for the outer core shells.

To offer an efficient visualization tool, we introduced f-localization domains (9), which we defined as formal bodies bounded by a given isosurface $\eta(\boldsymbol{r}) = f$ and enclosing points for which ELF $> f$. These localization domains[4] are the ELF analogs of Mezey's density domains (18). They are said to be reducible when they contain more than one attractor, irreducible when they contain one attractor. The graphical representation of the irreducible localization domains with color codes associated with the type of attractor provides explanatory pictures of the bonding in molecules and crystals.

A valence attractor is connected to a core attractor when the two following conditions are fulfilled.

(*i*) Their basins are bounded by a part of a common separatrix.

(*ii*) The valence attractor lies within the smallest (reducible or irreducible) valence f-localization domain that totally surrounds the core attractor basin in a chemically relevant region (i.e., within which the electron density is larger than 10^{-3} au (19)).

In principle, a core is always totally encapsulated by at least one valence basin and therefore propositions (*i*) and (*ii*) are redundant when f tends to zero unless the valence localization domains have already merged with a core domain. Figure 1 (see Plate 1) provides an example of the determination of

---

[2] A possible generalization of ELF, which is valid to any stationary state and which preserves the requirements of a well-defined local function, can be achieved by substituting $T_s[\rho]$ by the positive definite local kinetic energy density $G(\boldsymbol{r})$, which refers to interacting particles and is obtained from eq. [1] with $\hat{A} = \nabla_r \nabla_{r'}$:

$$D = \frac{1}{2}G(\boldsymbol{r}) - \frac{1}{8}\frac{|\nabla\rho(\boldsymbol{r})|^2}{\rho(\boldsymbol{r})}$$

D_σ derived accordingly is no longer the local excess of kinetic energy due to the Pauli repulsion but has the meaning of a local excess of kinetic energy due to both Fermi and Coulomb holes. Its physical signification is less clear because eq. [1] is not formally equal to the Laplacian of the single determinental conditional probability. This definition might be, however, useful in actual calculations where correlated wavefunctions and natural orbitals are available instead of Kohn–Sham orbitals.

[3] A gradient dynamical system is a vector field that is defined as the gradient field of a given function called the potential function. By analogy with a velocity field, one can build trajectories that form the phase portrait of the dynamical system. Of particular importance are the sets of points where the gradient vanishes. These critical points are either local minima (repellors), saddle points, or local maxima (attractors) of the potential function. The basin of an attractor is the set of points lying on the trajectories ending in the neighbourhood of this attractor. Basins are separated by manifolds called separatrices.

[4] In topology, a domain is defined as a set of points that satisfies the following property: for any pair of points a and b belonging to the domain, there exists at least a path joining a and b and totally contained in the domain.

Table 1. Nomenclature of valence attractors.

Synaptic order	Nomenclature	Symbol
0	Asynaptic	V
1	Monosynaptic	$V(X_i)$
2	Disnaptic	$V(X_i, Y_j)$
≥3	Polysynaptic	$V(X_i, Y_j, ...)$

the number of cores connected to a valence basin. The ELF maps of Li_2 and LiH are represented in a plane containing the internuclear axis. We expect a valence basin containing the proton and a core basin in LiH, a valence basin and two core basins in Li_2. In LiH, there are two ~0.5 localization domains that are bounded by the brick-red lines: the first one is an elongated disk that is contained in the lithium core basin; the second, corresponding to the space remaining outside of the blue zones of low ELF, is in the valence basin. The separatrix between the two basins lies within the blue ring. For Li_2, there are three such ~0.5 localization domains. In Li_2, any core basin is connected to the valence basin because (*i*) they share a common separatrix and (*ii*) the 10^{-3} au isodensity contour represented by the broken line is totally contained in the ~0.5 localization domain (and *a fortiori* in the 0.3 domain). We should say that the valence attractor (located at the midpoint of the internuclear distance) is connected to the two lithium cores. On the contrary, for LiH, though condition (*i*) is fulfilled, condition (*ii*) is not because the broken line crosses the blue and green zones and, therefore, the separatrix. Inside the 10^{-3} au isodensity, the *f*-bounding isosurface does not close up the core for any value of ELF above the valence-core merging and, thus, the valence protonated attractor is not connected to the lithium core.

The number of cores connected to a given valence attractor determines its synaptic order. To avoid misleading confusion between valence attractors and orbital vocabulary we have been moved to introduce a new nomenclature of valence attractors, which is given in Table 1. Hydrogen is a particular case because it is, with helium, the only coreless atom. Therefore, as in Lewis theory, it has to be considered as an exception. Hydrogenated attractors are intermediate between core and valence attractors. In our description of the chemical bond, an attractor whose basin contains a proton is considered as a valence attractor and will be designated as protonated; to establish its synaptic order the proton is counted as a formal core basin (for example: a C—H bond is characterized by an protonated disynaptic attractor). In the examples represented in Fig. 1 (see Plate 1), the Li_2 valence attractor is disynaptic whereas the LiH valence attractor is protonated and monosynaptic.

In the present paper, the attractors and their basins will be labeled as $T_{[i]}$(atom labels). T denotes the type of attractor, V for valence, C for core; *i* is an optional running number in the case of multiple attractors related to the same atom(s). For example, in the water molecule there is one core attractor for the oxygen *K*-shell labeled C(O), two protonated disynaptic attractors $V(H_1, O)$ and $V(H_2, O)$, and two monosynaptic attractors corresponding to the lone pairs $V_1(O)$ and $V_2(O)$. In ethane, the disynaptic attractor of the C—C bond will accordingly be named $V(C_1, C_2)$.

The classification of bonds previously proposed remains valid with this new nomenclature. The shared electron interaction is characterized by a di- or polysynaptic attractor. The lone pairs of electronegative atoms are monosynaptic attractors.

2.3. Localization basin integrated density and related properties

The partition of the molecular space into basins of attractors allows the calculation of related properties by integration of the densities of property over the basins (20). In particular, for a basin labeled Ω_A, one can define the average population as :

$$[7] \quad \bar{N}(\Omega_A) = \int_{\Omega_A} \rho(\boldsymbol{r})\, d\boldsymbol{r}$$

Within the framework of our theory, these average populations are referred to as core, bond, and nonbonding (i.e., lone pair) populations according to the type of attractor that defines the basin. Such average populations over ELF basins were first calculated by us (21, 22) and recently by Häussermann et al. for intermetallic solids (23). They are not expected to have integral values and the bond populations would be about twice the topologically defined bond orders (7, 8).

The RMS deviation $\sigma(\bar{N};\Omega_A))$ is defined by (24, 25):

$$[8] \quad \sigma^2(\bar{N};\Omega_A)) = \langle N^2\rangle_{\Omega_A} - \langle N\rangle^2_{\Omega_A}$$

It represents the quantum mechanical uncertainty on $\bar{N}(\Omega_A)$. The variance (or fluctuation) σ^2 was investigated by Bader in the framework of atomic basins (26). The variance is expressed in terms of the diagonal elements of the first ($\rho(\boldsymbol{x})$) and second-order ($\pi(\boldsymbol{x}_1,\boldsymbol{x}_2)$) density matrices (11) as:

$$[9] \quad \sigma^2(\bar{N};\Omega) = \int_\Omega d\boldsymbol{x}_1 \int_\Omega d\boldsymbol{x}_2 \pi(\boldsymbol{x}_1,\boldsymbol{x}_2) + \bar{N}(\Omega) - \left[\bar{N}(\Omega)\right]^2$$

in which $\boldsymbol{x}_i$ denotes the space and spin coordinates of the electron labeled *i*. For a single determinental wave function (i.e., Hartree–Fock or Kohn–Sham) $\sigma^2(\bar{N};\Omega)$ is the difference between the basin population and the integral over the basin of the exchange part of the second-order density matrix:

$$[10] \quad \sigma^2(\bar{N};\Omega) = \bar{N}(\Omega) - B(\Omega,\Omega)$$

In terms of the orbitals $\phi_i(\boldsymbol{r})$ and of the occupations n_i^α, n_i^β, $B(\Omega,\Omega)$ is given by:

$$[11] \quad B(\Omega,\Omega) = \sum_i \sum_j (n_i^\alpha n_j^\alpha + n_i^\beta n_j^\beta)\langle\phi_i|\phi_j\rangle_\Omega\langle\phi_j|\phi_i\rangle_\Omega$$

in which

$$[12] \quad \langle\phi_i|\phi_j\rangle_\Omega = \int_\Omega d\boldsymbol{r}\phi_i^*(\boldsymbol{r})\phi_j(\boldsymbol{r})$$

It is also convenient to define the interbasin integrated exchange density:

$$[13] \quad B(\Omega_A,\Omega_B) = \sum_i \sum_j (n_i^\alpha n_j^\alpha + n_i^\beta n_j^\beta)\langle\phi_i|\phi_j\rangle_{\Omega_A}\langle\phi_j|\phi_i\rangle_{\Omega_B}$$

The fluctuation in a superbasin $\Omega_A \cup \Omega_B$ is:

$$[14] \quad \sigma^2(\bar{N};\Omega_A \cup \Omega_B) = \sigma^2(\bar{N};\Omega_A) + \sigma^2(\bar{N};\Omega_B) - 2B(\Omega_A,\Omega_B)$$

and for the whole space

$$[15] \quad \sigma^2(\bar{N};\Omega_A \cup \Omega_B \cup \ldots) = 0$$

It follows from eq. [14] that for independent basins σ^2 is an extensive quantity. Following Bader (26), it is useful to introduce the relative fluctuation

$$[16] \quad \lambda(\Omega) = \sigma^2(\bar{N};\Omega)/\bar{N}(\Omega)$$

which is positive and also expected to be less than 1.

Another criterion of discrimination between basins is provided by the reduction of reducible domains. The reduction of a reducible localization domain occurs at a critical value of the bounding isosurface, over which the domain is split into domains containing fewer attractors. The localization domains are then ordered with respect to the ELF critical values, yielding bifurcations. Starting at a very low ELF value, we find only one localization domain (the whole space for $\eta(\boldsymbol{r}) = 0$) upon increase of the isosurface defining value, we meet a first separation between valence and core domains, and at higher ELF values the valence reducible domain is split in its turn. The hierarchy of the bifurcation can be visualized by a tree-diagram.

3. Results and discussion

The calculations were performed at the DFT level with Gaussian94 software (27). The standard 6-31G** basis set (28) was used in conjunction with Becke exchange (29) and Lee, Yang, and Parr correlation (30) functionals. All structures were fully optimized. The labeling of atoms that will be used to label the attractors of the ELF vector gradient field is given in Fig. 4.

Figure 2 (see Plate 1) displays the $\eta(\boldsymbol{r}) = 0.8$ localization domains of ethylene, allyl cation, and *trans*-butadiene whereas the $\eta(\boldsymbol{r}) = 0.5$ and $\eta(\boldsymbol{r}) = 0.8$ localization domains of benzene are represented in Fig. 3 (Plate 1). The representation provided by the topological analysis of ELF does not correspond to the conventional picture of a double bond made into σ and π bonds. This latter description is not invariant upon a unitary transformation of the molecular orbitals; alternative representations such as "banana double bonds" have been shown to be equivalent (3).

3.1. Ethylene

In ethylene there are two core attractors, labeled $C(C_1)$ and $C(C_2)$, four protonated disynaptic attractors, $V(C_i, H_j)$, and two disynaptic attractors $V_1(C_1, C_2)$ and $V_2(C_1, C_2)$. The attractor basins that surround $C(C_1)$ are $V(C_1, H_1)$, $V(C_1, H_2)$, $V_1(C_1, C_2)$, and $V_2(C_1, C_2)$ whereas around $C(C_2)$ we find $V(C_2, H_3)$, $V(C_2, H_4)$, $V_1(C_1, C_2)$, and $V_2(C_1, C_2)$. Therefore, the $V(C_i, H_j)$ and the $V_i(C_1, C_2)$ are disynaptic, according to the definition given in a previous section. The basin populations, their standard deviation and relative fluctuations are listed in Table 2. The basins of the two disynaptic attractors have been gathered together in the superbasin labeled $V_{1\cup2}(C_1C_2)$. The basin population corresponding to

Fig. 4. Atomic labels of ethylene, propene, allyl cation, *trans*-butadiene, and benzene.

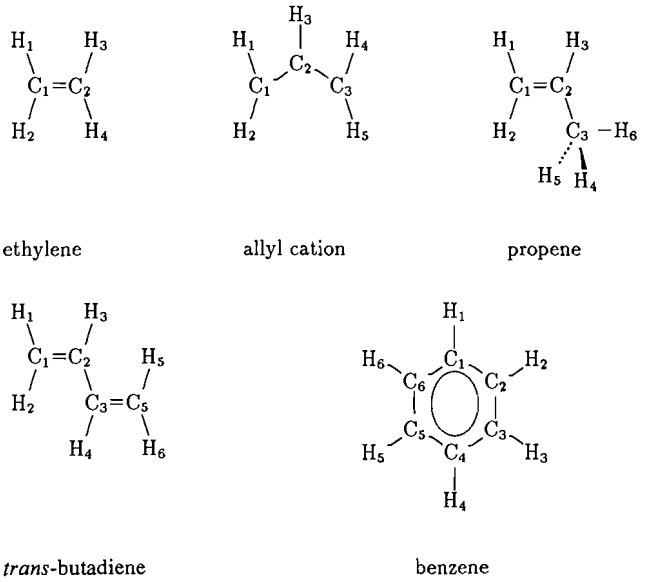

Table 2. ELF value at attractor, basin population, standard deviation, and relative fluctuations of the basin populations of ethylene.

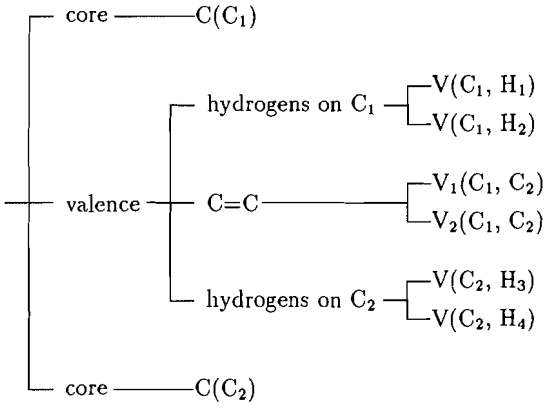
	ELF	$\bar{N}$	$\sigma(\bar{N};\Omega)$	$\lambda(\Omega)$
C(C)	1.0	2.09	0.51	0.12
$V(C_1, H_1)$	1.0	2.04	0.94	0.43
$V(C_1, C_2)$	0.93	1.81	1.12	0.70
$V_{1\cup2}(C_1, C_2)$	0.93	3.62	1.47	0.40

the C=C double bond is less then 4, whereas the core and hydrogen basins are slightly greater than 2. The topological bond orders of Cioslowski and Mixon (7) and of Angyán et al. (8) calculated with the same carbon basis set at the SCF level are, respectively, 1.958 and 1.984. With a 6-31++G** basis these values are reduced to 1.881 and 1.918 whereas the C—H bond order is increased by 0.012 e^-. The discrepancy with our value (1.79) is due in part to different definitions and also to the fact that in our calculation the core population is independently treated. The relative fluctuation in the population of the core basins is low. On the contrary, for basins of the disynaptic attractors of the C=C bond the relative fluctuation is very high (0.7). These two basins are strongly correlated and their aggregation lowers the relative fluctuation from 0.70 to 0.40.

The bifurcation graph (Fig. 5) provides a hierarchy that is consistent with the relative fluctuation values. At $\eta(\boldsymbol{r}) = 0.06$, there is a first partition into core and valence basins. The valence basin is split into two protonated reducible domains $V(C_1, H_1) \cup V(C_1, H_2)$, $V(C_2, H_3) \cup V(C_2, H_4)$, and the $V_{1\cup2}(C_1, C_2)$ one $V_1(C_1, C_2) \cup V_2(C_1, C_2)$ at $\eta(\boldsymbol{r}) = 0.64$. This bifurcation is immediately followed at $\eta(\boldsymbol{r}) = 0.65$ by the reduction of the two protonated domains. Finally, $V_{1\cup2}(C_1, C_2)$ is reduced at $\eta(\boldsymbol{r}) = 0.92$, a value very close to that of the attractors.

Fig. 5. Localization domain reduction tree-diagram of ethylene.



3.2. Propene

The basin populations, their standard deviation, and relative fluctuations of propene are given in Table 3. As for ethylene, the basins of the two disynaptic attractors of the double bond have been merged. The $V_{1\cup2}(C_1, C_2)$ population is larger in propene than in ethylene by 0.1 e^-. The relative fluctuation for this basin, 0.41, is very close to the corresponding value in ethylene. The same value is also found for the $V(C_2, C_3)$ basin, which corresponds to the single C—C bond. The lowering of the molecular symmetry from D_{4h} in ethylene to C_s in propene weakens the correlation between the allylic hydrogen basins; their relative fluctuations decrease by about 0.1. An important correlation remains between the two methyl hydrogens symmetric with respect to the σ plane.

The bifurcation graph of the localization domains of propene is shown in Fig. 6. After the core–valence separation at $\eta(r) = 0.06$, the valence domain undergoes a second separation into three domains at $\eta(r) = 0.65$. These domains correspond to the central carbon hydrogen, the methyl group, and the allyl group. The methyl group domain is reduced at $\eta(r) = 0.67$ into two components $V(C_2, C_3)$ and the domain of the three hydrogens from which the in-plane hydrogen is separated at $\eta(r) = 0.69$, the two out-of-plane being ultimately split for $\eta(r) = 0.70$. On the allyl side, hydrogens detachments occur successively at $\eta(r) = 0.67$ and $\eta(r) = 0.69$ and the reduction of the C=C domain at $\eta(r) = 0.93$.

3.3. Allyl cation

In ethylene and propene the number of attractors is equal to the number of occupied Kohn–Sham orbitals; in allyl cation, there are 10 attractors for 11 doubly occupied orbitals. One disynaptic attractor with a basin population of 2.6 (Table 4) is found for each C—C bond. The value of ELF at the attractor is slightly less than that of the propene single bond. The relative fluctuation for the basins of these attractors, 0.55, is higher than for a double or a single C—C bond in the absence of conjugation, indicating a noticeable delocalization. Delocalization over hydrogen basins is of the order found in propene since the corresponding relative fluctuations are both of the order of 0.30.

The localization domain reduction pattern (Fig. 7) reflects the symmetry of the system. As in propene, the first splitting of the valence domain at $\eta(r) = 0.59$ is due to the detachment of the central carbon hydrogen. The second valence separation ($\eta(r) = 0.645$) involves hydrogens linked to the terminal carbon, which are immediately ($\eta(r) = 0.65$) followed by domains containing the disynaptic C—C attractors. At ($\eta(r) = 0.66$) the domains are totally reduced. It is worth noting that delocalization delays the separation of the $V(C_1, C_2)$ and $V(C_2, C_3)$ domains with respect to the allyl–methyl separation in propene.

Table 3. ELF value at attractor, basin population, standard deviation, and relative fluctuations of the basin populations of propene.

	ELF	$\bar{N}$	$\sigma(\bar{N}; \Omega)$	$\lambda(\Omega)$

$V(C_i, H_i)$	1.0	2.08	0.80	0.31

that of propene. On the one hand, the ELF values at the attractors are identical in *trans*-butadiene and in propene and the populations of the hydrogen basins are equal to that of the allylic hydrogens; on the other hand, the populations of the double bond attractors are less than that of propene by 1/8 e^-, whereas the single bond basin population is increased by 1/4 e^-. This reorganization of the basin population is an indication of the delocalization along the carbon skeleton. Note also, the increase with respect to propene of the relative fluctuation of the single C—C bond basin.

The localization domain reduction diagram of *trans*-butadiene (Fig. 8) is very similar to that of propene. After the core–valence separation at $\eta(\boldsymbol{r}) = 0.06$, the domains of the protonated disynaptic attractors linked to the carbons of the single bond part from the valence domain at $\eta(\boldsymbol{r}) = 0.63$. The next step, at $\eta(\boldsymbol{r}) = 0.64$, isolates the disynaptic attractor of the C—C single bond from two allylic fragments. At higher ELF values, the two allylic fragments are split in accordance with the way followed in propene, except that the two hydrogen basins are simultaneously detached from the C=C domain.

3.5. Benzene

There are 18 attractors in benzene: 6 core, 6 protonated disynaptic, and 6 C—C disynaptic. Each V(C—C) has a basin population of 2.83 e^-, which compares with the topological bond order, ~ 1.4(7, 8). Delocalization along the skeletal ring is indicated by a rather high relative fluctuation, 0.47 (Table 6). The ELF analysis does not give evidence for any σ and π systems in benzene.

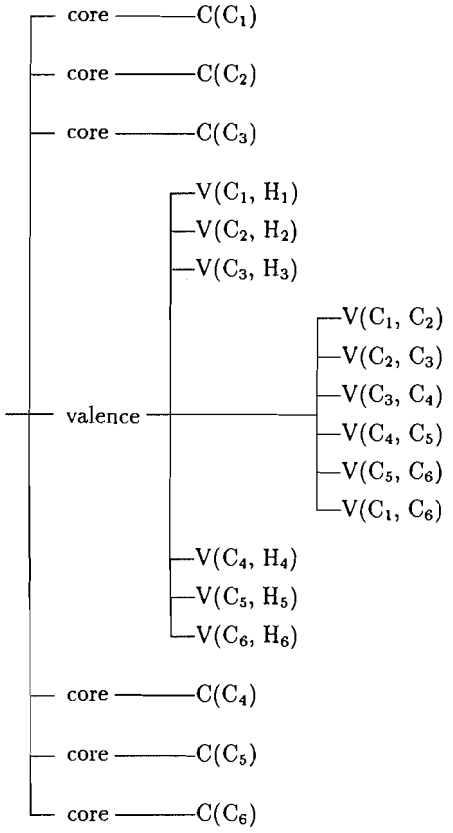
The reduction of the localization domains in benzene, presented in Fig. 9, is very simple and is ruled by the molecular symmetry. At $\eta(\boldsymbol{r}) = 0.06$ the core domains are separated from the valence domain, which undergoes two successive splittings. The first one at $\eta(\boldsymbol{r}) = 0.65$ plucks off the hydrogen, the second, at $\eta(\rho) = 0.68$ unties the $V(C_i, C_j)$ domains.

4. Conclusion

For the electron density produced by a given potential of the nuclei, ELF provides a structuring of the molecular space into basins that may be roughly associated with the electron-pairing regions and have therefore a chemical meaning. The average number of electrons per basin is obtained by integration of the electron density function over the basins. For the systems investigated here, it corresponds roughly to the number of electrons expected on chemical grounds.

Quantum mechanical uncertainty yields standard deviations that typically range from 0.5 for the well-separated

Fig. 9. Localization domain reduction tree-diagram of benzene.



core basins to 1.2 for the valence basins. The core basins are well separated from the valence basins because the value of ELF on the separatrix (i.e., at the border) is always very low, ~0.06. This is not the case between valence basins that are separated at higher ELF values, about 0.6–0.7 for the systems presented here. Following Bader (26), we found that the relative fluctuation is a good measure of the delocalization. It is of the order of 0.1 for core basins, 0.3 for basins of the protonated disynaptic attractor of the C—H bonds, 0.4 for basins related to single and double C—C bonds, and 0.5 for delocalized bonds. Of course, the relative fluctuation is not the only measure of delocalization, which is also reflected by the average basin populations of the C—C bonds (e.g., 2.8 for benzene).

This work illustrates the importance of Richard Bader's contribution to theoretical chemistry. Beyond the theory of Atoms in Molecules, he demonstrated the importance of topological analysis for scrutinizing molecular space and he introduced tools, such as fluctuation analysis, that are very useful complements to the topological approach.

Approximate kinetic energy density functionals generated by local-scaling transformations

E.V. Ludeña, R. López-Boada, and R. Pino

Abstract: Different stages in the development of density functional theory are succinctly reviewed for the purpose of tracing the origin of the local-scaling transformation version of density functional theory. Explicit kinetic energy functionals are generated within this theory. These functionals are analyzed in terms of several approximations to the local-scaling function and are applied to a few selected first-row atoms.

Key words: density functional theory, kinetic energy density functionals, local-scaling transformations, explicit kinetic energy functionals, kinetic energy of first-row atoms.

Résumé : On fait une revue succincte des divers stades du développement de la théorie de la fonctionnelle de densité dans le but de déterminer l'origine de la version de la théorie de la fonctionnelle de densité basée sur la transformation d'échelle locale. Des fonctionnelles explicites de l'énergie cinétique sont générées à l'intérieur de cette théorie. On analyse ces fonctionnelles en termes de plusieurs approximations à la fonction d'échelle locale et on les applique à quelques éléments choisis de la première période.

Mots clés : théorie de la fonctionnelle de densité, fonctionnelles de densité de l'énergie cinétique, transformations d'échelle locale, fonctionnelles explicites de l'énergie cinétique, énergie cinétique des éléments de la première période.

1. Introduction

A very demanding problem in density functional theory concerns the adequate treatment of the kinetic energy term of quantum mechanical many-particle systems. Indeed, the problem is so difficult that actual treatments of these systems are carried out within the Kohn–Sham approach where the kinetic energy is handled in terms of noninteracting particles, thus bypassing the construction of the kinetic energy density functional. Nevertheless, both from a fundamental point of view as well as from a practical one, it would be desirable to find this functional or sufficiently accurate approximations to it.

We deal in the present paper with the generation of energy density functionals in the context of the local-scaling transformation version of density functional theory. The latter is a constructive approach that allows one to obtain explicit density functionals, which can be devised to approximate as closely as one wishes the exact functional provided, that is, to ensure that one starts from a good enough "generating" wave function for the system at hand.

In Sect. 2, we review some stages in the development of density functional theory in order to sketch the appropriate background against which to assess the local-scaling transformation version. In Sect. 3, we formulate the general problem of obtaining kinetic energy density functionals by means of these transformations. In Sect. 4, we apply these transformations to selected first-row atoms and investigate various types of approximations that can be introduced both to these functionals and to the generating wave functions. The results presented here should be regarded as first attempts at modelling the kinetic energy functional without having to rely on previous calculations of "generating" wave functions.

2. Stages in the development of DFT

As is well known, density functional theory (1–4) has become one of the most promising methods for dealing with the quantum-mechanical many-particle problem. One may describe its development in terms of the following four stages.

Heuristic stage

This stage was initiated in 1927 in the classical works of Thomas (5) and Fermi (6); it was continued in the thirties by Dirac (7), Wigner (8), and von Weizsäcker (9), and it was further developed in the following decades by Kirzhnitz (10), Hodges (11), and others (12–14). In this stage, within the framework of a "statistical" approximation, the bases were laid for writing heuristic expressions of the energy as a functional of the one-particle density $\rho(\boldsymbol{r})$. Much of the work that

Received October 12, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

followed the initial formulation of Thomas and Fermi had to do with how to include inhomogeneous corrections as well as many-particle correlation effects in these energy functionals.

Formal nonconstructive stage

This stage came into being with the formulation in 1964 of the Hohenberg–Kohn theorem (15), which proved the existence of an energy density functional that yields the exact ground-state energy when evaluated at its extremum, i.e., when $\rho(\boldsymbol{r})$ is the exact ground-state density. Although this theorem lent support to the earlier heuristic approach, due to the fact that it is just an existence theorem, it failed to provide the means for a systematic approach to the construction of energy density functionals. Moreover, the Hohenberg–Kohn-based formulation of density functional theory led to a misconception concerning the existence of a "universal" functional that, purportedly, was capable of expressing through the same formula the ground-state energy of any many-electron system, regardless of its number of particles or of its symmetry (the latter, for example, in the case of atoms is described in terms of angular momentum, spin, and parity operators).

The Hohenberg–Kohn theorem establishes a one-to-one correspondence between the exact ground-state one-particle density $\rho_0^v(\boldsymbol{r})$ and the external potential $v(\boldsymbol{r})$. This means, furthermore, that the density also determines the Hamiltonian $\hat{H}_v = \hat{T} + \hat{U} + \sum_{i=1}^{N} v(\boldsymbol{r}_i)$ and hence the exact ground-state wave function Ψ_0^v (through $\hat{H}_v\Psi_0^v = E_0^v\Psi_0^v$). Note, however, that in this "existence" proof, the exact wave function is still the solution to the Schrödinger equation and can be obtained only by solving this equation.

This one-to-one correspondence between the exact one-particle density and the exact ground-state wave function provided a *nonconstructive proof* (16) of the existence of a density functional $E[\rho]$ for the electronic energy. The question of whether it is possible to obtain the energy density functional without having to resort to previous knowledge of the exact wave function is in fact left open in Hohenberg and Kohn's work.

Implicit constructive stage

This question, however, lies at the basis of the density functional theory formulation advanced by Levy (17) (see also Lieb, Payne, and the early work of Percus (18, 19, 33)). The constrained search approach of Levy advocates the *implicit construction* (16) of the functional $E[\rho] = F[\rho] + \int v\rho$, where the auxiliary functional $F[\rho]$ is defined as the internal energy corresponding to the kinetic energy and electron–electron interaction operators:

$$[1] \quad F[\rho] = \min \{\langle \Phi_\rho \,|\, \hat{T} + \hat{U} \,|\, \Phi_\rho \rangle\}, \qquad \Phi_\rho \in \mathscr{L}_N$$

$$= \langle \Phi_\rho^{\min} \,|\, \hat{T} + \hat{U} \,|\, \Phi_\rho^{\min} \rangle$$

Clearly, wave functions appear in Levy's formalism in the definition of $F[\rho]$. Notice that in order to calculate $F[\rho]$ for a given and fixed ρ, the internal energy must be evaluated scanning over all wave functions Φ_ρ (in Hilbert space $\mathscr{L}_N$) that yield the fixed density ρ. Among these wave functions there exists a minimizing wave function $\Phi_\rho^{\min}$, which yields $F[\rho]$.

When the fixed density is selected to be $\rho = \rho_0^v$, i.e., the exact ground-state density, then $F[\rho_0^v] = \langle \Psi_0^v \,|\, \hat{T} + \hat{U} \,|\, \Psi_0^v \rangle$, where the minimizing wave function is the exact ground-state wave function Ψ_0^v.

Certainly, if the exact auxiliary functional $F[\rho_0^v]$ depends upon the exact wave function Ψ_0^v for a particular N-particle system (corresponding to a given external potential $v(\boldsymbol{r})$), it follows that this functional is not "universal," namely, that it is not the same for all N-particle systems. (Gill and Pople (20) have verified the non-universality of the exchange functional for the hydrogen atom — which can be calculated exactly.) This non-universality of the functional $F[\rho]$ (for any fixed density ρ and not only for ρ_0^v) is a consequence of the specificity of the minimizing wave function defining $F[\rho]$. Although the external potential does not appear explicitly in the calculation of this functional, it affects the wave function in view of the fact that the external potential determines the density.

Explicit constructive stage

The implementation of Levy's constrained search approach to density functional theory requires that a procedure be set up such that all wave functions in Hilbert space $\mathscr{L}_N$, yielding a fixed density ρ, are spanned. An interesting approach in this direction was carried out by Zumbach and Maschke (21) who, essentially, by resorting to particular forms of density transformations applied to a plane-wave wave function, were able to obtain energy functionals that depended on the density. The type of reference wave function (based on plane waves) did not allow, however, for an accurate representation of actual systems such as atoms and molecules whose densities vary quite markedly in the intra-shell and inter-shell regions. Another attempt to build approximate functionals based on density transformations was that of Ludeña in 1983 (22). Independently, also Nyden and Parr (23) and Gosh and Parr (24) dealt with this same problem (see also the pioneer work of March and Young (25) and the later work of Kozlowski and March (26)).

Density transformations are generalizations of scaling transformations. There is a long history, which starts with the work of Macke in 1955 (27, 28), of their use in relation to the many-body problem in quantum mechanics (18, 21–25, 27–37). Local-scaling transformations are a particular type of the more general density transformations.

The formalization of the *explicit constructive stage* was brought about through the formulation of the local-scaling transformation version of density functional theory. The initial paper setting up this new approach was that of Petkov, Stoitsov, and Kryachko (1986) (38) (see also ref. 1). The theory was further developed in the works of Kryachko and Ludeña (39) and of Kryachko, Ludeña, and Koga (see ref. 40, and references therein; for some recent developments see refs. 41 and 42).

A constructive formulation that is quite similar to the local-scaling transformation version of density functional theory was advanced independently in 1988 by Cioslowski (43–45; also ref. 16) and it is known as the density-driven approach. The connection between these two approaches was investigated by Kryachko and Ludeña in 1991 (46).

3. Explicit kinetic energy density functionals

There have been many attempts to reduce the kinetic energy, which is a natural functional of the 1-matrix, to a functional of the one-particle density (for a recent review see ref. 47 and references therein). Although functionals that yield an accuracy of 1% have been advanced, chemical precision demands that much more accurate functionals be devised. In this vein, we discuss in the present work the use of local-scaling transformations for the generation of kinetic energy functionals (expressed as functionals of just the one particle-density) and analyze some approximate forms of these functionals. We carry out illustrations for selected first-row atoms.

Local-scaling transformations are generalizations of the well-known scaling transformations. The latter carry a vector $\boldsymbol{r}$ into a transformed vector $\lambda\boldsymbol{r}$, where λ is a constant. The constancy of λ means that the vector $\boldsymbol{r}$ is modified uniformly in each point of the Euclidean space $\mathscr{R}^3$. On the other hand, local-scaling transformations distort the vector $\boldsymbol{r}$ at each point of $\mathscr{R}^3$, so that the transformed vector becomes $\boldsymbol{f}(\boldsymbol{r}) = \lambda(\boldsymbol{r})\boldsymbol{r}$. In this case λ is a function.

As discussed elsewhere (48) local-scaling transformations correspond to density transformations that keep the direction of the transformed vector $\boldsymbol{f}(\boldsymbol{r})$ constant. Thus, they satisfy the following equation relating densities $\rho_1(\boldsymbol{r})$ and $\rho_2(\boldsymbol{r})$ (see ref. 1, Sect. 7.1.d):

$$[2] \quad \rho_2(\boldsymbol{r}) = J(\boldsymbol{f}(\boldsymbol{r});\boldsymbol{r})\rho_1(\boldsymbol{f}(\boldsymbol{r}))$$

where $J(\boldsymbol{f}(\boldsymbol{r});\boldsymbol{r})$ is the Jacobian of the transformation and is given by

$$[3] \quad J(\lambda(\boldsymbol{r})\boldsymbol{r};\boldsymbol{r}) = \begin{vmatrix} \frac{\partial\lambda(\boldsymbol{r})x}{\partial x} & \frac{\partial\lambda(\boldsymbol{r})y}{\partial x} & \frac{\partial\lambda(\boldsymbol{r})z}{\partial x} \\ \frac{\partial\lambda(\boldsymbol{r})x}{\partial y} & \frac{\partial\lambda(\boldsymbol{r})y}{\partial y} & \frac{\partial\lambda(\boldsymbol{r})z}{\partial y} \\ \frac{\partial\lambda(\boldsymbol{r})x}{\partial z} & \frac{\partial\lambda(\boldsymbol{r})y}{\partial z} & \frac{\partial\lambda(\boldsymbol{r})z}{\partial z} \end{vmatrix} = \lambda^3(\boldsymbol{r})[1 + \boldsymbol{r}\cdot\nabla_r \ln\lambda(\boldsymbol{r})]$$

From eqs. [2] and [3] we can obtain the following expression for $\lambda(\boldsymbol{r})$:

$$[4] \quad \lambda(\boldsymbol{r}) = \left[\frac{\rho_2(\boldsymbol{r})}{\rho_1(\lambda(\boldsymbol{r})\boldsymbol{r})(1 + \boldsymbol{r}\cdot\nabla_r \ln\lambda(\boldsymbol{r}))}\right]^{1/3}$$

Equation [4] is a first-order differential equation for the transformation function $\lambda(\boldsymbol{r})$. An iterative solution for $\lambda(\boldsymbol{r})$ can be obtained through:

$$[5] \quad \lambda^{(i)}(\boldsymbol{r}) = \left[\frac{\rho(\boldsymbol{r})}{\rho_g(\lambda^{(i-1)}(\boldsymbol{r})\boldsymbol{r})(1 + \boldsymbol{r}\cdot\nabla_r \ln\lambda^{(i-1)}(\boldsymbol{r}))}\right]^{1/3}$$

with $\lambda^{(0)}(\boldsymbol{r}) = 1$.

Let us now consider the kinetic energy expressed as a functional of the first-order reduced density matrix

$$[6] \quad T[\Psi_\rho] \equiv T[D^1_\rho] = \frac{1}{2}\int d^3\boldsymbol{r}_1 \nabla_{r_1}\nabla_{r'_1} D^1_\rho(\boldsymbol{r}_1,\boldsymbol{r}'_1)|_{r'_1=r_1}$$

where $D^1_\rho(\boldsymbol{r}_1,\boldsymbol{r}'_1)$ is the first-order reduced density matrix associated with the N-particle wave function Ψ_ρ (the latter is a wave function in Hilbert space $\mathscr{L}_N$ that yields the one-particle density $\rho(\boldsymbol{r})$. Our aim is to express eq. [6] as an explicit functional of the one-particle density $\rho(\boldsymbol{r})$. For this purpose, let us also consider the arbitrary and finite orbital set $\{\phi_{g,k}(\boldsymbol{r})\}_{k=1}^m$ with $m > N$ (the subindex g stands for "generating", as we shall denote this orbital set as the "generating" set). Out of this set, let us form the set of N-particle Slater determinants $\{\Phi^g_K\}$ (where K stands for the set of ordered single-particle labels). Let us further consider the generating wave function Ψ_g expanded in terms of the Slater determinants:

$$[7] \quad \Psi_g = \sum_{K=1}^{M} C^g_K \Phi^g_K$$

For the time being, let us consider the expansion coefficients $\{C^g_K\}$ as arbitrary parameters. Denoting by $D^1_g(\boldsymbol{r}_1,\boldsymbol{r}'_1)$ the "generating" 1-matrix associated with Ψ_g, we readily see that in terms of the generating orbital set, it is given by

$$[8] \quad D^1_g(\boldsymbol{r},\boldsymbol{r}') = \sum_{i=1}^{N}\sum_{j=1}^{N} n^g_{ij}\phi_{g,i}(\boldsymbol{r})^*\phi_{g,j}(\boldsymbol{r}')$$

The corresponding "generating" one-particle density is

$$[9] \quad \rho_g(\boldsymbol{r}) == \sum_{i=1}^{N}\sum_{j=1}^{N} n^g_{ij}\phi_{g,i}(\boldsymbol{r})^*\phi_{g,j}(\boldsymbol{r})$$

The local-scaling transformation connecting the "generating" density $\rho_g(\boldsymbol{r})$ and the "final" density $\rho(\boldsymbol{r})$ satisfies eq. [4] with $\rho_1(\boldsymbol{r}) \equiv \rho_g(\boldsymbol{r})$ and $\rho_2(\boldsymbol{r}) \equiv \rho(\boldsymbol{r})$. Moreover, applying this local-scaling transformation to the "generating" orbital set, we obtain the following transformed one-particle set:

$$[10] \quad \phi_{\rho,k}(\boldsymbol{r}) = [J(\lambda(\boldsymbol{r})\boldsymbol{r};\boldsymbol{r})]^{1/2}\phi_{g,k}(\boldsymbol{f}(\boldsymbol{r})) = \left[\frac{\rho(\boldsymbol{r})}{\rho_g(\lambda(\boldsymbol{r})\boldsymbol{r})}\right]^{1/2}\phi_{g,k}(\lambda(\boldsymbol{r})\boldsymbol{r})$$

It can be readily shown that the 1-matrix $D^1_\rho(\boldsymbol{r}_1,\boldsymbol{r}'_1)$ can be written in terms of the transformed orbitals as:

$$[11] \quad D^1_\rho(\boldsymbol{r},\boldsymbol{r}') = \sum_{i=1}^{N}\sum_{j=1}^{N} n^g_{ij}\phi_{\rho,i}(\boldsymbol{r})^*\phi_{\rho,j}(\boldsymbol{r}')$$

Similarly, the one-particle density becomes:

$$[12] \quad \rho(\boldsymbol{r}) == \sum_{i=1}^{N}\sum_{j=1}^{N} n^g_{ij}\phi_{\rho,i}(\boldsymbol{r})^*\phi_{\rho,j}(\boldsymbol{r})$$

It follows from eqs. [10] and [11] that the 1-matrix $D^1_\rho(\boldsymbol{r}_1,\boldsymbol{r}'_1)$ can be rewritten as:

$$[13] \quad D^1_\rho(\boldsymbol{r},\boldsymbol{r}') = \left[\frac{\rho(\boldsymbol{r})\rho(\boldsymbol{r}')}{\rho_g(\lambda(\boldsymbol{r})\boldsymbol{r})\rho_g(\lambda(\boldsymbol{r}')\boldsymbol{r}')}\right]^{1/2} \times D^1_g(\lambda(\boldsymbol{r})\boldsymbol{r},\lambda(\boldsymbol{r}')\boldsymbol{r}')$$

Substituting eq. [13] into eq. [6] one obtains

$$[14]\quad T[D_\rho^1] = \frac{1}{8}\int d^3r \frac{[\nabla_r \rho(r)]^2}{\rho(r)} + \frac{1}{2}\int d^3r \rho(r) \nabla_r \nabla_{r'} \tilde{D}_g^1(f(r), f(r'))|_{r'=r}$$

where $f(r) = \lambda(r)r$ and where $\tilde{D}_g^1$ is the non-local part of the "generating" 1-matrix evaluated at the transformed vectors:

$$[15]\quad \tilde{D}_g^1(f(r_1), f(r_1')) = \frac{D_g^1(f(r_1), f(r_1'))}{[\rho_g(f(r_1))]^{1/2}[\rho_g(f(r_1'))]^{1/2}}$$

Notice that in eq. [14] the first term is the well-known von Weizsäcker contribution (9) to the kinetic energy, which is a local term (49). The second term corresponds to the non-local contribution to the kinetic energy.

To transform eq. [15] into a functional of $\rho(r)$, let us first change, using the chain rule, the derivatives in the second term of eq. [15] (defined with respect to r) to those depending on the vector $f(r) = \lambda(r)r$: $\nabla_r = \nabla_r f \nabla_f$. Because the transformed vector $f(r)$ maintains the same direction as the original one, namely, since $f(r) = f(r)\hat{1}_r$ (where $\hat{1}_r$ is the unit vector along r), one can write

$$[16]\quad \nabla_r = \frac{\partial f(r)}{\partial r}\nabla_f = \frac{r^2}{f^2(r)}\frac{\rho(r)}{\rho_g(f)}\nabla_f$$

Substituting eqs. [18] and [16] into eq. [14], we obtain the following expression for the kinetic energy

$$[17]\quad T[D_\rho^1] = T_W[\rho] + \frac{1}{2}\int d^3r \frac{\rho(r)^3}{\rho_g^3(f(r))}\frac{r^4}{f^4(r)} \times \left[\sum_{i=1}^{m}\sum_{j=1}^{m} n_{ij}^g \nabla_f \phi_{g,i}(f(r)) \nabla_f \phi_{g,j}^*(f(r)) - \frac{1}{4}\frac{(\nabla_f \rho_g(f(r)))^2}{\rho_g(f(r))}\right]$$

Our task of expressing the kinetic energy as a functional of the one-particle density can be accomplished by introducing eq. [4] into eq. [17]. This leads to

$$[18]\quad T[D_\rho^1] = T_W[\rho] + \frac{1}{2}\int d^3r \rho^{5/3}(r) \times (1 + r\cdot\nabla_r \ln\lambda(r))^{4/3}\tau([\rho(r)]; r)$$

where

$$[19]\quad \tau(f(r)) = \frac{1}{\rho_g^{5/3}(f(r))} \times \left[\sum_{i=1}^{m}\sum_{j=1}^{m} n_{ij}^g \nabla_f \phi_{g,i}^*(f(r)) \nabla_f \phi_{g,j}(f(r)) - \frac{1}{4}\frac{(\nabla_f \rho_g(f(r)))^2}{\rho_g(f(r))}\right]$$

A very appealing characteristic of eq. [18] is that the Thomas–Fermi term $\rho^{5/3}(r)$ emerges in a very natural way. In addition, there arises a second factor that depends on the local-scaling function $\lambda([\rho]; r)$. Moreover, these first two factors are "universal" as they depend only on ρ (or $\lambda([\rho]; r)$). The particular traits of the N-body problem are manifested through the form of the "modulating" factor $\tau([\rho(r)]; r)$. Clearly, this factor is not universal since it contains the "generating" orbitals for the particular problem at hand and the "generating" one-particle density $\rho_g(f(r))$.

Table 1. Parameters of the Raffenetti-type RT^a "generating" orbitals for selected first-row atoms.

Atom	α_s RT^a	β_s RT^a	α_p RT^a	β_p RT^a
Li	0.452 246	1.290 937		
Be	0.582 434	1.318 837		
B	0.790 699	1.305 542	0.508 345	1.422 519
F	1.308 402	1.447 490	1.006 690	1.508 533
Ne	1.328 402	1.487 490	1.016 690	1.518 533

Let us note that eq. [18] can be transformed into an explicit, albeit approximate, functional of the one-particle density $\rho(r)$ by replacing $\lambda(r)$ by the first iterative solution, i.e., $\lambda^{(1)}(r)$ in eq. [5] (assuming that $\lambda^{(0)}(r) = 1$):

$$[20]\quad \lambda^{(1)}(r) = (\rho(r)/\rho_g(r))^{1/3}$$

When this is done, the product of the Thomas–Fermi term times the second term in eq. [18] takes the form:

$$[21]\quad \rho(r)^{5/3}(1 + r\cdot\nabla_r \ln(\rho(r)/\rho_g(f))^{1/3})^{4/3}$$

Clearly, these approximations to $\lambda(r)$ (or equivalently to the transformation function $f(r)$) can also be introduced into $\tau([\rho]; r)$. In this manner, we can generate explicit iterative representations of the kinetic energy functional.

4. Calculations and results for first-row atoms

Although the expressions derived in the previous section are general, we shall illustrate the present approach by calculating the Hartree–Fock kinetic energy of selected first-row atoms. In that case, the "orbit-generating" set is $\{\phi_{g,k}(r)\}_{k=1}^N$. The single Slater determinant that we can construct using these locally scaled orbitals is

$$[22]\quad \Phi_\rho^{SD}(r_1, \cdots, r_N) \equiv \frac{\det}{\sqrt{N!}}[\phi_{\rho,1}(r_1)\cdots\phi_{\rho,N}(r_N)]$$

The 1-matrix corresponding to this wave function is

$$[23]\quad D^{1SD}(r, r') = \sum_{j=1}^{N}\phi_j^*(r)\phi_j(r')$$

As in the previous section, this leads to the following expression for the kinetic energy functional

$$[24]\quad T[D_\rho^{1SD}] = T_W[\rho] + \frac{1}{2}\int d^3r \rho^{5/3}(r) \times (1 + r\cdot\nabla_r \ln\lambda(r))^{4/3}\tau_N([\{\phi_{g,i}(f(r)\}_{i=1}^N]; r)$$

where

$$[25]\quad \tau_N([\{\phi_{g,i}(f(r))\}_{i=1}^N]; r) = \frac{1}{\rho_g^{5/3}(f(r))} \times \left[\sum_{j=1}^{N}|\nabla_f \phi_{g,j}(f(r))|^2 - \frac{1}{4}\frac{(\nabla_f \rho_g(f(r)))^2}{\rho_g(f(r))}\right]$$

Table 2. Parameters of the Raffenetti-type RT^b and RT^c "generating" orbitals for selected first-row atoms.

[d]Clementi–Roetti results (57).

In the present case, the modulating factor $\tau_N([\{\phi_{g,i}(\lambda(\boldsymbol{r})\boldsymbol{r})\}_{i=1}^N];\boldsymbol{r})$ depends upon the N "generating" orbitals $\{\phi_{g,i}(\boldsymbol{f}(\boldsymbol{r}))\}_{i=1}^N$ evaluated at the transformed vector $\boldsymbol{f}(\boldsymbol{r}) = \lambda(\boldsymbol{r})\boldsymbol{r}$.

We choose Raffenetti-type orbitals (50) as the generating orbitals:

$$[26]\quad R_{ns}([\alpha_s, \beta_s, \{C_{nsj}\}]; r) = \sum_{j=1}^{M} C_{nsj}(2\alpha_s\beta_s^j)^{3/2}/(2)^{1/2}\exp(-\alpha_s\beta_s^j r)$$

for the R_{ns} orbitals and

$$[27]\quad R_{np}([\alpha_p, \beta_p, \{C_{npj}\}]; r) = \sum_{j=1}^{M} C_{npj}(2\alpha_p\beta_p^j)^{5/2}/(24)^{1/2} r\exp(-\alpha_p\beta_p^j r)$$

for the R_{np} orbitals. In the present calculations, we consider three sets of such Raffenetti-type (RT) orbitals: the set RT^a, RT^b, and RT^c. The first set is defined as follows:

$$[28]\quad RT^a \equiv \{\text{Li}: 12s;\quad \text{Be}: 12s;\quad \text{B}: 12s, 8p;\quad \text{F}: 8s, 6p;\quad \text{Ne}: 8s, 6p\}$$

and the sets RT^b and RT^c are given by

$$[29]\quad RT^{b,c} \equiv \{\text{Li}: 6s;\quad \text{Be}: 6s;\quad \text{B}: 4s, 4p;\quad \text{F}: 4s, 4p;\quad \text{Ne}: 4s, 4p\}$$

In Table 1 we list the parameters α_s, β_s, α_p, and β_s that characterize the set RT^a. These parameters were determined by a constrained-density energy optimization of the Hartree–Fock energy within the scheme of local-scaling transformations (51). The fixed Hartree–Fock density was taken to be that of Boyd (52). In Table 2, we list the orbital parameters for the sets RT^b and RT^c. The former is the extended triple-zeta (ETZ) set of Raffenetti (50) and the latter is a variant of this set where the parameters have been chosen arbitrarily. The orbital expansion coefficients for set RT^b are taken from ref. 50, whereas the coefficients of the set RT^c were determined by a Schmidt orthonormalization of the Raffeneti ETZ set. The approximate Hartree–Fock energies obtained from the "generating" orbitals making up the sets RT^a, RT^b, and RT^c are listed in Table 3, where for completeness, we have also included the Clementi–Roetti Hartree–Fock energies.

The energies reported in Table 3 reflect the quality of the wave functions employed (which for simplicity we have restricted to be of the Raffenetti type). In general, we observe that the functions belonging to the set RT^b are closer to the Clement–Roetti Hartree–Fock wave functions (where we assume that the energy is an adequate criterion for measuring "closeness"). By this same criterion, wave functions of set RT^a are farther apart and, clearly, those of set RT^c, i.e., functions with arbitrarily chosen parameters, differ the most from the Clementi–Roetti wave functions.

In Table 4, we list the kinetic energies evaluated by means of eq. [24] for various approximations of the local-scaling function $\lambda(r)$. Note that $\lambda(r) = 1$ corresponds to the zeroth-order iterative solution, namely, $\lambda^{(0)}(r)$ of eq. [5]. Similarly, $\lambda(r) = (\rho/\rho_g)^{1/3}$ is the first-order iterative approximation $\lambda^{(1)}(r)$.

The kinetic energy corresponding to λ_{exact} in Table 4 is precisely $T[D_\rho^{\text{ISD}}]$ of eq. [24] calculated using the locally scaled transformed single Slater determinant given by eq. [22]. Note that the final density for the determination of λ_{exact} is $\rho(r)_{\text{Boyd}}$ [52], that is, a representation of the densities associated with Clementi–Roetti's Hartree–Fock wave functions.

Table 4. Kinetic energies (in hartrees) evaluated by means of eq. [24] for selected first-row atoms using different approximations for the local scaling function $\lambda(r)$.

[a,b,c]Raffenetti-type sets defined in text.
[d]Clementi–Roetti results (57).
[e]Raffenetti results for triple-zeta orbitals (50).

For this reason, the kinetic energies for the set RT^b in Table 4 do not coincide with the Raffeneti ETZ values listed in the last column of this table. When we use as our " object" densities the ETZ densities of Raffenetti, however, we obtain exactly the Raffenetti ETZ kinetic energy values. Again for λ_{exact}, we observe in Table 4 that the kinetic energy values obtained using the *arbitrary* set RT^c are as good or better than those obtained from improved local-density approximations (53) or even from non-local ones (47, 54). In this sense, the present method clearly shows that it is possible to develop approximations to the kinetic energy functional that are both economical and accurate.

It follows from Table 4 that the use of $\lambda = 1$ introduces slight modifications in the kinetic energy values. These changes are observed to increase for the first-order iterative correction $\lambda = (\rho/\rho_g)^{1/3}$. It is interesting to observe in Table 4 that there arise significant deviations for the kinetic energy values of RT^a of F and Ne for the zeroth- and first-order approximations to λ. Now, these approximations enter either in the second factor $(1 + \boldsymbol{r} \cdot \nabla_r \ln \lambda_{exact}(\boldsymbol{r}))^{4/3}$ or in the third factor $\tau_N([\{\phi_{g,i}(\boldsymbol{f}(\boldsymbol{r})\}_{i=1}^N]; \boldsymbol{r})$ of the kinetic energy expression given by eq. [24]. To assess the relative importance of the terms appearing in eq. [24], we list in Table 5 the kinetic energy values calculated according to the expression

Fig. 1. Behavior of the modulating function $A(r) = r^2\rho_g^{5/3}(f)\tau_N(f)$ for the sets RT^b and RT^c of the lithium atom.

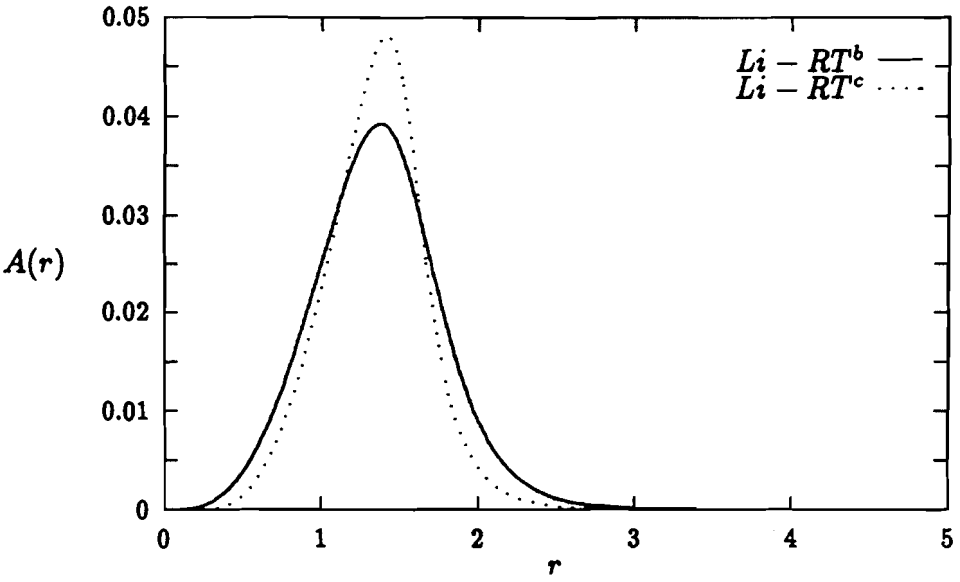

Fig. 2. Behavior of the modulating function $A(r) = r^2\rho_g^{5/3}(f)\tau_N(f)$ for the sets RT^b and RT^c of the neon atom. On the present scale only the first hump is visible.

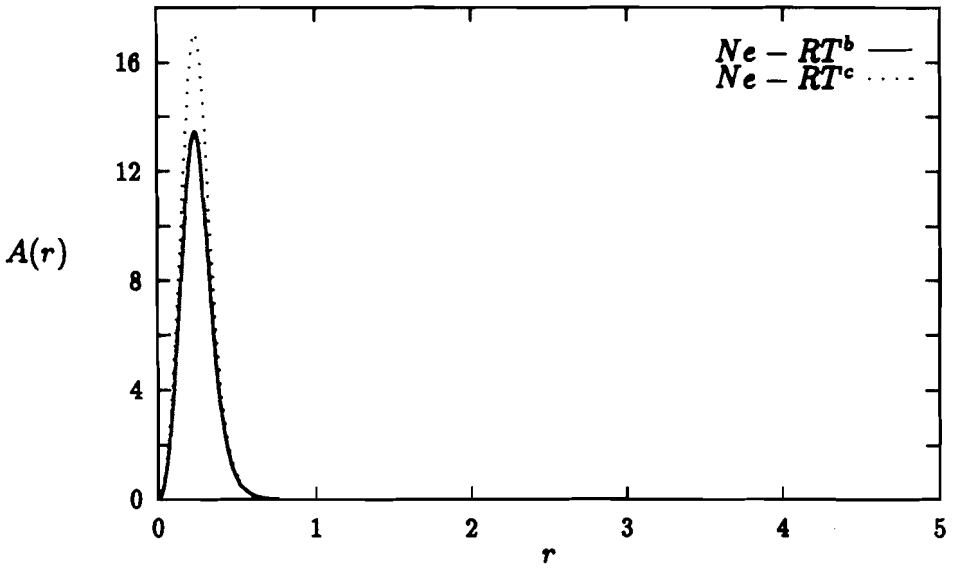
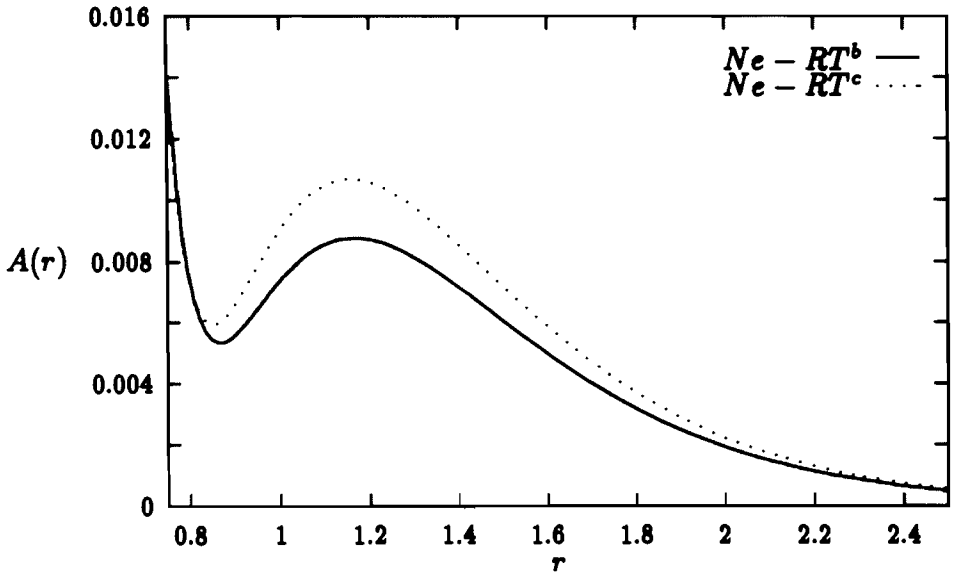


$$[30]\quad T[D_\rho^{\mathrm{LSD}}] = T_W[\rho] + \frac{1}{2}\int d^3\boldsymbol{r}\rho^{5/3}(\boldsymbol{r}) \times (1 + \boldsymbol{r}\cdot\nabla_r \ln\lambda_{\mathrm{exact}}(\boldsymbol{r}))^{4/3}\tau_N([\{\phi_{g,i}(\boldsymbol{f}(\boldsymbol{r})\}_{i=1}^N];\boldsymbol{r})$$

Notice that in the above expression we have introduced λ_{exact} in the second factor such that we are able to make approximations for λ only in the modulating factor τ_N.

In Table 5 we observe that, for example, in the case of the Ne atom, there is a considerable improvement in the kinetic energy values for the set RT^a with respect to equivalent values listed in Table 4. It is clear in this case that the effect of approximating λ is not crucial for the modulating factor τ_N as it is for the second factor of eq. [30]. In fact, we observe that there is an improvement as $T = 132.569040$ (in Table 4) goes into $T = 128.541870$ (in Table 5). That this is not always the case becomes evident when we consider the case of F for the set RT^a for $\lambda = (\rho/\rho_g)^{1/3}$. The kinetic energy becomes worse in Table 5: $T = 109.411291$ as compared to $T = 103.559724$ in Table 4. A possible explanation of this situation may be advanced in terms of a cancellation of errors between the second and third terms in eq. [30].

Fig. 3. Behavior of the modulating function $A(r) = r^2\rho_g^{5/3}(f)\tau_N(f)$ for the sets RT^b and RT^c of the neon atom. The scale is magnified at the tail to enhance the presence of a second hump.



The preliminary results presented in this work demonstrate the subtleties of the kinetic energy functional. It is clear that the modulating factor has to do with the creation of a pointed peak in the intershell region. This can be clearly observed in Fig. 1 where we have plotted $A(r) = r^2\rho_g^{5/3}(f)\tau_N([\{\phi_{g,i}(f(r)\}_{i=1}^N];r)$ vs. r for the sets RT^b and RT^c for the lithium atom. One sees that the form of this function is that of a bell-shaped curve with a maximum located approximately in the intershell region. In Fig. 2 we show the behavior of this function for the Ne atom, again for the RT^b and RT^c sets. Although barely visible in Fig. 2, there is a second hump further out in this atom (as well as in the boron and fluorine atoms studied here, i.e., atoms that possess an L shell). This slight protuberance is illustrated in Fig. 3, for the sets RT^b and RT^c of Ne.

It seems that the presence of the bell-shaped modulating function in the intershell region is a necessary ingredient for the existence of shell structure in atoms. Let us mention that, in contexts different from the present, similar humps had already been observed in the analysis of the kinetic energy density (55, 56). A detailed investigation of the modulating functions and their relationship with shell structure is currently underway. One of the promising possibilities is that of constructing approximate energy density functionals by modelling the modulating factor by some simple function of $\lambda(r)$ (i.e., as a function of the one-particle density).

The results presented here, although preliminary, clearly indicate that it is quite feasible to obtain accurate models for the kinetic energy functional within the context of local-scaling transformations of the density. The elucidation of the subtleties underlying the construction of the kinetic energy functional is, however, an important prerequisite toward this end.

Dedication

It is a pleasure to dedicate this article to Richard Bader on the occasion of his 65th birthday. His undying enthusiasm, his penetrating intelligence, and his love for life are attributes that have shaped him into a very special human being and a highly original scientist.

Zero-temperature equation-of-motion of electron pair in the BCS theory of superconductivity

Akitomo Tachibana

Abstract: By projecting the BCS ground state of superconducting electron condensate on the N-electron Hilbert space, a real-space equation-of-motion is obtained for the electron pair function $\phi(1, 2)$ at absolute zero temperature ($T = 0$):

$$i\hbar \frac{\mathrm{d}\phi(1,2)}{\mathrm{d}t} = h_\phi(1,2)\phi(1,2)$$

$$h_\phi(1,2) = \frac{1}{2m}\boldsymbol{p}(1)^2 + \frac{1}{2m}\boldsymbol{p}(2)^2 + v_\phi(1,2)$$

$$v_\phi(1,2) = v(1) + v(2) + \frac{e^2}{r_{12}} + \int\left(\frac{e^2}{r_{13}} + \frac{e^2}{r_{23}}\right)\rho^{N-2}(3)\mathrm{d}\tau_3$$

where ρ^{N-2} denotes electron density of the $(N-2)$-electron condensate given as

$$\rho^{N-2}(1) = (N-2)\int|\phi(1,2)|^2\mathrm{d}\tau_2$$

Since the exchange-correlation potential is given as an explicit functional of electron density, this equation represents the fundamental working equation for the new density functional theory of superconductivity. The 2nd-order density matrix $\Gamma^N(1,2|1',2')$ projected on the N-electron Hilbert space satisfies

$$\Gamma^N(1,2|1',2') = \frac{N(N-1)}{2}c^N(1,2)c^{N*}(1',2')$$

$$c^N(1,2) = \frac{1}{\sqrt{2!}}A\phi(1,2)\alpha(1)\beta(2) = \phi(1,2)\frac{1}{\sqrt{2!}}(\alpha(1)\beta(2) - \beta(1)\alpha(2))$$

so that asymptotically

$$\lim_{|R^{\mathrm{CM}}_{1,2} - R^{\mathrm{CM}}_{1',2'}|\to\infty}\Gamma^N(1,2|1',2') = \text{finite}$$

where $R^{\mathrm{CM}}_{1,2}$ denotes the center-of-mass coordinate of electrons e_1 and e_2; this is considered the ODLRO (off-diagonal long-range order) at $T = 0$ projected on the N-electron Hilbert space. A new attractive potential analysis for the two-electron scattering problem (A. Tachibana, Bull. Chem. Soc. Jpn. **66**, 3319 (1993); Int. J. Quantum Chem. **49**, 625 (1994)) is straightforwardly applicable to the present equation-of-motion, and we can also plug in the vibronic interaction for the enhancement of the attractive force. Our approach is purely mathematical and basic, restricted merely at $T = 0$, but proves to serve as a real-space analysis of the pair function itself.

Key words: equation-of-motion of electron pair, BCS theory, superconductivity, electron pair function, density functional theory.

Résumé : En projetant l'état fondamental BCS du condensat superconducteur sur l'espace de Hilbert à N-electron, on obtient un équation du mouvement en espace réel pour la fonction de la paire d'électrons, $\phi(1, 2)$, à la température du zéro absolu ($T = 0$) :

Received October 10, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

$$i\hbar \frac{d\phi(1,2)}{dt} = h_\phi(1,2)\phi(1,2)$$

$$h_\phi(1,2) = \frac{1}{2m}\boldsymbol{p}(1)^2 + \frac{1}{2m}\boldsymbol{p}(2)^2 + v_\phi(1,2)$$

$$v_\phi(1,2) = v(1) + v(2) + \frac{e^2}{r_{12}} + \int\left(\frac{e^2}{r_{13}} + \frac{e^2}{r_{23}}\right)\rho^{N-2}(3)d\tau_3$$

dans laquelle ρ^{N-2} correspond à la densité électronique du condensat électronique $(N-2)$ obtenu sous la forme de

$$\rho^{N-2}(1) = (N-2)\int|\phi(1,2)|^2 d\tau_2$$

Puisque le potentiel de la corrélation d'échange est donnée sous la forme d'une fonctionnelle explicite de la densité électronique, cette équation est au moins aussi bonne que l'équation de travail fondamentale de la nouvelle théorie fonctionnelle de la densité de la superconductivité. La matrice de densité du deuxième ordre, $\Gamma^N(1,2|1',2')$ projetée sur l'espace de Hilbert à N-électron satisfait les équations

$$\Gamma^N(1,2|1',2') = \frac{N(N-1)}{2}c^N(1,2)c^{N*}(1',2')$$

$$c^N(1,2) = \frac{1}{\sqrt{2!}}A\phi(1,2)\alpha(1)\beta(2) = \phi(1,2)\frac{1}{\sqrt{2!}}(\alpha(1)\beta(2) - \beta(1)\alpha(2))$$

ce qui signifie que, d'une façon asymptotique,

$$\lim_{|R^{CM}_{1,2} - R^{CM}_{1',2'}|\to\infty}\Gamma^N(1,2|1',2') = \text{finite}$$

dans laquelle $R^{CM}_{1,2}$ correspond à la coordonnée du centre de masse des électrons e_1 et e_2 ; ceci est considéré comme l'« ODLRO » (off-diagonal long range-ordre), à $T = 0$ projeté sur l'espace Hilbert à N-électron. Une nouvelle analyse du potentiel attractif pour le problème de la diffusion de deux électrons (A. Tachibana, Bull. Chem. Soc. Jpn. **66**, 3319 (1993); Int. J. Quantum Chem. **49**, 625 (1994)) peut s'appliquer directement à la présente équation de mouvement et on peut y introduire l'interaction vibronique pour l'augmentation de la force attractive. Notre approche est purement mathématique et fondamentale, elle n'est restreinte qu'à $T = 0$, mais il s'avère qu'elle peut même servir dans une analyse de temps réel de la fonction de paire.

Mots clés : équation de mouvement d'une paire d'électron, théorie BCS, superconductivité, fonction d'une paire d'électron, théorie fonctionnelle de la densité.

[Traduit par la rédaction]

I. Introduction

There are two fundamental prerequisites for electrons to reach the superconducting state (1, 2). First, there must be an attractive force between a pair of electrons to form a Boson pair state. According to the conventional picture in the physics of condensed matter, the medium is somehow polarized through interaction with the electron, and the polarization is slow to relax compared with the time scale of the motion of the electron. This retardation works to bind a pair of electrons effectively despite the Coulomb repulsion between them.

Second, there must be a certain value of hopping integral for electrons to delocalize and form a band of finite width. The Boson pairs can then go through a process of condensation, collectively forming a lower energy state like the process of Bose condensation.

In the BCS theory of superconductivity (3), these two actions take place simultaneously, where the BCS ground state demonstrates the strong overlap between the electron pair wave functions $\phi(1, 2)$'s (1).

The aim of this paper is to give a rigorous equation-of-motion for the electron pair function $\phi(1, 2)$ at absolute zero temperature ($T = 0$). This equation is found to be dependent on an explicit function of electron density, so that the application of density functional theory (4) should be of direct interest. As a concrete example, using the jellium model of the background medium and the associated homogeneous electron density, the $\phi(1, 2)$ is found to be given as the Rutherford scattering wave function. Polarization of the medium surely affects the pairing potential; it may strengthen or weaken the electron pairing according to the situation considered (5–8). In particular, the vibronic interaction will be demonstrated to strengthen the electron pairing. The BCS ground state is characterized by the ODLRO (off-diagonal long-range order) (9), so that a mean field theory is of great help in describing the phase transition process itself (1, 3, 10, 11). Our approach is purely mathematical and basic, restricted merely at $T = 0$, but is proven to serve as a real-space analysis of the pair function itself for application to various kinds of present

or future superconductors that are important in the field of materials science (12).

II. Electron pair function

A. Singlet s-wave pairing state of electron gas

The wave function of the pairing state of N (even number assumed) electrons is given as (1, 2):

$$[1] \quad |N\rangle = \frac{1}{\sqrt{N!}} A\phi(1,2)\alpha(1)\beta(2)\phi(3,4)\alpha(3)\beta(4)\cdots \phi(N-1,N)\alpha(N-1)\beta(N)$$

where A denotes the antisymmetrizer and $\phi(i,j)$ denotes the orbital part of the singlet wave function of the electron pair. The $\phi(i,j)$ is symmetric with respect to the interchange of electrons:

$$[2] \quad \phi(j,i) = \phi(i,j)$$

which property is a prerequisite for low-energy stable pair formation as analyzed by Fano (13); this situation has also been analyzed by Wannier (14) in a purely two-electron escape problem from the atomic core (15). This wave function is of course invariant under lattice translation:

$$[3] \quad T\phi(i,j) = \phi(i,j)$$

where T denotes the lattice translation operator (16) for the lattice. In the jellium model, the wave function $\phi(i,j)$ of the electron pair is represented as the superposition of products of one-electron orbitals with which equal and opposite wave vectors are paired; this is in general referred to as time-reversal pairing (1, 2, 17, 18):

$$[4] \quad \phi(i-j) = \sum_k g_k e^{ikr_i} e^{-ikr_j} = \sum_k g_k e^{ik(r_i - r_j)}$$

It should be noted that the s-wave pairing state in the jellium model satisfies

$$[5] \quad \boldsymbol{p}_{ij}\phi(i-j) = 0$$

with $\boldsymbol{p}_{ij}$ being the relative momentum of the ith electron with respect to the jth electron:

$$[6] \quad \boldsymbol{p}_{ij} = \boldsymbol{p}_i - \boldsymbol{p}_j$$

According to the presence of crystal structure of its unique translational symmetry, the Bloch theorem is applied to the pairing wave function. The Bragg reflection may be a possible obstruction to the occurrence of stable electron pairing (1).

B. Electron field operators

The equation-of-motion of the electron field operator is now given for the space spanned by the pairing states of electrons.

Let the electron Hamiltonian be H_e and the time-evolution of the N-electron state $|N(t)\rangle$ be given as

$$[7] \quad i\hbar \frac{d|N(t)\rangle}{dt} = H_e|N(t)\rangle$$

$$[8] \quad H_e = \int a^+(1)h_e(1)a(1)d\tau_1 + \frac{1}{2}\int\int a^+(1)a^+(2)\frac{e^2}{r_{12}}a(2)a(1)d\tau_1 d\tau_2$$

where $a(1)$, $a^+(1)$ denote the electron field operators and $d\tau$ the volume element, and where $h_e(1)$ denotes the one-electron Hamiltonian including the kinetic energy and the nuclear attraction potential $v(1)$:

$$[9] \quad h_e(1) = \frac{1}{2m}\boldsymbol{p}(1)^2 + v(1)$$

C. Equation of motion

The equation-of-motion of the electron field operators $a(1)$, $a^+(1)$ is given as

$$[10] \quad i\hbar \frac{da(1)}{dt} = [a(1), H_e] = h_{ee}(1)a(1)$$

$$[11] \quad i\hbar \frac{da^+(1)}{dt} = [a^+(1), H_e] = -a^+(1)h_{ee}(1)$$

where

$$[12] \quad h_{ee}(1) = h_e(1) + \int \frac{e^2}{r_{13}}\rho(3)d\tau_3$$

with

$$[13] \quad \rho(3) = a^+(3)a(3)$$

Therefore we obtain

$$[14] \quad i\hbar \frac{da(1)a(2)}{dt} = [a(1)a(2), H_e] = \left[h_e(1) + h_e(2) + \frac{e^2}{r_{12}} + \int\left(\frac{e^2}{r_{13}} + \frac{e^2}{r_{23}}\right)\rho(3)d\tau_3\right]a(1)a(2)$$

and its complex conjugate.

Now, the pair function in the 2nd-order density matrix is given as the transition amplitude of $a(1)a(2)$ between the N-electron state vector $|N\rangle$ and some ith $(N-2)$-electron state vector $\langle i^{N-2}|$,

$$[15] \quad c_i^N(1,2) = \langle i^{N-2}|a(1)a(2)|N\rangle$$

The 2nd-order density matrix can then be written as

$$[16] \quad \Gamma^N(1,2|1',2') = \langle N|a^+(2')a^+(1')a(1)a(2)|N\rangle = \sum_i c_i^N(1,2)c_i^{N*}(1',2')$$

Here, it should be noted that we are treating the complete pairing states at $T = 0$, so that the specification i of the state is uniquely determined to be the state with one pair lost:

$$[17] \quad c_i^N(1,2) \propto c^N(1,2) \ : \text{ independent of } i$$

with

[18] $\langle c^N(1,2)|c^N(1,2)\rangle = 1$

and the 2nd-order density matrix can then be written as

[19] $\Gamma^N(1,2|1',2') = \frac{N(N-1)}{2}\, c^N(1,2)c^{N*}(1',2')$

where $N(N-1)/2$ is the degeneracy of the pair function. This is the characteristic situation distinct from the case of the normal state of many-electron systems (19, 20). The pair function is now identified with the singlet wave function of the electron pair given in eq. [2]:

[20] $c^N(1,2) = \frac{1}{\sqrt{2!}} A\phi(1,2)\alpha(1)\beta(2)$

$$= \phi(1,2)\frac{1}{\sqrt{2!}}(\alpha(1)\beta(2) - \beta(1)\alpha(2))$$

Thus the equation-of-motion of the pair function is obtained as

[21] $i\hbar \frac{d\phi(1,2)}{dt} = h_\phi(1,2)\phi(1,2)$

where

[22] $h_\phi(1,2) = \frac{1}{2m}\boldsymbol{p}(1)^2 + \frac{1}{2m}\boldsymbol{p}(2)^2 + v_\phi(1,2)$

[23] $v_\phi(1,2) = v(1)+v(2)+\frac{e^2}{r_{12}}+\int\left(\frac{e^2}{r_{13}}+\frac{e^2}{r_{23}}\right)\rho^{N-2}(3)d\tau_3$

[24] $\rho^{N-2}(3) = \langle N-2|\rho(3)|N-2\rangle$

In the general case of the ODLRO (off-diagonal long-range order) (9), the $\Gamma(1,2|1',2')$ satisfies asymptotically

[25] $\Gamma(1,2|1',2') \approx \alpha_0 c(1,2)c^*(1',2'); \qquad \alpha_0 \gg 1$

so that

[26] $\lim_{|R^{CM}_{1,2} - R^{CM}_{1',2'}|\to\infty} \Gamma(1,2|1',2') = \text{finite}$

where $R^{CM}_{1,2}$ denotes the center-of-mass coordinate of electrons e_1 and e_2. Therefore, eq. [19] is considered the ODLRO at $T = 0$ for the Hilbert space of fixed electron number N.

III. Electron pair potential

The stability of the electron pair is now examined for the potential $v_\phi(1, 2)$ given by eq. [23]. Imagine for the sake of simplicity the jellium model of the background medium for the electron pair and the associated homogeneous electron density for ρ^{N-2}. Then the interelectron interaction is solely governed by the following term $v_{int}(1, 2)$ in $v_\phi(1, 2)$:

[27] $v_\phi(1,2) = v_{int}(1) + v(1) + v(2)$

$$+ \int\left(\frac{e^2}{r_{13}}+\frac{e^2}{r_{23}}\right)\rho^{N-2}(3)d\tau_3$$

with

[28] $v_{int}(1,2) = \frac{e^2}{r_{12}}$

This is because the residual terms in eq. [27], aside from eq. [28], are merely constant under the condition "the jellium model of the background medium for the electron pair and the associated homogeneous electron density for ρ^{N-2}."

Let θ be the angle between the position vectors $\boldsymbol{r}_1$, $\boldsymbol{r}_2$ of the electrons e_1, e_2:

[29] $r_{12} = \sqrt{r_1^2 + r_2^2 - 2r_1 r_2 \cos\theta}$

The "distance" of the electron pair as a whole from the scattering center may be measured by the hyperspherical radius r:

[30] $r = \sqrt{r_1^2 + r_2^2}$

Then using the variable transformation of Wannier (14) as

[31] $r_1 = r\cos\left(\frac{\chi}{2}\right)$

[32] $r_2 = r\sin\left(\frac{\chi}{2}\right)$

with

[33] $0 < \chi < \pi$

eq. [28] reduces to

[34] $v_{int}(1,2) = \frac{e^2}{r\sqrt{1-\sin(\chi)\cos(\theta)}}$

It is easily found that the configuration P defined as

[35] $P : \{\chi = \pi/2, \theta = \pi\}$

corresponds to the minimum of $v_{int}(1, 2)$:

[36] $\left.\frac{\partial v_{int}}{\partial\theta}\right|_P = \left.\frac{\partial v_{int}}{\partial\chi}\right|_P = 0$

[37] $\left.\frac{\partial^2 v_{int}}{\partial\theta^2}\right|_P = \left.\frac{\partial^2 v_{int}}{\partial\chi^2}\right|_P = \frac{1}{4r^2}\frac{e^2}{\sqrt{2}}\, r > 0$

This configuration P exactly dictates the time-reversal configuration for the electron pair with respect to the scattering center: the radial vectors point to mutually opposite directions with the same distance, $r_1 = r_2$, from the scattering center. It should be noted that if the scattering center is identified with the center-of-mass of the electron pair, then the configuration P is mandatory because of s-wave condition eq. [5]. Therefore, we should consider eq. [37] as the stability of the configuration P against small perturbations. If the perturbation to the interelectron potential is of short-range character, then this stability mechanism remains valid because the long-range Coulomb interaction overwhelms in

the asymptotic scattering region. For example, if an electron density fluctuation occurs, the electron pair is stable if such a condition is satisfied. Indeed, for the case of the isolated electron pair problem, the stability of the configuration P has been clearly demonstrated (6–8).

It should be noted that although the resultant equation-of-motion, eq. [21], is that for the usual Rutherford scattering under the condition "the jellium model of the background medium for the electron pair and the associated homogeneous electron density for ρ^{N-2}," which we have adopted here, and therefore the analytical solution is given in any standard textbook, the scattering center is not fixed in space. Instead, by definition of the situation considered, the scattering center is homogeneously distributed in space, so that this verifies the underlying condition "the homogeneous electron density" in its rigorously self-consistent manner.

IV. Vibronic attraction

If the stability of the electron pair as demonstrated in Sect. III is not strong enough, then some subsidiary mechanism should be invoked to ensure time-reversal electron pairing. This is the electron–phonon coupling (1, 3) or instantaneous vibronic coupling (5). In the context of the density functional theory, Kohn, Gross, et al. have explicitly treated this subsidiary force as W in their working equation (21). As a concrete and interesting example of W, we shall in this section explicitly demonstrate the instantaneous vibronic interaction for the subsidiary attractive force in our basic equation, eq. [13]. The vibronic interaction is treated as the internal potential, not the external potential, so that the Mermin entropy principle works and hence our density functional theory remains valid in due course.

According to the theory of the vibronic Hamiltonian (5), let eqs. [7] and [8] be modified as

$$[38]\quad i\hbar\,\frac{\mathrm{d}|N(t)\rangle}{\mathrm{d}t} = H_\kappa|N(t)\rangle$$

$$[39]\quad H_\kappa = H_e + \Delta H_\kappa$$

where ΔH_κ is the vibronic term that is represented by W in ref. 21:

$$[40]\quad \Delta H_\kappa = \frac{1}{2}\sum_{m,n=1}^{f}\sum_{i,j} a^{mn}\hat{a}_i^+\hat{a}_j\left\langle\frac{\partial\psi_i}{\partial q^m}\,|\,\frac{\partial\psi_j}{\partial q^n}\right\rangle - \frac{1}{2}\sum_{m,n=1}^{f}\sum_{i,j,k,l} a^{mn}\hat{a}_i^+\hat{a}_k^+\hat{a}_l\hat{a}_j\left\langle\psi_i|\,\frac{\partial\psi_j}{\partial q^m}\right\rangle\left\langle\psi_k|\,\frac{\partial\psi_l}{\partial q^n}\right\rangle$$

where $\{\psi_i(1)\}_{i=k\sigma}$ denotes an orthonormal complete set of spin functions with $\boldsymbol{k}$ for the momentum and σ for the spin,

$$[41]\quad \langle\psi_i|\psi_{i'}\rangle = \delta_{ii'} = \delta_{kk'}\delta_{\sigma\sigma'}, \qquad i = \boldsymbol{k}\sigma$$

that are used to expand the field operators as follows:

$$[42]\quad a_\sigma(1) = \sum_k \hat{a}_{k\sigma}\psi_{k\sigma}(1)$$

$$a_\sigma^+(1) = \sum_k \hat{a}_{k\sigma}^+\psi_{k\sigma}^*(1)$$

The q^m ($m = 1,2,\ldots, f$) denote the internal coordinates that describe the vibrational motion of nuclei, the degrees of freedom being f, while a^{mn} denotes the kinetic tensor (5). It should be noted that the vibronic Hamiltonian is given in a closed form, namely, we are free from the perturbation series treatment using a small amplitude approximation for nuclear displacements. For the sake of easier application to eq. [13], eq. [39] is rewritten as follows:

$$[43]\quad H_\kappa = \int a^+(1)h_\kappa(1,1')a(1')\mathrm{d}\tau_1\mathrm{d}\tau_{1'} + \frac{1}{2}\int a^+(1)a^+(2)v_\kappa(1,2;1',2')a(2')a(1')\mathrm{d}\tau_1\mathrm{d}\tau_{1'}\mathrm{d}\tau_2\mathrm{d}\tau_{2'}$$

$$[44]\quad h_\kappa(1,1') = h_e(1)\delta(1-1') + \frac{1}{2}\sum_{m,n=1}^{f}\sum_i a^{mn}\frac{\partial\psi_i(1)}{\partial q^m}\frac{\partial\psi_i^*(1')}{\partial q^n} = h_\kappa^*(1',1)$$

$$[45]\quad v_\kappa(1,2;1',2') = \frac{e^2}{r_{12}}\delta(1-1')\delta(2-2') + \frac{1}{2}\sum_{m,n=1}^{f} a^{mn}\kappa_m(1,1')\kappa_n(2,2') = v_\kappa(2,1;2',1') = v_\kappa^*(1'2';1,2)$$

where κ_m is given as

$$[46]\quad \kappa_m(1,2) = \frac{1}{2}\sum_i\{[\pi_m\psi_i(1)]\psi_i^*(2) + \psi_i(1)[\pi_m\psi_i(2)]^*\} = \kappa_m^*(2,1)$$

where π_m denotes the quantum mechanical momentum operator with respect to q^m (5).

It should be noted that the asymptotic behavior of the subsidiary term to the interelectron potential is in general indefinite,

$$[47]\quad \lim_{r_{12},r_{1'2'}\to\infty} v_\kappa(1,2;1',2') = \frac{e^2}{r_{12}} + (\text{indefinite sign}) \text{ terms}$$

However, just for the time-reversal electron scattering, it will be negative definite, as shown in the following eq. [52].

First, the vibronic one-electron equation-of-motion is modified from eq. [10] to

$$[48]\quad i\hbar\,\frac{\mathrm{d}a(1)}{\mathrm{d}t} = [a(1),H_\kappa] = \int h_{\kappa\kappa}(1,3')a(3')\mathrm{d}\tau_{3'}$$

$$[49]\quad h_{\kappa\kappa}(1,3') = h_\kappa(1,3') + \int a^+(4)v_\kappa(1,4;3',4')a(4')\mathrm{d}\tau_4\mathrm{d}\tau_{4'}$$

Second, the vibronic two-electron equation-of-motion is modified from eq. [13] to

$$[50]\quad i\hbar\,\frac{\mathrm{d}a(1)a(2)}{\mathrm{d}t} = [a(1)a(2), H_\kappa]$$
$$= \int h_\kappa(1,3')a(3')a(2)\mathrm{d}\tau_3 + \int h_\kappa(2,3')a(1)a(3')\mathrm{d}\tau_{3'}$$
$$+ \int v_\kappa(2,1;3',4')a(4')a(3')\mathrm{d}\tau_{3'}\mathrm{d}\tau_{4'}$$
$$+ \int v_\kappa(1,4;3',4')a^+(4)a(2)a(4')a(3')\mathrm{d}\tau_{3'}\mathrm{d}\tau_4\mathrm{d}\tau_{4'}$$
$$+ \int v_\kappa(4,2;3',4')a^+(4)a(1)a(4')a(3')\mathrm{d}\tau_{3'}\mathrm{d}\tau_4\mathrm{d}\tau_{4'}$$

Using eq. [45], eq. [50] is rewritten as

$$[51]\quad i\hbar\,\frac{\mathrm{d}a(1)a(2)}{\mathrm{d}t} = \left[h(1)+h(2)+\frac{e^2}{r_{12}}+\int\left(\frac{e^2}{r_{13}}+\frac{e^2}{r_{23}}\right)\rho(3)\mathrm{d}\tau_3\right]a(1)a(2)$$
$$+\frac{1}{2}\sum_{n,m=1}^{f} a^{mn}\left(\begin{array}{l}\displaystyle\sum_i\left(\int\frac{\partial\psi_i(1)}{\partial q^m}\frac{\partial\psi_i^*(3')}{\partial q^n}a(3')a(2)\mathrm{d}\tau_{3'}+\int\frac{\partial\psi_i(2)}{dq^m}\frac{\partial\psi_i^*(3')}{\partial q^n}a(1)a(3')\mathrm{d}\tau_{3'}\right)\\ \quad+\displaystyle\int\kappa_m(2,3')\kappa_n(1,4')a(4')a(3')\mathrm{d}\tau_{3'}\mathrm{d}\tau_{4'}\\ \quad+\displaystyle\int\kappa_m(1,3')\kappa_n(4,4')a^+(4)a(2)a(4')a(3')\mathrm{d}\tau_{3'}\mathrm{d}\tau_4\mathrm{d}\tau_{4'}\\ \quad+\displaystyle\int\kappa_m(4,3')\kappa_n(2,4')a^+(4)a(1)a(4')a(3')\mathrm{d}\tau_{3'}\mathrm{d}\tau_4\mathrm{d}\tau_{4'}\end{array}\right)$$

The attractive force for the time-reversal pair of electrons is observed among the last terms in eq. [51]:

$$[52]\quad \frac{1}{2}\sum_{m,n=1}^{f} a^{mn}\int\kappa_m(2,3')\kappa_n(1,4')\psi_{-k\beta}(4')\psi_{k\alpha}(3')\mathrm{d}\tau_{3'}\mathrm{d}\tau_{4'}$$
$$= -\frac{1}{2}\sum_{m,n=1}^{f} a^{mn}\frac{\partial\psi_{k\alpha}(2)}{\partial q^m}\frac{\partial\psi_{-k\beta}(1)}{\partial q^n}$$

where we have explicitly highlighted the $\{k\alpha, -k\beta\}$ pair. The same conclusion is reached in a different context in ref. 5.

V. Density functional theory

In Sect. III, using a concrete example, we have shown the simple self-consistent picture of the stability of the pairing state. According to eqs. [36] and [37], the BCS ensemble of pairing states is at least "metastable" in constructing the local minimum, if not the global minimum, in the subset of the grand canonical ensemble of electrons. Any tiny but finite relaxation of electron cloud is not mandated at all for a probe electron. This governs even the s-wave pairing; extension to higher angular momentum wave pairing is straightforward using standard partial wave analysis of the Rutherford scattering wave function and the associated spin function. If we need a more powerful attractive force in order to arrive at the global minimum, see for example Sect. IV.

The equation-of-motion of the pair function is obtained in eq. [21]. The potential $v_\phi(1, 2)$ for this equation is given as an explicit functional of electron density, eq. [23], so that eq. [21] becomes the fundamental working equation for the density functional theory of superconductivity (10, 11, 21). The superconducting phase transition process is characterized as the change of description of electron from the independent particle orbital to the pair function as shown in eq. [4]. The self-consistent picture of this change of description should be related to a certain mathematical structure of the Bogoliubov–Valatin transformation (1, 21). A precise description of the change in electron density will also be obtained.

Indeed, in our density functional theory of superconductivity (10, 11), the crucial mathematical strategy was to find the zeros of the order parameter G_k (defined for the quasi particles in eq. [65] below) or, equivalently, the zeros of the weight function w_k (defined in eq. [66] below) in the complex Gaussian plane of the x_k (defined in eq. [57] below), while keeping the order parameter F_k (defined for the electrons in eq. [56] below) nonzero. This is distinct from the BCS ensemble where the zeros of the w_k distribute uniformly on the real positive axis of the x_k, because the G_k is identically zero for the BCS ensemble, which is the very definition of the BCS ensemble according to the mathematical theory of Valatin (22). On the other hand, in the normal grand canonical ensemble that we use, the zeros of the w_k never exactly touch the real positive axis of the x_k. This clarifies our mathematical point of view when the superconducting phase transition is declared to occur if the zeros of the w_k infinitely approach the real positive axis of the x_k (10, 11).

We use the normal grand canonical ensemble, not the BCS ensemble. Thus we can appeal to the Mermin entropy principle and arrive at our own density functional theory where we use analytic continuation of the electron density in the complex Gaussian plane (10, 11). Then, the onset of electron pairing is detected by monitoring the change in the description of the electron density as in the standard Landau approach to phase transition. Therefore, it may be visualized that the manner in which our density functional theory of superconducting phase transition is related to the BCS theory resembles the relation of Lee–Yang theory to the Mayer theory of condensation. Namely, one theory treats the phase transition as the mathematical limit of some thermodynamic function that is under analytic continuation in the complex Gaussian plane, while the other treats it as a completely distinct ensemble in which phase transition has already occurred. Indeed, our density functional theory of superconductivity treats the electron density as under analytic continuation in the complex Gaussian plane. We shall elaborate this as follows, whereby we further relax to allow the complex number for w_k that was restricted to be real in our original paper (10, 11). This permits the logical framework of our density functional theory of superconductivity to be sufficiently complete to be applicable to a more general situation that may occur in the future development of the theory. For example, eq. [72] below is the rigorous expression of the r_k defined in eq. [62] below for the mixing ratio of quasi particles to electrons.

The electron density $\rho(1)$ is the diagonal part of the first-order density matrix, and hence given as

$$[53]\quad \rho(1) = \sum_{\sigma}^{\alpha\beta} \sum_{k} f_{k\sigma} |\psi_{k\sigma}(1)|^2 + \sum_{\sigma}^{\alpha\beta} \sum_{k \neq k'} f_{k'\sigma k\sigma} \psi^*_{k'\sigma}(1) \psi_{k\sigma}(1)$$

$$f_{k\sigma} = f_{k\sigma k\sigma}, \qquad f_{k'\sigma' k\sigma} = \langle \hat{a}^+_{k'\sigma'} \hat{a}_{k\sigma} \rangle$$

in which we have used eqs. [41] and [42].

Using the grand canonical ensemble, the field operators are defined in Fock space where the number of electrons is not fixed, in sharp contrast to Hilbert space where the number of electrons is fixed, say N. In Fock space, therefore, the total electron number is given as the ensemble average,

$$[54]\quad \langle N \rangle = \int \rho(1) d\tau_1 = \sum_{\sigma}^{\alpha,\beta} \sum_{k} f_{k\sigma}$$

Therefore, $f_{k\sigma}$ plays the role of occupation number for $\psi_{k\sigma}$ (1). Moreover, the following probability amplitude of the variable electron number should appear in general:

$$[55]\quad F_{i'i} = \langle \hat{a}_{k'\sigma'} \hat{a}_{k\sigma} \rangle, \qquad F^*_{i'i} = \langle \hat{a}^+_{k\sigma} \hat{a}^+_{k'\sigma'} \rangle$$

which should disappear in a Hilbert space:

$$[56]\quad F_{i'i} = F^*_{i'i} = 0, \qquad \text{in a Hilbert space}$$

It should be noted that in the BCS theory of superconductivity, the following Bogoliubov–Valatin transformation is performed for the description of a collective particle in Fock space:

$$[57]\quad \hat{a}_\kappa = \frac{\hat{c}_\kappa + g^*_k \hat{c}^+_{-\kappa}}{\sqrt{1+x_k}}, \qquad \hat{a}^+_\kappa = \frac{\hat{c}^+_\kappa + g_k \hat{c}_{-\kappa}}{\sqrt{1+x_k}}$$
$$\hat{a}_{-\kappa} = \frac{\hat{c}_{-\kappa} - g^*_k \hat{c}^+_\kappa}{\sqrt{1+x_k}}, \quad \hat{a}^+_{-\kappa} = \frac{\hat{c}^+_{-\kappa} - g_k \hat{c}_\kappa}{\sqrt{1+x_k}}, \quad x_k = |g_k|^2$$

where we used the convention of time-reversal symmetry (22)

$$[58]\quad \kappa = k\alpha \text{ and } -\kappa = -k\beta, \qquad \text{or } \kappa = -k\alpha \text{ and } -\kappa = k\beta$$

Conversely, we get

$$[59]\quad \hat{c}_\kappa = \frac{\hat{a}_\kappa - g^*_k \hat{a}^+_{-\kappa}}{\sqrt{1+x_k}}, \qquad \hat{c}^+_\kappa = \frac{\hat{a}^+_\kappa - g_k \hat{a}_{-\kappa}}{\sqrt{1+x_k}}$$
$$\hat{c}_{-\kappa} = \frac{\hat{a}_{-\kappa} + g^*_k \hat{a}^+_\kappa}{\sqrt{1+x_k}}, \qquad \hat{c}^+_{-\kappa} = \frac{\hat{a}^+_{-\kappa} + g_k \hat{a}_\kappa}{\sqrt{1+x_k}}$$

The new collective particles are also fermions that satisfy the same anticommutation relationship as the original electrons. The occupation numbers of the collective particles are similarly given as

$$[60]\quad d_{k\sigma} = d_{k'\sigma' k\sigma} = \langle \hat{c}^+_{k'\sigma'} \hat{c}_{k\sigma} \rangle$$

The occupation numbers are found to satisfy the difference rule:

$$[61]\quad f_\kappa - f_{-\kappa} = d_\kappa - d_{-\kappa}$$

Now, let us introduce and estimate the ratio of mixing in the level of occupation number as follows:

$$[62]\quad f_\kappa = \frac{d_\kappa + r_k(1 - d_{-\kappa})}{1 + r_k}, \qquad f_{-\kappa} = \frac{d_{-\kappa} + r_k(1 - d_\kappa)}{1 + r_k}$$

where r_k is the ratio of mixing so defined. These satisfy the sum rule:

$$[63]\quad f_\kappa + f_{-\kappa} - 1 = \frac{1 - r_k}{1 + r_k} (d_\kappa + d_{-\kappa} - 1)$$

The converse relationship is found if $r_k \neq 1$; then

$$[64]\quad d_\kappa = \frac{f_\kappa - r_k(1 - f_{-\kappa})}{1 - r_k}, \qquad d_{-\kappa} = \frac{f_{-\kappa} - r_k(1 - f_\kappa)}{1 - r_k}$$

where if $r_k = 1$ the right-hand-side of each equation is indefinite. In order to get the form of r_k, the following probability amplitudes should appear in general:

$$[65]\quad F_k = \langle \hat{a}_{-\kappa} \hat{a}_\kappa \rangle$$
$$G_k = \langle \hat{c}_{-\kappa} \hat{c}_\kappa \rangle$$

which are related in such a way that

$$[66]\quad G_k = \frac{1}{2} \omega_k F_k$$

where ω_k is the weight function thus defined. It should be noted that the BCS ground state (1, 3, 22) is characterized as the zero of G_k, i.e., of ω_k:

$$[67]\quad G_k = 0, \qquad \text{i.e., } \omega_k = 0$$

while

[68] $F_k \neq 0$

for the BCS ground state.

In general, the functional relationship is found to be

[69] $$F_k(g_k)^2 + g_k(1 - f_\kappa - f_{-\kappa}) + \left\{ \frac{1 + x_k}{2}\, \omega_k^* - 1 \right\} F_k^* = 0$$

Taking the complex conjugate of this equation and, next, summing and subtracting with the original equation, we then obtain

[70] $$(g_k F_k + g_k^* F_k^*)(x_k - 1) + 2x_k(1 - f_\kappa - f_{-\kappa}) + \frac{1 + x_k}{2}\,(\omega_k g_k F_k + \omega_k^* g_k^* F_k^*) = 0$$

and

[71] $$g_k F_k - g_k^* F_k^* - \frac{1}{2}\,(\omega_k g_k F_k - \omega_k^* g_k^* F_k^*) = 0$$

After some manipulation, we finally obtain

[72] $$r_k = \frac{g_k F_k + g_k^* F_k^* + \frac{1}{2}\,(\omega_k g_k F_k + \omega_k^* g_k^* F_k^*)}{g_k F_k + g_k^* F_k^* - \frac{1}{2}\,(\omega_k g_k F_k + \omega_k^* g_k^* F_k^*)}\, x_k$$

where of course we assume the nonzero denominator of the right-hand-side expression. It should be noted that the BCS ground state (1, 3, 22) leads to

[73] $r_k = x_k$

for the BCS ground state.

The most significant characteristic of the BCS theory of superconductivity is that eq. [67] holds for any temperature where not only the BCS ground state is involved:

[74] $\omega_k = 0, \qquad$ i.e., $r_k = x_k$

for the BCS ensemble at $T \neq 0$. This is possible only when the electronic state for any electron number N that is involved in the BCS ensemble should possess the same pair function $\phi(1, 2)$ as demonstrated in eq. [1].

To conclude, in our density functional theory of superconductivity (10, 11), the zeros of ω_k were sought for the electron density that is under analytical continuation in the complex Gaussian plane. If the zeros of ω_k infinitely approach the real positive axis of x_k, we can declare that superconducting phase transition has just occurred. In other words, the situation described in eq. [74] holds at that temperature of phase transition in the sense of the "limit." At that limiting situation, the grand canonical ensemble infinitely approaches the BCS ensemble. It should be noted here that the BCS ensemble is not exactly the same as the usual grand canonical ensemble even at the temperature of phase transition. However, the difference is not significant there. Therefore, it is of great interest to study how the BCS wave function given in eq. [1] or, more precisely, how the pair function $\phi(1, 2)$ in it is described in terms of the electron density. As far as the author is aware, the equation-of-motion of the pair function $\phi(1, 2)$ for the BCS ensemble has not been published in the literature, although its derivation is disarmingly easy, as shown in eq. [21]. The potential for the pair function $\phi(1,2)$ is given as an explicit function of the electron density. Thus the deterministic eq. [21] obtained in this work should be the fundamental working equation for density functional theory that allows the continuous analytical description of a superconducting phase transition (10, 11), in which the weight function ω_k that is, in general, complex was assumed to be real.

The power of our theory lies in its predictability, slightly over and above that of BCS theory. First of all, after the superconducting phase transition occurs, our theory reduces to BCS theory. Nothing new happens. Thus the new phenomena should be related to the pre-BCS regime, namely, the gray zone between the normal Fermi liquid and the complete pairing state. Actually, we can predict the presence of the metastable pairing state at temperature T_b, higher than the well-defined critical temperature T_c, where the electronic specific heat C should show a negative jump in sharp contrast to the positive jump at T_c.

Thus, once the electron pair becomes created according to eq. [13] for a certain time-reversal combination, say $\{k\alpha, -k\beta\}$, then even if its lifetime is short, namely, even if it is not in the ground state, the vibronic attractive force will be plugged in as shown in eq. [52]. If this subsidiary attractive force overwhelms the interelectron repulsive force, then a net attractive force will be created and the firm superconducting condensate should be brought about. For metastable electron pairing, the absolute value of the x_k that gives the zero of the ω_k as for the limiting situation of eq. [74] should not be very large. After stable electron pairing is attained, the absolute value of the x_k that gives the zero of the ω_k as for the limiting situation of eq. [74] should be considerably larger. Therefore the $T_b(> T_c)$ in refs. 10 and 11 should be the temperature for metastable electron pairing because it is associated with a small value of x_k, while the T_c associated with a large value of x_k should be that for the complete electron pairing.

The possible consequence in an explanation of certain experimental data will be briefly shown as follows, when we may first show the prediction in Fig. 1, and its experimental evidence in Fig. 2. Experimentally, T_b = 93 K and T_c = 89 K for that sample (23). We cannot predict how high the T_b is, compared with the T_c, until the detailed data pertinent to the sample are available. We can only say at this moment that, mathematically, if it occurs, then Fig. 1 results. Then, the detailed mechanism follows. Figure 3 shows the spectrum of the quasi-particle that is cast in the pairing state. Its temperature dependence is determined by the x in eq. [57], whose functional relationship is deduced by our density functional theory (10, 11). The x itself also depends on temperature as shown in Fig. 4. At $T = T_b$, nonzero x emerges but is not large enough to bind electrons, and at $T = T_c$, the x becomes large enough to form the real bound state of electrons as shown in Fig. 3. Finally, at $T = 0$, the x may converge to a finite value or diverge to infinity, when the behavior is denoted as curve A or B, respectively, in Figs. 3 and 4. The zeros of ω are shown in Fig. 5. For conventional low-T_c superconductors, only those electrons lying in the very vicinity of the Fermi level are combined to form the pairing state, and hence the T_b and T_c may coalesce. This is the reason

Fig. 1. Predicted behavior of the electronic specific heat C as a function of temperature T.

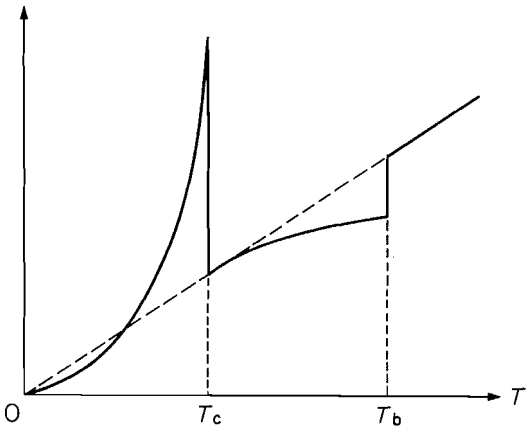

Fig. 2. Experimental evidence of the 93 K anomaly of C for high-T_c (89 K) superconductor.

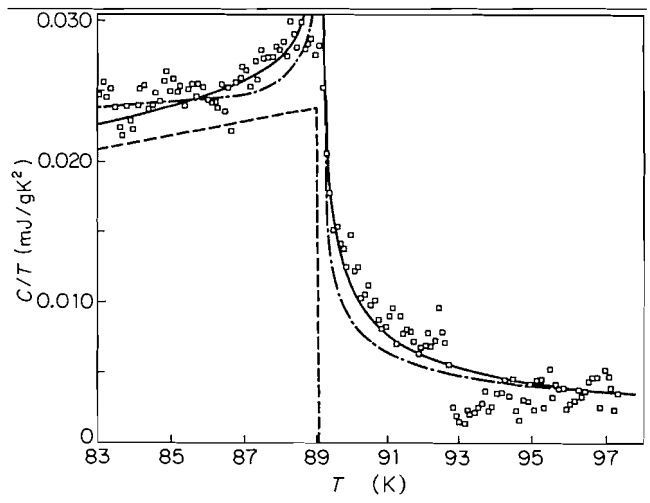

Fig. 3. Predicted behavior of the spectrum of quasi-particle in the pairing state as a function of temperature T.

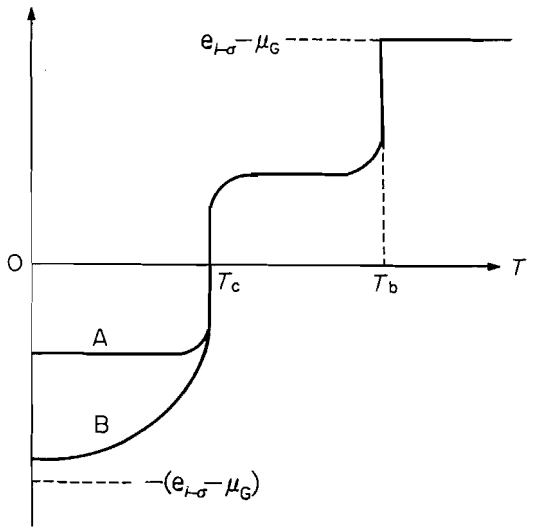

Fig. 4. Assumed behavior of x as a function of temperature T.

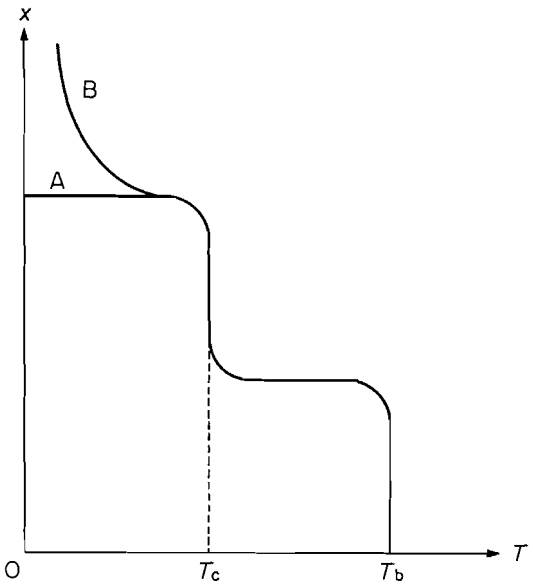

Fig. 5. The distribution of the zeros of ω in the complex Gauss plane of x.

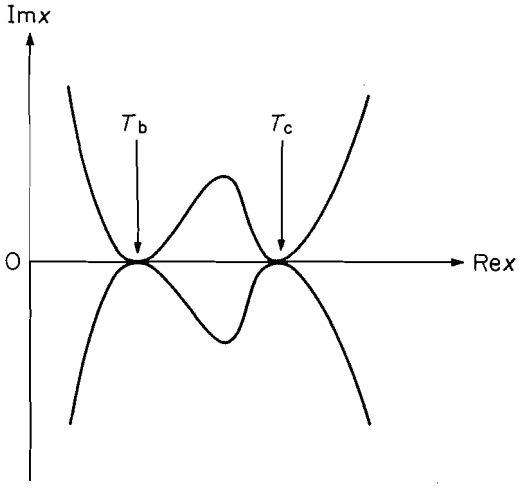

why the T_b anomaly is not observed for conventional low-T_c superconductors.

VI. Conclusion

A rigorous equation-of-motion, eq. [21], is given for the time-reversal electron pair function $\phi(1, 2)$ of the superconducting electron condensate projected on the N-electron Hilbert space at $T = 0$. Since the exchange-correlation potential is given as an explicit functional of electron density, this eq. [21] represents the fundamental working equation for the new density functional theory of superconductivity (10, 11). New stability analysis of the two-electron scattering problem (6–8) is straightforwardly applicable to the present equation-of-motion, and we can directly observe the intrinsic stability

or "rigidity" of the time-reversal electron pair in the superconducting electron condensate (18). The pairing wave function given in eq. [1] was also analyzed in the mean-field theory of superconductivity by Schafroth and Blatt and in the Kohn–Luttinger theory of superconductivity, in the sense that s-wave pairing is, in general, allowed (24–26). Plasmon should strengthen the electron pairing (27). The instantaneous vibronic coupling (5) should, as well, strengthen the attractive force for electron pairing, which is demonstrated explicitly in this paper.

The topology of the valence shell and the electric field gradient at the nitrogen nucleus in aziridines

Félix Rosillo, Yosslen Aray, Jesús Rodríguez, and Juan Murgich

Abstract: The ab initio molecular charge density $\rho(r)$ of substituted aziridines was calculated at the MP2 level for R = -H, -CH_3, -CF_3, -Cl, -NO_2, -CN, -OH, -NO, and -F. The use of the topology of the Laplacian of $\rho(r)$ allowed the analysis of the electric field gradient (EFG) at the nitrogen nucleus directly in terms of its valence shell charge concentration. The EFG changed sign and the orientation of its *y*- and *z*-axes with respect to aziridine when R = -Cl, -NO_2, -CN, -OH, -NO, and -F. The changes in the EFG in these aziridines upon substitution were correlated with those calculated in the valence charge concentrations along the direction of the N—R bond. The sign of the q_{zz} component and the orientation of the principal axes of the EFG tensor were found to be determined by the relative value of the contributions from the charge concentrations at the points in the valence shell along the N—C and N—R bond directions.

Key words: molecular charge distribution, aziridines, Laplacian of the charge density, electric field gradient.

Résumé : On a calculé la densité de charge moléculaire ab initio, $\rho(r)$, d'aziridines substituées au niveau MP2, pour R = -H, -CH_3, -CF_3, -Cl, -NO_2, -CN, -OH, -NO et -F. L'utilisation du laplacien de $\rho(r)$ a permis d'analyser le gradient du champ électrique (GCE) au niveau du noyau d'azote en termes de la concentration de la charge sur les couches de valence. Lorsque R = -Cl, -NO_2, -CN, -OH, -NO et -F, le GCE change de signe et ses axes *y* et *z* changent d'orientation par rapport à l'aziridine. On a pu établir une corrélation entre les changements dans le GCE dans ces aziridines par substitution et ceux calculés dans les concentrations de la charge de valence dans la direction de la liaison N—R. On a trouvé que la composante $q_{z,z}$ et l'orientation des axes principaux du tenseur du GCE sont déterminées par la valeur relative des contributions des concentrations de charge aux points de la couche de valence le long des directions des liaisons N—C et N—R.

Mots clés : distribution de charge moléculaire, aziridines, laplacian de la densité de charge, gradient du champ électrique.

Introduction

The electric field gradient tensor EFG at the nuclei has been employed extensively (1) in studies of the molecular charge distribution $\rho(r)$. The EFG tensor can be measured by means of NQR, NMR, EPR, and other techniques and has provided important information about $\rho(r)$ in many different types of compounds (1).

Almost all the resulting data have been interpreted in terms of the Mulliken population of localized atomic orbitals (1) or by using molecular orbitals (2) centered at the atom containing the quadrupolar nucleus. Nevertheless, the orbitally based populations are not physical observables as defined by quantum mechanics. It is well known that this type of population analysis is not invariant under unitary transformations. Thus, the interpretation of the EFG obtained with one set of orbitals may be not easily related to, or may even differ from, that obtained with another set. Clearly, information obtained about the charge distribution by means of theories based on arbitrary partitions of subsets of Hilbert space is open to serious questions based on sound quantum mechanical principles. The use of localized orbitals in the interpretation of the EFG presents the additional problem of "tails" located away from the main body of the orbitals (3). These "tails" can make sizable contributions to the EFG and obscure the analysis of more important contributions to it (3).

A better way of obtaining information is the direct interpretation of the EFG in terms of the electronic charge distribution $\rho(r)$ or quantities directly related to it. One of the main advantages of this approach is that $\rho(r)$ is a physical observable and is independent of the orbital model used in its calculation. The EFG present at the nitrogen nucleus has been interpreted in terms of the topology of $\rho(r)$ and its associated fields (4–6) in several N-containing compounds. The study of the distribution of the Laplacian of the charge density $\nabla^2\rho(r)$ allows the location in space of the electronic shells (7). As the EFG present at the nucleus reflects, primarily, the departure from spherical symmetry of its electronic shells (1), a connection between the extremes in the $\nabla^2\rho(r)$ of the valence shell and the

gradient at the quadrupolar nucleus was found for several types of nitrogen coordination (4–6). In this work, the EFG data for the N atom in nine substituted azidiridines (see Fig. 1) has been interpreted in terms of the $-\nabla^2\rho(\boldsymbol{r})$ distribution. Recently three aziridines were studied and the results interpreted in terms of Boys's localized orbitals (8, 9). In the present work, an observable such as $\rho(\boldsymbol{r})$ and a derived quantity such as $\nabla^2\rho(\boldsymbol{r})$ are used in the interpretation of the EFG. This approach has the advantage that the interpretation of the gradient is not linked to any particular orbital description and its conclusions may be tested against other experimental results related to the charge distribution.

Computational methods

The ab initio molecular orbitals at MP2 level calculations for the aziridines (see Fig. 1) were obtained on a Silicon Graphics Indigo^2 R-4400 workstation using the Gaussian 92 program (10) with a 6-31G+(d,p) basis set (11). Optimized geometries were obtained by the SCF gradient method (10) with the 6-31G** set. The topological properties of the Laplacian of the electronic density were calculated with the AIMPAC 94 package.[3]

Theory

The EFG is a traceless, second-rank tensor (1) whose *ij*-th component at the origin is

$$[1] \quad q_{i,j} = \int \frac{\partial^2}{\partial x_i \partial x_j}\left(\frac{\rho(\boldsymbol{r})}{\boldsymbol{r}}\right) \mathrm{d}v$$

where $\rho(\boldsymbol{r})$ is the charge density at point $\boldsymbol{r}$. The principal axes of the EFG tensor are such that $|q_{zz}| \geq |q_{yy}| \geq |q_{xx}|$. The independent components of this tensor are two diagonal terms and three direction cosines linking the principal axes system with an arbitrary frame of reference (1). The nuclear quadrupole coupling constant, e^2qQ/h, (where Q is the nuclear electric quadrupole moment, and $eq = q_{zz}$) plus the asymmetry parameter, $\eta = |(q_{yy} - q_{xx})/q_{zz}|$ are usually determined experimentally (1).

The EFG has the symmetry of its source charges and presents, by definition, even parity (12). Any charge distribution may be divided into its odd and even parity components. Then, due to the parity of the EFG, one has to consider only the contribution of the even part of $\rho(\boldsymbol{r})$ because the other integrates to zero for symmetry reasons (12). In an isolated molecule, the charge distribution of the N atom may be separated into two parts: (*i*) a spherically symmetric core, formed by the nitrogen shells, that is not deformed by bonding; (*ii*) the deformed part represented by the extremes in the charge distribution in the nitrogen valence shell produced by bonding. The spherical core will not generate a field gradient at the N nucleus for symmetry reasons already mentioned (12). The charge from neighboring atoms generates a small EFG because the contribution of the nuclei is mostly compensated by that of the electrons (6). The r^{-3} dependence of the EFG operator (1) further decreases the contribution from those sources that are located away from the shells of the N atom. As we are interested only in the main contributions to the EFG at the nucleus in N atoms of aziridines, we will not consider these contributions here.

The topology of the charge distribution

The topological properties of $\rho(\boldsymbol{r})$ or $\nabla^2\rho(\boldsymbol{r})$ scalar fields are reflected in their critical points (7) $\boldsymbol{r}_c$, (where $\nabla\rho(\boldsymbol{r})$ and $\nabla[\nabla^2\rho(\boldsymbol{r})] = 0$). These points are classified according to their type (*m*, *n*) by stating their rank *m* and signature *n*. The rank is the number of non-zero eigenvalues of the Hessian matrix at $\boldsymbol{r}_c$ while the signature is the algebraic sum of the signs of the eigenvalues (7). Two types of critical points in the $\rho(\boldsymbol{r})$ field are found in the nitrogen valence shell, the (3,−1) saddle points related to the interaction of N with the neighboring atoms and a (3,−3) point representing a maximum at the position of the nucleus. More complex is the topology of the Laplacian field of $\rho(\boldsymbol{r})$ for the N valence shell because it also exhibits (3,+1) saddle points in aziridines. From the topology of the $\nabla^2\rho(\boldsymbol{r})$ field, one can recover the chemical model of the localized bonded and nonbonded pairs (7). Moreover, this type of field helps to characterize the regions of local concentration ($-\nabla^2\rho(\boldsymbol{r}) > 0$) and of depletion ($-\nabla^2\rho(\boldsymbol{r}) < 0$) of the atomic and molecular $\rho(\boldsymbol{r})$ (7).

The $\nabla^2\rho(\boldsymbol{r})$ distribution of a free atom reflects the quantum shell structure by exhibiting the corresponding number of alternating pairs of shells of charge concentration and depletion (7). Upon bonding, local maxima and minima are formed in the valence shell of the bonded atom. The number, type, location, and $-\nabla^2\rho(\boldsymbol{r})$ value at these extremes are functions of the linked atoms. The sets of these extremes in each atom form the basis of its atomic graph. This graph contains information about the atom's Lewis model and displays the connectivity of the extremes of the valence shell (7).

In a free atom, the charge distribution of the valence shell is uniform over the surface of a sphere (7) and the EFG at its nucleus is, by symmetry, equal to zero. In light bonded atoms, the EFG at the nucleus is produced mainly by the departure of the valence shell from spherical symmetry. Then, a connection exists between the local charge extremes that are reflected in the $-\nabla^2\rho(\boldsymbol{r})$ values of the atomic graph and the EFG present at the corresponding nucleus (4–6).

Results

The atomic graph of the N atom of the aziridines studied in this work and shown in Fig. 2 has four (3,–3) critical points in its valence shell charge concentration (VSCC). Two are located in the direction of the ring bond with the -CH_2 groups b_1 and b_2, and one in the direction of substituent R. The fourth critical point is found in the direction of the nonbonded concentration ("lone pair") N_b. These points form a tetrahedral atomic graph in the nitrogen valence shell as seen in Fig. 2. This type of graph is similar to that found for the N atom in

[3] R.F.W. Bader. Private communication, 1993.

Fig. 2. Atomic graph of the $-\nabla^2\rho(\mathbf{r})$ distribution of the valence shell of the N atom in aziridines. The maxima are denoted by a dot (●) and the saddle points by an asterisk (*). The N nucleus is in the center of the sphere and the three covalent bonds and the "lone pair" are shown as parallel lines joining the nucleus with these extremes of the valence shell.

NH_3 and other symmetrically substituted amines (13). The values of $-\nabla^2\rho(\mathbf{r})$ for the different critical points of the nitrogen VSCC in some aziridines are reported in Table 1.

The charge concentration at the b_i points of the nitrogen graph increased with respect to aziridine for substituents more electronegative than H such as -Cl, $-NO_2$, -CN, -OH -NO, and -F. The values of the $-\nabla^2\rho(\mathbf{r})$ at the N_b point for these aziridines changed only slightly upon substitution while those at the R point showed much larger fluctuations. In another group of aziridines (R = $-CH_3$ and $-CF_3$) substitution produced small changes in the values of $-\nabla^2\rho(\mathbf{r})$ at the N_b points, a decrease in its value at the R point, and a small increase at the b_i points.

Table 2 shows the components of the EFG for the aziridines studied in this work. From this table, one sees that the nitrogen EFG in aziridines may be divided into two different sets: one with $q_{zz} < 0$ (R = -H, $-CH_3$, and $-CF_3$) and another with $q_{zz} > 0$ (R = -Cl, $-NO_2$, -CN, -OH -NO, and -F). The modifications introduced in the nitrogen charge distribution by groups or atoms more electronegative than H produce not only a change in the signs of the components of the EFG tensor, but also a significant reorientation of its axes, as seen in Fig. 3. In the aziridine and in some substituted aziridines (R = $-CH_3$ and $-CF_3$), the z-axis points within a few degrees along the direction of "lone pair" N_b as in several other nonplanar but symmetrical amines (13). When the substituent is more electronegative than H, the z-axis is rotated away from the N_b direction by a significant amount as shown by the Θ values found in Table 2 and in Fig. 3. The principal z- and y-axes in all the aziridines studied in this work are located in a plane perpendicular to the ring plane. When substitution with the more electronegative groups occurs, the z- and y-axes are rotated in that plane in such a way that now the y-axis points close to the N_b point (see Fig. 3).

Discussion

The changes in the EFG upon substitution can be related to the variations in magnitude and position of the nitrogen VSCC points (4–6). It was found in this work that the variations in the position of these points with respect to the N nucleus upon substitution in aziridines are negligible so they do not seem to be the cause of the modifications observed in the EFG.

On the other hand, the values of the $-\nabla^2\rho(\mathbf{r})$ at the b_i points

vary up to 30%, those at the N_b points by only 13%, and at R by a factor of four upon substitution, as seen in Table 1. When substitution occurs, the main changes, as expected, are observed in the charge distribution of the point R of the N valence shell. Nevertheless, changes in this region of the valence shell also propagate (4–6) to concentrations along the N—C bond directions and at the "lone pair" N_b (4–6). A linear correlation between the values of the Laplacian of $\rho(r)$ in these two points for the aziridines shows how the perturbation introduced by substitution propagates to the other part of the valence shell. It was found that $\nabla^2\rho(r)_{b1} = 2.171 - 0.417\nabla^2\rho(r)_R$ with $r = 0.959$. This correlation implies that the decrease in the charge concentration produced by more electronegative atoms or groups at the R point in the N valence shell produces an increase at the points found in both N—C directions. An opposite behavior in these points was found for electron-donating groups such as $-CH_3$ or $-CF_3$. A linear correlation was also obtained between the values of $\nabla^2\rho(r)_R$ and the nonbonded concentration at N_b, with $\nabla^2\rho(r)_{Nb} = 3.477 - 0.298\nabla^2\rho(r)_R$ but with $r = 0.795$. In this case, the charge at the N_b point is increased when the concentration at the R point is decreased although the correlation is not as good as in the other extremes. It is likely that additional factors may influence the values of $\nabla^2\rho(r)$ at the N_b point upon substitution and thus lower the correlation.

The correlations found between the changes in the R point with the other extremes show that substitution at the N position of atoms or groups more electronegative than H in aziridines draws electrons from the ring toward the N valence shell with some additional increase of concentration at the N_b point. The substitution of $-CH_3$ or $-CF_3$ groups produced, instead, a decrease in the charge concentration at the R point and a slight increase in the points along the N—C bond directions while at N_b only small changes were found.

We can summarize the effects of substitution in aziridines as perturbing primarily the valence shell along the N–R direction plus inducing changes at the other extremes. As these extremes are the sources of the EFG, it is reasonable then to assume that the changes found in q_{zz} upon substitution are produced mainly by the variations of the charge concentration at the R point with contributions from the remaining points of the valence shell.

From Tables 1 and 2, we see that the aziridines with $q_{zz} > 0$ have a rather large charge concentration in the N valence shell along the N–R direction and a relatively low value at the b_i points. The opposite behavior is found for the aziridines with $q_{zz} < 0$ as seen in the same tables. A linear regression among the six $q_{zz} > 0$ values and those of the Laplacian at the R point gave $q_{zz} = 1.359 - 0.438\nabla^2\rho(r)_R$ with $r = 0.942$. The same type of analysis for the b_i points in the same aziridines gave $q_{zz} = -0.697 + 0.923\nabla^2\rho(r)_{bi}$ with $r = 0.986$ while for the N_b point, $q_{zz} = -1.378 + 0.723\ \nabla^2\rho(r)_{Nb}$ with $r = 0.828$.

It is expected that the q_{zz} at the nucleus will be generated mainly by the N "lone pair" (1, 2). The other extremes produced by bonding in the N valence shell also contribute to q_{zz} but their contribution is expected to be smaller with regard to that generated by the "lone pair." This later charge concentration represents the largest deviation from the uniform distribution found over the valence shell surface in the free atom. Consequently, it produces an important part of the EFG found in N upon bonding. The other critical points represent, instead, smaller departures as seen in Table 1, and consequently their contribution to the EFG is, in general, smaller. The total EFG tensor contains all these contributions plus a geometrical factor that takes into account the spatial localization of the critical points (13). This geometrical factor reflects the specific type of atomic graph that the N atom has. The existence of the geometrical factor explains why, in certain types of graphs, the contribution of some points is compensated by that produced by others (13). In this case, the total EFG reflects only the presence of the uncompensated critical points. The importance of the geometric factor becomes greater as the number of concentration points in the N valence shell increases. In the high symmetry cases, such as an atomic graph having T_d symmetry (i.e., the N atom in the N^+H_4 ion), the contributions of all the different charge concentration points are equal but the geometric factor cancels them out. For the tetrahedral atomic graph found in the four-coordinated N atom in N^+R_3X compounds, the role of the nonbonded charge concentration is taken by that found along the N—X bond direction (13). The larger the difference between the local maxima in the N–R and N–X directions, the larger was the calculated value of q_{zz}. The geo-metrical factor of a tetrahedral atomic graph is still operative in this case but the charge concentrations in the different points of the valence shell are not equal and a finite EFG is found at the nucleus. In the case of aziridines, we have even larger differences in the charge concentrations than in the N^+R_3X case so that they may generate a larger contribution to the EFG. The geometric factor is the same for the different atoms and groups R, so the changes observed in the orientation and sign of the EFG upon substitution in aziridines are the result of the variations observed in $\rho(r)$ at the different local extremes of the N valence shell. It seems that the values of charge concentration along the N–C and N–R directions are such that $q_{zz} < 0$ for the more electronegative substituents, and the principal y-axis is located near the "lone pair." This is a result of the contributions arising from the uncompensated extremes existing in the tetrahedral atomic graph found in the N valence shell. For the less electronegative substituents or for a more symmetric substitution (13), the z-axis points along or near the "lone pair" direction and the resulting value of q_{zz} is positive.

Conclusions

The use of the topology of $-\nabla^2\rho(r)$ allowed the analysis of the EFG in aziridines directly, in terms of the VSCC present in the N atomic graph. For R = $-CH_3$ and $-CF_3$, the orientation and components of the EFG were similar to those of aziridine. It was found that the q_{zz} component changed sign and the orientation of its z- and y-axes when -Cl, $-NO_2$, -CN, -OH, -NO, and -F substituted the H atom in aziridine. The changes in the EFG in these aziridines were found to be correlated with those in the VSCC point located along the direction of the N—R bonds. The sign of the q_{zz} component and the orientation of the principal axes of the EFG tensor were found to be determined by the relative value of the contributions from the charge concentrations that were at the points in the valence shell along the N—C and N—R bond directions.

Quantum chemical valence indices from the one-determinantal difference approach

Roman F. Nalewajski, Janusz Mrozek, and Grzegorz Mazur

Abstract: The recently introduced *quadratic* (two-electron) *valence indices*, ionic and covalent, derived from the Hartree–Fock finite-difference approach, are applied to selected organic and inorganic molecules to demonstrate their utility in monitoring chemical bonding patterns in molecular systems. The indices are defined in terms of differerences between simultaneous probabilities of finding two electrons on specified atoms, calculated from the molecular and *separated-atom-limit* (SAL) wave functions, respectively, in the UHF approximation. The total quadratic valence number represents the overall number of chemical bonds in the system under consideration; it is interpreted as the molecular expectation value of the difference operator of the molecular and SAL density operators. This interpretation leads to a new set of ionic atomic and diatomic valence components; these modified valence numbers are discussed using the two-orbital model in the UHF scheme. A new procedure is proposed for dividing the one-center contributions to the bond valences; it generates effective bond orders in qood agreement with chemical expectations. The new valence quantities are tested on selected typical molecules and prototype hydrogen-bonded dimers. A more extensive study has been carried out on small-ring propellanes, to examine changes in bond valences between bridgehead atoms in selected systems.

Key words: chemical valence: UHF difference approach; chemical bond: two-electron model; bond multiplicities; ionic/covalent bond components; propellanes: valence study.

Résumé : Les *indices de valence quadratique* (deux électrons), ionique et covalente, dérivés de l'approche d'une différence finie de Hartree–Fock, sont appliqués à des molécules organiques et inorganiques choisies afin de démontrer leur utilité dans l'évaluation des patrons de liaison chimique dans des systèmes moléculaires. Les indices sont définis en termes de différences entre des probabilités simultanées de trouver deux électrons sur des atomes donnés et elles sont calculées à partir des fonctions d'onde respectivement moléculaires et à la *limite de la séparation des atomes* (LSA), dans l'approximation UHF. Le nombre de valence quadratique total représente le nombre global de liaisons chimiques dans le système étudié; on l'interprète comme la valeur de l'expectative moléculaire de l'opérateur de la différence des opérateurs de densité moléculaire et LSA. Cette interprétation conduit à un nouvel ensemble de composantes de valence atomique ionique et diatomique; on discute de ces nombres de valence modifiés en faisant appel au modèle à deux orbitales du schéma UHF. Une nouvelle méthode de diviser les contributions provenant d'un centre aux valences de liaison, elle génère des ordres de liaison effectives qui sont en bon accord avec les attentes chimiques. On a évalué les nouvelles valeurs de valence sur des molécules typiques choisies et des dimères prototypes à liaison hydrogènes. Afin d'examiner les changements dans les valences de liaison entre les atomes en tête de pont de systèmes choisis, on a effectué une étude plus étendue sur des propellanes à petits cycles.

Mots clés : valence chimique : UHF; liaison chimique : modèle de deux électrons; multiplicités de liaison; parties constituants de liaison : ionique et covalent; propellanes : étude de valence.

