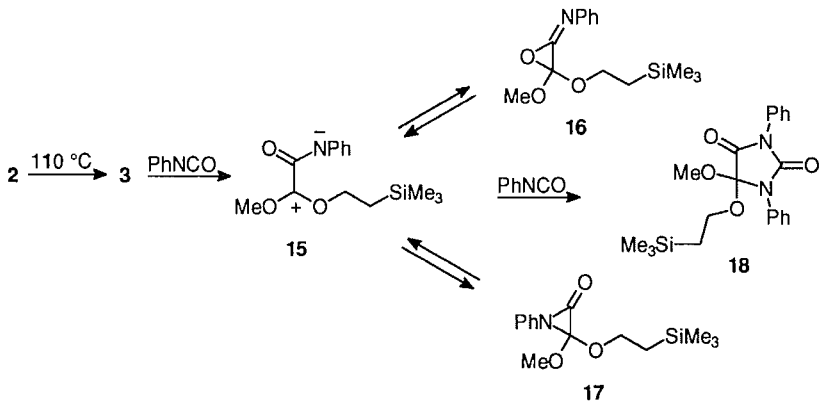
Phenyl isocyanate captured carbene **3** with 2:1 stoichiometry to afford hydantoin **18**, Scheme 5. It was readily identified with reference to the spectra of the dimethoxy analogue (from dimethoxycarbene) that had been reported by Hoffmann's group (6*c*). For example, the infrared spectrum showed carbonyl absorption (1825 and 1750 cm^{-1}) consistent with the hydantoin ring system and the ^{13}C NMR spectrum showed carbonyl carbons in the expected range of chemical shifts. A molecular ion signal could not be found in the MS, a feature also consistent with the structure that, as the "ketal" of an amide, would be expected to lose an alkoxy group. Formation of **18** is rationalized in terms of Hoffmann's mechanism for formation of the corresponding dimethoxyhydantoin from reaction of dimethoxycarbene with phenyl isocyanate, Scheme 5. Whether or not the dipolar intermediate **15** is equilibrated with the corresponding iminooxirane (**16**) and α-lactam (**17**), Scheme 5, is not known.

As expected, carbene **3** was intercepted with phenol and with *tert*-butyl alcohol by overall OH insertion, Scheme 6. The orthoformates so formed were sensitive to hydrolysis and their purification by chromatography failed. Orthoformate **19**, from phenol, was assigned on the basis of ^1H NMR spectroscopy alone while orthoformate **20**, from *tert*-butyl alcohol, was assigned on the basis of ^1H and ^{13}C NMR spectra.

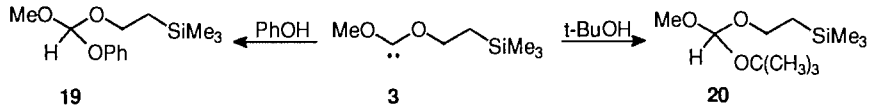
In summary, thermolysis of oxadiazoline **2** affords carbene **3**. The latter acts as a nucleophile toward α,β-unsaturated carbonyl compounds but it also reacts with phenyl acetylene. During reaction of **3** with *N*-phenylmaleimide, the trimethylsilylethyl group is transferred from oxygen to carbon in a novel [2, 3] type of rearrangement of a ketene acetal. Whether or not the trimethylsilylethyl group will migrate during other reactions of **3** is under investigation.

Evidence for operation of the β-effect of the TMS group on

Scheme 5.



Scheme 6.



the properties of carbene **3** or on the properties of dipolar intermediates (**5**, **7**, **10**, **15**) was not obtained from studies of the final products but the operation of such an effect on the rate constants and equilibrium constants (e.g., **10** ⇄ **14**) is not excluded.

Experimental

^{1}H NMR and ^{13}C NMR spectra were obtained with solutions in $CDCl_3$ containing TMS. The former were run at 200 MHz and the latter at 50 MHz unless otherwise specified. Infrared spectra of oils were obtained from thin films of neat materials while those of solids were obtained by the KBr pellet method.

2-Methoxy-5,5-dimethyl-2-(2-trimethylsilyl)ethoxy-Δ^3-1,3,4-oxadiazoline (2)

To a solution of crude **1** (7.5 g, 39.9 mmol, 68% pure, containing 1-(1-acetoxy-1-methyl)ethyl-2-methoxycarbonyldiazene (1) in dry CH_2Cl_2 (75 mL) under argon was added 2-(trimethylsilyl)ethanol (3.21 g, 27.1 mmol). Molecular sieves (2 g, 4 Å) and *p*-toluenesulfonic acid (0.516 g, 2.71 mmol) were added and the resulting mixture was stirred for 15 h. After filtration and concentration in vacuo, a viscous yellow oil was obtained. Column chromatography (silica gel, ether:hexane, 1:6) afforded **2** as a colourless oil, 3.2 g, 48%; R_f 0.38 (ether:hexane, 1:6); IR (cm^{-1}): 2989–2840, 1577 (N=N); ^{1}H NMR, δ: 0.27 (s, 9H), 0.97 (t, J = 8.3 Hz, 2H), 1.48 (s, 6H), 3.40 (s, 3H), 3.67–3.86 (m, 2H, diasterotopic OCH_2); ^{13}C NMR, δ: −1.48, 18.10, 24.03, 51.76, 62.48, 118.65, 137.10; MS (EI) *m/z*: 231 ($M^+ - CH_3$, 2), 129 ($M^+ - OCH_2CH_2SiMe_3$, 13), 84 (33), 73 (100); MS (EI, HR): 231.1159; calcd. for $C_{10}H_{22}N_2O_3Si - CH_3$: 231.1165; MS (CI, NH_3) *m/z*: 231 ($M^+ - CH_3$, 2), 194 (8), 166 (14), 149 (16), 106 (5), 90 (100), 60 (8).

Dihydrofuran diastereomers 6

A solution of **2** (0.35 g, 1.42 mmol) and DMAD (0.41 g, 2.89 mmol) in dry benzene (35 mL) was heated at 110°C in a sealed tube for 24 h. Removal of the solvent and chromatography of the residue (Chromatotron, 2 mm plate, 5% EtOAc in hexane) afforded **6** (0.39 g, 62%) as a pale yellow oil. R_f 0.11 (10% EtOAc in hexane); IR (cm^{-1}): 3006–2844, 2110 (C≡C), 1733 (C=O); ^{1}H NMR (major diasteromer) δ: 0.04 (s), 0.8–1.0 (m, overlap with signal from minor isomer), 3.40 (s, 3H), 3.56 (s, 3H), 3.62–3.75 (m), 3.76 (s, 3H), 3.82 (s) and 3.84 (s) overlapping with signals from minor isomer; ^{1}H NMR (minor diastereomer) δ: 0.04 (s), 0.8–1.0 (m), 3.39 (s, 3H), 3.55 (s, 3H), 3.62–3.75 (m), 3.78 (s, 3H), 3.82 (s), 3.84 (s), diastereomer ratio 1.4:1.0, from the three sets of distinct methoxy singlets; ^{13}C NMR (δ): −1.56, 17.71, 17.86, 17.87, 51.50, 51.76, 52.88, 52.99, 62.18, 62.37, 77.44, 78.66, 99.66, 99.71, 123.03, 123.12, 135.18, 140.98, 152.56, 152.57, 153.64, 159.79, 161.66; MS(EI) *m/z*: 413 ($M^+ - OCH_3$, 12), 385 ($M^+ - CO_2Me$, 100), 372 (10), 327 ($M^+ - OCH_2CH_2SiMe_3$, 13), 281 (15), 253 (8), 157 (46), 111 (12), 89 (22), 73 (98), 59 (40); MS (CI, NH_3) *m/z*: 462 ($M^+ + NH_4$, 48), 445 ($M^+ + H$, 63), 413 ($M^+ - OCH_3$, 16), 385 ($M^+ - CO_2Me$, 100).

Ketal 9*a*

A solution of **2** (0.25 g, 1.02 mmol) and methyl propiolate (0.175 g, 2.08 mmol) in dry benzene (10 mL) was heated in a sealed tube at 110°C for 20 h. The oil that remained after removal of the solvent was chromatographed (Chromatotron, 2 mm SiO_2 plate, 10% EtOAc in hexane) to afford 0.21 g (62%) of **9*a*** as a colourless oil. R_f 0.28 (10% EtOAc in hexane); IR (cm^{-1}): 3001–2838, 2238 (C≡C), 1727 (C=O), 1436; ^{1}H NMR (δ): 0.02 (s, 9H), 0.92 (m, 2H), 3.92 (s, 3H), 3.57 – 3.63 (m, 2H, diastereotopic OCH_2), 3.73 (s, 3H), 3.75 (s, 3H), 6.28 (d, J = 15.7 Hz, 1H), 6.74 (d, J = 15.7 Hz, 1H); ^{13}C NMR (δ): −1.45, 17.99, 49.73, 50.85, 51.86, 61.44, 77.12, 80.93, 95.08, 124.81, 142.73, 152.97, 165.85; MS (EI) *m/z*: 269 ($M^+ - CO_2Me$, 11), 217 (9), 211 ($M^+ - OCH_2CH_2SiMe_3$, 100), 183 (9), 151 (9), 113 (10), 89 (15), 73 (72), 59 (12);

MS (EI, HR) *m/z*: 211.0582; calcd. for $C_{10}H_{11}O_5$ (M^+ – $OCH_2CH_2SiMe_3$): 211.0606.

Ketal 9*b*

A procedure like the one described above, with phenylacetylene instead of methylpropiolate and involving elution of a radial chromatography plate with 2% EtOAc in hexane, afforded **9***b* as a colourless oil. R_f 0.53 (10% EtOAc in hexane); IR (cm^{-1}): 3010 – 2835, 2104 (C≡C), 986; ^1H NMR (δ): 0.02 (s, 9H), 0.90–1.10 (m, 2H), 3.39 (s, 3H), 3.80–3.95 (m, 2H), 6.30 (d, J = 16 Hz, 1H), 7.04 (d, J = 16 Hz, 1H), 7.30–7.65 (m, 10H); ^{13}C NMR (δ): −1.60, 17.48, 54.43, 60.73, 85.77, 97.54, 120.97, 127.85, 128.15, 128.24, 128.55, 128.63, 128.74, 129.03, 131.88, 132.92, one expected signal not seen; MS (EI) *m/z*: 349 (M^+ – CH_3, 15), 247 (M^+ – $OCH_2CH_2SiMe_3$, 100), 215 (12), 187 (16), 160 (21), 73 (72); MS (HR) *m/z*: 247.1131; calcd. for $C_{18}H_{15}O$ (M^+ – $OCH_2CH_2SiMe_3$): 247.1123.

Thermolysis of 2 in presence of *N*-phenylmaleimide

A solution of **2** (0.300 g, 1.22 mmol) and *N*-phenylmaleimide (0.234 g, 1.35 mmol) in dry benzene (5 mL) was heated at 110°C in a sealed tube for 24 h. Removal of the solvent and chromatography of the residue (Chromatotron, 1 mm plate, 5% EtOAc in hexane) gave **13** (0.28 g, 69%) as a white solid, mp 127–128°C, from EtOAc–hexane. R_f 0.28 (15% EtOAc in hexane); IR (cm^{-1}): 2955–2840, 1717 (C=O), 1688 (C=O); ^1H NMR (δ): 0.02 (s, 9H), 0.32–0.51 (m, 2H), 2.08 (t, J = 8.5 Hz, 2H), 2.78 (d, J = 18.4 Hz, 1H), 3.32 (d, J = 18.4 Hz, 1H) 3.81 (s, 3H), 7.20–7.55 (m, 5H); ^{13}C NMR (gated, 75 MHz) δ: −1.97 (q, ^1J = 119 Hz, $(CH_3)_3Si$), 10.54 (t, ^1J = 118 Hz, $SiCH_2$), 28.91 (t, ^1J = 132 Hz, CH_2), 37.40 (t, ^1J = 135 Hz, CH_2), 53.38 (q, ^1J = 148 Hz, OCH_3), 56.52 (s, quat), 126.37 (m), 128.82 (m), 131.73 (m), 129.17 (m), 170.09 (t, ^2J = −6.5 Hz ($CH_2\underline{C}O$), 174.15 (s), 174.61 (s); MS (EI) *m/z*: 318 (M^+ – CH_3, 100), 305 (M^+ – CO, 65), 290 (90), 274 (M^+ – CO_2Me, 26), 246 (35), 233 (M^+ – $Me_3SiCHCH_2$, 24), 201 (26), 171 (12), 119 (15), 89 (31), 84 (40), 73 (77); MS (EI, HR) *m/z*: 318.1152; calcd. for $C_{15}H_{20}NO_4Si$ (M^+ – CH_3): 318.1161; MS (CI, NH_3) *m/z*: 351 ($M^+ + NH_4$, 100), 334 (M^+ + H, 100), 318 (M^+ – CH_3, 43), 305 (26), 290 (18)).

Hydantoin 15

A solution of **2** (0.410 g, 1.67 mmol) and phenyl isocyanate (0.460 g, 3.84 mmol) in dry benzene (6 mL) was kept at 110°C for 24 h. Removal of the solvent and chromatography on SiO_2 (Chromatotron, 1 mm plate, 2% EtOAc in hexane) afforded **18** (0.51 g, 77%) as a colourless oil. R_f 0.43 (15% EtOAc in hexane); IR (cm^{-1}): 3030–2840, 1825 (C=O), 1750 (C=O); ^1H NMR (δ): 0.03 (s, 9H), 0.91–0.96 (m, 2H), 3.56 (s, 3H), 3.85–3.90 (m, 2H), 7.20–7.64 (m, 10H); ^{13}C NMR (δ): −1.51, 17.91, 52.32, 62.98, 103.66, 125.20, 126.14, 127.08, 128.50, 128.98, 129.12, 130.66, 133.38, 152.28, 165.66; MS (EI) *m/z*: 339 (15), 281 (M^+ – $OCH_2CH_2SiMe_3$ – OCH_2, 100), 223 (33), 192 (34), 73 (72); MS (HR) *m/z*: 281.0931; calcd. for $C_{16}H_{13}N_2O_3$ (M^+ – $OCH_2CH_2SiMe_3$): 281.0926.

Orthoformate 19

A solution of **2** (0.20 g, 0.81 mmol) and phenol (0.096 g, 1.0 mmol) in dry benzene (10 mL) was kept at 110°C for 24 h. Extraction of excess phenol with cold dilute base, drying of the benzene layer, and removal of the benzene left 0.12 g, ca. 58%, of crude **19** as an oil. R_f 0.50 (10% EtOAc in hexane); ^1H NMR (δ): 0.03 (s, 9H), 0.95 – 0.99 (m, 2H), 3.43 (s, 3H), 3.73 – 3.80 (m, 2H), 5.12 (s, 1H), 7.18–7.32 (m, 5H).

Orthoformate 20

A solution of **2** (0.25 g, 1.02 mmol) and *tert*-butyl alcohol (0.12 g, 1.62 mmol) in dry benzene (10 mL) was kept at 110°C for 20 h. Concentration of the solution in vacuo afforded 0.17 g (83%) of **20** as a colourless oil. R_f 0.62 (10% EtOAc in hexane); IR (cm^{-1}): 2972–2836, 1250, 1093, 1055, 860; ^1H NMR (δ): 0.03 (s, 9H), 0.85–0.95 (m, 2H), 1.23 (s, 9H), 3.23 (s, 3H), 3.52–3.57 (m, 2H), 5.24 (s, 1H); ^{13}C NMR (δ): −1.50, 17.92, 28.67, 49.73, 60.47, 109.12, one expected signal not seen.

Acknowledgements

Financial support for this work was drawn from a Natural Sciences and Engineering Research Council of Canada (NSERC) Operating Grant. The authors gratefully acknowledge the assistance of Drs. Donald Hughes and Richard Smith and of Mssrs. Brian Sayer and Fajar Ramelan with some aspects of the NMR spectroscopy and the mass spectrometry.

New investigation of the reaction of 2-amino-2-oxazolines with isocyanates and isothiocyanates. Evidence of a transposition during the second step

Jean-Jacques Bosc, Christian Jarry, Jamal Ouhabi, Michel Laguerre, and Alain Carpy

Abstract: The reaction of some 2-amino-2-oxazolines with isocyanates and arylisothiocyanates yields 3-monosubstituted or 2,3-disubstituted 2-iminooxazolidines depending on the experimental conditions and on the nature of the electrophile reactants. The structures of a mono- and a disubstituted derivative were established by X-ray analysis. The chemical behaviour of the compounds was investigated by molecular and quantum mechanics calculations. An intramolecular transposition during the second step of the reaction was found.

Key words: 2-amino-2-oxazolines, iso(thio)cyanates, transposition, X-ray structure, MOPAC calculations.

Résumé : Par réaction de diverses 2-amino-2-oxazolines avec des isocyanates et des arylisothiocyanates ont été préparées des 2-iminooxazolidines monosubstituées en position 2 et disubstituées en positions 2,3. L'accès à ces composés dépend des conditions expérimentales et de la nature des réactifs électrophiles. Les attributions structurales reposent en particulier sur l'établissement de deux structures cristallines par radiocristallographie. Une étude conformationnelle est rapportée, elle utilise les résultats des calculs énergétiques réalisés en particulier par mécanique quantique. Une transposition intramoléculaire a été mise en évidence lors de la réaction du propylisocyanate sur une 3-phénylcarbamoyl-2-iminooxazolidine.

Mots clés : 2-amino-2-oxazolines, iso(thio)cyanates, transposition, réarrangement, structure cristallines, calculs OM.

Introduction

Alkylation and acylation reactions of ambident nucleophiles with similar sites often result in problems of uncertain regiochemistry. Investigating in detail the reaction of 2-amino-2-thiazoline with phenylisothiocyanate and phenylisocyanate Rasmussen et al. concluded that the addition at low temperature occurred on the endocyclic nitrogen (1). The elucidation of the structure was based on the X-ray structural analysis of one reaction product (2). The resulting 2-imino-*N*-phenylthiazolidinecarboxamide was significantly more stable than the 2-imino-*N*-phenylthiazolidinecarbothioxamide, but nevertheless both compounds underwent an intramolecular N–N′ rearrangement to form thermodynamically stable ureas. The reaction of 2-arylamino-2-thiazolines with phenylisothiocyanate and phenylisocyanate and the structural assignment of the condensation products were recently reported (3).

The reaction of 2-amino-2-oxazolines with iso(thio)cyanates has been less studied. It was first reported by Fromm et al. (4), later by Yamamoto and Reiko (5), and was used to prepare anticonvulsant ureas (6) and anhydronucleosides (7). All results concerned the introduction of a carbamoyl or a thiocarbamoyl substituent on the heterocyclic ring. The structural results agreed with the regioselectivity observed with 2-amino-2-thiazolines: the initial reaction occurred exclusively at the endocyclic sp^2 nitrogen to produce the corresponding 3-carbamoyl- or, 3-thiocarbamoyl-2-iminooxazolidines and these compounds rearranged, on heating, to the corresponding urea isomers.

In the course of our work on 2-amino-2-oxazolines we have investigated the different reactivity of the two nitrogen atoms as nucleophilic centers (8–10). In the present work we report the synthesis of 2,3-diphenylcarbamoyl- and 2,3-dipropylcarbamoyl-2-iminooxazolidines in two ways: (*i*) a one-step reaction of 5-substituted-2-amino-2-oxazolines with two equivalents of isocyanates; (*ii*) a two-step reaction involving the isolation of the mono-substituted intermediates.

Few 2,3-disubstituted-2-iminooxazolidines have been described (11,12). They were synthesized in a one-pot reaction and the corresponding 3-monosubstituted-2-iminooxazolidines were not isolated. We took advantage of our ability to isolate these 3-monosubstituted-2-iminooxazolidines to introduce a different substituent on the *exo* nitrogen atom, which

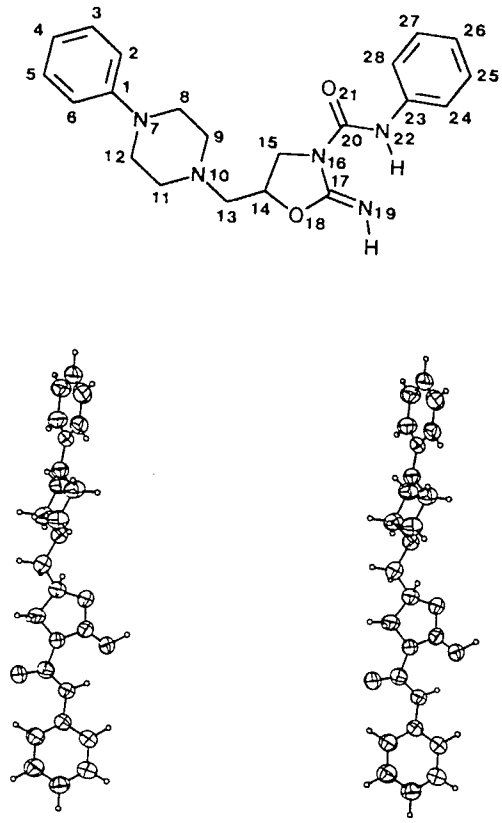
permitted us to observe a transposition occurring during the second attack. The assignment of the structures was supported by an X-ray study. The relative stability of the 3-monosubstituted-2-iminooxazolidines vs. their urea isomers was estimated using molecular and quantum mechanics.

Results and discussion

5-Substituted-2-amino-2-oxazolines **1** were allowed to react with an equimolar quantity of aryl- or (iso)propylisocyanates at 0°C in ethanol (Scheme 1). The reaction products were the 5-substituted-3-arylcarbamoyl-2-iminooxazolidines **2**(*a–d*) or the 5-substituted-3-(iso)propylcarbamoyl-2-iminooxazolidines **2**(*e*,*f*). 5-[(1-Phenyl-4-piperazinyl)methyl]-3-arylthiocarbamoyl-2-iminooxazolidines **2**(*g*, *h*) were obtained in the same way from arylisothiocyanates. We noticed that the nature of the C-5 substituent of 2-amino-2-oxazolines had no influence on the advancement of the reaction. In particular we tried to avoid the conversion of 2-iminooxazolidines **2** into ureas by an intramolecular N–N′ rearrangement. As already described, this rearrangement is essentially quantitative after heating (1, 4). We observed that the use of ethanol as a solvent, the choice of anhydrous conditions, and the rigorous control of the temperature increased the yields in compounds **2**. All compounds except **2***e* and **2***f* were insoluble in ethanol, and a rapid separation from the reaction mixture minimized the isomerization.

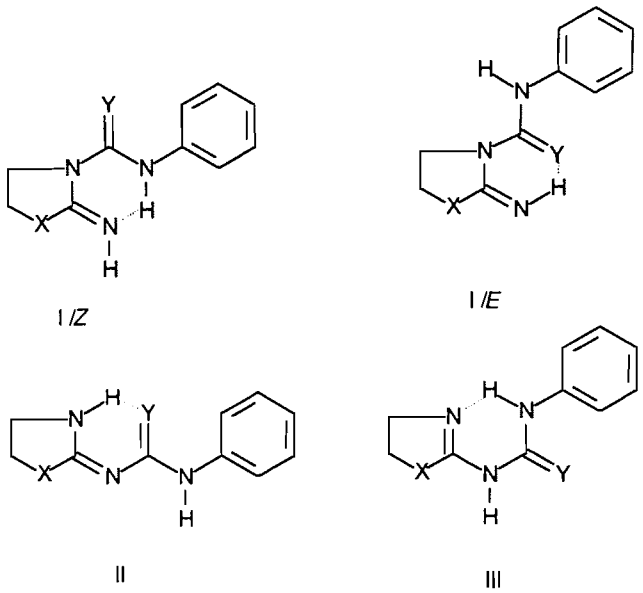
The structure of **2***a* was established by X-ray crystallography (Fig. 1). The exocyclic C(17)—N(19) bond is 1.251(5) Å. An electron delocalization occurs on bonds N(16)—C(17) = 1.391(5) Å and C(17)—O(18) = 1.344(5) Å (C(15)—N(16) = 1.449(5) Å and C(14)—O(18) = 1.344(5) Å). The five-membered heterocycle is almost planar, C(14) and C(15) being, respectively, a distance of −0.083(4) and 0.013(4) Å from the mean plane defined by N(16), C(17), O(18), and N(19). The *N*-phenylcarbamoyl moiety is coplanar with the heterocycle (C(15)-N(16)-C(20)-O(21) = 1.7(3)°, N(16)-C(20)-N(22)-C(23) = 176.0(3)°, C(20)-N(22)-C(23)-C(24) = 2.0(4)°).

Fig. 1. Stereoscopic view of molecule **2***a* and numbering of atoms.



The oxygen atom of the amide group O(21) points away from N(19). The amide group is *trans*. There are two short dis-

Scheme 2. 2/3-Monosubstituted phenylcarbamoyl compounds, H-bonds indicated by dotted lines.



tances N(19)...N(22) = 2.700(4) Å and N(19)...H(122) = 1.900(4) Å with an angle N(19)...H(122)-N(22) = 138(3)° characteristic of an intramolecular H-bond. Consequently there is a pseudo six-membered cycle N(19), C(17), N(16), C(20), N(22), H(122).

The piperazine ring is *chair* with N(7) and N(10) −0.619(3) and 0.685(3) Å away from the mean plane defined by C(8), C(9), C(11), and C(12). The orientation of the phenyl ring vs. the piperazine ring is defined by the torsion angle C(2)-C(1)-N(7)-C(8) = 27.8(3)°. The orientation of the oxazolidine ring vs. the piperazine ring is defined by the two torsion angles C(9)-N(10)-C(13)-C(14) = 173.7(3)° and N(10)-C(13)-C(14)-C(15) = 172.5(3)°.

The C(1)—N(7) bond is 1.406(5) Å. The bond angles around N(7) are 118.6(3)°, 118.6(3)°, and 111.4(3)°. N(10) is hybridized sp^3 with its lone pair *axial*.

To gain information about the relative stability of the 3-monosubstituted-2-iminooxazolidines vs. their urea isomers we performed energy calculations using molecular and quantum mechanics .

The compounds were built and roughly minimized using the MM2* force field implemented in MacroModel and, as the parameters are of poor quality for conjugated systems, the compounds were fully minimized using MOPAC/AM1.

Compounds **I** (X = O) can exist as *Z* or *E* isomers, but only the *Z* isomers were found by X-ray crystallography (Scheme 2). Accordingly, at least for oxazolidines, the *E* isomers appeared less stable than their *Z* counterparts (Table 1). On the other hand, concerning the intramolecular N–N′ rearrangement of **I** into the corresponding ureas **II** / **III**, it appears in all cases that form **I** is the least stable isomer and, except when X = S and Y = O, that form **III** is the most stable one. When X, Y = O, the two tautomeric forms have almost the same energy. This could explain the equilibrium between **II** and **III** evidenced by the X-ray structure.

Table 1. Energy (kJ mol^{-1}) after minimization with MOPAC/MNDO.

Series	X = S Y = S	X = S Y = O	X = O Y = S	X = O Y = O
I / *Z*	375.28	130.50	216.44	−26.29
I / *E*	379.54	125.52	241.85	−9.41
II	345.77	93.46	214.77	−38.58
III	340.08	101.62	199.30	−39.29

When Y = S, the S...H—N_{endo} hydrogen bond in form **II** is avoided from the final minimized structure.

The second part of the work concerns the behaviour of the 5-substituted-3-phenylcarbamoyl- **2**(*a–c*), the 5-[(1-phenyl-4-piperazinyl)methyl]-3-propyl- **2***e*, and the 5-[(1-phenyl-4-piperazinyl)methyl]-3-phenylthiocarbamoyl-2-iminooxazolidine **2***g* towards isocyanates and phenylisothiocyanate (Scheme 1).

The reaction of **2**(*a–c*) with phenylisocyanate and the reaction of **2***e* with propylisocyanate led to the 2,3-diphenylcarbamoyl-2-iminooxazolidines **3**(*a–c*) and to the 2,3-dipropylcarbamoyl-2-iminooxazolidine **3***e*.

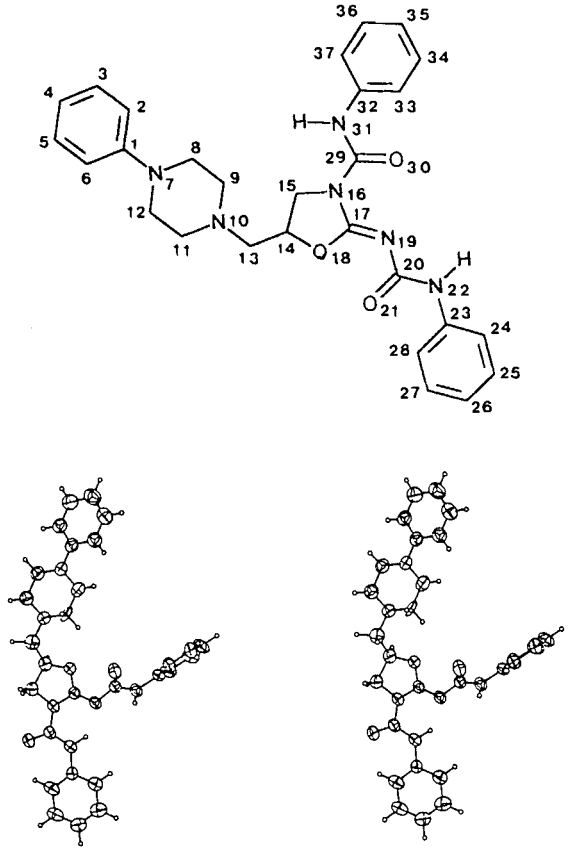
The structure of **3***a* was established by X-ray crystallography (Fig. 2). The exocyclic C(17)—N(19) bond is 1,272(3) Å. As in **2***a*, an electron delocalization occurs on bonds N(16)—C(17) = 1.368(3) Å and C(17)—O(18) = 1.333(3) Å (C(15)—N(16) = 1.463(4) Å and C(14)—O(18) = 1.476(4) Å). Contrary to **2***a*, the five-membered heterocycle is not perfectly planar, C(14) and C(15) being, respectively, a distance of −0.256(4) and 0.100(4) Å from the mean plane defined by N(16), C(17), O(18), and N(19). The phenylcarbamoyl moiety at N(16) is in the same plane as these four atoms (C(15)-N(16)-C(29)-O(30) = 0(1)°, N(16)-C(29)-N(31)-C(23) = −172(1)°, and C(29)-N(31)-C(32)-C(33) = −170(1)°). The terminal phenyl ring makes an angle of 161(1)° with this plane. Consequently the electron delocalization observed in the oxazolidine ring expands in the lateral chain up to nitrogen N(31).

The oxygen atom of the amide group O(30) points opposite to N(19). The amide group including C(29) and N(31) is *trans*. There are two short distances N(19)...N(31) = 2.712(4) Å and N(19)...H(131) = 1.91(4) Å with an angle N(19)...H(131)-N(31) = 137(4)° characteristic of an intramolecular H-bond. Consequently, as in **2***a*, there is a pseudo six-membered cycle N(19), C(17), N(16), C(29), N(31), H(131).

The configuration at the imine bond is *Z*. The orientation of the second phenylcarbamoyl moiety at N(19) is defined by the four torsion angles O(18)-C(17)-N(19)-C(20) = −20(1)°, C(17)-N(19)-C(20)-O(21) = −58(1)°, N(19)-C(20)-N(22)-C(23) = −172(1)°, and C(20)-N(22)-C(23)-C(24) = −40(1)°. The mean-plane of atoms N(19), C(20), O(21), and N(22) makes an angle of 122(1)° with that of the heterocycle and an angle of 34(1)° with the terminal phenyl ring.

The piperazine ring is *chair* with N(7) and N(10) −0.543(5) and 0.695(5) Å away from the mean plane defined by C(8), C(9), C(11), and C(12). The orientation of the phenyl ring vs. the piperazine ring is defined by the torsion angle C(2)-C(1)-N(7)-C(8) = −2(1)°. The orientation of the oxazolidine ring

Fig. 2. Stereoscopic view of molecule **3***a* and numbering of atoms.



vs. the piperazine ring is defined by the two torsion angles C(9)-N(10)-C(13)-C(14) = 78(1)° and N(10)-C(13)-C(14)-C(15) = 172(1)°. The C(1)—N(7) bond is 1.403(4) Å. The bond angles around N(7) are 115.4(3), 118.3(3), and 113.1(3)°. N(10) is in an intermediate hybridization state between sp^2 and sp^3 with its lone pair *axial*.

Both reactions of **2***a* with propylisocyanate and of **2***e* with phenylisocyanate led to the same 2,3-disubstituted compound **3***i* and showed a transposition during the second attack in one of the reactions of **2**. As suitable crystals could not be obtained, the structural assessment of **3***i* was based on the ^{1}H NMR spectra of the reaction products. For the monosubstituted compounds the ^{1}H δ of the NH-CO groups were the following (Schemes 2 and 3):

formula **I** and a phenyl substituent, δ = 11.6 ± 0.1 ppm (singlet)

formula **I** and a propyl substituent, δ = 9.1 ppm (singlet)

formula **II** and an aryl substituent, δ = 9.3 ppm (triplet, ^3J = 5.4 Hz) (9).

For the symmetrically disubstituted compounds, the ^{1}H δ were as follows:

phenyl substituents, δ NH endo = 10.7 ppm and δ NH *exo* = 7.5 ± 0.1 ppm (all singlets)

Scheme 3. 2,3-Disubstituted-2-iminooxazolidines, H-bonds indicated by dotted lines.

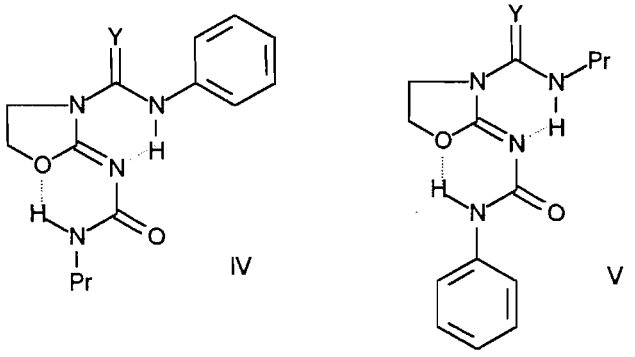


Table 2. Energy (kJ mol^{-1}) after minimization with MOPAC/MNDO and MOPAC/AM1.

Structure	MOPAC/MNDO	MOPAC/AM1
IV	−307.15	−176.60
V	−318.93	−180.00

propyl substituents, δ NH *endo* = 8.5 ppm and δ NH *exo* = 5.1 ppm (all triplets, ^3J = 5.5 and 6.0 Hz).

For the unsymmetrically disubstituted compound **3***i*, we found a triplet at δ = 8.6 ppm (^3J = 5.4 Hz) and an NH singlet at δ = 7.1 ppm, which could be explained by the alkyl substituent on the *endo* nitrogen and by the aryl substituent on the *exo* nitrogen (formula **V**).

To verify this assumption, energy calculations were performed using quantum mechanics (Table 2). Even if molecular mechanics is not adapted to highly conjugated heteroatomic systems, calculations using the MM2* force field (with and without the GB/SA continuum solvation model (13) in chloroform) were performed and showed that form **V** is always more stable than form **IV** (Δ*E* = 30 kJ/mol with chloroform and 10.7 kJ/mol without solvent).

In the particular case of **2***g*, when the second reactant was the phenyl- or the propylisocyanate, only **2***a* or **2***e* was obtained. As an oxidation of the thiocarbonyl function was suspected, we repeated the reaction of **2***g* with 4-chlorophenylisocyanate. Thus **2***d* was isolated and we suppose that, in this case, a transposition followed by an elimination took place. In the case of **2***g*, when the second reactant was phenylisothiocyanate, we isolated only the starting material. We did not know whether a transposition/elimination had occurred, or no reaction at all. However, we proved that the latter (no reaction) had occurred by mixing **2***g* with 4-methylphenylisothiocyanate and isolating the starting oxazolidine **2***g* unchanged.

Conclusion

In this work the reactions of some 2-amino-2-oxazolines with isocyanates and arylisothiocyanate, giving, in a first step, 3-aryl/alkylcarbamoyl- and 3-arylthiocarbamoyl-2-iminooxazo-

lidines, were studied. As 2-iminooxazolidines are more stable than 2-iminothiazolidines (1), the experimental conditions were selected to prevent the classical N–N′ intramolecular rearrangement giving the urea isomers (14). When the reaction was conducted with phenyl/propylisocyanate, two phenyl/propylcarbamoyl substituents were successively introduced, the first on the endocyclic sp^2 nitrogen, the second on the exocyclic nitrogen, giving 2,3-diphenyl/dipropylcarbamoyl-2-iminooxazolidines. Using X-ray crystallography, we confirmed the structures of a 3-phenylcarbamoyl- and of a 2,3-diphenylcarbamoyl-2-iminooxazolidine, and we found that they exist as *Z* isomers. An intramolecular transposition was observed during the reaction of propylisocyanate with the 3-phenylcarbamoyl-2-iminooxazolidine. With phenylisothiocyanate, the first substitution on the *endo* nitrogen occurred, but it was impossible to substitute the *exo* nitrogen atom. Starting from the 3-phenylthiocarbamoyl-2-iminooxazolidine, the reaction with a second phenyl/propylisocyanate resulted in the replacement of the phenylthiocarbamoyl group by a phenyl/propylcarbamoyl one.

Experimental

To prevent secondary hydrolysis reactions all experiments were conducted in an inert, controlled-atmosphere, chamber. Microanalyses were carried out at the Service central d'analyse CNRS, Vernaison, France. Melting points were determined with a Kofler hot stage apparatus and were uncorrected. The IR spectra were obtained with a Bruker IFS 25. NMR spectra were recorded with a Bruker AC-200 and a Brucker AMX-500 spectrometer. All signals were expressed in ppm with respect to TMS. ^{1}H assignments for the piperazine nucleus were obtained by HMBC experiment for **2***a* via the ^3J ^{13}C–^{1}H coupling between N-CH_2 and the piperazine protons.

Crystal structure determinations

Colourless single crystals of **2***a* and **3***a* were obtained by slow evaporation from diisopropyl ether or ethanol solution, respectively. The crystallographic data are the following:

2*a*: $C_{21}H_{25}N_5O_2$, M_r = 379.5, triclinic symmetry; space group P_1, with a = 8.996(3), b = 10.156(3), c = 10.672(3) Å, α = 99.68(2)°, β = 95.50(2)°, γ = 94.75(3)°, V = 951.7(3) Å^3, Z = 2, D_x = 1.32 g cm^{-3}, CuKα, λ = 1.54178 Å, μ = 7.1 cm^{-1}, T = 300 K. Dimensions of the crystal 0.25 × 0.25 × 0.10 mm.

3*a*: $C_{28}H_{30}N_6O_3$, M_r = 498.6, monoclinic symmetry; space group $P2_1/n$, with a = 14.709(7), b = 9.618(2), c = 18.187(8) Å, β = 94.57(4)°, V = 2565.2(2) Å^3, Z = 4, D_x = 1.29 g cm^{-3}, CuKα, λ = 1.54178 Å, μ = 7.1 cm^{-1}, T = 300 K. Dimensions of the crystal 0.50 × 0.37 × 0.20 mm.

In both cases, the unit cell dimensions were determined using the least-squares fit from 25 reflections (θ < 25°). Intensities were collected with an Enraf–Nonius CAD-4 diffractometer using CuKα radiation and a graphite monochromator up to θ = 65° (scan type ω/θ, scan width 2° and 1.6°). With both crystals, no intensity variation of two standard reflections monitored every 90 min was observed. The intensities were corrected for Lorentz and polarization effects but not for absorption. Of 3252 (**2***a*) and 4367 (**3***a*) measured reflections, 1463 (**2***a*) and 2574 (**3***a*) were considered as observed (3σ(*I*) criterion) and included in the refinement. Both structures were determined by direct methods using MULTAN 80 (15). The scattering factors were taken from ref. 16. C, N, and O atoms were refined anisotropically. H atoms were placed in theoretical positions or were located from difference Fourier maps and were refined isotropically. The unweighted agreement factors were R = 0.042 (**2***a*; 853 refined parameters) and R = 0.040 (**3***a*; 454 refined parameters); R_w = 0.053 (**2***a*) and 0.061 (**3***a*). The convergence largest Δ/σ were <1 (on Bs), the highest peaks in final difference maps were 0.3 (**2***a*) and 0.4 (**3***a*) e Å^{-3}. The atomic coordinates have been deposited with the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 IEZ, U.K.

Theoretical calculations

Calculations were performed on an SGI Indigo R4000 Elan workstation running MacroModel version 4.5 (13) and Biosym softwares version 3.5.[4] Molecules were built *ex nihilo* (without the oxazolidine C-5 substituent) using MacroModel and minimized with a standard method: 1000 cycles, using the TNCG method (Truncated Newton Conjugate Gradient) to a 0.005 kJ Å^{-1} mol^{-1} RMS gradient. Despite some low-quality parameters the MM2* (17) force field was preferred to MM3* (18) which lacks several parameters.

MacroModel files were converted into a CSSR format and exported into Insight[4] where MOPAC/AM1 calculations were made. Energy calculations were performed with minimization of the full *Z*-matrix (default parameters: SCF iterations = 200, energy convergence = 0.00001, gradient norm minimization = NLLSQ, and minimization method = BFGS) (Broyden–Fletcher–Goldfarb–Shanno method).

General procedure for the preparation of 5-substituted-3-phenylcarbamoyl- or 5-substituted-3-phenylthiocarbamoyl-2-iminooxazolidines

To a cold (0°C) stirring solution of 0.1 mol of 2-amino-2-oxazoline in 200 mL of ethanol under argon was slowly added 0.1 mol of isocyanate or phenylisothiocyanate in 20 mL of ethanol. The reaction mixture was stirred for 1 h at room temperature. The precipitate was rapidly collected, washed with anhydrous ether, and recrystallized.

5-[(1-Phenyl-4-piperazinyl)methyl]-3-phenylcarbamoyl-2-iminooxazolidine (**2***a*): mp 146°C (diisopropyl ether); yield: 51%; IR (KBr) cm^{-1}: 3340 (NH), 1700 (C=O), 1680 (C=N), ^{1}H NMR (chloroform-*d*) δ ppm: 11.66 (s, 1H, N*H*), 7.19 (m, 10H, Ar-*H*), 6.01 (s, 1H, N*H*), 4.7 (m, 1H, 5-*H*), 4.26 and 3.82 (2dd, 2H, J = 10.4, 8.2, 7.2 Hz, 4-*H*), 2.97 (m, 10H, NCH_2); ^{13}C NMR (chloroform-*d*) δ ppm: 154.88 (CO), 151.05 (C-2), 150.05, 138.26, 129.09, 128.93, 123.16, 118.84, 115.44 (Ar), 73.16 (C-5), 60.16 (C-5-CH_2), 53.20, 48.18 (CH_2 pip), 46.62 (C-4). General procedure for the preparation of 5-substituted-2,3-diphenylcarbamoyl-2-iminooxazolidines 3(*a–c*) and 5-[(1-phenyl-4-piperazinyl)methyl]-2,3-dipropylcarbamoyl-2-iminooxazolidine 3*e*

From the corresponding 5-substituted-2-amino-2-oxazolines **1**: to a cold (0°C) stirring solution of 0.1 mol of 2-amino-2-oxazoline in 200 mL of dry acetone under argon was slowly added 0.2 mol of phenyl- or propylisocyanate. The reaction mixture was stirred for 24 h at room temperature. The collected solid was recrystallized from a suitable solvent.

From the corresponding 5-substituted-3-phenylcarbamoyl-2-iminooxazolidines **2**: to a cold (0°C) stirred solution of 0.01 mol of 2-iminooxazolidine in 100 mL of dry acetone under argon was slowly added 0.01 mol of phenyl- or propylisocyanate. The reaction mixture was stirred for 3 h at room temperature. The collected solid was recrystallized from a suitable solvent.

5-[(1-Phenyl-4-piperazinyl)methyl]-2,3-diphenylcarbamoyl-2-iminooxazolidine **3***a*: mp 168°C (C_2HCl_3); yield: 67%; IR (KBr) cm^{-1}: 3410, 3250 (NH); 1715, 1660 (C=O); 1640 (C=N); ^1H NMR (chloroform-*d*) δ ppm: 10.76 (s, 1H, N*H*), 7.4 (s, 1H, N*H*), 7.21 (m, 15H, Ar-*H*), 4.82 (m, 1H, 5-*H*), 4.15 and 3.90 (2 dd, 2H, *J* = 10.7, 8.6, 7 Hz, 4-*H*), 3.10 and 2.70 (2 m, 10H, NCH_2); ^{13}C NMR (chloroform-*d*) δ ppm: 155.59 (C-2), 152.74 (N_{exo}-CO), 148.69 (N_{endo}-CO), 150.77, 139.37, 137.34, 128.72, 128.52, 123.70, 122.50, 119.90, 118.63, 118.48, 115.19 (Ar), 76.26 (C-5), 59.28 (C-5-CH_2), 53.21, 48.09 (CH_2-pip), 46.21 (C-4). Anal. calcd. for $C_{22}H_{25}N_5O_4$: C 62.41, H 5.91, N 16.55; found: C 62.52, H 76.20, N 16.60.

5-[(1-Phenyl-4-piperazinyl)methyl]-2,3-dipropylcarbamoyl-2-iminooxazolidine **3***e*: mp 121°C (heptane); yield: 42%; IR (KBr) cm^{-1}: 3410, 3300 (NH); 1700, 1635 (C=O); 1640 (C=N); ^1H NMR (chloroform-*d*) δ ppm: 8.55 (t, 1H, J = 5.5 Hz, N*H*), 7.17 (m, 5H, Ar-*H*), 5.11 (t, 1H, J = 6 Hz, N*H*), 4.83 (m, 1H, 5-*H*), 4.15 and 3.84 (2 dd, 2H, J = 10.3, 8.2, 7.2 Hz, 4-*H*), 3.19 and 2.68 (2m, 14H, NCH_2), 1.55 (m, 4H, CH_2CH_3), 0.92 (t, 6H, J = 7.3 Hz, CH_2CH_3); ^{13}C NMR (chloroform-*d*) δ ppm: 158.90 (N_{exo}-CO), 152.65 (N_{endo}-CO), 151.09 (C-2), 151.78, 129.08, 119.78, 116.05 (Ar), 75.98 (C-5), 60.18 (C-5-CH_2), 54.07, 49.14 (CH_2 pip), 46.92 (C-4), 42.23, 41.86 (NH-CH_2), 22.99, 22.93 (CH_2CH_3), 11.41, 11.32 (CH_2CH_3). Anal. calcd. for $C_{22}H_{34}N_6O_3$: C 61.40, H 7.91, N 19.53; found: C 61.35, H 8.0, N 19.56.

5-[(1-Phenyl-4-piperazinyl)methyl]-2-propylcarbamoyl-3-phenylcarbamoyl-2-iminooxazolidine **3**i

Preparation of **3***i* was conducted following the same procedure as described above for 2,3-disubstituted-2-iminooxazolidines, either from **2***a* with propylisocyanate or from **2***e* with phenylisocyanate; mp 126°C (CCl_4); yield: 75%; IR (KBr) cm^{-1}: 3410, 3250 (NH); 1700, 1645 (C=O); 1640 (C=N); ^1H NMR (chloroform-*d*) δ ppm: 8.57 (t, 1H, J = 5.4 Hz, N*H*), 7.72 (m, 10H, Ar-*H*), 7.06 (s, 1H, N*H*), 4.72 (m, 1H, 5-*H*), 4.10 and 3.89 (2 dd, 2H, J = 10.3, 8.2, 7.2 Hz, 4-*H*), 3.25 (m, 2H, NH-CH_2), 3.13 (m, 4H, NCH_2), 2.71 (m, 6H, NCH_2), 1.58 (m, 2H, CH_2CH_3), 0.92 (t, 3H, J = 7.4 Hz, CH_2CH_3); ^{13}C NMR (chloroform-*d*) δ ppm: the assessment of ^{13}C NMR chemical shift for quaternary carbons in **3***i* was made using the QUAT non-decoupled technique (observation of ^{13}C–^1H couplings). Thus C(2) was coupled with *H*-C(4) and *H*-C(5) (^3J = 2 Hz in the two cases). Then N_{endo}-CO was coupled with *H*-C(4) (^3J = 4.1 Hz). The quaternary carbons of the phenyl rings were coupled with the corresponding meta protons (^3J = 9.1 and 8.5 Hz). Nevertheless we did not observe any coupling for N_{exo}-CO, which permitted us to assign it as: 156.31 (N_{exo}-CO), 153.98 (N_{endo}-CO), 151.06 (C-2), 151.55, 138.39, 129.04, 128.94, 123.57, 119.73, 118.98, 116.01 (Ar), 76.33 (C-5), 60.03 (C-5-CH_2), 54.05, 49.09 (CH_2 pip), 46.88 (C-4), 41.94 (NH-CH_2), 22.92 (CH_2CH_3), 11.39 (CH_2CH_3). Anal. calcd. for $C_{25}H_{32}N_6O_3$: C 64.66, H 6.90, N 18.10; found: C 64.45, H 7.02, N 17.72.

Preparation, spectroscopic properties, and ion chemistry of 3-diazo-1,1,1-trifluoro-2-propanone

Paolo Strazzolini, Angelo G. Giumanini, Alberto Gambi, Giancarlo Verardo, and Giovanni Cerioni

Abstract: The title compound (**1**) is prepared in satisfactory yield by reacting CH_2N_2 with trifluoroacetic anhydride in Et_2O; the *d*-analog was obtained by exchange with D_2O. ^1H, ^{13}C, ^{15}N, ^{17}O, and ^{19}F NMR spectra of **1** were studied, as well as its IR spectrum. A single isomer is present corresponding to the more stable *Z* configuration. The structural assignment was made on the basis of quantum mechanical calculations, which revealed that the *Z* form is some 13.4 kJ mol^{-1} more stable than the *E* form and the activation energy for the $E \rightarrow Z$ transition is 64.2 kJ mol^{-1}. Mass spectra under different experimental conditions were recorded and breakdown pathways of the parent ion of **1** charted.

Key words: 3-diazo-1,1,1-trifluoro-2-propanone; 3-*d*-3-diazo-1,1,1-trifluoro-2-propanone; structure; ^1H, ^{13}C, ^{15}N, ^{17}O, and ^{19}F NMR; EI-MS.

Résumé : On a préparé le composé mentionné dans le titre (**1**), avec un rendement satisfaisant, en faisant réagir le CH_2N_2 avec de l'anhydride trifluoroacétique dans l'éther; on a obtenu l'analogue deutéré par échange avec du D_2O. On a étudié les spectres RMN du ^1H, du ^{13}C, du ^{15}N, du ^{17}O et du ^{19}F ainsi que son spectre IR. Il n'existe qu'un seul isomère correspondant à la configuration *Z* la plus stable. On a fait les attributions de structure en se basant sur des calculs de mécanique moléculaire quantique; ils ont mis en évidence que la forme *Z* est environ 13,4 kJ mol^{-1} plus stable que la forme *E* et que l'énergie d'activation pour la transition $E \rightarrow Z$ est égale à 64,2 kJ mol^{-1}. On a enregistré les spectres de masse dans diverses conditions et on présente les voies de décomposition de l'ion parent du composé **1**.

Mots clés : 3-diazo-1,1,1-trifluoropropan-2-one; 3-*d*-3-diazo-1,1,1-trifluoropropan-2-one; structure; RMN du ^1H, du ^{13}C, du ^{15}N, du ^{17}O et du ^{19}F; SM-IE.

[Traduit par la rédaction]

Introduction

One of the simplest diazoketones is 3-diazo-1,1,1-trifluoro-2-propanone (**1**), bp 25°C at 133 Pa (1), which was described in 1953 as being the product (62.5% yield) of the reaction of CF_3COCl with CH_2N_2. Surprisingly, after that distant birth the compound has not received any attention, as can be established by its remarkable absence in the Chemical Abstracts. In view of the synthetic potential of this small building block, we set out to find a convenient synthetic procedure for it, to record and study some of its spectroscopic and mass spectrometric properties, also with the purpose of elucidating its actual structure.

Results and discussion

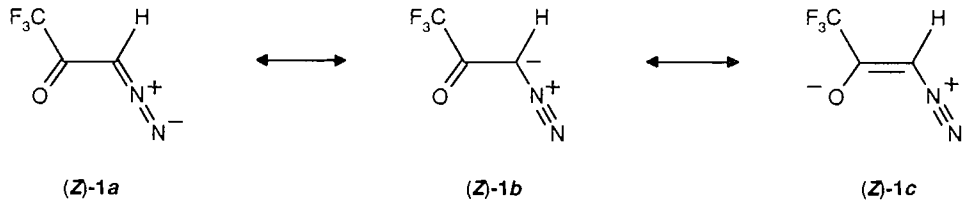
Compound **1**, for which *E* and *Z* geometric isomers may be expected, due to a possibly restricted rotation about the (O)C—C(H) bond of the five-center π system, may be described by a suitable mixing of the canonical formulas **1***a–c* (here reported for the *Z* isomer, Scheme 1).

It could be easily obtained from $(CF_3CO)_2O$ and CH_2N_2 in ether solution; careful evaporation of the solvent and the formed methyl trifluoroacetate (**2**), followed by a conventional distillation at slightly reduced pressure, gave **1** in good yield. The yellowish liquid obtained was conveniently ana-

$$(CF_3CO)_2O + 2\,CH_2N_2 \rightarrow \underset{\mathbf{1}}{CF_3COCHN_2} + \underset{\mathbf{2}}{CF_3CO_2CH_3} + N_2$$

lyzed by GC at relatively low injector and column temperatures, using an FID detector, and found to be homogeneous; use of an electron capture detector proved to be suitable, whenever a magnification of the sensitivity is required: the approximate ratio of the responses of the two detectors was found to be close to ca. 50. Under these conditions, the peak for **1** was highly symmetric and the EI-MS spectra at 70 eV recorded along the elution profile showed an absolutely constant pattern. Derivatives of diazoalkanes are expected to yield

Scheme 1.



(*Z*)-1*a* (*Z*)-1*b* (*Z*)-1*c*

mixtures of geometric isomers, which may interconvert more or less rapidly (2). The free energy of activation ΔG_{act} is essentially determined by its ΔH_{act} term, which is in turn strictly related to the amount of energy necessary to break the π-component of the relevant C—C bond. Thus a higher ΔG_{act} is an indication of a larger π bond order between these two centers, which in valence bond (VB) descriptive terms corresponds to a larger contribution of the mesomeric form **1***c*. Interconversion of geometric isomers of the respective positive ion, obtained by electron impact, is generally so fast that mass spectrometry is unable to generate different spectra for any two isomers.

Pure **1** appeared to be relatively thermally stable: in fact, a chlorobenzene solution did not show any sign of transformation after 2 h at reflux. Differential scanning calorimetry (DSC) in nitrogen atmosphere revealed that exothermic reactions with traces of molecular oxygen set in at 117.1°C and 148.0°C; the compound underwent a strong exothermic decomposition at 199.0°C. The deuterio analog of **1** (*d*-**1**) could be easily obtained by repeated exchanges with D_2O without any catalyst at room temperature during 15 min. This is a fortunate event because base-catalyzed exchange (3) may induce a haloform reaction (4).

Admission of **1** through a GC column into the electron impact ion source of a mass spectrometer, with the precaution of keeping the temperatures of all sections of the whole system as low as possible and injecting the smallest amount that can generate clean spectra in order to avoid thermal and collision-induced decompositions and material exchanges, produced a simple spectrum at 70 eV, consisting essentially of the parent ion at *m/z* 138, a peak at *m/z* 69, and one at *m/z* 41. Under these conditions the appearance of peaks at *m/z* 110 (loss of N_2) and 91 were minimized and practically negligible, as well as the quasimolecular ion MH^+ at *m/z* 139 (**5**), which appeared related to a peak at *m/z* 70 (Fig. 1). Wulfman and Poling (5) had already found that no loss of N_2 is present in the mass spectra of ethyl diazoacetate and dimethyl diazomalonate recorded in an all-glass system.

The spectrum of **1** obtained at the ionization energy value of 20 eV is reported in Fig. 2: slightly less stringent working conditions produced a richer fragmentation pattern, which is made up of the true spectrum of **1** superimposed with the product(s) of its thermal decomposition in the ion source, a fact which may well affect most of the reported spectra of diazoketones (5). Thus, the ion **4** at *m/z* 110 (**1** − N_2) is most likely the parent ion in the fragmentation process of the Wolff rearrangement product trifluoromethyl ketene (**3**), essentially yielding the cascade at *m/z* 91, 82, and 63 (Scheme 2).

Metastable ion, MIKE, and B^2/E experiments ruled out any appreciable contribution of the observable *m/z* 110 ion (**4**) to an electron impact induced decomposition of the parent ion of

Fig. 1. EI (70 eV) mass spectrum of **1** (GC inlet).

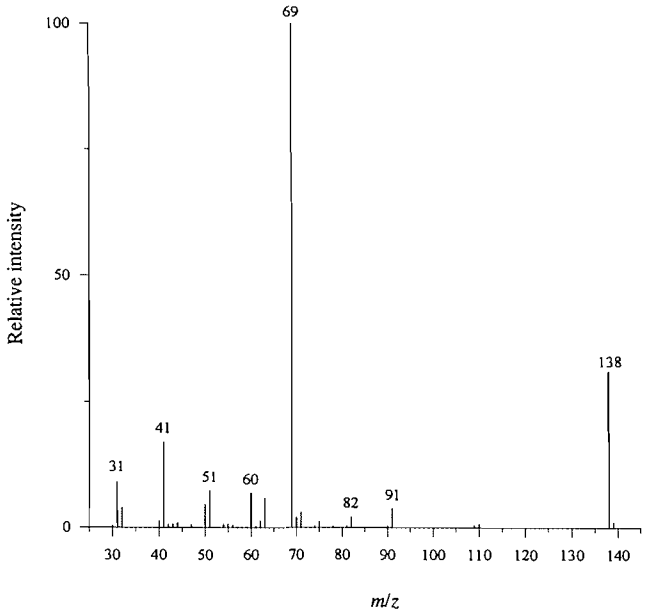


Fig. 2. EI (20 eV) mass spectrum of **1** (GC inlet).

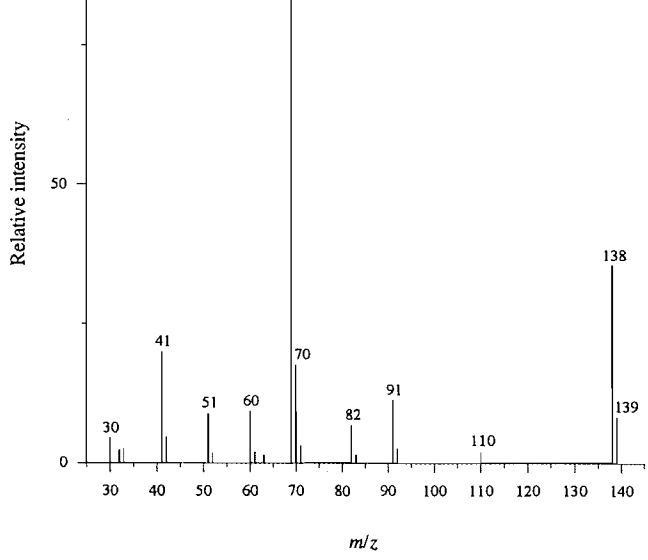
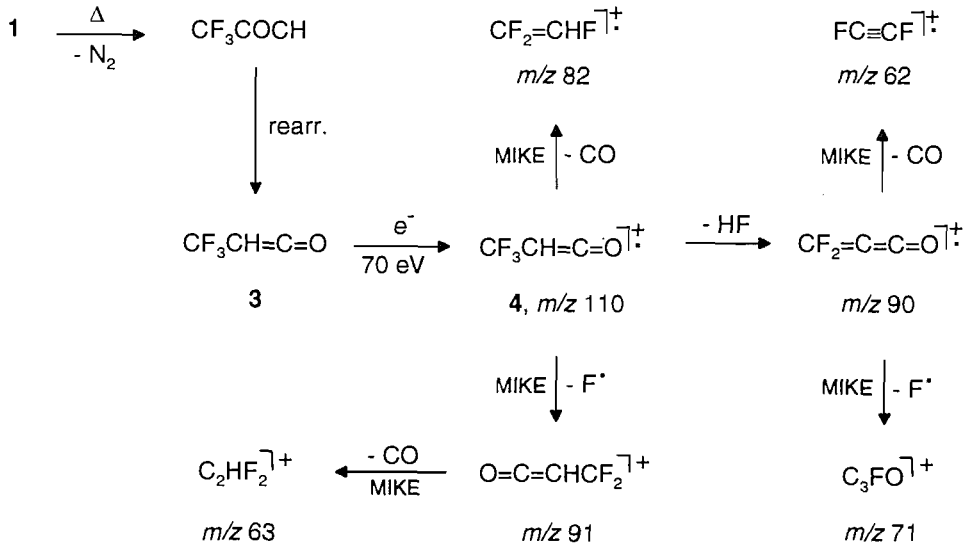
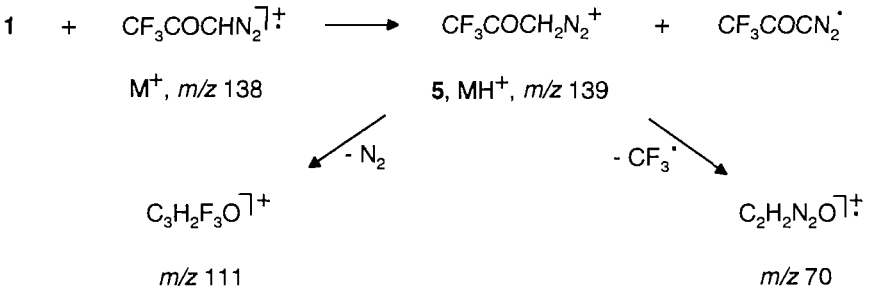


Scheme 2.



Scheme 3.

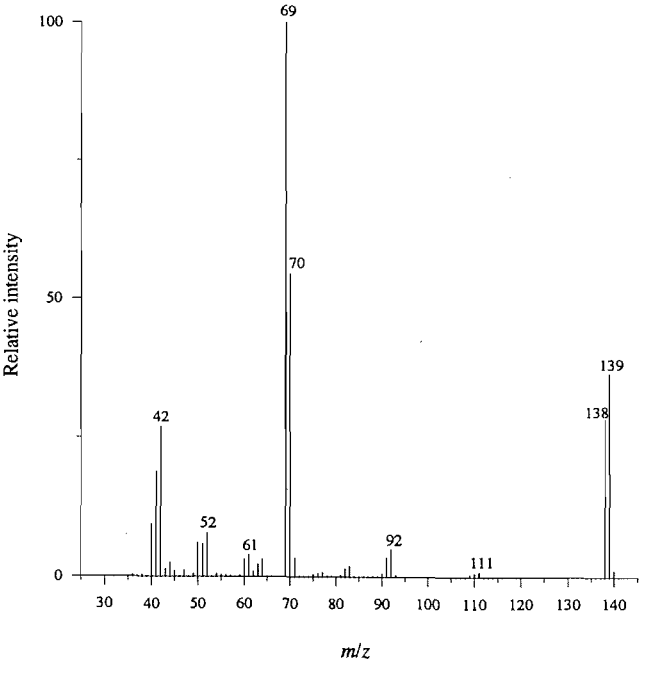


1. A MIKE spectrum correctly related the appearance of the peak at *m/z* 69 to this parent ion. The great efficacy in performing a hydrogen abstraction upon ion–molecule exchange is also borne out by examination of the spectrum of Fig. 2, where the MH^+ ion (**5**) is definitively outstanding, as well as its decomposition product at *m/z* 70 (Scheme 3).

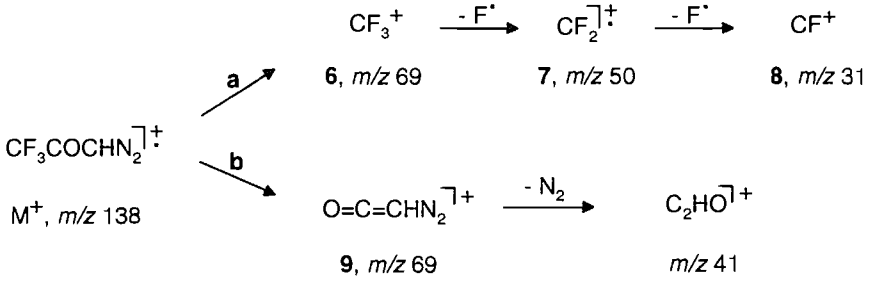
Molecules having the CF_3 group frequently show the corresponding positive ion at *m/z* 69 (**6**) in their mass spectra: confirmation of the ion composition comes from the accompanying presence of the ions at *m/z* 50 (**7**) and 31 (**8**); but the ion at *m/z* 41, whose composition should be C_2HO, indicated as its possible precursor an ion of composition C_2HN_2O (**9**) isobaric with CF_3 (Scheme 4). Confirmation of the hypothesis came from the spectrum of partially deuterated **1**, admitted into the ion source under exactly the same conditions of the spectrum of Fig. 1, showing a doubling of the ion at *m/z* 69, now accompanied by the ion at *m/z* 70; similar splitting was observed for the ion at *m/z* 41 (Fig. 3).

From the ratio of the intensity of the peaks at *m/z* 138 and 139, the relative incidence of the ion decomposition paths **a** and **b** was calculated to be ca. 1.33:1.00. Accurate mass measurements of the ion at *m/z* 69 gave a final confirmation of our observations. The ion at *m/z* 71, whose intensity is strictly related to the appearance of the Wolff product, was found to originate from the ion at *m/z* 91 by loss of HF from the appro-

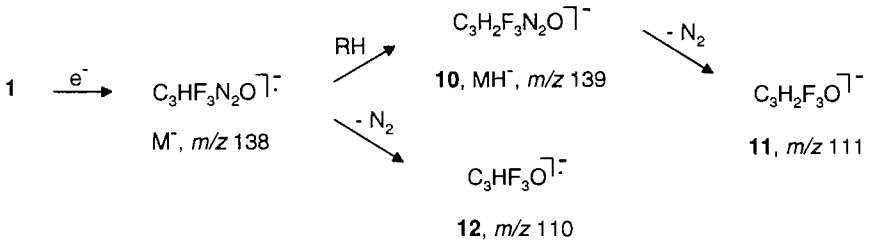
Fig. 3. EI mass spectrum of *d*-**1** (recorded in the same conditions of the spectrum in Fig. 1).



Scheme 4.



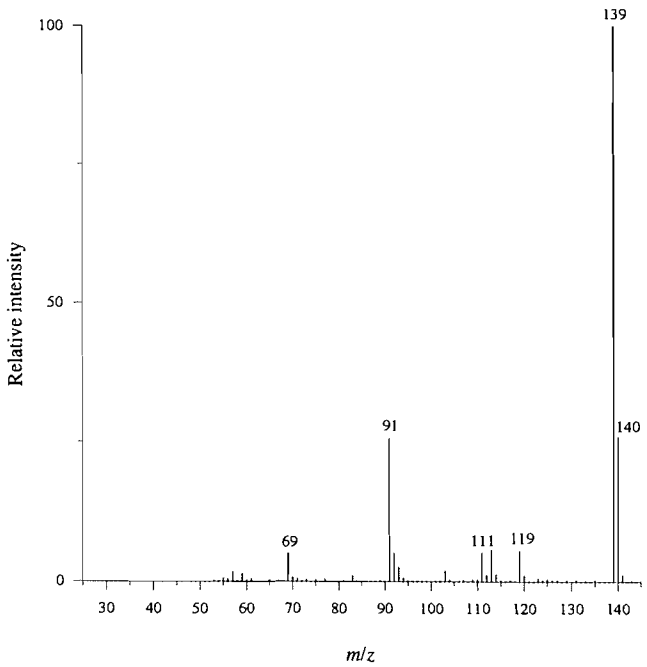
Scheme 5.



priate MIKE experiment. Incidentally, extensive Wolff rearrangement was correlated (ref. 2, p. 124) with the presence of a *Z* conformer in the mixture actually undergoing decomposition. When neat CF_3COCDN_2 was admitted into the ion source through a nonpolar silicon rubber column in an amount such that ion–molecule collisions were minimized, as can be ascertained by the invariancy of the ion at *m/z* 138 vs. 139 or 69 vs. 70 intensity ratios, these ratios could be considered a good indication of the isotopic composition of the material reaching the ion source. Identical amounts of the protic substance, as determined by the electron multiplier counts, reduced to the purely isotopic content the peaks at *m/z* 139 and 70, a proof of the practical absence of ion–molecule collision with hydrogen donation to the ion. The 70 eV spectrum for the deuterated molecule could therefore realistically be reconstructed. From this spectrum the ratio of the fragmentation ions CF_3 vs. $COCDN_2$ could be determined: this ratio should also hold for the protic ion. Moreover, the ion at *m/z* 41 of the protic material moved to *m/z* 42 for the deuterated molecule. The ratio of intensities of *m/z* 41 vs. *m/z* 138 was very close to the ratio *m/z* 42 vs. *m/z* 139, respectively, for the protic and deuterated molecule: an indication both for the quality of the obtained spectrum of the latter and for the essential correspondence of the two fragmentations even in terms of cleaving propensities.

A chemical ionization positive ion spectrum of **1** was obtained in CH_4 as ionizing gas (Fig. 4). The quasimolecular ion (MH^+, *m/z* 139) was the base peak, with little decomposition taking place. Of interest, some 20% as intense as this was a peak at *m/z* 140 (MH_2^+). The main decomposition pathway leads to the ion at *m/z* 91, with the intermediacy of loss of HF from MH^+, followed by loss of N_2. Interestingly, the direct loss of N_2 from MH^+ was definitively a minor process, perhaps a valuable indication for experiments in condensed phase. A negative ion spectrum (Scheme 5), on the other hand, exhibited only two ions: the base peak being at *m/z* 110 (**12**) with a companion at *m/z* 111 (**11**); an ion of very minor intensity was

Fig. 4. CI-(CH_5^+) mass spectrum of **1**.



present in the neighbourhood of the parent ion at *m/z* 137. Although **1** is made up of a good cluster of electronegative atoms, it appears unable to accommodate an extra electron in a reasonably stable anion of the same composition. The same and only loss of N_2 occurred both from the parent ion and the negative quasimolecular ion (**10**).

Ions kept in a mass trap may often pick up hydrogen by collision with unionized donors present there, due to the relatively long time of residence, eventually showing decom-

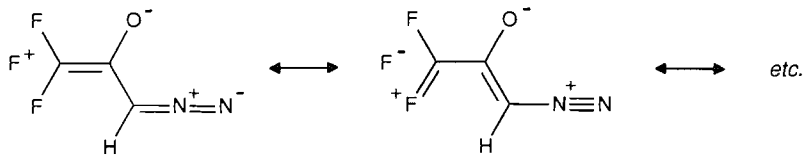
position of the quasimolecular ion MH^+. This process was most efficient when our **1** was admitted to one such spectrometer (Fig. 5): the M^+ disappeared altogether, to be replaced by the MH^+, which decomposed to *m/z* 91 by loss of N_2 followed by fast loss of HF. Beside the base peak at *m/z* 69, the fragmentation of MH^+ showed a peak at *m/z* 70, assumed to have the composition CF_3H^+, and one at *m/z* 113. The latter, for which we assume the composition $C_2F_3O_2$, was possibly generated by the collision of the parent ion of **1** or the ion $C_3H_2F_3N_2O^+$ (MH^+) with neutral CF_3COOH, somehow admitted into the ion trap.

NMR spectroscopy data are collected in Table 1. The ^1H NMR spectrum of **1** at room temperature in $CDCl_3$ exhibited only one peak at 5.86 ppm with a line width at half-height of 4.2 Hz, a location in close agreement with those reported (6) for α-protons of α-diazoketones. ^{13}C NMR signals can be easily assigned from their shifts and ^1H and ^{19}F couplings. The ^{13}C NMR chemical shifts of carbonyl groups in α-diazoketones are shielded compared to *normal* ketones, e.g., acetophenone (196.9 ppm) (7) and ω-diazoacetophenone (186.4 ppm) (8); an analogous shielding is observable also for **1** (176.2 ppm) compared to 1,1,1-trifluoroacetone (187.7 ppm) (7). The same effect, but in a more pronounced fashion, is exhibited by aldehydes, e.g., acetaldehyde (200.5 ppm) (7) vs. diazoacetaldehyde (184.1 and 183.8 ppm for the *E* and *Z* forms, respectively) (8). On the contrary, this shielding is strongly reduced by the contemporary presence of another conjugated group as is the case for, e.g., ethyl acetate (170.3 ppm) (7) vs. ethyl diazoacetate (167.6 ppm) (8). The large upfield shift usually observed (9) for the C_{ipso} is partly relieved by the carbonyl group through the contribution of resonance formulas **1***c*, as discussed below for the ^{17}O NMR results. The value of $^1J_{(^{13}C-^1H)}$ is quite high for an sp^3 hybridized atom and higher than other $^1J_{(^{13}C-^1H)}$ measured for some diazo compounds (8), thus reflecting both a contribution of canonical formula **1***c* as well as the electron-withdrawing effects of the diazo and trifluoroacetyl groups (7). Owing to the lack of literature data, it is difficult to get information from the $^nJ_{(^{13}C-^{19}F)}$ values; nevertheless, we can observe that $^1J_{(^{13}C-^{19}F)}$ is identical for **1** and 1,1,1-trifluoroacetone (10): the large value observed for the latter coupling constant has been attributed to a π-bond contribution between carbon and fluorine. The value of $^2J_{(^{13}C-^{19}F)}$ fits a rough correlation observed (10) between $^1J_{(^{13}C-^{19}F)}$ and $^2J_{(^{13}C-^{19}F)}$. Neither $^3J_{(^{13}C-^{19}F)}$ nor $^3J_{(^{13}C-^1H)}$ has been measurable and we do not have a definite rationale for this observation. The C_{ipso} signal shows a remarkable half-height line width (12.3 Hz), which seems not to be due to slow exchange between *cisoid* and *transoid* rotamers, since on going down to −60°C neither any splitting nor any

Scheme 6.



13*a* **13*b***

line sharpening was observed. Kaplan and Meloy (11) experimentally determined a *Z*:*E* ratio of 9:1 for diazoacetone, theoretically confirmed by Csizmadia et al. (12). A further significant increase of this ratio in the case of **1** might prevent observation of the less favoured rotamer by NMR. A possible explanation for the large values observed for the half-height line width of C_{ipso} and for the signal of the ^1H spectrum could thus be that in our system vicinal couplings and $^4J_{(^1H-^{19}F)}$, respectively, have values so small as to prevent their observation but large enough to cause broadening of the respective lines.

The ^{19}F NMR shift is better compared with 1,1,1-trifluoroacetone and CF_3COOEt ($\delta = -83$ and -78 ppm, respectively) (10) or with $CF_3COCF{=}CF_2$ ($\delta = -80.1$ ppm) (13), all reflecting similar situations.

A certain amount of literature data on ^{15}N NMR for diazo groups is available, but only five entries concern diazoketones or diazoesters (8). We observe that both nitrogen atoms are more shielded for these two classes than for diazoalkanes. A full rationalization of variation of shielding in diazo groups resulting from structural variations has not yet been reached, except for the case of the effects observed when a conjugation among diazo and electron-withdrawing groups was present (14). In our case, there is a close similarity of ^{15}N chemical shifts with ethyl diazoacetate ($\delta = -132.6$ and $+3.6$ ppm for $N_{(a)}$ and $N_{(b)}$, respectively) (15). We have also measured, at natural isotopic abundance, $^2J_{(^{15}N-^1H)}$ and $^3J_{(^{15}N-^1H)}$ values. For diazo compounds we are aware of only one other observation (15) of such couplings, i.e., for an ^{15}N enriched sample of ethyl diazoacetate, in which values were found to be 2.8 and 1.0 Hz for $^2J_{(^{15}N-^1H)}$ and $^3J_{(^{15}N-^1H)}$, respectively. The $^2J_{(^{15}N-^1H)}$ value observed for **1** (1.8 Hz, some 64% the value of 2.8 Hz reported in the quoted paper) is in favour of an increased charge on $N_{(a)}$ compared with $N_{(a)}$ of diazoacetate, since an effective removal of the lone pair from the nitrogen atom causes a significant reduction of the values for $^2J_{(^{15}N-^1H)}$ (ref. 11, p. 72).

^{17}O NMR data are in agreement with the previously discussed importance of the resonance structure **1***c*. The strong shielding observed for the carbonyl group of diazoketones, in comparison with ketones lacking the diazo group, has in fact been shown to be due to this reason (16). Moreover, we observe for **1**, compared with 1,1,1-trifluoroacetone (17), a $\Delta\delta^{17}O$ of ca. 160 ppm whilst for α-diazoketones this $\Delta\delta^{17}O$ is usually smaller, ca. 110 ppm (16*b*). In this case, the CF_3 group operates in a direction that is opposite to that observed when comparing acetone (18) and 1,1,1-trifluoroacetone, the latter being actually deshielded by ca. 20 ppm compared to the former. A possible explanation could be found in the not negligible importance of hyperconjugative resonance formulas, such as **13**, which further contribute to diminish the double bond character of the carbonyl group of **1** (Scheme 6). Support for the possibility of a contribution of formulas **13**, particularly **13***b*, to the real structure of **1** can be found also in the high value found for $^1J_{(^{13}C-^{19}F)}$, as previously discussed.

An absorption maximum was found in the UV spectra of **1** recorded in EtOH, $CHCl_3$, and *c*-hexane in the range 273–278 nm; a large increase of the value for the extinction coefficient was observed in *c*-hexane. In addition, a shoulder was quite evident both in EtOH at 247 nm and *c*-hexane (256 nm), but was absent in $CHCl_3$ (Table 2). The location of the maxima and shoulders are those expected from literature data for diazoketones (ref. 2, pp. 115, 116).

The room temperature IR spectra of liquid **1** and its deuterated analog are reported in Figs. 6 and 7, respectively. The spectrum of compound **1** (Fig. 6) exhibits a system of two bands both in the ν_{CH} region and in the ν_{NN} region. The spectra of solid **1** showed only the lower frequency component in the ν_{CH} region, the position of this band being consistent with a hybrid sp^2 carbon. Also the infrared gas-phase spectrum shows only one component with an AB-hybrid type contour, confirming the planar skeleton of the molecule. The disappearance of the higher frequency component can be explained either on the basis of a change in the Fermi resonance, although in this case the total disappearance would be difficult to explain, or, better, by the presence of molecular associates in the liquid phase. The band at lower frequency is definitively broader. Compound *d*-**1** exhibited a ν_{CD} band at 2350 cm^{-1}, which may be compared with a value of 2312 cm^{-1} found for 3-diazo-3-*d*-2-propanone (19).

The IR spectra of diazoketones are characterized by a band around 2100 cm^{-1} (ref. 2, pp. 116, 117) attributed to the ν_{NN} fundamental, and H- and D-α-diazoketones present a band in the range 2104–2114 cm^{-1} (20). The strong band at 2134 cm^{-1} should be assigned to the stretching of the NN bond: the relatively high value of the frequency of this absorption indicates the importance of mesomeric structures with a triple bond between the nitrogen atoms. This result may be ascribed to the effect of the very electronegative nature of the substituent on the neighbouring carbon atom; in fact, the absorption frequency is quite close to that observed for the CN triple bond (21). The relatively high frequency (ca. 1670 cm^{-1}) of the absorption band of the C=O group seems to favour an increased contribution of resonance hybrids with a carbon–oxygen double bond, in comparison with other diazoketones and in contrast with the results of the ^{17}O NMR spectroscopy. However, as discussed by Foffani and co-workers (22), a carbonyl–diazo group field interaction can be of significance and help to overcome the apparent contrast between the results

Table 2. UV properties of **1** in *c*-hexane, $CHCl_3$, and EtOH.

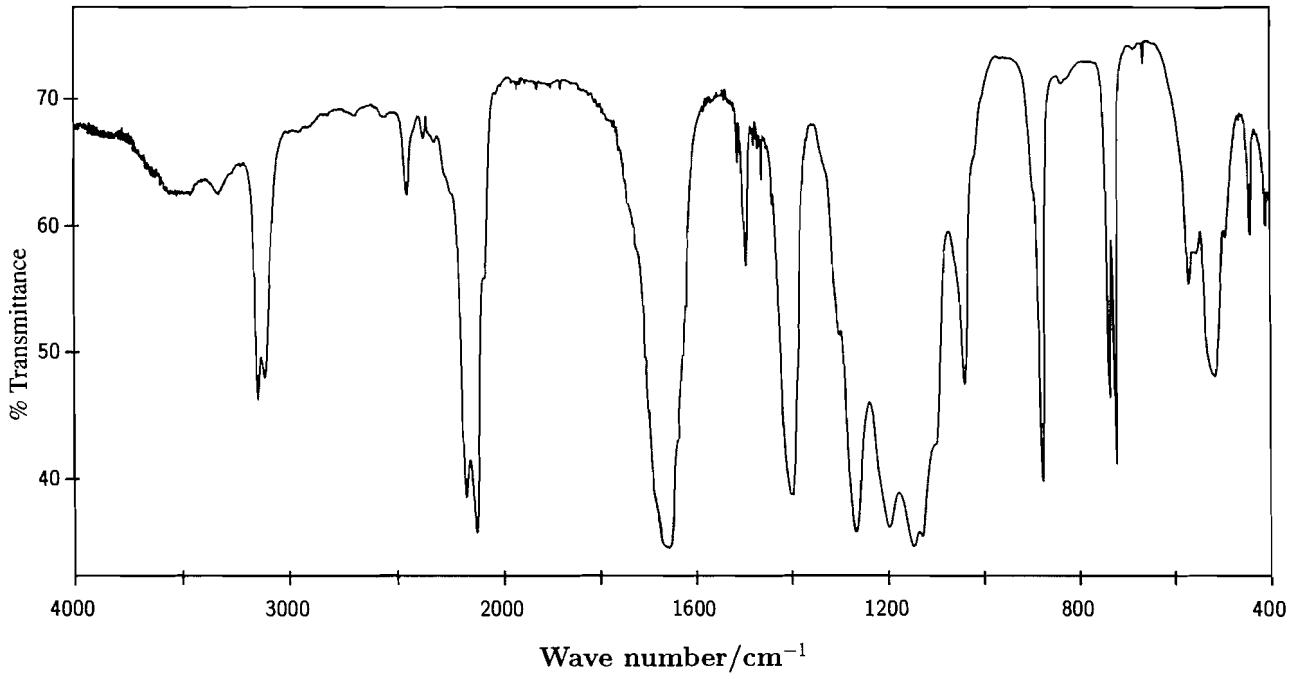
Fig. 6. IR spectrum of neat liquid **1**.



obtained by the two different spectroscopic methods. The higher frequency component of the band system about 2180 cm^{-1} is present also in the solid state and in the gas phase and its intensity does not depend on the temperature; it might be assigned to a Fermi resonance of (1277 + 900) or (1137 + 1043) cm^{-1} combination bands with the near fundamental.

The NMR data and IR spectral features in the CH (CD) stretching, as well as other characteristic absorptions in other regions, induced us to favour the hypothesis of the presence of a single isomer, possibly in the *Z* configuration. Simultaneous presence of two conformers in equilibrium was observed for other diazoketones in a number of studies by several authors

Fig. 7. IR spectrum of neat liquid *d*-**1**, from which background of traces of **1** was subtracted.

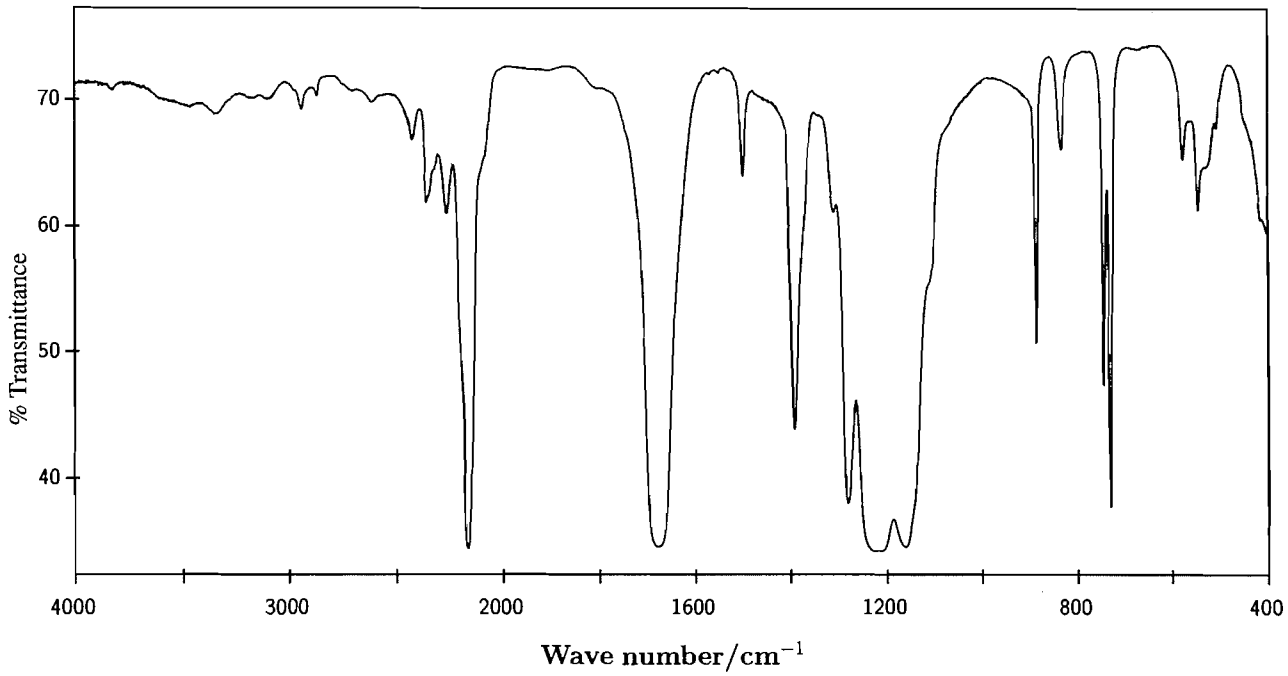


Fig. 8. Geometric structure of the *Z* form of **1**.

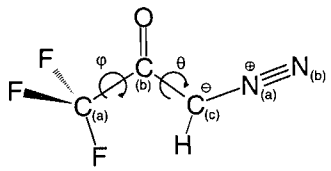

Fig. 9. Interconversion energy barrier of the two conformers (*E* and *Z*) of **1**.

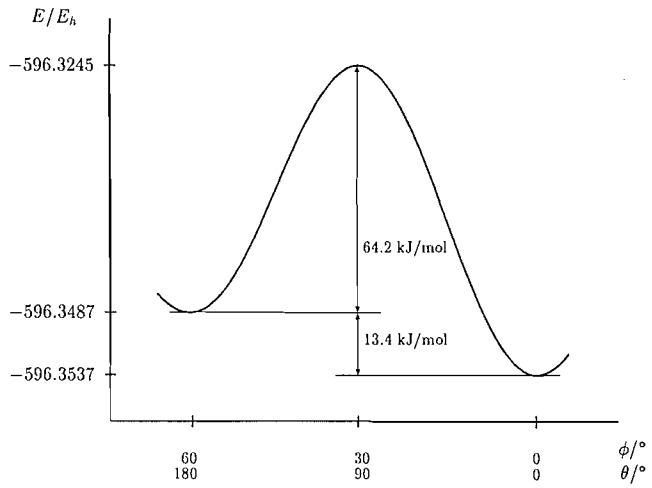

using various physical techniques (11, 23, 24): determination of the dipole moments and theoretical calculations (25) then allowed more precise inferences about the actual structures present at equilibrium. The *Z* form was always more stable than the *E* one. To achieve more certain and detailed information on the actual structure of **1**, we then moved in two different directions. The IR spectrum of **1** in the gas phase was recorded and studied in greater detail. Theoretical calculations, on the other hand, were carried out in order to produce information on the geometry of the *E* and *Z* forms of **1**, their energies, and the activation enthalpy of the $E \rightarrow Z$ transformation. Energy values for the different conformers of **1** are reported in Table 3 and the optimized geometric structures in Table 4.

The theoretical approach was based on Hartree–Fock ab initio calculations aimed at elucidating the conformational and vibrational spectroscopic side of the problem of the structure of **1**, using the GAUSSIAN 92 computer program package (26). The geometric structure of the *Z* form of compound **1** is reported in Fig. 8 and is drawn with $\varphi = \theta = 0°$; the structure of the *E* form is obtained when the dihedral angle θ (defined as H-$C_{(c)}$-$C_{(b)}$-$C_{(a)}$) is 180°. The other dihedral angle φ (defined as F-$C_{(a)}$-$C_{(b)}$-$C_{(c)}$) is relative to the rotation of the CF_3 group and may range from 0° to 60°. The *z*-axis, not shown in the representation of the molecule, points out of the plane of the C-(CO)-CHN_2 core.

The calculations showed that the more stable configuration is a (**Z**)-**1**, having $\varphi = \theta = 0°$; on the other hand, in the case of (***E***)-**1**, the less stable configuration, a minimum of energy is achieved when $\varphi = 60°$ and $\theta = 180°$. From the data collected in Table 3 the enthalpy difference between the two conformations is found to be 13.4 kJ mol^{-1}, a result amply justifying the appearance of only (**Z**)-**1** at equilibrium. The barrier to interconversion of (***E***)-**1** to (**Z**)-**1** is evaluated at 64.2 kJ mol^{-1}, a value that compares well with others previously determined

Table 3. Energy values for the different conformers of **1**.

[a]Bond distances are given in Ångstroms and bond angles in degrees.

(Fig. 9). Interestingly, the angle φ, associated with the conformation of the CF_3 group, showed peculiar and definite preferences: a CF bond invariable lies in the plane of the π-core centers on the less hindered side, i.e., pointing towards the H in (*Z*)-**1** and the O in (*E*)-**1**. These results were obtained thanks to the use of a relatively high theoretical level, employing the 6-311G(d,f) large basis set. Bond lengths (Table 4) appeared to be uninfluenced by configuration, as well as all but two angles showing large variations (∠($C_{(b)}$-$C_{(c)}$-H), ∠($C_{(b)}$-$C_{(c)}$-$N_{(a)}$)), corresponding to rotations of H and the N_2 group about $C_{(c)}$ in the plane of the molecules. Since the (*E*)-**1** shows practically ideal sp^2 orbital alignments of the substituents about the carbon center, the closer approach of N_2 to O in (*Z*)-**1** may well be due to an electrostatic interaction.

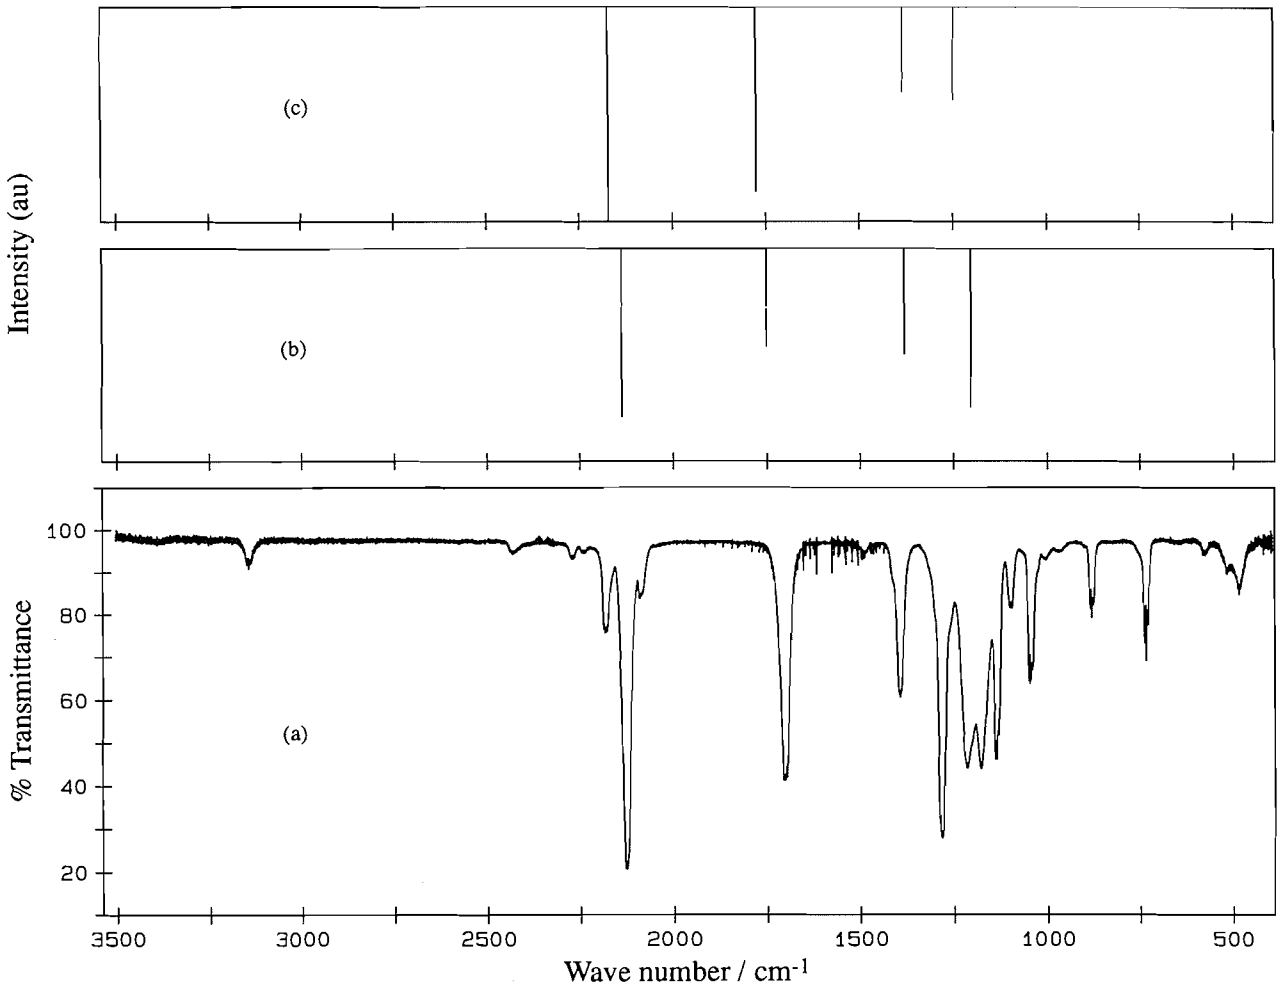
Once the geometric optimization was achieved, we resumed computation of vibrational frequencies by determining the second derivatives of the energy with respect to the Cartesian nuclear coordinates and then transforming to mass-weighted coordinates. The intensities of the vibrational modes are evaluated along with the computed fundamentals. To compare the observed IR spectrum of **1** with the calculations relative to the (*E*)-**1** and (*Z*)-**1** forms, we considered the synthetic spectra obtained from the four strongest vibrations of the two forms, the computed wave numbers having also been scaled by ca. 10% in order to compensate for the harmonicity of the calculated values. The intensity patterns of the spectra, reported in Fig. 10, allowed the attribution of the *Z* configuration (*b*) to our product **1**. The band shapes in the gas phase spectrum may be classified as AB-hybrid envelopes and pure C-type profiles, confirming the planarity of the molecule.

Experimental

General methods

All reagents used were commercially available (Aldrich, Milano-I) and were used as received unless otherwise specified. Trifluoroacetic anhydride was freshly distilled prior to use; anhydrous K_2CO_3 was activated by heating at 250°C during 4 h. Careful determinations of bp were made by observing the slow distillation temperature of the center cut of a suitable amount of pure **1**. GC analyses were carried out with a Carlo Erba HRGC gas chromatograph using a 0.32 mm i.d. × 30 m Supelcowax™ 10 (0.25 μm phase film) or a 0.32 mm i.d. × 30 m Supelchem™ SE-54 (0.25 μm phase film) fused silica capillary column (Supelchem, Milano-I); operative conditions were: injection temperature 150°C, isothermal elution at 85°C or 50°C, respectively, detection temperature 200°C. Quantitative analyses for the determination of the concentration of solutions of **1** were performed by the internal standard technique (chlorobenzene), using the Supelcowax™ column: under these conditions, quite suitable in assessing the purity of **1**, complete D/H exchange occurred when *d*-**1** of at least 95% isotopic purity was chromatographed in an isotherm at 85°C. An analogous observation was made with 3-diazo-3-*d*-2-propanone (19). During this experiment we observed that the molecular ion of **1** has a great propensity to pick up a hydrogen atom in the collisions even with unionized molecules of **1**: in isotopic analysis it is therefore mandatory to inject the least amount that can be easily detected in order to avoid mistakes. The phenomenon was also confirmed by the use of an ion trap mass spectrometer. IR spectra were recorded on a Nicolet FTIR Magna 550 spectrophotometer using the KBr technique. In the case of the gas phase IR spectrum, a 5.0 cm path length cell filled with ca. 10 kPa of substance was employed. All calculations were carried out using a CRAY C90 computer system. UV spectra were recorded with a Jasco digital spectrophotometer UV–visible UVIDEC-505 equipped with a derivative scanner model DER-1 and a optical path of 1 cm; spectral data are reported in Table 2. NMR spectra were recorded using a Varian VXR-300 spectrometer equipped with a 10 mm broad-band probe or a 5 mm (^{1}H and ^{19}F) probe, at room temperature (probe temperature = 294 K) and at natural isotopic abundance for all nuclei, or, alternatively, a Bruker AC-200 spectrometer. Solutions of **1** were generally ca. 4.0 M in $CDCl_3$ and spectroscopic parameters for each nucleus examined were as follows. ^{1}H and ^{13}C spectra were obtained under routine conditions, at a nominal frequency of 299.249 and 75.429 MHz, respectively. Proton chemical shifts are reported in ppm on the δ scale relative to TMS as an internal reference (0.00); carbon chemical shifts are reported in ppm relative to the center line of the $CDCl_3$ triplet (77.00). The ^{19}F spectra were recorded at 282.203 MHz, pulse length 5.0 μs (ca. 45°), spectral width 50 kHz, acquisition time 0.3 s, relax-

Fig. 10. Gas phase IR spectrum of **1** (*a*), in comparison with the synthetic spectra of the four strongest calculated fundamentals (see text) for the *Z* (*b*) and *E* (*c*) forms.



ation delay 4 s, collecting 16 scans; the signal was referenced to internal CCl_3F. ^{15}N spectra were recorded at 30.406 MHz. In the INEPT sequence, pulse length was 24.0 μs (90°), spectral width 15 kHz, acquisition time 2.0 s, relaxation delay 2.0 s, the *J* value used was 1.8 Hz; 3200 and 3840 scans, respectively, for the ^1H decoupled and coupled spectra were collected and the signals were related to external CH_3NO_2. The ^{17}O spectra were recorded at a nominal frequency of 40.662 MHz, pulse length 28 μs (ca. 90°), spectral width 36 kHz, acquisition time 10 ms, preacquisition delay 100 μs, collecting 15 000 scans; the spectra were recorded on a spinning sample without lock and decoupling. The signal-to-noise ratio was improved by applying a 30 Hz exponential broadening factor to the FID prior to transformation; the data point resolution was improved to 0.08 ppm by zero filling to 18 000 data points. The signal was referenced to external deionized water. Coupling constants are reported in hertz (Hz). All NMR data are collected in Table 1. MS spectra in the EI positive and negative ion mode were obtained with a Fisons TRIO-2000 mass spectrometer operating at 70 or 20 eV. CI spectra using CH_4 were obtained from the same instrument. The ion source filament was switched on just before peak elution in order to keep the ion source chamber temperature as low as possible. The actual amount of **1** injected was also kept as low as possible in order to avoid collision-induced decompositions and ion–molecule reactions. Notwithstanding these precautions, we observed that the peak intensities of the ions at *m/z* 138 and 110 differed conspicuously when revealed on different instruments, a fact apparently due to the thermal reactions linked to the geometry and actual temperature of the ion sources. Furthermore, the intensity ratios of peaks related to the fragmentation of the ion at *m/z* 110 also changed drastically. Accurate mass measurements and metastable ion studies were performed on a double focusing, reverse geometry, VG ZAB2F spectrometer (VG, Altrincham, UK): metastable ion transitions were studied by means of mass-analyzed ion kinetic (MIKE) spectra; product and precursor ion spectra were obtained by B/E = const. and B^2/E = const. linked scans, respectively. Metastable scanning MIKE and B^2/E spectra allowed us to rule out formation of the ion at *m/z* 110 from the parent ion, derived from **1**. The ion trap mass spectrometer used for some experiments was a GC–MS Varian Saturn operating with a filament current of 10 μA and a target value set at 20 000. The temperatures of different sections of the instru-

ment were carefully set between 60 and 150°C in order to obtain reproducible results. Tabulated mass spectra report the five most intense peaks with bracketed relative intensities. DSC data were obtained on a Du Pont TA2000 DSC module, operating with a heating rate of 10°C/min in a N_2 atmosphere (N_2 flow: 10°C/min).

Preparation of CH_2N_2

An alcohol-free anhydrous ethereal solution of CH_2N_2 was prepared and titrated essentially according to a described procedure (Method 3) (27), with minor modifications: solid KOH (6.6 g) was dissolved in 2-(2-ethoxyethoxy)ethanol (150 mL) avoiding the addition of H_2O; the required amount of Diazald^R (Aldrich) was dissolved in 225 mL of Et_2O and the ethereal solution of CH_2N_2 obtained was made anhydrous by passing it twice over 10 g anhydrous K_2CO_3.

*3-Diazo-1,1,1-trifluoro-2-propanone (**1**)*

A 0.33 M ether solution of CH_2N_2 (182 mmol) was slowly added from a dropping funnel with all parts made of polished glass and using a PTFE stopcock and cork to a well-stirred ether solution of trifluoroacetic anhydride (85 mmol) of similar molarity kept at ca. 0°C in a dry argon atmosphere in a well-ventilated hood. At the end of the addition, when also gas evolution had subsided, the solvent was gently removed, by heating at 40°C in a stream of argon, through a 50 cm Vigreux column. When the solution was suitably concentrated, it was finally kept at ca. 16 kPa in order to eliminate all the solvent. A final distillation of the residual oil gave a GC homogeneous liquid, 64% yield, bp 70°C at 20 kPa (lit. (1) bp 25°C at 133 Pa), mp (uncorrected) 0°C. Inversion of the order of addition of reactants, as well as the use of one equivalent of Et_3N to neutralize forming acidity, led to much lower conversions. Compound **1** was found to be stable in refluxing chlorobenzene. Differential scanning calorimetry in air showed two transitions before the decomposition curve, likely due to reaction with oxygen, at ca. 117 and 148°C; thermal decomposition of **1** occurred very rapidly in inert atmosphere at ca. 202°C. UV properties of **1** are reported in Table 2; the IR spectrum is reported in Fig. 6; NMR data are collected in Table 1; mass spectra are reported in Figs. 1, 2, 4, and 5. Negative ion MS of **1** (CH_4, 70 eV): *m/z* 137 (M^- − H, 1%), 112 (1), 111 (21), 110 (100), and 69 (2).

*3-d-3-Diazo-1,1,1-trifluoro-2-propanone (d-**1**)*

Suitably anhydrous NaCl and Na_2SO_4 were obtained by storing in vacuo at 200°C for 4 h before use. ^1H and ^{13}C NMR spectra were initially recorded on a solution containing pure **1** (2.03 mmol), CH_2I_2 (1.05 mmol, internal proton standard, δ_H = 3.89 ppm and δ_C = −66.26 ppm), and TMS in $CDCl_3$ (2.0 mL). The integral ratio observed for H singlet peaks was 0.93:1.00 (**1** vs. CH_2I_2). This solution was equilibrated five times at room temperature, for 15 min each time, with D_2O (1.0 mL) containing NaCl (1.0 mmol), then finally dried over Na_2SO_4. ^1H NMR spectrum: ratio H(**1**):H(CH_2I_2) = 0.0028 (indicating a practically complete H/D exchange); ^{13}C NMR spectrum: C(=O), C(F_3), and C(H_2I_2) resonated at the same frequencies with patterns unchanged from the original solution; C-D (triplet, J_{CD} = 30.1 Hz) at 55.70 (central peak) ppm. H-D interchange was equally successful when neat **1** was shaken five times during 15 min at room temperature with the same ratio of D_2O (NaCl) and subsequently dried over Na_2SO_4. The IR spectrum of *d*-**1** is reported in Fig. 7 and the EI mass spectrum in Fig. 3.

Probe of cadmium(II) binding on soil fulvic acid investigated by ^{113}Cd NMR spectroscopy

Kun H. Chung, Seog W. Rhee, Hyun S. Shin, and Christopher H. Moon

Abstract: Binding of cadmium(II) on soil fulvic acid (FA) was investigated over a range of fulvate-to-cadmium concentration ratios (8 – 59 equiv. mol^{-1}) using ^{113}Cd NMR spectroscopy. The ^{113}Cd chemical shift of cadmium bound on fulvate was observed in a more downfield region (δ −20.4 to −15.6) than that bound on synthetic polymers, poly(acrylic acid) (PAA: δ −36.6 to −38.2), poly(methacrylic acid) (PMAA: δ −34.0 to −25.4), and poly(vinyl benzoic acid) (PVBA: δ −34.7 to −31.2). The calculated values of individual chemical shifts for the species CdL^+ and CdL_2 (L: carboxylate) formed in Cd(II)–carboxylate systems (e.g., acetate, benzoate) are δ −22 to −24 and δ −39 to −40, respectively. The relative downfield shift of cadmium(II)–fulvate suggests that functional groups (e.g., hydroxyl and neutral N donor) other than carboxylates may be involved in cadmium coordination. The chemical shifts of cadmium complexes of hydroxycarboxylates (e.g., glycolate) or carboxylates containing neutral N donor (e.g., picolinate) were generally observed in more downfield regions than their carboxylate counterparts.

Key words: fulvic acid, polyfunctionality, binding sites, chemical shift, ^{113}Cd NMR.

Résumé : On a étudié, par spectroscopie de RMN du ^{113}Cd, les sites de liaison du cadmium(II) sur l'acide fulvique (AF) impur en utilisant un intervale de concentration de fulvate : cadmium (8–59 équiv. mol^{-1}). On a observé que les déplacements chimiques du ^{113}Cd, du cadmium lié au fulvate, se situent à champ plus faible (δ −20,4 à −15,6) que les polymères synthétiques, acide polyacrylique (APA : δ −36,6 à −38,2), acide polyméthacrylique (APMA : δ −34,0 à −25,4) et acide polyvinylbenzoique (APVB : δ −34,7 à −31,2). Les valeurs calculées des déplacements chimiques individuels des espèces CdL^+ et CdL_2 (L = carboxylate) formées dans le système Cd(II)–carboxylate (acétate, benzoate par exemple) sont respectivement δ −22 à −24 et δ −39 à −40. Le déplacement chimique relativement faible du complexe cadmium(II)–fulvate suggère que des groupes fonctionnels (par exemple hydroxyle et un donneur neutre d'azote) autres que les carboxylates peuvent être impliqués dans la coordination du cadmium. Les déplacements chimiques des complexes de cadmium des hydrocarboxylates (par exemple le glycolate) ou des carboxylates contenant des donneurs neutres d'azote (par exemple un picolinate) sont généralement observés à des champs plus faibles que leur contrepartie carboxylates.

Mots clés : acide fulvique, polyfonctionnalité, sites de liaison, déplacement chimique, RMN du ^{113}Cd.

Introduction

Heavy metal contamination of the environment is caused by the wide usage of heavy metals in industries to meet the demands of modern society. In wastewater matrices, the speciation of some heavy metals is dominated by organic complexes, and their characterization is an important aspect of speciation in such matrices (1). In soil matrices, the biological availability of environmental trace metals is influenced strongly by complexes formed with soil organic matters such as humic substances (2). Complexation of trace metals by humic substances is also important in determining their fate in the environment (3).

Studies of the complexation of trace metals (e.g., Cu^{2+}, Cd^{2+}, Pb^{2+}) with humic substances are reported in the literature (4–8). The stability constants of the complexes thus formed have been evaluated using many different modeling techniques, leading to some conflict in the information obtained (9, 10). One cause of uncertainty is in regard to the nature of metal ion binding by humic substances. From the results of base titration, Stevenson et al. indicated the formation of 1:1 and 1:2 complexes (CuL^+ and CuL_2: L are active sites) when Cu^{2+} ions are bound to humic acid (2). Marinsky and Anspach found CuL_2 to be predominant when Cu^{2+} ion is complexed to PMAA gel at a higher neutralization range (11). More recently a joint study with Miyajima was carried out by us on cadmium(II) binding by PAA using potentiometric titration, and the preliminary result shows the formation of 1:1 and 1:2 complexes. By contrast, Perdue and Lytle applied a multiligand model for binding of proton and metal ions by humic acid (12).

In this work, we report the result of our study of the binding of cadmium(II) by a soil fulvic acid as characterized by ^{113}Cd NMR spectroscopy. ^{113}Cd NMR spectroscopy has been used in studies of the structure and dynamics of inorganic and bioinorganic molecules (13–16). The utility of ^{113}Cd NMR as a metallobioprobe is due to the ability of cadmium(II) ion to form complexes over a range of conformation and ligand numbers: ^{113}Cd has a spin of 1/2 with no quadrupolar contri-

bution to cause NMR relaxation, which broadens the NMR signals. A chemical shift range of over 900 ppm has been observed for ^{113}Cd, depending upon the nature, number, and geometric arrangement of the coordinated ligands (17–22). Fulvic acids possess a variety of functional groups that can bind with metal ions (3). Several types of carboxylic acids, polyfunctional carboxylic acids, and synthetic polymers were used as model ligands in this study.

Experimental

Materials

Fulvic acid used in the experiment was isolated from air-dried soil from the Okchun Basin as described previously (23). Briefly, humic substances were extracted from air-dried soil (1.5 kg) with 15 dm^3 of 0.1 mol dm^{-3} NaOH under N_2 atmosphere. The humic acid fraction was separated by acid precipitation (pH 1) with 6 mol dm^{-3} HCl. The FA fraction remaining in the supernatant was isolated by sorbing it on a column of XAD-8 resins. The sorbed FA fraction was eluted with 0.1 mol dm^{-3} NaOH, and converted to a protonated form using a cation exchange column of Dowex 50X8 (H^+) to remove Na^+. The protonated final product was freeze-dried (C: 51.2 ± 0.5%, H: 4.5 ± 0.2%, O: 41.0 ± 1.0%, N: 2.2 ± 0.1%, and S: 0.2 ± 0.1%). PAA (MW: 5000 daltons) and organic acids were purchased from Aldrich and were used without further purification. PMAA and PVBA were prepared by a radical polymerization technique with AIBN (azobisisobutyronitrile) in ethanol solution and characterized according to procedures given in the literature (24). Cadmium solution was prepared by dissolving $Cd(ClO_4)_2 \cdot 6H_2O$ (Alfa) in doubly deionized water. The isotopically enriched cadmium solution was prepared by dissolving 95.8% ^{113}Cd-enriched metal (Isotec Inc.: Product No. 77-066-01-7; 0.5 g) in an aliquot of hot concentrated $HClO_4$, then diluting with doubly deionized water to 0.10 mol dm^{-3}.

Instrumentation

The ^{113}Cd NMR investigation was performed on a Brucker AM 300 spectrometer operating at 66.576 MHz. All NMR measurements were made with an outer 10 mm NMR tube containing the sample solutions, and a sealed 5 mm inner tube with 0.1 mol dm^{-3} $Cd(ClO_4)_2$ aqueous (D_2O) solution; 0.1 mol dm^{-3} $Cd(ClO_4)_2$ was the reference material and D_2O solvent was used as an external lock to keep the field of homogeneity. The temperature of the samples was kept constant at 24°C by flowing heated air around the tube mounted coaxially in the probe head. Positive chemical sifts are downfield from the reference and indicate decreased shielding. The spectra for Cd(II) – organic acids were obtained using a 30° pulse width (6 μs), acquisition time of 0.885 s, and a relaxation delay of 2.2 s (0.2 s for Cd(II)–polymers and Cd(II)–fulvate). The spectra of Cd(II)–polymers and Cd(II)-fulvate required 50 000–60 000 transients. The solid state ^{113}Cd NMR spectrum was obtained from ca. 0.5 g of a freshly prepared moist precipitate of Cd(II)–fulvate using MAS technique. The delay time was 5 s and the rotor speed was set at 4.0 kHz (collected number of scans, 1500).

Sample preparation

Stock solutions of FA, PMAA, PAA, and PVBA (50.0 cm^3, 0.30 equiv. dm^{-3}) were prepared as follows: 1.990 g of FA was dissolved in 8.0 cm^3 of 1.0 mol dm^{-3} NaOH and diluted with doubly ionized water to a final volume of 50.0 cm^3 and the pH adjusted to 6.0. The total acidity of the acids was measured by pH titration (25) and these values were used to obtain stock solutions with the same concentration given in equiv. dm^{-3}: The measured total acidity of FA, PMAA, PAA, and PVBA is 7.6, 12, 14, 7.0 mequiv. g^{-1}, respectively. An initial sample solution was prepared by mixing 4.0 cm^3 of the stock solution with 1.0 cm^3 of 0.1 mol dm^{-3} cadmium perchlorate solution (95.8% ^{113}Cd-enriched). Subsequently all other sample solutions of a series were prepared by dilution of the initial solution with the stock polymer solution, thereby changing the cadmium concentration in the sample while keeping the polymer concentration constant at 0.24 equiv. dm^{-3}. The sample solutions were kept in darkness over 2 days, with occasional shaking, to equilibrate. Approximately 2 cm^3 of each sample was placed in a 10 mm NMR tube for NMR analysis. A series of sample solutions were also prepared for each organic acid used as model ligand, where $Cd(ClO_4)_2$ was kept constant at 5.56×10^{-2} mol dm^{-3} and the organic acid concentration was varied from 0.025 to 0.6 mol dm^{-3}. All the sample solutions were adjusted to pH 6.0 using $HClO_4$ and NaOH (carbonate free, Baker Co.), and the pH was measured using a glass electrode coupled to a digital pH meter (Metrohm type 632).

Results and discussion

The ^{113}Cd NMR spectra of Cd(II)–fulvate were obtained over a fulvate-to-cadmium ratio of 8–59 equiv. mol^{-1} and they are shown in Fig. 1. At concentration ratios of 8 equiv. mol^{-1} and above (up to 59 equiv. mol^{-1}), Cd(II)–fulvate remained stable in solution, and it was possible to obtain a single averaged chemical shift. A plot of the chemical shift change (δ −20.4 to −15.6) versus fulvate-to-cadmium ratio is shown in Fig. 2. Below 8 equiv. mol^{-1}, the Cd(II)–fulvate formed precipitates. The spectrum of a freshly prepared precipitate of Cd(II)–fulvate is shown in Fig. 3. A freeze-dried precipitate gave a very broad and unresolved spectrum, but moistening the precipitate with a little water (w/w 15%) produced a spectrum of good signal-to-noise ratio with a chemical shift of δ −25 for the solid sample.

Majidi et al. investigated the metal–algae binding site using ^{113}Cd NMR spectroscopy, and observed a chemical shift of δ −10 to −18 for cadmium(II) bound on cell walls, indicative of the metal uptake by carboxylate groups (26). In the characterization of Cd(II) binding sites on *Datura innoxia*, Ke and Rayson obtained chemical shift data indicative of carboxylate–Cd(II) interaction in a 2:1 ratio (27). The observed chemical shift of Cd(II)–fulvate in solution (δ −20.4 to −15.6) and as solid (δ −25) seem to indicate that the bound cadmium ions are coordinated to carboxylate groups. Recently, an investigation of Cd(II)–carboxylate systems (mono- and di-carboxylic acids) in aqueous solution was carried out using ^{113}Cd NMR spectroscopy (28). A single averaged chemical shift was obtained even at reduced temperature (25° to −90°C in ethanol), showing that the species formed in Cd(II)–carboxylate systems are undergoing rapid exchange in solution. Using known stability constants, the individual chemical shifts were calculated to be in the range δ −22 to −24 and δ −39 to −40 for CdL^+ and CdL_2 (L = carboxylate) species. In Cd(II)–car-

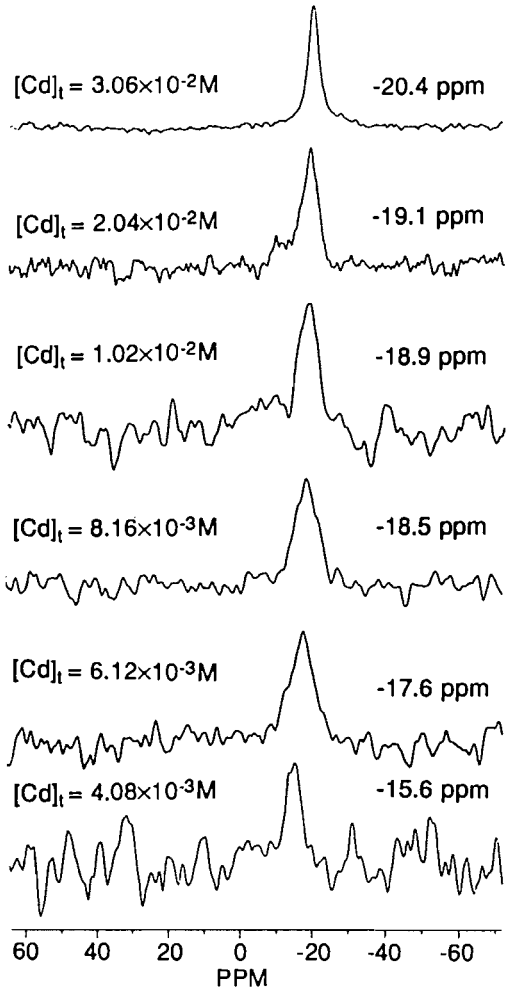

Fig. 2. Plots showing the ^{113}Cd chemical shift changes due to variation of the [polymer]/[Cd(II)] ratio: (*a*) FA, (*b*) PMAA, (*c*) PVBA, and (*d*) PAA.

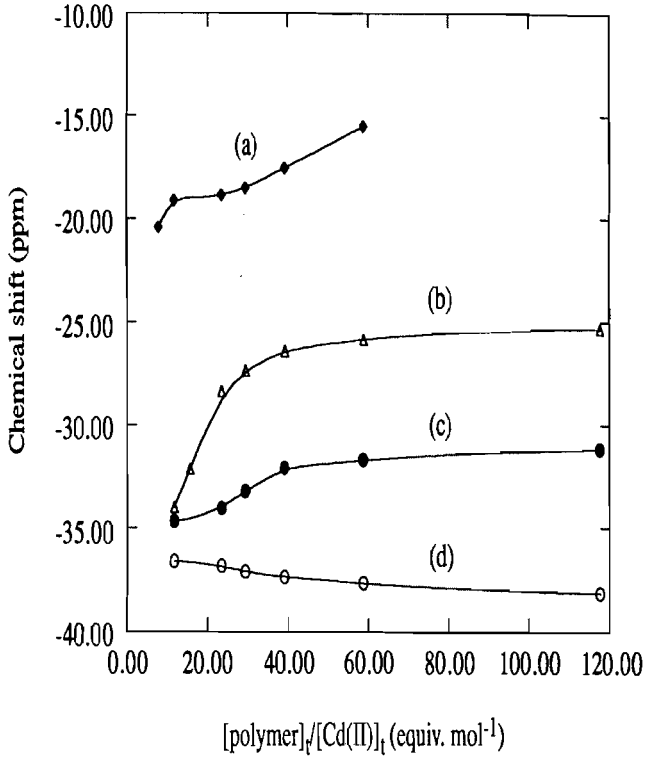

Fig. 3. ^{113}Cd MAS NMR spectrum of Cd(II)–fulvate precipitate.

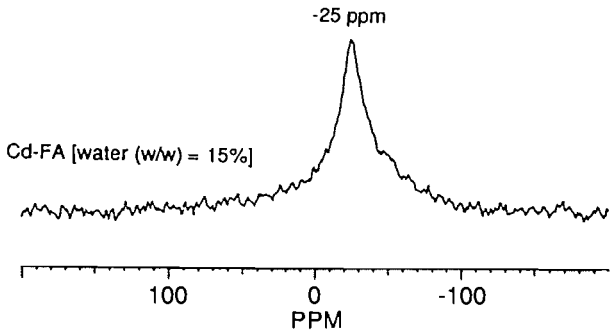
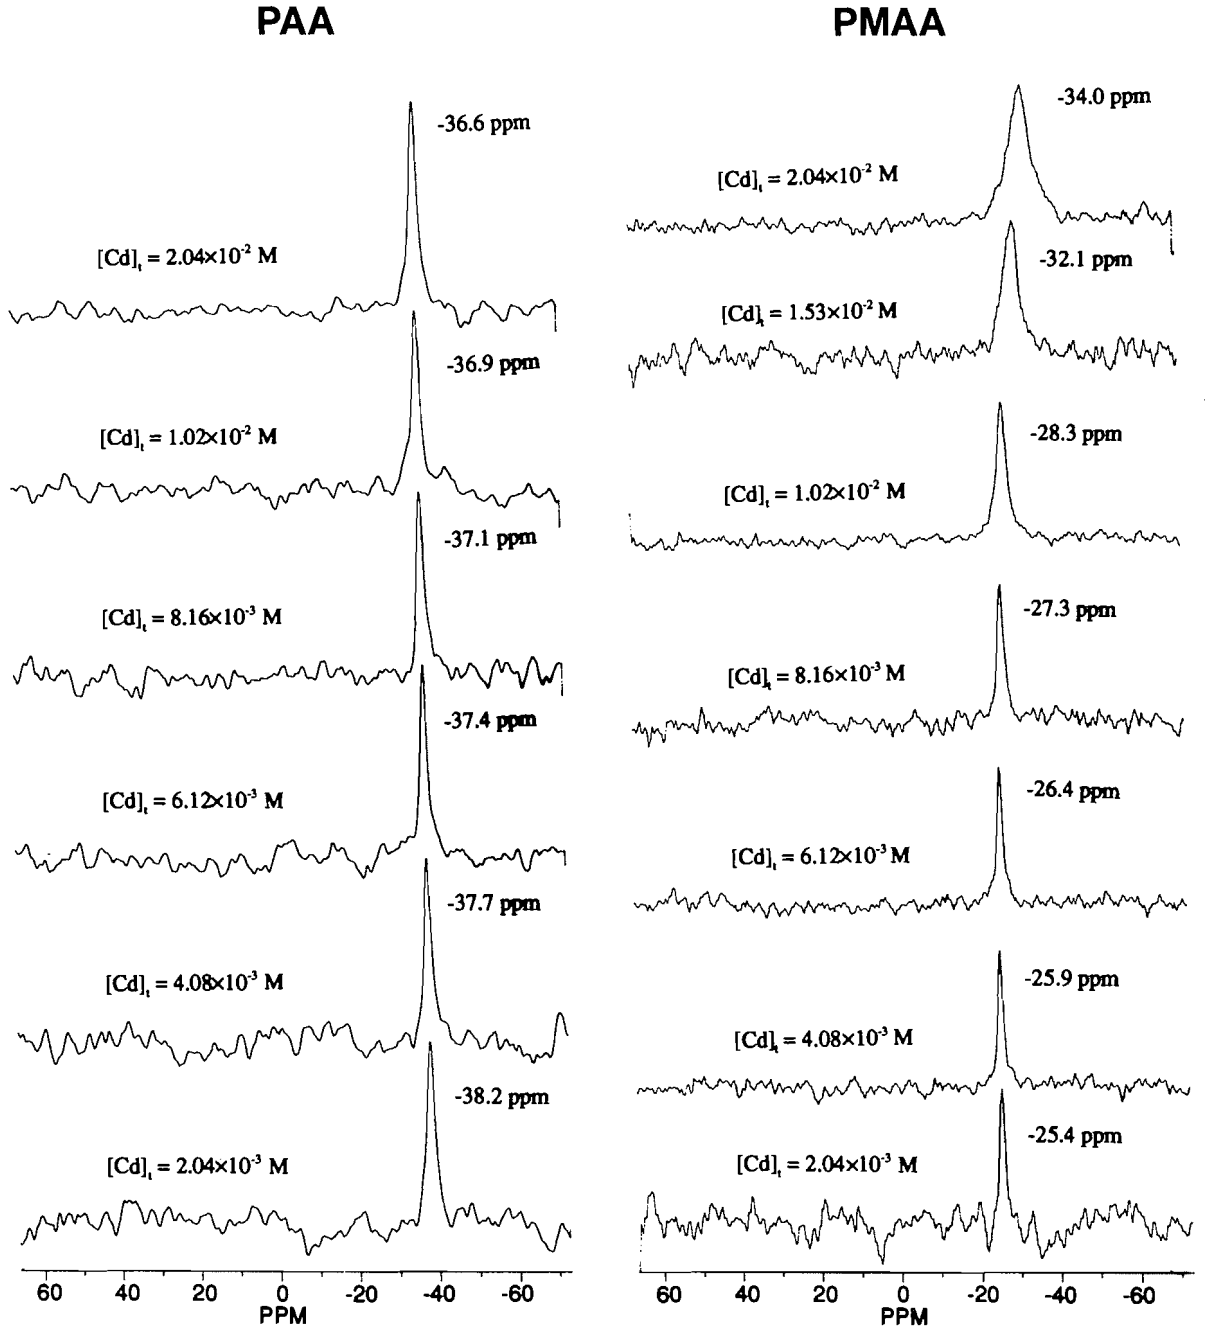


boxylate systems, an increase in the carboxylate-to-cadmium ratio caused the chemical shift to move towards an upfield region: the cadmium ion becomes more shielded when coordinated water molecules are displaced by carboxylates. However, quite the opposite trend was observed for the Cd(II)–fulvate system: an increase of fulvate-to-cadmium ratio caused the chemical shift to move towards a downfield region (less shielding). From surface pressure and viscosity measurements, Ghosh and Schnitzer proposed a model changing humic substances from a flexible "linear molecule" to a rigid "spherocolloid" (29). The ^{113}Cd NMR spectra of cadmium bound on synthetic model polymers PAA, PMAA, and PVBA were obtained at the concentration ratio 12 to 118 equiv. mol^{-1}. The ^{113}Cd NMR spectra of Cd(II)–PAA and –PMAA are shown in Fig. 4 as examples. In the Cd(II)–PAA system, an increase in the PAA-to-cadmium ratio caused the chemical shift towards an upfield region (more shielding) in a manner observed in Cd(II)–carboxylate systems. However, quite different chemical shift changes were observed in the Cd(II)–PMAA and –PVBA systems: an increase of polymer-to-cadmium ratio caused the chemical shift to change to a downfield region (less shielding). The cause for this apparent difference in the chemical shift change behaviour of PMAA and PVBA, and PAA remains unclear. Different chemical shift behavior was also reported for the binding of sodium ion on PMAA and PAA investigated by ^{23}Na NMR, and this was attributed to their structural differences (30).

The ^{113}Cd NMR chemical shift is highly sensitive to the types of donor atoms, coordination number, and geometry (17–22). The results of the ^{113}Cd NMR study with model carboxylate ligands (monomers and polymers) show that when the coordination environment of the cadmium ion is made up solely of carboxylates and water molecules, then the chemical shifts seem to appear at a more upfield region (more shielding) than for Cd(II)–fulvate. This apparent difference in the chem-

Fig. 4. ^{113}Cd NMR spectra of cadmium(II) bound on PAA and PMAA in aqueous solution: $[polymer]_t = 0.24$ equiv. mol^{-1} and pH = 6



ical shift may be caused by the presence of a diversity of functional groups (carboxylate, phenolic -OH, alcoholic -OH, and minor amounts of N) of fulvic acid, creating a multiligand coordination environment for the cadmium ion. There are several examples of cadmium(II) complexes formed by other model ligands that gave chemical shifts in more downfield regions. One such example may be coordination of cadmium(II) by a malonate-like moiety of fulvic acid. This moiety is shown in one of the average structures proposed for Suwannee River fulvic acid by the U.S. Geological Survey (31). Malonate is capable of forming a six-membered chelate ring (η^5) with cadmium ion. An increase of the malonate-to-cadmium ratio caused the chemical shift to change more gradually towards an upfield region and approached a steady value of δ −19 (28), which lies close to the chemical shift range of Cd(II)–fulvate. The second group of examples may be complexes of cadmium(II) formed by hydroxycarboxylic acids as ligands: specifically those with an -OH attached to the α- and β-carbons (e.g., glycolic, gluconic, 3-hydroxybutanoic, and malic acids) are observed in a more downfield region than

Fig. 5. Plots showing the ^{113}Cd chemical shift change of Cd(II)–hydroxycarboxylate and –carboxylate complexes: (*a*) glycolic acid, (*b*) gluconic acid, (*c*) malic acid, (*d*) 3-hydroxybutanoic acid, (*e*) acetic acid, (*f*) propanoic acid, and (*d*) succinic acid.

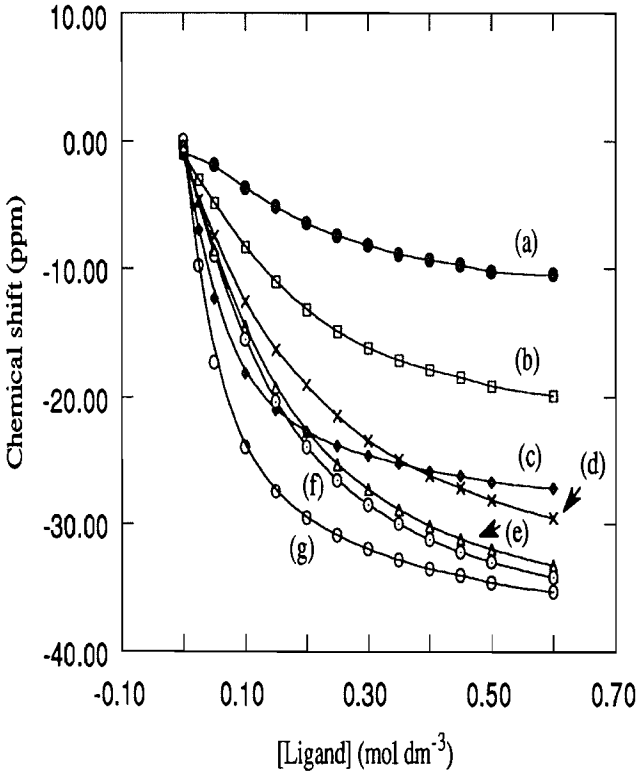


Fig. 6. Plots showing the ^{113}Cd chemical shift change of Cd(II)–carboxylates possessing a neutral N donor: (*a*) picolinic acid, (*b*) methylpicolinic acid, (*c*) dipicolinic acid, and (*d*) nicotinic acid.

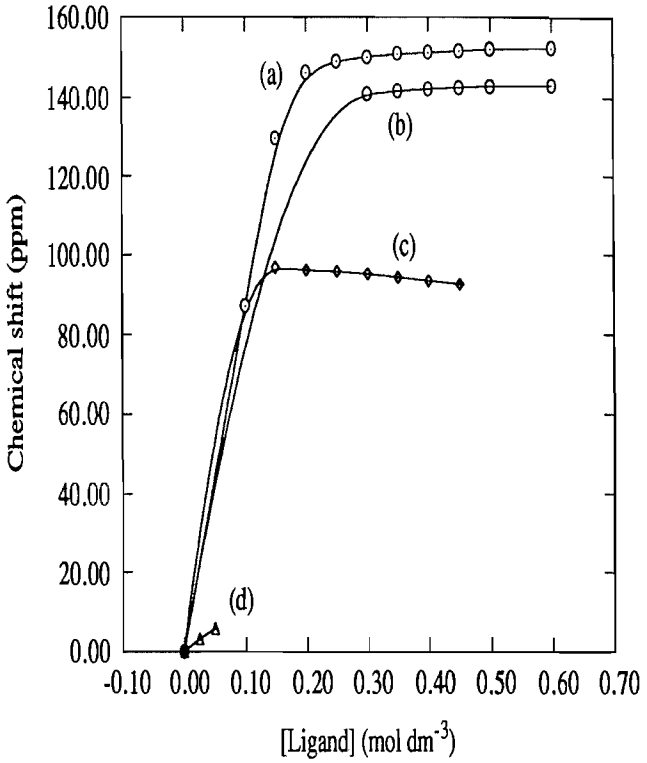

their carboxylic acid counterparts (e.g., acetic, propanoic, and succinic acids). Plots of chemical shift change versus ligand concentration are shown in Fig. 5. The changes for cadmium(II) complexed to those ligands capable of forming five- and six-membered chelate rings (η^4 and η^5) are displayed more downfield. It has been suggested that a probable strong copper(II) binding site may include the phenolic group (4, 5, 32). A salicylate-like moiety may be a possible strong binding site for cadmium ion, but this was not investigated due to precipitate formation. Other possible examples are those complexes of cadmium coordination by a neutral N donor: The minor sites of fulvic acid are said to include neutral N donors. The soil fulvic acid contained approximately 2.2% nitrogen, and the proposed average structure included a neutral N donor (23). The chemical shift changes of complexes of cadmium(II) coordinated to carboxylic acids containing a neutral N donor (e.g., nicotinic, picolinic, and dipicolic acids) are shown in Fig. 6. Much larger downfield shifts are observed in these cadmium(II) complexes: cadmium(II) ion is deshielded by coordinating the neutral N donor group of these ligands (17, 18, 33).

Summary

^{113}Cd NMR spectroscopy has been applied to a study of cadmium(II) binding by a fulvic acid. The chemical shifts of Cd(II)–fulvate seem to reflect the rapidly exchanging conditions in aqueous solution and involve many species that formed by a diversity of functional groups of fulvic acid.

The acid-catalyzed demetalation of 1-(tri-*n*-butylstannyl)-2-phenylethyne. A surprisingly small β-stannyl effect

I. Egle, V. Gabelica, A.J. Kresge, and T.T. Tidwell

Abstract: Rates of conversion of 1-(tri-*n*-butylstannyl)-2-phenylethyne to phenylethyne in H_2O and D_2O solutions of perchloric acid were found to be proportional to acid concentration, giving the hydronium ion rate constant $k_{H^+} = 1.85 \times 10^{-2}$ M^{-1} s^{-1} and the isotope effect $k_{H^+}/k_{D^+} = 3.10$. The magnitude of this isotope effect suggests that the reaction occurs by rate-determining hydron transfer to the substrate, producing a vinyl carbocation; this carbocation then loses its tributylstannyl group, giving phenylacetylene as the only detectable aromatic product. The hydronium ion rate constant, when compared to the rates of protonation of phenylethyne and 1-(trimethylsilyl)-2-phenylethyne, gives a β-stannyl stabilizing effect of $\delta\Delta G^{\ddagger} = 6.6$ kcal mol^{-1} and a differential β-stannyl/β-silyl effect of $\delta\Delta G^{\ddagger} = 3.2$ kcal mol^{-1}. These stabilizations are very much smaller than previously reported β-stannyl effects. Possible reasons for the difference are suggested.

Key words: β-stannyl effect, β-silyl effect, carbocation stabilization, protodemetalation.

Résumé : On a trouvé que les vitesses de conversion du 1-(tri-*n*-butylstannyl)-2-phényléthyne en phényléthyne, en solutions d'acide perchlorique dans du H_2O et dans du D_2O, est proportionnelle à la concentration d'acide; la constante de vitesse de l'ion hydronium $k_{H^+} = 1{,}85 \times 10^{-2}$ M^{-1} s^{-1} et l'effet isotopique $k_{H^+}/k_{D^+} = 3{,}10$. L'amplitude de cet effet isotopique suggère que la réaction se produit par une étape déterminant la vitesse au cours de laquelle il y a transfert d'un hydron au substrat conduisant à la formation d'un carbocation vinylique; ce carbocation perd alors son groupe tributylstannyle ne donnant que du phénylacétylène comme seul produit aromatique pouvant être détecté. Lorsqu'on compare la constante de vitesse de l'ion hydronium aux vitesses de protonation du phényléthyne et du 1-(triméthylsilyl)-2-phényléthyne, on en déduit l'effet stabilisant du groupe β-stannyle, $\delta\Delta G^{\ddagger} = 6{,}6$ kcal mol^{-1}, ainsi que la différence entre les effets β-stannyle et β-silyle, $\delta\Delta G^{\ddagger} = 3{,}2$ kcal mol^{-1}. Ces stabilisations sont beaucoup plus faibles que celles rapportées antérieurement pour les effets β-stannyles. On suggère diverses raisons possibles pour la différence.

Mots clés : effet β-stannyle, effet β-silyle, stabilisation du carbocation, protodémétallation.

[Traduit par la rédaction]

It is well known that silyl substituents in the β-position stabilize carbocations strongly (for reviews, see ref. 1), and other Group IV A metals lying below silicon in the periodic table have even more powerful effects. For example, a stannyl substituent in the β-position was found to accelerate the rate of solvolysis of a cyclohexanol ester over that of the unsubstituted substrate by a factor much in excess of 10^{14} (2), and the remarkably large stannyl/silyl rate ratio of 10^8 was observed in the protonation of metalated acetylenes (3). We were surprised to discover, therefore, that the stannyl group in 1-(tri-*n*-butylstannyl)-2-phenylethyne raises the rate of vinyl cation formation by protonation of this substance, eq. [1]1 (X = $SnBu_3$), over that for phenylacetylene, eq. [1] X = H, by a factor of only 6.5×10^4, and that comparison with the corresponding silyl system, eq. [1] X = $SiMe_3$, gives a stannyl/silyl rate ratio of only 2.1×10^2.

Experimental section

Materials

1-(Tri-*n*-butylstannyl)-2-phenylethyne was prepared by treating lithium phenylacetylide with tributyltin chloride (4). All other materials were best available commercial grades.

Kinetics

Rates of demetalation of 1-(tri-*n*-butylstannyl)-2-phenylethyne were determined by monitoring the decrease in its absorbance at λ = 266 nm. Measurements were made using a Cary 2200 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.05°C. Reactions were initiated by adding 10-μL aliquots of acetonitrile solutions of substrate to 3-mL quantities of perchloric acid solutions contained in quartz cuvettes, which had first been allowed to come to temperature equilibrium with the spectrometer cell compartment. The substrate was poorly soluble in both acetonitrile and aqueous acids, and dissolution was promoted by a few seconds' immersion in an ultrasonic bath. The kinetic data conformed well to the first-order rate law and observed rate constants were eval-

uated by least-squares fitting of an exponential function. Acid concentrations of the reaction mixtures were determined by titrating weighed aliquots.

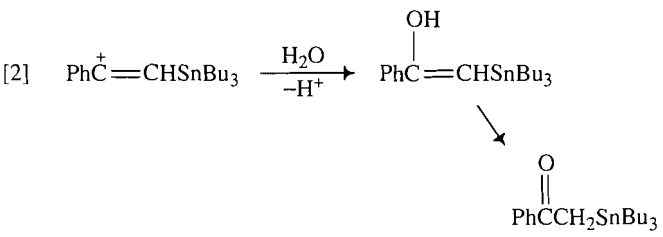
Results and discussion

Reaction mechanisms

Rates of reaction of 1-(tri-*n*-butylstannyl)-2-phenylethyne were measured in H_2O and D_2O solutions of perchloric acid over the concentration range [Acid] = 0.03 – 0.2 M. The data are summarized in Table S1[2] and are displayed in Fig. 1. It may be seen that observed first-order rate constants are accurately proportional to acid concentration in both solvents. Linear least-squares analysis of the data gave the hydronium ion rate constants $k_{H+} = (1.85 \pm 0.04) \times 10^{-2}$ M^{-1} s^{-1} and $k_{D+} = (5.96 \pm 0.20) \times 10^{-3}$ M^{-1} s^{-1}, whose ratio provides the isotope effect $k_H/k_D = 3.10 \pm 0.12$.

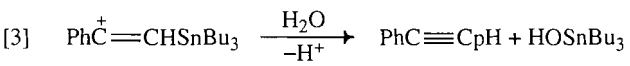
Isotope effects on hydron transfer from the hydronium ion consist of an inverse ($k_H/k_D < 1$) secondary component in addition to the normal ($k_H/k_D > 1$) primary component (5), and overall values consequently tend to be small. The effect determined here is, in fact, close to the maximum expected value, and this provides strong evidence that the process under examination is indeed a rate-determining hydron transfer from the hydronium ion to the substrate, as shown in eq. [1].

The cation formed in this process will then either be captured by water, giving an enol that will subsequently tautomerize to a stannyl-substituted ketone, as shown in eq. [2], or the cation will lose its stannyl group giving phenylacetylene and



[2] $PhC^{+}{=}CHSnBu_3 \xrightarrow[-H^+]{H_2O} PhC(OH){=}CHSnBu_3 \rightarrow PhCCH_2SnBu_3$ (O)

tributylstannanol, as shown in eq. [3]. HPLC analysis of spent reaction mixtures showed phenylacetylene to be the only aro-



[3] $PhC^{+}{=}CHSnBu_3 \xrightarrow[-H^+]{H_2O} PhC{\equiv}CpH + HOSnBu_3$

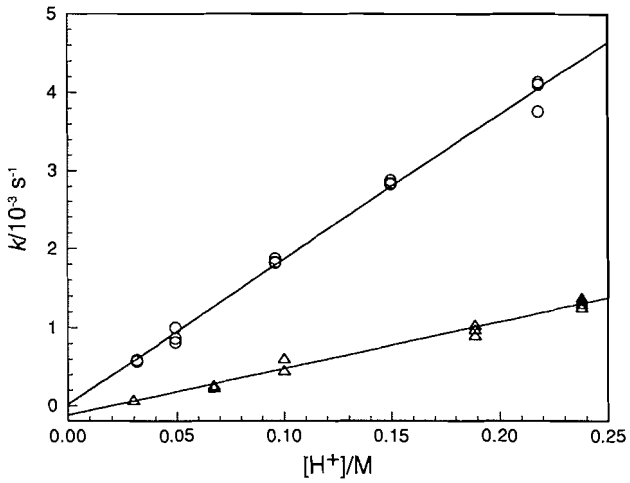
matic product formed, indicating that the reaction is indeed a demetalation as shown in eq. [3].

Reactivity

The presently determined rate constant for the protonation of 1-(tri-*n*-butylstannyl)-2-phenylethyne, when compared to the rate of protonation of its unmetalated analog, phenylacetylene (6), shows that the stannyl group accelerates the rate of reaction some 65 000-fold and gives a β-stannyl effect of $\delta\Delta G^{\ddagger} = 6.6$ kcal mol^{-1}. Comparison with the corresponding trimethylsilyl analog, 1-(trimethylsilyl)-2-phenylethyne (7), shows the stannyl substituent to be better than the silyl group by a factor of 210 and gives a differential β-stannyl/β-silyl effect of $\delta\Delta G^{\ddagger} = 3.2$ kcal mol^{-1}.

[2] Table S1 of rate data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Fig. 1. Relationship between rates of protonation of 1-(tri-*n*-butylstannyl)-2-phenylethyne and acid concentration in aqueous perchloric acid solution at 25°C; ○: H_2O, Δ: D_2O.



These are substantial effects, but they pale in comparison to the much larger β-stannyl stablizations observed in other systems (2, 3). The difference between the present result and the previously reported stannyl/silyl rate ratio of 5.1×10^7, corresponding to $\delta\Delta G^{\ddagger} = 10.5$ kcal mol^{-1}, is especially striking, for in both cases the reaction examined involved proton addition to a carbon–carbon triple bond.

There are, however, important differences between the present and this previous system. The previous study involved proton addition to a trimethylsilylacetylene with either another trimethylsilyl group or a tributylstannyl group at the other end, eq. [4], while in the present case addition was to a phenylacetylene with the metallic group at the other end, eq. [5]. In the previous system therefore, the vinyl cation formed had its positive charge next to a silyl substituent, whereas in

[4] $Me_3SiC{\equiv}CMR_3 \xrightarrow{H^+} Me_3Si\overset{+}{C}{=}CHMR_3$

[5] $PhC{\equiv}CMR_3 \xrightarrow{H^+} Ph\overset{+}{C}{=}CHMR_3$

the present case the charge was next to a phenyl group. Since silicon is not very effective at stabilizing an adjacent positive charge (1), while phenyl stabilizes such charge very well, there would be less demand for additional stabilization from the metallic substituent in the phenyl system and the β-metal effect would consequently be reduced. A similar phenyl-induced reduction of the β-silyl effect has been found in the protonation of additionally substituted trimethylsilylacetylenes, eq. [6], where a change from R = Me or *n*-Bu to R = Ph

[6] $RC{\equiv}CSiMe_3 \xrightarrow{H^+} R\overset{+}{C}{=}CHSiMe_3$

cut the β-silyl effect in half, from $\delta\Delta G^{\ddagger} = 6.5$ kcal mol^{-1} to $\delta\Delta G^{\ddagger} = 3.4$ kcal mol^{-1} (8).

Another difference between the previous study involving proton addition to acetylenes and the present work is that the previous reactions were carried out in chloroform solution while in the present case the solvent was water. Water is much more polar than chloroform and consequently much better at solvating ions such as the vinyl cations formed in these reac-

tions. The stabilization provided by the better solvation in the present case would once again reduce the demand for additional stabilization from the metal and lead to a smaller β-metal effect.

A reaction mechanism in which proton addition to the acetylene is concerted with metallic group loss would also lead to a reduced β-metal effect, for such a process would lower the amount of positive charge generated on the substrate in the position β to the metal. It is unlikely, however, that the metallic group would leave unassisted as a free cation, and such a process would consequently probably involve nucleophilic displacement at the metal by a water molecule, as shown in eq. [7]. In the transition state of this process, the attacking water

[7] 
molecule would be taking on positive charge, and that would contribute an additional normal ($k_H/k_D > 1$) component to the solvent isotope effect. The large solvent isotope effect actually observed is consistent with this explanation. On the other hand, it is not clear why such nucleophilic assistance should not have occurred in the previously studied systems, reducing the magnitude of the β-silyl effect there as well. Nucleophilic assistance by the carboxylic acid proton donor was in fact suggested in one of the previous studies (3) as a possible explanation for the observation that the rate of reaction decreased with increasing bulk of the aliphatic ligand attached to the metal,

Acid-catalyzed hydrolysis of 4-diazo-3-isochromanone: the effect of coplanarity on the carbon protonation of α-phenyl-α-carbonyldiazo compounds

E.A. Jefferson, A.J. Kresge, and S.W. Paine

Abstract: Hydrolysis of the cyclic α-phenyl-α-carbonyl-diazo compound, 4-diazo-3-isochromanone, in dilute aqueous perchloric acid solutions was found to give the hydronium ion isotope effect $k_{H^+}/k_{D^+} = 2.12$, which shows that this reaction occurs by rate-determining hydronation of the substrate on the carbon atom α to its diazo group. Comparison of the rate constant obtained, $k_{H^+} = 2.48 \times 10^{-3}$ M^{-1} s^{-1}, with that for the corresponding acyclic analog, methyl phenyldiazoacetate, indicates that the cyclic compound is 57 times less reactive. Semi-empirical AM1 molecular orbital calculations suggest that this difference in reactivity is caused by enforced near-coplanarity of the diazo and phenyl groups in the cyclic substrate, as opposed to a staggered arrangement of these groups in the acyclic analog; this coplanarity then enhances delocalization of negative charge from the diazo α-carbon atom into the phenyl group, which reduces the negative charge density on the α-carbon atom and slows the rate of reaction.

Key words: hydrolysis, diazoalkanes, charge delocalization, AM1 calculations.

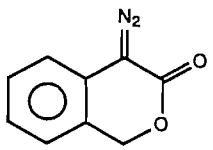
Résumé : On a trouvé que l'hydrolyse du composé α-phényl-α-carbonyldiazo cyclique, 4-diazo-3-isochromanone, en solutions diluées d'acide perchlorique est accompagnée d'un effet isotopique de l'ion hydronium $k_{H^+}/k_{D^+} = 2{,}12$ qui indique que l'étape déterminant la vitesse de réaction implique une hydronation du substrat au niveau de l'atome de carbone en α du groupe diazo. Une comparaison de la constante de vitesse obtenue, $k_{H^+} = 2{,}48 \times 10^{-3}$ M^{-1} s^{-1}, avec celle de l'analogue acyclique correspondant, le phényldiazoacétate de méthyle, indique que le composé cyclique est 57 fois moins réactif. Des calculs semi-empiriques d'orbitales moléculaires AM1 suggèrent que cette différence de réactivité résulte du fait que, dans le substrat cyclique, les groupes diazo et phényles sont maintenus dans une position pratiquement coplanaire alors que, dans l'analogue acyclique, ils adoptent un arrangement décalé; cette coplanérité augmente la délocalisation de la charge négative de l'atome de carbone en α du diazo vers le groupe phényle, ce qui a pour effet de réduire la densité de la charge négative au niveau de l'atome de carbone en α et de réduire la vitesse de la réaction.

Mots clés : hydrolyse, diazoalcanes, délocalisation de la charge, calculs AM1.

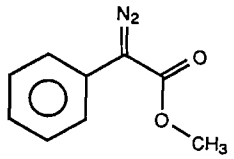
[Traduit par la rédaction]

There is much current interest in the chemistry of ketenes (see, for example, ref. 1), which are a useful class of substances that can be made by the Wolff rearrangement of α-carbonyldiazo compounds (for a brief review, see ref. 2). The utility of α-carbonyldiazo compounds in this respect, however, is limited by the fact that they also undergo facile acid-catalyzed hydrolysis. Information on the nature of this acid-catalyzed reaction, especially how its rate depends on substrate structure, is consequently of some practical value.

In this paper we report the results of an investigation of the hydrolysis of 4-diazo-3-isochromanone, **1**, catalyzed by the hydronium ion in aqueous solution. We have found that this reaction is substantially slower than the corresponding hydrolysis of the acyclic analog, methyl phenyldiazoacetate, **2** (3).



1



2

Semi-empirical AM1 molecular orbital calculations suggest that this difference in reactivity is due to an enforced near-coplanarity of the diazo and phenyl groups in the cyclic substrate **1**, as opposed to a staggered structure adopted by the acyclic substance **2**.

using a literature procedure (4). The product, an orange solid, mp 48–49°C, was obtained in 63% yield. Its spectral properties are: IR, ν/cm^{-1}: 2092 (C=N_2), 1692 (C=O); ^{1}H NMR (200 MHz, $CDCl_3$); δ/ppm: 7.41–6.92 (m, 4H, Ar), 5.32 (s, 2H, CH_2); ^{13}C NMR (50 MHz, $CDCl_3$); δ/ppm: 164.93 (CO), 133.88 (CN_2), 128.98 (Ar), 125.48 (Ar), 125.23 (Ar), 124.59 (Ar), 122.33 (Ar), 118.71 (Ar), 69.81 (CH_2); MS (EI); *m/e*: 174 (58, M^+), 146 (12, $M^+ - CO$), 118 (55, $M^+ - CON_2$), 90 (100, $C_6H_5CH_2$); HRMS: M^+, for $C_9H_6N_2O_2$, *m/e*: 174.0429 (calcd.), 174.0422 (found).

4-Hydroxy-3-isochromanone was obtained by conjugate addition of water to the ketocarbene produced by photodediazotization of 4-diazo-3-isochromanone and subsequent ketonization of the lactone enol so produced, eq. [1], in analogy to a corresponding set of reactions that convert methyl phenyldiazoacetate to methyl mandelate, eq. [2] (5). A solution of 4-diazo-3-isochromanone (100 mg) in acetonitrile (0.3 mL) and water (3.0 mL) was photolyzed for 30 min through a Pyrex filter in a Rayonet apparatus operating at λ = 300 nm. Removal of the solvent by rotary evaporation and recrystallization of the residue from ethanol–pentane gave a colorless solid, mp 82–83°C, in 64% yield. Its spectral properties are: ^{1}H NMR (200 MHz, $CDCl_3$); δ/ppm: 7.67–7.23 (m, 4H, Ph), 5.42–5.16 (m, 3H, CH_2 + CH), 3.51 (s, 1H, OH); ^{13}C NMR (100 MHz, $CDCl_3$); δ/ppm: 173.55 (CO), 133.94 (Ph), 129.25 (Ph), 127.75 (Ph), 124.44 (Ph), 123.66 (Ph), 69.23 (CHOH), 67.86 (CH_2); HRMS: M^+, for $C_9H_8O_3$, *m/e*: 164.0473 (calcd.), 164.0477 (found).

All other materials were best available commercial grades.

Kinetics

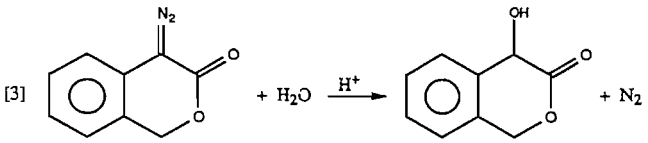
Rates of hydrolysis of 4-diazo-3-isochromanone were determined spectroscopically by monitoring the decrease in strong absorbance of the diazo compound at λ = 304 nm. Measurements were made using a Cary 2200 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.05°C. The rate data fit the first-order rate law well, and observed first-order rate constants were calculated by nonlinear least-squares fitting of an exponential function.

Molecular orbital calculations

Semi-empirical AM1 (6) molecular orbital calculations were performed using the program MOPAC 93 (7) in conjunction with a Hewlett Packard 755 computer. The geometries of the singlet ground state for all molecules studied were fully optimized, and energy minima were identified as having all positive eigenvalues and all positive vibrational frequencies.

Results

The hydrolysis of 4-diazo-3-isochromoanone catalyzed by the hydronium ion is expected to occur according to eq. [3], giving



3

4-hydroxy-3-isochromoanone, **3**, as the reaction product. This was confirmed here by subjecting a spent reaction mixture to HPLC analysis. Only one product was found, and spiking with an authentic sample showed it to be **3**.

Rates of this hydrolysis reaction were measured in H_2O and D_2O solutions of perchloric acid over a range of acid concentrations. The data are summarized in Table 1. Observed first-order rate constants proved to be accurately proportional to acid concentration, and linear least-squares analysis gave the hydronium ion catalytic coefficients $k_{H^+} = 2.48 \times 10^{-3}$ M^{-1} s^{-1} and $k_{D^+} = 1.17 \times 10^{-3}$ M^{-1} s^{-1}, whose ratio provides the isotope effect $k_{H^+}/k_{D^+} = 2.12$.

Semi-empirical AM1 molecular orbital calculations were performed to obtain minimum energy structures for 4-diazo-3-isochromanone and methyl phenyldiazoacetate. 4-Diazo-3-isochromanone was found to be a nearly planar molecule with, as Fig. 1 shows, its diazo and carbonyl groups situated only small distances to one side and the other of the benzene ring. The dihedral angles between the diazo group and its benzene ring and carbonyl group substituents produced by these calculations are listed in Table 2, and selected charge distributions obtained from the molecular potential field (8) are given in Table 3.

For methyl phenyldiazoacetate, two minimum energy structures were found, corresponding to *s-cis* and *s-trans* isomerism about the bond connecting the diazoalkane and carbomethoxy groups. The *s-trans* isomer was marginally the more stable, with a difference in heats of formation of $\delta\Delta H_f = 0.94$ kcal/mol^{-1}. As Figs. 2 and 3 show, both isomers had markedly nonplanar structures with diazo and carbonyl groups strongly disposed to opposite sides of the benzene ring. The relevant dihedral angles are listed in Table 2, and selected charge distributions are given in Table 3.

Discussion

The present results show that the hydronium-ion-catalyzed

hydrolysis of 4-diazo-3-isochromanone occurs with a substantial kinetic isotope effect in the normal direction: k_{H^+}/k_{D^+} = 2.12. This indicates that hydron transfer is rate determining in this reaction and implies that the process occurs by the standard mechanism for diazoalkane hydrolysis, involving rate-determining hydronation on α-carbon followed by rapid displacement of nitrogen by a molecule of water, eq. [4] (9). Another mechanism sometimes found for diazoalkane hydrolysis consists of rapid and reversible α-carbon protonation followed by rate-determining loss of nitrogen, but such a scheme would give an inverse isotope effect, $k_{H^+}/k_{D^+} < 1$ (10), contrary to what has been observed.

It was found previously (3) that the hydronium-ion-catalyzed hydrolysis of the acyclic analog of the presently studied substrate, methyl phenyldiazoacetate, also gives an isotope effect in the normal direction, k_{H^+}/k_{D^+} = 2.72, and that this reaction therefore also occurs by rate-determining hydron transfer to carbon. Comparison of rate constants for the two substrates shows that 4-diazo-3-isochromanone is 57 times less reactive than its acyclic counterpart.

This difference in reactivity can be understood in terms of the structures produced by the AM1 calculations carried out here. Diazoalkanes undergo α-carbon protonation because the diazo group delocalizes negative charge onto the α-carbon

Table 2. Dihedral angles between the diazo group and its phenyl and carbonyl substituents in AM1 optimized structures.

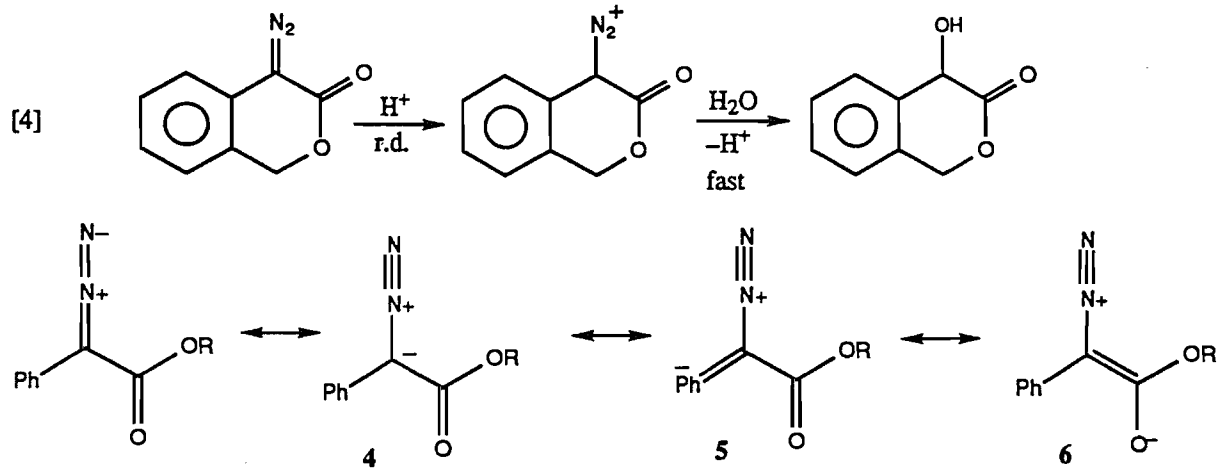
atom, as shown in resonance structure **4**, and it is reasonable to expect that the rate of reaction will be governed by the magnitude of the negative charge on this atom, being greater than the greater charge. This charge, however, can also be delocalized further into an adjacent phenyl group, as shown by resonance structure **5**, and this further delocalization will reduce the reaction rate.

Such further delocalization will be most efficient when the *p*-orbital of the α-carbon atom bearing the negative charge is parallel to the *p*-orbitals of the phenyl group and the dihedral angle between the phenyl and diazo groups is zero. The AM1 structures determined here show a fairly small dihedral angle for the cyclic substrate, 4-diazo-3-isochromanone, but considerably larger ones for its acyclic analog, methyl phenyldiazoacetate (see Table 2). If, as is commonly believed, the strength



of such conjugative interactions varies as the cosine of the dihedral angle squared, then this interaction will be 93% of its maximum zero-dihedral-angle value for the cyclic substrate but only 60% and 48% of that value for the acyclic *s-trans* and *s-cis* analogs. These expectations are supported by the charge densities listed in Table 3: it may be seen that the negative charge on the α-carbon atom rises from −0.419 electron for the cyclic substrate to −0.573 for the acyclic *s-trans* analog and further to −0.596 for the acyclic *s-cis* substrate. These changes, moreover, occur at the expense of reductions in negative charge in the phenyl group, which becomes progressively more positive along the cyclic to acyclic *s-trans* to acyclic *s-cis* series.

Negative charge can also be delocalized from the α-carbon atom into an adjacent carbonyl group, as shown in resonance structure **6**, and the small dihedral angles between the diazo and carbonyl groups listed in Table 2 indicate that this delocalization is quite efficient. It is interesting that this delocalization becomes stronger in going from the cyclic to the acyclic substrates, in compensation for the weakened delocalization into the phenyl groups. The changes in the carbonyl group interaction are small, however, because the structure of this part of the system is not very different in the cyclic and acyclic substrates, and the extent of delocalization into the phenyl group remains the dominant effect controlling reactivity.

Carbon protonation of some phenylynamines in concentrated aqueous perchloric acid solution. Lowering of the upper limit for the pK_a of phenylynammonium ions

A.J. Kresge and S.W. Paine

Abstract: Rates of carbon protonation of five phenylynamines ($PhC{\equiv}CNH_2$, $PhC{\equiv}CNH^iPr$, $PhC{\equiv}CNHC_6F_5$, $PhC{\equiv}CN(CH_2CH_2CN)_2$, and $PhC{\equiv}CNMeC_6F_5$) were determined in concentrated aqueous perchloric acid solution and the data were analyzed by the Cox–Yates method using the X_0 acidity function. The extrapolated hydronium-ion catalytic coefficients so obtained are consistent with values measured directly in dilute acid solution, and the slopes of the Cox–Yates plots are similar to predictions made with the aid of Marcus rate theory for reactions originating from free ynamine initial states but unlike those predicted for reactions starting from nitrogen-protonated ynammonium ion initial states. This shows that none of these phenylynamines are protonated in even the most acidic solutions used (4 M) and sets new upper limits as low as $pK_a \leq -3.1$ for the conjugate acids of these ynamines. Comparison of the pK_a limit for $PhC{\equiv}CNH_3^+$ with a literature value for the corresponding saturated compound, $PhCH_2CH_2NH_3^+$, gives a base-weakening effect for the phenylethynyl group of at least 12.5 pK units.

Key words: acetylenic amines, concentrated acids, X_0 excess acidity scale, Cox–Yates method, Marcus rate theory.

Résumé : Opérant en solutions concentrées d'acide perchlorique aqueux, on a déterminé les vitesses de protonation des carbones de cinq phénylynamines ($PhC{\equiv}CNH_2$, $PhC{\equiv}CNH^iPr$, $PhC{\equiv}CNHC_6F_5$, $PhC{\equiv}CN(CH_2CH_2CN)_2$ et $PhC{\equiv}CNMeC_6F_5$) et on a analysé les données en faisant appel à la méthode de Cox–Yates de la fonction d'acidité X_0. Les coefficients catalytiques extrapolés de l'ion hydronium ainsi obtenus sont en accord avec les valeurs mesurées directement en solution diluée d'acide et les pentes des courbes de Cox–Yates sont semblables à celles qui sont prédites à l'aide de la théorie des vitesses de Marcus pour des réactions qui ont l'ynamine libre initiale comme origine; elles diffèrent toutefois des valeurs prédites pour des réactions dont les états initiaux sont les ions ynammonium de l'azote protoné. Ce résultat démontre qu'aucune de ces phénylynamines n'est protonée, même dans les solutions les plus acides utilisées (4 M) et fixe de nouvelles limites supérieures pour les pK_a des acides conjugués de ces ynamines qui pourraient ne pas dépasser $-3{,}1$. Une comparaison de la limite du pK_a du $PhC{\equiv}CNH_3^+$ avec une valeur tirée de la littérature pour le composé saturé correspondant, $PhCH_2CH_2NH_3^+$, suggère que le groupe phényléthynyle aurait au effet d'abasissement de la basicité d'au moins 12,5 unités de pK.

Mots clés : amines acétyléniques, acides concentrés, échelle d'acidité en excès X_0, méthode de Cox–Yates, théorie des vitesses de Marcus.

[Traduit par la rédaction]

Previous work performed in our laboratory has shown that the acetylenic group has remarkably strong acid-strengthening (1) and base-weakening (2) effects (for theoretical analyses, see ref. 3). The magnitude of these effects could not be assessed directly by standard methods for determining acid–base dissociation constants because the substances involved, ynols **1** and ynamines **2**, have very short lifetimes in solution. Some information could be obtained, however, from the rate profiles of

$ArC{\equiv}COH$ (**1**) $\quad PhC{\equiv}CNR_2$ (**2**)

Received January 16, 1996.

the rapid reactions of these substances in acidic and basic solutions. It was found, for example, that the carbon protonation of ynamines to form keteniminium ions, **3**, eq. [1], was first-order in hydronium ion, and that the direct dependence of rate

[1] $$PhC{\equiv}CNR_2 + H^+ \longrightarrow \underset{\mathbf{3}}{PhCH{=}C{=}NR_2^+}$$

on hydronium ion concentration showed no sign of the saturation expected when nitrogen protonation converts the ynamine to the much less reactive ynammonium ion, **4**, eq. [2]. This set an upper limit on the pK_a of the ynamine conjugate acid equivalent to the highest acid concentration used.

[2] $$PhC{\equiv}CNR_2 + H^+ \rightleftharpoons \underset{\mathbf{4}}{PhC{\equiv}CNHR_2^+}$$

This previous work was done in dilute perchloric acid solutions up to an acid concentration of 0.1 M. We have now

extended that study by examining the carbon protonation of some phenylynamines in concentrated perchloric acid solutions up to 4 M. Our results still provide no evidence of nitrogen protonation.

Experimental section

Materials

Phenylynamines were generated as before (2) by flash photolytic photodecarbonylation of the corresponding phenylaminocyclopropenones, eq. [3],

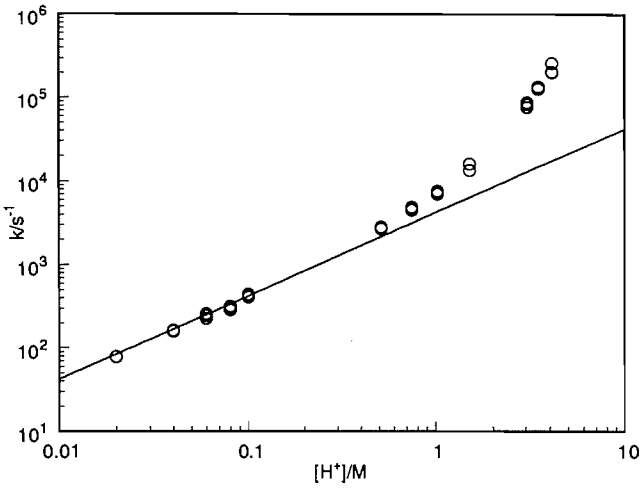
[3] 
directly in the acid solutions where the rate measurements were made. The phenylcyclopropenones used were samples that had been prepared before (2*b*). All other materials were best available commercial grades.

Kinetics

Rates of reaction of phenylynamines were determined using both conventional (microsecond) (4) and laser (nanosecond) (5) systems that have been described before. For primary and secondary ynamines, the rise in absorbance at λ = 260–270 nm due to ketenimine product formation was monitored, and for tertiary ynamines, which do not give ketenimine products, the drop in ynamine absorbance at λ = 300 nm was monitored. All of the rate data except some for 1-(*N*-isopropylamino)-2-phenylacetylene conformed well to the first-order rate law, and observed first-order rate constants were determined by nonlinear least-squares fitting of single exponential expressions. 1-(*N*-Isopropylamino)-2-phenylacetylene was the most reactive ynamine studied, and its lifetime in the three most concentrated acid solutions used was comparable to the duration of the flash photolysis laser pulse. The data were therefore analyzed by fitting a double exponential function; the faster of the two rate constants so obtained, $k \cong 5 \times 10^7\ s^{-1}$, could be attributed to formation of the ynamine during the laser pulse, and the second, to the carbon protonation reaction of present interest.

The temperature of the reacting solutions was controlled at 25.0 ± 0.05°C.

Fig. 1. Relationship between acid concentration and observed first-order rate constants for the carbon protonation of 1-(*N*-methyl-*N*-pentafluorophenylamino)-2-phenylacetylene in aqueous perchloric acid solutions at 25°C. The line drawn is based on data of ref. 2*b* for the concentration range [acid] = 0.02–0.10 M.



Results

Rates of carbon protonation of the five phenylynamines listed in Table 1 were measured in aqueous perchloric acid solution over the concentration range [acid] = 0.1–4 M.[2] Four to eleven different acid concentrations were used and duplicate or triplicate measurements were made at each concentration. The data are summarized in Table S1.[3]

As Fig. 1 illustrates, rates of reaction in these concentrated acid solutions increased more rapidly than in direct proportion to acid concentration. This is commonly the case for proton transfer to carbon, and acidity functions are therefore generally used to correlate the data. The Cox–Yates X_0 scale (6) appears to be the best function currently available for this purpose (7), and the present data were consequently analyzed using the standard Cox–Yates function, shown in eq. [4],

[4] $$\log(k_{obs}/[H^+]) = k_H^+ + mX_0$$

where k_H^+ is the hydronium-ion catalytic coefficient applicable in dilute solution and m is a slope parameter. Figure 2 shows that the data conform well to this relationship. The parameters determined by these correlations are listed in Table 1; it may be seen that the hydronium-ion catalytic coefficients obtained in this way are consistent with values determined before from rate measurements made in dilute acid solutions (2*b*).

[2] [Acid] = 0.04–1.6 M for 1-(*N*-isopropylamino)-2-phenylacetylene; above 1.6 M, rates of reaction of this substance become too fast to be determined accurately by our laser flash photolysis system.

Discussion

Figure 2 shows that rates of reaction for all of the phenylynamines examined here give linear Cox–Yates plots with positive slopes. This is the behavior expected for simple carbon protonation of these substances with free ynamine as the initial state, as opposed to the negative slopes that might be anticipated if significant nitrogen protonation were taking place. In the latter situation, the initial states of the reactions would be phenylynammonium ions, **4**, eq. [5], whose equilibrium ionization to free ynamine prior to the rate-determining

[5] $$\underset{\mathbf{4}}{PhC{\equiv}CNHR_2^+} \rightleftharpoons PhC{\equiv}CNR_2 + H^+ \longrightarrow PhCH{=}C{=}NR_2^+$$

carbon-protonation step would contribute a negative component to the Cox–Yates slope. This negative component would be offset by a positive contribution for the rate-determining step, but it is unlikely that this positive contribution would be strong enough to cancel the negative component completely.

These considerations can be put on a quantitative basis by making numerical estimates of the slopes involved, using our current, fairly good understanding of phenomena in concentrated acids, as outlined, for example, in a recent review (8). It is known that the magnitude of Cox–Yates slopes for the equilibrium protonation of amines increases in inverse proportion to the number of positively charged N—H bonds available for solvolytic stabilization of the amine conjugate acids through hydrogen bonding to water molecules, and that the nominal values $m = 1.00$, $m = 1.20$, and $m = 1.40$ generally apply to primary, secondary, and tertiary amines, respectively. This leads to the negative Cox–Yates slopes $m = -1.00$, -1.20, and -1.40 for the equilibrium ionization of the corresponding phenylynamines in the first step of the reaction scheme of eq. [5]. The subsequent rate-determining carbon-protonation step puts positive charge back on the amine nitrogen atom, but now there is one less N—H bond in the reaction product than there was in the ynammonium ion in the pre-equilibrium step and $m = 1.20$ will consequently apply to primary phenylynamine systems and $m = 1.40$ to secondary systems. For tertiary ynamines, whose carbon-protonation products have no positively charged N—H bonds, we shall use $m = 1.70$, borrowed from the carbon protonation of olefins and aromatics whose cationic products also have no positively charged N—H bonds.

The *m* values for reaching the transition states of the rate-determining steps of the process of eq. [5] will of course be lower than these estimates for full carbon protonation because only a fraction of the positive charge will have been placed on the ynamine at the transition state. This fraction may be identified with the Brønsted exponent α for the process (9), and an estimate of α may be supplied by Marcus rate theory (10). The relevant Marcus relationships are given by eqs. [6] and [7],

[6] $$\Delta G^{\ddagger} = w^r + (1 + \Delta G^0/4\Delta G^{\ddagger}_0)^2 \Delta G^{\ddagger}_0$$

[7] $$\alpha = (1 + \Delta G^0/4\Delta G^{\ddagger}_0)/2$$

in which $\Delta G^{\ddagger}$ is the free energy of activation, w^r is the work required to bring the reactants together to form a reaction complex, ΔG^0 is the free energy of reaction within this reaction complex, and $\Delta G^{\ddagger}_0$ is the intrinsic reaction barrier. Elimination of ΔG^0 between eqs. [6] and [7] leads to eq. [8], and use of $\Delta G^{\ddagger}$ derived from the hydronium ion catalytic coefficients of

[8] $$\alpha = \sqrt{(\Delta G^{\ddagger} - w^r)/4\Delta G^{\ddagger}_0}$$

Table 1 together with $w^r = 8.11$ kcal mol^{-1} and $\Delta G^{\ddagger}_0 = 3.26$ kcal mol^{-1} (*2b*) gives the α values listed in Table 2. These results may then be used to estimate *m* for the rate-determining carbon protonation step as the product of α and *m* for full carbon protonation, and *m* for the overall reaction of eq. [5] may

be evaluated as the sum of m for the pre-equilibrium step plus that for the carbon-protonation step. These results are also listed in Table 2.

It may be seen that all of the values of m predicted in this way are negative, in strong contrast to the positive values actually observed. Values of m predicted for the carbon-protonation step, on the other hand, are much more similar to the observed results and they also provide a similar pattern of dependence on the structure and reactivity of the substrate. The mean difference between observed m values and those predicted for the carbon-protonation step is only $\langle \delta m \rangle = 0.1$, whereas that between observed and predicted overall m values is an order of magnitude greater, $\langle \delta m \rangle = 1.0$. It would appear safe to conclude, therefore, that no significant amount of nitrogen protonation of these phenylynamines had occurred up to the highest acidity used and that the ynamines were in their free unprotonated forms in the initial states of the reactions studied.

This conclusion allows us to set upper limits on the pK_a's of the conjugate acids of these ynamines. On the rather conservative assumption that 10% nitrogen protonation could not have been detected, these limits are p$K_a = -2.7$ for phenylynamine, p$K_a = -1.6$ for the *N*-isopropyl derivative (which unfortunately could not be studied in acids as concentrated as the other ynamines because its rate of carbon protonation became too fast), p$K_a = -2.9$ for the other secondary ynamine, and p$K_a = -3.1$ for the tertiary ynamines.

Comparison of this limit for the pK_a of the conjugate acid of phenylynamine, **5**, with p$K_a = 9.8$ for that of 2-phenylethyl-

$PhC{\equiv}CNH_3^+$ **5** $PhCH_2CH_2NH_3^+$ **6**

amine (11) gives the phenylethynyl group a base-weakening effect of at least 12.5 pK units.

Platinum(II) complexes of the tridentate thioether ligands $RS(CH_2)_3S(CH_2)_3SR$ (R = Et, iPr, Ph). Structures of $[PtCl(iPrS(CH_2)_3S(CH_2)_3SiPr)][BF_4]$, $[PtI(PhS(CH_2)_3S(CH_2)_2SPh)][BF_4]$, and $[Pt(PPh_3)(iPrS(CH_2)_3S(CH_2)_3SiPr)][BF_4]_2 \cdot CH_2Cl_2$

Stephen J. Loeb and James R. Mansfield

Abstract: The tridentate thioether ligands $RS(CH_2)_3S(CH_2)_3SR$ (L^1, R = Et; L^2, R = iPr, L^3, R = Ph) were synthesized by nucleophilic addition of thiolate, SR^-, to the ditosylate $TsO(CH_2)_3S(CH_2)_3OTs$. The complexes $[PtX(L^n)][BF_4]$ were prepared by displacement of 1,5-COD from $[PtX_2(1,5\text{-COD})]$ (X = Cl, I) in the presence of one equivalent of $AgBF_4$ and one equivalent of thioether ligand. $[PtCl(L^2)][BF_4]$ crystallized in the monoclinic space group $P2_1/c$ with a = 10.409(6), b = 14.180(4), c = 13.726(8) Å, β = 104.49(4)°, V = 1961(2) Å^3, and Z = 4. The structure refined to R = 5.62% and R_w = 6.86% for 2121 reflections with $F_o^2 > 3\sigma(F_o^2)$. $[PtI(L^3)][BF_4]$ crystallized in the monoclinic space group $P2_1/n$ with a = 13.415(4), b = 12.350(5), c = 14.316(5) Å, β = 107.48(3)°, V = 2262(1) Å^3, and Z = 4. The structure refined to R = 4.85% and R_w = 6.33% for 2168 reflections with $F_o^2 > 3\sigma(F_o^2)$. In both compounds, the thioether ligand acts as a tridentate chelator occupying three of the four sites of the square-planar Pt(II) complex. Variable temperature $^{13}C\{^1H\}$ NMR verified that there are three possible stereoisomers for these complexes resulting from inversion at sulphur: *meso*-A, *meso*-B, and *racemic*. Thermodynamic parameters were calculated for the interconversion among isomers of $[PtCl(L^2)][BF_4]$ by a full line-shape analysis. Removal of chloride ligand from $[PtCl(L^2)][BF_4]$ with Ag^+ in the presence of PPh_3 yielded the phosphine adduct $[Pt(PPh_3)(L^2)][BF_4]_2$, which crystallized in the triclinic space group $P\bar{1}$ with a = 13.266(3), b = 11.315(2), c = 13.970(2) Å, α = 106.04(2)°, β = 84.95(2)°, γ = 86.56(2)°, V = 1999.7(7) Å^3, and Z = 2. The structure refined to R = 4.22% and R_w = 5.38% for 4493 reflections with $F_o^2 > 3\sigma(F_o^2)$. Unlike the two halide complex structures, which crystallized in the *meso*-B form, $[Pt(PPh_3)(L^2)][BF_4]_2$ crystallized in the *racemic* form.

Key words: tridentate thioether ligand, crystal structure, platinum(II) halide, dynamic NMR spectroscopy.

Résumé : On a synthétisé les coordinats thioéthers tridentates $RS(CH_2)_3S(CH)_2)_3SR$ (L^1, R = Et; L^2, R = iPr, L^3, R = Ph) par addition nucléophile de thiolate, SR^-, sur le ditosylate $TsO(CH_2)_3S(CH_2)_3OTs$. On a préparé les complexes $[PtX(L^n)][BF_4]$ par déplacement du 1,5-COD à partir du $[PtX_2(1,5\text{-COD})]$ (X = Cl, I) en présence d'un équivalent de $AgBF_4$ et d'un équivalent de coordinat thioéther. Le composé $[PtCl(L^2)][BF_4]$ appartient au groupe d'espace monoclinique $P2_1/c$ avec a = 10,409(6), b = 14,180(4), c = 13,726(8) Å, β = 104,49(4)°, V = 1961(2) Å^3 et Z = 4. On a affiné la structure jusqu'à des valeurs de R = 5,62% et de R_w = 6,86% pour 2121 réflexions avec $F_o^2 > 3\sigma(F_o^2)$. Le composé $[PtI(L^3)][BF_4]$ appartient au groupe d'espace monoclinique $P2_1/n$ avec a = 13,415(4), b = 12,350(5), c = 14,316(5) Å, β = 107,48(3)°, V = 2262(1) Å^3 et Z = 4. On a affiné la structure jusqu'à des valeurs de R = 4,85% et de R_w = 6,33% pour 2168 réflexions avec $F_o^2 > 3\sigma(F_o^2)$. Dans les deux composés, le coordinat thioéther agit comme un chélatant tridentate occupant trois des quatre sites d'un complexe de Pt(II) carré plan. La RMN du $^{13}C\{^1H\}$ à température variable permet de vérifier que ces complexes ont trois stéréo-isomères possibles : *méso*-A, *méso*-B et *racémique*. On a calculé les paramètres thermodynamiques pour l'interconversion des isomères du $[PtCl(L^2)][BF_4]$ par une analyse de la forme totale. L'enlèvement du chlore du coordinat $[PtCl(L^2)][BF_4]$ par l'ion Ag^+ en présence de PPh_3 conduit à l'adduit phosphine $[Pt(PPh_3)(L^2)][BF_4]_2$ qui cristallise dans le groupe d'espace triclinique $P\bar{1}$ avec a = 13,266(3), b = 11,315(2), c = 13,970(2) Å, α = 106,04(2)°, β = 84,95(2)°, γ = 86,56(2)°, V = 1999,7(7) Å^3 et Z = 2. On a affiné la structure jusqu'à des valeurs de R = 4,22% et de R_w = 5,38% pour 4493 réflexions avec $F_o^2 > 3\sigma(F_o^2)$. Contrairement aux structures des deux complexes halogénés qui cristallisent dans la forme *meso*-B, le complexe $[Pt(PPh_3)(L^2)][BF_4]_2$ cristallise sous la forme *racémique*.

Mots clés : coordinat thioéther tridentate, structure du cristal, halogénure de platine(II), spectroscopie de RMN dynamique.

Introduction

Macrocyclic thioether ligands such as 1,4,7,10,13,16-hexathiacyclohexadecane, [18]aneS_6, 1,4,8,11-tetrathiatetradecane, [14]aneS_4, and 1,4,7-trithiacyclononane, [9]aneS_3 have been used to enforce a homoleptic MS_x environment at a metal centre and are therefore ideal for studying the electronic effects of coordinated thioethers (1–4).

However, if one wishes to study the effect thioether coordination has on the reaction chemistry of a metal, at least one coordination site must remain unoccupied or contain a labile ancillary ligand (5). To this end, we have prepared a series of simple, open-chain, tridentate thioether ligands designed to coordinate to a metal centre in a *meridional* fashion and hence occupy three of four coordination sites of a four-coordinate, square-planar complex. This paper describes the synthesis of these ligands, preparation of platinum(II) complexes of the type $[PtX(RS(CH_2)_3S(CH_2)_3SR)][BF_4]$ (L^1, R = Et; L^2, R = iPr, L^3, R = Ph; X = Cl, I, PPh_3), and the characterization of these species in the solid state by X-ray diffraction and in solution by variable temperature ^{13}C NMR spectroscopy.

Experimental section

$[PtCl_2(1,5\text{-COD})]$ (6) and $[PtI_2(1,5\text{-COD})]$ (6) were prepared by literature methods. 1-Bromopropanol, sodium sulfide nonahydrate, *p*-toluenesulphonyl chloride, thiophenol, 2-propanethiol, 1,5-cyclooctadiene, K_2PtCl_4, and all deuterated solvents were purchased from Aldrich and used as received. All reactions were carried out under an atmosphere of N_2 using standard Schlenk techniques, and all solvents were dried and degassed prior to use. ^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$, and $^{195}Pt\{^1H\}$ NMR spectra were recorded at 300.1, 75.4, 121.5, and 64.5 MHz on a Brüker AM300 spectrometer locked to the deuterated solvent. Variable temperature ^{13}C NMR line-shape fitting calculations were performed using a locally modified version of DNMR3 (7). Infrared spectra were recorded on a Perkin–Elmer 781 grating spectrometer. GC–MS experiments were performed on a Hewlett–Packard HP 5970 Series MSD coupled to an HP 5890a gas chromatograph. Elemental analyses were performed by Canadian Microanalytical Services, Delta, British Columbia.

Synthesis of 4-thiaheptane-1,7-diol

The following is a modification of the literature preparation (8). 3-Bromopropanol (64.9 g, 476 mmol) and $Na_2S{\cdot}9H_2O$ (54.8 g, 228 mmol) were refluxed in anhydrous ethanol (750 mL) for 18 h. The mixture was cooled, filtered, and the solvent removed in vacuo. The resulting liquid was extracted with CH_2Cl_2, filtered, and the solvent removed in vacuo. The resulting clear, oily liquid was vacuum distilled (bp 134–138°C, 1 Torr (1 Torr = 133.3 Pa)). Yield 23.3 g, 65%. ^1H NMR ($CDCl_3$) δ: 3.64 (s, 2H, OH), 3.61 (t, 4H, OCH_2, $^3J = 6.2$ Hz), 2.54 (t, 4H, SCH_2, $^3J = 7.2$ Hz), 1.74 (q, 4H, CH_2). $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ: 60.91 (CH_2OH), 31.88 (SCH_2), 28.36 (CH_2).

Synthesis of 4-thia-1,7-heptaneditosylate·CH_2Cl_2

4-Thiaheptane-1,7-diol (22.65 g, 151 mmol) was dissolved in freshly distilled, dry pyridine at 0°C and *p*-toluenesulphonyl chloride (57.50 g, 302 mmol) added over a period of 2 h. The reaction mixture was poured over ice (900 g) and set aside until the ice melted. The resulting sticky white solid was filtered and then dissolved in CH_2Cl_2 (300 mL). This solution was washed with 0.1 M HCl(aq) (2 × 160 mL) and distilled water (2 × 100 mL). The aqueous fractions were collected and washed with fresh CH_2Cl_2 (100 mL). The combined organic portions were then dried over anhydrous $MgSO_4$, treated with decolourizing charcoal, filtered, and the solvent removed in vacuo. The resulting liquid was dissolved in an equal volume of diethyl ether and cooled to −10°C for 12 h. The crystallized white solid was collected and washed with anhydrous ethanol (50 mL) and dried in vacuo. Yield 38.42 g (59%). ^1H NMR ($CDCl_3$) δ: 7.78 (d, 4H, aromatic, $^3J = 8.0$ Hz), 7.34 (d, 4H, aromatic), 4.10 (t, 4H, OCH_2, $^3J = 6.0$ Hz), 2.46 (t, 4H, SCH_2, $^3J = 7.1$ Hz), 2.44 (s, 6H, CH_3), 1.86 (q, 4H, CH_2). $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ: 144.83, 132.86, 129.84, 127.81 (aromatic), 68.64 (CH_2O), 28.75 (SCH_2), 27.77 (CH_2), 21.61 (CH_3). Anal. calcd. for $C_{21}H_{28}Cl_2O_4S_3$: C 49.31, H 5.51, S 18.80; found: C 51.59, H 5.58, S 20.14.

Synthesis of 3,7,11-trithiatridecane, L^1

Na metal (1.55 g, 67.4 mmol) was dissolved in anhydrous ethanol (700 mL) and ethanethiol (4.9 mL, 4.11 g, 66.2 mmol) was added to this solution. This mixture was then added dropwise over 2 h to a slurry of 4-thiaheptane-1,7-ditosylate (14.2

g, 33.3 mmol) in anhydrous ethanol (200 mL). The reaction mixture was stirred overnight at 40°C. The solvent was removed in vacuo and the residue redissolved in CH_2Cl_2 (200 mL). The CH_2Cl_2 solution was washed with water (130 mL), dried over anhydrous $MgSO_4$, filtered, and the solvent removed in vacuo. The resulting clear, viscous liquid was vacuum distilled (bp 115–122°C, 1 Torr). Yield 6.16 g (78%). ^1H NMR ($CDCl_3$) δ: 2.47 (t, 4H, $EtSCH_2$, ^3J = 7.2 Hz), 2.47 (t, 4H, CH_2SCH_2), 2.38 (q, 4H, CH_3CH_2, ^3J = 7.4 Hz), 1.70 (q, 4H, SCH_2CH_2), 1.10 (t, 6H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ: 30.45 ($EtSCH_2$), 29.96 (CH_2SCH_2), 28.90 (SCH_2CH_2), 25.24 (CH_3CH_2), 14.41 (CH_3). MS, *m/e*: 238. Anal. calcd. for $C_{10}H_{22}S_3$: C 50.37, H 9.30, S 40.33; found: C 50.20, H 9.21, S 39.40.

Synthesis of 2,12,-dimethyl-3,7,11-trithiadecane, L^2

Na metal (1.23 g, 53.5 mmol) was dissolved in anhydrous ethanol (550 mL) and 2-propanethiol (4.6 mL, 3.77 g, 49.5 mmol) was added to this solution. This mixture was then added dropwise over 4 h to a slurry of 4-thiaheptane-1,7-ditosylate (10.5 g, 24.5 mmol) in anhydrous ethanol (50 mL). The reaction mixture was stirred overnight at 40°C and then the solvent removed. The residue was redissolved in CH_2Cl_2 (160 mL) and the solution filtered. The filtrate was washed with water (2 × 100 mL), dried over anhydrous $MgSO_4$, treated with activated charcoal, filtered, and the solvent removed in vacuo. The resulting amber viscous liquid was vacuum distilled to give a clear colourless oil (bp 122–129°C, 1 Torr). Yield 4.62 g (71%). ^1H NMR ($CDCl_3$) δ: 2.87 (m, 2H, CH, ^3J = 6.7 Hz), 2.58 (t, 4H, CH_2SCH_2, ^3J = 7.2 Hz), 2.57 (t, 4H, i-$PrSCH_2$), 1.81 (q, 4H, SCH_2CH_2) 1.22 (d, 12H, CH_3). $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ: 34.73 (CH), 30.94 (i-$PrSCH_2$), 29.64 (CH_2SCH_2), 29.24 (SCH_2CH_2), 23.32 (CH_3). MS, *m/e*: 266. Anal. calcd. for $C_{12}H_{26}S_3$: C 54.08, H 9.83, S 36.09; found: C 54.37, H 10.15, S 35.55.

Synthesis of 1,9-diphenyl-1,5,9-trithianonane, L^3

Na metal (1.25 g, 54.4 mmol) was dissolved in anhydrous ethanol (600 mL) and thiophenol (5.4 mL, 5.74 g, 52.1 mmol) was added to this solution. This mixture was then added dropwise over 3 h to a slurry of 4-thiaheptane-1,7-ditosylate (11.1 g, 26.0 mmol) in anhydrous ethanol (100 mL). The reaction mixture was stirred overnight at room temperature and then the solvent removed. The residue was redissolved in CH_2Cl_2 (160 mL) and the solution filtered. The filtrate was washed with water (2 × 100 mL), dried over anhydrous $MgSO_4$, treated with activated charcoal, filtered, and the solvent removed in vacuo. The resulting dark amber oil was vacuum distilled to give a clear colourless oil (bp 209–212°C, 1 Torr). Yield 5.99 g (69%). ^1H NMR ($CDCl_3$) δ: 7.38 (m, 4H, aromatic), 7.23 (m, 6H, aromatic), 3.04 (t, 4H, $PhSCH_2$), 2.63 (t, 4H, CH_2SCH_2, ^3J = 7.1 Hz), 1.92 (q, 4H, SCH_2CH_2). $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ: 135.98, 128.99, 128.67, 125.74 (aromatic), 32.16 ($PhSCH_2$), 30.51 (CH_2SCH_2), 28.55 (SCH_2CH_2). MS, *m/e*: 334. Anal. calcd. for $C_{18}H_{22}S_3$: C 64.62, H 6.63, S 28.75; found: C 64.54, H 6.51, S 27.84.

Synthesis of $[PtCl(L^1)][BF_4]$

L^1 (0.616 g, 2.583 mmol) was dissolved in CH_2Cl_2 (20 mL) and this solution was added to a flask containing $[PtCl_2(1,5\text{-COD})]$ (0.787 g, 2.103 mmol) and $AgBF_4$ (0.419 g, 2.152 mmol). This mixture was stirred for 2 h and then filtered through Celite to remove precipitated AgCl(s). The volume of the solution was reduced to ca. 4 mL and small portions of diethyl ether added until a light yellow precipitate formed. The mixture was then cooled to −10°C for 12 h. The pale yellow microcrystals formed were collected and washed with diethyl ether. Yield 0.919 g (79%). A satisfactory elemental analysis could not be obtained for this material.

Synthesis of $[PtCl(L^2)][BF_4]$

L^2 (1.456 g, 5.463 mmol) was dissolved in CH_2Cl_2 (15 mL) and this solution was added to a flask containing $[PtCl_2(1,5\text{-COD})]$ (2.006 g, 5.361 mmol) and $AgBF_4$ (1.066 g, 5.476 mmol). This mixture was stirred for 1 h and then filtered through Celite to remove precipitated AgCl(s). The solvent was removed and the residue left under vacuum to remove traces of 1,5-COD. The residue was dissolved in CH_2Cl_2 (4 mL) and small portions of diethyl ether were added until a light yellow precipitate formed. The mixture was then cooled to −10°C for 12 h. The yellow microcrystals formed were collected and washed with diethyl ether. Yield 2.856 g (91%). Anal. calcd. for $C_{12}H_{26}BClF_4PtS_3$: C 24.69, H 4.49, S 16.47; found: C 24.69, H 4.61, S 16.60.

Synthesis of $[PtCl(L^3)][BF_4]$

L^3 (0.560 g, 1.67 mmol) was dissolved in CH_2Cl_2 (5 mL) and this solution was added to a flask containing $[PtCl_2(1,5\text{-COD})]$ (0.624 g, 1.67 mmol) and $AgBF_4$ (0.324 g, 1.67 mmol). This mixture was stirred for 1 h and then filtered through Celite to remove precipitated AgCl(s). The solvent was removed and the residue was left under vacuum to remove traces of 1,5-COD. The residue was dissolved in CH_2Cl_2 (2 mL) and small portions of diethyl ether were added until a light yellow precipitate formed. The product was collected and washed with diethyl ether and isolated as the CH_2Cl_2 solvate. Yield 0.724 g (67%). Anal. calcd. for $C_{19}H_{24}BCl_3F_4PtS_3$: C 30.97, H 3.28, S 13.05; found: C 30.85, H 3.32, S 10.29.

Synthesis of $[PtI(L^3)][BF_4]$

L^3 (0.603 g, 1.80 mmol) was dissolved in acetone (6 mL) and this solution was added to a slurry of $[PtI_2(1,5\text{-COD})]$ (1.000 g, 1.80 mmol) in acetone (20 mL). $AgBF_4$ (0.375 g, 1.83 mmol) was added and the solution was stirred for 3 h and then filtered through Celite to remove precipitated AgCl(s). The volume of the solution was reduced to ca. 10 mL and the solution cooled to −10°C for 12 h. The resulting yellow microcrystals were collected and washed with diethyl ether. Yield 0.936 g (70%). Anal. calcd. for $C_{18}H_{22}BF_4IPtS_3$: C 29.08, H 2.98, S 12.94; found: C 29.86, H 3.09, S 12.73.

Synthesis of $[Pt(PPh_3)(L^2)][BF_4]_2$

To a flask containing $[PtCl(L^2)][BF_4]$ (0.297 g, 0.509 mmol) and triphenylphosphine (0.134 g, 0.511 mmol) was added CH_2Cl_2 (15 mL) with stirring. After 1 h, $AgBF_4$ (0.100 g, 0.514 mmol) was added and the mixture was stirred for an additional hour during which time a white precipitate of AgCl(s) formed. The solution was filtered through Celite and the solvent removed in vacuo. The resulting clear colourless oil was redissolved in a minimum volume of CH_2Cl_2 and

diethyl ether was added slowly until a white powder precipitated. The solid was collected and washed with diethyl ether. Yield 0.334 g (73%). Anal. calcd. for $C_{30}H_{41}B_2F_8PPtS_3$: C 40.15, H 4.60, S 10.71; found: C 39.95, H 4.70, S 10.23.

General X-ray crystallography

Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite monochromatized Mo Kα radiation. Initial unit cell constants and orientation matrices were obtained from 15 machine-centred reflections selected from rotation photographs. Partial rotation photographs around each axis were used to determine the crystal system. Following this, 30 high-angle reflections were used to obtain the final lattice parameters and orientation matrices for data collection. Instrument parameters, crystal data, and data collection parameters are summarized in Table 1. The intensities of three standard reflections were recorded every 197 reflections and showed no statistically significant changes over the duration of the data collections. The intensity data were collected in four shells ($2\theta < 30°$, 40°, 45°, and 50°). Empirical absorption coefficients were calculated and absorption corrections applied to the data. The data were processed using the TEXSAN software package running on an SGI Challenge XL computer system.[2] Refinements were carried out by using full-matrix, least-squares techniques on F by minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma^2(F_o)$ and F_o and F_c are the observed and calculated structure factors. Atomic scattering factors (9) and anomalous dispersion terms (10, 11) were taken from the usual sources. Fixed H-atom contributions were included with C—H distances of 0.95 Å and thermal parameters 1.2 times the isotropic thermal parameter of the bonded C atoms. No H atoms were refined, but all values were updated as refinement continued.

X-ray structure determination of $[PtCl(L^2)][BF_4]$

Pale yellow crystals of $[PtCl(L^2)][BF_4]$ suitable for X-ray diffraction were grown by vapour diffusion of diethyl ether into a CH_2Cl_2 solution of the complex. Preliminary photography was consistent with a monoclinic crystal system. Observed extinctions were consistent with space group $P2_1/c$. A total of 2707 reflections were collected and 2121 reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. The position of the platinum atom was determined using a Patterson synthesis and remaining non-hydrogen atoms were located from successive difference Fourier calculations. In the final cycles of refinement, the BF_4^- anion was input as a rigid group and all non-hydrogen atoms were assigned anisotropic thermal parameters. This resulted in $R = 5.62\%$ and $R_w = 6.86\%$ at convergence. A goodness-of-fit calculation resulted in a value of 2.28, and a final difference Fourier map calculation showed a maximum residual of +2.5 e/Å^3 associated with the Pt atom; largest trough was −2.1 e/Å^3. Atomic positional parameters and selected bonding parameters are summarized in Tables 2 and 3. Thermal parameters and hydrogen atom

parameters are deposited as supplementary material in Tables S-1 and S-2.[3]

X-ray structure determination of $[PtI(L^3)][BF_4]$

Orange-yellow crystals of $[PtI(L^3)][BF_4]$ suitable for X-ray diffraction were grown by vapour diffusion of diethyl ether into an acetone solution of the complex. Preliminary photography was consistent with a monoclinic crystal system. Observed extinctions were consistent with space group $P2_1/n$. A total of 3196 reflections were collected and 2168 reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. The position of the platinum atom was determined using a Patterson synthesis and remaining non-hydrogen atoms were located from successive difference Fourier calculations. In the final cycles of refinement, all non-hydrogen atoms were assigned anisotropic thermal parameters. This resulted in R = 4.85% and R_w = 6.33% at convergence. A goodness-of-fit calculation resulted in a value of 1.84, and a final difference Fourier map calculation showed a maximum residual of 1.5 e/Å^3 associated with the Pt atom; largest trough was −1.9 e/Å^3. Atomic positional parameters and selected bonding parameters are summarized in Tables 4 and 5. Thermal parameters and hydrogen atom parameters are deposited as supplementary material in Tables S-3 and S-4.[3]

X-ray structure determination of $[Pt(PPh_3)(L^2)][BF_4]_2$

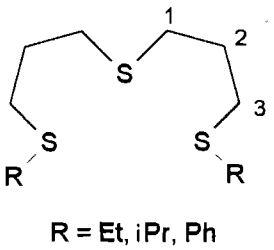
Orange-yellow crystals of $[Pt(PPh_3)(L^2)][BF_4]_2$ suitable for X-ray diffraction were grown by vapour diffusion of diethyl ether into a 2:1 CH_2Cl_2–acetone solution of the complex. Preliminary photography was consistent with a triclinic crystal system. Space group $P\bar{1}$ was assumed initially and verified by a successful structure solution and refinement. A total of 5260 reflections were collected and 4493 reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement. The position of the platinum atom was determined using a Patterson synthesis and remaining non-hydrogen atoms were located from successive difference Fourier calculations. In the final cycles of refinement, all non-hydrogen atoms were assigned anisotropic thermal parameters. This resulted in R = 4.22% and R_w = 5.38% at convergence. A goodness-of-fit calculation resulted in a value of 1.75, and a final difference Fourier map calculation showed a maximum residual of +2.4 e/Å^3 associated with the Pt atom; largest trough was −1.6 e/Å^3. Atomic positional parameters and selected bonding parameters are summarized in Tables 6 and 7. Thermal parameters and hydrogen atom parameters are deposited as supplementary material in Tables S-5 and S-6.[3]

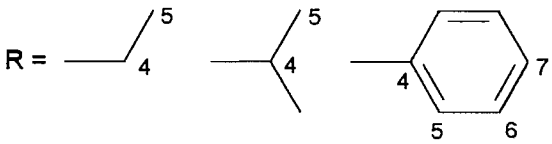
Results and discussion

Synthesis

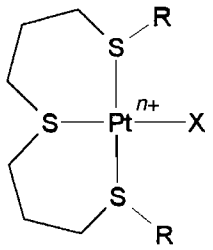
The three open-chain ligands were easily prepared by a three-step process from commercially available starting materials according to eqs. [1]–[3] (R = Et, iPr, Ph; Ts = tosylate).

Scheme 3.





Scheme 4.



X = Cl, I, PPh_3; R = Et, iPr, Ph

[1] $2\ BrCH_2CH_2CH_2OH + Na_2S \rightarrow S(CH_2CH_2CH_2OH)_2 + 2\ NaBr$

[2] $S(CH_2CH_2CH_2OH)_2 + TsCl \rightarrow S(CH_2CH_2CH_2OTs)_2 + 2\ HCl$

[3] $S(CH_2CH_2CH_2OTs)_2 + 2\ RSH \rightarrow S(CH_2CH_2CH_2SR)_2 + 2\ NaTs$

The ligands L^1, L^2, and L^3 are colourless oils that can be isolated in good yields and are pure by NMR and elemental analysis after one vacuum distillation. The ^1H and ^{13}C NMR spectra of these compounds are first order at the field strength employed and peak assignments were straightforward except for a slight overlap of the H1 and H3 protons for L^1. The $^{13}C\{^1H\}$ NMR spectrum of L^1 exhibits two distinct resonances for the corresponding C1 and C3 nuclei.

The IR spectrum of L^2 showed characteristic peaks attributable to an iPr group at υ = 1370, 1390 cm^{-1}, which were useful for identification purposes in the complexation studies. Mass spectra (EI) of all three ligands showed a parent M^+ ion at the appropriate *m/e* value and observed fragmentation patterns were consistent with the assigned structures. The yellow- to orange-coloured complexes $[PtX(L)][BF_4]$ were easily prepared by reacting an acetone or CH_2Cl_2 suspension of $[PtX_2(1,5\text{-COD})]$ with one equivalent of L and one equivalent

of $AgBF_4$. After removal of precipitated AgCl, the complexes were isolated by recrystallization from acetone or CH_2Cl_2 and diethyl ether. Dicationic complexes of the type $[Pt(PPh_3)(L)][BF_4]_2$ were prepared by treating the complexes $[PtX(L)][BF_4]$ with a further equivalent of $AgBF_4$ in CH_2Cl_2 solution in the presence of one equivalent of PPh_3.

Stereochemical considerations

A system containing three chiral centres can have a maximum of 8 (2^3) stereoisomers. For a system containing three chiral centres and a potential internal plane of symmetry, this maximum is reduced to three pairs of possible diastereomers (see Scheme 5). All three are possible in this system, although they need not be present in equal proportions. When coordinated to Pt the two terminal sulfur atoms, S(1) and S(3), are chiral centres and, depending upon which lone pair is coordinated to the metal centre, can be of either *R* or *S* absolute configuration. The central S(2) sulfur atom will also be a chiral centre *if* the two terminal S-atoms are of opposite configuration and the absolute configuration at S(2) can be designated noting that *R* chiral groups have precedence over *S* chiral groups. If this is the case, that S(1) and S(3) are of opposite configuration, a plane of symmetry exists through the Pt—S(2) bond perpendicular to the square plane and these are *meso* diastereomers. Since there are two possible sets of *meso* diastereomers, we have arbitrarily designated the isomers with all three lone pairs on the same side of the metal square plane as *meso*-A (*SSR/RRS*) and the isomers with two terminal S-atoms on the same side of the square plane and the central lone pair on the opposite side as the *meso*-B isomer (*SSR/RRS*). The third possibility is that the terminal S-atoms have the same absolute configuration, which orients the *R*-groups and necessarily the lone pairs on opposite sides of the square plane. In this situation, S(2) is *not* a chiral centre and the two possible conformations are enantiomers (*RR* and *SS*) and are therefore referred to as *racemic*.

X-ray structures of $[PtCl(L^2)][BF_4]$, $[PtI(L^3)][BF_4]$, and $[Pt(PPh_3)(L^2)][BF_4]_2$

An ORTEP drawing of the cation $[PtCl(L^2)]^+$ is shown in Fig. 1 with the atom numbering scheme. The geometry at the Pt(II) centre is a slightly distorted square planar with the S-atoms of L^2 occupying three of the sites and a chlorine atom filling the fourth site opposite the central S(2) atom of the thioether ligand. The ligand is in the *meso*-B conformation in this structure which positions the *S*-isopropyl groups on the same side of the square plane, a *syn* arrangement. The terminal S-atoms are chemically equivalent and the Pt—S(1) and Pt—S(3) distances are equal within experimental error: Pt—S(1), 2.302(3) Å; Pt—S(3), 2.306(4) Å. The Pt—S(2) distance of 2.256(4) Å is significantly shorter than the two terminal Pt—S bonds, presumably due to the *trans* influence of the chloride ligand.

There is a very slight tetrahedral distortion evident in the *trans* angles of 173.3(2)° for Cl(1)-Pt(1)-S(2) and 170.9(2)° for S(1)-Pt(1)-S(3).

An ORTEP drawing of the cation $[PtI(L^3)]^+$ is shown in Fig. 2 with the atom numbering scheme. The geometry at the Pt(II) centre is a slightly distorted square planar with the S-atoms of L^3 occupying three of the sites and an iodine atom filling the fourth site opposite the central S(2) atom of the thioether ligand. The ligand is in the *meso*-B conformation in this structure which positions the S-phenyl groups on the same side of the square plane, a *syn* arrangement. The terminal S-atom distances, Pt—S(1) 2.293(4) Å and Pt—S(3) 2.289(4) Å, are equivalent within experimental error and the Pt—S(2) distance is significantly shorter at 2.280(5) Å due to the *trans* influence of the iodide ligand. The Pt—I(1) distance is 2.602(2) Å. There is a very slight tetrahedral distortion evident in the *trans* angles of 170.8(2)° for I(1)-Pt(1)-S(2) and 169.6(2)° for S(1)-Pt(1)-S(3).

An ORTEP drawing of the dication $[Pt(PPh_3)(L^2)]^{2+}$ is shown in Fig. 3 with the atom numbering scheme. The geometry at the Pt(II) centre is a slightly distorted square planar with the S-atoms of L^2 occupying three of the sites and the triphenylphosphine P(1) atom filling the fourth site opposite the central S(2) atom of the thioether ligand. The ligand is in the *racemic* conformation in this structure, which positions the *S*-isopropyl groups on opposite sides of the square plane, an *anti* arrangement. In this conformation, the chemically equivalent, terminal Pt—S bonds, although very similar, are significantly different: Pt—S(1), 2.343(2) Å, Pt—S(3), 2.328(2) Å. The Pt—S(2) distance of 2.339(2) Å is also similar to but still significantly different from the terminal Pt—S bond distances. There is a very slight tetrahedral distortion evident in the *trans* angles of 170.98(9)° for P(1)-Pt(1)-S(2) and 176.31(7)° for S(1)-Pt(1)-S(3).

A number of bonding parameters change systematically as the ancillary ligand changes from Cl to I to PPh_3. The most obvious is the bond distance for the central S-atom *trans* to the ancillary ligand in which the Pt—S(2) distance lengthens from 2.256(4) to 2.289(4) to 2.339(2) Å on changing the *trans* ligand from Cl to I to PPh_3. This simply follows from the variation in *trans* effect; P > I > Cl. The terminal Pt—S bond distances also lengthen but to a lesser degree due to this change in

trans effect for the ancillary group. There appear to be only small structural differences due to a change in *S-R* substituent and only a slight variation in terminal Pt—S distances for the two observed ligand conformations, *meso*-B and *racemic*.

Evaluation of the fluxional behaviour of $[PtCl(L^2)][BF_4]$ by NMR spectroscopy

The room temperature ^1H and $^{13}C\{^1H\}$ NMR spectra of the $[PtX(L)]^{n+}$ complexes are characteristic of a system that is exchanging on the NMR time scale. Each coordinated sulfur atom is in a tetrahedral environment as seen from the X-ray analysis and as such has two lone pairs with which to bind to the metal centre. Exchange between the lone pair bound to the metal and the uncoordinated lone pair amounts to inversion at sulfur and interconverts absolute configurations at sulfur. The three possible isomers, *meso*-A, *meso*-B, and *racemic*, can be interconverted by inversion at sulfur as outlined in Scheme 5.

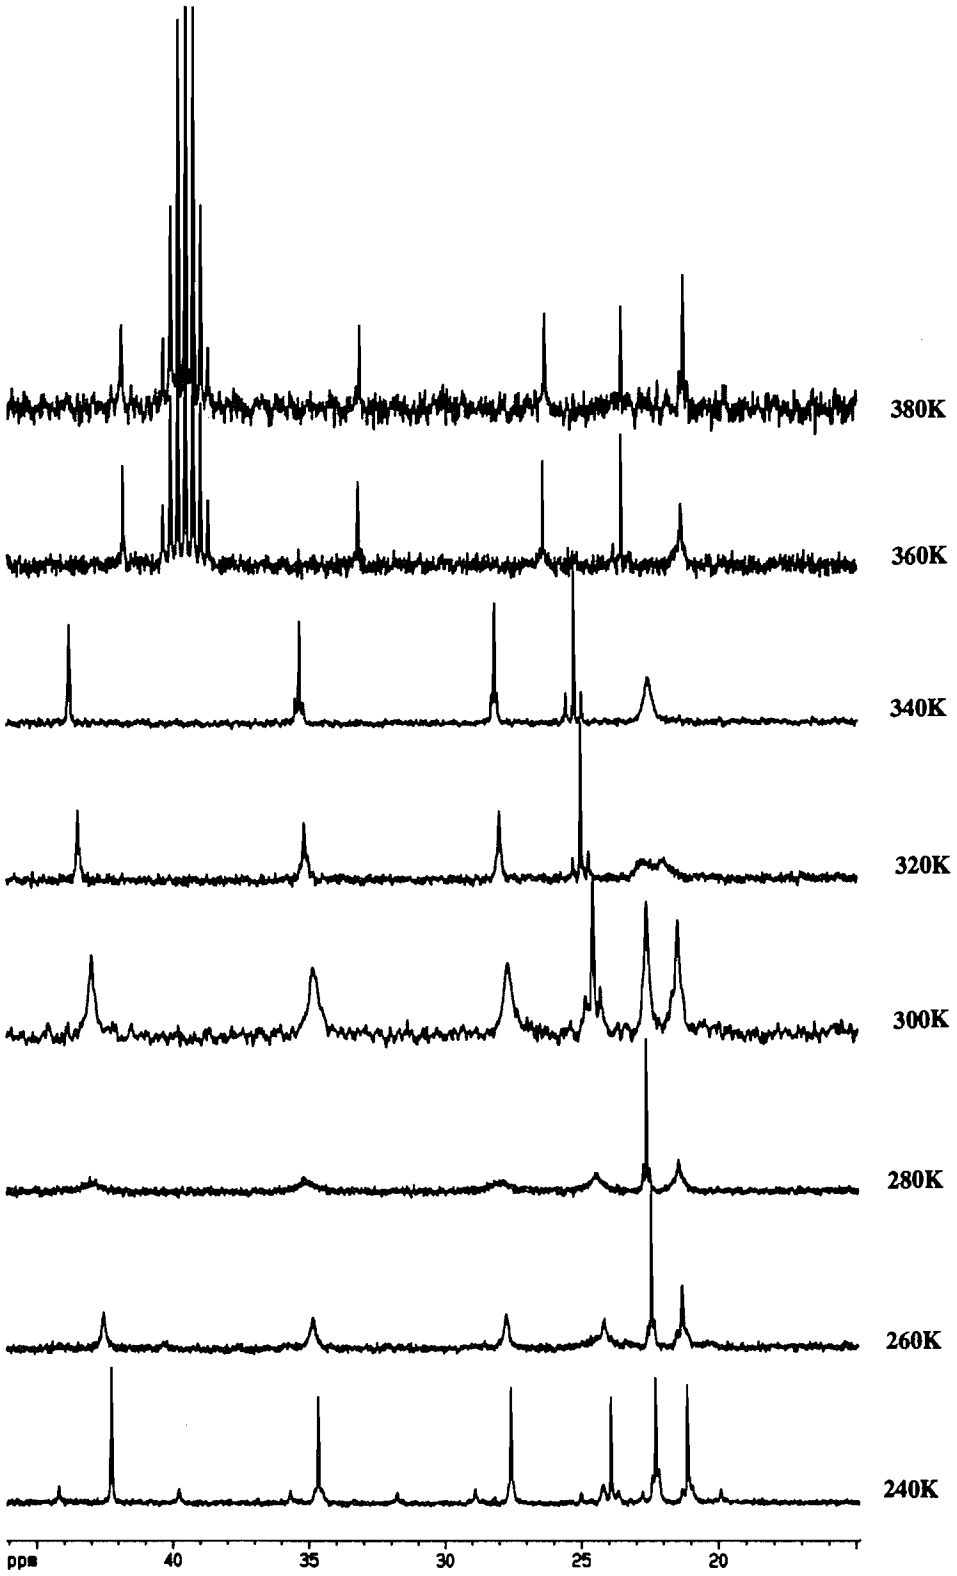
At elevated temperatures (380 K), the ^1H and ^{13}C NMR spectra of the complex $[PtCl(L^2)][BF_4]$ are simple and first order. For example, a simple doublet due to the methyl protons is observed at δ 1.53 ppm in the ^1H NMR spectrum while the same methyl groups exhibit single resonance at δ 21.14 in the ^{13}C NMR spectrum.

In Fig. 4, it can be seen that the high-temperature ^{13}C NMR spectrum contains five resonances, some of which show ^{195}Pt satellites, and at this temperature the sulfur atoms can be considered to be in an "averaged planar" conformation as a result of rapid inversion at the coordinated S centres on the NMR time scale. As the temperature is lowered, these five reso-

Fig. 4. Variable temperature $^{13}C\{^1H\}$ NMR spectra of $[PtCl(L^2)][BF_4]$. Spectra from 240 to 340 K were recorded in CD_3CN. Spectra at 360 and 380 K were recorded in DMSO-d_6 and the septet at δ 39.5 is due to residual solvent.



nances broaden and collapse in turn. At lower temperatures, the single peak for the methyl groups has become a six-line system and all the other resonances have split into three separate resonances. The three sets of resonances observed for each of the ligand backbone, methylene carbons, and the isopropyl methine carbons can be assigned to separate reso-

[a]Isomers are listed in order of population from highest to lowest.
[b]Two values are listed for prochiral methyls of the iso-propyl groups.
[c]Aromatic carbon resonances for complexes of L^3 could not be resolved and are not listed.

nances from each of the three possible isomers, *meso*-A, *meso*-B, and *racemic* (Scheme 5). The observation of six methyl resonances is due to the prochiral nature of the isopropyl groups. Since prochiral groups attached to a chiral centre are inequivalent and, barring chance overlap, anisochronous, the methyl groups of *each isomer* are inequivalent, giving rise to the observed six-line pattern.

A full line-shape fitting calculation was performed on the methine carbon resonance of $[PtCl(L^2)][BF_4]$. Spectra at nine temperatures from 230 to 340 K were fitted and the corresponding exchange coefficients used in an Arrhenius-type plot to calculate thermodynamic parameters for the interconversions shown in Scheme 5. The methine carbon resonance was used since it had the smallest $^2J_{Pt,C}$ coupling. The populations used in the calculations were 0.107, 0.775, and 0.118 for the resonances at δ 39.35, 42.09, and 44.13, respectively, and the relaxation (T_2) was calculated from the peak width at half-height of the largest methine peak at 230 K. A plot of $\ln(k/T)$ versus $1/T$ yielded a straight line of the form $y = mx + b$, where $\Delta H^{\ddagger} = -mR$ and $\Delta S^{\ddagger} = R[b - \ln(k_B/h)]$. Values of $\Delta G^{\ddagger}_{300} = 56.6 \pm 4.2$ kJ/mol, $\Delta H = 56.2 \pm 3.6$ kJ/mol, and $\Delta S = -1.3 \pm 8.3$ kJ/mol were obtained. These results are in general agreement with those obtained for bidentate thioether ligands on Pt(II); for example, a $\Delta G^{\ddagger}$ value of 65.6 kJ/mol has been reported (12) for $[PtCl_2(MeS(CH_2)_3SMe)]$.

All the Pt(II) complexes in this series exhibit the type of fluxional behaviour diagrammed for $[PtCl(L^2)][BF_4]$ in Scheme 5. Once the nature of the fluxional process was understood, peak assignments in the $^{13}C\{^1H\}$ NMR spectra of the other complexes were relatively straightforward and are summarized in Table 8. All three isomers were not always observed. For the complex $[Pt(PPh_3)(L^2)][BF_4]_2$ only one isomer was observed while for $[PtI(L^3)][BF_4]$ and $[PtCl(L^3)][BF_4]$ only two isomers were observed at low temperature. There are two possible explanations for this: first, the populations of the unobserved isomers are much smaller than those of the observed isomers at the low-temperature limit; secondly, the peaks due to the minor isomers are still too broad for observation at low temperature. The former is more likely since the barrier to inversion at sulfur is likely very similar for all isomers. Attempts to observe these isomer distributions using ^{195}Pt or ^{31}P NMR spectroscopy were unsuccessful. The ^{195}Pt NMR spectrum (300 K) of $[PtCl(L^2)][BF_4]$ showed a single resonance at −3981 ppm with a width at half-height of 30 Hz. At lower temperatures, this peak broadened but could not be resolved. The ^{31}P NMR spectrum (300 K) of $[Pt(PPh_3)(L^2)][BF_4]_2$ exhibited a single resonance at 13.8 ppm with coupling to ^{195}Pt of 2971 Hz, but again only a single peak was observed even at low temperature.

Conclusions

The thioether ligands $RS(CH_2)_3S(CH_2)_3SR$ (R = Et, iPr, Ph) are easily synthesized by nucleophilic addition of thiolate, SR^- (R = Et, iPr, Ph), to the ditosylate $TsO(CH_2)_3S(CH_2)_3OTs$. Complexes of the type $[PtX(RS(CH_2)_3S(CH_2)_3SR)][BF_4]$ can be readily prepared by displacement of 1,5-COD from $[PtX_2(1,5\text{-COD})]$ (X = Cl, I) in the presence of one equivalent of $AgBF_4$ and the thioether ligand. As designed, these ligands act as tridentate chelators occupying three coordination sites of a square-planar Pt(II) complex. The dynamic behaviour of these complexes, produced by the presence of rapidly inverting chiral thioether centres bound to platinum, can be rationalized in terms of a simple model describing a maximum of three pairs of diastereomers. The thermodynamic parameters obtained for this process are in good agreement with other simpler systems involving Pt(II)-bound thioether ligands.

Finally, preliminary synthetic experiments have shown that these simple halide complexes can act as starting materials for the preparation of square-planar complexes with three sites occupied by thioether donors and the fourth site available for ancillary two-electron donors. This basic coordination geometry should be applicable to more reactive square-planar sys-

tems such as Rh(I) and Ir(I) and offers the opportunity to study the effect of a thioether coordination sphere on bound substrates in an "open coordination site." In this regard, preliminary results show that $[Rh(L)(CO)][BF_4]$ can be prepared fairly easily and the chemistry of this and other Group 9 complexes will be reported in the future.

Études des réactions d'oxydation du *n*-heptane et de l'isooctane

Yves Simon, Gérard Scacchi et François Baronnet

Résumé : Dans le but d'aboutir à une meilleure compréhension du mécanisme des phénomènes d'autoinflammation et afin d'améliorer l'adéquation moteur-carburant, nous avons étudié les mécanismes d'oxydation de deux hydrocarbures d'indices d'octane très différents : le *n*-heptane (indice : 0) et l'isooctane (indice : 100). L'étude expérimentale a été menée, à 923 K, en utilisant un montage comprenant un réacteur continu auto-agité par jets gazeux. Les mécanismes d'oxydation du *n*-heptane et de l'isooctane ont été simplifiés en utilisant en premier lieu des considérations purement cinétiques, puis grâce à un logiciel de simulation de mécanismes réactionnels. Le comportement très différent de ces deux hydrocarbures a finalement été attribué à la présence, dans les produits de réactions d'oxydation de l'isooctane, d'alcènes qui agiraient comme des composés antidétonants en formant des radicaux stabilisés par résonance.

Mots clés : réaction d'oxydation, *n*-heptane, isooctane, auto-inflammation, modélisation.

Abstract: The oxidation mechanisms of two alkanes that have quite different octane numbers: *n*-heptane (0) and isooctane (100), were investigated to obtain a better understanding of the chemical mechanism of autoignition phenomena and to improve the compatibility of the available fuels with the engines. The experimental study was performed at 923 K in a setup equipped with a jet-stirred reactor. The oxidation mechanisms of *n*-heptane and isooctane were simplified first by a purely kinetic analysis based on the product formation and then by using a software of simulation of reaction mechanisms. The very different behaviour of these two hydrocarbons was explained by the presence, in the products of isooctane oxidation, of alkenes, which would have an antiknock effect due to the formation of resonance-stabilized radicals.

Key words: oxidation reaction, *n*-heptane, isooctane, autoignition, modelling.

Introduction

Une meilleure compréhension de l'auto-inflammation spontanée des mélanges air–hydrocarbure en fin de cycle de compression, à l'origine du phénomène de «cliquetis», devrait permettre l'amélioration de l'adéquation moteur-carburants dans le cas des moteurs à allumage commandé. Si les problèmes liés à l'approvisionnement énergétique avaient déjà suscité des recherches dans les années 70 (1, 2), le développement des carburants sans plomb, nécessaires lors de l'utilisation de pots catalytiques, a donné depuis quelques années une nouvelle impulsion à ces recherches (3, 4).

Par ailleurs, la modélisation des phénomènes complexes dans les chambres de combustion des moteurs, incluant les phénomènes d'échange de chaleur, de transfert de matière, de turbulence..., fait appel à des codes de calcul particulièrement complexes. Si un modèle cinétique suffisamment complet est nécessaire de manière à être prédictif, il doit rester d'une dimension limitée (au maximum quelques dizaines de processus élémentaires) pour pourvoir être inséré dans les codes de calcul. Ceci nécessite donc une compréhension fondamentale des phénomènes et paramètres gouvernant les délais d'auto-inflammation et en aucun cas un modèle empirique ne peut suffire.

Dans cette optique, il nous a semblé intéressant d'étudier les mécanismes d'oxydation de deux hydrocarbures d'indices d'octane très différentes : le *n*-heptane (indice : 0) et l'isooctane (indice : 100) qui sont les références des échelles d'indice d'octane des essences.

Le mécanisme d'oxydation des hydrocarbures est très largement dépendant de la température de la phase gazeuse au moment de l'auto-inflammation. Malheureusement, les mesures de température effectuées in situ dans les chambres de combustion sont très imprécises, comme le montrent les études de J.J. Marie et M.J. Cottereau (5). Cette température varie selon les auteurs de 800 K à 1100 K. Nous avons donc choisi, pour cette étude, une température moyenne de 923 K.

Pour conserver, à cette température relativement élevée, des avancements de réaction raisonnables, nous avons opté pour l'utilisation de la technique du réacteur continu auto-agité par jets gazeux.

Conditions expérimentales

L'oxydation du *n*-heptane et de l'isooctane a été étudiée à 923 K dans un réacteur continu auto-agité par jets gazeux. Ce réac-

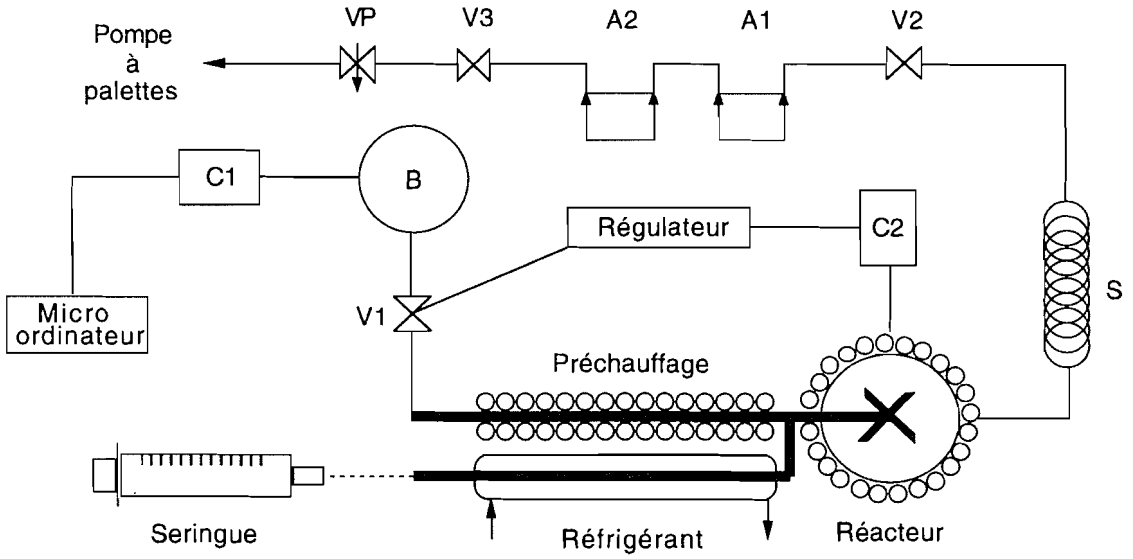
Fig. 1. Schéma de l'appareillage expérimental. A.1, A.2 : Ampoules d'échantillonnage B : Ballon de réserve d'air C.1, C.2 : Capteurs de pression V.1 : Vanne de régulation V.2, V.3 : Vannes d'arrêt VP : Vanne pointeau S : Volume tampon.



teur sphérique, en silice, a un volume de 23 cm^3 et possède huit injecteurs. Le chauffage du réacteur est assuré par deux coquilles demi-sphériques réalisées avec des résistances électriques isolées de marque «Thermocoax».

Le réacteur est alimenté par deux circuits d'alimentation en réactifs distincts: l'un en hydrocarbure et l'autre en air (voir Fig. 1.).

L'air est stocké dans un ballon de réserve B et débite dans le réacteur en passant par la vanne de régulation V1 dont l'ouverture et la fermeture sont commandées par un régulateur électronique de manière à conserver une pression totale constante dans le réacteur (mesurée par le capteur C2). La pression dans le ballon de stockage B est mesurée par le capteur C1. On détermine alors le flux molaire d'air entrant dans le réacteur en mesurant la variation de pression dans le ballon de réserve, lorsque celui-ci est isolé.

L'hydrocarbure est, par contre, injecté sous forme liquide entre le réacteur et le préchauffage d'air grâce à un pousse-seringue. Au contact de l'air préchauffé, l'hydrocarbure liquide s'évapore et est entraîné, sous forme gazeuse, à l'intérieur du réacteur, où le mélangeage est assuré par les huit injecteurs.

Les composés étudiés, *n*-heptane et isooctane, sont liquides à température ambiante. Pour éviter la condensation de ces réactifs dans les canalisations en verre de l'appareillage expérimental, il convient de travailler avec des pressions partielles de *n*-heptane et d'isooctane inférieures à leurs tensions de vapeur à température ambiante qui sont de l'ordre de 40 Torr (1 Torr = 133,3 Pa). En conséquence, nous avons choisi de fixer la pression partielle de ces deux hydrocarbures à 20 Torr dans le réacteur.

La pression partielle de l'oxygène a été choisie de façon à obtenir un rapport HC/O_2 de 1/2; soit une pression partielle d'air de 200 Torr.

La prise d'échantillon s'effectue dans deux ampoules de chromatographie A1 et A2 montées en série à la sortie du réacteur. Nous avons utilisé, pour l'étude des produits de réaction condensables, une ampoule métallique à quatre voies dont l'étanchéité est assurée par un joint en Téflon. Cette ampoule, réalisée au Laboratoire, permet de supprimer la dissolution de ces composés dans les graisses utilisées sur les robinets des ampoules de verre.

Ces ampoules sont encadrées par deux vannes éléctromagnétiques V2 et V3 qui se ferment successivement afin d'isoler le flux gazeux sortant du réacteur. Le contenu des ampoules d'échantillonnage est analysé par chromatograhie en phase gazeuse.

Enfin, le circuit se termine par une vanne pointeau VP qui permet de modifier le débit total des gaz dans le réacteur.

Résultats expérimentaux

Les produits de réaction ont été dosés par chromatographie en phase gazeuse pour des temps de passage dans le réacteur variant de 0,1 à 0,9 s dans le cas de l'étude de l'oxydation du *n*-heptane et de 0,1 à 1,1 s pour celle de l'isooctane. L'avancement de la réaction varie de 5% à 45% pour les deux hydrocarbures étudiés.

Cas de l'oxydation du *n*-heptane

Cette étude a permis d'identifier et de doser 16 produits d'oxydation différents : hydrogène, méthane, éthylène, éthane, propène, butène-1, pentène-1, hexène-1, heptène-1, heptène-3 *cis* et *trans*, eau, monoxyde et dioxyde de carbone, éthanal, propanal. Les courbes de formation des produits de réaction (à l'exception de H_2 dont la formation, quoique notable, est très irreproductible) sont représentées sur les figures 2, 3 et 4. Il faut noter que l'éthylène n'a été dosé que pour des temps de passage inférieurs à 0,5 s car, au-delà, la quantité d'éthylène formée est trop importante et sature le détecteur du chromatographe.

Fig. 2. Oxydation du *n*-heptane à 923 K. Courbes de formation de CH_4, C_2H_4, C_2H_6, C_3H_6, 1-C_4H_8 et 1-C_5H_{10}.

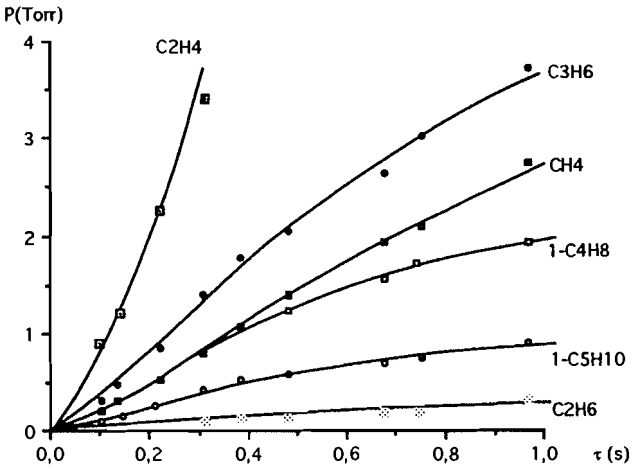


Fig. 3. Oxydation du *n*-heptane à 923 K. Courbes de formation de H_2O, CO, CO_2 et 1-C_6H_{12}.

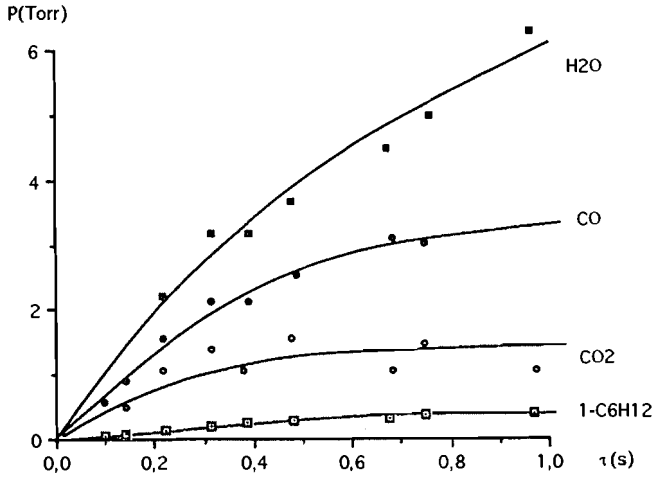

Fig. 4. Oxydation du *n*-heptane à 923 K. Courbes de formation de CH_3CHO, C_2H_5CHO, 1-C_7H_{14}, 3-C_7H_{14} *cis* et *trans*.

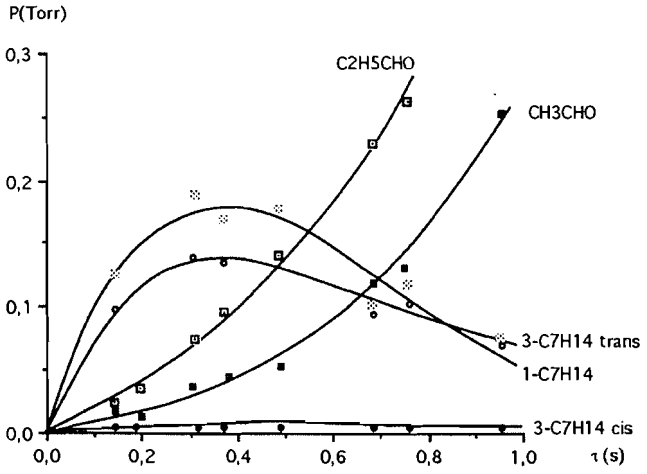

Fig. 5. Oxydation du *n*-heptane à 923 K. Répartition des produits de réaction les plus importants en fonction du temps de passage.

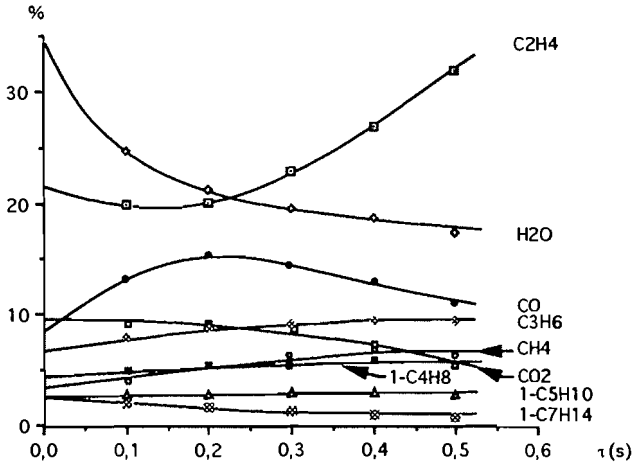

Fig. 6. Oxydation du *n*-heptane à 923 K. Répartition des produits de réaction mineurs en fonction du temps de passage.

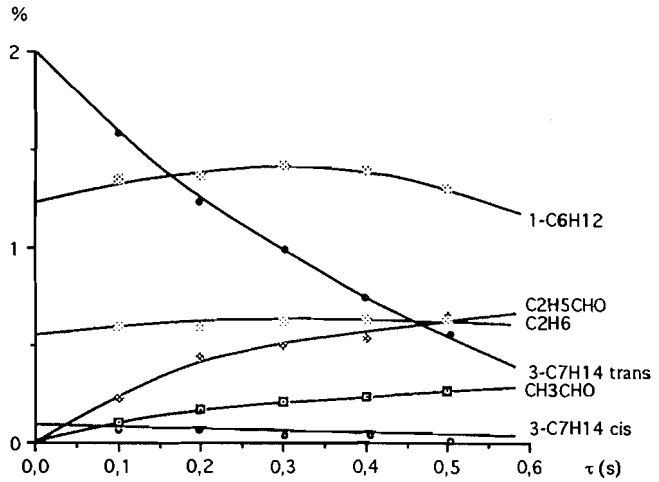


Les «diagrammes horizontaux» correspondant aux produits de réaction sont représentés sur les figures 5 et 6. Ces diagrammes sont tracés en portant le pourcentage molaire du produit considéré par rapport à l'ensemble des produits dosés (réactifs non compris) en fonction du temps de passage. Sur ces diagrammes, le caractère primaire de la formation d'un composé est caractérisé par une courbe ne passant pas par l'origine, alors que, au contraire, le caractère secondaire se distingue par une courbe passant par l'origine. Ces figures montrent que seuls deux produits de réaction sont secondaires : l'éthanal et le propanal.[3]

3. Un produit de réaction est dit «primaire» lorsqu'il est formé à partir des réactifs ou radicaux libres uniquement. Il est dit «secondaire» lorsqu'il est formé à partir des produits primaires. Un produit primaire se caractérise par une vitesse de formation initiale non nulle, alors qu'un produit secondaire possède une vitesse de formation initiale nulle.

Cas de l'oxydation de l'isooctane

Dans cette étude, nous avons identifié et dosé également 16 produits de réaction différents : hydrogène, méthane, éthylène, éthane, propène, propane, isobutène, isobutane, diméthyl-2,4 pentène-1, diméthyl-2,4 pentène-2, diméthyl-4,4 pentène-2, triméthyl-2,4,4 pentène-1, triméthyl-2,4,4 pentène-2, eau, monoxyde et dioxyde de carbone. Les courbes de formation de ces composés (à l'exception de H_2, pour la raison déja invoquée) sont représentées sur les figures 7, 8 et 9 et les «diagrammes horizontaux» correspondant sur les figures 10 et 11. Ces figures montrent que seuls deux produits de réaction sont secondaires : l'éthylène et le propane. Contrairement à l'étude de la réaction d'oxydation du *n*-heptane, aucun aldéhyde n'a pu être identifié ici.

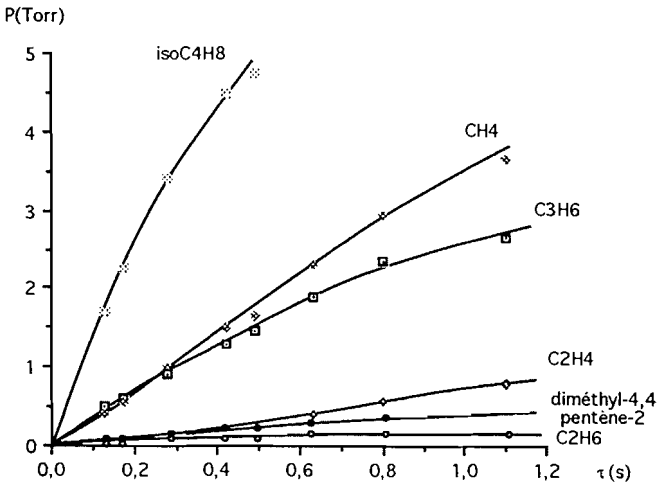
Exploitation des résultats expérimentaux

Les réactions d'oxydation des hydrocarbures dépendent fortement de la température et l'analyse de la littérature fait apparaître deux types de mécanismes fondamentalement différents en fonction du domaine de température exploré :

(*i*) un mécanisme dit de «*haute température*», valable audessus de 1000 K, proposé par Westbrook, Pitz et coll. (6–15) et Warnatz (16–18).

(*ii*) un mécanisme dit de «*basse température*», valable audessous de 800 K et qui constitue l'aboutissement des travaux de Fish (19–22) dans les années 60 puis repris par Quinn et Halstead (2) dans les années 70 et enfin Cox et Cole (23) en 1985.

Fig. 7. Oxydation de l'isooctane à 923 K. Courbes de formation de iso-C_4H_8, CH_4, C_3H_6, C_2H_4, C_2H_6 et diméthyl-4,4 pentène-2.



La présence de ces 2 mécanismes résulte de la réversibilité du processus:

$$R^{\cdot} + O_2 \rightleftharpoons RO_2^{\cdot}$$

Ces mécanismes peuvent être schématisés de la façon suivante (Schéma 1) :

Schéma 1. Mécanisme général de l'oxydation des alcanes.

Le radical alcoyle R˙ est formé par le processus d'amorçage à partir de la molécule d'hydrocarbure RH. Ce radical de départ R˙ peut être, dans le cas du *n*-heptane : 1-C_7H_{15}˙, 2-C_7H_{15}˙, 3-C_7H_{15}˙ ou 4-C_7H_{15}˙ et dans le cas de l'isooctane : ˙CH_2-$C(CH_3)_2CH_2$-$CH(CH_3)_2$, $(CH_3)_3C$-CH˙-$CH(CH_3)_2$, $(CH_3)_3C$-CH_2-C˙$(CH_3)_2$ ou $(CH_3)_3C$-CH_2-CH-(CH_3)(CH_2˙).

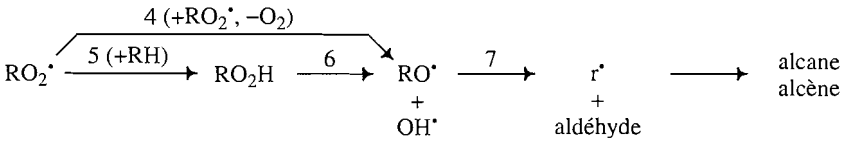
Nous avons donc tenté d'établir, à partir de considération purement cinétiques puis en utilisant les résultats expérimentaux, quels sont les processus importants dans les mécanismes d'oxydation des deux hydrocarbures étudiés : le *n*-heptane et l'isooctane. Plus particulièrement, nous avons essayé de déterminer l'importance relative des deux mécanismes d'oxydation de *haute et basse température*.

Cas de l'oxydation du *n*-heptane

En considérant le mécanisme d'oxydation de chaque radical alcoyle formé par l'initiation, nous avons calculé le rapport entre la vitesse de réaction V_B suivant le mécanisme de *basse température* et la vitesse de réaction V_H suivant le mécanisme de *haute température*. Les calculs ont été menés en écrivant l'AEQS pour les différents radicaux libres, et en utilisant des constantes de vitesse, soit tirées de la littérature, soit estimées par les méthodes de la cinétique thermochimique (24). Ce calcul fournit, dans le cas du *n*-heptane, une valeur du rapport V_B/V_H variant entre 0,4 et 1,8 suivant le radical R˙ de départ considéré. Ces résultats semi-quantitatifs montrent que les calculs cinétiques ne permettent pas de privilégier l'un des deux mécanismes.

Cependant, ce mécanisme d'oxydation peut être simplifié en analysant les résultats fournis par l'expérience et plus particulièrement, le caractère primaire ou secondaire des produits formés. Prenons le cas de la décomposition du radical alcoyloxy RO˙ (Schéma 2) :

Schéma 2. Formation et décomposition des radicaux RO˙.

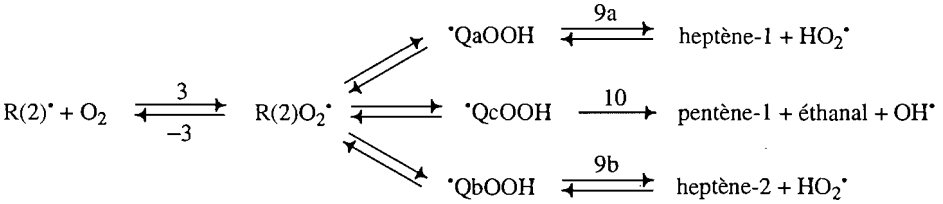


Les radicaux alcoyles r˙ se décomposent essentiellement par rupture d'une liaison C—C pour former, entre autres, du méthane, de l'éthane, et surtout de l'éthylène. Tous les produits formés par la séquence réactionnelle regroupant les processus 5, 6 et 7 sont secondaires puisque provenant de la décomposition d'un produit primaire : l'hydroperoxyde RO_2H. Or, les diagrammes horizontaux (Figs. 5 et 6) montrent sans ambiguïté que l'éthylène est primaire, alors que l'éthanal et le propanal sont secondaires. Cette séquence de processus semble donc minoritaire. La production d'éthylène est due, pour la plus grande part, au mécanisme de haute température et seule la formation des aldéhydes, présents en faible quantité, pourrait provenir essentiellement de cette voie.

Dans le cas de la voie réactionnelle représentée par les processus 4 et 7 tous les produits formés sont primaires, ce qui est en désaccord avec l'allure des diagrammes horizontaux relatifs aux aldéhydes (Fig. 6.). De plus l'éthanal et le propanal ne sont formés expérimentalement qu'un faible quantité, alors que la formation d'éthylène est bien plus importante. Cette séquence réactionnelle peut donc être également considérée comme minoritaire.

Considérons, maintenant, la formation de produits de réaction à partir des processus 8, 9 et 10 (Schéma 1) et prenons l'exemple du radical heptényl-2, noté R(2)˙ (Schéma 3) :

Schéma 3. Décomposition d'un des radicaux RO_2˙ dans l'oxydation du *n*-heptane.



La comparaison des constantes de vitesse des processus d'isomérisation des radicaux $R(2)O_2$˙ montre que les valeurs de ces constantes sont similaires. En considérant que chaque radical ˙QO_2H ne possède qu'une seule voie de décomposition possible, les vitesses d'isomérisation et de décomposition sont égales. La vitesse de formation de l'heptène conjugué (processus 9a ou 9b) par décomposition d'un radical ˙QO_2H, ainsi que celles du pentène-1 ou encore de l'éthanal (processus 10) sont du même ordre de grandeur.

La formation de l'éthanal est secondaire et ne peut pas être interprètée par cette séquence de processus. De plus, la vitesse de formation de pentène-1 par cette voie est théoriquement identique à celle de l'éthanal, alors qu'expérimentalement, la production de pentène-1 est 17 fois plus grande que celle de l'éthanal. Ces deux produits de réaction ne sont donc manifestement pas formés par cette voie.

De même, les vitesses de formation d'éthanal, d'heptène-1 et d'heptène-2 sont théoriquement voisines. La part de production d'éthanal par cette voie est, comme nous l'avons vu, très faible dans la production totale d'éthanal qui ne représente pas plus de 2% des produits formés par la réaction. L'heptène-1 et l'heptène-2 ne sont donc produits, par cette voie, qu'à l'état de traces dans le milieu réactionnel et leur mécanisme de formation, n'ayant aucune influence cinétique, pourra être négligé.

Les réactions d'isomérisation des radicaux $R(2)O_2$˙ pourront donc être négligées dans le mécanisme final. Des raisonnements similaires peuvent être faits dans le cas des trois autres radicaux alcoyles formés par l'amorçage. En résumé, ces simplifications portent exclusivement sur le mécanisme de *basse température* qui se révèle être presqu'entièrement minoritaire. Le mécanisme d'oxydation du ***n*-heptane** peut alors être représenté par le schéma général suivant (Schéma 4).

Cas de l'oxydation de l'isooctane

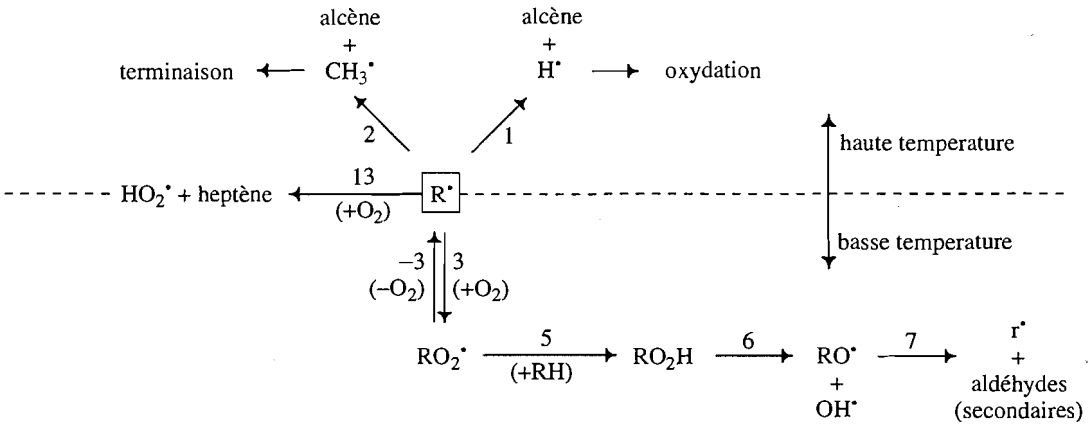
De façon à déterminer l'importance relative des deux mécanismes de *haute et basse température*, nous avons déterminé, en utilisant la même méthodologie que pour le *n*-heptane, le rapport V_B/V_H pour chacun des 4 radicaux alcoyles formés par l'amorçage. Le rapport obtenu pour les différents radicaux R˙ varie de 0,2 à 2,6. Ces résultats, trop proches de 1, ne permettent donc pas de conclure à une prédominance d'un des deux mécanismes par rapport à l'autre.

Nous avons, alors, comme celà a été fait pour l'oxydation du *n*-heptane, tenté de simplifier le mécanisme réactionnel en utilisant les résultats expérimentaux. Nous avons vu, lors de l'interprétation des résultats expérimentaux de l'oxydation du *n*-heptane, que les courbes de formation des aldéhydes apportaient de précieux renseignements sur l'importance d'un grand nombre de processus de ce mécanisme d'oxydation. Par contre, l'étude expérimentale de la réaction d'oxydation de l'isooctane n'a pas permis de révéler la présence d'aldéhydes. Nous avons alors tenté de déterminer les processus négligeables, par la seule comparaison des courbes de formation des hydrocarbures.

Reprenons le cas de la décomposition du radical RO˙ présentée sur le schéma 2. Les radicaux r˙ se décomposent ici pour former : CH_4, C_3H_6, C_3H_8, $isoC_4H_8$ et $isoC_4H_{10}$.

La voie réactionnelle représentée par la série de processus 5, 6 et 7 conduit à la formation de produits de réaction secondaires. Or, les diagrammes horizontaux (Figs. 10 et 11) mon-

Schéma 4. Mécanisme d'oxydation du *n*-heptane, simplifié en tenant compte des résultats expérimentaux.

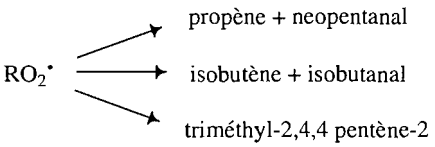


trent que CH_4, C_3H_6, $isoC_4H_8$ et $isoC_4H_{10}$ sont de caractère primaire et que seul C_3H_8 pourrait être formé par un mécanisme secondaire. Cette voie réactionnelle semble donc prendre une part négligeable dans la formation de la plupart des hydrocarbures, mais peut cependant expliquer la formation de propane secondaire. La proportion de propane formé étant inférieure à 0,1%, nous pourrons globalement négliger la séquence de processus précédente.

Par contre, la voie passant par les processus 4 et 7 conduit uniquement à la formation de produits primaires et rien ne permet donc de conclure sur l'importance relative de cette séquence de processus.

