TMS is a stable compound with a very high vapour pressure (boiling point of 26.5°C). Its structure is well known: T_d symmetry with a Si—C bond length of 1.875(2) Å as determined from electron diffraction analysis (20). TMS was used as a test case for our experimental and data analysis procedures.

As described in Sect. 3, the EXAFS data ($k^{2.5}$ weighted) have been fitted in both R-space and k-space (Fig. 5) using a single Si–C shell model. Figure 5(*a*) shows the R-space data and fit. Figure 5(*b*) shows the k-space normalized data and the fit. Figure 5(*c*) shows the Fourier filtered data and the k-space fit. A Hamming window has been applied as a filter in the analysis. Some of the side lobes of the main peak in Fig. 2(*e*) have disappeared in Fig. 5(*a*) due to the application of the filter window, but the bump at around 3 Å is present in both figures, indicating that it is a true peak. This peak is most probably due to the (Si-C-C-Si) triangle scattering path. No fitting attempt was made for it is too weak to obtain quantitative results.

The k-space (with Fourier filtering) and R-space fitting results, which are given in Table 1 together with those for $Ge[Si(CH_3)_3]_4$, are practically the same. The number of relevant independent points N_{pts}, calculated based on the data range ($2 + 2\Delta k\Delta R/\pi$) (14), is also listed in Table 1. The bond length, 1.883(15) Å (average of k- and R-space results), is in good agreement with the electron diffraction (ED) data 1.875(2) Å (20). The coordination number is slightly higher than 4, but it is within a reasonable range (20% uncertainty) for N in EXAFS analysis. This is because coordination number N, the atomic backscattering amplitude f_j (k_j,π) and the Debye–Waller factor are highly correlated and it is often difficult to separate them unequivocally.

It should be noted that the σ^2 in the Debye–Waller factor, which is approximated as a Gaussian, represents the mean-square relative displacement of the interatomic distance (21). Although it should contain all vibrational mode contributions as well as static disorder in principle, the dominant one in TMS and tetrahedral molecules is the mean-square relative displacement resulting from the totally symmetric vibration mode of the Si—C bonds. The theoretical mean square relative displacement resulting from the totally symmetric vibration at a given temperature can be calculated from its vibrational frequency (1250 cm^{-1} for Si–CH_3) and the result thus obtained is σ^2_{vib} = 0.0009 Å^2 for TMS according to the theory (22). This result sets the lower bound for this value. The fact that it is smaller than the value obtained from the EXAFS analysis indicates that we have not underestimated the σ^2 in the analysis.

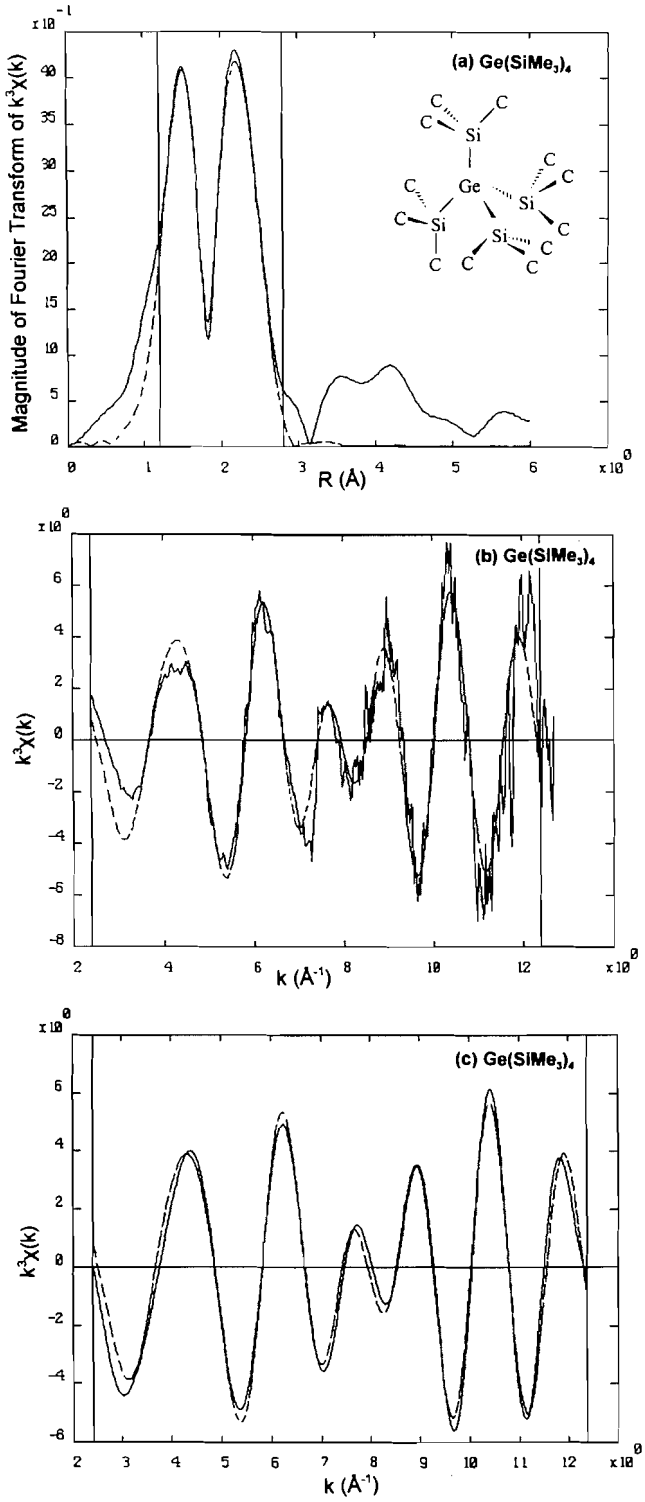
The error bars for all the parameters listed in Table 1 were determined using the method described in Sect. 3. They are probably too conservative. For each of the parameters, a well-defined minimum was found, so we conclude that we have found a very good fit for TMS. With the result of the TMS analysis, which is very satisfactory, we are confident that our experimental and data analysis procedures will work for other compounds. A similar procedure has been used for $Ge[Si(CH_3)_3]_4$, $Si[Si(CH_3)_3]_4$, and $Si[Ge(CH_3)_3]_4$. These results are presented below.

4.2.2. $Ge[Si(CH_3)_3]_4$

From the molecular structure of $Ge[Si(CH_3)_3]_4$, it is expected that there should be two major single backscattering shells for each of the four chemically equivalent Si atoms in the molecule, the Si–C and the Si–Ge shell. From Figs. 2(*c*) and (*g*), which show a simple beating of two sinusoidal waves and two

[4] The methyl hydrogen, due to its lack of core electrons, has little scattering power to high-energy electrons, therefore contributes little to the EXAFS. The Si–C single scattering pathway in $Si[Ge(CH_3)_3]_4$ is too long to make a significant contribution to the overall amplitude because of the $1/R_j^2$ dependence and short attenuation length of the electrons.

Fig. 6. (*a*) Magnitude of the Fourier transform (solid line) and the fit (broken line) in *R*-space (transform range is 2.4–12.4 Å^{-1}); (*b*) k^3-weighted data (solid line, the sharp feature at $k = 7.3$ is due to a glitch of the monochromator) and the fit (broken line) in *k*-space; (*c*) Fourier filtered data (solid line) and the fit (broken line) (filtering window range is 1.2–2.8 Å) for $Ge(SiMe_3)_4$. The vertical lines define the fitting range. The insertion in (*a*) shows the schematic structure of the molecule (hydrogen atoms were neglected).



maxima in the Fourier transform (FT), respectively, it is apparent that a two-shell model should be adequate to account for most of the spectral features. The contribution of the Si–C-C-Si triangle path is ignored by properly limiting the *R*-space fitting range and the filtering range for *k*-space fitting. A two-shell fit was carried out for $Ge[Si(CH_3)_3]_4$. Due to the strong correlation of the parameters, only six parameters were allowed to vary independently in the fitting. The σ^2 for the Si–C shell was fixed at 0.003, the same as TMS. This is not an unreasonable assumption, since the Si–C bond in these two compounds should be very similar. We also allowed ΔE_0 of the Si–Ge shell to be the same as that of the Si–C shell; since they have the same central Si atom, ΔE_0 should not vary significantly. Figure 6(*a*) shows the *R*-space data and fit. Figure 6(*b*) shows the *k*-space normalized data (k^3 weighted) and the fit. Figure 6(*c*) shows the Fourier filtered data and the *k*-space fit.

It can be seen from Table 1 that both *k*-space (with Fourier filtering) and *R*-space fits gave similar results. The Si—Ge bond length is determined to be 2.396(15) Å (average of *R*- and *k*-space results), which is comparable to the reported 2.370(1) Å in $Ge(SiH_3)_4$ as determined by electron diffraction (ED) analysis (23), and close to the reported average bond length of 2.405 Å in a series of strained-layer $(Si_m/Ge_n)_p$ superlattices (1). The Si—C bond length for $Ge[Si(CH_3)_3]_4$ is the same as that of TMS within experimental uncertainty. The σ^2 for the Si—Ge bond is larger than for the Si—C bond. Using the same method as that for TMS (22), the calculated F^2_{vib} for $Ge[Si(CH_3)_3]_4$ is about 0.0011 Å^2 based on the stretching frequency of 312 cm^{-1} (24) for the Si–Ge pair. The number of nearest neighbours is larger than theory. It should be noted, however, that both the Debye–Waller factor and the coordination number are within the range of acceptable uncertainty (2). As for TMS, a well-defined minimum was found for each of the parameters. It is reassuring to find that the magnitude of the error bar for $Ge[Si(CH_3)_3]_4$ is comparable to that of TMS, although the former has more fitting variables.

4.2.3. $Si[Si(CH_3)_3]_4$

From Figs. 2(*b*) and (*f*), we observe a similar EXAFS pattern for $Si[Si(CH_3)_3]_4$ as for $Ge[Si(CH_3)_3]_4$, with the beating occurring at different *k* values. In $Si[Si(CH_3)_3]_4$, there are two different kinds of Si atoms: Si^a (bonded to four Si) and Si^b (bonded to one Si and three CH_3 groups). The observed $\chi(k)$ of $Si[Si(CH_3)_3]_4$ is the sum of $\chi(k)$ of Si^a and $\chi'(k)$ of Si^b. The χ' for Si^b should be slightly different from the χ for Si^a despite the fact that the bond length and the mean-square relative displacement along the bond are the same in both cases, this is because they have different threshold energies E_0, and they are chemically different locally. The central atom Si^a exhibits a 1 eV shift to lower binding energy relative to the surrounding four Si^b atoms as deduced from both XANES (this work) and photoelectron measurements (25).

A multi-shell fit (one shell for Si^a and two shells for Si^b) was carried out for $Si[Si(CH_3)_3]_4$: Si^a–Si^b (core hole on Si^a), Si^b–C (core hole on Si^b), and Si^b–Si^a (core hole on Si^b). The calculated backscattering amplitude for these three shells (Si^a–Si^b, Si^b–C, and Si^b–Si^a) using the FEFF scheme has been weighted by 0.2, 0.8, and 0.8, respectively, so that the coordination number, N_j, given in the fitting should be 4 for the Si^a–Si^b shell, 3 and 1 for the Si^b–C shell and the Si^b–Si^a shell,

Table 2. EXAFS fitting range and results for $Si^a(Si^b(CH_3)_3)_4$[a] and $Si(Ge(CH_3)_3)_4$ in *k*-space (with Fourier filtering) and *R*-space.

Molecule		Parameter	*k*–space	*R*–space
$Si^a(Si^b(CH_3)_3)_4$	N_{pts} = 11	Data range	2.4–10.8 $Å^{-1}$	0.9–2.7 Å
	Si^a–Si^b shell	ΔE_0 (eV)	6.4 ± 5	6.8 ± 1.5
		R (Å)	2.364 ± 0.015	2.364 ± 0.005
		σ^2 ($Å^2$)	0.004 ± 0.003	0.004 ± 0.001
		N	4 (fixed)	4 (fixed)
	Si^b–C shell	ΔE_0 (eV)	5.7 ± 2	6.5 ± 0.8
		R (Å)	1.875 ± 0.012	1.875 (fixed)
		σ^2 ($Å^2$)	0.0015 ± 0.002	0.0016 ± 0.0015
		N	3 (fixed)	3 (fixed)
	Si^b–Si^a shell	ΔE_0 (eV)	5.7[b]	6.5[b]
		R (Å)	2.364[c]	2.364[c]
		σ^2 ($Å^2$)	0.004[c]	0.004[c]
		N	0.8 ± 0.6	0.8 ± 0.2
$Si(Ge(CH_3)_3)_4$	N_{pts} = 8	Data range	4.1–10.1 $Å^{-1}$	1.2–3.0 Å
	Si–Ge shell	ΔE_0 (eV)	4.4 ± 6	2.6 ± 5
		R (Å)	2.38 ± 0.03	2.37 ± 0.03
		σ^2 ($Å^2$)	0.004 ± 0.004	0.004 ± 0.003
		N	2.9 ± 1	2.8 ± 0.6

[a]The uncertainties of the parameters for this compound are decided differently (see text).
[b]The difference between this value and that of the Si^b–C shell was fixed at zero in fitting.
[c]The difference between this value and that of the Si^a–Si^b shell was fixed at zero in fitting.

respectively. By fixing and linearly constraining some of the parameters, the number of independent variables in the fitting was reduced from 12 to 7 and 6 in *k*-space and *R*-space, respectively (see Table 2), to obtain a fit (Fig. 7). The results are tabulated in Table 2. The uncertainty estimation scheme described in Sect. 3 broke down for ΔE_0 and *R*, probably because there are too many shells and the correlations between the parameters are too strong. The uncertainties listed in Table 2 for the ΔE_0's for both shells were obtained when the *R*'s were fixed at 2.364 and 1.875 Å for Si—Si and Si—C bonds, while those for the *R*'s were obtained by fixing the ΔE_0's at 6.4 eV (*k*-space) and 6.8 eV (*R*-space) for the Si^a–Si^b shell and 5.7 eV (*k*-space) for the Si^b–C shell.

The Si—Si and Si—C bond lengths of 2.364(10) and 1.875(12) Å (average of *k*- and *R*-space results) agree very well with the ED results (26) of 2.361(3) and 1.889(3) Å and X-ray crystallography results (27) of 2.346(1) and 1.879(4) Å. It should be noted that this particular compound is a very interesting case for testing the additive model of EXAFS in that altogether there are 8 Si—Si single scattering paths with identical interatomic distances and mean-square relative displacement, yet there is a small difference in the E_0 between the two absorbing Si atoms. The result of the analysis indicates that the small difference is clearly noticeable in the near-edge region but does not have a noticeable effect in *k*-space EXAFS, particularly in the high-*k* region where a 1 eV difference in $(E - E_0)^{1/2}$ has little effect on its corresponding *k* value.

4.2.4. $Si[Ge(CH_3)_3]_4$

This compound has a very low vapour pressure and a relative low mass percentage of Si, which makes it difficult to obtain very high-quality data under our experimental conditions. The ionization chamber was maintained at about 65°C to get a reasonable signal-to-noise ratio in the EXAFS region with multiple scans. The fluctuation of temperature (±1°C) may contribute slightly to the noisier data compared to those of the other compounds. Fortunately the data set is dominated by a single sinusoidal wave arising from the Si–Ge pair as expected. The $k^{0.5}$-weighted data were fitted with a single Si–Ge shell. Figure 8 and Table 2 show the fit and the parameters. As expected, the error bar for the parameters is a little larger than that of TMS and $Ge[Si(CH_3)_3]_4$ because of the data quality. Noticeably, the coordination numbers obtained from both *k*- and *R*-space fits are lower than the theoretical value, in contrast to the trend found in TMS and $Ge[Si(CH_3)_3]_4$. This is probably due to the large uncertainty in normalizing the edge jump because, for $Si[Ge(CH_3)_3]_4$, the signal-to-background ratio is considerably smaller than those for the other compounds reported here.

Figure 9 shows the phase shift and amplitude functions of the Si–Ge pair derived experimentally using the BAN program (10), where

$$\text{Amplitude} = \frac{N}{kR^2} S_0^2 S(k) f(k)\, e^{-2k^2\sigma^2} e^{-2R/\Lambda}$$

with $N = 4$ and $R = 2.38$ Å for the Si–Ge pair and phase shift is $\phi(k)$ ($2kR$ term was subtracted).

Since the EXAFS function of $Si[Ge(CH_3)_3]_4$ results from a dominant single Si–Ge shell backscattering, the phase shift

Fig. 7. (*a*) Magnitude of the Fourier transform (solid line) and the fit (broken line) in *R*-space (transform range is 2.4–10.8 Å^{-1}); (*b*) k^3-weighted data (solid line) and the fit (broken line) in *K*-space; (*c*) Fourier filtered data (solid line) and the fit (broken line) (filtering window range is 0.9–2.7 Å) for $Si(SiMe_3)_4$. The vertical lines define the fitting range. The insertion in (*a*) shows the schematic structure of the molecule (hydrogen atoms were neglected).

The vertical lines define the fitting range. The insertion in (*a*) shows the schematic structure of the molecule (hydrogen atoms were neglected).

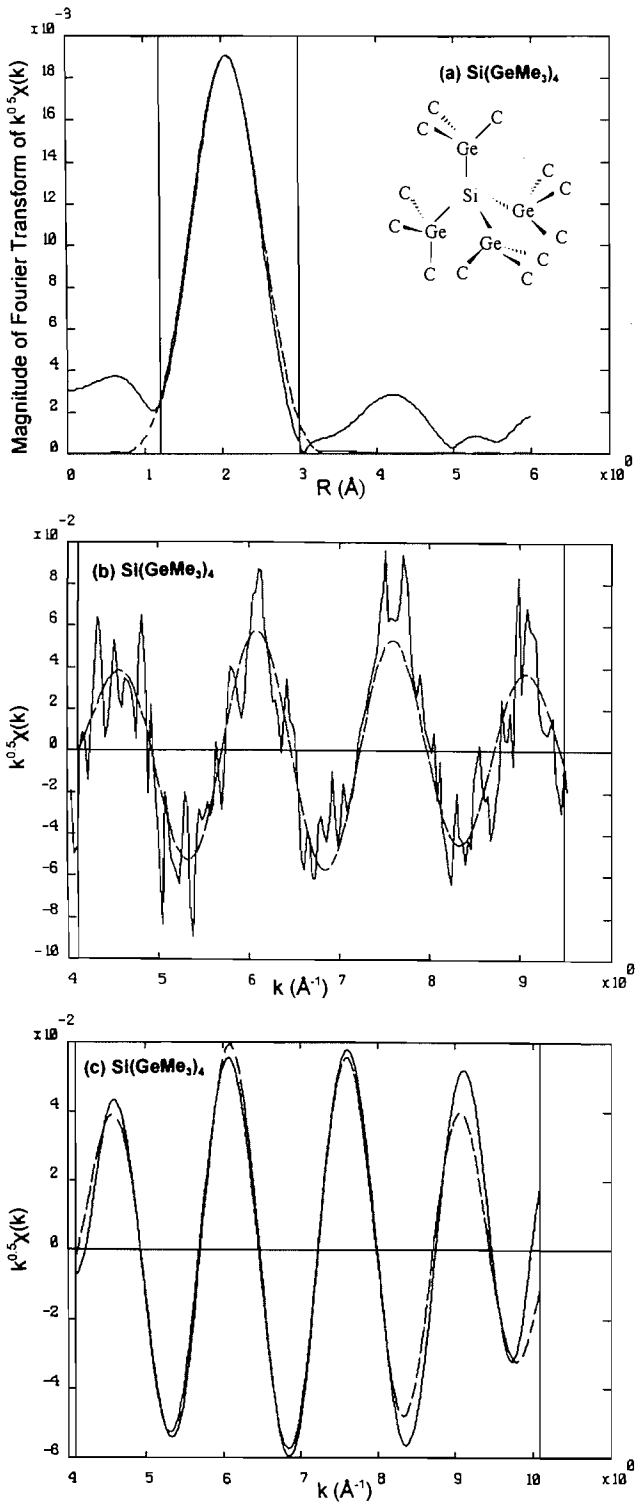


Fig. 9. Experimental (*a*) amplitude and (*b*) phase shift functions (see text for definitions) for the Si–Ge pair extracted from the EXAFS of $Si(GeMe_3)_4$.

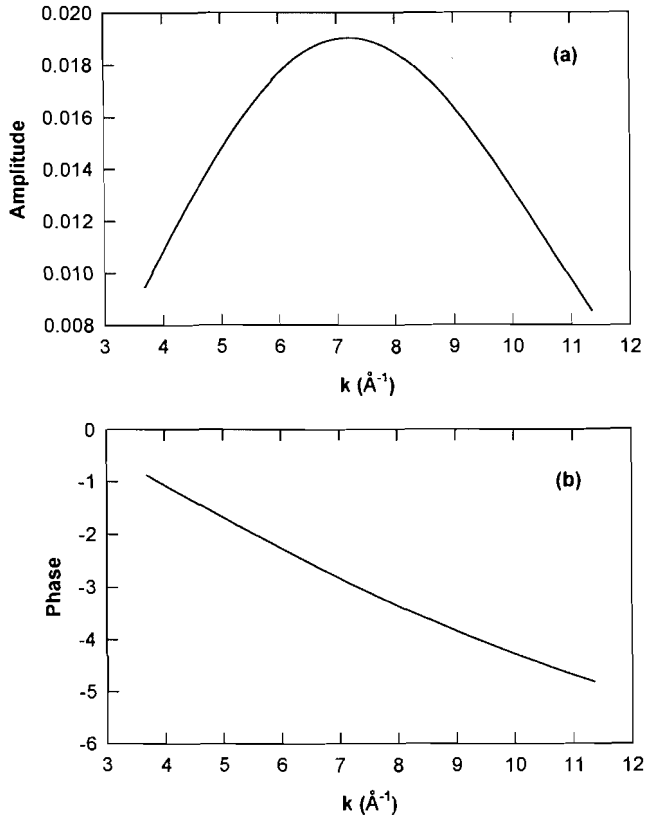

and amplitude functions can be obtained with fewer artifacts relative to $Ge[Si(CH_3)_3]_4$, where the Si–C shell and the Si–Ge shell are difficult to separate. As discussed in Sect. 3, these functions may be a very helpful reference in analyzing the structure of more complicated Si–Ge systems.

4.3. Comparison of Si—Si and Si—Ge bond lengths in molecules and in solid state semiconductors

From the above analysis it is clear that Si K-edge EXAFS indeed provides accurate local structural information about bond length and related parameters for these molecules. The $Si[Si(CH_3)_3]_4$ results (Si—Si bond length = 2.364(10)Å) are in good agreement with the electron diffraction result of 2.361(3) Å (26) and the X-ray crystallography result of 2.346(1) Å (27). The Si—Ge bond lengths are reported for these compounds for the first time.

The Si—Si bond length values reported here are in fact comparable within experimental uncertainty with the Si—Si bond length found in related organosilicon compounds: 2.373(2) and 2.390(2) Å for the peripheral and central Si—Si bonds in $[(CH_3)_3Si]_3Si—Si[Si(CH_3)_3]_3$ (27) and 2.340(9) Å in $(CH_3)_3Si—Si(CH_3)_3$ (28).

Let us compare the Si—Si bond length of Si—Si in $Si[Si(CH_3)_3]_4$ (of which the central Si has the same local structure as that of Si in crystalline Si) with that of crystalline Si (2.350Å) (29). It is immediately apparent that the crystalline value falls within the range of values exhibited by organosilicon compounds. Thus it is quite reasonable to state that in the absence of significant steric effects, the Si—Si bond in an organosilicon compound is comparable to that of crystalline silicon. Returning to Fig. 3, it is interesting to see how dramatic an effect the long-range Si–Si interaction in the semiconductor has on the XANES (the splitting of the threshold resonance that was absent in the organometallic compounds). It is quite clear that the interatomic distance observed in these systems is not very sensitive to long-range electronic interactions.

A similar comparison can be made between the Si—Ge bond lengths reported here, 2.396(15) Å for $Ge[Si(CH_3)_3]_4$ and 2.38(3) Å for $Si[Ge(CH_3)_3]_4$, and the average nearest neighbour distance in the relaxed Si–Ge alloys with the same Si—Ge stoichiometry grown on Si (2.372 Å for 20% Ge and 2.430 Å for 20% Si in $Si_{1-x}Ge_x$) (1). Taking into account the fact that the solid state value includes some relatively short Si—Si and long Ge-Ge bonds, and the experimental uncertainty, the molecular results are comparable to the solid state results. Since the observed Si—Ge bond length for these molecular systems is typical of bond lengths found in organosilicon compounds containing Si—Ge bonds, 2.384(1), 2.394(1), and 2.416(1) Å for $(C_6H_5)_3Ge—Si(CH_3)_3$, $(C_6H_5)_3Si—Ge(CH_3)_3$, and $(C_6H_5)_3Ge—Si[Si(CH_3)_3]_3$, respectively (30), this observation again suggests that the Si—Ge bond length in organometallic compounds is comparable to the Si—Ge interatomic distance in solid state Si–Ge semiconductors. The Si XANES in the solid state compounds (16), however, exhibits the threshold splitting characteristic of long-range electronic interaction as was the case in crystalline silicon. Thus, the bond length (derivable from EXAFS) is not very sensitive to the long-range electronic interaction but the Si K-edge XANES is.

5. Summary and conclusions

We have reported Si K-edge XAFS spectra for a series of organosilicon compounds containing Si—Si and Si—Ge bonds and have shown that reliable structural and bonding properties can be extracted from the EXAFS and the XANES of these compounds, respectively, without the use of high-quality single crystals. Comparison of the gas phase results with solid state results reveals that the Si—Si and Si—Ge interatomic distances in the latter fall within the range of corresponding bond lengths found in the molecular system. Thus the bond length is not very sensitive to the extended electronic interaction in the solid state. The Si K-edge XANES, however, clearly reveals the difference between the more localized electronic structure (molecular orbitals) in the molecular system and the delocalized electronic structure (densities of states) in the solid state semiconductors. The EXAFS amplitude and phase for the Si–Ge absorber–backscatterer pair has been extracted from the experimental data. These functions may be of some use for the extraction of EXAFS parameters in systems containing the Si—Ge bond.

Variable-energy photoelectron spectroscopy of $CpM(CO)_3$ (M = Mn, Re) and $CpFe(CO)_2I$

Yong-Feng Hu, G. Michael Bancroft, Kim H. Tan, John S. Tse, and Dong-Sheng Yang

Abstract: Photoelectron spectra of the valence, inner-valence, and core levels of $CpM(CO)_3$ (M = Mn, Re) and $CpFe(CO)_2I$ were obtained using He I radiation and synchrotron radiation between 21 eV and 150 eV photon energies. The high-resolution Mn 3*p*, Fe 3*p*, and I 4*d* core level spectra are reported. Broadening of the I 4*d* spectrum is due to vibrational and ligand field splittings. Observation of the 3*p* spectra is critical to fully interpreting the *np*→*nd* resonance effect in the valence band spectra. This resonance effect is very useful for assigning the metal *d* orbital bands in the valence spectra. A Xα-SW calculation of $CpMn(CO)_3$ was used to confirm the assignment of the valence and inner-valence orbitals. The experimental and theoretical branching ratios are in good agreement. The general trend of the metal *d* orbital ionization potentials for $CpML_3$ (M = transition metal) complexes is also discussed.

Key words: photoelectron, synchrotron radiation, $CpMn(CO)_3$, $CpRe(CO)_3$, $CpFe(CO)_2I$, *np*→*nd* resonance, Xα-SW calculation.

Résumé : On a obtenu les spectres photoélectoniques de valence, de valence interne et des niveaux d'énergie de l'atome central des complexes $CpM(CO)_3$ (M = Mn, Re) et $CpFe(CO)_2I$ en utilisant une radiation He I et une radiation du synchrotron avec des énergies de photon se situant entre 21 eV et 150 eV. On rapporte les spectres à haute résolution des niveaux d'énergie Mn 3*p*, Fe 3*p* et I 4*d*. L'élargissement du spectre du niveau I 4*d* est dû au dédoublement du champ vibrationnel et du champ du ligand. L'observation des spectres 3*p* est critique pour interpréter entièrement l'effet de résonnance *np*→*nd* dans le spectre de la bande de valence. Cet effet de résonnance est très utile pour l'attribution des bandes de l'orbitale *d* du métal dans les spectres de valence. On a utilisé un calcul Xα-SW du composé $CpM(CO)_3$ pour confirmer l'attribution des orbitales de valence et de valence interne. Les rapports expérimentaux et théoriques de ramification sont en parfait accord. On discute également de la tendance générale des potentiels d'ionisation de l'orbitale *d* du métal dans le complexes $CpML_3$ (M = métal de transition).

Mots clés : photoélectron, radiation du synchrotron, $CpM(CO)_3$, $CpRe(CO)_3$, $CpFe(CO)_3I$, résonnance *np*→*nd*, calcul Xα-SW.

Introduction

The electronic structures of transition metal cyclopentadienyl carbonyl complexes have been the subject of a wealth of photoelectron spectroscopic (1) and theoretical studies (2). $CpMn(CO)_3$ and $CpFe(CO)_2L$ are central complexes not only for the understanding of the electronic structure of these complexes, but also because they are widely used in transition-metal-aided organic synthesis. Conventional He I/He II photon energies have been used exclusively to obtain the photoelectron spectra of these complexes, and the assignments of the spectra have been aided by comparing the relative He I/He II band intensities. However, the He I/He II spectra, even combined with various theoretical calculations, have failed to yield firm assignments of the valence spectra of some relatively simple molecules, such as $CpPtMe_3$ (3) and $Ni(C_3H_5)_2$ (4). The definitive assignment can only be obtained by combining the variable-energy synchrotron radiation spectra and Xα-SW intensity calculations (3*b*, 4*c*).

The variable-energy synchrotron photoelectron spectra of $CpPtMe_3$ (3*b*) showed that the lowest binding energy peak arises from an MO of largely ligand character, in contrast to the previous experimental and theoretical study that assigned this peak to Pt 5*d* orbitals (3*a*). This result is not consistent with the well-established, qualitative MO descriptions for molecules with general formula $CpML_3$ (M is a transition metal and L is an arbitrary ligand with only σ-donor capability (2*e*)), which shows that the HOMO is a metal orbital. To examine the periodic trend in metal *d* binding energies, we have undertaken detailed variable-energy photoelectron studies of organometallic molecules across and down the transition metal series. We recently published the $M(\eta^3\text{-}C_3H_5)_2$ (M = Ni, Pd, Pt) (4*c*) and $CpM(CO)_2$ (M = Co, Rh, Ir) (5) spectra. In the present study, we investigate the electronic structures of earlier transition metal complexes $CpM(CO)_3$ (M = Mn, Re) and $CpFe(CO)_2I$, using variable-energy photoelectron spectroscopy and Xα-SW calculations. In addition, we wanted to demonstrate the use of synchrotron radiation to study the

inner-valence and core level spectra of organometallic complexes. For example, the high intensity of synchrotron radiation is critical to observing the broad, weak, inner-valence spectra. The high intensity is also essential in observing the Mn 3*p* and Fe 3*p* peaks, which are important in studying the effects of the *np*→*nd* resonance in the valence band spectra (6). The high resolution of synchrotron radiation is also essential in discussing the causes of the broadening in the I 4*d* spectra.

Experimental section

High-purity samples are purchased from Aldrich Chemicals Co., and used directly without further purification.

The photoelectron spectra were measured using two different photoelectron spectrometers. He I spectra were obtained using our McPherson ESCA-36 photoelectron spectrometer. The Ar $2p_{3/2}$ at a binding energy (BE) of 15.759 eV is used for internal calibration with a resolution of ~23 meV. The spectra at higher photon energies (22–150 eV) were obtained with our modified ESCA-36 spectrometer (7) at the Canadian Synchrotron Radiation Facility (CSRF) at the Aladdin storage ring, University of Wisconsin – Madison (8). A 600 g/mm grating gave photon energies between 22 and 72 eV, and a 1800 g/mm grating gave photon energies between 70 and 150 eV. The Xe 5*s* line at a BE of 23.397 eV was used as the calibrant when the 600 g/mm grating was employed, giving a total line width of ~70 meV at 45 eV photon energy. The Kr $3d_{5/2}$ line at a BE of 97.795 eV was used as the calibrant when the 1800 g/mm grating was employed, giving a resolution of ~230 meV at 128 eV photon energy. A Quantar no. 36 position sensitive detector (9) was used to enhance greatly the intensity of the signal, which allowed us to record a broad-scan spectrum spanning 40–50 eV in about 10 min.

All the samples were introduced through the heatable probe into the gas cell of the spectrometer. $CpMn(CO)_3$ was volatile enough to obtain spectra at room temperature. $CpRe(CO)_3$ and $CpFe(CO)_2I$ were less volatile and required heating at temperatures of 50 and 85°C, respectively. The pressure in the sample chamber was controlled at around 3×10^{-5} Torr, while the pressure in the gas cell was around 5×10^{-3} Torr (1 Torr = 133.3 Pa).

Spectra were deconvoluted with a Gaussian–Lorentzian lineshape using a nonlinear least-squares procedure described previously (10). Band areas were taken from the above fitting results and the experimental branching ratios were calculated based on the branching ratio definition ($BR_i = A_i/\Sigma A_i$).

Computational details

A transition state Xα-SW calculation (11) for $CpMn(CO)_3$ was performed to calculate the valence orbital energies, compositions, and theoretical cross sections. The bond distances and bond angles were taken from the crystal structure of $CpMn(CO)_3$ reported by Berndt and Marsh (12). The molecule was idealized to have C_s symmetry. The exchange α parameters were chosen from the literature (13). An l_{max} of 3 was used for outer sphere, and l_{max} values of 2, 1, 1, and 0 were used for Mn, C, O, and H atoms, respectively. The Xα-SW cross sections were calculated using Davenport's program (14) with a Latter tail added to correct the asymptotic behaviour. The resulting partial ionization cross sections (σ_i) were then used to calculate the theoretical branching ratios ($BR_i = \sigma_i/\Sigma\sigma_i$) for each orbital.

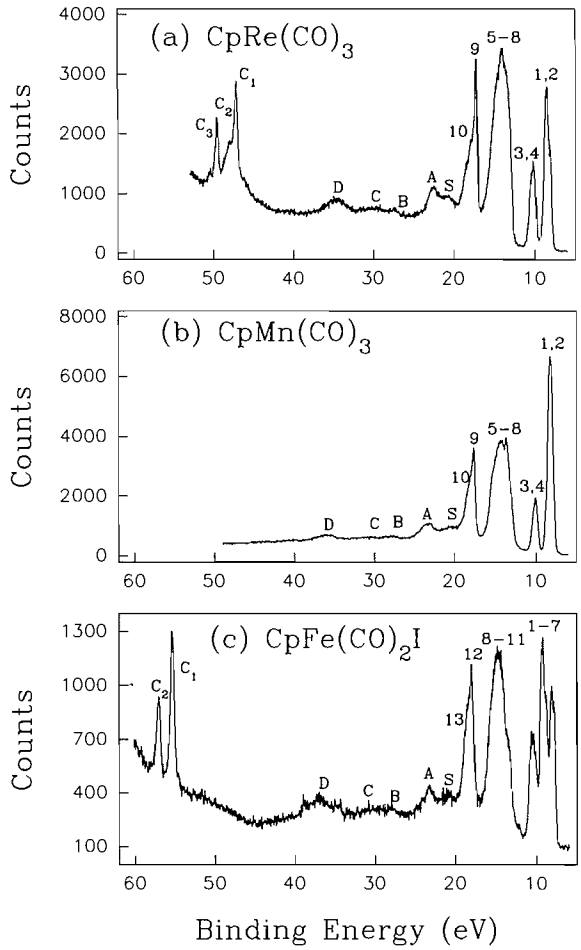

Fig. 1. The high-resolution broad-scan photoelectron spectra of (*a*) $CpRe(CO)_3$ at 72 eV photon energy, (*b*) $CpMn(CO)_3$ at 72 eV photon energy, and (*c*) $CpFe(CO)_2I$ at 70 eV photon energy. See text for explanation of the labelling.

Results and discussion

A. General features of the spectra

Photoelectron spectra of (*a*) $CpRe(CO)_3$, (*b*) $CpMn(CO)_3$, and (*c*) $CpFe(CO)_2I$ spanning 7 eV to 50–60 eV binding energies (BE) are presented in Fig. 1. These spectra were taken at a total resolution of ≤0.2 eV. It is evident that our spectra clearly show three distinctive regions: the intense, relatively narrow valence levels with BE less than 20 eV (labelled 1–13 and S), the weak, broad inner-valence levels with BE between 20 and 40 eV (labelled A–D), and the core levels with BE greater than 40 eV in Figs. 1(*a*) and (*c*) (labelled C_1, C_2, C_3).

The general features of the valence levels in Fig. 1 are in very good agreement with the previous He I/He II studies of these molecules (2*a*, 15). The bands between 7 and 12 eV BE show very different peak shapes and intensities and they are sensitive to metal and ligand substitution. In contrast, the bands from 13 to 20 eV are very similar and therefore insensitive to metal and ligand substitution. Lichtenberger et al.

assigned the valence levels up to 17 eV BE of these molecules based on the He I/He II techniques and a Fenske–Hall calculation (2*a*). The results in the following sections will generally confirm Lichtenberger's previous assignments, but also clarify the assignments of two peaks in the $CpFe(CO)_2I$ spectrum.

The inner-valence spectra of these d^6 cyclopentadienyl metal carbonyl complexes are very similar in peak shapes and positions, like the high-BE valence region. We have shown that the inner-valence spectra of $Re(CO)_5X$ (X = Cl, Br) complexes (16) are dominated by the contribution of carbonyl satellites and CO 3σ orbitals, but not the halogen *s* orbitals. Similarly, a contribution from the I 5*s* orbital around 20 eV BE cannot be seen in the inner-valence region of $CpFe(CO)_2I$. Therefore, the inner-valence spectrum of $CpFe(CO)_2I$ can be assigned in the same way as the spectra of $CpM(CO)_3$ (M = Mn, Re) and $CpM(CO)_2$ (M = Co, Rh and Ir) (5) complexes. That is, the peak (peak S) around 20 eV BE is the shakeup peak from CO 1π and 5σ orbitals; the next peak A around 23 eV is a CO satellite peak but has a higher percentage of Cp ring character; the next two peaks between 24 and 31 eV are the satellite peaks due to CO 4σ orbitals; and the broad and relatively intense peak around 35 eV is due to the CO 3σ orbital (also see Sec. C).

The remaining ionization bands of $CpRe(CO)_3$ and $CpFe(CO)_2I$ in Figs. 1(*a*) and 1(*c*) belong to the core levels, and they can be assigned easily. Two sharp peaks at 47.21 and 49.63 eV BE in Fig. 1(*a*) are the two Re 4*f* spin-orbit components. The shoulder on the higher BE side of $4f_{7/2}$ at 47.5 eV is due to the Re $5p_{3/2}$ ionization. These results are in very good agreement with our high-resolution Re 4*f* results for $Re(CO)_5X$ (X = $(CO)_5$, Cl and Br) complexes (16). The I 4*d* spin-orbit components of $CpFe(CO)_2I$ can be found at 55.20 and 56.92 eV BE in Fig. 1(*c*). The broadening effect of the I 4*d* peaks will be discussed in the next section.

B. Core level study

Recently we demonstrated the importance of high resolution and high intensity in the study of core level photoelectron spectra of organometallic complexes. Vibrational fine structure was resolved on the metal 4*f* core level of heavy metal carbonyl compounds (17). Ligand field broadening was also shown to be present in the Os 4*f* core level of $Os(CO)_5$ (16). In the present paper, we wanted to show: first, the importance of high intensity of synchrotron radiation in the observation of the Mn 3*p* and Fe 3*p* core levels, which are important to the valence level $3p \rightarrow 3d$ resonance studies (6, 16) (see next section); second, the importance of the high resolution of synchrotron radiation in the study of the broadening of the I 4*d* spectrum; and third, the importance of the tunability of synchrotron radiation in a core level cross-section study of the Fe 3*p* and I 4*d* levels in $CpFe(CO)_2I$.

Observation of metal core *p* levels has been shown to be important in the study of $np \rightarrow nd$ resonances (6, 16). However, due to the extremely low cross section of these 3*p* levels at Al Kα energies (~0.02 Mb (18)), these spectra have not been observed in the gas phase. With synchrotron radiation, we can tune the photon energy to the maximum of the 3*p* cross section (~1 Mb at 120–150 eV (18)), and obtain these weak spectra for the first time. Figure 2 presents the high-resolution (total instrumental resolution <0.3 eV) Mn 3*p* spectrum of $CpMn(CO)_3$ at 130 eV photon energy. Our Mn 3*p* BE of 56.3 eV is much larger than the Mn 3*p* BE for Mn metal of 47.2 eV referenced to the vacuum level (19). The broad line width of 2.32 eV is due to the very short lifetime of the 3*p* hole state.

Fig. 2. Photoelectron spectrum of the Mn 3*p* level of $CpMn(CO)_3$, taken at 130 eV photon energy.

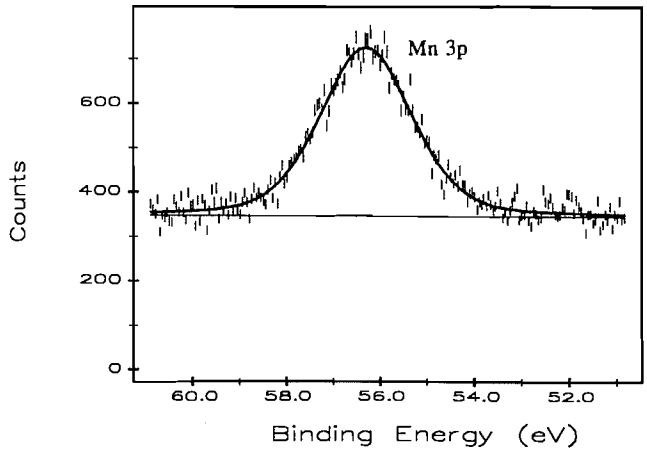

Fig. 3. Core level photoelectron spectra of $CpFe(CO)_2I$ at (*a*) 130, and (*b*) 150 eV photon energies, showing the increase of the relative intensity of Fe 3*p* orbital relative to those of I 4*d* orbitals.

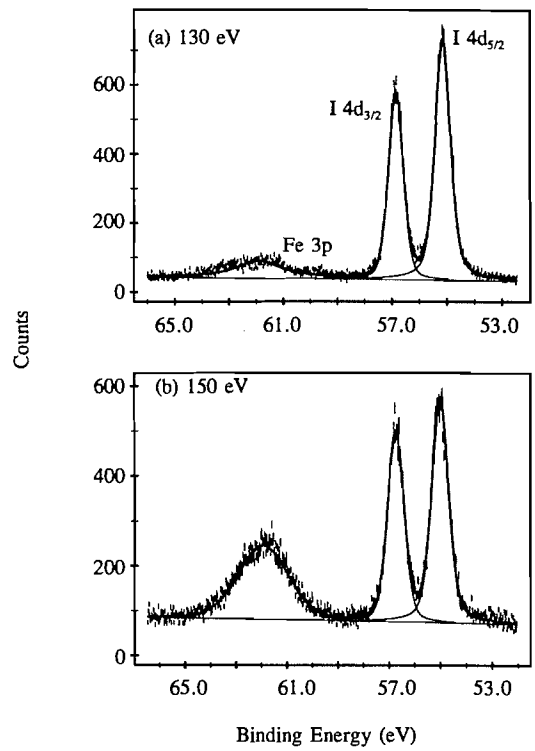

Figure 3 illustrates the Fe 3*p* and I 4*d* core level spectra of $CpFe(CO)_2I$: the broad Fe 3*p* level at 62.0 eV, and the I $4d_{5/2}$ and $4d_{3/2}$ levels at 55.20 and 56.92 eV, respectively. The Fe 3*p* BE will again be useful for studying the $np \rightarrow nd$ resonance effects on the valence band (see next section). These spectra were taken at medium resolution, and gave I 4*d* line widths of 0.75 eV in Fig. 3(*b*). I 4*d* spectra taken at 106 eV photon energy and ≤0.15 eV resolution gave I $4d_{5/2}$ and $4d_{3/2}$ line-

widths of 0.52 and 0.54 eV, respectively. The I $4d_{5/2}$ binding energy of 55.20 eV is much smaller than that of other small covalent molecules such as HI and I_2 (Table 1). However, assuming that the differences in I $4d_{5/2}$ and $3d_{5/2}$ binding energies are the same, the calculated I $3d_{5/2}$ BE for $CpFe(CO)_2I$ is 625.3 eV, in good agreement with that previously observed for $Mn(CO)_5I$ (20), and midway between the I $3d_{5/2}$ BE for I_2 and CsI (Table 1). The $CpFe(CO)_2I$ BE shows that the I atom is really rather negative for a covalent molecule, in agreement with conclusions from ^{129}I and ^{127}I Mossbauer spectroscopy on transition metal iodine compounds (21, 22).

The I $4d_{5/2}$ and $4d_{3/2}$ total line widths (0.54 and 0.52 eV) are very broad compared to the I 4*d* inherent line widths of <0.2 eV, or the total line widths of ~0.2 eV previously observed at similar resolution for I_2 and ICl (23). As for CF_3I, the large line widths are due to a combination of vibrational broadening and ligand field splitting (23), with the major part of this broadening due to unresolved vibrational broadening (23, 24). Using the core equivalent approximation (24), the core equivalent of I 4*d* core-ionized $CpFe(CO)_2I$ is $CpFe(CO)_2Xe^+$. The Fe—Xe^+ bond length is likely to be much longer than the Fe—I bond length of 2.66 Å (2*a*). This would yield a long Fe–Xe^+ vibrational progression (the Fe–I symmetric stretching frequency is only 202 cm^{-1}) (25). It is also possible that CO vibrational splitting could broaden the I 4*d* line, as was seen in the W 4*f* spectrum in $W(CO)_6$ (17).

Ligand field splitting will also contribute to the broadening of these lines. The larger line width of the I $4d_{5/2}$ line is an indication of the importance of this effect. A semiquantitative estimate of the ligand field splitting (as expressed by C_2^0) (23) can be made because C_2^0 is proportional to the nuclear quadrupole coupling constant, e^2qQ at the I nucleus (23). Thus, we can write

$$[1]\quad \frac{C_2^0[CpFE(CO)_2I]}{C_2^0[I_2]} = \frac{e^2qQ[CpFe(C)^2I]}{e^2qQ[I_2]}$$

C_2^0 and e^2qQ are well known (Table 1), and we assume that e^2qQ for $CpFe(CO)_2I$ is close to that for cis-$Fe(CO)_4I_2$ (Table 1). Substituting into eq. [1], C_2^0 for $CpFe(CO)_2I$ is 17.5 meV. This value gives a $4d_{3/2}$ splitting of only 0.14 eV, and $4d_{5/2}$ splittings of less than this. Fitting five peaks to the doublet with these splittings gives an individual line width of 0.45 eV, showing that vibrational broadening is still the dominant broadening mechanism.

Fig. 4. Comparison of the theoretical and experimental branching ratios of Fe 3*p* and I 4*d* orbitals of $CpFe(CO)_2I$. Errors are ±2%.

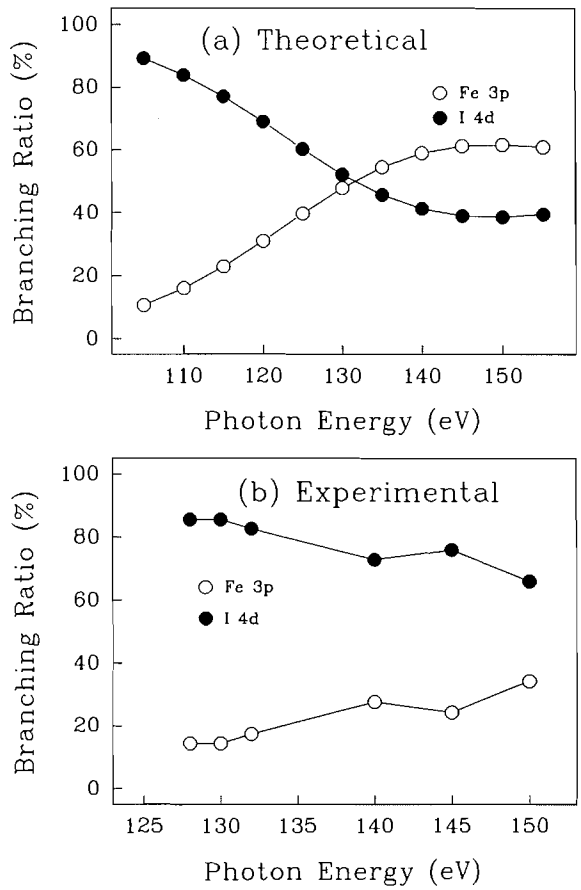

Figure 3 shows the increase in the relative intensity of Fe 3*p* compared with those of I 4*d* from 130 to 150 eV photon energy. This phenomenon is expected when compared with the atomic cross sections of these orbitals. Figure 4 plots the experimental and theoretical (18) branching ratios of Fe 3*p*

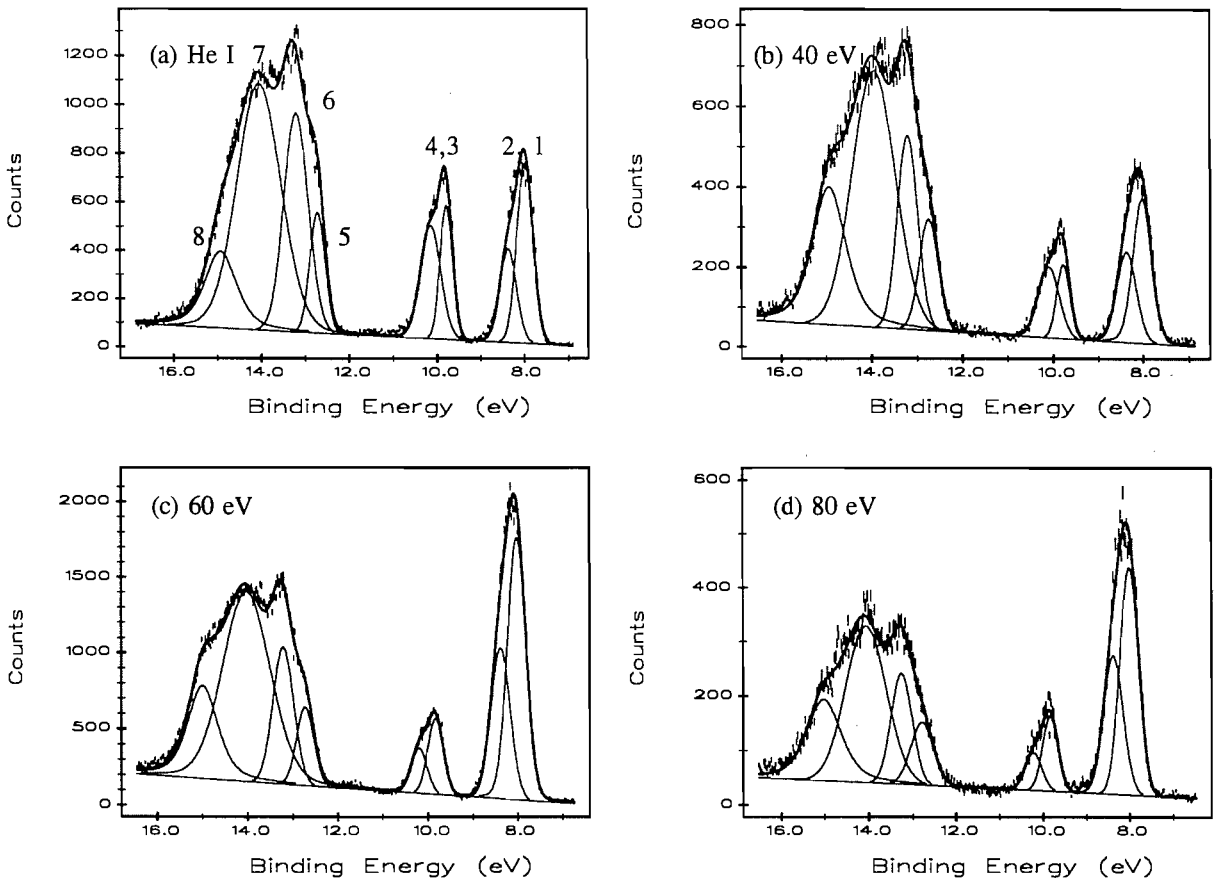
Fig. 5. Representative valence-level photoelectron spectra of $CpMn(CO)_3$ at (*a*) 21.22, (*b*) 40, (*c*) 60, and (*d*) 80 eV photon energies.



and I 4*d* orbitals. It is obvious that the intensity of the Fe 3*p* orbital peak increases between photon energies of 100 and 145 eV, while the intensity of I 4*d* decreases continuously in the same region. Branching ratios of these orbitals cross each other at about 130 eV photon energy theoretically, but well above 150 eV from our experimental results. Clearly, the position of the I 4*d* Cooper minimum is at higher energy than predicted from the atomic calculation. Shifts in the Cooper minimum from atomic values have recently been seen on the Pd 4*d* orbitals in $Pd(\eta^3\text{-}C_3H_5)_2$ (4*c*, 26).

C. Variable photon energy results

(a) $CpM(CO)_3$ (M = Mn, Re) complexes

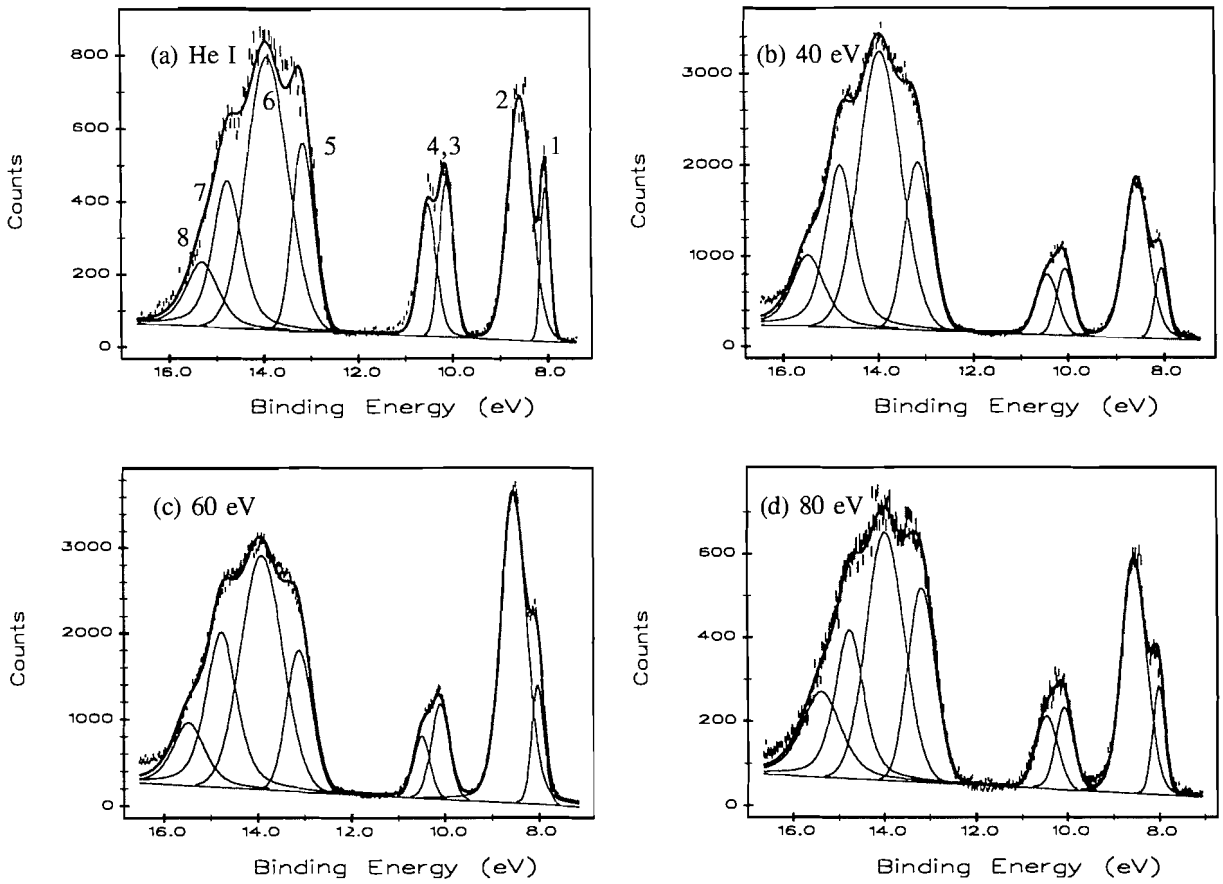
Representative variable-energy photoelectron spectra at 21.22, 40, 60, and 80 eV photon energies of $CpMn(CO)_3$ and $CpRe(CO)_3$ are presented in Figs. 5 and 6. These four photon energies were typically chosen to represent the spectra taken (*a*) by He I radiation with the best resolution, (*b*) by He II radiation, (*c*) at a photon energy higher than the threshold of the *np*→*nd* resonance, and (*d*) at a photon energy well above the *np*→*nd* resonance. It is immediately obvious that the relative intensities of the bands vary dramatically with the photon energy. Especially noticeable is that the relative intensities of the first band in Fig. 5 and 6 increase continually with the increase of the photon energy between 21.22 and 60 eV photon energy, and then show a decrease in the relative intensity from 60 to 80 eV photon energy. This provides us with direct experimental evidence for the assignment of the metal *d* orbitals to peaks 1 and 2.

Using synchrotron radiation, we observed the metal *np*→*nd* resonance on the first band (peaks 1 and 2) to be around 58 eV photon energy for $CpMn(CO)_3$ and around 50 eV for $CpRe(CO)_3$, respectively, also indicating that peaks 1 and 2 arise from orbitals of very high *d* character compared with the other peaks (16). This assignment is in agreement with Lichtenberger's previous He I/He II studies combined with a Fenske–Hall calculation (15).

Xα-SW calculations have proven to be a useful tool for assignment of the valence-level photoelectron spectra of organometallic molecules (27), and we have successfully utilized this technique in the calculation of photoionization cross sections in the study of variable-energy synchrotron radiation photoelectron spectra of some organometallics (3*b*, 4*c*, 5, 28). We performed an Xα-SW calculation on $CpMn(CO)_3$ to further confirm the valence band assignment, to assign the inner valence peaks, and to explain the experimental branching ratio results.

In Table 2, we list the Xα-SW orbital energies and the composition of the resulting wave functions for the upper valence orbitals of $CpMn(CO)_3$. The experimental ionization potentials and the assignments of valence-level bands are also pre-

Fig. 6. Representative valence-level photoelectron spectra of $CpRe(CO)_3$ at (*a*) 21.22, (*b*) 40, (*c*) 60, and (*d*) 80 eV photon energies.



sented in Table 2. The first two MOs in the ground state of $CpMn(CO)_3$ are almost degenerate in energy and both have high (65%) Mn 3*d* contribution. They are derived from Mn $3d_{x^2-y^2}$ and $3d_{xy}$ orbitals and assigned as peak 1 in Fig. 5(*a*). The next MO 18*a*′ is 0.18 eV lower than the HOMO, and this MO also has high Mn 3*d* character (80%). This orbital interacts more with the CO group, but very little with the Cp ring. This orbital can be assigned to peak 2, which is mostly derived from the Mn $3d_{z2}$ orbital. Our Xα results are in good agreement with the previous INDO-type calculation result (2*d*) and strongly support the conclusion that peaks 1 and 2 are the metal *d*-based peak from our variable-energy synchrotron radiation study. The next pair of MO orbitals 11*a*″ and 17*a*′ are almost degenerate in energy and have about 50% Cp ring character. These two orbitals can be easily assigned to peaks 3 and 4, which has also been assigned by Lichtenberger et al. (2*a*) as predominantly ring e_1″ ionization. Peaks 5, 6, 7, and 8 relate to the MO orbitals mainly from CO and Cp groups, and we must point out that the labelling of these peaks and their assignments is somewhat arbitrary because of the many overlapping orbitals involved in this region. However, our Xα results do show that the first three MO orbitals 16*a*′, 10*a*″, and 15*a*′ all have very high Cp ring contribution compared to the rest of the MO orbitals. This allows us to firmly assign these three orbitals to peak 5, since a distinct shoulder between 11 and 13 eV BE has been observed in methyl-substituted ring compounds (2*a*).

The Xα-SW orbital energies and compositions of outer-valence and inner-valence levels of $CpMn(CO)_3$ are listed in Table 3. The inner-valence levels of the three titled compounds are very similar in BE and all are very weak in intensity compared with the valence levels. They were not studied before due to the limitations of the photon source. The first peak (peak 9, see Fig. 1) at 17.63 eV BE is derived from three Cp ring-based orbitals. Peak 10 is at the shoulder of peak 9. It has a BE of 18.23 eV and can be assigned to the contribution of the three CO 4σ orbitals. The next four peaks (peaks S, A, B, C) were assigned previously to the contributions of CO shakeup and satellite peaks that our calculation does not address. However, our Xα results show that there are three Cp orbitals overlapping with the first CO satellite peak at 23.4 eV. The last band in the inner-valence level at 35.6 eV can be assigned readily to the well-known CO 3σ orbitals.

The Xα-SW branching ratio (BR) calculation has been shown to be very valuable for the confirmation of the Xα-SW energy orbital assignment for many molecules. The photoionization cross sections of $CpMn(CO)_3$ were calculated using the Xα-SW method. The BRs of peaks 1, 2 and 3, 4 were then calculated based on the cross sections. Figure 7 presents the comparison of the experimental and theoretical BRs of peaks 1, 2 and 3, 4 for $CpMn(CO)_3$. Both the experimental and Xα calculation BRs show that the BR of peaks 1 and 2 generally increases with photon energies between 20 and 55 eV, while the reverse holds true for peaks 3 and 4. This can be easily

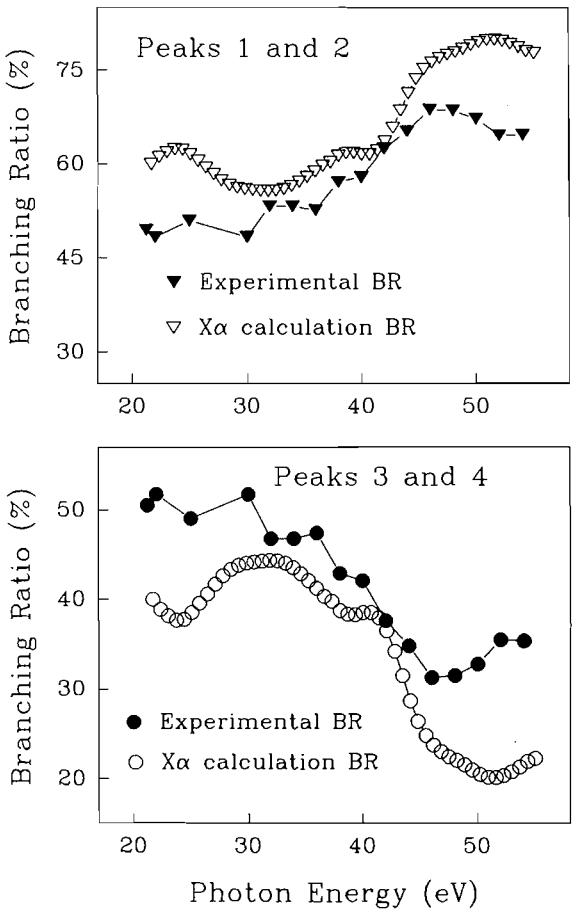
explained because the atomic cross section of Mn 3*d* increases from its threshold to about 60 eV photon energy, while the atomic cross sections of ligand orbitals decrease in the same region. It is noteworthy that only BRs up to 55 eV photon energy are presented in Fig. 7 in order to avoid the interference of Mn 3*p*→3*d* resonance at band 1 after about 56 eV photon energy. The good agreement between the experimental and Xα-calculated BRs strongly confirms once again that peaks 1 and 2 arise from mainly metal-based orbitals and peaks 3 and 4 arise from orbitals with higher ligand character.