Introduction

The chemical valence represents a central electronic structure concept reflecting both bond multiplicity and the effective (promoted) states of *atoms-in-molecules* (AIM). It was originally introduced on an intuitive basis (1); later its quantum-mechanical interpretations (2–13) were also developed. The two-electron valence measures (10–14) directly connect to the original, electron-pair concept of Lewis (1) by relating chemical bond orders to changes in the electron pairings in a molecule, relative to those in isolated constituent atoms. This Hartree–Fock difference approach (10–14) compares the two-electron distribution among AIM with the reference *separated atoms limit* (SAL). It provides absolute valence indices (covalent and ionic) reflecting the associated changes in the simultaneous probabilities of finding two electrons on specified atoms. These absolute valence numbers can subsequently be used to calculate relative valences, e.g., changes in bond orders due to ionization or change in the system geometry, by subtracting absolute values of compared systems. These so called *quadratic valence indices* (QVI) (11–14) represent contributions to the overall second-order change in the pair-diagonal two-electron density matrix in a molecule, relative

to the SAL. In the one-determinantal (HF or DFT) approximation they can be expressed as quadratic forms in terms of differences of the relevant one-particle *charge-and-bond-order* (CBO) matrix elements in the basis set of *orthogonal atomic orbitals* (OAO). Accordingly, the three-electron, *cubic valence indices* (CVI), measuring contributions to the corresponding third-order change in the diagonal part of the three-electron density matrix, are similarly represented by the corresponding cubic forms of the molecular CBO displacements relative to the SAL. It has been demonstrated (11–14) that these two-electron valence numbers reproduce intuitive chemical expectations quite adequately for typical molecules and model transition states of simple chemical reactions. The corresponding UHF three-electron corrections have been shown to be small (13). Recently (14) the QVI have been implemented in the Kohn–Sham (LSDA) scheme (15). It has been concluded that the novel bond valence measures provide a very useful and easy-to-implement diagnostic tool for monitoring changes in the bonding pattern of both isolated molecules and reactants in a model catalytic system.

The main purpose of the present paper is to examine more closely the expectation value interpretation of the QVI proposed in ref. 14, and to present and test the appropriate schemes for partitioning atomic contributions among the bond valences. The set of typical organic molecules exhibiting various C—C bond multiplicities includes hydrocarbons (acetylene, ethylene, ethane, benzene, and simple propellanes); we also consider the B_2H_6 molecule and simple inorganic dimers of HF and H_2O to test whether the proposed bond multiplicities discriminate between strong chemical interactions and weak hydrogen bonds.

Difference approach to valence indices

The recently proposed set of QVI (11) measures changes in the two-electron simultaneous probability distribution in a molecule, relative to the SAL reference state (^{0}), reflected by the pair-diagonal elements $\Delta\Gamma(\mu,\nu) \equiv \Delta\bar{\Gamma}(\mu\nu|\mu\nu)$, of the spinless two-electron density matrix in the OAO representation $|\boldsymbol{\lambda}\rangle = |\mu,\nu,\ldots\rangle = |\boldsymbol{a},\boldsymbol{b},\ldots\rangle$; throughout the paper the Löwdin normalization is assumed, and $|\boldsymbol{a}\rangle = |a,a',\ldots\rangle$ denotes OAO associated with atom A.

The RHF/LDA QVI (11, 14) have been defined in the framework of the second-order Taylor expansion,

$$[1]\quad \Delta\boldsymbol{\Gamma} \equiv \boldsymbol{\Gamma} - \boldsymbol{\Gamma}^0 = \left\{\sum_{\mu,\nu}^{\mathrm{OAO}} \left(\frac{\partial\boldsymbol{\Gamma}}{\partial P_{\mu\nu}}\right)^0 \Delta P_{\mu\nu}\right\} + \left\{\frac{1}{2}\sum_{\mu,\nu}^{\mathrm{OAO}}\sum_{\rho,\tau}^{\mathrm{OAO}} \Delta P_{\mu\nu}\left(\frac{\partial^2\boldsymbol{\Gamma}}{\partial P_{\mu\nu}\partial P_{\rho\tau}}\right)^0 \Delta P_{\rho\tau}\right\} \equiv \{\Delta\boldsymbol{\Gamma}^{(1)}\} + \{\Delta\boldsymbol{\Gamma}^{(2)}\}$$

in terms of powers of the CBO displacements, $\Delta\boldsymbol{P} \equiv \boldsymbol{P} - \boldsymbol{P}^0$; the related UHF/LSDA QVI are similarly defined by the quadratic expansion of $\Delta\boldsymbol{\Gamma}(\Delta\boldsymbol{P}^\sigma)$, where $\Delta\boldsymbol{P}^\sigma = \boldsymbol{P}^\sigma - \boldsymbol{P}^{0,\sigma}$, $\sigma = \alpha,\beta$, are the corresponding spin-resolved CBO shifts: $\Delta\boldsymbol{P} = \Delta\boldsymbol{P}^\alpha + \Delta\boldsymbol{P}^\beta$. In what follows we denote by $\Delta\boldsymbol{n} = (\Delta n_A, \Delta\boldsymbol{n}_B, \ldots)$ and $\Delta\boldsymbol{q} = (\Delta P_{\mu\mu}, \Delta\boldsymbol{P}_{\nu\nu}, \ldots)$ the corresponding changes in the AIM electron populations and the orbital occupations, respectively. The RHF/LDA QVI monitor the second-order atomic and diatomic contributions to $\Delta\boldsymbol{\Gamma}$,

$$[2]\quad \Delta\boldsymbol{\Gamma}^{(2)}_{\mathrm{RHF}} = \Delta\boldsymbol{\Gamma}(\{\Delta n_A\ \Delta n_B\}, \{(\Delta q_\mu)^2\}, \{(\Delta P_{\mu\nu})^2\})$$

with the obvious slight modification in the UHF case:

$$[3]\quad \Delta\boldsymbol{\Gamma}^{(2)}_{\mathrm{UHF}} = \Delta\boldsymbol{\Gamma}(\{\Delta n_A\ \Delta n_B\}, \{(\Delta q^\sigma_\mu)^2\}, \{(\Delta P^\sigma_{\mu\nu})^2\})$$

This difference approach gives the following expressions for the resulting valence indices:
(*i*) in the RHF/LDA theories:

$$[4]\quad V_A^{\mathrm{ion}} = \frac{1}{2}\left[(\Delta n_A)^2 - \frac{1}{2}\sum_a^A (\Delta q_a)^2\right]$$

$$[5]\quad V_A^{\mathrm{cov}} = -\frac{1}{2}\sum_{a<a'}^{A}\sum^{A} (\Delta P_{aa'})^2$$

$$[6]\quad V_{AB}^{\mathrm{ion}} = \Delta n_A \Delta n_B$$

$$[7]\quad V_{AB}^{\mathrm{cov}} = -\frac{1}{2}\sum_a^A\sum_b^B (\Delta P_{ab})^2$$

(*ii*) in the UHF/LSDA theories:

$$[8]\quad V_A^{\mathrm{ion}} = \frac{1}{2}\left\{(\Delta n_A)^2 - \sum_a^A [(\Delta q_a^\alpha)^2 + (\Delta q_a^\beta)^2]\right\}$$

$$[9]\quad V_A^{\mathrm{cov}} = -\sum_{a<a'}^{A}\sum^{A} [(\Delta P^\alpha_{aa'})^2 + (\Delta P^\beta_{aa'})^2]$$

$$[10]\quad V_{AB}^{\mathrm{ion}} = \Delta n_A \Delta n_B$$

$$[11]\quad V_{AB}^{\mathrm{cov}} = -\sum_a^A\sum_b^B [(\Delta P^\alpha_{ab})^2 + (\Delta P^\beta_{ab})^2]$$

The ionic indices depend solely on $\Delta\boldsymbol{n}$ and $\Delta\boldsymbol{q}$ (diagonal CBO displacements) while the covalent valence numbers are defined exclusively by the diagonal quadratic forms in terms of the off-diagonal CBO displacements, $\mu \neq \nu$. They originate from the Coulombic and exchange parts of $\Delta\boldsymbol{\Gamma}^{(2)}$, respectively. By definition, the negative (positive) QVI contributions, in terms of electronic pairs, are bonding (antibonding).

It has been shown recently (14) that the overall QVI representing the sum of all valence contributions,

$$[12]\quad V = \sum_{\mu,\nu}^{\mathrm{OAO}} \Delta\Gamma^{(2)}_{\mu,\nu} = \sum_A^{\mathrm{AIM}} (V_A^{\mathrm{ion}} + V_A^{\mathrm{cov}}) + \sum_{A<B}^{\mathrm{AIM}}\sum (V_{AB}^{\mathrm{ion}} + V_{AB}^{\mathrm{cov}}) \equiv \sum_A^{\mathrm{AIM}} V_A + \sum_{A<B}^{\mathrm{AIM}}\sum V_{AB}$$

can be given alternative interpretation as the average CBO displacement. For example, in the RHF case

$$[13]\quad V = -\frac{1}{4}\,\mathrm{Tr}(\Delta\boldsymbol{P})^2 = -\frac{1}{2}\,\mathrm{Tr}(\boldsymbol{P}\Delta\boldsymbol{P}) \equiv -\frac{1}{2}\,\langle\Delta\hat{\mathrm{P}}\rangle$$

where $\langle \Delta\hat{P} \rangle$ stands for the molecular expectation value of

$$[14] \quad \Delta\hat{P} = \hat{P} - \hat{P}^0 = N(\hat{\rho} - \hat{\rho}^0) \equiv N\Delta\hat{\rho}$$

and the CBO operators, expressed in terms of the canonical molecular and SAL orbitals, $|\varphi\rangle = |\lambda\rangle C$ and $|\varphi^0\rangle = |\lambda\rangle C^0$, respectively, are

$$[15] \quad \hat{P} = |\varphi\rangle d\langle\varphi| \equiv N\hat{\rho}, \qquad \hat{P}^0 = |\varphi^0\rangle d^0\langle\varphi^0| \equiv N\hat{\rho}^0$$

Here N is the number of electrons, d, d^0 represent the diagonal matrices of molecular orbital occupations, and $\hat{\rho}, \hat{\rho}^0$ are the corresponding density operators. Another interesting expression for V is in terms of the difference between two expectation values of $\Delta\hat{P}$, the SAL and molecular (14):

$$[16] \quad V = \frac{1}{4}\left[\langle\Delta\hat{P}\rangle^0 - \langle\Delta\hat{P}\rangle\right]$$

Here $\langle\Delta\hat{P}\rangle^0 \equiv \mathrm{Tr}\,(P^0\Delta P)$.

The overall valence number of eq. [13] can be naturally decomposed into atomic ($\bar{V}_{AA}$) and diatomic ($\bar{V}_{AB}$) contributions:

$$[17] \quad V = -\frac{1}{4}\sum_{A}^{AIM}\sum_{B}\left[\sum_{a}^{A}\sum_{b}^{B}(\Delta P_{ab})^2\right] \equiv \sum_{A}^{AIM}\sum_{B}\bar{V}_{AB}$$

These modified atomic contributions consist of both ionic and covalent components (see eqs. [4]–[7]),

$$[18] \quad \bar{V}_{AA} = \left[V_A^{ion} - \frac{1}{2}(\Delta n_A)^2\right] + V_A^{cov} \equiv v_A^{ion} + V_A^{cov}$$

thus the new ionic index, v_A^{ion} differs from V_A^{ion} (eq. [4]) by the missing global atomic population term. The modified diatomic contributions are purely covalent:

$$[19] \quad \bar{V}_{AB} + \bar{V}_{BA} \equiv V_{AB}^{cov}$$

so that the global AIM charge contributions of eq. [6] do not appear in this new set of indices:

$$[20] \quad \{v_A^{ion}, V_A^{cov}, V_{AB}^{cov}\}$$

$$V = \sum_{A}^{AIM}(v_A^{ion}, +V_A^{cov}) + \sum_{A<B}^{AIM}\sum V_{AB}^{cov} \equiv \sum_{A}^{AIM} v_A + \sum_{A<B}^{AIM}\sum V_{AB}^{cov}$$

Therefore, this new partitioning scheme recovers the orbitally resolved parts of the RHF/LDA valence numbers of eqs. [4]–[7], without the atomic global population terms that do not contribute to the overall valence V,

$$[21] \quad \sum_{A}^{AIM}\sum_{B}\Delta n_A \Delta n_B = (\Delta N)^2 = 0$$

since both the molecular and SAL states correspond to the same number of electrons: $\Delta N = N - N^0 = 0$.

This new development indicates that one could alternatively consider a set of three types of the RHF/LDA indices of eq. [20], $\{v_A^{ion}, V_A^{cov}, V_{AB}^{cov}\}$, to characterize the bonding structure in a molecule, instead of the four valence numbers of eqs. [4]–[7]. This new set gives rise to the same overall valence and it removes a somewhat arbitrary V_{AB}^{ion} term, which appears in the *absolute valences* even at large distances between two molecular subsystems, to be eventually cancelled when calculating the relative valence indices defined as the difference between the overall valences of the combined system and those of the separated subsystems. Similar modified valence indices are obtained in the UHF/LSDA theory, by removing the global atomic population term in eq. [8] and neglecting the diatomic ionic valence number of eq. [10]. Removal of the global atomic population contributions leaves only valence numbers that are quadratic diagonal forms in terms of the CBO displacements.

The above difference approach introduces a dependence of valence numbers upon the choice of the SAL, with both specific orbital occupations of the open-shell atoms or ions, and the mutual (interatomic) arrangements of spins of unpaired electrons affecting the one-center QVI. This dependence should not come as a surprise, since bond valence (bond order) is the difference quantity with respect to the SAL state. It is common in all chemical processes involving bond formation (bond breaking). As we have shown before (11–14) this dependence can be managed by an appropriate averaging scheme or through a selection of a single, representative reference state in the SAL. For example, one can average the resulting valence quantities over all admissible spin orientations and orbital electron configurations (11–13) or one can adopt the *minimum AIM valence state promotion principle* (14), which selects the promoted (P)-SAL state generating the minimum CBO reorganization in a molecule, measured by the magnitude of the atomic global valence numbers, V_A or v_A (eqs. [12], [20]). The latter, P-SAL perspective, has been shown to generate numerical values of the bond valences in slightly better agreement with chemical intuition (14).

Our definition of $\Delta\hat{P}$ (eq. [14]) gives negative values of the overall and bond valences, in accordance with our previous definitions (10–13). Clearly, a simple change of order of terms in this definition would reverse the signs, thus bringing our sign convention into conformity with other valence definitions.

The underlying main purpose, of a fast extraction of the difference valence numbers from molecular RHF/UHF or LDA/LSDA calculations, is only practical when one fixes the ground-state SAL orbitals φ^0 (from separate atomic calculations), when selecting the P-SAL or averaging over admissible SAL orbital configurations. Such a *frozen SAL orbital approximation* is used throughout the paper.

Typical calculations of the QVI involve molecular calculations, e.g., UHF or LSDA, in a given non-orthogonal basis set $|\chi\rangle$, consisting of specified atomic subsets $\{|\chi_A\rangle\}$, to calculate molecular CBO matrices, and separate atomic calculations in the same atomic basis sets, to determine the SAL CBO information. Symmetrical Löwdin orthogonalizations are carried out to obtain the corresponding OAO data. In principle, both molecular and SAL CBO in the $|\chi\rangle$ basis set should be transformed using the common (molecular) or-

thogonalization transformation, which includes the effects of the AIM overlaps at finite separations. However, this would produce in the SAL the artificial, and unphysical, tails in the atomic wave functions from basis functions of the remaining atoms, thus contradicting the assumed separated (noninteracting) character of atoms in this reference state. Therefore, we have performed separate atomic orthogonalizations in the SAL, including only the atomic overlap blocks, $\langle \chi_A | \chi_A \rangle$, in accordance with vanishing interatomic overlap integrals at infinite (or sufficiently large) separations.

When calculating bond valences, the most important quantities for chemical purposes, one faces the problem of partitioning atomic valence numbers between all bonds in which the atom participates; these bond-order indicators also include the corresponding two-center component(s). Obviously, a partitioning of atomic valences, $v_A = v_A^{cov} + V_A^{ion}$ or $V_A = V_A^{ion} + V_A^{cov}$, is arbitrary. The most obvious, bond partitioning by equally dividing one-center terms, say V_A, among all k_A chemical bonds A—B formed by the atom A, $V_A^{(I)}(AB) = V_A/k_A$, defines the Scheme I of calculating bond valences (13):

$$[22] \quad V_b^{(I)}(AB) \equiv [V_A^{(I)}(AB) + V_B^{(I)}(AB)] + [V_{AB}^{cov} + V_{AB}^{ion}] \equiv [V_{AB}^{(1)}(I)] + [V_{AB}^{(2)}]$$

where $V_{AB}^{(1)}(I)$ and $V_{AB}^{(2)}$ stand for the one- and two-center contributions to the bond valence estimated in this scheme. Obviously, this partitioning requires an advanced knowledge of the bonding pattern, which is generally unavailable. Therefore, one has to have alternative unbiased schemes that do not suffer from this severe limitation.

Another *weighted* (w) division of one-center valence contributions is obtained when one partitions them proportionally to the two-center contributions, $V_A^w(AB) = V_A w_{AB}$, where the weighting factors can be linked either to the total diatomic contribution (Scheme II), $w_{AB} = w_{AB}^{(II)} \equiv V_{AB}^{(2)} / \sum_{C \neq A} V_{AC}^{(2)}$ or to its covalent part only (Scheme III), the total diatomic part in the modified valence indices of eq. [20]: $w_{AB} = w_{AB}^{(III)} \equiv V_{AB}^{cov} / \sum_{C \neq A} V_{AC}^{cov}$. Replacing $V_X^{(I)}(AB)$ by $V_X^w(AB)$ in eq. [22] gives the corresponding weighted bond valences $V_b^{(II)}$ and $V_b^{(III)}$ estimated within Schemes II and III, respectively. These two totally unbiased bond valence measures should reflect more realistically the valence asymmetry between the single and multiple bonds in which a given atom is involved. We shall test numerically all three partitioning schemes on selected molecular systems.

Replacing V_A by v_A in the above three partitioning schemes gives rise to bonding valences corresponding to the new set of valence indices (eq. [20]).

Two-orbital model of a single bond

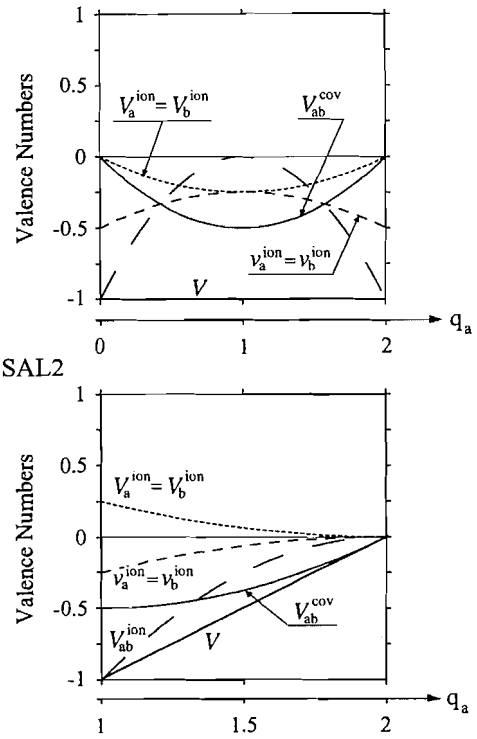
Following our previous development (10–13), let us consider an illustrative case of the two OAO models corresponding to the singly occupied molecular spin orbitals of the UHF/LSDA approximation:

$$[23] \quad \varphi^\alpha = (a + \gamma b)/(1 + \gamma^2)^{1/2}, \qquad \varphi^\beta = (\delta a + b)/(1 + \delta^2)^{1/2}$$

with $\varphi^\alpha \rightarrow a$, and $\varphi^\beta \rightarrow b$ in the SAL. The two independent parameters γ and δ, to be determined variationally, can be expressed in terms of the electron population and spin polarization on a given atom, say, $q_a = q_a^\alpha + q_a^\beta = 2 - q_b$ and $\sigma_a = q_a^\alpha - q_a^\beta = -\sigma_b$. In terms of these more informative degrees-of-freedom of the system electronic structure, the CBO matrix elements are

$$[24] \quad q_\mu^\alpha = \frac{1}{2}(q_\mu + \sigma_\mu), \qquad q_\mu^\beta = \frac{1}{2}(q_\mu - \sigma_\mu), \qquad \mu = a, b$$
$$P_{ab}^\sigma = (q_a^\sigma q_b^\sigma)^{1/2}, \qquad \sigma = \alpha, \beta$$

Fig. 1. The RHF/LDA ($\sigma_a = 0$) valence diagrams from the two-orbital model.



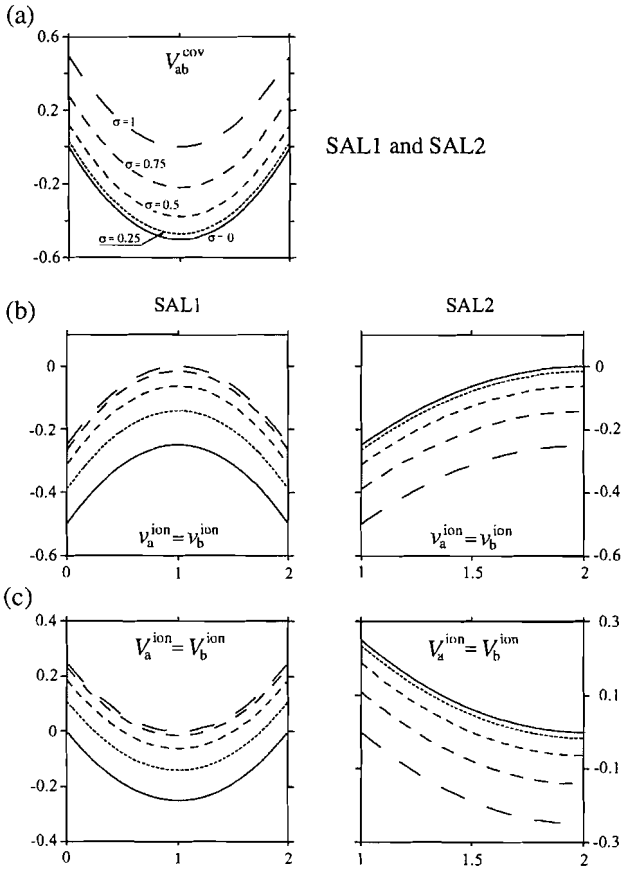
As before (10–13) let us consider the following two choices of the SAL:

(*i*) SAL1 (Å + B̊), defined by $\mathbf{P}^{0,\alpha} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$; $\mathbf{P}^{0,\beta} = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix}$, i.e., $q_a^0 = q_b^0 = 1$ and $\sigma_a^0 = 1 = -\sigma_b^0$, corresponding to a covalent A—B bond;

(*ii*) SAL2 (Ä + B), defined by $\mathbf{P}^{0,\alpha} = \mathbf{P}^{0,\beta} = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}$, i.e., $q_a^0 = 2, q_b^0 = 0$, and $\sigma_a = \sigma_b = 0$, corresponding to the donor–acceptor (coordination) bond, A → B.

In both SAL cases $\Delta P_{ab}^\sigma = P_{ab}^\sigma$, $\sigma = \alpha, \beta$, due to the vanishing SAL values of these CBO matrix elements, and $\Delta q_a^\alpha = (\sigma_a + q_a - 2)/2$, due to the identical $q_a^{0,\alpha}$ values. The remaining CBO displacements are $\Delta q_a^\beta = q_a^\beta$ [SAL1], $\Delta q_b^\alpha = q_b^\alpha$, and $\Delta q_b^\beta = q_b^\beta$ [SAL2]. Using these CBO shifts and the valence number expressions of eqs. [7]–[11] and [20] allows one to construct the valence diagrams of Figs. 1 and 2 for nonvanishing valence components plotted as functions

Fig. 2. The valence diagrams of the spin polarization ($\sigma \equiv \sigma_a$) dependent V_{ab}^{cov} (panel (*a*)), $v_{a(b)}^{ion}$ (panel (*b*)), and $V_{a(b)}^{ion}$ (panel (*c*)) indices from the two-orbital model.



of q_a for the assumed values of σ_a. They correspond to the physically and chemically interesting regions of $0 \leq q_a \leq 2$, $0 \leq \sigma_a \leq 1$ (SAL1), and $1 \leq q_a \leq 2$, $0 \leq \sigma_a \leq 1$ (SAL2). The extreme values of σ_a represent spin equalization (as in SAL2 or in the RHF/LDA limit) and total spin polarization (as in SAL1). The valence diagrams in the RHF/LDA limit of $\sigma_a = \sigma_b = 0$ are shown in Fig. 1.

The resulting model expressions for the difference valence indices in the UHF/LSDA theories are ($V_A^{cov} = V_B^{cov} = 0$)

$$[25] \quad V_{ab}^{cov} = \frac{1}{2}\,[q_a(q_a - 2) + \sigma_a^2] \qquad \text{(SAL1 and SAL2)}$$

$$[26] \quad v_a^{ion} = -\frac{1}{2}\left[\frac{1}{2}\,(q_a^2 + \sigma_a^2) - (\sigma_a + q_a) + 1\right] = v_b^{ion} \qquad \text{(SAL1)}$$

$$[27] \quad V_a^{ion} = v_a^{ion} + (q_a - 1)^2/2 = V_b^{ion} \qquad \text{(SAL1)}$$

$$[28] \quad V_{ab}^{ion} = -(q_a - 1)^2 \qquad \text{(SAL1)}$$

$$[29] \quad v_a^{ion} = -\frac{1}{4}\,[(q_a - 2)^2 + \sigma_a^2] = v_b^{ion} \qquad \text{(SAL2)}$$

$$[30] \quad V_a^{ion} = v_a^{ion} + \frac{1}{2}\,(q_a - 2)^2 = V_b^{ion} \qquad \text{(SAL2)}$$

$$[31] \quad V_{ab}^{ion} = -(q_a - 2)q_b \qquad \text{(SAL2)}$$

By putting $\sigma_a = 0$ one obtains the corresponding RHF/LDA expressions plotted in Fig. 1.

Reference to Fig. 1*a* shows that the model single covalent bond in the limit of the RHF orbitals is partitioned into the diatomic covalent part, V_{ab}^{cov}, which reaches its maximum bonding magnitude at $q_a = q_b = 1$ and vanishes for the lone-pair configurations ($q_a = 2$ or $q_b = 2$), and the equal atomic ionic contributions, $v_a^{ion} = v_b^{ion}$, which exhibit the largest bonding effect when both electrons are localized on a single atom. The bonding atomic contribution at $q_a = q_b = 1$ is due to delocalizations of the α-spin electron (A → B) and the β-spin electron (A ← B), from the total spin separation in the SAL1 to the full spin equilibration ($\sigma_a = \sigma_b = 0$) in the RHF/LDA wave function, eq. [18]. Furthermore, eq. [26] shows (see also Fig. 2) that the spin polarization in a molecule ($0 \leq \sigma_a \leq 1$) raises the RHF/LDA V_{ab}^{cov} and v_a^{ion} curves by $\sigma_a^2/2$ and $\sigma_a(2 - \sigma_a)/4$, respectively, thus diminishing the overall bonding valence of the spin-polarized solution by the net shift σ_a. One can clearly see the competition between the ionic and covalent valences of the model for the changing electronic structure, with a loss of bonding measure in one component being exactly compensated by the complementary increase in the bonding character of the other component.

The role of spin delocalization in the model valences becomes clearer when one examines separately the (α, β)-spin components of the UHF/LSDA expressions for $v_a^{ion} = v_b^{ion}$,

$$[32] \quad v_a^{ion} = -\frac{1}{2}\,[(\Delta q_a^{\alpha})^2 + (\Delta q_a^{\beta})^2] \equiv v_{a,\alpha}^{ion} + v_{a,\beta}^{ion}$$

and V_{ab}^{cov},

$$[33] \quad V_{ab}^{cov} = -[(P_{ab}^{\alpha})^2 + (P_{ab}^{\beta})^2] = V_{ab,\alpha}^{cov} + V_{ab,\beta}^{cov}$$

Expressing the above spin-resolved components in terms of the spin delocalization measures, (q_b^{α}, q_a^{β}) for SAL1, and (q_b^{α}, q_b^{β}) for SAL2, gives:

$$[34] \quad v_{a,\alpha}^{ion} = -\frac{1}{2}\,(q_b^{\alpha})^2, \qquad \text{(SAL1)}$$

$$[35] \quad v_{a,\beta}^{ion} = -\frac{1}{8}\,(q_b^{\alpha} + q_b^{\beta})^2, \qquad \text{(SAL1)}$$

$$[36] \quad v_{a,\sigma}^{ion} = -\frac{1}{2}\,(q_b^{\sigma})^2, \qquad \sigma = \alpha, \beta, \qquad \text{(SAL2)}$$

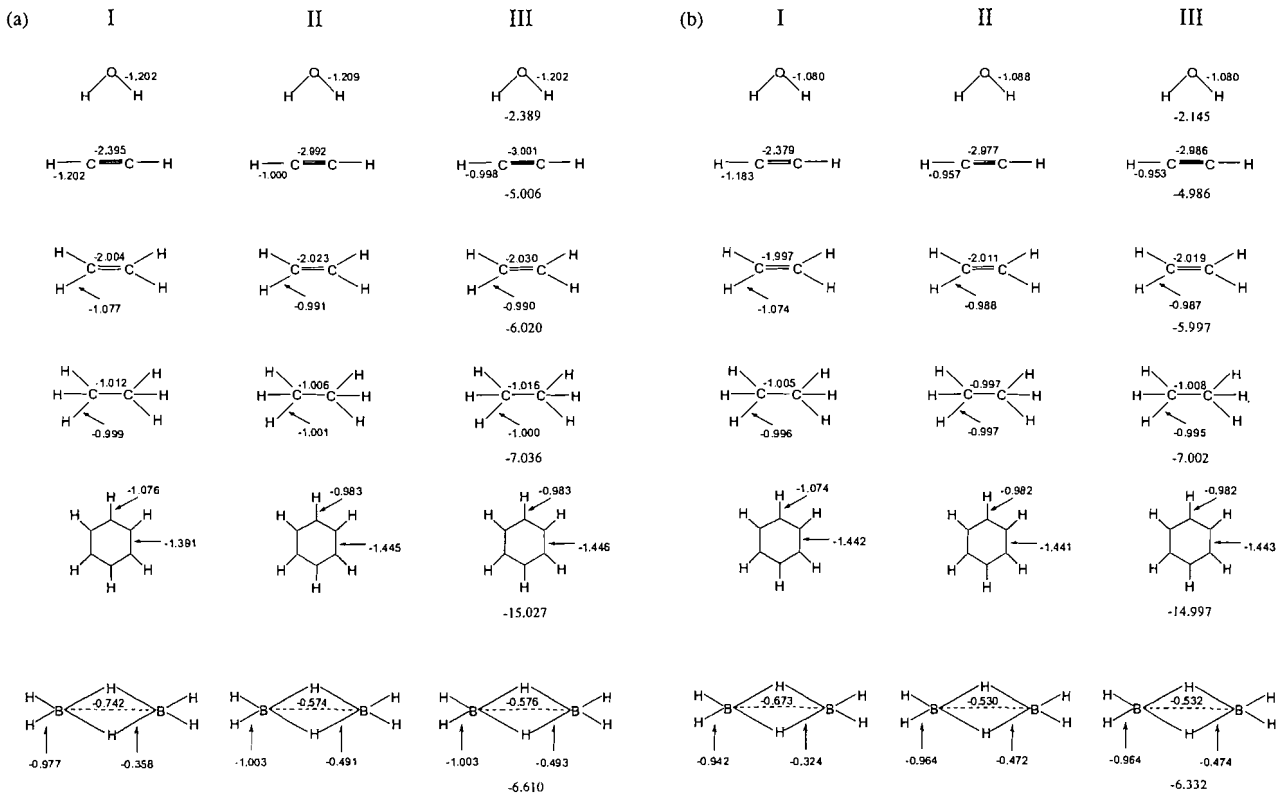
$$[37] \quad V_{a,b\alpha}^{cov} = q_b^{\alpha}(q_b^{\alpha} - 1)^2, \qquad \text{(SAL1 and SAL2)}$$

$$[38] \quad V_{a,b\beta}^{cov} = q_a^{\beta}(q_a^{\beta} - 1), \qquad \text{(SAL1)}$$

$$= q_b^{\beta}(q_b^{\beta} - 1), \qquad \text{(SAL2)}$$

It follows from the above equations that all nonvanishing model valences are explicitly determined by the degree of CT and spin delocalization. It follows from panels in the first column of Fig. 2 that the increase in the spin polarization $\sigma = \sigma_a$ increases all nonvanishing valence contributions (decreases their bonding character).

Fig. 3. A comparison of the predicted bond and overall valences for selected molecules; the overall valence is listed below the molecular diagram in the last column. Panels (*a*) and (*b*) correspond to the UHF indices of eqs. [8]–[11] for the averaged and promoted SAL reference states, respectively; panels (*c*) and (*d*) refer to the UHF indices of eqs. [9] and [11] and the v_A^{ion} index defined by eq. [18], again for the averaged and promoted SAL choices, respectively. The Scheme I (column I) and the weighted partitioning Schemes II and III (columns II and III) are compared to establish the partitioning schemes or reference state choice giving the best agreement with chemical intuition.



Consider now the SAL2 valence diagrams of Fig. 1*b*, exhibiting the same diatomic covalent curve as that in panel *a* of the figure. Here the atomic ionic contributions $v_a^{ion} = v_b^{ion}$ increase their bonding magnitude with increasing A → B *charge transfer* (CT). However, since the SAL2 already corresponds to the equalized spin distribution, $\sigma_a = \sigma_b = 0$, which is preserved within the RHF/LDA approximation, the ionic bonding is solely due to the CT, and therefore must exactly vanish for $q_a = 2$. We would like to point out (see eq. [29] and Fig. 2) that a given nonvanishing spin polarization ($\sigma_a \neq 0$) increases the bonding character of the ionic components; this shift in ionic valence due to spin polarization is exactly cancelled by an accompanying decrease in the bonding magnitude of the covalent component. Therefore, the overall model valence measure with respect to SAL2 remains unaffected by the spin polarization.

We would like to emphasize that the two sets of indices ($V_a^{ion} = V_b^{ion}, V_{ab}^{ion}, V_{ab}^{cov}$) and ($v_a^{ion} = v_b^{ion}, V_{ab}^{cov}$) are fully equivalent, giving rise to the same overall valence: $V = -1 + \sigma_a$ (SAL1) and $V = -q_b$ (SAL2). The first set is linked to changes in the electron pair distribution, while the second monitors molecularly averaged shifts in the CBO matrix structure, relative to the SAL.

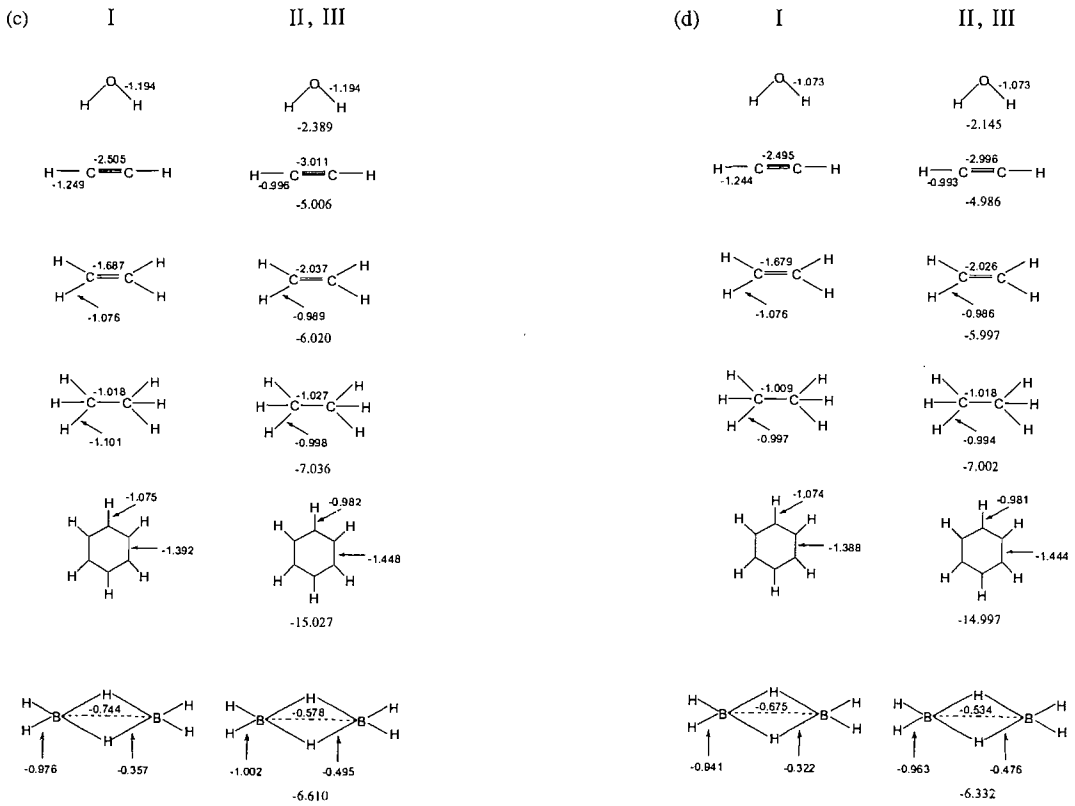
Computational details

The numerical calculations were carried out using the standard GAMESS program (16).[2] STO-6G minimum basis sets were used in the valence calculations for typical molecules reported in Figs. 3 and 4. The remaining systems, including the water and the hydrogen fluoride dimers (Fig. 5), as well as the propellanes (Fig. 6), were studied using the 3-21G basis set (optimized geometries). Löwdin symmetrical orthogonalization was used to determine the molecular and SAL CBO data. Throughout the paper atomic units are used, unless stated otherwise.

Bond valences

In Fig. 3 we compare the predicted overall and bond valences for a set of representative molecules including water, acetylene, ethylene, ethane, benzene, and B_2H_6. The four panels of the figure explore the two SAL options (averaged and promoted) and the two types of ionic indices. Each panel also examines the three partitioning schemes of the atomic valences, denoted by the respective Roman numerals; the weighted Schemes II and III become identical for the new set of three types of indices (eq. [20]), with atomic ionic indices of eq. [18] replacing those defined by eqs. [8] and [10].

[2] See also: General Atomic and Molecular Electronic Structue System GAMESS: user's guide. North Dakota State University, Fargo, N. Dak., and Iowa State University, Ames, Iowa.



The overall negative valences, as already seen in Figs. 3*a* and *b*, are in good agreement with the total number of bonds predicted by chemists. This is particularly so in hydrocarbons, where the ionic interactions contribute less to the molecular bonding pattern. Larger deviations are observed for water and B_2H_6, which exhibit a more pronounced charge polarization. We would like to emphasize that the result for boron hydride correctly predicts roughly one bonding electron pair for each B-H-B bridging bond. A comparison between the respective overall valences reported in panels *a* and *b* (identical to those in panels *c* and *d*, respectively) shows that the average and promoted SAL approaches generate similar overall valence numbers; thus, specific choice of the reference state only weakly affects the predicted overall valences.

The extra total bonding, beyond the chemical intuitive value, may be attributed to the ionic component. Indeed, the largest deviations from the "chemical" values are detected for water and boron hydride; they are reduced in the P-SAL calculations, relative to the averaged atomic reference state scheme.

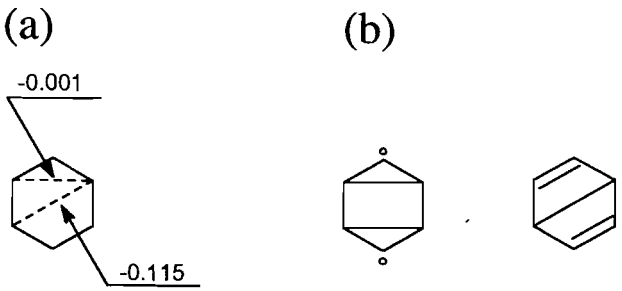
A reference to Fig. 3*a* also shows that predictions from the weighted partitioning schemes of atomic valences are in much better agreement with chemical intuition, particularly in the case of acetylene, in which a carbon atom participates in bonds exhibiting extreme (minimum and maximum) multiplicities. A similar conclusion follows from an examination of both the direct (B—B) and H-bridging bonds in B_2H_6. Namely, the approximately half-bond valence predictions for B—B and B—H (bridge) bonds appear to be closer to chemical expectation. We would like to point out that the boron atomic contributions in Scheme I have been equally divided into four BH contributions, thus assuming the absence of a partial direct B—B bond; the very algorithm of Schemes II and III takes into account all atomic pairs, including also the B–B interactions. In ethane molecule Scheme I works well due to a single character of all bonds involving carbon atoms. In general, the predictions in columns II and III are in good agreement with accepted chemical values, with single bonds being identified by approximately one bonding electron pair, a double bond exhibiting roughly two bonding pairs, and the triple bond originating from practically three bonding electron pairs. The bond order in the intermediate case of the C—C bond in benzene is also correctly reproduced. A slightly higher magnitude of the bond valence in the water molecule may be attributed to a more pronounced ionic component; however, as seen in Fig. 3*b*, it is reduced in the P-SAL case (compare also OH valences in Figs. 3*c*, *d*), so that the value −1.2 is partly due to the SAL averaging procedure. In conclusion, a comparison of Fig. 3*a* unequivocally points towards Schemes II and III as the preferred schemes for chemical applications.

The P-SAL results of Fig. 3*b* (columns II and III) are of comparable quality relative to those reported in panel *a*, thus also indicating a relatively weak dependence upon the selected SAL reference state.

A comparison between numerical values of the bond valences reported in Figs. 3*a*, 3*b* and 3*c*, 3*d*, respectively, shows that the predictions following from the two alternative ionic indices are very similar and basically equivalent for all practical purposes.

An additional test of the present valence indices involves a comparison of the nonbonding valences between the benzene ring carbons (Fig. 4). In all SAL and partitioning options the

Fig. 4. The average nonbonding C_{meta}—C_{meta}, C_{para}—C_{para} bond valences in benzene (*a*) and the relevant valence-bond structures (*b*) that can be used to rationalize the observed differences.



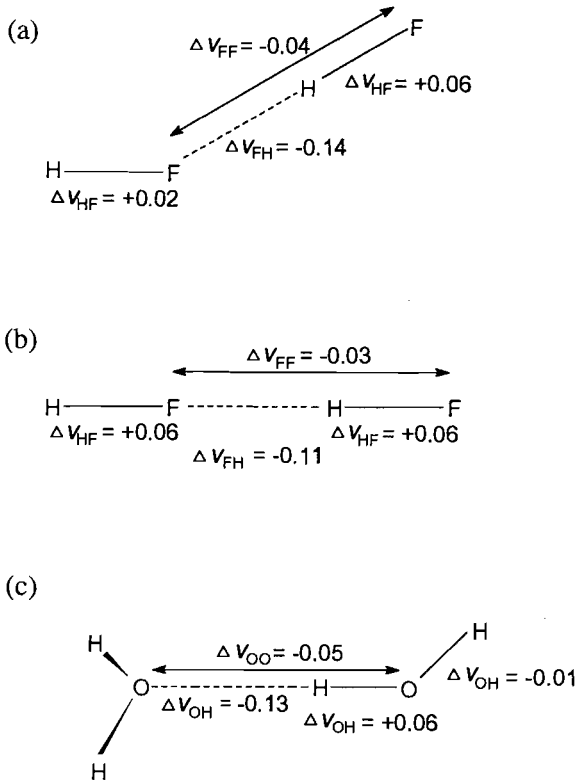
valences between carbons in the mutual *para* positions are much stronger than those predicted for the two carbons in the mutual *meta* positions. This prediction can be rationalized in terms of the relative participation of the valence bond structures shown in Fig. 4. Namely, the *meta–meta* partial bond can be achieved only through the diradical valence structure, in which the π electrons of the two carbons are localized, as in the Wheland intermediate. No such localization is required when one considers the partial *para–para* bond, as in the second covalent structure. Therefore, the diradical configuration is expected to have much higher energy, and thus much lower participation in the ground-state wave function. This explains the observed differences in the cross-ring valences. These preferences are independent of both the SAL and the assumed division of the atomic contributions.

To summarize, we advocate the averaging Schemes II and III for bond valence calculations in general molecular systems, when no a priori information about bonding is available. Scheme I of equally dividing atomic valences, is in fact more subjective than the remaining schemes, since one has to postulate a specific distribution of bonds (without specifying their multiplicity) to use it. In this respect Schemes II and III are totally objective, by not a priori discriminating between any atomic pair in the system under consideration.

We have also examined the prototype hydrogen-bonded dimers of water and hydrogen fluoride, to test how discriminatory are our valence indices in distinguishing between strong chemical and weak hydrogen bonds, respectively. The dimers of hydrogen fluoride in bent (ground state) and linear (hypothetical) arrangements are shown in panels *a* and *b* of Fig. 5; the geometry of the water dimer is shown in Fig. 5*c*. All these structures are UHF 3-21G optimized, with the linear constraint being imposed in the hypothetical model of $(HF)_2$. The figure reports changes in the P-SAL bond valences (Scheme III) obtained from the new valence indices of eq. [20], relative to separated monomers.

The calculated overall valence for the hydrogen fluoride (V[HF] = −1.12) gives the corresponding two separated molecules value V[HF + HF] = −2.23; it can be compared with the corresponding value $V[(HF)_2]$ = −2.34 (bent geometry) and −2.27 (linear geometry). This comparison gives rise to the following values of the relative overall valence measure $\Delta V = V$[dimer] − V[separated monomers]: −0.11 (bent, ground state structure) and −0.03 (linear, displaced structure). These extra valence changes are in qualitative agreement with the corresponding dimerization energies: ΔE = −0.018 66 (bent) and ΔE = −0.015 45 (linear). The relatively small values of the dimerization valence numbers show that present finite-difference indices do indeed discriminate between chemical and hydrogen bonds, predicting bond valences differing by an order of magnitude.

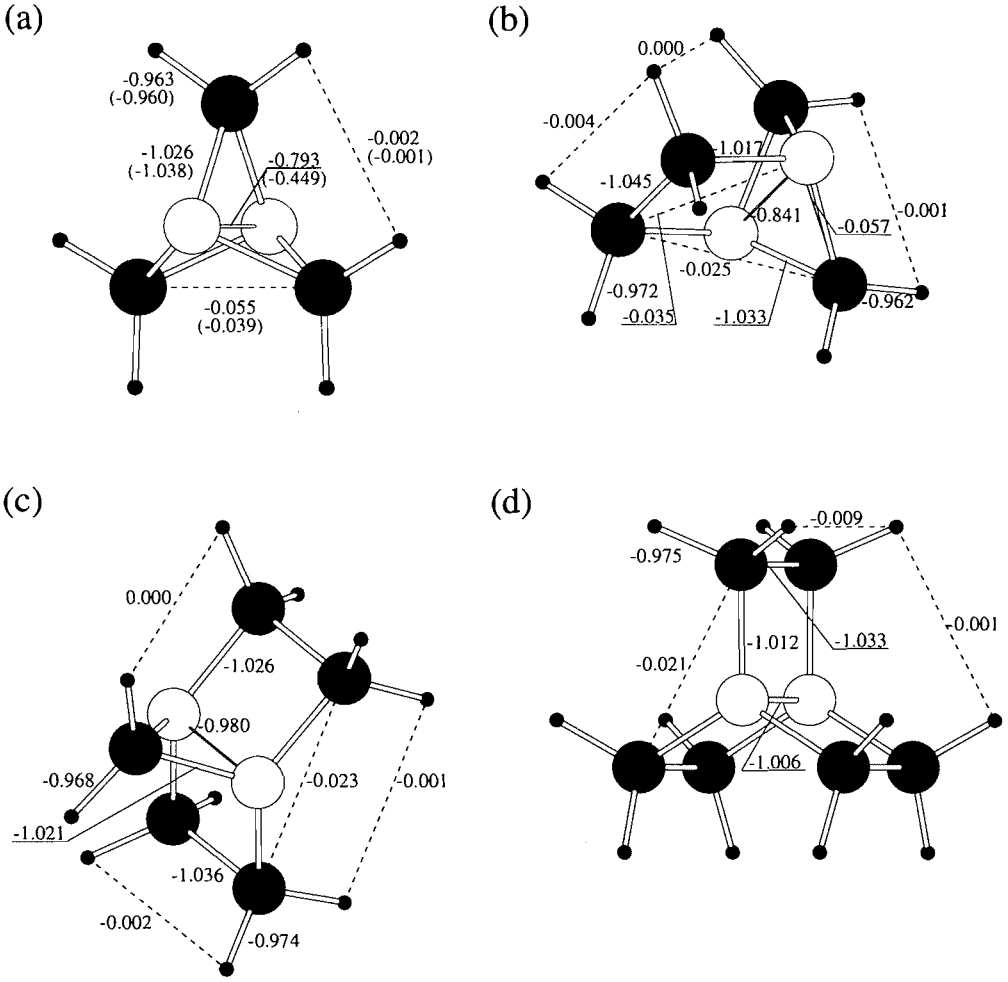
Fig. 5. Changes in the bond valences (P-SAL, Scheme III, ionic valence from eq. [18]) in prototype hydrogen-bonded dimers of HF and H_2O, relative to the separated monomers limit.



As seen in Fig. 5*a*, most of the extra bonding valence in the bent structure comes from the F--H and F--F intermonomer interactions; these are accompanied by asymmetric changes in the bond valences (both decreasing the bond order) within the interacting monomers. These intramonomer changes should be expected, due to the competition effect between the bond being formed and the intramonomer bonds. Namely, the monomer linked by proton to the other molecule is more destabilized than its bonding partner, since hydrogen can participate in the hydrogen bonding only at the expense of the HF bond; the other monomer linked by fluorine to the hydrogen of the other molecule can form a new bond using the lone-pair electrons, thus less affecting its intramonomer bond.

In the linear dimer (Fig. 5*b*) both monomers are seen to have increased their overall valence (decrease of the bond order) by practically the same amount. This is due to the symmetry constraints preventing a use of the lone-pair p_π orbitals of the hydrogen-bond fluorine, in a new bond with the hydrogen of the other monomer. Thus, the new bond and the associated accumulation of the electron density can be

Fig. 6. Calculated bond valences (for calculation specifications see caption to Fig. 5) in [1.1.1]propellane (*a*), [2.1.1]propellane (*b*), [2.2.1]propellane (*c*), and [2.2.2]propellane (*d*). The numbers in parentheses reported in panel (*a*) correspond to 1,3-diborabicyclo[1.1.1]pentane. The bridgehead atoms are shown as open circles.



achieved only by partly weakening both the intramonomer bonds.

Similar conclusions follow from the valence numbers of the water dimer reported in Fig. 5*c*. The dimerization energy, $\Delta E = -0.017\ 48$, is due to the corresponding increase in the magnitude of the dimer overall valence relative to the separated monomers value, $\Delta V = -0.10$. This net extra bonding effect is mainly due to the new bonding valence between the terminal, interacting atoms of both monomers, $\Delta V_b^{(III)}(OH) = -0.13$, the interaction between oxygen atoms, $\Delta V_b^{(III)}(OO) = -0.05$, and a small increase in bonding valence of one of the peripheral OH bonds, accompanied by a more pronounced weakening of the other OH bond of the same monomer. The bonds inside the other monomer are practically unaffected by the hydrogen bond, due to the "buffering" influence of the oxygen lone pairs.

These illustrative applications show that typical hydrogen bonds exhibit bonding valence by an order of magnitude smaller than those corresponding to a single chemical bond, in agreement with chemical intuition.

Propellanes

Theoretical studies on properties of the then hypothetical propellane molecule and related derivatives began 10 years prior to the synthesis of [1.1.1]propellane by Wiberg and Walker (17, 18). Research has also been carried out on propellanes containing boron and heavier elements (Si, P, S, Sn, Ge) in bridge and (or) bridgehead positions (19, 20). The computed length of the C1—C3 bond in [1.1.1]propellane (Fig. 6*a*) is very close to that of typical single carbon–carbon bonds; depending on the method used it varies from 1.65 to 1.54 Å. The C1—C3 bond energy estimated by Feller and Davidson (21) by comparing total energies of [1.1.1]propellane and bicyclo[1.1.1]pentane is about 59 kcal/mol, thus amounting to approximately 70% of the corresponding value for a single C—C bond (~84 kcal/mol). The X-ray crystallographic study by Chackrabarti et al. (22) indicates that there is little deformation density between bridgehead carbons; Jackson and Allen (19) have rationalized this through their σ-bridged-π description of the overall C1—C3 bond in [1.1.1]propellane.

However, as pointed out by Wiberg et al. (23), in reality the charge density between bridgehead carbons is around 80% of that corresponding to the C2—C3 bond in *n*-butane; this density accumulation, due mainly to a superposition of atomic densities, can also produce a partial bond between the bridgehead atoms (central bond). Indeed, the Bader analysis (24; see also ref. 25) of the Laplacian of the molecular density indicates a presence of the bond critical point in the [1.1.1]propellane central region (23).

This short outline indicates that the problem of the central bond in propellane systems constitutes a challenging case for testing the utility of the present difference valence indices. Of interest also is how the nature of the central bond changes with both an increase in the bridge sizes (a series of [1.1.1], [2.1.1], [2.2.1], and [2.2.2]propellanes) and the bridge character (2,4,5-trioxa[1.1.1]propellane). We have also examined a change in the bridgehead atoms (1,3-diborabicyclo[1.1.1]pentane and bicyclo[1.1.1]pentane), in which the central bond should disappear in accordance with chemical expectations.

A comparison between the central bond valences of [1.1.1]propellane and bicyclo[1.1.1]pentane, −0.793 and −0.083, respectively, indeed shows a substantial central bond in the first case and its practical absence in the second system. A reference to Fig. 6*a* shows a substantial reduction (−0.449) of the central bond valence magnitude in the 1,3-dibora[1.1.1]cyclopentane representing the propellane system with more electron-deficient bridgeheads. Finally, the corresponding central bond valence in the 2,4,5-trioxa[1.1.1]propellane assumes an intermediate value, −0.666; at the same time the bridge C—O bond valence is strengthened (−1.081).

A reference to Fig. 6 also shows that an enlargement of the bridges leads to a gradual increase in the magnitude of the bridgehead bond valence: −0.793 ([1.1.1]propellane), −0.841 ([2.1.1]propellane), −0.980 ([2.2.1]propellane), and −1.006 ([2.2.2]propellane). Therefore, in the last two systems one can already talk about the single central bond.

To summarize, our present valence predictions clearly identify at least a partial bond between the bridgehead atoms in all these propellane systems, in qualitative agreement with the previous result from the Bader topological analysis (23–25). The present and previous studies convincingly demonstrate a practical utility of this type of quantum mechanical valence indices in rationalizing the network of bonds in a molecule. It also shows that a lack of appreciable changes in the difference density diagrams, $\Delta\rho$, in the region between the bridgehead atoms is not sufficient to claim the absence of the chemical bond. Our results, previous (11–14) and present, convincingly demonstrate that the present simple functions of the CBO displacements relative to the SAL do indeed carry all the relevant chemical information needed to generate the bonding pattern in any molecular system, including molecules, transition states, catalytic systems, etc. This numerical validation constitutes a good prognosis for future routine applications of this difference approach as an inexpensive tool for chemical interpretations, supplementing standard Hartree–Fock or DFT calculations.

Atomic origins of molecular polarizabilities[1]

Keith E. Laidig

Abstract: We demonstrate that the multipole polarizability tensors of a molecule are expressible as a sum of atomic contributions, each of which is based upon the change in the spatial distribution of electronic charge within each atom resulting from the application of electric fields and field gradients. The use of the spatially defined atoms of subsystem quantum mechanics correctly partitions molecular polarizabilities into physically meaningful atomic contributions. It is shown that the origin of any molecular polarizability tensor may be understood from an investigation of these contributions and the general expressions for the summation of atomic components to yield molecular polarizabilities are presented. Their use is demonstrated by the construction and investigation of the axial components of the dipole–dipole, dipole–quadrupole, and quadrupole–quadrupole polarizability tensors of carbon monoxide and carbon sulfide.

Key words: atomic polarizabilities, atoms-in-molecules, molecular polarizabilities.

Résumé : On démontre que les tenseurs de polarisabilité multipolaire d'une molécule peuvent être exprimés sous la forme d'une somme de contributions atomiques, chacune étant basée sur le changement dans la distribution spatiale de la charge électronique dans chaque atome résultant de l'application de champs électriques et de gradients de champs. L'utilisation d'atomes définis dans l'espace de la mécanique quantique d'un sous-système permet de faire une partition correcte des polarisabilités en contributions atomiques ayant une signification physique. On a montré qu'il est possible de comprendre l'origine de tout tenseur de polarisabilité moléculaire en examinant ces contributions et on présente les expressions générales pour la sommation des composantes atomiques qui conduisent aux polarisabilités moléculaires. On démontre leur utilisation en contruisant et en étudiant les composantes axiales des tenseurs des polarisabilités dipôle–dipôle, dipôle–quadripôle et quadripôle–quadripôle du monoxyde de carbone et du sulfure de carbone.

Mots clés : polarisabilités atomiques, atomes dans des molécules, polarisabilités moléculaires.

Introduction

The significant forces at work during the interaction of two molecules in the "long-range" regime (the distances at which interactions vary as R^{-n}) arise from the interaction of one molecular charge distribution with the electric fields and field gradients produced by the other molecule. This includes electrostatic, inductive, and dispersive interactions (1). The theory of these interactions has been well established and is typically base upon the multipole moments of the molecular charge distribution and the response of these moments to external fields (1). If the external field $\boldsymbol{F}$ is uniform, the dipole moment, μ_α, can be written as a power series in $\boldsymbol{F}$ (2):

$$[1] \qquad \mu_\alpha(\boldsymbol{F}) = \mu_\alpha + \alpha_{\alpha\beta}F_\beta + \tfrac{1}{2}\beta_{\alpha\beta\gamma}F_\beta F\gamma + \tfrac{1}{6}\gamma_{\alpha\beta\gamma\delta}F_\beta F_\gamma F_\delta + \cdots$$

where $\alpha_{\alpha\beta}$ is the linear dipole–dipole polarizability and $\beta_{\alpha\beta\gamma}$ and $\gamma_{\alpha\beta\gamma\delta}$ are the associated quadratic and cubic response tensors, respectively. The latter two terms are also referred to as the first and second hyperpolarizabilities.

The fields generated by an approaching molecule are not uniform, yielding additional distortions of the electronic charge distribution. The dipole moment then also depends on higher order linear polarizabilities that respond to the electric field gradients and field Hessians of the approaching molecule. Expanding μ_α in powers of a non-uniform $\boldsymbol{F}$ yields (2):

$$[2] \qquad \mu_\alpha(\boldsymbol{F}_\beta, \boldsymbol{F}_{\beta\gamma}, \boldsymbol{F}_{\beta\gamma\delta}, \ldots) = \mu_\alpha + \alpha_{\alpha\beta}F_\beta + \tfrac{1}{2}A_{\alpha,\beta\gamma}F_{\beta\gamma} + \tfrac{1}{15}E_{\alpha,\beta\gamma\delta}F_{\beta\gamma\delta} + \cdots$$

where $A_{\alpha\beta,\gamma}$ is the dipole–quadrupole polarizability, $F_{\alpha\beta}$ is the field gradient, etc. Similarly, the quadrupole moment $\Theta_{\alpha\beta}$, is expandable in powers of a non-uniform $\boldsymbol{F}$ as (3)

$$[3] \qquad \Theta_{\alpha\beta}(F_\beta, F_{\beta\gamma}, F_{\beta\gamma\delta}) = \Theta_{\alpha\beta} + A_{\alpha\beta,\gamma}F_\gamma + C_{\alpha\beta,\gamma\delta}F_{\gamma\delta} + \tfrac{1}{15}H_{\alpha\beta,\gamma\delta\epsilon}F_{\gamma\delta\epsilon} + \cdots$$

where $C_{\alpha\beta\gamma\delta}$ is the quadrupole–quadrupole polarizability, and so on.

Aside from their intrinsic interest as the terms which dictate intermolecular interaction, the origins of molecular polarizabilities yield insight into the intramolecular interactions and their change under the influence of external forces and fields. The partitioning of molecular polarizabilities in terms

Received September 28, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

[2] E-mail: laidig@u.washington.edu

of atomic (3–7) and bond (8–11) contributions have been investigated. As part of our continuing development of a general methodology for the construction and representation of molecular charge distributions and their polarizabilities, we have generalized the expression for the spatial partitioning of molecular polarizabilities into atomic and functional group contributions, based upon the atomic partitioning of subspace quantum mechanics. A similar approach has been presented recently in which the dipole polarizability is evaluated by integration of the polarizability density directly and expanding the contributions into spherical harmonics (12). This approach provided results in general agreement with earlier work using finite fields (3). Here we present a general expression for the spatial partitioning of molecular polarizabilities using Cartesian multipole moments and their changes under the application of finite, uniform fields. The general expression of molecular moments and multipole moments has been presented previously and will form the basis of our development (13).

Theoretical overview

The general expression for an arbitrary moment, $\zeta^{(n)}$, of a distribution of charges, when expanded to consider the nuclei and electrons within the distribution, is

$$[4]\qquad \zeta^{(n)}_{\alpha\beta\gamma\ldots\nu} = \sum_{\Omega} Z^{\Omega} X^{\Omega}_{\alpha} X^{\Omega}_{\beta} X^{\Omega}_{\gamma} \ldots X^{\Omega}_{\nu} - \int r_{\alpha} r_{\beta} r_{\gamma} \ldots r_{\nu} \rho(\boldsymbol{r}) d\tau$$

where Z^{Ω} is the charge on nucleus Ω, X^{Ω}_{α} is the α component of the displacement of nucleus Ω from the origin of the property evaluation, r_{α} is the α component of the displacement vector from the origin, and $\rho(\boldsymbol{r})$ is the electronic charge density in electrons per unit volume. The molecular moment may be expressed in terms of atomic contributions by breaking the integration over all space into integrations over the regions of space associated with each atom within the molecule (13), the atom's basin. Effectively, we are substituting $X^{\Omega}_{\alpha} + r^{\Omega}_{\alpha}$ for r_{α}, where r^{Ω}_{α} is the position vector within the atomic basin and a superscript Ω denotes an atomic-based property or position vector. We also use the notation $P(\alpha\beta\gamma\ldots)$ to imply summation over all permutations of the tensor components; thus $P(\alpha\beta\gamma)X_{\alpha\beta\gamma} = X_{\alpha\beta\gamma} + X_{\alpha\gamma\beta} + X_{\beta\gamma\alpha} + X_{\beta\alpha\gamma} + X_{\gamma\alpha\beta} + X_{\gamma\beta\alpha}$.

The general expression for an arbitrary moment then becomes:

$$\begin{aligned}[5]\qquad \zeta^{(n)}_{\alpha\beta\gamma\ldots\nu} = &\sum_{\Omega} \zeta^{(0)}(\Omega) X^{\Omega}_{\alpha} X^{\Omega}_{\beta} X^{\Omega}_{\gamma} \ldots X^{\Omega}_{\nu} \\ &+ P(\alpha)\zeta^{(1)}_{\alpha}(\Omega) X^{\Omega}_{\beta} X^{\Omega}_{\gamma} \ldots X^{\Omega}_{\nu} \\ &+ P(\alpha\beta)\zeta^{(2)}_{\alpha\beta}(\Omega) X^{\Omega}_{\gamma} \ldots X^{\Omega}_{\nu} \\ &+ \ldots P(\alpha\beta\gamma\ldots\mu)\zeta^{(m)}_{\alpha\beta\gamma\ldots\mu}(\Omega) X^{\Omega}_{\nu} + \zeta^{(n)}_{\alpha\beta\gamma\ldots\nu}(\Omega)\end{aligned}$$

where we're used the following definitions for the various atomic moments:

$$[6]\qquad \zeta^{(0)}(\Omega) = q(\Omega) = Z(\Omega) - \int_{\Omega} \rho(r) d\tau$$

$$[7]\qquad \zeta^{(1)}_{\alpha}(\Omega) = M_{\alpha}(\Omega) = Z(\Omega) - \int_{\Omega} r_{\alpha} \rho(r) d\tau$$

$$[8]\qquad \zeta^{(2)}_{\alpha\beta}(\Omega) = Q_{\alpha\beta}(\Omega) = Z(\Omega) - \int_{\Omega} r_{\alpha} r_{\beta} \rho(r) d\tau$$

We've defined $q(\Omega)$ as the atomic charge, M_{α} is the α component of the atomic first moment, $Q_{\alpha\beta}$ is the $\alpha\beta$ component of the atomic second moment, and so on. Each of these atomic, tensoral contributions to the molecular property tensor is based upon the form of the charge distribution within the basin of the atom and the relative location of that atom from the origin. Any molecular moment may be seen as the tensorial summation of these associated atomic contributions, in that each contribution is based upon the distribution of electronic charge within the associated atom and its relation to the molecular origin.

Molecular multipole moments

Multipole moments represent the anisotropic contributions to the molecular moments of a given rank (1). A general expression of the multipole moments of the charge distributions in terms of its atomic contributions is an extension of the development above. The general expression for a multipole moment is

$$[9]\qquad \xi^{(n)}_{\alpha\beta\gamma\ldots\nu} = \frac{(-1)^n}{(n!)} \left\langle \boldsymbol{r}^{(2n+1)} \nabla_{\alpha} \nabla_{\beta} \nabla_{\gamma} \ldots \nabla_{\nu} \frac{1}{\boldsymbol{r}} \right\rangle$$

which when expanded to explicitly express both nuclear and electronic distributions yields

$$[10]\qquad \xi^{(n)}_{\alpha\beta\gamma\ldots\nu} = \frac{(-1)^n}{(n!)} \left[\sum_{\Omega} Z^{\Omega} \boldsymbol{X}^{(2n+1)} \nabla_{\alpha} \nabla_{\beta} \nabla_{\gamma} \ldots \nabla_{\nu} \frac{1}{\boldsymbol{X}} - \int \boldsymbol{r}^{(2n+1)} \nabla_{\alpha} \nabla_{\beta} \nabla_{\gamma} \ldots \nabla_{\nu} \frac{1}{\boldsymbol{r}} \rho(\boldsymbol{r}) d\tau \right]$$

In parallel with the development above, the expansion of this to atomic-based integration yields

$$\begin{aligned}[11]\qquad \xi^{(n)}_{\alpha\beta\gamma\ldots\nu} &= \sum_{\Omega} [\xi^{\Omega(n)}_{\alpha\beta\gamma\ldots\nu}] \\ &= \frac{(-1)^n}{(n!)} \sum_{\Omega} Z^{\Omega} X^{\Omega^{(2n+1)}} \nabla_{\alpha} \nabla_{\beta} \nabla_{\gamma} \ldots \nabla_{\nu} \frac{1}{X^{\Omega}} \\ &\quad - \int (r^{\Omega} + X^{\Omega})^{(2n+1)} \nabla_{\alpha} \nabla_{\beta} \nabla_{\gamma} \ldots \nabla_{\nu} \\ &\quad + \frac{1}{(r^{\Omega} + X^{\Omega})} \rho(r) d\tau\end{aligned}$$

where the scalars are denoted by a lack of subscript. Once the particular moment has been chosen, the expansion may be completed using the procedures discussed in the previous section for the molecular moments by substitution of the various atomic moments, etc. (13). The quadrupole moment is given here in terms of the atomic contributions as an example:

$$\begin{aligned}[12]\qquad \Theta_{\alpha\beta} &= \sum_{\Omega} [\Theta^{\Omega}_{\alpha\beta}] = \tfrac{1}{2} \sum_{\Omega} [3Q^{\Omega}_{\alpha\beta} - Q^{\Omega}_{\gamma\gamma}\delta_{\alpha\beta}] \\ &= \tfrac{1}{2} \sum_{\Omega} 3\{q(\Omega) X^{\Omega}_{\alpha} X^{\Omega}_{\beta} + M_{\alpha}(\Omega) X^{\Omega}_{\beta} \\ &\quad + M_{\beta}(\Omega) X^{\Omega}_{\alpha} + Q_{\alpha\beta}(\Omega)\} \\ &\quad - \{q(\Omega)(X^{\Omega})^2 + 2X^{\Omega}\langle r^{\Omega}\rangle_{\Omega} + \langle (r^{\Omega})^2\rangle_{\Omega}\}\delta_{\alpha\beta}\end{aligned}$$

Molecular multipole polarizabilities

The response of a molecular charge distribution to the electric field or field gradient of another molecule can be conveniently addressed in terms of changes of the molecular multipole moments, yielding the multipole polarizabilities. Following the development of Buckingham (1), we define the multipole polarizability to be the multipole moment induced by unit magnitude of the appropriate uniform field or field gradient. Given this, the dipole–dipole, dipole–quadrupole, and quadrupole–quadrupole polarizabilities may be respectively expressed as

$$[13] \qquad \alpha_{\alpha,\beta} = \frac{\partial \mu_\alpha}{\partial F_\beta}$$

$$[14] \qquad A_{\alpha,\beta\gamma} = \frac{\partial \mu_\alpha}{\partial F_{\beta\gamma}} = A_{\alpha,\beta\gamma} = \frac{\partial \Theta_{\beta\gamma}}{\partial F_\alpha}$$

$$[15] \qquad C_{\alpha\beta,\gamma\delta} = \frac{\partial \Theta_{\alpha\beta}}{\partial F_{\gamma\delta}}$$

where we use comma to distinguish between the molecular moment and the applied field.

If we consider the polarizabilities as arising from the application of a finite field, each of these response tensors may then be generalized into atomic contributions, as outlined above, yielding

$$[16] \qquad \alpha_{\alpha,\beta} = \sum_\Omega [\alpha^\Omega_{\alpha,\beta}] = \frac{\Delta \mu^\Omega_\alpha}{\Delta F_\beta} = \sum_\Omega \left[\frac{\Delta q(\Omega) X^\Omega_\alpha + \Delta M_\alpha(\Omega)}{\Delta F_\beta} \right]$$

$$[17] \qquad A_{\alpha,\beta\gamma} = \sum_\Omega [A^\Omega_{\alpha,\beta\gamma}]$$

$$= \sum_\Omega \left[\frac{\Delta \mu^\Omega_\alpha}{\Delta F_{\beta\gamma}} \right] = \sum_\Omega \left[\frac{\Delta q(\Omega) X^\Omega_\alpha + \Delta M_\alpha(\Omega)}{\Delta F_{\beta\gamma}} \right]$$

$$= A_{\beta\gamma,\alpha} = \sum_\Omega \left[\frac{\Delta \Theta^\Omega_{\beta\gamma}}{\Delta F_\alpha} \right]$$

$$= \frac{1}{2} \sum_\Omega \frac{3\{\Delta q(\Omega) X^\Omega_\beta X^\Omega_\gamma + \Delta M_\beta(\Omega) X^\Omega_\gamma + \Delta M_\gamma(\Omega) X^\Omega_\beta + \Delta Q_{\beta\gamma}\} - \{\Delta q(\Omega)(X^\Omega)^2 + 2X^\Omega \Delta \langle r^\Omega \rangle_\Omega + \Delta \langle (r^\Omega)^2 \rangle_\Omega\} \delta_{\beta\gamma}}{\Delta F_\alpha}$$

$$[18] \qquad C_{\alpha\beta,\gamma\delta} = \sum_\Omega [C^\Omega_{\alpha\beta,\gamma\delta}] = \sum_\Omega \left[\frac{\Delta \Theta^\Omega_{\alpha\beta}}{\Delta F_{\gamma\delta}} \right]$$

$$= \frac{1}{2} \sum_\Omega \frac{3\{\Delta q(\Omega) X^\Omega_\alpha X^\Omega_\beta + \Delta M_\alpha(\Omega) X^\Omega_\beta + \Delta M_\beta(\Omega) X^\Omega_\alpha + \Delta Q_{\alpha\beta}\} - \{\Delta q(\Omega)(X^\Omega)^2 + 2X^\Omega \Delta \langle r^\Omega \rangle_\Omega + \Delta \langle (r^\Omega)^2 \rangle_\Omega\} \delta_{\alpha\beta}}{\Delta F_{\gamma\delta}}$$

Analogously, the general expression of the linear multipole polarizabilities resulting from nonuniform field is

$$[19] \qquad \frac{\partial \xi^{(n)}_{\alpha\beta\gamma\ldots\nu}}{\partial F_{\tau\nu\ldots\omega}} = \sum_\Omega \left[\frac{\Delta \xi^{\Omega(n)}_{\alpha\beta\gamma\ldots\nu}}{\Delta F_{\tau\nu\ldots\omega}} \right]$$

$$= \frac{(-1)^n}{(n!)} \sum_\Omega \frac{Z^\Omega X^{\Omega(2n+1)} \nabla_\alpha \nabla_\beta \nabla_\gamma \ldots \nabla_\nu \frac{1}{X^\Omega} - \int (r^\Omega + X^\Omega)^{(2n+1)} \nabla_\alpha \nabla_\beta \nabla_\gamma \ldots \nabla_\nu \frac{1}{(r^\Omega + X\Omega)} \Delta\rho(r) d\tau}{\Delta F_{\tau\nu\ldots\omega}}$$

The related expression for the partitioning of nonlinear polarizabilities is

$$[20] \qquad \frac{\partial \xi^{(n)}_{\alpha\beta\gamma\ldots\nu}}{\partial F_\tau \partial F_\nu \ldots \partial F_{\bar{\omega}}} = \sum_\Omega \left[\frac{\Delta \xi^{\Omega(n)}_{\alpha\beta\gamma\ldots\nu}}{\Delta F_\tau \Delta F_\nu \ldots \Delta F_{\bar{\omega}}} \right]$$

$$= \frac{(-1)^n}{(n!)} \sum \frac{Z^\Omega X^{\Omega(2n+1)} \nabla_\alpha \nabla_\beta \nabla_\gamma \ldots \nabla_\nu \frac{1}{X^\Omega} - \int (r^\Omega + X^\Omega)^{(2n+1)} \nabla_\alpha \nabla_\beta \nabla_\gamma \ldots \nabla_\nu \frac{1}{(r^\Omega + X^\Omega)} \Delta\rho(r) d\tau}{\Delta F_\tau \Delta F_\nu \ldots \Delta F_{\bar{\omega}}}$$

The application of this later equation to nonlinear contributions to molecular multipole moments is the subject of ongoing work in our laboratory.

Quantum mechanics of open systems

The reader will note that this derivation of atomic decomposition of molecular polarizabilities has not required that the atom to be used arise from a particular theory or model. It requires only that each atom have a distinct, spatial volume and that the partitioning exhaust all space. The general expansion demonstrates that each order of the Taylor's series expansion depends upon the displacement of the lower order terms. This derivation also demonstrates that the simple charge separation model, often used to describe dipole and higher polarizabilities, is only appropriate when the atoms have spherical charge distributions and thus can not be used in a general manner. We propose that any spatial partitioning of molecular polarizabilities must recover these relationships if the regions defined are to be physically meaningful.

Sub-system quantum mechanics, as implemented in the theory of atoms in molecules (14), generalizes quantum mechanics to sub-systems, atoms or groupings of atoms, within a total system. Atoms are open quantum mechanical systems that exchange electronic charge and momenta with other systems that share their bounding surface. The atom is bounded by a surface through which there is zero flux in the gradient vector field of the charge density at each point on the surface:

$$[21] \qquad \nabla\rho(\boldsymbol{r}) \cdot \boldsymbol{n}(\boldsymbol{r}) = 0$$

This boundary condition appears as a constraint in the generalized variation of the quantum action integral and is equally valid for the total system as well as for each atom within the system (14, 15).

The physical observables, their average values, and the theorems that determine the mechanics of a sub-system in a stationary state are produced in analogy to those for the total system (16–18). For each observable, the associated property density, which is the average of the property over the motions of all the particles within the system, is determined at each point in real space. When integrated over the basin of the atom, this yields the atomic average value of the property. In this manner, the properties and mechanics of the atoms, and indeed the total system, are predicted by quantum mechanics (14).

We have chosen to use sub-system quantum mechanics to provide our spatial partitioning because of the quantum mechanical basis of the atoms so defined (19). It has been demonstrated that the populations defined by the theory of atoms in molecules are physical observables (20). This proof may be generalized to show that any moment of the quantum atom is also a physical observable. Similarly, the atomic contributions to a moment are the sum of expectation values multiplied by the associated displacement vectors. The form of the spatial distribution of charge within each atom is used as the basis to describe the spatial distribution of charge within the molecule. The change in the contributions to the molecular properties made by each atom under the stress of internal or external forces is the result of the changes in these physical observables. This provides a procedure that is applicable to studying the change in the charge density, independent of the way in which the density is represented. It is independent of the form of the wave function, orbital sets, localizations of the orbitals, or choice of basis functions and can be used on experimentally determined charge distributions as well. This brings a physical and quantum mechanical basis to the investigation of the origin of the molecular polarizabilities that might be otherwise difficult to uncover.

In addition to being the expectation values of physical observables, the atomic properties predicted by theory enjoy the advantage of transferability between similar systems, as do all the atomic properties predicted using sub-system quantum mechanics (3, 14, 18, 20–22). As the atoms of theory are defined in real space, they represent the physical characteristics of the charge distribution within the space. And, insofar as two atoms are the same, so too are their contributions to molecular properties. This is the physical basis for the success of the presented work and the theory of atoms in molecules in general, namely, that the form of the charge distribution within a region of space determines the contribution of that region to the properties of the molecule. Thus to the degree that the charge distributions in two atomic basins are the same, so too will be their contributions to the physical properties of the molecule. The atoms bounded by surfaces of zero flux in the gradient vector field of the charge density have been shown to be nearly constant in their properties between different systems and that other choices of surfaces for partitioning decrease the constancy of atomic properties between systems (21, 22).

Methodology

Each molecule was optimized using the 6-311++G** basis (23) with the GAMESS (24) and CADPAC5 (25) program packages. The wave functions were produced at the same level of theory using the ANVIL5 properties package (26) and then analyzed using the AIMPAC (27) program suite. The atomic contributions to the molecular energetics for all the molecules are given below and their summation is accurate throughout the series to 0.0005 electrons in population and within 0.3 kcal/mol in total energies.

The molecular polarizabilities were determined analytically using CADPAC5. The atomic properties were determined from individual wave functions by application of finite electric fields and field gradients along the molecular axis (±0.001 au). The atomic contributions were then determined by finite difference in comparison with the unperturbed values. Only a subset of the tensors is presented and discussed, those components associated with application of fields along the molecular axis. Only the dipole–dipole multipole polarizability is origin independent, but for convenience the center of mass is chosen as the origin of property evaluation. In this work it is our intention to focus upon the properties of the molecular polarizabilities predicted using the HF/6-311++G**//HF/6-311++G** wave function rather than try to reproduce the experimentally observed values.

Results and discussion

The atomic coordinates and properties of the molecules, as well as atomic contributions to the molecular moments, are listed in moments, see Table 1 for carbon monoxide (CO) and Table 2 for carbon sulfide (CS). The total electronic charge density of CO and CS is shown in Figs. 1*a* and 2*a*, respectively, and the Laplacian of the charge density for the two is shown in Figs. 1*b* and 2*b*, respectively. The molecular prop-

[a]Atomic sum is the sum of atomic contributions, Molecular value is the independently determined molecular value for the given property. All values are in atomic units.

[b]Z^{Ω} is the atomic coordinate, $N(\Omega)$ is the atomic population, $E(\Omega)$ is the atomic energy, $q(\Omega)$ is the atomic charge, $M_{\alpha}(\Omega)$ is the atomic first moment, $Q_{\alpha\beta}(\Omega)$ is the atomic second moment, μ^{Ω}_{α} is the atomic contribution to the molecular dipole moment, $\Theta^{\Omega}_{\alpha\beta}$ is the atomic contribution to the molecular quadrupole moment.

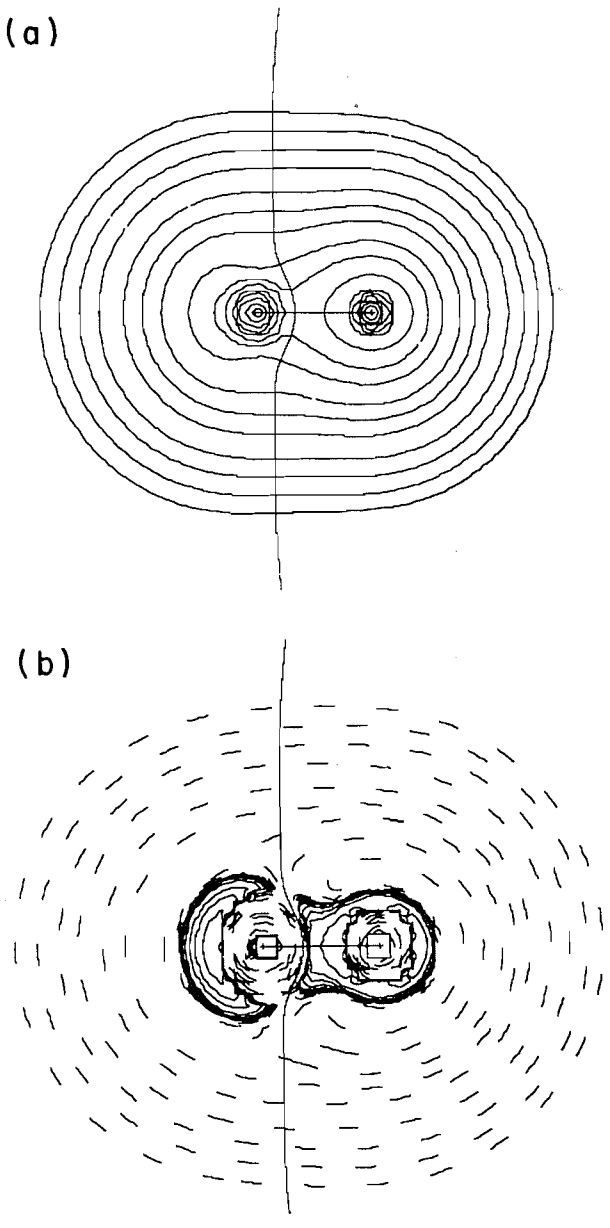
Fig. 1. Contour diagrams of (*a*) the total charge density and (*b*) the Laplacian of the carbon monoxide along the molecular axis. The regions of negative Laplacian (in which charge is locally concentrated) are shown in solid lines and those regions of positive Laplacian (in which charge is locally depleted) are shown in broken lines. The bond path joining the two nuclei and the interatomic surface partitioning the molecule into individual atoms are both overlaid upon the contour diagrams. The outer contour value is 0.2×10^{-3} and they increase as 0.4×10^{-3}, 0.8×10^{-3}, 0.2×10^{-2}, etc.

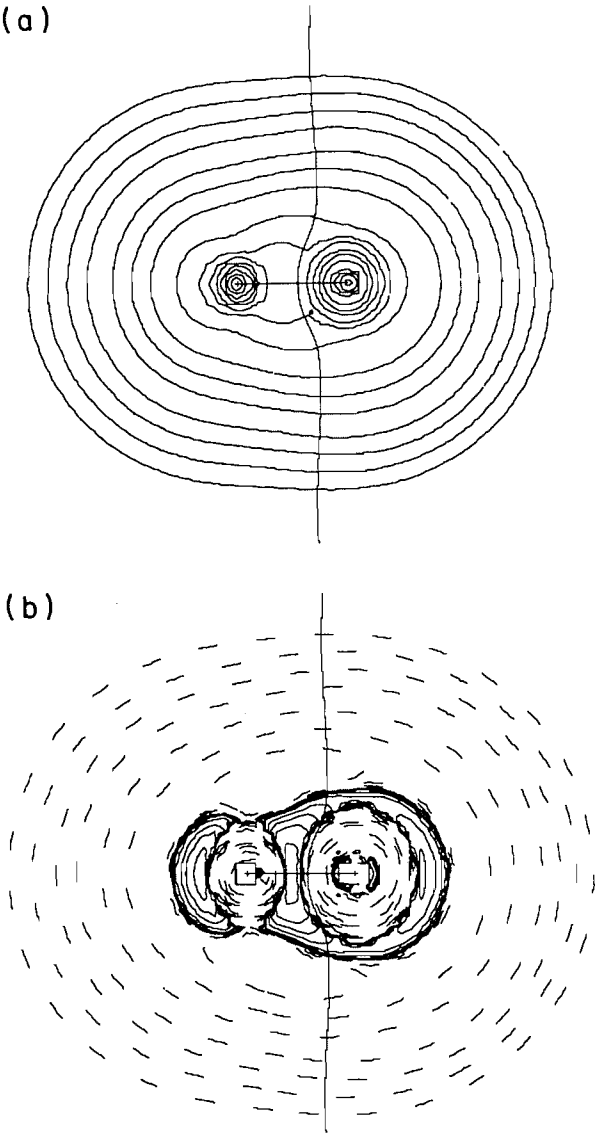


erties are recovered by the summation of atomic contributions to within 2% in general. The molecular polarizabilities are also recovered with summation of the same atomic contributions and their derivatives with respect to applied fields, see Table 3 for CO and Table 4 for CS.

Molecular moments

The origins of the dipole and quadrupole moment of CO and CS have been reported previously (3, 28) and will be briefly reviewed here for clarity. For the dipole moment of CO, the contribution of the transfer of charge from C to the more electronegative O, $q(\Omega)^*X^{\Omega}$, produces a large contribution in the expected direction (recall that the dipole moment, as defined by quantum mechanics, points from the negative "pole" to the positive "pole" (29), opposite to the definition typically used in organic chemistry texts). The nearly

Fig. 2. Contour diagrams of (*a*) the total charge density and (*b*) the Laplacian of the carbon sulfide along the molecular axis. See the caption of Fig. 1.



zero dipole moment is the result of the opposing contribution from the large polarization of the remaining charge on C in the opposite direction of the charge transfer. This polarization of charge on carbon can be seen in the Laplacian of the CO charge distribution, Fig. 1*b*, and is the reason for the nucleophilic character of that carbon atom. In the case of CS, the dipole moment has its largest contributions from the transfer of charge from sulfur to carbon. This is offset by a large polarization of sulfur in opposition to the transfer of charge, but this contribution is only ~50% that of the charge transfer to C. The charge density plot of CS in Fig. 2*a* shows that the interatomic surface is much closer to S than to C, which indicates that C is more electronegative than S.

The quadrupole moment of CO is large and negative, indicating that the molecular charge density is preferentially polarized along the molecular axis and contracted along the orthogonal axes. The large transfer of charge from C to O gives

Table 3. Atomic contributions to molecular polarizabilities of carbon monoxide along molecular axis.[a]

CO	Carbon	Oxygen	Atomic sum[a]	Molecular values[a]
$\alpha_{z,z}$	7.947	6.024	13.970	13.995
ΔCT[b]	3.697	2.774	6.470	
ΔM	4.250	3.250	7.500	
$A_{zz,z}$	−21.994	8.168	−13.826	−13.804
ΔCT	−5.038	2.836	−2.202	
ΔM	−11.584	6.646	−4.938	
ΔQ	−12.686	4.800	−7.886	
ΔI	−43.937	26.511	−17.426	
$A_{z,zz}$	−17.509	3.749	−13.759	−13.804
ΔCT	−2.981	−2.282	−5.263	
ΔM	−14.350	5.850	−8.500	
$C_{zz,zz}$	26.73	7.55	34.286	34.240
ΔCT	1.330	−0.577	0.753	
ΔM	12.087	3.213	15.299	
ΔQ	13.100	0.650	13.750	
ΔI	26.083	−5.247	20.863	

[a]All atoms are in atomic units. The subscript notation reads as follows, $\xi_{\alpha\beta,\gamma\delta}$ is the response of the moment $\xi_{\alpha\beta}$ to the applied field, $F_{\gamma\delta}$. For example, $A_{z,zz}$ is the response of the z component of the dipole moment to the application of a field gradient F_{zz}.

[b]ΔCT is the charge transfer contribution, ΔM is the displacement of first moment contribution, ΔQ is the polarization of the second moment contribution, and ΔI is the change in isotopic terms associated with the atomic quadrupole moment. The total contributions of $A_{zz,z}$ and $C_{zz,zz}$ are summed from the atomic contributions as 1/2*(3*(ΔCT + ΔM + ΔQ) − ΔI).

a large charge transfer contribution from C which deemphasizes the polarization along the molecular axis. But this is not as large as the contribution from the displaced first moment contribution from C, as it polarizes away from O. The contributions from the O atom are primarily the result of the atomic second moment of O. Thus, it is the large first moment contribution of C and the second moment of O that determine the negative quadrupole moment of CO. The quadrupole moment of CS is also negative, but roughly half as large as CO. Here, the transfer of charge is from S to C and this results in a large deemphasizing contribution from S, over twice as large as the emphasizing contribution from C. The dominant contribution to polarization along the molecular axis is from the displaced first moment term of S due to the polarization of S away from the C atom. The second moment of S produces half again as large a contribution to Q^{Ω}_{xx} and Q^{Ω}_{yy} as to Q^{Ω}_{zz}, and this dampens the polarization along the axis.

Molecular dipole–dipole polarizability

The axial component of the dipole–dipole polarizability, α_z, of CO has also been discussed (3). Briefly, the atomic contribution of C is larger than that of O, Table 3, with the polarization of the diffuse charge within C providing the largest atomic contribution and the charge transfer contribution, $q(C)^*X^C$, being the next largest. The more tightly held charge in O provides smaller contributions to the polarizability from both transfer of charge and the polarization of charge under the application of an external field.

Table 4. Atomic contributions to molecular polarizabilities of carbon sulfide along molecular axis.[a]

CS	Carbon	Sulfur	Atomic sum[a]	Molecular values[a]
$\alpha_{z,z}$	14.803	9.680	24.482	24.500
ΔCT[b]	11.003	4.130	15.133	
ΔM	3.800	5.550	9.530	
$A_{zz,z}$	9.070	−1.694	7.569	7.567
ΔCT	4.174	−0.588	3.586	
ΔM	2.883	−1.581	1.303	
ΔQ	6.525	−4.213	2.313	
ΔI	22.608	−15.756	6.852	
$A_{z,zz}$	−18.162	25.744	7.582	7.567
ΔCT	4.638	8.094	12.732	
ΔM	−22.800	17.650	−5.150	
$C_{zz,zz}$	36.699	38.408	75.107	74.996
ΔCT	−1.176	3.580	2.404	
ΔM	11.558	15.612	27.170	
ΔQ	15.267	18.467	33.733	
ΔI	3.549	36.158	39.707	

[a]All values in atomic units. The subscripts notation reads as follows, $\xi_{\alpha\beta,\gamma\delta}$ is the response of the moment $\xi_{\alpha\beta}$ to the applied field, $F_{\chi\delta}$. For example, $A_{z,zz}$ is the response of the z component of the dipole moment to the application of a field gradient F_{zz}.

[b]ΔCT is the charge transfer contribution, ΔM is the displacement of first moment contribution, ΔQ is the polarization of the second moment contribution, and ΔI is the change in isotopic terms associated with the atomic quadrupole moment. The total contributions of $A_{zz,z}$ and $C_{zz,zz}$ are summed from the atomic contributions as 1/2*(3*(ΔCT + ΔM + ΔQ) − ΔI).

The dipole–dipole polarizability of CS, Table 4, is nearly twice that of CO. While this is not surprising, the origin of the difference in polarizability along the molecular axis is. The charge transfer term of C is more than twice the magnitude of the other contributions and dominates the molecular tensor. This reflects the ease with which charge may be pushed onto or taken from the less electronegative S. The polarization contribution of S, while large, is only half the charge transfer term of C.

That charge transfer provides large, often dominant contributions to axial polarizabilities has been observed elsewhere (3, 5). This term is crucial in the axial components of both molecular tensors for CO and CS, and is dominating in the latter. This demonstrates that the atomic polarization, while important in describing molecular polarizabilities, is secondary to the transfer of charge between approximately electroneutral atoms within molecules. This term becomes less important as the system becomes more ionic, as in CO. In the limit of ionic interactions, the charge transfer becomes relatively unimportant and the polarization of charge in the atomic basins becomes the dominant contribution (3). Clearly, this has important implications for the design and implementation of representations of molecules for dynamic simulations. Efforts towards inclusion of polarizability within classical force fields would be advised to take into account the differing atomic and functional group origin of these molecular tensors.

Molecular dipole–quadrupole polarizability

The tensor $A_{\alpha,\beta\gamma}$ describes both the change in the quadrupole moment with applied field and the change in the dipole moment with applied electric field gradient. This "cross-term" provides a useful test of the generality of the atomic partitioning described here, as there are two different ways of yielding the same molecular response tensor. The two pathways provide complementary and consistent information about the response of the molecule to external fields.

The quadrupole moments of the two molecules behave differently under the application of an axial electric field. For CO, Table 3, there is an increase in the axial quadrupole component; the molecule polarizes along the axis and contracts along the orthogonal axes. The increased polarization of the charge transfer contribution, the first moment contribution, and the second moment of C along the molecular axis dictate the molecular polarizability. All three of the oxygen contributions are in opposition to this quadrupolar polarization, making contributions to depolarizations along the molecular axis and polarization along the orthogonal axes. This expansion of the torus of charge around the oxygen atom away from the molecular axis cannot overcome the polarizations along the molecular axis by the diffuse charge on the carbon atom. The molecular quadrupole of CS, in contrast, contracts along the molecular axis and expands along the orthogonal axes. The C atom also dominates $A_{zz,z}$ in CS, Table 4, but here provides large contributions for quadrupolar polarization away from the molecular axis. The largest contributions are the charge transfer and the second moments of C. All the contributions from the S atom provide contributions for polarization along the molecular axis with contractions along the orthogonal axes.

Viewing the same tensor as the change in the molecular dipole with applied electric field gradient yields a complementary picture. In CO, the polarization of the C atom along the molecular axis yields the largest contribution to the molecular value. There is a depolarization of O, the same quadrupolar polarization seen in the application of an electric field, but this is roughly one third the size of the C atom's contribution. For CS we find the large dipole depolarization of S is overcome by the large charge transfer contributions of C. The S atom also contributions a large charge transfer contribution in support of the polarization term of C.

For CO, both ways of looking at the tensors find the quadrupolar polarization of O away from the molecular axis overcome by the polarization of the diffuse charge on C along the molecular axis. This diffuse charge concentration, Fig. 1*b*, dictates the response tensors of this molecule. The case of CS is more general in that no single character of the molecule dictates is response to the differing external fields. When under the application of an electric field, which pushes along the molecular axis, the C atom polarizes away from the direction of force. Inspecting Fig. 2*b*, one sees that the bonding charge density within the C basin adjacent to the interatomic surface is distributed such that an axial field will cause that charge to expand away from the molecular axis. (In contrast, the entire bonding charge concentration between C and O is within the basin of O and it is that atom which shows quadrupolar polarization away from the molecular axis.) In the face of a field gradient, which pushes charge so as to yield a quadrupolar polarization of an isolated atom, there

is a large polarization of C along the molecular axis. But the quadrupolar polarization of the S and the charge transfer contributions of both C and S against the direction of the field gradient overcome the contributions of the polarization of C.

Molecular quadrupole–quadrupole polarizability

The effect of a field gradient upon the quadrupole moment yields the quadrupole–quadrupole polarizability tensor, $C_{zz,zz}$, $C_{zz,zz}$ for CS is twice as large as that for CO, primarily through the difference in behavior of O and S. Both molecules experience quadrupole polarizations away from the molecular axis with application of the field gradient, F_{zz}. In both molecules the contributions of the first and second moments of C are large, as the relatively diffuse charge on the C atom polarizes away from the molecular axis in the direction of the field gradient. The tightly held charge of O yields relatively small quadrupolar polarization contributions in CO, while those of the first and second moment contributions of S dominate the tensor in CS. As expected, the less tightly held charge of S yields large polarization contributions through the first and second moment contributions.

Conclusions

Molecular polarizabilities can be partitioned into atomic contributions, each of which depends upon the change in the distribution of electronic charge within the individual atoms under the application of an external field. Each of the atomic contributions is the result of the change in the moments of the individual atoms and there are no other nonphysical terms that emerge within the formalism. The contributions of each atom are based upon the physical observables of that atom, the charge, the first moment, etc., and their change under the application of external fields.

This approach provides a detailed understanding of the origin of molecular polarizabilities based upon the contributions made by atoms and functional groups. This has important implications in the design and development of representations of molecules for mechanical modeling and dynamic simulations. This method will provide one of the foundations of our general methodology for the construction and representation of very large molecules for use in static and dynamic simulation.

Analysis of molecular polarizabilities and polarizability derivatives in H_2, N_2, F_2, CO, and HF, with the theory of atoms in molecules

Kathleen M. Gough, Margaret M. Yacowar, Richard H. Cleve, and Jason R. Dwyer

Abstract: Ab initio molecular orbital calculations have been performed on the title molecules at the SCF-HF and MP2 levels to obtain molecular polarizabilities and the derivatives associated with bond stretch. The wave functions from these calculations have been analyzed with the theory of atoms in molecules (AIM). Both the polarizability and its derivative are successfully reconstructed from AIM terms representing the transfer of charge between atoms (CT = charge transfer) and the rearrangement of charge within an atomic basin (AD = atomic dipole). The results for the diatomics are compared to each other and to the alkanes studied previously. Equilibrium polarizabilities are qualitatively explained with reference to atomic electronegativity and type of bonding. While derivatives of the mean molecular polarizability differ by a factor of two at most, individual contributions vary by an order of magnitude. The derivatives along the bond axis for H_2 are $\Delta CT = 2.06$ and $\Delta AD = -0.62 \times 10^{-30}$ C m/V, while for N_2 they are $\Delta CT = 13.77$ and $\Delta AD = -10.00 \times 10^{-30}$ C m/V. The common feature observed is that as the induced dipole due to charge transfer increases, the induced dipole due to changes in the atomic dipole also increases and *opposes* it.

Key words: diatomic molecules, molecular polarizability, molecular polarizability derivative, theory of atoms in molecules, ab initio molecular orbital calculations.

Résumé : Afin d'obtenir les polarisabilités moléculaires et les dérivés associées à l'élongation des liaisons, on a effectué des calculs d'orbitales moléculaires ab initio, aux niveaux SCG-HF et MP2, sur les molécules mentionnées dans le titre. On a analysé les fonctions d'onde obtenues à partir de ces calculs à l'aide de la théorie des atomes dans les molécules (ADM). On a pu reconstituer avec succès la polarisabilité ainsi que sa dérivé à partir de termes d'ADM qui représentent le transfert de charge entre les atomes (TC = transfert de charge) et le réarrangement de la charge à l'intérieur du basin atomique (DA = dipôle atomique). On compare les résultats pour les molécules diatomiques entre eux et avec ceux obtenus antérieurement pour les alcanes. On peut expliquer qualitativement les polarisabilités d'équilibre en faisant référence à l'électronégativité atomique et au type de liaison. Les dérivés de la polarisabilité moléculaire moyenne diffèrent, au plus, par un facteur de deux; toutefois, les contributions individuelles varient par un ordre de grandeur. Pour le H_2, les dérivés le long de l'axe de liaison correspondent à $\Delta TC = 2{,}06$ et $\Delta DA = -0{,}62 \times 10^{-30}$ C m/V, alors que, pour le N_2, elles sont égales à $\Delta TC = 13{,}77$ et $\Delta DA = -10{,}00 \times 10^{-30}$ C m/V. La caractéristique commune observée est que, lorsque le dipôle induit dû au transfert de charge augmente, le dipôle induit dû aux changements dans le dipôle atomique augmente aussi et qu'il s'y *oppose*.

Mots clés : molécules diatomiques, polarisabilité moléculaire, derivé de la polarisabilité moléculaire, théorie des atomes dans les molécules, calculs d'orbitales moléculaires ab initio.

[Traduit par la rédaction]

Introduction

Molecular polarizabilities (α) and their derivatives play an important role in many phenomena. We have been investigating structural and conformational dependencies of derivatives of the mean molecular polarizability ($\partial\bar{\alpha}/\partial r$, where $\bar{\alpha} = (1/3)[\alpha_{xx} + \alpha_{yy} + \alpha_{zz}]$) in hydrocarbons: methane, ethane, propane (1*a*,*b*), butane (1*a*), cyclohexane (1*c*), pentane (1*d*), ethene and ethyne (2), and the methyl halides (CH_3X, X = F, Cl, Br) (3*a*,*b*). The experimental values of the derivatives are obtained from absolute intensity measurements in gas phase Raman spectra, while theoretical values are obtained from ab initio SCF-HF molecular orbital (MO) calculations. Further insight into the nature of the derivatives is obtained by analyzing the resulting wave functions with the theory of atoms in molecules (AIM), introduced by Richard Bader (4, 5). With the AIM analysis, we are able to examine the charge redistribution which constitutes both α and $\partial\bar{\alpha}/\partial r$. Several interesting trends have been discovered that throw serious doubt on the reliability of the bond polarizability model, conventionally used as a means of interpreting Raman scattering intensities (1–3).

Received November 3, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

There is little experimental information available for molecules larger than methane and, even for small molecules, the theoretical data far outnumber the experimental. In an endeavor to broaden the scope of our study, we have now undertaken a theoretical analysis of five diatomic molecules: H_2, F_2, HF, N_2, and CO. The data on their equilibrium molecular polarizabilities have been well characterized experimentally (6–11) and theoretically (12–23); reasonable basis sets exist for the MO calculations; some data on $\partial\alpha/\partial r$ exist for all five molecules (24–30); and, finally, they embody an interesting range and variety of fundamental characteristics. The equilibrium values of α have already been examined to some extent with AIM (1*a*, 18) with slightly smaller basis sets than those employed in the present work. A study of the distributed atom–atom multipolar polarizability of CO has been reported recently (13) and our equilibrium results are quite similar. Our intent here is to reconsider α, with particular emphasis on a comparison between the equilibrium polarizabilities and the derivatives.

Computational method

Choice of basis set

For accurate calculations of the electronic properties, the basis set must be large and well polarized (12–23). Computational limitations in our previous work (1–3) on small alkanes necessitated the use of a relatively small basis: D95**, the Dunning (31) contraction of the Huzinaga (32) basis set (9*s*5*p*1*d*)/[4*s*2*p*1*d*]. With the diatomics, size and speed of computation presented less of an obstacle, and a new larger basis was sought. A recent article (12) has outlined some guidelines for basis set design and provided an extensive survey of the literature for, among others, H_2 and HF.

We calculated α with a number of published basis sets and selected the polarized set developed by Sadlej (23) specifically for the calculation of electronic properties. Our calculations were performed prior to the publication of the work of Papadopoulos et al. (12); however, we note that this basis set yields values for α that are about as good as theirs, at the SCF-HF level. A useful criterion (19) for the quality of the basis set is the magnitude of $\Delta\alpha = \alpha_{//} - \alpha_{\perp}$ where, for a linear molecule, $\alpha_{xx} = \alpha_{yy} = \alpha_{\perp}$ and $\alpha_{zz} = \alpha_{//}$. A poorly polarized basis set may lead to an apparently good value for $\bar{\alpha}$, due to overestimation of $\alpha_{//}$ and underestimation of $\alpha_{\perp}$. Our choice was based on the energy of the molecule and the magnitudes of both α and $\Delta\alpha$; however, we did not examine higher order properties, which would provide further criteria for assessment.

Electron correlation

Depending on the molecule, electron correlation may have considerable influence on higher order moments. For comparison, our calculations were repeated at the MP2 level, both at the optimized geometries from the SCF-HF calculations and at geometries reoptimized for the MP2 level. It is unfortunate that the version of code for AIM theory currently available (33) does not accommodate electron correlation contributions, restricting the analysis to the SCF-HF wave functions. While this introduces greater uncertainty into the absolute values calculated below, the results provide interesting and useful qualitative information.

Calculation of α and $\partial\bar{\alpha}/\partial r$ through AIM

All MO calculations were performed with Gaussian 90 (34). Geometry optimization preceded the calculation of any electronic properties. The dipole (or linear) polarizability was calculated analytically through the coupled perturbed Hartree–Fock theory implemented in the Gaussian 90 program. Values of the derivatives could be obtained analytically; however, it was our intent to examine both the polarizability and the derivative within the context of the AIM theory. To do this, we require the wave functions for the molecule both in the presence and absence of an electric field (to determine α) and at equilibrium and stretched or compressed bond lengths (to determine $\partial\bar{\alpha}/\partial r$). The procedure followed was the same as that described in earlier work (1*a*–*d*), and we present only a brief synopsis.

The wave functions were obtained from the Gaussian read-write file and analyzed with the AIMPAC suite of programs (33). The AIM theory provides a method for defining the volume of the electronic charge distribution associated with each nucleus in a molecule (5). It has been shown (5) that all properties that may be calculated for the molecule (e.g., electron population, dipole moment, etc.) may be calculated for an atomic basin. Molecular properties are found as the sum of the atomic contributions. The parameters of interest here are (*i*) the atomic electron population: the total number of electrons found within an atomic basin, and (*ii*) the atomic dipole moment: the way in which that charge is distributed throughout the atomic basin.

Molecular polarizability is the measure of the ease with which the charge in a molecule may be displaced in response to an external electric field. The contribution of atom Ω to the ijth element of the molecular polarizability tensor may be written as:

$$[1]\quad \alpha_{ij,\Omega} = \underbrace{\frac{[-(N_i - N_0)]\cdot r_{j,\Omega}}{\mathscr{E}_i}}_{\text{charge transfer}} + \underbrace{\frac{(\mu_{ij} - \mu_{0j})_\Omega}{\mathscr{E}_i}}_{\text{atomic dipole}}$$

where i denotes the direction of the applied field, while 0 implies zero field. The first term represents the charge transferred into or out of the atomic basin due to the applied field; the second term, the change in atomic first moment ($\Delta\mu$). N_i and N_0 are the atomic electron populations for the given fields, r_j is the position on the jth axis, for atom Ω. For the molecules studied here, the internuclear bond is directed along the z-axis, producing a diagonal polarizability tensor, with $\alpha_{xx} = \alpha_{yy} < \alpha_{zz}$.

From calculations of α at the optimized geometry ($r = r_e$) and at $r_e \pm 0.005$, ± 0.010, and ± 0.020 Å, it was verified that the polarizability was changing linearly, to within the precision reported. The derivative is calculated from the numerical difference ($\Delta\alpha_{ij}$) between the polarizability at the equilibrium geometry and that for a geometry in which the nuclei have been displaced by 0.010 Å, divided by the magnitude of the displacement:

$$[2]\quad \partial\alpha_{ij}/\partial r \approx \Delta\alpha_{ij}/\Delta r$$

All AIMPAC calculations were performed at the limits of accuracy possible with the current versions of the code.

Experimental data

Molecular polarizabilities have been measured by a variety of methods (6–11). Polarizability derivatives are obtained from absolute scattering cross sections in Raman spectra (24–27). The $\partial\bar{\alpha}/\partial r$ values require separate measurement of isotropic (or trace) and anisotropic scattering intensities, which in turn require measurement of the differences in the parallel ($I_{//}$) and perpendicular ($I_{\perp}$) components of the Raman scattered light:

[3] $$I_{//} \propto 45(\partial\bar{\alpha}/\partial r)^2 + 4(\partial\gamma/\partial r)^2$$

[4] $$I_{\perp} \propto 3(\partial\gamma/\partial r)^2$$

The anisotropic scattering, $(\partial\gamma/\partial r)$, is more difficult to measure experimentally and the calculation is subject to a greater relative error (1*a–d*, 2), hence our decision to examine only $(\partial\bar{\alpha}/\partial r)$.

Results and discussion

Molecular polarizability

There are three sets of α and $\partial\bar{\alpha}/\partial r$ to be considered: (*a*) experimental values, (*b*) those obtained analytically from the MO program, and (*c*) those constructed from the AIM analysis of the MO wave functions. The latter two should be identical. The degree to which the AIM results recover the analytical values is a measure of the completeness of the integrations over the atomic basins. Since the change in α due to these small displacements is only 1–3% of the equilibrium value, any meaningful analysis of the AIM data on the derivatives can take place only if the recovery of α at each point is better than 99.5%.

The molecular polarizabilities from SCF-HF and MP2 calculations from the AIM analysis of the SCF-HF wave functions for the five molecules are listed in Table 1. Experimental values and selected calculated values from the literature are presented for comparison.

The SCF values obtained with Sadlej's basis set are of comparable quality to those of other calculations at this level. Small differences arise from our use of optimized rather than experimental bond lengths. Overall, the SCF results are quite reasonable, as is the anisotropy ($\alpha_{//} - \alpha_{\perp}$), which is best for H_2 and N_2, and poorest for HF.

Our MP2 results are reported for the bond lengths obtained by reoptimization at this level. All bond lengths are slightly longer, and this alone accounts for about half of the difference between the SCF and MP2 values. As has been noted by others (12), it is clear that the polarizability of H_2 is little altered by the inclusion of electron correlation. N_2 is only changed by about 5%, and CO slightly more; however, electron correlation significantly changes the calculated polarizability for F_2

Table 2. Experimental (references as noted) and calculated values of the derivative of the mean molecular polarizability ($\partial\bar{\alpha}/\partial r$), in units of 10^{-30} C m/V.

Molecule	SCF	SCF-AIM	MP2	Expt.	Ref. no.

Table 3. Breakdown of molecular polarizability and polarizability derivatives in terms of charge transfer and atomic dipole contributions (units: α: 10^{-40} C m^2/V; $\partial\bar{\alpha}/\partial r$: 10^{-30} C m/V).

Molecule	Charge transfer		Atomic dipole		Total	
: property	⊥	//	⊥	//	⊥	//
H_2: α	0	1.058	0.741	0.054	0.741	1.112
$\partial\bar{\alpha}/\partial r$	0	2.86	1.17	−0.62	1.17	2.25
N_2: α	0	1.527	1.558	0.869	1.558	2.396
$\partial\bar{\alpha}/\partial r$	0	13.77	1.45	−10.00	1.45	3.77
F_2: α	0	1.484	0.892	0.533	0.892	2.017
$\partial\bar{\alpha}/\partial r$	0	4.65	0.24	−0.25	0.24	4.40
CO: α	0	1.042	1.814	1.302	1.814	2.344
$\partial\bar{\alpha}/\partial r$	0	2.59	1.02	0.89	1.02	3.48
HF: α	0	0.408	0.716	0.513	0.716	0.921

and HF (10–20%). Any AIM analysis of the polarizability must be considered as less reliable for the latter two compounds.

There is little experimental data available on the polarizability derivatives, particularly the $\partial\bar{\alpha}/\partial r$ values calculated in this work. The best data are presented in Table 2 along with our values calculated at SCF and MP2 levels of theory, and those recovered by the AIM analysis of the SCF wave functions. The error estimates in the experimental data are about 5%. Once again, the results for F_2 and HF are most affected by electron correlation.

In all cases, the AIM analysis enables us to reconstruct the equilibrium molecular polarizability to the level of accuracy required for valid interpretation. For HF, the recovery of non-equilibrium polarizabilities, required for the derivative, was only 98–99%, and interpretation of the AIM derivative data was not considered to be warranted.

AIM analysis of α and $\partial\bar{\alpha}/\partial r$

The breakdown of the polarizability and the polarizability derivatives in terms of charge transfer and atomic dipole components, as given in eq. [1], is presented in Table 3. Both the charge transfer and the atomic dipole contributions to the equilibrium polarizability are positive. This initially appears to be in direct contrast to the situation found with the alkanes, but in fact is not surprising.

In the alkanes, the principal contributions to the molecular polarizability were found to be a large *positive* contribution from charge transfer between the (exterior) hydrogens, a small *positive* contribution from their induced atomic dipoles, and a large *negative* contribution from the atomic dipole of the (interior) carbon atoms. Essentially, the alkanes behave as small units of dielectric material. The presence of an external field causes a surface charge polarization to appear (field-induced charge transfer between exterior atoms) that is balanced in part by the response of the internal atoms to the local external field (field-induced changes in atomic dipole moments). Diatomic molecules exhibit only the positive charge transfer and atomic dipole contributions of exterior atoms.

The $\partial\bar{\alpha}/\partial r$ of H_2 is less than half that of N_2, yet at its equilibrium geometry H_2 exhibits the largest // charge transfer. In contrast, the ⊥ atomic dipole contribution is quite small and

the // atomic dipole contribution is almost negligible. The ⊥ contribution to the polarizability is greatest in N_2 and CO, which are triply and doubly bonded, respectively.

It is interesting to note that while SCF-HF calculations produce a molecular dipole for CO that is opposite to that observed experimentally (35), the molecular polarizability is of reasonable magnitude and sign, as is the derivative. The problem with the dipole moment rests in part with its small size, where a small error in calculated value can result in a sign change. Electron correlation is required to obtain the correct dipole moment (35) but makes a change of only 6% in the derivative. Thus while there is some error in the assignment of the electrons to the nuclei, the shift in electron population in response to an applied field is as expected.

The // charge transfer contribution to the polarizability derivative for H_2 is about 2.9×10^{-30} C m/V and is opposed by a // atomic dipole contribution of about -0.6×10^{-30} C m/V, while the corresponding terms in N_2 are $+13.8 \times 10^{-30}$ and -10.0×10^{-30} C m/V. This is not unlike the behavior found in the alkanes when a CH bond is stretched, in that increases in charge transfer between carbon atoms are generally offset by decreases in the atomic dipoles on the attached hydrogen atoms. However, the similarity is only qualitative. The relative magnitudes of the terms are surprisingly different.

The polarizability derivatives of the diatomics studied here exhibit some general similarities. In all cases, $\bar{\alpha}$ of a molecule increases as the bond is stretched. This arises from an increase in the amount of charge transferred between atoms for a field applied along the bond axis, and an increase in the induced atomic dipoles for a field applied perpendicular to the bond. However, as the amount of charge transfer increases, so too does the induced atomic dipole opposing the charge transfer. Thus the net results are quite similar, despite differences of an order of magnitude in individual terms.

On comparing the homonuclear diatomics, it may be noted that F_2, the most electronegative element with the smallest molecular polarizability, exhibits the smallest tendency to both charge transfer and atomic dipole rearrangement, whether at equilibrium or during the stretching vibration. The only exception is the derivative of the parallel charge transfer contribution, which is about double that in H_2. The derivative (Table 2) is calculated to be the smallest of the four analyzed with AIM. In this, it is similar to HF, where the equilibrium polarizability is found to be quite small and the SCF and MP2 values for the derivative are also small, in agreement with the experimental results. The derivative for F_2 decreases by 30% when electron correlation is included, thus any SCF-HF data should not be overinterpreted. The qualitative results are as expected for this molecule.

Conclusions

The theory of atoms in molecules is found to provide interesting insights into the nature of molecular polarizability and the polarizability derivative. The dipole induced in a molecule by the presence of an external field has been broken down into a dipole contribution due to charge transfer between atomic basins and a contribution due to reorientation of charge within an atomic basin. The polarizability of diatomic molecules is similar to that of the alkanes studied previously, in that, as exterior atoms, both the charge transfer and atomic dipole contributions are positive. Variations in the magnitude of the individual terms may be rationalized in light of the electronegativity of individual atoms and the number of bonds (single, double, or triple). The mean molecular polarizability derivatives differ at most by a factor of two, but individual changes in both charge transfer and atomic dipole terms differ by an order of magnitude. In general, an increase in the charge transfer along a stretched bond is offset, at least in part, by an increase in the atomic dipole *opposing* that of the charge transfer. These findings are quite intriguing, and illustrate the usefulness of the theory of atoms in molecules as a probe of molecular electronic behavior. A most desirable extension to the AIMPAC suite of programs would be the capacity to perform calculations on wave functions that include electron correlation effects.

Acknowledgments

K.M.G. is happy to express her gratitude to Professor Richard Bader, for the two stimulating and enjoyable years she spent as an NSERC post-doctoral fellow in his research group (1987–1989), and for the cordial friendship and assistance which he has offered ever since. R.H.C. is grateful to the Natural Sciences and Engineering Research Council of Canada for an undergraduate summer research award (1994). This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada.

Charge density in crystalline citrinin from X-ray diffraction at 19 K

Pietro Roversi, Mario Barzaghi, Felicita Merati, and Riccardo Destro

Abstract: For the fungal metabolite citrinin, $C_{13}H_{14}O_5$, the total experimental electron distribution $\rho(\boldsymbol{r})$ and its Laplacian $\nabla^2\rho(\boldsymbol{r})$ have been obtained from an extensive set (36 564 measurements) of single-crystal X-ray diffracted intensities at a temperature of 19 ± 2 K. Relevant steps in data collection and processing are reported. The resulting 7698 independent intensity data have been analysed with a multipole (pseudoatoms) formalism. The topological properties of $\rho(\boldsymbol{r})$ have been determined according to the quantum theory of atoms in molecules. CC and CO bond path lengths have been obtained by numerical integration; their values are found to be well correlated with those of the electron density at the bond critical points. Topological features have been used to characterize the extension of the conjugated system of the molecule, and to confirm the stability of its rings, particularly the two formed by intramolecular H bonds. Maps of $\nabla^2\rho(\boldsymbol{r})$ are presented, showing details in the valence charge distribution and providing a very sensitive tool for analysing dependence of the density on the model adopted to interpret X-ray data. The known chemical reactivity of the molecule towards nucleophiles at a Csp^2 atom is confirmed by the shape of the molecular reactive surface (the zero envelope of $\nabla^2\rho(\boldsymbol{r})$).

Key words: experimental electron density, low-temperature X-ray diffraction, topological analysis, Laplacian of ρ.

Résumé : En se basant sur un ensemble extensif (36 564 mesures) d'intensités de diffraction des rayons X par un cristal unique obtenues à une température de 19 ± 2 K, on a obtenu la distribution expérimentale totale, $\rho(\boldsymbol{r})$, ainsi que son laplacien, $\nabla^2\rho(\boldsymbol{r})$, pour le métabolite de champignon citrinine, $C_{13}H_{14}O_5$. On a ensuite analysé les 7698 données indépendantes d'intensité à l'aide du formalisme multipôle (pseudoatomes). On a déterminé les propriétés topologiques de $\rho(\boldsymbol{r})$ suivant la théorie quantique des atomes dans les molécules. On a déterminé les longueurs des liaisons CC et CO par leur intégration numérique; on a trouvé que leurs valeurs donnent une bonne corrélation avec celles obtenues à partir de la densité électronique des points critiques de liaison. On a utilisé des caractéristiques topologiques pour caractériser l'extension du système conjugué de la molécule et pour confirmer la stabilité de ses noyaux, particulièrement les deux formés par les liaisons hydrogènes intramoléculaires. On présente des cartes de $\nabla^2\rho(\boldsymbol{r})$ qui montrent les détails de la distribution de charge de valence et qui fournissent un outil très sensible pour analyser la dépendance de la densité sur le modèle adopté pour interpréter les données de diffraction des rayons X. En se basant sur la forme de la surface moléculaire réactive (l'enveloppe zéro du $\nabla^2\rho(\boldsymbol{r})$), on a confirmé la réactivité connue de la molécule vis-à-vis des nucléophiles au niveau d'un atome de carbone sp^2.

Mots clés : densité électronique expérimentale, diffraction des rayons X à basse température, diffraction, analyse topologique, laplacien de ρ.

[Traduit par la rédaction]

Introduction

This paper reports the results of a topological study of the *total experimental* charge distribution $\rho(\boldsymbol{r})$ in a medium-size molecule. In particular, the following features of Bader's quantum theory of atoms in molecules, QTAM (1), are explored: (*i*) number and nature of critical points (cp's); (*ii*) values (ρ_b) of the electron density at the bond critical points, and its curvatures (λ's) and Laplacian ($\nabla^2\rho_b$); (*iii*) correlations between ρ_b values and bond path lengths; and (*iv*) topology of rings and ring stability. A brief description is also given of the dependence of some topological features on the model adopted to interpret the X-ray diffraction data. Finally, the relationship between chemical reactivity — in the present case a nucleophilic attack at a C sp^2 atom — and $\nabla^2\rho(\boldsymbol{r})$ is discussed.

We are well aware of the remark (2) that a density obtained from X-ray diffraction data by a multipolar fit is not a pure quantum object, hence differs from the proper quantity dealt with in Bader's theory. However, the topological analysis of such a density can afford very useful information about the ground state of the system under study, provided that all configurations spanned by the nuclei in thermal motion within the crystal belong to the same crystalline structure around equilibrium, so that the corresponding densities all possess equivalent molecular graphs. In other words, if the nuclei do not reach unstable points in configuration space, the network of

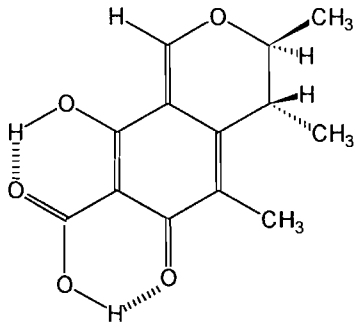
Scheme 1.



bond paths defining the crystal structure remains unique (1, 3), and the topology of the vibrationally averaged density can be safely assumed to be equivalent, in terms of number and type of cp's, to the one at the equilibrium geometry.

For the quantities used in the topological analysis of $\rho(\boldsymbol{r})$ we have adopted the definitions recently summarized by Bader (4). Numerous applications of the same concepts to the study of experimental electron densities in crystals have already appeared in the literature, e.g., in the case of urea, imidazole, 9-methyladenine, and benzene (2), L-alanine (5), 2-methyl-4-nitroaniline (6), 1-methyluracil (7), molecular chlorine (8), danburite (a borosilicate) (9), *syn*-1,6:8,13-biscarbonyl-[14]annulene (10), and metallic beryllium (11).

To reduce the chances that artifacts, rather than genuine features, be described by the topological analysis of $\rho(\boldsymbol{r})$, extensive sets of high-quality X-ray data are essential. This implies that diffracted intensities must be measured and processed with great and special care. For this reason, we devote part of the paper to a detailed description of some crucial steps of data acquisition and treatment.

As reported below, our X-ray measurements have been performed at temperatures of 17–20 K; an average temperature of 19 K can therefore reasonably be assumed as that of the whole experiment. The great advantages, especially for a detailed structural analysis of organic molecular crystals, of data collection with closed-cycle helium refrigerators, hence at temperatures below 30 K, have been recently discussed (12).

Citrinin (Scheme 1) appears particularly well suited for a study of the electron distribution: the molecule contains a variety of CC and CO bonds, two fused six-membered rings, each formed by six covalent bonds, and two rings of different type, where one of the sides is a rather short, intramolecular hydrogen bond. It has been shown (13) that at room temperature a tautomeric equilibrium occurs in crystals of citrinin, and that at 147 K only one of the two tautomers can be detected by X-ray diffraction experiments. Based on those data, on measurements at 240 K, and on a partial set of intensities diffracted at 20 K, the thermodynamic parameters of the tautomeric equilibrium have been evaluated (14): the presence of structural disorder at 17–20 K, the temperatures of the experiments described in this paper, can be unquestionably excluded.[3]

[3] Very recent results (R. Poupko, Z. Luz, and R. Destro, submitted for publication) of a solid state NMR study have fully confirmed the thermodynamic parameters obtained by X-ray studies alone (14).

Table 1. Crystal data and details of data collection for citrinin at 19 K.

Formula	$C_{13}H_{14}O_5$
M_r	250.25
Space group	Orthorhombic $P2_12_12_1$
Z	4
D_{calcd}(g cm^{-3})	1.428
a (Å)	13.2552(11)
b (Å)	7.2377(7)
c (Å)	12.1360(21)
V (Å^3)	1164.29(25)
Diffractometer	Syntex $P\bar{1}$
Radiation	MoK_α (graphite monochromated)
Scan range (2θ, deg)	2.4 + $S_{\alpha1-\alpha2}$[a]
Scan rate (2θ, deg/min)	3
$(\sin\theta/\lambda)^{Mo}_{max}$ (Å^{-1})	1.14[b]

Set	No. of data	P range (Pa)	T range (K)
hkl	11274	(2×10^{-5})–(1×10^{-4})	19.7–20.2
$hk\bar{l}$	8368	$<10^{-1}$	18.7–19.2
$\bar{h}kl$	8242	(2×10^{-6})–(1×10^{-4})	17.3–18.0
$\bar{h}k\bar{l}$	8680	(2×10^{-6})–(5×10^{-4})	17.2–18.2

[a] $S_{\alpha1-\alpha2}$ is the α_1,α_2 separation in the intensity profile.
[b] Corresponding to $(2\theta)^{max}_{MoK\alpha1}$ = 108°.

Experimental

Pale-yellow crystals of citrinin were grown from an ethanol solution. A specimen was ground to a sphere of radius 0.18 mm and mounted on a four-circle Syntex $P\bar{1}$ diffractometer modified for low-temperature measurements (15). Relevant features, operative conditions, and performance of the instrument have been described elsewhere (16).

Data collection

After a preliminary room-temperature data collection, lowering of the temperature at the sample crystal from 290 to 20 K was achieved in about 100 min, the maximum cooling rate being about 15 K min^{-1} between 90 and 25 K. The temperature was decreased at similar rates in all subsequent cooling operations, after intermediate warming to 290–292 K (see below). A check upon proper alignment of the crystal at low temperature was given by the angular settings for reflections centered at both positive and negative 2θ values.

Four sets of 15 reflections were employed for accurate determination of the cell dimensions. A fit of the $\sin^2\theta$ values for these reflections gave the results reported in Table 1, together with other crystal data and parameters for the data collection. Unit-cell dimensions do not differ significantly from those given in a preliminary report (17).

Intensities were collected by ω–2θ scans and the monochromator was in the configuration corresponding to ε = 90° (18). The X-ray generator was set to nominal values of 50 kV and 25 mA. Seven reflections whose diffracted intensities exceeded the range of linearity of the counter were measured at 30 kV and 3 mA, together with other reflections for subsequent scaling of the data. Four sets of equivalent intensities were collected, with the sample exposed to X-rays for more

than 200 h during each data collection. Warming to room temperature before each set of intensity measurements allowed an appropriate degassing of the chamber, so that the temperature could be kept stable within ±1 K during the recording of each set. A ϕ-shaft with a lower thermal conductivity was employed for the first data collection; hence the temperature in that experiment was higher than in the other three cases (see Table 1). The vacuum shroud was continuously evacuated by a cryogenic pump during data collections 1, 3, and 4, and the pressure within the chamber remained in the range 10^{-4}–10^{-6} Pa, with occasional leakages leading to temporary excursions up to 10^{-1} Pa. During data collection 2 the cryopump broke down, and the cold station of the cryostat itself accomplished the gas condensation; the pressure was accordingly higher, around 10^{-1} Pa.

The intensities of three standards were measured every 47 reflections. Decay at the end of each set of data never exceeded 3% (see below).

Data processing

High-order diffracted intensities are expected to suffer from scan truncation losses due to the finite range of the scan. In the hypothesis that thermal diffuse scattering can be neglected at T<25 K, an appropriate treatment of accurately measured profiles can provide a means of correcting for this well-known systematic error, and achieve a more accurate evaluation of integrated intensities (16, 19, 20). A second, more approximate procedure can be adopted, which employs only average background distributions, and gives a substantially equivalent evaluation of truncation losses under the peak of the reflection profiles (16, 19).

This second procedure was followed in the present case: individual backgrounds of reflections with $I_{net} < 10\sigma(I_{net})$, corresponding to a total of 40 738 measurements from both sides of experimental profiles, were used to evaluate average distributions, where both 2θ and χ dependences were taken into account (16). Background anomalies for 2θ ≅ 10° and 2θ ≅ 30°, typical of the instrumental configuration adopted in our laboratory, also appear in the present case: they have been shown to be due to scattering from the specimen support, that is, a Pyrex glass fiber, 0.15 mm in diameter, and epoxy glue.

We stress the general low level of background for the present experiments, around 3.5 count s^{-1} at high angles, to be compared with values of about 1 count s^{-1} for a tube setting of 45 kV and 15 mA (19), and about 6 count s^{-1} for 50 kV and 30 mA (16). Such an excellent instrumental performance is certainly related to the use of aluminum-coated Kapton foils as windows of the cryostat.

Average backgrounds were substituted for those individually measured, and net intensities recomputed. A contribution was also included, at this stage, to take into account scan truncations at the tails of the intensity profiles. The latter quantity, up to a correction of 4% for the net intensities at higher 2θ values, was evaluated according to previous studies and analyses of experimental profiles (16, 19, 20).

The set of diffracted intensities corrected for scan truncation losses underwent conventional data processing, and yielded the experimental values for structure factor amplitudes. A linear fit of the intensities of the three standards vs. time was performed for each set of data, and corrections for decay computed accordingly. Apart from decay, statistical oscillations did not exceed 2% for all check reflections. Decay from the beginning of the experiment to the end of the fourth data collection amounted to about 10%, and was never higher than 3% within each set of data. High- and low-power measurements were merged after appropriate scaling, the average ratio of intensities common to the two subsets being around 40. Variances due to statistical counting were increased by an additional term, depending on intensity under the peak and velocity of the scan:

$$\sigma^2(I_{net}) = \sigma^2_{sc}(I_{net}) + (0.02 I_{peak} v_{scan})^2$$

The intensities were corrected for Lorentz and polarization factors, but not for absorption, and symmetry-equivalent structure factor amplitudes were then merged, with weights taken as inverse variances of individual measurements, and $\sigma^2(\langle F^2\rangle) = [\sum_{equiv.\ i} 1/\sigma^2(F_i^2)]^{-1}$. Friedel pairs were also merged. Each independent structure factor amplitude came, on average, from 4 measurements, only 19 values being measured but once. The merge index amounted to 1.07%, thus confirming the overall excellent agreement between the different sets of data. Among the resulting 7954 independent structure factor amplitudes, 256 had $|F^2| < 0$, and 5941 (about 75% of the total) had $|F^2| > 6\sigma(F^2)$.

Multipolar refinements

The electron density was modelled with a multipolar expansion of atom-centered functions (21–23), according to the pseudoatom formalism of Stewart (24). An approximate absolute scale factor had been previously determined by a conventional spherical atom refinement. Three different models were adopted for multipolar refinements: they will be denoted A, B, and C in the following.

A: This model employed a multipolar expansion up to the octopolar level on carbon and oxygen atoms. Core and valence monopole one-electron density functions were taken equal to the Hartree–Fock expansions of Clementi (25). Core electron population parameters for all C and O atoms were constrained to be equal. Single exponential functions, $r^n \exp(-\alpha r)$, were adopted as radial parts of the higher multipoles. Values for n were 2, 2, and 3 for dipole, quadrupole and octupole, respectively; values for α were 4.50 and 3.44 $bohr^{-1}$ for O and C, respectively (26).