Analysons, maintenant, le cas des processus 8, 9 et 10 (Schéma 1). Par similitude avec le raisonnement établi dans le cas de l'oxydation du *n*-heptane, nous pouvons supposer que les vitesses de formation de produits issus de la décomposition d'un même radical $^\bullet QO_2H$ sont approximativement égales (les constantes de vitesse des processus d'isomérisation d'un radical $RO_2^\bullet$ sont voisines). Prenons le cas du radical $RO_2^\bullet$ formé à partir du radical $(CH_3)_3C\text{-}CH^\bullet\text{-}CH(CH_3)_2$ (Schéma 5) :

Schéma 5. Décomposition d'un des radicaux $RO_2^\bullet$ dans l'oxydation de l'isooctane.



Si ces réactions sont majoritaires dans la formation du propène, de l'isobutène et du triméthyl-2,4,4 pentène-2, nous devrions obtenir expérimentalement des pressions partielles voisines pour ces 3 alcènes; ce qui n'est pas le cas. En effet, pour un temps de passage de l'ordre de 0,2 s on observe : 2,5 Torr d'isobutène, 0,7 Torr de propène et 2×10^{-3} Torr de triméthyl-2,4,4 pentène-2.

Nous pouvons donc supposer que, dans la formation d'isobutène et de propène, la plus grande part est fournie par le mécanisme de *haute température* et considérer la voie précédente comme minoritaire. Des raisonnements identiques peuvent être faits pour les voies utilisant les trois autres radicaux $R^\bullet$ possibles.

L'étude des résultats expérimentaux a ainsi montré que le mécanisme *haute température* était prépondérant dans le mécanisme d'oxydation de **l'isooctane**. Ce mécanisme peut être schématisé de la façon suivante (Schéma 6).

Modélisation des réactions d'oxydation du *n*-heptane et de l'isooctane

L'approche précédente a permis un certain nombre de simplifications concernant particulièrement le mécanisme de *basse température*. Cependant, nous n'avons pas pu conclure sur l'importance de certaines voies réactionnelles par un raisonnement basé uniquement sur les résultats expérimentaux directs. Afin d'aller au-delà dans la simplification de ces mécanismes, nous avons simulé ces résultats expérimentaux.

Les mécanismes d'oxydation simplifiés représentés sur les schémas 4 et 6 ont servi à modéliser les résultats expérimentaux grâce au logiciel de simulation MORSE mis au point au DCPR (25, 26). Ce logiciel permet, à partir d'un mécanisme théorique, d'obtenir les concentrations courantes de tous les produits de réaction et donc les courbes de formation de ces produits. Ces courbes peuvent alors être comparées aux courbes de formation expérimentales.

Le mécanisme de départ ayant servi à cette simulation comporte 199 processus élémentaires dans le cas de l'oxydation du *n*-heptane et 152 processus dans le cas de l'oxydation de l'isooctane. Ces mécanismes, non exhaustifs, ne comportent essentiellement que des processus primaires (à l'exception des processus de formation de CO, CO_2 et du processus 6), donnant naissance à des produits de réaction identifiés expérimentalement. Les constantes de vitesse ont été ajustées raisonnablement de façon à obtenir des courbes de formation théoriques aussi proches que possible des courbes expérimentales (Figs. 12 et 13). Il convient, cependant, de remarquer que les courbes de formation expérimentales reflètent l'intervention de processus secondaires dès que l'avancement devient notable (20% d'advancement à 0,3 s), ce qui explique l'éloignement croissant avec le temps de passage, entre les courbes expérimentales et théoriques. Il n'a, par contre, pas été possible de simuler quantitativement les courbes de formation de CO, CO_2, et dans une moindre mesure H_2O, en utilisant un mécanisme primaire réaliste.

L'analyse de sensibilité, effectuée sur les constantes de vitesse a alors permis de simplifier considérablement ces mécanismes, par la recherche de processus négligeables. Ainsi, le mécanisme d'oxydation du ***n*-heptane** ne comporte

Fig. 12. Oxydation du *n*-heptane à 923 K. Courbes de formation simulées.

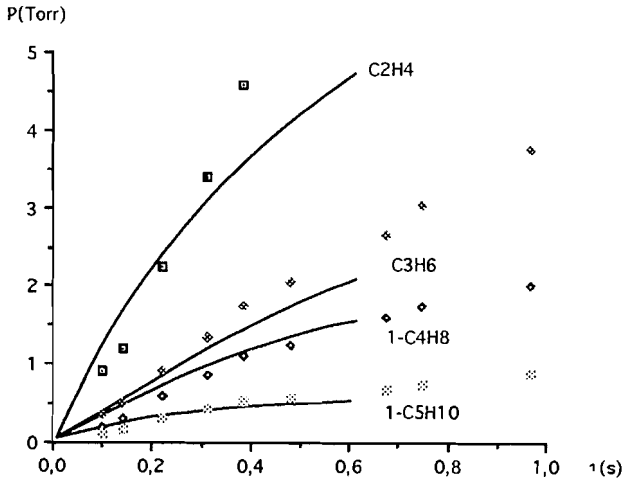


Fig. 13. Oxydation de l'isooctane à 923 K. Courbes de formation simulées.

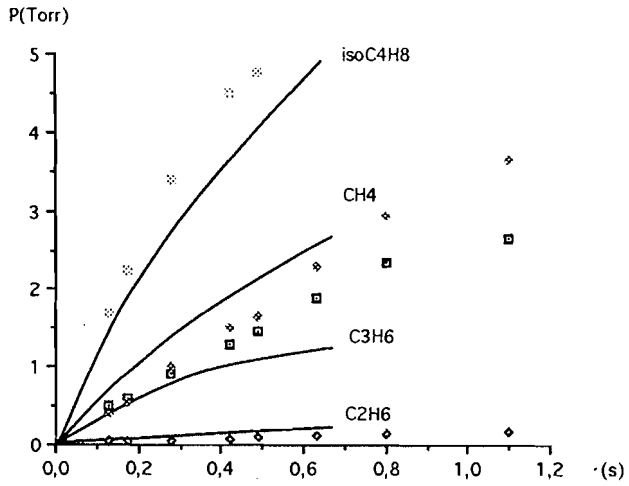

Schéma 6. Mécanisme d'oxydation de l'isooctane, simplifié en tenant compte des résultats expérimentaux.

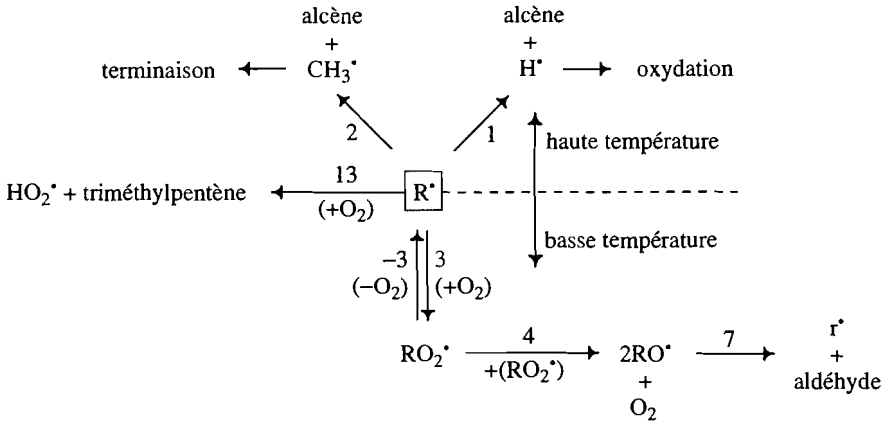

Schéma 7. Mécanisme final d'oxydation du *n*-heptane et de l'isooctane.

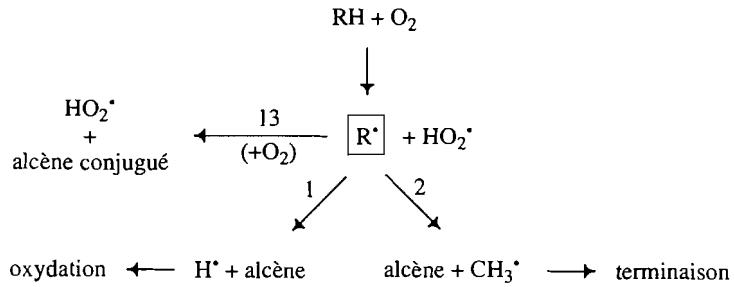

plus finalement que 76 processus élémentaires et celui de **l'isooctane** 71 processus élémentaires (tableaux 1 et 2). Dans les deux cas, les processus d'oxydation du radical R˙ suivant le mécanisme de *basse température* se sont avérés être négligeables. Les deux mécanismes d'oxydation du *n*-heptane et de l'isooctane relèvent donc d'un schéma identique (Schéma 7), correspondant au mécanisme de *haute température*. Ce schéma final correspond, par ailleurs, à celui représentant les mécanismes d'oxydation du *n*-heptane et de l'isooctane dans des conditions de pression plus élevées (27).

Discussion et conclusion

Les mécanismes primaires d'oxydation du ***n*-heptane** et de

$HO_2^{\cdot} + HO_2^{\cdot} \rightarrow H_2O_2 + O_2$	$2,0 \times 10^{12}$

Tableau 1 (*suite et fin*).

NOTA : RH représente la molécule de *n*-heptane. R1', R2', R3' sont respectivement les radicaux heptényles 1, 2, 3 et 4.

l'isooctane sont donc tout à fait similaires, y compris les ordres de grandeur des constantes de vitesse des processus élémentaires et ne permettent pas d'expliquer l'écart de comportement entre ces deux hydrocarbures. Il faut noter également que, pour des temps de passages identiques, ces deux réactions possèdent des taux de conversion tout à fait comparables. La seule différence qui peut être observée dans les réactions d'oxydation du *n*-heptane et de l'isooctane se situe au niveau des *produits primaires formés par la réaction* (essentiellement des oléfines). On remarque, en effet, que la réaction d'oxydation du *n*-heptane forme essentiellement des hydrocarbures insaturés en chaîne linéaire (éthylène, propène, butène-1 ...), alors que la réaction d'oxydation de l'isooctane forme aussi des hydrocarbures insaturés ramifiés (isobutène, diméthylpentènes, triméthylpentènes). Les produits oxygénés formés par l'oxydation de ces deux hydrocarbures sont de même nature et produits en quantités équivalentes.

En fait, la vitesse de réaction est étroitement dépendante des constantes de vitesse des processus d'amorçage, de propagation et de terminaison. Les processus d'amorçage ou de branchement des réactions d'oxydation du *n*-heptane et de l'isooctane sont de même nature et ont des constantes de vitesse voisines. Il en est de même des processus de propagation, puisque les réactions d'isomérisation :

$$R^{\cdot} + O_2 \rightleftharpoons RO_2^{\cdot} \rightleftharpoons {}^{\cdot}QO_2H$$

souvent rendues responsables de la différence de comportement des hydrocarbures, ont ici disparu. Seule la nature des processus de *terminaison* semble donc pouvoir expliquer, ici, la différence de comportement entre le *n*-heptane et l'isooctane et plus particulièrement la formation de radicaux libres très peu réactifs (stabilisés par résonance).

Tableau 2 (*suite et fin*).

NOTA : RH représente la molécule d'isooctane. R1˙, R2˙, R3˙ et R4˙ sont respectivement les radicaux˙ CH_2-$C(CH_3)_2$-CH_2-$CH(CH3)_2$, $(CH_3)_3$C-CH˙-$CH(CH_3)_2$, $(CH_3)_3$C-CH_2-C˙$(CH_3)_2$ et $(CH_3)_3$C-CH_2-$CH(CH_3)(CH_2˙)$

Tableau 3. Indice d'octane recherche de mélange des produits formés par l'oxydation du *n*-heptane.

Produit	% «Initial»	IORM (réf. 28)
Éthylene	20	—
Propène	8	—
Butène-1	5	144
Pentène-1	3	119
Heptène-1	3	68
Heptène-3	1,7	—
Hexène-1	1,3	97

Les alcènes formés par ces réactions pourraient, par l'intermédiaire de processus secondaires, inhiber ou non la réaction d'oxydation. En effet, la comparaison des tableaux 3 et 4 montre que les produits majoritaires des réactions d'oxydation du *n*-heptane et de l'isooctane sont : l'éthylène, le propène et l'isobutène. Le propène est présent en quantités voisines dans les deux cas (8% pour le *n*-heptane et 7% pour l'isooctane). Sa présence ne peut donc pas expliquer la différence de comportement existant entre le *n*-heptane et l'isooctane. Par contre, le produit majoritaire de l'oxydation de l'isooctane est l'isobutène (31%) qui conduit à la formation du radical isobutènyle stabilisé par résonance, alors que l'oxydation du *n*-heptane forme essentiellement de l'éthylène (20%) qui lui ne forme pas de radicaux stabilisés.

De plus, la comparaison de l'indice d'octane recherche de mélange (IORM) des alcènes produits par les réactions d'oxydation du *n*-heptane et de l'isooctane (Tableaux 3 et 4) montre que les produits formés par la réaction d'oxydation de l'isooctane ont des indices d'octane plus élevés que ceux produits par la réaction d'oxydation du *n*-heptane, en particulier l'isobutène (IORM : 170) formé en très grande quantité.

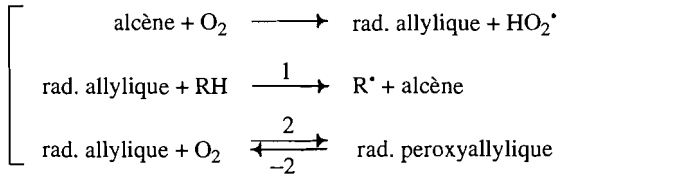
L'oxydation de l'isobutène est très difficile, car elle conduit

Tableau 4. Indice d'octane recherche de mélange des produits formés par l'oxydation de l'isooctane.

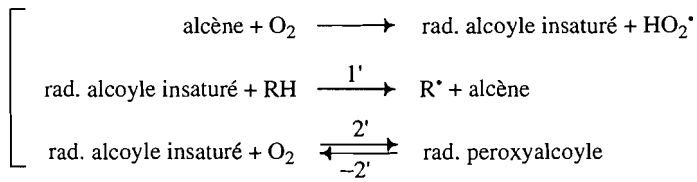
Produit	% «Initial»	IORM (28)
Isobutène	31	170
Propène	7	—
Diméthyl-4,4 pentène-2	2	—
Triméthyl-2,4,4 pentène-1	0,6	164
Triméthyl-2,4,4 pentène-2	0.5	148
Diméthyl-2,4 pentène-1 + Diméthyl-2,4 pentène-2	2	142 135

au radical isobutènyle, stabilisé par résonance. Plusieurs études de réactions de pyrolyse (29) ou d'oxydation (30, 31) ont, en effet, montré le caractère inhibiteur des radicaux allyliques. Le caractère antidétonant de l'éthylterbutyléther et du méthylterbutyléther a, par ailleurs, été expliqué par la formation d'isobutène (32–34).

En dehors de leur participation aux terminaisons, les radicaux allyliques s'oxydent plus difficilement que les radicaux alcoyles. Considérons, par exemple, la réaction d'oxydation de deux alcènes, l'un conduisant à un radical allylique et l'autre à un radical alcoyle. Ces deux radicaux peuvent, soit réagir avec le réactif RH, soit avec l'oxygène, suivant le schéma :



E = 18,8 kcal/mol (35)



E' = 10,4 kcal/mol (35)

On note, entre les processus 1 et 1′ une différence d'énergie d'activation de 8,4 kcal/mol en faveur du processus 1′ qui est donc plus facile que le processus 1. D'autre part, Benson (36) signale que la constante d'équilibre de la réaction 2′ est supérieure de deux ordres de grandeur par rapport à celle de la réaction 2 à 763 K.

En conclusion, tous les processus de propagation consommant les radicaux formés par décomposition des produits primaires de réaction seront plus rapides si ces radicaux ne sont pas stabilisés par résonance. Au contraire, une concentration élevée de radicaux stabilisés par résonance fera apparaître de nouvelles terminaisons.

La différence d'indice d'octane entre le *n*-heptane et l'isooctane pourrait donc s'expliquer par la présence de radicaux stablisés par résonance formés par décomposition des produits primaires de réaction et plus particulièrement par les alcènes.

Remerciements

Les auteurs remercient Shell Research Ltd pour le soutient financier accordé au cours de ce travail. Ils sont également reconnaissants au Dr. C. Morley (Thornton Research Center) pour des discussions stimulantes et constructives.

Determination of the visible spectra of electrode reaction products in strongly absorbing media by diffusion-controlled chronoabsorptometry

David H. Jones and A. Scott Hinman

Abstract: Chronoabsorptometry under diffusion-controlled conditions has been applied to determination of the difference in molar absorptivity between electrode reaction products and reactants. The technique allows complete determination of the ultraviolet–visible spectra of reaction products that are stable on the time scale of a few hundred milliseconds. The technique was implemented with a reflectance cell that employs quartz light pipes to minimize optical absorbance of the bulk solution without obstructing the current path between counter and working electrodes. The spectrum of one-electron oxidized chloro-(5,10,15,20-tetraphenylporphinato)Fe(III) is determined with the new technique and compared with that obtained by conventional thin-layer spectroelectrochemistry.

Key words: spectroelectrochemistry, chronoabsorptometry, thin-layer spectroelectrochemistry.

Résumé : On a appliqué la chronoabsorptométrie sous des contrôles par diffusion à la détermination de la différence d'absorptivité molaire entre les réactifs et les produits de la réaction à l'électrode. La technique permet de faire une détermination complète des spectres UV–visibles des produits réactionnels qui sont stables à l'échelle de temps de quelques centièmes de millisecondes. La technique a été appliquée à l'aide d'une cellule de réflectance qui fait appel à des conduits de lumière en quartz pour minimiser l'absorption optique de l'ensemble de la solution sans interférer avec le champ du courant entre les électrodes de référence et de travail. Faisant appel à cette technique, on a déterminé le spectre du chloro-(5,10,15,20-tétraphénylporphinate)Fe(III) oxydé par un électron et on l'a comparé à celui obtenu par la technique conventionnelle de spectroélectrochimie en couche mince.

Mots clés : spectroélectrochimie, chronoabsorptométrie, spectroélectrochimie en couche mince.

[Traduit par la rédaction]

Determination of the uv–visible spectra of electrochemical reduction or oxidation products of highly coloured species is most frequently accomplished using thin-layer spectroelectrochemical techniques. The short optical pathlength in thin-layer cells facilitates high optical throughput, which is important in maintaining good signal-to-noise ratios. There is, however, a finite time required to achieve complete electrolysis of the thin-layer cavity due to mass transport limitations (1). In practice, even this theoretical minimum time requirement is rarely achieved because of the high solution resistance associated with the thin-layer cavity (2). This delays the onset of electrolysis at points in the thin-layer cavity positioned furthest from the counter electrode with respect to those positioned closer to the counter electrode. The effect is particularly severe in highly resistive nonaqueous media, and increases as the working electrode dimensions increase. Thin-layer techniques are thus not well suited to determining the spectra of electrochemically generated products of limited stability.

Chronoabsorptometry under conditions of semi-infinite linear diffusion has been widely used for the in situ study of redox processes (3, 4), and affords access to much shorter time scales than are feasible with thin-layer techniques. In single potential step chronoabsorptometry, the potential is stepped to a region where the redox reaction under investigation proceeds at a diffusion-controlled rate (Cottrell experiment) and the absorbance of the diffusion layer is monitored as a function of time. In double potential step chronoabsorptometry, the potential is stepped back to the original value after a time, $t = \tau$, and absorbance is similarly monitored. Studies have normally employed a single wavelength, with the object of characterizing the kinetics of the redox process, rather than determining the spectra of products. Wavelengths are usually chosen where the electroactive precursor has negligible absorbance. This condition ensures maximum light throughput and therefore optimum signal-to-noise ratios in the absorbance–time transients (5).

When the starting material limits the optical throughput at the desired wavelength, consideration must be given to either shortening the optical pathlength, or reducing the concentration. Lowering the concentration will improve the optical throughput but will also reduce the absorbance change pro-

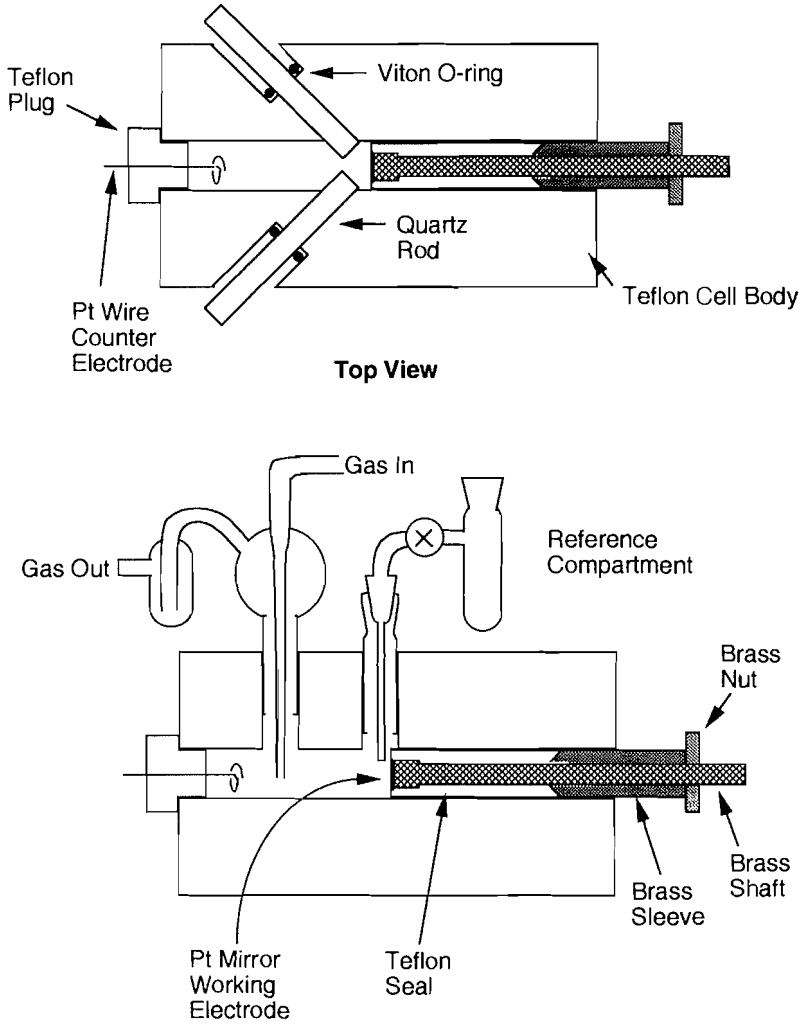
Fig. 1. Details of the chronoabsorptometric cell.



duced on electrolysis. In addition, effects due to impurities or adsorption may become more significant under conditions of high dilution.

Some workers using optically transparent electrodes (OTEs) have reduced the optical pathlength by using a light pipe (e.g., a quartz rod) to transmit light to within a short distance of the OTE surface without loss of throughput (5–7). With a transmission geometry, however, the light pipe obstructs the current path between the working and counter electrodes (5). With highly resistive solutions, or with very short optical pathlengths, this approach can result in uneven potential distribution at the electrode surface and limit the utility of the absorbance–time transients (5–7).

In the present work, we have incorporated the light pipe concept into a spectroelectrochemical cell employing a reflectance, rather than a transmission, geometry. This approach facilitates reduction of the total optical pathlength with little or no obstruction of the current path between the counter and working electrodes. Also, the absorbance change using reflectance is increased over that observed in transmission experiments by a factor of $2/\cos\theta$ (4), where θ is the angle of incidence with respect to the electrode surface normal. When strongly absorbing species necessitate the use of more dilute solutions, the increased sensitivity of the reflectance geometry can help to compensate for the resulting smaller optical changes.

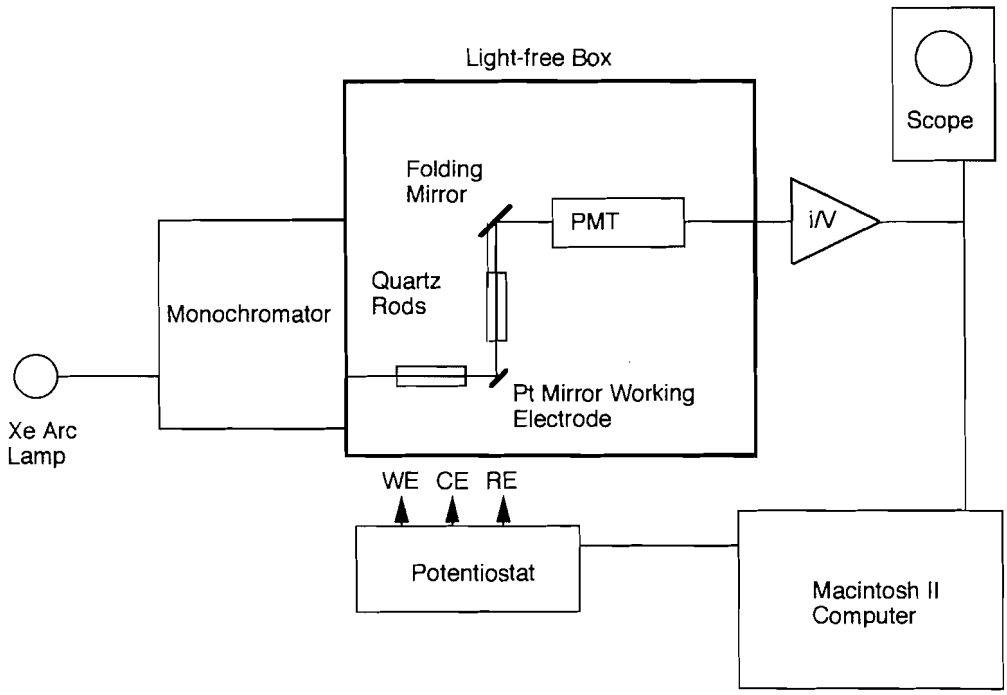
Our objective in this work was to demonstrate for the first time the utility of chronoabsorptometry for determining the complete visible spectrum of an electrochemically generated species on a time scale not normally accessible to thin-layer techniques. Also, we wished to demonstrate the feasibility of this approach to strongly absorbing and highly resistive solutions. The one-electron oxidation of chloro-(5,10,15,20-tetraphenylporphinato)iron(III) (TPPFeCl) in CH_2Cl_2 containing 0.1 M tetra-*n*-butylammonium perchlorate (TBAP) was chosen as the test system. TPPFeCl is strongly absorbing ($\varepsilon_{max} = 1.2 \times 10^5$) and its reversible one-electron oxidation has been well characterized.

Experimental

Cell design

Figure 1 presents a schematic of the spectroelectrochemical

Fig. 2. Schematic of the instrumentation and optics utilized for chronoabsorptometric measurements.



cell used for chronoabsorptometric measurements. The working electrode is a 7 mm diameter Pt disk silver soldered to the end of a brass shaft. This is press fitted into a Teflon seal. The electrode surface is polished to a mirror finish with 0.3 μm alumina polishing powder. The cell body is a Teflon block machined to accept the working electrode and other components illustrated in the figure. Two 5 mm diameter quartz rods, polished flat and clear at their ends, serve to guide incident radiation onto and then away from the Pt mirror electrode. Their longitudinal axes are oriented at 45 degrees with respect to the electrode surface normal. The quartz rods can be positioned to achieve total mean optical pathlengths as small as 3.5 mm, although this smallest optical pathlength maximizes the obstruction to the current path between the counter and working electrodes. In this work, the quartz rods were positioned to achieve a total mean optical pathlength of 1 cm.

Instrumentation and procedure for chronoabsorptometric experiments

Figure 2 illustrates the optical and instrumental configuration employed for chronoabsorptometric experiments. Light from a 75 W Xe arc lamp is focused onto the entrance slit of a GCA-McPherson model EU-701 monochromator. Monochromatic light from the monochromator passes through one of the quartz rod light pipes in the spectroelectrochemical cell and is specularly reflected from the Pt mirror working electrode through the second light pipe. Light emerging from the cell is reflected by a folding mirror onto a Hamamatsu R268 photomultiplier tube (PMT).

The PMT anode current is taken to a Keithley model 427 current amplifier. The output of the current amplifier is monitored with a Macintosh II computer fitted with a G.W. Instruments Macadios II input-output analog-digital interface card. A Think Pascal control program that accessed the Macadios II input-output and data-manipulation libraries was written to allow the generation of successive double potential steps of variable potential and duration with simultaneous collection of up to a 1000 point array at a fixed rate of 5 ms per point with real-time signal averaging. The generated potential step was fed to the adder input of a Hi-Tek model DT2101 potentiostat that controlled the working electrode potential with respect to the reference potential. The data arrays from the experiments could be saved as Microsoft Excel files that could then be further processed with a Microsoft Excel spreadsheet. Absorbance changes are calculated according to $\Delta A = \log(I_1/I_2)$, where I_1 is the light intensity reaching the detector immediately prior to the application of any potential step, and I_2 is the intensity following the potential step.

Other experiments

Conventional time-resolved thin-layer reflectance spectroelectrochemistry was employed to obtain the spectrum of one-electron oxidized TPPFeCl for comparison with that obtained by chronoabsorptometry. The spectroelectrochemical cell, instrumentation, and procedure have been described in detail elsewhere (8, 9).

The diffusion coefficient of TPPFeCl was obtained by chronoamperometry in the same cell as used for the chronoabsorptometry experiments. The electrode area was first calibrated by chronoamperometric oxidation of $K_4Fe(CN)_6$ in 1 M KCl using the well-established diffusion coefficient for the $Fe(CN)_6^{4-}$ species (10).

Reagents and solutions

TPPFeCl (11) was synthesized according to literature procedures. CH_2Cl_2 was shaken with alumina, distilled from P_2O_5

onto CaH_2, and stored over CaH_2 until ready for use. TBAP (Fluka) was recrystallized from isopropanol–water and dried at 80°C in vacuo for several days prior to use. All solutions for spectroelectrochemical experiments employed 0.1 M TBAP, and a home-built aqueous saturated calomel electrode was used throughout. The TPPFeCl concentration was 1.0 mM for the thin-layer spectroelectrochemical measurements. The TPPFeCl concentrations for chronoabsorptometric experiments were 1.06×10^{-5} M for data recorded at 410 and 430 nm, 2.10×10^{-5} M for experiments at 370 and 390 nm, and 9.44×10^{-5} M for all other experiments.

Results and discussion

For a reversible electrode reaction, the absorbance observed on appliation of a potential pulse is proportional to the total charge passed during the experiment (12). Chronoabsorptometry may thus be viewed as the optical analog of chronocoulometry. Winograd et al. (13) have considered transmission geometry where only the product of the electrochemical reaction absorbs and shown that the absorbance–time profile is given by multiplying the chronocoulometric charge–time profile by ε/nFA. Here, ε is the molar absorptivity of the redox product, n is number of electrons, and A is electrode area. Where the potential pulse is sufficient to drive the surface concentration of the reactant to zero, this leads to

$$[1] \quad A(t) = \frac{2\varepsilon C D^{1/2} t^{1/2}}{\pi^{1/2}}$$

In eq. [1], C is the bulk concentration of the reactant, and D is its diffusion coefficient. Where both product and reactant absorb, ε is replaced by the difference in molar absorptivity (14) between product and reactant, $\Delta\varepsilon = \varepsilon_{product} - \varepsilon_{reactant}$, and, if a reflectance geometry is used, the response is multiplied by $2/\cos\theta$ (4) to account for the increased optical pathlength. Equation [1] thus becomes

$$[2] \quad \Delta A(t) = \frac{4\Delta\varepsilon C D^{1/2} t^{1/2}}{\pi^{1/2} \cos\theta}$$

If the concentration and diffusion coefficient of the electrochemical reactant are known, then the slope of a plot of $\Delta A(t)$ vs. $t^{1/2}$ yields $\Delta\varepsilon$. Since the molar absorptivity of the reactant is determinable by conventional methods, the molar absorptivity of the product may be obtained.

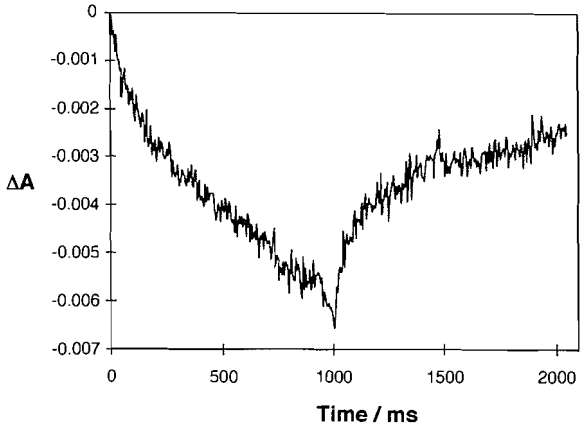
For a double potential step experiment, where the potential is returned to its initial value after a time τ, the cumulative absorbance change at times $t > \tau$ may similarly be derived by applying the considerations of refs. 12–14 to the known (15) chronocoulometric response. This leads to

$$[3] \quad \Delta A(t > \tau) = \Delta A(\tau) - \frac{4\Delta\varepsilon C D^{1/2}(\tau^{1/2} - t^{1/2} + (t - \tau)^{1/2})}{\pi^{1/2} \cos\theta}$$

Letting $\tau^{1/2} - t^{1/2} + (t - \tau)^{1/2} = \phi$, a plot of ΔA vs. ϕ for data obtained on the reverse step should have a slope equal in magnitude but opposite in sign to that for the ΔA vs. $t^{1/2}$ plot for the forward step. The plot intercepts the ordinate at $\Delta A = \Delta A(\tau)$, and the abscissa at $\phi = \tau^{1/2}$. This provides criteria for reversibility and lack of complications associated with the electrode reaction. By analogy to chronocoulometric theory, the ratio of the absorbance change at time $t = 2\tau$ to that observed at $t = \tau$ provides a simpler criterion. For a reversible system without complications, this ratio is given by

$$[4] \quad \frac{\Delta A(2\tau)}{\Delta A(\tau)} = 0.414$$

Fig. 3. Absorbance–time transient at 410 nm obtained for double potential step chronoabsorptometry of TPPFeCl in CH_2Cl_2 containing 0.1 M TBAP. The data are an average of 64 experiments.



In CH_2Cl_2 containing 0.1 M TBAP, TPPFeCl undergoes a reversible one-electron oxidation with a half-wave potential of 1.13 V vs. SCE. The oxidation product has been formulated as an iron(III) porphyrin π-cation radical (16). Figure 3 illustrates the absorbance–time transient observed for TPPFeCl during a 1 s potential pulse to 1.3 V vs. SCE, followed by a return of the potential to its initial value of 0.9 V. The data were recorded at 410 nm, close to the 415 nm absorbance maximum of TPPFeCl. The solution in the chronoabsorptometric cell had an absorbance of approximately 1.2. Of the wavelengths examined, this represents the worst case in terms of optical throughput, and hence in terms of noise.

Prior to further processing, the data of Fig. 3 were smoothed using an 11 point Savitzky–Golay quadratic smoothing routine (17). After smoothing, the ratio of the absorbance change at time 2τ to that at τ, $\Delta A(2\tau)/\Delta A(\tau)$, was 0.43, in good agreement with the theoretical value of 0.414 for a reversible reaction. Figure 4 presents the smoothed ΔA values plotted against $t^{1/2}$ for times $t < \tau$, and against ϕ for times $t > \tau$. The best-fit lines from linear least-squares regression are also shown in the figure. Good linearity is apparent for both the forward and reverse steps. For the forward step, the slope of the least-squares line was -5.82×10^{-3} absorbance units/$s^{1/2}$. A slope of 5.83×10^{-3} absorbance units/$s^{1/2}$ was obtained for the reverse step. The nearly identical magnitudes of the two slopes are as expected for a reversible electrode process. As is apparent in the figure, the intercepts of the plots are also close to the values expected for a reversible process.

In the present example, we have employed a relatively long duration pulse of 1 s. It is clear, however, that accurate determinations of ΔA transients can be made on a considerably

Fig. 4. Plots of absorbance change versus $t^{1/2}$ or ϕ obtained from the data of Fig. 3. The broken lines represent a linear least-squares fit.

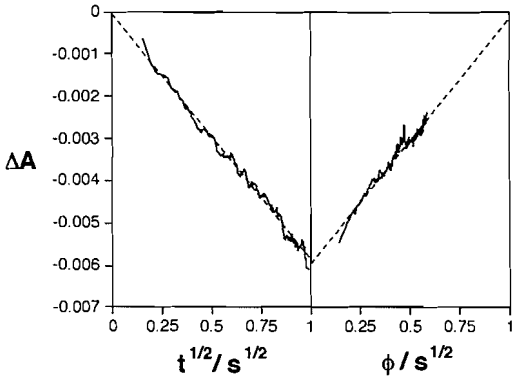


Fig. 5. Ultraviolet–visible spectrum of TPPFeCl (solid line) and its one-electron oxidation product (circles) calculated from chronoabsorptometric data.

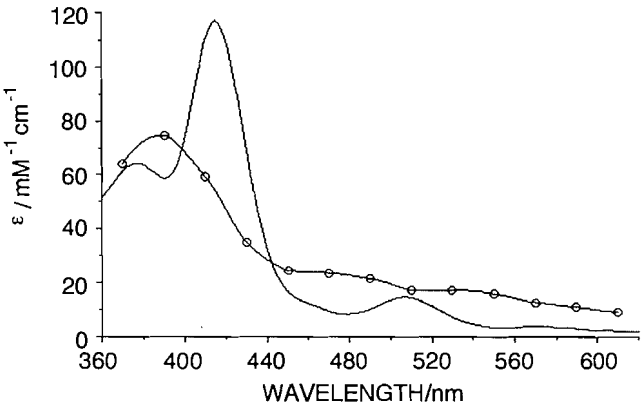

shorter time scale. For instance, the slope of the ΔA vs. $t^{1/2}$ plot obtained using only data from the first 500 ms of the transient of Fig. 3 was 5.84×10^{-3} absorbance units/$s^{1/2}$. This is within 0.4% of that obtained using all of the data recorded during the 1 s pulse. With additional signal averaging and careful attention to uncompensated solution resistance, which can delay the redox reaction during the early portions of the potential pulse, time scales much less than 500 ms should be accessible. Other workers (3, 4), for instance, have obtained accurate absorbance time transients from potential pulses on the order of a few milliseconds or less, although these experiments are normally carried out in more conductive solutions, and at wavelengths where bulk solution absorbance is negligible.

The uv–visible spectrum of TPPFeCl is shown in Fig. 5 together with the spectrum of the corresponding iron(III) porphyrin π-cation radical from the chronoabsorptometric $\Delta\varepsilon$ values and the measured ε values of the unoxidized porphyrin. The relative standard deviations of the molar absorptivities for the π-cation radical were calculated from the standard deviations of the slopes of the ΔA vs. $t^{1/2}$ plots. These were all less than 5%.

Fig. 6. Time-resolved thin-layer spectroelectrochemistry associated with the oxidation of 1 mM TPPFeCl in CH_2Cl_2 containing 0.1 M TBAP. The time between each spectrum is 2.7 s.

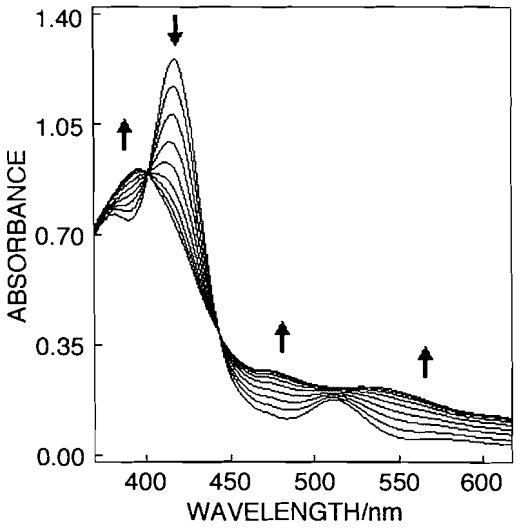

Figure 6 illustrates the time-resolved uv–visible spectral changes associated with electrolysis at 1.3 V vs. SCE of a 1 mM TPPFeCl solution in a thin-layer spectroelectrochemical cell. The oxidation proceeds with isosbestic points to produce a final spectrum of the iron(III) porphyrin π-cation radical. Comparison between the final spectrum of Fig. 6 and the reconstructed spectrum of the iron(III) porphyrin π-cation radical shown in Fig. 5 shows excellent agreement between spectra obtained by the two techniques.

It is clear that the described chronoabsorptometry experiment is capable of determining complete uv–visible spectra of electrochemically generated species that are stable on the time scale of a few hundred milliseconds. To the authors' knowledge, this is the first time chronoabsorptometry has been applied under conditions where the bulk solution possesses significant absorbance, and the first time it has been applied to determine the difference in molar absorptivity between electrochemical reactants and products. We are currently applying the technique to determination of the spectra of several metalloporphyrin oxidation products that have proved too unstable to characterize under thin-layer spectroelectrochemical conditions.

Electroréduction de dérivés dinitrés aromatiques. V. Influences du matériau d'électrode et de systèmes rédox sur les réductions du 4,4′-dinitrodibenzyle et de l'acide 4,4′-dinitrostilbène-2,2′-disulfonique

Anne-Marie Martre, Guy Mousset, Veronica Cosoveanu et Virginia Danciu

Résumé : Ce travail concerne les réductions du 4,4′-dinitrodibenzyle et de l'acide 4,4′-dinitrostilbène-2,2′-disulfonique dans différentes conditions expérimentales. D'une part, il a été envisagé, sur plusieurs matériaux d'électrode (étain, monel, mercure), la réduction électrochimique directe ou en présence d'un couple rédox (Ti^{3+}/Ti^{4+} ou Sn^0/Sn^{2+}) ce qui entraîne des changements dans la nature ou les proportions relatives des produits formés et d'autre part, la réduction chimique en solution par le réducteur Sn^0 préalablement électrogénéré. Les meilleures conditions d'obtention de di- et de mono-amines sont précisées, elles correspondent respectivement à des rendements de l'ordre de 90% pour les diamines, de 70% pour le 4-amino-4′-nitrodibenzyle et de 50% pour l'acide 4-amino-4′-nitrostilbène-2,2′-disulfonique. Une étude analytique préliminaire, sur électrode de mercure et dans les milieux des synthèses (H_2SO_4 5 N – EtOH 50/50, H_2SO_4 2,5 N et HCl à 10%), a permis de préciser et de comparer les caractéristiques électrochimiques des dérivés dinitrés et de chacun des composés $TiOSO_4$, $TiCl_4$, $SnCl_2$, promoteurs des couples rédox utilisés.

Mots clés : 4,4′-dinitrodibenzyle, acide 4,4′-dinitrostilbène 2,2′-disulfonique, électrochimie, réduction, systèmes rédox Ti^{3+}/Ti^{4+} et Sn^0/Sn^{2+}.

Abstract: This work concerns the electrochemical and chemical reductions of 4,4′-dinitrodibenzyl and 4,4′-dinitrostilbene 2,2′-disulfonic acid under various experimental conditions. On the one hand, the electrochemical reduction is realized on Sn, monel, and Hg electrodes with or without the presence of a redox couple, and on the other hand, the chemical reduction is performed by mean of an electrochemically generated reducing agent (Sn^0). According to the type of redox couple used (Ti^{3+}/Ti^{4+} or Sn^0/Sn^{2+}), important changes in the nature and the ratio of reaction products are observed. The best conditions for obtaining di- or mono-amines are defined, they correspond to 90% yield for the diamines, 70% and 50%, respectively, for 4-amino-4′-nitrodibenzyl and for 4-amino-4′-nitrostilbene-2,2′-disulfonic acid. The electrochemical behavior of the dinitro derivatives and of $TiOSO_4$, $TiCl_4$, and $SnCl_2$ used as precursors of the redox couples is studied under conditions of macroscale electrolyses (5 N H_2SO_4 – EtOH 50/50, 2.5 N H_2SO_4, and 10% HCl).

Key words: 4,4′-dinitrodibenzyl, 4,4′-dinitrostilbene 2,2′-disulfonic acid, electrochemistry, reduction, Ti^{3+}/Ti^{4+} and Sn^0/Sn^{2+} redox systems.

Introduction

La réduction des dérivés nitrés aromatiques a donné lieu depuis longemps à de multiples travaux et actuellement il en existe de nombreux qui ont encore comme objectif une meilleure connaissance des mécanismes des réactions ou la mise au point de nouvelles synthèses (1–13 et références citées).

Dans le cadre de recherches effectuées depuis quelques années sur la réduction de dérivés dinitrés aromatiques, nous nous sommes déjà intéressés au 4,4′-dinitrodibenzyle (DNDB) et à l'acide 4,4′-dinitrostilbène-2,2′-disulfonique (DNSS). Sur électrode de mercure, nous avons précisé leurs caractéristiques électrochimiques dans plusieurs milieux, l'importance des phénomènes d'adsorption à la surface de l'électrode et l'influence d'additions de molécules tensioactives (14–16). Nous avons également comparé leurs réductions électrochimiques (par transfert direct d'électrons ou en présence d'un couple rédox) et chimiques par un réducteur préalablement électrogénéré (16, 17). Une étude des cinétiques d'électroréduction du DNDB en milieu hydroalcoolique acide (18), sur des électrodes de Sn, Cu et Pb, en conditions potentiostatique et galvanostatique, a permis d'observer des modifications dans les mécanismes de réduc-

tion en fonction de la surtension d'hydrogène. La détermination de la constante de vitesse et celle de l'énergie d'activation indiquent que l'étain semble le meilleur «matériau cathodique».

L'acide 4,4′-diaminostilbène-2,2′-disulfonique (DASS), préparé essentiellement par réduction de l'acide 4,4′-dinitrostilbène-2,2′-disulfonique, le plus souvent par voie chimique (réduction de Béchamp, hydrogénation catalytique par divers réactifs tels que Pd, Pd–Ni, Ni, Pt–Rh, métaux de Raney), a donné lieu à plusieurs brevets et travaux (19–38) en raison de son utilisation comme constituant des colorants et teintures pour textiles. Son intérêt industriel actuel et celui du 4,4′-diaminodibenzyle (DADB) comme intermédiaire important dans la synthèse des polyuréthanes ont orienté nos recherches vers la synthèse de ces composés (16, 17, 39, 40). À la suite de ces travaux, il nous paraît maintenant intéressant de développer une nouvelle étude concernant l'utilisation d'électrodes solides, matériaux mieux adaptés aux technologies industrielles que le mercure. Nous comparons l'effet du couple rédox Sn^0/Sn^{2+} sur la nature et les rendements respectifs des produits de réduction avec celui de Ti^{3+}/Ti^{4+} et nous définissons la sélectivité de la réduction chimique selon le choix du réducteur et du milieu réactionnel. Toutefois, à des fins de comparaison et pour une meilleure connaisance des caractéristiques électrochimiques, des expériences doivent être également réalisées sur l'électrode de mercure.

A. Études analytiques

Des études analytiques préablables, dans les conditions des réductions préparatives (électrochimique à potentiel constant ou chimique), sont nécessaires pour connaître et comparer les caractéristiques électrochimiques de chacun des dérivés dinitrés et des couples rédox utilisés. Les milieux acides choisis sont respectivement H_2SO_4 5 N – EtOH 50/50 à 60°C pour le DNDB en raison de sa très faible solubilité dans l'eau et H_2SO_4 2,5 N ou HCl à 10% à 30°C pour le DNSS plus soluble. Dans ces solutions, seule l'électrode de mercure, pour laquelle la limite cathodique est à environ −1,0 V/ECS, permet une étude satisfaisante. Nous examinons le comportement électrochimique des ions Sn^{2+}, promoteurs du couple Sn^0/Sn^{2+}, pour le comparer à celui des ions Ti^{4+} ainsi qu'à celui des dérivés dinitrés qui ont déjà fait l'objet d'études antérieures (14, 16, 17).

Réduction de Sn^{2+}

En milieux H_2SO_4 5 N – EtOH 50/50 et H_2SO_4 2,5 N, les voltammogrammes de réduction de $SnCl_2$ sont représentés par les courbes (*a*) de la Fig. 1 (A et B). La réduction, qui met en jeu deux électrons par molécule, correspond au mécanisme

$$Sn^{2+} + 2e^- \leftrightarrows Sn^0$$

Dans les deux cas, la réaction est rapide et bien réversible, elle intervient à des potentiels assez voisins, respectivement : Ep_c = −0,40 V et −0,45 V ; Ep_a = −0,34 V et −0,40 V. L'intensité du pic de réoxydation en Sn^{2+} est fonction des limites en potentiel du cycle de balayage en raison de la formation d'un amalgame avec le mercure. Si le cycle est prolongé vers les potentiels positifs, les ions Sn^{2+} sont oxydés en Sn^{4+} à +0,16 V juste avant l'oxydation du mercure.

En milieu HCl, le chlorure d'étain se réduit comme dans l'acide sulfurique en une étape très réversible avec des potentiels de pics Ep_c = −0,53 V et Ep_a = −0,50 V. Les oxydations de l'électrode de mercure et des ions Cl^- ne permettent pas d'observer celle de Sn^{2+}. Une étude sur électrodes d'or et de platine (41) a montré l'influence des phénomènes importants d'adsorption sur l'oxydation du chlorure d'étain.

Réduction de Ti^{4+}

Nous avons montré précédemment (17) l'influence de l'électrolyte et de la concentration en alcool sur le comportement électrochimique de $TiOSO_4$. En milieux H_2SO_4 5 N – EtOH 50/50 et H_2SO_4 2,5 N, les voltammogrammes de réduction sont reproduits à titre de comparaison, courbes (*b*) de la Fig. 1 (A et B). La réduction a lieu en deux étapes lentes aux potentiels respectifs dans chacun des milieux : Ep_c (1) = −0,14 V et −0,45 V; Ep_c (2) = −0,65 V et −0,87 V. Dans les deux cas, au balayage retour, la réoxydation a lieu en une seule étape, respectivement aux potentiels Ep_a = −0,06 V et −0,02 V.

En milieu HCl à 10%, si le couple rédox Ti^{3+}/Ti^{4+} est obtenu à partir soit du sulfate de titanyle $TiOSO_4$ soit du complexe tétrachlorure de titane – tétrahydrofurane ($TiCl_4$, THF), les voltammogrammes de ces deux composés ont la même allure : la réduction est lente, les potentiels de pic sont respectivement −0,35 V pour $TiOSO_4$ et −0,44 V pour $TiCl_4$, THF; la réoxydation de Ti^{3+} apparaît vers −0,15 V et se superpose ensuite avec celle de l'ion Cl^-.

Les acides H_2SO_4 et HCl étant complexants, il y a formation d'espèces en équilibre dans la solution dont la nature et les proportions relatives dépendent, entre autres paramètres, de l'acidité et de la température (17, 42–44). Le mécanisme global de cette réduction met en jeu un électron par molécule

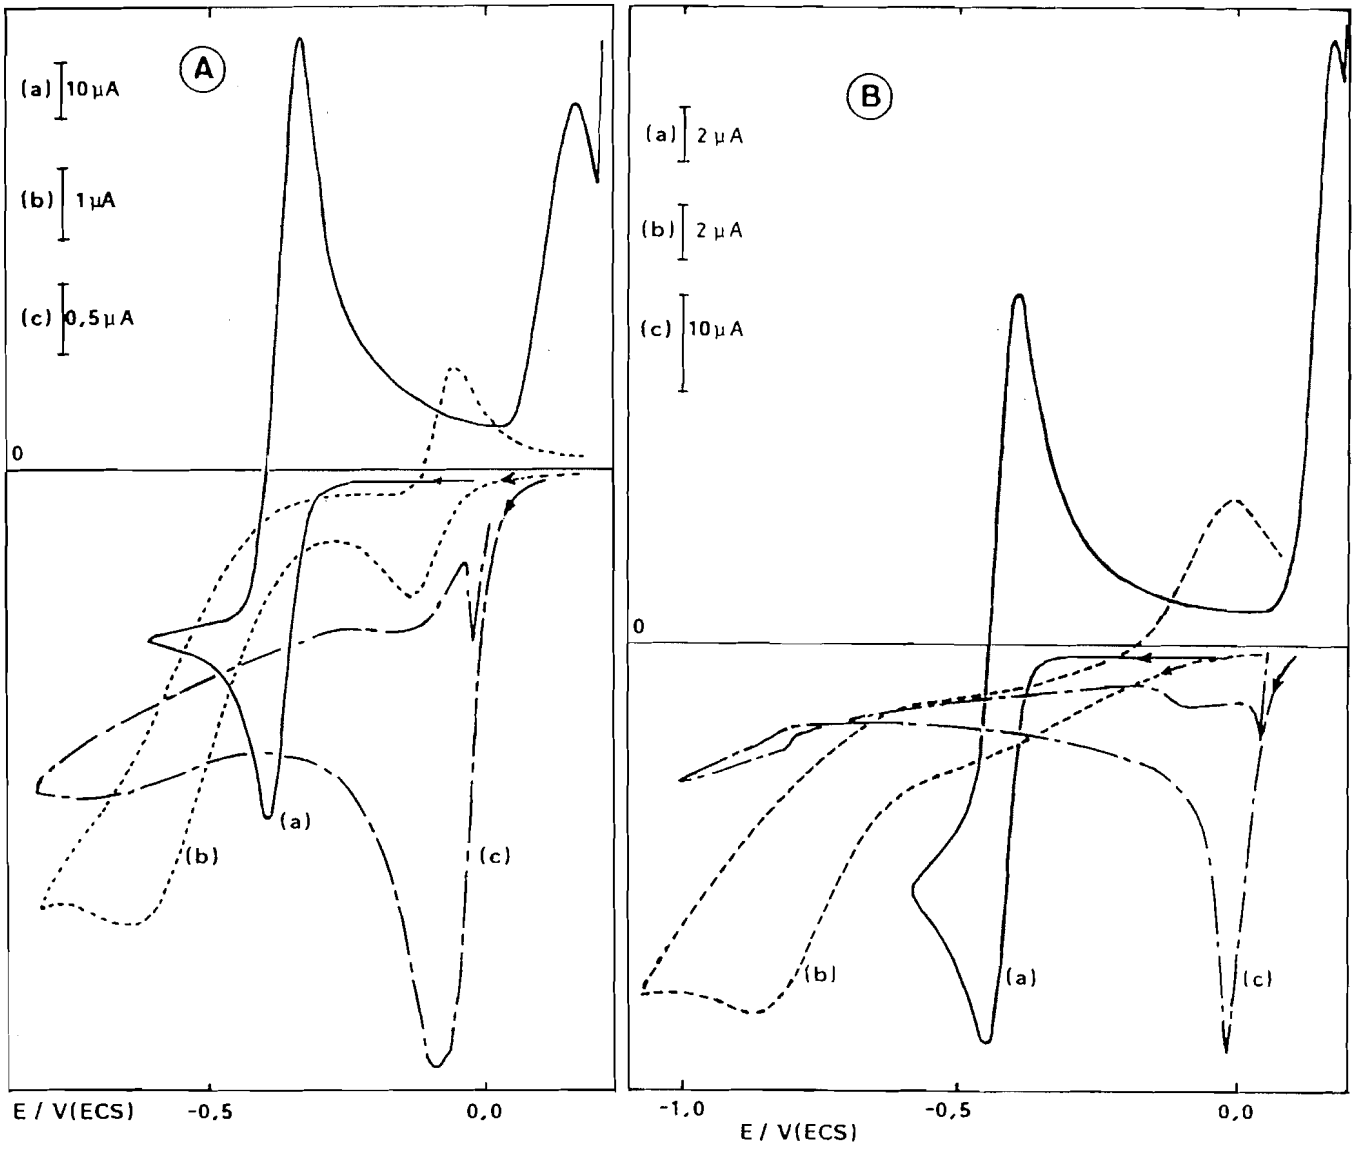
$$TiO^{2+} + 2H^+ + e^- \leftrightarrows Ti^{3+} + H_2O$$

Réduction des dérivés dinitrés

En solution de H_2SO_4 5 N – EtOH 50/50 à 60°C, la réduction du DNDB a lieu en deux étapes : la première est constituée de deux pics très rapprochés dont les potentiels sont compris entre −0,05 V et −0,10 V et la deuxième lente est très étalée en potentiel au voisinage de −0,73 V (Fig. 1A, courbe *c*). La réduction est irréversible. Au balayage retour, on peut constater la présence d'une anomalie vers 0 V qui correspond à la désorption de la molécule comme cela a été montré par les mesures tensammétriques (14). Les mécanismes de réduction déjà donnés (17) sont classiques : la première étape conduit à la formation de dihydroxylamine, la deuxième correspond à sa réduction en diamine. En présence des couples rédox, nous n'avons pas observé d'effets catalytiques. Compte tenu des conditions des voltammétries cycliques (v = 0,1 V s^{-1}), le transfert d'électrons en phase homogène entre Sn^0 ou Ti^{3+} et le dérivé nitré est certainement lent comparé à la réduction hétérogène de ce dernier.

En milieu H_2SO_4 2,5 N, le DNSS se réduit en une étape unique qui met en jeu approximativement 12 électrons par molécule (16). En raison de la forte conjugaison de la molécule, le potentiel de demi-vague polarographique est voisin de 0 V ($E_{1/2}$ = +0,05 V pour c = 10^{-4} M). En voltammétrie cyclique, la forme du pic (Fig. 1B, courbe *c*) et le déplacement de son potentiel avec la concentration sont caractéristiques

Fig. 1. Voltammogrammes de réduction sur électrode de mercure, $v = 0{,}1$ V s^{-1}. A : milieu H_2SO_4 5 N – EtOH à 60°C; (*a*) $SnCl_2$, $c = 5 \times 10^{-3}$ M; (*b*) $TiOSO_4$, $c = 5{,}6 \times 10^{-3}$ M; (*c*) DNDB, $c = 2 \times 10^{-4}$ M. B : milieu H_2SO_4 2,5 N à 30°C; (*a*) $SnCl_2$, $c = 1{,}3 \times 10^{-3}$ M; (*b*) $TiOSO_4$, $c = 9 \times 10^{-3}$ M; (*c*) DNSS, $c = 1 \times 10^{-3}$ M.



d'une forte adsorption qui a été confirmée par les mesures de capacité différentielle (16). Sur le voltammogramme, les deux pics de faible intensité, à +0,04 V et −0,80 V, sont de nature capacitive et délimitent la zone d'adsorption / désorption du dérivé nitré et (ou) de ses produits de réduction.

En milieu HCl à 10%, le potentiel de la réduction de l'acide dinitrostilbène disulfonique est très proche de celui de l'oxydation des ions Cl^- ce qui empêche la détermination précise de ce potentiel situé vers 0 V.

Les trois courbes des Fig. 1A et 1B permettent de comparer les réductions de chaque dérivé dinitré à celles des couples rédox dans les conditions utilisées. Les écarts relatifs de leurs potentiels, en particulier celui de la réduction des hydroxylamines, laissent prévoir des effets différents sur les mécanismes et par conséquent sur la nature des produits de réduction.

B. Influence des couples rédox et du matériau d'électrode sur la nature des produits formés

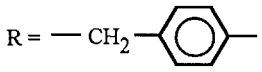
Comme dans la partie analytique, les électrolyses à potentiel constant du DNDB sont réalisées en solution H_2SO_4 5N – EtOH 50/50 à 60°C et à une concentration 1×10^{-3} M en raison de sa très faible solubilité et celles du DNSS, à 30°C en milieux H_2SO_4 2,5 N ou HCl à 10%, avec une concentration de 2×10^{-3} M. Elles sont réalisées sur électrodes de mercure, étain et monel. L'influence de la nature de l'électrode sur la réduction de dérivés nitrés a déjà fait l'objet de quelques travaux (45–50). Suivant les matériaux, sur lesquels la réduction des ions H^+ en hydrogène est plus ou moins difficile, on peut s'attendre à des mécanismes dif-

férents d'électronation–protonation ou d'hydrogénation électrocatalytique (51–55).

Électrolyses sur électrode de mercure

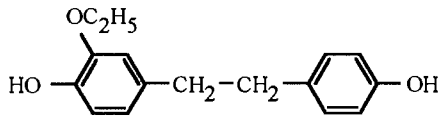
Réduction du dinitrodibenzyle

En absence de couple rédox, nous avons montré dans une étude précédente (17), que la réduction électrochimique a un rendement faradique de 90% calculé par rapport à la réduction en diamine et conduit à l'obtention de 75% de DADB, 1% de DNDB, 9% du produit amino-hydroxylé HO-R-R-NH_2 et 2% du produit dihydroxylé HO-R-R-OH avec

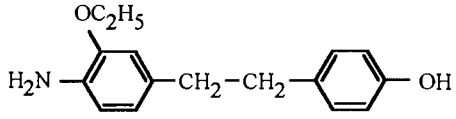


En présence de $TiOSO_4$, nous avons vu dans cette même étude que le pourcentage de DADB peut atteindre 92% tandis qu'il reste 2–5% de composé de départ. L'absence de produits hydroxylés permet d'isoler un DADB très pur.

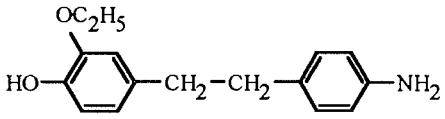
En présence de $SnCl_2$, le potentiel choisi pour l'électrolyse est celui de la réduction de Sn^{2+}, $E = -0{,}40$ V, et la réaction est effectuée jusqu'à la consommation d'une quantité d'électricité correspondant à celle nécessaire au passage du dérivé dinitré en dérivé diaminé. Après extraction, le produit brut de réaction est analysé par chromatographie en phase vapeur (CPV), RMN et spectrométrie de masse couplée à la CPV. Sa composition comprend une quantité de DADB qui ne dépasse pas 50%, celle du dérivé amino-hydroxylé HO-R-R-NH_2 peut atteindre 38% et le dérivé HO-R-R-OH n'existe qu'à l'état de traces. Ces composés n'ont pu être séparés les uns des autres. Parmi les sous-produits formés, la spectrométrie de masse indique pour quatre d'entre eux (11% au total), des masses molaires respectives $M = 258$, $M = 257$, $M = 257$, $M = 256$ ce qui permet, compte-tenu de la fragmentation, d'écrire les formules



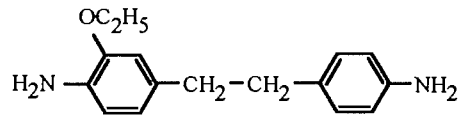
$M = 258$



$M = 257$

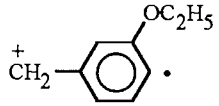


$M = 257$



$M = 256$

Pour les molécules de masses $M = 257$ et $M = 256$, on pourrait envisager des structures *N*-éthoxylées. Toutefois, dans la fragmentation du composé de masse $M = 257$, un pic à $m/z = 134$ correspondant à l'ion radical



nous fait penser que la position du groupement éthoxy sur l'atome d'azote est peu probable.

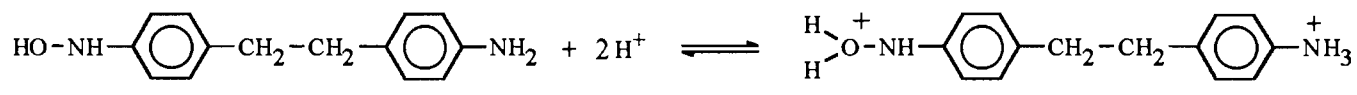
La formation des dérivés hydroxylés a été étudiée dans un travail précédent (17). Celle des composés éthoxylés peut être expliquée par l'hypothèse de mécanismes faisant intervenir, en premier lieu, des réactions de protonation compétitives de la fonction hydroxylamine qui conduisent à des structures de type quinone-imine ou à des attaques nucléophiles justifiant la substitution en position 4 ou 4′ par des fonctions hydroxyles :

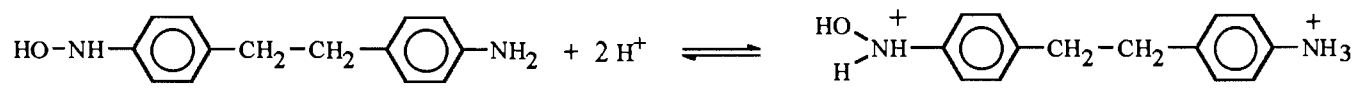
En présence d'éthanol, nous obtenons des composés qui possèdent un groupement -OC_2H_5 en position 3. Nous n'avons pas mis en évidence le dérivé hydroxylé correspondant qui résulterait d'une transposition de l'hydroxylamine. Une telle fixation préférentielle du groupement éthoxy a déjà été notée dans le cas de la réduction de nitronaphtalènes substitués en milieu H_2SO_4–EtOH 50/50 (56).

Le pourcentage élevé de ces sous-produits formés avec le couple rédox Sn^0/Sn^{2+} alors qu'avec Ti^{3+}/Ti^{4+} ils ne sont observés qu'à l'état de traces, peut être lié au fait que les sels d'étain réduisent très lentement les hydroxylamines en amines (57), ce qui permet aux attaques nucléophiles de se développer.

Réduction de l'acide dinitrostilbène disulfonique

En milieu H_2SO_4 2,5 N, au potentiel de $-0{,}05$ V, la réduction du DNSS en DASS est totale. Le produit de réduction précipite au fur et à mesure de sa formation en cours d'électrolyse ce





qui permet de l'isoler de manière simple par filtration avec un rendement de l'ordre de 90%. Aucun autre composé n'est détecté en fin d'expérience.

Alors que dans le cas du DNDB, la présence de $TiOSO_4$ améliore le rendement de la réaction en diamine en facilitant les contacts réducteur – dérivé dinitré puisque ce dernier est très peu soluble dans l'eau, sa présence n'a pas d'intérêt pour le DNSS. De même, des essais effectués avec $SnCl_2$ au potentiel $E = -0{,}20$ V, c'est-à-dire avant sa réduction en Sn^0, n'ont pas modifié de manière sensible les résultats. Le DASS est formé avec un rendement similaire à celui obtenu sans couple redox ce qui montre que le cation Sn^{2+} ne réduit pas le dérivé dinitré. Nous avons vérifié par ailleurs que dans les mêmes conditions, un contact prolongé entre le DNSS et $SnCl_2$ n'entraîne pas la formation de DASS. La spectrométrie de RMN permet de détecter, en plus du dérivé diaminé, la présence d'un autre composé de structure symétrique identifié à la dihydroxylamine par spectrométrie de masse ($m/2z = 200$). Lorsque la réduction est réalisée au potentiel de $-0{,}40$ V correspondant à la formation de Sn^0, le dérivé diaminé est obtenu de manière presque exclusive. Il est accompagné seulement de traces de dihydroxylamine.

En milieu HCl, au potentiel de $-0{,}10$ V, il se forme également un précipité dont l'analyse confirme qu'il s'agit de DASS. Une étude par RMN de l'ensemble des produits montre, en plus du DASS, la présence de la dihydroxylamine et parfois du composé amino-nitré mais toujours en très faibles quantités.

Électrolyses sur électrode de monel

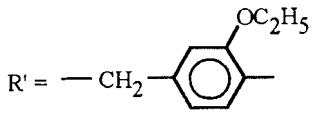
L'électrode de monel — alliage de nickel (2/3) et de cuivre (1/3) — est utilisée à l'échelle industrielle à cause de sa bonne résistance à la corrosion en milieu acide et de son coût relativement faible. Nous avons déjà étudié la réduction du nitrobenzène en aminophénol sur cet alliage (résultats non publiés). La surtension de l'hydrogène, peu importante sur ce type de matériau, laisse supposer une compétition entre le mécanisme d'hydrogénation électrocatalytique et celui d'électronation–protonation. Ainsi, au potentiel imposé $E = -0{,}65$ V à 60°C, après une consommation d'électricité égale à quatre fois la valeur théorique, la proportion de DNDB réduite est seulement de 50%. Si le rendement faradique n'est pas très intéressant, le produit de réduction est essentiellement le DADB pur avec un rendement par rapport au DNDB de l'ordre de 45%.

Avec cette électrode comme avec l'électrode de mercure, la présence de $TiOSO_4$ favorise grandement la formation du DADB dont le pourcentage atteint 90% si la concentration en $TiOSO_4$ est supérieure au double de celle en DNDB initial. Aux concentrations moindres en couple rédox, son effet est partiel, ainsi pour 6×10^{-4} M, le rendement en DADB et de 76% et l'on retrouve 6% de DNDB non réduit. Des produits secondaires apparaissent, en particulier les composés hydroxylés.

Dans le cas du DNSS, le potentiel imposé de $-0{,}30$ V, bien que faiblement négatif, ne permet pas non plus d'éviter la réduction du proton ce qui empêche que la réduction soit complète et abaisse le rendement faradique. Le produit obtenu est un mélange de diamine avec en moindres proportions de la dihydroxylamine et des dérivés amino-nitré et dinitré non réduit. La présence de $TiOSO_4$ favorise la formation de diamine qui précipite au cours de l'électrolyse. Le spectre de RMN du solide isolé après sa transformation en sel de sodium confirme ce résultat. Seules des raies supplémentaires correspondant à des traces de dihydroxylamine sont visibles sur le spectre.

Électrolyses sur électrode d'étain

La réduction du DNDB, en milieu H_2SO_4–EtOH 50/50 à 60°C, est effectuée au potentiel de $-0{,}65$ V. La réaction est lente mais l'intensité du courant décroît régulièrement en fonction du temps. La quantité d'électricité nécessaire pour réduire le dérivé dinitré en totalité est supérieure à la valeur théorique de 12 électrons par molécule à cause de la surtension d'hydrogène de l'électrode. Le rendement maximum en DADB n'excède pas 50%. L'analyse chromatographique des produits de réduction indique la formation de nombreux composés, les principaux ont été identifiés grâce à la spectrométrie de masse couplée à cette technique. Le DADB est toujours accompagné des composés mono et dihydroxylés HO-R-R-NH_2 et HO-R-R-OH dans des proportions respectives de l'ordre de 18% et 8%. Les quatre composés éthoxylés sont également formés, leur pourcentage total peut atteindre 15% et l'on peut envisager, à l'état de traces, l'existence des composés HO-R′-R′-NH_2 (M = 301) et HOHN-R-R′-NH_2 (M = 272) avec



et celle dérivés mono-nitrosés (M = 256). La présence de ces derniers a pu être confirmée par voltammétrie cyclique en milieu DMF. Nous retrouvons dans ces conditions un comportement semblable à celui observé lors de la réduction sur électrode de mercure en présence de $SnCl_2$.

En présence de $TiOSO_4$, à des concentrations supérieures à 2×10^{-3} M et au même potentiel de $-0{,}65$ V, la formation de DADB est favorisée au détriment de tous les produits secondaires qui se forment en son absence. Le rendement en DADB atteint 90%. Il est bien cristallisé et c'est pratiquement le seul produit qui soit extrait.

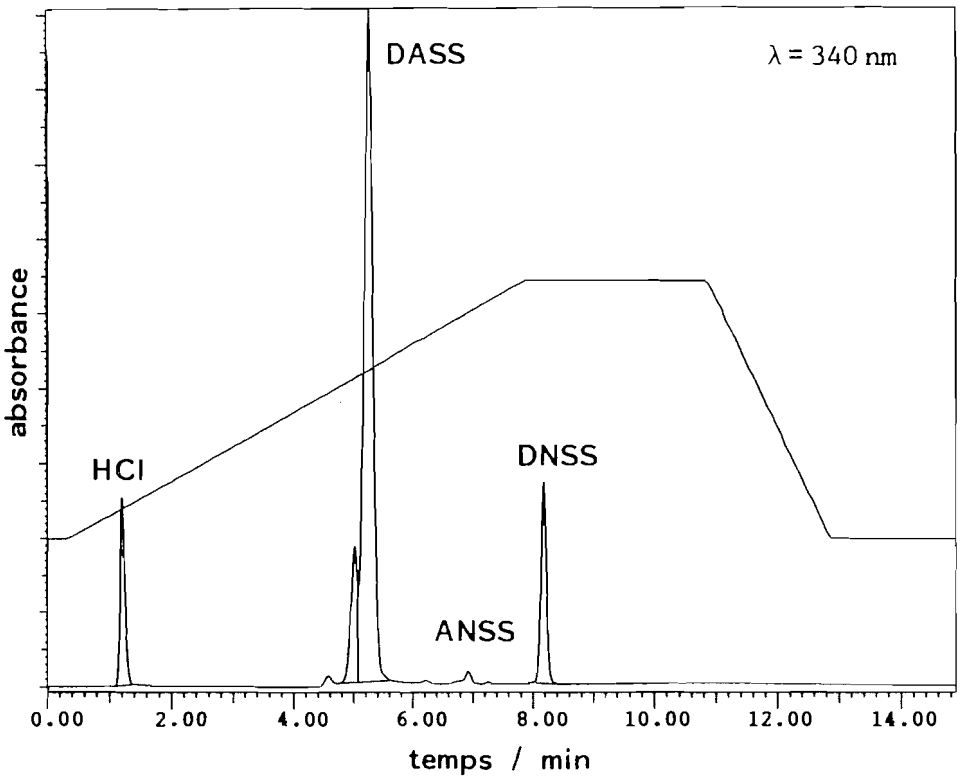
Au cours des *électrolyses du DNSS*, réalisées en milieu H_2SO_4 2,5 N au potentiel de $-0{,}65$ V, un dépôt se forme sur l'électrode. En fin de réaction, il est facilement détachable et laisse la surface de l'étain très brillante. Les analyses des extraits obtenus soit à partir de ce dépôt soit de l'électrolyte donnent des compositions similaires : la proportion de DASS est toujours majoritaire, les autres produits formés sont des composés di- et mono-nitrés et de la dihydroxylamine.

La présence de $TiOSO_4$ n'apporte pas de modifications : le dépôt sur l'électrode se forme de la même manière et les produits obtenus sont les mêmes.

En milieu HCl, des essais à plusieurs potentiels dans le domaine d'utilisation possible compris entre $-0{,}50$ et $-0{,}90$V n'ont pas mis en évidence d'effets significatifs de ce paramètre sur les produits formés, essentiellement le DASS avec des quantités plus ou moins importantes de dihydroxylamine.

La chromatographie liquide haute performance (HPLC), par analyse de paires d'ions sur silices greffées (58–63), s'est avérée être performante tant au niveau analytique, dans le suivi des réductions par les analyses d'échantillons périodiquement prélevés, qu'au niveau préparatif pour la séparation

Fig. 2. Analyse par HPLC au cours d'une réduction électrochimique du DNSS sur électrode d'étain en milieu HCl à 10% avec enregistrement du gradient de concentration de la phase mobile.



des différents composés de l'extrait. La figure 2 montre un exemple de chromatogramme obtenu au cours d'une réduction en milieu HCl. Elle correspond à l'analyse d'un prélèvement pendant une électrolyse sur électrode d'étain après consommation de 11 électrons par molécule. Les pics correspondant aux différents produits sont nettement caractérisés. Cette méthode nous a permis également de séparer les composés (Fig. 3) et en particulier d'isoler la dihydroxylamine (pic 1) afin de pouvoir l'analyser par spectrométrie de masse par ionisation électrospray. La diamine correspond au pic 3 du chromatogramme. Le pic 2 n'a pas été identifié avec certitude mais comme aucun autre composé n'est détecté sur les spectres de RMN, on peut envisager que ce pic corresponde à une forme de la diamine obtenue par échange de cations Na^+ et Bu_4N^+ par suite de la présence du réactif $Bu_4NH_2PO_4$ dans les éluants. Cet échange intervient en solution avec formation de paires d'ions qui possèdent des temps de rétention différents en HPLC. Cette hypothèse est confortée par le fait que la spectrométrie de masse met en évidence un composé $[DASS + Bu_4N]^-$ ($m/z = 610,5$).

C. Réduction chimique par le réducteur Sn^0 électrogénéré

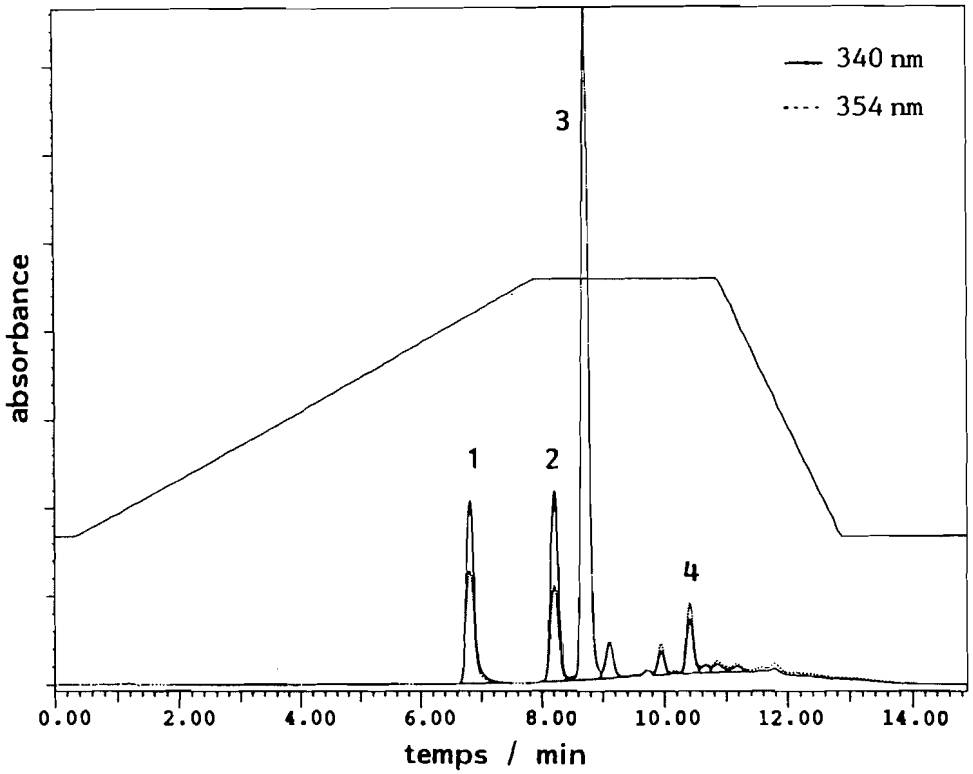
Les effets très différents des couples rédox Ti^{3+}/Ti^{4+} et Sn^0/Sn^{2+} sur les réductions électrochimiques nous ont incités à les comparer à ceux obtenus en réductions chimiques par les deux réducteurs Ti^{3+} et Sn^0 préalablement électrogénérés.

Réduction chimique du DNDB

Le chlorure stanneux est réduit électrochimiquement sur nappe de mercure au potentiel de −0,50 V à 60°C, dans la solution H_2SO_4 5 N – EtOH. Ensuite, après arrêt de l'électrolyse, le DNDB, solubilisé dans une petite quantité de DMF désoxygéné, est introduit dans cette solution. Après la réduction, l'extrait obtenu est toujours mal cristallisé, de couleur rouge foncé, il est pâteux et adhère aux parois de verre. Les mêmes méthodes d'analyses que précédemment — RMN, CPV et spectrométrie de masse couplée à la CPV — ont également permis de caractériser les produits formés. Le pourcentage de DADB n'est pas supérieur à 50% et l'on retrouve les mêmes sous-produits qu'en réduction électrochimique sur électrode d'étain ou sur électrode de mercure en présence de $SnCl_2$, c'est-à-dire les composés hydroxylés, principalement HO-R-R-NH_2 de l'ordre de 15% et quelques pourcents de HO-R-R-OH. Les composés éthoxylés se forment aussi, leurs pourcentages varient entre 15 et 20%. Plusieurs expériences avec des rapports Sn^0/DNDB différents n'ont pas permis d'obtenir le dérivé amino-nitré (ANDB) même à l'état de traces alors que sa proportion pouvait atteindre 70% avec Ti^{3+} (17); ceci peut être expliqué ici par la lenteur de la réduction de l'hydroxylamine ce qui permet au réducteur de réagir sur les deux groupements NO_2 en priorité. La quantité de DNDB non réduit est fonction de la proportion relative de Sn^0.

Des essais de séparation sur colonne de silice n'ont pas donné de résultats totalement satisfaisants. En effet, l'extrait est difficilement solubilisé dans l'éluant et les produits hydroxylés n'ont pu être séparés du DADB, qui n'est donc pas obtenu aussi pur qu'en réduction chimique par Ti^{3+}.

Fig. 3. Séparation par HPLC des produits formés lors d'une réduction électrochimique du DNSS sur électrode d'étain en milieu HCl. (1) dihydroxylamine; (2) [DASS + Bu_4N]$^+$; (3) DASS; (4) ANSS.



Réduction chimique du DNSS

La réduction chimique du DNSS a été réalisée dans les deux milieux H_2SO_4 2,5 N et HCl à 10%. Le réducteur Sn^0 est préalablement électrogénéré sur électrode de mercure à partir du chlorure stanneux au potentiel de −0,50 V.

Au cours de la réaction, pour des rapports Sn^0/DNSS de l'ordre de 6/1, il se forme un précipité composé principalement de diamine avec une faible quantité de dérivé amino-nitré (ANSS). La solution est traitée après filtration selon le mode opératoire décrit en partie expérimentale et nous identifions les composés mono- et di-aminés dans un rapport 65/35 accompagnés de DNSS non réduit qui peut atteindre 15 à 20%. Au total, la proportion ANSS/DASS est voisine de 60/40 soit légèrement inférieure à celle de 85/15 obtenue pour la réduction par Ti^{3+} dans les mêmes conditions (16). Cette différence peut s'expliquer par le fait que Ti^{3+} est un réducteur beaucoup plus efficace que Sn^0 pour la réduction des hydroxylamines (57).

La comparaison de ces résultats avec ceux de la réduction du dinitrodibenzyle montre d'importantes différences. En effet, la réduction chimique du DNDB par Sn^0 ne conduit pas à la formation du composé mono-aminé mais à celle de composés hydroxylés. Cette constatation peut être interprétée par le fait que la réduction de l'hydroxylamine, toujours lente, intervient dans une zone de potentiel relativement plus négative (entre −0,40 et −0,75 V) dans laquelle se situe celle du système Sn^{2+}/Sn^0, ce qui ne favorise pas le transfert d'électrons et permet à des réactions de substitutions de se développer, rendant la formation du dérivé mono-aminé plus difficile. Au contraire, dans le cas du DNSS, l'étude analytique a montré qu'en raison de sa conjugaison, ce dernier est réduit en milieu acide vers 0 V, en une étape unique mettant en jeu 12 électrons par molécule. De plus, la solubilité du DNSS, beaucoup plus grande que celle du DNDB, permet un meilleur contact avec le réducteur ce qui favorise le transfert d'électrons et par conséquent la formation du dérivé mono-aminé.

Conclusion

Le 4,4′-dinitrodibenzyle étant très peu soluble en milieu aqueux, la présence d'un couple rédox accélère dans tous les cas la réduction électrochimique vraisemblablement en raison d'associations de type donneur–accepteur qui facilitent les échanges électroniques. Chaque type de réducteur garde cependant sa spécificité et conduit à des mécanismes différents qui influent sur la sélectivité des réactions. Ainsi, quel que soit le matériau de l'électrode, $TiOSO_4$ favorise la formation de la diamine et permet de l'obtenir pure avec un rendement supérieur à 90%. L'effet de $SnCl_2$ est différent. La quantité de diamine n'excède pas 50% des produits formés et elle est toujours accompagnée de composés hydroxylés et éthoxylés.

Sur cathode de mercure, la diamine est le seul produit de réduction de l'acide 4,4′-dinitrostilbène 2,2′-disulfonique en milieu H_2SO_4. Elle est obtenue avec un très bon rendement et l'intervention de $TiOSO_4$ ou $SnCl_2$ n'a pas d'effet sur la réaction. L'utilisation d'électrodes solides, mieux adaptées en vue d'applications industrielles, permet également cette synthèse.

Sur l'électrode d'étain, le DASS est formé avec un meilleur rendement que sur l'électrode de monel mais sur cette dernière, les résultats sont améliorés par l'action du couple rédox Ti^{3+}/Ti^{4+} en solution. Les produits secondaires sont identifiés dans chaque cas et des méthodes de dosage et de séparation des produits (photodensitométrie, HPLC), mises au point pour cette étude, se sont avérées bien adaptées et performantes.

La méthode électrochimique permet de générer de manière simple des réducteurs dont le choix oriente la sélectivité de la synthèse. Ainsi, dans le cas du DNDB, le réducteur Sn^0 conduit aux mêmes produits que ceux obtenus par réduction électrochimique sur électrode d'étain ou sur électrode de mercure en présence de chlorure d'étain tandis qu'en choisissant la proportion du réducteur Ti^{3+}, il est possible de préparer le composé amino-nitré résultant de la réduction d'un seul groupement nitré. Les résultats sont différents dans le cas du DNSS pour lequel les deux réducteurs Sn^0 et Ti^{3+} permettent la synthèse de l'acide amino-nitrostilbène disulfonique. Le rendement est légèrement supérieur avec Ti^{3+}. Les résultats ne sont pas modifiés par la nature du milieu acide, H_2SO_4 ou HCl à 10%.

Partie expérimentale

Les principales caractéristiques des produits et des solvants ainsi que les techniques utilisées et les conditions des expériences ont déjà été décrites (14, 16, 17).

Appareils — conditions des expériences — produits

Nous rappelons seulement que les cellules électrochimiques sont thermostatées à 60°C pour la réduction du DNDB et à 30°C pour celle du DNSS. Les dimensions des plaques constituant les cathodes solides sont respectivement 40 × 50 mm pour celle de monel et 50 × 35 mm pour celle d'étain. La cathode de mercure a une diamètre de 72 mm. Les potentiels sont indiqués par rapport à l'électrode de référence au calomel saturé (ECS) et, dans toutes les électrolyses, l'anode est une plaque de plomb.

Le 4,4′-dinitrodibenzyle est un produit industriel recristallisé dans le toluène et le 4,4′-dinitrostilbène-2,2′-disulfonate de sodium est un produit commercial TCI. Les dérivés diaminés, qui ont permis de confirmer l'identification des produits de réduction, sont respectivement d'origines Aldrich et Lancaster. Pour chaque composé, les deux formes, acide et sel de sodium, ont la même abréviation dans le texte, soit DNDB et DNSS pour les dinitrés et DADB et DASS pour les diaminés. Le sulfate de titanyle $TiOSO_4, xH_2SO_4, xH_2O$ est un produit Aldrich. Le complexe tétrachlorure de titane – tétrahydrofurane et le chlorure stanneux dihydraté sont des produits Fluka.

Extraction, séparation et caractérisation des produits de réduction

Après les électrolyses ou les réductions chimiques, des polarographies ou des voltammétries cycliques effectuées sur la solution permettent de détecter la présence des composés réductibles (dérivés amino-nitré et dinitré non réduit).

Les solutions d'électrolyses sont concentrées puis neutralisées par une solution de soude et évaporées. Les produits de réduction du DNDB sont extraits à l'éther tandis que ceux du DNSS le sont avec du DMF. L'identification et la composition des extraits secs sont déterminées par spectrométrie de RMN ^1H ($CDCl_3$), chromatographie en phase vapeur (CPV) et spectrométrie de masse couplée à la CPV pour le DNDB. Dans le cas du DNSS, les caractéristiques de RMN ^1H (DMSO-d_6) des DNSS, DASS et ANSS ont été déterminées dans une étude précédente (16), celles de la dihydroxylamine (déplacements chimiques (en ppm) par rapport au TMS, avec les mêmes conventions que pour les autres dérivés) sont : 7,06 ($2H^{(3 \text{ et } 3')}$, doublet J = 2,4 Hz), 6,16 ($2H^{(5 \text{ et } 5')}$, doublet J = 2,4 Hz et doublet J = 8,2 Hz), 6,75 ($2H^{(6 \text{ et } 6')}$, doublet J = 8,2 Hz), 6,86 ($2H^{(\alpha \text{ et } \alpha')}$, singulet), 5,01 ($4H^{(NHOH)}$, singulet).

Les produits sont séparés par chromatographie sur colonne de silice et analysés par chromatographie sur couche mince sur plaque de silice avec comme éluants le mélange toluène–acétone 80/20 ou toluène–méthanol 90/10 dans le cas du DNDB et le mélange DMF–chloroforme 50/50 dans le cas du DNSS. La mise au point d'une méthode par photodensitométrie associée à cette dernière a permis le dosage des acides mono- et di-aminostilbènes disulfoniques (64). Le DASS, qui est insoluble en milieu acide, peut être isolé de la solution par filtration mais sa purification et sa caractérisation spectroscopique nécessitent sa mise sous la forme de sel de sodium.

La chromatographie liquide à haute performance (HPLC), technique nouvelle dans cette étude, a été effectuée sur un appareil Gilson équipé de deux pompes avec chambre de mélange, d'une vanne d'injection Rheodyne de 20 μL pour les mesures analytiques et de 500 μL pour les séparations de produits. Un détecteur spectrophotométrique UV117 permet deux détections simultanées, les longueurs d'onde choisies correspondent aux maxima d'absorbance du DNSS (λ = 354 nm) et du DASS (λ = 340 nm). Pour les mesures analytiques, la colonne de silice greffée de chaînes octadécyle C18, de granulométrie 5 μm, est de type Spherisorb, sa dimension est 100 × 4,6 mm. Pour les séparations à l'échelle préparative, la colonne est de modèle Rainin Instrument Company DYN FAST PCLC C18, de granulométrie 3 μm, de dimension 50 × 21,4 mm. La phase mobile est un mélange eau–méthanol contenant le contre-ion. L'eau est déionisée, distillée et passée dans une cartouche Millipore. Le méthanol, de qualité RS pour HPLC Carlo Erba, est désaéré aux ultra-sons. Le réactif de paire d'ions est une solution aqueuse d'hydrogénophosphate de tétrabutylammonium ($Bu_4NH_2PO_4$) et les éluants sont préparés suivant la méthode décrite par S.K. Hammond et al. (62). Les analyses chromatographiques sont programmées par le logiciel GILSON 715 GME. Le composé est mis en solution dans l'éluant aqueux et injecté. Les meilleurs résultats sont obtenus en gradient de concentration de 22% à 60% d'éluant méthanolique en 8 min, suivi d'un palier à 60% pendant 3 min et du retour aux conditions initiales en 2 min avec rééquilibrage de la colonne.

Intramolecular Diels–Alder reactions of 2*H*-thiopyran dienes

Dale E. Ward, Thomas E. Nixey, Yuanzhu Gai, Matthew J. Hrapchak, and M. Saeed Abaee

Abstract: A systematic survey of IMDA reactions of 4-[tris(2-methylethyl)silyl]oxy-2*H*-thiopyran derivatives with potential dienophiles tethered at the C-2, C-3, C-5, and C-6 positions is presented. Cycloaddition was not observed with a C_3 or C_4 tether and an unactivated terminal olefin as dienophile. IMDA adducts could be obtained when dienophiles activated by a carbomethoxy group were employed. Compounds having the activated dienophile attached via a C_3 tether to C-2 of the 2*H*-thiopyran gave adducts with high stereoselectivity. Substrates having the dienophile attached to C-3 with a C_3 or C_4 tether cyclized readily. With an (*E*)-enoate as the dienophile, the stereoselectivity was poor (*endo*:*exo* = 1.1–2.5:1) and essentially independent of reaction conditions (i.e., thermal vs. Lewis acid mediated). With the (*Z*)-enoate, a 7:1 mixture of *endo*:*exo* IMDA adducts was obtained under thermal conditions; with Lewis acid catalysis, isomerization of the dienophile was competitive with cycloaddition. Type II IMDA adducts were not observed with C-5 tethered substrates. Compounds having the dienophile attached to C-6 via a C_3 or a five-atom tether also failed to give IMDA adducts. No evidence for isomerization of the 2*H*-thiopyran dienes by [1,5] sigmatropic rearrangement was observed. The *endo* adducts from IMDA reactions of the C-3 tethered substrates can be desulfurized to obtain synthetically useful *trans*-fused hydrindans and decalins with angular methyl groups.

Key words: intramolecular Diels–Alder, 2*H*-thiopyran, *cis*-substituted 1,3-diene surrogate, *trans*-octahydro-3a-methyl-1*H*-indene derivatives, *trans*-decahydro-4a-methylnapthalene derivatives.

Résumé : On présente une étude des réactions DAIM des dérivés du 4-[tris(2-méthyléthyl)silyl]oxy-2*H*-thiopyrane avec des diénophiles potentiels attachés en positions C-2, C-3, C-5 et C-6. On n'observe pas de cycloaddition avec des laisses de 3 ou 4 atomes de carbone et une oléfine terminale désactivée comme diénophile. Les adduits DAIM peuvent être obtenus lorsque l'on utilise des diénophiles activés par un groupe carbométhoxy. Les composés ayant le diénophile attaché par une laisse de 3 carbones attachée au carbone en position 2 du 2*H*-thiopyrane donne des adduits avec une très grande stéréosélectivité. Les substrats ayant un diénophile attaché en C-3 avec une laisse de 3 ou 4 atomes de carbone se cyclisent rapidement. Si on utilise un (*E*)-énoate comme diénophile on obtient une faible stéréosélectivité (*endo* : *exo* = 1,1–2,5 : 1) qui est indépendante des conditions de réaction (c.-à-d., thermique versus une catalyse par acide de Lewis). Avec un (*Z*)-énoate on obtient un mélange d'adduits DAIM *endo* : *exo* dans la proportion de 7 : 1 par voie thermique tandis que la catalyse par un acide de Lewis conduit à une compétition entre l'isomérisation du diénophile et la cycloaddition. On n'a pas observé d'adduits DAIM de type II avec les substrats liés en C-5. Les composés ayant un diénophile attaché en C-6 via une liesse de 3 ou de 5 atomes de carbone ne donnent pas non plus d'adduits DAIM. On n'a pas pu mettre en évidence l'isomérisation des dienes 2*H*-thiopyranes par réarrangement sigmatropique [1,5]. Les adduits *endo* obtenus à partir des réactions DAIM des substrats liés en C-3 peuvent être désulfurisés pour obtenir des hydrindanes condensés en position *trans* et des décalines avec des groupes méthyles angulaires très utiles en synthèse.

Mots clés : Diels–Alder intramoléculaire, 2*H*-thiopyrane, substitut pour les dienes substitués en position *cis*, dérivés *trans*-octahydro-3a-méthyl-1*H*-indène, dérivés *trans*-décahydro-4a-méthylnaphtalène.

[Traduit par la rédaction]

Introduction

Despite its long history (1), the Diels–Alder reaction continues to be of fundamental importance to the theory and practice of organic chemistry (2). The increase in molecular complexity resulting from the simultaneous formation of two σ-bonds and up to four stereogenic centers coupled with the attributes of wide generality, atom economy, and predictable regio- and stereoselectivity contribute to the unrivaled synthetic utility of this reaction. One of the few limitations of the Diels–Alder reaction is the poor reactivity associated with *cis*-substituted dienes (3). As a consequence, certain stereochemical arrays are not readily generated by a Diels–Alder cycloaddition (see Scheme 1).

In an effort to address this problem, we have been investigating a strategy involving the use of 2*H*-thiopyrans as functional equivalents to *cis*-dienes (4–8). Previous work has established that the Diels–Alder adducts from reactions of 2*H*-thiopyrans with dienophiles are, after desulfurization, synthetically equivalent to adducts derived (in principle) from unreactive *cis*-dienes (Scheme 1). We have developed methods for the preparation of a wide variety of substituted 2*H*-thiopyrans

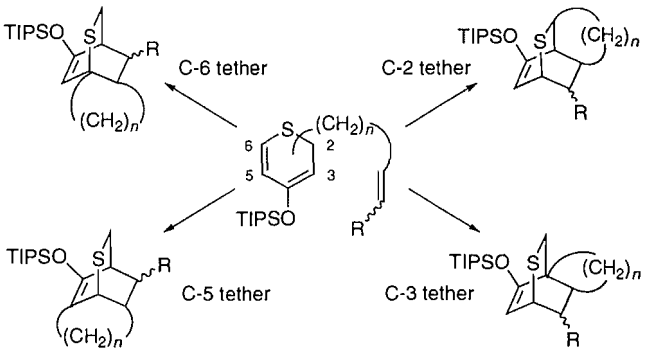
(4–9) and have systematically investigated their Diels–Alder reactivity under a variety of conditions (4–8). The reactions of 2*H*-thiopyrans bearing suitable activating substituent(s) with reactive dienophiles (e.g., maleic anhydride, maleimide) give predominantly *endo* adducts in good yield (4, 5). The reactions are slower using less reactive dienophiles (e.g., acrylate, crotonate) and modest yields are obtained because thermal decomposition of the diene competes effectively with cycloaddition (5). Lewis acid mediated reaction at lower temperatures is often satisfactory in these cases (6, 7).

The intramolecular Diels–Alder (IMDA) reaction has emerged as a powerful synthetic method for the stereoselective construction of polycyclic ring systems in a single step (10). The attenuated reactivity of *cis*-substituted dienes also limits the scope of the IMDA reaction, although not as severely as the intermolecular counterpart (10).[2] Relatively few examples of IMDA reactions involving conformationally mobile (i.e., capable of s-*cis* and s-*trans* conformers) *cis*-dienes (12) or 1,1-disubstituted-1,3-dienes (13) have been reported. Many of these examples involve particular structural elements that favor an s-*cis* conformation of the diene despite the *cis* substitution. Because (*Z*)-dienes often undergo IMDA cyclization with a much higher degree of stereoselectivity than the corresponding (*E*) isomers (10), the incorporation of a (*Z*)-diene moiety to serve as a stereochemical control element in an IMDA reaction can be an attractive tactic (10). However, this approach is limited by the reduced reactivity of (*Z*)-dienes, which can preclude IMDA reaction[3] in favor of competitive pathway(s) including the loss of stereochemical integrity by [1,5] sigmatropic rearrangement and (or) diene isomerization.[4] Preliminary results on the feasibility of using 2*H*-thiopyrans as surrogates for *cis*-dienes in IMDA reactions to address this limitation were reported (8). In this paper we present a full account of our investigations of IMDA reactions of 2*H*-thiopyrans.[5]

Fig. 1. Possible IMDA adducts from 4-(triisopropylsilyl)oxy-2*H*-thiopyran dienes with dienophiles attached at various positions.



Results and discussion

Our previous work on intermolecular Diels–Alder reactions of 2*H*-thiopyrans had established the 4-(triisopropylsilyl)oxy derivative as a moderately reactive but somewhat unstable diene (4–8). A systematic study of the reactivity of this diene in IMDA reactions was undertaken. A series of substrates with various dienophiles attached to each of the four possible positions of 4-(triisopropylsilyl)oxy-2*H*-thiopyran by a 3- or 4-atom tether were required (Fig. 1). Because our goal was to evaluate IMDA reactivity, we adopted a simple synthetic strategy to produce all of the isomeric compounds from common intermediates.

Unactivated terminal alkene dienophiles were chosen for the first series of substrates. The desired compounds were prepared from the known β-ketoester **1** (15) according to Scheme 2.[6] Alkylation (16) of **1** with 5-bromopentene (17) or 6-bromohexene (17) gave **2a** and **2b**, respectively, in modest yields along with products of *O*-alkylation and ring fragmentation (18). The decarboxylation of compounds such as **2** can be difficult (16*b*), and only a modest yield of **3** was obtained from **2** even using the recommended conditions (16*b*). Dehydrogenation of **3** by reaction with *N*-chlorosuccinimide (NCS) according to the known procedure (19) proceeded with poor regioselectivity, as expected (20), to give inseparable 1.2:1 mixtures of **4** and **5**, respectively. The mixtures of **4a/5a** and **4b/5b** were individually converted into 1.2:1 mixtures of **6a/7a** and **6b/7b** by treatment with triisopropylsilyl trifluoromethanesulfonate (TIPSOTf) and Et_3N (5). Alternatively, CuI mediated conjugate addition (21; see also ref. 16*b*) of the Grignard reagent derived from 5-bromopentene or 6-bromo-

[2] An often cited report (12*o*) claims similar IMDA reactivity for the methyl esters of (2*E*,7*E*)- and (2*E*,7*Z*)-2,7,9-decatrienoic acid. Interpretation of these results in light of those of Roush (11) leads to the conclusion that the 7*E* isomer is considerably more reactive than the 7*Z* isomer.

[3] For examples, see refs. 12*a*, 12*b*, and 13*c*.

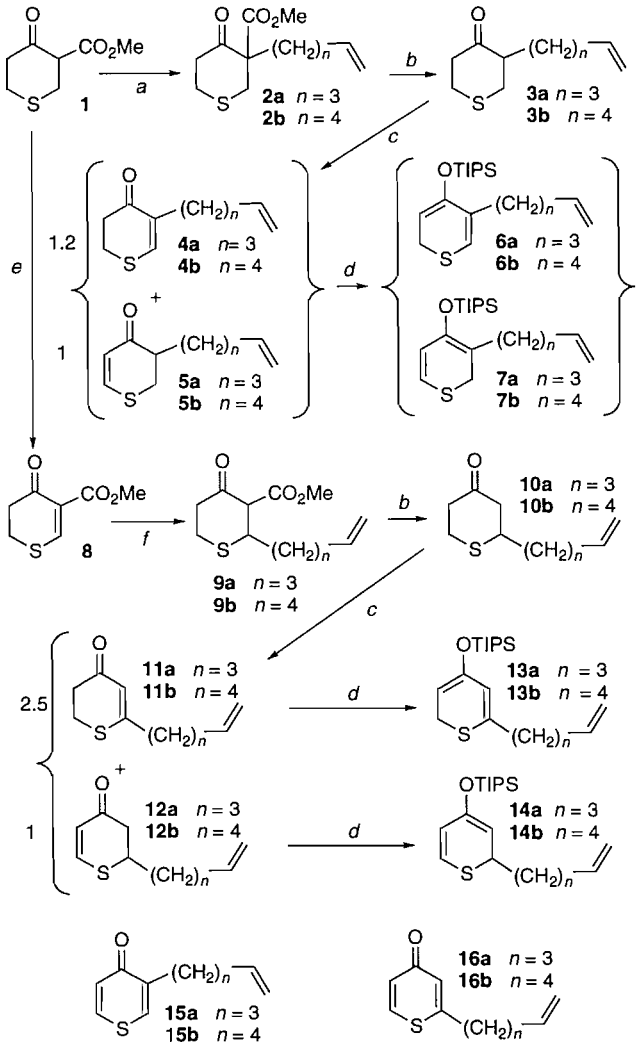
[4] For examples, see refs. 12*j*, 12*m*, and 12*n*.

[5] For a recent example involving IMDA reaction of 3*H*-benzofuro[3,2-*c*]thiopyran diene, see ref. 14.

[6] Reactions in Schemes 2–4 were not optimized. Considerable literature precedent suggests that many of these transformations would proceed in high yield if conditions were optimized for the particular substrate. Because our objective was to assess IMDA reactivity, the synthetic scheme was chosen to achieve diversity (as opposed to selectivity) and synthetic reactions were typically performed only once or twice using the published procedures "as is."

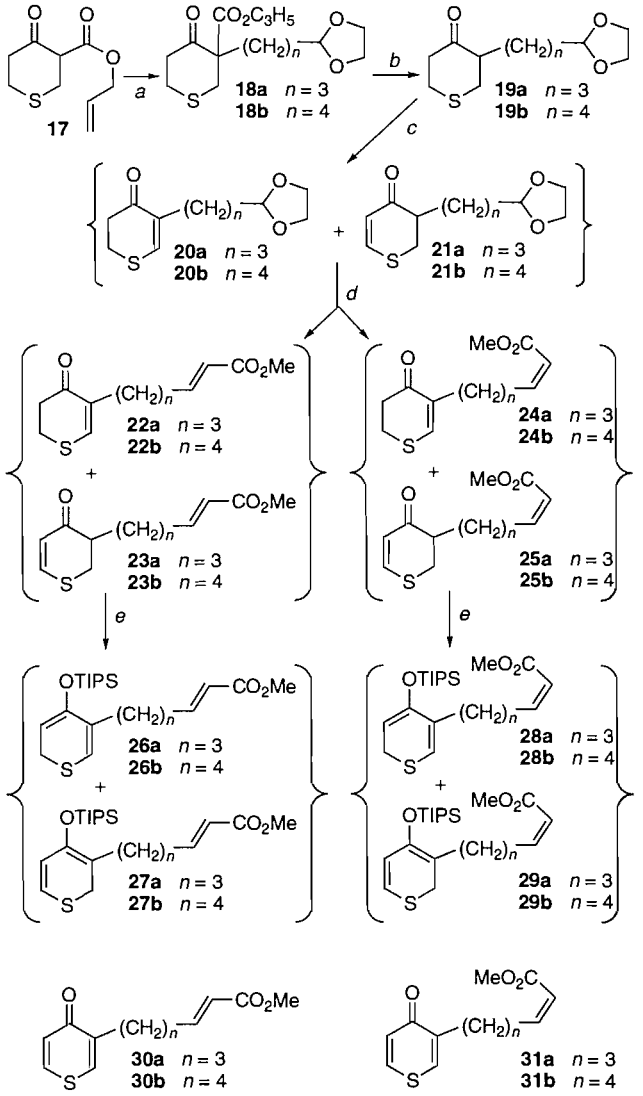
Scheme 2.

a: NaH, NaI, RX, acetone, reflux; *b*: LiI, 20% $DMF_{(aq)}$, reflux; *c*: NCS, pyridine, CH_2Cl_2; *d*: TIPSOTf, Et_3N; *e*: MnO_2, CH_2Cl_2; *f*: RMgBr, CuI, DMS.



Scheme 3.

a: NaH, NaI, RX, acetone, reflux; *b*: $(Ph_3P)_4Pd(0)$, morpholine, THF; *c*: NCS, pyridine, CH_2Cl_2; *d*: (i) $HClO_4$, acetone, (ii) $Ph_3P{=}CHCO_2Me$, MeOH; *e*: TIPSOTf, Et_3N.

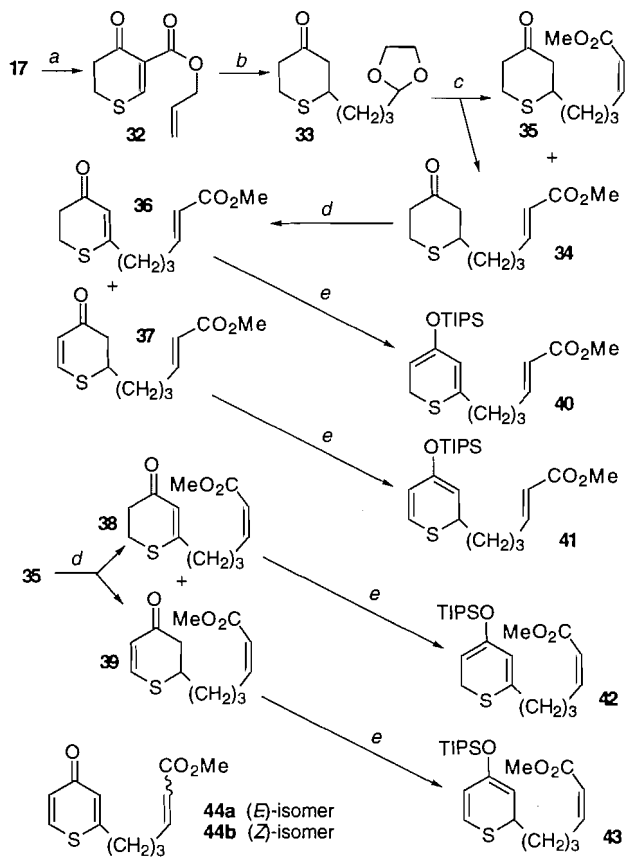


hexene to **8** (21) followed by decarboxylation of the resulting **9** produced **10**. Treatment of **10** with NCS gave separable mixtures of **11** and **12** with the former predominating by a ratio of ca. 2.5:1. The 6- and 2-substituted 2*H*-thiopyrans **13** and **14** were readily derived from **11** and **12**, respectively, by reaction with TIPSOTf. Individual solutions of the IMDA substrates **6a/7a**, **6b/7b**, **13a**, **13b**, **14a**, and **14b** in degassed C_6D_6 or $C_6D_5CD_3$ containing 2,6-di-*tert*-butyl-4-methylphenol (BHT) were heated in sealed NMR tubes at temperatures up to 200°C for several days, resulting in complete decomposition of the substrates. The reactions were monitored by ^1H NMR and, in no case, was the presence of an IMDA adduct indicated. Only products arising from desilylation (i.e., **4**, **5**, **11**, **12**) and oxidation (i.e., **15**, **16**) were detected (4, 5).

In an effort to enhance the IMDA reactivity, substrates with methyl 2-alkenoates as activated dienophiles were investigated. The preparation of compounds with the dienophile tethered at C-3 and C-5 of the 2*H*-thiopyran is outlined in Scheme 3.[6] Because of the low yields previously obtained in the decarboxylation of **2** and **9**, we began with the known allyl β-ketoester **17** (22). The Pd(0) catalyzed decarboxylation of alkylated derivatives of **17** is reported to be much more efficient than LiI–DMF decarboxylation of the analogous methyl esters (22). Alkylation of **17** with 2-(3-bromopropyl)-1,3-dioxolane (23) or 2-(4-bromobutyl)-1,3-dioxolane (24) gave **18a** and **18b**, respectively, in good yields. In each case, decarboxylation of **18** proceeded smoothly to give **19**, which reacted with NCS and pyridine to produce an inseparable mixture of enones **20** and **21** with a slight excess of the former. The individual mixtures of **20a/21a** and **20b/21b** were treated with aqueous acid to provide the corresponding aldehydes, which were immediately olefinated under conditions to maximize the proportion of (*Z*)-enoate formed (25). In both cases, a separable 1.7:1 mixture of (*E*)-enoates and (*Z*)-enoates was obtained. Neither the (*E*)-enoates (**22** and **23**) nor the (*Z*)-enoates (**24** and **25**) could be separated from each other and

Scheme 4.

a: MnO_2, CH_2Cl_2; *b*: (i) RMgBr, CuI, DMS, (ii) $(Ph_3P)_4Pd(0)$, morpholine, THF; *c*: (i) $HClO_4$, acetone, (ii) $Ph_3P{=}CHCO_2Me$, MeOH; *d*: NCS, pyridine, CH_2Cl_2; *e*: TIPSOTf, Et_3N.

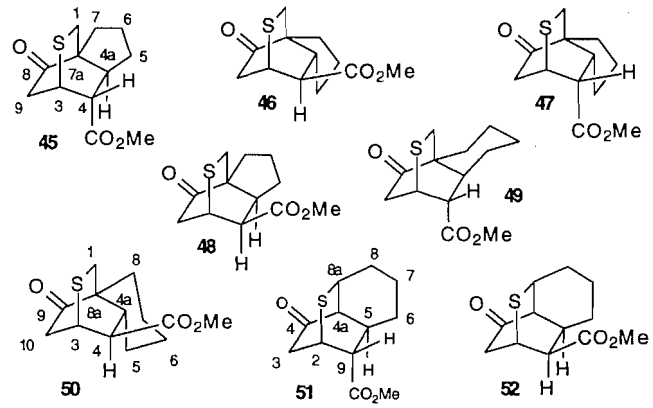


were isolated in the same ratio as that of the precursors **20** and **21** (i.e., **22**:**23** and **24**:**25** = ca. 1.25:1). The individual mixtures of **22a/23a**, **22b/23b**, **24a/25a**, and **24b/25b** were converted in the usual way into the corresponding mixtures of 2*H*-thiopyran isomers **26a/27a**, **26b/27b**, **28a/29a**, and **28b/29b**, respectively.

The preparation of 2*H*-thiopyrans with an activated dienophile attached at C-2 and C-6 is outlined in Scheme 4.[6] Conjugate addition of the Grignard reagent prepared from 2-(3-bromopropyl)-1,3-dioxolane to **32** (22) gave **33** in good yield. Hydrolysis and Wittig reaction of **33**, as described above, gave a separable 1.8:1 mixture of **34** and **35**, respectively. Oxidation of **34** with NCS gave **36** and **37** (2:1); a similar oxidation of **35** provided **38** and **39** (1.5:1). The IMDA substrates **40**–**43** were prepared by reaction of TIPSOTf with **36**–**39**, respectively.

The trienes **26**–**29** and **40**–**43** were produced in near quantitative yield as judged by ^1H NMR immediately after work-up; however, they were used immediately without further purification because of instability. In general, these IMDA substrates were highly prone to oxidation and were readily converted to the corresponding 4*H*-thiopyran-4-ones (i.e., **30**, **31**, **44**) upon heating in solution (or even on standing, especially neat). In the presence of BHT (4, 5), degassed solutions of the trienes at elevated temperatures were relatively stable towards oxidation for several days. The results of attempted IMDA reactions of **26**–**29** and **40**–**43** are presented in Table 1.

A C_6D_6 solution of a 1.2:1 mixture of **26a/27a** containing BHT (0.15 equiv.) was heated at 140°C. After 96 h, the ^1H NMR spectrum of the reaction mixture indicated the absence of **27a** and the presence of two products along with **26a** and a small amount of **30a**. Product isolation was facilitated by treatment of the crude reaction mixture with $HF_{(aq)}$ to hydrolyze the silyl enol ethers. The two IMDA adducts **45** and **46** were obtained in 55% and 43% yields, respectively (based on **23a**). In light of these results, analysis of the ^1H NMR spectrum of the mixture of **26a/27a** obtained by treatment of **22a/23a** with TIPSOTf (1.2 equiv.) in the presence of Et_3N revealed the presence of a small amount (<10%) of the same two products observed above and indicated that TIPSOTf alone could promote the IMDA reaction.[7] Reaction of the mixture of **22a/23a** with TIPSOTf (2 equiv.) for 2 h followed by HF work-up gave **45** (44%) and **46** (42%) in good yield (based on **23a**) in addition to recovered **22a** (81% based on **22a**). Similar results were obtained in a Lewis acid catalyzed reaction. Addition of $EtAlCl_2$ (0.4 equiv.) to a C_6D_6 solution of a 1.2:1 mixture of **26a/27a** resulted in consumption of **26a** within 3 min (^1H NMR) and **45** (38%) and **46** (34%) were isolated in 38% and 34% yields, respectively, after HF work-up and chromatography. Heating a 1.2:1 mixture of **28a/29a** as above (140°C, 96 h) gave the IMDA adducts **47** (70%) and **48** (10%). However, reactions promoted by TIPSOTF or $EtAlCl_2$ gave product mixtures and yields similar to those obtained from **26a/27a**, indicating that isomerization of the dienophile occurs faster than IMDA reaction under these conditions.[8]



Because of the short tether length and enforced unfavorable regiochemistry, type II IMDA adducts from **26a** (and **28a**) were not expected (27). However, Diels–Alder adducts could, in principle, be derived from **26a** by initial rearrangement to **27a** by a [1,5] sigmatropic H migration (or other mechanism).[9] To test this possibility, isomerically pure **26a** was prepared from **22a** recovered from the TIPSOTf mediated IMDA reaction of the **26a/27a** mixture. No IMDA adducts were detected after heating a C_6D_6 solution of **26a** containing BHT (0.15 equiv.) at 140°C for 4 days. Further heating up to 180°C only resulted in extensive decomposition. Similarly, treatment of **26a** with $EtAlCl_2$ failed to produce any IMDA adduct.

[7] For examples of silyl triflate mediated Diels–Alder reactions see ref. 26.

[8] **47** was shown to be stable to the $EtAlCl_2$ reaction conditions.

[9] For an example of isomerization of 2*H*-thiopyrans under similar conditions, see ref. 5.

Table 1. Attempted IMDA reactions of 4-(triisopropylsilyl)oxy-2*H*-thiopyran dienes.

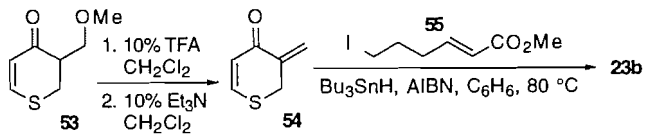
Entry	Substrate(s)	Conditions[a]	IMDA adduct(s) (% yield)[b]
1.	**6a/7a** or **6b/7b**	Thermal (150–200°C)	None
	13a or **13b**		None
	14a or **14b**		None
2.	**26a/27a** (1.2:1)	Thermal (140°C, 96 h)	**45** (55), **46** (43)
		TIPSOTf (2 h)	**45** (44), **46** (42)
		$EtAlCl_2$ (3 min)	**45** (38), **46** (34)
3.	**26b/27b** (1.3:1)	Thermal (140–180°C)	None[c]
		TIPSOTf (24 h)	None
		$EtAlCl_2$ (30 min)	**49** (40), **50** (15)
4.	**27b**	Thermal (170°C, 60 h)	**49** (37), **50** (14)
		$EtAlCl_2$ (30 min)	**49** (48), **50** (19)
5.	**28a/29a** (1.2:1)	Thermal (140°C, 96 h)	**47** (70), **48** (10)
		TIPSOTf (24 h)	**45** (44), **46** (43)
		$EtAlCl_2$ (3 min)	**45** (34), **46** (27), **47** (30), **48** (trace)[d]
6.	**28b/29b** (1.3:1)	Thermal (140–180°C)	None
		TIPSOTf (24 h)	None
		$EtAlCl_2$ (30 min)	**49** (ca. 25%)[e]
7.	**40**	Thermal (140–180°C)	None
		TIPSOTf (24 h)	None
		$EtAlCl_2$ (30 min)	None
8.	**41**	Thermal (175°C, 17 h)	**51** (86)
		TIPSOTf (13 h)	**51** (17)
		$EtAlCl_2$ (7 h)	**51** (34)
9.	**42**	Thermal (140–180°C)	None
		TIPSOTf (24 h)	None
		$EtAlCl_2$ (30 min)	None
10.	**43**	Thermal (180–210°C, 17 h)	**51** (30), **52** (33)
11.	**62a** or **62b**	Thermal (80–180°C)	None
		$EtAlCl_2$ (30 min)	None
12.	**63a** or **63b**	Thermal (80–180°C)	None
		$EtAlCl_2$ (30 min)	None

[a]See experimental section.
[b]Isolated yield based on the appropriate starting enone.
[c]This result likely due to inefficient deoxygenation (see text).
[d]Detected by ^1H NMR but not isolated.
[e]This compound was not pure; other isomers, if present, were not isolated.

Disappointingly, the expected IMDA adducts were not detected after heating C_6D_6 solutions of 1.3:1 mixtures of **26b/27b** or **28b/29b** at 140–180°C over several days. Only the oxidation products **30b** and **31b** were isolated after the usual HF work-up. Alternatively, $EtAlCl_2$ mediated reaction of a similar mixture of **26b/27b** gave **49** and **50** in 40% and 15% yields, respectively (based on **23b**). Similar treatment of **28b/29b** also produced **49** (ca. 25%) but any isomeric adducts, if present, could not be isolated. No IMDA adducts were detected or isolated after individual treatment of **22b/23b** or **24b/25b** with excess TIPSOTf in the presence of Et_3N even after prolonged reaction times (24 h). To clarify the IMDA reactivity of **27b**, a selective synthesis of **23b** was undertaken using our newly developed protocol (9). Thus, tin hydride mediated addition of **55** (28) to **54** gave **23b** directly in 45% yield (Scheme 5). Heating a degassed C_6D_6 solution of **27b** (prepared from **23b**) in a preheated oil bath at 170°C for 60 h resulted in the completed disappearance of **27b** and the adducts **49** and **50** were isolated in 37% and 14% yield, respectively, after HF work-up. The previous failure of a mixture of **26b/27b** to produce the same adducts under similar conditions is attributed to inefficient deoxygenation of the reaction solution, resulting in an increased rate of oxidation of the trienes at the expense of IMDA reaction. Treatment of **27b** with $EtAlCl_2$ gave **49** (48%) and **50** (19%) in a similar ratio and yield as previously obtained from a mixture of **26b/27b**.

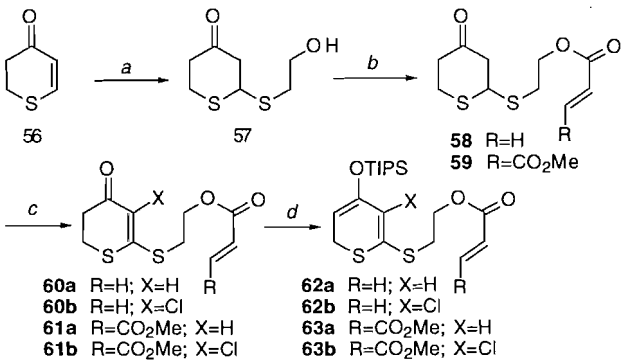
Attempted IMDA reaction of **40** under thermal (140–180°C, several days), $EtAlCl_2$, or TIPSOTf mediated conditions led only to decomposition. Similar results were obtained with **42**. Alternatively, **41** gave **51** as the only product after heating at 175°C for 17 h. The same product was obtained from **41** under Lewis acid mediated conditions. Thermal reaction of **43** is slow at 175°C and heating up to 210°C gave **52** (33%) along with **51** (30%). The formation of **51** in this reaction is due to competitive isomerization of **43** to **41** under the reaction conditions.

Scheme 5.



Scheme 6.

a: 2-Mercaptoethanol, NaH, THF; *b*: acryloyl choride or methyl fumaryl chloride, pyridine, CH_2Cl_2; *c*: NCS, CCl_4; *d*: TIPSOTf, Et_3N.



The failure of **40** and **42** to produce adducts (cf. **27**, **29**) is presumably the result of the unfavorable regiochemistry enforced by the short tether, thereby increasing the activation energy for IMDA reaction and precluding cycloaddition in favor of other pathways. To examine the possibility of effecting IMDA reaction of a C-6 tethered substrate that would allow favorable regiochemistry, compounds **62** and **63** were prepared according to Scheme 6. Addition of 2-mercaptoethanol to **56** (19) produced **57**, which was acylated with acryloyl chloride or methyl fumaryl chloride to give the unstable[10] **58** and **59**, respectively. Individual treatment of **58** and **59** with NCS produced a mixture[11] of **60a,b** and **61a,b**, respectively, which were converted into the corresponding 2*H*-thiopyrans by reaction with TIPSOTf. Adducts from IMDA reaction of **62a** and **63a** would be synthetically equivalent (via desulfurization) to adducts from an analogous intermolecular Diels–Alder reaction. Thus 2-mercaptoethanol represents a potential temporary tether of the diene to the dienophile.[12] Unfortunately, all attempts to effect IMDA reaction of **62** and **63** under thermal (in C_6D_6 or $(CD_3)_2SO$)[13] or $EtAlCl_2$ mediated conditions failed to produce any adducts. Presumably the 5-atom tether, the preference for an s-*trans* ester conformation (30),

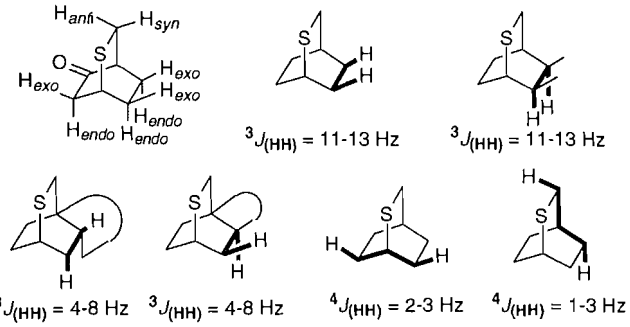
[10] These compounds were very prone to elimination to give **56** and other by-products.

[11] Chlorination under these conditions is precedented (20).

[12] For a review of the use of silicon-based temporary tethers in IMDA reactions, see ref. 29.

[13] For a review of solvent effects in IMDA reactions see ref. 30.

Fig. 2. Typical $^3J_{(HH)}$ and $^4J_{(HH)}$ coupling constants for 2*H*-thiopyran Diels–Alder adducts.



and the instability of **62** and **63** combine to favor other pathways in competition with IMDA reaction.

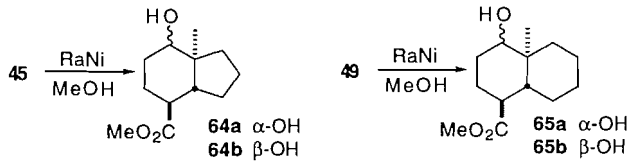
The IMDA adducts[14] **45–52** were identified on the basis of their spectroscopic properties (IR, MS, ^1H and ^{13}C NMR). In all cases, the spectral data were fully consistent with the proposed structure. In general, spectral features (especially ^1H and ^{13}C NMR) for **45–52** were similar to those from adducts obtained by intermolecular Diels–Alder reactions of 4-(triisopropylsilyl)oxy-2*H*-thiopyran with acrylate and crotonate dienophiles (7). Stereochemical assignments were based on the previously established trends (5, 7) in the $^3J_{HH}$ and $^4J_{HH}$ coupling constants outlined in Fig. 2.

Desulfurization of the IMDA adducts can potentially provide synthetically useful compounds. For example, *trans*-fused angularly methylated hydrindans (**64**) and decalins (**65**) are available by reactions of the *endo* adducts **45** and **49**, respectively, with Raney nickel (see Scheme 7). The synthetic utility of such a process will be dependent on the degree to which the diastereoselectivity (i.e., *endo* vs. *exo*) of the IMDA reaction can be controlled. Interestingly, the *endo* selectivities in the reactions of **27a** (ca. 1.1:1) and **27b** (ca. 2.5:1) are essentially independent of the reaction conditions (i.e., thermal vs. Lewis acid mediated) and are lower than **29a** (7:1).[15] As expected, only a single isomer results from cycloaddition of **41** and **43**.

[14] In principle, the same products could result from sequential Michael reactions (31). We favor a IMDA mechanism at present, because in no case have we detected or isolated the putative products from the "initial" Michael reaction. For a discussion see ref. 7.

[15] For comparison, the uncatalyzed intermolecular Diels–Alder reaction between 4-(triisopropylsilyl)oxy-2*H*-thiopyran and methyl acrylate is slightly *endo* selective (ca. 1.7:1); no adduct was obtained with methyl crotonate (7). Under Lewis acid mediated conditions (7), the reaction is *exo* selective with both methyl acrylate (1–1.6:1) and a crotonate derivative (2.5:1). In comparison to IMDA reactions of related acyclic dienes, thermal IMDA reactions of the methyl esters of (2*Z*,7*E*)- and (2*E*,7*E*)-2,7,9,-decatrienoic acids (i.e., C_3 tether) are unselective and the *endo* stereoselectivity for cycloaddition of the (2*E*,7*E*) isomer (but not the (2*Z*,7*E*) isomer) increases dramatically with Lewis acid catalysis (32*a*). Similarly, the uncatalyzed IMDA reactions (2*Z*,8*E*)- and (2*Z*,8*E*)-2,8,10-undecatrienoates (i.e., C_4 tether) are also unselective but the *endo* stereoselectivity for both isomers increases to ca. 9:1 under $EtAlCl_2$ mediated conditions (32*b*).

Scheme 7.



In conclusion, we have systematically investigated the IMDA reactions of derivatives of 4–(triisopropylsilyl)oxy-2*H*-thiopyran with potential dienophiles tethered at the C-2, C-3, C-5, and C-6 positions. Cycloaddition was only observed when dienophiles activated by a carbomethoxy group were employed. Compounds having the dienophile attached to C-2 with a C_3 tether gave adducts with high stereoselectivity. Substrates having the dienophile attached to C-3 via a C_3 or C_4 tether cyclized smoothly. With an (*E*)-enoate as the dienophile, the stereoselectivity was poor (*endo*:*exo* = 1.1–2.5:1) and essentially independent of reaction conditions (i.e., thermal vs. Lewis acid mediated). With the (*Z*)-enoate, a 7:1 mixture of *endo*:*exo* IMDA adducts was obtained under thermal conditions; with Lewis acid catalysis, isomerization of the dienophile was competitive with cycloaddition. Type II IMDA adducts were not observed with C-5 tethered substrates. Compounds having the dienophile attached to C-6 via a C_3 or a 5-atom tether also failed to give IMDA adducts. No evidence for isomerization of the 2*H*-thiopyran derivatives by [1,5] sigmatropic rearrangement was observed. The *endo* adducts obtained from the C-3 tethered substrates can be desulfurized to obtain synthetically useful *trans*-fused angularly methylated hydrindans and decalins.

Experimental

General methods

All solvents were distilled prior to use. Pyridine and Et_3N were distilled from CaH_2 and stored over KOH pellets. Anhydrous solvents were distilled under argon as follows: DMSO and DMF from CaH_2 under reduced pressure (10–15 Torr; 1 Torr = 133.3 Pa) and stored over 3Å molecular sieves; ether and tetrahydrofuran (THF) from benzophenone potassium ketyl; benzene, toluene, and CH_2Cl_2 from P_2O_5 and stored over 3Å molecular sieves; MeOH from $Mg(OMe)_2$. Benzene solutions were degassed by bubbling argon through the solvent (solution) followed by three freeze–thaw cycles under high vacuum (0.01 Torr). Unless otherwise noted, reactions were carried out under an atmosphere of argon and reaction temperatures refer to the bath. Concentration refers to removal of volatiles at water aspirator pressure on a rotary evaporator.

Preparative TLC was carried out on glass plates (20 × 20 cm) precoated (0.25 mm) with silica gel 60 F_{254}. Materials were detected by visualization under an ultraviolet lamp (254 nm) and (or) by treating a 1 cm vertical strip removed from the plate with a solution of phosphomolybdic acid (5%) containing a trace of ceric sulfate in aqueous sulfuric acid (5% v/v), followed by charring on a hot plate. Flash column chromatography (FCC) was performed according to Still et al. (33) with Merck Silica Gel 60 (40–63 μm). Medium pressure chromatography (MPC) was performed with minor modifications of the procedure reported by Taber (34). All mixed solvent eluents are reported as v/v solutions.

Spectral data

High-resolution (HRMS) spectra (exact mass measurement) were obtained on a double focussing VG 70E instument. Low-resolution mass spectra (LRMS) were recorded on a VG-70E or a single sectored, magnetic scanning MS-12. EI ionization was accomplished at 70 eV and CI at 50 eV with ammonia or isobutane as the reagent gas; only partial data are reported. IR spectra were recorded on a Fourier transform interferometer using a diffuse reflectance cell; only diagnostic peaks are reported. Unless otherwise noted, NMR spectra were measured in $CDCl_3$ solution at 300 MHz for ^1H and 75 MHz for ^{13}C. For ^1H NMR, residual $CHCl_3$ in $CDCl_3$ was employed as the internal standard (7.26 δ); for ^{13}C NMR, $CDCl_3$ was employed (77.0 δ). The ^1H NMR chemical shifts and coupling constants were determined assuming first-order behavior. Multiplicity is indicated by one or more of the following: s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), br (broad), ap (apparent); the list of coupling constants (*J*) corresponds to the order of the multiplicity assignment. ^1H NMR spectra were normally obtained with a digital resolution of 0.244 Hz/pt (sweep width = 4000 Hz, FID = 32 K data points) and coupling constants are reported to the nearest 0.5 Hz. The ^1H NMR assignments were made on the basis of chemical shift and multiplicity and were confirmed, where necessary, by homonuclear decoupling and (or) NOE experiments. The multiplicity of ^{13}C NMR signals refers to the number of attached H's (i.e., s = C, d = CH, t = CH_2, q = CH_3) and was determined by *J*-modulation (35). The ^{13}C assignments were made on the basis of chemical shift, multiplicity, and consistency within a series of similar structures. Assignments for ^{13}C signal of the same multiplicity and similar chemical shift (i.e., $\Delta\delta < 1$ ppm) are tentative. Elemental analyses were performed using a Perkin–Elmer 2400 CHN elemental analyzer.

Materials

Compounds **1** (15), **8** (21), **17** (22), **32** (22), **55** (28), **56** (19), 5-bromopentene (17), 6-bromohexene (17), 2-(3-bromopropyl)-1,3-dioxolane (23), 2-(4-bromobutyl)-1,3-dioxolane (24), 4-[(trimethylsilyl)oxy]-2*H*-thiopyran (5), and methyl fumaryl chloride (36) were prepared as reported. All other reagents were commercially available and, unless otherwise noted, were used as received.

*General procedure for alkylation of **1** and **17** (16)*

NaH (1.2 equiv.) was added to a solution of NaI (1.0 equiv.) and the β-ketoester **1** or **17** in acetone (5 mL/mmol of β-ketoester). After stirring for 5 min at room temperature (rt), the alkyl halide (3 equiv.) was added and the reaction mixture was heated under reflux for 24 h. The resulting mixture was diluted with H_2O, extracted with CH_2Cl_2 (×3), and the combined organic layers were dried over Na_2SO_4, concentrated, and fractionated by FCC to give the products **2** or **18**.

*General procedure for decarboxylation of **2** and **9** (16b)*

LiI (3 equiv.) was added to a solution of the β-ketoester in 20% (v/v) aqueous DMF (6 mL/mmol of β-ketoester) and the reaction mixture was heated under reflux until the starting material was consumed (3–5 days). The cooled (rt) reaction

mixture was diluted with CH_2Cl_2 and washed with water. The aqueous layer was extracted with CH_2Cl_2 (×2) and the combined organic layers were dried over Na_2SO_4, concentrated, and fractionated to give the products.

General procedure for decarboxylation of ***18*** *and the product from conjugate addition to* ***32*** *(22)*

A solution of tetrakis(triphenylphosphine)palladium(0) (0.05 equiv.), morpholine (10 equiv.), and the allyl β-ketoester in THF (8 mL/mmol of β-ketoester) was stirred at rt for 24 h. The reaction mixture was concentrated and fractionated to give the products.

General procedure for dehydrogenation of ***3, 10, 19, 34,*** *and* ***35*** *(19, 20)*

NCS (1.00 equiv.) was added to a stirred solution of the substrate and pyridine (1.05 equiv.) in CH_2Cl_2 (20 mL/mmol of substrate). After stirring for 10–30 min, the reaction mixture was washed with water, dried over Na_2SO_4, concentrated, and fractionated by FCC to give the products.

General procedure for conjugate addition to ***8*** *and* ***32*** *(21)*

A solution of the alkyl bromide (2.0 equiv.) in THF (1 mL/mmol of bromide) was added to a stirred suspension of Mg turnings (2.2 equiv.) in THF (2 mL/mmol of bromide) and the resulting mixture was heated under reflux for 90 min (on occasion I_2 crystals were added to initiate the reaction) and then was allowed to cool to rt.

Dimethyl sulfide (1.3 mL/mmol of CuI) was added dropwise over 5 min to a suspension of CuI (2.1 equiv.) in THF (0.65 mL/mmol of CuI) at −23°C. The resulting mixture was cooled to −78°C, and the Grignard reagent prepared above was added dropwise over 5 min. After 1.5 h, a solution of **8** or **32** in dimethyl sulfide (2 mL/mmol of ketoester) was added dropwise over a 10 min period. The reaction mixture was stirred at −78°C for 1.5 h and then was diluted with ether, warmed to 0°C, washed with $NH_4Cl_{(aq)}$ and with H_2O, dried over Na_2SO_4, concentrated, and fractionated to give the products.

General procedure for Wittig homologation of ***21*** *and* ***33***

A solution of the acetal and $HClO_4$ (0.3 M, 3 equiv.) in acetone (50 mL/mmol of acetal) was stirred at rt for 48 h. Half-saturated $NaHCO_{3(aq)}$ (ca. 1 mL) was added and most of the acetone was evaporated at reduced pressure. The resulting mixture was diluted with H_2O, extracted with CH_2Cl_2 (×2), and the combined organic layers were dried over Na_2SO_4 and concentrated to give a crude aldehyde(s) (^{1}H NMR). Methyl (triphenylphosphoranylidene)acetate (1.2 equiv.) was added to the solution of crude aldehyde(s) in MeOH (20 mL/mmol of acetal). After stirring for 3.5 h, the reaction mixture was concentrated and fractionated to give the *E* and *Z* enoates (ca. 1.5–2:1).

General procedure for preparation of 4-[tris(2-methylethyl)silyl]oxy-2H-thiopyrans

TIPSOTf (1.2 equiv.) was added to a solution of the enone and Et_3N (2.4 equiv.) in CH_2Cl_2 (ca. 10 mL/mmol of enone). The reaction was monitored by TLC and, when the enone was completely consumed (typically 10–20 min), the reaction mixture was diluted with CH_2Cl_2, washed with saturated $NaHCO_{3(aq)}$, dried over Na_2SO_4, concentrated, and placed under high vacuum (ca. 0.1 Torr) for 2 h. The crude products were characterized by ^{1}H NMR, which, in each case, indicated essentially complete conversion of the enone to the silyloxy diene(s). The dienes were unstable (especially neat) and were used directly without further purification.

General procedure for Diels–Alder reactions

Thermal reaction: A solution of the crude silyloxy diene(s) (0.1–0.2 mmol) and BHT (0.15 equiv.) in C_6D_6 or $C_6D_5CD_3$ (1 mL) was degassed by several freeze–thaw cycles and sealed under vacuum in an NMR tube. The mixture was heated in an oil bath and the progress of the reaction was monitored by ^{1}H NMR. When the diene was consumed, the reaction mixture was concentrated and the residue was dissolved in CH_3CN (2 mL) and HF (48–51% aqueous solution; 70 μL) was added. After stirring for 5 min, the reaction mixture was diluted with CH_2Cl_2, washed with saturated $NaHCO_{3(aq)}$, dried over Na_2SO_4, concentrated, and fractionated to give the products.

Lewis acid catalyzed reaction: $EtAlCl_2$ (1 M solution in hexanes, 0.4–1 equiv.) was added to a solution of the silyloxy diene(s) (0.1–0.2 mmol) in C_6D_6 or CH_2Cl_2 (1–2 mL) at rt. After a suitable reaction time, the mixture was diluted with CH_2Cl_2, washed with saturated $NaHCO_{3(aq)}$, dried over Na_2SO_4, and concentrated. The residue was dissolved in CH_3CN (2 mL) and HF (48–51% aqueous solution; 70 μL) was added. After stirring for 5 min, the reaction mixture was diluted with CH_2Cl_2, washed with saturated $NaHCO_{3(aq)}$, dried over Na_2SO_4, concentrated, and fractionated to give the products.

TIPSOTf catalyzed reaction: In this case the general procedure for the preparation of the silyloxy dienes was followed except 1.5–2.0 equiv. of TIPSOTf was used. After stirring for several hours, the reaction mixture was diluted with CH_2Cl_2, washed with saturated $NaHCO_{3(aq)}$, dried over Na_2SO_4, and concentrated. The residue was dissolved in CH_3CN (2 mL) and HF (48–51% aqueous solution; 70 μL) was added. After stirring for 5 min, the reaction mixture was diluted with CH_2Cl_2, washed with saturated $NaHCO_{3(aq)}$, dried over Na_2SO_4, concentrated, and fractionated to give the products.

IMDA reaction of ***26a/27a***

IMDA adducts were obtained after PTLC (0.8% MeOH in CH_2Cl_2). Thermal reaction of a 1.2:1 mixture of **26a** and **27a** (prepared from a 1.2:1 mixture of **22a** and **23a**; 37.8 mg, 0.157 mmol) at 140°C for 96 h gave **45** (9.3 mg, 55%) and **46** (7.4 mg, 43%). Lewis acid catalyzed reaction of a similar mixture of **26a** and **27a** (prepared from a 1.2:1 mixture of **22a** and **23a**; 55 mg, 0.23 mmol) for 10 min gave **45** (9.4 mg, 38%) and **46** (8.5 mg, 34%). TIPSOTf catalyzed reaction (2 h) of a 1.2:1 mixture of **22a** and **23a** (24 mg, 0.1 mmol) gave **45** (4.8 mg, 44%) and **46** (4.5 mg, 42%). In each case a fraction containing a mixture of **22a** and **30a** (^{1}H NMR), which could be further purified, was obtained.

IMDA reaction of ***28a/29a***

IMDA adducts were obtained after PTLC (50% ether in hexane). Thermal reaction of a 1.2:1 mixture of **28a** and **29a** (pre-

pared from a 1.2:1 mixture of **24a** and **25a**; 18 mg, 0.075 mmol) at 140°C for 96 h gave **47** (5.7 mg, 70%) and **48** (0.8 mg, 10%). Lewis acid catalyzed reaction of a similar mixture of **28a** and **29a** (prepared from a 1.2:1 mixture of **24a** and **25a**; 22 mg, 0.092 mmol) for 10 min gave **45** (3.4 mg, 34%), **47** (3.0 mg, 30%), and **46** (2.7 mg, 27%). TIPSOTf catalyzed reaction (24 h) of a 1.2:1 mixture of **24a** and **25a** (14.6 mg, 0.061 mmol) gave **45** (2.9 mg, 44%) and **46** (2.8 mg, 43%). In each case a fraction containing a mixture of **22a** (**24a** in the thermal reaction) and **30a** (**31b** in the thermal reaction) (^{1}H NMR) was obtained but not further purified.

*IMDA reaction of **27b***

IMDA adducts were obtained after FCC (20–75% EtOAc in hexane). Thermal reaction **27b** (prepared from **23b**; 58 mg, 0.23 mmol) at 170°C for 60 h gave **49** (23 mg, 40%) and **50** (8 mg, 14%) along with **23b** (11 mg, 19%) and **30b** (11 mg, 19%). Lewis acid catalyzed reaction of **27b** (prepared from **23b**; 13 mg, 0.041 mmol) for 30 min gave **49** (5 mg, 48%) and **50** (2 mg, 19%) along with **23b** (2 mg, 19%) and **30b** (0.8 mg, 8%). A similar reaction of a 1.3:1 mixture of **26b** and **27b** (prepared from a 1.3:1 mixture of **22b** and **23b**; 46 mg, 0.181 mmol) for 30 min gave **49** (8 mg, 40%) and **50** (3 mg, 15%). No adducts were obtained in TIPSOTf catalyzed reactions.

*IMDA reaction of **28b** and **29b***

No adducts were obtained from attempted thermal or TIPSOTf catalyzed reactions of a 1.3:1 mixture of **28b** and **29b**. A $EtAlCl_2$ mediated reaction of a 1.3:1 mixture of **28b** and **29b** (prepared from a 1.3:1 mixture of **24b** and **25b**; 23 mg, 0.089 mmol) for 30 min gave **49** (3 mg, slightly impure; ca. 25%) after fractionation (PTLC; 50% ether in hexane). Other isomers, if present, could not be isolated. Fractionation (PTLC; 50% ether in hexane) of an attempted thermal reaction of a 1.3:1 mixture of **28b** and **29b** yielded a 1:1 mixture of **30b** and **31b**.

*IMDA reaction of **41***

IMDA adducts were obtained after PTLC (50% ether in hexane). Thermal reaction of **41** (prepared from **37**; 11 mg, 0.046 mmol) at 175°C for 17 h gave **51** (9.5 mg, 86%). Lewis acid catalyzed reaction of **41** (prepared from **37**; 11.8 mg, 0.049 mmol) for 30 min gave **51** (8.1 mg, 68%). TIPSOTf catalyzed reaction (13 h) of **37** (11.8 mg, 0.049 mmol) gave **51** (2 mg, 17%).

*IMDA reaction of **43***

IMDA adducts were obtained after PTLC (1% MeOH in CH_2Cl_2). Thermal reaction of **43** (prepared from **39**; 21.6 mg, 0.090 mmol) at 180°C for 9 h and 210°C for 11 h gave **52** (7.2 mg, 33%) and **51** (6.5 mg, 30%). Due to the previously established propensity for isomerization of the enoates, Lewis acid mediated IMDA reactions were not attempted.

*Methyl tetrahydro-4-oxo-3-(4-pentenyl)-4*H*-thiopyran-3-carboxylate (**2a**)*: 192 mg (48%) from **1** (261 mg, 1.50 mmol) after FCC (25% ether in hexane): IR ν_{max}: 3075, 1729, 1712, 1201 cm^{-1}; ^{1}H NMR δ: 5.75 (1H, dddd, J = 6.5, 6.5, 10.5, 17 Hz, HC-4′), 5.00 (1H, br d, J = 17 Hz, HC-5′), 4.95 (1H, br d, J = 10.5 Hz, HC-5′), 3.77 (3H, s, H_3CO), 3.27 (1H, dd, J = 3, 13.5 Hz, HC-2), 3.00–2.75 (4H, m, HC-5, HC-6), 2.71 (1H, d, J = 13.5 Hz, HC-2), 2.04 (2H, ap dt, J = 6.5, 6.5 Hz, HC-3′), 1.92 (1H, ap dt, J = 4.5, 13.5 Hz, HC-1′), 1.64 (1H, ap dt, J = 4.5, 13.5 Hz, HC-1′), 1.42 (1H, ap dtt, J = 12, 4.5, 7 Hz, HC-2′), 1.21 (1H, ap dtt, J = 12, 4.5, 7 Hz, HC-2′); ^{13}C NMR δ: 205.3 (s, C-4), 171.5 (s, O=CO), 138.0 (d, C-4′), 115.0 (t, C-5′), 63.0 (s, C-3), 52.4 (q, CH_3O), 43.2 (t, C-5), 38.6 (t, C-1′), 33.9 (t, C-2), 33.9 (t, C-3′), 30.8 (t, C-6), 23.8 (t, C-2′); LRMS (CI, NH_3), *m/z* (relative intensity): 260 ([M+18]$^+$, 100), 243 ([M+1]$^+$, 85), 192 (12), 173 (16).

*Methyl 3-(5-hexenyl)-tetrahydro-4-oxo-4*H*-thiopyran-3-carboxylate (**2b**)*: 185 mg (42%) from **1** (300 mg, 1.72 mmol) after FCC (25% ether in hexane): IR ν_{max}: 3074, 1730, 1712, 1201 cm^{-1}; ^{1}H NMR δ: 5.77 (1H, ap ddt, J = 10.5, 17, 6.5 Hz, HC-5′), 4.95 (2H, m, HC-6′), 3.77 (3H, s, H_3CO), 3.28 (1H, dd, J = 2.5, 14 Hz, HC-2), 3.00–2.75 (4H, m, HC-5, HC-6), 2.71 (1H, d, J = 14 Hz, HC-2), 2.08–1.98 (2H, m, HC-4′), 1.98–1.86 (1H, m, HC-1′), 1.70–1.60 (1H, m, HC-1′), 1.45–1.10 (4H, m, HC-2′, HC-3′); ^{13}C NMR δ: 205.4 (s, C-4), 171.5 (s, O=CO), 138.6 (d, C-5′), 114.6 (t, C-6′), 63.0 (s, C-3), 52.4 (q, CH_3O), 43.2 (t, C-5), 38.6 (t, C-1′), 34.2 (t, C-2), 33.4 (t, C-4′), 30.8 (t, C-6), 29.1 (t, C-3′), 24.0 (t, C-2′); LRMS (CI, NH_3), *m/z* (relative intensity): 274 ([M+18]$^+$, 100), 257 ([M+1]$^+$, 84), 173 (24).

*Tetrahydro-3-(4-pentenyl)-4*H*-thiopyran-4-one (**3a**)*: 41 mg (29%) from **2a** (189 mg, 0.78 mmol) after FCC (35% ether in hexane): IR ν_{max}: 3074, 1715, 1424, 914 cm^{-1}; ^{1}H NMR δ: 5.76 (1H, ddt, J = 10, 17, 6.5 Hz, HC-4′), 5.03–4.90 (2H, m, HC-5′), 2.98–2.88 (3H, m, HC-2, H_2C-6), 2.74–2.60 (4H, m, HC-2, HC-3, H_2C-5), 2.04 (2H, ap dt, J = 6.5, 7 Hz, H_2C-3′), 1.90–1.82 (1H, m, HC-1′), 1.42–1.30 (3H, m, HC-1′, H_2C-2′); ^{13}C NMR δ: 210.4 (s, C-4), 138.3 (d, C-4′), 114.8 (t, C-5′), 52.9 (d, C-3), 43.8 (t, C-5), 35.9 (t, C-1′), 33.6 (t, C-3′), 31.0 (t, C-2), 28.9 (t, C-6), 26.2 (t, C-2′); LRMS (CI, NH_3), *m/z* (relative intensity): 202 ([M+18]$^+$, 100), 185 ([M+1]$^+$, 48), 116 (75).

*3-(5-Hexenyl)tetrahydro-4*H*-thiopyran-4-one (**3b**)*: 57 mg (48%) from **2b** (154 mg, 0.60 mmol) after FCC (35% ether in hexane): IR ν_{max}: 3016, 1707, 1464, 965 cm^{-1}; ^{1}H NMR δ: 5.75 (1H, ddt, J = 10, 17, 6.5 Hz, HC-5′), 5.04–4.89 (2H, m, H_2C-6′), 2.98–2.88 (3H, m, H_2C-6, HC-2), 2.76–2.58 (4H, m, HC-2, HC-3, H_2C-5), 2.04 (2H, dt, J = 6.5, 7 Hz, H_2C-4′), 1.93–1.82 (1H, m, HC-1′), 1.44–1.24 (5H, m, HC-1′, H_2C-2′, H_2C-3′); ^{13}C NMR δ: 210.4 (s, C-4), 138.7 (d, C-5′), 114.5 (t, C-6′), 52.9 (d, C-3), 43.8 (t, C-5), 35.9 (t, C-1′), 33.5 (t, C-4′), 31.0 (t, C-2), 29.2 (t, C-6), 28.8 (t, C-3′), 26.4 (t, C-2′); LRMS (EI), *m/z* (relative intensity): 198 ([M]$^+$, 49), 180 (11), 116 (100), 95 (22), 88 (28).

*2,3-Dihydro-5-(4-pentenyl)-4*H*-thiopyran-4-one (**4a**) and 2,3-dihydro-3-(4-pentenyl)-4*H*-thiopyran-4-one (**5a**)*: 9.7 mg (46%; as a 1.2:1 mixture of **4a** and **5a**, respectively) from **3a** (21 mg, 0.12 mmol) after PTLC (50% ether in hexane): ^{1}H NMR δ for **4a**: 7.15 (1H, s, HC-6), 5.79 (1H, ddt, J = 10, 17, 6.5 Hz, HC-4′), 5.07–4.92 (2H, m, H_2C-5′), 3.19–3.13 (1H, m, HC-2), 2.77–2.71 (1H, m, HC-3), 2.29 (1H, ap t, J = 7.5 Hz, HC-1′), 2.14–2.00 (2H, m, HC-3′), 1.64–1.37 (2H, m, HC-2′); δ for **5a**: 7.35 (1H, d, J = 10 Hz, HC-6), 6.11 (1H, d, J = 10 Hz, HC-5), 5.79 (1H, ddt, J = 10, 17, 6.5 Hz, HC-4′), 5.07–4.92

(2H, m, H_2C-5′), 3.31 (1H, dd, J = 4, 13.5 Hz, HC-2), 3.05 (1H, dd, J = 9, 13.5 Hz, HC-2), 2.53 (1H, dddd, J = 4, 5.5, 8, 9 Hz, HC-3), 2.14–2.00 (2H, m, H_2C-3′), 1.86 (1H, dddd, J = 5.5, 5.5, 10.5, 13.5 Hz, HC-1′), 1.64–1.37 (3H, m, HC-1′, H_2C-2′); ^{13}C NMR δ for **4a**: 193.6 (s, C-4), 140.3 (d, C-6), 138.5 (d, C-4′), 134.8 (s, C-5), 114.7 (t, C-5′), 38.4 (t, C-3), 33.6 (t, C-3′), 30.8 (t, C-1′), 28.2 (t, C-2′), 27.3 (t, C-2); δ for **5a**: 196.2 (s, C-4), 145.1 (d, C-6), 138.2 (d, C-4′), 123.2 (d, C-3), 114.9 (t, C-5′), 45.1 (d, C-3), 33.3 (t, C-3′), 31.8 (t, C-1′), 27.6 (t, C-2), 26.3 (t, C-2′).

*5-(5-Hexenyl)-2,3-dihydro-4*H*-thiopyran-4-one (**4b**) and 3-(5′-hexenyl)-2,3-dihydro-4*H*-thiopyran-4-one (**5b**)*: 15.2 mg (71%; as a 1.2:1 mixture of **4b** and **5b**, respectively) from **3b** (22 mg, 0.11 mmol) after PTLC (50% ether in hexane): ^{1}H NMR δ for **4b**: 7.14 (1H, br s, HC-6), 5.79 (1H, ddt, J = 10, 17, 6.5 Hz, HC-5′), 5.04–4.90 (2H, m, H_2C-6′), 3.19–3.13 (2H, m, H_2C-2), 2.77–2.71 (2H, m, H_2C-3), 2.32–2.34 (2H, m, H_2C-1′), 2.11–2.00 (2H, m, H_2C-4′), 1.64–1.30 (4H, m, H_2C-2′, H_2C-3′); δ for **5b**: 7.35 (1H, d, J = 10 Hz, HC-6), 6.11 (1H, d, J = 10 Hz, HC-5), 5.79 (1H, ddt, J = 10, 17, 6.5 Hz, HC-5′), 5.04–4.90 (2H, m, HC-6′), 3.31 (1H, dd, J = 4, 13.5 Hz, HC-2), 3.04 (1H, dd, J = 8.5, 13.5 Hz, HC-2), 2.52 (1H, dddd, J = 4, 5.5, 8.5, 9 Hz, HC-3), 2.11–2.00 (2H, m, H_2C-4′), 1.90–1.80 (1H, m, HC-1′), 1.64–1.30 (5H, m, HC-1′, H_2C-2′, H_2C-3′); ^{13}C NMR δ for **4b**: 193.6 (s, C-4), 140.0 (d, C-6), 138.9 (d, C-5′), 135.0 (s, C-5), 114.4 (t, C-6′), 38.4 (t, C-3), 33.6 (t, C-4′), 31.1 (t, C-1′), 28.6 (t, C-3′), 28.5 (t, C-2′), 27.3 (t, C-2); δ for **5b**: 196.3 (s, C-4), 145.1 (d, C-6), 138.7 (d, C-5′), 123.1 (d, C-5), 114.6 (t, C-6′), 45.2 (d, C-3), 33.6 (t, C-4′), 31.7 (d, C-1′), 28.8 (t, C-3′), 27.9 (t, C-2), 26.4 (t, C-2′).

*4-[[Tris(1-methylethyl)silyl]oxy]-5-(4-pentenyl)-2*H*-thiopyran (**6a**) and 4-[[tris(1-methylethyl)silyl]oxy]-3-(4-pentenyl)-2*H*-thiopyran (**7a**)*

Obtained as a 1.2:1 mixture of **6a** and **7a** from a 1.2:1 mixture of **4a** and **5a**: ^{1}H NMR ($C_6D_5CD_3$) δ for **6a** (partial data): 5.87 (1H, s, HC-6), 5.78–5.68 (1H, m, HC-4′), 5.05–4.91 (2H, m, HC-5′), 4.62 (1H, t, J = 5.5 Hz, HC-3), 2.99 (2H, d, J = 5.5 Hz, HC-2); δ for **7a** (partial data): 5.95 (1H, d, J = 10 Hz, HC-6), 5.87 (1H, d, J = 10 Hz, HC-5), 5.78–5.68 (1H, m, HC-4′), 5.05–4.91 (2H, m, HC-5′), 3.01 (2H, s, HC-2).

*5-(5′-Hexenyl)-4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran (**6b**) and 3-(5′-hexenyl)-4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran (**7b**)*

Obtained as a 1.2:1 mixture of **6b** and **7b** from a 1.2:1 mixture of **4b** and **5b**: ^{1}H NMR ($C_6D_5CD_3$) δ for **6b** (partial data): 5.86 (1H, s, HC-6), 5.75–5.65 (1H, m, HC-5′), 5.01–4.87 (2H, m, HC-6′), 4.61 (1H, t, J = 5.5 Hz, HC-3), 2.99 (2H, d, J = 5.5 Hz, HC-2); δ for **7b** (partial data): 5.92 (1H, d, J = 10 Hz, HC-6), 5.84 (1H, d, J = 10 Hz, HC-5), 5.75–5.65 (1H, m, HC-5′), 5.01–4.87 (2H, m, HC-6′), 3.04 (2H, s, HC-2).

*Methyl tetrahydro-4-oxo-2-(4-pentenyl)-4*H*-thiopyran-3-carboxylate (**9a**)*: 310 mg (88%) from **8** (250 mg, 1.45 mmol) after FCC (20% EtOAc in hexane): IR ν_{max}: 3075, 1746, 1714, 1649, 1609 cm^{-1}; ^{1}H NMR (a 1:2 mixture of keto:enol tautomers) δ: 12.69 (0.7H, s, HO[enol]), 5.88–5.68 (1H, m, HC-4′), 5.04–4.91 (2H, m, HC-5′), 3.88 (2H, s, H_3CO[enol]), 3.88 (1H, s, H_3CO[keto]), 3.48–3.41 (1.3H, m, HC-2, HC-3[keto]), 3.02–2.80 (1.7H, m, H_2C-6[enol], HC-6[keto]), 2.70–2.43 (2.3H, m, H_2C-5, HC-6[keto]), 2.17–1.95 (2H, m, H_2C-3′), 1.77–1.39 (4H, m, H_2C-1′, H_2C-2′); ^{13}C NMR δ for keto form: 203.7 (s, C-4), 168.8 (s, OC=O), 137.7 (d, C-4′), 114.8 (t, C-5′), 64.5 (d, C-3), 52.1 (q, CH_3O), 45.7 (d, C-2), 42.4 (t, C-5), 32.8 (t, C-1′ or C-3′), 32.7 (t, C-3′ or C-1′), 26.6 (t, C-6), 25.7 (t, C-2′); δ for enol form: 172.5 (s, C-4), 171.6 (s, OC=O), 138.4 (d, C-4′), 114.3 (t, C-5′), 102.6 (s, C-3), 51.5 (q, CH_3O), 36.1 (d, C-2), 35.0 (t, C-5), 32.8 (t, C-3′), 30.5 (t, C-1′), 27.1 (t, C-2′), 19.8 (t, C-6); LRMS (EI), *m/z* (relative intensity): 242 ([M]$^+$, 21), 173 (73), 141 (77), 83 (100).

*Methyl 2-(5-hexenyl)tetrahydro-4-oxo-4*H*-thiopyran-3-carboxylate (**9b**)*: 190 mg (85%) from **8** (150 mg, 0.871 mmol) after FCC (20% EtOAc in hexane): IR ν_{max}: 3074, 1746, 1714, 1649, 1609 cm^{-1}; ^{1}H NMR (a 1:2 mixture of keto:enol tautomers) δ: 12.64 (0.7H, s, HO[enol]), 5.85–5.67 (1H, m, HC-5′), 5.01–4.88 (2H, m, H_2C-6′), 3.74 (2H, s, H_3CO[enol]), 3.74 (1H, s, H_3CO[keto]), 3.45–3.36 (1.3H, m, HC-2, HC-3[keto]), 3.00–2.77 (1.7H, m, H_2C-6[enol], HC-6[keto]), 2.67–2.41 (2.3H, m, H_2C-5, HC-6[keto]), 2.08–1.97 (2H, m, H_2C-4′), 1.74–1.28 (6H, m, H_2C-1′, H_2C-2′, H_2C-3′); ^{13}C NMR δ for keto form: 203.9 (s, C-4), 169.0 (s, OC=O), 138.5 (d, C-5′), 114.6 (t, C-6′), 64.8 (d, C-3), 52.3 (q, CH_3O), 46.0 (d, C-2), 42.7 (t, C-5), 33.4 (t, C-1′), 33.4 (t, C-4′), 28.3 (t, C-3′), 26.9 (t, C-6), 26.1 (t, C-2′); δ for enol form: 172.7 (s, C-4), 171.9 (s, OC=O), 138.9 (d, C-5′), 114.3 (t, C-6′), 102.9 (s, C-3), 51.7 (q, CH_3O), 36.4 (d, C-2), 35.6 (t, C-5), 33.7 (t, C-4′), 30.8 (t, C-1′), 28.2 (t, C-3′), 27.6 (t, C-2′), 20.0 (t, C-6); LRMS (EI), *m/z* (relative intensity): 256 ([M]$^+$, 12), 197 (24), 173 (62), 141 (62), 84 (100).

*Tetrahydro-2-(4-pentenyl)-4*H*-thiopyran-4-one (**10a**)*: 45 mg (33%) from **9a** (180 mg, 0.743 mmol) after by FCC (30% ether in hexane): IR ν_{max}: 3075, 1712, 1643 cm^{-1}; ^{1}H NMR δ: 5.77 (1H, dddd, J = 6.5, 6.5, 10.5, 17 Hz, HC-4′), 5.00 (1H, br d, J = 17 Hz, HC-5′), 4.96 (1H, br d, J = 10.5 Hz, HC-5′), 3.07 (1H, dddd, J = 3.5, 6.5, 6.5, 10.5 Hz, HC-2), 3.00–2.82 (2H, m, H_2C-6), 2.73 (1H, ddd, J = 1, 3.5, 14 Hz, HC-3), 2.68–2.55 (2H, m, H_2C-5), 2.43 (1H, dd, J = 10.5, 14 Hz, HC-3), 2.10–2.00 (2H, m, H_2C-3′), 1.65–1.45 (4H, m, H_2C-1′, H_2C-2′); ^{13}C NMR δ: 208.7 (s, C-4), 138.1 (d, C-4′), 115.0 (t, C-5′), 50.7 (t, C-3), 44.7 (d, C-2), 43.4 (t, C-5), 35.0 (t, C-1′), 33.3 (t, C-3′), 28.1 (t, C-6), 26.0 (t, C-2′); LRMS (EI), *m/z* (relative intensity): 184 ([M]$^+$, 40), 141 (39), 128 (52), 115 (100).

*2-(5-Hexenyl)tetrahydro-4*H*-thiopyran-4-one (**10b**)*: 87 mg (74%) from **9b** (142 mg, 0.554 mmol) after fractionation by FCC (30% ether in hexane): IR ν_{max}: 3075, 1713, 1640 cm^{-1}; ^{1}H NMR δ: 5.77 (1H, dddd, J = 6.5, 6.5, 10.5, 17.5 Hz, HC-5′), 4.99 (1H, br d, J = 17.5 Hz, HC-6′), 4.94 (1H, br d, J = 10.5 Hz, HC-6′), 3.06 (1H, dddd, J = 3.5, 6.5, 6.5, 10.5 Hz, HC-2), 3.00–2.82 (2H, m, H_2C-6), 2.73 (1H, ddd, J = 1, 3.5, 14 Hz, HC-3), 2.68–2.55 (2H, m, H_2C-5), 2.43 (1H, dd, J = 10.5, 14 Hz, HC-3), 2.10–2.00 (2H, m, H_2C-4′), 1.65–1.35 (6H, m, H_2C-1′, H_2C-2′, H_2C-3′); ^{13}C NMR δ: 208.7 (s, C-4), 138.6 (d, C-5′), 114.6 (t, C-6′), 50.7 (t, C-3), 44.7 (d, C-2), 43.4 (t, C-5), 35.5 (t, C-1′), 33.5 (t, C-4′), 28.5 (t, C-3′), 28.1 (t, C-6), 26.3 (t, C-2′); LRMS (CI, NH_3), *m/z* (relative intensity): 216 ([M + 18]$^+$, 100), 198 (36), 141 (19), 115 (24), 83 (28).

*2,3-Dihydro-6-(4-pentenyl)-4H-thiopyran-4-one (**11a**) and 2,3-dihydro-2-(4-pentenyl)-4H-thiopyran-4-one (**12a**)*

11a (13 mg, 40%) and **12a** (6 mg, 18%) were obtained from **10a** (33 mg, 0.18 mmol) after FCC (50% ether in hexane).

For **11a**: IR ν_{max}: 3075, 1655, 1571 cm^{-1}; ^1H NMR δ: 6.08 (1H, s, HC-5), 5.78 (1H, ap ddt, J = 10.5, 17, 7 Hz, HC-4′), 5.08–5.98 (2H, m, H_2C-5′), 3.19–3.14 (2H, m, H_2C-2), 2.67–2.62 (2H, m, H_2C-3), 2.39 (2H, ap t, J = 7 Hz, H_2C-1′), 2.10 (2H, ap dt, J = 7, 7 Hz, H_2C-3′), 1.70 (2H, ap tt, J = 7, 7 Hz, H_2C-2′); ^{13}C NMR δ: 144.3 (s, C-4), 164.6 (s, C-6), 137.5 (d, C-4′), 121.9 (d, C-5), 115.5 (t, C-5′), 37.6 (t, C-1′), 36.8 (t, C-3), 32.8 (t, C-3′), 27.8 (t, C-2 or C-2′), 27.4 (t, C-2 or C-2′); LRMS (EI), *m/z* (relative intensity): 182 ([M]$^+$, 73), 128 (100), 126 (45), 100 (100), 85 (64).

For **12a**: IR ν_{max}: 3075, 1661, 1548 cm^{-1}; ^1H NMR δ: 7.42 (1H, d, J = 10 Hz, HC-6), 6.16 (1H, d, J = 10 Hz, HC-5), 5.76 (1H, dddd, J = 7, 7, 10.5, 17 Hz, HC-4′), 5.05–4.95 (2H, m, H_2C-5′), 3.53–3.45 (1H, m, HC-2), 2.78 (1H, dd, J = 3.5, 16 Hz, HC-3), 2.58 (1H, dd, J = 11.5, 16 Hz, HC-3), 2.07 (2H, ap dt, J = 7, 7 Hz, H_2C-3′), 1.78–1.68 (2H, m, H_2C-1′), 1.58–1.47 (2H, m, H_2C-2′); ^{13}C NMR δ: 194.6 (s, C-4), 145.6 (d, C-6), 137.7 (d, C-4′), 123.4 (d, C-5), 115.3 (t, C-5′), 44.5 (t, C-3), 43.0 (d, C-2), 33.3 (t, C-1′ or C-3′), 33.2 (t, C-1′ or C-3′), 25.8 (t, C-2′); LRMS (EI), *m/z* (relative intensity): 182 ([M]$^+$, 22), 154 (82), 126 (35), 113 (78), 86 (100).

*6-(5-Hexenyl)-2,3-dihydro-4H-thiopyran-4-one (**11b**) and 2-(5′-hexenyl)-2,3-dihydro-4H-thiopyran-4-one (**12b**)*

11b (45 mg, 60%) and **12b** (15 mg, 20%) were obtained from **10b** (76 mg, 0.38 mmol) after FCC (60% ether in hexane).

For **11b**: IR ν_{max}: 3074, 1653, 1571 cm^{-1}; ^1H NMR δ: 6.08 (1H, s, HC-5), 5.78 (1H, ap ddt, J = 10.5, 17, 7 Hz, HC-5′), 5.06–4.96 (2H, m, H_2C-6′), 3.18–3.13 (2H, m, H_2C-2), 2.67–2.62 (2H, m, H_2C-3), 2.38 (2H, ap t, J = 7 Hz, H_2C-1′), 2.07 (2H, ap dt, J = 7, 7 Hz, H_2C-4′), 1.66–1.55 (2H, m, H_2C-2′), 1.48–1.38 (2H, m, H_2C-3′); ^{13}C NMR δ: 194.4 (s, C-4), 164.9 (s, C-6), 138.3 (d, C-5′), 121.7 (d, C-5), 114.9 (t, C-6′), 38.2 (t, C-1′), 36.8 (t, C-3), 33.3 (t, C-4′), 28.1 (t , C-2′), 28.1 (t, C-3′), 27.4 (t, C-2); LRMS (EI), *m/z* (relative intensity): 196 ([M]$^+$, 24), 167 (22), 141 (46), 128 (100), 100 (99).

For **12b**: IR ν_{max}: 3075, 1663, 1548 cm^{-1}; ^1H NMR δ: 7.42 (1H, d, J = 10 Hz, HC-6), 6.16 (1H, d, J = 10 Hz, HC-5), 5.78 (1H, dddd, J = 7, 7, 10.5, 17 Hz, HC-5′), 5.05–4.95 (2H, m, H_2C-6′), 3.53–3.45 (1H, m, HC-2), 2.78 (1H, dd, J = 3.5, 16 Hz, HC-3), 2.58 (1H, dd, J = 11.5, 16 Hz, HC-3), 2.12–2.01 (2H, m, H_2C-4′), 1.71 (2H, m, H_2C-1′), 1.51–1.35 (4H, m, H_2C-2′, H_2C-3′); ^{13}C NMR δ: 194.7 (s, C-4), 145.7 (d, C-6), 138.4 (d, C-5′), 123.4 (d, C-5), 114.8 (t, C-6′), 44.5 (t, C-3), 43.1 (d, C-2), 33.8 (t, C-1′), 33.4 (t, C-4′), 28.4 (t, C-3′), 26.0 (t, C-2′); LRMS (EI), *m/z* (relative intensity): 196 ([M]$^+$, 11), 168 (9), 139 (10), 113 (52), 86 (100).

*4-[[Tris(1-methylethyl)silyl]oxy]-6-(4′-pentenyl)-2H-thiopy-ran (**13a**)*: ^1H NMR ($C_6D_5CD_3$) (partial data) δ: 5.86 (1H, d, J = 1 Hz, HC-5), 5.64 (1H, ddt, J = 10.5, 17, 7 Hz, HC-4′), 4.98–4.88 (2H, m, HC-5′), 4.52 (1H, dt, J = 1, 6.5 Hz, HC-3), 3.11 (2H, d, J = 5.5 Hz, HC-2).

*Methyl (*E*)-7-(3,4-dihydro-4-oxo-*2H*-thiopyran-3-yl)-2-heptenoate (**23b**)*

From **54**: A solution of Bu_3SnH (0.3 mL, 1.1 mmol) and AIBN (10 mg, 0.06 mmol) in dry deoxygenated benzene (5 mL) was added over 30 min to a solution of **54** (126 mg, 1 mmol) and **55** (382 mg, 1.5 mmol) in dry deoxygenated benzene (15 mL) heated under reflux in an oil bath preheated to 90°C. After 8 h, the reaction mixture was concentrated and fractionated by MPC (25% ethyl acetate in hexane) to give **23b** (116 mg, 45%) and **54** (23.5 mg, 19%). IR ν_{max}: 2930, 1721, 1658, 1554, 1272, 1202 cm^{-1}; ^1H NMR δ: 7.33 (1H, d, J = 10 Hz, HC-6′), 6.91 (1H, dt, J = 15.5, 7 Hz, HC-3), 6.07 (1H, d, J = 10 Hz, HC-5′), 5.78 (1H, dt, J = 15.5, 1.5 Hz, HC-2), 3.68 (1H, s, H_3CO), 3.27 (1H, dd, J = 3.5, 13.5 Hz, HC-2′), 3.00 (1H, ddd, J = 0.5, 9, 13.5 Hz, HC-2′), 2.52–2.44 (1H, m, HC-3′), 2.18 (2H, ap ddt, J = 1.5, 7, 7 Hz, HC-4), 1.88–1.76 (1H, m, HC-7), 1.56–1.30 (5H, m, H_2C-5, H_2C-6, HC-7); ^{13}C NMR δ: 196.0 (s, C-4′), 167.0 (s, C-1), 149.1 (d, C-3), 145.1 (d, C-6′), 123.1 (d, C-5′), 121.1 (d, C-2), 51.4 (q, CH_3O), 45.1 (d, C3), 31.9 (t, C-4), 31.7 (t, C-7), 27.9 (t, C-2′ or C-5), 27.8 (t, C-2′ or C-5), 26.4 (t, C-6); LRMS (EI), *m/z* (relative intensity): 254 ($[M]^+$, 20), 223 (9), 195 (12), 114 (100), 86 (91).

*Methyl (*E*)-6-[4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-5-yl]-2-heptenoate (**26b**) and methyl (*E*)-6-[4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-3-yl]-2-heptenoate (**27b**)*

Obtained as a 1.3:1 mixture from a similar mixture of **22b** and **23b**: ^1H NMR δ for **26b**: 6.96 (1H, dt, J = 15.5, 7 Hz, H-3), 6.05 (1H, s, H-6′), 5.80 (1H, d, J = 15.5 Hz, H-2), 4.76 (1H, t, J = 7 Hz, H-3′), 3.70 (3H, s, H_3CO), 3.19 (2H, d, J = 7 Hz, H_2C-2′), 2.25–2.15 (4H, m, H_2C-4, H_2C-7), 1.52–1.38 (4H, m, H_2C-5, H_2C-6), 1.30–0.90 (21H, m, $(H_3C)_2CHSi$); δ for **27b**: 6.96 (1H, dt, J = 15.5, 7 Hz, H-3), 6.18 (1H, d, J = 10 Hz, H-6′), 5.94 (1H, d, J = 10 Hz, H-5′), 5.80 (1H, d, J = 15.5 Hz, H-2), 3.70 (3H, s, H_3CO), 3.25 (2H, s, H_2C-2′), 2.25–2.15 (4H, m, H_2C-4, H_2C-7), 1.52–1.38 (4H, m, H_2C-5, H_2C-6), 1.30–0.90 (21H, m, $(H_3C)_2CHSi$).

*Methyl (*E*)-6-[4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-3-yl]-2-heptenoate (**27b**)*: ^1H NMR δ: 6.97 (1H, ddd, J = 7, 7, 15.5 Hz, HC-3), 6.18 (1H, d, J = 10 Hz, HC-6′), 5.95 (1H, d, J = 10 Hz, HC-5′), 5.82 (1H, dt, J = 15.5, 1.5 Hz, HC-2), 3.73 (3H, s, H_3CO), 3.28 (2H, s, H_2C-2′), 2.26–2.18 (4H, m, H_2C-7, H_2C-4), 1.50–1.38 (4H, m, H_2C-5, H_2C-6), 1.30–0.90 (21H, m, $(H_3C)_2CHSi$).

*Methyl (*Z*)-6-[4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-5-yl]-2-heptenoate (**28b**) and methyl (*Z*)-6-[4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-3-yl]-2-heptenoate (**29b**)*

Obtained as a 1.3:1 mixture from a similar mixture of **24b** and **25b**: ^1H NMR δ for **28b**: 6.21 (1H, dt, J = 15.5, 7 Hz, H-3), 6.05 (1H, s, H-6′), 5.78 (1H, d, J = 15.5 Hz, H-2), 4.76 (1H, t, J = 7 Hz, H-3′), 3.70 (3H, s, H_3CO), 3.19 (2H, d, J = 7 Hz, H_2C-2′), 2.78–2.60 (2H, m, H_2C-4), 2.23–2.13 (2H, m, H_2C-7), 1.52–1.38 (4H, m, H_2C-5, H_2C-6), 1.30–0.90 (21H, m, $(H_3C)_2CHSi$); δ for **29b**: 6.21 (1H, dt, J = 11.5, 7 Hz, H-3), 6.18 (1H, d, J = 10 Hz, H-6′), 5.94 (1H, d, J = 10 Hz, H-5′), 5.78 (1H, d, J = 11.5 Hz, H-2), 3.70 (3H, s, H_3CO), 3.25 (2H, s, H_2C-2′), 2.69 (2H, m, H_2C-4), 2.23–2.13 (2H, m, H_2C-7), 1.52–1.38 (4H, m, H_2C-5, H_2C-6), 1.30–0.90 (21H, m, $(H_3C)_2CHSi$).

*Methyl (*E*)-6-(4-oxo-4*H*-thiopyran-3-yl)-2-hexenoate (**30a**)*

A solution of a 1.2:1 mixture of **26a** and **27a** (8.3 mg, 0.021 mmol) in $C_6D_5CD_3$ (0.5 mL) was heated at 75°C for 24 h. ^1H NMR of the reaction solution showed essentially complete conversion to **30a**. The mixture was concentrated and fractionated by PTLC to give **30a** (4 mg, 75%). IR ν_{max}: 3024, 1718, 1605, 1272 cm^{-1}; ^1H NMR δ: 7.74 (1H, dd, J = 4, 10 Hz, HC-6′), 7.54 (1H, d, J = 4 Hz, HC-2′), 7.05 (1H, d, J = 10 Hz, HC-5′), 6.98 (1H, dt, J = 15.5, 7 Hz, HC-3), 5.86 (1H, dt, J = 15.5, 1.5 Hz, HC-2), 3.72 (3H, s, H_3CO), 2.64–2.58 (2H, m, H_2C-6), 2.28 (2H, ap ddt, J = 1.5, 7, 7 Hz, H_2C-4), 1.80–1.70 (2H, m, H_2C-5); LRMS (CI, NH_3), *m/z* (relative intensity): 256 ($[M+18]^+$, 25), 239 ($[M+1]^+$, 100), 83 (25).

*Methyl (*E*)-7-(4-oxo-4*H*-thiopyran-3-yl)-2-heptenoate (**30b**)*

Obtained as a minor by-product (<20% yield) from thermal

reaction of a mixture of **26b** and **27b**: IR ν_{max}: 3023, 2945, 1731, 1716, 1653, 1614, 1601, 1271 cm^{-1}; ^1H NMR δ: 7.74 (1H, dd, J = 4, 10 Hz, HC-6′), 7.53 (1H, d, J = 10 Hz, HC-2′), 7.04 (1H, d, J = 10 Hz, HC-5′), 6.94 (1H, dt, J = 15.5, 7 Hz, HC-3), 5.81 (1H, dt, J = 15.5, 1.5 Hz, HC-2), 3.69 (3H, s, H_3CO), 2.61–2.55 (2H, m, H_2C-7), 2.23 (2H, ap dt, J = 6.5, 6.5, 6.5 Hz, H_2C-4), 1.64–1.48 (4H, m, H_2C-5, H_2C-6); ^{13}C NMR δ: 179.3 (s, C-4′), 167.0 (s, C-1), 149.1 (d, C-3), 143.6 (s, C-3′), 136.8 (d, C-6′), 132.4 (d, C-2′), 130.4 (d, C-5′), 121.1 (d, C-2), 51.3 (q, CH_3O), 31.9 (t, C-4), 31.6 (t, C-7), 27.7 (t, C-5), 27.4 (t, C-6); LRMS (EI), *m/z* (relative intensity): 252 ($[M]^+$, 12), 221 (12), 193 (12), 154 (15), 153 (100).

*Methyl (*E*)-7-(4-oxo-4*H*-thiopyran-3-yl)-2-heptenoate (**30b**) and methyl (*Z*)-7-(4-oxo-4*H*-thiopyran-3-yl)-2-heptenoate (**31b**)*

Obtained as an ca. 1:1 mixture (<20% yield) from thermal reaction of a mixture of **28b** and **29b**: IR ν_{max}: 3043, 2929, 2858, 1720, 1656, 1608, 1271, 1200 cm^{-1}; ^1H NMR δ for **30b**: 7.73 (1H, dd, J = 6, 10.5 Hz, HC-6′), 7.54 (1H, d, J = 6 Hz, HC-2′), 7.04 (1H, d, J = 10.5 Hz, HC-5′), 6.95 (1H, dt, J = 15, 8 Hz, HC-3), 5.81 (1H, d, J = 15 Hz, HC-2), 3.72 (3H, s, H_3CO), 2.65–2.57 (2H, m, H_2C-7), 2.40–2.30 (2H, m, H_2C-4), 1.65–1.35 (4H, m, H_2C-5, H_2C-6); δ for **31b**: 7.73 (1H, dd, J = 10.5, 6 Hz, HC-6′), 7.53 (1H, d, J = 6 Hz, HC-2′), 7.04 (1H, d, J = 10.5 Hz, HC-5′), 6.22 (1H, dt, J = 11.5, 8 Hz, HC-3), 5.77 (1H, d, J = 11.5 Hz, HC-2), 3.72 (3H, s, H_3CO), 2.73–2.65 (2H, m, H_2C-4), 2.65–2.57 (2H, m, H_2C-7), 1.65–1.35 (4H, m, H_2C-5, H_2C-6).

*2-[3-(1,3-Dioxolan-2-yl)propyl]-tetrahydro-4*H*-thiopyran-4-one (**33**)*

In this case, the product obtained from addition of the cuprate derived from 2-(4-bromobutyl)-1,3-dioxolane to **32** (750 mg, 769 mmol) according to the general procedure was contaminated with 2-propyl-1,3-dioxolane. This crude product was directly subjected to decarboxylation according to the general procedure to obtain **33** (355 mg, 41%) after FCC (80% ether in hexane): IR ν_{max}: 1711, 1410, 1139 cm^{-1}; ^1H NMR δ: 4.84 (1H, dd, J = 4, 4.5 Hz, HC-2″), 4.00–3.80 (4H, m, H_2C-4″, H_2C-5″), 3.11–3.02 (1H, m, HC-2), 3.00–2.82 (2H, m, HC-6), 2.74 (1H, br dd, J = 3.5, 13.5 Hz, HC-3), 2.70–2.53 (2H, m, H_2C-5), 2.44 (1H, dd, J = 10.5, 13.5 Hz, HC-3), 1.70–1.50 (6H, m, H_2C-1′, H_2C-2′, H_2C-3′); ^{13}C NMR δ: 208.4 (s, C-4), 104.1 (d, C-2″), 64.8 (t ×2, C-4″, C-5″), 50.5 (t, C-3), 44.5 (d, C-2), 43.3 (t, C-5), 35.3 (t, C-1′), 33.3 (t, C-3′), 27.9 (t, C-6), 21.2 (t, C-2′); LRMS (EI), *m/z* (relative intensity): 230 ($[M]^+$, 11), 168 (32), 112 (21), 99 (23), 73 (100).

*Methyl (*E*)-6-(tetrahydro-4-oxo-2*H*-thiopyran-2-yl)-2-hexenoate (**34**) and methyl (*Z*)-6-(tetrahydro-4-oxo-2*H*-thiopyran-2-yl)-2-hexenoate (**35**)*

34 (48 mg, 47%) and **35** (27 mg, 26%) were obtained from **33** (125 mg, 0.534 mmol) after PTLC (50% ether in hexane, developed ×2).

For **34**: IR ν_{max}: 3031, 1715, 1656, 1272 cm^{-1}; ^1H NMR δ: 6.93 (1H, ap dt, J = 15.5, 7 Hz, HC-3), 5.84 (1H, ap dt, J = 15.5, 1.5 Hz, HC-2), 3.72 (3H, s, H_3CO), 3.11–3.01 (1H, m, HC-2′), 2.99–2.83 (2H, m, HC-6′), 2.73 (1H, dd, J = 3.5, 13.5 Hz, HC-3′), 2.72–2.55 (2H, m, HC-5′), 2.44 (1H, dd, J = 10.5, 13.5 Hz, HC-3′), 2.26–2.18 (2H, m, HC-4), 1.66–1.54 (4H, m, H_2C-5, H_2C-6); ^{13}C NMR δ: 208.4 (s, C-4′), 166.9 (s, C-1), 148.4 (d, C-3), 121.5 (d, C-2), 51.4 (q, CH_3O), 50.6 (t, C-3′), 44.5 (d, C-2′), 43.4 (t, C-5′), 34.9 (t, C-6), 31.7 (t, C-4), 28.0 (t, C-6′), 25.3 (t, C-5); LRMS (CI, NH_3), *m/z* (relative intensity): 260 ($[M+18]^+$, 100), 243 ($[M+1]^+$, 84), 211 (26).

For **35**: IR ν_{max}: 3032, 1717, 1644, 1197 cm^{-1}; ^1H NMR δ: 6.19 (1H, dt, J = 11.5, 7.5 Hz, HC-3), 5.79 (1H, dt, J = 11.5, 1.5 Hz, HC-2), 3.70 (3H, s, H_3CO), 3.15–3.05 (1H, m, HC-2′), 3.01–2.82 (2H, m, HC-6′), 2.73 (1H, br dd, J = 3.5, 13.5 Hz, HC-3′), 2.70–2.55 (4H, m, H_2C-4, H_2C-5′), 2.43 (1H, dd, J = 10.5, 13.5 Hz, HC-3′), 1.66–1.54 (4H, m, H_2C-5, H_2C-6); ^{13}C NMR δ: 208.5 (s, C-4′), 166.7 (s, C-1), 149.6 (d, C-3), 120.0 (d, C-2), 51.1 (q, CH_3O), 50.6 (t, C-3′), 44.5 (d, C-2′), 43.4 (t, C-5′), 35.0 (t, C-6), 28.4 (t, C-4), 28.1 (t, C-6′), 26.2 (t, C-5); LRMS (CI, NH_3), *m/z* (relative intensity): 260 ($[M+18]^+$, 100), 243 ($[M+1]^+$, 63), 211 (20), 199 (16).

*Methyl (*E*)-6-(3,4-dihydro-4-oxo-2*H*-thiopyran-6-yl)-2-hexenoate (**36**) and methyl (*E*)-6-(3,4-dihydro-4-oxo-2*H*-thiopyran-2-yl)-2-hexenoate (**37**)*

36 (22 mg, 63%) and **37** (10 mg, 29%) were obtained from **34** (35 mg, 0.14 mmol) after PTLC (50% EtOAc in hexane).

For **36**: IR ν_{max}: 3016, 1720, 1654, 1180 cm^{-1}; ^1H NMR δ: 6.92 (1H, dt, J = 15.5, 7 Hz, HC-3), 5.84 (1H, dt, J = 15.5, 1.5 Hz, HC-2), 6.06 (1H, s, HC-5′), 3.71 (3H, s, H_3CO), 3.19–3.13 (2H, m, H_2C-2′), 2.67–2.61 (2H, m, H_2C-3′), 2.39 (2H, ap t, J = 7.5 Hz, H_2C-6), 2.24 (2H, ap ddt, J = 1.5, 7, 7.5 Hz, H_2C-4), 1.77 (2H, ap tt, J = 7.5, 7.5 Hz, H_2C-5); ^{13}C NMR δ: 194.2 (s, C-4′), 166.8 (s, C-1), 163.8 (s, C-6′), 147.8 (d, C-3), 122.1 (d, C-5′), 121.9 (d, C-2), 51.5 (q, CH_3O), 37.6 (t, C-6), 36.8 (t, C-3′), 31.2 (t, C-4), 27.4 (t, C-2′), 26.9 (t, C-5); LRMS (CI, NH_3), *m/z* (relative intensity): 241 ($[M+18]^+$, 100), 180 (12).

For **37**: IR ν_{max}: 3031, 1720, 1659, 1271 cm^{-1}; ^1H NMR δ: 7.41 (1H, d, J = 10 Hz, HC-6′), 6.92 (1H, dt, J = 15.5, 7 Hz, HC-3), 6.17 (1H, d, J = 10 Hz, HC-5′), 5.84 (1H, dt, J = 15.5, 1.5 Hz, HC-2), 3.74 (3H, s, H_3CO), 3.53–3.42 (1H, m, HC-2′), 2.78 (1H, dd, J = 3.5, 16.5 Hz, HC-3′), 2.59 (1H, dd, J = 11.5, 16.5 Hz, HC-3′), 2.24 (2H, ap ddt, J = 1.5, 7, 7.5 Hz, H_2C-4), 1.80–1.55 (4H, m, H_2C-5, H_2C-6); ^{13}C NMR δ: 194.3 (s, C-4′), 166.9 (s, C-1), 148.0 (d, C-3), 145.3 (d, C-6′), 123.5 (d, C-5′), 121.8 (d, C-2), 51.5 (q, CH_3O), 44.4 (t, C-3′), 42.8 (d, C-2′), 33.3 (t, C-6), 31.6 (t, C-4), 25.1 (t, C-5); LRMS (CI, NH_3), *m/z* (relative intensity): 258 ($[M+18]^+$, 14), 241 ($[M+1]^+$, 100), 113 (20).

*Methyl (*Z*)-6-(3,4-dihydro-4-oxo-2*H*-thiopyran-6-yl)-2-hexenoate (**38**) and methyl (*Z*)-6-(3,4-dihydro-4-oxo-2*H*-thiopyran-2-yl)-2-hexenoate (**39**)*

38 (39 mg, 48%) and **39** (24 mg, 30%) were obtained from **35** (81 mg, 0.33 mmol) after PTLC (50% EtOAc in hexane).

For **38**: IR ν_{max}: 3032, 1718, 1649, 1198 cm^{-1}; ^1H NMR δ: 6.17 (1H, dt, J = 11.5, 7.5 Hz, HC-3), 6.04 (1H, br s, HC-5′), 5.79 (1H, dt, J = 11.5, 1.5 Hz, HC-2), 3.67 (3H, s, H_3CO), 3.18–3.12 (2H, m, HC-2′), 2.68 (2H, ap ddt, J = 1.5, 7.5, 7.5 Hz, H_2C-4), 2.64–2.58 (2H, m, H_2C-3′), 2.39 (2H, ap t, J = 7.5 Hz, H_2C-6), 1.73 (2H, ap tt, J = 7.5, 7.5 Hz, H_2C-5); ^{13}C NMR δ: 194.3 (s, C-4′), 166.6 (s, C-1), 164.2 (s, C-6′), 148.9 (d, C-3), 121.9 (d, C-5′), 120.3 (d, C-2), 51.1 (q, CH_3O), 37.8 (t, C-6), 36.8 (t, C-3′), 28.1 (t, C-4 or 5), 28.0 (t, C-4 or 5), 27.4 (t,

C-2′); LRMS (EI), *m/z* (relative intensity): 240 ([M]$^+$, 6), 208 (18), 180 (100), 141 (69), 128 (88).

*2,3-Dihydro-3-(methoxymethyl)-4H-thiopyran-4-one (**53**)*
A solution of anhydrous $ZnBr_2$ in ether (0.25 M, 0.16 mL, 0.040 mmol) was added to a solution of chloromethyl methyl ether (91 μL, 96 mg, 1.2 mmol) and 4-trimethylsilyloxy-2*H*-thiopyran (186 mg, 1.00 mmol) in dry CH_2Cl_2 (5 mL) at rt. After stirring for 30 min, the mixture was poured onto saturated $NaHCO_3$ and extracted with CH_2Cl_2. The combined organic layers were washed with H_2O, dried over Na_2SO_4, concentrated, and fractionated by MPC (30% EtOAc in hexane) to give **56** (10 mg, 9%) and **53** as a clear oil (110 mg, 70%): IR ν_{max}: 3029, 1657, 1555, 1204, 1118 cm^{-1}; ^1H NMR δ: 7.42 (1H, dd, J = 1.5, 10 Hz, HC-6), 6.15 (1H, d, J = 10 Hz, HC-5), 3.74 (1H, dd, J = 4.5, 9.5 Hz, HC-1′), 3.59 (1H, dd, J = 9, 9.5 Hz, HC-1′), 3.37 (3H, s, H_3CO), 3.33 (1H, ddd, J = 1.5, 4.5, 13.5 Hz, HC-2), 3.26 (1H, dd, J = 11, 13.5 Hz, HC-2), 2.87 (1H, dddd, J = 4.5, 4.5, 9, 11 Hz, HC-3); ^{13}C NMR δ: 193.8 (s, C-4), 146.3 (d, C-6), 123.7 (d, C-5), 69.6 (t, C-1′), 59.0 (q, CH_3O), 45.8 (d, C-3), 29.7 (t, C-2); LRMS (EI), *m/z* (relative intensity): 158 ($[M]^+$, 81), 126 (22), 125 (15), 113 (72), 86 (100), 58 (37).

*2,3-Dihydro-3-methlyene-4H-thiopyran-4-one (**54**)*
TFA (0.25 mL) was added to a solution of **53** (100 mg, 0.63 mmol) in CH_2Cl_2 (2 mL) at rt. After stirring for 5 days, the reaction mixture was concentrated and filtered through a short column of silica gel eluting with C_6H_6. The filtrate was concentrated and the residue dissolved in CH_2Cl_2 (2 mL). Et_3N (0.25 mL) was added and after stirring for 1–3 days, the reaction mixture was concentrated and fractionated by FCC (20% ether in hexane) to yield **54** as an oil (60 mg, 75%): IR ν_{max}: 3033, 2900, 1786, 1729, 1658, 1611, 1540, 1167 cm^{-1}; ^1H NMR δ: 7.48 (1H, br d, J = 10 Hz, HC-6), 6.25 (1H, br d, J = 10 Hz, HC-5), 6.06 (1H, br s, HC-1′), 5.51 (1H, br s, HC-1′), 3.87 (2H, br s, H_2C-2); ^{13}C NMR δ: 185.2 (s, C-4), 146.3 (d, C-6), 139.0 (s, C-3), 124.5 (d, C-5), 123.4 (t, C-1′), 34.2 (t, C-2); LRMS (CI, NH_3), *m/z* (relative intensity): 144 ($[M+18]^+$, 4), 127 ($[M+1]^+$, 100), 126 (14), 97 (4).

*2-(2-Hydroxyethylthio)-tetrahydro-4H-thiopyran-4-one (**57**)*
2-Mercaptoethanol (0.13 mL, 1.8 mmol) was added to a suspension of NaH (3 mg, 0.1 mmol) in THF (5 mL). Compound **56** (100 mg, 0.80 mmol) was added and the mixture was stirred at rt for 10 h. The reaction mixture was concentrated and the residue dissolved in CH_2Cl_2; the solution was washed with H_2O (×3), dried over Na_2SO_4, concentrated, and fractionated by FCC (35% EtOAc in hexane) to give **57** (92 mg, 55%): ^1H NMR δ: 4.27 (1H, br t, J = 4.5 Hz, HC-2), 3.64 (1H, s, HO), 3.52 (2H, ap t, J = 6 Hz, H_2C-2′), 3.04 (1H, ddd, J = 6.5, 7, 14 Hz, HC-6), 2.85 (1H, dd, J = 4.5, 14.5 Hz, HC-3), 2.72–2.55 (2H, m, HC-6, HC-1′,), 2.55–2.38 (4H, m, HC-3, H_2C-5, HC-1′); ^{13}C NMR δ: 206.4 (s, C-4), 61.1 (t, C-2′), 49.5 (d, C-2), 48.1 (t, C-3), 42.9 (t, C-5), 34.4 (t, C-1′), 26.0 (t, C-6); LRMS (EI), *m/z* (relative intensity): 192 ($[M]^+$, 10), 115 (100), 87 (41), 73 (35). HRMS *m/z* calcd. for $C_7H_{12}O_2S_2$: 192.0279; found: 192.0278. Anal. calcd. for $C_7H_{12}O_2S_2$: C 43.72, H 6.29; found: C 42.92, H 6.34.

*2-[(Tetrahydro-4-oxo-2H-thiopyran-2-yl)thio]ethyl propenoate (**58**)*
Compound **57** (75 mg, 0.39 mmol) was added to a stirred solution of acryloyl chloride (70 mg, 0.77 mmol) and pyridine (0.6 mL, 0.8 mmol) in CH_2Cl_2 (3 mL) at rt. After 5 h, the reaction mixture was washed with H_2O (5 mL), dried over Na_2SO_4, concentrated, and fractionated by FCC (25% EtOAc in hexane) to give **58** (43 mg, 45%; note: higher yields are obtained if the reaction is conducted at 0°C): ^1H NMR δ: 6.45 (1H, dd, J = 1.5, 17.5 Hz, HC-3), 6.15 (1H, dd, J = 10.5, 17.5 Hz, HC-2), 5.85 (1H, dd, J = 1.5, 10.5 Hz, HC-3), 4.55–4.20 (3H, m, H_2C-1′, HC-2″), 3.28–3.14 (2H, m), 3.13–2.95 (2H, m), 3.10–2.95 (2H, m), 2.90–2.55 (4H, m).

*2-[(Tetrahydro-4-oxo-2H-thiopyran-2-yl)thio]ethyl methyl (E)-butendioate (**59**)*
Methyl fumaryl chloride (535 mg, 4 mmol) was added dropwise to a solution of **57** (517 mg, 2.7 mmol) and pyridine (0.3 mL, 4 mmol) in CH_2Cl_2 at 0°C and the mixture was stirred at rt for 4 h. The mixture was diluted with CH_2Cl_2, washed with water, dried over Na_2SO_4, concentrated, and fractionated by FCC (30% EtOAc in hexane) to give **59** (1.02 g, 89%): ^1H

NMR δ: 6.77 (2H, ap s, HC-2, HC-3), 4.42–4.38 (1H, m, HC-2″), 4.37–4.18 (2H, m, H_2C-1′), 3.73 (3H, s, H_3CO), 3.21 (1H, ddd, J = 5, 9, 14 Hz, HC-6″), 3.01 (1H, dd, J = 5, 14.5 Hz, HC-3″), 3.00–2.92 (1H, m, HC-2′), 2.82–2.76 (1H, m, HC-2′), 2.78–2.69 (1H, m, HC-6″), 2.70–2.55 (3H, m, J = 5.5, 14.5 Hz, HC-3″, H_2C-5″); ^{13}C NMR δ: 205.0 (s, C-4″), 164.9 (s, C-1 or C-4), 164.3 (s, C-1 or C-4), 133.6 (d, C-2 or C-3), 133.0 (d, C-2 or C-3), 63.7 (t, C-1′), 51.3 (q, CH_3O), 49.1 (d, C-2″), 48.2 (t, C-3″), 42.8 (t, C-5″), 30.3 (t, C-2′), 25.8 (t, C-6″); LRMS (CI, NH_3), *m/z* (relative intensity): 322 ([M+18]$^+$, 52), 132 (9), 115 (100), 87 (9). HRMS *m/z* calcd. for $C_{12}H_{16}O_5S_2$: 304.0439; found: 304.0430. Anal. calcd. for $C_{12}H_{16}O_5S_2$: C 47.35, H 5.30; found: C 46.84, H 5.33.

*2-[(3,4-Dihydro-4-oxo-2*H*-thiopyran-6-yl)thio]ethyl propenoate (**60a**), 2-[(5-chloro-3,4-dihydro-4-oxo-2*H*-thiopyran-6-yl)thio]ethyl propenoate (**60b**), 2-[(3,4-dihydro-4-oxo-2*H*-thiopyran-6-yl)thio]ethyl methyl* (E)*-butendioate (**61a**), and 2-[(5-chloro-3,4-dihydro-4-oxo-2*H*-thiopyran-6-yl)thio]ethyl methyl* (E)*-butendioate (**61b**)*

NCS (1.0–1.2 equiv.) was added in portions to a stirred solution of **58** (30 mg, 0.12 mmol) or **59** (255 mg, 0.84 mmol) in CCl_4 (ca. 10 mL/mmol of **58** or **59**) at 0°C. After 15–20 h, the reaction mixture was diluted with CH_2Cl_2, washed with water, dried over Na_2SO_4, concentrated, and fractionated by PTLC (30% EtOAc in hexane) to give a mixture of **60a,b** or **61a,b**. Further fractionated by PTLC (%1 MeOH in CH_2Cl_2) gave the pure components **60a** (7 mg, 24%), **60b** (8 mg, 24%), **61a** (57 mg, 22%), and **61b** (63 mg, 22%).

For **60a**: ^{1}H NMR δ: 6.45 (1H, dd, J = 1.5, 17.5 Hz, HC-3), 6.29 (1H, s, HC-5″), 6.13 (1H, dd, J = 10.5, 17.5 Hz, HC-2), 5.89 (1H, dd, J = 1.5, 10.5 Hz, HC-3), 4.38 (2H, ap t, J = 6.5 Hz, H_2-C1′), 3.26 (2H, ap t, J = 6.5 Hz, H_2C-2′), 3.27–3.15 (2H, m, H_2C-2″), 2.77–2.69 (2H, m, H_2C-3″); ^{13}C NMR δ: 191.4 (s, C-4″), 165.6 (s, C-1), 161.4 (s, C-6″), 131.6 (t, C-3), 127.8 (d, C-2), 119.8 (d, C-5″), 62.1 (t, C-1′), 37.5 (t, C-3″), 32.6 (t, C-2′), 28.6 (t, C-2″); LRMS (CI, NH_3), *m/z* (relative intensity): 245 ([M+1]$^+$, 100), 172 (8.6), 147 (11), 115 (11). HRMS *m/z* calcd. for $C_{10}H_{12}O_3S_2$: 244.0228; found: 244.0231.

For **60b**: ^{1}H NMR δ: 6.47 (1H, dd, J = 1.5, 17.5 Hz, HC-3), 6.15 (1H, dd, J = 10.5, 17.5 Hz, HC-2), 5.90 (1H, dd, J = 1.5, 10.5 Hz, HC-3), 4.43 (2H, ap t, J = 6.5 Hz, HC-1′), 3.35 (2H, ap t, J = 6.5 Hz, HC-2′), 3.31–3.25 (2H, m, HC-2″), 2.98–2.92 (2H, m, H_2C-3″); ^{13}C NMR δ: LRMS (CI, NH_3), *m/z* (relative intensity): 281 ([M+1]$^+$, 50), 279 ([M+1]$^+$, 100), 206 (15), 147 (13), 99 (15). HRMS *m/z* calcd. for $C_{10}H_{11}{}^{35}ClO_3S_2$: 277.9838; found: 277.9836.

For **61a**: ^{1}H NMR δ: 6.87 (2H, ap s, HC-2, HC-3), 6.27 (1H, s, HC-5″), 4.41 (2H, ap t, J = 6.5 Hz, HC-2′), 3.82 (3H, s, H_3CO), 3.27 (2H, ap t, J = 6.5 Hz, H_2C-1′), 3.24–3.18 (2H, m, H_2C-2″), 2.77–2.71 (2H, m, HC-3″); ^{13}C NMR δ: 191.4 (s, C-4″), 165.1 (s, C-1 or C-4), 164.4 (s, C-1 or C-4), 161.1 (s, C-6″), 134.1 (d, C-2 or C-3), 132.8 (d, C-2 or C-3), 119.9 (d, C-5″), 62.8 (t, C-1′), 52.4 (q, CH_3O), 37.5 (t, C-3″), 31.1 (t, C-2′), 28.6 (t, C-2″); LRMS (EI), *m/z* (relative intensity): 302 ([M]$^+$, 30), 172 (36), 139 (50), 113 (60), 85 (100). HRMS *m/z* calcd. for $C_{12}H_{14}O_5S_2$: 302.0283; found: 302.283. Anal. calcd. for $C_{12}H_{14}O_5S_2$: C 47.67, H 4.67; found: C 47.87, H 4.41.

For **61b**: ^{1}H NMR δ: 6.87 (2H, ap s, HC-2, HC-3), 4.45 (2H, ap t, J = 6.5 Hz, H_2C-1′), 3.80 (3H, s, H_3CO), 3.34 (2H, ap t, J = 6.5 Hz, H_2C-2′), 3.31–3.25 (2H, m, H_2C-2″), 2.96–2.90 (2H, m, H_2C-3″); ^{13}C NMR δ: 183.5 (s, C-4″), 165.1 (s, C-1 or C-4), 164.4 (s, C-1 or C-4), 156.2 (s, C-6″), 134.2 (d, C-2 or C-3), 132.8 (d, C-2 or C-3), 119.9 (s, C-5″), 63.1 (t, C-1′), 52.4 (q, CH_3O), 38.4 (t, C-3″), 31.0 (t, C-2′), 28.1 (t, C-2″); LRMS (CI, NH_3), *m/z* (relative intensity): 338 ([M]$^+$, 20), 336 ([M]$^+$, 44), 208 (42), 206 (100), 157 (97), 113 (97). HRMS *m/z* calcd. for $C_{12}H_{13}{}^{35}ClO_5S_2$: 335.9893; found: 335.9892. Anal. calcd. for $C_{12}H_{13}ClO_5S_2$: C 42.79, H 3.89; found: C 43.03, H 4.05.

*2-[4-[[Tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-6-yl]thio]ethyl propenoate (**62a**)*: ^{1}H NMR δ: 6.42 (1H, dd, J = 1.5, 17.5 Hz, HC-3), 6.24 (1H, d, J = 1.5 Hz, HC-5″), 6.12 (1H, dd, J = 10.5, 17.5 Hz, HC-2), 5.84 (1H, dd, J = 1.5, 10.5 Hz, HC-3), 4.76 (1H, dt, J = 1.5, 5.5 Hz, HC-3″), 4.34 (2H, ap t, J = 7 Hz, H_2C-1′), 3.34 (2H, d, J = 5.5 Hz, H_2C-2″), 3.14 (2H, ap t, J = 7 Hz, H_2C-2′), 1.15–1.04 (21H, m, $(H_3C)_2$CHSi).

*2-[5-Chloro-4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-6-yl]thio]ethyl propenoate (**62b**)*: ^{1}H NMR δ: 6.40 (1H, dd, J = 1.5, 17.5 Hz, HC-3), 6.25 (1H, d, J = 1.5 Hz, HC-5″), 6.10 (1H, dd, J = 10.5, 17.5 Hz, HC-2), 5.85 (1H, dd, J = 1.5, 10.5 Hz, HC-3), 4.95 (1H, dt, J = 1.5, 5.5 Hz, HC-3″), 4.35 (2H, ap t, J = 7 Hz, H_2C-1′), 3.30 (2H, d, J = 5.5 Hz, H_2C-2″), 3.20 (2H, ap t, J = 7 Hz, H_2C-2′), 1.15–1.04 (21H, m, $(H_3C)_2$CHSi).

*2-[[4-[[Tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-6-yl]thio]ethyl methyl* (E)*-butendioate (**63a**)*: ^{1}H NMR δ: 6.86 (2H, ap s, HC-2, HC-3), 6.23 (1H, d, J = 1.5 Hz, HC-5″), 4.76 (1H, dt, J = 1.5, 5.5 Hz, HC-3″), 4.36 (2H, ap t, J = 6.5 Hz, H_2C-1′), 3.80 (3H, s, H_3CO), 3.33 (2H, d, J = 5.5 Hz, H_2C-2″), 3.13 (2H, ap t, J = 6.5 Hz, H_2C-1′), 1.15–1.04 (21H, m, $(CH_3)_2$CHSi).

*2-[[5-Chloro-4-[[tris(1-methylethyl)silyl]oxy]-2*H*-thiopyran-6-yl]thio]ethyl methyl* (E)*-butendioate (**63b**)*: ^{1}H NMR δ: 6.88 (2H, ap s, HC-2, HC-3), 4.98 (1H, dt, J = 1.5, 5.5 Hz, HC-3″), 4.38 (2H, ap t, J = 6.5 Hz, H_2C-1′), 3.80 (3H, s, H_3CO), 3.31 (2H, d, J = 5.5 Hz, H_2C-2″), 3.25 (2H, ap t, J = 6.5 Hz, H_2C-1′), 1.15–1.04 (21H, m, $(CH_3)_2$CHSi).

*Methyl (3a*S**,4*S**,7*R**,7a*R**)-octahydro-7-hydroxy-7a-methyl-1*H*-indene-4-carboxylate (**64a**) and methyl (3a*S**,4*S**,7*S**,7a*R**)-octahydro-7-hydroxy-7a-methyl-1*H*-indene-4-carboxylate (**64b**)*

Raney Ni (0.30 mL) was added to a stirred solution of **45** (5.7 mg, 0.024 mmol) in MeOH (1 mL) and the resuling suspension was heated under reflux for 1 h. The reaction mixture was filtered through Celite with the aid of MeOH. The combined filtrate and washings were concentrated and fractionated by MPC (28% ethyl acetate in hexane) to give **64a** (1.9 mg, 38%) and **64b** (3.1 mg, 62%).

For **64a**: IR ν_{max}: 3468, 2950, 2871, 1735, 1450, 1155 cm^{-1}; ^{1}H NMR δ: 3.67 (3H, s, H_3CO), 3.46 (1H, dd, J = 4.5, 11 Hz, HC-7), 2.28–2.21 (1H, m, HC-4), 1.93–1.25 (11H, m), 0.75 (3H, s, H_3CC-7a); ^{13}C NMR (125 MHz) δ: 176.3, 78.7, 51.4, 49.3, 46.1, 42.2, 37.8, 29.7, 28.5, 25.7, 19.6, 11.2; LRMS (CI, NH_3), *m/z* (relative intensity): 230 ([M+18]$^+$, 67), 227 ([M+1]$^+$, 59), 195 (82), 180 (100), 135 (88), 130 (92).

For **64b**: IR ν_{max}: 3515, 2950, 2874, 1735, 1165 cm^{-1}; ^{1}H NMR δ: 3.80–3.76 (1H, m, HC-7), 3.66 (3H, s, H_3CO), 2.34 (1H, ddd, J = 4, 10, 10 Hz, HC-4), 1.92–1.61 (9H, m), 1.40–

1.22 (2H, m), 0.77 (3H, s, H_3CC-7a); ^{13}C NMR δ: 176.1, 71.6, 51.3, 45.3, 43.4, 41.6, 32.6, 28.3, 25.4, 23.8, 19.2, 18.0; LRMS (CI, NH_3), *m/z* (relative intensity): 2230 ($[M+18]^+$, 61), 227 ($[M+1]^+$, 24), 195 (100), 135 (56), 130 (67).

Methyl (1S,R*,4aR*,8aS*)-decahydro-4-hydroxy-4a-methylnaphthalene-1-carboxylate (**65a**) and methyl (1S*,4S*,4aR*,8aS*)-decahydro-4-hydroxy-4a-methylnaphthalene-1-carboxylate, (**65b**)*

Raney Ni (0.15 mL) was added to a stirred solution of **49** (12.5 mg, 0.049 mmol) in MeOH (2 mL) and the resulting suspension heated under reflux for 1 h. The reaction mixture was filtered through Celite with the aid of MeOH. The combined filtrate and washings were concentrated and fractionated by MPC (20% ethyl acetate in hexane) to give **65a** (5.3 mg, 48%) and **65b** (5.3 mg, 48%).

For **65a**: IR ν_{max}: 3480, 2927, 2862, 1735, 1436, 1171 cm^{-1}; ^1H NMR δ: 3.65 (3H, s, H_3CO), 3.32 (1H, dd, J = 4.5, 11 Hz, HC-4), 2.23 (1H, dt, J = 4, 11 Hz, HC-1), 2.02–1.09 (13H, m), 0.85 (3H, s, H_3C); ^{13}C NMR δ: 176.6, 78.5, 51.4, 45.7, 44.4, 38.8, 37.1, 29.0, 28.0, 26.2, 25.2, 21.2, 10.3; LRMS (CI, NH_3), *m/z* (relative intensity): 244 ($[M+18]^+$, 100), 227 ($[M+1]^+$, 45), 209 (50), 194 (26).

For **65b**: IR ν_{max}: 3513, 2926, 2859, 1735, 1443, 1153 cm^{-1}; ^1H NMR δ: 3.65 (3H, s, H_3CO), 3.36 (1H, br s, HC-4), 2.30 (1H, ddd, J = 4, 4, 12 Hz, HC-1), 1.92–1.00 (13H, m), 0.87 (3H, s, H_3C); ^{13}C NMR δ: 176.4, 74.4, 51.2, 45.0, 39.1, 37.8, 34.8, 27.6, 26.3, 25.7, 23.9, 21.4, 16.7; LRMS (CI, NH_3), *m/z* (relative intensity): 244 ($[M+18]^+$, 37), 227 ($[M+1]^+$, 31), 209 (100).

Molecular motion in crown ethers. Application of ^{13}C and ^{2}H NMR to the study of 4-carboxybenzo-24-crown-8 ether and its KNCS complex in solution and in the solid phase[1]

G.W. Buchanan, A. Moghimi, and C.I. Ratcliffe

Abstract: Large-amplitude solid phase molecular motion has been detected in the macrocyclic ring of the title crown either via ^{13}C CPMAS NMR. To study the details of the dynamic processes, two selectively deuterated d_4 derivatives have been prepared and examined via ^{2}H NMR as a function of temperature. A phase change occurring around 277 K has been verified by differential scanning calorimetry (DSC) and a model for the motional processes has been developed involving equivalent two-site flips of the CD_2 groups. The amplitude of the CD_2 motions apparently decreases the closer the group is to the aromatic ring. The influence of KNCS complexation on the ^{13}C CPMAS spectrum and on ^{13}C spin lattice relaxation times in solution has been explored.

Key words: macrocyclic ethers, solid phase dynamics.

Résumé : La spectroscopie de RMN et de CPMAS du ^{13}C a permis de déceler un mouvement moléculaire de grande amplitude dans la phase solide du macrocycle de l'éther couronne mentionné dans le titre. Dans le but d'étudier le détail du processus dynamique, on a choisi de préparer deux dérivés deutérés d_4 et on les a étudiés par RMN du ^{2}H en fonction de la température. Il se produit un changement de phase vers 277 K que l'on a pu vérifier par calorimétrie à balayage différentiel (CBD) et on a mis au point, pour ce mouvement, un modèle impliquant deux sites équivalents de pliage des groupes CD_2. L'amplitude des mouvements des groupes CD_2 décroît apparemment lorsque le groupe est très près du cycle aromatique. On a étudié l'influence de la complexation par le KNCS sur le spectre CPMAS du ^{13}C et sur les temps de relaxation spin-réseau en solution du ^{13}C.

Mots clés : éthers macrocycliques, dynamique dans la phase solide.

[Traduit par la rédaction]

Introduction

Complexes of macrocyclic polyethers (crown ethers) are widely recognized as models for molecular recognition. Typically, these free macrocycles have highly flexible geometries in solution, and thus can adapt their conformations for optimum complexation of guest species.

Recent work from these laboratories has shown that a substantial degree of motional freedom also exists in the solid state for several complexes of 18-crown-6 (1–6) and 12-crown-4 (7) ether systems.

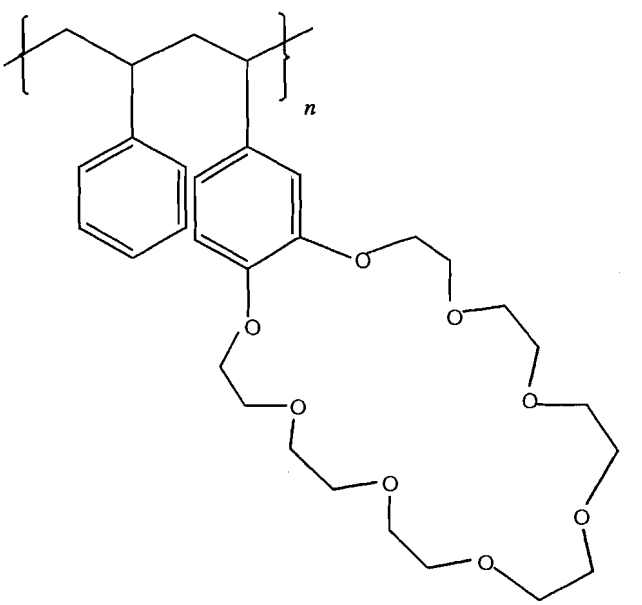
The first indication that motion might be taking place in the 24-crown-8 ether macrocycle in the solid phase came from a comparison of the normal and dipolar dephased (8) ^{13}C CPMAS NMR spectra of a copolymer of styrene and 4-vinylbenzo-24-crown-8 (below).



Normally, resonances for protonated carbons are lost in the dipolar dephased experiment. The dipolar dephased spectrum

of this material, however, showed a substantial residual intensity for some of the CH_2-O resonances indicative of some large-amplitude motion in the polyether macrocyle.

To examine the details of such motion in the 24-crown-8 macrocycle, a simpler molecular network that is solid over a wide range of temperatures is required. The 4-carboxybenzo-24-crown-8 molecule, **1**, meets these criteria.

Experimental

Materials

The synthesis of **1** was carried out starting with commercially available 3,4-dihydroxybenzaldehyde (Aldrich), which was condensed with 1,20-dichloro-3,6,9,12,15,18-hexaoxatetradecane. The resulting aldehyde was oxidized to **1**. Details follow. Initially, heptaethylene glycol was prepared according to the procedure outlined below.

A 1 L round-bottom three-necked flask, equipped with a condenser and a dropping funnel, was charged with diethylene glycol (Aldrich) (660.0 g, 6.2 mol) and crushed NaOH pellets (80.0 g, 2 mol), and was heated to 100°C while stirring under a nitrogen atmosphere for 2 h until most of the base had dissolved. Then 1,2-bis(2-chloroethoxy)ethane (Aldrich) (187.1 g, 1.0 mol) was added dropwise to the mixture over a period of 2 h while keeping the temperature at about 120°C. After refluxing for 4 h, the reaction mixture was cooled to room temperature and the water produced in the reaction was removed at reduced pressure. The resulting concentrate was diluted with CH_2Cl_2 (200 mL) and the NaCl was removed by filtration. The solution was dried over anhydrous Na_2SO_4 and, after removal of the drying agent, the solvent was removed by rotoevaporation. Fractional distillation at reduced pressure (0.7 Torr; 1 Torr = 133.3 Pa) yielded 135.0 g (41.4%) of heptaethylene glycol, bp 240–250°C. ^{13}C NMR ($CDCl_3$), δ_C: 72.4, 70.3, 70.1, 61.3. CIMS: M + 1 at 327 (100%).

Heptaethylene glycol was converted to 1,20-dichloro-3,6,9,12,15,18-hexaoxatetradecane according to the following method. Thionyl chloride (52.5 mL, 0.72 mol) was added dropwise with stirring to cooled heptaethylene glycol (108.6 g, 0.33 mol) under nitrogen. The mixture was stirred at room temperature for 14 h, then refluxed for 26 h. The excess thionyl chloride was removed at reduced pressure; the residue was poured onto ice (50 g) and then washed with CH_2Cl_2 (3 × 100 mL). The combined extracts were washed with saturated $NaHCO_3$ (3 × 20 mL), saturated NaCl (30 mL), and water (2 × 20 mL) and were dried over Na_2SO_4. Following solvent removal at reduced pressure, fractional distillation yielded 60.0 g (50.0%) of 1,20-dichloro-3,6,9,12,15,18-hexaoxatetradecane, bp 190–200°C (0.4 Torr). ^{13}C NMR ($CDCl_3$), δ_C: 71.3, 70.6, 70.5, 42.7. CIMS: M + 1 at 363 (62%).

4-Formylbenzo-24-crown-8 ether was prepared as follows: 3,4-dihydroxybenzaldehyde (2.35 g, 0.017 mol) and 18-crown-6 (0.1 g, 0.0003 mol) were dissolved in 500 mL of dry acetonitrile in a 1 L round-bottom two-necked flask equipped with a condenser, under N_2 atmosphere. To this was added K_2CO_3 (7.05 g, 0.051 mol) and 1,20-dichloro-3,6,9,12,15,18-hexaoxatetradecane (6.20 g, 0.017 mol) and the reaction mixture was refluxed for 5 days. Upon cooling, the mixture was filtered and the solvent was removed by rotoevaporation. Subsequent column chromatography on silica gel (grade 60, 230–400 mesh) eluting with ethyl acetate yielded 4-formylbenzo-24-crown-8 ether (3.6 g, 50.0%) as a pale yellow oil. ^{13}C NMR ($CDCl_3$), δ_C: 191.2, 154.9, 149.6, 130.6, 127.1, 112.7, 111.9, 71.7, 71.5, 71.3, 71.2, 71.1, 69.9, 69.8, 69.6. CIMS: M + 1 at 429 (100%).

Oxidation to **1** was carried out starting with Ag_2O (5.0 g, 0.022 mol) dissolved in 500 mL of 0.73 M NH_4OH in a 1 L Erlenmeyer flask covered by aluminum foil and stirred for 5 min. To this was added, dropwise, 4-formylbenzo-24-crown-8 ether (5.0 g, 0.012 mol) dissolved in 10 mL of absolute ethanol. After 30 min, the mirror started to form. The mixture was stirred for 16 h at room temperature, then filtered and washed with CH_2Cl_2 (6 × 50 mL). Evaporation of the solvent from the organic phase gave 1.5 g of mostly unreacted aldehyde. The aqueous phase was then acidified to pH 2 and washed with CH_2Cl_2 (4 × 100 mL). The solvent was removed by rotoevaporation, and the solid residue was kept under vacuum with occasional gentle warming to yield 3.0 g (56.3%) of **1**, mp 87–89°C. ^{13}C NMR ($CDCl_3$), δ_C: 170.6, 153.7, 148.6, 124.9, 122.6, 115.3, 112.6, 71.9, 71.5, 71.4, 71.1, 71.0, 70.9, 70.4, 69.9, 69.8, 69.6, 69.4. High-resolution MS: *m/z* calcd. for $C_{21}H_{32}O_{10}$ (M^+): 444.1996; found: 444.1967 (12.9%).

Preparation of ***1****-11,11′-*d_4

Initially, it was necessary to prepare the 7,7,14,14-d_4 derivative of 1,20-dichloro-3,6,9,12,15,18-hexaoxatetradecane. This was prepared as outlined schematically in Fig. 5 (*a*) and described below.

Ethylene glycol (3.1 g, 0.05 mol) and ethyldiazoacetate (10.5 mL, 0.10 mol) were dissolved in CH_2Cl_2 (100 mL), and the stirred solution was cooled in an ice bath. After addition of 3 drops of the catalyst $BF_3{\cdot}O(Et)_2$, an exothermic reaction occurred and the evolving N_2 gas was allowed to escape. Stirring was continued for another 30 min until no further gas had evolved. The solvent was then removed by rotary evaporation and the oily residue (11.5 g) was subjected to column chromatography on silica gel (grade 60, 230–400 mesh) using 1:1 hexane:diethyl ether as eluant. This gave 8.0 g (68.4 %) of 1,2-bis(ethylacetoxy)ethane. ^{13}C NMR ($CDCl_3$), δ_C: 170.3, 70.9, 68.6, 14.2. CIMS: M + 1 at 235 (100%).

Triethylene glycol-1,8-d_4 was then prepared as follows. All glassware for this reaction was dried in an oven overnight at 110°C. A 1 L round-bottom three-necked flask equipped with a strong magnetic stirrer, condenser, and a dropping funnel was charged with 500 mL anhydrous THF. Lithium aluminum deuteride (2.0 g, 0.048 mol) was added to the flask while the THF was being vigorously stirred under an N_2 atmosphere. The flask was then cooled in an ice–salt bath and 1,2-bis-(ethylacetoxy)ethane (11.8 g, 0.050 mol) dissolved in 20 mL of anhydrous THF was added over a period of 45 min. Two additional aliquots of 50 mL of dry THF were added to the reaction mixture to reduce the viscosity. The ice bath was removed and the temperature of the stirred reaction mixture was allowed to rise to 40°C over a period of 1 h. The excess $LiAlD_4$ was decomposed via slow addition of 1 mL of H_2O to the cooled reaction mixture. Subsequently, dilute (20%) H_2SO_4 (18 mL) was added dropwise to decompose the lithium alkoxide complex. The clear upper organic layer was separated and combined with the organic layers resulting from washing the lower viscous aqueous slurry with 3 × 50 mL of fresh THF. The solvent was removed by rotoevaporation and the resulting crude product was dissolved in 50 mL of H_2O

Fig. 1. Structures and numbering schemes for **1** and deuterated derivatives.

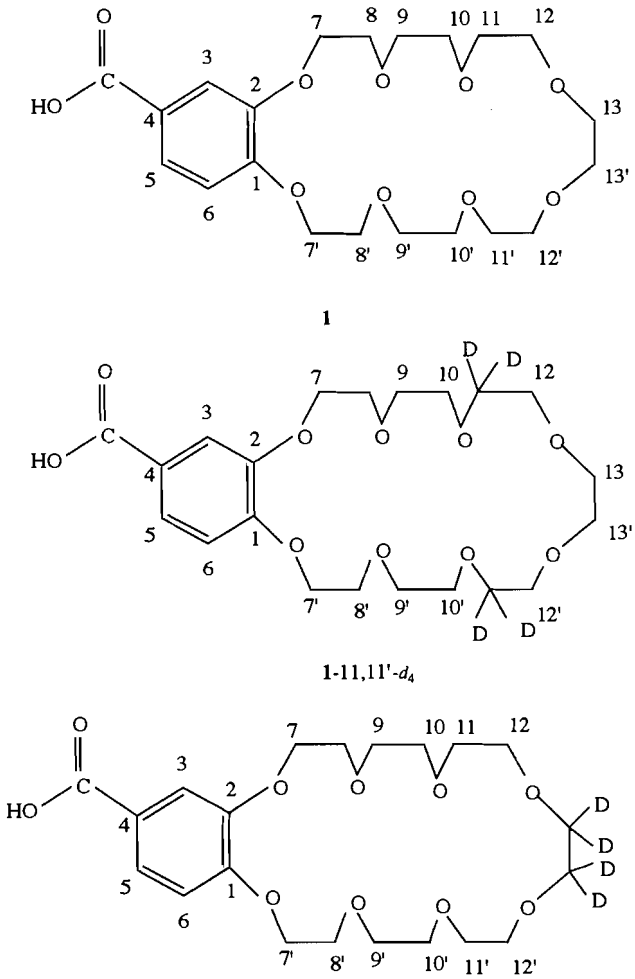


Fig. 2. (*a*): 400 MHz ^{1}H solution NMR spectrum of alphatic region of **1**. (*b*): 100 MHz ^{13}C solution NMR spectrum of alphatic region of **1**.

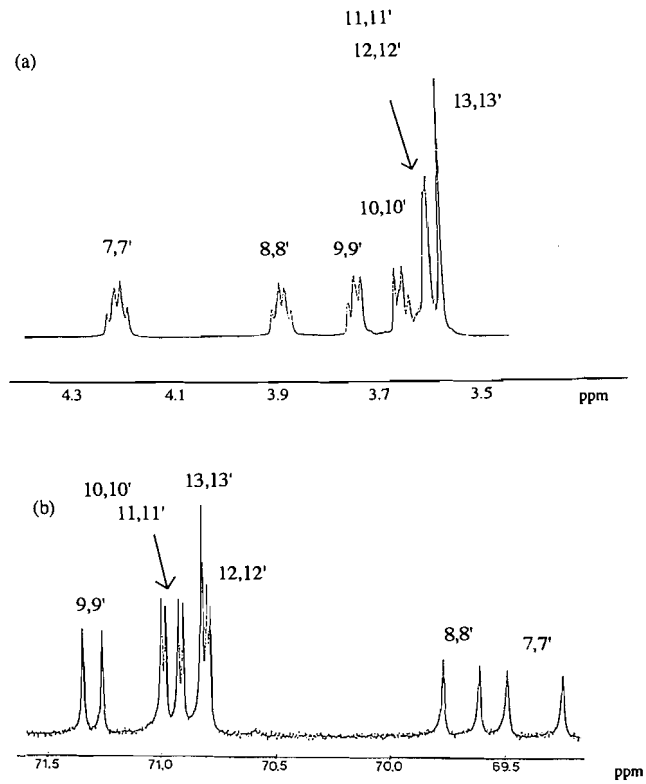

and washed with CH_2Cl_2 (20 mL). The water was removed by evaporation at reduced pressure and the residue was left under vacuum for 3 h, to yield 6.2 g of crude triethylene glycol-1,8-d_4.

This glycol was then converted to 1,8-dichloro-3,6-dioxaoctane-1,8-d_4, via reaction with thionyl chloride by standard methods to yield 5.92 g (80%) of product as a pale yellow liquid. ^{13}C NMR ($CDCl_3$), δ_C: 71.2. 50.6, 40.3 (quintet due to ^{13}C–^2H coupling). This dichloride was then condensed with diethylene glycol as described previously to yield heptaethylene glycol-7,7-14,14-d_4. Subsequent conversion to the 7,7,14,14-d_4 derivative of 1,20-dichloro-3,6,9,12,15,18-hexaoxatetradecane was carried out with $SOCl_2$. This material was then reacted with 3,4-dihydroxybenzaldehyde and oxidized using the same methods as for the nondeuterated compounds to yield **1**-11,11'-d_4. High-resolution MS: *m/z* calcd. for $C_{21}H_{28}O_{10}D_4$: 448.2247; found: 448.2260 (7.7%).

Preparation of ***1****-13,13'*-d_4

In this case it was necessary to synthesize the 10,10,11,11-d_4 derivative of 1,20-dichloro-3,6,9,12,15,18-hexaoxatetradecane as described below.

tert-Butanol (250 mL) was placed in a 500 mL round-bottom three-necked flask equipped with a condenser and a dropping funnel. To this was added a 57% suspension of NaH in mineral oil (4.88 g, 0.116 mol) and the mixture was stirred at room temperature under an N_2 atmosphere for 20 min. A mixture of ethylene glycol-d_6 (Cambridge Isotope Laboratories Inc.) (4.0 g, 0.058 mol) and 1,2-bis(2-chloroethoxy)ethane (Aldrich) (112.24 g, 0.600 mol) was added dropwise to the reaction flask over 1 min and the reaction mixture was refluxed for 5 days. After cooling, 200 mL H_2O was added and the mixture was extracted with CH_2Cl_2 (3 × 100 mL). The organic phase was then dried over anhydrous Na_2SO_4. Subsequent removal of the drying agent and solvent evaporation were followed by fractional distillation at reduced pressure to give a crude product, bp 180–210°C (0.5–0.7 Torr). This material was then subjected to column chromatography on silica gel (grade 60, 230–400 mesh) using 1:1 hexane:diethyl ether as eluent, to give 2.57 g (12.7%) of the 10,10,11,11-d_4 derivative of 1,20-dichloro-3,6,9,12,15,18-hexaoxatetradecane. ^{13}C NMR ($CDCl_3$), δ_C: 71.4, 70.8, 70.7, 70.6, 70.5, 69.7 (quintet), and 42.7. CIMS: M + 1 at 367 (42%).

Subsequently **1**-13.13'-d_4 was prepared in analogous fashion to that described previously. High-resolution MS: *m/z* calcd. for $C_{21}H_{28}O_{10}D_4$ (M^+): 448.2247; found: 448.2244 (4.6%).

Spectra

(a) Solution NMR spectra

These spectra were obtained using a Bruker AMX-400 spectrometer equipped with a 5 mm inverse probe and an Aspect X32 computer. An Aspect 3000 processing controller was employed and all standard microprograms used are in the Bruker Software Library.

^1H–^1H COSY experiments were run using N-type phase cycling with a 45° mixing pulse. Free induction decays were acquired over 1024 data points for each of the 256 values of the evolution time, with a digital resolution of 5 Hz/point. The raw data were zero filled in $F1$ prior to transformation using the qsine window function for both $F1$ and $F2$. The matrix was symmetrized about the diagonal.

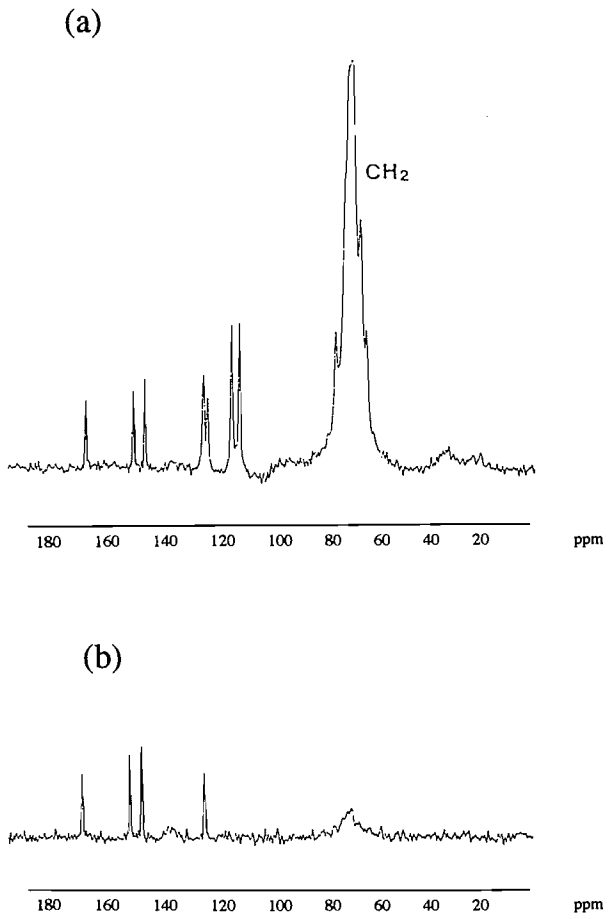
For the ^1H–^{13}C HETCOR experiments, the free induction decays were typically acquired over 1024 data points for each of the 512 values of the evolution time, with a digital resolution of ca. 8 Hz/point in $F2$ and 4 Hz/point in $F1$. The raw data were zero filled in $F1$ prior to transformation using the sine window function for both $F1$ and $F2$. The proton relaxation delays were set to 1 s. For one-bond couplings, delays were set to emphasize couplings of 140 Hz, while for the long-range HETCOR experiments, delays were set to correspond to couplings of 5 Hz.

^{13}C T_1's were measured at 100.6 MHz using the inversion–recovery method (9). In the NOESY experiments, the mixing times were selected to be consistent with the $1/T_1$ criterion (10) and, for **1**, this time was set at 0.3 s.

(b) ^{13}C CPMAS spectra

Solid state ^{13}C CPMAS (cross-polarization – magic angle spinning) NMR spectra were obtained at 45.3 MHz on a Bruker CXP-180 spectrometer with a 4.24 T cryomagnet, using a Doty Scientific Inc. 7 mm MAS probe (spin rate ca. 4.1 kHz) *or* at 50.29 MHz on a Bruker MSL-200 spectrometer with a 4.71 T cryomagnet, using a Chemagnetics 7 mm pencil probe (spin rate ca. 3.3 kHz). ^1H 90° pulse lengths were typi-

Fig. 4. (*a*) Normal and (*b*) dipolar dephased 45.3 MHz ^{13}C CPMAS NMR spectra of **1**·KNCS



cally 4.5 μs, cross-polarization times were 1–3 ms, and recycle times were 1–4 s. Dipolar dephased spectra (8) were obtained by interrupting the ^1H decoupling for 40 μs immediately after the cross-polarization sequence and before starting the data acquisition. Chemical shifts were measured relative to external solid hexamethylbenzene (HMB) and then corrected to the TMS scale (HMB methyl resonance at 16.9 ppm).

(c) ^2H powder spectra

These spectra were obtained at 46.05 MHz as a function of temperature using a Bruker AMX-300 spectrometer, equipped with a high-power transmitter, using a variable temperature N_2 gas flow probe (5 mm coil) and a Eurotherm temperature controller. A phase-alternated quadrupole echo pulse sequence (11) was employed, with a delay time of 30 μs between X and Y pulses of 2–2.2 μs.

(d) Differential scanning calorimetry (DSC)

A Seiko SSC5200 instrument was used for the DSC studies. The heating rate was 10°C per minute from −50°C to +110°C, with a nitrogen flow rate of 50 mL per minute. The cooling rate was 5°C per minute. Samples were analyzed in a crimped aluminum sample pan, and were heated gently for 1 h under vacuum to remove any trace of solvent before the DSC measurements were performed.

Results and discussion

The structures and numbering schemes for **1** and two selectively deuterated d_4 derivatives are shown in Fig. 1.

Solution ^{13}C NMR spectrum of 1

To aid in the analysis of the solid phase ^{13}C spectrum of this material, it is useful to examine the features of the solution counterpart. The ^1H solution spectrum can in turn be employed to aid in the analysis of the ^{13}C spectrum via HETCOR connectivities.

The aromatic region of the 400 MHz ^1H spectrum appears as an AMX pattern for protons 3, 5, and 6. H5 is coupled vicinally with H6 and then via a ^4J pathway to H3, giving a doublet of doublets centered at 7.88 ppm. H3 is centered at 7.61 ppm while H6 is at 6.91 ppm. The C3, C5, and C6 resonances can then be assigned directly via the ^1J HECTOR experiment. The quaternary carbons can be readily assigned via long-range HETCOR and the result are consistent with expectations based on well-documented effects of carboxyl and ether functions on ^{13}C shieldings (12).

In the aliphatic region, for each O-CH_2-CH_2-O network, the four protons represent an AA′BB′ spin system (13) and hence the patterns are rather complex. The solution ^1H and ^{13}C spectra of the aliphatic regions of **1** are presented in Fig. 2. For assignment of the methylene carbon resonances, a partial analysis can be obtained by starting with results of a ^1H–^1H NOESY experiment. In this experiment, there are connections between the H3 and H6 aromatic resonances and the aliphatic multiplet (4H integration) centered at 4.22 ppm. Thus it appears that the most deshielded aliphatic CH_2-O resonances correspond to those at C7 and C7′, which are closest to the aromatic ring, a result in accord with several earlier investigations (13–15). Subsequent ^1H–^1H COSY can be used to assign protons at the 8 and 8′ sites, and ^1J HETCOR establishes the resonances for the directly bonded carbons. Selective deuteration at the 11,11′ and 13,13′ sites permitted assignments for these protons and carbons as well as those on C12,12′. The solution ^{13}C NMR data are summarized in Table 1. The only resonances that cannot be unambiguously attributed are those for the 9,9′ and 10,10′ sites.

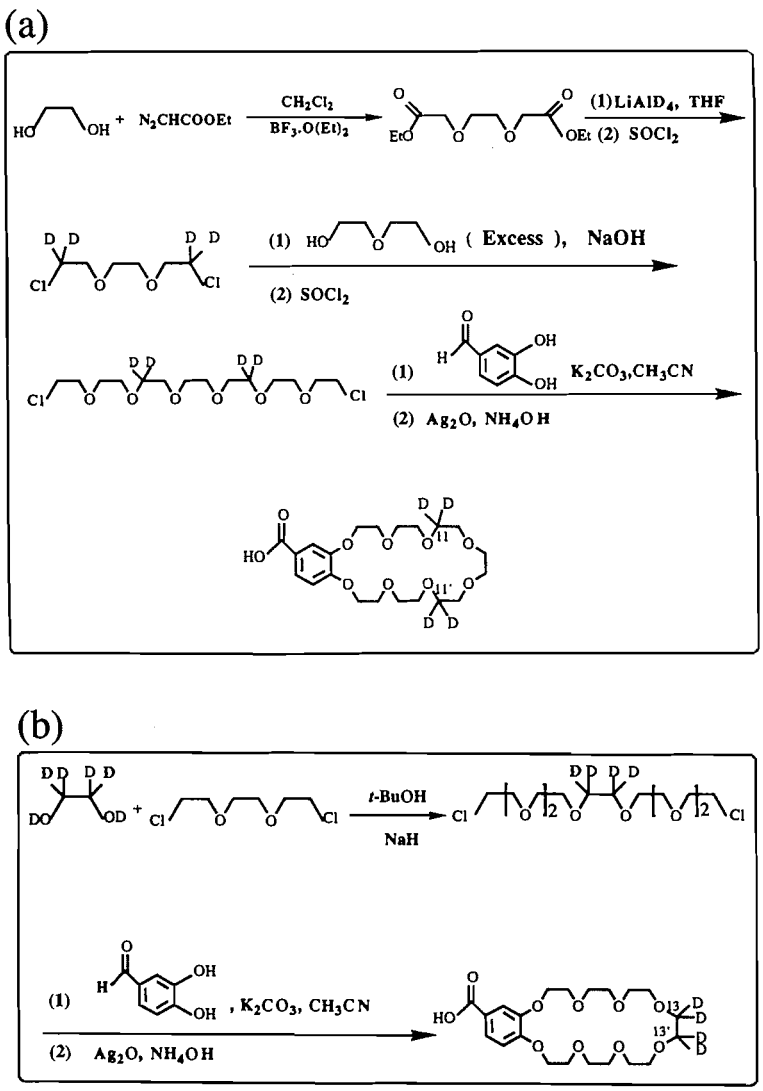
A comparison of the spin lattice relaxation times (T_1) for **1** and the KNCS complex in DMSO-d_6 solution at 298 K is presented in Table 2. The reduction of the observed T_1's for the CH_2O sites of the KNCS complex is consistent with a decrease in the mobility of the macrocycle upon complexation with the cation, assuming that we are in the motional narrowing region and that dipole–dipole relaxation is dominant (9, 16) for these carbons. Likewise, in both free **1** and its KNCS complex there is more mobility at sites 10–13′ than at sites 7–9′.

Solid phase ^{13}C spectra

The normal and dipolar dephased ^{13}C CPMAS NMR spectra of the aliphatic region of **1** and its selectively deuterated derivatives are shown in Fig. 3. Carbons with attached protons disappear from the spectrum, unless the C—H bonds involved are undergoing reorientations that reduce the dipolar coupling, in which case the lines are still present but with reduced intensity.

For **1**, the most notable feature of the dipolar dephased spectrum is the residual intensity observed in the CH_2O carbon region, resonating at values exceeding 70 ppm. There is a

Fig. 5. Synthetic routes to selectively deuterated derivatives of **1**.



disappearance of the most shielded resonances in the region 67.5–69.0 ppm, indicating that there is no large-amplitude motion present for these most shielded carbons. Using the solution assignments as a guide, we attribute the most shielded CH_2O lines to sites 7,7′ and 8,8′, which are in the closest proximity to the aromatic ring of **1**. It is intuitively reasonable that the least amount of motion in the 24-membered ring of **1** would be in the region of the macrocycle that is most closely bonded to the rigid aromatic moiety.

The spectra of the deuterated molecules show some subtle changes in relative intensities of the features. The CD_2 carbon lines should be affected by spin–spin coupling and residual dipolar coupling (17) and thus have intensity spread over a broader range (as a quintet) than the protonated species, though this is not resolved here. Furthermore, the spectra of the CD_2 carbons should remain unchanged in intensity in the dephased spectrum. Recall that only 2 out of the 14 CH_2O carbons are affected in this way.

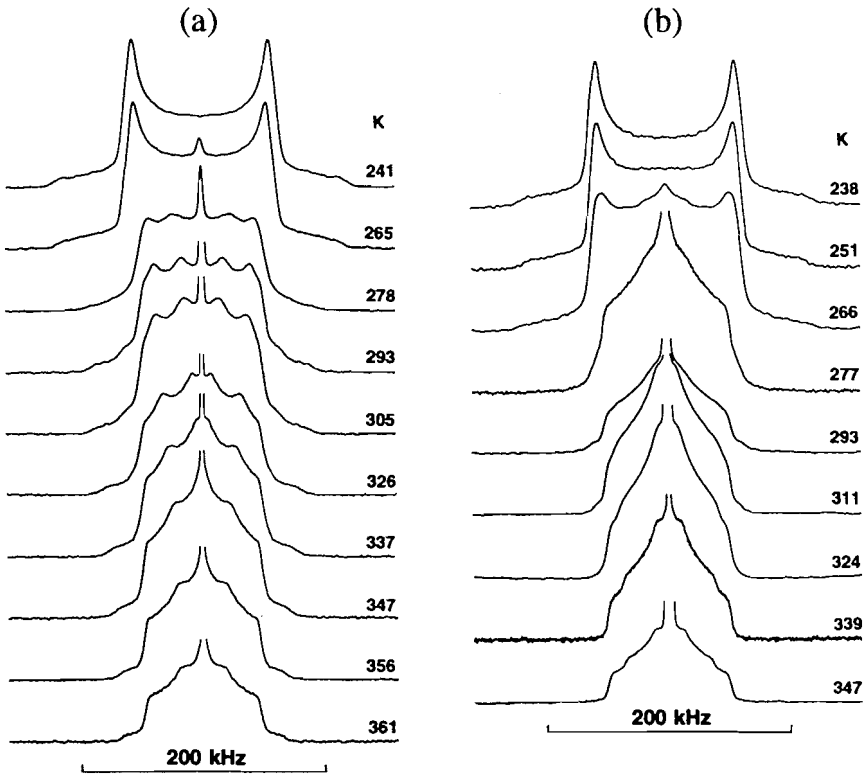
It is of interest to contrast these results with those obtained for the KNCS complex of **1** (Fig. 4) where almost all of the CH_2O intensity in the dipolar dephased spectrum has disappeared, indicating that complexation of the macrocycle with the K^+ ion has now also reduced the mobility of the methylene carbons at sites 9,9′ to 13,13′ in the solid phase.

The 11,11′-d_4 and 13,13′-d_4 derivatives of **1** were synthesized specifically to further explore the details of the motion of the macrocycle in the solid state by ^2H NMR. The synthetic scheme for their synthesis is depicted in Fig. 5.

Solid state ^2H NMR results

^2H (I = 1) NMR in solids is dominated by a perturbation in the Zeeman interaction by the quadrupole coupling tensor that arises from the interaction of the nuclear quadrupole moment with the electric field gradient (efg) tensor (18, 19). With a nuclear spin of 1 there are three energy levels and hence two transitions, displaced equally on either side of the Zeeman frequency by the quadrupolar interaction. The ^2H powder lineshape has either two or three pairs of characteristic features (edges, shoulders, and peaks) separated by frequencies

Fig. 6. ^{2}H NMR quadrupole echo spectra of (*a*) **1**-11,11′-d_4 and (*b*) **1**-13,13′-d_4 as a function of temperature (the sharp isotropic liquid line has been truncated in most of the spectra).



$$\begin{aligned} \Delta\nu_{zz} &= 3\chi/2 \\ \Delta\nu_{yy} &= 3\chi(1+\eta)/4 \\ \Delta\nu_{xx} &= 3\chi(1-\eta)/4 \end{aligned} \quad [1]$$

where χ is the quadrupolar coupling constant in Hz and the asymmetry parameter

$$\eta = (\Delta\nu_{yy} - \Delta\nu_{xx})/\Delta\nu_{zz}$$

The $\Delta\nu_{ii}$ are proportional to the absolute magnitudes of the principal axis components of the effective quadupole coupling tensor.

The dynamics of the molecule can cause narrowing of the ^{2}H NMR lineshape in a manner that is dependent on the specifics of the motion, such as the rate and the axis of reorientation (19–24). In the fast-motion limit (rates about 10^7 jumps/s) the line takes on a shape characteristic of an averaged effective tensor. We have given rather more detailed descriptions of the theory, as applied to crown ethers, before (6, 7).

In our previous papers (6, 7) it was possible to analyze the ^{2}H NMR data in terms of very specific dynamical models, largely because the systems studied were chosen for their apparent simplicity, symmetry, and known crystal structures. In the present compound we have neither symmetry nor a crystal structure, and in any case the benzoic acid group incorporated into the ring is expected to prevent overall rotation of the macrocycle. Thus from the outset it was anticipated that there could be difficulty in defining an exact dynamic model.

Nevertheless the results show conclusively that there is a large-amplitude motion of the CD_2 groups, and several other useful conclusions can be drawn. Inspection of the spectra (Fig. 6) of d_4 derivatives of **1** immediately shows several things.

(*a*) At low temperatures (<270 K) the lines have the characteristic parameters corresponding to CD_2 groups that are virtually static except for a small amount of narrowing due to small-amplitude librational motions. Within experimental error the quadrupole coupling tensors for **1**-11,11′-d_4 and **1**-13,13′-d_4 are identical with $\chi = 16.3 \pm 1.0$ kHz and $\eta = 0.065 \pm 0.009$. These values compare favourably with the values determined previously for 18-crown-6 and 12-crown-4 ether complexes (6, 7).

(*b*) In both cases there is a fairly sudden change from a nearly static lineshape to a dynamically averaged one between 265 and 277 K. This is strongly indicative of a solid–solid phase transition and indeed such a transition was later confirmed by Differential Scanning Calorimetry (DSC) for the undeuterated material (vide infra).

(*c*) Slight distortions of the static lineshape just below the phase transition also indicate the onset of a slow motion even in the low-temperature phase.

(*d*) Above the phase transition all the spectra show an isotropic central line whose intensity grows with increasing temperature. This is distinctly liquid-like behaviour and we strongly suspect that, although the crystals appeared to be dry, they contained small pockets of occluded solution. This should not cause any change in the lineshapes from the solid material, but any narrow features of the solid spectrum could be obscured by the presence of this isotropic line.

Fig. 7. Temperature dependence of the widths of pairs of features of the lineshapes of (*a*) **1**-11,11′-d_4 and (*b*) **1**-13,13′-d_4. The solid lines and their broken extrapolations do not represent rigorous mathematical fits.

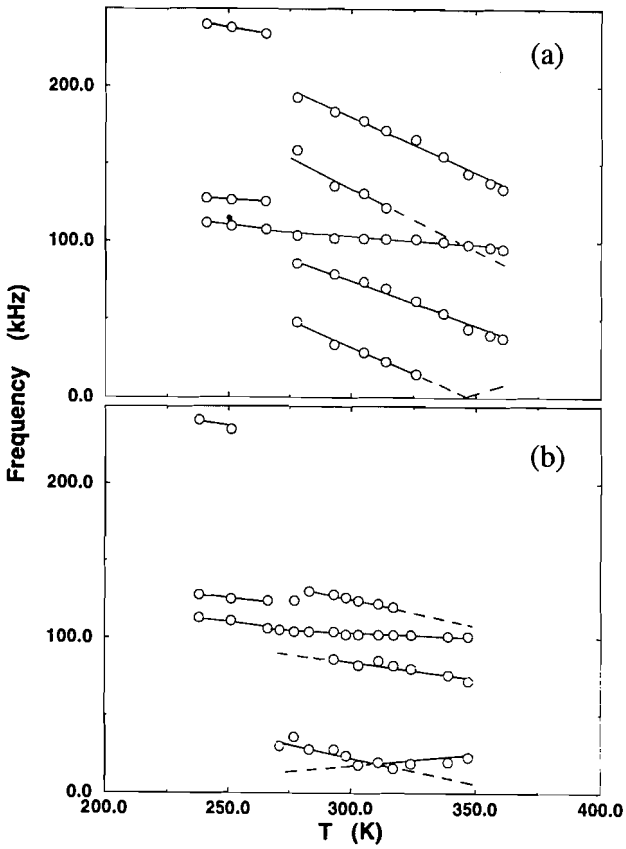


Fig. 8. Calculated lineshapes of (*a*) **1**-11,11′-d_4 and (*b*) **1**-13,13′-d_4 derived from the summation of the two tensors determined at various temperatures.

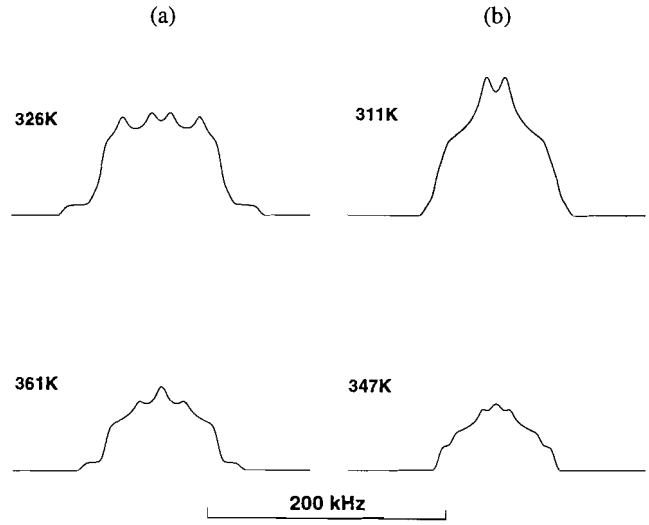


(*e*) Neglecting the isotropic line, we see that above the phase transition the solid spectra all show the effects of rapid dynamic averaging. However, the various features of the lineshapes show continuous variation with increasing temperature. The spectra are fairly complicated, with more than one tensor lineshape superimposed, and in many cases it is not immediately apparent which components are associated with a particular tensor. This is particularly so for the **1**-13,13′-d_4 case, where at 347 K, for example, three pairs of features can be discerned but these do not conform to a single tensor pattern. Note that in each case there are potentially four different tensors, since the lack of symmetry makes the four deuteriums inequivalent.