Fig. 7. Comparison of experimental (▼, ●) and Xα (▽, ○) branching ratios of peaks 1, 2 and 3, 4 of $CpMn(CO)_3$.



(b) $CpFe(CO)_2I$

We chose to study the electronic structure of $CpFe(CO)_2I$ using variable-energy synchrotron radiation for two reasons. Firstly, the valence level spectrum of $CpFe(CO)_2I$ is much more complex than that of the above two compounds (seven well-resolved peaks between 7.5 and 11.5 eV BE) and the previous assignment was not firm (2*a*). We will demonstrate the value of the observation of the *np*→*nd* resonance for confident assignment of these seven peaks. Secondly, as mentioned earlier, we want to study more and different types of $CpML_3$ complexes, using synchrotron radiation, to see the trend in M 3*d* IPs across the periodic table.

Variable-energy photoelectron valence spectra of $CpFe(CO)_2I$ at 21.22, 52, 60, and 80 eV photon energy are shown in Fig. 8, representing: (*a*) a high-resolution He I spectrum, and synchrotron radiation spectra corresponding to the photon energies of (*b*) before, (*c*) around, and (*d*) after the expected Fe 3*p*→3*d* resonance at ~62 eV from the Fe 3*p* BE. These spectra clearly demonstrate the different trends in the change of the relative intensity of different peaks. Especially noticeable is that the relative intensities of peaks 3 and 4 increase as the photon energy increases, suggesting that both peaks 3 and 4 arise from orbitals of high Fe 3*d* character.

In the previous He I study, Lichtenberger and Fenske (2*a*) assigned the valence spectrum of this compound based on the Fenske calculation and by comparison with the spectra of $Mn(CO)_5X$ complexes. Briefly, peaks 1 and 2 were due to ionizations from the Fe–I antibonding π levels. Peak 4 was assigned to the ionizations from two of the three orbitals of high Fe 3*d* character corresponding to peak 1 in $CpMn(CO)_3$. Peaks 6 and 7, around 10.5 eV BE, were assigned to the ionizations from cyclopentadienyl ring e_1'' orbitals, similar to those of $CpMn(CO)_3$ and $CpRe(CO)_3$. But no conclusive assignments could be made for peaks 3 and 5, since the He I spectrum alone could not distinguish between the predominant Fe 3*d* b_2 orbital and the Fe–I σ orbital, which is mostly of iodine character. Our variable-energy results in Fig. 8 show that the relative intensity of peak 3 increases with the photon energy compared with that of peak 5. This implies that peak 3 should be the predominantly metal b_2-type orbital, which can be confirmed with the observation of *np*→*nd* resonance results for this peak.

Figure 9 presents the valence spectra of $CpFe(CO)_2I$ close to the Fe 3*p* BE of 62.0 eV at 58, 60, 63, and 65 eV photon energy. It is obvious that the relative intensities of peaks 3 and 4 increase, relative to peaks 5, 6, and 7, on going from 60 to 63 eV photon energy, then begin to decrease on going from 63 to 65 eV photon energy. On the other hand, there is no noticeable increase in the intensity of shoulder 5 relative to peak 6. This observation supports the assignment of peak 3 as the Fe 3*d*-based b_2 orbital and peak 5 as the ligand-based a_1 orbital, without any further theoretical calculation.

It is also apparent that the intensities of peaks 1 and 2 increase relative to peaks 5, 6, and 7 above 60 eV photon energy (Fig. 8 and 9). This increase is perhaps unexpected because the I 5*p* cross section decreases sharply at these energies (18, 29). However, another multielectron effect — interchannel coupling — enhances the I 5*p* intensity above the I 4*d* ionizations at 55 eV (29). The I 4d cross section increases rapidly to ~90 eV photon energy, offsetting the expected decrease in I 5*p* cross section.

Conclusion

High-resolution photoelectron spectra of valence, inner-valence, and core levels of $CpM(CO)_3$ (M = Mn, Re) and $CpFe(CO)_2I$ have been studied using monochromatized synchrotron radiation (SR). The high intensity and tunability of SR is important for observing the weak inner valence and M 3*p* (M = Fe, Mn) core level spectra for the first time. The high resolution is critical in defining the broadening mechanisms on the I 4*d* spectrum. The tunability of the radiation is necessary for obtaining the relative intensity of the valence band peaks as a function of photon energy. These intensities, when combined with Xα-SW calculations, yield definitive assignments for the valence and inner-valence molecular orbital ordering. For example, the valence band MOs of $CpMn(CO)_3$ and $CpFe(CO)_2I$ can be readily assigned with the aid of the Xα-SW intensity calculations and the *np*→*nd* resonances. Apart from the I lone pair orbitals in $CpFe(CO)_2I$, the metal *d* orbitals in these complexes are the HOMOs, as predicted earlier (2). In the late second- and third-row transition metal organometallic complexes, such as $CpPtMe_3$ and $Pt(\eta^3\text{-}C_3H_5)_2$, the metal *d* orbitals are at appreciably lower BE (5), resulting in the HOMO being a ligand-based orbital.

Fig. 8. Representative valence-level photoelectron spectra of $CpFe(CO)_2I$ at (*a*) 21.22, (*b*) 52, (*c*) 60, and (*d*) 80 eV photon energies.

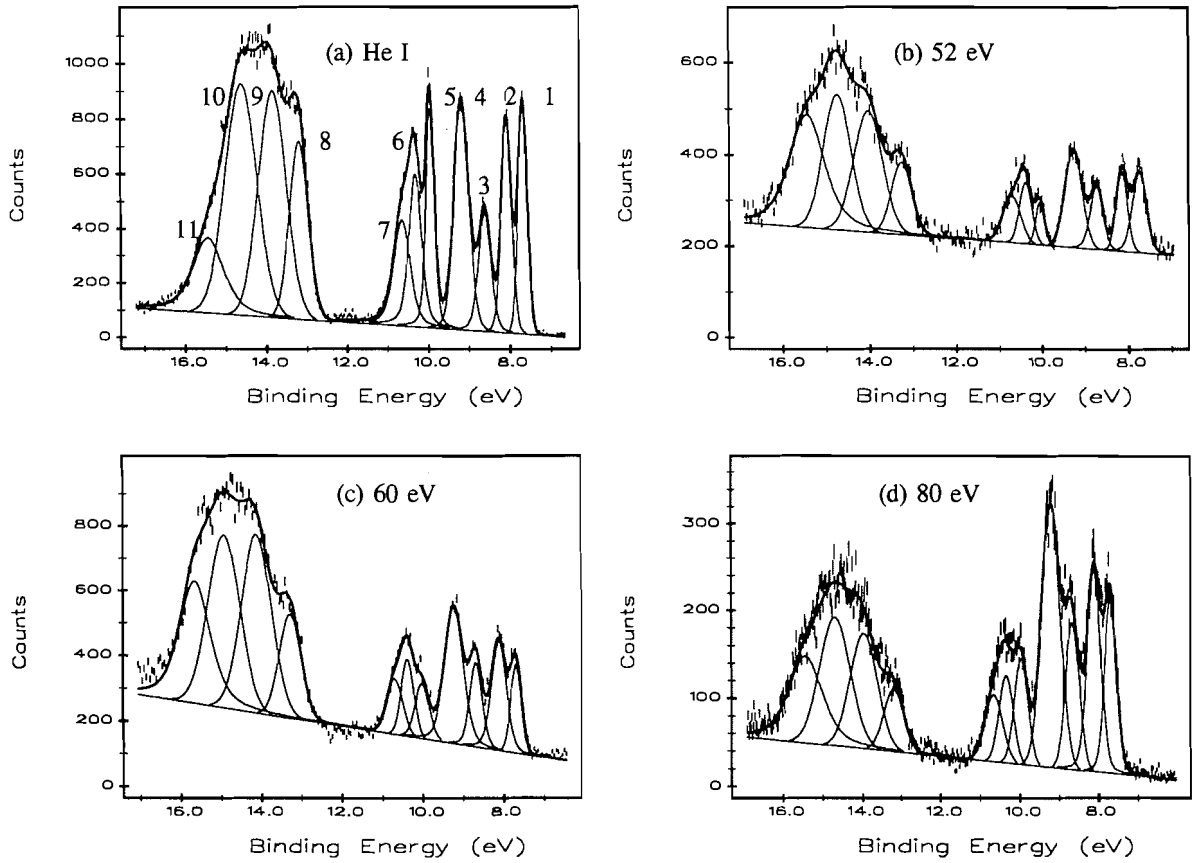


Fig. 9. The valence-level spectra of $CpFe(CO)_2I$ at (*a*) 58, (*b*) 60, (*c*) 63, and (*d*) 65 eV photon energy, showing the increase of the relative intensities of peaks 3 and 4 around 63 eV photon energy.

Redox activity of tryptophan residues in recombinant cytochrome c peroxidase and its W51F and W191F mutants

George Tsaprailis and Ann M. English

Abstract: Tryptophan oxidation mediated via the heme was initiated by adding 2, 6, and 20 equivalents of H_2O_2 to 5 μM recombinant CCP (CCP(MI)) and its W51F and W191F mutants at pH 7.0. Addition of the proteins to 8 M urea (pH 1.5) relieved heme quenching of Trp fluorescence. CCP(MI)-I, W51F-I, and W191F-I, the two-electron oxidized species (Fe^{IV}=O,$R^{\cdot+}$) formed on addition of 2 equivalents of H_2O_2, exhibited decreased fluorescence relative to the Fe^{III} forms. Loss of 0.7 Trp in CCP(MI)-I and W51F-I, and 0.2 Trp in W191F-I implies that $R^{\cdot+}$ is located on Trp191 in CCP(MI)-I and W51F-I. Spontaneous decay of the Fe^{IV}=O hemes back to Fe^{III}, followed by reaction with 2 more equivalents of H_2O_2 after 24 h, resulted in a *combined* loss of 2.7 (CCP(MI)), 1.5 (W51F), and ~1 (W191F) Trp. Also, addition of 6 equivalents of H_2O_2 to the *resting* Fe^{III} enzymes resulted in loss of ~2 Trps in CCP(MI) but only ~1 in W51F and W191F, suggesting that Trp51 becomes redox active in CCP(MI) when >2 equivalents of H_2O_2 are reduced. Addition of 20 equivalents of H_2O_2 resulted in a *total* loss of ~4, 2.5, and 2 Trp in CCP(MI), W51F, and W191F, respectively. Activity loss largely paralleled Trp loss, and the residual activity of CCP(MI) and W51F exposed to 20 equivalents of H_2O_2 was 5–19%, while W191F exhibited ~50% activity. SDS PAGE analysis revealed that oxidized CCP(MI) and W191F were 60–70% monomeric, and W51F 27% monomeric following its reaction with >2 equivalents H_2O_2. Amino acid analyses confirmed Trp loss and also showed significant Tyr, but *not* Met, loss in the oxidized proteins. Donors to the heme and pathways of electron migration are proposed based on the combined results.

Key words: cytochrome c peroxidase, Trp mutants, H_2O_2 oxidation, redox-active residues.

Résumé : On a induit l'oxydation du tryptophane par l'hème en ajoutant 2, 6 et 20 équivalents de H_2O_2 à 5 μM de recombinant CCP (CCP(M)) et ses mutants W51F et W191F à pH 7,0. L'addition de protéines à 8 M d'urée (pH 1,5) diminue l'extinction de la fluorescence du Trp par l'hème. CCP(MI)-I, W51F-I et W191F-I, les espèces oxydées à deux électrons (Fe^{IV}=O,$R^{\cdot+}$) formées lors de l'addition de deux équivalents de H_2O, exhibent une diminution de la fluorescence par rapport à la forme Fe^{III}. La perte de 0,7 Trp dans le CCP(MI)-I et dans le W51F-I et de 0,2 Trp dans le W191F-I implique que $R^{\cdot+}$ est localisé sur le Trp191 dans le CCP(MI)-I et dans le W51F-I. La dégradation spontanée de l'hème Fe^{IV}=O en Fe^{III}, suivie de la réaction avec deux équivalents supplémentaires de H_2O_2 après 24 h résulte en une perte *combinée* de 2,7 (CCP(MI)), de 1,5 (W51F) et d'environ 1 (W191F) Trp. De même, l'addition de 6 équivalents de H_2O_2 à l'enzyme Fe^{III} à l'état fondamental résulte en une perte d'environ 2 Trps dans le CCP(MI) mais la perte est seulement de l'ordre de 1 dans le W51F et dans le W191F, suggérant que Trp51 devient une agent redox actif dans le CCP(MI) lorsque plus de deux équivalents de H_2O_2 sont réduits. L'addition de 20 équivalents de H_2O_2 conduit à une perte *totale* d'environ 4, 2,5 et 2 Trp dans le CCP(MI), W51F et W191F respectivement. La perte d'activité va de pair avec la perte de Trp, et l'activité résiduelle du CCP(MI) et du W51F, lorsque ces substances sont soumises à 20 équivalents de H_2O_2, est de l'ordre de 5–19% tandis que le W191F exhibe une activité de 50% environ. L'analyse SDS PAGE révèle que le CCP(MI) et le W191F oxydés sont à 60–70% sous forme monomère et le W51F existe à 27% sous la forme monomère par suite de la réaction avec plus de deux équivalents de H_2O_2. L'analyse des acides aminés confirme la perte de Trp et révèle une perte significative de Tyr, mais *pas* de perte de Met, dans la protéine oxydée. Sur la base des résultats combinés on propose des donneurs pour l'hème et un mécanisme de migration d'électron.

Mots clés : cytochrome c peroxydase, mutants du Trp, H_2O_2 oxydation, résidus actifs comme agent redox.

Introduction

The identification of a Trp radical in yeast CCP-I[2] (1) was the first instance that a Trp residue was shown to play a redox-active role in an enzyme (2). Recently, however, a redox-active Trp has been identified in ribonucleotide reductase (3) and, in addition to Trp, a number of other amino acid radicals, including tyrosyl, cysteinyl, and glycyl radicals are known to play catalytic roles in enzymatic reactions (4). Reversible redox activity of protein residues involves the formation of one-electron oxidized free radical species, which are stabilized by the surrounding polypeptide. Thus, a full understanding of the use of protein free radicals in redox catalysis (free radical enzymology) requires characterization of their storage sites, and elucidation of their migration and quenching mechanisms in protein matrices.

The catalysis of two-electron redox chemistry by Fe^{III} heme centres necessitates the generation of radical species. Hence, small plant and fungal heme peroxidases can provide important insight into the reactivity of protein radicals in redox catalysis. Binding of H_2O_2 to the Fe^{III} ion in heme peroxidases (Fe^{III}, P) results in heterolytic cleavage of the O—O bond, and formation of a two-electron oxidized intermediate (Fe^{IV}=O,$P^{\cdot+}$), termed compound I (eq. [1]). Reduction of the latter in one-electron steps (eqs. [2] and [3]) back to the resting enzyme occurs via formation of the one-electron oxidized intermediate (Fe^{IV}=O,P), termed compound II.

[1] $Fe^{III}P + H_2O_2 \rightarrow Fe^{IV}{=}O,P^{\cdot+} + H_2O$

[2] $Fe^{IV}{=}O,P^{\cdot+} + 1e^- \rightarrow Fe^{IV}{=}O,P$

[3] $Fe^{IV}{=}O,P + 1e^- \rightarrow Fe^{III}P + H_2O$

In most heme peroxidases $P^{\cdot+}$ is initially a porphyrin π-cation radical, but a protein-based radical is observed for CCP-I (5, 6). Of the 7 Trps, Trp191, which is in van der Waals contact with the heme (Fig. 1), has been identified as the redox-active amino acid residue in CCP-I. The broad EPR signal characteristic of native CCP-I was not observed in the spectrum of W191F-I (7, 8), and this mutant also exhibited a transient porphyrin radical on reaction with peroxide (9). Trp51, which is only 4 Å from the heme (Fig. 1), was eliminated as the radical site since W51F-I exhibited EPR and ENDOR spectra almost identical to those of CCP(MI)-I (7).

We have shown previously that steady-state protein fluorescence can be used to probe the loss of Trp residues in H_2O_2-oxidized yeast CCP (10). Since heme is a highly efficient quencher of CCP fluorescence (11), protein denaturation in 8 M urea at pH 1.5 is required to relieve quenching and allow fluorescence loss to be equated with Trp loss. Furthermore, since denaturation of CCP occurs rapidly in 8 M urea, it is assumed that radical migration does not occur during this process (10), and that protein-based radicals are converted to stable oxidation products on exposure to the solvent.

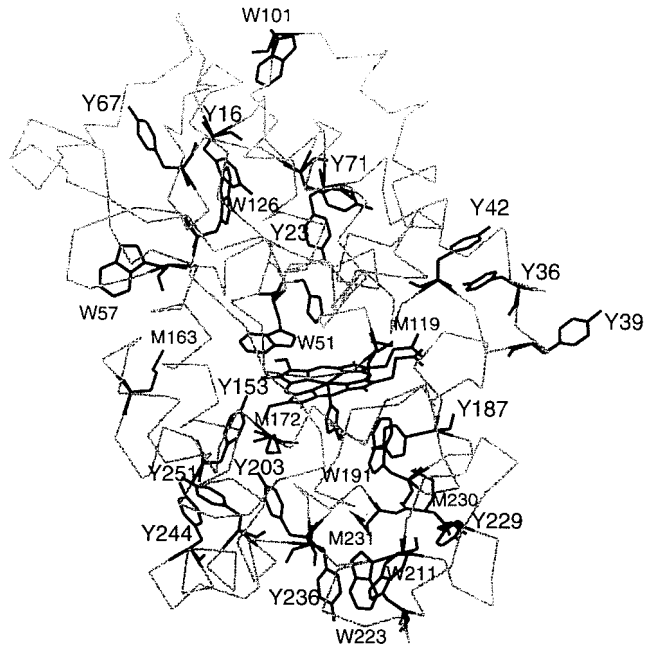

Fig. 1. The C_α backbone of CCP showing the location of the 7 Trp (W), 14 Tyr (Y), and 6 Met (M) residues relative to the heme.

The fluorescence measurements are extended here to the recombinant enzyme (CCP(MI)) and two mutants, W51F and W191F, in which the Trp residues closest to the heme are singly mutated to phenylalanine. In lignin peroxidase (LIP), where Phe46 and Phe193 correspond to Trp51 and Trp 191 (12), $P^{\cdot+}$ is a porphyrin π-cation radical in compound I (13). Since it is more difficult to oxidize the side chain of phenylalanine than the indole side chain of Trp (14), the rapid transfer of oxidizing equivalents from the porphyrin to a protein-based radical is presumably prevented in LIP-I (6). Despite the Trp191 → Phe mutation, a porphyrin π-cation radical is only transiently formed ($t_{1/2}$ ~14 ms) in W191F-I (9). The porphyrin radical is transferred to the protein, resulting in an EPR signal for W191F-I that has been assigned to a tyrosyl radical (7, 8). Hence, an examination of compound I of the two Trp → Phe mutants will provide a test of the EPR data and also demonstrate if fluorescence measurements on the denatured proteins can clearly distinguish between Trp and Tyr radicals.

In the absence of oxidizable substrates, CCP(MI)-I, W51F-I, and W191F-I spontaneously decay to give products with absorption spectra similar to their resting Fe^{III} forms. The half-life of the Fe^{IV}=O heme in CCP(MI)-I and W191F-I is ~3 h (15), but that of W51F-I is only ~3–4 s (16). EPR studies revealed that the protein radical signal in yeast CCP-I decays on a slightly faster time scale than the Fe^{IV}=O centre (17). However, a protein-based radical persists in W191F-I for only ~10 min (18), clearly indicating that the Fe^{IV}=O heme is not reduced by the removal of a second electron from the EPR-

[2] Abbreviations: ABTS, 2,2′-azinobis[3-ethylbenzthiazoline-6-sulfonic acid]; CCP(MI), recombinant cytochrome c peroxidase (EC 1.11.1.5) from *E. coli*; CCP(MI)-I, W51F-I, W191F-I, compounds I of CCP(MI), W51F, and W191F, where compound I is the two-electron oxidized species formed when stoichiometric H_2O_2 reacts with the peroxidases; CCP(MI)-II, compound II, species formed on one-electron reduction of compound I; ENDOR, electron-nuclear double resonance; EPR, electron spin resonance; LC–MS, liquid chromatography with mass spectrometric detection; LIP, lignin peroxidase; NATA, *N*-acetyltryptophanamide; SDS–PAGE, sodium dodecyl sulphate – polyacrylamide gel electrophoresis.

active species. To probe Trp loss due to the combined effects of protein radical decay and endogenous electron transfer to the Fe^{IV}=O heme, the decay products were examined by fluorescence at time intervals between 15 s and 24 h following the addition of H_2O_2. Furthermore, the 24-h decay products were exposed to another two oxidizing equivalents of H_2O_2 and rapidly unfolded to see if Trp residues were also electron donors in the decay products.

Millimolar H_2O_2 readily oxidizes methionine residues in proteins but not aromatic residues (19). However, yeast CCP reduces up to 20 equiv. of H_2O_2 at micromolar concentrations using endogenous donors on the polypeptide (20), including ~3 Trps (10). A mechanism consistent with the reduction of 2 equiv. of $H_2O_2$by compound I would be the following:

[4] $Fe^{IV},P^{\cdot+} \rightarrow Fe^{III},P^{\cdot+},P_x^{\cdot}$

[5] $Fe^{III},P^{\cdot+},P_x^{\cdot} + H_2O_2 \rightarrow Fe^{IV}=O,P^{\cdot+},P_x^{\cdot},P_y^{\cdot} + H_2O$

where $P_x^{\cdot}$ and $P_y^{\cdot}$ are additional protein-based radicals generated by the transfer of the two oxidizing equivalents from peroxide via the heme to the polypeptide. Exposure to 6 and 20 equiv. of H_2O_2 was undertaken to estimate the *maximum* number of Trp donors in each of the mutants examined here. As carried out previously with yeast wild-type CCP (10), amino acid analyses were performed to probe the loss of non-Trp residues, and ferrocytochrome c and ferrocyanide oxidizing activities were measured just prior to denaturation to compare fluorescence loss with activity loss. H_2O_2 titres and the extent of radical-mediated *intermolecular* protein cross-linking were also measured. Finally, interpretation of the combined data, in terms of possible sites of protein-based free radical formation and possible radical and electron migration pathways, is attempted.

Experimental

Materials

Wild-type recombinant cytochrome c peroxidase (CCP(MI)) and its W51F and W191F mutants, prepared as described (16), were generous gifts from Dr Mark Miller (University of California, San Diego). Horse heart cytochrome c (Type III), *N*-acetyltryptophanamide (NATA), and guanidinium chloride were obtained from Sigma; ABTS was purchased from Boehringer Mannheim as the diammonium salt, and analytical grade urea was purchased from Anachemia. All chemicals were used without further purification. Distilled water (specific resistance 18 MΩ cm) was prepared using a Banstead Nanopure system. SDS–PAGE was performed on 7.5% acrylamide gels using a Mini Protean II Electrophoresis Dual Slab Cell and silver staining (Bio-Rad). Densitometer tracings of the gels were obtained on a FisherBiotech transmission densitometer. Fluorescence and absorption measurements were carried out on a Shimadzu model RF 5000 spectrofluorometer and a Hewlett Packard 8451A diode-array spectrophotometer, respectively.

H_2O_2 oxidation

Protein stock solutions of 5 μM were prepared in 0.1 M sodium phosphate buffer (pH 7.0) using ϵ_{408} (mM^{-1} cm^{-1}) values of 102 (CCP(MI)), 141 (W51F) (16), and 109 (W191F) (21). Stock H_2O_2 solutions (0.2–2 mM) were prepared in the same buffer and H_2O_2 concentrations were determined spectrophotometrically by monitoring the CCP-catalyzed oxidation of excess ABTS ($\Delta\varepsilon_{405}$ = 36.8 mM^{-1} cm^{-1}). Protein and H_2O_2 stocks were mixed to give the desired ratios. Formation of Fe^{IV}=O heme was followed spectrophotometrically at 424 nm (17).

Enzyme activities

Assay solutions contained 180 μM H_2O_2, 25 μM ferrocytochrome c, or 20 mM ferrocyanide as reducing substrate and 25 nM native or oxidized peroxidase in 0.1 M phosphate buffer (pH 7.0). Activity measurements were performed by following substrate oxidation spectrophotometrically (ferrocytochrome c, $\Delta\varepsilon_{550}$ = 18 mM^{-1} cm^{-1} (22); ferrocyanide, $\Delta\varepsilon_{420}$ = 1.0 mM^{-1} cm^{-1} (23, 24)). Activities of the H_2O_2-oxidized enzymes are reported relative to the unoxidized enzymes maintained under the same conditions.

H_2O_2 turnover, H_2O_2 titres, SDS–PAGE, and amino acid analysis

ABTS (700 μM) oxidation was monitored at 724 nm to determine the time course and extent of H_2O_2 turnover by 5 μM enzyme. The 24-h decay products were titrated with H_2O_2 and the absorbance change at 424 nm monitored to determine the extent of Fe^{IV}=O heme formation. Cross-linking of the proteins following addition of H_2O_2 was investigated by SDS–PAGE (10), and amino acid analysis was carried out as previously described (10).

Relative fluorescence

At various time intervals (15 s – 24 h) after the addition of H_2O_2 to 5 μM protein in 0.1 M phosphate buffer (pH 7.0), the samples were diluted with urea to give a final concentration of 1 μM protein in 8 M urea at pH 1.5. Following 280-nm excitation, fluorescence intensities were measured at 350 nm, which is the emission maximum of CCP in urea (11). The Raman peak of water was subtracted from all emission spectra, and inner-filter effects were corrected using the formula (25):

[6] $F = F_o \text{ antilog}[A_{ex} + A_{em})/2]$

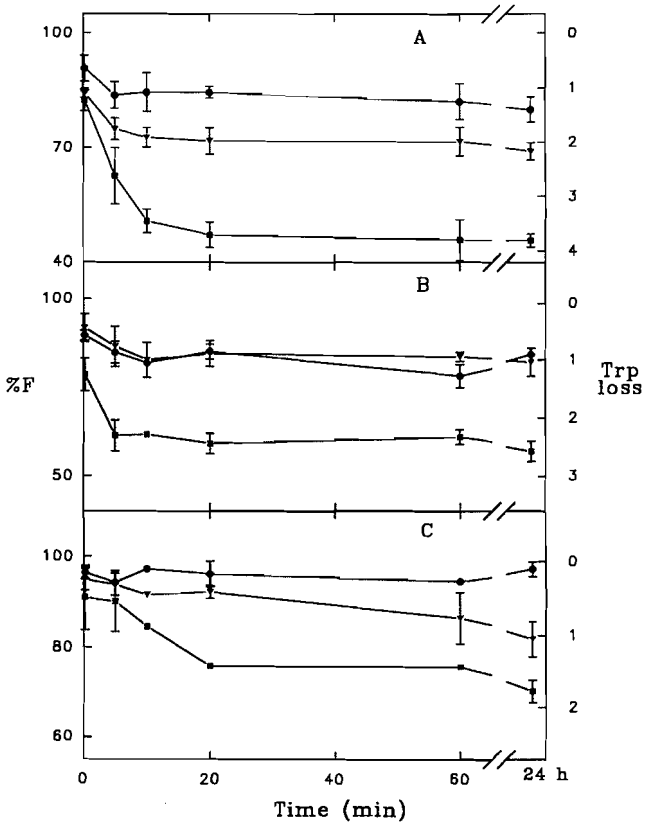
where F is the corrected fluorescence intensity, F_o the observed intensity, A_{ex} and A_{em} are the absorbances at the excitation and emission wavelengths, respectively. Relative fluorescence intensities (%F) were calculated assuming %F = 100 for unoxidized protein maintained under the same conditions.

Results

Relative fluorescence

The fluorescence increase, observed within the mixing time (2–3 s) upon denaturation of CCP(MI), W51F, and W191F in urea, is accompanied by a red shift in emission maximum to 350 nm, characteristic of Trp exposure to the aqueous environment (11). After correcting for inner-filter effects (eq. [6]), the proteins exhibit fluorescence intensities in 8 M urea at pH 1.5 equal to that of Trp model compound NATA, indicating that each of the 6 or 7 Trp residues in the denatured proteins possesses the same fluorescence quantum yield as NATA (10). Heme quenching is totally eliminated under these conditions

Fig. 2. Relative fluorescence intensities at 350 nm of 1 μM H_2O_2-oxidized protein in 8 M urea (pH 1.5) at 22°C. 5 μM protein was reacted with H_2O_2 in 0.1 M phosphate buffer, pH 7.0, and diluted with urea at various times after addition of H_2O_2. Circles, 2 equiv. of H_2O_2 added (compound I); triangles, 6 equiv. of H_2O_2 added; squares, 20 equiv. of H_2O_2 added. Data points are the corrected (eq. [6]) relative fluorescence intensities (*%F*) and represent the averages of four measurements. (*A*) CCP(MI), (*B*) W51F, and (*C*) W191F. Experimental conditions: 280-nm excitation; slits, 5 nm; scan rate, 114 nm/min.

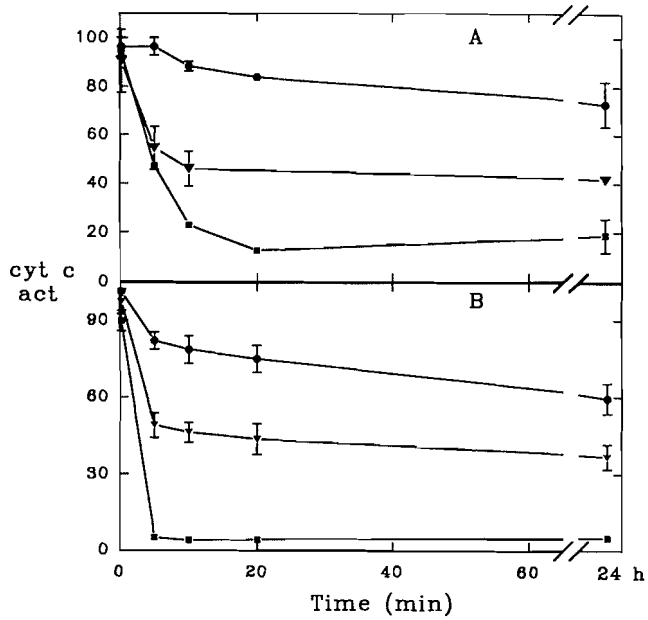


due to dissociation of the heme from the polypeptide as evidenced by the appearance of free-heme spectra (10).

Figure 2*A* summarizes the fluorescence intensities at 350 nm following denaturation of CCP(MI) at various time intervals after the addition of 2, 6, and 20 equiv. of H_2O_2. Addition of CCP(MI)-I to 8 M urea at pH 1.5 reveals loss of fluorescence due to heme-mediated Trp oxidation by H_2O_2 (10). CCP(MI)-I formed 15 s prior to denaturation retains 91 ± 3% fluorescence relative to resting CCP(MI), which corresponds to the oxidation of 0.7 ± 0.2 Trp residues. In the 24-h decay product of CCP(MI)-I the number of Trps lost increases to 1.4 ± 0.2. Addition of 6 equiv. of H_2O_2 to CCP(MI) 15 s and 5 min prior to denaturation resulted in loss of ~1 and 2 Trps, and when 20 equiv. of H_2O_2 were added for the same time intervals, ~1 and 3 Trps were oxidized; this increased to a total of ~4 when the 20:1 sample was denatured after 24 h. Clearly, the number of Trps oxidized increases with time and the amount of H_2O_2 added. Addition of aliquots of the CCP(MI)–H_2O_2 mixtures to an ABTS solution indicated that 3 H_2O_2 were turned over in ~1 min and 10 in ~5 min.

Upon denaturation 15 s following its generation, W51F-I exhibits 89 ± 1% relative fluorescence in 8 M urea (pH 1.5), indicating loss of 0.7 ± 0.1 Trps out of a total of 6. Samples of W51F-I denatured over 24 h exhibit loss of 1.0–1.3 Trps, and addition of 6 equiv. of H_2O_2 to W51F resulted in oxidized species with essentially the same fluorescence vs. time profile as W51F-I (Fig. 2*B*). The fluorescence loss 15 s after the addition of 20 equiv. of H_2O_2 to W51F reveals the immediate loss of ~1 Trp, and at longer times (≥5 min), a total loss of ~2.5 Trps is observed (Fig. 2*B*).

Fig. 3. Horse heart ferrocytochrome c oxidizing activities relative to unoxidized protein in 0.1 M phosphate buffer (pH 7.0) of the (*A*) CCP(MI) and (*B*) W51F samples in Fig. 2 just prior to denaturation.



W191F-I and its 24-h decay product retain 96–97% relative fluorescence in 8 M urea (pH 1.5), indicating oxidation of only ~0.2 Trp (Fig. 2*C*). The 6:1 and 20:1 W191F samples lose Trp slowly over time, resulting in the oxidation of ~1 and 2 Trps, respectively, in their 24-h decay products (Fig. 2*C*). Addition of aliquots of the W191F–H_2O_2 mixtures to an ABTS solutions indicated that 3 H_2O_2 were turned over in ~1 min and 10 in ~ 30 min.

Enzyme activities

Using ferrocytochrome c as reducing substrate, the activities of CCP(MI) and W51F are shown in Fig. 3. CCP(MI)-I and W51F-I formed 15 s before commencing the assays exhibit ~96% ferrocytochrome c oxidizing activity, but this is reduced to 60–70% in the 24-h decay products. Preincubation for 5–10 min with 6 equiv. of H_2O_2 further reduces the activity to 50–55%, and exposure to 20 equiv. results in 5% activity in W51F and ~19% activity in CCP(MI) (Fig. 3 and Table 1). W191F has negligible ferrocytochrome oxidizing activity because the presence of Trp191 is necessary for rapid reduction of the heme by ferrocytochrome c (18).

Ferrocyanide oxidizing activities of CCP(MI), W51F, and W191F as a function of preincubation time with 2–20 equiv. of H_2O_2 are summarized in Fig. 4. The overall dependence of activity on the number of oxidizing equivalents added and on

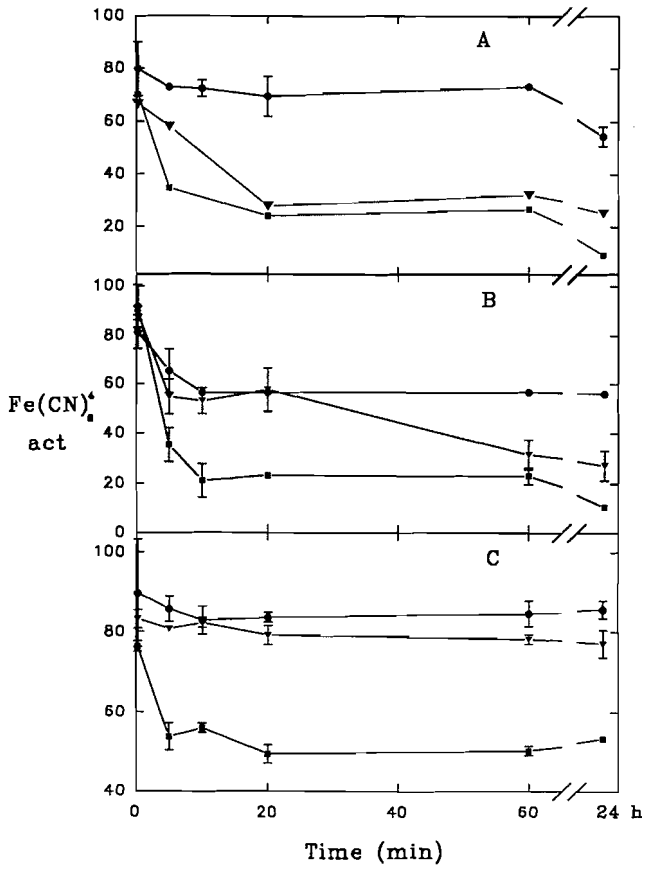
Fig. 4. Ferrocyanide oxidizing activities relative to unoxidized protein in 0.1 M phosphate buffer (pH 7.0) of the (*A*) CCP(MI), (*B*) W51F, and (*C*) W191F samples in Fig. 2 just prior to denaturation.



preincubation time is similar to that shown in Fig. 3. CCP(MI) and W51F shows similar activity vs. preincubation time profiles except that the 6:1 W51F samples lose activity more slowly than the corresponding CCP(MI) samples. The loss in ferrocyanide oxidizing activity of the W191F samples preincubated for only 15 s with H_2O_2 is comparable to that of the other mutants; however, W191F retains considerably greater activity after 2 h, with the 2:1, 6:1, and 20:1 samples exhibiting 86, 77, and 53% activity, respectively, compared to 55, 25, and 9% for CCP(MI) (Table 1).

H_2O_2 titres

Using the relative absorbance change at 424 nm (the maximum in the difference spectrum of the Fe^{III} and Fe^{IV}=O forms), the 24-h decay products of oxidized CCP(MI) and W191F were titrated with H_2O_2 to determine the extent of their ability to reform Fe^{IV}=O heme (reaction [1]). The decay products of W191F possess the highest titres, and these match the ferrocyanide oxidizing activities closely (Table 1). There is also a good correspondence between the titres and ferrocytochrome c oxidizing activities for CCP(MI), but its ferrocyanide oxidizing activities are significantly lower (Table 1). The instability of the Fe^{IV}=O heme of W51F ($t_{1/2}$ ~3–4 s) prevented measurement of its titre; nonetheless, the decay products of this mutant exhibit comparable activity to CCP(MI) with both reducing substrates (Table 1).

SDS–PAGE

Table 2 summarizes the percent monomer in the H_2O_2-oxidized enzymes at pH 7.0. Gels of CCP(MI)-I and its 24-h decay product showed no polymerized protein, whereas the monomeric content of the 6:1 and 20:1 24-h decay products is 60–70%. W51F-I gives rise to 85% monomeric protein when denatured within 15 s, but the monomeric content of its decay product is reduced to 60% within ≥1 h. The 6:1 and 20:1 W51F samples show extensive polymerization, with a monomer content of ≤28% after 24 h. The percent monomer in oxidized W191F falls within the narrow range of 60–80% for all samples (Table 2), with the remainder forming dimeric forms exclusively, in agreement with published results (18).

Amino acid analyses

Analyses of the 24-h decay products of CCP(MI) and W191F were carried out (insufficient W51F was available for these

analyses). For both proteins the Trp loss was in good agreement with that observed by fluorescence. Loss of 0.7, 1.5, and 4.4 Tyr was observed for the 2:1, 6:1, and 20:1 decay products of CCP(MI), and the 20:1 product also lost 0.8 Met but 0 Cys. The corresponding Tyr losses for W191F were 1.5, 2.0, and 3.8, but no peroxide-induced loss of Met or Cys was observed for this mutant. Although the side chains of Met and Cys residues are readily oxidized, the amino acid analyses suggest that the endogenous donors to the heme are largely Trp and Tyr residues, rather than Met residues (Fig. 1) or the single Cys residue in CCP.

Discussion

CCP(MI)-I exhibits 91 ± 3% fluorescence at 350 nm relative to unoxidized CCP(MI) in 8 M urea at pH 1.5, corresponding to the loss of 0.7 ± 0.2 Trp. This result is the same as that observed for yeast wild-type CCP (10), and supports the assignment of Trp191 as the redox-active residue in CCP-I and CCP(MI)-I (1). W51F-I exhibits the same Trp loss (0.7 ± 0.1) as CCP(MI)-I, but the fluorescence loss in denatured W191F-I is negligible (Fig. 2*C*). These results are consistent with the assignment of the EPR signals to a tyrosyl radical in W191F-I and an indolyl radical in W51F-I (7, 8), and confirm that Tyr- and Trp-based radicals can be distinguished by the fluorescence method employed here.

Dissipation of the oxidizing equivalents (Fe^{IV}=O,$P^{\cdot+}$) stored in compound I increases the Trp loss in CCP(MI)-I and W51F-I to ~1.4. The Fe^{III} heme of the decay products reacts rapidly with H_2O_2, and this leads to the immediate loss of 1.3, 0.5, and 0.7 extra Trps in CCP(MI), W51F, and W191F (Table 1), corresponding to a *combined* loss of 2.7, 1.5, and 0.9 Trps, respectively. Oxidation of Trp51 on addition of H_2O_2 to the decay product of CCP(MI)-I is likely since Trp51 → Phe mutation significantly decreases Trp oxidation on the addition of H_2O_2 to the decay product of W51F-I. Trp51 is also a possible electron donor in the 24-h decay product of W191F-I given that reaction with H_2O_2 results in the loss of ~0.7 Trp (Table 1).

Addition of 6 equiv. of H_2O_2 to the *resting* enzymes prior to denaturation results in the loss of ~2 Trps in CCP(MI) and ~1 in each of the mutants (Fig. 2). This provides further evidence that oxidizing equivalents generated at the heme are transferred to Trp191 and Trp51 in CCP(MI) by a mechanism such as that given in eqs. [4] and [5]. The ABTS results reveal that CCP(MI) and W191F turn over 6 equiv. of H_2O_2 in less than 1 min, and the amino acid analyses show loss of 1.5 and 2 Tyr residues in CCP(MI) and W191F, respectively, in addition to the Trps oxidized in these proteins. To reduce 6 equiv. of H_2O_2 would require that three oxidized aromatic residues act as two-electron donors. However, additional donors may have gone undetected, given the experimental errors associated with amino acid analyses and the fluorescence measurements (see error bars in Fig. 2). LC-MS characterization of the oxidized proteins using an electrospray source is under way to determine the nature and location of the modified residues.

After standing for 24 h, the 6:1 decay products were reacted with more H_2O_2. The results revealed that an additional Trp was oxidized in CCP(MI) (Table 1), to give a *combined* loss of >3 Trps. No extra Trps were oxidized in the mutants (Table 1), where only one Trp was initially oxidized (Fig. 2). Thus, both Trp191 → Phe and Trp51 → Phe mutation must shut down pathways of endogenous electron transfer to the heme that access redox-active Trp residues in the wild-type enzyme.

Following exposure to 20 equiv. of H_2O_2 a maximum Trp loss of ~4, 2.5, and 2 is observed for CCP(MI), W51F, and W191F, respectively (Fig. 2). Amino acid analysis shows that ~4 Tyr residues were lost in both CCP(MI) and W191F, and ~1 Met in CCP(MI), and the ABTS results reveal that the 20 equiv. of H_2O_2 are turned over by CCP(MI) and W191F in 5 and 30 min, respectively. Thus, in the absence of catalatic activity ($2H_2O_2 \rightarrow O_2 + 2H_2O$), 20 electrons would have to be transferred to peroxide via the heme. Two-electron oxidation of the 9 residues found to be lost in CCP(MI) would supply 18 electrons, but only 12 electrons would be available from the 6 residues lost in W191F. It has been shown previously that yeast wild-type CCP can turn over 20 equiv. of H_2O_2 with no detectable oxygen evolution, which eliminates turnover via catalatic activity (20). It is possible that CCP(MI) also turns over 20 equiv. of H_2O_2 by utilizing endogenous donors, but this is less likely for W191F, and possible catalatic activity of this mutant is under investigation. It is noteworthy that an extra Trp is oxidized in the 20:1 decay product of CCP(MI) compared to the yeast enzyme (10); furthermore, CCP(MI) turns over 20 equiv. of H_2O_2 almost five times faster than yeast CCP (10). Hence, despite the very similar X-ray structures of the two wild-type proteins (26), they may not utilize a common set of pathways for endogenous electron donation to

the heme.

Oxidation of amino acid residues significantly reduces the ability of CCP(MI), and that of W191F to a lesser extent, to undergo reaction with H_2O_2 (eq. [1]). This is reflected in the H_2O_2 titres of the 24-h decay products listed in Table 1. Since one of the oxidizing equivalents of peroxide is transferred to the protein in reaction [1], depletion of endogenous donors around the heme (Fig. 1) may inhibit further reaction with peroxide. In addition, oxidation of the distal His52 could prevent Fe^{IV}=O formation, since this residue plays a key role in the heterolytic cleavage of peroxide, and His52 → Leu mutation results in a 10^5-fold decrease in the rate of reaction [1] (27, 28). Amino acid analysis shows loss of 0.3–0.6 His in the decay products of CCP(MI) and 0.1–0.4 His in those of W191F. Thus, the slightly greater His loss in the wild-type enzyme, coupled with the greater loss of redox-active aromatic residues, may account for the lower H_2O_2 titres of the CCP(MI) decay products.

The ferrocytochrome c oxidizing activities of the 24-h decay products of CCP(MI), and the ferrocyanide oxidizing activities of the W191F products are similar to their H_2O_2 titres (Table 1). Hence, the decreased activities of these species can be attributed to the same factors that prevent Fe^{IV}=O heme formation. However, the ferrocyanide oxidizing activities of the CCP(MI) decay products are ~10–20% lower than the corresponding ferrocytochrome c oxidizing activities (Table 1), unlike oxidized yeast CCP where both activities were found to be the same (10). Ferrocyanide and ferrocytochrome c are oxidized at different sites on CCP. The small molecule diffuses up the peroxide-access channel and is oxidized at the δ-*meso* heme edge (29). Reconstitution of CCP with δ-*meso*-substituted heme groups blocks ferrocyanide oxidation and selectively inhibits the ferrocyanide oxidizing activity of the enzyme (29). Retardation of ferrocyanide oxidation would thus be possible by diminishing access to the heme in the decay products by a mechanism such as radical-mediated *intra*molecular cross-linking in the neighbourhood of the substrate channel.

Oxidation of ferrocytochrome c involves complex formation between the proteins. A putative electron transfer path via Trp191 has been proposed based on the X-ray structure of the CCP – cyt c complex (18, 30), in which the heme edges are separated by at least 17 Å (18). It has been demonstrated that formation of an indolyl radical at Trp191 is necessary for the efficient ferrocytochrome c oxidizing activity of CCP(MI) (18). Since Trp loss is observed for the three CCP(MI) decay products (Table 1), it is possible that Trp191 is not 100% *irreversibly* oxidized in the fractions with ferrocytochrome c oxidizing activity. However, it is also possible that new ferrocytochrome c oxidation sites open up in the decay products, which do not require that Trp191 remains unaltered.

A comparison of Figs. 2, 3, and 4 indicates that the time course of activity loss is similar to that for fluorescence loss. Both change rapidly over the first 10–20 min, and then slowly over the next 24 h. Hence, fluorescence is a good probe of the time course of other changes, in addition to Trp loss, induced in CCP(MI) and its mutants following reaction with peroxide.

Table 2 summarizes the radical-mediated *inter*molecular cross-linking in CCP(MI) and its mutants. The percent dimer observed in the oxidized W191F samples falls within the range of 20–40% at all time intervals, irrespective of the extent of H_2O_2 turnover. Approximately 30% dimerization of W191F-I has been reported previously (18), which is roughly the average of the values listed for this mutant in Table 2. CCP(MI) exhibits a similar amount of dimerization as W191F, and also a small fraction of polymerization to higher molecular weight species, following the loss of 2 or more Trps (exposure to 6 equiv. of H_2O_2 for ≥5 min). The reaction of metmyoglobin with H_2O_2 also produces protein-based radicals, and a Tyr151–Tyr151 intermolecular cross-link has been established in sperm whale myoglobin (31). Tyrosine radicals readily dimerize, so the dityrosine bond in myoglobin is assumed to arise from radical formation at Tyr151, which is 12 Å from the heme (31). Peptide mapping of the dimer formed in H_2O_2-oxidized yeast CCP indicated that an intermolecular cross-link is localized between residues 32 and 48 (23, 32), a sequence that includes Tyr36, Tyr39, and Tyr42. These three Tyr residues are highly solvent exposed and are within 5–14 Å from the heme (Fig. 1); hence, cross-linking in W191F and CCP(MI) is likely to involve dityrosine formation between these Tyr-rich regions. It is of note that ≤40% of oxidized CCP(MI) and W191F undergo cross-linking (Table 2). This suggests that the radical migration pathway(s) leading to cross-linking are shut down once alternate pathways are chosen, or that the proteins are heterogeneous. Variation in the extent of post-translational processing of the N-terminal Met (33) in CCP(MI) and its mutants has been detected by electrospray MS (G. Tsaprailis, unpublished results), and the effects of such heterogeneity are under investigation. W51F-I exhibits similar cross-linking behaviour to W191F-I (Table 2), but on exposure to 6 equiv. of H_2O_2, extensive conversion to higher molecular weight species is observed.

The fluorescence, activity, and cross-linking data presented here on oxidized CCP(MI) and its Trp mutants underscore the important role played by Trp residues in the redox chemistry of the enzyme. Previously, we had suggested that a ring of aromatic residues on the proximal side of the heme of yeast CCP act as donors to peroxide (10); these residues include the 3 proximal Trps (191, 211, 223) and 3 Tyr residues (187, 229, 236) (Fig. 1). The fluorescence results obtained here support the loss of the 3 proximal Trps in recombinant CCP(MI), and the distal Trp51 appears to be also oxidized on addition of more than 2 equiv. of H_2O_2 to CCP(MI), as discussed previously. At least 4 Tyr residues are oxidized in CCP(MI) and these could include three from the proximal side, and one from sequence 32–48, which is likely to be involved in intramolecular cross-linking.

Mutation of Trp191 → Phe results in immediate cross-linking on W191F-I formation. Thus, electron transfer from a Tyr residue in sequence 32–48 to the porphyrin is likely to occur in W191F-I. Since Trp loss is observed following addition of >2 equiv. of H_2O_2 to W191F, oxidation of Trp51 may follow that of the initial Tyr. It is difficult to speculate on the identity of the remaining Tyr and Trp residues oxidized in W191F; however, their oxidation does not lead to further cross-linking of the protein.

Mutation of Trp51 → Phe gives rise to a protein that undergoes extensive cross-linking following addition of >2 equiv. of H_2O_2. Loss of 1 Trp on denaturation of W51F-I suggests than Trp191 is the first protein-based radical formed, but formation and dissipation of additional protein radicals in this mutant results in over 70% polymerization of

the protein.

The ability of CCP to reduce more than 2 equiv. of H_2O_2 in the absence of its donor substrate may be important under conditions of oxidative stress in yeast (34). Another of CCP's proposed functions is the regulation of mitochondrial respiration rates by controlling the flow of reducing equivalents to cytochrome c oxidase, which CCP does by competing for the same reducing substrate, ferrocytochrome c (34). To carry out both of these functions, the presence of Trp51 and Trp191 is critical. Mutation of the former results in an enzyme that undergoes extensive cross-linking, presumably due to radical migration to its surface. Exposed radicals in vivo would lead to damage of other cellular components. Removal of Trp191 leads to a "well-behaved" mutant, but one with negligible ferrocytochrome c oxidizing activity.

Acknowledgments

We wish to thank Dr Mark Miller (University of California, San Diego) for providing us with the CCP(MI), W51F, and W191F proteins used in this study. This research was supported by a grant from the Natural Sciences and Engineering Research Council of Canada (NSERC) to A.M.E.

The metal-mediated conversion of octachlorocycloheptatriene into dodecachloroheptafulvalene: a synthetic, structural, and EHMO study

James A. Dunn, Hari K. Gupta, Alex D. Bain, and Michael J. McGlinchey

Abstract: Octachlorocycloheptatriene, C_7Cl_8, **3**, reacts with a variety of organometallic precursors, e.g., $Fe_2(CO)_9$, $Co_2(CO)_8$, $[(C_5H_5)Fe(CO)_2]^-$, to give dodecachloroheptafulvalene, $C_{14}Cl_{12}$, **12**, in yields ranging from 54 to 68%. There is no evidence to support the intermediacy of carbene complexes of the type $C_7Cl_6{=}ML_n$, and it is suggested that the reaction proceeds by the dechlorination of C_7Cl_8 to give hexachlorotropylidene, which dimerizes to the observed product. Extended Hückel molecular orbital calculations are used to show that the chlorinated carbene, C_7Cl_6, should be more stable than the corresponding parent system, C_7H_6. The EHMO calculations also reveal that planar heptafulvalenes are electronically disfavored and should exist preferentially in the *S-anti* conformation, as is the case for $C_{14}H_{12}$. The molecule $C_{14}Cl_{12}$, **12**, is shown by X-ray crystallography to be formed only as the *syn* conformer, which isomerizes to the *anti* structure only at high temperature. The conformations of the two seven-membered rings in **12** closely resemble that found in octachlorocycloheptatriene itself. C_7Cl_8, **3**, crystallizes in the orthorhombic space group *Pnma* with $a = 7.140(1)$ Å, $b = 13.329(3)$ Å, $c = 12.595(3)$ Å, and $V = 1198.7(4)$ Å^3 for $Z = 4$. **3** adopts a severely bent boat structure in which the planes C(1)-C(7)-C(6) and C(2)-C(3)-C(4)-C(5) make angles of 51.8° and 32.4°, respectively, with the C(1)-C(2)-C(5)-C(6) plane.

Key words: octachlorocycloheptatriene, heptafulvalenes, metal-mediated dimerization.

Résumé : L'octachlorocycloheptatrième C_7Cl_8, **3**, réagit avec divers précurseurs organométalliques, par exemple : $Fe_2(CO)_9$, $Co_2(CO)_8$, $[(C_5H_5)Fe(CO)_2]^-$, pour donner le dodécachloroheptafulvène, $C_{14}Cl_{12}$, **12**, avec des rendements allant de 54 à 68%. Il n'y a pas de preuve qui permet de confirmer la présence d'un complexe carbène intermédiaire du type $C_7Cl_6{=}ML_n$, et on suggère que la réaction s'effectue par la déchloration du C_7Cl_8 pour donner l'hexachlorotropylidène qui, par dimérisation, conduit au produit observé. On a utilisé des calculs étendus d'orbitale moléculaire de Hückel pour montrer que le carbène chloré, C_7Cl_6, doit être plus stable que le système apparenté correspondant, C_7H_6. Les calcluls OMEH révèlent également que les heptafulvènes plans sont défavorisés électroniquement et doivent exister préférentiellement dans une conformation *S-anti*, comme dans le cas du $C_{14}Cl_{12}$. On montre, par cristallographie de rayons X, que la molécule $C_{14}Cl_{12}$, **12**, existe uniquement sous forme de conformère *syn* qui s'isomérise seulement à haute température en une structure *anti*. La conformation des deux cycles à sept chaînons dans le composé **12** ressemble étroitement à celle trouvée dans l'octachlorocycloheptatrième lui-même. Le composé C_7Cl_8, **3**, cristallise dans le groupe d'espace orthorhombique *Pnma* avec $a = 7{,}140(1)$ Å, $b = 13{,}329(3)$ Å, $c = 12{,}595(3)$ Å, et $V = 1198{,}7(4)$ Å^3 pour $Z = 4$. Le composé **3** adopte une structure bateau fortement courbée dans laquelle les plans C(1)-C(7)-C(6) et C(2)-C(3)-C(4)-C(5) font respectivement un angle de 51,8° et de 32.4° avec le plan C(1)-C(2)-C(5)-C(6).

Mots clés : octachlorocycloheptatrième, heptafulvènes, dimérisation assistée par un métal.

[Traduit par la rédaction]

Introduction

In continuation of our studies on organometallic derivatives of seven-membered rings (1), we chose to prepare octachlorocycloheptatriene, C_7Cl_8, as an example of a sterically hindered molecule. Although perfluorinated ligands, such as C_5F_5, C_6F_6, or C_8F_8, have received considerable attention (2–4), perchlorinated systems appear to have been less thoroughly investigated. A number of perchlorocyclopentadienyl complexes, e.g., $(\eta^1\text{-}C_5Cl_5)Mn(CO)_5$, $(\eta^5\text{-}C_5Cl_5)Mn(CO)_3$, and $(\eta^5\text{-}C_5Cl_5)_2Ru$, are known (5, 6), and recently $(\eta^6\text{-}C_6Cl_6)Cr(CO)_3$ was obtained by repeated lithiation and chlorination procedures (7). We are unaware of any organometallic derivatives possessing a C_7Cl_7 ligand. It has been claimed (8) that $Fe_2(CO)_9$ reacts with perchloro(3,4-dimethylenecyclobutene) and with perchlorofulvene to give organo-iron complexes, but their identity has not been confirmed by X-ray crystallography. We here report the X-ray crystal structure of C_7Cl_8, its reaction with a series of metal carbonyls to give *syn*-

$C_{14}Cl_{12}$, and EHMO calculations to rationalize the observed nonplanar geometry of heptafulvalenes.

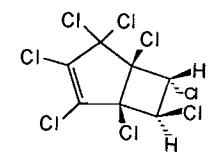
Results and discussion

The structure of C_7Cl_8

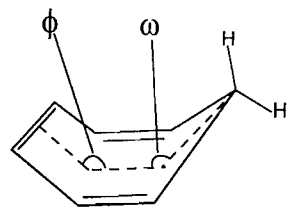
The synthesis of octachlorocycloheptatriene, first described by West and co-workers in 1968 (9, 10), involves the reaction of hexachlorocyclopentadiene, C_5Cl_6, with trichloroethylene to give the bicyclo[3.2.0]heptene, **1**, which can be dehydrochlorinated to produce the diene **2**, as in Scheme 1. Subsequent thermolysis in the presence of aluminum chloride yields octachlorocycloheptatriene, **3**, presumably by the symmetry-forbidden disrotatory ring opening of the intermediate cation to the heptachlorotropylium ion which can recapture a chloride from the chloroaluminate anion.

Although the position of the unique hydrogen in C_7Cl_9H, **1**, is not known with certainty, the structure of the related molecule $C_7Cl_8H_2$, **4**, has been established by an X-ray diffraction study (11). The two isomers of C_7Cl_8, namely **2** and **3**, give readily interpretable mass spectra since their chlorine isotope patterns are immediately evident. However, to characterize such highly chlorinated molecules, nuclear quadrupole resonance spectroscopy is arguably more useful than are the conventional NMR techniques. The NQR spectrum of **3** was described in the original synthetic report (10), but the signal-to-noise was rather unsatisfactory and we now report more accurate parameters. Figure 1 shows the ^{35}Cl NQR spectrum of octachlorocycloheptatriene, **3**, acquired on a solid state NMR spectrometer by removing the probe from the magnet and tuning to the ^{35}Cl frequency range. The excellent signal-to-noise ratio obtainable by this technique is evident, and five peaks are found in the expected 2:2:2:1:1 ratio; the first three resonances are found in the region for vinylic chlorines, while the latter two are typical of a CCl_2 moiety.

The boat-shaped geometry of cycloheptatriene, **5**, was originally established from electron diffraction measurements.



4



5

The dihedral angles between C(6)-C(7)-C(1) (plane 1), (C(1)-C(2)-C(5)-C(6) (plane 2), and (C(2)-C(3)-C(4)-C(5) (plane 3) are $\omega = 144°$ for (plane 1)/(plane 2), and $\phi = 140°$ for (plane 2)/(plane 3), respectively (12). In the severely hindered heptaphenyl analogue C_7Ph_7H, **6**, the corresponding values of ω and ϕ are 125° and 145°. That molecule is initially generated (see Scheme 2) as conformation **6a** whereby the unique phenyl substituent occupies an equatorial site; however, the ring flips irreversibly to the axial conformer **6b**, which has been structurally characterized (1).

There is a report that in hexachlorotropone, C_7Cl_6O, **7**, the bulky chlorines do not permit the ring to maintain the electronically favored planar geometry, but rather it adopts a boat conformation with ω and ϕ values of 151° and 156°, respectively.[2] Analogously, the seven-membered ring in the do-

decachloro[1.6.7]quinarene, **8**, is also markedly nonplanar (14).

Since we had in hand X-ray quality crystals of C_7Cl_8, **3**, we obtained diffraction data, and the resulting structure appears as Fig. 2. Crystallographic data, together with bond lengths and angles, are collected in Tables 1–3. Octachlorocycloheptatriene adopts a boat conformation in which the CCl_2 unit is bent up through 51.8° from the C(1)-C(2)-C(6)-C(7) plane, (i.e., $\omega = 128.2°$) while the C(3)—C(4) unit is bent up by 32.4° ($\phi = 147.6°$). There is clear bond alternation whereby the single bonds average 1.479 Å, and the mean double bond length is 1.336 Å. There is no indication of a norcaradiene-type structure, **9**, as is known for 7,7-dicyanocycloheptatriene (15). Overall, these data suggest that the steric hindrance within polychlorinated seven-membered rings is substantial, and that the system should exhibit a high barrier towards boat-to-boat conformational flipping.

Reactions of C_7Cl_8 with organometallics

We are aware of only a single reaction of C_7Cl_8, **3**, with a transition metal complex (16). Treatment of octachlorocycloheptatriene with nickelocene resulted in coupling of a C_5H_5 fragment with a C_7Cl_7 unit (see Scheme 3); subsequent intramolecular Diels–Alder addition yielded the cage compound **10**. The perchloro analogue of **10**, viz. **11**, has been characterized crystallographically as the product resulting from the reaction of **3** with tetrachlorodiazocyclopentadiene (17).