Positional and anisotropic displacement parameters (ADP's) were varied for all C and O atoms. H atoms were initially given scattering factors taken from the H_2 molecule (27); their positional parameters were varied together with isotropic U's. In the final stages of the refinement, H positions were kept fixed, and generalized scattering factors were employed for these atoms as well (at these later stages, there is no need to readjust H positions, the geometry being virtually unaffected by subsequent changes in the model employed). Expansion of the pseudoatom density for H atoms comprised one monopole and three dipole functions. Radial parts for all poles were again single exponentials, with n = 0,1 for monopole and dipole, respectively, and an α value of 2.48 $bohr^{-1}$ (26). An isotropic extinction parameter, of type I and Lorentzian "mosaic" distribution (28), was also varied. Besides this extinction term, the model comprised 162 positional and displacement parameters and 289 electron population parameters for the 18 non-H atoms of the molecule, plus 14 isotropic U's

and 56 electron population coefficients for H atoms. The total number of variables refined was 522.

B: On passing from model A to model B, only the description of the H atoms was changed. First, ADP's were evaluated for all 14 H nuclei. The procedure, based on a rigid-body fit (29) to the ADP's of the 10 non-H atoms of the two central rings of the molecule, and on spectroscopic information, will be described in detail in a forthcoming paper. As a check of the order of magnitude of the values obtained, equivalent U's were compared with the previously (model A) refined U_{iso}'s: the difference exceeded 3 esd's in only one case, the average $|\Delta/\sigma|$ being 1.6. In model B, positional parameters of the H nuclei were kept fixed at the values refined in early stages of refinement A, and the corresponding ADP's were kept at the calculated values. Quadrupoles were added on the multipolar expansion for the H atoms, with single exponential radial functions having $n = 2$ and $\alpha = 2.48$ bohr^{-1}. The number of variables was thus raised to 578.

C: Six additional refinable parameters were added in this model: a radial scaling parameter κ for the valence monopole radial density function of C atoms; a common α value for their dipole, quadrupole, and octopole functions; two corresponding κ and α parameters for O atoms; an α_H^0 for the monopole and a common α_H^1 value for the dipole and quadrupole radial functions on H atoms. Model C counted up to 584 variables.

All refinements were carried out using the VALRAY set of programs (30). The quantity minimized in the calculations was $\varepsilon = \Sigma w(F_o^2 - kF_c^2)^2$, based on the 7698 reflections with $I > 0$. Weights w were taken as $w = 1/\sigma^2(F_o^2)$. Convergence was assumed when the ratio between $\Delta\varepsilon$ from one cycle to the next and the value of ε itself was smaller than 5×10^{-6}. Full second derivatives were included in the calculation of the Hessian matrix of ε in the last cycles, to obtain accurate esd's in the refined parameters.

Results and discussion

Overall quality of the fits

Statistical comparison of the models

Reliability indexes for the three multipolar refinements are summarized in Table 2. For comparison of models A and B, and of A with C, application of the Hamilton ratio test (31) would not be adequate, in that the parameters of one model are not a subset of the parameters of the other: B and C employ fixed ADP's and refine quadrupoles on H atoms, while in A isotropic U values have been refined and the multipolar expansion is up to the dipole level on the same atoms. A more general statistical test (32) was then performed for the pairs A–B, A–C, and B–C. For each pair, least-squares estimates for the slope λ and its esd σ were obtained for the regression line $z = \lambda x$, with:

$$z = [F_o^2 - 0.5(F_{c1}^2 + F_{c2}^2)]/\sigma(F_o^2)$$

and

$$x = (F_{c1}^2 - F_{c2}^2)/\sigma(F_o^2)$$

where subscripts 1 and 2 denote the first and the second model of the pair. For the B–C pair, values for λ and σ are -0.466 and 0.045, respectively, and similar values were obtained for the other two pairs. A value of λ significantly different from 0 indicates better performance of one of the two models, limiting values being $-\frac{1}{2}$ (better fit by the second model) and $+\frac{1}{2}$ (opposite case). The hypothesis that two models gave equally good fits to the data was then tested making use of Student's t distribution for the ratio $t = |\lambda/\sigma|$. For all three pairs considered (A–B, A–C, B–C), the hypothesis could be rejected at the 0.5% significance level (33), confirming that the R indices of the second model of each pair are indeed significantly smaller than those of the first.

Table 2. Summary of least-squares refinements with models A–C.[a]

Model	A	B	C
N° of observations	7698	7698	7698
N° of parameters	522	578	584
Scale factor	1.0012(14)	1.0066(13)	1.0144(24)
Extinction coefficient[b]	0.318(7)	0.312(7)	0.309(11)
$\varepsilon = \Sigma w\Delta^2$	11258	10714	10106
$\lvert\Delta\varepsilon\rvert/\varepsilon$[c]	2.9×10^{-7}	8.6×10^{-8}	3.9×10^{-6}
$R(F)$	0.0286	0.0281	0.0277
$wR(F)$[d]	0.0168	0.0164	0.0159
$R(F^2)$	0.0229	0.0218	0.0216
$wR(F^2)$	0.0333	0.0325	0.0316
Goodness-of-fit	1.2525	1.2267	1.1919
Max. Δ/σ	0.0018	0.0010	0.0047
Average Δ/σ	<0.0001	<0.0001	<0.0001

[a]Radial parameters were fixed at the standard molecular value in models A and B. In model C final values were: $\kappa_C = 1.001(2)$, $\alpha_C = 3.087(28)$ bohr^{-1}; $\kappa_O = 0.988(1)$, $\alpha_O = 4.50(14)$ bohr^{-1}; $\alpha_H^0 = 2.39(2)$ and $\alpha_H^1 = 3.27(14)$ bohr^{-1}.

[b]In units of 10^{-4} rad^2.

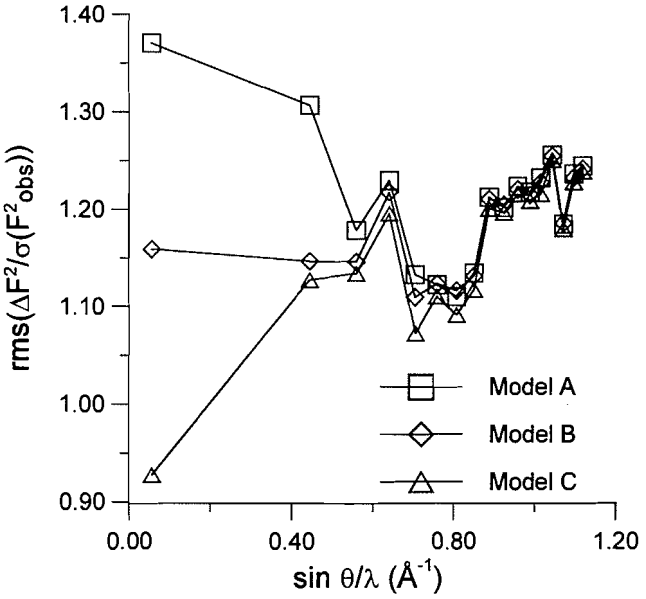
[c]$\Delta\varepsilon = \varepsilon_n - \varepsilon_{n-1}$; n is the number of the last cycle.

[d]Weights equal to $4F^2/\sigma^2(F^2)$.

Agreement as a function of resolution

Scattering at high resolution being dominated by core electrons, only positional and displacement parameters are expected to be sensitive to high-order data: the "effective" observations to parameters ratio (n/p) is in fact resolution dependent, and smaller than the nominal value of 7698/584 = 13.2 (model C). Indeed, a plot of the average ratio $|F_{core}^h|/|F^h|$ vs. resolution range for citrinin reaches unity around $(\sin\theta)/\lambda = 0.626$ Å^{-1}, suggesting that the subset of valence population parameters is in fact determined by a smaller number of observations than the total fitted. For model C, the n/p ratio would be lowered to 1828/420 = 4.35, if valence population parameters only and data up to $(\sin\theta)/\lambda = 0.626$ Å^{-1} were considered. It is precisely in the resolution range where valence multipoles are active that the major differences are observed when comparing residuals for different models. A plot of the root-mean-square (rms) $\Delta F^2/\sigma(F^2)$ values in resolution bins is reported in Fig. 1, where $\Delta F^2 = F_{obs}^2 - F_{calc}^2$. It is apparent that on going from model A to model C, rms values approach unity for reflections in the relatively low-resolution range $0.444 \leq (\sin\theta)/\lambda < 0.808$ Å^{-1}; a comparable improvement of the fit to low-order data upon variation of radial parameters has recently been observed in

Fig. 1. Root-mean-square $\Delta F^2/\sigma(F^2)$ vs. resolution for models A, B, and C. About 450 data were averaged in each resolution bin.



the case of the refinement of X-ray diffraction data at $T = 19$ K for *syn*-1,6:8,13-biscarbonyl[14]annulene (10). Residuals for high-order reflections are less sensitive, on average, to variations of the model. This is in keeping with the fact that the three models differ mainly in the description of valence electron density, while a common set of parameters active at high resolution has been employed. Indeed, virtually identical nuclear positions and displacement parameters for non-H atoms are obtained in the three fits. On passing, we notice that the values in Fig. 1 for high-angle data indicate a possible underestimation of the standard deviations by 15–20%.

It must be noticed that the three fits A, B, and C show negative average values of $\Delta F^2/\sigma(F^2)$ in all 16 resolution bins above (sin θ)/λ = 0.444 Å^{-1}, with an overall $\langle \Delta F^2/\sigma(F^2) \rangle$ of −0.19 in all three cases, while for the 530 reflections at the lowest resolution the average values amount to +0.16, +0.17, and +0.07, respectively, for A, B, and C. Opposite behaviour was observed for a fit performed on data not corrected for scan truncation losses with model B, which gave poorer reliability indexes ($R(F)$ = 0.0384; $wR(F)$ = 0.0208; $R(F^2)$ = 0.0279; $wR(F^2)$ = 0.0382; g.o.f. = 1.379), and instead showed positive values for the average $\Delta F^2/\sigma(F^2)$ at all resolution ranges (overall $\langle \Delta F^2/\sigma(F^2) \rangle$ = +0.20), except for the 480 data of the resolution bin with 0.444 < (sin θ)/λ ≤ 0.560 Å^{-1}, where the average value is −0.017. Diagonal ADP's for non-H atoms for this refinement are 1.8% larger, on average, than those coming from the refinement of the same model B against corrected data ($\langle (U^{ii}_{\text{uncorr}} - U^{ii}_{\text{corr}})/\sigma(U^{ii}_{\text{corr}}) \rangle$ = 1.08). All this might suggest that high angle data have been slightly overcorrected in the treatment of scan truncation losses.

Positivity of the density

The multipolar expansion does not ensure non-negative electron density everywhere in the crystal: a check for positivity of $\rho(\boldsymbol{r})$ was performed by sampling values on a uniform and orthogonal grid in the asymmetric unit, chosen as $0 \leq x \leq \frac{1}{2}$, $0 \leq y \leq 1$, $0 \leq z \leq \frac{1}{2}$, with steps of 0.1 Å along each axis. Far from atomic regions, small negative electron density values were found for models A and B, down to minima of $-0.03(14) \times 10^{-2}$ and $-0.93(54) \times 10^{-2}$ e Å^{-3}, respectively. It is seen that the value for model B, where quadrupolar deformation functions have been added on H atoms, amounts to almost twice its esd, but remains almost negligible. A search for the nuclei closest to the set of very few points having negative density in models A and B revealed that, with no exception, the closest was always a hydrogen nucleus, the distances ranging from 1.071 to 1.521 Å. By contrast, no negative values were found in the asymmetric unit for model C ($\rho_{\text{min}} = 1.98 \times 10^{-3}$ e Å^{-3}). We recall that in model C α^0_H and α^1_H parameters were refined: it is conceivable that the observed (see Table 2) contraction of dipoles and quadrupoles for these atoms, and the concomitant expansion of their monopoles, is mainly responsible for the observed disappearence of the cited regions of negative density in model C.

Correlation coefficients and deconvolution of static/dynamic features

Off-diagonal terms of the inverse of the full Hessian matrix of $\varepsilon = \Sigma w \Delta^2$ give correlation coefficients between the parameters varied. In the present case, coefficients greater than 0.707 in absolute value at the end of the least-squares refinement were rather few, in number 38, 24, and 18, respectively, for models A, B, and C. As was the case for *syn*-1,6:8,13-biscarbonyl[14]annulene (10), the largest correlation was that between the radial scaling parameter κ of the C atoms and the core population coefficient common to all the 18 non-H atoms (coefficient of 0.84). No other parameter involving C atoms has correlation coefficients greater than 0.707 in absolute value. Common to all three refinements are the correlations involving some of the parameters of the O atoms, namely, those between dipole populations and positional parameters (max. value 0.81), and between ADP's and quadrupole populations (up to 0.74).

The substantially small number of significant correlations increases our confidence in the overall reliability of the parameters obtained. We cite also the excellent results derived from the rigid-bond test of Hirshfeld (34) on ADP's from model C: none of the differences between mean-square amplitudes of vibration along the bond direction for all non-H bonded pairs is greater than 0.0006 Å^2, with only the exception of the C6—O7 value, which amounts to 0.0009 Å^2.

All these findings point to a more than satisfactory description of the atomic motions, and hence suggest that the deconvolution of dynamic from static features in the charge density of citrinin has been successfully attained.

Non-centrosymmetry and the phase problem

Odd-order poles that are invariant under crystal-class symmetry are known to give rise to a contribution to the structure factor having a phase shift of π/2 with respect to the sum of contributions from core, valence monopoles, and even-order poles invariant under crystal-class symmetry (ref. 35 and footnote 4). To first-order approximation, and in the limit of a completely negligible contribution from the non-invariant

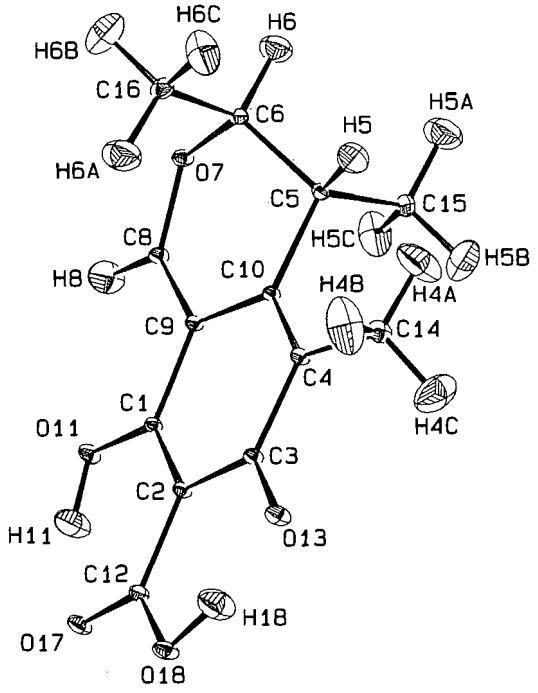
Fig. 2. ORTEP plot of citrinin at 19 K, with numbering scheme. Ellipsoids at 50% probability level; those for H atoms come from calculated anisotropic displacement parameters (ADP's).



poles, changes in the values of the population coefficients of invariant odd-order poles alter only the phase of the structure factor, without affecting its modulus (P. Roversi, unpublished results). In non-centrosymmetric structures, these population coefficients are therefore ill determined, to an extent depending on the relative amplitude of the contributions from invariant and non-invariant poles to the structure factor. In the present work, the only odd-order poles invariant under point symmetry 222 are the 18 octopolar functions *Oxyz*, centered on C and O atoms, while the total number of non-invariant poles for which population coefficients were refined is 364. For this structure, it could therefore be anticipated that the uncertainties on *Oxyz* values should not be too large. Indeed, esd's for these population coefficients were found to be only 1.5 times greater, on average, than those for non-invariant poles. None of the correlation coefficients between the populations for *Oxyz* centered on different atoms was greater than 0.67 in any of the three fits A, B, and C.

Geometry

An ORTEP plot (36) of the molecule is shown in Fig. 2. Positional parameters and U_{eq}'s at the end of refinement C are listed in Table 3.[5] As already anticipated, the geometry proved relatively insensitive to the choice of multipolar model: three sets equivalent within one esd resulted, for bond distances and angles, from the refinements we carried on.

[5] A table of anisotropic displacement parameters may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Structure factor amplitudes are no longer being deposited and may be obtained directly from the authors.

[a] U_{eq} is defined as 1/3 (U_{11} + U_{22} + U_{33}).

Values for bond lengths and angles from refinement C are reported in Tables 4 and 5. The former table also lists bond distances from ab initio optimizations, performed with GAUSSIAN94 (37) for an isolated molecule. Theoretical values come from HF/6-31G* and density-functional B3LYP calculations (38); details will be published elsewhere.[6] We only comment here on the fact that all C=C, CO, CH, and OH theoretical bond distances show very significant lengthening toward the experimental values on passing from the HF/6-31G* to the density-functional calculation, while the C—C bonds of the conjugated system are shortened, again in closer agreement with the experimental geometry. As for the other C—C bonds, it is seen that in four out of five cases, the B3LYP lengths are in poorer agreement with experiment than are the HF/6-31G* ones. The fifth bond, C4—C14, which is at least in part involved in the conjugated system (see below), behaves in the opposite way.

It is worth noting that CH and OH distances as obtained

[a]Distance of critical point from line A–B.
[b]Values refer to geometric distances and not to lengths along the bond path.

from the refinement employing the polarized H scattering factors (27) are in good agreement with average values from neutron diffraction studies (39). The values $d_{H5—C5}$ = 1.101(9) Å and $d_{H6—C6}$ = 1.093(8) Å are to be compared with that for secondary Csp^3—H distances, 1.099(4) Å; the value for $d_{H8—C8}$ = 1.100(9) is slightly longer than the average value 1.077(12) Å from a collection of 14 Csp^2—H bond distances. Methyl group CH distances are here in the range 1.073(10)–1.112(11) Å, all longer than the average neutron value 1.059(30) Å, but the latter quantity includes numerous contributions from experiments at temperatures much higher than 19 K. When only low-temperature neutron work is considered, significantly longer bond distances are usually observed: for example, in the case of 1-methyluracil at 15 K (40), CH bonds are 1.083(2) and 1.088(1) Å long. The OH distances are 0.974(11) Å and 1.056(10), respectively, for the alcoholic and acidic protons of citrinin, in qualitative agreement with the average values from neutron diffraction studies of systems with similar protons: 0.967(10) and 1.015(17) Å. Although these comparisons must be taken with some care (owing to H-bonding effects and temperature dependence of the bond lengths), they certainly indicate that the procedure adopted here, based solely on X-ray data, has led to a very satisfactory location of the H nuclei positions.

Topology of ρ(*r*)

The set of electron population coefficients obtained from the least-squares refinement C was employed to generate the electron density for a molecule extracted from the crystal.[7] Although the density obtained from the experimental data does not, as already noticed, pertain to a pure quantum state, in the following we shall discuss its topology in terms of the usual quantities employed to characterize ab initio densities, such as the number and kind of critical points (i.e., points where $\nabla\rho = 0$), the values of ρ, curvatures, and $\nabla^2\rho$ at the crit-

[7] A discussion of the virtual identity between the density for such an "isolated" molecule and that for the molecule surrounded by the neighbouring ones in the crystal has been presented in the case of L-alanine (41). For citrinin, no differences greater than 0.01 e/Å^3 were observed in density values at the critical points of bonds between non-H atoms, while Laplacian values at the same points showed shifts up to 2.0 esd's toward more negative values at all intramolecular bonds in the crystal.

Table 5. Bond path angles α_b and experimental bond angles α_e (degrees) for non-H atoms in citrinin.

[a] $\beta_1(\beta_2)$ = limiting values at the nucleus of the angle between the direction of $\nabla\rho$ on the bond path and the corresponding bond line (see text).

ical points, and bond ellipticities (1). Bonded radii, bond path lengths, and bond path angles will also be considered. All quantities of interest are listed in Tables 4–6.

The critical points of the density were searched via a Newton–Raphson algorithm, starting from a uniform orthogonal grid of points. A set of 35 (3,−1) or bond critical points (bcp's), and 4 (3,+1) or ring critical points (rcp's) was found; together with that of 32 maxima located at the nuclei, this set of critical points obeys the Poincaré–Hopf relationship for an isolated molecule (42). All the conventional covalent bonding interactions are thus recovered, together with the two intramolecular H bonds.

Bond path lengths and bonded radii

In Bader's QTAM, atomic interaction lines are traced by two $\nabla\rho$ trajectories originating from a (3,−1) critical point, and terminating at two neighbouring nuclear attractors. When an ab initio density for an equilibrium nuclear configuration is studied, atomic interaction lines are referred to as bond paths (1, 43). For citrinin, the bond path lengths (R_b) between all

pairs of bonded nuclear attractors were computed by numerical integration; values are reported in Table 4, together with the distances of the bond critical points from the straight lines connecting the nuclei. Values of the bonded radii (R_A and R_B), i.e., the distances *along the bond path* from the bcp to each of the two bonded nuclei, are also listed.

The difference between bond path length (R_b) and conventional bond length (R_e) values amounts here to a fraction of the esd of the latter, and in all cases is less than 0.07% of the value of R_e itself: in other words, all bond paths closely follow the straight line connecting the two nuclear attractors. Only for C6—O7 is the $R_b - R_e$ value moderately significant in terms of the esd of the bond length: $R_e = d_{C6—O7} = 1.4767(6)$ Å vs. $R_b = 1.4778$ Å. Here the bcp is displaced from the line connecting the nuclei by 0.023 Å, corresponding to about 1.6% of the bond length. Thus, this bond is slightly but sensibly curved.

The bonded radii of C atoms in CC bonds are in the range 0.64–0.80 Å; these bcp's are located approximately at the midpoint of the bonds, as is apparent from the R_A/R_b values, none of which is less than 0.47. A shift of the bcp position towards the C nucleus is observed in CO bonds, where the critical points are, on average, at a distance of about $0.39R_b$ from the C atom. This contraction is more pronounced for the keto and carboxylic CO bonds. The bond path lengths could not be successfully integrated for most of the CH bonds: reasons for such a behaviour are under investigation. The distances of the bcp's from the bonded C and H nuclei along the internuclear straight line were then taken as approximated bonded radii. A displacement toward the H nucleus is observed for all CH bcp's, whose distances from the H nucleus amount to $0.38R_e$ on average; an even greater shift in the same direction is shown by the two OH bcp's, at $0.26R_b$ and $0.23R_b$ from H18 and H11, respectively.

Correlation between density at bcp and bond path length

The accumulation of density between bonded nuclei balances the forces arising mainly from nuclear repulsion, and is therefore expected to increase with decreasing bond length (44). The existence of a correlation between ab initio values of the density (ρ_b) at the bond critical point and calculated or experimental equilibrium bond lengths has been demonstrated in a number of molecular systems for a variety of intra- and intermolecular bonds (44, 45*a–d*). Linear and power empirical laws have been employed to fit the data, thus allowing estimates of electron density values (and related properties) from experimental bond lengths: a power law of the form $\rho_b = A \cdot R_e^{-B}$ is the simplest model carrying the correct asymptotic behaviour as the bond length increases, but in some cases very good correlations have been found with the simpler linear model $\rho_b = a \cdot R_e + b$ (45*d*). The empirical correlation laws have been observed to be more closely satisfied in strained systems if bond path lengths instead of geometrical bond lengths are considered (44).

Plots of ρ_b vs. R_b for the 13 CC and 6 CO bonds of citrinin are shown in Figs. 3 and 4, respectively. It must be stressed that no esd's have been computed for bond path lengths nor for positions of the critical points; the esd's for ρ_b values come from the least-squares refinement.

CC bonds: the variation of ρ_b for the 13 CC bonds in citrinin is best represented by the straight line (Fig. 3) in atomic units:

Fig. 3. Values ρ_b of electron density at the CC bond critical points vs. bond path lengths (R_b). Model C, molecule extracted from the crystal. The esd's of ρ_b are reported as vertical bars.

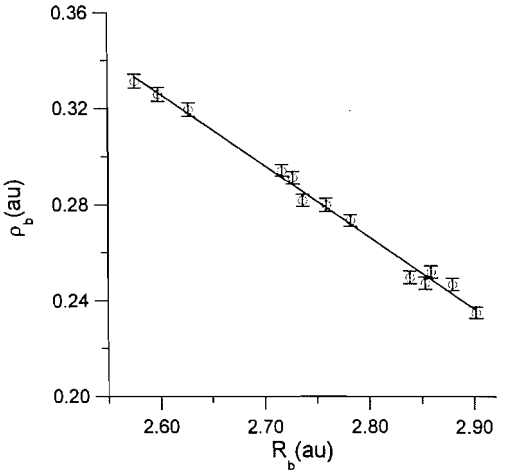

Fig. 4. Same as Fig. 3 for the CO bonds.

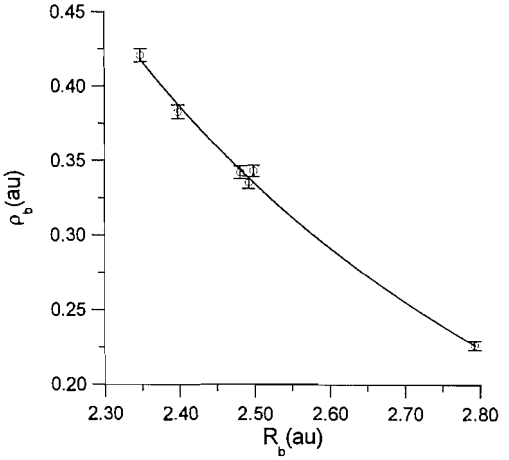

$$\rho_b = -0.297(8) \cdot R_b + 1.099(23)$$

with a correlation coefficient $r = -0.996$ and a rms residual $\sigma = 0.031$. Slope and intercept can be compared with those reported in the literature from a fit of ab initio 6-31G and STO-3G values for ρ_b and CC internuclear distances in ethane, ethylene, benzene, and acetylene (44): the 6-31G fit gave (in au) $a = -0.283$ and $b = 1.043$; the STO-3G fit gave $a = -0.184$, $b = 0.777$. Experimental values for CC bonds in citrinin are therefore in closer agreement with the 6-31G values.

On the basis of ρ_b and R_b values, CC bonds in citrinin can be clearly divided into three groups: C8—C9, C1—C2, and C10—C4, with $\langle\rho_b\rangle = 0.326$ e/(au)^3 and $\langle R_b\rangle = 2.60$ au (1.38 Å); C1—C9, C2—C3, C2—C12, C3—C4, and C9—C10, with $\langle\rho_b\rangle = 0.284$ e/(au)^3 and $\langle R_b\rangle = 2.74$ au (1.45 Å); and C5—C6, C10—C5, C4—C14, C5—C15, and C6—C16, with $\langle\rho_b\rangle = 0.246$ e/(au)^3 and $\langle R_b\rangle = 2.87$ au (1.52 Å). These three subsets may be clearly identified as the formally double and single CC bonds within the extended conjugated system of the molecule, and the single CC bonds not involved in conjugative interactions.

Table 6. Properties[a] of ρ at the bond critical points (bcp's) of citrinin (model C, molecule extracted from crystal).

Bond	ρ_b	λ_1	λ_2	λ_3	$\nabla^2\rho_b$	ε
C1—C2	2.16(2)	−17.20	−13.15	13.22	−17.1(9)	0.309
C4—C10	2.24(2)	−17.96	−13.26	13.34	−17.9(6)	0.355
C8—C9	2.20(2)	−17.55	−13.14	12.82	−17.9(9)	0.336

[a]Density (ρ_b), curvatures (λ's), Laplacian ($\nabla^2\rho_b$), and ellipticity (ε) of the density at the bcp's are reported. Density values in e Å^{-3}, curvatures and Laplacian in e Å^{-5}. For ρ_b and $\nabla^2\rho_b$ the esd's are in parentheses, and refer to the last significant digit. For comparison with the quantities reported in Figs. 3, 4, and 5, we recall that 1 e Å^{-3} ≡ 0.1482 au, and 1 e Å^{-5} ≡ 0.0415 au.

The linear fit for the six CO bonds gave (in au): $\rho_b = -0.417(29)\ R_b + 1.385(73)$, with $r = -0.990$ and $\sigma = 0.008$ e/(au)^3. A simple exponential was also fitted to the data for these bonds, and the fit improved considerably:

$$\rho_b = 8.433\ R_b^{-3.521}$$

with $r = -0.998$ and $\sigma = 0.011$ e/(au)^3 (Fig. 4). We are not aware of reported correlations for CO bonds in the literature. We stress that differences up to 0.1 Å in the position of bcp's for polar bonds were observed when comparing theoretical and experimental electron densities for L-alanine (41): the dependence of ρ_b on the R_b for CO bonds is therefore expected to be sensibly different if values from ab initio densities are considered.

CH bonds: no correlation could be found for these bonds

between ρ_b and R_e (the latter were used instead of R_b, owing to the already mentioned problems in bond path integration). This may be partly due to the relatively high uncertainty on H positions.

Bond path angles

The bond path angle α_b, defined as the limiting value of the angle subtended at a nucleus by two bond paths, provides a measure of the degree of strain induced on bonding density by the nuclear framework geometry (46). Bond path angles were computed from values of $\nabla\rho$ on the bond paths in vicinity of the nucleus. Values of α_b, and of the corresponding geometrical bond angles α_e at non-H atoms, are reported in Table 5. The differences $\Delta\alpha = \alpha_b - \alpha_e$ and the values of the angle β formed by the geometric bond line and the bond path at the nucleus are also reported in the same table. The β values give further insight into the relative proportions with which the two bond paths considered contribute to the bond angle strain and $\Delta\alpha$ value.

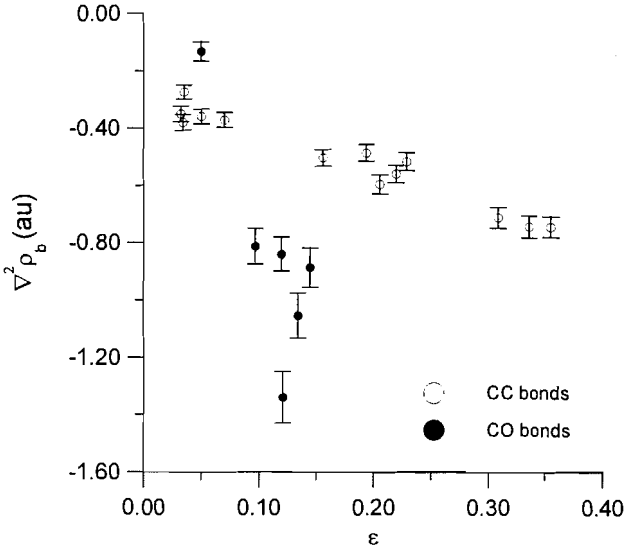
All bond path angles have values very close to the geometric values, and none of the $\Delta\alpha$ is greater in modulus than 4°: the bond strain induced on the molecule of citrinin, if any, can therefore be estimated fairly well on the basis of the geometry of the nuclear framework only. The largest departure of the bond path from the straight bond line occurs at C6 for the C6—O7 bond (β = 3.96°), giving additional evidence of the already mentioned small bending of this bond path, which is more curved on the C6 terminus. The value of $\Delta\alpha$ for the C5-C6-O7 angle is −3°, indicating a slightly larger strain than the geometrical angle would suggest.

Curvature of $\rho(\mathbf{r})$ *at the bcp's*

The eigenvalues λ of the Hessian matrix of ρ at a bcp and the associated eigenvectors are used in topological analysis to characterize chemical interactions (1). The eigenvectors relative to λ_1 and λ_2 define the *minor* and *major axis* of the bond, respectively. Deviation of the bond charge distribution from cylindrical symmetry, as well as conjugative interactions between single and double bonds, may be measured in terms of bond ellipticity at the bcp, $\varepsilon = (\lambda_1/\lambda_2) - 1$, and angles between major axes of neighbouring bonds (1, 46, 47). For citrinin, values of the principal curvatures of ρ at the bcp's (λ's), their sum (i.e., the Laplacian $\nabla^2\rho_b$), and ellipticities ε are reported in Table 6. For the CC and CO bonds, the values of ε and $\nabla^2\rho_b$ are also shown (in au) in Fig. 5.

It is apparent that on the basis of ellipticity and Laplacian values, CC bonds can again be clustered in three groups, as already observed when ρ_b and R_b values were considered. On passing from the single to the double CC bonds of the conjugated system, ellipticities increase, on average, from 0.20 to 0.33 (the average value for ε at the five single CC bonds outside the conjugated system is 0.04). These values reflect an increased contraction of the density towards the bond path with increasing bond order. The increase in λ_1 dominates that in λ_2, and leads to the observed trend for ellipticities: along the minor axis, the density at the bcp's of the double bonds is more curved than at those of the single bonds. The curvature of the density along the major axis (the one relative to λ_2, here directed orthogonally to the plane of the central rings) shows a less marked dependence on the alternation of double and single bonds along the π system. Similar behaviour was reported

Fig. 5. Values ($\nabla^2\rho_b$) of the Laplacian of the electron density at the bond critical point and bond ellipticity (ε) for CC and CO bonds. Model C, molecule extracted from the crystal. The esd's of $\nabla^2\rho_b$ are reported as vertical bars.



for the curvatures of ab initio ρ at the CC bcp's in the series ethane, benzene, ethylene (47): ε increased mainly because of greater λ_1 values, while λ_2 showed smaller variations with increasing bond order, their sign depending on the basis set adopted. Values of λ_3, the curvature along the direction of the bond, are nearly constant in the 13 CC bonds of citrinin, and remain in the range 12.8–13.7 e Å^{-5}. The observed variation is negligible if compared with the pooled esd of the Laplacian at these bcp's, 0.7 e Å^{-5} (no esd's were calculated for individual curvatures of the density).

For CO bonds, $\nabla^2\rho_b$ values span the range −19.6(15) to −32.3(22), with the exception of C6—O7, by far the longest of all CO bonds, for which the $\nabla^2\rho_b$ value is very close to zero, although still negative. The largest negative Laplacian values are those pertaining to keto and carboxyl C=O bonds, as would be expected on the basis of bond lengths and formal bond order (but ε's are of comparable magnitude for all CO bonds). The large parallel curvatures λ_3 at these two bonds are in keeping with the already observed pronounced displacement of bcp toward the C atoms, and clearly signal greater polarity here than at the alcoholic (C1—O11) and ether (C6—O7 and C8—O7) bonds.

The conjugated system: bond ellipticity and bond overlap

In citrinin, an extensive conjugated system is present, spanning the two fused rings of the molecule. The extension of the π system predicted on the basis of traditional chemical reasoning is confirmed by analysis of the overlap between neighbouring bonds, computed as the scalar product of the eigenvectors of λ_2 at the bcp's (1, 47), or, equivalently, as the angle between the same eigenvectors. Values of such angles smaller than 20° are reported in Fig. 6. Major axes are fairly well aligned for all CC and CO bonds of the planar part of the molecule, while overlap is lost in the C5-C6-O7 portion of the dihydropyrane ring. The overlap of CO bonds seems poorer than the average for the whole π system (this effect was less

Table 7. Topological properties at intramolecular ring critical points. Model C, molecule extracted from the crystal. Units for ρ, λ's, and $\nabla^2\rho$ as in Table 6.

Ring[a]	Σα[b]	d[c] (Å)	ρ	λ_1	λ_2	λ_3	$\nabla^2\rho$	Min ($\lvert r_{rcp} - r_{bcp}\rvert$)[d] (Å)

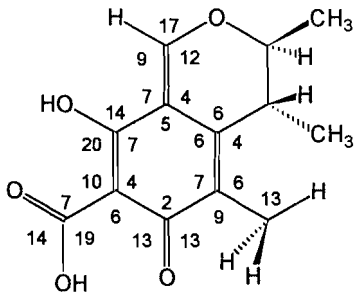
R4	360.04	0.047	0.159(6)	−0.50	1.54	2.02	3.06(3)	H18···O13	0.8368

[a]Atoms forming the rings: R1: C1, C2, C3, C4, C10, and C9; R2: C5, C6, O7, C8, C9, and C10; R3: C1, C2, C12, O17, H11, and O11; R4: C12, C2, C3, O13, H18, and O18.
[b]Σα = sum of bcp-rcp-bcp angles.
[c]*d* = distance of the rcp from the least-squares plane through the bcp's along the ring.
[d]Minimum distance from rcp to a bcp of the associated ring.

Fig. 6. Angles (degrees) between eigenvectors of λ_2 at the bond critical points of adjacent bonds. Only values smaller than 20° are reported. Values of the angles are shown between the two bonds to which they refer. Model C, molecule extracted from the crystal.



pronounced in models A and B, see discussion below). Interesting and unexpected features arise in connection with the exocyclic C4—C14 bond, linking the methyl group at C14 with the unsaturated system. The bond path length for this bond is the smallest and ellipticity the highest amongst the single C—C bonds of the molecule. Its major axis is aligned almost parallel to those of the C3—C4 and C4—C10 bonds within the ring (angles of 9° and 6°, respectively). These details, however small, may be interpreted as invoking some kind of hyperconjugative interaction (47*a*) of this methyl with the unsaturated system of citrinin, inducing a slight double bond character in what is formally a single bond. It is noticeable that even the major axes of the C14—H4A and C14—C4 bonds are fairly well aligned; the same is observed for the pair of H8—C8 and C8—C9 bonds. Both H4A and H8 atoms approximately lie in the plane of the quinonoid system, torsion angles τ(H8-C8-C9-C1) and τ(H4A-C14-C4-C10) being −7.04(4)° and −7.79(5)°, respectively. We recall that on the basis of the topology of ρ(***r***) at NH bonds, recent ab initio calculations have shown that in crystalline urea conjugation extends across the net of N—H···O bonds (48).

The intramolecular rings and ring critical points

Four six-membered topological rings are present in citrinin: the quinomethide ring R1, the dihydropyrane ring R2 condensed to it, and the two rings formed by the intramolecular hydrogen bonds H11···O17 (R3), and H18···O13 (R4). Topological properties at the corresponding ring critical points (rcp's) are summarized in Table 7. Each of these rcp's lies very close to the least-squares plane passing through the six bcp's along its associated ring; only for the rcp of R4 is this distance as high as 0.047 Å.

The ring R1 shows a remarkable degree of planarity: the maximum distance from the least-squares plane through the six nuclei is 0.037 Å for atom C9. An almost complete overlap between all bonds forming the ring, as already discussed in a previous section, is observed: all major axes are oriented perpendicularly to the ring. The C8-C9-C10-C5 portion of the dihydropyrane ring R2 is also fairly planar, while atoms C6 and O7 are 0.782 and 0.314 Å apart, respectively, from the least-squares plane through the other four atoms. An even greater degree of planarity is exhibited by rings R3 and R4, where no nuclei are further than 0.011 and 0.014 Å from the best plane through the six atoms in each ring.

Incipient ring opening through breaking of a given bond is known to be signalled by displacement of the rcp toward the bcp of that bond: the process occurs by coalescence of these two critical points, with annihilation of one of the positive curvatures at the rcp with a negative curvature at the bcp. An opening of the ring effected via rupture of the bond thus requires the negative curvature λ_2 along the direction pointing toward the rcp to become less and less negative as the rcp and the bcp approach, so that an increase in bond ellipticity at the same bcp is also observed (1, 46, 49).

In citrinin, the relatively high values of ellipticity at the O···H bcp's might suggest potential instability of both R3 and R4 ring structures. The rcp's for these rings are indeed found to be significantly displaced towards the corresponding O···H bcp's, at distances of 0.827 (in R3) and 0.837 Å (in R4), to be compared with values for the average distances from the remaining five bcp's along each ring, 1.187 and 1.172 Å, respectively. (For rings R1 and R2 all distances of the rcp's from the surrounding bcp's are in the range 1.21–1.27 Å and 1.18–1.24 Å, respectively: in both cases the rcp is located virtually in the middle of the six-membered ring.) And yet, values of the density and λ_2 curvatures at the bcp and rcp are sensibly different in both rings R3 and R4. Furthermore, no appreciable alignment is observed between the eigenvector relative to λ_2 at the rcp, and the major axis of the O···H bond.

Table 8. Properties[a] of ρ at the intermolecular bond critical points (bcp's) of citrinin (model C).

Bond	R_c (Å)	R_A (Å)[b]	R_B (Å)[b]	ρ_b	$\nabla^2\rho_b$	ε
H5[c]···O13	2.329(8)	0.946	1.384	0.070(4)	0.97(3)	0.23
H6A···O18[d]	2.399(10)	0.984	1.418	0.070(5)	0.86(3)	0.08
H6C[e]···O11	2.421(9)	1.002	1.423	0.060(4)	0.86(2)	0.05
H8[f]···O17	2.423(9)	1.015	1.410	0.060(3)	0.90(2)	0.14

[a]Density (ρ_b), Laplacian ($\nabla^2\rho_b$), and ellipticity (ε) of the density at the bcp's are reported. Units as in Table 6.
[b]As in note *b* of Table 4.
[c]H5 at $x + 1/2, -y + 1/2, -z$.
[d]O18 at $-x + 2, y + 1/2, -z + 1/2$.
[e]H6C at $-x + 3/2, -y + 1, z + 1/2$.
[f]H8 at $x + 1/2, -y + 1/2, -z + 1$.

These angles amount to 33° and 49°, respectively, for R3 and R4. It can be concluded that the two intramolecularly hydrogen-bonded rings in citrinin are topologically stable.

Dependence of topological properties on models

The overall picture of the bonds involving H atoms, as inferred from the values of the topological properties at the bcp's, more closely resembles that of covalent interactions once ADP's and quadrupoles are introduced to the H atoms, that is, on moving from model A to model B. The bond critical points of CH and OH bonds in model B are shifted toward H nuclei at about 3–8% of the value of their distance from H in model A. Values of ρ_b of CH and OH bonds are increased by 2.3 esd's, on average, and all $\nabla^2\rho_b$ values become more negative by more than 2 esd's. Topological properties at the bcp's of bonds between non-H atoms are instead virtually unchanged: ρ_b increases by about 0.2 esd's, on average, while $\nabla^2\rho_b$ values become more negative by about the same fraction of the associated esd, because of less pronounced parallel and larger perpendicular curvatures.

Figures 7*a* and 7*b* show maps of $-\nabla^2\rho(\boldsymbol{r})$ in a plane through rings R3 and R4, for models A and B, respectively. We recall that charge depletion and charge concentration regions in a given molecule appear as holes and lumps, respectively, in plots of $-\nabla^2\rho(\boldsymbol{r})$: charge is locally concentrated (depleted) in those regions of space where $-\nabla^2\rho$ is positive (negative) (1). The major differences between the pictures of charge concentration and depletion in the two maps are apparent in the regions around atoms H11 and H18: in Fig. 7*b*, the valence shells of these H atoms are connected to those of the bonded O atoms, and their shape is no longer circular (as it is in Fig. 7*a*), but is more realistically elongated toward the hydrogen bond acceptors O17 and O13. On the other hand, the same model B shows a negative region of $-\nabla^2\rho$ between atoms C1 and O11. Also, in the remaining CO bonds a contraction of the valence charge concentration away from the middle of the bond is observed on passing from model A to B, although the valence shells of these C and O atoms are still connected. Both maps show contours at $-\nabla^2\rho = 96.4$ e Å^{-5} (4 au) around the sp^2 atoms O13 and O17, on opposite sides with respect to the direction of the CO bond, and at about 120° from it. Such nonbonded valence charge concentrations correspond to the lone pairs for these atoms (1, 50, 51).

Upon introduction of radial parameters, the picture of all CC and CO bonds of the molecule becomes more polar: $\nabla^2\rho_b$ values become less negative; ellipticities decrease (both λ_1 and λ_2 become less negative, but the latter undergoes a larger percent shift, on average); the average ratio $\lambda_3/(\frac{1}{2}|\lambda_1+\lambda_2|)$ increases from 0.96 to 1.04. A slight loss of conjugation of CO bonds with the rest of the π system is signalled by an increase of the angle giving the overlap, whose average value at O atoms goes from 9.3° (model B) to 14.3° (model C). When comparing the maps of $-\nabla^2\rho(\boldsymbol{r})$ for models B and C (Figs. 7*b* and 7*c*) the increased polarity of the CO bonds is clearly visible: the trend already observed on passing from model A to model B is here enhanced, so that regions of charge depletion now intervene between atoms C3 and O13 and between atoms C12 and O18. Only C12—O17, the shortest of these CO bonds, still shows connected C and O valence charge concentration regions.

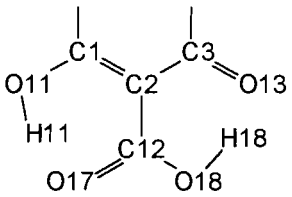
Intermolecular contacts and (3,–1) critical points in the crystal

A full topological characterization of the crystal structure, defined as the net of the bond paths obtainable for the density of the solid (3), has not been attempted. Reliable and robust algorithms have recently been proposed that would allow for a complete recovering of the net of critical points of the experimental density in the crystal (52, 53): none of them has been yet implemented in our version of VALRAY. Only a subset of the critical points of the crystalline electron density was therefore found by a conventional Newton–Raphson search.[8] The search was started between all symmetry-unique pairs of nuclei whose distance was smaller than the sum of the van der Waals radii. All pseudoatoms within a contact radius of 5 Å contributed to $\rho(\nabla\rho, \nabla^2\rho)$ at a given point. Iteration was deemed to have reached convergence if none of the components of the calculated shift was higher than 0.001 Å; if no critical point was found after 10 iterations, the search was stopped.

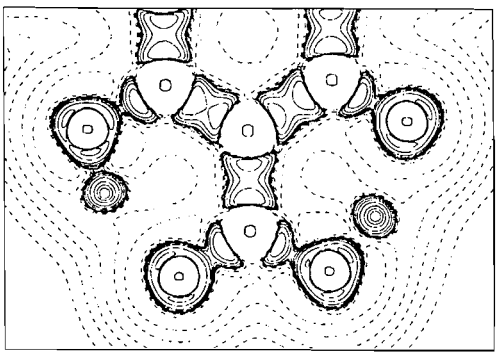
All of the 39 critical points already found when analysing the density of the molecule extracted from the crystal were also recovered in the solid: these critical points are equivalent in number and type, and their positions are virtually the same, as those of the critical points already discussed for the "isolated" molecule. A set of four (3,−1) critical points relative to intermolecular interactions was also recovered. Table 8

[8] For a discussion of the shortcomings of this technique when dealing with systems with non-trivial topology see ref. 52.

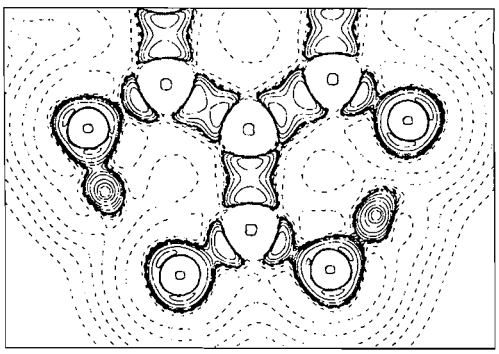
Fig. 7. Contour maps (7.2 × 5.0 Å) of $-\nabla^2\rho$ in the plane of rings R3 and R4 of citrinin, molecule extracted from the crystal. The plane is defined by atom C2 and by the (3,−1) critical points of bonds O11—H11 and C2—C12. Origin at the latter bcp. None of the atoms is further than 0.02 Å from the plane. Solid lines: negative Laplacian, contour lines at -4×10^{-1}, -2×10^{-1}, -8×10^{-2}, -4×10^{-2}, -2×10^{-2}, -8×10^{-3} au. Broken lines: positive Laplacian, contour levels at 2×10^{n}, 4×10^{n}, 8×10^{n} au, with n beginning at −2 and increasing in steps of unity up to $n = 0$. Zero contour omitted. (*a*) Model A; (*b*) model B; (*c*) model C.



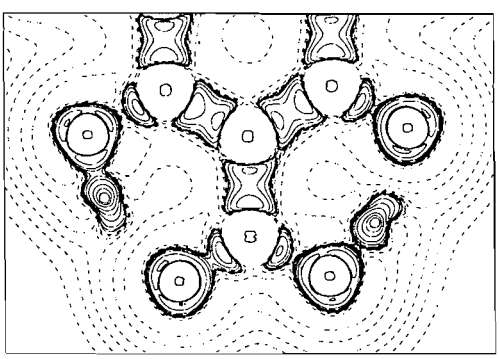
(a)



(b)



(c)

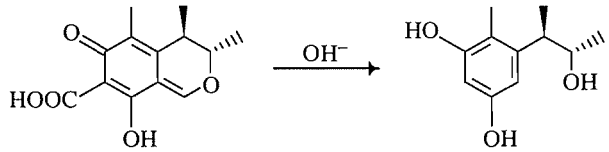


reports the main topological properties at these (3,−1) bcp's, all of which are located in between O and H atoms of neighbouring molecules, with O···H distances of 2.329(8) to 2.423(9) Å. Density values span the range 0.04–0.07 e Å^{-3}; the small and positive values of $\nabla^2\rho_b$ are characteristic of non-shared interactions dominated by the curvature along the internuclear direction. Also for these bonds an inverse relationship is observed between R_e and ρ_b values.

Finally, we mention that 14 (3,+1) and 3 (3,+3) symmetry-unique critical points were also found,[9] the former group including the four intramolecular rcp's. The Poincaré–Hopf relationship governing the type and number of critical points for an extended system (3, 54) is not satisfied by this set of critical points, in that four more cage critical points (3,+3) would be required, if all other cp's are assumed to have been recovered. We mention that the intermolecular (3,+1) and (3,+3) cp's are located in low-density and flat regions within the crystal. Curvatures there are often very close to zero, and the exact rank and signature of the critical point become uncertain.

Chemical reactivity and the molecular reactive surface

When treated with alkali, citrinin (**1**) is known to yield the alcohol (**2**) (55):



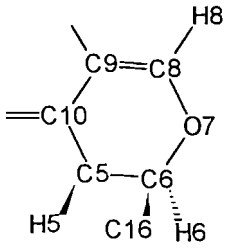
1 **2**

The reaction involves a nucleophilic attack at the C8 carbon atom in the dihydropyrane ring. It has been shown that the geometry of approaching reactants and the relative reactivity of different sites within a given molecule can be rationalized by making use of the distribution of $\nabla^2\rho(\boldsymbol{r})$ (1). We have not yet performed the topological analysis of the Laplacian of the experimental charge density for citrinin. Qualitative evidence about the electrophilic character of a given site can nevertheless be obtained from the values of the Laplacian function alone. A display of the *reactive surface* of the molecule, defined as the $\nabla^2\rho = 0$ isosurface, traces the separation between regions of charge concentration and charge depletion, and gives an effective description of the qualitative affinity of the various molecular portions toward Lewis acids and bases (1, 51).

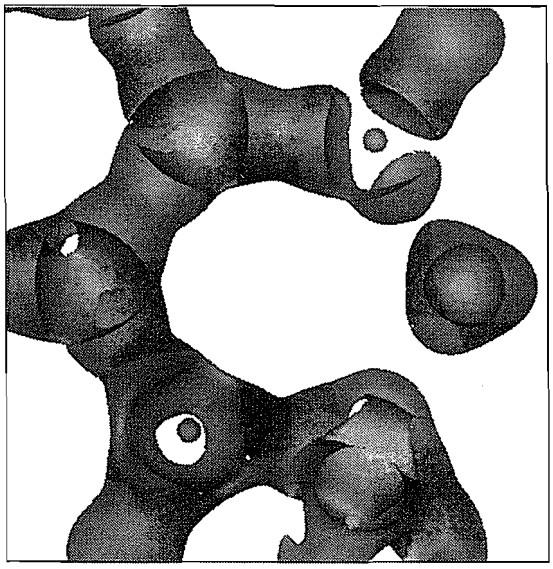
Figures 8*a* and 8*b* show plots of the reactive surface in the dihydropyrane ring R2 of citrinin, for densities from models C and A, respectively. In both maps the surface shows holes through which the inner zero surfaces between core charge concentration and core charge depletion for some of the C atoms are visible. No valence charge concentration region is encountered while moving away from these atoms along the viewing direction. In both plots, this feature is particularly

[9] A full specification of the atoms forming the rings (cages) associated with the points found would require tracing out the $\nabla\rho$ trajectories from the rcp's (cage cp's) and terminating at the surrounding attractors.

Fig. 8. Isovalue surface of $-\nabla^2\rho$ for citrinin. The surface drawn is the $-\nabla^2\rho = 0$ surface, the reactive surface. The values of the negative Laplacian were sampled on an orthogonal grid in a box of size 4.2 × 4.2 Å, and extending 1.35 Å above and below the plane defined by the atoms C6 and O7, and the ring critical point of the dihydropyrane ring R2. (*a*) Model C; (*b*) model A.



(a)



(b)

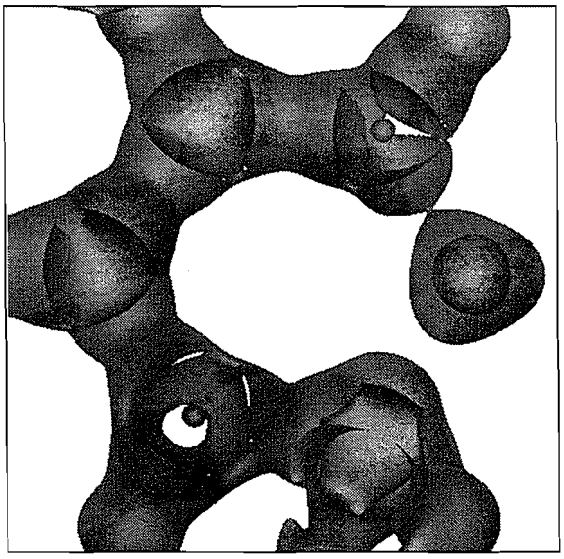


Fig. 9. $-\nabla^2\rho = 0$ isovalue surface for citrinin, isolated molelcule, model C. The values of the negative Laplacian were sampled on an orthogonal grid in a box of size 5.85 × 4.65 Å, and extending 1.35 Å above and below the plane mapped in Fig. 7.

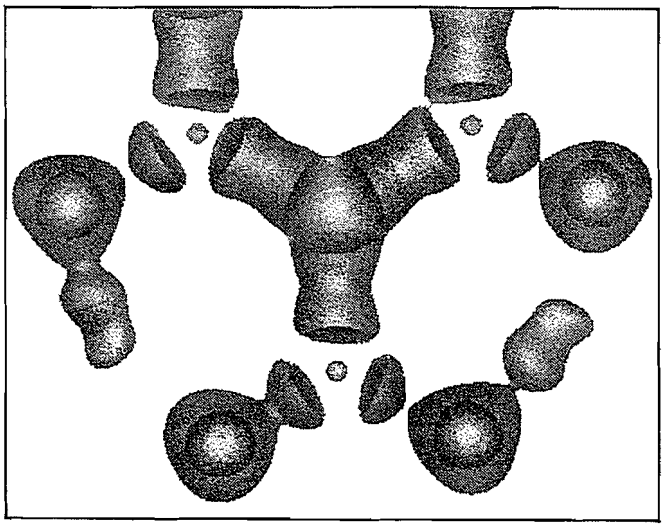

pronounced around atom C8, which is therefore predicted to be the most suitable site for nucleophilic attack in this portion of the molecule. We emphasize the striking difference between this atom and other C atoms in the ring, e.g., C9 (which has similar sp^2 hybridization) or C6 (which is bonded to the same oxygen O7). A completely equivalent image of the reactive surface is obtained when viewing it from the other side of ring R2, again indicating carbon C8 as the most electrophilic site in this ring.

Figure 9 shows the reactive surface (model C) for the molecular portion containing rings R3 and R4. Around all carbon atoms bonded to oxygen in the mapped region, the zero envelope of the Laplacian shows pronounced holes and missing valence charge concentration regions along directions approximately orthogonal to the plane of the rings. As far as can be judged from the display of the reactive surface, these carbon atoms are also indicated as possible sites of nucleophilic attack. It is seen that the experimental picture of the charge density distribution in citrinin is in keeping with the known chemical reactivity of the molecule in alkali, although quantitative predictions about the preferred site of nucleophilic attack must await a thorough analysis of the $-\nabla^2\rho$ field.

Concluding remarks

The wealth of chemical information obtainable from careful and accurate measurement and processing of low-temperature diffraction intensities has been demonstrated in the case of citrinin. Valence deformation terms are sensitive to data up to about 0.8 Å resolution only, but the number and quality of higher order data are essential to attain a satisfactory deconvolution of the dynamic features from the experimental density. Although of minor importance in the system under study, where no significantly strained bonds are present, bond path lengths and bond path angles have been shown to usefully complement the information given by the traditional bond lengths and angles computed from the nuclear geometry.

Other important chemical features of the system under study, such as conjugation and hydrogen bond stability, have been shown to be successfully redescribed in terms of topological quantities at the bcp's of the experimental density. Good agreement with published theoretical results for the inverse correlation between ρ_b and R_b values for CC bonds has been obtained, and a similar relationship for the CO bonds established.

Adoption of calculated ADP's and concomitant multipolar expansion up to the quadrupolar level on H atoms has yielded a more realistic shape of their valence charge concentration region. However, only a variation of the standard radial dependence of monopole and higher poles radial functions could prevent the density from acquiring small negative values in regions far from the non-H atoms.

Topological analysis has proven very valuable in revealing the sometimes subtle dependence of the picture of the density upon the model adopted in interpreting the X-ray data. The tracing of bond paths in the solid and the implementation of robust and automatic algorithms to locate all kinds of critical points and calculate interatomic surfaces in the bulk are the main directions along which we plan our future work, to achieve a complete topological analysis of experimental electron densities.

The picture we obtain for CO bonds in citrinin closely resembles that of polar interactions, with pronounced parallel curvature and considerable contraction of density toward the nuclei. The charge depletion intervening in the middle of these bonds is at variance with ab initio results (1): the shape we find might be an artifact due, at least in part, to inability of our radial functions to fit the density in these bonding regions. Further investigation of the role played by these radial functions in modelling experimental densities is therefore demanded.

For the first time (to our knowledge), a reactive surface has been plotted from values of the Laplacian of an experimental density. The shape of the surface has been found to be in agreement with the known electrophilic character of one of the C atoms of the molecule under study. On the other hand, only a complete analysis of the topology of the Laplacian of the density would allow the charge density study to be of help in rationalizing chemical reactivity in a more quantitative way.

Acknowledgements

One of us (P.R.) wishes to thank for warm hospitality the Medical Research Council – Laboratory of Molecular Biology in Cambridge, England, where part of the computational work was done. We also thank G. Bricogne and C. Gatti for enlightening comments and fruitful discussions. Thanks are also due to C. Scolastico and F. Aragozzini for a generous gift of crystalline citrinin.

A theoretical study of some X—H···π hydrogen-bonded complexes using the theory of atoms in molecules

Ting-Hua Tang and Yun-Ping Cui

Abstract: π-Type hydrogen-bonded complexes consisting of hydrogen halide HX (X = Cl, F) and the carbon–carbon triple or double bond of vinyl acetylene (1-buten-3-yne, HC≡C-CH=CH_2) have been studied. The vinyl acetylene molecule contains two possible π-bonding sites (C≡C and C=C). It offers three possible structures of C_4H_4···HX that comprise two T-type bonds to C≡C (*endo* and *exo* approaches) and one T-type bond to C=C (perpendicular approach). The optimized geometries and the hydrogen-bond stabilization energies, based on MP2(FULL)/6-311++G(d,p)//6-31G(d,p) calculations, indicate that the π-type hydrogen bond to a C≡C triple bond leads to a more stable complex than for an analogous bond to C=C. The calculated global minima for the complexes with HF and HCl correspond to the H—X moiety lying along a bisector of the C≡C triple bond in the *endo* approach, predictions that are in good agreement with the reported FTMS results. The topological properties of the electron density distributions of these two systems have been analyzed in terms of the theory of atoms in molecules. The nature of π-type hydrogen bonds has also been discussed using the Laplacian of the electron density, $\nabla^2\rho$. The complexes C_2H_2···HX and C_2H_4···HX as well as the hydrogen-bonded complex consisting of 2-butyne (CH_3-C≡C-CH_3) and HCl were also studied for comparison.

Key words: ab initio calculation, hydrogen bonding, topological analysis of electron density, vinyl acetylene, 2-butyne.

Résumé : On a étudié les complexes à liaisons hydrogènes de type π formés par des halogénures d'hydrogène (HX, X = Cl, F) et la liaison carbone–carbone double ou triple du vinylacétylène (but-1-èn-3-yne, HC≡C-CH=CH_2). La molécule de vinylacétylène comporte deux sites possibles de liaisons π (C≡C et C=C). Il existe trois structures possibles de C_4H_4···HX qui comprennent deux liaisons de type T par rapport à C≡C (approches *endo* et *exo*) et une liaison de type T par rapport à C=C (approche perpendiculaire). Les géométries optimisées et les énergies de stabilisation de la liaison hydrogène, basées sur des calculs MP2(FULL)/6-311++G(d,p)//6-31G(d,p) indiquent que la liaison hydrogène de type π à une liaison triple C≡C conduit à un complexe plus stable que celle pour une liaison C=C analogue. Les minima globaux calculés pour les complexes avec HF et HCl suggèrent que, dans l'approche *endo*, la portion H—X se trouve sur une bissectrice de la liaison triple C≡C, une prédiction qui est en bon accord avec les résultats de FTMS déjà rapportés. On a analysé les propriétés topologiques des distributions de densité électronique de ces deux systèmes en termes de la théorie des atomes dans les molécules. On a discuté de la nature des liaisons hydrogènes de type π en faisant appel au laplacien de la densité électronique, $\nabla^2\rho$. De plus, pour fins de comparaison, on a étudié les complexes C_2H_2···HX et C_2H_4···HX ainsi que le complexe à liaison hydrogène formé entre le but-2-yne (CH_3-C≡C-CH_3) et le HCl.

Mots clés : calculs ab initio, liaison hydrogène, analyse topologique de la densité électronique, vinylacétylène, but-2-yne.

[Traduit par la rédaction]

Introduction

X—H···π type hydrogen-bonded complexes, consisting of a hydrogen halide molecule HX as proton donor and the carbon–carbon multiple bond as proton acceptor, are usually considered to be the initial stage of an electrophilic addition to the alkene or alkyne, with an X-H orientation that is perpendicular to the CC multiple bond. These complexes were studied experimentally by traditional thermal analysis almost four decades ago (1); more recently, for more reliable determinations, by Fourier transform microwave spectroscopy (FTMS) as well as IR spectroscopy in the gaseous state (2–5); and most recently by X-ray scattering in the crystal (6). Theoretically based ab initio calculations have also been reported in the literature (7–10). In our previous study (10), the calculated (MP2/6-31G(d,p)//6-31G(d)) π-type hydrogen-bond stabilization energies for C_2H_2·HF, C_2H_4·HF, C_3H_6·HF, and C_6H_6·HF were reported and the nature of the π-type hydrogen bond was discussed in a preliminary fashion on the basis of topological property analysis of the electron density distribution in the theory of atoms in molecules (AIM) (11). Lin and

Bytheway (12) very recently reported the analysis of the Laplacian of the electron density of C_2H_4·HCl, which was then compared with the C_2H_4·ClBr system.

Experimentally, vinyl acetylene (1-buten-3-yne, HC≡C-CH=CH_2), which is a molecule with both double and triple carbon–carbon bonds, has been used to determine which of the two sites and which of the two approaches (*exo* or *endo*) for the C≡C triple bond was the most attractive for T-type hydrogen-bond formation with HCl (4) and HF (5). From these reported FTMS experimental results (4, 5), both HX molecules (X = Cl, F) preferably attach to the C≡C triple bond in vinyl acetylene in an *endo* approach. Also, an X-ray crystal structure determination of 2-butyne·HCl has been reported (6) in which the solid-state T-shape geometry of Cl—H···π type hydrogen bonding was convincingly displayed. It is necessary to deepen our understanding of the structure, the nature of bonding, and the energetics of these π-type hydrogen-bonded complexes. To further characterize the chemical nature of π-type hydrogen bonding in these complexes we have carried out a topological analysis of their electron density, $\rho(\boldsymbol{r})$. The analysis of topological properties of the critical points of ρ and its associated Laplacian $\nabla^2\rho(\boldsymbol{r})$ is a useful tool for the characterization of atomic interactions within molecules (11). It is the purpose of the present paper to give further insight into the details of the bonding in these π-type hydrogen-bonded complexes.

Methods

All geometries were optimized at the 6-31G(d,p) level of theory (13). The hydrogen-bonded stabilization energy is defined in the thermodynamic sense as the difference between the total energy of the hydrogen-bonded complex and the sum of the total energies of the HX (X = F, Cl) and the hydrocarbon molecule that form the complex. The correlation-energy corrections were obtained by using Møller–Plesset perturbation theory at the second-order level (MP2) (14). For π-type hydrogen-bond stabilization energy calculations, single-point MP2(FULL)/6-311++G(d,p) (15) (MP2(FULL)/6-311++G-(2d,2p) for the 2-butyne·HCl complex) calculations, in which all electrons are included, were performed on 6-31G(d,p) fully optimized geometries. All ab initio calculations were performed using GAUSSIAN 90 (16*a*) and GAUSSIAN 92 programs (16*b*).

Recently, inter-, intra-, and π-type hydrogen bonding have been analyzed using the theory of atoms in molecules (AIM) (10, 11, 17) to elucidate the nature of the hydrogen bonding. In this theory, the topological properties of the electron density distribution of a molecule are based on the gradient vector field of the electron density $\nabla\rho(\boldsymbol{r})$, and on the Laplacian of the electron density $\nabla^2\rho(\boldsymbol{r})$. Several excellent reviews have been published (11) on this subject and it has been discussed in detail elsewhere; therefore only a brief description of some selected topological parameters pertinent to the present work is given here. The electron density distribution of a molecule is described by $\rho(\boldsymbol{r}, \boldsymbol{X})$ where $\boldsymbol{r}$ is a vector in ordinary three-dimensional space and $\boldsymbol{X}$ represents a particular set of nuclear coordinates in the space corresponding to the nuclear configurations of the molecule in question. An atom in a molecule is defined as a region of real three-dimensional space bounded by a zero-flux surface. The points on this surface satisfy $\nabla\rho(\boldsymbol{r})\cdot\boldsymbol{n}(\boldsymbol{r}) = 0$ where $\boldsymbol{n}(\boldsymbol{r})$ is the unit vector normal to the surface at $\boldsymbol{r}$. Two interacting atoms in a molecule form a critical point in the electron density, where $\nabla\rho = 0$, called a bond critical point (BCP). The pairs of gradient paths that originate at a BCP and terminate at neighbouring nuclei define a line, called an atomic interaction line, through which electron distribution, $\rho(\boldsymbol{r})$, is a maximum with respect to any lateral displacement. The presence of such a line, linking two nuclei in a molecule, which exists in a minimum energy geometry, implies that two atoms are bonded to one another and in this instance this line is called a bond path. The necessary condition for two atoms to be bonded to one another is therefore that their nuclei be linked by a bond path. The network of bond paths for a molecule in a given nuclear configuration $\boldsymbol{X}$ defines the molecular graph, which essentially is the union of the closures of the bond paths. Such a topological graph usually corresponds to the commonly drawn chemical bond network.

The electron density, $\rho(\boldsymbol{r})$, at the BCP is related to the bond order and therefore to the bond strength (18). The eigenvalues associated with the second derivatives of ρ, at the BCP (λ_1, λ_2, and λ_3) indicate how rapidly the density changes on moving away from the BCP and represent the curvatures of electron density along different directions. For a normal single bond, such as the C—C bond in ethane, the two negative curvatures (λ_1 and λ_2), which are perpendicular to the bond line, are approximately equal. However, if there is a double bond, one curvature (in the direction of the π-bond) will be much smaller than the other. This difference may be described by the ellipticity, ε, of the bond, which is defined as $\varepsilon = \lambda_1/\lambda_2 - 1$, in which λ_2 is the curvature of smaller magnitude. For a single bond, $\lambda_1 \cong \lambda_2$; therefore $\varepsilon \cong 0$. For a double bond, $\lambda_1 > \lambda_2$; therefore $\varepsilon > 0$. For aromatic systems, in general, ε is in between a typical single and a typical double bond. For symmetrical triple bonds, since $\lambda_1 \cong \lambda_2$, ε is equal or close to zero. In practice, the trace or the sum of the second partial derivative values of $\nabla^2\rho(\boldsymbol{r}_b) = \Sigma_{j=1,3}\partial^2\rho\,(\boldsymbol{r}_b)/\partial x_j^2$ at the BCP, denoted by $\boldsymbol{r}_b$, is negative for a covalent interaction. The trace of $\nabla^2\rho(\boldsymbol{r}_b)$ is positive for an interaction between closed-shell systems. A critical point, at which $\rho(\boldsymbol{r})$ has one negative curvature and two positive curvatures, can be defined as a ring critical point. The existence of a ring critical point, at which the density $\rho(\boldsymbol{r})$ is smaller than that of all surrounding BCPs, indicates that the molecule contains a ring structure. Of particular interest to the present study is the Laplacian of the electron density, the quantity at any point, $\nabla^2\rho(\boldsymbol{r}) = \Sigma_{j=1,3}\partial^2\rho(\boldsymbol{r})/\partial^2 x_j^2$, that determines the regions of space wherein the electron density is locally concentrated or depleted. From the definition of a second derivative, one finds that $\rho(\boldsymbol{r})$ is greater than the average of its values over an infinitesimal sphere centered on $\boldsymbol{r}$, when $\nabla^2\rho(\boldsymbol{r}) < 0$, and $\rho(\boldsymbol{r})$ is less than this average when $\nabla^2\rho(\boldsymbol{r}) > 0$. Thus a local maximum (or minimum) in $-\nabla^2\rho(\boldsymbol{r})$ signifies a local concentration (or depletion) of electron density. It has been reported (11, 19) that these magnitudes of $-\nabla^2\rho(\boldsymbol{r})$ can be used to study the preferred orientation of electrophilic and nucleophilic attack. The site of Laplacian depletion favors nucleophilic and the site of Laplacian concentration favors electrophilic attack. Moreover, in some series of closely related molecules the Laplacian can give quantitative formation concerning relative protonation energies (20). On the other hand, the use of the Laplacian $\nabla^2\rho(\boldsymbol{r})$ for the study of hydrogen-bonded complexes has been reported (17*e–i*). This

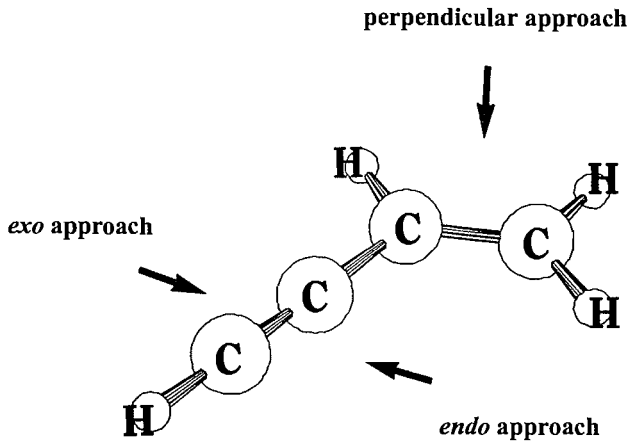
method is superior to some conventional models (21–23). In the above method using the Laplacian $\nabla^2\rho(r)$, no models are employed and no parameters are used, as it is determined by the electron density, for predicting chemical behaviour of hydrogen-bonded complexes. The numbers, locations, and relative sizes of the bonded and nonbonded concentration of charge in the valence shell of a bonded atom, as determined by the Laplacian of $\rho(r)$, are found to be in generally good agreement with the corresponding properties ascribed to bonded and nonbonded pairs in Gillespie's VSEPR model of molecular geometry (24).

The AIMPAC program[3] was employed for the electron density topological analysis, using the electron densities obtained from the MP2(FULL)/6-311++G(d,p) calculations (MP2-(FULL)/6-311++G(2d,2p) for the 2-butyne·HCl complex).

Results and discussion

1. Optimized geometries and π-type hydrogen-bond energies

For vinyl acetylene, HC≡C-CH=CH_2 (C_4H_4), there are three possible approaches for the incoming HX forming C_4H_4·HX π-type hydrogen-bonded complexes. These are *endo* and *exo* approaches to the carbon–carbon triple bond as well as a perpendicular approach to the carbon–carbon double bond at the other end of the molecule.



The full geometry optimizations for the aforementioned molecules and their hydrogen-bonded systems were carried out using the 6-31G(d,p) basis set. The results of geometry optimization of the C_4H_4·HX (X = F, Cl) systems, considering different approaches by HX to form C_4H_4·HX complexes, together with the optimized geometries of HX, C_2H_2, C_2H_4, C_4H_4, C_2H_2·HX, C_2H_4·HX, C_4H_6·HCl, are shown in Fig. 1. The hydrogen-bond energies for the 11 systems mentioned above are tabulated in Table 1. It can be seen from the first two columns of Table 1 that increasing the size of the basis set decreases the hydrogen-bond energy. It seems that if the basis set used is smaller, then the basis set superposition error (BSSE) is larger — which erroneously provides an extra stabilization energy. Thus the larger basis set results are more reliable. The third column contains hydrogen-bond energies that include correlation-energy corrections.

[3] Available from Professor R.F.W. Bader's laboratory, McMaster University, Hamilton, ON L8S 4M1, Canada.

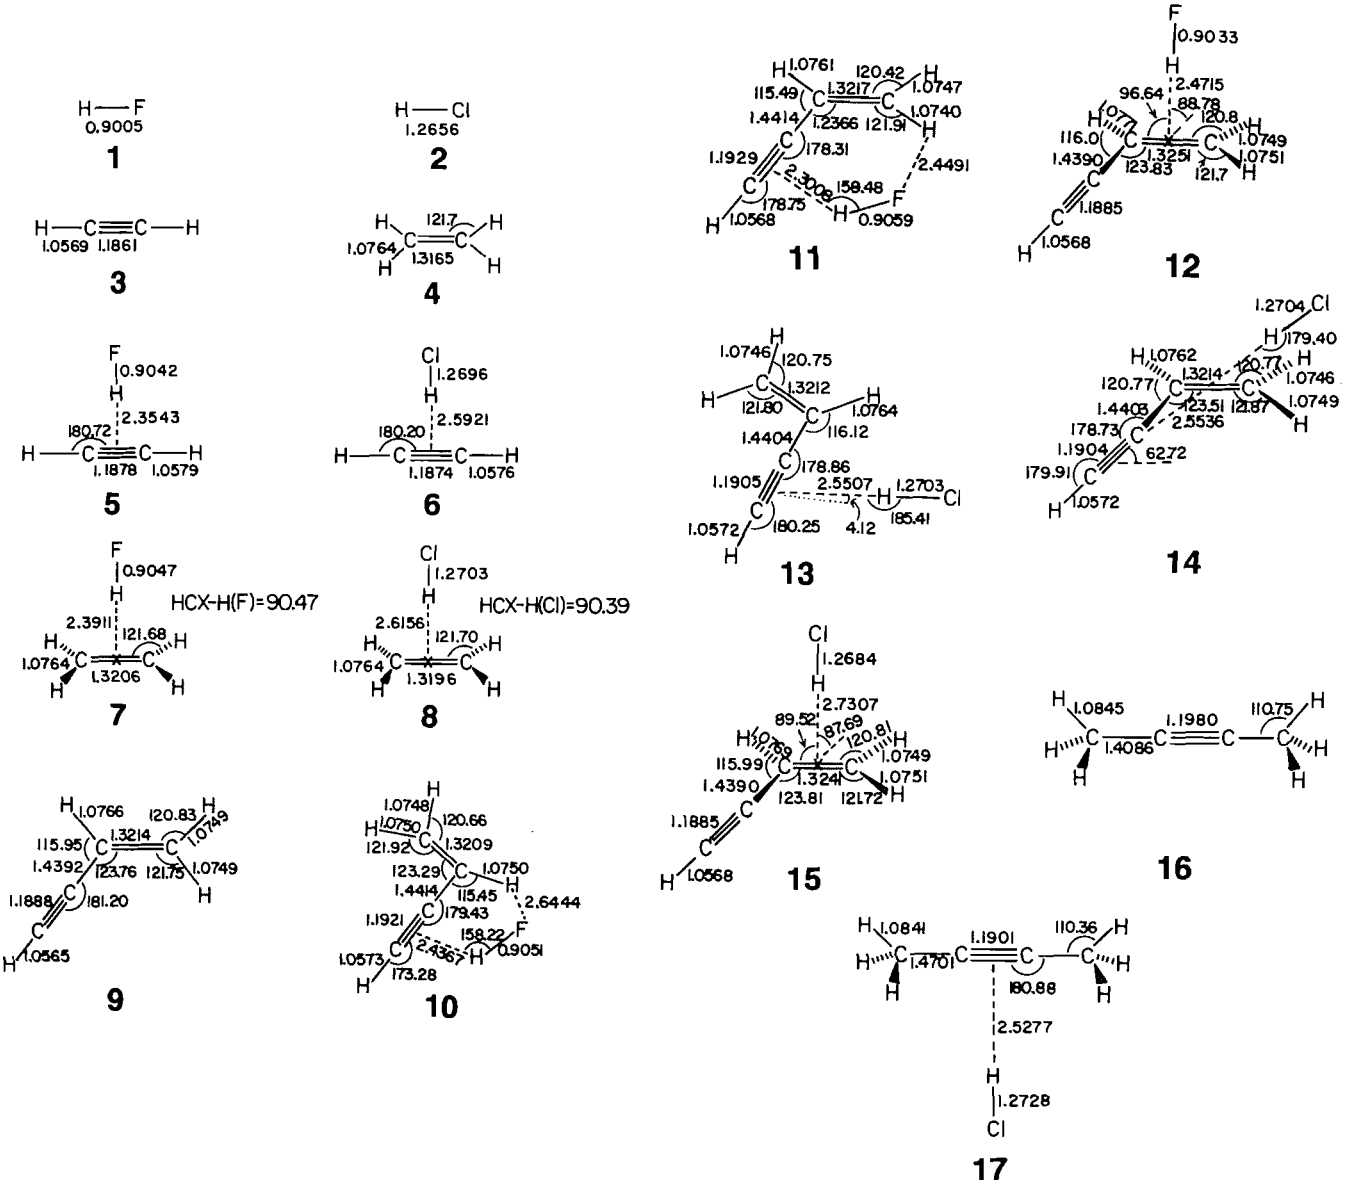
It was reported earlier (17*f*, 25) that if the basis set has diffuse functions and polarization functions on each of the atoms, then the BSSEs are quite small and these will not influence the trends in the computed hydrogen-bond energies. From Table 1 it can be seen, very clearly, that the π-type hydrogen bond to the C≡C bond among vinylacetylene·HX (C_4H_4·HX) complexes (**10–15**) leads to a more stable complex than for an analogous complex involving the C=C bond. For the sake of comparison, the hydrogen-bond energies of C_2H_2·HX and C_2H_4·HX complexes (**5–8**) were also calculated. The calculated global minima for these C_4H_4·HX complexes, with HF and HCl (complexes **11** and **14**), correspond to the HX moiety lying along a bisector of the C≡C bond in the *endo* approach. Moreover, in these optimized geometries of complexes **11** and **14**, the $R_{C\equiv C\cdots F}$ equals 3.161 Å and the $R_{C\equiv C\cdots Cl}$ equals 3.824 Å. These predictions are in good agreement with the reported FTMS experimental results (4, 5). Also there is a significant amount of hydrogen-bond energy (−4.87 kcal/mol) for the 2-butyne·HCl (C_4H_6·HCl, **17**) complex. Obviously it is a stable complex that is, in fact, in good agreement with the X-ray determination of its solid-state geometry (6).

2. Molecular graphs of π-type hydrogen-bonded complexes

The topological properties of the electron density distributions of these 11 (**5–8**, **10–15**, **17**) complexes have been analyzed in terms of the theory of atoms in molecules. For these hydrogen-bonded systems the location of all BCPs and attractors were determined,[4] and the molecular graphs were mapped out for the hydrogen-bonded systems studied. These molecular graphs of the C_2H_2·HX, C_2H_4·HX, C_4H_4·HX (X = F, Cl), and C_4H_6·HCl complexes are shown in Fig. 2. As shown in this figure, π-type hydrogen bonding does exist and it is perpendicular to the C≡C and C=C bonds. All of them have the same "conflict type" structure. In particular, it is found, for C_4H_4·HF complexes, that both the *endo* and *exo* approaches lead to complexes that are nearly planar, with the proton of HF directed towards the triple C≡C bond in vinyl acetylene, forming a π-type hydrogen bond. Furthermore, a second hydrogen bond is formed between H of a C—H bond and F of

[4] For the monomers and complexes containing a carbon–carbon triple bond, there is an exceptional local maximum in $\rho(r)$ on the axis between two acetylenic carbons at the 6-31G(d, p) level of theory. For example, in acetylene, there is a local maximum in $\rho(r)$ at the midpoint of the C≡C bond (ρ = 0.4180 au) and two (3, −1) critical points, besides this maximum, at which ρ = 0.4146 au. In better approximations (MP2/6-311++G(d,p) or MP2/6-311++G(2d,2p)) for these monomers and complexes, these spurious maxima are no longer present. Similar results were reported (18*a*) previously for acetylene and its methyl derivative at the STO-3G level of approximation. For a comparison of HF-SCF, CI, and DFT, it was reported recently (26, 27) that the electron density in the BCP regions is overconcentrated by HF-SCF (probably it causes the existence of an exceptional local maximum in $\rho(r)$ on the axis between two acetylenic carbons) and is reduced correctly by DFT. In our further calculations, there is no exceptional local maximum at all in $\rho(r)$ on the axis of the C≡C bond in C_2H_2, $C_2H_2\cdots$HF, and $C_2H_2\cdots$HCl systems using DFT at the B3LYP/6-31G(d,p) level of theory. In the monomer, C_2H_2, there is only one (3, −1) BCP at the midpoint of the C≡C bond, at which ρ = 0.4023 au.

Fig. 1. The 6-31G(d,p) optimized geometries of C_2H_2·HX, C_2H_4·HX, C_4H_4·HX, and C_4H_6·HX hydrogen-bonded complexes and their components: **1**, HF; **2**, HCl; **3**, C_2H_2; **4**, C_2H_4; **5**, C_2H_2·HF; **6**, C_2H_2·HCl; **7**, C_2H_4·HF; **8**, C_2H_4·HCl; **9**, C_4H_4; **10**, C_4H_4·HF (*exo* approach); **11**, C_4H_4·HF (*endo* approach); **12**, C_4H_4·HF (perpendicular approach); **13**, C_4H_4·HCl (*exo* approach); **14**, C_4H_4·HCl (*endo* approach); **15**, C_4H_4·HCl (perpendicular approach); **16**, C_4H_6; and **17**, C_4H_7·HCl. Bond lengths are in Å and angles are in degrees.



HF and a ring critical point is found, which confirms a ring structure (Figs. 2*e* and 2*f*). No second hydrogen bond is found in the HCl complexes. In Figs. 2*g* and 2*h*, the HX perpendicular approach to the C=C bond yields a hydrogen-bonded system. Since a conflict structure is an unstable structure (11, 18*a*), perturbation from the acetylenic group is strong enough to cause the hydrogen bond path to switch to the carbon of CH_2 and it no longer points towards to the centre of the C=C bond as is the case in C_2H_4·HX (Figs. 2*c* and 2*d*).

3. The nature of π-type hydrogen bonds

The values that are characteristic of hydrogen bonds, associated with the BCPs for C_2H_2·HX, C_2H_4·HX, and C_4H_4·HX (X = F, Cl), are given in Table 2 as computed at the MP2/6-311++G(d,p) level of theory as well as for the C_4H_6·HCl system computed at the MP2/6-311++G(2d,2p) level.

The nature of these hydrogen bonds, both π- and σ-type, can be further investigated from the distributions of the Laplacian of the electron density, $\nabla^2\rho(\boldsymbol{r})$. *Firstly*, in general, at the BCP, covalent bonding (shared interaction) is characterized by $\nabla^2\rho(\boldsymbol{r}_b) < 0$, while the interaction of two closed-shell atoms is characterized by $\nabla^2\rho(\boldsymbol{r}_b) > 0$ (11). Indeed, the values of $\nabla^2\rho(\boldsymbol{r}_b)$, where $\boldsymbol{r}_b$ denotes the BCP of the hydrogen bonds in these complexes, are all positive as in Table 2. These values clearly show that these hydrogen bonds, in the above-mentioned complexes, both π- and σ-type, result from the interaction of two closed-shell systems. *Secondly*, it was reported (17*e*) that in the Lewis base·HX complexes the nonbonded

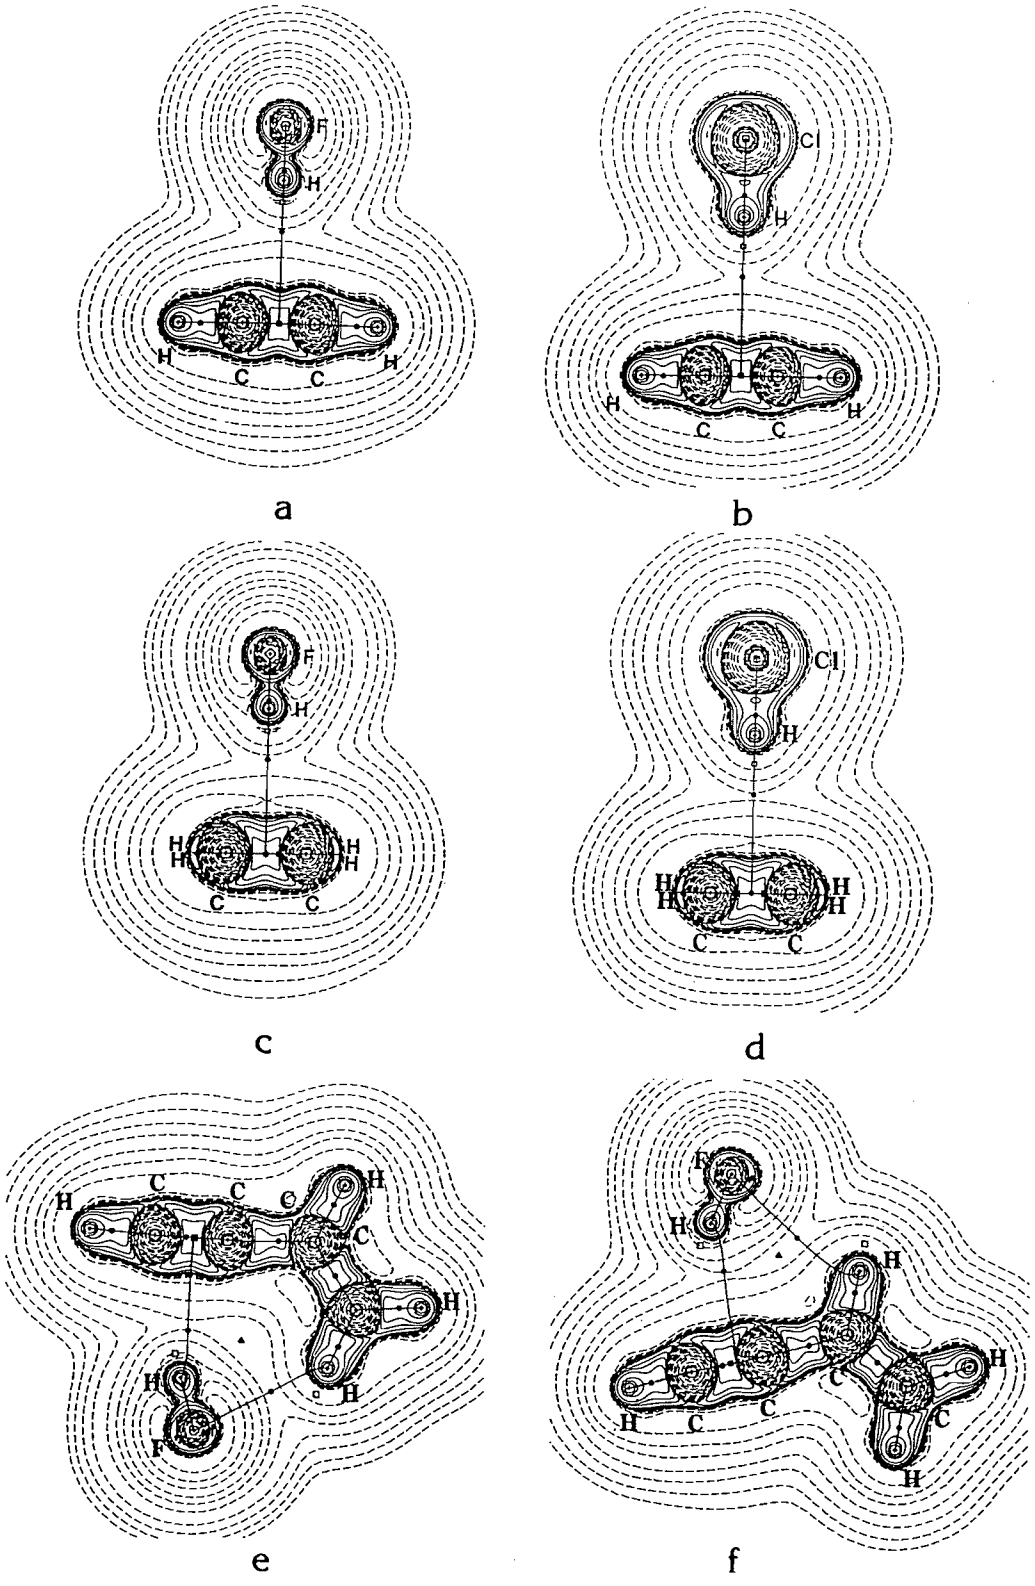

Fig. 2 (*concluded*).

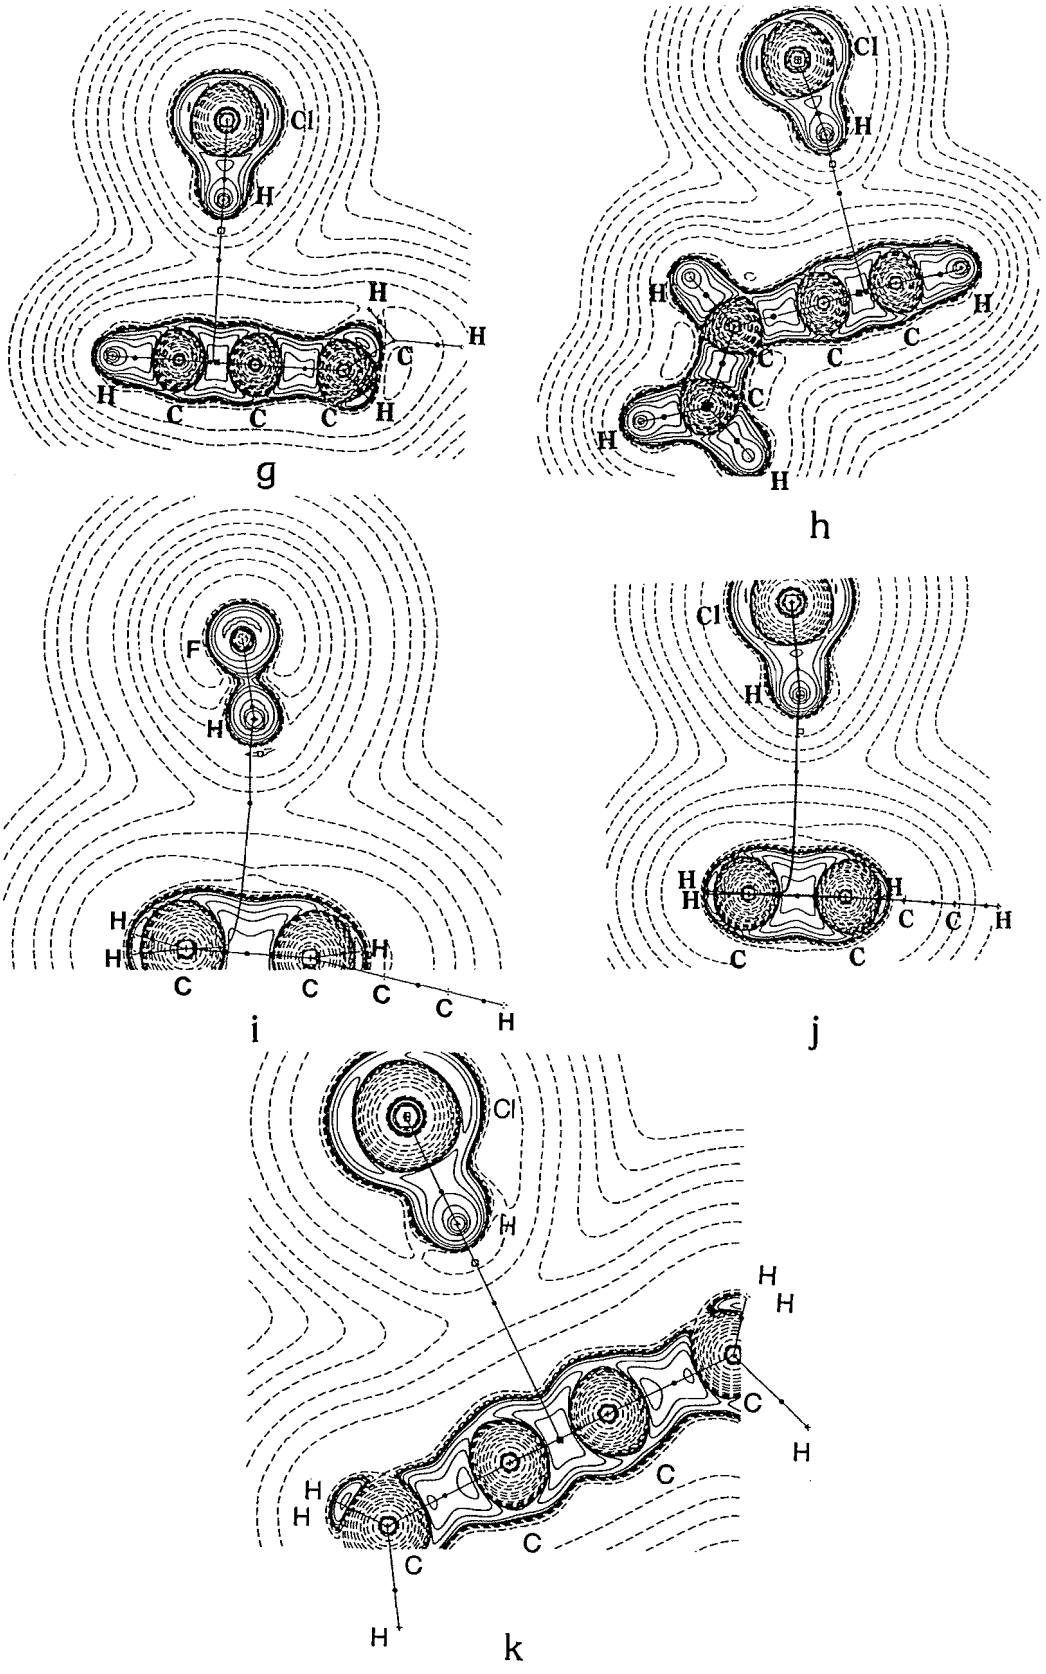

Fig. 3. The Laplacian of electron density profiles along the multiple CC bond in (*a*) C_2H_4, (*b*) C_2H_2, (*c*) C_2H_4·HF, (*d*) C_2H_2·HF.

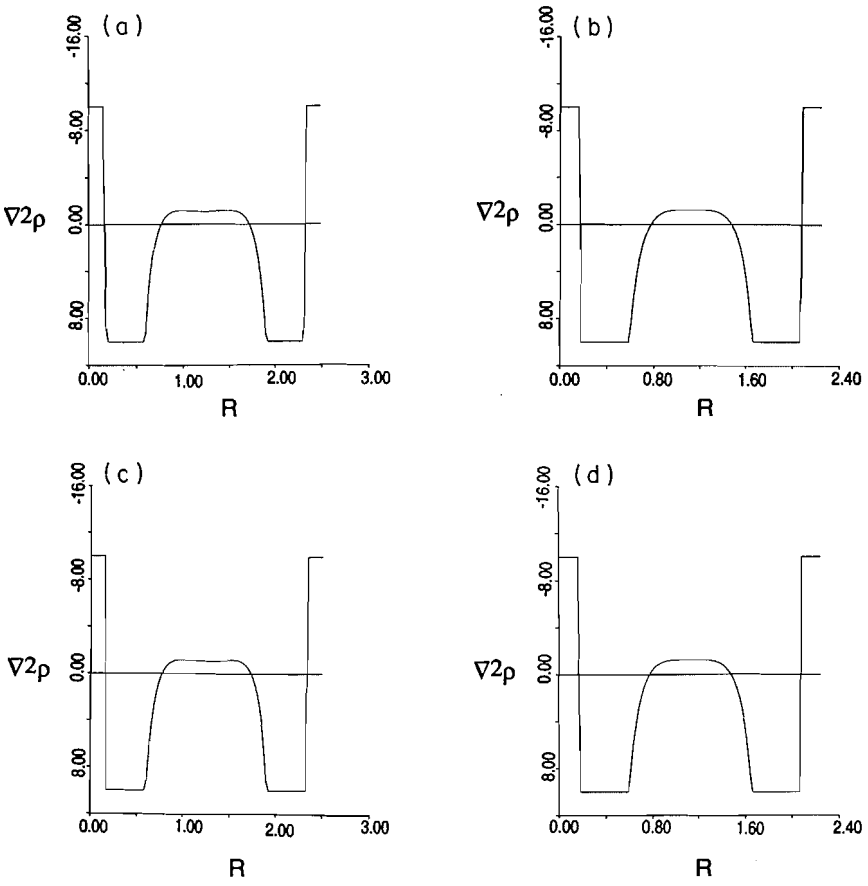

Laplacian concentration (the maximum of $\nabla^2\rho(\boldsymbol{r})$) in the Lewis base is predicted to be the site of electrophilic attack and the approach of the Brønsted acid proton is such as to align the Laplacian depletion (the minimum of $\nabla^2\rho(\boldsymbol{r})$) on H of HX with the chosen Laplacian concentration of the Lewis base. This is the case for σ-type hydrogen bonding. However, in π-type hydrogen bonding there is no nonbonded Laplacian concentration, but bonded Laplacian concentration(s) of the electron density at the multiple carbon–carbon bonds: only one located at the midpoint of the C≡C bond and two Laplacian concentrations close to each carbon of the C=C, respectively. It seems, for C_2H_2·HX and C_2H_4·HX systems, that the direction of attack of the Laplacian depletion on the H of the Brønsted acid, HX, is towards the bonded concentration at the C≡C bond in C_2H_2·HX systems, or equally to two bonded concentrations at the C=C bond in C_2H_4·HX systems (see Fig. 2*a*–2*d*). The Laplacian of the electron density profiles between two carbons along the C=C and C≡C bonds for C_2H_2, C_2H_4, C_2H_2·HF, and C_2H_4·HF systems are shown in Fig. 3. From Fig. 3 it is clear that there is only one Laplacian maximum along the C≡C bond in both the C_2H_2 monomer and the C_2H_2·HF complex but there are two Laplacian maxima present along the C=C bond in both the C_2H_4 monomer and the C_2H_4·HF system. Based on the MP2/6-311++G(d,p)//6-31G(d,p) calculations, further discussion of the nature of π-type hydrogen bonding can be exemplified by the following systems. For the C_2H_2·HF complex (Fig. 2*a*) there is a Laplacian depletion, namely a (3, +3) critical point in $-\nabla^2\rho(\boldsymbol{r})$, located 0.356 Å away from the position of the proton of HF on the HF bond axis and $-\nabla^2\rho(\boldsymbol{r}) = +0.2167$ au. Also, there is a Laplacian concentration, a (3,−3) critical point in $-\nabla^2\rho(\boldsymbol{r})$, located at the midpoint of the C≡C bond (equally 0.594 Å away from each of the carbon atoms with $-\nabla^2\rho(\boldsymbol{r}) = -1.2508$ au). For the C_2H_4·HF complex (Fig. 2*c*), again there is a Laplacian depletion located 0.356 Å away from the proton of HF on the HF bond axis with value of $-\nabla^2\rho(\boldsymbol{r}) = +0.2150$ au. On the other side of the complex, there are two Laplacian concentrations on the C=C bond that are equally 0.522 Å away from each of the carbon atoms on the C=C bond axis, each with a value of $-\nabla^2\rho(\boldsymbol{r}) = -1.1633$ au. For the C_4H_4·HF (*endo* approach) complex (Fig. 2*e*), there is a Laplacian depletion located "outside," 0.350 Å away from the proton of HF on the bond axis of HF, at which the $-\nabla^2\rho(\boldsymbol{r})$ has a value of +0.2307. On the C_4H_4 part of this complex, there is a Laplacian concentration located at the C≡C bond that is 0.624 Å away from the CH carbon and 0.568 Å from the internal acetylenic carbon, with a value of $-\nabla^2\rho(\boldsymbol{r}), = -1.2300$ au. The hydrogen bond path still links to this C≡C bond perpendicularly although the Laplacian concentration is no longer located at the midpoint of this C≡C bond. However, for the C_4H_4·HF (*exo* approach) complex (Fig. 2*f*), there is a Laplacian depletion that is 0.356 Å from H of HF along the bond axis of HF, with value $-\nabla^2\rho(\boldsymbol{r}) =$

+0.2161. On the other part of this complex, a Laplacian concentration is located at the C≡C bond that is 0.622 Å away from the CH carbon and 0.569 Å from the internal acetylenic carbon at which $-\nabla^2\rho(r) = -1.2293$ au. In this case, which is different from the previous, the hydrogen bond path switches to the internal acetylenic carbon. For the C_4H_4·HF (perpendicular approach) complex (Fig. 2*i*), there are two Laplacian concentrations on the C=C bond. One of them is 0.518 Å away from the middle acetylenic carbon atom, with a $-\nabla^2\rho(r)$ value of −1.1805 au, and the second one is 0.524 Å away from the CH_2 carbon, with $-\nabla^2\rho(r) = -1.1380$. There is a Laplacian depletion 0.357 Å away from the proton of HF on the HF bond axis at which $-\nabla^2\rho(r) = +0.2157$. In this complex (**12**), the direction of attack of the Laplacian depletion on the H of the Brønsted acid HF is located towards two different bonded concentrations at the C=C bond of the C_4H_4 part, in an unequal fashion. Most likely the perturbation from the acetylenic group changed the positions and values of these two bonded concentrations and then caused the hydrogen bond path to switch to the carbon atom of the CH_2. *Thirdly*, it is quite clear that in the C_4H_4·HF complexes (**10** and **11**), in both *endo* and *exo* approaches, a second hydrogen bond is formed between H of a C—H and F of HF that is a σ-type hydrogen bond. Finally, it was reported earlier (17*h*, 18*b*) that the ρ value at the BCP is related to the bond order and therefore to the bond strength. From Table 2, the $\rho(r_b)$ values of both π-type and σ-type hydrogen bonds in C_4H_4·HF (*endo* approach, **11**) are larger than in C_4H_4·HF (*exo* approach, **12**). Consequently, it is understandable that complex **11** is energetically more stable than **12**.

Acknowledgement

The calculations were mostly carried out on the HP-750 computer at the Department of Chemistry, University of Toronto. We would like to thank Professor Imre G. Csizmadia for his interest in this work.

Topological analysis of the experimental electron density

Vladimir G. Tsirelson

Abstract: Methods of topological analysis of the experimental electron density reconstructed from X-ray diffraction data are described. Their advantages and drawbacks are discussed and the results for organic and inorganic crystalline solids are presented.

Key words: topological analysis, experimental electron density.

Résumé : On décrit des méthodes d'analyse topologique de densités électroniques expérimentales reconstruites à partir de données de diffraction des rayons X. On discute de leurs avantages et de leurs limitations et on présente les résultats obtenus à l'aide de solides cristallins organiques et inorganiques.

Mots clés : analyse topologique, densité électronique expérimentale.

[Traduit par la rédaction]

Introduction

Richard Bader opened a new avenue in chemical physics when he used Schwinger's principle of stationary action (1) for the description of many-electron systems (2, 3). According to this principle, the quantum action integral

$$W_{12}[\Psi] = \int_{t_1}^{t_2} dt \int L(\Psi, \nabla\Psi, \Psi^*, t)d\boldsymbol{r}$$

($L(\Psi, \nabla\Psi, \Psi^*, t)$ is the many-particle Lagrangian density) does not depend upon infinitesimal variation of the state function Ψ within the time interval $t_2 - t_1$; rather, it depends on the action of the infinitesimal generator of transformation at time points t_1 and t_2. Using an additional condition $d\Psi = d\Psi^* = 0$ at finite points of a time interval, Bader has shown that from one universal dynamical principle, $dW_{12} = 0$, one can obtain both equations of motion and expected values of observed quantities as well as determine the expected values of physical characteristics of the fragments of a total system.

For a description of ground state many-electron systems it is sufficient to use the one-particle Lagrangian density, $L(\boldsymbol{r})$. It is connected by the relation

$$[1] \quad L(\boldsymbol{r}) = -(\hbar^2/4m)\nabla^2\rho(\boldsymbol{r})$$

with the ground state electron density (ED) $\rho(\boldsymbol{r})$. Consideration of the virial of the force density results in the expression (4)

$$[2] \quad -L(\boldsymbol{r}) = 2G(\boldsymbol{r})+V(\boldsymbol{r})$$

Received October 31, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

were $G(\boldsymbol{r})$ and $V(\boldsymbol{r})$ are the densities of electron kinetic energy and electron potential energy, respectively, at point $\boldsymbol{r}$. From expressions [1] and [2] there follows a local form of the virial theorem:

$$[3] \quad 2G(\boldsymbol{r}) + V(\boldsymbol{r}) = (\hbar^2/4m)\nabla^2\rho(\boldsymbol{r}).$$

It shows that densities of kinetic and potential energies in any point of position space are related via the Laplacian of ED.

An important role of the ED and its derivatives led Bader to a thorough analysis of the topological properties of ED. The many features of function ρ are described by a number and type of critical points (CP), $\boldsymbol{r}_c$, points at which $\nabla\rho(\boldsymbol{r}_c) = 0$. The type of CP is determined by its rank, l, and signature s. Rank l equal to the number of non-zero eigenvalues of a 3×3 curvature (Hessian) matrix of $\rho(\boldsymbol{r})$. Signature s is a difference between the numbers of positive and negative eigenvalues of this matrix. The ED shows four types of nondegenerate CP with $l = 3$: maxima $(3, -3)$; saddle points $(3, -1)$ and $(3, +1)$; minima $(3, +3)$.

Application of the Gauss theorem (5) to eq. [3] gives

$$[4] \quad \int (2G(\boldsymbol{r}) + V(\boldsymbol{r}))d\boldsymbol{r} = \oint_S \nabla\rho(\boldsymbol{r})\cdot n(\boldsymbol{r})\, dS(\boldsymbol{r})$$

The right-hand side of this expression vanishes in molecules and crystals if the surface S covers them completely or if the ED gradient vector flux through these surfaces is zero. It has been postulated (6) that local ED maxima, corresponding to $(3,-3)$ CP, are present at nuclei positions only.[2] This results from the asymptotic condition describing the local behaviour of true ED near the nuclei (11–13). Since vector $\nabla\rho$ indicates the direction of greatest increase in ED, the ED areas embracing nuclei happen to be separated in many-nuclear systems by the surfaces on which vector $\nabla\rho$ changes its direction. The zero-flux surfaces S are taken as boundaries of bonded atoms, the latter coincide with an atom defined according to the sta-

[2] The existence of the non-nuclear local ED maxima has been discussed in refs. 7–10.

tionary action principle modified by Bader. The Hohenberg–Kohn theorem (14) as well as virial theorem (15) are valid for such atoms and the total energy and other properties of a system are expressed as a sum of atomic contributions.

The pairs of gradient lines starting from the same (3, −1) CP and terminating at two neighbouring nuclei are determined by eigenvectors corresponding to a single positive eigenvalue of the Hessian at this point. They form the atomic interaction lines, along which the ED decreases for any lateral displacements. The saddle point on this line in a stable system is called the bond critical point (BCP). The set of bond lines yields a molecular graph, which thus has a hard physical basis and usually coincides with the structural formula used in the classical chemical theory of molecular structure [16].

Critical points of types (3, +1) and (3, +3) arise only in the presence of rings and cages. A significant number of these points always exist in crystals (17–19).

Three Hessian eigenvalues, $\lambda_1 < \lambda_2 < \lambda_3$, characterize three ED curvatures at the point considered as well as three corresponding mutually orthogonal eigenvectors, u, directed along the principal curvatures. The sign of the $\nabla^2\rho = \lambda_1 + \lambda_2 + \lambda_3$ depends on the relation between these three items. In the (3, −1) BCP, the eigenvalues λ_1 and λ_2, corresponding to eigenvectors normal to the bond line, are negative. The λ_3 is positive and the corresponding eigenvector is directed along the bond line. When $|\lambda_1| + |\lambda_2| > 1$, the ED is concentrated at BCP; in the opposite case the ED is depleted here. Thus, the sign of $\nabla^2\rho$ can be related to the character of the atomic interactions, i.e., the character of the chemical bond. This results in a natural division of the atomic interactions into two types (20). Negative λ_1 and λ_2 values measure the degree of contraction of ED toward the BCP, perpendicular to the bond path. The positive λ_3 value measures the degree of ED contraction toward each of the neighbouring nuclei. If the ED is locally concentrated in the region of the BCP, it is then shared by both nuclei. The local electronic potental energy in the BCP region is more than twice in excess of the local kinetic energy in this case. Such a picture is typical for a covalent bond. If the positive curvature dominates in the BCP, the ED is concentrated in each of atomic basins separately and a relatively large positive contribution to the local kinetic energy of a system takes place. Such closed-shell interactions are usually observed in ionic and hydrogen bonds and van der Waals interactions.

The spatial distribution of the Laplacian of ρ characterizes concentration and depletion of the ED at each point of a system. It reveals the nonevident peculiarities of ED distribution such as shell structure of atoms (21, 22), localized electron pairs (23), etc. and points out areas where the local potential energy dominates in bonded systems. Additionally, the $\nabla^2\rho$ is connected with local electron energy, $H_e(\boldsymbol{r}) = G(\boldsymbol{r}) + V(\boldsymbol{r})$ (15, 24) by the simple expression

$$[5] \quad H_e(\boldsymbol{r}) = [V(\boldsymbol{r}) + (\hbar^2/4m)\nabla^2\rho(\boldsymbol{r})]/2$$

The sign of $H_e(\boldsymbol{r})$ shows whether kinetic or potential energy dominates at a given point of a space: if $V(\boldsymbol{r})$ dominates in the internuclear region, the $H_e(\boldsymbol{r}) < 0$ here and the accumulation of electrons is stabilizing. In a bonded system the local electron energy density is negative at the covalent bond critical points independent of the sign of $\nabla^2\rho$: the relation $(1/4)\nabla^2\rho < |V(\boldsymbol{r})|$ is fulfilled in this case even if $\nabla^2\rho > 0$. Unfortunately, the positive values of $\nabla^2\rho$ and of H are observed in closed-shell interactions at the (3, −1) points, therefore it is impossible, considering $H_e(\boldsymbol{r})$, to separate the ionic, hydrogen, and van der Waals bonds from one another.

Thus, in order to characterize the chemical bond it is necessary to calculate the topological characteristics of ED in a space of the molecule or crystal or, sometimes, only at the critical points.

Topological theory has been applied mainly to analysis of theoretical electron densities, as was reviewed in refs. 2 and 25–28. However, starting from the first earlier work (29, 30), it is increasingly being applied to treatment of the experimental ED obtained from X-ray diffraction data. Topological analysis of the experimental ED has same specificity, which should be taken into account in interpretation of the data obtained. This approach is discussed in the present work.

When the absolute values of kinematic structure amplitudes are obtained from intensities of reflection measured and their phases are calculated with any crystal structural model, the problem of crystal ED reconstruction is reduced to the calculation of the Fourier series with complex structure amplitudes $F(\boldsymbol{H})$ as coefficients, or to fitting some model of ED to these structure amplitudes. Correspondingly, there are three different methods in topological analysis of the experimental ED (29, 31). One of them consists of differentiation of Fourier series with respect to coordinates. The second method consists of the calculation of $\nabla\rho$ and $\nabla^2\rho$ represented as a sum of contributions from spherical atom superposition (promolecule) ED, $\rho_o(\boldsymbol{r})$, in the position space and the Fourier series for deformation ED. The third method is based on the use of the multipole model presenting ED in simple analytical form. Let us consider these approaches in detail.

Calculation of the topological characteristics with Fourier series

Fourier decomposition of the ED has the form

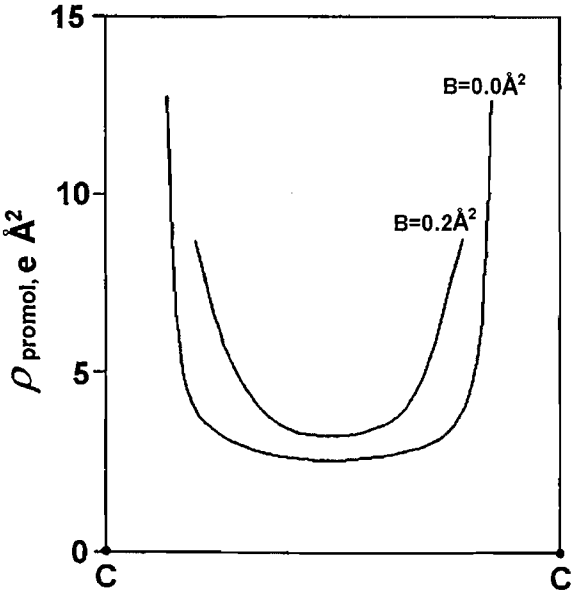
$$[6] \quad \rho(\boldsymbol{r}) = (1/V) \sum_{\boldsymbol{H}} F(\boldsymbol{H}) \exp(-2\pi i \boldsymbol{H}\boldsymbol{r})$$

(V is the unit cell volume). At infinite summation limits in eq. [6], ρ has the same sign over the whole space, and satisfies the condition of electroneutrality of the unit cell: $\int\rho(\boldsymbol{r})\, d\boldsymbol{r} = N$, and, therefore, is N-representable (it can be described by an antisymmetric many-electron wave function (32, 33)).

The experimental ρ is a dynamic function because it includes the thermal motion effect. The question arises: can the topological theory be applied to dynamic ED? The answer, fortunately, is "yes." The molecular graphs for all nuclear configurations in the neighbourhood of equilibrium geometry are equivalent (2). Therefore, the same set of the critical points describes both static and dynamic systems. The quantitative values of topological characteristics depend, of course, on the thermal motion of the nuclei (34, 35). The last point is illustrated the Fig. 1. Hence, for the general case, low-temperature X-ray diffraction data are preferable for obtaining the thermally independent topological characteristics of the ED.

Only a limited number of reflections are measured inside the reciprocal space sphere with $q = (\sin\theta/\lambda) < 1/\lambda$, where λ is the radiation wavelength. At the wavelengths applied in accurate X-ray structure analysis, a resolution in experimental ED

Fig. 1. Influence of the thermal atomic motion on the electron density along the C–C line in the promolecule (the superposition of spherical atoms) of ethylene, C_2H_4 (B is the isotropic thermal parameter of the C atom). Thermal motion diminishes the curvature of the electron density in the interatomic region.



of $\lambda/3 \sim 0.2$ Å is achieved, according to the Rayleigh criterion. This results in false maxima and minima in the ED picture, which are especially significant in those regions of space where ρ varies most rapidly, for instance, near nuclei. These distortions will be much more evident in functions $\nabla\rho$ and $\nabla^2\rho$ (5). Simple extension of the Fourier series by adding theoretical values of structure amplitudes is not effective (36) and leads to an increase of the function variance (37). Moreover, although the derivatives of ρ exist, in fact, a formal differentiation of eq. [6] with respect to x, y, z results in divergent Fourier series for $\nabla\rho$ and $\nabla^2\rho$.

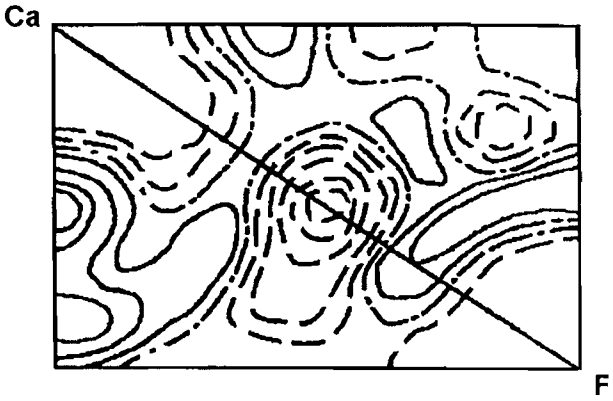
In addition, due to the presence of random errors in the structure amplitudes, the summation of approximate values in the Fourier series, eq. [6] is unstable (38) and the calculation of ρ and its derivatives with this series is a so-called ill-posed problem.

Thus we wish to reconstruct the topological characteristics of the experimental ED distorted by the Fourier series truncation effect and by statistical errors. The Lanczos method of calculating the derivatives of finite Fourier series by averaging over a "false" wave period (39) and the theory of regularization (38) allow one to obtain the mathematically correct solution of this problem. The Lanczos method gives the derivatives of the functions, presented as limited Fourier series, that are as close to the correct ones as is possible at the resolution achieved. For example, writing the second derivative of the Fourier series in a finite-difference form and averaging, we arrive at the following expression (29):

$$[7] \quad \nabla^2\rho(\boldsymbol{r}) = -(4\pi^2/V)\sum M_{hkl}L_{hkl}F(hkl) \times \exp[-2\pi i(hx + ky + lz)]$$

with

Fig. 2. Laplacian of the electron density in fluorite crystal, CaF_2, determined with Fourier series: the map contains the Ca—F ionic bond. The broken lines correspond to points with $\nabla^2\rho > 0$. The lines around atomic centers are omitted.



$$[8] \quad L_{hkl} = \sum_i \{\sin^2[\pi h_i/(H_i + 1)]/[\pi h_i/(H_i + 1)]^2\}(h_i/a_i)^2$$

Here $a_i = a, b, c$ are crystal unit cell parameters, and H_i are maximal values of Miller indicies h, k, l in the structure amplitude set. It is seen that the L_{hkl} factors actually provide the convergency of series [7].

The introduction in series [7] the regularising (filtering) factors M_{hkl} (40):

$$[9] \quad M_{hkl} = \begin{cases} |F(hkl)|^2/[|F(hkl)|^2 + \sigma^2(|F(hkl)|] & |F| > \beta\sigma(|F|) \\ 0 & |F| \le \beta\sigma(|F|) \end{cases}$$

according to general theory (38) allows the influence of random errors to diminish. The M-factors smoothly depend on the level of error in the X-ray diffraction data: $\beta < 3$, if the random errors in a structure amplitudes set are distributed according to Gauss' law (which can be checked by means of statistical tests (41)).

The method outlined allows calculation of the best approximation to the "true" Laplacian of ED directly from the X-ray structure amplitudes. The results remain dependent on the series truncation effect, and the shell structure of bonded atoms is lost in this method. At the same time, the ED curvature in the internuclear space is properly reproduced. Studies of fluorite, CaF_2 (29), spinels $MgAl_2O_4$, $CoAl_2O_4$, and $FeAl_2O_4$ (42), and a few garnets (43, 44) have shown that the correct sign of the function $\nabla^2\rho$ is obtained in between atoms. The map of the Laplacian of ρ in the (110) plane of fluorite calculated by formula (7) is shown in Fig. 2. There are no typical "false" waves around the nucleus position in this map ($\sin\theta/\lambda < 1.164$ Å^{-1}); simultaneously, a well-localized area of positive $\nabla^2\rho$ values is observed in the centre of the Ca–F line. In accordance with general theory (2), a depletion of electrons takes place here. Together with location of the negative $\nabla^2\rho$ regions near the ion positions, these are typical features of the ionic bond.

The method discussed was used in ref. 45 to investigate the

weak secondary atomic interactions in spinels $MgAl_2O_4$, $FeAl_2O_4$, and $CoAl_2O_4$. The spinel AB_2C_4 structure (space group *Fd3m*) can be considered as close packing of C-type anions with 2- and 3-valent cations in tetrahedral (A) and octahedral (B) positions, respectively. The magnetic properties of the spinels are usually explained phenomenologically by indirect exchange interactions between A and B sublattices via nonmagnetic anions (46). This indirect exchange leads, as a rule, to antiferromagnetism and, sometimes, in ferrimagnetism. The magnetic ordering in $FeAl_2O_4$ and $CoAl_2O_4$ occurs at very low (helium) temperatures; however, the corresponding true magnetic structures are still unknown. The indirect exchange channel A-O-B-O-A, the A-O-B angle being ~121°, is most probable for spinels with a nonmagnetic B-cation (47). An additional direct exchange channel A-A can, in principle, take place as well (48).The distance between two A cations in spinels is about 3.5 A and direct interaction is weak, nevertheless it should manifest itself in specific ED distribution between the A cations. The deformation ED maps have supported the indirect exchange picture; however, they did not offer an explanation of the interactions in the A-A area of $FeAl_2O_4$ and $CoAl_2O_4$ (49).

Figure 3 presents the $\nabla^2\rho$ distributions between A-A cations in MAl_2O_4 spinels (M = Mg, Fe, Co). The region of positive $\nabla^2\rho$ values is revealed between both nonmagnetic A-cations in Mg-spinel and the magnetic one in Co-spinels. At the same time, negative $\nabla^2\rho$ areas are observed here in $FeAl_2O_4$. It is evident that ED concentrates between magnetic Fe cations and favours the direct A-A interactions in $FeAl_2O_4$. A polarized neutron study is needed to confirm this observation.

Combination of the Fourier and position space presentations

Fourier series truncation and thermal smearing are strong disadvantages of the approach just described. To avoid these drawbacks, the use of a combination of Fourier and position space presentations of ρ was suggested (50). The ED is presented as a sum of the superposition of atoms (promolecule), ρ_0, and deformation ED, δρ. Then, the expression for the Laplacian of ρ has the form

$$[10] \quad \nabla^2\rho(\boldsymbol{r}) = \nabla^2\rho_0(\boldsymbol{r}) + \nabla^2\delta\rho(\boldsymbol{r})$$

The first term on the right-hand of eq. [10] is easily calculated using tabulated atomic wave functions (51) or the Fourier transform of the atomic scattering amplitudes, expressed in parametric form (52). The second term in eq. [10] is presented in the Fourier series form in analogy with eq. [7]. The Fourier series for $\nabla^2\delta\rho$ converges much better than that for $\nabla^2\rho$ and

can be regularized in the same manner as the series for ρ. As well, calculations (34, 53) have confirmed Stewart's prediction (54) that the experimental deformation ED, which follows mainly lattice modes and suffers less from thermal smearing, can be considered as near pseudostatic. Moreover, the $\nabla^2\rho$ can be calculated from static model structure amplitudes. Since the ED of the promolecule is calculated as a static function as well, the consequences of thermal smearing are to a great extent rejected for derivatives of ρ.

The approach described was used for the first time in the study of monoclinic modification of ethane, C_2H_6 (55). This compound crystallizes at 90 K and only a small temperature gap exists between the melting point and X-ray measurement temperature of 85 K (56). Therefore the thermal smearing significantly distorts the ED curvature. Despite that, the (3, −1) CP were found on C—C and C—H bonds in crystalline ethane (Table 1) and values of $\nabla^2\rho$ at these points proved to be in agreement with the corresponding values calculated nonempirically for the free molecule. The agreement for C—H bonds is worse due to a larger thermal smearing effect for bonds with a light H atom, as can be expected. The overall experimental picture of the Laplacian of ρ agreed with theory as well (Fig. 4). At the same time, the crystal environment distorts the axial ED symmetry of the formally single bond in the ethane crystal. The quantitative measure of preferential concentration of electrons in a plane perpendicular to the interatomic line is ellipticity $\varepsilon = \lambda_1/\lambda_2 - 1$ (2). If the axes associated with λ_1 and λ_2 are symmetrically equivalent, as in the C—C bond of the free ethane molecule, then $\lambda_1/\lambda_2 = 1$ and $\varepsilon = 0$. However, the experimental ellipticity of this bond in a crystal is different from zero. The eigenvector, directed along the minimal decrease of the ED, deviates only at 15° from the direction toward the nearest-neighbour molecule in the crystal; at the same time the axes of the tensor of the C atom thermal vibra-

tions are oriented in other directions. Therefore, the ED polarization observed can be treated as a manifestation of intermolecular interaction in solid ethane. Thus, the ellipticity describes the mutual molecule influence as well as the π character of a chemical bond and conjugative and superconjugative effects, as stated in ref. 57.

The molecule of 9-azido-*m*-carborane, N_3-*m*-$C_2B_{10}H_{11}$, depicted in Fig. 5(*a*) is an example of a system where all types of critical points are present. The BCP are found, using the method discussed, on all interatomic lines in three-membered rings forming the icosahedron surface (Table 2) as well as on external B9—N1, N1—N2, and N2—N3 bonds; only the B9—N1 bond is characterized by a positive value of $\nabla^2\rho$ and, therefore, has ionic character. The icosahedron BCP lie outside lines connected to the nuclei in three-membered rings; large ellipticity values are observed at these points. The (3, +1) CP are located near the center of the B_3 rings (Fig. 5(*b*); the ED values at these points differ on average by only 0.08 e A^{-3} from those at the (3, −1) CP. All bonds with participation of the B atom are characterized by a relatively low value of the ED due to an electron deficiency of these bonds. Simultaneously, a small displacement of the ED to the more electronegative C atom is observed. The (3, +3) CP, a local minimum of the ED (ρ = 0.106 e A^{-3}), is sited approximately in the centre of the icosahedron. The Laplacian of the ED here is positive, $\nabla^2\rho$ = 3.87 e A^{-5} (Fig. 5(*c*); correspondingly, the depletion of the ED takes place inside the icosahedron. Thus, topological treatment of the X-ray experimental data (57) shows that the electron cloud is significantly delocalized on the surface of the icosahedron in 9-azido-*m*-carborane, as was predicted in ref. 16. Analysis of more simple *closo*-carboranes on the basis of nonempirical calculations (58) has resulted in the same topological picture.

Topological analysis of the model electron density

The parametric models of the ED, reconstructed by fitting to the experimental structure amplitudes, are to a large extent free from the effects of limited resolution of Fourier series, thermal smearing, and experimental statistical errors (31). One of these

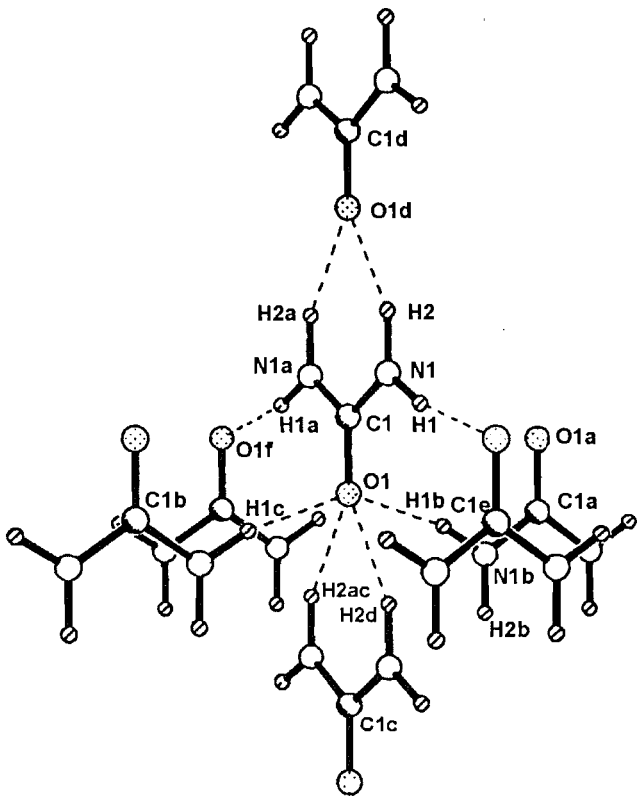
[a]The experimental and theoretical values are presented in the first and second lines, respectively. R_A is the distance from the first atom in the A–B interaction to the critical point.

Fig. 6. Fragment of the urea crystal.



models, the multipole model, describes the ED of a crystal as superposition of the nuclear-centered pseudoatomic electron densities. The valence part of each pseudoatom is presented in the form of a Laplacian series; the radial dependence of each member of the series is described by the function

$$R_l(r) = Nr^{n_l} \exp(-\alpha r)$$

and angle dependence is described by spherical harmonics, $y_{lm}(\theta, \phi)$ (59–61):

$$[11] \quad \rho(\boldsymbol{r}) = \sum_i \{\rho^i_{\text{core}}(\boldsymbol{r}) + \sum_{lm} C^i_{lm} R^i_l(\boldsymbol{r}) y^i_{lm}(\theta, \varphi)\}$$

The electron populations C_{lm} and exponential factors α_l are determined by model refinement over low- and middle-angle X-ray reflections, while thermal parameters are found in the high-angle region. This allows the distortion of electronic parameters by thermal motion to diminish. The derivatives of the ED, presented as expansion [11], can be easily calculated analytically. Therefore, the use of this approach, proposed in refs. 30 and 50, in the topological analysis of the ED is most attractive and is now widely used (see, for example, refs. 31, 36, and 49).

An earlier topological analysis of ethylene, C_2H_4, and acetylene C_2H_2, compounds typical of a covalent bond, carried out by this method in ref. 50 by using low-temperature X-ray diffraction data from refs. 62 and 63, showed a negative sign of the $\nabla^2\rho$ in all BCP. However, agreement between experimental and theoretical topological values was only marginal due to incomplete elimination of the thermal smearing effect. Fortunately, much better agreement is achieved when the thermal motion effect is properly accounted for. Experimental (148 K) (64) and theoretical (65) studies of the urea crystal, CH_4N_2O (Fig. 6), support this statement. As can be seen from Table 3, quantitative agreement of the topological characteristics of both types is observed for this compound.

The interesting point of atomic interactions in solid urea is the unusual hydrogen bond picture. The planar urea molecules, linked in the crystal to each other through O...H2 hydrogen bonds, form indefinite planar types. The latter are connected with adjacent, mutually orthogonal, types by out-of-plane O—H1 hydrogen bonds. Thus, each carbonyl oxygen atom participates in four closed-shell interactions. Topological analysis shows that ED concentrations related to O-atom lone pairs take place in the molecular plane: they are responsible for formation of in-plane hydrogen bonds. The additional O...H1 interactions result from a good alignment of the saddle point sites in the valence shell of the O atom to ED minima near the H1 atoms. Hence, hydrogen bonds of nearly the same lengths may have a different nature.