Fortunately, things become much clearer with the aid of plots of the approximate widths of the pairs of discernable features (peaks, shoulders, edges) of the ^{2}H spectra as a function of temperature (Fig. 7). These plots show the phase transition very clearly, since all the components except $\Delta\nu_{xx}$ are discontinuous. The continuity of $\Delta\nu_{xx}$, its identical value in both cases, and the fact that it shows the least variation over the whole temperature range is particularly informative. From previous work (6) we know the orientation of the eft tensor in the CD_2 group, viz. the *zz* component along the C—D bonds and the *xx* component perpendicular to the CD_2 plane. Consequently the fact that $\Delta\nu_{xx}$ shows little variation suggests that the principal mode of motion causing line narrowing is about an axis parallel to the *xx* component. This also means that the two deuteriums on a CD_2 group behave identically, i.e., their dynamically averaged tensors will be identical. Thus we should see no more than two overlapping tensors in each lineshape, corresponding to each of the two CD_2 pairs at the primed and unprimed sites. Furthermore this *xx* component will be common to *all* the averaged tensors. With this in mind it is easy to pick out two sets of parameters corresponding to two tensors for the **1**-11,11′-d_4 case, where five components are visible between 278 and 315 K. Also it is relatively easy to determine where the less obvious components should be by extrapolation (broken lines in Fig. 7). Similarly, extrapolations help to find the five components needed to define the two tensors **1**-13,13′-d_4.

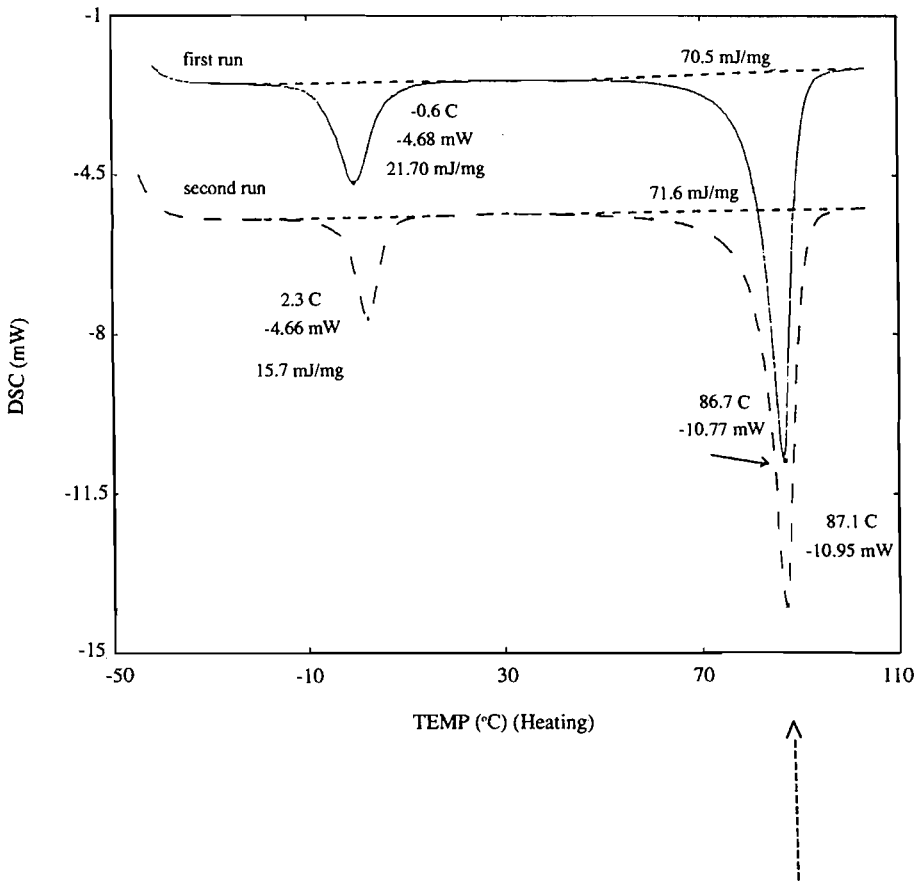
We can now also see the reason for the initial difficulty in assignment of components for the **1**-13,13′-d_4 case; various components cross at particular temperatures and in these regions the features arising from the two components coalesce. The very narrow components are also obscured by the isotropic "liquid" line.

Figure 8 shows simulated spectra based on the sums of two tensor lineshapes. The comparison with experiment is remarkably good.

Considering the fact that the aromatic ring fixes the molecule so that overall molecular rotation is highly unlikely, the most probable motion of the CD_2 groups about an axis parallel to the direction of the *xx* component would be an up/down two-site flip, as part of a conformational change in the macrocycle. This implies a dynamic disorder in the room temperature phase that would likely show up as partial occupancy of two sites for each C atom in an X-ray crystal structure. This type of flip was found to be involved in the dynamics of 18-crown-6·2$CH_2(CN)_2$ and 12-crown-4·LiNCS (6, 7). Since no crystal structure is available in the present case, we do not know if the two sites are symmetry equivalent, so a unique model cannot be developed.

Two possibilities exist. (*i*) If the molecule has two inequivalent conformations with an energy separation ΔE, they will

Fig. 9. Differential scanning calorimetry of **1**.



melting point 87-89°C

then have different populations. This could account for the temperature dependence of the averaged lineshape. However, after developing the equations describing the averaging for this kind of situation, we found that no one value of ΔE will simultaneously fit all the data if the flip angle for each CD_2 is kept constant with temperature. If the model is relaxed by allowing the angles to increase with temperature, then a unique fit is no longer possible (though an upper limit to ΔE of about 0.85 kJ/mol can be estimated).

(*ii*) Alternatively, if the two sites were equivalent, one can derive their angular separation using a simple two-site model. Here the temperature dependence arises from an increasing flip angle. A situation in which the two sites are symmetrical could arise if the molecule has a mirror plane in the crystal, perhaps the plane defined by the aromatic ring. Equivalent two-site flips are a simple case to treat and many examples are known (19, 24–26). We will simply give the equations that relate the averaged efg tensor components V_{ii}' to the static tensor components V_{ii} and the half-angle β between the two sites:

$$V_{yy}' = V_{yy} \sin^2\beta + V_{zz} \cos^2\beta$$

$$V_{zz}' = V_{yy} \cos^2\beta + V_{zz} \sin^2\beta$$

The static components themselves have a small temperature dependence due to small-angle librational motions, so "static" values for 300 and 350 K were obtained by extrapolation from low temperatures. The averaged values at these two temperatures were taken from the plots in Fig. 7 and the corresponding values of β were calculated. Two values of β will fit the equations but in all cases the larger value can be discarded as being unrealistic. The calculated values of 2β (below) give an idea of the amplitude of the two-site flip.

	2β (°)	
Sites	300 K	350 K
11/11′	42	54
	61	75
13/13′	65	70
	79	82

If this model is applicable,. three things are evident from these β values. (*i*) The amplitude of motion increases with increasing temperature as expected. (*ii*) The amplitude at sites

13/13′ is greater than at 11/11′, implying greater flexibility the further the CD_2 unit is from the aromatic ring. This also is intuitively reasonable. (*iii*) The significant difference between 11 and 11′ or between 13 and 13′ must reflect crystal packing effects (different environments).

Differential scanning calorimetry (DSC) results

Figure 9 shows the DSC results. The melting point in the vicinity of 87°C is clearly evident along with a phase change at 272.3 K (average of two runs). The phase change is in the temperature range indicated by the ^2H solid state NMR findings.

Excited state carbon acid dissociation and competing photorearrangements of 5*H*-dibenzo[*a,c*]cycloheptene derivatives

David Budac and Peter Wan

Abstract: The first examples of dissociating excited state carbon acids were reported by our group. A necessary structural feature is the 5*H*-dibenzocycloheptene ring system where the incipient carbanion is formally an antiaromatic system in S_0. In this work, structure–reactivity studies of the excited singlet state carbon acid dissociation and competing formal di-π-methane rearrangement of several 5*H*-dibenzo[*a,c*]cycloheptene derivatives have been carried out in order to gain more insights into the photochemistry displayed by these compounds. Photolysis of 7-deuterio-5*H*-dibenzo[*a,c*]cycloheptene (**9**) in aqueous solution showed that the photogenerated carbanion is allylically delocalized. Derivative **7** was found to be less reactive than **3** with respect to carbon acid dissociation whereas **8** was unreactive. Ethanolamine (in CH_3CN) was found to be an effective base in catalyzing carbon acid dissociation for **3**, **7**, and **9**, as indicated by higher yields of deuterium incorporation and rates of fluorescence quenching. Binaphthyl derivatives **10** and **11** displayed contrasting photobehaviour. Photolysis of binaphthyl **11** resulted in only efficient ($\Phi_p = 0.47$) formal di-π-methane rearrangement under all conditions and no evidence was found for carbon acid dissociation, even in the presence of ethanolamine as base. On the other hand, the formal di-π-methane reaction was very inefficient for binaphthyl **10** ($\Phi_p < 0.001$). Due to the conformational rigidity inherent in **10**, the methylene protons at the 3-position are NMR resolvable as pseudo-axial and pseudo-equatorial protons. Photolysis in the presence of ethanolamine (in D_2O–CH_3CN) resulted in stereoselective deprotonation of the pseudo-axial proton ($\Phi_{ex} \approx 0.02$), as indicated by deuterium exchange studies. The results show that excited state carbon acid dissociation is an observable general reaction of dibenzo and dinaphtho cycloheptenes only if more favourable photochemical pathways are not competing.

Key words: excited state carbon acid, di-π-methane rearrangement, carbanion, stereoelectronic effect, fluorescence quenching.

Résumé : Notre groupe de travail a déjà publié une étude sur les premiers exemples de dissociation acide du carbone dans l'état singulet. Le système cyclique 5*H*-dibenzocycloheptène est une caractéristique structurale nécessaire dans laquelle le carbanion naissant est formellement un système anti-aromatique de type S_0. Dans ce travail nous avons réalisé des études de structure–réactivité sur la dissociation acide du carbone dans l'état singulet excité et le réarrangement di-π-méthane formel compétitif de plusieurs dérivés des 5*H*-dibenzo[*a,c*]cycloheptènes. Cette étude devrait nous permettre d'acquérir de nouvelles connaissances sur la photochimie de ces composés. La photolyse du deutéro-5*H*-dibenzo[*a,c*]cycloheptène (**9**) en solution aqueuse montre que le carbanion généré photochimiquement est délocalisé en position allylique. On a trouvé que le composé **7** est moins réactif que le composé **3** en ce qui a trait à la dissociation acide du carbone tandis que le composé **8** ne montre aucune réactivité. Les vitesses d'extinction de la fluorescence et les rendements élevés obtenus lors de l'incorporation du deutérium montrent que l'éthanolamine est une base efficace pour catalyser la dissociation acide du carbone des composés **3**, **7** et **9**. Les dérivés binaphtyles **10** et **11** exhibent à l'opposé un comportement photochimique. La photolyse du binaphtyle **11** conduit uniquement à un réarrangement di-π-méthane formel efficace ($\Phi_p = 0{,}47$) dans toutes les conditions et on n'a pas pu mettre en évidence la dissociation acide du carbone même en présence d'éthanolamine utilisée comme base. Par ailleurs, la réaction di-π-méthane formelle est inefficace avec le binaphtyle **10** ($\Phi_p < 0{,}001$). En raison de la rigidité conformationelle inhérente du composé **10**, les protons éthyléniques en position 3 sont résolvables, en RMN, comme des protons pseudo axial et pseudo équatorial. Les études réalisées sur l'échange de deutérium indiquent que la photolyse en présence d'éthanolamine (dans le D_2O–CH_3CN) conduit à une déprotonation sélective du proton pseudo axial ($\Phi_{ex} \approx 0{,}02$). Les résultats montrent que la dissociation acide du carbone dans l'état excité est une réaction générale des dibenzo et dinaphto cycloheptènes et n'est observable uniquement qu'en l'absence d'un processus photochimique plus favorable.

Mots clés : acide carbonique dans l'état excité, réarrangement di-π-méthane, carbanion, effet stéréoélectronique, extinction de la fluorescence.

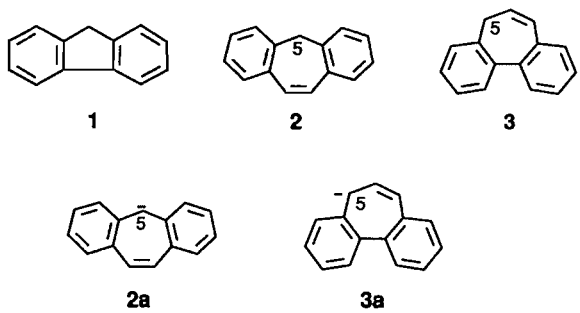
Introduction

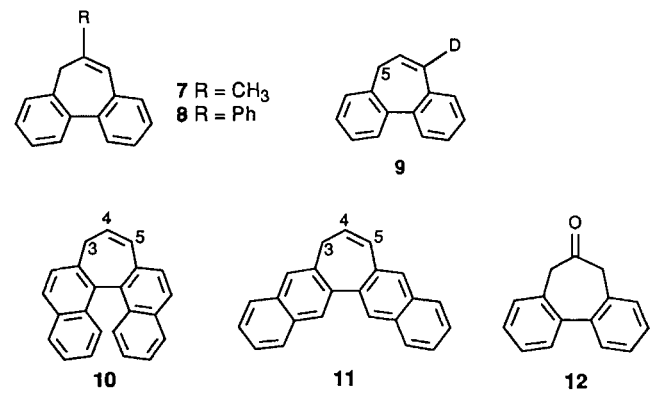
Carbanions and their associated carbon acids have been studied extensively in the ground state because of their fundamental importance in organic chemistry (1). Very little experimental data is available for excited state carbon acids although Förster cycle calculations of hydrocarbons related to fluorene (**1**) suggest that the benzylic protons of these systems are very acidic in the excited singlet state ($pK_a(S_1) \approx -6$) (2). However, it is known that fluorene and related compounds do not undergo benzylic C—H bond exchange upon excitation (2) and it has been suggested that this is due to the short lifetimes of excited singlet since C—H bond dissociation is known to be intrinsically slow (1, 2). We published the first examples of dissociating excited state carbon acids (from the 5-position) in *5H*-dibenzo[*a,d*]cycloheptene (**2**) and *5H*-dibenzo[*a,c*]cycloheptene (**3**) (3, 4*a*). We discovered that in order to observe excited state carbon acid dissociation, the incipient carbanion should be formally antiaromatic in the



ground state (3, 4*a*). Carbanions generated from **2** and **3** (**2a** and **3a**, respectively) satisfy this requirement whereas the fluorenyl carbanion from **1** does not. We offered a rationalization based on the relative stabilities of $4n$ vs. $4n + 2$ π systems in the excited state in order to explain the difference in carbon acid reactivity observed in these benzannelated systems (3, 4*a*).

Of particular interest was the finding that in addition to excited state proton exchange observed for **3** at the 5-position, a competing formal di-π-methane rearrangement to give dibenzonorcaradiene **4** was also observed (Scheme 1) (4*a*). In 100% CH_3CN, only rearrangement to **4** was observed. Addition of D_2O (acting as the base) resulted in a decrease in the yield of **4** and formation of **5**. Using 6-deutero-*5H*-dibenzo[*a,c*]cycloheptene (**6**), we showed that formation of **4** via S_1 involved an initial 1,7-hydrogen shift followed by electrocyclic ring closure, which gave **4a** (Scheme 2) (4a). Formation of **4** via T_1 involved a true di-π-methane pathway, which gave **4b** (Scheme 2) (4*a*). The general mechanistic problem of competition between a true di-π-methane pathway versus one involving initial sigmatropic shift followed by electrocyclic ring closure was originally delineated by Zimmerman and Pincock (4*b*).

Additional studies of this interesting reaction are warranted. To this end, we have prepared several derivatives of **3**. Compounds **7** and **8** were prepared to study the effect of substitu-



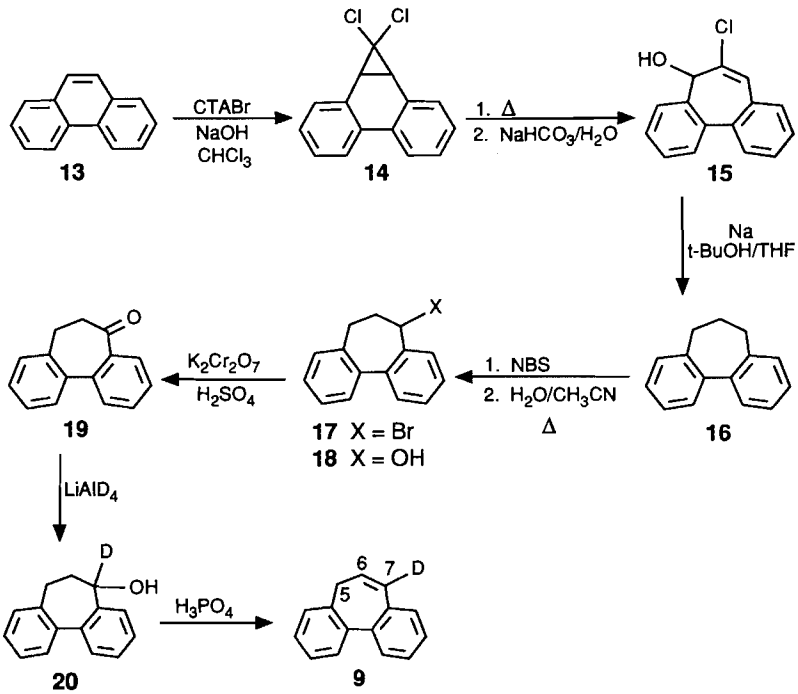
tion at the 6-position on photoreactivity whereas **9** was prepared to probe the degree in which the initially photogenerated carbanion at position 5 (**3a**) is delocalized into the 7-position. Finally, the more unusual binaphthyl systems **10** and **11** were prepared for exploratory studies into the effect of using highly benzannelated chromophores on the photochemistry. The results of this study provide new insights into understanding the reactivity of excited state carbon acids based on the dibenzo[*a,c*]cycloheptene system.

Results and discussion

Syntheses

The parent compound **3** was prepared via a literature method and described in our previous study (4*a*). The 6-methyl and 6-phenyl-*5H*-dibenzo[*a,c*]cycloheptenes (**7** and **8**) were prepared by reaction of MeLi or PhLi with ketone **12** according to the procedure of Tolbert and Ali (5). The synthesis of 7-deuterio-*5H*-dibenzo[*a,c*]cycloheptene (**9**) is outlined in

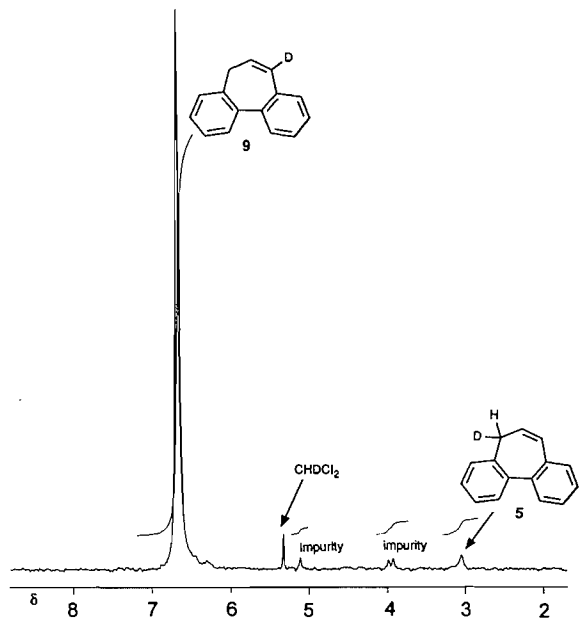
Scheme 3.



Scheme 3. Conversion of phenanthrene (**13**) to dibenzo[*a*,*c*]cycloheptane (**16**) followed literature methods (6–8). Bromination of **16** with NBS gave **17**, which was hydrolyzed in H_2O–CH_3CN to give **18**. Oxidation of **18** with Jones reagent provided the known ketone **19**. Simple functional group manipulations via alcohol **20** gave the required **9**. ^1H (360 MHz) NMR, ^2H NMR, and MS are consistent with the assigned structure. The ^1H spectrum was identical to the spectrum for **3** except for the lack of the resonance signal at the 7-position (δ 6.7) and associated proton couplings. The ^2H NMR showed one major signal at δ 6.7 along with several minor resonances including a signal at δ 3.05 (≈ 4%) representing deuterium at the 5-position (formation of **5**), indicating some isomerization had taken place during the dehydration step (Fig. 1). The minor amount of **5** present does not interfere with the product studies to be performed for this compound.

Scheme 4 outlines the synthesis of *3H*-cyclohepta[2,1-*a*:3,4-*a*']dinaphthalene (**10**). The initial step involves bromination of 2-methylnaphthalene (**21**), to give **22** (9), followed by formation of the Grignard reagent and subsequent coupling with **22** using $NiCl_2(PPh_3)_2$ catalyst (10) to give **23**. Bromination of **23** with NBS gave dibromide **24**. Bestmann and Both (11) prepared **10** in two steps from **24**. However, numerous attempts by us to duplicate their method were unsuccessful. Therefore, we adapted published methods by Mislow and McGinn (12) for converting **24** to **27**. The key step is the treatment of **24** with KCN, which initially gave the dicyano derivative. Under the action of cyanide ion, a Thorpe–Ziegler condensation of the dicyano groups gave aminonitrile **25**. Standard hydrolysis of **25** gave **26**, which was converted to **27** using standard methods. Treatment of **27** with PBr_3 gave bromide **28**, which was then converted to **10** using potassium *tert*-butoxide.

Fig. 1. ^2H NMR of synthesized **9** showing a small amount (4%) of the deuterium at the 5-position due to **5**.



Since we anticipated that the steric requirements of the two naphthalene rings would impart a substantial twist on the cycloheptene ring thereby locking it into a fixed conformation (from analysis of molecular models), we decided to obtain an X-ray crystal structure of **10**. Crystals of **10** were grown in toluene–EtOH and the X-ray parameters of the solved structure are listed in Table 1 with the ORTEP drawing shown in Fig. 2.

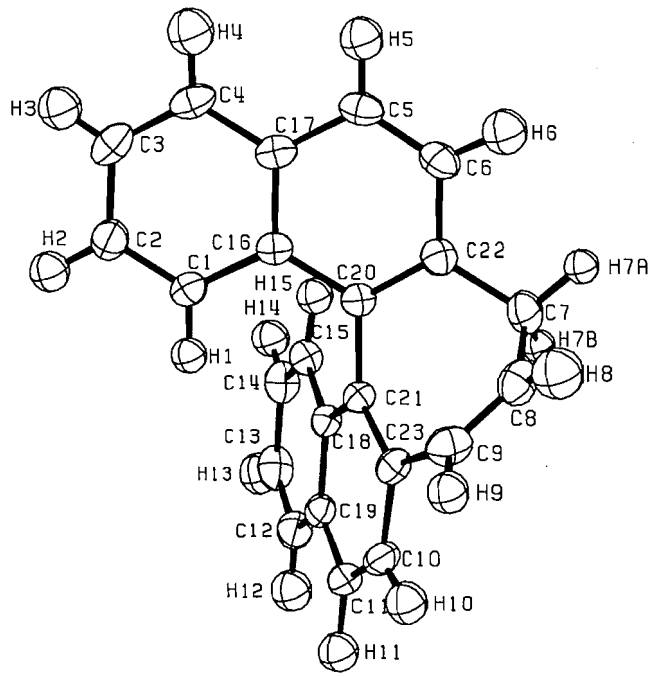
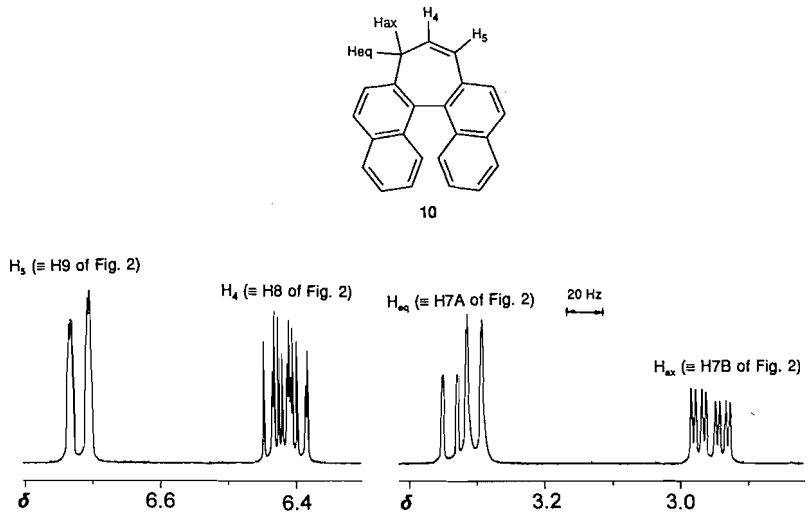
Fig. 2. ORTEP diagram of **10** showing the twisted cycloheptene ring giving rise to two ^{1}H NMR differentiable protons at the 3-position, H7B (H_{ax}) and H7A (H_{eq}).



The crystal structure confirms many of the predictions based on simple molecular models. The naphthalene rings have a dihedral angle of 64° and the cycloheptene ring is highly distorted, with the methylene carbon (3-position of **10**) protons taking up pseudo-axial and pseudo-equatorial positions (labelled as H7B and H7A, respectively, on the ORTEP diagram, Fig. 2). The crystal structure also indicates that the axial proton (H7B, Fig. 2) is oriented above the plane of the opposite naphthalene ring, which should result in an upfield shift of this proton relative to the equatorial proton (H7A, Fig. 2).

Fig. 3. ^{1}H (360 MHz) NMR of the aliphatic region of **10** showing the higher field resonance of H_{ax} (δ 2.95) versus H_{eq} (δ 3.32). Note also the larger coupling of H_{ax} (2.2 Hz) to H_5 compared to that of H_{eq} (<1 Hz) to H_5.



Indeed, two proton signals are observed for the methylene carbon, one for the axial proton (δ 2.95, H7B ≡ H_{ax}), and one for the equatorial proton (δ 3.32, H7A ≡ H_{eq}) (Fig. 3). The larger allylic coupling constant (2.2 Hz) observed in the former suggests that our assignment is correct since the magnitude of 3-carbon allylic couplings (to H9 of Fig. 2) depend on the angle between the allylic protons (H7A and H7B) and the vinyl proton (H9 of Fig. 2) and is largest when they are orthogonal (13).

As far as we are aware, *3H*-cyclohepta[2,1-*b*:3,4-*b'*]dinaphthalene (**11**) has not been reported in the literature. The synthetic route that was used (Scheme 5) is similar to that employed for the synthesis of **10**. The required 2-bromo-3-methylnaphthalene (**31**) was prepared via an established literature method from commercially available **29** (14). Coupling of **31** was then attempted using the procedure employed for **23**. However, only a minor amount of coupling product was observed. The yield was enhanced considerably by concurrent addition of one equivalent of 1,2-dibromoethane with two equivalents of Mg during formation of the Grignard reagent. The remaining steps were identical to those used in Scheme 4. A major undesired product obtained in the last step was the ring-opened isomer **38** (45% yield in last step), which proved difficult to separate from the required **11** via chromatography. However, repeated recrystallization of the mixture in toluene–EtOH provided **11** with >98% yield by GC and NMR. The ^{1}H (360 MHz) NMR showed the expected three signals (δ 3.37, (d) H3; 6.42, (m) H4; and 6.81 (d) H5) outside the aromatic region. Indeed, the splitting patterns observed for these signals resemble the patterns observed for the parent system **3** and is unlike that observed for **10**. Thus, it was not possible to resolve pseudo-axial or pseudo-equatorial protons at the methylene position of **11**, which is consistent with a much more flexible ring system compared to **10**.

Product studies

*7-Deuterio-5*H*-dibenzo[*a,c*]cycloheptene (9)*

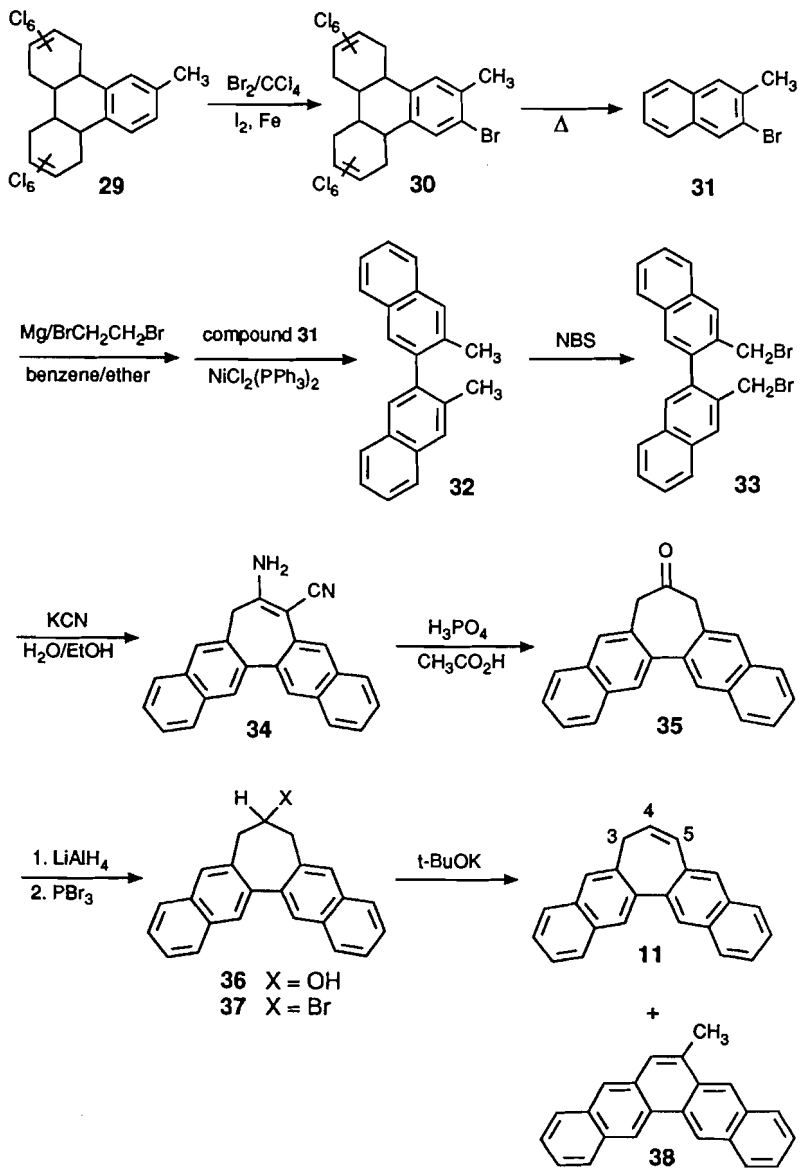
In our initial report (4*a*) of the excited state carbon acid behaviour observed for **3**, the question of extent of delocalization of photogenerated **3a** was not addressed. Carbanion **3a** is formally antiaromatic (5) and therefore should be a less delocalized carbanion in the ground state. The extent to which delocalization of photogenerated **3a** is observed would provide insight into the question of whether **3a** is generated initially on the excited state surface or the photoreaction is completely diabatic, in which case little delocalization of the carbanion is expected. Photochemical 1,3-hydrogen shifts of allylic systems catalyzed by amines in dihydronaphthalenes and dihydrophenanthrenes have been reported by Laarhoven and co-workers (15) although, in their examples, it is not well established whether a photogenerated carbanion is a required intermediate. Reaction via initial electron transfer to form radical ion pairs seems to be the likely mechanism.

Direct photolysis (254 nm; 15 min) of **9** in 100% CH_3CN resulted in a complex product mixture consisting of **4a** and **4b** (total of 64%) and minor amounts of 9-deuterophenanthrene (6%) and **6** (6%), as determined by ^{2}H NMR. These products are expected based on initial formation of **4** via formal di-π-methane rearrangement, which on direct photolysis involves initial 1,7-hydrogen shift followed by electrocyclic ring closure (4*a*). Formation of **5** was not observed at all conversions. Direct photolysis of **9** in 50% H_2O–CH_3CN under otherwise identical conditions gave **5** as the major product (30%), **4a** and **4b** (18%), and traces of **6** (4%) and 9-deuterophenanthene, as determined by ^{2}H NMR (Fig. 4). The efficient formation of **5** in 1:1 H_2O–CH_3CN is consistent with reaction via carbanion **3a** in this solvent, which now competes with the formal di-π-methane rearrangement (4*a*). Thus, photogenerated carbanion **3a** is significantly delocalized to position 7 (Scheme 6).

*6-Methyl-5*H*-dibenzo[*a,c*]cycloheptene (7)*

Direct photolysis of **7** in 100% CH_3CN (254 nm, 15 min) gave three products (Scheme 7). The major product observed was cyclopropane **40** (25%), which is the product expected via di-π-methane rearrangement from T_1. Minor products **41** and **42** (3% each) can be thought to arise via secondary photolysis of

Scheme 5.



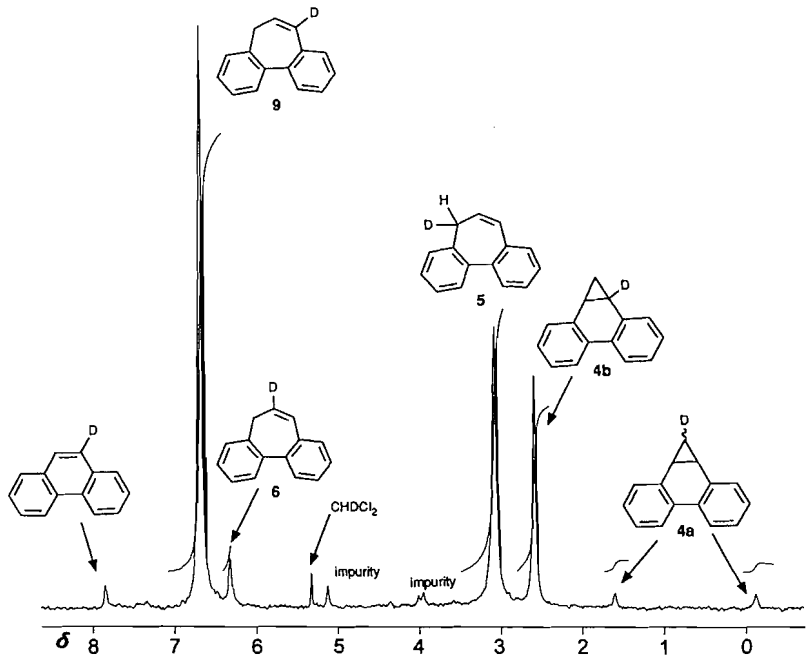
40, the former via carbene extrusion and the latter via initial bond cleavage of the cyclopropane followed by a hydrogen shift. Triplet sensitization of **7** in 100% with 2-benzoylbenzoic acid at 350 nm where **7** does not absorb gave only **40**, consistent with the expectation that this cyclopropane is formed via T_1. The rearrangement product expected from S_1 (viz. **39**), via initial 1,7-hydrogen shift, was not observed in direct photolysis experiments of **7**. One possible reason is the increased steric demand for such a shift when the methyl group is present at the 4-position. Another is an increased rate of intersystem crossing for this compound, which is suggested by a much lower fluorescence quantum yield and lifetime (vide infra).

Photolysis of **7** was carried out in H_2O–CH_3CN to determine if this system exhibited excited state carbon acid behaviour as was observed for **3**. Direct photolysis of **7** in 25% H_2O – CH_3CN (254 nm, 15 min) gave about the same product mixture as observed on photolysis in 100% CH_3CN shown in Scheme 7 (higher % H_2O could not be used due to the low solubility of this compound). In contrast, addition of H_2O (acting as a base) competed for rearrangement products in the photochemistry of **3**, resulting in a lower yield of formal di-π-methane products when water is added to CH_3CN (*4a*). Photolysis of **7** in 25% D_2O – CH_3CN showed ≈10% deuterium incorporation in recovered **7**, significantly less than what was observed for **3** under similar conditions. Thus substitution of a methyl group at the 4-position also results in decreased efficiency with respect to carbon acid dissociation.

6-Phenyl-5H-dibenzo[a,c]cycloheptene (8)

Direct photolysis of **8** in 100% CH_3CN (254 nm, 30 min.) gave only minor products and the substrate could be recovered essentially unchanged. Analysis of the photolysate by ^1H NMR gave no evidence for any trace of cyclopropanes expected from rearrangement of the cycloheptene ring system.

Fig. 4. ^{2}H NMR of product mixture from direct photolysis of **9** in 1:1 H_2O–CH_3CN for 15 min (254 nm).



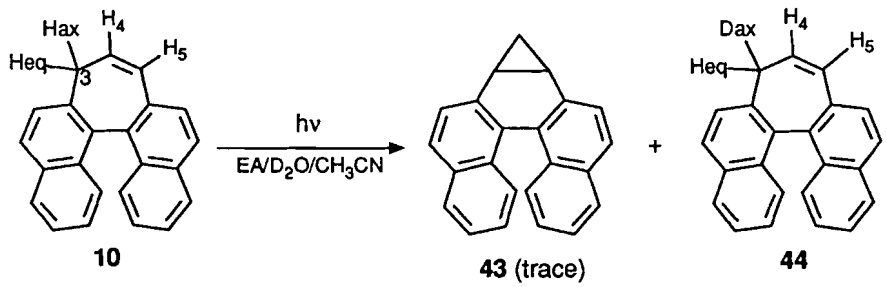
Photolysis in 40% D_2O – CH_3CN gave no measurable deuterium incorporation in substrate. Thus, substitution of a phenyl group at the 4-position not only retards carbon acid dissociation, but also the formal di-π-methane reaction.

3H-Cyclohepta[2,1-a:3,4-a′]dinaphthalene (10)

Photolysis of **10** in 100% CH_3CN (254 nm, 4 h) gave only trace yields (<5%) of the expected formal di-π-methane rearrangement product **43** based on ^{1}H (360 MHz) NMR (eq. [1]). Since extended photolysis failed to result in buildup of **43**, it is likely that **43** is unstable and returns to **10** either thermally or photochemically. Simple molecular models show that **43** is highly strained because the cyclopropyl ring forces the two naphthalenes into a more planar geometry, which is unfavourable due to the interaction of the peri-hydrogens. Photolysis of **10** in 50% D_2O – CH_3CN for 1 h resulted in no observable deuterium incorporation. Under these conditions, **3** exchanged significantly (4*a*). The highly twisted cycloheptene ring system may account for the lack of excited state carbon acid dissociation since the π systems of the naphthalene rings and the alkene moiety are not well disposed for conjugation as in **3**.

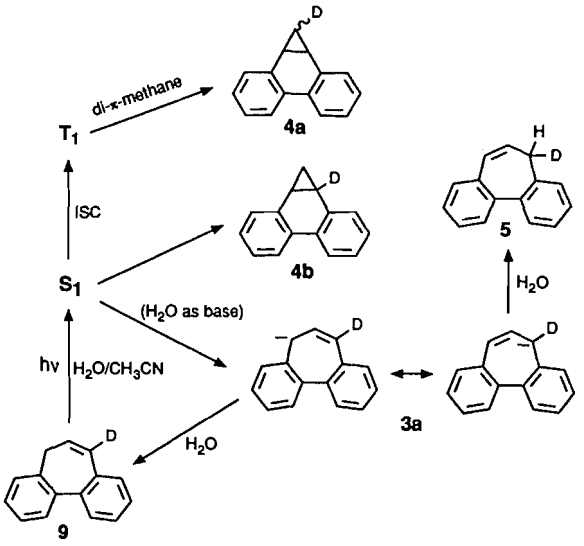
Recent studies from our group (16) have shown that primary amines such as ethanolamine (EA) and *n*-propyl amine efficiently catalyze the excited state proton exchange of **2** and related compounds. To determine if **10** exhibited excited state carbon acid dissociation in the presence of a stronger base,

[1]

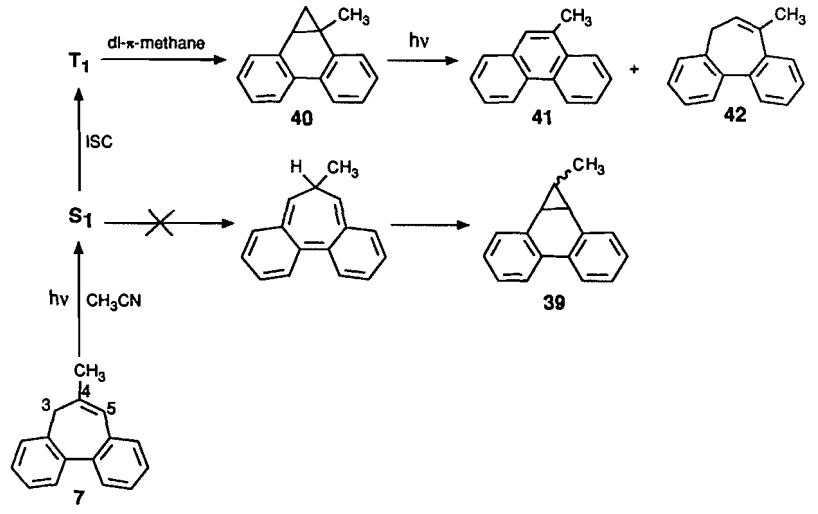


photolyses were carried out in 10% (5.0 M EA – D_2O)–CH_3CN. A series of ^{1}H (360 MHz) NMR spectra of the product mixture showed that the axial proton (H_{ax}) is selectively replaced on photolysis (Fig. 5). The equatorial proton (H_{eq}) and vinyl protons H_4 and H_5 exhibited little change in their relative intensities except at high conversion whereupon the signal due to H_5 and H_{eq} started to show depletion compared to H_4 and H_{ax} (Fig. 5). Analysis of the reaction mixture by ^{2}H NMR showed that deuterium incorporation takes place predominantly at the axial position (H_{ax}), with only minor deuteration at H_{eq} and H_5 at higher conversion (Fig. 6). A plot of relative deuterium incorporation into **10** at the three positions H_{ax}, H_{eq}, and H_5 is shown in Fig. 7. It is clear that deuteration at the axial position occurs much more efficiently. This is consistent with

Scheme 6.



Scheme 7.



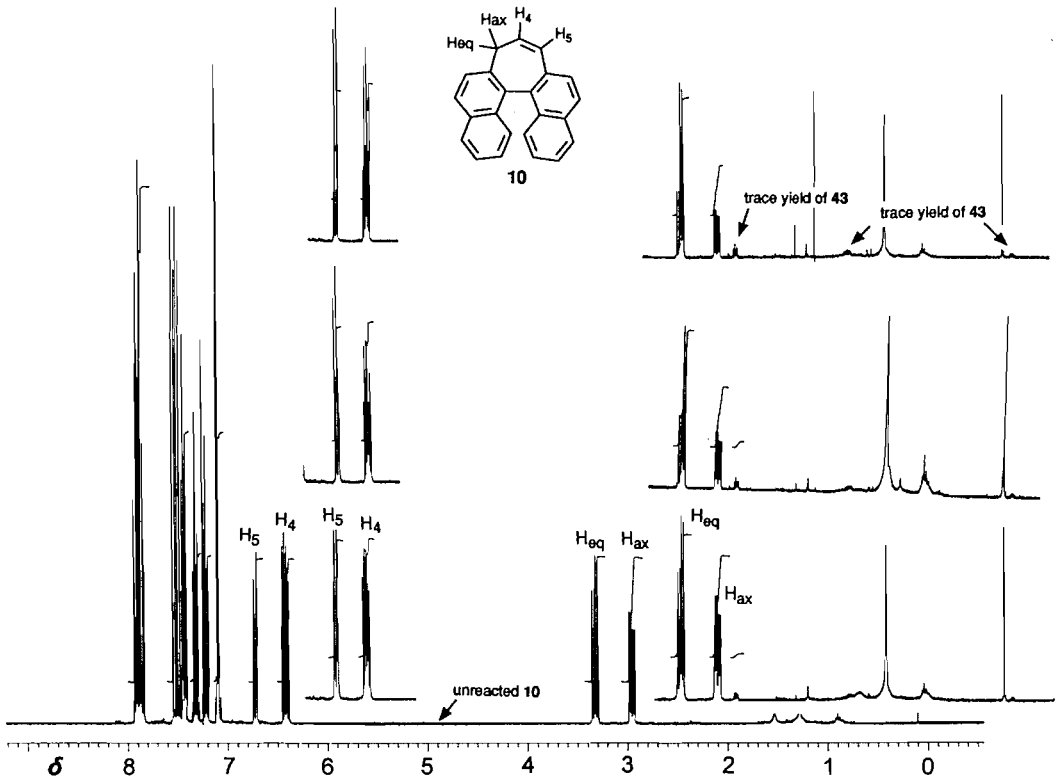
deprotonation at this position as the *primary* photochemical reaction, to generate a carbanion that is hydrogen bonded to the base. Exchange of the departing proton with deuteron in the hydrogen-bonded complex followed by deuteration results in deuterium incorporation exclusively at the axial position. A free carbanion intermediate is unlikely as we have shown that the photochemical exchange of suberene (**2**) involves a high degree of internal return (*4a*). Subsequent deuteration at H_{eq} and H_5 is most likely a *secondary* photochemical reaction.

Shown in Scheme 8 is the proposed mechanism for the deuterations observed in Fig. 7. Stereoelectronic preference for deprotonation of the axial proton (H_{ax}) allows for maximum overlap of the incipient carbanion with the alkene and one of the naphthalene rings (note that delocalization of the negative charge to the other allylic position converts it to its enantiomer and hence would not be distinguishable by NMR). Similar stereoelectronic effects have been noted for ground state reactions involving proton (17) and hydrogen (18) abstractions from carbon. Deuteration at H_{eq} can arise via either a sigmatropic 1,3-shift of D_{ax} or a photoinduced ring flip of the cycloheptene ring system. Deuteration at H_5 can arise via a 1,3-shift of H_{eq}. The greater yield of D_5 is consistent with competition of 1,3-shifts since a primary isotope effect would be expected, resulting in a higher yield of D_5 over D_{eq}. It is not possible to rule out a contribution from a photo-induced ring flip although such a contribution would be very minor considering that D_{eq} is formed in only very small amounts even on prolonged photolysis. In addition, we have not ruled out dideuteration via the carbanion obtained from deprotonation of H_{eq} of **44** or ring opening of deuterated **43** as responsible for the signals at D_5 and D_{eq}.

*3H-Cyclohepta[2,1-b:3,4-b′]dinaphthalene (**11**)*

Photolysis of **11** in 100% CH_3CN efficiently gave the corresponding formal di-π-methane rearrangement product **45** in >90% yield (eq. [2]), according to both ^1H NMR and GC. The ^1H NMR exhibited three new aliphatic proton resonances at δ 0.18 (1H), 1.63 (1H), and 2.77 (2H) with splitting pat-

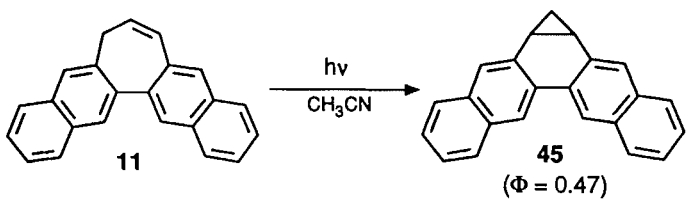
Fig. 5. ^{1}H (360 MHz) NMR spectra of photolysis of **10** in 10% (5 M EA – D_2O)–CH_3CN as a function of photolysis time. Each spectrum represents about 30 min photolysis at 254 nm.



terns that are clearly assignable to **45** (see experimental section). UV–VIS traces of the reaction in 100% CH_3CN also show a clean and efficient reaction with good isosbestic points (Fig. 8). The cyclopropane product **45** has a longer wavelength absorption (330–360 nm) than **11** that is consistent with its more planar structure, allowing for better conjugation of the two naphthalene rings. The much more efficient formal di-π-methane rearrangement observed for **11** compared to **10** is consistent with a less sterically demanding and less strained ring system in **11**; i.e., ring closure to **45** does not lead to the kind of steric interactions as expected for **10** for which the formal di-π-methane product was formed only in trace yield.

Photolysis of **11** in 10% (5 M EA in D_2O) – CH_3CN resulted in no observable deuterium incorporation into substrate by GC–MS; only efficient rearrangement to **45** was observed with no observable change in efficiency compared to a photolysis in 100% CH_3CN. It would appear that binaphthyl cycloheptenes are prone to formal di-π-methane rearrangement unless steric effects prohibit the reaction as in **10**. In such a case, use of an amine base promotes excited state carbon acid dissociation. The above results show that excited state carbon acid dissociation is highly sensitive to structure effects and is observed only in the most favourable cases where competing reactions are absent. This may in part be due to the inherently slow rates of carbon acid dissociation that cannot compete with much faster photochemical pathways when they are feasible.

[2]



Quantum yield measurements

Quantum yields for deuterium exchange (Φ_{ex}) and for formal di-π-methane rearrangement (Φ_p) were measured in low conversion (<25%) experiments using 254 nm photolysis in a Rayonet RPR 100 photochemical reactor (Table 2). The photochemical exchange reaction of 5,5-dideuterosuberene in 1:1 H_2O–CH_3CN was used as secondary actinometer (Φ = 0.035) (3*b*). Analyses for deuterium incorporation were carried out

Fig. 6. Representative ^2H NMR spectrum taken after photolysis of **10** in 10% (5 M EA – D_2O)–CH_3CN showing formation of three deuterated products, with deuteration of H_{ax} (to give **44**) being the major pathway. Although the peaks assigned for D_{eq} and D_5 are broad and weak, they grow in intensity with prolonged photolysis.

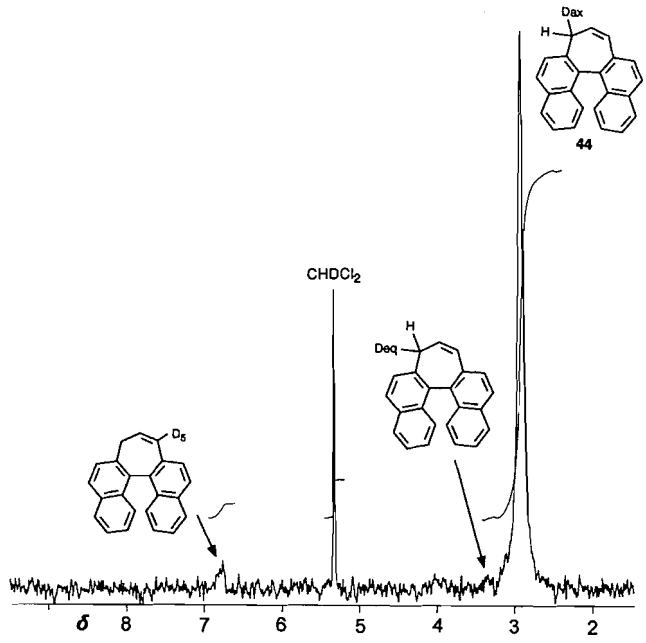


Fig. 7. Plot of relative yield of deuteration at the H_{ax}, H_{eq}, and H_5 positions of **10**.

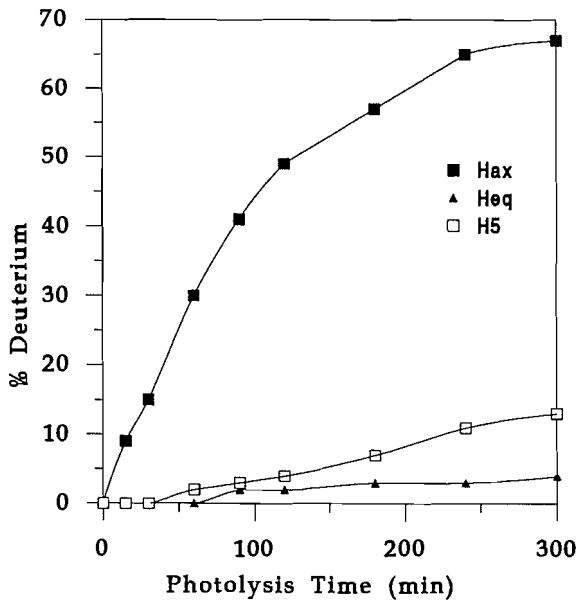


by ^1H (360 MHz) NMR and by GC for formal di-π-methane rearrangement products. For **3**, **7**, and **10**, quantum yields for exchange (Φ_{ex}) increased significantly from using D_2O as base to ethanolamine (EA) without affecting Φ_p to any measurable degree.

Fluorescence measurements

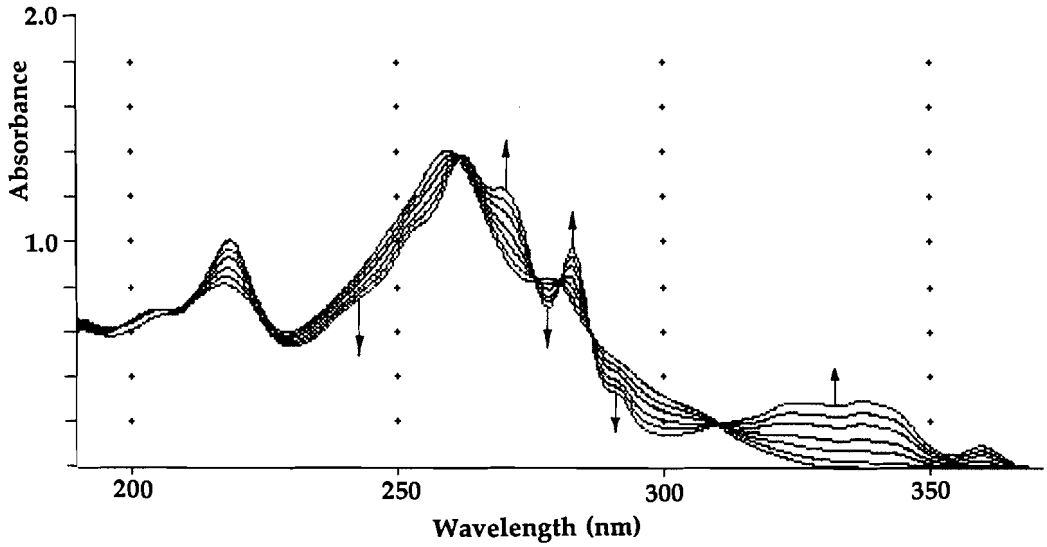
In previous studies (3, 4*a*) of excited state carbon acid dissociation, fluorescence measurements provided a direct method for measuring rates of deprotonation of carbon acids in S_1 since we found that fluorescence quenching by added bases (in CH_3CN) was the direct result of deprotonation of the C—H bond. These fluorescence quenching rate constants (k_q) were equatable to k_H, the bimolecular rate constant for C—H bond deprotonation by the base. Related compounds such as fluorene and diphenylmethane which failed to undergo carbon acid dissociation also had no measurable k_q values (3, 4*a*).

Fluorescence parameters for **3**, **7**, **8**, **10**, and **11** are given in Table 3. Substitution of **3** at the 6-position with methyl or phenyl substituents resulted in a decrease in Φ_f. This is presumably caused by additional internal conversion pathways due to rotations of the 6-substituent. The fluorescence emission spectra of **3** and **7** are structureless and essentially identical with broad λ_{max} = 360–370 nm. However, the fluorescence emission of **8** consists of two bands at 340 nm and 370 nm, each with a different excitation spectrum. This observation along with the fact that biexponential decays were observed in lifetime measurements (Table 3) for this compound is consistent with emission from two distinct chromophores, viz. biphenyl and stilbene moieties (Fig. 9). One of the factors responsible for lack of carbon acid dissociation of **8** may be due to the efficient energy transfer to the stilbene excited state, which is unreactive. However, a detailed photophysical study is required to completely understand the nature of the excited states available for this compound.

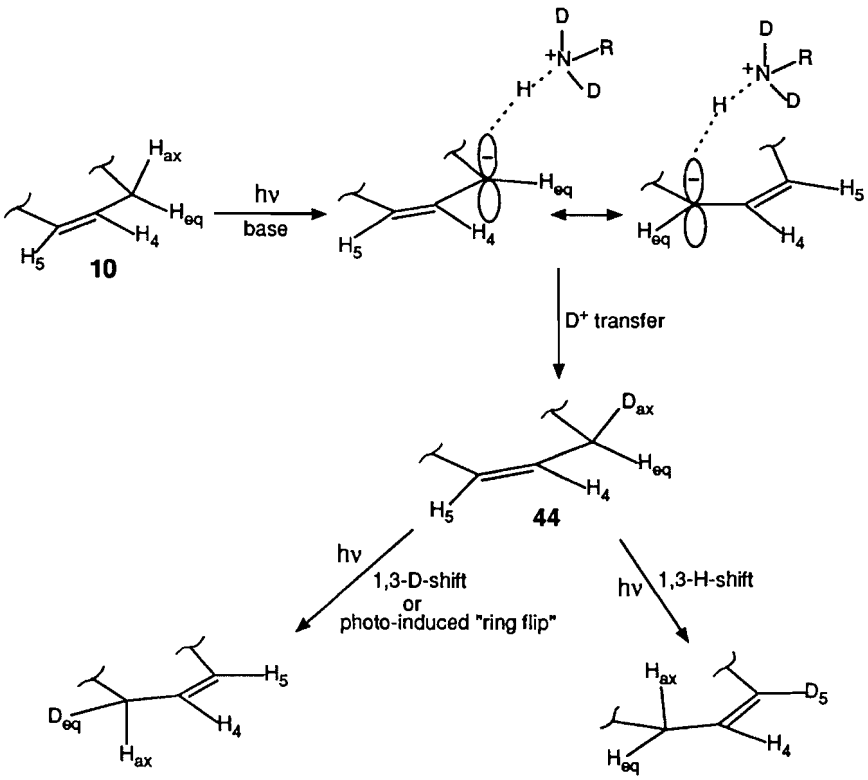
The fluorescence excitation and emission spectra of **10** and **11** in CH_3CN are broad and essentially structureless (Fig. 10). Although the fluorescence quantum yields (Φ_f) are the same, their fluorescence lifetimes differ substantially, consistent with the general observation that binaphthyls joined at the 1-position are short-lived (≈2 ns) whereas those joined at the 2-position are much longer lived (≈30 ns) (19). The 15 ns lifetime measured for **11** is consistent with an efficient formal di-π-methane rearrangement occurring for this compound whereas the photoinert **10** (in CH_3CN) has a measured lifetime essentially the same as other nonreactive 1,1′-binaphthyls reported in the literature (19).

The fluorescence quenching rate constants of **3** by primary amines EA and $H_2NCH_2CH_2NH_2$ are more than an order of magnitude larger than for H_2O, consistent with the much higher basicity of the amines (Table 4). The increased quenching efficiency for EA is reflected in the higher quantum yield for deuterium incorporation when EA is used in the exchange studies (Table 2). A similar observation is made for **7** although in this case quenching with H_2O was small and a k_q could not be reliably calculated. No fluorescence quenching was observed using H_2O as base for all of **8**, **10**, and **11**, consistent with the complete lack of deuterium exchange for these compounds when photolyzed in D_2O–CH_3CN. Use of EA as quencher resulted in fluorescence quenching only for **10** ($k_q = 0.86 \times 10^9$ M^{-1} s^{-1}) consistent with deuterium incorporation observed only for this compound in EA–D_2O–CH_3CN. However, its k_q value is an order of magnitude smaller than for **3**, indicating that binaphthyls are intrinsically weaker excited state carbon acids even in favourable cases such as **10**.

Fig. 8. UV–VIS traces for the photolysis of **11** in 100% CH_3CN, showing clean and efficient formation of **45**.



Scheme 8.



Summary

Study of excited state carbon acid dissociation of **9** has shown that the photochemically generated carbanion **3a** is allylically delocalized. Carbon acid dissociation of **3** was found to be highly sensitive to substituents at the 6-position since **7** was found to be less reactive and **8** completely unreactive with respect to this reaction. Use of EA as base resulted in enhanced rates of carbon acid deprotonation for **3** and **7**. Studies of binaphthyls **10** and **11** have shown that excited state carbon dissociation is observable even in naphthocycloheptene systems if formal di-π-methane rearrangement is retarded and a suitable base such as EA is used. Thus the positive results observed for **10** indicate that excited state carbon acid dissoci-

Table 2. Quantum yields for deuterium incorporation (Φ_{ex}) and product formation (Φ_p) for **3**, **7**, **8**, **10**, and **11**.

Compound	Solvent	Φ_{ex}[a]	Φ_p[a]
3	25% D_2O – CH_3CN[b]	0.03 ± 0.01	0.023 ± 0.006
	10% (5 M EA – D_2O) – CH_3CN	0.08 ± 0.02	0.029 ± 0.008
7	25% D_2O – CH_3CN	0.006 ± 0.002	0.018 ± 0.006
	10% (5 M EA – D_2O) – CH_3CN	0.07 ± 0.02	0.016 ± 0.005
8	40% D_2O – CH_3CN	0.000	< 0.02[c]
10	50% D_2O – CH_3CN	0.000	< 0.001[d]
	10% (5 M EA – D_2O) – CH_3CN	0.02 ± 0.01[d]	< 0.001[d]
11	100% CH_3CN	0.000	0.47 ± 0.05
	10% (5 M EA – D_2O) – CH_3CN	0.000	0.47 ± 0.05

[a]Quantum yields for deuterium incorporation (Φ_{ex}) and for product formation (Φ_p) (formal di-π-methane rearrangement) were measured by photolyzing samples at 254 nm in a Rayonet RPR 100 reactor using the carbon acid exchange reaction of 5,5-dideuterosuberene in 1:1 H_2O – CH_3CN as secondary actinometer (Φ_{ex} = 0.035) (3*b*). Analyses were performed by ^1H (360 MHz) NMR for Φ_{ex} and GC for Φ_p.

[b]Measured in 25% D_2O – CH_3CN for comparison with **7** since **7** was found to be insoluble in more aqueous mixtures.

[c]Estimated based on ^1H (360 MHz) NMR. No formal di-π-methane rearrangement products were observed. Instead, photodecomposition to several minor products was observed as shown by GC.

[d]Estimated based on ^1H (360 MHz) NMR.

Table 3. Fluorescence parameters measured for **3**, **7**, **8**, **10**, and **11**.[a]

Compound	Φ_f[b]	τ[c]
3	0.12 ± 0.02[d]	4.5 ± 0.1[d]
7	0.07 ± 0.01[e]	1.6 ± 0.1
8	0.006 ± 0.002[f]	4.0/20.7[g]
10	0.13 ± 0.02[e]	2.4 ± 0.1
11	0.14 ± 0.02[e]	15.0 ± 0.3

[a]Measured at ambient temperature (20 ± 2°C) in dry CH_3CN (λ_{ex} = 260–280 nm, λ_{em} = 360–370 nm, depending on the substrate).

[b]Fluorescence quantum yields were measured relative to **3** as the secondary standard since the spectra distributions were all similar.

[c]Measured via single photon counting. All decays were good first order unless otherwise indicated.

[d]From ref. 4, for comparison purposes.

[e]Measured using **2** as reference (Φ_f = 0.86 ± 0.05) (3*b*).

[f]Measured using **7** as reference.

[g]Biexponential decays observed. At λ_{ex} = 260 nm and λ_{em} = 370 nm, the short-lived component accounted for 63% of the emission. The percentage of the emission from each component changed with λ_{em} consistent with the presence of two emitting chromophores for this compound, as observed in the steady-state fluorescence spectra.

Table 4. Rates of fluorescence quenching (k_q) measured for **3**, **7**, **8**, **10**, and **11** in CH_3CN from Stern–Volmer analysis.[a]

Compound	Quencher	k_q, 10^9 (M^{-1} s^{-1})
3	H_2O	0.21 ± 0.03[b]
	$H_2NCH_2CH_2OH$ (EA)	6.9 ± 0.2
	$H_2NCH_2CH_2OCH_3$	8.1 ± 0.2
7	H_2O	< 0.05
	EA	3.2 ± 0.1
8	H_2O	< 0.01[c]
	EA	< 0.01[c]
10	H_2O	< 0.01[c]
	EA	0.86 ± 0.04
11	H_2O	< 0.01[c]
	EA	< 0.01[c]

[a]Measured at ambient temperature (20 ± 2°C) in dry CH_3CN.

[b]From ref. 4, for comparison purposes.

[c]Estimate upper limit. No observable quenching up to 0.2 M EA in CH_3CN.

ation is a general reaction for larger benzannelated cycloheptenes but reaction efficiency will be reduced compared to the parent systems **2** and **3**.

Experimental section

General

^1H and ^{13}C NMR spectra were taken on Perkin–Elmer R32 (90 MHz), Bruker WM250 (250 MHz), or AM360 (360 MHz) spectrometers. ^2H NMR spectra were obtained on the Bruker AM360 instrument. MS, GC–MS, and HRMS were taken on a Finnigan 3300 (CI) or Kratos Concept 1H instrument (EI). GC was performed on a Varian 3700 gas chromatograph using a SE-54 capillary column and a Hewlett–Packard 3390A integrator. Preparative thin layer chromatography (TLC) was carried out on 20 × 20 silica gel GF Uniplates (Analtech). IR spectra were obtained on a Perkin–Elmer 283 spectrophotometer using NaCl solution cells. UV spectra were obtained on a Cary 5 spectrophotometer.

Materials

Phenanthrene (**13**), 2-benzoylbenzoic acid, 2-methylnaphthalene (**21**), diphenic anhydride and 2-methylnaphthalene-bis(hexachlorocyclopentadiene) adduct (**29**) were purchased from Aldrich.

Fig. 9. Fluorescence excitation and emission spectra observed for **8** indicative of two emitting chromophores.

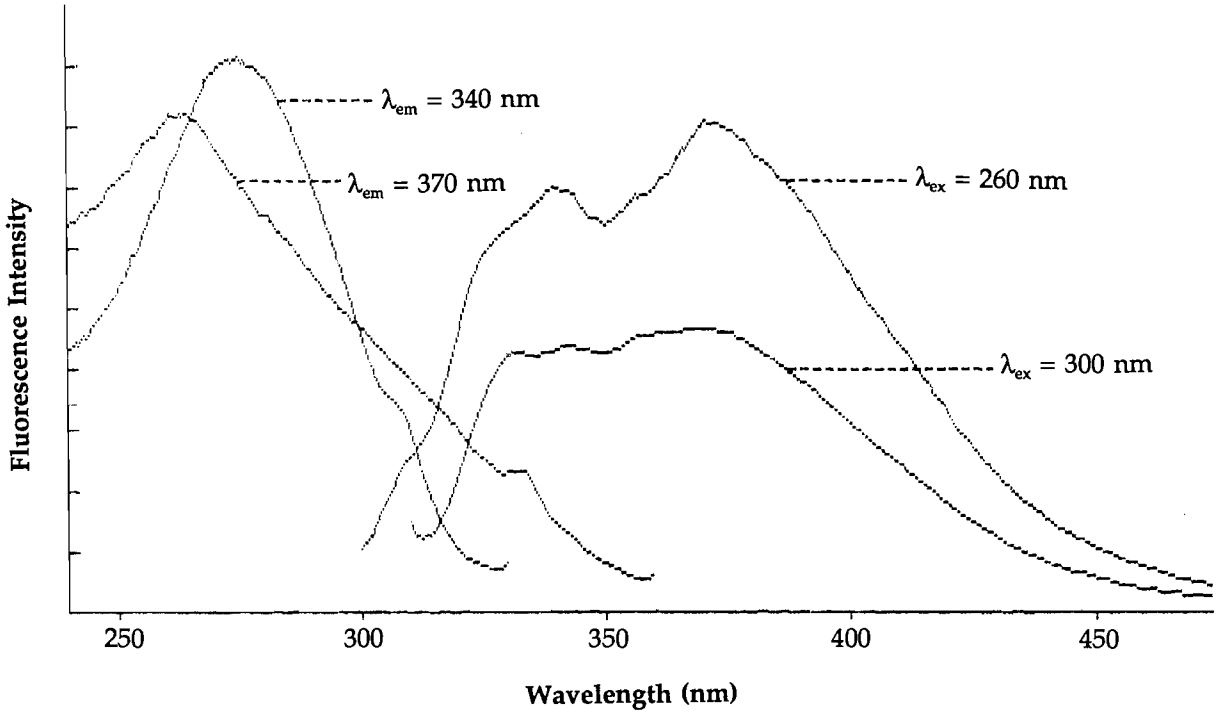


Fig. 10. Fluorescence excitation and emission spectra of **10** and **11** in 100% CH_3CN (λ_{ex} = 280 nm; λ_{em} = 400 nm).

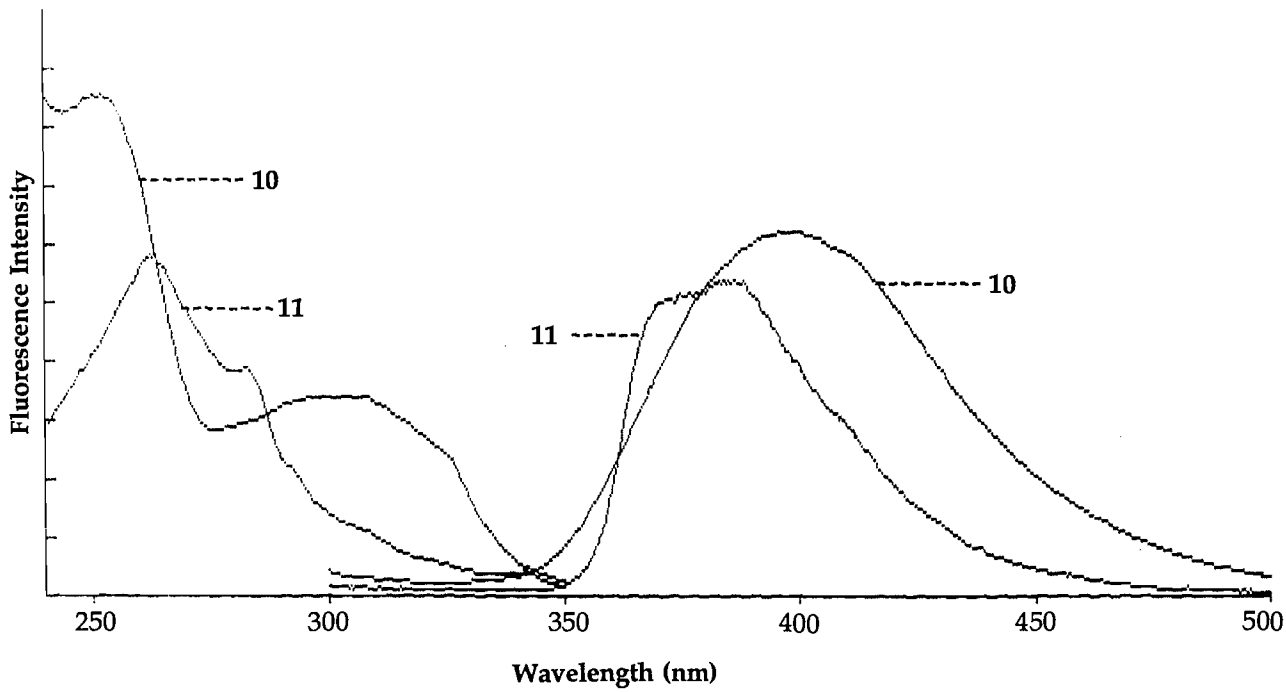

*7,7-Dichlorodibenzo[*a,c*]bicyclo[4,1,0]heptane (**14**)*
The method of Halton and Officer (6) was used for the synthesis of **14** from **13**. The ^{1}H NMR of the material obtained was identical to the literature spectrum (6).

*6-Chloro-5*H*-dibenzo[*a,c*]cyclohepten-5-ol (**15**)*
Alcohol **15** was prepared from **14** following the procedure of Coburn and Jones (7). The ^{1}H NMR of the product was identical to the literature spectrum (7).

*6,7-Dihydro-5H-dibenzo[a,c]cycloheptene (**16**)*
Alcohol **15** (2.4 g, 0.0098 mol) was converted to **16** using the procedure of Griffin and Horn (8). A clear oil (1.5 g, ≈80% yield) with a purity of 99% by GC was obtained, ^{1}H NMR (90 MHz) δ: 1.9–2.6 (m, 6H, $(CH_2)_3$), 7.1–7.4 (m, 8H, arom.); MS (CI) (*m/z*): 195 (M^++1).

*5-Bromo-6,7-dihydro-5H-dibenzo[a,c]cycloheptene (**17**)*
Hydrocarbon **16** (0.5 g, 0.0026 mol) was brominated with NBS in CCl_4 in the presence of benzoyl peroxide (50 mg). The reaction mixture was refluxed overnight. Upon cooling, the solution was filtered and evaporated to give crude **17** (≈50%), as indicated by a new multiplet at δ 5.0 assignable to the benzylic proton substituted with bromine. The crude bromide was used without further treatment in the next step.

*6,7-Dihydro-5H-dibenzo[a,c]cyclohepten-5-ol (**18**)*
All of the bromide **17** from the previous step was dissolved in 1:1 H_2O–CH_3CN (40 mL) and gently refluxed for 1 h. Upon addition of NaCl, the mixture was extracted with CH_2Cl_2, which gave the crude alcohol **18** in 100% conversion by ^{1}H NMR. This material was used in the next step without further treatment. The multiplet at δ 5.0 of **17** moves upfield to δ 4.6 consistent with substitution of bromine by H_2O.

*6,7-Dihydro-5H-dibenzo[a,c]cyclohepten-5-one (**19**)*
The crude alcohol (**18**) (1.0 g, 0.0048 mol) was dissolved in ether (40 mL) and 20 mL of 10% chromic acid added dropwise over a 10 min period. After stirring the solution overnight, the organic layer was separated and the aqueous layer washed with 2 × 50 mL ether. The organic layers were combined and washed with saturated sodium bicarbonate and saturated NaCl solutions. Drying and evaporation of the solvent gave crude ketone **19** (0.60 g, 60%). Purification of **19** was achieved by column chromatography (silica), first eluting with hexanes to wash out nonpolar components of the product mixture and then with 50% CH_2Cl_2–hexanes for the final separation. The material obtained was >95% pure by GC with the ^{1}H NMR identical to the literature spectrum (7), δ: 2.90 (s, 4H, CH_2CH_2), 7.19–7.72 (m, 8H, arom.).

*5-Deuterio-6,7-dihydro-5H-dibenzo[a,c]cyclohepten-5-ol (**20**)*
Ketone **19** (1.5 g, 0.0072 mol) was reduced with $LiAlD_4$ (0.3 g) in ether to give **20** (1.5 g, 100%), whose ^{1}H NMR was identical to that of **18** except for the absence of the methine proton resonance and its associated couplings.

*7-Deuterio-5H-dibenzo[a,c]cycloheptene (**9**)*
Alcohol **25** (200 mg, 0.95 mmol) was dissolved in 50 mL toluene in a round-bottom flask and fitted with a Dean-Stark trap. After addition of 20 mL 85% H_3PO_4 the reaction mixture was refluxed for 3 h, cooled, poured onto ice, and the aqueous fraction extracted with hexanes (2 × 50 mL). The organic fractions were combined and washed with saturated sodium bicarbonate. Drying and evaporation of the solvent provided crude **9** as an oil. Kugelrohr distillation gave a clear oil (110 mg, 60%) with >97% purity by GC (96% deuterium at the 7-position by ^{2}H NMR, see Fig. 1), ^{1}H NMR (360 MHz) δ: 3.08 (br s, 2H, CH_2), 6.27 (t, *J* = 6.9 Hz, 1H, vinyl), 7.22–7.32 (m, 1H, arom.), 7.35–7.44 (m, 5H, arom.), 7.53–7.62 (m, 1H, arom.), 7.71–7.77 (m, 1H, arom.); MS (CI) (*m/z*): 194 (M^++1).

*6-Methyl-5H-dibenzo[a,c]cycloheptene (7) and 6-phenyl-5H-dibenzo[a,c]cycloheptene (**8**)*
Both **7** and **8** were prepared from diphenic anhydride via the procedure used for the synthesis of **8** by Tolbert and Ali (5). Purification of **7** and **8** was achieved using column chromatography (silica) with hexanes as eluent. A clear oil was obtained for **7** with a purity of >97% by GC, UV (CH_3CN) λ_{max} (ε): 238 nm (36 700), 254 (11 600), 292 (1330); ^{1}H NMR (360 MHz) δ: 2.10 (d, *J* = 1.6 Hz, 3H, CH_3), 3.02 (s, 2H, CH_2), 6.36 (q, *J* = 1.6 Hz, 1H, vinyl), 7.23–7.41 (m, 6H, arom.), 7.54–7.59 (m, 1H, arom.), 7.69–7.73 (m, 1H, arom.); MS (CI) (*m/z*): 207 (M^++1). Pure **8** was a white solid, purity >98% by GC, mp 82–83°C (lit. (5) mp 92–94°C); UV (CH_3CN) λ_{max} (ε): 228 nm (21 400), 250 (28 500), 293 (16 300); ^{1}H NMR (250 MHz) δ: 3.28 (br s, 1H, CH), 3.76 (br s, 1H, CH), 6.88 (s, 1H, vinyl), 7.25–7.78 (m, 13H, arom.); MS (CI) (*m/z*): 269 (M^++1).

*1-Bromo-2-methylnaphthalene (**22**)*
Bromination of 2-methylnaphthalene (**21**) (50 g, 0.35 mol) at the 1-position was carried out using the procedure of Adams and Binder (9). Distillation of the crude product mixture gave **22** as a clear oil (71 g, 91%); ^{1}H NMR (90 MHz) δ: 2.56 (s, 3H, CH_3), 7.2–7.8 (m, 5H, arom.), 8.2–8.3 (m, 1H, arom.); MS (CI) (*m/z*): 221 (M^++1, ^{79}Br), 223 (M^++1, ^{81}Br). The spectroscopic data agree with literature values (9, 20).

*2,2′-Dimethyl-1,1′-binaphthyl (**23**)*
Coupling of **22** (178 g, 0.81 mol) via the Grignard reagent was carried out according to the method of Maigrot and Mazaleyrat (10). Unreacted **21** and **22** were removed by Kugelrohr distillation to give crude **23** (86 g, 38%). Further purification was achieved by elution through a silica gel flash column with hexanes to provide **23** with >95% purity by GC. The ^{1}H NMR (90 MHz) agreed with the literature spectrum (20).

*2,2′-Bis(bromomethyl)-1,1′-binaphthyl (**24**)*
Bromination of **23** (86 g, 0.30 mol) with NBS using the procedure for **17** above gave **24** (114 g, 85%). The product was recrystallized in 1:3 benzene–hexanes to give yellowish crystals with a purity of >95%. The ^{1}H NMR (90 MHz) agreed with the literature spectrum (20).

*5-Cyano-4-amino-3H-cyclohepta[2,1-a:3,4-a′]dinaphthalene (**25**)*
To a refluxing solution of KCN (40 g) in 30% H_2O – EtOH (160 mL) was added a 200 mL acetone solution of **29** (24 g, 0.055 mol) via an addition funnel over 2 h period. After addition, most of the acetone was removed by leaving one of the necks of the round-bottom flask open. The solution was then refluxed overnight. The reaction mixture was poured into 2 L of water and the precipitate filtered to give crude **25** (11 g, 60%), IR (CH_2Cl_2) (cm^{-1}): 3495, 3390 (NH_2), 2163 (CN); ^{1}H NMR (90 MHz) δ: 3.11 (d, *J* = 12 Hz, 1H), 3.37 (d, *J* = 12 Hz, 1H), 5.07 (br s, 2H, NH_2), 7.0–8.1 (m, 12H arom.); MS (CI) (*m/z*): 333 (M^++1). This material was used in the next step without further purification.

*3H-Cycloheptan-4-one[2,1-a:3,4-a′]dinaphthalene (**26**)*
Preparation of **26** from **25** (16 g, 0.048 mol) was accomplished using the procedure of Mislow and McGinn (12). Recrystallization of **26** (12 g, 80%) in acetone gave a brown powder (purity >95%) that by ^{1}H NMR (90 MHz) is consistent with

26; IR (CH_2Cl_2) (cm^{-1}): 1710 (s, carbonyl str.); δ: 3.61 (two overlapping doublets, both J = 15 Hz, 4H, $2CH_2$), 7.1–7.6 (m, 8H, arom.), 7.8–8.0 (m, 4H, arom.); MS (CI) (*m/z*): 309 (M^++1).

3H-Cycloheptan-4-ol[2,1-a:3,4-a′]dinaphthalene (27)
Reduction of **26** (2 g, 0.0065 mol) with $LiAlH_4$ in THF gave alcohol **27** (1.8 g, 40%). The product was shown to be sufficiently pure for the next step by ^{1}H NMR (90 MHz), δ: 1.55 (s, 1H, OH), 2.1–3.1 (m, 4H, $2CH_2$), 4.3–4.7 (m, 1H, CH), 7.1–7.6 (m, 8H, arom.), 7.8–8.0 (m, 4H, arom.); MS (CI) (*m/z*): 293 (M^+ − OH).

4-Bromo-3H-cyclohepta[2,1-a:3,4-a′]dinaphthalene (28)
The alcohol **27** (2 g, 0.0065 mol) was dissolved in $CHCl_3$ (100 mL) and PBr_3 (2 g) added dropwise with a pipette. The resulting mixture was refluxed overnight and poured into 200 mL of water. The organic layer was separated and the aqueous portion extracted with CH_2Cl_2. The combined organic extracts were dried over $MgSO_4$ and the solvent evaporated off to obtain crude **28** (2.2 g, 90%), ^{1}H NMR (90 MHz), δ: 2.5–3.4 (m, 4H, $2CH_2$), 4.5–4.8 (m, 1H, CHBr), 6.9–8.1 (m, 12H, arom.). This material was used in the next step without further treatment.

3H-Cyclohepta[2,1-a:3,4-a′]dinaphthalene (10)
Bromide **28** (2.2 g, 0.0059 mol) was dissolved in 150 mL *t*-BuOH with 2 g of t-BuO^-K^+ and refluxed overnight. The reaction mixture was then poured into 100 mL water and the resulting solution extracted with CH_2Cl_2. Evaporation of the solvent gave crude **10** (1.2 g, 70%). The material was recrystallized from toluene–EtOH to give colourless crystals with a purity >99% by GC (mp 166–168°C, (lit. (11) mp 163–164°C)); UV (CH_3CN) λ_{max} (ε): 208 nm (sh, 38 900), 225 (77 600), 251 (35 300), 303 (10 600); ^{1}H NMR (360 MHz), δ: 2.96 (ddd, J = 12.8, 5.6, 2.2 Hz, axial CH), 3.33 (ddd, J = 12.9, 7.9, 0.6 Hz, equatorial H), 6.42 (ddd, J = 9.8, 7.9, 5.6 Hz, 1H, vinyl), 6.72 (dd, J = 9.7, 2.3 Hz, 1H, vinyl), 7.09–7.11 (m, 2H, arom.), 7.19–7.24 (m, 1H, arom.), 7.29–7.35 (m, 1H, arom.), 7.41–7.56 (m, 4H, arom.), 7.84–7.83 (m, 4H, arom.) (the ^{1}H NMR was essential identical to that reported in ref. 11); ^{13}C NMR, δ: 33.9 (CH_2), 124.3, 125.3, 125.4, 125.5, 125.6, 126.5, 127.1, 127.8, 127.9, 128.1, 128.6, 128.8, 129.5, 134.8, 130.3, 131.5, 132.0, 133.0, 135.4, 143.6; MS (EI) (*m/z*): 292 (M^+).

2-Bromo-3-methylnaphthalene-bis(hexachlorocyclopentadiene) adduct (30)
The procedure discussed by Smith et al. (14) was used to make **30** and **31**. Commercially available **29** (200 g) was brominated according to the procedure used for **21**. The product **30** (196 g, 85%) was used in the next step without purification, ^{1}H NMR (90 MHz), δ: 2.39 (s, 3H, CH_3), 3.48 (d, J = 9 Hz, 2H, 2CH), 3.89 (d, J = 9 Hz, 2H, 2CH), 7.58 (s, 1H, arom.), 7.93 (s, 1H, arom.); MS (EI) (*m/z*): 766 (M^+).

2-Bromo-3-methylnaphthalene (31)
The brominated product **30** (100 g, 0.13 mol) was heated using a bulb-to-bulb distillation setup on a rotary evaporator (aspirator vacuum) with a cooled trapping bulb as the receiving flask connected above the flask containing **30**. A heat gun was used to effect distillation, which gave **31** as an oily white solid (23 g, 80%). Recrystallization from hexanes gave pure **31** as white crystals, ^{1}H NMR (90 MHz), δ: 2.49 (s, 3H, CH_3), 7.3–7.8 (m, 5H, arom.), 8.01 (s, 1H, arom.); MS (EI) (*m/z*): 220, 222 (M^+).

3,3′-Dimethyl-2,2′-binaphthyl (32)
As in the synthesis of **23**, the method of Maigrot and Mazaleyrat (10) was used to make **32**, with the modification that during preparation of the Grignard, one equivalent of 1,2-dibromoethane was added and an extra equivalent of Mg was used. Unreacted **31** and 2-methylnaphthalene (**21**) from incomplete bromination were removed from the desired **32** by Kugelrohr distillation. The residue was purified by passing through a silica gel column using hexanes, to give a yellowish brown solid (≈40% yield from **31**), ^{1}H NMR (90 MHz), δ: 2.17 (s, 6H, $2CH_3$), 7.3–7.9 (m, 12H, arom.); MS (CI) (*m/z*): 283 (M^++1).

3,3′-Bis(bromomethyl)-2,2′-binaphthyl (33)
Bromination of **32** (4.5 g, 0.016 mol) with NBS using the same procedure as for **23** gave **33** as an oil (6 g, 85%) that solidified on standing. The product was sufficiently pure to be taken to the next step without further treatment, ^{1}H NMR (90 MHz), δ: 4.2–4.6 (m, 4H, CH_2Br), 7.3–8.1 (m, 12H, arom.).

5-Cyano-4-amino-3H-cyclohepta[2,1-b:3,4-b′]dinaphthalene (34)
Cyclization of **33** (0.5 g, 0.0011 mol) was carried out using the method outlined for **25**. The product **34** (0.15 g, 40%) was obtained as a brown solid (>90% pure); IR (CH_2Cl_2) (cm^{-1}): 3500, 3400 (m, NH_2), 2190 (m, CN); ^{1}H NMR (90 MHz), δ: 2.15 (d, J = 13 Hz, 1H), 2.66 (d, J = 13 Hz, 1H), 5.00 (br s, 2H, NH_2), 7.1 – 8.2 (m, 12H, arom.); MS (CI) (*m/z*): 333 (M^++1).

3H-Cycloheptan-4-one[2,1-b:3:4-b′]dinaphthalene (35)
Ketone **35** (4.5 g, 80%) was prepared from **34** (6 g, 0.018 mol) according to the method described for **26** (6 g, 80%); IR (CH_2Cl_2) (cm^{-1}): 1720 (s); ^{1}H NMR (250 MHz), δ: 3.4–3.9 (m, 4H, overlapping doublets, $2CH_2$), 7.5–7.6 (m, 4H, arom.), 7.74 (s, 2H, arom.), 7.8–8.0 (m, 4H, arom.), 8.13 (s, 2H, arom.); MS (CI) (*m/z*): 309 (M^++1).

3H-Cycloheptan-4-ol[2,1-b:3,4-b′]dinaphthalene (36)
Standard $LiAlH_4$ reduction of ketone **35** (3 g, 9.7 mmol) gave alcohol **36** (2.7 g, 40%), which was purified by passing through a silica gel column with hexanes followed by CH_2Cl_2, to give **36** in >95% purity; ^{1}H NMR (90 MHz), δ: 2.1–3.1 (m, 5H, $2CH_2$ and OH), 4.32 (quintet, J = 6 Hz, 1H), 7.2–8.0 (m, 12H, arom.).

4-Bromo-3H-cyclohepta[2,1-b:3,4-b′]dinaphthalene (37)
Reaction of **36** (2.5 g, 8.1 mmol) with PBr_3 using the method described for **28** gave **37** (2.6 g, 85%). Purification was carried out by passing the material through a silica gel column using hexanes, to give **37** in >95% purity, ^{1}H NMR (90 MHz), δ: 2.8–3.5 (m, 4H, $2CH_2$), 4.6–4.9 (m, 1H, CHBr), 7.3–8.4 (m, 12H, arom.).

3H-Cyclohepta[2,1-b:3,4-b']dinaphthalene (11)
As in the synthesis of **10**, elimination of HBr from **37** (0.5 g, 1.3 mmol) using *t*-BuO^-K^+ gave **11** (0.22 g, 55%). The major by-product (45%) was **38**, as shown by GC and ^{1}H NMR. Purification of **11** was achieved by repeated recrystallization from toluene–EtOH, which gave a purity of >99% (by GC), mp = 169–170°C; UV (CH_3CN) λ_{max} (ε): 209 nm (sh, 24 700), 219 (40 100), 260 (59 500), 280 (sh, 36 100) 303 (sh, 13 600); ^{1}H NMR (360 MHz), δ: 3.37 (d, J = 6.9 Hz, 2H, CH_2), 6.42 (dt, J = 10.2, 6.9 Hz, 1H, vinyl), 6.81 (d, J = 10.3 Hz, 1H, vinyl), 7.47–7.58 (m, 4H, arom.), 7.68 (s, 1H, arom.), 7.81 (s, 1H, arom.), 7.83–8.01 (m, 4H, arom.), 8.09 (s, 1H, arom.), 8.25 (s, 1H, arom.); ^{13}C NMR, δ: 33.4, 124.3, 125.4, 126.1, 126.3, 126.8, 127.4, 127.7, 127.9, 129.1, 129.8, 130.1, 132.3, 132.0, 132.4, 132.7, 134.5, 138.2, 142.0; HRMS (EI) (*m/z*): 292.1254 (calcd. 292.1252). By-product **38** was isolable from the fractional recrystallizations, ^{1}H NMR (90 MHz), δ: 2.63 (s, 3H, CH_3), 7.3–7.7 (m, 5H, arom.), 7.8–8.2 (m, 5H, arom.), 8.30 (s, 1H, arom.), 9.08 (s, 1H, arom.), 9.13 (s, 1H, arom.); MS (CI) (*m/z*): 293 (M^++1).

X-ray crystallography

X-ray diffraction studies involving **10** were performed using a Nonius diffractometer with ω–2Θ scan for collection of data (1613 reflections). Of these reflections 1372 were used to refine the structure. NRC Solver (21) was used to solve the crystal structure and the SHELX least-squares program (22) was used to refine the structure. X-ray crystallographic data are given in Table 1 and an ORTEP drawing in Fig. 2.[2]

Product studies

Preparative photolyses were carried out in a Rayonet RPR 100 photochemical reactor using 254, 300, or 350 nm (for triplet sensitization) lamps and 100 or 200 mL quartz tubes (Pyrex tubes for triplet sensitization). Analytical runs were carried out in 3 mL Suprasil quartz cuvettes on an optical bench using an Oriel 200W Hg arc lamp and an Applied Physics monochromator set at either 254 or 280 nm with 5 nm slits. Solutions for preparative photolyses were cooled with a cold finger (≈15°C) and purged with argon before and during the photolysis. Analytical runs were purged with argon prior to irradiation. In general, any effect of oxygen in the photoreactions was minimal. A number of runs were repeated in the absence of light to check for thermal reaction and none were observed. Representative examples of photolysis experiments are provided below.

*Photolysis of **3** in D_2O–CH_3CN and EA–D_2O–CH_3CN*
Photolysis of **3** (30 mg) in 25% D_2O – CH_3CN solution (254 nm, 15 min) gave **4** (30%), **5** (49%), and phenanthrene (5%), as indicated by ^{1}H NMR (360 MHz). Photolysis of **3** in 10% (5 **M** EA – D_2O) – CH_3CN for 5 min gave **4** (14%), **5** (40%), and phenanthrene (1%), thereby demonstrating base catalysis of deuterium incorporation.

*Photolysis of **9** in 100% CH_3CN and 50% H_2O – CH_3CN*
Photolysis of **9** (50 mg) in 100 mL of 100% CH_3CN with 254 nm lamps (15 min.) gave products shown in or derived from Scheme 6, as indicated by ^{2}H NMR of the photolysate, δ: −0.14, 1.59 (two isomers of **4a**, 6%), 2.57 (**4b**, 58%), 6.31 (**6**, 6%), 7.83 (9-deuterophenanthrene, 6%). Photolysis of **9** in 50% H_2O – CH_3CN under otherwise identical conditions gave a different product mixture, ^{2}H NMR, δ: −0.14, 1.59 (two isomers of **4a**, 2%), 2.57 (**4b**, 16%), 3.08 (**5**, 50%), 6.31 (**6**, 4%), 7.83 (9-deuterophenanthrene, 1%).

*Photolysis of **7** in 100% CH_3CN*
Photolysis of **7** (50 mg) in 100 mL of 100% CH_3CN (254 or 300 nm, 15 min) gave three major products according to GC–MS and ^{1}H NMR: **40** (25% at 254 nm; 4% at 300 nm), **42** (3% at 254 nm; 13% at 300 nm), and **41** (3% at 254 nm; 4% at 300 nm). The products were not separated and the ^{1}H NMR (360 MHz) signals that could be assigned to each compound are listed as follows: **40**, δ: 0.07 (m, 1H, cyclopropyl methylene proton), 1.45 (dd, J = 9.0, 3.8 Hz, cyclopropyl methylene proton), 1.65 (s, 3H of CH_3), 2.34 (dd, J = 9.0, 5.0 Hz, cyclopropyl methine proton); **42**, δ: 2.11 (m, 3H of CH_3), 2.80 (m, axial H of CH_2), 3.05 (dd, J = 13.1, 8.2 Hz, equatorial H of CH_2), 6.08 (m, 1H, vinyl H); **41**, δ: 2.75 (d, J = 1.0 Hz, CH_3), 6.68 (m, aryl H at C10). Additional studies using ^{1}H COSY NMR showed the required correlations in the assigned signals.

*Photolysis of **7** in D_2O–CH_3CN and EA–D_2O–CH_3CN*
Photolysis of **7** (30 mg) in 25% D_2O – CH_3CN (254 nm, 15 min) gave **40** (22%), **42** (3%), and **41** (3%) according to GC and ^{1}H NMR. Integration and comparison of the ^{1}H NMR signals due to the protons at the vinyl and 5-position of **7** in unreacted substrate and in photolyzed material gave ≈10% deuterium incorporation at the 5-position. Photolysis in 10% (5 M EA – D_2O) – CH_3CN (254 nm; 30 min.) gave **40** (29%), **42** (4%), and **41** (12%). GC–MS and ^{2}H NMR analysis of the product mixture indicated extensive deuterium incorporation in the starting material **7** (73% at the 5-position) and in **51** (36% at the cyclopropyl positions). A 5 min photolysis resulted in 36% deuterium incorporation at the 5-position in recovered **7**.

*Photolysis of **8** in 100% CH_3CN and D_2O–CH_3CN*
The product mixture obtained after irradiation of **8** (50 mg) in either CH_3CN or 50% D_2O – CH_3CN was complex (GC and ^{1}H NMR) with no major product (taken up to 20% conversion). Analysis by GC–MS of recovered **8** showed no measurable deuterium incorporation. Due to the complexity of the product mixture and the lack of excited state carbon acid behaviour, no further experiments were carried out to delineate the photochemistry of this compound.

*Photolysis of **10** in EA–D_2O–CH_3CN*
Photolysis of **10** (50 mg) in 10% (5 M EA – D_2O) – CH_3CN (254 nm, 1 h) gave a trace of **43** and deuterium incorporation

[2] Tables of fractional atomic coordinates, interatomic distances, bond angles, and anisotropic temperature parameters are available and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. With the exception of the table of anisotropic temperature parameters, these supplementary data have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

predominantly at H_{ax} of **10** (Fig. 5). Kinetic runs were carried out by photolyzing 300 mg of **10** in 400 mL of 10% (5 M EA – D_2O) – CH_3CN and withdrawing samples at different photolysis times for analysis by ^1H and ^2H NMR. The results are shown in Figs. 5–7.

*Photolysis of **11** in 100% CH_3CN and EA–D_2O–CH_3CN*

Photolysis of **11** (30 mg) in 100 mL 100% CH_3CN (254 nm, 30 min) gave **45** (44%) as the only product by GC and ^1H NMR. Product **45** was not separated from **11** but was characterized based on the characteristic cyclopropyl ring protons in the ^1H NMR of the photolysate, δ: 0.18 (td, J = 5.4, 4.2 Hz, methylene proton of cyclopropyl ring), 1.63 (td, J = 8.9, 4.1 Hz, methylene proton of cyclopropyl ring), 2.77 (dd, J = 8.9, 5.0 Hz, methine protons of cyclopropyl ring), 7.89 (s, 2H, arom.), 8.63 (s, 2H, arom.). The remaining eight aromatic protons were in the same region as those for **11**; GC–MS (CI) (*m/z*): 293 (M^++1). Photolysis of **11** in 10% (5 M EA in D_2O) – CH_3CN using a quartz cuvette showed no deuterium incorporation in recovered **11** by GC–MS when the conversion to **45** was taken to 25%. Photolysis of **11** in 100% CH_3CN under identical conditions also resulted in 25% conversion to **45**.

*Triplet sensitization of **7** in 100% CH_3CN*

A solution of **7** (40 mg) and 2-benzoylbenzoic acid (1 g) in 100 mL 100% CH_3CN was photolyzed at 350 nm in a Pyrex tube for 1 h. After photolysis, CH_3CN was evaporated and the residue taken up in CH_2Cl_2. The sensitizer was removed by extraction of with aqueous NaOH. The major product was **40** (10%), as indicated by GC and ^1H NMR.

Quantum yields for deuterium exchange and di-π-methane rearrangement

Quantum yields for deuterium exchange (Φ_{ex}) and formal di-π-methane rearrangement (Φ_p) were measured using semi-preparative photolyses in a Rayonet reactor using 254 nm lamps. The substrate (10^{-4} mol) dissolved in the appropriate solvent in a 100 mL quartz tube was irradiated to give 5–20% conversion. The amount of deuterium incorporation was calculated by ^1H NMR (360 MHz) and GC was used to monitor for yield of formal di-π-methane products. Light intensities were measured by using the exchange reaction of 5,5-dideuterosuberene in 50% H_2O – CH_3CN (Φ_{ex} = 0.035 ± 0.005) (3). Light intensities varied by less than 5% during the day and were typically 1.57×10^{-4} einsteins–min, which is similar to light intensities measured with potassium ferrioxalate used in previous studies.

Fluorescence measurements

Steady-state fluorescence spectra (uncorrected) were taken on a Perkin–Elmer MPF-66 fluorescence spectrophotometer at ambient temperature (20 ± 2°C). The fluorescence quantum yields of **3**, **7**, **10**, and **11** were measured using **2** (Φ_f = 0.86 ± 0.05 in CH_3CN) (3*b*) as the secondary fluorescence standard. Due to its low fluorescence intensity, the fluorescence quantum yield of **8** was measured relative to **7**. Fluorescence lifetimes (τ) measured were measured using the time-correlated single-photon counting technique on a Photon Technology International (PTI) LS-1 instrument with a hydrogen flash lamp. Analyses were carried out using software supplied by PTI. All decays were good first order except for decays observed for **8** (Table 3).

Hydrogen isotope fractionation between methanol and diphenylphosphine or dimethylphosphine in the gas phase and in aprotic solvents

Andrzej Wawer and Jerzy Szydłowski

Abstract: D/H fractionation factors between MeOH and Ph_2PH in dilute solutions of tetrachloroethylene, benzene, tetrahydrofuran, pyridine, and acetonitrile and T/H fractionation factors between MeOH and Me_2PH vapors were measured. The experimental results agree very well with values calculated from the statistical theory of isotope effects formulated by Bigeleisen and Mayer. There are correlations between observed fractionation factors and solvent polarity, and the interaction energy of methanol with the given solvent. Another correlation has been found between enthalpy of the exchange reactions and the interaction energy between methanol and the given solvent.

Key words: isotope effects, fractionation factor, diphenylphosphine, methanol.

Résumé : On a mesuré les facteurs de fractionnement D/H entre le MeOH et le PH_2PH, dans des solutions diluées de tétrachloroéthylène, de benzène, de tétrahydrofurane, de pyridine et d'acétonitrile, ainsi que les facteurs de fractionnement T/H entre les vapeurs de MeOH et de Me_2PH. Les résultats expérimentaux sont en bon accord avec les valeurs calculées sur la base de la théorie statistique des effets isotopiques formulée par Bigeleisen et Mayer. Il existe des corrélations entre les facteurs de fractionnement observés et les polarités des solvants ainsi que l'énergie d'interaction du méthanol avec un solvant donné. On a aussi observé une corrélation entre l'enthalpie des réactions d'échange et l'énergie d'interaction entre le méthanol et le solvant donné.

Mots clés : effets isotopiques, facteur de fractionnement, diphénylphosphine, méthanol.

[Traduit par la rédaction]

Introduction

A knowledge of tritium/protium or deuterium/protium fractionation factors in H-exchanging systems is an important aid to understanding the mechanism of chemical and biochemical reactions, and the effects of molecular structure and intermolecular interactions (1–4). A great deal of interest has been devoted to the determination of the D/H fractionation between compounds with exchangeable H-atoms and protic solvents (3, 4). Hydrogen isotope partitioning between chemical species dissolved in aprotic solvents has been less thoroughly studied (4). A cardinal rule in the theory of isotope effects is that isotope substitution does not change the force field (5). On the other hand it is clear that change of aprotic solvents will modify the force field and lead to differences in the zero-point energy (ZPE) of H-isotope exchanging molecules. It is interesting to ask just which physicochemical properties of aprotic solvents determine isotope fractionation.

Phosphines interact very weakly with their environment (6) and this simplifies further discussion. For the present study we chose the alcohol–phosphine system and have studied H/D fractionation between diphenylphosphine (DPP) and methanol (MA) in benzene, tetrachloroethylene, tetrahydrofuran, pyridine, and acetonitrile. Due to the very low vapor pressure of DPP, gas phase exchange reactions with methanol could not be carried out. Instead, the exchange of tritium between dimethylphosphine (DMP) and MA vapors has been studied. The high sensitivity of the radiometric determination of tritium makes such measurements possible even at low vapor pressure. This system forms a convenient reference as well.

Experimental

Hydrogen exchange reaction in the gas phase can be conveniently carried out by using tritium together with appropriate radiometric detection techniques (7). DMP was prepared by a two-step protonation–methylation reaction starting from phosphine (8). Tritium-labelled DMP was synthesized by exchange of Me_2PH with KOH* in $H_2O(T)$ (9).[4] DMP* and MA were dried and degassed. The exchange experiments were

[4] The asterisk denotes tritium labelling.

carried out in the same manner as for CH_3OH and H_2S vapors (7). In all experiments the ratio of the partial vapor pressure of DMP to MA was kept equal to 1.5. The total pressure was always smaller than the saturated vapor pressure of any of the components at the given temperature. The radioactivity of DMP was measured in the internal GM gas counter (7) with a standard deviation of ±1.5%.

Most H/D exchange experiments employed an NMR technique. MeOD (product of Isotope Distribution Center, 99.75% of D), Ph_2PH (Aldrich product), and solvents were carefully dried and degassed. The samples were sealed in NMR tubes. Concentrations of the solutions, in which D-exchange between DPP and MA was studied, was about 1 mol/dm^3. All operations were carried out in a glove box in a dry nitrogen atmosphere. The ^1H spectra were recorded by a JEOL Co FX 90Q spectrometer equipped with a temperature probe. The PH (doublet at 5.08 ppm, $^1J_{PH} = 216$ Hz) (10) and OH signals were observed separately. All NMR conditions for quantitative determination of the I^{PH}/I^{OH} ratio were fulfilled[10] ("I" is an integrated intensity of the signal). The reproducibility of the I^{PH}/I^{OH} was better than 1%. Temperature was determined to better than ±0.5°C.

The tritium fractionation factor for the gas phase reaction:

[1] $MeOH(v) + Me_2PH^*(v) = MeOH^*(v) + Me_2PH(v)$

is calculated from the equation:

[2] $\alpha^T_{MA/DMP}(v) = A^{MA}_\infty/A^{DMP}_\infty$

where A_∞ denotes specific tritium radioactivity at isotope equilibrium. Because only A^{DMP}_0 and A^{DMP}_∞ were measured, A^{MA}_∞ was determined from the isotope balance relation (7).

The deuterium fractionation factors for the reaction:

[3] $MeOD(s) + Ph_2PH(s) = MeOH(s) + Ph_2PD(s)$

are defined as

[4] $\alpha^D_{MA/DPP}(s) = (m_D/m_H)/(n_D/n_H)$

where m and n are the numbers of moles of MA and DPP, respectively; subscripts H and D refer to H and D isotopomers at isotope equilibrium. For the exchange process studied we can define the following material and isotope balance relations: (I) $m = m_H + m_D$, (II) $n = n_H + n_D$, (III) $m_H = n_D$, and (IV) $I^{OH}/m_H = I^{PH}/n_H$. Relation (III) is valid in the present case because the exchange reactions are carried out with fully deuterated methanol (CH_3OD). Starting from eq. [4] and using the above relations, in a few successive steps m_D, m_H, n_D, and n_H can be eliminated. At first, n_D is eliminated by using relation (III), then the use of (IV) eliminates m_H, and in the next step using (I) we eliminate m_D. Finally, defining $n_H = nI^{PH}n/(I^{OH} + I^{PH})$ from (II), (III), and (IV), we obtain eq. [5] expressed in the experimentally measured values only:

[5] $$\alpha^D_{MA/DPP}(s) = \left(\frac{I_{PH}}{I_{OH}}\right)\left(\frac{m\,I_{PH}}{n\,I_{OH}} + \frac{m-n}{n}\right)$$

m and n are as defined above and $I^{PH(OH)}$ denotes the integrated intensities of the PH(OH) hydrogen signals. The standard deviation of α^D was ±1%.

Calculations

It is interesting to compare the experimental fractionation factor with the theoretical value expressed in terms of the reduced partition function ratio (RPFR), $(s/s')f$ (5):

[6] $\alpha^D = (s/s')f_{MA}/(s/s')f_{DPP}$

RPFR is given by the equation:

[7] $$(s/s')f = \prod \frac{u_i}{u_i'}\frac{1-\exp(-u_i')}{1-\exp(-u_i)}\exp\frac{u_i'-u_i}{2}$$

where $u_i = hc\omega_i/kT$, and ω_i are the normal mode vibrational frequencies; the prime refers to the light isotopic molecule.

The calculation of the fractionation factor for the exchange between methanol and DPP in solution encounters certain difficulties. To begin with, the vibrational spectra of liquid MA are complex due to strong hydrogen bonding, and spectral data for methanol in the solvents of interest are incomplete. To our best knowledge there are no vibrational data for DPP. On the other hand, gas phase vibrational data for both methanol and DMP are available. The gas phase spectra of MeOH/MeOD reported by Serralah, Mayer, and Gunthard (11) have been used for the calculation of $(s/s')f_{MeOH}(v)$ (7). The gas phase spectra of Me_2PH were studied by Durig and Saunders (12) and those of Me_2PD by Clark and Drake (13). However, the assignments proposed by both sets of authors are doubtful. A better assignment, confirmed by a subsequent force field calculation, was given by McKean and McQuillan (14). Their data were used in our calculation of $(s/s')f_{DMP}(v)$.

Results and discussion

The experimental fractionation factors of deuterium and tritium over the temperature range of 283–330 K are collected in Table 1. Calculated values are also presented in Table 1. The experimental points deviate by 1–1.5% from the calculated ones. The fractionation factor, $\alpha_{MA/DPP}$, was used as the reference point for discussion of isotope fractionation in solution. It is equal to the ratio of $\alpha_{MA/DMP}(v)/\alpha_{DPP/DMP}(v)$ in which experimental values of $\alpha_{MA/DMP}(v)$ and the estimated D/H fractionation factor between DPP and DMP, $\alpha_{DPP/DMP} = 0.98$, at 250–330 K have been used. In addition, for greater completeness, the fractionation factors between liquid MA and DPP determined earlier (9) have also been included.

For all systems studied the fractionation factors are much larger than unity, which means that deuterium(tritium) accumulates in the hydroxyl group of methanol regardless of its solvation character. There is relatively little change between gas phase and solution values. The temperature dependence of the fractionation factors between methanol and diphenylphosphine in gas and in solution is shown in Fig. 1. The fractionation factors decrease regularly on going from gas to acetonitrile. In every case the temperature dependence can be described by a simple linear relation,

[8] $$\ln \alpha^{D}_{MA/DPP} = \frac{A}{T} + B$$

and *A* and *B* values are collected in Table 2. Equation [8] enables us to calculate isotope effects on the enthalpy changes for reaction [1] or [3]. Values ranging between 1.4 and 1.7 kJ/mol are reported in Table 2. It is worth noting that $\Delta(\Delta H^0)$ for deuterium exchange between methanol and hydrogen sulphide (2.4 kJ/mol) (7) is remarkably larger than that observed for the present solutions. Such a result could have been anticipated from the ZPE differences. There is a much smaller change in ZPE for the Ph_2PH/Ph_2PD pair than for the HSH/HSD one. Another interesting observation is the relatively small change in $\Delta(\Delta H^0)$ that occurs in the series from vapor through the range of solvents, C_2Cl_4 to pyridine (Fig. 1).

Before entering upon the discussion of these effects, let us first consider the experimental conditions. Usually the mole fractions of MA and DPP in C_6H_6, $(CH_2)_4O$, C_5H_5N, and CH_3CN were in the range of 0.04–0.08 and only in C_2Cl_4 solution were they larger (0.10–0.15). In such dilute solutions DPP exists mainly as monomer. It was shown earlier (6) that DPP interacts as a weak proton donor with various electron donors (for example tri-*n*-butylphosphine or diethylphosphide) with an energy of about 3 kJ/mol. It is likely in the present case that the interaction of DPP with the solvents used is also weak, and results in small or negligible differences between individual cases. The same refers to the solutions of deuterated DPP.

Table 2. The values of A and B parameters in the $\ln \alpha^D = A/T + B$ equation for the MA/DPP system and enthalpy changes $\Delta(\Delta H^0)$ in various solvents.

Solvent	A (K)	B	$\Delta(\Delta H^0)$ (kJ/mol)
Vapor*	199 ± 1	0.103 ± 0.002	1.67 ± 0.01
Vapor**	194 ± 7	0.108 ± 0.008	1.63 ± 0.06

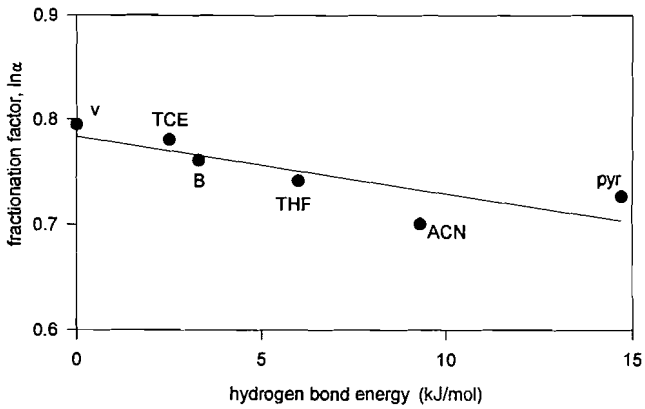
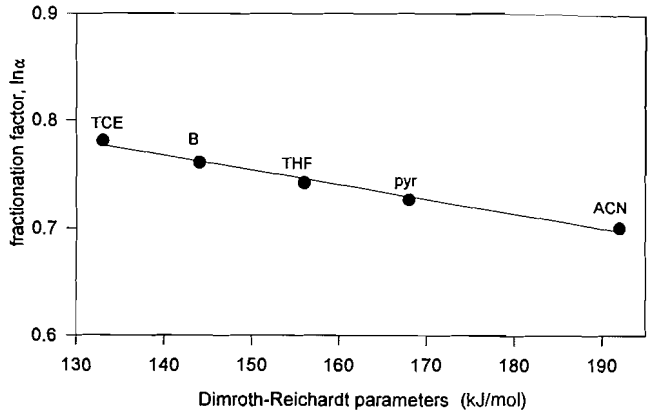
(v)*, (v)**, (v)*** have the same meaning as in Table 1.

Fig. 2. The correlation between the fractionation factor and hydrogen bond energy for the given methanol–solvent system (temperature 298 K).



For MA, on the other hand, the OH group interacts with the π-electrons of C_2Cl_4 and C_6H_6 and interacts via O—H...O and O—H...N hydrogen bonds with $(CH_2)_4O$, C_5H_5N, and CH_3CN. These interaction energies (6, 15–19) and, consequently, the solvation energies differ greatly and this should affect the observed fractionation factor. As can be seen from Fig. 2 there is a correlation between the fractionation factor and hydrogen bonding energy (15, 18, 19). An especially good correlation is found between the fractionation factor and the Reichardt E_T parameters (20) (Fig. 3). It is worth noting that an excellent correlation between fractionation factor and hydrogen bond energy was found earlier for $HX_2 + DX$ (X = F, Cl, Br, I) exchange reactions (21). Analysis of the isotope effect calculated from the vibrational data nicely confirms the suggested one-to-one correspondence between isotope effect and force field. The strongest correlation is with the stretching force constant. Even small changes in hydrogen bonding seriously affect the stretching force constant and this is reflected in the isotope effect. Therefore these results clearly show how the given solvent influences the intermolecular force field between methanol and solvent. The second correlation, which is evident between the fractionation factor and E_T, shows that

Fig. 3. The correlation between the fractionation factor and Dimroth–Reichardt parameters of the solvent (temperature: 298 K).



the isotope effect may be a very sensitive indicator of the electron charge distribution. In general, E_T parameters define the electron acceptor properties of the solvent and therefore this correlation is surprising. We would more likely expect a correlation with Gutman DN parameters (22). In this particular case E_T increases from TCE to pyridine; the isotope effects decrease in the same direction. It means, again, that the interaction between solvent and solute molecules seriously affects the solute force field. However, this time it is not the specific interaction centered on the hydrogen atom (more correctly, the OH bond) but the interaction involving oxygen electrons.

As far as the enthalpies of reaction are concerned, we observe some differences over the range of solvents studied. The changes are small but the tendency is clear: more polar solvents lower the enthalpy change. In general $\Delta(\Delta H)$ values correlate poorly with solvent parameters based on electron charge distribution.

It is worth noting that previously determined fractionation factors for the neat liquid MA/DPP system are consistent with the present results. They are placed between acetonitrile and pyridine, in qualitative agreement with the correlations described above (hydrogen bond energy in liquid methanol is reported as 9.3 kcal/mol (23)). It may be of some interest to compare the fractionation factor for the liquid MA/DPP system with those existing in the literature concerning hydrogen exchanges in OH, NH, SH, and PH groups. Most of these reactions were carried out with water; therefore the present result should be recalculated. This can easily be done since the fractionation factor between liquid methanol and water has been accurately determined ($\alpha_{MA/W} = 1.12$ at 298 K (24)). The simple calculation gives $\alpha_{W/DPP} = 1.81$. Since water is used as the reference substance it would be more appropriate to take the reciprocal of the latter, hence $\alpha_{DPP/W} = 0.55$. This is a very low value when compared with exchanges in OH and NH groups where, in most cases, values close to unity have been reported (25). For systems with very strong hydrogen bonding, fractionation factors much smaller than unity have been found (26). Although a small fractionation factor between H_2S and water in the gas phase ($\alpha_{HS/W} = 0.46$ (27)) has been also reported, its low value comes from the low stretching force constant of the SH bond. On the other hand, $\alpha_{DPP/W}$ can be

fairly well compared with the value 0.61 reported for PH_3(gas) + HDO(liquid) exchange (28). It seems, therefore, that the peculiar properties of the PH bond and very weak intermolecular interactions involving this group are responsible for the small value presently reported.

In conclusion, it seems that the most striking feature of the results obtained is the role of the solvent and its effect on the fractionation factor and enthalpy changes. We suggest that it is not the specific interaction between the OH(OD) group of methanol and the solvent but the charge redistribution of each molecule in the solvent shell that determines the force field shifts that result in the final isotope fractionation factor.

The thermolysis of ε-halodisilanes: a preference for 1,2-Si Si→O rearrangement or Si—O cleavage over Si=O bond formation

Christopher Roos, Graham A. McGibbon, and Michael A. Brook

Abstract: Tris(trimethylsilyl)-2,2,2-trifluoroethoxysilane **6**, tris(trimethylsilyl)-2-fluoroethoxysilane **7**, and tris(trimethylsilyl)-2-chloroethoxysilane **8** were synthesized and characterized by ^{1}H, ^{13}C and ^{29}Si NMR, IR spectroscopy, and EI and CI mass spectrometry. Thermodynamic considerations would suggest that, as a result of the driving force provided by the formation of a Si—F or Si—Cl bond, the thermolyses of these compounds would lead to the formation of bis(trimethylsilyl)silanone **4**. To examine this question, gas chromatography – mass spectrometry was as used a detection technique for products resulting from the high-pressure thermolyses of **6–8**. The elimination of $(Me_3Si)_3SiCl$ appears to be the major thermolytic pathway of decomposition for **8** at ambient or higher pressures, although it is accompanied by the formation of other products, some of which could have arisen from the addition of various halosilanes to a silanone. Neither **6** nor **7** thermolyzed cleanly; the former compound was essentially unreactive under the thermolysis temperatures used (850°C). Of the products produced in the thermolysis of **7**, no evidence for the formation of the silanone was obtained. Independently, mass spectrometry was used to study unimolecular reactions of molecular ions derived from **6–8**. The major route to solitary ions appears to involve a 1,2-trimethylsilyl migration from Si to O (**9→10**) prior to decomposition, for example, of the *m/z* 346 parent ion in the decomposition of **6**. The preparation of the ionized silanone may be a minor pathway. Some of the other fragmentation pathways for **6–8** are discussed.

Key words: gas phase thermolysis, ion rearrangements, silyl group migration, silanone, halosilane.

Résumé : On a synthétisé le tris(triméthylsilyl)-2,2,2-trifluorosilane, **6**, le tris(triméthylsilyl)-2-fluoroéthoxysilane, **7**, et les tris(triméthylsilyl)-2-chloroéthoxysilane, **8**, et on les a caractérisés par la RMN du ^{1}H, du ^{13}C et du ^{29}Si, par la spectoscopie IR et par spectrométrie de masse sous IC et IE. Les considérations thermodynamiques portent à penser que la thermolyse de ces composés pourrait conduire à la formation de bis(triméthylsilyl)silanone, **4**, en raison de la force directrice créé par la formation des liaisons Si—F ou Si—Cl. Pour vérifier cette hypothèse, on a utilisé comme technique de détection, la spectrométrie de masse couplée à la chromatographie en phase gazeuse, pour les produits résultant des thermolyses à haute pression des composés **6–8**. L'élimination du $(Me_3Si)_3SiCl$ semble être le processus thermolytique principal de décomposition du composé **8** à température ambiante ou à de plus hautes pressions, bien qu'il se forme d'autres produits dont quelques uns proviennent de l'addition de divers halosilanes sur la silanone. Ni le composé **6** ni le composé **7** ne subissent nettement la thermolyse; le premier composé ne réagit pas du tout aux températures de thermolyse utilisées (850°C). On n'a pas pu mettre en évidence la présence de silanone parmi les produits résultants de la thermolyse du composé **7**. D'une façon indépendante on a utilisé la spectrométrie de masse pour étudier la réaction unimoléculaire des ions moléculaires produits par les composés **6–8**. La principale voie d'accès aux ions solitaires semble impliquer une migration 1,2-triméthylsilyl à partir de Si à O (**9→10**) avant la décomposition, par exemple, de l'ion parent à *m/z* 346 résultant de la décomposition du composé **6**. La préparation de la silanone ionisée peut être un processus minoritaire. On discute de quelques autres voies de fragmentation.

Mots clés : thermolyse en phase gazeuse, réarrangement des ions, migration du groupe silyle, silanone, halosilane.

[Traduit par la rédaction]

Introduction

Since the turn of the century when Kipping first described materials alleged to contain the Si=O bond (1) (originally named silicones in analogy to ketones, now called silanones), much effort has been expended trying to observe these elusive species. The intermediacy of free silanones has been proposed for many reactions (2–9; however, see ref. 10). Much of the evidence for silanone formation is inferred from the presence of small silicone cyclics in reaction mixtures. Thus, hexamethylcyclotrisiloxane (D_3) and octamethylcyclotetrasiloxane (D_4) have been observed in the thermosylates of silylketenes (Scheme 1A, 11) and silylperoxides (Scheme 1B, 12), in the thermal decomposition of siloxetanes (Scheme 1C, 13), as products of retroene reactions (14), and in other reactions (Scheme 1D, 15, 16). Some of the clearest evidence for silanone formation results from the thermal decomposition of D_4; $Me_2Si{=}O$ formation is inferred from the initial first-order kinetics for the formation of D_3 (17, 18).

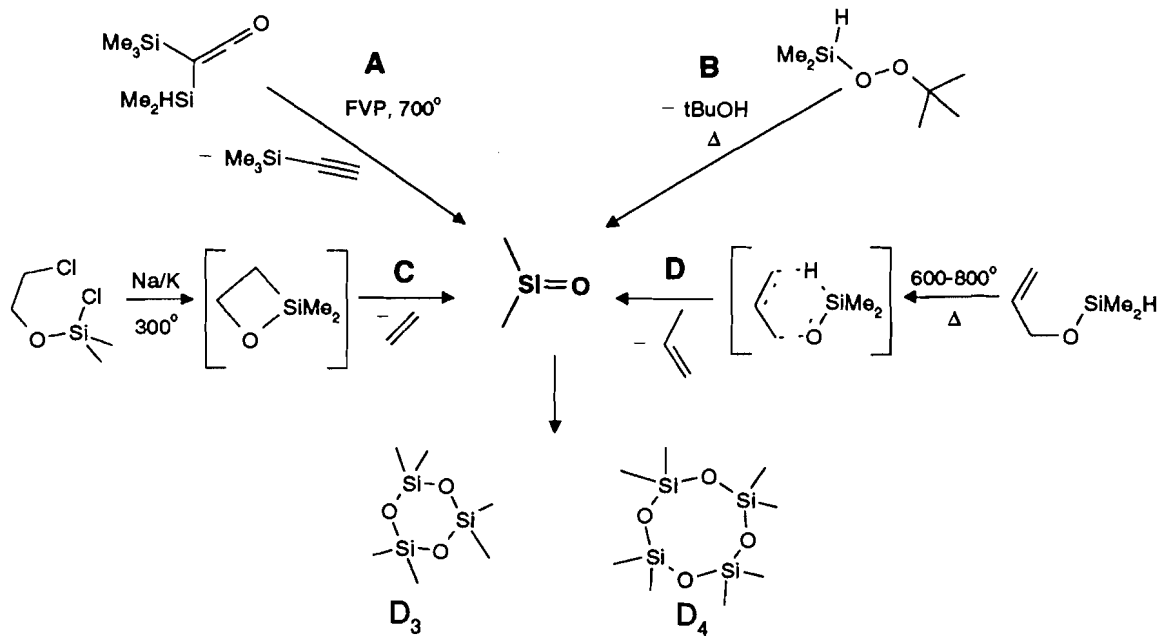
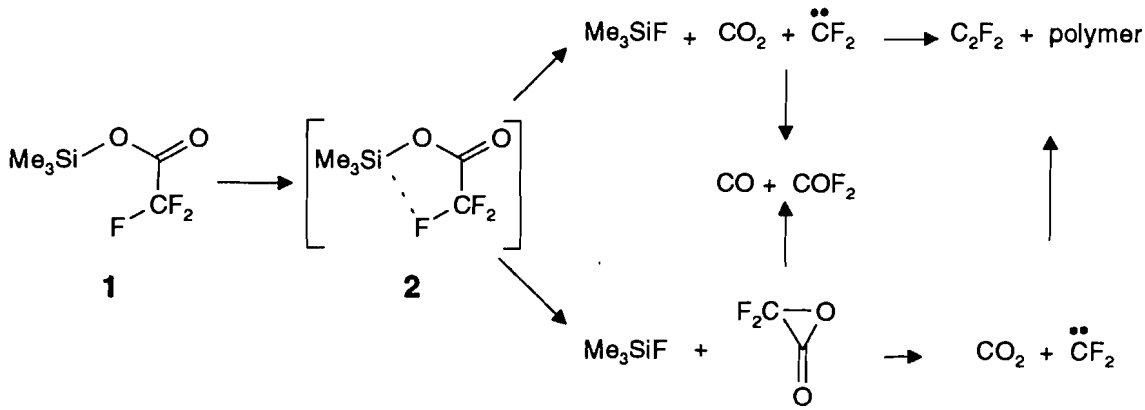
Scheme 1.



Scheme 2.



Although a few simple silanones ($R_2Si{=}O$, R = H, Me, Hal) have been characterized by a variety of spectroscopic techniques, including infrared spectroscopy at low temperature (19, 20), the bulk of the present knowledge of silanone properties originates from studies on transients (21, 22); the radical anion of $(t\text{Bu})_2Si{=}O$ has also been reported (23). Thus, unlike other silicon-based reactive intermediates (21), silanones constitute one of the few classes of compounds for which synthetic routes to stable species have yet to be developed.

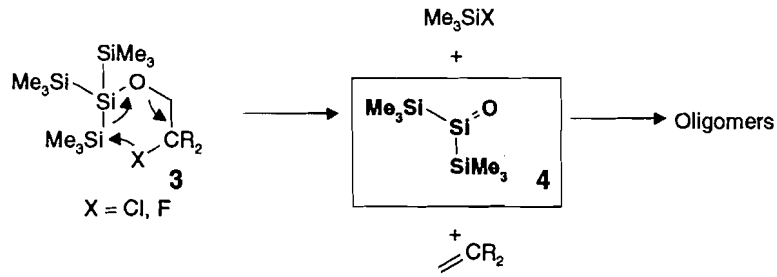
Fluoride-induced reactions

A variety of silicon-based, reactive intermediates have been generated by the rearrangement of suitable precursor molecules. Rearrangements and other reactions at silicon can be driven by the addition of silylnucleophiles (24). Many cleavage reactions involving Si—X (X = C, O, etc.) (25, 26) are known in silicon chemistry to be promoted by the formation of the very strong Si—F bond (~160 kcal mol^{-1}) (27). For instance, the rate of extrusion of Si—F from fluoroalkylsilanes has been measured (28, 29) and this approach has been used to drive the formation of bis(trimethylsilyl)diphenylsilene from (tris(trimethylsilyl)methyl)diphenylfluorosilane (30) via loss of Me_3SiF.

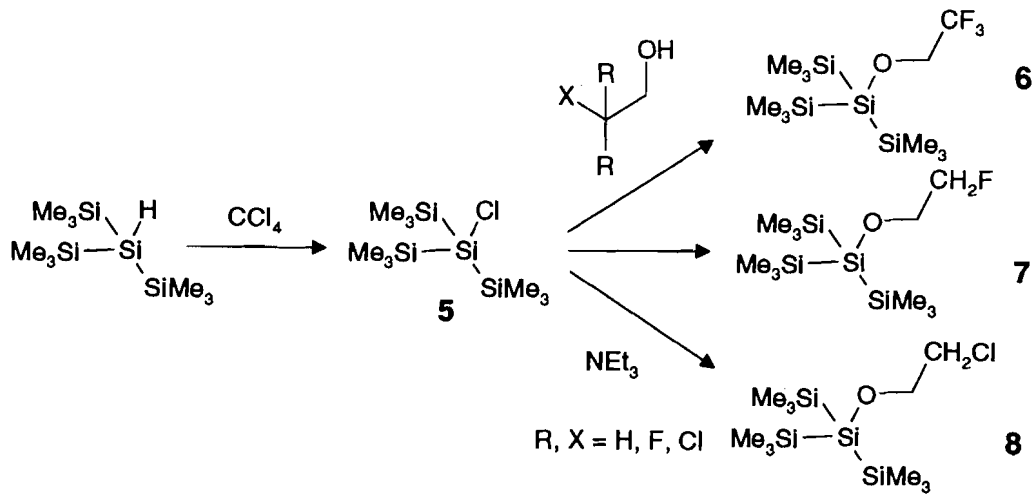
We have previously demonstrated that the thermal decomposition of esters can be facilitated by the formation of Si—F bonds (31). The decomposition of $F_3CCO_2SiMe_3$ **1** occurs at <725°C to give Me_3SiF whereas the nonfluorinated compound $H_3CCO_2SiMe_3$ was stable to >800°C. Similar results were observed with alkylsulfonic ester derivatives. The observed products from **1** are explained by the mechanisms proposed in Scheme 2. The reactions occur quite cleanly in spite of the fact that several features of these compounds disfavour reaction. For instance, the transition state must be a 5-membered ring **2** with a non-optimal geometry. Moreover, the thermodynamics of the formation of the three-membered ring are not very favourable.

The remarkable lack of side reactions in the examples shown above suggested the use of a similar mechanism to create silanones under comparably mild conditions and with as few by-products as possible. In this respect, compounds of

Scheme 3.



Scheme 4.



type **3** have several potential advantages (Scheme 3). A significant driving force for the reaction should be the formation of a Si—X bond. Although the absolute value for the Si=O π-bond strength is somewhat controversial (σ+π Si=O 90–190 kcal mol^{-1} estimated (21, 32, 33), 38–63 kcal mol^{-1} π-bond experimental (17, 18, 34)), our estimate of the overall enthapy of the decomposition of **3** (Scheme 3, X = F) is −42 kcal mol^{-1} (Si=O bond strength = 191 kcal mol^{-1} (π 63 + σ 128 kcal mol^{-1})) (21, 27). Secondly, the reaction should occur in a 6-membered ring transition state with a near optimal geometry (Scheme 3). This would yield bis(trimethylsilyl)silanone **4**, which will presumably oligomerize (8, 9). Thirdly, if followed, this reaction mechanism would yield at least two gaseous products (at room pressure). By removing the gaseous products, the probability of reactions between silanone and the by-products would be reduced and, additionally, the reaction would be forced to the product side. Finally, the entropy of the reaction should be very favourable, producing three molecules from one.

Our exploration of the thermal behaviour of compounds of type **3** is presented below. By changing the number and the kind of halides substituted at carbon-2 of the ethoxy group, we have attempted to relate the influence of halide substitution to thermal reactivity at different pressures. In addition to silanone formation, this study allows the exploration of other reaction pathways that could be initiated by Si—X bond formation: silicon compounds are known to undergo rearrangements in the gas phase (35). The reactions were examined using direct thermolysis and, additionally, molecular ions under mass spectrometric conditions.

Results and discussion

Preparation of compounds

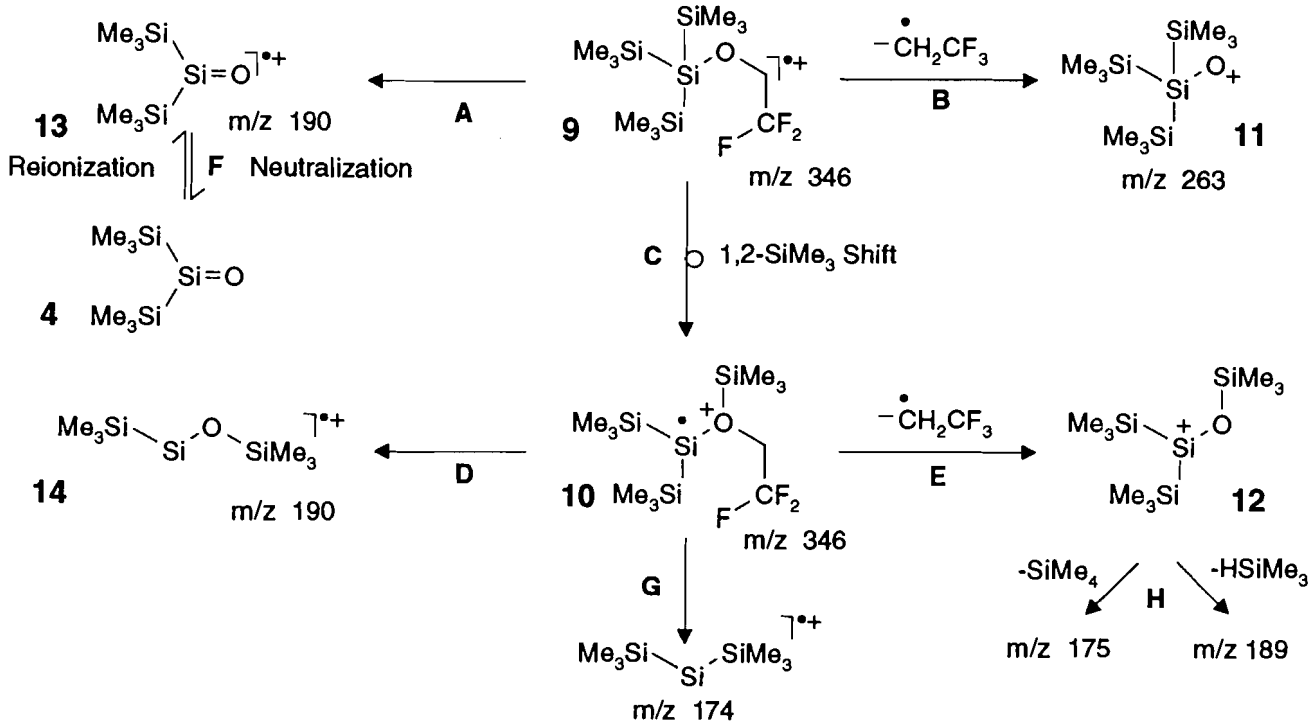
The sisyl (tris(trimethylsilyl)silyl) derivatives **6–8** were prepared from the readily available compound $(Me_3Si)_3SiCl$ **5** (Scheme 4). The reaction of the appropriate haloalcohols with **5** in the presence of base led to excellent yields of the compounds **6–8**. These compounds possess the requisite 1,6-halosilane relationship.

Unimolecular reactions of ions derived from 6–8

We initially chose to examine compounds **6–8** under conditions in which decomposition is unimolecular, in a sector field mass spectrometer. Under gas phase conditions, organosilicon ions have a high proclivity to rearrange (35). Therefore, in contrast to carbon-based ions, the reaction mechanisms involving silicon ions are, with some exceptions, poorly understood (36) in spite of the fact that labelling experiments have been utilized.

The mass spectra reported below were obtained on a ZAB-R spectrometer with BE_1E_2 geometry (37). We have examined the spectra of ions from the ion source and, additionally, metastable ion (MI) mass spectra to get more detailed information about the most energetically favourable dissociation pathways of the molecular and daughter ions. Very low vapour pressure

Scheme 5.



pyrolysis experiments were also performed.[3] The products were analysed by subsequent ionization and MS/MS experiments (metastable ion (MI)/collisionally activated dissociation (CAD), and Neutralization Reionization Mass Spectrometry (NRMS)) (38). The suggested structures for the ions in the various spectra below were based on comparison with examples for decomposition of related organosilicon ions (Scheme 5) (36, 37, 39).

Normal mass spectra of ***6–8***

The electron impact (EI) mass spectrum of **6** showed a molecular ion peak (M^+; *m/z* 346). Although in the EI mass spectra of **7** and **8** only relatively weak molecular ion peaks were observed, the chemical ionization spectra (CI) clearly showed peaks for the protonated molecules (*m/z* 310 and 327, respectively). The fragment ion peaks and corresponding abundances are reported in the experimental section. For **6**, **7**, and **8**, peaks at *m/z* 263, 131, and 117 were observed with similar abundance ratios in the EI spectra; not surprisingly, all spectra showed an abundant *m/z* 73 peak (Me_3Si^+). A high-resolution measurement of *m/z* 263 from **6** indicated the elemental composition $Si_4C_9H_{27}O$, which could correspond to either of the ions **11** and **12** (Scheme 5). We note that these ions are the Si- and O-trimethylsilylated ions of bis(trimethylsilyl)silanone, respectively.

MI and CAD mass spectra

Clearly, the ability to determine and distinguish isomeric ion structures would allow reaction mechanisms to be tested. MI mass spectra provide information about the most favourable (low energy) decomposition pathways. Therefore, MI spectra of *m/z* 346 and 263 from **6** were obtained.

The MI mass spectrum of the *m/z* 346 ion **9** and (or) **10** showed *m/z* 263 as the only intense peak. This decomposition step involving the loss of 83 mass units may be explained by the α-cleavage of the C—O bond and the loss of the radical $^{\bullet}CH_2CF_3$ (Scheme 5B,E) (40) with a prior or concomitant 1,2-$SiMe_3$ shift to yield **11** and (or) **12**. The latter is expected to be more stable than the former since the positive charge is on the silicon, although **11** cannot be excluded; the parent system H_3SiO^+ has been shown to favour the O-protonated silanone structure, $H_2Si{=}OH^+$, analogous to **12** (41).

There was also a very weak peak (5% of base peak *m/z* 263) at *m/z* 190 in the MI spectrum of the molecular ion of **6** (Scheme 5A). This fragment was not observed in the MI spectrum of *m/z* 263. The most optimistic interpretation for the *m/z* 190 peak is that its origin is the ionized silanone $(Me_3Si)_2Si{=}O^{\bullet+}$ **13** formed by a mechanism (Scheme 5A) analogous to that shown in Scheme 3. Based on the ionization potentials of the three proposed products, if formed, the silanone would be expected to be observed as the charged species; the relative ionization potentials are $(Me_3Si)_2Si{=}O$ 8.47 eV,[4] Me_3SiF 10.31 eV (31), and CH_2CF_2 10.29 eV (42). Unfortunately, due to its low intensity, we could not investigate the *m/z* 190 ions produced by metastable dissociation of the molecular ions in the second field free region of the instrument. Instead MI and CAD spectra were obtained from ions *m/z* 190 generated in the ion source.

CAD is commonly employed for ion structure determination (40). For CAD to be reliable, precursors leading to ions of

[3] Attempts to pyrolyze **6** in the mass spectrometer up to 520°C led to no significant change in its EI spectrum, consistent with its behavior in the DSC. Above this temperature minor changes in the intensities appeared but due to instrumental limitations it was not possible to raise the temperature any further than 580°C.

[4] Calculated using MOPAC (AM1), see experimental section.

unambiguous structure are required. Unfortunately, such precursors are not available in this case. Moreover, the propensity for organosilicon ions to rearrange renders CAD a less than definitive probe of structure (35). Perhaps not surprisingly, therefore, the CAD spectrum provided little help in establishing the structure of the *m/z* 190 ion.

NRMS is a technique that can facilitate structure determination and may also be utilized for the preparation of elusive neutrals. In the hope of observing a neutral silanone **4** from ion *m/z* 190, a NRMS experiment (43) was performed (Scheme 5F). Unfortunately, in the experiment on *m/z* 190, no survivor ion was observed. It is therefore impossible to draw a firm conclusion regarding the stability of the neutral (44).

The CAD spectrum of *m/z* 346 from **6** was dominated by *m/z* 263 and 174. Although the direct extrusion of $TMSOCH_2CF_3$ from **9** giving *m/z* 174 is possible, a more likely scenario is that *m/z* 174 arises from the rearranged *m/z* 346 ion **10** by direct bond cleavage yielding $Me_3SiSiSiMe_3^{+\bullet}$ **14**, a silylene radical cation (Scheme 5G).

The base peak in the CAD spectrum of *m/z* 263 is *m/z* 73 $SiMe_3^+$, leaving the structural elements of the silanone as the neutral. The picture is complicated, however, by the observation of abundant peaks at *m/z* 117, 131, 147, 175, and 189. The latter two of these, which correspond to the elimination of Me_3SiH and Me_4Si, respectively, are also observed in the MI spectrum of *m/z* 263 from **6**, indicating that rearrangement takes place prior to dissociation (Scheme 5D).

Fragmentation pathways

Based on the results from **6**, there are two low-energy, decomposition pathways occurring under these conditions. The first, albeit minor pathway, may involve the desired decomposition of the molecular ion **9** to, among other things, the silanone derivative $(Me_3Si)_2Si{=}O^{\bullet+}$ (Scheme 5A). Our results, however, do not permit the distinction between this structure and the isomeric silylene derivative $Me_3SiSiOSiMe_3^{\bullet+}$ (Scheme 5D). Calculations on the parent compounds (H replacing Me groups) suggest that while the two structures are nearly isoenergetic, there is an extremely high energy barrier to interconversion (32).[5] Thus, if the silanone is formed in the rearrangment, it is unlikely to isomerize. The second and major pathway involves initial migration of $SiMe_3$ in the molecular ion to give **10**. Subsequent daughter ions are consistent with this proposal (Scheme 5). We believe the presence of strong *m/z* 263 peaks in the normal mass spectra of **6–8** suggests the Me_3Si Si→O migration is occurring in the decomposition paths of ions derived from all three molecules.

Thermolysis under ambient or elevated pressure: GC–MS characterization

The compounds **6–8** were also thermolysed at higher pressure in a sealed tube for the purposes of comparison with the low-pressure thermolysis results described above. Under such conditions, more complex reactions will clearly occur. While it was impossible under such circumstances to conclusively determine if silanones were present, we report here preliminary results that are consistent with product derived from silanones, arising from the reaction shown in Scheme 3.

Differential scanning calorimetry (DSC)

To determine the decomposition temperatures of the three compounds, DSC measurements (45) of each were taken from 25–600°C. Compound **6**[3] showed essentially no reactivity in this temperature range whereas **7** showed endothermic signals at 297°C and 320°C and an exothermic signal at 322–327°C. The DSC of **8** shows an exothermic signal between 220 and 250°C and a sharp endothermic signal at 264.6°C.

Sealed tube thermolysis

The three compounds were thermolysed in sealed tubes above their decomposition temperatures: **6** was heated at 850°C,[3,6] **7** and **8** at 350°C for a period of 10 min, respectively. The thermolysis of **6** yielded a brown solid, the constituents of which could not be ascertained, **7** a colourless oil, and **8** a yellow oil. The volatile products of the latter two compounds were separated under vacuum and analysed by mass spectrometry; the oils were analysed by GC–MS (45). Only the major products are taken into consideration in the discussion.

Compounds **7** thermolysed to a number of products (Table 1, Table 3) most of which were minor components. There were two primary products in addition to recovered starting material (total yield 75%). In addition to the difficulties in identifying the structure of silicon-containing ions mentioned above, fluorine-containing compounds often have the characteristic of showing a weak molecular ion peak in their mass spectra. The proposed structures of the two species **15** and **16** shown in Table 1 are consistent with the mass spectral data. The formation of **15** and **16** could have arisen from the insertion of $(Me_3Si)_2Si{:}$, analogous to **14** (vide supra), into the starting material and $(Me_3Si)_3SiF$, respectively. No peak at *m/z* 190 was observed in the mass spectra of any of the compounds. The presence of fluorine-containing fragments that do not contain the CH_2CH_2 fragment in **15** suggests that while extrusion of Si-F compounds is occurring, it is the wrong silicon that is undergoing reaction for formation of the silanone (i.e., $FSi(SiMe_3)_3$ versus $FSiMe_3$).

The decomposition of **8** was not nearly as clean as that of **7** as can be seen from Table 4. The major product of the thermolysis of **8** could be clearly identified as tris(trimethylsilyl)chlorosilane **5** by comparison to the GC and MS data of the pure compound. Three other compounds are of particular interest. For instance, the compound obtained at 9.1 min could be an addition product of silanone **4** and chlorotrimethylsilane with *m/z* 298 (M^+) as highest ion mass (**17**, Table 2). The remaining two, the products **18** and **19** at 11.8 and 17.2 min, respectively, have peaks at *m/z* 299 and thus also incorporate the constituents of $(Me_3Si)_2Si{=}O$ and a halosilane. One can envision higher molecular weight products containing these fragments that could have arisen during the thermolysis. Although many pathways could lead to **19**, it is not only tantalizing but reasonable to consider the possibility that it was indeed formed from the addition of **5** to the silanone. Otherwise, its formation would have to involve C—O bond cleavage, a rearrangement, and a bimolecular hydrogen, methyl, or chloride exchange.

[5] The high barrier is present for the neutrals and in this argument we assume that a reasonably high barrier to interconversion will also exist for the analogous ion; the simplest silanone/silylene cations and neutrals do not interconvert in similar MS experiments (41).

[6] It was not possible to establish the threshold decomposition termperature for **6**.

Scheme 6.

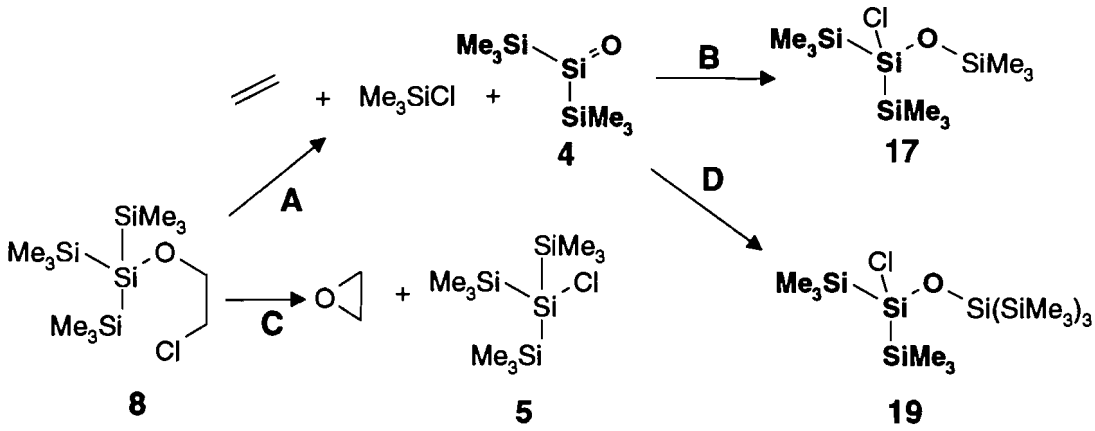


Table 1. Major product distribution of the thermolysis of **7**.

Time (min)	% Composition	Proposed structure
12.7	46.6	**7**
27.0	14.4	 **15**
29.6	23.3	 **16**

Table 2. Major product distribution of the thermolysis of **8**.

Time (min)	% Composition	Probable structure
9.1	6.4	**17** $(Me_3Si)_2SiClOSiMe_3$
11.5	28.1	**5** $(Me_3Si)_3SiCl$
11.8	5.8	**18** Cl,[a] 3 × $SiMe_3$, O
17.2	14.8	**19** Cl,[a] 3 × $SiMe_3$, O

[a]The indication Cl, indicates the fragment contains Cl as shown by the isotopic pattern for $^{35}Cl/^{37}Cl$.

Similarly, the other products could arise by addition of a silanone to a halosilane.

The mechanistic proposal outlined above suggested that the formation of a Si=O bond could be driven by the formation of a Si–halogen bond (Scheme 6A). While the migration of a halogen to a $Si(SiMe_3)_3$ group seems to have been the dominant process in the decomposition of **8**, and may also be occurring in the thermolysis of **7**, it was not the desired reaction (Scheme 6C). Nonetheless, the product mixture from **8** contains species that are likely to have arisen from the coupling of silanone **4** with halosilanes (Scheme 6B,D) suggesting that silanone formation is a minor reaction pathway in this thermolysis.

Conclusion

High-pressure thermolysis

There is little experimental evidence to support the involvement of the six-membered transition state as more than a minor decomposition pathway (Scheme 3) for compounds **6–8**. The reaction products of the sealed tube thermolysis of **8** were the most encouraging; many adducts could have arisen from a silanone addition or insertion reaction. The major product of decomposition, however, was $(Me_3Si)_3SiCl$, which would have involved a five-membered transition state if formed in a unimolecular reaction.

In the case of the fluoro compounds **6** and **7**, none of the products of a sealed tube thermolysis showed any indication of involving silanones in their formation. Although low reactivity is often associated with fluoroalkanes (the "Teflon effect"), reflecting the strength of the CF bond, it is somewhat surprising that the even greater bond strength of the SiF bond that would be formed in reactions like that in Scheme 3 was not strongly manifested in the reactions examined. We attribute this observation to a kinetic stability, and believe our original proposal that it should be possible to drive this reaction on enthalpic grounds remains valid: a more reactive intramolecular fluoride delivery system is needed.

Ion decomposition

At low pressures, the unimolecular decomposition of all three compounds followed two major pathways. The most important of these seemed to involve a Si→O $SiMe_3$ migration prior to subsequent decomposition. The minor pathway might involve the desired decomposition to silanone.

Experimental

For preliminary quality checks, ^1H NMR spectra were obtained on a Varian EM-390 (90 MHz) continuous wave spectrometer with $Si(CH_3)_4$ or $CHCl_3$ as an external reference. Otherwise, ^1H and ^{13}C NMR spectra were obtained on Bruker AC-200 (200.1 MHz for ^1H NMR or 50.3 MHz for ^{13}C NMR) spectrometer. Spectra were referenced to the solvent signal of chloroform (contaminant in $CDCl_3$, at 7.24 ppm for ^1H NMR; at 77.0 ppm (t) for ^{13}C NMR) or C_6H_6 in benzene-d_6 (at 7.15 ppm (br) for ^1H NMR). ^{29}Si NMR were performed on a Bruker AC-300 (at 59.63 MHz for silicon) using tetramethylsilane as external standard. NMR data are given in ppm and coupling constants are recorded in hertz. The abbreviations s = singlet, d = doublet, t = triplet, dd = doublet of doublets, dt = doublet of triplets, m = multiplet, and br = broad are used in reporting the spectra. Infrared spectra of a neat film on a KBr window or

of solids as KBr pellets were run on a Perkin–Elmer 283 spectrometer or on a BioRAD FTS 40 spectrometer equipped with a SPC 3200 data station; peaks are noted as strong s, medium m or weak w. The IR data are given in cm^{-1}. Ultraviolet–visible spectra were recorded on a Hewlett Packard HP 8451A Diode Array spectrophotometer.

EI (70 eV), CI (NH_3), and high-resolution mass spectra were obtained on a VG analytical ZAB-E mass spectrometer with a VG11-250 data system. The theoretical mass of the molecular ion was calculated from the masses of the most common isotopes (46). Pyrolysis – mass spectrometric experiments and metastable ion (MI), collisional activated dissociation (CAD), and neutralization–reionization (NRMS) mass spectrometry were performed on a VG Analytical ZAB-R instrument that has BE_1E_2 geometry (B=magnetic, E=electric sector). *N,N*-Dimethylaniline was used for neutralization while O_2 was used as a collision gas (transmission = 70% at each collision) for reionization and CAD.

Gas chromatography – mass spectrometry was performed on a Hewlett Packard 5890 Series II gas chromatograph, using a DB-5, 30 m column, 0.20 mm i.d., attached to a Hewlett Packard 5971A mass selective detector. Gas chromatography was performed on a Hewlett Packard 5890 gas chromatograph with a TCD detector and a Hewlett Packard 3393A integrator using a SPB-1, 30 m, 1.0 μm i.d. column and helium as reference and carrier gas. Melting and decomposition points were measured by a General V4.1C DuPont 2100 differential scanning calorimeter (DSC).

Sources of materials

2-Chloroethanol, 99% $ClCH_2CH_2OH$; triethylamine, 99+% $(CH_3CH_2)_3N$; 2,2,2-trifluoroethanol, 99+% F_3CCH_2OH; and tris(trimethylsilyl)silane, 97% $(Me_3Si)_3SiH$ were obtained from Aldrich and were used from a freshly opened bottle without further purification. The purity was checked by TLC, ^1H NMR, and GC. 1,1,1,3,3,3-Hexamethyldisilazane, 98% $((CH_3)_3)_2SiNH$, was obtained from Aldrich and was distilled before use. $CDCl_3$ (99.8 at.% D), cyclohexane-d_{12} (99.6 at.% D), and benzene-d_6 (99.6 at.% D) were obtained from Isotec Inc. and were used without purification from a new fresh bottle or from freshly opened ampoules.

Purification of solvents

Hexanes and diethyl ether were freshly distilled over sodium–benzophenone under a nitrogen atmosphere. Carbon tetrachloride was stirred hot with 10% by volume of concentrated alcoholic KOH, washed with water, dried over $CaCl_2$, and freshly distilled from P_2O_5 under a nitrogen atmosphere (47).

General experimental procedures for synthesis

Due to the instability of the reagents towards hydrolysis, all syntheses were performed with dry glassware under an atmosphere of anhydrous nitrogen. Addition and transfer of solvents and reagents were done using syringe-septa techniques or using a glove-bag that was dried with anhydrous phosphorus pentoxide (P_2O_5) and continuously purged with anhydrous nitrogen.

The reactions were followed by thin-layer chromatography (TLC) using a closed TLC chamber, hexanes–ether (1:2) as solvent, and Merck plastic-backed aluminum oxide, 60 F254 neutral (type E) precoated, 6.5 × 2.5 mm TLC sheets. For the separation and purification of the products a Chromatotron (model 7924T) of Harrison Research Inc. was used. The plates, 0.1 or 0.4 mm thick, were prepared with silica gel 60 PF254, containing gypsum.

*Synthesis of tris(trimethylsilyl)chlorosilane ($(Me_3Si)_3SiCl$) **5***

The method of Bürger et al. (48) was used to synthesize **5** as follows: In a 50 mL round-bottom flask equipped with reflux condenser, tris(trimethylsilyl)silane (8.63 mL, 0.028 mol) was added dropwise with stirring to dry CCl_4 (11.6 mL, 0.12 mol) and stirred for 20 h. After the evaporation of $HCCl_3$ and excess CCl_4, 6.45 g (0.0228 mol, 76%) of a white solid remained. The product was cleaned by sublimation; mp ~50°C (48); IR (KBr) ν: 2952 s, 2924 s, 1458 w, 1257 m, 1247 s, 839 vs, 746 w, 692 m, 622 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.21 (s); MS (*m/z* reported for the ^{28}Si and ^{35}Cl isotope (%)): EI *m/z*: 282 (8) (M^+), 267 (30), 247 (20), 174 (100), 159 (35), 131 (23), 117 (15), 73 (70), 59 (10); CI *m/z*: 282 (12), 264 (13), 191 (68), 174 (25), 133 (28), 90 (100), 73 (20), 52 (17).

*Synthesis of tris(trimethylsilyl)-2,2,2-trifluoroethoxysilane ($(Me_3Si)_3SiOCH_2CF_3$) (**6**)*

In a 50 mL two-neck round-bottom flask **5** (1.00 g, 3.54 mmol) was dissolved in dry hexanes (3 mL). Slowly 2,2,2-trifluoroethanol (0.51 mL, 7.06 mmol) and triethylamine (0.49 mL, 3.53 mmol) were added dropwise with stirring. The reaction mixture formed two layers. After 24 h of vigorous stirring, the solid was filtered off and the solvent and remaining reagents were removed under vacuum. A white waxy solid (0.873 g, 2.54 mmol, 72%) remained. The product was purified on the Chromatotron using hexanes as solvent; mp 112°C; bp 311°C; IR (KBr) ν: 2952 s, 2855 m, 1454 w, 1397 w 1290 s, 1246 s, 1156 vs, 1130 vs, 964 m, 835 vs, 762 m, 724 m, 688 m, 622 w, 543 w cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.18 (s, 27 H), 3.74 (q, 2 H, $^3J_{F-H}$ = 8.6 Hz); ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ: 109.39 (s), 65.61 (q, $^1J_{F-C}$ = 35.6 Hz), 0.02 (s); ^{29}Si NMR ($CDCl_3$, 59.6 MHz) δ: 12.13 (s), −14.76 (s); MS (*m/z* reported for the ^{28}Si isotope (%)): EI *m/z*: 346 (6) (M^+), 331 (10), 263 (33), 251 (32), 247 (19), 193 (32), 174 (100), 159 (23), 131 (29), 73 (48), 59 (4); CI, *m/z*: 364 (9) ($M^+ - NH_4$), 348 (3), 331 (13), 264 (43), 210 (10), 191 (33), 174 (25), 148 (16), 133 (14), 90 (100), 73 (38), 59 (15); HRMS calcd. for $C_{11}H_{29}OSi_4F_3$: 346.1248; found: 346.1261.

*Synthesis of tris(trimethylsilyl)-2-fluoroethoxysilane ($(Me_3Si)_3SiOCH_2CH_2F$) (**7**)*

Synthesis similar to **6**: **5** (1.646 g, 5.83 mmol), with dry hexanes (5 mL), 2-fluoroethanol (0.68 mL, 0.012 mol), triethylamine (0.81 mL, 5.81 mmol), with 1.644 g (5.3 mmol, 91%) of a white waxy solid remaining; mp 122°C; bp 296°C; IR (KBr) ν: 2951 s, 2895 m, 2857 w, 1449 w, 1397 w, 1368, w, 1246 vs, 1123 vs, 1104 s, 1055 m, 937 m, 866 vs, 838 vs, br, 711 m, 688 s, 623 m, 469 w cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.18 (s, 27 H), 3.67 (dt, $^3J_{F-H}$ = 27.43, $^3J_{H-H}$ = 4.4 Hz), 4.38 (dt, $^2J_{F-H}$ = 47.6, $^3J_{H-H}$ = 4.3 Hz); ^{13}C NMR ($CDCl_3$, 50.3 MHz) δ: 83.09 (s), 66.94 (d, $^1J_{F-C}$ = 21.0 Hz), 0.20 (s); ^{29}Si NMR ($CDCl_3$, 59.6 MHz) δ: 5.70 (s), −15.61 (s); MS (*m/z* reported for the ^{28}Si isotope (%)): EI, *m/z*: 263 (23), 251 (6), 193 (7), 175 (9), 131 (44), 117 (11), 73 (100); CI, *m/z*: 328 (48), 311 (100), 264 (98), 251 (30), 192 (11), 148 (13), 128 (13), 90 (45), 73 (17); HRMS (no molecular ion was visible (in EI)) calcd. for $C_9H_{27}OSi_4$: 263.1139; found: 263.1142.

[a] **20** ($Me_3SiOCH_2CH_2Cl$) was not observed.
[b] The designation Cl indicates the fragment contains chlorine; there is a corresponding peak 2 amu higher with an abundance in the correct ratio for $^{35}Cl/^{37}Cl$.

added dropwise under stirring into 2-chloroethanol (2.54 mL, 3.052 g, 37.8 mmol). The evolution of a gas (basic on pH paper) and the formation of a white solid was observed. After no more evolution of gas (NH_3) was observed, a cooling trap (acetone – Dry Ice) was added to the gas outlet and a smooth stream of nitrogen was passed through the system for 24 h. Every 6 h the trap was emptied. The first fraction had to be cleaned by distillation due to contamination by starting material; the last three fractions were pure product: 4.962 g (3.25 mmol, 86%) of a colourless liquid were obtained; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.11 (s, 9H), 3.78 (t, 2 H, $^3J_{H-H}$ = 6.1 Hz), 3.51 (t, 2 H, $^3J_{H-H}$ = 6.1 Hz).

Reactions

MI/CAD and NRMS experiments
These experiments were performed as previously reported (37).

Thermolysis at ambient pressure
DSC experiments of **6**, **7**, and **8** were performed in a temperature range from 25 to 600°C. **6** showed no reactivity in this temperature range, whereas **7** showed an endothermic signal at 320°C that changed to exothermic. The DSC of **8** showed an exothermic signal between 220 and 250°C and a sharp endothermic signal at 265°C.

Thermolysis at elevated pressure
6 (0.066 g, 0.19 mmol), **7** (0.062 g, 0.20 mmol), or **8** (0.06 g, 0.18 mmol) was independently sealed in a quartz tube with a volume of 25.5 cm^3 under pressure of 10^{-6} Torr (1 Torr = 133.3 Pa). **6** was heated at 850°C, **7** and **8** at 350°C for 10 min. **6** yielded a dark brown solid, **7** a colourless oil, and **8** a yellow oil. The tubes were cooled with liquid nitrogen, opened, and connected to a distillation apparatus. The volatile products were separated under vacuum. The remaining oils were analyzed by GC–MS. The chromatogram of **7** and **8** showed 39

and 57 compounds, respectively, most of them with less than 3 area%. The MS fragment patterns of the major products are shown in Table 3 and Table 4, respectively, with spectral assignments when these are clear; only the major products were taken into consideration in the discussion.

AM1 calculations of 4

Semi-empirical calculations of **4** were carried out on a Comptech 88486/33 MHz computer system with DOS 6.2 as operating system using Hyperchem™ (AM1) under MS Windows. The initial geometries were obtained by molecular mechanics calculations using PC-Model (version 3.1; Serena Software; Bloomington, Ind.) under DOS 6.2.

(Alkylthio)- and (phenylthio)methoxycarbenes from oxadiazolines

Hui-Teng Er, David L. Pole, and John Warkentin

Abstract: Four 2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines bearing an alkylthio or arylthio group at C2 were prepared. The oxadiazolines undergo thermolysis at 60–80°C in solution to afford the corresponding oxythiocarbene intermediates. In the absence of carbene traps, dimers of the carbenes were formed. The carbenes were trapped with ethyl crotonate, with dichloromaleic anhydride, with dimethyl acetylenedicarboxylate, and with phenyl isocyanate. Phenyl isocyanate traps methoxy(methylthio)carbene to form two types of adducts, both fundamentally different from the product obtained from reaction of dimethoxycarbene with phenyl isocyanate. All of the adducts have structures consistent with nucleophilic behaviour of the carbenes.

Key words: oxythiocarbene, oxadiazoline, thermolysis, nucleophilic.

Résumé : On a préparé quatre 2-méthoxy-5,5-diméthyl-Δ^3-1,3,4-oxadiazolines portant un groupe alkylthio ou arylthio en C2. Les oxadiazolines subissent une thermolyse vers 60 à 80°C, en solution, pour conduire aux oxythiocarbènes intermédiaires correspondants. En présence de pièges à carbène, il y a formation des dimères des carbènes. Les carbènes peuvent être piégés par le crotonate d'éthyle, l'anhydride dichloromaléique, l'acétylènedicarboxylate de diméthyle et l'isocyanate de phényle. L'isocyanate de phényle piège le méthoxy(méthylthio)carbène pour former deux nouveaux types d'adduits qui sont tous deux fondamentalement différents du produit obtenu par réaction du diméthoxycarbène avec l'isocyanate de phényle. Tous les adduits ont des structures qui sont en accord avec le comportement nucléophile des carbènes.

Mots clés : oxythiocarbène, oxadiazoline, thermolyse, nucléophile.

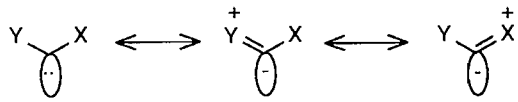
[Traduit par la rédaction]

Introduction

Singlet carbenes bearing donor substituents can have ambiphilic or nucleophilic properties (1). These properties result from conjugative donation of electron density into the formally vacant *p*-orbital of the singlet, Scheme 1. The importance of the dipolar contributor is a factor that determines the philicity of the carbene carbon. Dimethoxycarbene, for example, attacks phenyl isocyanate (2) as depicted in Scheme 2, and it reacts with maleic anhydrides (3) as shown in Scheme 3. The products are readily accounted for in terms of initial carbonyl addition to form a dipolar intermediate.

The availability of the exchange method (Scheme 4) for synthesis of various dioxy oxadiazolines from 2-acetoxy-2-methoxy-Δ^3-1,3,4-oxadiazolines (**1**) (4) suggested that it might be possible to prepare 2-alkylthio- and 2-arylthio-2-methoxy-Δ^3-1,3,4-oxadiazoline analogues of **2**, Scheme 4. Their thermolysis would be expected to take the cycloreversion – ylide fragmentation sequence that 2,2-dialkoxy oxadiazolines appear to follow (2*a*, 3–5), leading to (alkylthio)methoxycarbene analogues of **3***a* and corresponding

Scheme 1.



(arylthio)methoxycarbene analogues of **3***b*, Scheme 4, for convenient study of their chemical reactions. Such carbenes have not been reported, to the best of our knowledge.

Methods, results, and discussion

2-Acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**) containing ca. 30% of acyclic by-product **4** was prepared by oxidation of the methoxycarbonyl hydrazone of acetone with Pb^{IV} acetate in CH_2Cl_2 as previously described (4), Scheme 5.

Treatment of the mixture of **1** and **4** with the appropriate thiol (Scheme 6) afforded **5** contaminated with **4**. Destruction of **4** with aqueous base and chromatography of the residue afforded pure **5** in yields ranging from 44 to 80% for the exchange step of Scheme 6. Their spectroscopic properties are given in the experimental section.

Thermolysis of compounds **5***a–c* in benzene was followed by ^1H NMR spectroscopy. Disappearance of **5** was first order in each case and the first-order rate constants were the same within experimental error: $k(60°C) = 2.07(\pm 0.09) \times 10^{-5}$ s^{-1}. While the effect of the sulfur-bound group (R) at C2 on the thermolysis rate constant is very small, the sulfur atom itself has a significant rate-enhancing effect, for 2,2-dimethoxy-5,5-

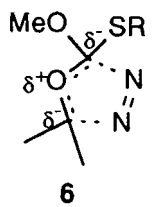
dimethyl-Δ^3-1,3,4-oxadiazoline undergoes thermal cycloreversion with a comparable rate constant at a temperature 40° higher, i.e., 100°C (2*a*). One potential source of the rate enhancement by a thio substituent is the polarizability of sulfur. Most likely, negative charge develops at positions 2 and 5 of the oxadiazoline as the ylide-like transition state (**6**) develops. Sulfur substitutents exert an anion-stabilizing role, as in anion equivalents generated from 1,3-dithiane. A second source of the rate enhancement could be a ground state energy difference between thio and oxy analogues. The 2,2-dimethoxy oxadiazoline has four electronegative moieties attached to C2, compared to three plus a sulfur-bound group for **5***a*–**5***c*. Clumping electronegative groups on the same carbon atom has the surprising effect of increasing thermodynamic stability (6).

Thermolysis of **5** in benzene afforded the corresponding carbene dimers **7** and **8** (Scheme 7), in yields ranging from 55 to 65%. The *E*:*Z* ratios ranged from 1.2 to 1.8, Table 1.



6

Table 1. Yields and isomer ratios.

Oxadiazoline	Thermolysis product		*E* : *Z*
5*a*: R = Ph	**7***a*: 35%	**8***a*: 20%	1.8
b: R = CH_2Ph	*b*: 32%	*b*: 27%	1.2
c: R = Et	*c*: 38%	*c*: 27%	1.4
d: R = Me	*d*: 32%	*d*: 27%	1.2

Preliminary assignment was based on the observation that the major product was eluted first during chromatography and that it ought to be the *E* isomer, in which all dipole vectors should cancel. That assignment was subsequently confirmed by means of the single crystal X-ray structure of **7***b*.[2] The fact that carbene dimers and acetone were major products suggests that all four oxadiazolines (**5**) fragment thermally to form N_2 and a carbonyl ylide, and that the latter fragments efficiently to afford the appropriate carbene and acetone (Scheme 7). A competitive 1,3-dipolar cycloreversion of **5***a* afforded methyl phenylthio carbonate (**9**) and, presumably, 2-diazopropane, Scheme 8.

In the ^{13}C NMR spectra of the carbene dimers, the vinyl

[2] Publication of the crystal and molecular structures will be delayed in the expectation that the data could be made more meaningful by inclusion of the structure of a *Z* isomer.

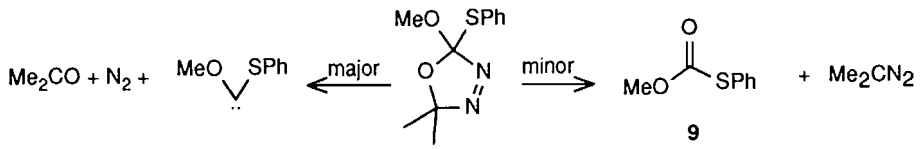
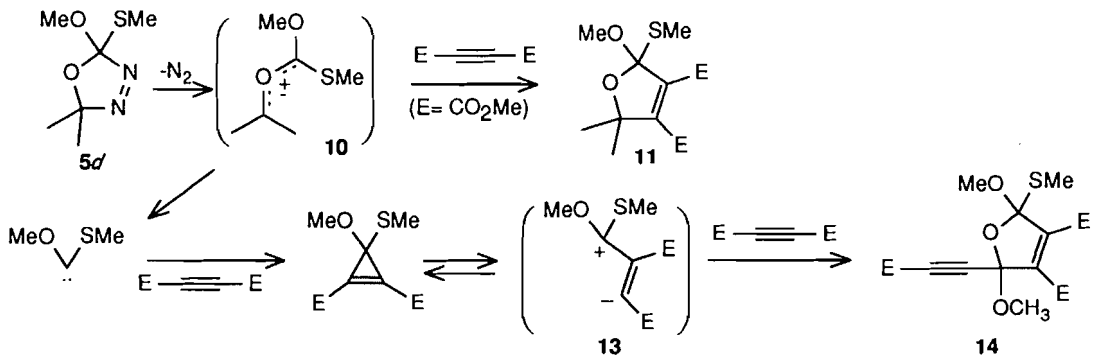
Scheme 8.



Scheme 9.



carbon signals are near δ = 143 in **7**(*a–d*) and **8**(*a–d*). For comparison, the vinylic signals of 1,2-dimethoxy-1,2-diphenoxyethenes occur near δ = 138, and those of tetraalkoxyethenes near δ = 141 (7).

Experiments designed to intercept reactive intermediates were revealing. Initial cycloreversion to N_2 and a carbonyl ylide (**10**) was inferred for the case of **5***d* from a reaction with dimethyl acetylenedicarboxylate (DMAD). The reaction mixture was complex, but it was possible to isolate what is formally the ylide–DMAD adduct (**11**), Scheme 9, along with some carbene–DMAD adduct (**14**). This result indicates that a concerted mechanism recently proposed by Smith (8), leading from a 2,2-dialkoxyoxadiazoline analogue of **5** *directly* to carbene, N_2, and acetone, may not be general. However, there is an alternative mechanism for formation of **11**, involving cycloaddition of a carbene–DMAD dipolar adduct to acetone. The fact that the acetone concentration started at zero, and remained below the final DMAD concentration throughout, makes that mechanism less likely. Nevertheless, additional experiments are needed to secure the origin of **11**.

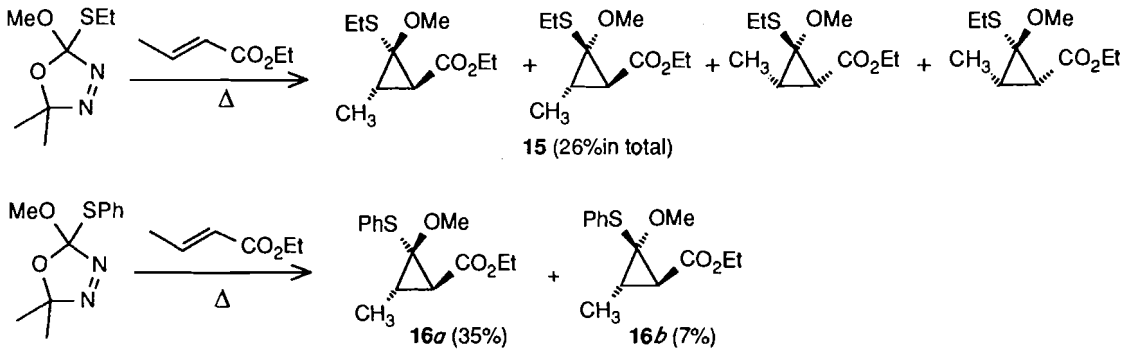
Cycloadducts from an ylide intermediate were not obtained with the other trapping agents, ethyl crotonate, dichloromaleic anhydride, or phenyl isocyanate. Possibly the fragmentation of the ylide to carbene and acetone is fast and only very reactive dipolarophiles can compete at relatively low concentrations (ca. 0.1 M). The overall 1:2 stoichiometry leading to **14** (Scheme 9) for reaction of (methoxy)methylthiocarbene with DMAD has been reported for the case of dimethoxycarbene by Hoffmann et al. (9). A dipolar adduct similar to **13**, with vinyl carbene character, was proposed (9), Scheme 9. The reason for addition to a carbonyl group of DMAD in the second step, rather than to the triple bond, is not well understood. Steric hindrance may be responsible, in part.

Ethyl crotonate intercepted carbene intermediates although not their carbonyl ylide precursors. Thus, thermolysis of **5***a* in the presence of ethyl crotonate afforded four diastereomeric ethyl cyclopropanecarboxylates (**15**), Scheme 10, in 26% total yield. The diastereomers could not be separated but the relative yields (1:2:1.6:3.2) could be obtained from the ^{1}H NMR spectrum of the mixture by integration of the four methoxy signals. The EI and the CI mass spectra gave the appropriate $[M]^+$ and $[M + H]^+$ signals. Both carbene dimers (**7***c*, **8***c*) were detectable as minor coproducts, indicating that reaction of (ethylthio)methoxycarbene with ethyl crotonate is relatively slow. Formation of all four diastereomers of **15** is in keeping with a stepwise mechanism of cyclopropanation, as proposed by Hoffmann (9) to account for the observation that dimethoxycarbene reacts with diethyl maleate to afford only the *trans* product of cyclopropanation.

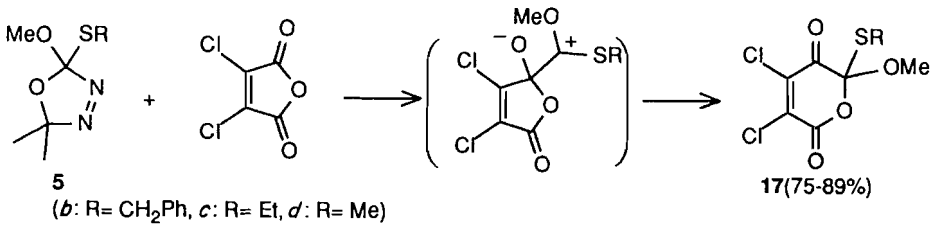
Thermolysis of **5***a* in dry benzene containing ethyl crotonate gave two diasteromeric cyclopropanes (**16***a*, **16***b*) in yields of 35 and 7%. Again, separation of those diastereomers was not achieved and the spectra of the individual isomers were gleaned from the spectra of the mixture. Assignment of structure **16***a* to the major diastereomer is tentative (Scheme 10).

An important feature that determines the different outcomes of trapping with DMAD and trapping with ethyl crotonate is

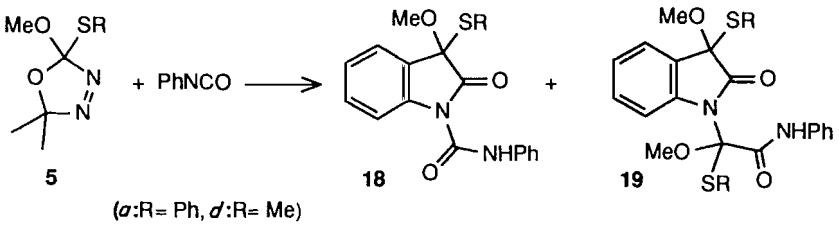
Scheme 10.



Scheme 11.



Scheme 12.



the thermal instability of cyclopropenes. Thus, whereas both reactions presumably result initially in formation of a three-membered ring, cyclopropenes with ester groups at C1 and C2 are thermally labile (10), Scheme 9, whereas cyclopropanes are relatively robust. The former therefore undergo eventual irreversible reaction through a dipolar intermediate (Scheme 9), to afford 1:2 adducts.

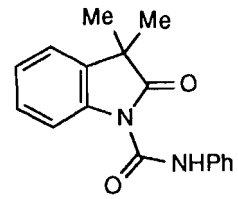
Reactions of the carbenes with dichloromaleic anhydride do not mimick the ones with ethyl crotonate. Overall insertion into the ring C—O bond occurs, presumably by nucleophilic addition to carbonyl carbon (3) followed by 1,2-acyloxy migration, Scheme 11. The structure of **17***d* was secured by means of single crystal X-ray diffraction.[3] Possible reasons for the failure of ethyl crotonate to undergo analogous attack include the lower reactivity of esters compared to anhydrides and a slower follow-up step that might not compete well with reversal.

Thermolysis of **5***a* and of **5***d* in benzene containing excess phenyl isocyanate afforded three products in each case. Centrifugal chromatography led to ready separation of a rapidly eluting minor product identified as 2:1 adduct **18***a* from **5***a*, and **18***d* from **5***d*, Scheme 12. *N*-Phenylcarbamoyl oxindoles such as **18** are readily recognized, having NH absorption and an intense broad carbonyl band in the infrared spectrum. The ^{1}H NMR spectrum included, in each case, a low-field doublet ($\delta \simeq 8.3, J \simeq 8$ Hz) corresponding to the oxindolyl aryl hydrogen nearest to the phenylcarbamoyl group. *N*-Acyl indoles also have an especially deshielded aryl hydrogen for the same reason: the proximity of the amide carbonyl oxygen to an aryl hydrogen separated from it by five bonds (11). An analogous product (**20**) had already been observed, from reaction of 2-diazopropane with phenyl isocyanate (12). The fact that the 2:1 adduct was a minor product was surprising, Hoffmann's group (2*b*) having identified *only* a 2:1 adduct from reaction of dimethoxycarbene with phenyl isocyanate. Also surprising was the fact that Hoffmann's product was apparently a hydantoin (Scheme 2) whereas ours, from methoxy(methylthio)carbene, was clearly an oxindole. Thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline in benzene containing phenyl isocyanate afforded the Hoffmann hydantoin (65% yield), confirming that dimethoxycarbene and methoxy(methylthio)carbene, each generated thermally from an oxadiazoline precursor, afford quite different 2:1 adducts with phenyl isocyanate.

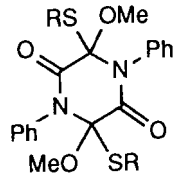
Equally surprising was the finding that the major products from thermolysis of **5***d* (or **5***a*) in the presence of phenyl isocyanate were 2:2 adducts (**19**) obtained as mixtures of diastereomers. In the case of **19***a* the diastereomers were separable by chromatography but **19***b* could not be separated. Attempts to grow a single crystal from either diastereomer of **19***a*, for single crystal X-ray diffraction, were not successful.

[3] Publication of the details will be delayed in the expectation that an analogous structure, from either a bis(alkylthio)carbene or an alkoxyaminocarbene, will become available for comparisons.

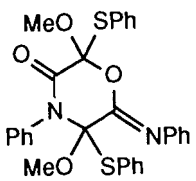
The spectra fit the oxindole structure (**19**) well, for diastereomeric products would be expected in each case, **19***a*, **19***d*. In both cases, the ^{13}C NMR spectra and the IR spectra suggested carbonyl groups in different environments. Those features rule out the 1,4-piperazine-2,5-diones (**21**) and their isomers **22**. The ring carbonyl group and the other amide carbonyl group are in quite different environments and the ^1H NMR spectra rule out the isomeric **23**. Structures such as **23** should also show the characteristic low-field doublet (ca. 8.3 ppm, *J* ca. 8 Hz) of carbamoyl oxindoles, outlined above. Moreover, compounds **19** showed a broad singlet (δ = 7.6 and 8.3 for **19***a* and **19***d*, respectively) in the ^1H NMR spectra, as expected for NH of an amide. Finally, the mass spectra included peaks at *m/z* = 119 and *m/z* = 120, for **19***a* and **19***d*, respectively, attributable to PhNCO and PhNHCO fragments expected from **19**, but not from **23**, as well as the appropriate molecular ions.



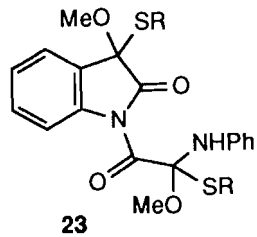
20



21



22



23

What structural features and mechanisms might account for the very different behaviours of dimethoxycarbene and methoxy(methylthio)carbene toward phenyl isocyanate? The connectivities of the products suggest a common first step: nucleophilic addition of the carbene to carbonyl carbon of the isocyanate to form a dipolar intermediate, as suggested by Hoffmann et al. (2*b*), Scheme 13. Presumably such an intermediate is equilibrated with the corresponding α-lactam and iminooxirane (not illustrated). We postulate that the dipolar intermediate of Scheme 2 is more stable than its analogue **24**, because the resonance contributors in the cationic portion of the former are equivalent and because the carbonyl double bond is much stronger than the thiocarbonyl double bond. As a consequence, the rate constant for intramolecular ring closure, to form the dialkoxy analogue of **25**, could be small enough to permit it to undergo intermolecular reaction (Scheme 2) with phenyl isocyanate to afford the hydantoin. On the other hand, **24** cyclizes rapidly to **25**, which cannot aromatize to **26** intramolecularly because a concerted 1,3-H shift would have to be antarafacial (13). It can accumulate, therefore, to react with **25** in an acid–base reaction, generating ion pair **27**. Collapse of the latter would generate the observed diastereomeric 2:2 adducts, **19**, Scheme 13. While this explanation is attractively simple, it is not unique and must be regarded as tentative.

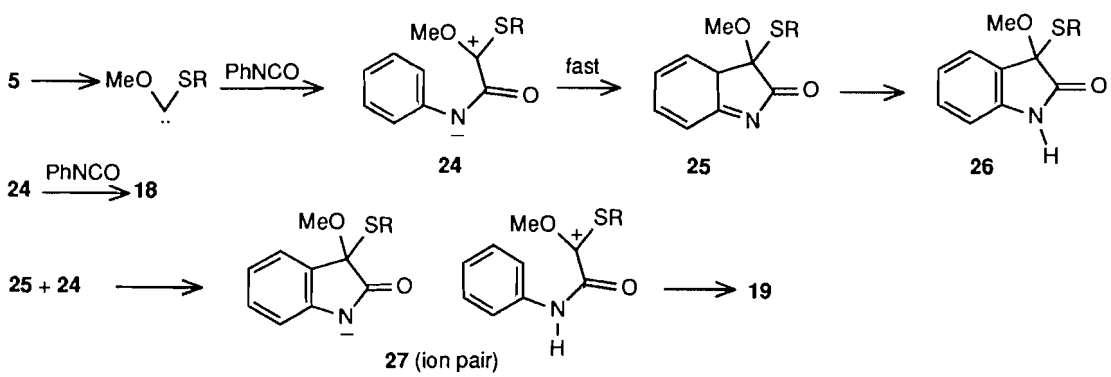
Experimental

^1H NMR spectra were run with $CDCl_3$ or C_6D_6 solutions, with a 200 or a 300 MHz Bruker spectrometer, and ^{13}C spectra were acquired at 50 MHz with a Bruker AC200 spectrometer. Infrared spectra were taken from solutions in CCl_4, in a cell of 0.5 mm path length, with a Biorad FTS-40 spectrophotometer. Solvent absorptions were subtracted. The IR bands are labelled qualitatively with the symbols s and m for strong and medium intensities, respectively. Weaker bands are not labelled and very weak bands are not included. Raman spectra were obtained from neat samples, with a Jobin Yvon/ISA Mole S-3000 spectrometer.

2-Methoxy-5,5-dimethyl-2-phenylthio-Δ^3-1,3,4-oxadiazoline (5*a*)

A solution of *p*-toluenesulfonic acid (pTSA, 0.40 g) in benzene (15 mL) was refluxed for about 1 h in a flask fitted with a Dean and Stark trap containing molecular sieves in the water trapping arm. After the solution had cooled, a solution of 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-oxadiazoline (**1**) containing **4** (total weight 5.0 g, 64% **1** by ^1H NMR assay) and thiophenol (2.0 mL) in dichloromethane (10 mL) was added. More dichloromethane (30 mL) was used to rinse traces of thiophenol solution into the flask containing pTSA and the reaction solution so obtained was refluxed under N_2 for 16 h. The solution was cooled, KOH pellets were added, and the heterogeneous mixture was stirred rapidly for 2 h. Water was added and the mixture was shaken vigorously before the organic layer was separated and extracted several times with

Scheme 13.



water. Drying over $MgSO_4$ and evaporation of the solvents left a residue that was chromatographed (Chromatotron, 4 mm plate, hexane) to afford the title compound as a white solid (69%), mp 38–39°C. IR (CCl_4) cm^{-1}: 3064, 2993, 2943, 2895, 2838, 1477, 1441, 1366, 1264, 1238, 1204, 1128s, 1064s, 1025, 976m, 959m, 911, 826, 692, 628, 581, 516, 479. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.14 (s, 3H), 1.50 (s, 3H), 3.52 (s, 3H), 7.28–7.34 (m, 3H), 7.57–7.63 (m, 2H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 22.6, 25.0, 52.2, 122.8 (C5), 128.8, 129.0, 129.2, 135.7, 137.2. MS (EI) *m/z*: 207 ($M^+ - OCH_3$, 5), 153 ($MeOCHSPh^+$, 24), 129 ($M^+ - SPh$, 69), 109 ($C_6H_5S^+$, 100).

2-Benzylthio-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (*5b*)

The procedure described above was followed. From 15 g of **1** plus **4** (63% **1**), benzyl mercaptan (5.9 mL), pTSA (1.0 g), and CH_2Cl_2 (120 mL) there was obtained, after refluxing overnight, a liquid product that was chromatographed (Chromatotron, 4 mm plate, 5% EtOAc in hexane) to afford 5.58 g (44%) of **5***b* as a clear liquid. IR (CCl_4) cm^{-1}: 3087, 3031, 2992, 2941, 2839, 1731, 1603, 1496, 1457, 1368, 1237, 1203, 1124s, 1069s, 979m, 910, 828, 703m, 625, 583, 465. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.53 (s, 3H), 1.57 (s, 3H), 3.40 (s, 3H), 4.09 (d, $^2J = -12.7$ Hz, 1H), 4.20 (d, $^2J = -12.7$ Hz, 1H), 7.24–7.36 (m, 5H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 23.1, 24.8, 34.8, 51.5, 122.6 (C5), 127.1, 128.4, 128.9, 136.6, 137.1. MS (EI) *m/z*: 221 ($M^+ - OCH_3$, 2), 183 ($M^+ - N_2 - C_3H_5$, 5), 167 ($MeOCHSCH_2Ph^+$, 14), 135 ($PhCH_2CS^+$, 17), 133 ($M^+ - N_2 - PhCH_2$, 37), 129 ($M^+ - SCH_2Ph$, 62), 91 (100), 73 (70). MS (CI, NH_3) *m/z*: 270 ($M^+ + NH_4$).

2-Ethylthio-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (*5c*)

The exchange method described above was used, with impure oxadiazoline **1** (15.0 g of **1** + **4**, containing 10.5 g, 0.056 mol of **1**), ethanethiol (4.69 mL, 0.062 mol, 97% pure), and pTSA (1.06 g, 5.6 mmol, dried by azeotropic distillation of a benzene solution) in CH_2Cl_2 (120 mL). Heating at reflux for 17 h, cooling, addition of KOH pellets (ca. 2 g), and stirring for several hours caused a change in colour to pale yellow. Addition of water, shaking, separation, and drying of the organic phase and evaporation of the solvent left a residual oil that was chromatographed on silica gel (5% EtOAc in hexane) to afford **5***c* as a clear liquid (6.05 g, 57%). IR (CCl_4) cm^{-1}: 2991, 2938, 2874, 2837, 1456m, 1371, 1268, 1237, 1203m, 1180, 1124s, 1070s, 977m, 910m, 827, 685, 580, 486. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.35 (t, $J = 7.5$ Hz, 3H), 1.54 (s, 3H), 1.57 (s, 3H), 2.81 (dq, $J = 7.5$ and -12.9 Hz, 1H), 2.95 (dq, $J = 7.5$ and -12.9 Hz, 1H), 3.44 (s, 3H). ^1H NMR (200 MHz, C_6D_6) δ: 1.17 (t, $J = 7.4$ Hz, 3H), 1.20 (s, 3H), 1.27 (s, 3H), 2.66 (dq, $J = 7.4$ and -13.0 Hz, 1H), 2.88 (dq, $J = 7.4$ and -13.0 Hz, 1H), 3.20 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 15.2, 23.0, 24.5, 24.7, 51.3, 122.0 (C5), 136.9 (C2). MS (EI) *m/z*: 129 ($M^+ - SEt$, 8), 105 (10), 84 (28). MS (CI, NH_3): 189 ($M^+ - H$).

2-Methoxy-2-methylthio-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (*5d*)

A solution of *p*-toluenesulfonic acid (1.0 g, 0.005 mol) in benzene (30 mL) was refluxed in a Dean and Stark apparatus. The dried portion was added to a solution of **2** (15 g of **1** (63%) containing **4**) in dry CH_2Cl_2 (120 mL). Cold methyl mercaptan, collected in a Dry Ice trap after passage of the gas through a tube packed with anhydrous $MgSO_4$, was added from a syringe. The reaction vessel was sealed and maintained at 45°C overnight in an oil bath. Its contents were then transferred to a 250 mL flask containing ca. 2 g of KOH pellets. Vigorous stirring for a few hours, followed by addition of water, shaking, separation, extraction of the organic phase with water, drying, and removal of the solvent, left a residue that was subjected to column chromatography to afford pure **5***d* as a clear liquid, 7.08 g (80%). IR (CCl_4) cm^{-1}: 2993, 2940, 2893, 1561, 1459, 1437, 1367, 1237, 1203, 1124, 1072s, 999, 980, 910, 827, 702, 682, 626, 581. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.55 (s, 3H) 1.57 (s, 3H), 2.33 (s, 3H), 3.46 (s, 3H). ^1H NMR (200 MHz, C_6D_6) δ: 1.20 (s, 3H), 1.25 (s, 3H), 2.09 (s, 3H), 3.20 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 12.9, 23.2, 24.9, 51.4, 122.6 (C5), 136.6 (C2). MS (EI) *m/z*: 176 (M^+, 1), 145 ($M^+ - OCH_3$, 3), 129 ($M^+ - SCH_3$, 24), 90 (34), 75 (100). MS (CI, NH_3) 177 ($M^+ + H$).

Thermolysis of 2-methoxy-5,5-dimethyl-2-phenylthio-Δ^3-1,3,4-oxadiazoline in benzene

A solution of **5***a* (0.209 g, 0.878 mmol) in benzene (10 mL) was refluxed overnight under N_2 in a Dean and Stark apparatus. The residue left after evaporation of the solvent consisted of methyl phenylthio carbonate **9** (0.0103 g, 7%), *E*-1,2-dimethoxy-1,2-di(phenylthio)ethene **7***a* (0.0467 g, 35%), and the corresponding *Z* isomer **7***b* (0.0267 g, 20%), as determined by chromatographic separation (Chromatotron, 1 mm plate).

A similar thermolysis, in which *p*-xylene served as ^1H NMR standard for integration, gave $k(60°C) = 2.04 \times 10^{-5}$ s^{-1} and yields (not isolated) of 8, 48, 40, and 62% for **9**, **7***a*, **7***b*, and acetone, respectively. Methyl phenylthio carbonate was a clear liquid. IR (CCl_4) cm^{-1}: 3066, 3008, 2954, 2888, 2836, 1730s, 1584, 1480, 1435, 1189m, 1143s, 1093, 1025, 689, 673, 556, 532. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.84 (s, 3H), 7.39–7.42 (m, 3H), 7.51–7.55 (m, 2H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 54.5, 127.6, 129.2, 129.6, 134.8, 170.2. MS (EI, GC/MS) *m/z*: 168 (M^+, 38), 137 ($M^+ - OCH_3$, 3), 124 (16), 109 (100), 91 (32), 78 (22), 69 (23), 65 (37). An authentic sample, synthesized by treating methyl chloroformate with thiophenol in the presence of pyridine, had matching spectral characteristics.

E *Dimer of (methoxy)phenylthiocarbene, 7*a

The *E* dimer was a white solid, mp 53–55°C. IR (CCl_4) cm^{-1}: 3065, 3007, 2963, 2932, 2892, 2830, 1796, 1718, 1657, 1583m, 1479m, 1442m, 1265, 1206s, 1146s, 1121, 1081, 1023, 1003, 954, 909, 870, 832, 692s, 520. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.55 (6H), 7.17–7.42 (m, 10H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 58.5, 126.7, 129.0, 129.5, 133.6, 142.8. MS (EI) *m/z*: 304 (M^+, 100), 261 [$(PhS)_2COMe^+$, 91], 218 (32), 195 (13), 153 (28), 109 (PhS^+, 75).

Z *Dimer of (methoxy)phenylthiocarbene, 8*a

Clear liquid. IR (CCl_4) cm^{-1}: 3066, 3004, 2965, 2935, 2894, 2832, 1774, 1725, 1581m, 1479m, 1442, 1264, 1198s, 1122 br, 1085, 1025m, 1006, 959, 880, 692m, 566. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.67 (s, 6H), 7.15–7.36 (m, 10H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 58.6, 126.4, 128.3, 129.1, 134.2, 143.2. MS (EI) *m/z*: 304 (M^+, 100), 261 (90), 195 (14), 109 (75).

Thermolysis of 5*a* in presence of ethyl crotonate

A solution of **5***a* (0.1201 g, 0.504 mmol) and ethyl crotonate (Aldrich, 96%, predominantly *E* isomer, 0.08 mL, 0.60 mmol) in benzene (10 mL) was sealed into a 100 mL glass tube that was then heated in an oil bath (70°C) overnight. The solvent was removed and the residue was chromatographed (Chromatotron, 1 mm plate, washed with Et_3N in hexane, elution with hexane). Five products were isolated: a pair of ethyl cyclopropane carboxylates, **16***a* and **16***b*, **9**, and the carbene dimers **7***a* and **8***a*.

E,Z-*Ethyl 2-methoxy-3-methyl-2-phenylthiocyclopropanecarboxylate (**16**a)*: Major product, 0.0469 g, 35% yield, clear oil. IR (CCl_4) cm^{-1}: 3064, 2981m, 2965m, 2934m, 2903, 2878, 2829, 1735s, 1584, 1480m, 1444m, 1416, 1367, 1318s, 1265m, 1228m, 1201m, 1170 br, 1117m, 1098m, 1049m, 1024, 998m, 911, 864, 692. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.25 (d, J = 6.4 Hz) overlapping δ 1.27 (t, J = 7.1 Hz), sum 6H, 1.83 (d, J = 6.8 Hz, 1H), 2.27 (5 lines, 1H), 3.37 (s, 3H), 4.181 (q, J = 7.1 Hz) overlapping 4.188 (q, J = 7.1 Hz), sum 2H, 7.15–7.28 (m, 3H), 7.44–7.48 (m, 2H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 14.2, 28.9, 36.5, 54.9, 60.9, 78.2, 110.7, 126.1, 128.6, 128.8, 134.7, 168.7. MS (EI) *m/z*: 266 (M^+, 3), 235 ($M^+ - OCH_3$, 18), 220 (100), 205 (25), 193 (85), 157 (89), 129 (45), 109 (50), 69 (47). MS (CI, NH_3) *m/z*: 284 ($M^+ + NH_4$, 74), 267 ($M^+ + H$, 39).

Z,E-*Ethyl 2-methoxy-3-methyl-2-phenylthiocyclopropanecarboxylate (**16**b)*: Minor diastereomer, ca. 7%. This product was obtained as a mixture with **16***a* and only a part of the ^1H NMR spectrum was assignable. ^1H NMR (200 MHz, $CDCl_3$) δ: 1.15 (t, J = 7.1 Hz, 3H), 1.27 (m), 1.87 (d, J = 7.2 Hz, 1H), 2.03 (5 lines, 1H), 3.48 (s, 3H), 4.02 (m, 2H), 7.17–7.58 (m).

Thermolysis of 5*a* in presence of phenyl isocyanate

A solution of **5***a* (0.204 g, 0.858 mmol) and phenyl isocyanate (0.19 mL, 1.7 mmol) in benzene (8 mL) was sealed into a glass tube that was then immersed overnight in an oil bath kept at 70°C. Evaporation of the solvent left a residue that was chromatographed (Chromatotron, 1 mm plate) on SiO_2 with hexane. After the first product (**18***a*) had been eluted the solvent was gradually changed to 5% EtOAc in hexane. Two additional products, diastereomers **19***a*, were eluted slowly. Yields of isolated materials were 10, 39, and 28%, respectively.

*3-Methoxy-1-phenylcarbamoyl-3-phenylthio-oxindole, (**18**a)*: White solid, 0.0335 g, mp 139–140°C, 10%. IR (CCl_4) cm^{-1}: 3260, 3064, 2948, 2891, 2832, 1748s, 1600m, 1552s, 1503, 1470m, 1448, 1340, 1310, 1277, 1243, 1204, 1163m, 1112, 1088, 1022, 970, 913, 693m, 574, 505. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.56 (s, 3H), 7.03–7.15 (m, 3H), 7.33–7.58 (m, 9H), 8.32 (d, J = 8.3 Hz, 1H), 10.36 (s, br, 1H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 53.8, 87.9, 116.8, 120.7, 124.2, 124.5, 124.7, 124.8, 128.8, 129.1, 130.0, 130.9, 136.6, 136.8, 138.5, 149.0, 173.6. MS (EI) *m/z*: 314 (3), 281 (15), 162 (100), 119 (52), 91 (18). MS (CI, NH_3) *m/z*: 391 ($M^+ + H$).

*Major diastereomer of oxindole **19**a*: White solid, mp 169–171°C, 39% (isolated). IR (CCl_4) cm^{-1}: 3411, 3362, 3063, 3034, 2962, 2943, 2891, 2833, 1746s, 1718m, 1604m, 1527s, 1468, 1442m, 1336, 1311, 1279, 1243, 1183, 1158, 1086 br, 1075m, 986, 909s, 692m, 660, 503. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.52 (s, 3H), 3.58 (s, 3H), 6.86–7.54 (m, 20H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 51.2, 54.2, 87.7, 99.0, 111.7, 119.6, 119.9, 123.5, 124.6, 124.8, 125.1, 128.6, 128.7, 128.8, 129.0, 129.6, 129.9, 130.3, 136.1, 136.8, 137.4, 139.7, 162.2, 172.2. MS (EI) *m/z*: 447 (18), 433 (26), 405 (55), 272 (13), 162 (100), 146 (37), 120 (65), 110 (81), 109 (67), 77 (40). MS (CI, NH_3) *m/z*: 560 ($M^+ + NH_4$).

*Minor diastereomer of oxindole **19**a*: White solid, mp 171–173°C, 28% (isolated). IR (CCl_4) cm^{-1}: 3413, 3396, 3061, 2961, 2891, 2830, 1744s, 1719m, 1604m, 1525s, 1468, 1442m, 1337, 1312m, 1281, 1243, 1193, 1117, 1087, 1087, 1066 br, 986, 947, 909, 824, 691m, 504. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.62 (s, 3H), 3.68 (s, 3H), 6.80 (m), 7.01–7.38 (m, 13H), 7.51–7.55 (m, 4H), 7.62 (s, br, 1H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 51.4, 53.6, 87.7, 99.6, 112.1, 119.6, 123.2, 124.2, 124.6, 125.0, 128.5, 128.7, 128.8, 129.0, 129.4, 129.6, 129.8, 130.0, 136.4, 137.0, 137.3, 139.5, 161.9, 171.9. MS (EI) *m/z* (rel. intensity): 433 ($M^+ - SPh$, 22), 405 (34), 272 (13), 162 (100), 110 (26), 109 (31), 77 (32). MS (CI, NH_3) *m/z*: 560 ($M^+ + NH_4$).

Thermolysis of 2-benzylthio-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline in benzene

A solution of **5***b* (0.1553 g, 0.615 mmol) in benzene (10 mL) was refluxed overnight under N_2 in a Dean and Stark apparatus. The final solution contained acetone and the *E* and *Z* isomers of 1,2-bis(benzylthio)-1,2-dimethoxyethene. Chromatography of the latter (Chromatotron, 1 mm plate, hexane) afforded the *E* isomer **7***b* followed by the *Z* isomer **8***b*. The ratio *E*:*Z* ranged from 1.38 to 1.19 from three runs.

E-*1,2-Bis(benzylthio)-1,2-dimethoxyethene (**7**b)*: White solid, mp 82–84°C, 0.0205 g, 32% yield. IR (CCl_4) cm^{-1}: 3086, 3064, 3031, 3003, 2962, 2933, 2894, 2827, 1716, 1601, 1496, 1454, 1427, 1263, 1238, 1203s, 1136s, 1112, 1071, 954m, 915, 871, 700, 672, 561, 472. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.21 (s, 6H), 3.75 (s, 4H), 7.15–7.30 (m, 10H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 35.9, 57.9, 126.9, 128.3, 128.8, 138.6, 143.5. MS (EI) *m/z*: 332 (M^+, 4), 241 ($M^+ - CH_2Ph$, 45), 91 ($PhCH_2^+$, 100). MS (CI, NH_3) *m/z*: 333 ($M^+ + H$).

Z-*1,2-Bis(benzylthio)-1,2-dimethoxyethene (**8**b)*: Yellow oil, 0.0173 g, 27% yield. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.54 (s, 6H), 3.63 (s, 4H), 7.19–7.31 (m, 10H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 37.1, 58.6, 127.0, 128.3, 129.0, 137.9, 144.1. MS (EI) *m/z*: 332 (M^+, 6), 241 ($M^+ - CH_2Ph$, 68), 91 ($PhCH_2^+$, 100). MS (CI, NH_3) *m/z*: 333 ($M^+ + H$, 100).

Thermolysis of 5*b* in presence of dichloromaleic anhydride

A solution of **5***b* (0.2046 g, 0.8106 mmol) and dichloromaleic anhydride (0.150 g, 0.898 mmol) in benzene (10 mL) was heated overnight at 80°C in a sealed tube. Removal of the solvent and Kugelrohr distillation of the residue gave a yellow crystalline product, 3,4-dichloro-6-benzylthio-6-methoxy-2*H*-pyran-2,5-(6*H*)-dione (**17***b*), mp 69–70°C, 75%. The product did not survive an attempt at chromatography on silica gel. IR (CCl_4) cm^{-1}: 3087, 3032, 2949, 2894, 2840, 1762s, 1721s, 1583s, 1497, 1457, 1414, 1273m, 1234m, 1196m, 1163s,

1040, 982m, 908, 885, 701s, 666m. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.54 (s, 3H), 3.75 (s, 2H), 7.29 (s, br, 5H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 35.0, 52.5, 108.9, 127.7, 128.7, 129.1, 135.0, 136.8, 141.3, 152.6, 173.5. MS (CI, NH_3) *m/z*: 354 (16), 352 (65), 350 (100) ($M^+ + NH_4$), 337 (8), 335 (25), 333 (35), (M^+ + H).

Thermolysis of 5*c* in benzene

A solution of **5***c* (0.1629 g, 0.856 mmol) in benzene (ca. 1 mL) was sealed into an NMR tube. Thermolysis at 60°C, followed by ^{1}H NMR spectroscopy, gave $k(60°C) = 2.1 \times 10^{-5}$ s^{-1}. Acetone and the diastereomeric 1,2-bis(ethylthio)-1,2-dimethoxyethenes were predominant products. Separation of the latter (Chromatotron, hexane) gave *E*-1,2-bis(ethylthio)-1,2-dimethoxyethene (**7***c*, 0.0304 g, 38%) and the *Z* isomer (**8***c*, 0.0250 g, 27%) as clear liquids.

E-*1,2-Bis(ethylthio)-1,2-dimethoxyethene* (**7**c): IR (GC/FTIR) cm^{-1}: 2976m, 2940s, 2887, 2832, 1457 br, 1383, 1310, 1267, 1188, 1079 br, 975, 937, 904, 825, 762, 712. Raman (neat) cm^{-1}: 1581.4, 653.4. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.25 (t, *J* = 7.3 Hz, 6H), 2.66 (q, *J* = 7.3 Hz, 4H), 3.61 (s, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 15.1, 25.4, 58.0, 143.1. MS (EI) *m/z*: 208 (M^+, 15), 193 ($M^+ - CH_3$, 4), 179 ($M^+ - CH_2CH_3$, 29), 165 (13), 135 (3), 49 (100). MS (CI, NH_3) *m/z*: 209 (M^+ + H).

Z-*1,2-Bis(ethylthio)-1,2-dimethoxyethene* (**8**c): IR (GC/FTIR) cm^{-1}: 2972, 2939m, 2887, 2836, 1579, 1457, 1381, 1265, 1194s, 1114 br, 1026, 967, 863, 764. Raman (neat) cm^{-1}: 1596, 655.7. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.27 (t, *J* = 7.3 Hz, 6H), 2.65 (q, *J* = 7.3 Hz, 4H), 3.68 (s, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 14.7, 26.4, 58.8, 143.4. MS (EI) *m/z*: 208 (M^+, 83), 193 ($M^+ - CH_3$, 15), 179 ($M^+ - CH_2CH_3$, 100), 165 (44), 135 (2). MS (CI, NH_3) *m/z*: 209 (M^+ + H).

Thermolysis of 5*c* in the presence of dichloromaleic anhydride

A solution of **5***c* (0.197 g, 1.03 mmol) in benzene (10 mL) containing dichloromaleic anhydride (0.190 g, 1.14 mmol) was heated at 70°C overnight. Kugelrohr distillation of the residue left after removal of the solvent afforded **17***c*, mp 71–74°C. IR (CCl_4) cm^{-1}: 2950, 2881, 1807, 1761s, 1722m, 1583, 1458, 1266, 1236, 1196, 1160m, 1102, 1040s, 982, 909, 886, 827, 667, 527, 478. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.24 (t, *J* = 7.5 Hz, 3H), 2.52 (dq, *J* = −12.8 Hz, 7.5 Hz, 1H), 2.60 (dq, *J* = −12.8, 7.5 Hz, 1H), 3.69 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 13.6, 24.7, 52.5, 109.0, 136.6, 141.2, 152.7, 173.6. MS (EI) *m/z*: 275 (M^+ + H, 2), 273 (M^+ + H, 4), 271 (M^+ + H, 6), 235 ($M^+ - {}^{35}Cl$, 6), 213 (13), 211 (28), 209 (19), 185 (20), 183 (73), 181 (100). MS (CI, NH_3) *m/z*: 292 (4), 290 (13), 288 (20), ($M^+ + NH_4$), 275 (20), 273 (95), 271 (100), (M^+ + H).

Thermolysis of 5*d* in benzene

A solution of **5***d* (0.37 g, 2.1 mmol) in benzene (15 mL) was refluxed overnight. Chromographic separation of the products (Chromatotron, 2 mm plate, hexane) gave the *E* and *Z* dimers of (methoxy)methylthiocarbene, 0.1225 g (32%) and 0.1005 g (27%), respectively, both oils.

E-*1,2-Bis(methylthio)-1,2-dimethoxyethene* (**7**d): IR (GC/FTIR) cm^{-1}: 3005, 2963, 2938m, 2909, 2839, 1445, 1319, 1203s, 1143s, 1023s, 960, 807. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.20 (s, 6H), 3.63 (s, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 14.5, 58.2, 142.8. MS (EI, GC/MS) *m/z*: 180 (M^+, 10), 165 ($M^+ - CH_3$, 22), 137 ($M^+ - CH_3CO$, 74), 75 (100). MS (CI, NH_3) *m/z*: 181 (M^+ + H).

Z-*1,2-Bis(methylthio)-1,2-dimethoxyethene* (**8**d): IR (GC/FTIR) cm^{-1}: 3002, 2938m, 2838, 1584, 1445, 1315, 1194s, 1115 br, 1030, 964, 866. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.21 (s, 6H), 3.68 (s, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 15.3, 58.8, 143.0. MS (EI, GC/MS) *m/z*: 180 (M^+, 10), 165 ($M^+ - CH_3$, 23), 137 ($M^+ - CH_3CO$, 79), 75 (100). MS (CI, NH_3) *m/z*: 181 (M^+ + H).

Thermolysis of 5*d* in the presence of dichloromaleic anhydride

A solution of **5***d* (0.2077 g, 1.18 mmol) and dichloromaleic anhydride (0.22 g, 1.3 mmol) in benzene (10 mL) was kept at 80°C, overnight, in a sealed tube. Evaporation of the solvent and Kugelrohr distillation of the residue gave 0.2575 g of **17***d* (85%) as a yellow solid, mp 89–91°C. IR (CCl_4) cm^{-1}: 3502, 2995, 2948, 2839, 1805m, 1762s, 1721s, 1631, 1584s, 1460, 1436, 1271s, 1236s, 1196s, 1162 br, 1042 br, 962, 909, 887, 826, 670m, 596, 526. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 2.06 (s, 3H), 3.70 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 12.9, 52.2, 108.6, 136.5, 141.2, 152.6, 172.7. MS (EI) *m/z*: 256 (M^+, 2), 225 ($M^+ - OCH_3$, 2), 223 (5), 221 ($M^+ - {}^{35}Cl$, 15), 213 (3), 211 (13), 209 ($M^+ - SCH_3$, 18), 199 (13), 197 (18), 185 (9), 183 (45), 181 (71). MS (CI, NH_3) *m/z*: 278 (6), 276 (20), 274 (28), 261 (15), 259 (56), 257 (100). Structure **17***d* was confirmed by single crystal X-ray diffraction.

Thermolysis of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline in the presence of phenyl isocyanate

A solution of the oxadiazoline (4) (0.010 g, 0.063 mmol) and phenyl isocyanate (0.051 g, 0.43 mmol) in benzene (0.5 mL) was degassed by means of freeze–pump–thaw cycles and sealed under vacuum into a glass tube. The tube was immersed in an oil bath, kept at 100°C, for 4 days. It was then opened, and the volatiles were distilled off under vacuum, with the maximum pot temperature limited to 100°C. The residue was chromatographed (Chromatotron, silica, hexanes) on a plate that had been pretreated with triethylamine in hexanes (1:20). The yield of the Hoffmann hydantoin (2) was 65% (by ^{1}H NMR), mp 131–132°C (lit. (2) mp 129–130°C).

5,5-Dimethoxy-1,3-diphenyl-2,4-imidazolidinedione (hydantoin): ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.56 (s, 6H), 7.24–7.57 (m, 8H), 7.61 (d, *J* = 1.5 Hz, 2H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 52.5, 103.9, 125.3, 126.1, 127.2, 128.6, 129.0, 129.1, 130.5, 133.2, 152.3, 165.3. MS (EI) *m/z*: 281 (M^+ − OMe), 193, 165, 116. The ^{13}C NMR spectrum is in excellent agreement with that reported by Hoffmann et al. (*2b*) for the analogue from *p*-tolyl isocyanate.

Thermolysis of 5*d* in the presence of phenyl isocyanate

A solution of **5***d* (0.50 g, 2.4 mmol) and phenyl isocyanate (0.63 mL, 5.8 mmol) in benzene (25 mL) was refluxed under N_2 for 16 h. The benzene was evaporated and methanol was

added (stirring for 1 h) to destroy excess isocyanate. Excess methanol was evaporated and the residue was chromatographed. Three products, a 2:1 adduct (**18***d*, 8%) and diastereomeric 2:2 adducts (**19***d*, 34%, mp 181–182°C (MeOH), diastereomer ratio 2:1) were found.

*3-Methoxy-3-methylthio-1-phenylcarbamoyloxindole (**18**d)*: Melting point 106–108°C. IR (CCl_4) cm^{-1}: 3298 br, 3259 br, 3145, 3082, 2959, 2931, 1748s, 1601s, 1553s, 1501, 1466m, 1448m, 1339m, 1311, 1277m, 1242m, 1209, 1166m, 1154, 1108m, 1087, 1024, 691, 677, 575, 506. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.38 (s, 3H), 3.43 (s, 3H), 7.14–7.61 (m, 9H), 8.37 (d, J = 8.0 Hz, 1H), 10.48 (br, 1H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 10.9, 53.1, 117.0, 120.6, 124.4, 124.7, 125.1, 129.1, 131.2, 136.9, 138.8, 149.1, 174.1. MS (EI) *m/z*: 328 (M^+, 6), 281 ($M^+ - SCH_3$, 48), 207 (4), 162 (100), 146 (6), 119 (24). MS (CI, NH_3): 346 ($M^+ + NH_4$, 14), 329 ($M^+ + H$, 17).

Major diastereomer of oxindole **19**d: IR (CCl_4, υ_{max}) cm^{-1}: 3414 br, 3061, 2931, 2832, 1746s, 1604m, 1525s, 1465, 1442m, 1338, 1309, 1279, 1243, 1196, 1180, 1117, 1095 br, 1073, 690. ^1H NMR (200 MHz, $CDCl_3$) δ: 2.12 (s, 3H), 2.39 (s, 3H), 3.33 (s, 3H) 3.54 (s, 3H). Minor diastereomer: 2.13 (s, 3H), 2.36 (s, 3H), 3.40 (s, 3H), 3.53 (s, 3H); composite signals: 7.08–7.61 (m), 8.23 (s, br), 8.41 (s, br). ^{13}C NMR of 2:1 mixture (50 MHz, $CDCl_3$) δ: 10.8, 12.5, 51.2, 51.3, 53.4, 53.9, 82.6, 83.1, 96.6, 96.7, 109.0, 110.0, 111.0, 112.4, 112.8, 119.8, 119.9, 123.9, 124.6, 124.7, 124.9, 125.1, 129.1, 129.2, 130.8, 136.4, 136.6, 140.1, 162.9, 163.1, 172.9. MS (EI) *m/z*: 387 (M^+ − OMe, 4), 371 (M^+ − SMe, 85), 343 (100), 298 (10), 270 (40), 210 (45), 208 (99), 162 (94), 119 (19), 77 (20). MS (CI, NH_3) *m/z*: 436 ($M^+ + NH_4$).

Thermolysis of 5*d* in the presence of dimethyl acetylenedicarboxylate

A solution of **5***d* (0.329 g, 1.87 mmol) and DMAD (0.46 mL, 3.7 mmol) in benzene (20 mL) was heated at 70°C for 16 h in a sealed tube. Thin-layer chromatography of the residue left after removal of the benzene showed five compounds. Only three of them were characterized, a minor compound that had the NMR properties expected for dihydrofuran **11**, and an inseparable mixture of diastereomers **14**.

*2-Methoxy-5,5-dimethyl-2-methylthio-3,4-bis(methoxycarbonyl)-2,5-dihydrofuran (**23**)*: Clear liquid, 6% yield. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.54 (s, 3H), 1.57 (s, 3H), 2.11 (s, 3H), 3.48 (s, 3H), 3.81 (s, 3H), 3.86 (s, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 13.1, 26.0, 27.3, 51.3, 52.5, 52.7, 88.5, 116.7, 137.7, 141.8, 162.2, 163.0.

cis- *and* trans-*2,5-Dimethoxy-3,4-bis(methoxycarbonyl)-5-[methyl(3-propiolato)]-2-methylthio-2,5-dihydrofuran (**14**, 10%)*: Isomer ratio 1.7:1.0; spectroscopic properties those of the mixture. IR (CCl_4) cm^{-1}: 3008, 2952, 2894, 2839, 1730 br, 1681, 1458, 1436, 1328, 1266 s, 1235 m, 1183, 1116, 1098, 1077, 1038, 1020, 988, 956, 918, 873, 692, 578. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.12 (s), 2.13 (s), 3.49 (s), 3.62 (s), 3.63 (s), 3.81 (s), 3.85 (s), 3.91 (s). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 12.4, 12.6, 52.8, 52.9, 53.0, 53.1, 77.9, 78.1, 78.3, 78.6, 102.1, 118.8, 132.9, 133.0, 143.1, 143.3, 152.8, 159.5, 159.6, 161.7. MS (EI) *m/z*: 374 (M^+, 2), 343 (9), 327 (100), 315 (7), 157 (61), 59 (22). MS (CI, NH_3): 392 ($M^+ + NH_4$, 7), 375 ($M^+ + H$, 8).

Acknowledgements

This work was supported by the Natural Sciences and Engineering Research Council of Canada. The authors are grateful to Mr. Fajar Ramelan and to Dr. Richard Smith for the mass spectrometric data. The assistance of Mr. George Timmins with Raman spectroscopy and the X-ray crystallography by Dr. Jim Britten are also gratefully acknowledged.

Structural diversity in thallium chemistry: structures of four chlorothallate(III) salts including a novel compound containing three geometrically different anions

Margaret Ann James, Jason A.C. Clyburne, Anthony Linden, Bruce D. James, John Liesegang, and Vilma Zuzich

Abstract: Four new thallium-containing salts with different alkyl ammonium cations have been prepared and characterized by X-ray crystallography: **1**: bis(*p*-toluidinium) pentachlorothallate(III), $[CH_3C_6H_4NH_3]_2$ $[TlCl_5]$, $M = 597.9$, monoclinic, $P2_1/c$, $a = 7.515(2)$, $b = 21.376(6)$, $c = 12.769(2)$ Å, $\beta = 92.13(2)°$, $V = 2050(1)$ Å^3, $Z = 4$, $D_{calc} = 1.937$ Mg m^{-3}, $\mu = 8.512$ mm^{-1}, $T = 293(1)$ K, $R = 0.046$; **2**: 1,5-pentanediammonium pentachlorothallate(III), $[NH_3(CH_2)_5NH_3]$ $[TlCl_5]$, $M = 485.83$, orthorhombic, $P2_12_12_1$, $a = 13.226(2)$, $b = 13.595(2)$, $c = 7.628(2)$ Å, $V = 1371.6(3)$ Å^3, $Z = 4$, $D_{calc} = 2.352$ Mg m^{-3}, $\mu = 12.84$ mm^{-1}, $T = 173(1)$ K, $R = 0.025$; **3**: pentakis(2-adamantaneammonium) bistetrachlorothallate(III) hexachlorothallate(III), $[C_{10}H_{18}N]_5$ $[TlCl_4]_2$-$[TlCl_6]$, $M = 1870.75$, monoclinic, $P2_1$, $a = 16.466(5)$, $b = 25.985(2)$, $c = 7.724(3)$ Å, $\beta = 90.14(3)°$, $V = 3305(2)$ Å^3, $Z = 2$, $D_{calc} = 1.880$ Mg m^{-3}, $\mu = 7.978$ mm^{-1}, $T = 173(1)$ K, $R = 0.056$; **4**: bis(piperazinium) decachlorodithallate(III) trihydrate, $[NH_2C_4H_8NH_2]_2$ $[Tl_2Cl_{10}]\cdot 3H_2O$, $M = 993.62$, monoclinic, $C2/c$, $a = 14.154(3)$, $b = 15.445(3)$, $c = 13.228(3)$ Å, $\beta = 114.44(1)°$, $V = 2632.7(9)$ Å^3, $Z = 4$, $D_{calc} = 2.506$ Mg m^{-3}, $\mu = 13.39$ mm^{-1}, $T = 173(1)$ K, $R = 0.026$. For most of the salts examined, formation of $[TlCl_5]^{2-}$ is possible; however, no isolated $[TlCl_5]^{2-}$ anions were observed. In most cases, high coordination numbers at thallium were observed (CN = 6), and these can be achieved *via* formation of anionic chains or through dimerization, giving $[Tl_2Cl_{10}]^{4-}$. Of particular interest is the solid state structure of salt **3** in which there are three geometrically different chlorothallate ions. Extensive hydrogen-bonding networks are observed in each structure.

Key words: thallium, thallium(III) chlorides, chlorothallate, hydrogen bonding, alkyl ammonium cations.

Résumé : On a préparé quatre nouveaux sels contenant du thallium et différents cations alkylammonium et on les a caractérisés par diffraction des rayons X: **1**, pentachlorothallate(III) de bis(*p*-toluidinium), $[CH_3C_6H_4NH_3]_2$ $[TlCl_5]$, $M = 597{,}9$, monoclinique, $P2_1/c$, $a = 7{,}515(2)$, $b = 21{,}376(6)$, $c = 12{,}769(2)$ Å, $\beta = 92{,}13(2)°$, $V = 2050(1)$ Å^3, $Z = 4$, $D_{calc} = 1{,}937$ Mg m^{-3}, $\mu = 8{,}512$ mm^{-1}, $T = 293(1)$ K, $R = 0{,}046$; **2**, pentachlorothallate(III) de pentane-1,5-diammonium, $[NH_3(CH_2)_5NH_3]$ $[TlCl_5]$, $M = 485{,}83$, orthorhombique, $P2_12_12_1$, $a = 13{,}226(2)$, $b = 13{,}595(2)$, $c = 7{,}628(2)$ Å, $V = 1371{,}6(3)$ Å^3, $Z = 4$, $D_{calc} = 2{,}352$ Mg m^{-3}, $\mu = 12{,}84$ mm^{-1}, $T = 173(1)$ K, $R = 0{,}025$; **3**, bistétrachlorothallate(III) hexachlorothallate(III) de pentakis(adamantane-2-ammonium), $[C_{10}H_{18}N]_5$ $[TlCl_4]_2$ $[TlCl_6]$, $M = 1870{,}75$, monoclinique, $P2_1$, $a = 16{,}466(5)$, $b = 25{,}985(2)$, $c = 7{,}724(3)$ Å, $\beta = 90{,}14(3)°$, $V = 3305(2)$ Å^3, $Z = 2$, $D_{calc} = 1{,}880$ Mg m^{-3}, $\mu = 7{,}978$ mm^{-1}, $T = 173(1)$ K, $R = 0{,}056$; **4**, trihydrate du décachlorodithallate(III) de bis(pipérazinium), $[NH_2C_4H_8NH_2]_2$ $[Tl_2Cl_{10}]\cdot 3H_2O$, $M = 993{,}62$, monoclinique, $C2/c$, $a = 14{,}154(3)$, $b = 15{,}445(3)$, $c = 13{,}228(3)$ Å, $\beta = 114{,}44(1)°$, $V = 2632{,}7(9)$ Å^3, $Z = 4$, $D_{calc} = 2{,}506$ Mg m^{-3}, $\mu = 13{,}39$ mm^{-1}, $T = 173(1)$ K, $R = 0{,}026$. Pour la plupart des sels examinés, la formation de $[TlCl_5]^{2-}$ est possible; toutefois, aucun anion $[TlCl_5]^{2-}$ n'a été isolé. Dans la plupart des cas, on a observé des nombres de coordination élevés pour le thallium (NC = 6) et on peut arriver à ceux-ci par le biais de la formation de chaînes anioniques ou par une dimérisation conduisant à du $[Tl_2Cl_{10}]^{4-}$. La structure du sel **3** à l'état solide est particulièrement intéressante parce qu'elle comporte trois ions chlorothallates géométriquement différents. Dans chacune des structures, on a observé des réseaux étendus de liaisons hydrogènes.

Mots clés : thallium, chlorures de thallium(III), chlorothallate, liaison hydrogène, cations alkylammoniums.

Introduction

Thallium, like most other main group metals and metalloids, can form a variety of polychlorinated anions (1), including $[TlCl_4]^-$, $[TlCl_5]^{2-}$, and $[TlCl_6]^{3-}$, all three species occurring in solutions of thallium(III) chloride in the presence of excess chloride ion (2). Perhaps the most interesting observation concerning the polychlorinated anions of thallium involves those with the $TlCl_5$ stoichiometry, which, when it is observed in solid samples isolated from donor solvents, might be expected to have the sixth coordination site of the metal occupied by a solvent molecule. Thus, discrete $[TlCl_5]^{2-}$ anions are rarely observed in the relatively small number of these compounds that have been characterized by X-ray crystallography. For example, DMSO (3) and water (4) have been shown to coordinate to $[TlCl_5]^{2-}$ fragments, giving six-coordinate species; however, in the calcium salt, $Ca[TlCl_5](H_2O)_7$, it is the calcium(II) ion, rather than the thallium centre, which engages the base (water), high coordination at thallium being realized via dimerization of two $[TlCl_5]^{2-}$ fragments to give the $[Tl_2Cl_{10}]^{4-}$ anion (5). An alternative mode of achieving high coordination at thallium is illustrated in the solid state structure of the salt Cs_2TlCl_5, where the sixth coordination site around thallium is occupied by a chloride ion from a neighbouring pentachlorothallate group, thus forming a chain of $[TlCl_5]^{2-}$ units (6). To date, the only complete report of a discrete $[TlCl_5]^{2-}$ ion is in the structure of the 4-chloropyridinium derivative (7). In addition, the tetraethylammonium salt $[Et_4N]_2[TlCl_5]$ is reported to be isomorphous (and presumably isostructural) with its indium analogue, which contains an isolated pentacoordinate $[InCl_5]^{2-}$ ion (8).

Investigations into the hydrogen-bonding arrangements that might be generated in solids arising from the interaction of thallium(III) chloride with other large organic base cations yielded some crystalline materials having apparent $TlCl_5$ stoichiometry. This paper reports the structures of four of these materials.

Experimental

Compounds **1**–**4** were synthesized by mixing solutions (molar ratio indicated) of the appropriate amine hydrochloride salts (ca. 5% excess) with thallium(III) chloride in a minimum volume of concentrated hydrochloric acid, warming as necessary. Solid materials that precipitated immediately were removed by filtration and the filtrates were allowed to evaporate slowly in an air stream. Generally, several crops of crystals were obtained, and these were isolated by filtration and dried in a vacuum desiccator. Elemental analyses were performed by Atlantic Microlabs Inc., Norcross, Ga.

1: *Bis(*p*-toluidinium) pentachlorothallate(III)*, (1:1, 2nd crop, mp 190–192°C, yellow prisms). Anal. calcd.: C 28.12, H 3.37, N 4.69, Cl 29.64%; found: C 28.23, H 2.99, N 4.46, Cl 29.93%.

2: *1,5-Pentanediammonium pentachlorothallate(III)*, (1:1, 3rd crop, mp 266–268°C, colourless prisms). Anal. calcd.: C 12.36, H 3.32, N 5.77, Cl 36.49%; found: C 12.33, H 3.30, N 5.73, Cl 36.58%.

3: *Pentakis(2-adamantaneammonium) bis[tetrachlorothallate(III)] hexachlorothallate(III)*, (2:1, 2nd crop, mp 262–263°C, slightly yellow prisms). Anal. calcd.: C 32.10, H 4.85, N 3.74, Cl 26.53%; found: C 34.03, H 5.19, N 3.86, Cl 27.18%.

4: *Bis(piperazinium) decachlorodithallate(III)*, (1:1, 2nd crop, mp 250–251°C, colourless prisms). Anal. calcd.: C 9.67, H 3.04, N 5.64, Cl 35.68%; found: C 9.64, H 3.04, N 5.52, Cl 35.75%.

Crystallography

Data for compound **1** were collected using a CAD-4 four-circle diffractometer and a Rigaku AFC5R system for **2**–**4**. Cell constants and orientation matrices for data collection were obtained from least-squares refinements using a number of carefully centred reflections (**1**, 25; **2**–**4**, 24) in the 2θ ranges **1**, 24°–30°; **3**, 38°–40°; and **2** and **4**, 39°–40°. For compound **1**, an empirical absorption correction (DIFABS) (9) was used; for compounds **2**–**4**, semi-empirical absorption corrections based on azimuthal scans of several reflections (10) were applied. Lorentz and polarization corrections were also applied. The intensities of three representative reflections were measured after every 150 reflections. Significant decay was observed only for **3** (ca. 15%) and a linear correction factor was calculated to account for this. Equivalent reflections were merged, apart from those from Friedel pairs for the non-centrosymmetric structures **2** and **3**.

The structures were solved by Patterson methods (11), which revealed the positions of the thallium atoms. All remaining non-hydrogen atoms were located in Fourier expansions of the Patterson solution (12). Except for **3**, described below, all of the non-hydrogen atoms were refined anisotropically. All hydrogen atoms bonded to carbon and nitrogen were fixed in geometrically calculated positions with a C–H or N–H distance of 0.95 Å. Hydrogen atoms bonded to oxygen in compound **4** were fixed in positions indicated by difference electron density maps. Each hydrogen atom was assigned an isotropic temperature factor having a value $1.2 \times U_{eq}$ of the atom to which it was bonded. Hydrogen atoms were not included for the disordered cation of compound **3** (see below). Extinction corrections were applied for **2** and **4** only. The final cycles of full-matrix least-squares refinements (13) were based on the observed reflections and variable parameters listed in Table 1 and converged with unweighted and weighted factors defined by:

$$[1] \quad R = \Sigma||F_o| - |F_c|| / \Sigma|F_o|$$

and

$$[2] \quad R_w = [(\Sigma w(|F_o| - |F_c|)^2 / \Sigma w F_o^2)]^{1/2}$$

All calculations were performed using the TEXSAN crystallographic software package (14). Figures are presented as ORTEP plots (50% probability ellipsoids) (15).

Structures **2** and **3** crystallized in non-centrosymmetric space groups. For **2**, the data collection included the measurement of the Friedel opposites of all reflections in the unique octant, but for **3**, severe decomposition of the crystal precluded the measurement of any Friedel opposites. The correct choice for the direction of the polar axis was confirmed in each case by an additional refinement of the completed structures

using the program CRYSTALS (16) in which it is possible to refine the enantiopole, or Flack's x, parameter (17, 18). This parameter converged to −0.011(6) for **2** and 0.24(4) for **3**. The reliability of this parameter for **3** is poor, but the correct direction of the polar axis was further confirmed by the refinement of the inverse structure, which resulted in significantly higher R-factors (R = 0.063, R_w = 0.059).

The refinement of compound **3** presented special difficulties. One of the cations exhibited disorder over two sites having a common centroid. It was not possible to successfully build the disordered cation from the electron density peaks alone; therefore a rigid group was constructed to represent the idealized cation by combining several cyclohexane templates from the database of the TEXSAN program. Two of these adamantane rigid groups were then oriented to two sets of three electron density peaks that could be identified as belonging to the two disordered orientations of the cation. The result agreed well with the original peaks observed in this region, and it was possible to refine the individual isotropic temperature factors of the atoms within the rigid groups, but attempts to relax the rigid group constraints led to unsatisfactory results.

The atoms of the anions of **3** were refined anisotropically, while the atoms of all cations were refined isotropically. Attempts to refine the ordered cations anisotropically did not reduce the R-factor significantly and led to several of these atoms having non-positive definite displacement parameters. It is possible that all of the cations, and not just one, are disordered to some extent.

Differential scanning calorimetry curves for compound **2** were obtained using a Mettler-Toledo TA 8000 instrument after sealing a crystalline sample (ca. 10 mg) in a standard aluminum pan. Several heating–cooling cycles (10°C min^{-1}) were carried out that showed that the phase change profiles were reversible. Integration of the 45°C endotherm was performed with the instrument software.

Discussion

Four new salts containing polychlorothallate anions have been isolated and characterized by X-ray crystallography. In general, the products are easily prepared and isolated from acidic solution. Crystal data are presented in Table 1, and fractional atomic coordinates for each of the chlorothallate(III) compounds **1–4** are presented in Tables 2–5, respectively. Perti-

nent bond lengths and angles for the chlorothallate anions of each salt are presented in Table 6. Hydrogen bonds (N—H---Cl) are evident in each structure, and these are summarized in Table 7. The following information has been deposited for compounds **1**–**4**:[2] complete experimental details; positional parameters for all atoms including hydrogens; anisotropic thermal parameters of nonhydrogen atoms where applicable; isotropic temperature factors of hydrogen atoms and other atoms where applicable; bond lengths, bond angles, and torsion angles.

[2] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. With the exception of anisotropic thermal parameters and torsion angles, these data have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Table 4. Fractional atomic coordinates and equivalent isotropic temperature factors (Å^2) for compound **3**. U_{eq} is defined as one third of the trace of the orthogonalized U_{ij} tensor.

To make a comparison of the structural features of the four salts, it is first useful to consider the structure of 4-chloropyridinium pentachlorothallate(III), which has a discrete pentacoordinated $[TlCl_5]^{2-}$ anion (7). This anion exhibits a slightly distorted square pyramidal geometry with Tl—Cl distances that range from 2.443(4) to 2.551(5) Å, the shortest distance being the apical Tl—Cl bond. The two longest basal Tl—Cl bonds are involved in hydrogen bonds to the cation, giving cation-anion-cation units.

Fig. 1. Formula unit of salt **1** (ORTEP) highlighting the octahedral coordination environment around the thallium centre (Cl(3) and Cl(4) are on inversion centres, and are shared as bridging atoms). Hydrogen atoms on carbon centres have been removed for clarity.

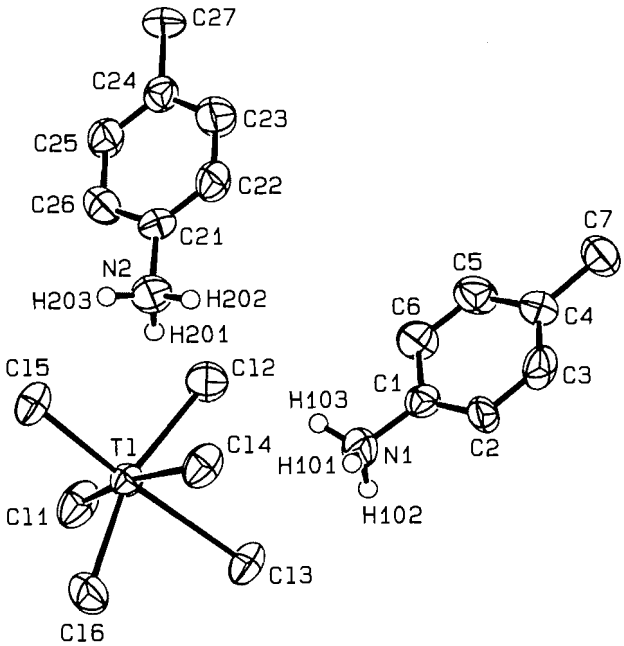

Fig. 2. Packing diagram of salt **1** (projection on (001) plane) showing the anionic *cis* chains.

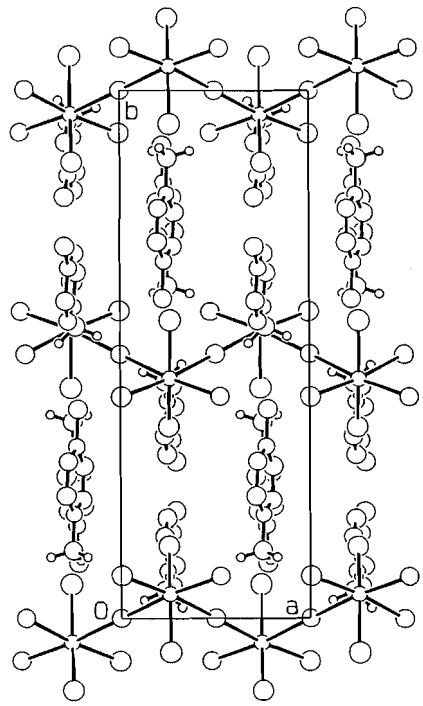

The asymmetric unit of salt **1** (Fig. 1) contains two symmetry-independent *p*-toluidinium cations and a $[TlCl_5]^{2-}$ fragment. In the structure, two chlorine atoms lie on crystallographic inversion centres, and therefore each forms a bridge between two thallium centres. In this way, the chlorine atoms form a distorted octahedron about each thallium tom, giving the overall stoichiometry for the anions of $[TlCl_4Cl_{1/2}Cl_{1/2}]^{2-}$. The two bridging Tl—Cl distances are long (2.8073(7) and 2.7986(7) Å)) while the terminal Tl—Cl distances are close to 2.5 Å, which is typical of six-coordinated Tl(III) (19). A projection of the structure on the (001) plane (Fig. 2) shows that the chlorothallate(III) anions form infinite, one-dimensional *cis*-linked (zigzag) chains (i.e., a Wells type (ii) chain) (20) that run parallel to the *a* axis (Fig. 2). Structural features for the cation are consistent with previous studies (21). The cations lie approximately parallel to the (100) planes, and they are linked via hydrogen bonds to the anionic chain such that all chlorine atoms act as hydrogen-bond acceptors. The anionic chains are not cross-linked by any hydrogen bonds.

Compound **2** contains a $[TlCl_5]^{2-}$ anion and a pentanediammonium dication in its asymmetric unit (Fig. 3). The anions are distorted square pyramidal, with four terminal Tl—Cl distances varying from 2.482(1) to 2.530(1) Å, while the Tl—Cl(3) distance is longer (2.655(1) Å). The angles made

Fig. 3. Asymmetric unit (ORTEP) of salt **2**. Hydrogen atoms on carbon centres have been removed for clarity.

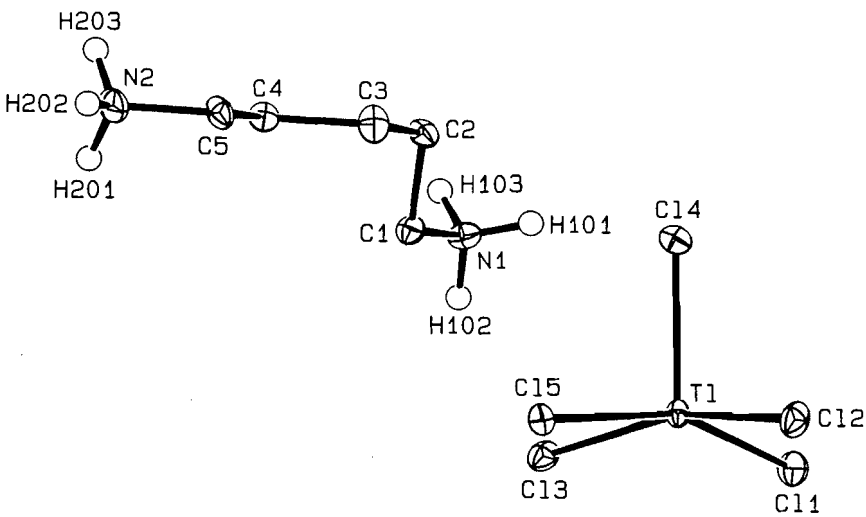

Fig. 4. Packing diagram of salt **2** (projection on (100) plane) illustrating the formation of the anionic chains through bridging Cl(3) sites. Hydrogen atoms on carbon centres have been removed for clarity.

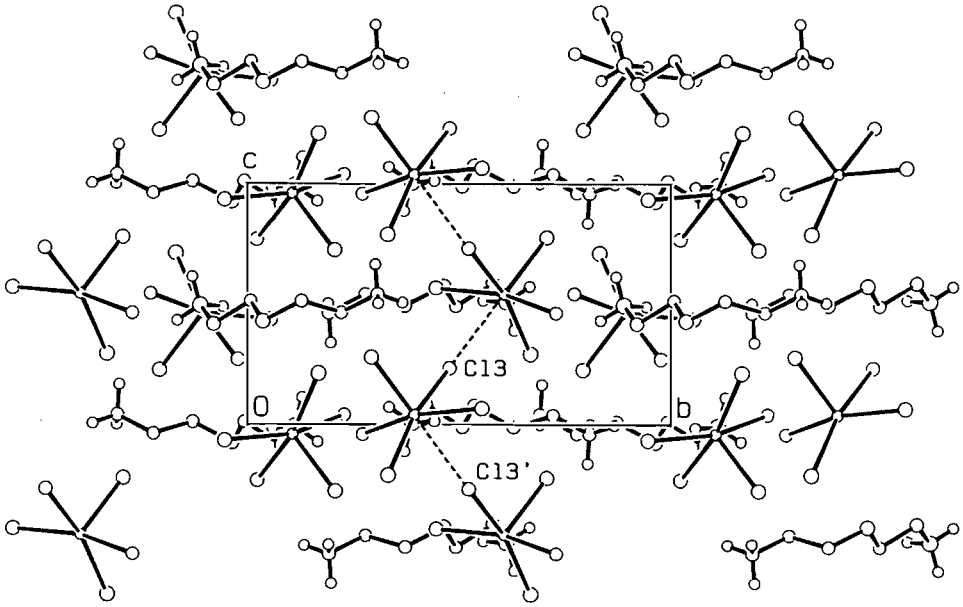


between the apical Tl—Cl(4) bond and those bonds in the basal plane vary from 85.52(5) to 103.12(5)°. The calculated distance of the Tl atom from the basal plane is 0.388(1) Å, while the mean deviation of the four basal Cl atoms from the plane is 0.037 (2) Å.

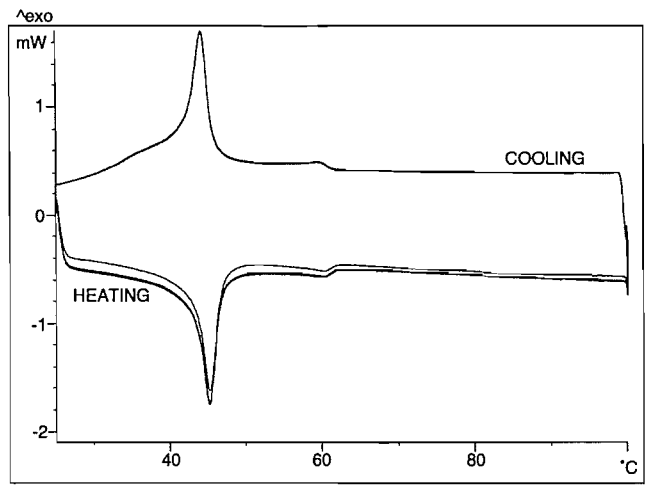
Each $[TlCl_5]^{2-}$ anion is related to another by a twofold screw axis along the *c* axis, giving a Tl---Cl(3′) contact distance of 3.225(5) Å. Thus Cl(3) forms a lopsided bridge between two thallium centres, and the longer Tl—Cl(3) distance 2.655(1) Å is typical for a TlCl asymmetric bridging bond (5). A helical or zigzag anionic chain extending along the *c* axis is formed (Fig. 4), but the contact distances suggest considerably weaker $[TlCl_5]^{2-}$---$[TlCl_5]^{2-}$ interactions than those in both **1** and Cs_2TlCl_5. Each chain of poly $[TlCl_5]^{2-}$ cross links via hydrogen bonding from N(1)—H to Cl(3) (N(1)---Cl(3) = 3.306(5) Å) in one chain to Cl(3′) (N(1)---(Cl3′) = 3.283(5) Å) in a neighbouring chain, thus forming a planar hydrogen-bonded network parallel to the *ab* plane. There are no Tl---Cl–Tl interactions between the anionic chains. The N(1) hydrogen atoms are also involved in hydrogen bonding to Cl(1), Cl(4), and Cl(5) (Table 7). All five chlorine atoms are hydrogen-bond acceptors from the N(2) hydrogen atoms, although not from the same asymmetric unit. The overall result is a complex three-dimensional network of hydrogen bonding connecting anions and cations within the *ab* layers and between the layers (Fig. 4). An alternative way of describing this system would be as an anion---cation---anion linkage where the anion is poly $[TlCl_5]^{2-}$.

Compound **2** crystallizes in a non-centrosymmetric space group (the absolute structure has been determined) with two cell dimensions of comparable length. Such compounds may display piezoelectric effects. Several halogenometallate compounds have been shown to undergo order–disorder phase transitions (such as K_2SnCl_6) (22) and hydrogen-bonded materials constitute a significant group of piezoelectric compounds. For example, in methylammonium trichloromer-

Table 8. Cell Constants for compound **2** at different temperatures.

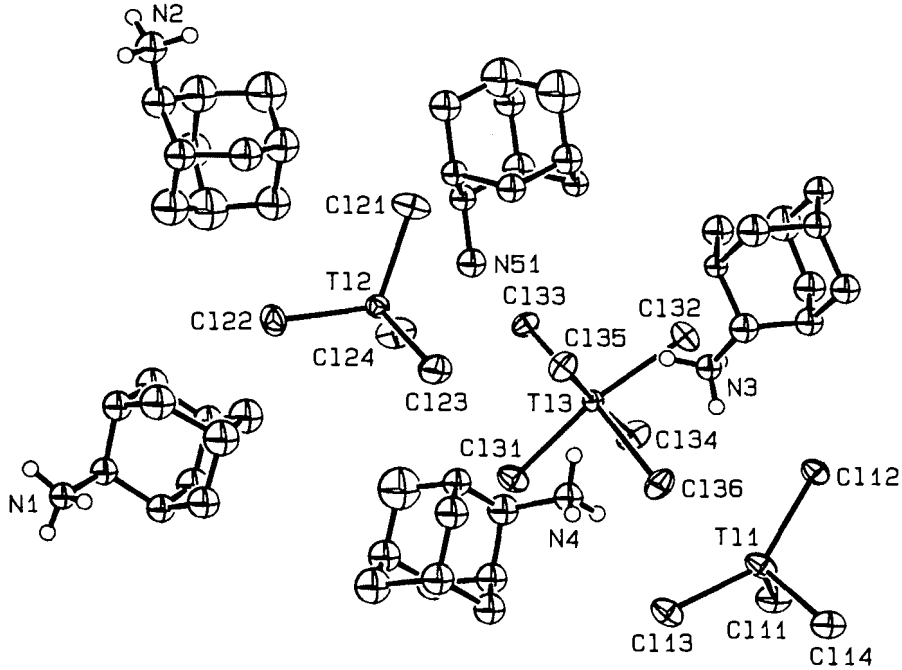
Temperature, °C	*a*, Å	*b*, Å	*c*, Å
−100	13.226(2)	13.595(2)	7.628(2)
10	13.313(2)	13.555(3)	7.695(1)
30	13.332(3)	13.526(3)	7.7192(8)

Fig. 5. Differential scanning calorimetry curve for salt **2**.



curate(II), N—H---Cl hydrogen bonding appears to be the ordering mechanism by which ferroelectricity is established (23). Although piezoelectricity has not been confirmed for salt **2**, measurements of the cell constants at three different temperatures (Table 8) suggest that the parameters *a* and *b* might, at some point, become equal and thus convert the unit cell to a tetragonal system, especially since the *b* axis contracts with increasing temperature. A phase transition was not observed in the differential scanning calorimetry data (Fig. 5) between

Fig. 6. Asymmetric unit (ORTEP) of salt **3**. Hydrogen atoms on carbon centres have been removed for clarity.

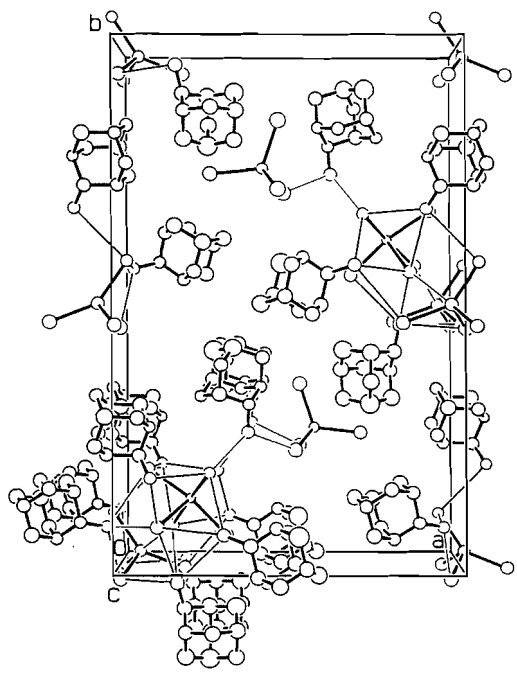


room temperature and −180°C, but a significant endothermic event (ca. 2.2 kJ mol^{-1}), which might be associated with ion reorientation, was observed at 45°C. A marked "shoulder" observed on this peak near 35°C suggests that there may be a gradual approach to the transition, similar to that proposed by Strømme for sodium perchlorate (24). This, together with a smaller (possibly second-order) transition at ca. 58°C, indicates that the thermal behaviour of the material is complex. In view of its high melting point (266°C) this compound is worthy of further investigation as a phase change material.

The asymmetric unit of salt **3** (Fig. 6) contains two structurally different $[TlCl_4]^-$ groups and one $[TlCl_6]^{3-}$ fragment, together with five 2-adamantaneammonium groups, one of which is disordered. The tetrahedral geometry of one of the $[TlCl_4]^-$ groups is regular, whereas the other (Tl(1)) is severely distorted (Table 6). The distorted tetrahedral $[TlCl_4]^-$ anion weakly bridges two regular $[TlCl_6]^{3-}$ octahedra via two long Tl---Cl contacts. This allows the distorted tetrahedral species to adopt a pseudo-octahedral geometry. In turn, each $[TlCl_6]^{3-}$ fragment bridges two distorted $[TlCl_4]^-$ fragments. The bridging Tl—Cl bond lengths of the $[TlCl_6]^{3-}$ ions are 2.657(5) and 2.667(5) Å, and the bridging Tl(1)---Cl contacts are 3.115(5) and 3.109(5) Å. The bridges therefore have the same asymmetric nature as those observed in compound **2**. The $[TlCl_6]^{3-}$ and $[TlCl_4]^-$ ions thus form a chain parallel to the *c* axis by vertex sharing such that the linkages are *cis* related in both the $[TlCl_4]^-$ and $[TlCl_6]^{3-}$ species (Fig. 7). To our knowledge, this type of chain has not been described previously for chlorothallate anions.

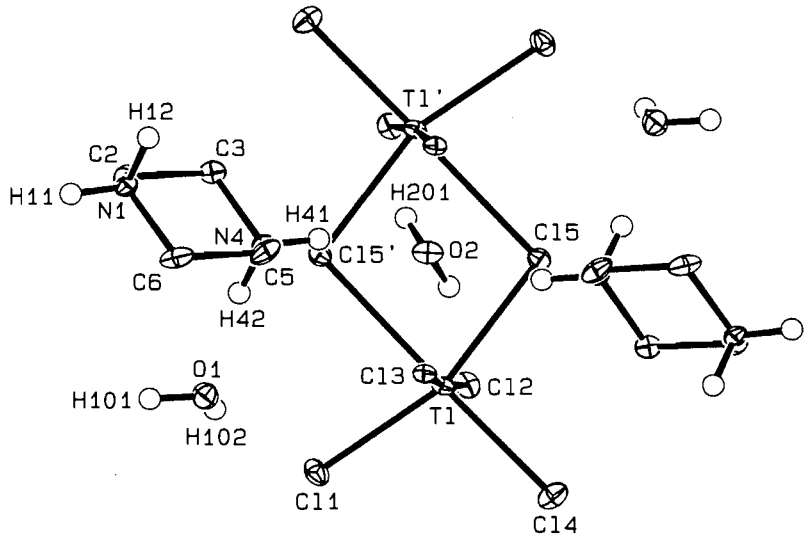
The hydrogen-bonding network in compound **3** is complex. Two of the chlorine atoms in the regular tetrahedral $[TlCl_4]^-$ anion are not involved in N—H---Cl hydrogen bonding (Table 7). The disordered cation (N(51)) is hydrogen bonded to two of the regular $[TlCl_4]^-$ fragments as well as to two of the chlorine atoms in the $[TlCl_6]^{3-}$ species. In addition, this latter anion receives hydrogen bonds from the cations containing N(3) and

Fig. 7. Packing diagram of salt **3** (projection on (001) plane). All hydrogen atoms have been removed for clarity. Thin lines between anions and cations represent hydrogen bonding. An additional set of cations has been added in the lower left side of the figure, as well as an extra $[TlCl_4]^{1-}$ in the middle of the figure to illustrate the anionic columns and cation---anion---cation chains which run parallel to the *c* axis.