In an attempt to prepare metal carbonyl complexes possessing a C_7Cl_7 fragment, we treated **3** with a number of organometallic precursors, viz. $[(C_5H_5)Fe(CO)_2]^-$, $Fe_2(CO)_9$, $Co_2(CO)_8$, $(acac)Rh(C_2H_4)_2$, and $(Ph_3P)_2Rh(CO)Cl$. In all cases, the sole organic product isolated was *syn*-perchloroheptafulvene, **12**. This molecule, previously found in 80% yield from the reaction of C_7Cl_8 with methyllithium, had been structurally characterized by X-ray diffraction, despite a crystallo-

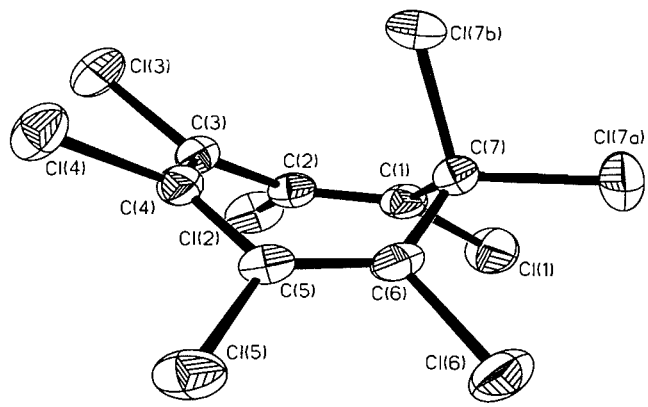

graphic disorder problem (18). Since we had obtained crystals by a different route, we collected a data set in the hope of resolving the disorder but encountered the same difficulty. The bivalvular (clam-shaped) geometry allows the molecules to pack randomly with the central double bond "up" or "down," as indicated in Fig. 3. The structure can be modelled by assigning half occupancies to all atoms except C(3), C(6), C(10), C(13), and their attached chlorines. Figure 3 illustrates this crystallographic disorder (showing only the carbon framework for clarity), while Fig. 4 depicts the geometry of a single

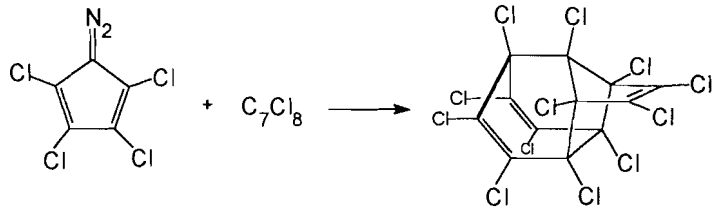
10



11

molecule of **12**. The seven-membered rings are severely bent with interplanar angles ω and ϕ of 124.7° and 147.5°, respectively. The central carbon–carbon double bond is markedly pyramidal such that the atoms C(1) and C(8) lie 0.09 Å out of the plane containing C(2), C(7), C(9), and C(14). Another way to describe this facet of the structure is to define an angle θ (= 173.5°) between the plane containing C(1), C(2), and C(7), and the C(1)═C(8) vector. Each Cl-C═C-Cl moiety is essentially planar and appears to be isolated from its neighboring double-bonded fragment.

It has been suggested (18) that *syn*-$C_{14}Cl_{12}$, might arise by lithiation at one of the dichloro positions of C_7Cl_8 to give C_7Cl_7Li that, in turn, could attack a second molecule of **3** to produce perchloroditropyl, **14**, as in Scheme 4. A second lithiation, followed by *cis* elimination of LiCl, could yield **12**. Prolonged heating of *syn*-$C_{14}Cl_{12}$, **12**, yields the known *anti*-$C_{14}Cl_{12}$, **13**, originally described by West, Dahl, and their colleagues (19). Continued heating of **13** to 340°C brings about loss of chlorine and rearrangement to decachlorophenanthrene.

Our own speculations have focussed on the possible intermediacy of a hexachlorotropylidene–metal complex. Analogous C_7H_6 carbene complexes of iron, tungsten, and ruthenium have been synthesized (20), as typified in Scheme 5. However, despite repeated efforts, we have been unable to obtain any evidence for such perchlorocarbene complexes; the metal-containing products are merely well-known materials such as $CoCl_2$ or $FeCl_2$. Moreover, if *syn*-$C_{14}Cl_{12}$ arises as the result of a metal–template-induced coupling, one must still account for the observed *syn* stereochemistry. On the other hand, if, as we suspect, the metal merely dechlorinates C_7Cl_8 to give hexachlorotropylidene, C_7Cl_6, then one must consider the possible fate of this carbene intermediate. It is relevant to note that the reaction of decachloro(4-allylidenecyclopentene), **15**, with $Fe_2(CO)_9$ leads to the cyclization product octachlorobicyclo[3.3.0]octa-1,3,7-triene, **16** (21). One could envisage metal-promoted dechlorination, as in Scheme 6, to produce an intermediate carbene **17** that inserts into a C—Cl bond and, after a chlorine [1,5] sigmatropic shift, yields the bicyclo species **16**.

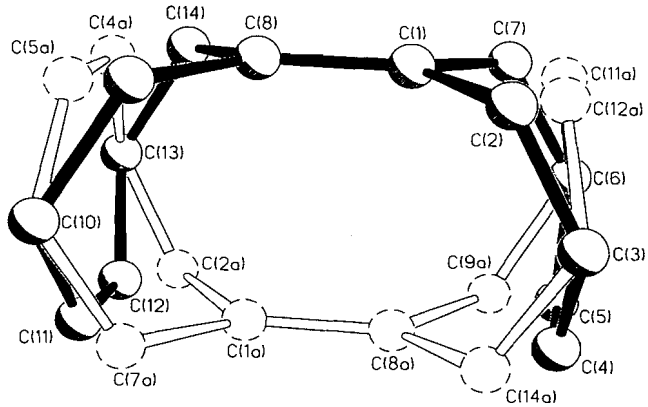

Fig. 4. X-ray crystal structure of *syn*-$C_{14}Cl_{12}$, **12**, showing the atom numbering scheme.

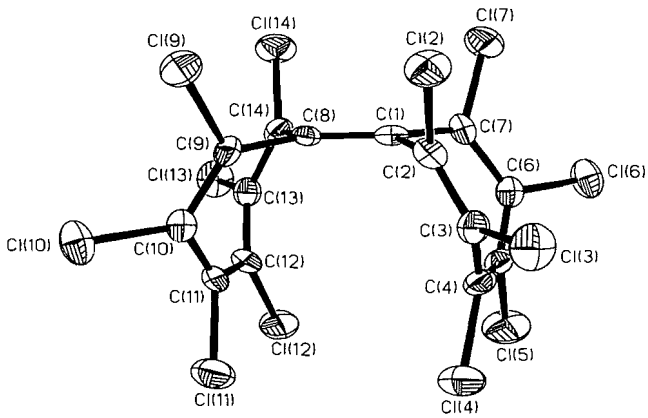

In recent years, the chemistry of the so-called "nucleophilic carbenes" has received much attention (22). These species, typified by $(MeO)_2C$:, have singlet character whereby the electron deficiency at the carbene center is considerably alle-

Scheme 4. Proposed lithiation route to *syn*-$C_{14}Cl_{12}$, **12**, and its isomerization to *anti*-$C_{14}Cl_{12}$, **13**.

viated by π donation from adjacent oxygen (or nitrogen) atoms to the formally vacant p_z orbital on carbon. These carbenes are sufficiently long lived that, in the absence of a suitable trap, they can give good yields of dimer. We show in Fig. 5 a comparison of the EHMO-derived frontier orbital patterns for planar C_7H_6 and for C_7Cl_6.

The structure of C_7H_6 has been intensively studied with respect to the relative stabilities of the planar tropylidene carbene and the allene-like cyclohepta-1,2,4,6-tetraene (23).

Scheme 7. Proposed route to heptafulvalene via a cyclic allene dimer.

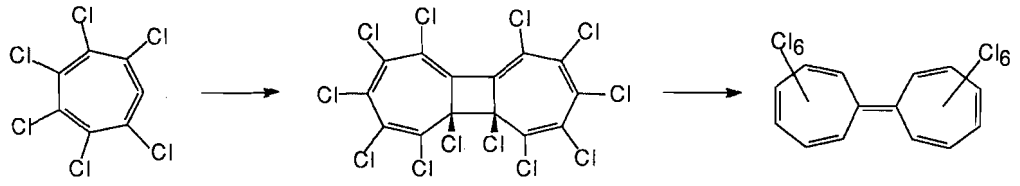

Fig. 5. Frontier orbitals of C_7Cl_6 and of C_7H_6.

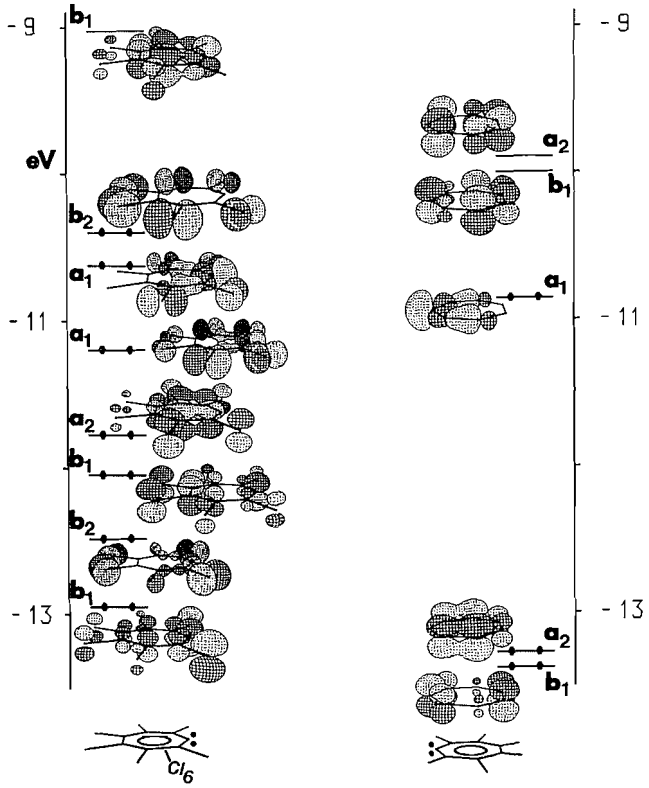
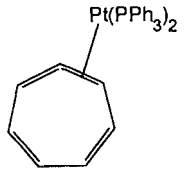




18

Indeed, it has even been claimed that the carbene form does not represent an energy minimum, but rather is merely the transition state for the interconversion of enantiomeric allenes (24*a*).[3] As mentioned previously, numerous metal–tropylidene systems have been described (20), but there is a report that the cyclohepta-1,2,4,6-tetraene form has been trapped as a stable $(Ph_3P)_2Pt(C_7H_6)$ complex, **18** (25).

When we compare the planar tropylidenes, we note that, in C_7H_6, the HOMO has a large in-plane component on the carbene carbon, while the LUMO has predominant π^* character (23). By way of contrast, in C_7Cl_6 the HOMO is localized entirely on the peripheral chlorines, and lies just above the "σ lone pair" on the carbene carbon, as anticipated for a singlet species. We see from Fig. 5 that there is a markedly enhanced HOMO–LUMO gap in the chlorinated system that can be traced to participation of the chlorine p_z orbitals with the π manifold of the ring. One may conclude that C_7Cl_6 should be a relatively long-lived nucleophilic carbene with a high propensity to dimerize. Such an interaction between two carbenes would presumably involve donation of the in-plane lone pair of electrons on the carbene carbon of one C_7Cl_6 fragment into the LUMO of its reaction partner. Moreover, the *syn* stereochemistry may well arise as the result of secondary orbital interactions — a phenomenon commonly invoked to account for the formation of *endo* adducts in the Diels–Alder reaction (26). An alternative scenario would invoke dimerization of the cyclic allenes to give a tricyclic system that could open up to give the observed heptafulvalene, as in Scheme 7 (27). Calculations to clarify these aspects are in progress.

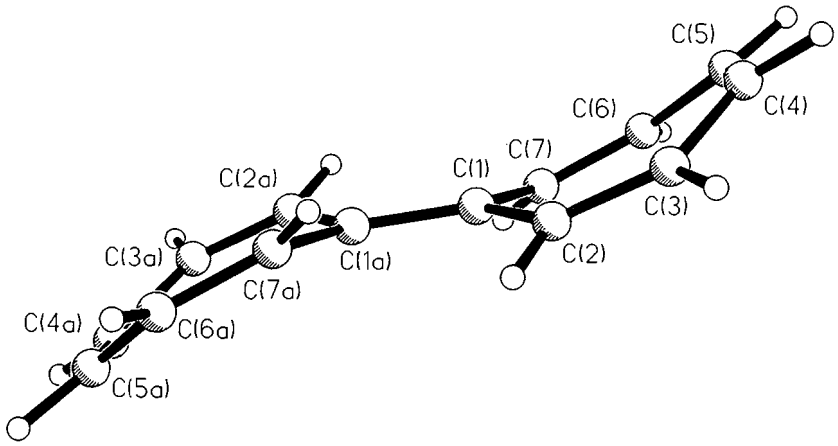
It is noteworthy that the conversion of *syn*-$C_{14}Cl_{12}$, **12**, to *anti*-$C_{14}Cl_{12}$, **13**, requires prolonged heating at 275°C (19); clearly, this process has a very large activation energy! Of course, the steric problems encountered by a planar C_7Cl_6 moiety as it manoeuvers its way past the neighboring chlorines in the other half of the molecule impose a large barrier but, even in the absence of large chlorine substituents, heptafulvalenes are not planar. Early calculations by Dewar and Gleicher suggested that planar $C_{14}H_{12}$ would exhibit bond fixation rather than a delocalized structure in which all bond lengths were rather similar (28). A subsequent X-ray crystal structure confirmed this prediction of alternating single and double bonds, but also showed the molecule to be nonplanar (29). As shown in Fig. 6, $C_{14}H_{12}$ adopts the *anti* conformation with interplanar angles θ, ω, and ϕ of 173°, 155°, and 164°, respectively.

This result may be rationalized with the aid of molecular orbital calculations at the extended Hückel level. Figure 7 presents a Walsh diagram depicting the gradual flattening of $C_{14}H_{12}$. The energy minimum is found for θ, ω, and ϕ values each within one degree of those found in the X-ray crystal structure. We see that bending the molecule symmetrically into an *S* shape (i.e., after breaking the D_{2h} symmetry of the planar molecule we preserve C_{2h} symmetry throughout the process) stabilizes the HOMO and raises the LUMO. In the planar molecule, the HOMO reveals a substantial π^* overlap between the central C=C moiety and the two outer fragments; this destabilizing interaction is decreased as the molecule bends. Concomitantly, the LUMO loses some degree of in-phase π-type overlap, and the net result is to augment the HOMO–LUMO gap. The bent structure is calculated to be approximately 8.5 kcal mol^{-1} more stable than the planar form.

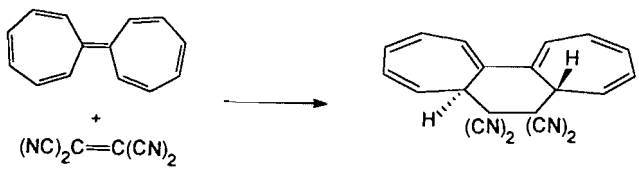
These effects are not just the result of crystal packing

[3] For a very recent summary of the current status of the C_7H_6 problem, see ref. 24*b*.

Fig. 6. X-ray crystal structure of *anti*-$C_{14}H_{12}$; data taken from ref. 29.



forces; heptafulvalene is known to undergo symmetry-allowed $[_{\pi}14_a+_{\pi}2_s]$ cycloaddition with tetracyanoethylene whereby the twisted shape of the $C_{14}H_{12}$ is ideally suited for *antara* addition to the 14π system to give the adduct **19**.[4]



19

In conclusion, we report that octachlorocycloheptatriene, **3**, adopts a severely bent boat conformation, closely analogous to that found for C_7Ph_7H. Treatment of C_7Cl_8 with metal carbonyls does not yield isolable organometallic complexes but rather leads to dechlorination and dimerization to *syn*-perchloroheptafulvalene, **12**. The high barrier to conformational change from **12** to its *anti*-isomer **13** may be attributed principally to unfavorable steric interactions between chlorines. However, it is also shown that electronic factors favor nonplanar conformations for heptafulvalenes.

Experimental section

All reactions were carried out under an atmosphere of dry nitrogen employing conventional benchtop and glovebag techniques. All solvents were dried according to standard procedures before use (31). Silica gel (particle size: 20–45 μm) was employed for flash column chromatography. ^1H and ^{13}C solution NMR spectra were recorded on a Bruker AC-200 spectrometer. Mass spectra were obtained on a VG analytical ZAB-ZE spectrometer.

NQR spectra were run on a Bruker MSL 100 NMR spectrometer equipped with a 10 mm wideline solenoid probe and a fast digitizer. Approximately a gram of sample was used, and good spectra were obtained in under 10 min. The low-power transmitter in the spectrometer gave a null in the signal, which is similar to a 180° pulse in NMR (32), at a pulse width of 17 μs. Spectra were obtained with a 1 μs pulse and digitized over a sweep range of 1 MHz, with a delay between pulses of 50 ms.

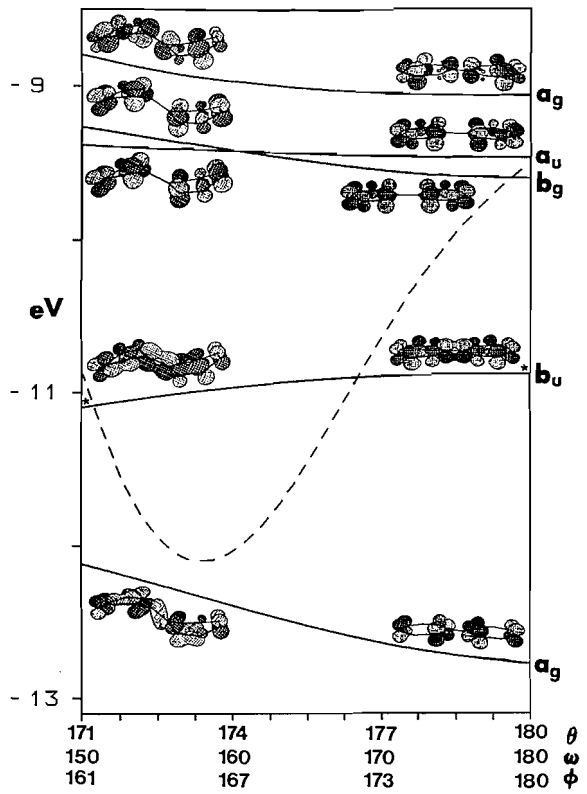
Fig. 7. EHMO-derived Walsh diagram depicting the symmetrical flattening of *anti*-$C_{14}H_{12}$ from a C_{2h} geometry to D_{2h}. The HOMO is marked with an asterisk. (The broken line represents the total electronic energy and is drawn to a different scale.)



Reaction of C_7Cl_8 with $Fe_2(CO)_9$

Octachlorocycloheptatriene (0.184 g, 0.50 mmol), prepared by West's method (10) and $Fe_2(CO)_9$ (0.182 g, 0.50 mmol) were heated under reflux in tetrahydrofuran (THF) (10 mL) for 24 h. The mixture was cooled, filtered to remove the inorganic salts, and the volume was reduced under vacuum. Addition of hexane eventually led to the precipitation of light yellow crystals of $C_{14}Cl_{12}$, **12**, (0.080 g, 0.134 mmol, 54%). ^{13}C NMR (CD_2Cl_2) δ: 137.0, 132.8, 128.6, 124.0. Mass spectrum *m/z* (%): 588 $[M]^+$, 553 $[M - Cl]^+$, 518 $[M - 2Cl]^+$, 483 $[M - 3Cl]^+$, 448 $[M - 4Cl]^+$, 378 $[M - 6Cl]^+$, 294 $[C_7Cl_6]^+$,

259 $[C_7Cl_5]^+$, 224 $[C_7Cl_4]^+$, 189 $[C_7Cl_3]^+$. Peaks quoted are in each case the lowest mass in the envelope and correspond to ^{35}Cl; the observed isotopic abundances correctly matched the pattern required for the number of chlorines in the fragment ion.

Reaction of C_7Cl_8 with $Co_2(CO)_8$

$Co_2(CO)_8$ (0.372 g, 1.09 mmol) dissolved in THF (30 mL) was added to a solution of C_7Cl_8 (0.400 g, 1.09 mmol) in THF (10 mL) and allowed to stir at room temperature for 24 h. Filtration, concentration to half volume, and treatment with hexane gave a crude solid that was purified by flash chromatography (hexanes) to yield as the sole product $C_{14}Cl_{12}$, **12**, (0.177 g, 0.30 mmol, 55%), identified by its mass spectrum.

Reaction of C_7Cl_8 with $(Ph_3P)_2Rh(CO)Cl$

A mixture of $(Ph_3P)_2Rh(CO)Cl$ (0.345 g, 0.50 mmol) and C_7Cl_8 (0.184 g, 0.50 mmol) in THF (20 mL) was heated under reflux for 24 h. Filtration, concentration to half volume, and treatment with hexane gave a crude solid that was recrystallized from $CHCl_3$ to yield as the sole product $C_{14}Cl_{12}$, **12**, (0.095 g, 0.16 mmol, 64%), identified by its mass spectrum.

Reaction of C_7Cl_8 with $Na[Fe(CO)_2(C_5H_5)]$

To a solution of $[(C_5H_5)Fe(CO)_2]_2$ (0.145 g, 0.40 mmol) in THF (10 mL) was added excess Na–Hg. The resulting red solution was filtered, treated with C_7Cl_8 (0.270 g, 0.80 mmol), and allowed to stir at room temperature for 3.5 h, after which time the solution had become brown. Filtration, concentration to half volume, and treatment with hexane gave a crude solid that was purified by flash chromatography (hexanes) to yield as the sole product $C_{14}Cl_{12}$, **12**, (0.133 g, 0.224 mmol, 56%), identified by its mass spectrum.

Reaction of C_7Cl_8 with $(acac)Rh(C_2H_4)_2$

A mixture of $(acac)Rh(C_2H_4)_2$ (0.129 g, 0.50 mmol) and C_7Cl_8 (0.184 g, 0.50 mmol) in THF (10 mL) was heated under reflux for 24 h. Filtration, concentration to half volume, and treatment with hexane gave a crude solid that was recrystallized from $CHCl_3$ to give X-ray quality crystals of $C_{14}Cl_{12}$, **12**, (0.125 g, 0.34 mmol, 68%), identified by its mass spectrum.

X-ray crystallography

X-ray crystallographic data for **3** and **12** were collected on a Siemens R3m/V diffractometer with Ag Kα radiation (λ = 0.560 86 Å). The structures were solved by using the Direct Methods routine contained in the SHELXTL-PLUS program library (33). Crystal data collection parameters for C_7Cl_8 are listed in Table 1. Atom coordinates and selected bond lengths and angles for **3** are collected in Tables 2 and 3. Anisotropic displacement parameters for **3** have been deposited as supplementary material.[5] The molecular parameters for **12** were in agreement with those previously published (18); however, in that report, the molecular disorder was not clearly illustrated, and we show this phenomenon in Fig. 3.

[5] Copies of this table may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Molecular orbital calculations

These calculations were performed via the extended Hückel method using weighted H_{ij}'s (34); orbital drawings were obtained by use of the program CACAO (35).

Acknowledgements

Financial support from the Natural Sciences and Engineering Research Council of Canada, and also from the donors of the Petroleum Research Fund, administered by the American Chemical Society, is gratefully acknowledged. Mass spectra were obtained courtesy of Dr. Richard Smith of the McMaster Regional Centre for Mass Spectrometry. We thank Dr. J.F. Britten for X-ray crystallographic advice, and Dr. Carlo Mealli, CNR, Florence, Italy, for the program CACAO.

Photoinduced oxidative degradation of unsaturated $M_3(dppm)_3CO^{2+}$ clusters (M = Pd, Pt) by chlorocarbons and chloride ion

Pierre D. Harvey, Réjean Provencher, Jonathan Gagnon, Tianle Zhang, Daniel Fortin, Karine Hierso, Marc Drouin, and Steve M. Socol

Abstract: Both $M_3(dppm)_3CO^{2+}$ clusters (M = Pd, Pt) photoreact with chlorocarbons (Cl—R; R = CCl_3, $CHCl_2$, CH_2Cl, C_6H_5, $C_{10}H_{15}$ (adamantyl)) and chloride ion (slowly) to produce the oxidized mononuclear species $M(dppm)Cl_2$ as a sole isolated M-coordinated inorganic product. Such reactions do not proceed in the dark, except for R = $CH_2C_6H_5$. Among the organic products, the coupling compound R–R (R = C_6H_5) is observed along with many phosphine compounds such as $P(C_6H_5)_3$. In an attempt to elucidate the photoinduced mechanism at the early stage of the phototransformations, the following have been investigated : the ground state binding constants (K_{11} for M = Pd in methanol), the photochemical quantum yields of cluster disappearance (Φ_{dis} for M = Pd) as a function of substrates, substrate concentrations, excitation wavelengths, solvents (ethanol vs toluene), and presence of CO, and the emission lifetimes (τ_e for M = Pt) at 77 K as a function of substrate concentrations (CH_2Cl_2 and $CHCl_3$) in ethanol and toluene. Some of the experimental conclusions have also been corroborated theoretically using density functional theory. Geometry optimization calculations have been performed for the model compounds $Pd_3(PH_3)_6CO^{2+}\cdots Cl^-$, $Pd_3(PH_3)_6^{2+}$, $Pd_3(PH_3)_6CO^{2+}\cdots Cl^0$, $Pd_3(PH_3)_6CO^{2+}\cdots Cl\text{-}CH_3$, and $Pd_3(PH_3)_6CO^{3+}$ in their ground states.

Key words: atom abstraction, photochemistry, C-Cl bond, clusters, host-guest.

Résumé : Les agrégats $M_3(dppm)_3CO^{2+}$ (M = Pd, Pt) photoréagissent tous les deux avec les chlorocarbones (Cl-R; CCl_3, $CHCl_2$, CH_2Cl, C_6H_5, $C_{10}H_{16}$ (adamantyle)) et avec l'ion chlorure (lentement) pour conduire à des espèces mononucléaires oxydées $M(dppm)Cl_2$ qui correspondent au seul produit inorganique M-coordiné à être isolé. Ces réactions ne se produisent pas à la noirceur, excepté pour le composé R = $CH_2C_6H_5$. Parmi les composés organiques, on observe le composé de couplage R–R (R = C_6H_5) ainsi que plusieurs phosphines telle que la $P(C_6H_5)_3$. Dans le but d'élucider le mécanisme photoinduit dans l'étape initiale des phototransformations, on a examiné les caractéristiques suivantes : les constantes d'association dans l'état fondamental (K_{11}, pour M = Pd dans le méthanol), les rendements quantiques photochimiques pour la disparition des agrégats (Φ_{dis} pour M = Pd) en fonction des substrats, des concentrations de substrat, des longueurs d'onde d'excitation, des solvants (éthanol vs. toluène) et de la présence de CO et les durées de vie d'émissions (τ_e pour M = Pt), à 77 K, en fonction des concentrations de substrat (CH_2Cl_2 et $CHCl_3$) dans l'éthanol et le toluène. Un certain nombre de conclusions expérimentales ont aussi été corroborées d'une façon théorique en faisant appel à la théorie de la densité fonctionnelle. On a effectué des calculs d'optimisation de géométrie pour les composés modèles $Pd_3(PH_3)_6CO^{2+}\cdots Cl^-$, $Pd_3(Ph_3)_6^{2+}$, $Pd_3(PH_3)_6CO^{2+}\cdots Cl^0$, $Pd_3(PH_3)_6CO^{2+}\cdots Cl\text{-}CH_3$ et $Pd_3(PH_3)_6CO^{3+}$ dans leurs états fondamentaux.

Mots clés : enlèvement d'atome, photochimie, liaison C—Cl; agrégats, hôte–invité.

[Traduit par la rédaction]

Introduction

The photoinduced oxidation of bi- and polynuclear organometallic complexes has been a topic of long term interest (1). The two possible mechanisms are the electron transfer from the excited complex to the substrate, and the atom transfer from the substrate to the excited complex (1). These key processes occur in the early stage of the transformations, and the elucidation of which mechanism is proceeding requires carefully designed experiments. In metal–metal bonded complexes, another pathway is possible, and involves photoinduced homolytic metal–metal bond scission in the excited states (1), generating radical species that exhibit redox and atom transfer properties that are different from those of the ground state metal–metal bonded species. Relevant to this study are recent photochemical and spectroscopic studies reported by our group (2, 3) and others (4, 5) on low-valent Pd–Pd bonded isocyanide complexes, and which have demonstrated the rich photochemistry that these species offer and the diversity of primary photoinduced processes that have been observed. More recently, our group has been interested in the photoactivation of small molecules, notably $O_2(g)$ by the low-valent $Pd_3(dppm)_3CO^{2+}$ cluster (dppm = $((C_6H_5)_2P)_2CH_2$) (6).

The observed product was the $Pd_3(dppm)_3(O_2)_2^{2+}$ species, which was formed with a quantum yield efficiency of about 3% (at λ_{exc} ~500 nm). This work extends the photochemistry of the $M_3(dppm)_3CO^{2+}$ clusters (M = Pd, Pt) towards the activation of chlorocarbon molecules, and provides a series of experiments that help elucidate the possible mechanisms responsible for the phototransformations *at the early stage* of the photoinduced processes. Density functional theory is also used in order to corroborate some of the experimental findings by the means of geometry optimization computations of some proposed intermediate species. This work will provide experimental evidence for a double- pathway mechanism, one involving a photoinduced Cl atom abstraction followed by a degradation of the cluster, and another involving a fragmentation followed by subsequent reaction with the chlorocarbon molecules.

Experimental

Materials

$[Pd_3(dppm)_3CO](Y = CF_3CO_2,PF_6)_2$ (7) and $[Pt_3(dppm)_3CO](PF_6)_2$ (8) were prepared according to literature procedures. Methanol (BDH), dichloromethane (BDH), chloroform (BDH), carbon tetrachloride (Anachemia), sodium chloride (Fisher), benzyl chloride (Aldrich Chem. Co.), chlorobenzene (BDH), and 1-chloroadamantane (1-Cl-ada; Aldrich Chem. Co.) were purchased at the highest purity grade possible (eg., spectrograde) and were used as received. Ethanol (Les alcools de commerces, 95%) and toluene (BDH) were dried over Na(s) and distilled by fractionation. The formation of a glass at 77 K, with no sign of cracking, was used as the test of solvent dryness.

The complex $[Pd_3(dppm)_3(CO)(N_2C_6H_4NEt_2)](CF_3CO_2)_2(BF_4)$ was prepared via a direct reaction between $[Pd_3(dppm)_3CO](CF_3CO_2)_2$ and the diazonium salt [*para*-$N_2C_6H_4NEt_2](BF_4)$ (Aldrich Chem. Co) in methanol in a 1:1 stoichiometric ratio for 2–3 h. The complex has been characterized by IR ($\nu(N\equiv\overset{+}{N})$ = 2162 cm^{-1}, ν(CO) = 1830 cm^{-1} (solid state)); ^1H NMR ($\delta(CH^aH^bP_2)$: 4.75 and 4.98 ppm (AB quartet; $^2J(H^aH^b)$ = 15 Hz in $(CD_3)_2CO$)), and UV visible spectroscopy (λ_{max} = 464 (br), 380, and 308 nm). The complex $[Pd_3(dppm)_3(CO)(Cl)]BF_4 \cdot 2CH_2Cl_2$ was prepared from daylight irradiation of $[Pd_3(dppm)_3(CO)N_2C_6H_4NEt_2](CF_3CO_2)_2(BF_4)$ in neat CH_2Cl_2. This reaction does not proceed in the dark. The product was characterized by X-ray crystallography using single crystals formed during the photoreaction as CH_2Cl_2 solvate. Its report is appropriate at this time for the purpose of this work (supplementary material, see footnote 4). The full characterization and investigation of the diazonium adducts will be reported in due course.

Instrumentation

The emission spectra were measured on a PTI LS 100 spectroflurometer. The emission lifetimes (τ_e) were measured on the same instrument fitted with a tungsten EG & G model FX-280 microsecond flash-lamp source (~1 μs fwhm) and a phosphorimeter component. To obtain data that are of sufficient quality for this work, multi-scanning and pulsing techniques were employed.

Photochemical studies

The photochemical reactions were performed with a home-made immersion cell using an Ace Hanovia Hg–Xe 200-W lamp. The photoreactions proceeded with broadband irradiation using a uranium sleeve glass filter (λ_{cutoff} ~340 nm). For the quantum yield measurements, ferrioxalate actionometry was employed (9–11). The actinometer excitation slits were set at 0.5 mm, and excitation was set at 488 nm for all samples and standards unless stated otherwise. The excitation wavelength was selected using a Aminco-Bomem monochromator, also equipped with a Hg–Xe 200-W lamp. The absorbance of the complex and standard solutions was adjusted to a value of ~0.4–0.5 at λ_{max} ~487 nm for M = Pd and at λ_{max} ~380 nm for M = Pt prior the measurements. Typical concentrations range from 1.5×10^{-5} to 2.0×10^{-5} M. The calibrations of the standard ferrioxalate actinometric solutions were performed carefully in the dark. The absorbance change at a given irradiation time was followed by UV–visible spectroscopy (Hewlett–Packard 8452A) at a value of λ_{max} that varied between 466 and 490 nm depending upon the nature of the solvent mixture. All measurements and calibration experiments were performed at least 3 times and before 10% photoconversion.

Binding Constant Measurements

The K_{11} measurements were performed by UV–visible spectroscopy (12) at room temperature, and were extracted by plotting the Benesi–Hildebrand graphs (~$1/\Delta A$ vs. 1/[substrate] with ΔA as the absorbance change upon the increase in substrate concentration). The ratio intercept/slope in this plot gives K_{11}. As a counter check, the K_{11} values were also evaluated using Scatchard and Scott plots ($-\Delta A$/[substrate] vs. $-\Delta A$, K_{11} = −slope (Scatchard); −[substrate]/ΔA vs. [substrate], K_{11} = slope/intercept (Scott)). The measured K_{11} values are all found to be the same within the experimental uncertainties, generally ±10% based upon the maximum and minimum values obtained, except for the Cl^- ion, which turned out to be irreproducible (see text below). Typically between 6 and 10 data points were acquired for each measurement, which was repeated three times. Details on the methodology employed can be found in ref. 13.

Computational details

The reported density functional calculations were all carried out utilizing the program called Amsterdam Density Functional that was developed by Baerends et al. (14, 15) and vectorized by Raveneck (16). The numerical integration procedure applied for the calculations was developed by te Velde and co-workers (17). The geometry optimization procedure was based on the method developed by Versluis and Ziegler (18). The electronic configurations of the molecular systems were described by an uncontracted double-ζ basis set (19) on palladium for 4*s*, 4*p*, and 5*s*, and triple-ζ for 5d. Double- ζ STO basis sets (20) were used for chloride (3*s*, 3*p*), phosphorus (3*s*, 3*p*), oxygen (2*s*, 2*p*), carbon (2*s*, 2*p*), and hydrogen (1*s*), augmented with a single 4*d* polarization function for Cl and P, a single 3*d* one for O, and C, and a 2*p* function for H. No polarization function was used for palladium. The $1s^2\ 2s^2\ 2p^6\ 3s^2\ 3d^{10}$ configuration on palladium, the $1s^2\ 2s^2$ configuration on chloride and on phosphorus, and the $1s^2$ configurations on oxygen, carbon, and nitrogen were treated by the frozen-core approximation (15). A set of auxiliary (21) *s*, *p*, *d*, *f*, and *g* STO functions, centered on all nuclei, was used

in order to fit the molecular density and present Coulomb and exchange potentials accurately in each SCF cycle. Energy differences were calculated by including the local exchange-correlation potential by Vosko et al. (22). No nonlocal exchange and correlation corrections were made for the geometry optimizations.

Crystal structure of $[Pd_3(dppm)_3(\mu\text{-}CO)(\mu\text{-}Cl)](BF_4)\cdot CH_2Cl_2$

Intensity data were collected at 190 K on an Enraf–Nonius CAD-4 automatic diffractometer using graphite monochromated Mo$K\alpha$ radiation. The NRCCAD (23*a*) programs were used for centering, indexing, and data collection. The unit cell dimensions were obtained by least-squares fit of 24 centered reflections in the range of $30° \leq 2\theta \leq 36°$. During data collection, the intensities of two standard reflections were monitored every 60 min. No significant decay was observed. The structure was solved by the application of direct methods using the NRCVAX (23*b*) program and refined by least squares. The atomic scattering factors in stored NRCVAX are from Cromer and Waber (International tables for X-ray crystallography, Vol IV). Hydrogen atoms were geometrically placed at idealized position and not refined. At convergence the final discrepancy indices were $R = 0.063$, $wR = 0.066$, and $SC = 1.55$. The residual positive and negative electron densities in the final maps were 1.27 and -1.67 e/Å^3 and were located in the vicinity of the BF_4^- anion. The C═O bond distance was fixed at 1.15 Å in the refinement. The ORTEP (23*c*) diagram was generated from NRCVAX. The crystal has one solvent molecule (CH_2Cl_2). The BF_4^- molecule is disordered and was treated as a B atom surrounded by two interlocking ideal tetrahedra of F atoms (all U_{ij} restrained to be equal) with B---F distances restrained to 1.36 Å; a 63:37 occupancy ratio is observed. Only the higher occupancy site was retained. Restrain refinement was used on U_{ij} to be all equal for C1 to C6 atoms because of thermal motion leading to large U parameters.

Results and discussion

1. Photoreactions

The $M_3(dppm)_3CO^{2+}$ clusters undergo photooxidative degradation in the presence of chlorocarbons either as a neat solvent or in acetonitrile solutions, and also in the presence of Cl^- ions. These photoinduced chemical processes form the known corresponding $M(dppm)Cl_2$ complexes as sole isolated metal-coordinated inorganic products (for M = Pd, Pt) as identified from comparison of ^1H and ^{31}P NMR spectra with authentic samples (eq. [1]).

$$[1] \quad M_3(dppm)_3CO^{2+} \xrightarrow[h\nu]{\text{R-Cl or } Cl^-} M(dppm)Cl_2$$

The reactions do not proceed in the dark. To establish the mechanistic step of the $Pd_3(dppm)_3CO^{2+}$ photoconversion to $Pd(dppm)Cl_2$, the model system $Pd_3(dppm)_3(CO)(Y)^{3+}$ (Y = $N_2C_6H_4NEt_2$) (13) was investigated. This compound is prepared from the binding of $Pd_3(dppm)_3CO^{2+}$ with $[N_2C_6H_4NEt_2]^+$ (as the BF_4^- salt) (13). This complex is surprisingly unstable to light in the presence of CH_2Cl_2 to slowly form $[Pd_3(dppm)_3(CO)(Cl)]BF_4$ as identified by X-ray crystallography (as a CH_2Cl_2 solvate). This cationic cluster is essentially identical to that reported by Puddephatt and co-workers (24) and the bulk of the data have been deposited as supplementary material.[4] Only minor structural differences have been noticed such as the absence of disorder between the Cl^- ion and CO group, and minor changes in bond lengths and angles. Further light irradiation of the cluster also forms $Pd(dppm)Cl_2$. This later photoreaction is significantly slower. Based upon these observations, it is believed that this Cl^- adduct species may be one of the intermediate products prior to the formation of the final oxidized mononuclear $M(dppm)Cl_2$ complex.

By GC–MS, one of the organic products was identified as biphenyl for the chlorobenzene substrate. Possibly due to volatility problems, the expected ethylene and acetylene products for dichloromethane and chloroform were not observed under the same experimental conditions. The presence of biphenyl indicates the formation of the highly reactive radical phenyl group. Numerous other organics (for M = Pd) are also unselectively photoproduced, but their identity is not known at this time. This was not the purpose of this work. By GC–MS, the molecular weights of the fragments indicate that large organic molecules have been generated, along with various phosphine-containing compounds such as $P(C_6H_5)_3$. For the Cl^- substrates, the photolyses are very slow and only $Pd(dppm)Cl_2$ and dppm decomposition products are observed (as expected). There was no evidence of acetonitrile solvent participation in the products.

2. Thermodynamics

The emission spectra of the $M_3(dppm)_3CO^{2+}$ clusters reveal that the triplet energies (E_T) are determined from emission band maxima, located at 1.76 eV (14 200 cm^{-1}, M = Pd) and 1.91 eV (16 100 cm^{-1}, M = Pt) (25). From cyclic voltammetry, both clusters exhibit an irreversible electrochemical oxidation wave at +1.38 V and +1.05 V vs. SCE for the $Pd_3(dppm)_3CO^{2+}$ and $Pt_3(dppm)CO^{2+}$, respectively, both as PF_6^- salts, in degassed acetonitrile solutions containing 0.1 M tetrabutylammonium hexafluorophosphate. The coulometric experiments establish that the electrochemical process is a multielectron process, which places an upper limit for the one-electron oxidation of the clusters (i.e., $\leq$+1.38 V (M = Pd) and $\leq$+1.05 V (M = Pt) vs. SCE). The excited state driving forces in the lowest energy triplet excited state ($E^{*/+}$) would then be evaluated to be in the order of 0.38 V and 0.86 V vs. SCE for M = Pd and Pt, respectively. These values are not great enough to spontaneously reduce most simple chlorocarbons such as C_6H_5Cl ($E^{0/-} = -2.32$ V vs. NHE), CH_2Cl_2 ($E^{0/-} = -2.23$ V vs. NHE), $CHCl_3$ ($E^{0/-} = -1.67$ V vs. NHE), and CH_3Cl ($E^{0/-} = -2.23$ V vs. NHE) (26). In these cases, the photoinduced electron transfer mechanism from the $M_3(dppm)_3CO^{2+}$ cluster in their lowest energy $^3A_2$ states to the chlorocarbon molecules is clearly thermodynamically unfavorable. This is obviously also true for the cluster oxidation in the presence of the Cl^- anion. Con-

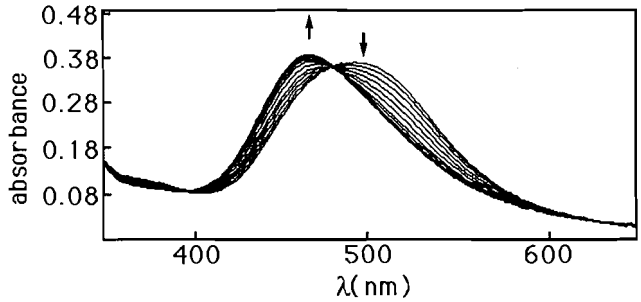
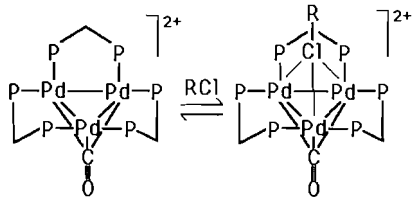


Scheme 1.



versely, substrates such as $C_6H_5CH_2Cl$ ($E^{o/-} = -1.0$ V vs. SCE (27)) and CCl_4 ($E^{0/-} = -0.78$ and -1.67 V) offer the possibility that such a photoinduced process occurs for $Pt_3(dppm)_3CO^{2+}$. For CCl_4, the presence of a fourth Cl atom renders the molecule an excellent electron scavenger. For $C_6H_5CH_2Cl$, scission of the reduced species generates the Cl^- ion and the benzyl radical ($C_6H_5{\cdot}CH_2$), which is stabilized by resonance. In these cases, electron transfer could also be considered.

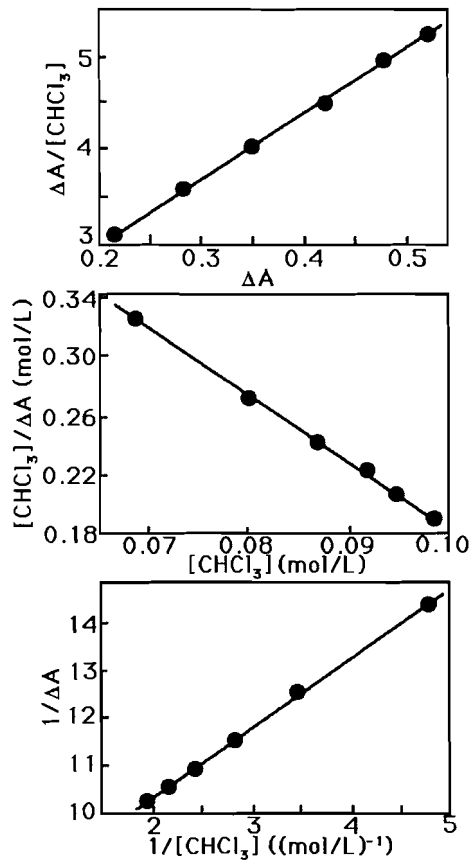
3. Binding studies

From a thermodynamic standpoint, a photoinduced atom abstraction mechanism must be considered. In such a mechanism, the substrate R—Cl *must* physically approach the excited M_3^{2+} center. Recently published flash photolysis measurements indicate that the excited state lifetimes range from 25 (M = Pd) to a few hundred picoseconds (M = Pt) (25), which are not long enough to allow a diffusion of the $M_3(dppm)_3CO^{2+*}$ ($^3A_2$) species to the substrates. The photoprocess (atom abstraction) must be *unimolecular*, involving a ground state preassembling of the clusters and the substrates. Since the chromophoric unsaturated M_3^{2+} center is located at the bottom of a cavity formed by six dppm-phenyl groups, the substrate must act as a guest molecule in this pocket.

This section addresses the ground state host–guest behavior of the $M_3(dppm)_3CO^{2+}$–chlorocarbon systems. The cluster of choice is $Pd_3(dppm)_3CO^{2+}$ since its absorption spectrum exhibits a well-defined absorption band at around 480 nm, where isosbestic points can be clearly observed upon association with a substrate (13). Methanol was chosen as solvent since previous studies established that this solvent interacts the least with the cavity (13), and offers good solubility for the cluster and substrates.

Figure 1 shows UV–visible spectra changes upon addition of chloroform. Clear isosbestic points are evident at ~479 and ~398 nm, indicating a 1:1 stoichiometric ratio (Scheme 1).

Fig. 2. Typical Benesi–Hildebrand, Scatchard, and Scott plots associated with the addition of $CHCl_3$ to a solution of $Pd_3(dppm)_3CO^{2+}$ in methanol at 298 K.



The K_{11} values extracted from the Benesi–Hildebrand plots (Fig. 2) are listed in Table 1. These constants have also been verified by also extracting them from the Scatchard and Scott plots (Fig. 2). Except for Cl^-, reversibility can be observed from the displacement of the substrate by adding a second substrate monitoring the progression by UV–visible spectroscopy (each substrate exhibits its own λ_{max}). In the Cl^- case, the binding constant is very large (>10 000 M^{-1}) and somewhat hard to obtain with precision. There is no obvious trend between the molecular dimension and K_{11} (Table 1). However, some rationalization can be made. Chloride is the smallest substrate of this series and is charged ($Cl^-\cdots Pd_3^{2+}$); it is the most efficient guest of the series. C_6H_5Cl compares structurally to toluene, which was investigated earlier ($K_{11} = 0.08 \pm 0.02$ M^{-1} (13)). The slight increase in K_{11} here ($K_{11} = 0.16 \pm 0.01$ M^{-1}) could be associated with some extra binding between the Cl atom and the Pd_3 center. Furthermore, adding extra Cl atoms on a given substrate should then slightly increase K_{11} if the substrate is not too sterically demanding. This is indeed observed for CH_2Cl_2 (0.25 ± 0.03 M^{-1}) and $CHCl_3$ (4.9 ± 0.5 M^{-1}). However, a slight decrease is observed for CCl_4 (3.4 ± 0.1 M^{-1}), which could be due to the slight increase in molecular dimensions.

Two unexpected results come from 1-Cl-ada (35 ± 5 M^{-1}) and $C_6H_5CH_2Cl$ (7.3 ± 0.1 M^{-1}), which were used for their bulkiness (1-Cl-ada), and low bond dissociation energy and reduction potential ($C_6H_5CH_2Cl$), respectively. The increase

Table 1. Comparison of K_{11} values and substrate sizes.

Substrate	K_{11}/M^{-1}[a]	Dimensions[b]
Cl^-	[c]	van der Waals diam. = 3.6 Å, ionic diam. = 3.4 Å
CH_3Cl	Not measured	Average diameter ~4.7 Å
CH_2Cl_2	0.25 ± 0.03	Average diameter ~5.2 Å
$CHCl_3$	4.9 ± 0.5	Average diameter ~5.7 Å
CCl_4	3.4 ± 0.1	Average diameter ~6.1 Å
1-Cl-ada	35 ± 5	Average diameter ~6.5 Å
C_6H_5Cl[d]	0.16 ± 0.1	Assuming a rectangular shape ~8.7 × 3.6 × 6.9 Å
$C_6H_5CH_2Cl$	7.3 ± 0.1	Assuming a rectangular shape ~9.4 × 3.6 × 6.9 Å

[a]The uncertainties are defined by the difference between the average value and the maximum and minimum values measured.

[b]The average diameters have been calculated by averaging the four dimensions (diameters) of the four tetrahedral axes. These tetrahedral dimensions have been calculated using r_{vdw} (H) = 1.30 Å and r_{rdw} (Cl) = 1.80 Å, and bond length extracted from the PC MODEL computer software.

[c]Not accurate since the system is not reversible. However, the few data extracted from the Benesi–Hildebrand plots indicate that K_{11} is very large (>10 000 M^{-1}).

[d]A slow thermal reaction has been observed at high concentrations. At low concentrations (~10^{-3} M in $C_6H_5CH_2Cl$ for ~10^{-5} M in cluster) no reaction is observed.

Table 2. Comparison of Φ_{dis} with E(C—Cl) and $E^{0/-}$.

[c]The E(C—Cl) for CH_3CH_2Cl is 81 kcal mol^{-1} (CRC handbook).

[d]$E^{0/-}$ for chlorobicyclo[7,1^{1,5}]heptane is −1.99 V. It is highly suspected that $E^{0/-}$ for 1-Cl-ada is also ~−2 V.

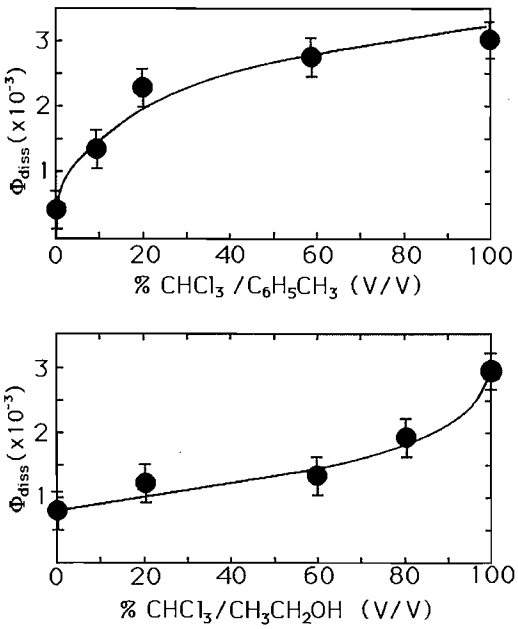
[e]From ref. 27.

by at least one order of magnitude on going from Cl—CH_2Cl (0.25 M^{-1}) to C_6H_5—CH_2Cl (~7.3 M^{-1}) is not unprecedented. The K_{11} increases from acetate to benzoate, nitroethane to nitrobenzene, and acetonitrile to benzonitrile are also all around an order of magnitude (13). Cooperation between the binding of the Cl atom with the Pd_3 center, and the binding of the hydrophobic phenyl group and the cavity dppm-phenyl groups, appears to be responsible for this phenomenon. Finally, the unexpectedly large K_{11} value for 1-Cl-ada can only be explained by a binding involving only the hydrophobic portions of the host–guest pair. In this case the multiple hydrophobic intermolecular contacts could lead to a large K_{11} value. No attempt was made to further investigate this phenomenon.

4. Quantum Yields

The photochemical quantum yields (Φ) were measured by ferrioxalate actinometry following the rate of $Pd_3(dppm)_3CO^{2+}$ consumption by UV–visible spectroscopy (λ_{max} ~ 480 nm). First, $Pd_3(dppm)_3CO^{2+}$ was investigated in neat solvents (Table 2). We noticed that in neat $C_6H_5CH_2Cl$, $Pd_3(dppm)_3CO^{2+}$ reacted slowly (thermally) at room temperature, so no Φ value could be measured. However, at [R—Cl] ~ 10^{-3} M (typical concentration range for K_{11} measurements), no detectable reaction was noticed. This reactivity is tentatively attributed to the relatively high stability of the benzyl radical ($C_6H_5CH_2^{\cdot}$); and it is concluded that the homolytic C—Cl bond cleavage by $Pd_3(dppm)_3CO^{2+}$ is facile in this case. For C_6H_5Cl, CH_2Cl_2, and $CHCl_3$, Φ increases with both the decrease in E(C—Cl) and $E^{0/-}$ values. Surprisingly, Φ decreases for CCl_4 while E(C—Cl) and $E^{0/-}$ continue to decrease in this series. This result further supports the conclusion that the primary process in the mechanism cannot be an

Fig. 3. Graph of $\Phi_{dis}(Pd_3(dppm)_3CO^{2+})$ vs. % $CHCl_3$ (V:V) in toluene (top) and ethanol (bottom).

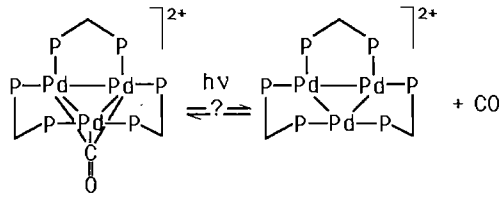


decrease in this series. This result further supports the conclusion that the primary process in the mechanism cannot be an outer-sphere electron transfer. On the other hand, an atom transfer mechanism is not ruled out since "steric considerations" can also affect the rates of reaction. One has to note that the K_{11} data also arise from measurements that also consider the steric effects in the complex stability. By ignoring the experimental uncertainties, Φ varies as $C_6H_5Cl < CH_2Cl_2 < CCl_4 < CHCl_3$ in neat solvents, which parallels the trend in K_{11}. For the chloride substrate, at $[Cl^-] = 0.86$ M (as Bu_4N^+ salt) in ethanol, $\Phi \sim 1.5 \times 10^{-5}$ (extremely weak)! Again no reaction is observed in the dark. One has to note that the Cl^- ion is very strongly bonded to the $Pd_3(dppm)_3CO^{2+}$ cluster, so no direct comparison of the Φ values can be made. The extremely low Φ value indicates that the photodecomposition is slow. This is indeed observed during the bulk photolysis reactions for $Pd_3(dppm)_3(CO)(Cl)^+$ (i.e., the photoproduct of the $Pd_3(dppm)_3(CO)(N_2C_6H_4NEt_2)^{3+}$ photodecomposition in CH_2Cl_2, believed to be one of the intermediates).

For comparison purposes, Φ's for the photochemical reactions between $Pt_3(dppm)_3CO^{2+}$ and $CHCl_3$, and CH_2Cl_2 (neat) were also measured. As expected, the Φ value is greater for M = Pt with $CHCl_3$ ($\Phi = 0.0041 \pm 0.0005$ at $\lambda = 380$nm) than that of $Pd_3(dppm)_3CO^{2+}$ (0.0030 ± 0.0005). For CH_2Cl_2, Φ is about the same for both clusters, considering the uncertainties. Both the triplet energy and the excited state driving forces are greater for $Pt_3(dppm)_3CO^{2+}$. These experiments did not provide any evidence of one mechanism or another.

Based upon the hypothesis that an atom transfer mechanism involves a physical approach of the R-Cl molecule towards the M_3 center, Φ should be sensitive to the presence of a competitive molecule (solvent). Figure 3 shows the relationship of Φ for the $Pd_3(dppm)_3CO^{2+}$–$CHCl_3$ photoreactions as a function of the % (V/V) for two different solvents (toluene and ethanol). The toluene graph shows an upward curvature, while the

Scheme 2.



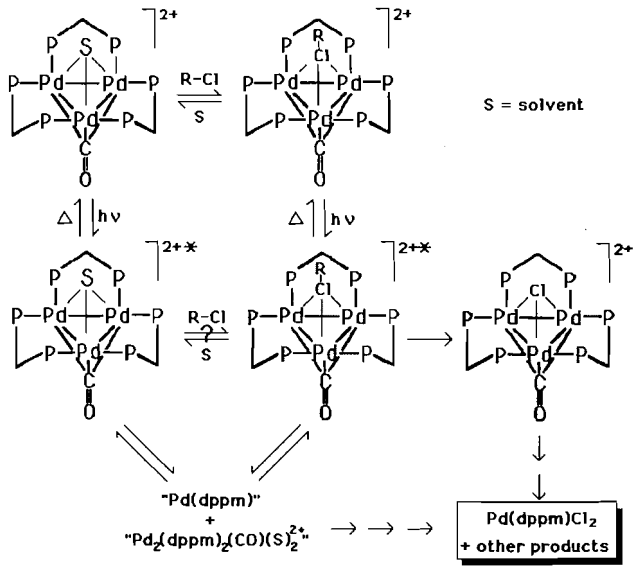
ethanol graph shows a downward curvature, with the increase in %(V/V), in $CHCl_3$, confirming the expected difference. Except for CH_2Cl_2, the other substrates were not investigated as a function of %(V/V) substrate and solvent. For CH_2Cl_2, Φ increases (slightly) with % (V/V) CH_2Cl_2, but the large uncertainties prevent us from determining the curvature trend. Based upon the K_{11} measurements reported elsewhere (13), ethanol appears to be a better binder than toluene with $Pd_3(dppm)_3CO^{2+}$. Figure 3 indicates that ethanol inhibits the increase in Φ values with the increase in $[CHCl_3]$. On the other hand, the sharp increase in Φ's in the toluene graph at low $[CHCl_3]$ indicates that toluene does not efficiently inhibit the photoreactions. These results are also consistent with this substrate–cavity model where toluene does not compete as efficiently as ethanol for the cavity.

The most surprising result is the non-zero value at 0% quantity of $CHCl_3$ (~0.0005), indicating that $Pd_3(dppm)_3CO^{2+}$ is photo-consumed even in the absence of chlorocarbons. We note that these values are even greater than that of the Cl^- substrate stated above. This observation clearly indicates the presence of a second photochemical pathway since with short periods of time in the dark, this instability does not occur. This pathway is clearly inefficient with such low quantum yields, but cannot be neglected for the CH_2Cl_2, CCl_4, 1-Cl-ada, and C_6H_5Cl substrates. The design of experiments in order to elucidate this second pathway is not obvious. Two proposed mechanisms can be anticipated: (*i*) photolabilisation of the CO group (Scheme 2) as observed in many organometallic polynuclear complexes (1) followed by a breakdown of the cluster, and (*ii*) photoinduced fragmentation of the cluster according to eq. [2]:

$$[2] \quad Pd_3(dppm)_3CO^{2+} \underset{\text{dark}}{\overset{h\nu}{\rightleftharpoons}} \text{"Pd(dppm)"} + \text{"}Pd_2(dppm)_2(CO)(S)_2^{2+}\text{"} \longrightarrow \text{products}$$

where S is a two-electron donor (counter anion or solvent molecule). This second reaction is essentially the last step prior to the synthesis of the $Pd_3(dppm)_3CO^{2+}$ cluster as demonstrated by Puddephatt and co-workers (7, 8). The following experiments are performed: (*i*) measurements of Φ in the presence of CO(g), and (*ii*) measurements of Φ for the PF_6^- and $CF_3CO_2^-$ salts. The first set of experiments (Φ vs. CO(g)) demonstrates that Φ is independent (within the experimental uncertainties) in the presence of 1 atm of CO(g) (1 atm = 101.3 kPa). The synthesis of $Pd_3(dppm)_3CO^{2+}$ does not require high pressures of CO (7). This experiment was attempted in order to slow down the CO loss, if any. The most revealing experiments are the measurements of Φ for $Pd_3(dppm)_3CO^{2+}$ as a PF_6^- and as a $CF_3CO_2^-$ salt. Using different solvents (ethanol and acetonitrile) and atmospheres (Ar, CO_2, O_2, CO, and H_2), we find that

Scheme 3.



is a better binder than PF_6^- (13) which should indicate that the cavity is competitively blocked by the carboxylate molecule, if one assumes the host–guest mechanism. However, this result is consistent with eq. [2] shifting the reaction to the right when S is a better two-electron donor. Interestingly we find Φ (ethanol) > Φ (toluene) (at [substrate] = 0, see Fig. 3), where ethanol is a two-electron donor. The next question is whether or not the formation of $Pd_3(dppm)_3^{2+}$ (first scenario: Scheme 2) can lead to an *efficient* subsequent fragmentation of the cluster. Theory predicts that it cannot (see section below), corroborating the experimental results (Φ vs. CO(g)). Then, will the intermediates generated in eq. [2] subsequently react with R—Cl to produce the final observed products? Previous studies strongly indicate that it is indeed possible. The highly reactive "Pd(dppm)" species is expected to be thermally active towards R—Cl based upon the known chemistry for "$Pd(R_2PCH_2CH_2PR_2)$" where R = C_6H_{11} (28). For the CO bridged d^9-d^9 proposed intermediates (eq. [2]), a recent work on an isoelectronic CNR bridged "$Pd_2(dppm)_2$" d^9-d^9 compound demonstrated that this complex was efficiently photoconverted to $Pd(dppm)Cl_2$ in the presence of CH_2Cl_2 (29). Thus, experimental and literature results favor scenario (*ii*) for the second pathway of R—Cl activation. The overall proposed pathways are summarized in Scheme 3. The C—Cl homolytic bond cleavage involves the formation of the $Pd_3(dppm)_3(CO)(Cl)^{2+}$ intermediate, which represents one of the mechanistic steps of the photoinduced photodegradation of the cluster.

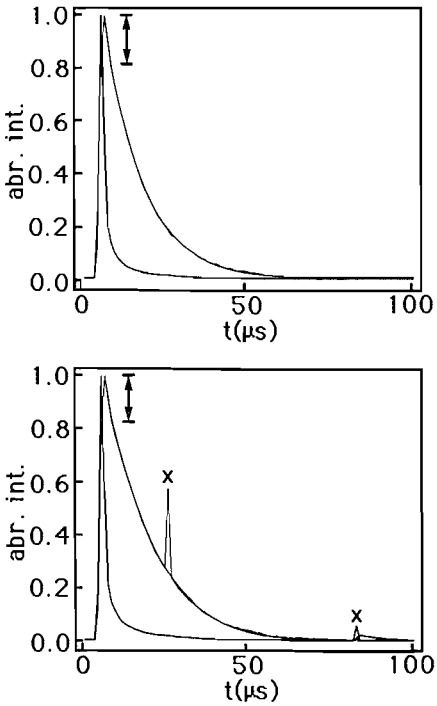
Considering the K_{11} measured for 1-Cl-ada, one would expect Φ to be large. However, the binding does not necessarily involve the C-Cl bond oriented inside the cavity. Indeed, Φ(1-Cl-ada) = 0.000048 ± 0.000010 for [1-Cl-ada] = 3.43 M in toluene. This value is by far the smallest one (excluding the Cl^- case). Further, the CPK models demonstrate that the bulkiness of 1-Cl-ada precludes strong R—Cl··Pd_3^{2+} interactions, confirming that homolytic bond cleavage by $Pd_3(dppm)_3CO^{2+*}$ ($^3A_2$) is not anticipated to be efficient.

5. Emission lifetimes

This section addresses the first proposed pathway (host–guest chemistry). Perturbation studies of the photophysical properties of the $M_3(dppm)_3CO^{2+}$ complexes indicate that the presence of a substrate in the cavity always induces a decrease in excited state lifetimes (25). This general behavior has also been observed for metal complexes of calix[4]arene derivatives for which a metal atom is located at the lower rim acting either as a luminescent probe (Ir(I); ref. 30) or a strong Lewis acid (W = O (31)), and the recently investigated $Cu_3(dppm)_3OH^{2+}$ cluster (32). This phenomenon is attributable to the "loose bolt effect" (for small perturbations) or to the formation of an "exciplex" (for larger change in lifetimes) (33). For $Pt_3(dppm)_3CO^{2+}$ both 298 K flash photolysis and 77 K emission lifetime measurements established that toluene as a pure solvent provided the shortest lifetimes among the solvent molecules investigated (25). The hypothesis is that toluene binds more strongly to $Pt_3(dppm)_3CO^{2+}$ than do most common solvents. This difference with $Pd_3(dppm)_3CO^{2+}$ is not understood at this time.