Intermolecular interaction in the Cl_2 crystal gives another

Fig. 7. Maps of the Laplacian of ρ in molecular layer of crystalline Cl_2: (*a*) theoretical (the 6-21G* basis set), (*b*) calculated from the multipole model fitted to the experimental structure factors. interesting example of closed-shell atomic interactions. The structure of solid chlorine is layered, with molecules in planes parallel to the (100) plane in an orthorhombic unit cell. Short intermolecular contacts of 3.28 Å, a value significantly less than twice the accepted van der Waals radius of 1.8 Å, are observed in the (100) plane. This indicates the presence of a specific intermolecular bonding in the Cl_2 crystal, the structure of which is not described in terms of a nondirectional van der Waals potential. Indeed, it was shown both experimentally and theoretically (19) that an intermolecular interaction line connects the lone-pair charge concentration on each Cl atom with a charge depletion at the end of the neighbouring molecule; each atom participates in two such interactions in the (100) plane (Fig. 7). It is important that topological consideration of the $(Cl_2)_2$ dimer, based on the theoretical ED, allows prediction of a layered structure and geometrical characteristics of the Cl_2 crystal. Additionally, the shape of the Cl atom in both dimer and crystal proved to be far from spherical. The observations mentioned explain why spherical van der Waals potentials are not applicable to a description of the structure of solid Cl_2.

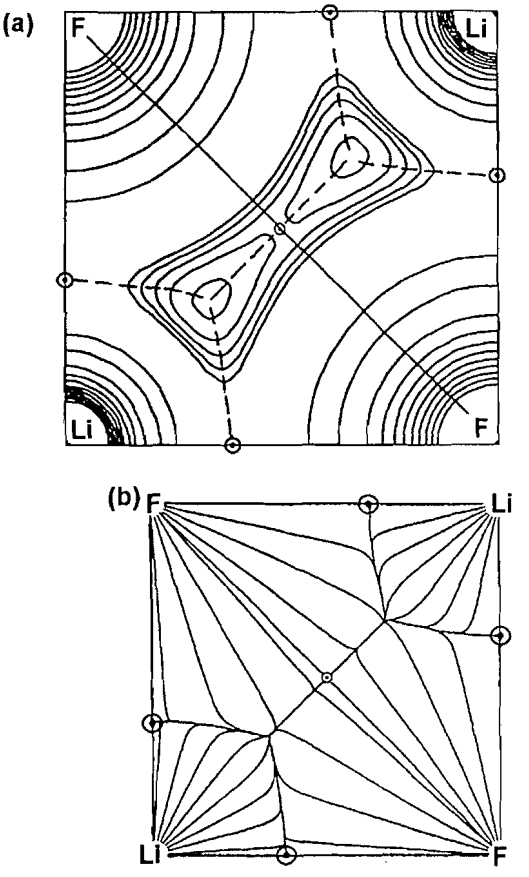
As was noted earlier, topological analysis allowed us to

Fig. 8. Topological characterization of LiF crystal: (*a*) the bond paths and (3, −1) critical points imposed on the experimental electron density; (*b*) theoretical gradient vector field and (3,−1) critical points (20).



identify the secondary interactions in spinels. This can be done in other ionic crystals as well. The nearest-neighbour F nuclei in LiF, for example, are connected by a set of bond paths (Fig. 8) in addition to the expected Li—F bond paths. The general network of bond paths results in the LiF crystal model consisting of close-packed anions with small cations in the holes. The radii of bonded ions in LiF, determined from the experimental ED as distances to the corresponding BCP along the Li–F lines, are 0.769 (Li^+) and 1.243 Å (F^-). These are very close to the Shannon and Prewitt values of 0.90 and 1.19 Å. Thus, topological analysis can provide a basis for some conclusions that are reached in traditional crystal chemistry.

Concluding remarks

Topological analysis of the experimental electron density supports the main conclusions concerning a description of the chemical bond and intermolecular and secondary interactions in crystals, based on the topological theory of Bader, applied to the theoretical ED. The use of multipole representation of the ED provides semi-quantitative agreement between the experimental and theoretical topological values obtained. Combination of theoretical and experimental approaches in order to approach an understanding of the complicated crystal structures observed in terms of their constituent parts now seems the next problem to be addressed.

Anisotropic and isotropic triple-dipole dispersion energy coefficients for all three-body interactions involving He, Ne, Ar, Kr, Xe, H_2, N_2, and CO

Sean A.C. McDowell, Ashok Kumar, and William J. Meath

Abstract: Formulae for the computation of isotropic and anisotropic dipolar dispersion energy coefficients, for two-body and three-body interactions involving H_2, N_2, CO, and the rare gases, are presented in an average energy approximation. These coefficients are computed to within 1% of the reliable values for these coefficients, which are obtained by using the relevant dipole oscillator strength distributions, with the exception of a few that are recorded in tabular form. The input data required for these formulae are the isotropic and anisotropic polarizabilities and average energies for the interacting species. The results provide the first reliable anisotropic triple-dipole dispersion energy coefficients for interactions involving molecules.

Key words: non-additive, anisotropic, interaction energies, triple-dipole dispersion energies.

Résumé : On présente des formules permettant de calculer, en approximation d'énergie moyenne, les coefficients d'énergie de dispersion dipolaire isotropique et anisotropique pour des interactions à deux et à trois corps impliquant le H_2, le N_2, le CO et les gaz rares. On peut calculer ces coefficients en deçà de 1% des valeurs fiables pour ces coefficients qui sont obtenues en utilisant les distributions des forces d'oscillateurs dipolaires appropriés, à l'exception d'un certain nombre qui ont été enregistrés sous des formes de tableaux. Les données nécessaires pour ces formules sont les polarisabilités isotropiques et anisotropiques ainsi que les énergies moyennes des espèces qui interagissent. Les résultats fournissent les premiers coefficients fiables d'énergie de dispersion anisotropique à triple dipôle pour des interactions impliquant des molécules.

Mots clés : non additif, anisotropique, énergies d'interaction, énergies de dispersion à triple dipôle.

[Traduit par la rédaction]

1. Introduction

We recently derived a computationally convenient expression for the exact triple-dipole dispersion energy (DDD) for interactions involving linear (Σ-state) molecules (1). It involves the isotropic triple-dipole dispersion energy coefficient for the interaction, C_9, and, in the most general case, seven anisotropic triple-dipole dispersion energy coefficients Γ. The coefficients C_9 and the Γ's are expressed in terms of the isotropic and anisotropic dipole oscillator strengths and excitation energies of the interacting species. Part of the purpose of this paper is to present reliable results for all the triple-dipole dispersion energy coefficients for all three-body interactions involving He, Ne, Ar, Kr, Xe, H_2, N_2, and CO. They are evaluated through the use of available isotropic and anisotropic dipole oscillator strength distributions for the interacting species (2–7).

Rather than present the large number of isotropic and anisotropic triple-dipole dispersion energy coefficients explicitly, average energy approximations (8, 9), which require a minimal amount of input data, are derived for them. The approach is first tested for the isotropic and anisotropic dipole–dipole dispersion energy coefficients for all two-body interactions involving the species of interest (Sect. 2). This average energy approximation is then adapted to the three-body interactions in Sect. 3. The average energy input parameters are listed in tables and consist of the isotropic, parallel, and perpendicular polarizabilities and average energies for each individual atom or molecule. Usually the average energy results reproduce the directly calculated triple-dipole dispersion energy coefficients to within their estimated uncertainty of ~1%. The coefficients are explicitly tabulated only for those cases (26 out of a total of 286 unique coefficients) for which this reliability is not achieved in the average energy approximation. Section 4 contains a brief discussion of our results and a comment on their overall importance.

2. A test of an average energy approximation for C_6

Here we test an average energy approximation for the calculation of anisotropic dipole–dipole dispersion energy coefficients with the view toward the extension to the triple-dipole dispersion energy (Sect. 3). The approximation is tested for the various two-body interactions arising from the species He, Ne, Ar, Kr, Xe, H_2, N_2, CO.

The long-range dipole–dipole dispersion energy, which is dependent on the relative orientations of the two interacting linear Σ-state molecules, is given (10, 11) by

$$[1]\quad E^{ab}_{\mathrm{dis},R^{-1}} = -\frac{C_6(a,b)}{R^6} \times \left[1 + \Gamma_{ab}P_2(\cos\theta_a) + \Gamma_{ba}P_2(\cos\theta_b) + \Delta_{ab}\left(\frac{4\pi}{5}\right)\sum_{m=-2}^{m=2}(3-|m|)Y_2^m(\theta_a,\phi_a)Y_2^{-m}(\theta_b,\phi_b)\right]$$

where R is the distance between the interacting molecules, P_2 and Y_2^m are Legendre and spherical harmonic functions of the spherical polar angles (θ_a,ϕ_a) and (θ_b,ϕ_a) specifying the relative orientations of the molecules a and b (as detailed in refs. 11, 12). $C_6(a,b)$ is the isotropic dipole-dipole dispersion energy coefficient (3, 4, 10, 11),

$$[2]\quad C_6(a,b) = \frac{2}{3}\left(C_{ab}^{\parallel,\parallel} + 2C_{ab}^{\parallel,\perp} + 2C_{ab}^{\perp,\parallel} + 4C_{ab}^{\perp,\perp}\right)$$

and

$$[3]\quad \Gamma_{ab} = \frac{2}{3}(C_{ab}^{\parallel,\parallel} + 2C_{ab}^{\parallel,\perp} - C_{ab}^{\perp,\parallel} - 2C_{ab}^{\perp,\perp})/C_6(a,b)$$

$$[4]\quad \Gamma_{ba} = \frac{2}{3}(C_{ab}^{\parallel,\parallel} + 2C_{ab}^{\perp,\parallel} - C_{ab}^{\parallel,\perp} - 2C_{ab}^{\perp,\perp})/C_6(a,b)$$

$$[5]\quad \Delta_{ab} = \frac{2}{3}(C_{ab}^{\parallel,\parallel} - C_{ab}^{\perp,\parallel} - C_{ab}^{\parallel,\perp} + C_{ab}^{\perp,\perp})/C_6(a,b)$$

where the anisotropic dispersion energy coefficients $C_{ab}^{\zeta,\zeta'}$, ζ, $\zeta' = \parallel, \perp$, can be expressed in terms of integrals involving the $\parallel$ and $\perp$ dipole oscillator strength distributions (DOSDs) of the interacting species a and b (3, 4, 10, 11).

Since the DOSDs contain both discrete and continuum contributions, it is computationally more convenient, without loss of accuracy, to evaluate the $C_{ab}^{\zeta,\zeta'}$ coefficients by using pseudo-DOSDs that provide a discrete representation of the original DOSDs for the molecules (3, 4, 12, 13). For molecule a, say, the ζ-component of the pseudo-DOSD is given by $\{E_{k_a}^{\zeta}, f_{k_a}^{\zeta}\}$ where the $E_{k_a}^{\zeta}$ and the $f_{k_a}^{\zeta}$ are the excitation energy – oscillator strength pairs defining the pseudo-DOSD (3, 4, 12, 13). The coefficients $C_{ab}^{\zeta,\zeta'}$ are given by (3, 4)

$$[6]\quad C_{ab}^{\zeta,\zeta'} = \frac{1}{4}\sum_{k_a=1}^{N_a}\sum_{k_b=1}^{N_b}\frac{f_{k_a}^{\zeta}f_{k_b}^{\zeta'}}{E_{k_a}^{\zeta}E_{k_b}^{\zeta'}\left[E_{k_a}^{\zeta}+E_{k_b}^{\zeta'}\right]}$$

If one of the species is isotropic (say a), then $C_{ab}^{\zeta,\zeta'}$ may be written as $C_{ab}^{0,\zeta'}$ and is given by eq. [6] with the ζ-pseudo-DOSD for a replaced by the isotropic atomic DOSD (3, 4).

The Unsöld average energy approximation (8) may now be applied to eq. [6] to give

$$[7]\quad C_{ab}^{\zeta,\zeta'} = \frac{1}{4}\sum_{k_a=1}^{N_a}\sum_{k_b=1}^{N_b}\frac{f_{k_a}^{\zeta}}{(E_{k_a}^{\zeta})^2}\frac{f_{k_b}^{\zeta'}}{(E_{k_b}^{\zeta'})^2}\frac{U_a^{\zeta}U_b^{\zeta'}}{(U_a^{\zeta}+U_b^{\zeta'})} = \frac{1}{4}\alpha_a^{\zeta}\alpha_b^{\zeta'}\frac{U_a^{\zeta}U_b^{\zeta'}}{(U_a^{\zeta}+U_b^{\zeta'})}$$

where U_a^{ζ} is an atomic ($\zeta = 0$) average energy or a molecular ($\zeta = \parallel$ or $\perp$) average energy independent of k_a, and α_a^{ζ} refers to either the isotropic dipole polarizability $\bar{\alpha}_a$ ($\zeta = 0$) or the anisotropic dipole polarizability (for a being a molecule; $\zeta = \parallel$ or $\perp$).

The atomic average energies, U_a and U_b (we drop $\zeta = 0$ for atoms) of atoms a and b, can be related to the isotropic $C_6(a,b)$ dispersion energy coefficient by (9, 14)

$$[8]\quad C_6(a,b) = \frac{3}{2}\frac{U_aU_b}{(U_a+U_b)}\bar{\alpha}_a\bar{\alpha}_b$$

If we now consider the dispersion energy interaction between two like atoms a we obtain from eq. [8]

$$[9]\quad U_a = \frac{4C_6(a,a)}{3\bar{\alpha}_a^2}$$

Thus, we can calculate an average energy for each of the rare gas atoms from reliable values (2, 15, 16) of the isotropic C_6 coefficients and isotropic dipole polarizabilities. For linear Σ-state molecules we introduce average energies, $U_a^{\parallel}$ or $U_a^{\perp}$, which can be determined from $C_{aa}^{\parallel,\parallel}$ and $C_{aa}^{\perp,\perp}$. Using eq. [7]

$$[10]\quad U_a^{\zeta} = \frac{8C_{aa}^{\zeta,\zeta}}{(\alpha_a^{\zeta})^2}$$

where $\zeta = \parallel$ or $\perp$. Thus, we can calculate $U_a^{\parallel}(U_a^{\perp})$ for H_2, N_2, and CO from eq. [10] using reliable values of the anisotropic polarizabilities and the $C_{aa}^{\zeta,\zeta}$ that have been computed from pseudo-DOSDs for the molecules (3, 4).

The atomic and molecular polarizabilities, α_a^{ζ}, and average energies U_a^{ζ}, are listed in Tables 1 and 2. To test the validity of the average energy approximation we compute all the dispersion energy coefficients $C_6(a,b)$, Γ_{ab}, Γ_{ba}, and Δ_{ab} for all two-body interactions involving the rare gases, H_2, N_2, CO through the use of Tables 1 and 2, eq. [7], and eqs. [2]–[5]. The results were then compared with reliable results in refs. 2–4 from which the average energies were obtained for like-species interactions using $C_{aa}^{\zeta,\zeta}$, $\zeta = \parallel$, $\perp$, and $C_6(a,a)$ only.

There are 66 unique two-body dispersion energies for the

Table 1. (*a*) Atomic and (*b*) molecular polarizabilities (in atomic units) (2–4). The isotropic polarizability $\bar{\alpha} = \frac{1}{3}(\alpha^{\parallel} + 2\alpha^{\perp})$.

(*a*)

Polarizability	He	Ne	Ar	Kr	Xe
$\bar{\alpha}$	1.379	2.669	11.08	16.79	27.16

(*b*)

3. An average energy approximation for the triple-dipole dispersion energy coefficients

In this section the average energy approximation developed for the dipole–dipole dispersion energy coefficient is adapted to the triple-dipole case. Direct use of the average energies obtained in the last section does not yield adequate results for the isotropic and anisotropic triple-dipole dispersion energy coefficients.

An exact computationally viable expression for the triple-dipole dispersion energy (DDD) between three interacting linear Σ-state molecules has been recently developed and may be written (1) as

$$[11]\quad \mathrm{DDD} = \frac{(1+3\cos\theta_A\cos\theta_B\cos\theta_C)C_9(a,b,c)}{R_{ab}^3R_{bc}^3R_{ac}^3}\,\mathrm{Re}[1-\Gamma(a)W(\theta_a,\phi_a,\theta_A,\theta_B)-\Gamma(b)W(\theta_b,\phi_b,\theta_A,\theta_B)$$
$$-\Gamma(c)W(\theta_c,\phi_c,\theta_A,\theta_B)+\Gamma(a,b)W(\theta_a,\phi_a,\theta_b,\phi_b,\theta_A,\theta_B)+\Gamma(a,c)W(\theta_a,\phi_a,\theta_c,\phi_c,\theta_A,\theta_B)$$
$$+\Gamma(b,c)W(\theta_b,\phi_b,\theta_c,\phi_c,\theta_A,\theta_B)-\Gamma(a,b,c)W(\theta_a,\phi_a,\theta_b,\phi_b,\theta_c,\phi_c,\theta_A,\theta_B)]$$

where Re[...] indicates the real part of [...], θ_A, θ_B, θ_C are the internal angles of the triangle formed by the centres of mass of molecules *a*, *b*, and *c*, and R_{ab} represents the distance between molecule *a* and molecule *b*. The coefficients, *W*, are functions of the relative orientations of the interacting molecules (through the spherical polar angles (θ_a,ϕ_a), (θ_b,ϕ_b), (θ_c,ϕ_c)). The C_9 and Γ's are the isotropic and anisotropic triple-dipole dispersion energy coefficients. For complete details see ref. 1.

The isotropic triple-dipole dispersion energy coefficient $C_9(a,b,c)$ is given (1) by

$$[12]\quad C_9(a,b,c) = \frac{1}{9}\left[C_{abc}^{\parallel,\parallel,\parallel} + 2C_{abc}^{\parallel,\parallel,\perp} + 2C_{abc}^{\parallel,\perp,\parallel} + 4C_{abc}^{\parallel,\perp,\perp} + 2C_{abc}^{\perp,\parallel,\parallel} + 4C_{abc}^{\perp,\parallel,\perp} + 4C_{abc}^{\perp,\perp,\parallel} + 8C_{abc}^{\perp,\perp,\perp}\right]$$

where

$$[13]\quad C_{abc}^{\zeta,\zeta',\zeta''} = \frac{1}{2}\sum_{k_a=1}^{N_a}\sum_{k_b=1}^{N_b}\sum_{k_c=1}^{N_c}\frac{f_{k_a}^{\zeta}f_{k_b}^{\zeta'}f_{k_c}^{\zeta''}\left[E_{k_a}^{\zeta}+E_{k_b}^{\zeta'}+E_{k_c}^{\zeta''}\right]}{E_{k_a}^{\zeta}E_{k_b}^{\zeta'}E_{k_c}^{\zeta''}\left[E_{k_a}^{\zeta}+E_{k_b}^{\zeta'}\right]\left[E_{k_a}^{\zeta}+E_{k_c}^{\zeta''}\right]\left[E_{k_b}^{\zeta'}+E_{k_c}^{\zeta''}\right]}$$

with $\zeta, \zeta', \zeta'' = \parallel$ or $\perp$. The anisotropic interaction coefficients appearing in eq. [11] are defined (1) by

[14] $$\Gamma(a) = \frac{1}{9}\left[C_{abc}^{\|,\|,\|} + 2C_{abc}^{\|,\|,\perp} + 2C_{abc}^{\|,\perp,\|} + 4C_{abc}^{\|,\perp,\perp} - C_{abc}^{\perp,\|,\|} - 2C_{abc}^{\perp,\|,\perp} - 2C_{abc}^{\perp,\perp,\|} - 4C_{abc}^{\perp,\perp,\perp}\right]/C_9(a,b,c)$$

[15] $$\Gamma(c) = \frac{1}{9}\left[C_{abc}^{\|,\|,\|} - C_{abc}^{\|,\|,\perp} + 2C_{abc}^{\|,\perp,\|} - 2C_{abc}^{\|,\perp,\perp} + 2C_{abc}^{\perp,\|,\|} - 2C_{abc}^{\perp,\|,\perp} + 4C_{abc}^{\perp,\perp,\|} - 4C_{abc}^{\perp,\perp,\perp}\right]/C_9(a,b,c)$$

[16] $$\Gamma(a,b) = \frac{1}{9}\left[C_{abc}^{\|,\|,\|} + 2C_{abc}^{\|,\|,\perp} - C_{abc}^{\|,\perp,\|} - 2C_{abc}^{\|,\perp,\perp} - C_{abc}^{\perp,\|,\|} - 2C_{abc}^{\perp,\|,\perp} + C_{abc}^{\perp,\perp,\|} + 2C_{abc}^{\perp,\perp,\perp}\right]/C_9(a,b,c)$$

[17] $$\Gamma(b,c) = \frac{1}{9}\left[C_{abc}^{\|,\|,\|} - C_{abc}^{\|,\|,\perp} - C_{abc}^{\|,\perp,\|} + C_{abc}^{\|,\perp,\perp} + 2C_{abc}^{\perp,\|,\|} - 2C_{abc}^{\perp,\|,\perp} - 2C_{abc}^{\perp,\perp,\|} + 2C_{abc}^{\perp,\perp,\perp}\right]/C_9(a,b,c)$$

[18] $$\Gamma(a,b,c) = \frac{1}{9}\left[C_{abc}^{\|,\|,\|} - C_{abc}^{\|,\|,\perp} - C_{abc}^{\|,\perp,\|} + C_{abc}^{\|,\perp,\perp} - C_{abc}^{\perp,\|,\|} + C_{abc}^{\perp,\|,\perp} + C_{abc}^{\perp,\perp,\|} - C_{abc}^{\perp,\perp,\perp}\right]/C_9(a,b,c)$$

where $\Gamma(b)$ is obtained from $\Gamma(a)$, and $\Gamma(a,c)$ from $\Gamma(b,c)$, by interchanging a and b.

Applying the Unsöld average energy approximation (8) to eq. [13] gives (1)

[19] $$C_{abc}^{\zeta,\zeta',\zeta''} = \frac{1}{2}\,\frac{\left[U_a^{\zeta} + U_b^{\zeta'} + U_c^{\zeta''}\right]U_a^{\zeta}U_b^{\zeta'}U_c^{\zeta''}}{\left[U_a^{\zeta} + U_b^{\zeta'}\right]\left[U_a^{\zeta} + U_c^{\zeta''}\right]\left[U_b^{\zeta'} + U_c^{\zeta''}\right]}\alpha_a^{\zeta}\alpha_b^{\zeta'}\alpha_c^{\zeta''} = \frac{1}{2}\,U_{abc}^{\zeta,\zeta',\zeta''}\,\alpha_a^{\zeta}\alpha_b^{\zeta'}\alpha_c^{\zeta''}$$

where the U_a^{ζ}'s are average energies that are yet to be defined.

For three-body interactions involving only atoms the parameter $U_{a,b,c}^{\zeta,\zeta',\zeta''}$ may be replaced by U_{abc} since for isotropic interactions $U_{a,b,c}^{\zeta,\zeta',\zeta''}$ is independent of ζ, ζ', ζ''. Following Stogryn (9), we may now write U_{abc} in terms of the isotropic $C_9(a,b,c)$ coefficient and isotropic polarizabilities,

[20] $$U_{abc} = \frac{2C_9(a,b,c)}{3\bar{\alpha}_a\bar{\alpha}_b\bar{\alpha}_c}.$$

Using this result, U_a for each rare gas atom can be related to $C_9(a,a,a)$ by considering the interaction between three like atoms a. That is

[21] $$U_{aaa} = \frac{3}{8}\,U_a = \frac{2C_9(a,a,a)}{3\bar{\alpha}_a^3}$$

which gives

[22] $$U_a = \frac{16C_9(a,a,a)}{9\bar{\alpha}^3}.$$

Analagous to the two-body interactions involving linear Σ-state molecules (see Sect. 2) we can compute average energies ($U_a^{\|}$,$U_a^{\perp}$) from the anisotropic triple-dipole dispersion energy coefficients ($C_{aaa}^{\|,\|,\|}$, $C_{aaa}^{\perp,\perp,\perp}$). Using eq. [19]

[23] $$U_a^{\zeta} = \frac{16C_{aaa}^{\zeta,\zeta,\zeta}}{3(\alpha_a^{\zeta})^3}$$

where $\zeta = \|$ or $\perp$. The average energy U_a for each rare gas atom can be determined from eq. [22] from reliable values (2, 15, 16) for the isotropic C_9 triple-dipole coefficients and the isotropic polarizabilities. The $U_a^{\|}(U_a^{\perp})$ for H_2, N_2, and CO can be calculated from eq. [23] using reliable values of the anisotropic polarizabilities and the $C_{aaa}^{\zeta,\zeta,\zeta}$ that have been computed from the pseudo-DOSDs for these molecules (3,4).

The atomic and molecular polarizabilities, α_a^{ζ}, and triple-dipole average energies U_a^{ζ}, are listed in Tables 1 and 4, respectively. All the triple-dipole dispersion energy coefficients (C_9 and Γ's) for *all* three-body interactions involving the rare gases H_2, N_2, and CO were computed through the use of Tables 1 and 4, eq. [19], eq. [12], and eqs. [14]–[18]. The results were then compared with reliable values obtained through use of the pseudo-DOSDs (2–4) in eq. [13] (and from which the average energies were obtained for like-species interactions and for $\zeta = \zeta' = \zeta'' = \|$ or $\perp$), and eq. [12] and eqs. [14] – [18].

Table 4. (*a*) Atomic and (*b*) molecular average energies obtained from like atom–atom–atom (2) and like molecule–molecule–molecule (computed here using the DOSDs of refs. 3 and 4 and eq. [13]) triple-dipole dispersion energy interaction coefficients (see the main text for definitions and, in particular, eqs. [22] and [24]). All quantities in atomic units.

(*a*)

Average energy	He	Ne	Ar	Kr	Xe
U_a	0.9988	1.117	0.6771	0.5904	0.4947

(*b*)

Average energy	H_2	N_2	CO
$U_a^{\|}$	0.5002	0.6389	0.6130
$U_a^{\perp}$	0.5676	0.7151	0.5874

There are 286 unique three-body dispersion energy coefficients for the interactions considered. Of these 259 can be generated, to within a 1% uncertainty, by the average energy approximation; the only rare gas atom – rare gas atom – rare gas atom isotropic C_9 coefficient outside this error margin is for the He–He–Xe interaction and it is 1.3% smaller than the reliable value. The reliable DOSD results for the remaining 26 coefficients are listed in Tables 5–7, together with the percentage difference ($\lesssim \sim 3.6\%$) between them and the results obtained from the average energy approximation values.

In Tables 5–7 non-zero triple-dipole dispersion energy coefficients for each type of interaction, e.g., rare gas – rare gas – molecule, rare gas – molecule–molecule, and molecule–

Table 5. Reliable anisotropic triple-dipole dispersion energy coefficients for rare gas – rare gas – molecule interactions, defined by eqs. [12]–[18] and the main text and evaluated using the DOSDs of refs. 2–4, which were not reproduced to within 1% by the average energy approximation through the use of eqs. [12]–[19] and Tables 1 and 4 (see the main text).[a] The percentage difference, $(\frac{\text{reliable}-\text{approximate}}{\text{reliable}}) \times 100\%$, is shown in parentheses. The reliable C_9 coefficients for He–He–CO and He–Ne–CO are 11.47 (1.2%) and 22.78 (1.01%) atomic units, respectively. All quantities are in atomic units.

a–b–c		*a–b–c*

Ne–CO–H_2	$\Gamma(c)$ = 0.1036 (–1.3%)		$\Gamma(b, c)$ = 0.0092 (–2.6%)

[a]Only unique non-zero results included; the non-zero coefficients are C_9, $\Gamma(b)$, $\Gamma(c)$, and $\Gamma(b, c)$. If $b = c$, $\Gamma(b) = \Gamma(c)$.

Table 7. Reliable anisotropic triple-dipole dispersion energy coefficients for molecule–molecule–molecule interactions, defined by eqs. [12]–[18] and the main text and evaluated using the DOSDs of refs. 2–4, which were not reproduced to within 1% by the average energy approximation through the use of eqs. [12]–[19] and Tables 1 and 4 (see the main text).[a] The percentage difference, $(\frac{\text{reliable}-\text{approximate}}{\text{reliable}}) \times 100\%$, is shown in parentheses. All quantities are in atomic units.

a–b–c		*a–b–c*	
CO–CO–H_2	$\Gamma(a, b, c)$ = 0.0010 (1.1%)	H_2–H_2–N_2	$\Gamma(a, b, c)$ = 0.0015 (1.02%)
CO–H_2–H_2	$\Gamma(a, b, c)$ = 0.0012 (1.3%)	N_2–N_2–H_2	$\Gamma(a, b)$ = 0.0143 (1.04%)
CO–N_2–H_2	$\Gamma(a, b, c)$ = 0.0012 (1.2%)		$\Gamma(a, b, c)$ = 0.0017 (1.3%)
CO–N_2–N_2	$\Gamma(a, b, c)$ = 0.0013 (1.2%)		

[a]Only unique non-zero results included. Three types of interactions need to be considered here, i.e., *a–a–a*, *a–b–b*, and *a–b–c*. For *a–a–a* there are four unique coefficients: C_9, $\Gamma(a)$, $\Gamma(a, a)$, and $\Gamma(a, a, a)$, and for *a–b–b* there are six unique coefficients, namely C_9, $\Gamma(a)$, $\Gamma(b)$, $\Gamma(a, b)$, $\Gamma(b, b)$, and $\Gamma(a, b, b)$. All nine of the triple-dipole dispersion energy coefficients, C_9 and the Γ's, are necessary to describe the *a–b–c* interaction.

molecule–molecule, are given, where an (*a–b–c*) order is implied for each interaction. Interactions involving the same species, in a different *a b c* ordering, are related to these by symmetry. For example, the coefficients for a *c–b–a* interaction are identical to the *a–b–c* interaction coefficients with the *a* and *c* molecules interchanged, so that for the CO–H_2–N_2 (*a–b–c*) interaction $\Gamma(a)$, $\Gamma(c)$, $\Gamma(a, b)$, $\Gamma(b, c)$ are identical to $\Gamma(c)$, $\Gamma(a)$, $\Gamma(c, b)$, $\Gamma(b, a)$, respectively, of the N_2–H_2–CO (*c–b–a*) interaction; the C_9, $\Gamma(b)$, $\Gamma(a, c)$ and $\Gamma(a, b, c)$ coefficients are the same for both interactions.

4. Discussion of results

Reliable results for the isotropic and anisotropic triple-dipole (DDD) dispersion energy coefficients for interactions involving H_2, N_2, CO, and for interactions involving H_2, N_2, CO, and one or two rare gases, have been obtained using literature (2–4) pseudo-dipole oscillator strength distributions for these species. An average energy approximation has been used to (usually) reliably represent the large number of DDD interaction coefficients so obtained.

An average energy approximation has been developed for the isotropic and anisotropic dipole–dipole and triple-dipole dispersion energy coefficients. The required input is the isotropic and anisotropic average energies and polarizabilities of the interacting species, which are provided in tabular form for He, Ne, Ar, Kr, Xe, H_2, N_2, and CO. The average energy approximation expressions, with the provided input, reproduce most of the two- and three-body dispersion energy coeffficients to within the 1% accuracy claimed for the results obtained directly from the isotropic and anisotropic dipole oscillator strength distributions for the interacting species. Fifty-three of the 66 unique two-body dispersion energy coefficients, and 259 out of the 286 unique non-additive three-body dispersion energy coefficients, for all the interactions arising from the rare gases, H_2, N_2, and CO, are reproduced reliably in the average energy approximation. The coefficients not reproduced to within 1% are provided in tabular form (Table 3 and Tables 5–7 for the dipole–dipole and triple-dipole coefficients, respectively). The results in this paper provide the first reliable anisotropic triple-dipole dispersion energies for three-body interactions involving molecules.

The use of the average energy approximation to represent the reliable DOSD results for the triple-dipole dispersion energy clearly works well. It is of interest to discuss, briefly, the principal source of the difficulty in our application of this approach. For interactions involving at least one molecule, our average energy approach yields results for the individual $C_{abc}^{\zeta,\zeta',\zeta''}$ coefficients, defined by eq. [13], that are reliable to within 1% for all cases except $C_{abc}^{0,0,\perp}$, for He–He–CO (1.5%), He–Ne–CO (1.3%), Ne–Ne–CO (1.4%); $C_{abc}^{0,0,\parallel}$(Ne–Ne–H_2) (1.1%); and $C_{abc}^{0,\perp,\perp}$ for He–CO–CO (1.2%) and Ne–CO–CO (1.1%). The principal source of error in obtaining the overall triple-dipole coefficients, defined by eqs. [12]–[18], is due to cumulative errors arising from summing the individual $C_{abc}^{\zeta,\zeta',\zeta''}$ to obtain the overall coefficients. For example, the percent difference of −3.6% between the reliable DOSD and the average energy results for $\Gamma(c)$ for Ne–Ne–CO is due to the accumulation of errors from the individual coefficients $C_{abc}^{0,0,\parallel}$ (0.4%), $C_{abc}^{0,0,\perp}$ (1.4%), and C_9 (1%) occurring in the expression, eq. [15], for $\Gamma(c)$.

It is relevant to mention that the average energies for the dipole–dipole dispersion energy coefficients, Table 2, are different from those for the triple-dipole coefficients, Table 4. Use of Table 2 in the evaluation of the triple-dipole dispersion energy coefficients, in the average energy approximation, leads to significant errors. That is, 251 out of the 286 triple-dipole coefficients so obtained disagree with the reliable values by more than 1%.

Non-additive interaction energies are important for many properties of bulk matter (17–25). The triple-dipole energy is one of many competing non-additive interactions relevant to such properties (24–29). Others include non-additive higher order dispersion energies and non-additive induction energies, the charge overlap corrections to all multipolar non-additive energies, and first order and higher order electron exchange energies (23–30). It is important to quantify as many of these non-additive effects as possible so that experiments can be used to study computationally more difficult non-additive energies (24–26). This paper, see also ref. 1, is a recent contribution towards this goal.

Topological analysis of electron momentum densities and the bond directional principle: the first-row hydrides, AH, and homonuclear diatomic molecules, A_2

Jiahu Wang, B. James Clark, Hartmut Schmider, and Vedene H. Smith, Jr.

Abstract: Topological analysis of electron momentum densities of the first-row hydrides and homonuclear diatomic molecules has been carried out. The densities and their curvatures were calculated from wave functions of near Hartree–Fock quality using a Slater basis. The bond directional principle has been discussed through the topological properties of electron momentum densities. Basis set effects on the topological features have also been addressed.

Key words: electron momentum density, the bond directional principle, topological analysis, first-row hydrides, homonuclear diatomic molecules.

Résumé : On a effectué une analyse topologique des densités des moments électroniques des hydrures et des molécules diatomiques homonucléaires des éléments de la première couche périodique. On a calculé les densités et leurs courbures à partir de fonctions d'onde de qualité se rapprochant de celle de Hartree–Fock, en utilisant une base de Slater. On a discuté du principe de la liaison directionnelle par le biais des propriétés des densités des moments électroniques. On a aussi examiné les effets des ensembles de bases sur les caractéristiques topologiques.

Mots clés : densité du moment électronique, le principe de la liaison directionnelle, hydrures de la première période, molécules diatomiques homonucléaires.

[Traduit par la rédaction]

1. Introduction

Topological analysis of electron densities in position space has received much attention (1). Atoms (2, 3), molecules (1), as well as solids (4, 5) have been investigated. Through the study of the Laplacian at the critical points and the Laplacian distribution of an electron density, information about chemical bonding (6) and chemical reactivity (7) can be obtained. The electron momentum density (EMD), which provides a complementary description of electron motion to the electron charge distribution in position space, has only recently been studied through topological analysis. Sagar et al. (8) reported the topological features of the EMDs of atoms and ions. It has been found that, differing from its position space counterpart, the origin of an EMD is not always a local maximum. Quite often, it is a local minimum (9). More recently, Gadre and co-workers (10, 11) reported the topological properties of the EMDs of a few simple molecules with Gaussian basis sets. These authors have also studied the implication of the additional inversion symmetry (12) of an EMD on its topological properties (13).

Because of their relation to the Compton profile under the impulse approximation, EMDs have been the subject of extensive theoretical studies since the 70s. The development of (e,2e) (also called electron momentum spectroscopy) experiments further stimulated such investigations. Accurate wave functions have been employed to predict the momentum space properties (14, 15) and the agreement between theory and experiment is satisfactory. To facilitate the analysis of EMDs of atoms and molecules and the changes in EMDs upon formation of chemical bonds, Epstein and Tanner (16) have proposed several principles. Among them, the bond directional principle (BDP) has received most attention. The BDP states that "the momentum of an electron in a chemical bond is more likely to be directed perpendicular to than along the bond axis. Furthermore, in the chemical bond there is greater density at low momentum along the bond and greater density at high momentum perpendicular to the bond than was the case in the isolated atoms." Since then, various momentum space quantities, such as zero-point Compton profile anisotropy $\Delta J(0)$ (17–19), $J(0)$ surface (20), kinetic energy anisotropy (21), kinetic energy tensor (22), Husimi second moment of momentum tensor (23), have been chosen

Received January 2, 1996.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

for the study of the directional characteristics of molecular EMDs. Exceptions to the bond directional principle have been reported (see ref. 24 for a summary). More recently, Tanner (24) has modified the aforementioned BDP and the revised one states: "in a chemical bond in a bound molecule in its equilibrium configuration, there are values $\boldsymbol{p}_m$ of momentum which are more probable, i.e., which correspond to local maxima of $\pi(\boldsymbol{p})$. Those values are determined by both the geometric and electronic symmetries of the molecule. For momenta, $\boldsymbol{p} = \boldsymbol{p}_m + \delta\boldsymbol{p}$, near a maximum it is more likely that $\delta\boldsymbol{p}$ is perpendicular rather than parallel to the bond axis." According to this new interpretation, we should pay attention to the directional characteristics of local maxima or (3, −3) critical points when analyzing an EMD.

The purpose of this paper is to introduce the curvatures of EMDs as an alternative measure of anisotropy of molecular EMDs.

2. Curvatures of EMDs and the BDP

Each topological feature of an EMD is associated with a critical point, $\boldsymbol{p}_c$, in momentum space, where the first derivatives of $\pi(\boldsymbol{p})$, $\nabla\pi(\boldsymbol{p}_c) = 0$. A critical point is characterized by the curvatures of $\pi(\boldsymbol{p})$. The principal axes and their corresponding curvatures at a critical point are obtained as the eigenvectors and the corresponding eigenvalues through the diagonalization of the Hessian matrix of $\pi(\boldsymbol{p}_c)$. The type of a critical point is determined by its rank, ω, and signature, σ, and is labeled by (ω, σ). Rank ω is equal to the number of nonzero curvatures of π, whereas signature σ is simply the algebraic sum of the signs of the curvatures at the critical point. There are four types of nondegenerate critical points: local maxima (3, −3); saddle points (3, −1), saddle points (3, +1), and local minima (3, +3). A critical point with $\omega < 3$ is said to be degenerate.

In the vicinity of a critical point, $\boldsymbol{p}_c$, the EMD can be written as

$$[1]\quad \pi(\boldsymbol{p}_c + \delta\boldsymbol{p}) = \pi(\boldsymbol{p}_c) + \frac{1}{2}\nabla^2\pi(\boldsymbol{p}_c)\delta\boldsymbol{p}^2 + \mathcal{O}(\delta\boldsymbol{p}^3)$$

$$= \pi(\boldsymbol{p}_c) + \frac{1}{2}[\lambda_1\delta p_x^2 + \lambda_2\delta p_y^2 + \lambda_3\delta p_z^2] + \mathcal{O}(\delta\boldsymbol{p}^3)$$

where λ_1, λ_2, and λ_3 are the curvatures of $\pi(\boldsymbol{p})$ at $\boldsymbol{p}_c$. The subscripts x, y, z indicate the three principal axes. δp_i is the projection of $\delta\boldsymbol{p}$ on the axis i.

For linear molecules locating along the z-axis, EMDs display $D_{\infty h}$ symmetry with p_z being the unique axis. Thus, p_z will always be a principal axis. We may choose two mutually orthogonal directions in the plane perpendicular to the p_z axis as the other principal axes, p_x and p_y. Supposing the momentum distributions follow the BDP formulated by Tanner (24), we then have

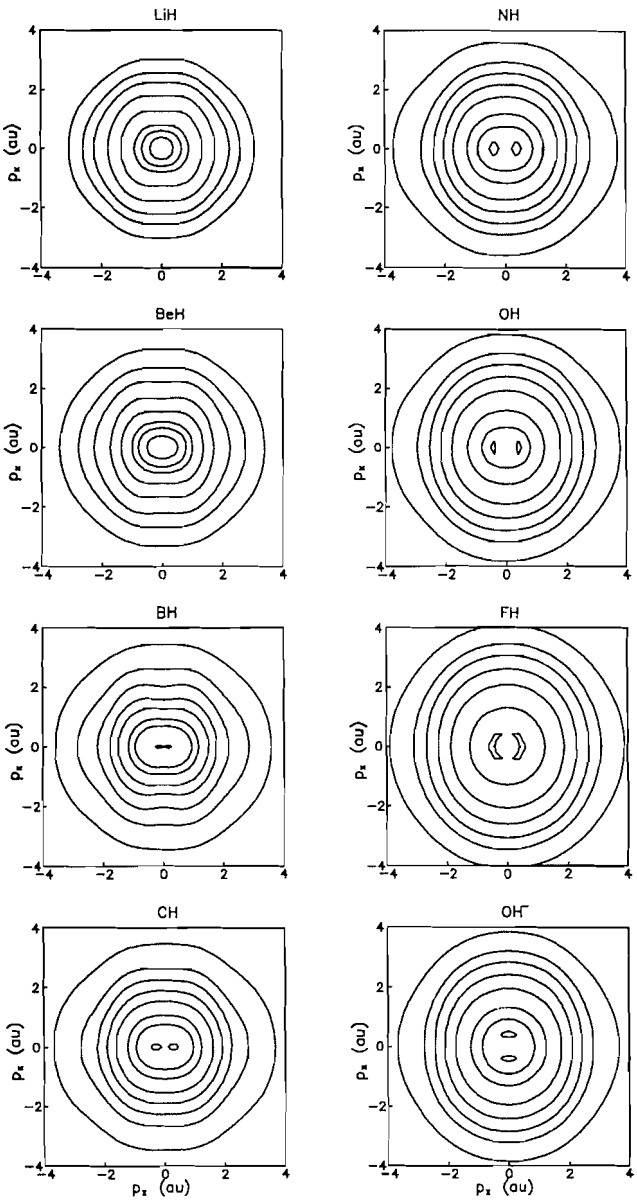
$$[2]\quad \lambda_3 < \lambda_1 (= \lambda_2)$$

at the (3, −3) critical points.

Due to the inversion symmetry of EMDs, the origin is always a critical point. Through the application of eq. [1], information about the anisotropy of EMDs at small momenta can be obtained.

The present momentum space quantities were obtained with near Hartree–Fock quality wave functions (25, 26) using Slater basis. Since we focus on the BDP of EMDs, only the topological properties at $\boldsymbol{p} = 0$ and local maxima are presented. Atomic units are used throughout this paper.

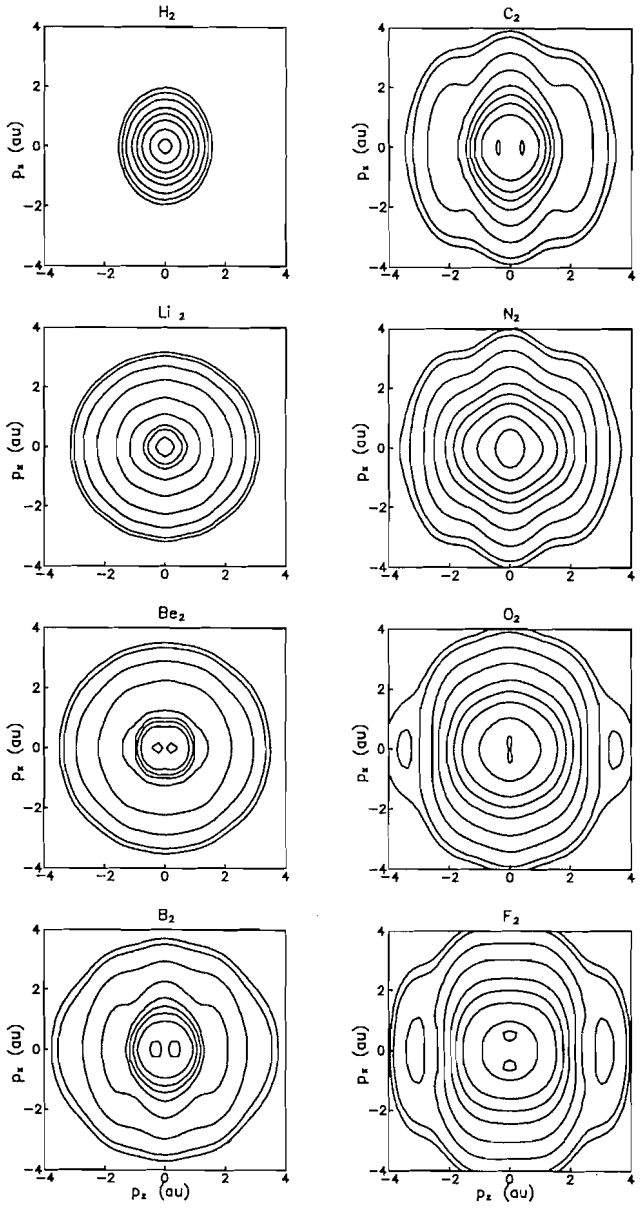
Fig. 1. The EMDs of the first-row hydrides. The innermost contour value is 1.50, 1.50, 2.50, 1.40, 0.90, 0.64, 0.46, and 1.00 for LiH, BeH, BH, CH, NH, OH, FH, and OH^-, respectively. The remaining contour values, from the outermost, are 0.003, 0.006, 0.01, 0.02, 0.05, 0.2, 0.5, respectively.



3. EMDs of the first-row hydrides and homonuclear diatomic molecules

Ramirez studied the EMDs of the first-row hydrides (27) and homonuclear diatomic molecules (28) and also discussed the chemical bonding through the EMD difference maps. Contour maps of the EMDs of LiH ($X^1\Sigma^+$), BeH ($X^2\Sigma^+$), BH ($X^1\Sigma^+$), CH ($X^2\Pi$), NH ($X^3\Sigma^-$), OH ($X^2\Pi_i$) and FH ($X^1\Sigma^+$), Li_2 ($X^1\Sigma_g^+$), Be_2 ($^1\Sigma_g^+$), B_2 ($X^3\Sigma_g^-$), C_2 ($X^1\Sigma_g^+$), N_2 ($X^1\Sigma_g^+$), O_2 ($X^3\Sigma_g^-$), and F_2 ($X^1\Sigma_g^+$) at their experimental equilibrium

Fig. 2. The EMDs of H_2 and the first-row homonuclear diatomic molecules. The innermost contour value is 1.00, 5.00, 5.50, 2.50, 1.50, 1.00, 0.92, and 0.64 for H_2, Li_2, Be_2, B_2 C_2, N_2, O_2, and F_2, respectively. The remaining contour values, from the outermost, are 0.005, 0.006, 0.01, 0.02, 0.05, 0.10, 0.20, 0.50, except for H_2. The starting contour value for H_2 is 0.006.



separation (except Be_2 for which experimental data are unavailable) were shown. However, many important features of the EMDs were not presented. We plotted again the EMDs on the p_x–p_z plane for the first-row hydrides and OH^- in Fig. 1 and for H_2 and the first-row homonuclear diatomic molecules in Fig. 2. In addition to those contour values used before (27, 28), we include an extra contour at the innermost region to show the important topological features of each EMD.

Similar to the earlier findings for the first-row hydrides by Ramirez (27), the EMDs tend to be more diffuse from LiH to FH. This behavior is just the opposite to the change in position space. In position space, due to the increase of the nuclear charge of the heavier atom in the hydrides, electrons are more likely to move closer to the heavier atom. In the complementary momentum space, the higher the nuclear charge of the heavier atom, the faster the electrons will move. In other words, it is more probable for electrons to appear at higher momenta.

It is clear that several features of the EMDs in Fig. 1 have been newly revealed. In LiH and BeH, the EMD displays a global maximum at $\boldsymbol{p} = 0$. From the topological point of view, $\boldsymbol{p} = 0$ is a (3, −3) critical point. Starting from BH, the origin is no longer a (3, −3) critical point. The local maxima move away from the origin along the p_z axis except for OH^-, for which the local maxima are located on the plane perpendicular to the p_z axis. More features of the topological properties are addressed in the next section.

Because a variety of chemical bonds can be formed in the homonuclear diatomic molecules, the EMDs in Fig. 2 display more complicated features than in Fig. 1 for the hydrides. Nevertheless, it can be seen that from Li_2 to F_2 (excluding Be_2), electrons are more likely to move perpendicular to than along the bond axis, a tendency that is more obviously portrayed in the EMD of H_2. According to the BDP by Epstein and Tanner (16), this anisotropy signifies the chemical bonding in these molecules. On the other hand, the EMD of an unbound system, Be_2, shows a preference for moving along, rather than perpendicular to, the bond axis. It is also interesting to note the gradual shift of the locations of maxima from Li_2 to F_2. Similar trends can be observed in Fig. 1 as well.

4. Curvature of EMDs at local maxima and the BDP

The topological features of the first-row hydrides and homonuclear diatomic molecules at the origin are summarized in Table 1. Besides BH, the momentum density at the origin, $\pi(0)$, has the same value as reported by Ramirez (27, 28). The $\pi(0)$ of BH has been calculated to be 2.5273, compared to the previous value of 2.5200.

In Table 1, the origin appears as a local maximum for the EMD of H_2, Li_2, N_2, LiH, and BeH. The first four molecules also share the property of $\lambda_3 < \lambda_1$, in agreement with the revised BDP formulated by Tanner (24). BeH is an exception, as previously noted by Tanner (24). For LiH, λ_1 and λ_3 have been found to be very close and this may be traced to the strong ionic character of its molecular structure. Besides being a local maximum, the other three types of nondegenerate critical points all show up in Table 1. According to eq. [1], this may indicate that, in general, there is no preferential direction of electron movement at small momentum regions in a bound system.

As seen from Figs. 1 and 2, several molecules have maximal EMDs away from the origin. The topological properties for those that have (3, −3) critical points along p_z are given in Table 2. Because of the inversion symmetry of EMDs, these critical points are paired by an inversion. The locations of the maxima, however, are dependent on the nuclear charges of the molecule. There is a clear trend for the (3, −3) critical points to move to higher momentum regions from BH

Table 1. Summary of the topological properties of EMDs at the origin.

Molecule	Bond length	$\pi(0)$	Signature	$\lambda_1(=\lambda_2)$	λ_3
H_2	1.4	1.2299	(3, −3)	−8.034	−9.416
Li_2	5.051	18.7836	(3, −3)	−574.985	−710.878
N_2	2.068	1.4079	(3, −3)	−1.011	−6.292
LiH	3.015	3.8198	(3, −3)	−54.948	−55.990
BeH	2.538	3.4007	(3, −3)	−40.617	−15.545
Be_2	4.0	4.9209	(3, −1)	−64.591	165.712
BH	2.336	2.5273	(3, −1)	−24.467	7.202
CH	2.214	1.3440	(3, −1)	−3.806	6.885
NH	1.9614	0.8215	(3, −1)	−0.029	4.752
O_2	2.282	0.9297	(3, +1)	0.953	−4.196

OH^-	1.781	0.6346	(3, +3)	15.219	7.535
FH	1.7328	0.3742	(3, +3)	1.755	1.849

Table 2. Summary of the topological properties of EMDs at the (3, −3) critical points, $\boldsymbol{p}_c = (0, 0, \pm p_z)$.

Molecule	p_z	$\pi(\mathbf{p}_c)$	$\lambda_1(=\lambda_2)$	λ_3
Be_2	0.2602	7.1465	−102.588	−160.799
B_2	0.3295	3.1751	−18.236	−47.885
C_2	0.4177	1.5892	−2.370	−15.474
BH	0.1965	2.5907	−24.797	−10.901
CH	0.3141	1.4873	−6.754	−8.182
NH	0.3928	0.9706	−2.563	−5.032
OH	0.4546	0.6589	−0.618	−2.912
FH	0.5114	0.4696	−0.116	−1.783

Table 3. Summary of the topological properties of EMDs at the (2, −2) degenerate critical points, $\boldsymbol{p}_c = (p_x, p_y, p_z)$.

Molecule	$\sqrt{p_x^2 + p_y^2}$	p_z	$\pi(\boldsymbol{p})$	λ	λ_3
O_2	0.2983	0.0000	0.9490	−1.440	−3.799
F_2	0.5157	0.0000	0.6688	−1.628	−1.165
OH^-	0.4092	0.0000	1.0869	−10.479	−2.410

to FH and from Be_2 to C_2. Of these eight molecules, all but BH (another exceptional case noted by Tanner (24)) have the property that $\lambda_3 < \lambda_1$. This includes also the unbound Be_2 molecule.

The EMDs of O_2, F_2, and OH^- have local maxima in the plane perpendicular to the p_z axis. Because of the cylindrical symmetry of linear molecules, those critical points are degenerate. The rank ω is equal to 2 in this case. The topological properties of these three species are summarized in Table 3. The curvature along the p_z axis is still labeled as λ_3. λ is used to refer to the nonzero curvature in the perpendicular plane. We expect to see $\lambda_3 < \lambda_1$ if the revised BDP is followed. However, only O_2 shows such characteristics.

As the above discussion shows, the revised BDP can account for the EMDs of many bound molecular systems. However, exceptions also exist. More importantly, the revised BDP appears unable to distinguish the unbound molecule from the bound ones.

Before concluding this section, we would like to mention a few words about the basis set effects. Gadre and co-workers (10, 11) carried out the topological analysis of EMDs with double zeta or triple zeta Gaussian basis sets. For N_2, they (10, 11) predicted the origin of the EMD to be a (3, +1) saddle point. The signature of the local maximum was given as (2, −2). These contradict the present and other earlier studies (15, 29). The EMD of OH^- were studied twice (10, 11) using a 4-31G and triple-zeta basis set, respectively. Only the second study (11) located the (2, −2) degenerate local maxima. The first study actually found (3, −3) critical points in the EMD of OH^-. Inconsistent results were also reported for HF (10, 11). EMDs are, in general, quite sensitive to the basis sets used. It is also well known that Gaussian basis sets suffer from the fact that they do not represent the correct asymptotic behavior in position space. This will inevitably affect the description of EMDs in the small-momentum region, the same region where most of the topological features of a molecule are in evidence. We would like to call for caution when studying topological properties of EMDs with Gaussian basis sets.

5. Summary

The electron momentum densities (EMDs) of the first-row hydrides and homonuclear diatomic molecules were calculated with near Hartree–Fock quality wave functions. Important features in the EMDs, which were not shown previously, are presented. The bond directional principle (BDP) was discussed through the curvatures of EMDs at their local maxima. It has been shown that the revised BDP is able to account for the momentum distributions for many bound systems (H_2, Li_2, N_2, LiH, B_2, C_2, CH, NH, OH, FH, O_2). However, exceptions to the revised BDP, including cases of both the bound (BeH, BH, F_2, OH^-) and unbound (Be_2) molecules, are also found. Topological analysis with Gaus-

sian basis sets should be carried out with care as the quality of basis sets can strongly influence the results.

Oxidative damage to the glycyl α-carbon site in proteins: an ab initio study of the C—H bond dissociation energy and the reduction potential of the C-centered radical

D.A. Armstrong, D. Yu, and A. Rauk

Abstract: The C—H bond dissociation energies ($D_{C—H}$) of a series of model glycyl proteins were derived from selected isodesmic reactions based on high level ab initio calculations. At 298 K, the recommended values of $D_{C—H}$, in kJ mol^{-1} are: NH_2CH_2CHO, 308; $NH_2CH_2C(O)NH_2$, 336; $HC(O)NHCH_2CHO$, 331; $HC(O)NHCH_2C(O)NH_2$, 350; $CH_3C(O)NHCH_2C(O)NH_2$, 347; $HC(O)NHCH_2C(O)NHCH_3$, 349; and $CH_3C(O)NHCH_2C(O)NHCH_3$, 346. The average of the last four values, 348 kJ mol^{-1}, is the predicted bond dissociation energy of the α-C—H bond of a glycyl protein. The reduction potential in aqueous medium at 298 K and pH 7 for the process, $R^\bullet + H^+ + e^- = RH$, where $R^\bullet$ = $XNHCH^\bullet C(O)Y$ and X and Y represent extension of the protein chain, is $E^{0\prime} = 0.8$ V. This result suggests that the α-C—H bond of a glycyl protein is susceptible to attack by RS•, ROO•, tyrosyl, and OH• radicals, whose reduction potentials for the analogous process are higher. The present study has established that the molecule $HC(O)NHCHRC(O)NH_2$ (R = an amino acid side chain) serves as an accurate model for the α-C environment of an amino acid residue in a protein, and that a reliable $D_{C—H}$ value for the α-C—H bond may be obtained from calculations on this model at the B3LYP/6-31G(D) level of theory in conjunction with an isodesmic reaction using neutral glycine as reference.

Key words: glycine, peptide, amino acid, bond energy, radicals, ab initio, computation.

Résumé : On a dérivé les énergies de dissociation de liaisons C—H ($D_{C—H}$) d'une série de protéines glycyles modèles à partir de réactions isodesmiques choisies et reposant sur des calculs ab initio à des niveaux élevés. À 298 K, les valeurs recommandées de $D_{C—H}$, en kJ mol^{-1}, sont : NH_2CH_2CHO, 308; $NH_2CH_2C(O)NH_2$, 336; $HC(O)NHCH_2CHO$, 331; $H(CO)NHCH_2C(O)NH_2$, 350; $CH_3C(O)NHCH_2C(O)NH_2$, 347; $HC(O)NHCH_2C(O)NHCH_3$, 349 et $CH_3C(O)NHCH_2C(O)NHCH_3$, 346. La moyenne des quatre dernières valeurs, 348 kcal kJ mol^{-1}, correspond à la valeur prédite pour l'énergie de dissociation de la liaison α-C—H d'une protéine glycyle. Le potentiel de réduction, en solution aqueuse, à 298 K, à un pH de 7, pour le processus, $R^\bullet + H^+ + e^- = RH$, dans laquelle $R^\bullet$ = $XNHCH^\bullet C(O)Y$ et X et Y correspondent à une extension de la chaîne de la protéine, est $E^{0\prime} = 0{,}8$ V. Ce résultat suggère que la liaison α-C—H d'une protéine glycyle est susceptible d'être attaquée par les radicaux RS•, ROO•, tyrosyles et OH• dont les potentiels de réduction, pour des processus analogues, sont élevés. La présente étude a permis d'établir que la molécule $HC(O)NHCHRC(O)NH_2$ (R = une chaîne latérale d'un acide aminé) est un excellent modèle pour l'environnement α-C d'un résidu d'acide aminé dans une protéine et que l'on peut arriver à une valeur fiable de $D_{C—H}$ pour une liaison α-C—H par des calculs sur ce modèle au niveau B3LYP/-31(D) de la théorie en relation avec une réaction isodesmique, en utilisant de la glycine neutre comme référence.

Mots clés : glycine, acide aminé, énergie de liaison, ab initio, calculs.

[Traduit par la rédaction]

Introduction

Oxidative damage to proteins has been implicated in physiological processes and pathological disorders, such as protein turnover, tissue injury during ischemia–reperfusion, atherosclerosis, and cataractgenesis (1). Oxidation of proteins in the presence of oxygen leads to the formation of alkyl peroxides and (or) hydrogen peroxide, and to peptide cleavage (1– 3). It is generally initiated by hydrogen atom abstraction of OH• radicals, which may be produced intra-cellularly by a Fenton-type reaction or by other radicals formed enzymatically (1, 4–7). Ultraviolet and ionizing radiation may also produce oxidizing radicals (8).

The site at which H-abstraction occurs depends to some extent on the structure and conformation of the protein (1, 8). However, the α-carbon center of exposed amino acid residues is known to be a preferred site of attack (1, 3, 9). Its susceptibility to oxidation has been emphasized in recent experiments with the peptide glutathione (GSH), which show that in basic solutions an H atom can be transferred intramolec-

ularly from an α-carbon center to the S-centered GS• radical (10). Because S—H bonds are usually more labile than C—H bonds and hydrogen transfer normally goes from S—H to carbon-centered radicals (8, 11), viz:

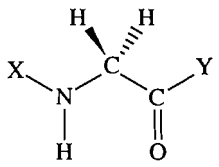
[1] $P^{\bullet} + GSH = PH + GS^{\bullet}$

GSH has traditionally been considered to be a protector. The observation of equilibrium lying in the opposite direction means that the dissociation energy of one (or more) of the C—H bonds in GSH is a few kJ mol^{-1} below that of the S—H bond. Dissociation energies of S—H bonds attached to aliphatic structures do not vary widely (12), and that of GSH must be close to 368 kJ mol^{-1}. This places the energy of the above C—H bond below 368 kJ mol^{-1}, somewhat lower than that expected for a secondary or tertiary C—H of a hydrocarbon (~397, ~389 kJ mol^{-1}, respectively, ref. 13). Intramolecular H transfer from α-C—H groups to sulfur has now also been reported in homocysteine and cysteine (14) and 2-mercaptoethanol (15). Also Zhao et al. have shown (14) that S-centered radicals are able to abstract α-C—H hydrogen atoms from the anions of glycine and alanine, and have estimated a value of 356 kJ mol^{-1} for the tertiary α-C—H bond dissociation energy of $H_2NC(CH_3)HCO_2^-$.

The above experimental results all confirm that the X-NH-C(R)H-C(O)-Y structure must contribute to a significant weakening of the α-C—H bond. The presence of the electron-donating -NH group on one side and the electron-withdrawing -CO group on the other identifies the X-NH-C(R)•-C(O)-Y radical as one that will be subject to stabilization by the captodative effect (16–19). However, the relative magnitude of the effect for specific X and Y groups, where the groups represent the extension of the protein backbone, needs to be determined. The object of this paper is to use modern ab initio methods to determine the α-C—H bond dissociation energy for the glycyl residue in a nonterminal (~mid-chain) position of a protein, and also to determine which X and Y groups satisfactorily represent the continuing peptide chain. This will enhance our understanding of the relative susceptibility of the peptide backbone to H-abstraction and oxidative damage, and at the same time provide a practical model for such studies on other amino acid residues.

Calculations carried out with the Gaussian 92 molecular orbital package (20) yield reliable structural information. They can also be used to provide thermochemical data for both closed- and open-shell species. When absolute G2(MP2) energies are used in isodesmic reactions in conjunction with reliable (preferably but not necessarily experimentally determined) heats of formation for related systems, they can be expected to provide thermochemical data that are reliable to within ± 10 kJ mol^{-1} (21). Previously these methods were used by us in detailed investigations of the structure and thermochemistry of glycine (22) and of its ionic and free radical forms in the gas phase (23) and in solution (24). Earlier predictions (16) of the stabilizing effect of the $-NH_2$ and -C(O)OH groups on the α-C—H bond dissociation energy were confirmed (23) and the stabilization was shown to be diminished in the $H_2NCH^{\bullet}CO_2^-$ radical anion. This investigation represents an extension to the more complex glycine polypeptide.

The basis sets required in the ab initio calculations in order to achieve the desired level of accuracy must be 6-31G(D)



or better. Hence there are limitations to the size of peptide for which calculations at the desired level (G2(MP2)) can be performed, and it was necessary to define the minimum sizes of the X and Y subsections of the polymeric backbone on either side of the $-NH-CH_2-C(O)-$ residue, for which the chemistry at the α-carbon atom would be representative of its actual behavior at a mid-chain point in a large protein. This was a second objective of the present study. At the same time, we decided to determine whether a computationally more economical reduced level procedure that would give the same reliability in isodesmic reaction calculations as the G2(MP2) level could be devised. This became the third objective.

Computational details

All ab initio calculations presented here were performed with the Gaussian 92 molecular orbital packages (20). The geometry optimizations were carried out at the HF/6-31G(D), MP2/6-31G(D), and B3LYP/6-31G(D) (a hybrid HF-DFT procedure) levels as implemented in the Gaussian 92/DFT molecular orbital packages. Vibrational frequencies were calculated at the HF/6-31G(D) level for all the species under study. For systems containing up to six heavy atoms, the correlation corrections were estimated at the G2(MP2) level. The G2(MP2) procedure (25) includes: a geometry optimization with the standard Hartree–Fock method and the 6-31G(D) split-valence basis set (HF/6-31G(D)); a vibrational frequency calculation at the HF optimized geometry; MP2/6-31G(D) geometry optimization; two single-point post-HF calculations, i.e., QCISD(T)/6-311G(D,F) and MP2/6- 311+G(3DF,2P), on the MP2 optimized geometry in order to obtain an accurate estimate of the correlation energy. The vibrational frequencies calculated at the HF/6-31G(D) level were scaled by a factor of 0.89 in considering the zero-point energy.

As a means of reducing residual errors due to basis set and correlation effects, the bond dissociation energies were derived from the heats of isodesmic reactions (26). In the context of bond dissociation energies (BDEs), these reactions can be represented by process [2]:

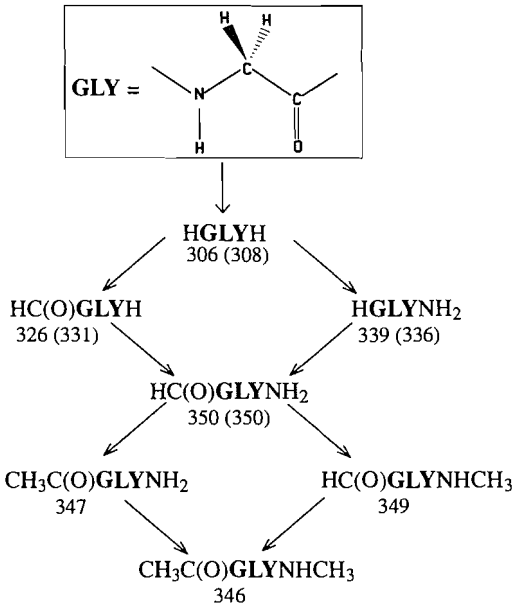
[2] $P^{\bullet} + HA \rightarrow HP + A^{\bullet}$

in which HP is the species for which the BDE, $D_{C-H}(HP)$, is desired, and HA is a reference molecule for which the BDE, $D_{C-H}(HA)$, is known accurately. For each HP and HA the heat of reaction, $\Delta H_R(2)$, was evaluated from ab initio calculations. $D_{C-H}(HP)$ is then given by:

[3] $D_{C-H}(HP) = D_{C-H}(HA) - \Delta H_R(2)$

The highest accuracy would be achieved if A and P are as similar as possible and the theoretical method is as high as possible. The former point suggests that A also should incorporate captodative effects since these were previously

Fig. 1. Definition of **GLY** and relations between structures under study. $D_{C—H}$ reported in kJ mol^{-1} from isodesmic reactions at the B3LYP/6-31G(D)//B3LYP/6-31G(D) and the G2(MP2) (in parentheses) levels.



found to incur higher than average errors in calculated heats of formation (23). The latter point suggests that the G2(MP2) procedure (25) should be used.

The limits of application of G2(MP2) are restricted by the requirement of carrying out a QCISD(T) calculation with a large basis set, 6-311G(D,P), the most time-consuming step. Because the G2(MP2) procedure could not be applied to a key compound in the present study, a "reduced" G2(MP2) procedure, G2(MP2)′, was devised and tested. In this, the QCISD(T) and corresponding MP2 calculations were carried out with the smaller 6-31G(D,P) basis set rather than the 6-311G(D,P) basis set of the standard G2(MP2) method (25). The vibrational frequencies and other parameters were treated in the same way as in the standard G2(MP2) method. The reliability of G2(MP2)′ and of calculations at lower levels (MP2 and B3LYP) with respect to the calculation of C—H bond dissociation energies was evaluated by comparisons with G2(MP2) level results for smaller systems.

To obtain $\Delta H_R(2)$ values at 298 K, $H^0_{298}-H^0_0$ were required. These quantities, as well as the entropies needed in the evaluation of reduction potentials, were calculated by standard statistical thermodynamic methods based on the rigid rotor – harmonic oscillator model (27) and using the frequencies obtained at HF/6-31G(D) level. These frequencies are scaled by a factor of 0.89 in the calculation of these thermodynamic functions.

Results and discussion

Structures

The species for which the optimized structures of the peptide and its α-C-centered radical have been calculated are presented in Fig. 1 and Table 1. For simplicity the common fragments, -NH-CH_2-C(O)- and -NH-C$^{\bullet}$H-C(O)- of the parent and radical are denoted as **GLY** and **GLY$^{\bullet}$**, respectively,

while the formulae of the increasingly complex X and Y end groups are given explicitly.

The optimized geometric parameters of each species obtained with 6-31G(D) basis sets at the HF, MP2, and B3LYP levels were all similar, indicating that the geometric parameters were not sensitive to the correlation levels. Also the structures of the different species resembled each other in the region of the α-C center. Those of $HC(O)NHCH_2C(O)NH_2$ (HC(O)**GLY**NH_2) and HC(O)NHC·HC(O)NH_2 (HC(O)-**GLY**·NH_2) are presented in Fig. 2 as examples, with the **GLY** and **GLY**· sections defined by broken lines. For all the species, the optimized Ramachandran angles (Φ and Ψ of Fig. 2) have values near 180°. Thus the optimized structures in many cases have C_s symmetry or C_1 symmetry with minor deviation from C_s.

Energies

The vibrational ZPEs evaluated at the HF/6-31G(D) level and the total energies calculated at the B3LYP/6-31G(D) and MP2/6-31G(D) levels are listed in Table 1. For the small systems, **HGLY**H, **HGLY**NH_2, HC(O)**GLY**H, and HC(O)**GLY**NH_2 and their radicals, the energies at the G2(MP2)′ and G2(MP2) levels are also reported.

$H^0_{298} - H^0_0$ and S^0_{298}

The calculated values of $H^0_{298} - H^0_{298}$ are given in Table 2. It may be noted that $H^0_{298} - H^0_0$ for the parent and radical species are usually similar, which means that in most cases the $H^0_{298} - H^0_0$ corrections to $\Delta H_R(2)$ are less than 1 kJ mol^{-1}.

C—H bond dissociation energies (BDEs)

As asserted above, to obtain the most accurate values of the BDEs, the reference molecules used in the isodesmic reaction [2] should be as closely related as possible to the glycyl protein fragments under investigation. Ideally they should have both an adjacent amino group and a carbonyl group so that the special feature of the donor–accepter stabilization can be taken into account. The five reference molecules (HA) adopted for use in reaction [2] and their α-C—H bond dissociation energies (in kJ mol^{-1}), were $CH_3CH_2NH_2$ (374.5), $CH_3C(O)OH$ (407.0), $CH_3C(O)CH_3$ (395.0), $NH_2CH_2C(O)O^-$ (363.0), and $NH_2CH_2C(O)OH$ (331.0). Although none of them has a full -C(O)-NH-CH_2-C(O)-NH-structure, three of the reference molecules manifest at least one of the required aspects, either -$NHCH_2$- ($CH_3CH_2NH_2$), or -$CH_2C(O)$- ($CH_3C(O)CH_3$ and $CH_3C(O)OH$). The value for the BDE of $CH_3CH_2NH_2$ is

[a] D_{C-H}(HA) at 298 K are 374.5, 407.0, 395.0, 331.0, and 363.0 kJ mol^{-1} for $NH_2CH_2CH_3$, CH_3COOH, CH_3COCH_3, NH_2CH_2COOH, and $NH_2CH_2COO^-$, respectively. See text.

[b] The 6-31G(D,P) basis set was used in place of 6-311G(D,P) for QCISD(T) and corresponding MP2 calculations in the standard G2(MP2) procedure, see text.

based on $\Delta_f H^0_{298}$ for the parent and radical from Lias et al. (28). For CH_3COCH_3, $\Delta_f H^0_{298}$ of the parent (−217.6) was from Lias et al. (28) while the value for the radical (−41.0) was from Orlov et al. (29). The BDE of $CH_3C(O)OH$ is from a critical examination of experimental and theoretical results by Yu et al. (21, 23). The BDE of the glycyl species, $H_2NCH_2C(O)O^-$ and $H_2NCH_2C(O)OH$, which also exhibit the captodative stabilization, are not directly available from experiment, and were derived from G2(MP2) calculations in combination with isodesmic reactions in which two of the present species, $CH_3C(O)OH$ and $CH_3CH_2NH_2$, as well as CH_4 and CH_3NH_2, were used as references (23).

During the course of the investigation it became clear that a very accurate value for the BDE of $HCONHCH_2CONH_2$ (HCO**GLYNH$_2$**) was required, and that the large size prohibited application of the G2(MP2) procedure. For this reason, the G2(MP2)′ procedure was devised (see above). As a method of testing the G2(MP2)′ procedure for the calculation of BDEs, the values of D_{C-H} for $H_2NCH_2C(O)OH$ and $H_2NCH_2C(O)O^-$ were reexamined by the isodesmic reaction method with $CH_3CH_2NH_2$, $CH_3C(O)CH_3$, and $CH_3C(O)OH$ as reference species. The average values with the G2(MP2)′ procedure were the same as previously reported by Yu et al. (23), namely, 331 and 363 kJ mol^{-1} for $H_2NCH_2C(O)OH$ and $H_2NCH_2C(O)O^-$, respectively, using G2(MP2). The maximum difference between the G2(MP2)′ and G2(MP2) results for any one reference was 1 kJ mol^{-1}. The standard deviations of the values for both $H_2NCH_2C(O)OH$ and $H_2NCH_2C(O)O^-$ with the three references were 2.8 kJ for G2(MP2)′, versus 2.7 kJ mol^{-1} for G2(MP2). These results demonstrate that the G2(MP2)′ procedure has basically the same accuracy as G2(MP2) when used in isodesmic reactions, and reconfirm the reliability of the D_{C-H} values for $H_2NCH_2C(O)OH$ and $H_2NCH_2C(O)O^-$.

HGLYH, HGLYNH$_2$, HCOGLYH, and HCOGLYNH$_2$

These four species represent the first steps toward glycyl protein modelling, and the practical limit for which the most accurate theoretical levels are applicable. The values of D_{C-H} from the isodesmic reactions and ab initio energies calculated at different levels are reported in Table 3. For **HGLYH**, **HGLYNH$_2$**, and HC(O)**GLYH** the G2(MP2) and G2)MP2)′ level results with the five isodesmic reactions in columns 5 and 6 all fall in the narrow range of 5.3 kJ mol^{-1}. The maximum difference between the G2(MP2)′ and G2(MP2) values is less than 2 kJ mol^{-1}. For HC(O)**GLYNH$_2$**, where the highest level of calculation was G2(MP2)′, the range is the same, from 347.6 to 352.9 kJ mol^{-1}. These narrow ranges indicate that at these levels the cancellation of residual errors for all of the standards in the isodesmic reactions was very effective. Therefore, the average value over the isodesmic reactions of the G2(MP2) or G2(MP2)′ results, shown in

Table 4. D_{C-H}(HP) at 298 K in kJ mol^{-1} from isodesmic reactions P$^{\cdot}$ + $NH_2CH_2C(O)OH \rightarrow$ HP + $NH_2CHC(O)OH^{\cdot}$.

HP	B3LYP/6-31G(D)//B3LYP/6-31G(D)	MP2/6-31G(D)//MP2/6-31G(D)
HC(O)**GLY**NH_2	349.8	349.8
$CH_3C(O)$**GLY**NH_2	347.4	346.2
HC(O)**GLY**$NHCH_3$	349.0	348.1
$CH_3C(O)$**GLY**$NHCH_3$	346.4	344.6

bold face in Table 3, may be taken as the "standard" against which the level of accuracy of other calculation methods (i.e., B3LYP and MP2) can be examined.

One can anticipate that the more closely bond types are conserved between P$^{\cdot}$ and HA, and HP and A$^{\cdot}$ in reaction [2], the more complete would be the cancellation of residual errors. Breakdown in this process can be expected to show up more strongly as the level of calculation falls, and the results in Table 3 show that this happens at the B3LYP and MP2 levels. The D_{C-H} values for the four model peptide species obtained at the B3LYP/6-31G(D) level have a maximum deviation of 11.8 kJ mol^{-1} and an average of 7.7 kJ mol^{-1}. The corresponding values at the MP2/6-31G(D) level are 16.4 and 9.3 kJ mol^{-1}, respectively. There is therefore some preference for the B3LYP/6-31G(D) level calculations as they are less scattered. At the same time, the D_{C-H}(HP) values derived at the B3LYP/6-31G(D) level with $NH_2CH_2C(O)OH$ as the reference molecule show the least deviation compared with the averaged G2(MP2) results: the maximum difference between B3LYP and G2(MP2)(′) for the four systems is 5.1 kJ mol^{-1} and the average deviation is 2.4 kJ mol^{-1}. Thus, the B3LYP/6-31G(D) level calculations with $NH_2CH_2C(O)OH$ as standard in the isodesmic reaction seem best able to reproduce the correct D_{C-H} values (assumed to be the same as derived with the G2(MP2) and G2(MP2)′ procedures).

It may be noted that in the course of the present study, results from other levels including B3LYP/6-311G(D,P), MP2/6-311G(D,P), MP2/6-311+G(3DF,2P), QCISD(T)/6-31G(D,P), and QCISD(T)/6-311G(D,P), as single calculations at the B3LYP/6-31G(D) or MP2/6-31G(D) optimized geometries, were also examined in detail. In general, using basis sets larger than 6-31G(D) with B3LYP or MP2 methods did not improve the results. Only at the QCISD(T) level did D_{C-H} parallel the G2(MP2) values for all reference isodesmic systems. Thus for larger systems where the QCISD(T) and G2(MP2) calculations are not practical and lower theoretical levels must be used, the most accurate D_{C-H}(HP) values can be derived with the combination of B3LYP/6-31G(D) theoretical level and $NH_2CH_2C(O)OH$ as isodesmic reference. D_{C-H} values thus derived should fall within 10 kJ mol^{-1} of the correct values.

C—H bond dissociation energies of $CH_3C(O)$GLYNH_2, HC(O)GLY$NHCH_3$, and $CH_3C(O)$GLY$NHCH_3$

These three systems represent extension of the protein chain from HC(O)**GLY**NH_2 to include the next α-C in one or both directions (as modelled by a methyl group). Table 4 collects the central C—H bond dissociation energies for HC(O)**GLY**NH_2 as well as $CH_3C(O)$**GLY**NH_2, HC(O)-$NHCH_3$, and $CH_3C(O)$**GLY**$NHCH_3$, derived at the B3LYP/6-31G(D) level with the glycine molecule ($NH_2CH_2C(O)OH$) as the reference. For these four species, the D_{C-H} values at the MP2/6-31G(D) level are consistent with those of B3LYP/6-31G(D), as was also true for H**GLY**NH_2, but not for H**GLY**H and HC(O)**GLY**H (Table 3). The values of D_{C-H} and the implication of these results for choice of protein model are discussed below.

Effects of X and Y Groups on D_{C-H}

As stated in the Introduction, the bond dissociation energy of a secondary C—H bond in an unsubstituted hydrocarbon is ~397 kJ mol^{-1}. The value of 308 kJ mol^{-1} for D_{C-H} for H**GLY**H (Fig. 1) demonstrates the occurrence of a very strong captodative stabilization (~90 kJ mol^{-1}) for the C-centered radical when the electron-donating group is -NH_2 and the electron-withdrawing group is -C(O)H.

It is convenient to use the H**GLY**H structure as a reference point in discussing the systems studied here. Clearly, altering X by adding the electron-withdrawing C—O group will reduce the electron-donating ability of the -NH- group. Indeed, D_{C-H} increases by 20 kJ mol^{-1} when X = H is replaced by X = HC(O) (Fig. 1). Likewise, changing the group attached to the carbonyl from Y = H to Y = NH_2, the better electron donor group, is expected to diminish the electron-withdrawing power of the -C—O- group and raise the BDE. In accord with expectations, D_{C-H} increases by 33 kJ mol^{-1} when Y = H is replaced by Y = NH_2 (Fig. 1). Replacing both groups causes D_{C-H} to increase by 44 kJ mol^{-1}. Since D_{C-H} is the same for HC(O)**GLY**NH_2 and HC(O)**GLY**$NHCH_3$, changing the -NH_2 to -$NHCH_3$ in the Y end group has no further effect. Similarly, altering the electron-withdrawing group on the amino end from X = HC(O)- to X = $CH_3C(O)$-, or making both replacements simultaneously, also has only a small effect. The last results suggest that addition of the methyl groups, which model the α-C of the next amino acid residue in each direction, is not necessary. It is anticipated therefore that the same "chain extending" groups, X = HC(O) and Y = NH_2, would serve to model the α-C environment of all of the other amino acid residues as well.

The value of D_{C-H} for nonterminal glycyl in a long-chain peptide

A primary objective is to obtain a value for D_{C-H} at a nonterminal or mid-chain position in a glycyl peptide. Based on the BDE values given in Fig. 1, it is evident that further extensions of the X and Y groups beyond X = $CH_3C(O)$ and Y = $NHCH_3$ will have minimal, if not negligible, effects. Therefore, the best estimate is D_{C-H} = 348 kJ mol^{-1}, taken as the average of the D_{C-H} values of the four species in Table

4. The uncertainty in this result should not exceed ±10 kJ mol^{-1}. This indicates a stabilization of ~50 kJ mol^{-1} for the glycyl α-C-centered radical. For the reasons discussed above, this is smaller than for free neutral glycine, $H_2NCH_2C(O)OH$ (~66 kJ mol^{-1}), but it is still substantial. It means, for example, that the α-C position will be vulnerable to H atom abstraction by RS•, RO•, and some phenoxyl and peroxyl radicals, for which the parent compounds have bond dissociation energies in excess of 350 kJ mol^{-1} (12, 13). The feasibility of those processes is best examined in terms of the reduction potential, which is estimated below.

Relevance to proteins

The present theoretical procedure predicts the C—H bond dissociation energy of a model protein fragment containing glycine in the gas phase from the difference between the energies of the parent fragment and the corresponding α-C-centred radical, both in their fully relaxed geometries. The effect of an aqueous environment is estimated in the next section. The relaxed geometry of both the radical and neutral glycine-based model correspond to Ramachandran angles (Φ and Ψ of Fig. 2) equal to 180° (planar geometry). The radicals of other amino acids should also have planar geometries, although this will not be true of the neutral species because of the chirality at the α-C centre. In a real protein, the backbone chain may be rigidly anchored by hydrogen bonds that form the secondary and tertiary structure, with Φ and Ψ far from 180°, particularly in the case of α-helical segments (average values, $\Phi = -60°$ and $\Psi = -45°$). A recent survey of 78 protein structures (30) from the Brookhaven Protein Structure Databank (BPSD) (31) revealed many instances of amino acids whose Φ, Ψ values were within 30° of 180°, a region of conformational space close to the β-sheet structure (average values, $\Phi = -150°$ and $\Psi = +150°$). Values close to 180° correspond approximately to minima on the radical potential energy surface but may be far from minima of the undamaged amino acid residue. α-C—H bonds at such sites will be especially weak and susceptible to damage by free radicals generated internally in mitochondria or through the action of external sources of radiation. We have examined 10 proteins from BPSD with different proportions of α-helical and β-sheet structure for instances of glycine with dihedral angles near 180°. These are very common in proteins high in β-sheet content, especially in silk fibroins that also have a high proportion of glycine (and alanine) (32). Indeed, 30% of the glycine (and also of the alanine) residues of one of the theoretical models of silk fibroin of Scheraga and coworkers (33) are within 30° of the locally planar geometry. Since near-planar geometries do not occur in α- helical segments, one may infer that these are less susceptible to oxidative damage than β-sheets. We are examining the effect of angular constraints on α-C—H bond strengths as a function of Φ and Ψ.

The reduction potential of a nonterminal α-C-centered radical in a long-chain peptide

The standard free energy change at 298 K, ΔG^0_{298}, of the reaction:

[4] $XNHCH^{\bullet}C(O)Y_{(g)} + \frac{1}{2}H_{2(g)} = XNHCH_2C(O)Y_{(g)}$

can be estimated from the above values of $D_{C—H}$ together with ΔS^0_{298} (Table 2). ΔG^0_{298} is given by expression [5],

[5] $\Delta G^0_{298} = -D_{C—H} - T\Delta S^0_{298} + \Delta_f H^0_{298}(H^{\bullet}_{(g)})$

The difference in entropy of $XNHCH_2C(O)Y$ and $XNHCH^{\bullet}C(O)Y$ was also estimated from those of $HC(O)\mathbf{GLY}NH_2$, $CH_3C(O)\mathbf{GLY}NHCH_3$, and their radicals (Table 2). $\Delta_f H^0_{298}(H^{\bullet}_{(g)})$ has a value of 218 kJ mol^{-1} (34) and the other correction term $(-T\Delta S^0_{298})$ in eq. [4] amounts to 16.5 and 15.5 kJ mol^{-1}, respectively, for $HC(O)\mathbf{GLY}NH_2$ and $CH_3C(O)\mathbf{GLY}NHCH_3$. The difference between the values for the two peptides is negligible. Using a net correction of 234 kJ mol^{-1}, ΔG^0_{298} for reaction [4] is found to be −114 kJ mol^{-1}.

The free energies of solution of the $XNHCH^{\bullet}C(O)Y$ radical and its $XNHCH_2C(O)Y$ parent are unlikely to differ by more than a few kJ mol^{-1}, so that ΔG^0_{298} for reaction [6]

[6] $XNHCH^{\bullet}C(O)Y_{(aq)} + \frac{1}{2}H_{2(g)} = XNHCH_2C(O)Y_{(aq)}$

can also be estimated to be −114 kJ mol^{-1}. ΔE^0 for this reaction, 1.2 V, is obtained from $-\Delta G^0_{298}/F$, where F is the Faraday constant, and has an uncertainty of less than ±0.2 V. This is also E^0 for the half reaction [7]:

[7] $XNHCH^{\bullet}C(O)Y_{(aq)} + H^+_{(aq)} + e^- = XNHCH_2C(O)Y_{(aq)}$

which was our objective.

Correcting to the pH of 7 gives $E^{0'} = 0.8$ V for reaction [7]. For comparison, RS•, ROO•, and tyrosyl radicals have $E^{0'}$ values in reaction [8]

[8] $R^{\bullet}_{(aq)} + H^+_{(aq)} + e^- = RH_{(aq)}$

of 0.92 V (35, 36), 1.06 V (37), and 0.97 V (38), respectively. Those $E^{0'}$ values indicate that these other radicals, as well as $OH^{\bullet}$ ($E^{0'}(OH^{\bullet}, H^+/H_2O) = 2.3$ V, ref. 39), are potentially able to abstract H atoms from the glycyl α-CH_2 group. Since these radicals are less reactive than OH• due to the smaller driving force, their effects will be more apparent in biological systems, where the radical concentrations are usually lower than in chemical experiments and time scales for reactions are long.

Finally it may be noted that the α-CH group of an N-terminal amino acid is strongly protected by protonation, since this totally destroys the electron-donating ability of the amino group and eliminates the possibility of captodative stabilization of the C-centered radical. As an example, from the results of Armstrong et al. (24) $E^{0'}$ is expected to rise from 0.8 V for reaction [9]

[9] $H_2NCH^{\bullet}CO_2^-{}_{(aq)} + H^+_{(aq)} + e^- = H_2NCH_2CO_2^-{}_{(aq)}$

to 1.5 V on protonation of the amino group (see reaction [10]);

[10] $H_3N^+CH^{\bullet}CO_2^-{}_{(aq)} + H^+_{(aq)} + e^- = H_3N^+CH_2CO_2^-{}_{(aq)}$

This effect of protonation is undoubtedly the reason why H atom transfers from α-CH groups in $H_2NCH_2C(O)$- structures to S-centered radicals only occur at high pH, where the amino groups are deprotonated (10, 14).

Summary

At the present time there are no experimental bond dissociation energies specifically for peptide α-C—H bonds, which could be used in isodesmic reaction [2] to determine $D_{C—H}$ values in proteins. Until they become available, the best approach is therefore to use the glycine molecule, $H_2NCH_2C(O)OH$, which has itself been studied by the isodesmic reaction method. Based on a number of isodesmic reactions involving different experimental data (16, 23) the value of $D_{C—H}$ for glycine is 331 kJ mol^{-1} at 298 K with a standard deviation of 3.5 kJ mol^{-1}. In the present work we have established, by use of high-level theoretical procedures, isodesmic reactions, and convergent molecular modelling, that $D_{C—H}$ for the mid-chain region of a glycyl protein is 348 kJ mol^{-1} at 298 K. The low value of $D_{C—H}$ means that the α-C position will be vulnerable to H atom abstraction by RS$^{\bullet}$, RO$^{\bullet}$, and some phenoxyl and peroxyl radicals, for which the parent compounds have bond dissociation energies in excess of 350 kJ mol^{-1}. This result is also expected in aqueous solution, since the best estimate of E^0 at neutral pH for the bond-forming reaction [7] gives $E^0 = 0.8$ V, which is lower than experimentally determined E^0 values for RS$^{\bullet}$, ROO$^{\bullet}$, tyrosyl, and OH$^{\bullet}$ radicals.

The present work has established that the minimum suitable model for the local environment of the α-C region of an amino acid residue in a protein requires that the CO_2^- group be converted to $C(O)NH_2$ and the NH_2 group be converted to HCONH. In other words, the properties of the α-CH in the molecule, $HC(O)NHCHRC(O)NH_2$, where R is an amino acid side chain, effectively mirror the local properties of a protein.

The B3LYP/6-31G(D) procedure in combination with an isodesmic reaction with the glycine molecule can reliably predict the α-C—H bond dissociation energy of a protein-like molecule. As implemented in the Gaussian package of programs, it is feasible to apply this procedure to all of the other amino acid residues. This work is in progress.

Interpretation of neighboring group interactions in crystal structures. A solid state and quantum-chemical study of "incipient nucleophilic attack" in 2-diazonium benzoic acid and its benzoate[1]

Rainer Glaser and Christopher J. Horan

Abstract: The concept of the Bürgi–Dunitz angle of attack on carbonyls is compatible with the electronic structure of carbonyls. However, it is argued here that the generalization asserted to describe the interaction of nucleophiles with diazonium ions is inappropriate. Distortions in crystal structures of diazonium ions with proximate nucleophiles were interpreted by an incipient nucleophilic attack (INA) on the formally positive-charged N_α. This "N_α attraction model" relies on the assumption that the *formal* charge in the most commonly used Lewis structure of diazonium ions represents *actual* charge. We proposed that the close approach of the proximate nucleophile to the diazonium group occurs to enhance attractive 1,3-(C,N_β)-bridging interactions and despite repulsion between N_α and the proximate oxygen (O_{pr}). The present study combines theoretical analysis of rotamers of 2-diazonium benzoic acid and its conjugate base with experimental results *on the same system* to provide compelling evidence that the more general conclusions drawn from analyses of neighboring group interactions in propenoic acid models are fully warranted. The crystallographic record is more fully consistent with the "1,3-bridging attraction model." Combined analysis of solid state and gas phase structures reveals the intrinsic features due to INA. Both electrostatic models can account for these features but with different postulates about the electron density distribution. While the structural analysis alone cannot distinguish between the alternative interpretations, the study of the electronic structure allows one to clearly differentiate between these competing interpretations. A method (ESI) for the quantitative evaluation of electrostatic neighboring group interactions has been devised and this ESI concept employs atomic electrical moments (charges, dipoles, and quadrupoles) determined via topological electron density analysis. The results of the ESI analysis support the 1,3-bridging attraction model and eliminate the N_α attraction model.

Key words: electrostatic interactions, electron density analysis, atoms in molecules, X-ray crystallography, ab initio molecular orbital theory, incipient nucleophilic attack, bonding models, ESI analysis.

Résumé : Le concept de l'angle d'attaque sur les carbonyles de Bürgi–Dunitz est compatible avec la structure électronique des carbonyles. Il a toutefois été suggéré que la généralisation proposée pour décrire l'interaction des nucléophiles avec les ions diazonium est inappropriée. Les distorsions dans les structures cristallines des ions diazonium avec des nucléophiles à proximité ont été interprétées par une attaque nucléophile incidente (ANI) sur le N_α qui est formellement chargé positivement. Ce «modèle d'attraction N_α» se base sur l'hypothèse que la charge *formelle* dans la structure de Lewis la plus couramment utilisée pour les ions diazonium représente la charge *réelle*. Nous avons proposé que l'approche du nucléophile à faible proximité du groupe diazonium se produit pour augmenter les interactions attractives 1,3-(C,N_β) qui font le pont et malgré la répulsion entre le N_α et l'oxygène à proximité (O_{pr}). La présente étude combine une analyse théorique des rotamères de l'acide 2-diazoniumbenzoïque et de sa base conjuguée avec des résultats expérimentaux *sur le même système* qui fournit des données suggèrent fortement que les conclusions plus générales tirées de l'analyse des interactions des groupes avoisinants dans les modèles de l'acide propénoïque sont pleinement justifiées. Les données cristallographiques disponibles sont en meilleur accord avec le «modèle d'attraction à pont-1,3». Une analyse combinée des structures en phases solide et gazeuse met en relief les caractéristiques intrinsèques dues à l'ANI. Les deux modèles électrostatiques peuvent expliquer ces caractéristiques, mais en se basant sur des postulats différents concernant la distribution de la densité électronique. Même si l'analyse structurale seule ne permet pas de distinguer entre ces interprétations alternatives, l'étude de la structure électronique permet de bien différencier entre ces interprétations en compétition. La méthode (ESI) d'évaluation quantitative des interactions électrostatiques des groupes avoisinants a été mise au

Introduction

The Bürgi–Dunitz angle of attack of a nucleophile on a carbonyl group was first described over 20 years ago (2), the feature was well established, and it is now "common knowledge." The trajectory of a nucleophile approaching a carbonyl in its π plane is not perpendicular but encloses an angle of 109° with the C=O σ-bond (Scheme 1). The angle of attack was determined both by a systematic analysis of crystal structures of compounds that contain either intra- or intermolecular nonbonded interactions between nucleophilic centers and carbonyl groups, and also by quantum-mechanical potential energy surface explorations. It was suggested that chemical reaction paths could be determined by examination of distortions in structural parameters caused by the presence of the two reactive centers in the "frozen" environment of the crystal lattice. Bürgi and Dunitz found the attack angle of 109° to be rather general for various nucleophiles and consistent distortions occurred for carbonyls in different environments. As the nucleophile's distance to the carbonyl decreased, the C=O distance increased and carbonyl C pyramidalization occurred. The idea of an "incipient nucleophilic attack" on a carbonyl center was demonstrated by Dunitz's elegant description of nucleophile–electrophile interactions in 1,8-disubstituted naphthalene and quinoline systems (3). In the seven systems studied, the distortions were consistent and characteristic of an initial nucleophilic attack. There was a splaying outward of the electrophilic carbonyl group and a splaying inward of the proximate nucleophile. The carbonyl carbon was also displaced toward the nucleophile and out of the plane of its three bonded atoms.

The Bürgi–Dunitz model for attack of nucleophiles on carbonyls is easily accepted as it is in agreement with the known electronic structure of carbonyls. The C=O bond is highly polar (4) for reasons of electronegativity and nucleophiles will be attracted to the electron-deficient carbonyl C. The nonperpendicular attack angle might be seen as a reflection of repulsive interactions between the nucleophile and the negatively charged carbonyl O. Because of its simplicity, this model quickly was applied to related systems as well. The attack of a nucleophile on a nitrile group can be discussed from this vantage point since the C≡N and C=O bonds show similar polarities (5). In fact, the concept of incipient nucleophilic attack has been broadened (6) to include not only nucleophilic attack on polar $^{\delta+}CX^{\delta-}$ or $^{\delta+}YO^{\delta-}$ multiple bonds but on all kinds of multiple bonds and to include dative bond formation as well.[3] In Scheme 2, a few examples of incipient nucleophilic attack on electron-deficient S centers are illustrated. The X-ray structure of the monosulfoxide suggests incipient sulfurane formation. The ease of oxidation of the disulfides was explained by incipient S—S bond formation (8). In a study of the directional preference of the approach of nucleophiles to sulfonium ions (9), 22 sulfonium ion crystal structures were analyzed for close contacts and interpreted as representing early stages of either an addition or a displacement reaction. Methylmethionine with its short C···O contact in the crystal exemplifies an early stage of facile conversion to a lactone.

Wallis and Dunitz asserted the generalization that an attack of a nucleophile on an NN triple bond will occur in a similiar fashion as with the carbonyls. Quinoline-8-diazonium-1-

oxide tetrafluoroborate (10) was discussed in complete analogy to the respective carbonyl system (Scheme 1) to argue that an incipient attack would occur at N_α (the central N). Several other cases of incipient nucleophilic attack on diazonium ions will be discussed below. This reasoning reflects the formal similarities of the Lewis structure (11) of diazonium ions with its formally positive-charged N_α and of the C=O bond polarity — this *formal* similarity is illustrated in a compelling fashion in Scheme 1. The explanation of distortions of diazonium ions by incipient nucleophilic attack relies on the assumption that N_α carries a positive charge and postulates an attractive interaction between the nucleophile and N_α (Scheme 3). Hence, this "N_α attraction model" would imply that the *formal* charge in the Lewis structure is a good representation of the *actual* charge distribution. Based on electronic structure analyses of diazonium ions, we argued that this assumption is not warranted and that the simple electrostatic model cannot be correct.

We proposed a bonding model for diazonium ions based on Bader's topological electron density analysis (12, 13) (TEDA) that emphasizes dative C←N bonding between a carbenium ion acceptor and an N_2 group donor that is internally polarized in the fashion $N_\alpha^{\delta-}$—$N_\beta^{\delta+}$ (14). This bonding model has since been shown to be general, fully consistent with all chemical and physical properties of diazonium ions,[4] and we argued for its preferability over purely formal bonding notations such as the Lewis notation (14*d*). In this context, we have been studying incipient nucleophilic attack in diazonium ions to probe their electronic structures. We first reported a theoretical study of neighboring group interactions in the rotamers of 3-diazonium propenoic acid and the zwitterionic conjugate base (1*a*). These systems were particularly suitable as they allowed for a variation of the nucleophilicity of the proximate O-atom (O_{pr}: C-O̲H, C=O̲, C-O̲$^-$) in the proximity of the N_2 group without major skeleton changes. Secondly, an aliphatic unsaturated molecule was selected because it allowed us to study the incipient nucleophilic attack in the *cis* isomer in comparison to the *trans* isomers as reference. We provided compelling evidence that the distortions occur in order to optimize the electrostatic interactions associated with the quadrupolar charge arrangement of the N_2 group and the C—O_{pr} bond. We showed that the close approach of the proximate nucleophile to the diazonium group occurs to enhance attractive 1,3-(C,N_β)-bridging interactions and *despite* N_α–O_{pr} *repulsion* (Scheme 3). We succeeded in the determination of the X-ray structures of the first β,β-disubstituted vinyldiazonium ions (16) but the synthesis and crystallization of β-*mono*substituted vinyldiazonium ions remain elusive. To corroborate our arguments, we thought it necessary to undertake a theoretical and experimental study on the *same* molecule and we resorted to aromatic diazonium systems. The crystal structures of 3-carboxy-2-naphthalenediazonium salt reported by Gougoutas and Johnson (17) were appealing but somewhat large from the viewpoint of computational demands. Hence, we focused on the *ortho*-carboxyl benzenediazonium ions and we report here on the interpretation of the distortions present in their quantum-mechanically determined gas phase structures and their experimental solid state structures. The three gas phase structures considered (Scheme 4) are the rotamer of 2-diazonio

benzoic acid in which the hydroxyl O is close to N_2, **1**, the other rotamer of this acid, **2**, and the conjugate base 2-diazonium benzoate zwitterion, **3**. We were able to determine the crystal structures of one rotamer of the benzoic acid derivative, the monohydrate of 2-carboxybenzenediazonium chloride (1*b*), **4**·Cl^-·H_2O, and of the conjugate base, the explosive 2-carboxylatobenzenediazonium ion hydrate (1*d*), **6**·H_2O. In addition, we solved the structure of **5**·Cl^-, which can be seen as the 1:1 complex between **4**·Cl^- and **6** (1*c*). The nucleophilicity of the proximate oxygen in **5** should be in between those of **4** and **6**. Details of the solid state structures were communicated (1*b–d*). With the theoretical data, we can now distinguish between intrinsic and packing-related distortions and probe the consistency of the competing explanations. While the structural analysis alone cannot distinguish between the alternative interpretations, a method for the quantitative evaluation of electrostatic neighboring group interactions has been devised for this purpose. The ESI concept employs atomic electrical moments determined via topological electron density analyses and the results of the ESI analysis do provide independent information that strongly supports the 1,3-bridging attraction model and eliminates the N_α attraction model.

Computational methods

Restricted Hartree–Fock (RHF) ab initio calculations were carried out on IBM RS-6000 systems with the program Gaussian92/DFT (18, 19) and electron density analyses were performed on Silicon Graphics Indigo workstations. Geometries were optimized in C_s symmetry and the Hessian matrices were computed analytically for each of the structures to confirm that an extremum had indeed been located and to characterize the stationary structures via the number of negative eigenvalues. Optimizations and vibrational analyses were performed with the basis sets 3-21G and 6-31G*. Total energies and vibrational zero-point energies of **1–3** are listed in Table 1 and their RHF/6-31G* geometries are listed in Table 2 together with the solid state structural data. The electronic structure analyses were performed at the RHF/6-31G* level. Topological and integrated properties were determined using various modules of the Proaim program (20). Graphical representations of the integrated atomic moments were generated with the program Dipoles.[5] The analysis of the electrostatic interactions between neighboring groups was performed with our program ESI[6] and the theoretical background will be discussed below.

Results and discussion

Incipient nucleophilic attack in crystal structures of diazonium ions

In crystal structures of salts of diazonium ions that contain a proximate nucleophile, the N_2 group is bent in a way that was interpreted as the result of *intramolecular* incipient nucleophilic attack on N_α. As with the interpretation of the structure of quinoline-8-diazonium-1-oxide tetrafluoroborate (vide supra), Gougoutas and Johnson (17) attributed distortions in 3-carboxy-2-naphthalenediazonium salts and the corresponding zwitterion **I** mainly to attractive interactions between N_α and the carbonyl O and also between N_β and the counterion. *Intermolecular* incipient nucleophilic attack of sulfonate O on N_α has been discussed for **II** (21). The close O–N_α contact might equally well be explained as the result of minimization of the distances between the sulfonate O and the atoms N_β and $C(N_2)$. The placement of nucleophiles in 1,3-bridging positions is common, and structures are known of several diazonium ions with polyfluoro anions in which the F atoms are placed successively in the two CNN bridging positions and, if both of these are occupied, in the proximity of N_β. The crystal structures of **III** (22) and **IV** (23) both contain F atoms in such bridging positions with nearly equal F–N_α and F–N_β distances. The crystal structure of $PhN_2^+BF_4^-$ (24), **V**, provides an excellent example for the placement of counterions in the proximity of both N_2 group nitrogens and this bridging was regarded as the result of electrostatic interactions of F with N_α and N_β. Haymore and coworkers (25) studied host–guest assemblies **VI** formed by 18-crown-6 ethers and diazonium ions and the crystal structure[7] showed the N_2 group inserted into the cavity of the crown ether such that each O atom assumes a 1,3-bridging position between N_β and C_{ipso}.[8]

Most recently, Wallis, Easton, and Dunitz (10*b*) reported the crystal structures of three 8-substituted naphthalene-1-diazonium ions, **VII**a, and the authors reiterated their previously stated view that the distortions are due to the attack of the electron-rich nucleophiles on the electron-deficient N_α. It was recognized that the functional groups are on opposite sides of the best molecular plane and this observation was said to be indicative of "attractive interactions between an electron-rich atom ... and the α-N atom of the diazonium group." In the earlier paper (10*a*) on the quinoline **VII**b, this feature was thought to disfavor their interpretation and downplayed as it "only increases the O(1)···N(1) separation by 0.017 Å." We pointed out (1*a*) that placing the two functional groups on opposite sides of the plane of the aromatic ring is *not* supportive of the suggested attractive interaction. In the crystal structure of 8-nitronaphthalene-1-diazonium ion, a system that is very closely related to the carboxyl-substituted structures, the NO_2 group is rotated out of the aromatic plane by 33°. This feature was said to assist in decreasing the distance between the nitro O and the diazonium α-N-atom. Certainly, rotating the nitro group out of the plane (and out of conjugation) only increases its distance from the N_2 group and this distortion is clearly not consistent and, in fact, is in contradiction to the idea of an attractive interaction between the nucleophile and N_α.

Neighboring group interactions in 2-diazonium benzoic acid derivatives

Crystal structures

The X-ray structures of the *ortho*-carboxy benzenediazonium ions **4–6** are shown in Fig. 2. Several types of distortions are pertinent to our discussion. The first two concern *in-plane deformations* of bond angles and specifically (*a*) the deviations from CNN linearity and (*b*) the splaying apart of the angles ∠(N_2-C═C) and ∠(C═C-CO_2). Two further types of distortions concern *out-of-plane displacements* of the functional groups and they include (*c*) the positioning of the two functional groups on opposite sides of the molecular plane and

Fig. 1. Examples of incipient nucleophilic attack in crystal structures of diazonium ions (charges on counterions omitted): 3-carboxylate-2-naphthalenediazonium zwitterion (**I**); 2-diazonium-4-phenolsulfonate monohydrate (**II**); *para*-bromobenzene tetrafluoroborate (**III**); *para*-diethylaminobenzenediazonium hexafluorophosphate (**IV**); benzenediazonium tetrafluoroborate (**V**); 18-crown-6 ether complexed benzenediazonium ion (**VI**); naphthalene-1-diazonium ions (**VII**a) and 8-substituted quinoline diazonium ions (**VII**b).

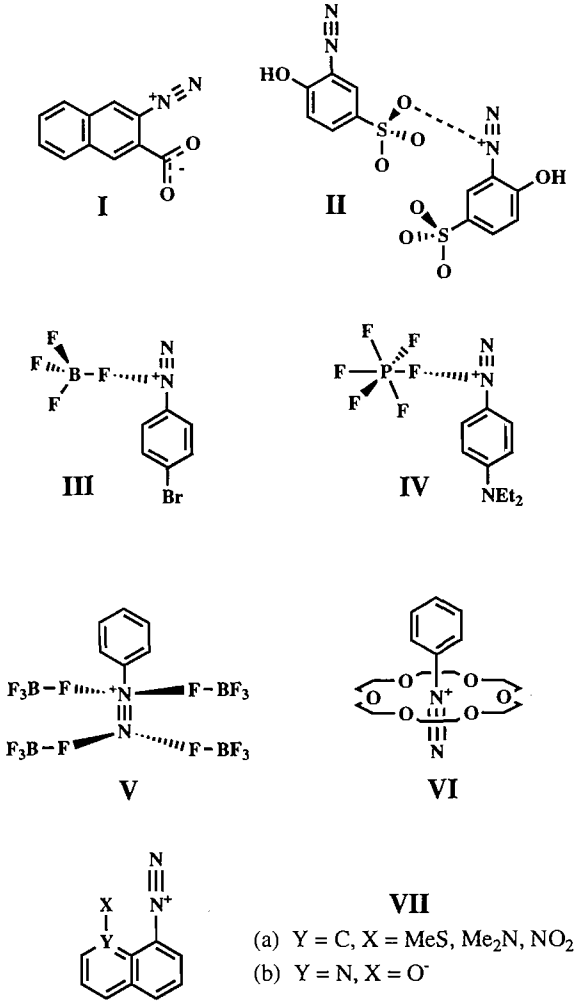

Fig. 2. Perspective view of the cations **4**–**6** contained in 2-carboxybenzenediazonium chloride monohydrate, $\mathbf{4}\cdot Cl^{-}\cdot H_2O$, in the symmetrically H-bridged system formed by 1:1 complex formation between 2-carboxybenzene-diazonium chloride and benzenediazonium-2-carboxylate, $\mathbf{5}Cl^{-}$, and in the 2-carboxylatobenzenediazonium ion hydrate, $\mathbf{6}^{-}H_2O$. Thermal ellipsoids are drawn at the 50% probability level.

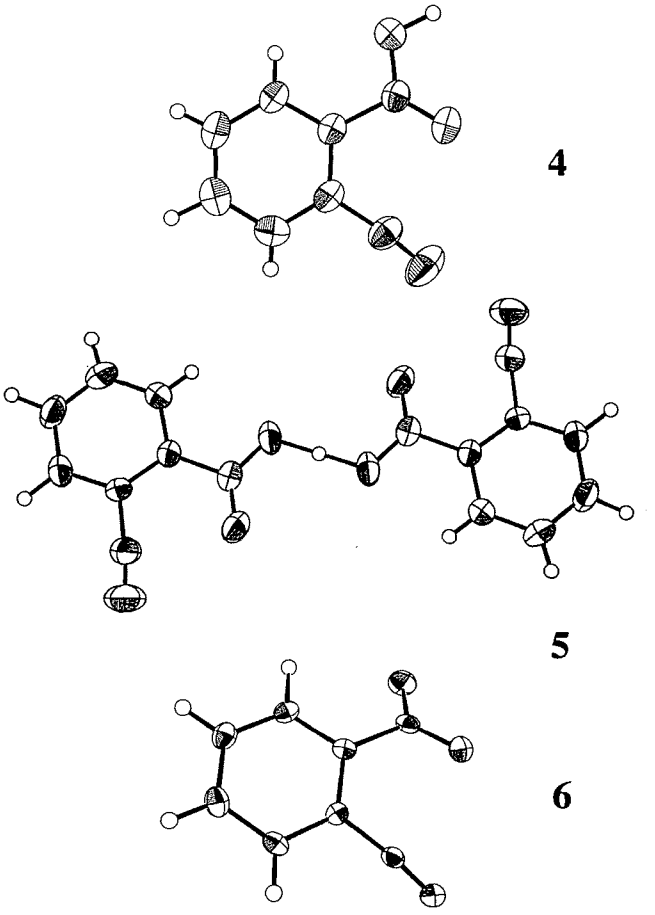
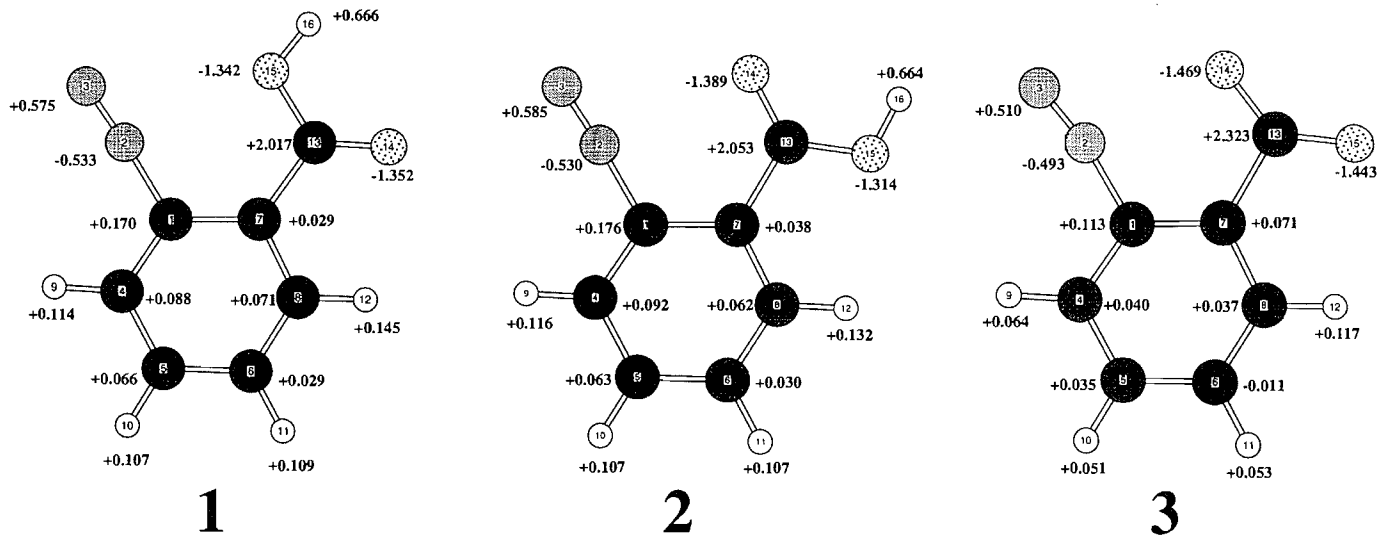


(*d*) the rotation of the carboxyl groups about the C(7)—C(13) bonds.

Primarily, the in-plane deformations were considered as evidence for an attraction between O_{pr} and N_{α}. In **4**–**6**, N_{β} is displaced away from the carboxyl group resulting in deviations of the C(1)-N_{α}-N_{β} skeleton from linearity by 5–7°. Benzenediazonium ions are well known to exhibit widened C-C_{ipso}-C angles at the N_2 bearing C atom (1*c*). It is because of *this* effect on the C(4)-C(1)-C(7) angles (>124.8°) that the other angles at C(1) have to be less than 120°. We find the angles N(2)-C(1)-C(4) and N(2)-C(1)-C(7) to be about 115° and 119°, respectively, and they differ in a way that would position N_{α} *further away* from O_{pr}. The C(1)=C(7)-C(13) angles all are larger than the sp^2 angle of 120°. Hence, considering all of the crystallographic evidence, the in-plane deformations of the angles N(2)-C(1)-C(7) and C(1)-C(7)-C(13) certainly do not allow one to argue in favor of an attraction of O_{pr} to N_{α} but these angle widenings would increase the distance between the two neighboring groups.

The N_2 groups and the carboxyl groups are on opposite sides with regard to the best molecular plane with N(2)-C(1)-C(7)-C(13) dihedral angles of 7.4–5.1° for **4**–**6**. This displacement increases the N_{α}–O_{pr} distance. Another significant dihedral angle describes the carboxyl group rotation out of the plane of the aromatic ring and its value can be as high as 25.9°. These rotational distortions are due to *intermolecular* interactions and, in any case, it is clear that the rotational distortions certainly cannot be interpreted as evidence of N_{α}–O_{pr} attraction since O_{pr} is rotated *away* from the N_2 group.

Fig. 3. Molecular models of the RHF/6-31G* optimized planar minimum structures of **1–3** with integrated atomic charges.



Calculated gas phase geometries

All the optimized planar structures **1–3** are minima[9] (Table 1 and Fig. 3) and we conclude that the out-of-plane distortions for **4–6** are due to packing. Basis set effects on structures are minimal, the agreement between theory and experiment is excellent, and, moreover, corresponding bond lengths in **1–3** differ only slightly (Table 2). The significant in-plane deformations found in **4–6** also occur in **1–3** (Table 2). The C(1)-N_α-N_β backbones are not linear (177° for **1** and **2**, 170.4° for **3**), there is a slight widening of the C(4)-C(1)-C(7) angles to values >124°, and the C(1)-C(7)-C(8) angles of 115.0°±0.5° are larger than in the parent benzenediazonium ion.

Intrinsic INA features and their interpretations

The combined analysis of the solid state and of the gas phase structural data shows that the intrinsic features associated with incipient nucleophilic attack on diazonium ions are the CNN nonlinearity and the widening of the in-plane angles. These features result in the nonbonded distances summarized in Table 3 and we note that the N_α–O_{pr} distances in all systems remain substantially less than the sum of the van-der-Waals radii of N and O (2.9 Å). Both the N_α attraction model and the 1,3-bridging attraction model account for these features with different postulates concerning the electron density distribution. The former explains the kink in the CNN backbone and the short N_α–O_{pr} contact with an attraction of the nucleophile to the positively charged N_α atom. The 1,3-bridging attraction model differs fundamentally in that it reflects the polarity $C(+)N(^{\delta-})N(^{\delta+})$ and it is slightly more complicated as it considers not just the interaction between O_{pr} and N_α, which is repulsive in this model. The C—O_{pr} and N_α—N_β bonds are arranged in a nearly perfectly aligned quadrupolar arrangement with roughly identical N_α–C and N_β–O_{pr} distances. The short N_α–O_{pr} distance results from the optimization of the 1,3-bridging O_{pr}–N_β and O_{pr}–C(N) attractions and N_α–$C(O_{pr})$ attraction as well. Note that the latter interaction provides a straightforward explanation of the kink in the CNN backbone. It is evident that *the structural characteristics can be interpreted based on different assumptions concerning the electronic structures*. A corollary statement would be that structure distortions *alone* do not allow one to make any deductions concerning electron density distribution. On the other hand, the study of the electronic structure will allow one to clearly differentiate between competing interpretation of the structural distortions.

Quantitative evaluation of electrostatic neighboring group interactions

AIM and the ESI concept

Both the N_α attraction model and the 1,3-bridging attraction model are electrostatic in nature. To formulate these models in quantitative terms, one needs to assign electrostatic moments to the atoms and evaluate their interactions. The concept of "atomic charge" is of paramount importance in discussions of all aspects of chemistry and many methods have been proposed to partition molecules into atoms and to assign charges to the atoms. Basis set partitioning and density partitioning methods have been developed (27). To the class of basis set partitioning methods belong, for example, the historically significant Mulliken population analysis and the modern Natural Population Analysis (28). The density partitioning methods do not rely on properties of the Hilbert space but consider directly the observable molecular electron density distribution in Cartesian space. As far as the partitioning of the molecular electron density distribution into atomic components is concerned, two schools of thought seek to recover either "spatially

[9] The conformational preference energy of 3.6 kcal/mol in favor of **2** compared to **1** is nearly the same as for the respective propenoic acid derivatives (3.8 kcal/mol). The proton affinity of 259.9 kcal/mol of **3**, however, is significantly higher than the value of 238.5 kcal/mol (ref. 1*a*) obtained at the same level for the aliphatic system.

extended" or "spatially constrained" atom-shaped objects. The approaches by Parr (29) and by Walker and Mezey (30) exemplify the former and Bader's topological Atoms in Molecules theory (12, 13) (AIM) is the most rigorous formulation of the latter. For the discussion of the majority of chemical problems, the AIM method is especially well suited and its widespread usage emphasizes this point. An aspect of the topological electron density analysis (TEDA) that is particularly appealing concerns its ability to deal with atom anisotropies (31, 32). Many population analyses merely describe atomic charges and few attempts have been made to include higher moments (33). For example, the extended Mulliken electron population analysis proposed by Huzinaga et al. produces a point charge model that correctly reproduces the molecular electric dipole moment (34). There have also been reports on the extensions of the Mulliken population analysis to include atomic polarizations to recover the molecular dipole moment.[10] The topological method allows for a more refined representation of the atom in a molecule since not only the charge but higher atomic moments as well can be determined. We will be interested in charges, dipoles, and quadrupoles of the atoms but still higher moments can also be determined.

Arguments based on charges and electrical moments can become rather involved as many values "with direction" need to be considered. It is thus important to define and discuss parameters that incorporate all of this information. As the basis for such parameters, we are studying the electrostatic interaction energy[11] between atoms i and j, ESI_{ij}, defined by the equation

$$ESI_{ij} = CC_{ij} + CD_{ij} + DD_{ij} + QC_{ij} + QD_{ij} + QQ_{ij}$$

where CC_{ij} is the Coulomb energy between the atomic charges q_i and q_j, CD_{ij} is the sum of the energies associated with the interaction of q_i with atomic dipole μ_j and of q_j with μ_i, and DD_{ij} is the interaction energy between the dipoles μ_i and μ_j. The remaining terms consider the interactions of the atomic quadrupoles with the charges (QC_{ij}), dipoles (QD_{ij}), and quadrupoles (QQ_{ij}).

Topological analysis and determination of electrical moments

The quantitative evaluation of electrostatic neighboring group effects[12] requires knowledge of the ESI_{ij} values, which in turn depend on the atomic properties evaluated by the AIM theory. We have determined all of the topological and integrated atomic properties and pertinent results are summarized in Tables 4 and 5. The analysis begins with the characterization of topological features of the electron density distribution based on the properties of the gradient vector field. The collection of all gradient vector field lines originating at a given atom, the attractor, define the associated zero-flux surfaces as the boundaries of the atoms in the molecules. Bond critical points occur at the intersection between the zero-flux surfaces and the so-called bond paths. A bond path connects two attractors and is defined as the line traced out by following the direction of positive curvature of the electron density (λ_3) beginning at the bond critical point. *In praxis*, one first locates all bond critical points and then traces out the zero-flux surfaces following the directions associated with the two negative principal curvatures of the density, λ_1 and λ_2. Properties of the bond critical points, such as the density at that point, ρ_b, and its distances r_A and r_B from the atoms, are commonly used to characterize electron density distributions and such information is collected in Table 4 for **1–3**. With the atomic regions defined, atomic properties are determined by numerical integration within the basins and this aspect is the most time-consuming step (36). Integrated properties are summarized in Table 5 and include the atomic charge and dipole moments. The directions of the dipole moments are shown in Fig. 4. The atomic quadrupole moments also were determined and employed in the ESI_{ij} evaluations but, for brevity, they are not documented.

Analysis of the data presented in Tables 4 and 5 shows the great similarity of the electronic structures of **1–3** and the respective propenoic acid derivatives. In fact, the electronic structures of aromatic and aliphatic diazonium functions are rather general (14). The N_α basins extend greatly into the C—N bonding region ($F_{CN} \approx 0.31$) and modestly ($F_{N\alpha N\beta} \approx 0.56$) into the N—N bonding region. Fairly typical ρ_b values of about 0.22 and 0.68 are found for all of the C—N and N—N bond critical points. Negative N_α charges in the range from -0.53 to -0.49 are found for **1–3** and the N_β charges are positive, just slightly larger in magnitude, and in the range between +0.51 and +0.58 (Fig. 3). Hence, the N_2 groups exhibit a large internal polarization but only a modest overall charge (< +0.055). The N_2 group polarization and the dative N→C bonding are manifested in the atomic moments of **1–3**. The vector $\mu(N_\alpha)$ is directed toward N_β and the $\mu(N_\beta)$ vector is antiparallel and much larger, and $\mu(C1)$ is directed toward N_α. The electron density within the basins of N_α and N_β is

[10] Compare the discussion of ethylene in ref. 32*b*.

[11] A similar approach was described by Cooper and Stutchbury in their study of hydrogen-bonded van de Waals complexes (35).

[12] Penetration effects are neglected in the present discussion. We found that the electron density between nonbonded atoms provides a good indication for assessing the importance of penetration effects. If the electron density is as low as in the present cases (between N_α and O_{pr}), then the neglect of penetration effects is warranted to a first approximation even though the N_α–O_{pr} distance is less than the sum of the van der Waals radii. One has to keep in mind that the sum of the van der Waals radii provides only a rather crude parameter for the assessment of steric effects because the van der Waals radius of an "N_α in a diazonium ion" is different from "the van der Waals radius of prototypical N" and so forth.

[a]Distances r_A and r_B in Ångstroms between each critical point and atoms A and B, respectively. F is defined as $F = r_A/(r_A + r_B)$. The electron density at the critical point, ρ_b, is given in e au^{-3}. The curvatures of the electron density at the locations of the critical points, λ_i, are given in e au^{-5}. The ellipticity, ε, is defined as $\varepsilon = \lambda_1/\lambda_2 - 1$ and given for all (3,+1) bond critical points.

[b]The locations of (3,−1) ring critical points within the benzene rings are characterized with respect to C1, the carbon that carries the diazonio function, and the "*para*-carbon".

[c]The locations of (3,−1) ring critical points between functional groups are characterized with respect to C1, the carbon that carries the diazonio function, and the proximate O14 or O15.

polarized into the CN bonding and the lone pair regions, respectively. The -CO_2H groups show large $q(C) \approx +2$, negative OH charges of about −0.66, and carbonyl-O charges of −1.39 (**1**) and −1.34 (**2**) that are more than twice as high. Since the acidic hydrogens carry positive charges of 0.66 in **1** and **2**, deprotonation adds only 0.34 electron to the fragment [$N_2C_6H_4CO_2$]. Since the electron populations of the CO_2 groups *decrease* from −0.68 and −0.65 in **1** and **2**, respectively, to −0.59 in **3** and since $q(N_2)$ remains indifferent, it follows that *deprotonation serves to reduce the electron deficiency in the phenyl ring*. This is quite a remarkable result: In the absence of the proton, it is no longer beneficial to accu-

mulate as much excess density on the CO_2 fragments, and the CO_2 population and the charge on the phenyl ring are both reduced drastically. While the CO_2 population is reduced in **3**, the data in Table 5 also indicate a higher polarization, and the negative charges on O_{pr} (a measure of their nucleophilicity) increase in the order −1.34, −1.39, and −1.47 in going from **1** to **3**. The μ vectors of the carboxyl C-atoms all are more or less parallel to the C—CO_2 bond and directed into the region between the oxygens, and the μ vectors of the carbonyl and carboxylate oxygens are directed away from the carboxyl C. Note that the dipoles $\mu(N_\beta)$ and $\mu(O_{pr})$ are large and antiparallel whereas the dipoles $\mu(N_\alpha)$ and $\mu(O_{pr})$ are parallel to each other.

The similarities and differences between the electronic structures of the aromatic systems **1–3** and of the aliphatic propenoic acid derivatives come clearly to the fore. The electronic structures of the functional groups are very similar and the only significant difference lies with the assignment of positive charge to the hydrocarbon fragments C_6H_4 and C_2H_2 in the two series. While the positive charge necessarily remains local in the C_2H_2 groups, the positive charge is well dispersed in the phenyl groups.

Electrostatic interaction analysis

We determined the interaction terms for **1–3**, and in Tables 6–8 are listed the various electrostatic contributions due to each pair of atoms within the two functional groups together with their sum $\Sigma = ESI_{ij}$. These ESI_{ij} values are shown in Fig. 4. Most importantly, *this analysis provides compelling evidence that the more general conclusions we drew from our analyses of the neighboring group interactions in the propenoic acid models are fully warranted and completely corroborated by the present combined experimental and theoretical studies*. The interaction between N_α and the proximate oxygen nucleophile is repulsive. Strong 1,3-bridging attractions occur between N_β and O_{pr} and C(1) and O_{pr}. It is for these two statements that the interpretation based on the 1,3-bridging attraction model is consistent with the electronic structure while the N_α attraction model is eliminated. At the same time, one also must realize that *every* model presents a simplification. The 1,3-bridging attraction model does describe the dominant interactions in **II–VI**. However, Fig. 4 shows that there are other interactions between the neighboring groups that are quite large and that suggest that one needs to consider the bridging interactions not just of O_{pr} but also of the highly electron-deficient carboxyl-C atom with the atoms of the C-N-N fragment. Substantial repulsions occur between the carboxyl C and N_β and C(1) while there is strong attraction between N_α and the carboxyl C. The overall electrostatic interactions between O_{pr} with C(1) and the N-atoms are −42.0, −48.0, and −34.3 kcal/mol for **1–3**, respectively. The interactions of the carboxyl C with the CNN fragment are +37.1, +47.1, and +21.5 kcal/mol, respectively, for **1–3**. Two observations are noteworthy: The interaction between O_{pr} and the neighboring group is attractive in all cases but it does not parallel O_{pr} nucleophilicity and, similiarly, the interactions of the carboxyl C with the neighboring group all are repulsive but also do not parallel the charge on the carboxyl C. This observation reflects

that a linear change in one component of a multi-interaction situation does not necessitate a linear response. Secondly, the interactions of O_{pr} and of the carboxyl C with the CNN fragment are of the same magnitude. This observation emphasizes the general problem of *over*simplification in attempts to reduce a complicated scenario to the "essential" parts. Model building and interpretation is thus a matter of *balanced* reasoning. Some models can be eliminated because they are

inconsistent with the electron density distributions, but there remains the difficult choice of selecting the best model among the ones that are consistent with the electron density distribution.

1,3-Bridging and steric interactions with the 2-position

As can be seen in Fig. 5, there occurs a bond path connecting N_α and the carbonyl-O in the molecular graph of **2**. The electron density at the bond critical point is 0.018 e au^{-3} and it is only marginally higher than the ρ_b value at the ring critical point (0.015 e au^{-3}). Equally small ρ_b values are found for the respective critical points in **1** and **3** (Table 4). What does this feature contribute to the discussion of the neighboring group interactions? Proponents of the N_α attraction model might

tend to be guided again by formalities and interpret the "bond path" in support of incipient bond formation between the O_{pr} donor and the electron-deficient N_α acceptor. We address this issue by analysis for consistency with the electron density distribution, by consideration of interaction lines (37) between interacting closed-shell systems, by citation of precedent for the occurrence of interaction lines between sterically interfering groups, and, finally, by citation of precedent for steric interference with the 2-position in optimizations of 1,3-bridging attractions.

The idea of incipient bond formation between the O_{pr} donor and the electron-deficient N_α acceptor is inconsistent with the electronic structures (vide supra). The N_α atom is not an acceptor but it is negatively charged. As the O_{pr} nucleophilicity increases, the negative charge of N_α *decreases* and, moreover, $q(N_\alpha)$ for **1–3** all are *less* negative than $q(N_\alpha) = -0.54$ in the parent benzenediazonium ion (14*d*). These features are not consistent with $O_{pr} \rightarrow N_\alpha$ electron donation but these electron density shifts are consistent with minimization of electron–electron repulsion between N_α and O_{pr}, that is, closed-shell or steric repulsion. The helium dimer is the simplest system for studying closed-shell interactions. Simple logic shows that there must be a "bond path" between the He atoms for *all* distances no matter whether the He atoms are far apart and essentially not bonded, in the region of the bound van-der-Waals dimer, or in the repulsive domain. The occurrence of a line connecting two attractors does not make any statement about the mode of interaction. The line just indicates "an interaction" and the better term for "bond path" is in fact "interaction line." Intramolecular interaction lines between nonconnected closed-shell systems were reported and associated with steric interactions (38).

Allyl alkali metals (39) and some of their heteroanalogues (40) prefer π-complexes in which the metal cation is located in a 1,3-bridging position between the negatively charged termini and above the best molecular plane of the allyl anion. In these cases, the distance between the metal and the C-atom at the 2-position is shorter than the contacts between the metal and the terminal carbons. The 1,3-bridging attraction model is very closely related to, and in fact can be seen as a polarity-reversed analogue of, the allyl metal bonding scenario.

Conclusion

The Bürgi–Dunitz angle of attack presents a useful concept that is easily accepted as it is in agreement with the electronic structure of carbonyls. Successful generalizations to other systems with the same bond polarity have also been described. We have argued, however, that the generalization asserted to describe the interaction of nucleophiles with diazonium ions cannot be correct. The N_α attraction model discussed by the groups of Dunitz and of Gougoutas is based on formal similarities of the C=O bond polarity and of the most commonly used Lewis structure of diazonium ions with its formally positive-charged N_α. This model relies on the assumption that the *formal* charge in the Lewis structure represents the *actual* charge distribution and the results of electronic structure analyses show that this assumption is not warranted.