N(4). The N(3) and N(4) containing cations are also involved with hydrogen bonding to the distorted $[TlCl_4]^-$ anion. The N(1) and N(2) containing cations are hydrogen bonded to the distorted $[TlCl_4]^-$ groups as well as to the $[TlCl_6]^{3-}$ moiety. As a result, there is a chain of anionic $--[TlCl_6]^{3-}---[TlCl_4]^-$---

Fig. 8. Formula unit (ORTEP) of salt **4**. Hydrogen atoms on the carbon centres have been removed for clarity.



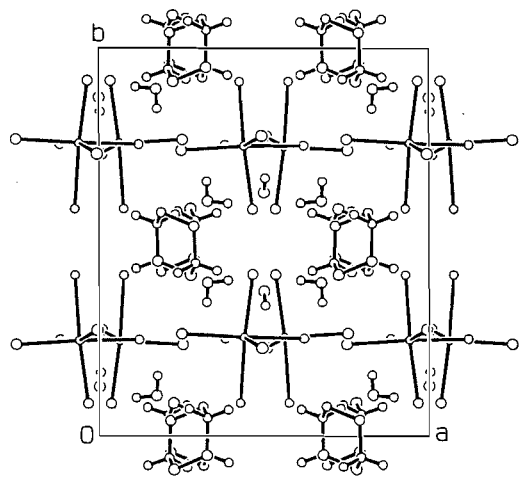
$[TlCl_6]^{3-}$-- units hydrogen bonded to four of the five surrounding adamantaneammonium cations that thus forms a thick column running along the *c* axis. The regular tetrahedral $[TlCl_4]^-$ ion and the disordered cation (Fig. 7) form another chain via hydrogen bonding, giving a cation---anion---cation linkage. The two chains run parallel to each other, and these are cross-linked through hydrogen bonding via the disordered cation. The regular tetrahedral $[TlCl_4]^-$ ion engages in hydrogen bonding with only the disordered cation.

The asymmetric unit of salt **4** contains the $[TlCl_5]$ fragment, one piperazinium cation, and 1.5 water molecules. The formula unit is related to the asymmetric unit by a twofold axis: the anion has twofold symmetry and one of the water molecules lies on a twofold axis. The resulting solid state structure (Fig. 8) is thus composed of piperazinium cations, H_2O molecules, and $[Tl_2Cl_{10}]^{4-}$ anions, the dimeric alternative to $[TlCl_5]^{2-}$. The dimerization results in the thallium centres having distorted octahedral coordination, and the bridging Tl—Cl distances are 2.562(1) and 2.894(1) Å. Alternating layers of cations and anions are clearly visible (Fig. 9) in the projection on the (001) plane. The cations are involved in hydrogen bonding to water molecules and to the chlorine atoms of the anion. The dimeric anion in salt **4** is similar to those observed previously in $CaTlCl_5(H_2O)_7$ and in "pyridinium enneachlorodithallate(III)" (25). The piperazinium dication adopts the "chair" conformation and displays structural parameters comparable to those in previous reports (see for example, ref. 26). The unique water molecule plays a central role in the hydrogen-bonding array. Its hydrogen atoms interact with the terminal Cl atoms of different $[Tl_2Cl_{10}]^{4-}$ units, while the oxygen atom interacts with the piperazinium N-H group. In addition, the symmetrical water molecule (O(2)) links the anion chains in the *c*-direction.

Conclusion

Three of the compounds (**1**, **2**, and **4**) possess the $TlCl_5$ stoichiometry, but none contains the isolated $[TlCl_5]^{2-}$ anion. In addition, three of the structures reported here (**1**, **2**, and **3**) possess

Fig. 9. Packing diagram of salt **4** (projection on 001 plane). Hydrogen atoms on the carbon centres have been removed for clarity.



anions that are linked into chains, all of the "vertex-sharing" type. In general, the factors that govern the formation of any particular chain in these anionic coordination complexes are not known. In the case of the chlorothallates, however, it is clear that entry of a chloride ion into the metal's coordination sphere is often favoured over that of water, but this trend is cation dependent, as shown by the contrasting structures of the potassium and rubidium salts that have the $[TlCl_5(H_2O)]$ formula (4). As a result, catenation of some type so as to produce a polynuclear system is more often observed than the mononuclear $[TlCl_5{:}OH_2]^{2-}$ anion. In the context of the structures for compounds having the $TlCl_5$ stoichiometry, the non-chain arrangement in the 4-chloropyridinium salt (7) now appears to be the exception rather than the rule, although the chain observed in compound **2** is probably rather weak. The steric requirements of the cation may also have a significant influence on the structure adopted around the thallium centre. Recently, a series of arene$[SbCl_3]_2$ complexes has been

examined, and the steric demands of the arene as well as the formation of Cl_3Sb---Cl–$SbCl_2$ contacts were identified as key factors affecting the observed solid state structural features (27). Hydrogen-bonding arrangements observed in all four chlorothallate structures reported here also have an unpredictable effect on the structure of the resulting thallium anion, but it is likely that a subtle balance exists between Tl---Cl and N—H---Cl contact formation. In view of these diverse effects, a careful crystallographic reexamination of other salts containing weakly coordinating anions including the tetraethylammonium pentachlorothallate(III) salt would be of interest (8).

The synthesis and high-resolution NMR spectroscopy of ethyl *N*-(2-triphenylmethylthio)ethanoyl-*O*-{4′-[4″-(1″-bis(2‴-chloroethyl)amino)phenyl]butanoyl}-L-seryl-*S*-benzyl-L-cysteine: a chelate–chlorambucil complex for use as a ligand for ^{99m}Tc radio-imaging

Russell A. Bell, Donald W. Hughes, Colin J.L. Lock, and John F. Valliant

Abstract: A potential agent for the imaging of tumours has been synthesized from the antineoplastic agent chlorambucil. Standard peptide coupling techniques were used to synthesize a tripeptide covalently coupled to chlorambucil in 10 steps. The final product was characterized by high-resolution NMR spectroscopy.

Key words: ethyl *N*-triphenylmethylthioethanoyl-*O*-{4′-[4″-(1″-bis(2‴-chloroethyl)amino)phenyl]butanoyl}-L-seryl-*S*-benzyl-L-cysteine, NMR spectroscopy, synthesis, radio-imaging agent.

Résumé : Utilisant l'agent antinéoplasique, on a synthétisé un agent pouvant éventuellement servir dans l'imagerie des tumeurs. On a utilisé les techniques standard de couplage des peptides pour synthétiser, en 10 étapes, un tripeptide lié d'une façon covalente à du chlorambucil. On a caractérisé le produit final à l'aide de la spectroscopie RMN à haute résolution.

Introduction

There are a number of approaches to the synthesis of technetium complexes that may act as radio-imaging agents. Of these, one of the most important is the synthesis of relatively small molecules that can chelate the technetium atom and that, typically, have three, four, or five coordinating atoms (1, 2). Examples are the ligands based on the *N*,*N*′-bis(mercaptoethyl) ethylenediamine framework, which has two nitrogen and two sulphur coordinating atoms (3). A second, important method is to bind one of these small chelating groups to a biologically significant molecule, often through a spacer chain. The biological molecule should have a well-defined receptor in the human body and, preferably, the nature of the binding site in the biological molecule should be known. The chelant group is bound to the biological molecule at a position distant from the binding site, and one hopes that the chelated metal is sufficiently far away that it does not interfere markedly with binding of the combined molecule to the receptor. Radio-imaging agents based on monoclonal antibodies, naturally occurring biological molecules, and drugs have all been prepared (4). An increasingly popular, third alternative is to synthesize relatively small polypeptides, with one end providing the site that binds to the receptor and the other end providing the chelant groups. In this paper we describe a combination of the two last procedures where we have used a tripeptide to provide the chelant group and the anti-cancer drug chlorambucil (5, 6) as the biological molecule.

Results and discussion

The first method used to try to synthesize **1** (see Fig. 1) was to make the tripeptide fragment and attach chlorambucil subsequently. This led, however, to an inseparable mixture, despite the coupling method used.[3] In the successful approach the pro-

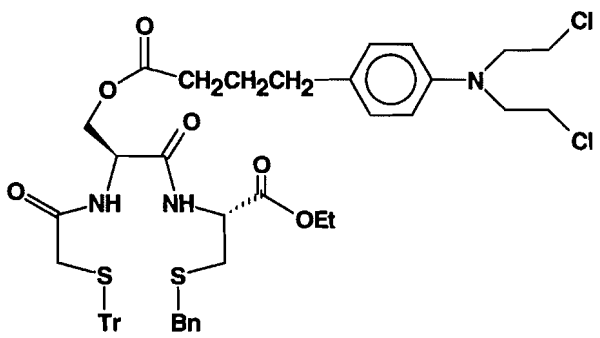
[3] The methods used the following combinations of coupling reagents: oxalyl chloride – dimethylformamide , DCC–DMAP, EDAC-HCl–DMAP.

Fig. 1. Ethyl *N*-(2-triphenylmethylthio)ethanoyl-*O*-{4′-[4″-(1″-bis(2‴-chloroethyl)amino)phenyl]butanoyl}-L-seryl-*S*-benzyl-L-cysteine, **1**.



tected dipeptide L-Ser-L-Cys[4] was coupled to chlorambucil before the addition of the mercaptoethanoic acid fragment.

The synthesis of the dipeptide–chlorambucil molecule is outlined in Fig. 2. The ethyl ester of *S*-benzyl-L-cysteine, **3**, was produced as the tosylate salt. The free amine of the cysteine derivative was subsequently coupled to *N-tert*-butoxycarbonyl-L-serine, in 80% yield, with ethyl-3-(3-dimethyl-amino)propylcarbodiimide hydrochloride (EDAC-HCl). The use of the water-soluble carbodiimide resulted in a product that could be isolated by recrystallization. This was in contrast to reactions in which the coupling reagent was dicyclohexylcarbodiimide (DCC), where repeated chromatography was required in order to remove residual dicyclohexylurea. The protected dipeptide **5** contained a free hydroxyl group and was now ready for formation of the chlorambucil ester **6**. The initial approach, which had limited success, was the preparation of the ester through the acid chloride (8). The improved procedure used EDAC-HCl and 4-dimethylaminopyridine (DMAP) as coupling reagents and gave **6** in 71% yield.

N-Hydroxysuccinimido-2-(triphenylmethylthio)ethanoate, **8**, has been reported to be a useful material with which to introduce protected mercaptoethanoic acid into a molecule (9). The literature procedures for the protection and activation of mercaptoethanoic acid are low-yield reactions that leave the final product contaminated with starting material and (or) dicyclohexylurea. In our approach to the protection of mercaptoethanoic acid (Fig. 3), the acid and triphenylcarbinol were dissolved in a mixture of acetic acid and dichloromethane, followed by the addition of boron trifluoride etherate. The use of dichloromethane as a cosolvent allowed reaction to occur at ambient temperatures rather than at 80°C, as the literature suggested, and resulted in a very pure product that was obtained in high yield. Compound **8** was produced by coupling **7** and *N*-hydroxysuccinimide in acetronitrile with EDAC-HCl: the product precipitated in high yield and purity in a short reaction time.

The addition of the final fragment, **8**, required the removal of the carbamate on the dipeptide–chlorambucil adduct (Fig. 4) and this was accomplished with trifluoroacetic acid and triethylsilane (9). The product, **9**, after extraction with acqueous sodium carbonate solution, was coupled to **8** and gave the tripeptide–chlorambucil adduct, **1**. The overall yield from *S*-benzyl-L-cysteine was 30%. Compound **1** was subjected to high-resolution NMR analysis.

NMR spectroscopy

The Bruker DRX-500 spectrometer, with its gradient capability, allowed the acquisition of two-dimensional spectra in remarkably short time periods. The gradient-COSY (10–13) and HSQC (14–16) spectra for compound **1** were each acquired in 5.5 min on approximately 15 mg of sample. The majority of the aliphatic ^{1}H and ^{13}C signals of **1** were assigned (Tables 1 and 2) by the aforementioned two-dimensional techniques and these were consistent with assignments made for the synthetic precursors. There remained several assignments in both the proton and carbon atom spectra of **1** that could not be made unambiguously. Consequently, a Heteronuclear Multiple Bond Correlation (HMBC) (17) experiment and a Heteronuclear Multiple Quantum Coherence – Total Correlation Spectroscopy (HMQC–TOCSY) (18) experiment were performed (Figs. 5 and 6).

The use of the HMBC pulse sequence with a low-pass *J* filter allowed proton resonances to be correlated with neighbouring carbon atom resonances through spin coupling interactions of $^{2}J_{H-C}$ and $^{3}J_{H-C}$ (Fig. 5). The initial use of the HMBC experiment was to assign the four carbonyl signals that corresponded to the two amide and two ester groups. The ethyl ester carbonyl peak (C-24) was assigned by correlation of the quartet of the methylene group of the ester (4.146 ppm) and the carbon atom signal at 169.9 ppm. The amide carbonyl signals were assigned by the observation of a two-bond correlation with the adjacent α proton signal. The α proton chemical shifts had been assigned previously to the appropriate amino acid by use of the COSY experiment. The remaining carbonyl signal belonged to the ester between the chlorambucil unit and the serine hydroxyl group. The HMBC experiment also facilitated the assignment of all the carbon atom signals in the aromatic systems as well as confirming the assignments of H-6, H-12, and H-19.

The HMQC–TOCSY experiment (Fig. 6) was used to corroborate the ^{1}H and ^{13}C assignments. For example, the proton resonance at 4.382 ppm was assigned as the α proton of serine (H-9). In the HMQC–TOCSY experiment, H-9 exhibited a HMQC correlation to C-9, the carbon to which it is directly bound. As a result of the TOCSY portion of the pulse sequence, H-9 also showed correlation with H-8 and H-10, the amide and β protons of serine, respectively. The proton signal assigned as H-10 also correlated to its directly bound carbon

[4] In this paper we have used a number of abbreviations. These are: AcOH, acetic acid; ACQ, acquire; BIRD, bi-linear rotation decoupling; Bn, benzyl; Boc, *tert*-butoxycarbonyl; COSY, correlation spectroscopy; DCC, dicyclohexylcarbodiimide; DCI, direct injection chemical ionization; DMAP, dimethylaminopyridine; EDAC, ethyl-3-(3-dimethylamino)propylcarbodiimide; Et, ethyl; FID, free induction decay; HMBC, heteronuclear multiple bond correlation; HMQC, heteronuclear multiple quantum coherence; HRDEI, high-resolution direct injection electron impact; HSQC, heteronuclear single quantum coherence; NMR, nuclear magnetic resonance; NOESY, nuclear Overhauser effect spectroscopy; TFA, trifluoroacetic acid; TLC, thin–layer chromatography; TOCSY, total correlation spectroscopy; Tr, triphenylmethyl; TsOH, *p*-toluenesulphonic acid. In addition, the standard three-letter abbreviations for amino acids are used (7).

Fig. 2. The synthetic pathway to ethyl *N-tert*-butoxycarbonyl-*O*-{4′-[4″-(1″-bis(2‴-chloroethyl)amino)phenyl]butanoyl}-L-seryl-*S*-benzyl-L-cysteine, **6**.

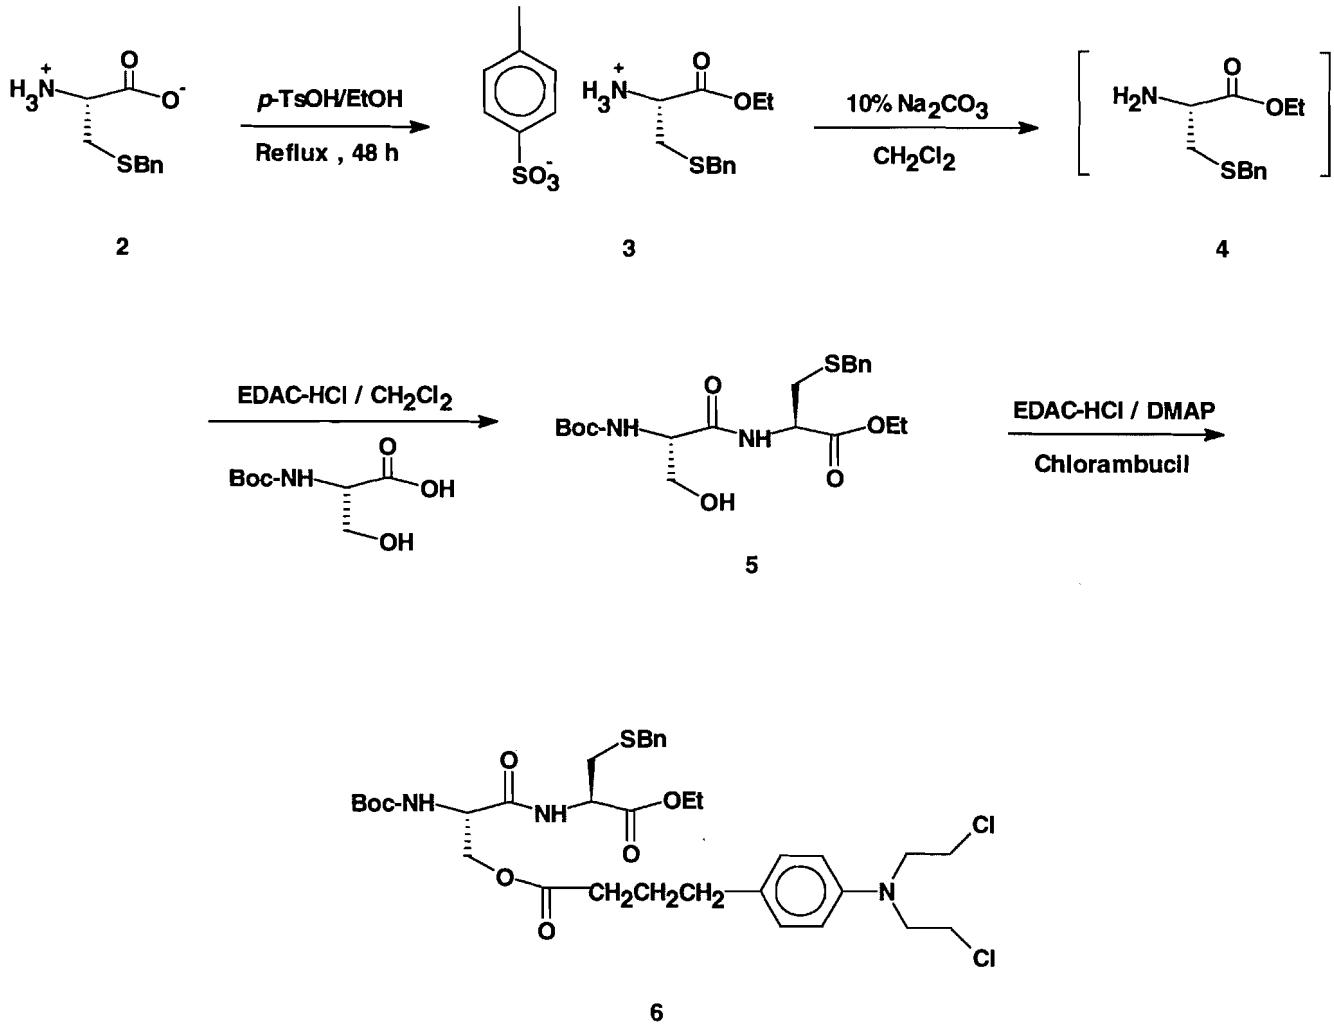


Fig. 3. Synthesis of *O*-(*N*-hydroxysuccinimido)-2-(triphenylmethylthio)ethanoate, **8**.

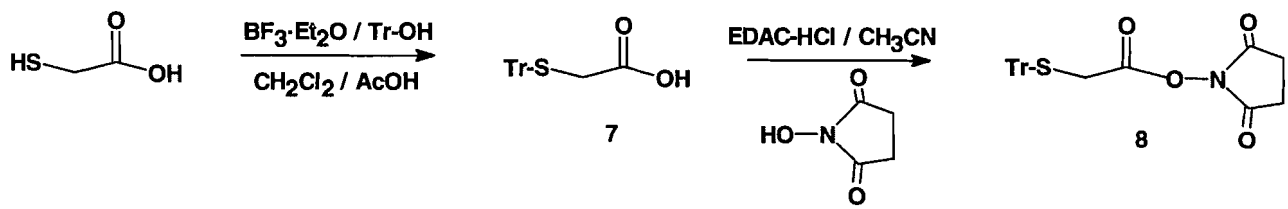

atom. As a result, all the proton and carbon atom signals within the serine portion of the molecule could be assigned. The results of the HMQC–TOCSY experiment were consistent with the assignment made in Tables 1 and 2.

The one-dimensional NOE difference spectra and the two-dimensional NOESY (19) spectra of **1** in $CDCl_3$ were entirely consistent with the assignments presented above. The presence of strong NOEs between H-9 and H-22, and between H-8 and H-6 and the complete absence of NOEs between H-9 and H-6, and H-9 and H-23, showed the anticipated preponderance of the *Z* geometric isomers of the two amide groups. Otherwise the molecule appeared to be relatively flexible with no particularly demanding conformational preferences. Thus the *ortho* protons on each of the aromatic rings showed NOEs to side-chain protons that were on carbon atoms one, two, and three bonds removed from the ring but there was no evidence for NOEs over longer distances. Likewise there were no observable NOEs between one set of aromatic protons and another that might have arisen from any possible stacking of the aromatic rings.

Fig. 4. The deprotection of **6** to yield **9** and subsequent coupling to **8** to yield ethyl *N*-(2-triphenylmethylthio)ethanoyl-*O*-{4′-[4″-(1″-bis(2‴-chloroethyl)amino)phenyl]butanoyl}-L-seryl-*S*-benzyl-L-cysteine, **1**.

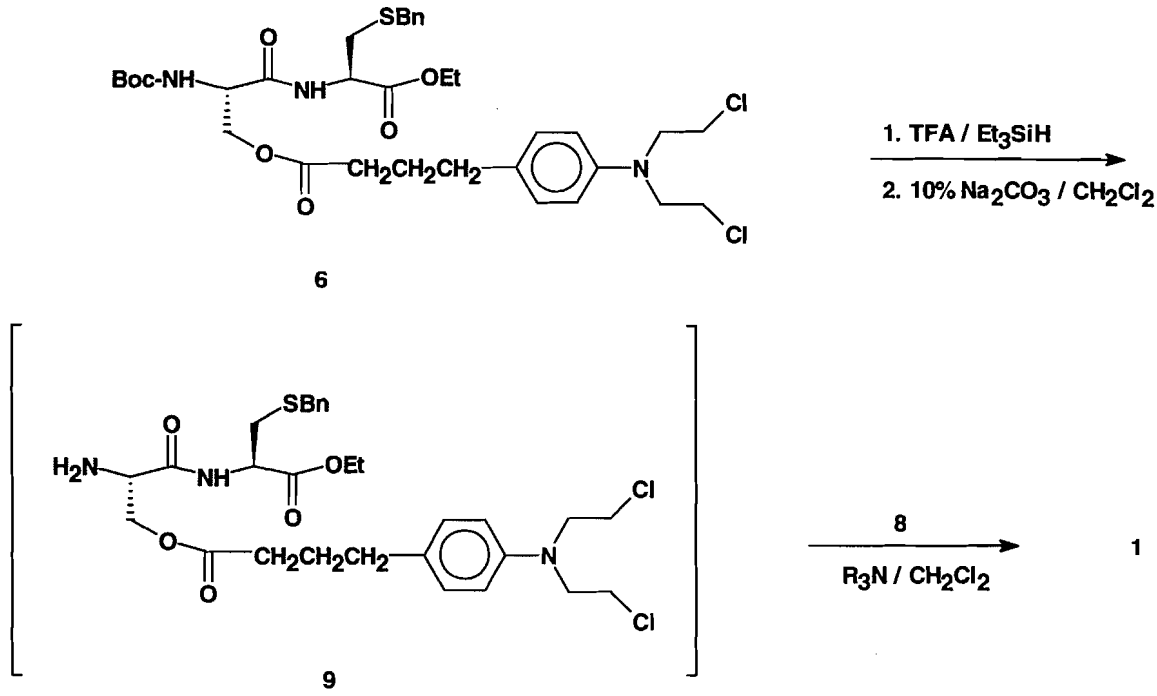

Fig. 5. The gradient HMBC spectrum of **1**.

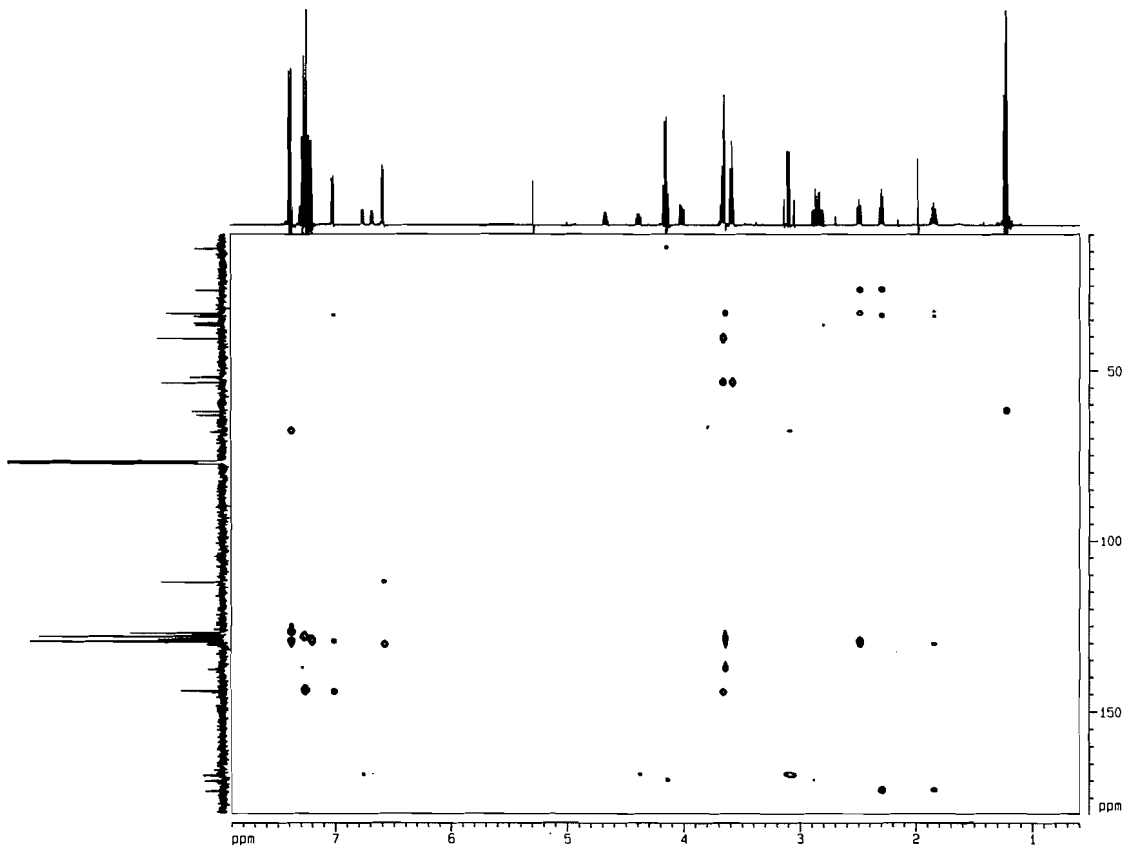

Fig. 6. The HMQC–TOCSY spectrum of compound **1**.

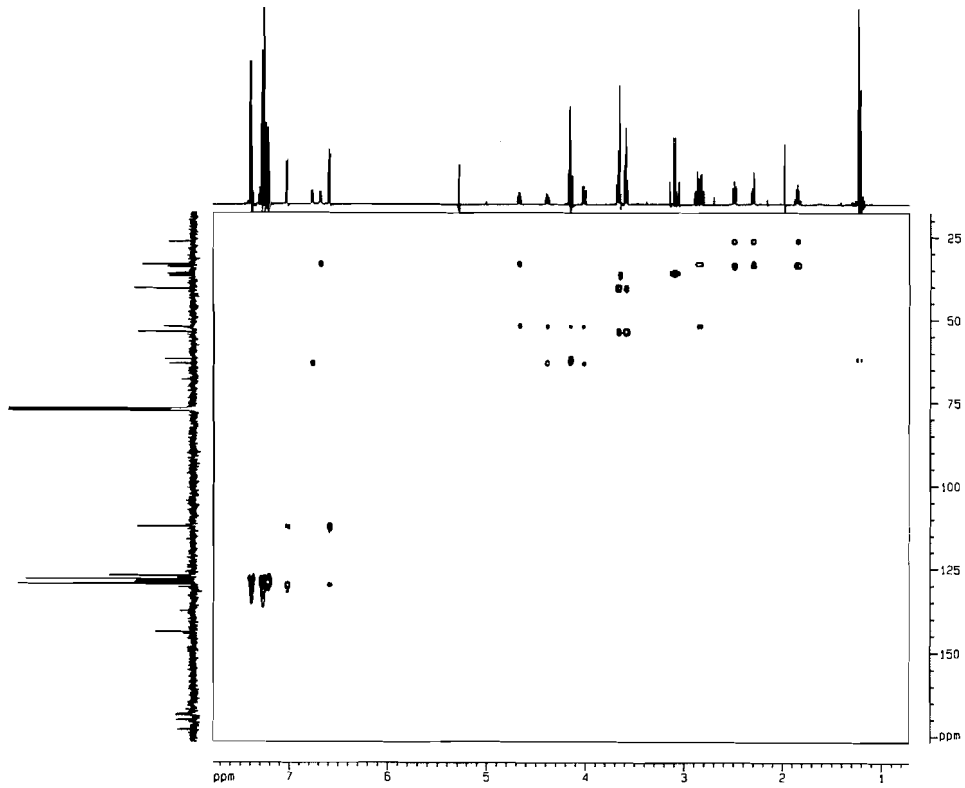

Thus, the synthesis of **1** was completed in 10 steps with 30% overall yield. A combination of two-dimensional NMR techniques was used to assign completely the proton and carbon atom spectra. As a result of the spectrometer's gradient capability the entire collection of spectra, ^{1}H, ^{13}C, COSY, HMQC, HMBC, HMQC–TOCSY, were collected within 6 h on a moderately dilute sample (15 mg/mL). The use of this compound as a reagent for the early detection of breast cancer is currently being investigated.

Experimental section

Analytical TLC was performed on silica gel 60-F_{254} (Merck) with detection by long-wavelength ultraviolet light. Chromatography was performed with a chromatotron (Harrison Research model 7924T) that used a 4 mm plate (EM Science silica gel 60 PF_{254} that contained gypsum). All commercial reagents were used as supplied. Solvents were distilled, under nitrogen, from calcium hydride. Nitrogen was dried by passing it through calcium sulphate. All reactions were protected from light and carried out under a slow flow of nitrogen. Solvents were evaporated with a rotary evaporator (20 Torr; 1 Torr = 133.3 Pa) at elevated temperatures (30–50°C).

The NMR spectra of **1** were recorded on a Bruker Avance DRX-500 spectrometer. Proton spectra were acquired at 500.130 MHz with a 5 mm broadband inverse probe with triple axis gradient capability. Spectra were obtained in eight scans in 32K data points over a 4.006 kHz spectral width (4.096 s acquisition time). Sample temperature was maintained at 30°C by a Bruker Eurotherm variable temperature unit. Gaussian multiplication (line broadening: −1.5 Hz, Gaussian broadening: 0.2) was used to process the free induction decay (FID), which was zero-filled to 64K before Fourier transformation.

Proton COSY two-dimensional NMR spectra were recorded in the absolute value mode with the pulse sequence 90°–t_1–45°–ACQ and included pulsed field gradients for coherence selection. Spectra were acquired in one scan for each of the 256 FIDs that contained 2K data points in $F2$ over the previously mentioned spectral width. The ^{1}H 90° pulse width was 6.6 μs. A 1.0 s relaxation delay was employed between acquisitions. Zero-filling in $F1$ produced a 1K × 1K data matrix with a digital resolution of 3.91 Hz/point in both dimensions. During two-dimensional Fourier transformation a sine-bell squared window function was applied to both dimensions. The transformed data were then symmetrized.

Carbon-13 NMR spectra were recorded at 125.758 MHz with a 5 mm broadband inverse probe with triple axis gradient capability. The spectra were acquired over a 28.986 kHz spectral width in 32K data points (0.577 s acquisition time). The ^{13}C pulse width was 4.0 μs (30° flip angle). A relaxation delay of 0.5 s was used. Exponential multiplication (line broadening: 4.0 Hz) was used to process the FID, which was zero-filled to 64K before Fourier transformation.

Inverse detected ^{1}H–^{13}C two-dimensional chemical shift correlation spectra were acquired in the phase-sensitive mode and used the pulsed field gradient version of the HSQC pulse sequence. The FIDs in the $F2$ (^{1}H) dimension were recorded over a 3.655 kHz spectral width in 1K data points. The 128 FIDs in the $F1$ (^{13}C) dimension were obtained over a 21.368 kHz spectral width. Each FID was acquired in two scans. The fixed delays during the pulse sequence were a 1.0 s relaxation

Table 1. The proton NMR assignments for ethyl *N*-(2-triphenylmethyl-thio)ethanoyl-*O*-{4′-[4″-(1″-bis(2‴-chloroethyl)amino)phenyl]butanoyl}-L-seryl-*S*-benzyl-L-cysteine, **1**.

[a]In the case of diastereotopic pairs of protons, the symbols A and B refer to the downfield and upfield signals, respectively, where these could be resolved.

delay and a polarization transfer delay of 1.786 ms. The 90° ^{1}H pulse was 6.6 μs while the ^{13}C 90° pulse was 11.6 μs. The data were processed with a sine-bell squared window function shifted by π/2 in both dimensions and linear prediction to 256 data points in *F*1 followed by zero-filling to 1K.

The pulsed field gradient version of the HMBC pulse sequence was used to acquire the inverse detected ^{1}H–^{13}C two-dimensional chemical shift correlation spectra through two- and three-bond coupling interactions in the absolute value mode. The FIDs in the *F*2 (^{1}H) dimension were recorded over a 3.655 kHz spectral width in 1K data points. The 128 FIDs in the *F*1 (^{13}C) dimension were obtained over a 21.368 kHz spectral width. Each FID was acquired in two scans. The fixed delays during the pulse sequence were a 1.0 s relaxation delay, a 3.3 ms delay for the low-pass *J*-filter, and 0.08 s delay to allow evolution of the long-range coupling. The 90° ^{1}H pulse was 6.6 μs while the ^{13}C 90° pulse was 11.6 μs. The data were processed with a sine-bell window function in both dimensions and linear prediction to 256 data points in *F*1 followed by zero-filling to 1K.

The HMQC–TOCSY spectra were acquired in the phase-sensitive mode. The FIDs in the *F*2 (^{1}H) dimension were recorded over a 4.006 kHz spectral width in 1K data points. The 128 FIDs in the *F*1 (^{13}C) dimension were obtained over a 21.368 kHz spectral width. Each FID was acquired in 32 scans. The fixed delays during the pulse sequence were a 1.0 s relaxation delay, a 0.3 s delay between the BIRD pulse and HMQC pulse sequence, and 3.571 ms for polarization transfer. The TOCSY spin lock was 100 ms. The 90° ^{1}H pulse was 6.6 μs while the ^{13}C 90° pulse was 11.6 μs. The ^{1}H spin lock 90° pulse width was 27.0 μs. The data were processed with a sine-bell squared window function shifted by π/2 in both dimensions and linear prediction to 256 data points in *F*1 followed by zero-filling to 1K.

Proton–proton NOE difference spectra were obtained by subtraction of a control FID from an on-resonance FID. The decoupler in the control FID irradiated a position in the spectrum where there was no proton signal. The on-resonance FID was obtained while the proton of interest was selectively saturated. In both cases the same decoupler power and duration of saturation (5.0 s) were used. This saturation period also served as the relaxation delay for both the control and on-resonance

Table 2. The carbon-13 NMR assignments for ethyl *N*-triphenylmethylthioethanoyl-*O*-{4′-[4″-(1″-bis(2‴-chloroethyl)amino)phenyl]butanoyl}-L-seryl-*S*-benzyl-L-cysteine, **1**.

Chemical shift (ppm)	Carbon atom	Chemical shift (ppm)	Carbon atom

14.1	C-26		

FIDs. The decoupler was gated off during acquisition. Eight scans were acquired for both the control and on-resonance FIDs and were repeated four times for a total of 32 scans for the final difference spectrum. A 90° ^{1}H pulse width of 6.6 μs was used. The FIDs were processed with exponential multiplication (line broadening: 4.0 Hz) and were zero-filled to 64K during Fourier transformation. The sample was not degassed.

Two-dimensional NOESY spectra were acquired in the phase-sensitive mode with use of the pulse sequence: 90°–t_1–90°–τ–90°–ACQ. Phase-sensitive data were obtained with time proportional phase incrementation (TPPI) (20, 21). The mixing time τ was 0.8 s. In the *F*2: dimension 2K data points were used during the acquisition of the 256 FIDs. Each FID was acquired in 32 scans over 4.006 kHz spectral width using a 1.0 s relaxation delay. Zero-filling in the *F*1 dimension produced a 1K × 1K data matrix after 2-D Fourier transformation of the phase-sensitive data. This resulted in an *F*2 digital resolution of 3.91 Hz/point. During the 2-D Fourier transform a sine-bell window function shifted by π/2 was applied to both dimensions. The transformed data were not symmetrized.

The compounds used in this study were dissolved in $CDCl_3$ (Isotec, Inc.) to a concentration of approximately 15.0 mg/mL. Chemical shifts are reported in ppm relative to TMS. The residual solvent signals at 7.24 and 77.0 ppm were used as internal references for the ^{1}H and ^{13}C spectra, respectively.

All other NMR spectra were recorded on a Bruker AC-200 spectrometer. Proton spectra were acquired at 200.133 MHz with a 5 mm dual frequency probe. Spectra were obtained in eight scans in 16K data points over a 2.403 kHz spectral width (3.408 s acquisition time). Spectra were acquired at ambient probe temperature. The free induction decay (FID) was processed with exponential multiplication (line broadening: 0.1 Hz) and was zero-filled to 32K before Fourier transformation.

Carbon-13 NMR spectra were recorded at 50.323 MHz with the 5 mm dual frequency probe. The spectra were acquired over a 12.195 kHz spectral width in 16K data points (0.672 s acquisition time). The ^{13}C pulse width was 1.5 μs (42° flip angle). A 0.5 s relaxation delay was used. The FIDs were processed with exponential multiplication (line broadening: 3.0 Hz) and zero-filled to 32K before Fourier transformation.

Synthetic procedures

2-(Triphenylmethylthio)ethanoic acid, 7

Triphenylcarbinol (24 g, 92.3 mmol) and mercaptoethanoic acid (8.5 g, 92.4 mmol) were dissolved in dichloromethane (50 mL) and glacial acetic acid (50 mL). A deep red solution was formed when boron trifluoride etherate (16 mL, 130 mmol) was added. The solution was allowed to stir at room temperature for 1 h, during which a precipitate formed. The dichloromethane was removed in vacuo and water (100 mL) was added to the residue. The product was collected by filtration and washed with water (3 × 100 mL), acetonitrile (50 mL), and cold diethyl ether (20 mL). The product was recrystallized from benzene. Yield: 26.68 g, 87%; mp 155–157°C (lit. (9) mp 158.5–160.0°C); TLC: R_f = 0.33 (10:90 v:v CH_3OH/CH_2Cl_2); ^{1}H NMR (200 MHz) ($CDCl_3$, δ: 7.25 (m, 15H, aryl), 2.90(s, 2H, S-CH_2); ^{13}C NMR (50 MHz) ($CDCl_3$), δ: 175.77 (COOH), 144.09–128.05 (C-aryl), 67.44 (CPh_3), 34.67 (S-CH_2).

O-*(N-Hydroxysuccinimido)-2-(triphenylmethylthio)-ethanoate, 8*

N-Hydroxysuccinimide (1.72 g, 15 mmol) was added to 2-(triphenylmethylthio)ethanoic acid (5.01 g, 15 mmol) in acetonitrile (20 mL). Solid ethyl-3-(3-dimethylamino)propylcarbodiimide hydrochloride (EDAC-HCl) (3.16 g, 16.5 mmol) was added to the mixture and the solution became transparent after 5 min. Shortly thereafter a precipitate was seen. After the suspension was allowed to stir for 2 h the precipitate was collected by filtration. The colourless solid (3.88 g, 60%) was washed with cold acetonitrile (15 mL). After cooling the filtrate to 4°C overnight an additional crop of product was collected by filtration (1.62 g, 25%); mp 183–185°C; TLC: R_f = 0.46 (2:98 v:v CH_3OH/CH_2Cl_2); ^{1}H NMR (200 MHz) ($CDCl_3$, δ: 7.17 (m, 15H, H-aryl), 3.08 (s, 2H, S-CH_2) 2.47 (s, 4H, CH_2-C=O)$_2$); ^{13}C NMR (50 MHz) ($CDCl_3$), δ: 165.0 ((CH_2-*C*=O)$_2$), 163.00 (SCH_2*C*OON), 143.49 (C-ipso), 129.42 (C-*ortho*), 128.17) C-*meta*), 127.08 (C-*para*), 67.98 (*C*Ph_3), 31.35 (S-CH_2), 25.45 ((CH_2-C=O)$_2$).

Ethyl S*-benzyl-*L*-cysteine* p*-toluenesulphonate, 3*

p-Toluenesulphonic acid (10.8 g, 56.8 mmol) was added to *S*-benzyl-L-cysteine (3.0 g, 4.2 mmol) in absolute ethanol (100 mL). The mixture was heated to reflux for 48 h. The solution was then evaporated to dryness and diethyl ether (100 mL) was added. The resulting white precipitate was collected by filtration and washed with ether (200 mL). Yield: 4.67 g, 80%; mp 131–134°C: ^{1}H NMR (200 MHz) (CD_3OD), δ: 7.299 (m, 9H, H-aryl), 4.155 (q, 2H, O*C*$H_2$$CH_3$), 4.102 (m, 1H, H_2N-*C*H), 3.752 (s, 2H, S*C*H_2Ph), 2.886 (m, 2H, CH-*C*H_2S), 2.319 (s, 3H, CH_3-Ph), 1.232 (t, 3H, OCH_2*C*H_3); ^{13}C NMR (50.3 MHz) (CD_3OD), δ: 169.12 (*C*O_2Et), 143.15 (C-SO_3H (*p*TsOH-*para* C) 141.90 (Bn-ipso C), 138.61 (*p*TsOH-ipso C), 130.16 (pTsOH-*meta* C), 129.85 (Bn-*ortho* C), 129.66 (*p*TsOH-*ortho*), 128.42 (Bn-*para* C), 126.95 (Bn-*meta* C),

63.86 (OCH_2CH_3), 53.29 (H_2N-*C*H), 36.79 (SCH_2Ph), 32.06 ($CHCH_2S$), 21.31 (*p*TsOH-CH_3), 14.30 (OCH_2CH_3).

Ethyl N-tert-*butoxycarbonyl-L-seryl*-S-*benzyl-L-cysteine, 5*

Aqueous sodium carbonate (40 mL of 10%) was added to a suspension of **3** (5.0 g, 12.2 mmol) in dichloromethane (80 mL). The mixture was shaken until everything dissolved. The aqueous layer was back-extracted with dichloromethane (2 × 40 mL) and the organic layers combined and dried over anhydrous sodium sulphate. The organic layers were combined and evaporated to dryness. The resulting yellow oil was then diluted with dichloromethane (50 mL). *N-tert*-Butoxycarbonyl-L-serine (2.27 g, 11.1 mmol) and EDAC-HCl (2.33 g, 12.2. mmol) were added to this solution. The solution was stirred under nitrogen and protected from light for 16 h. The solution was extracted with 1 N HCl (2 × 20 mL), 1 N $NaHCO_3$ (2 × 20 mL), and distilled water (2 × 20 mL). The organic layer was evaporated to dryness and the resulting solid recrystallized from acetonitrile. Yield: 3.7 g, 80%; mp 78–79°C; TLC: R_f = 0.58 (10:90 v:v CH_3OH/CH_2Cl_2); ^1H NMR (200 MHz) ($CDCl_3$), δ: 7.308 (s, 5H, H-aryl), 5.485 (d, ^3J = 7.15, 1H, amide NH), 4.740 (m, 1H, $CHCH_2S$), 4.155 (q, 2H, OCH_2CH_3), 4.066 (m, 1H, $CHCH_2OH$), 3.688 (s, 2H, SCH_2Ph), 3.650 (m, 2H, $CHCH_2OH$), 2.851 (m, 2H, $CHCH_2S$), 1.751 (bs, OH), 1.436 (s, 9H, $C(CH_3)_3$), 1.243 (t, $^3J_{18,19}$ = 7.12, 3H, OCH_2CH_3); ^{13}C NMR (50 MHz) ($CDCl_3$), δ: 171.18 (*C*OOEt), 170.54 (amide C=O), 155.78 (carbamate C=O), 137.42 (C-ipso), 128.86 (C-*ortho*), 128.03 (C-*meta*), 127.17 (C-*para*), 80.36 (*Ct*Bu), 62.89 (OCH_2CH_3), 61.91 (CH_2OH), 55.34 ($CHCH_2S$), 51.74 ($CHCH_2OH$), 36.27 (SCH_2Ph), 32.97 ($CHCH_2S$), 28.19 ($C(CH_3)_3$), 13.95 (OCH_2CH_3); MS (NH_3-DCI), *m/z* (RI%): 444 (15, M+1+ NH_3), 427 (100, M+1), 327 (30, M+1−Boc).

Ethyl N-tert-*butoxycarbonyl*-O-*{4'-[4''-(1''-bis(2'''-chloroethyl)amino)phenyl]butanoyl}-L-seryl*-S-*benzyl-L-cysteine, 6*

A solution of EDAC (100 mg, 0.52 mmol) and DMAP (6 mg, 10 mol%) in dichloromethane (5 mL) was added to **5** (200 mg, 0.47 mmol) and chlorambucil (136 mg, 0.45 mmol) in dry dichloromethane (15 mL). The reaction was stirred under a nitrogen atmosphere and protected from the light for 6 h. The solution was then extracted with 1 N HCl (2 × 10 mL), 1 N $NaHCO_3$ (2 × 10 mL), and distilled water (2 × 10 mL). The organic layer was concentrated and the product purified by chromatography (1% CH_3OH in CH_2Cl_2) to yield a colourless oil. Yield: 237 mg, 71%; TLC: R_f = 0.80 (5:200 v:v CH_3OH/CH_2Cl_2); ^1H NMR (200 MHz) ($CDCl_3$), δ: 7.269 (s, 5H, H-aryl), 6.997 (d, 2H, aniline-*meta*), 6.997 (d, 1H, amide NH), 6.584 (d, ^3J = 8.77, 2H, aniline-*ortho*), 5.210 (m, ^3J = 7.18, 1H, Boc-NH), 4.710 (m, 1H, $CHCH_2O$), 4.431 (m, 3H, CH-CH_2O and $CHCH_2S$), 4.154 (q, 2H, OCH_2CH_3), 3.659 (s, 2H, SCH_2Ph), 3.609 (m, 8H, CH_2CH_2Cl), 2.893 (m, 2H, $^3J_{AX}$ = 4.90, $^3J_{BX}$ = 5.71, $^2J_{AB}$ = −19.6, CH_2S), 2.497 (t, 2H, ^3J = 7.77, CH_2Ph), 2.307 (t, ^3J = 7.68, 2H, $C(O)CH_2$), 1.852 (m, 2H, $CH_2CH_2CH_2$), 1.434 (s, 9H, $C(CH_3)_3$), 1.233 (t, ^3J = 7.16, 3H, OCH_2CH_3); ^{13}C NMR (50 MHz), δ: 173.18 ($C(O)CH_2CH_2CH_2$), 170.12 ($C(O)OCH_2CH_3$), 168.96 (amide-C(O)), 154.37 (Boc-C(O)), 144.26 (aniline-ipso), 137.52 (aniline-*para*), 130.33 (benzyl-ipso), 129.60 (benzyl-*ortho*), 128.85 (benzyl-*meta*), 128.52 (aniline-*meta*), 127.21 (benzyl-*para*), 112.08 (aniline-*ortho*), 80.60 ($C(CH_3)_3$), 63.79 ($CH_2OC(O)$), 61.85 (OCH_2CH_3), 53.49 (CH_2Cl), 51.79 ($CHCH_2S$ and $CHCH_2O$), 40.43 (NCH_2), 36.47 (SCH_2Ph), 33.80 (CH_2Ph), 33.21 ($C(O)CH_2$ and $CHCH_2S$), 28.18 ($C(CH_3)_3$), 26.41 ($CH_2CH_2CH_2$), 14.00 (OCH_2CH_3); MS (HRDEI), calcd.: 711.2540; found: 711.2526.

Ethyl N-*(2-triphenylmethylthio)ethanoyl*-O-*{4'-[4''-(1''-bis(2'''-chloroethyl)amino)phenyl]butanoyl}-L-seryl*-S-*benzyl-L-cysteine, 1*

Triethylsilane was added dropwise to a solution of **6** (50 mg, 0.070 mmol) in trifluoroacetic acid, TFA (5 mL), until the yellow solution became colourless. The reaction mixture, which was protected from light, was allowed to stir for 2 h before the TFA was removed in vacuo. The resulting oil was diluted with dry dichloromethane (20 mL) and the reaction mixture extracted with aqueous Na_2CO_3 (10 mL, 10%). The aqueous layer was back-extracted with dichloromethane (2 × 10 mL) and the organic layers combined and evaporated to dryness. The resulting oil was diluted to 10 mL with dichloromethane and compound **8** (28 mg, 0.064 mmol) was added together with freshly distilled diisopropylethylamine (9.1 mg, 0.070 mmol). The reaction was stirred under nitrogen and protected from light for 24 h. The product was isolated by chromatography (1% CH_3OH in CH_2Cl_2). Yield: 33 mg, 50%; TLC: R_f = 0.71 (2:98 v:v CH_3OH/CH_2Cl_2). Anal. calcd.: C 64.7, H 5.9, N 4.5%; found: C 65.2, H 6.1, N 4.6%. For NMR data see Tables 1 and 2.

A gas-to-solid phase methanolysis method for the analysis of small amounts of oligosaccharides

Daniel Derbie Asres and Hélène Perreault

Abstract: A gas-to-solid phase methanolysis method for the analysis of oligosaccharides is presented. The advantages of using this new gas-to-solid phase method, as opposed to conventional bulk phase techniques, are described, along with comparisons of results obtained from both techniques. The reliable bulk phase methanolysis methods are used as benchmarks for assessing the extent of completion of the gas-to-solid reactions. Gas chromatographic – mass spectrometric (GC–MS) data show that, in general, higher temperatures and longer reaction times are required for completion of the gas-to-solid methanolysis process than for completion of the bulk phase reaction. On the other hand, the gas-to-solid procedure requires only minimal amounts of substrate that would be difficult to characterize using bulk phase methanolysis due to losses during clean-up procedures. Gas-to-solid methanolysis reactions of permethylated di- and trisaccharides were investigated (GC–FID and GC–MS), following initial experiments performed in order to characterize the GC retention times and mass spectra of permethylated standard monosaccharides. Conversion of neutral disaccharides, as well as neutral and acidic trisaccharides, to their respective monosaccharides was successful using the gas-to-solid method. The GC–FID and GC–MS traces show that the gas-to-solid method gives a cleaner reaction than the bulk phase method.

Key words: oligosaccharides, methanolysis, permethylation, gas chromatography – mass spectrometry, mass spectrometry.

Résumé : Le développement et l'optimization d'une méthode phase gazeuse – phase solide pour la méthanolyse d'oligosaccharides sont décrits. En se basant sur un méthode de méthanolyse conventionnelle pour fins de comparaison, le degré de complétion des réactions phase gazeuse – phase solide a pu être étudié en fonction du temps et de la température. Les résultats d'analyses par chromatographie à phase gazeuse couplée à la spectrométrie de masse (GC–MS) montrent qu'en général, la méthanolyse complète en phase gazeuse – phase solide requiert plus de temps et des températures plus élevées que la méthanolyse conventionnelle en phase liquide. La méthode phase gazeuse – phase solide a été appliquée à des di- et trisaccharides perméthylés, après que des standards de monosaccharides perméthylés ait été étudiés relativement à leurs temps de rétention en chromatographie gazeuse couplée à un détecteur à ionisation par flamme (GC–FID) et en GC–MS. La méthode de méthanolyse phase gazeuse – phase solide permet de briser les liens glycosiques au sein d'oligosaccharides neutres et à caractère acide. De plus, cette méthode permet d'utiliser des quantités de substrat moindres qu'avec la méthode de méthanolyse conventionnelle en phase liquide grâce à l'omission des procédures d'extraction nécéssaires en phase liquide.

Mots clés : oligosaccharides, méthanolyse, perméthylation, chromatographie gazeuse – spectrométrie de masse, spectrométrie de masse.

Introduction

Structural analysis of oligosaccharides by mass spectrometry (MS) and tandem mass spectrometry (MS–MS) is useful for providing information on the total molecular weight and sequence of monosaccharides, but with limited ability in the latter case for distinguishing between different hexose or pentose isomers. In some cases (1–3), MS–MS allows for precise determination of the sequence of monosacharides by comparison with compounds of known structure, although this procedure becomes impossible in the absence of standards. Tandem MS experiments can also be used to indicate branching patterns in oligosaccharides (4, 5).

The important and characteristic carbohydrate features left uncertain after direct mass spectrometric analysis of an oligosaccharide are the position and anomericity of glycosidic bonds and, most often, the exact nature of the monosaccharides involved in the sequence. Some differentiation between different types of hexoses (e.g., mannose vs. glucose vs. galactose, etc.) by methods using mass spectrometry can be achieved, provided that chemical modification such as periodic acid oxidation (6) is performed prior to mass spectral analysis.

Sugar composition of a given oligosaccharide molecule may also be determined by means of methanolysis (7, 8) or acetolysis (9) followed by chromatographic analysis. These methods break the glycosidic bonds between sugar units (monosaccharides) and the products obtained can then be separated by chromatography and identified according to their GC retention times and mass spectra using GC–MS. In general, native (underivatized) monosaccharides present a prob-

lem in routine chromatographic analysis since they decompose at the high temperatures used in GC. Moreover, they contain no chromophores for ultraviolet (UV) detection in high-performance liquid chromatography (HPLC). It is therefore necessary to perform derivatization following methanolysis or acetolysis. Trimethylsilylation (10) has so far been the most popular method used to derivatize monosaccharides for GC with flame ionization detection (FID), and for GC–MS analysis, although methylation (11), acetylation (12), and other methods have also been used. For HPLC–UV analysis, it is preferable to label the monosaccharides obtained from glycosidic cleavage with chromophores. Examples of reagents that have been used for this purpose include benzoyl chloride (13), benzoyl anhydride (14), 4-nitrobenzoyl chloride (15), and benzyl chloride.

This paper reports a new gas-to-solid phase methanolysis procedure that minimizes the amount of substrate required for determination of sugar content. The method was used to cleave oligosaccharides that were permethylated prior to methanolysis. A very thin layer of solid substrate, containing a few nanomoles of the material, was deposited on the walls of an open capillary tube and exposed to the gas phase reagents. The products remained as solids on the surface of the tube and pumping at high vacuum was used to remove excess reagents and by-products. For this technique to be successful the reagents used must boil at much lower temperatures than those at which the substrates melt or decompose. Cleavage of the disaccharide lactose (α and β) was studied in order to determine the conditions necessary for complete reaction. Permethylated lactoses were sufficiently volatile to be analyzed by GC and could be observed in the chromatograms in cases where methanolysis remained incomplete. Permethylated trisaccharides and higher order carbohydrates did not elute at temperatures up to 275°C. Conditions that yielded complete methanolysis of lactose (gas-to-solid, 80°C, 18 h) also seemed to break all glycosidic bonds in trisaccharides, judging from the absence of disaccharide peaks in the corresponding chromatograms.

The compounds of interest for this study were investigated by fast atom bombardment (FAB) MS, GC–FID, and GC–MS. FAB-MS experiments were useful for the determination of the molecular weights of permethylated substrates. The FID and total ion current (TIC) chromatograms provided retention times, whereas the mass spectra obtained from GC–MS analyses were useful for elucidation of some structural features.

Experimental

Chemicals

Monosaccharides L(−)fucose, D(+)galactose, D(+)glucose, and *N*-acetyl neuraminic acid (sialic acid) were obtained from Sigma Chemicals (St. Louis, Mo.). Lactoses (α and β) were also purchased from Sigma. Trisaccharides 2′-fucosyllactose and 6′-sialyllactose were obtained from Oxford Glycosystems (Rosedale, N.Y.). Methyl iodide was obtained from Aldrich Chemicals (St. Louis, Mo.) and 0.5 M methanolic HCl was purchased from Supelco Inc. (Bellafonte, Pa.). Solvents were glass distilled or HPLC grade and were obtained from Pierce Chemicals (Rockfort, Ill.; dimethyl sulfoxide) and Mallinckrodt (Paris, Ky.; chloroform, dichloromethane, acetonitrile, and methanol).

Permethylation of mono-, di-, and trisaccharides

The method employed was derived from that of Larsson et al. (11). Briefly, the saccharides (10–25 nmol) were dissolved in dimethyl sulfoxide (200 μL), and NaOH powder (10 mg) was added. The mixture was sonicated for 10 min and methyl iodide (50 μL) added, followed by sonication at room temperature for 2.5 h. Water (1.5 mL) chloroform (1.5 mL) were added to the reaction mixture and the chloroform layer, containing the permethylated compounds, was extracted 3 times with water (1.5 mL). The solvent was then evaporated in vacuo, and the residue redissolved in acetonitrile or dichloromethane to give a concentration of ca. 0.2 nmol/μL.

Conventional bulk phase methanolysis

The method used in this study is a modification of the technique introduced by Fournet et al. (7) and reviewed by Dell et al. (9). The permethylated di- and trisaccharides (10–25 nmol) in acetonitrile (ca. 100 mL) were placed in screw-cap culture tubes and the solvent evaporated *in vacuo*. Methanolic HCl (0.5 M, ca. 20 μL) was added to the substrate and the mixtures heated at 65°C for 3 h. Methanol and hydrochloric acid were removed under vacuum and the methanolysis products were redissolved in dichloromethane for GC–MS analysis.

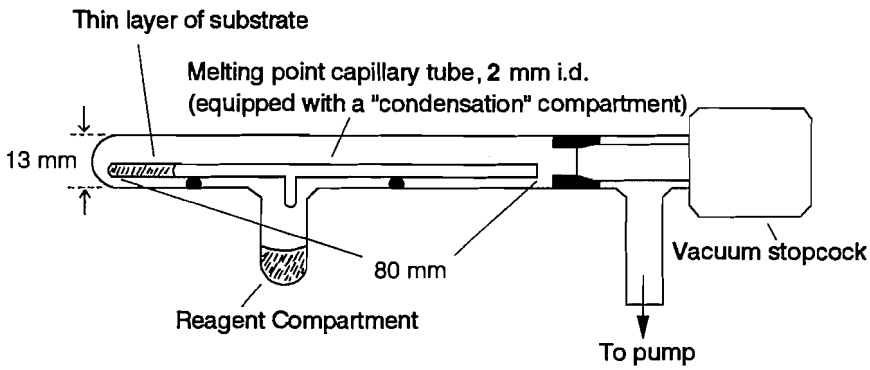
Gas-to-solid reactions

These reactions were conducted with an adapted model of the apparatus developed by Vath for microderivatization of peptides and proteins (16) and later used by Domon, Vath, and Costello (17) and Perreault and Costello (5) for derivatization of glycosphingolipids. The use of this apparatus has been described elsewhere (18). Briefly, the apparatus is built based on a hydrolysis tube (Pierce Chemicals, Rockford, Ill.) modified by the addition of a reagent well in its middle section. A model of the apparatus is shown in Diagram 1. A few microlitres of solution of the substrate are placed in a melting-point capillary and the solvent is evaporated under vacuum. The reagent is deposited in the well and the capillary tube is inserted in the main cavity of the apparatus. The reagent is frozen with liquid nitrogen, and the apparatus evacuated and sealed. The reagent is then allowed to thaw and degas under vacuum, and the freeze–pump–thaw cycle is repeated. The apparatus is then placed in an oven and the reaction allowed to take place at a pre-chosen temperature. At the end of the reaction time, the reagent well is frozen again and any condensation on the walls of the apparatus removed by evacuation. The capillary tube containing the product is removed, and the product transferred to a 10 cm^3 screw-cap culture tube with solvent. The solvent, remaining reagent, and any by-products are removed under vacuum. The sample is then redissolved in either acetonitrile for FAB analysis, or dichloromethane for GC–MS analysis.

Gas-to-solid method for methanolysis

The permethylated di- and trisaccharides (10–15 nmol) were deposited on the walls of a melting point capillary tube open at one end by evaporation from a solution. Methanolic HCl (0.5 M, 250 μL) was pipeted into the reagent well of the reaction apparatus. The reaction was completed following the general procedure described above (18) by heating at 80°C for periods of time varying from 6 to 22 h.

Diagram 1. Apparatus used for gas-to-solid phase methanolysis (16–18).



GC–FID analyses

Aliquots of solution (1 μL) of permethylated/methanolyzed compounds in dichloromethane (ca. 0.2 nmol/μL) were injected into a Varian 3400CX gas chromatograph equipped with a megabore (530 μm film thickness, 3 m long DB-1 column (100% methyl-silicone); J&W Scientific), a flame ionization detector, and a Varian Star 4.0 Windows-based data system.

GC–MS analyses

Two different GC–MS systems were used in this study. Chromatographs in both systems were equipped with DB-5 columns (95% methyl-, 5% phenyl silicone; J&W Scientific) with 250 mm i.d. and 0.25 μm film thickness. The first GC–MS system consisted of a Varian 3400 chromatograph and Finnigan Mat Ion Trap Detector 800. The DB-5 column described above was 60 m long and the data system used was Finnigan Mat ITDS, version 4.10. The second GC–MS apparatus used consisted of a Hewlett Packard (HP) 5890 chromatograph (30 min long DB-5 column) linked to a HP 5988A quadrupole mass analyzer. For both GC–MS instruments, repetitive 1 s scans were effected on a range of 50–650 Da. Electron impact (EI) ionization sources were kept at 260°C and electron energy was set at 70 eV.

For all three of the chromatographs used, oven temperatures were programmed as follows: Initial temperature of 80°C kept constant for 10 min, followed y a linear temperature ramp to 280°C at the rate of 7°C/min, and temperature held constant at 280°C for 10 min.

Fast atom bombardment (FAB) analyses

FAB experiments were performed with a VG Analytical 7070E mass spectrometer of E-B geometry. The matrix used was 3-nitrobenzyl alcohol (Sigma, St. Louis, Mo.). The FAB gun (Xe^0) was operated at 8 kV with a current of 1 mA. Conventional scans were at the rate of 2s/decade and the *m/z* range convered was from 50 to 1000 Da. The data system used was PDP11-based 11-250J from VG Analytical.

Results and discussion

Four different monosaccharides were investigated in order to lay the groundwork for the methanolysis of larger species. Permethylation of D(+)-galactose, D(+)-glucose, L(−)-fucose, and *N*-acetylneuraminic acid was carried out and the products analyzed by gas chromatography and mass spectrometry. Electron impact mass spectral data on these compounds have been reported in the MS libraries of the National Institute for Science and Technology (NIST) (19). These reference spectra were used for comparison purposes with the data obtained in this study. GC–MS retention times of the permethylated monosaccharides were measured for further comparison with those of methanolysis products.

Permethylated monosaccharides

Permethylation of D(+)galactose and D(+)glucose was expected to produce anomeric compounds in each case, due to the formation of α and β methyl glycosides. Determination of molecular weights by FAB-MS showed that both glucose and galactose had been pentamethylated, possibly suggesting a closed ring with an a or b methoxy group on C1. The anomericity of the C1—OCH_3 bonds was not differentiable by either EI or FAB when samples were introduced as a mixture of anomers. In fact, permethylated D(+)galactose and D(+)glucose produced very similar FAB fragmentation patterns GC–MS analysis provided more details on these aspects and will be discussed later.

The permethylation and (or) methanolysis products were analysed by GC–FID prior to GC–MS since this technique was much more rapid owing to the use of a shorter column (3 m) than that used for GC–MS (30 and 60 m).

The GC–FID chromatograms obtained for permethylated D(+)galactose and D(+)glucose each showed the presence of two major compounds, possibly the α and β glycosides of each species. The data are reported in Table 1, columns B and C. Permethylation of galactose yielded products eluting over the 12.8–13.5 min time range. The major peak at 13.30 min in fact covers two peaks (resolved on a longer column as will be shown later) and corresponds to the two principal forms of the products while minor peaks at 13.02 and 13.48 min possibly correspond to isomers of the main products. The two major forms of permethylated glucose elute earlier than galactose. The main products from permethylated galactose are observed at 12.54 and 12.97 min, respectively, whereas a less important product elutes at 12.70 min. Three injections were performed for each sample and there is a corresponding ±0.05 min error on retention time values reported.

The GC–MS results obtained for the permethylated monosaccharide standards galactose and glucose showed the same general trends in both total ion current (TIC) and FID

traces. The capillary columns used for GC–MS in this study were longer (30 min and 60 m instead of 3 m for GC–FID) and had a narrower bore, such that longer retention times were observed and better resolution and efficiency were achieved. Also, inversions of relative peak intensities from FID to TIC chromatograms were observed due to the difference in relative detection efficiencies (FID current vs. TIC). The data are reported in Table 2, columns B and C.

Interestingly, permethylated galactose (chromatogram shown in Fig. 1*a*) yielded two major peaks instead of the one peak observed in GC–FID owing to the increase in resolution. The electron impact spectra taken at the apex of both peaks are somewhat different (Fig. 2) and could be interpreted as making up two components of the spectrum found in the literature (19*a*, *b*) for methyl 2,3,4,6-tetra-*O*-methyl (β and α) D-galactopyranoside. The main difference between the spectra of Fig. 2 is the occurrence of abundant ions at *m/z* 88 (Fig. 2*a*, corresponding to 27.13 min retention time) while these ions do not appear significantly in the other spectrum (Fig. 2*b*). Also, ions at *m/z* 111 are present only in the spectrum of Fig. 2*a*. Library spectra of tetramethylated D-galactose, non-methylated in position 1, were searched and indeed contain abundant *m/z* 111 ions (19*c*). However, significant higher mass ions of these library spectra could not be found in the spectrum of Fig. 2*a* and therefore the possibility of undermethylation was rejected. In support of this, an undermethylated product would have a

Diagram 2. Suggested structures for the *m/z* 101 ions observed in the case of permethylated (*a*) D(+)galactose (Fig. 1*b*) and (*b*) L(−)fucose (Fig. 4*b*).

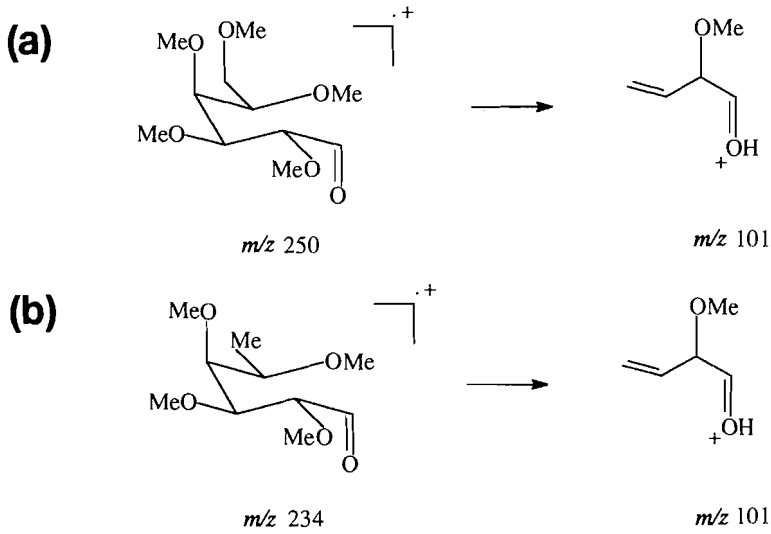

Fig. 1. Portions of the GC–MS total ions chromatograms obtained for permethylated (*a*) D(+)galactose and (*b*) D(+)glucose. Data obtained with the Varian 3400 GC/Finnigan Mat ITD-800 MS system.

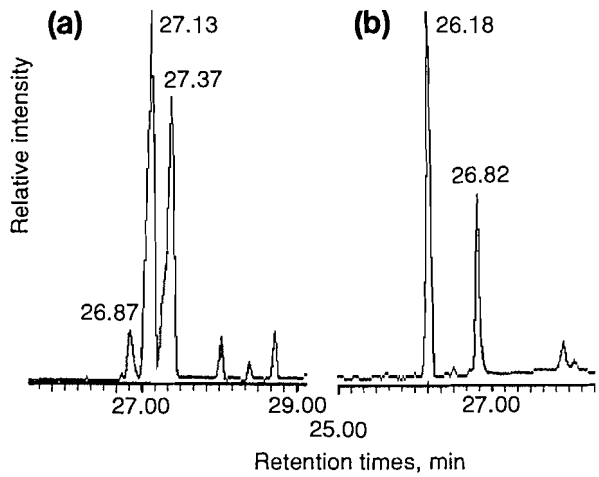

Fig. 2. Electron impact mass spectra recorded at the apex of the GC/TIC peaks observed in Fig. 1*a* (*a*) Peak at 27.13 min; (*b*) peak at 27.37 min.

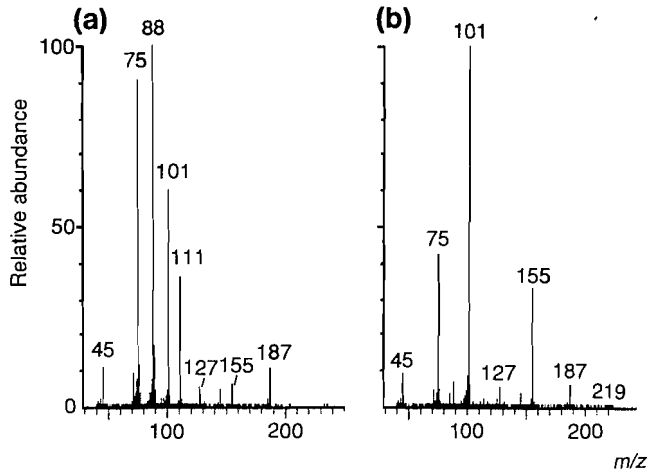

higher boiling point than its permethylated analog, and therefore elute later, which is the reverse of what is observed here. Ions with *m/z* 111 have been observed in the FAB spectra of permethylated oligosaccharides and glycolipids (3, 5) and interpreted as cyclic aromatic ions. The *m/z* 88 ions, also observed in Fig. 2*a*, are found as the major ions in the library spectra of permethylated galactose (19*a*, *b*). The spectrum of Fig. 2*b*, which features predominant *m/z* 101 and 155 ions and corresponds to the apex of the second peak of Fig. 1*a*, could not be matched with any spectrum of the NIST library (19). Diagram 2*a* suggests a possible structure for the ions at *m/z* 101 observed in Fig. 2*b*, whose precursor would be non-cyclic. Globally, permethylation of D-galactose according to these results would yield two unresolved anomers, pyranosides according to the reference spectra (19*a*, *b*) (peak at 27.13 min in Fig. 1*a*), and another product, possibly acyclic but not yet characterized (peak at 27.37 min in the same figure).

As for GC–MS analysis of permethylated glucose, two intense and well-separated peaks were found in the TIC trace (Fig. 1*b*), which was very similar to that obtained by GC–FIB. The mass spectrum at the maxima of the first peak of importance (26.18 min) corresponded well with the library spectra of methyl 2,3,4,6-tetra-*O*-methyl (α- and β) glucopyranose (19*d*, *e*). The second peak, at 26.82 min, showed absence of *m/z* 88 ions and predominance of *m/z* 101 species, suggesting again the formation of a permethylated product that is different from the pyranosidyl anomers, as suggested in the case of galactose.

In the case of fucose, two major peaks were also obtained in the FID (Fig. 3) and TIC traces. The spectrum of the first

Fig. 3. Portion of the GC–FID chromatogram obtained for permethylated L(−)fucose.

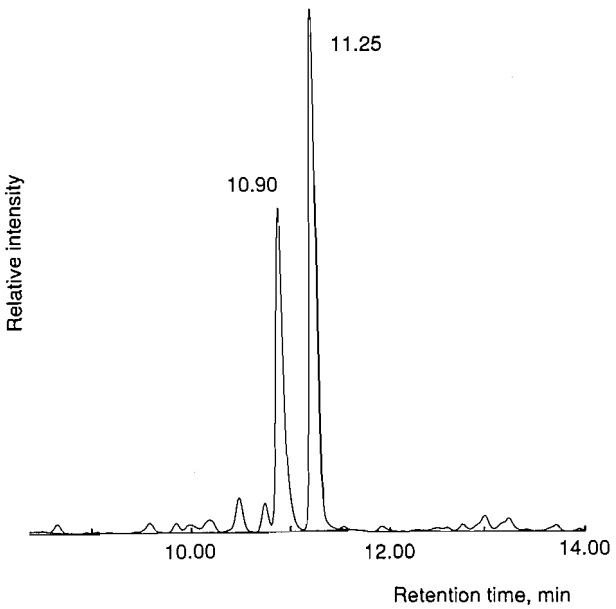

Fig. 4. Electron impact mass spectra obtained from GC–MS of permethylated L(−)fucose. (*a*) Peak at 24.07 min; (*b*) peak at 24.47 min.

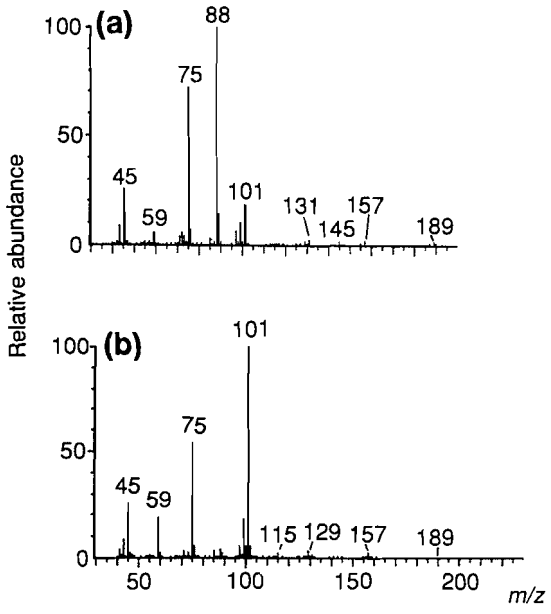


eluted compound (Fig. 4*a*) features the rearrangement ion peak at *m/z* 88 and corresponds with the library spectra of methyl 2,3,4-tri-*O*-methyl-6-deoxy-α- and -β-mannopyranoside (19*f*,*g*). The spectrum of the other product (Fig. 4*b*) again showed predominant ions at *m/z* 101 and no significant ions at *m/z* 88. Diagram 2*b* shows how the ionic species at *m/z* 101 could be formed from acyclic permethylated fucose. As in the case of galactose and glucose, this product has not yet been further characterized. Retention times obtained by GC–FID and GC–MS for permethylation of fucose are shown in column A of Tables 1 and 2.

Permethylation of sialic acid yielded a more complicated chromatographic picture than the other monosaccharides. The most abundant peak in the GC–FID chromatogram had its centroid at 22.01 min (see Table 1, column D) and was almost 0.73 min wide at half height (in comparison, fucose peaks have a half-height width of 0.09 min). The GC–MS results obtained for the permethylation of sialic acid (Table 2, column D) resemble those obtained by GC–FID and show that the main peak occurs at around 39 min, and is almost 1 min wide at half height. The mass spectra taken from one end (38:53 min) and the other (39:09 min) are shown in Fig. 5, (*a*) and (*b*). They are similar to each other in spite of variations in the relative ionic abundances. No major structural differences can be deduced from comparison of these spectra; however, they can be used qualitatively to verify the presence of a sialic acid related residue upon methanolysis of an unknown oligosaccharide. The main component of permethylated sialic acid has a predicted molecular weight of 407 (see structure in Fig. 5), and there are molecular ions at *m/z* 407 in both spectra of Fig. 5. Ions at *m/z* 422 are possibly formed from opening of the ring upon methylation as illustrated by the proposed structures, also in Fig. 5. No ions indicating undermethylation (*m/z* 392) are observed and therefore the large GC peak widths presumably arise form the presence of two compounds (MW 407 and MW 422).

Permethylated disaccharides and methanolysis

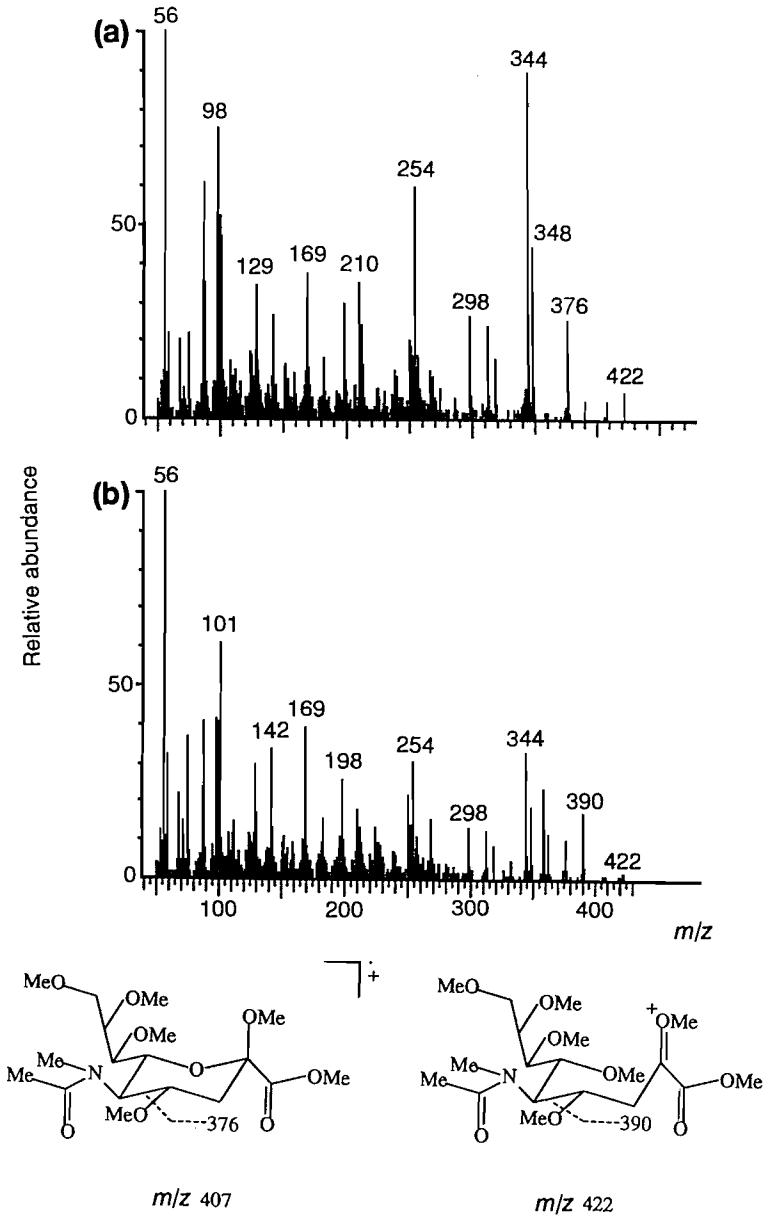
This second section of the study was aimed at clarifying two general points, (*i*) the ability to identify the products according to their retention times, elution patterns, and mass spectra and (*ii*) the degree of completion and success of the gas-to-solid phase methanolysis. It was important to first establish retention times for permethylated α- and β-lactose, the dimers under investigation, on the GC–FID and GC–MS systems. It was also important to determine the molecular weight of the permethylation and methanolysis products by FAB-MS. The FAB spectra of permethylated α- and β-lactose were very similar and exhibited $[M + H - CH_3OH]^+$ (*m/z* 423) ions as well as "B_1" ions resulting from glycosidic breakage (16).

In GC–FID, permethylated α- and β-lactose produced almost identical chromatograms, each with two peaks at the same retention times (see Table 1, column E, and Fig. 6*a*). As there was no difference between the results obtained for the two lactose isomers, only the data for β-lactose have been reported. The two peaks possibly arise from anomeric methyl glycosides on the glucose ring. If this is the case the α- and β-methylated anomeric products have the same retention times for both α- and β-lactoses.

With the use of a longer GC column (30 m), two well-resolved major peaks were obtained for each of the permethylated lactoses. Although the spectra of permethylated lactose species were not found in NIST library, the spectrum of a similar compound 2,3,4,6-tetra-*O*-methyl α-D-glucopyranosyl 2,3,4,6-tetra-*O*-methyl α-D-glucopyranoside (19*h*), closely matched the spectra observed here. Since identical products were obtained whether the substrate was α- or β-lactose, it appears that the permethylation process isomerizes the glycosidic bonds.

GC–MS results obtained with the 60 m column showed the

Fig. 5. Electron impact mass spectra obtained from GC–MS analysis of permethylated sialic acid; (*a*) peak at 38.53 min; (*b*) peak at 39.09 min. Data obtained with the Varian 3400 GC/Finnigan Mat ITD-800 MS system.

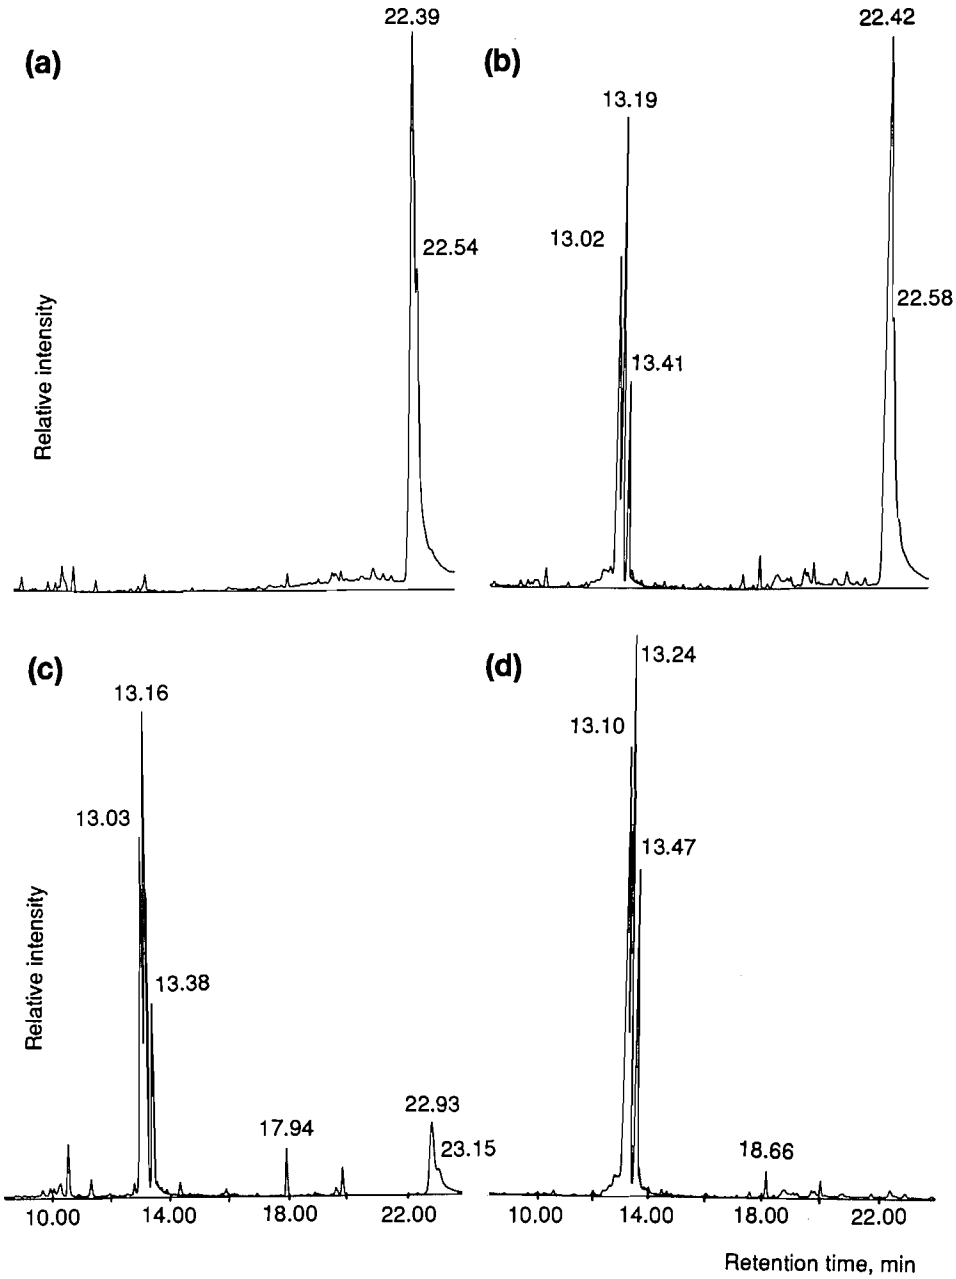


presence of four peaks instead of two (Fig. 7); the four peaks appeared in two pairs. For each pair of peaks, the mass spectra at the maxima showed different fragment ions from one spectrum to the other. The first spectrum of each pair (identical) resembled that of that of the permethylated disaccharide found in the library (19*h*); the second spectrum of each pair (also identical) could not be matched with library data; the combination of the two spectra in each pair gave rise to a spectrum much better matched to the library data (19*h*) than that taken from the first peak only. The permethylation products giving rise to the second peaks in each pair have not yet been further characterized.

Bulk-phase methanolysis, performed according to a well-established method (7), yielded 100% glycosidic bond cleavage in both α- and β-lactoses. GC–FID analysis of methanolyzed α- and β-lactose gave rise to three main peaks at retention times 13.04, 13.17, and 13.38 min and no peaks at around 22 min, the average retention time of permethylated lactoses with this GC–FID system. According to Table 1, column C, the first peak corresponds to a form of permethylated glucose, the second to one of permethylated galactose, and the third to a minor form observed in the chromatogram of permethylated galactose.

Gas-to-solid phase methanolysis required longer reaction times and slightly higher temperatures than the conventional method (see experimental section), but gave rise to a complete reaction. The GC–FID chromatograms of Fig. 6 show the results at the beginning (*a*), at an intermediate stage (*b*), and at

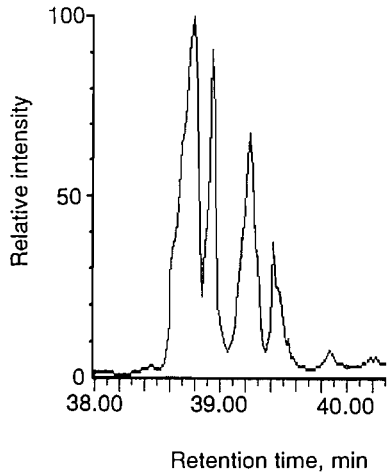
Fig. 6. Portions of the GC–FID traces obtained for methanolysis of β-lactose (permethylated); (*a*) before reaction, permethylated β-lactose; (*b*) after 2 h of gas-to-solid phase reaction; (*c*) after 6 h of gas-to-solid reaction; and (*d*) completed reaction after 18 h of gas-to-solid reaction.



the end of the reaction (*c*). The peaks obtained from breakage of the glycosidic bonds in both α- and β-lactose correspond to those observed for products from the conventional methanolysis method. For either the α or β disaccharide, the three peaks obtained in the chromatograms of the reaction products appear at the same retention times and with similar relative intensities, meaning that the products from one isomer are possibly identical to products from the other isomer. The important fact here is that products obtained from both bulk and gas-to-solid phase methanolysis are the same, and although the reaction completion time was longer with gas-to-solid conditions, the substrate never went into solution and no work-up procedure was required for recovery of the methanolysis products. Moreover, the FID trace of the gas-to-solid reaction products exhibited less background noise and showed that products were cleaner than when performing methanolysis using the conventional method, with the same amount of substrate.

The GC–MS TIC trace of bulk phase methanolysis products from either permethylated α-lactose or β-lactose (Fig. 8*a*) again shows three peaks, whose corresponding mass spectra

Fig. 7. GC–MS total ion chromatogram of permethylated β-lactose, performed on the Varian 3400 GC/Finnigan Mat ITD-800 MS system.



are shown in Fig. 8*b*, *c*, and *d*. The peaks obtained appear at the same retention times and with the same relative intensities (identical chromatograms) whether the products originate from methanolysis of permethylated α-lactose, β-lactose, or methanolysis of a permethylated mixture of the two isomers. The mass spectrum corresponding to the earliest of the three peaks (Fig. 8*b*) and corresponding to a retention time of 26.73 matched the library spectra of permethylated α- and β-glucose (19*d*, *e*). The second peak to appear in the chromatogram (27.18 min) has a mass spectrum (Fig. 8*c*) that is qualitatively similar to the first one and matches the library spectrum of permethylated α- and β-galactose (19*a*, *b*). The third peak (27.35 min) is wider than both first ones and produces a mass spectrum (Fig. 8*d*) that contains ions at *m/z* 173 and 205, suggesting the presence of undermethylated species formed during methanolysis. Given the large peak width, and given also the presence of ions at *m/z* 187 and 219 in the spectrum, it is reasonable to suggest that two compounds coelute and produce the third peak: an undermethylated form of galactose, and another uncharacterized form of permethylated galactose. The spectrum of Fig. 8*d* indeed resembles a combination of the spectrum of Fig. 2*b* (one of the forms of permethylated galactose) and the spectrum of undermethylated galactose (19*c*).

Trisaccharides

Permethylated fucosyllactoses and sialyllactoses were not sufficiently volatile as intact compounds for GC–FID or GC–MS analysis under the operating conditions used in this study. Therefore, gas-to-solid phase methanolysis was effected using the optimal conditions found for the complete breakage of the permethylated lactoses, i.e., 18 h at 80°C.

2′-Fucosyllactose

In Table 1, columns A, F, and G, a comparison has been attempted between the GC–FID retention times observed for permethylated fucose, galactose, and glucose as well as methanolysis products of permethylated 2′-fucosyllactose. An important point is raised by comparing the cleanliness of the chromatograms between that of the conventional bulk phase methanolysis method (Fig. 9*a*) and the trace of the gas-to-solid-phase products (Fig. 9*b* and *c*). The chromatogram of Fig. 9*c*, showing almost complete methanolysis, is less ambiguous, contains fewer products, and is thus easier to characterize than that of Fig. 9*a*. Bulk phase methanolysis gives rise to a hexose/fucose ratio that is higher than that of the gas-to-solid method. However, peaks observed at ca. 19.5 min in the chromatograms and interpreted as arising from fuc-hex moieties (from incomplete methanolysis) are present in the chromatogram of the bulk phase products (Fig. 9*a*) whereas they are absent from the other chromatogram (Fig. 9*c*). The contribution of fucosyl units to these disaccharide products explains the lower fucose/hexose abundance ratio for bulk phase products. Lactose-related products, occurring at 22.3–22.4 min, are observed in Fig. 9*a* and *b*, whereas in the third chromatogram they are in very low abundance, suggesting again that the 18 h gas-to-solid reaction yielded almost complete methanolysis.

Data in Table 1 show that the number of possible products formed increases with the number of glycosidic bonds broken around a given monosaccharide residue. In 2′-fucosyllactose (Diagram 3*a*), the galactose moiety is originally attached to two sugar rings, whereas the glucose is bonded only to one residue. Table 1 shows a larger spreading of galactose-related peaks than peaks derived from glucose-related species. This spreading of products could possibly be attributed to distribution of anomericity upon glycosidic breakage.

The GC–MS analysis of gas-to-solid phase methanolysis products of 2′-fucosyllactose was performed on the Varian 3400 GC/Finnigam Mat ITD-800 system. The TIC trace (Fig. 10*a*) was very similar to that of Fig. 9*c*, in that two major pairs of peaks were obtained, the first for fucose-related residues at around 24 min, and the second at ca. 26–27 min for glucose- and galactose-related residues. The large fucose peak appearing at 11.01 min in Fig. 9*c* is now separated on the longer GC column, producing two peaks 8 s apart. The pattern of hexose compounds is similar to that of the FID trace. Column F in Table 2 lists the peaks observed with this particular GC–MS system for permethylated fucosyllactose. The mass spectra of the fucosyl entities from methanolysis of 2′-fucosyllactose (Fig. 10, *b* and *c*) both exhibit characteristics of the library spectra of α- and β-fucose (19*f*, *g*).

6′-Sialyllactose

The last compound investigated in this study was 6′-sialyllactose (structure given in Diagram 3*b*). GC–FID results for the methanolysis products (gas-to-solid phase method) show that four peaks appear in the hexose retention time zone, i.e., from 13.0 to 13.8 min. Their respective retention times are 13.04, 13.44, 13.66, and 13.80 min, as presented in Table 1, column H. The four peaks do not coincide entirely with respect to retention times (rt) with those of methanolyzed lactose and fucosyllactose, and it appears that three galactose species are formed whereas only one glucose species is observed at rt = 13.04. The peaks corresponding to sialic acid arises at rt = 21.98 min, while the permethylated sialic acid standard showed its major peak at rt = 22.01 min (Table 1, column D).

The GC–MS analysis of the methanolysis products of permethylated sialyllactose showed the same pattern for both the TIC and FID traces. Mass spectra were obtained for each of the major peaks in the trace. The glucose- and galactose-

related species produced spectra similar to the corresponding library data (19*a*, *b*; 19*d*, *e*); also, minor peaks indicated the presence of small amounts of undermethylated products.

The spectrum assigned to the sialic acid moiety was also very similar to that of the permethylated sialic acid standard discussed above. Results obtained for methanolysis of 6′-sialyllactose using the conventional bulk phase reaction method yielded the same FID/TIC pattern as products from the gas-to-solid method; however, the reaction was never as complete since low amounts of permethylated lactose and what are believed to be sialyl-hexoses appeared in the chromatograms. The gas-to-solid method, on the other hand, yielded clearer traces, exempt from these residual dimeric compounds. As for fucosyllactose, the optimal conditions found for lactoses were used in order to complete methanolysis.

The FAB mass spectra obtained for permethylated monosaccharides, disaccharides, and trisaccharides all exhibited $[M + H]^+$ and $[M + H - CH_3OH]^+$ ions, as well as fragment ions arising from cleavage of the glycosidic bonds (B_1 and B_2 ions) (3, 17). Interestingly, permethylated compounds that produced more than one chromatographic peak in GC–FIC or GC–MS produced spectra that seemed to reflect the presence of individual compounds in FAB. In other words, the isomeric forms were indistinguishable by FAB. The nonseparated products obtained from methanolysis of α- or β-lactose, 2′-fucosyllactose, and 6′-sialyllactose were also characterized by FAB. The spectra obtained showed sets of $[M + H]^+$ and $[M + H - CH_3OH]^+$ ions that corresponded in the proper proportions to the monosaccharides contained in the substrates. The lower *m/z* portions of the spectra were obscured by the presence of matrix-related peaks that often coincided with fragment ions associated with the analytes.

Conclusion

It has been demonstrated that it is possible and useful to perform gas-to-solid phase methanolysis of small oligosaccharides. In general, the gas-to-solid methanolysis method described here produces cleaner chromatographic traces than bulk phase techniques, although longer reaction times and higher temperatures are required for complete reaction. One of the most important features of using the gas-to-solid apparatus, as already point out for other derivatization methods previously developed (5, 16–18), is that less starting material is required than for a bulk phase reaction in order to produce equally clear and informative mass spectra and (or) chromatographic traces. Owing to avoidance of bulk-phase work-up procedures and direct contact with the reagent(s), the loss of reacted material is minimized, its purity maximized, and products can be analyzed by GC or MS by sampling them directly out of the reaction capillary after addition of solvent. In our hands, the amount of substrate needed for successful methanolysis/analysis has been estimated to be 10 times less than the quantity required for conventional bulk phase methods.

The chromatographic and mass spectral behavior of the substrates and methanolysis products has been closely examined since the use of higher resolution GC techniques often led to separation of a peak, previously thought to be single component, into two peaks with different mass spectra. In some cases the spectra of the separated components could not be reasonably matched to spectra in the NIST library. Electron impact and fast atom bombardment mass spectra of permethylated monosaccharides and methanolysis products have conventionally been interpreted as arising from single components. High-resolution gas chromatography now indicates that some of these products exist in forms other than the cyclic anomers to which library spectra are assigned (19). It is also noted that, for a given type of hexose contained in an oligosaccharide, methanolysis yields products whose diversity and retention times vary with the position and number of substituent(s) on the ring.

The scope of this study was to evaluate the performance of gas-to-solid phase methanolysis and to use the method to summarily characterize the sugar contents of small oligosaccharides. At this point in our study, only FAB-MS and GC–MS (electron impact) have been used to characterize the methanolysis products, whose exact chemical nature remains uncertain. However, at this stage and from a bioanalytical viewpoint, comparison of retention times, peak patterns, and mass spectra gives rise to sufficient information to provide a good estimate of the sugar contents. Further characterization of the methanolysis products is underway by means of insolating individual components using HPLC and capillary electrophoresis (CE) and analyzing their structures by FAB-MS–MS and nuclear magnetic resonance (NMR). These studies should help to clarity structural uncertainties highlighted above. Future work will also be directed toward application of this gas-to-solid phase methanolysis method to the determination of sugar contents of oligosaccharides originating from glycoproteins and glycosphingolipids.

An estimate of the spin–spin coupling constant, $^1J(^1H,^{13}C)$, in gaseous benzene

Ted Schaefer, Guy M. Bernard, and Frank E. Hruska

Abstract: An excellent linear correlation ($r = 0.9999$) exists between the spin–spin coupling constants $^1J(^1H,^{13}C)$, in benzene dissolved in four solvents (R. Laatikainen et al. J. Am. Chem. Soc. **117**, 11006 (1995)) and Ando's solvation dielectric function, $\varepsilon/(\varepsilon - 1)$. The solvents are cyclohexane, carbon disulfide, pyridine, and acetone. $^1J(^1H,^{13}C)$ for gaseous benzene is predicted to be 156.99(2) Hz at 300 K.

Key words: spin–spin coupling constants, $^1J(^1H,^{13}C)$ for benzene in the vapor phase; spin–spin coupling constants, solvent dielectric constant dependence of $^1J(^1H,^{13}C)$ in benzene; benzene, estimate of $^1J(^1H,^{13}C)$ in the vapor; nuclear magnetic resonance, estimate of $^1J(^1H,^{13}C)$ in gaseous benzene.

Résumé : Il existe une excellente corrélation linéaire ($r = 0,9999$) entre les constantes de couplage spin–spin $^1J(^1H,^{13}C)$ du benzène dissous dans quatre solvants (R. Laatikainen et al., J. Am. Chem. Soc. **117**, 11006 (1995)) et la fonction de solvatation diélectrique d'Ando, $\varepsilon(\varepsilon - 1)$. Les solvants sont le cyclohexane, le disulfure de carbone, la pyridine et l'acétone. On prédit que $^1J(^1H,^{13}C)$ pour le benzène à l'état gazeux sera 156,99(2) Hz, à 300 K.

Mots clés : constantes de couplage spin–spin, $^1J(^1H,^{13}C)$; dépendance des constantes de couplage de benzène sur la constante diélectrique du solvant; benzène, évaluation de $^1J(^1H,^{13}C)$ en phase vapeur; résonance magnétique nucléaire.

[Traduit par la rédaction]

Introduction

Since the time of its estimate as 159 ± 5 Hz (1), the precision of the measurement of $^1J(^1H,^{13}C) = {}^1J$ in benzene has steadily improved. In 1983 it was remarked that the precision had now improved by three orders of magnitude: the value of ^1J in neat benzene was given as 158.354(1) Hz (2). More recently, ^1J was measured for a number of solutions of benzene (3). The root-mean-square error in the spectral peak assignments was an order of magnitude lower than that of 1983.

Progress in the computation of spin–spin coupling constants has also been made, as described in a recent review (4). However, it appears that ^nJ is rather more difficult to compute accurately from first principles (5) than is the nuclear shielding constant (6). Nevertheless, for first-row elements, values of increasing are being calculated. In particular, reasonably good numbers for $^nJ(H,C)$ and $^nJ(H,H)$ have appeared (4) for the isolated ethylene molecule, judging by the coupling constants measured for solutions in CCl_4 (7).

It is well known (8) that many coupling constants are solvent dependent. Perturbations by the surrounding medium vitiate any stringent comparisons between theory and experiment unless the former can include perturbations or the latter can measure them. Benzene, of course, is an important molecule in chemistry and therefore accurate computations of $^nJ(^1H,^{13}C)$, $^nJ(^1H,^1H)$, and $^nJ(^{13}C,^{13}C)$ may well appear in the near future. While the medium dependence of $^nJ(H,H)$ is small (3), that of ^1J is significant. It is shown below that a good number for ^1J in isolated benzene can be deduced, a number probably difficult to measure with high precision in the vapor phase.

Results and discussion

Table 1 displays ^1J in four solvents (3) of various dielectric constants, ε, and the function $(\varepsilon - 1)/\varepsilon = x$ for the pure solvent; also as corrected for the presence of the benzene solute molecules. The quantity x comes from the solvation model of Ando and Webb (8), which also allows for a minor quadratic dependence of ^1J on x. A linear dependence of ^1J on x is found, as in eqs. [1] and [2]. The correlation coefficient is

$$[1] \quad {}^1J = 1.792x + 157.013(15), \qquad r = 0.9993$$

$$[2] \quad {}^1J = 1.833x + 156.992(6), \qquad r = 0.9999$$

somewhat higher for eq. [2], which uses the x values adjusted for the presence of the solute. The standard deviation for eq. [1] is 0.015 Hz, that for eq. [2] is 0.006 Hz. The second equation yields ^1J as 156.99 Hz for the vibrating molecule at 300 K and $x = 0$, that is, for $\varepsilon = 1$. Note that $0 \leq x \leq 1$ for media of $1 \leq \varepsilon \leq 100$ and that a relatively nonpolar dielectric such as cyclohexane has an $x \sim 0.5$.

^1J for neat benzene is not included; it is known that, in dielectric continuum models of the solvent, benzene behaves as if it had a varying ε, sometimes as high as 7.5 (9): the ^1J of 158.380 Hz in neat benzene implies an effective dielectric constant of 4.1. The satisfactory inclusion of the pyridine solu-

tion in the correlation suggests that any complex formation between benzene and pyridine molecules favors the one in which the pyridine C—H bonds interact with the benzene π electrons and not vice versa (3).

The hybridization model (10) of one-bond coupling constants between protons and carbon-13 nuclei, in which ^1J is proportional to the fractional *s* character of the carbon hybrid orbital used in the C—H bond, must be modified to accommodate the increase ^1J caused by electronegative substituents as, for example, in methane derivatives. One explanation (11, 12) of the increase in ^1J attributes it to an increase in the effective nuclear charge of the carbon atom, corresponding to an increase in *s* electron density at the nucleus, presumably also to an increased polarity of the C—H bond. It is therefore interesting, yet perhaps coincidental, that our self-consistent isodensity – polarizable continuum model or SCI–PCM (13, 14) computations (15) yield increasing polarity of the $^-C—H^+$ bonds of benzene as the dielectric constant of the medium rises. As an example, for single point MP2/6-31G* computations (on correlation gradient geometries of the isolated molecule) a linear relationship exists between ^1J and the total Mulliken charge on the carbon atom ($r = 0.995$) if the dielectric constants in Table 1 are employed in the computations.

Another possibility, that the solvent dependence of ^1J is dominated by changes in the C—H bond length, likely can be discounted because it appears that, in methane at least, an increase of 0.1 Å in the length would augment ^1J by only 1.2 Hz (16). A change of more than 1% in the benzene geometry in solution is probably an upper limit (17, 18). Qualitatively, however, one might expect an increase in the C—H bond length as its polarity increases.

Gaussian- and Slater-type bases for ground and certain low-lying excited states of positive and negative ions of the atoms H through Xe based on the generator coordinate Hartree–Fock method

A.B.F. da Silva and M. Trsic

Abstract: We applied a discretized version of the generator coordinate Hartree–Fock (GCHF) method to generate Gaussian- and Slater-type functions for mono positive and mono negative ions of the atoms H through Xe. The basis sizes for Slater-type functions are (12*s*, 10*p*, 10*d*) for positive ions, and (13*s*, 11*p*, 10*d*) for negative ions. In the case of Gaussian-type functions the bases are (18*s*, 12*p*, 11*d*) for both positive and negative species. Ground and excited state Hartree–Fock energies are calculated with these bases and the results compared with the best atom-optimized calculations and numerical HF results available. A discussion on the role of weight functions in the evaluation of electronic energies emphasizes the integral character of the GCHF method.

Key words: Slater-type bases, Gaussian-type bases, generator coordinate Hartree–Fock, atomic ions.

Résumé : On a appliqué une version numérique de la méthode de la coordonnée génératrice Hartree–Fock (GCHF) pour générer des fonctions des types de Gauss et de Slater des mono-ions tant positifs que négatifs des atomes allant de H à Xe. Les tailles des ensembles de base pour les fonctions de type Slater sont (12*s*, 10*p*, 10*d*) pour les ions positifs et (13*s*, 11*p*, 10*d*) pour les ions négatifs. Dans le cas des fonctions de type de Gauss, les bases sont (18*s*, 12*p*, 11*d*) tant pour les espèces positives que négatives. Utilisant ces bases, on a calculé les énergies Hartree–Fock de états tant fondamentaux qu'excités et on a comparé les résultats avec les meilleurs résultats disponibles de calculs optimisés des atomes et de résultats numériques de HF. Une discussion sur le rôle des fonctions de pois dans l'évaluation des énergies électroniques met en relief le caractère intégral de la méthode du GCHF.

Mots clés : fonctions du type de Slater, fonctions du type de Gauss, coordonnée génératrice Hartree–Fock, ions atomiques.

[Traduit par la rédaction]

1. Introduction

The generator coordinate (GC) method for the nuclear bound state was introduced in 1957 by Griffin and Wheeler (1). In this method the variational trial function is an integral transform over a nucleonic wave function and a weight function depending on a parameter (generator coordinate), i.e., $f(\alpha)$. In such a manner, the common variational principle, $\delta E/\delta\alpha = 0$, was, a priori, made more powerful with the requirement $\delta E/\delta f(\alpha) = 0$, leading to an integral equation. Most applications in nuclear physics (for a review see, for instance, Wong (2)) relied on the Gaussian overlap approximation (GOA), although there were some attempts at numerical solution (3), and later Lathouwers discussed the GC method against the background of the Fredholm theory of linear integral equations (4).

Perhaps the earliest application of GC to electrons in a molecular (hydrogen molecule) system was due to Laskowski (5). In 1978 Chattopadhyay et al. (6) applied the method to several model problems, including the He atom, with special emphasis on various aspects of the discretization technique. Further developments in discretization techniques were made by Broeckhove, Deumens and co-workers (7).

On the other hand, as early as 1968, Somorjai (8) had introduced the integral transform method, closely related to GC, for atomic and molecular systems. In the applications, Somorjai chose explicit forms for $f(\alpha)$ (such as the delta function), which led to a variational treatment for the integration limits. An extensive bibliography on the method may be found in ref. 9. In the context of this method, accurate correlated functions for two- and three-electron atomic systems were obtained by Thakkar et al. (10).

The generator coordinate Hartree–Fock (GCHF) method was introduced in 1986 (11), and one of the first applications was in the generation of Gaussian- and Slater-type orbital

(GTF and STF) universal basis sets for the first and second rows of the periodic table (12, 13). Later, da Silva and Trsic presented GTF and STF universal basis sets encompassing the atoms from H through Xe for atomic and molecular nonrelativistic calculations (14, 15). Also, the GCHF method was recently tested successfully in the generation of universal Gaussian basis sets for relativistic calculations (16–19). Here it is important to mention that the concept of the universal basis set was first introduced by Silver, Wilson, and Nieuwpoort (20).

In this work we are extending the bases of ref. 4 to embrace the positive and negative ions of the atoms H through Xe. The total HF energies of the ground and some excited states are calculated and compared with the best HF values available. We also present a further discussion on the importance of the weight functions in evaluating atomic energies.

2. Results and discussion

2.1. Total energies

The total energies reported in this section were calculated by using Slater-type functions (STF) and Gaussian-type functions (GTF) generated with the GCHF method. In this methodology, the one-electron functions are chosen as integral transforms, i.e.,

$$[1] \quad \psi_i(1) = \int d\alpha\, \phi_i(1,\alpha) f_i(\alpha), \qquad i = 1, \ldots, n$$

where the ϕ_i are the generator functions (they may be STF, GTF, or other types of functions), the f_i are the weight functions, and α is the generator coordinate. Using eq. [1] to build a Slater determinant for the multi-electronic wave function, and minimizing the total energy E with respect to f_i, one obtains the Griffin–Wheeler–HF (GWHF) equations or integral HF equations (11, 14).

The GWHF equations are solved by discretization through a technique called integral discretization (21), which preserves the continuous representation (integral character) of the Generator Coordinate Method (GCM) (1, 22). This technique is implemented through a relabelling of the generator coordinate space, i.e.,

$$[2] \quad \Omega = \frac{\ln \alpha}{A}, \qquad A > 1$$

Here, an equally spaced N-point mesh $\{\Omega_i\}$ is selected for each s, p, and d symmetry. The integration range is then characterized by an initial point, Ω_{min}, an increment, $\Delta\Omega$, and N (discretization point number). The scaling factor A is the same (A = 6.0) for all calculations. We also note from eq. [2] that the numerical integration of the GWHF equations provides a set $\{\Omega_i\}$ and simultaneously an exponent set $\{\alpha_i\}$ for the basis functions.

Since eq. [1] represents a continuous and infinite superposition, we do not need, in the GWHF equations, to specify the principal quantum numbers, n, for the various symmetries of the generator functions, ϕ_i, as the weight functions, f_i, distinguish the n states. Thus, our bases in this work consist of the simplest 1s, 2p, and 3d STF or GTF.

The basis size for STF positive ions is (12s, 10p, 10d) with the following discretization parameters (i.e., orbital exponents):

Symmetry	Ω_{min}	$\Delta\Omega$	N
s	−0.11	0.07	12
p	0.00	0.07	10
d	−0.11	0.07	10

The GTF (18s, 12p, 11d) basis for positive ions is generated with:

Symmetry	Ω_{min}	$\Delta\Omega$	N
s	−0.55	0.16	18
p	−0.40	0.16	12
d	−0.55	0.16	11

The basis size for STF negative ions is (13s, 11p, 10d) with discretization parameters as follows:

Symmetry	Ω_{min}	$\Delta\Omega$	N
s	−0.21	0.07	13
p	−0.10	0.07	11
d	−0.05	0.07	10

The GTF (18s, 12p, 11d) basis for negative ions is generated with:

Symmetry	Ω_{min}	$\Delta\Omega$	N
s	−0.75	0.16	18
p	−0.55	0.16	12
d	−0.75	0.16	11

The basis sets (discretization parameters) for STF and GTF positive ions are the same as those we previously employed for neutral atoms (14). This coincidence was to be expected, as the ionization produces orbital contraction, and thus the bases for the neutral atoms were adequate for describing the total energies for ground and low-lying excited states of positive ions. For negative ions, therefore, it was not possible to describe the total energies by employing the same basis sets as for neutral atoms. This is a consequence of the entrance of one electron in the frontier atomic orbital, making it more diffuse; thus, lower values for Ω_{min} are required for STF and GTF bases.

In Tables 1–4 we present the total STF and GTF HF energies for ground and low-lying excited states of positive and negative ions. Our results are compared with the numerical results of Koga et al. (23) and, only when numerical results are not available, with the atom-optimized values of Clementi and Roetti (24). One can see from Tables 1–4 that our STF energy values (ground and low-lying excited states) compare very favorably with the numerical results and with the atom-optimized results of Clementi and Roetti, often being lower than

[a]This column shows $\Delta E = |E(\text{NHF}) - E(\text{calculated})|$.
[b]This column shows the values of $\Delta = |2 + \text{virial ratio}|$.
[c]Calculated energy is lower than CR energy.

those obtained with the latter. Our GTF energies are only slightly above the STF values in spite of a rather modest increase in the number of basis functions.

For the case of positive ions (Tables 1 and 2), we notice a better performance for both STF and GTF bases for excited states than for ground states when compared with the Clementi and Roetti results. Also for positive and negative ions, the STF energy values are close to the numerical results and competitive with the excited state values of Clementi and Roetti. This capacity to describe excited states with the GCM was commented on in previous papers (6, 14, 21).

We would also like to make a comparison between the STF energy results obtained in this work for the ground state of cations and anions and the STF energy results obtained recently by Koga et al. (25) using doubly even-tempered basis sets for the same ionic species. Here it is important to pay attention to the fact that we are working with universal STF basis sets, and thus the sizes of our basis sets are always the same, namely, (12s, 10p, 10d) for the cations and (13s, 11p, 10d) for the anions. In his work, Koga is working with atom-adapted basis sets, and thus his STF basis set size increases with increase in Z (atomic nuclear charge).

For the cations with s and p orbitals, Koga's basis set size varies from (7s, 5p) to (11s, 7p) for C^+ through Ca^+. For the cations with s, p, and d orbitals, Koga's basis size varies from (11s, 7p, 5d) to (13s, 12p, 8d) for Sc^+ through Xe^+. In general, for the cations, our STF energy results are on average one decimal figure more accurate than Koga's results but, although

[a]This column shows $\Delta E = |E(\text{NHF}) - E(\text{calculated})|$.

[b]This column shows the values of $\Delta = |2 + \text{virial ratio}|$.

our results are better for the cations lighter than Zr^+, one has to recognize that Koga used smaller basis sets. From Zr^+ on, Koga's basis set size becomes more similar to our universal basis size (12s, 10p, 10d).

The average errors in our STF energies with respect to the numerical HF energies for the cations are, respectively, 0.000 012, 0.000 121, 0.001 36, and 0.023 87 millihartrees for the first, second, third, and fourth rows. The average errors in the energies found by Koga are 0.0004, 0.0063, 0.061, and 0.113 millihartrees for the respective first-, second-, third-, and fourth-row cations.

For the anions, Koga's basis set size varies from (8s, 6p) to (11s, 9p) for B^- through Cl^-, and for K^- it is (12s, 8p). For Sc^- through I^-, it varies from (12s, 8p, 6d) to (14s, 13p, 9d). When we compare our STF energy results with Koga's results for the anions, we notice that our results are on average one decimal

[c]Calculated energy is lower than CR energy.

figure more accurate than Koga's results from H^- to Se^-. From Br^- to Ag^-, both STF basis set sizes become more similar and, in general, our results have the same accuracy as Koga's results. From In^- on, Koga's results become more accurate than our results, but he is working with a slightly larger basis set (14s, 13p, 9d) than our universal basis set (13s, 11p, 10d).

The average errors in our STF energies with respect to the numerical HF limits for the anions are, respectively, 0.000 044, 0.001 757, 0.0026, and 0.3784 millihartrees for the first, second, third, and fourth rows. Koga found, for the respective first-, second-, third-, and fourth-row anions, the following average errors in the energies: 0.000 68, 0.0063, 0.087, and 0.112 millihartrees.

In conclusion, we would like to say that comparison of our results with Koga's results brings to attention the fact that when we are developing a universal basis set instead of a fully optimized basis set, we face the penalty of using, mainly for lighter atomic systems (from H through Ca), a larger number of basis functions than a fully optimized basis set needs to obtain the same degree of accuracy. Indeed, our experience in developing universal basis sets always showed that this penalty is reduced when we work with atomic systems from the third row on (14, 16–19).

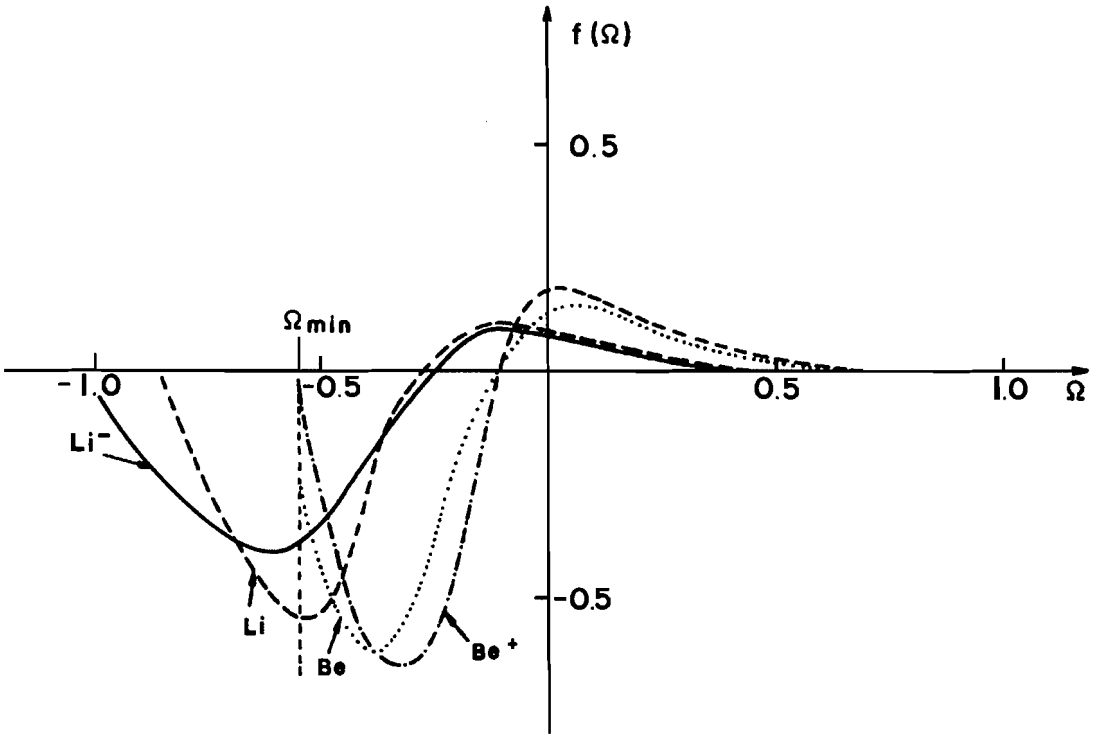
2.2. The role of the weight functions in the evaluation of the total electronic energies

Since the GWHF equations are obtained from the minimization of the functional E with respect to the weight functions, f_i, the description of f_i governs the quest for the total energies for any atomic system. Achieving the best HF energy for an atomic system means obtaining the best description of f_i through the numerical approximation outlined in Sect. 2.1.

The quest for the best weight function associated with any atomic orbital is implemented by the integral discretization described previously, and the discretization parameters Ω_{min}, $\Delta\Omega$, and N are responsible for attaining the best weight function. When the GCHF method is employed to generate basis sets, the number of points N determines the size of the basis and, certainly, the larger the value of N, the lower is the ground state energy obtained. But the chosen value of N is a compromise between accuracy and size of the basis set.

In ref. 14 we presented a series of weight functions generated by the integration mesh of the neutral atoms, H through Xe, and discussed some practical aspects and properties of the weight functions. All the observations of that paper are valid with respect to the weight functions of the positive and negative ions studied here but, at this time, we add a few relevant

Fig. 1. The 2*s* Gaussian weight functions for Be^+, Be, Li, and Li^-. The point $\Omega_{min} = -0.55$ for *s* functions is indicated.



remarks especially related to the ionic species, and we will focus our remarks on the Gaussian weight functions.

In Fig. 1 we have plotted the Gaussian 2*s* weight functions for the isoelectronic species Be^+ and Li and Be and Li^-. It appears that the integration interval with $\Omega_{min} = -0.55$ is satisfactory for the Be^+ and Be species, but it is not adequate for the alkaline atom, and it is particularly insufficient for the negative ion of Li. This is a feature that also appears for the highest occupied orbital of the other alkaline atoms considered, i.e., Na through Cs. For this reason, it was necessary to shift Ω_{min} for the GTF basis set of the negative ions to $\Omega_{min} = -0.75$ for *s* symmetry (Ω_{min} for *s* symmetry STF weight functions was shifted to -0.21). The *p* and *d* symmetry weight functions also required a revision of the integration limits for the negative ions (see discretization parameters in Sect. 2.1).

In Fig. 2 we show how the Gaussian 2*s* weight functions obtained in this work for the species Li and Li^- compare with the corresponding fully integrated weight functions. Both for Li (this work) and Li^- (this work) there appears the need for higher values of the weight functions to compensate the truncation of the integration range. In view of our goal of generating "universal" (a unique set of exponents to be used for all atoms under consideration) bases of tractable size, we opted to retain Ω_{min} values that, in a few cases, did not accomplish a complete numerical integration. It is relevant to point out that this limitation of the Ω_{min} values has little effect on the total HF energy, even for the alkaline atoms and negative ions. Of course, the present selection of lower limits for the numerical integration range should be reconsidered with caution if properties demanding very diffuse orbitals were of interest (26). Otherwise, for most of the atoms and ions considered, the numerical integration ranges were adequate. This is illustrated in Fig. 3 with the example of the Gaussian 2*p* weight functions for neutral and charged fluorine atoms.

3. Concluding remarks

We have obtained STF and GTF basis sets for mono-charged positive and negative atomic species from H through Xe. Our bases stand comparison with numerical results and the best atom-optimized bases available, both for ground and low-lying excited states.

The bases for the positive ions are the same as those that we generated in ref. 14 for neutral atoms. In the case of the negative ions, the numerical integration range, which defines a basis set, was shifted to lower values of the Ω generator coordinate to accommodate the need for very diffuse orbitals.

The weight functions play a very important role in evaluating the total electronic energies. In fact, plots of the weight functions will provide adequate ranges for the numerical integration of the GWHF equations, and consequently we will have accurate basis sets for atomic species.

A penalty is faced when we are developing universal instead of fully optimized basis sets, mainly when we are working with atoms of the first and second rows. The penalty is characterized by the number of extra basis functions needed in the universal basis set to obtain the same degree of accuracy as in a fully optimized basis set.

Spectroscopic and crystallographic studies of phosphino adducts of indium(III) iodide

Martyn A. Brown, Dennis G. Tuck, and Edward J. Wells

Abstract: Indium(III) iodide forms both 1:1 and 1:2 adducts with triphenylphosphine, depending on the reaction conditions, and especially on the solvent used. The complex $InI_3 \cdot PPh_3$ involves four-coordination at indium; the structure is trigonal, with a = 15.105(4) Å, c = 16.769(7) Å, V = 3313(2) Å^3, Z = 6, and space group $R\bar{3}$. Crystals were also obtained in which $InI_3 \cdot PPh_3$ and $InI_3(PPh_3)_2$ are present in a 1:1 ratio; these are also trigonal, a = 15.473(4) Å, c = 41.701(7) Å, V = 8646.1(1.8) Å^3, Z = 3 + 3 and space group $R\bar{3}$. The 1:2 adduct has approximately D_{3h} symmetry in the InI_3P_2 kernel. The bond distances and angles are discussed; in particular, the In—P bonds are extremely weak in the 1:2 adduct. This compound has been shown by ^{31}P NMR to undergo complete dissociation in solution to $InI_3 \cdot PPh_3$ and PPh_3. The addition of R_4NI (R = n-C_3H_7, n-C_4H_9) causes quantitative conversion to InI_4^- and free Ph_3P. Similar experiments are reported for the compound InI_3(dppe) (dppe = 1,2-bis(diphenylphosphino)ethane), whose structure is an infinite chain of InI_3 units linked through In-P-C_2H_4-P-In coordination. The crystal structure showed that InI_3(dppe) cocrystallizes with an equimolar quantity of dppe; these crystals are cubic, a = 41.445(14) Å, b = 15.944(8) Å, c = 16.533(11) Å, β = 102.02(4)°, V = 10 685(9) Å^3, Z = 4 + 4, space group C_2/c. Solid state and solution phase results are discussed in terms of the coordination chemistry of indium(III).

Key words: indium, phosphorus, coordination chemistry, multinuclear NMR, X-ray crystallography.

Résumé : L'iodure d'indium(III) réagit avec la triphénylphosphine pour former, suivant les conditions expérimentales et particulièrement du solvant utilisé, des adduits 1 : 1 ou 1 : 2. Le complexe $InI_3 \cdot PPh_3$ implique un tétracoordination au niveau de l'indium; la structure est trigonale, groupe d'espace $R\bar{3}$, avec a = 15,104(4) et c = 16,769(7) Å, V = 3313(2) Å^3 et Z = 6. On a aussi obtenu des cristaux dans lesquels $InI_3 \cdot PPh_3$ et $InI_3(PPh_3)_2$ sont présents dans un rapport de 1 : 1; ces cristaux sont trigonaux, groupe d'espace $R\bar{3}$, avec a = 15,473(4) et c = 41,701(7) Å, V = 8646.1(1,8) Å^3 et Z = 3 + 3. La symétrie de l'adduit 1 : 2 est approximativement D_{3h} et elle comporte un noyau InI_3P_2. On discute des longueurs et des angles des liaisons; dans l'adduit 1 : 2, on note, en particulier, que les liaisons In—P sont extrêmement faibles. Faisant appel à la RMN du ^{31}P, il a été démontré que, en solution, ce composé subit une dissociation complète en $InI_3 \cdot PPh_3$ et en PPh_3. L'addition de R_4NI (R = n-C_3H_7, n-C_4H_9) provoque une conversion quantitative en InI_4^- et de PPh_3 libre. Des expériences semblables ont été effectuées avec le composé InI_3(dppe) (dppe = 1,2-bis(diphénylphosphino)éthane) dont la strcture correspond à une chaîne infinie d'unités InI_3 liées par une coordination P-C_2H_4-P-In. La structure cristalline montre que le InI_3(dppe) cocristallise avec une quantité équimolaire de dppe; ces cristaux sont cubiques, groupe d'espace C_2/c, avec a = 41,445(14), b = 15,944(8) et c = 16,533(11) Å, β = 102,02(4)°, V = 10 685(9) Å^3 et Z = 4 + 4. On discute des résultats obtenus à l'état solide et en solution en termes de la chimie de coordination de l'indium.

Mots clés : indium, phosphore, chimie de coordiantion, RMN multinoyaux, cristallographie, rayons X.

[Traduit par la rédaction]

Introduction

The formation of adducts with neutral or anionic donor ligands is an important feature of the chemistry of the elements of Group III (or 13), with both applied and fundamental implications (1). The behaviour of derivatives of indium(III) halides and pseudo-halides has been of especial interest in this laboratory. The features of the problem which are most closely relevant to this paper are the range of coordination numbers that is possible, and the dissociation which can occur in nonaqueous solvents, involving loss of either halide or neutral ligand (2). Each of these processes is strongly affected by the nature of both halide and neutral donor atom, and by the solvent. Halide effects are also clearly seen in both the solid state and solution chemistry of anionic indium(III) complexes (1).

The present paper reexamines some of the early work (2) on triphenylphosphine and bis(diphenylphosphino)ethane (dppe) adducts of indium(III) iodide, using the experimental techniques of X-ray crystallography and multinuclear magnetic resonance which were not previously available. The new information on the solution phase behaviour of these substances is relevant to other work in this laboratory on adduct formation and dissociation of the derivatives of Group III and IV halides with ortho- and paraquinones.[3]

Experimental section

General techniques

Indium(III) iodide was prepared by reacting gram quantities of the elements in refluxing xylene (3). Triphenylphosphine and bis(diphenylphospino)ethane (Aldrich) were recrystallized before use. Solvents were distilled from suitable drying agents, and stored over molecular sieves.

Microanalysis was by Guelph Chemical Laboratories Ltd. Phosphorus-31 and indium-115 NMR spectra were recorded on Bruker AC 200L and 300L instruments, operating at 81.0 and 43.8 MHz, respectively. The reference standards for these nuclei were, for ^{31}P, 85% $H_3PO_4 = 0$ and, for ^{115}In, $InCl_4^- = 0$ (4). Infrared spectra were run on a Nicolet 4DX instrument. Raman spectra of finely ground solids were recorded with a Jobin Yvon S3000 spectrometer. Mass spectrometry involved heated samples in a Shimadzu 14-B spectrometer operating in the EI mode, with Sun Sparc software.

Conductivity measurements were made on a YSI 3400 model 31 conductivity bridge, using a YSI cell with Pt-Ir alloy electrodes coated with platinum black. Solutions were approximately 1 mmol L^{-1}. The cell constant was checked with a 1 mM aqueous solution of KCl after conditioning the electrodes for ca. 5 min.

Preparative

(i) Triphenylphosphine adducts

A solution of InI_3 (0.99 g, 2 mmol) in ethyl acetate (50 mL) was added dropwise to a stirred solution of Ph_3P (1.20 g, 4.6 mmol) in the same solvent. The yellow solid which precipitated was collected after 1 h, washed with ethyl acetate, and dried in vacuo. This solid is $InI_3(PPh_3)_2$, yield 1.56 g, 77%. Anal. calcd. for $C_{36}H_{30}P_2InI_3$ C 42.4, H 2.96; found: C 42.2, H 2.80. The mass spectrum of this compound (sample temp. 100°C) showed important ions based on *m/e* 262 (Ph_3P^+), 183 (Ph_2P^+-2), and 108 (PhP^+), but no peaks attributable to InI_3 or its derivative ions were observed.

When this product was recrystallized from cyclohexane, colourless crystals of the 1:1 adduct $InI_3 \cdot PPh_3$ were obtained. Anal. calcd. for $C_{18}H_{15}PInI_3$: C 28.5, H 2.00; found: C 28.5, H 1.90. The mass spectrum again has significant peaks at *m/e* 262, 183, and 108, but no ions derived from InI_3.

Recrystallization from ethyl acetate gave yellow crystals, whose analysis corresponded to an equimolar mixture of $InI_3 \cdot PPh_3$ and $InI_3(PPh_3)_2$. Anal. calcd. for $C_{54}H_{45}P_3In_2I_6$ C 36.5, H 2.55: found: C 37.5, H 2.61. The composition of these crystals was confirmed by X-ray crystallography (see below).

(ii) Bis(diphenylphosphino)ethane adduct

The procedure followed that for triphenylphosphine, using ethyl acetate as solvent; the white powdery product was InI_3(dppe), yield 1.05 g, 59%. Anal. calcd. for $C_{26}H_{24}P_2InI_3$: C 34.9, H 2.71; found: C 34.7, H 2.80. The mass spectrum had important features at *m/e* 398 (diphos$^+$), 262, 183, and 108 (Ph_3P^+ and derivatives). The molar conductivity of this compound in dichloromethane was 3.8 $ohm^{-1}\ mol^{-1}\ cm^2$.

Recrystallization from a mixture of ethyl acetate and toluene (50:50, v/v) gave, on cooling, crystals suitable for X-ray study. This study, and the results of elemental analysis, showed that these crystals contained equimolar quantities of InI_3(dppe) and dppe. Anal. calcd. for $C_{52}H_{48}P_4InI_3$, C 48.3, H 3.74; found: C 48.8, H 3.83.

Crystallographic analysis

(i) In the study of $InI_3 \cdot PPh_3$, 1, a colourless crystal mounted on a glass fibre was sited in a Rigaku AFC6S diffractometer, equipped with graphite monochromated Mo-Kα radiation (λ = 0.71069 Å) and a rotating anode generator. Cell constants, and orientation matrices for data collection, were obtained from least-squares refinements, using 20 carefully centred reflections in the range $8.59 < 2\theta < 16.07°$. Based on the systematic absences hkl: $-h + k + l \neq 3n$, the space group was uniquely identified as $R\bar{3}$ (No. 148), and this was confirmed by subsequent solution and refinement of the structure. Details of the intensity collection for all substances studied are given in Table 1.

The intensities of three representative reflections were measured after every 150 reflections. Over the course of data collection, the standards increased 1%, and a linear correction factor was applied to the results. The linear absorption coefficient (53.3 cm^{-1}) was such that an absorption correction using PSI Scan was applied, with transmission factors ranging from 0.80 to 1.00. The results were also corrected for Lorentz and polarization effects. The structure was solved by direct methods, and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically; hydrogen atoms on carbon were included in ideal positions but were not refined. The final cycle of full-matrix least-squares refinement was based on 555 observed reflections ($I > 3\sigma(I)$) and 71 variable parameters, and the solution converged at $R = 0.034$ and $R_w = 0.029$. A final Fourier difference map calculation showed no peaks of chemical significance; the maximum and minimum peaks corresponded to 0.68 and −0.45 e $Å^{-3}$, respectively.

(ii) The structural study of crystals of $InI_3 \cdot PPh_3 + InI_3(PPh_3)_2$, **2**, followed essentially the same procedure. The space groups are identical. No decay correction was applied, since the intensities of three representative reflections remained constant throughout the data collection, indicating crystal and electronic stability. The data were corrected for absorption, Lorentz, and polarization effects. The structure was solved by direct methods. The indium, iodine, and phosphorus atoms were refined anisotropically, and carbon atoms were refined isotropically; hydrogen atoms on carbon were initially included in ideal positions, and subsequently refined isotropically. After several cycles of refinement, the structure converged to $R = 0.047$ and $R_w = 0.036$. A final Fourier difference map calculation showed no peaks of chemical significance.

(iii) Similar methods were used in the characterization of InI_3(dppe) + dppe, **3**. Corrections were made for decay (−0.4%), Lorentz and polarization effects, and for absorption (range 0.747–1.000). Indium, iodine, and phosphorus atoms were refined anisotropically, and carbon atoms isotropically. The structural refinement converged at $R = 0.060$, $R_w = 0.060$. The maximum and minimum peaks in the final Fourier map were +0.43 and −0.72 e $Å^{-3}$, and there were no peaks of chemical significance.

In each set of calculations, neutral-atom scattering factors were taken from Cromer and Waber (5). Anomalous dispersion effects were included in the calculations (6); the values for $\Delta f'$ and $\Delta f''$ were those published by Cromer (7). All calculations were performed using the TEXSAN (8) crystallo-

graphic software package. The structure of the molecules are shown in Figs. 1, 2, and 3; the positional parameters are in Tables 2, 4, and 6 and important bond distances and angles in Tables 3, 5, and 7.

Tables of hydrogen-atom coordinates and thermal parameters, and anisotropic thermal parameters for other atoms, are available as supplementary data.[4]

[4] These data can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The data fro H-atom coordinates have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

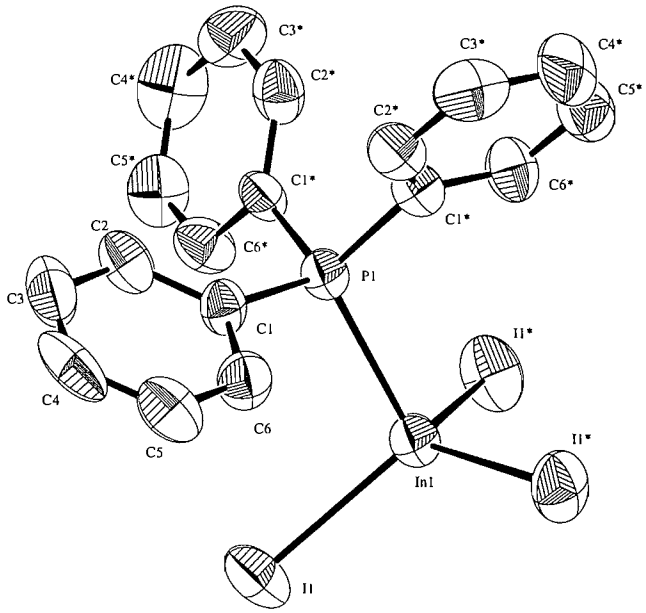
Results and discussion

Crystallographic studies

The structure of $InI_3 \cdot PPh_3$, **1** (Fig. 1), shows that the stereochemistry at both indium and phosphorus is close to tetrahedral. The indium(III)–iodine bond distance (2.677(1) Å) is in keeping with the values in the literature for other four-coordinate derivatives, for which the range is 2.68 ± 0.04 Å (9). More particularly, the results reported for $InI_3 \cdot PHPh_2$ (r(In–I) (avg.) = 2.673(5) Å, *r*(In-P) (avg.) = 2.599(9) Å), and for

Fig. 1. The molecular structure of $InI_3 \cdot PPh_3$, showing the numbering system; ORTEP diagram, with 30% probability ellipsoids.



$InI_3 \cdot PHBu^t_2$ (r(In–I) (avg.) = 2.674(5) Å, r(In–P) = 2.586(6) Å)(10) are in good agreement with the values in Table 3.

The substance **2** is unusual, in that the lattice contains equal proportions of $InI_3 \cdot PPh_3$ and $InI_3(PPh_3)_2$. There are some important differences between the results for the $InI_3 \cdot PPh_3$ moiety (Table 5) and those for the pure compound given in Table 3. The In–I bond distance of 2.691(2) Å is significantly longer than in **1**, as is In—P (2.616(9) compared with 2.603(7) Å). There are also interesting changes in the bond angles; I-In-I, which is 115.11(3)° in the isolated molecule in **1** changes to 113.92(5)° in the mixed lattice, while the corresponding values for In-P-C are 111.8(5)° and 110.18(1)°, so that the molecule is slightly flattened at both pseudo-tetrahedral sites in this mixed lattice, relative to the pure substance.

The 1:2 complex is directly comparable with the compound $InI_3(PMePh_2)_2$, for which r(In—I) = 2.736(4), 2.762(2), 2.776(2) Å, and r(In-P) (avg.) = 2.716(4) Å (11). Both show a significant lengthening of the In—I bond relative to the values for the various 1:1 adducts, in keeping with the increased coordination number at indium (cf. ref. 9). Surprisingly, the two In—P bonds are of quite different lengths (2.86(1) and 2.99(1) Å), and these values are both much larger than the average of 2.65 Å derived from work on $InI_3(PMePh_2)_2$, $InBr_3(PMe_2Ph)_2$ (11), $InCl_3(PMe_3)_2$ (12), and $InCl_3(PPh_3)_2$ (13). We return to these results below.

The structure of compound **3** reveals the presence of an infinite chain in which planar InI_3 units are linked by bridging dppe bidentate donors. The presence of isolated dppe molecules allows a comparison between the coordinated and the free state. Apart from a slight contraction of the P—C_6H_5 bonds, there are in fact no significant differences; the total P–P distance is essentially constant at ~5.2 Å in the two molecules. It is also interesting to compare the structure of $[InI_3(dppe)]_\infty$ with that of $(InI_3)_3(dppe)_2$ (12), which represents a sub-unit of the infinite chain structure. The stereochemistry at indium and phosphorus is almost identical in both cases, and the average bond distances in $(InI_3)_3(dppe)_2$ (r(In–I) = 2.731(15) Å, r(In–P) = 2.809(10) Å and r(P–C_6H_5) = 1.83(1) Å are very close to those in Table 7.

The values for In—P bond length in these adducts call for some comment. We first note that the P—C bond distances in all the present structures give an average value of 1.84 Å, which is close to the sum of the covalent radii (0.77 + 1.10 = 1.87 Å), in keeping with the expected formation of single bonds. The covalent radius of indium in tetrahedral InX_4^- species (X = Cl, Br, I) can be calculated from the known average In—X bond lengths (2.350(2), 2.479(2), 2.71(1) for X = Cl, Br, and I, respectively (14)) as 1.36(2) Å, in which case r(In–P) in a tetrahedral environment should be ca. 2.46 Å, which is significantly smaller than the values found in the present work for $InI_3 \cdot PPh_3$ in **1** and **2** (2.603(7), 2.616(9) Å) (Tables 3 and 5). For the five-coordinate species, r(In–P)(avg.) = 2.92(5) in **2** and 2.76(1) in **3** , again substantially greater than that calculated. An alternative approach uses the conventional single bond covalent radii for these elements (15), from which r(In–I) = 1.50 + 1.33 = 2.83 Å, and r(In–P) = 1.50 + 1.09 = 2.59 Å. These values therefore substantially underestimate r(In–I) in both four- and five- coordinate species, while the calculated r(In–P) is slightly lower than the experimental value in $InI_3 \cdot PPh_3$, and significantly so in the other adducts. The large bond distance in the five-coordinate molecules implies the presence of very weak In–P interactions in these species in the crystalline state, which has important implications for the solution studies reported below.

NMR studies on $InI_3(PPh_3)_2$

The ^{31}P resonance of a solution of $InI_3(PPh_3)_2$ in $CDCl_3$ at 293 K is a broad singlet, half width approximately 33 Hz, −16.85 ppm from the reference solution of 85% H_3PO_4 = 0; the comparable values for PPh_3 under the same conditions are δ = −5.44 ppm and $\omega_{1/2}$ = 7.5 Hz. Both the chemical shift (Fig. 4*A*) and the line width (Fig. 4*B*) of a solution of the 1:2 complex change with temperature until, at 213 K, the half width is ca. 100 Hz, and the chemical shift is −15.5 ppm. Below this temperature, the precipitation of crystalline material, identified as the 1:1 complex $InI_3 \cdot PPh_3$, was observed, and the slight maximum observed in Fig. 4*A* at 223 K may have been caused by the presence of small quantities of solid in the solution phase at this temperature.

The significant line width, the increase of this with decreasing temperature, the precipitation of $InI_3 \cdot PPh_3$, and the change in the average chemical shift towards the value for free PPh_3, are all in keeping with the existence in solution of the equilibria

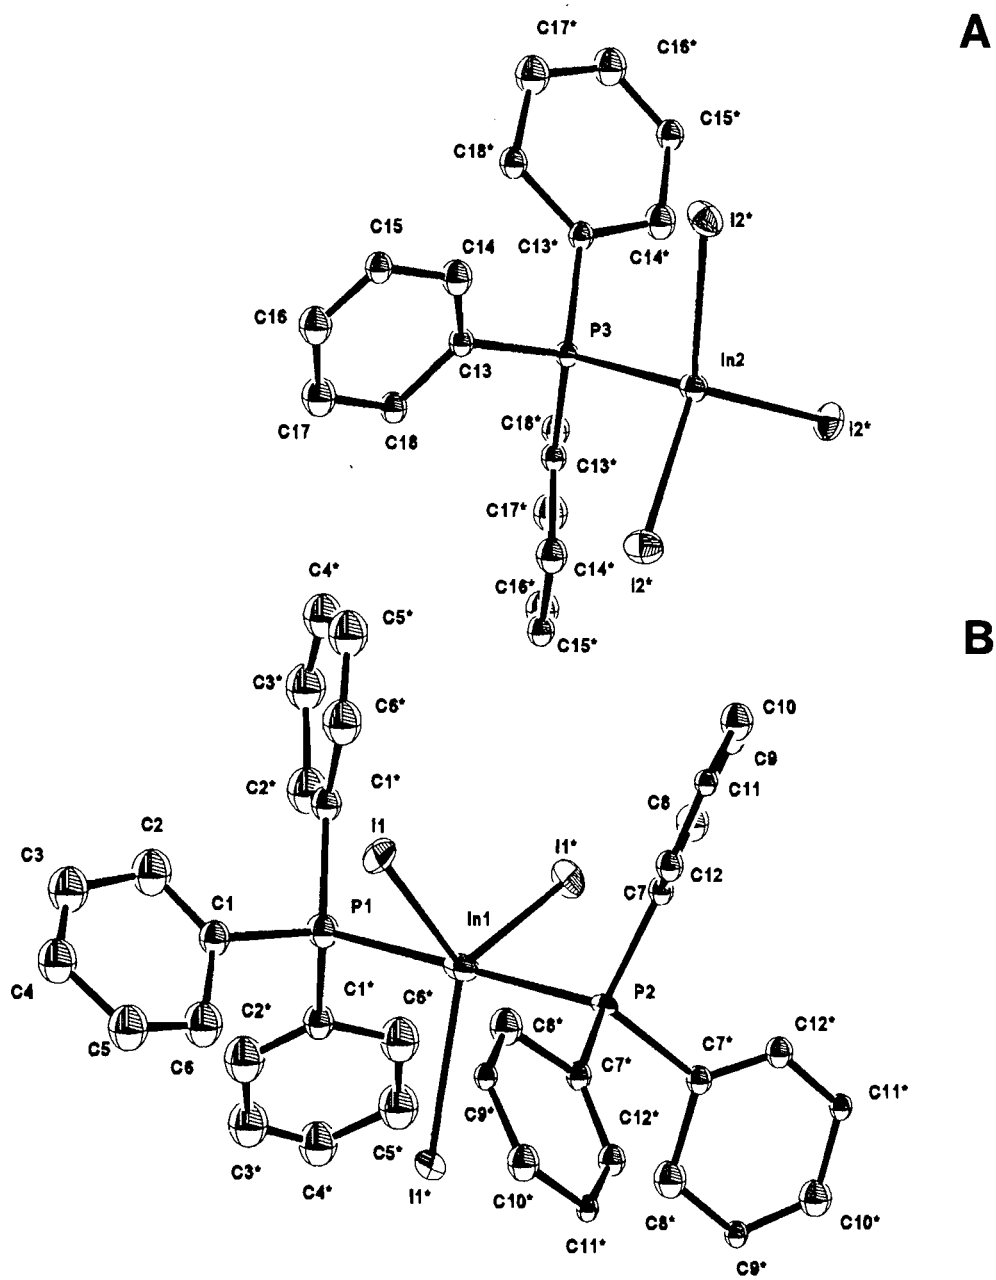
[1] $InI_3(PPh_3)_2 \leftrightarrows InI_3 \cdot PPh_3 + PPh_3$

[2] $InI_3 \cdot PPh \leftrightarrows InI_3 + PPh_3$

The change in the line width with decreasing temperature indicates that the rapid exchange observed at room temperature is being slowed, but clearly we were not able to achieve conditions under which the signals of the individual species could be observed.

The effect of adding PPh_3 to a solution of $InI_3(PPh_3)_2$ in $CDCl_3$ (0.1 M, room temp.) is illustrated in Fig. 5. For reasons

Fig. 2. The structure of **2** showing the numbering system for (*A*) $InI_3 \cdot PPh_3$ and (*B*) $InI_3(PPh_3)_2$; ORTEP diagram, with 30% probability ellipsoids.



that will be discussed below, this diagram shows both the average ^{31}P chemical shift (5*A*) and the width at half-height (5*B*) as a function of the mole ratio of Ph_3P to the 1:1 complex $InI_3 \cdot PPh_3$, and both parameters move monotonically as a function of this ratio. The limiting chemical shift (−5.4 ppm) is identical to that for free PPh_3. The changes in $T_{1/2}$ show that the exchange processes in solution persist over the range studied, while the sharpening at high ligand: complex ratios indicates that the overall exchange is enhanced under these conditions.

When iodide ion, in the form of either *n*-Pr_4NI or *n*-Bu_4NI, is added to a solution of $InI_3(PPh_3)_2$ in $CDCl_3$, two important phenomena are observed. The ^{31}P chemical shift (Fig. 6*A*) changes linearly as I^- is added, to a point of inflexion at which the quantities of iodide and complex are equal. The ^{31}P resonance at this point, and subsequently, is at −5.2 ppm, indicating the presence of free PPh_3 in the solution. The line width also changes during the addition of iodide, with the results shown in Fig. 6*B*. The point of inflexion again occurs when equimolar quantities of I^- and $InI_3(PPh_3)_2$ are present. The line width beyond that point ($\omega_{1/2}$ = 23 Hz) is similar to that for free PPh_3 under the same conditions.

Studies of the ^{115}In resonance of these solutions showed that no signal could be detected with a solution of $InI_3(PPh_3)_2$

Fig. 3. The structure of **3** showing the numbering system for (*A*) InI_3(dppe) and (*B*) dppe; ORTEP diagram, with 30% probability ellipsoids.

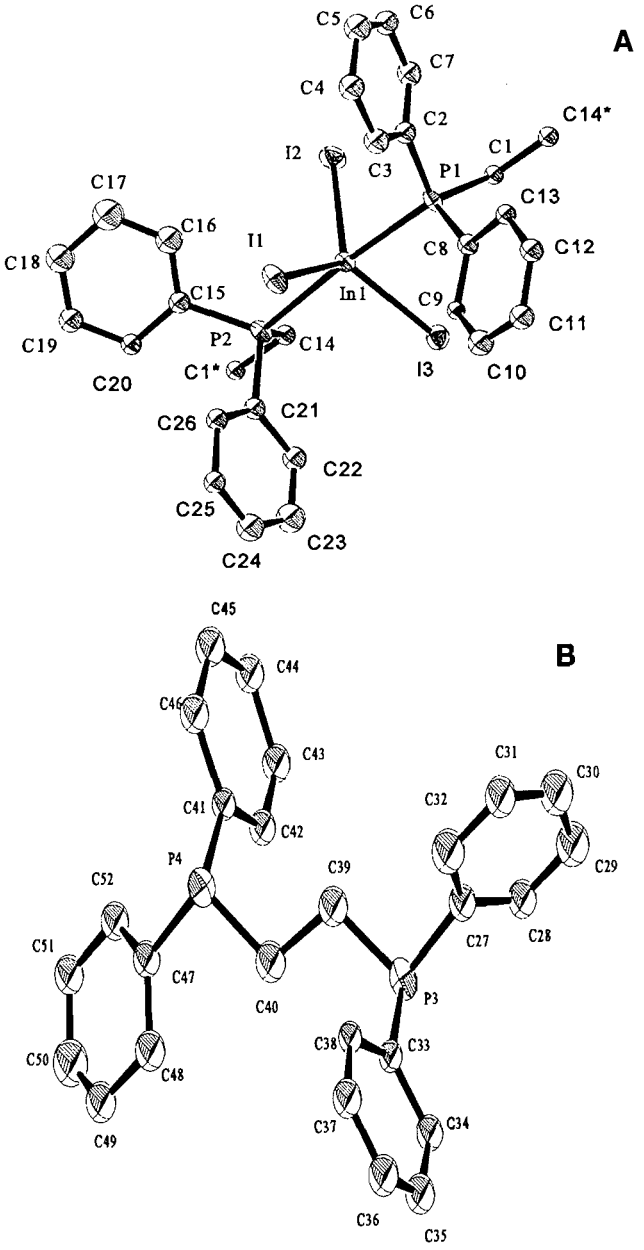


Fig. 4. Effect of temperature on ^{31}P NMR spectrum of a solution of $InI_3(PPh_3)_2$, 0.1 M in $CDCl_3$; (*A*) change in chemical shift, (*B*) change in line width at half-height.

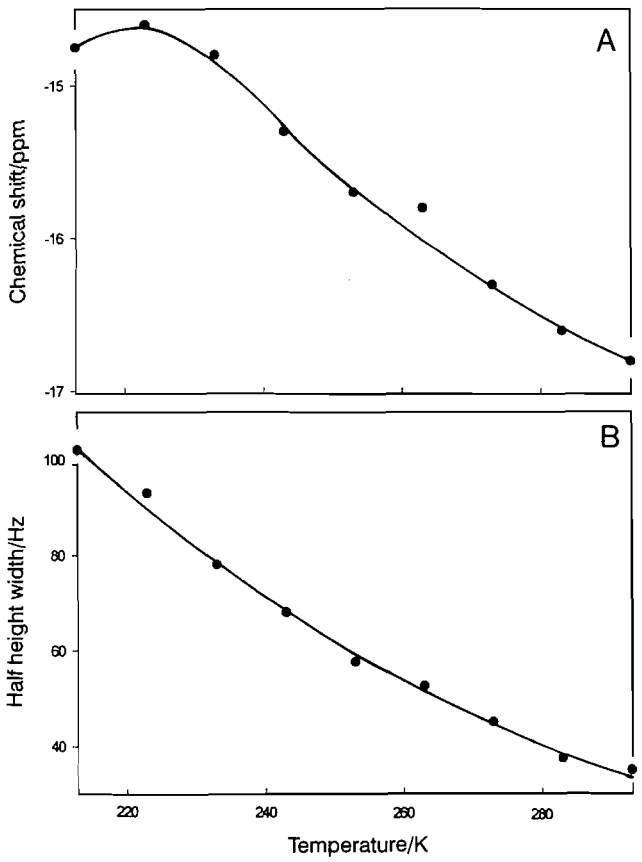

in $CDCl_3$, which is in keeping with earlier observations by many workers that this resonance is only detectable in species of high symmetry because of the high nuclear spin ($I = 9/2$). As I^- was added, however, a signal was detected at −980 ppm relative to $InCl_4^- = 0$ (see ref. (14), indicating the formation of InI_4^- in the solution. The intensity of this signal increased with further addition of R_4NI, and again reached a maximum when the concentration of $InI_3(PPh_3)_2$ and R_4NI were equal. Further addition of R_4NI caused the precipitation of $R_4N[InI_4]$, identified by the characteristic Raman spectrum (139 s, 186 w cm^{-1}; cf. lit. values $\nu_1 = 139$, $\nu_3 = 186$ cm^{-1} (16)), and in the case of *n*-$Pr_4N[InI_4]$ by indium analysis (calcd. In 14.2%; found: In 14.0). These results all show that the process [3] takes place,

[3] $InI_3(PPh_3)_2 + I^- \rightarrow InI_4^- + 2\ PPh_3$

apparently quantitatively, under the conditions used.

The 1:1 complex $InI_3 \cdot PPh_3$ is insufficiently soluble in $CDCl_3$ for ^{31}P investigations, but results were obtained with solutions in acetone. The 1:1 adduct in this solvent shows a sharp resonance at room temperature at −28.8 ppm, $\omega_{1/2}$ = 16.5 Hz. This is significantly sharper than the 1:2 species ($\omega_{1/2}$ = 105 Hz), and we conclude that the dissociation and ligand exchange are absent in this solution, so that eq. [2] lies to the left. The effect of adding PPh_3 to this solution is shown in Fig. 7. As with the 1:2 adduct, there are changes in both δ and $\omega_{1/2}$. The chemical shift of a mixture containing equimolar quantities of $InI_3 \cdot PPh_3$ and PPh_3 is −23.5 ppm, to be compared with the value for a solution of the 1:2 complex in $CDCl_3$ of −16.85 ppm. Given the effect of solvent on the equilibria involved, there is little to be gained by discussing this difference; the more important point is that addition of PPh_3 to $InI_3 \cdot PPh_3$ shifts the resonance towards that of the 1:2 complex. The increasing half width (Fig. 7B) with addition of ligand is evidence of ligand exchange, in keeping with eq. [1].

Dissociative equilibria involving $InI_3(PPh_3)_2$

The present results, and those from the earlier investigations (2), show clearly that eqs. [1], [2], and [3] describe partially

Fig. 5. Effect of adding PPh_3 to a solution of $InI_3(PPh_3)_2$ (0.1 M in $CDCl_3$) at room temperature; (*A*) change in ^{31}P chemical shift, and (*B*) change in line width.

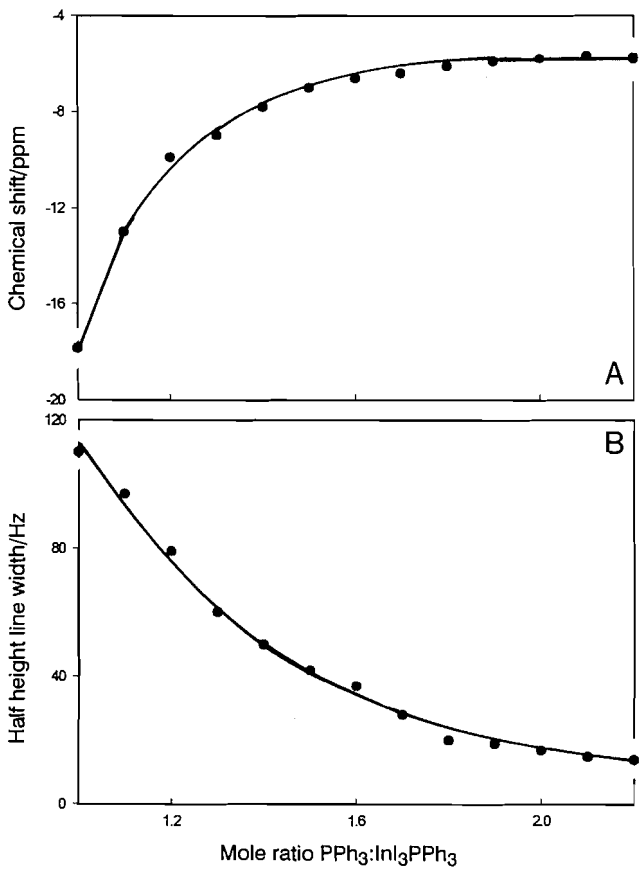

Fig. 6. Effect of adding *n*-Bu_4NI to a solution of $InI_3(PPh_3)_2$ (0.1 M in $CDCl_3$) at room temperature; (*A*) change in ^{31}P chemical shift, (*B*) change in line width.

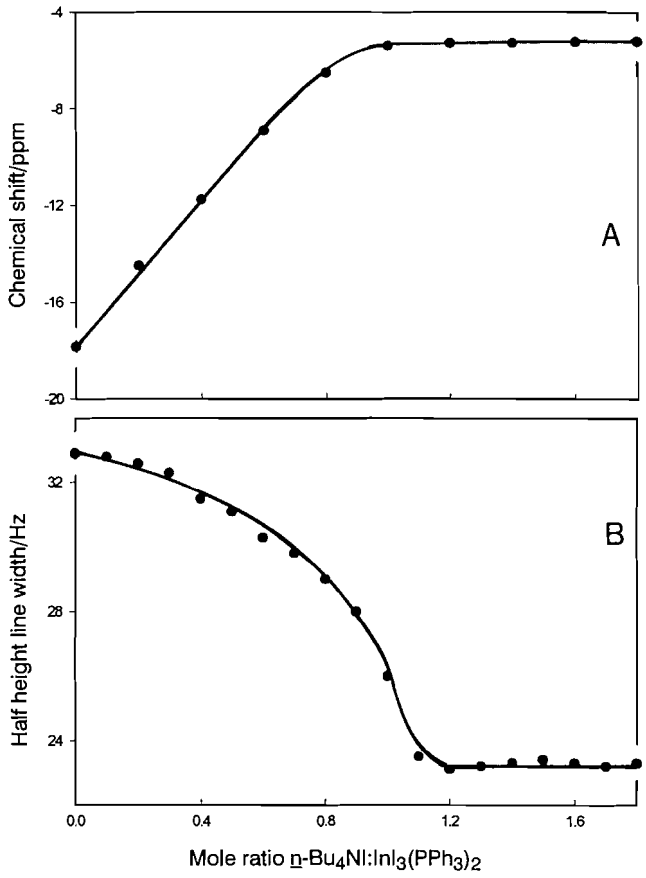


the solution chemistry of $InI_3(PPh_3)_2$. For this system, the possible equilibria can be summarized as

$$[4] \quad InX_3L_{n-1} + L \leftrightarrows InX_3L_n \leftrightarrows InX_2L_n + X^-$$

We note first that the dissociation into ionic species is established by the small but significant electrical conductivity in nitromethane and nitrobenzene (2). Such dissociation is germane to the present discussion only to the extent that free or associated charged species can be assumed to be present in the solvents used in the NMR investigations.

The preparative scale work on the InI_3/PPh_3 system showed that the reaction between these substances in ethyl acetate gives the 1:2 complex, which on recrystallization from the same solvent yields an equimolar solid lattice of 1:2 and 1:1 adducts that is also in keeping with the existence of this same equilibrium in ethyl acetate. Recrystallization of a solution of the 1:2 complex from cyclohexane gives only the 1:1 adduct. These effects, which have been discussed elsewhere (1), are a general feature of the adducts of indium trihalides and related compounds, and serve to emphasize the difficulty of identifying the "most stable" species in a series of possible adducts and (or) coordination numbers.

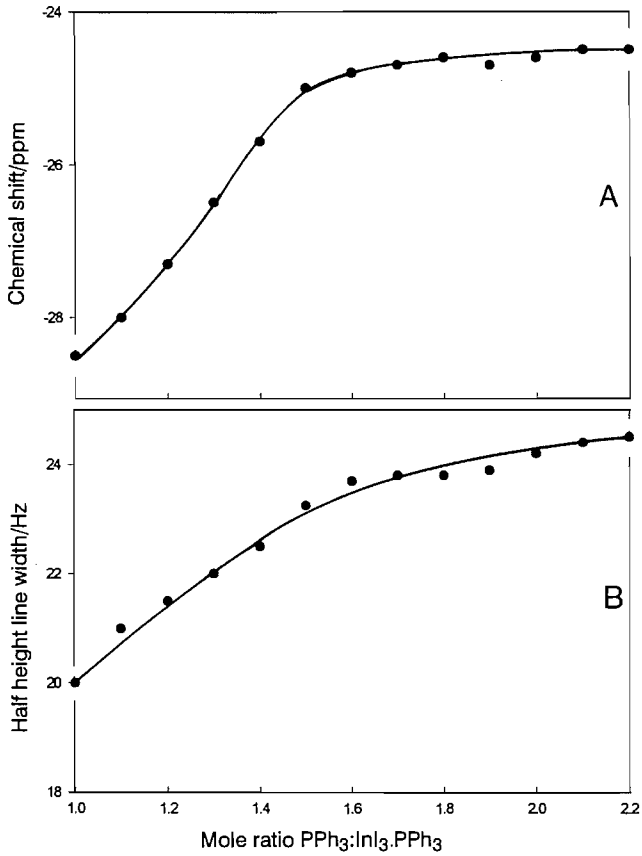
A quantitative analysis of the various results is hindered by the different solvents which were necessarily used in the various aspects of the work, and by the different concentration ranges involved ($\sim 10^{-3}$ M for conductivity measurements, $<10^{-2}$ for molecular weight determination, $>10^{-1}$ M for NMR studies, and >1 M in the preparative work). We take as a starting point the molecular weight determinations reported earlier (2) for two different sets of conditions. In chloroform at room temperature, the observed value is 614, and in benzene at the freezing point (5.5°C), $M_{obs} = 526$. If the only significant equilibrium is that of eq. [1], then

$$[5] \quad M_{obs} = \frac{(1-x)M_2 + M_1 + xL}{1+x}$$

where M_2, M_1, and M_L are the molecular weights of $InI_3(PPh_3)_2$, $InI_3 \cdot PPh_3$ and PPh_3 respectively, and x is the degree of dissociation of $InI_3(PPh_3)_2$. A value of $M_{obs} = 526$ corresponds to $x \rightarrow 1$ ($M_2 = 1020$, $M_1 = 758$, $M_L = 262$ to the nearest integer), and the result for chloroform is rather similar, so that the conclusion is that, at such dilutions, $InI_3(PPh_3)_2$ undergoes essentially complete dissociation to the 1:1 complex and free triphenylphosphine. This interesting result correlates nicely with the weak In—P bonding in the 1:2 complex (see above).

The ^{31}P NMR results show that the various phosphorus-containing species are undergoing rapid exchange under all

Fig. 7. Effect of adding PPh_3 to a solution of $InI_3 \cdot PPh_3$ (0.1 M) in acetone at room temperature; (*A*) change in ^{31}P chemical shift, (*B*) change in line width.



the conditions studied. The presence of substantial quantities of free PPh_3 as the result of the dissociation discussed above provides an obvious mechanism for this exchange. The observed chemical shift in any of these solutions is the weighted average of the individual shifts of the contributing species

$$[6] \qquad \delta_{obs} = \sum_i p_i \delta_i$$

where p_i is the fractional population of the ^{31}P spins present as the *i*th species with characteristic chemical shift δ_i, and one should therefore be able to calculate p_i or δ_i, depending on the assumptions made. If we assume that this solution is completely dissociated into InI_3PPh_3 and PPh_3, following the results just discussed, then from

$$[7] \qquad \delta_{obs} = p_2\delta_2 + p_1\delta_1 + p_L\delta_L$$

where the subscripts refer to the 1:2 and 1:1 complexes and the free ligand, we have $p_2 = 0$, and $p_1 = p_L = 0.5$, so that

$$[8] \qquad \delta_{obs} = 0.5\delta_1 + 0.5\,(-5.44) = -16.85 \text{ ppm}$$

from which $\delta_1 = -28.2$ ppm in $CDCl_3$. The value in acetone is -29.0 ppm (see above), and the agreement is satisfying (assuming no large solvent effect), so that the ^{31}P NMR results are in keeping with the molecular weight determinations in that both imply complete dissociation via eq. [1].

The addition of Ph_3P to a solution of $InI_3(PPh_3)_2$ can then be treated as increasing the concentration of PPh_3 in a solution initially containing equimolar quantities of $InI_3 \cdot PPh_3$ and PPh_3. For this reason, Fig. 5 deals with the results in terms of the mole ratio of these two components. A quantitative analysis of the chemical shift results in Fig. 5 appears impossible in the absence of a value for δ_2, but the curve cannot be reproduced by assuming that PPh_3 is being added to $InI_3 \cdot PPh_3$ without formation of the 1:2 complex. The more acceptable model assumes the formation of the 1:2 complex by the reverse of eq. [1], which then leads to the conclusion that δ_2 must be close to δ_L, and, given the weak long-range nature of this In–P interaction in the solid state, this seems reasonable. It was not possible to further analyze the NMR results to derive the equilibrium constant for eq. [1].

The addition of R_4NI to a solution of $InI_3(PPh_3)_2$ causes δ_{obs} to move in a linear fashion, reaching a constant value when the quantity of I^- added is equal to the initial quantity of $InI_3(PPh_3)_2$ (Fig. 6). Given the complete dissociation of the latter at $[I^-]_{ad} = 0$, we can write

$$[9] \qquad InI_3L + L + I^- \rightarrow InI_4^- + 2L$$

for the limit at $[I^-]_{ad} = [InI_3L_2]_0$. For intermediate conditions, where the quantity of added $I^- = x$, for complete conversion, one has

$$[10] \qquad \delta_{obs} = (1 - x)\delta_1 + (1 + x)\delta_L$$

which leads to a linear plot, as is observed in Fig. 6. This quantitative formation of InI_4^- is in keeping with the known behaviour of indium(III)–iodide systems, in which this tetrahedral anion is observed as an extremely stable species (1), and in the present situation much favored over the $InI_3 \cdot PPh_3$ adduct.

NMR studies of InI_3(dppe)

In view of the differing crystalline forms of this substance, it is important to note that all NMR studies discussed below refer to solutions of the compound InI_3(dppe), as initially prepared (see Experimental). The ^{31}P spectrum of a 0.1 M solution of this compound in $CDCl_3$ at room temperature is a sharp singlet, with $\delta = -15.9$ ppm and $\omega_{1/2} = 5$ Hz. The corresponding shift for dppe in the same solvent is -13.0 ppm, and the small change caused by coordination is in keeping with the structural similarities between free and bound ligand in the solid state (see above). The effect of lowering the temperature is illustrated in Fig. 8; the signal broadens gradually, with a sharp change at 223 K corresponding to the appearance of solid material, while the chemical shift changes by about 2 ppm over the same range. The studies of triphenylphosphine adducts of InI_3 discussed above clearly demonstrate that the four-coordinate species is thermodynamically more stable than the five-coordinate derivative, and the spectrum of InI_3(dppe) can be interpreted in this light. A non-fluxional four-coordinate mononuclear complex would show two ^{31}P resonances, as would a five-coordinate species with apical and equatorial phosphorus atoms; the observation of a single sharp resonance at room temperature and the relatively small tem-

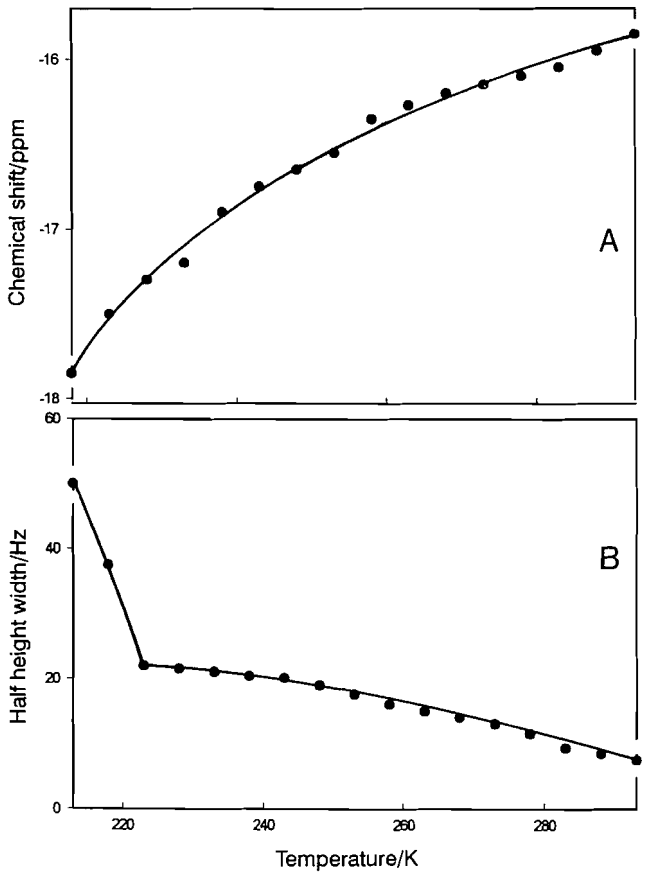
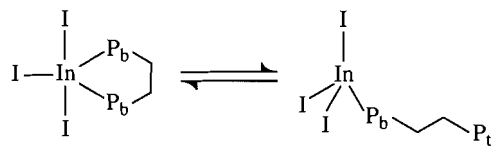


Scheme 1.

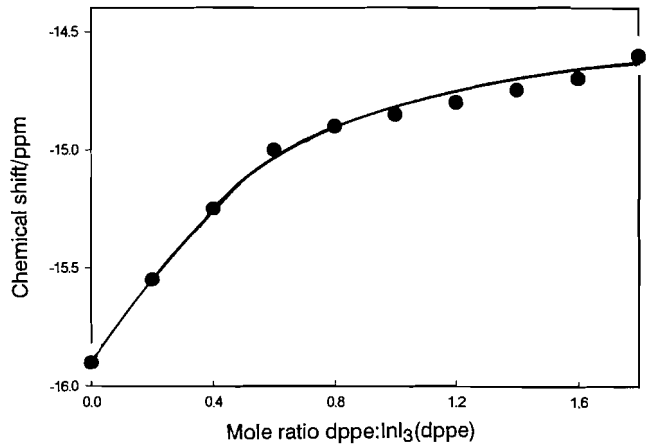


IA **IB**

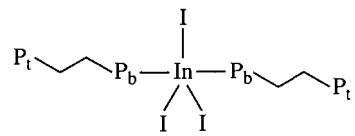
perature effect in the spectra of $InI_3(dppe)$ itself are taken as evidence of the presence of the rapidly interconverting species (Scheme 1).

Ring-opening processes of this type have been shown to be a feature of the solution chemistry of other indium(III) compounds, and reflect the changes in coordination numbers associated with different ligand environments (17–19). The chemical shift observed is then the appropriately weighted average of the individual shifts of I*A* and I*B* and there will be two values for P_b and P_t in I*A*. The broadening of the signal with decreasing temperature (Fig. 8B) indicates the expected slowing of the exchange process, but it was not possible to identify these as separate resonances in the temperature range available to us. The addition of dppe (Fig. 9) produces a small change in δ, and the curve approaches asymptotically a value

Fig. 9. Effect of adding dppe to a solution of $InI_3(dppe)$ (0.1 M in $CDCl_3$) at room temperature; change in ^{31}P chemical shift.



Scheme 2.

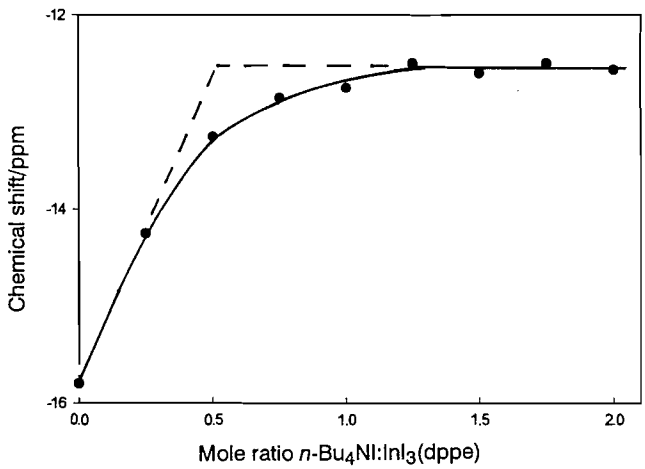


II

of ca. −14.5 ppm. In the absence of a bonding interaction leading to higher complexes between $InI_3(dppe)$ and free ligand, one would expect the linear relationship seen at low dppe concentrations in Fig. 9. There is an obvious deviation from this as the quantity of dppe is increased, but it is clear that an extrapolation to the chemical shift for free dppe would require the addition of large excess of this ligand. The addition of dppe (Fig. 9) also causes line broadening, and a shift in δ_{obs} that is almost linear with the dppe: complex ratio and corresponds to an averaging of δ_L and δ_C, the chemical shifts of the free ligand and the complex at low [dppe]. But at high ligand: complex mole ratios, δ_{obs} falls away from this linearity, which may be due to the formation in solution of species in which InI_3 is coordinated by two dppe ligands. In view of the preparative and crystallographic results, which show that $InI_3(dppe)$, $(InI_3)_3(dppe)_2$, and $[InI_3(dppe)]_\infty$ are readily interconverted, and that indium is five-coordinate in at least two of these systems, such a complex would likely involve two monodentate ligands present in small but not insignificant proportions (Scheme 2). The average ^{31}P chemical shift in such a species would presumably lie between the values for dppe (−13.0) and $InI_3(dppe)$ (−15.9 ppm).

The addition of strong σ-donor ligands, such as dimethyl sulphoxide, dimethylformamide, pyridine, or γ-picoline, to a solution of $InI_3(dppe)$ in $CDCl_3$ leads to the quantitative release of free dppe, as shown by the ^{31}P chemical shift changes. As in the InI_3–PPh_3 system, addition of iodide ion, as *n*-Bu_4NI, also results in the release of dppe and the formation of InI_4^-, by the ^{115}In resonance at −980 ppm. There is a quantitative difference from the InI_3/PPh_3 case, in that the dependence of δ on the complex: iodide mole ratio is not linear (Fig. 10). Extrapolation of the initial and final linear portions of this

Fig. 10. Effect of adding *n*-Bu_4NI to a solution of InI_3(dppe) (0.5 M in $CDCl_3$) at room temperature; change in ^{31}P chemical shift.



graph gives a point of inflexion at a mole ratio of I^-: complex = 0.5, which can be interpreted in the following way. Firstly, we note that direct nucleophilic attack by I^- on a five-coordinate InI_3(dppe) (structure **IB**) would involve the formation of a six-coordinate InI_4P_2 intermediate, which seems most unlikely in the context of the known coordination chemistry of indium(III). An interaction between I^- and four-coordinate InI_3(dppe) (i.e., structure **IA**) might appear more favorable, but this would not give the reaction stoichiometry observed, and it may well be that steric blocking by dppe at the indium(III) centre would prevent this reaction pathway. We therefore propose that the first step is the weak dissociation of the complex.

[11] $InI_3(dppe) \leftrightarrows InI_3 + dppe$

It is known that in non-coordinating solvents, the dimerization

[12] $2\ InI_3 \rightarrow In_2I_6$

lies completely to the right. Two spectroscopic studies (20, 21) have shown that adduct formation by Ga_2X_6 (X = Cl, Br) involves as a first step the coordination of the donor at one of the metal atoms of the dimer, and that dissociation of the latter (i.e., the reverse of eq. [12]) is not a prerequisite. For the present system, one then has

[13] $In_2I_6 + I^- \rightarrow InI_3 + InI_4^-$

as the final step, so that the overall stoichiometry is

[14] $2\ InI_3(dppe) + I^- \rightarrow InI_4^- + 2\ dppe + 1/2\ In_2I_6$

in keeping with the results shown in Fig. 10. The differences in the behaviour of $InI_3(PPh_3)$ and InI_3(dppe) in this respect are therefore a consequence of the different initial interactions, which are themselves a function of the coordination chemistry of indium(III).

General conclusions

The preparative studies on $InI_3 - PPh_3$ adducts demonstrate that here, as in other related systems, the influences of both solvent and ligand on apparently simple equilibria are complex, and not readily predictable with our present knowledge. The detailed information obtained from the NMR investigations for both PPh_3 and dppe derivatives emphasizes the difficulty of interpreting such matters in a quantitative manner. The most important general conclusion is that the interactions of such seemingly simple molecules are much more complicated than is apparent from a superficial examination, and that further studies of related systems would be profitable.

Acknowledgments

The present NMR work on $InI_3 - PPh_3$ systems is an extension of earlier studies carried out at Simon Fraser University; we wish to thank Mr. Victor Verigin for carrying out these experiments. Dr. S.J. Loeb (University of Windsor) is thanked for his help in the crystallographic studies. The research was supported in part by Research Grants (to D.G.T.) from the Natural Sciences and Engineering Research Council of Canada.

Synthesis of glycosylated cationic porphyrins as potential agents in photodynamic therapy

Khalid Driaf, Robert Granet, Pierre Krausz, Mourad Kaouadji, François Thomasson, Albert José Chulia, Bernard Verneuil, Marenglen Spiro, Jean-Claude Blais, and Gérard Bolbach

Abstract: Trisalkylpyridinium porphyrins substituted by one glycosyl (glucosyl, maltosyl, and lactosyl) moiety have been prepared in acceptable yields. These glycosylated cationic porphyrins have been synthesized from pyrrole condensed with 4-pyridinecarboxaldehyde, and suitable *ortho*- or *para* peracetylglycosyloxybenzaldehyde derivatives in refluxing propionic acid – Ac_2O followed by action of alkyliodide in DMF. Deprotection of the glycosylated moieties led to a new class of representative glycosylated porphyrins.

Key words: porphyrins, cationic, glycosylated; phototherapy, cancer.

Résumé : On a préparé des tris(alkylpyridinium)porphyrines substituées par une portion glycosyle (glucosyle, maltosyle et lactosyle) avec des rendements acceptables. On a synthétisé ces porphyrines cationiques glycosylées à partir de pyrrole condensé avec un pyridine-4-carboxyaldéhyde et des dérivés *ortho*- ou *para*-peracétylglycosyloxybenzaldéhydes appropriés, par reflux dans de l'acide propanoïque – Ac_2O, suivi par l'action d'un iodure d'alkyle dans le DMF. La déprotection des portions glycosylées conduit à une nouvelle classe de porphyrines glycosylées représentatives.

Mots clés : porphyrines, cationique, glycosylé; photothérapie, cancer.

[Traduit par la rédaction]

Introduction

Tetrapyrrolic macrocycles and their metallic complexes have been long investigated largely on account of their thermo- or photocatalytic properties. The continuing progress in porphyrin chemistry in recent years has caused a growing interest for such compounds. Porphyrins and their analogs have attracted much attention as phototherapeutic (1) and anti-HIV agents (2).

Photosensitizing porphyrins are a potential treatment in tumor therapy. Photodynamic therapy is based on the principle that these porphyrins become concentrated in tumor cells and, upon subsequent irradiation with visible light in the presence of oxygen, specifically destroy the cells (3). To have an efficient photosensitizing effect, porphyrins must exhibit excellent hydrophilic properties (4). Thus it is of great interest to synthesize new water-soluble molecules.

Cationic porphyrins are highly soluble and the presence of a carbohydrate moiety improves specific receptor targeting (5) and increases plasmatic life time (6). The presence of hydrophilic and hydrophobic parts in the compounds facilitates membrane penetration. In addition, cationic porphyrins have different binding modes with nucleic acids than have neutral porphyrins due to their enhanced affinity for DNA (7). These porphyrin–DNA interactions are of great importance in photodynamic therapy (PDT) (8), anticancer therapy (9), selective cleavage of nucleic acids (10), and as antiviral agents (HIV-1) (11). Since the first work of Mironov et al. (12), a vast and ever-increasing literature on glycosylated porphyrins has been reported (13), although, until now, no work has been devoted to unsymmetrical *O*-glycosylated cationic porphyrins. In a preliminary paper we reported the first synthesis of alkyl pyridinium 4-yl porphyrins bearing a carbohydrate moiety (14). In connection with our research program on glycosylated porphyrins we have extended the range of structures of glycosyl and alkyl substituents. In the present paper we report full experimental data concerning the synthesis and characterization of a series of free base cationic glycosylated porphyrins based on tris 4-(alkyl pyridiniumyl) porphyrin. These unsymmetrical molecules contain one *meso*-phenyl group bearing a mono- or disaccharide in the *ortho* or *para* position and three *meso*-alkyl pyridinium groups with a linear or branched alkyl chain.

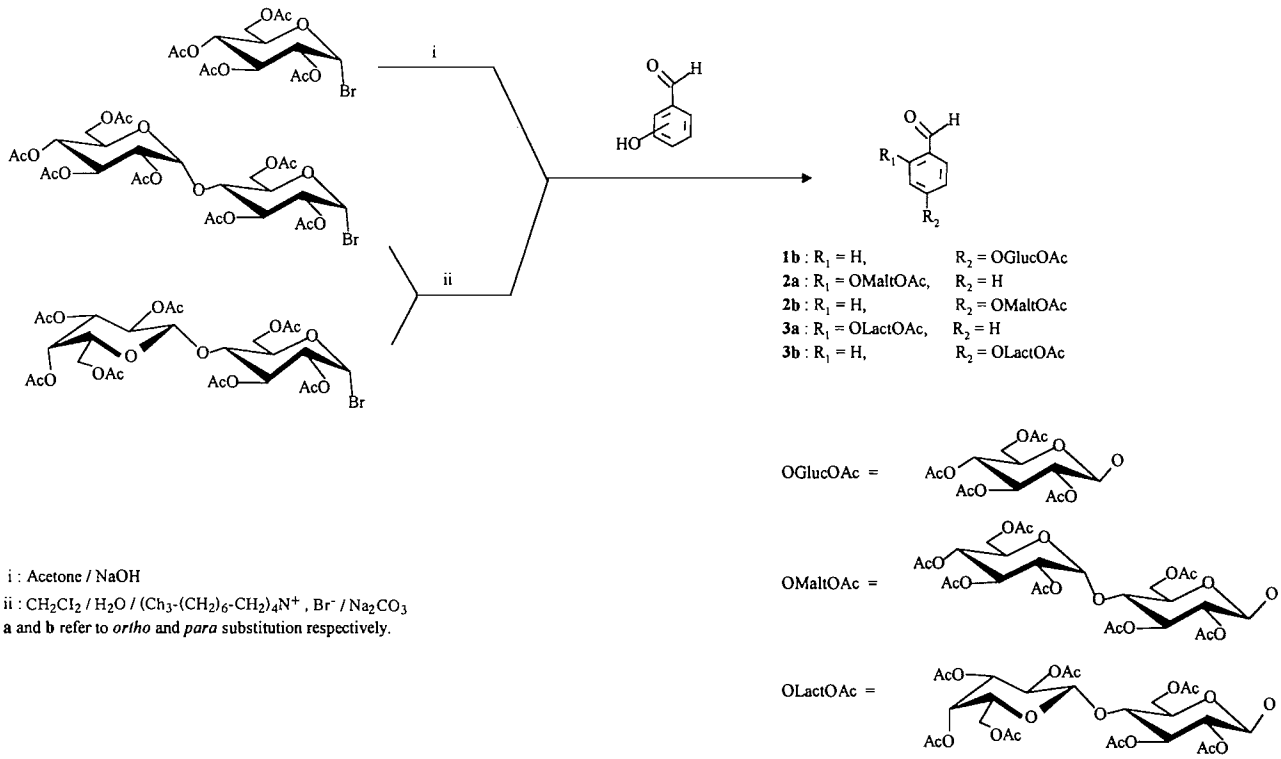
Results and discussion

Synthesis

The different porphyrins were prepared according to the gen-

Scheme 1.



eral route outlined in Schemes 1 and 2. The suitably glycosylated benzaldehydes **1–3** were synthesized following different pathways (Scheme 1). Aldehyde **1a** was prepared from commercially available helicin (2-(β-D-glucopyranosyloxy)benzaldehyde) by acetylation at 0°C during 1.5 h with acetic anhydride in dry pyridine (yield 90%). 4-(2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosyloxy)benzaldehyde **1b** was synthesized from 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide and 4-hydroxybenzaldehyde (2.5 equiv.) in acetone in the presence of 7% aqueous NaOH. After 24 h, the expected compound was obtained in 40% yield. Treatment of hydroxybenzaldehyde with bromoacetylated maltosyl or lactosyl in the same manner gave products **2a,b** and **3a,b** in low yields; therefore, another route to prepare these compounds was selected. 2,3,6,2′,3′,4′,6′-Hepta-*O*-acetyl-β-D-maltosyl or lactosyl benzaldehydes were produced by reaction of *ortho* or *para* hydroxybenzaldehyde with bromoacetylated maltosyl or lactosyl in phase transfer catalysis. This reaction was carried out in a biphasic system of water–chloroform (1:1) in the presence of 1 M aqueous Na_2CO_3 and tetraoctylammonium bromide as catalyst. After the usual work-up, glycosylated benzaldehydes **2a,b** and **3a,b** were obtained with an improved yield for the *para* compounds. Compounds with the disaccharidic substituent in the *ortho* position did not have a similar result probably due to steric hindrance.

With the suitably glycosylated benzaldehydes, pyridyl porphyrin derivatives were then synthesized (Scheme 2). Unsymmetrical porphyrin derivatives **4a,b, 5a,b**, and **6a,b** with three pyridyls and a protected mono- or disaccharide glycosylated group were prepared following the method of Little et al. (15). These syntheses were carried out by condensation of **1a,b–3a,b** (1 equiv.) with 4-pyridinecarboxaldehyde (2 equiv.) and pyrrole (2.6 equiv.) in propionic acid with 10% acetic anhydride, which served to prevent deacetylation of the glycosylated moiety. The yields of chromatographically pure porphyrins were about 6–7%. Such yields are acceptable in comparison to other similar preparations (10*a*). Attempts to use Lindsey's method (16) (condensation of aldehydes and pyrrole in the presence of BF_3–Et_2O in CH_2Cl_2 followed by addition of DDQ) did not lead to the expected compounds **4a,b–6a,b**.

Treatment of glycosylated pyridylporphyrins **4a,b–6a,b** with a large excess of methyl iodide in dry DMF gave the expected cationic glycosylated *N*-methylpyridinium porphyrins **7a,b–9a,b**. These compounds were purified by precipitation in diethyl ether. In a second series of experiments, the alkyl substituents of pyridyl porphyrins **4a,b** were modified. Thus, when treated with a large excess of either isopropyl iodide or *n*-octyl iodide, **4a** and **4b** yielded the corresponding cationic porphyrins **10a,b** as well as **11a,b** in about 70% yield. *N*-Isopropyl derivatives **10a** and **10b** were purified as described for **7a,b–9a,b**; however, *n*-octyl porphyrins were extracted with the mixture *n*-BuOH–AcOH–H_2O (4:1:5) (upper phase) due to their lower polarity with respect to the *N*-methyl and *N*-isopropyl homologues.

Finally, compounds **4–11** were deprotected with Et_3N–MeOH–H_2O (10:10:1) at 0°C, which after purification, led to the unprotected porphyrins **12–19** in nearly quantitative yields.

Acetylated cationic porphyrins were soluble in water with the exception of the *n*-octyl derivatives (**11a,b**), which were soluble in organic solvents such as chloroform, methylene

chloride, and ether. The disaccharide acetylated cationic porphyrins **8a,b** and **9a,b** were slightly soluble in methylene chloride. All deacetylated neutral and cationic porphyrins were water soluble.

Mass analysis

Conventional mass spectral analysis (EI and CI) of relatively nonvolatile compounds such as porphyrins requires considerable heating of the sample, which can lead to its degradation. Consequently, ionization modes such as SIMS, FAB, and MALDI (Matrix Assisted Laser Desorption Ionization) were used for characterization of the porphyrins.

Acetylglycosylated neutral porphyrins were analyzed in the SIMS mode (positive and negative). Acetylglycosylated cationic porphyrins were characterized by FAB mass spectrometry. The mass spectra of the deacetylated porphyrins, both neutral and cationic, were obtained in the MALDI mode, the FAB mode being ineffective. In addition to the protonated (positive mode) or deprotonated (negative mode) molecules, an ion corresponding to elimination of an acetylated sugar unit was observed in the SIMS spectrum of acetyl glycosylated porphyrins (**4a,b–6a,b**). Acetylated cationic porphyrins (**7a,b–11a,b**) were characterized by FAB MS in positive mode. In all cases, a protonated quasi molecular ion $(M + H)^+$ was detected. In addition, peaks corresponding to an elimination of one, two, and three alkyl groups (Me, i-Pr, or *n*-Oct) were observed.

In the MALDI mass spectra of deacetylated porphyrins (**12a,b–19a,b**) the molecular peak $(M - 3I^-)^+$ was always observed; no fragment ions were observed.

^{1}H NMR analysis

The ^{1}H NMR data of pyridyl and alkylpyridinium porphyrins were recently published (4) but to the best of our knowledge there exists no information about the ^{1}H NMR of glycosylated pyridylporphyrins.

The ^{1}H NMR of porphyrins **4a,b**, **7a,b**, **10a,b**, and **11a,b** were measured at 200 MHz in DMSO-d_6. The detailed resonance assignments are based on integration, selective homonuclear decoupling, as well as NOE and 2D homonuclear COSY experiments. According to the two substituted phenyl ring groups of *ortho*-tetra-*O*-acetylglucosyl or *para*-tetra-*O*-acetylglucosyl, significative shifts occur for the phenyl substituent as well as for the carbohydrate moiety, the pyridinyl units, and the macrocycle. Such differences in the NMR spectra are consequent to the orientation of the osidic unit with respect to the tetrapyrrolic ring. In the series of related compounds characterized by *p*-tetra-*O*-acetylglucosyl substitution (**4b**, **7b**, **10b**, and **11b**), the ^{1}H NMR spectrum is readily assigned because of the relative high symmetry (C_{2v} group) of each molecule (Tables 1 and 2). This is well illustrated in the ^{1}H NMR of **4b**, taken in $CDCl_3$, by the occurrence of only two sets of protons appearing as doublets ($J = 5.3$ Hz) at δ 9.04 (H-2,6) and δ 8.15 (H-3,5) of the pyridinyl moieties and at δ 8.10 (H-2,6) and δ 7.36 (H-3,5) with $J_{ortho} = 8.7$ Hz for the *p*-disubstituted phenyl ring. Due to their proximity, the pyrrole protons are divided into 2 × 4H exhibiting either a doublet or a singlet. Pyrrole rings in which one proton is near the *p*-(tetra-*O*-acetylglucosyloxy)phenyl and the other is close to a pyridine have their proton resonances split into two doublets ($J =$ 4.5 Hz) at δ 8.91 (H-3,7) and δ 8.81 (H-2,8); in parallel and due to symmetry, pyrrole rings surrounded by two pyridinyl substituents display uncoupled protons appearing as a singlet at δ 8.83 (H-12,13,17,18). Finally, as for *p*-(tetra-*O*-acetylglucosyloxy)benzaldehyde **1b**, the carbohydrate exhibits the expected well-resolved resonances at δ 4.05 (H-5), 4.30 (H-6_A), and 4.41 (H-6_B). The remaining sugar protons are responsible for the overlapped multiplet centered at δ 5.35 (H-1,2 and H-3 or H-4) near to the triplet at δ 5.30 (H-3 or H-4). Change in the substitution of the phenyl ring, by the sugar from the *para* to the *ortho* position with respect to the porphyrin, results in considerable changes in the ^{1}H NMR chemical shifts and (or) in patterns relative to most of the nuclei. This phenomenon reflects a diminished symmetry induced by the orientation of the sugar that in turn leads to an unsymmetrical folded structure because of steric hindrance. Such magnetic perturbations are encountered in the ^{1}H NMR spectra of the related series of compounds, **4a**, **7a**, **10a**, and **11a**, containing *ortho*-tetra-*O*-acetylglucosyloxyphenyl substituent. In comparison with the ^{1}H NMR data of the above-mentioned **4b**, those relative to the homologue **4a** show striking differences in connection with each part of the molecule (Table 2). The pyridinyl protons (H-3,5) close to the macrocycle are shifted downfield by 0.67 ppm, in contrast to the unaffected H-2,6 (δ 9.06). The β-pyrrole proton signals are converted into three doublets ($J =$ 4.9 Hz) at δ 8.94 (H-3), 8.90 (H-7), 8.84 (H-2,8) as well as two singlets at δ 8.83 and 8.78 for H-12,13,17,18. All the sugar protons experience a particularly pronounced shielding from −0.28 ppm (H-6_A) to −1.19 ppm (H-2). These nuclei are obviously located well within the range of the shielding current above the porphyrin macrocycle. Two acetyl groups that would otherwise show a larger shift towards 2.0 ppm are also influenced by the ring current (δ 1.26 and δ −0.97). It is worthwhile noting that the latter group, exhibiting a negative chemical shift value like the typical inner NH protons (δ −2.88), can be unambiguously identified as AcO-2 as predicted by the space-filling model. The ^{1}H NMR spectra of *ortho*- and *para*-protected monoglucosides **4a** and **4b** taken in DMSO-d_6 (Table 1) exhibit chemical shift variations generally entitled solvent effects. This behavior seems to be due to the binding of the polar solvent in the hindered cavity of the macrocycle as indicated by the significative upfield shift (Δδ −0.10 to −0.14 ppm) experienced by the NH groups in both compounds. As a consequence, all the pyrrolic protons are shifted downfield by +0.10 to +0.13 ppm in the *para* isomer. Conversely, only one β-proton of the macrocycle, H-2, displays a significative upfield shift (Δδ −0.11 ppm) in the *ortho* derivative. This phenomenon probably results from the change in the geometry of the macrocycle, whose deformation in the presence of DMSO is more pronounced in **4b** than in **4a** because the orientation of the sugar moiety close to the porphyrin ring in the *ortho* isomer prevents the solvent effect to be clearly expressed on the β-protons. In both compounds, however, the most significant chemical shift variations recorded in the polar solvent are those relative to the pyridinyl and the osidic protons as well as to two particular acetyl groups in **4a** only. Such variations may be partially understood in terms of some combination of steric effect and anisotropy. A consideration of the anisotropy of the sulfoxide function, which acts to cause shielding or deshielding of the protons lying in or out of the cone, seems to be more probable. Regardless of the nature of the effect, the pyridinyls H-3,5 undergo an

[a]Assignments with the same superscript in one column may be interchanged.

upfield shift by −0.56 ppm in **4a** in contrast with those in **4b**, which occur at lower field by +0.29 ppm along with the 2,6-protons, displaced by only +0.12 ppm. Finally, the paramagnetic shifts associated with several osidic protons are more striking than those related to the above-mentioned nuclei. This is well illustrated by the marked dependence of H-1 and H-5, which are shifted downfield by +0.72 and +0.54 ppm, respectively, for **4a** and +0.61 and +0.40 ppm respectively for **4b**.

Replacement of the protected monoglucosyl substituent by a protected diglycosyl group has no significative consequence on the chemical shift values relative to the other parts of the glycosides. In comparison with monoglucosides **4a,b**, the behavior of the β-D-glucosyl protons of the (1→4) diglycoside-protected maltosides **5a,b** and lactosides **6a,b**, is similar except for the H-4 upfield shift due to the loss of the corresponding acetyl group replaced by the interglycosidic linkage (Table 2). As expected, the β-D-glucosyl protons are more shielded in the *ortho* compounds **5a** and **6a** than in the *para* homologues **5b** and **6b** because of the above-mentioned macrocycle ring current (Table 1). They are shifted upfield by ca. 0.2–1.4 ppm for maltoside **5a** and by ca. 0.1–0.9 ppm for lactoside **6a**, the highest Δδ values obviously corresponding to H-2. Shielding of the latter proton in maltoside **5a** (δ 3.72) and in lactoside **6a** (δ 4.32) seems also to be related to the orientation of the second sugar unit: α-glucose for maltoside **5a** and β-galactose for lactoside **6a**. Such a difference for the related proton in the two bioses is cancelled when there is no steric hindrance between the osidic part and the porphyrin core as indicated by the H-2 δ values of 5.16 ppm in maltoside **5b** and 5.18 ppm in lactoside **6b**.

In comparison with the spectra of the non-cationic series run in DMSO-d_6 (Table 1), only two sets of protons moved in the cationic group (Tables 2 and 3). Besides the expected lowfield displacement for the pyridinium nuclei H-2,6 (Δδ 0.30–0.45) and H-3,5 (Δδ 0.58–0.77) (See Experimental), all the β-pyrrolic protons generally exhibited a significative deshielding falling between 0.10 and 0.28 ppm. The most affected nuclei (H-12,13,17,18) were obviously those surrounded by two pyridiniumyl rings and, consequently, by the electron-withdrawing pyridinium nitrogens, which thus were prevented from increasing the electron density in the porphyrin macrocycle.

UV–visible

The data in Table 4 show that the visible absorption bands have positions that in a first approximation are identical to the corresponding non-glycosylated porphyrins even when the substituent is a disaccharidyl group. For the *para*-glycosylated porphyrins in the pyridyl series as well as in the alkylpyridinium series, the relative intensities of the Q(III) and Q(II) bands show an *etio* type ($\varepsilon_{III}/\varepsilon_{II} > 1$). These observations are in interesting contrast to *ortho*-glycosylated porphyrins for which normal pure *etio* spectra were not always observed. For neutral *ortho* peracetyl glycosylated porphyrins **4a**, **5a**, and **6a**, the ratio of $\varepsilon_{III}/\varepsilon_{II} < 1$ corresponds to pure *phyllo* type. For the other *ortho*-glycosylated porphyrins **7a–19a**, the ratio of $\varepsilon_{III}/\varepsilon_{II}$ is always lower than that of the corresponding *para* compound measured in the same solvent. Thus the spectra of *ortho*-glycosylated porphyrins tend toward *phyllo*-type porphyrins.

This phenomenon could result from steric interaction between the glycosyl substituents and the macrocycle, which would affect the solvation (17). However, a significant macrocyclic distortion (18) caused by the steric hindrance of the glycosylated substituents is strongly supported by these results.

Conclusions

In this paper we describe the synthesis and characterization of a new class of water-soluble porphyrins that can be considered as potential agents in cancer phototherapy. These cationic tetrapyrrolic macrocycles are *O*-glycosylated in order to increase cell membrane interactions. Substitutions in the *ortho* or *para* positions lead to further insights into cell membrane interaction. The various lipophilic substituents, such as methyl, isopropyl, and *n*-octyl, allow for increased penetrability of the porphyrins across the cell membrane.

The present strategy may be easily used for preparation of other cationic glycosylated porphyrins, which could interact more specifically with the cellular glycans. The PDT activity of these novel porphyrins is currently under investigation.

Experimental section

General methods

The UV–visible spectra were recorded on a Hewlett Packard 8452A spectrophotometer using 1 or 0.1 cm quartz cells. The rotatory dispersions were measured in chloroform at 22°C in a 10 cm cell with a Jasco (DIP-370) polarimeter. Melting points were determined by capillary tube apparatus and were not corrected. Proton NMR spectra were recorded on a Bruker AC 200 (200 MHz) or on Bruker 300 WM FT (300 MHz) instrument with tetramethylsilane as internal standard. The chemical shifts are given in ppm and coupling constants in Hz in the indicated solvent.

SIMS mass spectra were recorded on a time-of-flight instrument as reported previously (19). MALDI mass spectra were performed with a home-built linear time-of-flight instrument using a nitrogen laser (20). Samples were prepared by mixing equal volumes of the porphyrin solution (ca. 10^{-4} M in THF or H_2O) and a matrix solution (ca. 10^{-1} M 2,5-dihydroxybenzoic or cyano-4 hydroxycinnamic acid in THF or H_2O–acetonitrile 1:4 V/V). One microlitre of the final solution was deposited onto a stainless steel probe and introduced in the mass spectrometer.

FAB^+ mass spectra were performed on ZAB 2 -BEQ at the "Service Central d'Analyse" CNRS Solaize using *meta*-nitrobenzyl alcohol as matrix, and E.I mass spectra at the "Laboratoire Départemental d'Analyse" Limoges on a Shimadzu QP 1000 apparatus.

Elemental analyses were carried out by the "Service Régional de Microanalyse" Université Pierre et Marie Curie, Paris.

Chemicals

All solvents and reagents were purchased from Aldrich, Prolabo, or Janssen. Pyrrole was distilled under reduced pressure immediately before use. Acetic anhydride was distilled and kept over calcium chloride. DMF was distilled over CaH_2 under reduced pressure and kept over 4Å molecular sieves.

Chromatography

Analytical thin-layer chromatography (TLC) was performed on silica gel (Merck, $60F_{254}$) or PEI-Cellulose F (Merck). Col-

umn chromatography was carried out with silica gel 60ACC (15–40 μm) (Merck), or with Sephadex LH20 (Pharmacia) as stationary phase, preparative HPLC on reverse phase (Lichroprep RP18: 15–40 μm) (Merck). The following solvent systems were used as eluents: A: ethyl acetate – petroleum ether (1:1); B: ethyl acetate – petroleum ether (1:1) + 1% of 2-propanol; C: ethyl acetate – petroleum ether (2:1); D: chloroform–ethanol (95:5); E: methylene chloride – ethanol (95:5); F: acetic acid – pyridine (1:1); G: acetic acid – methanol–water (3:2:1); H: *n*-butanol – acetic acid – water (4:1:5) (upper phase); I: methanol–water (7:3); J: methanol–water (95:5); and K: acetone–water (9:1).

Synthesis

*2-(2,3,4,6-Tetra-*O*-acetyl-*β*-D-glucopyranosyloxy)-benzaldehyde (**1a**)*

Acetylation of salicylaldehyde β-D-glucoside (helicin) was carried out according to the literature (21). Helicin (500 mg, 1.76 mmol) and 1.34 mL (14.2 mmol) of acetic anhydride in 1 mL of pyridine were stirred at 0°C for 1.5 h. After evaporation of the solvent, the crude product was dissolved in ethyl acetate (40 mL) and washed several times with ice water (3 × 50 mL). The organic extract was then dried on $MgSO_4$, filtered, and concentrated under reduced pressure. The crude product was recrystallized in ethanol to give 720 mg, (90%) of **1a**. R_f 0.41 (SiO_2, eluent: A); mp 142°C (lit.(22) mp 142°C); $[\alpha]_D$ −30 (*c* = 0.5, $CHCl_3$). ^{1}H NMR (C_6D_6) δ: 10.60 (s, 1H, CHO), 7.91 (dd, 1H, *J* = 7.8 and 1.9 Hz, H-6 Ar), 7.08 (dt, 1H, *J* = 7.4 and 1.9 Hz, H-4 Ar), 6.89 (dd, 1H, *J* = 8.3 and 0.6 Hz, H-3 Ar), 6.74 (dt, 1H, *J* = 7.9 and 0.6 Hz, H-5 Ar), 5.46 (dd, 1H, *J* = 9.0 and 7.9 Hz, H-2 ose), 5.37 (t, 1H, *J* = 9.8 Hz, H-3 ose), 5.22 (t, 1H, *J* = 9.8 Hz, H-4 ose), 4.68 (d, 1H, *J* = 7.5, H-1 ose), 4.16 (dd, 1H, *J* = 12.3 and 5.1 Hz, H-6_A ose), 3.97 (dd, 1H, *J* = 12.3 and 2.5 Hz, H-6_B ose), 3.23 (ddd, 1H, *J* = 7.6, 5.1 and 2.5 Hz, H-5 ose), four singlets integrating each for three protons at 1.69, 1.68, 1.66, and 1.65 (4 AcO). MS (EI) *m/z*: 452 M^+, 409 $(M - AcO)^+$, 122 $(M - GlucOAc + H)^+$. Anal. calcd. for $C_{21}H_{24}O_{11}$: C 55.75, H 5.31; found: C 55.66, H 5.42.

*4-(2,3,4,6-Tetra-*O*-acetyl-*β*-D-glucopyranosyloxy)-benzaldehyde (**1b**)*

Glucosylation of *p*-hydroxylbenzaldehyde was carried out according to the literature (23). 2,3,4,6-Tetra-*O*-acetyl-α-D-glucopyranosyl bromide (800 mg, 1.94 mmol, 1 equiv.) and *p*-hydroxybenzaldehyde (610 mg, 5 mmol, 2.6 equiv.) were mixed in 40 mL of acetone and 10 mL of (7%) aqueous NaOH and then stirred at room temperature for 24 h. Afterward, the solution was added to 100 mL of ice water and stirred for 1 h. The precipitated crude product was then recrystallized from MeOH–H_2O (1:1); 350 mg (40%) of **1b** were obtained. R_f 0.31

(SiO_2, eluent: A); mp 144°C (lit.(21) mp 144–145°C); $[\alpha]_D$ −33.5 (c = 0.5, $CHCl_3$). ^1H NMR ($CDCl_3$) δ: 9.90 (s, 1H, CHO), 7.85 (d, 2H, J = 8.5 Hz, H-3,5 Ar), 7.10 (d, 2H, J = 8.5 Hz, H-2,6 Ar), 5.20–5.40 (m, 4H, H-1, H-2, H-3, and H-4 ose), 3.90 (ddd, 1H, J = 10.0, 5.6, and 2.6 Hz, H-5 ose), 4.15 (dd, 1H, J = 12.0 and 5.6 Hz, H-6_A ose), 4.27 (dd, 1H, J = 12.0 and 2.6 Hz, H-6_B ose), three singlets at 2.06 (×3H), 2.05 (×6H), 2.03 (×3H) (AcO). MS (EI) m/z: 452 $(M + H)^+$, 121 $(M - GlucOAc)^+$. Anal. calcd. for $C_{21}H_{24}O_{11}$: C 55.75, H 5.31; found: C 55.61, H 5.38.

General procedure for preparation of maltosyl and lactosyl benzaldehyde

All per-*O*-acetylglycobiosylbromides were prepared from peracetylated compounds according to the standard procedure (24) by using 33% HBr in acetic acid. Reaction times do not exceed 30 min (23). The crude products were used without further purification. To a solution of acetylated α-glycobiosylbromide (3 g, 4.29 mmol, 1 equiv.) and tetraoctylammonium bromide (2.34 g, 4.29 mmol, 1 equiv.) in CH_2Cl_2 (14.5 mL) were added 1 M Na_2CO_3 aqueous solution (14.5 mL) and hydroxybenzaldehyde (1.37 mL, 13 mmol, 3 equiv.). The two-phase reaction mixture was vigorously stirred at room temperature for 2.5 h. The complete conversion was shown by TLC (SiO_2, eluent C). CH_2Cl_2 (50 mL) was then added and the organic phase was successively washed with 1 M NaOH aqueous solution (50 mL), water (2 × 100 mL), and a saturated solution of NaCl (40 mL). The combined organic extracts were then dried on $MgSO_4$, filtered, and concentrated under reduced pressure to afford crude products. The purification of the products was achieved by using column chromatography (SiO_2, eluent B) and then by preparative high-pressure liquid chromatography (HPLC) using I and J as eluents for maltosyl and lactosyl compounds, respectively.

*2-(2,3,6,2′,3′,4′,6′-Hepta-*O*-acetyl-β-D-maltosyloxy)benzaldehyde (**2a**)*: 1.11 g, (35%); R_f 0.40 (SiO_2, eluent B); mp 141–143°C; $[\alpha]_D$ +19.6 (c = 0.35, $CHCl_3$). ^1H NMR ($CDCl_3$) δ: 10.3 (s, 1H, CHO), 7.85 (dd, 1H, J = 7.7 and 1.6 Hz, H-6 Ar), 7.56 (ddd, 1H, J = 8.4, 7.8, and 1.8 Hz, H-4 Ar), 7.24 (dd, 1H, J = 8.4 and 1.0 Hz, H-3 Ar), 7.14 (br t, 1H, J = 7.8 Hz, H-5 Ar), 5.43 (d, 1H, J = 4.0 Hz, H-1′ ose), 5.37 (t, 1H, J = 10.7 Hz, H-3′), 5.35 (t, 1H, J = 8.1 Hz, H-3 ose), 5.24 (d, 1H, J = 7.4 Hz, H-1 ose), 5.17 (d, J = 7.4 Hz, H-2 ose), 5.04 (t, 1H, J = 9.7 Hz, H-4′ ose), 4.86 (dd, 1H, J = 10.5 and 4.0 Hz, H-2′ ose), 4.50 (dd, 1H, J = 12.1 and 2.8 Hz, H-6a ose), 4.25 (ddd, 1H, J = 6.6, 3.9, and 1.4 Hz, H-5 ose), 4.20–4.30 (m, 1H, H-6_B ose), 3.79–4.10 (m, 2H, H-$6'_A$ and H-$6'_B$ ose), 3.84–3.96 (m, 1H, H-5′ ose), four singlets at 2.09 (3H), 2.07 (3H), 2.04 (9H), 2.02 (3H), 2.00 (3H)(CH_3CO). *General procedure for formation of pyridyl porphyrins **4a,b**, **5a,b**, and **6a,b***

In a typical experiment, a mixture of per-*O*-acetyl glycosylated benzaldehyde (3.3 mmol) in propionic acid (30 mL) and acetic anhydride (3 mL) was heated under reflux with vigorous stirring. To this solution was added slowly 4-pyridinecarboxaldehyde (2 equiv.) and freshly distilled pyrrole (2.6 equiv.). After 1.5 h, the solvent was evaporated to dryness and the crude product was purified by chromatography on SiO_2 using $CHCl_3$ and then D as eluents.

*5-[2-(2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosyloxy)phenyl]-10,15,20 tris(4-pyridyl)porphyrin (**4a**)*: **1a** (1.5 g, 3.3 mmol), 4-pyridinecarboxaldehyde (0.635 mL, 6.6 mmol), and pyrrole (0.610 mL, 8.8 mmol) afforded pure product **4a** 150 mg, (6%); R_f 0.22 (SiO_2, eluent D). UV–visible (see Table 4). ^1H NMR (see Table 1). MS (SIMS positive) m/z: 965 $(M + H)^+$,

634 (M − GluOAc + H)$^+$ and SIMS (negative) *m/z*: 963 (M − H)$^-$, 632 (M − GlucOAc − H)$^-$. Anal. calcd. for $C_{55}H_{45}N_7O_{10}\cdot 0.5H_2O$: C 67.89, H 4.77, N 10.08; found: C 67.82, H 4.74, N 10.01.

*5-[4-(2,3,4,6-Tetra-*O*-acetyl-*β*-D-glucopyranosyloxy)phenyl]-10,15,20 tris(4-pyridyl)porphyrin (**4b**)*: **1b** (1.5 g, 3.3 mmol), 4-pyridinecarboxaldehyde (0.635 mL, 6.6 mmol), and pyrrole (0.610 mL, 8.8 mmol) gave **4b** 150 mg, (7%); R_f 0.18 (SiO_2, eluent D). UV–visible (see Table 4). ^{1}H NMR (see Table 1). MS (SIMS positive) *m/z*: 965 (M + H)$^+$, 634 (M − GluOAc + H)$^+$ and SIMS (negative) *m/z*: 963 (M − H)$^-$, 632 (M − GlucOAc − H)$^-$. General method for alkylation of pyridyl porphyrins ***4a,b – 6a,b***

To a stirred solution of porphyrins **4a,b**, **5a,b**, or **6a,b** in freshly distilled DMF was added a large excess of alkyl iodide and the reaction mixture was heated at 40°C for 3 h for methylation and at 100°C for 12 h and 24 h for isopropylation and *n*-octylation, respectively. The reaction progress was monitored using TLC. After the reactions were complete, the trimethyl and triisopropyl pyridinium porphyrins **7a,b**, **8a,b**, **9a,b**, and **10a,b** were precipitated with diethyl ether. After filtration the compounds were dissolved in methanol and precipitated again with diethyl ether. The compounds were then washed several times with diethyl ether and by CH_2Cl_2 for **7a,b** and **10a,b**. All the products were dried under reduced pressure. For trisoctyl derivatives **11a,b**, DMF was removed under reduced pressure, coevapored with dry toluene, and the resulting compound was dissolved in *n*-BuOH–AcOH–H_2O (4:1:5) (upper phase) and then extracted with diethyl ether.

*5-[(2-(2,3,4,6,-Tetra-*O*-acetyl-*β*-D-glucopyranosyloxy)phenyl)-10,15,20 tris(4-*N*-methylpyridiniumyl)]porphyrin, triiodide (**7a**)*: **4a** (20 mg, 0.021 mmol) and 1.3 mL of methyliodide gave 25 mg of **7a** (90%); R_f 0.3 (SiO_2, eluent G). *General procedure for deacetylation of compounds **4–11***

Ten milligrams of protected mono (**4**, **7**, **10**, and **11**) or disaccharide (**5**, **6**, **8**, and **9**) compounds were dissolved, respectively, at 0°C in 15 mL or 30 mL of Et_3N–MeOH–H_2O (10:10:1) and the reaction mixtures were stirred vigorously for 24 h. Deacetylations were followed by TLC. After complete deacetylation the solvent was evaporated and passed through a Sephadex column using methanol as eluent. The products were then precipitated from methanol–ether (1:5).

3,4-Disubstituted derivatives of 1,2,5-thiadiazole 1,1-dioxide. Ethanol addition reactions and electroreduction of 3-methyl-4-phenyl and 3,4-dimethyl derivatives in acetonitrile and ethanol solvents

José Alberto Caram, María Virginia Mirífico, Silvia Lucía Aimone, and Enrique Julio Vasini

Abstract: 3-Methyl-4-phenyl-1,2,5-thiadiazole 1,1-dioxide (**TMP**), as well as 3,4-dimethyl-1,2,5-thiadiazole 1,1-dioxide (**TMM**), react with ethanol (EtOH), which adds to one of their C=N double bonds. The equilibrium constants for the addition reaction are measured in mixed acetonitrile (ACN) – EtOH solvents by means of UV spectroscopy in the case of **TMP**, and by ^{13}C NMR spectroscopy in the case of **TMM**, since **TMM** presents only terminal UV absorption. Both equilibrium constants are also estimated through cyclic voltammetry (CV) experiments. In the case of **TMP**, the ethanol molecule adds to the C=N bond located on the methyl-substituted side of the substrate, according to ^{13}C NMR spectroscopy and CV results. The electroreduction characteristics of the substrates and their ethanol addition products are studied using CV techniques in ACN, EtOH, and ACN–EtOH solvent mixtures. The radical anion formed by the first electron transfer to **TMM** is unstable and decomposes rapidly while that corresponding to **TMP** undergoes a relatively slow homogeneous second-order reaction with the substrate ($k = 3 \times 10^2$ M^{-1} s^{-1}). The equilibrium constant for EtOH addition and the voltammetric properties of the substrates are compared with those of the previously studied 3,4-diphenyl derivative (**TPP**).

Key words: electrochemistry, thiadiazoles, structure–reactivity relations, kinetics.

Résumé : Le 1,1-dioxyde de 3-méthyl-4-phényl-1,2,5,thiadiazole (**TMP**) aussi bien que le 1,1-dioxyde de 3,4-diméthyl-1,2,5-thiadiazole (**TMM**) réagissent avec le méthanol qui s'additionne sur une de leurs doubles liaisons. On a mesuré les constantes d'équilibre de la réaction d'addition dans un mélange d'acétonitrile et d'éthanol comme solvant (ACN)–EtOH, en faisant appel à la spectroscopie UV dans le cas du **TMP** et à la spectroscopie de RMN du ^{13}C dans le cas du **TMM** puisque ce dernier ne présente que des absorptions terminales en UV. On a également évalué les constantes d'équilibre à l'aide d'expériences de voltamétrie cyclique. Dans le cas du **TMP**, la molécule d'éthanol s'additionne sur la double liaison C=N située du côté du méthyle substitué sur le substrat en accord avec les résultats obtenus par spectroscopie de RMN du ^{13}C. Faisant appel aux techniques de CV dans du ACN, EtOH et du ACN–EtOH comme solvants, on a étudié les caractéristiques de l'électroréduction des substrats et de leurs produits résultant de l'addition de l'éthanol. L'anion radicalaire formé lors du premier transfert d'électron vers le **TMM** est instable et se décompose rapidement tandis que le **TMP** correspondant donne avec le substrat, une réaction d'ordre deux homogène relativement lente ($k = 3 \times 10^2$ M^{-1} s^{-1}). On a comparé les constantes d'équilibre de l'addition d'éthanol et les propriétés voltamétriques des substrats avec celles dérivés 3,4-diphényles (**TPP**) étudiés précédemment.

Mots clés : électrochimie, thiadiazoles, relations structure–réactivité, cinétiques.

Introduction

The 1,1-dioxides of 1,2,5-thiadiazoles belong to a group of heterocycles containing the sulfamide moiety that present interesting chemical properties and a variety of applications as biologically active compounds and as fine chemicals. A detailed review has been written by Aran et al. (1). Several pharmacological uses have been suggested and patented for 1,2,5-thiadiazole 1,1-dioxides, but their chemical properties are largely unexplored and "only a heterogeneous series of generally unrelated reactions are known" (1).

Our previous work has shown, through UV and ^1H and ^{13}C NMR spectroscopy (2), that 3,4-diphenyl-1,2,5-thiadiazole 1,1-dioxide (**TPP**) in acetonitrile (ACN) – ethanol (EtOH) solvent mixtures is in equilibrium with the thiadiazoline (3-ethoxy-3,4-diphenyl-1,2,5-thiadiazoline 1,1-dioxide: **TPPH·OEt**) formed through the addition of ethanol to one of its C=N double bonds. The formation equilibrium constant at

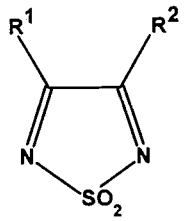
25.0°C is 3.3 M^{-1}.[2] Thus **TPP** exists in EtOH solution as the thiadiazoline **TPPH·OEt**.



$R^1 = R^2 = Ph$: **TPP**
$R^1 = Me$; $R^2 = Ph$: **TMP**
$R^1 = R^2 = Me$: **TMM**

TPP (3, 4) is voltametrically reduced in ACN solution, in two successive peaks, to a radical anion and to a dianion at ca. −0.8 V (vs. Ag^+ (0.1 M ACN) / Ag), while **TPPH·OEt** in EtOH presents two reduction peaks at ca. −1.7 and −1.9 V.

In this work, the EtOH addition reactions and the electroreduction properties of the related compounds 3-methyl-4-phenyl-1,2,5-thiadiazole 1,1-dioxide (**TMP**) and 3,4-dimethyl-1,2,5-thiadiazole 1,1-dioxide (**TMM**) are studied in ACN and in EtOH solution and compared with those of **TPP**. Interesting differences related to the presence of a methyl group bonded to a very electron-deficient carbon atom are observed.

Experimental

TMP and **TMM** were synthesized, purified, and characterized according to published procedures (5). Standard methods of purification were used for ACN and EtOH solvents.

^1H and ^{13}C NMR spectra were measured with a Bruker 200 MHz instrument.

Conventional cyclic voltammetry techniques were employed. A L.Y.P. M2 potentiostat, a 3-module L.Y.P. sweep generator, and a Houston Omnigraphic 2000 pen recorder were used.

Voltammetric experiments were performed in an undivided, gas-tight, glass cell swept by purified nitrogen. The cell was kept in a dry glove box, where all solution preparation and other experimental manipulations were made. The reference electrode (r.e.) was Ag^+ (0.1 M ACN)/Ag. It was separated from the cell solution by a porous-glass plug. A 2 cm^2 Pt foil was the counter electrode and the working electrode (w.e.) was a Teflon encapsulated vitreous carbon disk of 0.074 cm^2.

Bulk electrolysis experiments were performed in a divided cell. The anodic and cathodic compartments were separated by a sintered glass plate. The cathode was a vitreous carbon rod (0.3 cm diameter and 1.5 cm length) and the anode was a 8 cm^2 Pt foil. The reference and the working electrode described above for cyclic voltammetry were included in the cathodic compartment and were used to measure the concentration of the substrate at convenient intervals during the electrolysis.

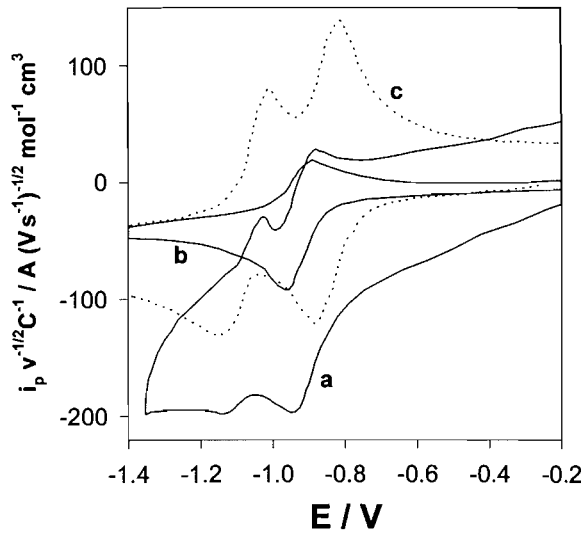
Results and discussion

(a) TMP

Voltammetric and bulk electrolysis results in ACN solution

The results of typical voltammetric experiments performed with solutions of **TMP** in ACN are shown in Fig. 1*a* and *b*. Published results corresponding **TPP** are also included in Fig. 1*c* for comparison. As can be observed, under the experimental conditions of Fig. 1*a*, **TMP** presents two redox couples

Fig. 1. Cyclic voltammograms, current function vs. potential, for **TMP** (at selected low and high experimental concentration) and for **TPP**. ACN solvent; 0.25 M $NaClO_4$ supporting electrolyte; vitreous carbon disk w.e.; Ag^+(0.1 M ACN)/Ag r.e.; $v = 0.2$ V s^{-1}. (*a*) **TMP**: 1.06 mM; (*b*) **TMP**: 13.7 mM; (*c*) (····) **TPP**: 1.51 mM.



(Ic/Ia; IIc/IIa), which, as in the case of **TPP**, can be assigned to the charge transfers:

$$\mathbf{TMP} + e = \mathbf{TMP}^{\cdot-} \quad \text{Ic/Ia} \qquad E_1$$

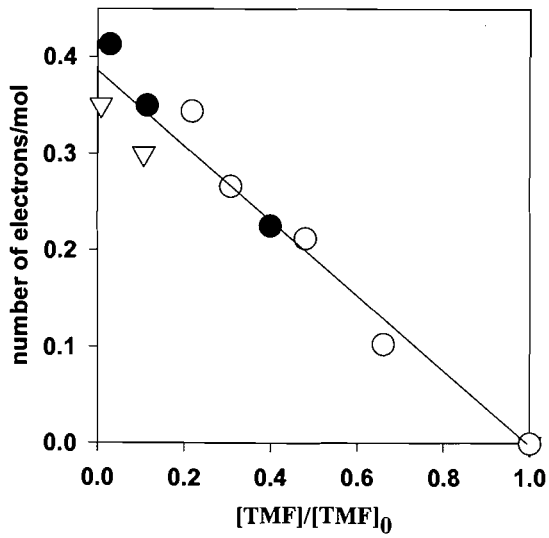
$$\mathbf{TMP}^{\cdot-} + e = \mathbf{TMP}^{2-} \quad \text{IIc/IIa} \qquad E_2$$

The first couple is clearly observed under all experimental conditions. The second couple (IIc/IIa) is always less intense and less well defined than the first. It is distinctly observed at low concentrations and high sweep rates, but its current intensity decreases at the higher experimental concentrations. Under the conditions of Fig. 1*b* it is no longer observable. This behavior, although less pronounced, was also observed with **TPP** and was related to interactions of the dianion of **TPP** with the cations of the supporting electrolyte and to adsorption processes (4). Only the processes related to the first couple will be studied in this work.

The current function of the cathodic peak (Ic) of the first couple does not change appreciably with concentration (in the range 1.06–37.7 mM, i_p(Ic) $v^{-1/2}$ C^{-1}/A (V s^{-1})$^{-1/2}$ (mol cm^{-3})$^{-1}$ = 83 ± 6). The diffusion coefficient, calculated with the equation for a reversible voltammetric wave, is 1.7×10^{-5} cm^2 s^{-1}, which is similar to that found for **TPP** (1.2×10^{-5} cm^2 s^{-1}).

Controlled potential electrolysis experiments at −0.9 V in ACN solvent were run with **TMP** initial concentrations ([**TMP**]$_0$) of 21 and 2.2 mM. A duplicate electrolysis experiment with 2.2 mM **TMP** in which water (1.55 M) was added to the ACN solvent was also performed. All three experiments were coincident, within the experimental error (Fig. 2), indicating that *ca.* 0.4 electrons/mol **TMP** are consumed in the bulk electrolysis.

Fig. 2. Bulk electrolysis of **TMP** in ACN solution. Number of moles of electrons vs. relative concentration of **TMP** as measured through the voltammetric current intensity of peak Ic at several intervals during the electrolysis. $[\mathbf{TMP}]_0$: ∇:21 mM; ○:2.2 mM; ●:2.2 mM + 1.55 M water.



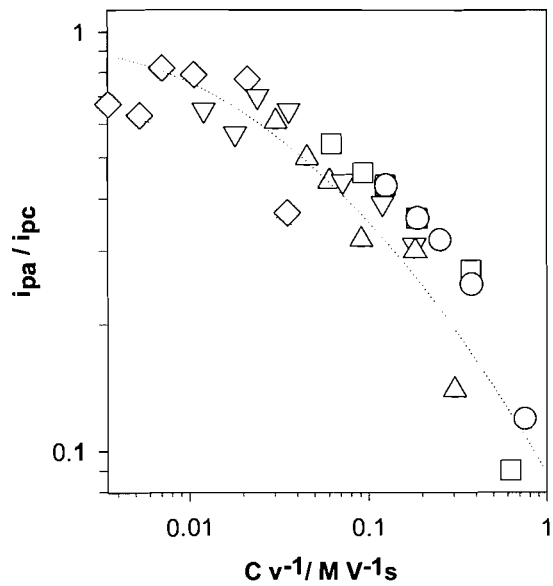
From the very beginning of the electrolysis experiments, the catholyte solution develops a dark red-brown color that originates near the cathode and increases in intensity as the electrolysis progresses. The color intensity decreases and turns yellowish on exposure of the electrolyzed solution to air. Thin-layer chromatographic analysis of the solution at the end of the experiments reveals a complex mixture. Initial efforts to isolate the components have been unsuccessful, but our work in this direction continues in connection with additional studies on the homogeneous reaction kinetics of **TMP**.

The first charge transfer for **TMP** takes place at a more negative potential than that of **TPP** ($E_{pIc[TPP]} - E_{pIc[TMP]} \cong 0.16$ V). This can be related to structural characteristics of the substrates and the radical anions formed.

van der Waals molecular models and X-ray crystal studies of both compounds (6) show that the two phenyl rings of **TPP** cannot be accommodated in the plane of the heterocycle (**TPP** dihedral angles: phenyl–phenyl = 51.9°; phenyl–heterocycle = 34.2 and 41.4°), and that the methyl group in **TMP** hinders the planar disposition of the phenyl ring and the heterocycle to a very similar extent (**TMP** dihedral angle: phenyl–heterocycle = 40.9°). It is reasonable to suppose that the electron transferred to the substrates to form the radical anions should favor a location associated with an electron-deficient heterocyclic carbon atom bonded to a phenyl group (because of charge dispersal reasons). Since more stabilization energy will be gained by delocalizing the additional electron, the phenyl ring involved should be more in the plane of the thiadiazole ring than in that of the parent neutral compound. This can be achieved in **TPP** by the concerted rotation of both rings, but it is not possible in **TMP**.

The peak current intensity ratio ($R_i = i_{pIa}/i_{pIc}$) of the first couple is always smaller than unity and decreases when the cathodic switching potential is made increasingly negative. R_i is also a function of **TMP** concentration and sweep rate as

Fig. 3. Influence of sweep rate and concentration in the ratio of anodic to cathodic peak current intensity (R_i) of the first voltammetric couple of **TMP** for a constant switching potential $E_s = -1.04$ V; ACN solvent; 0.25 M $NaClO_4$ supporting electrolyte; vitreous carbon disk w.e.; Ag^+(0.1 M ACN)/Ag r.e. [**TMP**]: ○:37.7; □:13.7; Δ:9.13; ∇:3.61; ◇:1.06 mM. The dotted line represents the result of a digital simulation for a radical–substrate reaction mechanism with rate constant $k = 3 \times 10^2$ M^{-1} s^{-1} (see also Fig. 6).



shown in Fig. 3 for a constant switching potential (−1.04 V) that does not include the second couple.

The data shown in Fig. 3 suggest the consumption of $\mathbf{TMP}^{\cdot-}$ by a second-order reaction that, at a constant sweep rate; causes the decrease of R_i with increasing concentration, reflecting the increase in reaction rate; conversely, R_i tends to increase up to unity when the time window is decreased through an increase of the sweep rate. The dotted line in Fig. 3 represents the results of a digital simulation for a radical–substrate second-order reaction, which is justified in the following:

The mechanism of the reaction can be further characterized through the slopes $\delta E_p/\delta \log (v)$ and $\delta E_p/\delta \log [\mathbf{TMP}]$. Figure 4 shows the dependence of the potential of peak Ic with sweep rate at several **TMP** concentrations. A 28.5 mV/dec (r = 0.986; 9 points) $\delta E_p/\delta \log (v)$ slope is observed for [**TMP**] = 37.7 mM for the whole range of experimental sweep rates. At lower concentrations the slope is similar for the lower sweep rates, but $\delta E_p/\delta \log (v)$ tends to zero when the sweep rate is increased. Finally, for [**TMP**] = 1.06 mM, the peak potential does not change with sweep rate.

The $\delta E_p/\delta \log[\mathbf{TMP}]$ slope is shown in Fig. 5 for sweep rates of 0.005, 0.01, and 0.02 V s^{-1}, in the concentration range in which irreversible voltammetric signals are observed. The observed slopes are 43, 34, and 29 mV/dec, respectively. Given the observed $\delta E_p/\delta \log(v)$ slope, the expected $\delta E_p/\delta \log[\mathbf{TMP}]$ slopes for the well-known simple second-order reaction mechanisms are either 19.7 or 29.6 mV/dec (7).

Obviously the slopes are closer to 29.6 mV/dec, which corresponds to a radical–substrate reaction. The discrepancy

might be due to a more complex mechanism or it may be an artifact due to the complex reaction observed in the controlled potential electrolysis experiments. This seems reasonable since the slope departs increasingly from the expected value at decreasing sweep rates.

If the radical–substrate reaction is accepted as the dominant mechanism, a rate constant, k_1, for the reaction:

[1] **TMP**$^{\cdot-}$ + **TMP** = products

can be calculated from the sweep rate (v_i) at which the E_p vs. log ($C\,v^{-1}$) slope changes (7), or, as is shown in Fig. 6, a more detailed view of the fitness of the radical–substrate mechanism can be furnished by a digital simulation that takes into account the electron transfer E_1, followed by reaction [1] and a fast electroreduction of the product (i.e., $E^0_{(product)} \gg E_1$). The simulation results, indicated in Fig. 6 with a solid line, correspond to $k_1 = 3 \times 10^2\ M^{-1}\ s^{-1}$.

The methyl protons of **TMP**, being bonded to a very electron-deficient carbon atom, are weakly acidic. Thus, the radical–substrate reaction might consist of a proton transfer (reaction [1]). The reaction will also be driven forward by the fast electroreduction of the radical **TMPH**$^{\cdot}$ at $E_3 > E_1$.

Anions of the 3-oxo derivatives of 1,2,5-thiadiazole 1,1-dioxides are well known (1). Anion **I**$^-$ has a similar structure although it must be much less stable. Follow-up reactions involving anion **I**$^-$ such as an aldolic-type condensation (reaction [2]), are also possible and have been observed in related compounds (8). The consumption of the substrate by the follow-up reactions can account for the reduced number of electrons per mole observed in the electrolysis experiments.

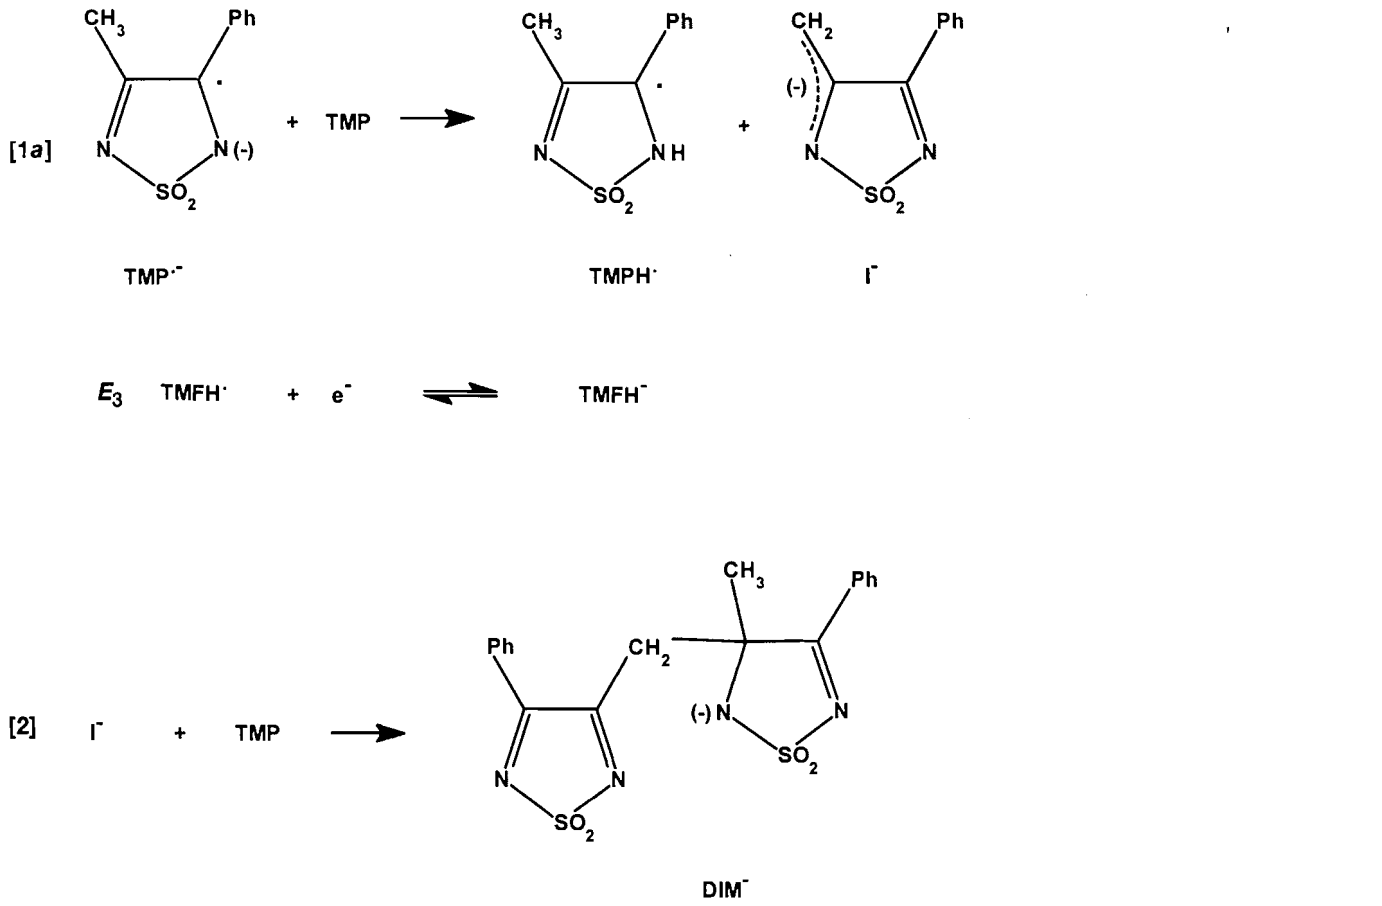
Voltammetric results in EtOH and ACN/EtOH solutions

The voltammetric results in EtOH solvent are presented in Fig. 7*a* (solid line). The results obtained with **TPP** (4), which have already been discussed, are included for comparison (Fig. 7*a*; dotted line). As was the case for **TPP**, the EtOH molecule adds to one of the C=N double bonds of **TMP** to form a thiadiazoline:

[3] **TMP** + EtOH = **TMPH·OEt**

which is voltammetrically reduced in two peaks (IIIc and IVc) that are very similar to those found with the **TPP** substrate.

When EtOH is added to ACN solutions of **TMP**, the voltammograms evolve in time in essentially the same way as was



observed for **TPP** (4), that is, the **TMP** voltammetric peaks are observed initially and peak IVc at −1.94 V starts to develop (Fig. 7*b*, solid line). This is followed by the decrease and disappearance of peak IIc, while peak IVc increases. After the disappearance of peak IIc, peak IIIc appears at ca. −1.65 V and grows while the current intensity of peak Ic decreases

Fig. 4. Peak potential for the first couple of **TMP** (E_pIc), vs. Ag^+ (0.1 M ACN)/Ag, as a function of sweep rate for several concentrations of **TMP** in ACN solution; 0.25 M $NaClO_4$ supporting electrolyte; vitreous carbon disk w.e. [**TMP**]: ○:37.7; □:13.7; Δ:9.13; ∇:3.61; ◇:1.06 mM. Solid line through ○ is a least-squares regression (r: 0.986; slope: 28.5 mV/dec); solid line through ◇ is the average of peak potentials for [**TMP**] = 1.06 mM (E_p (mean) = −0.933 V).

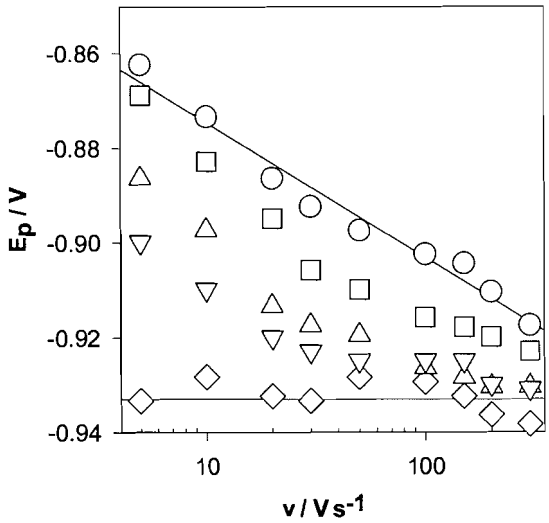


Fig. 5. Peak potential for the first couple of **TMP** (E_pIc), vs. Ag^+(0.1 M ACN)/Ag, as a function of the concentration of **TMP** for several sweep rates in ACN solution; 0.25 M $NaClO_4$ supporting electrolyte; vitreous carbon disk w.e. Sweep rates: ○:0.005; ●:0.010; Δ:0.020 V s^{-1}. The concentration ranges from the highest experimentally used to the lowest in which irreversible peaks are still observed at each sweep rate. Solid lines are least-squares regressions with the following slopes and regression coefficients: 43 mV/dec; r = 0.975 (8 points); 34 mV/dec, r = 0.941 (7 points); Δ:29 mV/dec, r = 0.943 (5 points).

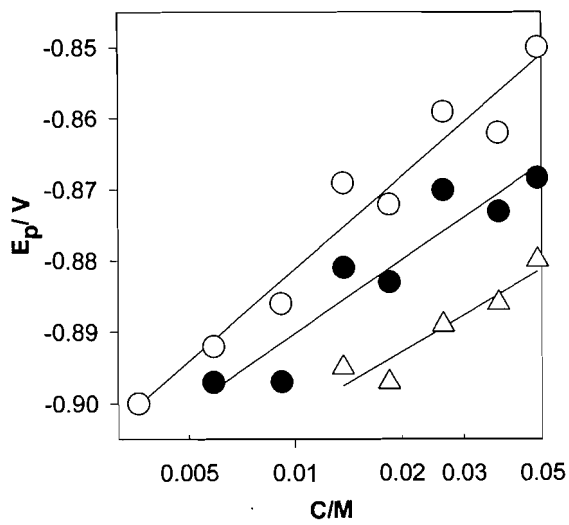

slightly. Finally an equilibrium voltammogram is obtained (Fig. 7*b*, dotted line).

The time evolution described can be interpreted by a reaction mechanism essentially identical to that proposed for **TPP** in ACN–EtOH solvent mixtures. Thus at peak I (Fig. 7*b*) **TMP** is reduced and the radical anion formed reacts

Fig. 6. Peak potential for the first couple of **TMP** (E_pIc), vs. Ag^+ (0.1 M ACN)/Ag as a function of the ratio of **TMP** concentration to sweep rate in ACN solution. [**TMP**]: ○:37.7; □:13.7; Δ:9.13; ∇:3.61; ◇:1.06 mM; (—): digital simulation with k = 3×10^2 M^{-1} s^{-1}.

Table 1. Experimental voltammetric results and calculated values of the equilibrium constant K_{TMP} (uncontrolled room temperature, ca. 20°C) for the reaction: **TMP** + EtOH = **TMPH·OEt**.

$[EtOH]_0$/M	$[TMP]_0$/mM	v/(V s^{-1})	i_p(Ic)/(μA)	i_p(IIIc)/(μA)	K_{TMP}/M^{-1}
2.96	3.60	0.10	27.0	27.5	1.03
1.30	3.65	0.10	56.0	25.0	1.46
2.83	3.75	0.10	18.0	25.0	1.33

with EtOH. The product is further reduced at a potential $E_3 > E_1$.

$$\mathbf{TMP}^{\cdot-} + \text{EtOH} = \mathbf{TMPH}^{\cdot} + \text{EtO}^- \qquad C_4$$

$$\mathbf{TMPH}^{\cdot} + e^- = \mathbf{TMPH}^- \qquad E_3$$

If some **TMPH·OEt** has been formed through reaction [3], it reacts with the strong EtO^- base:

$$\text{EtO}^- + \mathbf{TMPH{\cdot}OEt} = \text{EtOH} + \mathbf{TMP{\cdot}OEt}^- \qquad C_5$$

The remaining $\mathbf{TMP}^{\cdot-}$ is further reduced at E_2 (peak IIc). The anions produced at E_3 and C_5 ($\mathbf{TMPH}^-$ and $\mathbf{TMP{\cdot}OEt}^-$) are further reduced at peak IVc. If some **TMPH·OEt** remains it will be reduced at peak IIIc:

$$\mathbf{TMPH{\cdot}OEt} + e^- = \mathbf{TMPH{\cdot}OEt}^{\cdot-} \qquad E_4$$

$$\mathbf{TMPH{\cdot}OEt}^{\cdot-} = \mathbf{TMPH}^{\cdot} + \text{EtO}^- \qquad C_6$$

The $\mathbf{TMPH}^{\cdot}$ formed in C_6 will be immediately reduced to $\mathbf{TMPH}^-$ (E_3).

Thus, once peak IIc is no longer observed, peak Ic will be a two-electron $E_1C_4E_3$ peak, and its intensity will depend on the **TMP** concentration. Likewise, peak IIIc will be a two-electron $E_4C_6E_3$ peak and its current intensity will depend on the actual **TMPH·OEt** interfacial concentration, i.e., its bulk concentration minus the depletion caused by reaction C_5.

The equilibrium constant of reaction [3], k_{TMP}, can be calculated using the same relation of peak intensities used for **TPP** (4), specifically:

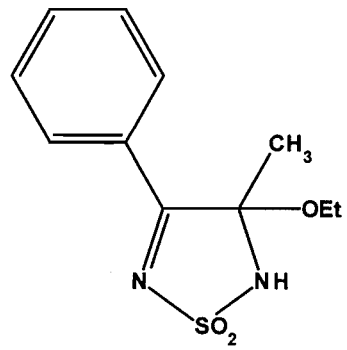
$$K_{TMP} = \frac{[\mathbf{TMPH{\cdot}OEt}]}{[\text{EtOH}][\mathbf{TMP}]}$$

$$= (2 \times \{i(\text{IIIc}) + i(\text{Ic})/2\}/[\text{EtOH}]_0 \times i(\text{Ic}))$$

The experimental peak intensities and calculated K_{TMP} for several EtOH concentrations are shown in Table 1.

The equilibrium constant K_{TMP} was also calculated using UV spectral measurements and a Hildebrand-type equation, as has been done with **TPP**. The details will be reported elsewhere, but the spectroscopically measured value, 1.4 M^{-1} at 25.0°C, agrees with the voltammetric value of Table 1.

The resonance of the heteronuclear methyl substituent in ^{13}C NMR measurements of **TMP** is, in benzene-d_6 solution, observed at δ = 17.6 ppm, and in methanol-d_4 solution at δ = 26.5 ppm. The direction and magnitude of the observed shift (Δδ = 8.9 ppm) is in agreement, according to the additivity rules for ^{13}C chemical shifts (9), with the addition of MeOH to the C=N double bond on the methyl "side" of the molecule. Thus the thiadiazoline **TMPH·OEt** has the structure:



TMP.EtOH

It can be observed that the π-system of **TMPH·OEt** is very similar to that of **TPPH·OEt**, This rationalizes the above-mentioned similarities between the voltammetric responses of both thiadiazolines. The similarity of the delocalization energy increment in going from the thiadiazoles to the thiadiazolines is also shown in the values of the equilibrium constants of the EtOH addition reactions. Thus, k_{TPP} is approximately two times larger than K_{TMP}, as can be expected if only symmetry factors are important.

(b) TMM

Voltammetric results for TMM in ACN solutions

The cyclic voltammetry of **TMM** in ACN solutions results in a single, diffusional, totally irreversible voltammetric peak at ca. −1.00 V under all experimental conditions. The peak shifts cathodically 30 mV/dec of sweep rate and its potential does not depend on the substrate concentration. Its current function ($i_p\, v^{-1/2}\, C^{-1}$) decreases slightly but steadily with the increase in concentration from 71 A V^{-1} $s^{1/2}$ mol^{-1} cm^3 at 1.01 mM, to 66 at 11.2 mM, and then drastically to 40 A V^{-1} $s^{1/2}$ mol^{-1} cm^3 at the highest concentration used (17.1 mM). This is apparently related to an increase in the rate of fouling of the electrode with increasing concentration. In effect, the second voltammetric cycle at all concentrations shows a decrease in current intensity that increases in magnitude when the concentration is increased. The current is restored to its first-cycle value when the electrode surface is cleaned.

These results suggest a one-electron charge transfer followed by a fast chemical reaction and allow the calculation of

a diffusion coefficient, $D_{(TMM)} = 1.2 \times 10^{-5}$ cm^2 s^{-1}, which is similar to those of **TPP** and **TMP**. Thus, as seems reasonable because of the lack of delocalization possibilities, the radical anion of **TMM** is unstable.

Voltammetric results for TMM in EtOH solutions

As found for **TPP** and **TMP**, the current intensity of the voltammetric peak of **TMM** in ACN–EtOH solvent mixtures decreases initially with time and reaches a stable equilibrium value that is lower the higher the EtOH concentration. No new peaks are observed and, since a thiadiazoline is formed according to the NMR evidence given below, it must be concluded that the 3,4-dimethyl thiadiazoline can not be reduced at potentials more anodic than the solvent cutoff.

The ^{1}H NMR spectrum of **TMM** provides evidence of an addition reaction of EtOH to one of the C=N double bonds of **TMM**. A single methyl signal at $\delta = 2.63$ ppm is observed in ACN-d_3, while two methyl signals are present in ethanol-d_6, at $\delta = 2.35$ ppm (assigned to the methyl on the unsubstituted side) and 1.68 ppm (assigned to the methyl on the ethoxyl-substituted side). In ACN-d_3–ethanol-d_6 solvent mixtures the original substrate methyl signal is also observed at 2.62 ppm. A study (at an uncontrolled room temperature of *ca.* 20°C) of the relative intensities of these three signals in ACN-d_3–ethanol-d_6 solvent mixtures with 13.3, 30.0, and 60.0 wt.% ethanol-d_6 allowed an evaluation of $K_{TMM} = 0.3$ M^{-1} (individual measurements were 0.26, 0.30, and 0.32 M^{-1}, respectively).

UV–VIS spectroscopic techniques cannot be used to study the addition reaction, since **TMM** presents only terminal absorption at $\lambda < 300$ nm, but an equilibrium constant can be estimated from voltammetric experiments if the equilibrium peak current intensity (corrected for the viscosity change of the solvent by means of independent measurements of the intensity of the ferrocene couple in the same solvent mixtures, as already described (4)) of the **TMM** peak in ACN–EtOH solvent mixtures is taken as a measure of its equilibrium concentration.

Four voltammetric experiments in ACN–EtOH solvent mixtures with 9.9, 21, 42, and 75.6 wt.% EtOH were performed. The K_{TMM} values (uncontrolled room temperature, ca. 20°C) calculated were 0.16, 0.15, 0.18, and 0.20 M^{-1}. Due to the assumptions involved, this estimate of K_{TMM} can be considered to be in reasonable agreement with the more direct NMR experiments.