To further understand the difference between the photochemical quantum yield behavior in toluene and ethanol, the emission decay traces for $Pt_3(dppm)_3CO^{2+}$ at 77 K in the presence of CH_2Cl_2 and $CHCl_3$ were investigated. $Pt_3(dppm)_3CO^{2+}$ was selected because of its greater emission quantum yield at 77 K (34). At such a temperature, cluster degradation is not anticipated to be an inefficient mechanism for the excited state deactivation; solely the Pt_3^{2+}···Cl—R interactions are governing the changes in τ_e with [Cl—R]. In pure solvent, the emission decays are rigorously monoexponential (τ_e = 10.2 ± 0.5 μs, toluene; τ_e = 18.0 ± 0.1 μs, ethanol). In the presence of $CHCl_3$ or CH_2Cl_2, the carefully measured decays become biexponential (Fig. 4). The biexponential behavior is demonstrated from deconvolution decay analysis. The emission spectra exhibit no band shift but show a gradual decrease in intensity with chlorocarbon concentration. The long component exhibits a τ_e value of 10.2 or 18.0 μs characteristic of the solvent, and does not change (within ±0.5 μs) with an increase in chlorocarbon concentration up to 40% (V/V). Such a result further rules out the possibility of an outer-sphere electron transfer in the excited state in these cases ($CHCl_3$, CH_2Cl_2), since generally the emission decay traces exhibit monoexponential behaviors with lifetimes decreasing with the substrate concentration. The short component exhibits a lifetime of 450 ± 150 ns for both CH_2Cl_2 and $CHCl_3$. The relative intensity ratio for short component/long component after deconvolution increases proportionally with the chlorocarbon/solvent ratio (V/V). This experiment demonstrates that the short and long components are associated with the luminescence of $Pt_3(dppm)_3CO^{2+}$ interacting (or hosting) a chlorocarbon and a solvent molecule, respectively. The very short lifetimes in the $Pt_3(dppm)_3CO^{2+}$··· chlorocarbon cases strongly indicate the formation of exciplexes. The exciplex emissions appear to be weak since the emission intensity of the mixture steadily decreases with the increase in chlorocarbon concentration. Also these emissions are anticipated to be located very close to the $Pt_3(dppm)_3CO^{2+}$··· solvent emissions, since no change in λ_{max} emission was observed in all the experiments. The most important finding is that the short component/long component intensity ratio always differs greatly between the two solvents (ethanol, toluene) at a given chloro-

Fig. 4. Typical emission decay traces for the $Pt_3(dppm)_3CO^{2+}$ clusters at 77 K. Top: in toluene containing 30% CH_2Cl_2 (V:V) Bottom: in ethanol containing 3% CH_2Cl_2 (V:V). The peaks marked with an X are instrumental artifacts. The double arrow markings indicate the short-lived components (~18% of the total intensity).



carbon/solvent ratio. As a typical example, Fig. 4 compares two 77 K emission decays of $Pt_3(dppm)_3CO^{2+}$: the first in toluene containing 30% CH_2Cl_2, and the second in ethanol containing 3% CH_2Cl_2. Both decays exhibit the same short component/long component ratio (~18%). This result indicates that the halocarbon molecule competes relatively more efficiently to occupy the $Pt_3(dppm)_3CO^{2+}$ cavity in ethanol. Essentially, this confirms that ethanol is a weaker binder for $Pt_3(dppm)_3CO^{2+}$ than toluene and further supports the above hypothesis.

6. Geometry optimizations

Density functional theory was used to optimize geometries in the ground state of some proposed intermediates in order to explain and corroborate some experimental results. For $Pd_3(dppm)_3CO^{2+}$ in its ground ($^1A_1$) and lowest energy triplet excited states ($^3A_2$, (T_1), $^3E_2$ (T_2)), the geometry compounds have already been computed (35). The computations compared very favorably with the experimental data, particularly for the Pd—Pd bond lengths. For comparison purposes, these data are reported in Table 3. The geometry of the model $Pd_3(PH_3)_6(CO)(Cl)^+$ cluster has also been optimized (Table 3 and Fig. 5) in order to address the weak interactions between the Pd_3^{2+} center and the substrate. The comparison of the Pd—Pd bond lengths is also excellent, but some differences are noted for the covalent Pd—P and Pd—C bonds. These differences can be up to 0.055 Å. For the more ionic Pd···Cl interactions, the computed Pd···Cl distance is significantly shorter

Fig. 5. Optimized ground state geometry of the model compound $Pd_3(PH_3)_6(CO)(Cl)^+$. The geometry for $Pd_3(PH_3)_6(CO)(Cl)^{2+}$ is the same except that some distances and angles have changed (see details in Table 4).

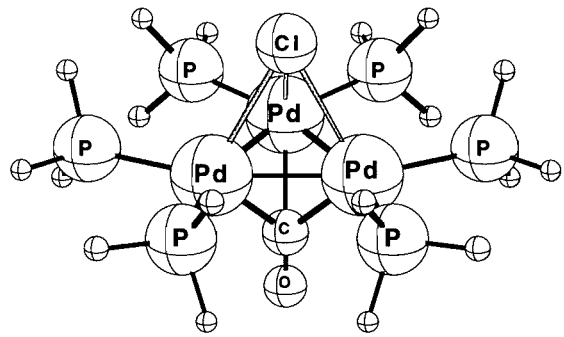


Fig. 6. Optimized geometry of the model association complex $Pd_3(PH_3)_6(CO)^{2+}\cdots ClCH_3$ in the ground state.

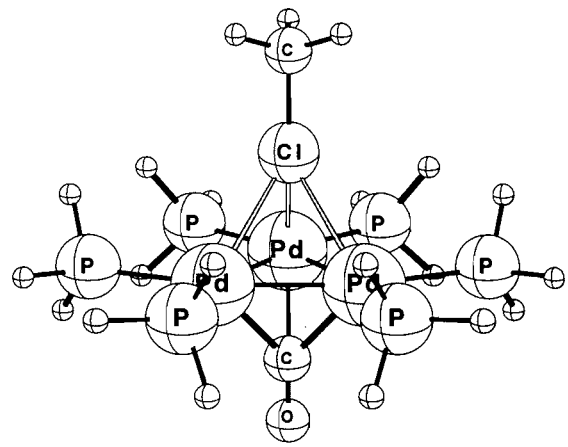

than that of the crystal structures. The differences are up to 0.23–0.26 Å from the average X-ray values. Steric effects with the H-dppm atoms and the nature of the theoretical methods employed are likely to be at the origin of these differences. Investigations should concentrate mainly on the metal–metal bonds.

The first optimization considered is the ground state interactions between $Pd_3(PH_3)_6CO^{2+}$ and chloromethane (Fig. 6). The number of atoms is kept low in order to reduce the computer time, and the optimization was performed under the restricted C_{3v} symmetry. The results of the computations are compared in Table 4. The first and most important prediction is that the Pd···Cl interactions are expected to be very weak as the computed Pd···Cl distances are in the order of 2.83 Å. This distance compares to average distances of the X-ray results reported for $Pd_3(dppm)_3(CO)(Cl)^+$ (Table 3), but is in fact larger than that of the $Pd_3(PH_3)_6(CO)(Cl)^+$ computed distance (2.628 Å). This result may be due to the lack of electrostatic interaction between Pd_3^{2+} and neutral $ClCH_3$. The calculated Pd—Pd bond length (2.63 Å) compares favorably to that of most "$Pd_3(dppm)_3CO^{2+}$" complexes reported so far (see ref. 36 for examples). The r(Pd—P), r(C═O), and r(Pd—C) calculated values also compare with the $Pd_3(PH_3)_6(CO)(Cl)^+$ and

$Pd_3(PH_3)_6(CO)^{2+}$ data. We conclude that the interactions between the Cl atom of R—Cl and the Pd_3^{2+} center is very weak, causing little perturbation to the host skeleton. The following set of calculations addresses the possibility of the photoinduced labilization of CO (Scheme 2). The optimized geometry of $Pd_3(PH_3)_6^{2+}$ was calculated and the results at convergence (Table 4) indicate that the Pd—Pd and Pd—P distances undergo practically no, or very little, perturbation (within 0.03 Å). If the Pd—Pd bond length had significantly increased, one may have suspected that fragmentation would occur. This is not the case.

To shed light on the steps following the homolytic C—Cl bond cleavage, the geometries of the model compounds $Pd_3(PH_3)_6CO^{3+}$ and $Pd_3(PH_3)_6(CO)(Cl)^{2+}$ were also investigated. The question is, what may happen after the Cl· radical starts interacting with the Pd_3^{2+} center? One hypothesis is an intramolecular electron transfer from the Pd_3^{2+} center to the strongly oxidant Cl· radical. To test this hypothesis, the structure of the $Pd_3(PH_3)_6CO^{3+}$ compound is optimized (Table 4). While the r(Pd—P), r(C·O), and r(Pd—C) data resemble the rest of the data reported in Table 4, the calculated Pd—Pd distance has significantly increased to ~2.73 Å. This distance is very close to the limit of a formal Pd—Pd single bond (see data reported in ref. 3). It is also close to the distance found experimentally in the $Pd_3(dppm)_3CO^{2+}$ cluster in its lowest energy triplet excited state ($^3A_2$; ~2.78 Å) (35). If a formal electron is indeed transferred from the Pd_3^{2+} to the Cl· center to form the Pd_3^{3+} and Cl^- species, then the calculated Pd—Pd bond length in $Pd_3(PH_3)_6(CO)(Cl)^{2+}$ should be close to 2.73 Å also. This is not quite the case as the computed distance converges to 2.68 Å, indicating that the structure is an intermediate between the two forms ($Pd_3^{2+}\cdots Cl^{\cdot}$ and $Pd_3^{3+}\cdots Cl^-$). The r(Pd—P), r(Pd—C), and r(C═O) data are also "normal" (Table 4), but the Pd···Cl distance has significantly decreased, down to ~2.54 Å. This increase in interactions may appear to be due to an increase in electrostatic interactions (i.e., $Pd_3^{3+}\cdots Cl^-$ form). Nonetheless, with a distance of ~2.68 Å typical for a Pd—Pd dppm bridged single bond, the homolytic scission of the Pd—Pd bond after the Cl abstraction does not seem obvious at this point. However, the electrochemical cyclic voltammograms recorded for both $M_3(dppm)_3CO^{2+}$ clusters (M = Pd,Pt) exhibit irreversible oxidation waves, suggesting that further events are obviously taking place after the transfer of the first electron ($Pd_3^{2+} \rightarrow Pd_3^{3+} + 1e^-$). The intramolecular electron transfer between the Pd_3^{2+} and Cl· centers forming Pd_3^{3+} and Cl^-, which subsequently degrade into products, still appears as a possible mechanism of photoinduced fragmentation.

Final remarks

The photoinduced degradation of $M_3(dppm)_3CO^{2+}$ in the presence of chlorocarbons and chloride ion proceeds via very complicated pathways. This work has addressed only a fraction of them, notably for the primary steps. There is no evidence of an electron transfer mechanism involving the excited clusters in their $^3A_2$ states and the R—Cl and Cl^- substrates. On the other hand, the series of measurements performed were all consistent with an atom abstraction mechanism. The well-established host–guest behavior of the cluster was used to confirm this mechanism in the $^3A_2$ states. To our knowledge such a strategy does not seem to have been employed before.

[a]Data for $Pd_3(PH_3)_6(CO)(Cl)^+$ are also compared in Table 3, and data for $Pd_3(PH_3)_6(CO)^{2+}$ are from ref. 35. All calculations were performed under a C_{3v} restricted geometry.

One very important observation is clearly the very low photochemical quantum yields, demonstrating the rather inefficient capacity of the clusters to photoactivate the C—Cl bond. For stronger C—X bonds (such as C—H), this observation allows us to predict that the cleavage of this C—X bond will simply not occur, but rather the second pathway (primary photoinduced fragmentation of the cluster) may become dominant in order to promote reactivity in these cases. Thus cluster degradation and decomposition should be observed. This is consistent with the nature of the organic photoproducts observed with the chloride substrate, which are all phosphine derivatives (issued from the coordinated dppm). This decomposition mechanism is complex since high molecular weight fragments are observed (higher than dppm in some cases), indicating that the processes involved formation of free radicals. The very low photochemical quantum yields (Φ) have been commented on in one of our studies on O_2 activation (6). There are many possible explanations for the low Φ values: (*i*) the excited state lifetimes are found to be extremely short ($\tau_1 < 40$ ps, M = Pd; $\tau_1 < 40$ ps, $70 < \tau_2 < 400$ ns, intensity ratio for $\tau_1/\tau_2 = 95/5$, M = Pt; (ref. 25)); (*ii*) access to the lumophore is sterically hindered by another interacting substrate in the ground and excited states; and (*iii*) the biradical-type excited state is delocalized over three metal centers, not localized as in the case of the $M_2(CO)_{10}$ dimers ($2 \times M(CO)_5$; M = Mn, Re; ((ref. 1*a*)). Further studies in this area are in progress.

Tungsten and molybdenum oxo complexes of tetrakis(phenyldiazenyl)calix[4]arene substituted derivatives : EHMO calculations, spectroscopic characterization, and perturbations of the photophysical properties by neutral guest molecules

Pierre D. Harvey, Jonathan Gagnon, Réjean Provencher, Bing Xu, and Timothy M. Swager

Abstract: Bowl-shaped chromophores fabricated with tungsten and molybdenum oxo complexes of calix[4]arenes substituted at the *para* positions with phenyldiazenyl ($R_2C_6H_3N_2$) derivatives are investigated. The nature of the lowest energy excited states has been addressed theoretically using Extended Hückel Molecular Orbital (EHMO) calculations and experimentally using UV–visible, luminescence, and polarized emission spectroscopy at 77 K. The lowest energy excited states are intraligand (azobenzene fragment) $\pi\pi^*$ (S_2 and T_2) and $n\pi^*$ states (S_1 and T_1). The compounds are weakly luminescent in the 600–630 nm range exhibiting emissions arising from the $^1(\pi\pi^*)$ states ($S_2 \rightarrow S_0$, $1 < \tau_e < 4$ ns, and $3 \times 10^{-4} < \phi < 3 \times 10^{-3}$). The region located above 900 nm was not investigated. Evidence for guest–host chemistry has been demonstrated by ^{1}H-NMR spectroscopy, and the binding constants for two of the compounds with pyridine in toluene as a solvent were obtained by UV–visible spectroscopy. The presence of a guest molecule inside the luminescent metal oxo complex of a calix[4]arene hosts decreases the emission lifetimes.

Key words: host–guest, photophysics, calix[4]arene, EHMO, fluorescence

Résumé : On a étudié des chromophores en forme de bol préparés à partir de complexes oxo-tungstène et oxo-molybdène de calix[4]arènes substitués en positions *para* par des dérivés phényldiazényles ($R_2C_6H_3N_2$). On a étudié la nature des états excités de plus faible énergie par le biais de calculs d'orbitales molécules étendues de Hückel («EHMO») ainsi que par des expériences faisant appel aux spectroscopies UV–visible, de luminescence et d'émission polarisée à 77 K. Les états excités de plus faible énergie sont les états intraligands (fragment azobenzène) $\pi\pi^*$ (S_2 et T_2) et les états $n\pi^*$ (S_1 et T_1). Les composés sont faiblement luminescents dans le région de 600 à 630 nm et ils présentent des émissions dérivant des états $^1(\pi\pi^*)$ $S_2 \rightarrow S_0$, $1 < \tau_e < 4$ ns et $3 \times 10^{-4} < \phi < 3 \times 10^{-3}$). On n'a pas étudié la région située en dessus de 900 nm. On a mis en évidence de la chimie hôte–invité grace à la spectroscopie RMN du ^{1}H et, faisant appel à la spectroscopie UV–visible, on a déterminé les constantes de liaison de deux des composés avec la pyridine dans le toluène comme solvant. La présence d'une molécule invitée à l'intérieur du complexe luminescent oxo-métal d'un hôte calix[4]arène diminue la durée de vie d'émission.

Mots clés : hôte–invité, photophysique, calix[4]arène, EHMO, fluorescence,

[Traduit par la rédaction]

Introduction

The chemistry of calixarene compounds is well established (1), and has been exploited over the past few years in order to take advantage of the guest–host interactions that these compounds provide (2). Applications include cation extractions and alkali metal sensors. These compounds can be considered as bifunctional recognition devices where the lower rim acts as an ionophoric cavity and the upper rim behaves as a hydrophobic pocket. Molecules such as chloroform and toluene have been found to bind in the cavities of various calixarene compounds (1, 2*i*). More recently much progress has been made in improving the sensorial and binding properties of these compounds by attaching metal or organometallic centers (3). Tungsten oxo complexes of calix[4]arene derivatives have been used to produce bowlic liquid crystals (4).

We now wish to report the spectroscopic and photophysical properties of a series of metal oxo complexes of tetrakis(phe-

nyldiazenyl)calix[4]arene derivatives (M = W, Mo) (Scheme 1). These systems exhibit multifunctional properties, two of which are designed for the binding of organic substrates (the M = O groups are strong Lewis acids, and the phenyl groups provide hydrophobic pockets), and one for the luminescent probe at 77 K (azobenzene). The metal centers were observed to influence the absorption and emission band maxima (λ_{max}) and the emission lifetimes (τ_e). The photophysical properties are also found to be somewhat sensitive to the solvent (methylcyclohexane, pyridine, butyronitrile, etc.). Finally, one of the tungstenoxocalix[4]arene derivatives was investigated in its polymeric associated form where the molecules act as both guests and hosts at the same time and organize in a head-to-tail fashion.

Experimental section

Materials

The syntheses of the free ligands and the complexes have been reported (4), or will be reported, elsewhere (5), except for compound **2**, which is described below. Compounds **1–4** are solvated by one dimethylformamide molecule (DMF) inside the cavity as demonstrated by ^{1}H NMR integration.

Compound 2

To a solution of $NaBF_4$ (11.5 g, 104.7 mmol) in 30 mL of water cooled with an ice bath was added 18 mL of concentrated hydrochloric acid followed by 3,4-dimethylaniline (10 g, 82.5 mmol). To this mixture $NaNO_2$ (5.72 g, 82.5 mmol) in 15 mL of water was slowly added while keeping the reaction temperature below 10°C. After 0.5 h, the reaction mixture was filtered, then washed with 50 mL of a cool $NaBF_4$ solution, then with 50 mL of cool methanol, finally with 50 mL of ether, and finally dried and cooled in a desiccator with cooling to obtain 3,4-dimethylbenzene-diazonium tetrafluoroborate as a white solid. This product was dissolved in 100 mL THF, cooled to 0°C, and then pyridine (4 mL) and calix[4]arene (2 g, 4.7 mmol) were added. After 3 h, the solution was filtered and washed with THF and methanol. The solid was dissolved in pyridine and treated with activated carbon, filtered, and evaporated, and was then dispersed in 200 mL of 5% HCl and stirred for 1.5 h at room temperature. Filtering and drying gave 2.1 g of tetrakis-3,4-dimethylphenydiazenylcalix[4]arene as a red-orange solid (47% yield). ^{1}H NMR (DMSO-d_6): 7.70 (s, Ph, 8H), 7.59 (s, Ph, 4H), 7.50 (d, Ph, 4H), 7.22 (d, Ph, 4H), 3.61 (s, $PhCH_2$, 8H), 2.23 (s, CH_3, 12H), 2.21 (s, CH_3, 12H). Tetrakis-3,4-dimethylphenylazocalix[4]arene, 0.5 g (0.52 mmol), and $WOCl_4$, 178 mg (0.52 mmol), in 15 mL of dry toluene were then refluxed for 12 h under argon. Evaporation of the solvent gave a residue that was recrystallized from DMF, to give 0.45 g of tungstenoxotetrakis-3,4-dimethylphenydiazenylzocalix[4]arene as a yellow solid (70% yield). ^{1}H NMR ($CDCl_3$): 7.70 (s, Ph, 8H), 7.61 (s, Ph, 4H), 7.59 (d, Ph, 4H), 7.23 (d, Ph, 4H), 4.84 (d, $PhCH_2$, 4H), 3.56 (s, $PhCH_2$, 4H), 2.30 (s, CH_3, 24H), and 8.0, 4.1 (formyl H of DMF), 2.95, 2.85, 1.30, 0.55 (methyl H of DMF).

Preparation of the pyridine complex

The pyridine complex of tungstenoxodidodecanoxylbenzenediazenylcalix[4]arene was obtained by recrystallizing tungstenoxodidodecanoxylbenzenediazenylcalix[4]arene in pyridine – THF – MeOH. ^{1}H NMR ($CDCl_3$) 8.58, 7.65, 7.25 (free pyridine), 7.9–6.7 (m, phenyl H of azocalix[4]arene and guest pyridine, 25H), 5.00, 4.82, 4.43 (d, d, d, $PhCH_2$, 4H), 4.2–3.8 (m, OCH_2, 16H), 3.63, 3.43 (d, d, $PhCH_2$, 4H), 2.0–0.8 (m, alkyl H). The upfield shift of the pyridine protons is indicative of the binding of the molecule in the cavity. For other examples of this effect see ref. 4.

Instruments

The absorption spectra were acquired on a Hewlett Packard 8452 A diode array spectrophotometer. The emission and excitation spectra were obtained using either a Spex Fluorolog II spectrometer or a PTI LS100 spectrometer. The emission lifetime measurements were performed on a photon counting system coupled with the PTI LS100 instrument, using a homemade N_2(g) flash lamp source under the following conditions: electrode gap, 1.6 mm; gas, 15 Torr (1 Torr = 133.3 Pa); applied voltage, 40 kV; repetition rate, 40 kHz. Under these conditions, the lamp pulse exhibits a full width at half-maximum (fwhm) of 2.5 ns (when the electrodes are freshly cleaned). A PTI software package for the deconvolution technique was used to extract the lifetimes from the data. Each lifetime measurement was performed at least three times from the same freshly prepared samples. The reproducibility was found to be within ±0.05 ns. The FT-Raman spectrum was obtained with an IFS 55 FRA106 Bruker instrument.

Experimental procedures

The emission quantum yields were measured using 9,10-diphenylanthracene as the standard according to published procedures (6). The polarization ratios (N) were measured according to literature procedures (see examples in ref. 7). The binding constants were determined using the methodology outlined in details in ref. 8.

Computational details

All MO calculations were of the extended Hückel type (EHMO) using a modified version of the Wolfsberg–Helmholz formula (9). The atomic parameters used for C, H, O, N,

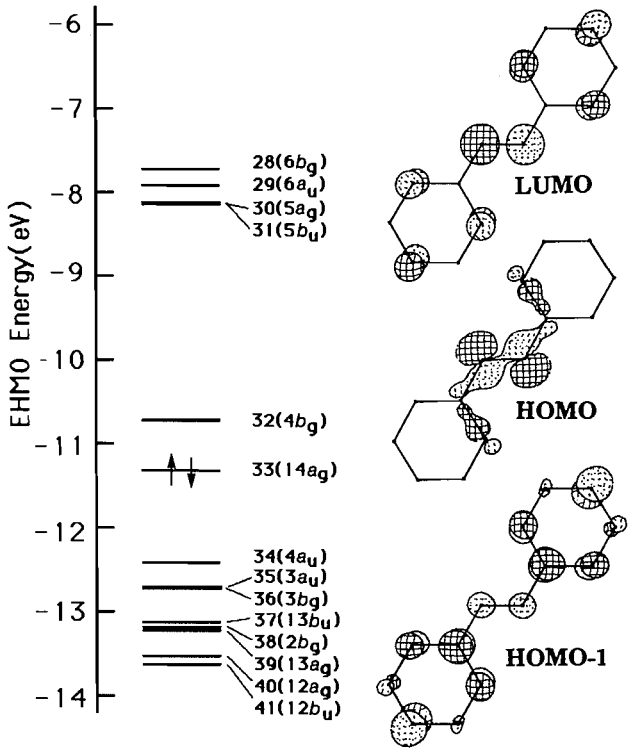

Fig. 2. EHMO energy levels for the tungsten oxo complex of the tetrakis-(phenyldiazenyl)calix[4]arene.

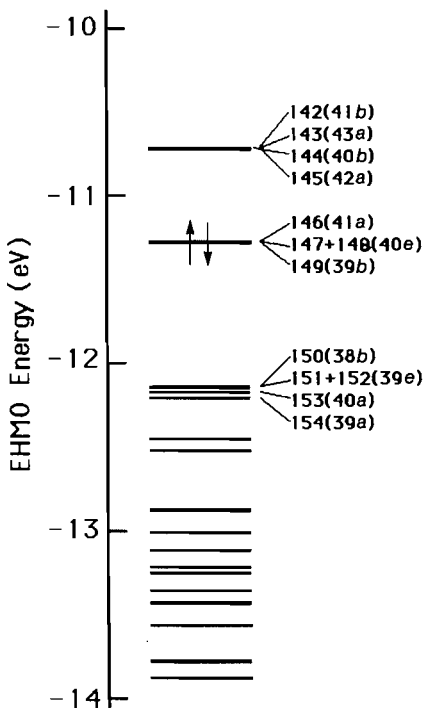

and W are taken from refs. 9 and 10. The bond lengths and angles used for the computations are those found crystallographically in the literature (3*f*) and are *r*(C—C) = 1.4 Å, *r*(C—O) = 1.47 Å, *r*(C—H) = 1.05 Å, *r*(N=N) = 1.25 Å, *r*(W=O) = 1.70 Å, *r*(W—O) = 1.89 Å, ∠O-W-O = 181°, ∠W-O-C = 135°, ∠C-C-C = 120°. The long alkyl chains and methylene groups were not included in the computations, since they are of very little consequence to the lowest energy excited states. Pictorial representations of the orbitals were obtained using the CACAO graphics package included in the software (11). The absorption spectrum of compound **1** was calculated using Heller's time-dependent theory, giving equivalent results to a traditional Franck–Condon analysis (12 and, for a recent applications, ref. 13).

Results and discussion

1. Excited state characterization (EHMO)

The nature of the frontier MO's has been addressed theoretically using the Extended Hückel Molecular Orbital methods (EHMO). The electronic structures of the *trans*-azobenzene compound (C_{2h}), the tungsten oxo complex of the mono(phenyldiazenyl)calix[4]arene (C_1), and the tungsten oxo complex of the tetrakis(phenyldiazenyl)calix[4]arene (C_4) have been investigated. The tungsten oxo complex of the mono(phenyldiazenyl)calix[4]arene was investigated because it exhibits an intermediate level of complication (i.e., low number of MOs) between the *trans*-azobenzene and the tungsten oxo complex of the tetra-substituted ligand.[2] A summary of the key results is presented here.

The EHMO calculations for all three model compounds indicate that the energy ordering of the three MOs of interest in this work is that of the intraligand π(HOMO-1), *n*(HOMO), and π*(LUMO) MOs localized in the azobenzene fragments (Figs. 1–3). The HOMO and LUMO are localized at −11.26 and −10.70 eV, respectively, for all three computed compounds. In the tetrakis(phenyldiazenyl)calix[4]arene case, the HOMO defined as MO no. 33 ($14a_g$) in Fig. 1 becomes MOs no. 146–149 (41*a*, 40*e*, 39*b*). These four MOs, all *n* in nature, have the same EHMO energy (accidently degenerate Fig. 2). The LUMO defined as MO no. 32 ($4b_g$) for azobenzene becomes MOs no. 142–145 (41*b*, 43*a*, 40*b*, 42*a*), also with the same energy, for the tungsten oxo complex of tetrakis(phenyldiazenyl)calix[4]arene. The π(HOMO-1) (MOs no. 34; $4a_u$) for azobenzene is located at –12.18 eV according to the EHMO calculations. This MO becomes MOs no. 150–153 (38*b*, 39*e*, 40*a*) in the tungsten oxo complex of the calix[4]arene derivative. These MOs are all π systems. The MO representations of one of the π* systems (designated as LUMO for analogy with the azobenzene molecule), one of the *n* systems (designated as HOMO), and one of the π systems are presented in Fig. 3. These are not described here since they are very similar to that of the well-known azobenzene molecule. Above the LUMO in the tungsten oxo complex of the tetra- and mono(phenyldiazenyl) compounds are localized a

[2] Supplementary information: as a typical example, the MO energies, atomic contributions, occupancies, and MO drawings for six of the frontier MOs for the tungsten oxo complex of the mono(phenyldiazenyl)calix[4]arene are supplied. Fig. 3. EHMO pictures for the LUMO (MO no. 149; 39*b*), the HOMO (MO no. 150; 38*b*), and MOs no. 151 + 152 (39*c*) designated by HOMO-1 for the tungsten oxo complex of the tetrakis (phenyldiazenyl)calix[4]arene.

series of MOs that are a W═O π* system using the W d_{xz}, and the O p_y and p_x atomic orbitals. The atomic contributions are in the order of ~84% W and ~7% O. These contributions are the square of the LCAO coefficients used in the EHMO approximations; these are normalized to 100%. These MOs are localized ~2 eV above the LUMO π* system, and are also of little consequence to this work. For the π*, *n*, and π systems designated by the LUMO, HOMO, and HOMO-1 for all three model compounds, the atomic contributions are very similar from one compound to the other (see Figs. 1 and 3; tables for atomic contributions for the tungsten oxo complex of the mono(phenyldiazenyl) compound are supplied in the Supplementary Information as examples).

To summarize, the EHMO computations predict that the metal oxo complexes of the tetrakis(phenyldiazenyl)-calix[4]arene derivatives should exhibit absorption spectra where the lowest energy bands arise from $n \rightarrow \pi^*$ electronic transitions localized in the azobenzene fragments, followed by higher energy absorptions assignable to $\pi \rightarrow \pi^*$ transitions, also localized primarily within the ligand.

2. Excited state characterization (UV–vis spectra)

Typical absorption spectra and data are shown in Fig. 4 and Table 1, respectively. The spectra are characterized by a strong absorption ($78\,000 < \varepsilon$ (M^{-1} cm^{-1}) $< 108\,000$, toluene at 298 K) in the 370–440 nm region, which exhibits some poorly resolved features attributable to the presence of vibrational progressions. Due to the large intensity, the $n \rightarrow \pi^*$ band assignment is readily ruled out (14). Rather a $\pi \rightarrow \pi^*$ assignment is more appropriate (14). The $n \rightarrow \pi^*$ band was not located at 298K. To insure our assignments, as well as to locate the $n \rightarrow \pi^*$ absorption band, the spectra at 77 K were measured (Fig. 5) and calculated using Heller's time-dependent theory (12). At 77 K, the spectra are somewhat better resolved, and a vibrational progression is readily seen with a spacing of 1500 cm^{-1}, which is consistent with an excited state C═C stretching mode and not an Ṅ═Ṅ mode. Figure 6 compares the experimental spectrum for **1** and the calculated band located at 400 nm (i.e., 25 000 cm^{-1}). In this analysis we define a model using the lowest number of parameters to correctly calculate the experimental spectra, consisting of two-dimen-

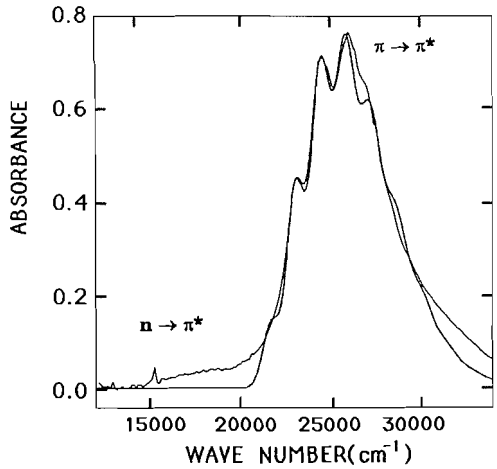
sional harmonic oscillator potential energy surfaces for both the ground and excited electronic states. No satisfactory results were obtained using a single Franck–Condon active mode. In the two-mode model, the vibrational frequencies were fixed at 1510 and 1110 cm^{-1}, for the calculations that are close to the vibrational frequencies observed in the Raman spectrum (peaks observed at 1590 and 1152 or 1107 cm^{-1}).[3] A variation of these frequencies by more than 10% does not affect the agreement between calculated and experimental spectra. The Huang–Rhys parameters, S (15), for both vibrational modes were treated as adjustable parameters in the fitting process, using the 15 000 – 35 000 cm^{-1} region of the absorption spectrum. The agreement between calculated and experimental spectra (Fig. 6) is excellent in view of the simple model with only two adjustable parameters. At the best fit, values of 1.99 and 1.10 were obtained for S along the excited electronic 1510 and 1110 cm^{-1} modes, respectively. If one lowers all S values by 2-3%, the agreement between experiments and calculations is no longer acceptable; an augmentation of 2–3% also leads to unacceptable calculations. These modes are easily assigned to ν(C=C) (1590, and 1152 or 1107 cm^{-1} in the ground state), and the possibility of ν(N=N) as potential assignment is ruled out since this mode is generally found at around 1400 cm^{-1} (16). We conclude that the 400 nm band undoubtedly arises from an intraligand $\pi \rightarrow \pi^*$ type electronic transition. The excited state distortions (ΔQ) are calculated, and are 0.12 and 0.11 Å for the two modes, respectively. These values are of the same order of magnitude as that

[3] The solid state FT-Raman spectrum is provided as supplementary information (see footnote 2).

Fig. 6. Comparison between the experimental (full line) and calculated spectra (full line with dotted line on top using Heller's time-dependent theory) for compound **1**. The $n \rightarrow \pi^*$ band belonging to the N = N groups becomes apparent at ~18 000 cm^{-1} (~550 nm).



reported for the $Ru(bpy)_3^{2+}$ cation (bpy = bipyridine) for which a lowest energy metal-to-ligand charge transfer (MLCT) excited state is assigned (17). In this case, ΔQ averages ~+0.07 Å along the C—C bonds in the bpy ligands (17). Since the MOs associated with this $\pi \rightarrow \pi^*$ electronic transition (HOMO-2 and LUMO) are C—C bonding and anti-bonding, respectively, the ΔQ values calculated must be positive (i.e., C=C bond lengthenings).

The two regions where agreement between the calculated and measured spectra are poor (~20 000 cm^{-1} (~500 nm) and ~33 000 cm^{-1} (~300 nm)) are due to the presence of overlapping electronic bands. With respect to the ~300 nm feature, other $\pi \rightarrow \pi^*$ electronic bands are likely to appear in this region, based upon the EHMO findings. The second region (~20 000 cm^{-1}; ~500 nm) is of more interest since it indicates the presence of a low-intensity electronic transition (~5% of the 400 nm band) that we confidently assign to $n \rightarrow \pi^*$ (N=N). The energy gap between this band and the 400 nm band (~800 – 900 cm^{-1}) measured at ν_{max} is essentially the same as that reported for azobenzene (18). No other absorption band was observed below 15 000 cm^{-1}. No attempt was made to deconvolute these higher and lower energy bands.

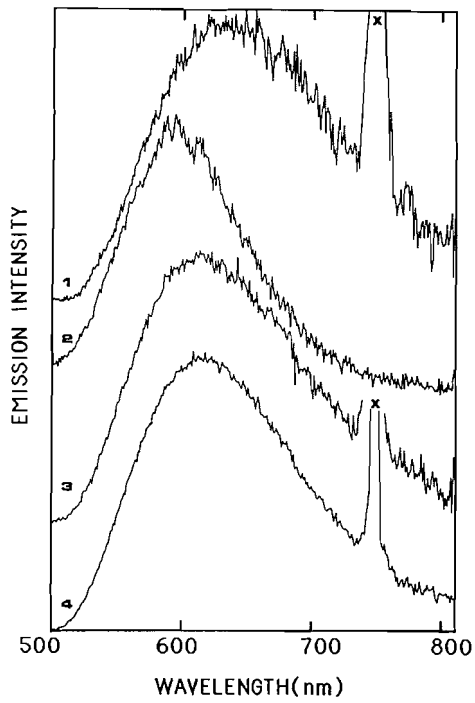
A comparison of **1**, **3**, and **4** (Table 1) shows weak metal dependence on λ_{max} of the absorption (400 nm $\pi \rightarrow \pi^*$) band. On the other hand, the substituent effect observed between compounds **1** and **2** ($OC_{10}H_{21}$ vs. CH_3) on λ_{max} clearly indicates the presence of a greater substituent perturbation on the (azobenzene) chromophore, which reinforces this assignment.

3. Emission properties

The compounds are found to be weakly emissive in the 600–630 nm range at 77 K (Fig. 7. $3 \times 10^{-4} < \phi_e < 3 \times 10^{-3}$), while no luminescence was observed at room temperature either in solution or in the solid state. Although the absence of vibronic structure in the emission spectra would suggest that the luminescence does not arise from a $\pi\pi^*$ state (15), polarized emission photoselection spectroscopy (7) is used for assignment. By knowing that the transition moments for $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ electronic transitions (without a change of spin multiplicity) are polarized parallel and perpendicular to the aromatic plane, respectively, and that these same electronic transitions with a multiplicity change (singlet–triplet) are perpendicular and parallel polarized to the plane, respectively, one can predict the relative polarization of the two electronic bands (14). Since the 400 nm band is securely assigned ($\pi \rightarrow \pi^*$), one can use its in-plane polarization as a reference point. Scheme 2 shows all possible scenarios for the relative polarization of the emission transition moment for both fluorescence and phosphorescence.

The polarization ratio, N, is given by $(I_{BB}/I_{BE})_V \cdot (I_{EE}/I_{EB})_H$, where $(I_{BB}/I_{BE})_V$ is the ratio of the intensities of vertically to horizontally polarized emission when excited with vertically polarized light, and $(I_{EE}/I_{EB})_H$ is the ratio of the intensities of

Fig. 7. Emission spectra for compounds **1–4** in ethanol at 77 K. The intensities have been normalized and baselines have been adjusted vertically for clarity.



Scheme 2.

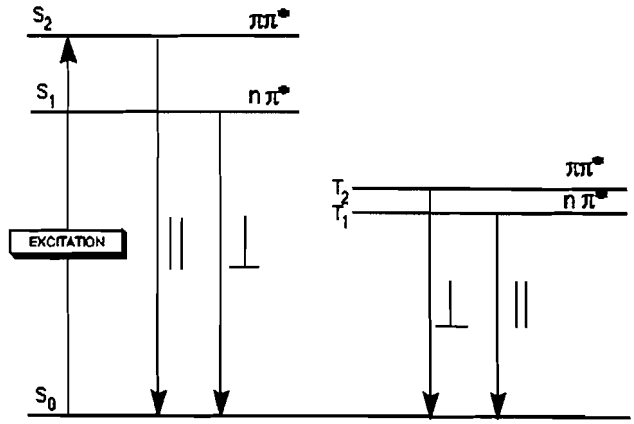


Fig. 8. Polarization ratio for the emission spectra for compound **1** using λ_{exc} = 430 nm (top), for compound **1** using λ_{exc} = 375 nm (middle), and for compound **4** also using λ_{exc} = 375 nm. Solvent was ethanol.

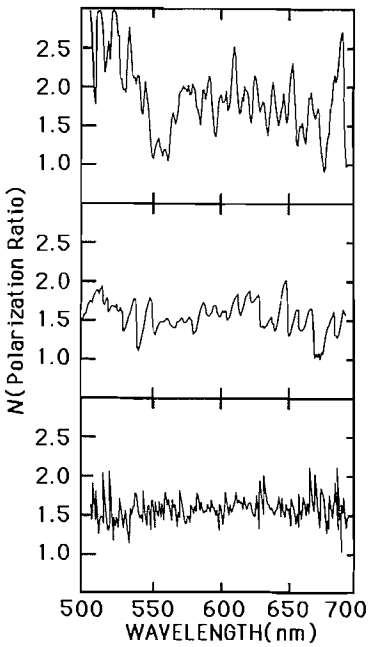

parallel and perpendicular polarized emission with horizontally polarized excitation. N is then related to the relative orientation of the transition moments in absorption and emission. The theoretical value of $N = 3$ indicates that absorption polarized on a single molecular axis is followed by an emission along the same axis. $N = 0.5$ indicates that single axis absorption is followed by emission along a perpendicular axis. In practice, the theoretical values were never obtained due in part to the natural depolarization of the glass. In a situation where N = 1.0, then the emission is depolarized. For this work, it is assumed that absorption is followed by an emission arising from the same azobenzene lumophore group (no energy transfer from one azobenzene center to another in the calix[4]arene), and two different λ_{exc} at 375 and 430 nm were used for comparison purposes. Figure 8 shows N vs. λ for compounds **1** and **4**. Referring to Figs. 5, and 6, the 430 nm absorption region appears to be free from overlap with other absorption bands, and it is reasonable to assume that the polarization of the absorbed light is pure. For compound **1** when λ_{exc} = 430 nm, N varies from ~3 at 500 nm, to ~2 at λ_{max}, to ~1.5 at ~700 nm (Fig. 8), indicating that the emission exhibits a significant component polarized parallel to the absorption ($S_0 \rightarrow S_1$, $\pi \rightarrow \pi^*$). The signal-to-noise ratio is poor because of the lower emission quantum yield. The decrease in N with λ could be indicative of the presence of a non-totally symmetric vibrational mode under the emission band envelope (7). At λ_{exc} = 375 nm, the polarization ratios are now ~1.5, and appear to be constant with λ_{emi}. The 375 nm region (~26 700 cm^{-1}) exhibits a difference between the calculated (full line with dotted line on top) and experimental (full line) absorption spectrum (Fig. 6), which is due to the fact that other absorption bands are not taken into account. Excitation is taking place in two different absorption systems at 375 nm (26 700 cm^{-1}), and mixing of the polarized light will occur (if the transition moments are not parallel).[4] Similar results are also obtained for compound **4** (the free ligand). Hence, the emission is polarized parallel to the absorption, thereby leaving only two possible assignments for the luminescence: $^1\pi\pi^* \rightarrow$ ground state or $^3n\pi^* \rightarrow$ ground state.

The emission spectra of azobenzene ($C_6H_5N{=}N\text{-}C_6H_5$) are known and are described as follows: the first emission is an $S_2 \rightarrow S_0$ fluorescence (high-energy emission) arising from the $^1(\pi\pi^*)$ state with λ_{max} ~425 nm (23 500 cm^{-1}), and τ_F <5 ps; the second emission (low-energy emission) is an $S_1 \rightarrow S_0$ fluorescence arising from the $^1(n\pi^*)$ state with λ_{max} >800 nm (<12 500 cm^{-1}), and $\tau_F \approx$ 25 ps (18). At room temperature the $S_0 \rightarrow S_2$ ($\pi\pi^*$) absorption is localized at ~320 nm (31 300 cm^{-1}) in azobenzene (18). For all compounds investigated, this $\pi\pi^*$ absorption, which fits the one for the azobenzene, is localized at ~380 nm (26 300 cm^{-1}). The difference represents a ~60 nm red shift (i.e., ~5000 cm^{-1}). Such a shift would place the high-energy emission band at ~540 nm (i.e., 23 500 (azobenzene) – 5000 = 18 500cm^{-1}) for the investigated complexes. The emission maxima are observed between 600 (167 00 cm^{-1}) and 630 nm (15 900 cm^{-1}; Table 2)! The emission arising from the $^1(n\pi^*)$ state (if observed) is also expected to red shift with respect to the unsubstituted azobenzene. Similarly a 5000 cm^{-1} red shift of the low energy emission band going from azobenzene to the investigated compounds would place the $^1(n\pi)^* \rightarrow S_0$ fluorescence band in the 7500 cm^{-1} range (or lower), which is well above 900 nm; a range that was not investigated here. The lowest energy triplet state in azobenzene, $^3(n\pi^*)$, is located at 990 nm (i.e., 10 100 cm^{-1}) according to literature (18). Based upon these λ_{max} considerations, the emission bands are assigned to $S_n(^1\pi\pi^*) \rightarrow S_0$ transitions similar to that of the high-energy fluorescence observed in azobenzene. The absence of vibronic structure could be indicative of a change in conformation in the $^1(\pi\pi^*)$ state. Azobenzene is known to undergo photoinduced *cis-trans* isomerization (18*b*).

The photophysical data (Table 2) for **4** indicate very low values for τ_e (emission lifetime) and ϕ_e (emission quantum yield). These low values are also consistent with an $S_n \rightarrow S_0$ fluorescence (14, 18). Here S_n indicates an higher energy $\pi\pi^*$ singlet excited state, bypassing the $n\pi^*$ singlet and triplet states. From then on, this S_n emissive state will be designated as "S_2" by analogy with azobenzene. In comparison with the reported data for azobenzene ($\tau_F < 5$ ps, $\Phi_F < 1 \times 10^{-4}$) (18*b*), the larger values in the study are due to an increase in both medium (77 K glass) and molecular rigidity. It is not possible to comment on the Φ_e, τ_e, k_r (radiative rate constants), and k_{nr} (non-radiative rate constants) data due to the low number of compounds investigated. Heavy-atom effects, "loose bolt effects," molecular rigidity, and host–guest interactions may affect the magnitude of these values. Further investigation is necessary.

4. Guest–host chemistry

Typically one can assign the intraligand bands ($\pi \rightarrow \pi^*$ vs.

[4] Allowed $\pi \rightarrow \pi^*$ electronic transitions can be polarized in-plane with respect to an aromatic molecule, but the relative polarization of these may be different (*x*-polarized vs. *y*-polarized).

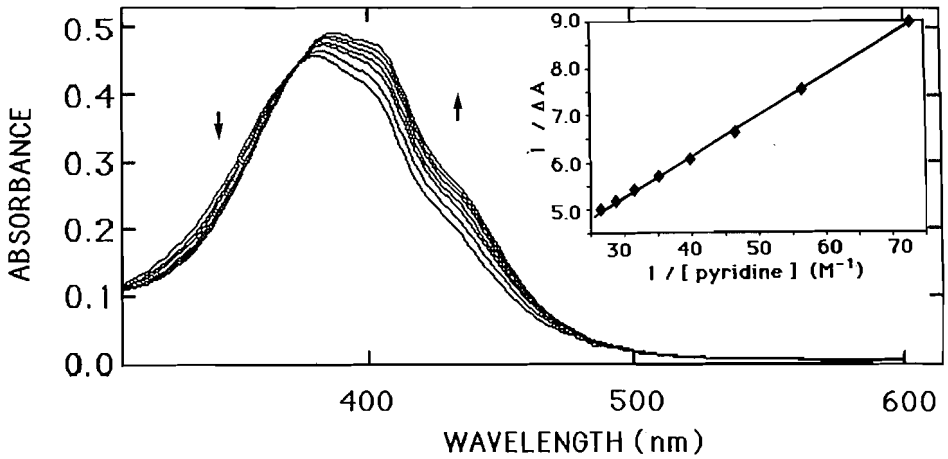
Fig. 9. Typical example of the spectroscopic changes that occur in the absorption spectra for compound **1** when pyridine is added to the toluene solutions. Inset: typical Benesi–Hildebrand plot used for the K_{11} measurements.



$n \rightarrow \pi^*$) on the basis of band shift with of polarity the medium (14, 19). However, this was not possible in this work due to the presence of guest molecules in the cavities of the calix[4]arene moieties. In fact, the measurements of λ_{max} (of the 400 nm band) as a function dielectric constant of the medium lead to a quasi-random relationship. Such behavior is not new to us since similar behavior was also observed previously with the $M_3(dppm)_3CO^{2+}$ clusters (M = Pd, Pt; dppm = $((C_6H_5)_2P)_2CH_2$) (8*a*), where the guest–host chemistry was well established with X-ray crystal structures and UV–vis spectroscopy (20).

The binding constants, K_{11}, were measured for the following ground state associated complexes: compound **1** – pyridine and compound **4** – pyridine using UV–visible spectroscopy, and toluene as solvent. Typical pyridine concentrations used for compound **1** ranged from 0.010 to 0.050 M and, for compound **4**, from 0 to 0.11 M. The K_{11} data were extracted from the Benesi–Hildebrand plots (8*a*,*b*) and confirm that the associated complexes are 1:1 stoichiometric complexes. The data are as follows: compound **1** – pyridine, $K_{11} = 35 \pm 4\ M^{-1}$; compound **4** – pyridine, $K_{11} \leq 1\ M^{-1}$. The host concentration in toluene solutions was kept constant for all measurements (the absorbance was ~0.45–0.50 at λ_{max}). A typical set of spectroscopic changes and plots is presented in Fig. 9. The increase in K_{11} (≥35-fold) on going from compound **4** to compound **1** clearly demonstrates that the $W^{+6}\cdots N$ interactions are present and contribute to the binding. The rigidity could also contribute to the increase in the K_{11} value.

Table 3 compares the 77 K emission lifetimes for compounds **1–4** in various solvents. For comparison purposes, methylcyclohexane was also investigated because of its size, its lack of Lewis basicity, its ability to form glass at 77 K (when dry), and the solubility of the compounds in this solvent. It is reasonable to assume that methylcyclohexane is a very weak binder within the calix[4]arene cavity. From Table 3 a clear trend is observed: τ_e(methylcyclohexane) > τ_e(ethanol) > τ_e(butyronitrile). All decay traces were monoexponential. By adding pyridine (proven above to be acting as guest molecule) up to 20% in volume, the emission lifetimes decrease further regardless of the solvent or the compound. For instance, compound **1** in ethanol exhibits a decrease from 1.56 to 0.81 ns, and compound **3** in butyronitrile presents a change from 1.85 down to 0.71 ns. This observation is consistent with the previously reported data for $Pd_3(dppm)_3CO^{2+}$, which showed that the addition of an interacting substrate within the cavity always resulted in a decrease in excited state lifetimes (20*b*).

The last system investigated is compound **1** quenched from

Table 3. Solvent dependence of the emission lifetimes for compounds **1**–**4**.[a,b]

Compound	τ_e Ethanol	τ_e Butyronitrile	τ_e Methylcyclohexane

the liquid crystal state. Upon heating, the guest DMF molecule escapes the cavity and the host molecule self-assembles in a head-to-tail fashion to form an associated material exhibiting mesomorphic properties (4). Computer modeling (Fig. 10) clearly indicates that W═O···W═O close contacts are not possible in this self-assembly (the WO···WO distance is in the order of 4.35 Å while the C···C contacts are set to 3.55 Å, similar to graphite). The 77 K emission band for this material is red shifted to 650 nm along with the absorption maxima, which is red shifted by 30 nm (at 298 K). The 77 K emission lifetime is 1.98 ± 0.05 ns (compared to 1.56 ns for compound **1** in its monomeric form). This datum suggests that DMF binds more strongly to the host molecule than the host itself. This result is consistent with the fact that the mesomorphic properties vanish when DMF is added to the material (4), and with the fact that the associated structure is mostly based upon hydrophobic interactions with little or no W anchoring contribution.

Concluding remarks

The chromophoric centers in these host molecules are the diazobenzene fragments with practically no, or very little, perturbation of the metal atoms on the MOs. The nature of the lowest excited states is $\pi\pi^* > n\pi^*$, identical to that of diazobenzene. The observed ~615 ± 15 nm weak emissions arise from an upper singlet $\pi\pi^*$ state, not from the lowest energy triplet $n\pi^*$ state. Only the 400–900 nm range was investigated. The emissions arising from the $n\pi^*$ states are expected to be located above 900 nm. Finally, the photophysical data establish that additions of a neutral substrate inside the cavity of the calix[4]arene moieties result invariably in a decrease in τ_e.

Parallel vs. perpendicular alkyne coordination in binuclear complexes. The first examples of reactivity differences in isomers differing in their alkyne coordination modes

Darren S.A. George, Robert McDonald, and Martin Cowie

Abstract: The reaction of $[Ir_2(CO)_3(dppm)_2]$ (dppm = $Ph_2PCH_2PPh_2$) with dimethyl acetylenedicarboxylate (DMAD) first yields $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2]$ (**2**) in which the alkyne is bound parallel to the metal–metal axis and the diphosphines are bound in a *trans* arrangement at both metals. This metastable isomer slowly rearranges to the stable form, $[Ir_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-DMAD})(dppm)_2]$ (**3**), in which the alkyne is now bound perpendicular to the metals and the diphosphines are bent back in a *cis* arrangement at both metals. The analogous species can be prepared by substituting hexafluoro-2-butyne (HFB) for DMAD; however, for the HFB adduct the isomer having the parallel geometry is seen only as a transient species; only $[Ir_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-HFB})(dppm)_2]$ (**5**) was isolated. Compound **2** reacts readily with PMe_3 to yield $[Ir_2(CO)(PMe_3)(\mu\text{-CO})(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2]$, and with $CH_3OSO_2CF_3$ to yield $[Ir_2(CH_3)(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2][SO_3CF_3]$, whereas **3** reacts with neither reagent. Both **2** and **3** react with $HBF_4{\cdot}OEt_2$ to yield the respective alkyne-bridged hydrides, $[Ir_2H(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2][BF_4]$ and $[Ir_2H(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-DMAD})(dppm)_2][BF_4]$, in which the gross structural features and the alkyne coordination mode of the precursor are retained in each case. The latter species rearranges readily at ambient temperature, via migratory insertion, to give the vinyl-bridged product, $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-RC = C(H)R})(dppm)_2][BF_4]$ (R = CO_2Me); however, the former is inert under these conditions, yielding the above vinyl species together with other decomposition products only upon reflux in benzene for several hours. Protonation of the perpendicular hexafluoro-2-butyne adduct also yields the corresponding vinyl product, together with decomposition products. The structure of **3**, as the methylene chloride disolvate, was established by X-ray analysis. Crystal data are as follows. $\mathbf{3}{\cdot}2CH_2Cl_2$: $C_{60}H_{54}Cl_4O_6P_4Ir_2$, monoclinic, $P2/c$, a = 26.088(5) Å, b = 9.896(4) Å, c = 23.954(3) Å, β = 109.27(1)°, Z = 4, $R(F)$ = 0.038, $R_w(F^2)$ = 0.0997 (all data).

Key words: diiridium alkyne complexes, parallel and perpendicular alkyne coordination.

Résumé : La réaction du $[Ir_2(CO)_3(dppm)_2]$ (dppm = $Ph_2PCH_2PPh_2$) avec l'acétylènedicarboxylate de diméthyle (ADDM) donne en premier lieu le $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-ADDM})(dppm)_2]$ (**2**) dans lequel l'alcyne est lié parallèlement à l'axe métal–métal et les diphosphines sont liés selon un arrangement *trans* par rapport aux deux atomes métalliques. Cet isomère métastable se transpose lentement pour donner l'isomère stable $[Ir_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-ADDM})(dppm)_2]$ (**3**), dans lequel l'alcyne se retrouve lié perpendiculairement aux deux atomes métalliques et les diphosphines sont ramenés à un arrangement *cis* au niveau des deux atomes métalliques. On peut préparer les espèces analogues en remplaçant l'ADDM par l'hexafluoro-2-butyne (HFB), cependant dans l'adduit HFB, l'isomère ayant la géométrie parallèle semble uniquement une espèce transitoire; on a seulement isolé le $[Ir_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-HFB})(dppm)_2]$ (**5**). Le composé **2** réagit facilement avec PMe_3 pour donner $[Ir_2(CO)(PMe_3)(\mu\text{-CO})(\mu\text{-}\eta^1\text{:}\eta^1\text{-ADDM})(dppm)_2]$, et avec $CH_3OSO_2CF_3$ pour donner $[Ir_2(CH_3)(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-ADDM})(dppm)_2][SO_3CF_3]$, tandis que le composé **3** ne réagit pas avec aucun de ces réactifs. Les composés **2** et **3** reagissent avec le $HBF_4{\cdot}OEt_2$ pour conduire respectivement aux hydrures avec le groupe alcyne en position de pont : $[Ir_2H(CO)_2(\mu\text{-}\mu^1\text{:}\eta^1\text{-ADDM})(dppm)_2][BF_4]$ et $[Ir_2H(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-ADDM})(dppm)_2][BF_4]$, dans lesquels les caractéristiques structurales principales et le mode de coordination de l'alcyne du précurseur sont retenus dans chacun des case. La dernière espèce se transpose facilement à la température ambiante, via une insertion migratoire, pour donner le produit avec un groupe vinyle en position de pont $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-RC=C(H)R})(dppm)_2][BF_4]$ (R = CO_2Me); toutefois le premier composé est inerte dans ces conditions et donne l'espèce vinylique ci-dessus ainsi que d'autres produits de décomposition uniquement au reflux du benzène pendant plusieurs heures. La protonation de l'adduit hexafluoro-2-butyne perpendiculaire donne également le produit vinylique

Received June 3, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

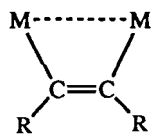
correspondant ainsi que des produits de décomposition. On a établi la structure du composé **3** comme produit de solvatation double du chlorure de méthylène. Les données cristallines sont les suivantes : **3**·2CH_2Cl_2 : $C_{60}H_{54}Cl_4O_6P_4Ir_2$, monoclinique, groupe d'espace *P2/c*, a = 26,088(5) Å, b = 9,896(4) Å, c = 23,954(3) Å, β = 109,27(1)°, Z = 4, $R(F)$ = 0,038, $R_w(F^2)$ = 0,0997 (tous les données).

Mots clés : complexes de diiridium alcyne, coordination parallèle et perpendiculaire de l'alcyne.

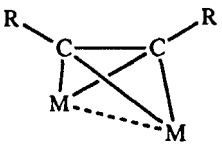
[Traduit par la rédaction]

Introduction

The ability of transition-metal complexes to facilitate important transformations of unsaturated substrates has provoked much interest in complexes containing coordinated alkynes (1–4). In such complexes, coordination to a metal centre serves to activate the alkyne group, so it follows that reactivity should depend on the nature of the alkyne binding. In binuclear complexes, which constitute the simplest systems in which more than one metal can be involved, three simple bonding modes can be distinguished. In the first, the alkyne can coordinate terminally to one metal, in which case the bonding is readily described in terms of the Dewar–Chatt–Duncanson model, originally proposed for olefin binding (5). Introduction of the second metal also introduces two alkyne bridging modes, in which the alkyne is oriented either parallel to (μ-η^1:η^1-coordination), or perpendicular to (μ-η^2:η^2-coordination), the metal–metal axis. These are sometimes referred to as dimetallacyclobutene and dimetallatetrahedrane structures, respectively, when there is an accompanying metal–metal bond, or *cis* dimetallated olefins and dimetallabicyclobutanes, respectively, when there is no metal–metal bond. As was pointed out by Hoffmann et al. (6), the preference for one orientation over the other is a function of the electronic requirements of the metals. The parallel-bound alkyne can be



μ-η^1:η^1



μ-η^2:η^2

considered as a *neutral* two-electron donor (or alternatively as a *dianionic* four-electron donor), while in the perpendicular orientation it is normally viewed as a *neutral* four-electron donor, and the preference for one or the other will often depend on the number of electrons needed by the metals to achieve a favourable electron count. In addition, the bridging alkyne can modulate its donor ability by changing binding modes upon gain or loss of ancillary ligands, in order to satisfy the electron demands of the metals (7).

Reactions of alkynes with diphosphine-bridged, homo- and heterobinuclear complexes of rhodium and iridium have been of long-standing interest to this research group (8), with a view towards developing an understanding of how the alkyne coordination mode influences its subsequent reactivity. In the majority of diphosphine-bridged complexes characterized, the alkyne has been found to coordinate in the parallel orientation, although the dirhodium complexes, $[Rh_2(CO)_2(\mu\text{-}RC{\equiv}CPh)(dppm)_2]$(dppm = $Ph_2PCH_2PPh_2$, R = H, Ph) (9), are notable exceptions, resembling a number of dicobalt analogs (10) in having a perpendicular alkyne binding mode. This bonding for the dirhodium species is even more surprising when comparison is made to the isoelectronic Pd and Pt complexes $[MM'Cl_2(\mu\text{-}CF_3C_2CF_3)(dppm)_2]$ (MM' = Pd_2 (11), PtPd (12), Pt_2 (13)), which have a parallel binding mode for the alkyne. A metastable isomer of $[Rh_2(CO)_2(\mu\text{-}HC{\equiv}CPh)(dppm)_2]$, which was proposed to have a parallel-bound alkyne, was prepared from $[Rh_2(CO)_2(\mu\text{-}H)_2(dppm)_2]$ (9); however, it rearranged readily to the more stable isomer having a perpendicular alkyne.

We undertook a related study, attempting to prepare the diiridium alkyne complexes, $[Ir_2(CO)_2(\mu\text{-}RC_2R)(dppm)_2]$ (R = CO_2Me, CF_3). In these target complexes a perpendicular alkyne binding mode would result in an Ir(0) oxidation state assignment for both metals, whereas the parallel geometry could be viewed as giving rise to an Ir(+1) formulation. It was felt that by using an alkyne such as dimethyl acetylenedicarboxylate (DMAD) or hexafluoro-2-butyne (HFB), having strongly electron-withdrawing substituents, the dianionic formulation of the ligand and the corresponding Ir(+1) oxidation state might be favoured. In this context, it had previously been noted in the Pd_2 complexes, that the parallel alkyne geometry had only been obtained with alkynes having electronegative substituents (11*b*). In addition, it was reasoned that the use of a third-row metal should favour the higher oxidation state, and the lower lability of Ir compared to Rh may assist in deterring any rearrangement from a parallel to a perpendicular alkyne coordination, as occurred in the dirhodium system. It was also of interest to establish whether the different alkyne binding modes would give rise to reactivity differences. Surprisingly, no study has yet addressed this relationship between reactivity and the two different bridging modes.

Experimental section

All solvents, including deuterated solvents used for NMR experiments, were dried, degassed, and distilled before use and were stored under N_2. Reactions were carried out using standard Schlenk procedures. Dinitrogen was passed through columns of Ridox and 4A molecular sieves to remove traces of oxygen and water, respectively. Carbon monoxide (Matheson) was used as received. Hydrated iridium(III) chloride was purchased from Engelhard Scientific, ammonium hexachloroiridate (IV) was obtained from Victoria Precious Metals, and bis(diphenylphosphino)methane (dppm) was purchased from Organometallics Inc. Dimethyl acetylenedicarboxylate (DMAD) was obtained from Aldrich and stored under N_2 over molecular sieves in the dark. The complex $[Ir_2(CO)_3(dppm)_2]$ (**1**) was prepared as previously reported (14). All other chemicals were used as received without further purification.

NMR spectra were recorded on a Bruker AM-400 spec-

trometer operating at 400 MHz for ^1H and $^1H\{^{31}P\}$ spectra and at 161.9 MHz for $^{31}P\{^1H\}$ spectra; $^{13}C\{^1H\}$ spectra were obtained on Bruker WH-200 and AM-400 instruments operating at 50.32 and 100.61 MHz, respectively. In these cases an internal deuterated solvent lock was employed. Phosphorus chemical shifts are reported with respect to external 85% H_3PO_4, while carbon and proton shifts are with respect to TMS with the solvent as internal standard. Infrared spectra were run on a Nicolet 7199 Fourier transform interferometer, as either solids (Nujol mulls on KBr disks) or solutions (KCl cell windows, 0.5 mm path length). A Perkin–Elmer 883 infrared spectrophotometer was also employed to monitor the progress of some reactions. Elemental analyses were performed by the microanalytical service within the department.