The brief review of the crystallographic record on diazonium ion salts containing proximate nucleophiles shows that the distortions in their solid state structures are more fully consistent with the 1,3-bridging interaction model than with the N_α attraction model. In particular, combined analysis of solid state and of gas phase structures allows one to identify intramolecular interactions from packing effects and reveals that the intrinsic features associated with INA in diazonium ions are the CNN nonlinearity and the widening of the in-plane angles. Both of the electrostatic models can account for these features but in doing so different postulates are made concerning the electron density distribution. While the structural analysis alone cannot distinguish between the alternative interpretations, the study of the electronic structure allows one to clearly differentiate between competing inter-

Fig. 4. Electrostatic interaction energies ESI_{ij} (in kcal/mol) between pertinent pairs of atoms are shown for **1–3**. Solid (broken) arrows and negative (positive) interaction energies indicate attraction (repulsion). Values given in italics are the charge components CC_{ij} of ESI_{ij}. Atomic dipole moments are superimposed on the structures and they are directed from "o" to "•".

pretations of structural distortions. A method for the quantitative evaluation of electrostatic neighboring group interactions has been devised for this purpose and this ESI concept employs atomic electrical moments determined via topological electron density analysis. The results of the ESI analysis provide independent information that strongly supports the 1,3-bridging attraction model and eliminates the N_α attraction model.

The interpretation of neighboring group effects in crystal structures remains a matter of balanced reasoning. The discussion shows that some models can be eliminated because they are inconsistent with the electron density distributions, but the difficult challenge remains of identifying and selecting the best model among those that are consistent with the electron density distribution. The ESI method should prove particularly valuable for the development of electrostatic models as it is firmly based in quantum chemistry. It is hoped that these electrostatic models will allow for a better understanding of important stereochemical issues in a variety of chemical and biochemical problems.

Origin of depressed dipole moments in five-membered, unsaturated heterocycles

Keith E. Laidig, Peter Speers, and Andrew Streitwieser

Abstract: The smaller molecular dipole moments of cyclopentadiene, pyrrole, furan, and thiophene, relative to their saturated analogs, are investigated using the HF/6-311++G**//HF/6-311++G** level of theory. Investigation of the atomic origins of the molecular dipole moments demonstrates that the decreased dipole moments of the unsaturated heterocycles result from simple perturbations of the butadiene fragment, rather than a delocalization of hetero-atom lone pairs into the π system. Comparison with the origins of the molecular dipole moments of the saturated analogs shows that a special delocalization mechanism is not necessary.

Key words: ab initio, atoms-in-molecule, electronic effects, delocalization, polarization.

Résumé : Opérant au niveau HF/6-311++G**//HF/6-311++G** de la théorie, on a étudié les moments polaires moléculaires du cyclopentadiène, du pyrrole, du furane et du thiophène qui sont plus faibles par rapport à ceux des leurs analogues saturés. L'étude sur les origines atomiques des moments dipolaires moléculaires démontre que les moments dipolaires plus faibles des hétérocycles insaturés résultent de perturbations simples du fragment butadiène plutôt que d'une délocalisation des paires d'électrons non partagées des hétéroatomes dans le système π. Une comparaison avec les origines des moments dipolaires moléculaires des analogues saturés montre qu'il n'est pas nécessaire de faire appel à un mécanisme spécial de délocalisation.

Mots clés : ab initio, atomes dans les molécules, effets électroniques, délocalisation, polarisation.

[Traduit par la rédaction]

Introduction

Recent investigations into the consequences of methyl carbon deprotonation in methyl vinyl sulfide found that there was little delocalization of electronic charge from the anionic center to the vinyl group in the resulting anion (1). This suggests that the sulfur atom acts as an insulator between the anionic methylene center and the π system of the vinyl fragment, effectively isolating the two moieties (Fig. 1). One surprising implication applies to the physical properties of the five-membered heterocycles, pyrrole, furan, and thiophene, relative to their saturated analogs. Typically, the differences are attributed to a significant delocalization of the hetero-atom lone pairs into the π system of the five-membered ring. This implication prompted the present investigation of the distribution of electronic charge within five-membered heterocycles with an emphasis upon the consequences of delocalization upon the observable physical properties of these molecules (2–5).

One physical property that has often been linked to the delocalization of the hetero lone pairs into π systems is the dipole moment of the unsaturated five-membered ring heterocycles (6). The dipole moments are compared to the saturated analogs in Fig. 2 (7).

The differences have been attributed to a superposition of a π-moment opposed to the σ-moment to give a smaller resulting moment, and in the case of pyrrole a net moment in the opposite direction. The effect in pyrrole is also symbolized by the polarization resonance structures in Fig. 3 that show a dipole moment contribution whose direction is from nitrogen to the ring. The corresponding saturated system has no such mechanism available and so the σ-moment dominates, resulting in less dampening of molecular dipole moment.

Any multipole moment of a molecule may be broken into the contributions of the constituent atoms in a rigorous and physically meaningful manner using subsystem quantum mechanics (8–10). This is done by expanding the $\boldsymbol{r}$-weighted, spatial integration of the electronic charge density in terms of integrations over the spatial regions defined by the boundary conditions of the quantum subsystems, the atoms of the molecule. Explicitly, the dipole moment is broken into two terms, the displacement of charge from the origin, $q(\Omega)X_\alpha{}^\Omega$, and the polarization of the charge within each atom, $M_\alpha(\Omega)$, eq. [1].

$$[1] \quad \mu_\alpha = \sum_\Omega [q(\Omega)X_\alpha{}^\Omega + M_\alpha(\Omega)]$$

Such a breakdown of the molecular moment allows for a detailed investigation of the origins of that moment and its relation to the properties of the atoms of the systems. In the

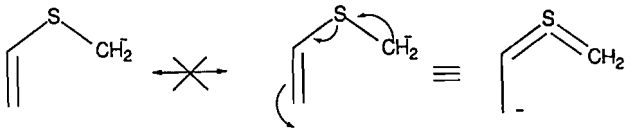

Fig. 2. A depiction of the direction and magnitude of the dipole moments (in D) of the saturated and unsaturated five-membered ring systems. Values shown are for the gas phase except for pyrrolidine (cyclohexane) and tetrahydrothiophene (benzene) (7). Numbers in parentheses are the calculated values from this work. The saturated heterocycles are not planar and their dipole moments do not lie in the plane of the figure.

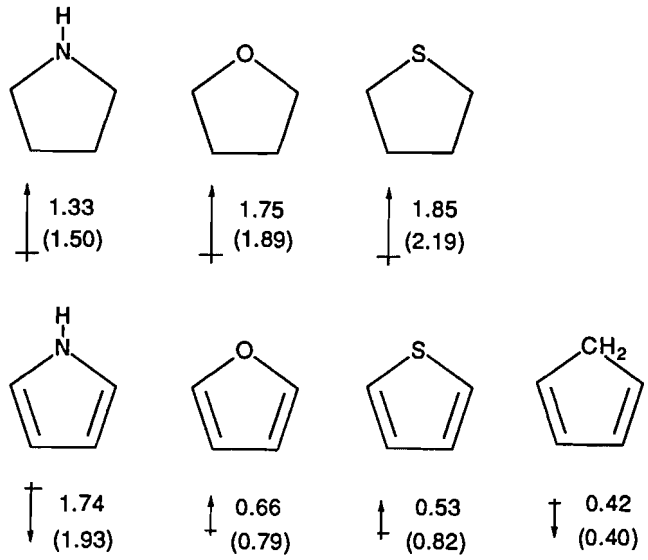

present work we apply this approach to investigate the origin of the depressed dipole moment in unsaturated five-membered ring heterocycles.

Methodology

We consider the unsaturated series, cyclopentadiene, pyrrole, furan, and thiophene, and the corresponding saturated series of cyclopentane, tetrahydropyrrole, tetrahydrofuran, and tetrahydrothiophene, as well as *cis*-butadiene as our prototypical butadienoid fragment. All of the atomic and molecular properties were determined from the triple-zeta, polarized, diffuse, and balanced HF/6-311++G** wave functions (11–14) determined at conformations optimized using the same level of theory. The potential surfaces were characterized via the determination of the analytical second derivatives, and each structure was found to be a minimum on its potential energy surface. The molecular calculations were performed using the Gaussian92 (15) and GAMESS (16) program suites. The HF/6-311++G** wave functions were used to determine the properties of the charge distribution and the atomic properties with the AIMPAC (17) suite of programs. Although the molecular dipole moments of neutral molecules are independent of origin, all dipole moments were determined using the center of mass.

The particular terms used in this study are defined as follows: $q(\Omega)$ is the atomic charge and $M_\alpha(\Omega)$ is the atomic dipole moment. These properties are determined by integration over the space of the atom bounded by zero-flux surfaces of the electronic charge density and the position-weighted charge density, for the atomic population (which is subtracted from the nuclear charge to yield the atomic charge) and the atomic dipole moment, respectively. The atomic contribution each atom makes, M_α^Ω, to the molecular dipole moment is the sum of $q(\Omega)*X_\alpha^\Omega$ and $M_\alpha(\Omega)$. The first term is a charge displacement term, which individually is dependent upon the origin, but whose sum is origin independent. The origin dependence of the individual terms reflects the fact the dipole moment describes the spatial distribution of electronic charge within the molecule. A change of origin does not change the physical distribution of electronic charge within a molecule or within the individual atoms. Instead, an origin shift changes the manner in which the moment, which is a tensor, is expanded mathematically. Clearly, care should be taken in comparing the origin-dependent terms in dissimilar systems. In the present case, the center of mass is a convenient choice since it provides the minimum set of mass-weighted distances to each atom, the molecules are similar in shape and size, and it corresponds to the origin generally used in experiment.

Results

The molecular dipole moments and their atomic contributions are listed in Tables 1 and 2, respectively. The molecular dipole moments reproduce the observed trends, with the dipole moments of the unsaturated systems being depressed relative to the corresponding saturated molecule. The experimental results are given in Fig. 2 (2.542 D = 1 au).

The dipole moment of tetrahydrofuran is dominated by the atomic contribution of the O atom, $M_z^\Omega(O)$. Its contribution is opposed by the contributions of C_α and H_α and is enhanced by those of C_β and H_β. The contribution O makes to the molecular dipole is the sum of a large charge displacement, reflecting the displacement of the large atomic charge from the molecular center of mass, and a small opposing polarization of O back towards the center of the ring. The transfer of charge from

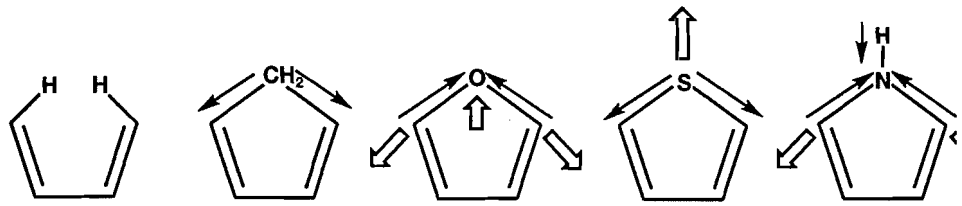
both C_α to the more electronegative O atom causes the charge displacement contribution from C_α to be in opposition to that of the O contribution. As is typical for atoms that lose charge to more electronegative bonded neighbors, the remaining charge within the C_α basin is polarized in opposition to the direction of charge transfer to the bonded O atom, further adding to the opposing contribution of C_α. In the case of C_β, the transfer of charge away from these sp^3 atoms to their more electronegative bonded hydrogens provides a charge displacement contribution in support of that of O ($q(C_\beta)$ is both the opposite sign and on the opposite side of the center of mass, thus its charge displacement contribution is of the same sign as $q(O)*Z^\Omega(O)$).

In furan, the total contribution of the O atom is also the dominant term. The C_α provides an opposing contribution, as does H_β, while H_α and C_β contribute relatively little to the molecular moment. As in the saturated system, the charge transferred from C_α to O yields a strong contribution to the overall molecular polarization towards the O atom. But the atomic polarization of the O atom back towards the center of the ring is twice as large as in tetrahydrofuran. Again, both the charge displacement and atomic polarization contributions from C_α are in opposition to the contribution from oxygen. The sp^2 β carbons of the unsaturated heterocycles are more electronegative than the sp^3 carbons of their saturated counterparts, resulting in less charge transferred to the β hydrogens

Fig. 4. Electronic effects treated as perturbations of butadiene.



and therefore only small charge displacement contributions to the molecular moment.

The dipole moment of tetrahydrothiophene is dominated by the contribution of large first moment of S, M_z(S), while the nearly neutral atomic charge contributes little. Unlike its O substituted counterpart, the C_α of tetrahydrothiophene makes little contribution to the molecular moment. Since S is roughly electroneutral in comparison to sp^3 C, there is only a small charge transfer from C_α and the first moments of that atom are also small. In common with tetrahydrofuran, the contribution from C_β results from charge transfer to its bonded H atoms and increases the magnitude of molecular polarization towards the S atom.

In the unsaturated thiophene, the atomic first moment M_z(S) is not as large as that in tetrahydrothiophene, but still dominates the contribution from S. The greater electronegativity of the neighboring sp^2 carbons results in a greater withdrawal of charge from S, creating a small dampening charge displacement contribution, $q(S)^* Z^\Omega(S)$. The C_α and C_β make only small contributions and the largest is the dampening coming from H_β, a result of the atom's charge and its displacement from the molecular center of mass.

The largest change in molecular dipole moment between saturated and unsaturated heterocycles is between tetrahydropyrrole and pyrrole. In the saturated system, the charge displacement contribution from N dominates the molecular moment, reflecting that N pulls charge from all three of its bonded neighbors. This effect is dampened by both the charge displacement and polarization contributions from the C_α atoms and a large contribution from H_N. The large amount of charge pulled from H_N and its distance from the center of mass creates this large charge displacement contribution. The C_β atoms provide a charge displacement contribution in the direction of N, in the same manner as in tetrahydrofuran and tetrahydrothiophene.

In pyrrole, the large charge displacement contribution of N is the largest individual term. The large transfer of charge from C_α to N and the strong polarization of the remaining charge on carbon away from N provide large dampening terms. As in the saturated system, the large positive charge of H_N and its distance from the molecular center of mass provide a large charge displacement dampening term $q(H_N)^* Z^\Omega(H_N)$. This dampening is larger in the planar, unsaturated system because the vector contributions are in direct opposition to the contributions of N. In contrast, in the nonplanar saturated system the dampening from H_N is not in direct opposition, but the vectors are less efficiently directed and the projection of this contribution against the N contribution is smaller in magnitude.

As a test of this interpretation of H_N of the nitrogen heterocycles, the dipole moment of protonated furan was calculated using the same level of theory. Our observations would lead to the prediction that protonation of furan should create a large charge displacement term, $q(H_O)^* Z^\Omega(H_O)$, which would contribute in opposition to the molecular dipole moment of furan. Although the dipole moments of such charged species are origin dependent, using the center of mass as the origin provides a common basis for comparison. The resulting dipole moment is heavily dampened (+1.047 au), and indeed is opposite in sign compared to furan; the result shows the behavior predicted.

Discussion

The primary origin of the dampened dipole moments in the unsaturated heterocycles arises from the difference in electronegativity of the sp^2 carbon centers. The greater electronegativity of the sp^2 C_α in the unsaturated molecules reduces the amount of charge transferred to O and to N, and increases the amount of charge withdrawn from S. The increasing charge displacement and the resulting polarizations act to dampen the contributions from the hetero atoms. Similarly, the sp^2 C_β centers do not transfer as much charge to their bonded neighbors and thus do not provide the enhancing contributions to the hetero-atom terms that are seen from the C_β atoms in the saturated analogs.

The dipole moments of the series of unsaturated five-membered heterocycles can be readily understood as simple perturbations of the atomic contributions to the dipole moment of a common butadiene fragment (see Fig. 4) (18).

As listed in Table 1, the dipole moment of *cis*-butadiene is nearly zero. Replacing two of the H atoms with a CH_2 group yields cyclopentadiene, whose dipole moment is small in magnitude and whose center of negative charge is displaced away from the CH_2 group. The replacement of the hydrogens with a less electronegative sp^3 carbon results in charge displacement towards the butadiene group and a resulting small molecular polarization with the positive end of the vector pointing towards the CH_2 group.

Replacing the CH_2 group by O pulls charge from the butadiene fragment. The resulting polarization of the C_α atoms is away from the direction of charge withdrawal. O is slightly polarized towards the direction of charge donation, but this and the contributions from C_α cannot overcome the large charge displacement contributions at O. Thus, the negative pole of the overall dipole moment points towards the O atom. In contrast, replacing the CH_2 group with the less electronegative S allows charge to be pulled into the butadiene fragment. Unlike the CH_2 fragment, the polarizable S can and does polarize away from the direction of charge withdrawal. This large atomic polarization dominates and the negative end of overall dipole moment vector points away from the S atom.

Finally, replacing the CH_2 group by NH again puts an electronegative group in the position to pull charge from the butadiene. In parallel with the origin of the dipole moment in furan, the transfer of charge from C_α and its resulting polarization provide dampening polarizations. But in this case, the withdrawal of charge from H_N puts a relatively large positive charge on the other side of the N atom. This provides a large contribution in opposition to the charge displacement terms of N, ultimately reversing the sign of the molecular dipole moment in comparison to that of furan. This can be clearly seen in the comparison between furan and protonated furan, in which this very mechanism reverses the sign of the molecular dipole moment.

This study demonstrates that the difference in molecular dipole moments between the saturated and unsaturated heterocycles can be readily understood in terms of the transfer of charge between atoms, their geometric relation to the molecular center of mass, and the atomic polarizations. A delocalization mechanism is not required to explain the dampening of the molecular dipole moments; arguments based upon pairwise interactions and their consequences suffice.

Conclusion

The present study has presented a dissection of the molecular dipole moment of five-membered heterocycles into atomic contributions using subspace quantum mechanics. The dipole moments were partitioned into atomic contributions, each of which is a physical observable in the quantum mechanical sense. A detailed comparison of the contributions to the dipole moments of the saturated and unsaturated five-membered ring heterocycles of nitrogen, oxygen, and sulfur shows that the changes of the molecular dipole moments of the unsaturated heterocycles can be readily understood in terms of the transfer of charge between atoms, the geometric relation of the atoms to one another, and the polarization of the atoms. A delocalization mechanism of the π-resonance type such as in Fig. 3 is not necessary to explain the observed dipole moment effects.

The anomeric effect in first-row/second-row acetal-like systems

Camilla Scott and Friedrich Grein

Abstract: Ab initio calculations were performed at the HF/6–31+G* level on first-row/second-row neutral, protonated, and anionic acetal-like systems. The neutral and anionic systems are of the general form $XH_mCH_2YH_n^{(-)}$ with XH_m = F, a-OH, s-NH_2, s-CH_3; YH_n = SH, PH_2; and YH_n^- = PH^-, SiH_2^-. For the protonated systems the general form is $XH_m^+CH_2YH_n$, with XH_m^+ = a-FH^+, s-OH_2^+, s-NH_3^+; and YH_n = SH, PH_2. In all cases the hydrogens on Y were rotated about the CY bond, and geometries were optimized for each setting of the YH_n dihedral angles. Following previously developed methods, the electronic part e of the anomeric stabilization was evaluated. For PH_2 rotation, $-e_P$ (e is always negative) is smaller than for corresponding nitrogen systems, whereas for SH rotation the $-e_S$ parameters are larger than for corresponding oxygen systems. In the case of protonated molecules, the energy associated with the reverse anomeric effect was estimated to be −4 kcal/mol for s-$OH_2^+CH_2SH$ and −3 kcal/mol for s-$NH_3^+CH_2SH$. For corresponding phosphorus systems they are close to −2 and −5 kcal/mol, respectively. The π-bonding model applied to neutral species shows that in the case of SH rotation the F and O systems clearly follow the trend of the π-bonded cation $CH_2{=}SH^+$. For PH_2 rotation, however, only the F system can be considered to correlate with such a model.

Key words: anomeric effect, reverse anomeric effect, first-row/second-row atoms, phosphorus, sulfur.

Résumé : On a effectué des calculs ab initio au niveau HF/6-31+G* sur des systèmes de types acétals neutres, protonés et anioniques d'éléments des deux premières périodes. Les systèmes neutres sont de la forme générale $XH_mCH_2YH_n^{(-)}$ pour lesquels XH_m = F, a-OH, s-NH_2, s-CH_3; YH_n = SH, PH_2 et $H_n^{(-)}$ = PH^- et SiH_2^-. Les systèmes protonés sont de la forme générale $XH_m^+CH_2YH_n$ pour lesquels XH_m^+ = a-FH^+, s-OH_2^+, s-NH_3^+ et YH_n = SH et PH_2. Dans tous les cas, on a fait subir une rotation aux hydrogènes sur Y autour de la liaison CY et on a optimisé les géométries pour tous les angles dièdres attribués aux YH_n. Suivant des méthodes développées antérieurement, on a évalué la partie électronique, e, de la stabilisation anomérique. Pour la rotation PH_2, la valeur de $-e_P$ (la valeur de e est toujours négative) est toujours plus faible que celle des systèmes azotés correspondants. Dans les cas de molécules protonées, l'énergie associée à l'effet anomérique inverse a été évaluée à −4 kcal mol^{-1} pour s-$OH_2^+CH_2SH$ et à −3 kcal mol pour le s-$NH_3^+CH_2SH$. Pour les systèmes phosphorés, ces valeurs sont plutôt près de −2 et −5 kcal mol^{-1} respectivement. Le modèle de la liaison π appliqué aux espèces neutres montre que, dans le cas du SH, la rotation des systèmes F et O suit bien la tendance du cation $CH_2{=}SH^+$ impliqué dans une liaison π. Pour la rotation du PH_2, on doit toutefois considérer que seul le système F donne une corrélation avec un tel modèle.

Mots clés : effet anomérique, effet anomérique inversé, éléments des deux premières périodes, phosphore, soufre.

[Traduit par la rédaction]

1. Introduction

The anomeric and related stereoelectronic effects, including some controversies surrounding these effects, have recently been reviewed by Juaristi and Cuevas (1) and Thatcher (2). In its simplest formulation, applicable to acetal-like systems $XH_mCH_2YH_n$, the anomeric effect (ae) stabilizes that conformation for which an sp^3 lone pair on X or Y is antiperiplanar (app) to the polar bond CY or CX, respectively.

Received October 6, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

Many ab initio studies have been performed on $XH_mCH_2YH_n$ systems with X and Y being first-row atoms, starting in 1971 with the work by Wolfe et al. (3) and Radom et al. (4). Also, there is a substantial amount of literature on first-row/second-row combinations (e.g., refs. 5, 6). Here, the general consensus is that the ae is still active; however, not as strongly as for their first-row/first-row counterparts. For example, bond separation energies calculated by Schleyer et al. (6) as energies of the reaction $XH_mCH_2YH_n + CH_4 \rightarrow CH_3XH_m + CH_3YH_n$, range from 11 to 18 kcal/mol for first-row/first-row systems (X, Y = N, O, F) while being 1–11 kcal/mol for first-row/second-row combinations (X = N, O, F; Y = P, S, Cl). In these reactions, the number and type of bonds stays the same, but the anomeric effect active in $XH_mCH_2YH_n$ is removed in the products.

In a recent series of papers (7–10), an attempt was made to separate the anomeric stabilization energy into steric, electrostatic, and electronic components. Both an energy decomposition scheme and a scheme based on Fourier analysis showed that the *electronic* component (absolute value) of the anomeric

effect decreases in the order X = F, O, N for fixed Y, as expected, and that it increases with increasing electronegativity difference between X and Y. For example, for X = F, O, N, and Y = O, the parameters e_O are −2.0, −1.0, and −0.7 kcal/mol, whereas for Y = N, the e_N parameters are −3.6, −1.9, and −1.0 kcal/mol.

The same ideas were also applied to corresponding protonated ($XH_{m+1}{}^+CH_2YH_n$) and anionic ($XH_mCH_2YH_{n-1}{}^-$) systems. For protonated molecules, the electronic component of the ae is much larger than for the corresponding neutral systems, due to the higher electronegativity (EN) of the positive ion. Also, an energy component for the reverse anomeric effect (rae), corresponding to the stabilization received by a lone pair on Y in synperiplanar (spp) position due to the positive charge on X, was obtained, with 7–8 kcal/mol for the $OH_2{}^+$/OH, $NH_3{}^+$/OH, and $NH_3{}^+$/NH_2 systems. For example, for $NH_3{}^+CH_2NH_2$, the conformation having the lone pair on NH_2 in spp position is more stable than the corresponding app conformation, indicating the rae to be strong.

For anionic systems $XH_mCH_2NH^-$, the electronic component of the ae lies between the values obtained for the corresponding neutral and protonated systems.

The reason for anomeric stabilization in $XH_mCH_2YH_n$ systems was seen in the tendency of the CH_2YH_n fragment of the molecule to form, as much as possible, a planar structure. If X is more electronegative than Y, electronic charge is moved from YH_n to XH_m, and CH_2YH_n acquires thereby a partial double-bond structure of type $CH_2{=}YH_n{}^+$, which prefers a planar geometry. It can be shown that, under rotation of the YH_n hydrogens about the CY bond, the CY bond distance and the charges on YH_n change in the same way, although not as dramatically, as in a rotation of the YH_n hydrogens around the CY bond in $CH_2{=}YH_n{}^+$. The same π-bonding model also applies to anomeric stabilization of protonated and anionic systems. The anomeric effect, as far as its electronic component is concerned, is driven by the desire of the electropositive fragment of the molecule to become planar. Therefore, and as seen from the Fourier analysis, conformations with a lone pair in spp position are, electronically, as stabilizing as those in antiperiplanar position. Experimental verification of this synperiplanar effect has recently been demonstrated by Deslongchamps and co-workers. (11–13).

In this paper, the analysis of the anomeric effect for systems $XH_mCH_2YH_n{}^{(\pm)}$, as previously performed for X, Y being first-row atoms, will be extended to first-row/second-row combinations. More specifically, X will be a first-row atom (F, O, N, and C for reference), and YH_n will be SH and PH_2 (PH^- and $SiH_2{}^-$ for anionic systems). In all calculations, the hydrogen(s) on Y will be rotated about the C—Y bond, whereas the XH_m group will remain in fixed conformational position. As before, neutral as well as protonated and anionic systems will be dealt with. Despite the fact that there is a greater EN difference between first- and second-row atoms than between corresponding first-row atoms, a weaker anomeric effect is expected since the less electronegative second-row atoms are considered to be relatively poor electron donors.

2. Methods

Geometry optimizations were carried out at the 6-31+G* level using the GAUSSIAN 86 programs (14). All bond lengths and angles, except for specified dihedral angles, were optimized. In particular, the dihedral angles of the XH_m hydrogens were held constant while the YH_n hydrogens were rotated about the C—Y bond.

Table 1. Relative energies ΔE in kcal/mol (first line), optimized C—S distances in Å (second line), and Mulliken charges on SH (third line), obtained by 6-31+G* geometry optimizations on XH_m-CH_2-SH, for SH dihedral angles of 0°, 60°, 120°, and 180°.

	0.013	0.003	0.008	−0.003

The nonrotating hydrogens of XH_m were held at dihedral angles φ (relative to XCZ; structure **1**) of 0° for a-OH and a-FH^+; at ±120° for s-NH_2 and s-$OH_2{}^+$, and at 0, ±120° for s-CH_3 and s-$NH_3{}^+$. The prefix a stands for anti and s for staggered. The rotating YH_n hydrogens were set to dihedral angles of 0°, 60°, 120°, and 180° for SH and PH^- (relative to YCZ), and to ±60° (0°); 0°, 120° (60°); 60°, 180° (120°), and ±120° (180°) for PH_2 and $SiH_2{}^-$. The numbers in parentheses are the φ values given in the tables, and refer to the midpoint between the two hydrogens. In structure **1**, a-$OHCH_2SH$ for φ = 0, and in structure **2**, s-$NH_2CH_2PH_2$, also for φ = 0, are shown. Structure **3** gives s-$CH_3CH_2PH_2$ for φ = 180°.

The Fourier constants V_1, V_2, and V_3 were calculated from the equation $\Delta E(\phi) = (V_1/2)(1 - \cos\phi) + (V_2/2)(1 - \cos 2\phi) + (V_3/2)(1 - \cos 3\phi)$, using the dihedral angles φ = 0°, 60°, 120°, and 180°.

3. Results

3.1 Neutral systems

Relative energies, C—S bond distances, and Mulliken charges for the XH_mCH_2SH systems are given in Table 1. The trends in relative energies and bond lengths are as expected, with the lowest energy and smallest bond length obtained for the 120° conformer. For the NH_2CH_2SH and CH_3CH_2SH systems the energy lowering from the 0° to the 120° conformer is small, and an energy barrier has developed at 60°. As well, there is little change in bond length. This indicates that the anomeric effect in these systems is weak or nonexistent. A discussion is to follow later.

The Fourier parameters V_1, V_2, and V_3 obtained from the relative energies in Table 1 are given in Table 2. The range of V_3 values lies between 1.51 and 1.64 kcal/mol, which is close to the energy difference of 1.28 kcal/mol between the eclipsed and staggered conformers of CH_3SH calculated at the

XH_m-CH_2-SH	V_1	V_2	V_3
F-CH_2-SH	−1.07	−3.29	1.58
a-OH-CH_2-SH	−1.59	−1.73	1.64
s-NH_2-CH_2-SH	0.49	−1.31	1.61
s-CH_3-CH_2-SH	−0.05	−0.39	1.51

6-31+G* level. The V_2 parameter has the greatest (absolute) value for the most electronegative F system and the smallest value for the least electronegative CH_3 system. No such regularity can be found for the V_1 parameter. The energy barrier at 60°, observed for the NH_2 and CH_3 systems, is explained by the V_3 parameter, describing the SH–CH_2 repulsion, being larger in magnitude than V_2, which describes the stabilizing electronic effect.

The relative energies, C—P bond distances, and Mulliken charges for the $XH_mCH_2PH_2$ systems are given in Table 3. The energies are as expected, with the 180° conformer having the lowest energy due to anomeric stabilization occurring at 180°. The greatest energy lowering occurs for the F and a-OH systems, as expected. For the s-NH_2 and s-CH_3 molecules there are 1,3-hydrogen repulsions at 180° that decrease any stabilization received from the anomeric effect at this angle, resulting in smaller energy differences. The C—P bond distances are smallest at the 180° conformer, due to the anomeric effect.

The Fourier values obtained from the relative energies in Table 3 are given in Table 4. The magnitude of V_3 (−2.28 to −2.58 kcal/mol) is close to the energy difference between the staggered and eclipsed conformers of CH_3PH_2, which was calculated to be −1.93 kcal/mol (6-31+G*). The V_2 parameter has the greatest value for the most electronegative XH_m, decreasing to the least electronegative. V_2 is positive due to the anomeric stabilization occurring at 180°.

3.2 Protonated systems and reverse anomeric effect

Tables 5 and 6 give energies, bond distances, charges, and Fourier constants for the protonated systems $XH_m{}^+CH_2SH$ under SH rotation.

As seen from the bond distances, all four conformers of a-FH^+CH_2SH form complexes of type $FH\cdots CH_2{=}SH^+$. Therefore, the calculated Fourier constants do not properly represent the required 1,3-interactions and have been omitted from Table 6. For the other two systems, stabilization at 60° and 120° relative to 0° is obtained, with appropriate changes in bond distances, indicating that the ae is active. This is confirmed by the rather large V_2 values. Later on, the V_1 parameters will be discussed in connection with the reverse anomeric effect.

Table 5 shows that there is no energy barrier at 60° for any of the protonated systems, whereas the NH_2 and CH_3 neutral systems (Table 1) showed such a barrier. The reason is seen in the strong electronic stabilization (V_2) experienced by protonated systems, compared to the rather normal CH_2–SH repulsion (V_3). The same argument applies to the anionic systems, to be discussed below.

Table 3. Relative energies ΔE in kcal/mol (first line), optimized C—P distances in Å (second line), and Mulliken charges on PH_2 (third line), obtained by 6-31+G* geometry optimizations on XH_m-CH_2-PH_2 for PH_2 dihedral angles of 0° (±60), 60° (0°,120°), 120° (60,180), and 180° (± 120°).

s-CH_3-CH_2-PH_2	0.06	0.34	−2.28

For PH_2 rotation in systems $XH_m{}^+CH_2PH_2$, energy differences, bond distances, charges, and Fourier parameters are given in Tables 7 and 8. As before, the a-FH^+ molecule optimizes to a complex (of type $FH\cdots CH_2{=}PH_2{}^+$) at all four dihedral angles, preventing a useful interpretation of Fourier constants. For the remaining two systems, V_2 parameters of 7.6 and 4.9 kcal/mol are obtained, again much larger than for the corresponding neutral systems.

In previous papers of this series (8, 9), energy estimates were obtained for the reverse anomeric effect (rae) in protonated systems. Briefly, the rae has been defined as the energy of stabilization of the $\phi = 0°$ conformer over the $\phi = 180°$ conformer due to the lone pairs on SH or PH_2 being attracted by the positive charge on X when in *syn* position relative to CX. Therefore, the rae parameter v is V_1 with adjustments made for steric and electrostatic effects between lone pairs and hydrogen atoms on X and Y, as well as for the electronic part of the ae in the case of PH_2 systems. For example, for s-$NH_3{}^+CH_2OH$ (9), for which $\phi = 0°$ is the most stable conformer, v was calculated as $v = -V_1 - 2h + r$ to give about −7 kcal/mol (please note that in ref. 9 $\Delta E(180)$ was used instead of V_1). At 0° the internal hydrogen bond is described by the energy $2h$, and at 180° the 1,3 H–H repulsion is r. As outlined in previous papers, approximate values of 1 and −1 kcal/mol for r and h, respectively, were assumed.

Here, another approach to calculating v parameters will be given, with the purpose of reducing reliance on estimated energy parameters h and r. The problem is to separate v from regular steric and electrostatic energies contained in the Fourier constant V_1. This can be accomplished by comparing $V_1{}^{prot}$ (for the protonated system) with $V_1{}^{neut}$ (corresponding neutral system). Hydrogens and lone pairs on X and Y interact approximately in the same way in the neutral and protonated system, the big difference being the rae.

For X = N and Y = O or S, v can be calculated as $-v = V_1{}^{prot} - V_1{}^{neut}$. As a check, v_O gives $-(9.72 - 0.95) \cong -9$ kcal/mol for s-$NH_3{}^+CH_2OH$, compared with −7 kcal/mol (revised value) in ref. 9. For X = N and Y = N or P, the ae occurs at 180°, so $V_1{}^{prot} - V_1{}^{neut}$ needs to be corrected by the difference $e_+ - e$. Therefore, for s-$NH_3{}^+CH_2NH_2$, $-v_N = V_1{}^{prot} - V_1{}^{neut} + e_N - e_{N^+}$, to result in $v_N \cong -11$ kcal/mol, compared with −10 (revised value) in ref. 9.

In the present case, v_S for s-$NH_3{}^+CH_2SH$ is calculated as $v_S = -(3.61 - 0.5) \cong -3$ kcal/mol, and v_P for s-$NH_3{}^+CH_2PH_2$ is $v_P = -2.64 + 0.57 - 3.7 + 0.8 \cong -5$ kcal/mol. Both values are significantly smaller than for the corresponding OH and NH_2 systems.

For the s-$OH_2{}^+$ systems, v can, unfortunately, not simply be calculated as the difference of the V_1's, since the 1,3-hydrogen and lone-pair interactions of the neutral a-OH system do not match those of the protonated s-$OH_2{}^+$ system. To make the procedure easier, the neutral systems were recalculated with the OH hydrogen in *syn* rather than *anti* position relative to CY. For s-$OHCH_2SH$ (structure **4**), the values $V_1 = 1.01$, $V_2 = -5.40$, and $V_3 = 1.69$ kcal/mol were obtained, whereas for s-$OHCH_2PH_2$ the V's are 1.05, 4.36, and −2.21 kcal/mol. (It should be noted that the V_2's for the s-OH are much larger than for the a-OH molecules.) Now, for s-$OH_2{}^+CH_2SH$, $v_S \cong -\Delta V_1 - h$, to give $-(4.0 + 1.0) + 1.0 = -4$ kcal/mol. For s-$OH_2{}^+CH_2PH_3$, $v_P \cong -\Delta V_1 + r - h + e_P{}^+ - e_P = -1.7$ kcal/mol, using $e_P = -3.3$ kcal/mol, as obtained from V_2. As before, 1 and −1 kcal/mol were chosen for r and h, respectively.

3.3 Anionic systems

The relative energies, C—P bond distances, and Mulliken charges for the anioinic $XH_mCH_2PH^-$ systems are give in Table 9. As expected for a system that receives anomeric stabilization at 120°, the lowest energy, shortest C—P bonds, and most positive (least negative) charges on P are found for the 120° conformer. The greatest energy lowering for 120° occurs for the most electronegative system FCH_2PH^-, and the lowering decreases with decreasing electronegativity of X.

The Fourier parameters for these systems are given in Table 10. The V_3 values have the range of 1.63–1.96 kcal/mol, which is similar to the energy difference between the staggered and eclipsed forms of CH_3PH^-, calculated to be 1.43 kcal/mol (6-31+G*).

The V_2 values reflect the energy lowerings at 120°, with the most negative value of −5.71 kcal/mol for F, progressively decreasing to a value of −1.02 kcal/mol for the least electronegative system $CH_3CH_2PH^-$. All V_1 values are small, close to 0. This implies that steric and electrostatic interactions between X and Y are negligible.

Table 11 contains the relative energies, C—Si bond lengths, and Mulliken charges for the $XH_mCH_2SiH_2{}^-$ systems. The 180° conformers have the lowest energies and shortest C—Si

Table 5. Relative energies ΔE in kcal/mol (first line), optimized C—S/C—X distances in Å (second line), and Mulliken charges on SH (third line), obtained by 6-31+G* geometry optimizations on XH_m^+-CH_2-SH, for SH dihedral angles of 0°, 60°, 120°, and 180°.

SH or PH^- group is rotated from $\phi = 0°$ (H in app position, no anomeric effect) to $\phi = 120°$ (one lone pair in app position, anomeric effect), or when the PH_2 or SiH_2^- group is rotated from 60° (one H in app position, no ae) to 180° (lone pair in app position, ae).

Table 13 shows that the *e*-parameter drops when the atom X changes from F to C, as expected, reflecting the decreasing electronegativity of the first-row atoms. The *e*-parameters for protonated systems are larger (in magnitude) than for neutral systems, and the anionic systems lie in between. A comparison of the *e*-parameters calculated here for first-row/second-row systems, with those given earlier for first-row/first-row molecules, where both X and Y are F, O, N and C, is most interesting. For both the neutral and protonated SH systems, the electronic parameter *e* is larger (in magnitude) than for the corresponding OH systems. For example, e_S for FCH_2SH is −2.5, whereas e_O for FCH_2OH is −2.0 kcal/mol, and e_S for s-$OH_2^+CH_2SH$ is −6.8 compared with −6.2 kcal/mol for e_O of s-$OH_2^+CH_2OH$. As mentioned in the Introduction, such a trend would be expected on the basis of the larger electronegativity difference between first- and second-row atoms than between first-row atoms (e.g., ΔE_n (F-S) ≅ 1.5, ΔE_n (F-O) ≅ 0.5).

Against this speaks the expected lower electron-donating property of second-row atoms compared with the corresponding first-row atoms. Table 13 shows that the latter quality appears to win out in the phosphorus systems, since $|e_P|$ parameters for neutral and protonated systems are *smaller* than the corresponding $|e_N|$ results.

Based on this analysis, the conclusion can be drawn that sulfur is highly effective in promoting anomeric stabilization, even more effective than oxygen, whereas the capacity of phosphorus for anomeric stabilization is inferior to that of nitrogen. "Effectiveness" refers to the electronic part of the anomeric stabilization only. The total energy lowering between 0° and 120° is larger for XH_mCH_2OH than for XH_mCH_2SH, at least when X = F and O, thanks to larger negative V_1's in the OH case. For example, the energy lowering at 120° is −4.8 kcal/mol for FCH_2OH, and −3.3 kcal/mol for FCH_2SH. Using $\Delta E(120) = 0.75\ (V_1 + V_2)$, with $V_1 = -3.7$, $V_2 = -2.7$ for FCH_2OH, and $V_1 = -1.1$, $V_2 = -3.3$ kcal/mol for FCH_2SH, shows that $V_1 + V_2$ (absolute) is larger for the OH than the SH system, resulting in higher stabilization. It is reasonable to expect the electrostatic and steric 1,3-interactions, reflected in V_1, to decrease with increasing bond distances. However, the increase of the *electronic* interaction of S over O, despite larger bond distances, is unexpected.

When going from NH_2 to PH_2 systems, both $|V_1|$ and V_2 decrease, causing at 180° less stabilization for the PH_2 than the

Table 13. Electronic anomeric parameters e for neutral, protonated, and anionic systems $XH_m^{(+)}CH_2YH_n^{(-)}$ with first- and second-row atoms, in kcal/mol. Numbers in parentheses are for corresponding first-row/first-row systems.

	Neutral		Protonated		Anionic	
XH_m/XH_m^+	SH(OH)	$PH_2(NH_2)$	SH(OH)	$PH_2(NH_2)$	$PH^-(NH^-)$	$SiH_2^-(CH_2^-)$
F/a-FH^+	−2.5	−2.0	—[a]	—[a]	−4.3	−2.4
	(−2.0)	(−3.6)	(−20.5)	(−30.6)	(−16.5)	(−8.1)
a-OH/s-OH_2^+	−1.3	−1.0	−6.8	−5.7	−3.0	−1.7
	(−1.0)	(−1.9)	(−6.2)	(−17.3)	(−5.2)	(−5.3)
s-NH_2/s-NH_3^+	−1.0	−0.8	−4.3	−3.7	−1.8	−1.1
	(−0.7)	(−1.0)	(−3.5)	(−5.7)	(−2.7)	(−3.0)
s-CH_3	−0.3	−0.3	–	–	−0.8	−0.5
			–	–	(−1.0)	(−1.2)

[a]Since complexes were formed at all dihedral angles, e could not be evaluated.

NH_2 system (for X = F,O). Apparently, the electron donating properties of phosphorus are drastically reduced in comparison to sulfur.

In the last two columns of Table 13, the e_P- and $e_{Si}-$ values are shown for the anionic systems involving PH^- and SiH_2^- rotation. It is seen that such parameters are smaller than comparable e_{N-} and e_{C-} values.

4.2 The π-bonding model

For neutral and protonated first-row/first-row molecules $XH_m^+CH_2YH_n$, the π-bonding model showed that for systems undergoing anomeric stabilization, CY bond distances and charges on YH_n change in the same way, however, not as strongly, as those for $CH_2{=}YH_n^+$ when YH_n is rotated about the double bond. This indicates that the anomeric effect is caused by the tendency of the slightly positive CH_2-$YH_n^{(+)}$ fragment of the molecule to assume a near-planar structure.

In Table 14, energy differences, CS distances, and charges on SH are shown for $CH_2{=}SH^+$. The dihedral angle ϕ in $CH_2{=}SH^+$ is defined analogously to ϕ in XH_mCH_2SH compounds (see the CH_2SH moiety in structure **1** for illustration). It is seen that, relative to ϕ = 0, the CS distances decrease for 60° and 120°, and increase again for 180°. This is combined with significant stabilization at 60° and 120°. Relative to ϕ = 0, the charges on SH increase for 60° and 120°, and decrease for 180°. Referring to Table 1, the neutral systems with X = F and O show similar trends, whereas the remaining systems with X = N and C have an increase in CS distance and energy, and a substantial decrease of Q(SH), at 60°. Although the electronic parameter e_S is −1.0 kcal/mol for s-NH_2CH_2SH, the bond distances and energies in this system do not follow the π-bonding trend.

Table 15 gives corresponding data for $CH_2{=}PH_2^+$. Again, the dihedral angle ϕ is defined in the same way as in $XH_mCH_2PH_2$ compounds (see structure **2**). Here, the higher energies and larger CP distances occur at 60° and 120°, as expected. The charge on PH_2 decreases at 60°, and increases thereafter. In line with the weak electronic anomeric effect observed for $XH_mCH_2PH_2$, the energies and bond distances given in Table 3 do not always show the corresponding trend. For the F-system, the correlation of CP distances is good; for a-OH the CP distance at 60° is shorter than at 0°, whereas for the s-NH_2 and s-CH_3 systems a correlation with $CH_2{=}PH_2^+$ is neither seen nor expected.

Table 14. Relative energies ΔE in kcal/mol, optimized C—S distances in Å, and Mulliken charges on SH, for SH rotation in $CH_2{=}SH^+$, obtained from 6-31+G* calculations.

ϕ	0°	60°	120°	180°
ΔE	0.00	−36.36	−42.04	−7.70
R_{CS}	1.7519	1.6298	1.6197	1.7496
Q(SH)	0.422	0.602	0.612	0.585

Table 15. Relative energies ΔE in kcal/mol, optimized C—P distances in Å, and Mulliken charges on PH_2, for PH_2 rotation in $CH_2{=}PH_2^+$, obtained from 6-31+G* calculations.

ϕ	0°	60°	120°	180°
ΔE	0	14.52	5.01	−17.71
R_{CP}	1.6617	1.7047	1.7021	1.6807
$Q(PH_2)$	0.693	0.619	0.705	0.748

A comparison of the trends in stabilization energies and bond distances of the protonated systems given in Tables 5 and 7 with those of $CH_2{=}SH^+$ and $CH_2{=}PH_2^+$ in Tables 14 and 15 shows good agreement for all systems. As mentioned earlier, for protonated systems with fluorine, complexes are formed at all dihedral angles, and the anomeric effect can therefore not be evaluated.

4.3 Reverse anomeric effect in protonated systems

In Table 16, the four estimated values for the reverse ae in first-row/second-row systems are given, and compared with corresponding first-row/first-row values. It should be stressed that there is no straightforward method to calculate rae values, and that the given numbers can only be seen as a rough indication of the energy related to this effect.

Table 16. Estimated values v_S and v_P in kcal/mol for the reverse anomeric effect in systems s-$OH_2^+CH_2YH_n$ and s-$NH_3^+CH_2YH_n$, with YH_n = SH and PH_2. Numbers in parentheses are for corresponding first-row/first-row systems.

	SH(OH)	$PH_2(NH_2)$
s-OH_2^+	−4 (−7.5)	−2 (—)[a]
s-NH_3^+	−3 (−7)[b]	−5 (−10)[b]

[a]No value for O^+/N system available.
[b]Revised value, see text.

Having said this, the v_S and v_P numbers are reasonable, smaller than corresponding v_O and v_N values. The larger C—S/C—P distances compared to C—O/C—N are certainly partly responsible for the decrease in v values. The v_N value for s-$OH_2^+CH_2NH_2$ could not be obtained due to complex formation. The number obtained for s-$OH_2^+CH_2PH_2$ appears to be too small, not reflecting the trend of increasing v's as one goes from S to P.

5. Summary and conclusion

Previous theoretical work on the anomeric effect in acetal-like systems was extended to include the second-row atoms S and P.

The conformational energies obtained by rotating the SH or PH_2 hydrogens about the CY bond (the compounds are written as $XH_mCH_2YH_n$) were subjected to a Fourier analysis, from which the electronic energy portion of the anomeric stabilization was evaluated. Interestingly, for the SH systems this electronic component is *larger* (in absolute terms) than for corresponding OH systems, whereas for PH_2 rotation, the electronic component is *smaller* than for NH_2 rotation.

For molecules protonated on the first-row atom X, the same situation applies. For SH rotation the electronic component is larger (absolute) than for OH, and for PH_2 rotation smaller than for NH_2. The weaker electron-donating properties of phosphorus are also seen in the anionic systems, where PH^- leads to lower electronic stabilizations than NH^-. Judged by the π-bonding model, the anomeric effect is clearly working for SH systems with X = F and O, and for PH_2 systems with X = F. For the N/SH and O/PH_2, N/PH_2 combinations, a weak anomeric effect is still active, whereas for X being C, as expected, there is no more evidence for anomeric stabilization. According to the π-bonding/model and calculated stabilization energies, a strong anomeric effect is working in all protonated systems.

Estimates are also given for energy stabilization due to the reverse ae in protonated systems. Such stabilization is largest when the electron pair on Y is in *syn* position relative to XH_m^+. The v parameters are smaller than for corresponding first-row/first-row systems, likely due to the larger CY bond distances.

In conclusion, the SH group has shown remarkable anomeric stabilization properties for the neutral systems FCH_2SH and $OHCH_2SH$, and for protonated systems $XH_m^+CH_2SH$ with X = F, O, N. On the other hand, stabilization due to PH_2 is much weaker.

From topology to geometry

Mark Eberhart

Abstract: A systematic study of the charge density topologies corresponding to a number of transition metal aluminides with the B2 structure indicates that unstable crystal structures are sometimes associated with uncharacteristic topologies. This observation invites the speculation that the "distance" to a topological instability might relate to a metals phase behavior. Following this speculation, a metric is imposed on the topological theory of Bader, producing a geometrical theory, where it is now possible to assign a distance from a calculated charge density topology to a topological instability. For the cubic transition metals, these distances are shown to correlate with single crystal elastic constants, where the metals that are furthest from an instability are observed to be the stiffest.

Key words: crystal structure, charge density topology, mechanical properties, brittle/ductile failure.

Résumé : Une étude systématique des topologies des densités de charges correspondant à un certain nombre d'aluminures de métaux de transition de structure B2 indique que des structures cristallines instables sont quelquefois associées à des topologies qui ne sont pas caractéristiques. Cette observation nous amène à spéculer que la «distance» par rapport à une instabilité topologique pourrait être reliée à un comportement de la phase des métaux. À la suite de cette spéculation, on impose une «métrique» à la théorie topologique de Bader conduisant à une théorie géométrique grâce à laquelle il est alors possible d'attribuer une distance, par rapport à une topologie d'une densité de charge calculée, à une instabilité topologique. Pour des métaux de transition cubiques, il est démontré qu'il existe une corrélation entre ces distances et les constantes électriques des cristaux. Dans les cas où les métaux se trouvent les plus loin d'une instabilité, on observe qu'ils sont les plus durs.

Mots clés : structure cristalline, topologie des densités de charges, propriétés mécaniques, détaillance fragile/ductile.

[Traduit par la rédaction]

1. Introduction

All of chemistry is based on the molecular structure hypothesis, which simply stated is the following: a molecule or solid is a collection of atoms linked by a network of bonds, and all molecular properties result from this linked system of atoms. Accompanying this hypothesis are a number of models that seek to quantify these concepts of atoms and bonds and to correlate empirically determined properties with the models. While each of the models represents these concepts differently, they have all had considerable success in explaining the observed properties of matter.

Of the many models advanced in support of the molecular structure hypothesis, the most familiar is the Lewis model (1), in which a bond is pictured as a pair of valence electrons shared by two atoms. This representation of a chemical bond and its quantum mechanical extensions of directed valence (2) form the basis for understanding the chemistry of organic molecules. Structural, chemical, spectroscopic, and thermochemical data are interpreted using terms defined within the Lewis model of molecular structure.

Received October 4, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

While many attempts have been made to interpret metallurgical properties within the framework of the molecular structure hypothesis, none of these attempts can be called totally successful. In my opinion, this lack of success can be attributed to a less than rigorous definition of the metallic bond. However, the topological model of molecular and solid state structure advanced by Bader et al. (3–8) provides a rigorous definition for all classes of chemical bonds, of which the metallic bond is a subset. Believing that such a rigorous description of the metallic bond should provide the starting point for the application of chemical formalism to explain the structure and properties of metallic systems, we have sought a correlation between the topological properties of the charge density of metals and alloys and their respective properties (9–14).

In this paper, I briefly review the topological model of electronic structure developed by Bader, specifically applying this model to metallic crystals. While the Bader model of molecular structure is tremendously powerful, as a topological model it can only be used to compare two structures, where these structures either share the same topology or not. The concept of "distance" between two structures can not be determined from a topological theory. Yet the concept of distance is essential for a complete application of the molecular structure hypothesis. For example, the application of transition state theory is dependent on assessing the "closeness" of an electronic charge distribution to the transition state.

In an attempt to provide a measure by which two electronic charge distributions can be compared, a metric will be introduced that measures the distance from a bond to an instability in that bond. It will be shown that there is a correlation

between this distance and the elastic properties of the metal being modeled. Through the introduction of this metric, the Bader formalism is extended from a topological theory to a geometrical one.

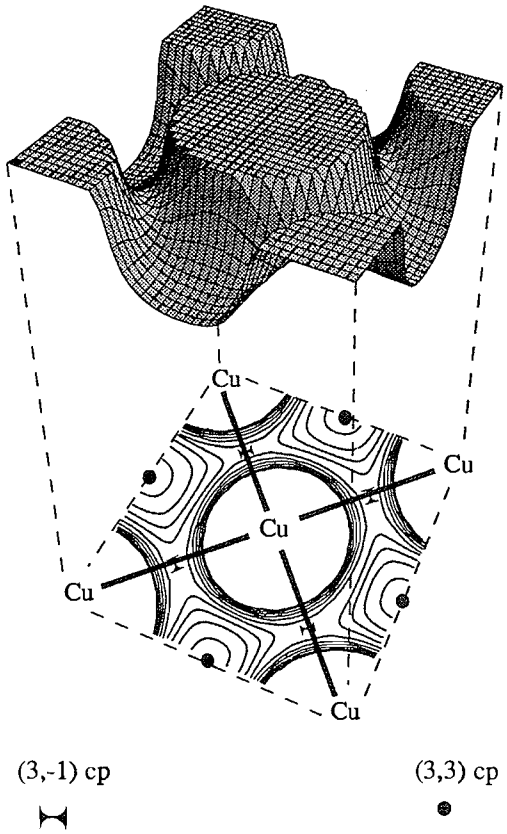
2. Charge density and topology

The Bader model of molecular structure makes use of the total charge density of a molecule or solid to determine its topology. The charge density is a scalar field, $\rho(r)$, which, as with any scalar field, possesses a unique topology. This topology is characterized in terms of its critical points, which are the zeroes of the gradient of the scalar field. There are four kinds of critical points in a three-dimensional space: a local minimum, a local maximum, and two kinds of saddle points. These critical points (cps) are denoted by an index that is the number of positive curvatures minus the number of negative curvatures; for example, a minimum cp has positive curvature in the three orthogonal directions; therefore, it is called a (3, 3) cp, where the first number is simply the number of dimensions of the space, and the second number is the net number of positive curvatures. A maximum would be denoted by (3, −3), since all three curvatures are negative. A saddle point with two of the three curvatures negative is denoted (3, −1), while the other saddle point is a (3, 1) cp.

Bader realized that bonds in molecules can be seen in terms of the topology of $\rho(r)$. A bond path connects two nuclei (where the charge density possesses (3, −3) cps) through a (3, −1) cp such that the charge density is always a maximum with respect to any neighboring path. Other types of critical points can be correlated with other features of molecular structure. A (3, 1) cp must be seen at the center of ring structures like benzene. Accordingly, this critical point is designated as a ring critical point. Cage structures are always characterized by a (3, 3) cp somewhere within the cage, and again have been given the descriptive name of cage critical points. A (3, −3) cp is always seen at a nuclei, but also, on occasion, local maxima are observed that are not associated with an atom; these are called pseudo-atoms.

Figure 1 shows the positions and type of critical points in a (100) plane of Cu. This topology is characteristic of all nonmagnetic FCC allotropic transition metals and therefore is designated as an FCC topology. The (3, −1) cps midway between nearest neighbors are indicative of bonds between these atoms. The bond paths are shown as lines connecting the bound atoms. These bonds form the edges of two types of polyhedra or cages: tetrahedra and octahedra, Fig. 2. At the center of each of these polyhedra is a cage critical point, i.e., a (3, 3) cp, with the octahedral cage critical points shown in Fig. 1. At the center of each of the faces of these two polyhedra are ring critical points. The entire set of critical points define specific bonding polyhedra, the packing of which gives rise to the FCC structure. The **topology** of these polyhedra is determined only by the number of corners, edges, and faces. As a convenience, a polyhedron is denoted by $\{c, e, f\}$. A polyhedron topologically equivalent to a regular tetrahedron will have four corners, six edges, and four faces, {4, 6, 4}. The total charge density will reflect these features with a (3, −3) cp at each corner, a (3, −1) cp along each edge, a (3, 1) cps in each face, and a (3, 3) cp within this polyhedron. The FCC topology is the result of packing two types of polyhedra, a {4, 6, 4} and a {6, 12, 8} (octahedron), with each face of the {4, 6, 4} shared with a {6, 12, 8}. Any structure whose charge density gives rise to the same set of bonding polyhedra, packed in the same manner, is topologically equivalent to the FCC structure.

Fig. 1. The charge density in a (100) plane of Cu. The critical points are marked by type. In this plane two types of critical points are shown, cage and bond critical points.



The BCC structure for all nonmagnetic transition metals is characterized by the topology represented by the polyhedron shown in Figure 3. This is a {6, 8, 4} polyhedron. Though it appears to be equivalent to an octahedron, it is not. This polyhedron has no bonds (edges) between second neighbors, rather there are four nonplanar faces.

3. Topologies of the B2 crystal structure

While the FCC and BCC structures of the transition metals appear to give rise to unique topologies, this is not a necessity. For most crystal structures there will be multiple topologies that can give rise to the structure.

As an example, consider the B2 structure: a simple cubic lattice with a two-atom basis. One of these atoms is usually pictured sitting on the corner of the cube with the other located at the body center, Fig. 4. Shown in Fig. 5 are several of the topologies available to the B2 structure. The first of these (**a**) corresponds to the case in which each atom A and B is bound only to its first coordination shell and therefore has 8 bonds from A to B. For such a case the "octahedral holes" of the B2 structure are characterized by local minima, i.e., (3, 3) cps, and the "tetrahedral holes" by ring (3, 1) cps. The B2 structure

Fig. 2. The bonding polyhedra characteristic of the FCC topology.

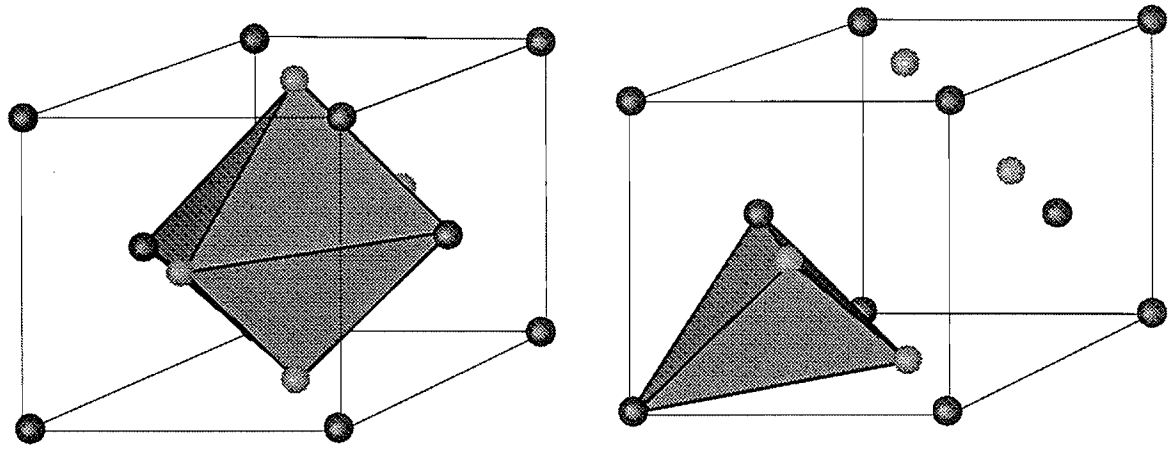


Fig. 3. The bonding polyhedron characteristic of the BCC structure. Note that there are four nonplanar faces.

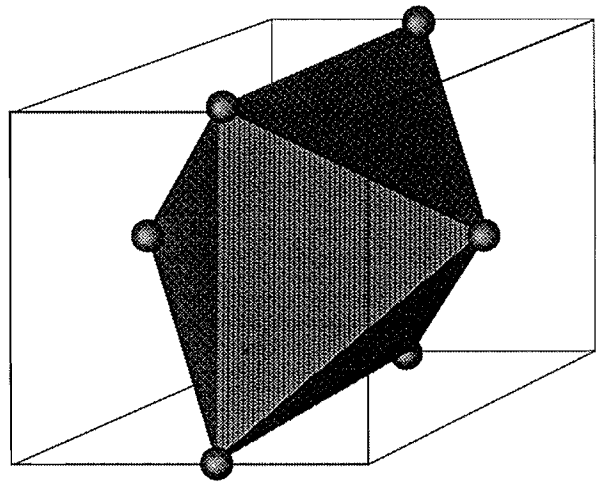

Fig. 4. The B2 crystal structure. This is a simple cubic structure with a two-atom basis. One atom is located at the corner of the cube while the other is at the body center.

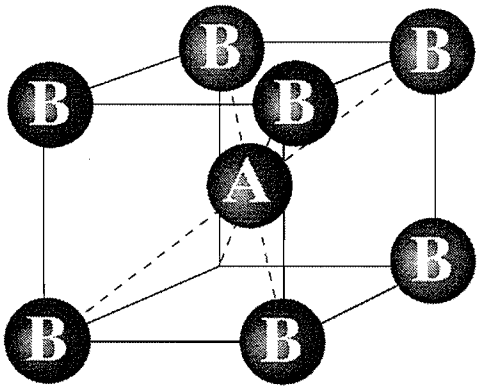


would be the result of packing one type of polyhedron with 6 corners, 8 edges, and 4 faces. Thus the B2 structure, along with one of its allowed charge density topologies, can be conveniently described as having 6 {6, 8, 4} polyhedra at each lattice point of the B2 structure.

An allowed alternative charge density topology would result when either atom A or atom B is bound to its 8 first neighbors and its 6 second neighbors, while the other atom remains bound to only its 8 first neighbors (**b**). For such a case the structure results from the packing of one type of polyhedron. This polyhedron has 5 corners, 8 edges, and 5 faces, i.e., a {5, 8, 5} polyhedron. A description of both the electronic structure and the crystallographic structure is provided by placing 6 {5, 8, 5} polyhedra on either site A or site B of the B2 structure.

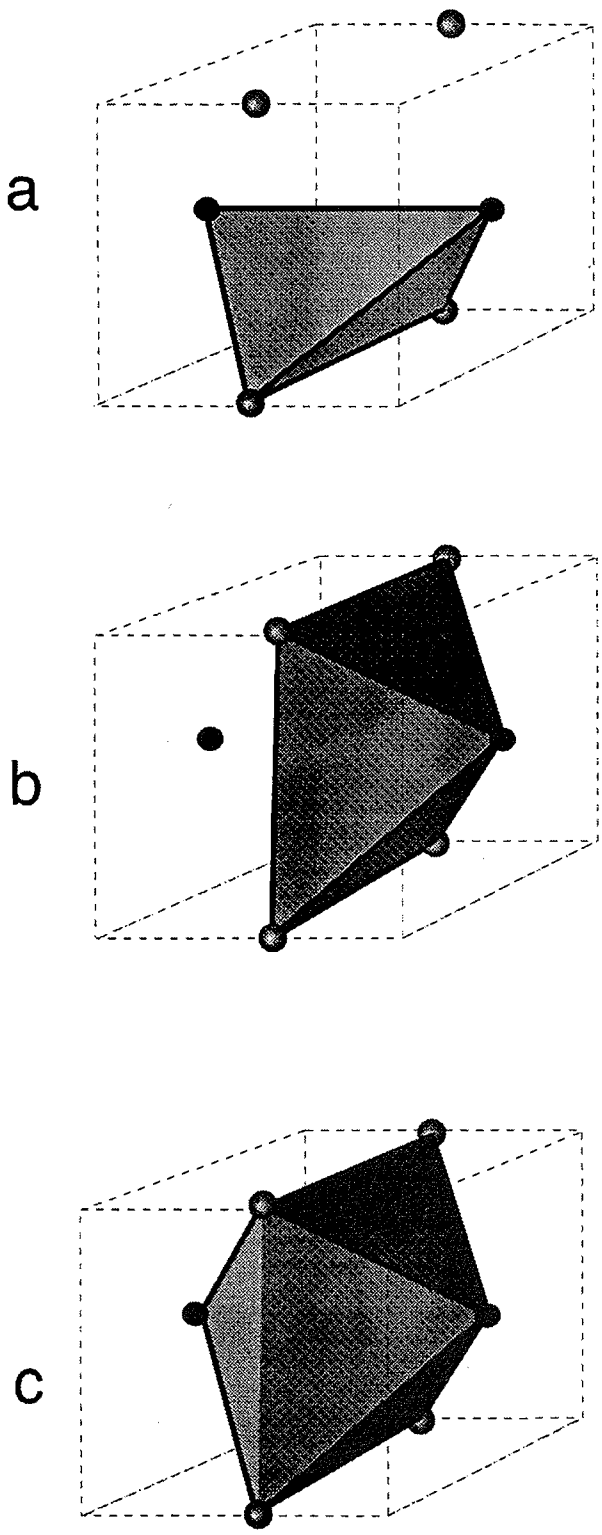
Finally, if both atoms A and B are bound to second neighbors (**c**), then the B2 structure along with its charge density topology can be described as resulting from 24 {4, 6, 4} polyhedra on each lattice point. These polyhedra are topologically equivalent to regular tetrahedra.

While each of the charge densities described above is topologically permitted, each is not necessarily energetically permitted. That is, there may be structure–property relationships between charge density topologies and crystallographic structure, through which only specific bonding polyhedra give rise to a particular crystallographic structure. This hypothesis is easily tested by performing quantum mechanical calculations on a number of B2 alloys, some of which are known to be stable and some of which are not, and correlating the resultant charge density topologies with the observed stability of the B2 structure. The series of B2 alloys used for this initial test are the transition metal aluminides TmAl where Tm is Sc, Ti, V, Ni, Re, Ru, Pt, or Pd.

Of the equiatomic transition metal aluminides, the late transition metals Fe through Ni, Ru through Pd, and Re through Pt all form a stable B2 phase, though it is not necessarily the ground state structure. Of the early transition metals, only Sc forms a B2 structure. In between Sc and the late transition metals there is an "island of instability" where the B2 structure is not observed, e.g., TiAl and VAl.

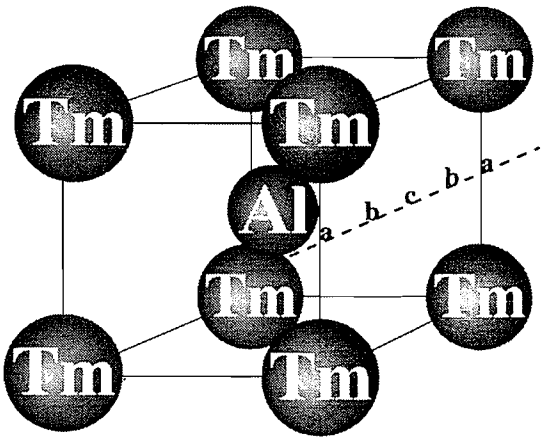
The B2 structure has been assumed for all of the above-mentioned aluminides, where the lattice constant is either

Fig. 5. The bonding polyhedra available to the B2 structure.



taken from experiment or assumed to be that which will give the same density compared to the observed structure(s) at the equiatomic composition. For each of these calculations, the charge density was determined using the Full Potential Linear Augmented Slater Type Orbital approach (15, 16).

Fig. 6. Distinguishing between the polyhedra of Fig. 5 is easily done by determining the charge density along the broken line shown. A maxima along this line at point *a* corresponds to a bond critical point between transition metal atoms, while a maxima at point *c* corresponds to a bond between aluminum atoms. Maxima at both points correspond to second-neighbor bonds between both types of atoms of the B2 structure.



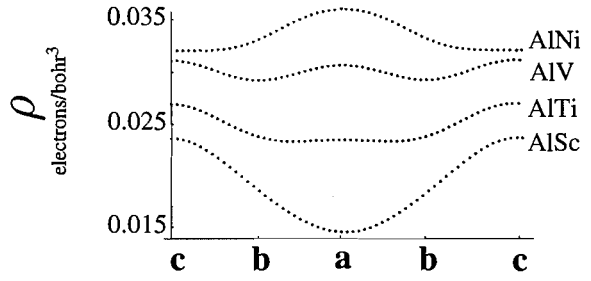
In the B2 structure there are two types of octahedral hole and one type of tetrahedral hole. The octahedral holes are characterized by a fourfold axis where either the A atoms or B atoms are located along this axis. These octahedral holes will be designated by the type of atom lying along the fourfold axis, i.e., either an Al or transition metal octahedral hole.

Each of the different allowed charge densities discussed above can be distinguished by the character of the critical point at the location of the tetrahedral and octahedral holes. If there is more charge density at either of the octahedral holes than at the tetrahedral hole, then one of the topologies resulting in second-neighbor bond formation will be seen, i.e., topologies **b** or **c** of Fig. 5. In turn, the character of the critical point in the center of each of these holes can be determined from a plot of the charge density along the line beginning at a midpoint of one edge of the conventional cubic unit cell and extending to the center of one of the cube faces, Fig. 6. The resultant plot will be sinusoidal in character. The minima along these lines will occur at the location of cage or ring critical points ((3, 3) or (3, 1) cps) and maxima at locations of (3, −1) cps, designating second-neighbor bonds.

The charge density for each of the compounds ScAl, TiAl, VAl, and NiAl along the designated line is shown in Fig. 7. For those compounds that do form the B2 structure, there is a single topology corresponding to second-neighbor bonds between only one of the pairs of atoms. In the case of ScAl the second-neighbor bond is between Al atoms, while in all other cases (both those shown and not shown in Fig. 7) the second-neighbor bond is between the transition metal atoms. In the case of TiAl the topology is consistent with the topology **b** of Fig. 5 and for VAl the topology is consistent with **c** of Fig. 5.

In terms of the topology of the charge density, as one moves from ScAl across the periodic table to NiAl one sees a continuous topological transformation. This transformation can be

Fig. 7. The charge density along the line shown in Fig. 6. Note that AlSc is characterized by second-neighbor bonds between the aluminum atoms while NiAl is characterized by second-neighbor bonds between Ni atoms only. AlV shows both types of second-neighbor bonds.



understood to represent a competition for electron density between the two different types of octahedral holes present in the B2 structure. Beginning with ScAl, the Al atoms compete more effectively for second-neighbor electron density than do the Sc atoms. The resulting structure gives rise to local and global minima in the charge density in the Sc octahedral holes and a bond critical point in the center of the Al octahedral holes. For NiAl, the transition metal is now more effectively competing for electron density and the Al octahedral holes have become cage critical points, i.e., global minima. To reach these two extremes, in a continuous fashion, it is necessary to pass through an intermediate region where both atoms of the B2 structure compete more or less equivalently for charge density. At VAl the competition is almost equal with second-neighbor bonds between both types of atoms, the tetrahedral holes becoming the location of the cage critical points, and both octahedral holes marked by (3, −1) cps. It is in this region where the B2 structure is not observed to be stable.

The island of instability can be understood to result from the necessary region of topological transition, bounding the allowed B2 charge density topology. On one side is the region where transition metal octahedral holes are cage critical points, on the other side, Al octahedral holes are cage critical points. There is no way to continuously distort the charge density without passing through a region in which the charge density adopts a unique topology uncharacteristic of stable B2 structures.

Within the topological model of structure, structure becomes a continuous variable, unlike the crystallographic description where structure is a discrete variable. As a continuous variable one would like to assign a "distance" between an observed topology and a topological instability, that is, develop a geometry of the charge density. It is anticipated that this distance will provide information related to the phase behavior of the alloy.

4. A charge density metric

The curvature of the charge density at a point is a tensor, the Hessian of the charge density $\mathscr{H}_{ij}\rho(\boldsymbol{r}) = \partial^2\rho(\boldsymbol{r})/\partial x_i \partial x_j$. This is a symmetric, rank-two tensor having the same transformation properties as the coefficients of a quadratic polynomial, often referred to as the representation quadric. At a bond critical point, one of the eigenvalues of $\mathscr{H}_{ij}\rho(\boldsymbol{r})$ will be positive while the two remaining eigenvalues are negative. The representation quadric at a (3, −1) cp for $-\mathscr{H}_{ij}\rho(\boldsymbol{r})$ is therefore an hyperboloid of one sheet. The 2-D cross section of this hyperboloid normal to the bond path is an ellipse, whose major and minor axes correspond to two of the principal axes of $\mathscr{H}_{ij}\rho(\boldsymbol{r})$, while the third principal axis is always parallel to the bond path.

In the FCC structure, for example, there are bonding cps midway between each pair of first-neighbor atoms. The principal axes of the Hessian tensor with negative curvature extend from this bonding cp toward the octahedral and tetrahedral holes. The curvatures in these directions are denoted here as ρ_{oo} and ρ_{tt}, respectively. The principal axis of positive curvature extends parallel to the bond, by definition. The curvature in this direction is denoted as $\rho_{\parallel\parallel}$. For the BCC structure the eigenvalues of negative curvature are degenerate and are denoted as $\rho_{\perp\perp}$. Table 1 summarizes the values of the principal components of the Hessian tensor at the bond cps for a variety of FCC and BCC metals.

To develop a measure of the distance from a specific charge density to a topological instability, begin by considering the possible topological changes available to a (3, −1) cp, a bond critical point. This critical point can change its character by a change in sign of one of the principal axes of the Hessian tensor at the bond cp. There are two possible changes that will lead to a loss of electron density at the bonding cp. These correspond to a change in sign of the negative eigenvalues. These changes will lead to transformation of a bond critical point to a ring or cage critical point, i.e., a (3, 1) or (3, 3) cp, depending on whether one or two negative eigenvalues changes sign. There is one topological change that will lead to an increase in charge density at a bond cp. This corresponds to a change in sign of the positive eigenvalue, resulting in the formation of a (3, −3) cp, i.e., a pseudo-atom. The topological changes leading to a loss of charge density are defined as electrophobic transformations, while transformations leading to an increase in charge density are defined as electrophilic transformations.

A measure for the distance to either an electrophobic or an electrophilic transformation can be associated with the angle between the directions of zero curvature at a bond critical point and the principal axes of the Hessian of the charge density. Because a bonding cp possesses one axis of positive curvature and two of negative curvature, there must be directions in which the curvature is zero. These directions have a particularly simple geometric interpretation. The representation quadric for the Hessian tensor at a (3, −1) cp is an hyperboloid. Along the line passing through the (3, −1) cp and parallel to the asymptotic surface that bounds this hyperboloid, the curvature is zero. For illustrative purposes consider any plane of the BCC structure that contains two bound atoms, Fig. 8. This plane must contain two of the principal axes of the Hessian tensor: the principal axis of positive curvature and one of the infinite number of degenerate axes of negative curvature. At the (3, −1) cp and lying in this plane there must be a pair of directions in which the curvature is zero. These directions correspond to the asymptotes of an hyperbola formed from the intersection of this plane with the representation quadric of the (3, −1) cp. The slope of the lines that lie in these directions is given by $(\rho_{\parallel\parallel}/\rho_{\perp\perp})^{1/2}$. Figure 8 shows these directions for a variety of BCC and FCC metals.

When the charge density is perturbed, either mechanically

Fig. 8. The directions of zero curvature at a bond critical point for the nonmagnetic FCC and BCC transition metals. Note that for a BCC metal the angle made by the direction of zero curvature with one of the principal axes of the Hessian will be constant regardless of the plane chosen. For FCC metals the angle will vary between two extremes, where one of the extreme planes contains the bond path and the principal axis extending into the tetrahedral hole (the plane shown in the figure) and the other contains the bond path and the principal axis extending into the octahedral hole.

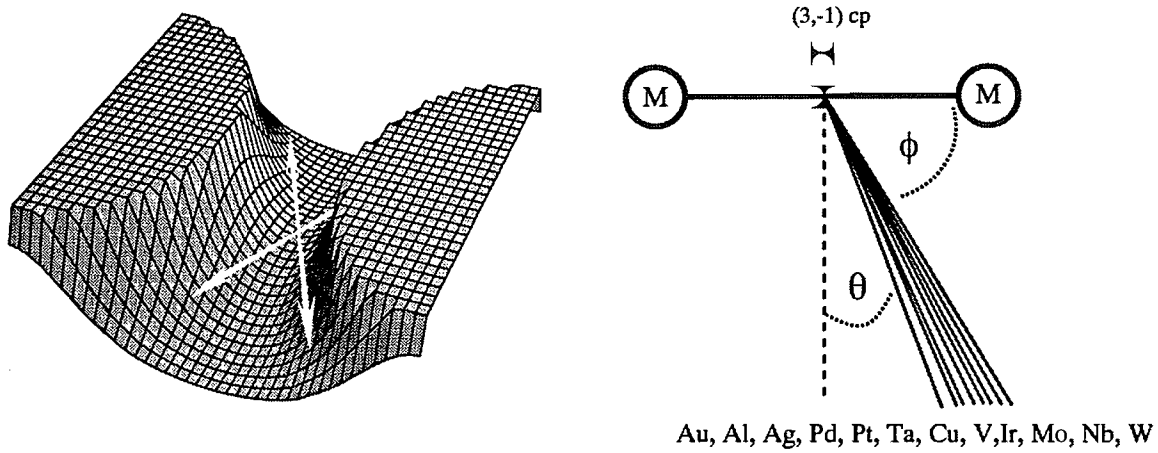


Fig. 9. Left: The correlation between one of the single crystal elastic constants of the BCC metals and the charge-scaled distance to an electrophobic transformation. Right: The same correlation between FCC metals and the charge-scaled distance to an electrophilic transformation.

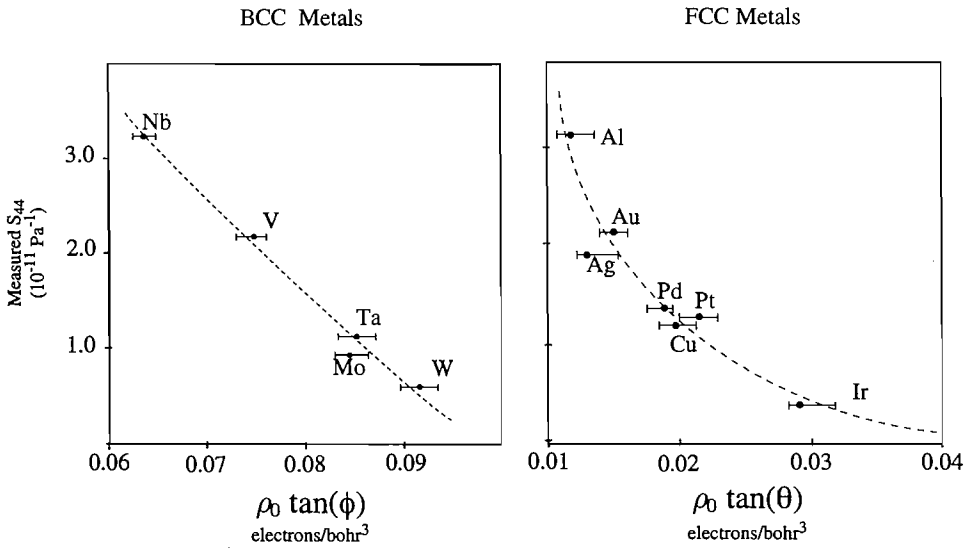

or chemically, the values of the curvature of the charge density at some bonding cps will change and the directions of zero curvature will also change, swinging toward or away from the principal axes of these cps. If these directions of zero curvature should coincide with one of the principal axes of the Hessian of the charge density, then the bond will become unstable and a topological change will follow. Accordingly, one can take the tangent of the angle between these two directions (the direction of zero curvature and one of the principal axes of the Hessian) as a measure of the distance to topological instability. Through this construction, the distance to two different topological instabilities is quantified. These represent the distances to an electrophobic and an electrophilic transformation, i.e., the vanishing of a positive or a negative eigenvalue, respectively. Using the designation in Fig. 8, these distances are given by $\tan(\phi) = (\rho_{\parallel\parallel}/\rho_{\perp\perp})^{1/2}$ and $\tan(\theta) = (\rho_{\perp\perp}/\rho_{\parallel\parallel})^{1/2}$. Table 1 gives the value of $\tan(\theta)$ for the FCC and BCC nonmagnetic transition metals.

The physical significance of these distances can be found by considering the elastic deformations of a metallic lattice. For two metals that deform by the same mechanism, chemical reaction theory dictates that the one that lies closest to an instability, i.e., the transition state, is the one that should be the most compliant (softest). Accordingly, the C_{44} elastic constant

Table 1. Charge density and eigenvalues of the Hessian of the charge density at the bond critical point for nonmagnetic FCC and BCC transition metals. For the purposes of computing the value of the electrophilicity, tan(θ), an average perpendicular eigenvalue is used for the FCC metals given by $\rho_{\perp\perp} = (\rho_{oo} + \rho_{tt})/2$.

(which measures the stiffness of a lattice in response to a specific deformation) of the cubic metals is expected to scale with either $\tan(\phi)/\rho_0$ or $\tan(\theta)/\rho_0$ depending on whether the metal is closer to an electrophobic or electrophilic transformation and where ρ_0 is the value of the charge density at the bond critical point. While the functional form of this relationship is not known, one can expect a power law relationship between the compliance, $S_{44} = 1/C_{44}$, and the distance to instability, as the compliance at zero distance should be infinite and at infinite distance should be zero. Thus S_{44} should vary hypobolically with either $\rho_0 \tan(\phi)$ or $\rho_0 \tan(\theta)$. Figure 9 gives plots showing the relationship between S_{44} and the charge-scaled distance to instability. From these plots one can conclude that the elastic constants of the BCC metals vary as the distance to electrophilic transformations while those of FCC metals vary as the distance to electrophobic transformations.

5. Conclusion

The Bader topological description of the charge density has been reviewed. It has been shown for a single example that unstable crystal structures are sometimes associated with topologies uncharacteristic of the structure. This observation motivated the development of a metric that measures the distance from a calculated charge density topology to topological instabilities. These distances have been found to correlate with the values of the single crystal shear constants for nonmagnetic FCC and BCC metals. Thus the cubic metal elastic constants are seen to be related to the closeness to alternative topologies and the crystallographic structures associated with these charge density topologies, with stiffer metals being further from structural transformations.

Molecules in high-intensity laser fields

T.-T. Nguyen-Dang, F. Châteauneuf, and S. Manoli

Abstract: The separability of a dressed molecule, a composite molecule + quantized radiation field system, at high field intensities is examined. Various forms of the Hamiltonian describing the dressed molecule are reviewed and are used to assess the zeroth-order separability of the dressed system. A new high-order adiabatic separation between the strongly coupled quantized field and molecular subsystems is derived. Qualitative manifestations of laser-induced molecular structures are discussed within this high-order adiabatic representation.

Key words: dynamics, dressed molecule, intense laser field, adiabatic separation, laser-induced molecular structure.

Résumé : La séparabilité des molécules habillées, super-systèmes «molécule + champ quantifié», est examinée dans un régime de hautes intensités. Différentes formes de l'hamiltonien de la molécule habillée sont rappelées et sont utilisées dans la discussion de la séparabilité dite d'ordre zéro du système habillé. Une séparation adiabatique d'ordre supérieur est démontrée. Des manifestations de la structure moléculaire laser-induite sont discutées qualitativement dans le cadre de cette représentation adiabatique d'ordre supérieur.

Mots clés : dynamique, molécule «habillée», champ laser intense, séparation adiabatique, structure moléculaire laser-induite.

1. Introduction

A central problem in the quantum description of interacting systems is the partitioning of the energy of interaction between the subsystems. In the theory of atoms in molecules developed by Bader et al. (1), these subsystems are molecular fragments defined in three-dimensional real space by the zero-flux surfaces of the molecular charge density, and their interactions are partitioned through the virial of the associated forces, ensuring that a virial theorem is satisfied in each subspace (2). The virial partitioning was introduced with the specific aim of defining atomic fragments within a bound molecular environment, fragments that retain a formal identity in spite of strong interactions with their environment. The same type of problem arises whenever strong interactions between formally defined subsystems prevent the identification of these subsystems as quasi-independent entities with physically meaningful individual properties.

One such problem arises in the study of molecular systems subjected to the influence of intense laser fields. In this problem, the quantized field and the molecule are identified at the outset through attributes associated with the separate entities in an asymptotic, noninteracting situation as subsystems of a composite super system, the dressed molecule (3, 4). This partitioning is thus dictated by the different nature of the two entities and is necessarily a partitioning in Hilbert space as opposed to a partitioning in the real configuration space, as is Bader's virial partitioning of a molecular system. In this sense, the problem may appear easier at first sight; however, it is not clear how one could still speak about the molecule and the field as separate entities at the high intensities delivered by present-day lasers. It is indeed expected that in an intense field a molecule will undergo distortions so strong that it will no longer be recognizable using traditional standards such as the basis states of the isolated field-free molecule. Thus, it was suggested that new molecular states and new species are created by the laser field and are responsible for newly observed phenomena such as the above-threshold ionization (ATI) or dissociation (ATD) of molecules (5–7), their stabilization with respect to ionization, and dissociation at high field intensities (8, 9). Furthermore, the distorted molecule acts as a source of new excitations in the field, giving rise to highly nonlinear effects such as the recently observed high-order harmonic generation phenomenon (10, 11).

Even at low intensities, the problem of separation between the field and the molecule persists since the external field may be of comparable magnitude to the intrinsic electromagnetic field radiated by the moving charges. A distinction between these two types of field that recognizes the inseparability of the molecule from its own field is achieved by a unitary transformation that defines the Pauli–Fierz or Bloch–Nordsieck representation (12–14). This transformation has also been used by Nguyen-Dang and Bandrauk in intense-field molecular dynamics (15, 16). In this paper, this representation is the starting point for the development of a high-order adiabatic separation between the two subsystems of a dressed molecule in the high-field-intensity regime. The

separation is analogous to the adiabatic separation between electrons and nuclei in the usual Born–Oppenheimer treatment of isolated molecules, with the field playing the role of the slow subsystem while the molecule plays the role of the fast one. With no further transformation of the Hamiltonian of the dressed system, such an adiabatic separation would require that the field be slowly varying in time, i.e., that the frequencies of the relevant field modes are smaller than the frequencies characterizing the molecular internal motions. To generalize this type of separation to include the case of a high-frequency field, a subsequent unitary transformation of the Hamiltonian of the dressed molecule is required. This type of transformation was first introduced by Maréchal in the study of proton transfer dynamics in hydrogen-bonded systems (17). It is a correction to the Born–Oppenheimer approximation. Physically, it corresponds to a phase shift between the response of the "fast" subsystem to the motions of the "slow" subsystem, a response that is considered instantaneous in the Born–Oppenheimer approximation. This procedure has subsequently been reformulated to make it noniterative and was applied to the study of energy transfer in model systems of anharmonically coupled oscillators (18, 19). In the present context the resulting separation gives an adiabatic representation that is called high order because a large part of the radiative coupling is implicitly resummed in the formal construction of the adiabatic states, leaving residual, nonadiabatic radiative couplings, which vanish as the intensity increases. Hence, the two subsystems are genuinely separable in the asymptotic limit of an infinite field intensity. At a finite, but sufficiently high intensity, they remain well defined as quasi-separate entities. One of these depends on the usual molecular attributes, such as the masses, charges, and coordinates of the particles, and is called the molecular subsystem or simply the molecule, while the other depends on the field attributes, its normal modes and frequencies, and is called the field subsystem. Due to the very nature of this partitioning in the dressed system's Hilbert space, separate equations of motion are obtained for the two subsystems from whose solutions the total wave function for the dressed system can be constructed.

2. Dressed-molecule Hamiltonian and radiative interactions

2.1. Dressed-molecule Hamiltonian: alternative forms

In the Coulomb gauge (14), a molecular system interacting with a quantized, single-mode radiation field is described by the following Hamiltonian

$$[1]\quad \hat{H} = \hat{T}_N + \hat{H}_{el} + \hat{H}_R - \sum_\alpha \left(\frac{Z_\alpha e}{m_\alpha}\right) \boldsymbol{p}_\alpha \cdot \boldsymbol{A}(\boldsymbol{r}_\alpha) + \sum_i \left(\frac{e}{m_e}\right) \boldsymbol{p}_i \cdot \boldsymbol{A}(\boldsymbol{r}_i) + \sum_\alpha \frac{Z_\alpha^2 e_\alpha^2}{2m_\alpha} \boldsymbol{A}^2(\boldsymbol{r}_\alpha) + \frac{e^2}{2m_e} \sum_i \boldsymbol{A}^2(\boldsymbol{r}_i)$$

where $\hat{T}_N$ is the nuclear kinetic energy operator, $\hat{H}_{el}$ the electronic Hamiltonian, and $\hat{H}_R$ the quantized field Hamiltonian. The remaining terms in eq. [1] describe the interaction of the field with the nuclei (of mass m_α and charge $Z_\alpha e$) and electrons. The quantized field Hamiltonian, $\hat{H}_R$, is

$$[2]\quad \hat{H}_R = \hbar\omega(\hat{a}^\dagger\hat{a} + 1/2)$$

Within the quantized field formalism, the transverse potential vector $\boldsymbol{A}(\boldsymbol{r})$ is an operator expressed in terms of the creation and annihilation operators $\hat{a}^\dagger$ and $\hat{a}$ as (14)

$$[3]\quad \boldsymbol{A}(\boldsymbol{r}) = \left(\frac{\hbar}{2\varepsilon_0\omega V}\right)^{1/2} (\hat{a}e^{i\boldsymbol{k}\cdot\boldsymbol{r}} + \hat{a}^\dagger e^{-i\boldsymbol{k}\cdot\boldsymbol{r}})\boldsymbol{\varepsilon}$$

where $\boldsymbol{\varepsilon}$ is the polarization of the field and $\boldsymbol{k}$ is the wave vector, which is related to the field frequency ω by $\omega = c|\boldsymbol{k}|$. Within the long-wavelength approximation (LWA), the dependence of $\boldsymbol{A}$ on $\boldsymbol{r}$ is neglected and eq. [3] reduces to

$$[4]\quad \boldsymbol{A} = \left(\frac{\hbar}{2\varepsilon_0\omega V}\right)^{1/2} (\hat{a} + \hat{a}^\dagger)\boldsymbol{\varepsilon} = \left(\frac{\hbar}{\varepsilon_0\omega V}\right)^{1/2} \boldsymbol{\varepsilon}\hat{P}$$

where

$$[5]\quad \hat{P} \equiv 2^{-1/2}(\hat{a} + \hat{a}^\dagger)$$

is the unitless, canonical momentum operator of the harmonic oscillator associated with the field mode. The corresponding coordinate operator of this oscillator is

$$[6]\quad \hat{Q} \equiv 2^{-1/2} i(\hat{a}^\dagger - \hat{a}).$$

Note that with these definitions, $[\hat{P}, \hat{Q}] = i$ such that, in the coordinate representation,

$$[7]\quad \hat{P} \equiv i\partial_Q$$

In terms of $\hat{P}$ and $\hat{Q}$, the Hamiltonian for the field, eq. [2], is

$$[8]\quad \hat{H}_R = \frac{\hbar\omega}{2}(\hat{P}^2 + \hat{Q}^2)$$

Introducing the coupling constants

$$[9] \quad \theta_e \equiv \frac{e}{m_e}\left(\frac{\hbar}{\varepsilon_0 \omega V}\right)^{1/2}$$

and

$$[10] \quad \theta_\alpha \equiv -\frac{Z_\alpha e}{m_\alpha}\left(\frac{\hbar}{\varepsilon_0 \omega V}\right)^{1/2}$$

eq. [1] can be rewritten as

$$[11] \quad \hat{H} = \hat{T}_N + \hat{H}_{el} + \frac{\hbar\omega}{2}(\hat{P}^2 + \hat{Q}^2) + \sum_\alpha \theta_\alpha(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\alpha)\hat{P} + \theta_e \sum_i (\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_i)\hat{P} + \left(\sum_\alpha \frac{m_\alpha\theta_\alpha^2}{2} + N_e\frac{m_e\theta_e^2}{2}\right)\hat{P}^2$$

where N_e is the number of electrons, such that the radiative interactions denote momentum coupling between the charges and the field. The last term in eq. [11] corresponds to the A^2 terms of eq. [1]. Since the LWA is used, including this term merely gives rise to a renormalization of the mass factor associated with the field oscillator. This term, as well as the momentum coupling terms in eq. [11], can be removed by applying the unitary transformation

$$[12] \quad \hat{U}_{EF} = \exp\left\{\frac{i}{\hbar}\left[\sum_\alpha m_\alpha\theta_\alpha(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\alpha) + m_e\theta_e\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_i)\right]\hat{P}\right\}$$

to $\hat{H}$. In this case, the transformed Hamiltonian

$$[13] \quad \hat{H}_{EF} \equiv \hat{U}_{EF}\hat{H}\hat{U}_{EF}^\dagger$$

$$= \hat{T}_N + \hat{H}_{el} + \frac{\hbar\omega}{2}(\hat{P}^2 + \hat{Q}^2) + \omega\left[\sum_\alpha m_\alpha\theta_\alpha(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\alpha) + m_e\theta_e\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_i)\right]\hat{Q}$$

has radiative interactions expressed in the so-called Electric Field (EF) gauge (20), since Q is related to the electric field $\boldsymbol{E}$ by

$$[14] \quad \hat{\boldsymbol{E}} = -\omega\frac{m_e\theta_e}{e}\boldsymbol{\varepsilon}\hat{Q} = -\omega\frac{m_\alpha\theta_\alpha}{Z_\alpha e}\boldsymbol{\varepsilon}\hat{Q}$$

Alternatively, the momentum interaction in the Radiation Field (RF) gauge (20) Hamiltonian of eq. [11] can also be removed by using the unitary transformation

$$[15] \quad \hat{U}_{BN} = \exp\left\{-\frac{i}{\hbar}\left[\sum_\alpha\frac{\theta_\alpha}{\omega}(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\alpha) + \frac{\theta_e}{\omega}\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_i)\right]\hat{Q}\right\}$$

yielding

$$\hat{H}_{BN} \equiv \hat{U}_{BN}\hat{H}\hat{U}_{BN}^\dagger = \hat{T}_N + \hat{T}_{el} + V_{coul}\left(\left\{\boldsymbol{r}_i - \frac{\theta_e}{\omega}\boldsymbol{\varepsilon}\hat{Q}, \boldsymbol{r}_\alpha - \frac{\theta_\alpha}{\omega}\boldsymbol{\varepsilon}\hat{Q}\right\}\right) + \frac{\hbar\omega}{2}[(1+\Delta)\hat{P}^2 + \hat{Q}^2]$$

where $\Delta = \left(\sum_\alpha m_\alpha\theta_\alpha^2 + N_e m_e\theta_e^2\right)/\hbar\omega$ and $(1+\Delta)$ denotes the renormalization of the field oscillator mentioned previously. Using a subsequent scaling transformation on the field variables alone, which maps $\hat{P}$ onto $(1+\Delta)^{1/4}\hat{P}$ and $\hat{Q}$ onto $(1+\Delta)^{-1/4}\hat{Q}$, and defining the renormalized field frequency $\omega' = \omega(1+\Delta)^{1/2}$, and coupling constants $\theta_k' = (1+\Delta)^{3/4}\theta_k$ ($k = e$ or α), the above equation for $\hat{H}_{BN}$ becomes

$$[16] \quad \hat{H}_{BN} = \hat{T}_N + \hat{T}_{el} + V_{coul}\left(\left\{\boldsymbol{r}_i - \frac{\theta_e}{\omega}\boldsymbol{\varepsilon}\hat{Q}, \boldsymbol{r}_\alpha - \frac{\theta_\alpha}{\omega}\boldsymbol{\varepsilon}\hat{Q}\right\}\right) + \frac{\hbar\omega}{2}(\hat{P}^2 + \hat{Q}^2)$$

exactly, where for clarity ω', θ' have been relabeled ω, θ. The transformation eq. [15] was first introduced by Bloch and Nordsieck (13), and then used by Pauli and Fierz (12) in a general, multimode formulation designed to resolve the so-called infrared divergence problem. At low field intensity, this transformation removes from the transverse field that part which is thought to be tied to the moving charges (14). It is this association of an intrinsic field with the charges that gives a satisfactory solution to the infrared divergence problem through a renormalization of the particles' masses. In intense-field molecular dynamics, it was used

by Nguyen-Dang and Bandrauk (15, 16), who identified the field mode in the Bloch–Nordsieck Hamiltonian, eq. [16], as an additional degree of freedom that parametrizes the electronic Hamiltonian in the same manner as the nuclear coordinates. In the quantized-field formalism, the Bloch–Nordsieck transformation is the counterpart of the Kramers–Henneberger transformation of semiclassical theory (21).

The general relationship between the present time-independent, fully quantum formulation in which the quantized field is included as part of a super system, the dressed molecule, and the semiclassical formulation, in which the field is treated as a classical, time-dependent, external field is established by the Mollow unitary transformation (14, 22, 23) defined as

$$[17]\quad \hat{T}_{\text{Mollow}}(t) = \exp\{i(\text{Re}\lambda(t)\hat{Q} - \text{Im}\,\lambda(t)\hat{P})\}$$

with

$$[18]\quad \text{Re}\lambda(t) = \left(\frac{\hbar}{\varepsilon_0\omega V}\right)^{-1/2} A_{\text{cl}}(t)$$

and

$$[19]\quad \text{Im}\lambda(t) = \left(\frac{\hbar\omega}{\varepsilon_0 V}\right)^{-1/2} E_{\text{cl}}(t)$$

with A_{cl} and $E_{\text{cl}} = -(1/c)\partial_t A_{\text{cl}}$ being the harmonic functions describing the amplitudes of the classical vector potential and electric field, respectively, which for example, may be

$$[20]\quad A_{\text{cl}}(t) = A_0\cos(\omega t), \qquad E_{\text{cl}}(t) = (\omega/c)A_0\sin(\omega t)$$

This transformation leaves the field hamiltonian $\hat{H}_{\text{R}}$ invariant in the sense that

$$[21]\quad \hat{T}_{\text{Mollow}}(t)\hat{H}_{\text{R}}\hat{T}^{\dagger}_{\text{Mollow}}(t) - i\hbar\,\hat{T}_{\text{Mollow}}(t)\partial_t\hat{T}^{\dagger}_{\text{Mollow}}(t) = \hat{H}_{\text{R}}$$

Hence, the results of transforming the various dressed Hamiltonians under $\hat{T}_{\text{Mollow}}$ are

$$[22]\quad \hat{H}(t) = \hat{T}_{\text{N}} + \hat{H}_{\text{el}} + \hat{H}_{\text{R}} + \sum_{\alpha}\left(\frac{Z_\alpha e}{m_\alpha}\right)(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\alpha)\boldsymbol{A}_{\text{cl}}(t) + \sum_i\left(\frac{e}{m_{\text{e}}}\right)(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_i)\boldsymbol{A}_{\text{cl}}(t) + \left\{\sum_\alpha \theta_\alpha(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\alpha) + \theta_{\text{e}}\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_i)\right\}\hat{P}$$

for the Hamiltonian of eq. [11],

$$[23]\quad \hat{H}_{\text{EF}}(t) = \hat{T}_{\text{N}} + \hat{H}_{\text{el}} + \hat{H}_{\text{R}} + \left[\sum_\alpha Z_\alpha e(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\alpha) - e\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_i)\right]E_{\text{cl}}(t) + \omega\left[\sum_\alpha m_\alpha\theta_\alpha(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\alpha) + m_{\text{e}}\theta_{\text{e}}\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_i)\right]\hat{Q}$$

for that of eq. [13], and

$$[24]\quad \hat{H}_{\text{BN}}(t) = \hat{T}_{\text{N}} + \hat{T}_{\text{el}} + V_{\text{coul}}\left(\left\{\boldsymbol{r}_i - \left(\frac{e}{m_{\text{e}}}\right)\boldsymbol{Z}_{\text{cl}}(t) - \frac{\theta_{\text{e}}}{\omega}\,\boldsymbol{\varepsilon}\,\hat{Q}, \boldsymbol{r}_\alpha - \left(\frac{Z_\alpha e}{m_\alpha}\right)\boldsymbol{Z}_{\text{cl}}(t) - \frac{\theta_\alpha}{\omega}\,\boldsymbol{\varepsilon}\,\hat{Q}\right\}\right) + \hat{H}_{\text{R}}$$

for the Bloch–Nordsieck Hamiltonian. In this last equation, $\boldsymbol{Z}_{\text{cl}}(t)$ is defined by

$$[25]\quad \boldsymbol{Z}_{\text{cl}}(t) = \boldsymbol{\varepsilon}\int_0^t A_{\text{cl}}(t')\text{d}t' = \boldsymbol{\varepsilon}\,\frac{1}{\omega}\,A_0\sin(\omega t)$$

The Mollow transformation maps a coherent state of the field corresponding to a classical intense field $\boldsymbol{E}_{\text{cl}}(t)$

$$[26]\quad |\boldsymbol{E}_{\text{cl}}(t)\rangle = \hat{T}_{\text{Mollow}}(t)|0\rangle$$

into the vacuum state so that the residual couplings between the quantized field and the molecule are negligible in comparison to the time-dependent radiative couplings exhibited explicitly in eqs. [22], [23], and [24]. The residual interactions between the molecule and the quantized field are responsible for spontaneous emission while the time-dependent radiative couplings are responsible for stimulated processes (23). In semiclassical theory, only stimulated processes are considered and the residual couplings between the quantized field and the molecule are completly neglected. In a sense, a separation between the quantized field and the molecule has been achieved. As a consequence, the quantized field remains in the vacuum state, i.e., it remains coherent, at all times. In reality, the Mollow transformation only achieves a separation between the nonimportant part of the field (the residual, unexcited quantized field) and the intense field, which becomes a classical time-dependent force that strongly drives the molecular system. The problem of the interaction of this intense field with the charges remains to be solved.

2.2 Molecular structure changes in intense field: Floquet descriptions

One approach to solving the molecular time-dependent Schrödinger equation in semiclassical theory begins with the fact that the time-dependent molecular Hamiltonian in the semiclassical theory is periodic in time with a period $T = 2\pi/\omega$, and exploits the Floquet theorem to express the time-dependent molecular state vector as (24)

$$[27] \quad |\Psi, t\rangle = \exp\left(-\frac{i}{\hbar}\varepsilon_{Fl}t\right)\sum_{n=-\infty}^{+\infty} e^{in\omega t}|\psi_n\rangle$$

yielding a set of coupled equations for the time-independent Floquet components $|\psi_n\rangle$ given by

$$[28] \quad \{\langle\hat{H}_{mol}(t)\rangle_{nn} + n\hbar\omega - \varepsilon_{Fl}\}|\psi_n\rangle = -\sum_{n'\neq n}\langle\hat{H}_{mol}(t)\rangle_{nn'}|\psi_{n'}\rangle$$

where $\hat{H}_{mol}(t)$ is the time-dependent molecular Hamiltonian of eq. [22], or [23] or [24] (with the residual quantized field–molecule interactions neglected), and

$$[29] \quad \langle\hat{H}_{mol}(t)\rangle_{nn'} = \frac{1}{T}\int_{-T/2}^{T/2} dt e^{i(n'-n)\omega t}\hat{H}_{mol}(t)$$

It is from these coupled equations that various forms of the laser-induced effects on the molecular structure were obtained. Figure 1 shows the dressed potential energy surfaces (PESs) of H_2^+ described in a model using just two field-free electronic states, the ground state $1\sigma_g$ and the first excited state $1\sigma_u$. Due to their displacements by the photon energy $n\hbar\omega$, as indicated on the left-hand side of eq. [28], the zeroth-order PESs cross each other at specific values of the internuclear distance R. At these crossings, the radiative couplings between the two electronic states are resonant. Diagonalizing the potential energy matrix, whose off-diagonal terms are the radiative interactions, at each value of R, removes these radiative interactions, and transforms the intersections into avoided crossings (7, 25, 26). This yields a new set of PESs called adiabatic dressed PESs which can support new vibrational states. In the case of the dihydrogen molecular ion illustrated in Fig. 1, the new electronic adiabatic channels and the new vibrational bound states are thought to play an important role in the ATD mechanism of this system (5–7, 27). Laser-induced molecular structure changes of a completely different type have been suggested for a high-frequency field in the Kramers–Henneberger representation where the semiclassical molecular Hamiltonian depends on time through displacements of the position vectors of the particles, as described in eq. [24]. For a high-frequency field, the Floquet blocks corresponding to different values of n in eq. [29] are well separated from each other so that their interactions, denoted by the nondiagonal matrix elements $\langle\hat{H}_{mol}(t)\rangle_{nn'}$ with $n' \neq n$, can be neglected. Restricting the problem to a single Floquet block, the electronic wave function of the molecule is governed by the "dressed" Coulomb potential

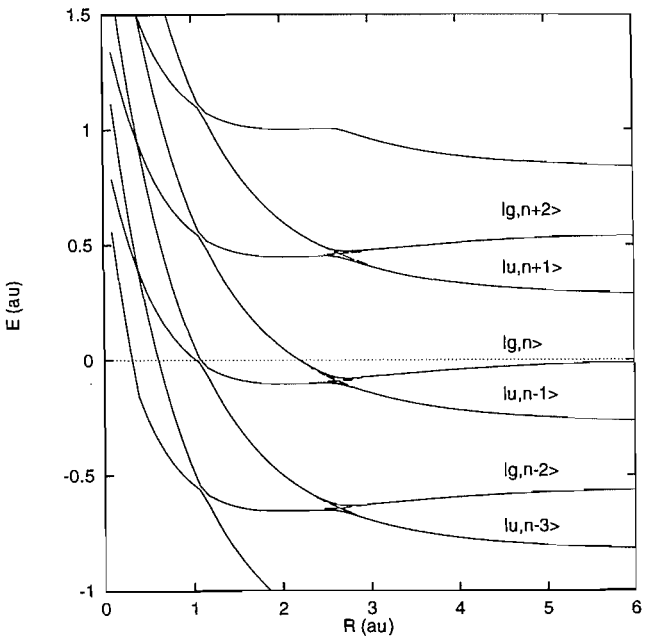

Fig. 1. Adiabatic (solid lines) and diabatic (broken lines) dressed PESs of H_2^+ in a two-state model of the photodissociation of the molecular ion in a field with λ = 164.85 nm, and $I = 4 \times 10^{13}$ W/cm^2. The labels refer to the dressed diabatic states $|K,n\rangle = |K\rangle|n\rangle, K = g,u$.

$$[30] \quad \langle V_{coul}\rangle_{nn} = \frac{1}{T}\int_{-T/2}^{T/2} dt V_{coul}\left(\boldsymbol{r}_i - \left(\frac{e}{m_e}\right)\boldsymbol{Z}_{cl}(t),\ \boldsymbol{r}_\alpha - \left(\frac{Z_\alpha e}{m_\alpha}\right)\boldsymbol{Z}_{cl}(t)\right)$$

As demonstrated by Gavrila and Zaminski (28) for an atomic system, and by Zuo and Bandrauk (29) for one-electron molecular ions, this "dressed" Coulomb potential exhibits new, non-nuclear wells giving rise to what can be described as non-nuclear attractors in the ground state electron density of the molecular system, using the terminology of Bader's topological theory of atoms in molecules (1).

While the current theories discussed in this section highlight the various manifestations of laser-intensity effects on molecular structure, they also point to their limitations: the new states and molecular species created at avoided crossings of dressed PESs are meaningful only insofar as the truncated electronic basis used in this picture is itself meaningful; the effects of the intense field on the ground state electron density as described in the single-block description of the laser-driven molecule using the Kramers–Henneberger frame are limited to high-frequency fields. Moreover, it is not clear how the laser-induced resonances and new bound electronic or vibrational states predicted by these Floquet solutions are prepared from an initially unexcited molecule. However, the central conceptual problem remains the lack of a clear demonstration of a separability of some sort between the molecular system and the intense radiation field. Once established, such a separability will lend support to the identification of laser-induced effects in molecular structure such as those mentioned above as real, observable phenomena.

3. Adiabatic separation at high intensities

3.1. Zeroth-order adiabatic representation

In the Bloch–Nordsieck form of the dressed Hamiltonian, eq. [16], the field-mode appears as an additional degree of freedom which parametrizes the electronic Hamiltonian in the same manner as the nuclear coordinates (15, 16). This suggests an adiabatic separation of the molecule–field system just as the electronic and nuclear motions are separated within the Born–Oppenheimer (BO) approximation. To explore this zeroth-order adiabatic representation, the eigenfunctions $\Psi_{\text{tot}}(\{\boldsymbol{r}_\alpha\}, Q)$ of $\hat{H}_{\text{BN}}$ are expressed in the form of a Born–Huang expansion

$$[31] \quad \Psi_{\text{tot}}(\{\boldsymbol{r}_i, \boldsymbol{r}_\alpha\}, Q) = \sum_I \chi_I(Q)\psi_I(\{\boldsymbol{r}_i, \boldsymbol{r}_\alpha\} \mid Q)$$

in the orthonormal eigenbasis $\{\psi_I(\{\boldsymbol{r}_i, \boldsymbol{r}_\alpha\} \mid Q)\}$ of $\hat{H}_{\text{mol}}(Q)$, i.e.,

$$\hat{H}_{\text{mol}}(Q)\psi_I = \varepsilon_I\psi_I$$

where

$$[32] \quad \hat{H}_{\text{mol}}(Q) \equiv \hat{T}_{\text{N}} + \hat{T}_{\text{el}} + V_{\text{coul}}\left(\left\{\boldsymbol{r}_i - \frac{\theta_e}{\omega}\boldsymbol{\varepsilon}Q,\ \boldsymbol{r}_\alpha - \frac{\theta_\alpha}{\omega}\boldsymbol{\varepsilon}Q\right\}\right)$$

and the parameter Q is the eigenvalue of the operator $\hat{Q}$, i.e., in the coordinate representation implied by the adiabatic scheme, $\hat{H}_{\text{mol}}$ is a local operator with respect to the field mode. The use of eq. [31] gives the following coupled equations for the field wave functions $\chi_I(Q)$

$$[33] \quad (\hat{H}_{\text{R}} + \varepsilon_I - E)\chi_I(Q) = \sum_J \frac{\hbar\omega}{2}\{\langle\psi_I|\partial_{QQ}^2|\psi_J\rangle\chi_J(Q) + 2\langle\psi_I|\partial_Q|\psi_J\rangle\partial_Q\chi_J(Q)\}$$

The adiabatic separation between the field and the charges is obtained by neglecting the nonadiabatic coupling terms in eq. [33]. Since $\hat{H}_{\text{mol}}(Q)$ is exactly a unitary transform (under $\hat{U}_{\text{BN}}$) of the field-free molecular Hamiltonian, its eigenvalues ε_I are independent of Q as are the matrix elements

$$\langle\psi_I|\partial_Q|\psi_J\rangle = -\frac{i}{\hbar}\langle\psi_I^0|\left[\sum_\alpha \frac{\theta_\alpha}{\omega}(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\alpha) + \frac{\theta_e}{\omega}\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_i)\right]|\psi_J^0\rangle$$

where the $\{\psi_I^0\}$ denote the field-free molecular eigenfunctions. Defining $\chi_{In}^0(Q)$ to be the field wave functions in this approximation, the $\chi_{In}^0(Q)$ denote the usual photon number states because ε_I is independent of Q. Thus, $\chi_{In}^0(Q) = \langle Q \mid n\rangle$ exactly. Hence, the magnitudes of the neglected nonadiabatic couplings are of the order of

$$[34] \quad -\langle\chi_{In}^0|\langle\psi_I|\partial_Q|\psi_J\rangle\,\partial_Q|\chi_{Jn'}^0\rangle = \frac{1}{\hbar}\langle\psi_I^0|\left[\sum_\alpha \frac{\theta_\alpha}{\omega}(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\alpha) + \frac{\theta_e}{\omega}\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_i)\right]|\psi_J^0\rangle\langle n|\hat{P}|n'\rangle = O(\theta_\alpha n^{1/2})$$

This estimate is to be compared with estimates of the radiative couplings in eqs. [11] and [13] when a basis of uncoupled molecule–field states $|\psi_I^0\rangle|n\rangle$ is used

$$[35] \quad \langle\psi_I^0|\left[\sum_\alpha \theta_\alpha(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\alpha) + \theta_e\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_i)\right]|\psi_J^0\rangle\langle n|\hat{P}|n'\rangle = O(\theta_\alpha n^{1/2})$$

$$[36] \quad \omega\langle\psi_I^0|\left[\sum_\alpha m_\alpha\theta_\alpha(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\alpha) + m_e\theta_e\sum_i(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_i)\right]|\psi_J^0\rangle\langle n|\hat{Q}|n'\rangle = O(\theta_\alpha n^{1/2})$$

Since the non-adiabatic couplings in eq. [34] are of the same order of magnitude as the radiative potential couplings in eqs. [35] and [36], the adiabatic representation defined by the eigenstates of $\hat{H}_{\text{mol}}(Q)$ does not offer a real advantage over the usual diabatic basis associated with the original RF Hamiltonian, eq. [11], or the EF Hamiltonian, eq. [13]. In fact, none of the three representations gives a convergent description in superintense fields: in the limit $I \to \infty$, i.e., $n \to \infty$, the radiative couplings in eqs. [34]–[36] all diverge. Note that these radiative couplings depend on the coupling constants θ_α, θ_e, and on the photon number n through the combination $\theta_a n^{1/2} (a = \alpha \text{ or } e)$. At low field intensities, for example when n is of the order of unity, the radiative interactions can be treated perturbatively because θ_a is weak ($\theta_e \simeq 10^{-7}$ ms^{-1} for a field with $\omega = 1000$ cm^{-1} in a 1 m^3 cavity; thus, for an electron with a kinetic energy of 10 eV in a field of intensity $I \simeq 1$ W cm^{-2}, the radiative coupling

is of order 10^{-7} eV). Henceforth, any quantity that is of order $(\theta_a n^p)^k$ with $p < 1/2, k \geq 1$ will be considered negligible, and a molecule–field separation with residual couplings that are negligible in this sense will be called a high-order separation.

3.2. High-order adiabatic molecule–field separation

To obtain a partial analytic summation of the nonadiabatic couplings, Maréchal proposed the introduction of a phase shift between the fast and slow motions that accounts for a delay in the response of the fast subsystem to the fluctuations of the slower one (17–19). In the present context, where the molecule is identified as the fast subsystem while the field mode is the slow one, Maréchal's ansatz,

$$[37]\quad \Psi_{\text{tot}}(\{\boldsymbol{r}_\kappa\}, Q) = \mathrm{e}^{-(i/\hbar) f(\{\boldsymbol{r}_\kappa\}, Q)\hat{P}} \Psi^M_{\text{tot}}(\{\boldsymbol{r}_\kappa\}, Q)$$

requires an appropriate function $f(\{\boldsymbol{r}_\kappa\}, Q)$ such that the new total wave function $\Psi^M_{\text{tot}}(\{\boldsymbol{r}_\kappa\}, Q)$ can be written in the form of a BO-like product $\chi_I(Q)\psi_I(\{\boldsymbol{r}_\kappa\} \mid Q)$. Henceforth, to simplify the notation, the subscript κ will denote either electronic or nuclear coordinates. The unitary transformation

$$[38]\quad \hat{U}_{\text{M}} = \exp\{-(i/\hbar) f(\{\boldsymbol{r}_\kappa\}, Q)\hat{P}\}$$

displaces Q by $f(\{\boldsymbol{r}_\kappa\}, Q)/\hbar$ while it leaves the coordinate vectors $\boldsymbol{r}_\kappa$ invariant and transforms the corresponding momenta $\boldsymbol{p}_\kappa$ into

$$[39]\quad \hat{U}_{\text{M}} \boldsymbol{p}_\kappa \hat{U}^\dagger_{\text{M}} \simeq \boldsymbol{p}_\kappa + \boldsymbol{\nabla}_\kappa f \hat{P}$$

If f is independent of, or is weakly dependent on, Q, then $\hat{U}_{\text{M}}$ also leaves the field momentum operator $\hat{P}$ invariant. These transformation properties of $Q, \hat{P}, \boldsymbol{r}_\kappa$, and $\boldsymbol{p}_\kappa$ under $\hat{U}_{\text{M}}$ give

$$[40]\quad \hat{U}_{\text{M}} \hat{H}_{\text{BN}} \hat{U}^\dagger_{\text{M}} = \sum_\kappa \frac{\hat{p}^2_\kappa}{2m_\kappa} + V_{\text{coul}}\left(\left\{\boldsymbol{r}_\kappa - \frac{\theta_\kappa}{\omega}\,\boldsymbol{\varepsilon}\left(Q + \frac{f}{\hbar}\right)\right\}\right) + \omega f Q + \frac{\omega}{2}\frac{f^2}{\hbar}$$
$$+ \frac{\hbar\omega}{2}\left[\left(1 + \sum_\kappa \frac{1}{m_\kappa \hbar\omega}(\boldsymbol{\nabla}_\kappa f)^2\right)\hat{P}^2 + Q^2\right] + \sum_\kappa \frac{1}{2m_\kappa}(\boldsymbol{\nabla}_\kappa f \cdot \boldsymbol{p}_\kappa + \text{h.c.})\hat{P}$$

This is the Hamiltonian governing the dynamics of the dressed system in the new representation, which will be called the Bloch–Nordsieck–Maréchal (BNM) representation. To see how a partial analytic summation of non-adiabatic couplings is possible in this representation, let the new total wave function $\Psi^M_{\text{tot}}(\{\boldsymbol{r}_\kappa\}, Q)$ be expressed in the form similar to that of eq. [31], i.e., as an infinite Born–Huang expansion in terms of the eigenstates of the new molecular Hamiltonian defined by

$$[41]\quad \hat{h}_{\text{mol}}(Q) \equiv \sum_\kappa \frac{\hat{p}^2_\kappa}{2m_\kappa} + V_{\text{coul}}\left(\left\{\boldsymbol{r}_\kappa - \frac{\theta_\kappa}{\omega}\,\boldsymbol{\varepsilon}\left(Q + \frac{f}{\hbar}\right)\right\}\right) + \omega f(\{\boldsymbol{r}_\kappa\}, Q)Q + \frac{\omega}{2}\frac{f(\{\boldsymbol{r}_\kappa\}, Q)^2}{\hbar}$$

This yields the set of coupled equations for the field wave functions $\chi_I(Q)$

$$[42]\quad (\hat{H}_{\text{R}} + \varepsilon_I - E)\chi_I = \sum_J \left\{\left[\langle\psi_I| \sum_\kappa \frac{1}{2m_\kappa}(\boldsymbol{\nabla}_\kappa f . \boldsymbol{p}_\kappa + \text{h.c.})|\psi_J\rangle + \hbar\omega\langle\psi_I|\left(1 + \sum_\kappa \frac{1}{m_\kappa\hbar\omega}(\boldsymbol{\nabla}_\kappa f)^2\right)\hat{P}|\psi_J\rangle\right]\hat{P}\chi_J\right.$$
$$\left. + \langle\psi_I|\left(1 + \sum_\kappa \frac{1}{m_\kappa\hbar\omega}(\boldsymbol{\nabla}_\kappa f)^2\right)\hat{P}^2 + \sum_\kappa \frac{1}{2m_\kappa}(\boldsymbol{\nabla}_\kappa f \cdot \boldsymbol{p}_\kappa + \text{h.c.})\hat{P}|\psi_J\rangle\chi_J + \langle\psi_I| \sum_\kappa \frac{1}{m_\kappa\hbar\omega}(\boldsymbol{\nabla}_\kappa f)^2|\psi_J\rangle\hat{P}^2\chi_J\right\}$$

The nonadiabatic coupling terms in eq. [42] arise from two sources: the parametric dependence of $\hat{h}_{\text{mol}}(Q)$ on Q, eq. [41], and the explicit momentum coupling term induced by the unitary transformation $\hat{U}_{\text{M}}$ in the Hamiltonian of the dressed system, (last term of eq. [40]). The interplay between these allows the partial cancellation of the nonadiabatic couplings, leaving residual interaction terms that are of higher order in the coupling constants θ_κ, or that behave as n^p, where $p < 0$. This partial cancellation determines f and yields a representation of the dressed system in which the total wave function can be written in the form of a BO product denoting an adiabatic response of the molecule to the field oscillations. The nonadiabatic decoupling condition

$$[43]\quad \langle\psi_I| \sum_\kappa \frac{1}{2m_\kappa}(\boldsymbol{\nabla}_\kappa f \cdot \boldsymbol{p}_\kappa + \text{h.c.}) + \hbar\omega\left(1 + \sum_\kappa \frac{1}{m_\kappa\hbar\omega}(\boldsymbol{\nabla}_\kappa f)^2\right)\hat{P}|\psi_J\rangle = 0$$

indicates that the leading term in f is linear in $\boldsymbol{r}_\kappa$ and is of first order in θ_κ. As a consequence, if f is defined in terms of a power series expansion as

$$[44]\quad f(\{\boldsymbol{r}_\kappa\}, Q) = \hbar \sum_\kappa [a_\kappa(\boldsymbol{\varepsilon} . \boldsymbol{r}_\kappa) + b_\kappa(Q)(\boldsymbol{\varepsilon} . \boldsymbol{r}_\kappa)^2 + \ldots]$$

where a_κ is of order θ_κ and b_κ and the coefficients of the higher powers of r_κ are assumed to be much smaller than a_κ, then all terms containing the products $a_\kappa b_\kappa, b_\kappa^2$, and so on can be considered negligible. The $(\nabla_\kappa f)^2$ terms in eqs. [42] and [43] are thus replaced by a_κ^2, so that the last term on the right-hand side of eq. [42] is diagonal and can be absorbed in $\hat{H}_R$. The $(\nabla_\kappa f)^2$ term in the nonadiabatic decoupling condition, eq. [43], is also negligible since $\hat{P}|\psi_J\rangle$ is already of first order in θ_κ. Thus, eq. [43] reduces to

$$[45] \quad \langle\psi_I|\sum_\kappa \frac{1}{2m_\kappa}(\nabla_\kappa f\cdot p_\kappa + \text{h.c.}) + \hbar\omega\hat{P}|\psi_J\rangle = 0$$

which, for $J \neq I$, is

$$[46] \quad \frac{\langle\psi_I|\left[\sum_\kappa \frac{1}{2m_\kappa}(\nabla_\kappa f\cdot p_\kappa + \text{h.c.}), \hat{h}_{\text{mol}}(Q)\right] + i\hbar\omega\partial_Q\hat{h}_{\text{mol}}(Q)|\psi_J\rangle}{\varepsilon_J - \varepsilon_I} = 0$$

Finally, the nonadiabatic decoupling condition requires that

$$[47] \quad \left[\sum_\kappa \frac{1}{2m_\kappa}(\nabla_\kappa f\cdot p_\kappa + \text{h.c.}), \hat{h}_{\text{mol}}(Q)\right] + i\hbar\omega\partial_Q\hat{h}_{\text{mol}}(Q) = 0$$

which represents an implicit equation governing the function f. Satisfying eq. [47] exactly will imply that the eigenvalues ε_I of $\hat{h}_{\text{mol}}$ are independent of Q. In practice, eq. [47] will be satisfied approximately, so that only a weak dependence of ε_I on Q is ensured. Thus, the decoupled equation

$$[48] \quad (\hat{H}_R + \varepsilon_I - E)\chi_I = 0$$

would still describe a simple harmonic oscillator and define field states χ_{In} identified by a photon number n, as in the free field case. As a consequence, a quadratic form of f, as in eq. [44], with $b_\kappa \propto 1/Q$ will correspond to a $n^{-1/2}$ behaviour of b_κ at high intensities, since for the values of n corresponding to these intensities, the decoupled wave functions χ_{In} of the field mode will be strongly localized at large values of $Q, |Q| \simeq n^{1/2}$. With this limited form of f and the further hypothesis that $b_\kappa/m_\kappa = C(Q) \propto 1/Q$, i.e., b_κ/m_κ is a common constant for a given value of Q, eq. [47] becomes

$$[49] \quad 0 = \left\{\omega\partial_Q - \sum_\kappa \frac{\hbar}{m_\kappa}[a_\kappa + 2b_\kappa(\boldsymbol{\varepsilon}.\boldsymbol{r}_\kappa)]\boldsymbol{\varepsilon}.\nabla_\kappa\right\}V_{\text{coul}} - 4\hbar C(Q)V_{\text{coul}} + \hbar\{\omega^2 - 8\hbar\omega C(Q)Q\}\sum_\kappa[a_\kappa(\boldsymbol{\varepsilon}.\boldsymbol{r}_\kappa) + b_\kappa(\boldsymbol{\varepsilon}.\boldsymbol{r}_\kappa)^2]$$
$$- \sum_\kappa \frac{\hbar^2\omega}{m_\kappa}[a_\kappa + 2b_\kappa(\boldsymbol{\varepsilon}.\boldsymbol{r}_\kappa)]\sum_{\kappa'}[a_{\kappa'}(\boldsymbol{\varepsilon}.\boldsymbol{r}_{\kappa'}) + b_{\kappa'}(\boldsymbol{\varepsilon}.\boldsymbol{r}_{\kappa'})^2] - 2\hbar^2\omega C(Q)\left(\sum_\kappa[a_\kappa(\boldsymbol{\varepsilon}.\boldsymbol{r}_\kappa) + b_\kappa(\boldsymbol{\varepsilon}.\boldsymbol{r}_\kappa)^2]\right)^2$$

In writing eq. [49], terms that are independent of r_κ and those that are proportional to $\hat{h}_{\text{mol}}$ have been ignored since the nonadiabatic decoupling condition, eq. [47], is to be satisfied in the sense of off-diagonal matrix elements in the orthonormal eigenbasis $\{|\psi_I\rangle\}$ of $\hat{h}_{\text{mol}}$. In this expression, the last two terms are of order $\theta_\kappa^2 n^0$ and $\theta_\kappa n^{-1/2}$, and they can be neglected. The second term can be removed by setting

$$[50] \quad \frac{b_\kappa}{m_\kappa} \equiv C(Q) = \frac{\omega}{8\hbar Q}$$

which determines b_κ. The remaining parameter in f, a_κ, is determined by the approximate cancellation of the terms involving the Coulomb potential in eq. [49]. The term $4\hbar C(Q)V_{\text{coul}}$ is clearly of order $1/Q$ or $n^{-1/2}$ and can be neglected. At first sight, the same conclusion seems to apply also to the term $(\hbar/m_\kappa)b_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa)(\boldsymbol{\varepsilon}\cdot\nabla_\kappa V_{\text{coul}})$. However, at this point, it is important to note that, in the Coulomb potential, r_κ is displaced by $(\theta_\kappa/\omega)\boldsymbol{\varepsilon}Q$ to first order in θ_κ. Consequently, a simple relation can be established between $\partial_Q V_{\text{coul}}$ and $\boldsymbol{\varepsilon}\cdot\nabla_\kappa V_{\text{coul}}$:

$$[51] \quad \partial_Q V_{\text{coul}} \simeq -\sum_\kappa \frac{\theta_\kappa}{\omega}\boldsymbol{\varepsilon}\cdot\nabla_\kappa V_{\text{coul}}$$

In addition, due to this displacement, in the eigenbasis $\{|\psi_I\rangle\}$ of $\hat{h}_{\text{mol}}$, it is the term $(\hbar/m_\kappa)b_\kappa(\boldsymbol{\varepsilon}\cdot[\boldsymbol{r}_\kappa - (\theta_\kappa/\omega)\boldsymbol{\varepsilon}Q])(\boldsymbol{\varepsilon}\cdot\nabla_\kappa V_{\text{coul}})$ which gives matrix elements of order $n^{-1/2}$ rather than the term $(\hbar/m_\kappa)b_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa)(\boldsymbol{\varepsilon}\cdot\nabla_\kappa V_{\text{coul}})$. With this in mind, eq. [49] is rewritten as

$$[52] \quad \sum_\kappa\left(-\theta_\kappa - \frac{\hbar}{m_\kappa}\left[a_\kappa + \frac{2b_\kappa\theta_\kappa}{\omega}Q\right]\right)\boldsymbol{\varepsilon}\cdot\nabla_\kappa V_{\text{coul}} + 2\hbar C(Q)\left\{\sum_\kappa\left(\boldsymbol{\varepsilon}\cdot\left[\boldsymbol{r}_\kappa - \frac{\theta_\kappa}{\omega}\boldsymbol{\varepsilon}Q\right]\right)\boldsymbol{\varepsilon}\cdot\nabla_\kappa V_{\text{coul}} - 2V_{\text{coul}}\right\} = 0$$

Neglecting the term containing $C(Q)$ and using eq. [49], we obtain from eq. [51]

$$[53]\quad a_\kappa = -\frac{5m_\kappa\theta_\kappa}{4\hbar}$$

In summary, in the BNM representation defined by eqs. [37]–[40] with

$$[54]\quad f(\{r_\kappa\},Q) = -\frac{5}{4}\sum_\kappa m_\kappa\theta_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\alpha) + \frac{\omega}{8Q}\sum_\kappa m_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\alpha)^2$$

the explicit field–molecule coupling terms induced by $\hat{U}_M$ cancel the most significant nonadiabatic coupling terms. The remaining nonadiabatic coupling terms are either of higher order in θ_κ or behave as n^p where $p < 0$. They should not significantly affect the dynamics of the dressed field–molecule system as described within this BO-type scheme. Thus, in this new high-order adiabatic representation, a genuine separation between the molecular system and the field has been achieved in spite of the strong coupling between these two subsystems as denoted by the interaction terms in the various dressed Hamiltonians, eqs. [11], [13], and [16]. These couplings have been explicitly resummed. The fact that residual nonadiabatic couplings behave as n^p, where $p < 0$, makes this representation particularly suitable for the description of the dynamics of molecules in high-intensity fields. The Maréchal transformation modifies the molecular portion, $\hat{H}_{mol}$, of the total Hamiltonian such that the effective Hamiltonian, $\hat{h}_{mol}$, embodies the effects of the intense field on the molecule yielding laser-induced molecular structure.

4. Laser-induced molecular structure

In the traditional analysis of molecular structure within the BO separation of electronic and nuclear motions, the fast subsystem, the electrons, exerts effective forces on the slow subsystem, the nuclei. These effective forces are derived from new potential functions for the nuclear motions, the well-known BO PESs. The fact that new Hellmann–Feynman forces are dynamically exerted on the slow subsystem by the fast subsystem is true for any zeroth-order adiabatic separation. In contrast, within the high-order adiabatic separation presented in this work, it is the slow subsystem, the field, which exerts an effective force on the fast one, the molecule. This role reversal results from the efficient decoupling between the two subsystems.