Influence of the addition of acids in the voltammetry of TMP and TMM in ACN, EtOH, and mixed ACN–EtOH solvents

TMP or TMM in ACN + acid: Experiments in which several concentrations of dry trifluoracetic acid (TFAcH) were added to ACN solutions of **TMP** or **TMM** were performed. In both cases a kinetic prepeak (ppIc), anodic to the first charge transfer, developed when less than equimolecular quantities of acid were added. The prepeak current intensity increased with increasing relative concentrations of acid and finally replaced the original peaks of the substrate when the relative concentration of acid ([TFAcH]/[**TMP**] or [TFAcH]/[**TMM**]) was 2 or greater. The current intensity of the prepeak under these conditions is twice that of the original peak Ic of the substrate.

At low ratios of acid to substrate concentration, the prepeak can be interpreted as the reduction of the substrate, followed by protonation of the radical anion, i.e., for **TMP**:

$$\mathbf{TMP} + e^- = \mathbf{TMP}^{\cdot-} \qquad E_1$$

$$\mathbf{TMP}^{\cdot-} + 2\,\mathrm{TFAcH} = \mathbf{TMPH}^{\cdot} + (\mathrm{TFAc})_2\mathrm{H}^- \qquad C_7$$

The **TMPH**$^{\cdot}$ radical can be further reduced to the anion and protonated to the thiadiazoline (**TMPH$_2$**) or it can disproportionate to form **TMPH$_2$** and regenerate the substrate, which will be reduced at E_1.

Reaction C_7 includes the well-known homoconjugation reaction of anions in ACN (10).

TMP, TPP, or TMM in ETOH + acid: Similar results are obtained if TFAcH is added to solutions of **TPP** or **TMP** in EtOH solvent. A prepeak (ppIIIc) develops and its associated current intensity increases on increasing the acid concentration. The original peaks (IIIc and VIc, Fig 7*a*) are completely replaced by the prepeaks (which double the current intensity of each original peak) when the acid concentration is more than twice that of the substrate. The prepeaks are interpreted as above by equations similar to E_1 and C_7, in which **TMP** is replaced by **TMPH·OEt**.

As already discussed, the voltammetric electroreduction of **TMMH·OEt** takes place beyond the solvent potential cutoff. The addition of TFAcH to solutions of **TMM** in EtOH solvent does not cause the appearance of new voltammetric peaks.

TMP or TPP in mixed ACN–EtOH + acid: In mixed ACN–EtOH solvents to which TFAcH (with ratios [TFAcH]/[**TMP**] or [TFAcH]/[**TPP**] ca. 4) has been added, it is possible to record voltammograms in which only both prepeaks, ppIc and ppIIIc, are observed.

Since ppIc responds to the concentration of the thiadiazole ([**TPP**] or [**TMP**]) and ppIIIc to the concentration of thiadiazoline ([**TPPH·OEt**] or [**TMPH·OEt**]), it follows that equilibrium constants for the EtOH addition reactions to **TPP** and **TMP** (K_{TPP} and K_{TMP}) can be measured voltammetrically in these mixed solvent solutions. K_{TMP}, for example, can be expressed as:

$$K_{TMP} = \frac{[\mathbf{TMPH{\cdot}OEt}]}{[\mathrm{EtOH}][\mathbf{TMP}]} = \frac{i(\mathrm{ppIIIc})/v^{1/2}}{\{i(\mathrm{ppIc})/v^{1/2}\} \times [\mathrm{EtOH}]}$$

The experimental results are given in Table 2. The calculated equilibrium constants for **TMP** and **TPP** agree with those calculated from the complex mechanism in mixed ACN–EtOH solvents for **TMP** (above) and **TPP** (4).

Polyhalide anions in crystals. Part 2. I_3^- asymmetry and N—H...I bonding: triiodides of the $Me_2NH_2^+$, Ph_2I^+, tropanium, *N,N,N′,N′*-Me_4-1,2-ethanediammonium, *N,N,N′,N′*-Me_4-1,3-propanediammonium, *N*-Me-piperazinium(2+), and *N,N′*-Me_2-piperazinium(2+) cations, and Me_2NH_2I[1]

Katherine N. Robertson, T. Stanley Cameron, and Osvald Knop

Abstract: Crystal-structure determinations are reported for $Me_2NH_2I_3$, $(Ph_2I)I_3$, tropanium·I_3, $[Me_2HN(CH_2)_2NHMe_2](I_3)_2$, $[Me_2HN(CH_2)_3NHMe_2](I_3)_2$, (*N*-Me-piperazinium) $(I_3)_2·H_2O$, (*N,N′*-Me_2-piperazinium)$(I_3)_2$, and Me_2NH_2I. The features of these and relevant literature structures are used to (1) classify triiodide structures by their ion-packing types; (2) analyze the relationship between the two I—I bond lengths *d* and *d** in the I_3^- anion; and (3) examine the effect of N—H(N)...I hydrogen bonding on the symmetry of the I_3^- anion. It is found that the *d,d** relationship can be represented to a high degree of correlation by the power function $d^* - d_0 = K(d - d_0)^{-c}$ ($d^* \geq d$, $d_0 = d$(I—I) in I_2(g)) based on the 3c4e model of the anion. An empirical correlation is shown to exist between the H(N)...I and N...I distances both for unbranched and branched N—H(N)...I bonds. Comparison of the degree of asymmetry of I_3^- in two samples, one containing H-bonded I_3^- anions, the other with H-bonding absent, leads to the conclusion that while H-bonding *is* a factor affecting I_3^- symmetry, it is not a *preferential* factor. The four 1:2 title triiodides have structures of, or related to, the CdI_2 type, in which the anions form infinite pseudo-hexagonal channels. The positioning of the divalent cations on the axes of these channels gives rise to an interesting "vernier" effect governed by the cation length and H-bonding ability. Bonding in centrosymmetric I_4 rings in $(Ph_2I)I_3$ and $(Ph_2I)I$ is examined.

Key words: crystal structures, hydrogen bond, iodine–iodine bonds, polyhalide anions, triiodides.

Résumé : On a déterminé les structures de $Me_2NH_2I_3$, $(Ph_2I)I_3$, tropanium·I_3, $[Me_2HN(CH_2)_2NHMe_2](I_3)_2$, $[Me_2HN(CH_2)_3NHMe_2](I_3)_2$, (*N*-Me-pipérazinium)$(I_3)_2·H_2O$, (*N,N′*-$Me_2$-pipérazinium)$(I_3)_2$ et Me_2NH_2I. On a utilisé les caractéristiques de ces structures et d'autres apparentées tirées de la littérature pour (1) classifier les structures des triiodures selon l'empilement de leurs ions; (2) analyser la relation entre les deux longueurs des liaisons I—I, *d* et *d** de l'anion I_3^- et (3) examiner l'effet des liaisons hydrogène N—H(N)...I sur la symétrie de l'anion I_3^-. On a trouvé que, en se basant sur le modèle 3c4e de l'anion, la relation *d,d** peut être représentée, avec un degré élevé de corrélation, par une fonction de puissance $d^* - d_0 = K(d - d_0)^{-c}$ ($d^* \geq d$, $d_0 = d$(I—I), pour I_2(g)). On a montré qu'il existe une corrélation empirique entre les longueurs des liaisons H(N)...I et N...I, pour les liaisons N—H(N)...I tant linéaires que ramifiées. Une comparaison du degré d'asymétrie du I_3^- dans deux échantillons, l'un contenant des anions I_3^- avec des liaisons hydrogène et l'autre dans lequel elles sont absentes, permet de conclure que, même si les liaisons hydrogène *affectent* la symétrie de I_3^-, il ne s'agit pas du facteur *préférentiel*. Les quatre triiodures 1 : 2 mentionnés dans le titre ont tous des structures du type (ou d'un type apparenté) CdI_2 dans lesquelles les anions forment des canaux pseudo-hexagonaux infinis. Le positionnement des cations divalents sur les axes de ces canaux donne lieu à un effet intéressant de vernier qui est gouverné par la longueur du cation et par la possibilité de former des liaisons hydrogène. On a examiné la formation des liaisons dans les cycles I_4 centrosymétriques du $(Ph_2I)I_3$ et du $(Ph_2I)I$.

Mots clés : structures cristallines, liaison hydrogène, liaisons iode–iode, anions polyhalogénés, triiodures.

In Part 1 (1) we showed that the type of ion packing in triiodides of compact, quasi-spherical cations generally depends on the volume V_I that is occupied in the crystal structure by one formula unit. Given the relative constancy of the amount of space occupied by the I_3^- anion, V_I represents a global measure, largely independent of the details of the cation shape, that can be used for classification and prediction of ion coordination in such structures. This is analogous to the use of the cation/anion size ratio for classifying structures consisting of spherical or quasi-spherical ions, e.g., alkali and similar halides. Although the ion-packing trend in the triiodide set in Part 1 was unmistakable, more detailed conclusions were precluded by the limited number and selection of suitable structures that were available; in particular, only cation/anion = 1 compounds were considered. Since the dependence of the ion-packing type on V_I was not the only interesting aspect of the triiodides studied in Part 1 that suffered from lack of structural information, we now supply, as a partial remedy, a number of crystal-structure determinations of both 1:1 and 1:2 organocation triiodides and of Me_2NH_2I (Table 1).

These determinations provide a significant and varied addition to the meagre body of information on hydrogen bonding to iodine. Based on these and literature results we examine, in the Discussion, the relationship of the two I...I bond lengths in I_3^- anions; the effect of N—H...I bonding on the symmetry of I_3^-; the effect of hydration on ion packing in $KIX_2 \cdot H_2O$ (X = I, Br, Cl); and the geometry of, and bonding in, the diphenyliodonium cation.

Crystal data of the title compounds are assembled in Tables 2 and 3, the positional parameters of nonhydrogen atoms in Table 4, and interatomic distances and bond angles in Table 5. Positional parameters and isotropic temperature factors of hydrogen atoms (Table A), anisotropic thermal parameters of nonhydrogen atoms (Table B), and the I...I bond lengths in a number of relevant triiodide structures (Table C) have been deposited.[3]

Individual structures

2MI

In this simple structure the ion packing is of a distorted CsCl type (Fig. 1). The cations (of symmetry C_2) are H-bonded to I^- anions to form discrete centrosymmetric ring dimers $[...I...H(N) - N - H(N)...]_2^0$ of symmetry C_{2h}. The structure may in fact be regarded as a molecular crystal consisting of these neutral ring dimers located at points of a primitive lattice defined by $\mathbf{a'} = \frac{1}{2}(\mathbf{a} + \mathbf{b})$, $\mathbf{b'} = \frac{1}{2}(-\mathbf{a} + \mathbf{b})$, $\mathbf{c'} = \mathbf{c}$.

The H(N)...I bonds are short, 2.51 Å; H(N)-I-H(N) ~ 75°. The difference between the H-bond system in 2MI and that in the other known Me_2NH_2X halide structure, 2MCl, is represented schematically in Fig. 2. In the ordered, orthorhombic low-temperature β-2MCl a C_2 rotation of alternate cations about one of their N—H...Cl bonds will convert the infinite H-bonded chain into a set of discrete ring dimers such as are found in 2MI. In the high-temperature tetragonal α-2MCl the orientational disorder of the cations gives rise to a variety of local situations, some of which will correspond to ring dimers and others that may be viewed as short segments of the β-2MCl chain. The H-bond connectivity in α-2MCl is thus statistically intermediate between those of 2MI and β-2MCl.[4]

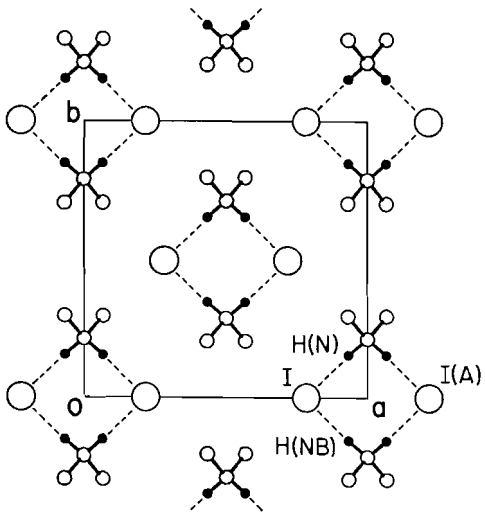
[e] Data/restraints/parameters; $I > 3\sigma(I)$.

[f] Residual electron density ($e/Å^3$) in final difference map.

Fig. 1. 2MI: projection on (001).



2MI3

The ion packing in this orthorhombic structure is of the NaCl type (Fig. 3). Interestingly, the NaCl arrangement is obtained directly from the corresponding undifferentiated atom arrangement in $Fm\bar{3}m$ by subgroup descent and splitting the undifferentiated atoms positions into two fourfold sets: $Fm\bar{3}m$,

Fig. 2. (*A*) $[...I...H—N—H...]_2$ ring dimers in 2MI, in a plane approximately $\parallel(20\bar{1})$. (*B*) Portion of the planar zigzag $[...Cl...H—N—H...]_\infty$ chain in β-2MCl, in the (001) plane. Breaking the H...Cl bonds at the marked points followed by rotation about the fictitious C_2 axes converts the chain into a sequence (*C*) of $[...Cl...H—N—H...]_2$ ring dimers analogous to those in 2MI. Large circles, halogen atoms; small circles, N and C atoms, the latter eclipsed in the projection. H atoms not shown.

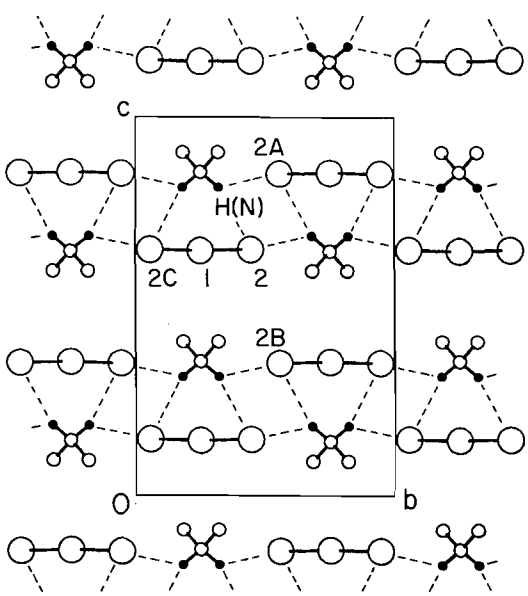
Fig. 3. 2MI3: projection on (100). Black circles, H(N) atoms. Broken lines indicate H(N)...I(2) bonds.



8(*c*) ⊃ *Fmmm*, 8(*f*) ⊃ *Cmca*, 8(*e*) [*abc* → *cab*] → *Abma*, 8(*e*) ⊃ *Pccn*, 4(*c*) + 4(*d*), with I(1) in 4(*c*) and N in 4(*d*), i.e., $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4}) \rightarrow (\frac{1}{4}, \frac{1}{4}, y)$ and $(\frac{1}{4}, \frac{3}{4}, \frac{1}{4}) \rightarrow (\frac{1}{4}, \frac{3}{4}, y)$. Both the cation and the anion have C_2 symmetry. The discrete anion is slightly bent.

Each of the two H(N) atoms is involved in a bifurcated H(N)...I(2),I(2A) bond. This results in the formation of [...I...H(N)...I...] helices ∥*a* and, in turn, of H-bonded twisted double chains ∥*b*. The chains are separated from one another by layers of CH_3 groups. Each terminal atom of an anion participates in an H-bond to the H(N) atoms of different cations, and the two terminal atoms of each anion are H-bonded to the two H(N) atoms of the same associated cation. The H(N)...I bonds are appreciably longer than the unbranched H(N)...I bonds in 2MI, 2.96 and 3.08 Å, respectively, as against 2.51 Å.[4]

TrI3

The ion packing in this chiral orthorhombic structure is of the *anti*-NiAs type, similar to that in 4MI3 and QI3 (Table 1 of ref. 1): $\frac{1}{2}(\mathbf{a_O} + \mathbf{c_O}) \rightarrow \mathbf{a_{H,1}}$, $\frac{1}{2}(-\mathbf{a_O} + \mathbf{c_O}) \rightarrow \mathbf{a_{H,2}}$, $\mathbf{b_O} \rightarrow \mathbf{c_H}$; $2b_O/(a_O^2 + c_O^2)^{1/2} = 1.798 \rightarrow a_H/c_H = 1.633$ (ideal), $a_O/c_O = 1.632 \rightarrow \sqrt{3} = 1.732$ (ideal). The smaller internal angle in the base of the pseudohexagonal cell is 63.0° instead of the ideal 60°.

The anions are arranged in homogeneous layers ∥(010), and ditto for the cation centroids (Fig. 4). Unlike the arrangement in 4MI3 and QI3, the I_3 units are inclined to *all three* crystal-

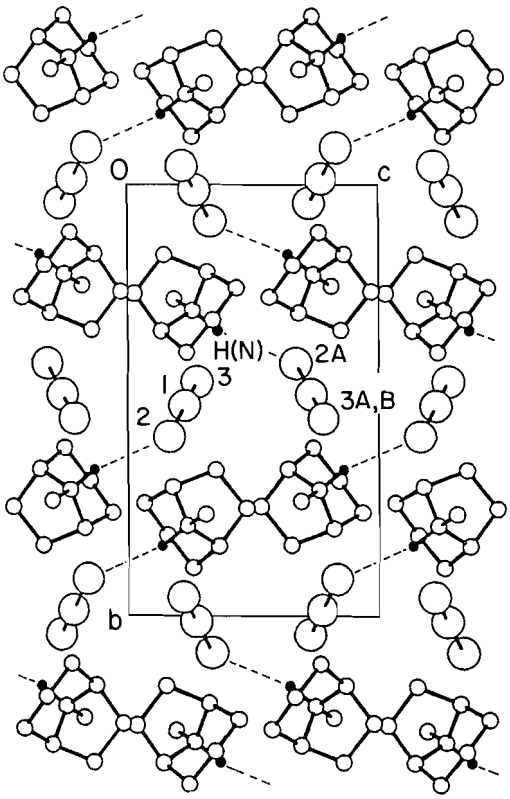
[a]Parameter values of atoms in special positions are not multiplied by 10^4.

Fig. 4. TrI3: projection on (100). Black circles, H(N) atoms. Broken lines indicate H(N)...I(2) bonds.



lographic axes. The anion is bent, I(2)-I(1)-I(3) = 176.0°, and discrete, the inter-anion I...I separations being all greater than 4.4 Å.

In the cation (of symmetry C_1), the H(N) atom is in axial position on the N atom of the 6-membered ring. The H-bond between H(N) and I(2A), 2.77 Å, is bent, N-H(N)-I(2A) = 162°. The H-bonding is restricted to cat/an pairs.

2PhII3

In this monoclinic structure layers of cations ||(010) alternate with layers of anions, the mean perpendicular separation of like layers being $\frac{1}{2}b$ = 8.89 Å (Fig. 5*A*). An interesting feature of the structure is the occurrence of four-membered centrosymmetric rings of I atoms formed by the terminal I(3) atoms of the anions and the I(4) atoms of the cations (Fig. 5*B*).[5] The I...I distances in these $[...I(3)...I(4)...]_2$ rings, 3.511 and 3.667 Å, respectively, qualify for weak I...I bonding interactions; they and the almost right I(3)-I(4)-I(3A) and I(4)-I(3)-I(4A) angles, 88.7° and 91.3°, respectively, are strongly reminiscent of similar distances and bond angles in higher organoammonium polyiodides (20). The rings are dimensionally closely similar to the corresponding $Ph_2I(\mu\text{-}I)_2IPh_2$ ring dimers in 2PhII (Figs. 5*C* and 6), except that the simple I^- ions in 2PhII are now replaced by the somewhat bent I_3^- anions approximately perpendicular to the ring plane (Fig. 5*B*; angle between ring plane and I(3)—I(2), 87°). The implications of the dimensional changes that are observed on replacing I^- by I_3^- are discussed below. The shortest *inter-anion* I...I distance is I(2)...I(2B) = 3.852 Å, across an inversion centre; I(1)-I(2)-I(2B) = 153°.

The cation symmetry is C_1. The I(4)—C(11) and I(4)—C(21) bond lengths, and the C(11)-I(4)-C(21) and C(β)-C(α)-C(β′) bond angles, are compared to those in other Ph_2I^+ salts in Table 6. The phenyl rings R1 and R2 are satisfactorily planar, the respective mean deviations of the C atoms from the best planes through the R1 and R2 skeletons being 0.007[4] and 0.008[4] Å; the deviations of the I(4) atom from these planes are −0.026 and 0.168 Å, respectively. The R2/R1 angle is 77.8° compared to 93.5° in 2PhII.

Mpip2I3w, 2Mpip2I3, and 4Men2I3

The structures of these 1:2 triiodides show striking similarities (Table 7, Fig. 7). The anions, which are roughly ||*c*, project on (001) into honeycombs of pseudohexagonal cells the centres of which are occupied by the projected cations. In turn, the projected cations divide the projections on (001) into triangular tilings. The structures can thus be viewed as monoclinic variants of the CdI_2 structure, with the cation centroids exactly or close to coplanar and at the corners of the pseudohexagonal cells.[6] The anions in these cells are in positions corresponding to $\pm(\frac{1}{3}, \frac{2}{3}, z)$ in the CdI_2 aristotype, but the z coordinate is not

[5] The geometry of these rings is analogous to that of the $[...N—H(N)...I...]_2$ rings in 2MI (cf. above).

[6] In Fig. 7 the pseudohexagonal cells are defined by the $(\frac{1}{2}, 0, 0)$ and $(0, \frac{1}{2}, 0)$ points of the corresponding pseudo-orthohexagonal cells shown.

well defined (i.e., not close to $\frac{1}{4}$) because the rod-like anions, aligned roughly $\perp(001)$, extend vertically into the adjacent cells. This results in the formation of anion strings with inter-anion I...I separations between ~3.58 and ~3.76 Å (Table 5) and thus qualifying for weak I...I bonding interactions such as are observed in linear polyiodide chains (e.g., refs. 20–23). The structures may therefore also be regarded as consisting of anion channels $\parallel c$ containing the cations.

Fig. 5. (*A*) 2PhII3: projection on (001). (*B*) the centrosymmetric [...I(3)...I(4)...]$_2$ ring dimer in 2PhII3. (*C*) The corresponding [...I(1)...I(2)...]$_2$ ring dimer in 2PhII. The I—I bond lengths are in Å.

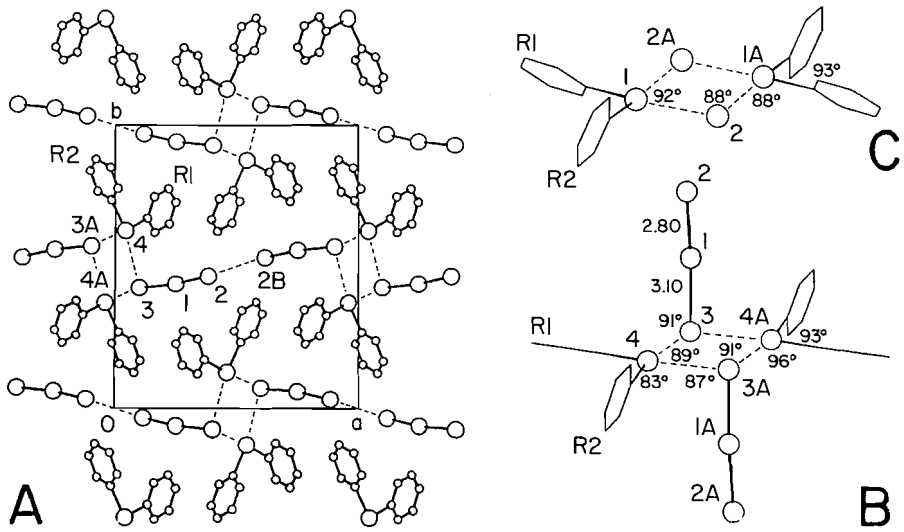

Fig. 6. I_4 ring dimers in 2PhII (top) and 2PhII3 (bottom): comparison of bond lengths and angles. Atom numbering in 2PhII as in ref. 6; in 2PhII3, as in Table 4.

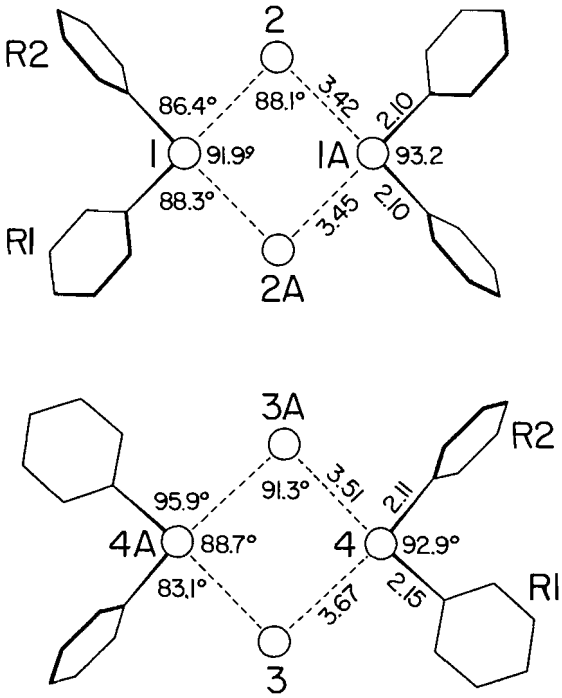

The above three structures are closely related to the structure of the unsubstituted piperazinium salt pip2IC12 reported almost 40 years ago (10). Its triclinic $P\bar{1}$ unit cell *T*, which contains the heteroatomic trihalide anion $IC1_2^-$, can be transformed into the "orthohexagonal" $C\bar{1}$ cell *O* shown in Fig. 7*D* by

$$\begin{pmatrix} a_O \\ b_O \\ c_O \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 \\ 2 & 0 & 1 \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} a_T \\ b_T \\ c_T \end{pmatrix},$$

$$\begin{pmatrix} x_O \\ y_O \\ z_O \end{pmatrix} = \begin{pmatrix} -\frac{1}{2} & 0 & 1 \\ \frac{1}{2} & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix} \begin{pmatrix} x_T \\ y_T \\ z_T \end{pmatrix} + \begin{pmatrix} \frac{1}{4} \\ \frac{1}{4} \\ 0 \end{pmatrix}$$

The inter-anion C1...C1 separation in the $IC1_2^-$ strings $\| c_O$ is ~3.3 Å.

While the above three triiodide structures are of the same ion-packing type, their particular features differ. The simplest of the three, 2Mpip2I3, can be derived from the CdI_2 aristotype by $P\bar{3}m1 \supset C2/m \supset P2_1/a$; the alternating orientations of the cations and the anions are most directly described in terms of the dichromatic space group P_C2_1/a–$C2/m|P2_1/a$. The anions, almost $\| c$, form hexagonal channels which enclose the cations lengthwise. The centrosymmetric *trans* cations are attached to the walls of the channels by short N—H(N)...I(2) bonds (N...I(2) = 3.50 Å, H(N)...I(2) = 2.51 Å, N-H(N)-I(2) = 163°) roughly perpendicular to the channel axis (Fig. 8*A*). The asymmetric, practically linear anions are arranged in strings $\| c$, in which the end-to-end I(2)...I(3A) separation is 3.637 Å; this is the shortest inter-anion I...I distance in the structure. The anion strings are not completely straight, I(1)-I(2)-I(3A) = 162.4°.

The $P2_1/a$ unit cell of 4Men2I3 is dimensionally closely similar to that of 2Mpip2I3. The overall organization of the two structures is the same (Figs. 7*A*, *B* and 8), and the H-bond geometries are comparable: in 4Men2I3, N...I(2) = 3.54 Å, H(N)...I(2) = 2.53 Å, N-H(N)-I(2) = 171°. The inter-anion I...I distance in the anion chains is slightly longer in 4Men2I3, I(2)...I(3A) = 3.780 Å, but the chains are not straighter than in

Table 6. Bond lengths (Å) and angles (deg) in diphenyliodonium cations.[a]

[a]See Table 1 for codes and references. The cation in all the above compounds is of C_1 symmetry, with the exception of 2PhITB, in which the cation symmetry is C_s.

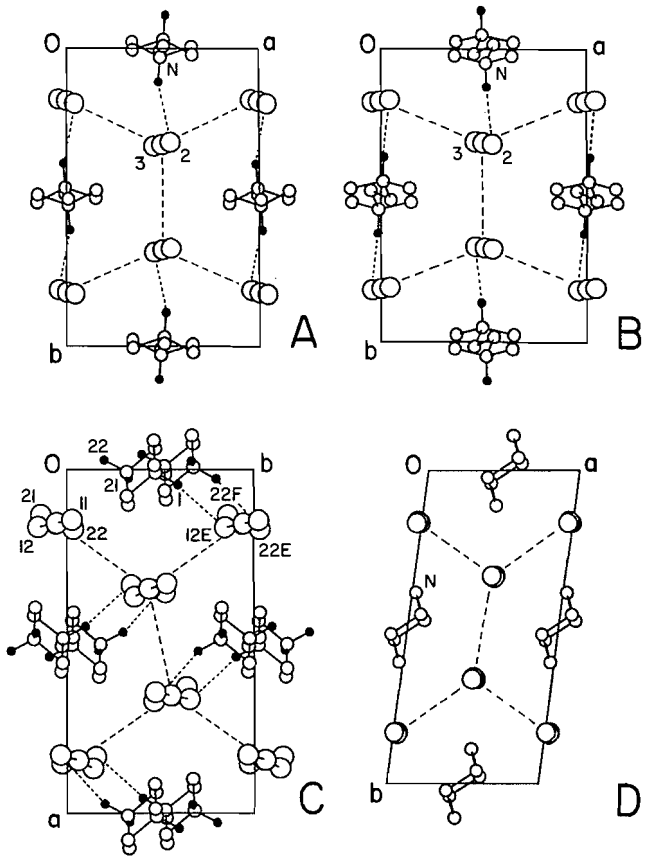
2Mpip2I3. The I—I bond lengths in the asymmetric but practically linear anion are almost the same as in 2Mpip2I3. The H-bond to the I(2) atom in the two structures would be expected to weaken the I(1)—I(2) bond (cf. ref. 1), and this is in fact observed: I(1)—I(2) = 3.05–3.09 Å, I(1)—I(3) = 2.83–2.84 Å.

The one important difference between the two structures is in the positioning of the cation in the hexagonal channels ||c relative to the anions. While the arrangements of the anion strings are almost identical, the presence of the extra *N*-Me groups in 4Men2I3 displaces the cation along the channel axis in such a way that the Me groups are at the same vertical height ||c as the gaps in the anion chains. More precisely, the cation centre on the channel axis is shifted with respect to the midpoint of the nearest I(1) positions in the associated anion string by $\delta z = -0.034 \sim 0.32$ Å in 2Mpip2I3 but by $\delta z = -0.253 \sim 2.41$ Å in 4Men2I3. This "vernier" effect in the more or less rigid anion framework depends on the length of the cation as well as on the number and positions of the *N*-methyls and thus on the opportunity for H-bond formation. It is present also in Mpip2I3w (Fig. 9, see below), where the offset $\delta z = -0.026 \sim 0.49$ Å accommodates the piperazinium ring (rather than the single terminal *N*-Me group or the H_2O molecule) in the gap between successive anions in the associated chain. The effect is also evident, though in a more complicated way because of the approximate match of the cation and anion lengths, in the 4Mpr2I3 structure (Fig. 10, see below).

In Mpip2I3w the *c* edge is doubled,[7] but the gross features of the structure strongly resemble those of 2Mpip2I3. The

[7] This doubling corresponds to a doubling of the CdI_2 cell: $P\bar{3}m1 \rightarrow P_c\bar{3}m1 \supset C_c2/m$.

Fig. 7. Four CdI_2-type structures projected on (001). (*A*) 2Mpip2I3, $P2_1/a$. (*B*) 4Men2I3, $P2_1/a$. (*C*) Mpip2I3w, $P2_1/n$; H_2O molecules omitted for clarity. (*D*) pip2IC12, $C\bar{1}$ (see text). Black circles, H(N) atoms; dotted lines, H(N)...I bonds. Broken lines indicate the hexagonal tesselations.



anions again form hexagonal channels ||c, but the cations enclosed in these channels are now joined by the water molecules to form centrosymmetric cat...$(H_2O)_2$...cat dimers (Fig. 9). The H(N1) and H(N22) atoms are bonded to the anions, while H(N21) is bonded to the water molecule. The structure contains two anions, a1 = I(11)-I(10)-I(12) and a2 = I(21)-I(20)-I(22), both asymmetric and slightly bent. In the anion strings ||c (Fig. 9), the end-to-end inter-anion I...I separations are I(11)...I(22D) = 3.578 Å and I(21)...I(12) = 3.711 Å. All the other inter-anion I...I distances are >4.3 Å.

The N—H(N)...I bonds are short and bent; the N—H(N)...O bond is almost straight (Table 5). The O...O distance in the centrosymmetric H_2O pair is 2.94 Å. Since the H(O) atoms were not seen in the difference map, the H-bonding at the water molecules is not established. However, it is plausible to assume that the observed O...O separation corresponds to an O—H...O bond with the H(O) atom disordered across the inversion centre. Thus, with the O...H(N21)—N(21) bond fixed (H(N21)-O-O(F) = 113°) and an O—H(O) bond pointed at O(F), the electron-density maxima expected at ~1 Å at O in the directions of the remaining two "tetrahedral" bond angles should correspond to $\frac{3}{4}$ H each and that between the two oxygen atoms to $\frac{1}{2}$ H (totalling 2 H on each oxygen), not easily discernible in a room-temperature hydrate structure.

4Mpr2I3

The coincidence, in 2Mpip2I3, 4Men2I3, and pip2IC12, of the cation centre of symmetry with a crystallographic inversion centre results in a simple CdI_2-type structure. In 2Mpip2I3 the cation is noncentrosymmetric, but two of its H(N) atoms are in a *trans* conformation, rendering the cation quasi-centrosymmetric. Although the cation noncentrosymmetry leads to a doubling of c, the packing arrangement still retains the CdI_2 character. In 4Mpr2I3, however, centrosymmetry of the cation is precluded by the odd number of CH_2 groups in the cation skeleton and the cation can adopt not even a *quasi* centrosymmetric conformation. As a consequence the structural arrangement in 4Mpr2I3 (Fig. 10) differs significantly from those in the other three structures, even though there are similarities in the gross features (compare Figs. 8 and 10).

The structure consists of two cations, c1 and c2, and four anions, a1–a4. The anions are only slightly distorted (Table 5). Two of them, a1 and a2, are H-bonded to the cations; a3 and a4 do not participate in H-bonding. The anions form infinite quasi-linear strings approximately ‖(130) (Fig. 10). Each string consists of four-anion segments, ...[a3...a1...a2...a4]..., in which the inter-anion I...I separations range from 3.77 to 4.01 Å (Table 5, Fig. 11). The anion sequences in adjacent strings are antiparallel by virtue of the crystallographic inversion centres. The terminal anions a3 and a4 in the four-segment are kinked with respect to the central anions a1 and a2. The inter-anion separation *between* successive four-segments, I(31C)...I(42B), is 6.11 Å, i.e., the four-segments in the chains are discrete. The shortest I...I distance between the chains is I(42)...I(21C) = 4.26 Å.

The cation N-C-C-C-N skeleton is planar to 0.097[55] Å in c1 and to 0.062[17] Å in c2. Cation c1 is H-bonded exclu-

Fig. 9. Mpip2I3w: projection on (010). Filled circles: large, O atoms; small, H(N) atoms. Hydrogen bonds are indicated by dotted lines, anion connectivity in the chains by broken lines. For codes see Table 5.

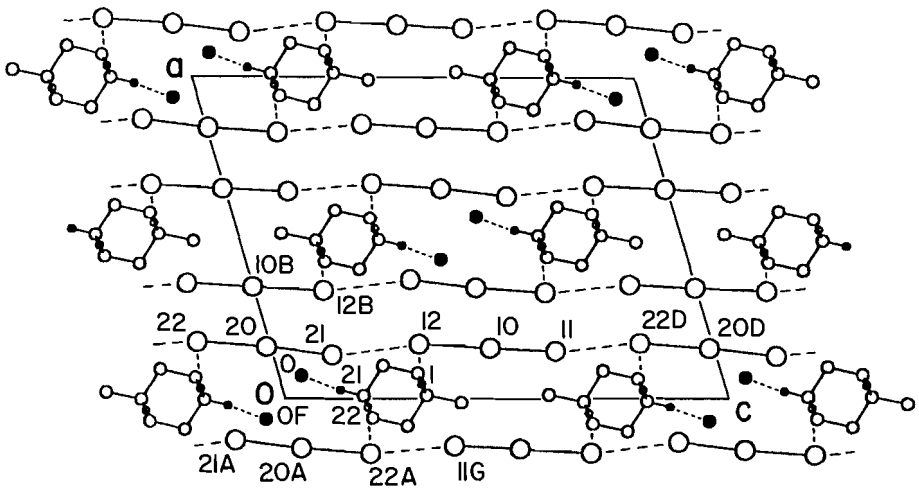

Fig. 10. 4Mpr2I3: projection on (001). For atom code see Table 5. The centre atoms of the anions, I(n0) (n = 0–4), are not numbered. Broken lines connect anions in the four-anion segments (see text).

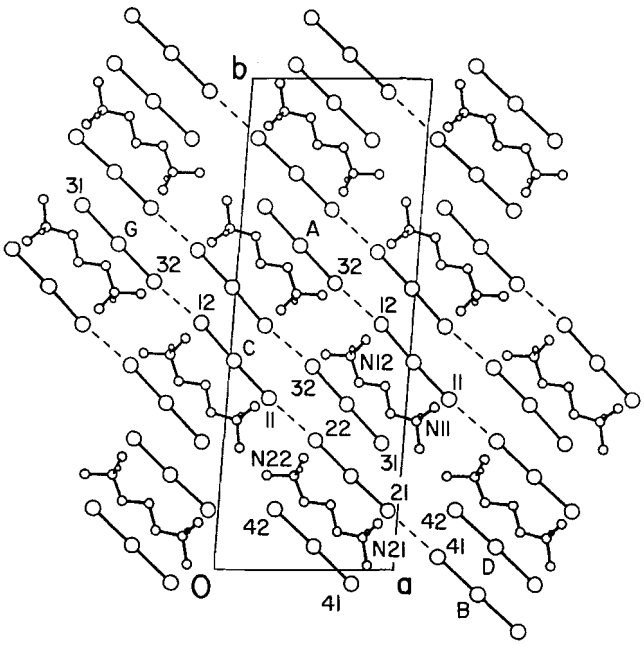


sively to a1, and c2 exclusively to a2 (Figs. 11 and 12). Anions of the same type are H-bonded in stacks ||c, so that all the cross-stapled anions are located in sheets approximately ||(130). These sheets occur in pairs, with the cations sandwiched inside a pair (cf. projection on (001), Fig. 10). The H-bonds in each cation are ipsolateral, but the cation orientations vis-à-vis their associate anions in a sandwich alternate as a result of the displacement, along the string, of the anion sequences in the sandwich-forming strings by half the four-segment period. Three of the H(N)...I bonds are short, ~2.6 Å, N-H(N)-I ~ 155–164°. The fourth bond, H(12)...I(12E), is longer, ~2.90 Å, N-H(N)-I = 149°.

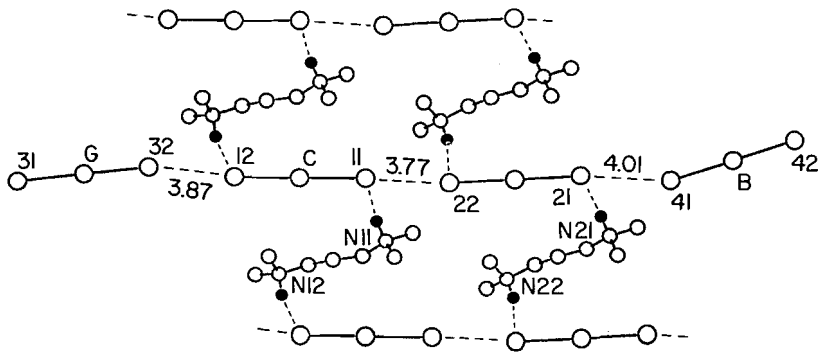
Discussion

I_3^- asymmetry revisited

In reports of crystal structures containing I_3^- the observed asymmetry of the anion is often duly noted but accepted without further comment as an experimental fact. The approximate constancy of the sum of the two I—I bond lengths d(I—I) and d^*(I—I) ($d^* \geq d$) in weakly asymmetric anions has been commented upon by various authors, as has the regularity of the variation of d^* with d, but otherwise little effort appears to have been made to investigate, systematically, the specific causes of the asymmetry beyond referring to the easy polarizability of the iodine atom. While it is possible that in practice detailed attributions cannot be made, it still seems worthwhile to see what *can* be said about the effect of *particular* factors influencing the geometry of the I_3^- anion in crystals. Since large departures from centrosymmetry are sometimes associated with the presence of X—H(X)...I hydrogen bonds in the triiodide structures (cf. ref. 1), it is natural to ask, can H-bonding be singled out as preferentially responsible for such distortions in the simultaneous presence of other factors (distribution and magnitude of Coulombic and dipolar interactions in the crystal, inter-anion I...I bonding interactions)?

Given the variety of anion environments in triiodides, an answer at present can be attempted only in statistical terms. To this end we have assembled (Table C) a d,d^* sample from 25 discrete (see below) I_3^- anions with demonstrated or probable N—H(N)...I bonds (sample HB) and a corresponding sample from 21 discrete anions in structures in which H-bonding is absent (sample NHB). The HB set covers reasonably completely the reported H-bonded anions, while the NHB set represents a more or less random selection of I_3^- anions with statistically significant (in terms of the stated esd's) asymmetry. Neither set contains anions with crystallographic symme-

Fig. 11. 4MPr2I3: a four-anion segment and N—H(N)...I motif, viewed approximately perpendicular to (130), the *c* axis vertical in the page. The code letters correspond to those in Fig. 10. The separation between successive four-anion segments in a chain (i.e., beyond I(31G) and I(42B), respectively) is 4.11 Å.



try other than C_1 or C_s (anion in *m*).[8] The two sets are presented in the d^* vs. d plots of Figs. 13*A*, *B* and again in Fig. 13*C*, where the bond-length *difference* $\Delta = d^* - d$ is plotted against the mean bond length $\Sigma = \frac{1}{2}(d + d^*)$.

The two samples contain appreciable scatter, but both a visual examination and a nonparametric test statistic $Z = r_s(n - 1)^{1/2}$ based on Spearman's rank correlation coefficient r_s show[9] unmistakable correlation of d and d^*, as does in a different way the Δ vs. Σ plot. To show whether or not HB and NHB come from the same population, i.e., whether or not H-bonding is a *preferential* factor affecting the symmetry of the anion, we shall assume that I_3^- is a 3c4e system in which *p–p* bonding dominates (24, 25) and in which the two bond lengths can be related by

$$[1] \quad d^* - d_0 = K(d - d_0)^{-c}$$

(the difference power fit DPF of ref. 26). Here d_0 is the asymptotic lower limit of the I—I bond length, taken as the d(I—I) in the free I_2 molecule, 2.667 Å.[10] Regressing $d^* - d_0$ on $d - d_0$ we obtain

Sample	*n*	r^2	*K*, Å	*c*	σ, Å	d_e, Å
HB	24*	0.918	0.09182	0.80219	0.018[11] ~ 7% range	2.933
HB**	24*	0.918	0.05652	1.14433	0.011[6] ~ 8% range	2.930
NHB	21	0.726	0.09304	0.77715	0.017[14] ~ 11% range	2.930
HB + NHB	45*	0.873	0.08906	0.81410	0.017[14] ~ 7% range	2.931

*No. 15 of Table C not included in the regression.

**Reverse regression, $d - d_0$ on $d^* - d_0$. The HB and NHB sets are replotted in a rectified form in Fig. 14.

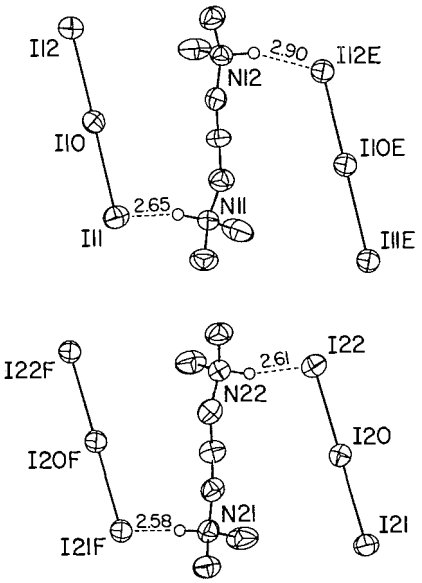
Two conclusions can be immediately drawn from these results. Both samples conform to the model function, HB closely, NHB adequately (the lower correlation for NHB stems from the scatter, not from inadequacy of the DPF function), hence the 3c4e hypothesis is not contradicted. Secondly, the difference between the HB and the HB + NHB regressions amounts to only the thickness of the HB regression line in Fig. 14, and the difference between NHB and HB + NHB, over the observed range, is very small. Thus, HB and NHB sample the same $d,d,^*$ population and the effect of H-bonding on the I_3^- symmetry cannot, *statistically*, be claimed to be a preferential factor, i.e., the variation of d^* with d follows eq. [1] regardless of the nature of the factor(s) responsible for the I_3^- asymmetry. A large asymmetry may appear for a variety of reasons, not only because of H-bonding, even though in the *present* HB and NHB samples the asymmetry in the H-bonded anions exceeds that in the non-bonded anions ($d^*(\mathrm{HB})_{max} - d^*(\mathrm{NHB})_{max} \sim 0.08$ Å, $\Delta(\mathrm{HB})_{max} - \Delta(\mathrm{NHB})_{max} \sim 0.1$ Å).

[8] Deviations of the anion from nonlinearity have not been taken into account. However, in HB and NHB the difference between $d + d^*$ and the distance between the terminal atoms of the anion does not exceed ~0.014 Å ~ 0.3% of $d + d^*$ (for no. 1) and in most cases is much smaller.

[9] r_s(HB) = 0.906, r_s(NHB) = 0.791; *Z* is approximately a standardized normal variable.

[10] The 3-parameter CSBO (constant sum of bond orders, eq. [4] of ref. 26) function would be theoretically more appropriate but, as explained in ref. 26, in practice the DPF and CSBO fits are statistically indistinguishable. Besides, the ground-state I—I bond length in I_2(g) is unlikely to be reduced by laboratory intervention: application of external pressure appears to have negligible effect on d(I—I) in I_2(s) (27–29). A more encompassing discussion of comprehensive d,d^* sets in *trans* bonds of polyiodide ions is planned for a sequel in this series.

Fig. 12. Hydrogen bonding and cation geometry in 4Mpr2I3 (50% probability thermal ellipsoids, bond lengths in Å). For code letters see Table 5.



Conformity of HB and NHB to eq. [1] makes it possible to estimate the bond length $d_e = d = d^*$ in the *centrosymmetric* I_3^- in crystals. The best estimate from the above regressions is 2.931[11] Å.[11] Adding to the 3σ of this value an assumed representative correction of 0.02 Å for the effect of thermal motion raises this estimate to an upper limit of 2.98 Å, which still falls ~0.06 Å short of the ab initio (effective core potential) value of 3.044 Å (25), making the latter an overestimate.[12]

In principle, an estimate of d_e should be obtainable directly from the experimental d(I—I) values for I_3^- anions of crystallographic symmetry (or subsymmetry) C_i, and also C_2 and C_s (anion halved by m), provided the I-I-I angle deviates only slightly from 180°.[13] In practice, however, the centre atom of the anion may be positionally disordered about the inversion centre (cf. for example refs. 31 and 32). Unless this possibility has been specifically ruled out, an asymmetric I_3^- anion may be incorrectly included in a sample of genuinely centrosymmetric anions. Secondly, uncorrected d_e values as low as 2.89 Å and as high as 2.95 Å have been reported for anions of crystallographic C_i symmetry, so the validity of a $\bar{d}_e$ estimate may depend critically on the adequacy of sampling. These problems are circumvented by using eq. [1] and asymmetric anions only, although the uncertainty in estimating the thermal correction may well wipe out whatever difference there may exist between the two estimates, d_e(PDF) and $\bar{d}_e(C_i)$.[14] In any event, a comprehensive sample of asymmetric anions will always be larger than a comprehensive sample of symmetric anions.

The bond order s of the d(I—I) = $d(s)$ bond can be estimated from eq. [1] in the form (cf. ref. 26)

$$[2]\quad (\ln s)/\ln s^* = [d(s) - d_0]/[d^*(s^*) - d_0] = K^{-1}[d(s) - d_0]^{c+1} = 11.228[d(s) - 2.667]^{1.8141}$$

$s^* = 1 - s$. Conversely,

$$[3]\quad d(s) = d_0 + K^{1/(c+1)}(\ln s)/\ln s^* = 2.667 + 0.2639(\ln s)/\ln s^*$$

The total range of d(I—I) in the I_3^- anions is thus $d_e - d_0$ = 0.264 Å. The bond order over the observed d range is indicated in Fig. 14.

Is the I_3^- anion discrete?

We now return to the question, are the I_3^- anions in the HB and NHB samples discrete? Increasing asymmetry of the anion depends on an increased interaction of the anion with its surroundings in the crystal. Since such interaction is always present and the anion cannot be asymmetric without it, the question of when an anion may be regarded as discrete, i.e., minimally affected by its neighbours in the crystal, is inextricably linked to the degree and nature of this interaction and to the presence of features in the crystal structure that would indicate directional bonding interaction, such as bonding to another I_3^- at admissible I...I distances and I-I-I bond angles (i.e., close to 180° or 90°). The limit below which an I...I distance may be regarded as bonding (and the anion as no longer discrete) is difficult to preassign unambiguously. For linear or quasi-linear I − I − I...I configurations it will be in the vicinity of 4 Å, while for right-angle configurations this limit may be appreciably shorter. In either case the limit will depend on the particulars of the structure and a discrete/nondiscrete assignment will at times be arbitrary.

With decreasing inter-anion I...I contacts the I_3^- ions may merge into anion polyiodide oligomers, chains or networks, with an attendant redistribution of the atom charges, e.g., with the formation of asymmetric local I...I − I − I aggregates in which the three-atom groups may no longer conform to the above regression function for "discrete" (i.e., 3c4e) I_3^- anions. The applicability of an (adjusted) extension of this function beyond the present d,d^* range is a matter for another investigation.

Hydrogen bonding

Since the range of N—H(N)...I geometries is not well established, it is useful to collect the results of this and previous

[11] A previous (30) estimate is 5.85[5] Å for $2\Sigma = 2d_e$.

[12] The lack of correction for thermal motion is responsible for some of the scatter in Fig. 14 and for some of the d values falling appreciably below d_e in Fig. 13, well below the experimental esd's of the respective I—I bond lengths. However, barring a transcription error in ref. 33, we are unable to explain the gross misfit of point Z in the plots of Figs. 13*A* and 14. This d,d^* pair, 2.868(6), 2.902(6) Å, pertains to an I_3^- anion in a zigzag "polyiodide" chain, which is inside a maltohexaoside antiparallel double helix and in which the inter-anion I...I separations are *long*, ~4.05 Å. The d,d^* in the other I_3^- anion of the chain in what otherwise appears to be a well-determined (p-nitrophenyl α-maltohexaoside)$_2$·Ba$(I_3)_2$·27 H_2O structure, are unexceptionable.

[13] Conversely, anions of C_2 and C_s (anion halved by m) symmetry with I-I-I angles appreciably smaller than 180° can be used to evaluate the angle dependence of d_e.

[14] For a general discussion of equivalence of the d_e obtained from a $d \neq d^*$ sample, the $\bar{d}_e$ from a $d = d^*$ sample, and the d_e obtained from the combined sample, see ref. 26.

Fig. 13. Correlation of d(I—I) and d^*(I—I) bond lengths in I_3^- anions. Structures with (*A*) and without (*B*) N—H(N)...I bonds. (*C*) HB + NHB points replotted as Δ vs. Σ. The 45° line in *A* and *B* corresponds to $d = d^*$. For number code see Table C.

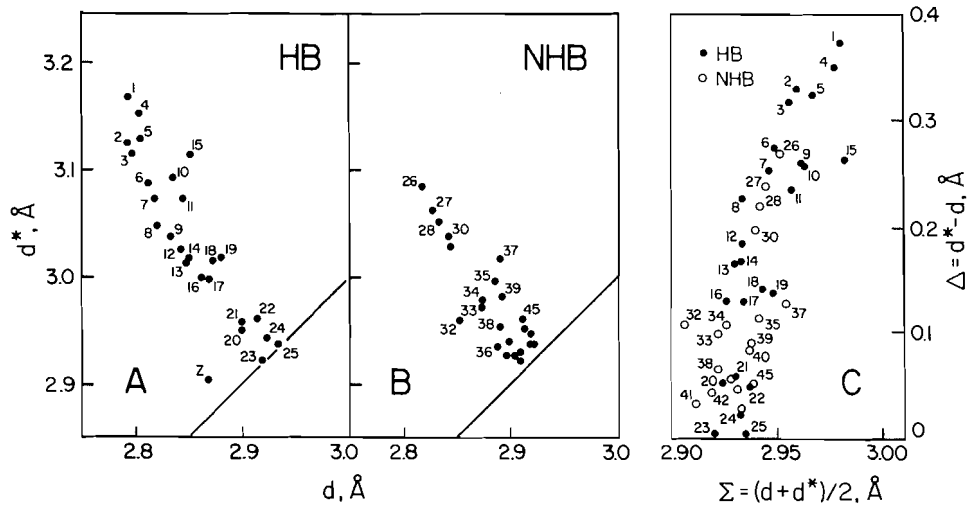


Fig. 14. Rectified correlation of d(I—I) and d^*(I—I) in I_3^-. Regression lines, eq. [1]. HB set: I_3^- in structures containing N—H(N)...I bonds. NHB set: I_3^- in structures without N—H(N)...I bonds. Broken lines, bond order $s(d)$ corresponding to the d(I—I) bond length, cf. eq. [3]. For point Z see text.

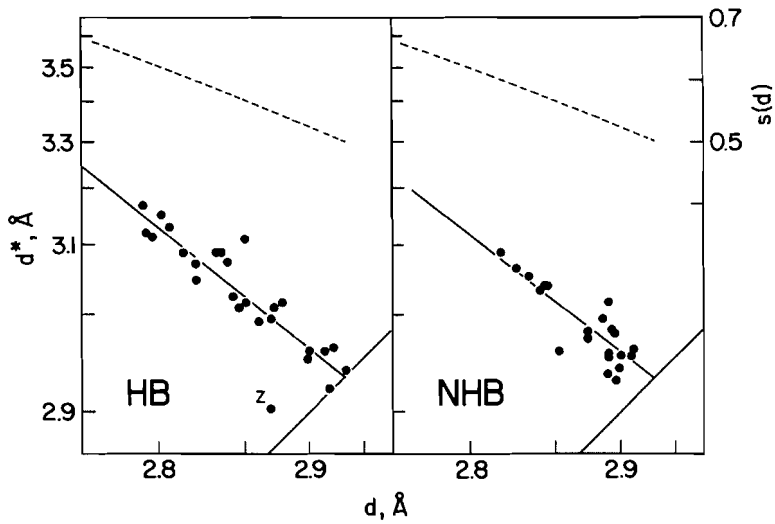
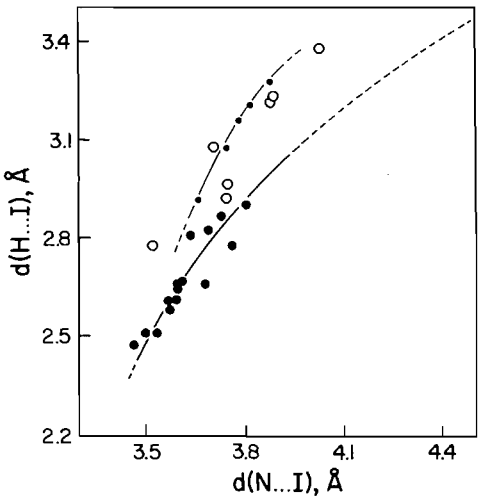


investigations (1–3) in Fig. 15. The H(N) atom has been located only in a few cases and then not too accurately, a typical esd on the H(N)...I bond length being 0.02–0.04 Å and 3° on the N-H(N)-I angle; where the H(N) atom was placed geometrically, the N—H(N) distance was taken to be mostly 1.02 Å. On the assumption that, with increasing d(N...I), the H(N)...I interaction weakens and d(N—H(N)) converges to its free value, a synthetic d(N...I) = 4.50 Å, d(H(N)...I) = 3.48 Å point was added to the set of Fig. 15, in order to ensure monotonic behaviour, and the augmented set was fitted parabolically: $r^2 = 0.97$, d(H(N)...I) = $-9.25 + 5.22d$(N...I) $- 0.5314$ $(d$(N...I))^2. The σ of this convenience fit, 0.03 Å ~ 7% of the actual d(H(N)...I) range, is comparable to the experimental esd's of the individual d(H(N)...I) values. In the present sample, d(N...I) in unbranched N—H(N)...I bonds extends over ~0.35 Å, and over ~0.43 Å for d(H(N)...I).

The locus of the points for the *bifurcated* N—H(N)...2I bonds in Fig. 15 appears to be shifted by 0.15–0.2 Å toward shorter N...I distances. The scatter here is appreciable and, if these few points were the only evidence, the existence of a correlation might well be questioned. However, support comes from the branched O—H(O)...I bonds in $KI_3 \cdot H_2O$, the structure of which was determined by single-crystal neutron diffraction (13). The asymmetrically trifurcated O—H(O)...3I and the asymmetrically bifurcated O—H(O)...2I bonds furnish five accurate d(O...I), d[H(O)...I] pairs, with d(O...I) ranging from ~3.66 to ~3.88 Å and d[H(O)...I] from 2.915 to 3.287 Å. Unconstrained quadratic regression yields

Fig. 15. Correlation of the H(N)...I and N...I distances in N—H(N)...I bonds in triiodide structures, and of H(O)...I and O...I in $KI_3 \cdot H_2O$ (neutron diffraction). For regression lines see text. Large filled circles, unbranched N—H(N)...I bonds; open circles, branched N—H(N)...I bonds; small filled circles, branched O—H(O)...I bonds (read O...I for N...I on the horizontal axis). Some of the N-H-I angles in the unbranched bonds deviate appreciably from 180°.



$d(\mathrm{H(O)...I}) = -41.48 + 21.95d(\mathrm{O...I}) - 2.6825(d(\mathrm{O...I}))^2$, $r^2 = 0.996$, $\sigma = 0.007[4]$ Å ~ 2% of range. This is a highly significant correlation and one based on a fully internally consistent set of interatomic distances from *the same structure* and involving the same oxygen atom. The corresponding correlation curve (Fig. 15) is compatible with the d(N...I), d(H(N)...I) points for the branched bonds; given the scatter of that set, the difference between d(N...I) and d(O...I) is inconsequential, and ditto for d(H(N)...I) and d(H(O)...I).

Ion packing in triiodide structures

As pointed out previously (1), the ion-packing type of an (unsolvated) 1:1 triiodide of a compact, symmetric cation can be related to the volume V_1 per formula unit: at small V_1 the NaCl type (at times strongly distorted) prevails, with the *anti*-NiAs type at intermediate V_1, and the CsCl type at large V_1 values. This rough scheme (now enlarged, Table 8) appears to hold up to $V_1 \sim 400$ Å^3, though with the inclusion of additional structures the lack of a clear-cut classification in the intermediate, $V_1 \sim 300$ Å, region becomes increasingly apparent. A closer analysis of factors other than cation volume at play in the transition region will have to await further accumulation of structural information. This is true a fortiori of the few 1:2 triiodide structures with cations suitable for our purpose that have been reported to date (Table 8). As would be expected, CdI_2 and CaF_2 are the principal aristotypes of the 1:2 compounds.

With cations smaller than Rb^+, hydration of the 1:1 triiodides is favoured under ordinary conditions, strongly for Li^+ and Na^+, less so for K^+; $KI_3 \cdot H_2O$ appears to be at the dividing line between the anhydrous and the hydrated salts. The structures of the mixed-anion monohydrates $KIBr_2 \cdot H_2O$ and $KICl_2 \cdot H_2O$ are also known (Table 1), but the effect of the single H_2O molecule on the packing type is not discussed in the original papers. We therefore take advantage of this serendipity to examine these trihalides in the light of the above concerns.

Table 8. Ion packing in simple triiodide structures.[a]

Compound	V_1, Å^3	Type	cat/an
1:1 Triiodides			
MI_3 (M = Tl, NH_4, Rb, Cs) (2, 34)	160–190	[NaCl]	1/1
2MI3	232	NaCl	1/1
4MI3	295	*anti*-NiAs	1/2
MCI3	310	[wurtzite]	1/1
N-Et-pyridinium I_3 (35)	310	not clear	1/1
Me_4PI_3 (1)	314	CsCl	2/3
$HMTI_3$ (36)	317	CsCl	1/1
QI3	318	*anti*-NiAs	1/2
TrI3	341	*anti*-NiAs	1/1
1,2,4-Me_3-pyridinium I_3 (35)	353	CsCl	1/1
$MHMTI_3$ (32)	354	CsCl	1/2
Et_4NI_3(*I*) (37)	380	CsCl	1/2
Et_4NI_3(*II*) (37)	383	CsCl	1/2
1-Azoniapropellane I_3 (1)	389	CsCl	6/7
$MeEt_2PhNI_3$ (38)	410	CsCl	1/2
1:2 Triiodides			
$[Zn(NH_3)_4](I_3)_2$ (39)	429	[b]	1/1
Da2I3	435	$[CaF_2]$	1/2
2Mpip2I3	462	CdI_2	1/1
Mpip2I3w	465	CdI_2	1/1
4Men2I3	484	CdI_2	1/1
4Mpr2I3	506	Not clear	2/4
[Ni(*N*-Me-imidazole)$_6$]$(I_3)_2$ (40)	1013	CaF_2	1/1

[a]See Table 1 for codes and references; cat/an, number of nonequivalent cations to number of nonequivalent anions. HMT, hexamethylenetetrammonium(1+); MHMT, 1-Me-hexamethylenetetrammonium(1+). Brackets indicate strong distortion of ideal packing type.

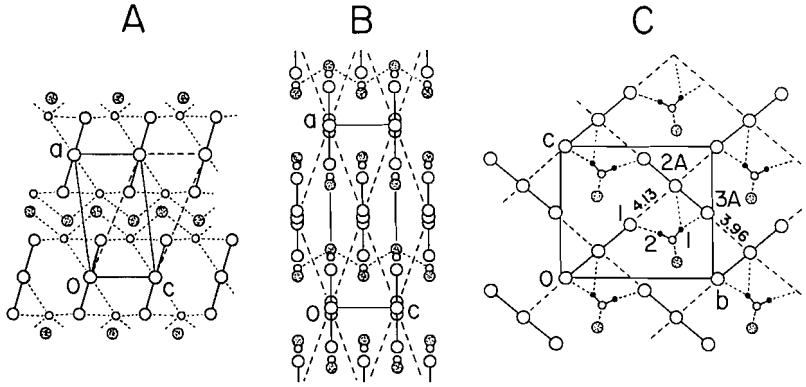
[b]Arrangement of cation and anion centroids strongly reminiscent of that in α-quartz (low-temperature, same space group).

The three structures are compared, in matching projections, in Fig. 16. In $KI_3 \cdot H_2O$ (neutron diffraction) the packing is of the CsCl type, with the anions in sheets ||(100) and the H_2O molecules and the K^+ ions alternating in infinite zigzag $[...K...OH_2...]_\infty$ chains ||*a*. The two O—H bonds and two K atoms at a mean K...O distance of 2.76[1] Å coordinate the O atom tetrahedrally, so that the structure can be formulated as a distorted CsCl arrangement of $[H_2O(K_{1/2})_2]^+$ cations and I_3^- anions. The shortest inter-anion I...I separation is 3.960(3) Å, between mutually perpendicular anions, i.e., the anions are discrete. The H(1) atom is involved in an asymmetrically trifurcated O—H(1)...I(3A), I(3B), I(2B) bond and H(2) in an asymmetrically bifurcated O—H(2)...I(1), I(1C) bond (see under Hydrogen bonding).[15]

The $KIBr_2 \cdot H_2O$ structure is of the *anti*-NiAs type. Its *Pnnm* unit cell *O*, like those of the isostructural 4MI3 and QI3, can

[15] Atom numbering as in the original reference. A, x, $1 - y$, $\frac{1}{2} + z$; B, $1 + x$, $1 - y$, $\frac{1}{2} + z$; C, $1 + x$, y, z.

Fig. 16. $KIX_2 \cdot H_2O$ structures (Table 1). (*A*) $KICl_2 \cdot H_2O$, $P2_1/m$, projection on (010), *anti*-NiAs type. (*B*) $KIBr_2 \cdot H_2O$, *Pnnm*, projection on (010), *anti*-NiAs type. (*C*) $KI_3 \cdot H_2O$, *Pc*, projection on (100), CsCl type; in the projection, atom I(2B) coincides with I(2A), and I(3B) with I(3A). Circles: large, halogen atoms; stippled, K; small open, O; small filled, H. Lines: solid, reported unit cells; broken, ion-packing cells; dotted, O—H(O)...X bonds (established or putative) and shortest K...O contacts. In the *A* and *B* ion-packing cells the anions at the cell corners represent two vertically superposed anions each, with their centre I atoms at $y = 0$ and $\frac{1}{2}$. Atom numbering as in the original references.



be converted into a pseudohexagonal cell *H* by the transformation described in ref. 1 (a_{OH}/c_{OH} = 2.775, ideal $\sqrt{3}$ = 1.732; $2b_O/(a_O^2 + c_O^2)^{1/2}$ = 2.015). All the atoms are located in 002 mirror planes at $z = 0, \frac{1}{2}$. Half the anions are ~||*b* and half are ~||(010). The oxygen atom is coordinated by two K atoms (O...K, 2.75(2) Å), two Br(1) atoms (O...Br(1), 3.64(2) Å), and two Br(2) atoms (O...Br(2), 3.60(2) Å).[16] The two H atoms, though not located, unless positionally disordered must also be in the mirror planes and involved in a symmetrically bifurcated bond each, H(1)...Br(1),Br(1′), H(2)...Br(2),Br(2′). The near coordination of the oxygen atom is thus tetrahedral. The ...O...K...sequences form zigzag chains ||*c*, and the ...an...O...an...O... sequences form folded chains ||*b*.

The monoclinic $P2_1/m$ unit cell of the simple $KICl_2 \cdot H_2O$ structure itself constitutes a distorted quasi-hexagonal *anti*-NiAs cell. The similarity with the aristotype is even more evident in the transformed cell of Fig. 16*A* (a/c = 1.842, $2b/(a^2 + c^2)^{1/2}$ = 2.106). The anions are approximately in 010 planes. The coordination of the O atom again is tetrahedral, with the two K atoms at 2.77 and 2.84 Å, respectively.[16] The two mirror-related H atoms were not located, but from geometric considerations they are almost certain to engage in trifurcated H-bonds: O...Cl = 3.41 and 3.68 Å, O...I = 3.86 Å. The K and O atoms form planar zigzag chains in 020 planes at $y = \pm\frac{1}{4}$.

The shortest K...O distance is almost the same in the three structures, 2.75–2.77 Å. The hydrated K^+ ion can thus be regarded as a composite cation and the structures can be reformulated as $[K(OH_2)]^+IX_2^-$. This is consistent with the ion packing types found for the three monohydrates: the *anti*-NiAs type corresponds to the smaller V_1 values, 167 and 174 Å^3 (for X = Cl and Br, respectively), and the CsCl type to V_1 = 201 Å^3 for X = I. A direct comparison of the mixed-halide salts with triiodides cannot be made because of the anion size mismatch, but it should be noted that $CsBr_3$, $CsIBr_2$, $CsBrI_2$, and CsI_3 (V_1 = 156, 164, 174, and 190 Å^3, respectively; refs. 34, 41–45) have all been reported as having the strongly distorted NaCl-type *Pnma* structures, while $CsICl_2$ (V_1 = 141 Å^3, refs. 46 and 47) is rhombohedral, $R\bar{3}m$, i.e., of a packing type characteristic of ABX_3 (X = O, S, Se, Te) compounds with small cations and considered to represent a transition type between NaCl and CsCl. This is in agreement with the general observation that the *anti*-NiAs triiodides have larger V_1 values than the distorted-NaCl triiodides (1). However, the V_1 = 201 Å^3 of $KI_3 \cdot H_2O$, which can be compared with the other triiodides in Table 8, is too small to be expected, on the V_1 criterion, to correspond to a CsCl-type packing. The reason for this discrepancy is not clear at present.

Bonding in 2PhII3

It is instructive to examine in some detail the changes that occur in the centrosymmetric $[...I(cat)...I(an)...]_2$ ring dimer when the simple I^- anion in 2PhII is replaced by the terminal I(3) atom of the I_3^- anion perpendicular to the ring plane in 2PhII3 (Figs. 5*B*, *C* and 6). The mean I(cat)...I(an) distance in 2PhII, 3.44 Å, is lengthened in 2PhII3 to 3.59 Å, i.e., by 0.15 Å ~ 4.5%. This increase is attributable to the weakening of the I(cat)...I(an) bonding interaction attendant on the decrease of the full anionic charge of −1 e on I^- to a partial charge on I(3). The net (Mulliken) charge ϵ on a terminal atom of a free, linear symmetric I_3^- anion has been estimated from ab initio calculations (25) to be −0.54 e. However, on I(3) it must be less, owing to the strong asymmetry of the anion. The asymmetry arises (though probably not exclusively) from a weakening of the I(3)—I(1) bond in consequence of an I(2)...I(2B) bonding interaction at the other end

[16] The interatomic distances and angles were calculated, or recalculated, from the atom coordinates in the original references. They do not always agree exactly with the distances and angles tabulated there.

of the anion in the 2PhII3 crystal (Fig. 5*A*; this point is discussed in ref. 1).

On the assumption that the bonding in I_3^- is of the 3c4e type, i.e., through p_z–p_z overlap (25), the interaction of I(3) with I(4) and I(4A) would be through the p_x, p_y orbitals on I(3) perpendicular to the I(3)—I(1) bond. This is supported by the closeness of the I(4)-I(3)-I(4A) angle to 90°. Some electron density might thus be diverted from the p_z orbital on I(3) to p_x and p_y, further weakening the I(3)...I(4) and I(3)...I(4A) bonding interactions.[17]

A conspicuous feature of the 2PhII3 and 2PhII structures is the coplanarity of the I—C(α) bond with the centrosymmetric ring dimer. Similar planarity is observed in 2PhICl and 2PhIBr, isostructural with 2PhII, and also in 2PhIN.[18] In the latter, the cation is part of an infinite, ipsolateral (*cis*) zigzag...O(2″)...I[C(α),C*(α)]...O(2)...I′[C(α′),C*(α′)]... chain; C(α)-I-C(α′) = 92.03(3)°, O(2)-I-O(2″) = 110.6(4)°, with the asymmetric IC(α)C(α′)O(2)O(2″) unit almost planar (mean deviation from the best plane, 0.07[5] Å).

The planarity of the I^+ coordination and the closeness of the C(α)-I-C(α′) angle to 90° suggest that the bonding at the I^+ atom, too, utilizes principally the *p* orbitals, so that the I^+—C(α) bond will be of the $p(I) - sp^3(C)$ type. When the X atoms completing the ring dimer are replaced by more diffuse ligands, e.g., in 2PhITB, the C(α)-I-C(α′) angle appears to increase, i.e., the bond character begins to change from $p(I)$ to $sp^3(I)$. While this interpretation is consistent with the observed coordination geometry at the I^+ atom, the geometric evidence that can be adduced at present in support of the above interpretation leaves something to be desired. This is due in part to the difficulty of locating, with sufficient accuracy, a C atom next to an I atom. Not only are the bond-length and bond-angle comparisons involving the C atoms tenuous, but, more generally, reliable means for I—C bond lengths of different orders do not exist as yet, thus preventing calibration of the observed I—C distances in the Ph_2I^+ structures.

The weighted means of *d*[I—C(α)] and C(β)-C(α)-C(β′), 2.105[24] Å and 122.8[8]°, respectively (Table 6), appear to fit in well with the findings of Domenicano et al. (48, 49) on the effects of exocyclic substitution on the benzene ring.

Information from ^{127}I NQR spectra

A number of triiodides (as well as heteroatomic trihalides) have been studied by ^{127}I NQR spectroscopy (50–53). By a fortunate coincidence they include 2MI3 and the previously (1) reported 4MI3.

Only two resonances were detected in the room-temperature spectrum of 2MI3 in the 70–600 MHz frequency region (52, 53). These were assigned as the ν_1 resonance frequencies of the centre and the terminal atoms, respectively, of a symmetric I_3^- anion, consistent with the result of our structure determination (Table 4). The two resonances persisted down to dry ice and liquid-nitrogen temperatures, pointing to the absence of a structural transition in the observed temperature range.

The 4MI3 structure at room temperature contains two nonequivalent centrosymmetric I_3^- anions. These would be expected to give rise to six resonances in the above frequency region, analogous to $Et_4NI_3(I)$ (37, 52, 53). However, *fifteen* resonance lines were observed in the 140–400 MHz region of the 4MI3 spectrum at liquid-nitrogen temperature, six of which were present also in the −77°C spectrum but disappeared at ca. −60°C; between ca. −196°C and −60°C their frequencies varied smoothly with temperature (52, 53). In contrast, only the six lines were reported in the 77 K spectrum of ref. 50. The presence of the 15 lines was interpreted as arising from 3 nonequivalent asymmetric I_3^- anions in the 4MI3 crystal. The apparent discrepancy between the two sets of spectra and the expectation from the room-temperature crystal structure can be reconciled if one recalls that in the room-temperature structure the cations are positionally disordered and the U_{ii} values of some of the I atoms are unusually high. It is therefore reasonable to assume that on cooling the structure will progressively order until somewhere below −77°C an order–disorder transition temperature is reached. The inability to observe more than six lines in the liquid-nitrogen spectrum of ref. 50 might have been due to instrumental factors or to rapid cooling of the sample that may have quenched the ordering process.

Conclusions

The results of the structure determinations of the title compounds have been used to consolidate the body of structural information on triiodides of small compact monovalent and, in particular, divalent cations. The *general* conclusions arising from the present and the preceding (1) investigations are as follows.

1. The ion-packing type of a triiodide of a small, compact cation can be related to the volume V_1 per formula unit. This permits a rough classification (Table 8): in 1:1 triiodides, small V_1 values correspond to the (distorted) NaCl type, intermediate V_1 values to the *anti*-NiAs type, and large V_1 values (up to $V_1 \sim 400$ Å^3) to the CsCl type. In the intermediate range the classification is not clear-cut and at present only provisional.

A comparable classification of 1:2 triiodide structures is tenuous owing to the paucity of data. Of the four 1:2 title compounds, three are clearly of the CdI_2 type, with strings of I_3^- anions forming hexagonal channels, which accommodate the cations. The cation centroids are positioned on the channel axes in a way that minimizes steric interference with the channel framework, i.e., the cation position relative to the gaps between successive anions in the strings varies with the cation geometry (the "vernier" effect). The fourth 1:2 structure, though more complex, is related to the other three.

2. The information on N—H(N)...I bonds provided by the structures of the title compounds has made it possible to demonstrate an unmistakable correlation between the H(N)...I and N...I distances, both in unbranched and branched H-bonds (Fig. 15).

3. On the supportable assumption that the I_3^- anion is a 3c4e system we have established the validity of the functional relationship between the two I—I bond lengths, *d*(I—I) and

[17] The question of how the presence of I...I bonding interactions perpendicular to the I_3^- axis affects the strength of the I—I bond in the anion, of crucial importance for bonding in the higher polyiodide anions, will be discussed in a later paper in this series.

[18] The mean deviations of the C(α) atoms from the halogen-ring planes are 0.06[2], 0.12[1], 0.13[5], and 0.21[3] Å for 2PhICl, 2PhIBr, 2PhII, and 2PhII3, respectively. In 2PhIN the mean deviation of the C(α) atoms from the I-O(2)-O(2″) plane is 0.16[4] Å.

d^*(I—I), in the ion: $d^* - d_0 = K(d - d_0)^{-c}$, where $d^* \geq d$ and d_0 is the bond length in the free I_2 molecule. Analysis of the available data for discrete I_3^- ions in crystals shows that the asymmetry of the anion can arise from various factors resident in the crystal, of which H-bonding is one but not a *preferential* one (Figs. 13 and 14).

4. An insight into the bonding in the centrosymmetric I_4 ring in the $(Ph_2I)I_3$ structure can be gained from a comparison with the structures of $(Ph_2I)I$ and other Ph_2I^+ salts.

Experimental

The title compounds were prepared by combining a solution of the appropriate iodide in a suitable solvent (mostly MeOH) with a stoichiometric amount of an MeOH solution of iodine, and allowing the resulting solution to crystallize by controlled evaporation at room temperature. The triiodides were recrystallized if required. However, controlling the size and quality of the crystals was not without problems, as large crystals had to be sectioned, not always with entirely gratifying results.

A Rigaku AFC5R system (2.4 kW sealed Mo-anode tube, λ(Mo Kα) = 0.710 690 Å, graphite monochromator; T = 21(2)°C) was used in the data acquisition. All intensities were corrected for Lorentz, polarization, absorption (ψ-scans), and secondary extinction as well as for time-decay effects when appropriate. The anisotropic temperature factor is defined as $\exp[-2\pi^2(U_{11}h^2a^{*2} + ... + 2U_{23}klb^*c^* + ...)]$. The structures were solved by direct methods (54) and refined by full-matrix least squares using the TEXSAN-TEXRAY software package (55) except for 4Men2I3, where the SHELXL-93 system (56) was used to model cation disorder (see below). The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with unit weights. Since the H atoms were placed geometrically (C—H, 1.08 Å, N—H, 1.02 Å) and not refined (U_{iso}(H) = $1.2U_{eq}$(C, N) of the attached atom), no esd's are quoted on distances and angles involving H atoms. The residual electron-density maxima were all close to the iodine atoms.

Tables of structure factors are available from the Editorial Office.

TrI3

The absolute structure parameter for the reported structure was −0.02(2). The thermal motion of the cation conforms moderately well to the rigid-body-motion model: rms(U_{ij}) = 0.0045 Å^2, rms[esd(U_{ij})] = 0.0064 Å^2 with all C atoms included; with the *N*-methyl carbon omitted, rms(U_{ij}) = 0.0037 Å^2, rms[esd(U_{ij})] = 0.0063 Å^2. The largest mean amplitude about a principal axis of libration was 5.5°. The mean librational correction to the bond lengths in the cation skeleton was 0.008[2] Å; that to the bond angles did not exceed |0.15|°.

4Men2I3

Straightforward refinement without constraints in $p2_1/a$ gave an acceptable structure, but some of the U_{ii} of the cation atoms, in particular U_{11}(C), were large and the C—N and C—C distances not reasonably close to expectation. Various attempts to resolve the difficulty by modelling positional disorder in the cation were made, none of them satisfactory. In the end the C—N and C—C distances were constrained and the structure refined in SHELXL-93, with the results as reported in Tables 4, A, and B. In this instance the function minimized was $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$ and the weighting scheme was $w^{-1} = \sigma^2(F_o^2) + (0.0427p)^2 + 7.74p$, $p = [(F_o^2)_{max} + 2F_c^2]/3$.

Synthesis of 1-alkoxy-1,2,3,4-tetrahydrocarbazoles by mercury(II) mediated heterocyclization of 2-cyclohex-2′-enyl-*N*-alkylanilines[1]

K.C. Majumdar and U. Das

Abstract: The title compounds **3**(*a–i*) were synthesized in high yields by the mercury(II) mediated heterocyclization of 2-cyclohex-2′-enyl-*N*-alkylanilines **2**(*a–g*), which in turn were obtained by the acid-catalyzed amino Claisen rearrangement of 3-*N*-alkylanilinocyclohexenes **1**(*a–g*). Additional supporting evidence for the structure of product **3** was obtained from chemical transformations.

Key words: 1-alkoxy tetrahydrocarbazole, mercury(II) mediated heterocyclization, amino Claisen rearrangement, 3-*N*-methylanilinocyclohexene.

Résumé : On a synthétisé les composés mentionnés dans le titre, **3***a–i*, avec des rendements élevés par le biais de l'hétérocyclisation catalysée par le mercure(II) de (2-cyclohex-2′-ényl)(*N*-alkyl)anilines, **2***a–g*, qui ont été par ailleurs obtenues par un réarrangement amino de Claisen, catalysé par les acides, des 3-*N*-alkylanilinocyclohexènes, **1***a–g*. Des transformations chimiques ont permis d'obtenir des données additionnelles relatives à la structure du produit **3**.

Mots clés : 1-alkoxytétrahydrocarbazole, hétérocyclisation catalysée par le mercure(II), réarrangement amino de Claisen, 3-*N*-méthylanilinocyclohexène.

[Traduit par la rédaction]

Introduction

Organomercurials (2) have been known since 1852 and many synthetic routes to these compounds presently exist. The ability of these compounds to accommodate a wide variety of functional groups and to tolerate quite diverse reaction conditions is well documented (3). Of the various processes involving organomercurials, solvomercuration–demercuration is the most widely used in organic synthesis (4). Aminomercuration–demercuration has been utilized for the synthesis of nitrogen heterocycles by employing unsaturated amine compounds (5). In the case of solvomercuration and aminomercuration, reduction is essential to get rid of mercury from the initial product (6).

During our work on sigmatropic rearrangements (7) we became interested in the cyclization of 2-(2′-cyclohexenyl)-*N*-methylaniline **2**; however, our attempt failed (8) although such a scheme had worked fairly well with oxygen analogues (9). We then considered mediation of mercury(II) for this heterocyclization. Herein we report the results of this investigation.

The starting materials 2-(2′-cyclohexenyl)-*N*-alkylanilines **2**(*a–g*) were prepared by the acid-catalyzed aza-Claisen rearrangement of 3-*N*-alkylanilinocyclohexenes **1**(*a–g*), by refluxing in ethanolic hydrochloric acid (10). The tertiary amines **1** were prepared from 3-bromocyclohexene and the appropriate amines by refluxing in acetone in the presence of anhydrous potassium carbonate (Scheme 1).

Results and discussion

It has been reported (6*a*, 11) that aminomercuration reactions can be performed in aqueous THF as well as under anhydrous conditions with no detectable formation of oxymercurated products. Our attempt to react substrate **2***a* with mercury(II)acetate in aqueous tetrahydrofuran or under anhydrous conditions resulted in the formation of only an amine complex. Barluenga et al. (12) established that aminomercuration of olefins with mercury(II) acetate is an irreversible process that only leads to kinetically controlled products, whereas oxymercuration leads to thermodynamically controlled products. Hence for the problem under consideration, our attention has been to divert the reaction by reducing the lone pair availability on the nitrogen of substrate **2***a*. To achieve this a small amount of acetic acid was added to the reaction mixture. Reaction was monitored by thin-layer chromatography (tlc); starting material was consumed in 48 h with precipitation of metallic mercury. Workup and chromatographic separation furnished **3***a*, mp 51°C in 80% yield, along with 10% of another product, mp 180°C, which is considered to be an N-

mercurated complex from its ^{1}H NMR and IR data. When an excess of acetic acid is added to the reaction mixture, compound **3***a* is exclusively obtained.

The product **3***a* showed absence of N-H (free) and indicated the presence of an ether linkage at 1050 and 1250 cm^{-1}. The ^{1}H NMR spectrum of **3***a* exhibited two singlets at δ 3.45(3H) and δ 3.72(3H) indicating the presence of -OCH_3 and -NCH_3, respectively. The triplet at δ 4.5(1H) is very characteristic and is assignable to the hydrogen at C-1 of the tetrahydrocarbazole derivative **3***a*. The mass spectrum of compound **3***a* showed a molecular ion at *m/e* 215 and a base peak *m/e* 184 (M−31), among others. The ^{13}C spectrum of compound **3***a* shows the presence of all 14 carbons in the molecule. From the DEPT experiment the presence of five C-H signals as well as one -OCH_3 and one -NCH_3 signal can be established. In addition it also reveals the presence of three -CH_2 signals. All these data are accommodated in terms of the following ^{13}C assignments: δ: 18.790 (C3), 20.930 (C4), 26.996 (C2), 28.874 (-NCH_3), 55.241 (-OCH_3), 70.214 (C1), 108.563 (C8), 112.042 (C4a), 118.285 (C6), 118.472 (C5), 126.136 (C4b), 127.467 (C7), 133.655 (C1a), 137.166 (C8a). These assignments were further supported by HETCOR experiment. Protonated carbon resonance assignments were established by direct correlation with proton resonances by HETCOR with normal one-bond C–H coupling, and nonprotonated resonances (C4a, C4b, C8a, and C9a) were assigned convincingly by comparison with literature chemical shifts of the indole alkaloid, indoloquinolizideine (13). The above spectral data and elemental analysis suggested this to be 1-methoxy-9-methyl-1,2,3,4-tetrahydrocarbazole **3***a* (Scheme 2). The following transformations were carried out to get further supporting evidence in favour of structure **3***a*. Dehydrogenation of product **3***a* with DDQ in refluxing xylene for 12 h afforded 1-methoxy-9-methyl carbazole, **4**, a viscous oil, in 83% yield. The same reaction when conducted for a longer period (20 h) with excess of DDQ furnished *N*-methyl carbazole (14), **5**, mp 85°C, yield 30%, and carbazole, **6**, mp 242°C, yield 60%. Dehydrogenation of product **3***a* with palladized charcoal in refluxing diphenyl ether gave only carbazole **6** in 20% yield (Scheme 3).

The reaction was repeated in ethanol and *n*-propanol to give products **3***b* and **3***c* as viscous oils in 85% and 75% yields, respectively. The reaction was generalized by using various substrates **2**(*b–g*) to give products **3**(*d–i*) in 70–82% yields (Scheme 2).

Mercuric acetate is a well-known oxidizing and dehydrogenating agent (15). The formation of **3** from **2** is easily explicable by "pathway a" through species **7**, **8**, **9**, **10**, and **11**. Intermediate **11**, being very unstable under the reaction conditions, becomes dehydrogenated by mercury(II) acetate to product **3**. An alternative "pathway b," where oxidation of **2** by mercury(II) acetate may give an imine **12** followed by cyclization to intermediate hexahydrocarbazole **11**, may also be considered.

The reaction of substrate **2***a* with mercuric acetate in methanol at room temperature without the addition of acetic acid (48 h) furnished product **3***a* in 30% yield. This reaction also gave oxidized product **5** (30%, mp 85°C) along with another inseparable mixture of products (Scheme 2). An attempt to cyclize **2** in a stronger acid, viz. trifluoroacetic acid, also gave the same product **3** but at a much faster rate (16 h instead of 24 h). We were also unsuccessful in our attempt on a similar cyclization of the N-acetyl derivative of **2**, in which there is no hydrogen on the nitrogen, to form the imine **12**.

Several alkoxycarbazoles, including 1-methoxycarbazole, are natural alkaloids (16) and their syntheses involve longer routes. It may be noted here that the simple heterocyclization reported here affords 1-alkoxytetrahydrocarbazoles in a single step and high yields. By using different alcohols as solvent, the reaction gives different 1-alkoxytetrahydrocarbazoles. The reaction has been found to be regioselective and a general one for the synthesis 1-alkoxytetrahydrocarbazoles.

Experimental

Melting points were determined in a sulphuric acid bath and are uncorrected. IR spectra were run on a Perkin–Elmer 1330 apparatus using KBr discs, and UV absorptions were recorded on a Hitachi 200-20 spectrometer for solutions in absolute ethanol. ^{1}H NMR spectra were determined for deuteriochloroform solutions with $SiMe_4$ as internal standard on Bruker WH-400 (400 MHz) or Jeol Fx-100 (100 MHz) instruments at the Indian Institute of Chemical Biology, Calcutta, and on a Bruker AC-250 (250 MHz) spectrometer at the Universität Konstanz, Germany. Elemental analyses and recording of mass spectra were carried out by R.S.I.C.(CDRI), Lucknow. Silica gel (60–120 mesh) and neutral alumina were obtained from SRL, India. Extracts were dried over anhydrous sodium sulphate. Petroleum ether refers to the fractions of bp 60–80°C. Compound **1***a* was prepared according to a published procedure (10).

General procedure for the preparation of 3-*N*-alkylanilinocyclohexenes 1(*b–g*)

A mixture of *N*-alkylaniline (0.1 mol) and 3-bromocyclohexene (0.1 mol) in dry acetone (150 mL) was refluxed in the presence of anhydrous potassium carbonate (10.0 g, excess) for 5 h. The reaction mixture was then cooled, filtered, and

General procedure for the preparation of 2-(2′-cyclohexenyl)-*N*-alkylanilines 2(*a–g*)

Compound **2***a* was prepared according to a published procedure (10). A mixture of compound **1**(*b–g*) (0.1 mol), concentrated HCl (0.8 mL), and ethanol (10 mL) was refluxed for 15 h. After neutralization and extraction with $CHCl_3$, the solvent was evaporated and the rearranged amines were isolated by column chromatography over silica gel using petroleum ether as eluant.

Compound **2**b: yield 88%, viscous liquid; λ_{max}: 211 (log ε 3.20), 248 (2.70), 300 (2.10) nm; ν_{max}: 3400, 3010, 2920, 1500, 1390, 800 cm^{-1}; ^1H NMR (100 MHz) δ: 1.56–1.88 (m, 4H), 2.04–2.16 (m, 2H), 2.24 (s, 3H), 2.84 (s, 3H), 3.04–3.72 (br s, 2H), 5.60–5.84 (m, 1H), 5.88–6.08 (m, 1H), 6.56 (d, 1H, J = 8 Hz), 6.80–7.08 (m, 2H); *m/z*: 201 (M^+). Anal. calcd. for $C_{14}H_{19}N$: C 83.53, H 9.51, N 6.96%; found: C 83.79, H 9.70, N 7.22%.

Compound **2**c: yield 50%, viscous liquid; λ_{max}: 209 (log ε 3.20), 256 (3.00), 309 (2.10) nm; ν_{max}: 3400, 3020, 2900, 1390, 1120, 790 cm^{-1}; ^1H NMR (100 MHz) δ: 1.60–2.00 (m, 4H), 2.04–2.20 (m, 2H), 2.84 (s, 3H), 3.12–3.40 (br s, 1H), 3.40–4.08 (br s, 1H), 5.56–5.88 (m, 1H), 5.88–6.12 (m, 1H), 6.50 (d, 1H, J = 8 Hz), 7.12–7.36 (m, 2H). Anal. calcd. for $C_{13}H_{16}BrN$: C 58.66, H 6.06, N 5.26%; found: C 58.92, H 5.79, N 4.98%.

Compound **2**d: yield 50%, viscous liquid; λ_{max}: 211 (log ε 3.20), 248 (2.70), 300 (2.10) nm; ν_{max}: 3380, 3020, 2920, 1400, 750 cm^{-1}; ^1H NMR (100 MHz) δ: 1.32–1.96 (m, 4H), 2.00–2.12 (m, 2H), 2.34 (s, 3H), 2.78 (s, 3H), 2.92–3.02 (m, 1H), 3.48–3.92 (br s, 1H), 5.60–5.84 (m, 1H), 5.84–6.08 (m, 1H), 6.80–7.16 (m, 3H); *m/z*: 201 (M^+). Anal. calcd. for $C_{14}H_{19}N$: C 83.53, H 9.51, N 6.96%; found: C 83.78, H 9.20, N 6.70%.

Compound **2**e: yield 90%, viscous liquid; λ_{max}: 209 (log ε 3.20), 247 (2.80), 293 (2.20) nm; ν_{max}: 3400, 3020, 2920, 1580, 1400, 740 cm^{-1}; ^1H NMR (100 MHz) δ: 1.24 (t, 3H, J = 7 Hz), 1.60–1.88 (m, 4H), 2.00–2.16 (m, 2H), 3.16 (q, 2H, J = 7 Hz), 3.32–3.56 (m, 1H), 3.56–3.96 (br s, 1H), 5.56–5.80 (m, 1H), 5.84–6.08 (m, 1H), 6.56–6.76 (m, 2H), 7.00–7.24 (m, 2H); *m/z*: 201 (M^+). Anal. calcd. for $C_{14}H_{19}N$: C 83.53, H 9.51, N 6.96%; found: C 83.85, H 9.22, N 7.22%.

Compound **2**f: yield 90%, viscous liquid; λ_{max}: 210 (log ε 3.20), 247 (2.80), 299 (2.20) nm; ν_{max}: 3380, 3020, 2920, 1400, 1260, 800 cm^{-1}; ^1H NMR (100 MHz) δ: 1.24 (t, 3H, J = 7 Hz), 1.60–1.88 (m, 4H), 2.00–2.12 (m, 2H), 2.22 (s, 3H), 3.14 (q, 2H, J = 7 Hz), 3.28–3.64 (br s, 2H), 5.60–5.80 (m, 1H), 5.88–6.08 (m, 1H), 6.56 (d, 1H, J = 8 Hz), 6.80–7.00 (m, 2H); *m/z*: 215 (M^+). Anal. calcd. for $C_{15}H_{21}N$: C 83.67, H 9.83, N 6.50%; found: C 83.48, H 10.01, N 6.75%.

Compound **2**g: yield 66%, viscous liquid; λ_{max}: 210 (log ε 3.30), 233 (3.10), 296 (2.50) nm; ν_{max}: 3400, 3040, 1600, 1400, 1320, 750 cm^{-1}; ^1H NMR (100 MHz) δ: 0.84–1.08 (t, 3H), 1.40–1.88 (m, 8H), 2.00–2.16 (m, 2H), 2.24 (s, 3H), 3.12 (t, 2H, J = 7 Hz) 3.15–3.64 (br s, 2H), 5.64–6.04 (m, 2H), 6.58 (d, 1H, J = 8 Hz), 6.84–7.04 (m, 2H); *m/z*: 243 (M^+). Anal. calcd. for $C_{17}H_{25}N$: C 83.90, H 10.35, N 5.75%; found: C 84.20, H 10.55, N 5.96%.

General procedure for the preparation of 1-alkoxy-9-alkyl-1,2,3,4-tetrahydrocarbazoles 3(*a–i*)

A solution of Hg(II) acetate (1.60 g, 5 mmol) in alcohol (50 mL) was added to a stirred solution of compound **2**(*a–g*) (5 mmol) and glacial acetic acid (0.3 mL) in the same alcohol (10 mL) at room temperature. Stirring was continued for 24 h during which time a black precipitate of mercury separated out. This was filtered off and the solvent was removed. The residue was extracted with chloroform. The chloroform extract was washed successively with sodium bicarbonate solution and brine, and dried (Na_2SO_4). Solvent was removed and the viscous oil obtained was subjected to column chromatography over silica gel using petroleum ether as eluant.

Compound **3**a: yield 80%, mp 50°C; λ_{max}: 242, 295 nm; ν_{max}: 2930, 1611, 1470, 1383, 1310, 1080 cm^{-1}; ^1H NMR (400 MHz) δ: 1.70–2.10 (m, 3H), 2.22–2.30 (m, 1H), 2.50–2.72 (m, 1H), 2.78–2.90 (m, 1H), 3.45 (s, 3H), 3.72 (s, 3H), 4.50 (t, 1H, J = 2.9 Hz, J = 3.6 Hz), 7.03–7.55 (m, 4H); ^{13}C NMR (vide supra); *m/z*: 215 (M^+). Anal. calcd. for $C_{14}H_{17}NO$: C 78.10, H 7.96, N 6.51%; found: C 78.41, H 8.16, N 6.73%.

Compound **3**b: yield 85%, viscous liquid; ν_{max}: 2950, 1660, 1600, 1472, 1385, 1320, 1090 cm^{-1}; ^1H NMR (100 MHz) δ: 1.20–1.35 (t, 3H), 1.75–3.10 (m, 6H), 3.70 (s, 3H), 3.44–3.82 (m, 2H), 4.60 (t, 1H), 7.00–7.60 (m, 4H); *m/z*: 229 (M^+). Anal. calcd. for $C_{15}H_{19}NO$: C 78.56, H 8.35, N 6.11%; found: C 78.88, H 8.01, N 6.36%.

Compound **3**c: yield 75%, viscous liquid; ν_{max}: 2950, 1470, 1380, 1315, 1085 cm^{-1}; ^1H NMR (100 MHz) δ: 0.92–1.05 (t, 3H), 1.64–2.84 (m, 8H), 3.72 (s, 3H), 3.40–3.84 (m, 2H), 4.60 (t, 1H) 6.96–7.56 (m, 4H); *m/z*: 243 (M^+). Compound **3**g: yield 75%, viscous liquid; λ_{max}: 209 (log ε 3.00), 229 (3.30), 288 (2.60) nm; ν_{max}: 2920, 1440, 1380, 1080, 780 cm^{-1}; ^1H NMR (100 MHz) δ: 1.28–1.44 (m, 3H), 1.84–2.24 (m, 4H), 2.56–2.88 (m, 2H), 3.44 (s, 3H), 4.00–4.28 (m, 2H), 4.44–4.60 (br s, 1H), 7.12–7.60 (m, 4H); *m/z*: 229(M^+). Anal. calcd. for $C_{15}H_{19}NO$: C 78.56, H 8.35, N 6.11%; found: C 78.33, H 8.12, N 6.24%.

Compound **3**h: yield 80%, viscous liquid; λ_{max}: 209 (log ε 2.80), 231 (3.00), 293 (2.30) nm; ν_{max}: 2920, 1400, 1080, 790 cm^{-1}; ^1H NMR (100 MHz) δ: 1.24–1.44 (m, 3H), 1.80–2.16 (m, 4H), 2.40 (s, 3H), 2.56–2.80 (m, 2H), 3.44 (s, 3H), 3.96–4.32 (m, 2H), 4.40–4.56 (br s, 1H), 7.04 (d, 1H, J = 2 Hz), 7.20–7.36 (m, 2H); *m/z*: 243 (M^+). Anal. calcd. for $C_{16}H_{21}NO$: C 78.97, H 8.70, N 5.76%; found: C 78.76, H 8.85, N 6.01%.

Compound **3**i: yield 82%, mp 82°C; λ_{max}: 209 (log ε 3.00), 216 (2.70), 234 (2.80) nm; ν_{max}: 3000, 2960, 2840, 1100, 780 cm^{-1}; ^1H NMR (250 MHz) δ: 0.97 (t, 3H, J = 7.3 Hz), 1.31–1.46 (m, 2H), 1.55–2.28 (m, 6H), 2.43 (s, 3H), 2.55–2.86 (m, 2H), 3.45 (s, 3H), 3.94–4.17 (m, 2H), 4.47 (t, 1H, J = 3.3 Hz, J = 3.6 Hz), 6.98 (d, 1H, J = 2 Hz), 7.01 (d, 1H, J = 2 Hz), 7.13 (d, 1H, J = 8 Hz). Anal. calcd. for $C_{18}H_{25}NO$: C 79.66, H 9.28, N 5.16%; found: C 79.96, H 8.96, N 5.44%.

Aromatization of 3*a* with DDQ, 4

The compound **3***a* (0.43 g, 2 mmol) was refluxed with DDQ (1.12 g, 4 mmol) in dry xylene (20 mL) for 12 h. The reaction mixture was cooled and filtered, and the residue was washed with chloroform (100 mL). The filtrate was washed with 10% potassium hydroxide solution and water, and dried (Na_2SO_4). The solution was then passed through a column of basic alumina and was eluted with chloroform to give a viscous oil.

Compound ***4***: yield 83%, viscous liquid; ν_{max}: 2950, 1610, 1315 cm^{-1}; ^1H NMR (100 MHz) δ: 3.96 (s, 3H), 4.12 (s, 3H), 7.20–7.84 (m, 7H); *m/z*: 211 (M^+). Anal. calcd. for $C_{14}H_{13}NO$: C 79.59, H 6.20, N 6.63%; found: C 79.36, H 5.94, N 6.88%.

Treatment of 3*a* with Pd–C in diphenyl ether, 6

To a solution of **3***a* (0.43 g, 2 mmol) in diphenyl ether (10 mL) was added 1 g of palladium charcoal (10%) and the mixture was heated at reflux for 4 h. The reaction mixture was filtered, diphenyl ether was removed, and the remaining mass was purified by column chromatography over basic alumina. Elution with petroleum ether furnished **6**.

Compound ***6***: yield 20%, mp 242°C; mixture mp and co-ir with authentic sample showed this to be carbazole.

The chemistry of cyclohexenediones produced by the blackleg fungus

M. Soledade C. Pedras

Abstract: Several oxidation products of metabolites produced by avirulent isolates of *Phoma lingam*, the blackleg fungus, are reported; in addition, the profile of metabolites common to *P. lingam* and *P. wasabiae* is clarified.

Key words: cyclohexenedione, *Phoma lingam, P. wasabiae*.

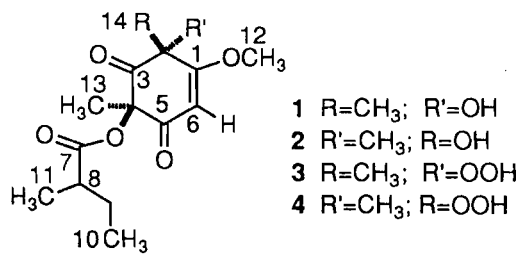
Résumé : On a étudié plusieurs produits d'oxydation tirés des métabolites produits par des isolats avirulents du *Phoman lingam*, un champignon; de plus, on a clarifié le profil des métabolites communs au *P. lingam* et au *P. wasabiae*.

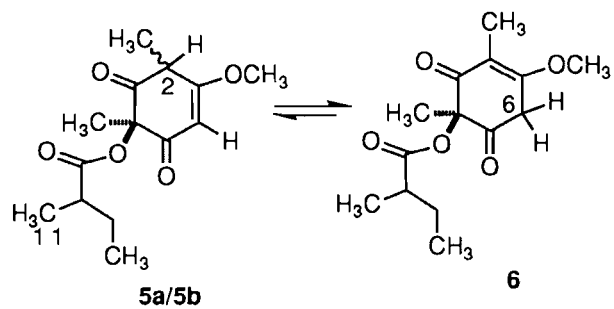
Mots clés : cyclohexènedione, *Phoma lingam, P. wasabiae*.

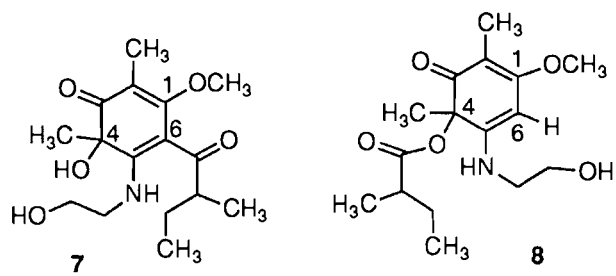
[Traduit par la rédaction]

Recent work on the so-called weakly virulent, avirulent, or nonaggressive isolates of the blackleg fungus (*Leptosphaeria maculans* (Desm.) Ces. et de Not., asexual stage *Phoma lingam* (Tode ex Fr.) Desm.) led to the isolation of several metabolites having a cyclohexenone ring as a common structural feature (1–3). Most importantly, this work revealed an unknown relationship between *P. lingam* and *P. wasabiae*. This unforeseen relationship[2] was also supported by analysis of particular DNA sequences of isolates of both species (3). As a consequence of that work, it was proposed that the avirulent isolates of *P. lingam* be formally reclassified (4).

As part of our continuing studies of the chemistry of the blackleg fungus,[3] it was important to determine the phytotoxicity of the cyclohexenones **1**, **2**, **5–8** produced by avirulent isolates. During the purification of these metabolites, unexpected products resulting from the slow oxidation of **5a/5b** and **6** were identified. Here is reported the transformation of phomaligadiones **5** and **6** and phomaligin A (**7**) to phomaligols **1** and **2**, and the intermediates of these oxidative transformations, as well as the products of reaction of phomaligadiones **5** and **6** with diazomethane. These results allow an important clarification regarding the structures of metabolites common to *P. wasabiae* and *P. lingam*. In addition, the implications of these findings on the biogenesis of the cyclohexenone-containing metabolites is discussed and the structures of metabolites common to *P. wasabiae* and *P. lingam* are noted.







Results and discussion

Phomaligols A (**1**) and A_1 (**2**), phomaligadiones A (**5a/5b**) and B (**6**), and phomaligin A (**7**) were obtained from culture extracts of *P. lingam*, as previously described (1, 3). Phomaligadiones constituted an inseparable yellowish mixture (**5a**:**5b**:**6**, ca. 3:1:2), homogeneous by TLC and HPLC, which

decomposed to a rather complex reddish mixture on standing. To determine the products resulting from decomposition of phomaligadiones, a solution of the mixture was left standing for 4 weeks at room temperature. Preparative TLC (CH_2Cl_2–MeOH, 97:3) of this mixture recovered 40% of phomaligadiones and four additional compounds. Analysis of the ^{1}H and ^{13}C NMR spectra of each compound revealed the structures of these components: phomaligols A (**1**) **and** $\mathbf{A_1}$ (**2**), and the corresponding hydroperoxides **3** and **4**. The structures of phomaligols A (**1**) and A_1 (**2**) were readily assigned by comparison of the ^{1}H and ^{13}C NMR spectra, and the optical rotation of each compound with data obtained previously (1). The structures of the hydroperoxides **3** and **4** were assigned from analysis of the spectroscopic data (NMR in Table 1) and reduction of the hydroperoxide groups to the corresponding alcohols, as described below.

The ^{1}H NMR spectra of compounds **3** and **4** were similar (within 0.05 ppm) to those of the corresponding alcohols **1** and **2** (1), except for H-6 at 5.67 ppm in **3** (5.53 ppm in **1**) vs. 5.71 ppm in **4** (5.53 ppm in **2**), and the D_2O exchangeable signals at 8.60 ppm in **3** (2.62 ppm in **1**) vs. 8.70 ppm in **4** (3.44 ppm in **2**). The molecular formula ($C_{14}H_{20}O_7$, obtained by HRCIMS) of each new compound, together with ^{1}H and ^{13}C NMR data, indicated that they might be hydroperoxides. Structures **3** and **4** were elucidated by analysis of the HMBC (6) and HMQC (7) spectra of each compound and by reduction of the hydroperoxide groups to the corresponding alcohols. Analysis of the HMBC and HMQC spectra of **3** and **4** indicated key correlations (Table 1) similar to those previously observed for **1** and **2** (1). For example, in compound **3** the methyl groups at δ_H 1.60 (H_3-13) and 1.59 (H_3-14) showed correlations with the carbonyl carbon at δ_C 202.8 (C-3); the methyl group at δ_H 1.59 displayed additional correlations with carbons at δ_C 84.6 (C-2) and δ_C 172.4 (C-1). The latter carbon (C-1) showed further correlations with an OMe group at δ_H 3.89 (H_3-12) and a methine proton at δ_H 5.67. The methine proton (H-6) was attached to a carbon at δ_C 102.0 (C-6) and displayed further correlations with carbons at δ_C 192.0 (C-5) and 81.0 (C-4) ppm. The methyl group at δ_H 1.60 (H_3-13) displayed an additional long-range correlation with the latter carbon (C-4). Similar correlations indicated in Table 1 were observed in compound **4**.

Finally the relative configurations of the C-2 and C-4 stereogenic centers of compounds **3** and **4** were assigned after reduction of the respective hydroperoxide groups with $P(OMe)_3$ and comparison of the spectroscopic data and optical rotation of each reaction product with those of **1** and **2**, respectively. Based on these results the relative configuration of compound **3** is *trans*, like that of **1**, and the relative configuration of compound **4** is *cis*, as is that of **2**. Similarly to phomaligadiones, phomaligin A (**7**) oxidized on standing. In attempting to purify a sample of **7**, which had been previously purified and stored at 0°C for several months, only 30% was recovered; alcohols **1** and **2**, (10%) and **8** (30%) were isolated, along with several minor unidentified products. A rearrangement of **7** to **8**, followed by oxidation and hydrolysis of the $NHCH_2CH_2OH$ group, would explain the spontaneous transformation of **7** to **1** and **2**.

Following the characterization of the oxidation products of phomaligadiones **5** and **6**, their reaction with diazomethane was examined. The reaction products were identified as the methyl ethers **9** and **10** and the adduct **11**. Methyl ethers **9** and **10** were initially characterized by ^{1}H NMR spectroscopy as a mixture (**9**/**10**, 3:1). The ^{1}H NMR spectrum of this mixture showed the expected resonances for two isomeric methyl ethers; however, the position of the newly introduced (O)Me

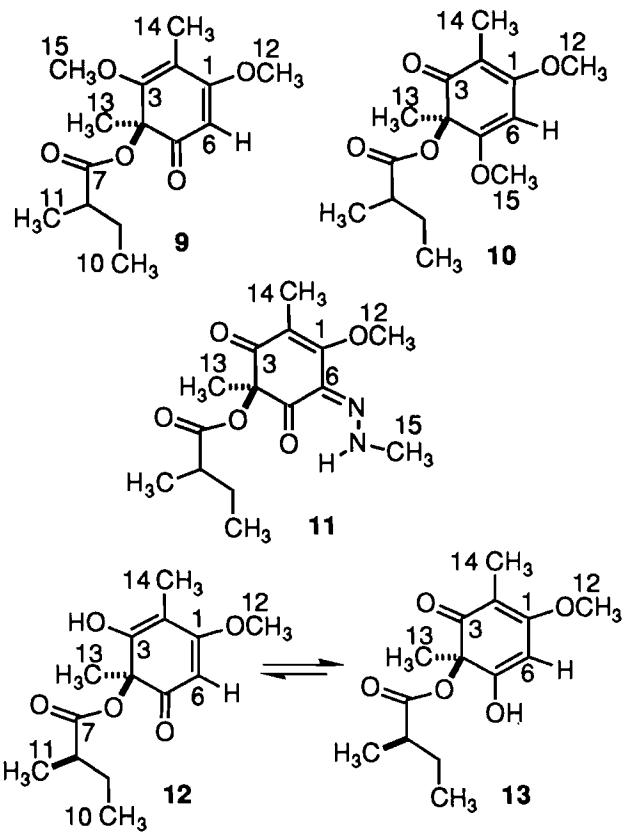
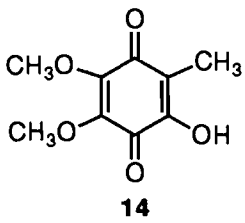
[a]Data recorded at 500 (^{1}H NMR) and 125.8 (^{13}C NMR) MHz, respectively. Values in parenthesis refer to J_{HH} in Hz.

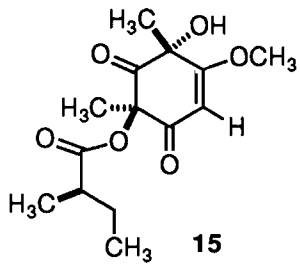


group in each isomer could not be determined unambiguously (i.e., C-3 or C-5). Further separation of the mixture of **9** and **10** yielded sufficient amounts of **9** to allow the unambiguous assignment of this structure. Firstly, the ^{1}H NMR spectrum of **9** (Table 2) displayed the resonances seen for the major product present in the initial mixture of **9** and **10**, that is, a *sec*-butyl group (9 hydrogens) in addition to two Me groups (δ_H 1.84 and 1.59), two Me(O) groups (δ_H 3.74 and 3.77), and a vinylic proton at δ_H 5.42. The proton decoupled ^{13}C NMR spectrum (Table 2) of compound **9** showed the expected 15 resonances, which corroborated the presence of 2 × Me, 2 × Me(O), and a *sec*-butyl group, as indicated in the ^{1}H NMR spectrum. In addition, signals attributable to four carbonyl groups or equivalents (δ_C 195.4, 175.6, 172.7, and 163.3), two sp^2 carbons (δ_C 112.8 and 96.1), and one oxygenated quaternary carbon (δ_C 79.2) confirmed that **9** was a methylated derivative of **5/6**. The EIMS of compound **9** revealed the molecular ion expected for $C_{15}H_{22}O_5$ at *m/z* 282. Finally, the structure of compound **9** was unambiguously assigned on the basis of its HMBC spectral data (Table 2). The location of the Me(O) at C-3 and not at C-5 was deduced from the long-range correlations of C- 3 (δ_C 163.3) with the methyl groups at δ_H 3.74 (H_3-15), δ_H 1.84 (H_3-13), and δ_H 1.59 (H_3-14), as well as the correlation of the lowest field carbonyl carbon (δ_C 195.4, C-5) with the methyl group at δ_H 1.84 (H_3-13). Although insufficient sample was recovered to obtain complete spectroscopic data for **10**, the ^{1}H NMR data attributable to the minor isomer of the methylation product mixture indicated the proposed structure.

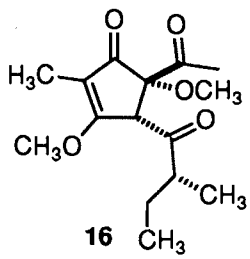
The major product of the reaction of phomaligadiones **5/6** with diazomethane was a bright yellow oil (**11**). The HREIMS of product **11** suggested the molecular formula $C_{15}H_{22}N_2O_5$, consistent with the formation of an adduct of **5/6** ($C_{14}H_{20}O_5$) with CH_2N_2. Analysis of the ^1H NMR spectrum of **11** showed the expected resonances for the cyclohexenedione substituents also present in the starting material (**5/6**): one *sec*-butyl group (9 hydrogens), two Me groups (δ_H 1.90 and 1.50), and one Me(O) group (δ_H 3.90). Two new signals at δ_H 3.41 (d, 3H) and 12.6 (bs, 1H, D_2O exchangeable) were attributed to the addition of CH_2N_2 to cyclohexenediones **5/6**, resulting in a =N-NH-Me substituent. The locations of the 2 × Me, MeO, *sec*-butyl-C(=O)O, and 2 × C=O groups on the cyclohexenedione were determined to be identical to those observed in **5/6**, by analysis of the proton decoupled ^{13}C NMR and HMBC spectral data (Table 2). Consequently, the *N*-methylhydrazone (=N-NH-Me) could only be located at C-6 (δ_C 123.5). In this way the structure of the major product was established as adduct **11**.[4]



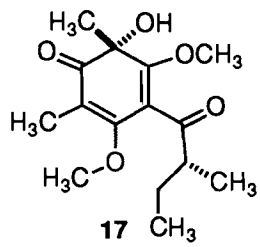
14



15



16 CH_3



17 CH_3

The products of the reaction of phomaligadiones **5/6** with diazomethane allowed further conclusions with respect to metabolites produced by *P. wasabiae*. It was reported that a compound named wasabidienone A, on treatment with diazomethane, yielded two Me ethers (1:1) having structures **9** and **10** (8). Later on, analysis of the p-nitrobenzoate derivative of wasabidienone A by X-ray crystallography allowed the assignment of its stereogenic centers (9). Based on these results (8, 9) the tautomeric forms **12** and **13** were assigned to wasabidienone A. Furthermore, it was reported that wasabidienone A on standing on a TLC plate decomposed to a brownish material, which was identified as a mixture of compounds **14** (purple) and **15** (colorless) (10). The structure of compound **15**, including absolute configuration, was determined by X-ray crystallography (10). The purple compound **14** had been previously reported as a metabolite of *P. wasabiae* (11[5] but, interestingly, **15** was never reported to be present in cultures of *P. wasabiae*. The NMR, IR, and optical rotation data reported for compound **15** are in close agreement with data obtained for phomaligol A (**1**) (1). In conclusion, wasabidienone A and phomaligadiones appear to be the same compound, existing, at least in $CDCl_3$, as a tautomeric mixture, described more accurately as **5** and **6**, since the resonances corresponding to C-2 in the former, and C-6 in the latter, are clearly due to sp^3 carbons (1), and not sp^2 carbons as in **12** and **13**. The data obtained for methyl ether derivatives **9** and **10** are in complete agreement with data reported previously (8); however, Soga et al. did not report adduct **11** (8). Because the conditions used to prepare these methyl ethers were not specified in that report (8), it is not possible to comment on those results. Our previous work (3) indicated that some of the compounds isolated from cultures of *P. lingam* were also present in cultures of *P. wasabiae*. Now it is clear that the profile of metabolites common to *P. wasabiae* and *P. lingam* is much broader; not only phomaligols (**1**, **2**) and phomaligadiones (**5**, **6**) are present in liquid cultures of both species, but also wasabidienones B_0 (**16**) and B_1 (**17**) (12) were present in similar liquid cultures.

Biogenetically, metabolites **1**, **2**, **5–8** may derive from a pentaketide that is further methylated and oxidized; however, the results reported here indicate that metabolites **1** and **2** can also result from non-enzymatic oxidation of **5–7**.[6] Furthermore, this work has uncovered a relationship for metabolites **1**, **2**, **7**, and **8**; that is, **8** could result from a non-enzymatic rearrangement of **7**, and could then be further oxidized to **1** and **2** (**7** → **8** → **1** + **2**). In fact, it is likely that the reddish pigments characteristic in liquid cultures of avirulent blackleg isolates (13) are most likely oxidation products of the metabolites **1–8** and (or) related ones such as **14**. The phytotoxicity of these metabolites to canola susceptible to blackleg was evaluated; phomaligols **1** and **2** did not cause obvious lesions even at relatively high concentrations (10^{-3} M), whereas **7** and **8** caused only slight lesions at similar concentrations.

Experimental

General

All chemicals were purchased from Aldrich Chemical Company, Inc., Madison, Wis. All solvents were HPLC grade and used as such. Preparative TLC: Merck Kieselgel 60 F_{254}, 20 × 20 cm × 0.25 mm; analytical TLC (Merck Kieselgel 60 F_{254}, aluminum sheets) 5 × 2 cm × 0.2 mm; compounds were visualized by exposure to UV and by dipping the plates in a 5% aqueous (w/v) phosphomolybdic acid solution containing a trace of ceric sulfate and 4% (v/v) H_2SO_4, followed by heating at 200°C. Flash column chromatography: Merck silica gel, grade 60, mesh size 230–400, 60 Å. NMR spectra were recorded on a Bruker AMX 500 or AM 300 spectrometer; δ

[4] No literature precedent was found for this mode of reaction of diazomethane (T. H. Black, Aldrichimica Acta, **16**, 3 (1983)). It may be a simple protonation of diazomethane, followed by enolate attack on the electrophilic terminal nitrogen.

[5] In the course of this work a reddish polar material was isolated, but due to further decomposition, its structure could not be assigned.

[6] The only indication that enzymatic oxidation might occur arises from detection of **1** and **2** in 2–3-day-old cultures, while **5/6** accumulated in 7–9-day-old cultures.

values were referenced to $CHCl_3$ (7.24 ppm) for ^1H (500 MHz), and referenced to $CDCl_3$ (77.0 ppm) for ^{13}C (125.8 MHz). Mass spectra (MS) were obtained on a VG 70-250 SEQ hybrid mass spectrometer or on a Finnigan Mat model 4500 mass spectrometer (high resolution (HR), electron impact (EI), fast atom bombardment (FAB), or chemical ionization (CI) with ammonia as carrier gas), employing a solid probe in both cases.

Air oxidation of phomaligadiones A (5a/5b) and B (6)

A solution of phomaligadiones A (**5a/5b**) and B (**6**) (28 mg in $CHCl_3$–MeOH, 1:1, 1 mL) was left standing for 4 weeks at room temperature. Preparative TLC (CH_2Cl_2–MeOH, 97:3, multiple development) of that mixture gave phomaligols **1** (2 mg; R_f 0.42, hexane–EtOAc, 1:1) and **2**(1 mg; R_f 0.28, hexane –EtOAc, 1:1), hydroperoxides **3** (3 mg; R_f 0.46, hexane–EtOAc, 1:1) and **4** (1 mg; R_f 0.34, hexane–EtOAc, 1:1), and a mixture of phomaligadiones **5a/5b** and **6** (12 mg; R_f 0.60, hexane–EtOAc, 1:1).

Reaction of phomaligadiones A (5a/5b) and B (6) with diazomethane

Diazomethane in ether was added (excess) to a stirred solution of phomaligadiones A (**5a/5b**) and B (**6**) (8 mg in CH_2Cl_2, 1 mL) at room temperature. After 30 min the solvents were removed with a stream of nitrogen and the reaction products were separated by preparative TLC (CH_2Cl_2–MeOH, 97:3, developed twice) to give a mixture of compounds **9** and **10** in one band (2 mg, 3:1) and adduct **11** (3.2 mg). Compounds **9** and **11** were further purified separately by preparative TLC (hexane–EtOAc, 7:3, multiple elution) to yield pure **9** (1.7 mg; R_f 0.75, hexane–EtOAc, 1:1), **10** (0.5 mg; R_f 0.5, hexane–EtOAc, 1:1), and **11** (2.1 mg; R_f 0.75, hexane–EtOAc, 1:1).

Reduction of hydroperoxides 3 and 4

$P(OMe)_3$ (2 mg in CH_2Cl_2, 1 mL) was added to a solution of the hydroperoxide **3** (2.4 mg in CH_2Cl_2, 1 mL) at room temperature. The solvent was immediately evaporated and the reaction product was purified by preparative TLC (hexane–EtOAc, 1:1, multiple elution) to give a pure compound (1.5 mg), identical to phomaligol A (**1**) in all respects, including optical rotation. Similar reaction with hydroperoxide **4** yielded a pure compound (1.1 mg), identical to phomaligol A_1 (**2**).

Phomaligol A hydroperoxide (3): colorless oil; HRCIMS *m/z* (relative intensity) measured: 301.1282 (301.1287 calcd. for $C_{14}H_{21}O_7$); FABMS *m/z* (relative intensity): 301 ($[M+1]^+$ 100; ^1H and ^{13}C NMR, see Table 1.

Phomaligol A_1 hydroperoxide (4): colorless oil; HRCIMS *m/z* (relative intensity) measured: 301.1283 (301.1287 calcd. for $C_{14}H_{21}O_7$); FABMS *m/z* (relative intensity): 301 ($[M+1]^+$ 100; ^1H and ^{13}C NMR, see Table 1.

Compound 9: light yellow film; ^1H NMR ($CDCl_3$) δ:5.44(s), 3.88(s), 3.72(s), 2.45 (ddq, J = 6.8, 7.0, 7.0 Hz), 1.84(s) 1.72(m), 1.59(s), 1.47(m), 1.13(d, J = 7.0 Hz), 0.90 (t, J = 7.5).

Compound 10: light yellow oil; EIMS *m/z* (relative intensity): 282 ($[M]^+$, 9%), 198 (20%), 155 (30%); ^1H and ^{13}C NMR, see Table 2.

Adduct 11: yellow oil; HREIMS *m/z* (relative intensity) measured: 310.1529 (310.1526 calcd. for $C_{15}H_{22}N_2O_5$); EIMS *m/z* (relative intensity): 310 ($[M]^+$, 15%), 209 (40%), 154 (28%); ^1H and ^{13}C NMR, see Table 2.

Interaction between tetracyanoethylene and naphthalene in reverse micelles of AOT in *n*-hexane. The electron-donor properties of AOT

M.A. Biasutti and Juana J. Silber

Abstract: The electron donor–acceptor (EDA) interaction between TCNE and naphthalene (Naph) in *n*-hexane and reverse micelles of AOT in n-hexane was studied by UV–visible spectroscopy with the aim of determining the influence of the micellar media on the EDA interaction. The spectra of the mixtures of TCNE–Naph in *n*-hexane show two typical maxima at 418 and 534 nm, assigned to the formation of a π–π EDA complex. In the micellar media a new band is observed at 398 nm. When the spectra of TCNE in *n*-hexane are studied in the presence of AOT two new bands at 398 and 418 nm are detected. These bands are consistent with an EDA interaction between TCNE and AOT as *n*-donor. The stability constants of this interaction were calculated for AOT concentrations below the CMC and in the micellar media at different W ($W = [H_2O]/[AOT]$). The results give evidence of the tendency of AOT to interact very strongly with electron acceptors. Moreover, in the system TCNE–Naph in the micellar media it is shown that Naph and AOT compete to form a complex with TCNE. The formation constants of the complexes of AOT–Naph in the micelle system were determined at $W = 0$ and 5. Despite the competition of AOT for TCNE the stability constant for the complex TCNE–Naph is higher than in homogeneous media, probably due to the high local concentration of the acceptor in the micelle.

Key words : reverse micelles, aerosol-OT, tetracyanoethylene, naphthalene, electron donor–acceptor complexes.

Résumé : Afin de déterminer l'influence du milieu micellaire sur l'interaction donneur d'électron–accepteur (DEA) et faisant appel à la spectroscopie UV–visible, on a étudié l'interaction DEA entre le TCNE et le naphtalène (Naph) dans l'hexane et des micelles inverses d'aérosol-OT (AOT) dans l'hexane. Les spectres des mélanges de TCNE–Naph dans l'hexane présentent deux maximums typiques à 418 et 534 nm, attribuées à la formation d'un complexe π–π DEA. Dans le milieu micellaire, on observe une nouvelle bande à 398 nm. Lorsqu'on a étudié les spectres du TCNE dans l'hexane en présence d'AOT, on a détecté deux nouvelles bandes à 398 et 418 nm. Ces bandes sont en accord avec une interaction DEA entre TCNE et AOT comme donneur *n*. On a calculé les constantes de stabilité de cette interaction pour des concentrations d'AOT inférieures à la CMC et, dans le milieu micellaire à différentes valeurs de W ($W = [H_2O]/[AOT]$). Les résultats fournissent des indications sur la tendance de AOT à interagir très fortement avec les accepteurs d'électrons. De plus, on a montré que, dans le système TCNE–Naph en milieu micellaire, Naph et AOT sont en compétition pour former un complexe avec TCNE. On a déterminé les constantes de formation des complexes AOT–Naph à $W = 0$ et 5. Malgré la compétition de AOT pour TCNE, la constante de stabilité pour le complexe TCNE–Naph est plus élevée dans le milieu homogène, probablement en raison de la concentration locale plus élevée de l'accepteur dans la micelle.

Most clés : micelles inverses, aérosol-OT, tétracyanoéthène, naphtalène, complexes d'électron donneur–accepteur.

[Traduit par la rédaction]

Introduction

Tetracyanoethylene (TCNE) is a well-known π acceptor that forms intensely colored complexes with alkenes and aromatic hydrocarbons. The color arises from electron donor–acceptor (EDA) complexes (1). For weak donors such as alkylbenzenes it has been shown that the complexes have only partial transfer of a π electron from the aromatic hydrocarbon to TCNE. On the other hand, with strong donors such as nickel carbonyl or iodide ion complete electron transfer occurs and the stable TCNE anion is formed (2). The acceptor properties of TCNE as well as its multiple applications in organic chemistry have been comprehensively reviewed (3). As in the case of other polycyano compounds, TCNE is used in the preparation of novel materials with unusual electrical and (or) magnetic properties (4). Some of the most studied EDA complexes of TCNE are with aromatic hydrocarbon donors such as alkylbenzene (5–7) and naphthalenes (4, 8, 9).

Multiple charge transfer bands are observed for alkylbenzene–TCNE complexes (5–7) as well as for polynuclear aromatic TCNE complexes (5, 8, 9). The presence of two charge transfer bands for alkyl-substituted benzenes with TCNE has been rationalized as due to the interactions with the π (b_1) and π (b_2) orbitals of the benzene ring (4, 7) or to isomeric complexes (10). In the case of naphthalenes the two bands are attributed to charge transfer transitions $^*\pi \leftarrow \pi_u$ and $^*\pi \leftarrow \pi_{bu}$ of the naphthalene ring with TCNE (1, 9).

The aim of the present contribution is to study the influence of the reverse micelles of AOT in *n*-hexane on the interaction between TCNE and naphthalene (Naph) by UV–visible spectroscopy. The complex of TCNE–Naph has been recognized as a model system for studying and understanding the interaction between TCNE and other donors (9). Moreover, since this EDA complex has well-characterized properties and spectra in several media, its behavior in a micellar system could give information about its microenvironment.

Reversed micelles have received considerable attention in recent years, mainly because of the possibility of performing chemical reactions essentially in an organic phase, but hosting the reactive species in the water pool, e.g. enzymatic reactions, photoelectron transfer reactions, proton transfer, singlet oxygen photosensitization, or inverse microemulsion polymerization (11). In previous work we studied the micropolarity of reversed micelles of AOT in *n*-hexane by following the solvatochromic behavior of chromophores of betaines (12). We showed that in these systems the polarity, as well as the hydrogen bond donor ability, of the AOT polar heads are the determining factors for inclusion of betaine probes in the micelle interface.

It is widely recognized that such properties of a solute as the electronic spectra, capability of forming EDA complexes, and chemical reactivity are dependent on the polarity of the solvent (13). In this sense, the main objective of this work was to examine what effect the AOT reverse micelle microenvironment may have on the stability constant of the TCNE–Naph EDA complex. In the course of this investigation a strong interaction between TCNE and AOT was also found. The spectral properties of this interaction were examined. They show that AOT is a strong electron-donor compound in homogeneous and micellar media.

Experimental

Sodium 1,4-bis(2-ethylhexyl)sulfosuccinate (AOT) was obtained from Fluka A. G. and further purified by the procedure described in ref. 14. Tetracyanoethylene (TCNE), 98%, and naphthalene (Naph) from Aldrich were purified by sublimation under vacuum. 8-Hydroxy-1,3,6-pyrenesulfonic acid trisodium salt (Pyranine) from Kodak was used as received. *n*-Hexane (Sintorgan, HPLC quality) was dried by distillation over metallic sodium just before use.

Water was first distilled over potassium permanganate and then bidistilled until a conductivity of 0.3–0.5 μmho cm^{-1} at 298 K was reached.

The solutions were prepared by weighing and dilution. Water was added to the appropriate solution by a calibrated microsyringe. The micelle solutions were completely stable for at least a day.

The absorption spectra were measured by using a Cary 17 spectrophotometer or HP 8452A and 1 cm path length cells. The working temperature was 25 ± 0.5°C. Fluorescence measurements were carried out with an Aminco Bowman spectrofluorometer.

Results and discussion

1. Absorption spectra of TCNE–Naph in *n*-hexane

Since the absorption spectrum of TCNE in *n*-hexane shows one band at 260 nm while Naph exhibits bands only below 310 nm, the region between 350 and 650 nm constitutes an excellent region for the study of the mixture.

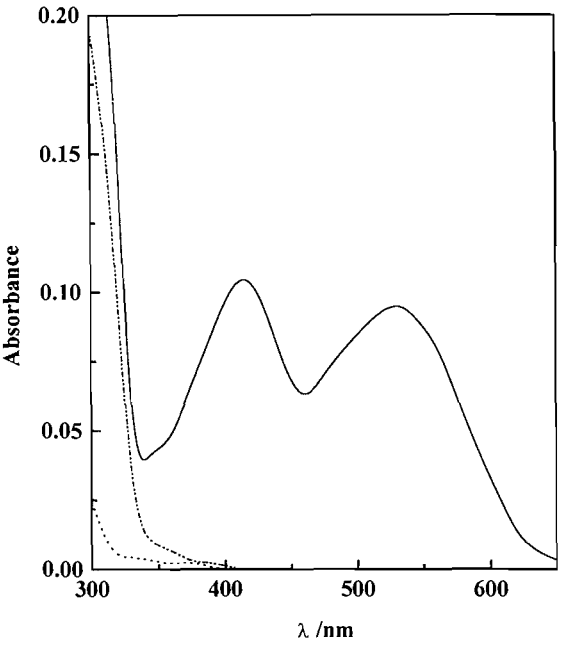

Fig. 1. Absorption spectra of (—·—) 1×10^{-4} M TCNE, (-----) 0.3 M Naph, and (———) mixture of 1×10^{-4} M TCNE and 0.3 M Naph in *n*-hexane.

Solvent	λ (nm)	$K_s(1)$ (M^{-1})	ε (M^{-1} cm^{-1})
n-Hexane	418	3.70 ± 0.20	1963 ± 67
	534	3.80 ± 0.26	1831 ± 82
$CHCl_3$[a]	432	1.07	
	558	0.97	
CCl_4[a]	430	3.79	
	560	4.23	

[a]From ref. 5.

The absorption spectrum of TCNE–Naph in *n*-hexane is shown in Fig. 1. The spectrum exhibits two maxima, one at 418 nm and the other at 534 nm. Similar bands were observed for this complex using $CHCl_3$ and CCl_4 as solvents (5) and they have been assigned to the π–π* electron donor–acceptor complex between TCNE and Naph.

Assuming a 1:1 complex, the stability constant, $K_s(1)$, was determined spectrophotometrically by following the change of absorbance of these new bands, working at constant $[TCNE]_0 = 2 \times 10^{-4}$ M and varying $[Naph]_0$ from 3×10^{-2} to 20×10^{-2} M. The value of $K_s(1)$ was calculated by an iterative procedure previously described (15). The results are shown in Table 1 where the values of the stability constants reported in other solvents are included for comparison.

It is seen that the K_s values obtained at both wavelengths are similar and consistent with the formation of the 1:1 complex

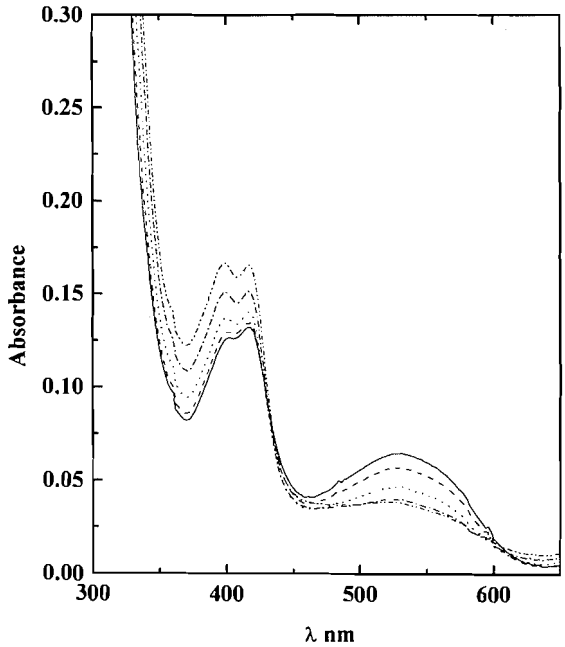

Fig. 3. Absorption spectra of TCNE in AOT–n-hexane at $[AOT]_0$: (*a*1) 0.0; (*a*2) 0.002; (*a*3) 0.003; (*a*4) 0.066; (*a*5) 0.132; (*a*6) 0.198; (*a*7) 0.200 M; $[TCNE]_0 = 2 \times 10^{-4}$ M, $W = 10$. (*b*) Spectrum of TCNE-free AOT–*n*-hexane; $[AOT]_0 = 0.200$ M.

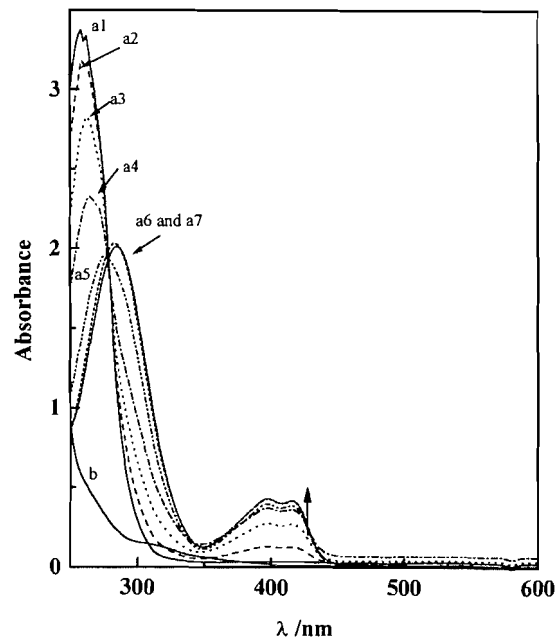

with the two characteristic charge tranfer bands (1, 9). Also, the magnitude of $K_s(1)$ in *n*-hexane is similar to that in CCl_4 but is greater than in the more polar $CHCl_3$, as expected for weak EDA complexes (16).

2. Effects of the AOT addition on TCNE–Naph interaction in the micellar region

The typical spectral changes obtained upon addition of AOT to TCNE–Naph solution in *n*-hexane are shown in Fig. 2.

A band at about 534 nm is still observed although its intensity decreases when the surfactant concentration increases. At concentrations higher than 0.06 M in AOT this band practically disappears. On the other hand, the band present originally at 418 nm for the TCNE–Naph system is seen to split into two with maxima at 416 and 398 nm. An isosbestic point is detected at 435 nm.

The observed decrease in intensity of the 534 nm band with increase in AOT concentration may be due to a competitive interaction of AOT with TCNE. It is well known that TCNE can interact with *n* donors such as alcohols, ethers (17), and amines (8a), giving *n*–π* type EDA complexes (16). As well, in the previously studied I_2-AOT system (18) we found that AOT may act as a "*n*" donor, probably through the free electron pair on carbonyl groups present in the ester functions. Also, an *n*–π* EDA interaction have been proposed between AOT and 7,7,8,8-Tetracyanoquinodimethane (TCNQ) in several organic solvents (19). Thus, it may be that AOT competes with Naph in the association with TCNE. Certainly, the spectra of TCNE in AOT–*n*-hexane systems (Fig. 3) show two bands at 398 and 416 nm that increase in intensity with increasing AOT concentration. Moreover, the 261 nm band of TCNE in hexane decreases in intensity as a new band at 283 nm develops, and an isosbestic point is observed at 278 nm. The spectrum of AOT in *n*-hexane at the highest concentration used is also shown in Fig. 3. New bands appear in the mixture at higher wavelength that those of the donor or the acceptor. Thus, the system TCNE–AOT in *n*-hexane shows the characteristic features that can be expected on formation of an EDA complex (16).

When the bands in the visible region for TCNE–AOT in *n*-hexane are compared with the absorption maxima positions for the system of TCNE with *n*-donors such as methanol,[2] aminopyridines (20), and diethyl ether (17) (Table 2), they all show similar spectra. Furthermore, it can also be concluded

Table 2. Position of the maximum UV–visible absorption band of TCNE with different "*n*" donors.

Solvent	System	λ_{max}/(nm)	λ_{max}/(nm)
CH_3OH[a]	TCNE–CH_3OH	412	394
$C_2H_2Cl_2$[b]	TCNE–2-BzNHPy	417	390
$(C_2H_5)O$[c]	TCNE – $(C_2H_5)O$		347
W = 0[d]	TCNE – AOT	416	398
W = 5[d]	TCNE – AOT	416	398
W = 10[d]	TCNE – AOT	416	398
W = 20[d]	TCNE – AOT	416	398

that the absorption band at 398 nm, which appears in the spectra of TCNE–Naph in AOT–hexane (Fig. 2), is due to interaction between TCNE and AOT. This interaction competes with TCNE–Naph complex formation in the reversed micelle medium. On the other hand, the band at 418 nm is probably due to the contribution of both interactions, TCNE – Naph and TCNE – AOT.

From the position of the absorption bands of the TCNE–AOT complex in *n*-hexane and using the empirical correlations found by Frey (21) for π or *n*-donor–TCNE complexes, (eq. [1]), the value of the molecular ionization energy (I_D) of AOT can be estimated.

$$[1] \quad \lambda_{CT}\,(\text{nm}) = 1240\,(\text{nm/eV}) / 0.810 I_D - 4.28$$

Values of 9.2 and 8.9 eV, which are quite typical for *n*-donors (21), are obtained. However, these values are much lower than the gas-phase I_D expected for the lone pair of a typical carboxylate ester (i.e., 10.10 eV for ethyl acetate) or even of a ketone (i.e., 9.69 eV for acetone) (22). On the other hand, AOT shows other properties such as its vibrational spectra (23) that are not those of a typical carboxylate, due to the asymmetric attachment of the sulfonate group to the succinate backbone and interactions with the Na^+ counterion. Also, even in "dry" hydrocarbon solution the polar head of AOT is expected to be partially hydrated (24). The combination of all these factors may account for the unusual donor behavior of AOT as compared with common esters.

On the other hand, this condition may arise from through-space oxygen–oxygen interactions when the succinate moiety is in an appropriate conformation (25). This may also explain the fact that the peaks in the 398–418 doublet are much narrower than a typical charge transfer band and resemble an intramolecular electronic–vibronic transition.[3] This would require a preferred and a rather fixed *gauche* conformation of the carboxylate groups, as has actually been observed (26, 27), particularly in nonpolar solvents.

It is noteworthy that the position of the maxima in the spectrum of TCNE in the system AOT–hexane is independent of W(= [H_2O/AOT]) as shown in Table 2. This indicates that TCNE is anchored in a similar microenvironment regardless of the amount of water in the micellar core. This is an important fact in considering where TCNE is located in the micelle, as discussed below.

3. Interaction TCNE–AOT in hexane

To obtain a quantitative description of the interactions between TCNE and AOT, studies were performed at different AOT concentrations in *n*-hexane, below the CMC concentration (i.e., 0.4×10^{-3} M) (27, 28).

In solutions of TCNE and AOT where the initial AOT concentration is below the CMC and consequently of the order of the initial $[TCNE]_0$, it can be assumed that a 1:1 complex between AOT and TCNE (eq. [2]) is formed.

$$[2] \quad \text{TCNE} + \text{AOT} \underset{}{\overset{K_s(2)}{\Longleftrightarrow}} \underset{\text{EDA complex}}{(\text{TCNE..AOT})}$$

[3] We thank a referee for suggesting this possibility.

Table 3. Stability constants, $K_s(2)$, and ε values for the complex 1:1 TCNE–AOT in *n*-hexane, T = 298 K.

W	$K_s(2)$ (M^{-1})	ε (M^{-1} cm^{-1})
5	700 ± 130	2090 ± 70
10	500 ± 100	2260 ± 145

The stability constant, $K_s(2)$, was determined spectrophotometrically by following the changes of absorbance of the band at 398 nm working at constant $[TCNE]_0 = 2 \times 10^{-4}$ M and varying $[AOT]_0$ in the range 1×10^{-6} to 2.5×10^{-4} M. Value of $K_s(2) = 2530$ M^{-1} amd $\varepsilon = 416$ cm^{-1} M^{-1} were obtained. The high value of $K_s(2)$ indicates a very strong interaction. These high values for the association constant of the complex are also unusual when comparing complexes formed between TCNE and donors such as ethers or alcohols (17). However, we have found a very high constant for the complex between AOT and I_2 (13). Moreover, although no $K_s(2)$ values were calculated, it has been shown that AOT interacts so strongly with TCNQ (19) that the spectra of the anion radical of this acceptor is detected in reverse micelle systems.

On the other hand, the results obtained at AOT concentrations higher than the CMC, ($[AOT]_0 = 1 \times 10^{-3}$ to 5×10^{-2} M and $[TCNE]_0 = 2 \times 10^{-4}$ M) at W 5 and 10 are shown in Table 3. As can be observed, $K_s(2)$ in the micellar system is somewhat smaller than in the homogeneous solution of AOT in hexane below the CMC. It should be noted that variations in $K_s(2)$ are observed up to $W = 10$. Thereafter, this stability constant is independent of water concentration. This behavior is characteristic of solutes that are located at the interface or for a process that occurs in the interfacial region of AOT reverse micelles. Previous studies performed by other authors (29) with 2-naphthol, located in the interfacial region of AOT reversed micelles, have shown how a substrate residing in the interface experiences environment changes induced by addition of water, due to the competition between the hydroxy group of the naphthol and water regarding localization in the vicinity of AOT ester groups. In this case, the changes were also more significant at $W < 10$. Recently, we found that the properties probed by 1-methyl-8-oxyquinolinium (12) and I_2 (18) in AOT reverse micelles in *n*-hexane are more significant in the micelle domain at $W < 10$ than at higher values of W.

Below $W \leq 10$ hydration of the AOT polar heads can be considered as the key process involving AOT. Thus, hydrogen bonds between water and AOT species could compete with the specific interaction between TCNE and AOT species and this may be the reason for the observed magnitude and variation in the $K_s(2)$ values. At values of W higher than 10, water forms "pools" with normal water properties (30) and no additional changes are observed.

4. Possible localization of TCNE in the reverse micelles of AOT

From the high stability constant calculated for the TCNE–AOT complex it can be assumed that most of the TCNE is in the micelle interior. As well, from the evolution of the band at 283 nm in the presence of increasing concentrations of AOT (Fig. 3) and the concomitant decrease in the typical band of TCNE in hexane at 261 nm it can be inferred that TCNE is

moving to a more polar environment that is near the interface.

Positron annihilation techniques in reversed AOT micelles in benzene (31) have shown that 63.7% of the TCNE is localized in the interfacial region but on the organic side of the micelle. Also, TCNE seems to show much less affinity with AOT in benzene than in hexane. This can be easily rationalized on the basis of the well-known π–π interaction between TCNE and benzene (32). On the other hand, since *n*-hexane can be considered as a relatively inert solvent, the conclusion that TCNE will be in the micelle interior toward the interface seems quite reasonable.

An independent means of estimating the location of TCNE in the AOT– *n*-hexane micelle was attempted using fluorescence quenching studies. Pyranine was used as a fluorescent probe and TCNE as a quencher. This probe has a negative charge and is expected to reside in the water pool. The measurements were performed by excitation at 375 nm and observing the emission at 425 nm. A large decrease in the fluorescence intensity was found, which indicates that TCNE can locate close the water pool. Unfortunately, no quantification of this effect could be performed because of the intense absorption of the TCNE–AOT band (≈398 nm) at the emission and excitation wavelengths that overlap with the observed fluorescence.

It can be concluded that the main driving force for the residence of TCNE in the micelle interior is formation of a strong complex between TCNE and AOT.

5. TCNE–Naph interaction in AOT–hexane reversed micellar system

In light of the results hitherto presented, the decrease in the absorption of the 534 band of the TCNE–Naph complex (Fig. 2) can be ascribed to the competition from the TCNE–AOT complex formation.

As can be observed in Fig. 4, by increasing the Naph concentration at constant AOT and TCNE concentrations, the band at 534 nm increases, its intensity while the band at 392 nm decreases, showing again the competition between Naph and AOT for TCNE.

When water is added to TCNE–Naph in AOT–hexane solution in the range of W from 0 to 10 (Fig. 5), the intensity of the band at 534 nm decreases. Its λ_{max} shifts bathochromically (about 6–8 nm) as expected for a π–π^* type transition. On the other hand, for $W \approx 10 - 20$ the changes are negligible. An isosbestic point is observed at ≈430 nm. Moreover, the intensity of bands at 418 and 398 nm increases and, whereas the first one remains in the same position, the second shifts hypsochromically as would be expected for an n–π^* type transition. The changes are much more significant in the micellar domain (at $W < 10$) than in the microemulsion domain.

Since for $W > 5$ the intensity of the band at 534 nm is quite small, the quantitative study of the TCNE–Naph interaction was performed at $W \leq 5$. The $K_s(1)$ values calculated in the micellar medium were 20 ± 2 M^{-1} (ε = 212 ± 17 M^{-1} cm^{-1}) and 13 ± 2 M^{-1} (ε = 229 ± 15 M^{-1} cm^{-1}) for W = 0 and 5, respectively. To understand the observed magnitude of $K_s(1)$ in the micelle medium there are two effects that should be taken into account. One is the partition process of the solute and the other is the polarity of the medium.

Thus, the increment found for $K_s(1)$ values in the micellar phase with respect to the homogeneous medium (Table 1) may be due to a variation in the local concentration of the reactants in the micellar phase. Actually a solute in this kind of system is distributed essentially among three environments or three sol-

Fig. 4. Effect of variable concentration of Naph on the absorption spectra of TCNE– Naph complex in reverse micelles of AOT–*n*-hexane. $[Naph]_0$ = (———) 0.043; (– – –) 0.069; (—·—·—) 0.143; (–·–·–) 0.178; (-----) 0.309 M; $[TCNE]_0 = 2 \times 10^{-4}$ M, W = 0, [AOT] = 0.02 M.

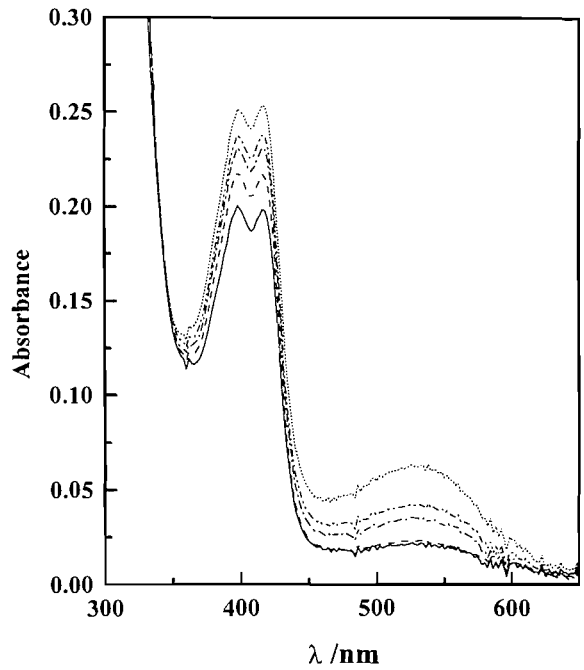

Fig. 5. Absorption spectra of TCNE– Naph complex in reverse micelles of AOT–*n*-hexane at W (1) 5; (2) 10; (3) 20. $[TCNE]_0 = 2 \times 10^{-4}$ M; $[Naph]_0$ = 0.29 M; [AOT] = 0.02 M.

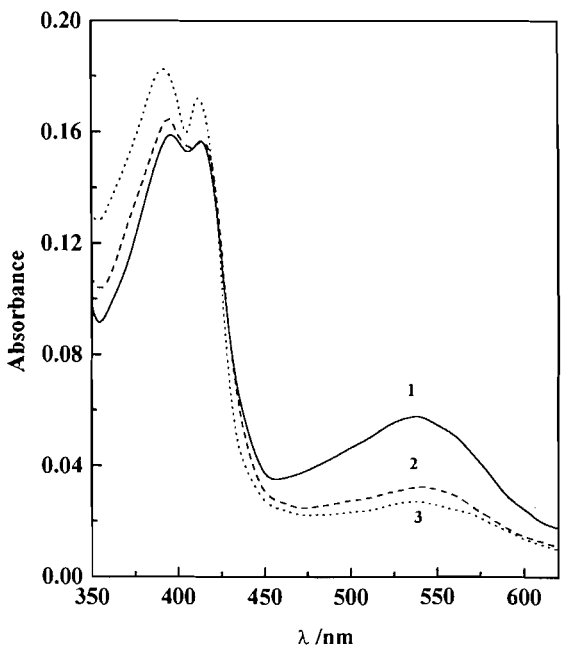

ubilization sites (33). These are (*i*) the micellar water pools, (*ii*) the reversed micellar interface, and (*iii*) the organic continuum. While Naph will be partitioned between the micellar interface and the organic medium, TCNE may be mostly in the micellar interface, as discussed before. The TCNE–Naph complex formation should be produced in the micelle interior and near the interface, where the local concentration of TCNE is greater than in the bulk.

On the other hand, as has already been determined (12), the micropolarity of these micelles increases on water addition. Thus, if the complex is formed in the micelle interior a decrease in $K_s(1)$ values is expected, as is actually observed. The same polarity effect on the stability constants was found by other authors (6) for the TCNE - hexamethylbenzene complex in CH_2Cl_2 and CCl_4.

Conclusions

The observed decrease in intensity of the band assigned to the TCNE–Naph complex at 534 nm by increasing the AOT concentration has been shown to be due to the competitive interaction between TCNE and AOT. The λ_{max} of absorption bands for the TCNE–AOT complex are consistent with the formation of an EDA complex where AOT may act as an *n*-donor. However, the ionization potential inferred from this interaction is lower than that expected for a common ester function and the association constants are much higher than for common oxygen donors. This gives the AOT–*n*-hexane systems quite unique behavior. AOT was also previously found to act as a good electron donor for a σ acceptor such as I_2 (18). Therefore any studies referring to the reverse micelle of AOT–hexane must take into account the possibility of AOT competing with a probe or a solute for a given acceptor. This effect may not be at all important for reverse micelles of AOT–benzene (31). The stability of the TCNE–AOT complex is higher in homogeneous media (at $[AOT]_0 < CMC$) than in the micellar domain. This shows that TCNE resides in a more polar environment, namely, the micelle interface. The effect of water addition is only noticeable until $W \cong 10$, that is, while the polar heads of AOT are involved in the hydration process.

Despite the competition of AOT for TCNE, the apparent stability constant of the TCNE–Naph complex is greater in the micellar media than in *n*-hexane. This is mostly attributed to an increase in the local concentration of AOT in the micelle.

Synthesis of 5-(1-azidovinyl) and 5-[2-(1-azirinyl)] analogs of 2′-deoxyuridine

Rakesh Kumar, Leonard I. Wiebe, and Edward E. Knaus

Abstract: The regiospecific addition of bromine azide to the vinyl substituent of 5-vinyl-3′,5′-di-*O*-acetyl- (or *tert*-butyldimethylsilyl)-2′-deoxyuridines (**2**) yielded the corresponding 5-(1-azido-2-bromoethyl)-3′,5′-di-*O*-protected-2′-deoxyuridines (**3**). Treatment of the 5-(1-azido-2-bromoethyl) compounds **3** with *t*-BuOK, to effect the base-catalyzed elimination of HBr, afforded the corresponding 5-(1-azidovinyl)-2′-deoxyuridines (**4**, **7**). Thermal decomposition of 5-(1-azidovinyl)-2′-deoxyuridine (**7**) at 110°C in dioxane yielded 5-[2-(1-azirinyl)]-2′-deoxyuridine (**9**). 5-(1-Azidovinyl)-2′-deoxyuridine (**7**) exhibited appreciable in vitro antiviral activities against herpes simplex virus type 1 (HSV-1) and varizella zoster virus (VZV). Athough **7** increased the length of survival of HSV-1 brain-infected mice, it did not decrease the mortality rate relative to placebo. 5-[2-(1-Azirinyl)]-2′-deoxyuridine (**9**) was an inactive antiviral agent.

Key words: azidovinyl, azirinyl, 2′-deoxyuridine, antiviral activity.

Résumé : L'addition régiospécifique de l'azoture de brome sur le substituant vinylique des 5-vinyl-3′-di-*O*-acétyl- (ou *tert*-butyldiméthylsilyl)-2′-désoxyuridines (**2**) conduit aux 5-(1-azido-2-bromoéthyl)-3′,5′-protégé-2′-désoxyuridines (**3**). Le traitement des composés **3** par le *t*-BuOK provoque une élimination basocatalysée de HBr qui conduit aux 5-(1-azidovinyl)-2′-désoxyuridines (**4**, **7**). La décomposition thermique de la 5-(azidovinyl)-2′-désoxyuridine (**7**), à 110°C, dans le dioxane, fournit de la 5-[2-(1-azirinyl)]-2′-désoxyuridine (**9**). La 5-(1-azidovinyl)-2′-désoxyuridine (**7**) présente des activités antiviral in vitro appréciables contre le virus de l'herpès simplex de type I (HSV-1) et le virus zoster varizella (VZV). Même si le composé **7** augmente le temps de survie des souris dont le cerveau a été infecté au HSV-1, il ne diminue pas le taux de mortalité par rapport au placebo. Le 5-[2-(1-azirinyl)]-2′-désoxyuridine (**9**) n'est pas actif comme agent antiviral.

Mots clés : azidovinyle, azirinyle, 2′-désoxyuridine, activité antivirale.

[Traduit par la rédaction]

The development of new methods for the synthesis of 2′-deoxyuridines that possess novel vinyl moieties at the C-5 position and exhibit potent antiviral activity represents an important area of drug design. 5-Vinyl-2′-deoxyuridine (**1***a*) has been shown to exhibit potent antiviral activity against herpes simplex virus type-1 (HSV-1), type-2 (HSV-2), and vaccinia virus (1). Among the many 5-substituted pyrimidine nucleosides that have been studied, (*E*)-5-(2-halovinyl)-2′-deoxyuridines (**1***b*; X = I (IVDU); X = Br (BVDU); X = Cl (CVDU)) are among the most active and selective in their action against HSV-1 (2). Incorporation of a methyl substituent at the 1-position of the 5-(2-bromovinyl) moiety of BVDU (**1***c*) (3), or a chloro substituent at the 1-position of the 5-vinyl moiety of VDU (**1***d*) (4), reduced activity against HSV-1. Structure–activity correlations for a group of 5-substituted-2′-deoxyuridines indicated that optimum antiviral activity against HSV-1 occurs when the C-5 substituent is unsaturated and conjugated with the uracil ring, is not larger than four atoms in length, has the (*E*) stererochemisty, and possesses a hydrophobic electronegative atom (3).

As part of an investigation to design broad-spectrum antiviral agents, an azido substituent located at the 1-position of a 5-vinyl moiety attracted our attention. The azido substituent possesses desirable physicochemical properties, relative to other substituents used routinely in structure–activity correlation studies, such as electronic (inductive effect *F* value), steric size (molar refractivity value), and lipophilic (π-value) effects, respectively (5), viz: N_3, 0.30, 10.2, 0.46; H, 0.00, 1.03, 0.00; Me, −0.04, 5.65, 0.56; F, 0.43, 0.92, 0.14; Cl, 0.41, 6.03, 0.71; Br, 0.44, 8.88, 0.86; I, 0.40, 13.94, 1.12; OH, 0.29, 2.85, −0.67. Thus, the electronic effect of azido is between that of OH and I, the steric effect is between that of Br, and I, and the lipophilic effect is between that of F and Me. These physical data suggest an azido group is a good isostere of I, Br, and Cl. Furthermore, the azido group maybe capable of electrostatic binding to an enzyme, such as thymidine kinase, that is not possible with a halogen such as I, Br, or Cl. In a previous study, it was reported that short exposure (<5 min) of 5-(1-azidovinyl)-2′-deoxyuridine treated FM3A thymidine positive (TK^+) cells to irradiation at λ = 254 nm enhanced the cytostatic effect 5-fold due to inhibition of thymidine synthase (TS). This photoaffinity approach may open new perspectives for the treatment of cutaneous disorders such as malignant melanoma with respect to azido-based chemotherapeutic agents that show increased cytostatic activity against HSV TK gene-transfected tumor cells upon short (1–5 min) UV light exposure (6). It was also envisaged that the 1-azidovinyl sub-

Received April 4, 1996.

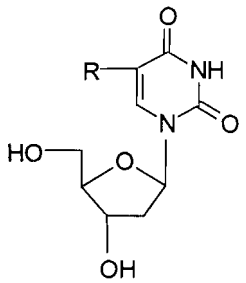
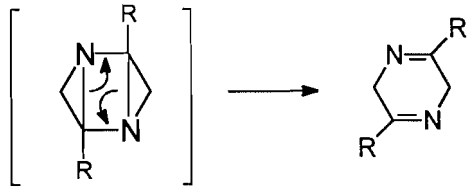
stituent should undergo intramolecular cyclization to yield 2′-deoxyuridine compounds possessing novel C-5 heterocyclic ring systems. We now report the synthesis of the novel 5-(1-azidovinyl)-2′-deoxyuridine (**7**) and the related 5-[2-(1-azirinyl)] (**9**) analog.



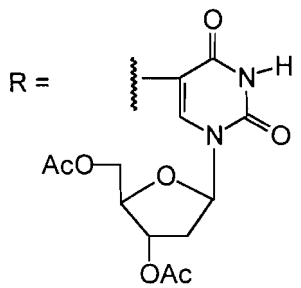
1*a*, R = -CH=CH$_2$
1*b*, R = (*E*)-CH=CHX
1*c*, R = (*E*)-C(Me)=CHBr
1*d*, R = -C(Cl)=CH$_2$

Our initial attempts to synthesize 5-(1-azidovinyl)-2′-deoxyuridine (**7**, Scheme 1) by treatment of 5-(1-azido-2-bromoethyl)-2′-deoxyuridine (**3***d*) with either *t*-BuOK or NaOH using DMSO or DME as solvent gave a low yield of **7** (11%) and the bicyclic compound **10** (66%), which could not be separated by silica gel column chromatography. 3′,5′-Di-*O*-acetyl- (**3***a*) and 3′,5′-di-*O*-*tert*-butyldimethylsilyl-5-(1-azido-2-bromoethyl)-2′-deoxyuridine (**3***b*) were therefore prepared to protect the sugar hydroxyl groups, which decreases the number of equivalents of base required to effect the base-catalyzed elimination of HBr from the 5-(1-azido-2-bromoethyl) moiety. The regiospecific addition of bromine azide to the 5-vinyl substituent of the 2′-deoxyuridine derivative (**2***a* and **2***b*) afforded the corresponding 5-(1-azido-2-bromoethyl)-2′-deoxyuridine analog (**3***a*, 88%) and **3***b* (82%), respectively. The ^{13}C NMR (*J* modulation) spectrum of **3***a* provided conclusive evidence for the regiospecific addition of bromine azide across the 5-vinyl substituent of **2***a*. Compound **3***a* is a mixture of two diastereomers, which differ in configuration (*R* and *S*) at the C-1 carbon atom of the 5-(1-azido-2-bromoethyl) moiety. For example, the bromine atom present in **3***a* is attached to a methylene carbon that showed dual resonances at δ: 33.97 and 34.46, whereas the azido substituent is attached to a methine chiral carbon that exhibited dual resonances at δ: 58.21 and 58.33. This regiospecific addition is consistent with reports that unsymmetrical olefins, capable of halonium ion formation, were found to favor an unsymmetrical bridged intermediate even in solvents having a high dipole moment (7, 8). Reaction of the 3′,5′-di-O-acetyl derivative **3***a* with *t*-BuOK in THF gave rise to three products. Thus, the direct elimination of HBr afforded 5-(1-azidovinyl)-3′,5′-di-*O*-acetyl-2′-deoxyuridine (**4***a*, 27%, Path A) whereas, intramolecular cyclization reactions gave rise to the bicyclic products 5-(3′,5′-di-*O*-acetyl-2′-deoxy-β-D-ribofuranosyl)-furano[2,3-*d*]pyrimidin-6(5*H*)-one (**5**, 13%, Path B) and 3-azido-2,3-dihydro-5-(3′,5′-di-*O*-acetyl-2′-deoxy-β-D-ribofuranosyl)furano[2,3-*d*]pyrimidin-6(5*H*)-one (**6**, 2.8%, Path C), respectively.

The base-catalyzed intramolecular cyclization reaction of **3***a* to **6**, as illustrated in Scheme 2, is analogous to the reported conversion of 5-[2-[(methylsufonyl)oxy]ethyl]uracil to 2,3-dihydrofurano[2,3-*d*]-pyrimidin-6(5*H*)-one using *t*-BuOK in DMSO (9). The mechanism responsible for the formation of the bicyclic compound **5** proceeds via an elimination reaction involving expulsion of HN$_3$ from **6** as illustrated in Scheme 3 since treatment of **6** with a saturated solution of NH$_3$ in MeOH gave the bicylic derivative **10**, rather than the azido compound **11** (see Scheme 1). To prevent the formation of the bicyclic products **5** and **6**, the N-3 position of 5-(1-azido-2-bromoethyl)-3′,5′-di-*O*-acetyl-2′-deoxyuridine (**3***a*) was protected by reaction of **3***a* with benzoyl chloride in dry pyridine, which gave the N-3 benzoyl derivative (**3***c*) in 93% yield. Reaction of **3***c* with *t*-BuOK in THF yielded the 5-(1-azidovinyl) analog **4***c* in higher yield (39%) than that obtained using **3***a* (27%). A similar reaction of the 5-(1-azido-2-bromoethyl)-3′,5′-di-*O*-*tert*-butyldimethylsilyl analog **3***b* gave the 5-(1-azidovinyl) product **4***b* (45%). Deprotection of **4***a* (NH$_3$–MeOH) and **4***b* (*n*-Bu$_4$N$^+$F$^-$–THF) yielded 5-(1-azidovinyl)-2′-deoxyuridine (**7**) in 76 and 86% yield, respectively. Thermal decomposition, using a procedure similar to that reported by Jordan (10) for the conversion of α-azidostyrene to phenylazirine, of the 5-(1-azidovinyl) compounds **4***a–c* in dry toluene at 110°C afforded the corresponding 5-[2-(1-azirinyl)] analogs **8***a–c* in 24, 84, and 54% yield, respectively. The possibility that the 5-[2-(1-azirinyl)] compounds (**8**, **9**) may undergo a [2 + 2] cycloaddition reaction to produce dimeric products **12** was ruled out since the fast atom bombardment (FAB) spectrum of **8***a* and **9** did not exhibit a molecular ion or mass fragmentation pattern indicating a dimeric structure **12**. The FAB spectra (**8***a*, **9**) exhibited the expected M + 1, 5-[2-(1-azirinyl)]uracil and sugar fragment, ions. Attempts to remove the 3′,5′-protecting groups present in compounds **8***a–c* using NH$_3$ in MeOH (**8***a*, **8***c*), NaHCO$_3$ in dry MeOH (**8***a*, **8***b*), or *p*-toluenesulfonic acid (**8***c*) were unsuccessful. In contrast, reaction of **8***b* with *n*-Bu$_4$N$^+$F$^-$ in THF afforded 5-[2-(1-azirinyl)]-2′-deoxyuridine (**9**) in 25% yield. The optimum yield of **9** was obtained by thermal decomposition of 5-(1-azidovinyl)-2′-deoxyuridine (**7**) in dioxane (37% yield).

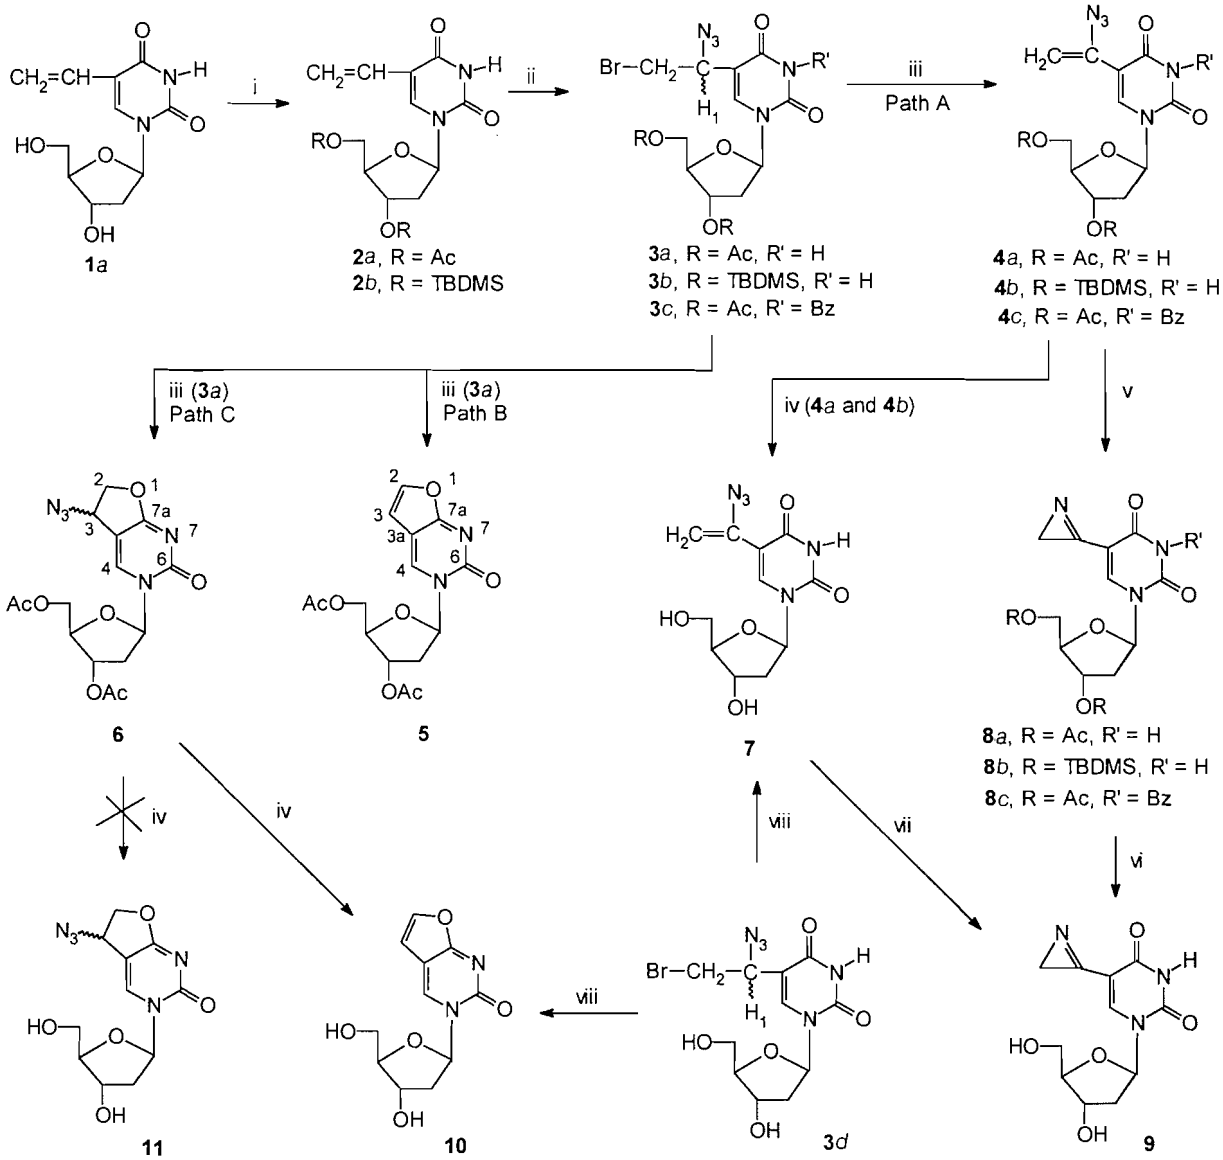


12



The in vitro antiviral activities of 5-(1-azidovinyl)- (**7**), 5-[2-(1-azirinyl)]-2′-deoxyuridine (**9**), and the related bicyclic analog 5-(2′-deoxy-β-D-ribofuranosyl)furano[2,3-*d*]pyrimidin-6(5*H*)-one (**10**) were determined against four viruses (herpes simplex virus type 1 (HSV-1), type 2 (HSV-2),

Scheme 1.



Reagents: i, *tert*-Butyldimethylsilyl chloride, imidazole, DMF, 25°C; ii, *N*-bromosuccinimide, sodium azide, DME, −5°C; iii, *t*-BuOK, THF, 0°C; iv, NH_3, MeOH, 25°C (**4***a*), *n*-$Bu_4N^+ F^-$, THF (**4***b*); v, toluene, 110°C; vi, NH_3, MeOH, 25°C (**8***a*, **8***c*); $NaHCO_3$, MeOH, 4°C (**8***a*, **8***c*); *p*-toluenesulfonic acid, MeOH, 25°C (**8***b*), *n*-$Bu_4N^+ F^-$, THF (**8***b*); vii, dioxane, 110°C; viii, NaOH, or *t*-BuOK, DMSO, 25°C.

cytomegalo virus (CMV), and varizella zoster virus (VZV)). The 5-(1-azidovinyl) compound (**7**) exhibited appreciable in vitro activity against HSV-1 (IC_{50} = 0.4 μM) and VZV (IC_{50} = 0.1 μM), but was inactive against HSV-2 (IC_{50} = 150 μM) and CMV (IC_{50} > 20 μM), relative to the reference drug IVDU (HSV-1, IC_{50} = 0.02 μM; HSV-2, IC_{50} = 70 μM; VZV, IC_{50} = 0.001–0.002 μM; CMV, IC_{50} > 20 μM (6). Elaboration of 5-(1-azidovinyl)-2′-deoxyuridine (**7**) and 5-vinyl-2′-deoxyuridine (**1a**) to the corresponding 5-[2-(1-azirinyl)] (**9**) and bicyclic analog (**10**) provided compounds that were inactive in the in vitro assays against HSV-1, HSV-2, VZV, and CMV. These results suggest that an acyclic C-5 substituent may be essential for broad spectrum antiviral activity. The observation that the 5-[2-(1-azirinyl)] compound (**9**) was an inactive antiviral agent was unexpected since the 1-azirinyl ring system is conjugated with the 5,6-olefinic bond and it is an electronegative hydrophobic moiety. The finding that the 5-[2-(1-azirinyl)] compound (**9**) is inactive is consistent with earlier studies that showed that 5-(2,2-dihalocyclopropyl)- and 5-(2-halocyclopropyl)-2′-deoxyuridines exhibit either weak antiviral activity against HSV-1 and HSV-2, or that they are inactive (11, 12).

The in vivo effect of 5-(1-azidovinyl)-2′-deoxyuridine (**7**), acyclovir as a reference drug, and a placebo upon the mortality of mice inoculated intraperitoneally with HSV-1 was determined. Treatment was initiated at 24 h post-inoculation using a twice daily 50 mg/kg ip dose of the test compound (**7** or acyclovir), or placebo, for 7 days. The percent mortality and mean day of death (MDD) were determined. Although, the 5-(1-azidovinyl) compound (**7**) did not protect the mice (93% mortality), the MDD was increased to 8.1 days ($p < 0.001$) relative to placebo (MDD = 6.1 days). In contrast, acyclovir administration as described above resulted in a decreased mortality (27%, $P < 0.1$) with a MDD of 6.8 days, which was not statistically different from placebo. The in vivo ability of 5-(1-azidovinyl)-2′-deoxyuridine (**7**) to increase the length of survival (MDD), but not mortality, could be due to its rapid catabolism (13) and (or) its limited ability to cross the blood brain barrier. The in vivo metabolism, biodistribution, and pharmacokinetics of **7** have not been investigated to date.

Experimental

Melting points were determined with a Buchi capillary apparatus and are uncorrected. Nuclear magnetic resonance spectra (^{1}H NMR, ^{13}C NMR) were determined on a Bruker AM-300 spectrometer using Me_4Si as an internal standard (^{1}H NMR). The assignment of all exchangeable protons (OH, NH) was confirmed by the addition of D_2O. ^{13}C NMR spectra were acquired using the *J* modulated spin echo technique where methyl and methine carbon resonances appear as positive peaks and methylene and quaternary carbons appear as negative peaks. Fast atom bombardment (FAB) and high-resolution electron impact (EI) mass spectra were determined on an AEI-MS-12 and AEI-MS-50 spectrometer, respectively. Preparative thin-layer chromatography (PTLC) was performed using Whatman PLK5F plates, 1.0 mm in thickness, and silica gel column chromatography was carried out using Merck 7734 silica gel (60–200 mesh). 5-Vinyl-3′,5′-di-*O*-acetyl-2′-deoxyuridine (**2*a***) (1) and 5-(1-azido-2-bromoethyl)-2′-deoxyuridine (**3*d***) (14) were prepared using literature procedures.

5-Vinyl-3′,5′-di-*O*-*tert*-butyldimethylsilyl-2′-deoxyuridine (**2*b***)

Imidazole (0.55 g, 8.0 mmol) and *tert*-butyldimethylsilyl chloride (TBDMSCl) (0.60 g, 4.0 mmol) were added to a solution of **1*a*** (0.5 g, 2.0 mmol) in DMF (20 mL) and the reaction was allowed to proceed at 25°C with stirring for 36 h. Removal of the solvent in vacuo and purification of the product by elution from a silica gel column using chloroform–methanol (99:1, v/v) as eluent gave **2*b*** as a viscous oil (0.80 g, 82.5%); ^{1}H NMR ($CDCl_3$) δ: 0.09, 0.10 and 0.11 (three s, 12H total, Si*Me*$_2$), 0.90 and 0.92 (two s, 9H each, C*Me*$_3$), 2.00–2.08 and 2.28–2.36 (two m, 1H each, H-2′), 3.75–3.91 (m, 2H, H-5′), 3.96–4.02 (m, 1H, H-4′), 4.38–4.42 (m, 1H, H-3′), 5.24 (d, J_{cis} = 11 Hz of d, J_{gem} = 2.1 Hz, 1H, CH=C*H*H′), 6.0 (d, J_{trans} = 18 Hz of d, J_{gem} = 2.1 Hz, 1H, CH=CH*H*′), 6.28–6.32 (m, 1H, H-1′), 6.35 (d, J_{trans} = 18 Hz of d, J_{cis} = 11 Hz, 1H, C*H*=CHH′), 7.66 (s, 1H, H-6), 8.32 (s, 1H, NH).

5-(1-Azido-2-bromoethyl)-3′,5′-di-*O*-acetyl-2′-deoxyuridine (**3*a***)

N-Bromosuccinimide (15 mg, 0.084 mmol) was added in small aliquots to a precooled suspension at −5°C, prepared by mixing a solution of **2*a*** (25 mg, 0.074 mmol) in DME (4 mL) with a solution of sodium azide (18.2 mg, 0.28 mmol) in water (100 μL). The initial yellow color observed faded away after each addition. After all of the 5-vinyl compound **2*a*** had been consumed, the reaction mixture was allowed to stand at 0°C for 30 min, prior to pouring onto ice-water (5 mL) and extraction with dichloromethane (3 × 25 mL). The dichloromethane extract was washed with cold water (5 mL), dried (Na_2SO_4), and the solvent was removed in vacuo to yield a residue that was purified by elution from a silica gel column using chloroform–methanol (99:1, v/v) as eluent to yield **3*a*** as a viscous oil (22 mg, 88%); ^{1}H NMR ($CDCl_3$) (mixture of two diastereomers in a ratio of 1:1) δ: 2.06–2.22 (m, 7H, H-2′, *Me*CO), 2.45–2.57 (m, 1H, H-2″), 3.52–3.62 and 3.62–3.72 (1:1 ratio) (two m, 1H total, C*H*H′Br), 3.75–3.88 (m, 1H, CH*H*′Br), 4.24–4.45 (complex m, 3H, H-4′, H-5′), 4.84–4.96 (m, 1H, C*H*(N_3)CH_2Br), 5.20–5.24 (m, 1H, H-3′), 6.28–6.40 (m, 1H, H-1′), 7.64 (s, 1H, H-6), 9.48 (s, 1H, NH); ^{13}C NMR ($CDCl_3$) δ: 20.59, 20.71 and 20.84 (CH_3CO), 33.97 and 34.46 (CH(N_3)CH_2Br), 37.91 (C-2′), 58.21 and 58.33 (*C*H(N_3)-CH_2Br), 63.86 and 63.90 (C-5′), 74.29 (C-3′), 82.63 and 82.68 (C-1′), 85.14 and 85.42 (C-4′), 111.01 and 111.17 (C-5), 137.86 (C-6), 149.57 and 149.66 (C-2 *C*=O), 161.49 (C-4 *C*=O), 170.33 and 170.41 (CH_3*C*O).

5-(1-Azido-2-bromoethyl)-3′,5′-di-*O*-*tert*-butyldimethylsilyl-2′-deoxyuridine (**3*b***)

Reaction of **2*b*** with *N*-bromosuccinimide, using the procedure

outlined for the preparation of **3***a*, and purification of the product by silica gel column chromatography using chloroform-methanol (98:2, v/v) as eluent afforded **3***b* as a viscous oil (0.8 g, 82.5%). Anal. calcd. for $C_{23}H_{42}BrN_5O_5Si_2 \cdot 3/2H_2O$: C 43.73, H 7.17, N 11.08; found: C 43.55, H 6.98, N 10.81.

5-(1-Azido-2-bromoethyl)-3-benzoyl-3′,5′-di-*O*-acetyl-2′-deoxyuridine (3*c*)

Benzoyl chloride (0.17 g, 1.21 mmol) and diisopropylethylamine (74 mg, 0.6 mmol) were added to a solution of **3***a* (0.2 g, 0.43 mmol) in dry pyridine (10 mL) at 0–5°C with stirring. The reaction mixture was allowed to warm to 25°C, the reaction was allowed to proceed at 25°C for 6 h, ice-water (5 mL) was added, and the solvent was removed in vacuo. The residue obtained was purified by silica gel column chromatography using hexane – ethyl acetate (70:30, v/v) as eluent to yield **3***c* (0.225 g, 93%) as a viscous oil; ^{1}H NMR ($CDCl_3$) δ: 2.15–2.32 (m, 7H, H-2′, CO*Me*), 2.50–2.62 (m, 1H, H-2″), 3.60–3.73 (m, 1H, C*H*H′Br), 3.80–3.88 (m, 1H, CH*H*′Br), 4.30–4.34 (m, 1H, H-4′), 4.36–4.50 (m, 2H, H-5′), 4.91–4.98 (m, 1H, C*H*N_3), 5.23–5.28 (m, 1H, H-3′), 6.28–6.38 (m, 1H, H-1′), 7.46–8.14 (m, 6H, benzoyl hydrogens, H-6). Anal. calcd. for $C_{22}H_{22}BrN_5O_8$: C 46.81, H 3.93; found: C 46.59, H 4.00.

5-(1-Azidovinyl)-3′,5′-di-*O*-acetyl-2′-deoxyuridine (4*a*), 5-(3′,5′-di-*O*-acetyl-2′-deoxy-β-D-ribofuranosyl)furano-[2,3-*d*]pyrimidin-6-(5*H*)-one (5), and 3-azido-2,3-dihydro-5-(3′,5′-di-*O*-acetyl-2′-deoxy-β-D-ribofuranosyl)furano[2,3-*d*]pyrimidin-6(5*H*)-one (6)

Potassium *tert*-butoxide (0.21 g, 1.87 mmol) was added to a suspension of **3***a* (0.42 g, 0.913 mmol) in dry THF (60 mL) at −5°C with stirring. The cooling bath was removed and the reaction mixture was stirred at 5°C for 24 h. Removal of the solvent in vacuo gave a residue that was dissolved in dichloromethane (25 mL), washed with cold water (10 mL), the dichloromethane fraction was dried (Na_2SO_4), and the solvent was removed in vacuo. The reaction mixture was separated by silica gel column chromatography using chloroform–methanol (99:1, v/v) as eluent to give three products as viscous oils that eluted in the following order:

*Fraction 1 (**4**a)*: (93 mg, 27%); ^{1}H NMR ($CDCl_3$) δ: 2.12 and 2.14 (two s, 3H each, CO*Me*), 2.15–2.28 (m, 1H, H-2′), 2.5–2.57 (m, 1H, H-2″), 4.28–4.30 (m, 1H, H-4′), 4.36–4.42 (m, 2H, H-5′), 5.10 (d, J_{gem} = 2 Hz, 1H, C(N_3)=C*H*H″), 5.26–5.30 (m, 1H, H-3′), 6.31–6.36 (m, 1H, H-1′), 6.40 (d, J_{gem} = 2 Hz, 1H, C(N_3)=CH*H*′), 7.9 (s, 1H, H-6), 9.88 (s, 1H, NH); ^{13}C NMR ($CDCl_3$) δ: 20.45 (*C*H_3CO), 20.86 (*C*H_3CO), 38.06 (C-2′), 63.96 (C-5′), 74.35 (C-3′), 82.63 (C-1′), 85.44 (C-4′), 102.0 (C(N_3)=*C*H_2), 108.84 (C-5), 135.97 (*C*(N_3)=CH_2), 136.84 (C-6), 148.89 (C-2 *C*=O), 159.97 (C-4 *C*=O), 170.18 and 170.33 (CH_3*C*O). Anal. calcd. for $C_{15}H_{17}N_5O_7 \cdot 3/4H_2O$: C 45.85, H 4.74, N 17.82; found: C 46.09, H 4.71, N 18.19.

*Fraction 2 (**5**)*: (40 mg, 13%); ^{1}H NMR ($CDCl_3$) δ: 2.06–2.22 (m, 7H, C*H*$_3$CO, H-2′), 2.97–3.06 (m, 1H, H-2″), 4.30–4.52 (m, 3H, H-4′, H-5′), 5.23–5.28 (m, 1H, H-3′), 6.35 (dd, *J* = 6 Hz, 1H, H-1′), 6.60 (d, *J* = 2.5 Hz, 1H, OC*H*=CH), 7.42 (d, *J* = 2.5 Hz, 1H, OCH=C*H*), 8.43 (s, 1H, H-6); ^{13}C NMR ($CDCl_3$) δ: 20.74 (*C*H_3CO), 20.83 (*C*H_3CO), 39.31 (C-2′), 63.61 (C-5′), 73.97 (C-3′), 83.31 (C-1′), 88.61 (C-4′), 104.37 and 105.90 (C-2, C-3a), 136.12 (C-4), 144.88 (C-2), 154.37 (C-6), 170.21 (CH_3*C*O), 170.36 (CH_3*C*O), 171.95 (C-7a). Anal. calcd. for $C_{15}H_{16}N_2O_7 \cdot 1H_2O$: C 50.84, H 5.11, N 7.90; found: C 50.81, H 4.84, N 8.21.

*Fraction 3 (**6**)*: (10 mg, 2.8%); ^{1}H NMR ($CDCl_3$) δ: 2.02–2.18 (m, 7H, C*H*$_3$CO, H-2′), 2.86–2.94 (m, 1H, H-2″), 4.32–4.52 (complex m, 3H, H-4′, H-5′), 4.64 (d, J_{gem} = 11 of d, J_{vic} = 2.7 Hz, 1H, furanyl CHCH*H*″), 4.8 (d, J_{gem} = 11 Hz of d, J_{vic} = 6.4 Hz, 1H, furanyl CHC*H*H″), 5.12 (dd, J_{vic} = 6.4 of d, J_{vic} = 2.7 Hz, 1H, furanyl C*H*N_3), 5.20–5.24 (m, 1H, H-3′), 6.26 (dd, *J* = 6 Hz, 1H, H-1′), 8.23 (s, 1H, H-6); ^{13}C NMR ($CDCl_3$) δ: 20.81 (*C*H_3CO), 29.67 (C-2), 39.05 (C-2′), 57.40 (C-3), 63.54 (C-5′), 73.82 (C-3′), 83.08 (C-1′), 88.02 (C-4′), 102.52 (C-3a), 139.20 (C-4), 155.62 (C-6), 170.39 (CH_3*C*O), 176.86 (C-7a). Anal. calcd. for $C_{15}H_{17}N_5O_7 \cdot 1/4H_2O$: C 46.93, H 4.59; found: C 46.72, H 4.80.

5-(1-Azidovinyl)-3′,5′-di-*O*-*tert*-butyldimethylsilyl-2′-deoxyuridine (4*b*)

Potassium *tert*-butoxide (0.29 g, 2.6 mmol) was added as a suspension of **3***b* (0.78 g, 1.32 mmol) in dry THF (350 mL) at −5°C with stirring. The cooling bath was removed and the reaction mixture was stirred at 5°C for 2 h. Removal of the solvent in vacuo gave a residue that was dissolved in chloroform and washed with water (20 mL), the chloroform fraction was dried (Na_2SO_4), and the solvent was removed in vacuo. Purification of the residue by elution from a silica gel column using chloroform–methanol (99:1, v/v) as eluent yielded **4***b* as a viscous oil (0.305 g, 45%); ^{1}H NMR ($CDCl_3$) δ: 0.098, 0.10, and 0.12 (three s, 12H total, *Me*$_2$Si), 0.90 and 0.91 (two s, 9H each, *Me*$_3$C), 2.00–2.10 and 2.32–2.40 (two m, 1H each, H-2′), 3.80–3.84 (m, 2H, H-5′), 4.00–4.04 (m, 1H, H-4′), 4.40–4.44 (m, 1H, H-3′), 5.08 (d, J_{gem} = 2 Hz, 1H, C(N_3)=C*H*H′), 6.25 (d, J_{gem} = 2 Hz, 1H, C(N_3)=CH*H*′), 6.28 (dd, *J* = 6 Hz, 1H, H-1′), 7.92 (s, 1H, H-6), 8.90 (s, 1H, NH). Anal. calcd. for $C_{23}H_{41}N_5O_5Si_2$: C 52.73, H 7.89, N 13.37; found: C 52.72, H 8.30, N 13.57.

5-(1-Azidovinyl)-3-benzoyl-3′,5′-di-*O*-acetyl-2′-deoxyuridine (4*c*)

Reaction of potassium *tert*-butoxide (90 mg, 0.8 mmol) with **3***c* (0.225 g, 0.4 mmol), using the procedure described for the preparation of **4***b*, and purification of the product using chloroform–methanol (98:2, v/v) as eluent afforded **4***c* as a viscous oil (75 mg, 39%). Anal. calcd. for $C_{22}H_{21}N_5O_8 \cdot 1/2H_2O$: C 53.65, H 4.49, N 14.22; found: C 53.64, H 4.39, N 13.89.

5-(1-Azidovinyl)-2′-deoxyuridine (7)

Method A

A solution of **4***a* (50 mg, 0.131 mmol) in a saturated solution of ammonia in methanol (5 mL) was stirred at 25°C for 6 h. Removal of the solvent in vacuo yielded a residue that was purified by silica gel column chromatography using chloroform–methanol (90:10, v/v) as eluent to yield **7** (30 mg, 76%) as a solid; mp 153–155°C (dec.); ^{1}H NMR (CD_3OD) δ: 2.20–2.40 (m, 2H, H-2′), 3.70–3.90 (m, 2H, H-5′), 3.94–4.00 (m, 1H, H-4′), 4.38–4.45 (m, 1H, H-3′), 5.03 (d, *J* = 2 Hz, 1H, C(N_3)=C*H*H′), 6.08 (d, *J* = 2 Hz, 1H, C(N_3)=CH*H*′), 6.30

(dd, J = 6 Hz, 1H, H-1′), 8.36 (s, 1H, H-6); ^{13}C NMR (CD_3OD) δ: 41.62 (C-2′), 62.71 (C-5′), 72.21 (C-3′), 87.01 (C-1′), 89.10 (C-4′), 101.54 ($C(N_3)=CH_2$), 109.38 (C-5), 139.03 ($C(N_3)=CH_2$), 140.65 (C-6), 151.32 (C-2 $C=O$), 163.03 (C-4 $C=O$). Anal. calcd. for $C_{11}H_{13}N_5O_5 \cdot 3/4H_2O$: C 42.79, H 4.72, N 22.68; found: C 43.09, H 4.41, N 22.47.

Method B

A solution of n-$Bu_4N^+F^-$ (0.5 mL of a 1 M solution) in THF was added to a solution of **4***b* (0.17 g, 0.33 mmol) in THF (60 mL) and the reaction was allowed to proceed with stirring for 6 h at 25°C. Removal of the solvent in vacuo and purification of the product as described in Method A gave **7** (90 mg, 86%). The mp and ^{1}H NMR spectrum for **7** were identical to that of **7** prepared according to Method A above.

5-[2-(1-Azirinyl)]-3′,5′-di-*O*-acetyl-2′-deoxyuridine (8*a*)

A solution of 4*a* (90 mg, 0.237 mmol) in dry toluene (25 mL) was heated at 110°C for 3 h. Removal of the solvent in vacuo gave a viscous oil that was purified by silica gel column chromatography. Elution with chloroform–methanol (97:3, v/v) gave impure 8*a*, which was further purified by PTLC using chloroform–methanol (95:5, v/v) as development solvent. Extraction of the ultraviolet visible spot yielded 8*a* as a pale yellow foam (23 mg, 28%); ^{1}H NMR ($CDCl_3$) δ: 1.56 and 1.62 (two d, J_{gem} = 8.4 Hz, 1H each, azirinyl hydrogens), 2.10 and 2.12 (two s, 3H each, CO*Me*), 2.22–2.32 and 2.64–2.74 (two m, 1H each, H-2′), 4.30–4.50 (m, 3H, H-4′, H-5′), 5.25–5.29 (m, 1H, H-3′), 6.32 (dd, J = 6 Hz, 1H, H-1′), 8.25 (s, 1H, H-6), 9.45 (br s, 1H, NH); ^{13}C NMR ($CDCl_3$) δ: 17.25 (azirinyl CH_2), 20.75 and 20.80 (CH_3CO), 38.58 (C-2′), 63.58 (C-5′), 74.03 (C-3′), 83.19 (C-1′), 86.40 (C-4′), 103.08 (C-5), 144.66 (C-6), 148.91 (C-2 $C=O$), 158.89 (azirinyl C-2), 159.16 (C-4 $C=O$), 170.12 and 170.30 (CH_3CO); MS (FAB) *m/z*: 352 (M + 1), 201 (3′,5′-di-*O*-acetyl-2′-deoxyribosyl), 151 (5-[2-(1-azirinyl)]uracil); MS (HRMS), calcd. for $C_9H_{13}O_5$ (3′,5′-di-*O*-acetyl-2′-deoxyribosyl): 201.0762; found: 201.0751; calcd. for $C_6H_5N_3O_2$ (5-(2-(1-azirinyl)]uracil): 151.0381; found: 151.0382. Anal. calcd. for $C_{15}H_{17}N_3O_7$: C 51.28, H 4.87; found: C 50.98, H 4.92.

5-[2-(1-Azirinyl)]-3′,5′-di-*O*-*tert*-butyldimethylsilyl-2′-deoxyuridine (8*b*)

A solution of **4***a* (0.1 g, 1.9 mmol) in dry toluene (25 mL) was heated at 110°C for 2 h. Isolation of the product, as described for the preparation of **8***a*, gave a residue. Purification of this residue by silica gel column chromatography using chloroform–methanol (98:2, v/v) as eluent afforded **8***b* (80 mg, 84%) as a viscous oil; ^{1}H NMR ($CDCl_3$) δ: 0.09, 0.10, and 0.11 (three s, 12H total, Me_2Si), 0.82–0.98 (m, 20H, Me_3C, azirinyl hydrogens), 2.02–2.14 and 2.42–2.50 (two m, 1H each, H-2′), 3.76–3.92 and 3.94–4.02 (two m, 1H each, H-5′), 4.04–4.08 (m, 1H, H-4′), 4.37–4.43 (m, 1H, H-3′), 6.26 (dd, J = 6 Hz, 1H, H-1′), 8.27 (s, 1H, H-6), 9.50 (s, 1H, NH). Anal. calcd. for $C_{23}H_{41}N_3O_5Si_2 \cdot 5/4H_2O$: C 53.30, H 8.26, N 8.10; found: C 53.72, H 8.71, N 7.78.

5-[2-(1-Azirinyl)]-3-benzoyl-3′,5′-di-*O*-acetyl-2′-deoxyuridine (8*c*)

A solution of **4***c* (40 mg, 0.082 mmol) in dry toluene (10 mL) was heated at 110°C for 2 h. Isolation and purification of the product, as described for the preparation of **8***a*, yielded **8***c* as a foam (20 mg, 54%); ^{1}H NMR ($CDCl_3$) δ: 1.62 and 1.68 (two d, J_{gem} = 8.4 Hz, 1H each, azirinyl hydrogens), 2.08 and 2.16 (two s, 3H each, *Me*CO), 2.25–2.36 and 2.63–2.73 (two m, 1H each, H-2′), 4.32–4.52 (m, 3H, H-4′, H-5′), 5.23–5.27 (m, 1H, H-3′), 6.30 (dd, J = 6 Hz, 1H, H-1′), 7.46–7.95 (m, 5H, benzoyl hydrogens), 8.32 (s, 1H, H-6). Anal. calcd. for $C_{22}H_{21}N_3O_8 \cdot 1/2H_2O$: C 56.89, H 4.76, N 9.04; found: C 56.49, H 4.75, N 8.87.

5-[2-(1-Azirinyl)]-2′-deoxyuridine (9)

Method A

A solution of **7** (80 mg, 0.27 mmol) in dry dioxane (50 mL) was heated at 110°C for 2 h. Removal of the solvent in vacuo gave a residue that was purified by silica gel column chromatography using chloroform–methanol (90:10, v/v) as eluent to give **9** (27 mg, 37%) as a light yellow hygroscopic solid; ^{1}H NMR (CD_3OD) δ: 1.46 and 1.50 (two d, J_{gem} = 8.4 Hz, 1H each, azirinyl hydrogens), 2.28–2.48 (m, 2H, H-2′), 3.74–3.80 and 3.84–4.02 (two m, 1H each, H-5′), 3.96–4.00 (m, 1H, H-4′), 4.40–4.44 (m, 1H, H-3′), 6.26 (dd, J = 6 Hz, 1H, H-1′), 8.94 (s, 1H, H-6); ^{13}C NMR (CD_3OD) δ: 16.35 (azirinyl C-3), 42.23 (C-2′), 62.06 (C-5′), 71.31 (C-3′), 87.89 (C-1′), 89.37 (C-4′), 102.67 (C-5), 150.09 (C-6), 151.13 (C-2 $C=O$), 160.33 (C-4 $C=O$), 161.75 (azirinyl C-2); MS (FAB) *m/z*: 267 (M^+), 117 (deoxyribosyl), 151 (5-[2-(1-azirinyl)]uracil). Anal. calcd. for $C_{11}H_{13}N_3O_5 \cdot 1/2H_2O$: C 47.82, H 5.10, N 15.21; found: C 47.96, H 4.92, N 14.83.

Method B (9)

A solution of n-$Bu_4N^+F^-$ (0.1 mL of a 1 M solution) in THF was added to a solution of **8***b* (40 mg, 0.08 mmol) in THF (20 mL) and the reaction was allowed to proceed with stirring for 6 h at 25°C. Removal of the solvent in vacuo and elution of the product from a silica gel column using chloroform–methanol (90:10, v/v) as eluent afforded **9** as a pale yellow solid (8 mg, 25%). The ^{1}H NMR spectrum for **9** was identical to that of **9** prepared using Method A.

Reaction of 5-(1-azido-2-bromoethyl)-2′-deoxyuridine with sodium hydroxide

A solution of NaOH (5 mg, 0.12 mmol) in water (12 μL) was added to a solution of **3***d* (34 mg, 0.09 mmol) in DMSO (5 mL) at ice-bath temperature with stirring. The reaction mixture was then stirred for 1 h at 25°C. Removal of the solvent under high vacuum gave a residue that was purified by silica gel column chromatography using chloroform–methanol (95:5, v/v) as eluent to yield a mixture of **7** (3 mg, 11%) and **10** (15 mg, 66%). The ^{1}H NMR spectrum for this mixture of **7** and **10** was identical to that of **7** and **10** prepared by other methods described in this study.

Reaction of 3-azido-2,3-dihydro-5-(3′,5′-di-*O*-acetyl-2′-deoxy-β-D-ribofuranosyl)furano[2,3-*d*]pyrimidin-6(5*H*)-one (6) with methanolic ammonia

A solution of **6** (0.379 g, 1.0 mmol) in a saturated solution of ammonia in methanol (10 mL) was stirred at 25°C for 5 h. Removal of the solvent in vacuo and purification of the residue obtained by elution from a silica gel column using chloro-

form–methanol (88:12, v/v) as eluent afforded **10** (0.202 g, 80%), which was identical (^{1}H NMR) to the spectral data reported previously (15).

Acknowledgments

We are grateful to the Medical Research Council of Canada (Grant No. MT-12304) for financial support of this research, and to the Pharmaceutical Manufacturers Association of Canada for a PMAC/MRC Fellowship to one of us (R.K.). We also thank the United States National Institutes of Health Antiviral Research Branch, which provided the antiviral test results.

Thermodynamic properties of micellization of sodium dodecyl sulfate in binary mixtures of ethylene glycol with water

Kim Gracie, Dale Turner, and R. Palepu

Abstract: Micellar properties of sodium dodecyl sulfate (SDS) in aqueous mixtures of ethylene glycol (EG) were determined using techniques such as conductivity, density, EMF, surface tension, viscosity, ultrasonic velocity, and spectroscopy (fluorescence). The effective degree of disssociation of micelles (α) was determined using three different methods. Thermodynamics of micellization were obtained from the temperature dependence of critical micelle concentrations (cmc) values. The difference in Gibbs energies of micellization (ΔG_M^0) of SDS, between water and mixed solvent systems, was calculated to evaluate the influence of cosolvent on the micellization process. Surfactant aggregation numbers (N_s) obtained from static fluorescence quenching methods indicated a decrease in the aggregation numbers with increasing concentration of ethylene glycol in the binary solvent mixtures. In addition, the micropolarity of the micellar interior was determined from the pyrene I_1/I_3 ratios. These values were consistent with a decrease in the micropolarity surrounding the probe molecule as the EG content in the solvent mixture was increased.

Key words: thermodynamics, micellization, aggregation numbers, ultrasonic velocity, degree of dissociation.

Résumé : Faisant appel à des techniques telles que conductivité, densité, FEM, tension superficielle, viscosité, vitesse ultrasonique et spectroscopie (fluorescence), on a déterminé les propriétés micellaires du dodécylsulfate de sodium (DSS) en solutions aqueuses d'éthylèneglycol (EG). On a déterminé le degré effectif de dissociation des micelles (α) en faisant appel à trois méthodes différentes. On a obtenue les données thermodynamiques relatives à la micellisation à partir de la dépendance des valeurs «cmc» sur la température. Afin d'évaluer l'influence du cosolvant sur le processus de micellisation, on a calculé la différence des énergies de Gibbs de micellisation (ΔG_M^0) du DSS, entre l'eau et des systèmes de solvants mixtes. Les nombres d'agrégation des agents de surface (N_s) ont été obtenus par des méthodes de piégeage statique de la fluorescence; ils indiquent que les nombres d'agrégation diminuent avec une augmentation de la concentration de l'éthylèneglycol dans les mélanges binaires de solvant. On a de plus déterminé la micropolarité de l'intérieur micellaire à l'aide des valeurs des rapports I_1/I_3 du pyrène. Ces valeurs sont en accord avec une diminution de la micropolarité aux environs de la molécule sonde lorsque la quantité d'EG dans le mélange de solvant augmente.

Mots clés : thermodynamique, micellisation, nombres d'agrégation, vitesse ultrasonique, degré de dissociation.

Introduction

It is well known that the micellar properties of both anionic or cationic surfactants are significantly influenced by the presence of various nonelectrolytes in solution (1, 2). There has recently been much research dealing with the effects of non-aqueous polar solvents on the formation of cationic micelles (3–22). Micelle or liquid crystal formation has been reported to occur in such solvents as hydrazine (3, 4), glycerol (5, 6), ethylene glycol (7, 8), and formamide (9–18), where all of the aforementioned solvents have high cohesive energy, dielectric constant, and a high degree of hydrogen bonding. Evans and co-workers (19) have indicated that the ability of a solvent to form hydrogen bonds is a necessary condition of micelle formation. However, it has been shown in the literature that the unique structure of water (H-bonding) is not a necessary condition for the aggregation process (23–26). Micelle formation has been reported in solvents such as acetone, acetonitrile, and dimethyl sulfoxide (18, 27, 28) where there is very little or no hydrogen bonding.

We recently investigated (29) the micellar properties of a cationic surfactant, hexadecylpyridium bromide (CPBr), in binary mixtures of water and ethylene glycol (EG) as a function of increasing percentage of EG in the solvent system. The present study deals with the effects of ethylene glycol on the micellar properties of sodium dodecyl sulfate (SDS) in water employing such techniques as conductivity, EMF, fluorescence spectroscopy, surface tension, density, ultrasonic velocity, and viscosity. Measurements were performed up to 60 wt.% of EG in the binary mixtures. Our results are consistent with the formation of aggregate in solvent mixtures containing less than 60% EG; beyond this concentration no aggregate for-

50 EG	2.31	0.66		

mation was observed. In the present study EG was regarded as a cosolvent rather than a cosurfactant forming mixed micelles.

Experimental section

Sodium dodecyl sulfate (BDH) was crystallized several times from hot methanol, further purified through Soxhlet extraction using diethyl ether for 72–100 h, and dried under vacuum. Freshly opened bottles of ethylene glycol (Aldrich 99%) were used. Water was nanopure.

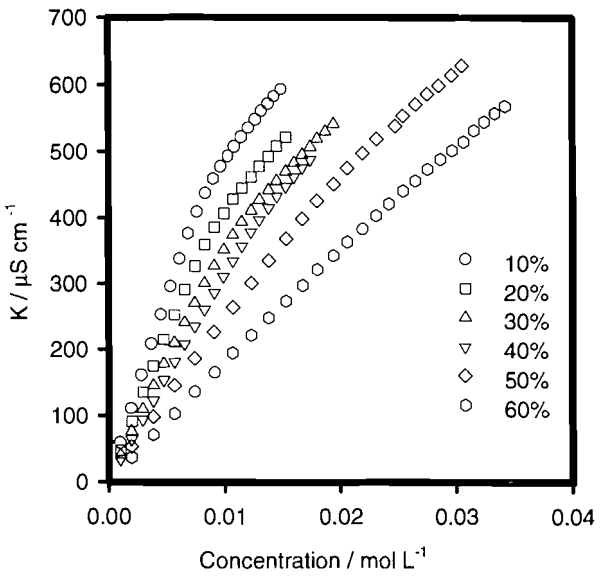
Equilibrium surface tension (γ) measurements were performed on a Cahn Dynamic Contact angle analyzer model no. 312 using the Wilhelmy plate technique. The solutions were placed in a thermostated beaker to maintain a constant temperature of 298–318 K. Viscosities of SDS in EG–H_2O mixtures at various concentrations were determined using modified Ostwald or Cannon–Fenske viscometers and a viscosity bath (Koehler Instrument). Conductivity measurements were made in a thermostated jacketed beaker with a dip cell having a cell constant of 0.978 cm^{-1} and an automatic conductivity CDM83 bridge operating at 1000 Hz. The conductivity titrations contained at least 20–25 different concentrations of surfactant at a fixed solvent composition and were measured at different temperatures. Density measurements were obtained using an Anton–Parr digital densimeter DMA45 operating in the static mode. The instrument was calibrated with nanopure water and dry nitrogen.

The sodium-ion activities were measured using a Fisher Na^+ ion electrode coupled with a double junction reference electrode (Fisher Scientific 13-620-47). Ammonium nitrate solution was used in the outer chamber of the double junction reference electrode to prevent the precipitation of potassium dodecyl sulfate. The solutions of surfactant were prepared, in the mixed solvent system, on a molal basis and converted to other units using the density data.

Luminescence quenching measurements were carried out on a Shimadzu specrtrofluorophotometer RF-1501. The probe used was pyrene (Aldrich 99%) and it was held at a constant concentration of $\cong 2 \times 10^{-5}$ M. The quencher used was 1-hexadecylpyridinium bromide (CPBr) and the concentration was held low enough so as not to interfere with the assembly of the micelles. Ratios of the intensities of the first and third peaks were measured using a Perkin Elmer MPF-66 fluorescence spectrophotometer to determine the micropolarity of the micellar interior.

Ultrasonic velocities were measured with a Nusonics (model 6080) concentration analyzer using the sing-around method.

Fig. 1. Specific conductance (K) vs. concentration of SDS in aqueous mixtures of ethylene glycol.



Results

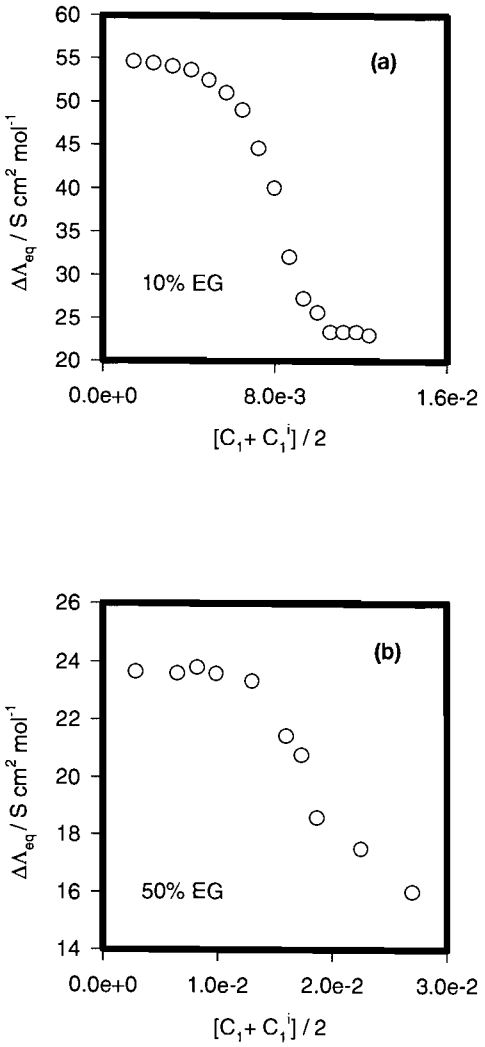
Conductivity

The critical micellar concentration (cmc) values were estimated from the break points in the plots of specific conductance (K) versus the concentration of surfactant (Fig. 1), and are presented in Table 1. The effective degree of dissociation of the counterion (α) was calculated from the ratio of the slopes before and after the cmc in the plots of K and versus C. To distinguish between a proper or cooperative micelle formation and a more gradual association (premicellar aggregation) prior to the cmc, the differential equivalent conductance ($\Delta\Lambda_{eq}$):

$$[1] \quad \Delta\Lambda_{eq} = 10^{-3} \frac{K_1 - K_1^i}{C_1 - C_1^i}$$

(where $K_1 - K_1^i$ and $C_1 - C_1^i$ represent the increment in conductivity and the increment in concentration, respectively) was plotted against the mean concentration. For a normal micellization process the plot of $\Delta\Lambda_{eq}$ vs. mean concentration $(C_1 + C_1^i)/2$ decreases vertically over a narrow concentration

Fig. 2. Differential equivalent conductance vs. mean concentration.



range (Fig. 2*a*), while for a more gradual aggregation the decrease occurs over a wider concentration range (30, 31), as observed at higher concentrations of EG (Fig. 2*b*).

The equivalent conductivity of SDS at infinite dilution (Λ_0) was calculated using the Onsager equation (32).

$$[2] \quad \Lambda = \Lambda_0 - (B\,\Lambda_0 + A)C^{1/2}$$

The values of Λ_0, obtained using eq. [2], are presented in Table 2.

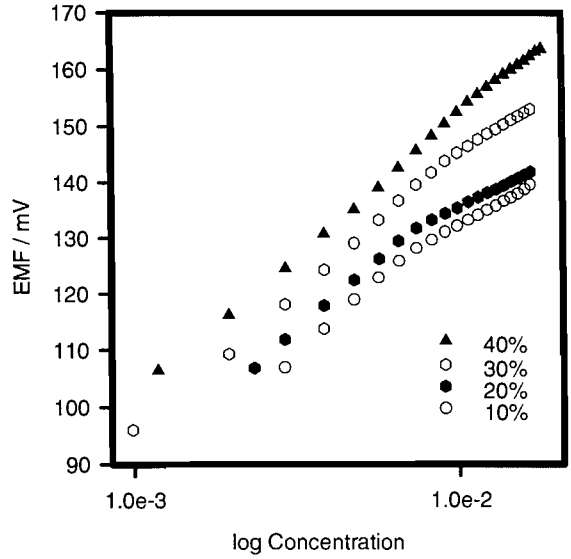
Activation energy of conduction (E_a)

The electrical conductance, as a function of temperature, may be expressed as an Arrhenius-type equation (33).

$$[3] \quad \sigma = \sigma_0 \exp(-E_a/RT)$$

where σ is the electrical conductivity, σ_0 is constant for a given surfactant, R is the gas constant, and E_a is the activation energy of conduction.

Fig. 3. EMF plots of the Na^+/DJ reference electrode system for SDS in EG + H_2O mixtures.



The values of E_a before and after the cmc were obtained from the plots of ln σ vs. $1/T$ and are presented in Table 2.

Electrochemical studies

Plots of EMF (mV) data as a function of log C of the surfactant at various compositions of EG (Fig. 3) show that at the higher weight percentage of EG there is a slight deviation from Nernstian behavior over a narrow concentration range, just before the cmc, indicating that the micellization process is not cooperative. The breakpoint in the plot of EMF vs. log C is indicative of micellar formation. At lower surfactant concentrations, i.e., below the cmc, the slopes of EMF vs. log C were close to Nernstian (56–59 mV/decade).

Effective degree of dissociation

The effective degree of dissociation of the counterion Na^+ as a function of surfactant concentration was determined by three different procedures. Method 1 refers to the conductometric method in which α was taken as the ratio of the slope of the conductivity vs. concentration plot above the cmc to the slope below the cmc (values listed in Table 1).

Method 2 (34) refers to the potentiometric determination of α. Plots of EMF vs. log SDS concentration below the cmc obeyed the Nernst equation:

$$[4] \quad E = E^0 + Y \log a = E^0 + Y \log (\gamma C)$$

where Y is the Nernstian slope, and a, γ, and C are the activity, activity coefficient, and concentration of Na^+, respectively. The values of γ were calculated using Davies equation (32):

$$[5] \quad \log \gamma = \frac{-AC^{1/2}}{1 + C^{1/2}}$$

where

$$[6] \quad A = \frac{1.8246 \times 10^6}{(\varepsilon_r T)^{3/2}}$$

Table 2. Apparent molar quantities and activation energies.

Wt.% EG	Λ_0 (S cm^2 mol^{-1})	E_a before cmc (kJ mol^{-1})	E_a after cmc (kJ mol^{-1})	ΔV_m (cm^3 mol^{-1})	ΔK_m (bar^{-1} cm^3 mol^{-1})
0	73.4	9.0	23.4	10.8	4.7
10	60.4	12.9	20.2	6.9	5.0
20	49.7	19.2	23.1	1.0	5.4
30	40.9	18.7	26.6	0.7	5.7
40	33.8	19.5	23.6	0.5	6.1
50	27.5				
60	19.1				

where ε_r is the dielectric constant of the mixed solvent system (EG + H_2O) and T is the absolute temperature. The values of ε_r were obtained from the literature (35). Once γ was found, the plots of E vs. log a were analysed by linear regression to calculate the values of Y and E^0 in different solvent mixtures. Rearranging the Nernst equation gives

$$[7] \quad a = 10^{(E - E^0)/Y}$$

which enables the calculation of Na^+ activity at all concentrations studied above the cmc. In this range, Na^+ activity is given by:

$$[8] \quad a = \gamma[C_{cmc} + \alpha(C - C_{cmc})]$$

where C_{cmc} is the concentration at the cmc and C is the bulk concentration of SDS. By differentiating the above equation with respect to C and assuming γ to be constant above the cmc, it can be shown that:

$$[9] \quad \alpha = \frac{1}{\gamma}\frac{da}{dC}$$

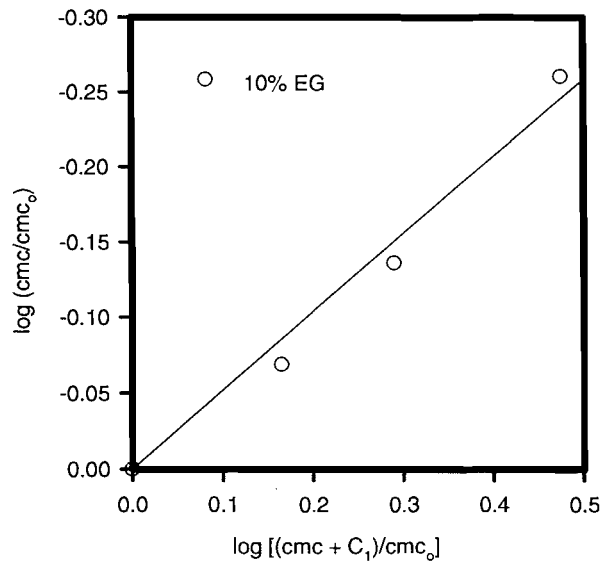
where da/dC is the slope of log a vs. concentration after the cmc and γ was calculated using the Davies equation with concentration equal to the critical micellar concentration.

In method 3 (34), the α value was determined by studying the effects of an increasing electrolyte concentration on the cmc. The cmc values, in the presence of an electrolyte, were determined using visible and fluorescence spectroscopic methods. The α values were obtained from the following equation:

$$[10] \quad \log\frac{cmc}{cmc_0} = -(1 - \alpha)\log\left[\frac{cmc + C_1}{cmc_0}\right]$$

where cmc_0 is the cmc in the absence of salt and C_1 is the salt concentration. The slope of a plot of log (cmc/cmc_0) vs. log [(cmc + C_1)/cmc_0] is equal to $-(1 - \alpha)$, from which the values of α were obtained (Fig. 4).

Fig. 4. Log (cmc/cmc_0) vs. log [(cmc + C_1)/cmc_0) plot for SDS in 10% EG + 90% H_2O mixtures.



Luminescent quenching

The static fluorescence quenching method originally proposed by Turro and Yekta (36) was used in determining the aggregation numbers of the micelles in the presence of additives. The authors derived a relationship between the bulk quencher concentration and the intensities as a function of the quencher concentration:

$$[11] \quad I = I_0 \exp(-[Q]/[M])$$

where I_0 is the intensity in the absence of quencher, I is the intensity at bulk quencher concentration [Q], and [M] is the micellar concentration and is inversely proportional to the slope of a plot ln (I_0/I) vs. quencher concentration (Fig. 5). Therefore the aggregation number (N_s) can be defined as follows:

$$[12] \quad N_s = \frac{C_{SDS} - cmc}{[M]}$$

The application of the Turro–Yekta method depends on agreement with two experimental criteria (37, 38); firstly, the luminescent probe and quencher must be solubilized in the micelle and be immobile, i.e., they must remain in the micelle

Table 3. Aggregation numbers (N_s), size of SDS micelles, and I_1/I_3 pyrene ratios.

% EG	N_s (±3)	R (Å^3)	a_0 (Å^2)	V/a_0l_c	I_1/I_3 EG	I_1/I_3 0.05 M SDS in EG

6	56	16.7	62.8	0.33	1.80	1.24
10	51	16.2	64.8	0.32	1.80	1.24
20	46	15.7	67.1	0.31	1.78	1.25
30	40	15.0	70.2	0.30	1.75	1.26
40	35	14.3	73.4	0.29	1.78	1.26
50	30	13.6	77.3	0.27	1.68	1.31

Fig. 5. In (I_0/I) vs. quencher concentration in binary mixtures of EG + H_2O containing 50 mM SDS.

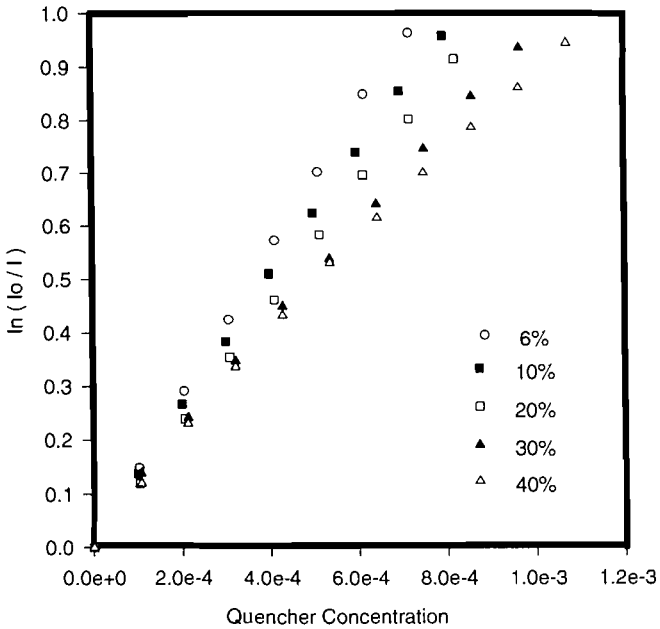

Fig. 6. Surface tension of SDS in 10% EG + H_2O mixtures at 298 K.

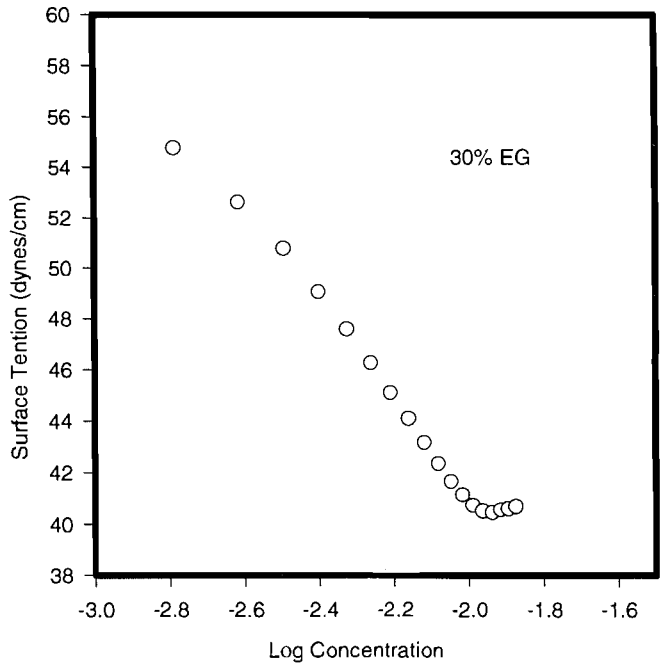

during the lifetime of the probe, and, secondly, quenching must be much faster than the decay of the liminescence intensity so that liminescence is observed only from those micelles that contain a probe and no quencher.

Generally, the application of the Turro–Yekta equation to the determination of micellar aggregation numbers is valid for probe–quencher pairs such as ruthenium tris(biphenyl) chloride – 9-methylanthracene (9-MA) and pyrene – cetylpyridinium ion (CP^+) in micellar systems whose aggregation numbers are less than 80. Aggregation numbers (N_s) of SDS, determined at various EG + H_2O binary mixtures by the static fluorescence quenching method, and the pyrene I_1/I_3 ratios are presented in Table 3. The hydrophobic chain volume of the micelle (v) and the critical chain length (l_c) were obtained using Tanford's equations (39)

[13] $v = 27.4 + 26.9\ n$ (Å^3)

[14] $l_c = 1.5 + 1.265\ n$ (Å)

where n is the number of carbon atoms of the chain. The micellar radius (R) and the surface area per head group (a_0) were obtained assuming spherical shape. The values of R and a_0 along with the values of critical packing parameter ($v/(a_0l_c)$), a parameter known to control the micellar shape (40), are presented in Table 3.

Surface tension

A representative plot of the surface tension (γ), at 298 K, of solution of SDS in a binary mixture of EG + H_2O versus the log of the bulk phase concentration of surfactant is shown in Fig. 6.

The maximum surface excess concentration, T_{max}, the minimum area per surfactant molecule, A_{min} (m^2), at the surfactant–solvent interface, and the value of the surface pressure at cmc, Π_{cmc}, were obtained using the surface tension data and the following equations:

Table 4. Surface excess concentrations (T_{max}), minimum area per molecule (A_{min}), and surface pressure at the cmc (Π_{cmc}) for sodium dodecyl sulfate in aqueous mixtures of ethylene glycol.

Composition (wt.% of EG)	T (K)	$T_{max}X$ (10^6/(mol m^{-2}))	$A_{min}X$ (10^{20}/m^2)	Π_{cmc} (mN m^{-1})
5	298	2.412	68.8	35.24
	308	2.004	82.8	31.37
	318	1.788	92.8	26.40
10	298	2.137	77.6	32.01
	308	1.820	91.2	27.90
	318	1.641	101.2	23.38
30	298	1.299	127.8	18.49
	308	1.125	147.6	14.58
	318	1.037	160.2	8.13

[15] $$T_{max} = -\frac{1}{\nu RT}\left[\frac{\delta\gamma}{\delta \ln C_{T,P}}\right]$$

[16] $$A_{min} = 1/N_a T_{max}$$

and

[17] $$\Pi_{cmc} = \gamma_0 - \gamma_{cmc}$$

where ν is the number of ions per surfactant molecule, R is the gas constant, N_a is Avogadro's number, and γ_0 is the surface tension of the pure solvent. In eq. [15] the term C is used in place of activity because it is assumed that for dilute solution the value of the mean activity coefficient of SDS is approximately equal to 1. The values of Π_{cmc}, A_{min}, and T_{max} are presented in Table 4.

Viscosity

Plots of the solution viscosity (η) vs. SDS concentration in various mixtures of EG and H_2O (Fig. 7) indicate that the cmc is the point of intersection of the two linear portions of the plots.

Information on the hydrodynamic volume of the micelle can be obtained from values of intrinsic viscosity, where the intrinsic viscosity of the micelle is defined by:

[18] $$[\eta]_{mic} = \lim_{C\to cmc}\left(\frac{\eta/\eta_0 - 1}{C - cmc}\right)$$

where η_0 is the viscosity of the media at the cmc and C is the total bulk surfactant concentration. By expressing the viscosity above the cmc as a power series and limiting it to the quadratic term the following equation is obtained:

[19] $$\eta = \eta_0 + a_1(C - C_{cmc}) + a_2(C - C_{cmc})^2$$

where a_1 and a_2 are constants. The intrinsic viscosities of the micelle, equal to a_1/η_0, were obtained by fitting experimental data to eq. [19] and are presented in Table 5.

Fig. 7. Plots of viscosity of SDS solution in EG + H_2O mixtures as a function of SDS concentration.

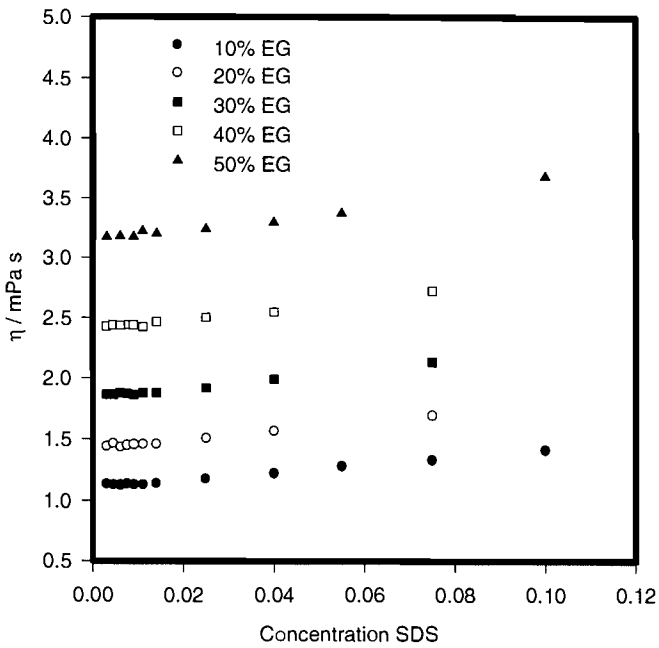

Table 5. Intrinsic viscosities as a function of ethylene glycol content.

Solvent system	$[\eta]$ (mL g^{-1})
H_2O	4.30
10% EG	3.01
20% EG	2.96
30% EG	2.28
40% EG	1.05
50% EG	0.90

Apparent molar volumes

Apparent molar volumes, ϕ_v, were determined from density data using:

$$[20] \quad \phi_v = \frac{M}{d} - \frac{10^3 (d - d_0)}{mdd_0}$$

where M is the molecular weight, d and d_0 are the densities of the solution and the solvent, and m is the molality. When ϕ_v is plotted against $C^{1/2}$, the gradient approaches zero at higher surfactant concentration and this limiting value is subjectively chosen as the apparent molar volume of the micelles (ϕ_v^{mic}) (41).

An alternative method (42) is to fit the data to the following function:

$$[21] \quad \frac{\phi_v}{\phi_v^{mic}} = \frac{m}{(a + m)}$$

where a is an empirical constant. Rearrangement of eq. [21] in the following form:

$$[22] \quad \phi_v = -a(\phi_v/m) + \phi_v^{mic}$$

allows ϕ_v^{mic} to be extrapolated from plots of ϕ_v vs. ϕ_v/m.

The apparent molar volumes at infinite dilution, ϕ_v^0, were determined numerically or graphically using the following equation:

$$[23] \quad \phi_v = \phi_v^0 + A_v C^{1/2} + B_v C$$

where A_v is the Debye–Hückel constant for a 1:1 electrolyte at 298 K, and B_v is an adjustable parameter.

The volume change, $\Delta V_m = \phi_v^{mic} - \phi_v^0$, associated with the formation of aggregates decreases with increasing EG content (Table 2).

Ultrasonic velocity

Ultrasonic velocity (U) data were fitted to the following equation:

$$[24] \quad U = U_0 + GC$$

where U_0 is the ultrasonic velocity in the pure solvent, G is Garnsey's constant, and C is the surfactant concentration. In the plots of U vs. C the intersection point of two straight lines at a definite surfactant concentration is taken as the cmc (Fig. 8*a*).

Adiabatic compressibility coefficients (β) were calculated employing the equation

$$[25] \quad \beta = 1/(U^2 d)$$

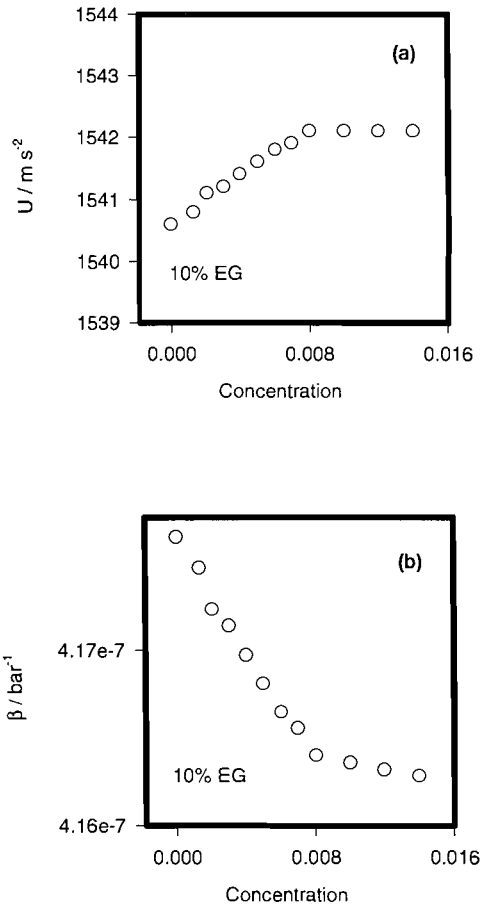
where U is the sound speed and d is the solution density (Fig. 8*b*).

Ultrasonic measurements of micellar solutions have been shown to be sensitive to the shape of the aggregate. In the present study, a definite break occurring at the cmc is indicated. The plot of adiabatic compressibility coefficient vs. concentration also shows a small but definite change in slopes at the cmc.

Apparent molar compressibilities

Apparent molar compressibilities, ϕ_k, were determined using the following equation:

Fig. 8. Plots of ultrasonic velocity (U) and adiabatic compressibilities (β) of SDS solutions in 10% EG + 90% H_2O mixture.



$$[26] \quad \phi_k = 1000\, C^{-1} (\beta - \beta_0) + \beta_0 \phi_v$$

where β and β_0 are the compressibility coefficients of the solution and the solvent. The apparent molar compressibility at infinite dilution (ϕ_k^0) and the micellar compressibility (ϕ_k^{mic}) (42, 43) values were obtained form the plots of ϕ_k as a function of concentration to calculate the compressibility change on micellization, ΔK_{mic} (Table 2).

Thermodynamics of micellization

The Gibbs free energy of micellization was calculated using the equation

$$[27] \quad \Delta G^0_{mic} = (2 - \alpha) RT \ln a\pm_{cmc}$$

where α is the effective degree of dissociation of the counterion (Na^+), R is the gas constant, T is the absolute temperature, and $a\pm$ is the mean activity of the counterion at the cmc. However, in this study, $a\pm_{cmc}$ was replaced by X_{cmc}. When calculating ΔG^0_{mic} at various temperatures, the temperature dependency of α was taken into account. The enthalpy and entropy of micellization (ΔH^0_{mic} and ΔS^0_{mic}) were calculated from the following equations:

Table 6. Thermodynamics of micellization of SDS in various ethylene glycol + water mixtures.

Wt.%	cmc (10^{-3})	ΔG^0 (kJ mol^{-1})	ΔH^0 (kJ mol^{-1})	ΔS^0 (J K^{-1} mol^{-1})	ΔG^0_M (kJ mol^{-1})
10 EG	8.2	−33.3	−11.5	73.1	3.35
20 EG	8.7	−31.0	−11.7	64.1	5.65
30 EG	10.7	−28.3	−13.0	53.4	8.35
40 EG	12.5	−26.1	−13.5	42.3	10.55
50 EG	18.7	−23.7	−13.9	32.9	12.95
60 EG	24.0	−20.1	−16.2	13.1	16.55

[28] $$\Delta H^0_{mic} = (2 - \alpha)R\left(\frac{\delta \ln X_{cmc}}{\delta(1/T)}\right)$$

[29] $$\Delta S^0_{mic} = (\Delta H^0_{mic} - \Delta G^0_{mic})/T$$

The effect of a cosolvent or additive on the micellization process, given by ΔG^0M, was calculated using the following equation:

[30] $$\Delta G^0_M = \Delta G^0_{mic(EG+H_2O)} - \Delta G^0_{mic(H_2O)}$$

The values of the aforementioned parameters are listed in Table 6.

Discussion

The values of the effective degree of dissociation (α) obtained by different methods are in good agreement (Table 1). The EG in the present study is acting as a cosolvent and a structure-breaking solute. Structure-breaking solutes are known to decrease the hydrophobic effect (considered to be the driving force for micellization). Structure breakers in the aqueous phase may disturb the dissolved hydrophobic group, causing a decrease in the entropy increase on micellization, resulting in larger cmc values as the content of EG increases. Another factor that causes the cmc to increase with EG content is a decrease in the cohesive energy or the solubility parameter of water with the addition of EG. Also, a decrease in the dielectric constant of the aqueous phase would result in an increase in the repulsion between the ionic head groups, leading to a delayed micellization. The formation of pre-aggregates before the cmc would also increase the cmc. This is substantiated in the plot of $\Delta\Lambda$ vs. the mean concentration (Fig. 2*a*). The gradual association of monomers before the formation of micelles is well established in pure EG from electrochemical studies (44). The values of Λ_0 (Table 2) show a decrease with increasing concentration of EG, indicating an association of the surfactant monomer with the EG cosolvent. The increase in the E_a after the cmc is due to the counterion binding with the micelle. Other factors involved in the E_a of conduction are the effective degree of dissociation of the counterion (α), the radius of the micelle, and the viscosity of the solvent system. At higher EG concentrations the effective degree of micellar dissociation (α) increases, resulting in more free Na^+ ions to carry the current, and also the aggregation numbers decrease with an increase in EG content, which allows for the lower value of E_a.

As the content of EG increases, the micellization process is less spontaneous, as indicated in the values of the Gibbs energies of micellization (Table 6). The equation used in the calculation of ΔG^0_{cmc} applies normally when the mean aggregation number is large but may not be valid at the higher EG content (9). Therefore, the values of ΔH^0_{mic} and ΔS^0_{mic}, obtained in the present study, should only be viewed as an approximation. From analysis of the present data some generalizations can be drawn. As the EG content increases, the values of ΔS^0_{mic} become less positive, whereas the values of ΔH^0_{mic} become increasingly negative, showing that at the higher EG contents ΔH^0_{mic} becomes a more dominating factor.

The positive values of ΔG^0_M indicate that the micellization process is less favorable in the EG + water mixtures. This is due to the hydrocarbon part of the surfactant being solvated by the hydrophobic part of the cosolvent and the hydrophilic part being solvated by water, so the ability of the cosolvent to associate is decreased. Also, as the amount of EG increases, the values of both Π_{cmc} and T_{max} decrease (Table 4), which is indicative of the hydrocarbon chain of the surfactant interacting with the EG, producing a shift of the surfactant molecules from the interface to the bulk of the solution.

For a spherical, rigid, uncharged, and unhydrated micelle the intrinsic viscosity value would be equal to 2.5 mL/g. However, in reality the micelle is often highly charged and strongly hydrated, ranging in shape from spherical to rodlike (45). The properties that affect the intrinsic viscosity are non-sphericity, flexibility of the micelle, micellar charge, and micellar hydration.

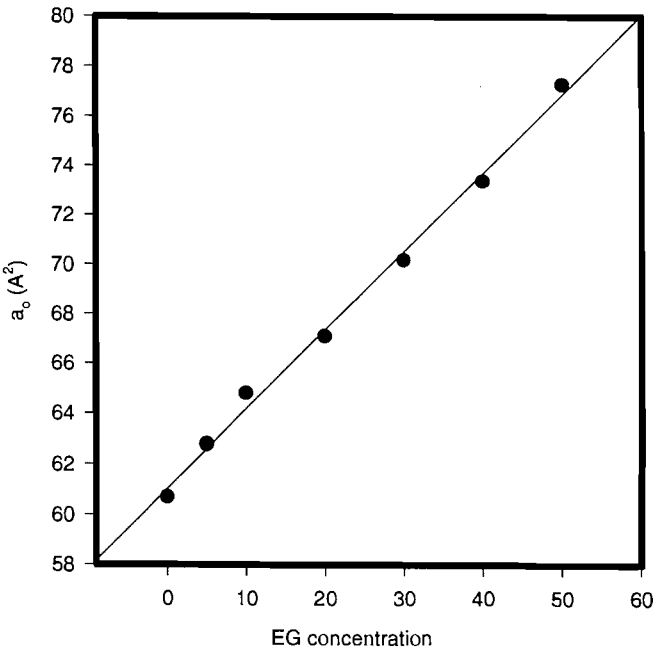
From the values of [η] (Table 5) obtained in the present study, the degree of hydration of the micelles in pure H_2O compared to hydration in the mixed solvent system (EG + H_2O) decreases as the EG content increases, and above 30% EG the micelles are very small and highly charged.

The decreasing values of ΔV_{mic} as the EG content increases (Table 2) suggest that there is less free space in the interior of the aggregates in the presence of EG than with water.

The compressibility charge on micellization, ΔK_{mic}, is positive and increases with EG content (Table 2); this indicates that in the presence of EG the interior of the micelle is more representative of a liquid hydrocarbon.

The decrease in the critical pacing parameter (Table 3) indicates that the addition of EG favors the formation of smaller spherical micelles. The surface area per headgroup increases linearly with EG content, as shown in Fig. 9, and this may be attributed to the replacement of some water molecules in the

Fig. 9. Surface area per head groups (a_0) of SDS micelles vs. EG composition.



solvation layers of the micelle headgroups by the ethylene glycol molecules, which are approximately 3.1 times larger than a water molecule. Analysis of the pyrene I_1/I_3 ratios (Table 3) gives information about the micropolarity of the environment surrounding the solubilized probe in the micelle. In the EG–H_2O binary system the I_1/I_3 ratios of the pyrene decrease with increasing EG content, indicating a lower polarity as sensed by the pyrene probe. At a given concentration of EG, in the presence of micelles, the polarity decreases as compared to the solvent system, indicating the pyrene is solubilized in the hydrophobic core of the micelle. However, in the ternary mixtures of SDS + EG + H_2O the I_1/I_3 ratios increase slightly with increasing EG content. This may be attributed to the inability of the pyrene to penetrate deep into the micelle, thereby sensing an increase in the polarity due to the location of the pyrene near the micelle–water interface or in the distribution of pyrene in the continuous phase.

In conclusion, the addition of ethylene glycol produces (*i*) an increase in cmc, which is mainly due to an increase in solubility of hydrocarbon tails of the surfactant; (*ii*) a decrease in the solvophobic effect (the difference in free energy for a hydrocarbon chain in oil and in the solvent in question) thereby decreasing the size of the SDS micelles; (*iii*) finally, a decrease in the micellar aggregation numbers, which may be attributed to the increase in the surface area per headgroup.

Theoretical and experimental approaches to the effects of solvation on the small internal rotational potential of benzal fluoride

Ted Schaefer, Guy M. Bernard, Younes Bekkali, and David M. McKinnon

Abstract: The internal rotational potential for benzal fluoride is computed at various levels of molecular orbital theory, including correlation-gradient, MP2 (frozen core) methods. The perturbations of the potential caused by solvents are calculated with the Onsager model (ellipsoidal cavity with $l = 6$ in the multipole expansion) as well as with the self-consistent isodensity – polarizable continuum model (SCI–PCM). Analysis of the ^{1}H and ^{19}F nuclear magnetic resonance spectra in cyclohexane-d_{12} and acetone-d_6 solutions yields long-range spin–spin coupling constants from which the expectation values of $\sin^2\phi$ can be derived. These expectation values can be compared with those calculated from the theoretical internal rotational potential. Reasonable agreement is found for potentials obtained from MP2/6-31G* approaches in both solvent models. Long-range coupling constants between ^{19}F and ^{13}C nuclei are also reported and provide very rough checks of the $\langle\sin^2\phi\rangle$ values. For the isolated molecule an additivity scheme based on the potential for benzyl fluoride reproduces much of the potential for benzal fluoride except for a deviation caused by the rather larger relative magnitude of the fourfold component in the latter. The minimum in the potential for benzal fluoride occurs for a torsional angle, ϕ, of 90°, corresponding to a conformation in which the C—H bond of the side chain lies in a plane perpendicular to the phenyl plane and is rationalized on the basis of electrostatic forces. The conformations of minimum energy for the benzyl and benzal fluorides and chlorides are compared and contrasted. The magnitudes of the internal potentials of the fluorides are only a little larger than thermal energies at 300 K and can become smaller than the latter in solution.

Key words: NMR spectroscopy, of benzal fluoride; spin–spin coupling constants, long range in benzal fluoride; solvent effects, on internal rotational potential in benzal fluoride; molecular orbital computations, structure, internal rotational potential, and its solvent perturbations in benzal fluoride; benzal fluoride, ^{1}H, ^{19}F, and ^{13}C NMR on, internal rotational potential, MO computations.

Résumé : On a estimé le potentiel de rotation interne du fluorure de benzal à divers degrés de la théorie des orbitales moléculaires, incluant les méthodes de corrélation-gradient, de MP2 (noyau gelé). On a calculé les perturbations du potentiel, provoquées par le solvant, avec le modèle de Onsager (cavité ellipsoïdale avec $l = 6$ dans l'expansion multipolaire) aussi bien qu'avec le modèle harmonisable du continuum isodensité – polarisable. L'analyse des spectres de RMN du ^{1}H et du ^{19}F, en solution dans le cyclohexane-d_{12} et dans l'acétone-d_6 donne les constantes de couplage spin–spin à longue distance à partir desquelles on a déduit les valeurs attendues de $\sin^2\phi$. On peut comparer ces valeurs attendues avec celles obtenues à partir du potentiel de rotation interne théorique. On a obtenu un accord raisonnable pour les potentiels calculés à partir de MP2/6-31G* dans les deux solvants modèles. On rapporte également les constantes de couplage à longue distance entre les noyaux de ^{19}F et de ^{13}C et ces constantes constituent une vérification grossière des valeurs de $\langle\sin^2\phi\rangle$. Pour la molécule isolée un schéma d'additivité, basé sur le potentiel du fluorure de benzyle, reproduit à peu près le potentiel du fluorure de benzal excepté la déviation provoquée par l'amplitude assez grande des quatre composés dans le dernier. Le minimum du potentiel du fluorure de benzal se produit pour un angle de torsion, ϕ, de 90° ce qui correspond à une conformation dans laquelle la liaison C—H de la chaîne latérale est dans un plan perpendiculaire au phényle et on rationalise ceci sur la base des forces électrostatiques. Les conformations du minimum d'énergie du benzyle et des fluorures et chlorures de benzal sont comparées et opposées. Les intensités des potentiels internes des fluorures sont seulement un petit plus élevées que les énergies thermiques à 300 K et peuvent devenir plus petites que ces dernières en solution.

Mots clés : spectroscopie de RMN, fluorure de benzal; constantes de couplage spin–spin, longue distance dans le fluorure de benzal; effets de solvant, sur le potentiel de rotation interne dans le fluorure de benzal; calculs d'orbitales moléculaires, structure, potentiel de rotation interne et ses perturbations par le solvant dans le fluorure de benzal; fluorure de benzal, sur la RMN du ^{1}H, du ^{19}F et du ^{13}C, potentiel de rotation interne, calculs MO.

Introduction

The primary purpose of this report is the characterization of the small (comparable to ambient thermal energies) internal rotational potential of benzal fluoride and its perturbation by polar and nonpolar media. To this end, molecular orbital computations on the isolated molecule, as well as those on the molecule embedded in a dielectric continuum, are performed. An experimental approach to the solutions of benzal fluoride depends on the measurements of long-range nuclear spin–spin coupling constants, sensitive to the internal rotational potential; these are described.

A secondary purpose is the comparison of the theoretical and experimental data for benzal fluoride with those known for benzyl fluoride, benzyl chloride, and benzal chloride.

That **2** should represent the stable conformer of benzal chloride is an intuitive prediction from the known behaviour of benzyl chloride. A single C—Cl bond entails a low-energy conformer in which this bond sits in a plane perpendicular to that of the phenyl group (1–4). In sharp contrast, the C—F bond in benzyl fluoride seeks a region near the phenyl plane in order to minimize the molecular energy (5, 6). Further (5–7), a sufficiently polar environment shifts the phase of the internal rotational potential of benzyl fluoride so as to produce a minimum at the perpendicular orientation of the C—F bond. Such an environment merely serves to further stabilize the perpendicular conformer of the chloride (1, 2).

The description of benzyl fluoride rests on the conformational dependence of the long-range spin–spin coupling constants between ^{1}H and ^{19}F nuclei in the side chain and ^{1}H or ^{13}C nuclei in the phenyl group. It is confirmed by molecular orbital computations of the internal barrier in the free molecule, as well as by computations of its alteration by solvents of low and high polarity. A similar approach is here described for benzal fluoride, a molecule not as yet characterized by any other physical methods.

Experimental

Benzal fluoride was prepared from benzyl alcohol and morpholinosulfur trifluoride (morph-DAST) by the standard procedure (8). Dilute solutions of this compound in six solvents of varying polarities (see Tables 1 and 2 for details) were filtered into 5 mm o.d. nmr sample tubes. The tubes were degassed by a minimum of five freeze–pump–thaw cycles on a vacuum line and were then flame-sealed to provide reasonably symmetrical tops.

^{1}H, ^{19}F, and proton-decoupled ^{13}C nmr spectra were obtained on a Bruker AM 300 spectrometer at 300 K. Shimming procedures employed the TMS or C_6F_6 free induction decays and yielded peak widths of about 0.04 Hz in the final ^{1}H nmr spectra; the ^{19}F peaks were generally somewhat wider. For ^{1}H and ^{19}F spectra, 32 decays, each acquired for 41 s, were coadded and followed by zero-filling to twice or four times the original data table. Digital resolution was 0.012 Hz/point. Resolution enhancements, often 0.6 LB and −0.1 GB, were applied to the final data. The ^{13}C nmr spectra came from the Fourier transformation of between 200 and 2500 decays, employing acquisition times of 10–12 s and digital resolution between 0.012 and 0.54 Hz per point.

The ^{1}H and ^{19}F nmr spectra corresponded to a AA'BB'CR X_2 spin system and were analyzed with the computer program NUMARIT (9), as modified for partial self-assignment by R. Sebastian and K. Marat (10). An attempted analysis of such spectra for the CS_2 solution proved unsatisfactory, most likely

Table 2. $^{13}C\{^1H\}$ nuclear magnetic resonance parameters for benzal fluoride at 300 K.[a]

Parameter	C_6D_{12}	CCl_4	CS_2	CD_2Cl_2	$(CD_3)_2C{=}O$	CD_3CN

^2J	22.45	22.40	22.35	22.22	22.18	22.18
^3J	6.04	6.05	6.01	6.12	6.12	6.16
^4J[c]	0.36	0.39	0.40	0.45	0.49	0.49
^5J	1.96	1.97	1.97	2.01	2.02	2.03

[a]All solutions were 5.0 mol% in benzal fluoride except for the acetone-d_6 solution, which was 2.5 mol%. In addition, each solution contained 0.5 mol% TMS and 0.25 mol% C_6F_6. The CCl_4 and CS_2 solutions also contained 10 mol% of C_6D_{12} as a lock material.

[b]At 75.4869 MHz, TMS at zero.

[c]It is likely that ^4J is negative (5, 6).

because of a near identity of some chemical shifts in the proton region. The $^{13}C\{^1H\}$ spectra consisted of simple first-order triplets.

Molecular orbital computations on benzal fluoride employed the programs GAUSSIAN 92 (11) nd GAUSSIAN 94 (12). Various basis sets[2] were employed in the HF SCF procedures. Internal rotational potentials were found by fixing the torsional angle ϕ in **1** at values between 0° and 90° in steps of 15°, and optimizing the values of other angles and bond lengths, with the constraint, however, that the phenyl moiety remain planar. Correlation-gradient computations, MP2/6-31G* and MP2/6-31G**, frozen core, were also performed on the isolated molecule. Two types of computations of solvent perturbations of the conformational energies were used. The first used the program SCRF PAC (15), interfaced to our copy of GAUSSIAN 92 by R. Sebastian. This approach (16, 17) is based on an elliptical solvent cavity in a dielectric continuum and allows electric moments higher than dipole (up to $l = 6$). The SCI–PCM (self-consistent isodensity – polarizable continuum model) is apparently equivalent to a multipole moment expansion of infinite order (18, 19). It was implemented[3] as given in our copy of GAUSSIAN 94. In these calculations the gas phase Hamiltonian is modified by the interaction of the electrons and nuclei of the solute with the reaction field of the solvent. It was of interest whether the two approaches to the energetic perturbations due to solvent are in approximate congruence.

Some INDO MO FPT (20, 21) computations of coupling constants, particularly of ^6J(H, H), ^6J(H, F), and ^5J(C, F), used the optimized 6-31G* geometries. Such calculations are not quantitatively reliable, yet are useful in assessing the qualitative dependence of long-range coupling constants on conformational angles (22).

Results and discussion

Spectroscopic results

Tables 1 and 2 present the ^1H, ^{19}F, and ^{13}C nmr spectral data obtained for benzal fluoride. Figure 1 displays the experimental and simulated spectra of the ring protons for the acetone solution, while the detail of the central band of the methine proton is shown in Fig. 2, illustrating the spectral fit obtainable in the analysis.