(a) Preparation of $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2]$ (2)

To a solution of **1** (35 mg, 28.3 μmol) in 4 mL of THF or benzene was added DMAD (3.6 μL, 29.3 μmol), followed by gentle warming of the solution in a water bath at 40–45°C, resulting in a colour change from orange to intense blue (about 3 min). The solution volume was then reduced to 1 mL by evaporation under a stream of nitrogen. Pentane (10 mL) was added, giving a blue microcrystalline precipitate (purple from benzene), which was washed twice with 10 mL aliquots of pentane and dried, first under nitrogen, then under vacuum. Due to the high air-sensitivity of this compound, an elemental analysis was not obtained. IR (THF solution): 1934 (s, Ir-CO), 1701 (s, ester CO) cm^{-1}. NMR (THF, 22°C), δ: $^{31}P\{^1H\}$: 5.28 (singlet); ^1H: 8.2–6.3 (multiplet, 40H, C_6H_5), 4.36 and 3.42 (multiplets, each 2H, CH_2), 2.70 (singlet, 6H, CH_3); $^{13}C\{^1H\}$: 191.0 (singlet, Ir-*C*O).

(b) Preparation of $[Ir_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-DMAD})(dppm)_2]$ (3)

To a solution of **1** (100 mg, 80.8 μmol) in toluene (10 mL) was added one equivalent of DMAD (9.9 μL, 11.5 mg, 80.8 μmol). An immediate darkening of the orange reaction mixture occurred, with a change to dark green within 5 min. The solution was then refluxed for 10 min, during which time the colour changed to dark blue then to lighter green. Upon slow cooling of the mixture to room temperature the green colour faded to light yellow, accompanied by formation of a pale yellow microcrystalline solid. Ether (20 mL) was added to complete precipitation, and the yellow solid obtained was recrystallized from CH_2Cl_2–Et_2O. The pale yellow powder was dried under an N_2 stream, then under vacuum, yielding 69 mg (64% isolated yield) of product. IR (Nujol mull): 1938 (vs, Ir-*CO*), 1682 (s, ester *CO*) cm^{-1}; (CH_2Cl_2 solution): 1943 (vs), 1690 (s) cm^{-1}. NMR (CD_2Cl_2, 22°C), δ: $^{31}P\{^1H\}$: –12.6 (singlet); ^1H: 7.45–6.87 (multiplet, 40H, C_6H_5), 5.70, 3.39 (multiplets, each 2H, CH_2), 3.61 (singlet, 6H, CH_3); $^{13}C\{^1H\}$: 173.8 (singlet, Ir-*CO*). Anal. calcd. for $C_{58}H_{50}Ir_2O_6P_4$: C 51.55, H 3.73, found: C 51.78, H 3.94.

(c) Preparation of $[Ir_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-HFB})(dppm)_2]$ (5)

A 50-mL flask was charged with 100 mg of **1** (80.8 μmol) and 30 mL of CH_2Cl_2. Hexafluoro-2-butyne was passed over the solution for a few minutes, and the solution was stirred for 4 days, over which time the solution slowly changed from orange to green to brown to orange. The solvent was removed under vacuum, and the residue recrystallized from 4 mL of benzene and 12 mL of pentane. The yellow precipitate was then washed twice with 10 mL of ether. Yield: 43 mg (39%). IR (Nujol mull): 1947 (Ir-CO) cm^{-1}; (CH_2Cl_2 solution): 1950 (Ir-CO) cm^{-1}. NMR (CD_2Cl_2, 22°C), δ: $^{31}P\{^1H\}$: –13.1 (m); ^1H: 8.0–6.9 (m, 40H, C_6H_5), 5.35 and 3.70 (m, each 2H, CH_2); ^{19}F: –48.56 (m).

(d) Reaction of 1 with HFB

An NMR tube was charged with **1** (21.2 mg, 17.1 μmol) and 0.5 mL of CD_2Cl_2 and was capped with a rubber septum. Hexafluoro-2-butyne (420 μL, 17.0 μmol) was added via gas-tight syringe, and the tube was sealed with Parafilm and shaken. After 45 min, the orange solution had acquired a slight green cast; however, the $^{31}P\{^1H\}$ NMR spectrum showed only starting material. After 1 day, the solution, which had been stored under nitrogen, had become a much darker green colour, and the NMR showed, in addition to starting material, a small amount of compound **5**, along with larger quantities of the known compound $[Ir_2(CO)_4(dppm)_2]$ (14) and a new compound **4** ($^{31}P\{^1H\}$: δ: 1.31 (s). $^{13}C\{^1H\}$: 190.2 (t, J_{CP} = 5.4 Hz, Ir-CO). ^1H: 3.55 and 3.85 (m, 2H each, CH_2)). After 5 days, this species had disappeared, leaving only **5** and the tetracarbonyl species, in a 1:1 ratio.

(e) Preparation of $[Ir_2(CO)(PMe_3)(\mu\text{-}CO)(\mu\text{-}DMAD)(dppm)_2]$ (6)

To an NMR tube charged with **2** (prepared from 53 mg (42.8 μmol) of **1**) in 0.5 mL of CD_2Cl_2 was added trimethylphosphine (4.5 μL, 43.5 μmol), causing a slow colour change from intense blue to a dark olive green, then to brown. This product was only characterized in solution owing to its high solubility and facile loss of trimethylphosphine. IR (CH_2Cl_2 solution): 1967 (s, Ir-CO), 1701 (s, Ir-CO, ester CO) cm^{-1}; IR (Nujol mull): 1964 (s, Ir-CO), 1702, 1677 (broad, s, μ-CO, ester CO) cm^{-1}. NMR (CD_2Cl_2, 22°C); δ: $^{31}P\{^1H\}$: –3.57 (dddd; J_{AB} = 109.6 Hz, J_{AC} = 64.5 Hz, J_{AD} = 14.6 Hz, J_{AE} = 27.1 Hz), –23.66 (dddd; J_{AB} = 109.6 Hz, J_{BC} = 7.9 Hz, J_{BD} = 52.5 Hz, J_{BE} = 4.54 Hz), –49.44 (dddd; J_{AC} = 64.5 Hz, J_{BC} = 7.9 Hz, J_{CD} = 82.2 Hz, J_{CE} = 24.2 Hz), –51.9 (dddd; J_{AD} = 14.6 Hz, J_{BD} = 52.5 Hz, J_{CD} = 82.2 Hz, J_{DE} = 3.15 Hz), –62.37 (m, PMe_3); ^1H: 8.2–6.3 (m, 40H, C_6H_5), 5.25, 4.55, 3.97, and 3.42 (m, each 1H, CH_2), 2.75 and 2.67 (s, each 3H, CO_2CH_3), 1.70 (d, 9H, $P(CH_3)_3$); $^{13}C\{^1H\}$: 182.8 (m, Ir-*C*O), 230.3 (t of m; J_{CP} = 63 Hz, μ-CO).

(f) Attempted reaction of 3 with PMe_3

An NMR tube was charged with 18 mg (13.3 μmol) of **3** and 0.5 mL of CD_2Cl_2. Trimethylphosphine (9.1 μL, 66.3 μmol) was added, resulting in no apparent reaction as seen by the lack of change in the $^{31}P\{^1H\}$ NMR spectrum over a 24 h period.

(g) Reaction of 2 with $CH_3O_3SCF_3$

To a solution of **2** (prepared from 30 mg (24.2 μmol) of **1**) in 4 mL of CH_2Cl_2 was added methyl triflate (2.8 μL, 24.7 μmol) at –80°C. The solution was stirred for 1 h, during which time the solution slowly turned a reddish orange. This was warmed to room temperature, and the solution volume reduced to 1 mL by evaporation under a rapid stream of nitrogen. The brown precipitate obtained by addition of ether (10 mL) was washed twice with ether and dried under nitrogen and under vacuum. The NMR spectrum of this sample showed it to be chiefly

$[Ir_2(CH_3)(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2][SO_3CF_3]$ (**7**), which has been previously characterized (15). IR (CH_2Cl_2 solution): 2009 (s), 1980 (s, Ir-CO), 1702, 1683 (broad, ester CO) cm^{-1}. NMR (CD_2Cl_2, 22°C) δ: $^{31}P\{^1H\}$: 7.69 (m), –9.34 (m); ^1H: 7.7–7.0 (m, 40H, C_6H_5), 4.30 and 3.45 (m, each 2H, CH_2), 3.00 and 2.25 (s, each 3H, CH_3), 0.60 (t, 3H, $IrCH_3$); $^{13}C\{^1H\}$: 193.6 (t, J_{CP} = 9.16 Hz, Ir-*C*O), 182.4 (t, J_{CP} = 7.9 Hz, Ir-*C*O).

(h) Attempted reaction of 3 with $CH_3O_3SCF_3$

An NMR tube was charged with **3** (20.4 mg, 15.1 μmol) and 0.5 mL of CD_2Cl_2. Methyl triflate (1.8 μL, 15.9 μmol) was added, and the mixture allowed to stand for several hours. Phosphorus-31 NMR showed only slight (≤10%) reaction to form **11**, probably due to adventitious water.

(i) Preparation of $[Ir_2(H)(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2][BF_4]$ (8)

A sample of compound **2** (synthesized as above, from 35 mg **1** and 3.6 μL of DMAD) was dissolved in 4 mL of CH_2Cl_2 and cooled to –80°C. Addition of tetrafluoroboric acid – diethyl ether complex (4.1 μL, 29.9 μmol) caused a colour change from intense blue to dark brown. This mixture was allowed to warm to room temperature, and the solvent was removed by evaporation under a stream of nitrogen, giving an orange solid that was recrystallized from dichloromethane and ether (v/v 1:10), and washed twice with ether. Yield: 33 mg (81%). IR (Nujol mull): 2022 (vs), 1991 (s, Ir-CO), 1702 (s, ester CO) cm^{-1}. NMR (CD_2Cl_2, 22°C) δ: $^{31}P\{^1H\}$: 11.84 (m), –5.90 (m); $^{13}C\{^1H\}$: 193.3 (t, $^2J_{CP}$ = 8.95 Hz), 181.5 (broad, Ir-*C*O): ^1H: 8.0–6.9 (m, 40H, C_6H_5), 2.41 and 2.34 (s each 3H, CH_3), –21.54 (t, $^2J_{HP}$ = 12.2 Hz, 1H).

(j) Preparation of $[Ir_2(CO)_3(H)(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2][BF_4]$ (9)

Carbon monoxide was passed over 5 mL of a CH_2Cl_2 solution of **8** (40 mg, 27.7 μmol), resulting in a colour change from orange to yellow. The solution was evaporated to 1 mL under a steady flow of nitrogen, and the product was precipitated by the addition of 15 mL of ether. IR (CH_2Cl_2 solution): 2051 (m), 2024 (s), 1984 (m, Ir-CO), 1706, 1690 (broad, ester CO) cm^{-1}; (Nujol mull); 2019 (broad, Ir-CO), 1695 (broad, ester CO) cm^{-1}. NMR (CD_2Cl_2, 22°C), δ: $^{31}P\{^1H\}$: –11.58 (m), –26.77 (m); ^1H: 8.0–6.9 (multiplet, 40H, C_6H_5), 4.40 and 4.55 (multiplets, each 2H, CH_2), 2.45 and 2.80 (singlets, each 3H, CH_3), –12.04 (triplet, $^2J_{HP}$ = 26.9 Hz, 1H).

(k) Low-temperature protonation of 2

An NMR tube was charged with a solution of **2** (prepared from 21 mg (17.0 μmol) of **1** and 2.1 μL of DMAD) in 0.5 mL of CD_2Cl_2 and cooled to –80°C. Triflic acid (1.5 μL, 17.0 μmol) was added, causing a colour change from blue to orange. By $^{31}P\{^1H\}$ NMR, this solution was shown to contain almost pure **8** at –80°C, with no intermediates detectable.

(l) Preparation of $[Ir_2(H)(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-DMAD})(dppm)_2][BF_4]$ (10)

To a solution of **3** (32 mg, 23.7 μmol) in 2 mL of CH_2Cl_2 (cooled to –10°C by a salt–ice bath) was added one equivalent of $HBF_4{\cdot}OEt_2$ (3.2 μL, 23.3 μmol). The solution changed colour from pale yellow to bright yellow immediately, and then turned golden brown over the course of about 5 min. This solution was stirred for 15 min, and the product precipitated by the addition of 20 mL of pentane. The supernatant was removed, and the brown precipitate was washed twice with pentane, then dried first under a flow of nitrogen, and then under vacuum. NMR (CH_2Cl_2, 22°C), δ: $^{31}P\{^1H\}$: 20.24 (m), 2.44 (m); $^{13}C\{^1H\}$: 174.9 (broad, Ir-*C*O), 167.2 (t, $^2J_{CP}$ = 8.8 Hz, Ir-*C*O); ^1H: 8.0–6.9 (m, 40H, C_6H_5), 4.18 and 3.45 (m, each 2H, CH_2), 3.45 and 2.75 (s, each 3*H*, CH_3), –21.20 (t, 1H).

(m) Preparation of $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}CH_3O_2CC{=}C(H)CO_2CH_3)(dppm)_2][BF_4]$ (11)

To a solution of **3** (50 mg, 37.0 μmol) in 15 mL of CH_2Cl_2 was added one equivalent of $HBF_4{\cdot}OEt_2$ (5.6 μL, 40.8 μmol). The solution changed colour from pale yellow to a clear golden brown, then quickly changed to clear bright yellow, and was stirred for half an hour. The solvent was reduced to about 1 mL by evaporation under a steady stream of nitrogen, and the compound precipitated by the addition of 15 mL of ether. The supernatant was removed, and the yellow precipitate was washed twice with ether. Yield 33 mg (62%). IR (Nujol mull): 1984, 1961 (vs, Ir-CO), 1656 (s, ester CO) 1552 (s, C=C stretch) cm^{-1}; (CH_2Cl_2 solution): 2004, 1978 (s, Ir-CO), 1710, 1688 (m, ester CO) 1550 (m, C=C) cm^{-1}. NMR (CD_2Cl_2, 20°C), δ: $^{31}P\{^1H\}$: –8.45 (apparent triplet, $J_{AB} = J_{AC}$ = 44.5 Hz), –9.68 (ddd, J_{AB} = 44.5 Hz, J_{BC} = 3.5 Hz, J_{BD} = 9.2 Hz), –18.96 (ddd, J_{BC} = 3.5 Hz, J_{AC} = 44.5 Hz, J_{CD} = 58 Hz), –24.53 (dd, J_{CD} = 58 Hz, J_{BD} = 9.2 Hz); ^1H: 7.7–6.8 (m, 40H, C_6H_5), 6.47, 5.39, 4.36 and 4.04 (m, each 1H, CH_2), 4.62 (m, vinyl), 3.18 and 2.42 (s, each 3H, CH_3); $^{13}C\{^1H\}$: 176.00, 175.39 (m, Ir-*C*O, J_{CC} = 9.41 Hz), 194.45, 175.21 (m, ester *C*O); Anal. calcd. for $C_{58}H_{55}O_8BF_4Ir_2P_4$: C 48.27, H 3.84, found: C 47.77, H 3.54.

(n) Low-temperature protonation of 3

An NMR tube was charged with **3** (17.1 mg, 12.7 μmol) and 0.5 mL of CD_2Cl_2 and cooled to –80°C. Triflic acid (1.1 μL, 12.4 μmol) was added, causing a colour change from pale yellow to bright yellow. The NMR of this yellow solution showed the presence of one symmetrical species (–70°C), δ: $^{31}P\{^1H\}$: –14.41 (s). $^{13}C\{^1H\}$: 170.33 (s). ^1H: 20.0 (s, 1H), 6.61 and 3.93 (broad, 2H each, CH_2), 3.38 (broad, 6H, CH_3)). Allowing this to warm up to –20°C caused it to convert to compound **10**, which, in turn, converted to compound **11**.

(o) Attempted protonation of 5

To an NMR tube containing 10.0 mg (7.3 μmol) of **5** dissolved in 0.5 mL of CD_2Cl_2 was added 1.0 μL (7.3 μmol) of $HBF_4{\cdot}OEt_2$. The $^{31}P\{^1H\}$ NMR spectrum showed the appearance of four resonances reminiscent of **11** after several hours. However, upon further standing a number of unidentified decomposition products began to appear. Based on the $^{31}P\{^1H\}$ and ^1H NMR spectra of the initial product, this species was shown to be the analogue of **11**, namely, $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}CF_3C{=}C(H)CF_3)(dppm)_2][BF_4]$. Owing to its instability this product was not characterized further. NMR (CD_2Cl_2, 20°C), δ: $^{31}P\{^1H\}$: –8.67 (apparent triplet, $J_{AB} = J_{AC}$ = 44.9 Hz), –9.46 (ddd, J_{AB} = 46.2 Hz, J_{BC} = 3.4 Hz, J_{BD} = 13.5 Hz), –16.25 (doublet of unresolved multiplets,

[b]Programs for diffractometer operation and data collection were those supplied by Enraf–Nonius.

[c]G.M. Sheldrick. SHELXL-93. Program for crystal structure determination. University of Göttingen, Germany, 1993. Refinement on F_o^2 for all reflections except for 15 having $F_o^2 < -3\sigma(F_o^2)$. Weighted *R*-factors wR_2 and all goodness of fit *S* are based on F_o^2; conventional *R*-factors R_1 are based on F_o, with F_o set to zero for negative F_o^2. The observed criterion of $F_o^2 > 2\sigma(F_o^2)$ is used only for calculating R_1, and is not relevant to the choice of reflections for refinement. *R*-factors based on F_o^2 are statistically about twice as large as those based on F_o, and *R*-factors based on ALL data will be even larger.

[d] Reference 16.

[e]$S = [\Sigma w(F_o^2 - F_c^2)^2/(n-p)]^{1/2}$ (n = number of data; p = number of parameters varied; $w = [\sigma^2(F_o^2) + (0.0376P)^2 + 20.0739P]^{-1}$ where $P = [\mathrm{Max}(F_o^2,0) + 2F_c^2]/3$).

[f]$R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^4)]^{1/2}$.

J = 52.4 Hz), –22.59 (broad unresolved multiplets); ^{1}H: 7.7–6.8 (m, 40H, C_6H_5), 5.85, 5.33, 4.38, and 3.80 (m, each 1H, CH_2), 4.65 (m, vinyl).

X-ray data collection

Diffusion of ether into a concentrated CH_2Cl_2 solution of complex **3** produced yellow prismatic crystals, several of which were mounted and flame-sealed in glass capillaries under N_2 and solvent vapor to minimize decomposition and (or) solvent loss. Data were collected on an Enraf–Nonius CAD4 diffractometer using Mo Kα radiation. Unit-cell parameters at 22°C were obtained from a least-squares refinement of the setting angles of 24 reflections in the range 19.9° ≤ 2θ ≤ 22.9°. The monoclinic diffraction symmetry and the systematic absences ($h0l$ $l \ne 2n$) were consistent with the space groups *Pc* or *P2/c* (the latter was confirmed as the correct space group by the successful solution and refinement of the structure).

Intensity data were collected as outlined in Table 1. Three

Anisotropically-refined atoms are marked with an asterisk (*). The form of the anisotropic displacement parameter is: $\exp[-2\pi^2(h^2a^{*2}U_{11} + k^2b^{*2}U_{22} + l^2c^{*2}U_{33} + 2klb^*c^*U_{23} + 2hla^*c^*U_{13} + 2hka^*b^*U_{12})]$.

reflections were chosen as intensity standards, being remeasured after 120 min of X-ray exposure time. Although one of these standards lost 10% of its original intensity, the other two remained constant; recentering the crystal did not lead to a significant change in intensities. Since this intensity loss was not uniform a decomposition correction was not applied to the data. Absorption corrections were applied to the data according to the method of Walker and Stuart (16).

Structure solution and refinement

The structure of **3** was solved in the space group *P*2/*c* using standard Patterson and Fourier techniques. The unit cell was found to contain two independent molecules of **3**, each located on a crystallographic twofold axis (vide infra). The structure was refined on F^2 using full-matrix least-squares methods.[2] Positional parameters for the hydrogens attached to the carbon atoms of the complex and solvent molecules were calculated from the geometries about the attached carbon. These hydrogens were given thermal parameters 20% greater than the equivalent isotropic *B*'s of their attached atoms, and included as fixed contributions.

The final model for complex **3**, with 685 parameters varied, converged to a value of $R = 0.038$. The positional and thermal parameters for the non-hydrogen core atoms are given in Table 2, and selected bond lengths and angles are given in Tables 3 and 4, respectively.[3]

[2] Programs used were those of SHELXL-93 by G.M. Sheldrick, University of Göttingen, Germany, 1993.

[3] Tables of atomic coordinates for all atoms, a complete listing of bond lengths and angles, anisotropic thermal parameters, derived positions for the hydrogen atoms, and ORTEP diagrams of molecule 2 of complex **3** are available as supplementary material and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Bond lengths and angles and hydrogen positions have also been deposited at the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, United Kingdom. Structure factors are no longer being deposited and can be obtained on request from the author.

Table 3. Selected interatomic distances (Å).

		Distance	
Atom 1	Atom 2	Molecule 1	Molecule 2
Ir(1)	Ir(1′)	2.6695(7)	2.6612(7)

C(2)	C(3)	1.476(11)	1.447(11)

Primed are related to unprimed atoms via the crystallographic twofold axis at (0, *y*, –¼) in molecule 1 and at (½, *y*, ¼) in molecule 2.

Along with two dichloromethane molecules of crystallization, the asymmetric unit in the structure of complex **3** contains half of each of two crystallographically independent molecules; the molecules are essentially mirror images of each other. Molecule **1** is generated by rotation of the unique moiety containing Ir(1) about the twofold axis at 0, *y*, –¼, while rotation of the corresponding unit containing Ir(2) about the twofold axis at ½, *y*, ¼ generates molecule **2**. The tables of bond lengths and angles list parameters for both independent molecules side-by-side; it can be seen that there are no significance differences between the geometries of the two.

Results and compound characterization

The addition of one equivalent of dimethyl acetylenedicarboxylate (DMAD) to a solution of $[Ir_2(CO)_3(dppm)_2]$ (**1**) in toluene produces an initially deep blue-green solution containing

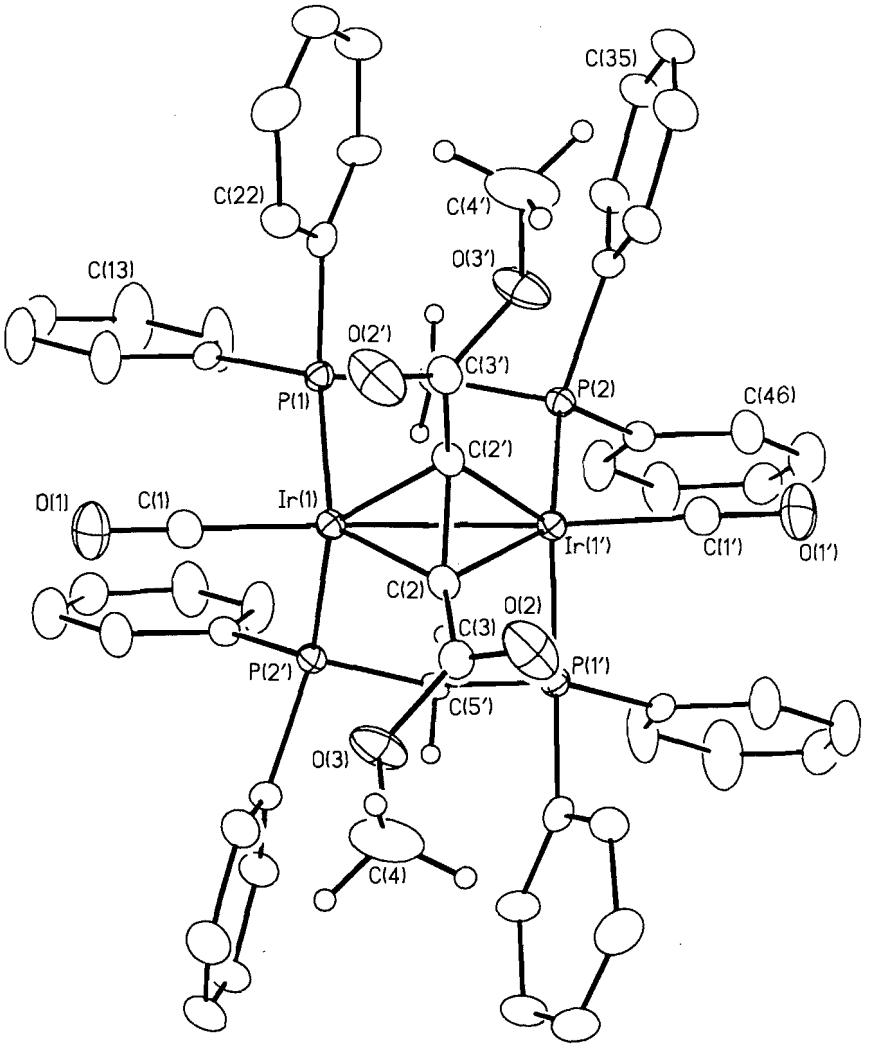
Primed are related to unprimed atoms via the crystallographic twofold axis at (0, *y*, –¼) in molecule 1 and at (½, *y*, ¼) in molecule 2.

$[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-DMAD})(dppm)_2]$ (**2**), which has been assigned the structure shown above. The $^{31}P\{^1H\}$ NMR spectrum of this species shows a singlet at δ 5.28, indicative of only one chemical environment for the phosphorus nuclei, and the ^1H NMR spectrum shows signals for two different types of methylene protons (multiplets at δ 4.36 and 3.42) and a singlet at δ 2.70 for the methyl protons of the alkyne ligand, in a 2:2:6 ratio of intensities, implying front–back asymmetry in the complex and a symmetrical orientation of the alkyne. The $^{13}C\{^1H\}$ NMR spectrum of species **2** (prepared by the addition of DMAD to ^{13}CO-enriched compound **1**) shows a singlet at δ 191.0, with no resolved coupling to the phosphorus atoms bound to iridium ($^2J_{P-C} < 2$ Hz). No additional resonances are observed, confirming that **2** contains only a pair of equivalent CO groups. The carbonyl stretch, at 1934 cm^{-1}, is consistent with the geometry shown; unfortunately, a C≡C stretch due to the coordinated acetylenic moiety (which would usually be observed in the region 1550–1650 cm^{-1}) could not be identified. Although these data alone do not distinguish between a formulation for the complex in which the alkyne is coordinated as a *cis*-dimetallated olefin or one containing a dimetallatetrahedrane unit, crystallographic characterization of complex **3**, which is subsequently formed from **2** (vide infra), confirms the latter geometry for **3**, implying a different geometry for **2**. Species **2** is thus an isoelectronic analogue of the structurally characterized compounds $[MM'Cl_2(\mu\text{-HFB})(dppm)_2]$ (MM′ = Pd, Pt; HFB = hexafluoro-2-butyne) (11–13) and is also analogous to the rhodium species $[Rh_2(CO)_2(\mu\text{-}HC_2Ph)(dppm)_2]$, previously reported (9*b*).

Compound **2** is unusual in that, although diphosphine-bridged rhodium or iridium A-frame complexes containing two terminal carbonyls and a dianionic bridge are well known (e.g., $[MM'(CO)_2(\mu\text{-S})(dppm)_2]$, MM′ = Rh_2 (17), Ir_2 (18), RhIr (19)), this is one of the few cases in which an alkyne is spanning the metals with no metal–metal bond or other bridging atoms present. Most of the previous examples do not involve bridging dppm ligands and have the alkyne in a perpendicular arrangement (20). Only the dppm-bridged complexes of Pd_2 (11), PtPd (12), Pt_2 (13), and Rh_2 (9*b*) have a parallel-alkyne arrangement and fit into this category. The only examples in which an alkyne is parallel in the absence of metal–metal bonding, but in which there are no dppm groups, are $[Ir_2(NO)_2(PPh_3)_2(\mu\text{-HFB})_2]$ (21) and $[Pt_2(COD)_2(\mu\text{-HFB})_2)]$ (22), which in fact have two parallel, bridging alkynes. Although the dirhodium compound has a structure exactly analogous to **2**, it was apparently not obtained from the reaction of the analogous tricarbonyl dirhodium precursor, but was obtained in the reaction of $[Rh_2(CO)_2(\mu\text{-H})_2(dppm)_2]$ with two equivalents of phenylacetylene, yielding styrene as the other product. Presumably, the metastable dirhodium analogue was not observed in reactions of $[Rh_2(CO)_3(dppm)_2]$ because, under the refluxing conditions necessary for reaction to be observed, facile transformation to the perpendicular-alkyne complex is expected. Related bis(dimethylphosphino)methane-bridged dirhodium complexes of formula $[Rh_2(CO)_2(\mu\text{-RCCR})(dmpm)_2]$ (R = CO_2Me, CF_3) have also been reported (8*k*) but the orientation of the alkyne group could not be unequivocally established based on the spectroscopic data. However, the dark purple colour of these dmpm species is reminiscent of both complex **2** and its Rh_2 analogue, suggesting a parallel alkyne arrangement for these products also.

Fig. 1. Perspective view of one of the two crystallographically independent $[Ir_2(CO)_2(\mu\text{-}CH_3O_2C\text{—}C\equiv C\text{—}CO_2CH_3)(dppm)_2]$ molecules (molecule 1) showing the atom labelling scheme. Primed atoms are related to unprimed ones via the crystallographic twofold axis (0, *y*, –¼) bisecting the Ir(1)—Ir(1′) and C(2)—C(2′) bonds. Non-hydrogen atoms are represented by Gaussian ellipsoids at the 20% probability level. Hydrogen atoms are shown with arbitrarily small thermal parameters for the carboxymethyl (C(4), C(4′)) and dppm methylene (C5, C(5′)) groups, and are not shown for the dppm phenyl groups.

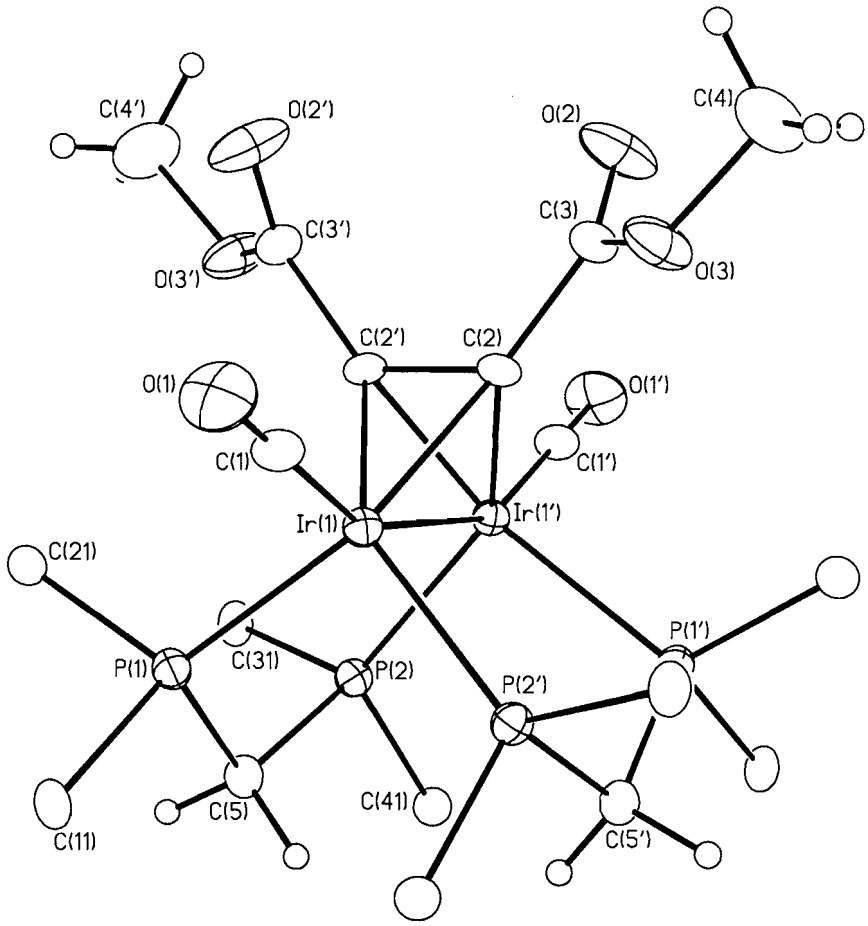


Solid samples of **2** are stable indefinitely in the absence of air, but slowly (1–2 days) turn to light orange-yellow in solution. Unfortunately, we have not yet succeeded in obtaining X-ray quality crystals of **2**. The orange-yellow product obtained from **2** upon standing has been identified as the isomer **3**, in which the alkyne now has a perpendicular orientation with respect to the metals, as has been established by an X-ray study. Compound **3** is obtained routinely in the reaction of **1** with DMAD in refluxing toluene.

As noted in the experimental section, compound **3** crystallizes with two independent molecules (each having a twofold axis bisecting the metal–metal and acetylenic C—C bonds). Figure 1 gives a view of one molecule showing all non-hydrogen atoms, whereas Fig. 2 is an alternate view in which only the ipso carbons of the dppm phenyl groups are shown. Similar views for the second molecule, which is essentially identical to the first, are given in the Supplementary Material.[3] Compound **3** is structurally reminiscent of the previously characterized compounds $[Rh_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-PhCCPh})(dppm)_2]$ (9), $[Co_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-MeCCMe})(dppm)_2]$ (10*a*), $[Co_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-PhCCPh})(dpam)_2]$ (10*b*) (dpam = bis(diphenylarsino)methane), $[Co_2(CO)_4(\mu\text{-}\eta^2\text{:}\eta^2\text{-PhCCPh})(dppm)]$ (10*b*), and $[Co_2(CO)_6(\mu\text{-}\eta^2\text{:}\eta^2\text{-RCCR})]$ (R = Ph (10*c*), Bu^t (10*d*)), having alkyne ligands oriented essentially perpendicular to the metal–metal bond. This binding mode of the DMAD ligand in **3** is accommodated by a bending back of the diphosphine ligands (P(1)-Ir-P(2′) = 98.32(8)°(98.70(8)°)[4] as observed in

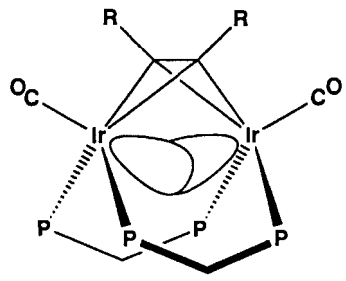
[4] In discussions of the structure, the first number given refers to molecule **1** and the number following, in parentheses, refers to molecule **2**.

Fig. 2. Alternate view of molecule 1, with only the *ipso* carbons of the dppm phenyl groups shown.



several of the above alkyne-bridged species, as well as in the complexes $[Ir_2(H)_2(CO)_2(\mu\text{-SiRPh})(dppm)_2]$ (R = H, Ph) (23), $[Rh_2(CO)_2(\mu\text{-SiHR})_2(dppm)_2]$ (R = Et, Ph) (24), $[Rh_2Cl_2(\mu\text{-X})_2(dppm)_2]$ (X = Cl, CH_3CO_2, $Ph_2P(C_6H_4)$ (25), $[(Rh(PNP))_2(\mu\text{-}\eta^1\text{:}\eta^1\text{DMAD})(\mu\text{-PNP})_2]$ (PNP = $(MeO)_2PN(Me)P(OMe)_2$) (26), $[Pt_2Me_4(dRpm)_2]$ (dRpm = dppm, dmpm) (27), and $[Ir_2(CNC_6H_3Me_2)_4(dmpm)_2]$ (28). Although a number of species having this diphosphine arrangement have been characterized, this nevertheless constitutes a relatively uncommon class of complexes (see also ref. 29). A number of complexes have also been characterized in which a *cis* arrangement is observed at one metal while the more normal *trans* arrangement is found at the other (30).

The coordination geometry about Ir(1) can be described as distorted trigonal bipyramidal, with C(1) and Ir(1′) acting as axial ligands while P(1), P(2′), and the C(2)—C(2′) unit (the latter being viewed as a neutral two-electron π donor to each of Ir and Ir′) occupy the equatorial sites. Distortions from this model, especially the severely acute Ir(1′)-Ir(1)-C(2) and Ir(1′)-Ir(1)-C(2′) angles 50.7(2)° (51.1(2)°) and 49.6(2)° (50.0(2)°), respectively, and the offset of the terminal carbonyl group C(1)O(1) from the Ir–Ir axis (Ir(1′)-Ir(1)-C(1) = 157.4(3)°, (157.2(2)°)), result from the bridging geometry of the alkyne. The deviation of the carbonyls from the Ir–Ir′ axis can be readily rationalized in terms of a "bent" metal–metal interaction as diagrammed below. In this view the axial site at each metal, opposite the carbonyl group, is the orbital that gives rise to the Ir—Ir bond. The tilting of the (alkyne) IrP_2 planes together with the Ir–CO vectors is suggestive of such a "bent" overlap. This view is not unlike that held for the carbonyl-bridged isomer of $Co_2(CO)_8$ (31), which has a very similar structure to that of the present species, with two bridging carbonyls replacing the alkyne bridge, and is supported by more recent theoretical studies (6, 32).



As expected, coordination to the metal centres has resulted in a change in the geometry of the DMAD group as a result of rehybridization of the acetylenic carbons. Furthermore, the acetylenic C(2)—C(2′) distances of 1.43(2) Å (1.43(2)Å) are much longer than observed in structures having the parallel geometry, in which values of near 1.34 Å, consistent with a

dimetallated olefinic formulation for this group, are normally observed (6, 8, 10, 33–39). These distances are even substantially longer than that reported (1.33(1) Å) in the dirhodium analogue (9) and in a number of related species (10, 40–43) having a bridging diphenylacetylene group, where distances near 1.35 Å appear typical. These distances in **3** are comparable to those between the acetylenic and carboxylate carbons (C(2)—C(3) = 1.48(1) Å (1.45(1)Å)), and as such are consistent with a loss of much of the multiple-bond character. The perpendicular binding mode is known to be more effective at lowering the alkyne bond order than the parallel mode, as seen from the significantly lower acetylenic C—C stretches in the IR spectra of the former (from ca. 1530–1642 cm^{-1} to ca. 1425 cm^{-1}). This can be understood on this basis of electron donation from *both* orthogonal π orbitals in the former case and concomitant π back-donation into *both* π^* sets. In the parallel mode one π bond remains intact and essentially unperturbed. The rehybridization at the alkyne carbons is also seen by the C(2′)-C(2)-C(3) angles of 126.8(5)°(129.1(5)°), which are distinctly more acute than is usually observed (133–145°); only $[Co_2(CO)_6(\mu\text{-}\eta^2\text{:}\eta^2\text{-}C_6F_6)]$ (C_6F_6 = 3,4,5,5,6,6-hexafluorocyclohexa-1-yne-3-ene) (44) possesses smaller C_{ac}-C_{ac}-R angles (118(2)°, 122(2)°), probably due to their endocyclic nature. In contrast, the closely related compound $[Rh_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-PhCCPh})(dppm)_2]$ shows a separation of only 1.33(1) Å between the acetylenic carbons, and the C_{ac}-C_{ac}-R angles (133.0(8)° and 134.2(8)°) are normal (9). Overall the Ir_2C_2 core of **3** can be described as a dimetallatetrahedrane unit, with the distortions from this model (especially from the ideal bond angles of 60°) arising mainly due to the inherent inequality of the Ir—Ir, Ir—C, and C—C bond lengths.

The Ir(1)—Ir(1′) distances of 2.6695(7) (2.6612(7)) Å are the shortest so far observed within the class of similar diphosphine-bridged systems involving these metals, for which the metal–metal distances usually fall within the range 2.77–2.89 Å (8*b*, 8*g*, 12, 38, 45); the distances observed herein are more comparable to that found in another perpendicular-alkyne bridged complex, $[Ir_2(CO)_4(PPh_3)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-PhCCH})]$ (Ir—Ir = 2.691(1) Å) (46) and to the Rh—Rh distance of 2.644(1) Å in $[Rh_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-PhCCPh})(dppm)_2]$ (9). Presumably the short metal–metal separation is a consequence of the bite imposed by the alkyne bridge, which requires a decreased Ir—Ir distance in order to maximize Ir—Ir and Ir—C overlaps, as mentioned above. In spite of the short metal–metal separation and the long distance between acetylenic carbons (vide supra), the Ir – alkyne carbon distances (2.065(7) – 2.110(7) Å) are within the range previously observed (2.05–2.13 Å) for iridium atoms bound to alkyne residues in related systems (8*b*,*d*,*g*,*h*). The Ir—P distances are similar to those observed in other $Ir_2(dppm)_2$ complexes, and despite the short Ir—Ir distance and the tilting of the equatorial planes at the metals, the intraligand P···P separations (3.059(3) Å (3.069(3) Å)) are normal.

The spectral data for the two isomers **2** and **3** serve to clearly distinguish the two. In the $^{31}P\{^1H\}$ NMR spectra the resonances for these species differ by almost 18 ppm. However, both appear as singlets owing to the chemical equivalence of the four phosphorus nuclei in both compounds, so yield no further structural information. The upfield chemical shift seen in the $^{13}C\{^1H\}$ NMR spectrum on proceeding from **2** to **3** (δ 191.10, 173.8) is unexpected in the context of the metal oxidation states. The lower oxidation state of Ir in compound **3** (0 versus +1) should give rise to more π back-donation to the carbonyls and a concomitant downfield ^{13}C shift (47). We propose that the alkyne group in the perpendicular mode functions as a better π acceptor by virtue of using both orthogonal sets of π^* orbitals. The lower electron density remaining for π back-donation to the carbonyls is then manifest in the upfield ^{13}C shift for the carbonyl resonances in **3**. Such an argument is also consistent with the solution IR spectra, which show a somewhat higher frequency carbonyl stretch for **3** (1943 cm^{-1}) than for **2** (1934 cm^{-1}). Of course, metal oxidation state assignments in such species are somewhat artificial, and **3** could equally well be viewed as a metallatetrahedrane complex having localized Ir—C σ bonds to the carbon atoms, in which case the metals could be viewed as Ir(+2).

The analogous hexafluoro-2-butyne complexes, $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-HFB})(dppm)_2]$ (**4**) and $Ir_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-HFB})(dppm)_2]$ (**5**) are prepared much as are the DMAD compounds, by reaction **1** with the alkyne. However, unlike the DMAD reaction, the reaction with HFB is very slow at ambient temperature, and only the final product **5** can be isolated. Intermediate **4**, analogous to the blue species **2**, appears at intermediate times (giving solutions a green tinge) but is always obtained together with varying amounts of starting material **1** and product **5**. Attempts to synthesize analogs of these parallel and perpendicular alkyne compounds, using alkynes such as phenylacetylene and diphenylacetylene, gave no indications of reaction at ambient or slightly elevated temperatures, even after 24 h. Refluxing compound **1** in the presence of these alkynes resulted in a large number of unidentified decomposition products.

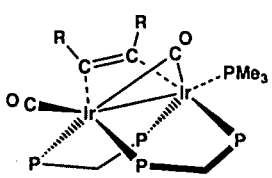
Although conversion from the parallel to the perpendicular alkyne-bridged coordination is irreversible in these compounds, the reversible transformation has been observed in a number of cases; the first examples were accompanied by ligand loss or gain (7), but recently two reports have appeared in which two isomers differed in their orientations of the alkyne groups (8*n*, 20*a*). In the former examples it is difficult to compare alkyne reactivities, owing to the differing ancillary ligand counts, however, such a comparison should be more meaningful in the isomeric compounds, where at least the ancillary ligands are the same. In a previous study on two RhMn-containing isomers, which differed in their alkyne binding, protonation gave different intermediates, but the same final product (8*n*). Compounds **2** and **3** in this paper offer another opportunity to compare the reactivities of an alkyne group in the two bridging coordination modes, since both species can be isolated free of the other. To our knowledge, no other study comparing such reactivities has been reported.

Possibly the most obvious difference in the two isomers (**2** and **3**) relates to the electron counts at the metals. With the alkyne functioning as a 2-electron donor in **2** the metals each have a 16-electron count, whereas in **3**, in which the alkyne is a 4-electron donor, both metals are saturated. This difference shows up clearly in the attempted reactions with PMe_3. Whereas compound **3** shows no reaction with excess PMe_3 over extended periods of time, compound **2** reacts readily with one equivalent of the phosphine to yield the adduct $[Ir_2(CO)(PMe_3)(\mu\text{-CO})(\mu\text{-DMAD})(dppm)_2]$ (**6**). This product displays five $^{31}P\{^1H\}$ resonances for the chemically distinct phosphorus nuclei. The maximum coupling between these

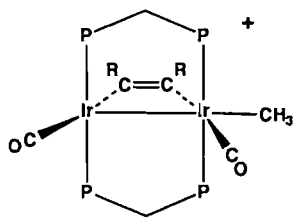
nuclei is found to be ca. 110 Hz, indicating a *cis* arrangement of the phosphines at each metal; by comparison, *trans* phosphines in such systems typically show coupling of ca. 300 Hz. The $^{13}C\{^1H^1\}$ NMR spectrum shows one terminal carbonyl resonance at δ 182.8 and one due to the bridging group at δ 230.3. This latter resonance displays large coupling (63 Hz) to P_A and P_B, indicating that these phosphorus nuclei are almost *trans* to this carbonyl (by comparison, *cis* $^2J_{P-C}$ values are typically less than 15 Hz). Movement of the one carbonyl from a terminal to a bridging site presumably results from the steric crowding upon coordination of PMe_3. We assume that this is also a major reasons for the transformation from *trans* to *cis* diphosphine groups that occurs. Complex **6** is chiral, but will be present as a racemic mixture, resulting from PMe_3 attack at either metal.

Attempts to generate a tricarbonyl species analogous to **6** by reacting **2** or **3** with CO failed, as no reaction was observed in either case. A species, believed to be a tricarbonyl, alkyne-bridged complex, was observed at intermediate times in the reaction of **1** with DMAD, having all carbonyls terminal ($^{13}C\{^1H\}$ NMR, δ: 199, 183, 178). However, owing to its facile loss of CO to yield **2**, this intermediate was incompletely characterized.

We next turned our attention to the reactions of **2** and **3** with the electrophiles, CH_3^+ and H^+, in attempts to obtain alkyl and hydride products. It was hoped that the alkynes in the two different bridging modes might display different tendencies to undergo migratory insertion with the alkyl or hydride moieties. Compound **2** reacts with methyl triflate to yield the alkyl product $[Ir_2(CH_3)(CO)_2(\mu\text{-DMAD})(dppm)_2][SO_3CF_3]$ (**7**), having the structure diagrammed below. This product is identical to the product previously obtained in the reaction of



6



7

$[Ir_2(CH_3)(CO)(\mu\text{-CO})(dppm)_2][SO_3CF_3]$ with DMAD (**15**) and is the product expected from electrophilic attack at a filled d_{z^2} orbital on one of the metal centres in **2**. All spectroscopic parameters are consistent with the structure shown. No migratory insertion of the alkyne and the methyl group has been observed in this or the previous study, in spite of a favourable mutually *cis* arrangement of the two groups.

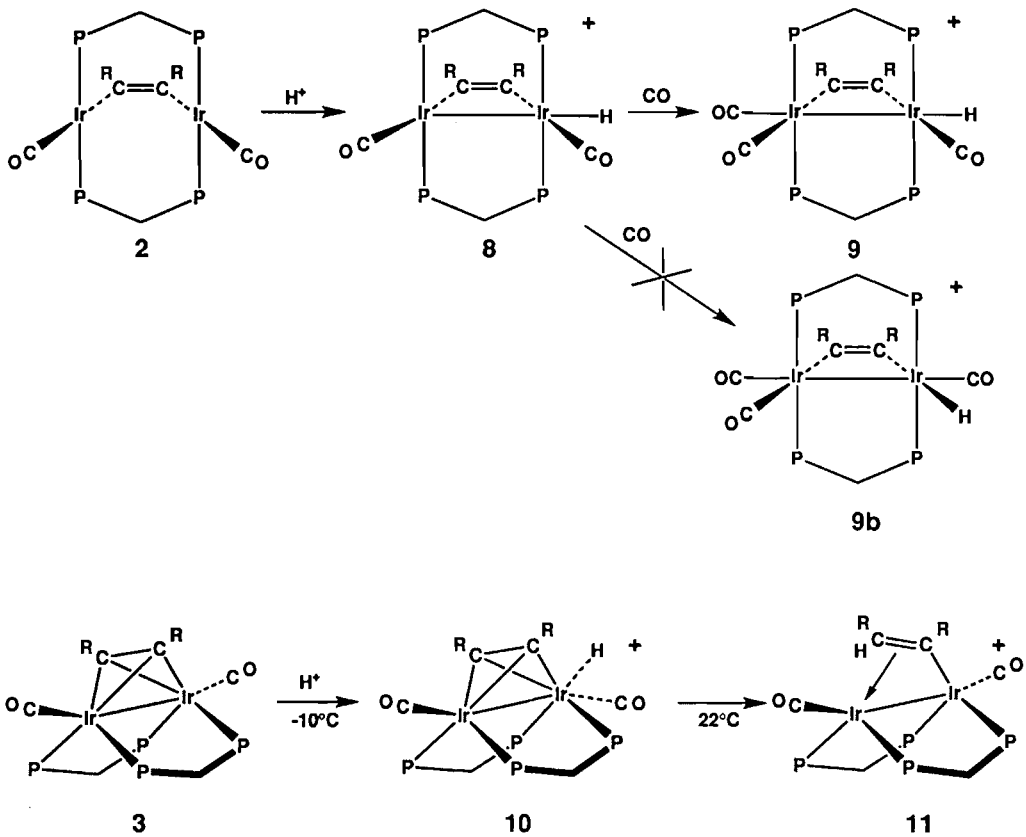
Surprisingly perhaps, compound **3** does not react with methyl triflate. We had expected that the 18e, formally Ir(0) centres would be susceptible to electrophilic attack, but this appears not to be case with Me^+. Possibly the reaction is inhibited by more severe steric crowding than is present in **2**.

Protonation also proceeds differently for the two isomers. Reaction of **2** with $HBF_4{\cdot}OEt_2$ yields the hydrido species $[Ir_2H(CO)_2(\mu\text{-DMAD})(dppm)_2][BF_4]$ (**8**) as shown in Scheme 1. The hydride is shown to be terminally bound to one metal, displaying coupling to only two adjacent ^{31}P nuclei. An alternate structure, in which the carbonyl and hydride ligands on one metal are interchanged, is ruled out for two reasons. First, the structure shown is analogous to that of the previously characterized methyl complex **7** (15), with both species having very comparable spectral parameters, and second, the reaction of **8** with CO yields the tricarbonyl $[Ir_2H(CO)_3(\mu\text{-DMAD})(dppm)_2][BF_4]$ (**9**), in which the hydride ligand remains adjacent to the DMAD unit. If complex **8** had the alternate geometry, its product upon reaction with CO would be the isomer **9b**, which has the hydrido ligand opposite the alkyne; this latter product has been previously characterized (48) and is clearly distinguishable from **9**. No migratory insertion of the alkyne and hydrido ligands in **8** is observed at ambient temperature in spite of their mutually *cis* arrangement. However, refluxing **8** in benzene for several hours yielded a mixture of products, one of which (in approximately 50% yield) was identified as the migratory insertion product **11** (vide infra).

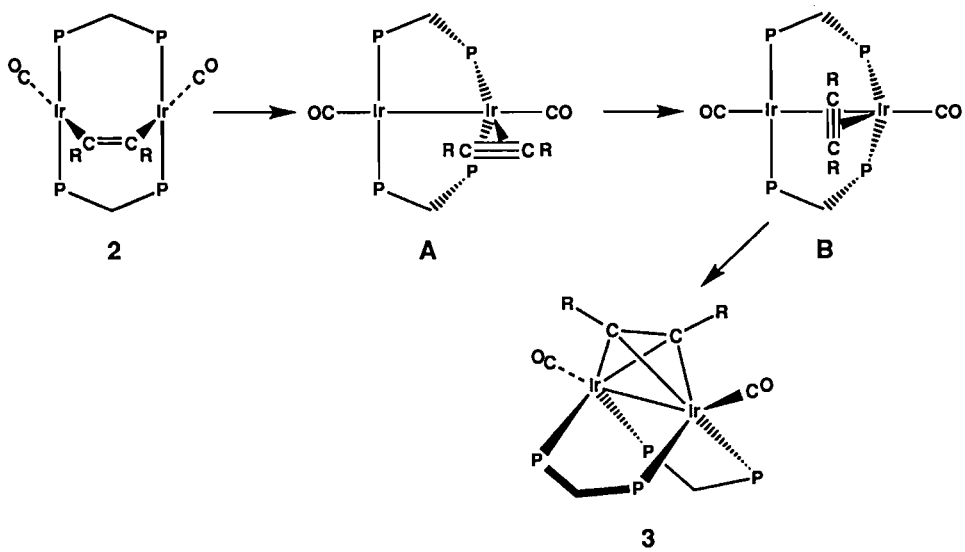
Compound **3** reacts readily with $HBF_4{\cdot}OEt_2$ at −10°C to yield $[Ir_2H(CO)_2(\mu\text{-DMAD})(dppm)_2][BF_4]$ (**10**) in which the hydride group is found to be terminally bound to one metal. Although the orientation of the alkyne group is equivocal, the facile conversion from **3** suggests that it has remained perpendicular to the metals. As such, compound **10** resembles the isoelectronic species $[RhMn(CO)_3(\mu\text{-}\eta^2\text{:}\eta^2\text{-}RC_2R)(dppm)_2]$ (R = CO_2Me, CF_3) (8*n*), in which the "$Mn(CO)_2$" moiety is replaced by "$IrH(CO)^+$". In addition, the final product (**11**) in the subsequent transformation of **10** is shown to also have a *cis*-diphosphine arrangement, so it seems likely that the diphosphines have remained *cis* in the transformation **3** to **10** to **11**. The appearance of two methyl resonances seems at first to be inconsistent with the structure shown for **10**, however, reference to Fig. 2 shows that one methyl group is tipped towards one metal whereas the second is aimed at the other; protonation at one metal would render these methyl groups inequivalent. Warming to ambient temperature results in the smooth transformation of **10** to $[Ir_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}(MeO_2C)C{=}C(H)CO_2Me)(CO)_2(dppm)_2][BF_4]$ (**11**) in which migration of the hydride to the alkyne group to give a bridging vinyl group has occurred. This transformation is accompanied by the disappearance of the hydride resonance of **10** and the appearance of the vinyl signal at δ 4.62 in the ^1H NMR spectrum. Also observed, is the C=C stretch of this vinyl group at ca. 1550 cm^{-1}; significantly, none of the alkyne-bridged species displayed the expected C—C stretches for these alkyne moieties. The $^{31}P\{^1H\}$ NMR spectrum shows four separate resonances, consistent with the structure shown, and the maximum coupling (58 Hz) between these nuclei confirms the *cis*–*cis* diphosphine arrangement. In the $^{13}C\{^1H\}$ NMR spectrum the carbonyls display a mutual coupling of 9.4 Hz, suggesting an arrangement in which both are approximately opposite the Ir—Ir bond, facilitating their coupling.

Protonation of **3** at temperatures below −20°C suggests that the initial site of protonation is at the DMAD carboxylate oxygens, as seen by the low-field shift of the proton at δ 20.0, which is consistent with a strongly hydrogen-bonded proton (49). Reference to Fig. 2 shows that protonation at these groups could easily give rise to a species in which the proton bridges both groups. The other spectroscopic parameters (^1H, ^{13}C, and ^{31}P) are all very similar to those of **3**, consistent with protonation occurring on the periphery of the molecule. Transfer of the proton from the carboxylate groups to one of the metals in **10** would require very little movement of any of the groups.

Scheme 1.



Scheme 2.



We had hoped that protonation of the HFB analogue $[Ir_2(CO)_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-HFB})(dppm)_2]$ (**5**) would yield the corresponding vinyl product, and that the additional NMR coupling involving the fluorine nuclei would yield additional information about the binding of the vinyl group. However, although the vinyl product $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^2\text{-}(CF_3)C{=}C(H)CF_3)(dppm)_2][BF_4]$ could be identified in the NMR spectra, its facile decomposition to several species did not allow the appropriate heteronuclear decoupling experiments to be carried out.

Discussion

At the outset, it was our intention to isolate an iridium ana-

logue of the blue, metastable $[Rh_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}RC_2R')(dppm)_2]$ (9), having a parallel alkyne bonding mode. This has been achieved using the activated alkyne, dimethyl acetylenedicarboxylate, generating $[Ir_2(CO)_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}DMAD)(dppm)_2]$ (**2**). With the closely related hexafluoro-2-butyne, the analogous product was observed as a transient species, but was never isolated. Attempts to prepare the phenyl- and diphenylacetylene adducts, more closely resembling the dirhodium compound, were unsuccessful, with no reaction observed at mild temperatures and decomposition occurring under harsher conditions. As anticipated, the combination of the activated alkyne and the less labile Ir centres allows the isolation of the target species **2**, although the effect of changing just the alkyne or the metal could not be assessed, since activated alkynes were not used in the dirhodium study. In spite of the extended lifetime of **2**, it still slowly rearranges (over a 24–48 h period) in solution to the more stable isomer **3**, having a perpendicular-alkyne bonding mode. The greater stability of the perpendicular product can be rationalized, at least for the activated alkynes, on the basis that this geometry allows the alkyne to function as a better π acceptor from the electron-rich Ir(0) centres, with donation into both orthogonal π^* orbitals. It should also be noted that the transformation from **2** to **3** should also be favoured by increased bond formation. In addition to more π back-donation, which formally corresponds to stronger Ir—C bonds, there is an additional metal–metal bond in **3**. Both effects should outweigh the concomitant slight weakening of the alkyne C—C bond that occurs. This being said, it nevertheless remains a mystery that the palladium and platinum analogues, $[MM'Cl_2(\mu\text{-}\eta^1\text{:}\eta^1\text{-}RC_2R)(dppm)_2]$, retain a *parallel*-alkyne geometry (11–13).

Superficially it would appear that rearrangement from **2** to **3**, via alkyne rotation and bending back of the phosphines, should be facile. This is not the case, taking up to 48 h in solution at ambient temperature. Hoffmann has argued that simple alkyne rotation by 90° in these binuclear systems is symmetry forbidden (6). We therefore propose that alkyne rotation occurs at a single metal centre, as shown in Scheme 2. The structures of proposed intermediates **A** and **B** are analogous to that of **1**, having a *cis* diphosphine arrangement at one metal and one carbonyl replaced by an η^2-alkyne. The bent-back diphosphine arrangement at one metal would facilitate alkyne rotation by moving the dppm phenyl rings away from the alkyne substituents. Alkyne rotation at a single metal has been reported (50), and is presumably analogous to the more studied olefin rotation (51). In the final step, movement of the perpendicular alkyne from one metal to the bridging position would then be accompanied by bending back of the diphosphines at the second metal.

The isolation of the two isomeric forms of $[Ir_2(CO)_2(\mu\text{-}RC{\equiv}CR)(dppm)_2]$ (R = CO_2Me), having either a parallel (**2**) or a perpendicular (**3**) alkyne-bridged arrangement, has allowed an investigation of the reactivity differences of the two species. Even the mere exposure to air shows a dramatic difference in the two, with the parallel isomer decomposing instantly, while the perpendicular isomer is stable indefinitely. It is well recognized that the two binding modes give rise to differing valence electron counts at the metals. In **2**, each metal has a 16e configuration so is coordinatively unsaturated, whereas the metals are saturated in **3**. In keeping with these configurations, **2** reacts readily with PMe_3, ultimately yielding saturated metal centres, whereas **3** fails to react. The product of PMe_3 attack on **2**, $[Ir_2(CO)(PMe_3)(\mu\text{-}CO)(\mu\text{-}DMAD)(dppm)_2]$ (**6**), retains the parallel-alkyne bridge although the diphosphines adopt a *cis* arrangement at both metals. Based on the data available, it is not possible to rationalize the transformation from *trans* to *cis*-diphosphines, in which the bridging carbonyl and DMAD groups end up in adjacent positions. We would have anticipated a *trans*-diphosphine arrangement, having the carbonyl and alkyne on opposite faces of the dimer.

Although we have rationalized the failure of **3** to react with PMe_3 as due to the saturation at both metals, this is only part of the story, since the analogous $[Cp_2Rh_2(\mu\text{-}CO)(\mu\text{-}CF_3C_2CF_3)]$ reacts with nucleophiles, in spite of the saturated metal configurations (4). It was proposed that rotation of the alkyne from perpendicular to parallel generates unsaturation, allowing ligand coordination. In compound **3** it seems that this alkyne rotation is very unfavorable, as noted above, so the metals retain their saturated configurations, and do not allow ligand addition to occur.

Not unexpectedly, the electron-rich species **2** and, to a lesser extent, **3** react with electrophiles such as CH_3^+ and H^+. In **2**, an orbital, corresponding to the filled d_{z^2} orbital on each square-planar Ir centre is the obvious site of electrophilic attack, and both CH_3^+ and H^+ react to yield analogous products $[Ir_2(E)(CO)_2(\mu\text{-}DMAD)(dppm)_2]^+$ (E = CH_3 (**7**), H (**8**)), in which the electrophile is coordinated at one metal, adjacent to the $\mu\text{-}\eta^1\text{:}\eta^1$-alkyne group. In neither case does migratory insertion, to give the appropriate vinyl ligand, occur. Although insertion involving a bridging alkyne and an alkyl group is not common, that involving a hydride is well documented (8*k*, 8*n*, 36, 52), so the failure of **8** to transform to a vinyl-containing product is surprising.

The reactivity of **3** with electrophiles is significantly different from that of **2**. First **3** does not react with methyl triflate, presumably owing to the greater congestion at the metals when the alkyne is perpendicular. Although the smaller proton does find access to one of the metals, yielding, at low temperature, a product analogous to **8** except having a perpendicular alkyne and a *cis*-diphosphine arrangement (see Scheme 1), warming to ambient temperature results in migratory insertion and formation of a vinyl-bridged product (**11**). The latter transformation is not surprising, but the failure of the isomeric **8** to undergo the analogous rearrangement is curious, particularly since a number of parallel alkyne-to-vinyl transformations have been reported (51). The reason for this difference is not understood.

In conclusion, we have for the first time demonstrated that the bridged, parallel and perpendicular, alkyne binding modes in binuclear complexes can give rise to significant reactivity differences. Although the failure of the isomer, containing the perpendicular-bound alkyne, to react with PMe_3 or $MeOSO_2CF_3$, can be rationalized based on the saturated metal configurations or the crowded metal environments, respectively, the different reactivities of the two isomers upon protonation remains a mystery. The facile conversion of the perpendicular alkyne to a vinyl group upon protonation, is in marked contrast to the failure of the other isomer, in which the parallel alkyne is adjacent to the terminal hydride ligand, to undergo migratory insertion to give a vinyl group under similarly mild conditions.