The effective force exerted on the molecule by the field gives rise to laser-induced molecular structure, which can be obtained from the eigenfunctions of the effective Hamiltonian, $\hat{h}_{mol}(Q)$. With f given by eq. [54]

$$[55]\quad \hat{h}_{mol}(Q) = \sum_\kappa \frac{\hat{p}_\kappa^2}{2m_\kappa} + V_{coul}\left(\left\{\boldsymbol{r}_\kappa - \frac{\theta_\kappa}{\omega}\boldsymbol{\varepsilon}\left(Q + \frac{f}{\hbar}\right)\right\}\right) - \omega\left[\frac{5}{4}\sum_\kappa m_\kappa\theta_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa)\right]Q + \left[\frac{\omega^2}{8}\sum_\kappa m_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa)^2\right] + \frac{\omega}{2}\frac{f^2}{\hbar}$$

The presence of the phase factor f in the Coulomb potential term and the last term of eq. [45] gives rise to higher order corrections that can be neglected; they will not contribute significantly to the laser-induced molecular structure. Thus eq. [45] becomes

$$[56]\quad \hat{h}_{mol}(Q) \simeq \sum_\kappa \frac{\hat{p}_\kappa^2}{2m_\kappa} + V_{coul}\left(\left\{\boldsymbol{r}_\kappa - \frac{\theta_\kappa}{\omega}\boldsymbol{\varepsilon}Q\right\}\right) - \omega\left[\frac{5}{4}\sum_\kappa m_\kappa\theta_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa)\right]Q + \left[\frac{\omega^2}{8}\sum_\kappa m_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa)^2\right]$$

It is convenient to rewrite this effective Hamiltonian in terms of the spatial coordinates $\boldsymbol{r}_\kappa$ displaced by $(\theta_\kappa/\omega)\boldsymbol{\varepsilon}Q$ as

$$[57]\quad \hat{h}_{mol}(Q) \simeq \sum_\kappa \frac{\hat{p}_\kappa^2}{2m_\kappa} + V_{coul}\left(\left\{\boldsymbol{r}_\kappa - \frac{\theta_\kappa}{\omega}\boldsymbol{\varepsilon}Q\right\}\right) - \omega\left[\sum_\kappa m_\kappa\theta_\kappa\boldsymbol{\varepsilon}\cdot\left(\boldsymbol{r}_\kappa - \frac{\theta_\kappa}{\omega}\boldsymbol{\varepsilon}Q\right)\right]Q + \frac{\omega^2}{8}\sum_\kappa m_\kappa\left(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa - \frac{\theta_\kappa}{\omega}Q\right)^2 - \sum_\kappa m_\kappa\theta_\kappa{}^2Q^2$$

In this way, $\hat{h}_{mol}$ is expressed clearly as the unitary transform of an undisplaced Hamiltonian $\hat{h}'_{mol}$

$$[58]\quad \hat{h}_{mol}(Q) = \exp\left\{-\frac{i}{\hbar}\sum_\kappa \frac{\theta_\kappa}{\omega}(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\kappa)Q\right\}\hat{h}'_{mol}(Q)\exp\left\{\frac{i}{\hbar}\sum_\kappa \frac{\theta_\kappa}{\omega}(\boldsymbol{\varepsilon}\cdot\boldsymbol{p}_\kappa)Q\right\}$$

where

$$[59]\quad \hat{h}'_{mol}(Q) \simeq \sum_\kappa \frac{\hat{p}_\kappa^2}{2m_\kappa} + V_{coul}(\{\boldsymbol{r}_\kappa\}) - \omega\sum_\kappa m_\kappa\theta_\kappa\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa Q + \frac{\omega^2}{8}\sum_\kappa m_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa)^2 - \sum_\kappa m_\kappa\theta_\kappa{}^2Q^2$$

The last term in this expression can be absorbed into the Hamiltonian for the field and the relationship between $\boldsymbol{E}$ and Q, eq. [14] expressed in the coordinate representation, can be used to give

$$[60]\quad \hat{h}'_{mol}(\boldsymbol{E}) = \sum_\kappa \frac{\hat{p}_\kappa^2}{2m_\kappa} + V_{coul}(\{\boldsymbol{r}_\kappa\}) - \sum_\kappa q_\kappa\boldsymbol{r}_\kappa\cdot\boldsymbol{E} + \frac{\omega^2}{8}\sum_\kappa m_\kappa(\boldsymbol{\varepsilon}\cdot\boldsymbol{r}_\kappa)^2$$

Fig. 2. Profile, along the field polarization, of the Coulomb potential for the single electron in H_2^+ distorted by the potential (*a*) $-e\boldsymbol{r}\cdot\boldsymbol{E} + (\omega^2/8)m(\boldsymbol{\varepsilon}\cdot\boldsymbol{r})^2$ (solid line); (*b*) $-e\boldsymbol{r}\cdot\boldsymbol{E}$ (broken line), induced by a field of wavelength $\lambda = 2270$ nm and intensity $I = 3.2 \times 10^{13}$ W/cm^2. The nuclei are at a fixed internuclear distance of $R = 2.0$ au. The horizontal line at $E = -0.6$ au marks the position of the field-free ground-state energy of the molecule.

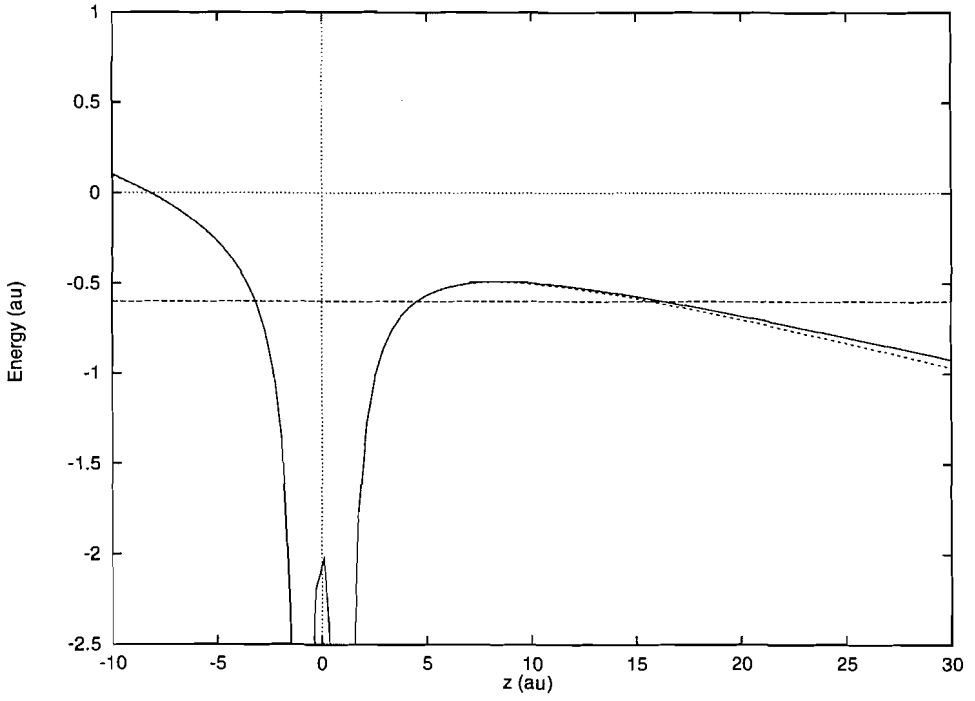

Fig. 3. Profile, along the field polarization, of the Coulomb potential for the single electron in H_2^+ distorted by the potential (*a*) $-e\boldsymbol{r}\cdot\boldsymbol{E} + (\omega^2/8)m(\boldsymbol{\varepsilon}\cdot\boldsymbol{r})^2$ (solid line); (*b*) $-e\boldsymbol{r}\cdot\boldsymbol{E}$ (broken line), induced by a field of wavelength $\lambda = 113.5$ nm and intensity $I = 4.0 \times 10^{15}$ W/cm^2. The nuclei are at a fixed internuclear distance of $R = 2.0$ au. The horizontal line at $E = -0.6$ au marks the position of the field-free ground-state energy of the molecule.

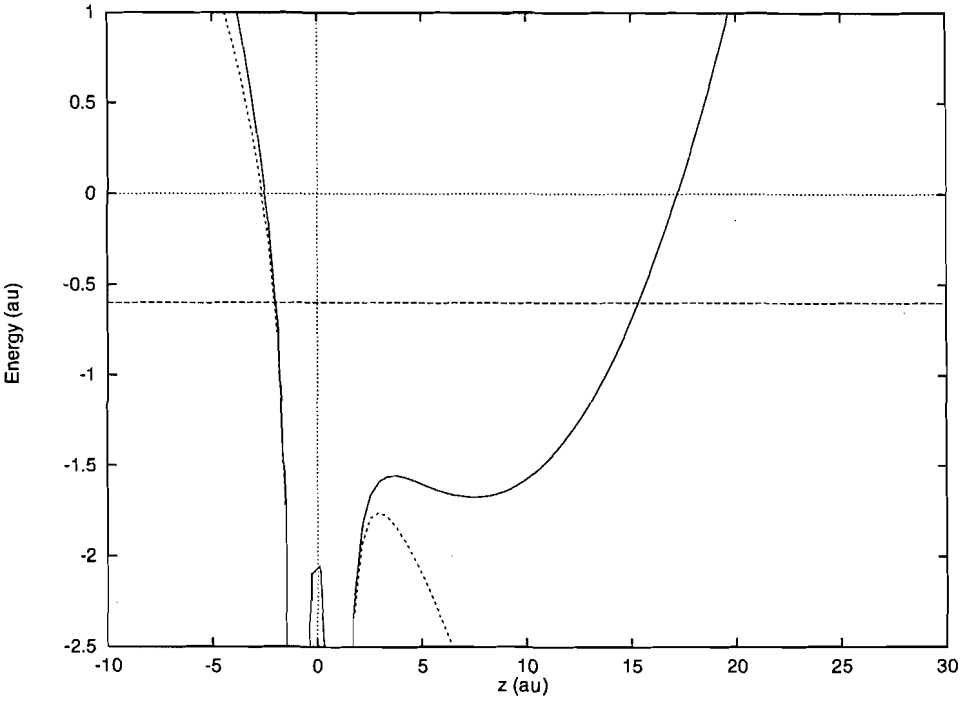

The last two terms in this effective Hamiltonian give rise to the effective force exerted by the field subsystem on the molecular subsystem, which, as discussed previously, are uncoupled in this adiabatic representation. Note that one component of this force appears as an electric field $\boldsymbol{E}$; however, it is not an interaction term between the field and the molecule in the dynamical sense: it no longer couples the eigenstates of $\hat{h}'_{\text{mol}}$ but directly defines them. The instantaneous electric field $\boldsymbol{E}$ is simply a parameter because, as noted previously, Q in $\hat{h}'_{\text{mol}}(Q)$ is the eigenvalue of the operator $\hat{Q}$ and hence, in the coordinate representation, $\boldsymbol{E}$ is a c-number vector. This intensity-dependent force component polarizes the charge distribution whereas the harmonic force component associated with the last term in eq. [60] confines the charges and forces them to oscillate. This term cannot be identified with an effective magnetic force because it is independent of the field intensity. The effects of these two terms on the Coulomb potential felt by the single electron in the dihydrogen ion H_2^+ are illustrated in Figs. 2 and 3. In both figures, the nuclei are at a fixed internuclear distance of $R = R_e$, the equilibrium bond length of H_2^+. In Fig. 2, the dihydrogen ion is in a field of wavelength $\lambda = 2270$ nm and intensity $I = 3.2 \times 10^{13}$ W/cm^2. The broken curves illustrate the effect of the polarization term $-\boldsymbol{er}\cdot\boldsymbol{E}$ alone. At this frequency, this term still dominates the harmonic term and is responsible for the efficient tunnel ionization of the molecular system. However, the effect of the harmonic term is to confine the ionized electron to finite but large distances from the nuclei. The electron oscillates in a shallow well centered far from the nuclei with a frequency imparted by the field. In Fig. 3, the ion is in a field of wavelength $\lambda = 113.5$ nm and intensity $I = 4.0 \times 10^{15}$ W/cm^2. At this higher frequency, it is the harmonic term which gives the dominant character of the laser-induced change in the molecular structure. The polarization term merely displaces the harmonic potential, which, in turn, strongly distorts the Coulomb potential. It is interesting to note that, even for energies that correspond to the field-free ionization continuum, the motion of the electron in a direction parallel to the polarization of the field can be bound. Since the potential well remains open in the other directions, the states describing this situation are resonances, i.e., quasi-bound states. These new quasi-bound states represent states of an electron subjected to oscillations imparted by the field but still under the influence of the Coulomb forces. In the neighborhood of the ground state energy of the field-free molecule, the Coulomb potential is distorted to such an extent that drastic changes can occur in the ground-state molecular charge distribution: A concentration in the charge distribution is expected in the neighborhood of the minimum of the displaced harmonic potential and can give rise to a non-nuclear maximum in the electron distribution. Moreover, the superposition of the harmonic potential with the Coulomb one introduces an asymmetry in the nuclear wells resulting in an asymmetrical electron distribution.

5. Summary and conclusions

From the Bloch–Nordsieck Hamiltonian for the dressed molecule, eq. [16], an adiabatic separation between the field and the molecule has been achieved after a further transformation of the Hamiltonian by the Maréchal unitary operator, eq. [38], whose generator is determined by the nonadiabatic decoupling condition, eq. [47]. Although this condition has been satisfied only approximately, the residual couplings are negligible at high field intensities. Some of these even tend to vanish as the field intensity increases. This trend is due to a $(1/Q)$ dependence of these residual coupling terms and to the well-known localization of the field amplitude at the turning points $Q \propto \pm n^{-1/2}$, for field states with large n that correspond to a high field intensity regime. Thus, the high-order adiabatic representation is only appropriate for high-intensity-field states and denotes an asymptotic separability between the molecule and the field. In this intensity regime, the adiabatic representation identifies genuinely separated molecular and field subsystems in the strongly coupled dressed molecule. The strong modifications of the properties of the molecule in the presence of the intense-field are reflected in the transformation of the molecular hamiltonian from the field free-form, $\hat{H}_{\text{mol}}(Q)$, eq. [32] to the effective form, $\hat{h}_{\text{mol}}$, eq. [55].

The feedback that these modifications have on the field subsystem corresponds to the deformation of the field Hamiltonian $\hat{H}_R$ by $\varepsilon_I(Q)$. As discussed previously, satisfying eq. [47] exactly would imply that the eigenvalues ε_I of $\hat{h}_{\text{mol}}$ are independent of Q. Since eq. [47] had been solved only up to order $\theta_a^2, a = e$ or α, ε_I will depend on Q only through terms that are at least of this order, i.e., the feedback of the changes in molecular structure induced by the laser field on the field is at least of second order in θ_a^2. As of yet, the interesting problem of the feedback that these molecular structure changes have on the quantized field has not been addressed. This problem is being investigated in current work.

Finally, the adiabatic representation developed in this work has a counterpart in semiclassical theory. Indeed, by applying the Mollow transformation to the BNM Hamiltonian, the effective Hamiltonian $\hat{h}_{\text{mol}}(Q)$ can be mapped onto a time-dependent operator that turns out to be approximately an adiabatic invariant, the Lewis invariant (30–32) of the laser-driven molecule treated semiclassically. Since the time evolution is diagonal in the basis of the eigenstates of a Lewis invariant, denoting an adiabatic transport of these eigenstates, an interesting relation exists between the high-order adiabatic molecule–field separation in the present time-independent fully quantized formalism, and the concept of high-order adiabatic time evolution of the molecule in semiclassical theory (33). In this way, laser-induced molecular structures associated with the time-independent effective Hamiltonian $\hat{h}_{\text{mol}}$ can be mapped onto corresponding time-dependent, dynamical molecular structures.

On the performance of molecular model core potential orbitals in spin-orbit and electron correlation studies

Dietmar Krause and Mariusz Klobukowski

Abstract: The role of improved parametrization and accurate basis sets in model core potentials was studied in calculations of the spin-orbit coupling constants (in PH, AsH, and SbH) and of the electron correlation effects (in P_2, As_2, and Sb_2). An effective method of identifying and removing the intruder quasi-core orbitals from the virtual orbital space was proposed in connection with the post-Hartree–Fock calculations. The results demonstrated that (*a*) the flexible valence basis sets allow evaluation of the spin-orbit effects without resorting to any scaling techniques and (*b*) the intruder quasi-core orbitals, even if left imbedded in the virtual space, have negligible effect on the values of the electron correlation energy.

Key words: effective core potentials, basis sets, spin-orbit effects, electron correlation.

Résumé : On a étudié le rôle d'une paramétrisation améliorée et d'ensembles de base précis dans les modèles des potentiels des noyaux dans les calculs des constantes de couplage spin-orbitale (dans le PH, AsH et le SbH) et les effets de corrélation des électrons (dans P_2, As_2 et Sb_2). En relation avec les calculs post-Hartree–Fock, on propose une méthode efficace d'identifier et d'enlever les orbitales quasi-nucléaires inopportunes de l'espace orbitalaire virtuel. Les résultats ont démontré que (*a*) les ensembles de base à valence flexible permettent d'évaluer les effets spin-orbitale sans faire appel à des techniques scalaires et (*b*) les orbitales quasi-nucléaires inopportunes, même si on les laisse dans l'espace virtuel, n'ont qu'un effet négligeable sur les valeurs de l'énergie de corrélation électronique.

Mots clés : potentiels efficace des noyaux, ensembles de base, effets spin-orbitale, corrélation électronique.

I. Introduction

Both the model core potential (MCP) method (1, 2) and the widely used effective core potential (ECP) method (3) treat only the valence electrons of an atomic or molecular system explicitly. Two distinctive features of the MCP method make it different from the ECP family of methods: (*a*) the capability of reproducing the full nodal structure of the valence orbitals and (*b*) the use of projection operators. The model potential orbitals not only reproduce the all-electron (AE) valence orbitals in the region around the outermost maximum but they also match the inner part of the AE valence orbitals, resulting in an improved description of the region near nuclei. (Depending on the basis set, the full nodal structure may be maintained in model potential orbitals.) The projection operator technique used in the MCP method shifts the core orbitals into the energy continuum, where in the finite basis set calculations they become mixed with the virtual orbitals.

To probe the region near the nucleus, we studied the spin-orbit coupling of the lowest $^3\Sigma^-$ state of PH, AsH, and SbH. These systems were the subject of a comparative study in the past (4), showing rather uneven performance of the model core potential method. In our present study, the performance of the model potential method is significantly improved by choosing a better parametrization scheme and employing a high-quality basis set.

Furthermore, in previous work (5, 6) we compared the performance of the model core potential method and the ECP method in studies of valence-electron correlation energies in atoms and molecules. Both methods were shown to yield essentially equivalent results. The question arose, however, whether the core orbitals, shifted into the virtual orbital (VO) space by the projection operators, might lead to overestimated correlation energies. Excitations of valence electrons into these quasi-core orbitals have no counterpart in all-electron CI calculations, and it was hoped that the corresponding correlation energies are negligible compared to the overall valence-electron correlation energies. To study the effect of the quasi-core orbitals, we performed CI-SD calculations of P_2, As_2, and Sb_2 with an active virtual orbital space containing only quasi-core orbitals, without quasi-core orbitals, and in full virtual orbital space. To observe the effect of higher excitations, Møller–Plesset calculations up to fourth order were done. For the model core potential calculations, an all-electron basis was employed that enables both

Table 1. Size and contraction of the all-electron well-tempered basis for P, As, and Sb.

Atom	Size	Contraction
P	23*s* 16*p*	(6,12,12,12,11111/ 3,8,8,11111)
As	26*s* 20*p* 14*d*	(9,12,12,12,12,11111/ 3,12,12,12,11111/ 14)
Sb	28*s* 23*p* 17*d*	(5,18,18,18,18,19,11111/ 18,18,18,18,11111/ 17,17)

an unambiguous assignment of the quasi-core orbitals and a direct comparison with the correlation energies obtained from all-electron SCF orbitals.

II. Details of calculations

A. Model core potential method

The detailed derivation of the model core potential method has been published (1, 2). In the following, only the terms that are relevant to the present work are defined.

The one-electron Hamiltonian h_i in the model core potential formalism contains the potential V_i^α and the projection operator P_i^α at the atomic center α:

$$[1] \quad h_i = -\frac{1}{2}\Delta_i + \sum_\alpha \left(-\frac{z_\alpha}{r_{i\alpha}} + V_i^\alpha + P_i^\alpha \right)$$

where z_α is the core charge of atom α (charge of the bare nucleus minus the number of core electrons).

The spherically symmetric local potential V_i^α, which approximates the exact atomic nonlocal core potential, has the form:

$$[2] \quad V_i^\alpha = z_\alpha \left\{ -\sum_I \frac{A_I}{r_{i\alpha}} e^{-\alpha_I r_{i\alpha}^2} - \sum_J A_J e^{-\alpha_J r_{i\alpha}^2} \right\}$$

where I and J refer to the sets of parameters $\{\alpha_I, A_I\}$ and $\{\alpha_J, A_J\}$.

In the projection operator

$$[3] \quad P_i^\alpha = \sum_{c \in \alpha} B_c |\psi_c(i)\rangle\langle\psi_c(i)|$$

the parameter B_c is taken as twice the absolute value of the atomic orbital energy of the core shell c on atom α.

An initial set of the model potential parameters $\{\alpha, A\}$ for a given atom was determined by fitting the potential V_i^α to a numerical core potential consisting of the core electron nuclear attraction, the core Coulomb and core exchange potentials acting on the valence p-type radial function. Further optimization of the parameters was done to maximize the overlap between the atomic model potential orbitals and the all-electron valence functions. The expectation values $\langle r^n \rangle$, with $n = \{-3, -2, -1, 1, 2\}$, of the model potential valence functions are within 1% of those obtained in atomic all-electron calculations using the same well-tempered basis set. The performance of the model potentials was assessed in SCF calculations of P_2, As_2, and Sb_2. The equilibrium distances are within 2% and the harmonic vibrational frequencies are within 10% of the corresponding all-electron results. A detailed description of the parametrization scheme of the model potentials and their performance in molecular calculations will be reported in a forthcoming paper.

B. Basis sets

Basis sets for all atoms were contracted to give the flexibility of five primitive Gaussian-type functions in the outermost valence region. For hydrogen, the well-balanced (12*s*) basis (7) was contracted to (711111) and augmented with a single p-type polarization function ($\zeta_p = 1.0$).

The basis sets for phosphorus, arsenic, and antimony were taken from the compilation of the well-tempered Gaussian basis sets (8–10). The size of the basis and the contraction of the all-electron basis are shown in Table 1. For the valence-electron basis, the s and p valence shells were uncontracted in the outermost region to yield one contracted shell plus five primitive Gaussian functions, e.g., for phosphorus (18,11111/11,11111). All basis sets, except for hydrogen, were augmented with two d-type polarization functions (11). For the electron correlation studies, we implemented the model core potential method into the HONDO (12) program package in order to take advantage of the ability of the HONDO system to remove the spherically symmetric contribution of Cartesian d-type Gaussian functions.

III. Results of calculations

A. Spin-orbit coupling

For the radicals PH, AsH, and SbH, the ground electronic configuration $\sigma^2\pi^2$ gives rise to the states $^3\Sigma^-$, $^1\Delta$, and $^1\Sigma^+$. The zero-field splitting of the $^3\Sigma^-$ state is dominated by the matrix element $\langle ^3\Sigma^- | H_{SO} | ^1\Sigma^+ \rangle$ of the one-electron spin-orbit Hamiltonian H_{SO}. The spin-orbit matrix elements of PH, AsH, and SbH at their experimental bond distances (1.42, 1.53, and 1.72 Å, respectively) were computed using the program package GAMESS (13), enhanced by the addition of the MCP one-electron integral modules. We used a minimal description of the CI wave functions, in which two determinants span the states $^1\Delta$ and $^1\Sigma^+$, and one determinant represents the $^3\Sigma^-$ state. The determinants were generated by the ground state SCF orbitals in a well-tempered basis for the all-electron calculations and in a valence basis for the model core potential calculations. In Table 2, the spin-orbit matrix elements, the energy gaps between the $^1\Sigma^+$ and $^3\Sigma^-$ states, and the second-order spin-orbit couplings of the $^3\Sigma^-$ states, based on the dominant spin-orbit matrix element, are reported. The model potential results agree within 1% with the respective all-electron values and it should be stressed that this excellent agreement was achieved without employing effective core charges different from the actual bare nucleus charges, and without using any other scaling factors.

The purpose of the present work was to establish degree

Table 2. Spin-orbit matrix elements, energy differences, and spin-orbit splitting of 0^+ and 1 states in PH, AsH, and SbH calculated using all-electron (AE) and model core potential (MCP) wave functions (all values are in cm^{-1}).

XH	Method	$\langle ^3\Sigma^-\|H_{so}\|^1\Sigma^+\rangle$	$\Delta E(^3\Sigma^-,^1\Sigma^+)$	Spin-orbit ($0^+ - 1$) splitting
PH	AE	288.2	20 408	4.070
	MCP	288.1	20 400	4.069
AsH	AE	1320	19 470	89.49
	MCP	1318	19 498	89.09
	CAS SCF/SOCI (14)		17 097	
	Experiment (16)			117.6–118
SbH	AE	2775	17 398	442.6
	MCP	2763	17 430	438.0
	Relativistic CI (15)			696
	Experiment (17)			655–660

of agreement between all-electron and MCP results. It is, nevertheless, interesting to compare the present results with both experimental values and results from earlier calculations. The two heavier systems were studied by Balasubramanian and Nannegari, who used CAS SCF followed by the second-order CI method for AsH (14) and relativistic CI for SbH (15). Their results are reported in Table 2, together with experimental values of the spin-orbit splitting between the states 0^+ and 1. The main difference between the present results and those of Balasubramanian is the larger separation between the $^3\Sigma^-$ and $^1\Sigma^+$ states; this difference is expected because of the extremely limited form of the wave function used in the present work. In consequence, the present values of spin-orbit splitting are smaller than the experimental ones.

B. Electron correlation energy

A model core potential and an all-electron SCF calculation of P_2 was performed at its equilibrium distance (1.89 Å) using the same all-electron well-tempered basis in both cases. The model potential valence orbitals reproduce almost exactly the corresponding all-electron orbitals; the deviation of the overlap from 1 is smaller than 4×10^{-4}. As expected, due to the flexibility of the all-electron basis set, all 10 core MOs could be found in the model potential virtual orbital space of P_2. These quasi-core orbitals could be assigned unambiguously, as the overlap with the corresponding all-electron occupied core MOs was larger than 0.999. After reordering the quasi-core VOs, a valence CI-SD calculation with an active virtual orbital space spanned only by the quasi-core orbitals was done. The correlation energy is 0.0009 au, which is less than 0.4% of the all-electron CI-SD correlation energy (0.2409 au) obtained with excitations from the valence space into the full virtual orbital space.

The selection of the quasi-core orbitals based on overlap with the all-electron core molecular orbitals requires that the all-electron calculations be performed. A simpler and more general technique of identifying and shifting the quasi-core orbitals was accomplished by a transformation within the virtual orbital space, using a procedure similar to the method of modified virtual orbitals (18): after the last SCF step, the canonical eigenvector matrix is saved and a new Fock matrix is constructed using model potential one-electron integrals based on scaled B_c parameters (see eq. [3]). The Fock matrix is then transformed into the virtual orbital space, diagonalized, and the resulting eigenvector matrix is transformed back into the AO (basis set) space. This procedure generates transformed virtual orbitals while leaving the occupied orbitals unchanged. Choosing a scaling factor of -100 for all B_c parameters results in a virtual orbital space containing the quasi-core orbitals as the energetically lowest virtual orbitals. The overlap between the canonical model potential SCF VOs and the transformed VOs deviates less than 6×10^{-4} from 1, so that we used this transformation method as a simple substitute for reordering VOs based on their overlaps. It must be stressed that this technique is more general than the one based on calculation of overlaps between the AE and MCP MOs as it does not require the all-electron calculations.

Applying the above transformation procedure, the correlation effects of quasi-core VOs were studied in P_2, As_2, and Sb_2 at their respective equilibrium distances (1.89, 2.10, and 2.34 Å) using model core potential CI-SD wave functions generated by single and double excitations from the valence space into the space spanned by the quasi-core VOs. The resulting correlation energies (Table 3) are smaller than 0.001 au, being less than 1% of the all-electron CI-SD correlation energies. The all-electron CI-SD wave functions were generated by excitations from the valence space of the all-electron SCF wave functions into the full virtual orbital space.

Using the same all-electron well-tempered basis sets, model potential CI-SD calculations were done employing the full virtual orbital space without the quasi-core VOs. This was achieved by using a large positive scaling factor for B (10^4 for P_2 and As_2, 10^7 for Sb_2) in the transformation of the VOs, resulting in the quasi-core VOs as the energetically highest orbitals.

These truncated model potential VO spaces have the same size as the corresponding all-electron full virtual orbital spaces. Consequently, the number of configuration state functions (CSFs) generated in the model potential CI-SD calculations is the same as the number of CSFs in the all-electron calculations. A direct comparison of the model potential correlation energies with the all-electron correlation energies is

therefore justified and gives a measure of the quality of the molecular model potential valence and virtual orbitals. The respective correlation energies (Table 3) agree within 0.001 au (a relative error of less than 1%).

In the next set of model potential CI-SD calculations the full virtual orbital space was employed, expanded in the same all-electron basis sets. The correlation energies obtained (Table 3) agree very well with those of the previous calculations, in which the quasi-core VOs were discarded. The deviations, smaller than 5% of the total AE CI-SD correlation energies (0.003 au for P_2, 0.006 au for As_2, and 0.007 au for Sb_2) are larger than the correlation energies resulting from excitations only into the quasi-core orbital space. The difference may be attributed to contributions from CSFs generated via mixed excitations connecting quasi-core orbitals with the remaining virtual orbitals. Furthermore, it is reassuring to see the good agreement between the all-electron and model potential correlation energies obtained in Møller–Plesset calculations up to fourth order (Table 4).

Finally, model potential CI-SD calculations were performed using the valence basis sets and employing the full virtual orbital space. A direct comparison with the all-electron correlation energies is not justified due to the different active spaces. Nevertheless, it can be seen from Table 3 that model potential orbitals, spanned by valence basis functions, are very well suited to recover the valence-electron correlation energy based on AE SCF orbitals. Furthermore, the Møller–Plesset correlation results (Table 4) based on model potential orbitals closely match the corresponding all-electron correlation energies.

IV. Conclusions

By reproducing the AE spin-orbit couplings of PH, AsH, and SbH within 1%, we demonstrated the usefulness of molecular model potential orbitals in the computation of properties that depend on the core region of the wave function.

The model potential correlation energies, calculated employing an all-electron basis, agree very well with the AE correlation energies, and the inclusion of quasi-core orbitals in the active virtual orbital space leads to only slightly (less than 5%) overestimated correlation energies. It should be noted that the all-electron basis sets are capable of generating all core orbitals, whereas the basis sets usually chosen for valence-electron calculations are, at most, flexible enough only to reproduce the core orbitals of the outermost core shell. Contamination of the virtual orbital space by the remaining quasi-core orbitals is expected to have a negligible effect on CI-SD calculations. The occupation numbers of the natural orbitals in the space of the quasi-core orbitals (MCP-AE/core results in Table 3) are smaller than 2×10^{-5}. Furthermore, our results from Møller–Plesset calculations up to fourth order do not indicate any problems in the evaluation of higher terms in the correlation energy expansion. We conclude that the occurrence of quasi-core orbitals in the canonical SCF virtual orbital space does not seem to be a drawback of the model core potential method in the study of valence-electron correlation energies.

Acknowledgments

The calculations were done on SUN 4/370 and RS/6000

workstations purchased with partial assistance from the Natural Sciences and Engineering Research Council of Canada (NSERC). This work was financed partly by a research grant from NSERC, and partly by the University of Alberta.

Comparative electronic analysis between hydrogen transfers in the CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- systems: on the electronic nature of the hydrogen (H^-, $H^{\cdot}$, and H^+) being transferred

Jordi Mestres, Miquel Duran, and Juan Bertrán

Abstract: A comparative electronic analysis of the generally termed hydrogen transfers between CH_4 and the CH_3^+, $CH_3^{\cdot}$, and CH_3^- fragments is presented. These systems are taken as simple models of hydride (H^-), hydrogen ($H^{\cdot}$), and proton (H^+) transfers between two carbon fragments (in these simple cases being modelized by two CH_3^+, $CH_3^{\cdot}$, and CH_3^- fragments, respectively). The study is mainly focused on analysis of the electronic nature of the type of hydrogen being transferred in each system, and for this reason a topological analysis of charge density distributions was performed. Computation of Bader atomic charges and construction of the charge density, gradient vector field, and Laplacian of the charge density maps reveal the specific features of the electronic nature of the transferring H^-, $H^{\cdot}$, and H^+. Moreover, characterization of the bond critical points on the charge density surface permits clarification of the differences in atomic interactions between H^-, $H^{\cdot}$, and H^+ and the carbon belonging to each CH_3^+, $CH_3^{\cdot}$, and CH_3^- fragment, respectively. A charge density redistribution analysis is also performed to quantify the reorganization of the electron density when going from the reactant complex to the transition state. Finally, effects of inclusion of the correlation energy at the MP2 and CISD levels are also discussed.

Key words: electron density, hydrogen transfer, topological density analysis, molecular similarity, Bader density analysis.

Résumé : On présente une analyse électronique comparative des transferts dits d'hydrogène entre le CH_4 et les fragments CH_3^+, $CH_3^{\cdot}$ et CH_3^-. On utilise ces systèmes comme des modèles simples pour les transferts d'hydrure (H^-), d'hydrogène ($H^{\cdot}$) et de proton (H^+) entre deux fragments carbonés (qui, dans ces cas simples, sont représentés respectivement par deux fragments CH_3^+, $CH_3^{\cdot}$ et CH_3^-). L'étude est orientée principalement vers l'analyse de la nature électronique du type d'hydrogène qui est transféré dans chaque système et, pour cette raison, on a effectué une analyse topologique des distributions des densités de charge. Des calculs de charges atomiques de Bader et la construction des contours de la densité de charge, du gradient du champ vecteur et du laplacien des contours de la densité de charge permet de mettre en évidence les caractéristiques principales de la nature électronique des H^-, $H^{\cdot}$ et H^+. De plus, la caractérisation des points critiques de liaison sur la surface de la densité de charge permet de clarifier les différences dans les interactions atomiques entre H^-, $H^{\cdot}$ et H^+ et le carbone appartenant à chacun des fragments CH_3^+, $CH_3^{\cdot}$ et CH_3^- respectivement. Une analyse de la redistribution de la densité de charge a aussi été effectuée pour quantifier la réorganisation de la densité électronique lorsqu'on passe du complexe des réactifs vers l'état de transition. Enfin, on discute des effets d'inclusion de l'énergie de corrélation aux niveaux MP2 et CISD.

Mots clés : densité électronique, transfert d'hydrogène, analyse topologique des densités, similarité moléculaire, analyse de densité de Bader.

Introduction

Hydrogen transfers are one of the most usual processes in general chemistry and biochemistry. Despite having been widely studied, the particular electronic nature of the hydrogen being transferred still remains a matter of controversy. For many years, these kinds of processes were formally differentiated into proton, hydrogen, and hydride transfers. However, few comparative studies analyzing the singular electronic features of each type of transfer have been performed so far. In a pioneering work, Bader and co-workers (1) considered the influence of substituents on isotope effects to distinguish between hydride and proton transfers and established the basic differences between the corresponding transition states in terms of bonding and electron charge density. More recently, Williams et al. (2) discussed, on the basis of qualitative molecular orbital theory, the trends in orbital energy changes for three-center C-H-C systems as a function of decreasing the C—C

distance and closing the C-H-C angle, for hydride and proton transfers.

One of the main difficulties in performing this kind of comparative study is to find systems having the same atomic composition that differ only in the number of electrons involved in the making and breaking of bonds, i.e., two electrons for the hydride transfer, three electrons for the hydrogen transfer, and four electrons for the proton transfer. Also, the degree of simplicity of the chosen common structural model will ultimately determine the level of theory from which the comparative analysis will be done. In this sense, Pain and Williams (3) performed a theoretical comparison of primary deuterium kinetic isotope effects between hydride and proton transfer processes in the structurally related $HNCH_2/HCNH^+$ and $HNCH_2/HCNH^-$ systems at the HF/3-21G level of theory.

Considering all the above-mentioned aspects, we present a comparative study between hydrogen transfer processes in the CH_4/CH_3^+, $CH_4/CH_3^\bullet$, and CH_4/CH_3^- systems, which are taken as the simplest models where hydride (H^-), hydrogen ($H^\bullet$), and proton (H^+) transfers can take place between two carbon fragments. For the sake of clarity, these three processes are illustrated in eqs. [1]–[3].

[1] $$CH_4 + CH_3^+ \rightarrow [CH_3\text{-}H\text{-}CH_3]^+ \rightarrow CH_3^+ + CH_4$$

[2] $$CH_4 + CH_3^\bullet \rightarrow [CH_3\text{-}H\text{-}CH_3]^\bullet \rightarrow CH_3^\bullet + CH_4$$

[3] $$CH_4 + CH_3^- \rightarrow [CH_3\text{-}H\text{-}CH_3]^- \rightarrow CH_3^- + CH_4$$

Equation [1] formally shows the transfer of a H^- between two CH_3^+ fragments, through a $[CH_3\text{-}H\text{-}CH_3]^+$ transition state. Accordingly, eq. [2] illustrates the transfer of a formal $H^\bullet$ between two $CH_3^\bullet$ fragments, through the $[CH_3\text{-}H\text{-}CH_3]^\bullet$ transition state. Finally, eq. [3] represents the formal transfer of a H^+ between two CH_3^- fragments, through a $[CH_3\text{-}H\text{-}CH_3]^-$ transition state. Several studies can be found in the literature dealing with these simple H-transfer models between carbons, although the extent of the treatment differs substantially from one system to another due to the particular electronic characteristics of each system.

Proton transfer between CH_4 and CH_3^- has been theoretically investigated from different viewpoints (4–6). In this system, the transition state is characterized by a symmetric linear structure, with an optimized distance between the two carbons involved in the H^+-transfer event of ca. 2.9 Å.

The potential hypersurface of the hydrogen transfer between CH_4 and $CH_3^\bullet$ has also been experimentally investigated (7) and a number of theoretical studies have tried to reproduce the experimental hydrogen abstraction barrier and provide some structural information about the different stationary points along the potential energy surface (8–13). In this case, the $H^\bullet$ transfer is found to evolve again through a symmetric linear transition state structure, where an average 2.7 Å optimized distance between the two carbons can be encountered.

On the other hand, computation of the unrestricted potential energy surface for the interaction between CH_4 and CH_3^+ does not permit one to naturally study the hydride transfer in this system (14). This is because the structure having the H^- in a position midway between the two CH_3^+ fragments is not a transition state but a minimum in this potential energy surface. For this minimum to exist, the possibility of different isomers has been widely investigated experimentally (15–18) and has been well characterized theoretically (19–23). In particular, evidence for the existence of a C_s symmetry isomer has been presented, this isomer having a distance between the two carbons of about 1.96 Å. Also, a D_{3d} symmetry isomer can be located at different levels of theory although it is not a minimum at correlated levels (22*d*). In this isomer the two carbon atoms come within 2.42 Å of one another. Because these species are minima, the study of the hydride transfer process in this system can only be achieved if the potential energy surface is constrained to a given C—C distance larger than the 2.42 Å found for the D_{3d} isomer, as has recently been reported (14).

From the collection of results discussed above it is evident that these systems show wide structural diversity due to the singular electronic features of each system. Thus, enforced by the fact that hydride transfer in the CH_4/CH_3^+ system can only take place under constrained C—C distance conditions, all three systems under study will be constrained to a given distance between the two carbons throughout the work. The final aim of this contribution is to gain a deeper insight into the characterization of the electronic nature of the transferring H and to try to contribute to the elucidation of the particular conditions under which it can be formally termed as hydride, hydrogen, or proton.

Computational details

The present work has been performed by means of ab initio molecular orbital calculations at the Hartree–Fock (HF) level, and electronic correlation effects have been introduced at the MP2 and CISD levels of theory. The restricted HF method was employed for closed-shell systems while the unrestricted HF method was used for the open-shell system. To minimize basis set effects, the 6-311++G** basis set (24) was used throughout. Restricted geometry optimizations were carried out using Schlegel's method (25), by means of the Gaussian 92 program (26). For MP2 and CISD calculations, generalized densities (27) were always used.

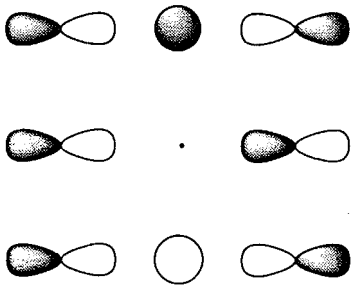
The topological Bader analysis (28) (including construction of charge density maps, location and characterization of bond critical points, gradient vector fields, Laplacian maps, and charge density difference maps between different levels of theory) was carried out through the use of the Electra program (29). In addition, Bader atomic charges were calculated using the Proaim package (30).

A charge density redistribution analysis was performed by computing the quantum molecular similarity measures (QMSMs) of the systems at the different stationary points. The QMSM is defined as the overlap integral between two electron density distributions

[4] $$S_{AB} = \int \rho_A(\boldsymbol{r})\rho_B(\boldsymbol{r})d\boldsymbol{r}$$

where ρ_A and ρ_B are, respectively, the electron density distributions of two molecules A and B (31). The similarity of density distributions ρ_A and ρ_B at a given relative orientation of molecules A and B can then be evaluated by computing the Euclidean distance between QMSMs as

Scheme 1



[5] $d_{AB} = (S_{AA} + S_{BB} - 2\,S_{AB})^{1/2}$

This methodology has recently emerged as a very useful tool for tackling all kinds of charge density redistribution problems (32). QMSM calculations were performed by means of the Messem program (33).

Structural analysis

As initially noted by Bader and co-workers (1), the number of electrons involved in the forming and breaking of bonds directly affects the strength of the interaction among the three reacting moieties along the reaction coordinate. These electrons systematically occupy the three molecular orbitals that result from the interaction of those three fragments implicated in the transfer process, namely, the H donor (a CH_3 fragment), the transferring H, and the H acceptor (the other CH_3 fragment). These three orbitals are depicted in Scheme 1.

In hydride transfer (where only two electrons are involved in the bond breaking and forming) the HOMO is the labelled bonding orbital in Scheme 1, while in proton transfer (where four electrons are involved in the forming and breaking bonds) the two additional electrons are accommodated in the labelled nonbonding orbital. The consequences of this electronic disposition on the structure of the transition states for the different processes have already been derived by Bader and co-workers (1): in hydride transfer, the three fragments cement together in a strong, short, highly covalent, and relatively nonpolarizable bond; in contrast, the resulting repulsion of the two additional electrons in proton transfer will lead to a weaker, longer, more ionic, and more polarizable three-center bond.

As mentioned above, Williams et al. (2) derived the same conclusions from a simplified Walsh diagram on the basis of qualitative molecular orbital theory. Quantitative results were also provided by Pain and Williams (3) in their theoretical comparison of structurally related hydride and proton transfers in the $HNCH_2/CHNH^+$ and $HNCH_2/CHNH^-$ systems. In that study, they found that the transition states for hydride and proton transfers are very similar, the main difference lying in the shorter C—C distance for hydride transfer (2.68 Å) as compared to that for proton transfer (2.91 Å).

This trend is also followed by the hydrogen and proton transfer systems considered in this study, but in this particular structural series a comparative study from complete relaxation of all systems is not possible because no transition state exists for the hydride transfer between CH_4 and CH_3^+. Thus, at this stage, in order to include hydride transfer in the comparative analysis, all transfer processes were constrained to evolve within a fixed C—C distance of 3.2 Å. The selection of this value comes from our previous experience in the constrained hydride transfer model system (14), to obtain a hydride transfer with a significant barrier at the three levels of theory employed. Under this constraint, the concept of stationary point is lost and thus, throughout this work, it will be referred to as the reactant complex at the point on the reaction coordinate where the hydrogen to be transferred begins to "notice" the polarization effect of the H-acceptor CH_3 fragment, and as the transition state at the point on the reaction coordinate where the hydrogen being transferred is midway between the two CH_3 fragments. Moreover, the use of a uniform structural constraint for the three types of transfer under study appears to have an additional advantage in that this will permit analyzing the processes from the same structural reference and performing the comparative study from equal structural conditions. In this sense, the three simple models chosen as being representative of hydride, hydrogen, and proton transfers between two carbons become structural artifacts in an attempt to understand the particular electronic characteristics of each H transfer under the same structural environment.

On this basis, the main structural parameters of all reactant complexes and transition states, at the three different levels of theory used, have been collected in Table 1. The nomenclature C^l and C^r stands for the two carbons at the left and right side of the H being transferred (H_t), respectively, under the convention that H_t is initially attached to C^l, so the transfer process proceeds from left to right.

For reactant complexes, the most interesting structural parameter turns out to be the distance between C^l and H_t, denoted as $R(C^l—H_t)$. This distance reveals clearly the strength of the polarization effect on the $C^l—H_t$ bond of the CH_4 fragment in reactant complexes due to the presence of a CH_3^+, $CH_3^\bullet$, or CH_3^- fragment at the constrained C—C distance of 3.2 Å. This polarization effect will strongly influence the transfer process because the larger the polarization effect, the smaller the distance that must be covered by the migrating H_t atom. Taking HF as the reference level of theory, an ordering of the strength of the polarization effect due to the presence of the three different CH_3 fragments can be established, $CH_3^+ > CH_3^- > CH_3^\bullet$, which in turn translates into an ordering of the travelling distance for the H_t being transferred, 0.9510 (H^-) < 1.0166 (H^+) < 1.0568 ($H^\bullet$). Inclusion of the correlation energy tends to enhance the above-mentioned polarization effect on the $C^l—H_t$ bond in reactant complexes, giving rise to a reduction of the distance to be covered for the transferring H_t. In essence, the ordering obtained at the HF level is maintained qualitatively when electron correlation is included to some extent, although MP2 seems to exaggerate the polarization effect with respect to the trend observed at the CISD level of theory.

Among the other structural parameters reported, the main differences are found in the $H\text{-}C^r\text{-}H_t$ angle for reactant complexes, where for proton transfer in the CH_4/CH_3^- system it gives the largest value in comparison with those values found for reactant complexes for the other two processes, due to the presence of a repulsive interaction induced by the two additional electrons furnished by the CH_3^- fragment. Another important difference evident from this table is the progressive opening of the $H\text{-}C\text{-}H_t$ angle for transition states, due to the different amount of electron charge density being accumu-

lated along the C-H_t-C region of space depending on each individual process. Interestingly, geometrical parameters obtained at the CISD level are intermediate between HF and MP2 structures regardless of the process, which reflects the well-known fact that MP2 calculations usually exaggerate the contribution of correlation energy to the electronic energy of molecules and complexes (32*c*).

Electronic analysis

In performing the comparative electronic analysis, more atten-

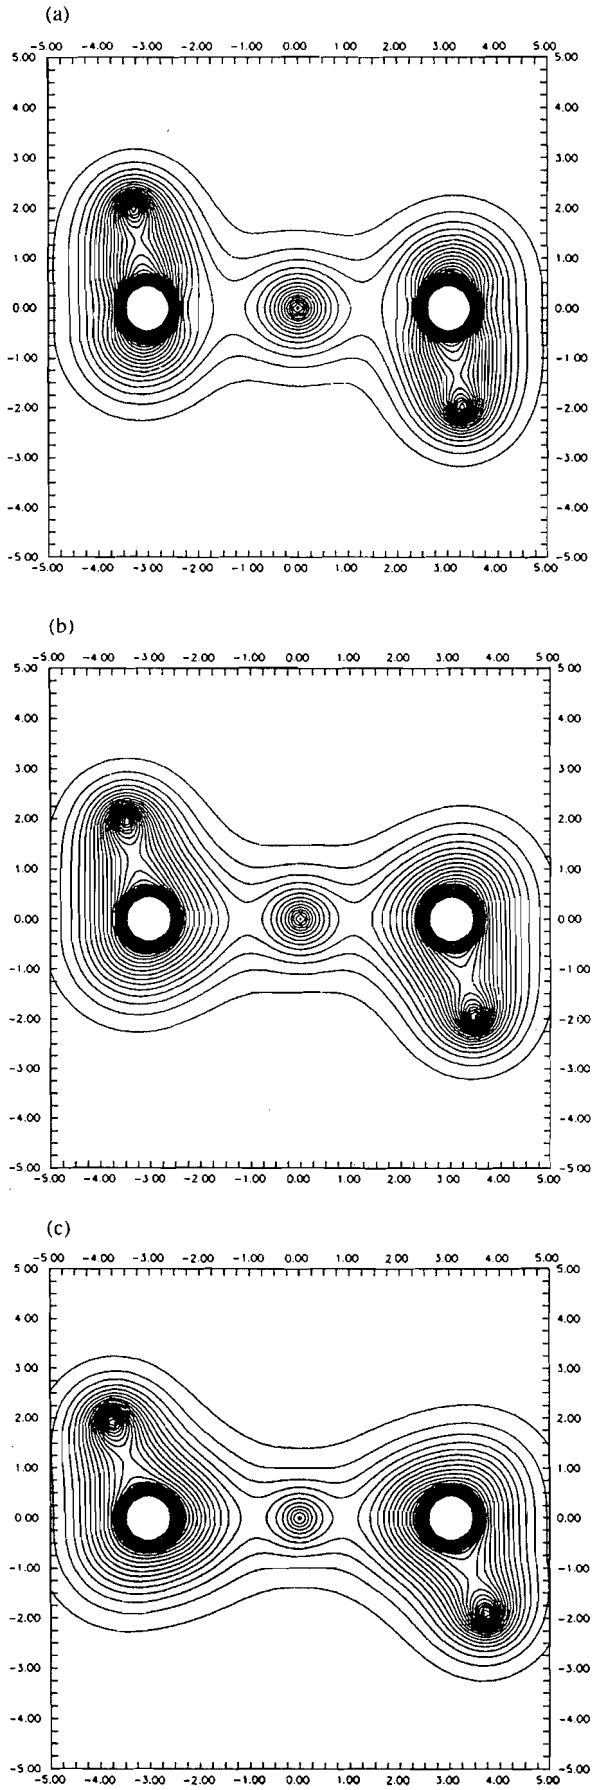

Fig. 1. Electron density maps for the (*a*) $[CH_3\text{-}H_t\text{-}CH_3]^+$, (*b*) $[CH_3\text{-}H_t\text{-}CH_3]^{\bullet}$, and (*c*) $[CH_3\text{-}H_t\text{-}CH_3]^-$ transition states of the corresponding systems at the HF level.

tion will be paid to transition states, because it is at the transition state point of the reaction coordinate where the migrating H_t reaches the midpoint between the two carbons in all three systems, and thus it is more suitable for comparative purposes. References to the results obtained at reactant complexes will be made in those cases where significant information can be extracted. To seek such a goal, electron density contour maps for the three midpoint H transfers of the systems under study have been gathered in Fig. 1, in a plane containing the maximum number of atoms. These maps clearly offer an attractive visual way of distinguishing among what are commonly termed hydride (Fig. 1*a*), hydrogen (Fig. 1*b*), or proton (Fig. 1*c*) transfers, depending on the accumulation of charge isodensity lines around the H_t being transferred.

The influence of correlation energy on the charge density map of each particular H-transfer has been estimated by depicting electron density difference maps. The fact that the three systems are constrained to a common C—C distance is found especially useful in this kind of analysis. Figure 2 shows this effect when correlation energy has been included at the MP2 level. Similar maps are obtained from the CISD electron densities but, as mentioned above, the MP2 level appears to be more suitable for visual purposes as the effect of correlation energy is found to be more exaggerated. The general trend shown by this figure is that inclusion of the correlation energy generally corrects the well-known exaggeration of the weight of ionic structures at the HF level. In valence bond language, HF exaggerates the contribution of the $C^+\ H^-\ C^+$ structure in the hydride transfer (14*a*), while it overestimates that of the $C^-\ H^+\ C^-$ structure in the proton transfer. This can be observed in Fig. 2: at the $[CH_3\text{-}H_t\text{-}CH_3]^+$ transition state (Fig. 2*a*), a diminution of the charge density around H_t is found when correlation energy is added, and it is in turn accumulated in those regions around the carbons; on the contrary, correlation energy concentrates charge density around H_t for the $[CH_3\text{-}H_t\text{-}CH_3]^-$ system (Fig. 2*c*) while it is depleted in the central regions of the C—H_t interaction. Moreover, it turns out that correlation energy has a smaller effect on the overall charge density distribution of the $[CH_3\text{-}H_t\text{-}CH_3]^{\bullet}$ system (Fig. 2*b*).

More precise quantitative information on the topological features of electron density maps can be extracted by locating and characterizing the bond critical points (BCPs) among the different C—H bonds of the three systems under consideration. The results of this analysis are collected in Table 2. Focusing our attention first on results obtained for the C—H_t bond in the three systems, several general trends are exhibited: (*i*) the location of the C—H_t BCP from H_t provides information on the spatial coverage of the particular H_t electronic domain, being found to obey the following order $r_c(C—H^-) > r_c(C—H^{\bullet}) > r_c(C—H^+)$, where a formal electronic character has been assigned to each H_t; (*ii*) the value of the charge density at the C—H_t BCP increases in the order $\rho(r_c)(C—H^-) < \rho(r_c)(C—H^{\bullet}) < \rho(r_c)(C—H^+)$; (*iii*) the values of the Laplacian of the charge density at this C—H_t BCP follow the order $\nabla^2\rho(r_c)(C—H^-) > \nabla^2\rho(r_c)(C—H^{\bullet}) > \nabla^2\rho(r_c)(C—H^+)$, indicat-

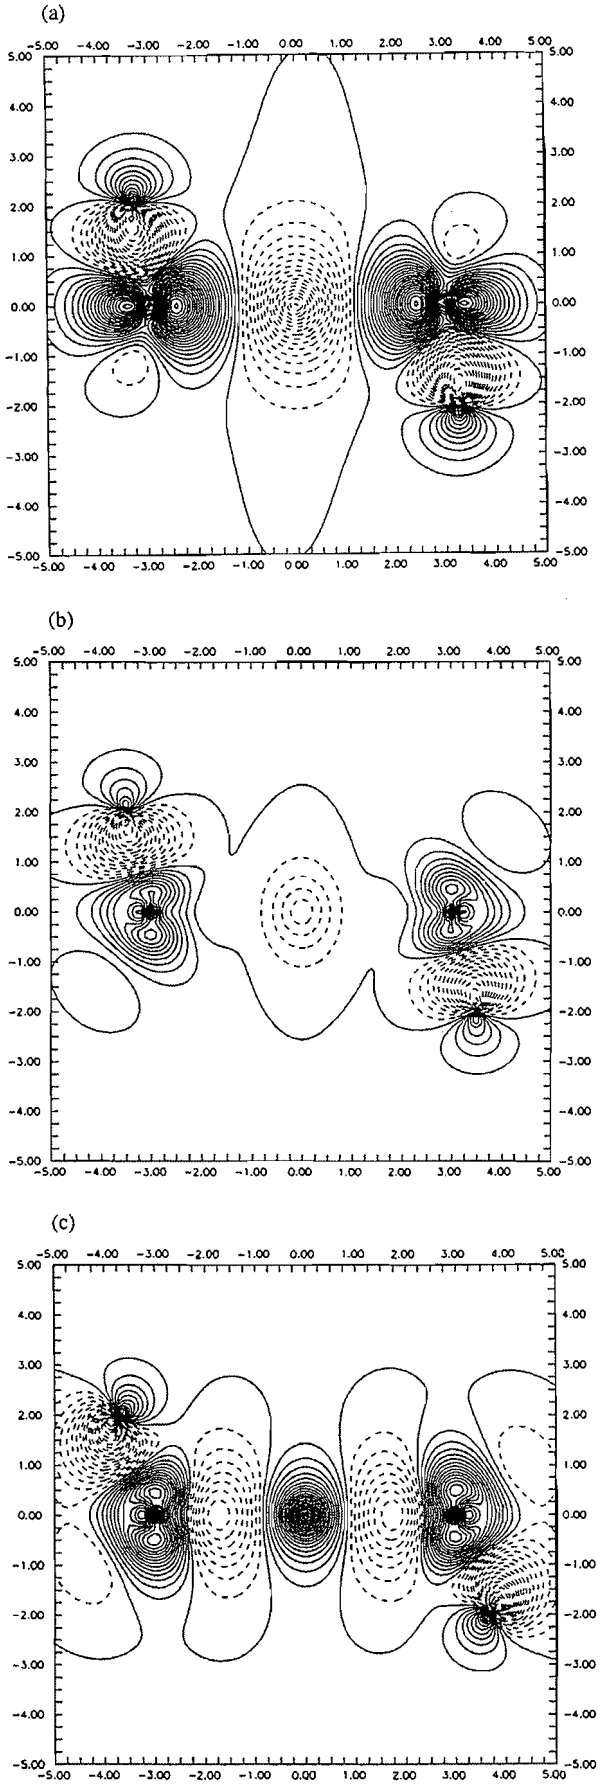

Fig. 2. Electron density difference maps between MP2 and HF ($\rho_{MP2} - \rho_{HF}$) for the (*a*) $[CH_3\text{-}H_t\text{-}CH_3]^+$, (*b*) $[CH_3\text{-}H_t\text{-}CH_3]^{\bullet}$, and (*c*) $[CH_3\text{-}H_t\text{-}CH_3]^-$ transition states of the corresponding systems. Positive values are represented by solid lines and negative values by broken lines.

ing an increasing local concentration of the charge density in this direction; and (*iv*) the $|\lambda_1|/\lambda_3$ values also follow the same trend found for electron densities of the BCPs. The whole ensemble of these results indicates that some amount of electron density tends to be accumulated in regions closer to H_t when going from H^-, $H^{\bullet}$, and H^+, and that the class of atomic interaction between H_t and the two carbon atoms is representative of so-called intermediate interactions (28*a*).

The same analysis can be performed for the six equivalent lateral C—H bonds and, interestingly, a completely opposite trend is observed: (*i*) location of the C—H BCP is closer to the H atom for hydride transfer in the $[CH_3\text{-}H_t\text{-}CH_3]^+$ transition state, and it progressively moves further away in the systems representative of hydrogen and proton transfers. (*ii*) At the same time the value of the charge density at the C—H BCP decreases in the same direction, and (*iii*) the Laplacian value becomes less negative, both factors being evidence of a progressive local depletion of electron density, which is also related to the fact that the C—H bond distance is increased in the same direction (Table 1). (*iv*) Finally, in this case $|\lambda_1|/\lambda_3$ gives values that are larger than unity, which, together with the relatively large values of the charge density and Laplacian, are clearly representative of the formation of typical C—H covalent bonds (28*a*).

The effect of correlation energy on the localization and characterization of BCPs can also be extracted from Table 2. Thus, what was qualitatively observed from the electron density difference maps discussed above (Fig. 2) can now be quantitatively evaluated. In general, all the differences among the topological features of the three types of H_t are now reduced. With respect to the HF level, (*i*) the most remarkable effect is that the location of the C—H_t BCP is found to be clearly closer to the H^-, while it moves apart from H^+. In a wider sense, this indicates that the formal H^-, atomic basin is significantly contracted, that of the formal H^+ is clearly expanded, and that of the formal $H^{\bullet}$ suffers only small differences; (*ii*) while an increment of the electron density is encountered at the C—H^- BCP, smaller electron density values are found at the C—H^+ BCP and no significant differences appear at the C—$H^{\bullet}$ BCP; (*iii*) values of the Laplacian of the charge density become more negative at the C—H^- BCP and less negative at the C—H^+ BCP; finally (*iv*) $|\lambda_1|/\lambda_3$ values at the C—H_t BCPs follow the same trend found for the electron densities. In summary, introduction of the effect of correlation energy makes the differences in the electronic nature of the three types of H_t being transferred even more diffuse than they were at the HF level.

From the above results it turns out that the larger the hydride character of the transferring H, the larger the proton character of the lateral Hs. This statement is clearly reflected in Table 3, where a Bader atomic charge population analysis at the reactant complexes and transition states is presented. Among other population analyses, Bader atomic charges have

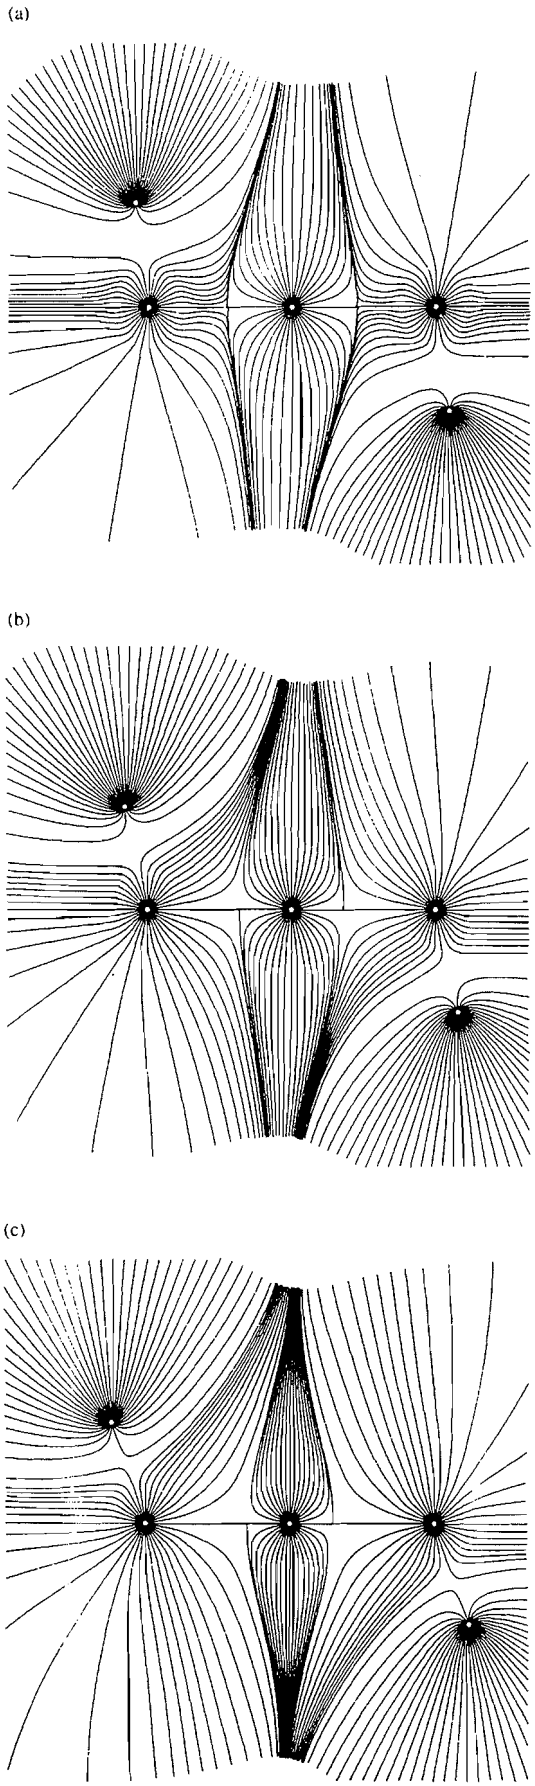

Fig. 3. Gradient vector fields for the (*a*) $[CH_3\text{-}H_t\text{-}CH_3]^+$, (*b*) $[CH_3\text{-}H_t\text{-}CH_3]^{\bullet}$, and (*c*) $[CH_3\text{-}H_t\text{-}CH_3]^-$ transition states of the corresponding systems at the HF level.

the advantage of being consistent with the topological description of the particular electron density distribution.

Comparing first the charges on H_t (q_{Ht}) at the transition states for the three systems, a gradual gain of positive charge is observed in going from the hydride, to the hydrogen, and finally to the proton transfer. However, neither does the hydride acquire an atomic charge of -1 nor does the proton acquire a charge of $+1$. On the contrary, it is found that differences in the electronic nature of the formally transferring H^-, $H^{\bullet}$, and H^+, despite being evident, are very subtle. As deduced from the topological analysis of Table 2, computation of Bader atomic charges on correlated electron density distributions would still lead to a more electronically similar H_t.

On the other hand, comparison of the atomic charges of the six equivalent lateral Hs (q_H) in the transition state leads to the same trend observed in the BCP analysis of Table 2: q_H changes to a less positive value when going from the system representative of hydride transfer to that of proton transfer. As a result, an interesting crossed relationship between each H_t and its lateral H partner is found: while q_H in the $[CH_3\text{-}H_t\text{-}CH_3]^+$ transition state has a value close to q_{Ht} in the $[CH_3\text{-}H_t\text{-}CH_3]^-$ transition state, q_H in the $[CH_3\text{-}H_t\text{-}CH_3]^-$ transition state approaches q_{Ht} in the $[CH_3\text{-}H_t\text{-}CH_3]^+$ transition state.

The atomic charges of H_t, H^l (lateral Hs attached to C^l), and H^r (lateral Hs attached to C^r) at reactant complexes (Table 3) provide a means of characterizing the evolution of each individual atomic charge along the reaction coordinate. This evolution can be visually reproduced by constructing what are called charge migration diagrams, as recently done in an electronic analysis of the hydride transfer in the CH_4/CH_3^+ system (14*b*). Focusing our attention on the transferring H_t, for the H^- in the CH_4/CH_3^+ system, a net gain of negative charge is observed at the HF level when going from the reactant complex to the transition state. For the $H^{\bullet}$ being transferred in the $CH_4/CH_3^{\bullet}$ system a clear accumulation of negative charge is also observed. Finally, a completely opposite evolution is observed for the transferring H^+ in the CH_4/CH_3^- system. In this case, an increase in positive charge is evident.

In Fig. 3 are presented the gradient vector fields for the three systems under study. The diagrams again provide a nice visual means of distinguishing between the hydride (left), hydrogen (center), and proton (right) transfers based upon the spatial extent of each particular H_t atomic basin. This figure clearly exhibits the limits of integration for computing the Bader atomic charges presented in Table 3. These limits were actually revealed when the location of BCPs was described (Table 2). Obviously, the relative size of the atomic basins is directly related to the atomic charges obtained from the Bader atomic charge population analysis (Table 3): the H_t atomic basin is reduced from the formal H^- to H^+ (which translates into a progressive loss of electron density), while the lateral H atomic basins are expanded (which gives a gradual gain of negative charge). Finally, although not reported, the effect of the electron-correlation energy on these maps tends to reduce the perceptible differences between the three H_t atomic basins

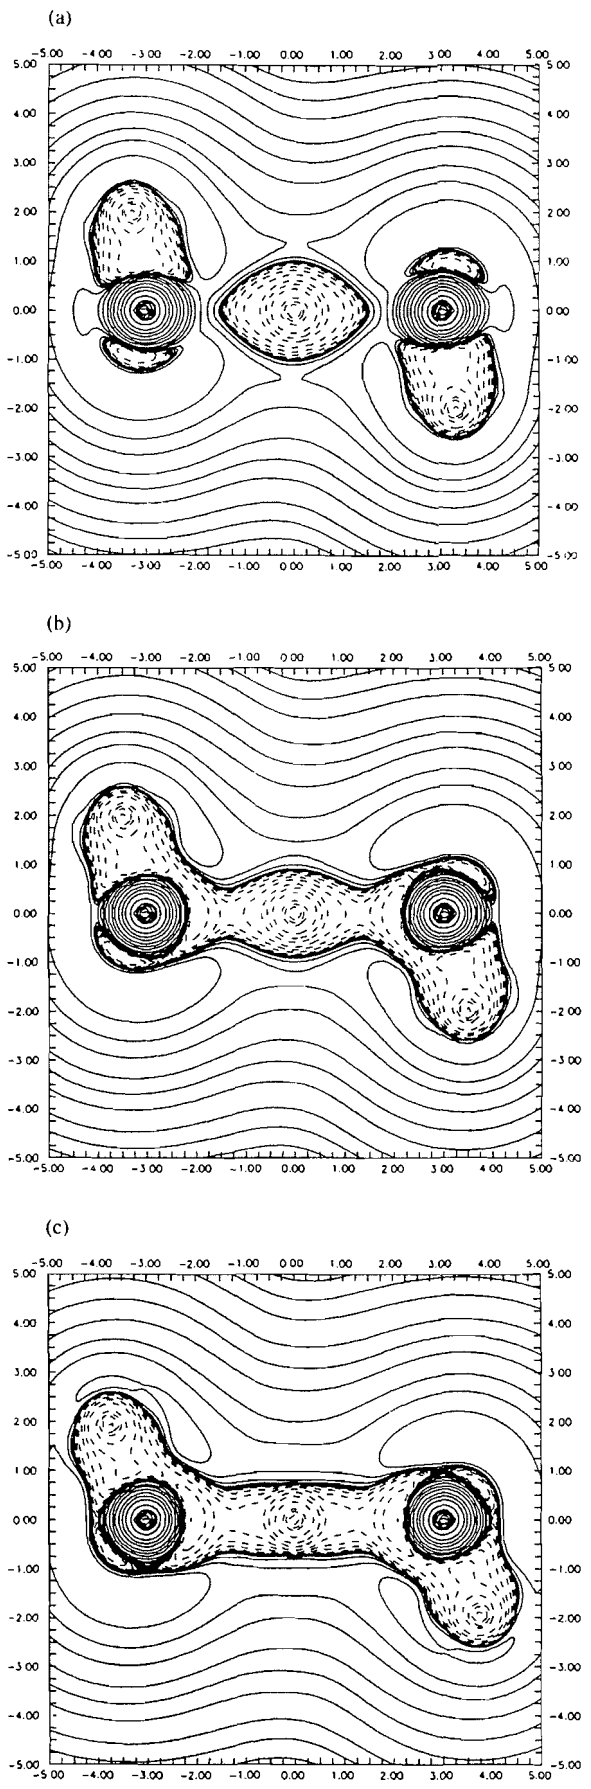

Fig. 4. Laplacian maps for the (*a*) $[CH_3\text{-}H_t\text{-}CH_3]^+$, (*b*) $[CH_3\text{-}H_t\text{-}CH_3]^{\bullet}$, and (*c*) $[CH_3\text{-}H_t\text{-}CH_3]^-$ transition states of the corresponding systems at the HF level. Positive values are represented by solid lines and negative values by broken lines.

(as was already extracted from the topological analysis of Table 2), which merely reflects the widely discussed fact that HF exaggerates the contribution of ionic structures.

A last stage in the topological electronic analysis is accomplished here by presenting the Laplacian maps for the three systems studied (Fig. 4). The usefulness of the Laplacian of the charge density lies in the fact that it exhibits the atomic shell structure and thus can be used as a visual tool to recognize distortions of these shells due to interactions with the neighbouring atomic nuclei. Moreover, its sign also reveals important information on where a local concentration of charge (negative values) or a local depletion of charge (positive values) occurs. On this basis, it is interesting to observe the polarization effect on the *s* shell of formal H^- (left), which appears clearly distorted from its original spherical symmetry, by adopting a football shape due to the interaction with the formal CH_3^+ fragments. The presence of positive Laplacian values between the lines connecting the carbons and the central H^- also gives a hint of the kind of long-range interaction that takes place at the $[CH_3\text{-}H_t\text{-}CH_3]^+$ transition state. Furthermore, the successive addition of one electron into the last system to yield the $[CH_3\text{-}H_t\text{-}CH_3]^{\bullet}$ and $[CH_3\text{-}H_t\text{-}CH_3]^-$ transition states produces an accumulation of charge density on the $C\text{-}H_t\text{-}C$ region that is manifested by the presence of negative Laplacian values all along this region and by the progressively stronger overlapping of the H_t *s* shell with the adjacent carbon shells. Thus, the subtle electronic differences between the three systems become evident from this point of view.

Charge density redistribution analysis

To complete the Bader electronic analysis, which is in widespread use at present, a charge density redistribution analysis is proposed using the methodology developed by Carbó and co-workers (31), briefly outlined in the methodology section.

Table 4 collects the values of the quantum molecular similarity measures (QMSMs) for reactant complexes and transition states together with the Euclidean distances between the two electron density distributions. A recent detailed study on the interpretation of QMSM reveals that this is actually a quantitative measure of the concentration of the electron density (32*e*): the larger the value of the QMSM, the more globally concentrated is the charge density in the molecule. Therefore, comparing QMSM values between reactant complexes and transition states, a general trend is found showing that the electron density is slightly more concentrated for reactant complexes than in transition states, regardless of the level of theory employed to obtain the particular electron densities. This is what, in principle, could be expected from a qualitative point of view, as the H_t migrates from the reactant complex to the transition state.

The result that QMSM values decrease only slightly when going from reactant complexes to transition states is due to the

Table 3. Bader atomic charge populations (q_{Ht}, q_{Hl} and q_{Hr}) for reactant complexes and (q_{Ht} and q_H) transition states at the HF level using the 6-311++G** basis set.

	Reactant complex			Transition state	
System	q_{Ht}	q_{Hl}	q_{Hr}	q_{Ht}	q_H

CH_4/CH_3^-	0.2217	−0.1147	−0.2064	0.3479	−0.1589

Table 4. Quantum molecular similarity measures (QMSM) for reactant complexes and transition states, together with the Euclidean distance between these points at the HF, MP2, and CISD levels using the 6-311++G** basis set.

System	$QMSM_{RC}$	$QMSM_{TS}$	$d_{RC,TS}$
	HF		
CH_4/CH_3^+	63.73463	63.68738	0.3666
$CH_4/CH_3^\cdot$	63.64183	63.54851	0.3563
CH_4/CH_3^-	63.62667	63.52637	0.2001
	MP2		
CH_4/CH_3^+	63.75098	63.69595	0.3158
$CH_4/CH_3^\cdot$	63.68821	63.59139	0.3449
CH_4/CH_3^-	63.68960	63.60923	0.1982
	CISD		
CH_4/CH_3^+	63.75761	63.70567	0.3355
$CH_4/CH_3^\cdot$	63.68628	63.59179	0.3508
CH_4/CH_3^-	63.68534	63.59494	0.2005

fact that the main contribution to the global charge redistribution arises from those few electrons involved in the breaking and forming bonds, i.e., two for H^-, three for $H^\cdot$, and four for H^+ transfer processes. The Euclidean distances provide a quantitative measure of the change undergone by the electron density along the reaction coordinate. The most interesting result is that hydride and hydrogen transfers experience about the same amount of charge density redistribution, while in the proton transfer process this redistribution is noticeably smaller. This is perfectly related to the changes in atomic charges observed from Table 3 and provides a quantitative measure of the fact that the formal hydride and the hydrogen are somehow travelling with a reasonable amount of charge density around them, while the proton leaves part of its initial charge density when moving from the reactant complex to the transition state.

Concluding remarks

This comparative electronic analysis between hydrogen transfers in the CH_4/CH_3^+, $CH_4/CH_3^\cdot$, and CH_4/CH_3^- systems, constrained to a fixed carbon–carbon distance, has clarified, from both qualitative (visual) and quantitative points of view, the subtle differences existing among the electronic natures of the formally termed hydride, hydrogen, and proton entities being transferred. Due to the fact that the chosen distance between carbons is not the natural distance at which the different processes occur, direct extrapolation of the present quantitative results has to be done with some care. However, the overall trends observed in this study are not likely to change qualitatively.

The particular features of each transfer have been revealed by a topological electronic analysis. It has been shown that, from a qualitative point of view, this kind of analysis is able to provide clear visual information by building up the electron density, gradient vector field, and Laplacian maps. Quantitative data can also be obtained by locating and characterizing the bond critical points on the three-dimensional electron density surface and calculating the atomic charges by integration of the electron density inside each atomic basin as delimited by its zero-flux surface. Finally, a charge density redistribution analysis is proposed as a natural extension of the widely established classical Bader electronic analysis.

All analyses have revealed that, although electronic singularities can be identified, differences between the electronic nature of the transferring hydride, hydrogen, and proton appear to be very subtle and rather diffuse in this aspect. In the end, what ultimately determines the formal kind of hydrogen transfer taking place is the a priori knowledge of the number of electrons involved in the breaking and forming bonds. On this basis, a hydrogen transfer involving the rearrangement of two, three, or four electrons can be formally called hydride, hydrogen, or proton transfer, respectively, without the assumption that what is really being transferred is a true hydride, hydrogen, or proton.

Variability of shapes and properties of atoms in molecules: a case study of the carbonyl oxygen

Boris B. Stefanov and Jerzy Cioslowski

Abstract: A comparative study of carbonyl oxygen atoms in diverse molecular environments is presented. The variability of shapes of oxygen atoms is quantified with a newly developed similarity measure that confirms the qualitative conclusions of visual assessment. Electronic properties of these atoms, such as charges, energies, and dipole moments, are computed and their possible correlations with the atomic shapes are studied. Factors that affect atomic shapes are investigated and found to be distinct from those influencing electronic properties of atoms in molecules. The kinetic energies of the atoms under study correlate poorly with the atomic charges. The second-neighbor effects on the atomic energies and charges are approximately additive. Both the theoretical considerations and the numerical results definitively rule out the possibility of the shapes of atomic basins unambiguously determining the properties of atoms in molecules. The consequences of this observation for the recently contemplated approaches to the prediction of electronic properties of large molecules are discussed.

Key words: atoms in molecules, properties of —; similarity of —; transferability of —.

Résumé : On présente les résultats d'une étude comparative des atomes d'oxygène de carbonyles dans divers environnements moléculaires. On a quantifié la variabilité des formes des atomes d'oxygène à l'aide d'une mesure de similarité développée récemment qui confirme les conclusions qualitatives de l'attribution visuelle. On a calculé les propriétés électroniques de ces atomes, telles que les charges, les énergies et les moments dipolaires et on a étudié leurs corrélations possibles avec les formes atomiques et on a trouvé qu'elles sont différentes de celles qui influencent les propriétés électroniques des atomes dans les molécules. La relation entre les énergies cinétiques des atomes examinés et leurs charges atomiques n'est pas bonne. Les effets du deuxième voisin sur les énergies et les charges atomiques sont approximativement additifs. Les considérations théoriques ainsi que les résultats numériques permettent d'éliminer définitivement la possibilité d'utiliser les formes des bassins atomiques pour déterminer sans ambiguïté les propriétés des atomes dans les molécules. On discute des conséquences de cette observation sur les approches contemplées récemment pour prédire les propriétés électroniques de grosses molécules.

Mots clés : atomes dans les molécules, propriétés des; similarités des; transférabilité des.

[Traduit par la rédaction]

Introduction

The introduction of the theory of atoms in molecules (AIM) by Richard W.F. Bader (1) has marked the advent of a new era in modern chemistry. The ability to discern atoms and functional groups within molecules has paved the way for quantitative understanding of chemical concepts. Consequently, properties such as charges and energies of atoms (1, 2), covalent bond orders (3), and electronegativities in situ (4) have been defined in a rigorous manner. Even more importantly, the meaning of fundamental concepts such as chemical bonds (1) and steric crowding (5) has been elucidated.

The process of identifying atoms in molecules commences with topological analysis of the electron density $\rho(\boldsymbol{r})$. In the course of this analysis all critical points at which the electron density gradient $\nabla\rho(\boldsymbol{r})$ vanishes are identified. Local maxima in $\rho(\boldsymbol{r})$ are called attractors, as they constitute the termini to most gradient paths, i.e., lines that are tangent at each point to $\nabla\rho(\boldsymbol{r})$. The attractors usually coincide with the nuclei present in a given molecule, although nonnuclear attractors are occasionally seen (6). The gradient paths that extend between attractors are known as bond paths or, more generally, attractor interaction lines. Each attractor interaction line passes through a bond critical point at which $\nabla\rho(\boldsymbol{r})$ vanishes and the electron density Hessian has two negative eigenvalues.

The Cartesian space $\mathscr{R}^3$ can be divided into disjoint atomic basins ($\{\Omega_A\}$, each containing an attractor and all the gradient paths that terminate at it. An atom in a molecule is defined as the union of a nuclear attractor and its basin (1). The atomic zero-flux surface, which is a boundary of an atom, encompasses all the bond critical points associated with the respective attractor, together with all the gradient paths for

Received October 26, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

B.B. Stefanov and J. Cioslowski.[1] Department of Chemistry and Supercomputer Computations Research Institute, Florida State University, Tallahassee, FL 32306-3006, U.S.A.

which those bond critical points serve as the termini. In other words, the atomic zero-flux surface Π_A is tangent everywhere to $\nabla\rho(\boldsymbol{r})$. One should note that each sheet of a given zero-flux surface is shared by two atoms. This sharing indicates the presence of either chemical bonding (1) or a strong steric repulsion (5) between these atoms.

A one-electron property P_A of an atom A in a molecule is given by the integral of the corresponding property density $\rho_P(\boldsymbol{r})$ over the atomic basin Ω_A

$$[1] \qquad P_A = \int_{\Omega_A} \rho_P(\boldsymbol{r})d\boldsymbol{r}$$

Since $\mathscr{R}^3 \equiv \cup_A \Omega_A$, the sum rule

$$[2] \qquad P = \int \rho_P(\boldsymbol{r})d\boldsymbol{r} = \sum_A P_A$$

is satisfied. The zero-flux property of the atomic boundaries $\{\Pi_A\}$ is a necessary and sufficient condition for the atoms in molecules to satisfy all theorems of quantum mechanics (1). In particular, the atomic virial theorem relates the energy E_A of an atom in a molecule to its kinetic energy T_A by

$$[3] \qquad E_A = -T_A$$

Like their intuitively defined counterparts, functional groups obtained by combining the atoms of Bader's theory are approximately transferable among sufficiently similar molecules. This important property has been empirically verified in a series of recent computational studies. In particular, the approximate transferability of charges and dipole moments (7), molar volumes (8), heats of formation (9), polarizabilities (10), and magnetic susceptibilities (11) of the methyl and methylene groups in normal hydrocarbons has been demonstrated. A method for a theoretical construction of polypeptide molecules from groups of atoms clipped from smaller systems has been proposed (12) on the basis of the observation that electronic properties of the glycil group are approximately transferable among several di- and tripeptides (12). An even bolder approach to the prediction of electronic properties of large systems has been put forward recently.[2] In that approach, large molecules are assembled from atomic fragments taken from a relatively small library of prototype atomic basins (which are extracted from calculations on small chemical species). After docking, the zero-flux surfaces of these prototype, almost-transferable atoms are adjusted to assure their perfect matching. Electronic properties of the adjusted atoms are obtained through semiempirical correlations that, for each prototype atomic basin, relate quantities such as the charge, the multipole moments, and the total energy to the extent of surface adjustment. In turn, electronic properties of the entire molecules are computed by summations over their constituent atoms, eq. [2].

Using the intuitively desirable "building blocks of chemistry" and thus appealing in its simplicity and elegance, the aforementioned method is nevertheless theoretically flawed, as it invokes the assumption that the shape of an atom (or, more precisely, the atomic zero-flux surface Π_A) uniquely determines the electron density within its basin Ω_A and consequently all of its electronic properties (see ref. 1, p. 3). The fallacy of this assumption is readily exposed by the following argument: Let $\rho(\boldsymbol{r})$ be the electron density within a given atomic basin Ω_A, and $\nabla\rho(\boldsymbol{r})$ be the corresponding electron density gradient. $\rho(\boldsymbol{r})$ uniquely determines the atomic zero-flux surface Π_A. Let α be an arbitrary positive constant different from one and $\tilde{\rho}(\boldsymbol{r}) = \alpha\rho(\boldsymbol{r})$ be the electron density within the basin $\Omega_{\tilde{A}}$ of a hypothetical atom $\tilde{A}$. Since the field of $\nabla\tilde{\rho}(\boldsymbol{r})$ is collinear with that of $\nabla\rho(\boldsymbol{r})$,

$$[4] \qquad \Pi_{\tilde{A}} \equiv \Pi_A$$

and

$$\Omega_{\tilde{A}} \equiv \Omega_A$$

At the same time, any one-electron property $P_{\tilde{A}}$ of the hypothetical atom $\tilde{A}$ is related to that of A by

$$[5] \qquad P_{\tilde{A}} = \int_{\Omega_{\tilde{A}}} \tilde{\rho}_P(\boldsymbol{r})d\boldsymbol{r} = \alpha \int_{\Omega_A} \rho_P(\boldsymbol{r})d\boldsymbol{r} = \alpha P_A$$

meaning that atoms with identical zero-flux surfaces and basins can differ in electronic properties. The above result is not surprising considering that the relationship between $\rho(\boldsymbol{r})$ with Ω_A and Π_A corresponds to a noninvertible $\mathscr{R}^3 \rightarrow \mathscr{R}^2$ mapping and therefore is not bijective. One could argue, however, for the possibility of statistically significant correlations between Π_A and P_A of *chemically realizable* atoms A. In this paper, using the example of oxygen atoms in carbonyl compounds, we dispel this notion as well.

Details of calculation

Electronic properties of 21 molecules with the general structure R_1COR_2, where R_1, R_2=H, CH_3, NH_2, Cl, CN, or OH, were calculated at the MP2/6-311G** level of theory with the GAUSSIAN92 (13) suite of programs. All geometries were fully optimized. In cases where several conformers were possible for a given system, the conformer with the lowest energy was selected for the present study. The newly developed variational approach (14) to the determination of atomic surfaces were used, producing properties of atoms in molecules with accuracy exceeding 10^{-4} (au). Calculations of the atomic similarity index (15) were carried out with the recently proposed algorithm (16).

Shapes of oxygen atoms in carbonyl compounds

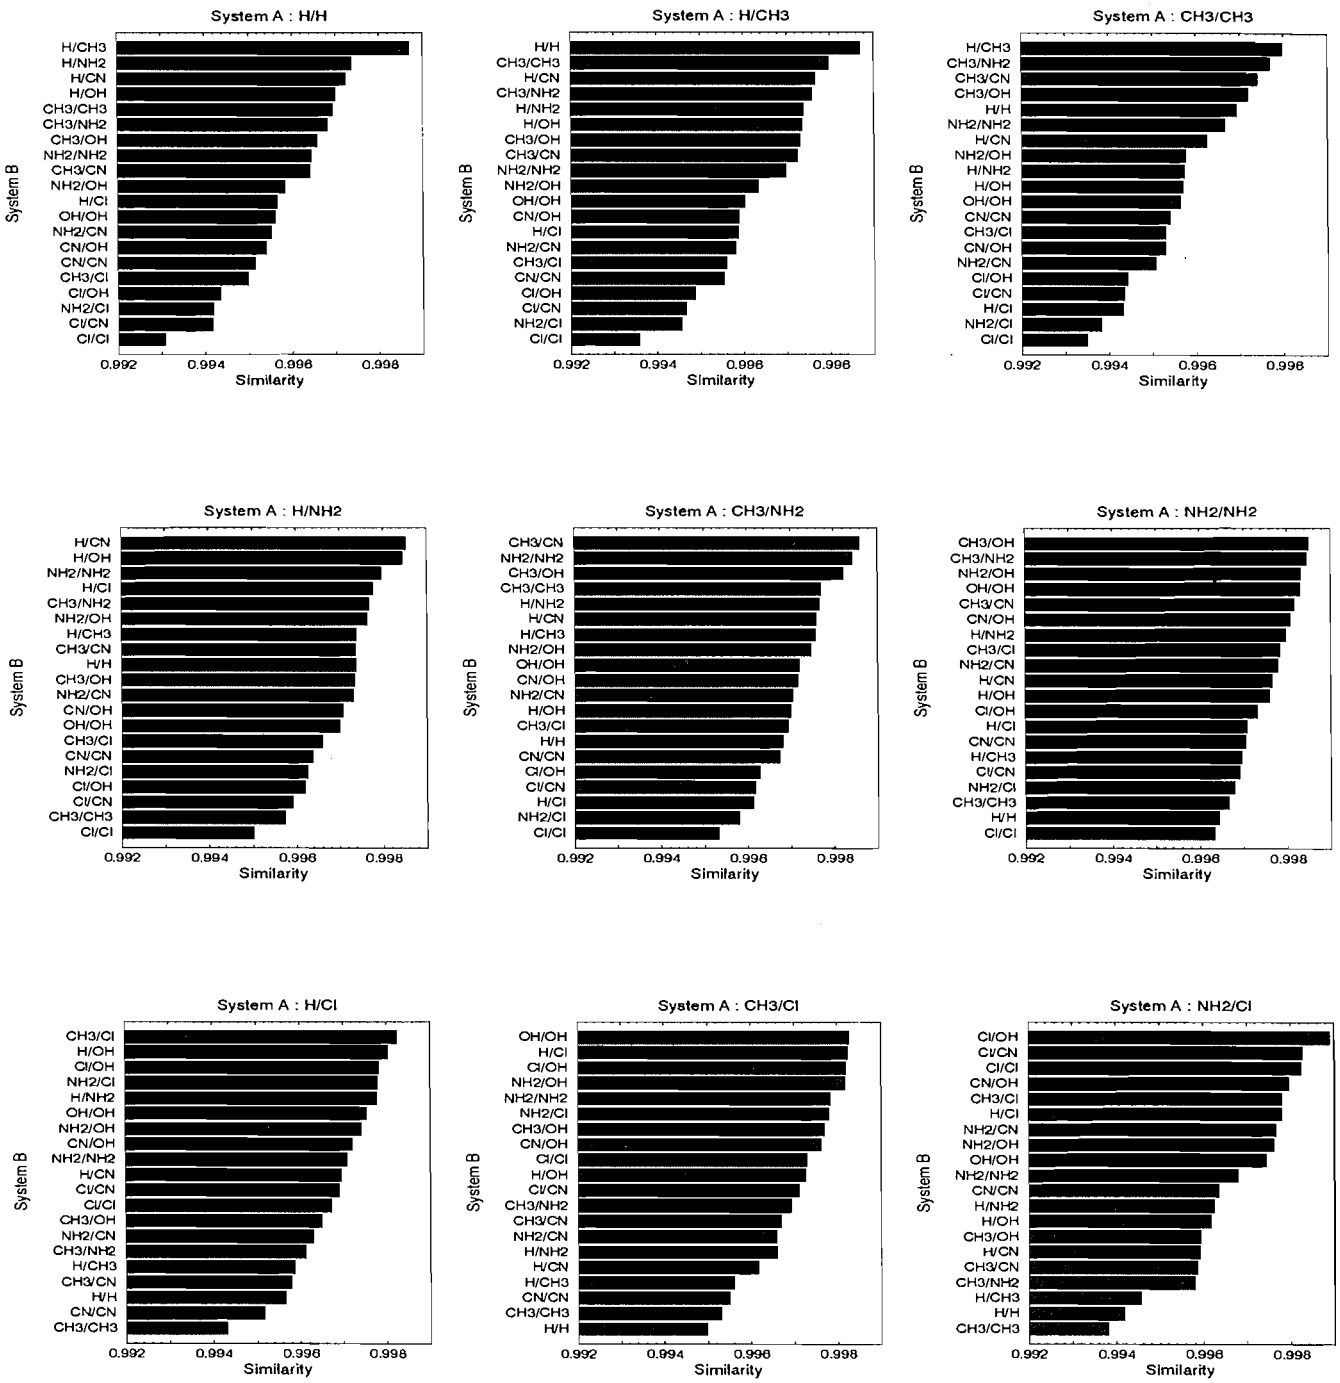
The difference between the shapes of two atoms A and B that are parts of molecules X and Y, respectively, can be readily assessed with the similarity measures $S_{A(X),B(Y)}$ obtained by maximizing the similarity index (15)

$$[6] \qquad S_{A(X),B(Y)} = \left[\frac{\int_{\Omega_{AB}} \rho_X(\boldsymbol{r})d\boldsymbol{r}}{\int_{\Omega_A} \rho_X(\boldsymbol{r})d\boldsymbol{r}}\right]\left[\frac{\int_{\Omega_{AB}} \rho_Y(\boldsymbol{r})d\boldsymbol{r}}{\int_{\Omega_B} \rho_Y(\boldsymbol{r})d\boldsymbol{r}}\right]$$

over all possible angular orientations of A with respect to B. In eq. [6], $\rho_X(\boldsymbol{r})$ and $\rho Y(\boldsymbol{r})$ are the electron densities in X and Y, respectively, and $\Omega_{AB} = \Omega_{BA} = \Omega_A \cap \Omega_B$ is the common

[2] C. Breneman, personal communication.

Fig. 1. Similarities between the carbonyl oxygen atoms in the systems under study. The notation R_1/R_2 is used to represent the molecule R_1COR_2.



part of the atomic basins Ω_A and Ω_B. Such a similarity measure satisfies the inequality

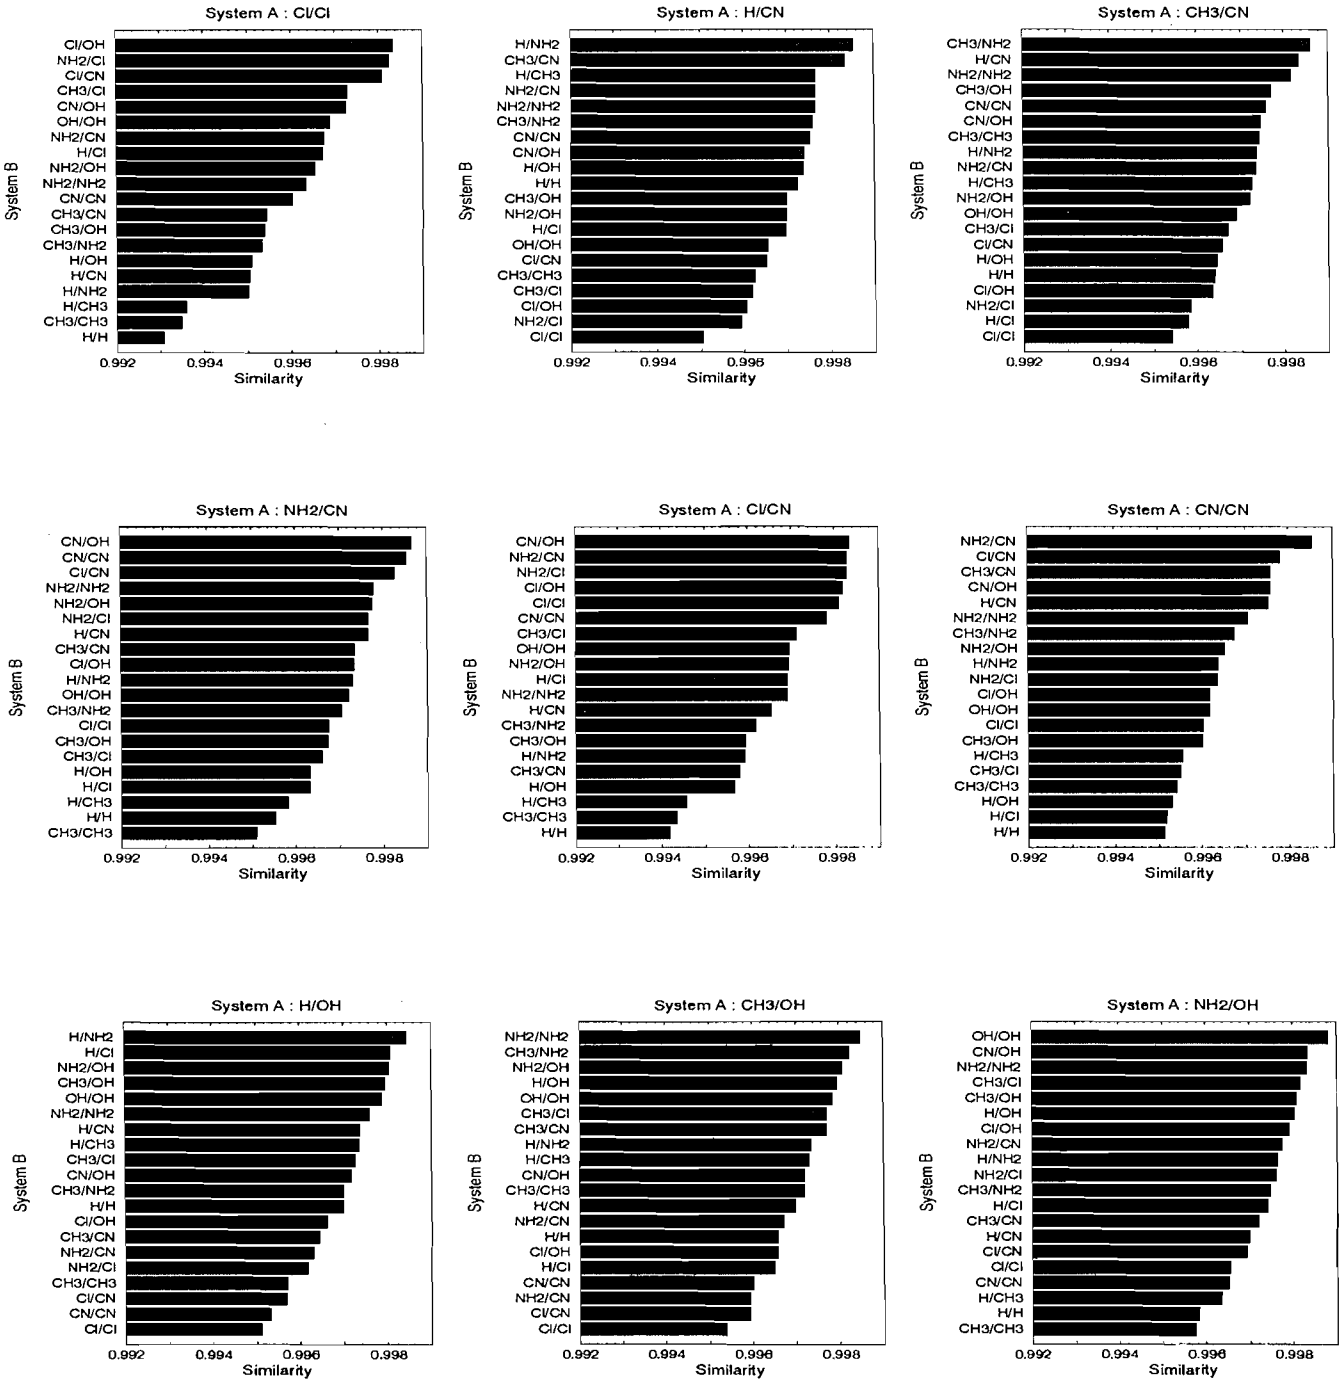
$$[7] \qquad 0 < S_{A(X),B(Y)} \leq 1$$

with the RHS equality attained only for A and B possessing identical shape. The fact that $S_{A(X),B(Y)}$ measures similarity of atomic shapes (rather than similarity of electron densities within atomic basins) is clearly demonstrated by its invariance with respect to linear scaling of $\rho(\boldsymbol{r})$.

It has been shown that the similarities $S_{A(X),B(Y)}$ of formally identical atoms connected to different first neighbors can be as low as 0.6 (15). On the other hand, similarities in excess of 0.99 are often found for pairs of atoms with identical first but different second neighbors. Although the oxygens of the present study represent the latter case, the second-neighbor effects are clearly discernible in the computed values of similarity measure thanks to the excellent numerical accuracy of our calculations.

Inspection of Fig. 1 reveals the lack of sensitivity of the atomic shapes to electronic effects due to substituents on the carbonyl carbon. In other words, these shapes are almost en-

Fig. 1 (*continued*).



tirely determined by steric effects. This phenomenon is well illustrated by the fact that the magnitudes of $S_{A(X),B(Y)}$ are almost identical for the HCHO vs. NH_2CONH_2 and HCHO vs. CH_3COCN pairs (Fig. 1) despite the presence of two electron-donating groups in NH_2CONH_2 and the combination of one weakly donating and one strongly withdrawing group in CH_3COCN. Consequently, in all cases displayed in Fig. 1, the most similar oxygens are found in systems with substituents of comparable sizes (see HCOCN vs. $HCONH_2$, OHCOOH vs. NH_2COOH, ClCOOH vs. NH_2COCl, etc.)

The aforedescribed trends are also observed in the similarity graph (Fig. 2), in which the relation X ← Y denotes the fact that, from among all systems under study other than X itself, Y possesses the carbonyl oxygen most similar to that in X. In the present case, the similarity graph consists of seven disjoint subgraphs. The compatibility of substituents within each of the three classes, namely "small" (H and CH3), "mid-size" (NH_2, CN, and OH), and "large" (Cl), is evident. Visual inspection of the computed zero-flux surfaces leads to the same conclusion. Therefore, one can unequivocally state

Fig. 1 (*concluded*).

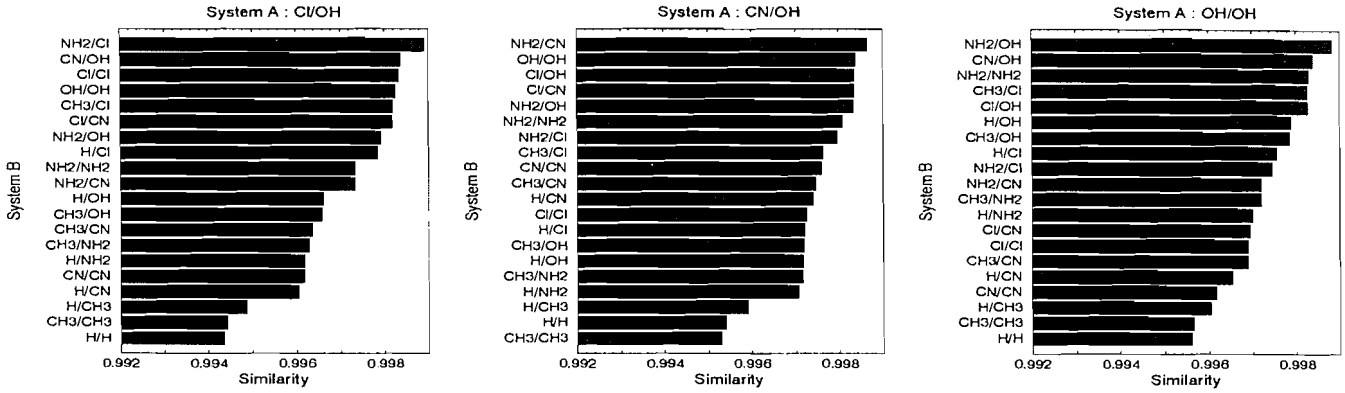


Fig. 2. Relations of maximal similarity between the carbonyl oxygen atoms in the molecules under study. See the text for an explanation of the notation X ← Y.

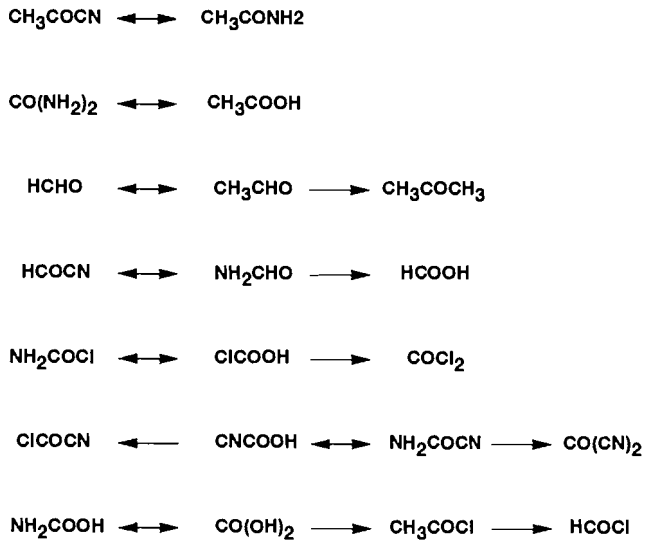
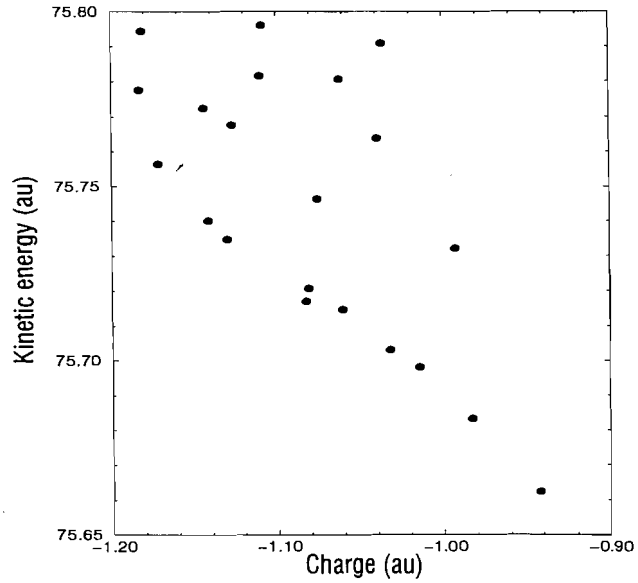


that the shapes of oxygen atoms in carbonyl compounds are determined almost exclusively by the combined bulkiness of their second neighbors, the bulkiness of a given substituent being determined by the magnitude and the spatial extent of its electron density.

Charges, kinetic energies, and dipole moments of the carbonyl oxygens

The calculated charges Q of oxygen atoms span the broad range of -1.18 – -0.94 (Table 1), in agreement with the large variation in Q that has been found in a recent study on carbonyl compounds (17). The electronic effects of the substituents on Q are conspicuous. Compared to hydrogen, OH, NH_2, and, to a lesser extent, CH_3 are electron donating to the oxygen, Cl has almost no effect on the oxygen charge, and CN is strongly electron withdrawing. These trends are in agreement with the commonly accepted signs and magnitudes of the inductive effects elicited by these substituents. The energies of the carbonyl oxygens (equal to the negative kinetic energies T, Table 1) are also markedly influenced by the electronic properties of the substituents. In general, the oxygen atom is destabilized by electron withdrawal. However, the correlation between T and Q is quite poor (Fig. 3).

Fig. 3. The kinetic energy T vs. the charge Q of the carbonyl oxygens in the molecules under study.



The formation of the carbonyl group is accompanied by a longitudinal polarization of the oxygen atom that lifts its spherical symmetry. The resulting atomic dipole moment is dominated by the component μ_z parallel to the CO bond. This component varies by as much as 20% in the series of molecules under study (Table 1). Inspection of Figure 4 reveals the absence of any correlation between the atomic charge and μ_z.

Although the charges and kinetic energies of the oxygen atoms in the R_1COR_2 systems fall between those of the oxygens in R_1COR_1 and R_2COR_2 in almost all instances (the only exceptions being the cases of R_1 = H or OH and R_2 = Cl), they often deviate significantly from the arithmetic averages of the properties pertinent to the symmetrically substituted compounds (Fig. 5). The slopes of the T vs. Q plots for the individual R_1COR_2, R_1COR_1, R_2COR_2 triads are highly variable. In other words, the effects of the second neighbors on the properties of the carbonyl oxygen atom are approximately additive, but the individual contributions of the substituents to Q and T appear to be totally uncorrelated.

Conclusions

The main conclusion of the present study is that the factors that influence shapes of atoms in molecules are distinct from those that determine their electronic properties. The shapes of atoms in molecules (as quantified by the atomic similarity measure) are affected predominantly by the sizes of their neighbors. The electronic properties of the second neighbors, such as their propensity toward electron donation or withdrawal, appear to be irrelevant in this case. Conversely, charges of atoms in molecules correlate well with the ability of the second neighbors to withdraw or donate electrons.

Several of the trends observed for the carbonyl oxygen are expected to carry over to other atoms. In general, atoms with more negative charges tend to possess lower energies, but the correlation is rather poor. *There is no correlation whatsoever between the shapes and the electronic properties of atoms in molecules.* Although the influences of the second neighbors on the electronic properties of a given type of atom are approximately additive, the additivity is far from being quantitative. There appears to be no correlation between the individual contributions of the second neighbors to the atomic charge and the respective contributions to the atomic kinetic energy.

Our study unequivocally demonstrates that any approach to the calculation of electronic properties of molecules that is based solely on docking of atoms or molecular fragments followed by the adjustment of their zero-flux surfaces is bound to fail. This is so because the knowledge of these surfaces alone is *insufficient* for the determination of properties of atoms (or fragments) in molecules. On the other hand, one can envision formalisms that would successfully predict electronic properties of molecules by employing approximately transferable electron densities taken from a limited number of standard types of atomic basins. However, in such approaches the atomic surfaces would be derived from the adjusted electron densities and thus would play only a secondary role. To reiterate, the electron densities within atomic basins unambiguously determine the shapes of atoms in molecules. The converse is not true from both theoretical and practical standpoints.

Fig. 5. The kinetic energy T vs. the charge Q of the carbonyl oxygens in the triads R_1COR_1 (●), R_2COR_2, (●), and R_1COR_2 (○). See Fig. 1 for the notation used for the individual systems. The points corresponding to the arithmetic average of the properties of the symmetric species are denoted by asterisks.

Charge and energy redistribution in sulfonamides undergoing conformational changes. Hybridization as a controlling influence over conformer stability

Curt M. Breneman and Lawrence W. Weber

Abstract: The redistribution of charge and electronic kinetic energy was studied during rotation about the S—N bonds of sulfonamide and fluorosulfonamide. The rotational potentials and electronic topological features of both compounds were evaluated at the HF/6-31G* level of theory and their electron densities partitioned into atomic contributions using FASTINT, an updated version of the PROAIM program. The results indicate that the stability of each rotamer is strongly dependent upon the hybridization of the sulfonamide nitrogen. The hybridization of the nitrogen was determined by examination of the positions and magnitudes of the electrostatic and Laplacian minima in the nonbonded region of the sulfonamide nitrogen atom. Independent assessments of hybridization were made using nitrogen pyramidalization altitudes. The rotational barriers in these compounds were found to arise mainly from energetic penalties resulting from adding electrons to already electron-rich sulfonyl oxygens while removing electron density from other more electronegative atoms. The fluorine-substituted analogue provided an example in which the sulfur and oxygen atoms were much less electron rich, causing an enhancement of the nitrogen rehybridization effects. The extent of covalent bonding between pertinent pairs of atoms in sulfonamide and fluorosulfonamide was assessed throughout the rotational pathway using the BONDER program. In contrast with much existing dogma, all of these findings were consistent with the same general model of charge and energy flow that has been shown to determine the internal rotational barriers in amides.

Key words: sulfonamide, electron density analysis, rotational barrier, hybridization, atoms-in-molecules calculations.

Résumé : On a examiné la redistribution de charge et d'énergie cinétique électronique accompagnant les rotations autour de liaisons S—N des sulfonamide et fluorosulfonamide. On a évalué les potentiels rotationnels et les caractéristiques topologiques électroniques des deux composés au niveau HF/6-31G* de la théorie et on a effectué une répartition des densités électroniques en contributions atomiques, en utilisant FASTINT, une version améliorée du programme PROAIM. Les résultats indiquent que la stabilité de chaque rotamère dépend beaucoup de l'hybridation de l'azote du sulfonamide. L'hybridation de l'azote a été déterminée par l'examen des positions et des amplitudes des minima électrostatiques et des laplaciens dans la région non liée de l'atome d'azote du sulfonamide. Des évaluations indépendantes de l'hybridation ont été faites en faisant appel aux altitudes de la pyramidalisation de l'azote. On a trouvé que les barrières rotationnelles de ces composés proviennent principalement des pénalités énergétiques qui résultent d'additions d'électrons aux atomes d'oxygènes du sulfonyle déjà riche en électrons accompagnées d'une diminution de la densité électronique d'autres atomes plus électronégatifs. L'analogue portant un atome de fluor est un exemple dans lequel les atomes de soufre et d'oxygène sont beaucoup moins riches en électrons; ceci provoque une augmentation des effets de réhybridation de l'azote. Le degré de liaison covalente entre les paires appropriées d'atomes du sulfonamide et du fluorosulfonamide a été évalué sur l'ensemble de la voie réactionnelle en faisant appel au programme BONDER. Malgré tous les dogmes existants, toutes ces observations sont en accord avec le modèle général d'écoulement de la charge et de l'énergie qui prévaut dans la détermination des barrières rotationnelles internes dans les amides.

Until the advent of the Atoms in Molecules (AIM) electron density partitioning technique (1), it had been difficult to identify and separate the underlying factors responsible for the relative stabilities of different molecular conformations. Most current models of molecular stability are based either upon stereoelectronic factors, as in the anomeric effect, or on a mixture of steric effects, field effects, inductive effects, and "resonance" effects. Work in our laboratory and those of others has shown that it is often more useful to observe changes in the ab initio molecular electron density distributions of molecules undergoing conformational changes. The results of such electron density analyses have even more predictive power when the torsionally induced electron density flow is examined on an atom by atom basis. The interatomic kinetic energy density flow that governs the conformational preferences of amides has been elucidated in this manner (2). Since it is often difficult and sometimes impossible to get good experimental electron density distribution data for a desired set of molecular conformations, such data are often obtained through HF/6-31G* ab initio calculations. Direct analysis of intramolecular molecular electron density flow is one technique in which it matters little whether the electron density information came from high-quality X-ray results[2] or from good ab initio quantum mechanical calculations. This progress is indicative of the large changes that have taken place in the field of molecular modeling in the past few years. Until recently, molecular orbital models were mostly used to formulate qualitative interpretations of experimental results, and often found their greatest uses as conceptual tools (4). The current computational environment has made it possible to determine ab initio accurate electron densities for medium-sized molecules in a reasonable amount of time. This flexibility has allowed chemists to make the necessary improvements to go beyond the orbital picture, providing in many cases reliable and comprehensive chemical information independent of experiment.

One application in which modern theoretical methods excel is that of reexamining unusual bonding situations. One such bond type that has received a considerable amount of recent attention is that of hypervalent bonding in oxidized sulfur-containing compounds (5). As a result of this interest, several groups have attempted to probe the phenomenon of hypervalent bonding and its sensitivity to structural perturbations. One fundamental question that was addressed by Reed and Schleyer (5) concerns whether *d*-orbital participation involves dsp^3 or d^2sp^3 hybridization, or if "negative hyperconjugation" is a better description of the bonding situation. From the results of that work, Schleyer was able to conclude that the "negative hyperconjugation" model provided the superior description of hypervalent bonding. An even more satisfying explanation is available through the use of AIM charge and energy flow analysis. The basis of this model of stability is that charge will flow from one atomic basin and into another in response to geometric changes that provide a means for rehybridization of the atoms involved and an energetic motivation for such charge flow. This means that in any conformation, atomic electron populations and their associated kinetic energies shift from one atom to another in such a way that the energy of the whole molecule is lowered. This is actually restatement of the Variational Principle, but it is usually not applied with respect to individual atoms in molecules. In the case of a simple amide, alignment of the nitrogen "lone pair" region with the carbonyl π-system allows a small amount of high-energy electron density to be passed from the nitrogen to the carbonyl group; this shift of <0.1 electron is enough to lower the electron repulsion within the nitrogen lone pair sufficiently to allow sp^2 rehybridization to take place. The consequent nitrogen hybridization causes a much larger electron withdrawal through the C—N σ-bond. For this reason, the amide nitrogen has a greater electron population (and integrated electronic kinetic energy) in the planar conformation than in either of the rotational transition states. The electron density gained by the nitrogen originates principally from the carbonyl carbon. In that investigation, it was determined that the electron density transferred to the nitrogen resulted in a 150 kcal/mol stabilization of that atom at the cost of 132 kcal/mol of destabilization of the rest of the molecule, 120 kcal of which came at the expense of the carbonyl carbon. The difference between 150 and 132 (18 kcal/mol) corresponds to the rotational barrier of formamide. Within the AIM paradigm, atomic volume definition is unique and discrete boundaries can be identified between atoms. When this interatomic surface moves in response to changes in the charge density distribution of the molecule, individual atomic populations and energies change (2). This accounts for the fact that while the charge distributions implied by examining the various canonical forms from resonance theory have come under serious scrutiny (6), many predictions made using that model are still sound. Indeed, if only electrostatic potential-derived monopoles are considered to represent "atomic charges," the resonance model for charge distributions generally holds true. This so-called external view of a molecular charge distribution (2) remains a beneficial educational tool that is still useful for describing qualitative effects. To get a full description of the electron density and electronic kinetic energy distribution throughout a molecule, however, an electronic topological approach such as Bader's Theory of Atoms in Molecules (7) must be applied.

Methods

SCF (8) calculations were performed either on a Vaxcluster running an early VMS version of the GAUSSIAN-90 (9) package or on a SUN 4/330 workstation running a later UNIX version of GAUSSIAN-90 (10). Numerical integrations were performed on either the SUN 4/330 workstation or an IBM RS/6000 320h workstation. In this work, a set of rotationally constrained structures were optimized by the Berny method at the HF/6-31G* (11) level of theory.[3] Checkpoint files generated by GAUSSIAN-90 were then used by the psichk90[4] program to obtain wave function files compatible with PROAIM and FASTINT.

The PROAIM program developed by Bader and co-workers (7) formed the basis for our locally developed code FASTINT.[5] The FASTINT program has more realistic distance and integral

[2] Experimental electron densities can be observed by low-temperature wide-angle scattering X-ray analysis, a rather tedious procedure; also, for an electron diffraction investigation, see ref. 3.

[3] The choice of contracted Gaussian basis sets for molecular calculations has been reviewed by Ahlrichs and Taylor (12).

cutoffs than the original PROAIM program and calculates fewer properties, but this combination of modifications allows the calculation of numerous atomic properties of the electron density within atomic basins up to 40 times faster than the original PROAIM code. Since both PROAIM and FASTINT utilize the same basic theory, which has been extensively treated in the literature, only an overview of the method is presented here.

It is important to emphasize that the key to molecular partitioning lies in the requirement that the resulting atomic pieces be valid quantum subsystems. A valid quantum subsystem is defined as a fragment of a larger system that behaves as a separate entity, and gives unique values for all of the operators associated with the larger system. In an atomic quantum subsystem, these values would be quantities like electronic kinetic energy, electron population, electric multipole moments, and electrostatic potentials. Quantum subsystems are said to be valid if the electron density within each separate atomic volume independently obeys the Virial Theorem ($-V/T = 2$, where V is potential energy and T is kinetic energy). For this condition to be met, the atomic fragments must be bound by surfaces of zero net flux in electron density (ρ), and contain an attractor (a nucleus). In the general sense, a zero-flux surface defines a region of space where the net flux of electron density normal to the surface is zero. A more practical definition states that the flux of electron density normal to such a surface is zero at all points on that surface. This can be summarized by the expression $\nabla\rho \cdot N = 0$, where N is the surface normal vector.

Determination of an atomic zero-flux surface begins with mapping the electronic topology of the molecule. Electronic topology mapping involves finding all of the stationary (critical) points in ρ, and identifying them according to their signatures. A critical point[6] signature is defined as the number of negative curvatures minus the number of positive curvatures in ρ at that stationary point. For generality, a prefix of "3" designates the dimensionality of the problem. Consequently, atomic nuclei are (3, 3) critical points, bond critical points have (3, −1) signatures, ring critical points have (3,1) signatures, and cage critical points have (3,−3) signatures. With the exception of (3,3) nuclear critical points, all of the other critical points exist on interatomic zero-flux surfaces. Interatomic surface definition routines make use of the fact that (3,−1) (bond) critical points represent local maxima of electron density on each interatomic surface. Consequently, all points on the path followed by a steepest descent walk originating in any direction perpendicular to the bond path are on an interatomic zero-flux surface. Both Bader's original PROAIM program (7) and our later FASTINT program[5] make use of this kind of surface definition. Once defined, the zero-flux surfaces provide boundaries for integration of the electron density properties of each separate atom within a molecule.

After partitioning of a particular molecular electron density distribution has taken place, the atomic overlap matrices for each atom could be used to calculate covalent bond orders using the recently introduced BONDER (13) program. Calculation of these covalent bond orders involves the following steps:

1. Evaluation of the atomic overlap matrices

$$[1] \quad \langle\phi_i|\phi_j\rangle_A = \int_{\xi_A} \phi_i^*(\boldsymbol{r})\phi_j(\boldsymbol{r})\, d\boldsymbol{r}, \qquad 1 \le i,j \le N$$

where $\{\phi_i,\ 1 \le i \le N\}$ are the occupied Hartree–Fock spin-orbitals, N is the number of electrons, and ξ_A is the atomic basin of the atom A.

2. Determination of localized spin-orbitals, $\{\phi_i,\ 1 \le i \le N\}$, which are related to the Hartree–Fock spin-orbitals through a unitary transformation C.

$$[2] \quad \varphi_i = \sum_{j=1}^{N} C_{ij}\phi_j, \qquad 1 \le i \le N$$

and maximization of the localization sum, eq. [3]

$$[3] \quad L = \sum_{i=1}^{N}\sum_{A} \langle\varphi_i|\varphi_i\rangle_A^2$$

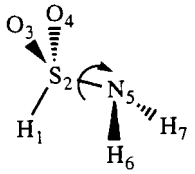
3. Calculation of the covalent bond orders, eq. [4]

$$[4] \quad P_{AB} = 2\sum_{i=1}^{N} \langle\varphi_i|\varphi_i\rangle_A\langle\varphi_i|\varphi_i\rangle_B$$

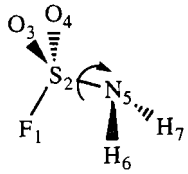
A combination of FASTINT and BONDER techniques can be used to give atomic populations and energies, as well as the covalent bond order between two atoms. Taken together with the values of ρ, $\nabla^2\rho$, and electrostatic potentials in crucial regions of space, we are able to arrive at a set of conclusions concerning the factors that control rotational preferences in conformationally flexible molecules.

Results and discussion

Exhaustive examination of the electron density distributions around the sulfur and amino groups of sulfonamide and fluorosulfonamide were performed at 10° increments of rotation about each S—N bond, as defined by the H6-N5-S2-H1(F1) dihedral angle as well as at each minimum and at both nitrogen inversion and N-H rotational transition states.



Sulfonamide



Fluorosulfonamide

The results show that the mechanism of conformer stabilization in sulfonamides is very similar to that reported earlier for amides (6), in which stabilization of the amide nitrogen was found to occur through σ withdrawal of electron density from an adjacent polarized atom. In the case of an amide, this atom is the carbonyl carbon. Such a result is not without controversy, however. Catalan and co-workers (14) reported that there is no similarity between amide and sulfonamide bonding. Catalan has also stated that the hybridization of the amino nitrogen in sulfonamide should have very little effect on the total energy of the sulfonamide system. In an effort to address

[6] As defined by the two negative curvatures and the single positive curvature, which is aligned along the bond path.

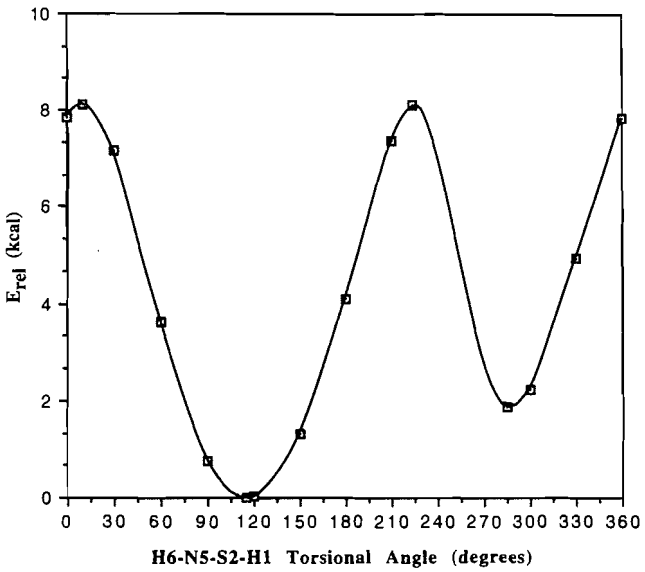

Fig. 2. Fluorosulfonamide rotational potential vs. torsional angle.

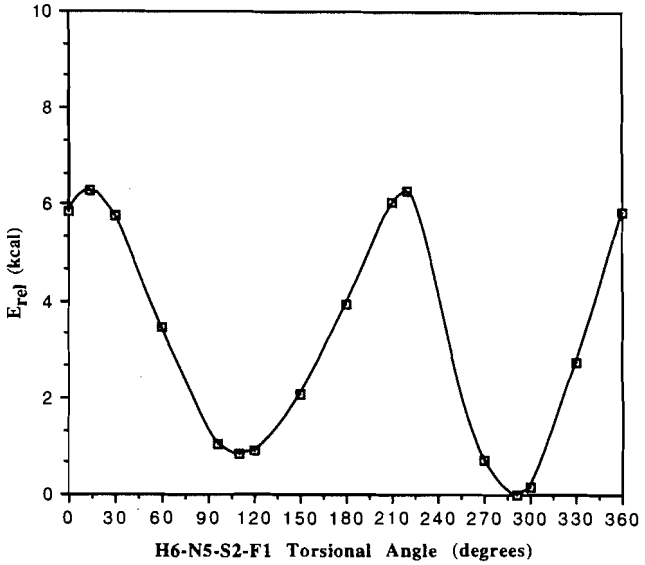

these points, ab initio calculations and electron density distribution analyses (2) were performed on both sulfonamide and fluorosulfonamide. The introduction of fluorine into the system allowed us to alter the normal electron populations of the sulfur and oxygens and to observe the effects on each atom during sulfur–nitrogen bond rotation. Prior to evaluating the interatomic charge flow data, the relative energies of each conformer were examined and the geometric stationary points were characterized. The rotational potentials shown in Figs. 1 and 2 were found to be quite similar in shape for sulfonamide and fluorosulfonamide. The important difference between the two curves is that the geometries at which the molecules reach their global and relative minima are reversed. The relative minimum of sulfonamide occurs at an H-N-S-H dihedral angle 285° while the global minimum occurs at 115°. In fluorosulfonamide, the relative minimum occurs at the corresponding H-N-S-F dihedral of 110° while the global minimum occurs at 291°. This means that sulfonamide is most stable when its

Fig. 3. Sulfonamide relative population by atom vs. torsional angle.

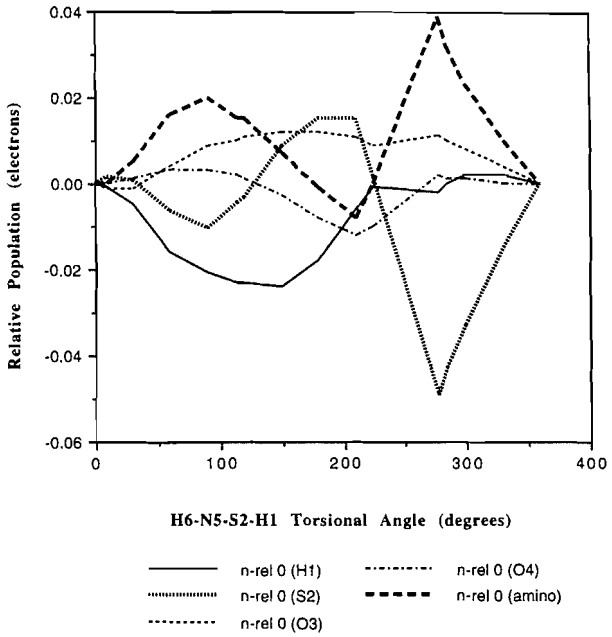

Fig. 4. Fluorosulfonamide relative population by atom vs. torsional angle.

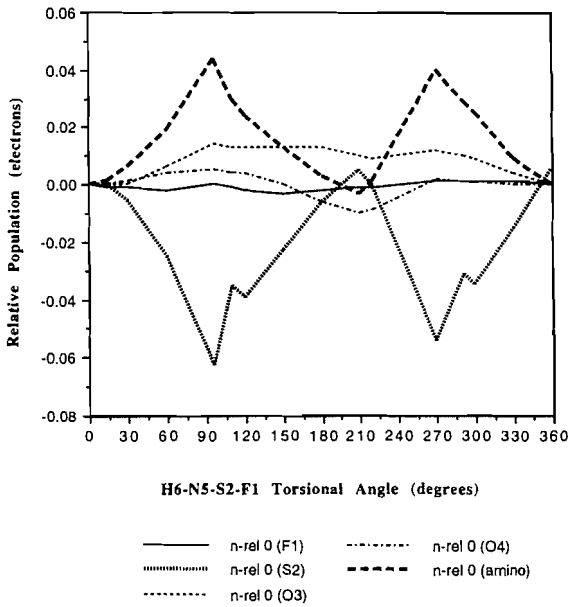

nitrogen lone pair is *syn* to the sulfur–hydrogen bond. The substitution of a fluorine atom for the hydrogen in fluorosulfonamide causes the global and relative minima to reverse in energy ordering. In this case, the molecule is most stable when the nitrogen lone pair is *trans* to the sulfur–fluorine bond. It is also important to note that the minima in both sulfonamide and fluorosulfonamide are very near their respective amino nitrogen inversion transition states, indicating a propensity for planarization of the nitrogen.

Upon examination of the FASTINT atomic integration results, an obvious intramolecular charge shift trend was observed. The data shown in Figs. 3 and 4 show a charge shift taking place between the sulfur and the amino group at geometries corresponding to both minima in fluorosulfonamide and the

Fig. 5. Sulfonamide relative energy by atom vs. torsional angle.

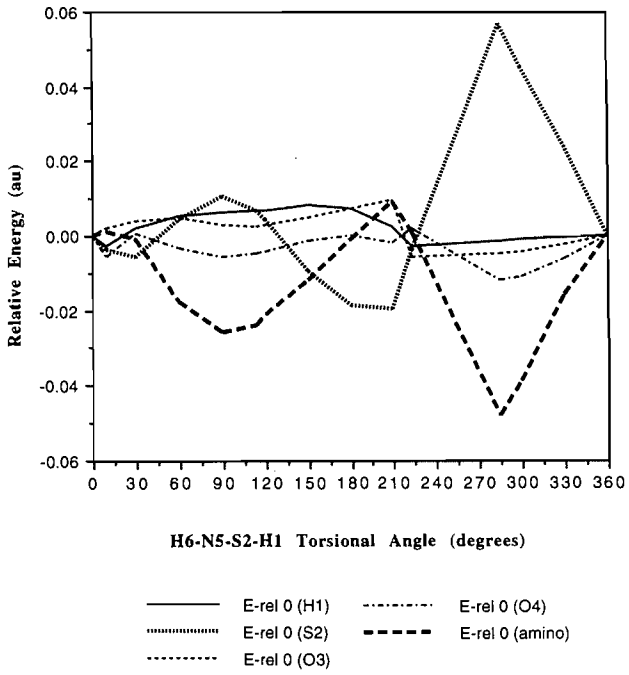

Fig. 6. Fluorosulfonamide relative energy by atom vs. torsional angle.