Internal motion and long-range coupling constants

A number of long-range coupling constants between nuclei in the side chain and those in the phenyl moiety of benzene derivatives are strongly dependent, sometimes exclusively, on a σ–π, or hyperconjugative, mechanism (23). These coupling constants are maximal in magnitude when the bonds in the side chain, carrying the nuclei, are situated in a plane perpendicular to that of the phenyl group. An example (23–25) is ^6J(H, H) for the methyl protons in toluene, which can be written as $^6J = {}^6J_{90}\sin^2\phi$, where $^6J_{90}$ corresponds to $\phi = 90°$ (see **1** for the definition of ϕ). Another is ^6J(H, F) in benzyl fluoride and some of its derivatives (6, 26), as is ^5J(C, F). The measured value of such a coupling constant is then determined by $^nJ_{90}$ and $\langle\sin^2\phi\rangle$, the expectation value of $\sin^2\phi$, which, in turn, depends on the potential governing how the bond in question samples the various angles ϕ at a given temperature. If the potential has a simple ϕ dependence, for example, is twofold in nature, then a knowledge of ^6J and its extremum yields the height of the potential directly (27). If, however, the potential contains a number of terms in ϕ, an ambiguity arises in that a range of combinations of these terms will yield the same ^nJ. Nevertheless, useful information about solvent perturbations of the potential can be gleaned from ^nJ, as follows.

[2] Descriptions of the various split-valence basis functions, their notation, references to them and to the MP2 method of assessing electron correlation are given in ref. 13. The semiempirical AM1 algorithm (14) was also used.

[3] An extensive review of methods based on solvent continua is available (18).

Fig. 1. The nmr spectrum at 300 K and 300 MHz of the ring protons of benzal fluoride, as a 2.5 mol% solution in acetone-d_6, is compared with the simulation based on the spectral parameters in Table 1.

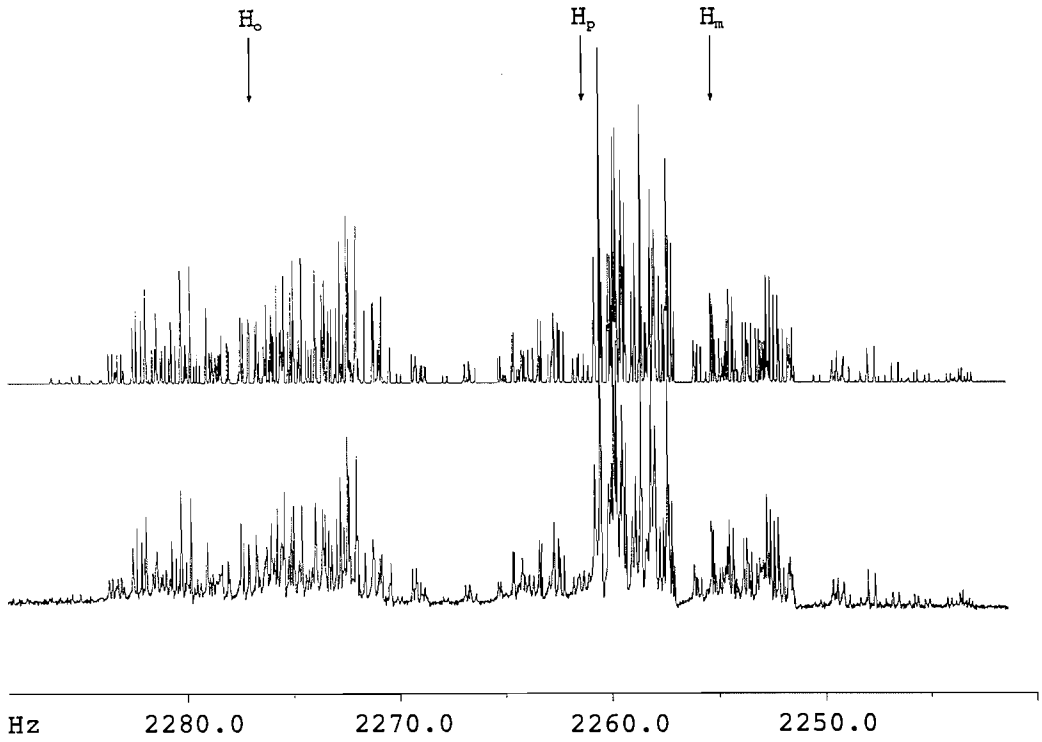

Fig. 2. The central band of the methine proton "triplet" for benzal fluoride in acetone-d_6 solution is shown at 300 MHz and 300 K. The linewidth at half height is ca. 0.04 Hz. There occur some small discrepancies in peak positions between experiment and simulation amounting to as much as 0.01 Hz in one instance.

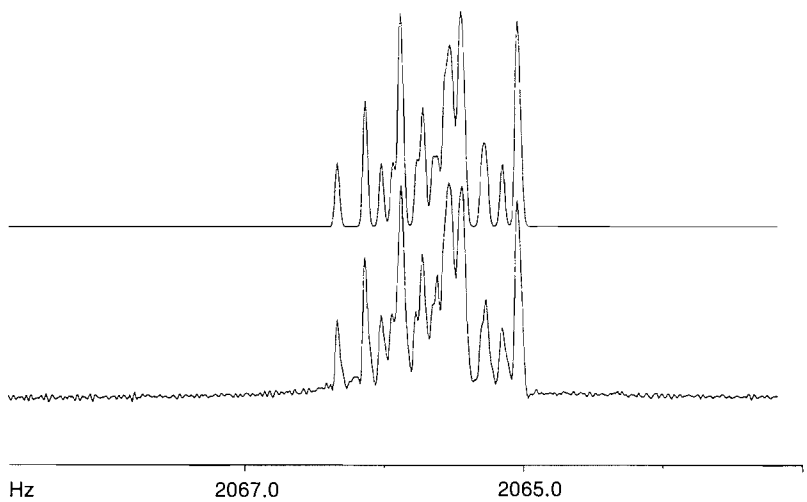

With reference to the data in Table 1, note that both ^4J(H, CH) and ^6J(H, CH) decrease in magnitude in passing from the nonpolar C_6D_{12} solution to that of the polar acetone-d_6. At the simplest level, this means that a polar environment shifts the internal potential such that conformers, in which the C—H bond lies in the ring plane, are more populated than they are in the nonpolar medium. In consequence, the C—F bonds, on average, now spend more time at larger torsional angles, ψ (see **1** and **2**). Hence the ^nJ(H,F) values must increase in magnitude in the more polar solution, given that they contain large components proportional to $\sin^2\psi$. This increase occurs.

Derivation of $\langle\sin^2\phi\rangle$ from ^nJ

bon atom implies $\langle\sin^2\phi\rangle = 1.5 - 2\langle\sin^2\psi\rangle$. Furthermore, write ^6J(H, CH) = $^6J_{90}\langle\sin^2\phi\rangle$ and ^6J(F, CH) = $^6J_{90}\langle\sin^2\psi\rangle$. Finally, on the assumption that $^6J_{90}$ values are invariant to solvent, an assumption borne out for benzyl fluoride, for example (6), one has four values of ^6J in two solvents. These are sufficient to determine $^6J_{90}$ (H,CH) as −0.402(2) Hz, $^6J_{90}$ (F,CH) as −2.551(3) Hz, and that $\langle\sin^2\phi\rangle$ is 0.638(3) in C_6D_{12} and 0.553(2) in acetone-d_6 solutions (the errors are formal, based simply on the standard deviations of the measured coupling constants.[4]

From Table 2, one may then deduce[5] that $^5J_{90}$ (F,C-4) is 4.40(14) Hz. Unfortunately, the range of ^5J(C, F) in the various solvents is very small, as compared to that (5) for ^5J(C, F) in benzyl fluoride, a consequence of the different potentials for the two molecules. It was intended to obtain a good value for $\langle\sin^2\phi\rangle = 1.5 - \langle\sin^2\psi\rangle$ in CS_2 solution from ^5J(C, F) because the ^{1}H and ^{19}F nmr spectra did not yield to analysis — many of the lengthy solvent calculations had already been done for a dielectric constant of 2.64, close to that of the CS_2 solution. Nevertheless, if the ^5J(C, F) value for this solution is used, one finds $\langle\sin^2\phi\rangle = 0.60 \pm 0.03$.

A check of this value is available from ^4J(C, F). For benzyl fluoride it is very likely (5) that ^4J(C, F) is proportional to $A\sin^2\psi + B\sin^2(\psi/2)$, corresponding to a σ,π term in $\sin^2\psi$ and a σ term in $\sin^2(\psi/2)$. On the assumption that a similar proportionality holds for benzal fluoride, the values of ^4J(C, F) in the C_6D_{12} and acetone-d_6 solutions yield ^4J(C, F) = $3.07\sin^2\psi - 1.92\sin^2(\psi/2)$. Here ^4J(C, F) is taken as positive. If it is negative the signs of the coefficients change but do not alter the value of $\langle\sin^2\psi\rangle$, namely, 0.443, obtained for the CS_2 solution. Hence $\langle\sin^2\phi\rangle$ is 0.614, within the range deduced from ^5J(C, F) above. Again, it happens that ^4J(C,F) has a small range, in contrast to ^4J(C, F) in benzyl fluoride.

A vanishing internal rotational potential would entail a $\langle\sin^2\phi\rangle$ of 0.5. A very large potential, with a minimum at ϕ = 0°, as in **2**, would push $\langle\sin^2\phi\rangle$ towards zero. For a purely twofold potential, the experimental values of $\langle\sin^2\phi\rangle$ correspond to a barrier of 2.9 kJ/mol in C_6D_{12} solution with **1** as the minimum, **2** as the maximum in the potential.[6] In the polar acetone-d_6 environment, the apparent twofold barrier drops to 1.0 kJ/mol, with **1** still at the minimum.

The experimental data indicate a small barrier to internal rotation and, most likely, that **1** is the conformation of lowest energy. Of course, a fourfold component in the potential does not contribute to the energy at ϕ = 90°. Nevertheless, although not expected to be larger in magnitude than the leading twofold component, a fourfold component will alter $\langle\sin^2\phi\rangle$. In the section below, recourse is had to theoretical potentials for the isolated molecule as well as for the molecule embedded in a dielectric continuum. Comparison with experiment then arrives at a reasonable description of the internal rotation of the molecule in a vacuum and in solution.

Theoretical internal rotational potentials

(a) The isolated molecule

Table 3 presents the computed internal rotational potentials, V, for various molecular orbital models, including first approximations to electron correlation. Geometries were optimized for each torsion angle, ϕ. Figure 3 plots the potentials.

Except for the minimal basis set, all other potentials have a minimum at ϕ = 90°, as in **1**. The opposite signs of twofold, V_2, and fourfold, V_4, terms produce a global maximum in V not far from ϕ = 45° when $|V_2/V_4|$ is small enough; in consequence, **2**, with ϕ = 0°, represents a local minimum for the larger ab initio basis sets. The values of $\langle\sin^2\phi\rangle$ at 300 K range from 0.470 for the STO-3G potential to 0.638 for that from the

[4] The INDO MO FPT computations agree that ^6J(H, CH) goes as $\sin^2\phi$. For ^6J(F, CH) such calculations yield numbers closely met by $-2.73\sin^2\psi - 0.40\sin 2\psi$, that is, the presence of the second, strongly polar, C—F bond is calculated to perturb the $\sigma-\pi$ interaction of the first. However, for the MP2/6-31G* internal rotational potential (see below), $\langle\sin 2\psi\rangle$ is only 0.26, introducing an error of less than 4% into the approximation used here, if INDO is correct.

[5] The nine values of $^6J_{90}$(H, CH, $^6J_{90}$(F, CH), and $^5J_{50}$(F, C) now a available for toluene, benzyl fluoride, and benzotrifluoride are discussed below.

[6] These numbers come from a hindered rotor model or a classical averaging procedure (27–29); the two methods give the same $\langle\sin^2\phi\rangle$ values for barriers of this magnitude at 300 K, as expected.

correlation-gradient, MP2/6-31G**, computations. The last number is coincidentally identical to that derived from the coupling constants in the nonpolar C_6D_{12} solution. In the absence of the following computations of solvent effects on the internal potential, the agreement might well have been taken as excellent.

(b) The molecule in solution

Table 4 presents the Onsager or SCRF (15–17) computations of the internal rotational potential for dielectric constants of 2.64 and 20.7, using a number of basis sets. Table 5 gives a somewhat larger data set for such computations, employing the more recent SCI–PCM approach (18, 19). The tables also contain expectation values of $\sin^2\phi$ at 300 K corresponding to the computed potentials, as well as dipole moments for conformers **1** and **2**. Figures 4 and 5 make comparisons of the potentials computed by the two solvent models for low and high dielectric constants, respectively, whereas Fig. 6 collates them for the SCI–PCM model using post-Hartree–Fock computations and four dielectric constants.

The results mainly have the following pattern. For the isolated molecule, the internal rotational potential is dominated by V_2, yielding a relatively deep minimum at $\phi = 90°$ (conformer **1**). V_4 is rather smaller than V_2 in magnitude, but of opposite sign, causing a maximum in the potential near $\phi = 40°$ (V_4 itself, of course, is largest at 45°). In the presence of solvent, $|V_4/V_2|$ increases and becomes larger than unity for a dielectric constant of 20.7 (acetone). Even at this solvent polarity, however, the minimum in the potential occurs at $\phi = 90°$, but only just, in some instances. At low dielectric constants the two models yield nearly coincident potentials (Fig. 4); at high, the SCI–PCM method predicts a larger $|V_4/V_2|$ than does the Onsager model (Fig. 5). In terms of **1** and **2**, with **2** having the higher theoretical dipole moment (Tables 3–5), a zero-order reaction field model entails the increasing energy of **1**. That is, a conformer of higher dipole is increasingly stabilized as the dielectric constant of the surrounding continuum rises. Yet, an attempt to simulate this situation with the Onsager model, using $l = 1$ in the SCRF computations (dipole moment only), was unsuccessful. We have no explanation of this negative result.

Table 6 presents a comparison of some $\langle\sin^2\phi\rangle$ values as derived from the theoretical potentials obtained from various levels of molecular orbital theory in the absence or presence of various dielectric continua. Both solvent models are represented, as are the $\langle\sin^2\phi\rangle$ numbers inferred from long-range coupling constants. Best agreement between experiment and theory is found for the post-Hartree–Fock potentials. It appears unnecessary to go beyond MP2/6-31G*. The two solvent models give closely similar $\langle\sin^2\phi\rangle$ values at this level (use of the Onsager model with the GAUSSIAN suite of programs requires an extra link to the SCRF PAC algorithm,

whereas the SCI–PCM computations form part of GAUSSIAN 94 and are easier to implement).

Qualitative discussion of the internal rotational potential

(a) The isolated molecule

As a preliminary, Fig. 7 shows the correlation-gradient, MP2/6-31G**, structures of two conformations of benzal fluoride. These may well be of interest to molecular spectroscopists. The figure caption gives further information.

A rationalization of the stability of the conformer of lowest energy in benzal fluoride goes as follows. It is convenient to begin with benzyl fluoride, whose most stable conformer has the C—F bond in the phenyl plane (5, 6). In terms of perturbational molecular orbital theory, it is expected that a benzylic anomeric effect will stabilize the perpendicular conformer (the C—F bond in a plane perpendicular to the phenyl plane) because the π system of the ring then interacts best with the antibonding σ orbital of the C—F bond (4). An analogous interaction contributes to the stabilization of the perpendicular conformer of benzyl chloride (4), although it has recently been shown (3) that other donor–acceptor interactions between the σ and π orbitals of the ring and the σ orbitals of the CH_2Cl group make significant contributions to its stabilization.[7]

Whatever the merits of such dissections of the energetic interactions between computed orbitals, a simple model based on electrostatics and on repulsive overlap of nonbonded atoms can also predict the conformer of lowest energy in benzyl fluoride, benzyl chloride, and benzal fluoride. The stability of the in-plane conformer of benzyl fluoride has been attributed (4)

[7] These other interactions are based on a natural bond orbital approach (33) in which appropriate orbitals of the ring and side chain are removed from the Fock matrix during a recalculation of the molecular energy.

Fig. 4. The solvent-perturbed MP2/6-31G* potentials from Tables 4 and 5 are plotted for a dielectric constant of 2.64. The Onsager model used geometry optimization while the self-consistent isodensity – polarizable continuum model (18, 19) did not (not an option at this level in GAUSSIAN 94). At a low polarity the two models nearly coincide in their predictions (compare Fig. 6). The abscissa gives the angle by which the α C—H bond twists out of the phenyl plane.

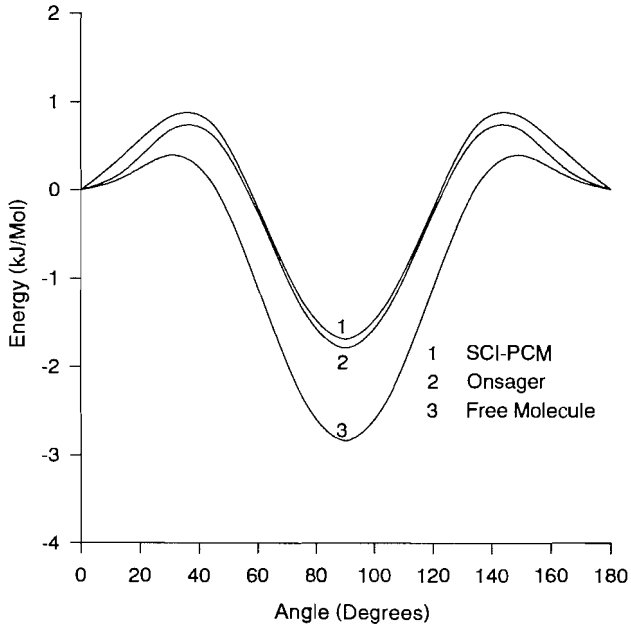

Fig. 5. As in Fig. 4 but for a dielectric constant of 20.7. Here the SCI–PCM approach perturbs the potential more than does the Onsager approach (compare with Fig. 4). Both models lower the magnitude of the negative twofold component and somewhat increase that of the positive fourfold component with respect to the isolated molecule.

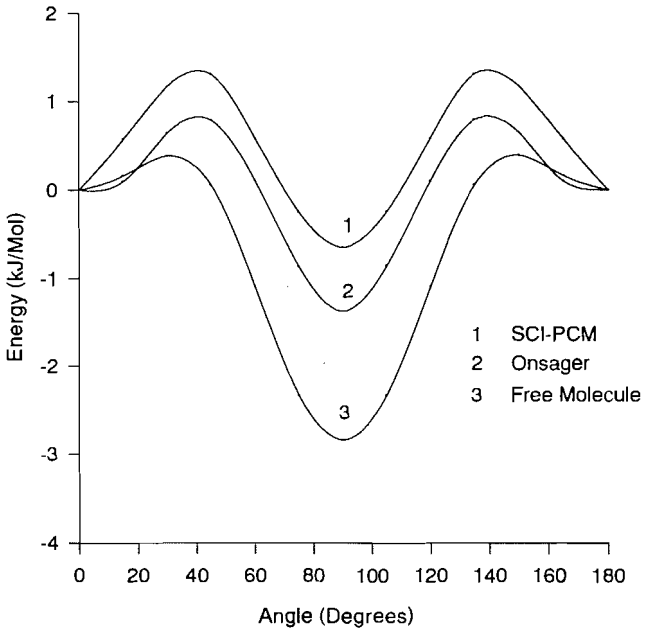

Fig. 6. As in Fig. 4 but, from bottom to top, for dielectric constants of 1.0, 2.0 (cyclohexane-d_{12}), 2.64 (CS_2), and 20.7 (acetone-d_6). The potentials come from SCI–PCM using single-point calculations with the correlation-gradient, MP2/6-31G*, geometries for the isolated molecule.

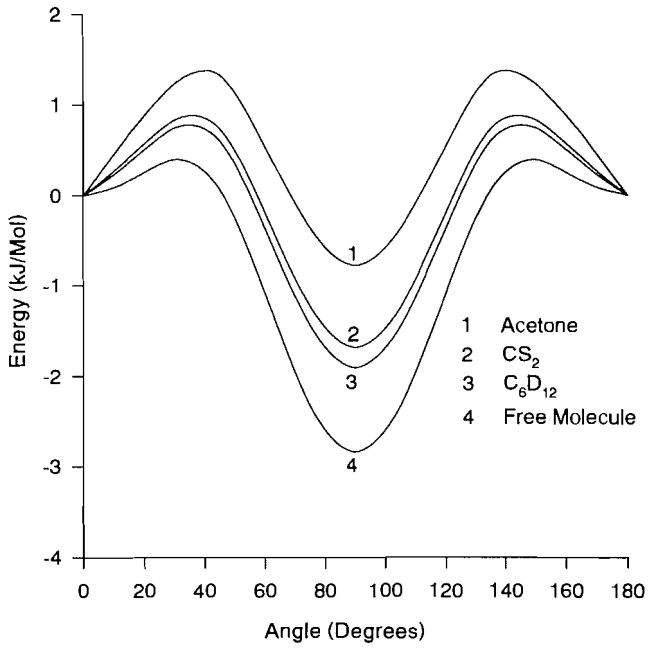


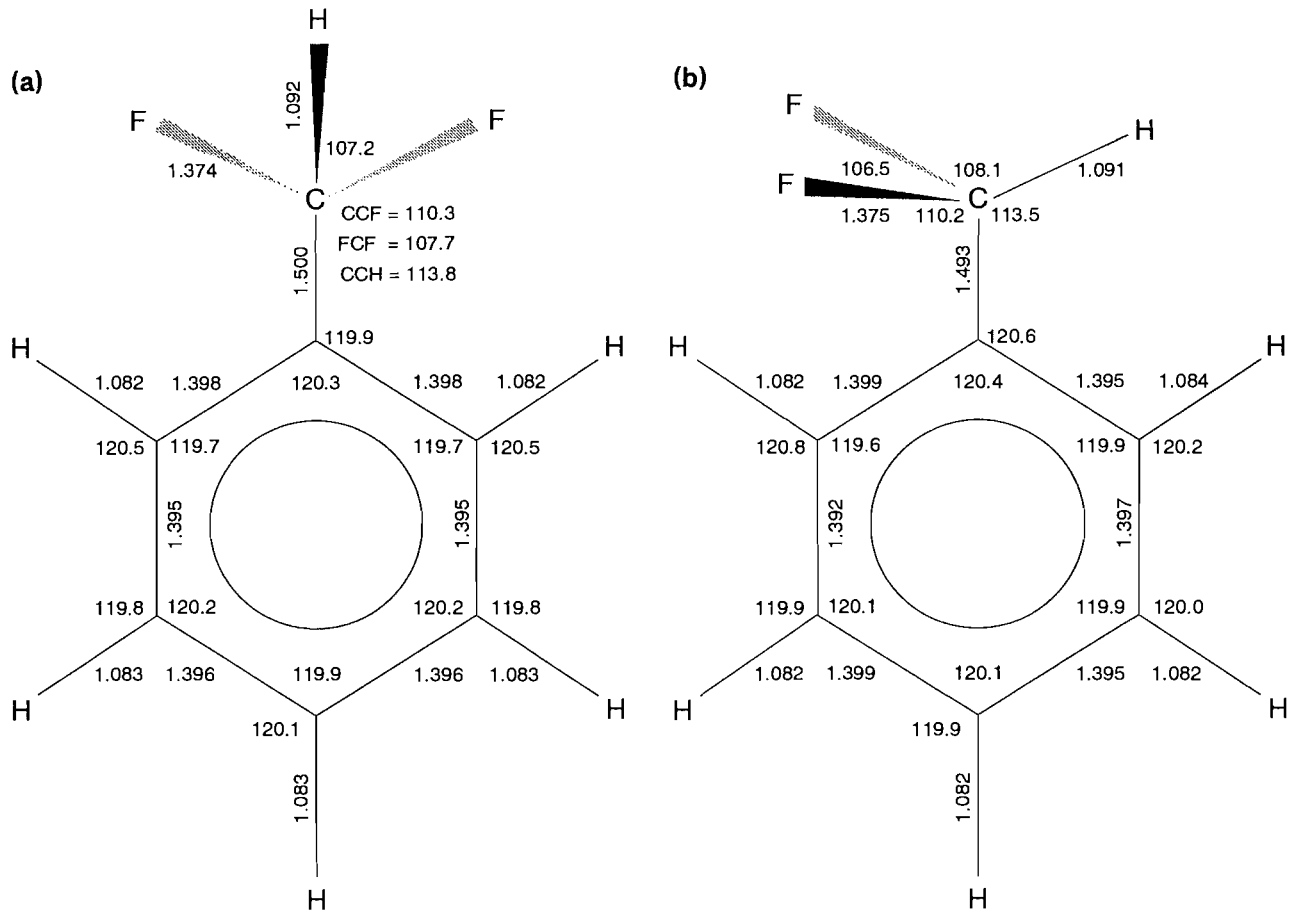
to the dominance of the attractive forces between the $^{+}C–F^{-}$ and the *ortho* $C^{-}–H^{+}$ dipoles in this conformer. In terms of the simple model, these forces dominate the repulsive nonbonded forces: the sum of the van der Waals radii of hydrogen and fluorine is 2.55 Å whereas the interatomic distance would be 2.4 Å for a regular geometry. For benzyl chloride, however, the interatomic distance is again very near 2.4 Å in the in-plane form, yet the sum of the van der Waals radii is 3.0 Å, so that repulsive overlap is now dominant leading to the perpendicular conformer as most stable.[8]

Returning to benzal fluoride, the simple model predicts **1** as the least energetic because it brings both C—F bonds very close to the *ortho* C—H bonds, maximizing electrostatic attractions. By way of contrast, the conformer analogous to **2** should be most stable for benzal chloride, as it is (3, 34), because it reduces the H, Cl distances to 3.0 Å, very near the sum of the nonbonded radii.

The requisite polarities of the C—H and C—F bonds in benzal fluoride are supported by molecular orbital computa-

[8] The simple model is not meant to *replace* the more elaborate one based on molecular orbitals, of course. Thus, the perturbational model might account for the somewhat lower preference for the in-plane conformers of 4-fluorobenzyl fluoride, compared to the parent molecule (6), via an enhanced benzylic anomeric effect in the perpendicular form, fluorine being a π donor. A valence bond model could attribute this to an enhanced contribution from a hyperconjugative bond, no-bond structure, whereas qualitative molecular orbital terminology would attribute the slight stabilization of the perpendicular form to a σ–π interaction aided by the π donor.

Fig. 7. The correlation-gradient, MP2/6-31G**, geometries (planar phenyl groups) are shown for two conformers for benzal fluoride. The hexagonal structure (internal angles) of the benzene moiety is less severely perturbed than by a methyl group; in toluene, the bond angle at the ipso position is 118.1° (30). The C—F bond lengths are 0.02 Å smaller than for benzyl fluoride (6), in the MP2/6-31G* structure as well. The C—H and C—C bond lengths of the phenyl group are rather close to those claimed to be the best (corrected) theoretical values for benzene itself (31). The exocyclic C—C bond is somewhat shorter in the conformer in which the C—H bond lies in the phenyl plane, consistent with stronger σ,π withdrawal in this conformer. As a matter of interest, the substitution structure of CH_2F_2 (32) has a FCF angle of 108.2°, a C—H length of 1.093(3) Å, and a C—F length of 1.357(1) Å. As to solvent effects on computed molecular structures, MP2/6-31G* calculations with the Onsager model for ε = 20.7 (for which geometry optimizations were possible) gave negligible changes in the geometry of the phenyl ring but angle changes at the α carbon atom of up to 2° and a 0.006 Å lengthening of the C—F bond; the latter is perhaps just within the level of significance.



tions. Figure 8 displays Mulliken charges on the atoms derived from the MP2/6-31G* computations for conformers **1** and **2**. The magnitudes are dependent on the basis set, as expected, and would also change somewhat if alternative methods were used to allocate electron probabilities. Nevertheless, it is most unlikely that the signs of the charges would change. The positive charge on the hydrogen of the methine C—H bond would then be an additional cause of the stability of **1** relative to **2** for benzal fluoride.

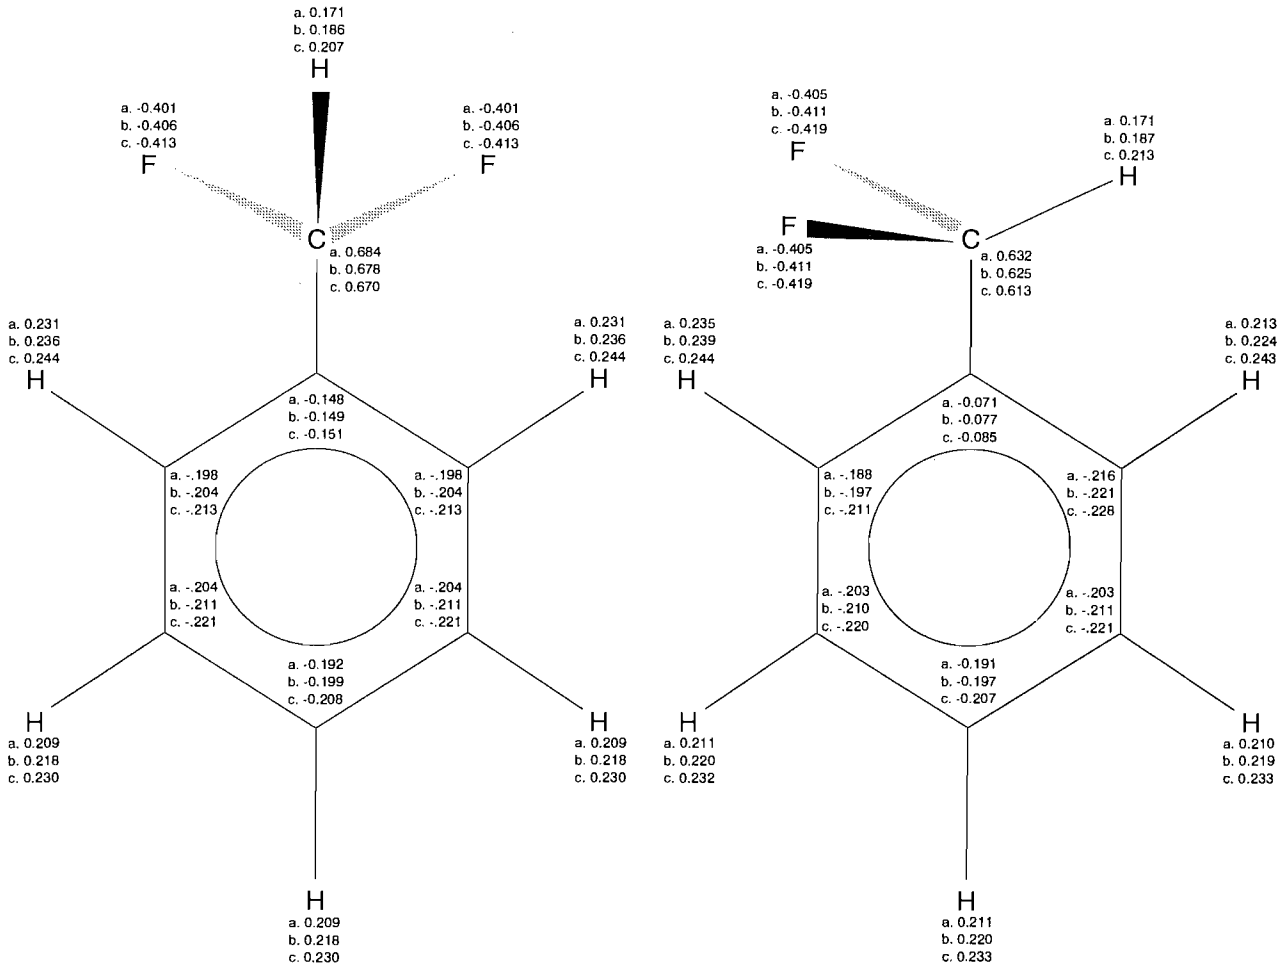
Notice also that in conformer **2**, in which the C—F bonds are closer to the perpendicular than in **1**, more charge is withdrawn from the phenyl group (particularly at the ipso site) in line with σ, π acceptance by the side chain. The Csp^2—Csp^3 bond also shortens somewhat in **1** (Fig. 7). The prediction is then that a π donor at the *para* position would tend to stabilize **2** relative to **1** and therefore to lower the internal rotational potential. On the other hand, electronegative substituents in the *meta* position could cause further polarization of the bonds *ortho* to the CHF_2 group and, on the electrostatic model, stabilize **1** relative to **2**. Such polarization apparently stabilizes the in-plane conformers of the 3,5-dichloro and 3,5-difluoro derivatives of benzyl fluoride (6, 26).

Whatever the merits of these adumbrations, it is interesting to note that addition of two potentials for benzyl fluoride, one being 120° out of phase with the other, yields a potential (curve (*a*) in Fig. 9) that approximates that of benzal fluoride (curve (*b*) in Fig. 9). However, the maximum near ϕ = 40° in the latter, arising from a relatively large fourfold component, is a nonadditive component.

(b) The molecule in solution

The computed dipole moments, many of which are found in Table 5, show, first, that the unstable conformer, **2**, is some 5% more polar than **1** and, second, that the solvent causes an

Fig. 8. The Mulliken total atomic charges are given for the isolated molecule in (*a*), for a dielectric constant of 2.10 in (*b*), and 20.7 in (*c*). The computations used the correlation-gradient optimized MP2/6-31G* structure for the free molecule and the SCI–PCM procedure. The absolute charges will depend on the basis set. The *changes* induced by solvent are of interest and are very similar for different bases and solvent models.



increase in charge separation (see also Fig. 8). A simple reaction field model (35), in which only the dipole of the solute molecule is considered ($l = 1$ in the Onsager model), has $\Delta E^V - \Delta E^S = (\mu^2 B - \mu^2 A)(\varepsilon - 1)/a^3(2\varepsilon + 1)$. Here, ΔE^V is the energy difference between conformers B and A, ΔE^S is the energy difference in the presence of a solvent of dielectric constant, ϵ, and a^3 is the cube of the molecular radius. The dipole moment of benzyl fluoride (36) is reasonably well reproduced by the 6-31G* basis (6). On the assumption that the dipole moment of benzal fluoride is also calculated reliably (Table 5), and taking is radius as 3.6 Å (slightly larger than deduced for benzyl fluoride from its liquid density), one finds that, relative to the vapor and **2**, the energy of **1** is raised by 0.7 kJ/mol in acetone-d_6 solution and by 0.3 kJ/mol in CS_2 solution. In this deduction, the enhanced dipole moments in the solvents are employed (Table 5). Comparison with, for example, the computed pontentials in Fig. 7 or the twofold MP2/6-31G* terms in Table 5 implies that these dipole energies are too low by about a factor of three. Higher order terms in the multipole moment expansion appear to play an important role in the solvent effect, not surprising for a noncompact molecule in which charge is not localized in a few proximate bonds.

In terms of an electrostatic model, the extent of the reduction in the field between the charges on the peripheral atoms (Fig. 8), caused by the dielectric, is problematical. Intuitively, the reduction occurs and destabilizes **1** relative to **2**. The conformation of the latter aids hyperconjugative electron withdrawal from the phenyl group because the C—F bonds lie nearer the perpendicular (Fig. 8) and cause additional charge separation in the more polar media.

The chemical shifts

A considerable literature (37, 38) exists relating ^{13}C and ^1H chemical shifts to computed atomic charges in benzene derivatives. The computations are done on the isolated molecules, the shifts are measured in solution. The *para* proton shielding in monosubstituted benzenes is well correlated with the σ electron density at the *para* hydrogen atom (37). With reference to the proton chemical shifts in C_6D_{12} and acetone-d_6 solutions in Table 1 and the computed σ electron densities in

Fig. 9. In (*b*) the correlation-gradient, MP2/6-31G*, internal rotational potential of benzal fluoride is plotted as a function of the angle by which the α C—H bond twists out of the phenyl plane. In (*a*) the potential, obtained by adding two benzyl fluoride potentials (6), one shifted by 120° from the other in torsional angle, agrees quite well with (*b*), except in the region near 40°; the larger $|V_4/V_2|$ ratio for benzal fluoride produces this divergence.

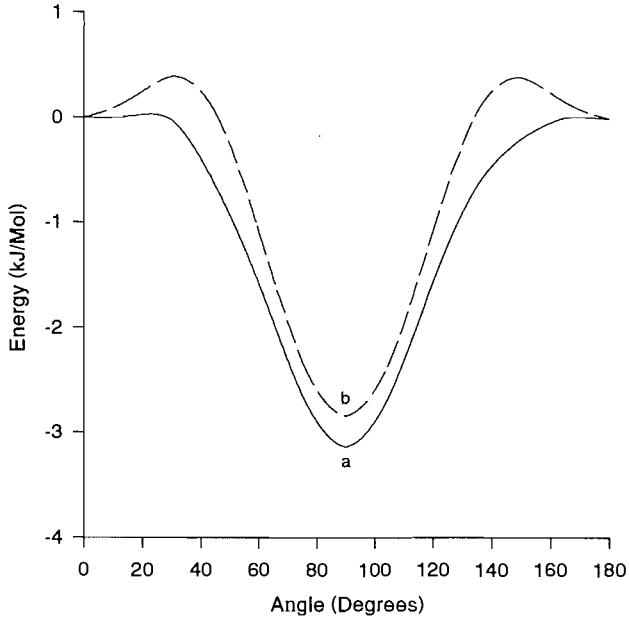


Fig. 8, one has the *para* ring proton less screened in acetone-d_6 solution by 0.215 ppm and the positive charge increased by 0.012_5 electron units. The ratio of these numbers is reasonable in that the screening of the proton in the hydrogen atom is 17.8 ppm. It is interesting that the methine proton is descreened by 0.443 ppm in passing from C_6D_{12} to acetone-d_6 solution, while the positive charge increases by 0.023 units. The two shift/charge ratios, *para* and methine protons, are 17.2 and 19.3 ppm/electron.[9] Of course, a rigorous procedure would average the charges over the computed potential.

Such comparisons might encourage an extrapolation of the shifts to the vapor using the charges computed for the isolated molecule (Fig. 8); gaseous shift values would be of interest to modern approaches to chemical shift calculations (40), rare though they still are for protons (40, 41), but see ref. 39. However, if computations on benzene itself are done, just as for those in Fig. 8, one finds again an increased charge of 0.012 on the protons. But the shift of benzene in C_6H_{12} is 7.211 ppm, is 7.352 ppm in acetone-d_6, and thus the decrease in screening is only 0.141 ppm. Hence the rough proportionality between increased positive charge and decreased screening noticed for the protons in benzal fluoride is likely a coincidence.

[9] There is no theoretical basis for a correlation of the shielding of a nucleus with the electron population of the atom carrying the nucleus in a molecule, but there may occur instances in which such a correlation occurs for protons (39) — perhaps in restricted cases as for the *para* proton in benzene derivatives.

It is conceivable that another basis set and a different method of deriving charges (42) from the density matrix could result in a consistent treatment of charge/shift ratios in benzene and its derivatives in solutions of various polarities; leading to reliable shifts in the vapor phase.

Turning to ^{13}C shifts, that of benzene in solution is usually given as 128.5 ppm (δ value, relative to TMS). The screening of the *para* ^{13}C nucleus is given as proportional to the π electron charge in monosubstituted benzenes as well as to the total electron density (37). The π and total charges are linearly related (37). The chemical shifts of C-4 in Table 2 therefore mean that the CHF_2 group is an electron-accepting substituent, similar, in fact, to the $CH_3S{=}O$ group (43). As the polarity of the solvent increases, C-4 is deshielded, yet the computed total negative charge (Fig. 9) increases. Unfortunately, we do not have the π electron densities because of our parsimony in print-outs of the computer output.

Other long-range coupling constants

(a) $^4J(H, CH)$

In toluene, $^4J(H, CH_3)$ can be written (25, 44) as $-1.08\langle\sin^2\phi\rangle - 0.32\langle\cos^2\phi\rangle$, the second term representing a σ electron contribution, the first the σ,π mechanism. Both of the coefficients in this relationship will be altered by the electronegative fluorine substituents in benzal fluoride. The values of $\langle\sin^2\phi\rangle$ are known for the latter compound in C_6D_{12} and in acetone-d_6, with the result that $^4J(H, CH) = -0.649\langle\sin^2\phi\rangle - 0.20\langle\cos^2\phi\rangle$. It is likely that the internal rotational potential in benzal fluoride is sensitive to *para* substituents, as it is in benzyl fluoride (6), so that $^4J(H, CH_2)$ in such derivatives may well be an alternative to $^6J(H, CH)$ in assessing changes in the potential, as it is for benzyl fluoride derivatives (6, 26).

(b) $^4J(F, CH)$

The magnitudes of $\langle\sin^2\phi\rangle$ (see **2**) in C_6D_{12} and acetone-d_6 solutions are 0.432 and 0.474, respectively. Combined with the corresponding $^4J(F, CH)$ numbers of −1.125(1) and −1.226(1) Hz, one has $^4J_{90}(F, CH)$ as −2.599 or −2.609 Hz. The implication, that $^4J(F, CH) = {}^4J_{90}\langle\sin^2\psi\rangle$, calls to mind a similar functional relationship established for $^4J(F, CH)$ in 3,5-dichlorobenzyl fluoride (26), in which, however, an additional, small, term in $\langle\sin^2\psi\rangle$ also occurs.

$^nJ_{90}$ values in toluene through benzotrifluoride

From the numbers given here (5, 6, 25, 45) it appears that the second fluorine substituent causes a rather larger perturbation of $^{5,6}J_{90}$ than does the first. Thus, $^6J_{90}(H, H)$ decreases in magnitude only from 1.20 Hz in toluene to 0.94 Hz in benzyl fluoride but to 0.40 Hz in benzal fluoride; similar statements apply to $^6J_{90}(H, F)$ and $^5J_{90}(C, F)$. In terms of a hyperconjuga-

	$^5J_{90}$(C, F)	$-^6J_{60}$(H, F)		$-^6J$(H, H)	
CH_2F	5.03(10)	2.85(1)		1.20(1)	CH_3
CHF_2	4.39(15)	2.55(1)		0.94(1)	CH_2F
CF_2	2.78(6)	1.31(3)		0.40(2)	CHF_2

tive model, the $\sigma-\pi$ overlap of the C—H or C—F bond orbitals with those of the phenyl group is reduced as the electronegative fluorine substituent polarizes the C—H or C—F bonds. A second fluorine substituent (changing CF_2F to CHF_2 for ^6J(H, H) and CHF_2 to CF_3 for ^6J(H, F) and ^5J(C, F)) is hence much more effective in reducing the $\sigma-\pi$ interaction, perhaps because a C—H bond responds more easily than a C—F bond to the perturbation. Reasonably linear correlations exist between the numbers in different columns above; their significance, if any, escapes us.

Suggested experiments

The internal rotational potential in benzal fluoride, small and sensitive to solvent, is most likely sensitive also to substituents, including those in *meta* and *para* positions. Such is the case with benzyl fluoride, in which electronegative *meta* substituents stabilize the in-plane conformer (6, 26), whereas a weak π donor in the *para* position favors the perpendicular form of the molecule (6). The prediction is then that electronegative substituents in the *meta* position will lower the energy of **1** relative to **2** for benzal fluoride; the opposite will occur in the presence of a *para* π electron donor. Of course, the presence of a solvent will alter the magnitudes of these relative energies. Useful contributions from molecular spectroscopists would entail the measurements of these potentials for the gaseous molecules, for comparison with the theoretical potentials and with the results of measurements in solution, as illustrated in this report.

Sulfonyl esters 7. The second and third sequences in the Trithioorthoformate Reaction

Kashyapa Ananda Ginige, John Edward Goehl, and Richard Francis Langler

Abstract: A previous report has established the intermediacy of a sulfide-sulfonate ester in the one-pot conversion of an aryl mercaptan and a sulfonate ester into the corresponding trithioorthoformate. This report describes evidence for the sequential intermediacy of a bissulfide-sulfonate ester and a dithiosulfene in the conversion of the sulfide-sulfonate ester into the trithioorthoformate. A new sulfonate ester is shown to give the highest yield of trithioorthoformate.

Key words: single electron transfer, sulfonate esters, sulfenes.

Résumé : Une publication antérieure a établi la participation d'un ester sulfure-sulfonate comme produit intermédiaire dans la conversion dans un seul récipient d'un mercaptan arylique et d'un ester sulfonate en trithioorthoformate correspondant. Cette publication décrit la preuve de la participation intermédiaire séquentielle d'un ester bisulfure-bisulfonate et d'un dithiosulfène dans la préparation du trithioorthoformate. On montre qu'un nouvel ester sulfonate donne les rendements les plus élevés de trithioorthoformate.

Mots clés : transfert d'électron unique, esters sulfonates, sulfènes.

[Traduit par la rédaction]

Introduction

In the course of exploratory work on reactions of mercaptans with sulfonic acid esters (1), we discovered the Trithioorthoformate Reaction (see eq. [1]). Scheme 1 outlines the pathway for the first sequence of the Trithioorthoformate Reaction, which produces the intermediate sulfide-sulfonate ester **2** as described earlier (2). We now disclose our findings and conclusions about the processes that transform the sulfide-sulfonate ester **2** into the trithioorthoformate **1**.

Results and discussion

To support our view that sodium hydride serves as an electron-transfer agent, the eq. [1] reaction was successfully rerun with sodium metal[2] (vide eq. [2]), which, presumably, must react as such an agent.

A. The second sequence of the trithioorthoformate reaction

The intermediacy of sulfide-sulfonate ester **2** (Scheme 1) was established after it was isolated cleanly by means of column chromatography (2). We were unable to isolate any other intermediates in this way. However, we repeatedly observed the presence of *p*-tolyl thiolformate in column fractions from routine reactions (vide eq. [3]).

Given the pathway of the first sequence (Scheme 1), it seemed very likely that the Trithioorthoformate Reaction proceeds through sequential sulfide-sulfonate esters as shown in eq. [4].

The failure to isolate **3**, coupled with the isolation of *p*-tolyl thiolformate would be explained by assuming the hydrolysis of **3** during column chromatography as shown in Scheme 2. Note that unimolecular dissociation of sulfonic acid esters with CS bond rupture has some experimental precedent (3).

Due to the apparent instability of **3** to column chromatography, we decided to gather evidence for the intervention of bissulfide-sulfonate esters like **3** by examining model sulfenylations with selected sulfones. Sulfone sulfenylations were selected in the hope that (*i*) $-SO_2R$ would facilitate α-sulfenylation nearly as well as $-SO_2OAr$ but that (*ii*) $-SO_2R$ would be a significantly poorer nucleofuge than $-SO_2OAr$ so that, in contrast to bissulfide sulfonate esters like **3**, product bissulfide sulfones might withstand column chromatography. A series of experiments on phenyl methyl sulfone was initiated (vide eq. [5]). The low consumption of phenyl methyl sulfone (eq.[5]) demonstrates the importance of the SO_2—O linkage for the redox steps that produce disulfide in the Trithioorthoformate Reaction (Scheme 1). Subsequent exploration of sulfenylations employed disulfide as portrayed in eq. [6]. To avoid reaction that might accompany column chromatography, **4** was routinely purified using double recrystallization, which permitted the preparation of clean product in 30% yield. Addition of authentic trithioorthoformate **1** to the crude product of eq. [6] confirmed that **1** *does not form* in detectable amounts (60 MHz nmr) in that reaction. Scheme 3 presents the result when that reaction was worked-up using column chromatography.

The trithioorthoformate **1** is a reaction product in reactions of sulfonic acid esters (eq. [1]) but an artifact produced by column chromatography in reactions of sulfones (Schemes 3 and 4). In addition to the evidence cited above, chromatography

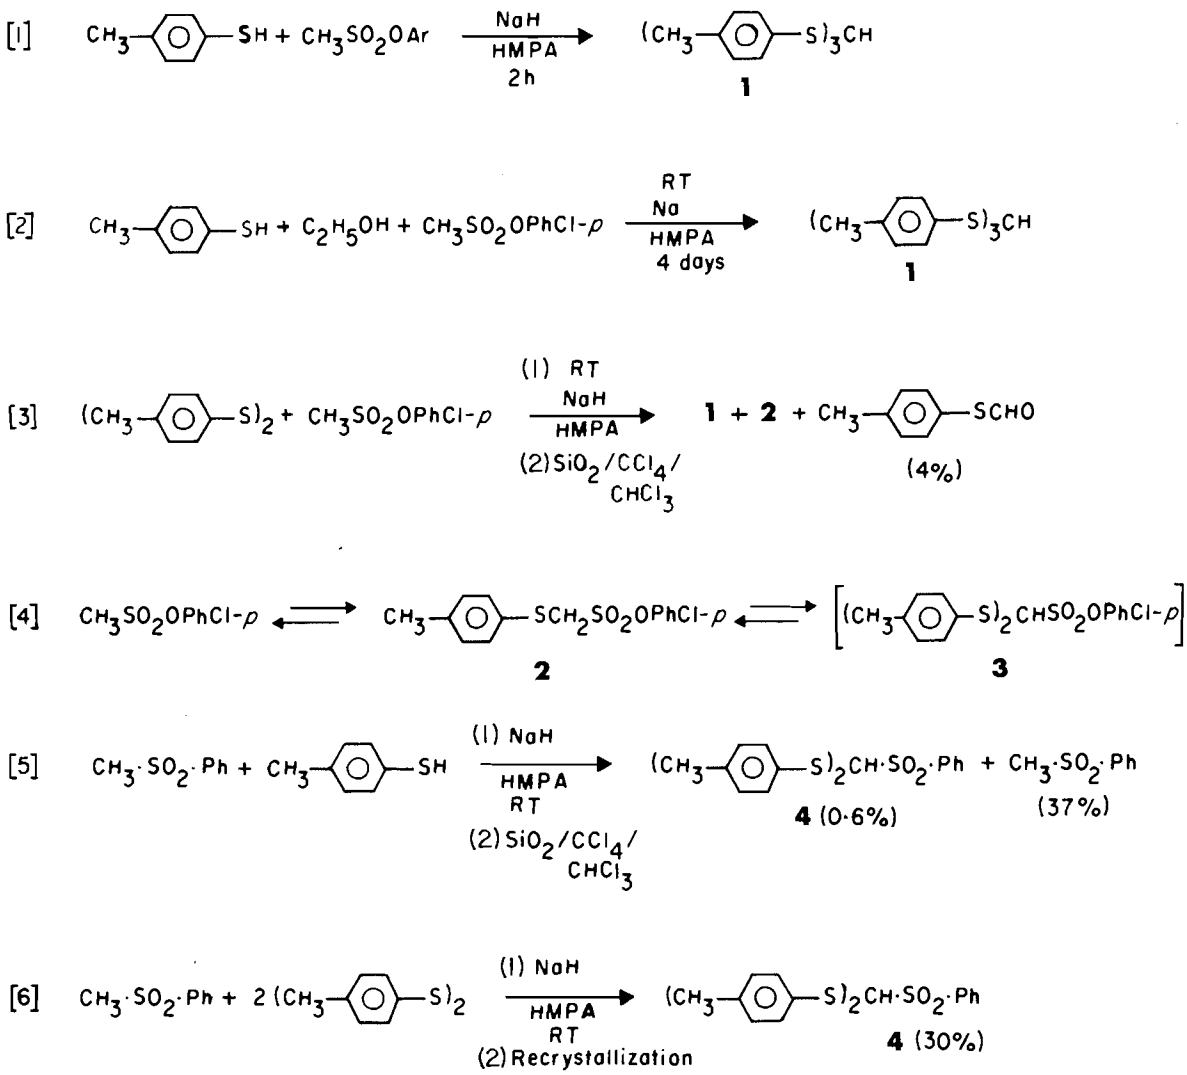
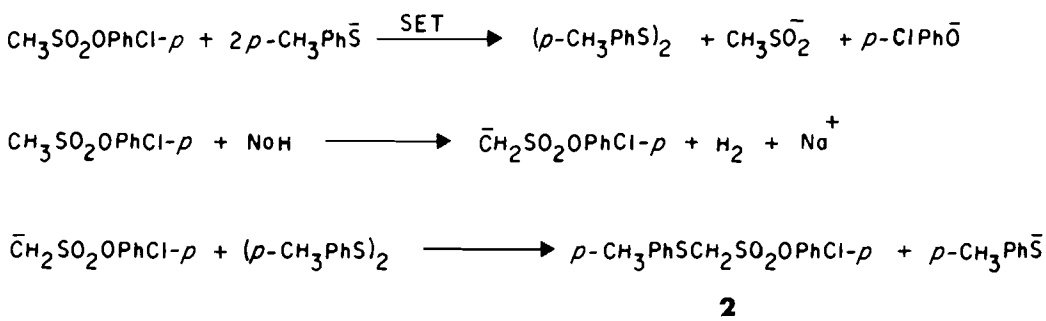
[2] In early experiments ethanol was present. It was shown to be a spectator species (2).

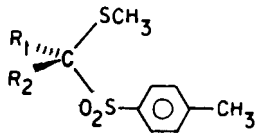


Scheme 1. The first sequence of the Trithioorthoformate Reaction.



itself provides an indication that **1** is an artifact in reactions producing **4**. Typically, our reactions on sulfonates furnish both *p*-tolyl disulfide and the trithioorthoformate **1**, which are eluted in immediately adjacent fractions using low-polarity solvents (e.g., see "Reaction of **2** with sodium *p*-tolyl mercaptide in the presence of *p*-chlorophenol" in ref. 2). However, elution of the products from the reaction depicted in Scheme 3 provided the disulfide and **1** separated by about 30 fractions. Furthermore, elution of **1** was intermittent, as was elution of *p*-tolyl thiolformate, clearly suggesting reaction during column chromatography. In accord with this evidence, tertiary sulfone sulfides **5** are known to hydrolyse in aqueous acid (4) or in the presence of moist silica gel (5).

One might have expected the reactions given in eq. [6] and Scheme 3 to produce significant amounts of the trissulfide sulfone **6***a* by base-induced sulfenylation of the carbanion



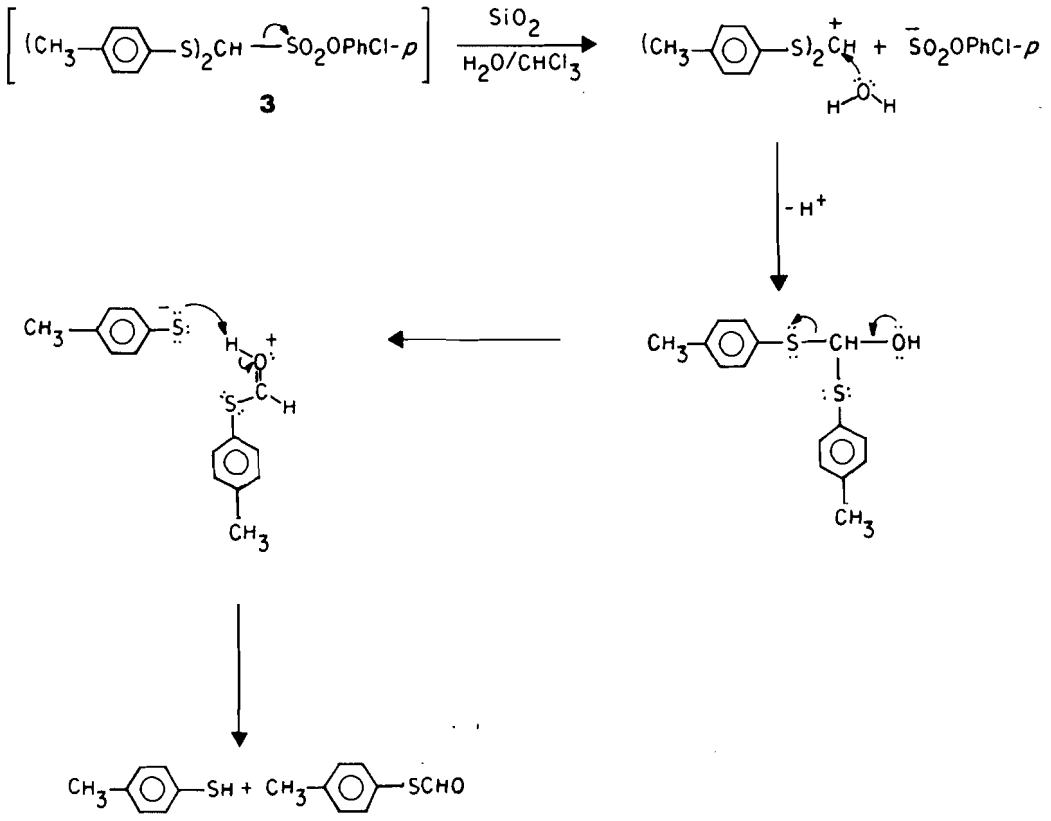
5

6a R=Ph
6b R=CH$_3$

7

8

Scheme 2.

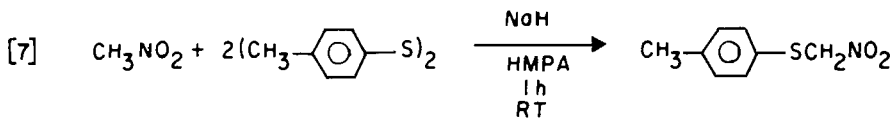


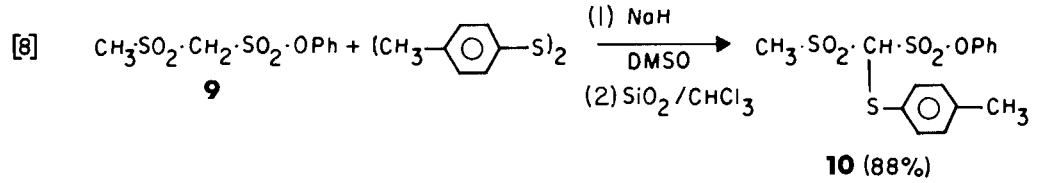
derived from **4**. No such compound was observed. Moreover, purification by column chromatography (Scheme 3) failed to furnish any known tetrathiomethane **7** (6), which would be expected to form from **6***a* by hydrolysis during column chromatography.

The failure of the carbanion derived from the bissulfide sulfone **4** to sulfenylate under conditions which sulfenylate the carbanion derived from **8**[3] can be rationalized on the grounds that the carbanion derived from **4** would enjoy stronger inductive stabilization and would be more hindered, thus making it less reactive.

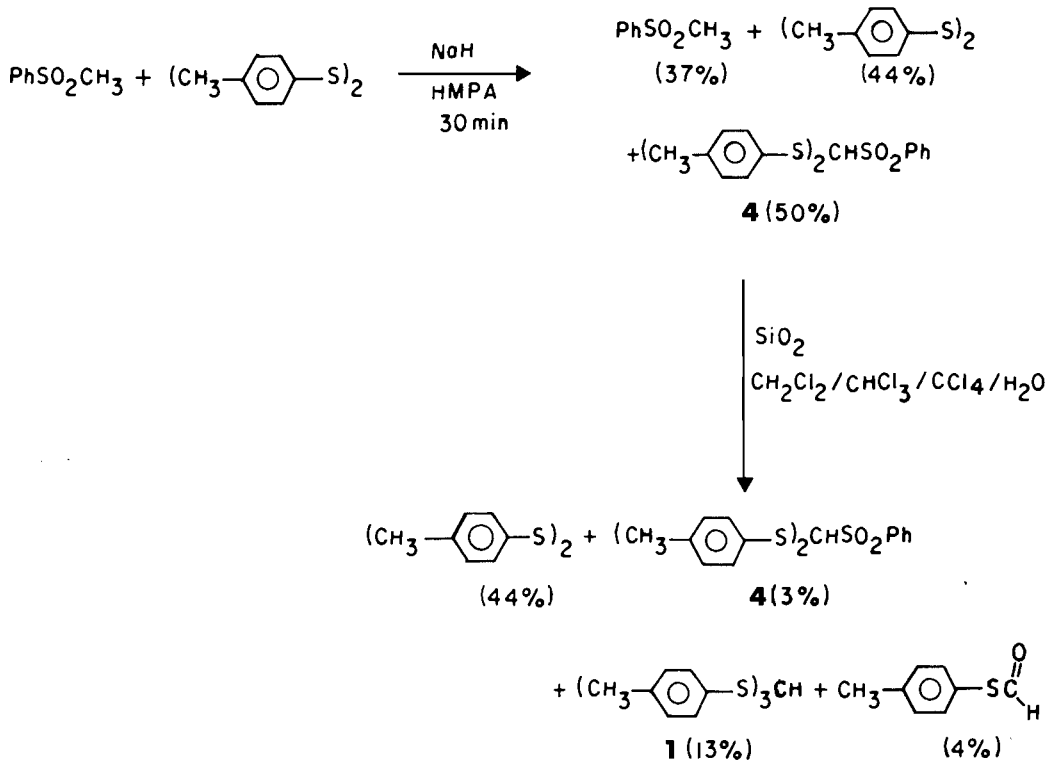
An earlier result (8) provides evidence for the detrimental effect of anion stability on sulfenylation (see eq. [7]). Despite the much smaller size of the nitro group (relative to sulfonyl) only monosulfenylation of nitromethane was observed. Consistent with both anion stability and steric arguments, sulfenylation of the sulfone-sulfonate ester **9** (eq. [8]) introduces only one thio-*p*-tolyl group. The viability of our proposed unimolecular dissociation of bissulfide sulfonates (Scheme 2) and bissulfide sulfones (Schemes 3 and 4) on moist silica gel rests, in large measure, on the stability of the cationic intermediates $(ArS)_2{}^+CH$. The sulfide-sulfonic acid ester **2** would hydrolyse on moist silica gel to form ArS^+CH_2, which is less stable than $(ArS)_2{}^+CH$. While **2** is moderatlely stable to column chromatography, there is no doubt that some of it

[3] Authentic **8** was available to us (7).

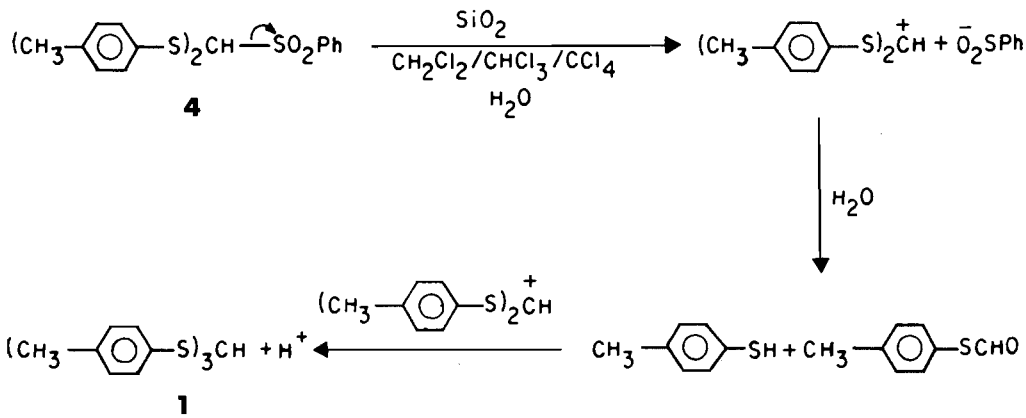




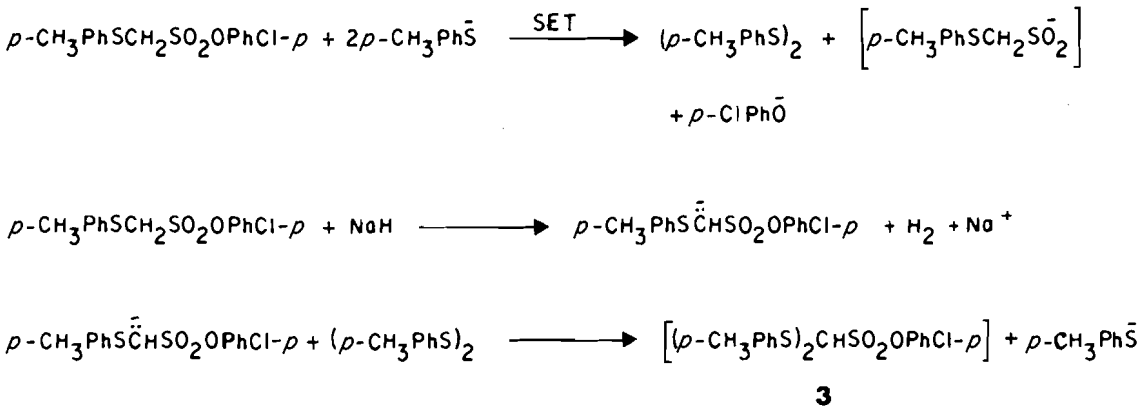
Scheme 3.



Scheme 4.

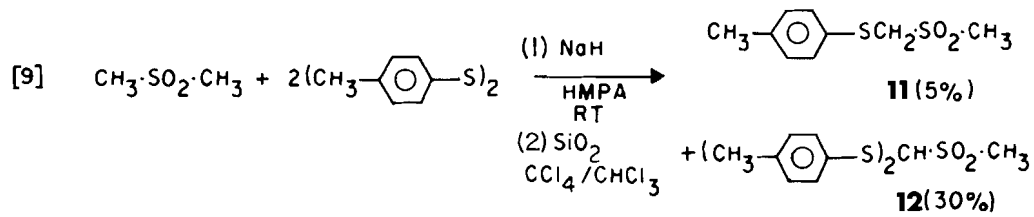


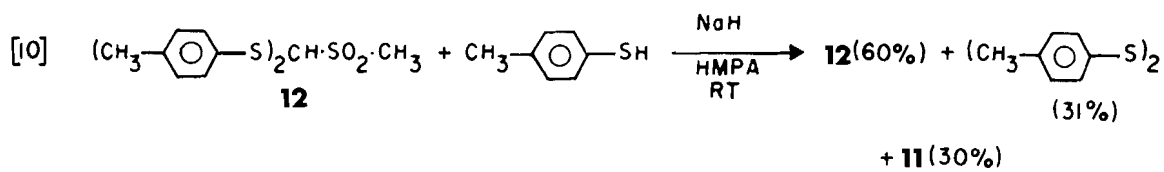
Scheme 5. The second sequence of the Triorthoformate Reaction.



hydrolyses during chromatographic purification, explaining, in part, the modest yields (ca. 30%) routinely obtained from optimized reactions (2). Corresponding behaviour would transform the sulfone-sulfide-sulfonate ester **10** into $ArSO_2^+CHSAr$. The presence of the powerfully destabilizing SO_2 group would make that cation much less stable than ArS^+CH_2. In harmony with this view, **10** is stable to column chromatography.

Given our experience with the Trithioorthoformate Reaction, in conjunction with the pK_a's of butanesulfinic acid and benzenesulfinic acid (2.1 and 1.2, respectively (9)), it seemed reasonable to presume the following order of nucleofugalities for bissulfide sulfonyl compound hydrolyses: $-SO_2OPhCl$-*p* > $-SO_2Ph$ > $-SO_2CH_3$. In an attempt to examine a sulfenylation that would give products with enhanced stability to column chromatography, the following reactions were conducted on dimethyl sulfone (eq. [9]). In the event, **11** and **12** were more stable to column chromatography. Reversibility for sulfone sulfenylations, under our reaction conditions, was established by the reaction shown in eq. [10].





Because the methyl sulfones (eqs. [6] and [9]) and the methanesulfonates (Scheme 1) are similar in acidity[4] and reactions at the α-carbon atoms are subject to similar steric congestion, the sulfones serve as good models for the methanesulfonates. It is now clear that (*i*) reversible sulfenylation, shown as **2**⇆**3** in eq. [4], is almost certainly the second sequence of the Trithioorthoformate Reaction. Additionally, the absence of trissulfide sulfones **6***a* and **6***b* in product mixtures from reactions [6] and [9] along with the absence of hydrolysis products (including $(ArS)_4C$) expected from reaction during column chromatography *strongly militates against the intervention of the trissulfide-sulfonate ester* **13** *in the Trithioorthoformate Reaction (eq. [1]).*

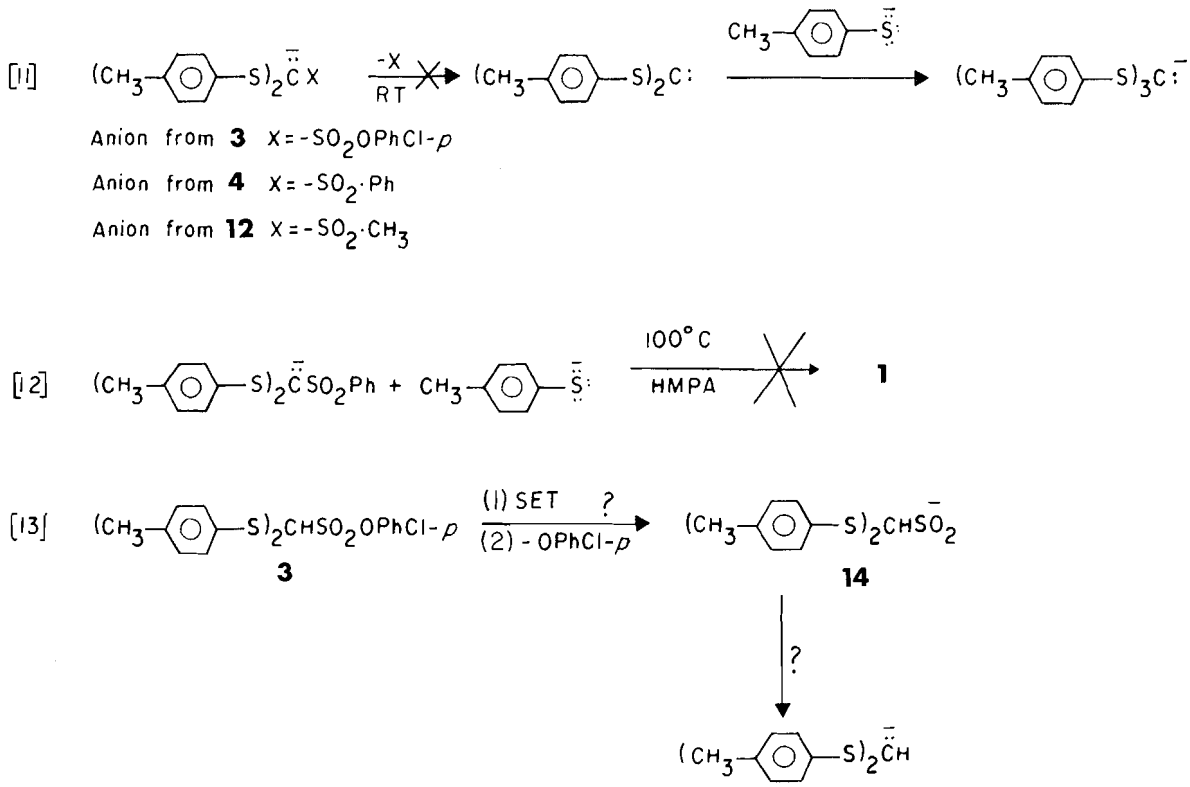
13

The second sequence is presented as Scheme 5.

B. The third sequence of the trithioorthoformate reaction

A priori, there are four reasonable intermediates through which the bissulfide sulfonate ester **3** might be transformed into the trithioorthoformate **1**, viz. (*i*) the trissulfide sulfonate **13**, which has already been dismissed from consideration, (*ii*)

[4] Dimethyl sulfone has a pK_a of 31.1 and phenyl methanesulfonate has a pK_a of 25.2 (10).



a dithiocarbene, (*iii*) a dithiomethyl carbanion, and (*iv*) a dithiosulfene.

The intermediacy of a dithiocarbene would follow from possible expulsion of a sulfonyl leaving group from a dithiosulfonyl carbanion as in eq. [11].

Based upon the chromatographic instabilities of **3** and **4** (rationalized in Schemes 2 and 4), it seems likely that $-SO_2OPhCl$-*p* and $-SO_2Ph$ have similar nucleofugalities. It follows that the carbanions derived from **3** and **4** should be similarly reactive with respect to dissociation as shown in step 1 of eq. [11]. Since no sulfone reaction conducted at room temperature furnished any trithioorthoformate **1** prior to column chromatography, we have treated the anion from the bissulfide sulfone **4** with *p*-tolyl mercaptide anions in hot HMPA (eq. [12]).

A similar reaction on the carbanion derived from the bissulfide sulfone **12** also failed to produce any trithioorthoformate **1**. We conclude that the carbanions derived from **4** and **12** have no effective way to reach **1** and that the Trithioorthoformate Reaction is unlikely to proceed through a dithiocarbene. In sharp contrast to these sulfone experiments, phenyl methanesulfonate produces no **1** at room temperature but converts *p*-tolyl mercaptide anions into **1** in 40% yield at 100°C (2).

The intermediacy of a dithiomethyl carbanion might be expected following single-electron transfer (SET) to the bissulfide sulfonate **3** (eq. [13]). However, the Trithioorthoformate Reaction completely consumes added NaH to produce carbanions and sulfenylated sulfonate esters. The bissulfide sulfonate **3** would be the strongest acid produced in the reaction and should be essentially quantitatively converted to the corresponding carbanion under the reaction conditions. This anion is an improbable one-electron acceptor. Desulfonylation of **14** would produce a very unstable carbanion[5] and is an unlikely process at ambient temperature. The dithiomethyl carbanion will not be considered further as an intermediate for the third sequence of the Trithioorthoformate Reaction.

A reasonable pathway involving dithiosulfene intermediacy is presented in Scheme 6. The chemistry of sulfenes has been the subject of a recent review (11). Sulfonic acid esters are well-established presursors for the formation of sulfenes (1, 12). Attack by mercaptide anions at the sulfene carbon (Scheme 6) is known as "carbophilic" attack (11) and has ample precedent (13). PM3 computations on CH_2SO_2 show it to have a near-degenerate pair of vacant frontier orbitals (Fig. 1). The coefficients shown in Fig. 1, along with the calculated atomic charge at sulfur (+2.33), lead to the view that sulfur may serve as the hard-acid site in sulfene while carbon serves as the soft-acid site. Optimized PM3 results for $(PhS)_2CSO_2$ are very similar to those just presented for sulfene itself. Note that the third sequence of the Trithioorthoformate Reaction is only the second example of nucleophile-induced CS rupture in a sulfonate ester reaction (see ref. 14 for the first example).

With a complete pathway proposal in hand, we turned our attention to the design and construction of a superior sulfonate. The Trithioorthoformate Reaction requires that the sulfonate ester serve as (*i*) an effective oxidizing agent for mercaptide anions and (*ii*) the source of the methine carbon. The first molecule selected for synthesis was the bissulfonate **15***a*, which has a tribromophenyl-sulfonate linkage for oxidation (15) and a methanesulfonate group for methine carbon.

[5] The following pK_a's come from ref. 10: $(PhS)_3CH$, 22.8; 2-phenyl-1,3-dithiocyclohexane, 30.6; $PhSCH_3$, 42.

Scheme 6. Proposed third sequence of the Trithioorthoformate Reaction.

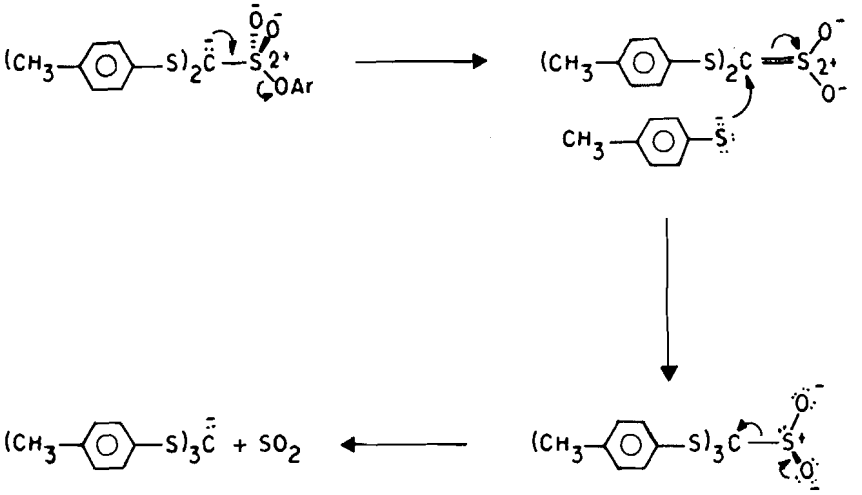


Fig. 1. PM3 vacant frontier and near-frontier orbitals for sulfene.

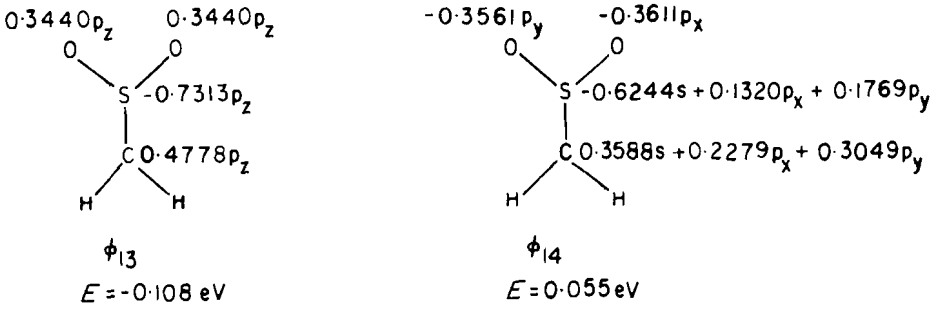
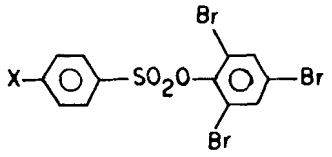


The sulfone sulfonate **15***b* was also targeted for synthesis. It should be a good oxidizing agent but should be unable to deliver methine carbon because it cannot form a dithiosulfene (see Scheme 6). Our approach to the synthesis of **15***b* is presented in eq. [14].



15a X = $CH_3SO_3^-$

15b X = $CH_3SO_2^-$

Earlier work (2) demonstrated that 2,4,6-tribromophenyl methanesulfonate was smoothly reduced by sodium hydride in HMPA. Both **15***a* and **15***b* were reacted with sodium hydride to confirm that these tribromophenyl sulfonates were effective oxidizing agents (eq. [15]). Prior to the experiment on **15***a*, the highest yield[6] of trithioorthoformate **1** (at room temperature) was 10.8 mol%, obtained with *p*-methylsulfonylphenyl methanesulfonate (2). The final experiments employed mixtures of *p*-tolyl mercaptan and *p*-tolyl disulfide in order to avoid exhausting the capacities of the sulfonate-esters to oxidize mercaptide anions (see first step, Scheme 5).

In consonance with our results on sulfones, **15***b* furnished **1** in very low yield[6] (eq. [16]). Trithioorthoformate isolated from this reaction was undoubtedly an artifact resulting from column chromatography.

Reaction with the bissulfonate ester **15***a* furnished the trithioorthoformate **1** in a yield[6] that was twice the magnitude of that obtained with *p*-methylsulfonylphenyl methanesulfonate (2) (eq. [17]). A complete detailed proposal for the pathway of the Trithioorthoformate Reaction has been advanced. Insights arising from the proposal have permitted the design of the best-known reagent, **15***a*, for the oxidative conversion of *p*-tolyl mercaptan into the trithioorthoformate **1**.

Methods

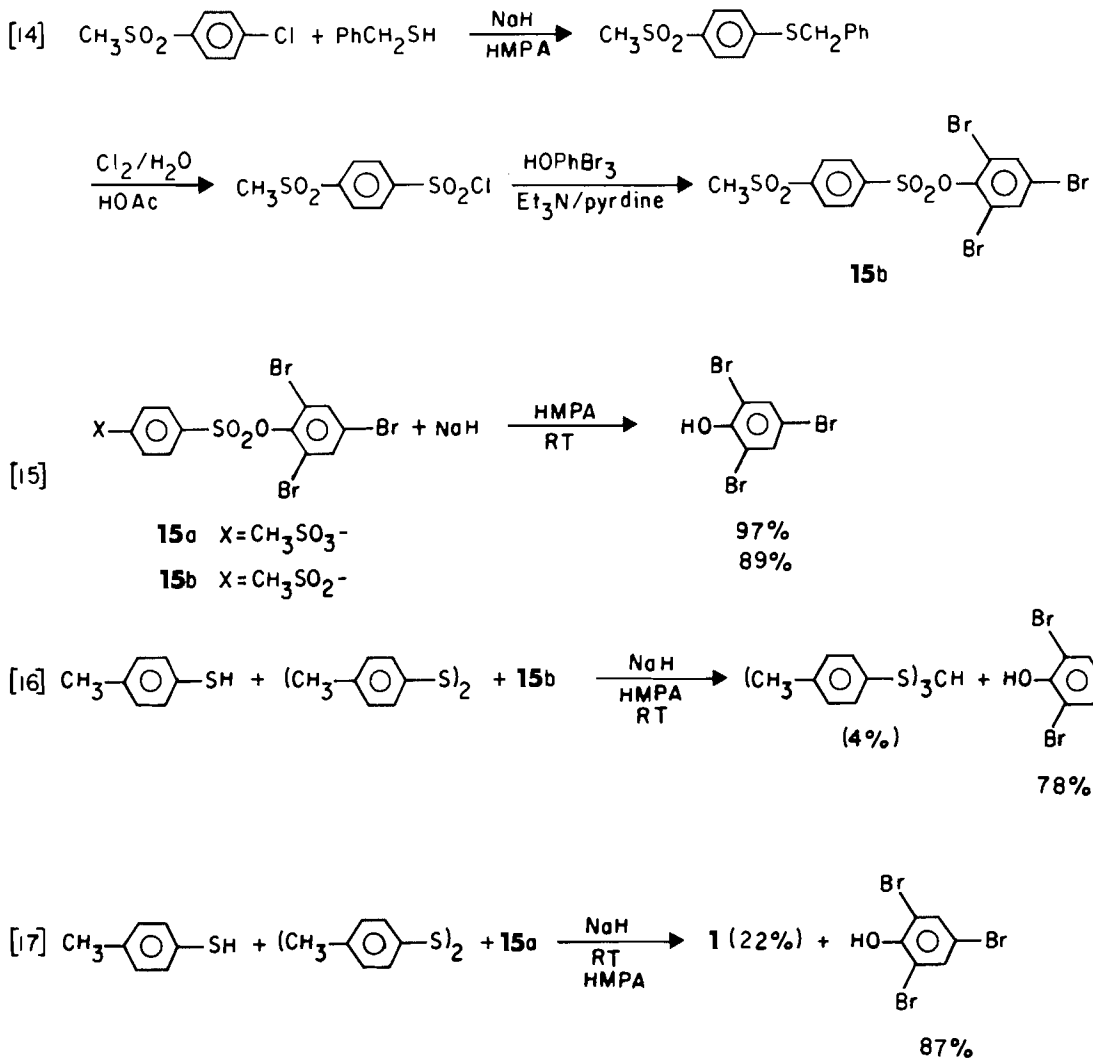
PM3 computations (16) on the two sulfene structures were fully optimized.

Experimental

General

The ir spectra were recorded on a Perkin–Elmer 237B grating spectrophotometer. The nmr spectra were obtained on a Varian EM360A instrument using TMS as the internal standard. Mass spectra were obtained on a Kratos MS 80 gc–ms system. Melting points were determined on a Gallenkamp MFB-595 capillary melting point apparatus and are uncor-

[6] Yields for this discussion are based on consumed sulfonic acid ester.



rected. Quantitative analysis of mixtures was accomplished as described elsewhere (17).

Standard work-up

The crude reaction mixture was poured into water (100 mL) and 10% HCl (10 mL). The resultant mixture was washed with diethyl ether (three 100-mL aliquots). The combined ether layers were concentrated and the residue poured into water (100 mL). The resultant mixture was extracted with diethyl ether (three 100 mL aliquots). The combined ether layers were washed with 2.5% NaOH (100 mL), dried ($MgSO_4$), and concentrated.

Trithioorthoformate reaction with Na metal

Sodium metal (0.693 g, 30.1 mmol) was suspended in HMPA (hexamethylphosphoramide) (2) (30 mL). A solution of absolute ethanol (0.638 g, 13.8 mmol) in HMPA (10 mL) was added dropwise over 10 min. A solution of *p*-tolyl mercaptan (1.698 g, 13.6 mmol) was added dropwise over 10 min. Upon completion of the addition the reaction mixture was stirred at ambient temperature for 5 min. *p*-Chlorophenyl methanesulfonate (2.802 g, 13.6 mmol) was added and the reaction mixture stirred at room temperature for 4 days, by which time the sodium was completely consumed.

Standard work-up furnished crude product (1.783 g), which was recrystallized from methanol (40 mL). Clean trithioorthoformate **1** (0.537 g, 1.4 mmol, 30.8%) was obtained and shown to be identical to authentic material by mp, nmr, and double-spotted tlc. The mother-liquor concentrate was chromatographed on silica gel (120 g) employing chloroform elution (100-mL fractions). Fractions **4** and **5** were combined and concentrated affording *p*-chlorophenyl methanesulfonate (0.416 g).

Preparation of p-*tolyl thiolformate*

Authentic *p*-tolyl thiolformate was prepared as described elsewhere (18).

Isolation of p-*tolyl thiolformate from the trithioorthoformate reaction*

Sodium hydride (0.679 g, 28.3 mmol) was suspended in HMPA (100 mL). *p*-Tolyl disulfide (3.375 g, 13.7 mmol) and then *p*-chlorophenyl methanesulfonate (2.828 g, 13.7 mmol) were added. The reaction mixture was stirred at ambient temperature for 1 h 10 min and subjected to standard work-up affording crude product mixture (3.633 g).

Crude product was chromatographed on silica gel (370 g) employing carbon tetrachloride elution (40 100-mL fractions)

and then chloroform (20 100-mL fractions). Fractions 9–22 were combined and concentrated, affording the trithioorthoformate **1** (1.591 g, 4.2 mmol). Recrystallized **1** was identical to authentic material by nmr, tlc, mp, and mixture mp. Fractions 23–25 were combined and concentrated, furnishing *p*-tolyl thiolformate (0.032 g, 0.2 mmol) that was identical to authentic material by ir and nmr. Fractions 26–28 were combined and concentrated, giving *p*-tolyl disulfide (0.143 g, 0.6 mmol). Fractions 47–50 were combined and concentrated, furnishing the sulfide-sulfonate ester **2** (0.264 g, 0.8 mmol). Recrystallized **2** had mp 74.6–75.2°C; ir ($CHCl_3$): 1360, 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.52 (2H, d, J = 8 Hz), 7.20 (4H, br s), 7.12 (2H, d, J = 8 Hz), 4.40 (2H, s), and 2.32 (3H, s); ms *m/e*, $M^{\cdot+}$ + 2: 330 (0.4%), 328 (1.2%), 137 (100%), and 91 (8.3%). Anal. calcd. for $C_{14}H_{13}ClO_3S_2$: C 51.13, H 3.98; found: C 51.03, H 4.00. Fractions 51 and 52 were combined and concentrated, providing an equimolar mixture (0.238 g) of **2** and *p*-chlorophenyl methanesulfonate. Fractions 53–57 gave *p*-chlorophenyl methanesulfonate (0.456 g).

Reaction of phenyl methyl sulfone with p-*tolyl mercaptan*

Sodium hydride (1.636 g, 68 mmol) was suspended in HMPA (75 mL) (2). A solution of *p*-tolyl mercaptan (4.267 g, 34.4 mmol) in HMPA (25 mL) was added dropwise over a period of 5 min. Phenyl methyl sulfone (2.136 g, 13.6 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h 10 min.

Standard work-up yielded crude product (1.047 g) that was chromatographed on silica gel (100 g), first employing 1:3 methylene chloride – carbon tetrachloride elution (30 100-mL fractions) and then chloroform elution (100-mL fractions). Fractions 2–4 were combined and concentrated, affording *p*-tolyl disulfide (0.087 g). Fractions 12–20 furnished the bissulfide sulfone **4** (0.037 g, 0.092 mmol, 0.6%). Recrystallized **4** had mp 117.4–118.5°C; ir ($CHCl_3$): 1360 and 1155 cm^{-1}; nmr ($CDCl_3$) δ: 8.00 (2H), 7.60 (3H), 7.31 (4H, d), 7.06 (4H, d), 5.00 (1H, s), 2.33 (6H, s). Anal. calcd. for $C_{21}H_{20}O_2S_3$: C 62.96, H 5.03; found: C 63.09, H 5.20. Unchanged phenyl methyl sulfone (0.786 g) was recovered from fractions 21–41.

Routine preparation of bissulfide sulfone 4

Phenyl methyl sulfone (1.506 g, 9.6 mmol) in HMPA (20 mL) (2) was added to a slurry of sodium hydride (0.470 g, 19.5 mmol) in HMPA (10 mL) and the mixture stirred for 5 min. *p*-Tolyl disulfide (4.725 g, 19.2 mmol) was added and the reaction mixture stirred for 1 h 10 min.

Standard work-up furnished crude product (4.624 g) that was recrystallized from methanol (41 mL) and carbon tetrachloride (5 mL), affording off-white crystals (1.886 g). Recrystallized **4** was again recrystallized from methanol (16 mL) and carbon tetrachloride (2 mL), affording clean sulfone bissulfide **4** (1.158 g, 2.8 mmol, 30%).

Reaction of phenyl methyl sulfone with p-*tolyl disulfide employing chromatographic work-up*

A solution of *p*-tolyl disulfide (3.149 g, 12.8 mmol) in HMPA (10 mL) (2) was added to a slurry of sodium hydride (0.310 g, 12.9 mmol) in HMPA (10 mL). Phenyl methyl sulfone (1.000 g, 6.4 mmol) in HMPA (10 mL) was added dropwise over 5 min. The reaction mixture was stirred at ambient temperature for 30 min.

Standard work-up yielded a yellow solid that contained the sulfone bissulfide **4** (50%), phenyl methyl sulfone (0.368 g, 37%), and *p*-tolyl disulfide (1.392 g, 44%). The yellow solid was chromatographed on silica gel (300 g) employing 1:3 methylene chloride – carbon tetrachloride (45 100-mL fractions) followed by chloroform (100-mL fractions). Fractions 4–8 furnished *p*-tolyl disulfide (1.392 g). Fractions 35–38, 49–51, and 66–67 were combined and concentrated, providing the trithioorthoformate **1** (0.325 g, 0.8 mmol, 13%). Fractions 54–57 and 69–71 were combined, giving *p*-tolyl thiolformate (0.038 g, 0.3 mmol, 4%). Fractions 75–79 gave the bissulfide sulfone **4** (0.083 g, 0.2 mmol, 3%). Fractions 81–87 were combined and concentrated, yielding phenyl methyl sulfone (0.368 g).

Reaction of sulfone-sulfonic acid ester 9 with p-*tolyl disulfide*

A solution of the sulfone-sulfonic acid ester **9** (1) (1.021 g, 4.0 mmol) in dimethyl sulfoxide (DMSO, 10 mL) was added dropwise to a slurry of sodium hydride (0.188 g, 7.8 mmol) in DMSO (20 mL). Upon completion of that addition, *p*-tolyl disulfide (0.971 g, 3.9 mmol) was added and the reaction mixture stirred at ambient temperature for 3 days.

Standard work-up *without base extraction* furnished crude sulfone-sulfide-sulfonic acid ester **10** (1.922 g). The crude product was chromatographed on silica gel (170 g) employing chloroform elution (100 mL fractions). Fractions 7–13 gave clean **10** (1.344 g, 3.6 mmol, 88%). Recrystallized **10** had mp 87.9–88.7°C; ir ($CHCl_3$): 1390, 1345, and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.65 (2H, d), 7.36 (5H, s), 7.16 (2H, d), 5.26 (1H, s), 3.26 (3H, s), and 2.30 (3H, s); ms *m/e*, $M^{\cdot+}$ − 1: 371 (6%), 228 (70%), 135 (76%), 123 (100%). Anal. calcd. for $C_{15}H_{16}O_5S_3$: C 48.36, H 4.32; found: C 48.08, H 4.27.

Reaction of dimethyl sulfone with p-*tolyl disulfide*

A solution of *p*-tolyl disulfide (3.141 g, 12.7 mmol) in HMPA (10 mL) (2) was added to a slurry of sodium hydride (0.309 g, 12.8 mmol) in HMPA (10 mL). Dimethyl sulfone (0.604 g, 6.4 mmol) in HMPA (10 mL) was added and the reaction mixture stirred at ambient temperature for 1 h 10 min. Standard work-up furnished a crude yellow oil (3.006 g).

Crude product was chromatographed on silica gel (300 g) employing carbon tetrachloride (60 100-mL fractions), then chloroform (100-mL fractions), for elution. Fractions 9–17 were combined and concentrated, giving *p*-tolyl disulfide (1.176 g). Fractions 65–67 yielded trithioorthoformate **1** (0.042 g). Fractions 88–91 afforded the bissulfide sulfone **12** (0.442 g, 1.3 mmol). Recrystallized **12** had mp 85.3–86.5°C; ir ($CHCl_3$): 1320 and 1150 cm^{-1}; nmr ($CDCl_3$) δ: 7.55 (4H, d), 7.20 (4H, d), 5.00 (1H, s), 3.10 (3H, s), and 2.40 (6H, s); ms *m/e* 259 (36%), 137 (63%), and 91 (100%). Anal. calcd. for $C_{16}H_{18}O_2S_3$: C 56.77, H 5.35; found: C 56.71, H 5.39. Fractions 92–97 furnished a mixture of **12** (0.209 g, 0.6 mmol) and the sulfide-sulfone **11** (0.073 g, 0.3 mmol, 5%). The identity of **11** was established by adding authentic material (7), which enhanced the appropriate signals in the nmr spectrum of the mixture.

Reaction of bissulfide sulfone 12 with p-*tolyl mercaptan*

A solution of *p*-tolyl mercaptan (0.138 g, 1.1 mmol) in HMPA (5 mL) (2) was added dropwise to a slurry of sodium hydride (0.035 g, 1.4 mmol) in HMPA (10 mL). After stirring for 5

min, the bissulfide sulfone **12** (0.499 g, 1.4 mmol) was added. The reaction mixture was stirred for 1 h 10 min and subjected to standard work-up, which provided a yellow oil (0.588 g).

The crude product was chromatographed on silica gel (120 g) employing carbon tetrachloride elution (15 100-mL fractions) followed by chloroform elution (100 mL fractions). Fractions 3–7 were combined and concentrated, furnishing impure *p*-tolyl disulfide. Recrystallization gave clean *p*-tolyl disulfide (0.113 g, 0.4 mmol, 31%). Fractions 27–35 were combined and concentrated, affording a mixture of the bissulfide sulfone **12** (0.303 g, 60%) and the sulfone sulfide **11** (0.098 g, 0.4 mmol, 30%) (7).

Preparation of p-*chlorosulfonylphenyl methanesulfonate*

4-(Methylmercapto)phenyl methanesulfonate (2.030 g, 9.3 mmol) (1) was suspended in glacial acetic acid (25 mL) and water (3 mL). Cl_2 (ca. 200 mL/min) was bubbled through the reaction mixture for 10 h. Ice/water cooling was used as necessary to maintain the reaction temperature below 30°C.

Water (50 mL) was added and the resultant mixture washed with chloroform (three 50-mL aliquots). The combined organic layers were washed with 2.5% W/V sodium hydroxide (two 50-mL aliquots). The organic layer was dried and concentrated.

The residue was chromatographed on silica gel (200 g) employing 1:1 methylene chloride – carbon tetrachloride (100-mL fractions) for elution. Fractions 9–11 were combined and concentrated, affording *p*-chlorophenyl methanesulfonate (0.128 g, 0.6 mmol, 7%). Upon recrystallization it was shown to be identical to authentic material by nmr, ir, mp, and mixture mp. Fractions 12–19 were combined, yielding *p*-chlorosulfonylphenyl methanesulfonate (0.923 g, 3.4 mmol, 37%). Recrystallized sulfonyl chloride sulfonate ester had mp 83–84.5°C; ir ($CHCl_3$): 1382, 1365, 1182, and 1152 cm^{-1}; nmr ($CDCl_3$) δ: 8.35 (2H, d), 7.70 (2H, d), and 3.33 (3H, s).

Preparation of p-*(2,4,6-tribromophenoxysulfonylphenyl) methanesulfonate* ***15****a*

Unchromatographed *p*-chlorosulfonylphenyl methanesulfonate (2.161 g) was added in small portions to a cooled solution of 2,4,6-tribromophenol (1.993 g) and dry triethylamine (0.602 g) in dry pyridine (50 mL). The reaction mixture was stirred at ambient temperature for 5 days.

Chloroform (100 mL) was added and the resultant mixture washed with 2.5% HCl (100-mL aliquots) until the aqueous pH remained acidic. The organic layer was washed with 2.5% NaOH (100 mL), dried ($MgSO_4$), and concentrated. Crude product was dissolved in hot methanol (90 mL) and half of the methanol distilled off. The concentrated solution was stored at room temperature overnight. Bissulfonate **15***a* (2.413 g) had mp 121.1–121.7°C; ir ($CHCl_3$): 1380 (br), 1190, 1180, and 1155 cm^{-1}; nmr ($CDCl_3$) δ: 8.20 (2H, d), 7.80 (2H, s), 7.60 (2H, d), and 3.30 (3H, s); ms *m/e*, $M^{\cdot+}$ + 4: 568 (56%), 566 (65%), 564 (65%), 562 (52%), 333 (53%), 331 (64%), 329 (64%), 327 (54%), 235 (84%), 171 (81%), 141 (100%), and 79 (76%). Anal. calcd. for $C_{13}H_9Br_3O_6S_2$: C 27.63, H 1.60; found: C 27.64, H 1.51.

Preparation of p-*methylsulfonylphenyl benzyl sulfide*

Benzyl mercaptan (3.3 mL, 26 mmol) in HMPA (10 mL) (2) was added dropwise to a slurry of sodium hydride (0.639 g, 26.6 mmol) in HMPA (30 mL). Upon completion of the addition, *p*-chlorophenyl methyl sulfone (4.797 g, 25.2 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h 10 min.

Standard work-up furnished crude *p*-methylsulfonylphenyl benzyl sulfide, which was recrystallized from methanol, affording clean sulfone sulfide (6.134 g, 22.0 mmol, 87%). *p*-Methylsulfonylphenyl benzyl sulfide had mp 128–130°C; ir ($CHCl_3$): 1320 and 1155 cm^{-1}; nmr ($CDCl_3$) δ: 7.76 (2H, d), 7.30 (2H, d), 7.28 (5H, s), 4.16 (2H, s), and 3.00 (3H, s); ms *m/e*, $M^{\cdot+}$: 278 (14%) and 91 (100%). Anal. calcd. for $C_{14}H_{14}O_2S_2$: C 60.40, H 5.06; found: C 60.21, H 5.15.

Preparation of p-*chlorosulfonylphenyl methyl sulfone*

p-Methylsulfonylphenyl benzyl sulfide (0.965 g, 3.4 mmol) was suspended in glacial acetic acid (35 mL) and water (3 mL). Cl_2 (ca. 200 mL/min) was bubbled into the reaction mixture for 45 min. Ice/ water cooling was employed as necessary, to maintain the temperature below 30°C.

Chloroform (100 mL) was added and the reaction mixture washed with 2.5% W/V sodium hydroxide (two 50-mL aliquots). The organic layer was dried ($MgSO_4$) and concentrated. The residue was dissolved in dry refluxing carbon tetrachloride (150 mL) and 50 mL of solvent distilled off. Clean crystals of the sulfone-sulfonyl chloride (0.650 g, 2.5 mmol, 74%) were obtained. The sulfone-sulfonyl chloride had mp 166.5–167.3°C; ir ($CHCl_3$): 1360, 1175, and 1158 cm^{-1}; nmr ($CDCl_3$) δ: 8.06 (4H, s) and 2.83 (3H, s); ms *m/e*, $M^{\cdot+}$ + 2: 256 (8%), 254 (18%), and 219 (100%). Anal. calcd. for $C_7H_7ClO_4S_2$: C 33.00, H 2.77; found: C 32.73, H 2.71.

Preparation of p-*(2,4,6-tribromophenoxysulfonylphenyl) methyl sulfone* ***15****b*

A solution of 2,4,6-tribromophenol (1.296 g, 3.9 mmol) and triethylamine (0.405 g, 4.0 mmol) in pyridine (50 mL) was cooled with an ice/water bath. *p*-Chlorosulfonylphenyl methyl sulfone (0.998 g, 3.9 mmol) was added in small portions over 5 min. The reaction mixture was allowed to return to ambient temperature and stirred for 7 days.

Chloroform (100 mL) was added and the resultant mixture washed with 2.5% HCl (100-mL portions) until the aqueous pH remained acidic. The organic layer was extracted with 2.5% sodium hydroxide (100 mL), dried ($MgSO_4$), and concentrated.

Crude sulfone sulfonate **15***b* was recrystallized from methanol (1100 mL), affording clean product (1.238 g, 2.2 mmol, 56%). Recrystallized **15***b* had mp 228.0–228.4°C; ir (KBr): 1400, 1310, 1195, 1180, and 1155 cm^{-1}; nmr ($CDCl_3$) δ: 8.16 (4H, s), 7.66 (2H, s), and 3.10 (3H, s); ms *m/e*, $M^{\cdot+}$ + 6: 552 (0.7%), 550 (1.3%), 548 (1.5%), 546 (0.4%), 219 (50%), 155 (77%), and 76 (100%). Anal. calcd. for $C_{13}H_9Br_3O_5S_2$: C 28.43, H 1.65; found: C 28.52, H 1.51.

Reaction of ***15****a or* ***15****b with NaH–HMPA*

15*a* and **15***b* were each reacted with sodium hydride as described below for the bissulfonate **15***a*.

The bissulfonate ester 15*a* (1.008 g, 1.78 mmol) in HMPA (2) (10 mL) was added dropwise to a slurry of sodium hydride (0.172 g, 7.1 mmol) in HMPA (20 mL). The reaction mixture was stirred at ambient temperature for 2 h 10 min.

The reaction mixture was poured into water (50 mL) and

10% HCl (10 mL). The resultant mixture was extracted with diethyl ether (three 50-mL aliquots). This extractive procedure was repeated twice, affording 2,4,6-tribromophenol (0.547 g, 1.73 mmol, 97%).

The trithioorthoformate reaction with ***15****a or* ***15****b*

15*a* and **15***b* were each reacted with *p*-tolyl mercaptan and *p*-tolyl disulfide as described below for the bissulfonate **15***a*.

p-Tolyl mercaptan (0.229 g, 1.8 mmol) in HMPA (2) (10 mL) was added dropwise to a slurry of sodium hydride (0.169 g, 7.0 mmol) in HMPA (20 mL). Five minutes after completion of the addition, *p*-tolyl disulfide (0.439 g, 1.8 mmol) was added. The bissulfonate ester **15***a* (1.000 g, 1.8 mmol) was added and the reaction mixture stirred for 2 h 10 min.

Standard work-up provided crude product (1.466 g). Crude product was chromatographed on silica gel (150 g) employing carbon tetrachloride elution (100-mL aliquots). Fractions 4–7 were combined and concentrated, furnishing *p*-tolyl disulfide (0.191 g). Fractions 13–19 were combined and concentrated, yielding 2,4,6-tribromophenol (0.506 g, 1.5 mmol). Fractions 23–37 were combined and concentrated affording the trithioorthoformate **1** (0.151 g, 0.4 mmol).

Furo-fused 2*H*-chromenes: synthesis and photochromic properties

Jean-Luc Pozzo, André Samat, Robert Guglielmetti, Vladimir Lokshin, and Vladimir Minkin

Abstract: New photochromic chromenes annulated with a furan ring have been synthesized. Thus, suitable heterocyclic phenols react with different propargylic alcohols in acidic medium to give the corresponding ethers, which cyclize into benzopyrans by thermal Claisen rearrangement. This synthetic approach was found to lead to a mixture of linear and angular chromenes that is strictly related to the nature of the phenol. However, regiospecificity could be obtained by reacting β-phenylcinnamaldehyde, in refluxing aprotic nonpolar solvents, with titanium(IV) salts of the former phenols. Electrocyclization of intermediately generated *o*-quinoid structures occurs on the α position towards the heterocyclic junction. All compounds exhibit photochromic behavior at room temperature. Furo-fused benzopyrans are particularly interesting with respect to naphthopyran parents in view of the bathochromically shifted and broadened absorption spectra of photoinduced forms. This trend is confirmed by the spectral data of several heterocyclospiro(7*H*-furo[3,2-*f*] chromenes). The achievable color depends significantly on the relative position of annulation on the chromenic moiety and substitution on the sp^3 carbon atom.

Key words: photochromism, heterocycle, regiospecificity, 2*H*-chromene, furan.

Résumé : De nouveaux chromènes photochromiques annélés par un noyau furanique, ont été synthétisés. Ils sont obtenus par réaction de phénols hétérocycliques et d'alcools propargyliques en milieu acide. Les éthers correspondants intermédiairement formés se cyclisent en composés benzopyraniques selon un réarrangement thermique de Claisen. Cette approche synthétique conduit à l'obtention d'un mélange de régioisomères angulaires et linéaires. La régiospécificité est obtenue, en faisant réagir les sels de titane(IV) de ces phénols avec le β-phénylcinnamaldéhyde au reflux de solvants aprotiques apolaires. L'électrocyclisation des *o*-quinoneallides n'est réalisée que sur la position en α de la jonction hétérocyclique. Tous les composés obtenus manifestent à température ambiante des propriétés photochromiques qui dépendent significativement du type de régioisomère et de la substitution sur le carbone sp^3. L'annelation du motif benzopyranique par un noyau furanique conduit à un élargissement significatif et à un déplacement bathochromique important du spectre visible par rapport aux naphtopyranes correspondants. L'allure des spectres d'absorption dans le visible des formes ouvertes photoinduites de plusieurs hétérocyclospiro(7*H*-furo[3,2-*f*]chromènes) confirme cette observation.

Mots clés : photochromisme, hétérocycle, régiospécificité, 2*H*-chromène, furane.

Introduction

2*H*-1Benzopyrans (or 2*H*-chromenes) are an important family of oxygenated heterocycles (1) particularly attractive because of their photochromic properties. Indeed, 2*H*-chromenes undergo a reversible ring opening of the pyran cycle (2). The Csp^3—O bond is cleaved by UV irradiation leading to opened coloured forms ("photomerocyanines"). The molecule reverts to its original form via a thermal pathway (Scheme 1).

Over several years 2*H*-chromenes were not considered to be interesting photochromic compounds for applications, and intensive research studies were preferably devoted to their spiroheteroanalogs (spiropyrans) (3). Indeed, the first described chromenes, 2,2-dimethyl-[2*H*]-chromenes and their benzoannulated derivatives (naphthopyrans), showed photochromic behavior only at low temperature (2) and, moreover, led to undesirable by- products (4). In fact, interest in research in this field developed only recently with the demand for industrial applications of materials that undergo variable optical absorption. For this purpose, the desirable properties could be summarized as follows: high efficiency for coloring in the near-ultraviolet region, low quantum yield for bleaching with visible light, and fast thermal fading at ambient temperatures. These kinds of requirements have led to several structural modifications in the chromene series. Particularly, improvement of photochromic properties was obtained by the annulation of the chromenic ring in the 7,8-positions (5), by appropriate substitutions of the naphthopyran cycle (6, 7), replacing the alkyl groups on the Csp^3 carbon atom by cyclopropyl groups (8), spiroadamantyl groups (9), and, overall, by aryl groups (10, 11). This last kind of substitution is nearly indispensable for observing good photochromic properties.

Our interest in benzopyran chemistry has been focused on the design and study of heterocyclo-fused analogues, in order

to modify the photochromic parameters (12, 13). Thus, the purpose of the present work was to introduce a furan ring in the C5-C6 position and to investigate its role with respect to photochromic properties and especially to the shape of absorption spectra in the visible region, for useful industrial applications.

Results and discussion

There has long been an interest in the chemistry of 2,2-disubstituted-[2*H*]-chromenes as a consequence of their widespread natural occurrence. These compounds can be obtained through a multistep sequence from chromanones, involving the Kabbe synthesis (14, 15). This method is not readily applicable to 2,2-diaryl analogues (10) and, alternatively, a thermal cyclization of propargylaryl ethers can be considered (16–18). This approach (method A), which appears particularly attractive because of availability of the starting phenols and chloro- or hydroxyalkynes, has been useful in synthesizing diaryl-naphthopyrans (9). The reaction is considered to proceed via a Claisen-like [3,3]-sigmatropic rearrangement which is followed by enolization and a [1,5]-sigmatropic shift. An electrocylization completes the process (19).

The benzopyran derivatives were prepared by heating the appropriate hydroxy-benzofuran with 1,1-diphenylpropyn-1-ol or 3-phenylbutyn-3-ol in an apolar organic solvent, such as toluene or xylene, in the presence of an acid catalyst under mild reaction conditions (Scheme 2). Sufficient time to complete the reaction varies between 2 and 6 h. Mixtures of the desired compounds were initially purified by flash chromatography. Nevertheless the "chromenylation" from furo-fused phenols is not markedly regiospecific since the two possible chromenes were obtained as outlined in Scheme 2. The difference of polarity being very weak, the chromenes were eluted in the same fraction by flash chromatography. The mixtures were recrystallized several times with appropriate solvents so that we were able to isolate pure samples of all angular chromenes (**3***a–d*), which were then fully characterized by electronic spectroscopy and ^{1}H and ^{13}C NMR. Some minor linear regioisomeric chromenes obtained from 2-hydroxydibenzofuran **1***a*, i.e., compounds **4***a*, *b*, were isolated after such specific recrystallization because of a sufficient amount in the starting mixture.

Regioisomer distribution varies from 60/40 to 90/10 as listed in Table 1. The ratio between both isomers, **3** and **4**, was

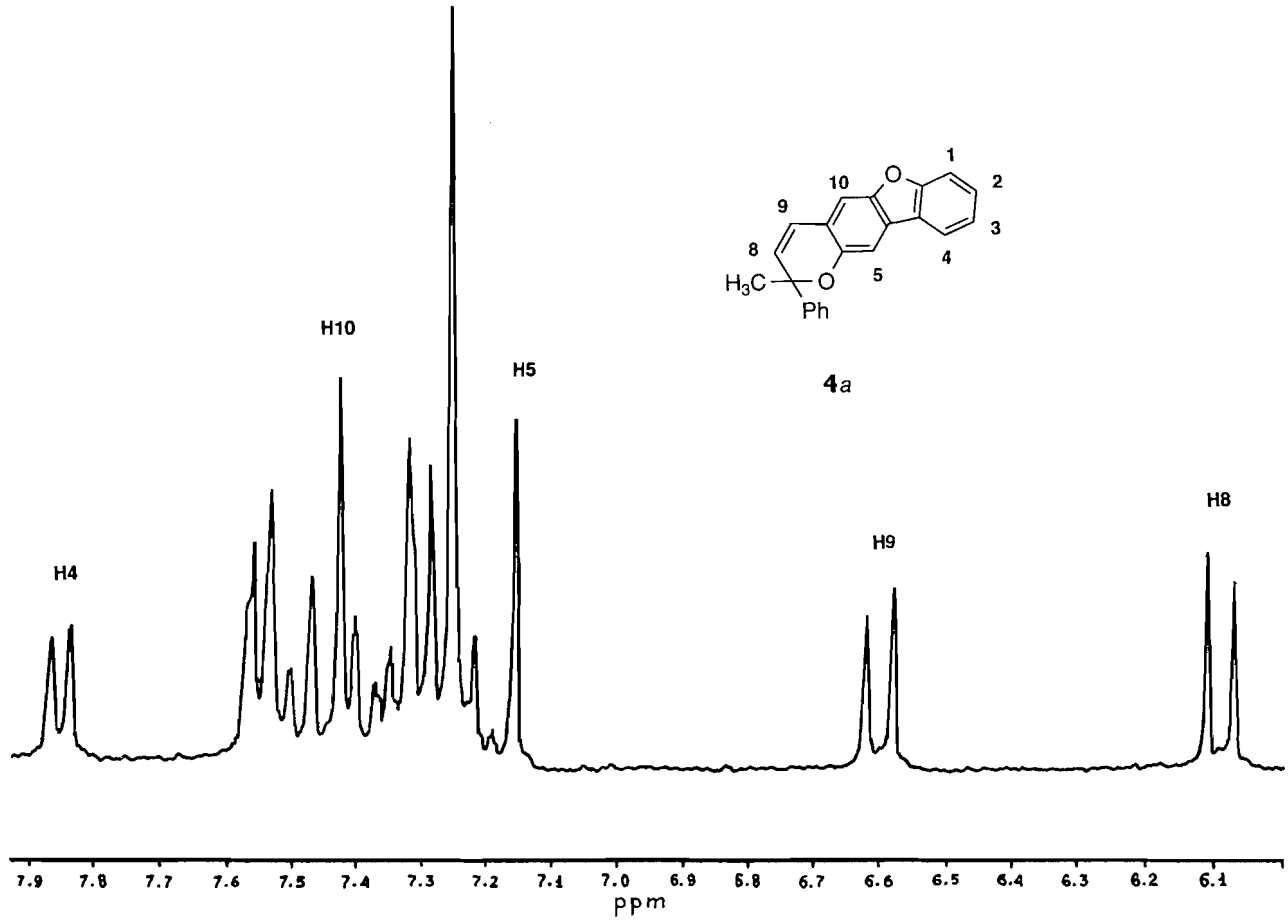
determined by HPLC using a reverse-phase C18 column and electron spectroscopy. Their structures were elucidated by NMR spectroscopy and allow us to conclude that angular chromene predominates in all cases. Indeed, both regioisomers, angular and linear chromenes, are readily distinguishable in the mixture, using ^1H NMR, by comparison with pure regioisomers. For example, the spectrum of the angular isomer (**3***a*) displayed two doublets centred, respectively, at δ 7.03 and 7.28 with a coupling constant of 8.6 Hz, each integrating for one proton and assigned to the protons H-5 and H-6 (see Fig. 1) of the ring directly linked to the pyran moiety, whereas the spectra of the other possible chromene (**4***a*) displayed two

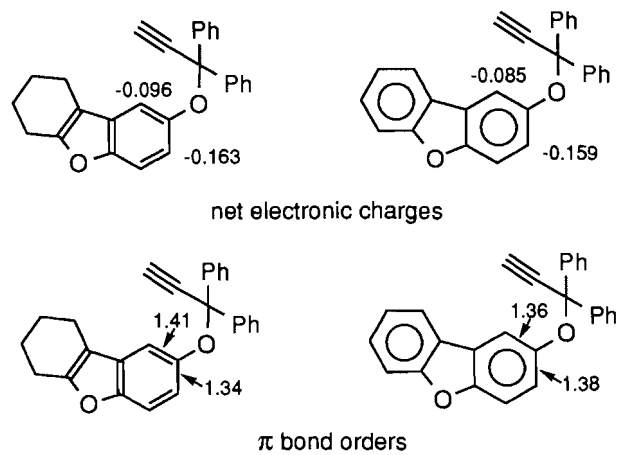
Fig. 2. ^{1}H NMR spectrum (250 MHz, $CDCl_3$) of **4***a*.



singlets centered at 7.16 and 7.43 that were assigned to H-5 and H-10, respectively (see Figs. 1 and 2). Furthermore, the chemical shift of the protons localized on the pyran ring are also characteristic and could easily be detected, being shielded with respect to the whole aromatic region. For the angular chromene, the ^{1}H NMR spectrum displayed a doublet accounting for one proton, at δ 6.19, with a coupling constant of 9.85 Hz, which is typical for the proton α (H-2) to the quaternary carbon of the pyran ring. An upfield shift, in comparison, is observed for the linear chromene as shown by the chemical shift of the proton H-8 (6.08 ppm). The same effects and trends are observed for the other compounds **3***b–d* and **4***b–d*, with a downfield shift due to the presence of a second phenyl group.

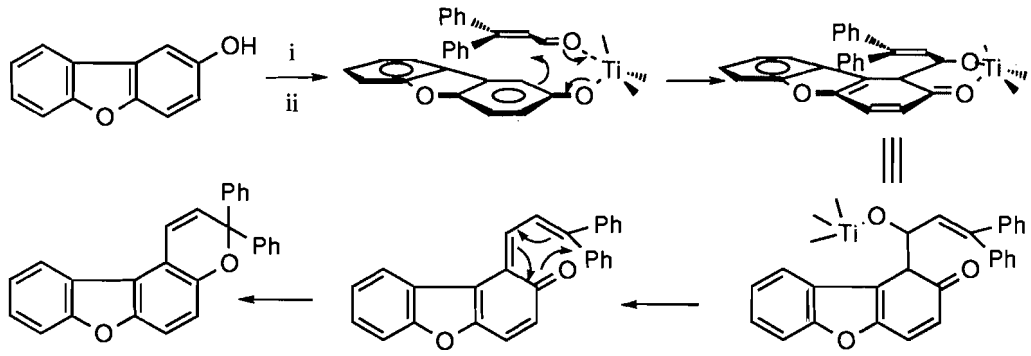
When starting from the naphthol derivatives, the synthetic route used has been reported to proceed in a regiospecific manner, leading to angular chromenes (10). With benzofuranic phenols, the lack of regiospecificity could be a consequence of the less marked difference of electron density at the aromatic termini of the [3,3] rearrangement. In fact, the ratio between angular and linear isomers varies as a function of starting phenolic substrates rather than of the propargylic compound. To understand these results, molecular modelling using semiempirical calculations was performed using the PM3 method. This showed, with no discrepancy, that there is no dramatic change of steric hindrance between the two possible cyclizations. Whatever the starting furo-fused phenol, the formation of one isomer could not be favoured by steric considerations.

Scheme 3.

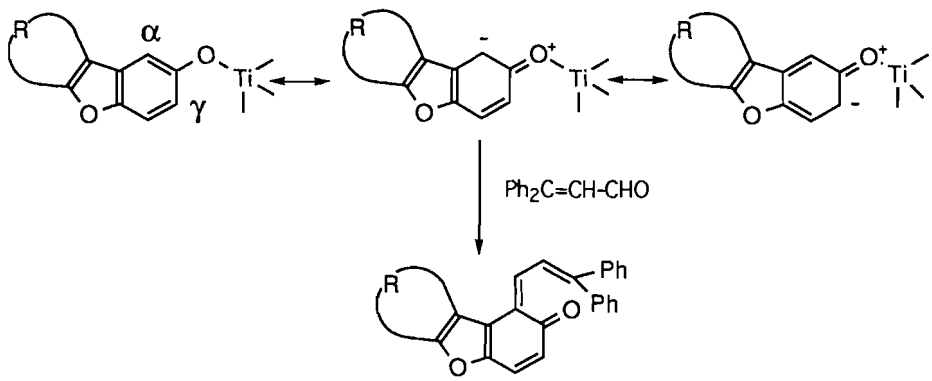


The stability of the transition state could play a significant role in determining the orientation of the final product. The different reactivities observed between the phenols could not be totally explained by charge repartition calculations on phenols or on their corresponding propargylic ethers. On the other hand, the calculated π-bond orders show a marked π-bond character between the C-4 and C-5 atoms rather than between the C-5 and C-6 atoms (Scheme 3) in the case of the cycloalkyl compound, whereas no difference was found for the corre-

Scheme 4. Mechanistic pathway for method B.



Scheme 5.



sponding bonds of the 2-propargylicdibenzofuran derivative. According to the proposed reaction mechanism of this intramolecular cyclization, this could lead to the observed mixtures of linear and angular chromenes.

Despite the report that this synthetic approach A is broadly applicable, it suffers, in our case, from the disadvantage of difficult and lengthy purifications of both isomers. Alternatively, the condensation of α,β-unsaturated carbonyl compounds with phenols has received much attention as a route to chromenes (1, 20). Another approach to obtain the desired compounds is to react α,β-unsaturated aldehydes with titanium(IV) salts of phenols (method B), as previously described for 2,2-dialkyl chromenes (21). However, the examples cited therein do not ensure the generality of this route, particularly concerning the furo-fused 2,2-diaryl-[2*H*]-chromenes.

The reaction (Scheme 4) involves the formation of the titanium(IV) salt of the heterocyclic phenol by azeotropic distillation of the ethanol formed. Then β-phenyl cinnamaldehyde is added and the reaction mixture is refluxed for ca. 3 h in toluene. *o*-Quinoid intermediates are generated in situ but are never directly observed, presumably due to their easy cyclization to benzopyran products. In our case, better yields were found using a stoichiometric amount of β-phenylcinnamaldehyde **5**, hydroxybenzofurans, and titanium tetraethoxide (22, 23). New compounds were initially purified by flash chromatography. The remaining solids were recrystallized from appropriate solvents and fully characterized by ^{1}H and ^{13}C NMR and electron spectroscopy. Corresponding yields are listed in Table 1. With this synthetic pathway, no trace of linear chromene was detected. An HPLC chromatogram of the crude reaction product and an ^{1}H NMR study show without doubt that this method affords only the angular chromene. This regioselectivity could be explained by the less carbanionic character at C-γ relative to C-α, arising from resonance stabilization (Scheme 5). The α,β-unsaturated carbonyl compound and heteroannulated phenolic substrate are each coordinated by the transition metal, which leads to univocal intramolecular reaction within the complex.

The approach B to pyran ring formation, despite more difficult work-up than with method A, appears to be the preferred means of preparing the title compounds regiospecifically.

Photochromic properties

All the described chromenes **3***a–d* and **4***a*, *b* exhibit photochromic behavior at room temperature in toluene. The maxima of absorption in the visible spectra of the "photomerocyanines," with an accuracy of 2 nm, and the rate constants of thermal bleaching (ring closure) k_Δ were determined using flash photolysis coupled to a spectrometer. The "colorability" is a function of quantum yield of coloration and the molar absorptivity of the colored species (24) and is evaluated by monitoring the absorbance A_0 at λ_{max} and λ_{sh} immediately after the flash. The experimental conditions are reported in the corresponding section. The photochromic properties for compounds **3***a–d* and **4***a*, *b* are listed in Table 2 and are compared with naphtho[2,1-b]pyrans **6***a*, *b* (10, 25) previously synthesized (Scheme 6).

Scheme 1 gives a very simple picture of photochromic equi-

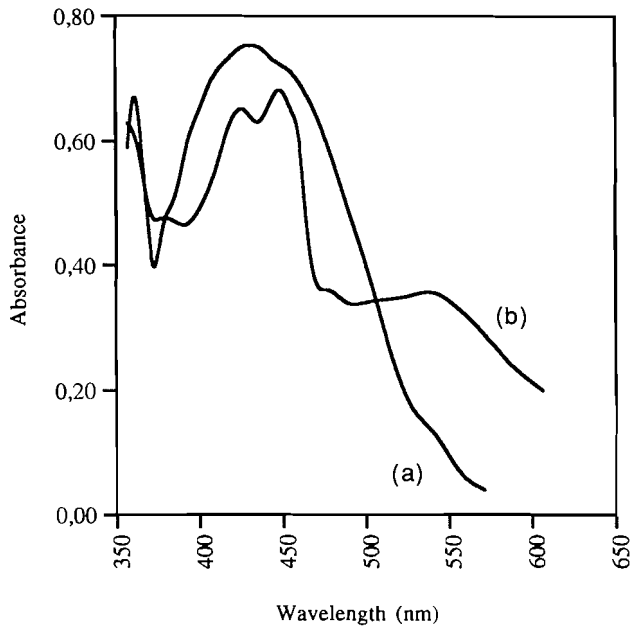
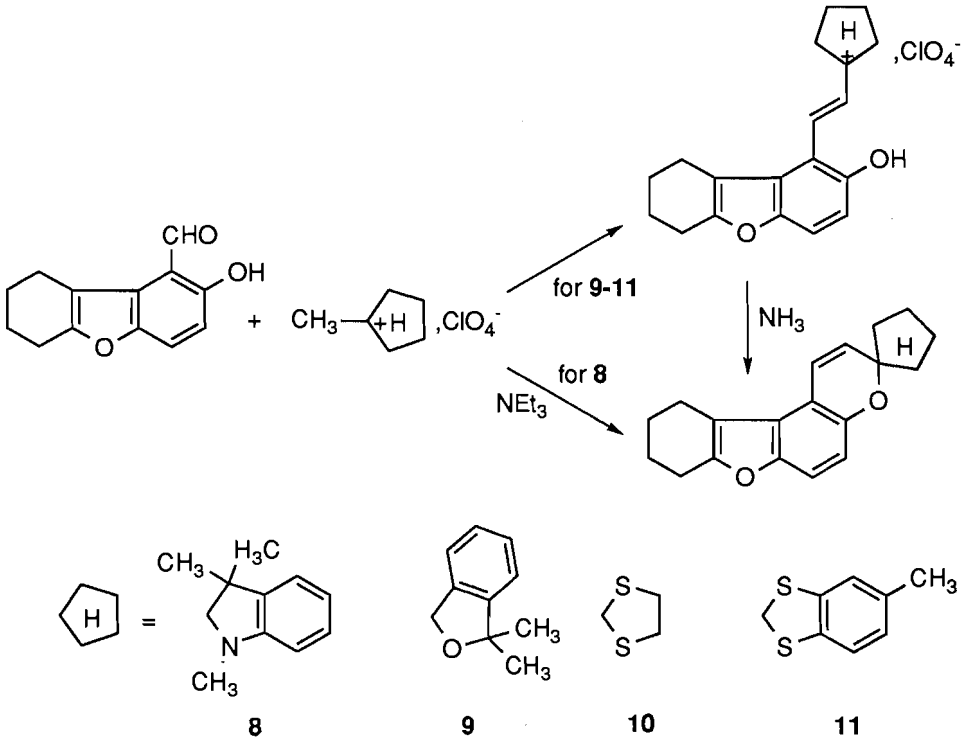
librium but the real phenomenon is more complex. For a complete understanding, it is necessary to take into account the electronic structures of open forms as well as their geometries. We are dealing here with different stereoisomers of *cisoid* configuration after the breaking of the C—O bond and of *transoid* configuration after isomerization. The *trans* isomer appears to be more stable because it minimizes the nonbonding interactions. The electronic distribution for photomerocyanines in chromenic series is believed to have mainly a quinoidal character (25). For furo-fused benzopyran, the photomerocyanines obtained by UV irradiation are characterized by a visible absorption spectrum consisting of two maxima. One is observed near 420 nm and the other near 520 nm. Based on the spectral data given in Table 2, such heteroannulation induces important changes in comparison with the corresponding 3,3-diphenyl-[3*H*]-naphtho[2,1-*b*]pyran **6***b*, which exhibits one absorption band centered at 432 nm (Fig. 3). The synthesized

Fig. 3. Electronic absorption spectra of the colored forms of chromenes **6***b* (*a*) and **3***b* (*b*) (isopentane/isopropanol 4:1, $c = 10^{-5}$mol L^{-1}, 77 K).

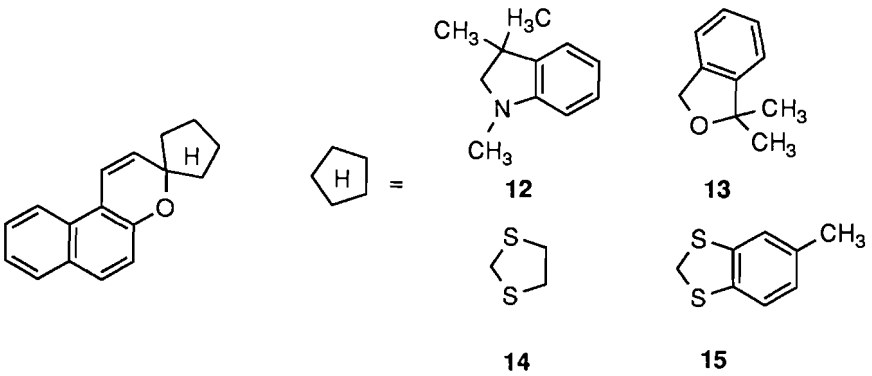


compounds cover a much larger range of wavelengths, as shown in Fig. 3. Because the effects observed for compounds that are benzoannulated or possess a cycloalkyl moiety are very similar, the broadening of the visible absorption spectra is believed to be strictly related to the furan ring annulated directly to the benzopyran part of the molecule, rather than being an extension of the chromophoric system. This assumption is substantiated by spectral data of the furo-fused naphthopyran derivative **7** (Scheme 7), for which the photochromic parameters are very close to those of parent compound **6***b*. For this latter compound, the furan ring induces a slight effect, so it acts as a substituent. Introduction of a second phenyl group on Csp^3 causes a deeper color and a bathochromic shift in the

Scheme 8.



Scheme 9.



visible spectra of their corresponding activated forms compared to the monoaryl substituted parents. This tends to cause an increase in the quantum yield for coloring in the ultraviolet light region, while providing a much slower thermal fade at ambient temperatures. Interestingly, Table 2 shows that visible absorption of **4***a* and **4***b* undergoes a bathochromic shift compared to that of **3***a* and **3***b*, respectively. The effect on thermal bleaching rates is also important: a significant destabilization of the opened form is observed which could be explained by their electronic structures having a pronounced 2,3-benzoquinoid character. Sometimes two kinetics are observed, attributed to different stereoisomers of the open form, the slower corresponding to the more thermally stable. The properties of this series of 2*H*-chromenes make furo-fused compounds useful in photochromic applications such as lenses.

To evaluate in a more general manner the influence of the annulation by a furan ring on the photoequilibrium parameters, we have prepared and studied some spiro(heterocyclo-furo-fused benzopyran)s (**8–11**) having a five-membered heterocycle as the left moiety. These compounds were obtained through condensation of the corresponding heterocyclic salts with 4-formyl-5-hydroxy-2,3-tetramethylenebenzofuran (26) (Scheme 8) under previously described conditions (27–30). The spiropyrans present two heterocyclic parts linked together by a common tetrahedral sp_3 carbon atom. After irradiation, both halves of the molecule give rise to a conjugated system responsible for a shift of the absorption towards the visible region. Although the structure of the "left" heterocycle has a major influence on the photochromic properties of spiropyrans, the phototransformation takes place on the chromene cycle and we could expect spectral changes for the furo-annulated derivatives similar to those observed in the case of the 2,2-diphenyl-[2*H*]-chromenes. The measured λ_{max} of the colored forms of spiropyrans **8–11**, compared to those of the benzoannelated compounds **12–15** (Scheme 9), are reported in Table 3. We observe that, effectively, whatever the structure

of the "left" heterocycle, the furo-annulation of the spiropyrans leads to the splitting into two bands of the electronic spectra with a significant bathochromic shift (Fig. 4).

Experimental

General experimental procedures

Melting points were determined in capillary tubes on a Buchi 510 apparatus and are uncorrected. ^1H and ^{13}C NMR spectra were recorded in deuterochloroform solution on a Bruker BM 250 or AMX 400 apparatus. UV–visible spectra were recorded on a Beckman DU 7500 on solutions in spectrophotometric grade ethanol (Carlo Erba, ACS quality). Photochromic measurements for chromenes compounds were performed on solutions in spectrophotometric grade toluene (UCB) at 25°C (± 0,2°C), monitored by a thermostat (Huber-ministat) using cylindrical cells having a 5 cm pathlength and a 10 mm section. The fading rate constants were measured at the λ_{max} of absorption of the colored form generated by flash photolysis (xenon tube, 50 μs, 150 J). The initial absorbances (A_0) were given for a standard concentration of 10^{-5} mol L^{-1}.The electronic spectra of colored forms of the chromenes were monitored on a Beckmann DU 7500 diode array spectrometer after irradiation by a Hg lamp (Arquantiel, 500 W). The electronic absorption spectra of spiropyrans at low temperatures were monitored on a Specord UV-visible spectrometer equipped with a thermostated cell. The irradiation source was a Hg DRS-250 lamp with a filter (λ = 313 nm).

The different solvents used were dried on molecular sieve (4Å). Flash chromatographic separations were performed on Merck 60H silica gel (5–40 m). Elemental analyses were performed by Microanalytical Services, University of Aix-Marseille III.

The starting 2-hydroxydibenzofuran was purchased from Aldrich. 5-Hydroxy-2,3-tetramethylenebenzofuran and 5-hydroxy-2,3-pentamethylenebenzofuran were prepared as described earlier (33). 2-Chloro-7-hydroxynaphtho[2,1-*b*]furan was obtained by demethylation, using boron tribromide, of the corresponding methoxy derivative, which was prepared according to the literature procedure (34).

*General procedure for furo-fused 2,2-disubstituted-2*H*-1-benzopyrans*

Method A: Propargylic alcohol (30 mmol) and phenol in slight excess (33–36 mmol) were dissolved in dry toluene (60 mL). Under an atmosphere of nitrogen, a catalytic amount of *p*-toluenesulfonic acid was added to the toluene solution, which was boiled under reflux for 3 h. The reaction solution was cooled and then washed sequentially with dilute (10%) sodium hydroxide and water. The organic layer was separated. The aqueous layer was extracted continuously with methylene chloride. The organic layers were combined, dried over anhydrous magnesium sulfate, and then filtered. The solvent was removed under reduced pressure. The crude product was purified by flash chromatography on silica gel using a 95:5 mixture of pentane and diethyl ether as eluent. The photochromic fractions were collected and the solvent was removed under reduced pressure. The crystalline residue was recrystallized twice from an appropriate solvent (the first time with decolorization by charcoal).

Method B: Under an atmosphere of nitrogen, titanium tetraethoxide (2.4 g, 10.4 mmol) in dry toluene (10 mL) was added over 10 min to the heterocyclic phenol (10.4 mmol) in dry toluene (40 mL). When the addition was complete the reaction mixture was boiled (15 min) and then slowly distilled to remove ethanol. Solvent (20 mL) was collected. The reaction

mixture was allowed to cool to room temperature and β-phenylcinnamaldehyde (2.17 g, 10.4 mmol) in dry toluene (50 mL) was added dropwise. When the addition was complete, the reaction mixture was boiled under reflux (2–5 h), allowed to cool, and poured into 2 M aqueous ammonium chloride solution (100 mL). The organic layer was separated, dried over anhydrous magnesium sulfate, and then filtered. The solvent was removed under reduced pressure. Further purification was done by flash chromatography on silica gel using pentane – diethyl ether (95:5) as eluent. The photochromic fraction was evaporated in vacuo to yield crystalline residue, which was recrystallized from an appropriate solvent.

*3-Methyl-3-phenyl-[3*H*]-benzofuro[3,2-*f*]chromene* **3**a: mp 155°C (from heptane); UV (EtOH) λ_{max} (ε/dm^3 mol^{-1} cm^{-1}): 204(30 540), 231(24 350), 251(15 880), 278(8350), 300(19 880), 312(21 320), 344(6790), and 361(4540) nm; ^{1}H NMR (400 MHz) δ: 1.80 (3H, s, CH_3), 6.19 (1H, d, J = 9.85 Hz, H-2), 7.03 (1H, d, J = 8.7 Hz, H-5), 7.24 (1H, m, H-10), 7.27 (2H, m, H-4′), 7.28 (1H, m, H-6), 7.31 (4H, m, H-3′), 7.36 (1H, d, J = 9.85 Hz, H-1), 7.40 (1H, td, $J_{8,9}$= 7.45 Hz, $J_{9,11}$= 0.9 Hz, H-9), 7.49 (4H, m, H-2′), 7.53 (1H, d, J = 7.5 Hz, H-8), and 7.93 (1H, dd, $J_{10,11}$= 7.45 Hz, $J_{9,11}$= 0.9 Hz, H-11); ^{13}C NMR (100 MHz) δ: 29.9 (CH_3), 79.8 (C-3), 110.9 (C-10), 111.2 (C-8), 116.1 (C-5), 115.8 (C-1a), 119.5 (C-1), 120.3 (C-11b), 121.7 (C-11), 122.1 (C-6), 124.5 (C-11a), 125.3 (C-9), 126.7 (C-2′), 127.4 (C-4′), 127.9 (C-2) 128.0 (C-3′), 147.9 (C-1′), 151.7 (C-4a), and 157.3 (C-7a). *4-Chloro-9,9-diphenyl-[9*H*]furo[2′,1′:5,6]naphtho[2,1-*b*]-pyran* **7**

This compound was prepared according to method A in 84% yield: mp 259°C (from toluene); UV (EtOH) λ_{max} (ε/dm^{-3} mol^{-1} cm^{-1}): 222(28 770), 287(9660), 310(6930), 323(7510), 355(7260), and 371(7740) nm; ^{1}H NMR (250 MHz) δ: 6.33 (1H, d, J = 10 Hz, H-10), 6.95 (1H, d, J = 0.7 Hz, H-5), 7.26 (2H, m, H-4′), 7.28–7.32 (5H,m, H-7, 3′), 7.35 (1H, d, J = 10 Hz, H-11), 7.49 (4H, m, H-2′), 7.56 (1H, dd, $J_{1,2}$= 8.8 Hz, $J_{2,5}$ = 0.7 Hz, H-2), and 7.83 (2H, m, H-1, 6); ^{13}C NMR (62.5 MHz) δ: 83.1 (C-9), 102.9 (C-5), 112.0 (C-1), 118.4 (C-7), 118.6 (C-11), 119.8 (C-2), 124.8 (C-6), 127.0 (C-2′), 127.6 (C-4′), 128.1 (C-3′), and 128.7 (C-10). Anal. calcd. for $C_{27}H_{17}O_2Cl$: C 79.31, H 4.19, Cl 8.67; found: C 79.35, H 4.18, Cl 8.55.

1′,3′,3′-Trimethyl-1,2-tetramethylenespiro[7H-furo[3,2-f]-2H-1-benzopyran-7,2′-indoline] ***8***

This compound was synthesized according to standard procedure (27), using stoichiometric amount of 1,3,3-trimethyl-2-methyleneindoleninium perchlorate (Fischer's base) and 4-formyl-5-hydroxy-2,3-tetramethylenebenzofuran, in 52% yield: mp 176–178°C (from ethanol); ^{1}H NMR (250 MHz) δ: 1.18, (3H, s, CH_3), 1.32 (3H, s, CH_3), 1.89 (4H, m, H-2″, 3″), 2.72 (2H, m, H-1″), 2.74 (3H, s, NCH_3), 2.84 (2H, m, H-4″), 5.67 (1H, d, J = 10.35 Hz, H-8), 6.52 (1H, d, J = 7.7 Hz, H-7′), 6.56 (1H, d, J = 8.75 Hz, H-5), 6.83 (1H, td, $J_{4',5'}$ = 6.7 Hz, $J_{5',7'}$ = 0.7 Hz, H-5′), 7.07 (1H, dd, $J_{4',5'}$ = 6.6 Hz, $J_{4',6'}$ = 0.8 Hz, H-4′), 7.09 (1H, d, J = 8.8 Hz, H-4), 7.17 (1H, td, $J_{6',7'}$ = 7.6 Hz, $J_{4',6'}$ = 1Hz, H-6′) and 7.27 (1H, d, J = 10.3 Hz, H-9); ^{13}C NMR (62.5 MHz) δ: 20.5-26.1 (*gem*-CH_3), 22.7–22.9 (C-2″, 3″), 23.2 (C-1″), 23.9 (C-4″), 29.2 (NCH_3), 51.8 (C-3′), 103.8 (C-7), 106.9 (C-7′), 110.8 (C-1), 110.9 (C-4), 111.4 (C-5), 112.8 (C-9a), 118.6 (C-5′), 119.2 (C-9), 121.7 (C-6′), 124.8 (C-1a), 126.3 (C-9), 127.3 (C-4′), 137.1 (C-3′a), 148.4 (C-1′a), 149.0 (C-3a), 150.3 (C-5a) and 155.5 (C-2). Anal. calcd. for $C_{25}H_{25}NO_2$: C 80.83, H 6.78, N 3.77; found: C 80.72, H 6.85, N 3.68.

3′,3′-Dimethyl-1,2-tetramethylenespiro[7H-furo[3,2-f]-2H-1-benzopyran-7,1′-[2]oxaindane] ***9***

1,3,3-Trimethyl-3*H*-isobenzofurylium perchlorate (2.61g; 10 mmol) (28) and 4-formyl-5-hydroxy-2,3-tetramethylenebenzofuran (2.38g; 11 mmol) were boiled under reflux for 5 min in 30 mL of acetic acid with 0.03 g of 70% perchloric acid. On cooling, the crude solution gave a precipitate, which was washed with diethyl ether and then dried. The solid was suspended in 30 mL of benzene, and totally dissolved by bubbling in dry ammonia. The solvent was removed under reduced pressure. The residue was chromatographed on alumina using benzene as eluent. The photochromic fraction (R_f =0.9) was recrystallized in heptane, affording the title compound in 75% yield: mp 213–214°C ; ^{1}H NMR (400 MHz) δ: 1.55 (3H, s, CH_3), 1.69 (3H, s, CH_3), 1.9 (4H, m, H-2″,3″), 2.74 (2H, m, H-1″), 2.84 (2H, m, H-4″), 5.88 (1H, d, J = 9.70 Hz, H-8), 6.75 (1H, d, J = 8.75 Hz, H-5), 7.21 (1H, d, J = 8.75 Hz, H-4), 7.29 (1H, d, J = 9.65 Hz, H-9), and 7.38–7.46 (4H, m, H-4′, 5′, 6′, 7′); ^{13}C NMR (100 MHz) δ: 22.5–22.6 (C-2″, 3″), 22.9 (C-1″), 23.7 (C-4″), 28.8–30.5 (*gem*-CH_3), 86.0 (C-7), 105.8 (C-Ar), 111.1 (C-4), 112.1 (C-5), 112.9 (C-Ar), 120.4 (C-4′), 121.1 (C-8), 123.3 (C-7′), 123.78 (C-9), 125.0 (C-Ar), 128.1–129.7 (C-5′, 6′), 140.0, 147.1, 148.0, 149.6, and 155.3 (C-Ar). Anal. calcd. for $C_{24}H_{12}O_3$: C 82.75, H 3.47; found: C 82.69, H 3.51.

1′,2′-Tetramethylenespiro[1,3-dithiolan-2,7′-7H-furo[3,2-f]-2H-1-benzopyran] ***10***

Methyl-1,3-dithiolylanium perchlorate (0.98g; 4,5 mmol) (29) and 4-formyl-5-hydroxy-2,3-tetramethylenebenzofuran (1.08g; 5 mmol) were boiled under reflux for 5 min in 30 mL of acetic acid with a catalytic amount of 70% perchloric acid. On cooling, the crude solution gave a precipitate, which was washed with diethyl ether and then dried. The solid was suspended in 15 mL of benzene, and totally dissolved by bubbling in dry ammonia. The solvent was removed under reduced pressure. The residue was chromatographed on alumina using benzene as eluent. The photochromic fraction (R_f =0.8) was recrystallized in isopropanol (67% yield): mp 193–194°C; ^{1}H NMR (250 MHz) δ: 1.87 (4H, m, H-2″, 3″), 2.71–2.77 (4H, m, H-1″, 4″), 3.46–3.65 (4H, m, H-4, 5), 6.09 (1H, d, J = 9.65 Hz, H-8′), 6.74 (1H, d, J = 8.7 Hz, H-5′), 6.94 (1H, d, J = 9.65 Hz, H-9′), and 7.18 (1H, d, J = 8.7 Hz, H-4′); ^{13}C NMR (62.5 MHz) δ: 22.4–22.5 (C-2″,3″), 22.8 (C-1″), 23.7 (C-4″), 40.0–40.1 (C-4, 5), 106.1 (C-Ar), 111.1-112.3 (C-4′,5′), 112.7, 112.8 (C-Ar), 123.2 (C-8′,9′), 124.9, 147.2, 150.1, and 155.9 (C-Ar). Anal. calcd. for $C_{17}H_{16}O_2S_2$: C 64.55, H 5.1, S 20.25; found: C 64.43, H 5.17, S 20.36.

5-Methyl-1′,2′-tetramethylenespiro[benzo-1,3-dithiol-2,7′-7H-furo[3,2-f]2H-1-benzopyran] ***11***

2,5-Dimethyl-1,3-benzodithiolylium perchlorate (35) and (1.62g; 6 mmol) 4-formyl-5-hydroxy-2,3-tetramethylenebenzofuran (1.41g; 6,5 mmol) were boiled under reflux for 35 min in 20 mL of acetic acid with a catalytic amount of 70% perchloric acid. On cooling, the crude solution gave a brownish precipitate, which was washed with diethyl ether and then dried in vacuum. The solid was suspended in 20 mL of benzene, and totally dissolved by bubbling in dry ammonia. The solvent was removed under reduced pressure. The residue was chromatographed on alumina using benzene as eluent. Further recrystallization from ethanol afforded the spiropyran in 66% yield: mp 191–192°C (from ethanol); ^{1}H NMR (250 MHz) δ: 1.87 (4H, m, H-2″,3″), 2.31 (3H, s, CH_3), 2.71 (1H, m, H-1″), 2.8 (2H, m, H-4″), 6.37 (1H, d, J = 9.65 Hz, H-8′), 6.69 (1H, d, J = 8.7 Hz, H-5′), 6.94 (1H, d, J = 7.95 Hz, H-6), 7.07 (1H, d, J = 9.65 Hz, H-9′), 7.09 (1H, s, H-4), 7.15 (1H, d, J = 8 Hz, H-7), and 7.19 (1H, d, J = 8.7 Hz, H-4′); ^{13}C NMR (62.5 MHz) δ: 20.5 (CH_3), 22.7–22.8 (C-2″, 3″), 23.2 (C-1″), 24.1 (C-4,5), 106.4 (C-Ar), 111.9–112.2 (C-4′,5′), 112.9, 113.1 (C-Ar), 121.6 (C6), 122.3 (C-8′,9′), 125.4 (C-7), 127.1 (C-4), 136.4, 137.7, 139.5, 147.8, 150.6, and 156.3 (C-Ar). Anal. calcd. for $C_{22}H_{18}O_2S_2$: C 69.80, H 4.80, S 16.95; found: C 69.80, H 4.75, S 16.9.

Shape-similarity analysis of 20 stable conformations of neutral β-alanine

Gerard A. Heal, P. Duane Walker, Michael Ramek, and Paul G. Mezey

Abstract: The family of 20 stable conformations of neutral β-alanine are analyzed in terms of their shape similarities using the topological Shape Group Method, a general molecular shape analysis technique as applied to the three-dimensional electronic density. Molecular electron densities are calculated using the 6-31G** basis set, followed by the determination of the shape groups of local curvature patterns for the entire chemically relevant range of electron density contour surfaces. The results of the shape group analysis are represented by two-dimensional shape maps. Discretized grids of these maps generate numerical shape codes, and comparisons of these numerical codes serve as measures of shape similarity of the various conformers of β-alanine. This technique is based on direct comparisons of the intrinsic shape features of molecules and requires no superposition of molecules for comparisons. Mathematically well-defined and unbiased similarity measures are obtained by this non-visual, computer-based method, useful for the detection, quantification, and analysis of electronic charge distribution similarities. The family of 20 stable conformers of β-alanine serves as a test case for the application of the methodology for a large number of conformers, representing a level of complexity analogous to that of typical conformational problems in computer-aided drug design and the screening of potential drug molecules for shape similarity.

Key words: similarity measures, shape groups, β-alanine, conformation analysis, molecular shape, electron density.

Résumé : On a analysé la famille de 20 conformations stables de la β-alanine neutre en fonction des similitudes de leur forme, en utilisant la Méthode de groupe de forme topologique. On a appliqué la technique d'analyse de la forme moléculaire générale à la densité électronique en trois dimensions. On a calculé les densités moléculaires électroniques en utilisant l'ensemble de base 6-31G**, suivi d'une détermination des groupes de forme du modèle de courbure locale pour tout le domaine chimiquement caractéristique des surfaces de contour de la densité électronique. On représente les résultats de l'analyse des groupes de forme par des diagrammes de forme en deux dimensions. Des grilles discontinues de ces diagrammes génèrent des codes de forme numérique et les comparaisons de ces codes numériques servent de mesure de la similitude de forme des divers conformères de la β-alanine. Cette technique est basée sur la comparaison directe des caractéristiques de formes intrinsèques des molécules et ne requiert pas, pour les comparaisons, la superposition des molécules. On a obtenu des mesures de similitude bien définies mathématiquement et sans influence par cette méthode non visuelle basée sur ordinateur, utile pour la détection, la quantification et l'analyse des similitudes de distribution de la charge électronique. La famille des 20 conformères stables de la β-alanine sert de cas type pour l'application de la méthodologie à un plus grand nombre de conformères, représentant un niveau de complexité analogue à celle des problèmes conformationnels typiques que l'on retrouve dans le dessin des médicaments assisté par ordinateur et dans la protection des molécules ayant un usage pharmaceutique potentiel en raison de la similitude de forme.

Mots clés : mesures de similitude, groupes de forme, β-alanine, analyse conformationnelle, forme moléculaire, densité électronique.

1. Introduction

Each molecule contains only a set of nuclei and an electron density distribution. The nuclear arrangement is fully reflected in the electron density, consequently, all information about a particular molecular conformation must be contained in the electron density; there is simply no other medium to encode information. Hence, in principle, a detailed enough shape analysis of electronic density clouds should be able to reveal all information about the given conformation of the molecule. The actual relations between electron density shape properties and other physical and chemical properties may be rather complex and not well understood; however, even without a detailed understanding of these relations, correlations between shape and other properties have predictive value, if based on rigorous shape analysis. This fundamental principle of the existence of shape–property relations is the basis of the Shape Group Method introduced earlier for molecular shape analysis (1–4). The Shape Group Method extracts the essential shape information for the whole chemically relevant range of electron density, and can be "tuned" to analyze shape in any detail and at any desired spatial resolution. The technique is rigorous as it has no inherent limitation; the only practical limitations

are the quality of the electron density used as input, and the spatial and density resolution set by the user (1–4).

Ramek (5) has shown via extensive ab initio SCF-type calculations, using both GAUSSIAN (6) and GAMESS (7–9) quantum mechanical program packages at the RHF/4-31G level, that as many as 38 stable conformers of the neutral species of β-alanine may exist, which include 20 conformational isomers with unique intrinsic geometry, disregarding optical isomers. These conformers involve a number of intramolecular interactions of different chemical nature that have been characterized in detail (5, 10).

In this work, a systematic shape analysis using the Shape Group Method (1–4) has been carried out for the electronic densities of all 20 geometric conformations of β-alanine, excluding mirror images. The geometries were taken from ref. 5, while the energies and electronic density distributions were recalculated using GAUSSIAN 92 (6) employing the 6-31G** basis set, in order to provide a more accurate electron distribution for the various conformations, while still allowing for direct comparison between this and earlier works (5). The Shape Group technique (1–4), as implemented in the computer program GSHAPE 90 (11, 12), has been applied to the computed electron densities of the 20 β-alanine conformers.

Besides being an important test case of the methodology, a rigorous shape classification of the possible conformations of β-alanine is desirable in its own right, since this amino acid is of considerable biological interest. The molecule of β-alanine is found in animal brain and liver tissue, as well as in plants, fruits, and insect cuticle (13–17). Like γ-amino butyric acid (GABA), β-alanine acts as an inhibitor in the nervous system (18–21) binding to the opiod receptors found in the brain. Furthermore, β-alanine can be enzymatically converted (22) into L-α-alanine, an amino acid that can be found in a large number of biologically important peptides.

The next section of this paper contains a brief review of the theory and methodology employed, Sect. 3 contains the results and discussion, and a short summary is given in Sect. 4.

2. A brief review of the Shape Group Method

The Shape Group Method (1–4) is a technique of shape characterization based on local curvature features (geometrical properties) analyzed in terms of the patterns that various curvature domains of the electron density generate (topological properties). The Shape Group algorithm provides a detailed and mathematically rigorous characterization of three-dimensional functions in terms of a family of topological invariants. In the actual case, each three-dimensional contour surface of the electron density is partitioned into domains based on local curvature thresholds. Removal of all domains of a specific curvature classification from the original surface produces a new object that typically shows a new set of topological features. These topological features are described by the shape groups (1–4) of the object, which are the homology groups (23, 24) of the truncated surface. This technique has been used for the shape analysis of many molecular properties described by contour surfaces, including electron density functions or nuclear and electrostatic potential functions (4).

Using the Shape Group Method, shape characterization of electron density is reduced to a two-dimensional (a, b) parameter map where a represents the value of the electron density for the various contour surfaces and b is a threshold for the local curvature of the isodensity surface. The determination of these (a, b) parameter maps is automated through the GSHAPE 90 package of computer programs (11, 12).

Given a fixed nuclear configuration K, and a density threshold value a, a molecular isodensity contour (MIDCO) surface $G(K,a)$ is made up of the collection of all points of the three-dimensional space where the electronic density $\rho(K,\mathbf{r})$ is equal to the constant value a,

$$[1] \quad G(K, a) = \{\mathbf{r}: \rho(K, \mathbf{r}) = a\}$$

By varying the parameter a through a range of relevant electron density values, a set of MIDCO surfaces is generated, each of which can then be classified based on its local shape characteristics.

Specifically, each point on the surface $G(K,a)$ is classified into one of three curvature domains $D_\mu(a,b)$, $\mu = 0,1,2$, depending on how curved the surface is at the particular point with respect to some reference curvature b. Curvature at each point of surface $G(K,a)$ is determined by comparing the eigenvalues of the local Hessian matrix of the surface to the curvature b of a reference tangent sphere with a radius $1/b$, where b is a variable parameter.

A point on the surface $G(K,a)$ is then assigned to a domain $D_2(a,b)$ if both of the eigenvalues of the local Hessian matrix are less than b, to a domain $D_1(a,b)$ if precisely one of the eigenvalues is less than b, and to a domain $D_0(a,b)$ if none of the eigenvalues is less than b. A domain $D_2(a,b)$ is said to be convex relative to reference curvature b. Similarly, a domain $D_1(a,b)$ is of the saddle type relative to reference curvature b, whereas a domain $D_0(a,b)$ is concave relative to reference curvature b.

Truncation of all domains of a given type μ, $\mu = 0, 1, 2$, generates a truncated surface that can be studied by simple topological means, for example, truncation of all domains of the type $D_\mu(a, b)$ generates the truncated surface $G_\mu(a, b)$, where the reference to the nuclear configuration K is omitted from the notation:

$$[2] \quad G_\mu(a, b) = G(a) \setminus \cup D_\mu(a, b)$$

The resulting surface $G_\mu(a, b)$ may consist of a single connected surface with several holes or may form a set of several disjointed surfaces. The surfaces $G_\mu(a, b)$ are in general topologically more distinctive than the original surface $G(a, b)$ and form the basis for evaluating similarities between MIDCO surfaces and, hence, between electron densities. Each surface $G_\mu(a, b)$ is characterized by the corresponding homology groups $H^j\mu(a, b)$ of algebraic topology (22), specifically, by using the one-dimensional Betti number, which is related to the number of holes (n_h) on each surface $G_\mu(a, b)$. The one-dimensional Betti number is the rank of the one-dimensional shape group for each piece of the truncated surface. These Betti numbers are used as numerical shape descriptors for the electron density. The Betti numbers, one for each piece of the surface $G_\mu(a, b)$, are collected into a vector, which is then taken as the shape descriptor for a specified (a, b) pair of parameters.

Although the curvature domain pattern changes as a func-

tion of both parameters a and b, there are invariance domains within a formal (a, b) parameter plane where there is no change in the shape group classification. In fact, for the entire density range and for the entire possible curvature range of each molecule, there are only a finite number of different shape groups. Consequently, it is possible to characterize in detail the shape of the entire electron density, described by a continuum of MIDCO surfaces, using a finite number of Betti numbers as shape descriptors. The parameter plane of electron density thresholds and reference curvature values can be represented by a discretized grid, leading to a finite classification scheme by a numerical shape code (4).

To simplify the task of shape comparison, the vectors representing the sets of Betti numbers are encoded into a single shape integer L. For a given conformation K of a molecule and for a pair of parameters a and b, the unique shape integer $L(K, a, b)$ is defined by the following formula:

$$[3] \quad L(K, a, b) = \prod_{i=0}^{M} (P_i)^{k(i)}$$

where $P_0 = 0$, and for $i > 0$, P_i is the ith prime number in the sequence 1, 2, 3, 5, 7, 11, ... where 1 is taken as an "honorary prime"; each Betti number of value $(i - 2)$ is assigned to the prime number P_i; the exponent $k(i)$ is the number of disconnected surface pieces having their one-dimensional Betti number equal to $(i - 2)$; and where the value of upper limit M is two greater than the largest first Betti number for any of the disconnected pieces of the MIDCO $G(a)$.

If the level of resolution is insufficient to ascertain the presence of one or more of the D_μ curvature domains unambiguously, then a negative sign is assigned to the integer $L(K, a, b)$. Using the Prime Factorization Theorem one can decode this shape integer $L(K, a, b)$, yielding the set of individual Betti numbers for the given pair of parameters a and b.

The (a, b) parameter maps themselves have been standardized using a grid containing 41 threshold values of density and 21 threshold values for curvature (4, 11, 12). The usual density range covered varies from $a_{min} = 0.001$ au to $a_{max} = 0.1$ au. The curvature parameter b covers two ranges, from -1 to -10^{-5} and from 1 to 10^{-5}. The negative region is associated with a reference tangent sphere curving inward against the isodensity surface, while the positive values of b are interpreted as the tangent reference sphere curving away from the isodensity surface.

To accommodate the large variance in scale of both parameters a and b, logarithmic transformations are used for the actual display of the (a, b) parameter maps. Since parameter b can take both positive and negative values, the logarithm of the absolute value of b is used. The value of $\log |b| = -5$, that is, $b = 10^{-5}$ or $b = -10^{-5}$, is taken to represent $b = 0$, so the two ranges of b are regarded as connecting along a single line on the map.

A detailed similarity analysis between molecular electron densities can be carried out by a simple comparison of the (a, b) parameter maps of any two molecular conformations, K and K' (4, 25, 26). By overlaying the two (a, b) parameter maps and assigning a value of 1 to each position (a, b) in the map where the two shape integers $L(K, a, b)$ and $L(K', a, b)$ match, and a value of 0 where the two shape integers are different, a binary map is generated that provides an overview of similarity between the two molecular electron densities. A total similarity measure is then given as

$$[4] \quad S(i, j) = \sum_{k=1}^{N_a} \sum_{k'=1}^{N_b} \Delta(i, j, a_k, b_{k'}) / (N_a N_b)$$

where N_a and N_b are the number of thresholds for the a and b values, respectively, and

$$[5] \quad \Delta(i, j, a, b) = 1 \quad \text{if } \mathbf{L}(i, a, b) = \mathbf{L}(j, a, b)$$
$$= 0 \quad \text{if } \mathbf{L}(i, a, b) \neq \mathbf{L}(j, a, b)$$

Using this procedure, the shape features of the two electron densities can be compared by an algorithmic technique based on detailed shape analysis, providing a method that complements the quantum similarity approaches of Carbó et al. (27–35) and alternative techniques proposed earlier (36–50).

The sensitivity of results obtained by a Shape Group analysis to the quality of electron density and the range of density considered has been studied earlier (12). The quality of basis set used in the computation of ab initio electron densities affects the results of shape analysis; however, for basis sets at and beyond the 4-31G level there is little change in the shape of the electronic density within the chemically relevant molecular density range of density domains (4). Hence, the approach of optimizing geometry at the 4-31G basis level and recalculating energies (as well as densities) at the 6-31G** level is regarded as a practical, as well as sufficiently accurate, approximation for most applications. Shape group analysis of electron densities at the 6-31G** level has been shown to provide excellent shape – toxicological activity correlations for a family of polycyclic aromatic hydrocarbons (51).[2]

Test calculations for a set of small molecules (12) have shown that most of the essential shape features relevant to molecular similarity analysis can be identified by taking the range 0.001–0.1 au (au = atomic unit) for electron density, and some computational savings can be achieved by reducing the wider range of density used in earlier studies. In most of the more recent Shape Group studies (25, 26), the standardized range of 0.001–0.1 au has been used universally for all molecules.

3. Shape characterization and similarity analysis of the stable conformations of β-alanine

Using the geometries of the 20 conformations of β-alanine, which represent local minima on the 4-31G potential energy surface (5), electron density distributions for these conformations have been calculated using the 6-31G** basis set as incorporated in the GAUSSIAN 92 program (6). Table 1 lists the absolute and relative 6-31G** energies of all 20 conformational isomers. For consistency with earlier studies of these conformers, the numbering scheme follows that of ref. 5. Not surprisingly, the change of basis set from 4-31G to 6-31G**

causes some conformers to change position in the energy-ordered list. Conformer **V**, which contains the N...H—O hydrogen bond, is slightly more stabilized in the 6-31G** description and becomes the third most stable species. Interestingly, the energy difference between the two conformers lowest in energy, both of which contain a weak N—H...O=C interaction, is significantly larger with the 6-31G** basis set than in the 4-31G case. This matches well with the observation that polarization functions sometimes provide higher estimates for nonbonded intramolecular interactions (52).

Figure 1 shows the nuclear positions of all 20 of these conformers along with the molecular isodensity contour (MIDCO) corresponding to a constant electron density value of $a = 0.1$ au. Figures 2 and 3 are the selected examples of the (a, b) parameter maps for conformations **I** and **II**, respectively. Note that the single integer entries within these (a, b) parameter maps follow the order of detection of each shape group type within each conformer, hence the actual comparison between (a, b) parameter maps involves decoding the single integer entries using the respective legend tables shown in the figures. Figure 4 shows the resulting similarity map of the overall similarity between these two conformers, which differ primarily in the orientation of the amino group. The similarity index resulting from this map is 0.824 out of a possible perfect match of 1.00. Whereas the high-density range of the MIDCOs shown in Fig. 1 does not provide many visual clues to shape differences in terms of local curvatures, the more diffuse, lower density contours G(**Y**,0.01) and G(**Y**,0.001), **Y** = **I**,**II**, shown in Fig. 5, reveal many subtle differences in the local curvatures of conformers **I** and **II** of β-alanine.

Table 2 provides the similarity index of all pairwise similarity tests for the 20 conformations of β-alanine. The two most

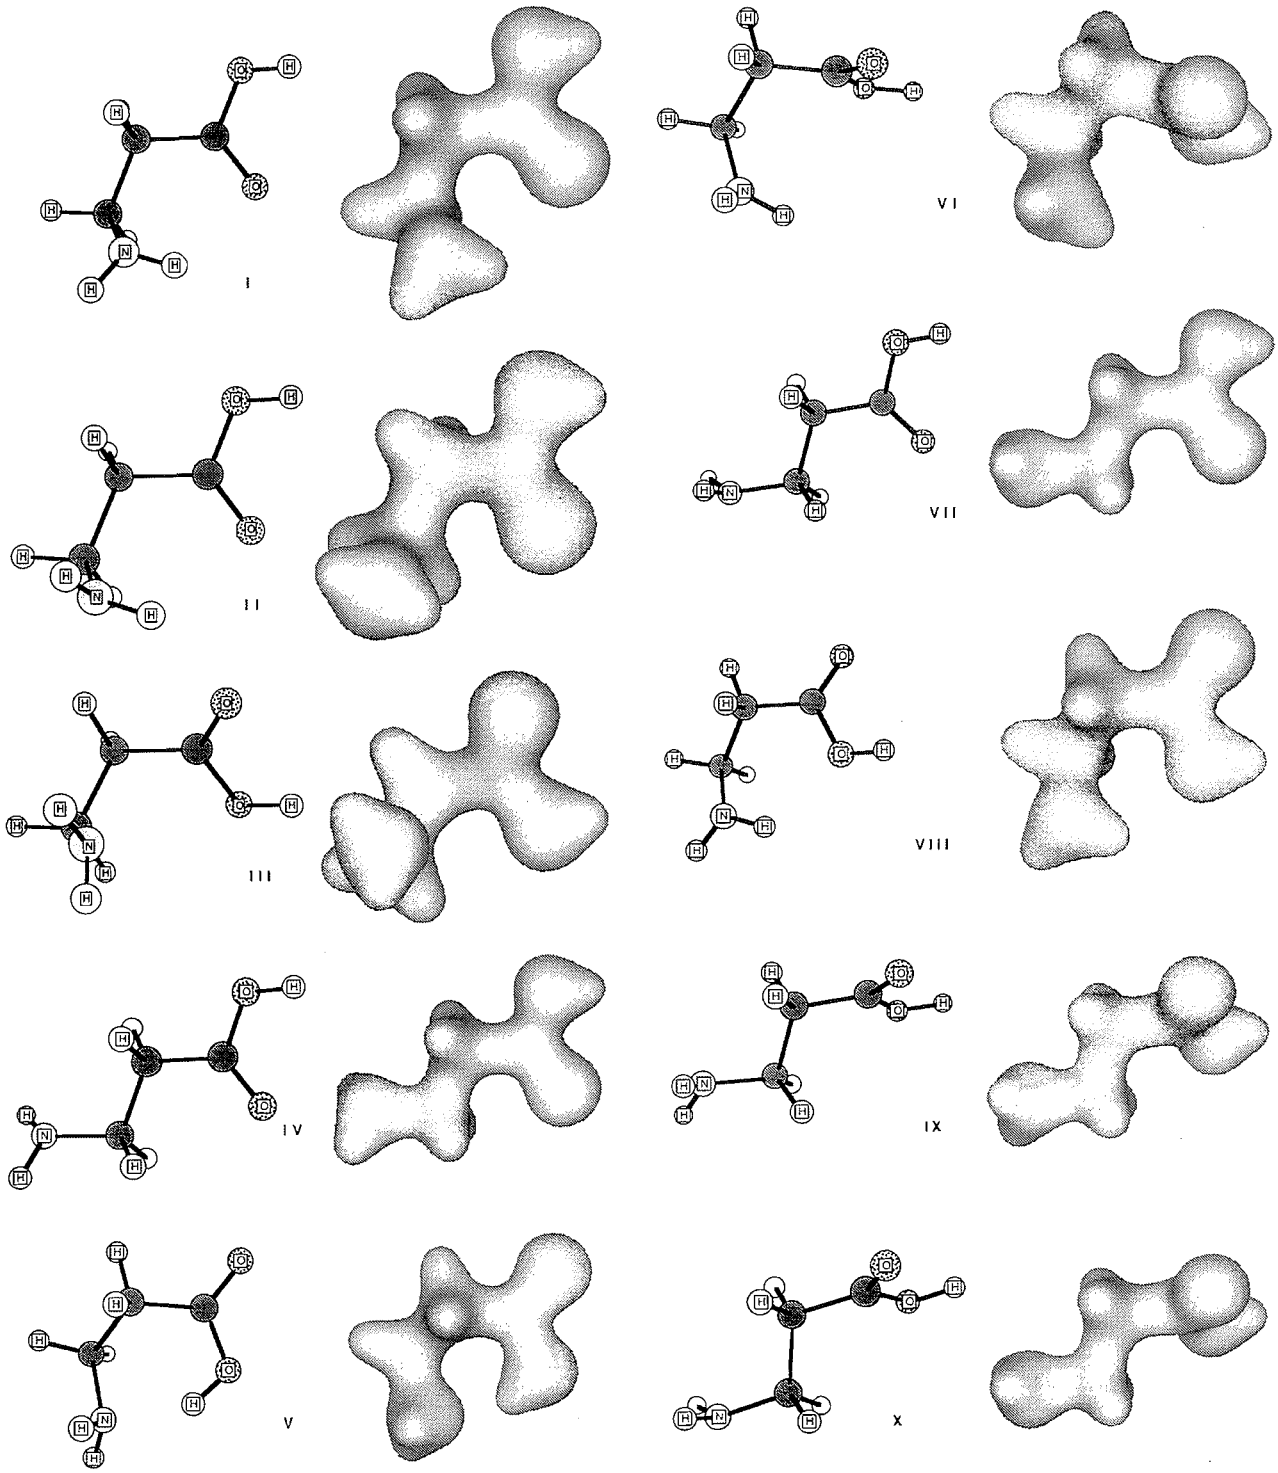
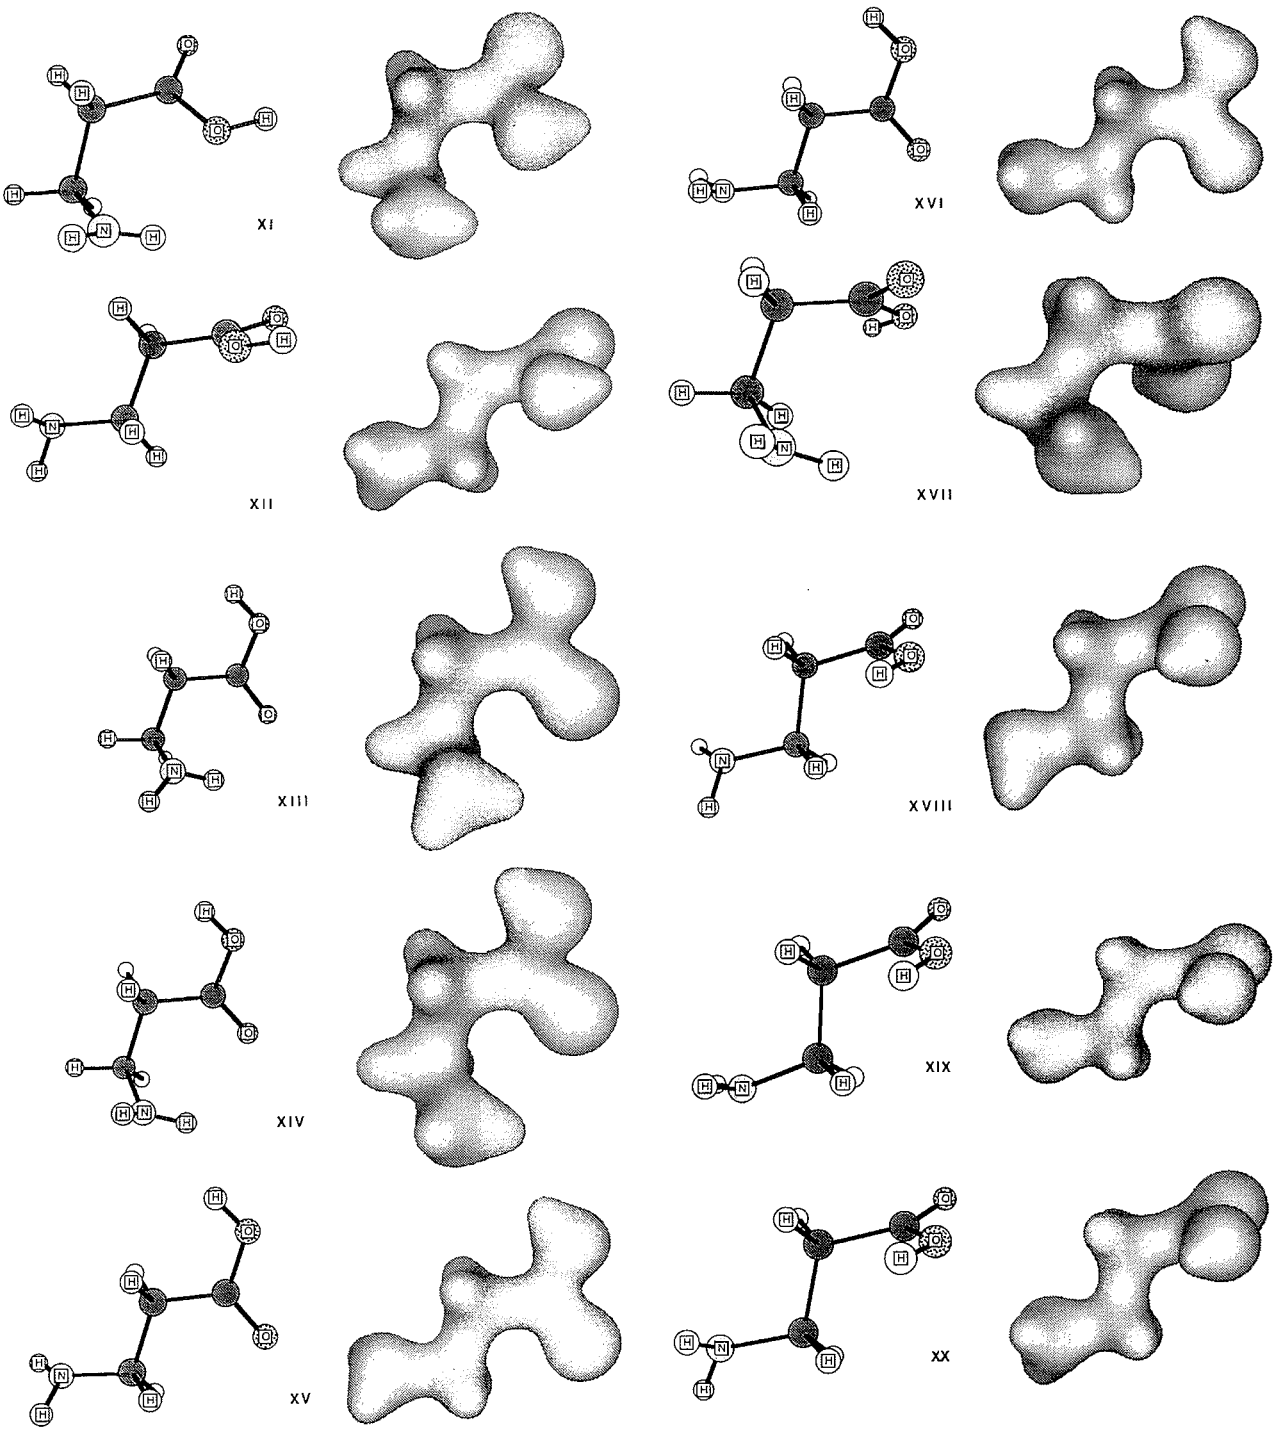
Fig. 1. The 20 stable conformers of β-alanine: nuclear positions and the 0.1 au MIDCO surfaces.



similar conformers based on this similarity criterion are conformers **IV** and **XV** having an overall similarity index of 0.872.

These indices immediately characterize **V** as an exceptional conformer: the similarity indices with all other conformers are below 0.7, whereas all other conformer pairs consistently have indices larger than this value. This characterization is very reasonable, because **V** is the only conformer stabilized by the N...H—O hydrogen bond, which has a major influence on reaction paths, potential barriers, bond lengths, and force constants, as pointed out in ref. 5. In a similar way, **III** and **VI** are also characterized as unusual conformers that show only low sim-

Fig. 1 (*concluded*).



ilarity with any of the other conformers: for **III**, the highest similarity index is 0.815 for the pair **II/III**, all other values are below 0.8; for **VI**, all indices are below 0.8. This classification does make chemical sense: **III** and **V** are the only conformers that cannot be transformed into a good approximation of any other form by a single internal rotation; for example, the conversion of **III** to **II**, which was mentioned above, requires a reorientation of the amino as well as the carboxy group. By contrast, **VI** participates in several conformational equilibria involving internal rotation of a single functional group; some of these equilibria are discussed below. The low similarity indices for **VI** are a manifestation of a peculiarity of a different kind, namely, a considerable degree of local steric interference in the nuclear arrangement, resulting in a peculiar shape of the electron density. This local steric congestion is manifested by the orientation of both the carboxy and the amino groups, and also

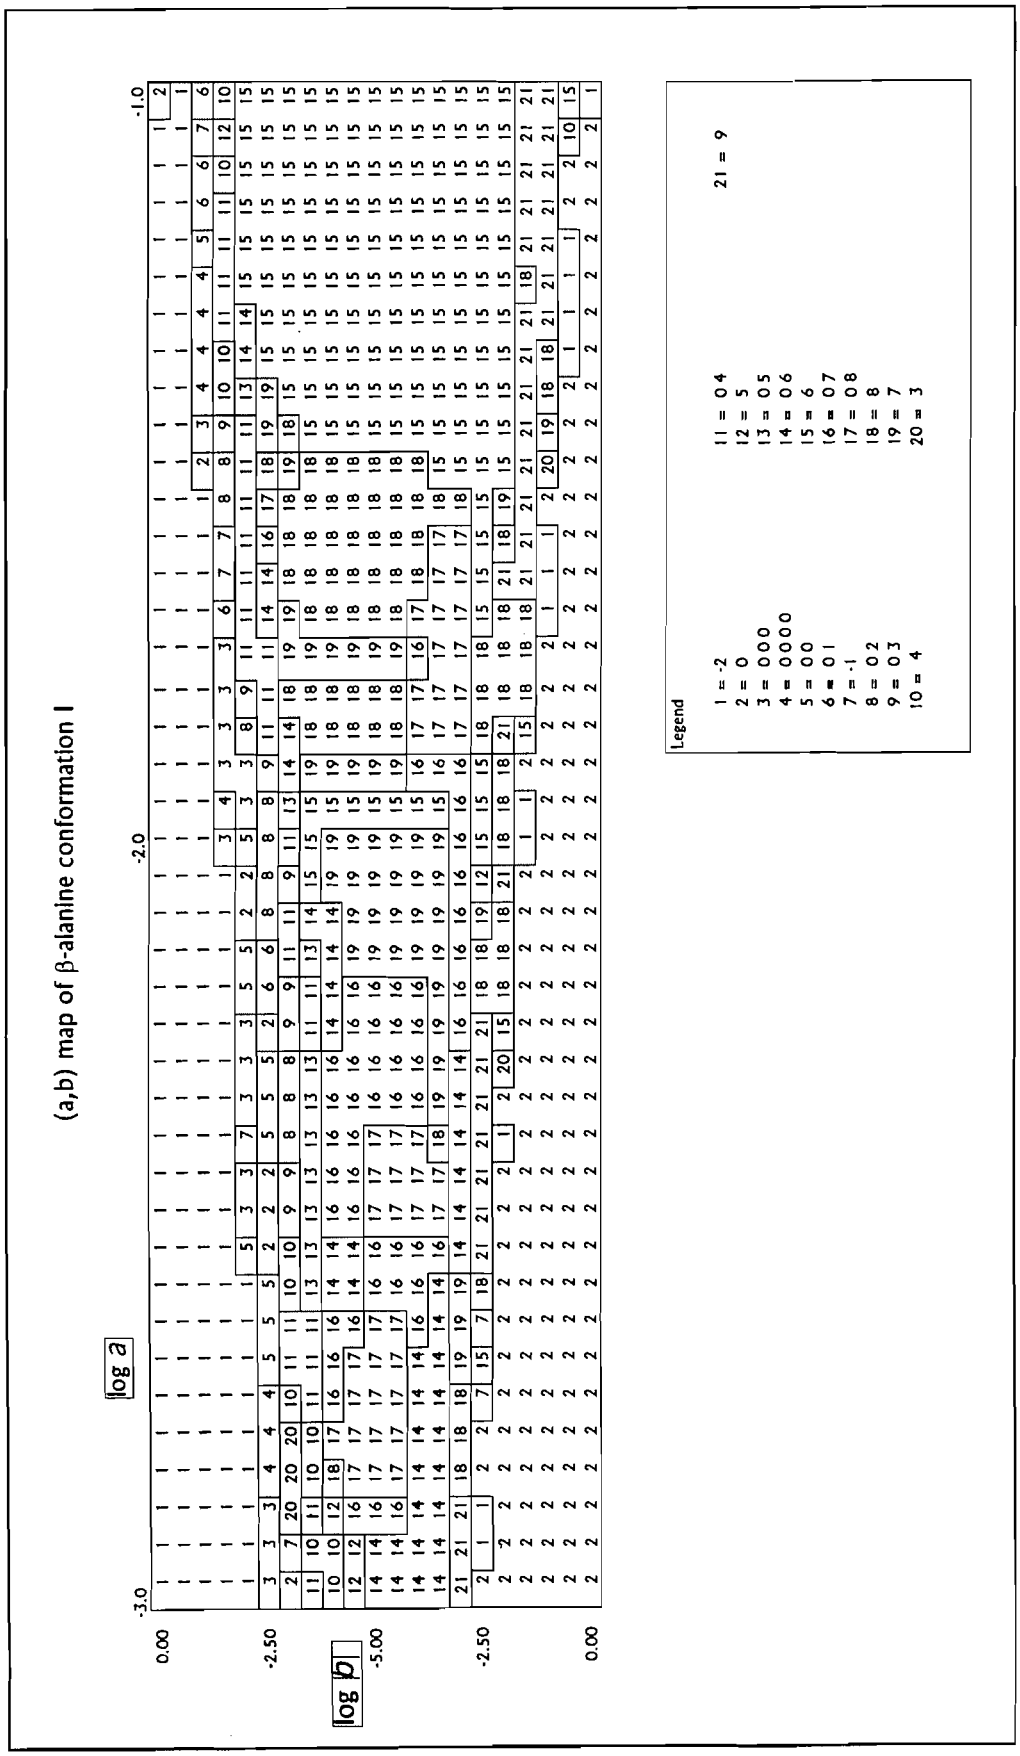


Fig. 2. The (*a*, *b*) parameter map for conformation **I** of β-alanine.

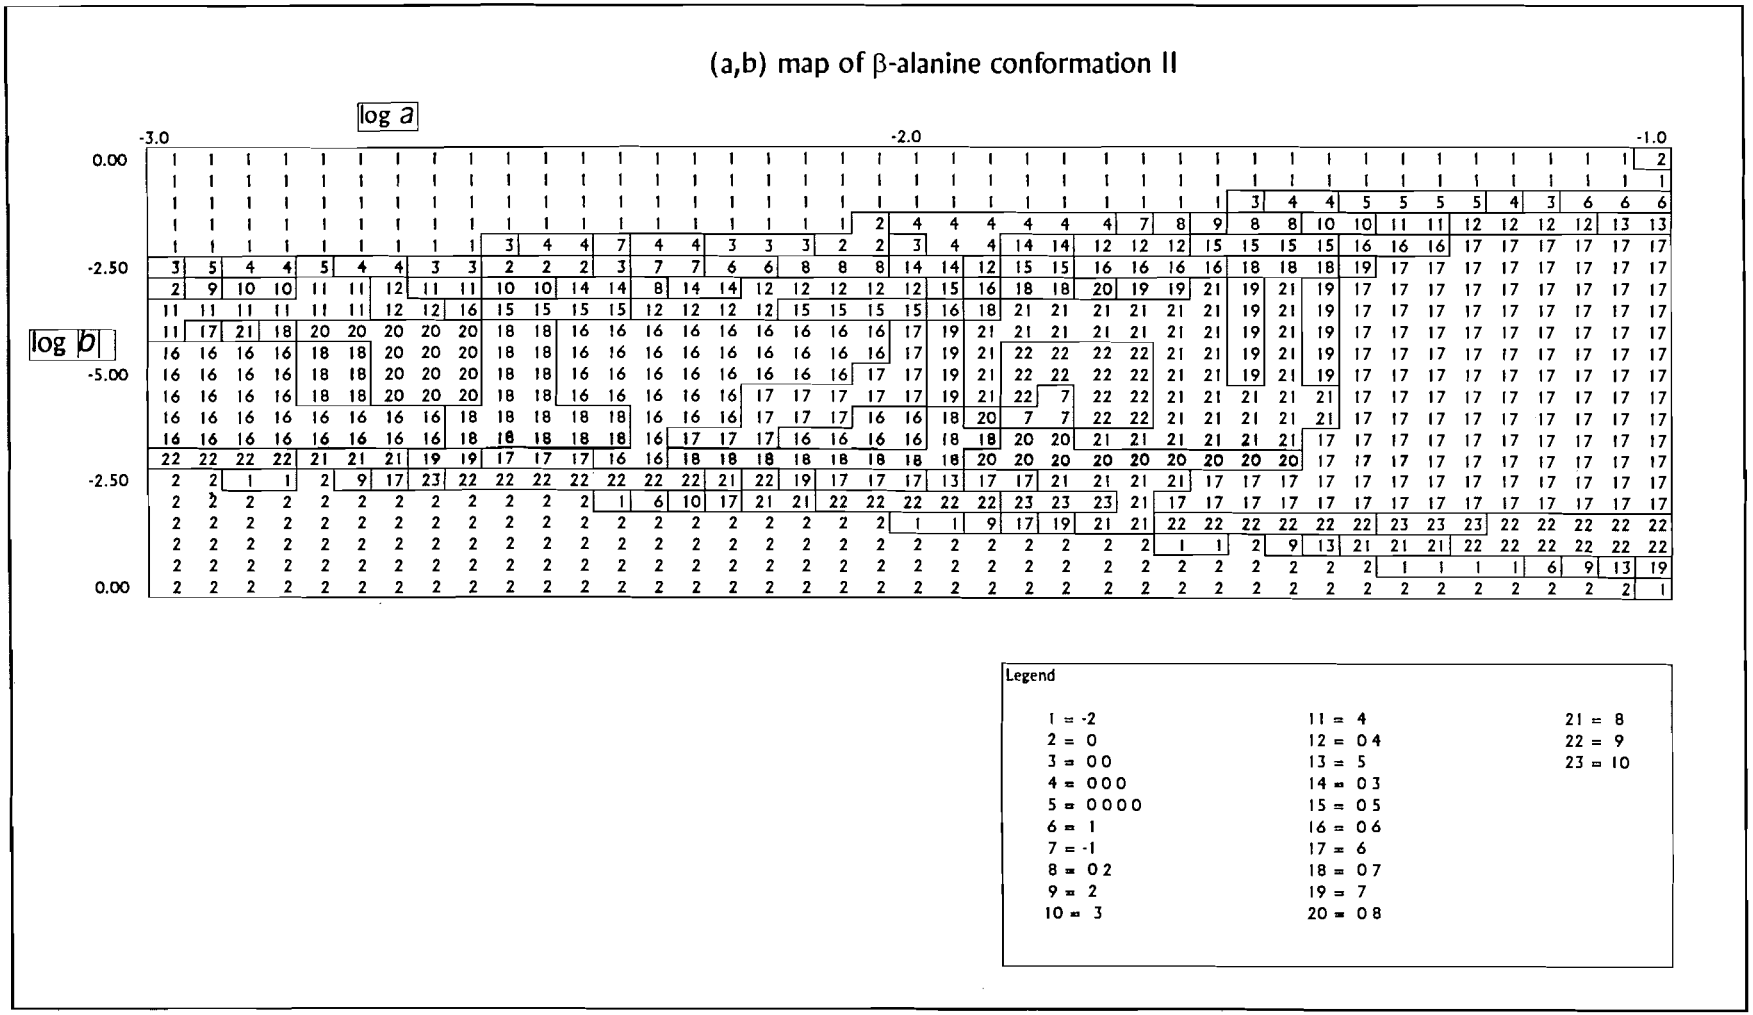
Fig. 3. The (*a*, *b*) parameter map for conformation **II** of β-alanine.



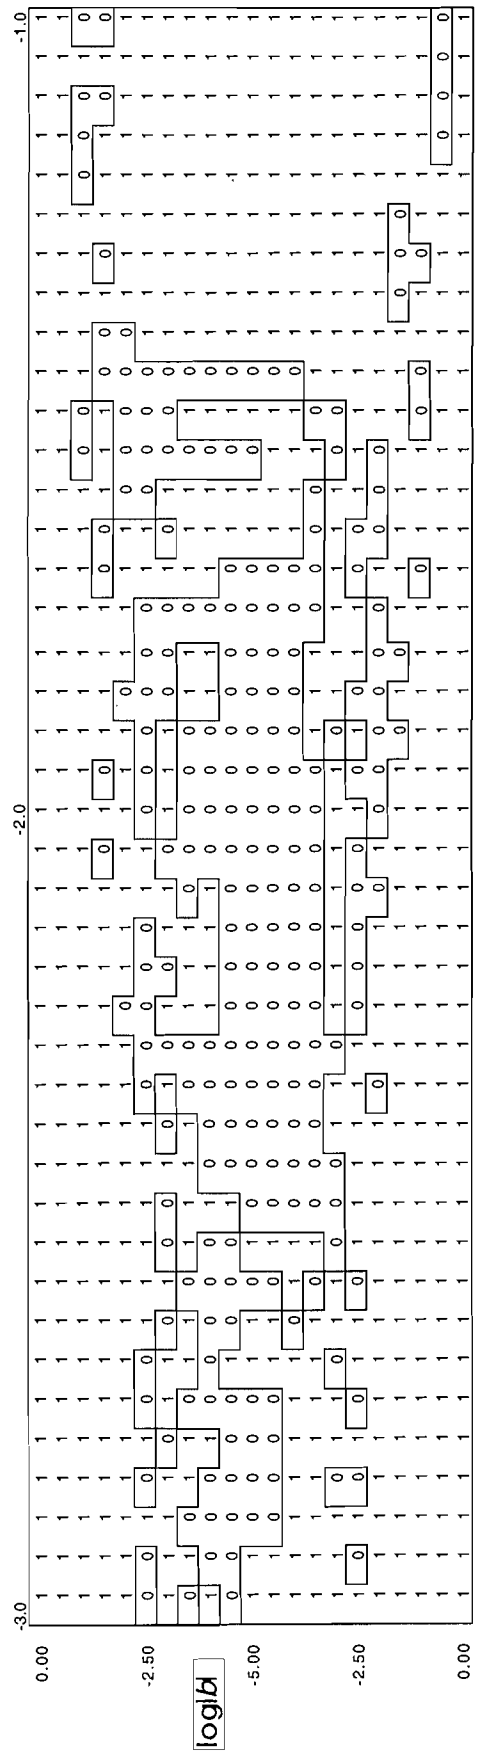


Fig. 4. The binary similarity map between conformations **I** and **II** of β-alanine showing in detail the similarity regions of MIDCO surfaces; "1" indicates a match whereas "0" indicates a mismatch between sets of Betti numbers encoded according to the legend tables in Figs. 2 and 3.

by the 6-31G** energies, as an indication of a formal "strain." In geometrical terms, **VI** shows the largest negative deviation of all β-alanine conformers for the two C-C-C-O torsions from their respective average values and at the same time the largest positive deviation for the H-N-C-C torsions. In terms of energy, **VI** also exhibits the largest increase in relative energy when changing from the 4-31G to the 6-31G** wave function.

As the case of **VI** shows, there is no strict relation between the similarity index values and the number of internal rotations necessary for the interconversion of the conformers involved. The following data strengthen this point: all conformer pairs, which can be transformed into each other by a rotation of the amino group only, are characterized by indices of 0.82 or higher; however, the pair **XII/XVIII** (differing in the amino and hydroxy group orientation) also ranks at 0.83. Rather than being linked to reaction paths, the similarity indices discussed here are obtained from a wide range of electron density values, hence they do reflect changes in intramolecular interactions rather accurately.

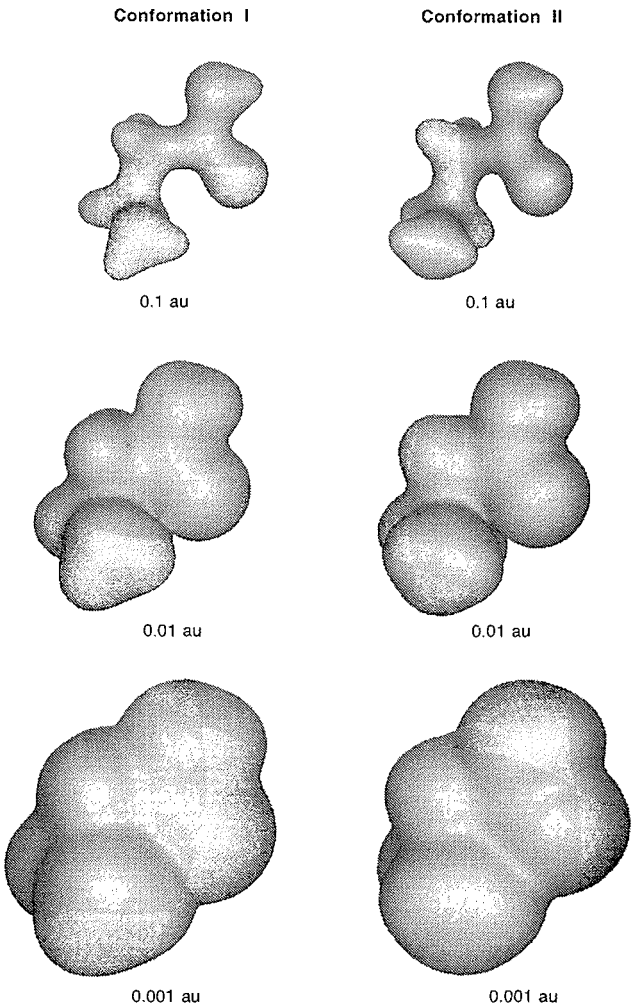
This is not only true for the strong intramolecular N...H—O hydrogen bond in **V**, but also true for much more subtle intramolecular interactions, e.g., those introduced by changing the -COOH group from a *syn*- to an *anti*-periplanar orientation. In the *syn* case, which is present in conformers **I–IV** and **VI–XII**, the dipoles of the groups O-H and C=O are in a very favorable orientation, which yields a stabilization of approximately 30 kJ/mol. In the *anti* case, this favorable orientation is no longer present and, except for **V**, the carboxylic hydrogen atom is brought into the vicinity of other hydrogen atoms. If the C-C-COOH arrangement is planar or almost planar, only minor H–H repulsion occurs, since the hydrogen atoms neighboring the carboxylic hydrogen atom point out of the C-C-COOH plane, whereas a rotation of the COOH group out of the C-C-C plane results in considerable H–H repulsion. As a consequence, conformers **XVII–XX**, which represent the latter case, are high in energy and exhibit the largest deviations of the H-O-C-C torsion from planarity. Looking at the similarity indices of those conformers, which form such *syn/anti* pairs, i.e., **I/XIII**, **II/XIV**, **IV/XV**, **VI/XVII**, **VII/XVI**, **IX/XVIII**, **X/XIX**, and **XII/XX**, one finds values of 0.832–0.872 for a planar C-C-COOH arrangement, but values between 0.769 and 0.826 for the nonplanar arrangement.

Other examples demonstrating the sensitivity of these similarity indices in monitoring changes in intramolecular interactions are the reaction cycles involving the conformers **II**, **VI**, and **XI** on the one hand and **IV**, **IX**, and **XII** on the other hand. The conformers in both sets are interconnected by an internal rotation of the carboxy group (in the latter case the mirror image of **IV** has to be considered, which is, however, characterized by the same numerical values as **IV**); in the case of **II**, **VI**, and **XI** significant changes in the interaction between the amino and the carboxy group take place along the reaction path (6), whereas the *trans* orientation of the N-C-C-C skeleton excludes such interactions in the case of **IV**, **IX**, and **XII**. The corresponding similarity indices mirror this difference: in one case they range from 0.771 to 0.795, whereas in the other case they are concentrated between 0.835 and 0.843.

4. Summary

In this work, the Shape Group Method (1–4) has been used to

Fig. 5. Three characteristic MIDCO surfaces, $G(\mathbf{Y},0.1)$, $G(\mathbf{Y},0.01)$, and $G(\mathbf{Y},0.001)$, $\mathbf{Y} = \mathbf{I}, \mathbf{II}$, for conformations **I** and **II** of β-alanine. The more diffuse, low density contours $G(\mathbf{Y},0.01)$ and $G(\mathbf{Y},0.001)$ show the differences in local curvatures resulting from the differences in the interactions between local charge density clouds.



analyze the electron density distributions of 20 symmetry-unique conformers of the neutral form of β-alanine. This particular molecule has a number of well-documented conformers (5) as well as a variety of intramolecular interactions in various conformers (5, 10). In earlier studies, the Shape Group Method was successfully applied for the similarity analysis of various compounds (25) and for conformational changes limited to single rotations (26). This study is the first in which the shape similarities of a large number of conformers are analyzed in a systematic manner.

The similarity indices obtained in the present study proved to be a good measure of similarity and a reliable tool for identifying outstanding conformers using an automated, unbiased algorithm. These similarity measures appear to be very sensitive to changes in nonbonded interactions. Detection of subtle changes in intra- or intermolecular interactions is expected to be of importance in computer-aided drug design, where the quantification of similarities or dissimilarities between differently substituted or differently oriented local groups in various compounds is essential, providing discrimination in their ability to bind to a known receptor.

The preparation and characterization of $SeCl_3SbF_6$, improved syntheses of $MCl_3(As/Sb)F_6$ (M = S, Se), and the X-ray crystal structure determination of $SeCl_3AsF_6$ and a new phase of SBr_3SbF_6

Jack Passmore, T. Stanley Cameron, Paul D. Boyle, Gabriele Schatte, and Todd Way

Abstract: Alternative and, in some cases, improved syntheses of the salts $MX_3(As/Sb)F_6$ (M = S, Se) and $SCl_3(SbCl_6/AlCl_4)$ are described. In addition, the synthesis of $SeCl_3SbF_6$ is reported. The compounds were characterized by FT–Raman spectroscopy and the X-ray crystal structures of $SeCl_3AsF_6$ (also ^{77}Se NMR)and a new phase of SBr_3SbF_6 were determined. Crystals of $SeCl_3AsF_6$ and SBr_3SbF_6 are monoclinic, space group $P2_1/c$ with [values for SBr_3SbF_6 in brackets] a = 7.678(1) [8.137(1)] Å, b = 9.380(3) [9.583(2)] Å, c = 11.920(3) [12.447(2)] Å, β = 98.19(2)° [97.36(1)]°, V = 849.72(3) [962.6(3)] Å^3, z = 4, D_x = 2.925 [3.502] Mg m^{-3}, R = 0.0525 [0.055], and R_w = 0.0554 [0.060] for 1151 [1472] observed reflections.

Key words: MX_3^+ salts, FT–Raman spectroscopy, X-ray crystal structures of $SeCl_3AsF_6$, SBr_3SbF_6, and preparation of $SeCl_3SbF_6$.

Résumé : On décrit de nouvelles synthèses, quelquefois améliorées, des sels $MX_3(As/Sb)F_6$ (M = S, Se) et $SCl_3(SbCl_6/AlCl_4)$. On rapporte de plus la synthèse du $SeCl_3SbF_6$. On a caractérisé les composés par spectroscopie Raman en transformation de Fourier et par diffraction des rayons X du $SeCl_3AsF_6$ (aussi RMN ^{77}Se) et d'une nouvelle phase du $SeBr_3SbF_6$. Les cristaux du $SeCl_3AsF_6$ et du SBr_3SbF_6 sont monocliniques, groupe d'espace $P2_1/c$ avec [valeurs pour SBr_3SbF_6 entre crochets] a = 7,678(1) [8,137(1)], b = 9,380(3) [9,583(2)] et c = 11,920(3) [12,447(2)] Å, β = 98,19(2)° [97,36(1)]°, V = 849,72(3) [962,6(3)] Å^3, z = 4, D_x = 2,925 [3,502] Mg m^{-3}, R = 0,0525 [0,055], et R_w = 0,0554 [0,060] pour 1151 [1472] réflexions observées.

Mots clés : sels de MX_3^+, spectroscopie Raman–FT, structures cristallines par diffraction des rayons-X de $SeCl_3AsF_6$, SBr_3SbF_6 et préparation de $SeCl_3SbF_6$.

[Traduit par la rédaction]

Introduction

During our work, we required AsF_6^- and SbF_6^- salts of MX_3^+ (M = S, Se; X = Cl, Br) as starting materials for the synthesis of $M_3X_3^+$ salts (1, 2). We report below alternative and, in some cases, improved syntheses of $MCl_3(As/Sb)F_6$ (M = S, Se) and $SCl_3(SbCl_6/AlCl_4)$, the synthesis of $SeCl_3SbF_6$, which was not reported previously, the FT–Raman spectra of MCl_3SbF_6 (M = S, Se), the X-ray crystal structure of $SeCl_3AsF_6$ and of a new phase of SBr_3SbF_6. The MX_3^+ (M = S, Se, Te; X = Cl, Br, I (excluding SI_3^+)) salts have been extensively studied (3–9), and are of interest in terms of the structure of the cations themselves, their solid state architectures, and degree of cation–anion interactions, and are starting reagents for both inorganic and organic reactions (e.g., the chlorination of aromatic systems; see ref. 4).

Experimental

General techniques and materials

All reactions were carried out in a one-piece apparatus consisting of two or three thick-walled round-bottom flasks (V = 25 mL) linked by a glass tube (o.d. 10 mm) incorporating a sintered glass filter disk (medium porosity). The three-bulbed vessel consisted of one primary bulb and two secondary bulbs, on the opposite side of the frit to the primary valve. The primary bulb was fitted with a 180° Pyrex glass valve with PTFE piston (diameter, 5 mm; PTT/5, J. Young, London, U.K.), and each secondary bulb with a 90° Pyrex glass valve with PTFE piston (diameter, 5 mm; PTT/5/RA, J.Young, London, U.K.).

Further details regarding general techniques and apparatus are described in refs. 10 and 11. All apparatus were rigorously dried. Moisture-sensitive materials, crystals suitable for X-ray analysis, and all solid products were manipulated in a Vacuum Atmospheres Dri-Lab equipped with a Dri-Train (HE-493) and an internal circulating drying unit containing 1 kg of 3 Å molecular sieves.

Sulfur dioxide (Matheson) and AsF_3 (Ozark-Mahoning) were vacuum distilled and stored over CaH_2 and NaF, respectively. Chlorine (Air Liquid Canada) and bromine (Fisher) were vacuum distilled onto and stored over P_4O_{10}. Selenium (Johnson Matthey, 1–3 mm, amorphous, ground to a powder, 99.999%), $SeCl_4$ (Johnson Matthey, 99.5%), S_2Cl_2 (Fisher Scientific), and AsF_5 (Ozark-Mahoning) were used as received. $AgSbF_6$ (Aldrich, 98%) was used as received, handled in the dark, and used in glass vessels wrapped in aluminum foil. Sulfur (precipitated; Fisher Scientific) was vacuum dried prior to use. Antimony pentafluoride (Ozark-Mahoning) was triple distilled in an all-glass apparatus and stored in a Pyrex glass vessel fitted with a Teflon valve (PTT/5, J. Young, U.K.) (11). Aluminum trichloride (Fisher Scientific) was sublimed under a nitrogen pressure of 40 mbar (1 bar = 100 kPa) through a section of granular Al metal (Fisher Scientific, 8–20 mesh) at a temperature of 175–180°C. The compound $S_3Br_3SbF_6$ was prepared as described in ref. 2.

Preparation of $SeCl_3AsF_6$ from $SeCl_4$, and AsF_5 in SO_2

An excess of AsF_5 (2.497 g, 14.69 mmol) was condensed onto $SeCl_4$ (2.197 g, 5.87 mmol) in SO_2 (8.9 g), producing a yellow solution over a white precipitate on warming to room temperature. The solution was filtered after stirring overnight, leaving 0.110 g of a less soluble product behind ($AsCl_4AsF_6$; FT–Raman). After removal of the volatile materials the resulting white soluble solid product was identified as $SeCl_3AsF_6$ containing small amounts of $AsCl_4AsF_6$ (FT–Raman). Pure $SeCl_3AsF_6$ (2.138 g, 5.71 mmol; 97.3% recovered yield based on $SeCl_4$) was obtained after recrystallization of the crude product (2.671 g) from SO_2 (5.6 g).

Crystals suitable for single-crystal X-ray diffraction were obtained from the reaction of selenium powder (1.007 g, 12.74 mmol) with a mixture of AsF_5 (3.361 g, 19.78 mmol) and Cl_2 (0.871 g, 12.28 mmol) in SO_2 (6.95 g) at −30°C originally designed to give $Se_6(AsF_6)_4$ (cf. $Te_6(AsF_6)_4$ (12)). Within 5 min the color of the solution turned from green into yellow and a light-yellow precipitate, which dissolved upon stirring for 1 h at room temperature. After stirring the light-yellow solution for 24 h at room temperature, slow removal of the solvent into the second bulb (ΔT = 20°C), produced large light-yellow crystals. Several light-yellow crystals were mounted in well-dried capillaries, flame-sealed under nitrogen atmosphere, and stored at −20°C prior to the X-ray analysis. The total product (3.466 g) consisted of 1.955 g (5.22 mmol) of crystalline $SeCl_3AsF_6$ and 1.511 g (2.3 mmol) $Se_4(AsF_6)_2$ (FT–Raman). The material has been stored at −10°C under a dry nitrogen atmosphere for more than 1 year without noticeable decomposition.

The identity of $SeCl_3AsF_6$ was confirmed by single-crystal X-ray diffraction (see below) and its melting point (195°C vs. 196°C reported in ref. 6). The FT–Raman spectrum of crystalline $SeCl_3AsF_6$ is shown in Fig. 1 and the frequencies listed in Table 1. The ^{77}Se FT–NMR spectrum of $SeCl_3AsF_6$ prepared in situ from $SeCl_4$ (0.5261 g, 2.38 mmol) and AsF_5 (1.006 g, 5.92 mmol; 39.7% excess) in SO_2 (4.22 g), at −40°C showed one resonance at δ = 1419 ppm. The NMR spectra were not obtained at lower temperatures since the compound precipitated out of solution and we were unable to obtain a ^{77}Se NMR spectrum of redissolved $SeCl_3AsF_6$ in SO_2.

Preparation of $SeCl_3AsF_6$ from Se, Cl_2, and AsF_5 in AsF_3 or SO_2

Arsenic pentafluoride, AsF_5 (0.719 g, 4.23 mmol, 3.9% excess based on eq. [2]), was condensed onto selenium (0.219 g, 2.71 mmol) in AsF_3 (8.67 g), forming a green solution on warming to room temperature. Chlorine Cl_2 (0.297 g, 4.19 mmol, 2.7% excess based on eq. [2]), was added, the yellow solution stirred overnight, and the volatiles removed, giving a yellow solid with a few orange crystals that turned into a greenish looking powder after removing all of the solvent. The product turned into a white, slightly greenish solid upon grinding. The total product consisted of 0.969 g (cf. expected 1.014 g, 2.71 mmol based on Se) of impure $SeCl_3AsF_6$ (FT–Raman; X-ray powder diffraction). The impurity (reasonably green $Se_8(AsF_6)_2$) was not detected by these methods.

In a similar experiment SO_2 was used as the solvent and in this case a green powder that contained the compound $SeCl_3AsF_6$ (FT–Raman) was obtained.

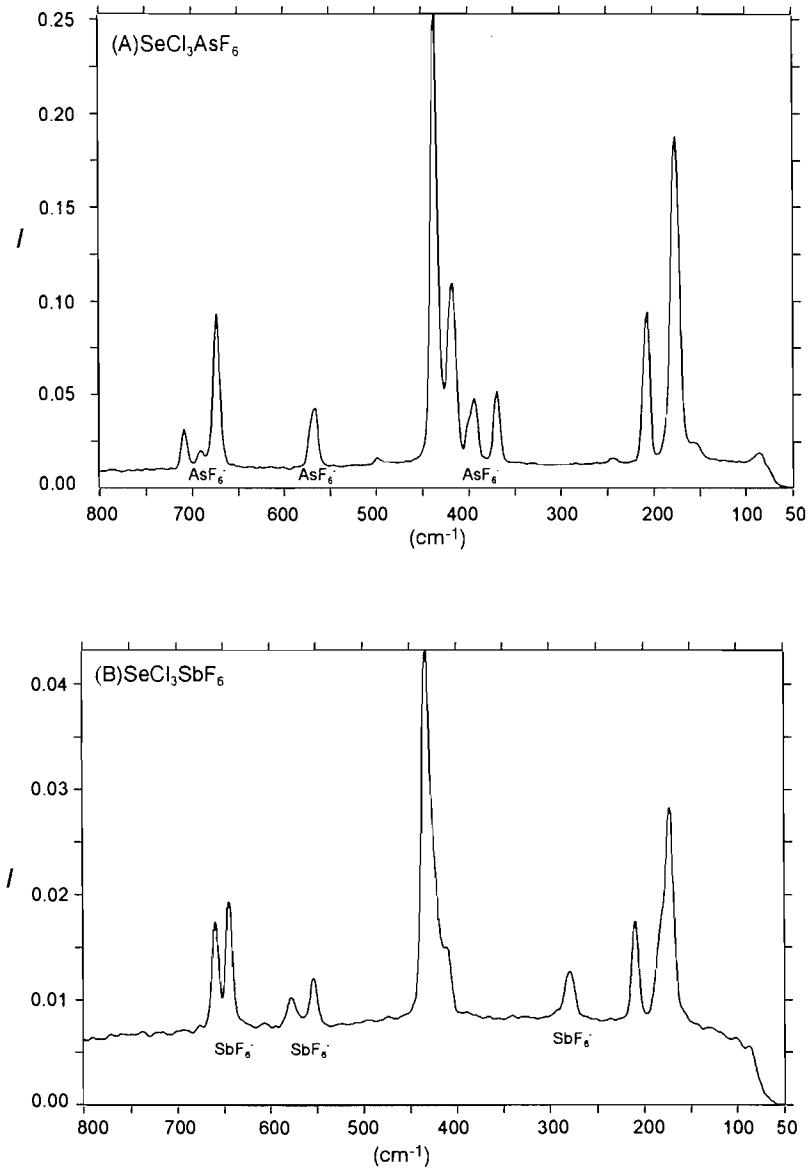
Preparation of $SeCl_3SbF_6$ from $SeCl_4$, and $AgSbF_6$ in SO_2

$SeCl_4$ (1.318 g, 5.97 mmol) and $AgSbF_6$ (2.061 g, 5.99 mmol) were added in the dark to one bulb of the two-bulb reaction vessel and the Teflon stem of the valve immediately replaced. Addition of SO_2 (5.37 g) gave a yellow solution with a white precipitate, which was stirred for 4 h at room temperature. The solution was filtered through the frit into the second bulb and the insoluble product (AgCl) left behind was washed with SO_2 until the solution became colorless. The volatile products were removed, giving a light-yellow soluble solid product ($SeCl_3SbF_6$, 2.333 g) and a greyish-white insoluble product (AgCl, 0.885 g) (FT–Raman). Pure $SeCl_3SbF_6$ (1.647 g, 5.71 mmol; 65.5% recovered yield based on $SeCl_4$) was obtained after recrystallization of the crude product (2.333 g) from SO_2 (5.8 g). The material was collected and stored at −10°C in a sealed glass tube in a dry nitrogen atmosphere.

Preparation of SCl_3AsF_6 from S_8, Cl_2, and AsF_3

The salt SCl_3AsF_6 was prepared from sulfur, chlorine, and AsF_3 by a modification of the method described in ref. 3. AsF_3 (1.732 g, 13.13 mmol) followed by Cl_2 (2.949 g, 41.6 mmol) were condensed onto the sulfur (0.397 g, 1.55 mmol). A very exothermic reaction occurred upon warming the mixture slowly to room temperature over 1 h, leading to a red solution, likely SCl_3AsF_6 dissolved in liquid $AsCl_3/Cl_2$, over a white precipitate. The mixture was stirred overnight and the volatiles removed, giving a crude product (SCl_3AsF_6 (1.683 g)) that was then dissolved in AsF_3 (7.427 g). Upon cooling this solution to −15°C, a crystalline white solid was formed. The solution was filtered through the frit into the second bulb and the solvent was subsequently removed by evacuation, giving 1.405 g (4.29 mmol; yield: 65.4% based on AsF_3) of pure SCl_3AsF_6 (FT–Raman, Table 1). The material is stable in a dry nitrogen atmosphere at −10°C for at least 6 months.

Fig. 1. FT–Raman spectra of the $SeCl_3AsF_6$ and $SeCl_3SbF_6$ salts measured at room temperature in a melting point tube (resolution: 4 cm^{-1}). The parameters for laser power (mW) and number of scans are: (A) 87 mW, 150; (B) 34 mW, 256.



Preparation of SBr_3SbF_6 from S_8, Br_2, and SbF_5 in SO_2

The salt SBr_3SbF_6 (2.714 g, 5.35 mmol; yield: 92% based on sulfur) was prepared by reacting sulfur (1.491 g, 5.81 mmol) with Br_2 (11.74 g, 73.5 mmol, 5.4% excess based on S_8) followed by addition of SbF_5 (18.07 g, 83.4 mmol, 7% excess based on S_8) according to eq. [*5b*] and similar to the reaction in ref. 8. The products SBr_3SbF_6 and the reduced antimony fluoride $(SbF_3)_3{\cdot}SbF_5$ (13) were identified by FT–Raman spectroscopy.

Crystals of SBr_3SbF_6 were obtained from an attempt to grow crystals of $S_3Br_3SbF_6$ (1.35 g, 2.36 mmol) by redissolving the latter in SO_2 (12.5 g). To facilitate crystal growth, the solvent had to be removed very slowly over a period of 18 h with a temperature gradient of 3°C using bulbs cooled to 0°C and −3°C, respectively. The slow removal of the solvent was required by the high solubility of $S_3Br_3SbF_6$, which during the course of the experiment partially decomposed to the crystalline SBr_3SbF_6 (FT–Raman) and S_2Br_2 (visually: red oil). The identity of SBr_3SbF_6 was further established by single-crystal X-ray diffraction. The material has been stored at −10°C in a dry nitrogen atmosphere for at least a year without noticeable decomposition. The stability at room temperature is in the range of a few weeks, as indicated by the presence of bromine.

Preparation of SCl_3SbF_6 from SBr_3SbF_6 and Cl_2 in SO_2 or from $AgSbF_6$, S_2Cl_2, and Cl_2 in SO_2

In one experiment a mixture of SO_2 (10.45 g) and Cl_2 (0.703 g, 9.91 mmol, large excess) was poured onto SBr_3SbF_6 (1.98 g,

Table 1. FT–Raman frequencies (cm^{-1}) of MX_3AF_6 (A = As, Sb; M = Se, S; X = Cl, Br) and $SCl_3AlCl_4/SbCl_6$ with relative peak heights in parentheses.[a]

[a] B_{eq} is the mean of the principal axes of the thermal ellipsoid.

3.90 mmol) cooled to −30°C, yielding an immediate red solution (probably bromine) with a white precipitate (SCl_3SbF_6, 1.46 g, 3.91 mmol, 100.3% yield). The vessel was immersed in a −30°C ethanol bath and gradually allowed to warm to room temperature over a period of 4–6 h. The reaction described here is very temperature and time dependent, and the desired product will not be obtained if the reaction conditions are not met (see preparation of SCl_3SbCl_6).

Alternatively, the compound can be prepared from the reaction of $AgSbF_6$ (4.0389 g, 11.75 mmol, 1.8% excess), S_2Cl_2 (0.7794 g, 5.77 mmol; density: 1.62 g/mL), and Cl_2 (1.2932 g, 18.23 mmol, 5% excess), in a three-bulbed vessel consisting of one primary bulb and two secondary bulbs located on the opposite side of the frit to the primary valve. $AgSbF_6$ was added to one of the secondary bulbs in the dry box and the valve closed. A slight excess of S_2Cl_2 was then added to the unused secondary bulb using a 1 mL syringe with an 18 gauge stainless steel needle in a fumehood. Excess S_2Cl_2 was removed under a dynamic vacuum until the desired amount remained. SO_2 (14.6 g) was then added to the primary bulb, followed by Cl_2. The two solutions were mixed and then poured onto the solid, which had been cooled to −60°C. The resultant mixture was a pale yellow solution over a white precipitate. The reaction was allowed to stir for 1 h, gradually warming from −60°C to 0°C. The soluble compound (3.829 g, 10.28 mmol, 88.6% based on S_2Cl_2) was separated from the insoluble AgCl (1.861 g, 12.98 mmol, 112.5% based on S_2Cl_2) by repeated washing of the solvent through a medium-porosity sintered glass frit followed by solvent removal. The soluble white solid contained SCl_3SbF_6 (FT–Raman, Table 1). The purity of the material may be improved by washing out the more soluble, unreacted excess $AgSb_6F$. The material has been stored under a dry nitrogen atmosphere for 1 week at 30°C, or indefinitely at −10°C.

Preparation of SCl_3SbCl_6 from SBr_3SbF_6 and Cl_2 in SO_2

The compound was prepared by the reaction of SBr_3SbF_6 (2.597 g, 5.12 mmol) with a mixture of Cl_2 (1.287 g, 18 mmol, large excess) and SO_2 (2.425 g) at −20°C. The mixture was warmed to room temperature and allowed to stir for 18 h, giving a white precipitate in a red solution. Removal of the volatiles yielded SCl_3SbCl_6 (2.393 g, 5.06 mmol, 98.85 % yield based on SBr_3SbF_6) as characterized by FT–Raman spectroscopy. Single-crystal X-ray diffraction produced a unit cell that was identical to the one previously reported in ref. 7. The stability of the compound on storage is similar to the SbF_6^- salt reported above.

^{19}F FT–NMR study of the reaction of SBr_3SbF_6 with Cl_2 in SO_2

The reaction was carried out in a 5-mm NMR tube fitted with a 90° J.Young valve. SO_2 (1.299 g, 20.2 mmol) and Freon-11 (0.0184 g, 0.134 mmol), as an internal reference, were condensed onto the solid SBr_3SbF_6 (0.0441 g, 0.086 mmol).

Finally, Cl_2 (0.554 g, 7.8 mmol) was added and the NMR tube flame sealed under vacuum with the contents kept at −196°C. A similar sample was prepared, omitting the addition of Cl_2, to determine the effects of Freon-11 on the sample. Both samples were allowed to warm to room temperature for 15 min prior to measurement at both −60°C and −70°C. The control sample showed peaks attributable to Freon-11 (δ = 0 ppm) and the anion, SbF_6^- ($\delta = -110$ ppm, $\Delta\nu_{1/2} = 940$ Hz). The chlorinated sample showed peaks attributable to the internal standard Freon-11, SbF_6^- ($\delta = -110$ ppm), and SOF_2 (δ = +74 ppm; 0.018 mmol). The ^{19}F NMR spectrum of the chlorinated sample recorded again after standing at −10°C for 5 days revealed

Table 5. Average M—X bond distances (Å), X-M-X bond angles (°), and the sum of the M···F bond valencies (valence units, v.u.) in all known $MX_3(As/SbF_6)$ salts (M = S, Se; X = Cl, Br) and the neutral group 15 $M'X_3$ trihalides.

[n]It has been shown that the strength of the S(IV)···F and Se(IV)···F contacts can be assessed by the relative magnitude of the bond valences (S) in valency units (v.u.) and is directly correlated to the localization of positive charge. An increase of positive charge on an atom leads to an increase in the sum of bond valences around the atom and this is accompanied by the formation of additional bonds and contacts (interionic and (or) intracationic) equal to the charge on the atom. The bond valence S in valence units (v.u.) is given by: $S = (R/R_0)^{-N}$, where R is the observed bond distance (Å), R_0 = 1.73 Å and N = 4 for Se(IV)···F and R_0 = 1.55 Å and N = 3.8 for S(IV)···F (see ref. 27).

peaks at δ = +74 ppm (SOF_2; 0.05 mmol), δ = +120 ppm (SO_2BrF; 0.01 mmol).

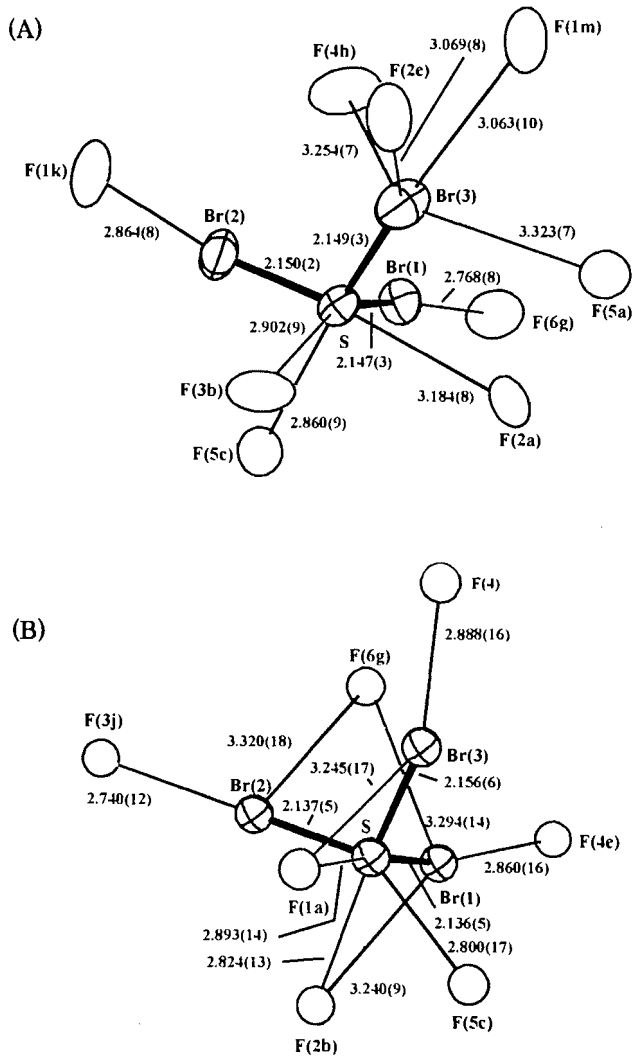
Preparation of SCl_3AlCl_4 from S_2Cl_2, Cl_2, and $AlCl_3$

The salt SCl_3AlCl_4 (1.04 g, 3.37 mmol, 90% yield vs. $AlCl_3$) (FT–Raman) was prepared by adding $AlCl_3$ (0.99 g, 7.45 mmol) to a secondary bulb of a three-bulbed vessel in the dry box. S_2Cl_2 (1.01 g, 7.55 mmol, 200% excess) was added to the other secondary bulb as described above, followed by Cl_2 (2.61 g, 36.7 mmol, 300% excess) via condensation. The bulb containing the solution was cooled to −80°C, preparing SCl_4 in situ (green solution over white precipitate). The $AlCl_3$ was then transferred into the cooled bulb containing the "SCl_4", and the solution was allowed gradually to warm to room temperature over 4 h, yielding a green liquid over a white precipitate, followed by filtration and removal of volatiles under dynamic vacuum.

FT–Raman, ^{19}F and ^{77}Se FT–NMR spectroscopy

FT–Raman spectra were obtained from neat samples sealed under nitrogen atmosphere in dried melting point capillaries on an FT–IR spectrometer (Bruker IFS66) equipped with an FT–Raman accessory (Bruker FRA 106) using a Nd-YAG laser (emission wavelength: 1064 nm; maximum laser power: 300 mW). The data were collected in the backscattering mode (180° excitation; resolution: 4 cm^{-1}) at room temperature

Fig. 2. Comparison of the two structures for the SBr_3^+ cation. (A) in the monoclinic unit cell (the letters a, b, c, e, g, h, k, m indicate symmetry-equivalent atoms: a, $-x$, $1.0 - y$, $1.0 - z$; b, $-x$, $0.5 + y$, $0.5 - z$; c, x, $0.5 - y$, $0.5 + z$; e, x, $1.5 - y$, $0.5 + z$; h, $1.0 - x$, $1.0 - y$, $1.0 - z$; k, $1.0 - x$, $0.5 + y$, $0.5 - z$; m, x, $1.00 + y$, $1.00 + z$); (B) in the orthorhombic unit cell (the letters a, b, c, e, j indicate symmetry-equivalent atoms: a, $-1.0 - x$, $0.5 + y$, $-0.5 - z$; b, $-0.5 - x$, $-y$, $-0.5 + z$; c, $-0.5 + x$, $-0.5 - y$, $-1.0 + z$; e, $0.5 + x$, $-0.5 - y$, $-1.0 - z$; j, x, $1.0 + y$, z) (21). Contacts that are less or slightly greater than the sum of the van der Waals radii for S···F ≤ 3.27 Å and for Br···F ≤ 3.32 Å are included (26). The values for the angles Br-S-Br (°) are (the values from ref. 21 are given in brackets): Br(1)-S(1)-Br(2), 103.81(13) (105.5(2)); Br(1)-S(1)-Br(3), 103.86 (15) (101.1(2)); Br(2)-S(1)-Br(3), 102.92(14) (101.6(2)) (additional angles including F atoms are given in the supplementary material). The thermal ellipsoids are scaled to enclose 50% of the probability density (ORTEP, included in the NRCVAX program package, see ref. 16).



between 4200 and 70 cm^{-1}. The ^{77}Se NMR samples were prepared in situ and measured as outlined in ref. 2. The procedure for measuring ^{19}F FT–NMR spectra is described in ref. 2.

Crystal structure determination

Space group and cell dimensions

The crystals of SBr_3SbF_6 are monoclinic, space group $P2_1/c$ with $a = 8.137(1)$ Å, $b = 9.583(2)$ Å, $c = 12.447(2)$ Å, $\alpha = \gamma = 90.00°$, $\beta = 97.36(1)°$, $V = 962.6(3)$ Å^3, $Z = 4$, $D_x = 3.502$ Mg m^{-3} and $T = 291$ K. Crystal size: $0.56 \times 0.32 \times 0.16$ mm. Empirical formula: Br_3F_6SSb. FW = 507.51. $F(000) = 903.89$. $\lambda(MoK_\alpha) = 0.71069$ Å. $\mu(MoK_\alpha) = 15.46$ mm^{-1}.

The crystals of $SeCl_3AsF_6$ are monoclinic, space group $P2_1/c$ with $a = 7.678(1)$ Å, $b = 9.380(3)$ Å, $c = 11.920(3)$ Å, $\alpha = \gamma = 90.00°$, $\beta = 98.19(2)°$, $V = 849.72(3)$ Å^3, Z (molecules per cell) = 4, $D_x = 2.925$ Mg m^{-3} and $T = 291$ K. Crystal size: $0.1 \times 0.2 \times 0.15$ mm. Empirical formula: $AsCl_3F_6Se$. FW = 374.21. $F(000) = 688$. $\lambda(MoK_\alpha) = 0.71069$ Å. $\mu(MoK_\alpha) = 92.162$ cm^{-1}.

Data collection, structure solution, refinement

Crystals were examined in a dry box using a Wild M3 microscope of long focal length mounted outside the dry box. A number of crystals were flame sealed in rigorously dried capillary tubes.

The data for SBr_3AsF_6 and $SeCl_3AsF_6$ were collected at room temperature on an Enraf–Nonius CAD-4 automated diffractometer operating in the $\omega/2\theta$ ($2\theta_{max}$, 50) scan mode with graphite-monochromated MoK_α radiation.

The data collection (1763 reflections) for SBr_3SbF_6 resulted in 1678 unique reflections, 1472 of which were considered observed ($I \geq 0.5\sigma(I)$). The crystal was indexed using the program DIRAX (14). The structure was solved by automated Patterson interpretation routine (SHELXS 86; PATT instruction) (15) and missing atoms were found by difference Fourier maps. The data were corrected for Lorentz and polarization effects. Refinement by full-matrix least squares led to residuals of $R = 0.055$, $R_w = 0.060$ for 1472 observed reflections and 100 parameters. All atoms were assigned anisotropic displacement parameters. The unit cell constants were obtained by least-squares refinement of the diffractor setting angles for 24 well-centered reflections at $29° < 2\theta < 35°$. Calculations were performed using the PC implementation of the NRCVAX (16) program package.

Cell constants and an orientation matrix for the data collection for $SeCl_3AsF_6$ were obtained from a least-squares refinement using the setting angles of 25 carefully centered reflections in the range $14° < 2\theta < 15°$. Of the 1664 reflections collected, 1484 were unique ($R_{int} = 0.058$). The structure was determined by direct methods (SHELXS 86) and the data were corrected for Lorentz and polarization effects and for absorption using the program DIFABS (17); the maximum and minimum corrections were 1.000 and 0.416, respectively. Refinement by full-matrix least squares with all atoms assigned anisotropic thermal parameters resulted in the final residuals $R = 0.0525$, $R_w = 0.0554$ for 1151 observed reflections ($I \geq 3F(I)$).

Scattering factors for the structure determinations were taken from ref. 18 and effects of anomalous dispersion were included in F_c using the values of Cromer (19).

Fig. 3. Molecular packing of $SeCl_3AsF_6$.

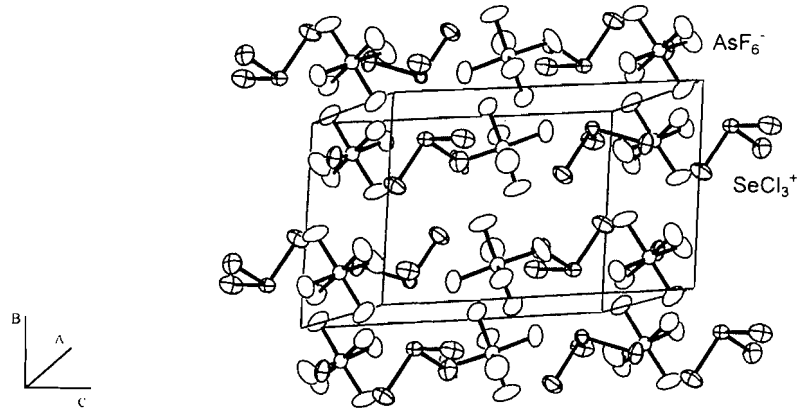


Fig. 4. Structure of the $SeCl_3^+$ cation showing cation–anion contacts (includes contacts that are less or slightly greater than the sum of the van der Waals radii for Se···F ≤ 3.37 Å and for Cl···F ≤ 3.22 Å). The values for the angles Cl-Se-Cl (°) are: Cl(1)-Se(1)-Cl(2), 100.38(10); Cl(1)-Se(1)-Cl(3), 98.39(10); Cl(2)-Se(1)-Cl(3), 100.53(10) (additional angles including F atoms are given in the supplementary material). The thermal ellipsoids are scaled to enclose 50% of the probability density (ORTEP, included in the NRCVAX program package, see ref. 16). The letters b, c, d, l, i indicate symmetry-equivalent atoms: b, x, $0.5 - y, 0.5 + z$; c, $-x$, $1.0 - y$, $-z$; d, $1.0 + x$, $0.5 - y$, $0.5 + z$; l, $-x$, $-y$, $-z$; i, $1.0 + x$, y, $-z$.

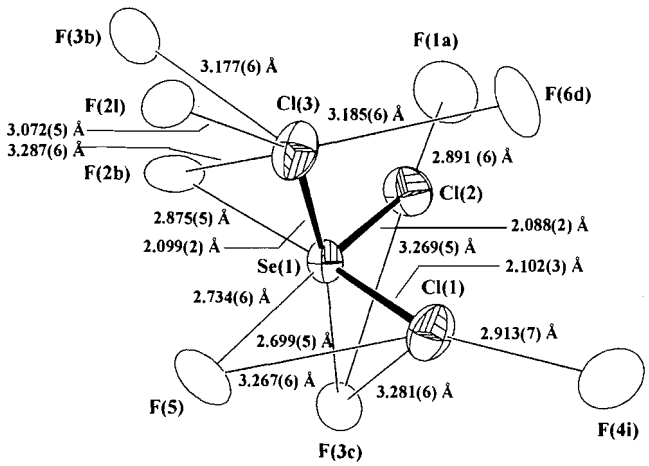

The final atomic coordinates are listed in Table 2. Available as supplementary material is a complete listing of thermal parameters, distances, and angles.[4]

[4] Complete sets of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The data have been also deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Discussion

We previously prepared MBr_3AsF_6 (M = S, Se, Te) by the stoichiometric reaction of M, Br_2, and AsF_5 according to eq. [1].

$$[1] \quad 3\,Br_2 + 2\,M + 3\,AsF_5 \xrightarrow{SO_2} 2\,MBr_3AsF_6 + AsF_3$$

The analogous reaction of selenium, chlorine, and arsenic pentafluoride according to eq. [2], leads to $SeCl_3AsF_6$ containing small amounts of green $Se_8(AsF_6)_2$ (11), although both FT–Raman spectroscopy and X-ray powder photography showed only the presence of $SeCl_3AsF_6$.

$$[2] \quad 3\,Cl_2 + 2\,Se + 3\,AsF_5 \xrightarrow{AsF_3} 2\,SeCl_3AsF_6 + AsF_3$$

Pure, white $SeCl_3AsF_6$ (in 97.3% yield) is best prepared by the reaction described in eq. [3].

$$[3] \quad 4\,SeCl_4 + 6\,AsF_5 \xrightarrow{SO_2} 4\,SeCl_3AsF_6 + AsCl_4AsF_6$$

The soluble $SeCl_3AsF_6$ was separated from the less soluble $AsCl_4AsF_6$ by filtration and then recrystallized from SO_2. The previously reported synthesis of $SeCl_3AsF_6$ (6) involved the reaction of $SeCl_4$ (generated in situ from Se and Cl_2) and $AsCl_4AsF_6$ (prepared in situ from AsF_3 and $AsCl_3$) in $AsCl_3$ as solvent; no yields were given.

SCl_3AsF_6 was obtained in 65% yield in a similar reaction as described in ref. 3, but using stoichiometric amounts of reagents, as shown in eq. [4].

$$[4] \quad 1/8\,S_8 + 2\,AsF_3 + 3\,Cl_2 \xrightarrow{SO_2} SCl_3AsF_6 + AsCl_3$$

SBr_3SbF_6 was previously prepared by the reaction of sulfur, bromine, and antimony pentafluoride and described as proceeding according to eq. [5*a*] although the identity of the SbF_3 was not established (8).

$$[5a] \quad 1/8\,S_8 + 3\,SbF_5 + 3\,Br_2 \xrightarrow{SO_2} SBr_3SbF_6 + SbF_3$$

It was later shown that the reduced antimony fluoride product

was in fact $(SbF_3)_3{\cdot}SbF_5$ (10, 13). In this work, the reaction was carried out as described in eq. [5*b*].

$$[5b]\quad 3/4\ S_8 + 9\ Br_2 + 10\ SbF_5 \xrightarrow{SO_2} 6\ SBr_3SbF_6 + (SbF_3)_3{\cdot}SbF_5$$

It was anticipated that the synthesis of SbF_6^- salts of MCl_3^+ (M = S, Se) from the reaction of chalcogen, chlorine, and antimony pentafluoride would be unsuccessful due to chlorine incorporation into the anion. However, SCl_3SbF_6 was prepared under carefully controlled temperature of −30°C, in quantitative yield by the chlorination of SBr_3SbF_6 according to eq. [6]. Warming to room temperature and stirring overnight led to SCl_3SbCl_6.

$$[6]\quad 2\ SBr_3SbF_6 + 3\ Cl_2 \xrightarrow{SO_2} 2\ SCl_3SbF_6 + 3\ Br_2$$

The preferred route to MCl_3SbF_6 (M = S, Se) with yields greater than 90%, is the reaction of $SeCl_4$ or SCl_4 (prepared in situ) with $AgSbF_6$ according to eqs. [7] and [8].

$$[7]\quad SeCl_4 + AgSbF_6 \xrightarrow{SO_2} SeCl_3SbF_6 + AgCl$$

$$[8]\quad 3Cl_2 + S_2Cl_2 + 2\ AgSbF_6 \xrightarrow{SO_2} 2\ SCl_3SbF_6 + 2\ AgCl$$

The SCl_3SbF_6 was previously obtained from the reaction of SH_3SbF_6 (prepared from HF, H_2S and SbF_5) (20) and Cl_2 in a Teflon/FEP vessel in unreported yields (5). The synthesis of $SeCl_3SbF_6$ has not been reported. SCl_3SbCl_6 was previously prepared by the reaction of As_4S_4 and $SbCl_5$ in SO_2 with unreported yields (7). The SCl_3AlCl_4 was prepared as described in ref. 4 according to eq. [9], but was adapted from an open system under a stream of dry nitrogen to a closed leak-tight and moisture-free vacuum system.

$$[9]\quad 3Cl_2 + S_2Cl_2 + 2\ AlCl_3 \xrightarrow{SO_2} 2\ SCl_3AlCl_4$$

In conclusion, reasonable preparative routes have been developed to $SCl_3^+$and $SeCl_3^+$ salts of MF_6^- (M = As, Sb) and to SCl_3SbCl_6 and SCl_3AlCl_4.

A possible reaction pathway for the reaction of SBr_3SbF_6 and Cl_2 leading to SCl_3SbF_6

The reaction described in eq. [6] which occurs at −30°C, may proceed by donation of the π^* electrons from Cl_2 to the empty π^* orbitals of SBr_3^+, leading to BrCl and $SClBr_2^+$ as shown in eq. [10]. The $Br^{\delta+}$—$Cl^{\delta-}$ may then undergo even more favorable reactions with $SBrCl_2^+$ because of the partial negative charge on the chlorine atom leading to the observed products.

[10] 
FT–Raman spectra of the MX_3^+ salts

The salts were all characterized by FT–Raman spectroscopy by comparison with previously reported spectra (see Table 1). The spectra of MCl_3SbF_6 (M = S, Se) are reported here for the first time. Overall, our FT–Raman data are better than previously published data, and our spectra include measurements of relative peak intensities (Table 1). The FT–Raman spectrum of $SeCl_3SbF_6$ allowed us to definitively assign the bands attributable to $SeCl_3^+$ in $SeCl_3AsF_6$ previously reported in ref. 6 (see Table 1 and Fig. 1). The symmetric and asymmetric SeCl stretching vibrations are assigned to the bands at 437 and 418 cm^{-1} (AsF_6^- salt) and at 433 and 410 cm^{-1} (SbF_6^- salt), respectively. The asymmetric SeCl stretching vibration was previously assigned to the band at 390 cm^{-1}, which is also observed in our FT–Raman spectrum of $SeCl_3AsF_6$ but in fact belongs to a vibration of the AsF_6^- anion since this band is missing in the FT–Raman spectrum of $SeCl_3SbF_6$. In addition, the presence of the possible impurities $AsCl_4AsF_6$ and $SeCl_4$ have been excluded by comparison with their FT–Raman spectra.[5]

The crystal structures of SBr_3SbF_6 and $SeCl_3AsF_6$

SBr_3SbF_6 is monoclinic, and isomorphous and isostructural with SBr_3AsF_6, and $SeBr_3AsF_6$. The previously reported structure of SBr_3SbF_6 was orthorhombic (21). The SBr_3^+ cation including distances and angles (in the caption of Fig. 2) and cation–anion contacts for both the monoclinic and orthorhombic structure are shown in Fig. 2. Additional bond distances and angles are listed in Table 3. The average S—Br bond distances and Br-S-Br angles in SBr_3AsF_6 and in both phases[6] of SBr_3SbF_6 are identical (see Table 5).

The X-ray crystal structure of $SeCl_3AsF_6$ is isomorphous and isostructural with $TeBr_3AsF_6$ (22). The structure contains alternating sheets of cations and anions tilted slightly out of the *ab* plane (Fig. 3). The $SeCl_3^+$ cation in $SeCl_3AsF_6$ has approximately C_{3v} symmetry. Figure 4 shows the $SeCl_3^+$ cation including distances and angles (in the caption of Fig. 4) and cation–anion contacts. Additional structural data are listed in Table 4. The observed average Se^+—Cl distance and Cl-Se-Cl angle in $SeCl_3AsF_6$ (2.096(2) Å, 99.77(10)°) are similar to those found in $SeCl_3SbCl_6$ (2.10(1) Å, 103.0(4)°) (7), $SeCl_3AlCl_4$ (2.103 Å, 99.2°) (23), and $SeCl_3AuCl_4$ (2.121(3) Å, 98.0(4)°) (24), but the average Se^+—Cl distance is significantly shorter than those found in $SeCl_3(MoOCl_4)$ (2.148(2) Å, no angles given) (25). With the structure of $SeCl_3AsF_6$ determined, the MX_3^+ (M = S, Se; X = Cl, Br) bond distances and angles in very weakly basic AsF_6^- and SbF_6^- salts and the relative strengths of the M···F interactions can now be compared (see Table 5). They now all show the expected trends

[5] FT–Raman data for $AsCl_4AsF_6$ and $SeCl_4$ (cm^{-1}) with relative intensities in parentheses: $AsCl_4AsF_6$: 680 (46) [AsF_6^-], 574 (6) [AsF_6^-], 523 (5), 499, {442 (25), 421 (100)}, {395 (9), 370 (21)} [AsF_6^-], 239 (6), 186 (89), 153 (65); $SeCl_4$: 387 (100), 371 (18), 357 (55), 341 (64), 216 (11), 211 (11), 168 (sh, 17), 161 (18), 128 (38), 98 (42). For detailed assignments see ref. 28.

[6] The two salts are different phases of SBr_3SbF_6. Their reciprocal lattices are not superimposable and the Sb···Sb distances are significantly different (Sb···Sb Å)): monoclinic, 5.578(1), 2 × 6.238(1), 6.275(1), 6.819(1); orthorhombic, 2 × 5.822(6), 2 × 6.326(4), 2 × 6.989(5), (from ref. 21).

discussed in ref. 10. The bond distances of the group 16 cations mirror the trends seen in the neutral group 15 trihalides (see Table 5), and are similar to the M—X distances calculated by the Schomaker–Stevenson equation given in ref. 10. The bond distances in the cations are shorter than the isoelectronic neutral group 15 trihalides, consistent with the smaller size of M^+ (M = elements of group 16) relative to that of M′ (M′ = elements of group 15). The shorter distances in the cation are reflected in the MX_3^+ Raman bands, which are at a higher frequency than the corresponding neutrals, with correspondingly higher force constants (N m^{-1}) for the trihalide cations than the trihalide neutrals (e.g., SBr_3^+ F_r 201.1(2); PBr_3 F_r 170.8(2); $SeBr_3^+$ F_r 168.1(1); $AsBr_3$ F_r 164.2(2) (9)). A comparison of the Raman spectra of the MX_3^+ and $M'X_3$ will be the subject of a future publication.[7] The X-M-X bond angles are conversely larger than those of the isoelectronic X-M′-X neutrals, consistent with the predictions of VSEPR theory (37). The larger effective electronegativity of the M^+ relative to M′ leads to a greater bond–bond repulsion, and a larger angle.

Differentiation of cerebroside isomers and study of fragmentation by liquid secondary ion mass spectrometry and mass spectrometry/mass spectrometry of selected derivatives

Hélène Perreault and Catherine E. Costello

Abstract: The possibility of distinguishing two cerebroside isomers, whose structural variation is in the sugar rings, was investigated by liquid secondary ion mass spectrometry (LSIMS) and tandem mass spectrometry (MS/MS). In addition to the native materials, four types of derivatives of these cerebroside isomers were prepared and studied using these techniques. A first level of comparison between isomers consisted of seeking differences in the conventional LSIMS spectra. Native compounds, galactosyl and glucosyl ceramides, did not yield consistent and meaningful elements of comparison and a few nanomoles of material were required to produce significant spectra. Permethylated cerebrosides gave rise to abundant ceramide ions that do not reveal information about sugar structure; relative abundances of low-mass sugar-related ions allowed isomeric discrimination to a limited extent. Peracetylated and perbenzoylated derivatives of both cerebrosides yielded several sugar-related ions whose relative abundances in the spectra varied systematically between species and allowed distinction of glucosyl- from galacto-cerebrosides. At a second level of comparison, collision-induced dissociation (CID) MS/MS spectra of selected ions containing the hexosyl residues and observed in the LSIMS spectra were recorded to study the extent and pathways of fragmentation for each isomer. Native and permethylated compounds led to disappointing results; on the other hand, peracetylated and perbenzoylated derivatives yielded informative spectra where isomeric differentiation was possible, mostly owing to the production of carbohydrate-related product ions, whereas native and permethylated compounds only produced ceramide-related ions upon CID MS/MS.

Key words: glycosphingolipids, cerebrosides, derivatization, mass spectrometry, MS/MS, LSIMS.

Résumé : La spectrométrie de masse à ionisation par bombardement d'ions (LSIMS) et la spectrométrie de masse en tandem (MS/MS) ont été utilisées dans l'étude de la distinction de deux cérébrosides isomériques. Les composés natifs (non-dérivés) ainsi que quatre types de dérivés de ces cérébrosides ont été charactérisés à l'aide de ces techniques. Une comparaison préliminaire des deux isomères a consisté à chercher les différences apparaissant dans les spectres LSIMS conventionnels. Les composés natifs, aussi désignés sous le nom de glucosyl- et galactosyl-céramide, ne produisent pas d'éléments spectraux intéressants permettant de faire la distinction entre isomères; de plus quelques nanomoles de matériel sont requises pour produire des spectres qualitativement acceptables. Les cérébrosides perméthylés produisent d'abondants ions caractérisant la partie céramide des composés, mais ces ions ne sont pas utiles pour l'étude de la portion hexosyl. Cette dernière produit toutefois des ions à très basse masse dont l'abondance relative aide à caractériser l'hexosyl. Les dérivés peracétylés et perbenzoylés des deux cérébrosides produisent plusieurs ions permettant de caractériser la portion sucre. Les abondances relatives de ces ions varient systématiquement entre les deux différentes espèces et permettent la distinction entre glucosyl- et galactosyl-cérébrosides. Dans une deuxième séries d'expériences, les spectres MS/MS obtenus de la fragmentation par collisions (CID) d'ions LSIMS présélectionnés et contenant la portion sucre des molécules ont été enregistrés dans le but d'étudier les patrons de fragmentation des deux isomères. Les cérébrosides natifs et perméthylés ont produit des résultats non-significatifs; par contre, les composés peracétylés et perbenzoylés produisent des spectres contenant beaucoup d'information et rendant possible la différentiation des isomères.

Mots clés : glycosphingolipides, cérébrosides, dérivé, spectrométrie de masse, MS/MS, LSIMS.

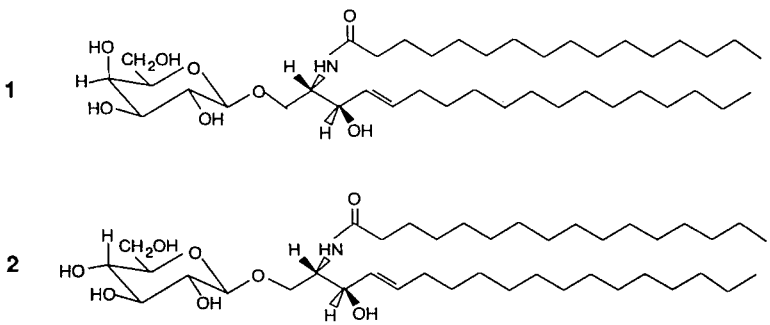
Scheme 1. Compounds investigated in this study. **1**: Galactosyl-ceramide (galacto-cerebroside) and **2**: glucosyl-ceramide (gluco-cerebroside).



Introduction

Cerebrosides constitute a specific class of glycosphingolipids (GSLs) and are formed by the combination of ceramides and monohexoside residues. Galacto-cerebrosides, which are the basis of formation of another important group of GSLs, the sulfatides, are commonly called "cerebrosides" with no further specification. Glucosyl ceramides, or gluco-cerebrosides, form an essential class of compounds since they precede formation of higher GSLs such as lactosides, globosides, gangliosides, and neolactosides, whose biological functions as receptors and exchangers in cell membranes have been well documented (1–3). Structural features of natural cerebrosides encompass the type of ceramide present in the molecule, and also the type of monohexoside linked to the latter by a glycosidic bond. Variations in ceramides can occur as differences in fatty acyl or sphingosine base chain length, degree of unsaturation, and hydroxylation at former sites of unsaturation, as in 4D-hydroxysphinganine, formerly known as phytosphingosine (4). The structures of isomeric monosaccharides such as glucose and galactose can be determined by ^{1}H nuclear magnetic resonance (NMR) (5), provided that sufficient quantities of sample, in the milligram range (micromoles), are available. Mass spectrometry, owing to the recent advent of sophisticated ionization techniques and derivatization methods, has significantly enhanced structural analysis of glycosphingolipids. In general, lower amounts of materials are required for mass spectral analyses than for NMR characterization; however, detection limits vary, depending on the ionization technique used. So far, matrix-assisted laser desorption/ionization coupled to time-of-flight analyzers (MALDI-TOFMS) and electrospray ionization (ESI) have achieved the highest sensitivity for characterization of derivatized GSLs (6, 7); the amounts of material detected were at the femtomole level. Due to low volatility, thermal lability, and polarity of GSLs, derivatization is often carried out prior to mass spectral analysis by any ionization method. We reported in an earlier study (8) that permethylation, peracetylation, and perbenzoylation enhance sensitivity by two orders of magnitude in liquid secondary ion mass spectrometry (LSIMS) and MALDI-TOFMS; the same observation has also been made in ESI (7) for permethylated GSLs. We also reported on the complementarity of structural information obtained from LSIMS and MS/MS fragmentation of different types of derivatives of the same analyte (8).

This paper focuses on isomeric discrimination of two palmitoyl cerebroside species whose structural difference resides in the monosaccharide moiety. Subnanomole to low nanomole levels of galactosyl and glycosyl ceramides were derivatized using four methods described previously (8) and were studied by positive LSIMS and tandem mass spectrometry (MS/MS) in order to investigate the possibility of isomeric discrimination from mass spectral information. MALDI-TOFMS was used for molecular weight confirmation immediately following derivatization.

Experimental

Chemicals and reagents

Galactosyl palmitoyl cerebroside or galactosyl *N*-palmitoyl (4*E*)-sphingenine (**1** in Scheme 1) was obtained from Sigma Chemicals (St. Louis, Mo.) and used without further purification. Glucosyl palmitoyl cerebroside or glucosyl *N*-palmitoyl (4*E*)-sphingenine (**2**) was graciously provided by R. Duclos and synthesized according to a procedure described elsewhere (9). Reagents methyl iodide, benzoic anhydride, benzoyl chloride, and *N*,*N*-dimethylaminopyridine (DMAP) were purchased from Aldrich (Milwaukee, Wis.), while dimethyl sulfoxide (DMSO) and acetic anhydride were obtained from Pierce Chemicals (Rockford, Ill.). HPLC-grade solvents (pyridine, toluene, hexane, chloroform, acetonitrile, and methanol) were obtained from Mallinckrodt (Paris, Ky). The LSIMS and MALDI matrices used in this study were, respectively, 3-nitrobenzyl alcohol (NBA) and 2,5-dihydroxy benzoic acid (DHB), both purchased from Aldrich.

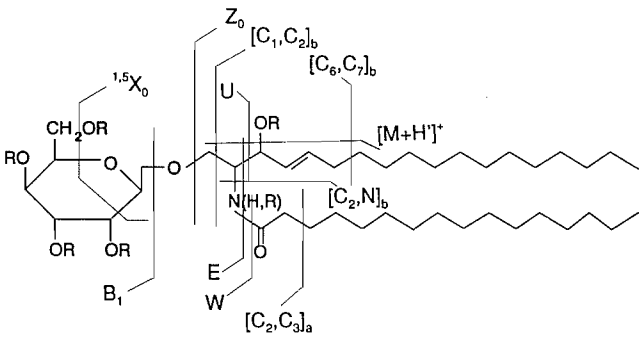
Derivatization methods

Bulk phase permethylation and gas phase peracetylation and perbenzoylation (using benzoyl chloride) were used as described previously (8). Perbenzoylation with benzoic anhydride and DMAP was performed in the liquid phase (8) due to low volatility of the reagents. Derivatization reactions were conducted using several aliquots of 800 pmol – 1 nmol of material to ascertain reproducibility between samples and consistency of the methods. Derivatized materials were dissolved in acetonitrile to concentrations between 0.1 and 0.2 nmol/μL. Products were verified and characterized using MALDI-TOFMS under the conditions described below.