Steric effects of bulky phosphines on ^{95}Mo NMR shieldings

Shuquan Song and Elmer C. Alyea

Abstract: Three sets of substituted molybdenum carbonyl complexes of the type $Mo(CO)_{6-n}(PY_3)_n$ (n = 1–3) with a wide range of phosphorus ligands (Y = Ar, R, OR, NR_2, Cl, H) were synthesized and their respective ^{95}Mo NMR spectral data were collected. The steric effect of PY_3 plays an unexpectedly important role in the paramagnetic shielding term determining $\delta(^{95}Mo)$, and is even observed in the least crowded $M(CO)_5(PY_3)$ complexes. It is deduced that the steric requirement reduces the commonly accepted π-ability of phosphites by weakening the M—P bonds, making $\delta(^{95}Mo)$ positions move toward higher frequency in going from $M(CO)_5(PY_3)$ to *fac*-$M(CO)_3(PY_3)_3$. A detailed correlation analysis in the case of phosphite ligands has shown that the free cone space to accommodate a PY_3 ligand may be as low as 95° in $Mo(CO)_{6-n}(PY_3)_n$ (n = 1–3) derivatives. The fair linearity of these correlations suggests indirectly that the σ-component in phosphite bonding is relatively less important. These linear correlations of $\delta(^{95}Mo)$ against the Tolman cone angle θ provide an empirical estimation of the bulkiness of any phosphite ligand.

Key words: metal–phosphorus bonds, ^{95}Mo NMR, steric effects.

Résumé : On a synthétisé trois ensembles de complexes de molybdène carbonyle substitués du type $Mo(CO)_{6-n}(PY_3)_n$ (n = 1–3) avec une grande variété de ligands phosphores (Y = Ar, R, OR, NR_2, Cl, H) et on a recueilli leurs données spectrales respectives en RMN du ^{95}Mo. L'effet stérique du PY_3 joue un rôle important inattendu dans le terme de blindage paramagnétique déterminant $\delta(^{95}Mo)$, et on l'observe même dans les derniers complexes $M(CO)_5(PY_3)$ encombrés. On en déduit que l'encombrement stérique réduit la tendance-π communément acceptée pour les phosphites en affaiblissant la liaison M—P de telle sorte que la position de $\delta(^{95}Mo)$ se déplace vers les plus hautes fréquences en allant de $M(CO)_5(PY_3)$ vers *fac*-$M(CO)_3(PY_3)$. Une analyse détaillée de corrélation dans le cas du ligand phosphite montre que l'espace conique libre pour accommoder le ligand PY_3 peut être aussi faible que 95° dans les dérivés $Mo(CO)_{6-n}(PY_3)_n$ (n = 1–3). La linéarité assez grande de ces corrélations suggère indirectement que la composante σ dans la liaison du phosphite est relativement moins importante. Ces corrélations linéaires de $\delta(^{95}Mo)$ contre l'angle θ du cône de Tolman fournissent une estimation empirique de l'encombrement de tout ligand phosphite.

Mots clés : lien métal–phosphore, RMN du ^{95}Mo, effet stérique.

[Traduit par la rédaction]

Introduction

The importance of steric effects of trivalent phosphorus ligands on various reactivities of phosphine complexes has been well studied and reviewed several times (1) since the introduction of the cone angle concept by Tolman (1*a*). At least five different steric parameters defining the bulkiness of these important ligands were proposed previously (1*d*) and, quite recently, another steric parameter, E_r, has been developed for trivalent phosphorus and nitrogen donors by T.L. Brown using molecular mechanics methods (2). The benefits and limitations for the various steric parameters have also been considered by various researchers in their interpretations of the thermodynamic and (or) kinetic behaviour of phosphorus ligands in the formation of (1, 3), isomerization (4), *trans* effects (5), and σ/π bonding (6), in transition metal complexes. Applications of these steric parameters have mainly been qualitative due to the inherent uncertainty of each parameter and the overlapping effect of electronic components. Previous studies suggest that the steric effect exerts a significant influence on magnetic shielding of the transition metal nucleus (7), which can be measured to high precision, and therefore steric contributions to M—P bonding might be estimated more precisely from ^{95}Mo and ^{31}P NMR spectrometry if a wide range of bulky P(III) ligands were investigated. This paper focuses on evaluations of the steric component in M—P bonding by analysis of ^{95}Mo NMR shielding parameters for a wide range of $Mo(CO)_{6-n}(PY_3)_n$ (n = 1–3) derivatives.

Received February 12, 1996.

This paper is dedicated to Professor Howard Clark in recognition of his contributions to Canadian chemistry.

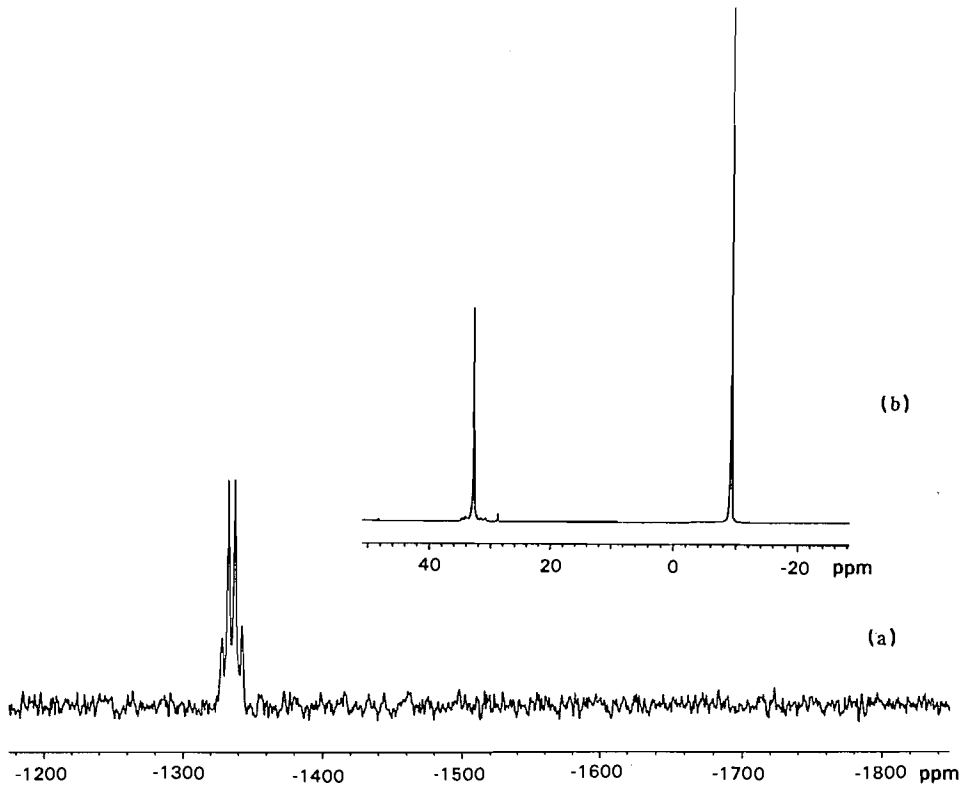
Experimental

The molybdenum carbonyl complexes $Mo(CO)_{6-n}(PY_3)_n$ (n = 1–3) of trivalent phosphine and phosphite ligands were prepared according to published procedures (8*b*, 8*c*). $Mo(CO)_3CHT$ (9*a*), $Mo(CO)_4NBD$ (9*a*), and $Mo(CO)_5NMe_3$

Fig. 1. ^{95}Mo (*a*) and ^{31}P (*b*) NMR spectra for *fac*-$Mo(CO)_3(PPh_2Bz)_3$ in dichloromethane; in the ^{31}P spectrum, the ^1J(Mo–P) coupling constants, which can be clearly resolved on an enlarged scale, are consistent with the values obtained directly from the ^{95}Mo spectrum, and the peak at higher field is due to free ligand.



(10) or $Mo(CO)_5$(piperidine) (9*b*) were used as precursors to make *fac*-, *cis*-, and mono displaced Mo derivatives, respectively, which are listed in Table 1. Many of them are known (11), as indicated in the footnotes to the table. The phosphite complexes are usually colourless and the phosphine complexes are yellowish. In most displacement reactions of $Mo(CO)_3$CHT, $Mo(CO)_4$NBD, and $Mo(CO)_5(NMe_3)$ or $Mo(CO)_5$(piperidine) by this class of ligands, a single product was formed, easily identified by IR and ^{31}P and ^{95}Mo NMR spectrometry. Several typical spectra are presented in Figs. 1–3. In some cases of very bulky ligands, such as $P(OSiMe_3)_3$ or $P(NMe_2)_3$, either the f3 and m3 were obtained together, as shown in Fig. 4, or c2 and t2 coexisted, as illustrated in Fig. 5. The isomers were still clearly differentiated by their ^{95}Mo and ^{31}P NMR spectra, although their IR bands in the carbonyl region were overlapped. Several Mo complexes were isolated and purified: *fac*-$Mo(CO)_3[PPh_2(C{\equiv}CPh)]_3$ (yield: 53%); *fac*-$Mo(CO)_3[P(OPh)_3]_3$ (yield: 80%); *fac*-$Mo(CO)_3(ETPB)_3$ (yield: 88%); *cis*-$Mo(CO)_4(ETPB)_2$ (yield: 79%); *cis*-$Mo(CO)_4(PPh_2Bz)_2$ (yield:68%); *cis*-$Mo(CO)_4[P(OSiMe_3)_3]_2$ (yield: 23%); *cis*-$Mo(CO)_4(PPh_2Cy)_2$ (61%); $Mo(CO)_5P$(2-MeO-Ph)$_3$ (43%). However, because of their air sensitivity and prior characterization, the spectral data for most complexes in Table 1 were collected in situ under a nitrogen atmosphere without further purification and isolation. Every species was unambiguously characterized in terms of geometry by ^{95}Mo, ^{31}P, ^{13}C NMR, and IR spectroscopy (13), but only representative data (Tables 4–6) are presented in this paper.

^{31}P and ^{13}C NMR spectra were obtained on a Varian Unity 400 MHz instrument at 161.9 and 100.6 MHz, respectively, using 85% aqueous H_3PO_4 and TMS in $CDCl_3$ as external standards. ^{95}Mo NMR spectra were collected at 26.08 MHz at 10 Hz/pt resolution in 10 mm tubes, using CH_2Cl_2 (normally) as solvent and concentrations as near 0.1 M as possible; the external standard was 2 M Na_2MoO_4 in D_2O (pH 11).

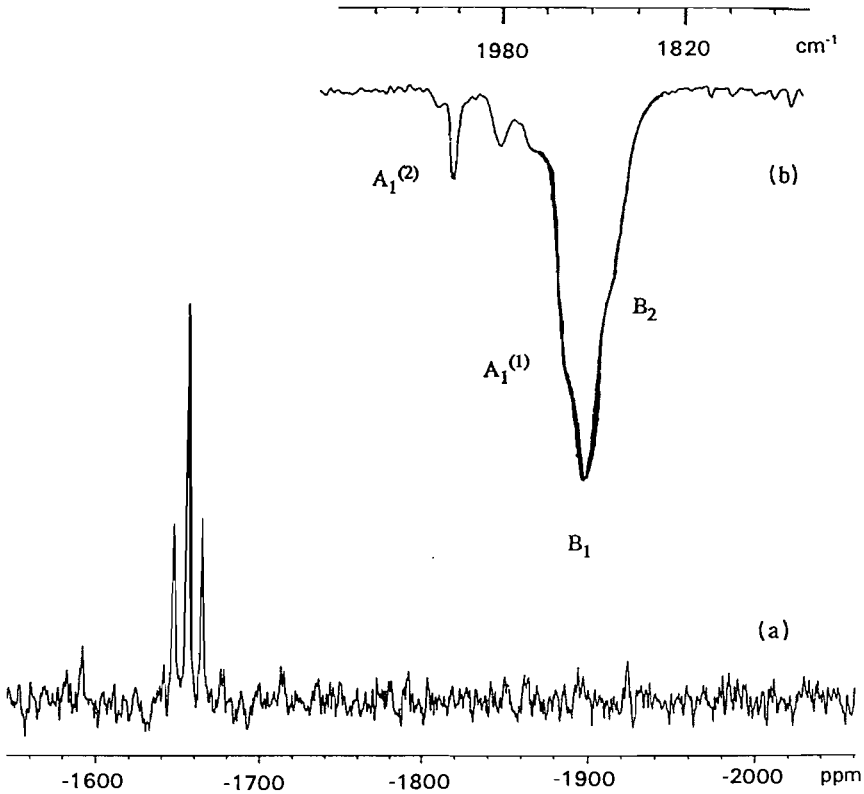
Data precision for the ^{95}Mo NMR spectral results has been described in related papers (7). To briefly summarize the line width data for the present $Mo(CO)_{6-n}(PY_3)_n$ (n = 1–3) complexes, $W_{1/2}$ had the following ranges: 5–120 Hz (n = 1), 10–490 Hz (n = 2), and 5–40 Hz (n = 3). Compared to the line width for m1 complexes, $W_{1/2}$ was, on average, 2.3 times greater for c2 complexes and 0.5 lower magnitude for f3 complexes.

Results and discussion

^{95}Mo NMR spectral parameters

Tables 1 and 2 list the ^{95}Mo NMR data for $Mo(CO)_{6-n}(PY_3)_n$ for a wide range of trivalent phosphorus ligands in the order of their Tolman cone angle. Immediately, a general trend is seen, as shown graphically in Fig. 6. As the degree of displacement (DD) increases from 1 to 3, the ^{95}Mo NMR chemical shifts move dramatically to high frequency with several crossovers for DD = 3. As observed previously by ^{31}P and ^{51}V NMR for carbonyl phosphine vanadium complexes (7*d*), the greatly reduced Mo—P bonding ability as DD increases (especially

Fig. 2. ^{95}Mo NMR spectrum (*a*) and IR bands in carbonyl region (*b*) for *cis*-$Mo(CO)_4(P(OSiMe_3)_3)_2$; both are in dichloromethane.



from 2 to 3) indicates that the steric component imposes a serious deshielding shift on $\delta(^{95}Mo)$, which is also the direction of weak π and weak σ effects of ligands such as chlorophenylphosphines (7*b*).

As commonly accepted (7, 8, 12, 13), ^{95}Mo NMR chemical shift trends as interpreted by the Ramsey equation ($\sigma = \sigma_d + \sigma_p$) are dominated by the paramagnetic (σ_p) term, since the diamagnetic term (σ_d) is small and constant for a similar series. Hence, factors affecting the average electronic excitation energy (ΔE) term of the σ_p expression mainly influence ^{95}Mo nuclear shielding.

We now hypothesize that there may be a quantitative expression such as eq. [1]:

$$[1] \quad \delta_M = A\,\theta + B\,\sigma + C\,\pi + D$$

which describes the multi-parameter dependencies of $\delta(^{95}Mo)$ (or screening constant, σ_p), in which θ, σ, and π are measures of steric, σ, and π components, respectively. An attempt to estimate the steric component in eq. [1] is the goal of this paper. This would form a significant basis for the future separation of σ and π contributions for the phosphorus ligands. Our detailed analysis of the magnetic shielding in the molybdenum complexes for a few selected phosphorus ligands is presented in the following order:

(*a*) Strong π-ligands: PF_3, ETPB, $P(OMe)_3$, and $P(OPh)_3$

(*b*) Strong σ- and (or) moderate π-ligands: PEt_3, $P(n\text{-}Bu)_3$, and PMe_3,

(*c*) Extra bulky ligands: $P(OSiMe_3)_3$, PCy_3, $P(2\text{-}Me\text{-}Ph)_3$, and $P(2,6\text{-}Me_2\text{-}OPh)_3$

(*a*) Strong π-ligands: PF_3(104°), ETPB(101°), $P(OMe)_3$(107°), and $P(OPh)_3$(128°)

These four ligands are well known as good π-acceptors, based on the high stretching frequencies of *trans* CO's in transition metal complexes (6, 13), shorter M—P bond distances (14), high stability of the M—P link (15, 16), high reactivity toward displacement of CO in metal carbonyl moieties (1, 3, 4), and other electrochemical (12*f*, 17) and spectroscopic studies (6, 8*a*, 18). In agreement with these observations and the expectation that the ΔE term in the σ_p term is enhanced by good π-acceptor ability, the phosphites indeed make the ^{95}Mo nuclei in their molybdenum carbonyl derivatives quite shielded compared with most other ligands, whether in m1 or f3 derivatives (Fig. 7). The folded lines for the three phosphites in Fig. 7 exhibit, in going from m1 to f3 geometry, the deshielding contributions of the steric component, already discussed in previous papers (7) but further reinforced below. However, it cannot be easily interpreted at this point that in its f3 complex the less bulky ETPB ($\theta = 101°$) brings σ_p to high frequency by 55 ppm with respect to PF_3 ($\theta = 104°$). Notably, the ^{95}Mo resonance for the m1–$P(OPh)_3$ complex occurs 45 ppm at high frequency compared to that for m1–$P(OMe)_3$ in this least bulky geometry and this relationship changes little in going to c2 and f3 geometries. This undoubtedly reflects the weaker bonding ability of $P(OPh)_3$ compared to $P(OMe)_3$ (and perhaps other small alkylphosphites). It will be shown that an important interligand repulsion exists even in $Mo(CO)_5L$ derivatives, usually considered to be steric-interaction-free structures. If the extra deshielding occurring in m1–$P(OPh)_3$ were due to steric factors, then the two δ/n folded lines for

Fig. 3. ^{95}Mo NMR spectrum (bottom) and IR carbonyl stretching bands (top) for $Mo(CO)_5(P(2\text{-}MeO\text{-}Ph)_3)$; both are in dichloromethane.

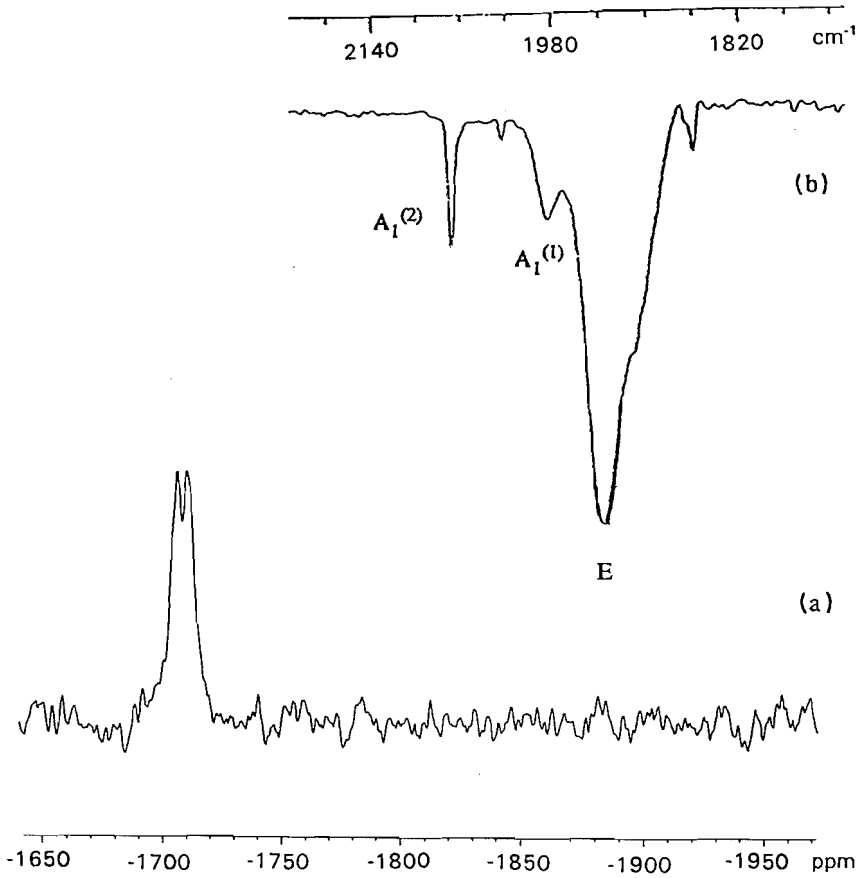


Fig. 4. The ^{95}Mo (bottom) and ^{31}P (top) NMR spectra recorded in dichloromethane in situ from an attempt to produce *fac*-$Mo(CO)_3(P(OSiMe_3)_3)_3$ using $Mo(CO)_3CHT$; the facial isomer could not be isolated, and only a mixture of *mer*-3 and *fac*-3 was obtained. The ^{31}P NMR spectrum unambiguously indicates the formation of the *fac*-3 complex; the stronger signal is due to free ligand and the singlet with six ^{95}Mo satellites is due to the three phosphorus ligands in the *fac*-3 complex. The ^{95}Mo resonances for *fac*-3 are obscured by those for the *mer*-3 isomer.

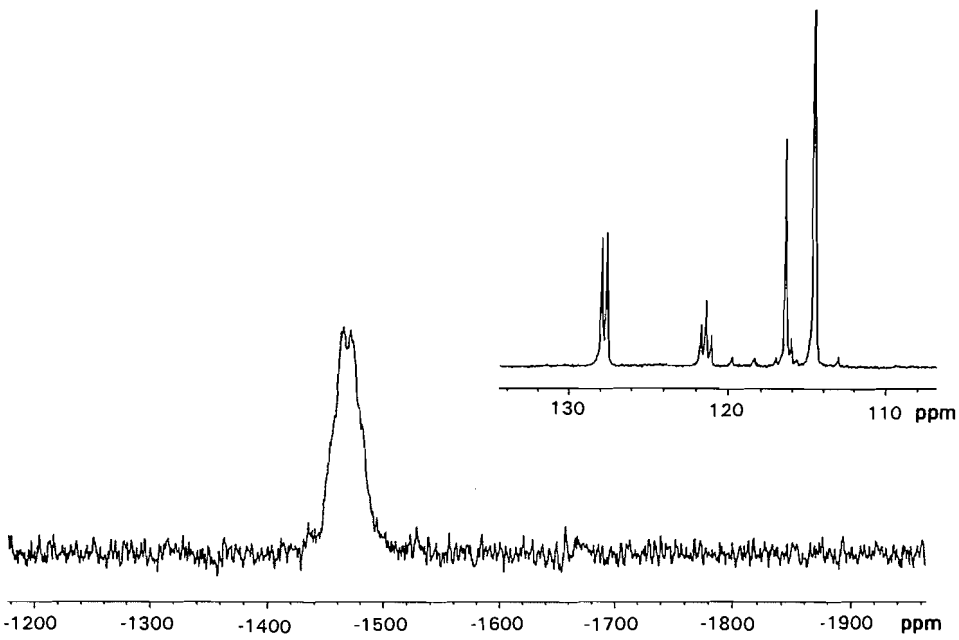

Table 1. ^{95}Mo NMR chemical shifts for molybdenum complexes of various P(III) ligands, $Mo(CO)_{6-n}(PY_3)_n$ (n = 1, 2, and 3) (in ppm).[a]

[a]In this table, 70% of δ(^{95}Mo) values were recorded in this work, including several remeasurements; others are taken from ref. 8*a* unless specifically noted. For the remeasurements, the literature values have always been taken instead of the values recorded here unless the former have been proved to be incorrect.

[b]Tolman cone angles from ref. 1*a*.

[c]C_{4v}, C_{2v}, and C_{3v} represent the ideal geometries for penta-, *cis*-L_2-tetra-, and *fac*-L_3-tri-carbonyl complexes.

[d]NR denotes no reaction was observed according to ^{31}P and ^{95}Mo NMR; or fast decomposition occurred even if the reaction took place, such as PCy_3 substitution from $Mo(CO)_4$NBD or $Mo(CO)_3$CHT precursors.

[e]The values in parentheses are estimated because no literature data were available.

[f]1,2-Dichloroethane has to be used for refluxing due to the low reaction rate at 40° in CH_2Cl_2.

[g]Taken from ref. 12*b*; a same value of −1825 ppm with ^1J(M–P) = 129 Hz was recorded here.

Table 1 (*concluded*).

[h]A value of −1765 ppm was reported for *trans*-$Mo(CO)_4[P(Cy)_3]_2$ in ref. 12*c*.

[i]Another broader unresolved resonance at −1706 ppm ($W_{1/2}$ = 7810 Hz) was observed; so the assignment might be either signal.

[j]This value is taken for *mer*-3 (see text) and is not used in the correlation analyses.

[k]*cis*-$Mo(CO)_4[P(Ph)_2Cy]_2$ is insoluble in the organic solvents tried.

[l]See ref. 7*a* for $P(X\text{-}Ph)_3$ derivatives.

[m]Taken from ref. 12*b*.

[n]−1655 ppm with ^1J(M–P) = 139 Hz was observed here.

[o]Taken from ref. 12*d*; −1412 ppm with ^1J(M–P) = 125 Hz and $W_{1/2}$ = 14 Hz was recorded here.

[p]The same value of −1522 ppm with ^1J(M–P) = 161 Hz was recorded here.

[q]The same value of −1427 ppm with ^1J(M–P) = 128 Hz and $W_{1/2}$ = 15 Hz was measured here.

[r]5-PhDBP = 5-phenyldibenzophosphole.

[s]Taken from ref. 12*e*.

[t]The same value of −1791 ppm with ^1J(M–P) = 163 Hz was obtained here.

[u]Two quite different values of −1677 (^1J(M–P) = 161 Hz, $W_{1/2}$ = 30 Hz) and −1707 ppm (^1J(M–P) = 153 Hz, $W_{1/2}$ = 40 Hz) were reported in ref. 8*a*. The listed value of −1670 ppm with ^1J(M–P) = 142 Hz was recorded here.

[v]Taken from ref. 12*f*; the same value of −1456 ppm with ^1J(M–P) = 142 Hz was recorded here.

[w]Another same value of −1765 ppm with ^1J(M–P) = 129 Hz and $W_{1/2}$ = 26 Hz was reported in ref. 12*d*.

[x]Taken from ref. 12*c*.

[y]The same value of −1751 ppm with ^1J(M–P) = 229 Hz and $W_{1/2}$ = 50 Hz was recorded here. Reported ^1J(M–P) of 250 Hz in ref. 12*b* is too high (see text).

[z]Taken from ref. 12*f*.

[aa]The same value of −1610 ppm with ^1J(M–P) = 184 Hz and $W_{1/2}$ = 18 Hz was measured here.

[bb]The same value of −1721 ppm was recorded here.

[cc]The same value of −1860 ppm with ^1J(M–P) = 224 Hz and $W_{1/2}$ = 8 Hz was recorded here.

[dd]Taken from ref. 12*g* (see also ref. 7*c*).

[ee]Estimated value by extrapolation.

[ff]95° was proposed by refs. 1*a* and 12*h*.

$P(OPh)_3$ and $P(OMe)_3$ should be more diverging (splayed) rather than parallel because the greater bulk of $P(OPh)_3$ (128°) relative to $P(OMe)_3$ (107°) should cause a large separation between the values for the most congested f3 derivatives. Thus, the weaker bonding ability of $P(OPh)_3$ may not be determined solely by the steric effect. On the other hand, the $\delta(^{95}Mo)$ (−1728 ppm) for f3–$P(O\text{-}i\text{-}Pr)_3$ (note that $P(O\text{-}i\text{-}Pr)_3$ (130°) has a similar ligand cone angle to $P(OPh)_3$) appears at 55 ppm lower frequency from the value for f3–$P(OPh)_3$ and only 28 ppm higher frequency from the f3-$P(OMe)_3$ value. This suggests that if the steric parameters for $P(OPh)_3$ and $P(O\text{-}i\text{-}Pr)_3$ were not underestimated and overestimated, respectively, the weaker bonding ability or the extra deshielding effect of $P(OPh)_3$ could only be attributed to a weaker σ component ($pK_a = -2.0$). It must be pointed out that there have already been many observations indicating the weak bonding ability (4, 16, 19) of the $P(OPh)_3$ ligand even though the short Cr—P distance in $Cr(CO)_5(P(OPh)_3)$ is usually interpreted in terms of strong π-acceptor character (20) of this common ligand. It was also noted experimentally in this work that the substitution of pyridines from *fac*-$Mo(CO)_3(Py)_3$ by $P(OPh)_3$ is much more difficult than by $P(OMe)_3$ or ETPB.

The IR stretching frequencies for *trans* carbonyls of phosphite complexes are approximately the same, within experimental error, for each of the three geometries (see Table 3) except that the f3–$P(OPh)_3$ complex does have higher ν_{co} (and force constant) values. The observation of this anomalous effect for $P(OPh)_3$ is in agreement with the previous suggestion that the stretching frequency is more likely reflecting the weak σ component (7). Only the A_1(highest) mode is used here because of a higher precision (sharper line), the lack of ambiguity in its assignment, and its relation to (covering) all force constants. Taking into account the recording error of ν_{co}'s and the ambiguous assignments of the IR bands, one can see again that IR parameters are not as reliable as NMR chemical shift data for evaluation of ligand effects. Although most common phosphites are thought to be strong π-ligands, ^{95}Mo NMR spectrometry shows, consistent with the weaker M—$P(OPh)_3$ bonding (4, 16, 19), that $P(OPh)_3$ has some special electronic property different from other phosphites. Unfortunately, there previously was no structural information on a higher displaced phosphite–molybdenum compound available in the literature. The crystal structures of *cis*-$Mo(CO)_4(P(OPh)_3)_2$ and *fac*-$Mo(CO)_3(P(OPh)_3)_3$ were recently determined in our laboratory (22). The Mo—P bond distances (both are 2.44 Å) are much shorter than most known Mo—P bonds (ca. 2.54 Å). As concluded for M—PCl_3 bonding (7*c*), the short distance may be partially caused by the weak σ ability of $P(OPh)_3$, without the need to invoke strong π bonding to rationalize the bond shortening. The P-Mo-P bond angles are 90° in both cases, though the range is 82–94° in the *fac* complex, indicating the more significant steric distortion in the latter complex. Many authors (4*d–f*, 16*d*) also observed that the reactivity of $P(OPh)_3$ (θ = 128°) toward transition metals is even lower than that of PPh_3 (θ = 145°) even though the latter is bulkier and supposedly a weaker π-acceptor. For example, the rate of substitution for diamine (N–N) from *cis*-$W(CO)_4$(N–N) by $P(OPh)_3$ is lower than by PPh_3, and much lower than by ETPB

[a]The ^1J(M–P) values have the same reference sources as chemical shifts in Table 1, unless otherwise designated.

[b] ^1J(M–P) = 228 Hz was obtained from ^{95}Mo satellite lines in the ^{31}P NMR spectrum because the Mo-95 resonance was overlapped by a dominant and poorly resolved quartet for the *mer* isomer.

[c]PR = "poorly resolved," which means there is probably a larger error in these values.

[d]U = "unresolved."

[e] ^1J(M–P) of 142 Hz for both c2 and f3 derivatives of this ligand was recorded in this work, while two values of 161 Hz (ref. 12*i*) and 153 Hz (ref. 12*j*) have been reported.

[f] ^1J(M–P) of 229 Hz for c2 derivative was recorded in this work.

Fig. 5. ^{95}Mo NMR spectrum for molybdenum complexes of the $P(NMe_2)_3$ ligand recorded in dichloromethane. The sample is from an attempt to make the *fac*-$Mo(CO)_3L_3$ derivative: (*a*) *trans*-$Mo(CO)_4L_2$; (*b*) *cis*-$Mo(CO)_4L_2$; (*c*) *mer*-$Mo(CO)_3L_3$.

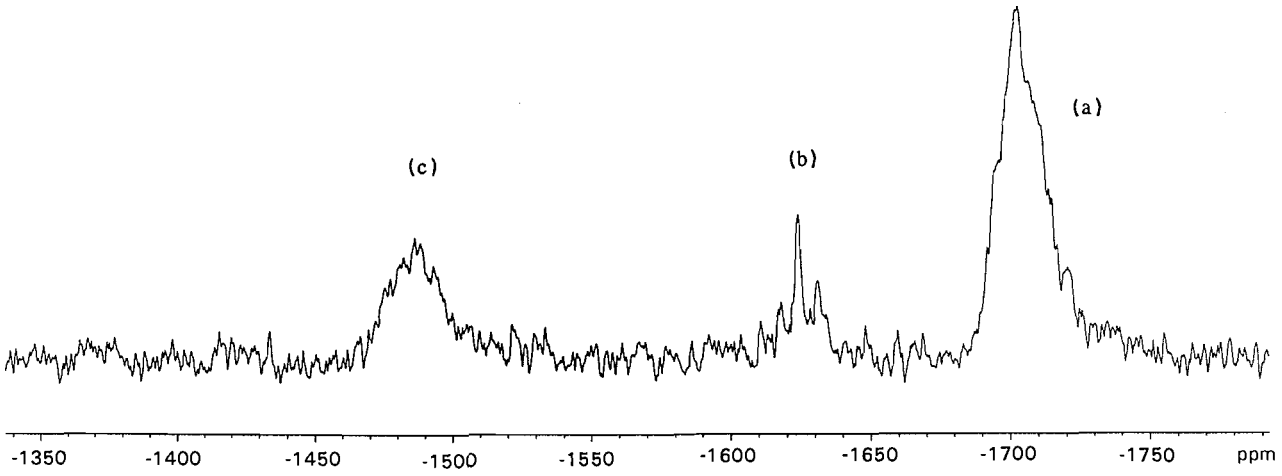

Fig. 6. An overview for the influence of ligand size on ^{95}Mo shielding with increasing degree of displacement (*n*). Py represents pyridine.

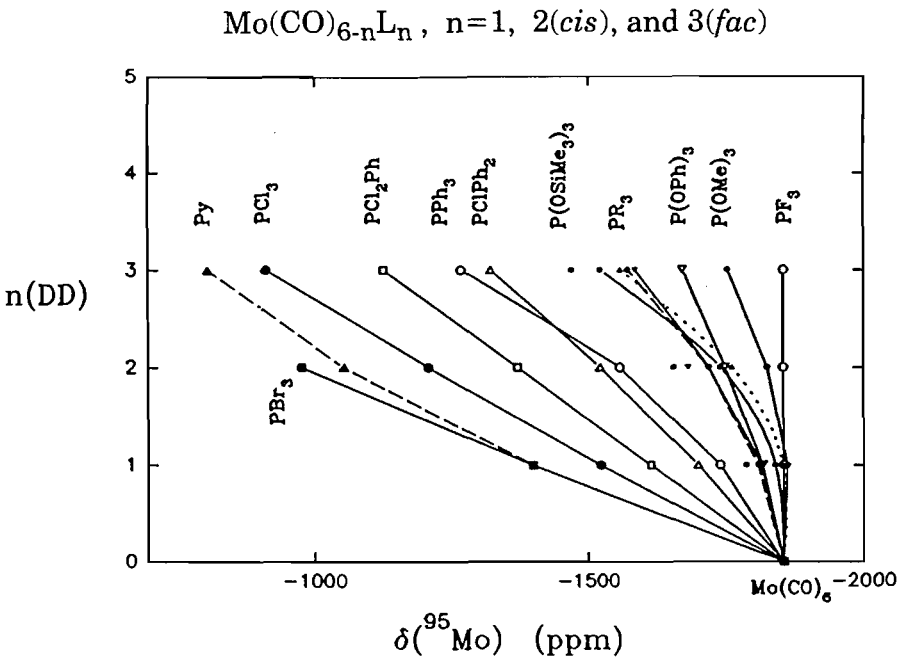

and $P(O\text{-}i\text{-}Pr)_3$. Thus, the weak σ character of $P(OPh)_3$ might play a dominant role in bonding (13). Although the ^{31}P NMR chemical shift is less sensitive than the corresponding ^{95}Mo shift to steric interaction (7*c*, 13) (see the text below), the smaller $\Delta\delta(^{31}P)$ value (16.6 ppm) for f3–$P(OPh)_3$ than that for c2–$P(OPh)_3$ (24.1 ppm), opposite to the trend of consistently increasing $\Delta\delta(^{31}P)$ values from m1 to f3 for the other three smaller ligands, indicates a detectable steric effect, at least in solution, active in the f3–$P(OPh)_3$ complex.

PF_3 gives rise to almost the same $\delta(^{95}Mo)$ value in $Mo(CO)_5L$ as ETPB and $P(OMe)_3$, but the CO stretching frequency for its m1 complex is 20 cm^{-1} higher than those for the other two analogues. Such a big difference is most likely due to a combination of the remarkably weak σ ability and strong π character of PF_3. As analyzed before (6), both strong π and weak σ character of a *trans* ligand enhance the infrared parameter of carbonyls. It is worth noting that the magnitude of ^1J(Mo—P) (where $^1J_{M-P}$ is normally assumed to be only

Table 3. Spectroscopic properties for Mo complexes of putatively strong π-acceptor ligands.[a]

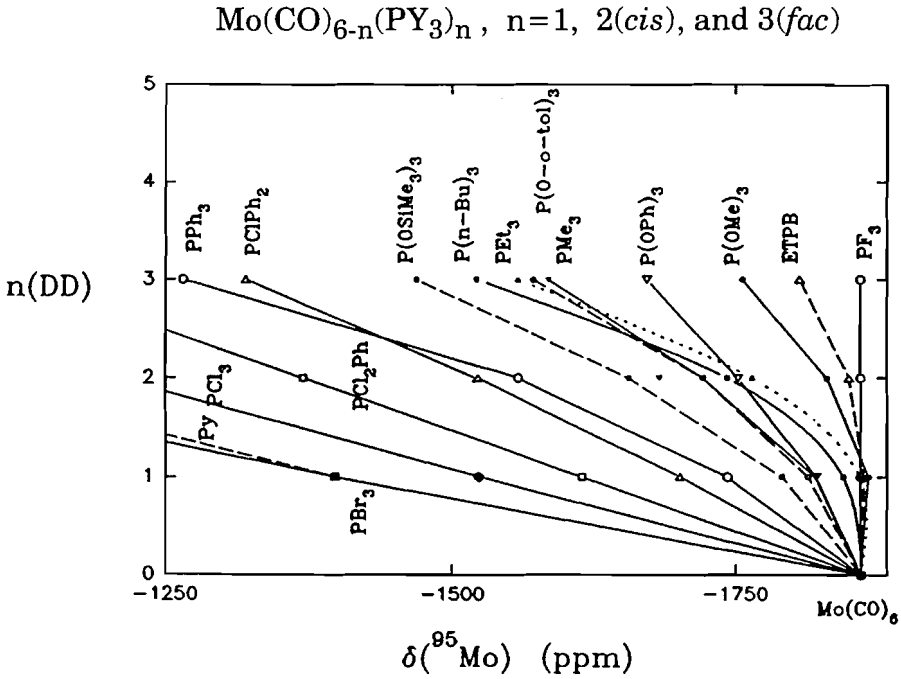
[b]m1 is mono, c2 is *cis*, f3 is *fac* isomer.

related to the *s* character) (6*a*, 7*b*) for different phosphorus ligands (23), is roughly correlated with that of ν_{co}, implying that these two parameters are somewhat similar in their correlations with the σ component.

(*b*) Strong σ- and (or) moderate π-ligands: PEt_3 (132°), $P(n\text{-}Bu)_3$ (132°), and PMe_3 (118°)

A noteworthy feature in Fig. 7 is the parallel $\delta(^{95}Mo)/n$ lines between PEt_3 and $P(n\text{-}Bu)_3$, and the overlapping lines between PMe_3 and $P(O\text{-}o\text{-}Tol)_3$. The dramatic shift of $\delta(^{95}Mo)$ for PEt_3 and $P(n\text{-}Bu)_3$ complexes to high frequency with higher DD starts even with their c2 derivatives, indicating that they might be bulkier than Tolman's estimation. There is no argument about the strong σ-donor ability of these two phosphines; probably they are the strongest ones among trivalent phosphorus ligands in complexes of octahedral geometry. (The stronger σ-donor ability of other extra bulky ligands such as $P(t\text{-}Bu)_3$ (pK_a = 11.4) and P(2,4,6-trimethoxy-Ph)$_3$ (pK_a = 11.2) (12*a*, 24) would only be exerted in much less sterically hindered situations.) It must be kept in mind, however, that strong electronic donation will always lead to magnetic shielding on the central metal nucleus through enhancement of LFSE (ΔE_σ) and expansion of *d* electrons. It is not yet clear at this point why $\delta(^{95}Mo)$ for m1–PEt_3 or m1–$P(n\text{-}Bu)_3$ occur on the shielding side by 38 ppm and 24 ppm, respectively, relative to m1–PMe_3, in spite of their similar pK_a values (8.69 and 8.43; 8.65 for PMe_3) and smaller cone angle for PMe_3. This anomaly might have its origin in the low proton affinity (PA) of PMe_3 in the gas phase (25). In other words, the high pK_a value of PMe_3 in aqueous solution may be overestimated due to solvation effects. If the σ ability of PMe_3 is truly lower than PPh_3, as argued by gas phase PA or gas phase IP, however, a great number of experimental observations such as stable M—PMe_3 bond strengths (16) are not easily explained. An answer to this anomaly is more likely related to the π ability of PMe_3 (6, 13, 26). The markedly high frequency shift of $\delta(^{95}Mo)$ for the f3 and c2 derivatives of PEt_3 and PBu_3 ligands can be attributed only to the steric interaction. Some researchers have estimated the cone angle of these two donors to be 142° (4*c*), 10° larger than the 132° originally calculated by Tolman (1*a*), based on their observation that the *trans*:*cis* ratio in the formation of $W(CO)_4L_2$ is much higher than expected for L = $P(n\text{-}Bu)_3$ or PEt_3. In the crystal structures of *cis*-$Mo(CO)_4L_2$ (L = PMe_3, PEt_3 and $P(n\text{-}Bu)_3$) determined in the early 1980s by F.A. Cotton et al. (27*a*), the M—P bond distances are 2.522(1), 2.544(4), and 2.552(8) Å, respectively; P-Mo-P bond angles are 97.54(4)°, 100.27(3)°, and 99.29(4)°, respectively. The differences have been ascribed to steric interactions. More notable is the conformation of PEt_3, and $P(n\text{-}Bu)_3$ in these complexes: within the same complex, the three β carbons of one phosphine are opened further along the P—C_α bonds while the three β carbons of the other phosphine tend to be closer. The smaller average C_α-P-C_α angle for PMe_3 is accounted for by its smaller bulk relative to those for PEt_3 and PBu_3. Meanwhile, the three β carbons of $P(CH_2CH_2CN)_3$ in $Mo(CO)_5L$ are opened (27*b*). This might mean that the "open" conformation is more energetically stable in the two free PEt_3 and $P(n\text{-}Bu)_3$ ligands and the closeness in highly displaced derivatives is the consequence of steric congestion. In fact, the anomalous steric effects of PEt_3 and PBu_3 have been noted in many other related studies (4*a*, 17*g*, 28). This steric feature of PBu_3 may have led to its initial designation by QALE (Quantitative Analysis of Ligand Effects) as a "π donor" (17*a*). Attempts to obtain crystals suitable for X-ray analysis for *fac*-

Fig. 7. A locally enlarged picture for the influence of ligand size on ^{95}Mo shielding with increasing degree of displacement (n).



$Mo(CO)_3(PR_3)_3$ of any of the three trialkylphosphines are still underway. It can be anticipated that the much more strained structural features, e.g., longer Mo—P bond distance, smaller C_α-P-C_α angles, and compressed β carbon orientations, or much lower Mo—P bond strengths, will be found more likely in *fac*-PEt_3 and *fac*-P(*n*-Bu)$_3$ complexes than in the *fac*-PMe_3 analogue. Fortunately, the molecular structure for *fac*-$Cr(CO)_3(PEt_3)_3$ has been reported (29). The longer Cr—P bond distance (2.429(8) Å) compared to other known Cr—P lengths suggests a weakening of the Cr—P bond due to steric interactions between the adjacent PEt_3 ligands. The shorter Cr—C_{trans} bond (1.829(8) Å) and longer O—C_{trans} bond can be associated with strong d_π–π^*(CO) back-donation. It is noted that the authors suggested that PEt_3 behaves essentially as a σ-donor ligand, with little or no π-acceptor capacity. The average P-Cr-P angle of 95.77(5)° is smaller than the P-Mo-P angle of 97.54(5)° in *cis*-$Mo(CO)_4(PMe_3)_2$ and much smaller than the P-Mo-P angle of 100.27(5)° in *cis*-$Mo(CO)_4(PEt_3)_2$ (12*h*). In addition to the smaller size of Cr relative to the Mo atom, this may also suggest that in f3 geometry a cone space of 180° (vide infra) can only accommodate three ligands having ca. 95° cone angle without steric interaction. The steric repulsion among nine alkyl groups forces their reorientation toward the three CO's, which, on the other hand, resist deformation because of three strong M—CO bonds.

The ν_{co} values for the three alkylphosphine derivatives in m1, c2, and f3 geometries are the same within experimental error (see Table 4). For both PEt_3 and P(*n*-Bu)$_3$ ligands, however, $\Delta\delta(^{31}P)$ and ^1J(Mo–P) values decrease greatly in the c2 and f3 derivatives. In contrast, only a small change occurs for the f3 geometry in $\Delta\delta(^{31}P)$, with a slight reduction in ^1J(Mo–P), for L = PMe_3. These decreases are most likely related, at least partly, to the greater steric bulk of the former two ligands (also discussed in refs. 7*a*–*c*, 13).

The bulky phosphite P(O-*o*-Tol)$_3$ (141°) and small PMe_3 (118°) ligands exhibit almost identical overall ^{95}Mo shielding patterns (−1818 vs. −1812 for m1, −1722 vs. −1722 for c2, and −1586 vs. −1572 for f3) despite a difference of 23° in their cone angles. Phosphite ligands are usually thought to be strong π-acceptors and the donor:acceptor ratio is much lower than for trimethylphosphine, which is commonly thought to be a strong σ-donor. The π ability of PMe_3 is still being debated (26). Why are these two ligands so similar in ^{95}Mo shielding? First, the increased $\Delta\delta(^{95}Mo)$ values between P(O-*o*-Tol)$_3$ and $P(OPh)_3$ from m1 to f3 (7 ppm, 30 ppm, and 101 ppm) can be attributed unambiguously to steric factors in the high DD derivatives for the former (see Fig. 7). Also, the consistently greater deshielding behaviour of $P(OPh)_3$ in all the three geometries (m1, c2, and f3) compared to $P(OMe)_3$ and P(O-i-Pr)$_3$ has been attributed to the weaker σ ability of $P(OPh)_3$ (see above). Thus, the greater ^{95}Mo shielding observed for $P(OPh)_3$ than for PMe_3 might be ascribed to a better π ability for $P(OPh)_3$. But as a strong-and-small σ donor, as well as a possible modest π-acceptor, PMe_3 ligand might not have an up to 87 ppm greater deshielding effect compared with bulkier $P(OPh)_3$ especially in the most congested f3 derivatives. If the π ability of $P(OPh)_3$ is considered to be the dominant factor, then the differences in m1 geometry should also be large and comparable to those for c2 or f3 geometries. Therefore, the anomalous deshielding behaviour of PMe_3 and the similarity of PMe_3 to P(O-*o*-Tol)$_3$ are more likely caused by two factors, i.e., either a practically larger cone angle (ca.125°–130°) or a weaker π character for PMe_3. Certainly, the practical π ability of P(O-*o*-Tol)$_3$ is smaller than that of $P(OPh)_3$, due to steric hindrance.

It is noted again that no differences are observed in ν_{co} and force constant values for the above three alkylphosphine complexes in each geometry, as pointed out earlier (Table

Table 4. Spectroscopic properties for Mo complexes of $P(alkyl)_3$ ligands.[a]

4). Moreover, ν_{co} and k values for the $P(O\text{-}o\text{-}Tol)_3$ complexes are remarkably greater than those for the alkylphosphine analogues, indicating the sensitive dependence of CO IR parameters on the σ component of the P(III) ligands.

(*c*) Extra bulky ligands ($\theta > 145°$)

As seen in the experimental section and the data in Tables 1–3, the bulkier the ligand, the more difficult is the multiple displacement, and the more the central molybdenum nucleus is deshielded. Fig. 8 presents many $\delta(^{95}Mo)/n$ plots for Mo complexes of extra bulky ligands. A significant deshielding trend, even in m1 derivatives, can be seen relative to the corresponding less bulky analogues (see Figs. 6 and 7). A dramatic shifting of $\delta(^{95}Mo)$ toward higher frequency with increased degree of displacement, n (such as for f3–PPh_2Bz (152°) and f3-$P(OSiMe_3)_3$ (172°)), is observed. Most f3 complexes of extra bulky phosphines with cone angles greater than 160° could not be synthesized except in the case of $P(OSiMe_3)_3$. The cone angle value for this ligand has not been reported, and a value of 172° (overestimated?) from the analogous phosphite, $P(O\text{-}t\text{-}Bu)_3$, is assumed in Fig. 8. Quite surprisingly, the crowded *fac*-$Mo(CO)_3[P(OSiMe_3)_3]_3$ complex, as well as the *mer* isomer, have been successfully generated in situ, according to ^{31}P NMR (see Fig. 4).

Several points can be summarized from Fig. 8:

(*i*) The $\delta(^{95}Mo)$ for m1–PCy_3 occurs at the most shielded position while the $\delta(^{95}Mo)$ for m1–$P(t\text{-}Bu)_3$ at the most deshielded position in defining the extremes for m1 complexes of a dozen extra bulky ligands. The huge difference in ^{95}Mo shielding observed between $Mo(CO)_5(P(t\text{-}Bu)_3)$ and $Mo(CO)_5(PCy_3)$ is important because these two ligands are both bulky and are both strong bases. There seems to be a very small steric influence on $\delta(^{95}Mo)$ in the m1–PCy_3 compound in spite of its large cone angle (170°). Many crystallographic studies have indicated a smaller cone angle (157°–168°) for the PCy_3 ligand in practice due to a suitable orientation to allow the intermeshing of the cyclohexyl groups and compression into each other (30). It has been pointed out many times by others that cyclohexyl ligands adopt stable configurations, which corresponds to a considerable interpenetration of their rings. Despite many attempts, the synthesis of the *cis* isomer of $Mo(CO)_4(PCy_3)_2$ has only recently been reported (10*d*, 31). The X-ray analyses shows extreme steric hindrance, with the Mo—P distance being elongated to 2.654(4) Å (31*d*). The complex $Pt(PCy_3)_3$ has been studied by X-ray crystallography (30*a*). A steric space of 240° by 180° for two P ligands in $Pt(PCy_3)_3$ is much larger than the 180° (estimated by 270-2(45), see below for the thresholds) by 90° measured for two P ligands in *cis*-$M(CO)_4L_2$. In contrast, the other bulky ligand, $P(t\text{-}Bu)_3$ (182°), also a strong base (pK_a 11.40, pK_a 9.70 for PCy_3), brings the $\delta(^{95}Mo)$ for its m1 complex 117 ppm to high frequency. This remarkable deshielding behaviour of $P(t\text{-}Bu)_3$ must be related to the steric rigidity of this ligand. As a matter of fact, PCy_3 is very similar to other alkylphosphines in shielding behaviour in their $M(CO)_5L$ analogues ($\delta(^{95}Mo)$, m1): −1829 ppm for $P(CH_2CH_2CN)_3$, −1842 ppm for $P(n\text{-}Bu)_3$, −1856 ppm for PEt_3, −1818 ppm for PMe_3, and −1825 ppm for PCy_3); the basicities for other alkylphosphines are only one pK_a unit lower than for PCy_3 (17). Thus, if there are considerable steric differences in $Mo(CO)_5(PCy_3)$ and $Mo(CO)_5(P(t\text{-}Bu)_3)$, the former would be expected to be more stable than the latter.

(*ii*) Although tribenzylphosphine PBz_3 ($pK_a = 6.0$, $\theta = 165°$) is larger than $P(NMe_2)_3$ (pK_a not measured, $\theta = 157°$), it promotes a 26 ppm greater shielding in c2 derivatives than does the latter. Possible reasons for the greater deshielding effect of

Table 5. $\delta(^{95}Mo)$ and $\delta(^{31}P)$ data for Mo complexes of some bulky phosphorus ligands.[a]

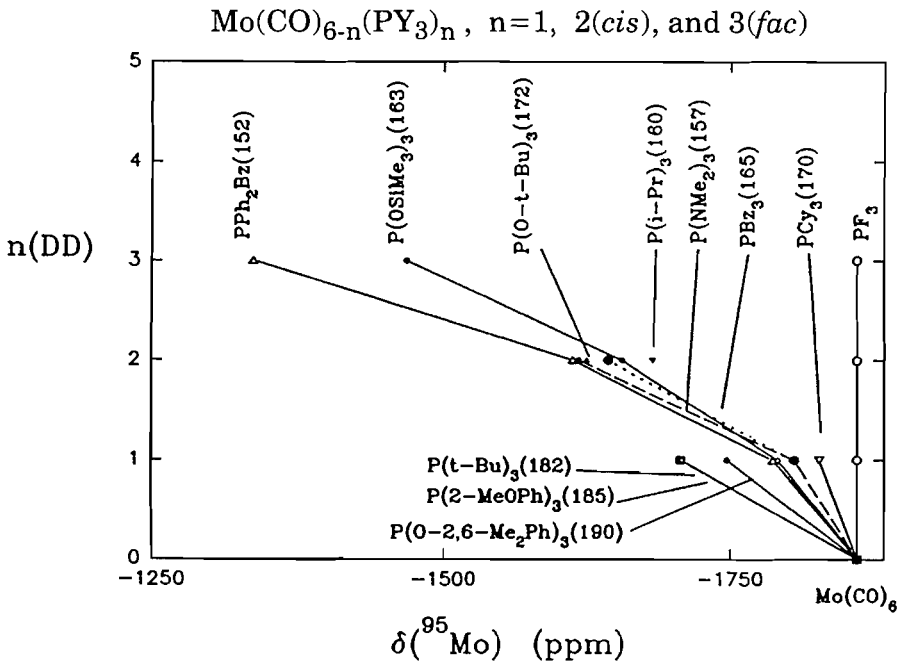
[a]See ref. 21 for the sources of $\Delta\delta(^{31}P)$ NMR information.

Fig. 8. Extra bulky effects of P(III) ligands on Mo shielding with increasing degrees of displacement (*n*).



the less bulky $P(NMe_2)_3$ (than PBz_3 and $P(i\text{-}Pr)_3$) are that the aminophosphine might have a weaker π-acceptor ability or that it has a more rigid molecular framework.

(*iii*) $P(2\text{-}MeOPh)_3$ (θ = 185°, estimated) shows a similar overall deshielding effect compared to $P(t\text{-}Bu)_3$ (θ = 182°) in its m1 complex. However, the $\delta(^{95}Mo)$ value for the even more sterically crowded m1–$P(O\text{-}2,6\text{-}Me_2Ph)_3$ (θ = 190° for L) lies at 30 ppm to lower frequency, implying that there is greater Mo—P π interaction in this phosphite complex.

(*iv*) The most deshielded value in Fig. 8 is observed for f3–PPh_2Bz. The steeper rise in $\delta(^{95}Mo)$ from m1 to f3 (double $\Delta\delta(^{95}Mo)$'s) for this ligand illustrates, once more, the significant contribution of steric bulk to the paramagnetic shielding term. It should be stressed here that if their cone angles are accurate, a 70 ppm (δ = −1265 ppm) deshielding for the less bulky PPh_3 (145°) in its f3 derivative compared with f3-PPh_2Bz (152°) is most likely due to the weaker π and (or) weaker σ ability of PPh_3. Similarly, the shielding power of the larger $P(OSiMe_3)_3$ (172°) in its highly displaced derivatives compared to PPh_2Bz (152°) can be attributed to the greater π-character of the former.

Table 5 lists the spectroscopic data for the Mo complexes of some extra bulky ligands (θ > 145°). It can be seen that all those complexes with phosphine ligands have large ^{31}P coordination chemical shifts (30-40 ppm), indicating a strong σ-donating property. In contrast, $\Delta\delta(^{31}P)$ values for phosphite derivatives are very small, reflecting fewer *sp* electrons available on phosphorus for σ-bonding. Such a small coordination

Fig. 9. Correlation of $\delta(^{95}Mo)$ for $Mo(CO)_5(PY_3)$ with ligand cone angle, θ. The phosphites complexes are labelled by square double points.

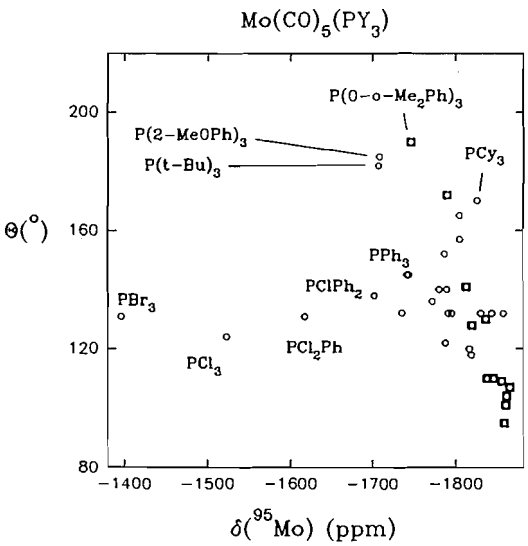


Fig. 10. Correlation of $\delta(^{95}Mo)$ for *cis*-$Mo(CO)_4(PY_3)_2$ with ligand cone angle, θ. The phosphites complexes are labelled by square double points.

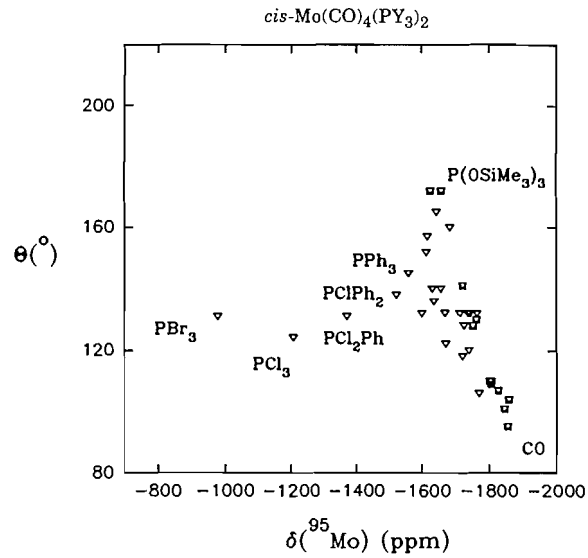


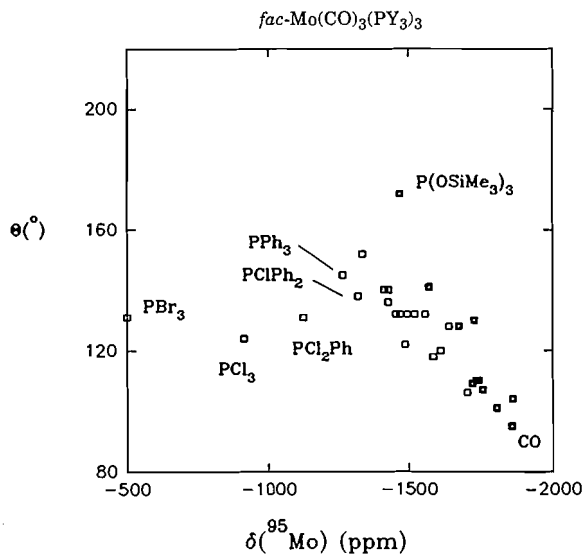
chemical shift for these bulky phosphite complexes is also due partially to the decreased π interaction (which should shift $\delta(^{31}P)$ to high frequency (7*c*)) under the high steric conditions. ^1J(Mo–P) data (Table 2) cannot provide firm information about the steric effects because the coupling constant is dominantly controlled by the electronegativity of substituent groups or *s* character (7*c*) and (or) the (small) variation of M—P bond distance. However, its magnitude does decrease when a significant steric requirement exists, such as in the f3–PPh_3 or f3–PPh_2R cases. Although some ^1J(Mo–P) values appear to get larger "abnormally" in quite bulky phosphite f3 derivatives such as the f3–$P(OSiMe_3)_3$ or f3–P(O-2-Tol)$_3$ complexes, these anomalous values may result from measurement error due to very poor resolution of the relevant resonances.

Why do *mer*-3 isomers have δ_M values quite close to those for corresponding *fac*-3 analogues? Also, the resonance for any *trans*-$M(CO)_4L_2$ is close to that for the *cis* isomer. In a *mer*-3 isomer, the steric strain is usually thought to be alleviated. Due to the steric contribution to deshielding, the *mer*-3 or *trans*-2 isomers should resonate at much lower frequency than their *fac*-3 and *cis*-2 analogues because of the lessened steric repulsion in *mer*-3 and *trans*-2 isomers. What makes the $\Delta\delta_M$ between *fac*/*mer* or *cis*/*trans* so small is possibly attributable to (*a*) the nearly invariable paramagnetic circulation density, which is reflected by the close E° between the t2 and c2 isomers (7*c*, 17*g*–*i*) or between the f3 and m3 isomers (12*f*, 17*h*–*i*); (*b*) the released but still existing steric effects, because only a free cone space of ca. 95° (see below) is available for each L.

Correlations of $\delta(^{95}Mo)$ with ligand steric parameters

To analyze, quantitatively, the dependence of ^{95}Mo magnetic shielding on the size of donating ligands, correlations of $\delta(^{95}Mo)$ for the three sets (m1, c2, and f3) of derivatives with Tolman cone angles were examined (Figs. 9–11). It can be seen very clearly that the magnetic deshielding trend or δ_M is proportional to both the steric size of phosphorus ligands in

Fig. 11. Correlation of $\delta(^{95}Mo)$ for *fac*-$Mo(CO)_3(PY_3)_3$ with ligand cone angle, θ. The phosphite complexes are labelled by square double points.



each set of derivatives and the degree of displacement, increasing from m1 (Fig. 9), c2 (Fig. 10) to f3 (Fig. 11).

Except for the chloro- or bromo-phosphorus ligands, the deshielding magnitude increases generally with the cone angles in each of the three series of complexes, and the rate of this increase is faster for *fac*-$Mo(CO)_3L_3$ than for *cis*-$Mo(CO)_4L_2$, and lowest for the $Mo(CO)_5L$ series in which the steric requirement is smallest. This offers firm evidence for an important steric contribution to δ_M (see also ref. 7). Examining Figs. 9–11 closely, one can delineate many significant features, which are summarized below. Again it must be kept in

mind whenever analyzing these correlations that (*i*) the values of $\delta(^{95}Mo)$ are much more accurate (*the experimental error is definitely smaller than the dimension of plot points!*) than other measures including steric bulk parameters cited here; and (*ii*) the σ/π electronic components definitely contribute to the magnetic shielding, being comparable to steric effects for the least congested structures.

(*a*) All the δ/θ points seem to fall in a fan area. The *phosphites* represented by double points (square) form a linear trend, indicating two important features. First, the π character of phosphites tends to stabilize Mo—P bonds, and so the ^{95}Mo nucleus resonates at lower frequency with respect to other complexes of isosteric ligands. Second, the roughly linear increase in deshielding on the Mo occurring for phosphite complexes with increased ligand cone angles is evidently a direct result of steric interaction. The strong interligand repulsion makes the Mo—P bonds longer and weaker for these good π-acceptor complexes, hence leading to a decrease in ΔE and a shrinking of the metal 4*d* orbitals. It should be emphasized that the primary reason for the above deshielding trend in phosphite complexes is a steric requirement, resulting in an indirect weakening of π ability in all of the three displacement sets. Although the basicities of various phosphites are quite different (pK_a varies from -2 to 4.5), they apparently make only a small contribution to the roughly linear trend. The steric interaction contributes to the $\delta(^{95}Mo)$ almost linearly even in $Mo(CO)_5L$ complexes of phosphites, although there is usually supposed to be no serious steric congestion in a $M(CO)_5L$ complex (more detailed discussion below).