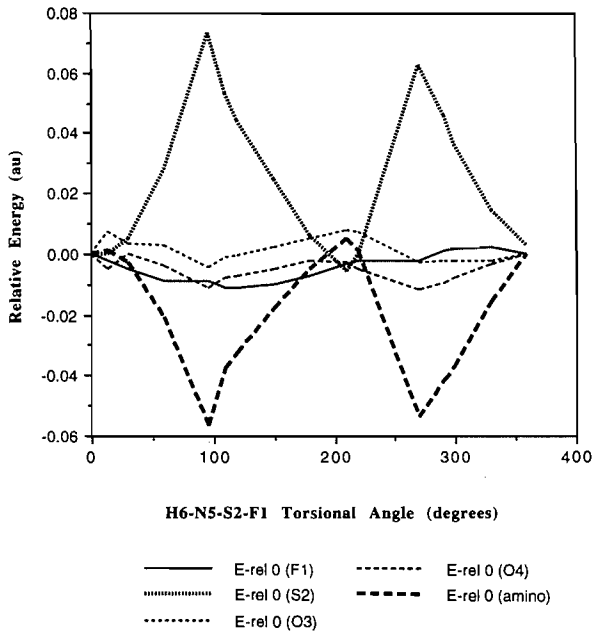

relative minimum in sulfonamide. At these geometries, the amino group is observed to gain electron population, while the sulfur population is depleted by a similar amount. The other atoms within the molecules show little change when compared to the sulfur and nitrogen. A less clear charge redistribution occurs at the conformer that corresponds to the sulfonamide global minimum conformation.

The relative energy by atom curves shown in Figs. 5 and 6 illustrates the electronic kinetic energy flow that comes about as a result of charge redistribution in Figs. 3 and 4. It is important to note that the kinetic energy flow closely follows the

Fig. 7. Sulfonamide total energy and amino group energy vs. torsional angle.

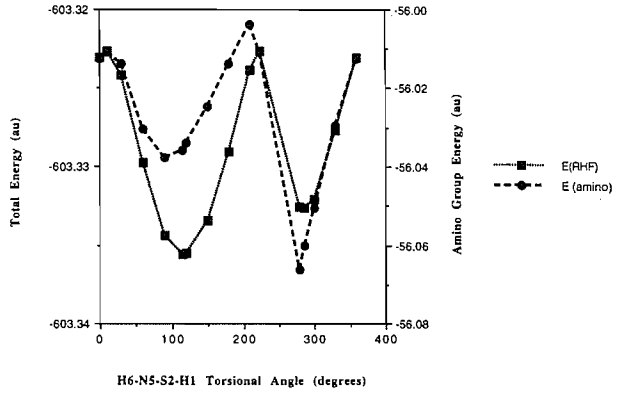

Fig. 8. Fluorosulfonamide total energy and group energy vs. torsional angle.

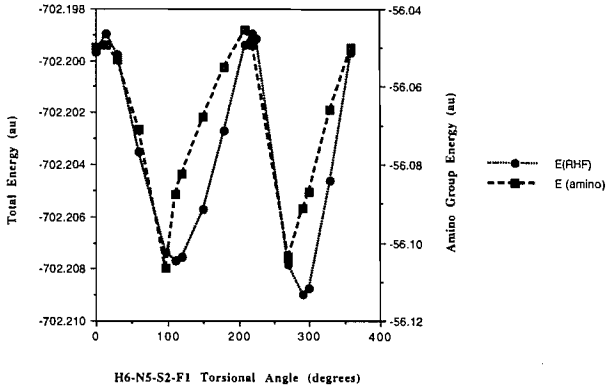

charge flow from atom to atom during S—N bond rotation. The charge and energy transfer interactions are mainly taking place between the sulfur and amino groups, with the amino group reaching a minimum in energy while the sulfur is reaching a maximum in energy. The maximum charge and energy transfer is observed near the minimum energy structures of both molecules. This is to be expected, because motion of electrons from a less electronegative atom (S) to a more electronegative atom (N) is favorable for the whole molecule as the amino group approaches planarity.

The pronounced sulfur–nitrogen interactions shown in Figs. 3–6 led us to focus our attention directly on the sulfur atoms and the amino groups. The data in Table 1 were used to directly compare the relative electronegativities of the sulfur atom and the amino group within sulfonamide and fluorosulfonamide during sulfur–nitrogen bond rotation. Since this definition of electronegativity describes how efficiently an atom or an atomic fragment stabilizes electron density, the slope of a line on an energy vs. electron population plot should give a relative electronegativity of the atom or atomic fragment. When the relative sulfur and amino group energies were analyzed with respect to their relative electron populations, the best-fit least-squares slopes showed that the amino group was 1.08 and 1.16 times more electronegative than the sulfur atom in sulfonamide and fluorosulfonamide, respectively (R^2 > 0.999 in each case). Therefore, for a given amount of electron density transferred, the amino group would gain 8–16% more stability than was lost by the sulfur.

This electronegativity difference suggests that the rotationally induced changes in the amino group and sulfur energies in sulfonamide and fluorosulfonamide should be examined in greater detail. Figures 7 and 8 show that the amino groups become more stable at those geometries where both sulfonamide and fluorosulfonamide are most stable. Additionally, the data in Table 1 show that the sulfur energy varies in the opposite way at those same conformations. Thus, there is evidence that sulfur destabilization is occurring in unison with the stabilization of the amino group. If relative electronegativity changes are affecting the stabilization of the amino group and the destabilization of the sulfur, then the bond connecting them is the most likely place to look for changes.

The data in Tables 2 and 5 clearly show that the sulfur–nitrogen bond gets shorter when both sulfonamide and fluorosulfonamide are in their most stable geometries. This bond length contraction implies that the bond is increasing in *s* character as the amino group becomes sp^2 hybridized. It is also important to note that for all conformers, the nitrogen–sulfur bond length in fluorosulfonamide is shorter than in sulfonamide. Additional geometric data are shown in Tables 3, 4, and 6.

The last column in Table 1 shows that the amino group altitude decreases as the group approaches planarity at the most stable geometries of both sulfonamide and fluorosulfonamide. At these geometries, (*i*) the amino group gains electron population while the sulfur atom loses electron population; (*ii*) the amino group becomes more stable while the sulfur atom becomes less stable; (*iii*) the sulfur-nitrogen bond shortens, and (*iv*) the amino group is most planar. These observations point to the conclusion that nitrogen rehybridization to a more nearly sp^2 structure increases its electronegativity and gains overall stability for the molecule.

Further study of the amino nitrogens revealed additional important information. The local minima in the Laplacian ($\nabla^2\rho$) and electrostatic potential were located in the "lone pair region" of space of the nitrogen by using a gradient search procedure. It can be seen in Table 1 that the nitrogen lone pair Laplacian and electrostatic potential minima approach a maximum value (least negative) at geometries where both sulfona-

mide and fluorosulfonamide are most stable. The positions of these maxima imply that nitrogen lone pairs exhibit the least "amine" character and thus are least basic at those geometries. These results also imply that the nitrogen lone pair has become more "*p*"-like and very slightly delocalized. One interpretation of these observations is that the delocalization of a small amount of π electron density allows the more electronegative amino group to withdraw a large amount of σ electron density from the less electronegative sulfur thereby increasing the amino group's overall electron population. This results in rehybridization of the amino nitrogen from sp^3 to nearly sp^2, thus increasing the *s* character of the sulfur–nitrogen bond. The amino group therefore becomes more planar and consequently more stable. The sulfur, having lost electron population, would be destabilized to a lesser degree, causing the molecule to become more stable overall.

This leaves but one question: Where did the small amount of delocalized nitrogen lone pair density go? The S—F bond length data given in Table 5 show that in fluorosulfonamide, the nitrogen lone pair could possibly have been partially donated into the sulfur–fluorine bond. This hypothesis is supported by the fact that in the global minimum structure, the sulfur–fluorine bond is favorably oriented with respect to the nitrogen lone pair to allow delocalization of the lone pair into the S—F antibonding orbital. This donation of nonbonded electron density would account for the observed increase of the S—F bond length. In sulfonamide, however, we do not see the corresponding S—H bond-elongation effect to such a large extent. Sulfonamide is most stable when its nitrogen lone pair is *syn* to the sulfur–hydrogen bond but *anti* to the vector sum of the sulfonamide S—O bonds. It is reasonable to postulate that the global minimum in sulfonamide may be controlled by the best electron sink available for the amino lone pair electrons. Since fluorine is more electronegative than oxygen, we can conclude that the fluorine is acting as a more efficient electron sink in fluorosulfonamide than the two oxygens are in sulfonamide. The effect of this sink is also revealed in the barrier to rotation in fluorosulfonamide. Figures 1 and 2 show that the fluorine substitution in fluorosulfonamide causes the nitrogen to undergo greater changes in hybridization and

energy than sulfonamide. The cause of this phenomenon is also seen in the sulfur–nitrogen bond lengths in Tables 2 and 5. The fact that the sulfur–nitrogen bond lengths are shorter for all conformers when compared to sulfonamide suggests that the more electronegative nitrogen underwent a greater degree of rehybridization in fluorosulfonamide than in similar geometries for sulfonamide. In sulfonamide, the two S—O bonds are not a good electron acceptor since the energy of its σ* nonbonding orbital is higher than that of the S—O and S—F bonds in fluorosulfonamide. Consequently, in fluorosulfonamide, donation of electron density into the sulfur–fluorine bond is more favorable, thus allowing the nitrogen to rehybridize more than the nitrogen in sulfonamide.

For this new model of sulfonamide stability to be valid, it must be able to reconcile Catalan's (14) recent results, which state that the hybridization of the amino nitrogen does not appear to be important to the total energy of the system. He reported testing this idea by looking at the extreme examples of totally sp^2 hybridized vs. totally sp^3 hybridized nitrogen atoms during the rotation about the S—N bond in sulfonamide. We must conclude that by not allowing his nitrogen atoms to change hybridization during rotation, Catalan inadvertently biased the results of his analysis.

To further address these points, the nitrogen rehybridization scenario proposed in this work was further tested by comparing the values of ρ and $\nabla^2\rho$ at the sulfur–nitrogen bond critical points in each conformer. Covalent bond orders were also calculated using the BONDER (13) method. On the basis of these data, it was possible to assess the degree and type of bonding between each pair of atoms. The results of the critical point electron density analyses are shown in Figs. 9 and 10. Both of these plots show increases of electron density (ρ) at the sulfur–nitrogen bond critical points for both sulfonamide and fluorosulfonamide when the torsional angles approached those of

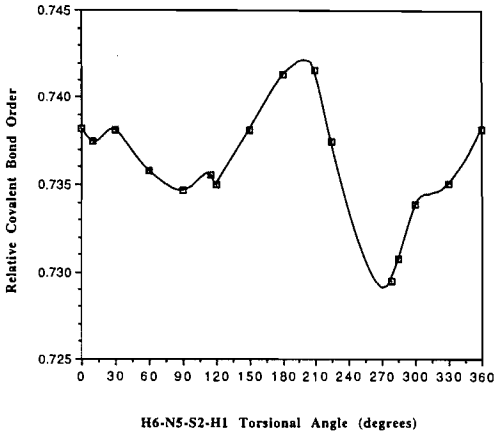
the minimum energy geometries. These increases in ρ indicate an increase in the total bond order of the sulfur–nitrogen bond at those minimum energy geometries. This observation is consistent with the hypothesis that donation of a small amount of

Fig. 11. Relative covalent bond order of S—N bond of sulfonamide vs. torsional angle.



nonbonded electron density from the nitrogen lone pair into the antibonding orbital of the sulfur–oxygen, sulfur–fluorine, or sulfur–hydrogen bonds is required to enable a comparatively larger withdrawal of σ density from the sulfur by the amino group. The withdrawal of this σ density along the sulfur–nitrogen bond would be expected to increase the *s* character of the bond, resulting in its growing shorter (Table 2).

The value of $\nabla^2\rho$ at a bond critical point can be interpreted as describing the relative nature (ionic or covalent) of a bond. The Laplacian data in Table 1 show that in sulfonamide and fluorosulfonamide, the $\nabla^2\rho$ at the bond critical point is at its most positive value where geometric evidence shows that nitrogen rehybridization to nearly sp^2 is taking place. These data imply that the covalent sulfur–nitrogen bond order is decreasing and the bond is becoming more ionic at these geometries. This observation further supports the hypothesis that suggests that electron withdrawal along the sulfur–nitrogen bond takes place during nitrogen rehybridization.

The BONDER results in Figs. 11 and 12 are consistent with the Laplacian results, and reveal that the S—N covalent bond order decreases dramatically at the most stable geometries of both sulfonamide and fluorosulfonamide. This implies that

less electron density is being shared between the two nuclei at these geometries and is therefore being more tightly held by the sulfur and the nitrogen. In the cases of sulfonamide and fluorosulfonamide, it is the more electronegative amino group which is becoming the anionic partner of the ionic portion of the bond, and is therefore acting as an electron sink. This σ polarization is manifest by increases of the electron density (ρ) at the sulfur–nitrogen bond critical points and by the more ionic sulfur–nitrogen bond apparent in Figs. 9 and 10. The increased ionic character of the sulfur–nitrogen bond was established by comparing the ρ and $\nabla^2\rho$ results with the BONDER covalent bond orders. The observed relationship between the *total* bond order and the value of ρ at the bond critical point allows separation of the total bonding scheme into variable ionic and covalent parts.

Thus, the results of ρ, $\nabla^2\rho$, and BONDER analysis all support the hypothesis that when a nitrogen is allowed to rehybridize by donating a small amount of its lone pair electron density into the σ^* orbital of another bond, the resulting increase of amino group electronegativity causes a large flux of σ electron density towards the nitrogen. This, in turn, results in the stabilization of the entire molecule, since the more electronegative amino group becomes stabilized at the expense of the sulfur.

Conclusions

Upon examination of charge density flow during rotational isomerism of sulfonamide and fluorosulfonamide, the redistribution of electron density and electronic kinetic energy between the sulfur and nitrogen atoms was found to be the controlling factor over conformational stability. The results showed that, in sulfonamide, at least one minimum was strongly dependent upon the hybridization of the amino nitrogen atom, whereas in fluorosulfonamide, both minima were clearly hybridization controlled. These results lead to the first conclusion: *the total stabilization of both molecules is directly related to the redistribution of charge density between the sulfur and amino nitrogens in a manner analogous to formamide stabilization.*

The sulfur–nitrogen bonds were found to be shortest at those geometries where both sulfonamide and fluorosulfonamide became most stable. This implied that in both molecules, the sulfur–nitrogen bond increased in *s* character, with the more stable conformers having the most *s* character.

The positions and magnitudes of electrostatic and Laplacian ($\nabla^2\rho$) minima in the vicinity of the nitrogen "lone pair" region, as well as the amino group pyramidalization altitudes were found to be reliable indicators of nitrogen hybridization. The fluorosulfonamide results demonstrated that the donation of a small amount of electron density from nitrogen's lone pair into the antibonding orbital of the sulfur–fluorine bond allowed for a comparatively larger withdrawal of σ density away from the sulfur atom to the more electronegative amino group. This, in turn, allowed the rotating nitrogen atom in fluorosulfonamide to undergo larger changes in hybridization at the minimum energy geometries.

All of the results presented in this work indicate that nitrogen rehybridization controls the torsional preferences in sul-

fonamide and fluorosulfonamide. The concept of *dynamic relative electronegativity* was found to rationalize the geometry of one minimum of sulfonamide and both minima of fluorosulfonamide. Within this interpretation, individual atomic stabilities are rearranged to serve the "greater good" of the total molecule. In this case, providing the more electronegative amino group with more electron density transferred from the less electronegative sulfur atom allows the nitrogen to rehybridize and stabilize the entire molecule.

The fact that fluorosulfonamide has a greater rotation barrier than sulfonamide is a direct result of the fluorine substitution in fluorosulfonamide. *The fluorine acts as an excellent lone pair electron sink* thereby allowing the amino nitrogen to rehybridize to a larger degree than is possible in sulfonamide. This result is seen in Tables 2 and 5 where the sulfur–nitrogen bonds in fluorosulfonamide are shown to be consistently shorter than those in sulfonamide at all geometries.

Through the implementation of these theoretical–computational methods, the dissimilar views of amide and sulfonyl stability control (resonance, negative hyperconjugation, *p-d* back bonding (3), etc.) have been replaced by one mechanism. Amide and sulfonyl stability were found to be controlled by the redistribution of electron density and its associated kinetic energy, thereby satisfying the intermolecular needs of the most *relatively electronegative* fragment. The result is the overall stabilization of the entire molecule.

Full PROAIM integration data for all rotamers have been deposited as supplementary material.[7]

Correlation and prediction of rate constants for organic reactions[1]

J. Peter Guthrie

Abstract: Marcus theory provides a framework for correlating rate and equilibrium constants, and thus the possibility of predicting rate from structure. This had been successful for a number of simple reactions, including the addition of hydroxide to carbonyl compounds, enolate formation from carbonyl compounds, and aldol addition and elimination reactions. The theory can be extended, as Multidimensional Marcus Theory, to cover concerted reactions such as E2 eliminations, the water-mediated proton switch, or the breakdown of the tetrahedral intermediate in amide hydrolysis. We have now found that Marcus theory can be applied not only to inter-molecular reactions but also to intra-molecular reactions. This is illustrated for aldol condensation and ester/lactone formation.

Key words: Marcus theory, concerted reactions, intramolecular reactions, aldol condensation, ester formation, proton transfer.

Résumé : La théorie de Marcus offre un système pour établir des corrélations entre les constantes de vitesse et d'équilibre et, de ce fait, la possibilité de faire des prédictions relatives aux vitesses à partir des structures. Cette approche a été couronnée de succès pour un certain nombre de réactions simples, y compris l'addition de l'ion hydroxyde à des composés carbonylés, la formation d'énolates à partir de composés carbonylés et les réactions d'addition et d'élimination aldoliques. On a étendue la théorie, sous la forme de la théorie multidimensionnelle de Marcus, pour couvrir les réactions concertées, comme les éliminations E2, l'échange de protons avec l'eau comme médiateur ou la dépyramidalisation de l'intermédiaire tétraédrique lors de l'hydrolyse des amides. On a trouvé que la théorie de Marcus peut être appliquée, non seulement aux réactions intermoléculaires mais aussi aux réactions intramoléculaires. On illustre ce point par la condensation aldolique et le formation d'ester/lactone.

Mots clés : théorie de Marcus, réactions concertées, réactions intramoléculaires, condensation aldolique, formation d'ester, transfert de proton.

[Traduit par la rédaction]

Introduction

There are two aspects to the problem of explaining the chemical origins of enzymic catalysis, as may be seen by examining the simple Michaelis Menton mechanism (1) for enzyme action, eq. [1]. This is despite the fact that, as written, this simple mechanism is so oversimplified that it is necessarily wrong for any real enzyme. An enzyme must bind its substrate using non-covalent interactions (hydrophobicity, electrostatics, hydrogen bonding, etc.) and then cause reaction within an enzyme substrate complex to occur much faster than reaction would occur for the same mechanism with the same reacting groups in an intermolecular reaction (2). It is generally believed that this rate enhancement is achieved by using more elaborate, more concerted mechanisms in the enzymic reaction than are observed in the non-enzymic process. Mechanisms involving simultaneous participation of two or three catalytic groups are often proposed (3). Since enzymes involve rate phenomena, they are part of the larger problem of predicting the rates of organic reactions from the structures of the reactants. Since concerted reactions with several groups simultaneously involved are often suggested, the question of what controls when a reaction is stepwise and when it is concerted is clearly relevant. Finally, the question of how much faster an intramolecular reaction is than is the corresponding intermolecular reaction is clearly at the heart of the problem of explaining enzymic catalysis (4).

$$[1] \quad E + S \underset{K_m}{\rightleftharpoons} ES \xrightarrow{k_{cat}} E + P$$

This paper will be focused on three conjectures that drive my current research. These are to varying degrees still unproven and even controversial, but, I will argue, worthy of exploration and rigorous test. They are part of the general problem of understanding the chemical origins of enzymic catalysis. The conjectures are:

1. **Marcus Theory is generally applicable to organic chemistry, and intrinsic barriers are transferable.** Marcus Theory permits prediction of a rate constant given the corresponding equilibrium constant and the intrinsic barrier evaluated for a similar reaction. Equilibrium constants are in

principle predictable from the structures of the species involved.

2. **Multidimensional Marcus Theory allows the concertedness or otherwise of a process to be predicted as well as the rate of the process.** By generalizing Marcus Theory to more than one potentially concerted bond-making/breaking process it is possible to calculate the nature and rate of the observable reaction.

3. **The effective molarity of an intramolecular reaction can be predicted given the equilibrium constant if data for intermolecular analogs are available. Intra- and intermolecular reactions are governed by the same Marcus intrinsic barrier.** Suitable extensions to the concept of the work term allow Marcus Theory to be applied to intramolecular reactions.

These conjectures, and the evidence supporting them, will now be discussed in turn.

Conjecture 1: Marcus Theory is generally applicable to organic chemistry, and intrinsic barriers are transferable

Marcus developed a theory relating rate and equilibrium for chemical reactions (5–7). In its simplest form this is expressed in eq. [2]

$$\Delta G^{\ddagger}_{corr} = \tilde{G}(1 + \Delta G^{\circ}_{corr}/4\tilde{G})^2$$

[2] $$\Delta G^{\ddagger}_{corr} = \Delta G^{\ddagger}_{obs} - w_R$$

$$\Delta G^{\circ}_{corr} = \Delta G^{\circ}_{obs} - w_R + w_P$$

This equation can be interpreted in terms of Fig. 1, which illustrates the situation for a reaction with two reactants and two products. The reactants must diffuse together, and the cost of bringing them together in an encounter complex is called the work term, w_R. This includes the entropic cost of bringing the two species together, as well as any electrostatic or other interactions between them, any partial desolvation required to get them close enough to react, and any conformational changes needed to achieve the reactive conformation. Similarly, the products are initially formed in an encounter complex, which differs from the products free in solution by another work term, w_P. Reaction occurs within the encounter complex and converts the encounter complex of reactants to the encounter complex of products. Marcus Theory applies to this reaction within an encounter complex, and thus involves a free energy change, ΔG°_{corr}, and a free energy of activation, $\Delta G^{\ddagger}_{corr}$, which need not be the same as the observable values, ΔG°_{obs} and $\Delta G^{\ddagger}_{obs}$.

Marcus Theory involves a parameter, the intrinsic barrier, which I symbolize $\tilde{G}$. This can be interpreted as the kinetic barrier that would result if there were no thermodynamic barrier, Fig. 2. Now it is simple algebra to calculate $\tilde{G}$ given ΔG°_{corr} and $\Delta G^{\ddagger}_{corr}$, or to calculate any of the three quantities given the other two. The problem is to obtain $\tilde{G}$ for a new reaction where one does not know both ΔG°_{corr} and $\Delta G^{\ddagger}_{corr}$. The approximation I have used is that for a class of "similar" reactions, where variation is "far enough" from the reaction center, and the intrinsic barrier is "approximately" constant and thus transferable. The weasel words in quotes are strikingly reminiscent of those used for the Hammett or Taft equations and, analogously to those cases, we have found that the assumption of transferable intrinsic barriers is good enough to permit the use of Marcus Theory for a wide range of organic reactions.

Fig. 1. Model for a reaction, A + B ⇌ A,B ⇌ C,D ⇌ C + D used in applying Marcus Theory. The reactants come together in an encounter complex (A,B) at a free energy cost w_R, and react within this complex to form (C,D), the encounter complex of products, which then separate, releasing free energy w_p. Marcus Theory applies to reactions within the encounter complex where $\Delta G^{\ddagger}_{corr}$ is determined by ΔG°_{corr} and the intrinsic barrier, $\tilde{G}$.

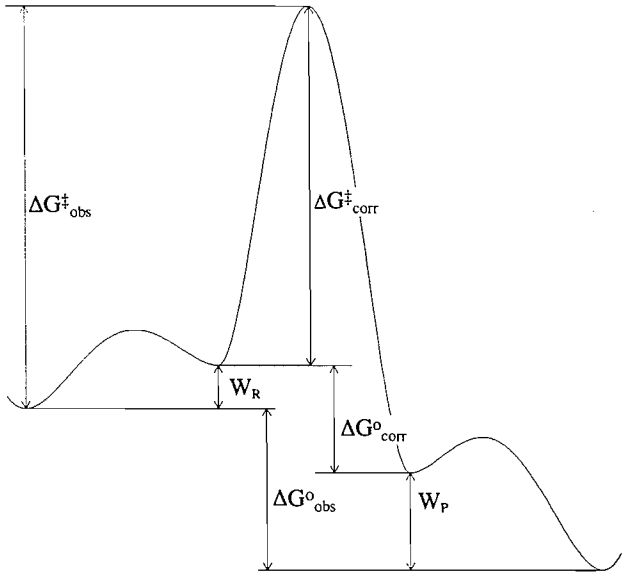

Fig. 2. Interpretation of the intrinsic barrier as the free energy of activation when $\Delta G^{\circ}_{corr} = 0$, even though ΔG°_{obs} is not zero in the case illustrated.

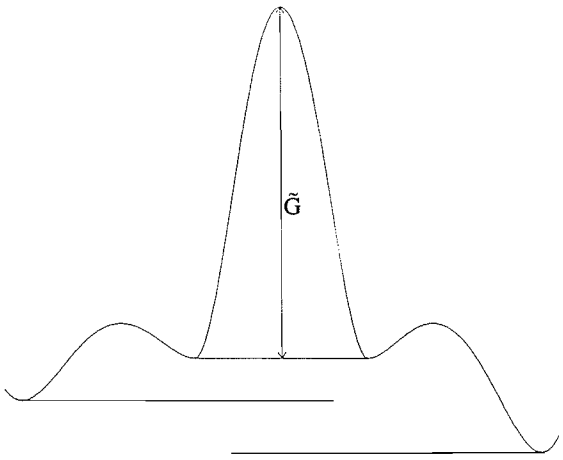

There have been numerous treatments of relations between rate and equilibrium, summarized in Jencks' acronym (8) BEMA HAPOTHLE (9–16). Marcus provided an equation that, if one knew the intrinsic barrier, allowed prediction of rate from equilibrium. He also provided a way, at least for systems where there was an identity reaction, to predict the intrin-

sic barrier. His equation has proven to be more general than the derivation seemed to justify.

It turns out that the work term and the intrinsic barrier are generally subject to covariance, so that if both are allowed to vary, many pairs of values will give very similar fits to the data. I calculated the work term for the most realistic practical model, and then varied only the intrinsic barrier. This means that the intrinsic barriers I report do depend on the model used for the work term, and this must be kept in mind whenever intrinsic barriers from different studies are compared.

To go the next step and apply the theory to concerted reactions we will need equations for the free energy at each point along the reaction coordinate. Several models have been used to provide such equations. One of the commonest is the inverted parabola model (10, 17–20) illustrated in Fig. 3 and eq. [3]. This model has the shape dictated by chemical intuition at the transition state, but looks unrealistic at the reactant and product ends. A model that is equivalent as far as the expression for transition state energy is concerned involves two intersecting parabolas with the same curvature (20), as illustrated in Fig. 4 and eq. [4]. This model seems intuitively more satisfying at the reactant and product ends, but seems too cusplike at the transition state. A third model, which seems likely to be more realistic at the three places where we think we know something, is based on a quartic equation (21–23), Fig. 5 and eq. [5].

$$G = (\Delta G^\circ + 4\tilde{G})x - 4\tilde{G}x^2$$

[3]

$$\Delta G^\ddagger = \tilde{G}\left(1 + \frac{\Delta G^\circ}{4\tilde{G}}\right)^2$$

$$G_1 = 4\tilde{G}x^2$$

[4] $$G_2 = \Delta G^\circ + 4\tilde{G}(1 - x)^2$$

$$\Delta G^\ddagger = \tilde{G}\left(1 + \frac{\Delta G^\circ}{4\tilde{G}}\right)^2 = \tilde{G}\left(1 + 8\left(\frac{\Delta G^\circ}{16\tilde{G}}\right) + 16\left(\frac{\Delta G^\circ}{16\tilde{G}}\right)^2\right)$$

$$G = (3\Delta G^\circ + 16\tilde{G})x^2 - (2\Delta G^\circ + 32\tilde{G})x^3 + 16\tilde{G}x^4$$

[5]

$$\Delta G^\ddagger = \tilde{G}\left(1 + 8\left(\frac{\Delta G^\circ}{16\tilde{G}}\right) + 18\left(\frac{\Delta G^\circ}{16\tilde{G}}\right)^2 - 27\left(\frac{\Delta G^\circ}{16\tilde{G}}\right)^3\right)$$

The first general examination of the applicability of Marcus Theory to organic chemistry was by Hine (24), who showed that for a wide range of organic reactions, the available data seemed to fit quite well to the Marcus model, with transferable intrinsic barriers. In his examination of the reaction of hydroxide with carbonyl compounds, he was limited at that time to data for additions to aldehydes and ketones, since these were the only compounds available. We were able to determine equilibrium constants for addition to esters (25, 26), thioesters (27), and amides (28), by an indirect method based on thermochemistry and thermodynamics (29). With additional data we were able to show that the Marcus correlation extended over 20 powers of 10 in equilibrium and 10

Fig. 3. Inverted parabola model for energy as a function of reaction coordinate. The reaction coordinate is a bond order coordinate, defined to be 0.0 at the reactants and 1.0 at the products.

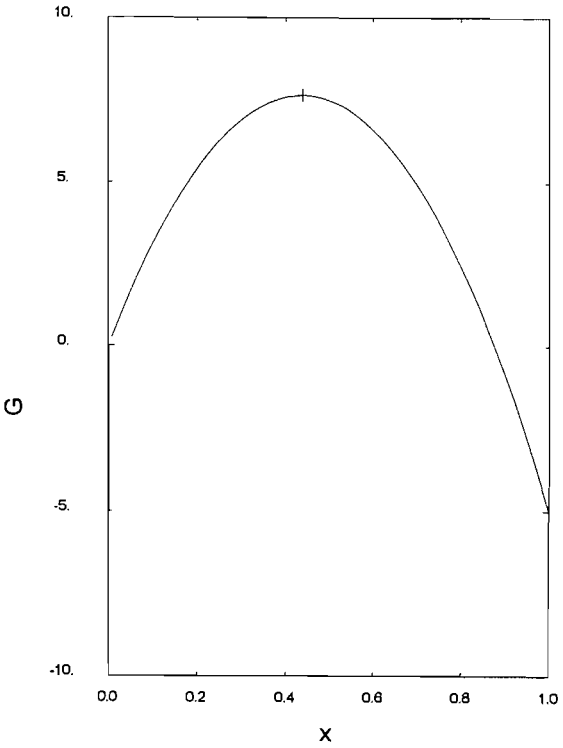

Fig. 4. Two intersecting parabola model for energy as a function of reaction coordinate. Both parabolas have the same curvature.

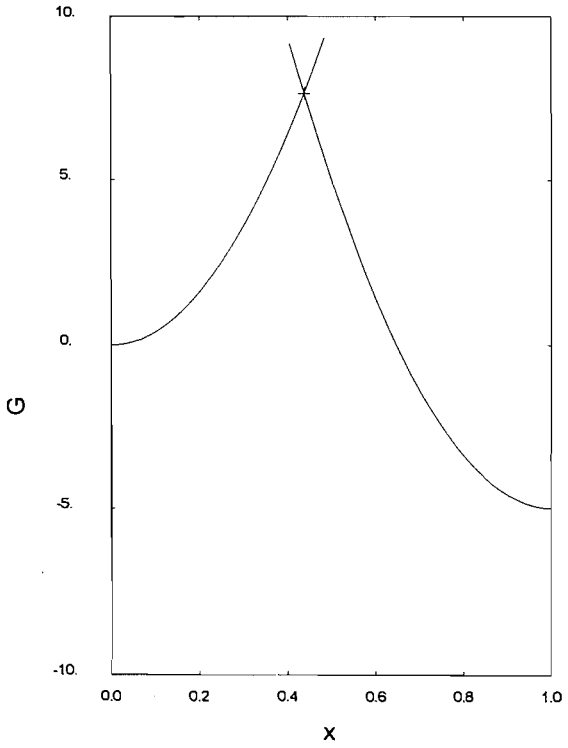

Fig. 5. Quartic model for the energy as a function of the reaction coordinate.

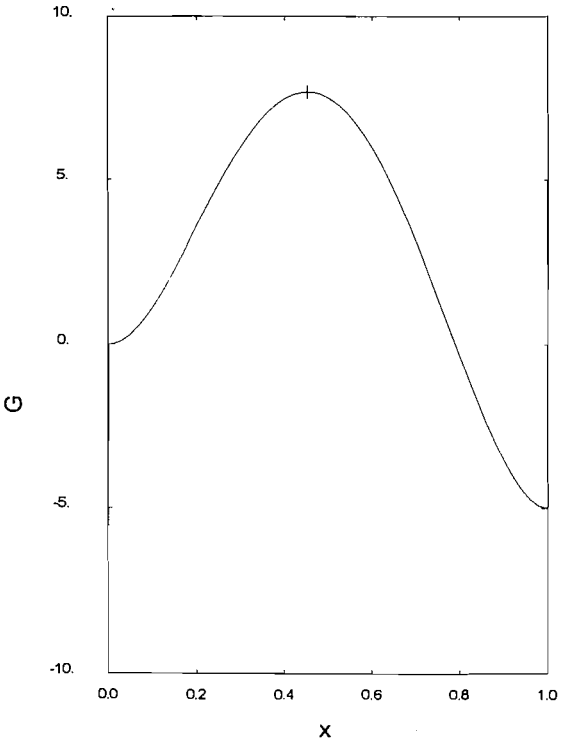

powers of 10 in rate (27); admittedly there were signs of dispersion into slightly different correlations for different groups of compounds. A more recent version of this correlation is shown in Fig. 6. The model for the encounter complex used in this plot involves partially desolvated hydroxide ion in contact with one of the two faces of the carbonyl group. The hydroxide ion must have lost one of its hydrogen-bonded waters in order to be ready to react with the carbonyl. The energy of this hydrogen bond is estimated from the difference in pK_a for water between water and DMSO (30). pK_a values for small, nonpolarizable acids are expected to be about the same in the two solvents: 1 pK_a unit higher because of the lower dielectric constant of DMSO (31); and 1 pK_a unit lower because of the greater basicity of DMSO (31). The source of the difference, which is commonly observed, is that DMSO cannot donate hydrogen bonds. In this way we can estimate that the energy of one of the three hydrogen bonds to hydroxide ion is 7.13 kcal/mol (32). Using this model, which we believe is more realistic, we find that the most reactive compounds deviate from the curve defined by less reactive species. I will argue (33) that this is because the reaction is in fact hydroxide as general-base-catalyzing attack by water, and that only for very reactive aldehydes is there evidence that the intrinsic barrier is smaller. Direct attack will give way to general base catalyzed attack when direct attack of hydroxide on the carbonyl becomes so fast that the main barrier would be formation of the complex with partial desolvation of the hydroxide. Under these circumstances, general-base catalysis provides a way to avoid this encounter complex, which would be a high-energy intermediate

The Marcus relation can also be used to correlate rate and equilibrium constants for enolate formation (32), as shown in

Fig. 6. Rate–equilibrium correlation for hydroxide addition to carbonyl compounds. Calculated for reaction within an encounter complex, with partially desolvated hydroxide. (□) amides, esters, and thioesters; (Δ) aldehydes. For the more reactive esters and aldehydes, the reaction is actually hydroxide-catalyzed attack of water with the hydroxide acting as general base. Only for the very most reactive aldehydes is the intrinsic barrier actually lower. The line is drawn using the average intrinsic barrier.

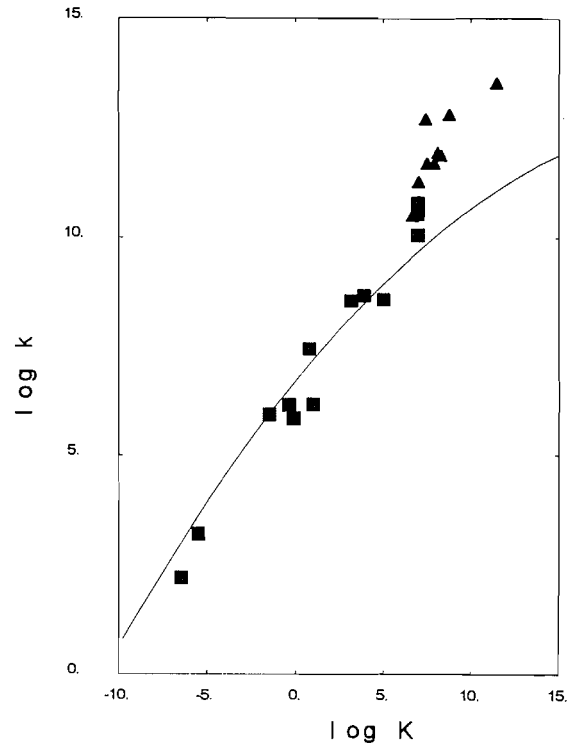

Fig. 7. The model used for the work term in these calculations is that hydroxide ion must be in one of two locations above or below the plane of the carbonyl group (24) and must have lost one of its waters of hydration. The intrinsic barrier for this process is 7.83 ± 0.11 kcal/mol.

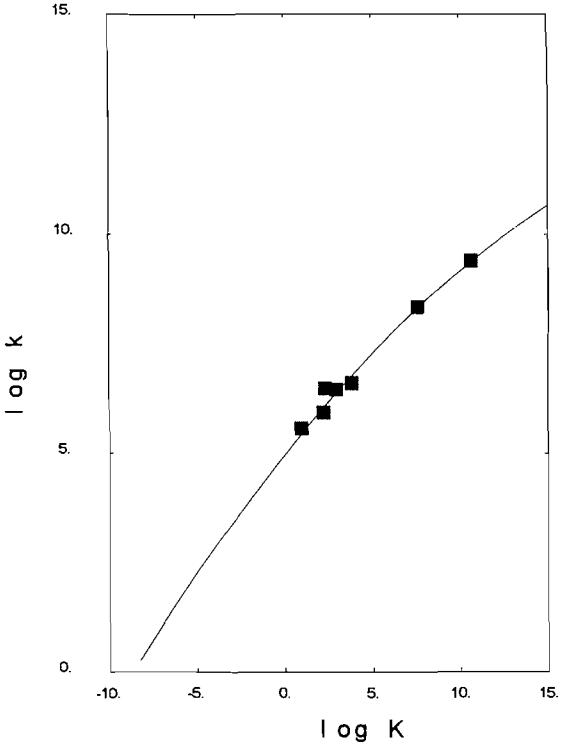
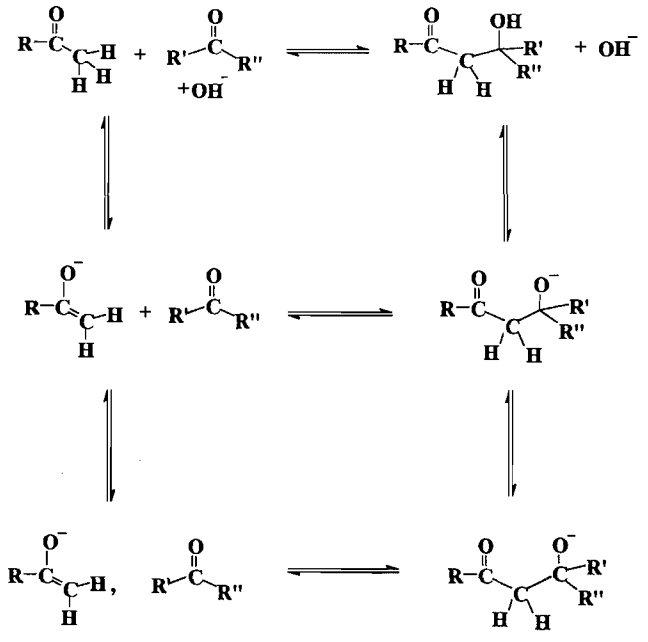
We next examine a carbon–carbon bond-forming reaction, the aldol condensation. The detailed mechanism that we use for this analysis is shown in Scheme 1. For the intermolecular aldol addition, the step to which Marcus analysis should be applied involves reaction of the enolate of one component with the other component in an encounter complex, to give the anion of the aldol/ketol. The pK_a of the ketol can be estimated from linear free energy relations (27); the pK_a's of the carbon acids have been determined by Keefe and Kresge (34). For the aldol elimination, the step to which Marcus analysis should be applied involves expulsion of hydroxide from the reactive conformation of the ketol enolate to give the encounter complex of enone with partially desolvated hydroxide; see Scheme 2. The reactive conformation of the ketol enolate has the C—O bond that is to cleave perpendicular to the plane of the enolate. The pK_a's of the ketols as carbon acids were estimated by linear free energy relations starting from the pK_a of 4-methoxybutanone, which was determined from the rate of exchange (35) by means of the Marcus relation for enolate formation described above (27).

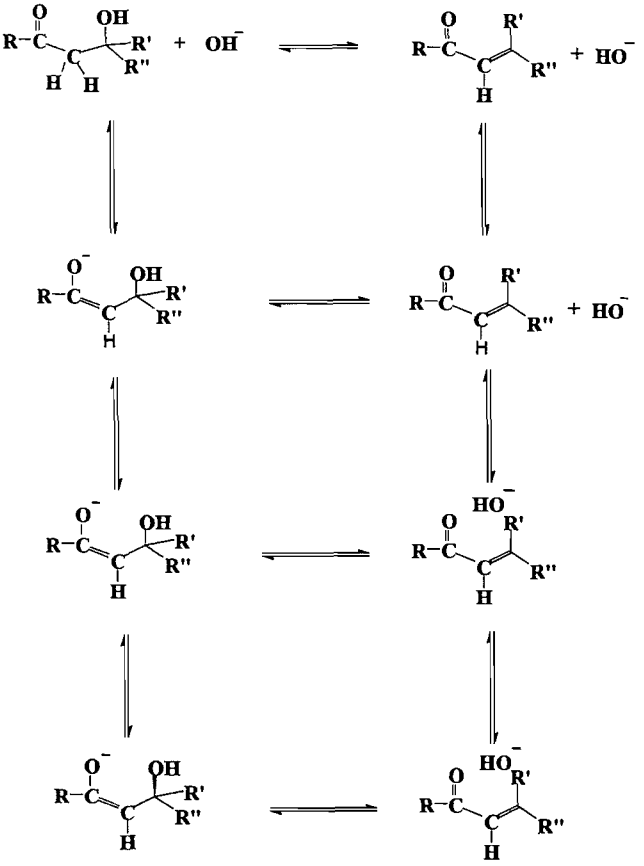
Fig. 7. Rate–equilibrium correlation for hydroxide-catalyzed enolate formation from aldehydes and ketones. The reaction was within an encounter complex with partially desolvated hydroxide ion. The line is calculated using an average value for the intrinsic barrier.



Scheme 1. Detailed mechanism for the aldol addition: horizontal arrows represent the C—C bond-forming process, while vertical arrows represent successive approximations to the microscopic bond-forming process, shown in the lowest line of the scheme.



Scheme 2. Detailed mechanism for the aldol elimination step: horizontal arrows represent the dehydration process, while vertical arrows represent successive approximations to the microscopic bond-breaking process, shown in the lowest line of the scheme.



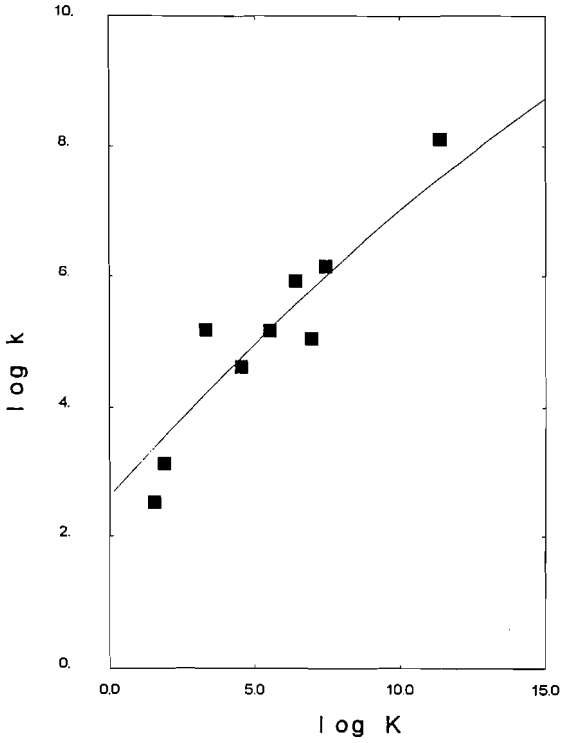
When the rate and equilibrium constants for the microscopic rate-determining step for aldol addition are plotted, Fig. 8, we find that they are in reasonable accord with the Marcus Theory. The intrinsic barrier in free energy terms is 13.89 ± 0.80 kcal/mole (32). The scatter reflects either the inadequacy of our assumption of constant intrinsic barrier, or that there are effects that we have not yet allowed for.

Similarly, when rate and equilibrium constants for the microscopic rate-determining step in the aldol elimination reaction are plotted, Fig. 9, we find that these too are in good accord with Marcus Theory. The intrinsic barrier, in free energy terms, is 14.13 ± 0.49 kcal/mol (32).

One of the attractive potentials of Marcus Theory is the possibility of predicting rates of reactions that have not yet been carried out. Based on equilibrium data for addition of other nucleophiles to trifluoroacetophenone (36), and information about the properties of acetone as a carbon nucleophile (37), I predicted the equilibrium constant for the aldol reaction of acetone with trifluoroacetophenone and, from this, the rate constant for the microscopic step (32). This step was predicted to be 9×10^3 times faster than the analogous rate constant for acetone plus acetophenone, for which we have measured the overall rate constant (38).

Testing this prediction proved to be a challenge because of the high reactivity of trifluoroacetophenone towards all

Fig. 8. Rate–equilibrium correlation for aldol addition. The reaction occurs within an encounter complex of enolate and carbonyl addend, and leads to the aldolate or ketolate anion. The line is based on the average value of the intrinsic barrier.

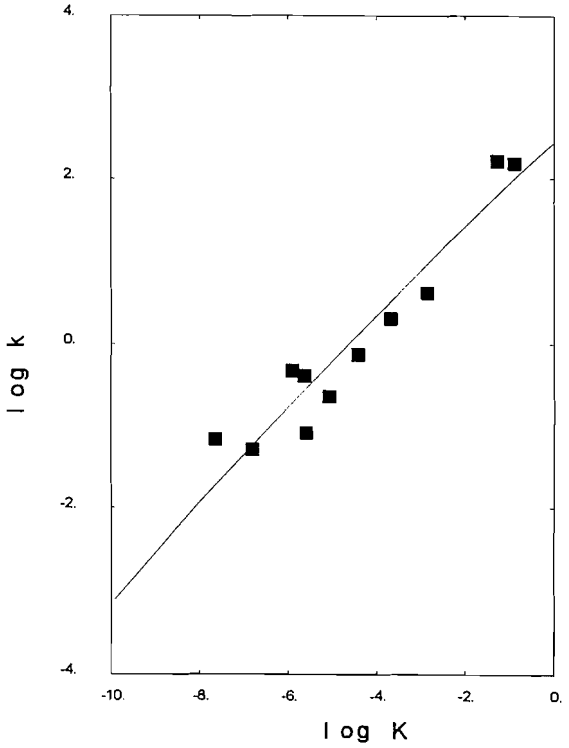


nucleophiles including hydroxide ion. The detailed kinetics have been worked out, and the rate constant for the reaction of acetone enolate with α,α,α-trifluoroacetophenone can be calculated; as predicted it is much faster than the corresponding rate constant for acetone plus acetophenone (38). The actual rate ratio is 7.5×10^3. The magnitude of the problem posed by this system is illustrated in Scheme 3, which shows the species that had to be considered in the analysis. Although trifluoroacetophenone is far more reactive in terms of the microscopic rate constant, it is actually less reactive in terms of the observable behavior under normal synthetic conditions because so much of the total trifluoroacetophenone is tied up as the carbonyl hydrate anion.

The successful prediction of a large rate enhancement means that application of Marcus Theory to aldol reactions has passed a stringent test. It suggests quite strongly that we have a general way to make approximate predictions of the rate constants for new reactions.

This conformity to Marcus Theory can be shown to apply to other carbon–carbon bond-forming reactions. We have determined rate and equilibrium constants for a set of Claisen condensations in methanol, which we believe is the first such study to have been carried out (39). Although the range of equilibrium and rate constants available so far is limited, the data are consistent with a single value of the intrinsic barrier, $\tilde{G} = 15.4 \pm 1.1$ (in methanol). Thus it seems as if a wide range of reactions of carbonyl compounds will fit the Marcus pattern, with transferable intrinsic barriers, although the barriers may differ somewhat from one class of reaction to another.

Fig. 9. Rate–equilibrium correlation for the aldol elimination reaction. The reaction starts with the conformation of the aldol or ketol enolate that has the OH group, which is to depart orthogonal to the plane of the enolate and leads to partially desolvated hydroxide ion in an encounter complex with the enone. The line is based on the average value of the intrinsic barrier.



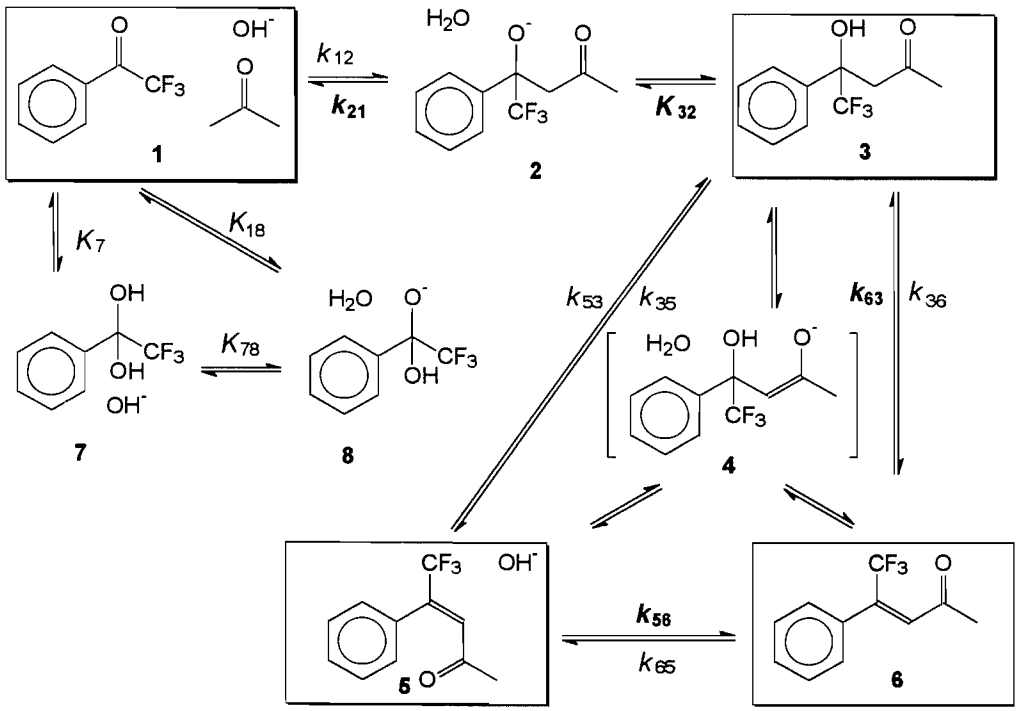
When the intrinsic barrier is large, as in the examples above, then curvature in the line relating rate and equilibrium is slight. Nonetheless, the Marcus curve involves only one adjustable parameter, where a simple linear correlation requires two. Marcus theory directs one to look at the microscopic rate-determining step within an encounter complex if one is to find a rate–equilibrium correlation. This gives a guide to improved predictability.

This has been a brief summary of our contributions to the application of Marcus Theory to organic reactions, which in combination with studies from other laboratories (5, 18, 24, 40–87), provides the basis for carrying on with the first conjecture. Although the application of Marcus theory is still not universally accepted, and has been vigorously challenged (88), there seems at the very least to be enough evidence to support a strong effort to test it further by examining additional reactions.

Conjecture 2: Multidimensional Marcus Theory allows the concertedness or otherwise of a process to be predicted as well as the rate of the process

We now turn to an examination of the requirements for a reaction to be concerted as opposed to stepwise, and of a method

Scheme 3. Acetone plus trifluoroacetophenone.



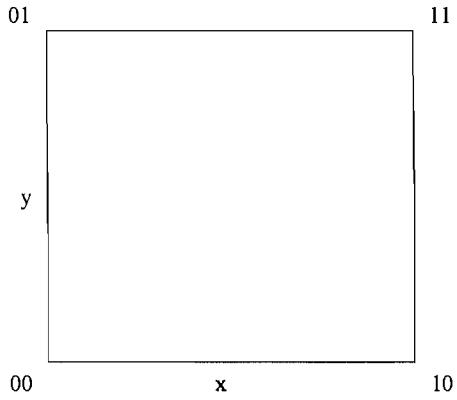
for predicting both concertedness and the rate constant for the concerted reaction. The method that I have developed for this purpose is Multidimensional Marcus Theory, a generalization of the theory to two, three, or even four reaction coordinate dimensions, as well as an energy dimension. Other approaches to handling concerted reactions in terms of multidimensional reaction coordinates have been reported in the literature (55, 63, 69, 89, 90).

The theory is based on four postulates:

1. Reactants are in equilibrium with starting material or product at each point along each reaction coordinate. This is the essential assumption in transition state theory.
2. At each section through the reaction hypersurface for which only one reaction coordinate changes, Marcus Theory will apply. This follows directly if Marcus Theory is applicable to simple organic reactions and postulate 1 is obeyed.
3. The intrinsic barrier for any reaction coordinate is independent of the values of the other reaction coordinates. This postulate is necessary to reduce the amount of empirical information needed to a manageable level. It seems to be justified by experience.
4. For any reaction coordinate chosen as progress variable, at fixed values of the other coordinates, the free energy will be a quartic function of the progress variable. This is a generalization of the quartic function assumption used for simple reactions.

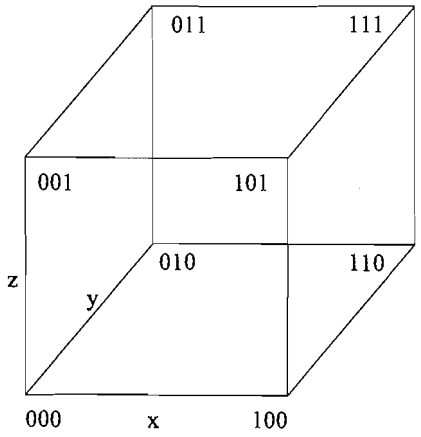
If a reaction can be described by two reaction coordinates, then the position of the transition state can be presented in terms of a reaction square, as illustrated in Fig. 10. These have become familiar as Albery (91) – More O'Ferrall (92) – Jencks (93) diagrams. The position of the transition state on such a diagram shows whether the transition state is central (a highly concerted reaction) or on an edge (a fully stepwise reaction) or has an intermediate character. Energy is of course a third dimension at right angles to the two shown.

Fig. 10. Two-dimensional reaction coordinate diagram. x and y are the two edge coordinates. [0,0] is the starting point, [1,1] is the product, and [1,0] and [0,1] are the corner intermediates corresponding to reaction along only one edge coordinate.



If a reaction requires three reaction coordinates for a satisfactory description, then one needs a reaction cube (89, 94–96), as illustrated in Fig. 11. Although energy is again an additional dimension at right angles to the other three, there is no simple way to show the energy for every point, although it is possible to show the contour for a particular value of the energy. The position of a transition state within the cube shows the nature of the transition state as we saw for the square. There are now three possibilities; a fully concerted reaction will have a transition state near the center of the cube;

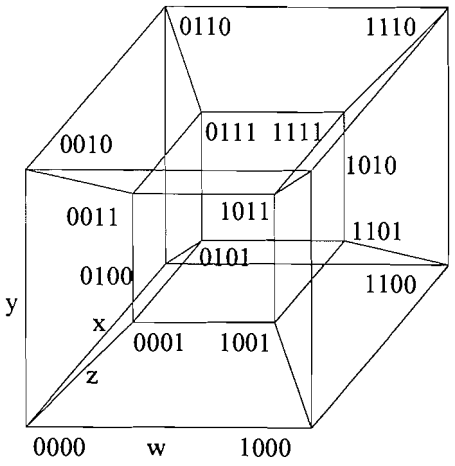
Fig. 11. Three-dimensional reaction coordinate diagram. *x*, *y*, and *z* are the three edge coordinates. [0,0,0] is the starting point, [1,1,1] is the product, [1,0,0], [0,1,0], and [0,0,1] are the corner intermediates corresponding to reaction along only one edge coordinate, and [1,1,0], [1,0,1], and [0,1,1] are the corner intermediates corresponding to reaction along two edge coordinates.



a reaction that is concerted in only two dimensions will have a transition state near the center of one of the 6 faces of the cube; a fully stepwise reaction will have a transition state located on one of the 12 edges of the cube.

Finally, if a reaction requires four reaction coordinates for a satisfactory description, and numerous reactions seem to need this many, then one needs a reaction hypercube. It is difficult to draw a four-dimensional figure on two-dimensional paper. To do so (97) we project one of the dimensions to a vanishing point in the center of the cube involving the other three dimensions. This leads to the diagram shown in Fig. 12. Fortunately we have found that one will essentially never encounter an actual reaction for which the transition state involves concerted change in four reaction coordinates at once. At least for a very symmetrical case it is possible to prove that the requirements for such a concerted reaction are so severe that they are unlikely ever to be met (98). It may still be very useful to use the four-dimensional version of Multidimensional Marcus Theory to find out which reduced dimensional region of the full reaction coordinate space is relevant to the nature of the transition state.

Fig. 12. Four-dimensional reaction coordinate diagram. *w*, *x*, *y*, and *z* are the four edge coordinates. [0,0,0,0] is the starting point, [1,1,1,1] is the product, [1,0,0,0], [0,1,0,0,], [0,0,1,0], and [0,0,0,1] are the corner intermediates corresponding to reaction along only one edge coordinate, [1,1,0,0], [1,0,1,0], [1,0,0,1], [0,1,1,0], [0,1,0,1], and [0,0,1,1] are the corner intermediates corresponding to reaction along two edge coordinates, and [1,1,1,0], [1,1,0,1], [1,0,1,1], and [0,1,1,1] are the corner intermediates corresponding to reaction along three edge coordinates.



Qualitatively, what one observes is that concerted reactions occur when a concerted path permits the reaction to avoid unstable intermediates. If the corner intermediates are not high energy relative to both starting material and product, then there is little advantage to be gained by avoiding them, and reaction is likely to be stepwise. If one intermediate is much higher energy than the others, then it will be avoided, and a lower dimensional or stepwise path will be followed.

The equations needed to prescribe the energy at each place in the reaction hyperspace can be deduced from the four postulates, but become increasingly complex as the number of dimensions rises. These equations, in their full mathematical beauty, are shown in eq. [6].

$$[6]\quad G = \sum_{i=1}^{N} \{(16\tilde{G}_i + 3\Gamma_i)u_i^2 + (-32\tilde{G}_i - 2\Gamma_i)u_i^3 + 16\tilde{G}_i u_i^4\} + \sum_{j=1}^{N-1}\sum_{k>j}^{N} \left\{9\Gamma_{jk}u_j^2u_k^2 + \sum_{h=1}^{h=2}(-6\Gamma_{jk})u_j^{2+\delta_{1h}}u_k^{2+\delta_{2h}} + 4\Gamma_{jk}u_j^3u_k^3\right\}$$

$$+ \sum_{j=1}^{N-2}\sum_{k>j}^{N-1}\sum_{l>k}^{N} \left\{27\Gamma_{jkl}u_j^2u_k^2u_l^2 + \sum_{h=1}^{h=3}(-18\Gamma_{jkl})u_j^{2+\delta_{1h}}u_k^{2+\delta_{2h}}u_l^{2+\delta_{3h}} + \sum_{h=1}^{h=3}12\Gamma_{jkl}u_j^{3-\delta_{1h}}u_k^{3-\delta_{2h}}u_l^{3-\delta_{3h}} + (-8\Gamma_{jkl})u_j^3u_k^3u_l^3\right\}$$

$$+ \sum_{j=1}^{N-3}\sum_{k>j}^{N-2}\sum_{l>k}^{N-1}\sum_{m>l}^{N} \left\{81\Gamma_{jklm}u_j^2u_k^2u_l^2u_m^2 + \sum_{h=1}^{h=4}(-54\Gamma_{jklm})u_j^{2+\delta_{1h}}u_k^{2+\delta_{2h}}u_l^{2+\delta_{3h}}u_m^{2+\delta_{4h}}\right.$$

$$\left. + \sum_{h=1}^{h=4}\sum_{\substack{g=2,\\ g>h}}^{g=4} 36\Gamma_{jklm}u_j^{2+\delta_{1h}+\delta_{1g}}u_k^{2+\delta_{2h}+\delta_{2g}}u_l^{2+\delta_{3h}+\delta_{3g}}u_m^{2+\delta_{4h}+\delta_{4g}} + \sum_{h=1}^{h=4}(-24\Gamma_{jklm})u_j^{3-\delta_{1h}}u_k^{3-\delta_{2h}}u_l^{3-\delta_{3h}}u_m^{3-\delta_{4h}} + 16\Gamma_{jklm}u_j^3u_k^3u_l^3u_m^3\right\} + \text{etc.}$$

where

$$\Gamma_i = G_{\delta_{i1}\delta_{i2}\delta_{i3}\delta_{i4}\ldots} - G_{0000\ldots}$$

$$\Gamma_{jk} = \sum_{h=0}^{h=1}\sum_{g=0}^{g=1}(-1)^{h+g}G_{\varepsilon_1\varepsilon_2\ldots\varepsilon_i\ldots\varepsilon_N}$$

$$\varepsilon_i = h\delta_{ij} + g\delta_{ik}$$

$$\Gamma_{jkl} = \sum_{h=0}^{h=1}\sum_{g=0}^{g=1}\sum_{f=0}^{f=1} -(-1)^{h+g+f}G_{\varepsilon_1\varepsilon_2\ldots\varepsilon_i\ldots\varepsilon_N}$$

$$\varepsilon_i = h\delta_{ij} + g\delta_{ik} + f\delta_{il}$$

$$\Gamma_{jklm} = \sum_{h=0}^{h=1}\sum_{g=0}^{g=1}\sum_{f=0}^{f=1}\sum_{e=0}^{e=1}(-1)^{h+g+f+e}G_{\varepsilon_1\varepsilon_2\ldots\varepsilon_i\ldots\varepsilon_N}$$

$$\varepsilon_i = h\delta_{ij} + g\delta_{ik} + f\delta_{il} + e\delta_{im}$$

with δ_{ij} being the Kronecker delta.

I have published several examples of the use of this approach to describe organic reactions. The first attempt at a two-dimensional version of Multidimensional Marcus Theory was used to describe the E2 elimination of ethyl, isopropyl, and *tert*-butyl bromides (23). This work led to a qualitative and semi-quantitative prediction of the nature and energy of the transition state, using only information from solvolysis reactions and estimated energies of the carbocation and carbanion "corner intermediates." One disturbing feature of this work is that to obtain sensible free energies of activation the intrinsic barrier for removal of a proton from carbon to give a localized carbanion had to be small, ca. 1 kcal/mol. This was disturbing because increasingly it was being suggested in the literature that the intrinsic barrier for proton transfer between oxygen and oxygen or oxygen and nitrogen was 5 kcal/mol (99–102), which would lead to free energies of activation for elimination reactions that were too high. I will return to this point.

Two-dimensional Multidimensional Marcus Theory was also applied to ester interchange reactions where an aryl ester reacts with an aryloxide ion (103). This analysis showed that the interchange reactions with anions of acidic phenols were concerted displacements, even though the hydrolysis reactions of the analogous aryl acetates followed the standard tetrahedral intermediate mechanism. pK_a values that would give the limiting stepwise mechanisms, either via a tetrahedral intermediate or via an acylium ion, could be deduced as well (103).

More recently I have applied Multidimensional Marcus Theory to proton transfer reactions involving oxygen or nitrogen species, and to water-mediated proton switch reactions in which a proton migrates from one atom of a molecule to another without ever escaping into solution (104). Such mechanisms have been shown to be important in exchange reactions that can be followed by nmr, and in carbinolamine forming processes. As I stated above, my examination of the E2 reaction, combined with a common organic prejudice that proton transfer along a preformed hydrogen bond should be very easy (24, 42, 43, 102, 105–107), led me to expect a small intrinsic barrier for "fast" proton transfers. However examination of the classic data from Eigen (108) on such proton transfers, interpreted in terms of the classic Eigen mechanism, with a chemical step preceded and followed by diffusional steps, showed that application of Marcus theory to the chemical step required a barrier of 4–5 kcal/mol. The way in which this apparent intrinsic barrier fits the data is shown in Fig. 13. This was a serious problem. The resolution came when I read a paper by Berg and Jencks (109). In this paper it was shown that the rate of proton exchange in amines was limited by the energy cost of moving a water out of contact with the amine, leaving a water-sized hole, into which a different water could diffuse. The activation energy for moving the water out was determined by the cavitation energy, the hydrogen bond energy, and the dispersion forces between amine and water. This gives a total very similar to the observed free energy of activation for exchange and also to the activation energy for diffusion. Suddenly the answer to the conundrum was clear. The Eigen mechanism could not lead to a contact hydrogen-bonded pair, because loss of the last water molecule separating the acid and base would be too slow, leading to a rate constant of about 10^7 M^{-1} s^{-1}, while the observed process has a rate constant greater than 10^9 M^{-1} s^{-1}. This water would be held by two hydrogen bonds, each worth just over 3 kcal/mol, and both would have to be lost in order for the last water to move out of contact with the acid and base. This meant that the proton transfer was a two-dimensional process involving motion of one proton to the bridging water and one from it. Analysis in terms of the appropriate square diagram permitted calculation of the activation energy for the proton transfer, giving results within 1 kcal of the true value, with an intrinsic barrier of 1 kcal/mol. A similar model, but with two bridging water molecules, permitted calculation of the rates of water-mediated proton switch reactions (104).

[7] $$AH + B \rightleftharpoons AH,B \rightleftharpoons AH,B \rightleftharpoons A + HB$$

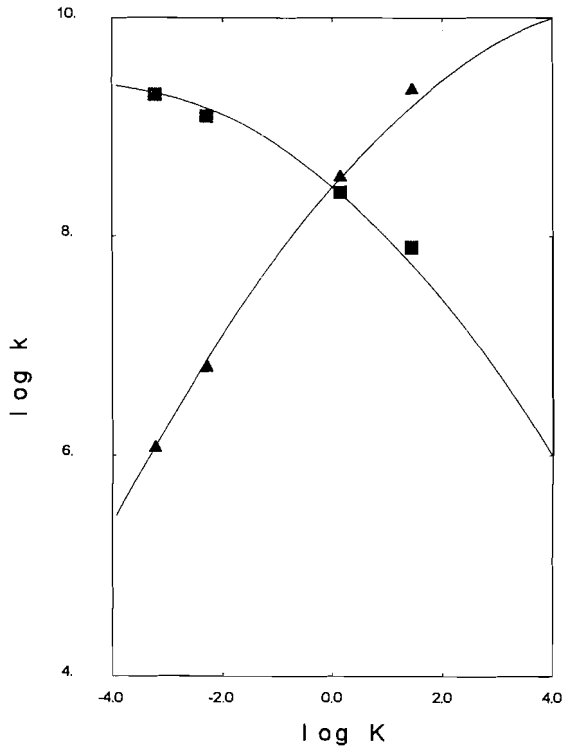
An examination of amide hydrolysis (110, 111), in collaboration with R.S. Brown and co-workers, led to a successful description of the alkaline hydrolysis in terms of a proton switch to give an anionic zwitterion that could then expel amine. The analysis suggested that the rate-limiting step was the proton switch, with breakdown of the anionic zwitterion being a very fast process (110, 112). This mechanism is shown in Scheme 4.

The application of Multidimensional Marcus Theory is much less advanced than the application of Marcus Theory. I hope that the mathematical and computational tools that I have developed will facilitate this approach. Thus far the results are very promising, and further testing on other reactions is an important goal for research in my laboratory.

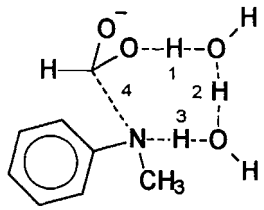
Conjecture 3: The effective molarity of an intramolecular reaction can be predicted given the equilibrium constant if data for intermolecular analogs are available. Intra- and intermolecular reactions are governed by the same Marcus intrinsic barrier

Now I will turn to the final conjecture, concerning intramolecular reactions. It is commonly found that intramolecular reactions are fast relative to their intermolecular analogs (4). The

Fig. 13. Rate–equilibrium correlation for proton transfer reactions involving acetic acid with (left to right) hydrazine, imidazole, aniline, and *m*-chloroaniline. The line is calculated for the mechanism AH + B ⇌ AH,B ⇌ A,HB ⇌ A + HB with Marcus Theory applied to the second step and the first and third processes being diffusion controlled. The line is calculated with an average intrinsic barrier of 5.23 kcal/mol.



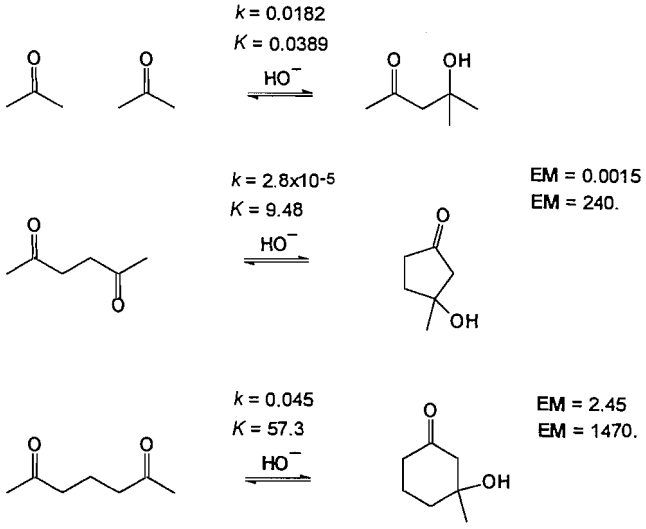
Scheme 4. Mechanism for breakdown of the tetrahedral intermediate in the base-catalyzed amide hydrolysis.



size of the rate enhancement is measured by the "effective molarity," which is the ratio of the first-order rate constant for the intramolecular reaction to the second-order rate constant for the analogous intermolecular reaction. Effective molarities can range from quite small, 10^{-3}, to very large, 10^{8} or even larger (4).

We have studied a series of intramolecular aldol reactions (113, 114), illustrated in Scheme 5. The striking phenomenon is that cyclization of 2,5-hexanedione to form a five membered ring ketol is very similar thermodynamically to cyclization of 2,6-heptanedione to form a six-membered ring ketol, yet is 1000 times slower. There is clearly not a simple rate–equilibrium correlation in terms of overall rates and equilibria. This is a situation governed by Baldwin's rules (115–118): the problem is that it is difficult to get the stereoelectronically required alignment of the planar carbonyl and planar enolate in order to form a five-membered ring, and much easier to get such an alignment to form a six-membered ring. In terms of Baldwin's rules, a 5-(enol *endo*)-*exo*-trig reaction is forbidden while a 6-(enol *endo*)-*exo*-trig reaction is allowed (118). We analyze these reactions in terms of a mechanism analogous to that used for the intermolecular aldols but, in place of encounter complex formation of enolate and carbonyl component, we have rotation to a conformation with the reacting atoms in van der Waals contact and able to react by a simple conrotatory motion, as shown in Scheme 6. The energies of the reactive conformations, with the reacting groups eclipsed for hexanedione, or in what is equivalent to a 1,3-diaxial arrangement for heptanedione, were calculated by MM3[3] (119–121) for the neutral enols. When Marcus Theory is applied to the microscopic rate and equilibrium process defined above, we find that the intrinsic barrier so calculated is the same as for the intermolecular aldol reaction.

Scheme 5. Inter- and intra-molecular aldol condensations.

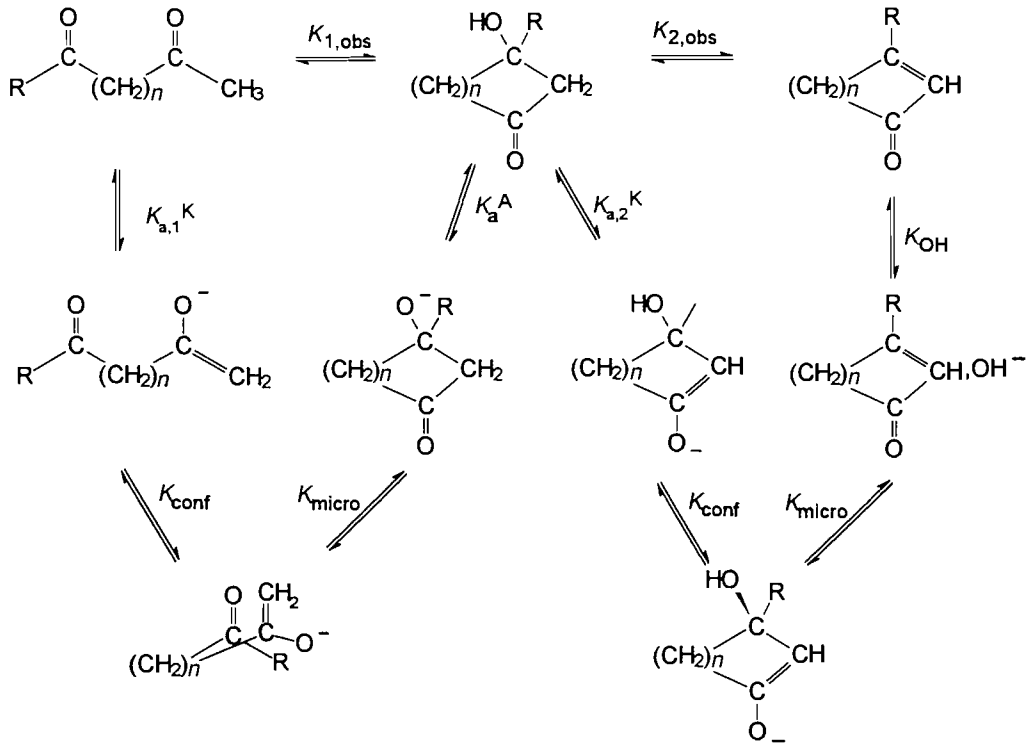


In work that is still in progress we are examining lactone formation. The classic study of this process was by Storm and Koshland (122), who reported the series shown in Scheme 7; to the data reported by Storm and Koshland we have added the rate and equilibrium constants (123) for δ-hydroxyvaleric acid/δ-valerolactone. The rate enhancements became quite dramatic as they moved along the series. The challenge was to see if these reactions also could be explained in terms of Marcus Theory with the same intrinsic barriers as for intermolecular reactions. We interpret these reactions in terms of the detailed reaction mechanism shown in Scheme 8. To apply Marcus Theory we must know the energies of the tetrahedral intermediates, and estimate pK_a values for all the protonated species encountered on the reaction path.

We are in the course of determining the energies of the tetrahedral intermediates for a series of lactonizations by our indirect thermodynamic method (25, 26, 29, 124) We start with the heats of formation for the corresponding orthoesters, determined by reaction calorimetry using the process in eq.

[3] As contained in MM3(89) as obtained from QCPE.

Scheme 6. Detailed mechanism for an intramolecular aldol condensation.



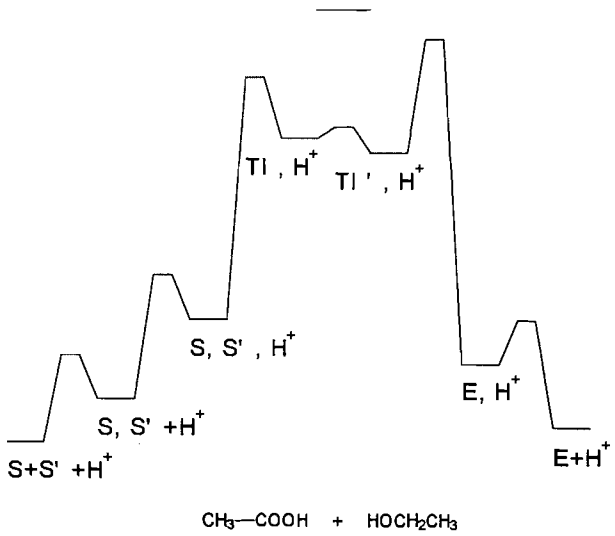
Scheme 7. Intramolecular esterification.

	k_{H+}	EM
CH_3—COOH + $HOCH_2CH_3$	1.8×10^{-5}	
	1.43×10^{-3}	79.
	2.21×10^{-3}	122.
	18.7	1.04×10^{6}

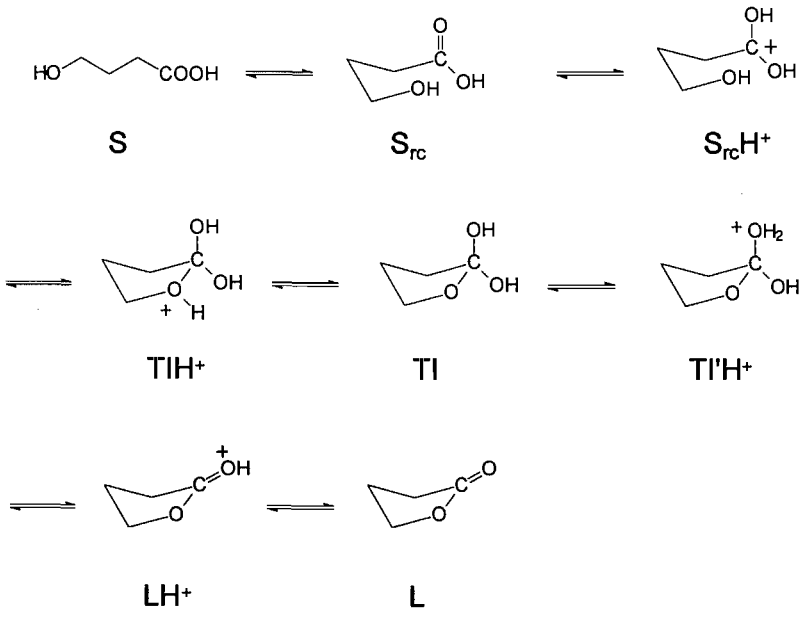
[8]. Then, by methods we used before, we could calculate the heats of formation for the liquids, heats of vaporization (125), entropies, free energies of transfer (126), and thus free energies of formation in aqueous solution. Then we could calculate the (small) free energy changes for the hypothetical hydrolysis reactions replacing OCH_3 by OH (29), eq. [9] and arrive at the free energies of formation of the tetrahedral intermediates.

pK_a values were estimated by linear free energy relations, as we have previously described (27). pK_{BH^+} values for the lactones are less well defined because there are no equilibrium studies of protonation of which I am aware. There are studies of methyl transfer equilibria relating cations, which show that the lactones are more basic than simple esters (127). Values of

Fig. 14. Calculated reaction coordinate diagram for the acid-catalyzed formation of ethyl acetate from ethanol and acetic acid. The mechanism assumed is the same as in Scheme 8. Activation barriers for proton transfers assume diffusion control in the favorable direction. Encounter complex formation is assumed to be diffusion controlled, and the equilibrium constant for encounter complex formation is estimated following Hine. The free energies of activation for the addition of alcohol and the expulsion of water were based on previously determined intrinsic barriers. The observed free energy of activation is shown and is within 2 kcal of the calculated value. Note that for this process expulsion of water is the rate-limiting step.



Scheme 8. Mechanism for intramolecular esterification.

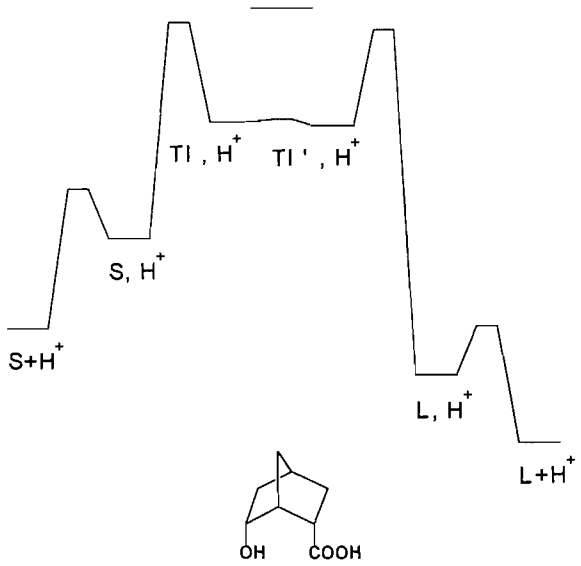


pK_{BH^+} for the lactones were estimated, but are unavoidably uncertain.

The intrinsic barriers for addition of water (33, 103) or methanol (103) (or hydroxide or methoxide) to carbonyl groups are known, and so we have all the information to calculate the full reaction coordinate diagram. We will focus on the cases of ethyl acetate and 2-*endo*-hydroxy[2.2.1]bicycloheptane-6-endocarboxylic acid. Figs. 14 and 15 show the calculated free energy levels for intermediates and transition states, as well as the experimentally observed transition state level. The model used for the carbon–oxygen bond-making/breaking processes was as shown in eq. [10]; by using Multidimensional Marcus Theory we could allow for either general or specific acid catalysis and either simple attack by water or hydroxyl or general-base-catalyzed attack, with water as general base. Clearly we are able to come quite close to the observed value. An additional complication is that the rate-determining steps are expected to be different in these two reactions; because of the lower intrinsic barrier for methoxide expulsion, attack of the alcohol is only rate limiting when lactone formation is strongly favored thermodynamically.

[8] 
[9] 
[10] 
Two examples do not constitute general proof but it is very encouraging that the first two cases to have been examined fit a pattern involving intrinsic barriers for intramolecular reactions that are the same as for the intermolecular analogs. If the intrinsic barrier is in general the same for an intramolecular reaction as for the analogous intermolecular reaction, then once we have the energies of the intermediates and products for the two reactions, and know the intrinsic barrier for the type of reaction involved, we can calculate the effective molarity for the kinetic process. In principle, and increasingly readily in practice, it will be possible to calculate the energies of stable species from structure, so our results hold out the

Fig. 15. Calculated reaction coordinate diagram for the acid-catalyzed formation of lactone from 6-*endo*-hydroxy-[2.2.1]bicycloheptane-2-endocarboxylic acid. The mechanism assumed is the same as in Scheme 8, and the calculations were as described in the legend to Fig. 14. The observed free energy of activation is shown and is within 1 kcal of the calculated value. Note that for this process addition of the alcohol is the rate-limiting step.



prospect of a complete explanation for intramolecular rate enhancements.

Although the conjectures that currently drive my research are still incompletely proven and controversial, the evidence to date is encouraging and will guide further research as I seek additional tests of these ideas.

Acknowledgments

The experimental studies that provided the data required to develop and test the ideas discussed in this paper have been carried out by a number of co-workers over the years, and I would like to acknowledge them here: J.A. Barker, J. Cossar, P.A. Cullimore, B.A. Dawson, J. Guo, A.P. Huntington, Y-C. Lee, J. Lu, D.C. Pike, K.F. Taylor, and X.P. Wang. I thank the Natural Sciences and Engineering Research Council of Canada for financial support of this work.

1995 McBryde Medal Award Lecture Solid phase microextraction — a unique tool for chemical measurements[1]

Tadeusz Górecki, Anna Boyd-Boland, Zhouyao Zhang, and Janusz Pawliszyn

Abstract: The paper presents recent advances in solid phase microextraction (SPME). The method utilizes a small fused silica fibre coated with a suitable polymeric stationary phase for analyte extraction from various matrices. The fibre is mounted in a syringe-like holder for protection. SPME has been used for the characterization of polymeric coating properties. Infinite-dilution weight-fraction activity coefficients have been determined for five solutes in two different stationary phases. Their values correlate well with the structure of the analytes and the coating. Other SPME uses include simultaneous determination of 60 pesticides in liquid matrices. A comparison between SPME, liquid extraction, and Soxhlet extraction for the analysis of Atrazine, Simazine, and Metolachlor in well water, as well as Metolachlor in soil samples, produced similar results for all three methods. The solvent-free character of SPME enables its use as sample introduction technique for fast GC analysis. Separations of BTEX in less than 9 s, and of volatile compounds described in EPA method 624 in 2.5 min, are described. SPME has also been used for the analysis of tetraethyllead and Pb(II) in water. Before the analysis, lead is derivatized with sodium tetraethylborate, and the tetraethyllead formed is extracted from sample headspace. Sub-ppb detection limits have been achieved with FID. Finally, SPME has been coupled to HPLC with the use of a specially designed interface. The combination has been tested on samples of polyaromatic hydrocarbons and surfactants in water. Very good precision of retention times and peak areas has been achieved.

Key words: solid phase microextraction, coating characterization, pesticide analysis, fast GC, lead and organolead compounds, SPME/HPLC.

Résumé : Dans ce travail, on présente les résultats récents obtenus en microextraction en phase solide (MEPS). La méthode fait appel à une petite fibre de silice fondue recouverte d'une phase stationnaire polymérique appropriée permettant de faire l'extraction de l'analyse à partir de diverses matrices. Pour sa protection, la fibre est montée dans un récipient en forme de seringue. La MEPS a été utilisée pour la caractérisation de propriétés de recouvrements polymériques. On a déterminé les coefficients d'activité à dilution infinie de la fraction massique pour cinq solutés, dans deux phases stationnaires différentes. Les valeurs présentent une bonne corrélation avec la structure des analytes et du recouvrement. La détermination de 60 pesticides dans des matrices liquides est une autre utilisation des MEPS. Une comparaison de la MEPS avec l'extraction liquide et l'extraction au Soxhlet pour l'analyse de l'Atrazine, de la Simazine et du Métolachlore dans l'eau de puits, ainsi que du Métolachlore dans des échantillons de sols, ont conduit à des résultats semblables pour les trois méthodes. Compte tenu du fait que les MEPS n'impliquent aucun solvant, cette méthode peut être utilisée comme technique d'introduction des échantillons pour des analyses en CG rapides. On décrit la séparation du BTEX en moins de 9 s et celle des composés volatils décrits dans la méthode de l'« EPA 624 » en 2,5 min. On a aussi utilisé la MEPS pour l'analyse du tétraéthylplomb et du Pb(II) dans l'eau. Avant l'analyse, le plomb est transformé en dérivé à l'aide de tétraéthylborate de sodium et le tétraéthylplomb formé est extrait de l'échantillon. On a atteint des limites de détection inférieures au ppb avec le «FID». Enfin, on a couplé la MEPS à la CLHP à l'aide d'une interface dessinée à cette fin. On a évalué la combinaison sur des échantillons d'hydrocarbures polyaromatiques et d'agents de surface dans l'eau. On a obtenu de très bonnes précisions pour les temps de rétention et pour les surfaces sous les pics.

Mots clés : microextraction en phase solide, caractérisation du revêtement, analyse des pesticides, CG rapide, composés du plomb et organoplombés, MEPS/CLHP.

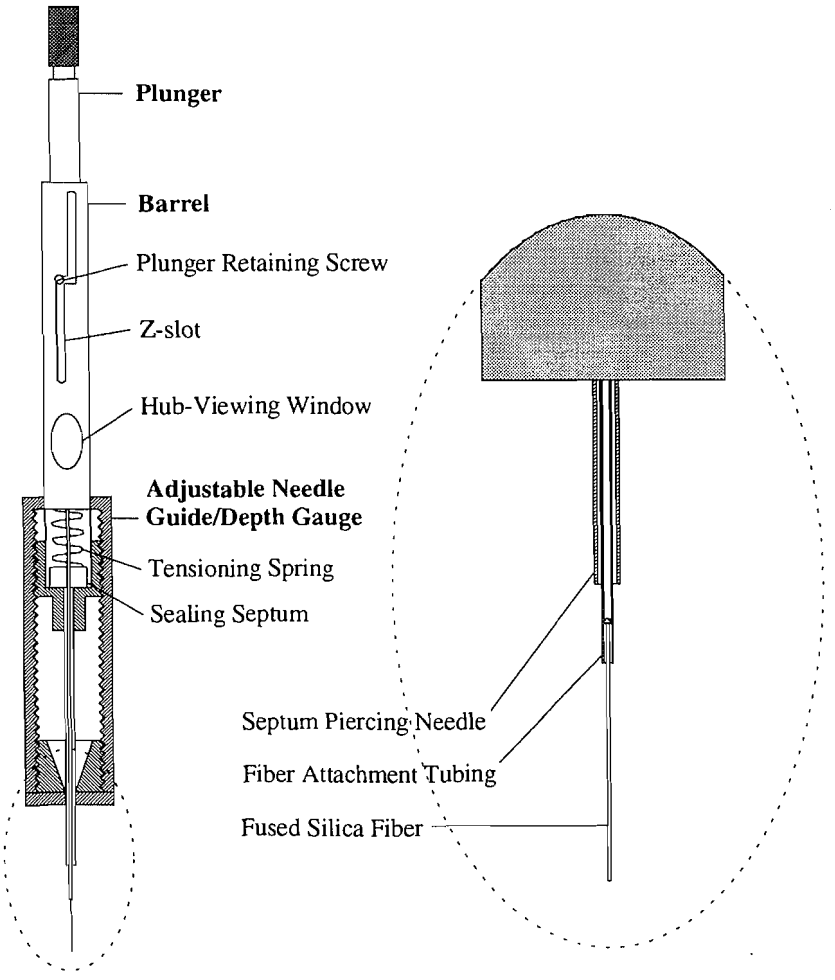
Fig. 1. Schematic diagram of the commercial SPME device.



Introduction

Analysis of trace components in natural liquid samples requires, in most cases, isolation and preconcentration of the analyte from the matrix. In the case of organic compounds, this is usually done by liquid–liquid extraction (including Soxhlet extraction), solid phase extraction, or headspace extraction (1). All these methods suffer from numerous drawbacks. Liquid–liquid extraction (LLE) requires large quantities of high-purity solvents, which are expensive to purchase and dispose of, and pose health and environmental hazards. Methods based on LLE are very laborious and time consuming. Their multistage character increases the potential risk of errors.

Solid phase extraction (SPE) is a much more modern approach. In this method analytes are isolated from the liquid matrix by adsorption onto a specially formulated material, usually packed in a cartridge or immobilized in a disk-shaped support. Application of SPE allows the time required for sample preparation to be significantly cut compared to LLE. However, the method is not completely solvent free, as a certain amount of solvent is necessary to liberate the trapped analytes prior to their chromatographic analysis. In many cases the eluate must be further concentrated by controlled evaporation of the solvent, which can pollute the atmosphere. Analyte losses may also occur at this stage. Suspended solids may cause plugging of the cartridges. The biggest SPE drawback, however, is the strong dependence of the breakthrough volumes on matrix composition.

Headspace extraction is, by its nature, limited to volatile and semivolatile analytes. Except static headspace, the method is difficult to automate. Dynamic headspace techniques are multistage, thus potentially error prone. Foaming can be a significant problem when analyzing natural samples. In some variations (closed-loop stripping analysis) small amounts of solvent have to be used for analyte desorption.

Solid phase microextraction

Solid phase microextraction (SPME) is a new approach, introduced about 6 years ago (2). It addresses most of the disadvantages of the methods mentioned above. SPME utilizes a small fused silica fibre, usually coated with a suitable polymeric stationary phase, for analyte extraction from a matrix. The fibre is mounted for protection in a syringe-like device. As the stationary phase is a liquid, analytes are absorbed by it until an equilibrium is reached in the system. The amount extracted

under such conditions is dependent on the partition coefficient between the sample and the coating. No total extraction occurs, thus problems related to breakthrough or limited sample capacity are virtually nonexistent.

Figure 1 presents the commercial SPME device, produced by Supelco, Inc. (Bellefonte, Pa.). The fibre, glued into a piece of stainless steel tubing, is mounted in a special holder. For protection during storage or piercing of a septum the fibre is withdrawn into the needle. During extraction the fibre is exposed to the sample by depressing the plunger. The analytes are allowed to partition into the coating for a predetermined time, and the fibre is then retracted into the needle. The whole device is next transferred to a GC, and the fibre is inserted into a hot injector, where thermal desorption of the trapped analytes takes place. The entire process is very simple and straightforward. It can be easily automated by using a properly modified syringe autosampler, commercially available from Varian (Varian Associates, Sunnyvale, Calif.).

SPME combines sample isolation and preconcentration into a single step, eliminating many potential sources of error. The technique is completely solvent free. Handling of the sample is minimal. Owing to the simple, cylindrical geometry of the sorbent, no plugging can occur. The potential matrix effects can be accounted for by standard addition. The technique requires no instrumental modifications, as regular GC injectors are used for analyte desorption. SPME has been used for many applications, including the determination of substituted benzene compounds (3, 4), caffeine in beverages (5), volatile organic compounds in water (6), polyaromatic hydrocarbons and polychlorinated biphenyls (7), chlorinated hydrocarbons (8), and phenols (9, 10). Sampling can be carried out directly from liquid samples, from their headspace, or from headspace over solid samples (11). Another promising field is application of SPME for the analysis of organic air pollutants (12).

The heart of SPME is the coating. Its physicochemical characteristics determine the suitability of the technique for the analysis of various classes of compounds. Six different coatings are currently available from Supelco: 7 μm, 30 μm, and 100 μm thick poly(dimethylsiloxane), 85 μm thick poly(acrylate), 65 μm thick poly(dimethylsiloxane)/divinylbenzene, and 65 μm thick Carbowax/divinylbenzene. Fibres coated with poly(dimethylsiloxane) are suitable for the analysis of nonpolar and moderately polar analytes. Poly(acrylate) coated fibres work best for analytes of intermediate to high polarity. Fibres containing divinylbenzene are best suited for the extraction of volatile polar and nonpolar compounds. New coatings are still being developed. Finding ones that are suitable for specific groups of analytes among the many possible polymers is not a trivial task. It requires a simple, cost-effective, and time-efficient method for characterization of partition and (or) adsorption properties of these materials. Interestingly, SPME offers new ways to characterize the properties of polymers used not only as coatings, but also as stationary phases in chromatography.

Application of SPME for physicochemical measurements (ref. 13)

Sorbent materials, used as stationary phases or coatings, are essential in the development of SPME, GC, and HPLC. The GC stationary phases are usually characterized by Kovats Indexes and Rohrschneider–McReynolds constants (14). These parameters are obtained by using standardized probe solutes, each representing a group of organic compounds. A similar concept is used for the characterization of coating materials for SPME. However, instead of conventional parameters, infinite-dilution activity coefficients of probe solutes are used to study the absorption or adsorption properties of selected coating materials.

The measurements of infinite-dilution activity coefficients of solutes in a stationary phase are usually made by a static gravimetric method or by a dynamic GC method. Both of these methods suffer from many disadvantages, including the large quantity of the phase required in the static method or the need to prepare a chromatographic column coated with the phase under examination in the GC method. Nowadays, the latter method is normally used for the determination of infinite-dilution activity coefficients.

SPME can be another tool for studying the properties of stationary phases. It has some advantages of both the static and the GC methods, while minimizing their drawbacks. The stationary phases of interest can be coated on fibres made of suitable materials (fused silica, stainless steel, etc.). The process of making fibres is much easier than that of columns. It requires very little material. The SPME device with a selected fibre coating can be used to extract a group of probe compounds, which are then separated on a standard commercially available column and quantified by a GC–MS. No extrapolation is necessary, as very low analyte amounts can be accurately determined.

The probe solutes used are McReynolds test solutes for GC stationary phases: benzene, butanol, 2-pentanone, nitropropane, and pyridine. The measurements consist of two steps. The first step is to measure the partition coefficients of the probe solutes between the stationary phase and the gas phase at near-infinite-dilution concentration levels. Then, from the partition coefficients, the corresponding activity coefficients are determined using the following equation:

$$[1]\quad \ln {}^{w}\gamma_1^{\infty} = \ln {}^{w}\gamma_p^{\infty} - \frac{p_1^0(B_{11} - v_1^0)}{RT} = \ln \frac{\rho_L RT}{K_R p_1{}^0 M_1} - \frac{p_1^0(B_{11} - v_1^0)}{RT}$$

where ${}^{w}\gamma_1{}^{\infty}$ is the virial corrected weight fraction infinite dilution activity coefficient of the solute; ${}^{w}\gamma_p{}^{\infty}$ is the weight fraction infinite dilution activity coefficient; p_1^0 is the solute saturated vapor pressure at temperature T; B_{11} is the second virial coefficient of the solute; v_1^0 is the bulk solute molar volume used to correct the second virial coefficient, R is the gas constant; ρ_L and M_L are the density and the molecular weight of the stationary phase, and K_R is the partition coefficient of the solute.

The measurement of K_R by SPME is straightforward. A gas sample is prepared by spiking n_0 mass of a solute into a capped vial of a volume V_g. SPME sampling is then performed until equilibrium is reached between the coating and the gas phase. If the volume of the vial is sufficiently large, the concentration change of the solute in the vial before and after SPME is negligible. The partition coefficient of the solute between the

[a]Not calculated because v_1^0 and B_{11} values are unavailable.

coating and the gas phase can be calculated from the following equation:

$$[2] \quad K_R = \frac{C_f}{C_g} = \frac{n_f}{V_f} \cdot \frac{V_g}{n_0}$$

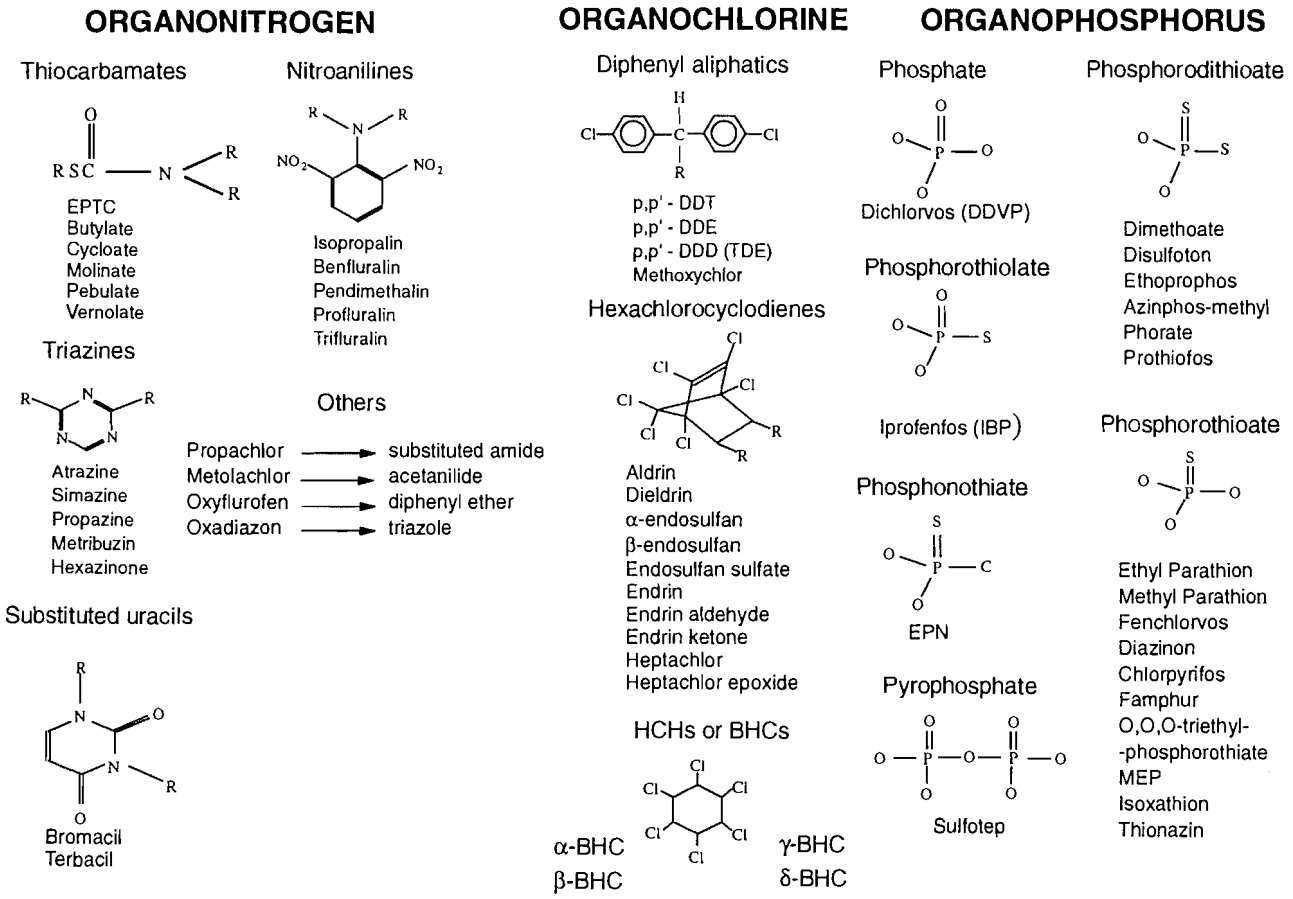
where C_f and C_g are the solute concentrations in the coating and the gas phase at equilibrium, respectively; n_f and n_0 are the mass extracted by the fibre coating and the mass spiked into the vial, and V_f and V_g are the volumes of the coating and the vial. To ensure that the concentration of the solute in the vial does not change during the measurement, the vial that contains the gas mixture has a volume about 10^6 times larger than the volume of the fibre coating. During the SPME measurements, the concentration of the solute in the fibre coating must be very low to ensure the validity of the assumption of infinite dilution.

Table 1 summarizes the infinite-dilution weight-fraction activity coefficients (ln $^{w}\gamma_p^{\infty}$) and their virial corrected counterparts (ln $^{w}\gamma_1^{\infty}$) of the five McReynolds solutes measured by SPME in two polymeric coating materials: one is 7 μm poly(dimethylsiloxane) bonded phase (equivalent to SPB-1), the other is 15 μm 50% phenyl-substituted poly(dimethylsiloxane) (equivalent to SPB-50). The weight-fraction infinite-dilution activity coefficients of the five probe compounds are indicators of how these compounds interact with the coating materials, thus can be used to characterize the properties of the coating. The $^{w}\gamma_p^{\infty}$ values of the five compounds in the 50% phenyl poly(dimethylsiloxane) are quite different from those in poly(dimethylsiloxane). The most obvious change is the substantial decrease of ln $^{w}\gamma_p^{\infty}$ values for benzene and pyridine. Compared to the poly(dimethylsiloxane) coating, the 50% phenyl coating provides a physicochemical "environment" more similar to their own molecular structure because of a large number of phenyl groups. Since the structural differences between the solutes and the solvent become smaller, the ln $^{w}\gamma_p^{\infty}$ values also become smaller.

Similar phenomena, although on a smaller scale, are also observed for nitropropane and 2-pentanone. In this case, the π-electrons of both compounds are interacting with phenyl groups and their delocalized π-electrons. The only compound with little change in ln $^{w}\gamma_p^{\infty}$ values is 1-butanol, which is the least polar among the compounds without a ring structure, and also the only compound without π-electrons. It is interesting to point out that for the four compounds (benzene, 2-pentanone, nitropropane, and pyridine) whose ln $^{w}\gamma_p^{\infty}$ values are reduced substantially in the 50% phenyl poly(dimethylsiloxane) coating, the temperature dependence of ln $^{w}\gamma_p^{\infty}$ is also less apparent. This is another indication that these solutes in the 50% phenyl poly(dimethylsiloxane) coating are in an environment more similar to their own molecular structure than in the other coating.

The above empirical discussion is not intended to explain in detail why and how the ln $^{w}\gamma_p^{\infty}$ values change. It indicates, however, that solution properties of the coating materials can be characterized by the ln $^{w}\gamma_p^{\infty}$ values of the five probe com-

Fig. 2. Structures of pepticides analyzed in the combined method.



pounds. SPME, while based on the coatings for extraction of analytes, provides at the same time a new, simpler way for evaluating the properties of coating materials.

Once the suitability of the given coating is confirmed, SPME can be used for the analysis of many different types of compounds. The scope of the technique can be broadened by new, nonconventional approaches to the analysis. Following is a brief presentation of some of the latest achievements in practical applications of SPME.

Application of SPME to pesticides analysis

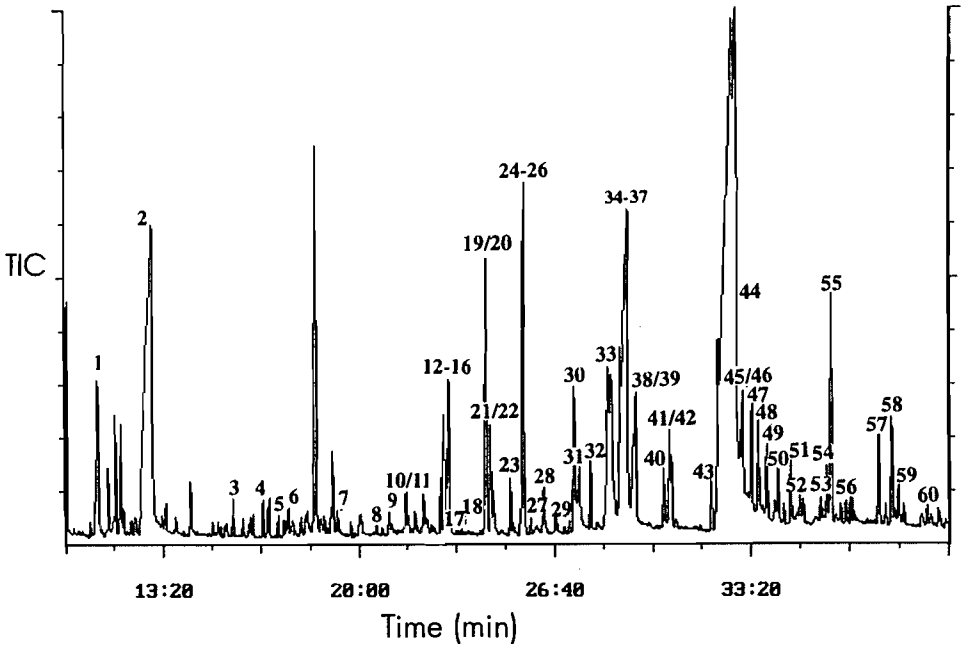
In the United States alone over 100 million hectares of agricultural land is treated with pesticides annually to prevent crop damage from a variety of insects, fungi, and noxious weeds (15). Pesticides are also frequently used for industrial and domestic purposes. The extensive use of pesticides has led to environmental concern because of their persistence and consequent presence in air, soil, and water. Typical concentration levels of pesticides in contaminated waters range from low ppt to low ppb (16–21) Pesticides are classified as either herbicides, insecticides, or fungicides. SPME has been successfully applied to the analysis of pesticides falling mainly into the first two groups.

In total 60 different pesticides have been analyzed by SPME methods developed in our laboratory. The target analytes can be broadly classified into three groups: organophosphorus, organochlorine, and organonitrogen. Within each of these groups, several classes of analytes were examined. Figure 2 shows the structures of the classes and lists the target pesticides that have been analyzed. These pesticides represent a broad range of organic compounds with widely different solubilities in water and polarities.

The development of SPME methods for different pesticides must thus be a carefully optimized process that considers the affinity of different classes of analytes for different coatings. It was observed that nitrogen-containing herbicides and organophosphorus pesticides were generally better extracted by the poly(acrylate) coated fibre (22, 23), whereas the organochlorine pesticides were generally better extracted by the poly(dimethylsiloxane) coated fibre (24). A wide linear range, typically over several orders of magnitude, is achievable for the organochlorine, organophosphorus, and organonitrogen pesticides. The methods developed have detection limits within the range required by the US EPA for most analytes when an FID detector is used. The use of a more selective detector, such as an ECD, NPD, or ion trap MS, enables detection limits that are considerably better than conventional EPA methods can achieve (i.e., low ppt levels). The precision of the methods is good, with RSDs of less than 20% for all analytes with all detectors.

In spite of the fact that some pesticides are better extracted by the poly(dimethylsiloxane) coating, and others by the

Fig. 3. Total ion chromatogram (TIC) of orange juice spiked with 60 pesticides, analyzed by SPME. 1, *o,o,o*-TEP; 2, Dichlorovos; 3, EPTC; 4, Butylate; 5, Vernolate; 6, Pebulate; 7, Molinate; 8, Thionazin; 9, Propachlor; 10, Ethoprofos; 11, Cycloate; 12, Trifluralin; 13, Benfluralin; 14, Sulfotep; 15, Phorate; 16, α-BHC; 17, Dimethoate; 18, Simazine; 19, Atrazine; 20, β-BHC; 21, Propazine; 22, Lindane; 23, Profluralin; 24, Diazinon; 25, δ-BHC; 26, Disulfoton; 27, Terbacil; 28, Iprofenfos; 29, Metribuzin; 30, Methyl Parathion; 31, Heptachlor; 32, Fenchlorovos; 33, Fenitrothion; 34, Bromacil; 35, Isoxathion; 36, Aldrin; 37, Metolachlor; 38, Chloropyrifos; 39, Ethyl Parathion; 40, Isopropalin; 41, Pendimethalin; 42, Heptachlor epoxide; 43, Endosulfan I; 44, Prothiofos; 45, *p,p'*-DDE; 46, Dieldrin; 47, Oxadiazon; 48, Oxyfluorofen; 49, Endrin; 50, Endosulfan II; 51, *p,p'*-DDD; 52, Endrin aldehyde; 53, Famphur; 54, Endosulfan sulfate; 55, *p,p'*-DDT; 56, Hexazinone; 57, Endrin ketone; 58, EPN; 59, Methoxychlor; 60, Azinphos-methyl.



poly(acrylate) coating, all the analytes can be extracted with both of the phases, so the choice of coating need not prohibit successful screening of all the target analytes by either of the commercially available fibres. This last fact enabled development of a method for the combined analysis of 60 pesticides in one mixture (25). Although it is not possible to achieve baseline separation of all the compounds with a relatively short chromatographic analysis, the use of MS detection enables resolution of all the analytes by selecting appropriate masses for quantitation. For some analytes the detection limits with one coating are substantially lower than for the other coating, but generally they are similar, and in all cases better than those required by the US EPA.

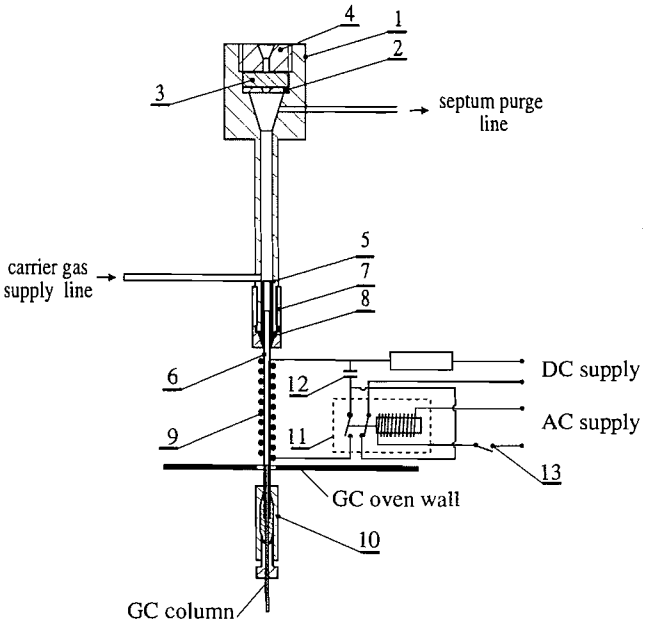
Environmental samples can be modified by altering the ionic strength or adjusting the pH of the sample in order to increase the amount extracted by the fibre coating. It was found that for many analytes, the addition of sodium chloride to the sample increased the amount extracted (18–21). This often allows the analyst to improve the extraction of analytes of particular interest whilst still allowing for detection of the other analytes present in the sample (ones for which salt addition does not affect the amount extracted, or reduce it). In general, there was no significant effect on the extraction efficiency at any pH in the range 2–11. The advantage of the SPME method over many other methods is that samples with any pH in the above range can be analyzed with confidence, and if pH modification of a matrix is required for other reasons, the method will not be affected.

The combined method has been applied for quantitative analysis of the 60 pesticides from water and as a screening procedure for the detection of low ppb levels of the target analytes in soil and other matrices. Figure 3 illustrates a chromatogram of the 60 target pesticides spiked into an orange juice sample and detected by SPME and GC–MS. Analyzing such a wide variety of analytes at once allows for rapid screening of environmental samples as well as an accurate determination of the pollutants that may be present. Quantitation of analytes in complex matrices can generally be performed by the use of the standard addition procedure.

Recently a comparison of LLE, immunoassay methods, and the SPME method for the analysis of Atrazine, Simazine, and Metolachlor was undertaken with the Canadian Ministry of Agriculture. Over 100 well-water samples were analyzed by the methods and the results were generally found to agree for the three techniques.[4] A comparison was also made between

[4] A.A. Boyd-Boland, S. Clegg, and J. Pawliszyn. Unpublished results.

Fig. 4. Schematic diagram of the injector 1, injector body; 2, washer; 3, septum; 4, nut; 5, needle guide; 6, 0.53 mm i.d. fused silica capillary; 7, nut; 8, ferrule; 9, heater (0.057 mm o.d. resistive wire); 10, butt connector; 11, relay; 12, capacitor; 13, switch.



SPME, liquid extraction (using hexane), and Soxhlet extraction for the analysis of Metolachlor in a contaminated core sample. The SPME extraction simply involved suspending the sample in water, stirring the slurry and exposing the SPME fibre directly to the slurry. The results obtained by all three methods were the same: 1.8 mg (Metolachlor)/kg (soil). This indicates that for relatively water-soluble analytes, such as Metolachlor, the SPME method can be used for quantitative analysis of soil samples by simply suspending the soil in water. Obviously this represents a considerably easier analysis procedure for pesticides in soil than those currently used.

Apart from vastly simplifying sample preparation, SPME can offer other advantages over existing techniques. Of great importance is the solventless injection. It allows, among others, a significant reduction of the analysis time, as discussed in the following paragraph.

SPME as a sample introduction technique for fast GC (refs. 26, 27)

Theoretical considerations (28) indicate that desorption of the analytes from the fibre can be very fast (<1 s). It is therefore possible to produce a very narrow injection band, compatible with the requirements of fast GC. To achieve fast desorption, the fibre must be heated very rapidly. Regular GC injectors (split/splitless, programmed-temperature vaporization injector (PTV), septum programmable injector (SPI)) are not capable of doing this, even when the fibre is rapidly introduced to a hot injector. A dedicated injector, presented schematically in Fig. 4 (25), was therefore designed and built. A segment of a fused silica capillary, 6, connected to the injector base and equipped with a heater, 9, coiled along the fused silica capillary constitutes the low-volume part where desorption takes place. The GC column is inserted through a butt connector, 10, into the capillary, 6. The injector is rapidly heated by discharging the capacitor, 12. The switch, 13, is mounted in such a way that the capacitor is discharged simultaneously with fibre withdrawal from the needle. Very low mass and heat capacity of the heated part of the injector assure heating rates better than 1000°C/s. Under optimized conditions, the injector enabled isothermal separation of a BTEX mixture (benzene, toluene, ethylbenzene, *o*, *m*, *p*-xylene) in less than 9 s using a 15 μm PDMS coated fibre and a 4 m × 0.25 mm × 0.25 μm SPB-5 column (27).

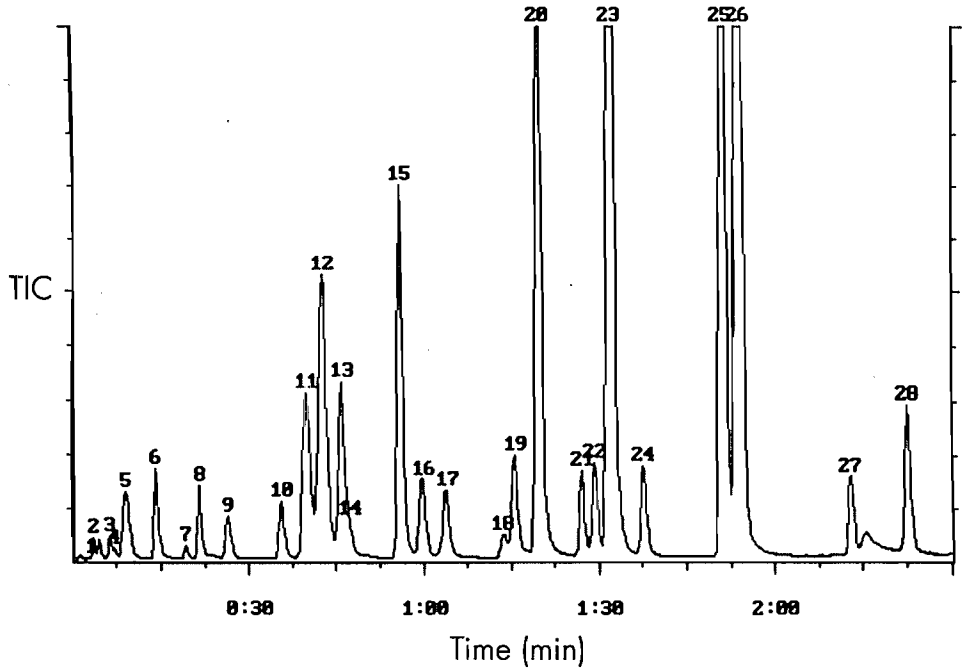
Fast separation of more complex mixtures requires columns of higher efficiency, therefore 2.5 m × 0.1 mm × 0.6 μm Vocol and SPB-1 columns were used for the separation of volatile organic compounds listed in EPA method 624: purgeables A (trichlorofluoromethane, 1,1-dichloroethene, dichloromethane, 1,1-dichloroethane, trichloromethane, tetrachloromethane, trichloroethene, 1,2-dichloropropane, 2-chloroethyl vinyl ether, 1,1,2-trichloroethane, tetrachloroethene, dibromochloromethane, chlorobenzene), purgeables B (1,2-dichloroethene, 1,2-dichloroethane, 1,1,1-trichloroethane, benzene, bromodichloromethane, *cis*-1,3-dichloropropene, toluene, *trans*-1,3-dichloropropene, ethylbenzene, tribromomethane, 1,1,2,2-tetrachloroethane), and purgeables C (chloromethane, vinyl chloride, bromomethane, chloroethane). Both isothermal and temperature-programmed separations were performed. Ion traps MS and FID were used for detection. In isothermal runs, purgeables A and B were separated in slightly above 4 min. Purgeables C, which are gases at room temperature, could not be efficiently separated in isothermal runs.

Figure 5 presents temperature-programmed separation of all 28 compounds on the Vocol column. The analysis is completed in ca. 2.5 min, compared to about 20 min required for regular separation (6). Together with cooling down and equilibration, this time is comparable to the sampling time required (4–5 min). It is therefore potentially possible to analyze 10–12 samples per hour. In the regulatory purge-and-trap method the analysis of one sample requires at least half an hour, hence the analytical throughput can be considerably improved by the application of SPME coupled with fast GC.

The repeatability of retention times is excellent. All compounds can be easily quantified when using ion trap MS for detection, even though one pair of compounds (benzene and 1,2-dichloroethane) coelutes on the Vocol column. Precision of peak area determination is generally good (much below 10% RSD), except for the early eluting peaks, in which case the number of data points acquired by the ion trap MS system per peak (3–4) is insufficient for accurate determination. When using FID, precision is directly related to peak area: it is very good for larger peaks, and worse for small peaks. Compared to ion trap MS, FID provides considerably worse sensitivity, as most of the components of the purgeables mix are organohalogen compounds. It should be possible to obtain much better results, without the need to use ion trap mass spectrometry, by the application of selective detectors (ECD or ELCD for organohalogens, PID for aromatics).

Fast desorption of the analytes from the fibre can be achieved not only by rapidly heating the injector, but also by heating the fibre directly. This can be accomplished by using a hollow fibre equipped with an internal microheater. Figure 6

Fig. 5. Separation of purgeables A, B, and C on a VOCOL column. Conditions: 0°C–30°/min–70°C; 2.1 atm, dedicated injector, capacitor voltage 24 V, MS detector, mass range 45–250. 1, chloromethane; 2, vinyl chloride; 3, bromomethane; 4, chloroethane; 5, trichlorofluoromethane; 6, 1,1-dichloroethene; 7, dichloromethane; 8, 1,2-dichloroethene; 9, 1,1-dichloroethane; 10, trichloromethane; 11, 1,1,1-trichloroethane, 12, tetrachloromethane; 13, benzene; 14, 1,2-dichloroethane; 15, trichloroethene; 16, 1,2-dichloropropane; 17, bromodichloromethane; 18, 2-chloroethyl vinyl ether; 19, *cis*-1,3-dichloropropene; 20, toluene; 21, *trans*-1,3-dichloropropene; 22, 1,1,2-trichloroethane; 23, tetrachloroethylene; 24, dibromochloromethane; 25, chlorobenzene; 26, ethylbenzene; 27, tribromomethane; 28, 1,1,2,2-tetrachloroethane.



presents the design of such an internally heated fibre, based on a commercial SPME holder (Supelco, Inc.). A 0.32 mm i.d. fused silica capillary, flame sealed at one end, is used as the fibre. The microheater, made of a 0.05 mm o.d. Ag wire, is coiled around another fused silica microcapillary (0.075 mm i.d., 0.15 mm o.d.). One end of the heating wire is passed inside the microcapillary, and the other is outside, which yields excellent electrical insulation between the two leads. The entire heating assembly is inserted inside the 0.32 mm fused silica capillary.

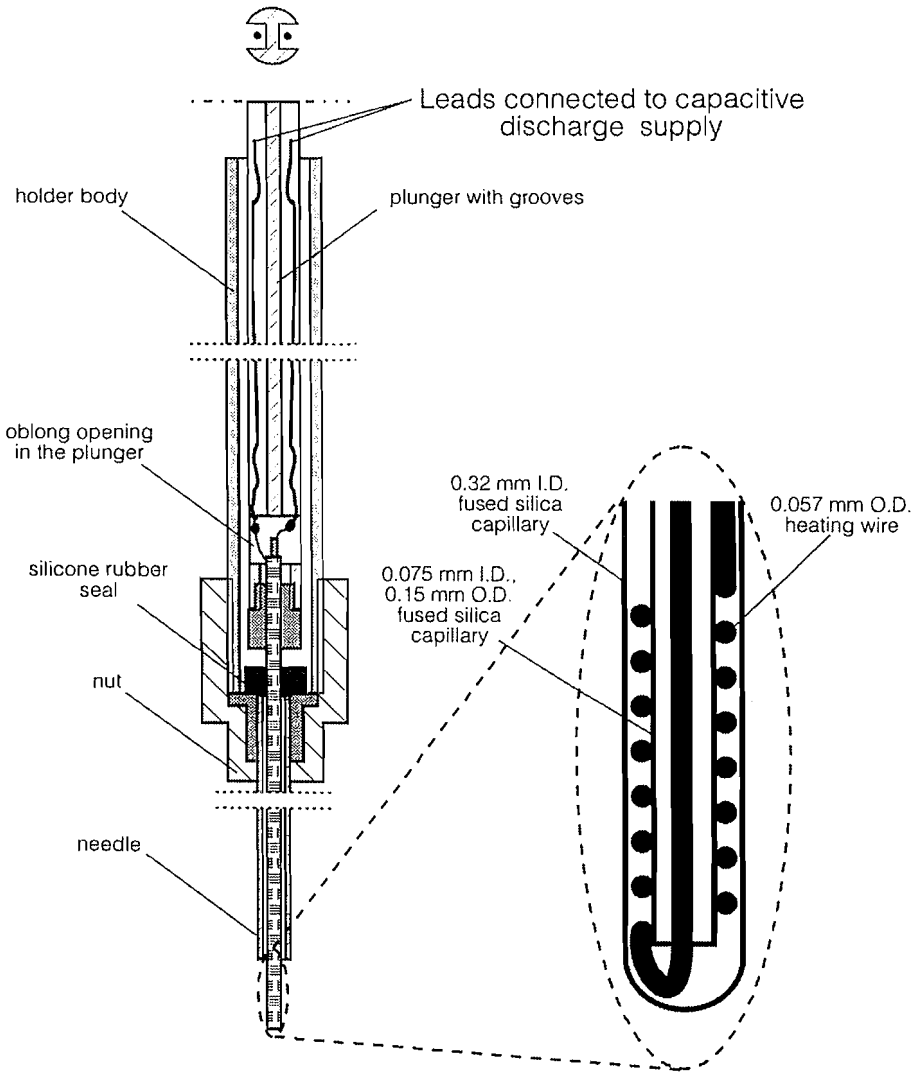
An internally heated fibre prepared in this way was custom coated with poly(dimethylsiloxane) stationary phase and tested on a BTEX mixture in air. Very good repeatability of retention times was achieved. The analysis time, equal to ~10 s, is comparable to the best results obtained with the dedicated injector. Repeatability of peak areas was worse than for the regular fibre used with the dedicated injector, probably because of inferior properties of the custom-made coating. The biggest advantage of the internally heated fibre is that no carryover is observed when using this device.

SPME coupled to GC is mainly suited for the analysis of volatile and semivolatile organic compounds of low to intermediate polarity. However, the scope of applications can be significantly broadened by using different approaches either to the extraction step, or to the final determination. One such possibility is derivatization of otherwise nonvolatile analytes, presented below.

Determination of tetraethyllead and inorganic lead in water by SPME/GC (ref. 29)

Alkylleads and inorganic lead are extremely dangerous environmental pollutants. In the environment alkyllead compounds are mostly of anthropogenic origin, but they may also be produced from biological transformation of Pb^{2+}. Tetraethyllead is still used in many parts of the world as an additive to gasoline. Inorganic lead is ubiquitous and can be found in air, water, and soils. Speciation of alkyllead compounds at low levels found in the environment is not a trivial problem. SPME seems very attractive for this task, as it requires virtually no sample preparation and is capable of achieving very high sensitivity and low detection limits. There are many established methods of Pb^{2+} determination, yet at trace levels they usually require very expensive instrumentation. None of the spectrometric methods of use (GFAAS, ICP–MS) can be adopted for field measurements. Electrochemical methods, especially anodic stripping volatammetry, are known for their high sensitivity and relatively low price, but they require clean, organic-free samples. Environmental samples usually require

Fig. 6. Schematic diagram of the Supelco SPME device modified to accommodate the internally heated fibre.



mineralization prior to the analysis, a task that is not easily accomplished in the field.

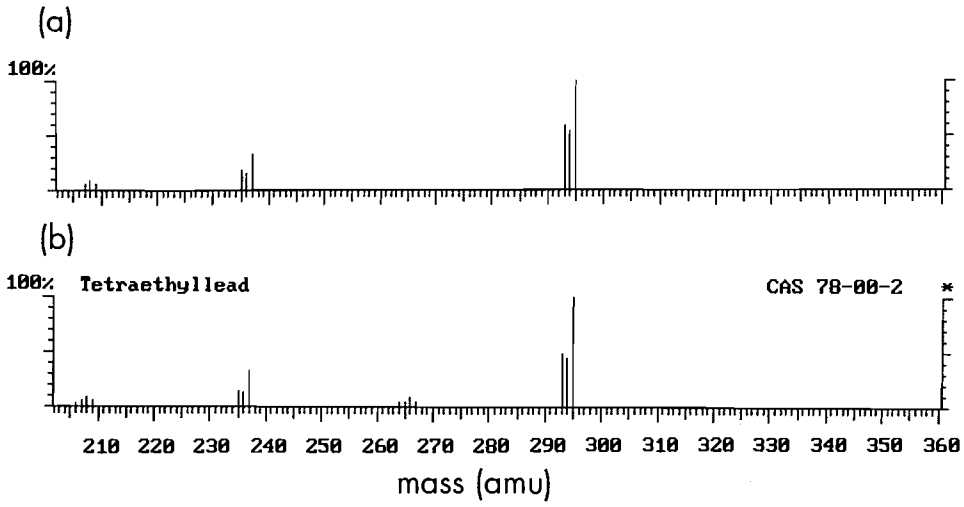
Rapsomanikis (30) pioneered the use of sodium tetraethylborate (STEB) for ethylation of ionic alkyllead, alkylmercury, as well as inorganic lead and mercury in the aqueous phase. The resultant organometallic compounds are poorly soluble in water and have relatively high vapour pressure, hence they should be easily extracted by SPME. Headspace extraction is favourable, since it avoids problems related to extraction of unwanted large molecular weight compounds that can be present in the sample. Tetraethyllead was chosen as a representative of alkyllead compounds, as its use is the most widespread, and it is the product of inorganic lead ethylation.

Experiments were performed using GC–FID and GC – ion trap MS. It has been found that tetraethyllead is easily extracted from the headspace over aqueous samples. With vigorous stirring, equilibrium is reached after ~7.5 min. The response for FID was found to be linear in the entire range examined, from 0.1 to 100 μg/L, as evidenced by the value of the correlation coefficient $R > 0.998$. The precision of tetraethyllead determination at the 50 ppb level was very good, RSD being equal to 2.4%. Ion trap MS offered excellent detection limits (below 5 ppt), yet its response to tetraethyllead was nonlinear due to secondary fragmentation of unstable ions stored in the trap.

Derivatization of Pb^{2+} was performed by adding STEB solution to a pH buffered sample. The evolved tetraethyllead was extracted by SPME from the headspace over the sample. The system reached equilibrium after ~15 min. The FID response was linear in the entire range examined, from 0.2 to 1000 ppb. The detection limit was found to be ~200 ppt Pb^{2+}. It was slightly adversely affected by the non-zero blank value, most probably related to the reagent used. Precision of the determination at a 50 ppb level, as estimated by the value of the RSD = 5.04%, was very good.

Ion trap MS confirmed the identity of the derivatization product. Figure 7 presents the mass spectrum of the product found after SPME extraction of a pH buffered sample contain-

Fig. 7. Comparison of the mass spectrum of the derivation product (*a*) with library spectrum of tetraethyllead (*b*).



ing 20 ppb Pb^{2+} and the derivatization reagent, and the library spectrum of tetraethyllead. The agreement is excellent. Ion trap MS response in the 5–100 ppb range was nonlinear for the reasons described above.

The results obtained indicate that SPME can be an invaluable tool for alkyllead and inorganic lead speciation in water. Native non-ionic alkyllead compounds can be analyzed first, followed by addition of the derivatizing reagent and determination of ionic alkyllead compounds and inorganic lead. According to the literature, it should be possible to use a similar procedure for the determination of other organometallic compounds, including those of mercury and tin (31). The whole procedure can be easily performed in the field with the use of a portable GC.