Mass spectrometry

LSIMS spectra were recorded with a JEOL HX110/HX110

Scheme 2. Fragmentation pathways of cerebrosides according to the nomenclature developed by Domon and Costello (12).



(E1B1-E2B2) tandem instrument operated at +10 kV accelerating voltage with −18 kV postacceleration at the detector. A JEOL cesium gun produced a primary beam of 15 keV Cs^+ ions. For acquisition of conventional mass spectra, the resolution was 1:3000 and the magnetic sector B1 was scanned at a rate of about 25 s/decade. The data system used was a MS-MP7000MD/MT (Complement, JEOL). Sample solutions of derivatized compounds (1 μL, 100–200 pmol) were mixed with 1 μL NBA on an LSIMS chilled probe that has been described in detail elsewhere (10). The use of this probe allowed stability of the signal over longer time ranges than a conventional LSIMS probe and thus the spectra presented here result from integration of at least 3 scans.

For collision-induced dissociation (CID) MS/MS experiments, 7 keV collisions were effected with helium in a cell located between E1B1 (MS1) and E2B2 (MS2). The pressure of helium employed was sufficient to reduce the abundance of the precursor beam to 40% of its original value. MS/MS spectra were obtained by B/E scans of MS2 at the rate of about 40 units/s. Both MS1 and MS2 were tuned for 1:1000 resolution.

MALDI-TOF mass spectra were recorded with a modified Vestec VT2000 (Vestec Corp., Houston, Tex.). A detailed description of this instrument, its optical system, and data processing system has been made elsewhere (6, 11). Desorption/ionization was accomplished using a nitrogen laser (Laser Science Inc., Newton, Mass.) with radiation at 337 nm. The sample (ca. 3 pmol, in 1 μL acetonitrile) was mixed with 1 μL of a 10 g/L solution of DHB matrix in water and applied to a polished metal surface, in order to create a sampling area of about 3 mm diameter. Ions were accelerated to +30 keV.

Results and discussion

The nomenclature system used here to describe fragmentation patterns of compounds **1** and **2** follows that developed by Domon and Costello (12) for GSLs. A few modifications were made to the nomenclature of long-chain cleavages with conservation of the charge on the nitrogen atom of the ceramide moiety (8) and are applied in this study. Scheme 2 summarizes the description of fragmentations according to this system. The prime (′) sign describes ions having lost one ROH molecule (water, methanol, acetic acid, benzoic acid, respectively, for native compounds; permethylated, peracetylated, and perbenzoylated derivatives). The double (″) and triple (‴) primes refer to loss of two and three ROH molecules, respectively. The slash (/) is employed to describe fragmentations occurring at more than one site.

A comparison of conventional LSIMS spectra was accomplished for native isomers and also for each type of derivative investigated in this study; any ion present in the conventional spectra and containing the hexosyl residue was investigated in more detail by CID MS/MS. Molecular ions $[M+H]^+$ were not studied since their $[M+H']^+$ homologs were generally more abundant in the LSIMS spectra and thus easier to characterize by MS/MS. The $[M+H']^+$ ions arise with loss of ROH from the ceramide moiety (8). These ions have fewer degrees of freedom than $[M+H]^+$ and stand a better chance of yielding information on the carbohydrate moieties and their structural differences.

Native isomers **1** and **2** produced very similar mass spectra, exhibiting $[M+H]^+$, $[M+H']^+$, Z_0, Z_0', and W'/C_1 ions. A list of these ions and associated relative abundances is presented in Table 1, Column A. A quantity of sample of 10 nmol was required in order to obtain spectra where, overall, presence of NBA matrix ions did not interfere in the interpretation and molecular weight information could be obtained without ambiguity. With the exception of $[M+H']^+$, fragment ions observed in these spectra did not contain the carbohydrate moieties of the molecules. MS/MS spectra of the latter species at *m/z* 682.5 were recorded (not shown), providing no information on glucosyl and galactosyl residues except ions at *m/z* 548, arising from $^{1,5}X_0$ cross-ring cleavages. Other ions observed are listed with their relative abundances in Table 2, Column A. The two spectra were so similar that they could not lead to any clear differentiation of isomers.

Permethylation of **1** and **2** allowed a sensitivity increase of an average factor of 75 under the same experimental conditions with either LSIMS or MALDI-TOFMS. Thus, for LSIMS analysis, it was possible to obtain informative spectra using 100 pmol of permethylated material; see Table 1, Column B, for more detail on fragmentation. Differences between the conventional spectra of permethylated **1** and **2** reside in the relative abundances of Z_0 and W'/C_1 ions versus the $[M+H]^+$ and $[M+H']^+$ species. However, these differences cannot easily relate to sugar structures since neither Z_0 or W'/C_1 ions contain hexosyl residues. B_1' ions also exhibit different relative abundances. We reported earlier (8) that highly unstable permethylated B_1 ions, which could be studied by MS/MS, decompose mainly by loss of one methanol molecule to form B_1' ions at *m/z* 187. According to Table 1, Column B, this decomposition occurs in the ion source to a greater extent for **2** than for **1**. The CID MS/MS spectrum of the B_1' species from **1** displayed in Fig. 1 is very similar to that obtained for **2** (not shown). Small differences occur, for instance, in the relative abundance of product ions at *m/z* 89 and 155. The similarity between the two spectra suggests that the B_1' precursors may have the same structure. It would be possible to obtain this common structure by elimination of methoxy in position 4 (and H in 5) as illustrated in Scheme 3, center line. Loss of a methanol molecule originating from positions 4 and 5 of the B_1' sugar ring would indicate that, whether *cis* or *trans*, the elimination would proceed preferentially from sites 4 and 5 to form a conjugated double bond system. If this hypothesis holds and B_1' ions of **1** and **2** are identical, then *m/z* 187.1 ions generated from permethylated manno-cerebroside should have a different structure because of the orientation of the methoxy in position 2. As no

[b]The calculated *m/z* appear in parentheses; the experimental *m/z* values were within 0.05% of calculated values.

Abbreviations: perMe = permethylated, PerAc = peracetylated, PerBz (Anh) = perbenzoylated with benzoic anhydride, PerBz(Cl) = perbenzoylated with benzoyl chloride.

manno-cerebroside was available for comparison, B_1'-equivalent (*m/z* 187.1) ions were generated from PME monosaccharides glucose, galactose, and mannose. The $[M+H'']^+$ ions were used as precursors for this purpose. Domon et al. have recently shown that loss of methanol from PME monosaccharides occurs in position 1 (13). This suggests that B_1'' ions from PME **1** and **2**, as well as $[M+H'']^+$ ions from PME galactose and glucose, are formed from similar precursors at *m/z* 219, as illustrated in the top portion of Scheme 3. Unimolecular dissociation MS/MS spectra of the $[M+H'']^+$ ions of PME glucose, galactose, and mannose were recorded. PME glucose and mannose produced very similar spectra while the spectrum of PME galactose showed some minor differences, which were more accentuated than in the case of the B_1' ions of **1** and **2**. These results suggest similar structures for the $[M+H'']^+$ ions of glucose and mannose, which would be possible with elimination of methoxy from position 2 (and H from 3) as shown in the bottom portion of Scheme 3. If the same 2,3-elimination occurred from the $[M+H']^+$ ring of galactose, the resulting $[M+H'']^+$ ion would be structurally different. To summarize, it was difficult to draw structural information from the CID MS/MS spectra of the B_1' ions of PME **1** and **2**. Similar CID MS/

[a]Relative abundances vs. W'/C_1.

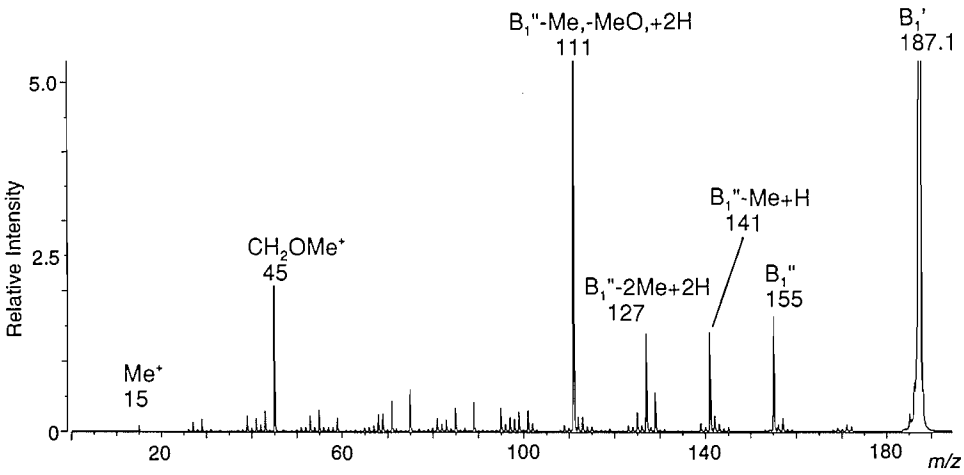
[b]The calculated *m/z* values appear in parentheses; the experimental values were measured as nominal.

Abbreviations: PerMe, PerAc, PerBz (Anh/Cl): see footnote of Table 1.

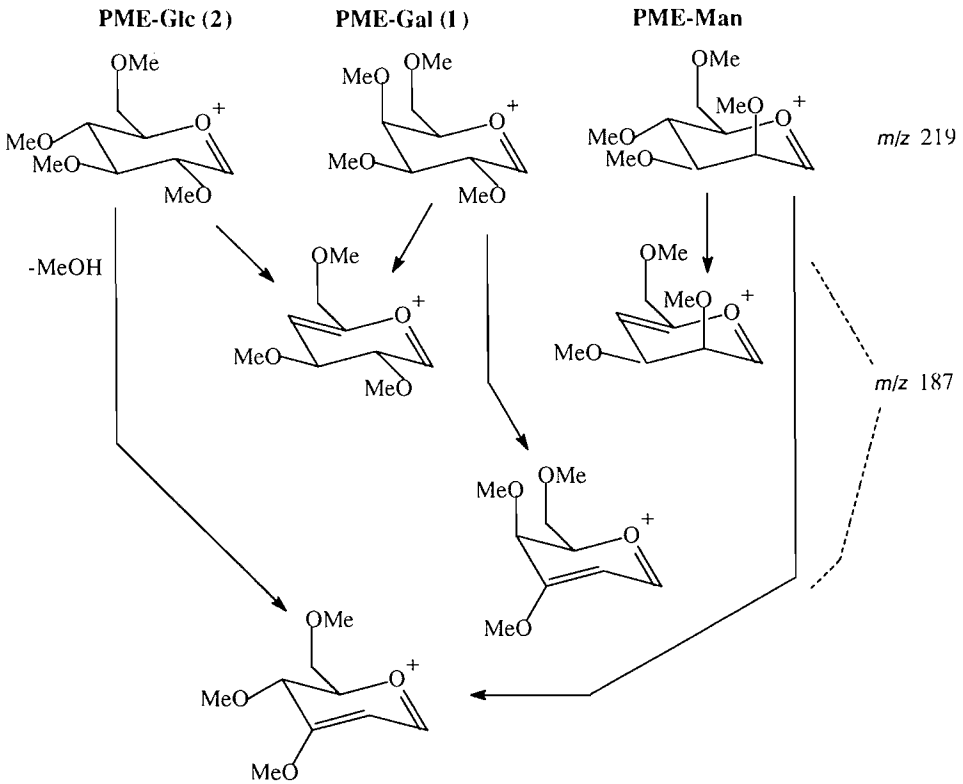
MS spectra as these could lead to false conclusions since they are easily linked to similar structures. In cases of doubt, unimolecular dissociation MS/MS spectra can yield more accurate information on the nature of a permethylated monosaccharide moiety than can CID MS/MS spectra.

Table 2, Column B enumerates the CID product ions

Fig. 1. CID MS/MS spectrum of B_1' ions generated from permethylated **1**. An almost identical spectrum was obtained for B_1' ions of **2**. The intensities are reported relative to the precursor ions (*m/z* 187.1).

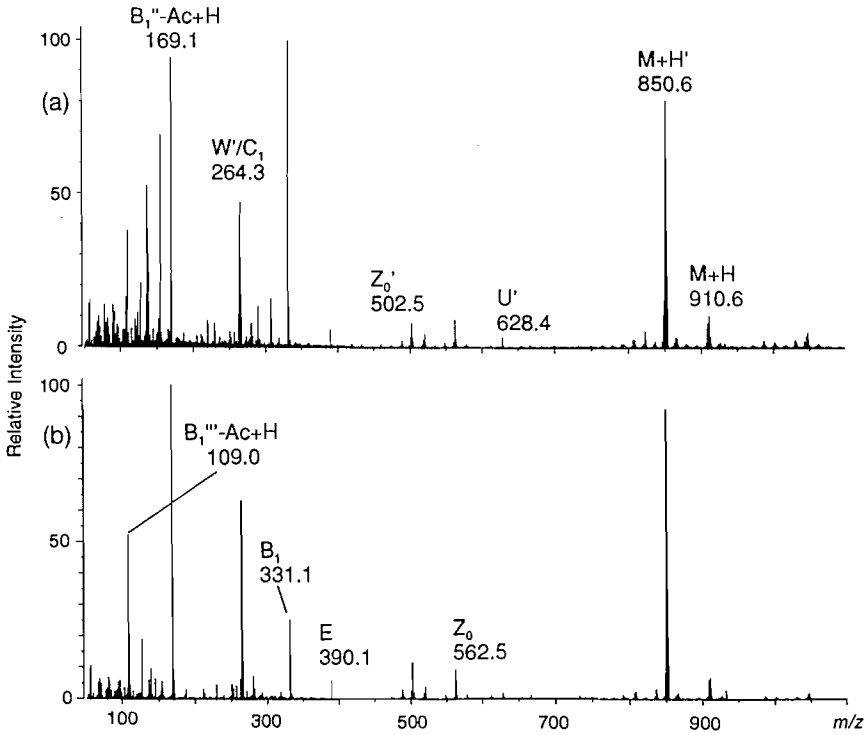


Scheme 3. Speculative model for loss of methanol from B_1 ions of permethylated **1** and **2** and $[M+H']^+$ ions of permethylated galactose, glucose, and mannose. Top line: *m/z* 219 precursors to *m/z* 187 ions. Middle line: unique structure proposed for the B_1' ions of glycosyl- and galactosyl-cerebrosides, suggested by MS/MS CID results; on the right, speculative structure of the B_1' ion of mannosyl-cerebroside. Bottom line: proposed structures for the $[M+H'']^+$ ions of permethylated glucose, galactose, and mannose as suggested by the unimolecular dissociation MS/MS results.

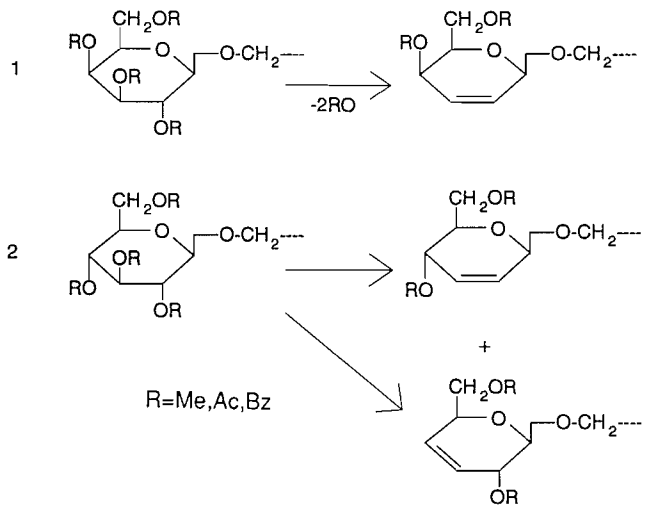


obtained for $[M+H']^+$ precursors of **1** and **2** and their relative abundances in the MS/MS spectra. Most ions observed in these spectra (not shown) were not associated with the isomeric portion of the precursors. Some major differences in relative abundances are observed for $[^{1,5}X_0']$ and $[C_1,C_2]_b'$, which are all produced from cleavages or eliminations in the vicinity of the isomeric center. One interesting species here is $[M+H'-2RO]$, which is more abundant when generated from

Fig. 2. LSIMS spectra of peracetylated (*a*) **1** and (*b*) **2**.



Scheme 4. Speculative model of loss of two RO radicals (R = methyl acetyl, benzoyl) by means of *trans*-elimination.



a glucosyl residue. According to Scheme 4, elimination of two RO radicals could be favored for **2**, providing more possible ways of undergoing *trans*-elimination to form a double bond (in either position 2 or 3). On the other hand, compound **1** bears only one possible site for such elimination of the radicals.

To summarize, permethylated cerebrosides yielded, under the experimental conditions employed in this study, restricted information relative to isomer recognition of species that differ in the sugar moieties. In conventional LSIMS spectra, the relative abundance of *m/z* 187 (B_1') ions can be an indicator for isomeric discrimination. However, permethylated GSLs are more useful in yielding molecular weight information on very small quantities of sample, and most abundant fragment ions are related to the ceramide moiety. Hence, permethylated GSLs can play a major role in differentiation of glycosphingolipid species with isomeric ceramides (14).

Peracetylated derivatives were the next investigated for their usefulness toward isomer discrimination. They yielded sensitivity improvement over native species comparable to that of permethylated derivatives. The conventional LSIMS spectra of **1** and **2** are shown in Fig. 2. The most distinct difference between them lies in the relative abundances of B_1 ions at *m/z* 331.1. In addition, $[M+H']^+$ species resulting from loss of acetic acid from the protonated molecular ions are more abundant for **2** than for **1**; production of U and W'/C_1 ions at *m/z* 628.4 and 264.3, respectively, is also observed to different extent for the two isomers. Column C of Table 1 gives an overview of these data. CID MS/MS experiments were conducted on precursors B_1 and $[M+H']^+$ and the corresponding spectra are displayed in Figs. 3 and 4, respectively. Peracetylated B_1 ions formed from oligosaccharides and generated by FAB or LSIMS have been studied in the past, in view of their fragmentation behaviour under CID MS/MS conditions (15, 16). The B_1 ions generated from cerebrosides in this study produced qualitatively the same fragmentation patterns as B_1 from oligosaccharides and Fig. 3 shows that relative abundances in their MS/MS spectra vary from one isomer to the other. The most significant difference is production of more abundant B_1' ions (*m/z* 271) from **2** than from **1**, a trend that was also observed by Guevremont and Wright (15). In that study, the differences between the CID spectra of peracetylated glucose and galactose were attributed to the differ-

[a]Relative abundances vs. B_1''–R,+H, ±5%.

[b]The *m/z* values in parentheses are the calculated monoisotopic values; the measured values were nominal and matched the values given above.

ence in the tertiary structures of B_1' ions. In the structures proposed (15), acetate is lost in position 3, forming a conjugated system with two double bonds in 1 and 3 instead of 1 and 5 for "identical" species. Reactivity of B_1' ions was attributed to extent of interaction between acetyl groups in concerted loss of ketene plus acetic acid (*m/z* 109, 169), and was different for the two B_1' isomers. Differences in relative abundances are also noticeable for *m/z* 109, 127, 259, and 289 ions. These

ions also appear in the conventional spectra of Fig. 2; however, matrix ions interfere with spectral interpretation with respect to relative ionic abundances, and its is necessary to perform MS/MS experiments in order to eliminate these interferences. Overall MS/MS results for B_1 species are summarized in Column A of Table 3. In Fig. 4, the CID MS/MS spectra of $[M+H']^+$ species of both peracetylated compounds (*m/z* 850.6) appear relatively similar at first observation. For **1** the relative abundance of B_1 ions (*m/z* 331) equals that of *m/z* 332 ions. Compound **2** produces lower abundance B_1 ions, leaving species at *m/z* 332 dominant. The latter ions have been interpreted as $W'/[C_5,C_6]_b$. This region of the spectra is shown with more detail on the figure.

Higher rates of B_1 cleavages for galacto- and than for glucocerebroside cannot be explained by lower extent of hydrogen bonding between the isomeric RO group in position 4 on the sugar ring and portions of the ceramides, since three-dimensional structures of both isomers (see Scheme 1 for reference) show the opposite trend. Relative reactivities of B_1 ions thus have to be invoked and can be related to extent of interaction between acetyl functions substituted on the rings. Other product ions of interest featuring in Fig. 2*b* are $^{1,5}X_0'$, resulting from cross-ring cleavages, and also $[C_1,C_2]_b'$, Z_0', $[C_3,C_4]_a$, and W'/C_1, the dominant species. Aromatic ions related to hexose groups are also observed, however, with similar relative abundances for the two isomers. The loss of two RO radicals from the sugar ring occurs to a larger extent for **2** than for **1**, as observed and discussed above for permethylated $[M+H']^+$ ions. In summary, it is possible to distinguish peracetylated compounds **1** and **2** by MS and MS/MS, owing to more facile production of B_1 ions in one case than the other, differences in the dissociation patterns of these B_1 ions, and other minor differences between the MS/MS spectra of isomeric precursor ions. Perbenzoylated derivatives of **1** and **2** prepared using benzoic anhydride were also investigated in this study. These compounds, like their peracetylated analogs, bear only five acetyl groups since the amide function is not modified upon derivatization. Qualitative aspects of their LSIMS conventional spectra have been discussed elsewhere (8) and fragmentation is summarized in Column D of Table 1. Figure 5 allows a comparison of the spectra obtained for perbenzoylated **1** and **2**. Protonated molecular ions $[M+H]^+$ (M+H on figure) are not clearly defined and form clusters along with other ions, among which they are the most abundant. Identification of the species is possible in light of $[M+H']^+$ species (M+H′ on figure, *m/z* 1098.7). U ions are not present in the spectra and, instead, formation of $[M+H']^+$ and Z_0 ions is observed. It is possible to distinguish one spectrum from another in view of the relative abundances of B_1 ions at *m/z* 579.2. As observed with peracetylated derivatives, their formation is more favored for **1** than for **2**. The CID MS/MS spectra of these isomeric B_1 ions are compared in Fig. 6. Qualitatively, the same ions are observed in both spectra, however, with different relative abundances. The relative abundances of the ions at *m/z* 335 and 231 are reversed from one spectrum to the other. Other more subtle variations are also observed, such as the presence of ions at *m/z* 311 for **1** and not for **2**, which rather produces ions at *m/z* 323. Collision-induced dissociation pathways observed in Fig. 6 are similar to those observed for peracetylated **1** and **2** (Fig. 3), in that they involve losses of ROH, losses of R with proton transfer (−R,+H), and losses of other ester-related species. Product ions from cross-ring cleavages, $^{1,5}X_0$, are observed for both types of derivatives. CID MS/MS experiments were also performed to study $[M + H']^+$ ions (*m/z* 1098.7) of perbenzoylated **1** and **2** since they are the only other species in the conventional spectra (Fig. 5) to contain the sugar moieties. Ions whose relative abundances are above 0.5% are listed in Column D of Table 2. Although the two spectra were almost identical, production of B_1 ions was still more accentuated for **1** than for **2** and interesting structural information could be obtained through W'/C_1, $[C_1,C_2]_b$, Z_0', $^{1,5}X_0'$, B_1, and $[C_2,C_3]_a$ ions among others. Compounds **1** and **2** perbenzoylated in the bulk phase with benzoic anhydride can thus be distinguished, mainly owing to the relative abundances of B_1 ions and the CID MS/MS fragmentation patterns.

Figure 7 shows the LSIMS conventional spectra obtained for **1** and **2**, perbenzoylated in the gas phase using benzoyl chloride. These compounds bear six benzoyl groups instead of five as in the two last types of derivatives discussed. Almost no intact molecular ions are produced and instead $[M + H']^+$ species are observed. The spectra are dominated by abundant W′, B_1, Z_0'−Bz,+H, B_1''−Bz,+H, and Bz+ ions, as listed in Table 1, Column E. Metastable formation of W′ ions, which are unique to spectra of such perbenzoylated GSLs (8), gives rise to a broad ion peak at apparent *m/z* 774, which in fact corresponds to $964.5^2/1202.7$. Obvious differences between the two spectra of Fig. 7 reside in the relative abundances of $[M+H']^+$, W′, and B_1 ions. Formation of B_1 is favored for **1** relative to **2**, following the same trend as observed for peracetylated derivatives and compounds perbenzoylated with benzoic anhydride, while more extensive production of W′ ions is observed for **2** than for **1**. The CID MS/MS spectra of W′ ions (*m/z* 964.5) are shown in Fig. 8. W′ ions constitute the products of the main fragmentation pathway of molecular species $[M+H']^+$, and are also, when collided with helium, precursors of several significant ions, some of which also appear in the conventional spectra of Fig. 7. Relative abundances of W'/C_1 and B_1 ions follow the same tendency as observed in Fig. 7, i.e., the ratio B_1: W'/C_1 decreases from **1** to **2**. Besides Bz^+ species, predominant ions in the spectra feature, among others, for example, $W'/[C_1,C_2]_b$ species, which are formed in preference to W'/C_1 ions. Rupture of the $[C_1,C_2]_b$ bond appears to be favored with benzoylated compounds, as was also observed with the *m/z* 488 product ions in Fig. 4 (peracetylated derivatives). In the proposed structure of W′ shown in Scheme 5, there is a double bond in $[C_2,C_3]_b$ that appears to trigger cleavage of the $[C_1,C_2]_b$ bond with proton transfer to the carbohydrate moiety. A structure for $W'/[C_1,C_2]_b$ is proposed, also in Scheme 4. In Fig. 8, loss of a benzoic acid moiety (W″, *m/z* 842) and of two benzoate groups (W′−2BzO, *m/z* 722) must originate from the sugar ring, since no other benzoate moiety is present on the ceramide portion of W′, and must form a double bond in the ring as illustrated above the Scheme 5. Two ion peaks resulting from cross-ring cleavage are observed. At *m/z* 414, $W'/^{1,5}X_0$ is present in both spectra whereas $W'/^{0,2}X_0$ at *m/z* 410 is relatively more abundant for **1** than for **2**, and carbohydrate-related ions at *m/z* 231 and 335 are relatively more abundant for **2** than **1**. This last trend suggests a greater reactivity in the case of benzoylated glucose, which could be at the origin of the low abundance of B_1 ions in the conventional and MS/MS spectra. Another low

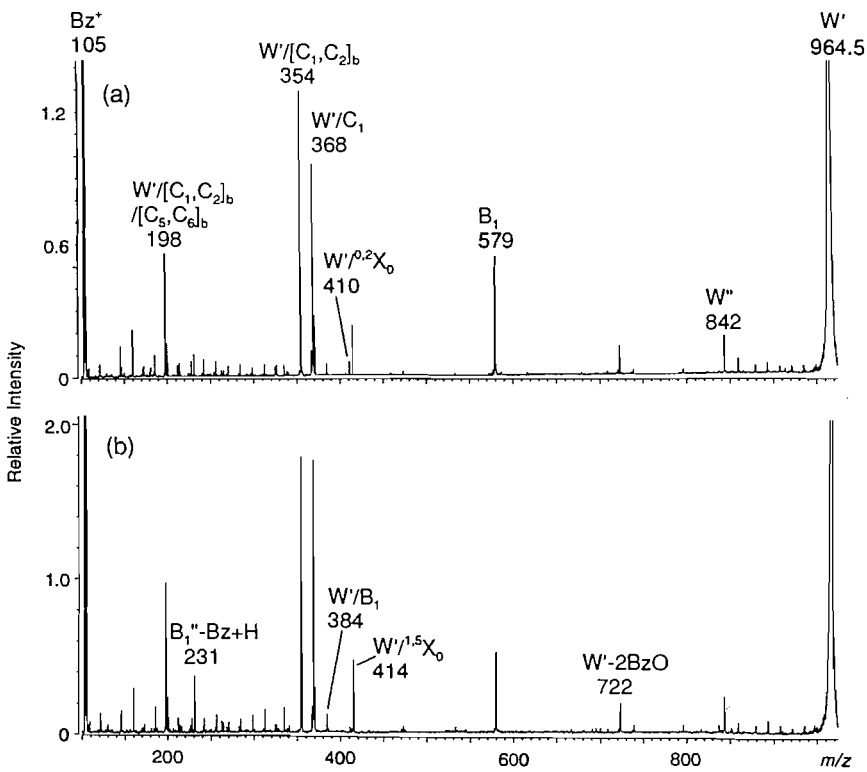
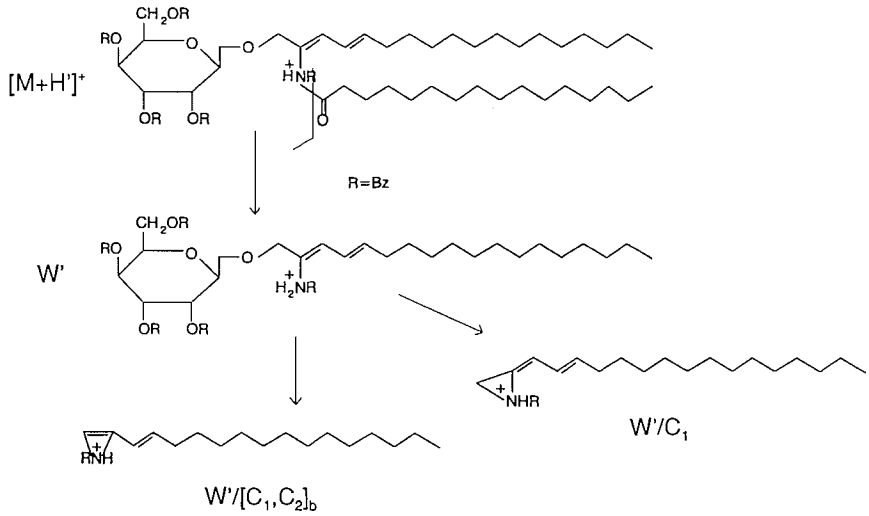


Scheme 5. Proposed structures for $[M+H']^+$, W', W'/C_1, and W'/$[C_1,C_2]_b$ ions generated from **1** and **2**, perbenzoylated using benzoyl chloride.



mass ion peak (*m/z* 198) results from Z_0 and $[C_6,C_7]_b$ cleavages, β to the double bond. These spectra are as informative as the CID MS/MS spectra of [M+H'] species (not shown). The latter produced the ions listed in Column E of Table 2. Differences in the relative abundances of B_1 ions still constitute the main insight to isomer recognition. There is an inversion in the abundances of W' and W'/C_1 that could be attributed to relative stabilities of these W-type ions with and without the isomeric hexosyl residue attached. A new type of fragment is observed at *m/z* 500, and can be interpreted by two different structures; the first corresponds to $Z_0'-Bz,-H$ (Z_0 − 106), and the other to Y_0' ions generated by $[M+H']^+$ ions having lost a benzoic acid molecule from the sugar ring instead of from position 2 of sphingosine. However, there is no evidence in the spectra that such precursors exist. The appearance of these unusual *m/z* 500 ions may to be due to a concerted elimination of hexose and benzaldehyde from the [M+H'] species, or to loss of benzaldehyde from Z_0'.

In brief, cerebrosides bearing six benzoyl groups yield interesting and informative fragmentation patterns and also allow a certain extent of isomeric comparison through observation of variations in the relative abundances of B_1 ions in LSIMS spectra and in the CID MS/MS spectra of W' and $[M+H']^+$ ions.

Conclusion

It is possible to make a distinction between galactosyl and glucosyl ceramides by mass spectrometry, provided a judicious choice of derivatization methods and ionization techniques is made. A certain degree of discrimination is obtained with permethylated derivatives; however, peracetylated and perbenzoylated compounds allow the most differences to appear in the mass spectra of cerebroside isomers. Ions whose formation is directly related to the carbohydrate structure are observed with different relative abundances, either in conventional spectra or CID MS/MS spectra of sugar-containing precursor ions. Since cerebrosides most commonly occur as galactosylated or glucosylated species, the study has not been extended to compounds with other types of hexosidyl residues, such as mannose or allose. The relative abundances of ions observed in this study may vary with the type of mass spectrometer used, due amongst other factors to the time frame of the instrument, energy of collisions in CID, and type of detection used. This type of study should be conducted with reference compounds in order to ascertain the relationship between isomeric form and abundance of the ions. It can also be extended to isomeric discrimination of larger GSL, by studying their B_n ions and related species by conventional mass spectrometry and MS/MS (16, 17). For simple GSL molecules such as cerebrosides, this study revealed that derivatization with benzoyl chloride amongst other techniques used yields the most informative MS and MS/MS spectra for general structural information and discrimination between the galactosyl and glucosyl ceramide isomers. Moreover, these derivatives are strongly UV-absorbent, which allows detection of very small amounts of material in chromatographic and electrophoretic separation techniques.

Zirconium complexes of a cyclopentadienyl-amido ligand with a pendant amine donor via amine and alkane elimination

Ying Mu, Warren E. Piers, Donald C. MacQuarrie, and Michael J. Zaworotko

Abstract: Zirconium complexes of the multidentate ligand $CpH^{NMe}SiN(H)R$ (SiNR = -$SiMe_2$N-*t*-butyl; NMe = -$CH_2CH_2NMe_2$, **1**) were prepared and characterized via amine and alkane elimination procedures. Reaction of **1** with $Zr(NMe_2)_4$ gave a mixture of bis-amido complexes **2** in which the ligand was 1,2 and 1,3 substituted. This mixture was converted to the analogous dichlorides **3** using $Me_2NH{\cdot}HCl$ and 1,3-**3** was purified at this stage; alternatively, 1,3-**3** was obtained in one pot from **1** and $Zr(NMe_2)_4$ in ≈70% yield. Conversion of 1,3-**3** to dimethyl compound $(Cp^{NMe}SiNR)Zr(CH_3)_2$, 1,3-**4**, was accomplished via reaction of the dichloride with methyllithium; methide abstraction with the Lewis acids $B(C_6F_5)_3$ and $[Ph_3C]^+[B(C_6F_5)_4]^-$ generated the cationic alkyls $[(Cp^{NMe}SiNR)Zr(CH_3)]^+[R'B(C_6F_5)_3]^-$ (R′ = CH_3, **6a**; C_6F_5, **6b**), which were characterized by NMR spectroscopy. Zirconium complexes containing **1** ligated as its 1,2 isomer were obtained from alkane elimination reactions between **1** and in situ prepared R_nZrCl_{4-n} (R = CH_3, n = 3; R = CH_2SiMe_3, n = 2). 1,2-**3** and the methyl chloride complex 1,2-$(Cp^{NMe}SiNR)Zr(CH_3)Cl$, **5**, were obtained in 18 and 30% yield, respectively. Complex **5** was characterized by X-ray crystallography (monoclinic, space group $P2_1/a$, a = 9.6951(10) Å, b = 14.3794(16) Å, c = 14.364(3) Å, V = 1990.3(5) Å^3, Z = 4, R = 0.046, R_w = 0.041.)

Key words: amine elimination, Cp-amido, zirconium complexes.

Résumé : On a préparé les complexes de zirconium du ligand multidentate $CpH^{NMe}SiN(H)R$ (SINR = -$SiMe_2$N-*t*-butyl; NME = -$CH_2CH_2NME_2$, **1**), et on les a caractérisés via les procédés d'élimination d'amine et d'alcane. La réaction du composé **1** avec le $Zr(NMe_2)_4$ donne un mélange de complexes bis-amido dans lequel le ligand est substitué en 1,2 et 1,3. On a transformé le mélange en dichlorures correspondants **3** en utilisant le $Me_2NH{\cdot}HCl$ et on a purifié à ce stade le composé 1,3-**3**. On a obtenu alternativement le composé 1,2-**3** dans un seul récipient à partir du composé **1** et du $Zr(NMe_2)_4$ avec un rendement de 70%. On a transformé le composé 1,3-**3** en composé diméthylé $(Cp^{NMe}SiNR)Zr(CH_3)_2$ via la réaction du dichlorure avec le méthyllithium; l'abstraction d'un méthylure par un acide de Lewis $B(C_6F_5)_3$ et par $[Ph_3C]^+[B(C_6F_5)_4]^-$ a généré les alkyles cationiques $[Cp^{NMe}SiNR)Zr(CH_3]^+[R'B(C_6F_5)_3]^-$ (R′ = CH_3, **6a**; C_6F_5, **6b**) que l'on a caractérisés par la spectroscopie de RMN. Les complexes de zirconium contenant le composé **1** lié comme son isomère 1,2 sont obtenus à partir d'une réaction d'élimination d'alcane entre le composé **1** et le R_nZrCl_{4-n} (R = CH_3, n = 3; R = CH_2SiMe_3, n = 2) préparé in situ. Introduction

The impact of metallocene-based catalyst technology on the polyolefin industry has been substantial in the past five years and continues to expand (1). Deployment of these catalysts on an industrial scale has necessitated the synthesis of complex (and temperamental!) organometallic compounds on a multi-kilogram scale, a non-trivial technological achievement and one that continues to be developed by a number of specialty chemical companies. New methods for ligand attachment are thus of considerable current interest.

Traditional methodology for attaching cyclopentadienyl, *ansa*-type bis-cyclopentadienyl and constrained geometry cyclopentadienyl-amido type ligands, involves generation of a group 1 or 2 metal salt of the ligand, followed by a salt elimination reaction with a suitable group 3 or 4 metal halide. Although this strategy undeniably works for the majority of catalyst targets, it suffers from some disadvantages. In some instances, the dimetal salt of the desired ligand is unstable or formed in low yields. This is particularly the case for Cp-amido type ligands, which may be prone to Si–N bond cleav-

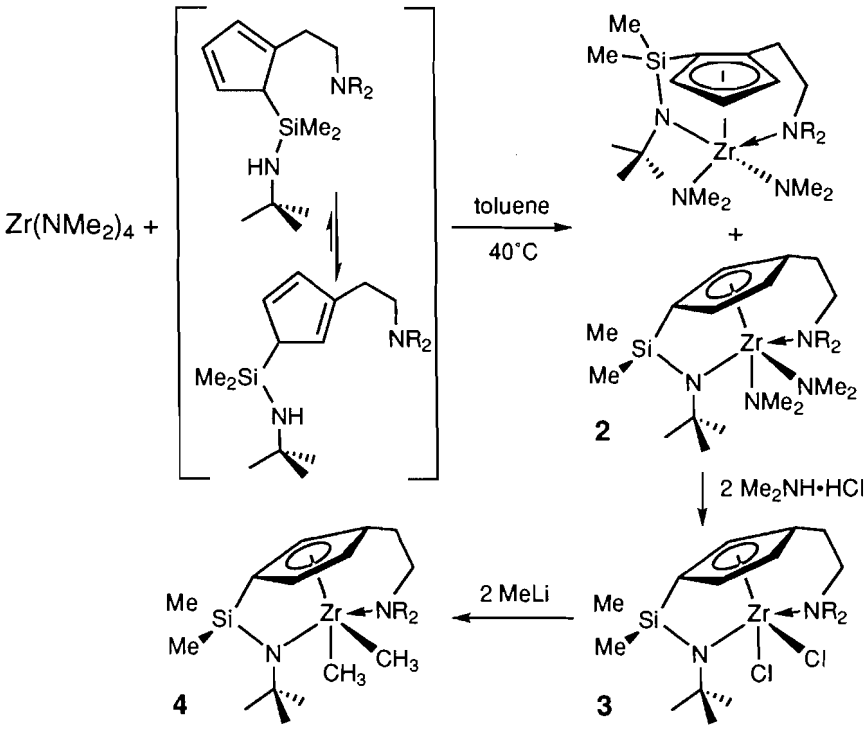
Scheme 1.



age upon treatment with alkyllithium deprotonating agents. The subsequent reaction with transtion metal halides is sensitive to several variables in reaction conditions, such as temperature, the concentration of donor solvents, and the nature of the group 1 or 2 metal employed. Thus, specific conditions are required for attachment of different ligands where more general procedures would be desirable. Finally, the eliminated salts MX_n are sometimes difficult to remove completely from the products.

To alleviate these problems, alternative strategies for ligand attachment have recently been reported. Taking a cue from some chemistry reported in the 60s by Chandra and Lappert (2), Teuben and co-workers (3) used amine elimination rather than salt elimination as a means to coordinate Cp-amido type ligands to group 4 metals. Other examples (4) of this method of ligand attachment have been reported since then, the most significant being the synthesis by Jordan and co-workers of *rac*-(EBTHI)$Zr(NMe_2)_2$ via reaction between diproteo ethylenebis(tetrahydroindenyl) and $Zr(NMe_2)_4$ (5). In a nice exhibition of synthetic ingenuity, the eliminated amine was allowed to remain in the reaction long enough to convert the kinetic products of the reaction to the thermodynamic (and desired) racemic product thus circumventing the problem of having to separate out the *meso* isomer.

While amine elimination is a promising method, potential problems associated with complete removal of eliminated amine persist. We have thus recently begun to examine alkane elimination as an alternative to the salt or amine elimination strategies described above. Although some examples of alkane elimination have been reported (6), this method has not been widely explored, perhaps because homoleptic alkyl complexes of early transition metals are somewhat unstable (7). We found that attachment of the tridentate Cp-amido ligand 1,3-$CpH^{NMe}SiN(H)R$ (SiNR = -$SiMe_2N$-*t*-butyl; NMe = -$CH_2CH_2NMe_2$, **1**) to scandium via alkane elimination from in situ generated $Sc(CH_2SiMe_3)_3$·2THF was facile (8). In this paper, we describe the synthesis of organozirconium derivatives of **1** via both amine and alkane elimination.

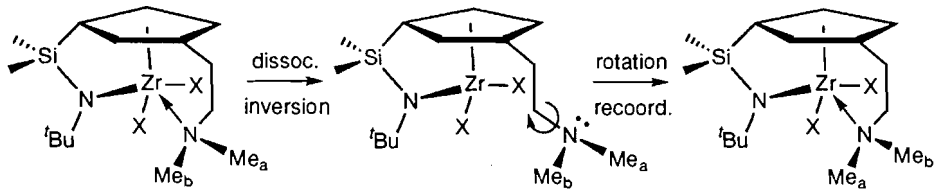
Results and discussion

Ligand attachment via amine elimination

The ligand **1** was prepared as described in detail previously (8). ^1H NMR spectra of these ligands are complex due to the presence of two isomers arising from 1,5-silatropic shifts (9) (Scheme 1) as well as various isomers of both 1,3 and 1,2 substitution arising from 1,2 prototropic shifts (10) (not shown in the scheme). For **1**, the ratio of 1,3:1,2 isomers was determined to be ≈7:3. Ligand **1** was found to be sensitive to heat and moisture, precluding purification by distillation or column chromatography. In addition, attempted deprotonation with the usual reagents (*n*-BuLi, KH, i-PrMgBr) did not lead to pure salts of the ligands, preventing the use of traditional salt elimination reactions for ligand attachment.

The rate of interconversion of the substitutional isomers, as well as the rates of reaction for each of the isomers with deprotonating agents, will dictate which isomer will bind to a metal. In scandium complexes of **1**, the 1,3 isomer attached almost exclusively. In contrast, the 1,2 isomer was active to a degree in amine elimination reactions between **1** and $Zr(NMe_2)_4$; this chemistry is summarized in Scheme 1. The bis-amide derivatives 1,2-**2** and 1,3-**2** were formed in a ≈1:9 ratio as an orange oil and were inseparable. Conversion of the bis-amides to the analogous dichlorides was carried out using Me_2NH·HCl (3). At this stage, the 1,3 isomer of **3** could be purified by recrystallization, since the dichlorides were white crystalline solids.

Scheme 2.



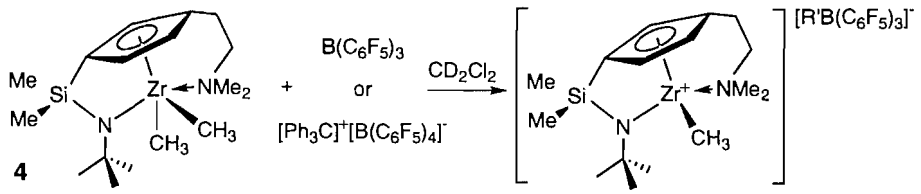
Complete removal of dimethylamine was affected by heating the crude solid product under dynamic vacuum for a brief period. Alkylation of the dichloride 1,3-(Cp^{NMe}SiNR)$ZrCl_2$ with methyllithium proceeded smoothly to yield 1,3-(Cp^{NMe}SiNR)$Zr(CH_3)_2$, 1,3-**4**.

Since the bis-amido complexes **2** were not readily purified, the stepwise procedure from $Zr(NMe_2)_4$ dichloride 1,3-**3** was adapted to a "one-pot" process that dispensed with isolation of the amido intermediates (see Experimental). Yields of 1,3-(Cp^{NMe}SiNR)$ZrCl_2$ from $Zr(NMe_2)_4$ and diproteo ligand **1** were in the 65–75% range and, by ^1H NMR spectroscopy, contained < 2% isomeric 1,2-**3**.

Table 1 gives ^1H and $^{13}C\{^1H\}$ NMR data for new, isolated compounds. The geometry about the zirconium center in these complexes cannot be deduced from this data. We presume, based on models and the solid state structure of the scandium hydride dimer [(Cp^{NMe}SiNR)ScH]$_2$ (8), that an approximately trigonal bypyramidal geometry is present. Because of the planar chirality associated with the unsymmetrical disubstitution of the Cp ring, groups with the same connectivity are diastereotopic in complexes 1,3-**2**, **3**, and **4**, with the exception of the N-methyl groups on the pendant amine arm of the ligand. In each case, a single resonance for these groups was observed in both the ^1H and the $^{13}C\{^1H\}$ NMR spectra at room temperature. This suggests that the amine is either not coordinated to zirconium in these complexes, or undergoes a rapid equilibration process on the NMR time scale. Since the amine arm of the 1,3-substituted ligand does coordinate in related scandium complexes, we favor the latter explanation; a plausible process which exchanges the N-methyl groups (but not the other diastereotopic groups in the molecule) is shown in Scheme 2. Dissociation of the amine, followed by inversion at nitrogen (a low barrier process) (11), bond rotation about C—N, and recoordination of the amine exchanges the N methyl groups.

Since amine dissociation is likely a chemically significant process in these compounds, it is perhaps surprising that dimethyl complex 1,3-**4** reacts rapidly with the Lewis acid activators $B(C_6F_5)_3$ and $[Ph_3C]^+[B(C_6F_5)_4]^-$ to effect methide abstraction (12) and produce the cationic alkyls [(Cp^{NMe}SiNR)$Zr(CH_3)]^+[R'B(C_6F_5)_3]^-$ (R' = CH_3, **6a**; C_6F_5, **6b**) as shown in eq. [1]. Cations **6a** and **6b** are isoelectronic with the neutral scandium alkyl derivative supported by 1,3-**1**, which we

[1]



4 **6a, b**

recently reported (8). The chemical shift for the zirconium methyl groups (0.56 and 0.57 ppm for **6a** and **6b**, respectively) are characteristic of cationic zirconium methyl groups (13); other ligand signals also shift downfield relative to those in **4** as a consequence of bonding to the more electropositive zirconium center. Interestingly, only one diastereomeric cation is produced, suggesting that either one of the two diastereotopic methyl groups was abstracted preferentially or that the resulting methyl cation mixture rapidly isomerizes to one diastereomer.

The cations **6a** and **6b** were stable for a few hours in CD_2Cl_2 before decomposition became apparent. The NMR tube scale reactions were quite clean but attempts to isolate these compounds in preparative scale reactions led to oily materials with complex NMR spectra. Since neither **3** nor **4** exhibited significant activity towards propene polymerization upon activation with MAO,[3] the chemistry of these cations was not pursued further.

Ligand attachment via alkane elimination

Our success in the use of alkane elimination protocols for generation of organoscandium complexes led us to develop procedures for ligand attachment to zirconium via this strategy. In the reactions we explored, the zirconium-containing products isolated incorporated ligand **1** as its 1,2-substituted isomer. In situ generated R_nZrCl_{4-n} (R = CH_3, n = 3; R = CH_2SiMe_3, n = 2) was allowed to react with the diproteo ligand **1** as a mixture of its 1,2 and 1,3 substituted isomers. Yields of pure products were quite low and 1,3 products were observed only as minor components of the crude product mixture. These poor yields may be a reflection of the thermal instability of the in situ generated zirconium alkyls; for example, when solutions of the methyl reagent were allowed to warm to temperatures above 0°C, discolouration ensued as the reagent decomposed. It is unclear why the 1,2 isomer of the ligand **1** appears to react faster with these zirconium alkyls than the 1,3 substituted species.

Compounds 1,2-**3** and **5** were identified by their distinct

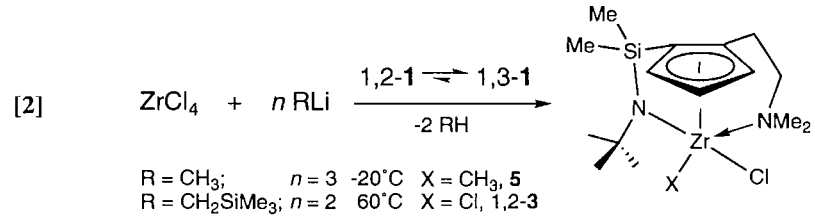

Fig. 1. ORTEP drawing of 1,2-($Cp^{NMe}SiNR$)$Zr(CH_3)Cl$, **5**.

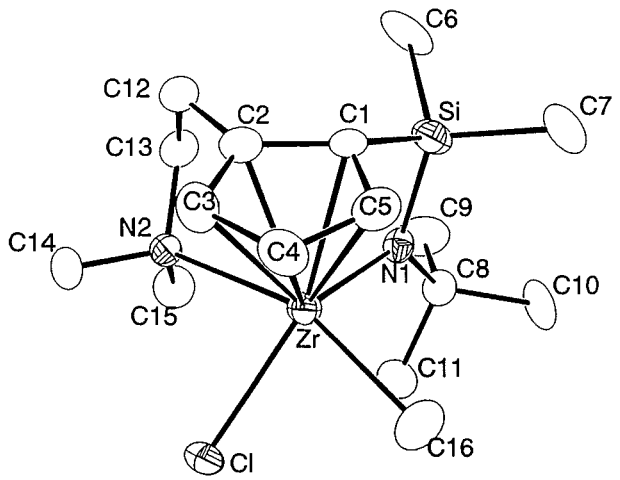

NMR spectra and by an X-ray structural determination of methyl chloride **5**. An ORTEP diagram of the molecular structure of **5** is shown in Fig. 1 and crystal data, atomic coordinates, and selected metrical data are given in Tables 2–4, respectively. If the centroid of the cyclopentadienyl donor is viewed as occupying one coordination site, the geometry about zirconium in this complex is closest to being square pyramidal, although the chlorine ligand tilts ≈25–30° out of the basal plane. This geometry is favoured by the 1,2 substitution on the cyclopentadienyl ring since the N1-Zr-N2 angle is 91.98(23)° compared to N_{amido}-Sc-N_{amine} angles of 111.74(17)° and 116.41(12)° in approximately trigonal-bipyramidal scandium complexes of 1,3-**1**. No disorder between the chloride and the methyl ligands was observed, nor was there any spectroscopic evidence for an isomer of **5** in which these ligands exchange positions.

The zirconium chlorine (14) and zirconium carbon (15) bonds in **5** are comparable to analogous bonds in Cp_2ZrX_2 compounds. The Zr—N_{amide} distance of 2.078(6) Å is much shorter than the Zr—N_{amine} length of 2.603(7) Å. While the former is within the expected range (2.00–2.08 Å) for zirconium amido nitrogen bond lengths (16), the latter is longer than normal (cf. the Zr—N distance of 2.434(3) Å in (η^8-COT)(η^4-COT)$Zr(NH_3)$ (17) and 2.421(9) Å in a zirconium complex containing a pendant pyrrolidine donor (4a)). This is suggestive of a very weak donor bond between zirconium and the amine ligand and is consistent with the observed equilibration of the diastereotopic N-methyl groups via the process given above in Scheme 2.

In conclusion, amine elimination is an effective means of attaching the tridentate ligand $Cp(H)^{NMe}SiN(H)R$ to zirconium, yielding predominately complexes of the 1,3 isomer of the ligand. On the other hand, the products isolated from the alkane elimination reactions are 1,2-isomer ligated complexes. The poor yields of the latter reactions suggest that more well-defined and stable alkane derivatives of zirconium may be required to improve efficiency.

Experimental

General

General techniques, drying of solvents, and analytical tools employed were as described previously (4*a*). All materials were purchased from Aldrich and used as recieved or purified by standard procedures (18). $Zr(NMe_2)_4$ (19), $B(C_6F_5)_3$ (20), and $Ph_3CB(C_6F_5)_4$ (21) were synthesized according to published procedures. Microanalytical data were obtained from Oneida Research Services, Inc., One Halsey Road, Whitesboro, NY 13492; however, like others (22), we found it difficult to obtain satisfactory analysis of carbon in these zirconium complexes due, presumably, to incomplete combustion.

Synthesis of ($Cp^{NMe}SiNR$)$Zr(NMe_2)_2$, 1,3-2

$CpH^{NMe}SiN(H)R$ (2.32 g, 8.7 mmol) in 25 mL of toluene was added to a solution of $Zr(NMe_2)_4$ (2.33 g, 8.7 mmol) in 10 mL of toluene at −78°C. The reaction mixture was allowed to warm to room temperature and then stirred at 40°C for 1 h. Solvent was removed and the residue was heated at 80°C under vacuum for several hours to remove the lower boiling-point impurities. [($Cp^{NMe}SiNR$)$Zr(NMe_2)_2$] (3.66 g, 8.2 mmol, 94%) was obtained as a yellowish oil that was >95% pure by ^1H NMR.

Synthesis of ($Cp^{NMe}SiNR$)$ZrCl_2$, 1,3-3

Method A

($Cp^{NMe}SiNR$)$Zr(NMe_2)_2$ (3.66 g, 8.2 mmol) was dissolved in 40 mL of THF. Anhydrous $Me_2NH{\cdot}HCl$ (1.35 g, 16.5 mmol) was added to the solution at −78°C. The mixture was allowed to warm to room temperature and stirred until the solid $Me_2NH{\cdot}HCl$ disappeared. The volatile materials were removed in vacuo and the residue was extracted with 50 mL of toluene. Insoluble materials were removed by filtration and the toluene was removed to give the crude product as an off-white solid. Pure product (2.74 g, 6.42 mmol, 77.8%) was obtained by recrystallization from hexane.

Method B

$ZrCl_4$ (2.62 g, 11.2 mmol) and $LiNMe_2$ (2.30 g, 45 mmol) were combined in a flask and 50 mL of Et_2O at was added by vacuum transfer at −78°C. The mixture was allowed to warm to room temperature and stirred for 3 h at which time the mixture was cooled again to −78°C. A solution of CpH^{NMe}-SiN(H)R (3.00 g, 11.26 mmol) in 20 mL of toluene was added

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

Synthesis of ($Cp^{NMe}SiNR$)$Zr(CH_3)_2$, 1,3-4

($Cp^{NMe}SiNR$)$ZrCl_2$ (1.2 g, 2.8 mmol) was suspended in Et_2O (60 mL) and MeLi (4.0 mL of a 1.4 M solution in Et_2O, 5.6 mmol) was added via syringe at −78°C. The mixture was stirred at −78°C for 4 h, then warmed slowly to room temperature. The solvent was removed and the product was extracted with hexanes. Insoluble materials were filtered off and the extract was reduced in volume to 2–3 mL and cooled to −40°C for several hours to precipitate the product. The pure product (0.74 g, 1.9 mmol, 69%) was obtained by cold filtration as an off-white crystalline solid. Anal. calcd. for $C_{17}H_{34}N_2SiZr$: C 52.93, H 8.88, N 7.26; found: C 52.32, H 8.74, N 7.23.

Synthesis of 1,2-($Cp^{NMe}SiNR$)Zr(CH_3)Cl, 5

$ZrCl_4(THF)_2$ (0.30 g 0.80 mmol) and solid MeLi (0.05 g, 2.4 mmol) were combined in a flask and Et_2O (30 mL) was vacuum transferred in at −78°C. The mixture was warmed to −20°C and stirred for 1 h. A solution of $CpH^{NMe}SiN(H)R$ (0.21 g, 0.80 mmol) in hexanes (10 mL) was added via syringe at −20°C. The mixture was slowly warmed to 0°C and stirred for 30 min, then warmed to room temperature. The solvent was removed and the residue was extracted with hexanes. The extract was reduced in volume to 2–3 mL and cooled to −40°C; the yellowish crystalline product (98 mg, 0.24 mmol, 30%) was collected via filtration and dried in vacuo. Anal. calcd. for $C_{16}H_{31}ClN_2SiZr$: C 47.31, H 7.69, N 6.90; found: C 47.99, H 7.98, N 6.70.

Synthesis of 1,2-($Cp^{NMe}SiNR$)ZrCl_2, 1,2-3

$ZrCl_4(THF)_2$ (0.10 g, 0.27 mmol) and solid $TMSCH_2Li$ (0.05 g, 0.53 mmol) were combined in a flask and Et_2O (20 mL) was vacuum transferred in at −78°C. The mixture was allowed to warm to room temperature and stirred for 1 h. The Et_2O was removed in vacuo and replaced with toluene (20 mL) and the undissolved solids were removed by filtration. A solution of $CpH^{NMe}SiN(H)R$ (71 mg, 0.27 mmol) in 5 mL of toluene was added via syringe. The mixture was stirred at 60°C for 1 h, during which period a white precipitate formed. The solution was concentrated and a few mL of hexanes were added; the white solid was collected on a frit and dried under vacuum (20 mg, 0.05 mmol, 18%). Anal. calcd. for $C_{15}H_{28}Cl_2N_2SiZr$: C 42.23, H 6.62, N 6.57; found: C 41.85, H 6.76, N 6.42.

X-ray crystallographic analysis of 1,2-($Cp^{NMe}SiNR$)Zr(CH_3)Cl, 5

Single crystals were mounted in thin-walled glass capillaries and placed on an Enraf Nonius CAD-4 diffractometer. Unit cell dimensions were determined via least-squares refinement of the setting angles of 24 high-angle reflections and intensity data were collected using the ω-2θ scan mode. Data were corrected for Lorentz, polarization, and absorption effects but not for extinction. Pertinent data collection and structure refinement parameters are presented in Table 2. The structure was solved using direct methods and all non-hydrogen atoms were refined with anisotropic thermal parameters. Aryl and methylene hydrogen atoms were placed in calculated postions (D_{C-H} = 1.00 Å). Methyl hydrogen atoms were located via difference Fourier map inspection. Hydrogen atoms were given isotropic temperature factors based upon the atom to which they are bonded, and fixed during least-squares refinement. A weighting scheme based upon counting statistics was used with the weight modifier k in kF_o^2 being determined via evaluation of variation in the standard reflections that were collected during the course of data collection. Neutral atom scattering factors were taken from *International tables for X-ray crystallography* (23). Values of R and R_w are given by $R = (F_o - F_c)/EF_o$ and $R_w = [E(w(F_o - F_c))^2/E(wF_o^2)]^{1/2}$. All crystallographic calculations were conducted with the PC version of the NRCVAX program package (24) locally implemented on an IBM compatible 80486 computer. Anisotropic thermal parameters and hydrogen atom parameters are available as supplementary material.[4]

Synthesis and biological evaluation of carbon-substituted C-4 derivatives of podophyllotoxin

Yvonne Lear and Tony Durst

Abstract: Several C-4 carbon-substituted analogues of podophyllotoxin, **1**, were prepared by treatment of **1** with allyltrimethylsilane or trimethylsilylcyanide in the presence of boron trifluoride etherate. Alternatively, carbon substituents were introduced via additions to the carbobenzyloxy-protected C-4′-dimethylated podophyllotoxone. These 4′-dimethylated derivatives showed promising in vitro antitumour activity and were equally active against human colon cell line HT116 and two multidrug resistant cell lines. The alcohol **6** was evaluated in vivo but was found to be inactive.

Key words: podophyllotoxin analogues, podophyllotox-4-one, C4 carbon substituted podophyllotoxins.

Résumé : On a préparé plusieurs analogues de la podophyllotoxine **1** substitués sur le carbone en position 4, en traitant le composé **1** avec l'allyltriméthylsilane ou le cyanure de triméthylsilane en présence de l'éthérate de trifluorure de bore. Alternativement, on a introduit les substituants sur le carbone via des additions sur la podophyllotoxone déméthylée en C-4′ et protégée par le groupe carbobenzyloxy. Ces dérivés déméthylés en C-4′ exhibent in vitro une activité anti tumorale prometteuse et sont également actifs contre la ligne cellulaire du colon humain HT116 et contre deux lignes cellulaires résistantes a de nombreux médicaments. On a évalué l'alcool **6** in vivo mais elle est inactive.

Mots clés : analogues de la podophyllotoxine, podophyllotox-4-one, podophyllotoxines substituées en C4.

[Traduit par la rédaction]

Introduction

The clinical use of Etoposide **1** as an antitumour agent (1–3) has spurred interest in the modification of its aglycone podophyllotoxin **2** in order to furnish derivatives possessing superior antitumour activity. These efforts have included a number of modifications at the C-4 position of the molecule. New derivatives have included ethers, esters (4), amines (5, 6), sulfides, sulfoxides, and sulfones (7). Except for an isolated example described in 1960 (8), there appear to have been no reports describing the synthesis of derivatives of podophyllotoxin bearing carbon substituents at C-4. Such derivatives should have greater chemical stability than the typical podophyllotoxin derivatives since the C-4 heteroatom bond is susceptible to heterolytic cleavage, which generates a benzylic carbocation intermediate and hence either new substitution or elimination products.

This report describes the synthesis of several derivatives of 4′-demethylpodophyllotoxin in which the OH bond at C-4 has been replaced by a carbon–carbon bond, and the evaluation of their biological activity. These new analogues retain the crucial structural features of the Etoposide aglycone, such as the *trans*-fused lactone (3) and the C-4′ hydroxyl group on the pendant aromatic ring (9). In addition, these derivatives have

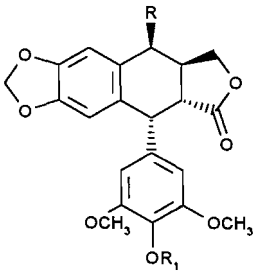
the preferred β stereochemistry at C-4 for optimal activity (10).

Results and discussion

The desired carbon substituents at C-4 were introduced using either podophyllotoxin or 4′-*O*-carbobenzyloxypodophyllotoxin as starting materials. Thus treatment of podophyllotoxin with allyltrimethylsilane in dichloromethane at 0°C in the presence of boron trifluoride etherate (11, 12), afforded 4-β-allyl-4-deoxypodophyllotoxin, **3**, mp 131°C, in 95% yield. The 4-β-stereochemistry was expected since trapping of the intermediate benzylic cation should occur preferentially from the sterically less hindered β side. This was confirmed by the 5.8 Hz coupling constant between H3 and H4, which is consistent with that observed for similar compounds (13). The coupling constants for the remaining C-ring protons ($J_{1,2}$ = 5.2 Hz and $J_{2,3}$ = 14.3 Hz) show that the podophyllotoxin stereochemistry has been retained.

The intermediate **3** was readily converted to the alcohol **4** in 90% yield by reaction with borane – methyl sulfide followed by $NaOH–H_2O_2$ work-up. Oxidation of **4** with Jones reagent gave the carboxylic acid **5**. Both **4** and **5** were demethylated at C-4′ using anhydrous HBr in dichloromethane to afford **6** and **7**, respectively. The demethylation of **5** to give **7** was highly problematic, giving low yields of the product **7**, which was impossible, due to decomposition, to purify completely either by silica gel chromatography or recrystallization. The spectroscopic properties of these compounds were in agreement with the assigned structures and are reported in the experimental section.



3	R = $CH_2CH{=}CH_2$	$R_1 = CH_3$
4	R = $CH_2CH_2CH_2OH$	$R_1 = CH_3$
5	R = CH_2CH_2COOH	$R_1 = CH_3$
6	R = $CH_2CH_2CH_2OH$	R_1 = H
7	R = CH_2CH_2COOH	R_1 = H
8	R = CN	$R_1 = CH_3$
9	R = $COOCH_2CH_3$	$R_1 = CH_3$
10	R = CN	R_1 = H
11	R = $COOCH_2CH_3$	R_1 = H
12	R = OH	R_1 = Cbz

The preparation of the 4-cyano and 4-carboethoxy derivatives **10** and **11**, respectively, has thus far been unsuccessful. The required 4-cyano-4-deoxypodophyllotoxin, **8**, was obtained in 88% yield from **2** upon treatment with trimethylsilylcyanide and boron trifluoride etherate. Unfortunately, the demethylation of the 4′-methoxy group with HBr under the usual conditions afforded only a small amount of a highly insoluble product, tentatively assigned as **10** on the basis of its MS and ^{1}H NMR data. Hydrolysis of **8** in refluxing ethanolic HCl gave **9** on the basis of MS and ^{1}H NMR data; unfortunately 4′-*O*-demethylation of **9** to provide target compound **11** using HBr or BBr_3 has not been successful.

4′-*O*-Carbobenzyloxypodophyllotoxone, **13**, available by pyridinium dichromate oxidation of the corresponding protected 4′-*O*-carbobenzoxyepipodophyllotoxin **12** (10), was converted into a compound presumed to be **15**, in 80% yield, upon reaction with lithium phenylacetylide. This intermediate was not characterized but was hydrogenated over palladium to remove the Cbz protecting group and reduce the alkyne at C-4 to give **17**, mp 163–164°C, whose structure was verified by NMR and mass spectral data. In a model study, reaction of podophyllotoxone (**8**) with *n*-BuLi gave a mixture of **16** and its C-4 epimer as the major products. A single crystal X-ray diffraction determined that the minor isomer had the α geometry at C-4. Based on this result, it was concluded that the larger phenyl acetylide anion would also give mainly the β geometry, hence products **15** and **17**.

Biological evaluation

The in vitro cytotoxicity of three of the above compounds was evaluated against the human colon cell line HCT 116 and two drug-resistant cell lines HCT116/VM46 and HCT116/VP35 (Table 1). The former exhibits multidrug resistance to lipophilic anticancer drugs such as taxol, Etoposide (VP-16), Teniposide (VM-26), doxorubicin, and vinblastine by overexpressing *p*-glycoprotein, which acts as a cell surface drug efflux pump to limit the accumulation of the above-mentioned drugs in cancer cells. The latter line has reduced levels of topoisomerase II and is resistant to topoisomerase-active drugs such as Etoposide and Teniposide. The results of the tests and comparison to Etoposide and Teniposide are shown in Table 1.

In these in vitro tests, the 4-hydroxypropyl derivative **6** was most active amongst the new structures against all three cell lines. While the alcohol **6** was approximately 4 times less active than Teniposide against the nonresistant strain, it was somewhat more active than Teniposide against the resistant strains. Compound **6** has comparable activity, with an IC_{50} of approximately 0.7 μM, against each of the three cell lines. The in vitro activity of the tertiary alcohol **17** is reduced by a factor of about 3 and that of the acid **7** by more than 10 relative to **6**. Interestingly for **17**, as for **6**, the response of the multidrug-resistant cell lines is similar to that of the nonresistant line HCT 116. This indicates that **6** and **17** are not substrates for the *p*-glycoprotein efflux pump or they inhibit the pump.

Compound **6** was subsequently evaluated in vivo against a distally implanted M109 tumour model in CDF1 mice by administering it interperitoneally as a solution in H_2O – carbomethoxy cellulose at dosages ranging from 50 to 120 mg/kg. Survival times at 50 and 80 mg/kg were identical to that of the control group (test/control, T/C = 100–105). At the highest

Table 1. In vitro toxicity of podophyllotoxin derivatives in human colon carcinoma cell lines.

Compound tested	IC_{50} (μM)		
	HCT116	HCT116/VM46	HCT116/VP35
6	0.76	0.76	0.66
7	9.5	13	11
17	2.2	2.4	2.2
Etoposide	1.5	8.6	7.4
Teniposide	0.18	0.92	0.76

dosage employed the T/C fell to 87. The other C-4 substituted derivatives were not tested in vivo. Biological testing was carried out by Bristol-Myers Squibb following established protocol.

Experimental

NMR spectra were recorded on either A Varian XL 300 or Bruker AMX 500 spectrometer. Melting points were recorded on a Thomas Scientific melting point apparatus. THF was freshly distilled from sodium and benzophenone prior to use. Chromatography solvents were distilled routinely prior to use. Podophyllotoxin was donated by Bristol-Myers Squibb, Wallingford, Connecticut.

4-β-Allyl-4-deoxypodophyllotoxin 3

Podophyllotoxin, **2** (1 g, 2.4 mmol, 1 equiv.) was stirred with boron trifluoride etherate (750 μL, 2.5 equiv.) and allyltrimethylsilane (80 μL, 2 equiv.) in dry CH_2Cl_2 (1 mL) over 4 Å molecular sieves at 25°C for 4 h. Water (3 mL) was added and the product was extracted with CH_2Cl_2, washed with H_2O, dried ($MgSO_4$), and evaporated to give a white solid. Chromatography on silica gel (1:1 hexane:ethyl acetate) and recrystallization from hexane – ethyl acetate afforded the pure compound (1.05 g, 95% yield); mp 137–138°C. IR: 1775 cm^{-1} (lactone). ^1H NMR ($CDCl_3$): 6.73 (s, 1H), 6.47 (s, 1H), 6.29 (s, 2H), 5.95 (s, 1H), 5.94 (s, 1H), 5.81 (m, 1H), 5.11–5.15 (m, 2H), 4.56 (d, $J_{1,2}$ = 5.2 Hz, 1H), 4.23–4.30 (m, 2H), 3.77 (s, 3H), 3.71 (s, 6H), 3.27–3.40 (m, 1H), 3.05–3.09 (m, 1H), 2.96–3.01 (m, $J_{2,3}$ = 14.3 Hz, $J_{3,4}$ = 5.8 Hz, 1H), 2.57–2.60 (m, 1H), 2.43–2.45 (m, 1H). ^{13}C NMR ($CDCl_3$): 175.1, 152.4, 147.0, 146.9, 137.0, 136.6, 136.1, 133.0, 130.8, 116.9, 110.1, 108.7, 108.4, 101.2, 69.0, 60.7, 56.2, 44.0, 42.2, 38.5, 37.7, 36.1. HRMS calcd. for $C_{25}H_{26}O_7$: 438.1679; found: 438.1681.

4β-(3-Hydroxypropyl)-4-deoxypodophyllotoxin 4

Borane methyl sulfide complex (100 μL 10 M solution) was added dropwise to a solution of **3** (925 mg, 2.1 mmol) in dry CH_2Cl_2 (6 mL) at 0°C. The solution was stirred at 25°C for 4 h, then diluted with 10 mL EtOH. The pH of the solution was maintained at 8 using 3 N aqueous NaOH while H_2O_2 (0.3 mL, 30% in H_2O) was added at 0°C. Water (10 mL) was added and the product extracted with CH_2Cl_2, dried ($MgSO_4$), and the solvent evaporated, leaving a white solid that was recrystallized from hexane – ethyl acetate to give the product (915 mg, 95% yield); mp 118–119°C. IR: 3612, 1775 cm^{-1}. ^1H NMR ($CDCl_3$): 6.69 (s, 1H), 6.43 (s, 1H), 6.25 (s, 2H), 5.92 (s, 1H), 5.90 (s, 1H), 4.53 (d, J = 4.8 Hz, 1H), 4.36 (dd, J = 8.5 Hz, 7.1 Hz, 1H), 4.08–4.13 (m, 1H), 3.77 (s, 3H), 3.72 (s, 6H), 2.95–3.00 (m, 1H), 2.85–2.95 (m, 2H). ^{13}C NMR ($CDCl_3$): 175.1, 152.4, 147.0, 146.8, 137.1, 136.2, 133.8, 130.5, 110.2, 108.8, 108.5, 101.2, 69.0, 62.5, 60.7, 56.2, 44.1, 42.2, 39.3, 36.2, 32.1, 29.7. HRMS calcd. for $C_{25}H_{28}O_8$: 456.1775; found: 456.1773.

4β-(3-Propanoic acid)-4-deoxypodophyllotoxin 5

Jones reagent (2 mL, 0.4 M) was added dropwise to a solution of 160 mg **4** dissolved in acetone until an orange colour persisted. Stirring was continued for 15 min. The reaction mixture was brought to pH 7 using saturated $NaHCO_3$ solution. The mixture was extracted using CH_2Cl_2. The organic layer was washed with H_2O, dried ($MgSO_4$), and the solvent evaporated. The product was isolated by column chromatography on silica gel using 5% MeOH, 63% ethyl acetate, and 32% hexanes as eluent and was recrystallized from hexane – ethyl acetate. Yield: 105 mg (66%); mp 197°C. IR (CH_2Cl_2): 2600–3300 cm^{-1}. ^1H NMR: 6.77 (s, 1H), 6.44 (s, 1H), 6.24 (s, 2H), 5.93 (s, 1H), 5.91 (s, 1H), 4.54 (br, 1H), 4.36 (m, 1H), 4.12 (m, 1H), 3.77 (s, 3H), 3.71 (s, 6H), 3.11 (br, 1H), 2.98 (br, 1H), 2.41–2.49 (m, 2H), 2.02–2.07 (m, 1H), 1.86–1.90 (m, 1H). ^{13}C NMR: 177.2, 174.7, 152.5, 147.1, 137.2, 136.1, 132.7, 130.3, 110.4, 108.8, 108.5, 101.3, 68.6, 60.8, 56.2, 44.1, 41.9, 38.5, 36.1, 32.7, 27.7. HRMS calcd. for $C_{25}H_{26}O_9$: 470.1577; found: 470.1590.

4β-(3-Hydroxypropyl)-4-deoxy-4′-demethylpodophyllotoxin 6

A solution of 10 mL dichloroethane and 3 mL diethyl ether saturated with anhydrous HBr at 0°C was added to 750 mg **4**. The solution was stirred at 0°C for 30 min and at 25°C for 90 min. The solution was neutralized by adding solid K_2CO_3. The organic layer was diluted with CH_2Cl_2 (10 mL) and washed with H_2O (×3), with brine, dried ($MgSO_4$), and the solvent evaporated. The compound was isolated by radial chromatography on silica with ethyl acetate as eluent and was recrystallized from CH_2Cl_2–hexane. Yield: 440 mg (60%); mp 129–130°C. IR: 3000–3500 (br) cm^{-1}. ^1H NMR ($CDCl_3$): 6.69 (s, 1H), 6.43 (s, 1H), 6.27 (s, 2H), 5.92 (s, 1H), 5.90 (s, 1H), 4.52 (d, $J_{1,2}$ = 4.7 Hz, 1H), 4.30–4.33 (m, 1H), 4.11–4.16 (m, 1H), 3.75 (s, 6H), 3.06 (m, 1H), 2.96 (m, 1H), 1.83 (m, 1H), 1.70 (m, 1H), 1.54–1.69 (m, 4H). ^{13}C NMR ($CDCl_3$): 146.3, 131.7,

110.2, 108.8, 108.1, 101.2, 68.9, 62.6, 56.4, 44.0, 42.3, 39.3, 36.1, 21.1, 29.7, 14.6. HRMS calcd. for $C_{24}H_{26}O_8$: 442.1614; found: 442.1630.

4β-(3-Propanoic acid)-4′-demethyl-4-deoxypodophyllotoxin 7

A solvent mixture of 25% ether in dichloroethane was saturated with HBr(g) at 0°C. The solvent mixture (10 mL) was added to 95 mg **5** and stirred at 0°C for 30 min and at 25°C for 2 h. The solution was neutralized with saturated $NaHCO_3$, extracted with CH_2Cl_2, dried ($MgSO_4$), and evaporated. Chromatography on silica gel (5% MeOH, 65% ethyl acetate, 30% hexanes as eluent) by preparative TLC and recrystallization from hexane – ethyl acetate yielded 20 mg (20%) of the impure demethylated compound **7**, which during each attempted purification decomposed considerably; mp 198–200°C, ^{1}H NMR: 6.69 (s, 1H), 6.44 (s, 1H), 6.27 (s, 2H), 5.92 (d, 1H), 5.90 (d, 1H), 4.53 (d, 1H), 4.31–4.33 (m, 1H), 4.12–4.18 (m, 1H), 3.75 (s, 6H), 3.05–3.08 (m, 1H), 2.97 (d, 1H), 2.94 (s, 1H). ^{13}C NMR: 191.0, 175.3, 146.3, 134.2, 133.0, 131.0, 110.2, 108.8, 108.1, 101.2, 68.9, 62.6, 56.4, 44.0, 42.3, 39.3, 36.1, 32.1, 29.7. HRMS calcd. for $C_{24}H_{24}O_9$: 456.1420; found: 456.1440.

4β-Cyano-4-deoxypodophyllotoxin 8

Boron trifluoride etherate (120 μL, 2 equiv.) was added to a solution of podophyllotoxin (200 mg, 1 equiv.) and trimethylsilyl cyanide (70 μL, 1.1 equiv.) in dry CH_2Cl_2 (3 mL) at 0°C. The solution was stirred for 20 min at 0°C and at 25°C for 1.5 h, when TLC showed that no starting material remained. Water was added (10 mL) and extraction carried out with CH_2Cl_2. The organic extracts were dried ($MgSO_4$) and the solvent evaporated to leave a yellow solid that was pure by NMR (180 mg, 88%); mp 158–159°C. IR: 2308, 1784 cm^{-1}. ^{1}H NMR ($CDCl_3$): 6.83 (s, 1H), 6.56 (s, 1H), 6.27 (s, 1H), 6.01 (s, 1H), 5.99 (s, 1H), 4.67 (d, $J_{1,2}$ = 4.6 Hz, 1H), 4.45–4.50 (m, 1H), 4.35 (d, J = 9.4 Hz, 1H), 4.21 (d, $J_{3,4}$ = 5.1 Hz, 1H), 3.80 (s, 3H), 3.74 (s, 6H), 3.05–3.15 (m, 1H), 2.90–3.05 (m, 1H). ^{13}C NMR ($CDCl_3$): 172.6, 152.4, 148.6, 147.7, 137.2, 134.4, 131.1, 122.1, 117.4, 110.7, 108.2, 107.9, 101.7, 68.5, 60.6, 56.0, 43.3, 43.1, 33.5, 33.0. HRMS calcd. for $C_{23}H_{21}O_7N$: 423.1301; found: 423.1314.

4β-Carboethoxy-4-deoxypodophyllotoxin 9

8 150 mg was refluxed in a solution of 3 mL HCl in 6 mL ethanol for 1 h. The solution was brought to pH 7 with saturated aqueous $NaHCO_3$ solution, extracted with CH_2Cl_2, dried ($MgSO_4$), and the solvent was evaporated to yield 95 mg white solid (57% yield); mp 138–139°C. IR: 1776, 1732 cm^{-1}. ^{1}H NMR: 7.11 (s, 1H), 6.47 (s, 1H), 6.07 (s, 1H), 5.94 (s, 1H), 5.92 (s, 1H), 4.44 (d, $J_{1,2}$ = 5.4 Hz, 2H), 4.1–4.2 (m, 1H), 3.83 (d, J = 9.2 Hz, 1H), 3.78 (m, 1H), 3.77 (s, 3H), 3.72 (s, 6H), 3.15–3.20 (m, 1H), 3.00 (dd, $J_{1,2}$ = 5.4 Hz, $J_{2,3}$ = 13.0 Hz, 1H), 1.25 (t, 3H). ^{13}C NMR: 175.6, 171.5, 153.0, 147.7, 147.2, 135.6, 130.5, 121.7. 109.4, 108.9, 106.4, 101.3, 70.2, 61.0, 60.8, 56.2, 46.8, 46.4, 42.2, 32.1, 29.7, 25.7, 14.2. HRMS calcd. for $C_{25}H_{26}O_9$: 470.1577; found: 470.1579.

4′-*O*-Carbobenzyloxypodophyllotoxone 13

A solution of 100 mg 4′-*O*-carbobenzyloxyepipodophyllotoxin **12** (10) and 300 mg pyridinium dichromate in 2 mL dry CH_2Cl_2 was stirred for 26 h at 25°C. Separation by silica gel column chromatography using hexane:ethyl acetate (1:1) and recrystallization from CH_2Cl_2–hexane afforded 82 mg desired product (82% yield); mp 99°C. IR (CH_2Cl_2): 1773, 1733 cm^{-1}. ^{1}H NMR ($CDCl_3$): 7.56 (s, 1H), 7.34–7.44 (m, 5H), 6.70 (s, 1H), 6.42 (s, 2H), 6.11 (s, 1H), 6.09 (s, 1H), 5.27 (s, 2H), 4.87 (d, $J_{1,2}$ = 4.3 Hz, 1H), 4.56–4.57 (m, 1H), 4.34–4.38 (m, 1H), 3.71 (s, 1H), 3.45–3.51 (m, 1H), 3.29 (dd, $J_{1,2}$ = 4.3 Hz, $J_{2,3}$ = 15.6 Hz, 1H). ^{13}C NMR ($CDCl_3$): 191.9, 172.6, 152.8, 151.7, 147.8, 140.7, 134.9, 134.6, 128.1, 127.9, 109.4, 106.7, 105.8, 102.1, 70.1, 66.6, 55.9, 46.3, 44.3, 43.0. FABMS (M + 1) calcd. 533.1369; found: 533.1397.

4′-*O*-Carbobenzoxy-4-(phenylethynyl)-epipodophyllotoxin 15

*n*BuLi (60 μL, 2 N in hexanes, 1 equiv.) was added to a solution of penylacetylene (20 μL, 1 equiv.) in dry THF (2 mL) at −78°C. A solution of 13 (90 mg, 1 equiv.) in dry THF (2 mL) was added and stirring continued at −78°C for 30 min. The reaction was quenched at −78°C with saturated aqueous NH_4Cl. The mixture was allowed to warm to room temperature and was extracted with CH_2Cl_2. The organic layer was washed with H_2O, dried ($MgSO_4$), and the solvent evaporated, leaving 82 mg white solid. The mixture was used for the next step without further purification.

4-Butyl-4-deoxypodophyllotoxin 16

To a solution of podophyllotoxone (6) (250 mg, 0.6 mmol, 1 equiv.) in 3 mL dry THF at −78°C was added 250 μL *n*-BuLi (2.4 M in hexanes, 0.6 mmol, 1 equiv.). The solution was stirred at −78°C for 15 min, then quenched with saturated NH_4Cl. Chromatography on silica gel using hexane:ethyl acetate (1:1) afforded 40 mg of the α-substituted isomer and 70 mg of the β-substituted isomer.

α Isomer: mp 105–106°C. IR: 3425br, 1777 cm^{-1}. ^{1}H NMR: 6.98 (s, 1H), 6.52 (s, 1H), 6.31 (s, 2H), 6.00 (s, 1H), 5.96 (s, 1H), 4.58 (d, $J_{1,2}$ = 4.69 Hz, 1H), 4.27–4.38 (m, 2H), 3.79 (s, 1H), 3.71 (s, 6H), 3.22 (dd, $J_{1,2}$ = 4.9 Hz, $J_{2,3}$ = 14.1 Hz, 1H), 2.88–2.97 (m, 1H), 1.77–1.84 (m, 2H), 1.05–1.4 (m, 4H), 0.89 (t, 3H). ^{13}C NMR: 175.4, 152.5, 147.9, 136.5, 135.1, 134.3, 132.5, 110.5, 107.8, 104.9, 101.5, 72.9, 67.1, 60.7, 55.9, 44.6, 41.7, 39.4, 39.3, 27.8, 23.1, 13.9.

β Isomer: mp 110°C. IR: 3593 br, 1774 cm^{-1}. ^{1}H NMR: 7.05 (s, 1H), 6.45 (s, 1H), 6.29 (s, 2H), 5.96 (s, 2H), 4.56 (d, $J_{1,2}$ = 4.9 Hz, 1H), 4.45 (dd, 1H), 4.27 (s, 1H), 3.78 (s, 3H), 3.73 (s, 6H), 3.08 (dd, $J_{1,2}$ = 4.9 Hz, $J_{2,3}$ = 14.9 Hz, 1H), 2.98 (m, 1H), 1.82–1.88 (m, 2H), 1.2–1.4 (m, 4H), 0.88 (t, 3H). ^{13}C NMR: 174.5, 152.5, 147.7, 147.4, 137.2, 136.3, 135.4, 131.3, 109.6, 108.4, 106.0, 101.4, 74.6, 67.7, 60.7, 56.3, 44.6, 44.5, 44.4, 39.4, 27.2, 23.25, 13.9. HRMS calcd. for $C_{26}H_{30}O_8$: 470.1954; found: 470.1967.

4-(2-Phenylethyl)-4′-demethylepipodophyllotoxin 17

A mixture of **15** (70 mg) and 10% Pd/C (25 mg) in ethyl acetate (5 mL) was stirred under hydrogen atmosphere for 20 min, when TLC showed that no starting material remained. Recrystallization from $CHCl_3$ gave the desired product (25 mg, 45% yield); mp 163–164°C. IR: 3529, 1778 cm^{-1}. ^{1}H NMR (acetone-d_6): 8.00 (s, 1H), 7.28 (s, 1H), 7.18–7.25 (m, 2H), 7.12–7.15 (m, 1H), 6.47 (s, 1H), 6.42 (s, 2H), 5.97 (s, 2H), 4.66 (a,

1H), 4.57 (d, 1H, $J_{1,2}$ = 5.6 Hz), 4.42 (d, 1H, J = 1.5 Hz), 4.40 (s, 1H), 3.70 (s, 6H), 3.36 (dd, 1H, $J_{1,2}$ = 14.9 Hz, $J_{2,3}$ = 5.7 Hz), 3.14–3.21 (m, 1H), 2.75–2.78 (m, 1H), 2.17–2.21 (m, 1H), ^{13}C NMR (acetone-d_6): 175.0, 147.9, 147.6, 147.5, 143.2, 138.1, 135.8, 132.6, 132.2, 128.9, 126.3, 110.0, 107.2, 101.9, 79.0, 74.2, 68.0, 56.5, 45.4, 45.0, 44.4, 41.4, 31.5. HRMS calcd. for $C_{29}H_{28}O_8$: 504.1780; found: 504.1764.

Biological testing

Biological testing was carried out at Bristol-Myers Squibb Laboratories. To determine in vitro cytotoxicity, the cell lines used were human colon carcinoma cell line HCT 116, the VM-26 resistant cell line HCT116/VM46, and the VP-16 resistant cell line HCT116/VP35. Cells were plated and 24 h later drugs were added and serially diluted. After 72 h of continuous drug exposure, the tetrazolium dye XTT was added. Since dehydrogenase enzyme in live cells reduces the XTT to a form that absorbs light at 450 nm, spectrophotometric methods can be used to determine to percentage of live cells. The results in Table 1 reflect drug concentration required to inhibit cell proliferation to 50% of that of untreated control cells.

Oxidation pathways of hydroxydopamines and their chloride and bromide salts: an electrochemical study in acidic solutions

Georgios Kokkinidis, Achilleas Papoutsis, and Evdoxia Coutouli-Argyropoulou

Abstract: The anodic oxidation of 6-hydroxydopamine and 5-hydroxydopamine and their chloride and bromide salts was studied in aqueous acidic solutions. The electrodes used were Pt and Pt/M (UPD) (M = Bi, Tl, Pb) modified surfaces. The electrochemical studies revealed that the first two-electron oxidation leads to formation of reactive quinoid intermediates. Reactions of these quinoid intermediates with nucleophiles yield substituted quinones that are not stable in solution. The reactions are initiated by the oxidation of the third hydroxyl group at more positive potentials. Cyclic voltammetry and rotating ring-disc electrode voltammetry were used to elucidate the reaction mechanisms. These techniques provide powerful tools to generate and detect transient intermediates and products and give valuable information regarding the pathways and mechanisms of the redox reactions.

Key words: 6-hydroxydopamine, 5-hydroxydopamine, voltammetry, electrolysis, oxidation mechanism, nucleophilic attack.

Résumé : On a étudié l'oxydation anodique de la 6-hydroxydopamine, de la 5-hydroxydopamine et de leurs chlorures et bromures en solutions aqueuses acides. On a utilisé les électrodes Pt et Pt/M (UPD)(M = Bi,Tl,Pb) à surfaces modifiées. Les études électrochimiques révèlent que la première oxydation à deux électrons conduit à la formation de quinoides intermédiaires. Les réactions de ces quinoides intermédiaires avec des nucléophiles donnent des quinones substituées qui ne sont pas stables en solution. Les réactions sont déclenchées par l'oxydation du troisième groupe hydroxyle à des potentiels plus positifs. On a utilisé la voltamétrie cyclique et la voltamétrie à électrode à disque annulaire rotatif pour élucider ces mécanismes. Ces techniques fournissent des outils puissants pour générer et détecter les intermédiaires transitoires et les produits, et donne des informations valables sur le processus et le mécanisme des réactions redox.

Mots clés : 6-hydroxydopamine, 5-hydroxydopamine, voltamétrie, électrolyse, mécanisme d'oxydation attaque nucléophile.

Introduction

Increasingly, 6-hydroxydopamine is becoming an interesting compound in neuropharmacology because it is suspected to be the aberrant metabolite of neurotransmitter catecholamines that is highly toxic to the central nervous system (1–3). It has been postulated to be an autooxidation product of dopamine (4, 5). The intermediate dopamine quinone undergoes nucleophilic attack by water at the C(6) position, which leads to 6-hydroxydopamine. This reaction is very slow and may only occur under electrochemical conditions in very acidic solutions (6–9). The high acidity hinders the intramolecular cyclization of dopamine quinone because it prevents the release of the proton from the protonated amino group of the side chain, which, generally, is the first step toward the intramolecular cyclization reaction of catecholamines at pH > 3 to produce indole derivatives (3, 7–11).

6-Hydroxydopamine is more easily oxidized than dopamine. The oxidation leads to the respective *p*-quinone, which is also susceptible to nucleophilic attack (12) and intramolecular cyclization (13, 14). Reactions of the *p*-quinone intermediate with nucleophilic groups of proteins (e.g., thiols) at physiological pH might be related to the neurotoxicity of 6-hydroxydopamine (12).

Previous studies of the electrochemical behaviour of 6-hydroxydopamine are restricted to this first two-electron oxidation and the fate of the *p*-quinoid product in solution (6, 13–15). However, 6-hydroxydopamine-*p*-quinone can undergo further oxidation at more positive potentials at the free phenolic hydroxyl group, which might accelerate secondary reactions with nucleophiles.

The present study was undertaken to give insights into the reactions involved in this potential range that might be of considerable interest for biologically relevant mechanistic information. In addition, 5-hydroxydopamine was also included in this study for the sake of comparison. To the best of our knowledge, 5-hydroxydopamine has not been studied electrochemically so far. The study was carried out in acidic solutions to preclude intramolecular cyclization. The electrodes

used were Pt and Pt/M(UPD) modified surfaces. It is known that underpotentially deposited (UPD) adlayers of Pb, Tl, and Bi on Pt improve markedly the kinetics of redox reactions (16–20) including the oxidation of catecholamines (20).

Experimental

Potentiostatic disc and ring-disc measurements were performed with a rotating Pt-Pt ring-disc electrode (EAD 10 000 from Tacussel). The electrode was activated by applying a continuous sweep (v = 1 V s^{-1}) between the potentials of hydrogen and oxygen evolution in 0.2 M $HClO_4$. The cell was double walled and thermostated at 25 ± 0.1°C, except where stated otherwise. An $Hg/Hg_2SO_4/Na_2SO_4$ (sat.) electrode, connected to the cell by a Luggin capillary and a Pt sheet served as the reference and the counter electrode, respectively. The solutions were thoroughly deoxygenated by purging the cell system with ultrapure nitrogen. Electrode potentials are given on the standard hydrogen electrode (SHE) scale.

The electronic setup consisted of a Tacussel bipotentiostat (Bi/Pad), with function generators from Bank Electronics (VSG-72) and an HP 7046B X-Y_1, Y_2 recorder.

The supporting electrolyte was prepared from triply distilled water and $HClO_4$ (Merck, suprapure). Stock solutions of perchlorate salts of Pb, Tl, and Bi were prepared from the respective oxides or carbonates (Merck, GR grade) and perchloric acid.

2,4,5-Trihydroxyphenethylamine hydrochloride (6-hydroxy-

dopamine hydrochloride, 6-OH-DA·HCl), 2,4,5-trihydroxyphenethylamine hydrobromide (6-hydroxydopamine hydrobromide, 6-OH-DA·HBr), 3,4,5-trihydroxyphenethylamine hydrochloride (5-hydroxydopamine hydrochloride, 5-OH-DA·HCl), and 3,4-dihydroxyphenethylamine hydrochloride (dopamine hydrochloride, DA·HCl) were purchased from Sigma Chemical Co. (St. Louis, Mo.). Halide-free solutions of 6-OH-DA, 5-OH-DA, and DA were prepared by replacing Cl^- ions with sulfates. This was achieved by adding the stoichiometric quantity of Hg_2SO_4 to the respective solutions and filtering. It was determined that the residual halide concentration was less than 10^{-6} M.

Results and discussion

Oxidation of 6-OH-DA and 5-OH-DA on Pt and Pt/M(UPD) electrodes

The electrochemical oxidation of 6-OH-DA and 5-OH-DA was first studied in the absence of halide ions. Since these compounds are purchased as hydrochloride or hydrobromide salts, halide-free solutions were prepared following the procedure described in the experimental section. Figure 1 shows cyclic voltammograms of 6-OH-DA and 5-OH-DA obtained on Pt and Pt/Bi(UPD) electrodes as a function of scan rate. A single oxidation peak, which is diffusion controlled, is obtained. The reaction involved is a simple two-electron oxidation to the respective 6-OH-DA-*p*-quinone and 5-OH-DA-*o*-quinone. A second oxidation peak may appear at more positive potentials (i.e., at around 1.1 V) corresponding to further oxidation of the hydroxy-quinones but this peak is nearly masked by the current due to platinum oxide formation. The oxidation peak of 6-OH-DA is followed on the reverse sweep by a reduction peak of equal height. In the case of 5-OH-DA the reduction peak greatly decreases in height, indicating that the electron-transfer reaction is followed by a rapid chemical reaction, i.e., the process proceeds via an EC mechanism.

The anodic and cathodic processes at bare Pt are irreversible. As can be seen in Fig. 1, the UPD of Bi improves the

reversibility of the redox reactions. This is readily verified by comparing the peak potentials for Pt/Bi(UPD) with those for bare platinum. Furthermore, although the peak potentials for bare Pt depend linearly on log *v*, for Pt/Bi(UPD) they remain constant at all potential scan rates (see inset *D* of Fig. 1). Also for Pt/Bi(UPD) the difference between the peak potential and half-peak potential for both the anodic and cathodic branches of the cyclic voltammograms is ≈30 mV at all scan rates, which is in good agreement with the theoretical value of 28.2 mV for a two-electron reversible process (21). Similar behaviour was also observed with Tl and Pb UPD adlayers.

As discussed previously (22) for analogous redox systems, the Bi(UPD) layer hinders the adsorption of the reacting molecules, thus leading to the change of the reaction mechanism from an "inner-sphere" mechanism, involving adsorbed intermediates on bare Pt, to an "outer-sphere" one without complications from the adsorption of the reacting molecules, which favours faster electron exchange at the electrode–solution interface. The UPD of Bi also improves the reversibility of the redox reactions of dopamine (DA) itself. This becomes evident from the ring voltammograms of DA, I_R vs. E_R at constant E_D = 1.1 V where DA is oxidized to the open-chain

Fig. 4. Disc voltammograms for the oxidation of (1) 6-OH-DA·HBr (10^{-3} M), (2) 6-OH-DA·HCl (10^{-3} M), and (3) LiBr (10^{-3} M) on Pt in 0.2 M $HClO_4$ ($|dE/dt| = 25$ mV s^{-1}). Rotation frequency $f = 50$ Hz.

quinone (Fig. 2). Under this condition, both DA and DA-quinone are collected by the ring electrode. A single oxidation–reduction wave is obtained on the Pt/Bi(UPD) ring. The slope of a plot of log $[(i_{L,a} - i)/(i - i_{L,c})]$ vs. E_R at $\omega = 25$ Hz is $\approx$32 mV/decade, which is in good agreement with the theoretical value (29.6 mV/decade) for reversible two-electron-transfer reactions exhibiting Nernstian behaviour.

Figure 3 shows rotating ring-disc electrode (RRDE) voltammograms for 6-OH-DA and 5-OH-DA. The ring potential was kept at $E_R = 0.2$ V where the oxidation of 6-OH-DA-*p*-quinone and 5-OH-DA-*o*-quinone are under diffusion control. The ring current was recorded as a function of the disc potential. Note again the positive catalytic effect of Bi(UPD) on the anodic processes. As can be seen, a second oxidation wave II_a appears in the disc voltammograms of both compounds at around 1.1 V. Its height is about half of that of the first wave I_a and does not depend linearly on the square root of the rotation rate, indicating kinetic character. Obviously, wave II_a corresponds to the oxidation of the third hydroxyl group of 6-OH-DA and 5-OH-DA at C(4) and C(3), respectively. Phenoxy radicals or phenoxonium cations are probably formed by losing one electron or two electrons, respectively, the fate of which is not predictable.

In the case of 6-OH-DA, the ring currents remain constant in the whole disc potential range and the collection efficiency was found to be $N = 0.20$ (disc area = 0.126 cm^2) as well as being independent of the rotation rate. This value is very close to the theoretical value (0.21) calculated according to Albery and Bruckenstein (23) from the geometric data of the electrode ($r_1 = 0.20$, $r_2 = 0.22$, and $r_3 = 0.24$ cm). On the contrary, in the case of 5-OH-DA the collection efficiency is smaller than the theoretical value and depends on both the rotation rate and disc potential.

The voltammetric behaviour of 6-OH-DA and 5-OH-DA described above is consistent with the mechanisms of Scheme 1.

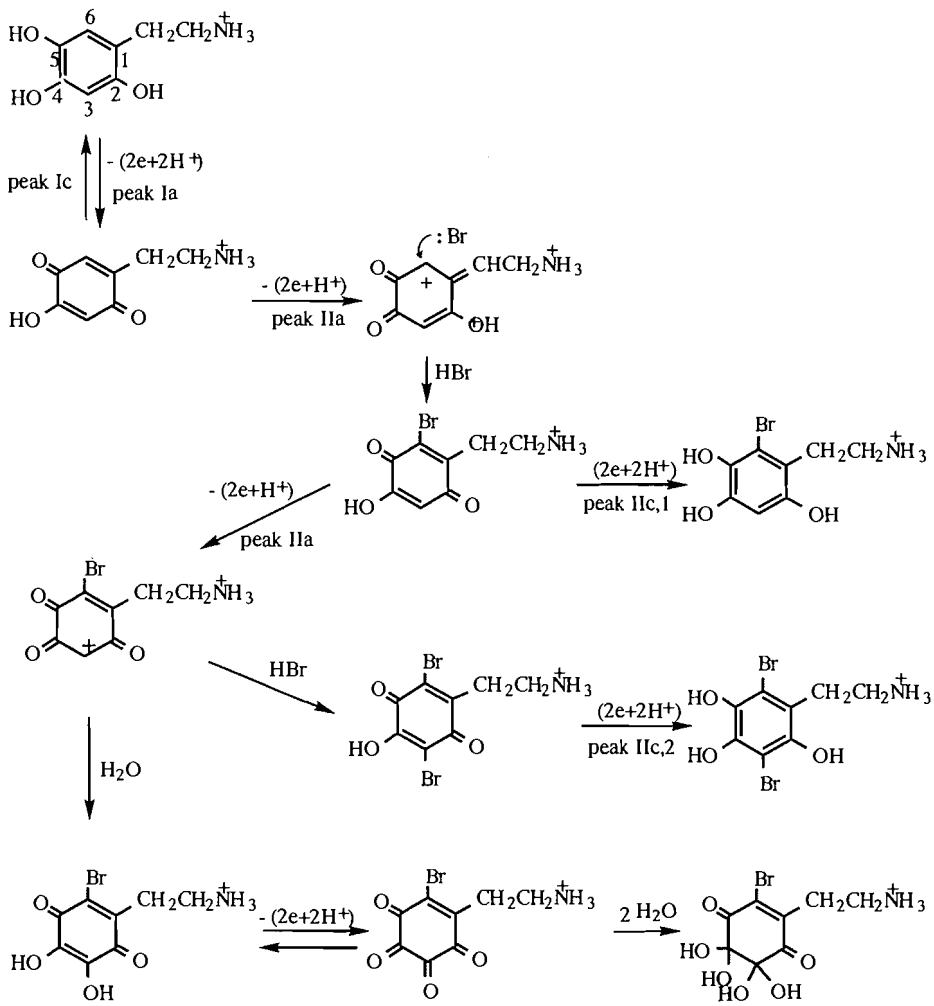
The oxidation of 6-OH-DA yields the corresponding *p*-quinone as the first product of reasonable stability. The solution of 6-OH-DA after exhaustive electrolysis at 0.75 V presents the oxidation wave II_a and a reduction wave of equal height and half-wave potential (of course on Pt/Bi(UPD) with the oxidation wave I_a that is due to the reverse reaction. The oxidation of 5-OH-DA yields the corresponding *o*-quinone, which is not stable in solution. It undergoes fast hydration, most probably at the carbonyl group at position C(4). The hydrated 5-OH-DA-*o*-quinone is electro-inactive, as indicated by CV and rotating-disc electrode voltammetry of the solution after bulk electrolysis at 0.9 V. This behaviour is similar to that observed for ascorbic acid (24, 25), the oxidation of which is followed by a pseudo-first-order chemical reaction due to the hydration of the carbonyl group of the oxidation product. Attempts to identify products of the second oxidation wave II_a were unsuccessful for both compounds. Bulk electrolysis at potentials on the plateau of wave II_a is difficult because of filming of the electrode by products of secondary reactions. However, in the case of 6-OH-DA an assumption could be made based on the results of the RRDE voltammetry. The fact that the currents of the ring electrode are constant, independent of the disc potential, enables us to assume the formation of a dimer by C(3) coupling of the phenoxy radical. Such a dimer should be reduced at the same potential with 6-OH-DA-*p*-quinone and this might explain why the ring currents remain unchanged when the sweep of the disc potential entered the region above 1.1 V.

The rate of the hydration of 5-OH-DA-*o*-quinone was determined from the ring-disc data by using the equation

$$\frac{N}{N_k} = 1 + 1.28\left(\frac{\nu}{D}\right)^{1/3}\frac{k}{\omega}$$

proposed by Albery and Bruckenstein (26) for the EC mechanism. In this equation N_k is the kinetic and N the ordinary collection efficiency and k is the rate constant of the first-order chemical reaction. Values of $N_k = i_R/i_D$ were evaluated from the ring-disc voltammograms of 5-OH-DA at $E_D = 0.95$ V. Plots of $1/N_k$ vs. $1/\omega$ ($\omega = 2\pi f$) at different temperatures are shown in inset *D* of Fig. 3. They are linear with a common intercept corresponding to the collection efficiency of the electrode ($N = 0.20$) and different slopes from which k_1 may be calculated. Values of k_1 are summarized in Table 1. The *D* values needed for this calculation were determined from the Levich plots (j_L vs. $\omega^{1/2}$)of wave I_a by means of the Gregory–Riddiford equation. The analysis taking into account the Arrhenius equation, results in a value of the activation energy E_a of $\approx$6.000 cal mol^{-1}.

Scheme 2.



Oxidation of 6-OH-DA·HBr and 6-OH-DA·HCl on Pt

The oxidation of 6-OH-DA·HBr and 6-OH-DA·HCl gives two waves. Typical rotating disc voltammograms in 0.2 M $HClO_4$ are shown in Fig. 4. The height of wave II_a is almost equal to the height of wave I_a for 6-OH-DA·HCl but its height is twice the height of wave I_a for 6-OH-DA·HBr. Wave II_a appears in the potential range where the oxidation of the OH group of 6-OH-DA-*p*-quinone commences in the absence of nucleophiles. It is worth noting that its potential in the presence of Br^- is less positive than the oxidation potential of Br^- itself.

Electrogenerated quinones frequently undergo nucleophilic attack. The nucleophile usually reacts by a Michael 1,4-addition to form a substituted hydroquinone (27, 28). If the substituent is such that the potential for oxidation of the product is lower than the oxidation potential of the hydroquinone from which the quinone is formed, then further oxidation and further addition may occur. In the case of hydroxy-substituted quinones the electrochemical oxidation of the hydroxyl group may accelerate the addition reactions, showing the same general picture of phenolic oxidations (29, 30). The oxidation of the hydroxyl group of electrogenerated 6-OH-DA-*p*-quinone probably enables the addition reactions of HBr and HCl to occur at a significant rate. The voltammetric behaviour indicates that products and kinetics of the reaction depend strongly on the nucleophile species.

Figure 5 shows the cyclic voltammogram of 6-OH-DA·HBr. Peaks I_a and I_c correspond to the first two-electron oxidation–reduction, which in the presence of Br^- form an almost reversible couple. After scanning through oxidation peak II_a, reduction peak I_c decreases in height and new peaks $II_{c,1}$ and $II_{c,2}$ appear at more positive potentials. Similar behaviour was observed with 6-OH-DA·HCl, except that the reduction peak $II_{c,2}$ does not appear in the cyclic voltammogram. The species responsible for reduction peaks $II_{c,1}$ and $II_{c,2}$ are probably the mono- and di-bromo-substituted 6-OH-DA-*p*-quinones. The initial two-electron oxidation of 6-OH-DA is followed by two successive bromination reactions at potentials above 1.0 V (Scheme 2).

The bromination supposedly proceeds through a phenoxonium cation. It is assumed that the first attack of bromide occurs at C(6). Between the two possible phenoxonium cation intermediates, **I** is expected to be more stable than **II** because **I** has a more extented conjugation than **II** in which, furthermore, the formation of a positive charge between two carbon-

Fig. 6. Disc currents j_D vs. E_D and ring currents i_R vs. E_D at constant $E_R = 0.1$ V for the oxidation of 6-OH-DA (10^{-3} M) obtained with a Pt-Pt rotating ring-disc electrode in 0.2 M $HClO_4$ ($|dE/dt| = 25$ mV s^{-1}). Rotation frequency $f = 50$ Hz.

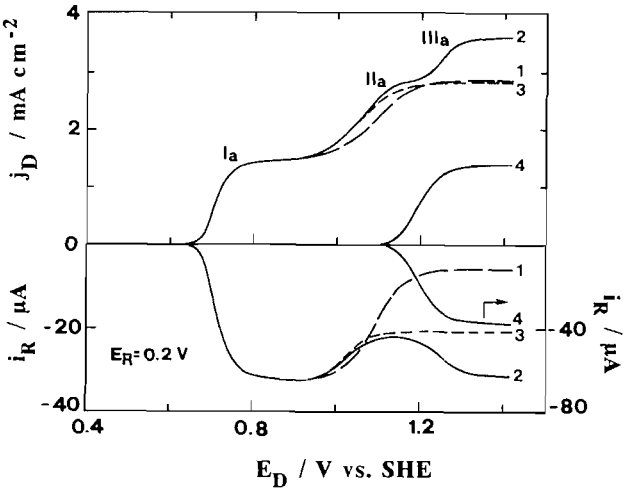
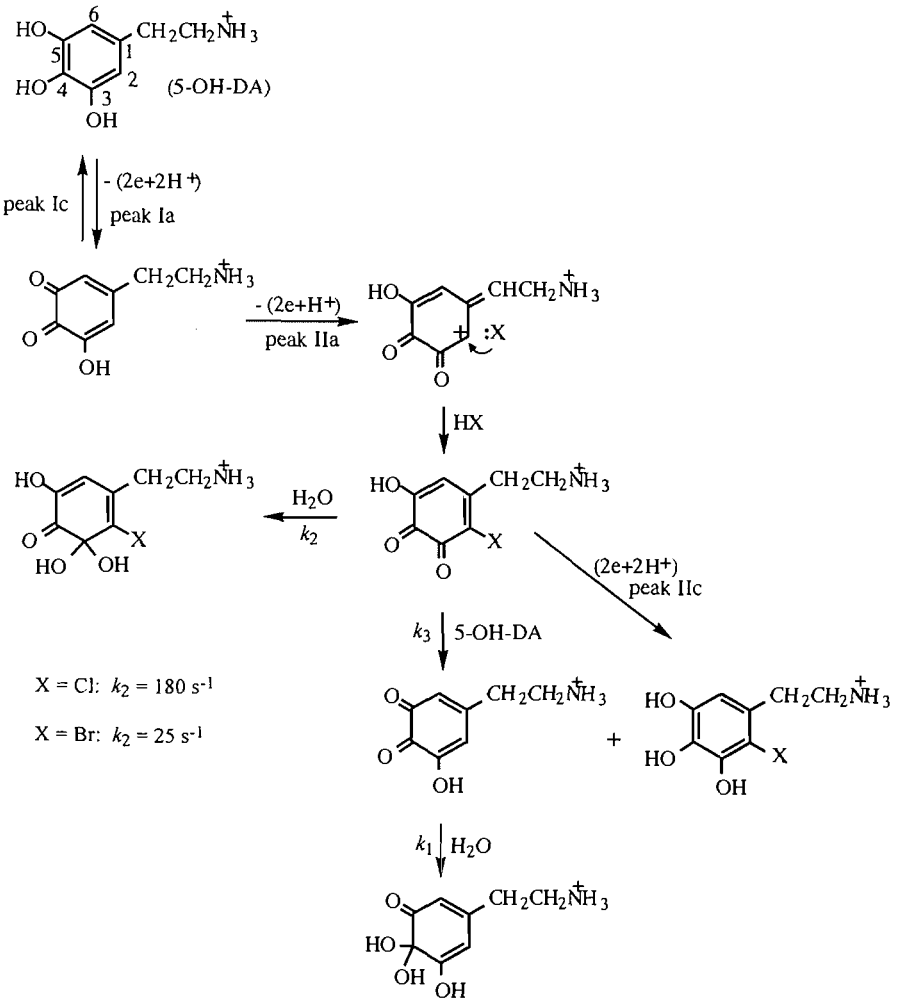
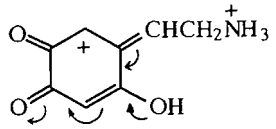


Scheme 3.

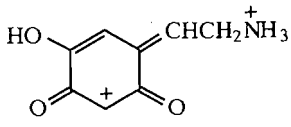


yls is disfavored. This assumption is supported by the fact that nucleophilic attack of glutathione on 6-OH-DA-*p*-quinone occurs at position C(6) (12).

Although diffusion of Br^- ions is faster than diffusion of 6-OH-DA molecules (compare, for instance, the j_L of the two-



I



II

electron oxidation wave I_a of 6-OH-DA with the j_L of the one-electron oxidation wave of Br^- ions in Fig. 4), the amount reaching the electrode–solution interface probably is not sufficient for complete bromination at C(3). As a result, partial hydroxylation may take place in parallel with the second bromination reaction. The addition of water is followed by further oxidation, which yields a tetraoxo derivative. This explains why the limiting current on the plateau of wave II_a exceeds slightly the six-electron level at low rotation rates (see the disc voltammograms in Fig. 6) and the ring current exceeds the two-electron level, when the disc potential is on the plateau of wave II_a. On the other hand, this behaviour further supports our initial assumption that the first attack of bromide occurs at C(6) and not at C(3). Otherwise, there is no possible route that could explain the results of the RRDE voltammetry.

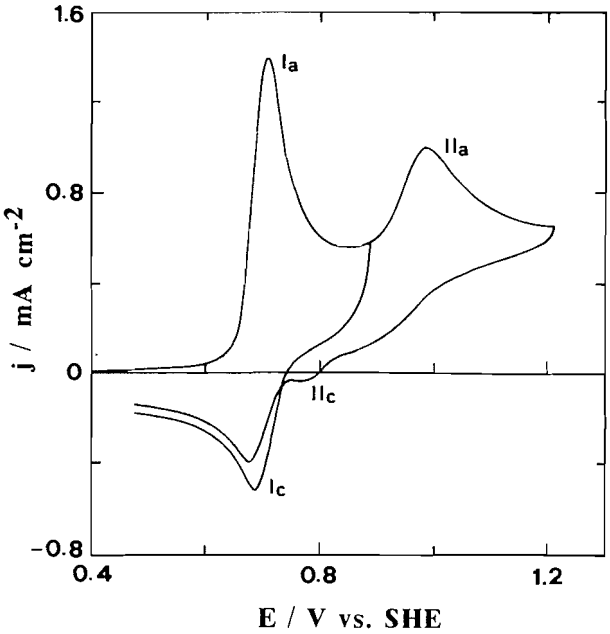
In the case of 6-OH-DA·HCl, only the first addition of HCl is fast enough; therefore, the voltammetric behaviour cannot give insights into the subsequent reactions. After electrolyses at the potential of wave II_a, attempts to isolate products from the electrolyzed solutions by common work-up, extraction, and lyophilization of the aqueous solutions were unsuccessful. The halogenated 6-OH-DA-*p*-quinones are probably unstable in solution. They are transformed to electro-inactive species, as indicated by CV of the solutions after electrolyses, which are presumed polymeric in nature.

Oxidation of 5-OH-DA·HCl and 5-OH-DA·HBr on Pt

Figure 7 shows ring-disc voltammograms of 5-OH-DA·HCl and 5-OH-DA·HBr. The ring potential was kept at 0.2 V to collect all oxidation products formed at the disc. The oxidation of 5-OH-DA in the presence of Cl^- and Br^- gives two waves I_a and II_a of equal height. The initial two-electron oxidation at 0.7 V is followed by a further two-electron oxidation-halogenation reaction (Scheme 3) at 1.1 V. The third anodic wave III_a that appears in the disc voltammogram of 5-OH-DA·HBr is due to the electrooxidation of unreacted Br^- ions. As pointed out in the case of 6-OH-DA·HBr, the diffusion of Br^- ions is much faster than the diffusion of hydroxydopamines. Wave III_a matches quite well with that of authentic LiBr, and disappears after the prior removal of the half concentration of bromide from the solution of 5-OH-DA·HBr. It should be noted that the oxidation of Br^- ions to Br_2 clearly occurs at more positive potentials (≈150 mV) than the oxidation–bromination reaction of 5-OH-DA-*o*-quinone.

The nucleophilic attack of Cl^- and Br^- ions occurs at position C(2) or C(6). The halogenated 5-OH-DA-*o*-quinone formed is reduced at less negative potentials than the unsubstituted 5-OH-DA-*o*-quinone. The broad peak II_c in the

Fig. 8. Cyclic voltammograms of 5-OH-DA·HCl (10^{-3} M) on Au in 0.2 M $HClO_4$. Scan rate $v = 400$ mV s^{-1}.



cyclic voltammogram of 5-OH-DA·HCl (Fig. 8) corresponds to this reduction. This peak may only be observed at a Au electrode and at relatively fast scan rates. The halogenated 5-OH-DA-*o*-quinones react with 5-OH-DA or undergo hydration (Scheme 3). The CV and the RRDE voltammetry indicate that the hydration reaction is much faster than the reaction with 5-OH-DA (e.g., $k_2 \gg k_3$). Its rate is even faster than the hydration of 5-OH-DA-*o*-quinone (Scheme 1) as can be concluded by the decrease of the ring currents at disc potentials above 1.0 V (Fig. 7). The rate of the hydration reaction was studied by the rotating ring-disc electrode. Values of N_k as a function of the rotation rate were evaluated at $E_D = 1.30$ V for 5-OH-DA·HCl and $E_D = 1.15$ V for 5-OH-DA·HBr taking into account four-electron oxidation at the disc and two-electron reduction at the ring.

The $1/N_k$ vs. $1/\omega$ plots are reasonably linear. The slopes give the following values of k_2:

For X = Cl: $k_2 = 180 \pm 30$ s^{-1} (25°C)

For X = Br: $k_2 = 25.0 \pm 5.0$ s^{-1} (25°C)

These values are, indeed, greater than the value of $k_1 = 3.4$ s^{-1} (Table 1) determined for the hydration of the unsubstituted 5-OH-DA-*o*-quinone. The hydration rate constant of the bromo derivative is smaller than that of the chloro derivative. This may be attributed to the steric hindrance of the voluminous bromo substituent. On the other hand, this suggests that the hydration occurs at the carbonyl group C(3), which is near to the substituent.

In conclusion, the electrochemical studies of 6-hydroxydopamine and 5-hydroxydopamine revealed that the first two-electron oxidation leads to formation of reactive quinoid intermediates. Reactions of these quinoid intermediates with nucleophiles yield substituted quinones that are not stable in solution. The reactions are initiated by the oxidation of the

third hydroxyl group. Cyclic voltammetry and rotating ring-disc electrode voltammetry were used to elucidate the reaction mechanisms. These techniques provide powerful tools for generating and detecting transient intermediates and products and give valuable information regarding the pathways and mechanisms of the redox reactions.

Substituted tetra-2,3-pyrazinoporphyrazines. Part II. Bis(tri-*n*-hexylsiloxy)silicon derivatives

Svetlana V. Kudrevich and Johan E. van Lier

Abstract: Dichlorosilicon complexes of substituted tetra-2,3-pyrazinoporphyrazines were obtained via condensation of 2,3-dicyanopyrazine, 2,3-dicyano-5,6-diphenylpyrazine, 2,3-dicyanoquinoxaline, 2,3-dicyano-benzo[*f*]quinoxaline, and 2,3-dicyano-dibenzo[*f,h*]quinoxaline with silicon tetrachloride in the presence of urea, quinoline, and tri-*n*-butylamine. Hydrolysis of the Si-Cl bond in concentrated H_2SO_4, followed by treatment with 0.01 N NaOH and aqueous NH_3, afforded the corresponding dihydroxides, which were converted to the bis(tri-*n*-hexylsiloxy)silicon derivatives via reaction with tri(*n*-hexyl)silane in 3-picoline (2,4,6-collidine) in the presence of tri-*n*-butylamine. The axial tri-*n*-hexylsiloxy substituents at the central silicon atom prevent aggregation in organic solvents, permitting detailed studies on the effects of structural modifications on the electronic spectra of tetraazaphthalocyanines. Our data show that each benzo ring addition, angularly condensed to the tetra-2,3-quinoxalinoporphyrazine, induces a hypsochromic shift (~10–15 nm) of the main absorption maximum.

Key words: phthalocyanine, aza analog, bis(tri-*n*-hexylsiloxy)silicon complex.

Résumé : Les dérivés substitués des tétra-2,3-pyrazinoporphyrazines du dichlorosilice ont été préparés via la condensation du 2,3-dicyanopyrazine, 2,3-dicyano-5,6-diphenylpyrazine, 2,3-dicyanoquinoxaline, 2,3-dicyano-benzo[*f*]quinoxaline et 2,3-dicyano-dibenzo[*f,h*]quinoxaline avec du tétrachlorure de silice en présence d'urée, de quinoléine et d'amine tri-*n*-butylique. L'hydrolyse de liaison Si–Cl dans du H_2SO_4 concentré, puis dans une solution de 0,01 N de NaOH et d'ammoniac, a produit des dihydroxydes appropriés qui ont été transformés en dérivés substitués de bis(tri-*n*-hexylsiloxy) via la réaction avec le tri-*n*-hexylsilane dans la 3-picoline (2,4,6-collidine) en présence d'amine tri-*n*-butylique. Les substituants axiaux tri-*n*-hexylsiloxy, attachés à l'atome de silicium central, empêchent complètement l'agrégation des molécules d'azaphtalocyanines dans les solvants organiques. Des études détaillées de l'influence de la modification structurelle sur les spectres électroniques du tétraazaphtalocyanine ont été effectuées. Il a été démontré que chaque anneau benzo angulaire, condensé au tétra-2,3-quinoxalinoporphyrazine, produit un déplacement hypsochromique (~10–15 nm) de la bande Q.

Mots clés : phtalocyanine, azaanalogue, complexe du bis(tri-*n*-hexylsiloxy)silice.

Introduction

The potential applications of silicon phthalocyanine (Pc), naphthalocyanine (Nc), and their aza analogs (azaPc's) to the sensitization and stabilization of semiconductor electrodes in photoelectrochemical cells (1), as media for optical data storage with a large capacity memory (2–6) and photosensitizers for photodynamic therapy of cancer (7–15) have been extensively studied over the past decade. These applications require well-defined properties of the substituted Pc's, including the solubility in lipophilic and hydrophilic media and absorbance in the required region of the visible spectrum. It is well known that phenyl substitution (16–18) and linear annelation (19–24) are effective means for *fine tuning* the visible spectra of the Pc and azaPc macrocycles. The effect of angular annelation on the electronic spectra of Pc and its analogs has more recently been addressed through the synthesis of a series of azaPc's differing in the number of angularly condensed benzo rings (16, 25, 26). Studies of the properties of these compounds permitted preliminary conclusions concerning the effect of aza substitution and angular annelation on the electronic spectra of Nc. However, more detailed studies on the spectral properties of the angularly annelated Nc analogs were hampered due to aggregation of the dye molecules in solution. This problem was overcome through *tert*-butyl substitution on the periphery of the macrocycle (26). Although double angular annelation of octaazaNc's was shown to cause a hypsochromic shift of the Q-band of about 25 nm, aggregation of the molecules still interfered, preventing us from estimating the effect of *sequential* annelation on the absorption maxima. Such substitutions appeared to be particularly useful in establishing the effect of phenyl substitution (linear and angular annelation) on the electronic spectra of tetra-2,3-pyrazinoporphyrazine and tetra-2,3-quinoxalinoporphyrazine. It is well known that axial substitution at the central silicon atom prevents the aggregation of Pc molecules in solutions. In this report we address the synthesis of axially substituted silicon complexes of azaPc's. The availability of a series of fully monomerized derivatives of tetraazaPc, containing the same silicon central atom, with good solubility in a single solvent, i.e., chloroform, allowed us to establish the effect of structural modifications about the macrocycle on the spectral properties.

Received March 29, 1996.

Results and discussion

The bis(tri-*n*-hexylsiloxy)silicon azaPc's **4***a–e* were prepared via straightforward synthetic routes as outlined in Scheme 1. The precursors of substituted tetra-2,3-pyrazinoporphyrazines, e.g., dinitriles of heterocyclic *o*-dicarboxylic acids, were prepared via dehydration of an appropriate diamide (2,3-dicyanoquinoxaline **1***c* (27)) or via the condensation of *o*-quinones with diaminomaleodinitrile (2,3-dicyano-5,6-diphenylpyrazine **1***b* (28), 2,3-dicyano-benzo[*f*]quinoxaline **1***d* (26), and 2,3-dicyano-dibenzo[*f,h*]quinoxaline **1***e* (28)).

The synthesis of the carbocyclic analogs, e.g., Pc(Nc) dichlorosilicon complexes, starting from the corresponding 1,3-diiminoisoindolines and silicon tetrachloride in tetrahydronaphthalene or quinoline, has previously been reported (1, 13, 29, 30). In our hands, this procedure failed in the case of the heterocyclic diiminoisoindolines. Instead, we found that the corresponding *o*-dinitriles **1***a–e* are good starting materials for the synthesis of dichlorosilicon complexes. Compounds **1***a–e* were condensed with $SiCl_4$ in the presence of urea using quinoline as a solvent and twofold excess of tri-*n*-butylamine as an acceptor of evolving HCl. The products **2***a–e* contain impurities and their thorough purification without modification of the Si—Cl bond was unattainable. Due to their poor solubility in organic solvents, recrystallization of **2***a–e* was impossible and, as we noted before (26), azaPc's cannot be sublimated. IR spectra of **2***a–e* all feature a characteristic band about 480 cm^{-1} (Si–Cl stretch). The products were of sufficient purity to be used as intermediates for the preparation of the dihydroxysilicon complexes **3***a–e*.

The hydrolysis of **2***a–e* was carried out by combining the methodology of Wheeler et al. (1) and Davison and Wynne (31). Heating **2***a–e* in concentrated H_2SO_4 for 2 h did not result in decomposition, suggesting that the aromatic system of silicon octaazaPc's is at least as stable as those of the carbocyclic analogs (1, 32). IR spectra of compounds **3***a–e* feature absorption bands at 3455–3475 cm^{-1} (O-H) and 844–850 cm^{-1} (Si-O). The microanalyses of the dihydroxysilicon azaPc's samples, purified in a Soxhlet extractor, were indicative of contamination with silica. Pure analytical samples of

[a]The samples were dried before analysing in vacuo (1 Torr) at 100°C for 4 h.

compounds **3***a–e* were obtained via hydrolysis of chromatographically purified bis(tri-*n*-hexylsiloxy)silicon complexes **4***a–e* (1). Solubility of **3***a–e* in organic solvents is much lower than that of the corresponding dichlorosilicon analogs. The former compounds are barely soluble in quinoline and only micromolar concentrations, suitable for spectral analysis, could be obtained. The visible spectra of dihydroxysilicon complexes **3***a–e* exhibit maxima at somewhat shorter wavelengths than their dichlorosilicon precursors, which is in accordance with literature data for the analogues $SiPcCl_2$ and $SiPc(OH)_2$ (29). The conversion of the dihydroxides **3***a–e* to the bis(tri-*n*-hexylsiloxy)silicon derivatives **4***a–e* was performed following the methodology of Wheeler et al. (1). Compounds **4***a–e* were purified chromatographically on silica gel and characterized by combustion analyses and spectroscopic data.

Comparison of the electronic spectra in the visible region of bis(tri-*n*-hexylsiloxy)SiPc **5** (λ_{max} 668 nm) (1) and its octaaza analog **4***a* (λ_{max} 624 nm), bis(tri-*n*-hexylsiloxy)SiNc **6** (λ_{max} 772 nm) (1) and its octaaza derivative **4***c* (λ_{max} 704 nm), shows that the magnitude of the hypsochromic shift due to the octaaza substitution of the CH groups adjacent to the porphyrazine macro-ring increases from 1080 cm^{-1} for the azaPc to 1250 cm^{-1} for the azaNc. This indicates that linear annelation renders the Pc aromatic system more responsive to aza substitution. Electron donating phenyl substituents, even when oriented out of the plane of the tetra-2,3-pyrazinoporphyrazine molecule, profoundly affect the absorption pattern. Thus, the octaphenyl-substituted compound **4***b* has a principal absorption maximum at 645 nm (bathochromic shift of 21 nm relative to **4***a*). It is interesting to note that the Soret band of **4***b* also undergoes a remarkable bathochromic shift. Addition of linearly condensed benzo rings to **4***a* results in a red shift of the Q-band (corresponding to quinoxaline structure of **4***c* fragments) of 1820 cm^{-1}. The corresponding value for the carbocyclic analogs **5** and **6** is 2015 cm^{-1}. It is evident that the electron-withdrawing character of the exocyclic nitrogen atoms is responsible for the decrease in sensitivity of the Pc aromatic system to the linear annelation.

Fig. 1. Electronic spectra of compounds **4***c* (-----), **4***d* (——), and **4***e* (— —) in chloroform (concentration ~10^{-6} M).

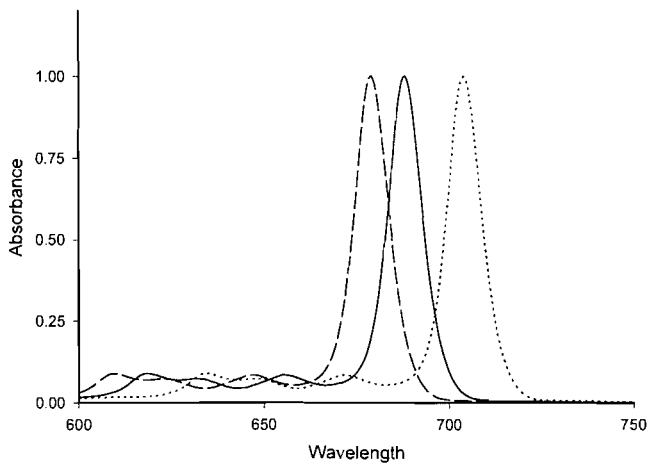

Figure 1 presents the visible region of the electronic spectra of compounds **4***c* (λ_{max} 704 nm), **4***d* (λ_{max} 688 nm), and **4***e* (λ_{max} 679 nm). Comparison of these spectra suggests that each angularly condensed benzo ring causes a *hypsochromic* shift of the main band of 10–15 nm. Compared to known metal complexes of the carbocyclic analogs of **4***c* and **4***e*, we also observe a blue shift of the Q-band of Nc upon double angular annelation: vanadyl Nc absorbs at 817 nm (33), whereas the main absorption maximum of vanadyl tetra-2,3-(dibenzo[*f,h*]naphthalo)porphyrazine is observed at 776 nm

(19) (both spectra in 1-chloronaphthalene). The carbocyclic analog of **4***b*, e.g., unsubstituted tetra-2,3-(benzo[*f*]naphthalo)porphyrazine, is unknown. On the other hand, angular annelation does not have the same effect in the case of Pc's. The Q-band maximum of PcCu is at 678 nm (in 1-chloronaphthalene) (34), 1,2-NcCu absorbs at 690 nm (in *o*-dichlorobenzene) (35), and *tert*-butyl substituted octabenzoPcCu absorbs at 700 nm (in *o*-dichlorobenzene) (36). Therefore, each benzo ring, angularly condensed to the Pc, causes a small shift of the main band, similar but of opposite sign to that observed for the Nc series.

Finally, we prepared a series of silicon complexes of substituted tetra-2,3-pyrazinoporphyrazines, featuring chloro-, hydroxy-, and tri(*n*-hexylsiloxy) axial ligands at the central atom. Tri(*n*-hexylsiloxy)silicon complexes are fully monomerized in chloroform, permitting us to evaluate the effect of angular annelation of tetra-2,3-quinoxalinoporphyrazine on the shift of the Q-band maximum in the electronic spectrum. These data should be particularly useful in the design of new Pc-related structures with *fine tuned* absorption maxima and selected solubility, as substrates for new materials.

Experimental

Materials and methods

FAB-MS were obtained on an LG Autospec Q mass spectrometer from the Department of Chemistry, Université de Montréal. ^{1}H NMR spectra were taken on a Bruker AC-300 (300 MHz) spectrometer using $CDCl_3$ as a solvent. UV–VIS spectra were recorded with a Hitachi U-2000 spectrophotometer. IR spectra were obtained on a Perkin Elmer 1600 spectrometer using KBr plates. Preparative chromatography was conducted on 70–230 mesh silica gel (Aldrich). TLC was performed on 0.25 mm thick Polygram SIL G/UV-254 plates (Macherey-Nagel, Germany). The solvents quinoline, 3-picoline, and 2,4,6-collidine were vacuum distilled from BaO under nitrogen.

2,3-Dicyanopyrazine **1***a* was obtained from a commercial source (Aldrich), 2,3-dicyano-5,6-diphenylpyrazine **1***b* (28), 2,3-dicyanoquinoxaline **1***c* (27), 2,3-dicyano-benzo[*f*]quinoxaline **1***d* (26), and 2,3-dicyano-dibenzo[*f*,*h*]quinoxaline **1***e* (28) were prepared by published methods. All the *o*-dinitriles were dried under high vacuum prior to complexation.

Dichlorosilicon complexes **2**a–e *(Table 1). General procedure*

o-Dinitriles **1***a–e* (7.5 mmol) were triturated with 0.5 g of urea, then dry tri-*n*-butylamine (3.6 mL, 2.78 g, 15 mmol), freshly distilled quinoline (5 mL), and silicon tetrachloride (0.86 mL, 1.28 g, 7.5 mmol) were added and the mixture was heated for 0.5–2 h in a flask protected with a $CaCl_2$ tube. The mixture was allowed to cool, the precipitate was collected, thoroughly washed with hot ethanol, and air dried. Compound **2***a* appears as a dark blue powder, **2***b* as very dark green, **2***c* as greenish-black, and **2***d* and **2***e* as brownish-green powders. The products contained some impurities but were suitable for use as intermediates for the preparation of bis[tri-(*n*-hexylsiloxy)silicon] complexes without further purification. IR spectra of **2***a–e* all contain a band around 480 cm^{-1} (m, Si-Cl).

Dihydroxysilicon complexes **3**a–e *(Table 2). General procedure*

Finely powdered **2***a–e* (1 g) were dissolved in concentrated H_2SO_4 (100 mL) and stirred at 50°C for 2 h. The mixture was filtered over a glass filter without prior cooling, poured over ice, and neutralized with aqueous NH_3. The precipitate was filtered, washed with hot water, acetone, and ethanol, resuspended in a mixture of 0.01 N aqueous NaOH-pyridine 1:1 (v:v), stirred at 50°C for another 2 h, then filtered, thoroughly washed with water, and vacuum dried. An attempt was made to purify analytical samples in a Soxhlet extractor using pyridine and acetone, but microanalysis showed that the samples were still contaminated with silica.

Hydrolysis of chromatographically purified bis[tri(*n*-hexylsiloxy)silicon] complexes **4***a–e* (1) (see below) afforded pure samples of the hydroxides **3***a–e*. IR (KBr): 3455–3475 cm^{-1} (O-H), 844–852 cm^{-1} (Si-O). Compounds **3***a–e* are barely soluble in quinoline (only in spectral concentrations, ~10^{-6} M).

*Bis[tri(*n*-hexylsiloxy)silicon] complexes* **4**a–e *(Table 3). General procedure*

A mixture of dihydroxides **3***a–e* (0.5 g, not Soxhlet-extracted), tri-*n*-hexylchlorosilane (2.5 mL), dry tri-*n*-butylamine (2 mL), and 50 mL of dry, freshly distilled solvent (3-picoline for **3***a–3d*; 2,4,6-collidine for **3***e*) was heated to 120°C for 24 h. The mixture was cooled to room temperature and filtered (the weight of dry residue was taken into account when yields of **4***a–e* were calculated). Methanol (25 mL) was added to the filtrate and the complexes were precipitated upon addition of a few drops of water. Chromatography over silica gel afforded pure compounds **4***a–e*. These complexes are brightly coloured (**4***a*, dichroic blue/red; **4***b*, grass green; **4***c*, dark green; **4***d* and **4***e*, yellow-green) and are highly soluble in toluene, chloroform etc.

Hydrogen vs. electron transfer mechanisms in the chain decomposition of phenacyl bromides. Use of isotopic labeling as a mechanistic probe

Jocelyn Renaud and J.C. Scaiano

Abstract: Ring-substituted α-bromoacetophenones react with alcohols in a chain reaction leading to the corresponding acetophenone, HBr, and the carbonyl compound from oxidation of the alcohol. Two different mechanisms, involving hydrogen or electron transfer by ketyl radicals, have been proposed in order to accommodate the unusual selectivities of these reactions. By studying the efficiency of isotope incorporation from deuterated alcohols, it has been possible to determine the relative contributions from both mechanisms. For example, electron transfer dominates in the case of 2-propanol, while hydrogen transfer is more important for methanol. The results demonstrate that ring substitution in the starting ketone is not a main contributing factor in the discrimination between the two mechanisms. The only parameter that seems to be playing a major role is the nature (reducing strength) of the ketyl radicals.

Key words: dehydrobromination, charge transfer, isotope effect, ketyl radicals.

Résumé : Les α-bromoacétophénones ayant des substituants sur le cycle réagissent avec les alcools selon une réaction en chaîne pour conduire à l'acétophénone correspondante, au HBr et au composé carbonylé résultant de l'oxydation de l'alcool. Dans le but d'expliquer la sélectivité inhabituelle de ces réactions, on propose deux mécanismes différents, impliquant le transfert d'hydrogène ou d'électron par le radical cétyle. L'étude de l'efficacité de l'incorporation isotopique à partir des alcools deutériés, a rendu possible la détermination des contributions relatives des deux mécanismes. Par exemple, le transfert d'électrons domine dans le cas du 2-propanol, tandis que le transfert d'hydrogène est plus important dans le cas du méthanol. Les résultats démontrent que la présence d'un substituant sur le cycle de la cétone de départ n'est pas le facteur contributif principal dans la discrimination des deux mécanismes. La nature (force réductrice) du radical cétyle semble être, dans ce cas, le seul paramètre important.

Mots clés : déhydrobromination, transfert de charge, radicaux cétyles.

[Traduit par la rédaction]

Introduction

The photodecomposition of α-bromoacetophenone and related phenacyl bromides provides a convenient source of phenacyl radicals, reaction [1] (1–3). These radicals are readily detectable because they have a characteristic absorption band in the 500 nm region (4). Bromine atoms, the other intermediates produced in this photoreaction, are invisible in laser photolysis experiments, but their presence can be confirmed by adding complexing reagents such as benzene or bromide ions (5–7).

[1] 
While the phenacyl radical has been written as a carbon-centered species, it can also be written in its canonical form, as an oxygen-centered radical (4), i.e.,

[2] 
Recent work has suggested that the "oxy" form of this radical may account for its absorption properties (4), which are reminiscent of those recently reported for cumyloxyl radicals (8, 9). While 4-methoxyphenacyl radicals may have a spin density as a high as 0.3 at the carbonyl oxygen, their reactivity is dominated by the radical character at the carbon site (1). Product studies on the addition of phenacyl radicals to olefins show that these reactions lead to C—C bond formation, thus showing typical carbon-centered radical behavior (10, 11). Methoxyphenacyl radicals have modest reactivity; for example, the addition of the *p*-methoxyphenacyl radical to the highly reactive double bond in 1,1-diphenylethylene occurs with a rate constant of 9.4×10^7 M^{-1} s^{-1} (1). In addition, they

are also modest hydrogen abstractors: an example showing their low reactivity towards hydrogen abstraction is observed in various alcohol solvents and acetonitrile as solvents. Typical half-lives for the *p*-methoxyphenacyl radical in solvents such as methanol, ethanol, 2-propanol, and acetonitrile are in the neighborhood of 10 μs (1).

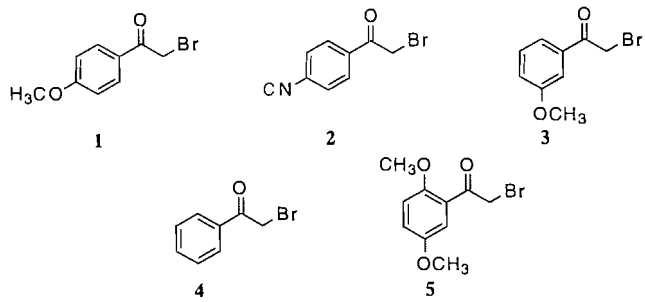
Although these carbon-centered radicals seem to be rather unreactive, our work with α-bromoacetophenones shows that steady-state irradiation in alcohol solvents leads to remarkably rapid consumption of the starting material with concomitant formation of the corresponding acetophenone. Typically, irradiation times for significant conversions are 20–50 times shorter in alcohols than in acetonitrile, thus suggesting the involvement of a chain reaction mechanism (3).

It should be noted that other bromo compounds are known to be able to carry similar chains. Chain lengths greater than 10 at temperatures between 30 and 60°C have been measured for systems studying the radical chain reaction of primary and secondary α-bromo esters by 2-propanol and 2-methyldioxolane (12). Also, using vicinal dibromides as starting materials, one can generate two bromine atoms per chain propagation step (13).

Earlier work reporting an exploratory study of this chain reaction mechanism for the dehydrobromination of ring-substituted α-bromoacetophenones in alcohols suggested a more complex mechanism than that originally anticipated (3). What seemed to be a simple electron transfer chain process turned out to be a somewhat more complex mechanism. To rationalize the unusual reactivity/selectivity of these reactions, we suggested a combination of two chain reactions involving hydrogen and electron transfer, taking place concurrently and competing for product formation. This chain reaction is mediated by the ketyl radicals derived by hydrogen abstraction from the alcohols by either the bromine atom or the phenacyl radical. In this article we make use of isotopic labeling in order to establish what fraction of the reaction proceeds by each mechanism; we combine these data with new and earlier results to provide a detailed understanding of these efficient reactions.

Our initial work on phenacyl radicals was stimulated by our interest in the photoinduced yellowing of papers manufactured from ultra-high-yield pulps. The yellowing process results largely from photoinduced reactions involving the chromophores in lignin; among these, mono- and dimethoxyphenols, methoxyacetophenones, and aryloxyanisoles are believed to play an important role (14). The absorption of light leads to various unstable intermediates, such as aromatic ketone singlets and triplets, phenoxyl, phenacyl, and peroxyl radicals, and presumably singlet oxygen. Ultimately, yellow products such as quinones, oligomers, and other degradation products are formed (14, 15). The knowledge of the kinetics and mechanisms of the reactions of unstable intermediates, particularly phenacyl radicals, should advance our understanding of lignin photochemistry in general, and ultimately lead to rational strategies to inhibit the photoyellowing of paper.

Phenacyl radicals can be produced in lignin by several reactions, including the photocleavage of structures containing the α-phenoxyacetophenone moiety. To study the behavior of this radical without the spectral and chemical interferences of the phenoxyl radical, ring-substituted derivatives of α-bromoacetophenones can be used as phenacyl precursors, where the primary photoprocess involves cleavage of the α-C—Br bond to yield the phenacyl radical and a bromine atom, reaction [1]. Ketones **1–5** are the subject of this work.



Experimental

Materials

The various substituted α-bromoacetophenones were obtained from either Lancaster or Aldrich and were recrystallized from hexane before use. Bromide ions were added as $(C_4H_9)_4NBr$ from Aldrich, which had suitable solubility in the alcohol solvents used. *n*-Dodecane was a BDH product, valerophenone; *p*-methoxyacetophenone, and *p*-cyanoacetophenone were purchased from Aldrich. Solvents were OmniSolv grade from BDH. Deuterated alcohol solvents were obtained from either Aldrich or Cambridge Isotope Laboratories.

General techniques

Competitive studies

Typical samples were 3 mL, containing 2–10 mM concentration of a ketone (**1–5**) in alcohol solvents. The samples were contained in Pyrex tubes and were deaerated (15 min) by bubbling with oxygen-free nitrogen. The samples were irradiated with two to six RPR-3500 lamps; irradiations were carried out in a "merry-go-round" apparatus to ensure that all samples received the same irradiation dose. Irradiation times varied between 1 and 5 min and were adjusted in order to obtain around 20% conversion of the starting material. Calculations of conversions were done using *n*-dodecane as an internal standard. The temperature of the irradiation chamber was in the 30–35°C range. The product ratios were analyzed by GC and (or) by GC–MS. Product identification was achieved by comparison of GC retention times with authentic samples and (or) GC–MS analysis.

Deuterium labeled product studies

Typical samples were 1 mL, containing 2 mM *para*-substituted α-bromoacetophenones in deuterated alcohol solvent. The samples were contained in Pyrex tubes and were deaerated (15 min) by bubbling with oxygen-free nitrogen. The samples were irradiated as described above. Sodium carbonate was added to each sample to prevent any acid-catalyzed isotopic exchange between the ketone product and the solvent. Substitution patterns were analyzed by GC–MS. Control samples were prepared to ensure that isotopic substitution remained intact throughout the experiment. This was done using a 2 mM solution of *p*-methoxyacetophenone in CH_3OD, CD_3OH, and

$CH_3CHODCH_3$, adding 1 mM HBr, purging for 15 min with oxygen-free nitrogen, and irradiating at 350 nm with two lamps for 2 min. The only system that did show deuterium incorporation was that involving CH_3OD as the solvent. CD_3OH and $CH_3CDOHCH_3$ were considered "clean" systems since any exchange with the solvent would not alter the substitution pattern. Control experiments using $CD_3CHOHCD_3$ were also carried out to verify that no atom transfer involving loss of hydrogen atom from the methyl group of the ketyl radical to form $CD_2{=}C(OH)CD_3$ would interfere in the deuteration pattern of the final ketone. This was done with the compounds **1** and **2** and, for both sytems, the M+1 peak was measured to be ~10%, as expected from the ^{13}C abundance. All calculations of percentage electron transfer took into consideration the natural abundance of ^{13}C, which was measured to be 9.5% (expected: 9.9% for **1**–**3**) using authentic samples of the corresponding acetophenones. Furthermore, no M − 1 contribution were observed for any mass spectra during this analysis.

Quantum yields

These were determined by two different experiments. In a first experiment, compound **1** was used as a starting material and the quantum yields were measured by comparing the acetophenone yields in cyclohexane with those obtained in alcohols. Irradiations were carried out at 350 nm and product concentrations determined as indicated below. The quantum yield for the primary photocleavage of the C—Br bond in cyclohexane was taken as 0.35, the same value determined earlier in methanol solvent (2). The second experiment involved using a reference system as an actinometer. Valerophenone in benzene yields acetophenone with a quantum yield of 0.30 (16). Compound **4** was used as a starting material and the quantum yields were measured in methanol, ethanol, and isopropanol. Both systems had concentrations adjusted to have an absorption of 1.5 at 350 nm. Concentrations of 25 mM for the α-bromoacetophenone system and 100 mM for the reference system were used throughout these experiments. Deaerated samples were irradiated side by side with one to six RPR-3500 lamps as described above. Irradiation times were varied between 10 s and 70 min. Calculations of conversions were done using *n*-dodecane as an internal standard. The ratios between acetophenone formation and internal standard were analyzed by GC and then plotted as a function of time. Comparing slopes between the two systems permitted measurement of chain lengths.

Gas chromatography

The competitive studies of ketone photodecomposition in alcohol solvents and quantum yield experiments using valerophenone as a reference system were quantitatively analyzed on a Perkin Elmer model 8320 capillary gas chromatograph equipped with a flame ionization detector (FID) and a DB-5 bonded-phase column of 15 m length (from J & W Scientific).

GC–MS

Analyses of samples, including those containing Bu_4NBr, were quantitatively performed on a Fisons Instruments 8000 series gas chromatograph with a capillary (DB-5, 15 m, 0.25 mm) column coupled with a MD-800 series mass spectrometer equipped with an EI ion source and a Dynolite detector, and controlled by a DEC/486 PC operating with Masslab software, release 1.12.

Cyclic voltammetry

Cyclic voltammetry measurements were carried out using a standard three-electrode cell with a glassy carbon working electrode 3 mm in diameter, a platinum coil counter electrode, and a platinum wire reference electrode in a Bu_4NBF_4 (0.1 M) – acetonitrile solution. The solvent for all measurements was distilled acetonitrile (EM Science) containing 0.1 M tetrabutylammonium perchlorate (TBAP/Fluka) as the supporting electrolyte, which was recrystallized twice from a CH_2Cl_2–ether mixture. Solutions were deoxygenated with a stream of dry argon. Measurements were made using a PAR model 173 potentiostat equipped with a PAR model 175 universal cell programmer. Voltammograms were recorded on a HP 7045B X–Y recorder. All potentials are reported with respect to the saturated calomel electrode (SCE). The voltammogram obtained for α-bromoacetophenone (**4**) at 200 mV s^{-1} showed two reduction peaks. The first cathodic peak, located at −0.78 V with respect to the saturated calomel electrode, is relevant to the irreversible reduction of compound **4**, and its height (measured with respect to the monoelectronic wave of ferrocene) corresponds to the consumption of one electron per molecule. The second peak that was observed corresponds to the reduction of acetophenone as shown by comparison with an authentic sample. The same cyclic voltammetric behavior was observed with compounds **1** and **2**. The results obtained by these experiments are summarized in Table 4 and were done at the National Research Council under the supervision of Drs. A. Houmam and D.D.M. Wayner.

Bond energy data analysis

Bond energies for the various ketyl radicals were calculated using the NIST Structures and Properties Database and Estimation Program, software version 1.1 (17).

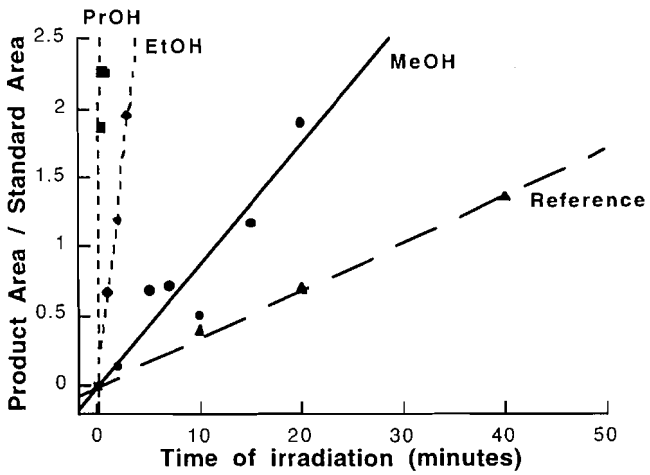
Results and discussion

It is well established that ketones **1**–**5** undergo efficient photodecomposition in alcohol solvents upon broad band irradiation centered at 350 nm. For example, in the case of compound **1**, the relative yields of *p*-methoxyacetophenone in various solvents were determined to be 1:4:97 for cyclohexane, methanol, and 2-propanol (3). Taking the quantum yield for the primary photocleavage of the C—Br bond in cyclohexane as 0.35 (2), the overall quantum yields are 1.4 and 34 for methanol and 2-propanol, respectively, showing a long chain in 2-propanol and a short one in methanol.

To achieve a better understanding of the chain lengths involved in these systems, valerophenone in benzene was chosen as an actinometer (16), since it gave the same photoproduct as our compound **4** in the alcohol systems of interest. Figure 1 shows the results obtained in three alcohol solvents using six UV lamps.

When comparing slopes for any given experiment with that for valerophenone (used as actinometer) one obtains relative chain lengths of 2.5 and 19 for methanol and ethanol, respectively, and a lower limit of $\geq$116 for isopropanol. In isopropanol, the conversion was so high that very short irradiation times had to be employed in order to minimize any interfer-

Fig. 1. Acetophenone yield ratios as a function of time of irradiation for valerophenone as a reference and for compound **4** in methanol, ethanol, and isopropanol irradiated with six RPR-3500 lamps.



ence from the photoproducts; exposure times were of the order of seconds as opposed to minutes for the other two solvents. Depletion of the starting material led to nonlinear production of acetophenone even after 30 sec. Taking into consideration the quantum yield of acetophenone formation of 0.30 for 100 mM valerophenone in benzene (16), values of 0.75, 5.7, and a lower limit of ≥35 were obtained as overall quantum yields of product formation. Again, short (or nonexistent) chain lengths in methanol and increasing chain lengths for ethanol and isopropanol were shown.

In a chain reaction mechanism involving photochemical initiation, the chain length is inversely proportional to the square root of the light absorbed, i.e.,

$$\text{Rate}_p \propto (\text{Rate}_i/k_t)^{1/2} \times k_p \times (\text{conc. term})$$

where the "concentration term" will usually contain one of the reactants. Rate_i is the rate of initiation. The chain length, λ, is given by:

$$\lambda = (\text{Rate}_p/\text{Rate}_i) = k_p/(\text{Rate}_i \times k_t)^{1/2} \times (\text{conc. term})$$

For a reaction initiated photochemically, the rate of initiation will be directly proportional to the light intensity absorbed (I_a) by the photoinitiator,

$$\text{Rate}_i \propto I_a$$

thus,

$$\lambda \propto 1/I_a^{1/2}$$

In a first, rather rough, approximation, I_a is proportional to the number of lamps used in the photoreactor, leading to:

$$\lambda \propto 1/(\text{no. of lamps})^{1/2}$$

To verify this mathematical relationship, the number of lamps was varied in a series of experiments. Table 1 shows the

Table 1. Chain lengths of compound **4** in various alcohol solvents.

Solvent	UV lamps	Slope ratio	Chain length
MeOH	1	5.3	1.6
i-PrOH	2	263	79
MeOH	6	2.5	0.75
EtOH	6	19	5.7
i-PrOH	6	>116	>35

results obtained in methanol and isopropanol. These results are in agreement with the mathematical relationship derived above, and therefore the chain length increased when fewer lamps were used in the photoreactor. Table 1 also includes results obtained in ethanol using six UV lamps.

It is well established that the primary photoprocess involves cleavage of the C—Br bond, as shown in eq. [1]. The radicals produced in this reaction can abstract hydrogen readily from alcohols and can initiate chain reactions by two distinct mechanisms. Schemes 1 and 2 illustrate the mechanism in the case of methanol.

Since both mechanisms involve the intermediacy of a common radical ($\cdot CH_2OH$), they cannot function as independent chains and we presume one of them will normally dominate. The final products from both reactions should be the same. Scheme 2 represents an electron transfer mechanism, which we anticipated would be favored in the case of electron-deficient molecules such as **2**. At low conversions, the reactions are quite clean, giving only the expected products.

Scheme 1. Bromine atom mechanism (hydrogen transfer).

$$Br^{\cdot} + CH_3OH \xrightarrow{k_2} HBr + \dot{C}H_2OH$$

$$\dot{C}H_2OH + ArCOCH_2Br \xrightarrow{k_3} Ar\dot{C}(OH)CH_2Br + CH_2O$$

$$Ar\dot{C}(OH)CH_2Br \xrightarrow{k_4} ArC(OH)CH_2 + Br^{\cdot}$$

$$\downarrow$$

$$ArCOCH_3$$

Scheme 2. Phenacyl radical mechanism (electron transfer).

$$ArCOCH_2^{\cdot} + CH_3OH \xrightarrow{k_5} ArCOCH_3 + \dot{C}H_2OH$$

$$\dot{C}H_2OH + ArCOCH_2Br \xrightarrow{k_6} CH_2O + H^+ + [ArCOCH_2Br]^{\dot{-}}$$

$$[ArCOCH_2Br]^{\dot{-}} \xrightarrow{k_7} ArCOCH_2^{\cdot} + Br^-$$

To distinguish between the mechanisms of Schemes 1 and 2, experiments were carried out in the presence of 10 mM bromide ions, added as Bu_4NBr. We assumed that the mechanism of Scheme 1 would be heavily influenced, since bromine atoms form the less reactive intermediate $Br_2^{\dot{-}}$ by complexation with bromide, i.e., (6, 13, 18),

$$[3] \quad Br^{\cdot} + Br^- \rightleftharpoons Br_2^{\dot{-}}$$

We found that in methanol solvent, addition of bromide ion caused a 4.5 times decrease in product formation in the case of **1**, but this was reduced to only a factor of 2.0 in the case of **2**.

These results suggest that the bromine atom mechanism must be dominant for **1** and possibly plays a role even in the case of the electron-deficient cyano-substituted compound **2**.

To determine the relative reactivity of ketones **1–5** towards ketyl radicals, we carried out a series of competitive experiments in which ketones **1–5** were irradiated in pairs, and the ratio of products was examined for various ratios of starting materials. The product ratio for ketones **A** and **B** is related to the ratio of precursors according to:

$$[4] \quad \frac{\phi_A}{\phi_B} = \frac{k_r^A}{k_r^B} \frac{[A]}{[B]}$$

where k_r^A and k_r^B represent the values of k_3 and k_6, since these are the only steps in which the two ketones compete for reaction with the ketyl radical, i.e.,

$$[5] \quad k_r^A = k_3^A + k_6^A$$

Clearly, product formation in both reaction schemes is determined by reaction of the ketyl radicals with the α-bromoacetophenones, regardless of which one is the predominant mechanism.

Figure 2 shows plots according to eq. [4] for representative pairs of ketones in methanol, while Fig. 3 shows the corresponding plots for **1** and **2** in methanol, ethanol, and 2-propanol. The values of k_r^A/k_r^B obtained from these studies have been summarized in Table 2. The *para*-substituted ketones follow the anticipated order of reactivity according to their electron-accepting ability, i.e., *p*-CN > *p*-H > *p*-CH_3O.

We were surprised by the results for **1–2** mixtures in the different alcohols. These results (see Table 2) show that the selectivity order is 2-propanol > ethanol > methanol. Assuming that the better reducing agent (2-propanol) will react faster, one would have anticipated the lowest selectivity in this case.

The fact that **1** is less reactive than **2** suggests that the reaction is not in the Marcus inverted region since the kinetics follow the normal dependence on driving force (19, 20), A more likely explanation for the unusual selectivity–structure dependence is that the hydrogen transfer mechanism of Scheme 1 is intrinsically less selective than the electron transfer process of Scheme 2. Further, we anticipate that the mechanism of Scheme 1 will be more likely to be favored over Scheme 2 in the case of methanol than for 2-propanol. This rationale is based on our analysis of bond energy data for the various ketyl radicals, where reaction [6] is not very sensitive to the detailed substitution pattern.

$$[6] \quad R^1R^2\dot{C}OH \longrightarrow R^1R^2CO + H$$

The ΔH_r for reactions is 30.3, 27.7, and 27.2 kcal/mol for the radicals from methanol, ethanol, and 2-propanol, respectively (17).

A quantitative approach to discriminating between these two schemes is to utilize deuterium-labeled alcohols, since both reaction pathways should give a distinct isotopic pattern. Under such isotopic labeling conditions, Schemes 1 and 2 would yield the same product, acetophenone, with one unit mass difference, and Schemes 3 and 4 show the reaction products for the case of compound **1** in CD_3OH.

Fig. 2. Dependence of product ratios following 350 nm irradiation of **1/2** (●) and **4/2** (■) mixtures in methanol.

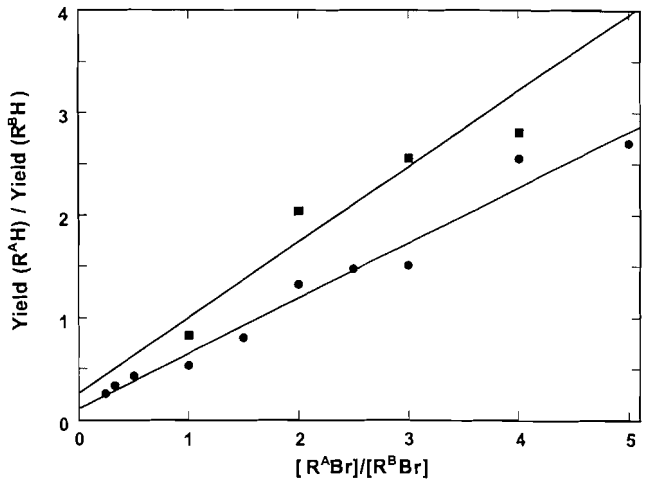


Fig. 3. Dependence of the product ratios following 350 nm irradiation of **1/2** mixtures in methanol, ethanol, and 2-propanol.

Table 3 shows the percentage of electron transfer measured for compounds **1** and **2** in *three* different deuterated alcohol solvents. The choice of substrates permitted study of both extremes of the electron-accepting capability of the *para*-substituted family, and the choice of alcohols permitted study of both extremes of the electron-donating capability of the ketyl radicals.

The percentage of electron transfer was determined by measuring and comparing the intensity (%TIC) of the molecular ion peaks corresponding to the parent and the mono-deuterated acetophenones. A measured natural abundance of ^{13}C of 9.5% was taken as the correction factor for adjusting these peaks. For example, the system studying the photochemistry of compound **1** in CD_3OH was analyzed as follows:

Product formation resulting from Scheme 3 gives a molecular ion peak of 150. Correcting for the ^{13}C content, the molecular ion peak now corresponds to:

$$M_{150} = M_{150\,(exp.)}\,(1 + 9.5\%)$$

Product formation resulting from Scheme 4 gives a molecular ion peak of 151. Correction of this peak corresponds to:

$$M_{151} = \{M_{151\,(exp.)}\,(1 - (M_{150\,(exp.)} \times 9.5\%))\} \times (1 + 9.5\%)$$

where the last multiplying factor takes into consideration the ^{13}C abundance present in the mono-deuterated peak.

Therefore the percentage of electron transfer (%et) is given by the following relationship:

$$\%et = M_{151} / (M_{150} + M_{151}) \times 100\%$$

and consequently the percentage of hydrogen transfer (%Ht) is given by:

$$\%Ht = 100\% - \%et$$

Clearly, these results demonstrate that the nature of the starting material is not a main contributing factor in the discrimination between the two schemes. The only parameter that seems to be playing a major role is the nature (reducing strength) of the ketyl radicals.

Table 3. Percent of electron transfer measured for compounds **1** and **2** in various deuterated alcohol solvents (^{13}C corrected).

Compound	CD_3OH	$CH_3CDOHCH_3$	$CH_3CHODCH_3$
1	21	81	96
	23	85	98
	22	77	96
Average	22	81	97
2	23	88	96
		89	94
		87	93
		82	
Average	23	86	94

Table 4. Reduction potentials[a] for compounds **1**, **2**, and **4** in acetonitrile – 0.1 M TBAP at 25°C, reported with respect to the saturated calomel electrode (SCE).

Compound	E (RBr / R·Br$^-$) V vs. SCE
1	−0.78
2	−0.68
4	−0.78

[a]Estimated irreversible reduction potentials, see experimental section.

Because of isotope effects, one can anticipate that the hydrogen transfer step in the overall mechanism (k_3) will be the one that is going to be influenced the most by the nature of the deuterated solvent. This effect will explain the differences in percentage of electron transfer between the two isopropanol solvents. In the case of $CH_3CHODCH_3$, that step is slowed down to the degree of being unable to compete anymore with the electron transfer step (k_6) and therefore we observe near-quantitative electron transfer for that system.

Cyclic voltammetry experiments were performed on the *para*-substituted family in order to verify that the starting material is an unimportant parameter in the overall chain reaction mechanism. Table 4 summarizes the results obtained for the reduction potentials measured in acetonitrile. These results are in agreement with the previous statement that the nature of the substrate is of little consequence in determining the reaction pathway chosen during the photodecomposition.

Conclusion

In conclusion, the photoinitiated reaction of ring-substituted α-bromoacetophenones with alcohols involves an efficient chain reaction leading to the corresponding acetophenone, HBr, and the carbonyl compound from oxidation of the alcohol. Two different mechanisms, involving hydrogen or electron transfer by ketyl radicals, were proposed in order to accommodate the unusual selectivities of these reactions. Studies of isotope incorporation from deuterated alcohols leads to the conclusion that electron transfer (Scheme 2) dominates in the case of 2-propanol, while hydrogen transfer (Scheme 1) is most important for methanol.The results demonstrate that ring substitution in the starting ketone is not a main contributing factor in the discrimination between the two

mechanisms; the observation is further corroborated by the relatively minor variations observed (see Table 4) in the reduction potentials. The only parameter that seems to be playing a major role is the nature (reducing strength) of the ketyl radicals.

Acknowledgments

This work has been supported by the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Canadian Networks of Centres of Excellence, through its program on Mechanical and Chemimechanical Wood Pulps. J.R. is the recipient of an NSERC graduate scholarship and J.C.S. of a Killam Fellowship awarded by the Canada Council. The authors thank Drs. A. Houmam and D.D.M. Wayner for help regarding the cyclic voltammetry measurements.

Synthesis of chemically and functionally diverse scaffolds from pentaerythritol

Stephen Hanessian, Hubli Prabhanjan, Dongxu Qiu, and Sudhir Nambiar

Abstract: Pentaerythritol (2,2-bis-hydroxymethyl-propane-1,3-diol) was converted into a series of mono-, di-, and trisubstituted derivatives, comprising allyl ethers and amino-alkyl ethers, by systematic chemical manipulation of the hydroxy groups. The remaining hydroxymethyl group in the case of the trisubstituted analog was functionalized with ether groups bearing terminal ω-carboxyl or ω-alkene groups. These derivatives are versatile templates and scaffolds for single, double, or triple substitution with appropriate ligands forming amides and esters, and allowing the attachment of the ω-alkene or ω-carboxyl group to solid support for combinatorial chemistry.

Key words: molecular diversity, scaffolds, templates and tris(2-aminoethyl)-pentaerythritol.

Résumé : Le pentaérythritol (2,2-bis-hydroxymethyl-propane-1,3-diol) a été converti en une série de dérivés mono-, di- et trisubstitués portant des groupes éther allylique et éther aminoalkyle par manipulation systématique des fonctions hydroxy. Le groupe hydroxyméthyle restant dans le cas des dérivés trisubstitués a été fonctionnalisé par un des groupes ethers avec un groupe terminal carboxy ou alcényle. Les dérivés sont utiles comme des sources de branchement des ligands pharmacologiquement actives par des liaisons amides ou ester. Des applications dans la chimie combinatorielle sur phase solide sont aussi envisageables.

Mots clés : diversité moléculaire, tris(2-aminoethyl)-pentaerythritol.

Recent interest in chemical diversity in conjunction with combinatorial methods of lead structure generation has instigated a search for readily available polyfunctional organic molecules that can be manipulated in a systematic manner (for recent reviews, see ref. 1). Such molecules can be utilized as templates or scaffolds onto which one can introduce variable functionality with spatially predetermined dispositions (2). For example, the incorporation of specific pharmacophores or related motifs at the extremities of such scaffolds can lead to binding at different receptor sites with potentially novel therapeutic applications (3). Alternatively, the attachment of the template or scaffold molecule to a polymer support through one of its arms, allows the voluntary elaboration of one or more remaining chains in a parallel or combinatorial mode for the discovery of biologically active sequences on growing chains. In the case of templates capable of replicating outwards from a core unit, it is possible to construct dendritic molecules (for selected examples, see ref. 4) with intriguing shapes and exciting physical properties.

In connection with our interest in the general area of chemical and functional diversity (5), we wished to prepare organic templates capable of accommodating one, or more, bioactive molecules in order to release them in a sustained manner in a chemically or enzymatically induced process. Another objective was to prepare polyfunctional molecules that could allow us to generate clusters of immunologically relevant haptens on a given template. We have previously shown that pentaerythritol can serve as an excellent anchor for clustering potential megacaloric nutrients upon its framework by ester linkages (6).

We report herein our studies in the systematic manipulation of the readily available pentaerythritol (2,2-bis-hydroxymethyl-propane-1,3-diol) **1**, and the introduction of versatile functionality through a series of O-substitution and S_N2 displacement reactions.

In spite of the low cost and versatile structure of pentaerythritol, relatively few differentially functionalized derivatives are known (7). Tetrabromo and tetraamino derivatives of pentaerythritol have been known for many years (8). Recently, Neumann, Woulfe, and co-workers (9) reported the synthesis of a triamino analog of pentaerythritol in conjunction with novel routes to 1,1,1-tris(aminomethyl)ethane (TAME), which is a well-known ligand for metal ions. Newkome et al. (10) recently reported the preparation of tetrakis (ω-bromoalkyl)methanes from pentaerythritol, and their utilization in carbon extension reactions to generate functionalized cascade core molecules. Finally, Kremers and Meijer (11) utilized pentaerythritol for the preparation of chiral dendrimers in their racemic forms.

Scheme 1 illustrates the sequence for the synthesis of monofunctionalized derivatives of tris(2-aminoethyl)pentaerythritol proceeding via the intermediacy of the corresponding tris(2-azidoethyl) ether of pentaerythritol. A variety of ether and ester functions could be introduced on the remaining hydroxymethyl group without affecting the resident azidoethyl groups.

Stoichiometrically controlled silylation of pentaerythritol **1**

with *tert*-butylchlorodiphenylsilane in DMF (12) gave the monosilylated derivative **2** in 84% yield, which was transformed into the tri-*O*-allyl derivative **3** under standard conditions. The allyl groups were oxidatively cleaved by ozonolysis and the resulting trialdehyde was reduced with $NaBH_4$ to give the triol **4** in good overall yield.

Conversion to the triazido derivative **5** was accomplished by treating **4** with mesyl chloride in pyridine at 0°C to form the trimesyl ester, followed by displacement by azide ion. After removing the *tert*-butyldiphenylsilyl group in **5** with TBAF, the resulting alcohol **6** was converted to allyl and 1-octenyl derivatives **7** and **8** in high yields, by treating with allyl bromide and 1-octenyl bromide, respectively. Finally, reduction of the azido functions in **7** and **8** with triphenylphosphine in THF (13) afforded the desired scaffold molecules **9** and **10**, respectively, as viscous light yellow syrups that were sufficiently pure to be used in subsequent transformations.

The triazido derivative **6** could be easily esterified with a fatty acid. Thus, treatment with stearic acid in the presence of DCC and DMAP gave the stearoyl derivative **11** in high yield. The terminal double bond in **8** was ozonolyzed, and the resulting aldehyde was oxidized to an acid **12** upon treatment with PDC. Esterification of the acid with methanol and benzyl alcohol individually gave the respective ester derivatives **13** and **14**.

We have used the monofunctional tris(2-aminoethyl) derivatives **9** and **10** as tripodal primary amines for amide bond formation with appropriate glycosylamino acid derivatives (14). Such clustered glycopeptide derivatives are interesting haptens for immunological studies in conjunction with the preparation of artificial vaccines (15) against certain types of tumors.

The preparation of a mono(aminoethyl) ether derivative of pentaerythritol involved a different strategy, which is illustrated in Scheme 2. Controlled allylation of diol **15** (16) with allyl bromide in DMF gave the monoallylated derivative **16** in 60% yield, which was in turn converted into diol **17**, by ozonolysis of the double bond to an aldehyde and subsequent reduction with $NaBH_4$. Treatment of **17** with *tert*-butylchlorodiphenylsilane in DMF led to the monosilylated derivative **18** without any detectable disilylation, undoubtedly due to the neopentylic nature of the other hydroxymethyl group. Hydrogenolytic cleavage of the benzyl groups over Pd–C gave the triol **19** in high yield.

In a parallel sequence of reactions similar to those leading to **18**, the two hydroxyl groups in **15** could be allylated under conditions described for **3** to give **20**. Oxidative cleavage of **20**, followed by reduction, gave a diol **21** that was converted to **22** by selective monosilylation. Mesylation of **22** followed by nucleophilic displacement with azide ion gave the azido ion derivative **23** in high overall yield. Treatment of **23** with thiolacetic acid (17) gave the corresponding N-acetyl derivative **24**, which was subjected to hydrogenolysis to give the diol **25**.

It was also of interest to prepare tris(1,1,1-aminomethyl)

ethanol, a triamino pentaerythritol in which one hydroxymethyl group was free for further elaboration into ether and acid groups with a view of conjugation to appropriate carriers or attachment to solid-phase matrices. The preparation of mono-*O*-benzyl triazido-trideoxy pentaerythritol and its reduction to the corresponding triamino derivative was described by Woulfe and co-workers (9), adopting the method of Fleischer (18) (NaN_3, diethylene glycol, 120°C, followed by Pd/C, H_2 in methanol).

Our protocol started with the tri-mesylation of **2** and subsequent displacement with sodium azide in DMF at 120°C to give **26** in good overall yield (Scheme 3). Treatment with fluoride ion removed the silyl ether group to give the triazido-derivative **27**, which was isolated as a syrup. Working in the mmol scale, we encountered no problems with the azido functions, although caution must be exercised at all times with polyazido compounds, especially with larger runs (8). The 1-octenyl ether **28** was readily prepared by alkylation in the presence of KH and tetrabutylammonium iodide in DMF at 0°C. Presumably, alkylation was accelerated by formation of the tetrabutylammonium alkoxide, which is more reactive than the corresponding potassium alkoxide (19). Ozonolytic cleavage of **28**, followed by oxidation and esterification, gave the corresponding carboxylic acid **29** and the benzyl ester **30**. Finally it was possible to achieve chemoselective reduction of the azido group in **28** by treatment with triphenylphosphine to afford the corresponding triamino derivative **31**.

The functionally differentiated derivatives of pentaerythritol shown in Schemes 1–3 should find utility in a number of areas relating to the expression of chemical diversity on polyfunctional scaffolds and templates. The presence of carboxylic acid, alcohol, and olefinic groups on tethers of appropriate chain lengths should allow the attachment of these pentaerythritol-derived motifs on solid supports and the further exploration of their chemistry.

Experimental

Melting points are uncorrected. ^1H NMR spectra were recorded at 300 MHz in $CDCl_3$ (unless otherwise indicated), with $CHCl_3$ as reference. ^{13}C NMR spectra were recorded at 75 MHz in $CDCl_3$ (unless otherwise indicated), with $CHCl_3$ as reference. Wherever necessary, ^1H NMR assignments were supported by appropriate homonuclear correlation experiments (COSY). IR spectra of samples were recorded as films. Mass spectra were recorded using electron ionization (EI) at 70 eV or by the fast atom bombardment (FAB) technique. Chromatography was performed on 230–400 mesh silica gel by flash technique (20). Thin-layer chromatography (TLC) was performed on glass plates coated with a 0.02 mm layer of silica gel 60 F-254. All solvents were freshly distilled before use.

2,2-Bis-hydroxymethyl-propane-1,3-diol mono *tert*-butyldiphenylsilyl ether (2)

To a solution of pentaerythritol **1** (3.1 g, 22.5 mmol) in 150 mL anhydrous DMF was added recrystallized imidazole (1.56 g, 24 mmol) followed by the dropwise addition of *tert*-butyldiphenylchlorosilane (3.15 mL, 12 mmol). The solution was stirred for 24 h, poured into 600 mL water, and extracted twice with ethyl acetate. The organic phase was washed with brine and water, and the extracts were dried ($MgSO_4$), filtered, concentrated, and purified by silica gel flash column chromatography (EtOAc–hexanes, 1:1) to give **2** as an oil that solidified on standing (3.76 g, 84%, on the basis of the reagent added). ^{1}H NMR ($CDCl_3$) δ: 7.67–7.63 (m, 6H), 7.43–7.40 (m, 6H), 3.71 (d, 2H), 3.63 (s, 2H), 2.75 (bn s, 1H), 1.07 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 135.5–127.7 (Ph), 65.2, 64.4 (O-CH_2-C), 45.5 (C quat.), 19.3 (-$(CH_3)_3$). HRMS (EI), calcd. for $C_{21}H_{31}O_4Si$ (M+H): 375.1984; found: 375.1960.

3-Allyloxy-2,2-bis-allyloxymethyl-propane-1-ol *tert*-butyldiphenylsilyl ether (3)

To a solution of **2** (3.76 g, 10 mmol) in 150 mL anhydrous DMF was added allyl bromide (4.3 mL, 50 mmol). The reaction mixture was cooled in an ice-water bath, and sodium hydride (60%, 1.76 g, 45 mmol) was added in three portions. The solution was stirred overnight at room temperature, and 2 mL of methanol was added dropwise. The solution was partially concentrated in vacuo, poured into cold water (500 mL), extracted with ethyl acetate, washed with water, dried over $MgSO_4$, and concentrated. The residue was purified by silica gel flash column chromatography (EtOAc–hexanes, 1:20) to give the tri-allylated product **3** as an oil (3.90 g, 66%). ^{1}H NMR ($CDCl_3$) δ: 7.70–7.67 (m, 5H), 7.42–7.37 (m, 5H), 5.86 (m, 1H), 5.28 (m, 6H), 3.97 (m, 6H), 3.7 (s, 2H), 3.49 (s, 2H), 1.04 (s, 9H). HRMS (FAB), calcd. for $C_{26}H_{33}O_4Si$ [M−C$(CH_3)_3$]: 437.2124; found: 437.2148.

3-(2-Hydroxy-ethoxy)-2,2-bis(2-hydroxy-ethoxymethyl)-propane-1-ol *tert*-butyldiphenylsilyl ether (4)

Ozone was bubbled through a solution of 3 (3.90 g, 7.9 mmol) in 150 mL dichloromethane–methanol 1:1 at −78°C until the solution was saturated. Argon was bubbled through the solution for 15 min to remove the residual ozone and an excess of methyl sulfide was added. The solution was allowed to warm to room temperature and concentrated to a syrup that was dissolved in ethanol (30 mL). Sodium borohydride (1.7 g, 45 mmol) was added in four portions to the cooled solution at 0°C. After stirring for 24 h at room temperature, the solution was acidified with 20% HCl to pH 6, then concentrated to a syrup that was partitioned between ethyl acetate and water. After the usual work-up, a syrupy material was obtained that was purified by silica gel flash column chromatography (EtOAc–hexanes, 1:20) to give the title product **4** as a syrup that solidified on standing (2.94 g, 76%). ^{1}H NMR ($CDCl_3$) δ: 7.64–7.64 (m, 10H), 3.67 (m, 6H), 3.64 (s, 2H), 3.55–3.63 (m, 12H), 1.06 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 135.4–127.5 (Ph), 72.4, 69.8, 61.3 (O-CH_2-C), 43.2 (C quat., *t*-Bu), 19.5 ($(CH_3)_3$). HRMS (FAB), calcd. for $C_{27}H_{43}O_7Si$ (M+H): 507.2773; found: 507.2780.

3-(2-Azido-ethoxy)-2,2-bis(2-azido-ethoxymethyl)-propane-1-ol *tert*-butyldiphenylsilyl ether (5)

To a solution of **4** (506 mg, 1 mmol) in anhydrous pyridine (5 mL) at 0°C was added mesyl chloride (0.248 mL, 3.6 mmol) dropwise. The reaction mixture was stirred for 4 h at 25°C, water (1 mL) was added after recooling the reaction mixture to 0°C, and stirring was continued for 30 min. The mixture was poured into ice-water and extracted twice with ethyl acetate. The combined organic layers were washed successively with 20% HCl and water, dried over $MgSO_4$, concentrated to a syrup, which was dissolved in anhydrous DMF (5 mL), and NaN_3 (390 mg, 6 mmol) was added. The mixture was heated at 130°C in an oil bath for 5 h, then cooled to room temperature. The contents of the flask were poured into ice-cold water, extracted with ethyl acetate, the organic layers were washed with water, dried over $MgSO_4$, concentrated, and the residue was purified by silica gel flash column chromatography (EtOAc–hexanes, 1:25) to give **5** as an oil (501 mg, 86%). ^{1}H NMR ($CDCl_3$) δ: 7.7–7.43 (10H), 3.75 (s, 2H), 3.63 (m, 6H), 3.55 (s, 6H), 3.3 (m, 6H), 1.1 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 135.4–127.4 (Ph), 70.3, 68.9, 61.7 (O-CH_2-C), 50.6 (-CH_2N_3), 45.9 (C quat.), 26.7 (C quat., *t*-Bu), 19.3 (-$(CH_3)_3$). HRMS (EI), calcd. for $C_{23}H_{30}O_4Si$ [M−C$(CH_3)_3$]: 524.2188; found: 524.2131.

3-(2-Azido-ethoxy)-2,2-bis(2-azido-ethoxymethyl)-propane-1-ol (6)

To a solution of **5** (581 mg, 1 mmol) in anhydrous THF (5 mL) was added tetra-*n*-butylammonium fluoride (2 mL, 1 M in THF) dropwise at 0°C. The solution was stirred overnight and then concentrated. The residue was purified by silica gel flash column chromatography (EtOAc–hexanes, 1:1) to give **6** as a semi-solid (331 mg, 97%) that was used as such in subsequent steps. ^{1}H NMR ($CDCl_3$) δ: 3.7 (s, 2H), 3.6–3.50 (t, 6H), 3.42 (s, 6H), 3.3 (m, 6H). ^{13}C NMR ($CDCl_3$) δ: 70.05 (C-CH_2-CH_2N_3), 69.9 (C-CH_2-O), 64.1 (C-CH_2-OH), 50.2 (CH_2N_3), 42.5 (C quat.). HRMS (FAB), calcd. for $C_{11}H_{22}N_9O_4$ (M+H): 344.1779; found: 344.1794.

3-[3-(2-Azido-ethoxy)-2,2-bis(2-azido-ethoxymethyl)-propoxy]-propene (7)

To a solution of **6** (1.24 g, 7.2 mmol) in anhydrous DMF (10 mL) was added allyl bromide (1 mL, 10 mmol), the solution was cooled to 0°C, and NaH (400 mg, 60% in oil) was added. The reaction mixture was stirred for 24 h at room temperature, methanol (3 mL) was added, and stirring was continued for 30 min. Solvent was removed under vacuum and the residue was partitioned between ethyl acetate and water. The organic layers were washed with water, dried, and concentrated to a syrup that was purified by silica gel flash column chromatography (EtOAc–hexanes, 1:10) to give **7** as an oil (1.93 g, 71%). ^{1}H NMR ($CDCl_3$) δ: 5.80 (m, 1H), 5.15 (m, 2H), 3.95 (m, 2H), 3.62 (t, 6H), 3.52 (s, 6H), 3.47 (s, 2H), 3.33 (s, 6H). This product was used in the next step as such.

3-[3-(2-Azido-ethoxy)-2,2-bis(2-azido-ethoxymethyl)-propoxy]-oct-1-ene (8)

To a solution of **6** (342 mg, 1 mmol) in anhydrous THF (5 mL) was added 5 mg of tetrabutylammonium iodide and 1-octenyl bromide (0.5 mL, 3 mmol) followed by KH (250 mg, 30% in oil) at 0°C. The reaction mixture was stirred for 48 h at room temperature and processed as for **7**. Purification by silica gel flash column chromatography (EtOAc–hexanes, 1:15) gave **8** as an oil (368 mg, 81%). ^{1}H NMR ($CDCl_3$) δ: 5.81 (m, 1H),

4.91 (m, 2H), 3.61 (t, 6H), 3.49 (s, 6H), 3.3–3.41 (s, 10H), 2.04 (m, 2H), 1.34–1.6 (m, 8H). ^{13}C NMR ($CDCl_3$) δ: 138.9 (=CH), 114.0 (=CH_2), 71.3, 70.3, 69.6, 68.7, (O-CH_2-C), 50.6 (CH_2N_3), 44.9 (C quat.), 33.6 (CH_2CH=CH_2), and 28.8, 25.9, 24.3 (alkyl chain CH_2). HRMS (EI), calcd. for $C_{19}H_{36}O_4N_9$ (M+H): 454.2890; found: 454.2920.

3-[3-(2-Amino-ethoxy)-2,2-bis(2-amino-ethoxymethyl)-propoxy]-propene (9)

To a solution of **7** (1.9 g, 4.96 mmol) in 50 mL of anhydrous THF was added PPh_3 (5 g). The mixture was stirred for 24 h at room temperature and 2 mL of water was added. Stirring was continued for another 24 h and the solvents were removed under vacuum. The residue was dissolved in water (20 mL), filtered over Celite, and the insolubles were washed with water. The combined water phase was washed with ethyl acetate and the organic phase was processed as usual to give **9** as a syrup (0.9 g, 60%). ^{1}H NMR (CD_3OD) δ: 5.80 (m, 1H), 5.16 (m, 2H), 3.88 (m, 2H), 3.45 (m, 14H), 2.75 (m, 4H), 1.99 (m, 6H). ^{13}C NMR ($CDCl_3$) δ: 134.8 (=CH), 116.2 (=CH_2), 73.1, 72.1, 69.8, 69.7, 69.6, 69.1 (O-CH_2-CH_2N_3), 45.3 (C quat.), 41.5 (CH_2), HRMS (FAB), calcd. for $C_{14}H_{31}N_3O_4$ (M+Na): 328.2192; found: 328.2212.

3-[3-(2-Amino-ethoxy)-2,2-bis(2-amino-ethoxymethyl)-propoxy]-oct-1-ene (10)

A solution of **8** (80 mg, 0.17 mmol) in 5 mL of anhydrous THF was treated with PPh_3 in a similar fashion as for compound **9** to afford **10** as a syrup (58 mg, 79%). ^{13}C NMR ($CDCl_3$) δ: 140.05 (=CH), 114.86 (=CH_2), 72.60 (O-CH_2-CH_2NH_2), 71.04 (C-O- CH_2), 70.62 (O-CH_2-C), and 70.53 (O-$CH_2(CH_2)_5$). HRMS (FAB), calcd. for $C_{19}H_{36}O_4N_9$ (M+HSCH$_2$CH(OH)CH$_2$OH+H): 485.3600; found: 485.3448.

Heptadecanoic acid 3-(2-azido-ethoxy)-2,2-bis(2-azido-ethoxymethyl)-propyl ester (11)

A solution of **6** (80 mg, 0.2 mmol) in dichloromethane–EtOAc (5 mL, 1:1) was treated with stearic acid (140 mg), DCC (40 mg, 0.2 mmol), and DMAP (5 mg) for 24 h at room temperature. The mixture was diluted with dichloromethane (10 mL), washed with water, dried ($MgSO_4$), and evaporated. The residue was purified by silica gel flash column chromatography (EtOAc–hexanes, 1:9) to give **11** as a semi-solid (106 mg, 81%). ^{13}C NMR ($CDCl_3$) δ: 70.3 (C-CH_2-CH_2N_3), 69.2 (C-CH_2-O), 50.5 (CH_2N_3) and 43.8 (C quat.). HRMS (FAB), calcd. for $C_{29}H_{56}N_9O_5$ (M+H): 610.4376; found: 610.4404.

7-[3-(2-Azido-ethoxy)-2,2-bis(2-azido-ethoxymethyl)-propoxy]-heptanoic acid methyl ester (13)

Ozone was bubbled through a solution of **8** (453 mg, 1.0 mmol) in 10 mL dichloromethane–methanol (1:1) at −78°C until TLC showed completion of the reaction. Argon was bubbled through the solution for 15 min to remove the residual ozone and an excess of methyl sulfide was added. The solution was allowed to warm to room temperature and concentrated to give an aldehyde intermediate. IR cm^{-1} (film): 2100 (N_3), 1740 (CHO). This residue was dissolved in dry DMF (5 mL), and treated with PDC (1.34 g). After being stirred for 24 h, the mixture was partitioned between ethyl acetate and water, and the organic layers were washed with water, dried ($MgSO_4$), and evaporated. Purification of the residue by silica gel flash column chromatography (EtOAc–hexanes, 3:7) gave **12** as a syrup (404 mg, 92%); IR cm^{-1} (film), 2100 (N_3), 1730 (COOH); A solution of **12** (210 mg, 0.42 mmol) in methanol was treated with freshly generated IR–120 (H^+) resin (200 mg) at room temperature for 24 h. The resin was filtered off, washed with methanol, and the filtrate and washings were concentrated. Purification of the residue by silica gel flash column chromatography (EtOAc–hexanes, 1:9) gave **13** an a syrup (171 mg, 70%). IR cm^{-1} (film): 2100 (N_3). ^{1}H NMR ($CDCl_3$) δ: 3.60 (m, 6H), 3.47 (s, 6H), 3.50 (s, 2H), 3.41 (s, 3H), 3.31 (t, 2H), 3.25 (t, 6H), 2.30 (t, 2H), 1.67–1.33 (8H). ^{13}C NMR ($CDCl_3$) δ: 71.0, 69.3, 68.5 ($CH_2CH_2N_3$), 50.5 (CH_2OCH_2 CH_2N_3), 44.7 (C quat.). HRMS (FAB), calcd. for $C_{19}H_{35}O_6N_9$ (M+H): 486.2799; found: 486.2788.

7-[3-(2-Azido-ethoxy)-2,2-bis(2-azido-ethoxymethyl)-propoxy]-heptanoic acid benzyl ester (14)

A solution containing **12** (150 mg, 0.3 mmol), DCC (80 mg, 0.4 mmol), benzyl alcohol (50 mg, 0.4 mmol), and 4-pyrrolidinopyridine (10 mg) in 10 mL of dry dichloromethane was stirred for 24 h. The reaction mixture was diluted with 25 mL of dichloromethane, the organic layers were successively washed with dilute HCl, $NaHCO_3$, and water, dried ($MgSO_4$), and evaporated. Purification of the residue by silica gel flash column chromatography (EtOAc–hexanes, 1:9) gave **14** as a syrup (100 mg, 60%). IR cm^{-1} (film), 2100 (N_3); ^{1}H NMR ($CDCl_3$) δ: 7.35 (s, 5H), 5.12 (s, 2H), 3.62 (m, 6H), 3.49 (s, 6H), 3.41 (s, 2H), 3.38 (t, 2H), 3.13 (t, 6H), 2.36 (t, 2H), 1.60–1.33 (m, 8H). ^{13}C NMR ($CDCl_3$) δ: 70.36 ($CH_2(CH_2)_5COOBn$), 69.7 ($CH_2CH_2N_3$), 68.7 ($CH_2CH_2N_3$), 65.99 (CH_2O-alkyl), 66.0 (CH_2Ph), 50.6 ($CH_2OCH_2CH_2N_3$), 44.5 (C. quat.). HRMS (FAB), calcd. for $C_{25}H_{39}O_6N_7$ (M−N_2): 533.2889; found: 533.2667.

3-Allyloxy-2,2-bis(benzyloxy-methyl)-propane-1-ol (16)

To a cooled (0°C) solution of **15** (7.1 g, 22.4 mmol) in dry DMF (180 mL) was added sodium hydride (4.8 g) and allyl bromide (1.9 mL, 20 mmol), and the mixture was stirred overnight at 0°C. The reaction mixture was quenched by adding 5 mL of methanol and stirring was continued for 1 h. Solvents were removed under vacuum and the residue was purified by flash chromatography on silica gel column (EtOAc–hexanes, 2:8) to afford **16** (4.8 g, 60%) as a syrup. ^{1}H NMR ($CDCl_3$) δ: 7.36–7.25 (m, 10H), 5.85 (m, 1H), 5.16 (m, 2H), 4.49 (s, 4H), 3.92 (m, 2H), 3.76 (s, 2H), 3.55 (s, 4H), 3.52 (s, 2H), 2.8 (br s, 1H). ^{13}C NMR ($CDCl_3$) δ: 140.01 (=CH), 139.8–126.7 (Ph), 115.1 (=CH_2), 44.1 (C quat.). HRMS (FAB), calcd. for $C_{22}H_{28}O_4$ (M+H): 357.2076; found: 357.2065.

2,2-Bis(benzyloxy-methyl)-3-(2-hydroxy-ethoxy)-propane-1-ol (17)

Compound **16** (1.83 g, 5.1 mmol) was subjected to ozonolysis to give an aldehyde that was subsequently reduced with $NaBH_4$, as described above, to give **17** (1.184 g, 64%) as a syrup. ^{1}H NMR ($CDCl_3$) δ: 7.34–7.27 (m, 10H), 4.45 (s, 4H), 3.62 (br s, 4H), 3.54–3.49 (m, 8H), 2.7 (br s, 2H). ^{13}C NMR ($CDCl_3$) δ: 140.01 (=CH), 138.8–126.4 (Ph), 72.9, 71.9, 70.2, 69.9, 64.6, 60.9 (-CH_2O-), 44.5 (C quat.). HRMS (EI), calcd. for $C_{21}H_{28}O_5$ (M+H): 361.2021; found: 361.2015.

2,2-Bis(benzyloxy-methyl)-3-(2-hydroxy-ethoxy)-propane-1-ol mono *tert*-butyldiphenylsilyl ether (18)

To a cooled solution of **17** (2.0 g, 5.5 mmol) in dry DMF (30 mL) was added *tert*-butyldiphenylchlorosilane (2.3 mL) and imidazole (2.8 g). The mixture was stirred at room temperature and monitored by TLC. After 6 h, ether (100 mL) was added, the organic layers were washed with water dried ($MgSO_4$), and evaporated. Purification of the residue by silica gel flash column chromatography (EtOAc–hexanes, 3:7) gave **18** (2.31 g, 69%) as a syrup. ^{1}H NMR ($CDCl_3$) δ: 7.76–7.27 (m, 10H), 4.50 (s, 4H), 3.79 (s, 2H), 3.76 (t, 2H), 3.59 (s, 2H), 3.59 (s, 4H), 3.52 (t, 6H), 2.3–2.5 (br s, 1H), 1.06 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 140.1–127.0 (Ph), 72.6, 72.4, 68.8, 68.0, 65.7, 62.7 (CH_2), 44.1 (C quat.), 18.1 (C quat., *t*-Bu), 16.18 (-$(CH_3)_3$). HRMS (FAB), calcd. for $C_{37}H_{46}O_5Si$ (M+H): 599.8; found: 599.3.

2-(2-Hydroxy-ethoxymethyl)-2-hydroxymethyl-propane-1,3-diol mono *tert*-butyldiphenylsilyl ether (19)

A methanolic solution of **18** (0.9 g, 1.5 mmol) was hydrogenolyzed in presence of 10% Pd/C (400 mg). Work-up and purification by silica gel flash column chromatography (EtOAc–hexanes, 3:7) gave **19** (0.433 g, 69%) as a syrup. ^{1}H NMR ($CDCl_3$): δ: 7.69–7.20 (m, 10H), 4.12 (dd, 2H), 3.73 (t, 2H), 3.71 (s, 4H), 3.55 (s, 4H), 2.98 (brs, 3H), 1.09 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 139.1–126.7 (Ph), 44.4 (C quat.), 19.5 (C quat., *t*-Bu), 16.6 (-$(CH_3)_3$). HRMS (FAB), calcd. for $C_{23}H_{34}O_5Si$ (M+Na): 441.5, found: 441.3.

3-(3-Allyloxy-2,2-bis-benzyloxy-methyl-propoxy)-propene (20)

Allylation of the dibenzylated diol **15** (15) (5.1 g, 16.4 mmol) in dry DMF, essentially as described for **2**, gave **20** (5.51 g, 88%) as an oil. ^{1}H NMR ($CDCl_3$) δ: 7.33–7.24 (m, 10H), 5.80 (m, 2H), 5.15 (m, 4H), 4.51 (s, 4H), 3.97 (m, 4H), 3.57 (s, 4H), 3.54 (s, 4H). ^{13}C NMR ($CDCl_3$) δ: 139.8–127.0 (=CH and Ph), 114.7 (=CH_2), 44.1 (C quat.); HRMS (FAB), calcd. for $C_{25}H_{32}O_4$ (M+H): 396.5292; found: 396.5298.

2-[2-(2-Azido-ethoxymethyl)-3-benzyloxy-2-(benzyloxy-methyl)-propoxy]-ethanol *tert*-butyldiphenylsilyl ether (23)

Compound **20** (0.9 g, 2.2 mmol) was ozonolyzed and reduced with $NaBH_4$, as described above, to give the diol **21** (0.68 g, 74%) as a syrup. A solution of **21** (0.2 g, 0.5 mmol) was monosilylated, essentially as described above for **17**, to give **22** (0.280 g, 84%) as a syrup. Compound **22** (1.1 g, 1.7 mmol) was mesylated and the resulting product was subsequently displaced with azide ion, essentially as described for **5**, to give the azido derivative **23** as an oil (0.843 g, 74%). IR cm^{-1} (film): 2100 (N_3). ^{1}H NMR ($CDCl_3$) δ: 7.74–7.23 (m, 10H), 4.49, 4.48 (s, 4H), 3.76 (s, 2H), 3.56 (m, 10H), 3.24 (m, 2H), 1.1 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 136.7–126.4 (Ph), 44.4 (C quat.), 19.4 (C quat., *t*-Bu), 18.5 (-$(CH_3)_3$). HRMS (FAB), calcd. for $C_{39}H_{49}O_5N_3Si$ (M+H): 668.4; found: 668.5.

***N*-{2-[2,2-B680is(benzyloxy-methyl)-3-(2-hydroxy-ethoxy)-propoxy]-ethyl}-acetamide *tert*-butyldiphenylsilyl ether (24)**

The azido compound **23** (123 mg, 0.19 mmol) was dissolved in a minimum volume of dichloromethane, thiolacetic acid (3 mL) was added at room temperature, and the reaction mixture was stirred for 48 h, then concentrated. Purification of the residue by silica gel flash column chromatography (EtOAc–hexanes, 7:3) gave **24** (102 mg, 78%) as a syrup. ^{1}H NMR ($CDCl_3$) δ: 7.71–7.24 (m, 10H), 5.82 (br s, 1H), 4.49 (s, 4H), 3.77 (s, 2H), 3.30–3.56 (m, 14H), 1.82 (s, 3H), 1.1 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 137.4–127.0 (Ph), 44.7 (C quat.), 23.5 (CH_3CONH), 20.4 (C quat., *t*-Bu), 17.4 (-$(CH_3)_3$). HRMS (FAB), calcd. for $C_{41}H_{53}O_6NSi$ (M+H): 684.3; found: 684.5.

***N*-{2-[3-(2-680Hydroxy-ethoxy)-2,2-bis-hydroxymethyl-propoxy]-ethyl}-acetamide *tert*-butyldiphenylsilyl ether (25)**

The benzyl groups in **24** (0.4 g, 0.58 mmol) were hydrogenolyzed as described above for **19** to give **25** (0.210 mg, 70%) as a syrup. ^{1}H NMR ($CDCl_3$) δ: 7.69–7.24 (m, Ph), 6.19 (br s, NH), 3.70 (s, -CH_2OTBDPS), 3.73–3.40 (m, CH_2), 2.63 (br s, OH), 1.96 (s, OCOCH_3), 1.1 (s, t-Bu). ^{13}C NMR ($CDCl_3$) δ: 170.8 (*C*=O), 135.8–128.3 (Ph), 45.3 (C quat.), 23.9 (CH_3CONH), 20.4 (C quat., *t*-Bu), 19.4 (-$(CH_3)_3$). HRMS (FAB), calcd. for $C_{27}H_{42}O_6NSi$ (M+H): 504.2781; found: 504.2798.

3-Azido-2,2-bis-azidomethyl-propane-1-ol-*tert*-butyldiphenylsilyl ether (26)

Tri-*O*-mesylation and subsequent azide displacement of the triol **2** (4.4 g, 11.8 mmol), essentially as described for **5**, gave **26** as a syrup (3.01 g, 57%). IR cm^{-1} (film): 2100 (N_3). ^{1}H NMR ($CDCl_3$) δ: 7.65–7.43 (m, 10H), 3.49 (s, 2H), 3.38 (s, 6H), 1.10 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 135.5–127.7 (Ph), 61.8 (CH_2OTBDPS), 51.0 (CH_2N_3), 45.14 (*C*CH_2N_3). HRMS (FAB), calcd. for $C_{21}H_{28}ON_9Si$ (M+H): 450.2186; found: 450.2238.

3-Azido-2,2-bis-azidomethyl-propane-1-ol (27)

The silyl group in **26** (450 mg, 1.0 mmol) was removed by treating with TBAF in THF, as described above for **6**, to give **27** as a syrup (200 mg, 95%). IR cm^{-1} (film): 2100 (N_3). ^{1}H NMR ($CDCl_3$) δ: 3.54 (m, 2H), 3.38 (s, 6H), 1.75 (m, 1H). ^{13}C NMR ($CDCl_3$) δ: 62.04 (CH_2OH), 51.4 (CH_2N_3), 44.41 (*C*CH_2N_3). HRMS calcd. for $C_5H_{10}ON_9$ (M+H): 212.1008; found: 212.0987.

8-(3-Azido-2,2-bis-azidomethyl-propoxy)-oct-1-ene (28)

]A solution of **27** (356 mg, 1.1 mmol) in 5 mL of THF was alkenylated as described for **8**, to give **28** as a syrup (285 mg, 53%). IR cm^{-1} (film): 2100 (N_3). ^{1}H NMR ($CDCl_3$) δ: 5.82 (m, 1H), 4.97 (m, 2H), 3.41 (t, 2H), 3.33 (s, 6H), 3.25 (s, 2H), 2.04 (dd, 2H), 1.58–1.30 (m, 8H). ^{13}C NMR ($CDCl_3$) δ: 138.9 (CH=), 114.1 (=CH_2), 71.4 (CH_2O-alkyl), 68.7 (OCH_2-$(CH_2)_5$CH=CH_2), 51.4 (CH_2N_3), 44.6 (*C*CH_2N_3). HRMS (FAB), calcd. for $C_{13}H_{24}ON_9$ (M+H): 322.2103; found: 322.2130.

7-(3-Azido-2,2-bis-azidomethyl-propoxy)-heptanoic acid (29)

Compound **27** (150 mg, 0.46 mmol) was subjected to ozonolysis to give an aldehyde that was subsequently oxidized to a carboxylic acid, in a similar fashion as described for **12**, to give **29** as a syrup (73 mg, 72%). IR cm^{-1} (film), 2100 (N_3), 1700 (COOH), ^{1}H NMR ($CDCl_3$) δ: 3.42 (t, 2H), 3.30 (s, 6H),

3.26 (s, 2H), 2.36 (m, 2H), 1.65–1.34 (m, 8H). ^{13}C NMR ($CDCl_3$) δ: 71.32 (CH_2O-alkyl), 68.91 ($OCH_2(CH_2)_5COOH$), 51.6 (CH_2N_3), 44.7 (CCH_2N_3). HRMS (FAB), calcd. for $C_{12}H_{22}O_3N_9$ (M+H): 340.1845; found: 340.1786.

7-(2-Azido-2,2-bis-azidomethyl-propoxy)-heptanoic acid benzyl ester (30)

The carboxylic acid function in **29** (210 mg, 0.6 mmol) was esterified with benzyl alcohol as described for **14**, to give **30** as a syrup (155 mg, 60%). IR cm^{-1} (film): 2100 (N_3). ^1H NMR ($CDCl_3$) δ: 7–7.26 (m, 5H), 5.12 (s, 2H), 3.40 (t, 2H), 3.32 (s, 6H), 3.25 (s, 2H), 2.36 (m, 2H), 1.66–1.25 (m, 8H). ^{13}C NMR ($CDCl_3$) δ: 154.5 (*C*OOBn), 128.42–128.1 (Ph), 71.3 (CH_2O-alkyl), 68.8 ($OCH_2(CH_2)_5COOBn$), 65.9 (CH_2Ph), 51.5 (CH_2N_3), 44.6 (C quat.). HRMS (FAB), calcd. for $C_{19}H_{27}N_9O_3$ (M+H): 430.4824; found: 430.4795.

8-(3-Amino-2,2-bis-aminomethyl-propoxy)-oct-1-ene (31)

Triphenylphosphine (0.4 g) was added to a solution of **28** (850 mg, 2.6 mmol) in dry THF and the reaction mixture was processed as usual to give the triamino compound **31** as a syrup (380 mg, 60%). ^{13}C NMR ($CDCl_3$) δ: 140.1 (CH=), 114.8 ($=CH_2$). HRMS (FAB), calcd. for $C_{16}H_{38}O_3N_3$ ($M+HSCH_2CH(OH)CH_2OH+H$): 352.2633; found: 352.2598.

Summary

The readily available pentaerythritol was systematically functionalized to give a series of azido, azidoalkyl, carboxyalkyl, and ω-alkenyl derivatives either as single substituents or in combination. These derivatives are versatile scaffolds and templates for further elaboration with a variety of ligands to produce chemical and molecular diversity.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for generous financial assistance through the Medicinal Chemistry Chair Program. We acknowledge the valuable assistance given by Dr. Gurijala V. Reddy in the preparation of this manuscript, and Heng Wang and Xinxia Cai for verification of correct nomenclature using the Autonom program (Beilstein).

Synthesis of clustered D-GalNAc (Tn) and D-Galβ(1→3)GalNAc (T) antigenic motifs using a pentaerythritol scaffold

Stephen Hanessian, Dongxu Qiu, Hubli Prabhanjan, Gurijala V. Reddy, and Boliang Lou

Abstract: The tris(aminoethyl) and triamino derivatives of pentaerythritol have been used as scaffolds or templates for the attachment of immunologically relevant carbohydrates such as D-Galβ(1→3)GalNAc (T) and GalNAc (Tn), through amide linkages with the respective α-glycolyl and α-*N*-acetyl-L-serinyl glycosides. These clustered glycosidic motifs are intended as haptens for use in the preparation of tumor specific carbohydrate antigens and vaccines.

Key words: glycoside synthesis, 2-thiopyridyl carbonate, glycosyl donors and glycopeptide motifs

Résumé : Les dérivés du tris(aminométhyl) et triamino du pentaérythritol ont été utilisés comme points d'attachement pour des carbohydrates immunoactifs tel que D-Galβ(1→3)GalNAc (T) et GalNAc (Tn) via des liens peptidiques avec des glycosides α-glycolyl et α-*N*-acetyl-L-serinyl. Ces motifs branchés ont été préparés avec l'intention de les utiliser comme des haptens et ultérieurement comme des vaccins contre des tumeurs portant des marqueurs carbohydrates antigéniques.

Mots clés : Synthèse de glycoside, de carbonate 2-thiopyridyl, donneurs de glycosyles et motifs glycopeptidiques.

The importance of specific carbohydrate antigens in understanding the etiology of cell surface phenomena during the proliferation of various types of cancers has been amply documented (1). Indeed, tumor-associated antigens are expressed to varying degrees on the surface of cancer cells, and their presence can be quantitatively related to tumor progression (2). Such tumor-associated antigens are D-GalNAc (Tn) (3, 4) and Thomsen–Friedenreich antigen D-Galβ(1→3)GalNAc (T) (3, 5), which are present as terminal units in glycoproteins expressed on the cell surface (6). Their presence, either alone or as sialyl glycosides such as sialyl Tn (7), and their overexpression has been demonstrated to be linked with certain types of tumors (see, for example, ref. 8).

In view of the immunological specificity of such tumor-associated antigens, we considered the incorporation of Tn and T glycosidic motifs in bi- and trianternary structures and their use as potential antigens. Administration of such antigens to patients in remission may produce enough circulating tumor-specific antibodies to protect them from recurring tumors. The notion of a "cancer vaccine" has been a subject of great interest over the years, and the prospects for its realization is a much sought after goal (9).

The potential of clustered antigens for cooperative binding to several protein receptors has been previously discussed, principally by Lee et al. (10*a*) and by Peter et al. (10*b*). The attachment of Tn and T glycosides to amino acid backbones has been described by Hakomori and co-workers (11), Ogawa and co-workers (12), Ciommer and Kunz (13), and Paulsen et al. (14). Examples with other backbones have been reported (see, for example, ref. 15).

In this paper, we report the synthesis of novel di- and trihaptenic clusters composed of Tn and T glycosides attached to linker arms derived from pentaerythritol (16). In the preceding paper (16) we described the synthesis of various podands prepared from pentaerythritol by suitable chemical modification. We have now selected two triamino derivatives **1** and **2** to form clusters containing two and three Tn and T carbohydrate residues that are glycosidically attached to serine and glycolic acid spacers **3** and **4** (Scheme 1). The length of the spacer between the cluster and the terminal carboxylic acid may have an influence on the efficacy of its coupling with proteins, and ultimately on its immunogenicity. Thus, we chose allyl and 1-octenyl chains as sources for the terminal carboxylic acids.

Synthesis of Galβ(1→3)GalNAc disaccharides

The synthesis of the disaccharide **7** was done by a classical Koenig–Knorr reaction with 2,3,4,6-tetra-*O*-acetyl-α-D-galactopyranosyl bromide **5** as a glycosyl donor and *tert*-butyldimethylsilyl 2-azido-2-deoxy-4,6-*O*-isopropylidene-α-D-galacto-pyranoside **6** (17*b*) as acceptor (Scheme 2). Glycosidations with Ag_2CO_3–$AgClO_4$ as promoter in dichloromethane afforded 71% of the desired disaccharide **7**, accompanied by about 13% of the (1→6) disaccharide **7a**. The formation of the latter was due to the intramolecular migration of the isopropylidene group of the acceptor molecule, thus exposing the 6-hydroxyl group as a competing nucleophile. With $Hg(CN)_2$ in a mixture of toluene and nitromethane (2:1) the yield was modest and variable amounts of the (1→6) disaccharide were also formed. Stereochemistry and position of

the glycosidic linkage in **7** were ascertained from the chemical shifts of H-1 and H-3 protons in ^{1}H NMR spectrum. A doublet at δ 4.61 ($J_{1,2}$ = 8.0 Hz) and a doublet of doublets at δ 3.21 were confirmative of a β (1→3) linkage in **7**. In addition, the chemical shift of the quaternary carbon in the acetal group was very different in **7** and **7a** (^{13}C δ 98.9 ppm and 110.7 ppm, respectively). After treatment with aqueous acetic acid and subsequent acetylation, the ^{1}H NMR spectrum of the peracetylated compound obtained from **7a** showed a very clear downfield shift (δ 4.56) for the H-3 proton due to the presence of an ester group, while the peracetate of **7** showed a doublet of doublets for H-3 at a relatively high field (δ 3.48) indicating that the C-3 hydroxyl was not esterified but glycosidically linked. Treatment of disaccharide **7** with tetrabutylammonium fluoride in THF at −20°C removed the silyl protection at the anomeric position to give **8** in high yield.

There are several reports on the synthesis of this disaccharide using different glycosylation and protective group strategies (17*a–f*). Generally, 4,6-*O*-benzylidene protected acceptors have given better results, perhaps due to a lesser tendency to undergo intramolecular migration to form a 3,4-*O*-acetal. However, Kinzy and Schmidt (17*b*) used 2-azido-2-deoxy-4,6-*O*-isopropylidene-β-D-galactopyranoside **6** as the glycosyl acceptor and reported disaccharide formation in high yield with 2,3,4,6-tetra-*O*-benzoyl-α-D-galactopyranosyl trichloroacetimidate as a glycosyl donor and BF_3·OEt as the promoter. By contrast, Paulsen and Paal (17*c*) also observed acetal migration.[2]

Stereoselective synthesis of α-serinyl and α-glycolyl glycosides of Tn and T

For the synthesis of Tn and T haptens with N-protected L-serine benzyl ester (18; see also refs. 17*a*, *b*, *e*) we used our recently developed (19)[3] 1,2-*cis*-selective glycosylation reaction in which the new anomeric 2-thiopyridyl carbonates (TOPCAT) were used as glycosyl donors. The 2-thiopyridyl carbonate derivatives **11** and **12** were easily prepared from the respective 1-OH precursors **8** and **10** by treatment with di-(thiopyridyl)carbonate **9** in the presence of triethylamine (Scheme 3).[4] Glycosidations of the N-Cbz protected L-serine derivative **3** with **11** and **12** in dry CH_2Cl_2 in the presence of AgOTf (20) afforded the desired α-glycosides **13** and **16** as major products and in acceptable yields accompanied by the corresponding β-glycosides as minor products. With benzyl glycolate **4** as the glycosyl acceptor, and TOPCAT as the leaving group, the glycolic ester α-D-glycosides **19** and **23** were formed as major products. The anomeric configurations of the above mentioned glycosides were ascertained by ^{1}H NMR studies.

The TOPCAT glycosyl donors offer a number of distinct advantages in stereocontrolled glycoside synthesis (19). They are easily prepared and purified by column chromatography to give stable, often crystalline, products of defined stereochemistry. They can be activated under mild conditions with silver triflate to generate reactive oxonium ion species, which lead to 1,2-*cis* glycosides as major products when in the absence of participating groups as in **11** and **12**. The presence of a chromophore and the generation of pyridine 2-thione as the reaction progresses allows easy monitoring by TLC. The fragmentation of the leaving group into a stable heterocycle and carbon dioxide constitutes an excellent driving force for the reaction.

The azido groups in **13** and **16** were reduced by treatment with hydrogen sulfide in aqueous pyridine (21), and the resulting amine was acetylated in presence of Ac_2O–pyridine to give 2-acetamido derivatives **14** and **17**, respectively. Reactions catalyzed by thiolacetic acid (22) also gave the desired products in similar yields. Hydrogenolytic cleavage of the benzyloxycarbonyl groups in **14** and **17** with Pd/C afforded the glycosyl amino acid derivatives, which were transformed to the N-Boc protected derivatives **15** and **18**. The N-Boc group was found to be compatible with the method of amide

bond formation (vide infra). It was not possible to use the N-acetyl serinyl glycosyl amino acids for coupling to the triamines because of the known propensity of the acetyl group for participation (11*a*).

Treatment of either **11** or **12** with benzyl glycolate in the presence of AgOTf led to the corresponding α-D-glycosides **19** and **23** as the preponderant anomers. Acid hydrolysis of the O-isopropylidene group in **19** followed by treatment of the resulting diol **20** with thiolacetic acid and peracetylation gave **21**. Similar reduction and N-acetylation of the azido functions in **20** and **23** gave the corresponding 2-acetamido-2-deoxy compounds **21** and **24**, respectively, in good yields. Hydrogenolytic cleavage of the benzyl ester groups with Pd–C afforded the free carboxylic acid derivatives **22** and **25**.

Synthesis of Tn and T clusters

Having successfully accomplished the synthesis of haptenic carboxylic acids, we next addressed the amide couplings with **1** and **2**. The initial coupling reactions using EDC and EEDQ as activators were very slow. Variations in the stoichiometry of the reagents and the activators, or variations in the reaction time, did not result in improvement in yield. We, therefore, investigated conditions for amide formation using the mixed anhydride method. The procedure consisted in initial activation of the respective acids with isobutyl chloroformate in the presence of *N*-methylmorpholine to form the mixed anhydride in DMF at 0°C for 30 min followed by addition of the amines. Monitoring the reactions by TLC showed that the desired products were formed in less than 30 min, accompanied with some urethanes arising from unreacted amines.

With a 1:1 solvent mixture of DMF and THF, coupling of triamines **1** and **2** with Tn and T-serinyl derivatives **18** and **15** proceeded smoothly to afford trimeric and dimeric products in each case. Chromatographic purification of products **26**, **32** and **29**, **35** including a Tn-hapten was not possible because of very close R_f values. These products were separated after conversion to N-acetyl derivatives and removal of protecting groups to give trimers **28**, **31**, and their corresponding dimers **34** and **37** (Scheme 4). Similar treatment of the serinyl T motifs with the triamine **2** gave **38** and **41**.

Characterization of the major amide coupling products containing three T and Tn units each showed the expected ^1H and ^{13}C NMR signals for both the linker and hapten moieties. The serine-containing Tn motifs **26**, **29**, **32**, and **35** were treated with TFA to remove the N-Boc groups and the products were acetylated to give fully O- and N-acetylated derivatives (Scheme 4). The isopropylidene groups in the T derivatives **38** and **41** were cleaved with TFA to give **39** and **42**, respectively. Treatment of the Tn clusters NaOMe in methanol and chromatographic purification led to dimeric (**34**, **37**, and **43**) and trimeric (**28**, **31**, and **40**) target compounds in high yields. Similar treatment of **39** and **42** gave the trimeric and dimeric Tn clusters **40** and **43**, respectively (Scheme 4).

Coupling of the glycolyl Tn motif **25** to **2** gave the expected trimeric hapten **44** (Scheme 5). The expected trimeric prod-

Scheme 4.

ucts **46** and **48** were formed by coupling of **1** and **2** with **22**, respectively. Variable amounts of coupling products containing two glycolyl T units **50** and **52** and a urethane moiety on the unreacted amino group were also formed. Chromatographic separation in each of the above couplings gave glycolic Tn and T trimeric clusters **44**, **46**, and **48**, and dimers **50** and **52**. Treatment of these products individually with sodium methoxide gave the desired T and Tn clustered motifs **45**, **47**, **49**, **51**, and **53** after chromatographic purification.

In summary, glycoside synthesis using the 2-thiopyridyl carbonate group as a glycosyl activator (19) has been successfully applied to the stereoselective synthesis of α-serinyl and carboxymethyl glycosides of Tn and T. These were clustered on a pentaerythritol template to give di- and tri-haptenic motifs, which have been coupled to KLH and HSA as carrier proteins. Results pertaining to their immunological properties will be reported in due course.

Experimental

Melting points are uncorrected. ^1H NMR spectra were recorded at 300 MHz in $CDCl_3$ (unless otherwise indicated), with $CHCl_3$ as reference. ^{13}C NMR spectra were recorded at 75 MHz in $CDCl_3$ (unless otherwise indicated), with $CHCl_3$ as reference. Wherever necessary, ^1H NMR assignments were supported by appropriate homonuclear correlation experiments (COSY). IR spectra of samples were recorded as films. Mass spectra were recorded by using electron ionization (EI) at 70 eV or fast atom bombardment (FAB) techniques. Optical rotations were measured at 25°C at the sodium line. Flash chromatography was performed on 230–400 mesh silica gel (23). Thin-layer chromatography (TLC) was performed on glass plates coated with a 0.02 mm layer of silica gel 60-F-254. All solvents were freshly distilled before use.

tert-Butyldimethylsilyl *O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-(1→3)-2-azido-2-deoxy-4,6-isopropylidene-β-D-galactopyranoside (7)

A suspension of 5 (16.3 g, 39.7 mmol) and 4 Å molecular sieves (7 g) in dichloromethane (75 mL) was stirred for 6 h at room temperature. A mixture of **6** (9.7 g, 27 mmol), silver carbonate (10.8 g, 39.7 mmol), silver perchlorate (8.25 g, 39.7 mmol), and 4 Å molecular sieves (14 g) in dichloromethane (100 mL) was prepared separately, and was treated with the above mixture containing **5** at 5–10°C. The stirred reaction mixture was permitted to attain room temperature and after 9 h the insolubles were filtered off (Celite), washed with CH_2Cl_2, and the filtrate and washings were concentrated. Flash column chromatography (EtOAc–hexane, 4:6) of the residue over silica gel column gave **7** (13.2 g, 71%); $[\alpha]_D$ +38.4 (*c* 0.68,

S-2-Pyridyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-β-D-galactopyranosyl thiocarbonate (12)

A mixture of 320 mg (1.04 mmol) of 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-D-galactopyranose **10**, 777 mg (3.12 mmol) of di-(2-thiopyridyl)carbonate **9**, and 435 μL (3.12 mmol) of Et_3N in 8 mL of CH_2Cl_2 was stirred at room temperature for 30 h. Concentration and flash chromatographic purification of

the residue over a silica gel column (EtOAc–hexane, 1:1) gave 330 mg (72%) of the desired product **12**; $[\alpha]_D$ +27.8 (*c* 1.1, $CHCl_3$); IR cm^{-1} (film): 2130 (N_3), 1750 (C=O). ^1H NMR ($CDCl_3$) δ: 8.64-8.62 (m, pyr-H-6), 7.78–7.76 (m, pyr-H-3 and H-4), 7.36–7.26 (m, pyr-H-5), 5.59 (d, $J_{1,2}$ = 8.4 Hz, H-1), 5.38 (dd, $J_{4,5}$ = 0.9 Hz, $J_{4,3}$ = 3.3 Hz, H-4), 4.90 (dd, $J_{3,2}$ = 10.8 Hz, $J_{3,3}$ = 3.3 Hz, H-3), 4.14 (m, H-6), 4.02 (dt, $J_{5,4}$ = 0.9 Hz, $J_{5,6}$ = 6.8 Hz, H-5), 3.87 (dd, $J_{1,2}$ = 8.4 Hz, $J_{2,3}$ = 10.9 Hz, H-2), 2.18, 2.08, 2.04 (OAc). ^{13}C NMR ($CHCl_3$) δ: 170.03, 169.69, 169.33 (CO), 150.1, 137.3, 128.2, 123.7 (Py), 94.7 (C-1), 71.7, 71.2, 65.9, 60.7 (ring carbons), 59.5 (C-2), and 20.3 (CH_3). HRMS (FAB), calcd. for $C_{18}H_{21}O_9N_4S$ (M+H): 469.1029; found: 469.1039.

Benzyl *N*-carbobenzyloxy-L-serinyl 3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-azido-2-deoxy-4,6-*O*-isopropylidene-α-D-galactopyranoside (13)

To a mixture of **11** (480 mg, 0.67 mmol) and 3 (330 mg, 1 mmol) in 20 mL of dichloromethane were added powdered 4Å molecular sieves and 260 mg (1 mmol) of AgOTf. The mixture was stirred at room temperature for 2 h. After addition of 0.5 mL of pyridine, the mixture was concentrated. Flash chromatographic purification of the residue over silica gel (EtOAc–hexane, 1:1) gave **13** and its β anomer (375 mg, 63%, α/β, 5:1). For **13** (300 mg): mp 70–72°C, $[\alpha]_D$ +59.1 (*c* 1.0, $CHCl_3$); IR cm^{-1} (film): 2130 (N_3), 1750 (C=O). ^1H NMR ($CDCl_3$) δ: 7.36 (m, Ph), 5.80 (d, *J* = 8.2 Hz, NH), 5.38 (d, $J_{4',5'}$ = 2.7 Hz, H-4′), 5.30 (dd, $J_{2',1'}$ = 7.9 Hz and $J_{2',3'}$ = 10.4 Hz, H-2′), 5.19 and 5.10 (s, CH_2Ph), 5.0 (dd, $J_{2,3'}$ = 10.5 Hz and $J_{3',4'}$ = 3.3 Hz, H-3′), 4.88 (d, $J_{1,2}$ = 3.3 Hz, H-1), 4.61 (d, $J_{1',2'}$ = 7.9 Hz, H-1′), 4.53 (m, Ser α-H), 3.70–4.30 (m, H-2, H-3, H-4, H-5′, H-6, H-6′ and Ser β-H), 3.40 (m, H-5), 2.14, 2.05, 2.02, 1.97 (OAc), 1.44, 1.37 (s, $C(CH_3)_2$). ^{13}C NMR ($CDCl_3$) δ: 170.0, 169.9, 169.5, 169.2 (CO), 128.5, 128.4, 128.2, 128.1, 127.9 (Ph), 102.7 (C-1′), 99.6 ($C(CH_3)_2$), 98.7 (C-1), 76.7, 70.8, 70.6, 69.3, 68.1, 67.5, 66.9, 66.7, 62.9, 62.3 and 60.1, 57.9 (C-2), 54.4 (*C*NH in Ser), 29.1, 20.8, 20.4, 17.9 (CH_3). HRMS (FAB), calcd. for $C_{41}H_{51}O_{18}N_4$ (M+H): 887.3198; found: 887.3258.

Benzyl *N*-carbobenzyloxy-L-serinyl 3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-acetamido-2-deoxy-4,6-*O*-isopropylidene-α-D-galactopyranoside (14)

Hydrogen sulfide gas was passed through a solution of **13** (2.9 g, 3.77 mmol) in pyridine–water (3:1, 30 mL) for 1 h at 0°C. The mixture was stirred for 10 h at room temperature and evaporated. The dry residue was stirred for 5 h in 30 mL of pyridine – acetic anhydride (2:1, 30 mL). Water (10 mL) was added and the mixture was further stirred for 1 h and extracted with ethyl acetate. The organic layers were successively washed with dilute HCl, saturated sodium carbonate, and water, dried over $MgSO_4$, and concentrated. The residue was purified over a silica gel column to afford compound **14** (2.4 g, 81%), which was directly used in the next step.

***N-tert*-Butoxycarbonyl-L-serinyl 3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-acetamido-2-deoxy-4,6-*O*-isopropylidene-α-D-galactopyranoside (15)**

A suspension containing **14** (2.2 g, 2.44 mmol) and Pd/C (10%, 500 mg) in dry THF–methanol (20 mL, 1:1) was stirred for 10 h under hydrogen. The catalyst was filtered off and washed with methanol. The combined filtrate and washings were concentrated to a residue that was redissolved in 30 mL of dry methanol and treated with 0.9 g of *tert*-butoxycarbonyl anhydride and 0.5 mL of Et_3N. After 4 h at room temperature, the solvents were removed and the residue was purified by flash chromatography over silica gel (toluene–MeOH–AcOH, 15:1:1) to give **15** (1.6 g, 84%) as a syrup; $[\alpha]_D$ +79.5 (*c* 1.0, MeOH). ^1H NMR (CD_3OD) δ: 7.2 (m, Ph), 5.37 (d, $J_{4',3'}$ = 2.9 Hz, H-4′), 4.80–5.10 (m, H-2′ and H-3′), 4.44 (d, $J_{1,2}$ = 3.6 Hz, H-1), 4.40 (dd, $J_{3,2}$ = 10.8 Hz, and $J_{3,4}$ = 3.6 Hz, H-3), 3.98 (dd, $J_{2,1}$ = 3.1 Hz and $J_{2,3}$ = 11.4 Hz, H-2), 2.13, 2.04, 2.03, 2.00, 1.96 (OAc), 1.46, 1.40 (s, $C(CH_3)_2$). ^{13}C NMR (CD_3OD) δ: 178.5, 172.0, 171.9, 171.5, 171.2, 171.1 (CO), 129.9, 129.2, 126.3 (Ph), 103.8 (C-1′), 100.1 ($C(CH_3)_2$), 99.9 (C-1), 77.3, 72.6, 71.9, 70.3, 70.1, 69.9, 68.8, 64.2, 63.8, 62.6, 29.6, 28.8, 23.3, 21.9, 20.9, 20.6, 20.5, and 18.9. HRMS (FAB), calcd. for $C_{33}H_{50}O_{19}N_2Na$ (M+Na): 801.2905; found: 801.3020.

Benzyl *N*-carbobenzyloxy-L-serinyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranoside (16)

To a mixture of **12** (1.045 g, 2.3 mmol) and *N*-benzyloxycarbonyl-L-serine benzyl ester **3** (0.913 g 2.77 mmol) in 50 mL of dichloromethane were added 3 g of powdered 4Å molecular sieves and 1.25 g (3.46 mmol) of AgOTf at room temperature and the mixture was stirred for 4 h. The mixture was treated with 0.2 mL pyridine, then filtered through a bed of Celite and concentrated. Flash chromatographic purification of the residue over silica gel (EtOAc–hexane, 1:1) gave 0.88 g (69%) of a 5:1 α:β anomeric mixture of the desired product that was easily separable. For the α anomer **16** (0.7g); $[\alpha]_D$ +75.8 (*c* 1.1, $CHCl_3$) (lit. (17*d*) $[\alpha]_D$ +73.5; (11*a*) $[\alpha]_D$ +92.6). IR cm^{-1} (film): 2120 (N_3), 1750 (C=O). ^1H NMR ($CDCl_3$) δ: 7.37–7.26 (m, Ph), 5.85 (d, *J* = 8.0, NH), 5.36 (d, $J_{4,3}$ = 3.1 Hz, H-4), 5.24–5.18 (m, H-3 and CH_2Ph), 4.88 (d, $J_{1,2}$ = 3.7 Hz, H-1), 4.63–4.60 (m, Ser α-H), 4.16–3.98 (m, H-5, H-6 and Ser β-H), 3.56 (dd, J_1 = 3.4 Hz and *J* = 11.2, H-2) 2.12, 2.05, 1.99 (OAc). ^{13}C NMR ($CDCl_3$) δ: 170.3, 169.8, 169.5, 169.2 (CO), 155.7, 135.9, 134.8, 128.5, 128.4, 128.1, 127.9 (Ph), 99.1 (C-1), 69.8, 67.7, 67.2, 67.0, 57.13, 54.13, 54.3, and 20.5. LRMS (FAB), calcd. for $C_{30}H_{35}O_{12}N_4$ (M+H): 643.2; found: 643.2.

Benzyl *N*-carbobenzyloxy-serinyl 3,4,6-tri-*O*-acetyl-2-acetamido-2-deoxy-α-D-galactopyranoside (17)

The azido group in compound **16** (1.5 g) was reduced and the resulting amine was subsequently acetylated, essentially as described for **14**, to give **17** as a syrup (1.16 g, 77%); $[\alpha]_D$ +53.7 (*c* 1.0, $CHCl_3$). ^1H NMR ($CDCl_3$) δ: 7.37–7.34 (m, Ph), 5.85 (d, *J* = 8.0 Hz, NH), 5.62 (d, *J* = 9.1 Hz, NH), 5.37 (d, $J_{4,3}$ = 3.3 Hz, H-4), 5.12–5.19 (m, CH_2Ph), 5.03 (dd, *J* = 2.8 and *J* = 11.4 Hz, H-3), 4.78 (d, $J_{1,2}$ = 3.6 Hz, H-1), 4.45–4.62 (m, Ser α-H), 3.85–4.12 (m, H-5, H-6 and Ser β-H), 4.47 (dd, *J* = 3.52 Hz and *J* = 11.4 Hz, H-2), 2.14, 1.99, 1.98, 1.90 (OAc and NAc). ^{13}C NMR ($CDCl_3$) δ: 171.5–169.5 (CO), 135.3, 134.7, 128.9, 128.7, 128.5 128.1 (Ph), 99.9 (C-1), 70.2, 69.1, 68.9, 68.7, 68.6, 62.6, 54.8, 48.1, 23.5, 20.2, and 20.1. HRMS (FAB), calcd. for $C_{32}H_{39}N_2O_{13}$ (M+H): 659.2477; found: 659.2452.

***N-tert*-Butoxycarbonyl-L-serinyl 3,4,6-tri-*O*-acetyl-2-acetamido-2-deoxy-α-D-galactopyranoside (18)**

Hydrogenation of **17** (3.6 g, 5.6 mmol) using Pd/C (0.8 g) gave

a product that was converted into the *N*-Boc derivative, essentially as described for **15**, to give **18** as an amorphous solid (2.1 g, 73%); $[\alpha]_D$ +73.7 (*c* 1.0, $CHCl_3$). ^1H NMR ($CDCl_3$ + 2 drops of CD_3OD) δ: 5.33 (d, $J_{4,3}$ = 3.0 Hz, H-4), 5.10 (dd, $J_{3,2}$ = 11.4 Hz, $J_{3,4}$ = 3.1 Hz, H-3), 4.93 (d, $J_{1,2}$ = 3.0 Hz, H-1), 4.38 (dd, $J_{2,1}$ = 3.0 Hz and $J_{2,3}$ = 11.6 Hz, H-2), 3.80–4.18 (m, H-5, H-6, Ser α- and β-H), 2.11, 2.02, 1.96, 1.94 (OAc and NAc), 1.42 (s, *tert*-butyl). ^{13}C NMR ($CDCl_3$ + 2 drops CD_3OD) δ: 173.9, 172.2, 172.1, 171.9 (CO), 99.5 (C-1), 80.5, 70.2, 69.7, 69.1, 68.6, 68.5, 67.9, 62.8, 56.8, 28.8, 27.8, 22.7, 20.6, 20.5, and 19.5. HRMS (FAB), calcd. for $C_{22}H_{34}N_2O_{13}Na$ (M+Na): 557.5074; found: 557.5132.

Benzyloxycarbonylmethyl 3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-azido-2-deoxy-4,6-*O*-isopropylidene-α-D-galactopyranoside (19)

Glycosylation of benzyl glycolic ester 4 (0.4 g, 2.4 mmol) with **11** (1.4 g, 1.96 mmol), essentially as described for **13**, gave the α anomer **19** (0.60 g, 59%) along with the β anomer (0.12 g, 12%). For the α anomer, $[\alpha]_D$ +47.0 (*c* 0.36, $CHCl_3$). IR cm^{-1} (film): 2100 (N_3), 1750 (C=O). ^1H NMR ($CDCl_3$) δ: 7.33–7.54 (m, Ph), 5.36 (d, $J_{4'3'}$ = 3.4 Hz, H-4′), 5.26 (dd, $J_{2',3'}$ = 10.44 Hz, H-2′), 5.15 (s, CH_2Ph), 5.05 (d, $J_{1,2}$ = 3.6 Hz, H-1), 4.95 (dd, $J_{3',2'}$ = 10.4 Hz, H-3′), 4.68 (d, $J_{1',2'}$ = 8.0 Hz, H-1′), 4.37 (d, $J_{4,3}$ = 3.1 Hz, H-4), 4.1 (dd, *J* = 16.3 Hz, CH_2COOBn), 3.96 (dd, H-2), 3.83 (dd, $J_{3,2}$ = 10.8 Hz, H-3), 2.13, 2.02, 2.00, 1.95 (OAc), 1.38, 1.43 ($C(CH_3)_2$). ^{13}C NMR (CD_3OD) δ: 170.7, 169.9, 169.3, 169.1 (CO), 134.9, 128.4, 128.3 128.2 (Ph), 102.8 (C-1′), 99.0 ($C(CH_3)_2$), 98.9 (C-1), 70.9, 70.7, 68.4, 68.3, 66.8, 66.7, 64.9, 63.2, 62.4, 61.3, 58.2, 29.1, 20.5, 20.4, and 18.0. HRMS (FAB), calcd. for $C_{32}H_{43}O_{16}N_3$ (M+H): 725.7082; found: 725.3496.

Benzyloxycarbonylmethyl 3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-acetamido-2-deoxy-4,6-di-*O*-acetyl-α-D-galactopyranoside (21)

Compound **19** (300 mg, 0.4 mmol) was dissolved in acetic acid–water (8:2, 100 mL), and the solution was heated at 60°C for 4 h and concentrated. Acetylation in the presence of Ac_2O and pyridine followed by flash chromatographic purification over silica gel column gave the fully acetylated derivative **20** as an amophous solid (289 mg, 90%); $[\alpha]_D$ +78.4 (*c* 1.1, $CHCl_3$). A mixture of **20** (0.563 g, 0.73 mmol) and thiolacetic acid (6 mL) was stirred for 48 h at room temperature after which time TLC showed that the reaction was complete. Concentration of the reaction mixture and flash column chromatography of the residue over silica gel (EtOAc–hexane, 7:3) gave the product **21** (369 mg, 65%); $[\alpha]_D$ +8.1 (*c* 0.49, $CHCl_3$). ^1H NMR ($CDCl_3$) δ: 7.35–7.26 (m, Ph), 6.21(d, *J* = 9.3 Hz, NH), 5.35 (d, $J_{4,3}$ = 2.7 Hz, H-4), 5.31 (d, $J_{4',3'}$ = 3.3 Hz, H-4′), 5.16 (s, CH_2Ph), 5.04 (dd, H-2′), 4.90 (dd, H-3′), 4.84 (d, $J_{1,2}$ = 3.58 Hz, H-1), 4.57 (d, $J_{1',2'}$ = 7.7 Hz, H-1′), 4.53 (dd, H-2), 3.92 (dd, H-3), 2.12, 2.10, 2.02 (2), 2.01, 1.97, 1.93 (OAc and NAc). HRMS (FAB), calcd. for $C_{35}H_{46}NO_{19}$ (M+H): 784.2688; found: 784.2664.

Carboxymethyl 3-*O*-(2,3,4,6-tetra-*O*-acetyl-β-D-galactopyranosyl)-2-acetamido-2-deoxy-4,6-di-*O*-acetyl-α-D-galactopyranoside (22)

To a cooled (0–10°C) solution of **21** (213 mg, 0.27 mmol) in THF–methanol (1:1, 10 mL) was added Pd/C 10% (100 mg) followed by addition of 100 μL of acetic acid. The mixture was hydrogenated for 2 h, and the catalyst was filtered off and washed with methanol. The combined filtrate and washings were concentrated to a syrup that was purified by flash column chromatography over silica gel (EtOAc–MeOH, 15:1) to yield **22** as an amorphous solid (179 mg, 90%); $[\alpha]_D$ +28.1 (*c* 0.5, $CHCl_3$). ^1H NMR (CD_3OD) δ: 5.40 (d, $J_{4,3}$ = 3.3 Hz, H-4), 5.34 (d, $J_{4'3'}$ = 3.3 Hz, H-4′), 5.04 (dd, $J_{3'2'}$ = 10.5 Hz, H-3′), 4.96 (dd, $J_{2',3'}$ = 10.5 Hz, H-2′), 4.84 (s, CH_2COOH), 4.79 (d, $J_{1,2'}$ = 3.8 Hz, H-1), 4.75 (d, $J_{1',2'}$ = 7.5 Hz, H-1′), 4.42 (dd, H-2), 1.93–2.12 (OAc and NAc). ^{13}C NMR (CD_3OD) δ: 171.2–177.9 ($COCH_3$, and $NHCOCH_3$), 99.1, 102.4 (C-1, C-1′), 75.1, 72.3, 71.8, 71.3, 70.3, 68.8, 68.7, 67.8 (ring carbons), 62.3, 63.9 (C-6, C-6′), 20.4-23.2 (7 $COCH_3$, and $NHCOCH_3$). Benzyloxycarbonylmethyl 3,4,6-tri-*O*-acetyl-2-azido-2-deoxy-α-D-galactopyranoside (23) and its β anomer

Glycosylation of benzyl glycolate **4** (0.5 g, 3.0 mmol) with **12** (1.36 g, 2.9 mmol), essentially as described for **13**, gave **23** along with the β anomer (0.972 g, 70%; α:β, >4:1) as an inseparable mixture. ^1H NMR ($CDCl_3$) δ: 7.37–7.26 (m, Ph), 5.15 (d, $J_{1,2}$ = 3.7 Hz, H-1α), 4.54 (d, $J_{1,2}$ = 8.0 Hz, H-1β), 3.73 (dd, $J_{2,1}$ = 3.5 Hz, $J_{2,3}$ = 11.1 Hz, H-2α), 2.13, 2.05, and 2.02 (OAc). ^{13}C NMR $CDCl_3$) δ: 102.2 (C-1β), 98.0 (C-1α). HRMS (FAB), calcd. for $C_{21}H_{26}O_{10}N_3$ (M+H): 480.1616; found: 480.1666.

Benzyloxycarbonylmethyl 3,4,6-tri-*O*-acetyl-2-acetamido-2-deoxy-α-D-galactopyranoside (24)

Treatment of compound **23** (α:β, >4:1; 0.9 g, 1.88 mmol) with thiolacetic acid (16 mL), in a similar fashion as described for compound **21**, afforded **24** as an oil after chromatographic separation (0.64 g, 69%); $[\alpha]_D$ +80.0 (*c* 1.0, $CHCl_3$); ^1H NMR ($CDCl_3$) δ: 7.35–7.34 (m, Ph), 6.18 (d, *J* = 9.5 Hz, NH), 5.38 (d, $J_{4,3}$ = 3.2 Hz, H-4), 5.20 (dd, $J_{2,1}$ = 3.2 Hz, and $J_{2,3}$ = 11.4 Hz, H-2), 5.19 (s, CH_2Ph), 4.91 (d, $J_{1,2}$ = 3.7 Hz, H-1), 4.62 (m, H-2), 4.04–4.25 (m, H-5, H-6, and OCH_2COO-), 2.16, 2.03, 1.99, 1.99 (OAc and NAc). ^{13}C NMR ($CDCl_3$) δ: 170.7, 170.4, 170.2, 169.4 (CO), 128.6, 128.3, 98.6 (C-1), 68.1, 67.3, 67.1, 66.9, 64.6, 61.6, 47.3, 23.1, 20.6, and 20.5. HRMS (EI), calcd. for $C_{23}H_{30}O_{11}N$ (M+H): 495.1725; found: 495.1725.

Carboxylmethyl 3,4,6-tri-*O*-acetyl-2-acetamido-2-deoxy-α-D-galactopyranoside (25)

Hydrogenation of **24** (50 mg, 0.1 mmol), in a similar procedure as described for compound **22**, gave **25** as an amorphous solid (38 mg, 94%); $[\alpha]_D$ +101.0 (*c* 1.0, $CHCl_3$). ^1H NMR ($CDCl_3$ + 2 drops of CD_3OD) δ: 5.33 (d, $J_{4,3}$ = 3.3 Hz, H-4), 5.17 (dd, $J_{3,4}$ = 3.3 Hz and $J_{3,2}$ = 11.4 Hz, H-3), 4.82 (d, $J_{1,2}$ = 3.5 Hz, H-1), 4.49 (dd, $J_{2,1}$ = 3.5 Hz and $J_{2,3}$ = 11.4 Hz, H-2), 3.82–4.17 (m, H-5, H-6, and OCH_2COO-), 2.12, 2.00, 1.94, 1.92 (OAc, NAc). ^{13}C NMR ($CDCl_3$ + 2 drops of CD_3OD) δ: 171.5, 170.7, 170.5 (CO), 97.8 (C-1), 68.3, 67.1, 66.4, 61.5, 47.0, 22.3, 20.4, and 20.3. HRMS (FAB), calcd. for $C_{16}H_{23}O_{11}NNa$ (M+Na): 428.1168; found: 428.1127.

Compounds 28 and 34

To a cooled solution of **18** (320 mg, 0.624 mmol) in dry THF–DMF (1:1, 3 mL) was added *N*-methylmorpholine (63 mg) fol-

lowed by isobutyl chloroformate (196 μL) at −20°C. Stirring was continued at −20°C until a fine precipitate was observed (20 min). After 5 min, a solution of the triamine **1** (48 mg, 0.15 mmol) in dry DMF (1 mL) was added and stirring was continued for 1 h. The reaction mixture was diluted with dichloromethane (20 mL) and washed successively with saturated $NaHCO_3$ solution and water, dried ($MgSO_4$), and evaporated to a syrup. Flash chromatography of the residue on silica gel (CH_2Cl_2–MeOH, 95:5) gave an inseparable 1:1 mixture of **26** and **32** (170 mg, 65%) as an amorphous solid. A solution of this mixture (360 mg) in 5 mL of TFA was stirred for 3 h at room temperature, after which toluene (10 mL) was added and the solvents were removed in vacuo. The residue was acetylated (Ac_2O–pyridine; 5 mL, 1:2) to give **27** and **33** as a mixture of trimer and dimer, respectively (280 mg). A portion of the above mixture (200 mg) was treated with NaOMe in methanol (4 mL) for 12 h at room temperature. The base was neutralized with IR-H^+ resin, filtered, washed with methanol, and concentrated. The residue was chromatographed on silica gel (CH_2Cl_2–MeOH, 1:1) followed by purification on Sephadex-LH-20 (CH_2Cl_2–MeOH, 3:2) to give **28** (15 mg, 80% from **27**) and **34** (100 mg, 65% from **33**) as amorphous solids. For **28**: $[\alpha]_D$ +56.3 (*c* 1.0, MeOH). ^{1}H NMR (CD_3OD) δ: 5.85 (m, CH_2=C*H*), 5.27–5.1 (m, CH_2=C*H*), 4.83 (d, $J_{1,2}$ = 3.3 Hz, H-1), 4.60 (m, Ser α-H), 4.25 (dd, $J_{2,1}$ = 3.7 Hz and $J_{2,3}$ = 10.9 Hz, H-2), 3.93–3.74 (m), 3.45–3.25 (m), 2.04, 2.02, 1.95 (NAc). ^{13}C NMR (CD_3OD) δ: 174.1, 172.0, 172.5 (NH*C*O), 136.2 (*C*H_2=*C*H), 116.6 (*C*H_2=CH), 100.0 (C-1), 73.4, 72.6, 70.9, 70.8, 70.6, 70.2, 69.8, 69.5, 62.9, 51.4, 46.7, 40.5, 22.9, and 22.7. HRMS (FAB), calcd. for $C_{42}H_{73}O_{21}N_7Na$ (M+Na): 1034.4758; found: 1034.4809. For **34**: $[\alpha]_D$ +62.9 (*c* 1.0, MeOH). ^{1}H NMR (CD_3OD) δ: 5.89 (m, CH_2=C*H*), 5.21 (m, C*H*$_2$=CH), 4.81 (d, $J_{1,2}$ = 3.3 Hz, H-1), 4.61 (m, Ser α-H), 4.26 (dd, $J_{2,1}$ = 3.7 Hz and $J_{2,3}$ = 10.9 Hz, H-2), 3.90–3.65 (m), 3.5–3.3 (m), 2.04, 2.02, 1.94 (NAc). ^{13}C NMR (CD_3OD) δ: 173.8, 173.2, 172.0 (CO), 136.5 (CH_2=*C*H), 116.7 (*C*H_2=CH), 100.1 (C-1), 73.4, 72.9, 70.9, 70.8, 70.3, 69.8, 69.6, 62.8, 54.8, 51.5, 49.7, 46.8, 40.6, 40.5, 23.0, 22.9, 22.8, and 22.7.

Compounds 31 and 37

A solution of **18** (561 mg, 1.08 mmol) in dry THF–DMF (3 mL, 1:1) was coupled with triamine **2** (128 mg, 0.34 mmol in dry DMF, 2 mL) as described for compounds **26** and **32**, to afford a mixture of **29** and **35** (380 mg, 76%) as an amorphous solid. A portion (255 mg) was treated with TFA, followed by N-acetylation as described for **27** and **33** to give 205 mg of **30** and **36** as a syrupy mixture which was treated with NaOMe, as described for **28** and **34**, to give **31** (120 mg) and **37** (20 mg). For **31**: $[\alpha]_D$ +73.4 (*c* 0.5, MeOH). ^{1}H NMR (CD_3OD) δ: 5.80 (m, CH_2=C*H*), 4.95 (m, CH=C*H*$_2$), 4.83 (d, $J_{1,2}$ = 3.7 Hz, H-1), 4.60 (m, Ser α-H), 4.20 (dd, $J_{2,1}$ = 3.7 Hz, $J_{2,3}$ = 10.9 Hz, H-2), 4.77–3.28 (m), 2.05, 2.02 (NAc), 1.88–1.31 (m, CH_2). ^{13}C NMR (CD_3OD) δ: 174.5, 174.0, 172.2 (CO), 140.2 (CH_2=*C*H), 114.9 (*C*H_2=CH), 99.5 (C-1), 72.6, 70.7, 69.8, 69.3, 68.9, 62.4, 62.3, 54.7, 51.2, 40.4, 23.1, and 22.8. HRMS (FAB), calcd. for $C_{58}H_{101}O_{28}N_9$ (M+Na): 1394.6653; found: 1394.6628. For **37**: $[\alpha]_D$ +68.0 (*c* 0.25, MeOH). ^{1}H NMR (CD_3OD) δ: 5.80 (m, CH_2=C*H*), 4.95 (m, CH=C*H*$_2$), 4.82 (d, $J_{1,2}$ = 3.6 Hz, H-1), 4.61 (m, Ser α-H), 4.20 (dd, $J_{2,1}$ = 3.6 Hz, $J_{2,3}$ = 11.1 Hz, H-2), 3.91–3.7 (m), 3.48–3.29 (m), 2.05, 2.04, 2.02 (s, NAc), 1.89–1.32 (m, CH_2). ^{13}C NMR (CD_3OD) δ: 174.6, 174.1, 172.1 (CO), 140.2 (CH_2=*C*H), 114.9 (*C*H_2=CH), 99.4 (C-1), 72.7, 72.6, 70.7, 70.6, 69.9, 69.2, 68.9, 62.4, 54.7, 51.1, 40.3, 23.0, and 22.3. HRMS (FAB), calcd. for $C_{47}H_{83}O_{21}N_7Na$ (M+Na): 1104.5538; found: 1104.5463.

Compounds 38 and 41

Compound **15** (850 mg, 1.09 mmol) was coupled with the triamine **2** (102 mg, 0.27 mmol) following the procedure described above, to give compound **38** after chromatographic separation (180 mg, 25%) and **41** (250 mg, 35%) as amorphous solids. For **38**: $[\alpha]_D$ +52.0 (*c* 0.5, $CHCl_3$); IR cm^{-1} (film): 3450 (NH), 1750 (C=O). 1230 (ester), 1670 and 1540 (amide). ^{1}H NMR (CD_3OD) δ: 5.80 (m, CH_2=C*H*), 5.37 (d, $J_{4',3}$ = 2.7 Hz, H-4′), 4.48 (m, Ser α-H), 4.16–3.3 (m), 2.14–2.04, 2.03, 1.99, 1.92 (OAc and NAc), and 1.45–1.34 (m, -CH_2(C*H*$_2$)$_4$ CH-). ^{13}C NMR (CD_3OD) δ: 172.7, 172.0, 171.9, 171.5, 171.1 (CO), 140.1 (CH_2=*C*H), 114.8 (*C*H_2=CH), 103.7 (C-1′), 100.7 (C-1), and 100.1 (*C*Me_2), 77.1, 72.6, 71.9, 71.1, 70.9, 70.5, 70.3, 69.9, 68.8, 67.6, 64.5, 63.8, 62.7, 40.6, 34.8, 30.1, 29.6, 28.8, 23.3, 20.9, 20.7, 20.4, and 19.0. For **41**: $[\alpha]_D$ +51.2 (*c* 0.25, $CHCl_3$); IR cm^{-1} (film): 3450 (NH), 1750 (C=O). 1230 (ester), 1670 and 1540 (amide). ^{1}H NMR (CD_3OD) δ: 5.80 (m, 1H, CH_2=C*H*), 5.37 (d, $J_{4',3}$ = 2.0 Hz, H-4′), 4.82 (m, Ser α-H), 5.1–3.3 (m), 2.14, 2.03, 1.99, 1.97, 1.92 (OAc and NAc), and 1.45–1.34 (m, -CH_2 (C*H*$_2$)$_4$ CH-). ^{13}C NMR ($CHCl_3$ + CD_3OD) δ: 172.8, 172.0, 171.9, 171.5, 171.1 (CO) 140.1 (CH_2=*C*H), 114.8 (*C*H_2=CH), 103.7 (C-1′), 100.6 (C-1), 100.1 (*C*Me_2), 77.1, 72.6, 71.2, 71.0, 70.9, 70.3, 69.9, 68.8, 67.6, 64.5, 63.8, 62.6, 40.6, 30.1, 29.6, 28.8, 23.4, 20.9, 20.7, 20.5, and 19.0.

Compounds 40 and 43

The *N*-*t*-Boc group and O-isopropylidene groups in **38** (130 mg, 0.05 mmol) and **41** (400 mg, 0.21 mmol) were individually removed by treating each compound with TFA followed by N- and O-acetylation, to give **39** (98 mg, 77%), $[\alpha]_D$ +25 (*c* 0.5, MeOH) and **42** (286 mg, 72%), $[\alpha]_D$ +51.2′ (*c* 0.25, MeOH). Treatment of **39** (75 mg, 0.028 mmol) and **42** (120 mg, 0.21 mmol) with NaOMe in MeOH, as described above, gave **40** (42 mg, 79%) and **43** (69 mg, 78%), respectively. For **40**: $[\alpha]_D$ +47.2 (*c* 0.25, H_2O). ^{1}H NMR (CD_3OD +D_2O) δ: 5.84 (m, CH_2=C*H*), 5.39 (d, $J_{4',3}$ = 3.3 Hz, H-4′), 4.90 (m, CH_2=C), 4.86 (d, $J_{1,2}$ = 3.5 Hz, H-1), 4.57 (m, Ser α-H), 4.42 (d, $J_{1',2'}$ = 7.5 Hz, H-1′), 4.33 (dd, $J_{2,1}$ = 3.5 Hz, $J_{2,3}$ = 10.9 Hz, H-2), 3.30–4.00 (m), 2.09, 2.01 (NAc), 1.25–1.60 (m, -CH_2(C*H*$_2$)$_4$ CH-). ^{13}C NMR (CD_3OD+D_2O) δ: 174.7, 173.6 (CO), 140.6 (CH_2=*C*H), 115.0 (*C*H_2=CH), 105.6 (C-1′), 99.9 (C-1). HRMS (FAB), calcd. for $C_{76}H_{131}O_{43}N_9Na$ (M+Na): 1880.8267; found: 1880.8214. For **43**: $[\alpha]_D$ +35.2 (*c* 0.25, H_2O). ^{1}H NMR (CD_3OD +D_2O) δ: 5.85 (m, CH_2=C*H*), 5.03 (d, $J_{4',3'}$ = 3.3 Hz, H-4′), 4.90 (m, CH_2=C), 4.83 (d, $J_{1,2}$ = 3.5 Hz, H-1), 4.57 (m, Ser β-H), 4.42 (d, $J_{1',2'}$ = 7.5 Hz, H-1′), 4.31 (dd, $J_{2,1}$ = 3.5 Hz, $J_{2,3}$ = 10.9 Hz, H-2), 4.28–3.27 (m), 2.04, 1.99–1.96 (NAc), 1.54–1.30 (m, -CH_2(C*H*$_2$)$_4$CH-). ^{13}C NMR (CD_3OD + D_2O) δ: 175.0, 174.6, 172.1 (CO), 140.9 (CH_2=*C*H), 115.0 (*C*H_2=CH), 105.6 (C-1′), 99.2 (C-1), 78.1, 76.0, 73.7, 72.8, 71.9, 71.7, 70.5, 70.4, 69.6, 69.5, 68.6, 62.1, 61.9, 54.7, 40.2, 34.1, 29.5, 29.1, 23.1, and 22.8. HRMS (FAB), calcd. for $C_{59}H_{103}O_{31}NNa$ (M+Na): 1428.6589; found: 1428.6445.