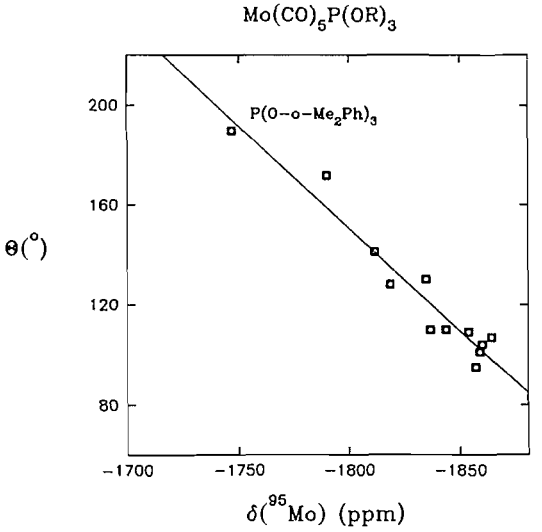
(*b*) The $\delta(^{95}Mo)$ chemical shifts for phosphine complexes are scattered over the entire fan area in all three sets of derivatives, as shown by the single open points in Figs. 9–11, instead of giving a linear pattern. The phosphines display an irregular and complicated shielding trend. However, a seemingly linear correlation between δ_M and θ for the f3 series in Fig. 11 reflects, strongly, the increasingly important role that steric factors play in paramagnetic shielding of ^{95}Mo in these most crowded derivatives. The increased irregularity of δ_M/θ plots for *cis*-$Mo(CO)_4L_2$, and particularly for the $Mo(CO)_5L$ derivatives, is undoubtedly an indication of a complicated combination of three factors: steric effects, and σ and π electronic effects.

(*c*) The weak σ and weak π effects in PX_3 (X = Cl, Br) complexes: the electronic and steric effects of the PX_3 ligands have been discussed in detail in a previous paper (*7b*). The three δ_M/θ correlations here indicate further that phosphorus trihalide ligands are quite different from other P(III) ligands. Actually a linear trend of δ_M/θ for PF_3, PCl_3, and PBr_3 exists for each of the three derivatives, as can be seen from Figs. 9–11. PF_3 happens to join the class of regular P(III) ligands that are good π-acceptors.

(*d*) As noted in Fig. 9, (*i*) the δ_M/θ correlation shows a more irregular relationship for m1-phosphines and slightly poor linearity for phosphite complexes (mainly due to several points for very small ligands at the bottom); and (*ii*) many phosphines such as PCy_3, PBz_3, $P(NMe_2)_3$, PEt_3, and $P(n\text{-}Bu)_3$ exhibit an unusually stronger shielding ability than their isosteric phosphites.

As to the above point (*i*), the more irregular $\delta(^{95}Mo)/\theta$ correlation for m1–phosphine complexes compared with those for c2's and f3's might be attributed to the minimum steric effects

Fig. 12. Correlation of $\delta(^{95}Mo)$ for $Mo(CO)_5(P(OR)_3)$ with respective ligand cone angles, θ.



and the variations in (not necessarily dominant) electronic effects, as pointed out previously. It is well known that the phosphine ligands PRR_1R_2 with various R groups have quite different σ and π electronic properties, which have been described by pK_a, Tolman's electronic parameter, χ_i, and electrochemical parameters. The electronic effects of phosphines are much more complex than those for phosphites and vary greatly from one to another. Usually the σ/π ratio for this class of ligands is larger than for phosphites, as concluded by a number of authors. However, whether the σ character is dominant and *whether the π character is actually weak for these phosphines* are not yet clear. Nevertheless, the more irregular correlation in Fig. 12 is simply an indication of increasingly important electronic effects with respect to the steric effects in m1 derivatives.

As to the above point (*ii*), it can be noted that so-called "strong" alkylphosphines are just strong σ-donors. Quite importantly, three phosphines, PEt_3, $P(n\text{-}Bu)_3$, and $P(CH_2CH_2CN)_3$, of the same size (132°) shield the Mo centre better than two isosteric phosphites, $P(OPh)_3$ (128°) and P(O-i-Pr)$_3$ (132°), which are putatively good π-acceptors. There should be no significant differences in steric interaction in the $M(CO)_5L$ geometry for these five ligands, which have virtually the same fairly small cone angles. There are two possible reasons for such a shielding difference. The former three phosphines may *also be good π-acceptors* and the synergic effect operates. Alternatively, the π ability of phosphites may be reduced seriously if their bulkiness exceeds a certain threshold, e.g., $\theta = 128°$ (?). A quantitative separation of these contributing σ and π electronic effects first needs to filter out the steric component.

Semiquantitative estimation of steric bulkiness

According to the above qualitative discussion and cited X-ray results, it is believed that intramolecular steric interactions in c2 and f3 geometries are important. In m1 derivatives, the steric effect can also be observed and estimated, as illustrated by the double points in Fig. 9, but with greater error. Three roughly linear relationships between $\delta(^{95}Mo)$ for phosphite complexes and θ are presented in Figs. 12–14 and eq. [2],

[a]Tolman cone angle taken from ref. 1*a*.

Fig. 13. Correlation of $\delta(^{95}Mo)$ for *cis*-$Mo(CO)_4(P(OR)_3)_2$ with respective ligand cone angles, θ.

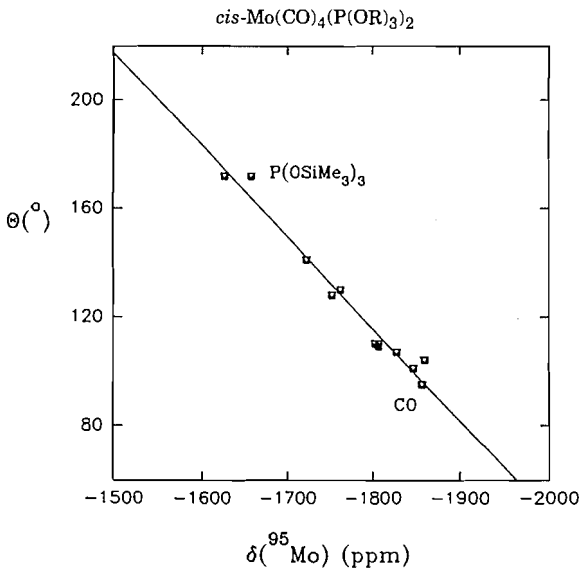

Fig. 14. Correlation of $\delta(^{95}Mo)$ for *fac*-$Mo(CO)_3(P(OR)_3)_3$ with respective ligand cone angles, θ.

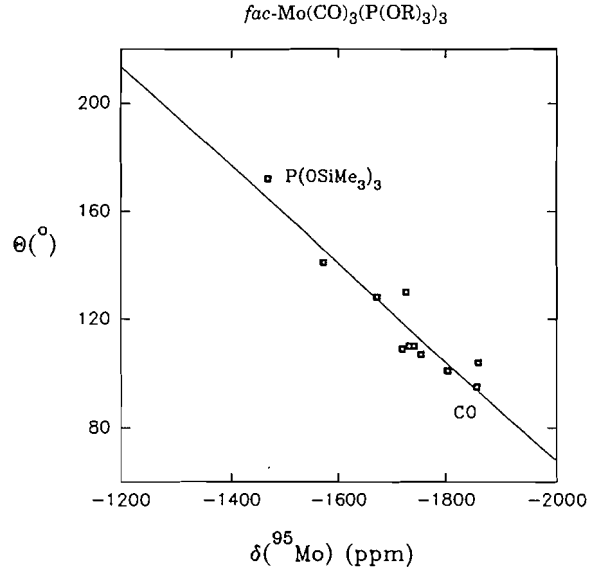

allowing for an approximate re-estimation of the steric parameters for phosphites.

[2] $\delta(^{95}Mo) = A\theta + B$

[2*a*] m1: $A = 1.14$, $B = -1974$; ($r = 0.968$, $N = 12$)

[2*b*] c2: $A = 2.86$, $B = -2130$; ($r = 0.986$, $N = 12$)

[2*c*] f3: $A = 4.90$, $B = -2302$; ($r = 0.945$, $N = 11$)

Table 6 lists many θ_s (steric size estimated by metal shielding) values for phosphites obtained by a linear analysis, as well as the original Tolman cone angles for the sake of comparison. As an experimentally derived value, θ_s will be a genuine (but approximate since it is combined with unisolated electronic effects) measure of interligand repulsion in pseudo-O_h geometry. If the electronic effects could be separated, then it should be a characteristic measure of both stable conformation and the interpenetration of ligands in solution.

An unexpected but important observation is that even for $Mo(CO)_5PY_3$ complexes, ^{95}Mo shielding has a roughly linear dependence on the size of phosphite ligands (Fig. 12). In agreement with the estimation by Cotton et al. (12*h*) and Tolman (1*a*), the cone angle for the small linear molecule CO is derived by extrapolation to be ca. 95° in *cis*-$Mo(CO)_4L_2$ (see the bottom line of Table 6 for relevant values). This value is consonant with the above observation of steric interaction existing in m1 derivatives; that is, *the maximum cone angle for an incoming ligand without interligand repulsion occurring is only ca. 95°*.

Conclusions

1. An analysis of $\delta(^{95}Mo)$ NMR values for a wide range of $Mo(CO)_{6-n}(PY_3)_n$ complexes indicates that steric effects play

an unexpectedly important role in the paramagnetic shielding terms. This cooperating contribution that causes deshielding has even been observed in the least crowded $M(CO)_5(PY_3)$ complexes. A detailed correlation analysis shows that the free cone space to accommodate an incoming ligand is equal to that estimated for CO itself in $Mo(CO)_{6-n}(PY_3)_n$ (n = 1–3) derivatives.

2. Three linear dependencies of $\delta(^{95}Mo)$ on phosphite cone angles, θ, have been observed, including even one for the m1 series. It can be inferred that the steric requirement reduces the commonly accepted π ability of phosphites by extending or weakening the M—P bonds, making $\delta(^{95}Mo)$ positions move toward lower field. The linearity of these correlations suggests that the σ component in phosphite bonding is relatively less important. Based on these linear correlations, a new set of more practical steric measures of phosphites were estimated.

In situ FTIR studies of 4-cyanopyridine adsorption at the Au(111) electrode

A.C. Chen, S.G. Sun, D.F. Yang, B. Pettinger, and J. Lipkowski

Abstract: In situ electromodulated reflectance Fourier transform infrared (FTIR) spectroscopy has been employed to study the adsorption of 4-cyanopyridine (4-CNPy) at an Au(111) electrode surface. The vibrational spectra have been used to study (*i*) the dependence of the band intensity on the surface coverage, (*ii*) the character of surface coordination, and (*iii*) the stability of adsorbed 4-CNPy molecules. It has been observed that the vibrational bands in the spectra acquired in the electroreflection experiment are significantly broader than the corresponding spectra acquired in a transmission cell. Some weaker bands seen in the spectra recorded in transmission were not observed in the electroreflectance experiment. The electroreflectance spectra were dominated by the two ring deformation bands observed at 1416 cm^{-1} and 1554 cm^{-1}. The intensities of these bands correlated well with the surface concentrations of 4-CNPy molecules determined from independent electrochemical studies. The integrated absorption intensities of the bands recorded in the electroreflection experiments were larger by a factor of five than the absorption intensities measured in the transmission cell. This indicates that the electric field of the photon acting on a molecule, present in front of the gold electrode, is significantly enhanced by reflection from the electrode. The infrared experiments suggest that at positive potentials the 4-CNPy molecules are coordinated to the metal surface through the nitrogen atom of the aromatic ring. The 4-CNPy molecules are oxidized at the Au electrode at potentials higher than 0.6 V (SCE) and are reduced to form $(4\text{-CNPy})^{-\bullet}$ ion at potentials lower than −1.1 V (SCE).

Key words: adsorption, infrared spectroscopy, 4-cyanopyridine, gold electrode.

Résumé : On a utilisé la spectroscopie infrarouge avec transformation de Fourier et réflectance électromodulée in situ pour étudier l'adsorption de la 4-cyanopyridine (4-CNPy) à la surface d'une électrode d'or(111). On fait appel aux spectres de vibration pour étudier : (*i*) l'influence du recouvrement de la surface sur l'intensité de la bande, (*ii*) le caractère de la coordination de la surface et (*iii*) la stabilité des molécules de 4-CNPy adsorbées. On a observé que les bandes de vibration dans les spectres enregistrés dans l'expérience d'électroréflexion sont de façon significative plus larges que celles des spectres enregistrés dans les cellules de transmission. Quelques bandes plus faibles apparaissant dans les spectres entregistrés par transmission n'apparaissent pas dans l'expérience d'électroréflectance. Dans les spectres d'électroréflectance on observe deux bandes importantes de déformations de cycle à 1416 cm^{-1} et à 1554 cm^{-1}. Les intensités de ces bandes correspondent bien avec les concentrations de surface des molécules de 4-CNPy déterminées à partir des études électrochimiques indépendantes. Les intensités d'absorption intégrées enregistrées dans l'expérience d'électroréflectance sont cinq fois plus élevées que les intensités d'absorption mesurées dans la cellule de transmission. Ceci indique que le champ électrique du photon agissant sur une molécule, présente en face de l'électrode d'or, est renforcé de façon significative par la réflexion à partir de l'électrode. Les expériences réalisées dans l'infrarouge suggèrent qu'à des potentiels positifs, les molécules de 4-CNPy sont coordonnées à la surface du métal via l'atome d'azote du cycle aromatique. Les molécules de 4-CNPy sont oxydées à l'électrode d'or à des potentiels plus élevés que 0,6 V (SCE) et sont réduites pour former l'ion $4\text{-CNPy}^{-\bullet}$ à des potentiels inférieurs à −1,1 V (SCE).

Mots clés : adsorption, spectroscopie infrarouge, 4-cyanopyridine, électrode d'or.

1. Introduction

FTIR spectroscopy is a powerful in situ technique to study electrified interfaces (1, 2). It has been used to identify intermediates and products of electrocatalytic oxidation of small organic molecules (3, 4). The electric field of the *s*-polarized IR photon has a zero strength at metal surfaces and hence the adsorbed molecules are optically inactive in this polarization. In contrast, the field has a nonzero strength in the solution and the molecules present in the solution are IR active for *s*-polarized radiation. Polarization-resolved IR spectroscopy has therefore been used to determine whether the intermediate (or product) of these reactions is an adsorbed or solution species (5–7). Finally, the surface selection rules of FTIR spectroscopy have been used to study the orientation of molecules adsorbed on the metal surface; for example, difluorobenzene at a polycrystalline platinum (8), isoquinoline (9) and flavine adenosine (10) at a mercury, and acetonitrile (11) at a gold electrode. Most of the past in situ FTIR studies were concerned with either the identification of species generated at the electrode surface or the determination of the character of their surface coordination. Less work has been done to develop FTIR spectroscopy as a tool for quantitative analysis of adsorbed species that could provide information about the composition of the interfacial region.

In this work, we will employ in situ FTIR spectroscopy to investigate adsorption of 4-caynopyridine (4-CNPy) at the Au(111) electrode surface. This study constitutes one part of a broader project the objective of which is to describe coordination of organic molecules to metal electrodes. The 4-CNPy was selected for the present study because we wanted to evaluate the relative strength of the surface coordination of this organic molecule through the CN group and through the nitrogen atom of the aromatic ring. We recently determined the surface concentrations of these molecules and observed that 4-CNPy assumes a flat π-bonded surface coordination at the negatively charged interface while at low bulk concentrations, and a vertical (N-bonded) orientation at the positively charged surface while at higher bulk concentrations (12). When potential is moved from a negative limit in the positive direction, the 4-CNPy molecules progressively reorient from the flat to the vertical position. The adsorption of 4-CNPy at Ag, Cu, and Pt electrodes has been investigated extensively by Raman spectroscopy (surface-enhanced Raman scattering (SERS)) (13–16). These studies revealed that 4-CNPy molecules may be reduced at these electrodes at negative potentials and various schemes were proposed to explain the mechanism of this reaction (13, 14). The specific objectives of our work were therefore threefold: (*i*) to correlate surface concentrations of 4-CNPy molecules determined from electrochemical studies in ref. 12 with the intensities of selected IR bands for adsorbed molecules to cross-check the surface concentration data, (*ii*) to employ surface selection rules of IR spectroscopy to study the potential-induced reorientation of the adsorbed molecules, and (*iii*) to use IR spectroscopy to determine the potential range within which the molecules are stable at the electrode surface and the potential of the onset of 4-CNPy reduction.

2. Experimental

Water and chemicals

All solutions were prepared from Milli-Q water. The supporting electrolyte was 0.1 M $KClO_4$ purified according to the procedure described in our previous papers (17, 18). The concentrations of 4-CNPy used in this study were 0.1 M and 0.01 M. The 4-CNPy was purified by sublimation twice under vacuum. The electrolyte solution was deaerated by purging argon for about 30 min prior to each experiment.

Cell and electrodes

A syringe-type IR cell with a flat CaF_2 window was used in the in situ FTIR studies. An Au(111) single-crystal electrode grown, cut, and polished in our laboratory was used as the working electrode. The working electrode was flame annealed and before each experiment it was additionally cleaned by applying slow (20 mV/s) repetitive oxidation–reduction cycles in the pure supporting electrolyte solution. During the IR experiment, the working electrode was pushed against the CaF_2 window to form a thin layer. A platinum foil was used as the counter electrode, and the reference electrode was a Ag/AgCl (3 M KCl saturated with AgCl) electrode. For the sake of comparison with previous electrochemical results, all potentials measured with respect to the Ag/AgCl were converted to the saturated calomel electrode (SCE) scale. All experiments were performed at 20±2°C.

Experimental procedures

In situ FTIR experiments were carried out on a Nicolet 20SX/C FTIR apparatus equipped with a MCT-B detector cooled by liquid nitrogen. The sample compartment of the FTIR apparatus was purged throughout the experiment using CO_2 and H_2O-free air provided by the Puregas Heatless Dryer. The electrode potential was controlled with the help of a PAR 173 potentiostat. Equipment and data processing procedures used to determine the cyclic voltammogram have been described in our previous publications (12, 17, 18).

Subtractively Normalized Interfacial Fourier Transform Infrared Spectroscopy (SNIFTIRS) was employed to record the IR spectra (1). The spectra were determined using a multiple potential step (MPS) procedure in which the electrode potential was stepped m times between a reference potential E_1 and a sample potential E_2. During a portion of the cycle the electrode potential was held either at potential E_1 or at E_2 while n interferograms were acquired. The acquisition was delayed for 30 s with respect to the time of the potential change to allow the interface to reach thermodynamic equilibrium at the imposed polarization. The change of the electrode potential was synchronized with the acquisition of the interferograms by connecting the external trigger port of the PAR 173 potentiostat to the communication port of a DX 486 computer that controlled the FTIR instrument. This procedure was repeated m times until a total number of $N = n \times m$ interferograms was acquired for each of the two potentials. Typical values of n and m employed in this study were $n = 100$ and $m = 20$. The interferograms were added, Fourier transformed, and used to calculate a relative change of the electrode reflectivity defined as:

$$[1] \quad \Delta R/R = (R(E_2) - R(E_1))/R(E_1)$$

where $R(E_1)$ and $R(E_2)$ are the electrode reflectivities at potentials E_1 and E_2, respectively. Since $\Delta R/R$ represents a difference between reflectivities at potentials E_1 and E_2, the sign of

$\Delta R/R$ may be positive or negative or may change with the wavelength. In the $\Delta R/R$ spectrum, the band that does not change its sign is referred to as a monopolar band. In contrast, a band that displays a change of sign is called a bipolar. The spectra were recorded with a resolution of 8 cm^{-1}, at an angle of incidence approximately equal to 60°. The transmission spectra were determined by squeezing an investigated solution between two flat CaF_2 windows. The thickness of the gap between the two tightly pressed CaF_2 windows was determined using the interference fringe method, where the frequency of the oscillations on the interference pattern were measured for the empty thin-layer cell. The gap thickness was determined to be 6 μm and its reproducibility was 10%. The gap thickness was additionally calibrated by filling the gap with neat benzene and recording the intensity of the band at 1960 cm^{-1}, which has an absorbance of 0.10 for every 0.01 mm thickness (19).

3. Results and discussion

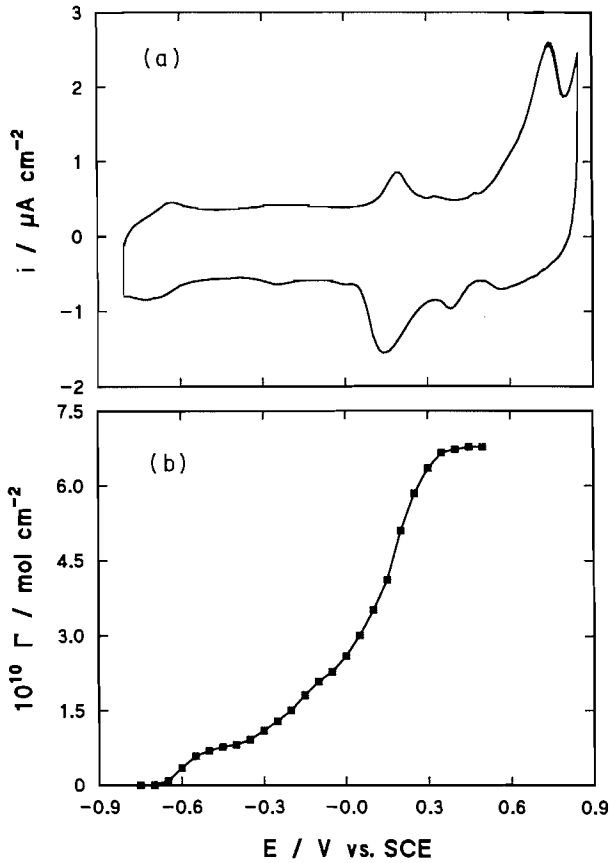
3.1. Adsorption of 4-CNPy at the Au(111) electrode surface

To determine experimental conditions for FTIR studies, the adsorption of 4-CNPy was initially characterized using cyclic voltammetry. Figure 1*a* shows the cyclic voltammogram (CV) recorded for the Au(111) electrode in 0.1 M $KClO_4$ + 0.01 M 4-CNPy solution. The CV was acquired employing the hanging electrolyte configuration in which only the Au(111) plane of the electrode was in contact with the electrolyte solution (12, 17). Multiple peaks can be seen on the CV curve. The nature of these peaks can be explained with the help of the adsorption isotherm taken from our previous work (12) and shown in Fig. 1*b*. The peaks located near −0.65 V(SCE) may be identified as corresponding to the adsorption/desorption of 4-CNPy. The peaks at about +0.2 V can be assigned to the reorientation of adsorbed molecules. In the half cycle moving in the positive direction, a large peak is seen at potentials close to +0.7 V(SCE); we will show later that this corresponds to the oxidation of 4-CNPy molecules. Figure 1 shows also that at a potential of −0.8 V (SCE) the organic molecules are desorbed from the electrode surface. The potential E_1 = −0.8 V (SCE) was therefore chosen as the reference potential for the FTIR experiments.

Figure 2 shows a series of subtractively normalized IR spectra determined for a 0.1 M $KClO_4$ + 0.01 M 4-CNPy solution, by stepping the potential between the reference potential (E_1 = −0.8 V (SCE)) and a sample potential (E_2) that varied from −0.60 to +0.75 V (SCE). To facilitate interpretation of these spectra, we additionally measured a spectrum of 4-CNPy solution in $CHCl_3$ and in the aqueous solution of the investigated electrolyte, using the thin-layer transmission cell. Figure 3 shows the transmission spectrum of 4-CNPy in $CHCl_3$ and two bands at 2245 cm^{-1} and at 1416 cm^{-1} for the aqueous solution of 4-CNPy. In the aqueous solution, all other bands of 4-CNPy overlapped with a much more intense water band and hence they are not shown in the figure. For comparison, a selected SNIFTIRS spectrum is also included in Fig. 3. The major features of the IR spectra may be summarized as follows:

(*a*) The SNIFTIRS spectra display four bands for 4-CNPy in the region between 1400 and 1610 cm^{-1} at frequencies 1416, 1505, 1554, and 1601 cm^{-1}, respectively. With the exception of the band at 1554 cm^{-1} the bands are blue shifted

Fig. 1. For the Au(111) electrode in 0.1 M $KClO_4$ + 0.01 M 4-CNPy solution: (*a*) cyclic voltammogram recorded at the sweep rate of 20 mV s^{-1}; (*b*) the Gibbs excess versus electrode potential plot.



with respect to the bands determined in transmission in $CHCl_3$. However, the band at 1416 cm^{-1} determined in reflection has the same position as the band measured in transmission for the aqueous solution of 4-CNPy. This feature suggests that the blue shift is due chiefly to the solvent effect. All bands determined in the electroreflectance experiments are significantly broader than the bands measured in the transmission experiments. The band broadening for molecules either adsorbed at or in front of a metal surface is a general behavior. It may be explained in terms of a reduced lifetime of the excited state due to the energy transfer to the metal (20). The bands at 1601 and 1505 cm^{-1} may be identified as bands of a_1 symmetry corresponding to the C–C stretching vibrations. The bands at 1416 and 1554 cm^{-1} may be assigned as bands of b_2 symmetry corresponding to anti-symmetric in-plane ring deformations (21). At potentials more positive than 0.15 V (SCE) another small band can also be seen at 1220 cm^{-1}; it could be assigned to the ring bending vibration α(CC), which has b_2 symmetry.

(*b*) When sample potential becomes greater than 0.60 V (SCE), a negative band appears in the spectrum near 2342 cm^{-1}. The intensity of this band significantly increases when the sample potential becomes more positive. This band can be assigned to the asymmetrical stretching of CO_2 (22). Its appearance indicates that 4-CNPy molecules are oxidized at E >0.6 V (SCE). This result suggests that the large

Fig. 2. SNIFTIRS spectra for 4-CNPy adsorbed at the Au(111) electrode from a 0.1 M $KClO_4$ + 0.01 M 4-CNPy solution. For each spectrum, the reference potential E_1 was equal to −0.8 V (SCE) and the value of E_2 is indicated in the figure.

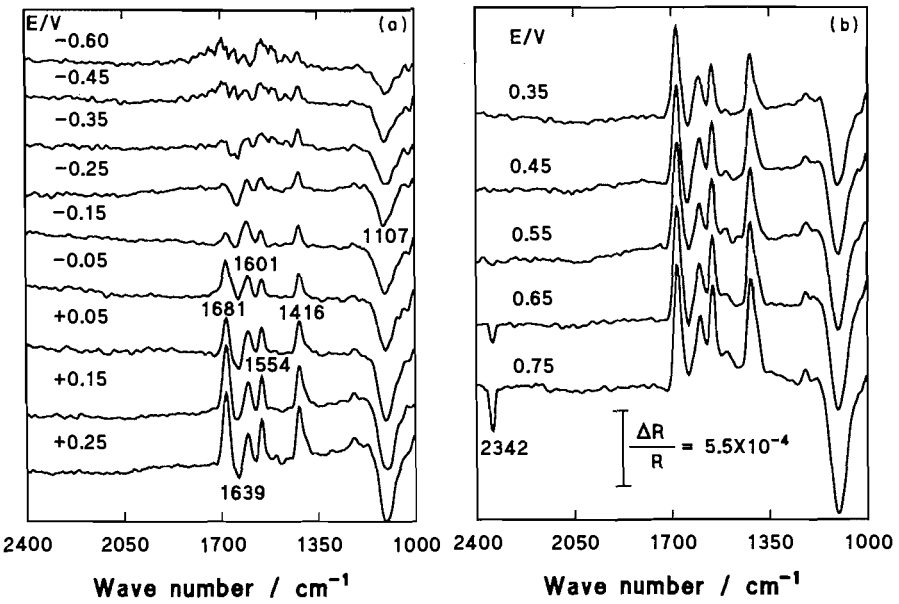


Fig. 3. Comparison of the transmission and SNIFTIRS spectra for 4-CNPy; (*a*) transmission spectrum (100 scans) for a 1.5 M 4-CNPy solution in $CHCl_3$, (*b*) selected bands of the transmission spectrum (100 scans) of a 0.1 M 4-CNPy + 0.1 M $KClO_4$ aqueous solution, (*c*) SNIFTIRS spectrum for a 0.01 M 4-CNPy + 0.1 M $KClO_4$ solution acquired using $E_1 = -0.8$ V (SCE) and $E_2 = 0.45$ V (SCE).

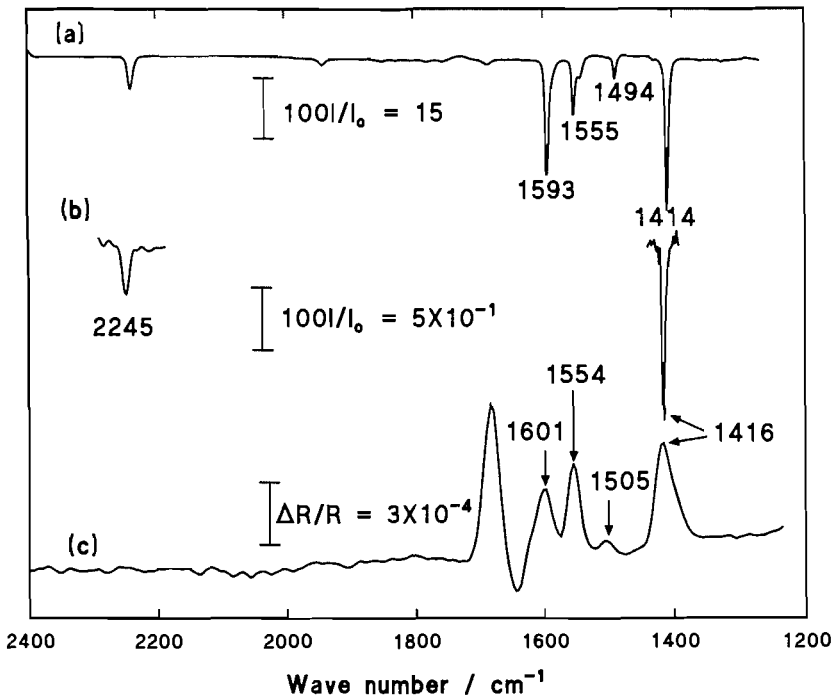

peak observed on the "positive-going" half cycle of the cyclic voltammogram at $E \approx 0.7$ V (SCE) is due to the oxidation of 4-CNPy.

(*c*) A negative band centered at 1107 cm^{-1} can be assigned to the vibrations of perchlorate ions (11). The band intensity increases with the electrode potential since the concentration of perchlorate ions in the double layer increases when E (and hence the electrode charge density) becomes more positive.

Fig. 4. Comparison of the SNIFTIRS spectra acquired in a 0.1 M $KClO_4$ + 0.01 M 4-CNPy solution using nonpolarized light for spectra (*a*) and (*c*) (2000 scans), and *s*-polarized light for spectra (*b*) and (*d*) (3000 scans). The spectra were determined using $E_1 = -0.8$ V (SCE) and $E_2 = 0.05$ V (SCE) for spectra (*a*) and (*b*) and $E_2 = 0.45$ V (SCE) for spectra (*c*) and (*d*).

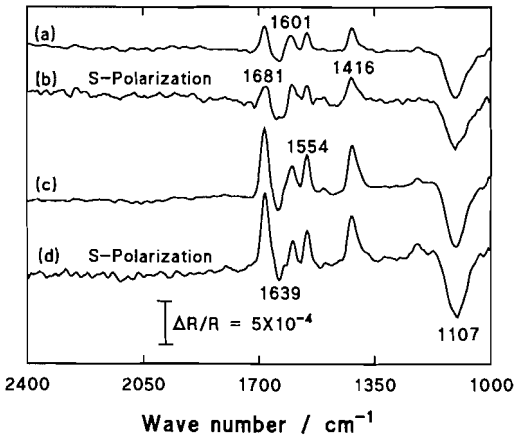

Fig. 5. Schematic diagram representing in-plane ring deformations for the 4-CNPy molecule corresponding to the bands at 1416 and 1554 cm^{-1}; squares represent the CN group, open circles the carbon atoms, and closed circles the nitrogen heteroatom. For the sake of clarity the hydrogen atoms are not shown in this diagram.

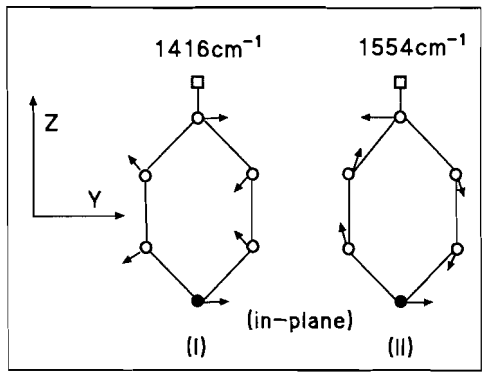


(*d*) A positive band at 1681 cm^{-1} can be assigned to the vibrations of chemisorbed H_2O (11). The potential-induced change of the water bands may be caused either by a substitution of water molecules at the surface by the adsorbed molecules of 4-CNPy or may be due to the change in the concentration of ions within the diffuse part of the double layer.

There are two other features of the IR spectra that are important to note. (*i*) The band due to the CN group stretching mode should be seen at approximately 2245 cm^{-1}; however, this band is absent in all SNIFTIRS spectra shown in Figs. 2 and 3. (*ii*) The intensity of all bands changes with the sample potential; in contrast, the frequencies of these bands are independent of E_2.

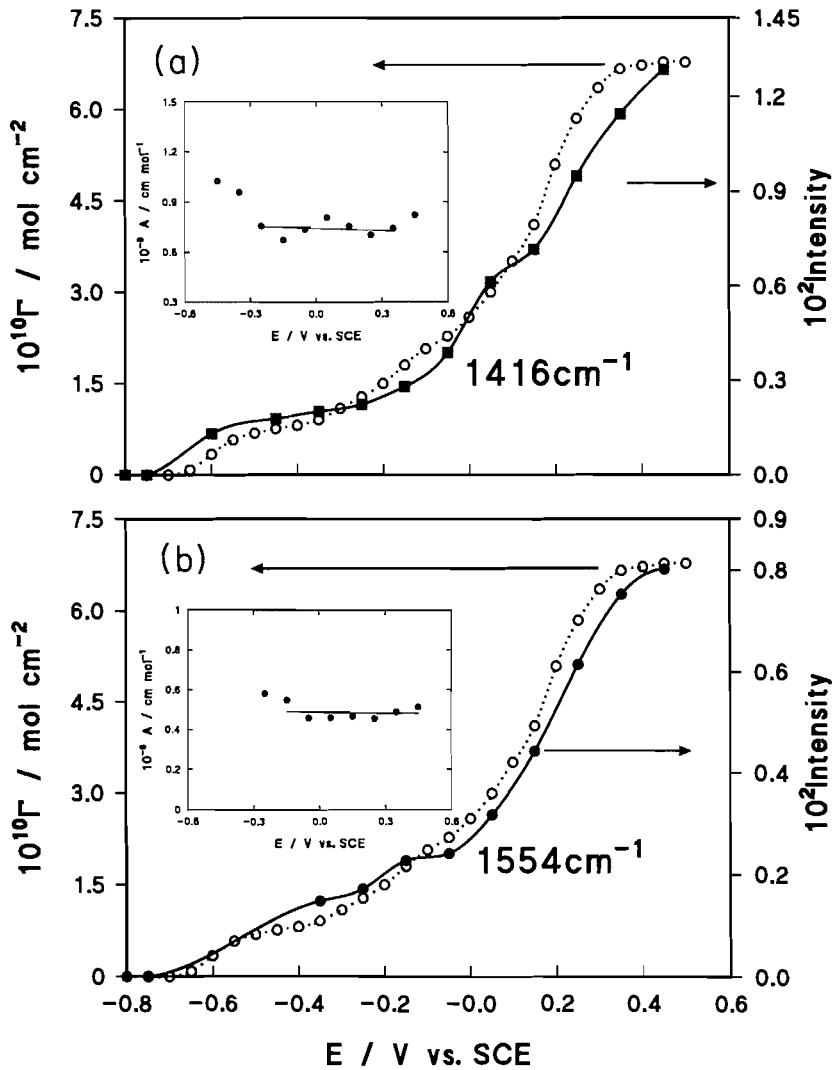
For 4-CNPy, the potential difference spectra shown in Fig. 2 may, as a good approximation, be equated to the difference between the absorbance of Γ molecules adsorbed at the sample potential E_2 and desorbed at the reference potential E_1:

$$[2] \quad \Delta R/R \approx 2.3\,\Gamma\,(\varepsilon_{des}(E_1) - \varepsilon_{ads}(E_2))$$

where ε_{des} and ε_{ads} are the molar absorption coefficients of the solution and the adsorbed species respectively. We use the term "desorbed" to describe molecules that at potential E_2 were adsorbed at the electrode surface and at potential E_1 are present in the bulk of the thin layer. The b_2 bands at 1220, 1416, 1554 cm^{-1} are apparently monopolar; they have a positive sign and the band frequency does not depend on the sample potential. These features suggest that the spectra are dominated by IR absorption from the solution species. To confirm this conclusion we performed a few additional experiments and acquired SNIFTIRS spectra using *s*-polarized photons. At the surface of a gold electrode, the electric field of an *s*-polarized photon is equal to zero and hence the adsorbed 4-CNPy is optically inactive for this polarization. Figure 4 shows the potential difference spectra acquired using nonpolarized and *s*-polarized IR radiation for two selected values of the sample potential E_2. In each case, the spectra acquired using either the nonpolarized or *s*-polarized radiation display the same features. This behavior indicates that all the b_2 bands correspond to IR absorption by the solution species. These data also indicate that the IR absorption bands for adsorbed 4-CNPy molecules are either much weaker than the bands of the solution species or that the adsorbed molecules are optically inactive.

We can employ surface selection rules to prove that vibrations corresponding to b_2 bands at 1416 and 1554 cm^{-1} are likely to be IR inactive in molecules adsorbed at the gold electrode surface. Figure 5 shows that the 1416 cm^{-1} band (Model I) is due to the deformation in which one semicircle of the ring is stretching while the other is contracting, and the 1554 cm^{-1} band (Model II) is due to the deformation in which opposite quadrants of the ring are stretching while the intervening quadrants are contracting (23). The two bands correspond to in-plane ring vibrations (18). Since the 4-CNPy molecule exhibits a planar structure and has C_{2v} symmetry the dipole moment for the vibration with b_2 symmetry changes along the *y* axis of the molecule (24). For a molecule adsorbed at a gold electrode, surface selection rules state that the vibration will be allowed if a change in the dipole derivative has a nonzero component in the direction normal to the surface (25). The 4-CNPy molecules are likely to assume either a flat (π-bonded) or a vertical (N-bonded) surface coordination. In the first case, the dipole moment will change in the direction parallel to the metal surface and its component in the direction normal to the surface will be zero. In the second case, depending on the magnitude of the tilt angle, the dipole moments of the two vibrations will change predominantly in the direction that is parallel to the surface. For adsorbed molecules, these two vibrations are expected to be IR inactive and $\varepsilon_{ads}(E_2)$ in eq. [2] will be equal to zero. In contrast, the molecules that are desorbed from the electrode surface and remain in the thin layer are randomly oriented. There is always a significant fraction of the molecules that are either far away from the electrode surface or whose dipole change has a nonzero component in the direction normal to the surface. Therefore the desorbed molecules are IR active and ε_{des} has a nonzero value. In conclusion, the subtractively normalized spectrum of a molecule that is IR inactive in the adsorbed state but is IR active in the

Fig. 6. The black points and solid lines show the dependence of the integrated intensities of the IR bands at 1416 cm^{-1} (Fig. 6*a*) and at 1554 cm^{-1} (Fig. 6*b*) on the electrode potential. The open points and broken lines show the potential dependence of the Gibbs excess of 4-CNPy molecules adsorbed at the Au(111) electrode from a 0.01 M 4-CNPy + 0.1 M $KClO_4$ solution. The inset represents the molar absorption coefficients calculated from the integrated intensities of the IR bands and the Gibbs excess values.



solution phase should be monopolar and its sign should be positive, consistent with the shape and sign of the spectra shown in Fig. 2.

Equation [2] shows that the intensity of a subtractively normalized spectrum that is dominated by the features of the desorbed species should be proportional to the surface concentration of molecules initially adsorbed at the sample potential E_2. The integrated intensity of the absorption bands at 1416 and 1554 cm^{-1} are plotted (black points and solid lines) against the sample potential in Figs. 6*a* and *b*, respectively. For comparison, open points and dotted lines in these figures represent the Gibbs surface excess of 4-CNPy determined from chronocoulometric experiments in ref. 12. The changes in the integrated band intensity follow the changes of the 4-CNPy surface concentration determined from chronocoulometic studies, which is consistent with the predictions from eq. [2]. The integrated band intensities and the Gibbs excess data may be used to calculate the integrated absorptivity A defined as:

$$[3] \quad A = \frac{1}{2.3\Gamma} \int_{\text{band}} \frac{\Delta R}{R} \, d\bar{\nu}$$

The integrated absorptivities are plotted against the electrode potential in the insets for Figs. 6*a* and *b*. Their values are apparently independent of the electrode potential and are equal to 7.2×10^6 mol^{-1} cm and 4.6×10^6 mol^{-1} cm for the bands at 1416 and 1554 cm^{-1}, respectively. In these calculations, we assumed that the desorbed molecules in the thin-layer cell experience a standing wave of IR photons and that the light makes only a single passage, rather than a double passage through the reflecting cavity. It is interesting to compare the

integrated absorptivities determined from the potential modulation experiments to the values obtained by means of transmission infrared measurements as defined by :

$$[4] \quad A = \frac{1}{bc} \int_{\text{band}} \log \frac{I_0}{I} \, d\bar{\nu}$$

where b is the thickness of the cell, c is the concentration of 4-CNPy, and I_0 and I are the incident and transmitted beam intensities. The integrated absorptivities, determined with the help of eq. [4], are equal to 1.5×10^6 mol^{-1} cm and 8.7×10^5 mol^{-1} cm for the two bands, respectively. The values determined from transmittance are about 5 times smaller than the values obtained from the relative change of the electrode reflectivity. Such differences between absorptivities determined in the transmission and reflection experiments are expected when the thickness of the thin-layer cavity of the spectro-electrochemical cell is comparable to the wavelength of the infrared radiation. These differences result from the strong spatial variation in the electric field vector of the light close to the reflecting metal surface. In the spectro-electrochemical experiment, the desorbed molecules are residing in a thin layer of solution (ca. 10 μm thick) in front of the electrode that acts as a reflecting mirror. The distance between the desorbed molecule and the mirror is comparable to the wavelength of the infrared radiation. The mirror changes the field of the infrared photons, resulting in the effective value of A being much larger than the value measured in a transmission experiment (25, 26). For the angle of incidence and the estimated thickness of the thin layer in the spectro-electrochemical cell an enhancement factor of five is consistent with the estimates reported in (refs. 25 and 26). This has serious implications for the use of IR spectroscopy as an analytical tool for measuring the amount of adsorbed species. Since the absorption coefficients measured in the transmission experiment and in the thin-layer electrochemical cell may differ significantly, IR spectroscopy may not be used to measure the absolute surface concentrations of adsorbed ions or molecules. On the other hand, insets to Figs. 4*a* and *b* show that the effective absorption coefficient is independent of the electrode potentials and, therefore, IR spectroscopy could be used as a good measure of a relative change in the electrode coverage by adsorbed ions or molecules. This point is well illustrated by studies of ionic adsorption at gold electrodes by Corrigan and Weaver (27, 28).

We have emphasized in the preceding paragraph that b_2 bands are expected to be IR inactive in adsorbed molecules and hence they cannot be used to study potential-induced reorientation of the 4-CNPy molecules. To extract information about the orientation of adsorbed molecules, we have to rely on the two bands of a_1 symmetry. For this symmetry, the dipole moment changes are in the plane of the molecule along the C_{2v} axis (z direction in Fig. 4). The a_1 bands for adsorbed molecules are therefore expected to be IR inactive for the flat (π-bonded) and to be IR active for the vertical (N-bonded) surface coordination. The first of the two a_1 bands (at 1601 cm^{-1}) overlaps with the band of water and hence it cannot be used to extract this structural information. The second band (at 1505 cm^{-1}) is weak; however, the signal-to-noise ratio in our experiments was large enough to allow the use of this band in the estimation of the surface orientation for the adsorbed molecules. Figure 7 shows enlarged sections of the SNIFTIRS spectra in the region corresponding to the position of the 1505 cm^{-1} band. The band is poorly discernible from the background for potentials that are more negative than 0.15 V (SCE), that is, in the region where the 4-CNPy molecules are expected to assume the π-bonded orientation. At more positive potentials, where 4-CNPy reorients to assume the vertical orientation, the band becomes much stronger than the background and displays well-defined bipolar features. The positive portion of this band corresponds to IR absorption by the desorbed species while the negative segment may be identified as corresponding to the vibrations of adsorbed molecules. The band for adsorbed species is apparently red shifted with respect to the position of the band for desorbed molecules. This shift may reflect the differences between the chemical environment of 4-CNPy molecules in the adsorbed and the desorbed states rather than a Stark effect. The negative portions of the bands correspond to the molecules adsorbed at positive potentials where they form a compact organic film at the electrode surface. The molecules in this film experience chiefly a nonaqueous environment. In contrast, the positive segment of the bipolar spectrum corresponds to the molecules desorbed from the electrode surface at $E_1 = -0.8$ V (SCE). The spectral properties of these molecules are in principle similar to their spectral behavior in an aqueous solution. The differences between the band positions for the adsorbed and desorbed species are likely to be of the same origin as the differences between the band frequencies for the aqueous and $CHCl_3$ solutions of 4-CNPy, seen in the transmission spectra shown in Fig. 3. Overall, the absence of the band at $E < 0.15$ V (SCE) and the appearance of the bipolar band at the more positive potential is consistent with the potential-induced

Fig. 7. SNIFTIRS spectra in the 1540–1440 cm^{-1} region, for 4-CNPy adsorbed at the Au(111) electrode from a 0.1 M $KClO_4$ + 0.01 M 4-CNPy solution. For each spectrum, the reference potential E_1 was equal to −0.8 V (SCE) and the value of E_2 is indicated in the figure.

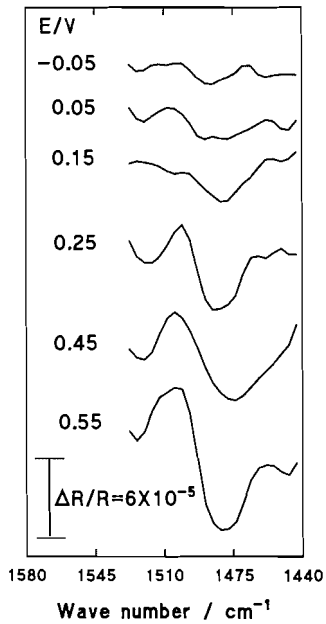


Fig. 8. SNIFTIRS spectra for a 0.01 M 4-CNPy + 0.1 M KClO4 solution acquired using E_1 = 0.4 V (SCE) and negative values of E_2 indicated in the figure for each spectrum.

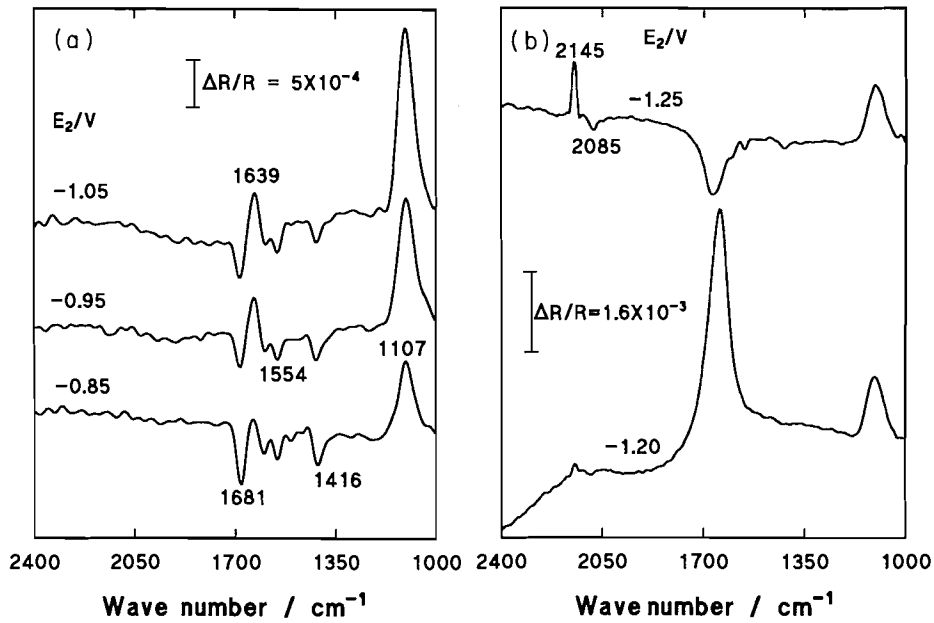


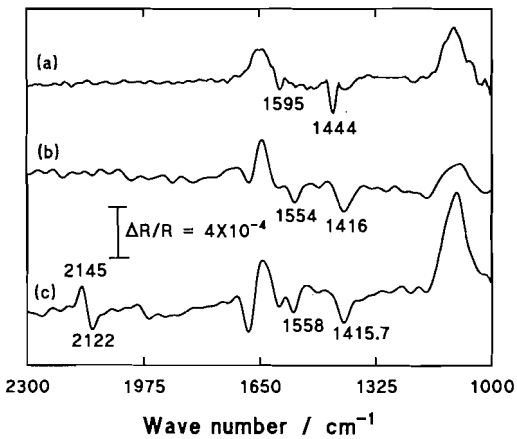
reorientation of the adsorbed molecules, from flat at negative potentials to a vertical position at the positive potentials. Some additional information about the orientation of adsorbed species may be obtained from the total absence of the CN stretching band on the SNIFTIRS spectrum, which should be observed at about 2245 cm^{-1} wave number. The CN stretching band has the same a_1 symmetry as the C–C stretching band at 1505 cm^{-1}. We note that on the transmission spectrum shown in Fig. 3, the two bands have approximately similar intensities. Therefore, the total absence of the CN band in the SNIFTIRS spectra, even for $E_2 > 0.15$ V, may be tentatively interpreted either in terms of a much more significant broadening of this band or as a result of a cancellation in the absorptivities of the adsorbed and solution species. For the vertical orientation of the molecules, a cancellation would be expected if the 4-CNPy molecules are coordinated to the metal surface through the N atom of the aromatic ring, with the CN group facing the solution side of the interface. In this orientation, the CN group would experience a predominantly aqueous environment. The band positions for the adsorbed and the desorbed species should be identical and, hence, if subtracted, they should cancel each other.

3.2. Reduction of 4-CNPy at the Au(111) electrode

Previous studies of 4-CNPy adsorption at Ag, Cu, and Pt electrodes revealed that 4-CNPy molecules may be reduced at these metals at negative potentials (13–16) and various reaction schemes were proposed to explain the mechanism of this reaction (28). For example it was suggested in ref. 13 that 4-CNPy molecules were reduced to give CN^- ion and pyridine molecule as the reaction products. In contrast, it was suggested in ref. 14 that the reduction leads to the formation of a $(4\text{-CNPy})^{-\cdot}$ radical ion. To determine the potential range in which the 4-CNPy molecules are stable at the Au(111) electrode surface, we employed SNIFTIRS to study the behavior of 4-CNPy molecules at very negative potentials. Figures 8*a* and *b* show SNIFTIR spectra obtained by choosing the reference potential E_1 = +0.40 V (SCE) and stepping to the sample potential E_2, which varied from −0.85 to −1.25 V (SCE). At the reference potential, the electrode surface is covered by a monolayer of adsorbed 4-CNPy molecules, and at the sample potentials, the molecules are mostly desorbed from the electrode surface.

For sample potentials that are higher than −1.1 V, the spectra shown in Fig. 8*a* are essentially mirror images of the spectra presented earlier in Figs. 2 and 3. They display the same absorption bands; however, since the direction of the potential step is changed, the bands in Fig. 8 are predominantly negative rather than positive. The shape of the spectrum changes when E_2 decreases below −1.05 V (SCE). The band at 1681 cm^{-1}, due to IR absorption by H_2O, becomes very strong at E_2 = −1.2 V (SCE). Hydrogen evolution takes place at this potential and the formation of H_2 bubbles in the thin layer can be observed. As a result, the concentration of water molecules in the thin layer changes significantly when the potential is stepped between E_1 and E_2. In addition, a new bipolar band appears in the spectrum. Its positive branch has a maximum at 2145 cm^{-1} and the negative portion has a minimum at 2085 cm^{-1}. These bands grow further by decreasing the potential to E_2 = −1.25 V. The bands are not observed on the spectra acquired using *s*-polarized radiation and hence they may be identified as corresponding to the adsorbed species. The positive branch of the band at 2145 cm^{-1} corresponds to the species adsorbed at the reference potential (E_1 = 0.4 V (SCE)), and the negative section at 2085 cm^{-1} is related to the species adsorbed at the sample potential E_2. According to ref. 13, the band at 2085 cm^{-1} may be assigned to CN^-, formed by the reduction of 4-CNPy molecules, which involves a cleavage of the CN–ring bond and the formation of a cyanide ion and a pyridine molecule (see also reduction scheme in ref. 29). However, accord-

Fig. 9. Comparison of three SNIFTIRS spectra recorded at the Au(111) electrode by stepping the potential between $E_1 = 0.4$ V (SCE) and $E_2 = -0.55$ V (SCE). Spectrum (*a*) corresponds to 3×10^{-3} M pyridine in 0.1 M $KClO_4$ solution. Spectra (*b*) and (*c*) correspond to 0.01 M 4-CNPy + 0.1 M $KClO_4$ solution; spectrum (*b*) was acquired without exposing the electrode to the very negative polarization; spectrum (*c*) was recorded after pre-electrolysis at $E = -1.2$ V (SCE).



ing to ref. 14 this band may also be assigned to the ν_{CN} mode of the $(4\text{-CNPy})^{\cdot -}$ radical anion. To test these two hypotheses, we have recorded SNIFTIRS spectrum for a 3×10^{-3} M solution of pyridine molecules. The potential was modulated between a value E_1 at which pyridine molecules form a compact monolayer at the Au(111) surface and a potential E_2 where they are desorbed from the surface (12). In Fig. 9, the spectrum for pyridine (curve (*a*)) is compared to the spectrum for 4-CNPy (curve (*b*)), corresponding to the potential modulation between $E_1 = 0.4$ V (SCE) and E_2 equal to –0.8 V. Curve (*c*) in Fig. 9 shows the spectrum recorded after a prolonged electrolysis at $E = -1.2$ V (SCE) used to generate the product of 4-CNPy reduction. The spectrum was acquired after this pre-electrolysis by stepping the potential between $E_1 = 0.4$ V (SCE) and $E_2 = -0.55$ V (SCE). The spectrum for pyridine displays a strong ring stretching band at 1444 cm^{-1}. In contrast, the ring stretching bands for the 4-CNPy molecule in spectra (*b*) and (*c*) are observed at 1416 and 1558 cm^{-1}. Apparently, the appearance of the bipolar band in the 2145–2122 cm^{-1} range, due to reduction of 4-CNPy at the negative potentials, is not accompanied by a change in the ring stretch frequencies. The ring stretching band characteristic for the pyridine molecule is not observed in spectrum (*c*), and this behavior indicates that the reduction of 4-CNPy molecules does not involve a cleavage of the CN–ring bond. The band at 2085 cm^{-1} may therefore be assigned to the formation of the $(4\text{-CNPy})^{\cdot -}$ radical anion. Overall, the spectral behavior of 4-CNPy molecules at negative potentials, described above for the Au(111) surface, are very similar to that observed for a Cu electrode by Rubim and Sala (14). In conclusion, our SNFTIRS experiments indicate that 4-CNPy molecules are stable at the Au(111) electrode surface in the potential range of -1.1 V (SCE) $< E <$ 0.6 V (SCE). The molecules are reduced at more negative potentials and are oxidized at more positive potentials.

4. Summary

Subtractively normalized Fourier transform infrared spectroscopy was employed to study adsorption of 4-cyanopyridine at the Au(111) electrode surface. In these experiments, the potential was modulated between the value $E_1 = -0.8$ V (SCE), at which 4-CNPy molecules are desorbed from the electrode, and the value E_2, at which 4-CNPy molecules are adsorbed at the Au(111) surface. The measured spectra were considered to be equal to the difference between the absorbance of the desorbed molecules at E_1 and the adsorbed molecules at E_2. The IR spectra were used to study (*i*) the dependence of the band intensity on the surface coverage, (*ii*) the character of surface coordination, and (*iii*) the stability of adsorbed 4-CNPy molecules. We observed that the IR bands acquired during the the electroreflectance experiments are significantly broader than the bands from a transmission cell. Some weaker bands recorded in transmission were not observed in the electroreflectance experiment. The electroreflectance spectra were dominated by four bands corresponding to the in-plane ring deformations. Two of them had b_2 symmetry while the other two had a_1 symmetry. All b_2 bands were monopolar in character and their sign was positive; they were dominated by the absorbance of the desorbed 4-CNPy molecules. The intensity of these bands correlated well with the surface concentrations of 4-CNPy molecules, determined from independent electrochemical studies. The integrated absorption intensities for these bands were larger by a factor of five than the absorption intensities of the bands recorded in the transmission cell. This indicates that the photon field, acting on the molecules in front of the gold electrode, is significantly enhanced by reflection from the electrode. One of the two a_1 bands overlapped with the band for water. The second a_1 at 1505 cm^{-1} was quite weak; however, the signal-to-noise ratio in our experiments was sufficiently large to study its potential-induced changes. The band was bipolar and its character varied with the electrode potential. The changes were consistent with a progressive reorientation of 4-CNPy molecules from a flat (π-bonded) coordination at negative potentials, to a vertical N-bonded geometry at positive potentials. The total absence of the band due to the CN stretch in the SNIFTIRS spectra suggested that, in the vertical orientation, 4-CNPy molecules are oriented with the nitrogen atom from the ring pointing towards the metal while the CN group faces the solution. The IR spectra acquired at either very negative or very positive potentials indicate that 4-CNPy is reduced at $E < -1.1$ V (SCE) and it is oxidized at $E > 0.6$ V (SCE).

The reactions of $[Pd_2Cl_2(\mu\text{-}PP)_2]$ (PP = dppm, dmpm) with $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution: X-ray crystal structures of $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ and hexakis(diethylamino)benzene, $C_6(NEt_2)_6$

Sean R. Klopfenstein, Constanze Kluwe, Kristin Kirschbaum, and Julian A. Davies

Abstract: The binuclear palladium(I) complex, $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ (dppm = bis(diphenylphosphino)methane), has been shown to react with bis(diethylamino)acetylene, $Et_2NC{\equiv}CNEt_2$, in methylene chloride solution to yield two isolable products, the known methylene-bridged complex, $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$, and hexakis(diethylamino)benzene, $C_6(NEt_2)_6$, both of which have been characterized crystallographically. The source of the bridging methylene group in $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ has been shown to be the methylene chloride solvent. A mechanism that accounts for the formation of the two isolable products is proposed. The complex, $[Pd_2Cl_2(\mu\text{-}dmpm)_2]$ (dmpm = bis(dimethylphosphino)methane), was similarly found to react with $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution to yield $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dmpm)_2]$, which was identified spectroscopically.

Key words: acetylene, palladium, cyclooligomerization, aminoacetylene, hexakis(diethylamino)benzene.

Résumé : On montre que le complexe binucléaire de palladium(I), $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ (dppm = bis(diphénylphosphino)-méthane, réagit avec le bis(diéthylamino)acétylène, $Et_2NC{\equiv}CNEt_2$, dans une solution de chlorure de méthylène pour donner deux produits que l'on peut isoler : un complexe avec un méthylène ponté $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ qui est connu, et l'hexakis(diéthylamino)benzène, $C_6(NEt_2)_6$; ces deux complexes sont caractérisés par cristallographie. On montre que le groupe méthylène en position de pont dans le complexe $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ vient du solvant. On propose un mécanisme qui tient compte des deux produits que l'on peut isoler. De façon similaire, on a trouvé que le complexe $[Pd_2Cl_2(\mu\text{-}dmpm)_2]$ (dmpm = bis(diméthylphosphino)méthane) réagit avec $Et_2NC{\equiv}CNEt_2$ en solution dans le chlorure de méthylène pour conduire au complexe $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dmpm)_2]$ que l'on a identifié par spectroscopie.

Mots clés : acétylène, palladium, cyclooligomérisation, aminoacétylène, hexakis(diéthylamino)benzène.

[Traduit par la rédaction]

Introduction

Binuclear palladium(I) complexes of the type $[Pd_2X_2(\mu\text{-}PP)_2]$ (X = anionic ligand, PP = dppm, dmpm, etc.) are known (1) to react with simple acetylenes bearing electron-withdrawing substituents (e.g., $-CF_3$, $-CO_2Me$) to yield the acetylene complexes, $[Pd_2X_2(\mu\text{-}RC{\equiv}CR)(\mu\text{-}PP)_2]$. Acid catalysis (2, 3) facilitates acetylene addition to the metal-metal bond of $[Pd_2X_2(\mu\text{-}PP)_2]$ and allows generation of $[Pd_2X_2(\mu\text{-}RC{\equiv}CR)(\mu\text{-}PP)_2]$ complexes from acetylenes *without* electron-withdrawing substituents (e.g., -H, -Ph), Fig. 1. We have shown (4, 5) that the heteroatom-substituted acetylene, $MeSC{\equiv}CSMe$, reacts with $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ to yield the acetylene complex, $[Pd_2Cl_2(\mu\text{-}MeSC{\equiv}CSMe)(\mu\text{-}dppm)_2]$, which undergoes a Lewis-acid-promoted rearrangement to the vinylidene isomer, $[Pd_2Cl_2(\mu\text{-}C{=}C\{SMe\}_2)(\mu\text{-}dppm)_2]$, Fig. 2. Vinylidene complexes, formed via 1,2-heteroatom shift reactions, have similarly been isolated from the reactions of haloacetylenes (6) with $[Pd_2Cl_2(\mu\text{-}dppm)_2]$.

Amino-substituted acetylenes and alkoxyacetylenes, $MeC{\equiv}CY$ (Y = NMe_2, OEt) have been shown (7) to undergo 1,2-heteroatom shifts in reactions with $[Mn_2(CO)_9(NCMe)]$. In these cases the 1,2-heteroatom shift reactions are accompanied by CO insertion into the C—Y bond of the newly formed vinylidene, Fig. 3. Such processes are not typical of the reactions of manganese carbonyls with heteroatom-substituted acetylenes. For example, $[Mn_2(CO)_{10}]$ reacts with $PhC{\equiv}CNEt_2$ to yield the expected acetylene complex, $[Mn_2(CO)_8(PhC{\equiv}CNEt_2)]$ (8). Other nitrogen-containing acetylenes have been shown (8) to react with metal carbonyl

complexes to yield products that arise either from acetylene oligomerization or from C-N bond cleavage, Fig. 4.