Determination of inorganic lead in water by SPME illustrates how the technique can be used for analytes that normally would not be amenable to extraction from water into an organic phase. Derivatization to a form that can be extracted by an SPME device can also be performed in other ways. For example, Hg^{2+} can be electrochemically reduced to Hg^0 using a thin, gold-plated wire in place of the regular SPME fibre. The metallic mercury formed dissolves in the gold layer forming an amalgam. Mercury can then be liberated from the gold layer by rapidly heating the wire to a high temperature. Experiments of this kind were performed using an ion trap MS as the detector. Rapid heating of the wire was achieved by discharging a capacitor directly through the wire, using a modified version of the injector presented in Fig. 4. Initial experiments demonstrated that the method is feasible and very sensitive. At the same time it allows speciation of mercury by choosing a proper potential during the reduction step.

Derivatization broadens the scope of SPME to compounds that cannot be extracted by regular SPME procedures. However, there are a number of compounds that can be easily extracted, but cannot be analyzed by GC due to nonvolatility or thermal instability. These compounds include pharmaceutical products, peptides, proteins, etc. Obviously, other separation and determination techniques should be used in such cases, including SFC, CE, and HPLC.

Coupling to HPLC

Coupling of SPME to HPLC (32) is a natural extension of the method, enabling new, exciting applications. However, in contrast to GC, the existing instrumentation cannot be used for this purpose without modification of the sample introduction system.

Thermal desorption is not feasible in conjunction with HPLC. The alternative is solvent desorption. To accomplish this, a special interface was designed and built. Schematic diagram of this interface is presented in Fig. 8. The heart of the device is a custom-made desorption chamber with three ports in a T-configuration, connected to a six-port valve in place of the sampling loop. With the valve in the "load" position, the desorption chamber is at atmospheric pressure. This enables the fibre assembly to be safely inserted to the chamber via the finger-tight PEEK union (c). The union seals the steel tubing in which the fibre is mounted strongly enough to withstand pressures up to 4500 psi (1 psi = 6.9 kPa). After switching the valve to the "injection" position, the mobile phase flows along the fibre upwards to avoid air bubbles being introduced to the system. The analytes present in the sample partition from the coating to the mobile phase and are swept away to the column.

Theoretical considerations (32) indicate that with properly selected solvent (one for which the affinity of the analytes is high) the desorption process can be very fast, the time required being less than 1 s. This has been proven in an experiment in which the desorption chamber was connected directly to the HPLC detector. For benzo[*a*]pyrene and CH_3CN/H_2O 90/10 used as the mobile phase, the desorption volume was 0.2 μL. This volume increased rapidly with increasing water content in the mobile phase due to poor solubility of benzo[*a*]pyrene in water.

The applicability of the method for real-life analysis was verified on a sample of 13 polycyclic aromatic hydrocarbons (PAH) listed in the EPA method 525. A 100 ppb standard solution of the PAHs in water was sampled with a 7 μm thick PDMS fibre for 30 min, followed by the HPLC analysis. The results were compared to those obtained for loop injection.

Fig. 8. Design of the SPME–HPLC system: (a) stainless steel (SS) T-joint; (b) SS tubing; (c) poly(ether ether ketone) (PEEK) tubing; (d) two-piece finger-tight PEEK union; (e) PEEK union with tubing.

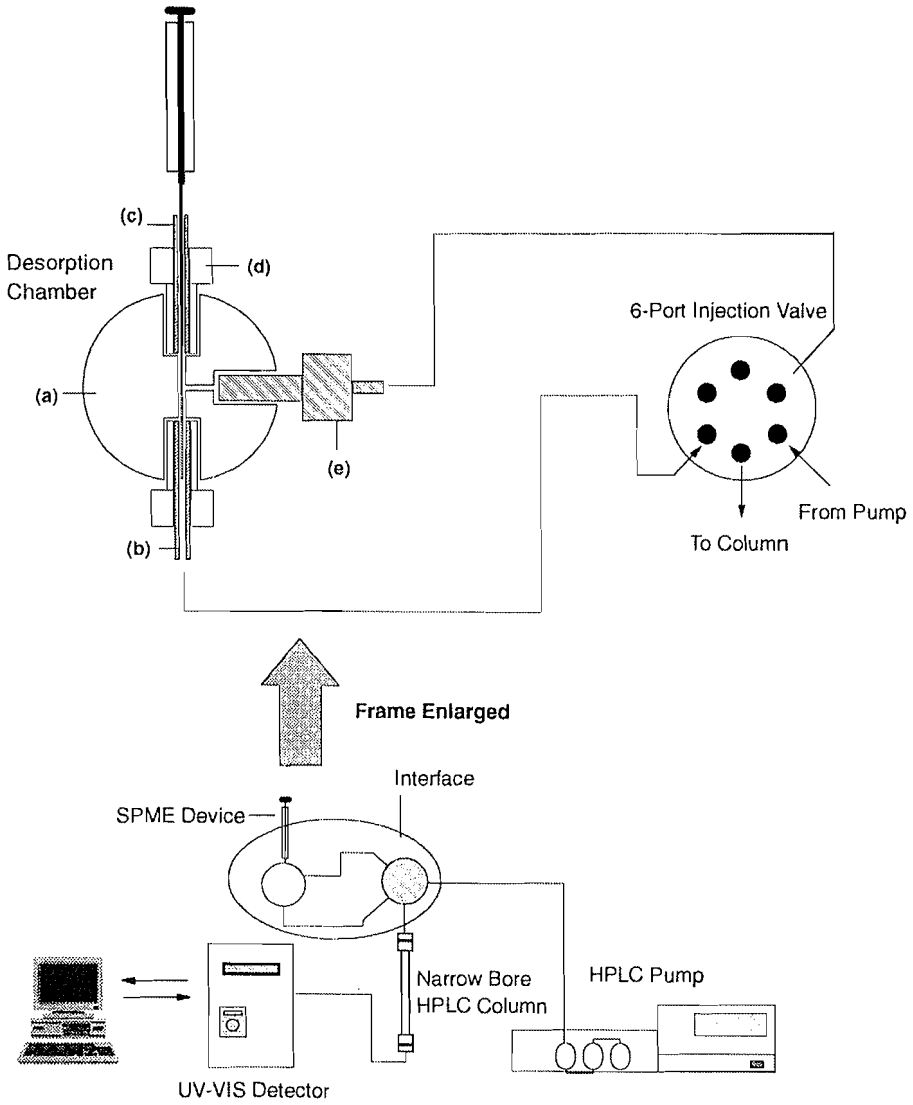


Figure 9 illustrates the chromatograms obtained for both samples. The agreement between the retention times of the analytes is excellent, which indicates that the interface does not contribute significantly to extracolumn effects. The differences in the relative peak areas for some of the analytes are related to the differing affinity of the analytes towards the coating.

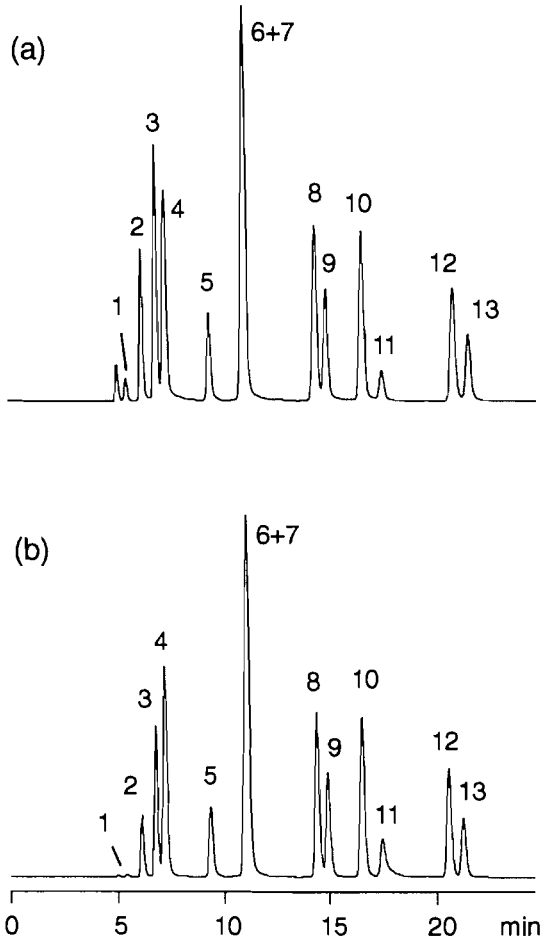
The repeatability of retention times and peak areas was examined for a sample of four PAHs (fluoranthene, pyrene, benz[*a*]anthracene, and benzo[*a*]pyrene). Relative standard deviations were very good, below 5% for retention times and below 7% for peak areas. This indicates that SPME coupled to HPLC can be used for both qualitative and quantitative analysis. Additionally, it has been found that there is no carryover when using solvent desorption for liberation of PAHs from the fibre coating. Small carryover was usually observed when thermal desorption was used for the liberation of PAHs from the coating in the GC analysis.

Coupling of SPME to HPLC is still a new technique, in the initial stage of development. A commercially available interface has been introduced by Supelco only recently. The results obtained so far indicate that it has a great potential. The applicability of the technique for samples not amenable to GC analysis has been verified in our laboratory using the example of surfactants in water (33). Very good sensitivity was obtained without complicated sample pretreatment. Work is under way on new, exciting applications.

Conclusions

Although still a young technique, SPME has proven its suitability for many analytical tasks. Since the commercialization of the technique in 1993, the number of papers published, utilizing this technique, has been growing very rapidly. This does not mean, however, that all its potential has already been explored. This paper presents some of the many new possibil-

Fig. 9. Separation of PAH mixture 525 with solvent gradient by (a) 1 μL loop injection of a 100 ppm solution, and (b) fibre injection; 7 μm PDMS fibre, 30 min extraction from a solution containing 100 ppb of each compound spiked into water. Chromatographic conditions: ODS column, 25 cm × 2.1 mm i.d., 5 μm particle diameter, flow rate 0.2 mL/min, detection UV, 254 nm, solvent program, CH_3CN/H_2P (80/20, v/v), linear gradient to 100% CH_3CN in 15 min. Peak identification: 1, acenaphthylene; 2, fluorene; 3, phenathrene; 4, anthracene; 5, pyrene; 6, benz[*a*]anthracene; 7, chrysene; 8, benzo[*b*]fluoranthene; 9, benzo[*k*]fluoranthene; 10, benzo[*a*]pyrene; 11, dibenzo[*ah*]anthracene; 12, indeno[1,2,3-*cd*]pyrene; 13, benzo[*g,h,i*]perylene.



ities offered by SPME. They include basic physicochemical research permitting easy characterization of the properties of stationary phases, simultaneous determination of 60 pesticides representing all the groups currently in use, fast separations made possible without complicated and expensive instrumentation, and analysis of entirely new types of analytes, normally not amenable to GC analysis, by utilization of derivatization in the aqueous phase, or coupling of SPME with HPLC. In our laboratory we are still developing new applications and approaches to SPME. Some of the possibilities include in situ derivatization SPME/electrochemistry and direct coupling of SPME with a mass spectrometer. We expect the scope of applications to be significantly broadened when new coatings are introduced to the market. SPME still remains a fascinating and promising new technology.

Bis(pyridine)difluoroboron, tris(pyridine)fluoroboron, and other (pyridine)haloboron cations. A systematic NMR study

Melvin J. Farquharson and J. Stephen Hartman

Abstract: The adducts pyr·BF_2Br and pyr·$BFBr_2$ (pyr = pyridine) form fluoroboron cations by displacement of Br^- by excess pyridine, the ease of cation formation being $pyr_2BF_2^+ \gg pyr_2BFBr^+ \gg pyr_3BF^{2+}$. Cl^- can be displaced from pyr·BF_2Cl and pyr·$BFCl_2$, but much less readily, to form $pyr_2BF_2^+$, pyr_2BFCl^+, and, under forcing conditions, a few percent of pyr_3BF^{2+}. Non-fluorine-containing mixed boron trihalide adducts of pyridine also form haloboron cations by heaviest-halide-ion displacement, for example pyr·$BClI_2$ giving pyr_2BClI^+, the ease of displacement always being $I^- > Br^- > Cl^-$, and displacement always occurring more readily from mixed boron trihalide adducts than from unmixed-halogen adducts. The mechanistic implications of this are discussed. *ortho* Substituents greatly reduce the ability of pyridine to displace heavy halide ion, so 2-methylpyridine gives 2-$Mepyr_2BF_2^+$ and 2-$Mepyr_2BFBr^+$ but not 2-$Mepyr_2BFCl^+$ or 2-$Mepyr_3BF^{2+}$, while 2,6-dimethylpyridine does not form any haloboron cations. ^{19}F spin-lattice relaxation times of the fluoroboron cations are much shorter than those of neutral boron trihalide adducts in the same solution, and provide a further diagnostic test for their presence.

Key words: fluoroboron cations, pyridines, mixed boron trihalide adducts, fluorine-19 NMR, boron-11 NMR.

Résumé : Les adduits pyr·BF_2Br et pyr·$BFBr_2$ (pyr = pyridine) forment des cations du fluorobore par déplacement de Br^- par l'excès de pyridine; la facilité de formation du cation est la suivante : $pyr_2BF_2^+ \gg pyr_2BFBr^+ \gg pyr_3BF^{2+}$. Il est possible de déplacer le Cl^- des adduits pyr·BF_2Cl et pyr·$BFCl_2$, pour former les $pyr_2BF_2^+$, pyr_2BFCl^+, et en forçant les conditions quelques pour cents du pyr_3BF^{2+}, mais la réaction est beaucoup plus lente. Les adduits de la pyridine avec des trihalogénures mixtes du bore ne contenant pas de fluor forment aussi des cations halobores par le déplacement de l'halogène le plus lourd; par exemple, le pyr·$BClI_2$ conduit au pyr_2BClI^+, la facilité de déplacement est $I^- > Br^- > Cl^-$ et le déplacement se fait toujours plus facilement à partir d'adduits trihalogénures mixtes du bore qu'à partir d'adduits non mélanges d'halogénures de bore. On discute des implications mécanistiques de ces résultats. Les substituants *ortho* ralentissent beaucoup la facilité de la pyridine à déplacer les ions halogénures lourds; ainsi, la 2-méthylpyridine conduit aux 2-$Mepyr_2BF_2^+$ et 2-$Mepyr_2BFBr^+$, mais pas aux 2-$Mepyr_2BFCl^+$ ou 2-$Mepyr_3BF^{2+}$ alors que la 2,6-diméthylpyridine ne forme aucun cations halobore. Les temps de relaxation spin-réseau du ^{19}F dans les cations du fluorobore sont beaucoup plus courts que ceux des adduits trihalogénures de bore neutres dans la même solution et ils fournissent une méthode supplémentaire pour diagnostiquer leur présence.

Mots clés : cations du fluorobore, pyridines, adduits des trihalogénures mixtes du bore, RMN du ^{19}F, RMN du ^{11}B.

[Traduit par la rédaction]

Introduction

In previous work (1, 2) we have shown that $R_3N{\cdot}BF_2Br$ adducts selectively and readily undergo bromide ion displacement by neutral (D′) and anionic (Z) donors of low steric hindrance to give difluoroboron cations $D_2BF_2^+$ and $DD'BF_2^+$ and neutral adducts $R_3N{\cdot}BF_2Z$ (eq. [1]).

[1] $D{\cdot}BF_2Br + D' \longrightarrow DD'BF_2^+ + Br^-$

We noted the contrast of the high reactivity of $R_3N{\cdot}BF_2Br$ with the lack of reactivity of the $R_3N{\cdot}BFBr_2$ and $R_3N{\cdot}BBr_3$ adducts present in the same solutions, and the extremely slow chloride ion displacement from $R_3N{\cdot}BF_2Cl$. In our preliminary communication (1) we noted that pyridine was particularly effective as a displacing ligand (D′ in eq. [1]), reacting much faster than any trialkylamine to displace bromide ion, consistent with steric hindrance rather than base strength of the attacking species being the decisive factor in the reaction. Many (R_3N)(substituted pyridine)BF_2^+ ions form readily in this way from $R_3N{\cdot}BF_2Br$ (2). We now report studies of heavy halide ion displacement from pyridine·BF_nX_{3-n} adduct systems that demonstrate even greater acceleration of heavy halide ion displacement when a low steric hindrance pyridine is the donor molecule in $D{\cdot}BF_2Br$ as well as the attacking

ligand D′. We also report formation of the less easily formed cations D_2BFBr^+, D_2BFCl^+, and D_3BF^{2+} from pyr·BFX_2 (X = Cl, Br) according to eq. [2].

$$D{\cdot}BFX_2 + D' \longrightarrow DD'BFX^+ + X^- \quad [2]$$

$$DD'BFX^+ + D' \longrightarrow DD'_2BF^{2+} + X^-$$

Pyridine-fluoroboron cations had not been reported until our work (1), although speculation about their formation has appeared (3). Systematic formation of these cations, by a halide ion displacement process analogous to that used by Ryschkewitsch and co-workers for the formation of hydroboron cations and heavier-halogen haloboron cations (4), requires mixed boron trihalide adducts (5) as starting materials. Unmixed-halogen boron trihalide adducts of pyridine and substituted pyridines have been known for a long time (6), and much has been known about tetrahedral boron-nitrogen compounds including various cations (7). The mixed boron trihalide adducts of 4-methylpyridine (4-Mepyr) were reported in 1972 from this laboratory (8), and are formed in a manner similar to aliphatic tertiary amine – mixed boron trihalide adducts (5, 9). Despite reports of a much wider range of boron cations in recent years, including many cations with three- and even two-coordination at boron (10), and extensive use of ^{11}B NMR to study such species (11), there were only a few scattered reports of four-coordinate fluoroboron cations and little was known about them until our method of synthesis starting from mixed boron trihalide adducts (1, 2, 9).

Experimental section

General

Pyridine, 2-methylpyridine, and 4-methylpyridine (BDH) were purified by fractional distillation and stored over KOH. The other substituted pyridines and other Lewis bases (BDH and Aldrich) were used as supplied. Moisture-sensitive materials were handled under dry nitrogen in a glove bag and (or) on a Schlenk line. Mixed boron trihalide adducts of the pyridines, precursors of the haloboron cations, were formed in solution as described for the corresponding adducts of aliphatic tertiary amines (2, 9). Difluoroboron cation salts containing these pyridines were isolated in a similar manner to the corresponding quinuclidine-containing $(R_3N)_2BF_2^+$ salts (2), and are moderately stable in water and ethanol. The only major difference was the use of the BF_nCl_{3-n} rather than the BF_nBr_{3-n} adduct system because pyr·$BFBr_2$, unlike $R_3N{\cdot}BFBr_2$, reacts with pyridine to form pyr_2BFBr^+ along with $pyr_2BF_2^+$. Use of the less reactive pyr·BF_nCl_{3-n} system and keeping the reaction time short gave $pyr_2BF_2^+$ with negligible pyr_2BFCl^+. When isolation of salts of the cations was not being undertaken, the entire cation formation procedure could be carried out in 5 mm NMR tubes, using 1 mL and 50 μL syringes to inject various reagents.

Halogen exchange and fluoroboron cation formation reactions were monitored in $CDCl_3$ solution by ^{19}F and ^{11}B NMR, supplemented by positive ion fast atom bombardment mass spectrometry (FAB). Elemental analyses for carbon, hydrogen, and nitrogen were consistently satisfactory but those for fluorine were erratic, some being in error by several percent, perhaps due to interference by boron.

Isolation of $D_2BF_2^+$ salts

Typically, water was added to a chloroform solution containing cations and neutral adducts, and extracted the ionic species preferentially. Evaporating the water extract under vacuum, followed by redissolving the residue in chloroform, eliminated all $D{\cdot}BF_nX_{3-n}$ species and any excess amine. Direct addition of hexane or petroleum ether to the new chloroform solution gave immediate precipitation of the cation salt, but of low purity. Higher purity material was obtained by slow evaporation of solvent, or by two-layer exchange: careful addition of a hexane or petroleum ether layer over the $CDCl_3$ layer and allowing the system to stand. The material was then recrystallized from acetone. Closed ground-glass vessels were used past the stage of redissolving in chloroform, to avoid hydrolysis. The pyridine-containing $D_2BF_2^+$ cations have a shorter lifetime in water than the tertiary-amine cations (2), so the time in contact with water was minimized. (This method is not successful if B—Cl or B—Br bonds are present, since cations containing Cl or Br are much more susceptible to hydrolysis.) The isolation of doubly charged cations and mixed-donor cations will be reported elsewhere (12). Elemental analyses (performed by Guelph Chemical Laboratories Ltd.) are as follows: $pyr_2BF_2{\cdot}BPh_4$: found: C 77.55, H 6.18, N 5.42, F 7.50; calcd.: C 77.60, H 5.75, N 5.32, F 7.22. $pyr_2BF_2{\cdot}PF_6$: found: C 34.53, H 2.92, N 7.93, F 43.44, calcd.: C 34.13, H 2.86, N 7.96, F 43.18. $(4\text{-Mepyr})_2BF_2{\cdot}BPh_4$: found: C 77.76, H 6.46, N 4.98, F 3.76; calcd.: C 78.01, H 6.18, N 5.05, F 6.85.

Instrumentation

Most ^{19}F spectra were obtained at 56.4 MHz on a Bruker WP-60 multinuclear Fourier Transform NMR spectrometer as described previously (2). Some were obtained at 188.29 MHz on a Bruker CXP-200 instrument in order to resolve overlapping multiplets. Typically, 8K FIDs were obtained with 100–500 30° pulses covering a 10 000 Hz spectral width; 0.5 Hz of line broadening was applied and 8K of zero filling was added before transforming into 8K spectra. ^{19}F chemical shifts are accurate to ±0.1 ppm and were internally referenced to C_6F_6 as a secondary standard (–162.7 ppm from $CFCl_3$), and are reported in ppm from $CFCl_3$.

^{19}F spin-lattice relaxation time studies were performed at ambient temperature on the WP-60 spectrometer at 56.4 MHz using the Nicolet T_1 Program II (developed by J.W. Cooper) with a $(180° - \tau - 90°\text{–}D_2\text{–})_n$ pulse sequence; 150–250 scans were obtained for each of 10–15 τ values, with a 12 s relaxation delay (D_2) between each sequence. Typical runs were 6–10 h in length. Auto shimming was applied, and τ values were sequenced in a random order. Errors in T_1 values vary with concentration of the various species, and are generally less than 10%. Solution viscosity measurements were carried out on the NMR samples after the T_1 determinations were completed, using a small-scale (0.5 mL volume) home-built Ostwald viscometer.

^{11}B NMR spectra were obtained on a Bruker WH-400 multinuclear Fourier Transform NMR spectrometer operating at 128.38 MHz. A spectral width of 10 000 Hz was used to obtain an 8K FID. The FIDs with 8K of zero filling were trans-

formed with 0.5 Hz of line broadening into 8K spectra. ^{11}B chemical shifts are accurate to ±0.1 ppm and were referenced to external $Et_2O{\cdot}BF_3$, which was prepared by reaction of BF_3 with diethyl ether and fractional distillation of the liquid adduct.

Calculations of ^{19}F and ^{11}B chemical shifts and ^{11}B–^{19}F coupling constants were carried out using empirical "pairwise interaction" parameters (13, 14) as described previously (2). Calculated values agreed well with experimental values and were helpful in assigning haloboron cation resonances.

Positive ion fast atom bombardment mass spectra (FAB spectra) were obtained on an AEI MS-30 mass spectrometer as described previously (2), with glycerol or tetramethylenesulfone as matrix liquid. The FAB spectrum of $pyr_2BF_2^+{\cdot}PF_6^-$ has been reported elsewhere as part of a study of gas phase displacement reactions in FAB (Fig. 2*a* of ref. 15). There are major peaks at *m/z* 207 ($pyr_2BF_2^+$) and 128 ($pyrBF_2^+$) as well as a cluster peak of two cations and an anion at *m/z* 559 ($[pyr_2BF_2^+]_2{\cdot}PF_6^-$). Most FAB spectra had peaks due to glycerol (e.g., *m/z* 93, 85, and 277) removed by spectral subtraction. Verification of the isotope cluster patterns was carried out by the BMASROS scheme in some cases to further confirm the identity of the assigned species. In the later stages of this work we obtained FAB spectra directly on the adduct/cation $CDCl_3$ solutions themselves. The spectra are highly selective for the cations over the neutral adducts, despite the neutral adducts usually being present in higher concentrations. This direct use of FAB is very useful in monitoring these systems and complements solution NMR, although FAB spectra can be complicated by reactions occurring in the gas phase (15, 16). Our FAB studies will be reported in detail elsewhere.

Results

Reactions of $pyr{\cdot}BF_nX_{3-n}$ (X = Cl, Br)

$Pyr{\cdot}BF_2Br$ in $CDCl_3$ solvent undergoes extremely rapid displacement of bromide ion by pyridine at ambient temperature to give $pyr_2BF_2^+$ (eq. [1]). Interestingly, a well-resolved $pyr_2BF_2^+$ ^{19}F 1:1:1:1 quartet can be observed even before all of the uncomplexed BF_nBr_{3-n} (present since the mixed boron trihalide adducts form only under excess-Lewis-acid conditions (2, 9)) is quenched by reaction with pyridine, at a stage when rapid halogen exchange is occurring among most species and usually only broad and exchanging ^{19}F NMR signals can be observed at ambient temperature. This shows that $pyr_2BF_2^+$ is less susceptible to fluorine exchange than the other species present, and also indicates that the reaction to form $pyr_2BF_2^+$ is competitive with donor–acceptor bond formation, normally considered to be diffusion controlled. This is striking and unusual behaviour compared to boron trihalide adduct systems that we have studied previously.

The reaction to give $pyr_2BF_2^+$ is far too fast for ambient temperature ^{19}F NMR monitoring of the changes in a solution containing excess pyridine, as could be done in corresponding aliphatic amine systems (2). Instead, the reaction was monitored by the addition of successive increments of pyridine, followed by equilibration each time before obtaining the ^{19}F spectrum (Fig. 1). Equilibration of most species, including pyr_2BFBr^+ from $pyr{\cdot}BFBr_2$, is achieved within 10 min to 1 h at ambient temperature, depending on the concentration of uncomplexed pyridine. Figure 1*a* shows large 1:1:1:1 quartets (arising from ^{11}B–^{19}F coupling) for all of the fluorine-containing mixed boron trihalide adducts $pyr{\cdot}BF_nBr_{3-n}$ (n = 1–3), all of which along with $pyr{\cdot}BBr_3$ are formed in situ by halogen redistribution when $pyr{\cdot}BF_3$ is reacted with uncomplexed BBr_3 (2, 5, 9). Just enough pyridine had been added to complex with all of the uncomplexed Lewis acid. The large 1:1:1:1 quartet of $pyr{\cdot}BF_2Br$ persists indefinitely under these conditions. A small 1:1:1:1 quartet of $pyr{\cdot}BF_2Cl$ is also present in Fig. 1*a*, showing that some Cl,Br exchange occurs between $pyr{\cdot}BF_2Br$ and the $CDCl_3$ solvent. NMR parameters of the $D_2BF_2^+$ cations are given in Table 1, and those of the boron trihalide adducts $D{\cdot}BX_nY_{3-n}$ (n = 0–3) in Table 2.

Addition of successive increments of pyridine initially

affects only the pyr·BF_2Br adduct; its ^{19}F NMR signal shrinks while that of $pyr_2BF_2^+$ grows, in accord with eq. [1] (Figs. 1*b*–1*d*). There is also a slight gain in intensity of the pyr·BF_2Cl resonance as Cl,Br exchange between pyr·BF_2Br and solvent proceeds. After the pyr·BF_2Br adduct is consumed, further pyridine reacts with the $BFBr_2$ adduct, giving initially pyr_2BFBr^+ (Fig. 1*e*) and eventually under stronger reaction conditions $pyr_3BF_2^+$ (Fig. 1*f*), consistent with eq. [2]. At the same time a trace of pyr_2BFCl^+ is formed (Fig. 1*e*), apparently from pyr·$BFBr_2$ by Cl,Br exchange with solvent to give pyr·BFClBr, followed by displacement of the remaining Br by pyridine.

^{11}B NMR spectra confirm the above peak assignments since the characteristic ^{11}B splitting patterns and ^{11}B–^{19}F coupling constants allow unambiguous matching of ^{11}B resonances to the corresponding ^{19}F resonances. An ^{11}B 1:2:1 triplet at 2.0 ppm, $J(^{11}B–^{19}F)$ = 48.4 Hz, assigned to pyr·BF_2Br, is replaced by another 1:2:1 triplet at 1.7 ppm, $J(^{11}B–^{19}F)$ = 22.9 Hz, assigned to $pyr_2BF_2^+$, in the early stages of the reaction sequence of Fig. 1. In the later stages, the 1:1 doublet of pyr·$BFBr_2$ and the 1:2:1 triplet of pyr·BF_2Cl disappear and new 1:1 doublets appear that are assigned to pyr_2BFBr^+, pyr_2BFCl^+, and pyr_3BF^{2+} (Fig. 2 and Table 3). Considerable $pyr_2BBr_2^+$ is also formed in the later stages. The $pyr_2BBr_2^+$ peak was assigned, and the others confirmed, by chemical shift calculations using pairwise interaction NMR parameters as described below.

The pyr·BF_nCl_{3-n} system reacts much more slowly with excess pyridine than the pyr·BF_nBr_{3-n} system. Again the most reactive species is the one with a single heavy halogen, pyr·BF_2Cl, giving $pyr_2BF_2^+$. Stepwise displacement of Cl^- from pyr·$BFCl_2$ is possible, first giving pyr_2BFCl^+. Initial attempts to get conversion of pyr·$BFCl_2$, first to pyr_2BFCl^+ and then to pyr_3BF^{2+}, were carried out by heating samples in capped NMR tubes at 40°C for several days. ^{19}F NMR monitoring showed that reaction of pyr·BF_2Cl to give $pyr_2BF_2^+$ is complete before any appreciable reaction of pyr·$BFCl_2$ occurs. Several days at 40°C give appreciable conversion of

Fig. 2. 128.4 MHz ^{11}B NMR spectrum of the solution of pyr·BF_nBr_{3-n} plus excess pyridine that gave rise to the ^{19}F NMR spectrum of Fig. 1*f* (D = pyridine).

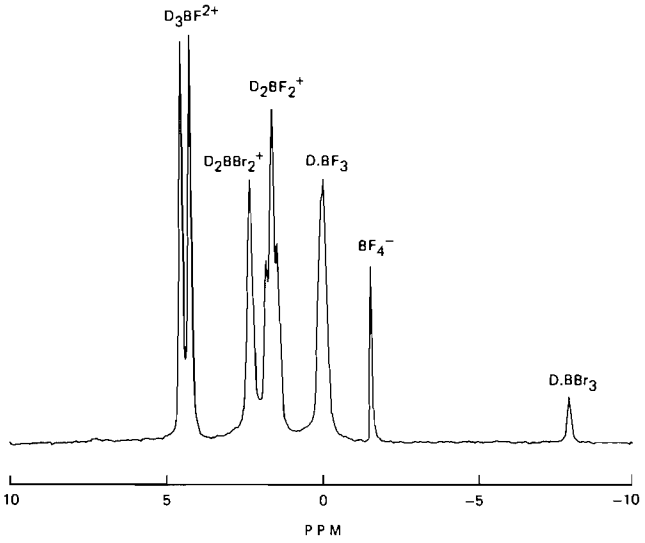

Fig. 3. Positive ion fast atom bombardment (FAB) mass spectrum of pyr_2BFCl^+, obtained directly from a solution of adducts and cations. Peaks at *m/z* greater than 82 are enhanced by a factor of 4 (D = pyridine).

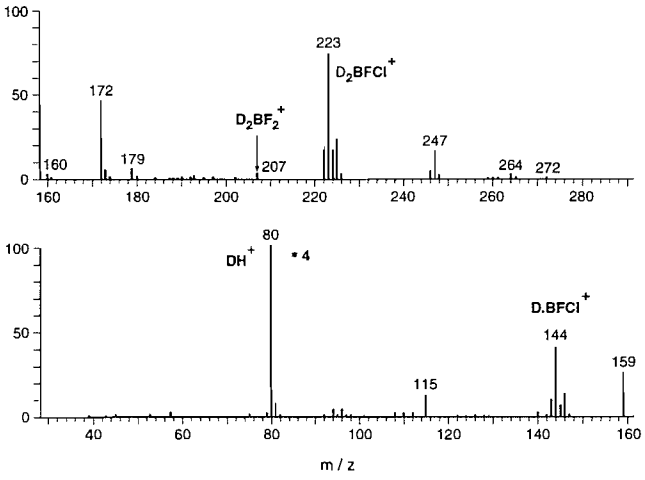

pyr·$BFCl_2$ to pyr_2BFCl^+, but also reversion of $pyr_2BF_2^+$ to pyr·BF_2Cl. It is of interest that the $pyr_2BF_2^+$ formation reaction (eq. [1]) is reversible, and that the reverse as well as the forward reaction is faster for $pyr_2BF_2^+$ than for pyr_2BFCl^+. Complete conversion of pyr·$BFCl_2$ to pyr_2BFCl^+ was achieved by carrying out the reaction in a sealed tube at 110°C, but only a few percent conversion to pyr_3BF^{2+} by further chloride displacement was possible even under these forcing conditions. The FAB spectrum of pyr_2BFCl^+, obtained directly from $CDCl_3$ solution following heating in a sealed tube, is shown in Fig. 3.

Attempted isomerization of pyr·BF_3 to $pyr_2BF_2^+·BF_4^-$

BF_3 complexes of a few Lewis bases, including HMPA·BF_3 (17) and TMU·BF_3 (18), can undergo reaction to form small amounts of their ionization isomers $D_2BF_2^+·BF_4^-$ in solution. Preliminary attempts to form $pyr_2BF_2^+·BF_4^-$ by disproportionation of pyr·BF_3 in the absence of a heavier boron trihalide, by analogy with these cases, were unsuccessful. The ^{19}F NMR spectra of pyr·BF_3 and 2-Mepyr·BF_3 did not change following (*i*) refluxing in toluene or (*ii*) refluxing in toluene with the addition of 1,1,1,3,3,3-hexamethyldisilazane, which has a high affinity for fluoride ion (19) and which we hoped would act as an irreversible extractant for F^- from pyr·BF_3, giving three-coordinate pyr·BF_2^+ that further pyridine could attack. With 1,1,1,3,3,3-hexamethyldisilazane present, 15 min of reflux in toluene did remove some fluorine from the adducts as shown by the presence of a small ^{19}F NMR peak assigned to Me_3SiF (larger in the 2-Mepyr case than with pyr itself), and the pyr·BF_3 resonances were broadened, suggesting some chemical exchange, but no ^{19}F signals arising from boron cations or BF_4^- could be observed.

^{19}F spin-lattice relaxation

Figure 4 shows variations in ^{19}F NMR spin-lattice relaxation

Fig. 4. Changes in the ^{19}F spin-lattice relaxation times of the species present in the pyr·BF_nBr_{3-n} system (0.8 M in total adduct species; $CDCl_3$ solvent; D = pyridine) following additions of pyridine. Some species are formed and consumed as shown in Fig. 1, so T_1 values of these could be obtained only at certain stages of the pyridine titration process.

times of the various fluorine-containing species present at various stages of the titration of the pyr·BF_nBr_{3-n} adduct system with excess pyridine, as described above and shown in Fig. 1. Some species disappear while others appear after further aliquots of pyridine are added and the solution is reequilibrated. T_1 values of individual species change greatly as solution viscosity changes with the addition of more pyridine, but the signals assigned to all three of the fluoroboron cations consistently have by far the shortest T_1 values. Moreover $pyr_2BF_2^+$, the only one of these cations that can be detected throughout the titration, shows far less variation in T_1 than the neutral adducts. T_1 values depend on molecular tumbling, which is very dependent on solution viscosity, which in turn is dependent on solute concentration and on the amount of pyridine added. Therefore relative T_1 values of different species present in the same solution should be compared rather than absolute values (i.e., compare points lined up vertically in Fig. 4, corresponding to different species present in the same solution). Viscosity, determined using a small-scale (0.5 mL) Ostwald viscometer, increases as the more viscous pyridine is added to the $CDCl_3$ solution. This is consistent with the decreases in T_1 of the same species as successive portions of pyridine are added (Fig. 4). Note that pyr_3BF^{2+} has by far the smallest T_1 value, while $D_2BF_2^+$ and D_2BFBr^+ species have intermediate values and the pyr·BF_nBr_{3-n} adducts have the largest values.

Substituted-pyridine and mixed-donor fluoroboron cations

Various mixed- and unmixed-donor $D_2BF_2^+$ cations such as (pyr)(4-Mepyr)BF_2^+ can be readily formed by titrating one pyr·BF_nX_{3-n} system with another (or the same) pyridine base. Non-*ortho*-substituted pyridines including 3-Mepyr, 4-Mepyr, and 4-Phpyr give very similar chemistry, and ^{19}F and ^{11}B NMR parameters, to pyridine itself when incorporated into BF_nX_{3-n} adducts and $D_2BF_2^+$ cations. Table 1 includes NMR parameters for many such ions. As with the pyridine system itself, Cl^- displacement from D·BF_2Cl occurs much less readily than Br^- displacement from D·BF_2Br. Rates of Cl^- displacement vary in the order 3-Mepyr ≥ pyr > 4-Mepyr > 4-Phpyr but the differences are not large.

Reaction is much slower when the pyridine has an *ortho* substituent. Thus reaction of 2-Mepyr·BF_2Br with 2-Mepyr requires 1–2 h at ambient temperature for complete formation of $(2\text{-Mepyr})_2BF_2^+$, similar to bromide displacement from tertiary-amine (quinuclidine and trimethylamine) BF_2Br adducts (2). We could form 2-Mepyr_2BFBr^+ but not 2-Mepyr_3BF^{2+} from 2-Mepyr·$BFBr_2$, and we could not form 2-MePyr_2BFCl^+ from 2-Mepyr·$BFCl_2$. The 2-ethylpyridine (2-Etpyr) BF_nBr_{3-n} system reacts somewhat more slowly than the 2-Mepyr system.

Although 2,6-dimethylpyridine and 2,4,6-trimethylpyridine readily form mixed boron trihalide adducts D·BF_nX_{3-n} (X = Cl, Br), we have not been able to detect any NMR signals consistent with their incorporation into difluoroboron cations, either as the only donor ($D_2BF_2^+$) or with another less sterically hindered donor (DD′BF_2^+). The presence of a second, less sterically hindered, pyridine in solution with adducts of 2,6-Me_2pyr or 2,4,6-Me_3pyr merely replaces the more hindered pyridine from its adducts, without any cation formation. Adducts of these highly hindered pyridines are

highly reactive, and frequently coagulation of the solvent occurs in the presence of excess base, under heating conditions that are successful in forming fluoroboron cations from less hindered pyridine adduct systems. All of the above is consistent with the greater ease of dissociation of highly sterically hindered adducts compared to unhindered ones. ΔH_f values for formation of BF_3 adducts with highly hindered pyridines are much lower than with less hindered ones: pyr·BF_3, 25.0 kcal/mol; 2-Mepyr·BF_3, 23.2 kcal/mol, 2,6-Me_2pyr·BF_3, 17.5 kcal/mol (20). Catalysis of side reactions at elevated temperatures, by the traces of uncomplexed boron trihalide formed by dissociation of the 2,6-Me_2pyr and 2,4,6-Me_3pyr adducts, likely causes the coagulation of solvent.

Various Lewis bases of low steric hindrance other than pyridines, such as dimethyl sulfoxide and tetramethylurea, can also displace halide ion from pyr·BF_2X. Table 1 includes NMR parameters of various (pyr)D′BF_2^+ ions formed in this way. We previously reported NMR parameters of similar mixed-base cations $(R_3N)(pyr)BF_2^+$ and $(R_3N)(D')BF_2^+$, formed by attack of pyridines and other donors on $R_3N{\cdot}BF_2Br$ (2).

Non-fluorine containing haloboron cations from pyr·BX_nY_{3-n}(X, Y = Cl, Br, I)

The adduct systems pyr·BCl_nI_{3-n} and pyr·BCl_nBr_{3-n} readily form haloboron cations via selective displacement of the heaviest halogen, and we have observed these ions by ^{11}B NMR, supplemented by FAB. ^{11}B chemical shifts are given in Table 4, along with values calculated from pairwise interaction parameters (13, 14) which support our assignments.

Figure 5 shows ^{11}B NMR spectra of the enormously reactive pyr·BCl_nI_{3-n} system. Initially a large amount of uncomplexed BCl_nI_{3-n} ($n = 0 - 3$) is present, as well as pyr·BI_3 and pyr·$BClI_2$ (Fig. 5*a*). BI_3 is the strongest Lewis acid of the boron trihalides and complexes preferentially with the limited amount of pyridine, followed by the next strongest Lewis acid of this series, $BClI_2$. Negligible BCl_2I or BCl_3 seems to be complexed, illustrating the pronounced changes in Lewis acid strength across the series. Minor peaks are present as well. Addition of enough pyridine to complex practically all of the boron trihalide gives a simple spectrum with all of the pyr·BCl_nI_{3-n} adducts as the only major boron-containing species (Fig. 5*b*). The spectrum looks much like the ^{11}B spectrum of any D·BCl_nI_{3-n} adduct system, since chemical shifts depend more on the number and type of halogens than on the specific donor molecule (5, 9, 14). A small amount of uncomplexed BCl_3 remains.

Addition of further pyridine leads to disappearance of the pyr·BCl_2I and pyr·$BClI_2$ signals (Figs. 5*c* and 5*d*), and considerable precipitate formation. It appears that haloboron cations are forming but are largely being precipitated so that their NMR signals do not become large. Small peaks are present that can be assigned to $pyr_2BCl_2^+$, pyr_2BClI^+, and $pyr_2BI_2^+$, consistent with calculated chemical shift values. The only adducts still present at the end of the process are the unmixed-halogen ones pyr·BI_3 and pyr·BCl_3 (Fig. 5*d*). This high selectivity, favouring reaction of the BCl_2I and $BClI_2$ adducts to give the BCl_2^+ and $BClI^+$ cations, was also observed in the much less reactive quinuclidine. BCl_nI_{3-n} system (Fig. 7 of ref. 2). Thus iodide displacement occurs as in eq. [3].

Table 4. Observed and calculated ^{11}B chemical shifts of some pyridine–haloboron cations.

	Observed[a]	Calculated[b]
$pyr_2BF_2^+$	1.7	2.1
pyr_2BFCl^+	6.2	5.5
pyr_2BFBr^+	4.9	4.9
$pyr_2BCl_2^+$	8.4	7.7
pyr_2BClBr^+	5.9	5.9
pyr_2BClI^+	−2.1	−1.6
$pyr_2BBr_2^+$	2.6	2.5
$pyr_2BI_2^+$	−20.2	−19.1
pyr_3BF^{2+}	4.6	4.6
pyr_3BCl^{2+}		7.6
pyr_3BBr^{2+}		7.3
pyr_3BI^{2+}		4.4
pyr_4BF^{3+}	[c]	7.4
(pyr)(2-Mepyr)BF_2^+	2.2	2.4
(pyr)(2-Mepyr)$BFBr^+$	5.2	5.0
2-$Mepyr_2BF_2^+$	2.4	2.8
2-$Mepyr_2BFCl^+$	2.4	2.9
2-$Mepyr_2BFBr^+$	5.9	5.4
(pyr)(3-Mepyr)BBr_2^+	2.6	[d]
(pyr)(quinuclidine)$BClI^+$	1.7	1.8
(2-Mepyr)$(Me_3N)BCl_2^+$	9.9	10.0
(2-Mepyr)(quinuclidine)BCl_2^+	9.7	9.7
3-$Mepyr_2BBr_2^+$	2.6	[d]
4-$Mepyr_2BBr_2^+$	2.4	[d]
(4-Mepyr)(3-Mepyr)BBr_2^+	2.3	[d]

[a]$CDCl_3$ solution; ppm to high frequency of external $Et_2O{\cdot}BF_3$.

[b]By pairwise interaction calculations.

[c]Not observed. However, the 4-Mepyr analogue (as the bromide) has an ^{11}B shift of 6.2 ppm.

[d]Insufficient data to determine meaningful $\eta_{donor,\ donor}$ pairwise terms involving 3-Mepyr and 4-Mepyr.

Again the heaviest halide ion is preferentially displaced. We

[3] pyr·BCl_nI_{3-n} ($n = 0 - 2$) + pyr ⟶ $pyr_2BCl_nI_{2-n}^+ + I^-$

cannot exclude some Cl^- displacement from pyr·BCl_3.

Of the minor peaks present in Fig. 5*a*, three unidentified peaks disappear as pyridine is added. These apparently arise from three-coordinate boron species, possibly pyr·BCl_2^+, pyr·$BClI^+$, and pyr·BI_2^+. Another peak at about 5.2 ppm increases in size as pyridine is added but never becomes major. This peak is tentatively identified as BCl_4^- in Fig. 4*a* on the basis of its chemical shift (21), but as the system becomes pyridine-rich (Figs. 5*c* and 5*d*) it is more likely to arise from a pyridine-rich species such as pyr_3BI^{2+}, pyr_3BCl^{2+}, or even pyr_4B^{3+}, all of which are predicted to absorb in this range (Table 4). We synthesized 4-$Mepyr_4B^{3+}$ as its bromide salt (22) and found its ^{11}B chemical shift in $CDCl_3$ to be 6.2 ppm. Since 4-Mepyr cations have similar ^{11}B NMR parameters to the corresponding cations of pyr itself this is a reasonable estimate for pyr_4B^{3+}, but does not exclude pyr_3BI^{2+} or pyr_3BCl^{2+}.

In contrast to the pyr·BCl_nI_{3-n} system, the pyr·BCl_nBr_{3-n} system reacts slowly with excess pyridine. The rate of cation formation is comparable to the formation of $pyr_2BF_2^+$ from pyr·BF_2Cl, and both $pyr_2BCl_2^+$ and pyr_2BClBr^+ are formed, consistent with Br^- displacement from both pyr·BCl_2Br and

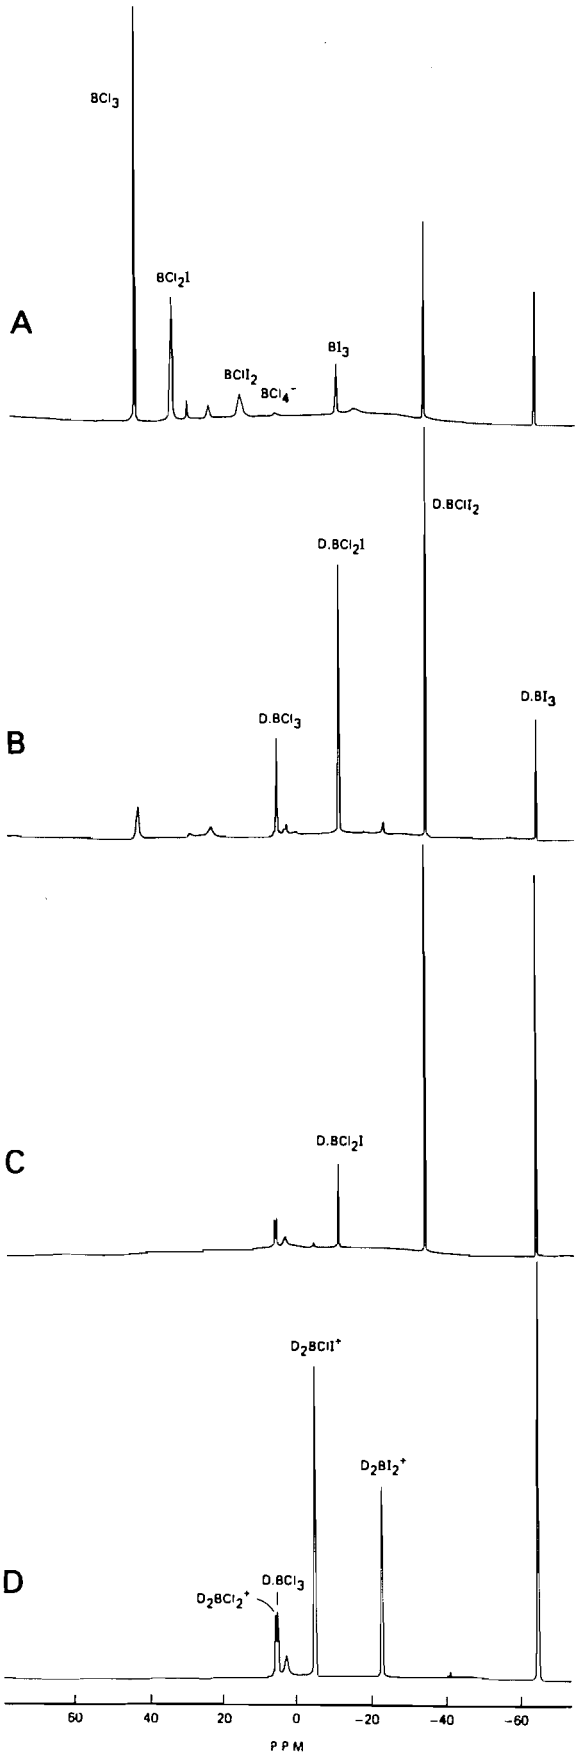

Fig. 5. 128.4 MHz ^{11}B NMR spectra of the pyr·BCl_nI_{3-n} system (0.8 M in total boron species; $CDCl_3$ solvent; D = pyridine). (*A*) Insufficient pyridine to complex all of the Lewis acid; (*B*) approximately equimolar pyridine and Lewis acid; (*C*) and (*D*), increasing excess of pyridine over total boron trihalide.

pyr·$BClBr_2$. Again it is the mixed boron trihalides that react preferentially and the heavier halide ion that is selectively displaced. Because of precipitate formation we do not have as complete a picture of these systems as of the fluorine-containing systems.

Discussion

General

With pyridine as the Lewis base, $D_2BF_2^+$ formation is strikingly accelerated compared to the R_3N-donor systems (1, 2), and additional reactions occur to give pyr_2BFBr^+, pyr_2BFCl^+, and pyr_3BF^{2+}. Low donor steric hindrance is critical, as confirmed by the pronounced drop in efficiency of halide ion displacement when the attacking pyridine has a 2-substituent, and by the absence of any displacement when either the attacking or the already-bonded pyridine is 2,6-disubstituted. This is consistent with earlier work by Ryschkewitsch and co-workers showing the importance of steric hindrance on formation of hydroboron and heavy-halogen haloboron cations by halide ion displacement (4). With 4-methylpyridine as donor they were able to displace all bromines from a BBr_3 adduct in refluxing toluene, giving the D_4B^{3+} ion (22). The effects of steric hindrance on other substitution reactions about boron (23), and similar effects with pyridine ligands about other central atoms (24), have been well documented. Pronounced steric effects on reactivity and equilibrium constants are well established in a wide range of coordination complexes (25, 26). The only previously reported D_2BFCl^+ cation was prepared by the reaction of elemental fluorine with $(Me_3N)_2BH_2^+·Cl^-$ (27).

Many species might exist as both ionic and covalent isomers, such as $CH_3CN·SbCl_5$, which is reported to be present as the ionic $(CH_3CN)_2SbCl_4^+·SbCl_6^-$ in nitrobenzene (28) but as the covalent adduct in nitromethane (29). The possibility of ionization isomers of Lewis acid–base complexes is easily overlooked. NMR, supplemented by FAB, is powerful in identifying haloboron cations and is useful in clarifying situations in which either ionic or covalent isomers (or both together) may be present. It should be kept in mind that unexpected ionic structures can be generated from neutral precursors (30). There have recently been several reports of replacement of a halide ion by a neutral ligand to give a cationic complex (31).

NMR parameters

Steric hindrance affects NMR parameters (25, 32), as observed in our ^{19}F and ^{11}B NMR studies of the mixed boron trihalide adducts (9). More pronounced effects occur in the fluoroboron cations (Table 1) than in the neutral adducts (Table 2). Thus successive methyl substitution in the pyridine 2-position causes high-frequency (low-field) shifts of 8.1 and 5.2 ppm (^{19}F) and 0.4 and 0.3 ppm (^{11}B) in the series $pyr_2BF_2^+$, $(pyr)(2\text{-}Mepyr)BF_2^+$, $2\text{-}Mepyr_2BF_2^+$, compared to shifts of

only 2.9 ppm (^{19}F) and –0.1 ppm (^{11}B) on going from pyr·BF_3 to 2-Mepyr·BF_3. (Other BF_nX_{3-n} adducts do show greater ^{19}F shifts as the donor changes from pyr to 2-Mepyr, however (Table 2), perhaps reflecting greater steric requirements of the heavier halogens compared to fluorine.) *meta* and *para* substitution on pyridine has very little effect on chemical shift. ^{11}B–^{19}F coupling constants are not as large as those of the corresponding more hindered tertiary-amine cations, and they increase appreciably as the pyridine steric hindrance increases, e.g., $pyr_2BF_2^+$, 22.9 Hz; (pyr)(2-Mepyr)BF_2^+, 25.4 Hz; 2-$Mepyr_2BF_2^+$, 28.8 Hz (cf. $(quinuclidine)_2BF_2^+$, 39.5 Hz (2)). There is no correlation of NMR parameters or of reactivity with the pK_b values of the pyridines (33), which are listed in Table 2.

Chemical shifts of many nuclei are not linearly additive with respect to the substituent groups, but nevertheless may be "pairwise additive," i.e., the chemical shift can be expressed as a sum of pairwise terms $\eta_{i,j}$, associated with substituents *i* and *j* and independent of all other substituents. The sum is taken over all possible pairs of substituents about the central atom, excluding the nucleus being observed in the NMR experiment (13). We showed that pairwise additivity applies to ^{19}F and ^{11}B chemical shifts and also to ^{11}B–^{19}F coupling constants in the mixed tetrahaloborate anions (21), and extended this to a wide range of boron trihalide adducts (14) and more recently to trialkylamine-haloboron cations (2). The halogen–halogen $\eta_{i,j}$ terms that apply to the tetrahaloborate anions are also applicable to the neutral adducts and the haloboron cations, with addition of donor–halogen $\eta_{i,j}$ terms for the adducts, and also donor–donor $\eta_{i,j}$ terms for the cations. Chemical shifts for trialkylamine-haloboron cations (2) and pyridine-haloboron cations, calculated using our $\eta_{i,j}$ terms (Table 5), agree well with experiment, the average deviation from the observed value being less than 0.5 ppm, although there are greater discrepancies with a few heavy-halogen-containing species. For the typical haloboron cation pyr_2BClI^+, all possible pairwise combinations of boron substituents are: 1 pyr,pyr; 2 pyr,Cl, 2 pyr,I and 1 Cl,I. Using values from Table 5, this gives $\eta_{pyr,pyr} + 2\eta_{pyr,Cl} + 2\eta_{pyr,I} + \eta_{Cl,I} = -1.6$ ppm for the ^{11}B chemical shift, as listed in Table 4. Pairwise interaction parameters have been used as a purely empirical method for identifying new boron (34) and other element (35) species. When there is a wide chemical shift range, assignments are unambiguous. Since the range of ^{11}B chemical shifts of the haloboron cations (excluding $pyr_2BI_2^+$) is only 12 ppm and overlaps the range of neutral adducts and tetrahaloborate anions, a few peak assignments remain ambiguous.

Table 5. Pairwise substituent NMR parameters η_{ij} for four-coordinate boron species.[a]

[a]Based on data for tetrahaloborate anions, neutral adducts, and haloboron cations. ^{19}F values refer to chemical shifts in ppm to high frequency of $CFCl_3$; ^{11}B, values refer to chemical shifts in ppm to high frequency of external $Et_2O{\cdot}BF_3$. pyr = pyridine, Q = quinuclidine, 2-Mepyr = 2-methylpyridine.

[b]Only one example of this interaction was available to calculate this η_{ij} value.

Spin-lattice relaxation

The distinctive short ^{19}F spin-lattice relaxation times (T_1's) of the fluoroboron cations (Fig. 3) support our structures, since fluorine in any $D_2BF_2^+$ or D_2BFX^+ ion is in the middle of a chain and can move much less freely than fluorine on the terminal boron of any D·BF_nX_{3-n} adduct. T_1's are frequently proportional to $1/\tau_c$, where τ_c is the correlation time for molecular reorientation. τ_c is proportional to r^3, r being the effective molecular size. Rapid rotation is possible about the D—B bond of D·BF_nX_{3-n} adducts, i.e., the effective molecular size of the BF_nX_{3-n} portion of the adduct is small, and hence T_1 should be relatively long. Substitution of fluorine with successive chlorines or bromines increases the moment of inertia of the rotating group and slows the rotation, so that these adducts have successively shorter T_1's as the number of heavy halogens increases. Rotation is far more restricted when a BF_2 group is between two large adduct molecules. Such fluorines are not free to rotate rapidly about either D—B bond because rotation is restricted by the second donor, which extends far out into the surrounding solvent. Hence the fluoroboron cations should have shorter T_1's than the neutral adducts, as observed. The even shorter T_1, by another factor of 2, of pyr_3BF^{2+} compared to $pyr_2BF_2^+$ and pyr_2BFX^+, is consistent

with **three** large groups anchoring the boron in place, further restricting the motion of the lone fluorine. The slower fluorine motion in the cations results in more efficient spin-lattice relaxation via a more favourable distribution of motional frequencies (36). This T_1 method is of general applicability in confirming the presence of any fluoroboron cation containing at least two donor molecules. While a number of factors including ion pairing (37) could affect T_1 values in these systems, a T_1 much shorter than all others in the same solution should be valuable in identifying fluoroboron cation resonances, especially in the many oxygen-donor systems in which splittings due to ^{11}B–^{19}F couplings are not resolved so assignments cannot be based on such splittings.

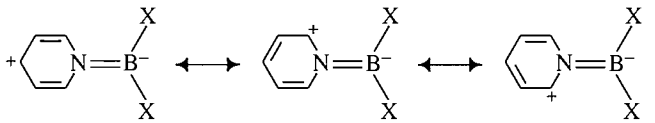
Mechanistic implications

The striking ability of one heavy and two light halogens on boron to maximize the ease of displacement of the heavy halogen can be attributed to stabilization of the transition state or reactive intermediate by π bonding from halogen to boron (2). Such π bonding is far more important with fluorine than with the heavier halogens, which makes BF_3 the weakest Lewis acid of the BX_3 series (6). We tentatively excluded a dissociative mechanism and three-coordinate intermediate on several grounds (2), and suggested an S_N2 reaction with a five-coordinate transition state:

[4] $D{\cdot}BF_2Br + D' \longrightarrow$  $\longrightarrow DD'BF_2^+ + Br^-$

Lowering of the energy of the transition state, by maximization of halogen-to-boron π bonding when the $D{\cdot}BF_2$ unit becomes planar, is crucial to high selectivity. As in a three-coordinate intermediate, the stabilization by π bonding should become greater as the number of fluorines increases, and can account for the high selectivity.

The far greater reactivity of pyr·BF_2Br with pyridine, compared to quinuclidine·BF_2Br with quinuclidine, will to some extent arise from the decreased steric hindrance of pyridine compared to quinuclidine, but the proposed transition state also predicts far greater reactivity of pyr·BF_2Br, independent of steric effects. Pyridine already attached to boron should be able to stabilize the transition state of eq. [4] due to the additional π bonding that is possible from pyridine to boron:



Thus pyridine acts much like fluorine in providing π bonding to stabilize the transition state, whereas a trialkylamine nitrogen cannot participate in π bonding, so that already bonded pyridine accelerates the reaction. This can also explain the observation that the mixed-donor cation (pyr)(Q)BF_2^+ (Q = quinuclidine) forms much more readily when the tertiary amine Q reacts with pyr·BF_2Br, than when pyridine reacts with Q·BF_2Br, despite steric effects in the transition state being essentially the same (2). The proposed five-coordinate transition state can also help to account for the readiness of pyr_3BF^{2+} and pyr_2BFX^+ (X = Cl, Br) to form, while the corresponding trialkylamine species do not. As the number of fluorines available to stabilize the transition state by π bonding decreases, the number of pyridines increases to compensate. One fluorine and one pyridine in the trigonal planar part of the transition state may be almost as effective as two fluorines in providing π bonding to boron. (The lower steric hindrance of pyridine compared to quinuclidine is of course also important, and its importance should increase as the number of Lewis base molecules in the cation increases from two to three.)

Recently the mechanism of reaction of boron trifluoride with pyridine has been analysed in detail by Ou, Wallace, and Janzen (38) on the basis of Janzen's coordination model of reaction mechanisms (39). The analysis, involving a set of plausible dissociation and recombination steps for the case of a 2:1 excess of BF_3 over pyridine, provides insight into why $pyr_2BF_2^+$ should be much slower to undergo chemical exchange than other species including free BF_3, pyr·BF_2^+, BF_4^-, and the fluorine-bridged pyr·BF_2--F--BF_3 that are expected to be present under excess-Lewis-acid conditions. Their analysis is in accord with our observation of a well-defined 1:1:1:1 ^{19}F quartet for $pyr_2BF_2^+$, together with broad ^{19}F signals consistent with rapid chemical exchange among other fluorine-containing species, in the presence of an excess of Lewis acid.

The most important difference between the mixed boron trihalide adducts and BF_3 adducts is that heavy halide ion is a favourable leaving group, while fluoride ion must be transferred among other species and does not exist independently in solvents such as $CDCl_3$. Janzen's coordination model (39), which rationalizes the reactions of a wide range of inorganic fluorides, does not allow displacement of naked F^- but only F^- transfer. The ready formation of pyridine-fluoroboron cations from the mixed boron trihalide adducts, but not from pyr·BF_3, is in accord with displacement of heavy halide ion in a manner that cannot be duplicated by fluoride ion.

Even in non-fluorine-containing $D{\cdot}BX_2Y$ adducts the transitions state would be preferentially stabilized if the lightest available halogens were involved in the planar $D{\cdot}BX_2$ unit, since π bonding from halogen to boron decreases in the order $F \gg Cl > Br > I$ (6). The heaviest halogen, least able to participate in π bonding stabilization of the transition state, would always be preferentially lost, as observed. The relative B—X bond strengths, B—F $\gg$ B—Cl > B—Br > B—I, are also important in favouring the loss of the heaviest halogen but this cannot be the sole effect because the same heavy halogen is lost much less readily from the unmixed rather than the mixed boron trihalide adducts. Because free fluoride is never displaced, halogen redistribution involving fluorine requires the presence of at least traces of uncomplexed Lewis acid so that a transitory B-F-B bridge can form (21, 38–40).

The minor ^{11}B NMR peaks in Fig. 5*a*, which disappear as pyridine is added, may arise from pyr·BCl_2^+, pyr·$BClI^+$, and pyr·BI_2^+. The existence of these species would be favoured by stabilization due to π bonding from pyridine to boron. No similar ^{11}B peaks were observed in the corresponding quinuclidine·BCl_nI_{3-n} system (2) in which π bonding from the donor is not possible. Any such stabilization of pyridine-containing three-coordinate boron cations would be another factor favouring ready formation of the four-coordinate boron cations, since they could easily add another pyridine molecule to

form $pyr_2BX_2^+$. If an analogous $pyr{\cdot}BF_2^+$ species can form readily, as proposed by Janzen and co-workers (38), this would be a factor favouring the observed facile formation of $pyr_2BF_2^+$ even when Lewis acid is present in excess.

Conclusions

Various 4-coordinate fluoroboron and other haloboron cations can be detected in solution under mild conditions by displacement of the heavier halogen as halide ion from pyridine – mixed boron trihalide adducts. Displacement of the heavy halogen is easiest when there are one heavy and two light halogens on boron. It is not yet clear whether kinetic or equilibrium factors are predominant in determining the reactivity patterns in these systems. While many cationic species can be prepared by the reactions described here, firm conclusions on mechanism must await further work.

Halide ion trapping of nitrenium ions formed in the Bamberger rearrangement of *N*-arylhydroxylamines. Lifetime of the parent phenylnitrenium ion in water

James C. Fishbein and Robert A. McClelland

Abstract: The acid reactions of five arylhydroxylamines (Ar = 2,6-$Me_2C_6H_3$, 2,5-$Me_2C_6H_3$, 2-MeC_6H_4, 2-ClC_6H_4, and C_6H_5) have been studied at constant ionic strength ($NaClO_4$) in the presence of varying amounts of NaBr and NaCl. Each system resulted in the corresponding *p*-aminophenol, the product of Bamberger rearrangement, as the only detectable product in the absence of halide. The addition of halide ion reduced the yield of this product, with the appearance of the corresponding *p*-haloaniline, *o*-haloaniline (where appropriate), and the parent aniline (predominantly with bromide). Rate constants for the reaction were measured in the case of the parent and 2,6-dimethyl systems and showed small decreases (chloride) or increases (bromide) with increasing halide concentration. These changes did not correlate with the change in products, implying that the rate variations were caused by specific salt effects. Product data were analyzed by a mechanism involving rate-limiting formation of the appropriate arylnitrenium ion followed by product-determining steps involving trapping by the solvent or by the added halide. The possibility that a portion of the halide-trapped products were derived from a pre-association mechanism was also included. Kinetic analyses then produced k_{Br}:k_w and k_{Cl}:k_w ratios for two limiting cases, one involving pre-association with an equilibrium constant K_{as} = 0.3, and one ignoring pre-association. From an azide:water ratio (k_{Az}:k_w) previously determined for the 2,6-dimethylphenylnitrenium, k_{Br} was concluded to lie in the range (4–5) × 10^9 M^{-1} s^{-1} for all of the nitrenium ions of this study. This range for k_{Br} then led to k_w values of (1–2) × 10^9 s^{-1} (2,5-Me_2), (2–3) × 10^9 s^{-1} (2-Me), and (4–8) × 10^9 s^{-1} (parent and 2-Cl), where the ranges reflect uncertainties in the exact value of k_{Br} and in the contribution from pre-association. The lifetime of the parent phenylnitrenium ion in water at one molar ionic strength is concluded to lie in the range 125–250 ps.

Key words: nitrenium ion lifetime, phenylhydroxylamine, phenylnitrenium ion, Bamberger rearrangement.

Résumé : Opérant à force ionique constante ($NaClO_4$) en présence de quantités variables de NaBr et de NaCl, on a étudié les réactions d'addition de cinq arylhydroxylamines (Ar = 2,6-$Me_2C_6H_3$, 2,5-$Me_2C_6H_3$, 2-MeC_6H_4, 2-ClC_6H_4 et C_6H_5). Pour chaque système, en l'absence d'halogénure, le seul produit détectable est le *p*-aminophénol correspondant, le produit du réarrangement de Bamberger. L'addition d'halogénure diminue le rendement en ce produit et il y a apparition de la *p*-halogénoaniline correspondante, de l'*o*-halogénoaniline (dans les cas appropriés) et de l'aniline parente (en prédominance avec le bromure). On a mesuré les constantes de vitesse dans les cas des systèmes parent et 2,6-diméthylés et celles-ci diminuent (chlorure) ou augmentent (bromure) légèrement avec une augmentation de la concentration de l'halogénure. Il n'y a pas de corrélation entre ces changements et les changements dans les produits; ceci implique que les variations dans le vitesses sont provoquées par des effets de sel spécifiques. Les données relatives aux produits ont été analysées à l'aide d'un mécanisme impliquant la formation de l'ion arylnitrénium approprié dans l'étape déterminant la vitesse, suivie par des étapes déterminant la nature des produits qui impliquent un piégeage par le solvant ou par l'halogénure ajouté. On a aussi inclus la possibilité qu'une partie des produits dérivant d'un piégeage de l'halogénure dérive d'un mécanisme de pré-association. Les analyses cinétiques ont alors conduit aux rapports k_{Br} : k_w k_{Cl} : k_w pour les deux cas limites, l'un impliquant une préassociation avec une constante d'équilibre, K_{as} = 0,3, et l'un ne tenant pas compte d'une pré-association. En se basant sur un rapport azoture : eau (k_{Az} : k_w) déterminé antérieurement pour le 2,6-diméthylphénylnitrénium, on a conclu que la valeur de k_{Br} est d'environ (4–5) × 10^9 M^{-1} s^{-1} pour tous les ions nitrénium examinés au cours de cette étude. Ces valeurs de k_{Br} conduisent alors à des valeurs de k_w de (1–2) × 10^9 s^{-1} (2,5-diméthyle), (2–3) × 10^9 s^{-1} (2-méthyle) et (4–8) × 10^9 s^{-1} (parent et 2-Cl) dans lesquelles les domaines sont un reflet des incertitudes dans la valeur exacte de k_{Br} et de la contribution de la pré-association. Le temps de vie de l'ion phénylnitrénium parent dans l'eau, à une force ionique molaire, est de l'ordre de 125–250 ps.

Mots clés : temps de vie des ions nitrénium, phénylhydroxylamine, ion phénylnitrénium, réarrangement de Bamberger.

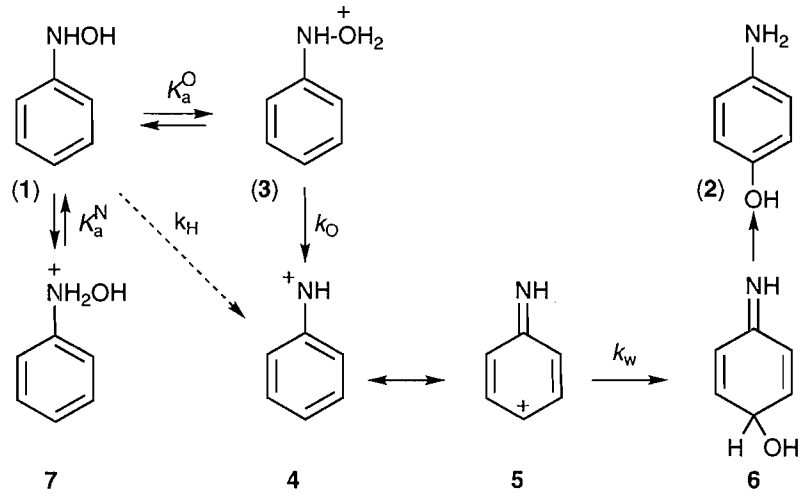
Scheme 1.



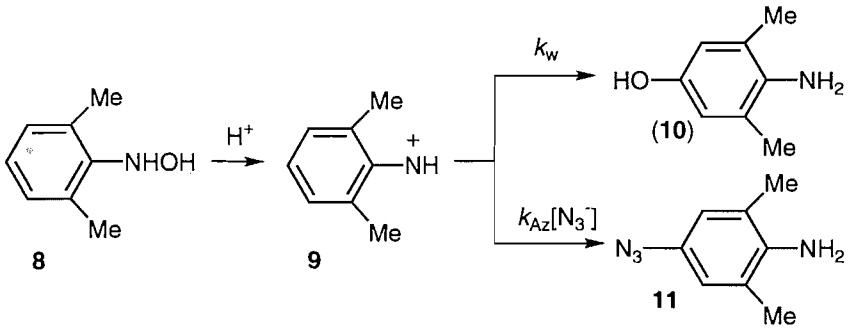
Bamberger reported 100 years ago that *N*-phenylhydroxylamine and its derivatives rearrange in aqueous acid solutions to give 4-aminophenols (1). With the parent compound (**1**) in aqueous sulfuric acid, 4-aminophenol (**2**) was the exclusive product observed, while both 4-chloroaniline and 2-chloroaniline were also formed with HCl as the acid (1, 2). A study by Ingold and co-workers in the 1950s showed that despite the formation of these chloroanilines, the rate was independent of chloride ion concentration (3). This ruled out mechanisms with N—O bond fission concerted with chloride ion attack and was more consistent with an S_N1 type of mechanism. Detailed studies carried out within the last 25 years have elaborated on this suggestion and have lead to the mechanism of Scheme 1. Key features are the activation of the hydroxylamine by O-protonation to form **3**, followed by N—O bond fission with loss of water to form an intermediate nitrenium ion **4**. This cation is trapped at the *para* position (i.e., through a carbenium resonance contributor **5**) to give the intermediate **6**, the tautomer of the ultimate product. In the case where the *para* position is substituted with a methyl group, the iminocyclohexadienol (e.g., 4-hydroxy-4-methyl-2,5-cyclohexadienone imine) can be observed, although this slowly hydrolyzes to the ketone (4).

One important finding was that the reaction occurs in an intermolecular fashion, since rearrangement of **1** in $H_2{}^{18}O$ resulted in full incorporation of solvent oxygen into the product *p*-aminophenol (5). This same study also showed that there was no exchange of ^{18}O into unreacted starting material, establishing that N—O bond fission is not reversible (5) (although a similar study with *N*-1-naphthylhydroxylamine (6) suggests that this is not always the case). Detailed kinetic studies showed that the reaction was first order in phenylhydroxylamine and first order in H^+ to pH 1–2, with the rate then becoming independent of acidity to acids with H_0 of about -1, at which point the rate began to increase again (7–9). Spectral measurements suggested that the initial levelling was associated with protonation to the unreactive N-protonated hydroxylamine **7**, with $pK_a{}^N = 1.90$ for the parent system (7, 9). The acid catalysis at higher acidities was explained by a mechanism involving a diprotonated intermediate $PhN^+H_2O^+H_2$ (7, 10), although a medium or salt effect could not be ruled out (9).

The occurrence of an S_N1-type mechanism leading to an arylnitrenium ion as an intermediate was suggested by several pieces of evidence, including solvent isotope effects (9) and entropies of activation (7, 8) in addition to the previously mentioned experiment in HCl by the Ingold group (3). Substituents in the aromatic ring have a significant effect, with large negative ρ values consistent with the development of considerable positive charge in the ring in the transition state for the reaction. As one example, log k_H for the rearrangement of *meta*-substituted phenylhydroxylamines had a ρ value of -5.8 (7). Arylnitrenium ions have also been proposed as intermediates in the solvolysis of a number of hydroxylamine derivatives — sulfonates $ArNR\text{-}OSO_2CF_3$ (11), sulfates $ArNR\text{-}OSO_3^-$ (12), carboxylates $ArNR\text{-}OOCR'$ (13–15) — as well as *N*-chloroanilines (16). As in the Bamberger rearrangement, these compounds solvolyze in water to products derived from addition of the solvent at the ring carbon *para* to the nitrogen, and large negative ρ values in the range -5 to -9 are observed.

Evidence that arylnitrenium ions can have lifetimes in water that make them viable as intermediates has appeared only recently. The first such experiment involved *N*-(2,6-dimethylphenyl)hydroxylamine (**8**) undergoing its Bamberger rearrangement in the presence of azide ion (17). Two products were observed, the expected *p*-aminophenol **10** and the *p*-azidoaniline **11**. The latter formed in increasing relative amount with increasing concentration of azide, but did so with no increase in the rate of reaction. This is classic evidence for an intermediate, in this case the nitrenium ion **9**, which forms in a rate-determining step and then partitions between the solvent and the added nucleophile in very fast reactions. The product data were fit by the standard equation for such a competition furnishing the partitioning ratio $k_{Az}:k_w$ as 7.5 M^{-1}. With carbenium ions as electrophiles, the assumption has been widely employed that azide ion reacts at the diffusion limit with k_{Az} approximately equal to 5×10^9 M^{-1} s^{-1} (18–20). The same assumption for arylnitrenium ions provided the lifetime of the 2,6-dimethylphenynitrenium ion (**9**) in water ($1/k_w$) as 1.5 ns. This number does indicate that

Scheme 2.

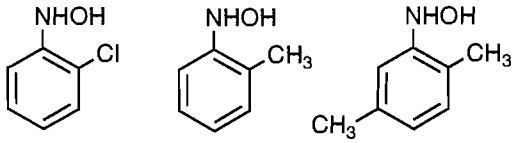


this nitrenium ion can exist as a free cation in water, although its lifetime is very short.

The Novak group has more recently applied the azide-clock approach to a number of arylnitrenium ions formed in the solvolysis of sulfate, pivalate, and *N*-chloro derivatives (21–23). With the above assumption for azide, they found lifetimes varying from the picosecond to the microsecond region. Substituents in the aryl ring exerted significant effects, but the lifetimes did not correlate well with the σ^+ value of the substituent (22). Unlike the case of the Bamberger rearrangement, these experiments form the nitrenium ion initially as an ion pair with the leaving group. With the more reactive nitrenium ions evidence was presented that the solvent and azide reactions were occurring at the ion-pair stage (23). We have also reported such a situation with some *N*-aroyloxy-2,6-dimethylphenylhydroxylamines (24, 25).

Arylnitrenium ions have not been observed under superacid conditions (26–28) although there have been reports of their spectroscopic characterization following the two-electron oxidation/deprotonation of diarylamines (29, 30) and a dimethylamino-stabilized biphenyl derivative (31). Within the last three years several examples have been detected in laser flash photolysis experiments (32–37). These included stabilized examples — the 4-biphenylyl- and 2-fluorenylnitrenium ions and their *N*-acetyl derivatives — that were sufficiently long-lived to be studied in aqueous solution (35, 36). These experiments furnished absolute rate constants for the reaction with water and azide ion, and indeed k_{Az} values of 5×10^9 M^{-1} s^{-1} were obtained, verifying the application of the "azide-clock" approach in competition kinetic experiments. Similar experiments have also verified the applicability of this approach to carbenium ions (38, 39).

In this paper we consider the Bamberger rearrangement of the parent *N*-phenylhydroxylamine (**1**), and the four derivatives **8**, **12–14** in the presence of chloride ion and bromide ion.



12 **13** **14**

The principal objective of this research was to provide an estimate for the lifetime of the parent phenylnitrenium ion in aqueous solutions. Recent research in our laboratories has established that this nitrenium ion is formed photochemically in aqueous acid solutions following irradiation of phenyl azide by rapid protonation of the so-formed singlet phenylnitrene (40). The phenylnitrenium ion, however, is too short-lived to be detected by laser flash photolysis using excitation sources with nanosecond pulse widths, although the cation might be detectable with faster systems. In principal, the Ingold data (3) from the 1950s should be capable of supplying a chloride:water partitioning ratio $k_{Cl}:k_w$. However, examination of these data shows that there is uncertainty since the amount of trapping by chloride ion is small and there is the possibility that salt effects may be perturbing the data. A second uncertainty is the value for k_{Cl} that would be used to convert the trapping ratio to an absolute rate constant for the solvent. Our approach therefore was to work from the 2,6-dimethyl system (**8**) where the $k_{az}:k_w$ previously measured provides a good estimate of k_w. Ideally we would have liked to have measured $k_{Az}:k_w$ for the parent phenylhydroxylamine. This, however, proved not to be possible since the acidities required for sufficient free azide ion to be present (pH > 4) were too low for the Bamberger rearrangement to occur at a significant rate. In this case, significant quantities of oxidation products are formed even with rigorous dearation (7, 9) and these complicate the analysis. One approach we considered was to move to a phenylhydroxylamine derivative where the phenylnitrenium ion forms by simple ionization, as has been done by the Novak group (21–23). This, however, adds the complication of trapping at the stage of an ion pair (23, 25). The formation of the nitrenium ion from the O-protonated hydroxylamine avoids this problem since the leaving group simply becomes part of the solvent in the solvation shell. Finally, our choice of substrates was dictated by a desire to avoid systems where the *para* position was substituted. In this way we obtained one major product, the *p*-aminophenol, from the reaction with solvent.

Results

Experiments were carried out at 25°C in aqueous solutions containing 0.5% acetonitrile and a mixture of $HClO_4$, $NaClO_4$, and either NaCl or NaBr. The total ionic strength was maintained constant at 1 M. The concentration of the hydroxylamine was 10^{-4} M, and reactions were carried out until there was complete disappearance of this substrate. Products were

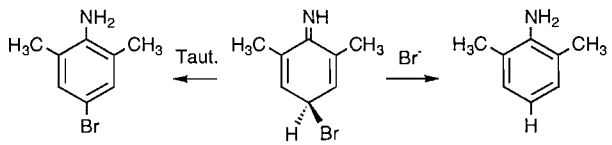
analyzed quantitatively by HPLC, by comparison of peak areas with areas obtained for authentic samples. Sets of experiments were conducted with the same concentration of $HClO_4$, and with varying concentrations of NaCl or NaBr starting from 0 M. The acid concentration was chosen to give a rate of reaction sufficient to avoid the formation of oxidation products, and mass balances for the nucleophilic products were in general excellent. The experimental data, product yields as a function of [NaCl] or [NaBr], are provided in Tables S1–S8 as supplementary material.[2] The following provides a brief description of the pertinent results with each hydroxylamine.

N-(2,6-Dimethylphenyl)hydroxylamine (8)

With chloride ion present, two products were observed, 4-amino-3,5-dimethylphenol (**10**) and 4-chloro-2,6-dimethylaniline (**15**). Rate constants were measured in a set of solutions containing 0.000324 M $HClO_4$, ionic strength = 1 M, by following a change in optical density at 280 nm in the UV absorbance spectra. The values of k_{obs} showed a small decrease on increasing chloride concentration, amounting in total to an 8% decrease on proceeding from 0 M to 0.888 M NaCl.

With bromide ion present, three products were observed, 4-amino-3,5-dimethylphenol (**10**), 4-bromo-2,6-dimethylaniline (**16**) and 2,6-dimethylaniline (**17**). As shown in eq. [1], both **16** and **17** are attributed to bromide ion trapping of the nitrenium ion to form the initial adduct **18**, followed by either tautomerization to **16** or reaction with a second bromide ion to give **17** and Br_2. The aniline is the product of formal reduction of the hydroxylamine. The occurrence of such a reaction was first reported by Pelecanou and Novak (41). Evidence for this mechanism in the present case is the increase in the ratio of the reduction product to the adduct ([**17**]:[**16**] with increased concentration of bromide ion.

[1]



16 18 17

Rate constants were again measured in the set containing 0.000324 M $HClO_4$. In this case there was a small, nonlinear, increase in k_{obs} with increasing bromide concentration. Overall, from 0 M to 0.475 M [Br^-], k_{obs} increased by 25%.

N-Phenylhydroxylamine (1)

With both halides, the only product derived from the solvent was 4-aminophenol (**2**), with 2-aminophenol not detected (<0.5%) in any experiments. With chloride ion present, 4-chloroaniline (**19**) and 2-chloroaniline (**20**) were also obtained, in relative yields that were independent of the concentration of the chloride ion: [**20**]:[**19**] = 0.444 ± 0.016. Similarly, 4-bromoaniline (**21**) and 2-bromoaniline (**22**) were observed with bromide ion, in a relative amount [**22**]:[**21**] = 0.614 ± 0.018. A small amount of the parent aniline (**23**) was also formed. We presume that this is arising from the mechanism of eq. [1], although here it can be noted that the ratio of reduction product to adduct does not change with bromide conentration. This may imply that there is another mechanism in operation for the reduction product.

In the reaction with chloride present, rate constants measured at constant acidity and ionic strength showed a small decrease with increasing chloride concentration. The rate constant at [Cl^-] = 0.93 M was 12% smaller than the one in the absence of chloride. With bromide ion present, small increases in rate constant were observed. The rate constant at [Br^-] = 0.95 M was 13% larger than the one in the absence of bromide.

N-(2-Methylphenyl)hydroxylamine (13)

As with the parent compound, the only product derived from the solvent was the *para* adduct, 4-amino-3-methylaniline (**24**). With chloride ion present, both the *para* adduct 4-chloro-2-methylaniline (**25**) and the *ortho* adduct 6-chloro-2-methylaniline (**26**) were observed, in a ratio [**26**]:[**25**] = 0.089 ± 0.005. The decreased *ortho*:*para* ratio compared to the parent system is undoubtedly associated with the increased steric congestion in this system where *ortho* addition requires three substituents on adjacent carbons of the aromatic ring. A small amount (maximum of 2%) of 2-methylaniline (**27**) was also observed. With bromide ion, the only bromide-containing product formed was the *para* adduct, 4-bromo-2-methylaniline (**28**), no *ortho* adduct (6-bromo-2-methylaniline (**29**) being detectable. In this case, substantial amounts (up to 12%) of the reduction product 2-methylaniline **27** were also formed.

N-(2,5-Dimethylphenyl)hydroxylamine (14)

In this case the only product that was quantitatively analyzed was the solvent adduct, 4-amino-2,5-dimethylphenol (**29**). With chloride ion, the HPLC traces showed the presence of only one other product. Since this could be shown not to be the parent aniline, we presume that it corresponds to the *para* adduct 4-chloro-2,5-dimethylaniline (**30**). The absence of the *ortho* adduct 2-chloro-3,6-dimethylaniline (**31**) makes sense, since this product requires four substituents at adjacent carbons. With bromide, the parent aniline was observed, along with one other product that we assume to be the *para* adduct.

N-(2-Chlorophenyl)hydroxylamine (12)

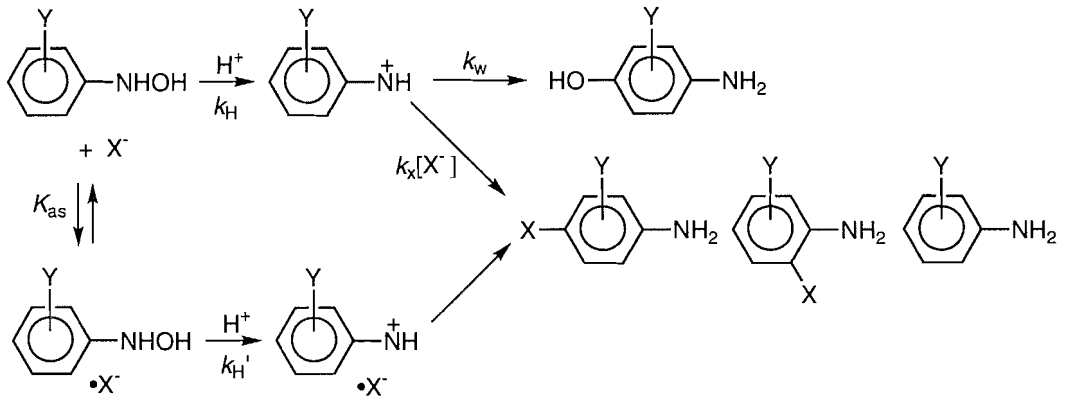
With this compound, just the reaction in the presence of chloride was studied. Three products were observed, 4-amino-3-chlorophenol (**32**), 2,4-dichloroaniline (**33**), and 2,6-dichloroaniline (**34**). The latter two formed in a ratio [**34**]:[**33**] = 0.27.

Discussion

We start by considering whether the halide-derived products are indeed obtained by trapping at the stage of an arylnitrenium ion. The evidence comes from a comparison of products and kinetics, the combination of these two experiments being carried out in this work with the parent hydroxylamine and the 2,6-dimethyl derivative. In each case, both halides were examined, with the kinetic experiments being performed under the same conditions as the product analyses. A constant acid concentration was employed, to ensure that rate variations could

[2] Supplementary material mentioned in the text can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Scheme 3.



not be attributed to changes in acidity. The ionic strength was also maintained constant, with $NaClO_4$ being replaced with an equivalent amount of NaCl or NaBr. In the case of chloride, the observed rate constants with both hydroxylamines actually decreased slightly with increased chloride content. Thus here there is no correlation with the appearance of chloride products. With bromide, however, increases in k_{obs} were observed. In the 2,6-dimethyl case this amounted to a 25% increase in k_{obs} at the highest concentration of bromide employed. At this concentration, however, 80% of the products are due to bromide trapping, and this requires a 400% or 5-fold increase in k_{obs} if the bromide products are due to some bimolecular mechanism. With the parent compound, a 13% increase was observed in k_{obs} at the highest [Br^-]. Under these conditions 50% of the products are due to the bromide reaction, so a doubling in k_{obs} is required if the reaction is bimolecular. These data therefore exclude the possibility that all of the bromide trapping is due to a bimolecular reaction. The slight rate increase that is observed may be caused by a specific salt effect associated with replacing perchlorate by halide. A slight contribution from a slow bimolecular process is also possible. Whatever the case, the majority of the products must be derived from reaction at the stage of the arylnitrenium ion.

We therefore analyze the product data according to the mechanism of Scheme 3, with rate-limiting formation of the arylnitrenium ion followed by product-determining steps involving trapping by the solvent or by the added halide. A recent paper from the Novak group (23) has demonstrated that pre-association can account for a significant portion of the products from added nucleophiles in the case of nitrenium ions with lifetimes in the region of the ones of this study, and such a possibility has been incorporated in Scheme 3. Pre-association involves the formation of a nucleophile–substrate complex prior to the formation of the nitrenium ion. In Scheme 3 this is shown as occurring at the stage of the neutral hydroxylamine, but a mechanism in which this takes place after protonation would be equivalent. As in the Novak study, Scheme 3 is written such that the nitrenium·halide pair, once formed, only reacts with the halide counterion. To explain the lack of kinetic dependence on halide concentration this mechanism also requires that the halide-substrate complex react to form nitrenium ion at the same rate as the substrate alone. This was also true with the systems involved in the Novak study (23).

In terms of this mechanism, the fractional yield of the *p*-aminophenol is given by eq. [2].

$$[2]\quad F(p\text{-aminophenol}) = \left(\frac{1}{1 + \left(\frac{k_x}{k_w}\right)[X^-]}\right) \times \left(\frac{1}{1 + K_{as}[X^-]}\right)$$

The second term on the right-hand side of this equation represents the decrease in the *p*-aminophenol product due to pre-association with the halide, while the first term represents the decrease associated with trapping of the free nitrenium ion. Equation [2] contains two adjustable parameters, k_x:k_w and K_{as}, and in principle these can be provided by nonlinear least-squares fitting to the experimental data. Our fitting program, however, failed to perform such an operation, since with the scatter in the experimental data the fits to eq. [2] were about equally as good for values of K_{as} ranging upwards from 0 to 0.4–0.6. The problem in the case of systems that show a significant decrease in *p*-aminophenol, such as 2,6-dimethyl with both halides, is that most of this decrease is due to trapping of the free nitrenium ion. Thus, a small contribution from pre-association cannot be distinguished experimentally from the case where there is none. In the case of systems where there is a smaller decrease in *p*-aminophenol, the problem is that the data cannot be extended to high enough halide concentrations to unequivocally define K_{as}.

The association constant K_{as} has been assumed to be 0.3 M^{-1} at 20°C (42, 43). (Novak et al. (23) found that a value of 0.25 provided a better fit to their data at a higher temperature, 50°C.) Accordingly, we took K_{as} as 0.3 and fit to eq. [2] with the trapping ratio as the adjustable parameter. The k_x:k_w ratios so produced are given in Table 1, along with ones obtained assuming no pre-association (i.e., K_{as} = 0). As noted above, the two values of K_{as} in most cases resulted in fits to the experimental data that were indistinguishable. Figure 1 shows the "best" case for pre-association, the parent plus bromide system, where the line produced with K_{as} = 0.3 produces a marginally better fit.

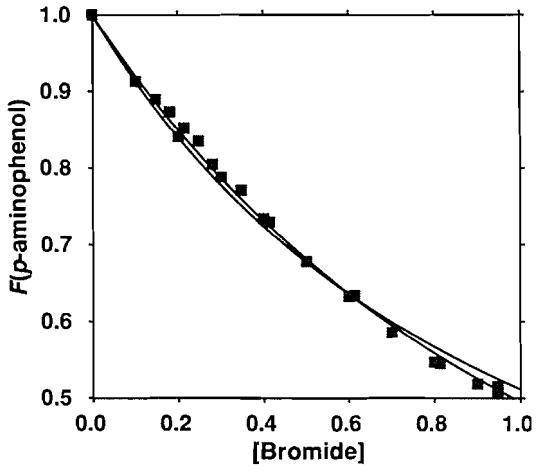
The mechanistic model including pre-association results in lower values for k_x:k_w compared with the one that ignores pre-association. This effect can be quite significant with substrates

Table 1. Trapping ratios for arylnitrenium ions.[a]

Parameter	2,6-Me_2	2,5-Me_2	2-Me	2-Cl	H
With K_{as} = 0					
$k_{Br}:k_w$ (M^{-1})	6.38 ± 0.22	2.95 ± 0.12	2.35 ± 0.12	—	1.05 ± 0.03
$k_{Cl}:k_w$ (M^{-1})	2.67 ± 0.05	1.35 ± 0.03	1.04 ± 0.03	0.65 ± 0.02	0.62 ± 0.02
$k_{Br}:k_{Cl}$	2.4	2.2	2.3		1.7
With K_{as} = 0.3					
$k_{Br}:k_w$ (M^{-1})	5.82 ± 0.17	2.44 ± 0.08	1.85 ± 0.09	—	0.63 ± 0.03
$k_{Cl}:k_w$ (M^{-1})	2.13 ± 0.07	0.91 ± 0.02	0.64 ± 0.02	0.30 ± 0.01	0.27 ± 0.01
$k_{Br}:k_{Cl}$	2.7	2.7	2.9		2.4
$10^{-9}k_w$ (s^{-1})	0.7[b]	1–2[c]	2–3[c]	4–8[d]	4–8[c]

[a]Ionic strength = 1.0 M, 25°C.
[b]From $k_{Az}:k_w$ = 7.5 (K_{as} = 0) to 7.0 (K_{as} = 0.3), with $k_{Az} = 5 \times 10^9\ M^{-1}\ s^{-1}$.
[c]Lower limit uses the value of $k_{Br}:k_w$ obtained with K_{as} = 0, and $k_{Br} = 4 \times 10^9\ M^{-1}\ s^{-1}$. Upper limit uses the value of $k_{Br}:k_w$ obtained with K_{as} = 0.3, and $k_{Br} = 5 \times 10^9\ M^{-1}\ s^{-1}$.
[d]Taken to be same as parent, since $k_{Cl}:k_w$ values are, within experimental error, the same.

Fig. 1. Fractional yields of *p*-aminophenol in the reaction of *N*-phenylhydroxylamine in the presence of bromide ion. The two lines have been drawn according to eq. [2] with K_{as} = 0 and 0.3, with the latter providing the better fit to the experimental data.



where trapping is relatively inefficient. For example, with the parent system, $k_x:k_w$ values calculated with K_{as} = 0.3 are ~50% of the ones with K_{as} = 0. With systems where there is more efficient trapping, the effect is relatively smaller.

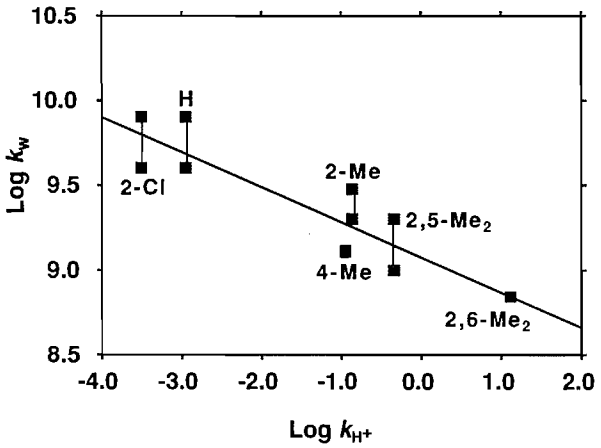
With the 2,6-dimethyl derivative, a value for k_w of 6.8×10^8 s^{-1} is obtained using the previously determined $k_{Az}:k_w$ ratio of 7.5 M^{-1} (17), with the assumption, now supported by direct measurements involving flash photolysis (35, 36), that k_{Az} is 5×10^9 M^{-1} s^{-1}. Inclusion of pre-association with K_{as} = 0.3 reduces $k_{Az}:k_w$ by only 7% to 7.0 M^{-1}, and results in a slightly larger value of k_w of 7.1×10^8 s^{-1}. These k_w values in turn provide rate constants for the two halides, k_{Br} as $(4.1–4.3) \times 10^9$ M^{-1} s^{-1} and k_{Cl} as $(1.5–1.8) \times 10^9$ M^{-1} s^{-1}. The lower value of each pair is the one obtained from the analyses with K_{as} = 0.3, the higher value from models with no pre-association. Thus, even with the 2,6-dimethylphenylnitrenium ion, the rate constants for the two halides exceed 10^9, and the value for bromide approaches the azide limit.

We argue that these two rate constants are likely already very close to their limits. The evidence comes from the observation (Table 1) that, within each mechanistic model, the ratios $k_{Br}:k_{Cl}$ are relatively constant, in spite of a considerable variation in nitrenium ion stability. If the reaction of the 2,6-dimethylphenylnitrenium ion with one or both of the halides was not occurring close to the limit, the further increases in reactivity that accompanied the change to the more reactive nitrenium ions should have appeared experimentally as a narrowing of the difference between the two halides. That the ratio remains constant at ~2 suggests that the situation has been reached with all of the nitrenium ions of this study where the rate constants are at their limit. Limiting rate constants below 5×10^9 M^{-1} s^{-1} have been suggested for cation–anion combination reactions, for cases where the anion component is well hydrated (44, 45). In the present case the order $Cl^- < Br^- \leq N_3^-$ certainly follows the order of diminishing hydration.

In consequence, k_w values have been calculated in two ways, a lower limit based on the higher $k_{Br}:k_w$ ratio obtained with K_{as} = 0 and a value of $k_{Br} = 4 \times 10^9$ M^{-1} s^{-1}, and an upper limit based on the lower $k_{Br}:k_w$ ratio obtained with K_{as} = 0.3, and a value of $k_{Br} = k_{Az} = 5 \times 10^9$ M^{-1} s^{-1}. These values are given in Table 1. Figure 2 shows a plot of log k_w versus log k_H, where k_H is the second-order rate constant for H^+ catalysis of the formation of the nitrenium ion from the neutral hydroxylamine (see Scheme 1). With the uncertainty in k_w, this plot is scattered, although there is a general correlation that increased k_H results in smaller k_w. There is, however, a significantly smaller variation in the latter, a reflection of the very different response of nitrenium ion formation and decay to changing substituents.

Our analysis results in a value of k_w for the parent phenylnitrenium ion in the range $(4–8) \times 10^9$ s^{-1}, corresponding to a lifetime in water of 250–125 ps. Novak et al. previously estimated k_w for the *N*-acetylphenylnitrenium ion as 1.7×10^{11} s^{-1}, based on a correlation of log ($k_{Az}:k_w$) with enthalpies calculated using ab initio methods (22). Considering that there is some uncertainty in the latter number, the $k_w(NCOCH_3):k_w(NH)$ ratio = 20–40 does appear consistent.

Fig. 2. Linear free energy correlation. The constant k_w represents the hydration of arylnitrenium ions. Values are from this work with the exception of 4-Me, which is taken from ref. 23. The constant k_H refers to the H^+-catalyzed formation of the nitrenium ion from the neutral hydroxylamine. Values are taken from ref. 8 with the exception of 4-Me, which is from ref. 9.



The other systems where this ratio has been obtained (23) are arylnitrenium ions substituted with a π donor at the *para* position: 4-Cl, $k_w(NCOCH_3):k_w(NH)$ = 8; 4-Me, $k_w(NCOCH_3):k_w(NH)$ = 6; and 4-Ph, $k_w(NCOCH_3):k_w(NH)$ = 3. Such substituents localize positive charge at the *para* carbon away from the nitrogen, and should therefore attenuate the effect of the electron-withdrawing acetyl group. This effect is especially important with 4-Ph, which provides an unexpectedly large amount of stabilization and results in relatively small difference in the the lifetimes of the *N*-acetyl and NH ions.

Experimental section

The *N*-arylhydroxylamines were prepared from the corresponding nitroarenes by zinc reduction in methanol:water containing ammonium chloride, followed by recrystallization from benzene:petroleum ether (7, 8). Products were commercially available or were obtained from catalytic hydrogenation of the appropriate nitro compound. Details of the HPLC separations and quantitative determinations of products have been previously published (24). In the present case, analyses were performed on a Waters Microbondapak C18 column, except for *N*(-2-chlorophenyl)hydroxylamine where a Hamilton PRP polyvinylstyrene column was employed. Quantitative measurements were based on standard curves constructed with at least three points. Product identifications were verified by spiking the reaction mixtures with authentic samples. Rate constants were measured as previously described (7–9), by following the change in optical density at an appropriate wavelength in the UV.

Carbon-13 chemical shifts of alkene carbons in 2-acylidene-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazoles and related benzothiazoles and -selenazoles, and their relationship to other push–pull alkenes

Jennifer L. Mueller, Martin S. Gibson, and J. Stephen Hartman

Abstract: Carbon-13 chemical shifts of alkene carbons are observed in the ranges 78–109 ppm (Cα) and 154–164 ppm (Cβ) for a series of 11 2-acylidene-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazoles, 3 2-acylidene-3-alkyl-2,3-dihydrobenzothiazoles, and 2 2-acylidene-3-alkyl-2,3-dihydrobenzoselenazoles of known geometry, indicating appreciable charge polarization in these compounds as in other push–pull olefins. Substitution that promotes more extensive charge delocalization results in the Cα signal shifting to the higher-frequency end of the chemical shift range. The observed shifts are compared with those calculated according to the Pretsch scheme.

Key words: carbon-13 NMR, chemical shifts, push–pull olefins, 1,3,4-thiadiazoles, benzothiazoles, benzoselenazoles.

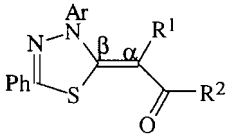
Résumé : On a observé les déplacements chimiques du ^{13}C des carbones des alcènes dans des régions allant de 78 à 109 ppm (Cα) et 156 à 164 (Cβ), d'une série de 11 2-acylidène-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazoles, de 3 2-acylidène-3-alkyl-2, 3-dihydrobenzothiazoles, et de 2 2-acylidène-3-alkyl-2,3-dihydrobenzosélénazoles de géométries connues; ces résultats indiquent qu'il existe une polarisation importante de la charge dans ces composés, comme dans les autres oléfines « push–pull ». La substitution qui provoque la plus grande délocalisation conduit à un déplacement du signal Cα vers les plus grandes fréquences de la plage des déplacements chimiques. On a comparé les déplacements chimiques observés avec ceux calculés à l'aide du schéma de Pretsch.

Mots clés : RMN du carbone-13, déplacements chimiques, oléfines « push–pull », 1,3,4-thiadiazoles, benzothiazoles, benzosélénazoles.

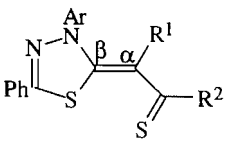
[Traduit par la rédaction]

Introduction

We have synthesized a number of 2-acylidene-3,5-diaryl-2,3-dihydro-1,3,4-thiadiazoles **1** and thioacyl analogues **2** in which, for the most part, the 3-aryl substituent is either 2,4-dibromophenyl or phenyl (1–5). Recently, from spectroscopic and X-ray crystallographic studies, it has been possible to assign (*Z*) configurations to these compounds and to confirm that they exist in the *s-cis* conformation (shown) as a result of stabilization through an S...O interaction (6). The main features of the four compounds studied (6) are (*a*) short S...O contacts (2.463–2.691 Å), (*b*) C(5)—S...O and S...O=C bond angles of approximately 165° and 100°, respectively, and (*c*) evidence of delocalization within the C(5)-C=C-C=O structural unit, but with C=O bond lengths close to normal. The energy associated with the "nonbonded" or "closed shell" S...O interaction need be no more than a few kcal/mol to account for the overwhelming predominance of the *s-cis* conformer (6–8).



1



2

Compounds such as **1** and **2** can be viewed as push–pull alkenes (9) in which the heterocyclic ring provides donor substituents and the acyl or the thioacyl substituent provides the acceptor. Push–pull alkenes have polarized charge distributions that arise from electron delocalization through the donor – double bond – acceptor system; the resulting π-electron distributions include large contributions from C—C single bonded formulae in the resonance hybrid such as those shown below for **1**. In this example, the resonance description implies some aromatic character on the heterocyclic ring. In the absence of a generally used notation for the olefinic carbons of push–pull olefins, in this paper we denote the olefinic carbon with acceptor groups Cα and the carbon with donor groups Cβ.

Related conjugated systems (push–pull polyenes) have recently become important in the study of nonlinear optical properties because these properties are enhanced by large changes in dipole moment and hence in charge distribution between the ground and excited states (10).

Push–pull alkenes have been widely studied by ^{1}H NMR spectroscopy since the 1960s (9, 11), and less extensively by ^{13}C NMR spectroscopy (12–19).[2] Of the ^{13}C NMR studies, the results of Kleinpeter and co-workers (12) span a fairly wide variety of compounds, while other workers have contributed data from more restricted ranges of compounds determined by their synthetic or other interests (13–19). In all cases, the alkene carbons of the push–pull system have ^{13}C chemical shifts at the outer limits of the alkene range: significantly more shielded (i.e., to low frequency) for the acceptor-substituted carbon Cα and less shielded (i.e., to high frequency) for the donor-substituted carbon Cβ, relative to the chemical shift range for the corresponding alkene without donor or acceptor substituents. These shifts are readily discernible even when not explicitly assigned (18). The shift difference between the two olefinic carbon atoms has been attributed to the sizable partial positive and negative charges that exist on these atoms, and its numerical value (ΔCβCα in our notation) has been used by some authors as a sensitive, if non-additive, parameter for this charge separation (12). Changes in ΔCβCα can be closely related to changes in charge separation within subsets of similar compounds (12), but ΔCβCα cannot in general be related solely to charge separation because of the many factors that contribute to ^{13}C chemical shifts (20). Quite large chemical shift differences can occur between pairs of olefinic carbons in olefins themselves, in the absence of electron-donating or -accepting substituents, because hydrocarbon substituents can have significant effects on chemical shift (20). Thus the significant part of ΔCβCα in a push–pull olefin, from the point of view of charge separation, must be that part which is over and above what would be observed in the corresponding hydrocarbon of identical structure.

^{13}C NMR spectroscopy thus, within the aforementioned limitations, provides an indication of charge separation within the push–pull systems of **1** and **2**. It was of interest to us in that it may indicate any effects of modification resulting from heteroatom "nonbonded" or "closed shell" interactions, which can result in conformational preference (6–8, 21). We now report ^{13}C NMR data for the series of compounds **1** and **2** and for the related benzothiazoles **3** and benzoselenazoles **4** and **5** (7).

Experimental

Compounds were taken from our collection of crystallized samples assembled over the years (1–7) which had been stored at room temperature in the dark. All were in good condition. Two related compounds, where melting point determinations and reference to previous NMR spectra revealed that transformations had occurred, were excluded from the study. A fresh sample of one of these compounds, 2-benzylidene-2,3-dihydro-3,5-diphenyl-1,3,4-thiadiazole, was prepared; this had mp 122–124°C (lit. (5) mp 121–124°C).

All ^{13}C NMR spectra were run on saturated solutions in $CDCl_3$ at 50.3 MHz on a Bruker AC-200 multinuclear Fourier Transform NMR spectrometer at 27°C, with a spectral win-

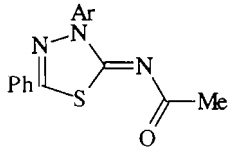
[a]In ppm from TMS; $CDCl_3$ solution. Calculated shifts are in parentheses.

dow of 12 500 Hz and 16 K of data memory, using the J-modulated spin echo sequence, and using the centre peak of the $CDCl_3$ 1:1:1 triplet (77.0 ppm from TMS) as an internal reference. Compound **1b** was also run in $CDCl_3$–DMSO-d_6 (5:1, v/v); this gave upfield shifts of 1.1–1.6 ppm for all signals, resulting in a change in ΔCβCα of only 0.4 ppm from the value in $CDCl_3$. Several of the compounds (**1***c*, **1***f*, **1***h*, **2***a*, **2***b*, **3***b*) fail to display the expected number of CH carbon signals in the aromatic region of the ^{13}C spectrum, and we attribute this to the coincidental superposition of signals.

Carbon-13 chemical shift calculations, using the approach of Pretsch et al. (22), were carried out using the Chemintosh program (Softshell International Ltd., Grand Junction, Colorado, U.S.A.). However, this program as currently set up does not incorporate selenium in its calculations and in fact provides invalid values for selenium-containing compounds.[3]

Results

The pertinent carbon-13 chemical shifts for compounds in the series **1** and **2** are summarized in Table 1, and for those in the series **3**–**5** in Table 2. Calculated chemical shifts (22) are included in parentheses. From Table 1, it is apparent that C-2 and C-5 in the thiadiazole ring have fairly similar chemical shifts. Our assignments are based on the consideration that replacing the acceptor-end olefinic carbon (Cα) by nitrogen as in **6** (Ar = 2,4-dibromophenyl) should have a greater effect on the shift of C-2 than on that of C-5. The spectrum of **6** shows



6

the two signals of interest at 156.3 and 165.0 ppm, thus enabling the assignment of C-5 in the related compound **1***a* as the lower-frequency signal at 154.2 and C-2 as the higher-frequency signal at 158.2 ppm. This is consistent with chemical shift calculations.

Replacing the 2,4-dibromophenyl substituent by phenyl, as in **1***a* and **1***b* and in **2***a* and **2***b*, gives no significant change in chemical shifts of the olefinic carbons. Accordingly, we assign C-2 (Cβ) as the signal to high frequency from C-5 for

[3] E. Pretsch, personal communication.

[a]In ppm from TMS; $CDCl_3$ solution. Calculated shifts are in parentheses.

the remaining compounds in the series **1***b*–**1***k*. This becomes ambiguous only when the difference between the chemical shifts for C-2 and C-5 is small, e.g., for **1***e* and **1***g*, but here the decision is less crucial as its influence on ΔCβCα is minimal. The same considerations apply to our assignments for **2***a* and **2***b* since it is unlikely that the shift positions of C-2 and C-5 would be reversed by substituting a thioacyl for an acyl group. In fact the shift difference between C-2 and C-5 widens slightly in the thioacyl series. Again, these assignments are consistent with the values calculated using the approach of Pretsch et al.

Discussion

Table 1 shows changes in the chemical shifts of the olefinic carbons within the series of thiadiazoles of general formulae **1** and **2**. The shifts for C=O, Cα, and Cβ are virtually the same for **1***a* and **1***b*, but in **1***c* small shifts to lower frequency are noted for both C=O and Cα. Changes in bond length within the C=C—C portion of the push–pull systems are likely to be involved (6), resulting in a change in the resonance description of **1***c*. The similar but more marked effect seen in **1***d* can be ascribed to resonance of the ester group and the resulting decreased ability of this group to lower electron density at Cα.

The entries for **1***e* and **1***f* show the effect of methyl substitution at Cα. Comparing **1***e* with **1***a*, we note a small higher-frequency shift of C=O, a higher-frequency shift for Cα, and a shift to lower frequency for Cβ, leading to a decrease in ΔCβCα of about 11 ppm. Discounting the change in 3-aryl substituent, we compare **1***f* with **1***c* and observe a higher-frequency shift for C=O, higher-frequency shift for Cα, and lower-frequency shift for Cβ resulting in a decrease in ΔCβCα of 13 ppm. For the effects of phenyl substitution at Cα, we compare **1***g* with **1***b*, and **1***h* with **1***c*. For the former, the C=O shift moves slightly to higher frequency, Cα moves to higher frequency, and Cβ to lower frequency, with a decrease in ΔCβCα of approximately 19 ppm; for the latter, the corresponding changes are a higher-frequency shift of C=O, a higher-frequency shift of Cα, and a lower-frequency shift of Cβ, resulting in a decrease in ΔCβCα of approximately 22 ppm. These effects display a trend towards increasing delocalization of the negative charge as one or more phenyl groups are incorporated in the structure, and are most significant for **1***g* and **1***h*. This is related to the ability of phenyl groups to stabilize a negative charge in the anions of phenylacetone and deoxybenzoin. However, competing steric effects can also arise from α substitution. These lead to some angle widening in the push–pull system to accommodate the α substituent, a shortening of the S...O distance, and some variation in C=C bond lengths, all of which will affect the resonance system (6).

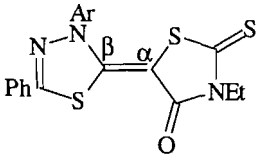
The presence of a nitro group in **1***i* has only a small effect on the corresponding shifts in **1***h* as this group is unable to participate directly in the push–pull system. Thus, the C=O and Cα shifts move slightly to lower frequency and the Cβ shift slightly to higher frequency. A similar effect has been noted elsewhere when comparing 4-nitrobenzoyl with benzoyl as acceptor in other push–pull systems (12, 23), and Kleinpeter and co-workers have correlated Cα and Cβ shift changes to Hammett σ values for nitro and other substituents.

The entries for **1***j* and **1***k* show the effect of further carbonyl substitution at Cα. For **1***j*, we see small higher-frequency shifts for C=O and Cβ and a marked higher-frequency shift for Cα (20.3 ppm) relative to **1***b*, resulting in a drop of approximately 16 ppm in ΔCβCα. This is to be expected given the greater ability of two carbonyl groups to delocalize negative charge (and hence to lower the energy barrier to rotation about the C=C bond: **1***j* shows *one* ^1H signal at δ 2.04 for the six methyl protons at ambient temperature, with evidence of restricted rotation at lower temperatures (6)). Discounting the change in 3-substituent, we next compare **1***k* with **1***d*. Here Cα moves to higher frequency by 10.5 ppm and Cβ moves to higher frequency by only 0.9 ppm, resulting in a decrease in ΔCβCα of 9.6, indicative again of the weaker acceptor ability of carboxylic ester groups than of keto groups; indeed, the effect of the two ester groups is little more in terms of chemical shift than that of one acetyl group, as in **1***a* or **1***b*, as also observed by others (9).

The last two entries in Table 1 show that changing the 3-

aryl substituent from 2,4-dibromophenyl to phenyl does not significantly affect the carbon shifts of interest. The C=S carbon signals appear notably to higher frequency from C=O, as is typical (refs. 13; 20, pp. 233–235; and Table 4.41). The Cα shifts for **2***a* and **2***b* are some 20 ppm to higher frequency of the corresponding shift in **1***c*, while the Cβ shifts are only slightly to higher frequency. This is consistent with other observations (12) that the C=S group is a better electron acceptor than the C=O group and this is thought to be associated with the greater tendency of the thiocarbonyl group to form C—S single bonds, and so assume negative charge despite the lower electronegativity of sulfur relative to oxygen.

One other compound in this series, the thiadiazole **7**, is of interest. In this compound, substitution at Cα is modified by inclusion of the α carbon atom within a rhodanine ring, which features a carbonyl group (acceptor) and sulfur atom (arguably a donor). This compound exhibits signals that we assign as follows: 83.8 ppm (Cα or C-2), 155.3 ppm (Cβ, with C-5 assigned on the same basis as before at 149.9 ppm), and signals at 189.2 and 166.1 ppm, assigned to C=S and C=O, respectively. For this compound, ΔCβCα is 69.5 ppm, indicating appreciable charge separation; this cyclic substitution pattern creates a weak acceptor.

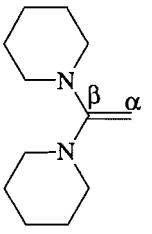


7

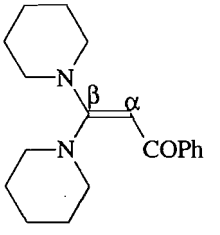
Similar effects are noted in Table 2 for analogous benzothiazole and benzoselenazole derivatives **3**–**5**. Comparisons of **3***a* and **3***c* (which exhibits virtually the same shifts as **3***a*) with **3***b*, and of **4***a* with **4***b*, reveal the same small higher-frequency shift of the carbonyl carbon noted in the thiadiazole series, while very small higher-frequency shifts for Cα and Cβ are noted between corresponding pairs when selenium is substituted for sulfur as donor atom in the ring. These lead to slightly smaller values of ΔCβCα for **4***a* and **4***b* than for **3***a* and **3***b*, perhaps because of modification of the resonance system resulting from the larger size of the selenium atom. Finally, the C=S carbon signal for **5** is significantly to lower frequency of the C=S shifts observed for **2***a* and **2***b* as a result of resonance of the thioamide group, mirroring the differences noted in the series **1***a*–**1***d* above. For all compounds listed in the tables, the olefin carbon shift more sensitive to substituent effects in the push–pull system is Cα, as expected since the donor portion of the molecules is substantially unchanged for the compounds within each table.

It has been observed that cyclization in the donor portion of related push–pull alkenes causes an increase in shift differences between Cα and Cβ as well as an increased barrier to rotation about the C=C bond (12). As an example, the five-membered -SCH_2CH_2S- group was compared with two MeS-groups. Abstracting the relevant chemical shifts from that work (12) for comparison with **1***c* (for which ΔCβCα is 74.5), we find comparable shifts for the -SCH_2CH2S- compound of 108.2 (Cα) and 168.0 (Cβ), with an ΔCβCα of 59.8. The larger shift difference for **1***c* (and for **3***b* and **4***b*) would suggest that the five-membered heterocyclic rings explored in our work are less effective donors than the -SCH_2CH_2S- group, and that the barrier to rotation about the C=C bond would be correspondingly increased.

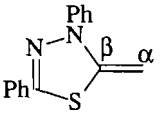
It is of interest to compare the shift differences observed for push–pull alkenes with related compounds lacking the acceptor group. An example is provided by 1,1-dipiperidinoethene, **8** (24), and its 2-benzoyl derivative **9** (23). For the former, the data are Cα 68.2 and Cβ 164.1 (ΔCβCα 95.9), while for the latter the data are Cα 83.8 and Cβ 164.1 (ΔCβCα 84.6), i.e., Cα is the carbon markedly affected by the substitution. Incorporating an acceptor diffuses the charge separation since the negative charge can now be delocalized away from Cα, and the value of ΔCβCα is somewhat decreased.



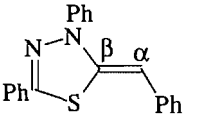
8



9



10



11

The magnitude of the charge separation in the double bond is largely dependent on the donor substituents. The piperidino group is a powerful donor, so **8** and **9** give large ΔCβCα values. The parent methine base **10** (chemical shift data not available due to instability) would have Cα somewhat further to higher frequency. For compound **11**, which contains a phenyl substituent on Cα, the relevant experimental δ values are Cα 90.6, and Cβ 142.8 (ΔCβCα = 52.2). Allowing for the shift to higher frequency associated with this substitution at Cα, estimated δ values for Cα and Cβ of **10** of approximately 75–80 ppm and 150–160 ppm would be of the right order (and are not inconsistent with calculated values: 76.9 and 149.2 ppm). On this basis, the acceptors that most effectively delocalize the negative charge associated with Cα are two acetyls (**1***j*), acyl–phenyl combinations (**1***g*, **1***h*, and **1***i*), and thiobenzoyl (**2***a* and **2***b*), while the least effective are ethoxycarbonyl (**1***d*) and the rhodanine unit (**7**).

The Pretsch–Chemintosh calculation scheme, which is based on additivity rules covering a wide variety of carbon atom types (22), is very convenient but gives at best a semi-quantitative estimate of the olefinic carbon chemical shifts in our compounds. Many calculated values are within 5 ppm but discrepancies can be much greater (Tables 1 and 2). As noted by Pretsch and co-workers themselves, their approach is unable to accommodate the presence of multiple and strongly interacting functional groups with any great accuracy. An obvious example of this in the present work is the calculated chemical shifts of the N-aryl carbons in compounds such as **1***b*

(actual aromatic CH carbon shifts, 125.5–130.7 ppm; calculated values *ortho*, 112.0; *meta*, 129.0, *para*, 118.9). The calculations are based on model compounds in which the nitrogen lone pair is available for delocalization into the benzene ring, whereas in our compounds it is incorporated into the π system of the heterocycle push–pull olefin instead.

The conclusion of Kleinpeter et al. (12), that changes in the parameter ΔCβCα within closely related series of push–pull olefins give a useful qualitative picture of differences in charge separation within the series, is supported by our work. The Pretsch chemical shift calculation scheme is useful but provides no new insights. At the level of accuracy possible with this scheme, no specific "push–pull" term is required. More sophisticated calculations might well require such a term but it would not be large since olefinic carbon shifts and ΔCβCα in push–pull olefins arise primarily as a sum of the individual substituent effects.

Considering that the chemical shift observed in liquids is merely the isotropic average of the three components of the chemical shift tensor, and each component can vary independently with changes in structure (25), it is perhaps surprising that observed chemical shifts agree as well as they do with values from purely empirical calculation schemes. We certainly cannot detect the hoped-for small chemical shift effects arising from nonbonded interactions (6, 7) because of much larger variations due to other factors.

Conclusions

The Pretsch ^{13}C chemical shift calculation scheme, like other correlation schemes, is a useful empirical guide to the assignment of ^{13}C chemical shifts. Despite becoming less accurate in polyfunctional compounds and not taking into account steric effects (22), this scheme predicts the existence of large chemical shift differences between the olefinic carbons of push–pull olefins. The discrepancies between observed and calculated ΔCβCα values are generally less than 15 ppm. Given the inaccuracies inherent in this calculation method, no special term for charge buildup effects in push–pull olefins need be applied.

Methoxy-(2-trimethylsilyl)ethoxycarbene. Reactions with Michael acceptors, with hydroxylic compounds, and with miscellaneous functional groups

David L. Pole, Pradeep K. Sharma, and John Warkentin

Abstract: Methoxy-(2-trimethylsilyl)ethoxycarbene reacts with two equivalents of dimethyl acetylene dicarboxylate, methyl propiolate, phenyl acetylene, or phenyl isocyanate without rearrangement of the carbene group. *N*-Phenylmaleimide captures the carbene with 1:1-stoichiometry. The structure of the product implies that a migration of the trimethylsilylethyl group from oxygen to carbon accompanies that reaction. A mechanism for that complex rearrangement is proposed. Phenol and *tert*-butyl alcohol afford the orthoformates expected from overall insertion of the carbene into the OH bond.

Key words: dialkoxycarbene, insertion into O—H, C—H bonds, rearrangement, *N*-phenylmaleimide, dialkoxyoxadiazoline.

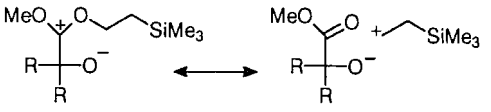
Résumé : Le méthoxy-(2-triméthylsilyl)éthoxycarbène réagit avec deux équivalents d'acétylènecarboxylate de diméthyle, de propiolate de méthyle, de phénylacétylène ou d'isocyanate de phényle sans réarrangement du groupe carbène. Le *N*-phénylmaléimide capture le carbène avec une stoechiométrie 1 : 1. La structure du produit implique qu'une migration du groupe triméthylsilyléthyle de l'oxygène au carbone accompagne cette réaction. On propose un mécanisme pour ce réarrangement complexe. Le phénol et l'alcool *tert*-butylique conduisent aux orthoformates attendus pour une insertion globale du carbène dans la liaison OH.

Mots clés : dialkoxycarbène, insertion dans les liaisons OH et CH, réarrangement, *N*-phénylmaléimide, dialkoxyoxadiazoline.

[Traduit par la rédaction]

Introduction

The ready availability of 2,2-dialkoxy oxadiazolines (1), particularly from a precursor such as 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**) (2) by means of substitution reactions with hydroxylic nucleophiles, prompted us to synthesize (3) 2-methoxy-5,5-dimethyl-2-(2-trimethylsilyl)ethoxy-Δ^3-1,3,4-oxadiazoline (**2**), Scheme 1. Analogous oxadiazolines undergo thermolytic fragmentation to N_2, acetone, and a dialkoxycarbene (2), which, in the case of **2**, would be methoxy(2-trimethylsilyl)ethoxycarbene (**3**, Scheme 1). Dialkoxycarbenes have nucleophilic properties (4) that are the result of conjugative delocalization in the singlet ground state. In the case of **3**, it seemed likely that the β-trimethylsilylethyl group would confer unusual properties onto the carbene itself, and particularly onto adducts of the carbene, if significant charge were to reside on the trimethylsilyl group, as illustrated with the "no bond" contributor **4***b* in terms of a dipolar adduct with a carbonyl compound.



4a **4b**

We now report that the chemistry of **3** includes an unusual feature that appears to reflect the β-effect (5) of the trimethylsilyl group in a ketene acetal intermediate.

Methods, results, and discussion

2-Methoxy-5,5-dimethyl-2-(2-trimethylsilyl)ethoxy-Δ^3-1,3,4-oxadiazoline (**2**) was prepared readily from crude 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**) (2) by treating it with 2-(trimethylsilyl)ethanol in dichloromethane containing catalytic *p*-toluenesulfonic acid (3).

Thermolysis of **2** in dry benzene at 110°C was complete in 24 h. Carbene trapping reactions were carried out in sealed glass ampoules containing 0.20–0.35 g of **2** (ca. 0.08 M) and excess substrate in dry benzene. The products were separated from excess substrate and (usually) from one another by chromatography. Structures were established by ^{1}H and ^{13}C NMR spectroscopy, infrared spectroscopy, and mass spectrometry, including high-resolution MS.

Thermolysis of **2** in the presence of dimethyl acetylenedicarboxylate (DMAD) afforded the 2:1 adduct **6** as a mixture of diastereomers that could not be separated (Scheme 2). The structure was established from the infrared spectrum as well as

the ^1H and ^{13}C NMR spectra, with reference to the analogous 2:1 adduct from reaction of DMAD with dimethoxycarbene (*6b*). The diastereomer ratio, estimated by averaging the heights of the larger and smaller methoxy signals in the ^1H NMR spectrum, was 1.4. An exact mass determination on the most intense fragment signal ($M^+ - CO_2Me$) was performed, the molecular ion signal being undetectable. Chemical ionization MS, with NH_3, afforded both $M^+ + H$ and $M^+ + NH_4$ signals.

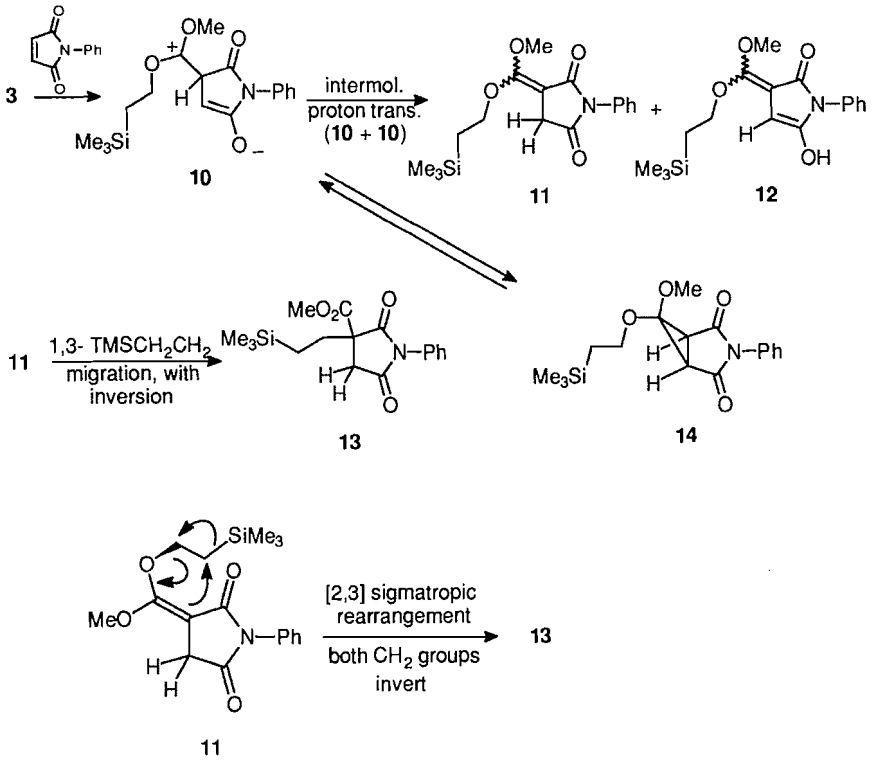
Formation of **6** presumably involves the cycloaddition of 1:1 adduct **5** to a carbonyl double bond of DMAD (6). Adduct **5**, which can also be written as a singlet vinylogous dialkoxycarbene, is presumably equilibrated with the corresponding cyclopropene (7), Scheme 2.

Thermolysis of **2** in the presence of methyl propiolate afforded the ketal of an enynone (*9a*). The E-geometry at the double bond followed from the coupling constant between the vinylic protons (15.7 Hz) and the rest of the structure could be assigned with confidence on the basis of the NMR, IR, and MS evidence. Product *9a* can be accommodated with a mechanism similar to that in Scheme 2, except for a proton transfer step, Scheme 3. Proton transfer from an alkyne to a nucleophilic site, as in **7**, is known (*6b*, 8). Apparently the intermediate dipolar adduct (**7**), which can also be expressed as a vinylcarbene, is more basic than carbene **3** and is protonated by the terminal alkyne to afford a short-lived ion pair (**8**) that collapses to **9**.

Phenyl acetylene reacted with carbene **3** to afford *9b*, a product similar to *9a*. Again, a large coupling constant (16 Hz) between vinylic protons indicated the *E*-geometry at the double bond.

Attack of carbene **3** on *N*-phenylmaleimide involved migration, at some stage, of the trimethylsilylethyl group. This result was immediately evident, for the characteristic signal from OCH_2 of the $OCH_2CH_2SiMe_3$ group was absent in the ^1H NMR spectrum of the product. That product was eventually identified as **13** on the strength of ^1H and ^{13}C NMR spectroscopy, which showed, unambiguously, a CH_2CO group

Scheme 4.



with a large J_{gem} but no other proton couplings. With the vinyl signals of *N*-phenylmaleimide no longer present, it was clear that the CC double bond was the site of attack, rather than carbonyl carbon, as in the case of attack of dimethoxycarbene on anhydrides (9). Analogy to attack at C(sp^2) sites that are electron poor (3, 4*j*, 6*b*) suggests that the first step is formation of a dipolar intermediate **10**, which then undergoes rearrangement to **13**. The mechanism of that rearrangement probably involves intermolecular proton transfer, between two units of **10** to form **11** and (or) its "enol", **12** (Scheme 4). There are many examples of similar intermolecular atom (or group) transfers in the literature (10, 11). While rearrangement of **11** to **13** could also be intermolecular, it is allowed to be a concerted, suprafacial reaction provided that the migrating methylene carbon is inverted in the process (12), Scheme 4. However, the geometry required is hard to attain, and the mechanism does not assign any special function to the TMS group.

There is another mechanistic option, in which the Me_3Si group migrates from one CH_2 group of the ethyl fragment to the other, in concert with migration of the $TMSCH_2CH_2$ moiety from oxygen to carbon. This [2, 3] sigmatropic rearrangement (12, 13), which is also illustrated in Scheme 4, requires inversion of both methylenes of the trimethylsilylethyl group. There is some precedent in the literature for such a complex rearrangement (13*c*) but whether or not it operates in the present case will not be known until one of the CH_2 groups of $TMSCH_2CH_2$ is labelled. Such exchange of labelled methylene groups is known from, for instance, the solvolysis of (2-bromoalkyl)silanes (14). In Scheme 4 it is also assumed that a dipolar intermediate such as **10** is equilibrated with cyclopropanone ketal (**14**) at 110°C.