Compound 44

To a solution of **25** (46 mg, 0.107 mmol) in dry DMF (3 mL, 1:1) cooled to −20°C was added *N*-methylmorpholine (10 mg), followed by isobutyl chloroformate (14 μL). Stirring was continued at −20°C until a fine precipitate was observed (20 min). In a separate flask, a solution of the triamine **2** (10 mg, 0.026 mmol) in dry DMF (1 mL) was mixed under anhydrous conditions with *N*-methylmorpholine (5 μL). This solution was gradually added to the above solution of **25** at −20°C under argon during a period of 10 min. Stirring was continued at room temperature for 90 min with occasional monitoring by TLC. The reaction mixture was diluted with dichloromethane (20 mL), washed successively with saturated $NaHCO_3$ solution and water, dried ($MgSO_4$), and evaporated to a syrup. Flash chromatography of the residue on silica gel (CH_2Cl_2–MeOH, 95:5) gave **44** as an amorphous solid (30 mg, 60%); $[\alpha]_D$ +72.3 (*c* 2.0, $CHCl_3$); IR cm^{-1} (film): 3450 (NH), 1750 (C=O). 1230 (ester), 1670 and 1540 (amide). ^1H NMR (CD_3OD) δ: 5.76 (m, CH_2=C*H*), 5.36 (d, $J_{4,3}$ = 2.8 Hz, H-4), 5.16 (dd, $J_{3,2}$ = 11.6 Hz, H-3), 4.95 (m, CH_2=CH), 4.88 (d, $J_{1,2}$ = 3.4 Hz, H-1), 4.58 (m, H-2), 4.2–3.2 (m, H-5, OCH_2 and NCH_2), 2.14–1.95 (OAc, NAc), 1.60–1.20 (m, -CH_2(CH_2)$_4$CH-). ^{13}C NMR (CD_3OD) δ: 170.9, 170.8, 170.6, 170.3, 169.1 (*C*OCH_3, and NH*C*OCH_3), 138.7 (CH_2=*C*H), 114.1 (*C*H_2=CH), 98.2 (C-1), 76.8, 76.3, 69.7, 69.6, 69.5, 67.8, 66.8, 66.7, 61.6, 60.3, 38.8, 33.5, 28.7, 28.6, 25.8, 22.5, 20.5, and 20.4. HRMS (FAB), calcd. for $C_{70}H_{112}O_{36}N_6S$·$HSCH_2CHOHCH_2OH$, (M+$CH_2SHCHOHCH_2OH$): 1644.6838; found: 1644.6869.

Compound 45

The acetyl groups in compound **44** (20 mg, 0.0113 mmol) were removed by treatment with NaOMe in methanol (2 mL) as described for **28** and **34**, to give **45** (15 mg, 96%) as a syrup; $[\alpha]_D$ +32.3 (*c* 1.0, MeOH), ^1H NMR (CD_3OD) δ: 5.80 (m, CH_2=C*H*), 4.90 (m, H-4, and CH_2=CH), 4.37 (dd, $J_{3,4}$ = 3.6 Hz, and $J_{3,2}$ = 11.0 Hz, H-3), 3.91 (d, $J_{1,2}$ = 2.8 Hz, H-1), 3.81 (m, H-2), 3.82–3.28 (m, H-5, H-6, CH_2), 2.02 (NAc), 1.60–1.20 (m, -CH_2(CH_2)$_4$CH-). HRMS (FAB), calcd. for $C_{52}H_{94}O_{27}N_6SNa$·$HSCH_2CHOHCH_2OH$, (M+Na+$CH_2SHCHOHCH_2OH$): 1289.5785; found: 1289.5646.

Compounds 47 and 51

A solution of **22** (200 mg, 0.3 mmol) in DMF was treated with triamine **1** (45 mg, 0.14 mmol) in dry DMF, in a similar fashion as described for compound **44**, to give **46** (93 mg, 41%); $[\alpha]_D$ +50.7 (*c* 1.1, MeOH) and **50** (76 mg, 30%); $[\alpha]_D$ +36.2′ (*c* 0.9, MeOH) each as an amorphous solid. The O-acetyl groups in compounds **46** (190 mg, 0.08 mmol) and **50** (60 mg) were removed by treating separately with NaOMe, as described above for compounds **28** and **34,** to give **47** (118 mg, 92%) and **51** (40 mg, quant.) as syrups after chromatographic separation. For **47**: $[\alpha]_D$ +82.5 (*c* 0.25, H_2O); ^1H NMR (CD_3OD–D_2O, 1:1) δ: 5.90 (m, CH_2=C*H*), 5.25 (m, CH_2=CH), 4.87 (d, $J_{1,2}$ = 3.1 Hz, H-1), 4.50–3.30 (m, H-1′; H-4, H-5, H-5′, H-6, H-6′), and 2.02 (NAc). ^{13}C NMR (D_2O) δ: 175.0, 172.1 (NH*C*OCH_3), 135.4 (CH_2=*C*H), 118.1 (*C*H_2=CH), 105.8 (C-1′), 99.0 (C-1), 78.1, 76.1, 73.8, 73.3, 72.3, 71.8, 70.6, 69.7, 67.3, 62.2, 39.7, and 23.1. HRMS (FAB), calcd. for $C_{62}H_{106}O_{40}N_6Na$ (M+Na): 1597.5569; found: 1597.5498. For **51**: $[\alpha]_D$ +66.0 (*c* 0.5, H_2O). ^1H NMR (CD_3OD–D_2O, 10:1) δ: 5.89 (m, CH_2=C*H*), 5.29 (m, CH_2=CH), 4.87 (d, $J_{1,2}$ = 3.6 Hz, H-1), 4.50–3.30 (m), 2.02 (NAc), 0.90 (d, *J* = 6.8 Hz, $CHCH_3$). ^{13}C NMR (D_2O) δ: 175.0, 172.1 (NH*C*OCH_3), 135.5 (CH_2=*C*H), 117.9 (*C*H_2=CH), 105.9 (C-1′), 99.1 (C-1), 78.2, 76.1, 73.9, 73.3, 72.3, 72.2, 71.9, 71.1, 70.6, 69.9, 69.8, 67.3, 62.2, 62.1, 39.7, 28.8, 23.1, and 19.3. HRMS (FAB), calcd. for $C_{51}H_{89}O_{30}N_5Na$ (M+Na): 1274.5437; found: 1274.5417.

Compounds 49 and 53

A solution of **22** (303 mg, 0.43 mmol) in dry DMF was treated with triamine **2** (58 mg, 0.15 mmol) essentially in the same fashion as described for compound **44**, to give **48** (173 mg, 50 %); $[\alpha]_D$ +40.6 (*c* 1.1, MeOH) and **52** (61 mg, 16%); $[\alpha]_D$ +82.0 (*c* 1.8, MeOH) each as an amorphous solid after chromatographic separation. The O-acetyl groups in **48** (73 mg, 0.03 mmol) and **52** (91 mg, 0.05 mmol) were removed by treating separately with NaOMe, in a similar fashion as described above for compounds **28** and **34**, to give **49** (42 mg, 84%) and **53** (56 mg, 90%) as amorphous solids. For **49**: $[\alpha]_D$ +52.8 (*c* 1.1, H_2O). ^1H NMR (D_2O) δ: 5.87 (m, CH_2=C*H*), 4.98 (m, CH_2=CH), 4.96 (d, $J_{1,2}$ = 3.3 Hz, H-1), 4.53 (d, $J_{1,2}$ = 7.7 Hz, H-1′), 3.94 (d, H-4), 4.4–3.4 (m), 2.13 (NAc), 1.46–1.23 (m, CH_2(CH_2)$_4$CH). ^{13}C NMR (D_2O) δ: 174.3, 171.3 (NH*C*OCH_3), 139.9 (CH_2=*C*H), 114.0 (*C*H_2=CH), 104.3 (C-1′), 97.7 (C-1), 78.9, 77.8, 72.3, 71.7, 71.1, 70.7, 69.8, 68.5, 68.4, 66.1, 60.8, 48.7, 45.0, 38.5, 28.4, 27.9, 25.4, and 22.0. HRMS (FAB), calcd. for $C_{67}H_{116}O_{40}N_6Na$ (M+Na): 1667.7079; found: 1667.7135. HRMS (FAB), calcd. for $C_{56}H_{99}O_{30}N_5Na$ (M+Na): 1344.6240; found: 1344.6198.

Summary

Immunologically relevant carbohydrates such as D-GalNAc(Tn) and D-Galβ(1→3)GalNAc(T) have been attached to triamino and tris(aminoethyl) pentaerythritol-based scaffolds through amide linkages with the aim of generating clustered haptenic motifs for use as tumor-specific carbohydrate antigens and vaccines.

The generator coordinate Dirac–Fock method applied to beryllium-like atomic species

F.E. Jorge and A.B.F. da Silva

Abstract: The recently formulated generator coordinate Dirac–Fock method for relativistic closed-shell atoms is applied to the Be atom and Be-like ions Ne^{6+}, Ar^{14+}, and Sn^{46+} in order to assess its efficacy for light atomic systems. The Dirac–Fock equations are integrated numerically in the generator coordinate Dirac–Fock method so as to generate Gaussian basis sets for the atomic species under study. The results obtained with the application of the generator coordinate Dirac–Fock method in this work for Dirac–Fock–Coulomb and Dirac–Fock–Breit energies for Be-like ions are in excellent agreement with Declaux's benchmark numerical calculations, and are better than the Dirac–Fock–Coulomb and Dirac–Fock–Breit energies obtained with even-tempered Gaussian-type function calculations. For the Be atom, the Dirac–Fock–Coulomb energy result obtained with the generator coordinate Dirac–Fock method is lower than the corresponding value obtained with the Declaux's numerical finite-difference program.

Key words: Dirac–Fock–Coulomb energy, Dirac–Fock–Breit energy, Gaussian basis sets, generator coordinate Dirac–Fock method.

Résumé : La méthode de la coordonnée génératrice Dirac–Fock récemment formulée, pour les atomes ayant une couche électronique relativement complète, est appliquée à l'atome de Be et aux ions ressemblant à l'atome de Be : Ne^{6+}, Ar^{14+} et Sn^{46+} dans le but de vérifier l'efficacité de cette méthode pour les systèmes atomiques légers. Les équations de Dirac–Fock sont intégrés numériquement dans la méthode de la coordonnée génératrice Dirac–Fock de façon à générer l'ensemble de base de Gauss pour les espèces atomiques étudiées. Les résultats obtenus avec la méthode de la coordonnée génératrice Dirac–Fock pour les énergies Dirac–Fock–Coulomb et Dirac–Fock–Breit pour les ions du type Be sont en parfait accord avec les calculs numériques de référence de Declaux et sont meilleurs que les énergies de Dirac–Fock–Coulomb et Dirac–Fock–Breit obtenues avec les calculs avec les fonctions de Gauss également tempérés. Dans le cas de l'atome de Be, l'énergie de Dirac–Fock–Coulomb obtenue avec la méthode de la coordonnée génératrice Dirac–Fock est plus basse que l'énergie correspondante obtenue avec le programme de différences finies numérique de Declaux.

Mots clés : énergie Dirac–Fock–Coulomb, énergie Dirac–Fock–Breit, ensembles de base de Gauss, méthode de la coordonnée génératrice Dirac–Fock.

[Traduit par la rédaction]

1. Introduction

Ab initio Dirac–Fock (DF) self-consistent-field (SCF) calculations for many-electron atoms have been carried out either by using numerical finite-difference or basis set expansion methods (1–4). Slater-type functions (STF) and Gaussian-type functions (GTF) that satisfy the relativistic boundary conditions have been used for ab initio DF calculations on atoms. However, as relativistic atomic and molecular calculations are based on the Dirac equation whose solutions for an electron in a finite nucleus have been shown to be Gaussian (5, 6), the GTF are the natural choice for ab initio relativistic atomic and molecular calculations. Besides, the GTF that satisfy the boundary conditions for the finite nucleus automatically satisfy the condition of the so-called kinetic balance for a finite speed of light (6).

In this letter we apply the generator coordinate Dirac–Fock (GCDF) method developed recently for us (7, 8) to calculate the ground state Dirac–Fock–Coulomb (DFC) and Dirac–Fock–Breit (DFB) energies of Be, Ne^{6+}, Ar^{14+}, and Sn^{46+} in order to evaluate its efficacy for light atomic systems. Our results for the total DFC and DFB energies obtained with the GCDF method surpass previous calculations for Ne^{6+}, Ar^{14+}, and Sn^{46+} using even-tempered GTF (9), and are competitive with the results obtained by using Declaux's numerical finite-difference program (9). For the case of the Be atom, the DFC energy computed with our GTF is lower than the corresponding value obtained by both even-tempered GTF and numerical finite-difference calculations.

The GTF exponents generated here with the GCDF method for Be, Ne^{6+}, Ar^{14+}, and Sn^{46+} represent the first set of GTF exponents for these species obtained directly from a relativistic environment (code), as the usual procedure in relativistic calculations, so far, has been to employ GTF exponents obtained from a nonrelativistic environment by variational optimization or other techniques and carry them over to relativistic calculations (9–16) as suggested primarily by

Matsuoka and Huzinaga (16). In that pioneer work, Matsuoka and Huzinaga showed that the same set of well-tempered GTF exponents obtained for a nonrelativistic atom could be carried over to the relativistic calculation.

2. Theoretical

In a previous paper we introduced the GCDF method for closed-shell atoms (7), and afterwards we included the Breit interaction term in the GCDF formalism in order to perform DFB calculations (8). This methodology is a result of applying the generator coordinate (GC) formalism (17), originally formulated for applications in nuclear physics, to the DF equations. For this purpose we chose the radial large and small components, $P_{n\kappa}(r)$ and $Q_{n\kappa}(r)$, respectively, as integral transforms, viz.

$$[1] \qquad P_{n\kappa}(r) = \int X_\kappa^{\mathrm{L}}(r, \gamma) f_{n\kappa}^{\mathrm{L}}(\gamma) \mathrm{d}\gamma$$

and

$$[2] \qquad Q_{n\kappa}(r) = \int X_\kappa^{\mathrm{S}}(r, \gamma) f_{n\kappa}^{\mathrm{S}}(\gamma) \mathrm{d}\gamma$$

where X_κ^{L} and X_κ^{S} are, respectively, the large (L) and small (S) generator functions (GTF or STF), $f_{n\kappa}^{\mathrm{L}}$ and $f_{n\kappa}^{\mathrm{S}}$ are, respectively, the large and small weight functions, and γ is the generator coordinate. In the GCDF method, although we resorted to a discretization technique for the solution of the integral DF equations

$$[3a] \qquad \int [F_\kappa^{\mathrm{LL}}(\gamma, \eta) f_{n\kappa}^{\mathrm{L}}(\eta) + F_\kappa^{\mathrm{LS}}(\gamma, \eta) f_{n\kappa}^{\mathrm{S}}(\eta)] \mathrm{d}\eta = \int \varepsilon_{n\kappa} S_\kappa^{\mathrm{LL}}(\gamma, \eta) f_{n\kappa}^{\mathrm{L}}(\eta) \mathrm{d}\eta$$

and

$$[3b] \qquad \int [F_\kappa^{\mathrm{SL}}(\gamma, \eta) f_{n\kappa}^{\mathrm{L}}(\eta) + F_\kappa^{\mathrm{SS}}(\gamma, \eta) f_{n\kappa}^{\mathrm{S}}(\eta)] \mathrm{d}\eta = \int \varepsilon_{n\kappa} S_\kappa^{\mathrm{SS}}(\gamma, \eta) f_{n\kappa}^{\mathrm{S}}(\eta) \mathrm{d}\eta$$

the continuous character of the original GC formalism (17) was retained. This was achieved by simply choosing equally spaced discretization points in an attempt to find an adequate numerical integration of the eqs. [3]. This approach is referred to as integral discretization (ID) (18) in contrast to the procedure of variationally optimizing orbital exponents, common in nonrelativistic calculations. The ID is implemented through a relabelling of the generator coordinate space γ

$$[4] \qquad \Theta = \ln \gamma / A, \qquad A > 1$$

In the new generator coordinate space Θ, an equally spaced N-point mesh $\{\Theta_w\}$ is selected, and the integration range is characterized by a starting point $\Theta_{\min}$, an increment $\Delta\Theta$, and N (number of points).

After the integral discretization, eqs. [3], for symmetry type κ, take the form

$$[5] \qquad \boldsymbol{F}_\kappa \boldsymbol{f}_\kappa = \boldsymbol{S}_\kappa \boldsymbol{f}_\kappa \boldsymbol{E}_\kappa$$

where the overlap matrix is given by

$$[6] \qquad \boldsymbol{S}_\kappa = \begin{pmatrix} \boldsymbol{S}_\kappa^{\mathrm{LL}} & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{S}_\kappa^{\mathrm{SS}} \end{pmatrix}$$

The DFC and the DFB matrices are

$$[7] \qquad \boldsymbol{F}_\kappa = \boldsymbol{o}_\kappa + \boldsymbol{t}_\kappa$$

and

$$[8] \qquad \boldsymbol{F}_\kappa = \boldsymbol{o}_\kappa + \boldsymbol{t}_\kappa + \boldsymbol{b}_\kappa$$

respectively. Where the one-electron part $\boldsymbol{o}_\kappa$ is

$$[9] \qquad \boldsymbol{o}_\kappa = \begin{pmatrix} \boldsymbol{V}_\kappa^{\mathrm{LL}} & c\boldsymbol{\Pi}_\kappa^{\mathrm{LS}} \\ c\boldsymbol{\Pi}_\kappa^{\mathrm{SL}} & \boldsymbol{V}_\kappa^{\mathrm{SS}} - 2c^2 \boldsymbol{S}_\kappa^{\mathrm{SS}} \end{pmatrix}$$

The two-electron part $\boldsymbol{t}_\kappa$, which consists of the matrices of two-electron Coulomb and exchange interactions, is given by

$$[10] \qquad \boldsymbol{t}_\kappa = \begin{pmatrix} \boldsymbol{J}_\kappa^{\mathrm{LL}} - \boldsymbol{K}_\kappa^{\mathrm{LL}} & -\boldsymbol{K}_\kappa^{\mathrm{LS}} \\ -\boldsymbol{K}_\kappa^{\mathrm{SL}} & \boldsymbol{J}_\kappa^{\mathrm{SS}} - \boldsymbol{K}_\kappa^{\mathrm{SS}} \end{pmatrix}$$

The frequency-independent Breit interaction leads to the term $\boldsymbol{b}_\kappa$ in the matrix SCF equation, eq. [5], viz.

$$[11] \qquad \boldsymbol{b}_\kappa = \begin{pmatrix} \boldsymbol{B}_\kappa^{\mathrm{LL}} & \boldsymbol{B}_\kappa^{\mathrm{LS}} \\ \boldsymbol{B}_\kappa^{\mathrm{SL}} & \boldsymbol{B}_\kappa^{\mathrm{SS}} \end{pmatrix}$$

The one- and two-electron matrix elements in eqs. [9]–[11] are expressed in terms of the generator coordinate γ, and have been shown elsewhere (7, 8). In the GCDF method the $\boldsymbol{b}_\kappa$ term is introduced in the SCF procedure according to the previous work of Quiney et al. (19), which showed that there is no necessity for the $\boldsymbol{b}_\kappa$ term to be treated as a first-order perturbation, as was widely believed. Later, Ishikawa et al. (20) developed the DFB SCF method including the $\boldsymbol{b}_\kappa$ term in the SCF procedure, as suggested by Quiney et al. (19), using GTF basis sets.

3. Some considerations about the even-tempered exponents and the ID technique

In this section we would like to draw attention to the similarity between the even-tempered technique and the ID technique used in the GCDF method. The definition for the even-tempered exponents is $\xi = \alpha\beta^{i-1}$, where α and β are constants to be determined, and $i = 1, 2, \ldots, N$. Thus, the increment $\Delta\xi$ is $\Delta\xi = \xi_{i+1} - \xi_i = \alpha\beta^{i-1}(\beta - 1) = \xi_i(\beta - 1)$, i.e., the basis function exponent ξ_i times a constant. In our case, the ID technique was proved to be particularly efficient with a relabelling technique of the generator coordinate space γ (see eq. [4]) with Gaussian generator functions, namely, $\gamma_i = \exp(A\Theta_i)$, and $\Delta\gamma = \gamma_{i+1} - \gamma_i = \exp(A\Theta_i)[\exp(A\Delta\Theta - 1)] = \gamma_i[\exp(A\Delta\Theta) - 1]$, i.e., again a basis function exponent times a constant. Despite the similarity between the two techniques, the even-tempered formula never aimed at the solution of a continuous problem (the parameters α and β are generally determined variationally), whereas our discretization parameters are determined through numerical integration in order to adequately simulate eqs. [3]. Thus, the even-tempered gen-

eration of basis function exponents is unrelated to ours. Indeed, the application of the two techniques to study the same atomic system will lead (for a finite basis set of fixed size) to different energy values, because the basis function exponents generated by each technique would be different.

It is important to mention that through our technique we are always able to generate accurate universal basis sets for a large number of atomic species (12–15, 21). On the other hand, to generate a universal basis set variationally with the even-tempered formula is almost impossible, as trying to do that implies finding variationally a unique set of parameters α and β that can describe the energy of a considerable number of atoms. This is the reason why papers published in the literature in which even-tempered basis sets are determined variationally always have one different set of parameters α and β for each orbital symmetry in each atomic system studied. In a unique case, Silver and Nieuwpoort in 1978 indeed generated a universal even-tempered basis set for 10 atoms using Slater-type functions, but the parameters α and β were chosen quite arbitrarily instead of being determined variationally (22).

4. Results and discussion

The DFC and DFB SCF calculations on Be and Be-like species Ne^{6+}, Ar^{14+}, and Sn^{46+} are performed by using the closed-shell GCDF method presented briefly in Sect. 2. The finite nuclear model of uniform proton charge distribution and kinetic balance constraints (5, 6, 19) are used in our calculations in this work. The atomic masses used for Be, Ne, Ar, and Sn nuclei are, respectively, 9.0, 20.0, 39.948, and 118.69 amu. The speed of light c is in all calculations taken to be 137.0370 au.

The GTF exponents generated here with the GCDF method for Be atom and Be-like ions can easily be reproduced by using eq. [4] and the discretization parameters Θ_{min} (starting exponent), $\Delta\Theta$ (increment), and N (number of exponents) shown in Tables 1–5 for each atomic species studied. The scaling parameter A in eq. [4] is used in all calculations as 6.0. From the discretization parameters shown in Tables 3–5, we notice that the starting exponent can differ from one ion to another, despite having a unique (universal) set of GTF exponents used for Ne^{6+}, Ar^{14+}, and Sn^{46+}. For each atomic species studied, we increased the number of exponents per $s_{1/2}$ symmetry until a total DFC energy value was obtained with an accuracy comparable to (or better than) that obtained with the numerical finite-difference program. Afterwards, we used the same set of exponents to perform the corresponding DFB calculations.

Table 1 shows the convergence pattern for Be, and Tables 2–5 display the results for DFC and DFB energies (E_{DFC} and E_{DFB}, respectively), $1s$ and $2s$ DFC and DFB orbital energies (ε_{1s} and ε_{2s}, respectively), and the Breit interaction energy (E_B) obtained with the GCDF method and other approaches for Be, Ne^{6+}, Ar^{14+}, and Sn^{46+}. $E_{B(SCF)}$ denotes the variational Breit interaction energy computed as the difference between E_{DFB} and E_{DFC}. $E_{B(PT)}$ is the first-order Breit interaction energy evaluated perturbatively (1, 9).

Table 1 displays the convergence pattern of the DFC, DFB, and E_B energies for the Be atom. One can see from Table 1 that the Be DFC and DFB energies converge to the lowest

limit of −14.575 893 06 and −14.575 189 86 hartrees, respectively, when the basis set size reaches $N = 28$. It is interesting to mention that for $N = 21$ the Breit interaction energy has already converged whereas the DFC and DFB total energies have not yet done so.

Table 2 contains several energy results for the Be atom computed with the GCDF method and other approaches. From Table 2 we can see that the DFC and DFB energy results obtained with the GCDF method are lower, respectively, by 1.49 and 0.73 μhartree than their counterparts obtained with even-tempered basis set (9), and by 1.09 and 0.37 μhartree than those obtained by using the numerical finite-difference method (9). The excellent performance of our GTF basis set in describing the DFC energy for the Be atom is attributed to the proper representation of the wave function inside the nucleus due to the higher numerical accuracy of the Gaussian basis functions generated here with the GCDF method. This evidence is not completely new, as in a previous paper Parpia and Mohanty (23) already verified the possibility of basis set functions being able to better rep-

resent the wave function inside the nucleus than numerical finite-difference calculations. The DFC and DFB orbital energies computed with the GCDF method for Be are slightly lower than the corresponding DFC and DFB orbital energies obtained with the other two approaches. The E_B obtained for Be with the GCDF method is in good agreement with the other values obtained with the even-tempered GTF and the perturbative approach (9).

Tables 3–5 display the results for the Ne^{6+}, Ar^{14+}, and Sn^{46+} ions using our GTF basis set generated with the GCDF method, the even-tempered GTF basis set (9), and the numerical finite-difference method (9). Here, it is interesting to draw attention to the fact that for Ne^{6+}, Ar^{14+}, and Sn^{46+} we have generated, with the GCDF method, a universal Gaussian basis set to describe this set of positive ions, while the even-tempered basis sets have a different set of parameters α and β for each one of the three positive ions studied, and these parameters are obtained variationally in a nonrelativistic environment. One can see from the footnotes of Tables 3–5 that Θ_{min} and $\Delta\Theta$ are always the same for the three ionic species studied here. From these tables, we see that our DFC energies are always better than the even-tempered GTF results and are very close to the results obtained with the numerical finite-difference method. On the other hand, our DFB energies obtained for these ionic species are always lower than the DFB energies obtained with the even-tempered GTF basis set and the numerical finite-difference method. For the three ions studied, the DFC and DFB orbital energies obtained with our GTF are in excellent agreement when compared to the corresponding orbital energies obtained with the numerical finite-difference approach. Besides, the E_B computed with our GTF is in good agreement with the perturbative approach despite the E_B obtained with the perturbative approach being slightly larger in magnitude than the E_B results obtained with the GCDF method. According to Ishikawa (9), the difference between the E_B calculated variationally and that calculated by using the perturbative approach indicates that first-order perturbation calculations overestimate the E_B, and the error is not negligible for a moderately high-Z atom (for Sn^{46+} the difference is 10^{-3} au). Quiney et al. (19) pointed out that this difference may be attributed to the inclusion of higher-order ($\alpha^4 \ldots$) covariant contributions in the SCF treatment of the Breit interaction that are absent in the first-order perturbation treatment.

We attribute the high accuracy of our GTF basis set, presented in this work for Be-like atomic species, to the ID technique of the GCDF method. In the GCDF, the ID technique is implemented inside the DF equations, and thus the GTF exponents are generated directly from a relativistic environment. We believe the reason why our DF energy results, obtained here for Be-like atomic species with the GCDF method, are better than the even-tempered basis set counterparts (9) is related to the fact that the ID technique of the GCDF method is implemented directly inside the DF equations. It is important to mention that the even-tempered GTF exponents used by Ishikawa (9) were originally inside a nonrelativistic environment, and afterwards transferred to the relativistic environment in order to perform DF calculations. Thus we see that the GCDF method is able to provide very accurate Gaussian basis sets for relativistic calculations, as presented here for light atomic systems and previously for heavy atoms (7, 8).

5. Conclusion

The DF energy values reported in this work for Be-like atomic species show that with a careful numerical integration of the DF equations in the GCDF method we are able to generate very accurate GTF to be used in relativistic atomic and

molecular calculations. With the GCDF method, the GTF exponents are generated by the discretization of the integral DF equations with the best numerical integration as a goal. Thus, in the GCDF formalism, the GTF exponents are not parameters to be variationally optimized as usual. The GCDF method represents an algorithm capable of generating GTF exponents directly from a relativistic environment (code).

The DFC and DFB energies obtained in this work with the GCDF method are competitive in accuracy with the corresponding values obtained with the numerical finite-difference method and better than the DFC and DFB energies obtained with an even-tempered GTF basis set. The excellent DFC and DFB energy results obtained here for the Be atom, when compared to the numerical finite-difference counterpart, are attributed to the higher accuracy of our GTF basis set due to the implementation of the ID technique inside the relativistic environment.

The chemistry of thujone. XIX.[1] Acid-promoted ring cleavage of thujone-derived cyclopropylcarbinols

James P. Kutney, Yong-Huang Chen, and Steven J. Rettig

Abstract: Thujone-derived cyclopropylcarbinols can cleave via three distinct pathways: the *exo* cleavage, the *endo* cleavage, and the interesting cyclopropylcarbinyl rearrangement. Factors determining which pathway is adopted under specific conditions are discussed. A short sequence leading to synthesis of the sesquiterpene (+)-β-cyperone is described.

Key words: thujone, cyclopropylcarbinols, cyclopropylcarbinyl rearrangement, β-cyperone synthesis.

Résumé : Les cyclopropylcarbinols dérivés de la thujone peuvent subir trois clivages distincts : le clivage *exo*, le clivage *endo* et l'intéressant réarrangement cyclopropylcarbinyle. On discute des facteurs qui déterminent le processus suivi dans des conditions spécifiques. On décrit une courte séquence conduisant à la synthèse du sesquiterpène (+)-β-cypérone.

Mots clés : thujone, cyclopropylcarbinols, cyclopropylcarbinyle, réarrangement, synthèse de la β-cypérone.

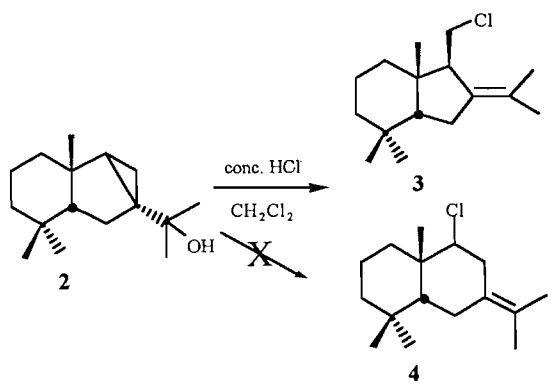
[Traduit par la rédaction]

In continuing the development of the monoterpene thujone (**1**)[3] as an efficient chiral building block (1), we discovered a novel procedure for functionalizing thujone and its derivatives of general structure (i) by ozonation (Fig. 1) (2). The ozonation procedure provides two valuable intermediates of general structures (ii) and (iii) amenable for synthetic exploitation. The cyclopropylcarbinols have been applied in the synthesis of antifeedant polygodial derivatives (2) and the fragrance compounds damascone and damascenone (2, 3). The cyclopropyl ketone derivatives, on the other hand, have been utilized in the synthesis of ambergris fragrances (2). In this article, we would like to detail our recent studies on acid-promoted ring cleavage of thujone-derived cyclopropylcarbinols.

Cleavage reactions, *exo* and *endo*

It is well known that cyclopropylcarbinols can be readily cleaved in the presence of acids (4). Thujone-derived nonsymmetrically substituted cyclopropylcarbinols of structure (ii) in Fig. 1 are expected to produce two regioisomers. For example, the nucleophilic attack of halide X^- at C5 in (ii) will lead to a homoallylic halide of a cyclohexyl skeleton, through cleavage of the C5—C1 bond (i.e., *endo* cleavage); the nucleophilic attack of halide X^- at C6 will form a homoallylic halide of a cyclopentyl skeleton, through cleavage of the C6—C1 bond (i.e., *exo* cleavage) (Fig. 2).

When the thujone-derived alcohol **2** was treated with concentrated hydrochloric acid in methylene chloride, homoallylic chloride **3** was obtained in 85% yield by the *exo*-cleavage pathway. The putative *endo*-cleavage product **4** was not isolated. In brief, the ^{1}H NMR spectrum of **3** showed two methyl singlets at δ 1.63 and 1.70 ppm, indicating the presence of an isopropylidene group, and a multiplet (2H, octet) at δ 3.55 ppm, characteristic of the A/B portion of an ABX system, corresponding to the chloromethylene group.



Treatment of another thujone-derived cyclopropylcarbinol **5** with concentrated HCl also gave the *exo*-cleavage product **6** as the major product (75% yield), the *endo*-cleavage product was not isolated.

Stirring of chloride **6** in the presence of silica gel in methylene chloride overnight regenerated the starting ketol **5** exclusively. The β orientation of the chloromethyl group of the *exo*-cleavage products was therefore verified.

[3] This natural product is actually a mixture of two epimers, (−)-α-thujone (α-methyl at C-4) and (+)-β-thujone (β-methyl at C-4) in a ratio of 10:1, respectively. However, any base-catalyzed condensation at C-4 leads to only one chiral isomer with the angular methyl group in a β orientation as shown in partial structure (i) (Fig. 1).

Fig. 1.

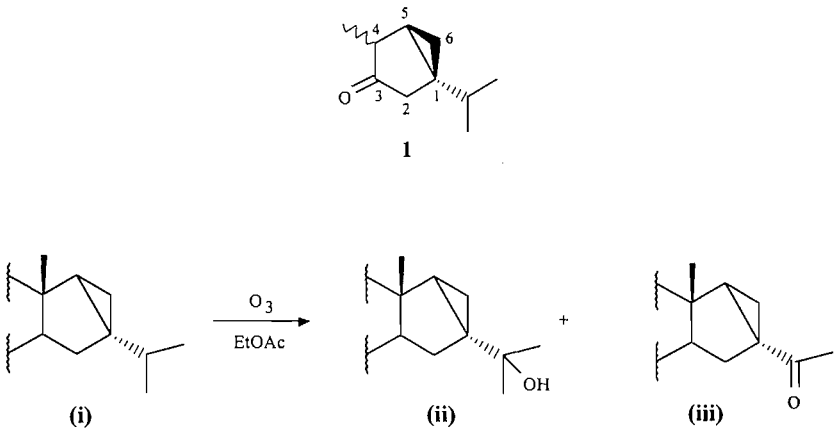

Fig. 2.

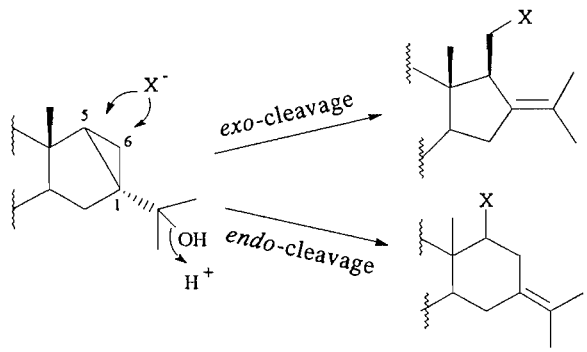

The hydrochloric acid promoted *exo*-cleavage reaction is applicable to other thujone-derived cyclopropylcarbinols with a saturated sp^3-hybridized C3 centre. For example, compound **7** was converted to chloride **8** in the synthesis of drimane antifeedant analogues (2). In a sequence leading to synthesis of the rose oil fragrances, β-damascone and β-damascenone (2, 3), thujone derivative **9** was converted into **10**.

It appears that the nucleophilic attack of chloride is concurrent with the cleavage of the C—C bond. Otherwise, if the C—C bond cleavage preceded the chloride attack, the *endo*-cleavage pathway would generate a more stable secondary carbocation as its intermediate and might become the dominant pathway. This conclusion is consistent with the previous observation with regard to the stereochemistry of the acid-promoted cleavage of 1-alkoxymethyl bicyclo[3.1.0]hexanes (5). Therefore, the preference for this *exo* cleavage is very likely due to the more exposed and accessible nature of the C6 methylene compared to the C5 methine in the cyclopropyl ring.

However, the regioselectivity of ring cleavage is altered under the same experimental conditions, when thujone-derived cyclopropylcarbinols are sp^2-hybridized at C3. Thujonol (**11**), which is a mixture of C4 epimers (**11**α and **11**β in a ratio of 10:1), was treated with concentrated hydrochloric acid at room temperature to give carvacrol (**12**) (6) and the chloro-enone **13** in 40 and 45% yields, respectively.

The chloro-enone **13** was rather unstable and therefore the ^1H NMR spectrum obtained was always contaminated with extra signals due to the presence of carvacrol (**12**). However, a "difference spectrum" between the "contaminated spectrum"and the spectrum of **12** clearly revealed all signals of **13**.

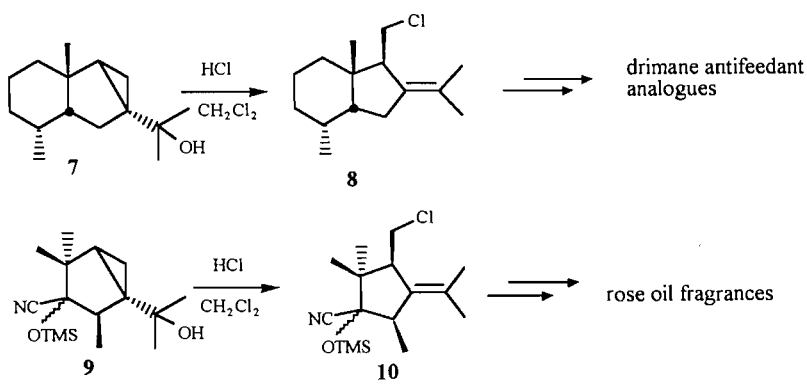

Fig. 3. A formal synthesis of (+)-β-cyperone (**17**).

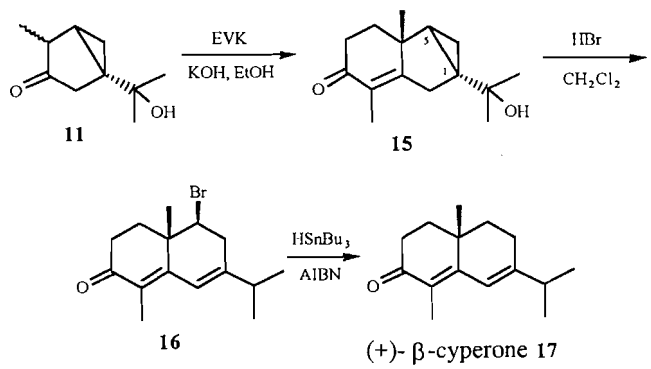

Fig. 4. The ring cleavage reaction of **15** via the *endo*-type cleavage pathway.

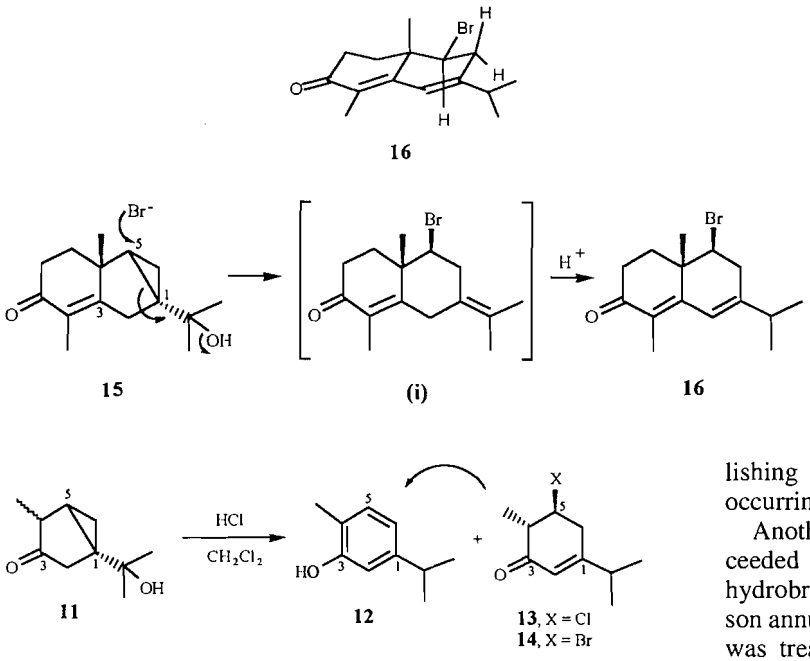


This difference spectrum of **13** showed a multiplet (doublet of triplet) at δ 4.06 ppm (1H, J = 4.4 and 9.8 Hz) corresponding to the methine proton at the chlorine bearing carbon (C5), and a broad singlet at δ 5.95 ppm (1H) due to the olefinic proton at C2. The splitting pattern of the methine at C5 indicated that the methyl group and the chlorine are in the *trans* configuration. The nucleophilic attack of the chloride anion from the back side of the cleaving C1—C5 bond should afford the designated β orientation of the chlorine as shown in **13**.

Thujonol (**11**) was also treated with concentrated hydrobromic acid in methylene chloride. Carvacrol (**12**) and the bromoenone **14** were isolated in 10 and 85% yields, respectively. The latter (**14**) is much more stable than the analogous chloroenone **13**. The ^{1}H NMR spectrum of **14** is very similar to that of **13**. A multiplet (doublet of triplet) signal at δ 4.19 ppm (J = 4.4 and 10.2 Hz) is due to the methine proton at the bromine-bearing carbon (C5) while a broad singlet at δ 5.97 ppm is clearly due to the olefinic proton at C2. The specific rotation of **14** was measured to be +42 (c = 0.29, $CHCl_3$), thereby establishing that a significant amount of racemization was not occurring in the conversion of **11** to **14**.

Another thujone-derived cyclopropylcarbinol also proceeded via the *endo*-cleavage pathway when treated with hydrobromic acid. Hydroxy-enone **15**, obtained from Robinson annulation of thujone (**11**) with ethyl vinyl ketone (EVK), was treated with hydrobromic acid in methylene chloride. Bromo-dienone **16** was isolated in 91% yield (Fig. 3). Compound **16** was previously reduced to (+)-β-cyperone (**17**) by tributyltin hydride in an earlier synthesis of (+)-β-cyperone from thujone (2). Thus, a new sequence to (+)-β-cyperone was completed in four steps using ozonation of thujone, Robinson annulation of thujonol (**11**), acid-promoted ring cleavage of **15**, and radical-mediated reduction of **16**.

The formation of **16** is similar to that of **13** and **14**. The ring cleavage reaction generates an unstable intermediate that then rearranges to the more stable dienone **16** with a fully conjugated dienone system (Fig. 4).

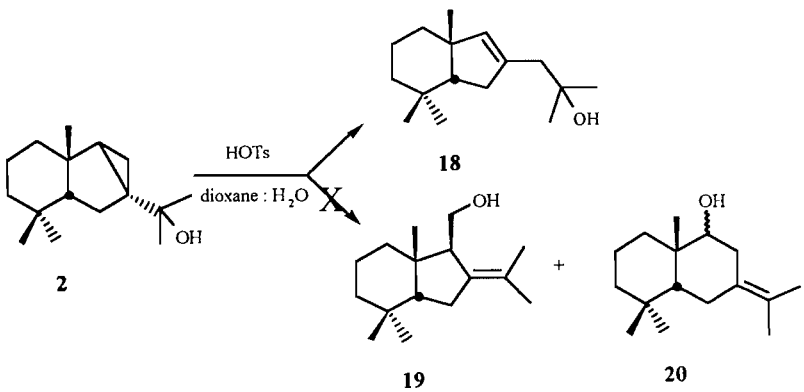
The reason for the *endo*-cleavage selectivity in the thujone-derived intermediates that possess an unsaturated system in ring A, that is, an sp^2-hybridized center at C3, is not well understood. Perhaps the interaction of the double bond *exo* to the bicyclo[3.1.0]hexane and the C1—C5 bond in hydroxy-enone **15** and thujonol (**11**) leads to the weakening of C1—C5 and eventually its facile cleavage under acidic conditions.

The cyclopropylcarbinyl rearrangement

Previous studies have shown that 1-alkyoxymethyl bicy-

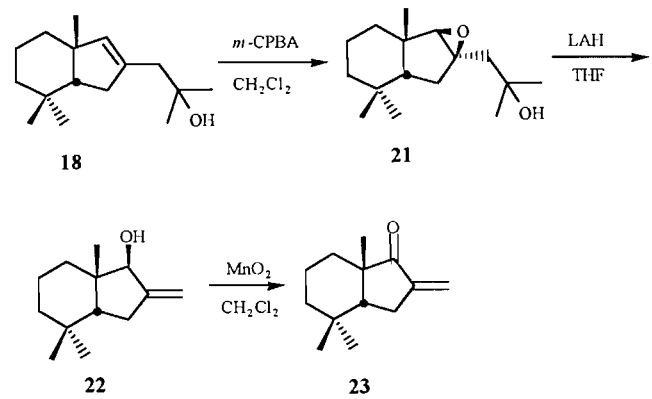
clo[3.1.0]hexanes can be cleaved through the *endo*-cleavage pathway by using non-nucleophilic conditions. There are examples in the literature showing the use of other solvolysis conditions (5). The poor nucleophilicity of the attacking groups such as H_2O and HOAc under this set of conditions may allow the ring cleavage reaction to occur in a less synchronized mechanism so that, in the transition state, the C—C bond cleavage to a carbocationic species becomes more predominant than bond formation between the carbon atom and the incoming nucleophile. The *endo*-type cleavage proceeds through a more stable transition state because the tertiary center C5 accommodates the developed partial charge better than the secondary center C6. Therefore, the *endo*-type cleavage prevails.

When the thujone-derived cyclopropylcarbinol **2** was treated with a catalytic amount of *p*-toluenesulfonic acid in dioxane:H_2O (1:1), a novel rearrangement product **18** was obtained in 85% yield. The two expected *exo*- and *endo*-cleavage products **19** and **20** were not isolated. The absence of any signals at δ 3.0–4.0 ppm in the NMR spectrum clearly revealed that the product obtained could not be a primary or secondary alcohol. The ^1H NMR spectrum contained a one-proton broad singlet at δ 5.33 ppm corresponding to the olefinic proton, and five methyl singlets at δ 0.87, 1.01, 1.17, 1.21, and 1.22 ppm. From the chemical shifts, it is obvious that none of the methyl groups is adjacent to the double bond.



To confirm the structure of **18**, a series of chemical conversions was carried out. Treatment of **18** with *m*-CPBA in methylene chloride produced a crystalline epoxide **21** in 90% yield. The NMR spectrum showed that the singlet olefinic signal at δ 5.33 ppm is replaced by the proton signal of the epoxide ring at δ 2.85 ppm. The orientation of the epoxide in **21** and, in turn, confirmation of the structure **18** were subsequently established by the X-ray crystal analysis of **21** (Fig. 5). The *cis* A/B ring junction in **21** and the β-orientation for the epoxide ring are clearly revealed. Details of the X-ray analysis will be published elsewhere.

When epoxide **21** was further treated with LAH in THF, an unexpected product, the allylic alcohol **22**, was obtained in



almost quantitative yield. The mass spectrum showed its molecular ion peak at *m/z* 194, corresponding to a loss of an acetone molecule (*m/z* = 58) from **21**. The IR spectrum displayed hydroxyl absorptions at 3100–3650 cm^{-1} while the ^1H NMR spectrum indicated only three methyl singlets at δ 0.82, 1.02, and 1.14 ppm, a one-proton singlet at δ 3.80 ppm corresponding to the allylic tertiary proton α to the hydroxyl group, and two olefinic one-proton singlets at δ 5.06 and 5.21 ppm. The β orientation of the hydroxyl group in **22** is clear from the mechanistic argument shown in Fig. 6.

Allylic alcohol **22** was subjected to allylic oxidation by manganese dioxide (7) in methylene chloride at room temperature to provide enone **23** in 70% yield. The mass spectrum showed the molecular ion peak at *m/z* 192. Its UV spectrum in methanol displayed an intense absorption at 235 nm (log ε = 4.0) and a weaker one at 278 nm (log ε = 2.5). The IR spectrum indicated a conjugated carbonyl absorption at 1710 cm^{-1}. The ^1H NMR spectrum confirmed the disappearance of the allylic tertiary proton signal previously noted in the spectrum of **22**.

To achieve a more conventional hydride-catalyzed opening of the epoxide, the β orientation of the epoxide ring in **21** dictates hydride attack from the very hindered concave α face. Consequently, the fragmentation reaction shown in Fig. 6 becomes the exclusive pathway. The epoxide **21** was treated with "superhydride" (lithium triethylborohydride) in order to see if the reduction rather than the fragmentation would take place. Again, the allylic alcohol **22** was obtained as the only product.

The rearrangement from **2** to **18** is a mechanistically novel process, a stepwise description of which is shown in Fig. 7. Initially the cyclopropylcarbinyl cation (i) is formed by a proton-catalyzed elimination of the hydroxyl group in **2**. The following 1,3-shift of the methylene on the cyclopropane ring would result directly in a spiro-cyclopropylcarbinyl cation (ii). The alternative rearrangement, via the cyclobutyl carbocation indicated, could also afford the cation (ii). This cat-

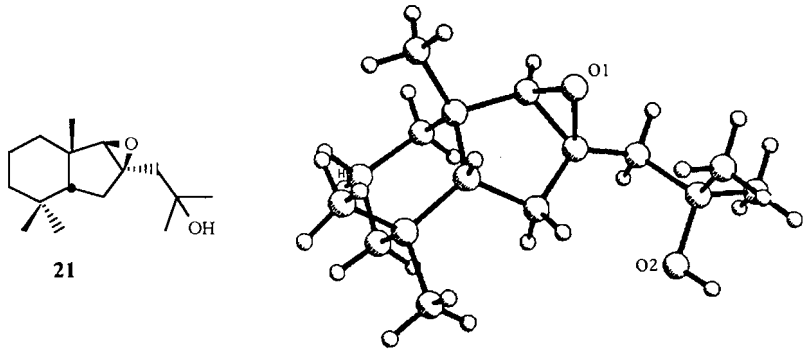

Fig. 6. Mechanism of the fragmentation of epoxide **21**.

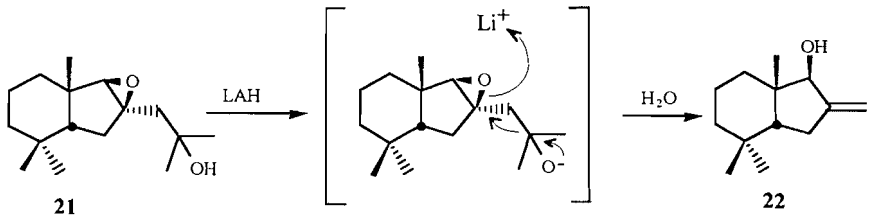

Fig. 7. The mechanism of the cyclopropylcarbinyl rearrangement reaction.

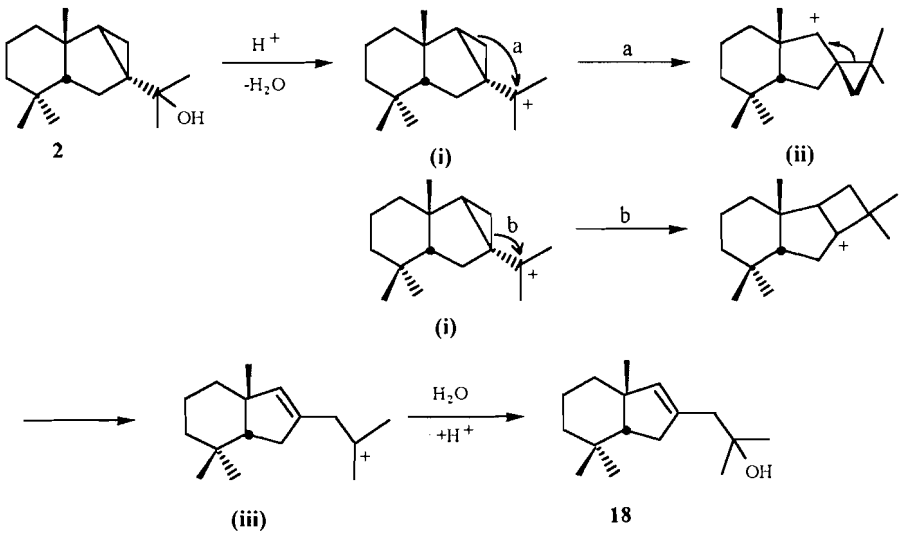


ion (ii) further cleaves regioselectively to form a more stable homoallylic cation (iii) and the latter, upon reaction with water, converts to **18**. The particular transformation between two cyclopropylcarbinyl cations in a manner similar to that between (i) and (ii), normally referred to as the cyclopropylcarbinyl rearrangement, was also termed as the "cyclopropane sliding reaction" by a Japanese group who studied this type of transformation in greater detail with their system (8). Mechanistic proposals involving this interesting reaction are also available in the literature (9) It seems that the thermodynamic stabilities among three carbocations (i), (ii), and (iii) determine the outcome of the solvolysis reaction.

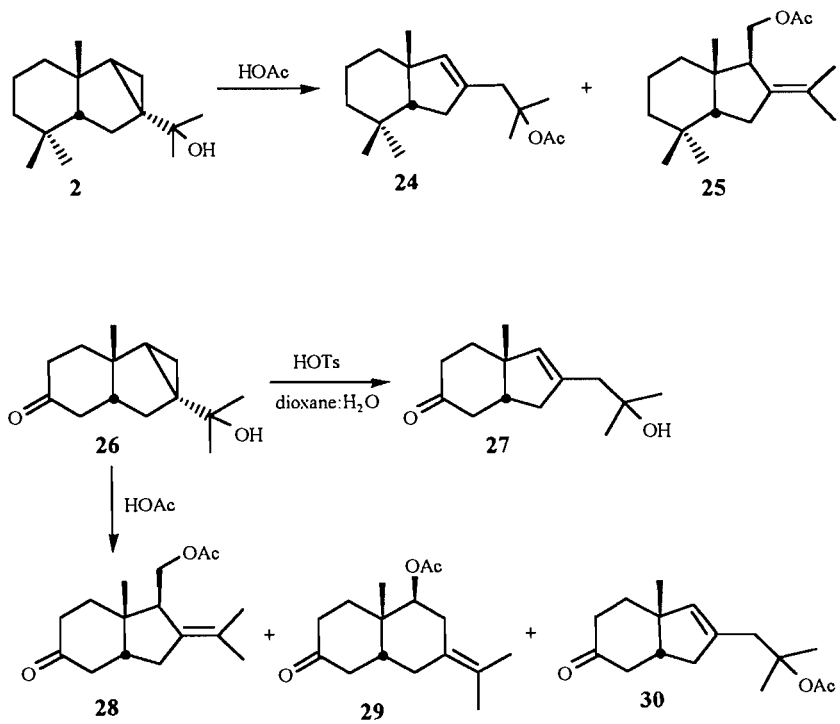
Acetic acid treatment of **2** at 85°C also produced the cyclopropylcarbinol rearrangement product **24** in 60% yield in addition to the *exo*-cleavage product **25** in 6% yield. The competition of *exo* cleavage in this case is likely, because **25** may only slowly convert to the cyclopropylcarbinyl-like cation (i) shown in Fig. 7 once it is formed. The *exo*-cleavage product **19** could not be isolated in the previous reaction. The ^{1}H NMR spectrum of **24** is similar to that of **18**, except that an additional three-proton signal at δ 1.97 ppm due to the acetyl group was noted. For the minor product **25**, a two-proton multiplet (octet) signal at δ 3.92–4.25 ppm, which has a splitting pattern characteristic of the A/B portion of an ABX

system, can be assigned to the methylene attached to the acetate group.

The rearrangement reaction is applicable to other thujone-derived cyclopropylcarbinols but rather specific conditions are required. For example, ketol **26** was converted into product **27** in 87% yield by employing a catalytic amount of *p*-toluenesulfonic acid in a dioxane:water (1:1) mixture. However, rather surprisingly, treatment of **26** with acetic acid gave mainly the *exo*-cleavage product **28** (56%) and the *endo*-cleavage product **29** (14%). Although a very minor peak at δ 5.17 ppm in the ^{1}H NMR spectrum of **28** indicated a possible presence of the rearrangement product **30**, the very minor amount prevented its isolation.

Summary

In summary, acid-promoted ring cleavage reactions of thujone-derived cyclopropylcarbinols proceed through three distinct pathways, including the *exo* cleavage, *endo* cleavage, and the novel cyclopropylcarbinyl rearrangement reaction. Both reaction conditions and substrate structures influence which pathway becomes dominant. The availability of these diverse cleavage patterns allows a more versatile utilization of such thujone-derived cyclopropylcarbinols as chiral synthetic intermediates in subsequent synthetic routes to various natural products and related compounds.



Experimental

Commercially available reagent grade solvents were used for chromatography without further purification. Unless otherwise stated, all reaction products were purified by "flash chromatography" using silica gel (230–400 mesh) supplied by E. Merck Co. with air pressure to obtain a suitable flow (10). Thujone was distilled from Western red cedar leaf oil, which was generously donated by Intrinsic Research and Development Incorporated.

Melting points were measured using a Kofler block melting point apparatus and are uncorrected. Optical rotations were recorded on a Perkin–Elmer 141 automatic polarimeter in chloroform solution using a quartz cell of 10 cm path length with the concentration (in g/100 mL) given in parentheses. The ultraviolet spectra were recorded on Cary 15 or Perkin–Elmer Lambda 4B UV/VIS spectrometers using quartz cells of 1 cm path length. The infrared spectra were recorded on Perkin–Elmer 710, 710B, and 1710 spectrometers in chloroform solution using NaCl cells of 0.1 mm path length or as thin film using NaCl plates. The ^{1}H NMR spectra were obtained from Bruker WH-400 or Varian XL-300 spectrometers with deuteriochloroform as solvent and the chemical shifts are reported in the delta (δ) scale in ppm relative to tetramethylsilane. The low- and high-resolution mass spectra were recorded on AEI-MS-9 and KRATOS-MS-50 spectrometers, respectively, using the electron impact ionization method while the chemical ionization mass spectra were recorded on a Delsi Nermag R10-1 OC spectrometer using ammonia as carrier gas. Elemental analyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

Chloride 3: the *exo* cleavage

Alcohol **2** (100 mg, 0.420 mmol) in methylene chloride (5.0 mL) was stirred with concentrated hydrochloric acid (5.0 mL) at room temperature for 30 min. Separation and concentration of the methylene layer gave the crude product, which was chromatographed with ethyl acetate:hexanes (1:8, v/v) to afford **3** as a colorless oil (92 mg, 85%).

The physical properties of **3** are as follows: $[\alpha]_D^{25}$ +33.5

(c = 1.00, $CHCl_3$). IR ν_{max} (film): 2910 (C-H stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.75–1.85 (22H, m, including 0.84 (3H, s), 1.04 (3H, s), 1.22 (3H, s), 1.63 (3H, s), and 1.70 (3H, s)), 2.04–2.55 (3H, m), 3.40–3.75 (2H, m). MS *m/z*: 256/254 (M^+, 4.8/14.8%), 241 (12.8%), 239 (37.6%), 203 (96.4%), 109 (100%). High-resolution mass measurement: calcd. for $C_{16}H_{27}{}^{37}Cl$: 256.1772; found: 256.1763; calcd. for $C_{16}H_{27}{}^{35}Cl$: 254.1801; found: 254.1801.

Chloroketone 6: the *exo* cleavage

Ketol **5** (78 mg, 0.33 mmol) in methylene chloride (5.0 mL) was stirred with concentrated hydrochloric acid (5.0 mL) at room temperture for 30 min. Water (20 mL) was added to quench the reaction. After methylene chloride extraction (2 × 10 mL), drying over magnesium sulfate, and evaporation of solvent in vacuo, the crude product was chromatographed with ethyl acetate:hexanes mixture (1:8, v/v) to afford the starting ketol **5** (15 mg, 19%) and chloride **6** (51 mg, 74%).

The physical properties of **6** are as follows: $[\alpha]_D^{25}$ +1.4 × 10^2 (c = 0.50, $CHCl_3$). IR ν_{max} (film): 1700, 1641 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.00 (3H d, J = 7.0 Hz), 1.05 (1H, m), 1.24 (1H, m), 1.44 (3H, s), 1.58–1.80 (7H, including 1.60 (3H, s) and 1.71 (3H, s)), 2.10 (6H, m), 3.45–3.65 (2H, m). MS *m/z*: 256/254 (M^+, 0.6%/2.2%), 239 (0.5%), 218 (34.6%), 203 (18.4%), 133 (85.0%), 41 (100%). High-resolution mass measurement: calcd. for $C_{15}H_{23}O^{35}Cl$: 254.1437; found: 254.1437; calcd. for $C_{15}H_{23}O^{37}Cl$: 256.1408; found: 256.1412.

Carvacrol (12) and chloroenone 13: the *endo* cleavage

Thujonol (**11**) (500 mg, 2.98 mmol) was treated with concentrated hydrochloric acid (25 mL) in methylene chloride (25 mL) at room temperature for 1.5 h. The methylene chloride solution was separated, dried over magnesium sulfate, and concentrated *in vacuo*. Column chromatography with ethyl acetate:hexanes (1:20, v/v) provide chloro-enone **13** (252 mg, 45%) and carvacrol (**12**) (177 mg, 40%).

The physical properties of **12** are as follows: IR (film) ν_{max}: 3400 (O-H stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.22 (6H, d, J = 6.6 Hz), 2.21 (3H, s), 2.82 (1H, septet, J = 6.6 Hz), 3.96 (1H, bs), 6.66 (1H, d, J = 1.8 Hz), 6.72 (1H, dd, J = 1.8 and 7.1), 7.04 (1H, d, J = 7.1 Hz). MS *m/z*: 150 (M^+, 35.5%), 135 (100%), 107 (15.6%). High-resolution mass measurement: calcd. for $C_{10}H_{14}O$: 150.1045; found: 150.1051.

The physical properties of **13** are as follows: IR (film) ν_{max} 1675 (C=O stretching), 1630 (C=C stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.09 (6H, d, J = 7.2 Hz), 1.30 (3H, d, J = 7.8 Hz), 2.43 (1H, septet, J = 7.2 Hz), 2.54 (1H, m), 2.78 (2H, m), 4.06 (1H, dt, J = 4.4 and 9.8 Hz), 5.95 (1H, bs) ppm. MS *m/z*: 188/186 (M^+, 5.8%/19.1%), 151 (100%), 135 (15.9%).

Carvacrol (12) and bromoenone 14: the *endo* cleavage

Thujonol (**11**) (600 mg, 3.57 mmol) in methylene chloride (25 mL) was stirred with concentrated (48%) hydrobromic acid (25 mL) for 1.5 h at room temperature. The organic layer was separated, dried over magnesium sulfate, and concentrated in vacuo. The crude product was purified by column chromatography using ethyl acetate:hexanes (1:15, v/v) mixture to provide bromoenone **14** (700 mg, 85%) and carvacrol (**12**) (51 mg, 10%).

The physical properties of **14** are as follows: $[\alpha]_D^{25}$ +42 (c = 0.29, $CHCl_3$). UV (MeOH, c = 20 mg/L) λ_{max}: 234 nm (log ε = 3.95). IR (film) ν_{max}: 1670 (C=O stretching), 1630 (C=C stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.11 (6H, d, J = 6.8 Hz), 1.34 (3H, d, J = 7.1 Hz), 2.43 (1H, septet, J = 6.8 Hz), 2.55 (1H, m), 4.19 (1H, dt, J = 4.4 and 10.2 Hz), 5.97 (1H, bs). MS *m/z*: 232/230 (M^+, 1.1%/1.3%), 151 (100%), 135 (33.6%), 123 (60.2%). High-resolution mass measurement: calcd. for $C_{10}H_{15}O^{81}Br$ and $C_{15}H_{15}O^{79}Br$: 232.0287 and 230.0130; found: 232.0280 and 230.0116.

Hydroxyenone 15: Robinson annulation

To 1-dimethylaminopentan-2-one iodomethane salt (2.84 g, 9.44 mmol) in ethanol (80 mL) was added the solution of ketol **11** (1.43 g, 8.51 mmol) in ethanol (20 mL). After potassium hydroxide (0.92 g, 80% pure, 13 mmol) was added, the mixture was refluxed under nitrogen for 3 h. Concentration of the reaction mixture in vacuo gave a yellow oil that was chromatographed using ethyl acetate:hexanes mixture (1:1, v/v) to provide compound **15** as a colorless oil (636 mg, 32%).

The physical properties of **15** are as follows: $[\alpha]_D^{25}$ +90.3 (c = 2.03, $CHCl_3$). UV (MeOH, c = 40.6 mg/L) λ_{max}: 248 nm (log ε = 4.04). IR (film) ν_{max}: 3200–3600 (O-H stretching), 1645 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 0.76 (1H, t, J = 4.7 Hz), 1.11 (3H, s), 1.20 (6H, s), 1.67 (3H, s) ppm. MS *m/z*: 234 (M^+, 1.2%), 216 (31.5%), 201 (48.0%), 173 (34.7%), 59 (100%). High-resolution mass measurement: calcd. for $C_{15}H_{22}O_2$: 234.1619; found: 234.1613.

Bromodienone 16: the *endo* cleavage

Hydroxy-enone **15** (39 mg, 0.17 mmol) in methylene chloride (5 mL) was stirred with concentrated (48%) hydrobromic acid (5 mL) at room temperature for 3 h. The methylene chloride layer was separated and the aqueous layer was extracted with methylene chloride (5 mL). The combined methylene chloride solution was dried over magnesium sulfate and concentrated in vacuo. Column chromatography of the crude product afforded bromo-dienone **16** (45 mg, 91%).

The physical properties of **16** are as follows: $[\alpha]_D^{25}$ +420 (c = 1.00, $CHCl_3$). UV (MeOH, c = 20 mg/L) λ_{max}: 293 nm (log ε = 4.40). IR (film) ν_{max}: 1660 (C=O stretching), 1620 (C=C stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.12 (6H, d, J = 6.0 Hz), 1.17 (3H, s), 1.86 (3H, s), 2.00–2.90 (7H, m), 4.14 (1H, dd, J = 6.0 and 10.0 Hz), 6.31 (1H, s). MS *m/z*: 298/296 (M^+, 80.0%/88.5%), 217 (100%), 175 (56.3%). High-resolution mass measurement: calcd. for $C_{15}H_{21}O^{79}Br$: 296.0775; found: 296.0768.

Alcohol 18: the cyclopropylcarbinyl rearrangement

To the solution of alcohol **2** (80 mg, 0.34 mmol) in a dioxane:water mixture solvent (4.00 mL, 1:1, v/v) was added *p*-toluenesulfonic acid hydrate (20 mg, 0.10 mmol, 0.30 equiv.). The mixture was heated at 85°C for 1 h and cooled to room temperature. Water (10 mL) was added and methylene chloride (2 × 10 mL) was used to extract the aqueous solution. The methylene solution was washed with brine (10 mL), dried over magnesium sulfate, and concentrated in vacuo. Column chromatography of the crude product with ethyl acetate:hexanes mixture (1:8, v/v) gave homoallylic alcohol **18** (70 mg, 87%).

The physical properties of **18** are as follows: $[\alpha]_D^{25}$ +45.2 (c = 1.00, $CHCl_3$). IR ν_{max} (film): 3100–3650 (OH stretching)

cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.88 (3H, s), 1.02 (3H, s), 1.07–1.70 (18H, m, including 1.18 (3H, s), 1.21 (3H, s) and 1.22 (3H, s)), 2.05–2.45 (4H, m), 5.33 (1H, bs). MS *m/z*: 236 (M^+, 0.1%), 218 (1.6%), 203 (5.0%), 178 (7.1%), 163 (100%), 135 (21.1%). High-resolution mass measurement: calcd. for $C_{16}H_{28}O$: 236.2140; found: 236.2145.

Epoxyalcohol 21: epoxidation

To a solution of alcohol **18** (172 mg, 0.729 mmol) in chloroform (5.0 mL) was added *m*-CPBA (243 mg, 80% pure, 11 mmol, 1.5 equiv.). The mixture was stirred at room temperature for 1 h. After addition of methylene chloride (5.0 mL) and washing with sodium bicarbonate solution (10 mL, 10%), the mixture was dried over magnesium sulfate and concentrated in vacuo. Column chromatography of the crude product with ethyl acetate:hexanes mixture (2:8, v/v) gave epoxide **21** (159 mg, 87%).

The physical properties of **21** are as follows: mp: 82–84°C. $[\alpha]_D^{25}$ +56.7 (*c* = 1.00, $CHCl_3$). IR ν_{max} (film): 3700 (O-H stretching) cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.70–1.70 (24H, m, including 0.80 (3H, s), 0.98 (3H, s), 1.20 (3H, s), 1.24 (3H, s) and 1.31 (3H, s)), 1.75–2.02 (2H, m), 2.04–2.15 (1H, dd, *J* = 7.2 and 13.6 Hz), 2.85 (1H, s). MS *m/z*: 252 (M^+, 0.2%), 234 (4.1%), 219 (6.9%), 194 (17.9%), 179 (19.8%), 161 (19.3%), 123 (100%), 109 (90.4%). High-resolution mass measurement: calcd. for $C_{16}H_{28}O_2$: 252.2089; found: 252.2088. Anal. calcd. for $C_{16}H_{28}O_2$: C 76.14, H 11.18; found: C 76.14, H 1.05.

Allylic alcohol 22: reductive fragmentation by LAH

Epoxide **21** (30.3 mg, 0.583 mmol) in anhydrous THF (1.0 mL) was added in a dropwise manner to a slurry of LAH (18.4 mg) in THF (1.0 mL) under nitrogen. The mixture was then heated at about 70°C (bath temperature) for 2 h. After cooling to room temperature, ethanol (5.0 mL) was added and stirring continued for 10 min. Subsequently, water (15 mL) was added and the resulting mixture was extracted with ethyl acetate (2 × 10 mL). The ethyl acetate solution was dried over magnesium sulfate and concentrated in vacuo. Column chromatography of the crude product with ethyl acetate:hexanes mixture (1:8, v/v) gave allylic alcohol **22** (20 mg, 87%).

The physical properties of **22** are as follows: $[\alpha]_D^{25}$ +5.4 (*c* = 1.00, $CHCl_3$). IR ν_{max} (film): 3100–3650 (O-H stretching), 3060 (C-H stretching, olefinic), 1650 (C=C stretching) cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.82 (3H, s), 1.02 (3H, s), 1.05–1.72 (13H, m, including 1.14 (3H, s)), 1.78 (1H, t, *J* = 8.8), 2.20–2.60 (2H, m). MS *m/z*: 194 (M^+, 13.1%), 179 (21.6%), 161 (13.0%), 123 (100%), 109 (85.5%). High-resolution mass measurement: calcd. for $C_{13}H_{22}O$: 194.1670; found: 194.1661.

Enone 23: allylic oxidation by MnO_2

Allylic alcohol **22** (29 mg, 0.15 mmol) in methylene chloride (2.0 mL) was treated with manganese dioxide (65 mg, 0.75 mmol). The slurry was stirred at room temperature for 72 h. After filtering the slurry and washing with methylene chloride (10 mL), the methylene chloride solution was concentrated in vacuo. Column chromatography of the crude product gave enone **23** (8.0 mg, 67% based on recovery) and starting allylic alcohol **22** (17 mg, 59% recovery).

The physical properties of **23** are as follows: $[\alpha]_D^{25}$ +57 (*c* = 0.58, $CHCl_3$). UV (MeOH), *c* = 23 mg/L) λ_{max}: 235 nm (log ε = 4.0), 278 (log ε = 2.5). IR ν_{max} (film): 1710 (C=O stretching), 1635 (C=C stretching) cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.75–1.70 (16H, m, including 0.85 (3H, s), 1.07 (3H, s), and 1.22 (3H, s)), 2.35–2.65 (2H, m), 5.37 (3H, bs), 6.07 (3H, bs). MS *m/z*: 192 (M^+, 49.9%), 177 (20.3%), 149 (28.9%), 123 (80.7%), 68 (100%). High-resolution mass measurement: calcd. for $C_{13}H_{20}O$: 192.1514; found: 192.1515.

Acetates 24 and 25: the cyclopropylcarbinyl rearrangement

A solution of alcohol **2** (60 mg, 0.26 mmol) in acetic acid (2.5 mL) was heated at 65°C for 2 h. After cooling to room temperature, methylene chloride (10 mL) was added and the mixture was extracted with 10% sodium bicarbonate solution (10 mL). The methylene chloride solution was dried over magnesium sulfate and concentrated in vacuo. Column chromatography of the crude product with ethyl acetate:hexanes mixture (1:25, v/v) yielded acetate **24** (41 mg, 60% based on recovery), acetate **25** (4.0 mg, 6% based on recovery), and the starting alcohol **2** (2.9 mg, 5%).

The physical properties of **24** are as follows: $[\alpha]_D^{25}$ +41.7 (*c* = 1.00, $CHCl_3$). IR ν_{max} (film): 1735 (C=O stretching), 1650 (C=C stretching) cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.85 (3H, s), 1.00 (3H, s), 1.03–1.60 (16H, including 1.15 (3H, s), 1.38 (3H, s), and 1.45 (3H, s)), 1.97 (3H, s), 2.02–2.35 (2H, m), 2.39–2.62 (2H, AB type, *J* = 7.2 Hz), 5.26 (1H, s). MS *m/z*: 218 (M−HOAc, 37.0%), 203 (100%), 175 (16.7%), 147 (21.5%). High-resolution mass measurement: calcd. for $C_{16}H_{26}$ ($C_{18}H_{30}O_2$ − HOAc): 218.2034; found: 218.2030. Chemical ionization (NH_3 as carrier gas): 279 ($M + H^+$), 219, 203.

The physical properties of **25** are as follows: $[\alpha]_D^{25}$ +63 (*c* = 0.20, $CHCl_3$). IR ν_{max} (film): 1730 (C=O stretching) cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.75–1.80 (22H, m, including 0.85 (3H, s), 1.03 (3H, s), 1.14 (3H, s), 1.61 (3H, s) and 1.69 (3H, s)), 2.01 (3H, s), 2.10–2.32 (2H, m), 2.39 (1H, t, *J* = 5.6 Hz). MS *m/z*: 278 (M^+, 0.3%), 218 (26.0%), 203 (100%). High-resolution mass measurement: calcd. for $C_{18}H_{30}O_2$: 278.2246; found: 278.2248.

Ketol 27: the cyclopropylcarbinyl rearrangement

To the solution of ketol **26** (82 mg, 0.37 mmol) in a dioxane:water mixture solvent (4.00 mL, 1:1, v/v) was added *p*-toluenesulfonic acid hydrate (22 mg, 0.11 mmol, 0.30 equiv.). The mixture was heated at 85°C for 3.8 h. After cooling to room temperature, the mixture was diluted with water (10 mL) and extracted with methylene chloride (2 × 10.0 mL). The methylene solution was extracted with brine (10 mL), dried over magnesium sulfate, and concentrated in vacuo. Column chromatography of the crude mixture with ethyl acetate:hexanes mixture (2:17, v/v) gave product **27** (72 mg, 87%).

The physical properties of **27** are as follows: $[\alpha]_D^{25}$ + 111 (*c* = 1.00, $CHCl_3$). IR ν_{max} (film): 3050–3650 (O-H stretching), 1700 (C=O stretching), 1650 (C=C stretching) cm^{-1}. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.10–1.90 (13H, m, including 1.20 (3H, s) and 1.23 (6H, two singlets)), 1.95–2.60 (7H, m), 2.75 (1H, dd, *J* = 8.8 and 17 Hz), 5.20 (1H, bs). MS *m/z*: 222 (M^+, 2.8%), 204 (13.6%), 189 (10%), 147 (100%), 133 (34.6%), 106 (47.4%). High-resolution mass measurement: calcd. for $C_{14}H_{22}O_2$: 222.1620; found: 222.1618.

Keto-acetates 28 and 29

A solution of alcohol **26** (65.2 mg, 0.294 mmol) in acetic acid (2.5 mL) was heated at 85°C for 2 h. After cooling to room temperature, methylene chloride (10 mL) was added and the mixture was extracted with 10% sodium bicarbonate solution (10 mL). The methylene chloride solution was dried over magnesium sulfate and concentrated in vacuo. Column chromatography of the crude product with hexanes:ethyl acetate (1:8, v/v) yielded acetate **27** (44 mg, 56%) and acetate **28** (11 mg, 14%).

The physical properties of **28** are as follows: $[\alpha]_D^{25}$ + 63.0 (c = 1.00, $CHCl_3$). IR $\nu_{max.}$ (film): 1735 (C=O stretching of the acetate group), 1705 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.28 (3H, s), 1.50–1.85 (8H, m, including 1.59 (3H, s) and 1.70 (3H, s)), 1.92 (1H, m), 2.06 (3H, s), 2.10–2.60 (7H, m), 3.95–4.20 (2H, m). MS *m/z*: 264 (M^+, 0.1%), 204 (23.6%), 189 (13.2%), 147 (100%), 134 (85.1%), 119 (44.4%). High-resolution mass measurement: calcd. for $C_{16}H_{24}O_3$: 264.1725; found: 264.1720.

The physical properties of **29** are as follows: $[\alpha]_D^{25}$ = + 30 (c = 0.66, $CHCl_3$). IR $\nu_{max.}$ (film): 1710 (C=O stretching) cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.17 (3H, s), 1.40–1.80 (8H, m, including 1.65 (3H, s), and 1.72 (3H, s)), 1.90–2.80 (12H, m, including 2.10 (3H, s)), 5.19 (1H, dd, J = 4.2 and 10.2 Hz). MS *m/z*: 204 (M − HOAc, 43.5%), 189 (19.2%), 147 (91.9%), 133 (100%), 119 (54.4%), 105 (51.2%). High-resolution mass measurement calcd. for $C_{14}H_{20}O$ (M − HOAc): 204.1514; found: 204.1508. Chemical ionization (NH_3): 282 ($M + NH_4^+$), 265 ($M + H^+$), 222 ($M - HOAc + NH_4^+$), 205 ($M - HOAc + H^+$).

COMMUNICATION

Novel, air-stable, lanthanide catalysts for the hetero Diels–Alder reaction

Claude Spino, Laurel Clouston, and David Berg

Abstract: Novel, air-stable, yttrium and ytterbium complexes were found effective in the catalysis of the typical hetero Diels–Alder reaction of crotonaldehyde and ethylvinyl ether. They represent an attractive solution to the problem of ligand lability in the realm of lanthanide catalysts.

Key words: lanthanide, catalyst, hetero Diels–Alder, yttrium, ytterbium.

Résumé : Deux nouveaux complexes d'yttrium et d'ytterbium, stable à l'air, se sont avérés très efficace comme catalyseurs d'une réaction typique de Diels–Alder hétéro impliquant la crotonaldéhyde et l'éther d'éthylevinyle. Ils représentent une solution attrayante au problème chronique de la labilité des ligands chez les catalyseurs de lanthanide.

Mots clés : lanthanide, catalyseur, Diels–Alder hétéro, yttrium, ytterbium.

Lanthanides are increasingly used in organic synthesis as mild reagents and catalysts that can spare many sensitive functional groups (1 and, for reviews, 2). Catalytic systems based on lanthanide metals have been found for many organic reactions, including the Friedel–Crafts reaction, acetal and ether formation, reduction and oxidation, and the Diels–Alder cycloaddition or, more particularly, the hetero Diels–Alder reaction involving an oxygen on the dienophile or diene (1, 3). Complex and sensitive molecules give high yields of products with few side reactions, testimony to the mildness of these catalysts (1–3). Asymmetric versions of the latter type of Diels–Alder reactions have been limited to only a few isolated examples (4–6) with little success in the cycloaddition of vinyl ethers to α,β-unsaturated aldehydes (3). All of the lanthanide complexes tried as catalysts were in fact either NMR shift reagents or commercially available complexes designed for other uses (1–3). Part of the obstacle to achieving high asymmetric induction with lanthanide catalysts can be attributed to the lability of the ligands around the metal. In reality, this lability confers a degree of uncertainty about the actual structure of the active catalyst. In addition, it may impair induction because of ligand displacement during catalysis.

We felt that a necessary step in designing efficient lanthanide catalysts for that reaction was to find suitable ligands with low lability and to make complexes of a well-defined structure. Only then could we rationally design chiral complexes with the hope of increasing the enantioselectivities so far achieved with lanthanide systems. We describe herein our success in synthesizing two novel, air-stable, and effective yttrium and ytterbium complexes that show low ligand lability and are efficient catalysts for the hetero Diels–Alder reaction. To the best of our knowledge, these are the first examples of well-defined hexadentate[2] ligand–metal complexes of a lanthanide or yttrium that are effective catalysts.[3] Their stability in air is a good indicator of low ligand lability and we believe they are strong forerunners of chiral complexes.

The rationale for using tripodal ligands was to contribute extra stability to the complex, in effect "locking" the ligand in place.[4] Well-defined monomeric tripodal structures would thus provide a solid base from which to design and develop highly effective chiral catalysts. Starting from the observation that lanthanide complexes derived from trifluoromethyl-β-diketone-type ligands are effective catalysts for the hetero Diels–Alder reaction (1, 2, 8), we initially believed that derivatives such as ligand **2** would be well suited for our purpose, being tripodal in nature, easily prepared, and easily altered for the eventuality of chiral design. Ligand **2** was prepared in 80% purified yield by refluxing 1,1,1-trifluoroacetoacetate in a benzene solution of tris(aminoethyl)amine **1** with concurrent

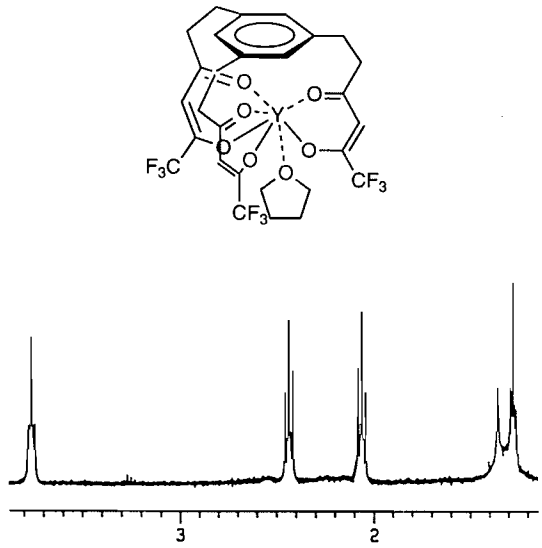
removal of water (Scheme 1). The metal complex **3** was prepared by mixing the ligand with a solution of yttrium tris(bistrimethylsilyl)amide (9) in tetrahydrofuran. It was characterized by single-crystal X-ray diffraction.

We were surprised to find that this complex showed no catalytic behaviour toward the cycloaddition reaction of crotonaldehyde and ethylvinyl ether (see Table 1). Several factors could be responsible for this lack of activity and we suspected that either the imine nitrogen or the coordinating amine nitrogen could electronically saturate the metal and thereby lower its Lewis acidity. Nevertheless, we reasoned that the needed ligand should possess the unaltered trifluoromethyl-β-diketone functionality. Such units could be linked by the end methyl group via a number of linkers, thereby leaving the β-diketone unit intact. 1,3,5-Tribromomesitylene **5** caught our attention as being a useful linker because of its relative ease of preparation and high reactivity toward alkylation.

We looked at several ligands before ultimately settling for the tribenzyltrifluoroacetoacetate ligand **6** (Scheme 2). Ligand **6** was thus prepared starting from 1,3,5-benzenetricarboxylic acid **4**. The aluminium salts resulting from the reduction of **4** with LAH are directly treated with aqueous hydrobromic acid to give an 80% yield of **5**.

The dianion of 1,1,1-trifluoroacetylacetone was generated using slight modifications of a standard procedure (10). Though its reactivity was lower than that of non-fluorinated β-diketones, effective alkylation in THF at room temperature

Fig. 1. Partial NMR spectrum of yttrium complex **7***a* showing a coordinated THF molecule.



with tribromomesitylene **5** could be achieved. The tripodal ligand **6** was thus obtained in 40% yield after recrystallization and sublimation at 140°C / 10^{-2} Torr (1 Torr = 133.3 Pa).

The metal complexes **7***a* (M = Y) and **7***b* (M = Yb) were prepared by mixing the ligand with a solution of yttrium or ytterbium tris(bistrimethylsilyl)amide in toluene (9). In each case, an instantaneous reaction occurred with concomitant precipitation of the complex, which was washed several times with toluene. Unfortunately, we could not grow crystals of adequate quality to perform a single-crystal X-ray crystallographic analysis on either of the complexes and neither were soluble in non-coordinating solvents. To secure the structure of the yttrium complex **7***a*, we prepared it in THF and isolated the powdery material by simple reduced pressure evaporation of the solvent. Although no X-ray quality crystals could be grown, the proton NMR analysis of the complex in benzene-d_6 was unequivocal and established the coordination of a molecule of THF (Fig. 1). Mass spectral data, Exact Mass measurement, and elemental analysis on this compound were satisfactory. The structure of the ytterbium complex **7***b* was inferred only from mass spectral data and by analogy to **7***a*.

Catalytic activities were tested on the hetero Diels–Alder cycloaddition of crotonaldehyde and ethylvinyl ether, the latter serving as solvent, with 2 mol% of catalyst (Table 1). In each example involving lanthanide or yttrium catalysts, with the exception of **3**, the isolated yields of the respective dihydropyran product **10** were excellent, testimony to their mildness (entries 2–4). In contrast, zinc chloride and BF_3-etherate gave 46 and 12% isolated yield, respectively, of **10** (entries 5 and 6). The thermal reaction proceeds at 175°C to give product **10** in 87% yield (8). The same reaction can also be carried out under high-pressure conditions (15 kbar (1 bar = 100 kPa), 75°C, 24 h) to give 89% of the *endo* adduct (11).

Each reaction was monitored by gas chromatography at specific time intervals. The yttrium catalyst **7***a* was superior to all others, including the commonly used $Yb(fod)_3$ (12), having the fastest conversion rate and giving a good isolated yield of **10** (entry 2). As expected, the product isolated was regiochemically and diastereomerically pure (racemic) and was derived from the *endo* approach of the dienophile as verified by proton NMR (12*a*). If dioxane was utilized as an internal standard for quantitative work, the reaction rate between **8** and **9** dropped (entries 7 and 8), indicating a competition for the active site between the coordinating solvent and crotonaldehyde **8**. We found that when the complexes **7** were prepared in or came in contact with coordinating solvents, the reaction rate dropped also, presumably due to the incorporation of a coordinating solvent molecule. In turn, this coordinating solvent molecule may compete with crotonaldehyde for the active site or simply reduce the Lewis acidity of the complex. More importantly, both catalysts **7** remained active even after several days of exposure to the ambient air (entries 9 and 10), even though the complexes may have picked up water molecules from exposure to air. A 3-month-old sample of complex **7***a* stored in an opened vial still retained complete catalytic activity. In contrast, all other catalysts including $Yb(fod)_3$ had to be kept in a rigorously dry atmosphere to remain active (entry 11). The air and moisture stability of these complexes is undoubtedly linked to the low pK_a coupled with the tripodal nature of the ligand **6**.

In conclusion, we have prepared the first lanthanide complexes that possess a tripodal ligand and are active catalysts. Their high stability, even in air, is not only desirable in terms of handling but is also very promising as a base from which to develop chiral catalysts showing high asymmetric induction.

1995 Fisher Scientific Award Lecture Reflections of an atmospheric chemist wondering why he won an analytical chemistry award[1]

H.I. Schiff

Abstract: The author recalls his scientific career starting with electrochemistry and gas phase kinetics and leading, largely by serendipity, to atmospheric chemistry and measurements in the atmosphere using rockets and stratospheric balloons. The scientific problems met along the way required measurements with instruments that were not commercially available and required development of new methods and techniques. These included mass spectrometry, chemiluminescence, and tunable Diode Laser Absorption Spectrometry (TDLAS) to measure trace concentrations of gases in the lower and upper atmosphere. TDLAS is considered to be the method of choice where freedom from interferences, high sensitivity, and fast time response are required. Lead salt laser diodes operate in the near infrared where most molecules of atmospheric interest have strong fundamental absorptions. The research groups at York University and at Unisearch Associates have been pioneers in applying this powerful technique to atmospheric measurements in a variety of environments including the pristine air over the Pacific, at the top of Mauna Loa, at the Grand Canyon, and the polluted air of Los Angeles and other major cities. The results of recent measurements of the emissions of two strong greenhouse gases, CF_4 and C_2F_6, from Quebec aluminium refineries are described. More recently a family of instruments based on near-infrared laser diodes have been developed that can make remote-sensing measurements of a number of pollutants in ambient air and industrial stacks. Examples of passive, on-road, remote-sensing measurements of automobile exhaust emissions of CO and CO_2 and of in-stack emissions of HF are presented. Another remote-sensing instrument that has been developed is an improved visible and UV Differential Optical Absorption Spectrometer (DOAS) capable of measuring, remotely and simultaneously, a number of important pollutants. Examples of measurements of NO, NO_2, O_3, benzene, and toluene are presented.

Key words: air measurements, instruments, remote sensing.

Résumé : L'auteur fait un historique de sa carrière scientifique en partant de l'électrochimie et de la cinétique en phase gazeuse conduisant, en grande partie par un heureux hasard, à la chimie atmosphérique et aux mesures dans l'atmosphère à l'aide de fusées et de ballons lancés dans la stratosphère. Les problèmes scientifiques rencontrés exigeaient des mesures à l'aide d'instruments non disponibles commercialement et requéraient de nouvelles méthodes et de nouvelles techniques. Celles-ci comprennent la spectrométrie de masse, la chimiluminescence et la spectrométrie d'absorption au laser à diode adjustable (SALDA) pour mesurer les très faibles concentrations des gaz présents dans la basse et la haute atmosphère. La SALDA est considéré comme étant une méthode de choix lorsqu'une réponse rapide sans interférence et de grande sensibilité est requise. Les lasers à diodes aux sels de plomb opèrent dans le proche infra-rouge, là où les molécules d'un intérêt atmosphérique ont de fortes absorptions fondamentales. Les groupes de recherche de l'université York et de l'Unisearch Associates ont été les pionniers dans l'application de cette puissante technique aux mesures atmosphériques de divers écosystèmes incluant l'air du Pacifique, non pollué par la civilisation, le sommet du Mauna Loa, le Grand Canyon et l'air pollué de Los Angeles et des grandes villes. On décrit les résultats de mesures récentes des émissions de deux gaz à effet de serre, CF_4 et C_2F_6, produites par les raffineries d'aluminium du Québec. Plus récemment on a mis au point une famille d'instruments basés sur les lasers à diodes opérant dans le proche infra-rouge et qui permettent de mesurer à distance un grand nombre de polluants dans l'air ambiant et dans les cheminées industrielles. On présente des examples de télémesures passives, sur la route, des gaz d'émission des voitures, CO et CO_2, et des émissions de HF à l'intérieur des cheminées. Un autre instrument de télémesure mis au point, est un spectromètre d'absorption optique différentielle (SAOD) opérant dans le visible et dans l'UV et capable de mesurer à distance et simultanément, un nombre important de polluants. On présente des exemples de mesure du NO, du NO_2, du O_3, du benzène et du toluène.

Mots clés : mesures de l'air, instruments télémesure.

Being named the Fisher Scientific Award Lecturer in analytical chemistry came as quite a surprise. Although my scientific career has taken a number of paths since I was awarded a Ph.D. in electrochemistry, many years ago, none of them bore the signpost "Analytical Chemistry." So receiving this award has made me reflect on how this unlikely event could have occurred.

It probably began when Gerhard Herzberg visited my laboratory in 1950 while I was a post-doctorate fellow at NRC with Dr. E.W.R. Steacie. I had been working on the gas phase kinetics of hydrogen atoms, which I made by passing hydrogen gas through an electric discharge. When Herzberg asked me to flow nitrogen through the apparatus I was amazed to find the entire apparatus filled with a bright yellow glow. He told me I was looking at "active nitrogen," which had been discovered around the turn of the century by Lord Rayleigh. Some 2000 papers had been written about active nitrogen but no one had been able to identify the chemically reactive species. N_3, which Kistiakowsky, an eminent Harvard kineticist and one of the pioneers of the atom bomb, had called *nozone*, was one popular suggestion.

A mass spectrometer seemed to me to be a likely analytical method for identifying the reactive species. Commercial mass spectrometers were not available in the 1950s so when I got my first academic appointment at McGill I built a mass spectrometer with help from Fred Lossing of NRC. The chemically reactive species turned out to be atomic nitrogen (1) and the glow was a result of the chemiluminescent reaction:

$$N + N \rightarrow N_2^* \rightarrow N_2 + h\nu$$

Since this was the only mass spectrometer in Quebec I supplemented my meagre assistant professor's salary by analyzing samples for a number of pharmaceutical and chemical companies in the Montreal area.

My research group went on to investigate the chemical kinetics of nitrogen atoms, oxygen atoms, and ozone. The next surprise came when the US Air Force offered to support my research, which I could not imagine would be of any interest to them. It turned out that the Russians had just launched "Sputnik" and the space race was on. This was before NASA had been established, and the three US military services were vying with one another to launch the first USA object into space. One question being asked was what sort of environment that object would encounter. The speculation was that a great deal of the oxygen and nitrogen might be present in the dissociated, atomic state but nobody really knew how these species might react with their hardware. The only research on the reactions of these atomic gases was that of an unknown assistant professor at a Canadian university who had been publishing papers on these reactions. So I suddenly found I was an atmospheric chemist.

One of the reactions we studied was that of O atoms with NO (2, 3), which was also accompanied by chemiluminescence.

$$O + NO \rightarrow NO_2^* \rightarrow NO_2 + h\nu$$

But this time the glow is greenish. The intensity of the light is first order in the concentrations of both O and NO and so, if you know the concentration of NO, you can use the intensity of the glow to determine the concentration of O atoms. We performed the first chemical titration of the upper atmosphere by releasing 25 kg of NO from a rocket at a height of 90 km over the desert at White Sands, New Mexico, and produced a green glow in the night sky about 2 km in diameter. It was bright enough to frighten the natives and produce headlines, of numerous sightings of UFOs, in the papers the next day. This experiment not only provided the first direct evidence for the presence of O atoms in the upper atmosphere but also gave an estimate of their concentration.

A related reaction that we studied (4) was between NO and O_3, which also produces a glow, this time in the red part of the spectrum:

$$O_3 + NO \rightarrow O_2 + NO_2^* \rightarrow NO_2 + h\nu$$

The intensity of the glow was also found to be first order in the concentration of both reactants. We used this property in the laboratory to measure the concentrations of either NO or O_3 by adding an excess of the other reagent and monitoring the light intensity. I was, however, not smart enough to recognize the commercial possibilities of this finding, but Arthur Fontijn, who had been working on this project as a post-doctorate fellow, was, as is usually the case, smarter than his research director. When he went to Aerochem in New Jersey he developed a commercial instrument for measuring NO based on this reaction that has since become the standard method around the world for measuring this important atmospheric pollutant. Arthur won the American Chemical Society award some 15 years ago for this development.

In 1972 the US government appointed me to a panel of 20 so-called experts to advise them on the environmental impacts of a fleet of supersonic aircraft (SSTs), designed to fly in the stratosphere. The chemists on the panel concentrated on the effects of water vapour from the contrails of these aircraft. But Harold Johnston, a prominent kineticist at the University of California, Berkeley, chastised the rest of us for failing to recognize that NO from the exhausts, rather than H_2O, constituted the major threat to the ozone layer. I was particularly guilty for this oversight because I had been studying these reactions in the laboratory. When I pointed out that no one knew how much NO was naturally present in the atmosphere, Johnston maintained that this did not matter. I had difficulty in understanding that there would be any major effects if the natural atmosphere contained hundreds of times as much NO as the SSTs would add. So I returned from this meeting determined that we had to measure the natural amount of NO in the stratosphere.

The commercial instruments based on the chemiluminescence of NO with O_3 were simply not sensitive enough for such measurements and so Brain Ridley, working with me as a post-doctorate fellow, designed and built a highly sensitive version of this instrument (5, 6). With funding from the US government we flew this instrument on a balloon in 1974 and made the first measurement of NO in the stratosphere (5, 6) over the altitude range of 20–40 km. It turned out that the mixing ratio of NO in the stratosphere was indeed very low and the proposed fleet of SSTs, according to our understanding of atmospheric chemistry at that time, did, indeed, pose a threat to the ozone layer.

Of course the fleet of SSTs never materialized, aside from

the few Concordes made by the French and English, and attention switched to chlorofluorocarbons (CFCs), used primarily as propellants in spray cans and as refrigerants, as the major threat to the ozone layer. I had the privilege of chairing the US Academy of Science Panel that reported on this threat (7) and led to the banning of nonessential uses of these chemicals in the USA and Canada.

Our laboratory now extended into the earth's atmosphere and we were looking for better and more universal methods for measuring trace species in the atmosphere. A promising new technique involved the use of tunable diode laser spectroscopy (TDLAS). Tunable diode lasers are small crystals, about 1 mm^2 in area, made of Pb containing small amounts of Group 4 elements such as Se S, Te, Sn. When a current is passed through these crystals at temperatures below 170 K they emit laser radiation in the mid-infrared region between about 3 and 20 μm. Changing the current through these diodes changes the wavelength of the radiation, permitting scanning the spectrum of the absorbing molecule over individual rotational–vibrational lines.

This technique had been used for laboratory high-resolution spectroscopic studies but had not previously been applied to atmospheric measurements although some laboratory work performed at McMaster University had shown its potential for air measurements. Since most molecules of atmospheric interest have strong, fundamental absorption in the 3–20 μm spectral region, it provides a universal method for measuring atmospheric gases. The high spectral resolution provides unequivocal identification of the selected gas free of interferences from other gases. The technique is also capable of making measurements in less than a second with sensitivities in the sub parts per billion concentration levels.

Our first successful use of this method was to make measurements of nitrogen oxides in the stratosphere with a TDLAS instrument carried on a balloon that flew to 35 km above the earth's surface. It then became apparent that this technique had applications for air measurements at ground level and might be of some commercial interest. So in 1980 we started a spin-off R&D company, called Unisearch Associates, and I suddenly found myself in the business world. My atmospheric interests had descended from the upper atmosphere through the stratosphere and troposphere to ground level and now, some of my academic colleagues would maintain, to the nether regions of crass commercialization.

Unisearch received its first contract from the Coordinating Research Council, a funding agency jointly sponsored by the three US auto manufacturers and five major oil companies. With their support we built a TDLAS system (8) and used it to measure a number of pollutants in the Los Angeles area. We were pioneers in the application of TDLAS to atmospheric measurements. Unisearch has sold TDLAS instruments to the Planck and the Fraunhoffer Institutes, to NASA, AES, OME, and the British Meteorological Service as well as a number of universities. We have also used our instruments to make measurements of pristine air over the Pacific from NASA aircraft (9–11) as well as from our mobile laboratory on the top of Mauna Loa, Hawaii, at the Grand Canyon, and in the polluted air of downtown Los Angeles (12).

One example of the use of the mid-infrared TDLAS system was a series of measurements of the emissions of CF_4 and C_2F_6 from aluminium smelting (13). These two perfluorocarbons are potent greenhouse gases, thousands of times stronger than CO_2. But, since the mixing ratios of these gases in the atmosphere are only about 80 pptv for CF_4 and 2–4 pptv for C_2F_6, they were not formerly believed to contribute significantly to global warming until it was recognized that there are no known removal processes for these compounds from the atmosphere. Their atmospheric lifetimes have been estimated to be at least 10 000 years and, as has happened in other cases such as nuclear waste disposal, there is a disproportionate concern about putting potentially harmful substances into the environment that will remain there for thousands of years.

The main source of CF_4 and C_2F_6 in the atmosphere appears to be the aluminium industry. Aluminium is produced by the reduction of alumina, Al_2O_3, in electrolytic cells. The alumina is dissolved in a mixture of molten cryolite (Na_3AlF_6) and AlF_3. Both anodes and cathodes are carbon. Normally, oxygen is released at the anode where it forms CO and CO_2. Periodically, however, when the concentration of alumina in the cell drops below a certain level, the voltage of the cell rises and fluoride ions are also discharged at the anode to form the perfluorocarbons, which are emitted in a sort of a burp, known as an anode event, that lasts anywhere from about 2 to 20 min. The amount of gas emitted depends both on the frequency and the duration of these anode effects.

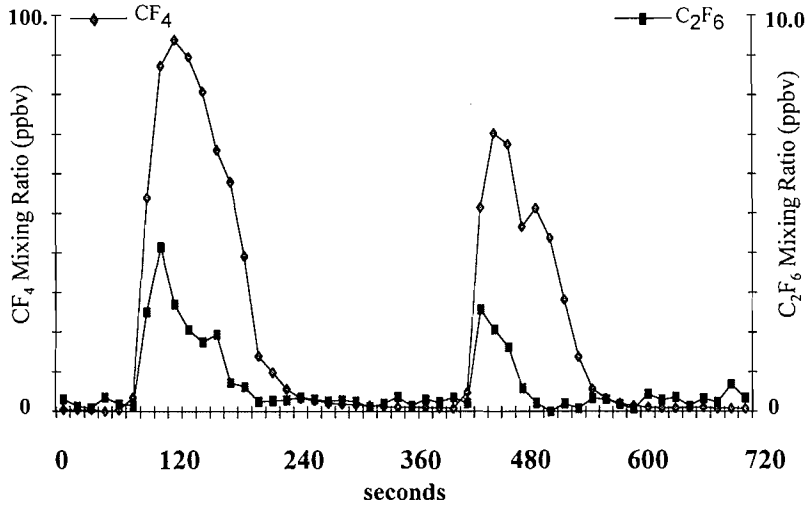
Determination of the contribution of the PFCs to global warming requires a knowledge of current emissions from aluminium production. Such data were largely lacking in the early 1990s, and in 1992 l'Association de l'Industrie de l'Aluminium de Québec commissioned Unisearch Associates to make measurements of emissions from eight smelter sites in Québec. The TDLAS was the instrument of choice since it allowed unequivocal measurements of the two gases in the presence of a very complex mixture with high precision and time resolution.

Figure 1 gives one example of the measurements (13) during several anode events. A large data base was accumulated with approximately 700 h of measurements and more than 200 000 individual observations.

When the emissions from each of the measured sites were combined with the respective production figures for each of the sites, an estimate could be made of the total annual emissions of these gases from Canadian aluminium production. We were also able to estimate that the contribution of these emissions to global warming from Canadian sources amounts to approximately 0.4% compared to the total contribution of other greenhouse gases.

Recently two new families of remote-sensing instruments have been developed by Unisearch. Most instruments that are currently being used to measure air quality are point-source monitors that sniff the air at a sampling point. Monitoring the emissions from stacks also uses these point-source instruments to sample the emissions by sucking out aliquots of the stack gases in a rather cumbersome extraction process. Remote-sensing instruments using optical techniques are rapidly gaining popularity over these point-source monitors for air quality networks, for area monitoring from landfills to entire cities, and for perimeter monitoring around industrial sites. For stack monitors, optical techniques are continuous, relatively simple, and can be readily adopted to process control functions. Remote-sensing monitors can also be used for passive, on-road monitoring of automobile exhausts.

Fig. 1. The measurements of CF_4 and C_2F_6 emissions from an aluminium smelter showing two "anode events."



We have developed a remote-sensing system based on tunable diode lasers (14, 15) but of the type used for the fibre optics communication industry and in domestic products such as CD players and laser printers. These laser diodes are based on Group V elements such as GA, As, and P, which emit radiation in the near-infrared (NIR) region between 0.59 and 2.5 μm. Unlike the Pb salt diodes they operate at ambient temperatures that can be controlled by small thermoelectric coolers. Moreover, they are of sufficiently high quality that high-frequency modulation techniques, which can be built with "off-the-shelf" television components, can be used. These features can be exploited to reduce both the size and cost of the instrument and to increase its sensitivity. The response of the system for most gases is in the range of a few parts per million per meter, which is more than adequate for most industrial applications. Another advantage of operating in the near-infrared is that pressure broadening does not present as large a problem as it does at the longer wavelengths, which makes it suitable for remote sensing at atmospheric pressure. Some of the gases that absorb in this spectral region include HF, HCl, CH_4, H_2S, CO, CO_2, CO, NH_3, C_2H_2, C_2H_4, and NO_2.

Three versions of the instrument have been developed — the LASAIR-R for remote sensing, the LASAIR-S for in-stack monitoring, and the LASAIR-P for point-source monitoring. All three versions use a common control unit that contains the diode laser and its temperature and current control circuits; the detector and its circuitry; the connectors to the launching and receiving optical fibres; the interface to the computer for automatic control, and data acquisition and logging; and a reference cell containing a known concentration of the gas.

The laser beam is brought to one or more of the measurement stations by fiber optics. A fiber optic multiplexer can be used to split the beam for operating several sensors at the same time in a time-sharing mode as shown in Fig. 2. A single controller can also contain and control several lasers that can feed the combined light to a single or several sensors simultaneously, providing a great deal of versatility and economy. This controller can be located at any suitable location within the site, such as the control room of a plant, and does not have to be protected from harsh climatic or hazardous environments. Since none of the sensors' heads have electrical parts or components, they can be mounted in an explosive or hazardous location and operated in virtually any climatic or environmental condition.

The point-source version of the instrument draws the measured air continuously through a White or Herriot-type multipass cell. The cell can be located either within the controller itself or at some remote location. A remote location can be chosen for one or more of the multipass cells if desired, and connected to the controller by fiber optics.

A 4 in. Schmidt–Cassgrain telescope is used in the LASAIR-R version to both transmit the beam to a retroreflector and to receive the returned beam. The use of a single telescope to both transmit and receive also provides the advantage of easy alignment as well as providing a very stable configuration that is insensitive to vibrations. An example of measurements made with the LASAIR-R is provided by an on-road intercomparison study of automobile exhausts (16). The intercomparison was made at the Ford Motor Company Dearborn Proving Grounds between the on-board monitoring systems installed in a Ford Aerostar test vehicle and LASAIR-R. The Aerostar contains an on-board, variable path, multi-pass FTIR, able to make continuous emissions of CO and CO_2. Comparisons were made of the concentrations of CO and CO_2. The on-board computer system controls engine air-to-fuel ratios and controls and monitors numerous engine operating parameters. These engine parameters, when combined with the emission data from the FTIR, provide a comprehensive and accurate account of the vehicle emissions and the conditions that produced them. The Aerostar van was operated at speeds in the range 15–35 mph, air/fuel rations (λ) between 0.8 and 1.0, and with the gear set in 1st, 2nd, or 3rd during a pass by. This provided CO emissions in the range 0.05–~8%. Over 120 passes were monitored to provide a comprehensive data set with a minimum of 6 measurements under identical conditions for statistical validation. The LASAIR measurements were made across a 25 ft single traffic lane.

Figure 3 shows some real-time data for two passages of the

Fig. 2. Schematic of LASAIR system showing several possible sensors operating from a common controller.

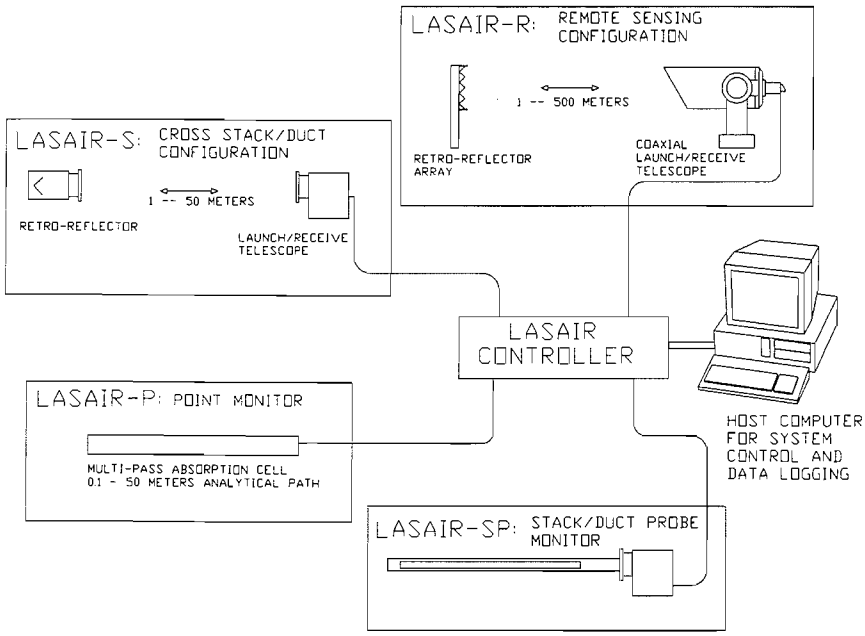


Fig. 3. Real-time remote-sensing measurements of CO and CO_2 in an automobile exhaust made with a LASAIR-R instrument across a 25 ft test track. The upper curve is with the test vehicle operating at an air-to-fuel ratio of 1.0 and the lower curve with the vehicle operating at a fuel-to-air ratio of 0.8.

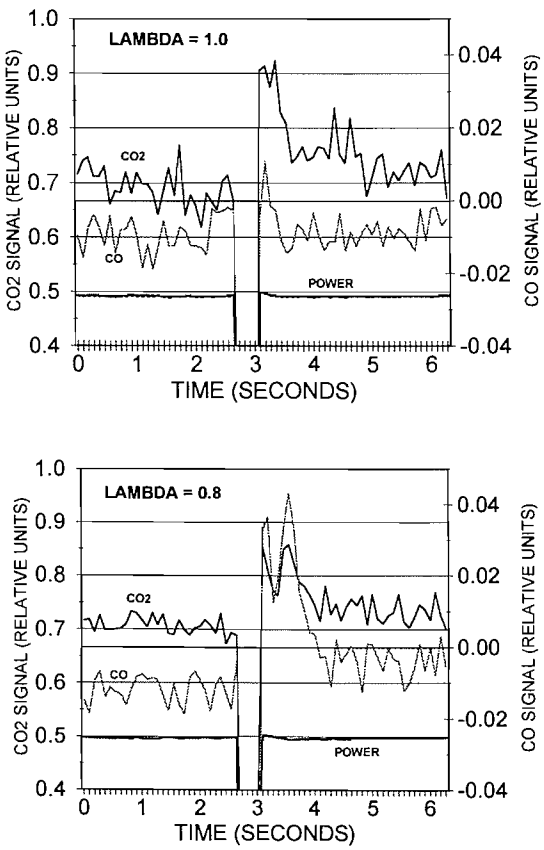

test vehicle, one when the vehicle was operated with an air-to-fuel ratio, λ, of 0.8 and the other with $\lambda = 1$. Measurements were made of CO and of CO_2 along with the power incident on the detectors at a sampling rate of 80 Hz and were averaged into 0.1 data points. The passage of the car was determined by the power dropping to less than 90% of its value. This signalled the data processing to start. To prevent an event being falsely identified if a cat or a person walked across the beam, values of CO_2 before and after the power drop were compared. If CO_2 increased by less than 5% after the beam was interrupted, the interruption was not identified as a motor vehicle event. We presumed that the cat does not give out this much CO_2. Passage of the vehicles is clearly indicated as are the increases in both CO and CO_2. For the case of stoichiometry the CO is very much smaller than for $\lambda = 0.8$. As CO goes down, CO_2 goes up.

Figure 4 shows the comparison between the CO/CO_2 ratio measured by the LASAIR-R and the on-board equipment with a vehicle speed of 35 mph. Each point represents the average of 6 passes of the vehicle under identical conditions. Good agreement is found for all data sets with the slopes of the regression lines indicating that the absolute values of the CO/CO_2 ratios by the two instruments agrees to within $\pm 3\%$, and the linearity was also excellent ($R^2 > 0.95$). The very small offset is probably due to the fact that the two instruments were not intercalibrated.

The LASAIR-S was developed for in-stack monitoring and process control. The diode laser and detector are both mounted in a control unit at some suitable location inside the plant. The laser beam is then transmitted to the stack by fibre optics, launched across the stack, and returned to the detector by fibre optics. Two options are available for transmission across the stack. One is an open path with the launching optics and the retroflector offset from the stack to prevent exposure to the

Fig. 4. Scatter diagram of the comparison between the CO/CO_2 ratios measured with the remote-sensing LASAIR-R and the on-board FTIR instrument taken on the Ford Motor Company Dearborn Proving Grounds. The speed of the vehicle was 35 mph and the air-to-fuel ratio was varied between 0.8 and 1.0. Data obtained at 10 Hz have been averaged over the time (~0.5 s) during which the exhaust plume impacted the measurement path.

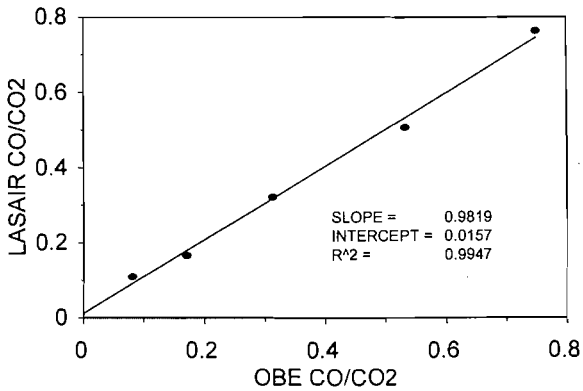

Fig. 5. Observed variation in the HF signal measured by the LASAIR-S in the stack emissions of an aluminium smelter when the number of filters in the stack were reduced from 9 filters at ~15:00, reduced again to 5 filters at 15:40, and subsequently increased back to 9 filters at ~16:00.

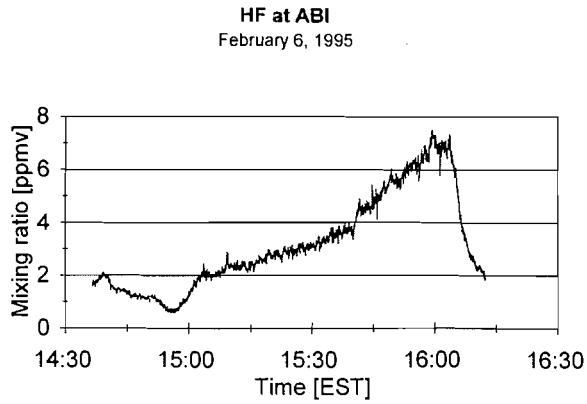
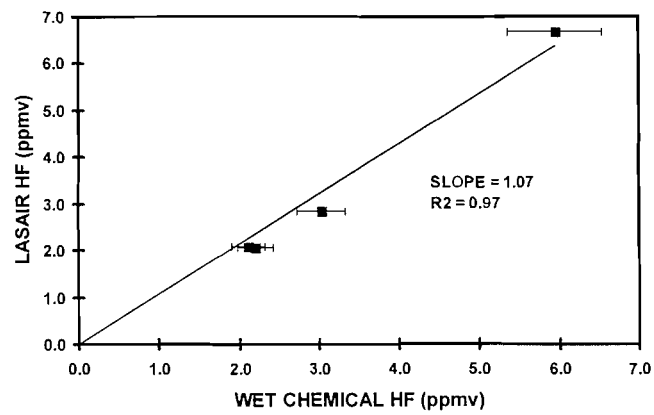


exhaust gases and temperature. An example of measurements made with the cross-stack version of the LASAIR-S is again provided by the aluminium industry. An installation was made in an aluminium smelter in Quebec for monitoring HF emissions from a 4 m stack. The complete installation was made in less than 1 h. The control unit and laser were located more than 1.5 km from the stack installation. In one test, the emissions from 120 pots were passed through up to 9 filter packs before being vented through the stack. The number of filters on line at any one time could be changed and variations due to such changes were monitored. Figure 5 shows the results of this test made in February, 1995. The HF level of about 2 ppmv was the normal operating level. The value decreased between 14:45 and 15:00 as some of the pots were shut off. The HF levels then rose between 15:00 and 16:00 as filters were removed in succession until all nine had been removed to produce an HF level of about 7 ppmv, after which the filters were reinstalled. Figure 6 shows an intercomparison made of HF mixing ratios measured by the LASAIR-S and an EPA-approved, wet chemical technique in the stack emissions from the same aluminium smelter. The agreement is excellent with the LASAIR providing considerably better precision than the wet chemical method.

Another remote-sensing instrument that has been developed by Unisearch, called the SENSAIR, is capable of measuring a number of pollutants simultaneously (17, 18). It is based on optical absorption in the visible and ultraviolet portion of the spectrum and has the generic name of Differential Optical Absorption Spectroscopy (DOAS). The method was originally developed by Professor Uli Platt of Heidelberg University and has been used successfully to make a number of important atmospheric measurements. Of particular interest these days is the ability of DOAS to measure aromatic compounds such as benzene, toluene, and the xylenes, which cannot be monitored adequately by alternative remote-sensing techniques such as Fourier Transform Infrared (FTIR) because of interference from ubiquitous water vapour and carbon dioxide. The conventional DOAS system uses a telescope to transmit a beam of broad-band light through the atmosphere. The transmitted

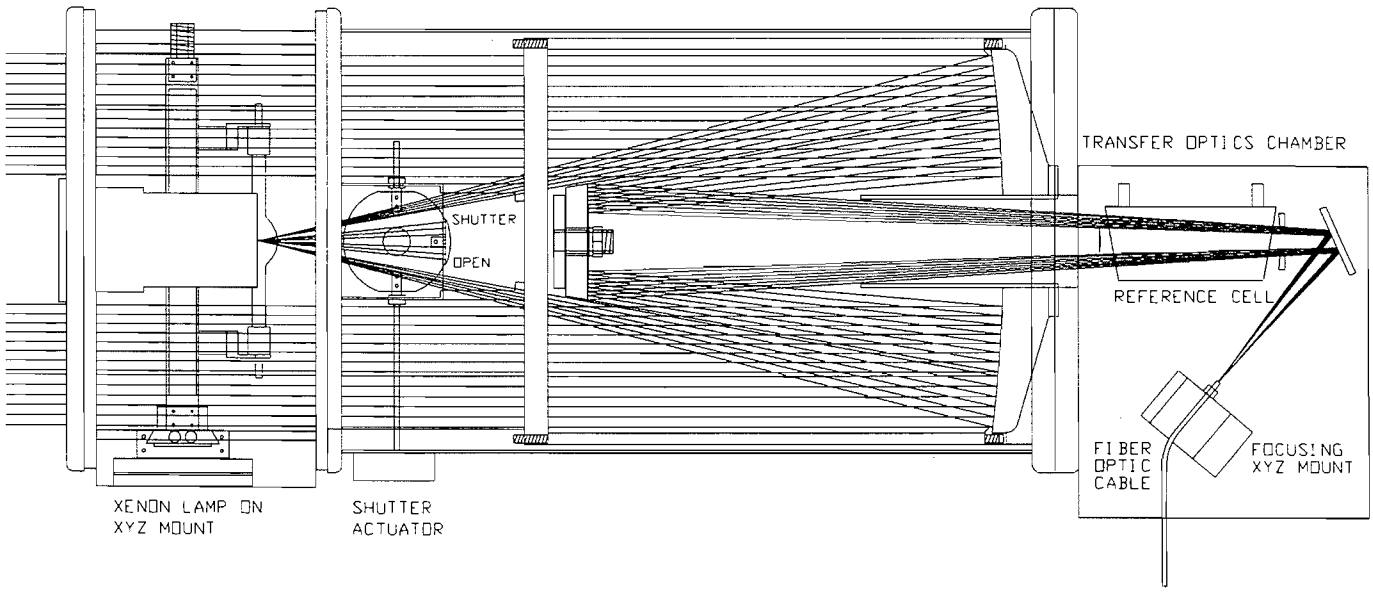
Fig. 6. Comparison of the HF mixing ratios measured by the LASAIR-S and the EPA-approved wet chemical method in the stack emissions of an aluminium smelter. The changes in the HF mixing ratio were created by removing recycled alumina from several of the stack filter units.



beam is then received by a similar telescope at the other end of a long path and disbursed by a spectrograph. Light paths of 500 m are commonly used for most molecules at concentrations encountered in rural and urban conditions. So we cannot claim to have invented this technique. What we think we have done is to make some very major improvements.

Our instrument has overcome the inconvenience of having to provide power and water cooling for the light source separated by long distances from the receiver, by the use of a retroreflector. The same telescope, shown schematically in Fig. 7, is used to both send the beam to a retroreflector and to receive the reflected light beam. The use of a single telescope has the additional advantage of ensuring that the sending and receiving optics remain coaxial, getting double the optical path for the same distance. We incorporated into this telescope a baffle that can be rotated to block the outgoing beam and that detects the light being emitted by the lamp. This gives, in essence, a zero path length and acts to provide the zero absorp-

Fig. 7. Schematic of the SENSAIR-DOAS remote-sending telescope. The telescope both launches the optical beam to a retroreflector placed at the other end of the optical path and directs the reflected beam to the fibre optic cable connected to the analysing spectrometer. A shutter can be activated to direct the beam directly into the telescope, which provides a zero-path reading. A calibration cell can also be inserted into the optical path.



tion in Beer's Law expression. In addition, a reference gas cell can be placed in front of the fiberoptic cable entrance for calibration. Since both outgoing and reflected beams traverse the same path the effect of air turbulences are minimized. In fact, the main problem encountered with any long-path measurement is the turbulence or scintillations of the air along the path that occur at time scales of 0.1–1 Hz.

In the original design, Platt and his group solved this problem by replacing the exit slit of the spectrometer by a rotating disc containing some 20 radial slits. Only one slit at a time is exposed to the spectrometer. Since the rotational speed of the disc is about 300 rpm, successive spectra are obtained at a frequency of about 100 Hz, which is much faster than the frequency of air turbulences. Several tens of thousands of scans are added over 10–15 min to get the desired sensitivity. The problems inherent with the wheel include the need to have all the slits identical in order to co-add successive spectra and, second, the rotational speed of the wheel must be maintained to a very high degree of accuracy for the same reason. These requirements add considerably to the size and cost of the system. Furthermore, the slits do not remain vertical as the wheel rotates, causing distortion of the spectrum. Each instrument must therefore be calibrated for each gas to be measured — not a trivial task.

We have "uninvented" the wheel. We have replaced it by a miniature, electrochemically swept slit, which provides a repetitive, bidirectional sweep of the spectrum in which the change of wavelength is linear with respect to time. The replacement of the wheel by a linear scanner reduces both the size and cost of the instrument. In addition, since the slit is always vertical and its displacement linear it is no longer necessary to calibrate the instrument for each gas; literature spectra can be incorporated into the library of the data-processing computer.

An example of some measurements made with this system is provided by a study we made to determine practical detection limits of the system for a number of important pollutant gases. Determining detection limits of a remote-sensing instrument in a polluted atmosphere can be a controversial issue. At trace levels close to the detection limit, it may be difficult to separate real variations in pollutant levels from the variations due to residual noise sources in the system. The least ambiguous method appears to be simultaneous measurements using two long-path instruments mounted side by side and probing essentially the same air mass.

Two DOAS telescopes and spectrometers were set up side by side on the second floor of the Unisearch facilities, both directed to the same retroreflector located on the roof of a neighboring building, providing a total path length of 314 m. The surrounding area, in suburban Toronto, is a light industrial zone with considerable vehicular traffic, providing a realistic situation where there is considerable variation in the pollutant concentrations. The study was made for a number of gases including NO, NO_2, O_3, benzene, and toluene. Figure 8 is a time plot of some of the toluene data taken with the two instruments. The very variable toluene peaks starting at 07:30 correspond with the start of daily industrial activity in this area and appear quite frequently. Figure 9 is a scatter plot of the same data. From this plot a standard error of 1.88 ppbv and a detection limit of 1.3 ppbv toluene for a single instrument are obtained.

In conclusion, I have tried to show you why I have never considered myself to be an analytical chemist. I have always been interested in trying to solve particular scientific problems — the nature of active nitrogen, the composition of the atmosphere, and the reactions that occur in that large laboratory either naturally or as a result of human activities. To answer these questions I needed to make measurements. In most cases

Fig. 8. Some real-time measurements of toluene made with two SENSAIR-DOAS instruments operating over a 314 m path in suburban Toronto in January. The variable toluene peaks starting at 07:30 correspond to the start of daily industrial activity in this area.

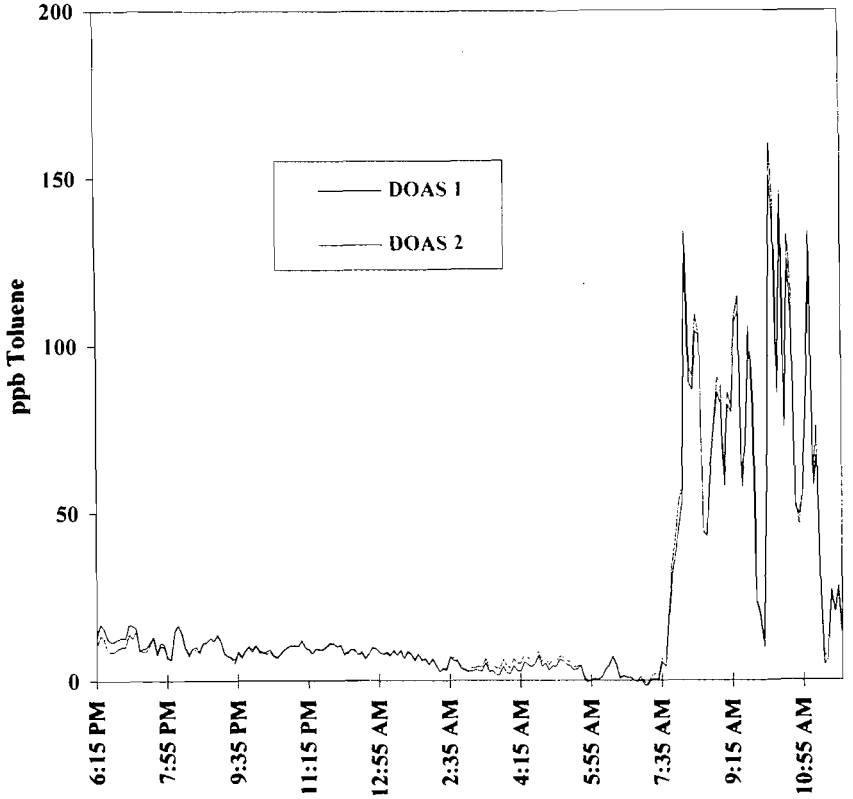


Fig. 9. Scatter diagram for the measurements of toluene made simultaneously over the same air path by two SENSAIR-DOAS instruments.

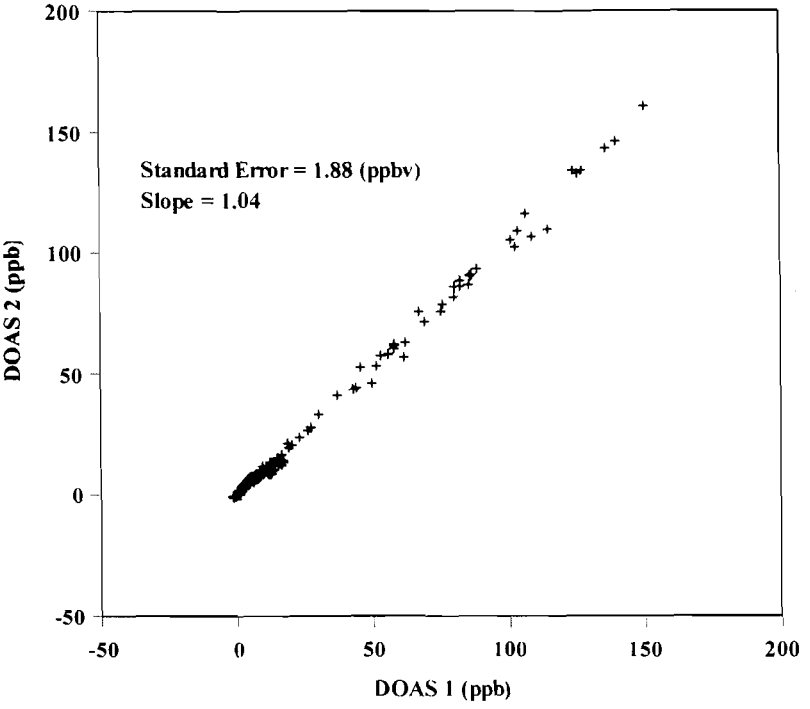

the instruments required to make these measurements simply were not available. So we had to design and build them. Fortunately for me, I always had students and colleagues who were much more skillful at this than I was.

If that makes me eligible for this prestigious award then all I can do is to thank the Society. Life is full of surprises!

The decomposition of aliphatic *N*-nitro amines in aqueous sulfuric acid. Bisulfate as a nucleophile[1]

Robin A. Cox

Abstract: In aqueous sulfuric acid, aliphatic *N*-nitro amines decompose to N_2O and alcohols. An excess acidity analysis of the observed rate constants for the reaction shows that free carbocations are not formed. The reaction is an acid-catalyzed S_N2 displacement from the protonated *aci*-nitro tautomer, the nucleophile being a water molecule at acidities below 82–85% H_2SO_4, and a bisulfate ion at higher acidities. Bisulfate is the poorer nucleophile by a factor of about 1000. Twelve compounds were studied, of which results obtained for nine at several different temperatures enabled calculation of activation parameters for both nucleophiles. The reaction appears to be mainly enthalpy controlled. The intercept standard-state rate constants are well correlated by the σ^* values for the alkyl groups; the slopes are negative, with a more negative value for the slower bisulfate reaction. Interestingly the $m^{\ddagger}m^*$ slopes also correlate with σ^*, although the scatter is bad.

Key words: *N*-nitro amines, excess acidity, bisulfate, nucleophiles, acid-catalyzed, kinetics.

Résumé : En solution dans l'acide sulfurique aqueux, les *N*-nitroamines aliphatiques se décomposent en N_2O et en alcools. Une analyse des constantes de vitesse de ces réactions par la méthode de l'excès d'acidité montre qu'il ne se forme pas de carbocations libres. La réaction est une substitution S_N2 acidocatalysée sur le tautomère *aci*-nitro protoné dans laquelle le nucléophile est une molécule d'eau à des acidités inférieures à 82–85% de H_2SO_4 et un ion bisulfate à des acidités supérieures. Comme nucléophile, le bisulfate est mille fois moins efficace. On a étudié 12 composés; les résultats obtenus à diverses températures avec 9 d'entre eux ont permis de calculer les paramètres d'activation pour les deux nucléophiles. Il semble que la réaction est principalement contrôlée par l'enthalpie. Dans les cas des groupes alkyles, les valeurs de σ^* permettent d'établir une bonne corrélation avec l'ordonnée à l'origine des constantes de vitesse de l'état standard; les pentes sont négatives et elles le sont encore plus pour la réaction plus lente du bisulfate. Il est intéressant de noter que les pentes $m^{\ddagger}m^*$ donnent aussi une bonne corrélation avec σ^*, même si l'éparpillement est mauvais.

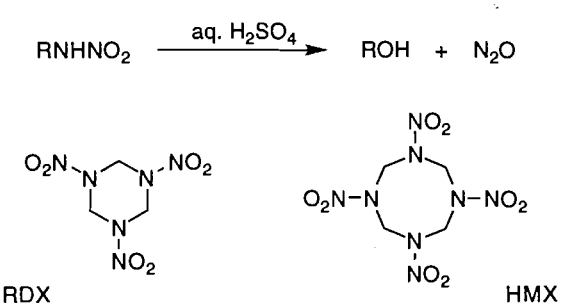
Mots clés : *N*-nitroamines, excès d'acidité, bisulfate, nucléophiles, acidocatalysé, cinétique.

[Traduit par la rédaction]

Introduction

As part of a continuing interest in the mechanisms of organic reactions in strong acids (1), this paper is concerned with the decomposition of monoalkyl nitramines to alcohols and nitrous oxide that takes place in concentrated aqueous sulfuric acid media.

Little information is available in the open literature concerning this functional group, probably because military explosives are often alkylnitramines, the two best known being RDX and HMX (2). In contrast, the parent molecule nitramide, NH_2NO_2, has been widely studied, and the results



have contributed greatly to the theory of acid–base catalysis (3). Interest in nitramide continues to this day (4–6). The rearrangement of aromatic nitramines to nitroanilines has also received some attention (7).

Apart from one early study (8), all of the information on the acid-catalyzed hydrolysis of alkylnitramines comes from the group of L. L. Kuznetsov (9–11) in what was then the Soviet Union. Kuznetsov's papers were published without an affiliation being given, which probably means that the work was carried out at a military facility; I eventually managed to track him down in Leningrad in 1987 and was able to discuss this work with him, as far as was possible through an interpreter in a hotel lobby with a KGB minder in the middle distance, and I

Received January 5, 1996.

This paper is dedicated, somewhat belatedly, to Professor John T. Edward of McGill University.

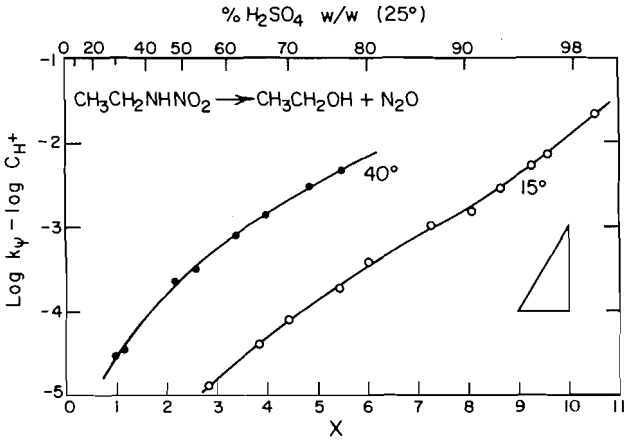
Fig. 1. Excess acidity plot of log log k_ψ − log C_{H^+} vs. X for the reaction of *N*-nitroethylamine in sulfuric acid at 15 and 40°C. For convenient reference a wt.% H_2SO_4 concentration scale is included at the top, and a line of unit slope at the right.



think that he is in substantial agreement with the analysis in this paper.

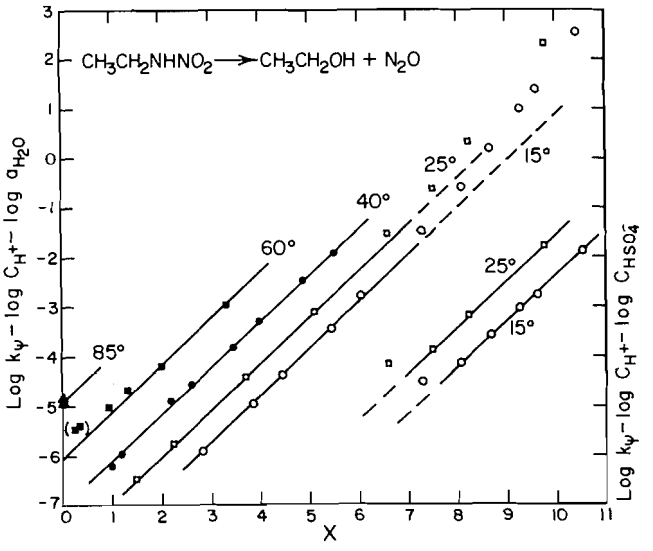
The results are analyzed using the excess acidity method (1), which has been widely applied to organic reactions in sulfuric acid in recent years, most recently to aromatic hydrogen exchange (12), phenylazo ether cleavage (13), imidazole cyclizations (14), and the hydrations of fluorinated alkyl vinyl ethers (15).

Results

The excess acidity method works by examining plots of of log k_ψ − log C_{H^+} against X, where k_ψ are observed rate constants as a function of acidity for the reaction in question. C_{H^+} is the molar proton concentration and X the excess acidity of the medium (1); values are given in Cox and Yates (16). If these plots are linear the reaction mechanism is A1 or A-S_E2, and if curved, A2 (1). Such a plot for the decomposition of *N*-nitroethylamine in sulfuric acid at two temperatures is shown in Fig. 1. This curves downward up to an acidity of ~85% H_2SO_4, and then starts to curve upward; this means that the reaction mechanism is clearly not A1 or A-S_E2. Once a mechanism is identified in this way as being A2, the species reacting with the protonated substrate at the transition state (Nu) can be positively identified by plotting log k_ψ − log C_{H^+} − log a_{Nu} against X (a = molar activity), trying different Nu until linearity is achieved (1). This is shown for the same *N*-nitroethylamine data in Fig. 2. A preliminary double linear regression using the most plentiful data, that for *N*-nitromethylamine at 25°C (9–11), with X as one variable and log a_{H_2O} as the other, gave the slope in the water activity, r, as being 0.965 ± 0.058, i.e., below ~85% H_2SO_4 Nu is one water molecule. The line deviates upwards after this point but, as shown, the deviant points become linear on the assumption that the Nu changes to one bisulfate ion above this acidity.

The *N*-nitroalkylamines in this study are identified by alkyl group in Table 1. The rate constants as a function of sulfuric acid concentration at 15, 25, 40, and 60°C used were those of Kuznetsov and co-workers (9), together with some additional data from his group for **5** at 25, 35, 45, and 55°C (10, 11), and some values obtained by Lamberton and co-workers for **1**, **3**, **4**, **5**, and **7** in dilute acid at 85°C (8). The data obtained by different groups at different times are in excellent agreement, as can be seen from Fig. 2. The results for the parent compound **9** are taken from the following paper (6). Tables 2 and 3 give the slope ($m^{\ddagger}m^*$) and intercept (log $k_0^{25°}$) data obtained from the Fig. 2 plots for **2**, **4**–**8**, and **10**–**12**. With results at several temperatures available for these compounds, activation parameters can be obtained as described previously (17), and these are also given in Tables 2 and 3. Since temperature-corrected values of X, log C_{H^+}, log a_{H_2O}, and log $C_{HSO_4^-}$ were used, these refer only to the reaction mechanism, medium effects having been eliminated (1, 17).

Fig. 2. Excess acidity plot for the reaction of *N*-nitroethylamine in sulfuric acid at several temperatures, assuming reaction with one water molecule (left axis and lines) or with one bisulfate ion (right axis, two rightmost lines).



Because data for **1** and **3** were only available at 85°C, the data in Tables 2 and 3 were used to evaluate log $k_0^{85°}$ values for the reaction with H_2O for the other compounds as well, and all of these intercept data are collected in Table 1. Also given there is statistical information regarding the data fit; for greater accuracy the program used rejects any points that have a 95% or greater probability of not being part of the same data set as the other points (points in parentheses in Fig. 2 and Table 1). Included in Table 1 are σ* values for the different alkyl groups obtained from ref. 18*a*; values for the alkyl groups not directly listed there (**8** and **10**) were calculated according to the procedure given in ref. 18*b*.

Linear free energy relationship plots against σ* for the standard-state intercept log k_0 values are given in Fig. 3. The ρ* values (slopes) are −1.71±0.19 for the 25°C intercepts and −1.29 ± 0.11 for the 85°C ones, both for Nu = H_2O and including results obtained for **9** (6), and −2.79 ± 0.35 for the 25°C, Nu = HSO_4^- case.

Discussion

The mechanism proposed for the decomposition of the alkylnitramines is shown below, an A2 reaction with Nu being one water molecule below, and one bisulfate ion above, ~85% H_2SO_4. Initial tautomerization to the *aci*-nitro form, proposed

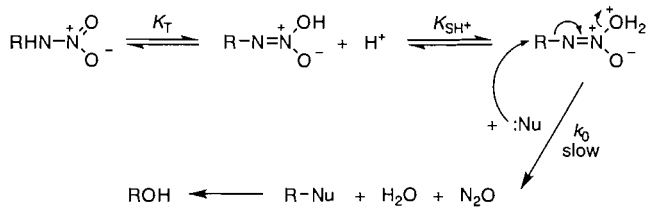
by analogy with the well-established mechanisms for base-catalyzed nitramide decomposition (4), is followed by protonation and rate-determining S_N2 attack.



The curvature seen in Fig. 1 immediately eliminates the previously proposed mechanisms for this process. Lamberton thought that fast nitrogen protonation was followed by rate-determining cleavage to a carbocation and NH_2NO_2, which subsequently decomposed to water and N_2O (8). This is an A1 process that would not give the Fig. 1 curvature, and if instead the NH_2NO_2 decomposition was rate determining, the different alkylnitramines would all decompose at the same rate, contrary to observation. Kuznetsov gives a mechanism like the one shown, except that the rate-determining log k_0 step is given as A1 carbocation formation, without nucleophile involvement (9). Apart from the lack of Fig. 1 curvature already mentioned, formation of free carbocations like $^+CH_3$ in these aqueous reaction media seems, on the face of it, highly unlikely.

Derivation of an excess acidity rate equation for the proposed mechanism is not difficult (1, 6), it is log k_ψ − log C_{H^+} − log a_{Nu} = log(k_0K_T/K_{SH^+}) + $m^{\ddagger}m^*$ X, where the term definitions have already been given, except for K_T and K_{SH^+}, which refer to the two equilibria in the reaction scheme above. This is the equation which gives the straight-line Fig. 2 plots. However, the intercepts, referred to for simplicity as log k_0 in the tables, and the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values derived from them, are in fact composites of log k_0 and these two equilibrium constants. Further separation is unfortunately not possible, since the two K's are not known. Not a lot is known about the nitro–*aci*-nitro tautomerism of the K_T process in any case (except that the pK_T

for nitramide itself has recently been estimated to be ~6 (4)). However, it is reasonable to assume that it is fast, since proton transfers to and from nitrogen and oxygen, known to be fast (19), are involved; only proton transfers at carbon (and possibly sulfur (20)) are slow. Protonation constants for alkylnitramines are not known either, beyond the fact that no signs of equilibrium protonation are visible in the acidity range covered by the experiments. In any event the OH group of the *aci*-nitro tautomer, at which protonation leads to further reaction, is unlikely to be the most basic site in the molecule.

Bisulfate ion is not normally thought of as being nucleophilic, and it is clear from Fig. 2 that for this reaction it is in fact some 1000 times worse than water as a nucleophile in the standard state (i.e., at $X = 0$), since the vertical separation of the H_2O and HSO_4^- lines in Fig. 2 is about three log units. (A more detailed calculation, averaging over all the compounds in this work that have data for both, gives the difference in nucleophilicity between 55.34 M water and 1 M bisulfate as being 3.031±0.056 log units in these sulfuric acid media.) Consideration of the concentrations of the various species in aqueous sulfuric acid (21) means that the change in nucleophile occurs at 82–85 wt.% H_2SO_4, a concentration at which mechanistic changes take place for many reactions (1, 21).

The activation parameters in Tables 2 and 3 indicate that the observed differences in reaction rates are primarily due to differences in the enthalpy of activation for the different compounds. In the Nu = H_2O case the entropies of activation are all the same, averaging to −13.39 ± 0.37 cal mol^{-1} K^{-1}. Although it may not look like it, the entropies of activation in the Nu = HSO_4^- case are not statistically different from one another either, when account is taken of the larger errors, and on weighting the numbers with their errors these average to −10.6 ± 2.3 cal mol^{-1} K^{-1}. This is less negative than for the Nu = H_2O case, as would be expected since charge destruction is taking place when Nu = HSO_4^-, freeing up solvating species; in fact I would have expected it to be zero or even positive, as has been found for amide hydrolysis (22). The $m^{\ddagger}m^*$ values in Tables 2 and 3 are near one; m^*, which refers to the equilibrium protonation behavior of the substrate, is unknown but for oxygen protonations a value of less than one would be expected (16). However, since m^* also contains an unknown contribution from the nitro–*aci*-nitro tautomerism, further comment as to the value of $m^{\ddagger}$ (referring to the transition state) seems unjustified, beyond noting that the combined values seem acceptable according to what is known about them (1, 16, 22).

The relative reactivity order given in Tables 1 and 2 and Fig. 3 for compounds **1**, **3**, **4**, **5**, and **12** is in exact agreement with the order found in very recent theoretical calculations (SCF–MO AM1) concerning the reactivity of these molecules under acidic conditions, *t*-Bu > i-Pr > Et > Me > CH_2CO_2H (23).[3] The ρ* values for the LFER plots in Fig. 3 seem about right for this type of reaction (18), and it is apparent that the differences between the different alkyl groups are due to polar rather than steric interaction with the reaction center. Poorer

[3] One of the referees comments that H:Me (and *t*-Bu:Me) rate ratios are very large in many solvolysis reactions, and thus it is quite surprising that the point for the H substituent (nitramide itself) falls on the same line with the other substituents. This is comparison of a base attack with the nucleophilic attack under consideration here (see following paper (6)), and thus too much significance should not be attached to this agreement as it may well be fortuitous (the activation parameters for nitramide (6) are quite different from those in Table 2).

agreement for the i-Pr and *t*-Bu derivatives **3** and **1** might have been expected because of the anticipated steric effect of these groups; it is unfortunate that only very few experimental measurements are available for these two compounds, and only at 85°C (8). The fact that the points for **1** and **3** *do* fall on the line is an argument in favor of an early transition state for the reaction, diminishing the importance of steric effects; the fact that single water molecules (rather than two or three acting in concert) act as nucleophiles is another argument for an early transition state, as discussed previously (1).

The ρ^* for the bisulfate reaction is more negative than that for the water reaction, implying greater influence for the substituents, which probably means that the weaker bisulfate nucleophile is putting more demand on them. The ρ^* for the faster water reaction at 85°C is less negative than the value at 25°C. Interestingly the $m^{\ddagger}m^*$ values in Table 3 are also linearly correlated with σ^*, although with some scatter; for clarity these plots are not included in Fig. 3. For Nu = H_2O the slope is 0.126 ± 0.023 (intercept 0.961 ± 0.008, correlation coefficient 0.89) and for Nu = HSO_4^- it is 0.294 ± 0.039 (intercept 0.931 ± 0.017, correlation coefficient 0.94). Since these $m^{\ddagger}m^*$ values are already LFER slope parameters (1), it is difficult to know what interpretation to put upon this observation, but it is worth noting that behavior like this has been seen before, in σ^+ plots (24), and so there may in fact be one.

The acid-catalyzed decomposition of nitramide

Robin A. Cox

Abstract: Much attention has been paid to the base-catalyzed decomposition of nitramide, but despite this it was not certain that a corresponding acid-catalyzed reaction even existed before the work described in this paper. The excess acidity method has been applied to nitramide decomposition rate constants obtained in aqueous perchloric acid media, and to a lesser extent in aqueous hydrochloric and sulfuric acids. This analysis shows that the decomposition in dilute acid solution is actually a base-catalyzed reaction, with water acting as the base (perhaps in a cyclic process involving two water molecules), with rate constants in good agreement with previous estimates. However, in more concentrated acid media a true acid-catalyzed reaction can be dissected out. Activation parameters are given for both mechanisms, and it is shown that the acid-catalyzed process is similar to the acid-catalyzed decomposition of alkylnitramines. In sulfuric acid the reaction is slightly faster than it is in the other acids, due to the presence of a base-catalyzed process involving sulfate.

Key words: nitramide, excess acidity, acid-catalyzed, base-catalyzed, kinetics.

Résumé : Même si on s'est beaucoup intéressé à la décomposition du nitramide catalysée par les bases, il n'est pas certain qu'une réaction acidocatalysée correspondante ait été rapportée avant celle décrite dans ce travail. On a appliqué la méthode de l'excès d'acidité aux constantes de vitesse de décomposition du nitramide obtenues dans un milieu d'acide perchlorique aqueux et, à un degré moindre, dans des solutions aqueuses d'acides chlorhydrique et sulfurique. Cette analyse démontre que la décomposition en solution acide dilué est, en fait, une réaction catalysée par les bases dans laquelle l'eau agit comme base (possiblement dans un processus cyclique impliquant deux molécules d'eau), pour laquelle les constantes de vitesse sont en bon accord avec les évaluations antérieures. Toutefois, dans des milieux acides plus concentrés, on peut mettre en évidence une vraie réaction acidocatalysée. On rapporte les paramètres d'activation pour les deux mécanismes et on démontre que le vrai processus acidocatalysé est semblable à la décomposition acidocatalysée des alkylnitramines. Dans l'acide sulfurique, la réaction est légèrement plus rapide que dans les autres acides; on attribue cette différence à la présence d'un processus catalysé par les bases impliquant l'ion sulfate.

Mots clés : nitramide, excès d'acidité, acidocatalysé, catalysé par les bases, cinétique.

Introduction

In connection with a recent study of the decomposition of alkylnitramines to alcohols and nitrous oxide that takes place in aqueous sulfuric acid media (1), it was also of interest to find out what happens to the parent compound nitramide, NH_2NO_2, under similar conditions. Although wholly inorganic, nitramide has the status of an "honorary" organic molecule amongst physical organic chemists, because of the contribution that the study of the base- and buffer-anion-catalyzed decomposition of this molecule has made to our understanding of acid–base catalysis (2). However, in spite of the many studies that have been made of this molecule, there is still new information to be obtained. Quite recently a whole new base-catalyzed decomposition mechanism was discovered for nitramide in strongly basic media (3). Theoretical calculations seem unable to agree on such basic matters as whether or not the molecule is twisted (4). It has only recently been discovered that the oxygens in the molecule are more basic than the NH_2 nitrogen, according to gas-phase protonation and ab initio studies (5).

Only two groups have reported kinetic studies of the decomposition of nitramide in acidic media, Marlies and La Mer (in 1935), and more recently the group of M. N. Hughes. The first group studied the reaction in dilute aqueous hydrochloric acid solutions at 25°C (6), and the second used aqueous perchloric, hydrochloric, and sulfuric acids at several temperatures (7). This paper is concerned with an excess acidity analysis (8) of these results, and represents an extension of the excess acidity kinetic method to perchloric and hydrochloric acid media, from the sulfuric acid solutions used almost exclusively until now.

Received January 5, 1996.

Dedicated to the memory of Professor John W. Bunting, 1943–1995.

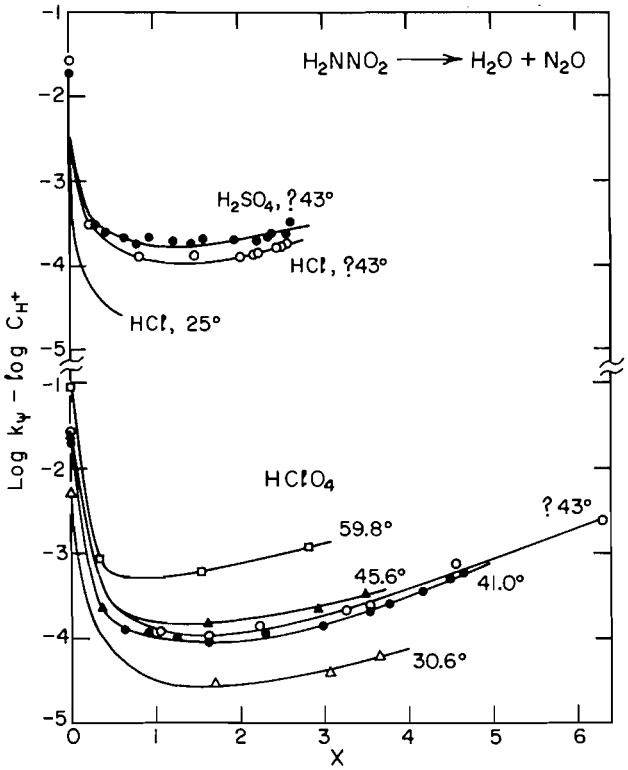
Results and discussion

The available rate constants, k_ψ, as a function of acid concentration and temperature (6, 7) are plotted against X in the excess acidity format, as $\log k_\psi - \log C_{H^+}$, in Fig. 1. (The data quoted as being measured at a temperature of ?43° in Fig. 1 are said to be 35°C values in the original paper (7), but this almost certainly is in error, since assuming a temperature of 43°C

Fig. 1. Excess acidity plots of log k_ψ − log C_{H^+} vs. X for the decomposition of nitramide in aqueous perchloric acid at several temperatures (lower) (7), and (upper) for the decomposition in aqueous sulfuric and hydrochloric acids at a temperature thought to be 43°C (7), and in aqueous hydrochloric acid at 25°C (6).

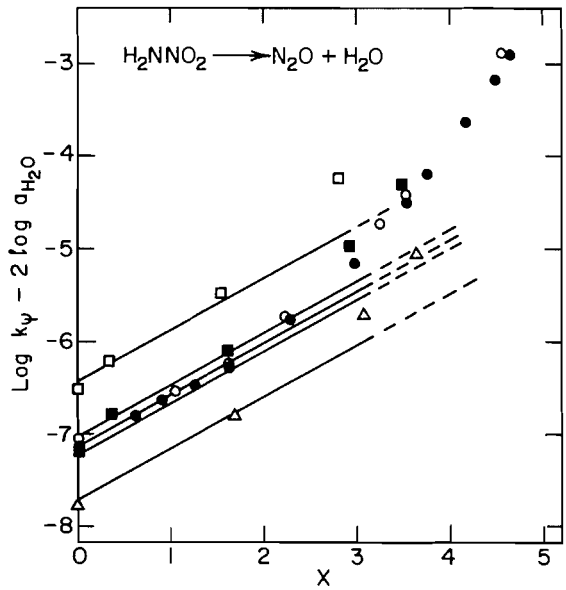


gives excellent agreement for these data with all of the rest; see below.) The excess acidities X for sulfuric and perchloric acid are from Cox and Yates (9), and values for hydrochloric acid are also available (10); all are corrected to the reaction temperature as before (11). Values of C_{H^+} are simply the acid molarities for the monobasic acids (10); quoted values are used for sulfuric acid (9), and all are corrected to temperature via the densities.

It is obvious from Fig. 1 that a sharp initial drop in rate is followed by a shallow increase. Nitramide is known to react with water alone (2, 3); Hughes realized this and subtracted the neutral water values from his data (7). This does not really change the Fig. 1 curvature, except for the initial points. Hughes reports that these corrected rate constants show good linearity with H_0, which he took as evidence for acid catalysis, but the resulting slopes are very shallow at ~0.3 (7). Marlies and La Mer (6) report similar behavior for their data. The picture is evidently more complicated than this, according to the Fig. 1 curvature; Fig. 1 does not represent an acid-catalyzed reaction with water acting as a base, since the plots would curve downwards rather than upwards in that case (1, 8). Consequently it was decided to develop an excess acidity rate equation for neutral water reacting with neutral nitramide in these acid media, to see if this could account for the observed behavior.

The mechanism of Scheme 1 is proposed for the water-cat-

Fig. 2. Excess acidity plots according to eq. [3], assuming reaction with two water molecules only, for the decomposition of nitramide in aqueous perchloric acid at (bottom to top) 30.6, 41.0, (probably) 43, 45.6, and 59.8°C.



alyzed reaction. Initial tautomerization to the *aci*-nitro form (1, 3) is followed by reaction with water in the rate-determining step. The two-water-molecule cyclic transition state is proposed on the basis of no evidence whatever, beyond the fact that it looks very plausible, involving no charge transfer, and by analogy with other cyclic proton transfers of this type commonly proposed (12, 13). In fact the analysis in this paper is unable to distinguish between one and two water molecules, good agreement with the experimental results being obtained on either assumption.

The rate equation derivation is straightforward (8). Using the terminology of Scheme 1, and with C = molar concentration, a = molar activity, and f = molar activity coefficient:

$$[1] \quad k_\psi C_S = k_0 a_T a_{H_2O}^2 (1/f_\ddagger)$$

where k_ψ are the observed rate constants and $f_\ddagger$ is the activity coefficient of the transition state. Substituting $a_T = K_T a_S$ and $a_S = C_S f_S$ into eq. [1] and taking logs gives

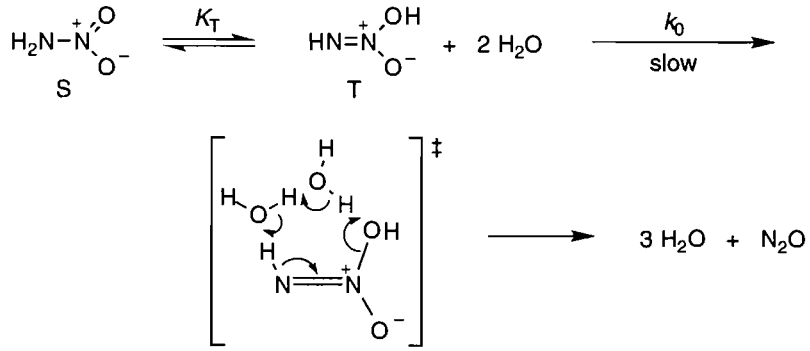
$$[2] \quad \log k_\psi - 2 \log a_{H_2O} = \log(k_0 K_T) + \log(f_S / f_\ddagger)$$

and it is known that all types of log activity coefficient ratio terms such as the rightmost one in eq. [2] are linear in X (8, 9, 14), so this becomes

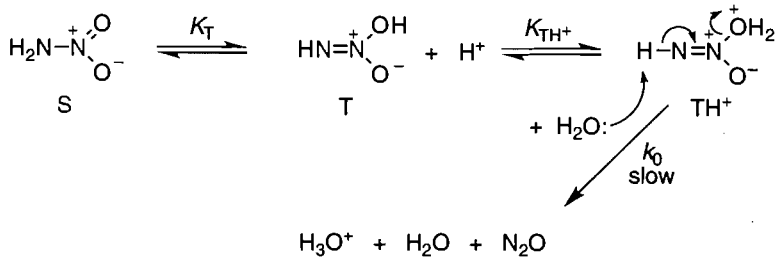
$$[3] \quad \log k_\psi - 2 \log a_{H_2O} = \log(k_0 K_T) + mX$$

Plots of the perchloric acid data according to eq. [3] are shown in Fig. 2. Water activities at 25°C are available for all three acid systems from several sources (15); the 25°C data were used because as yet only water activities in sulfuric acid can be calculated at other temperatures (16). (This is not a major problem because the water activities in sulfuric acid at differ-

Scheme 1.



Scheme 2.



ent temperatures are almost the same as one another at the relatively low acidities used here, and presumably the behavior of perchloric and hydrochloric acids would be similar.) The values of the excess acidity X used are corrected to the reaction temperature (11), which means that the same slope m applies at all temperatures (11), and thus all the lines in Fig. 2 are necessarily parallel.

As can be seen from Fig. 2, the data are linear in eq. [3] but only up to a point, beyond which an upward deviation is apparent. Two water molecules are assumed to be involved; since the variation of water activity with acidity is barely observable in these dilute acid solutions, plots on the basis of one water (or any other number) look just the same. The different intercepts obtained at the different temperatures enable activation parameters for the reaction to be calculated; they are $\Delta H^{\ddagger}$ = 19.67 ± 0.68 kcal mol^{-1} and $\Delta S^{\ddagger} = -29.1 \pm 2.3$ cal mol^{-1} K^{-1}. This large negative $\Delta S^{\ddagger}$ seems quite reasonable for the cyclic transition state proposed. (The ?43° data in Fig. 2 agree very well with the rest if the temperature is assumed to be 43°C, but certainly do not if the quoted temperature of 35°C (7) is used.) The slope m is 0.557 ± 0.017, but the magnitude of this number is not meaningful as there is nothing with which to compare it; this is the first use of eq. [3] in kinetic analysis. Using the activation parameters to calculate a standard-state (i.e., $X = 0$) value for k_{H_2O} gives a value of 3.16×10^{-5} s^{-1} at 25°C (value in 55.34 M water), which compares adequately with listed values, e.g., $(4.632 \pm 0.015) \times 10^{-5}$ s^{-1} (3, 17), and the value of $(4.741 \pm 0.002) \times 10^{-5}$ s^{-1}, which is the intercept of a plot of the data of Marlies and La Mer (6) against [HCl].

Since the values in Fig. 2 deviate upwards at the higher acidities, it is reasonable to assume that an acid-catalyzed process is taking over, and by analogy with the alkylnitramines (1) the mechanism in Scheme 2 is proposed, with one water molecule acting as a base. (This might also be a cyclic process; imagine a proton added to Scheme 1.) A rate equation for this is readily derived (8). Using the terminology of Scheme 2:

$$[4] \quad k_{\psi} C_S = k_0 a_{TH^+} a_{H_2O} (1 / f_{\ddagger})$$

Substituting $a_{TH^+} = a_T a_{H^+} / K_{TH^+}$, $a_T = K_T a_S$, $a_{H^+} = C_{H^+} f_{H^+}$, and $a_S = C_S f_S$ into eq. [4] and taking logs gives

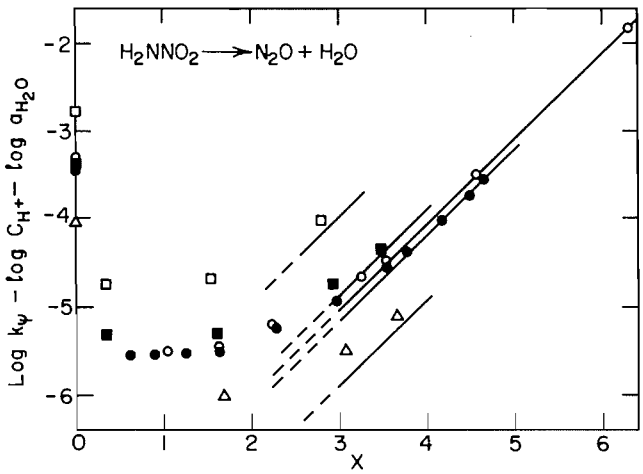
$$[5] \quad \log k_{\psi} - \log C_{H^+} - \log a_{H_2O} = \log(k_0 K_T / K_{TH^+}) + \log(f_S f_{H^+} / f_{\ddagger})$$

It is known (8) that $\log(f_S f_{H^+} / f_{\ddagger}) = m^{\ddagger} \log(f_S f_{H^+} / f_{SH^+}) = m^{\ddagger} m^* X$, so eq. [5] becomes

$$[6] \quad \log k_{\psi} - \log C_{H^+} - \log a_{H_2O} = \log(k_0 K_T / K_{TH^+}) + m^{\ddagger} m^* X$$

The perchloric acid data are plotted according to eq. [6] in Fig. 3. As can be seen, the points that deviate from linearity in Fig. 2 become linear in Fig. 3, so the supposition that the mechanism changes from a water-catalyzed process to an acid-catalyzed one is justified. (All the lines in Fig. 3 are parallel for the same reason as given above for Fig. 2.) As before, standard-state (8) activation parameters can be calculated from the intercepts at different temperatures: $\Delta H^{\ddagger} = 29.7 \pm 1.3$ kcal mol^{-1} and $\Delta S^{\ddagger} = -1.0 \pm 4.3$ cal mol^{-1} K^{-1}. These are different from the alkylnitramine values (1) in that the activation enthalpy is somewhat higher and the activation entropy considerably less negative. A closer correspondence cannot really be expected, since the reaction under consideration here is a base attack rather than a nucleophilic one; perhaps the transition state is later here, thus partaking more of the larger number of species present in the product state (two species

Fig. 3. Excess acidity plot according to eq. [6], assuming an acid-catalyzed reaction with one water molecule, for the decomposition of nitramide in aqueous perchloric acid at (bottom to top) 30.6, 41.0, (probably) 43, 45.6, and 59.8°C.



become three), and explaining the much less negative $\Delta S^{\ddagger}$ value. The latter value also rules out any type of cyclic mechanism for the acid-catalyzed process.

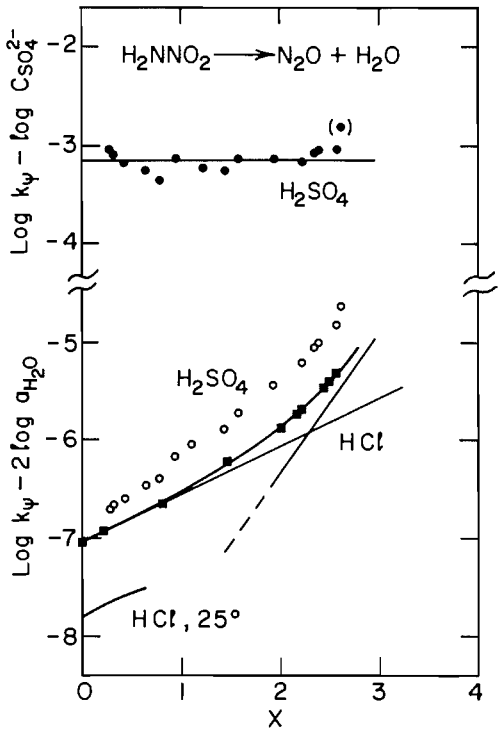
From the activation parameters can be calculated log $k_0^{25°} = -7.48 \pm 0.11$ and log $k_0^{85°} = -3.758$. These numbers, with the $m^{\ddagger}m^*$ slope of 0.972 ± 0.018, fall on the same σ^* correlation lines as the 11 alkylnitramines studied in the previous paper (see Fig. 3 of ref. 1). This may be a coincidence, but it is certainly suggestive with respect to the interpretation of this reaction as a true acid-catalyzed decomposition.

The standard curve-fitting computer program used (18) fits all 33 perchloric acid data points simultaneously (none were rejected (1)) using 6 coefficients, 2 being equivalent to the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values (intercepts) and 1 to the m value (slope) of eq. [3] and Scheme 1, and 2 to the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ and 1 to the $m^{\ddagger}m^*$ of eq. [6] and Scheme 2; the overall fit was very good, with a root-mean-square difference of only ± 0.045 between the experimental points and the theoretical fit.

Far fewer data at only one (uncertain) temperature were available for the nitramide decomposition in hydrochloric acid (7); using only three coefficients (Scheme 1 slope and intercept, Scheme 2 intercept, slope assumed to be one) gave the fit to the HCl data indicated by the lines through the squares in Fig. 4. The Scheme 1 slope was 0.496 ± 0.018, not that different from the perchloric acid number given above, and the intercept is equivalent to a log k_0 value of -3.47, again not that different from the value of -3.65 that can be calculated from the perchloric acid data at 43°C. As can be seen from Fig. 4, the data of Marlies and La Mer (6) do not extend to high enough acidities to show an acid-catalyzed process.

Figure 4 also shows that the results obtained in sulfuric acid (7) are consistently above those obtained at the same temperature in hydrochloric acid (and in perchloric acid). Accordingly the hydrochloric acid results were used to calculate values for the overall rate constants at the sulfuric acid X values, on the assumption that the water and acid-catalysis rates should be the same in the two acids, and these were subtracted from the experimental numbers. Assuming that the resulting difference

Fig. 4. Excess acidity plots according to the mechanisms established in perchloric acid for the decomposition of nitramide in aqueous hydrochloric (6, 7) and sulfuric (7) acid media, in the latter case illustrating the reaction with sulfate ion.



represents a sulfate ion base-catalyzed process, sulfate concentrations (19) were subtracted from these and the resulting corrected log k_ψ − log $C_{SO_4^{2-}}$ values are plotted in the upper part of Fig. 4. The slope of this line is zero, which means that activity coefficient effects are unimportant, and the intercept is -3.157 ± 0.007, which means that sulfate as a base catalyst ($pK_a = 1.99$ (20)) has a catalytic coefficient of 7.0×10^{-4} M^{-1} s^{-1}, rather better than that of water ($pK_a = -1.74$), $k_{H_2O} = 3.16 \times 10^{-5}$ s^{-1} at 25°C in 55.34 M water, see above.

A deuterium NMR study of guest molecular dynamics in tris(5-acetyl-3-thienyl) methane inclusion compounds

Paul S. Sidhu, Jason Bell, Glenn H. Penner, and Kenneth R. Jeffrey

Abstract: Deuterium nuclear magnetic resonance (NMR) spectra and spin-lattice relaxation times (T_1) are used to investigate the guest molecular dynamics of tris(5-acetyl-3-thienyl) methane (TATM) inclusion compounds. The seven guests: acetonitrile, nitromethane, dimethyl sulfoxide, benzene, mesitylene, *ortho*-xylene, and *para*-xylene show a wide variety of motional behaviour. The reorientation of acetonitrile in TATM and nitromethane in TATM were both modelled as precession on a cone, the base of which is more elliptical in shape for nitromethane, as would be expected considering their molecular symmetries. DMSO in TATM does not undergo any reorientation other than methyl rotation at the temperatures investigated. At low temperatures, the ^{2}H lineshape and the deuterium spin-lattice relaxation time both depend on the rate of methyl rotation. Activation barriers of 11.7 (±0.4) kJ/mol and 11.2 (±0.5) kJ/mol were found from the two techniques, respectively. Benzene undergoes sixfold reorientation about the principal molecular axis; however, the rate is still greater than 10^8 Hz down to 113 K. The spin-lattice relaxation time profile does not reach a minimum on decreasing temperature to 112 K, while the slope of this plot provides an activation energy of 4.1 (±0.4) kJ/mol for the sixfold reorientation. The deuterium NMR spectra of mesitylene-d_9 in TATM can be simulated using a model where the guest occupies two different sites in the TATM lattice, with the guest molecules performing in-plane C_3 rotation either very rapidly ($k > 10^8$ Hz) or very slowly ($k < 10^3$ Hz), with the relative populations of each changing with temperature. Another model proposed suggests the possibility that there is a continuous distribution of motional rates, the median of which is increasing with temperature. This second model is more realistic; however, too many parameters are present to consider a detailed fit. Finally, both *o*-xylene and *p*-xylene are rigidly held in the TATM clathrate, while rotation of the methyl groups is rapid.

Key words: inclusion compounds, solid state deuterium NMR spectroscopy, molecular dynamics.

Résumé : On a utilisé les spectres de résonance magnétique nucléaire du deutérium (RMN) et les temps de relaxation spin-réseau (T_1) pour étudier la dynamique de l'invité moléculaire des composés d'inclusion du tris(5-acétyl-3-thiényl)méthane (TATM). Les sept invités (acétonitrile, nitrométhane, diméthylsulfoxyde, benzène, mésitylène, *ortho*-xylène et *para*-xylène) présentent des comportements de mouvement très différents. On a développé un modèle pour la réorientation de l'acétonitrile et du nitrométhane dans le TATM; il implique la précession sur un cône dont la forme de la base est plus ellipsoïdale dans le cas du nitrométhane, comme on pourrait s'y attendre en considérant les symétries moléculaires. Dans le TATM, aux températures étudiées, le DMSO ne subit pas de réorientation autre que la rotation du méthyle. À basses températures, la forme de la raie du ^{2}H et le temps de relaxation spin-réseau du deutérium dépendent tous les deux sur la vitesse de rotation du méthyle. Sur la base de données obtenues à l'aide de chacune de ces deux techniques, on a évalué que les barrières d'activation sont respectivement de 11,7 (±0,4) et de 11,2 (±0,5) kJ mol^{-1}. Le benzène subit une réorientation sextuple autour de l'axe moléculaire principal; toutefois, à des températures allant jusqu'à 113 K, la vitesse est encore supérieure à 10^8 Hz. Le profil du temps de relaxation spin-réseau n'atteint pas de minimum lorsqu'on abaisse la température jusqu'à 112 K; la pente de cette courbe fournit une énergie d'activation de 4,1 (±0,4) kJ mol^{-1} pour la réorientation sextuple. On peut simuler les spectres de RMN du deutérium du mésitylène-d_9 dans le TATM en faisant appel à un modèle dans lequel l'invité occupe deux sites différents dans réseau de TATM et les molécules invitées subissant des rotations C_3 dans le plan qui peuvent être très rapides ($k > 10^8$ Hz) ou très lentes ($k < 10^3$ Hz); les populations relatives de chacune varient avec la température. Un autre modèle a été proposé; il suggère la possibilité d'une distribution continue des vitesses de mouvement dont la médiane augmenterait avec la température. Ce dernier modèle est plus réaliste; toutefois, pour le moment, il manque trop de paramètres pour pouvoir considérer la possibilité d'effectuer un

[Traduit par la rédaction]

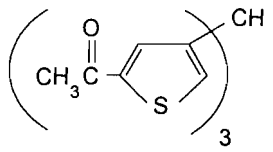
Introduction

Inclusion compounds are structures in which one type of molecule (the "host") forms cages, or cavities, in a regular or repeating pattern, on the molecular scale. In some cases, a "guest" molecule of the right dimensions is able to occupy the cages of the host, and an interaction of appreciable strength can occur (1). In general, there is a larger proportion of host to guest molecules, and the structure is held together by van der Waals forces, or in some cases by hydrogen bonding. Inclusion compounds are generally prepared by dissolving the solid host in a solution of the guest, with subsequent slow evaporation of the excess solvent. The enclathrated guest molecule generally experiences considerable motional freedom in its cage. These dynamics can be investigated through a number of techniques, such as deuterium NMR spectroscopy (2, 3), ^{13}C CP/MAS (magic angle spinning) NMR (4, 5), relaxation time measurements (6, 7), X-ray crystallography (8, 9), and differential scanning calorimetry (10, 11). The study of the dynamics of a guest molecule in a clathrate compound provides insight into the guest–host interaction. For example, when they involve hydrogen bonding, the potential for rotation is undoubtedly hindered. These intermolecular forces are important because they determine the stability (or instability) of the inclusion compound.

In the last decade, deuterium NMR has become a very popular technique for the study of dynamic processes in the solid state (12). This method makes possible the investigation of different motional modes occurring over a wide range of rates of reorientation. Dynamic processes occurring with rates in the range 10^3–10^8 Hz (i.e., when the motional rate is comparable in magnitude to the deuterium quadrupolar coupling constant) can be studied by lineshape analysis of the deuterium NMR spectrum of a polycrystalline powder (13). For motion on the order of, and greater than, 10^8 Hz (when the rate approximates the deuterium Larmor precession frequency), the lineshapes become independent of the exchange rate, and an analysis of the deuterium spin-lattice relaxation time as a function of temperature is used to discriminate among the types and rates of motion (14). With the availability of computer programs (15) capable of simulating ^2H lineshapes as a function of motional rates, molecular geometry, and dynamic models, deuterium NMR spectroscopy has developed into an excellent probe for the study of dynamic processes. In addition, selective deuteration of the deuterium isotopomer at specific sites in the molecule makes this technique even more attractive (16).

In this paper, the molecular motion of seven guest molecules: acetonitrile, nitromethane, dimethyl sulfoxide, mesitylene, benzene, *o*-xylene, and *p*-xylene, in the host tris(5-acetyl-3-thienyl) methane are studied.

Tris(5-acetyl-3-thienyl) methane (TATM), **1**, was first synthesized by Yakubov et al. in 1973, from 2-acetyl thiophene and chloroform, in the presence of excess aluminum chloride. It was also noted that TATM forms inclusion compounds on recrystallization from various solvents (17). In 1977, Bin Din and Meth-Cohn found that TATM forms 2:1 host:guest clathrates with a wide variety of organic compounds (18). The guest molecules reside in cavities formed by the TATM molecules. Furthermore, their study, to that point in time, failed to reveal a solvent that was not incorporated. Although the pure host compound melts at about 55°C, TATM inclusion compounds generally melt at temperatures above 100°C.



1

Recently, four crystal structures of TATM with various guests have been reported (19–22). In the presence of guest molecules, the TATM molecules generally take up a lattice of triclinic symmetry. In each of the crystal structures, there was only one guest molecule per unit cell. In addition, their inability to precisely identify the positions of the guest atom led them to conclude that the guest molecules are disordered. The TATM molecules form cavities of different sizes and shapes, depending on the guest molecule included. To the best of our knowledge, no further studies on TATM inclusion compounds have been reported.

Theoretical background

Solid state deuterium NMR spectroscopy is one of the principal techniques used to study guest motion in inclusion compounds. Deuterium (nuclear spin $I = 1$) has a nuclear quadrupole moment, and it is the interaction of this moment with the electric field gradient arising from the surrounding charge distribution that gives rise to the quadrupolar coupling.

In a typical deuterium NMR experiment, the external applied magnetic field strength, and therefore the nuclear Zeeman interaction, is sufficiently strong that the quadrupole interaction may be treated as a perturbation. The resulting NMR spectrum is a doublet symmetrically placed about the Larmor frequency with a quadrupole splitting of

$$[1] \quad \Delta\nu_Q = \frac{3e^2qQ}{4h}(3\cos^2\beta - 1 + \eta\sin^2\beta\cos 2\alpha)$$

The electric field gradient (EFG) in the principal axis system (PAS) is described in terms of its principal component eq and the asymmetry parameter η, where

$$[2] \quad eq = \partial^2V/\partial z^2$$

and

$$[3] \quad \eta = (\partial^2V/\partial x^2 - \partial^2V/\partial y^2) / \partial^2V/\partial z^2$$

V is the electric potential at the nucleus, while the quantity eQ

is the magnitude of the nuclear quadrupole moment. The angles α and β describe the orientation of the PAS in the laboratory frame of reference defined by the applied magnetic field. In aliphatic compounds, the electric field gradients are usually axially symmetric ($\eta = 0$) about the bond axis, with coupling constants given by $\chi = e^2qQ/h = 170$ kHz. In aromatics, the EFGs are slightly asymmetric, with $\eta \sim 0.05$ and coupling constants $\chi = e^2qQ/h = 185$ kHz are typical.

In a powder, the C—D bonds are randomly distributed, and the resulting spectrum is a superposition of doublets corresponding to the many possible bond directions. The resulting powder pattern, often referred to as a "Pake doublet," has two 90° orientation spikes that are separated by $3e^2qQ/4h$.

If molecular motion occurs, the angles α and β become time dependent. In an isotropic system, the average quadrupolar interaction is zero, and a single spectral line at the Larmor frequency is observed. To consider the effects of molecular motion in an anisotropic environment, it is convenient to use two transformations of coordinates. The first transforms from the PAS to a conveniently defined time-independent intermediate frame, while the second transforms from the intermediate frame to the lab frame. The intermediate frame is chosen so that its z-axis coincides with an axis of motional symmetry. In a powder sample, the observed spectrum will reveal the influence of both the motion about axes of motional symmetry and the random orientation of these axes in the laboratory frame. Motional narrowing occurs when the rate of motion, k, is greater than the quadrupole coupling constant. When the motional rates are of the order of the QCC, the lineshapes cannot easily be predicted analytically, and are highly sensitive to the reorientation rate and the details of the motional process. Fortunately, elaborate computer programs, such as MXQET (15), have been developed to simulate deuterium quadrupolar split powder patterns in this intermediate regime.

The simplest type of motion involves exchange of a deuterium nucleus between three or more equivalent sites. In the fast rate limit, the asymmetry parameter averages to zero, and the spectrum is compressed by a factor of $\frac{1}{2}(3\cos^2\theta - 1)$, where θ is the angle between the X—D bond and the rotation axis. In between the two extremes, a slow evolution of the spectrum from one form to the other is observed. Examples include three-site exchange of the deuterons in a methyl group (14) ($\theta = 70.5°$), and in-plane six-site exchange of the deuterons on a benzene ring (23) ($\theta = 90°$).

An example of asymmetric motion is exchange of a deuteron between only two equivalent sites. When $k > 10^8$ Hz, a non-zero asymmetry parameter is observed. For instance, consider the two-site exchange of the *ortho* and *meta* deuterons of a monosubstituted benzene ring (24) ($\theta = 60°$). The effective asymmetry parameter η and the quadrupolar coupling constant χ in the averaged spectrum depend on the angle θ for the motion involved (25).

Enclathrated guest molecules often undergo a precessional type of motion. It can be thought of as rotation of the principal symmetry axis on a cone, which may have a circular or elliptical shape. This type of motion usually has a very small activation energy, and is only encountered in the fast rate limit at working temperatures. The motion can most simply be broken down into two components: precession on a circular cone and a two-site libration (26).

A further complicating factor in considering the motion of guest molecules is the possibility of unequal populations of the sites taken up by the exchanging deuterium nucleus (27). Since this leads to more or less preferred orientations for the guest, it introduces asymmetry into the powder spectrum. The justification for unequal populations can be either a non-uniform guest–host interaction, or when a rotation axis is not a symmetry axis.

The quadrupolar interaction and the molecular reorientation also determine the deuterium spin-lattice relaxation rate, which can be written as (in the case where the static EFG is axially symmetric)

$$[4] \quad \frac{1}{T_1} = \frac{3\pi^2}{10}\left(\frac{eqQ}{h}\right)^2 [J_1(\omega_0) + 4J_2(2\omega_0)]$$

The influence of the molecular motion is contained in the spectral density functions, J_1 and J_2, which are defined with respect to the direction of the applied magnetic field. Torchia and Szabo have derived expressions for the spectral density functions encompassing a wide variety of models of molecular reorientation (14). It is often convenient to assume that the correlation function describing the motion is exponential, and to analyze T_1 data using the general BPP (Lorentzian) spectral density functions (28). The resulting equation is

$$[5] \quad \frac{1}{T_1} = K\left[\frac{\tau_c}{1 + \omega_0^2\tau_c^2} + \frac{4\tau_c}{1 + 4\omega_0^2\tau_c^2}\right]$$

K is a constant that depends on the static quadrupolar coupling constant and the mode of molecular reorientation, while ω_0 is the Larmor precession frequency. The use of this equation is really an oversimplification, which averages over any angular dependence of the spin-lattice relaxation. Assuming that the molecular motion is a rate-activated process

$$[6] \quad \tau_c = \tau_\infty \exp(E_a/RT)$$

In this equation, τ_c is interpreted as the correlation time for the motion ($\tau_c \propto k^{-1}$), τ_∞ is the correlation time at infinite temperature, and E_a is the activation energy for the motion causing modulation of T_1.

Experimental

TATM was prepared according to the method of Yakubov et al. (17). 2-Acetyl thiophene and chloroform (6.2 equivalents) were refluxed for 24 h, in the presence of excess aluminum chloride (2.5 equivalents). After refluxing, 10% HCl was added to dissolve the remaining $AlCl_3$. The TATM was then extracted with chloroform, and the organic phase was washed with saturated NaCl aqueous solution. Following this procedure, the organic phase was dried, filtered, and excess $CHCl_3$ was removed by rotary evaporation. The resulting plaque was then recrystallized from ethanol. Finally, heating under vacuum for 12 h at 130°C removed enclathrated ethanol. The resulting amorphous solid was ground to yield an orange powder that had a broad melting point range of 52–58°C. The purity was confirmed by solution NMR.

Mesitylene-d_9 was prepared according to a literature procedure (29), which involved refluxing 10 mL of dry DMSO-d_6 with mesitylene (5 mL), for 24 h at 100°C, in the presence of sodium hydride (0.5 g). The reaction mixture was washed with

D_2O, and then with ordinary water. Finally, the organic layer was dried over sodium. The extent of deuteration of the methyl groups, approximately 67%, was determined by ^1H and ^2H NMR. All other deuterated guest compounds were obtained commercially (Aldrich).

Inclusion compounds were prepared by dissolving approx. 200 mg of the host solid in 2–3 mL of the deuterated guest, followed by slow evaporation. Verification of inclusion was done by ^1H NMR of isotopically normal dissolved inclusion compound. Samples were packed in 5 mm o.d. NMR tubes that had been cut to lengths of 2–3 cm.

The deuterium spectra and spin-lattice relaxation times were determined using a home-built, phase-coherent pulsed NMR spectrometer operating at 44.7 MHz. The spectrometer was used with a 50 mm bore, 6.1 T (Bruker/Nalorac) superconducting magnet. The nuclear signal was digitized in a Nicolet Explorer digital oscilliscope, which was interfaced to an IBM/pc. The computer was programmed to provide automatic temperature regulation for the sample and data acquisition. The sample probe was designed to study powder samples over a temperature range of −160 to 200°C. The sample chamber was surrounded by a thick-walled copper container. Channels had been milled into the copper vessel, and cold N_2 gas was passed through these, to cool the sample chamber. The temperature of the sample was electronically regulated to within ±0.1°C over the course of a measurement by a heater wound nonconductively on the copper vessel and a copper–constantan thermocouple attached to it. A second separate thermocouple located near the sample itself was used to record the actual sample temperature, which was known to within ±0.5°C.

The deuterium NMR spectra were obtained using the quadrupolar echo pulse sequence (30): $(\pi/2)_{\pm x}$–τ_Q–$(\pi/2)_y$–τ_Q–acquire. The length of the $\pi/2$ pulses were approximately 3.5 μs. At each temperature, the echo signals were collected using a τ_Q value of 50 μs, and the echo signals were Fourier transformed, after applying a linebroadening of 100 Hz, to obtain the spectra. To obtain symmetric spectra the signal collected in the imaginary channel was set to zero before Fourier transformation. Between 400 and 1000 scans were acquired and coadded for each spectrum.

The deuterium T_1 data were acquired using an inversion recovery pulse sequence modified for quadrupolar nuclei: $(\pi)_x$–τ–$(\pi/2)_{\pm x}$–τ_Q–$(\pi/2)_y$–τ_Q–acquire. Typically, 12 values of τ were used to determine T_1 at each temperature. The pulse spacing, τ_Q, for the T_1 determination was 50 μs. The time between repetitions of the pulse sequence was always greater than $5T_1$. The amplitude of the signal for each τ value was determined from the integral over the echo peak. These echo integrals were fit using a nonlinear least-squares algorithm employing an exponential fitting function to obtain the relevant relaxation time parameters.

Lineshape simulations of quadrupolar echo spectra were carried out by standard methods using the program MXQET (15). Simulated spectra were visually matched to experimental lineshapes. These simulations took into account the effects of finite pulses and the pulse spacing, τ_Q.

Results and discussion

Acetonitrile–TATM and nitromethane–TATM

Acetonitrile and nitromethane are two guest molecules of TATM somewhat related in that their respective dynamic characteristics are similar. The deuterium NMR powder spectra, along with simulations, for acetonitrile-d_3–TATM and nitromethane-d_3–TATM are presented in Figs. 1 and 2 respectively. It is clearly evident, from the observed spectral averaging, that they both exhibit methyl rotation with rates greater than 10^8 Hz, down to 173 K.

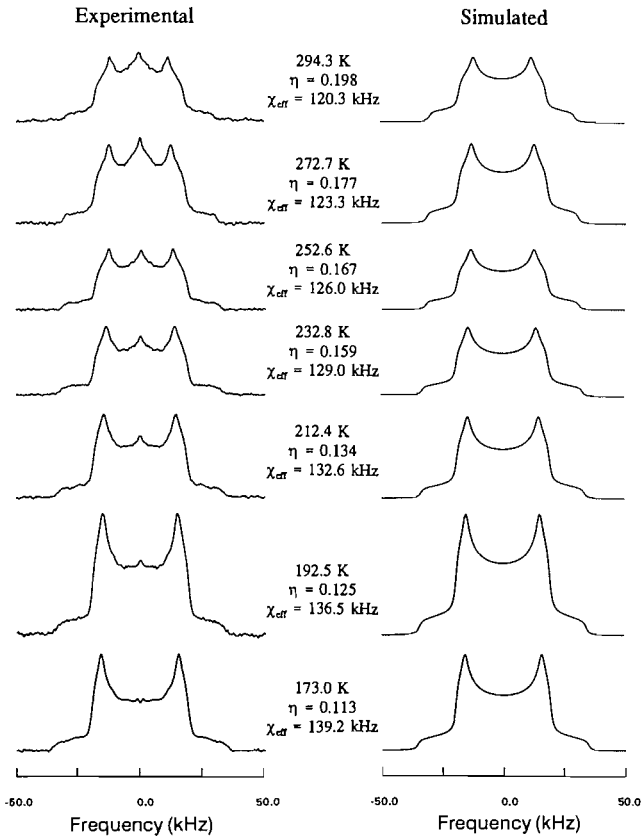


Fig. 1. Deuterium NMR spectra for the acetonitrile-d_3–TATM inclusion compound, at various temperatures, together with simulations.

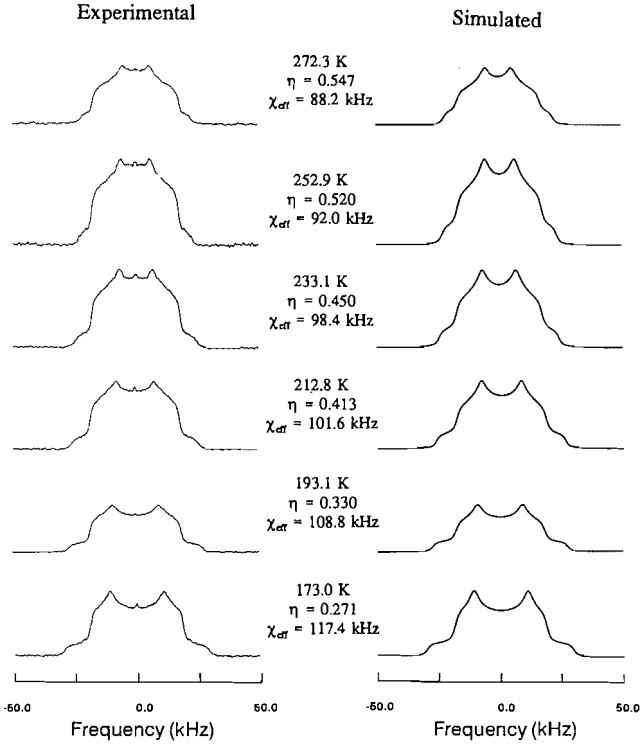
The other type of common motion is precession of the principal molecular symmetry axis, which affects both χ_{eff} and η_{eff}. Although the precessional motion is best described as diffusion within a cone, where the possible angles, ψ, are governed by a distribution function $g(\psi)$, a simpler model was used, in which the molecule is allowed to precess about a cone of half-angle ψ.

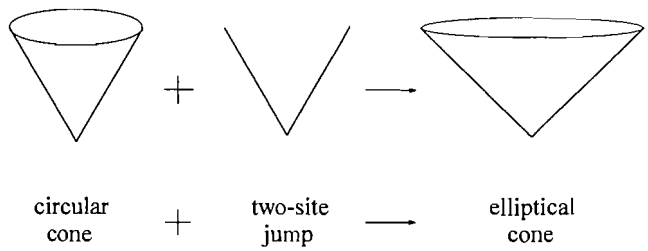
Many guest molecules in inclusion compounds undergo this type of precessional motion. A more realistic description of the reorientation would be a small-amplitude whole-body librational motion, but the model of precession employed here gives a simple analytical model. The precession can be thought of as a rotation of the principal symmetry axis on a cone, the base of which is either circular or elliptical. This type of motion has a very small activation energy, and the rate of reorientation is usually of the same order as the rate of vibrational motion of a molecule inside a potential energy well, about 10^{12} Hz.

The motion can be broken down into two components, precession on a circular cone (corresponding to the angle θ), and a two-site libration (the magnitude of which is proportional to

Fig. 2. Deuterium NMR spectra for the nitromethane-d_3–TATM inclusion compound, at various temperatures, together with simulations.



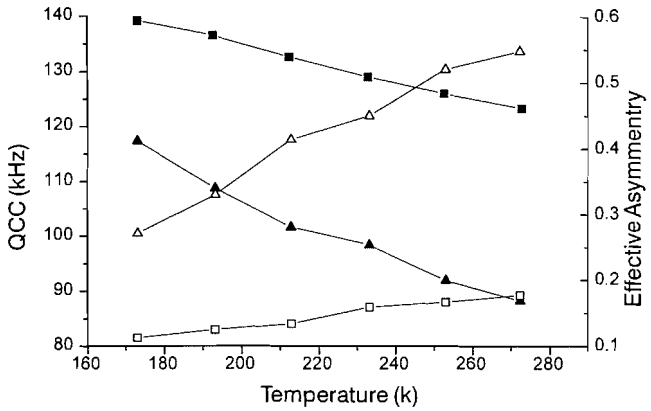
Scheme 1.



the angle ϕ), which transforms the circular base cone into an elliptical cone (see Scheme 1). In the elliptical case, the precession leads to a non-zero asymmetry parameter, since it is motion in a preferred direction.

We calculated the matching ^{2}H NMR simulations by allowing the guest molecule to reorient between two sites ϕ degrees apart. On top of this, we incorporate the circular cone wobble by simply using a motionally averaged effective quadrupolar coupling constant, and calculating the angle θ from $\chi_{eff}/\chi_{static} = (3\cos^2\theta - 1)/2$. Rather than reporting the angles θ and ϕ at each temperature, we have chosen to present values of the spectral asymmetry η (proportional to ϕ) and the effective quadrupolar coupling constant (inversely proportional to ϕ), as these parameters can be measured easily from the deuterium powder spectrum. From simulations, we were able to extract the angles θ and ϕ, for both guests, at each temperature. As mentioned before, the angle ϕ is directly proportional to the spectral asymmetry observed, while the angles θ and ϕ together determine the averaging of χ_{eff} observed in the experimental ^{2}H powder spectrum. In Fig. 3, we plot the effective asymmetry parameter, η_{eff}, and

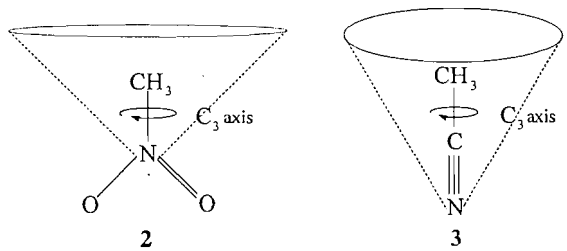
Fig. 3. Graph of the effective asymmetry, η_{eff}, and the effective quadrupole coupling constant, χ_{eff}, as a function of temperature, for TATM guests acetonitrile and nitromethane. The lines serve as a guide to the eye. Legend: η(acetonitrile) : open square; η(nitromethane) : open triangle; χ(acetonitrile) : filled square; χ(nitromethane) : filled triangle.



the effective quadrupole coupling constant, χ_{eff}, for each guest, as a function of temperature.

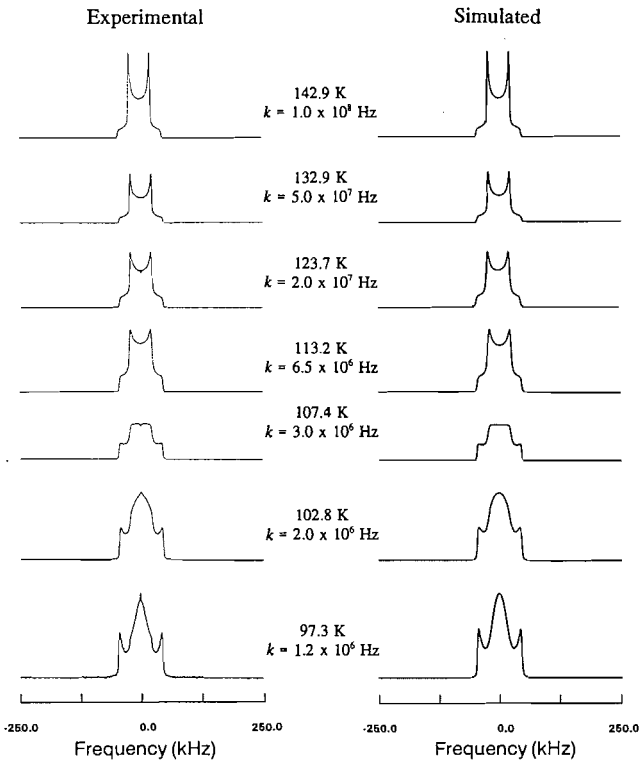
A number of trends are evident from Fig. 3. First, the effective asymmetry parameter observed for nitromethane-d_3–TATM is greater than that for acetonitrile-d_3–TATM, at all temperatures studied. This suggests that the cone on which nitromethane precesses, **2**, is much more elliptical than that for acetonitrile, **3**. This is to be expected, based on a comparison of their molecular symmetries. Nitromethane would prefer to librate parallel to the NO_2 plane, because a parallel libration minimizes the motion of the oxygen atoms, compared to a perpendicular libration. Acetonitrile, with its axial symmetry, should show no preferred precessional direction. The reason that the spectra of acetonitrile show some asymmetry (note that $\eta \propto \phi$), is due to its non-uniform interaction with a TATM cavity of low symmetry.

Nitromethane: Acetonitrile:



As far as the effective quadrupole coupling constants are concerned, Fig. 3 shows that χ_{eff} is much greater for acetonitrile (than nitromethane) at all temperatures investigated. This is a surprising result, as one would have expected acetonitrile, being a smaller molecule than nitromethane, to show more motional averaging (i.e., a smaller effective quadrupole coupling constant). Therefore, this trend may instead be due to the size, or symmetry, of the host's cavity. In the four determinations of crystal structures from X-ray diffraction available for TATM inclusion compounds, the shape of the host cavity is different for each of the four included guests (19–22). If the TATM cavity formed to enclose nitromethane is larger than

Fig. 4. Simulated and experimental ^2H NMR spectra for dimethyl sulfoxide-d_6 in the TATM inclusion compound, at the temperatures indicated. The threefold flipping rates determined from the simulations are also given.

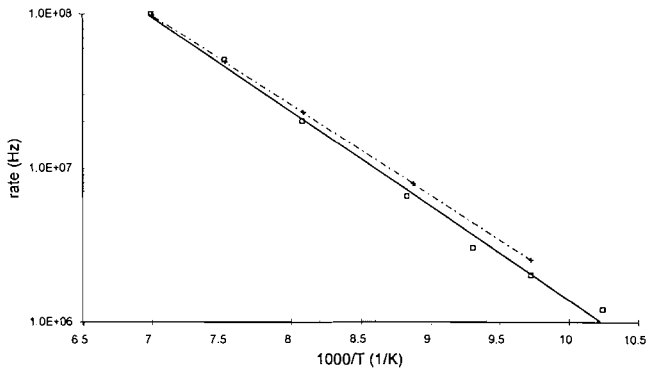


that to enclose acetonitrile, nitro-methane would be more easily able to engage in large-amplitude librational motions. This would spectrally manifest itself as a smaller effective quadrupole coupling constant for nitro-methane, which is observed experimentally. In addition, from X-ray crystallographic data, it was noted that the TATM molecules were unable to completely enclose benzene in the benzene–TATM inclusion compound (20). Thus TATM may not only form a larger host cavity for nitromethane, but it may instead be unable to completely enclose the nitromethane guest, which would again result in greater molecular motion, and consequently a smaller effective quadrupole coupling constant.

Dimethyl sulfoxide – TATM

The deuterium NMR powder spectra of dimethyl sulfoxide-d_6 in the TATM inclusion compound are presented in Fig. 4, along with simulations. The spectrum at room temperature is a Pake doublet with an effective quadrupolar coupling constant $\chi_{eff} = 51.3$ kHz. This implies that the motion giving rise to lineshape changes below 143 K is internal rotation of the methyl groups of DMSO. Indeed, the ^2H NMR spectra were simulated on the basis of this model. The rate of methyl rotation is indicated along with each spectrum in Fig. 4. Note that we were only able to obtain spectra down to a rate of 1.2×10^6 Hz (at 97.3 K). Below this temperature, in the intermediate exchange regime, the intensity of the echo becomes very weak, as the *effective* transverse relaxation time approaches the magnitude of the interpulse spacing (50 μs) in the quadrupole echo pulse sequence. This precluded the acquisition of spectra below 97

Fig. 5. A plot of the rate of internal rotation of the methyl groups of dimethyl sulfoxide in TATM, determined independently from ^2H NMR spectra and deuterium-spin lattice relaxation time data. A best fit solid line for the ^2H NMR spectral data is included. The dotted line joins the T_1 data points. Legend: open square: ^2H NMR spectral data; asterisk: spin-lattice relaxation time data.



K. By plotting ln k vs. $1000/T$ (Fig. 5), we calculate an activation barrier to methyl rotation of 11.7 (±0.4) kJ/mol. This compares to an activation energy of 12.0 kJ/mol determined for dimethyl sulfoxide in the gas phase (31). In the solid state, the two methyl groups of pure DMSO are crystallographically and dynamically inequivalent (32). It was determined from variable temperature proton spin-lattice relaxation times that the activation energy for the C_3 rotation of one methyl group was 13.3 kJ/mol ($\tau_\infty = 5.6 \times 10^{-13}$ s), while the other methyl group had a significantly higher activation barrier of 21.7 kJ/mol ($\tau_\infty = 6.8 \times 10^{-14}$ s) (33). In the TATM inclusion compound and in the gas phase, the activation energy is determined primarily by intramolecular interactions, whereas in the pure solid the rotation of one of the methyl groups must be significantly hindered by intermolecular forces.

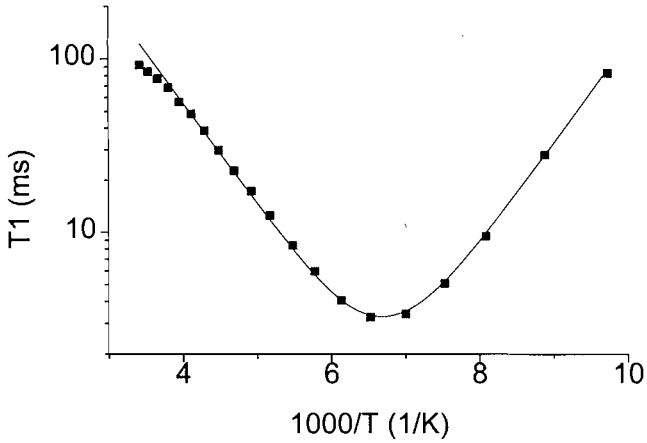
In addition, note that the spectrum at 142.9 K has an effective asymmetry parameter $\eta_{eff} = 0$. This implies that the methyl groups are not distorted from tetrahedral geometry, in contrast to acetone in TATM, where the dihedral angle between two of the deuterons goes from 120° to 124°, giving rise to an asymmetry parameter $\eta = 0.14$, when the methyl rotation rate is in the fast rate limit (34).

From the deuterium NMR spectra, there seems to be no motion other than methyl rotation present that is causing modulation of the lineshape. This again is in contrast to acetone in the same host, where the guest was observed to undergo twofold flips about the carbonyl bond (34). The lack of a similar motion in DMSO may be due to the fact that dimethyl sulfoxide is much larger than acetone. Therefore, DMSO would likely interact more strongly with the TATM host molecules, and be more restricted in its motion.

The spin-lattice relaxation time data for dimethyl sulfoxide-d_6 in TATM appears in Fig. 6. Only one minimum is observed, due to the internal rotation of the methyl groups. Proof of this statement comes from a consideration of the activation energy determined from the best-fit curve, which is 11.2 (±0.5) kJ/mol, as compared to 11.7 (±0.4) kJ/mol determined from ^2H spectral simulations. The correlation time at infinite temperature is 2.7×10^{-13} s, and the constant K (see eq. [5]) is approximately 8×10^{10} s^{-2}.

It is possible to derive explicit expressions for T_1 and the

Fig. 6. Deuterium spin-lattice relaxation times for perdeuterated dimethyl sulfoxide, in TATM, plotted against 1000/*T*. From the best fit curve, a barrier to rotation of 11.2 (±0.5) kJ/mol was determined.



spin-lattice relaxation time minimum value by considering the situation where a C—D bond can jump between three equivalent sites. The expression for T_1 is (14):

$$[7]\quad 1/T_1 = (\omega_Q^2/8)\{g(\tau_c,\omega_0)[A_1B_4 + A_2B_5 - 8A_3B_3\cos 3\phi] + g(\tau_c,2\omega_0)[4A_1B_5 + A_2B_6 + 8A_3B_3\cos 3\phi]\}$$

where $\tau_c = (3k)^{-1}$, ω_0 is the deuterium Larmor precession frequency, and $\omega_Q = 3\chi/4$. The angles θ and ϕ describe the orientation of the static magnetic field in the crystal-fixed axis system. The C–D bond makes an angle Θ with respect to the C_3 rotational axis. The angular functions A_i and B_i depend on θ and Θ, and are given in ref. 14. It is the cos 3ϕ term in eq. [7] that, in principle, leads to non-exponential recovery of the magnetization; however, this effect is small, and it is reasonable to average over the angles θ and ϕ. The angle Θ is set to 109.5°, the tetrahedral angle. This leads to:

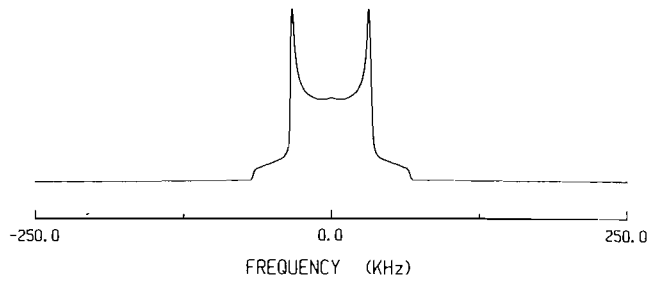
$$[8]\quad \frac{1}{T_1} = \frac{\chi^2}{15}\left[\frac{\tau_c}{1+\omega_0^2\tau_c^2} + \frac{4\tau_c}{1+4\omega_0^2\tau_c^2}\right]$$

Thus, the constant K in eq. [5] is given by $\chi^2/15$. Using the value of K from the T_1 fit of 8×10^{10} s^{-2}, we calculate that the static quadrupolar coupling constant should be about 174 kHz (for Θ = 109.5°). If the angle between the C—D bond and the threefold axis is increased to 111.5°, the calculated value for χ would increase to approximately 178 kHz, in good agreement with the experimental value, determined from the splitting of the deuterium NMR spectrum, as 178.2 kHz. This compares with a static deuterium quadrupole coupling constant of 177 kHz determined for DMSO-d_6 in the DMSO–kaolinite intercalation compound, obtained from ^{2}H solid state NMR spectra (35).

In addition, the value of the T_1 minimum is given (36) by:

$$[9]\quad \frac{1}{T_{1\min}} = \frac{1.42}{15}\times\frac{\chi^2}{\omega_0}$$

Fig. 7. Deuterium NMR spectrum of benzene-d_6 in the TATM inclusion compound at 294 K.



If we use the experimental value of 178.2 kHz for the quadrupolar coupling constant, and the deuterium spectrometer frequency of 44.667 MHz, the value of T_1 at the minimum should be about 2.2 ms. This compares with the experimental value of 3.2 ms at about 148 K. The DMSO-d_6 guest in the kaolinite intercalate was found to go through a T_1 minimum of approximately 7.2 ms, around 205 K (35).

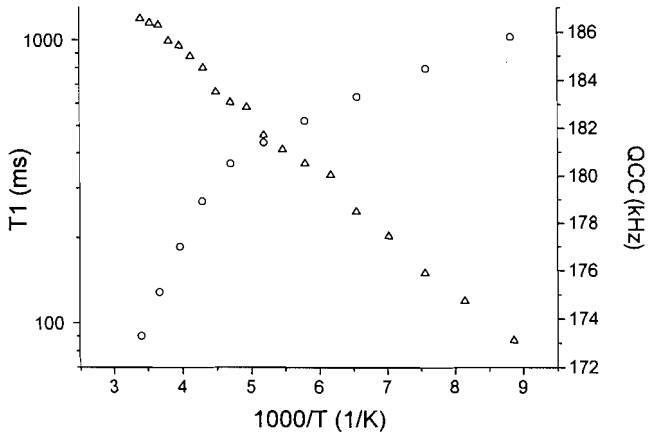
It would be useful to compare the motion of DMSO-d_6 in TATM with that of pure dimethyl sulfone, $SO_2(CH_3)_2$. It is known that dimethyl sulfone, with its tetrahedral geometry, undergoes jumps about its unique C_2 axis to exchange the two methyl groups and the two oxygens, respectively (37). In comparison, DMSO is a molecule of much lower symmetry (C_s). It has no proper axis of symmetry about which to reorient. This is accompanied by a lack of motion, to the best of our knowledge, of the DMSO molecule in TATM, other than methyl rotation, at the temperatures investigated. The activation energy for methyl rotation in dimethyl sulfone was found from ^{1}H spin-lattice relaxation time measurements to be 17.0 kJ/mol ($\tau_\infty = 1.5 \times 10^{-13}$ s) (38).

Benzene–TATM

The room temperature deuterium spectrum of benzene-d_6, in the TATM inclusion compound, is shown in Fig. 7, and it indicates that the benzene molecules are likely performing in-plane 60° jumps about the molecular C_6 axis. This type of reorientation results in a ^{2}H spectrum that is 50% of the width of the static spectrum (i.e., ½(3 cos$^2\theta$ − 1) = 0.50), with no change in lineshape ($\theta \sim 90°$). The appearance of the spectrum does not change from room temperature down to 113 K, suggesting that the sixfold reorientation is proceeding at a rate greater than 10^8 Hz to the lowest temperature measured. The populations of the six sites are equal, as they must be by the symmetry of the guest molecule. However, χ_{eff} is 86.8 kHz at room temperature and 92.9 kHz at the lowest temperature measured (113 K). This suggests that the benzene molecules are engaged in small-amplitude librational motions while in the TATM cavity, to cause further spectral averaging on top of the C_6 reorientation. The experimental value of χ_{static} at 113 K is 185.8 kHz, which is a typical value for a static aromatic deuteron. The value of the static quadrupole coupling constant as a function of inverse temperature is depicted in Fig. 8. At low temperatures, the graph is becoming flat, suggesting that the precessional motion is being frozen out.

The deuterium spin-lattice relaxation times for benzene-d_6–TATM also appear in Fig. 8. Notice that the T_1 curve does not reach a minimum down to the lowest temperature measured. The motion is always in the extreme narrowing limit (i.e., $\omega_0\tau_c$

Fig. 8. Graph of ^2H spin-lattice relaxation time for the benzene-d_6–TATM clathrate, along with the effective quadrupole coupling constant at each temperature.



<< 1.) This complements the ^2H spectral data, as it indicates that the rate of sixfold rotation is likely larger than the Larmor precession frequency ($\sim 4 \times 10^7$ Hz) down to 115 K. The lack of a T_1 minimum precluded us from performing a complete T_1 fit; however, the slope of the curve provided us with an activation energy of 4.1 (±0.4) kJ/mol for the C_6 rotation of benzene-d_6 in TATM. This compares with an activation energy of 16.5 kJ/mol (39) and 16.8 kJ/mol (40), for pure, solid benzene, determined from ^2H powder NMR and relaxation time measurements, respectively. When benzene is in an inclusion compound, E_a varies from 4.0 kJ/mol in the tri-*ortho*-thymotide clathrate (41), to 24.9 kJ/mol in 1,3-cyclohexanedione (39). A consequence of the very low activation barrier for the reorientation of benzene in TATM is that we were unable to slow the reorientation rate below even 10^8 Hz down to 113 K.

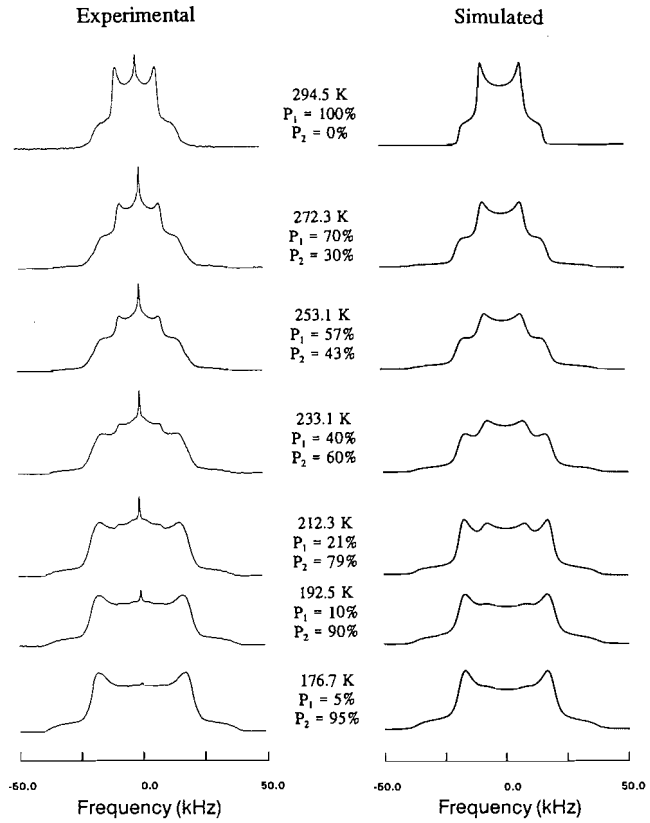
An X-ray determination of the crystal structure was performed on benzene–TATM (20). This study indicated that the TATM thienyl rings did not completely enclose the benzene molecule, as they do for ethanol, hexane, and ethyl acetate (19, 21, 22), where the thienyl rings form globular cavities in which the guest resides. The inability of TATM to completely surround the benzene guest may give an indication of why the benzene–TATM activation energy is very low compared to most other studies of the dynamics of benzene.

Mesitylene–TATM

The ^2H NMR spectra of mesitylene-d_9 (deuterated on the methyl groups) in TATM appear in Fig. 9. It is expected that mesitylene (1,3,5-trimethyl benzene) would reorient by 120° in plane rotational jumps to exchange the methyl groups about the molecular C_3 axis. However, this type of motion (or 60° jumps for that matter) leads to simulations that do not match the experimental spectra at intermediate rates (10^4–10^6 Hz).

A model that may be considered is that there are two dynamically distinct types of mesitylene molecules. One is performing C_3 rotation at a rate that is fast on the ^2H spectral time scale ($k > 10^8$ Hz), and the other is rotating slowly ($k < 10^3$ Hz). There are no mesitylene molecules in the intermediate exchange region. This model would require the existence of two different sites in the TATM lattice. The proportion of these two sites (and hence the ratio of the two dynamically different types of mesitylene molecules) is changing with temperature. At high temperatures, most of the mesitylene molecules are moving rapidly, while at the lowest temperature the majority are in the rigid lattice limit. The percentage of molecules moving rapidly (P_1), and the percentage moving slowly (P_2), at each temperature, are indicated with the simulations in Fig. 9. Note that this model contradicts information obtained for other TATM inclusion compounds, by X-ray crystallography, which suggests that there is only one guest molecule per unit cell in all four TATM inclusion compounds investigated to this point.

Fig. 9. Simulated and experimental ^2H NMR spectra for mesitylene-d_9 in the TATM inclusion compound, at the temperatures indicated, along with the percent populations of fast moving (P_1) and slow moving (P_2) mesitylene molecules.



However, it is important to note that this model is the simplest one we could consider. There may be a continuous distribution of jump rates. The molecules that are performing C_3 rotation at rates between approximately 10^4 Hz and 10^6 Hz would contribute very little to the overall spectral intensity, compared to the molecules rotating rapidly or slowly, due to the fact that the echo intensity is attenuated considerably for molecules in the intermediate exchange region. This model is physically more reasonable, because small differences in the guest–host interaction from one cavity to the next could result in a distribution of motional rates. In Fig. 10, the normalized echo intensity is plotted as a function of jump rate, calculated for in-plane 120° jumps of the mesitylene molecule. It can be seen that the echo (and thus spectrum) intensity, at 5×10^4 Hz, falls to only 15% of that at very fast C_3 motional rates. Therefore there would be very little contribution to the spectral

Fig. 10. Plot of normalized echo intensity, as a function of jump rate, calculated for in-plane C_3 rotation of a mesitylene molecule.

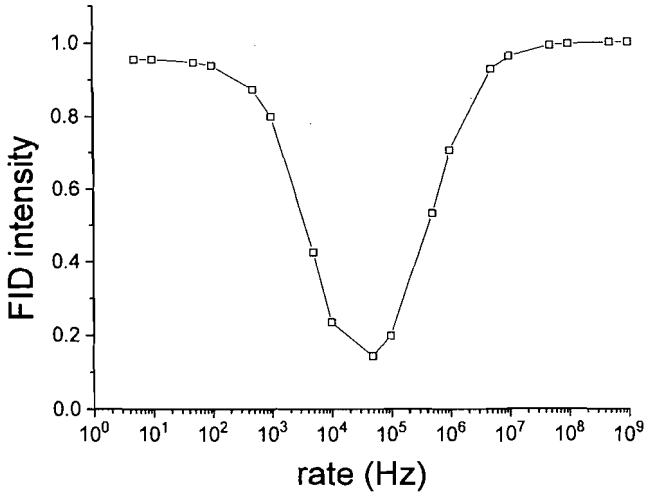


Fig. 11. Simulated ^{2}H spectra for C_3 rotation of a mesitylene molecule, with an equal population distribution over five rates, weighted by the echo attenuation at each rate.

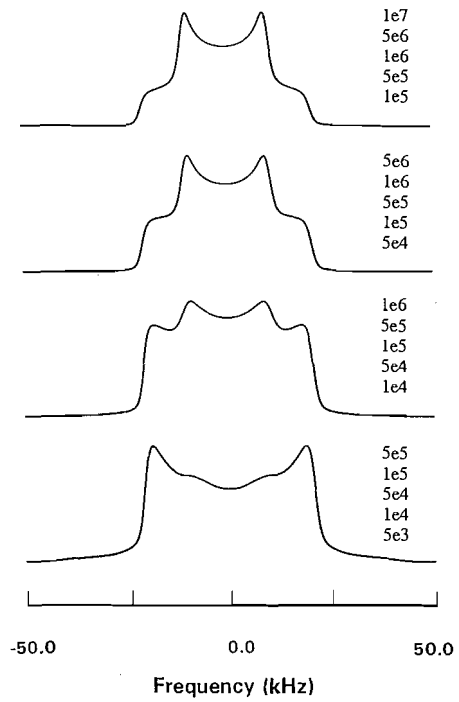
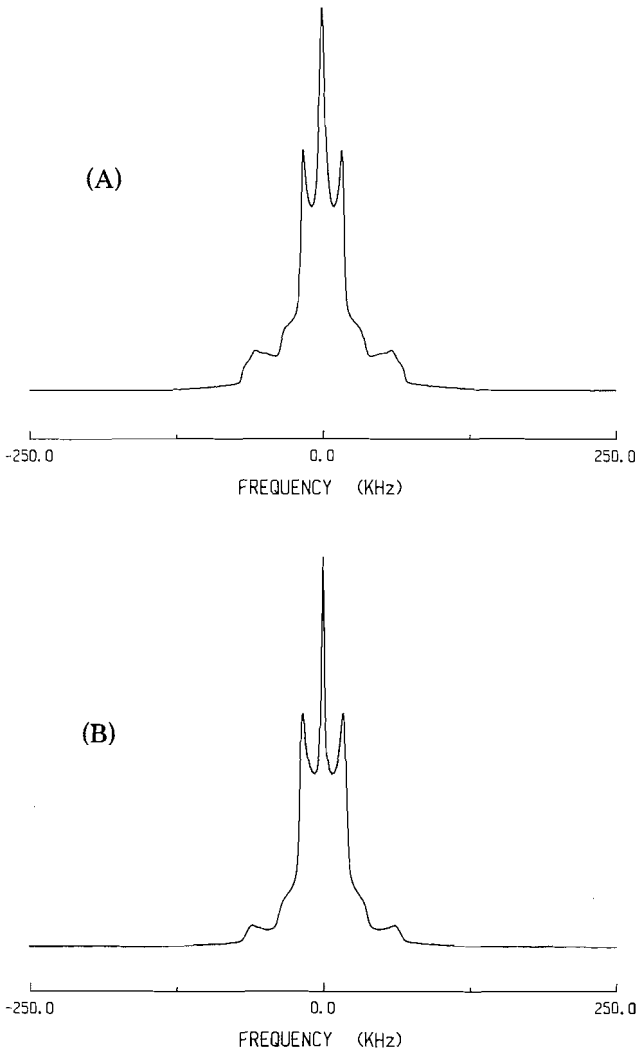


intensity at intermediate rates, where the agreement between simulated and experimental spectra is at its weakest. It would seem instructive to investigate this matter further.

In Fig. 11, we present simulations based on equal populations of mesitylene molecules over five rates, with the distribution slowly changing from faster rates to slower rates (corresponding to a decrease in temperature). Although the populations of the five sites/rates are equal in each spectrum (as indicated in the figure), the contributing spectra have been properly weighted according to the attenuation of the echo intensity at intermediate rates. By comparing these simulations with the experimental spectra in Fig. 9, it can be seen that

Fig. 12. *A*: Experimental ^{2}H NMR spectrum for *o*-xylene-d_{10}–TATM at room temperature. *B*: Experimental ^{2}H NMR spectrum for *p*-xylene-d_{10}–TATM at room temperature.



the agreement is quite good. This model is somewhat more elaborate than the one described above, but it is more realistic to consider the population distribution as Gaussian, rather than the rectangular one we have chosen. However, there are simply too many variables to consider a detailed lineshape fit with this scheme.

ortho-Xylene–TATM

The ^{2}H spectrum of *o*-xylene-d_{10} (*o*-dimethylbenzene) in the TATM inclusion compound, at room temperature, is depicted in Fig. 12*A*. Note that there are two spectral components, aside from the isotropic-type line at zero frequency. The inner component (χ_{eff} = 47.4 kHz) is typical of methyl groups that are undergoing fast methyl rotation. Because χ_{eff} is less than 56.7 kHz, the guest molecule is probably undergoing a librational motion, of half angle $\theta = 19.3°$ at room temperature. The outer component corresponds to the four static phenyl deuterons, with a non-zero static asymmetry parameter η = 0.06 commonly observed for aromatic deuterons. Their effective quadrupolar coupling constant was found to be 165 kHz. This is

Table 1. Host–guest ratios for TATM inclusion compounds, determined from ^{1}H NMR solution spectra of isotopically normal clathrates dissolved in $CDCl_3$, along with experimentally observed melting points.

Guest molelcule	Host:guest ratio	Melting point (°C)
Acetone	2:1	99–104
Acetonitrile	2:1	103–106
Benzene	2:1	115–118
1,2-Dichloroethane	2:1	116–119
Dimethylformamide	2:1	105–108
Dimethyl sulfoxide	2:1	113–116
Mesitylene	2:1	79–81
Methylene chloride	2:1	107–114
Methylene bromide	2:1	114–116
Methylene iodide	2:1	111–113
Nitromethane	2:1	106–109
Pyridine	2:1	114–117
Toluene	2:1	116–118
ortho-Xylene	2:1	111–112
meta-Xylene	2:1	84–86
para-Xylene	2:1	94–95

smaller than a typical value of 190 (±5) kHz for aromatic deuterons, also suggesting some motional averaging due to a librational motion (a librational angle of 17.2° is implied).

para-Xylene–TATM

The ^{2}H spectrum of *p*-xylene-d_{10} (*p*-dimethylbenzene)–TATM, at room temperature, is shown in Fig. 12*B*. Note the general similarity to the spectrum of *o*-xylene–TATM. The inner component, again from the six methyl deuterons, is indicative of methyl rotation as the only motion being present. The quadrupolar coupling constant, 50.5 kHz, indicates that the guest is wobbling, about an axis normal to the ring plane, with a half angle $\theta = 15.7°$ at room temperature. The χ_{eff} value for the ring deuterons is 175 kHz (suggesting $\theta = 13.3°$), again indicating a partial averaging due to the wobbling motion.

Summary

In summary, we have investigated the dynamic behaviour of acetonitrile, nitromethane, dimethyl sulfoxide, benzene, mesitylene, *ortho*-xylene, and *para*-xylene, included in a solid TATM host, by deuterium NMR lineshape and T_1 analysis. The reorientational motion of each guest molecule is restricted to some degree, the extent of which is influenced by the guest–host interaction. Acetonitrile, nitromethane, dimethyl sulfoxide, *ortho*-xylene, and *para*-xylene undergo reorientation of the methyl groups, in addition to some degree of overall librational motion of the molecule. Benzene and mesitylene reorient about an axis perpendicular to the phenyl ring plane.

Acknowledgements

We are very grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC), for financial support. In addition, we would like to thank Professor Otto Meth-Cohn for providing us with his procedure for the synthesis of TATM.

Conformational behaviour of highly hindered ethanes: *meso*- and racemic-2,2,2′,2′-tetramethyl-1,1′-biindanyl

T. Bruce Grindley, Paula J. MacLeod, James A. Pincock, and T. Stanley Cameron

Abstract: MM3(94), AM1, and STO-3G calculations on racemic 2,2,2′,2′-tetramethyl-1,1′-biindanyl (**1**) show that seven minima are present on its conformational potential energy surface. **1** crystallizes in the space group *Pbcn* (no. 60) with cell parameters $a = 11.190(7)$, $b = 11.679(7)$, $c = 13.19(1)$ Å, $V = 1724(3)$ Å^3, $Z = 4$, $R = 0.0357$, $R_w = 0.0362$ in the conformation predicted to be the global minimum by STO-3G and AM1, but not by MM3(94). Application of the Karplus equation and observation of a deshielded proton signal indicate that the same conformation is the major species present in solution, perhaps along with another conformation. The *meso* isomer **2** shows evidence of slow exchange between conformers in its room temperature NMR spectra. Barriers to exchange were obtained from ^{13}C NMR coalescence experiments and from ^{1}H NMR line shape analysis of the exchanging AB pattern. The potential energy surface for **2** was calculated as for **1** and used to determine the nature of the process observed. The slow exchange was calculated to be between two enantiomeric conformers. The populated conformers for both **1** and **2** had the benzene rings from the two halves of the dimer stacked in an offset manner and the favourable interactions associated with this stacking may be a factor in the relative stabilities of these conformations.

Key words: MM3, molecular mechanics, hindered rotation, dialkyldiphenylethanes, X-ray crystal structure.

Résumé : Des calculs MM3(94), AM1 et STO-3G sur le 2,2,2′,2′-tétraméthyl-1,1′-biindanyle (**1**) mettent en évidence la présence de sept minimums sur sa surface d'énergie potentielle conformationnelle. Le composé **1** cristallise dans le groupe d'espace *Pbcn* (no. 60) avec $a = 11,190(7)$ et $b = 11,679(7)$, $c = 13,19(1)$ Å, $V = 1724(3)$ Å^3, $Z = 4$, $R = 0,0357$, $R_w = 0,0362$, dans la conformation qui est prédite par le minimum global d'énergie par STO-3G et AM1, mais pas par la méthode MM3(94). L'application de l'équation de Karplus et l'observation d'un signal correspondant à un proton déblindé indiquent que la même conformation serait l'espèce majeure présente en solution; il est possible qu'une autre conformation lui soit associée. Dans le cas de l'isomère *méso*, **2**, les spectres RMN à la température ambiante suggèrent qu'il existe un échange lent entre les conformères. On a déterminé les barrières pour l'échange à partir d'expériences de coalescence des spectres RMN du ^{13}C et d'une analyse de la forme des raies des spectres RMN du ^{1}H du patron AB des atomes qui s'échangent. Comme dans le cas du produit **1**, on a déterminé la surface de l'énergie potentielle du composé **2** et on l'a utilisée pour déterminer la nature du processus observé. On a calculé que l'échange lent se fait entre les deux conformères énantiomères. Les conformères les plus populeux des composés **1** ainsi que **2** comportent des noyaux benzéniques des deux parties du dimère empilées de façon décalée; il est possible que les interactions favorables associées à cet empilement soient un facteur dans les stabilités relatives de ces conformations.

Mots clés : MM3, mécanique moléculaire, rotation empêchée, dialkyldiphényléthanes, détermination d'une structure cristalline, diffraction des rayons-X.

[Traduit par la rédaction]

Introduction

The relative importance of aryl–aryl interactions in the aggregation of compounds containing aromatic rings has attracted considerable attention (1, 2). The two molecules discussed in this publication can exist in conformations that have two benzene rings either stacked in an offset face-to-face stack or distant from each other. Calculations on benzene dimers in the gas phase using electrostatic plus nonbonded terms suggested that the offset face-to-face stack was one of the most favourable geometries for these interactions, only slightly less favourable than the best arrangement, the edge-to-face dimer (3, 4). Recently, high-level ab initio calculations with electron correlation have indicated that the parallel-displaced dimer, fairly similar in geometry to the offset stack possible here, is the most stable arrangement, 9.6 kJ mol^{-1} more stable than two monomers (5).

The title compounds **1** and **2**, two of the six products from the photolyses of 2,2-dimethyl-1-indanyl acetate and pivalate, were isolated by column chromatography on silica gel (6). These two compounds are the diastereomeric dimers formed from coupling of 2,2-dimethyl-1-indanyl radicals; the former

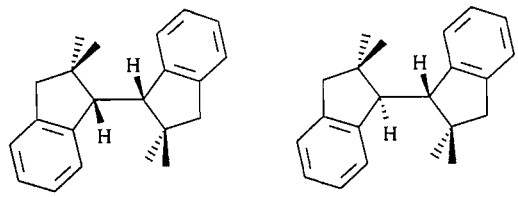
is a racemic mixture of compounds having (*R,R*) or (*S,S*) configurations at the two new stereogenic centres, while the latter is a *meso* (*R,S*) compound. The former mixture will be called the racemic dimer.



1 **2**

Surprisingly, the ^{1}H NMR spectra of these very similar dimers were very different at room temperature; one contained only sharp lines while the other consisted of broadened signals. It will be demonstrated that the signals were broadened because of slow exchange between conformations arising from barriers to rotation about the C—C bond joining the two halves of the symmetrical dimer. The variable temperature ^{1}H and ^{13}C NMR spectra of both dimers have been investigated and an X-ray diffraction analysis was performed on dimer **1**, establishing its structure unambiguously.

There has also been considerable interest about various properties of compounds having highly congested sp^3—sp^3 single bonds. Large barriers to rotation (>40 kJ mol^{-1}) about this type of single bond have been observed in many compounds (7–12) and a number of compounds, particularly substituted triptycene or dihydroanthracene derivatives, even have high enough barriers that two conformational isomers can be isolated (7). In most of the compounds with high barriers, the two carbon atoms in the bond about which rotation is hindered are quaternary. Barriers about bonds between two tertiary carbons are normally much lower; for instance, the barrier for rotation about the bond between the two isopropyl groups in 2,3-dimethylbutane is about 18 kJ mol^{-1} (10). Where higher barriers were observed about bonds between two tertiary carbons, several very large groups have always been present at both ends of the bond and the barriers observed have often resulted from correlated motion of several groups (8, 11, 13–15). There has also been considerable interest in bond lengths (16, 17), in bond dissociation energies (11, 15), and in the applicability of molecular mechanics calculations (18) to compounds containing sterically congested bonds of this type.

The potential energy surface for rotation around the central carbon–carbon bond in dimers **1** and **2** was evaluated, using both the AM1 semi-empirical method and the MM3(94) molecular mechanics force field. Surprisingly, the results of AM1 calculations were in closer agreement with experimental observations on which conformers were populated and on the size of the barriers between conformers, even though the geometries predicted for the saturated parts of the molecules were much poorer than predicted by MM3. The causes of these surprising observations will be discussed.

Results and discussion

Racemic dimer (1) — crystallography

One of the dimers (**1**) crystallized easily from hexanes, the other resisted all attempts at crystallization and remained an oil. The crystal structure was solved by direct methods and refined to $R = 3.57\%$. Full details of the structure solution have been deposited.[3] The atomic coordinates are given in Table 1 and some structural data are located in Table 2. An ORTEP representation of one of the molecules in the unit cell is given in Fig. 1 where the structure pictured is the *R,R* stereoisomer. The crystalline sample is the racemic compound **1**. In the crys-

tal, the two halves of the dimer are related by a crystallographic twofold axis through the central C(1)—C(1′) bond. The C(1) — C(1′) bond length is 1.554(5) Å, though the effective esd is larger than the quoted value because of the twofold axis. The five-membered ring is in an envelope conformation. As expected, the four carbon atoms of this ring, C(1), C(3), C(4), and C(9), that are part of, or bonded to, the aromatic ring are coplanar with a mean deviation from the least-squares plane of 0.003(3) Å. The fifth atom is 0.537 Å from the plane. The two halves of the molecule, connected through the C(1)—C(1′) bond, have a C(9)- C(1)- C(1′)- C(9′) torsion angle of −23.0(6)°. The unit cell contains two *S,S* molecules and two *R,R* molecules.

Racemic dimer (1) — NMR results

The ^{1}H NMR spectrum of the racemic dimer at 20°C, shown in Fig. 2, is simple because the two halves of the molecule are equivalent by virtue of its C_2 symmetry. No significant changes in the spectrum were observed upon heating or cooling in the range from −60°C to +45°C. The methyl groups give rise to two singlets at 1.00 and 1.30 ppm. The protons of the CH_2 group appear as an AB quartet (J = −15.0 Hz) centered at 2.80 ppm, very close to the chemical shift of the methylene group hydrogens in 2,2-dimethylindane, 2.75 ppm. The geminal coupling constant is assumed to have a negative sign (19). The CH signal is a singlet at 3.07 ppm, with a ^{13}C satellite 61.0 Hz to higher frequency. The satellite at lower frequency was obscured by the methylene signals. Confirmation that this small peak, having approximately 0.5% of the intensity of the main peak, was indeed a ^{13}C satellite, was obtained by recording the spectra at both 250 and 400 MHz, and also by measuring $^1J_{C,H}$ from the coupled ^{13}C NMR spectra. The value obtained was 122 Hz, twice the separation of the satellite from the main CH signal. The satellite signal was not split, indicating that the H(1)—H(1′) vicinal coupling constant was <1 Hz. The aromatic region consists of two doublets and two triplets as expected for a first-order pattern of a 1,2-disubstituted aromatic ring. The absorption of one pair of *ortho* hydrogens is considerably shielded, appearing as a doublet at 6.52 ppm. In comparison with the chemical shift of the two equivalent *ortho* hydrogens of 2,2-dimethylindane, a very large Δδ of −0.65 is observed. The ^{13}C NMR solution spectrum, shown in Fig. 3*a*, contains 11 signals, consistent with the C_2 molecular symmetry.

A CP/MAS ^{13}C NMR spectrum of this dimer in the solid state is shown in Fig. 3*b*. The spectrum is very similar to the solution spectrum, except that spinning side bands from the

[a]Note that conformers in the **a** and **c** families have C_2 symmetry while those in the **b** family have no symmetry.
[b]With respect to the global MM3 minimum, conformer **a2**.
[c]With respect to the global AM1 minimum, conformer **c1**.
[d]With respect to the global STO-3G minimum, conformer **c1**.
[e]The signs of the torsional angles for the crystal structure have been reversed in this column to match those from the calculations, which are for the (*S,S*) enantiomer. The crystal structure diagram (Fig. 1) and the coordinates of **1** (Table 1), are of the (*R,R*) enantiomer.

aromatic carbons are present. Chemical shift anisotropies of aromatic carbons are much larger than those of the aliphatic carbons (20), making removal of spinning side bands of aromatic carbons by MAS more difficult.

Theoretical calculations for the racemic dimer (1)

The coordinates for several conformations of the (*S,S*) diastereomer of the racemic dimer (**1**) were initially generated using the molecular mechanics program pcmodel.[4] These coordinates were used as input for calculations using MM3(94) (21) in which the carbons in the benzene rings were treated as conjugated (type 2 carbons). All conformational minima had the five-membered rings in envelope conformations, with one atom, C(2) or C(2′), out of the plane. Thus, in all conformational minima, two torsional angles in each of these rings, C(1)-C(2)-C(3)-C(4) and C(3)-C(2)-C(1)-C(9), were calculated to be large, of approximately equal magnitude between 27° and 40°, and of opposite sign. The potential energy surface was explored by performing dihedral angle driver calculations using the angles C(2)-C(1)-C(1′)-C(2′), C(1)-C(2)-C(3)-C(4), and C(1′)-C(2′)-C(3′)-C(4′). Three unique families of conformations were found, termed families **a**, **b**, and **c**, which for the *S,S* stereoisomer have both C(1)-C(2)-C(3)-C(4) and C(1′)-C(2′)-C(3′)-C(4′) torsional angles positive, one positive and one negative, and both negative, respectively. When this angle is positive in an (*S,S*) diastereomer, the flap of the five-membered ring envelope, that is, C-2 or C-2′, is directed away from the other half of the dimer and the bond joining the two halves of the dimer, C(1)—C(1′), is in a quasi-axial orientation with respect to that five-membered ring. This will be termed an "out" orientation of the five-membered ring. When the angle is negative and the same bond, C(1)—C(1′), is now quasi-equatorial, the envelope is flapped toward the other half of the dimer in what will be termed an "in" orientation.

The **a** or "out,out" family contained three minima with C(2)-C(1)-C(1′)-C(2′) torsional angles of 101.4° (**a1**), 170.5° (**a2**), and 294.9° (**a3**). ATOMS representations of two conformers of the "out,out" family, **a1** and **a2**, are shown in Fig. 4. The **a2** is calculated to be the global minimum, but **a1** is only 1.1 kJ mol^{-1} higher in energy. The third minimum, **a3**, is 17.2 kJ mol^{-1} higher. The second or "out, in" family contains two minima with C(2)-C(1)-C(1′)-C(2′) torsional angles of 136.0° (**b1**) and 295.8° (**b2**) calculated to be 22.6 and 28.1 kJ mol^{-1}, respectively, higher in energy than the global minimum (**a2**). The third or "in,in" family contains two minima with C(2)-C(1)-C(1′)-C(2′) torsional angles of 139.6° (**c1**) and 302.1° (**c2**) calculated to be 15.6 and 58.1 kJ mol^{-1} higher in energy than the global minimum (**a2**). Information about these conformations is shown in Table 2.

The coordinates for the seven MM3 minima were used as input for AM1 (22) calculations and geometry optimizations

were performed. Results are also shown in Table 2. There are several significant differences from the MM3 results. Most importantly, the conformer stability order is changed. The **c1** is now the global minimum, 0.3 kJ mol^{-1} more stable than the MM3 global minimum **a2**. This conformation (**c1**) has a dihedral angle for C(2)-C(1)-C(1′)-C(2′) similar to that in the solid state (131.0°). However, other geometric features are not reliably reproduced. First, the AM1 five-membered rings were unrealistically flat, as indicated by the small torsional angles through C(2) and C(2′). As a result, two of the higher energy MM3 minima were not AM1 minima but changed during the optimization process to other conformers, **c2** to **b2**, and **b1** to **a2**. In addition, the central C(1)—C(1′) bond length, 1.520 Å, was considerably shorter than the bond length observed by X-ray diffraction (1.554 C). This bond length was, however, well reproduced by the MM3(94) force field (1.555 Å).

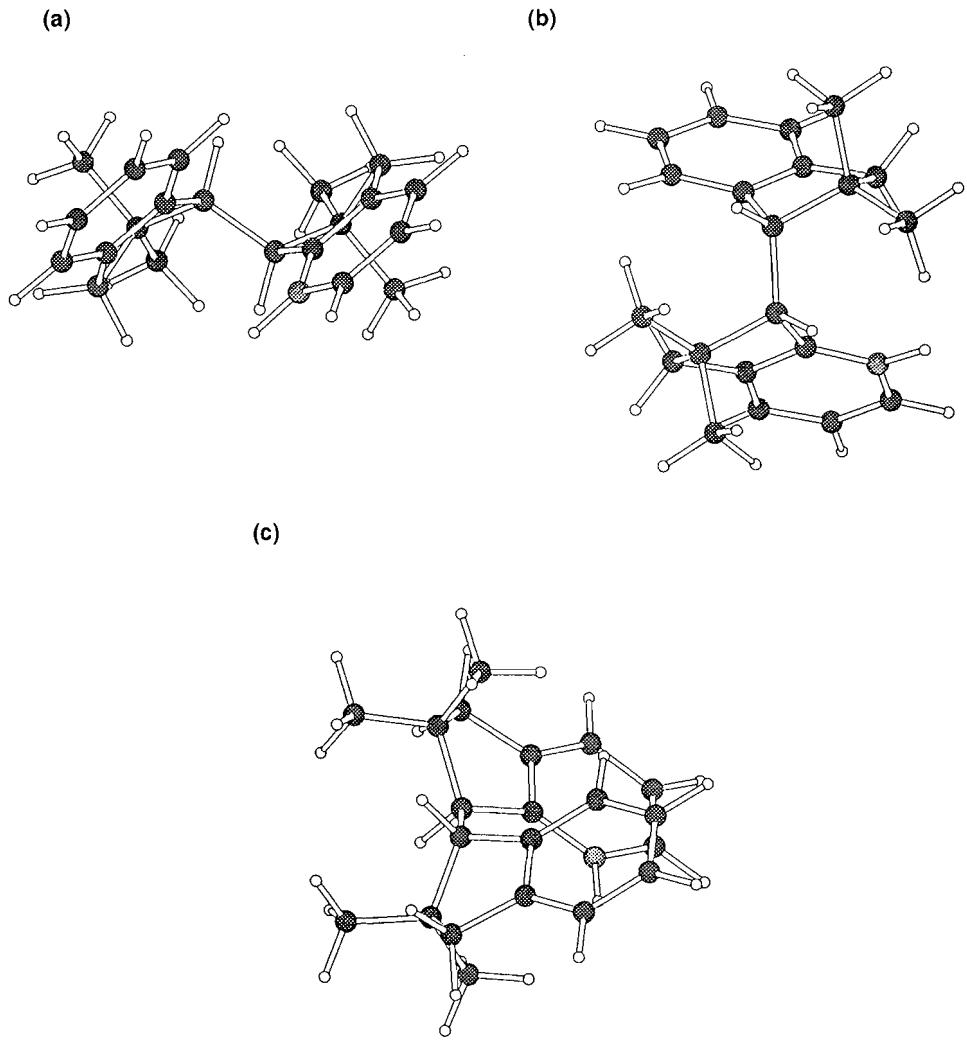
STO-3G optimizations were performed on several of the low-energy conformations. These calculations give the same stability order as AM1 but, unlike the AM1 method, also reproduce reasonably well the nonplanar geometry of the five-membered rings observed in the X-ray structure of **1**. For the absolute values of the four largest torsional angles in the five-membered rings, the STO-3G results average 0.7° lower than the X-ray results, AM1 results average 15.4° low, and MM3 results average 3.2° high. Agreement between the calculated and experimental C(1)—C(1′) bond lengths was also reasonably good, 1.565 Å in **c1**, compared to 1.554(5) Å in the X-ray results and 1.555 and 1.520 Å by MM3 and AM1, respectively. In *meso*-1,2-di-*tert*-butyl-1,2-diphenylethane, the central C—C bond length varies from 1.573 to 1.577 Å in different molecules in the unit cell, while it is 1.589 Å in the racemic isomer (15), suggesting that the current molecules are less strained. In addition, the critical C(2)-C(1)-C(1′)-C(2′) angle is only 1.6° larger in the STO-3G results than measured by X-ray diffraction.

Discussion for the racemic dimer (1)

The lowest energy MM3 minimum is not the conformer observed experimentally. The X-ray structure combines a C(2)-C(1)-C(1′)-C(2′) torsional angle of 131.0(4)° with symmetry-related C(1)-C(2)-C(3)-C(4) and C(1′)-C(2′)-C(3′)-C(4′) torsional angles of −31.9(3)°, opposite in sign to that of the C(2)-C(1)-C(1′)-C(2′) torsional angle, and therefore this structure belongs to the "in,in" conformational family. Conformer **c1** fits the X-ray data fairly closely, even though it was calculated to be 15.6 kJ mol^{-1} less stable than **a2** and 14.5 kJ mol^{-1} less stable than **a1**. In contrast, both the AM1 and STO-3G methods calculate that **c1** is the global minimum, if only by a slight amount.

There are two pieces of evidence that indicate that the pop-

Fig. 4. ATOMS representation of MM3 geometries of conformers of the racemic dimer (**1**): from the **a** or "out,out" family: (*a*) the **a1** conformer, (*b*) the **a2** conformer; and from the **c** or "in,in" family: (*c*) the **c1** conformer.



ulated conformations in solution are either **c1** alone or a **c1**–**a2** mixture. The H(1)–H(1′) $^3J_{H,H}$ value, obtained from a ^{13}C satellite of the H(1), H(1′) is <1 Hz, consistent with a dihedral angle close to 90°. By MM3, this angle is calculated to be 95.0° (104.5° by AM1 and 98.7° by STO-3G) in **c1**, but 153.9° (145.1° by AM1 and 132.8° by STO-3G) and 72.5° (95.1° by AM1 and 86.4° by STO-3G) in **a1** and **a2**, respectively. If conformation **a1** is significantly populated, an observable $^3J_{H\text{-}1,H\text{-}1'}$ value would have been obtained. However, conformation **a2** would also give a very small coupling constant, particularly if the STO-3G torsional angle is close to the actual angle. In addition, an *ortho* hydrogen was shielded by 0.65 ppm, consistent with its presence in the shielding cone of a second benzene ring. Models show that this arrangement is only possible in **c1**, not in **a1** or **a2**. Thus, experimental evidence indicates that **c1** is the global minimum, but perhaps only by a small amount. The MM3 energies must be incorrect by at least 16 kJ mol^{-1} in disfavouring the offset π-stacked conformer **c1**. The AM1 and STO-3G energies fit the experimental observations well.

In the global minimum (**c1**), the two phenyl rings are slightly tilted away from being parallel with each other and are offset such that one of the two *ortho* hydrogens from each benzene ring lies over C(8) and C(9) at the end of the other benzene ring. Distances of this hydrogen to these two carbons are 2.86 and 2.81 Å, respectively, from MM3. However, the smaller C(2)-C(1)-C(1′)-C(2′) torsional angle in the X-ray structure brings the two rings slightly closer together. Distances between planes of about 3.5 Å have previously been calculated to be optimal for offset π stacking (3, 4).

NMR results for the *meso* dimer (2)

The NMR spectra of this compound were surprisingly complex. The ^1H NMR spectrum at 25°C is shown in Fig. 5*b*. Broadened signals were observed that can be interpreted only in terms of a conformational barrier to interconversion of S_{axis}-related conformers, largely by rotation about the C(1)—C(1′) bond. The broad signals split, then sharpened as the temperature was lowered. The ^1H NMR spectrum at −40°C is shown in Fig. 5*c*. Assignments for the low-temperature spectrum were made on the basis of integration and a HETCOR experiment. As summarized following, the low-temperature spec-

trum was consistent with a structure that had no symmetry. Four signals assigned to methyl groups appeared at 1.35, 1.09, 1.00, and 0.82 ppm. In comparison, the methyl groups in 2,2-dimethylindane absorb at 1.18 ppm. Therefore, one methyl group is significantly shielded and another somewhat deshielded. A singlet at 2.32 ppm integrates for two protons and is assigned to the methylene group in one of the five-membered rings; the methylene groups in 2,2-dimethylindane absorb at 2.75 ppm. The two protons in this methylene group are accidentally isochronous. An AB quartet with absorptions at 3.07 and 2.65 ppm and $J = -16.1$ Hz is assigned to the methylene group in the other five-membered ring. Unlike the other signals, a resonance at 3.17 ppm due to the two methine protons was relatively sharp at room temperature. It decreased in intensity and broadened slightly upon cooling and then split at about −30°C into two distinct bands that sharpened into an AB quartet, with $\Delta\nu = 0.0270$ ppm and $J_{A,B} = 2.0$ Hz at −55°C. The remainder of the signals are assigned to the aromatic protons and it is evident that there are more than four environments for aromatic protons in the populated conformer at −40°C, consistent with lack of symmetry. An interesting feature was a doublet at 6.07 ppm assigned to an *ortho* proton. The $\Delta\delta$ value of −1.10 ppm for this signal with respect to the value for the *ortho* protons of 2,2-dimethylindane is considerably larger than that observed for the corresponding signal from the racemic dimer.

The ^{1}H NMR spectrum recorded at 45°C is shown in Fig. 5*a*. By this temperature, the signals of the aromatic protons have coalescesed. In the methyl group region of the spectrum, a sharp signal due to a pair of methyl groups is now superimposed on the broad hump arising from the coalescence of the signals of the two remaining methyl signals, which had a much larger chemical shift difference at −40°C. The methine signals have not quite reached coalescence at this temperature.

The ^{13}C NMR spectrum of this compound at room temperature also contained broadened signals. In contrast, at −40°C, 22 sharp lines were observed, one for each of the carbon atoms in the molecule. Chemical shifts and assignments have been given previously (6).

The magnitude of the barrier to conformational motion was obtained by two methods in order to give a wide range of rate constants. Rate constants at temperatures from 15 to 47°C

were obtained from the coalescence temperatures of most of the aliphatic ^{13}C NMR (62.5 MHz) signals using equations [1] and [2] (23).

$$[1] \quad k(s^{-1}) = \frac{\pi \Delta \nu}{\sqrt{2}}$$

$$[2] \quad \Delta G^{\ddagger}(\text{kJ/mol}) = RT\left[23.76 + \ln\left(\frac{T}{k}\right)\right]$$

T is the coalescence temperature of the signals. The $\Delta\nu$ values were taken from the −40°C spectra and assumed to be temperature invariant. The ^{13}C NMR spectra were recorded from −40°C to 55°C, increasing the temperature in 5° steps except close to a coalescence point where they were recorded at intervals of 2°C or around 47°C, in 1° intervals.

Rate constants from −30°C to −15°C were obtained by line shape analysis of the coalescence of the AB pattern due to H(1) and H(1′) using the program Quabex (24) modified to run on a PC. The chemical shift differences for this AB pattern were measured from −60°C to −35°C and the linear plot (r = 0.9998) was extrapolated into the exchange region. The results of both treatments are shown in Table 3. The values of $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ for the conformational motion were determined from a plot of $\ln(k/T)$ vs. $1/T$ as outlined in eq. [3]. The values obtained from this analysis are $\Delta H^{\ddagger} = 42.8 \pm 1.8$ kJ mol^{-1} and $\Delta S^{\ddagger} = -61.6 \pm 6.5$ J K^{-1} mol^{-1}. The uncertainties are based on the regression analysis only. These values yield a $\Delta G^{\ddagger}$ of 61.2 kJ mol^{-1} at 298 K.

$$[3] \quad \ln\left(\frac{k}{T}\right) = 23.76 - \frac{\Delta H^{\ddagger}}{8.31\,T} + \frac{\Delta S^{\ddagger}}{8.31}$$

As will be discussed later, the NMR data for the *meso* dimer provided considerable information about the structure of the low-temperature conformer and the kinetics of the hindered rotation.

Table 3. Kinetic data from NMR measurements for the *meso* dimer.

Signal	Δν (Hz)	T (K)	$\Delta G^{\ddagger}$ (kJ mol^{-1})	k_c (s^{-1})