In this paper, the reactions between the palladium(I) complexes, $[Pd_2Cl_2(\mu\text{-}PP)_2]$ (PP = dppm, dmpm), and bis(diethylamino)acetylene, $Et_2NC{\equiv}CNEt_2$, in methylene chloride solution are described. Neither acetylene complexes nor the vinylidene isomers could be identified among the reaction products. Two compounds were isolated from the reaction of $Et_2NC{\equiv}CNEt_2$ with $[Pd_2Cl_2(\mu\text{-dppm})_2]$ in CH_2Cl_2, the known methylene-bridged complex, $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dppm})_2]$, **1**, and hexakis(diethylamino)benzene, $C_6(NEt_2)_6$, **2**, both of which were characterized crystallographically (**1**·$2CH_2Cl_2$ and **2**). From the reaction of $[Pd_2Cl_2(\mu\text{-dmpm})_2]$ with $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution the analogous methylene-bridged complex, $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dmpm})_2]$, was isolated and characterized spectroscopically.

Experimental

Materials

All solvents were deoxygenated prior to use. Reactions were performed under argon or nitrogen using standard Schlenck techniques. Methylene chloride was distilled from calcium carbide under nitrogen. Diethyl ether was distilled from sodium ribbon under nitrogen. Diethylamine was dried over finely ground potassium hydroxide and used without further purification. The compounds $[Pd_2Cl_2(\mu\text{-dppm})_2]$ (9) and $[Pd_2Cl_2(\mu\text{-dmpm})_2]$ (10) were prepared by literature methods. Bis(diethylamino)acetylene was prepared by a procedure modified from three published reports (11–13), as detailed below.

Physical measurements

NMR spectra were measured on Varian VXR-400, Varian Gemini-200, and JEOL FX-90Q NMR spectrometers. Internal tetramethylsilane was employed as a shift standard in ^1H and $^{13}C\{^1H\}$ NMR measurements and $^{31}P\{^1H\}$ NMR spectra were referenced to external 85% phosphoric acid. Data for GC–MS experiments were collected on a HP-5890 instrument with mass-sensitive detector.

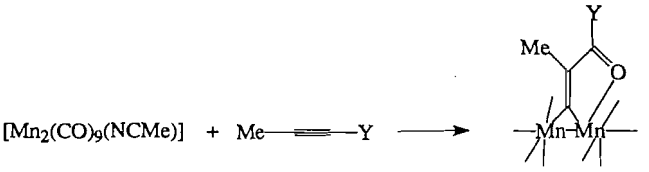

Fig. 4. Reactions of nitrogen-containing acetylenes with metal carbonyl complexes.

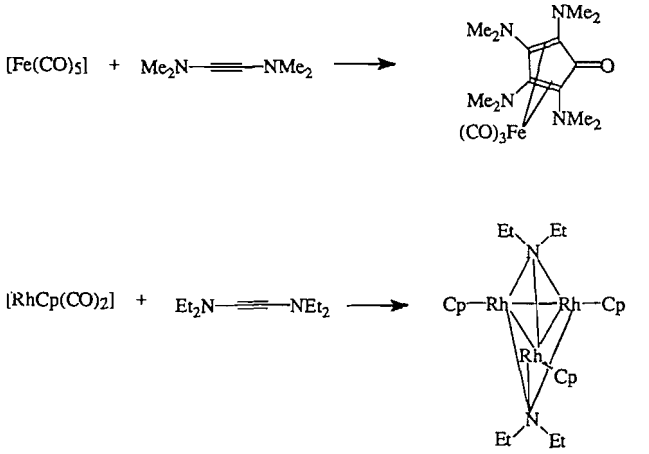

X-ray crystallography[2]

General methods

Single crystals of 1·$2CH_2Cl_2$ and 2 were selected for data collection and mounted on glass fibers in random orientations. X-ray diffraction data were collected with an Enraf–Nonius CAD4 diffractometer in the ω–2θ mode. Data were collected for 1·$2CH_2Cl_2$ to a maximum of 2θ of 44° and for 2 to a maximum of 2θ of 52°. Lorentz and polarization corrections were applied to the data. Absorption effects were corrected by a semiempirical method on the basis of a series of ψ-scans. The structures were refined in full-matrix least squares where the function minimized was

$$\Sigma\omega(|F_o| - |F_c|)^2$$

[2] Copies of tables of all bond distances and angles and thermal parameters may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Tables of bond distances and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

and the weight ω was defined as $4F_o^2/\sigma^2(F_o^2)$. Scattering factors were taken from the standard literature (14). Anomalous dispersion effects were included in F_c. The unweighted and weighted agreement factors are defined as

$$R = \Sigma||F_o| - |F_c||/\Sigma|F_o|,\ R_w = (\Sigma\omega(|F_o| - |F_c|)^2/\Sigma\omega(|F_o|^2)^{1/2}$$

All calculations were performed on a VAX 3100 computer using MolEN (15).

Synthesis of bis(diethylamino)acetylene

(i) Preparation of lithium diethylamide

A three-necked, 300-mL, round-bottomed flask was equipped with a magnetic stirrer bar, dropping funnel, gas inlet, and mineral oil bubbler. The flask was charged with diethylamine (10.5 mL, 0.20 mol) and freshly distilled diethyl ether (50 mL). The contents of the flask were cooled to 0°C and a solution of *n*-butyllithium in hexanes (50 mL, 0.20 mol) was added dropwise under an atmosphere of argon. The resulting lithium diethylamide was used directly in the next step.

*(ii) Preparation of 1,2-dichloro-1-(*N,N*-diethylamino)ethene*

A three-necked, 1000-mL, round-bottomed flask was equipped with a mechanical stirrer, reflux condenser, gas inlet, and mineral oil bubbler. An atmosphere of argon was maintained throughout the procedure. To the flask was added freshly distilled diethyl ether (120 mL), and trichloroethylene (18 mL, 0.20 mol). The solution was cooled to −90°C with a Dry Ice – diethyl ether cooling bath. To the stirring solution, the lithium diethylamide solution (see above) was added via cannula over a period over 10 min while maintaining a temperature below −70°C. Additional diethylamine (21 mL, 0.4 mol) was then added and the flask allowed to warm slowly to 30°C using a water bath. The mixture was allowed to stir for 45 min at 30°C and then the water bath was removed and the reaction flask allowed to come to room temperature over a period of 1 h. The resulting brown, heterogeneous mixture was filtered through a coarse frit covered with dry, finely ground, potassium carbonate. The flask and frit were washed with three 20-mL portions of dry diethyl ether and the washings combined with the filtrate. The filtrate was concentrated to a volume of 100 mL with a rotary evaporator while maintaining a bath temperature below 40°C. The resulting brownish-red solution was analyzed by GC–MS and used without further purification for conversion to the chloroketeneaminal.

(iii) Preparation of 2-chloro-1,1-bis(diethylamino)ethene

The product from (*ii*) was placed in a three-necked, 250-mL, round-bottomed flask with diethylamine (15 mL, 0.30 mol). The flask was equipped with a magnetic stirrer bar and a reflux condenser while an atmosphere of argon was maintained. The contents of the flask were brought to reflux by use of a water bath maintained at 70°C. After 1 h of reflux, some separation of solid material was noted. Additional diethylamine (15 mL, 0.30 mol) was then added in three equal portions over a period of 1 h. The mixture was allowed to reflux for 12 h at which time additional diethylamine (5 mL, 0.10 mol) was added and reflux continued for 8 h longer. The water bath was removed and the flask allowed to cool to room temperature over a period of 1 h. The mixture was then filtered through a coarse frit and the reaction flask and frit were washed with three 20-mL portions of dry diethyl ether and the washings combined with the filtrate. The filtrate was then reduced to a volume of 50 mL with a rotary evaporator while maintaining a bath temperature below 40°C. The resulting brown-red solution was analyzed by GC–MS and used without further purification for the final step.

(iv) Preparation of bis(diethylamino)acetylene

To a three-necked, 250-mL, round-bottomed flask equipped with a magnetic stirrer bar, dropping funnel, gas inlet, and mineral oil bubbler, the chloroketeneaminal (50 mL, 80% by GC–MS) was added with freshly distilled diethyl ether (75 mL). The flask was cooled to 0°C with an ice bath and freshly prepared lithium diethylamide (10.5 mL, 0.20 mol, see (*i*), above) was added via cannula. The solution was allowed to warm to room temperature and stirred overnight under flowing argon. Analysis by GC–MS showed complete conversion. The brown suspension was filtered through a coarse frit covered with Celite using a water aspirator equipped with a potassium hydroxide tube for protection. The Celite was washed with three 10-mL portions of diethyl ether and the washings combined with the filtrate. The solvent was removed by distillation through a 40-cm Vigreux column while maintaining the bath temperature below 70°C. The resulting red-brown liquid (40 mL, 84% by GC–MS) was transferred via cannula to a 100-mL, three-necked, round-bottomed flask equipped for vacuum distillation. The acetylene distilled as a clear oil at 30°C and 0.25 Torr (1 Torr = 133.3 Pa). Yield: 28 mL, 25 g, 74%. ^{1}H NMR ($CDCl_3$): δ 1.1 (CH_3, t), 2.8 (CH_2, q); J(H, H) 7.15 Hz; $^{13}C\{^1H\}$ NMR ($CDCl_3$), δ: 12.9 (CH_3), 49.6 (CH_2), 74.3 (-C≡C-); MS: M* = 168 (100%).

Reaction of $[Pd_2Cl_2(\mu\text{-dppm})_2]$ with $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution

$[Pd_2Cl_2(\mu\text{-dppm})_2]$ (0.135 g, 1.3×10^{-4} mol) was placed in a 25-mL, argon-filled Schlenck tube containing a magnetic stirrer bar and freshly distilled methylene chloride (25 mL) was added. The solution was cooled to −78°C in a Dry Ice – acetone bath. In a separate flask, freshly distilled methylene chloride (10 mL) was added to bis(diethylamino)acetylene (0.24 mL, 0.22 g, 1.3×10^{-3} mol, 10× excess). The acetylene solution was added via cannula to the cooled solution of $[Pd_2Cl_2(\mu\text{-dppm})_2]$. The reaction mixture was allowed to warm to room temperature by slow evaporation of carbon dioxide from the cooling bath over a period of 6 h. The color of the reaction mixture changed from orange to red. The reaction mixture was then filtered via cannula into a Schlenk flask and concentrated to a volume of 7 mL on a vacuum line. Freshly dried diethyl ether (25 mL) was layered onto the methylene chloride solution and the flask cooled in a freezer for 24 h. A solid precipitate formed that was filtered from the orange supernatant liquid (see below). The yellow-gold solid was washed with two 10-mL portions of diethyl ether and dried under vacuum for 3 h. The product was identified as $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dppm})_2]$ as follows: $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 14.9; ^{1}H NMR (CD_2Cl_2): δ 1.65 (quintet) (μ-CH_2), $J_{(P,H)}$ = 7.7 Hz, δ 7.90 (m), 7.64 (m), 7.42 (m), 7.28 (m) 7.13 (t) (Ph_2P-), δ 3.5 (m) (P-CH_2-P), $J_{(P,H)}$ = 4.7 Hz, $J_{(H,H)}$ = 14 Hz, δ 2.8 (m) (P-CH_2-P) $J_{(P,H)}$ = 3.4 Hz, $J_{(H,H)}$ = 14 Hz. Anal. calcd. (found) for $C_{51}H_{46}Cl_2P_4Pd_2$: C 57.4 (56.9), H 4.3

(4.3). Yield = 39.2 mg (36% based on Pd). Crystals of $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dppm})_2]{\cdot}2CH_2Cl_2$ suitable for X-ray diffraction experiments were obtained by slow evaporation of methylene chloride.

The orange supernatant liquid (see above) was reduced in volume to 2 mL under vacuum. The resulting oily liquid was cooled in a freezer at 0°C for 7 days during which time clear, colorless crystals formed that were found to be suitable for X-ray diffraction and were identified as hexakis(diethylamino)benzene (<5% yield).

X-ray crystallography

(i) $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]{\cdot}2CH_2Cl_2$ ($1{\cdot}2CH_2Cl_2$)

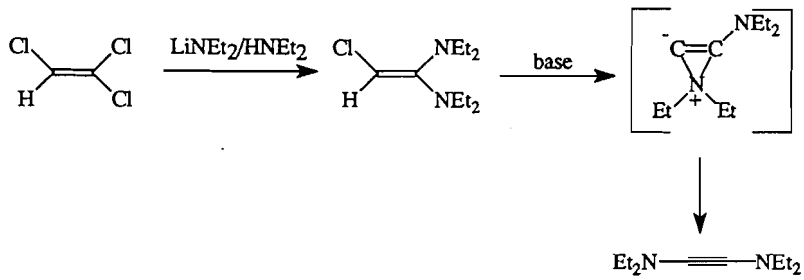
Slow evaporation of the solvent, CH_2Cl_2, yielded yellow single crystals. The crystals diffracted X-rays poorly. They lost solvent and turned into a yellow powder within about 10 min at room temperature. Rapid handling and cooling (190 K) circumvented this problem. The tetragonal unit cell constants and the orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections in the range $10 < \Theta < 13°$. As a check on crystal stability the intensities of three representative reflections were measured every 60 min, indicating a total loss in intensity of 1.9%. An anisotropic decay correction was applied with correction factors on I in the range from 0.963 to 1.103. A total of 4340 reflections were collected, of which 4077 were unique. Intensities of equivalent reflections were averaged, the agreement factors were 3.0% based on I and 2.1% based on F_o. A total of 3321 reflections with $F_o^2 > 3.0\sigma(F_o^2)$ were used in the calculations.

Structure solution and refinement: The positions of the two palladium atoms were found by direct methods. The remaining atoms were located by repeated least-squares refinements followed by difference Fourier syntheses. A total of two equivalents of highly disordered CH_2Cl_2 were found per metal complex. The disorder was modeled and refined in the following ways. C(60), Cl(5), Cl(5a), Cl(6), and Cl(6a) comprised 3/4 equivalent of CH_2Cl_2 disordered over two positions with occupancies for C(60) of 3/4, for Cl(5) and Cl(6) of 1/2, and for Cl(5a) and Cl(6a) of 1/4. Similarly, another 3/4 equivalent of CH_2Cl_2 included C(61) (multiplicity = 3/4), Cl(7) and Cl(8) (occupancy = 1/2), as well as Cl(7a) and Cl(8a) (occupancy = 1/4). C(62), C(19) and Cl(10) represented another 1/2 equivalent of CH_2Cl_2. The atomic positions of the solvent were fixed and only isotropic thermal parameters were refined. The relatively high maximum residual electron density (1.83 e/Å^3) might be due to further small quantities of disordered solvent that we were unable to include in our model. The carbon atoms, C(2), C(7), C(11), C(41), C(47), C(50), and C(51), of the metal complex were refined with isotropic thermal parameters. All other non-hydrogen atoms were refined with anisotropic thermal parameters. The positions of the hydrogen atoms of the metal complex were calculated and included in the least-squares refinement as riding atoms, $U_{iso} = 1.3U_{eq}$ (bonding atom). The hydrogen positions for the disordered CH_2Cl_2 were not calculated. The final cycle of refinement included 509 variable parameters and converged with unweighted and weighted agreement factors of $R = 0.062$ and $R_w = 0.096$. Further details are given in Table 1.

*(ii) $C_6(NEt_2)_6$ (**2**)*

Cooling a solution of **2** in CH_2Cl_2 yielded colorless single crystals. The rhombohedral unit cell constants and the orientation matrix for data collection were obtained from least-squares refinement, using the setting angles of 25 reflections in the range $4 < \Theta < 15°$. As a check on crystal stability the intensities of three representative reflections were measured every 60 min, indicating a total gain in intensity of 0.2%. An

Fig. 5. Synthesis of $Et_2NC{\equiv}CNEt_2$.



anisotropic decay correction was applied with correction factors on I in the range from 0.983 to 1.035. A total of 1111 reflections were collected, of which 1011 were unique. Intensities of equivalent reflections were averaged, the agreement factors were 1.6% based on I and 1.6% based on F_o. A total of 624 reflections with $F_o^2 > 3.0\sigma(F_o^2)$ were used in the calculations.

Structure solution and refinement: The positions of six atoms were found by direct methods. The remaining atoms were located in succeeding difference Fourier syntheses. The molecule lies on a $\bar{3}$. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were refined with isotropic thermal parameters. The final cycle of refinement included 95 parameters and converged with unweighted and weighted agreement factors of $R = 0.038$ and $R_w = 0.044$. Further details are given in Table 1.

Reaction of $[Pd_2Cl_2(\mu\text{-dmpm})_2]$ with $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution

$[Pd_2Cl_2(\mu\text{-dmpm})_2]$ (0.110 g, 2.0×10^{-4} mol) was placed in a 100-mL, nitrogen-filled Schlenck tube containing a magnetic stirrer bar, and freshly distilled methylene chloride (25 mL) was added. Bis(diethylamino)acetylene (50 μL, 2.65×10^{-4} mol) was added slowly via syringe over a period of 5 min. The reaction mixture was allowed to stir for 6 h at room temperature. The color of the reaction mixture changed from yellow to dark red. The reaction mixture was then filtered via cannula into a Schlenck flask and concentrated to a volume of less than 10 mL on a vacuum line. Freshly dried diethyl ether (15 mL) was layered onto the methylene chloride solution and the flask allowed to stand at room temperature overnight followed by cooling in a freezer for 24 h. A solid precipitate formed that was filtered from the orange supernatant liquid. The yellow-black solid was washed with two 10-mL portions of diethyl ether and dried under vacuum for 2 h. The solid was then dissolved in the minimum amount of methylene chloride and allowed to stand overnight during which time a black precipitate formed. The yellow supernatant was filtered from the black solid via cannula, and diethyl ether (15 mL) was layered onto the methylene chloride solution. After 24 h at room temperature a yellow solid had formed that was isolated by cannula filtration, washed with two 25-mL portions of diethyl ether, and dried under vacuum for 8 h. The product was identified as $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dmpm})_2]$ as follows: $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ −4.1; ^1H NMR (CD_2Cl_2): δ 1.3 (quintet) (μ-CH_2), $J_{(P,H)}$ = 7.7 Hz, δ 1.7 (s) 1.6 (s) (Me_2P-), δ 2.26 (m), 1.52 (m) (P-CH_2-P), $J_{(P,H)}$ = 4.7 Hz, $J_{(H,H)}$ = 14 H. $^{13}C\{^1H\}$ NMR (CD_2Cl_2): δ 20.9 (s) (μ-CH_2), δ 23.0 (t) (P-CH_2-P), δ 15.6 (qn), 14.6 (qn) (Me_2P-). Anal. calcd. (found) for $C_{11}H_{30}Cl_2P_4Pd_2$: C 23.2.(23.3), H 5.3 (5.2). Yield = 28.6 mg (25.3% based on Pd).

Results and discussion

Simple acetylenes, such as $CF_3C{\equiv}CCF_3$, react with dinuclear palladium(I) complexes of the type $[Pd_2X_2(\mu\text{-PP})_2]$ to yield acetylene-bridged products (1–3), as illustrated in Fig. 1, while the sulfur-substituted acetylene MeSC≡CSMe reacts according to the pathways illustrated in Figure 2, with formation of a vinylidene-bridged complex under Lewis-acid-promoted conditions (4, 5). Other heteroatom-substituted acetylenes, such as IC≡CI (6), ClC≡CCl (16), PhC≡CCl (17), MeSC≡CMe (4, 5), and MeOC≡CMe[3] have also been shown to yield vinylidene-bridged products in reactions with $[Pd_2X_2(\mu\text{-PP})_2]$ complexes via 1,2-heteroatom shifts under certain conditions. Since the nitrogen-substituted acetylene, $MeC{\equiv}CNMe_2$, is known (7) to undergo a 1,2-heteroatom shift in the reaction with $[Mn_2(CO)_9(NCMe)]$, we sought to investigate the reactions of nitrogen-substituted acetylenes with dinuclear palladium(I) complexes. Our work with sulfur-substituted acetylenes has revealed significant differences in reactivity between symmetrically substituted acetylenes and unsymmetrically substituted acetylenes (e.g., MeSC≡CSMe vs. MeSC≡CMe (4,5)) and so we first began to investigate the reactivity of the symmetrically substituted, nitrogen-containing acetylene, $Et_2NC{\equiv}CNEt_2$, with $[Pd_2X_2(\mu\text{-PP})_2]$ (X = anionic ligand, PP = dppm, dmpm) complexes.

The synthesis of $Et_2NC{\equiv}CNEt_2$, detailed in the experimental section, was derived from literature reports (11–13) and followed the pathway outlined in Fig. 5. Our modifications to the reported methods led to isolation of $Et_2NC{\equiv}CNEt_2$ in a 74% overall yield.

The reaction of $[Pd_2Cl_2(\mu\text{-dppm})_2]$ with a tenfold excess of $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution was investigated. The reaction was monitored by removal of aliquots and measurement of the $^{31}P\{^1H\}$ NMR spectra, which revealed a complex mixture of species in solution. Precipitation with diethyl ether allowed isolation of a single complex (δP = 14.9 ppm) whose ^1H NMR spectrum revealed, in addition to resonances attributed to the bridging dppm ligands, a quintet at

[a]Refers to the Pd(1)·····Pd(2) separation.

1.65 ppm. A comparison to literature data (18–20) suggested that this signal could be attributed to a methylene group bridging the palladium centers and that the complex, isolated in 36% yield, was $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$. Single crystals of $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]\cdot 2CH_2Cl_2$ ($\mathbf{1}\cdot 2CH_2Cl_2$) suitable for X-ray diffraction were obtained from a methylene chloride solution by slow solvent evaporation. The structure of $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ is shown in Fig. 6, selected bond angles and distances are presented in Table 2, and positional parameters and B_{eq} are shown in Table 3.

The two palladium centers are spanned by two bridging dppm ligands and the bridging methylene group. The structure adopts the typical "A-frame" coordination mode common to related systems. Each palladium center is approximately square-planar with terminal chloride ligands *trans* to the bridging methylene group. The most significant deviations from square-planar geometry occurred in the angles P1-Pd1-P2 (174.3(2)°), P3-Pd2-P4 (174.2(2)°), Cl1-Pd1-P2 (95.3(2)°), P1-Pd1-C1 (88.1(6)°), and P2-Pd1-C1 (86.2(6)°). These deviations most likely arise from the incompatibility of the optimum Pd·····Pd separation and the ideal tetrahedral geometry of the bridging methylene group. The structure corresponds closely to that reported previously for the platinum analog (21).

The origin of the methylene bridge in $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ was shown to be the methylene chloride solvent by repeating the reaction of $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ with $Et_2NC{\equiv}CNEt_2$ in d_2-methylene chloride solution. The resulting product exhibited an identical $^{31}P\{^1H\}$ NMR spectrum to that described above ($\delta P = 14.9$ ppm), but the ^1H NMR spectrum lacked the quintet at 1.65 ppm, confirming incorporation of a $\mu\text{-}CD_2$ group in place of $\mu\text{-}CH_2$. In the absence of $Et_2NC{\equiv}CNEt_2$, $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ was shown to be unreactive towards methylene chloride under conditions comparable to those employed in the reaction. Thus, stirring a methylene chloride solution of $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ at room temperature for 3 weeks or refluxing a methylene chloride solution of $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ overnight gave no evidence for formation of $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ by $^{31}P\{^1H\}$ NMR spectroscopy. These data suggest that $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ reacts with $Et_2NC{\equiv}CNEt_2$ to generate one or more species capable of further reaction with methylene chloride to form $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$.

The second product isolated in low yield from the reaction of $[Pd_2Cl_2(\mu\text{-}dppm)_2]$ with a tenfold excess of $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution was identified crystallographically as hexakis(diethylamino)benzene, the cyclotrimerization product derived from $Et_2NC{\equiv}CNEt_2$. The structure of $C_6(NEt_2)_6$ is shown in Fig. 7, selected bond angles and distances are presented in Table 4, and positional parameters and B_{eq} are shown in Table 5.

The molecule possesses approximate C_{6h} symmetry. The bond lengths and angles have normal values and correspond well to those reported for $C_6(NMe_2)_6$ (22). The diethylamino substituents adopt a conformation such that the nitrogen lone pair does not participate in the aromatic π-system and the C_{Ar}—N bond distances reflect the single bond character.

Palladium-promoted cyclotrimerization reactions of acetylene are well known (23) but much of the reported work concerns reactions of simple acetylenes promoted by complexes of palladium(0) or palladium(II). Reactions of functionalized

acetylenes and reactions promoted by palladium(I) are much less common. The cyclotrimerization of the dimethyl ester of acetylene dicarboxylic acid to yield hexamethyl mellitate, promoted by [Pd_2Cl_2(μ-dppm)$_2$], has been described and a mechanism proposed (24). In the case of the cyclotrimerization of $Et_2NC{\equiv}CNEt_2$, a comparable mechanism suggests pathways by which [Pd_2Cl_2(μ-CH_2)(μ-dppm)$_2$] might be formed. Fig-

Fig. 7. ORTEP diagram of $C_6(NEt_2)_6$ (**2**).

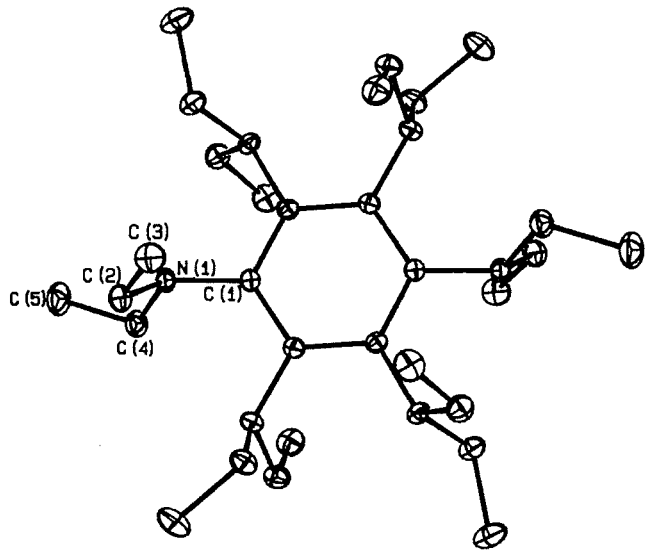

Fig. 8. Possible mechanism for cyclotrimerization of $Et_2NC{\equiv}CNEt_2$.

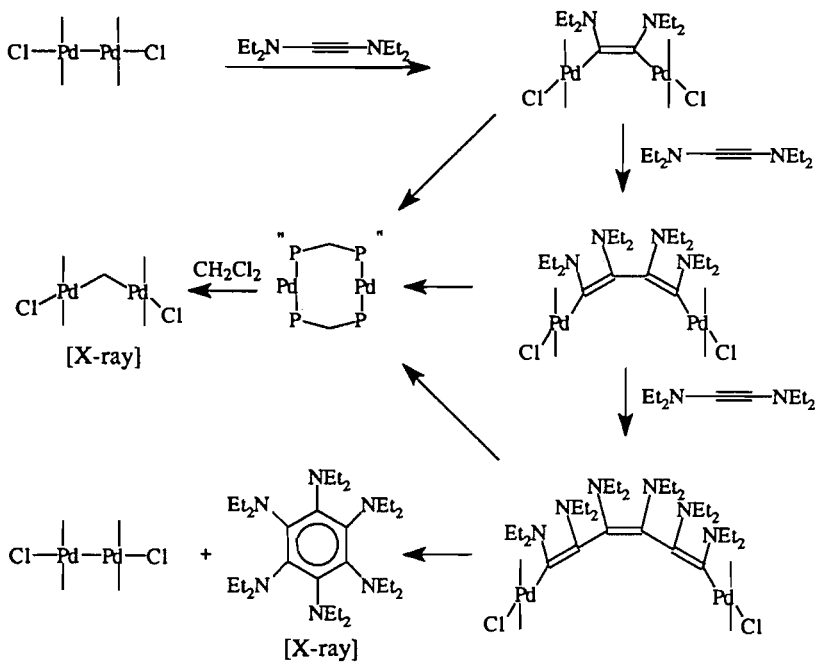

ure 8 outlines a possible mechanism for cyclotrimerization of $Et_2NC{\equiv}CNEt_2$ that is based upon that proposed for hexamethyl mellitate formation (24).

Included in the pathway are intermediates capable of reductive elimination of chlorinated organic fragments. Such processes would lead to the generation of palladium(0) species that might subsequently react with methylene chloride to form $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$. It is noteworthy that $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-}dppm)_2]$ was synthesized earlier by the reaction between the binuclear palladium(0) complex, $[Pd_2(\mu\text{-}dppm)_3]$, and methylene chloride (21). Binuclear palladium(0) complexes of the type $[Pd_2(\mu\text{-}PP)_2]$, although not known with dppm as the bridging ligand, have been isolated and characterized crystallographically with the sterically demanding

$Cy_2P(CH_2)_2PCy_2$ ligand to provide kinetic stabilization (25). Thus, the mechanism illustrated in Fig. 8 appears to be a reasonable pathway, which accounts for the formation of both $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dppm})_2]$ and $C_6(NEt_2)_6$ from the reaction between $[Pd_2Cl_2(\mu\text{-dppm})_2]$ and $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution. However, all attempts, by GC–MS, to detect chlorinated organic products resulting from the various reductive elimination pathways in Fig. 8 failed (26) and so the possibility exists that reactive palladium(0) species, capable of oxidative addition of methylene chloride, arise from other pathways distinct from those illustrated in Fig. 8. Similarly, we cannot exclude the possibility that cyclotrimerization is promoted by a palladium-containing decomposition product.

The complex $[Pd_2Cl_2(\mu\text{-dppm})_2]$ was found to be unreactive towards $Et_2NC{\equiv}CNEt_2$ in chloroform and monitoring a $CHCl_3$ solution of these compounds by $^{31}P\{^1H\}$ NMR spectroscopy over a period of several hours gave no evidence for any reaction. $[Pd_2Cl_2(\mu\text{-dmpm})_2]$ was found to react with $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution and $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dmpm})_2]$ could be isolated in pure form from the reaction mixture in 25.3% yield.

Conclusions

The palladium(I) complex, $[Pd_2Cl_2(\mu\text{-dppm})_2]$, has been shown to react with $Et_2NC{\equiv}CNEt_2$ in methylene chloride solution to yield the product of acetylene cyclotrimerization, $C_6(NEt_2)_6$, and the methylene-bridged complex, $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dppm})_2]$, as isolable products. Formation of $C_6(NEt_2)_6$ suggests initial generation of an acetylene complex capable of further reaction, via two insertion steps and a reductive elimination step, to generate the hexasubstituted benzene. Isolation of $[Pd_2Cl_2(\mu\text{-}CH_2)(\mu\text{-dppm})_2]$ is suggestive of a deactivation pathway that involves generation of a palladium(0) intermediate capable of oxidative addition of the methylene chloride solvent. The results, together with those extant in the literature (24) show that binuclear palladium(I) complexes serve as promoters for the synthesis of hexasubstituted benzenes by acetylene cyclotrimerization and that this reaction is possible even with heteroatom-substituted acetylenes that lead to highly functionalized aromatics. In the case described here, however, the possibility of catalysis by unidentified palladium-containing decomposition products cannot be excluded.

Thiophenophane metal complexes. IV. Effects from ligand changes outside the coordination sphere

C. Robert Lucas and Shuang Liu

Abstract: Preparation of two thiophenophane polythioether macrocycles and 11 of their complexes of Cu(I), Cu(II), Ag(I), and Pd(II) is described. The single crystal X-ray structure of $[(CuBr)_2(L1)]_x$ is reported: space group *Pcma*, $a = 8.7120(6)$, $b = 10.7791(5)$, $c = 12.0929(5)$ Å, $Z = 2$, $R_f = 0.052$, $R_w = 0.036$ for 521 reflections. Variable-temperature magnetic susceptibility measurements for $[(CuCl_2)_2(L1)]$ and $[(CuCl_2)_2(L2)]$ reveal weak antiferromagnetic and weak ferromagnetic coupling, respectively. Cyclic voltammograms of these compounds display two unequal waves in acetonitrile solvent but only one in nitromethane or dimethyl sulfoxide. ^{1}H NMR spectra of $\{[(\eta\text{-}C_3H_5)Pd]_2(L1)\}\{PF_6\}_2$ and $\{[(\eta\text{-}C_3H_5)Pd]_2(L2)\}\{PF_6\}_2$ in various solvents show different temperature responses. These magnetic, electrochemical, and NMR effects are discussed in the light of structural differences at sites in the two ligands that are outside the coordination spheres.

Key words: magnetic susceptibility, copper, thioether, electrochemistry.

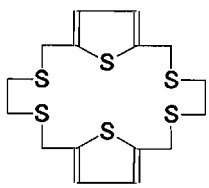
Résumé : On décrit la préparation de deux thiophénophanes, des polyéthers macrocycliques, et de onze le leurs complexes de Cu(I), Cu(II), Ag(I) et Pd(II). On rapporte la structure par rayons X sur un cristal unique du complexe $[(CuBr)_2(L1)]_x$. Le cristal appartient au groupe d'espace *Pnma* avec $a = 8{,}7120(6)$, $b = 10{,}7791(5)$, $c = 12{,}0929(5)$ Å, $Z = 2$. $R_f = 0{,}052$, $R_w = 0{,}036$ pour 521 réflexions. Les mesures de susceptibilité magnétique à température variable révèlent que les composés $[(CuCl_2)_2(L1)]$ et $[CuCl_2)_2(L2)]$ ont respectivement de faibles couplages antiferromagnétiques et ferromagnetiques. Les voltampérogrammes cycliques de ces composés montrent deux ondes inégales dans l'acétonitrile comme solvant, mais seulement une onde dans le nitrométhane ou dans le diméthylsulfoxyde. Les spectres de RMN du ^{1}H des complexe $\{[(\eta\text{-}C_3H_5)Pd]_2(L1)\}\{PF_6\}_2$ et $\{[(\eta\text{-}C_3H_5)Pd_2(L2)\}\{PF_6\}_2$ dans différents solvants donnent des résultats différents selon la température. On discute des effets magnétique, électrochimique et RMN à la lumière des différences structurales au niveau des sites qui, dans les deux ligands, sont en dehors des sphères de coordination.

Mots clés : susceptibilité magnétique, cuivre, thioéther, électrochimie.

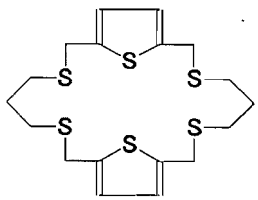
[Traduit par la rédaction]

Introduction

Changes in bond lengths and angles in the coordination sphere have been widely studied as a means of tuning the properties of metal complexes once the gross features of these properties have been determined by the choice of a metal, its oxidation state, and its donor atoms (1). We have been interested for some time in the often more subtle effects that can be achieved by changes in a ligand's skeleton or its conformation at sites that are remote from the coordination sphere (2, 3). These changes can have quite dramatic effects and are believed to be involved, in ways that are not yet well understood, in long-range (>10 Å) transmission of magnetic or electronic influences through enzymes and other large structures (4, 5). In this report, we describe studies of the consequences of structural change at sites in the ligands L1 and L2 that are outside a coordination sphere.



L1



L2

Experimental

Commercially available reagents were obtained from the Aldrich Chemical Co. Inc., or from Morton Thiokol Alfa Products Inc. and were used without further purification.

Received November 6, 1995.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

Those used for cyclic voltammetry measurements were spectroscopic grade. Spectroscopic data were obtained by using the following instruments: IR, Mattson Polaris FT; UV–VIS, Cary model 17; ESR, Bruker ESP-300 X-band spectrometer operating at ~9.5 GHz; NMR, General Electric 300-NB; mass spectra, VG micromass 7070 HS. FAB mass spectra were obtained by using a matrix composed of glycerol and *p*-toluenesulfonic acid (PTSA). Solution "glasses" for ESR measurements were prepared by plunging sealed capillaries containing ~10^{-4} mol/L solutions into liquid nitrogen. Magnetic susceptibility data were obtained at room temperature by the Faraday method. Variable-temperature magnetic susceptibility data on powder samples were obtained in the range 5–300 K by using an Oxford Instruments superconducting Faraday magnetic susceptibility system with a Sartorius 4432 microbalance. Main solenoid fields of 1.5 and 2.0 T and a gradient field of 10 T m^{-1} were employed and the susceptibility data were corrected for diamagnetism by using Pascal constants. A value of 60 × 10^{-6} cgsu/mol of copper atoms was used as a correction for temperature-independent paramagnetism (TIP) (6). The calibrant was $HgCo(NCS)_4$. Curve fittings were carried out by using a locally modified program for nonlinear weighted least squares as proposed by Wentworth (7) on the basis of work by Deming (8). Electrochemical measurements were carried out under a nitrogen atmosphere at room temperature by using a Cypress Systems, Inc., CS-1087 computer-controlled potentiostat. Solution concentrations were 10^{-3} mol/L in complex and 0.1 mol/L in supporting electrolyte (tetraethylammonium perchlorate). Voltammograms were recorded in acetonitrile by using a glassy carbon working electrode that was pre-polished with 0.3 μm Al_2O_3, a platinum counter electrode, and an aqueous saturated calomel reference electrode checked periodically relative to a 1.0 × 10^{-3} mol/L solution of ferrocene in acetonitrile containing 0.1 mol/L tetraethylammonium perchlorate for which the ferrocene/ferrocenium reduction potential was 400 mV. The reference electrode was separated from the bulk of the solution by a porous Vycor tube. Junction potential corrections were not used. Voltages reported versus the normal hydrogen electrode were obtained by adding 244 mV to the potential measured versus SCE. Analyses were performed by Canadian Microanalytical Service Ltd.

Ligands

(a) (Ligand L1)

Sodium (2.35 g, 0.102 mol) was dissolved in commercial absolute ethanol (300 mL) under an atmosphere of dry nitrogen. To this solution 1,2-ethanedithiol was added slowly and, after the addition was complete, the solution was refluxed gently for 10 min. To the refluxing solution 2,5-bis(chloromethyl)thiophene (9) in commercial absolute ethanol (200 mL) was added with vigorous stirring over 10 h. The mixture was refluxed for an additional 12 h. and then volatiles were removed under reduced pressure. The solid residue was dissolved in $CHCl_3$ and the solution washed several times with water before being dried over $CaCl_2$. The solvent was removed under reduced pressure, leaving a white solid that was recrystallized from benzene to give needle-like crystals; mp 126–127°C. Yield 2.11 g (20.8%). NMR: ($CDCl_3$, ppm from TMS internal standard, assignments based on ^{13}C–^1H heteronuclear correlation and attached proton test, position identification from Fig. 1), ^{13}C: 142.9 C2, 125.2 C1, 32.3 C4, 31.6 C3; ^1H: 6.70 (s) C1 (4H), 3.87 (s) C3 (8H), 2.67 (s) C4 (8H). Mass spectrum: parent ion $[C_{16}H_{20}S_6]^+$, calcd., *m/z*: 404; found, *m/z*: 404. Anal. calcd. for $C_{16}H_{20}S_6$: C 47.48, H 4.98; found: C 47.89, H 5.07.

(b) (Ligand L2)

The procedure was similar to that for L1 (above) except that 1,3-propanedithiol (5.50 g, 0.0501 mol) was used and, after removing ethanol, the residue was dissolved in CH_2Cl_2 instead of $CHCl_3$. Recrystallization from benzene gave white needle-like crystals; mp 122–123°C. Yield 2.69 g (24.8%). NMR: ($CDCl_3$, ppm from TMS int. std., assignments based on ^{13}C-^1H heteronuclear correlation and attached proton test, position identification from Fig. 1), ^{13}C: 141.9 C2, 125.7 C1, 30.9 C3, 30.1 C4, 28.3 C5; ^1H: 6.75 (s) C1 (4H), 3.86 (s) C3 (8H), 2.49 (t, J = 7.2 Hz) C4 (8H), 1.72 (q, J = 7.2 Hz) C5 (8H). Mass spectrum: parent ion $[C_{18}H_{24}S_6]^+$, calcd., *m/z*: 432; found, *m/z*: 432. Anal. calcd. for $C_{18}H_{24}S_6$: C 49.96, H 5.59; found: C 50.01, H 5.66.

Complexes

NOTE: *Perchlorate salts are often treacherously explosive (10) and although we have been unable to cause the compounds described below to detonate from shock or heat we recommend suitable precautions be taken whenever perchlorates are handled.*

(a) [$(CuCl_2)_2$(L1)]

To a solution of $CuCl_2 \cdot 2H_2O$ (70 mg, 0.41 mmol) in the mixed solvent tetrahydrofuran–methanol (15 mL:2 mL) was added a solution of L1 (81 mg, 0.20 mmol) in CH_2Cl_2 (5 mL). The dark-green solution was filtered immediately and the filtrate was allowed to evaporate slowly in air until dark-green crystals formed that were collected by filtration, washed with small amounts of chloroform and then diethyl ether, and dried in air; mp 140–143°C (dec.). Yield 105 mg (78%). Anal. calcd. for $C_{16}H_{20}Cl_4Cu_2S_6$: C 28.53, H 2.99, Cl 21.06 Cu 18.87; found: C 29.34, H 3.16, Cl 21.29, Cu 18.40.

(b) [$(CuCl)_2$(L1)]

To a solution of CuCl (25 mg, 0.25 mmol) in acetonitrile (20 mL) was added a solution of L1 (51 mg, 0.13 mmol) in CH_2Cl_2 (5 mL). The yellow-coloured solution of cuprous chloride darkened to a deeper yellow upon addition of the ligand and after filtration this solution was left standing in air to evaporate solvent. Dark yellowish-brown crystals were deposited and were separated by filtration. The crystals were washed with small amounts of dichloromethane and then diethyl ether and dried in air; mp 200–205°C (dec.) Yield 67 mg (89%). Anal. calcd. for $C_{16}H_{20}Cl_2Cu_2S_6$: C 31.89, H 3.34, Cl 11.77, Cu 21.09; found: C 32.18, H 3.44, Cl 12.30, Cu 20.08.

(c) [$(CuBr)_2$(L1)]$_x$

To a solution of $CuBr \cdot S(CH_3)_2$ (60 mg, 0.29 mmol) in acetonitrile (15 mL) was added a solution of L1 (50 mg, 0.12 mmol) in dichloromethane (5 mL). The solution was filtered and left standing in air to evaporate solvent. Light-yellow crystals formed that were separated and washed with small amounts of dichloromethane and then diethyl ether and dried in air; mp 191–194°C (dec.) Yield 70 mg (84%). Anal. calcd. for

$C_{16}H_{20}Br_2Cu_2S_6$: C 27.79, H 2.91, Br 23.11, Cu 18.38; found: C 28.16, H 2.92, Br 23.89, Cu 17.8.

(d) [Ag(L1)][ClO$_4$]

To a solution of $AgClO_4 \cdot H_2O$ (41 mg, 0.18 mmol) in acetonitrile (10 mL) was added a solution of L1 (81 mg, 0.20 mmol) in CH_2Cl_2 (5 mL). The colourless solution was filtered and left standing in air to evaporate solvent. Colourless crystals formed that were separated and washed with small amounts of dichloromethane and then diethyl ether and dried in air; mp 176–180°C (dec.). Yield 105 mg (95%). Anal. calcd. for $C_{16}H_{20}AgClO_4S_6$: C 31.40, H 3.29, Ag 17.63; found: C 31.54, H 3.39, Ag 18.7.

(e) {[(η-C$_3$H$_5$)Pd]$_2$(L1)}{PF$_6$}$_2$

To a solution of $[(\eta\text{-}C_3H_5)PdCl]_2$ (74 mg, 0.20 mmol) in acetonitrile (10 mL) was added a solution of $AgPF_6$ (105 mg, 0.42 mmol) in acetonitrile (10 mL). A white precipitate formed immediately and after stirring for 5 min the precipitate was removed by filtration. To the filtrate was added a solution of L1 (81 mg, 0.20 mmol) in CH_2Cl_2 (5 mL). The solution was filtered and left standing in air to evaporate solvent. Bright-yellow crystals formed that were separated and washed with small amounts of CH_2Cl_2 and then diethyl ether and dried in air; mp 170–175°C (dec.) Yield 152 mg (77%). Anal. calcd. for $C_{22}H_{30}F_{12}P_2Pd_2S_6$: C 26.70, H 3.06; found: C 27.10, H 3.05.

(f) [(CuCl$_2$)$_2$(L2)]

To a solution of $CuCl_2 \cdot 2H_2O$ (43 mg, 0.25 mmol) in tetrahydrofuran (10 mL) was added a solution of L2 (108 mg, 0.25 mmol) in CH_2Cl_2 (5 mL). The deep-green solution was filtered and left standing in air to evaporate solvent. The deep green crystals that formed were separated and washed with small amounts of CH_2Cl_2 and then diethyl ether and dried in air; mp 140–145°C (dec.) Yield 67 mg (76%). Anal. calcd. for $C_{18}H_{24}Cl_4Cu_2S_6$: C 30.81, H 3.45, Cl 20.21, Cu 18.10; found: C 31.62, H 3.51, Cl 19.46, Cu 17.6.

(g) [(CuCl)$_2$(L2)]

To a solution of CuCl (25 mg, 0.25 mmol) in acetonitrile (10 mL) was added a solution of L2 (56 mg, 0.13 mmol) in CH_2Cl_2 (5 mL). The resulting solution was filtered and left standing in air to evaporate solvent. The light brown crystals that formed were separated, washed with small amounts of CH_2Cl_2 and then diethyl ether, and dried in air; mp 200–205°C (dec.) Yield 65 mg (82%). Anal. calcd. for $C_{18}H_{24}Cl_2Cu_2S_6$: C 34.28, H 3.84, Cl 11.24, Cu 20.15; found: C 33.97, H 3.81, Cl 10.93, Cu 19.6.

(h) [Ag(L2)][ClO$_4$]

To a solution of $AgClO_4 \cdot H_2O$ (45 mg, 0.20 mmol) in acetonitrile (10 mL) was added a solution of L2 (87 mg, 0.20 mmol) in CH_2Cl_2 (5 mL). The colourless solution was filtered and left standing in air to evaporate solvent. The colourless crystals that formed were separated, washed with small amounts of CH_2Cl_2 and then diethyl ether, and dried in air; mp 150–153°C (dec.) Yield 81 mg (94%). FAB mass spectrum: calcd. for $[C_{18}H_{24}{}^{109}AgS_6]^+$ and $[C_{18}H_{24}{}^{107}AgS_6]^+$, *m/z*: 541 and 539; found; *m/z*: 541 and 539. Anal. calcd. for $C_{18}H_{24}AgClO_4S_6$: C 33.78, H 3.78; found: C 34.13, H 3.87.

(i) [(PdCl$_2$)$_2$(L2)]

To a refluxing solution of $PdCl_2$ (89 mg, 0.50 mmol) in CH_3CN (60 mL) was added dropwise a solution of L2 (108 mg, 0.25 mmol) in CH_2Cl_2 (20 mL). The solution was refluxed for a further 4 h during which time the colour changed to orange. The hot solution was filtered, concentrated to 30 mL, and cooled in an ice bath to give orange crystals that were separated, washed with a little diethyl ether, and dried in air; mp 147–155°C (dec.) Yield 124 mg (63%). Anal. calcd. for $C_{18}H_{24}Cl_4Pd_2S_6$: C 27.46, H 3.07; found: C 27.81, H 3.10.

(j) {[(η-C$_3$H$_5$)Pd]$_2$(L2)}{PF$_6$}$_2$

To a solution of $[(\eta\text{-}C_3H_5)PdCl]_2$ (74 mg, 0.20 mmol) in acetone (15 mL) was added $AgPF_6$ (105 mg, 0.42 mmol) in acetone (5 mL). The white precipitate that formed was removed by filtration and to the filtrate was added L2 (45 mg, 0.10 mmol) in CH_2Cl_2 (10 mL). The solution was filtered and left standing in air to evaporate solvent. The yellow crystals that formed were separated, washed with small amounts of CH_2Cl_2 and then diethyl ether, and dried in air; mp 163–167°C (dec.) Yield 62 mg (71%). Anal. calcd. for $C_{24}H_{34}F_{12}P_2Pd_2S_6$: C 28.33, H 3.37; found: C 28.60, H 3.38.

(k) [Cu$_2$(L2)][ClO$_4$]$_2$·6CH$_3$CN

To a solution of CuCl (50 mg, 0.50 mmol) in acetonitrile (15 mL) was added $AgClO_4 \cdot H_2O$ (113 mg, 0.50 mmol) in acetonitrile (15 mL). The white precipitate that formed was removed by filtration and to the filtrate was added L2 (108 mg, 0.25 mmol) in CH_2Cl_2 (15 mL). The solution was filtered and left standing in air to evaporate solvent. The brown crystals that formed were separated, washed with small amounts of CH_2Cl_2 and then diethyl ether, and dried in air; mp 185–190°C (dec.) Yield 191 mg (76%). Anal. calcd. for $C_{30}H_{42}N_6Cl_2Cu_2O_8S_6$: C 35.85, H 4.21, N 8.36, Cu 12.65; found: C 35.49, H 4.20, N 7.82, Cu 12.4.

X-ray

A summary of crystallographic data for $[(CuBr)_2(L1)]_x$ is found in Table 1. X-ray diffraction data were collected by using a Nonius CAD-4 diffractometer. All measurements were made with graphite monochromated Mo Kα radiation and the θ–2θ scan technique with profile analysis (11) at a scan speed of 4°/min. Three standards were measured after every 100 reflections and no significant crystal decay was detected. Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement of the setting angles of 20 carefully centred reflections in the range $30.00° < 2\theta < 40.00°$, corresponded to an orthorhombic cell with dimensions as shown in Table 1. The space group was determined by systematic absences, a statistical analysis of intensity distribution, packing considerations, and the successful solution and refinement of the structure. Of the 1011 reflections collected 779 were unique. The data were corrected for Lorentz and polarization effects but no corrections were made for absorption.

The structures were solved with MULTAN (12) plus a difference Fourier map and refined by full-matrix least squares with counting statistics weights. All calculations were performed with the NRC VAX Crystal Structure programs (13). Non-hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was based on 521 observed

[b]Goodness of fit = $[\Sigma w(|F_o| - |F_c|)^2/(\text{no. of reflections} - \text{no. of parameters})]^{1/2}$.

reflections ($I > 2.50\sigma(I)$) and 64 variables and converged with unweighted and weighted agreement factors ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)]^{1/2}$) equal to 0.052 and 0.036, respectively. Neutral atom scattering factors were from the usual source (14). A description of the experimental procedure, anisotropic thermal parameters, and a full listing of bond lengths and bond angles are available as supplementary data.[3]

Discussion

The X-ray study of $[(CuBr)_2(L1)]_x$ reveals (Fig. 1) a two-dimensional polymeric structure consisting of an extended series of fused rings, some of which contain Cu_2Br_2 subunits and some of which contain thiophene subunits. For the macrocyclic ligand, all thioether sulfur lone pairs are exocyclic in a manner reminiscent of other thiophenophanes as free ligands or in some of their complexes (15–19). Rigidity imposed by the thiophene units on the macrocyclic ring limits the ring's ability to place its thioether electron pairs endocyclic during complex formation, as has been noted previously in thiophenophane complexes (15).

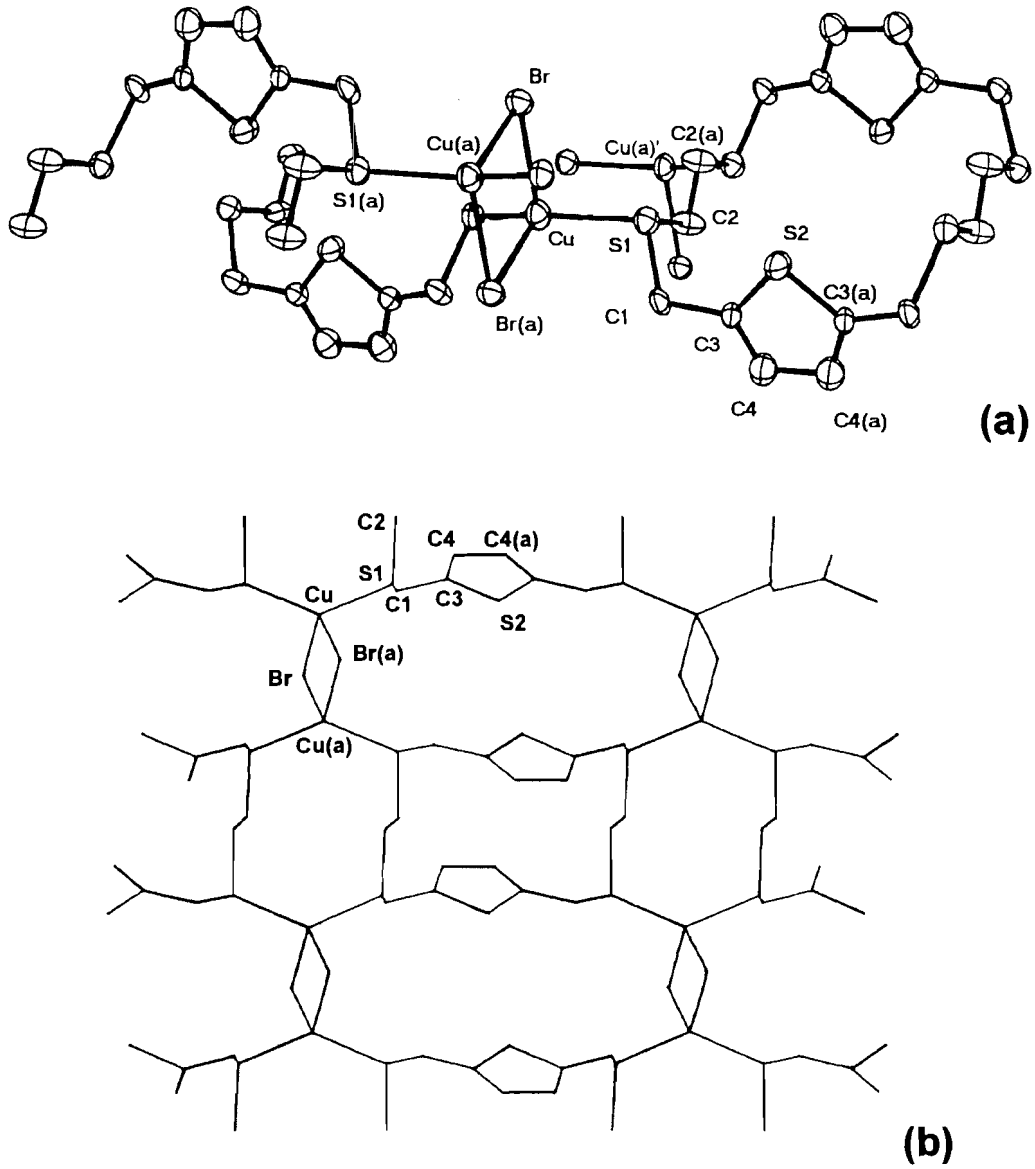
Overall, the structure of $[(CuBr)_2(L1)]_x$ can be described as a series of sheets stacked in such a way that one is slipped with respect to the next along one axis only (the vertical axis in Fig. 1) so that the macrocyclic ligand ring cavities in every second sheet are superimposed. The coordination geometry about copper is distorted tetrahedral. Each copper atom is coordinated to two thioether sulfur atoms in two different macrocyclic rings with a bond angle at copper that is substantially larger (134.93(21)°) than the tetrahedral angle. One pair of equivalent S-Cu-Br angles is closed slightly (99.94(11)°) while the remaining equivalent pair is less disturbed at 105.36(12)°. The Cu_2Br_2 rings are roughly at right angles to the plane of the polymer sheet and have internal angles of 109.52(13)° at copper and 70.48(10)° at bromine. This structure may be compared to that of $[Cu(L)Br]_x$ (L = 1,4,8,11-tetrathia[11](3,6)pyridizinophane) (20), which is also a two-dimensional extended polymer with Cu_2Br_2 and macrocyclic ligand rings and distorted tetrahedral coordination about each copper consisting of two bromines and two thioether sulfurs from separate macrocycles. The Cu–S distance of 2.298(4) Å in our $[(CuBr)_2(L1)]_x$ is somewhat shorter than the Cu–S distances in $[CuBr(L)]_x$ (2.321(2) and 2.315(2) Å) and is in fact shorter than the Cu–S distances in [Cu(L′)Cl] (L′ = 2,5,8-trithia[9](1,2)benzenophane (2.303(2), 2.311(2), 2.398(2) Å) (21) or the shortest Cu-S distance in $[Cu(L'')_2]^+$ (L″ = 2,5,8-trithia[9](2,5)thiophenophane) (2.301(3) Å) (16). It is longer, however, than the shortest Cu–S distances in $[Cu([15]aneS_5)]^+$ (2.243(5) Å) (22) or in $[Cu(DTO)_2]^+$ (DTO = 3,6-dithiaoctane) (2.280(4) Å) (23). The Cu—Br distances in the Cu_2Br_2 rings of $[(CuBr)_2(L1)]_x$ are unequal (2.490(4) and 2.577(3) Å) and slightly longer than the comparable pair of unequal Cu—Br distances in $[Cu(L)Br]_x$ (2.458(1) and 2.507(1) Å) (20).

The structures of $[(CuCl)_2(L1)]$ and $[(CuCl)_2(L2)]$ were not determined but their poor solubility in all solvents is similar to that of $[(CuBr)_2(L1)]_x$ and it is assumed that they too are polymeric with solid state structures analogous to that of $[(CuBr)_2(L1)]_x$. Likewise, structures of $[Cu(L2)][ClO_4]$, $[Ag(L1)][ClO_4]$ and $[Ag(L2)][ClO_4]$ have not been determined but probably also involve exocyclic ligand electron lone pairs and oligomeric or polymeric natures. The fact that the FAB mass spectrum of $[Ag(L2)][ClO_4]$ detected a mononuclear parent ion is not proof of a mononuclear structure since the thiophenophane complex $[Ag_2(L)_2][ClO_4]_2$ (L = 2,5,8,11-tetrathia[12](2,5)thiophenophane), which is known to be dinuclear from X-ray studies, also gives a mononuclear parent ion under similar conditions (15).

The IR spectrum of $[(CuCl_2)_2(L1)]$ has strong bands at 312 and 288 cm^{-1} that are similar to those in other dinuclear copper(II) species having asymmetric double Cl-bridges, which we have described previously (19). Those substances and, by inference, $[(CuCl_2)_2(L1)]$ as well involve-square pyramidal coordination about each copper by two bridging chlorines, a terminal chlorine, and two thioether donors. The bridging is asymmetric and goes from apex to base through both bridges.

[3] A complete set of data may be purchased from: The Depository of Unpublished Data, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Except for the anisotropic thermal parameters, the data mentioned above have also been deposited with the Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Fig. 1. X-ray structure for $[(CuBr)_2(L1)]_x$. (*a*) Details near the Cu coordination sphere. (Thermal ellipsoids at 50% probability level.) (*b*) A single polymer sheet.



This geometry is similar to that described above for $[(CuBr)_2(L1)]_x$ except that a terminal Cu–halogen bond is missing from each copper's coordination sphere as would be expected since $[(CuBr)_2(L1)]_x$ involves Cu(I), not Cu(II). The spectrum of $[(CuCl_2)_2(L2)]$ has a single strong, broad band at 340 cm^{-1} that may or may not represent two unresolved bands plus a weak band at 312 cm^{-1}. In either case, it suggests that the bridge bond lengths and angles of the Cu_2Cl_2 system in $[(CuCl_2)_2(L2)]$ are probably just slightly different from those in $[(CuCl_2)_2(L1)]$. This conclusion is of importance with respect to subsequent interpretation of the temperature-dependent magnetic properties of this substance.

Electronic spectral details for the two copper(II) compounds are given in Table 4. The energies of both charge transfer and *d–d* envelope bands and the shapes of the *d–d* envelopes are very similar to those observed previously (19) for species discussed above in connection with the infrared spectra. The electronic spectral data therefore also indicate that the coordination spheres in $[(CuCl_2)_2(L1)]$ and $[(CuCl_2)_2(L2)]$ are similar to each other and to those in the substances described previously. A slight difference in the position of the *d–d* envelopes also indicates distortional differences in otherwise similar coordination spheres as did the infrared spectra.

ESR spectra are consistent with the results from infrared and electronic spectroscopy and indicate axial systems in both solids and *N,N*-dimethylformamide (DMF) solutions. The spectra of solid $[(CuCl_2)_2(L1)]$ and $[(CuCl_2)_2(L2)]$ are indistinguishable at 77 K and at 278 K as are those of DMF solutions at room temperature or as "glasses" at 77 K. At both 77 K and 278 K, all spectra of solid samples have $g_{\|} = 2.174$ and $g_{\perp} = 2.025$, which gives $g_{av} = 2.076$. In DMF solution at room temperature, the spectra are isotropic with $g_{iso} = 2.172$. In

DMF solution "glass" at 77 K, overlapping signals due to two components can be seen. The major component has $g_{\|} = 2.343$, $g_{\perp} = 2.051$ and $A_{\|} = 120 \times 10^{-4}$ cm^{-1}, giving $g_{av} = 2.148$. The minor component has $g_{\|} = 2.396$, $g_{\perp} = 2.052$, and $A_{\|} = 126 \times 10^{-4}$ cm^{-1} giving $g_{av} = 2.167$. The major component is $[CuCl{\cdot}n(DMF)]^+$ and the minor component is $[CuCl(L)]^+$. These components are commonly seen in solutions of related substances and arise from a solvent-driven dissociative equilibrium (3, 24).

Cyclic voltammograms of $[(CuCl_2)_2(L1)]$ and $[(CuCl_2)_2(L2)]$ show interesting similar solvent dependencies (Table 5). In acetonitrile, each compound gives two unequal waves but in nitromethane or dimethyl sulfoxide (DMSO) only one is detected. The possibility that there is a stepwise reduction of the dinuclear species in acetonitrile is unlikely because of the inequality of the two waves and the large separation of the two $E_{1/2}$ values (~500 mV). No evidence for a (Cu(II)/Cu(I)) dinuclear species (25, 26) has been found by either electrochemical or chemical reduction methods and the two waves are therefore due to two different electroactive species in solution. The species giving the larger current response in each case (Components 1, Table 5), have wave characteristics ($E_{1/2}$, ΔE_p) similar to each other and to those of several CuS_2Cl^+ solvates that we have studied previously (24). The Component 2 species are slightly different in each case but are more like each other than they are like Components 1. The Component 2 wave is not produced as a result of ligand conformation changes in solution because the wave shape does not change with scan rate (27). It is most likely therefore, that the Component 2 waves arise from further solvolysis of the dominant Component 1 species (28–31). Whether this involves loss of the second chloride or loss of a thioether donor is unclear and electronic spectra (Table 4) shed no light on this question except to indicate that the chromophore in solution is different from that in the solid state. We have, however, observed only single waves for three square-pyramidal $[CuS_2Cl_2]_2$ species with thiophenophane ligands, similar except for their hydrocarbon parts to those in the present study, which give two waves. Thus, there is a factor involving the ligand skeleton rather than the coordination sphere that controls the rate of solvolysis and hence the presence or absence of the second wave.

That solvent also plays a vital role in the electrochemical response of these substances is readily apparent from the solvent dependence of their electrochemical parameters (Table 5). Comparison of the results of our studies (3, 24) of solution structures with those of others (29–31) suggests that coordination spheres of the solvated species are quite dependent on the nature of the solvent, which influences, among other things, the degree to which original ligands are lost, the extent of solvation, and the stereochemistry.

Results from variable-temperature magnetic susceptibility experiments for $[(CuCl_2)_2(L1)]$ and $[(CuCl_2)_2(L2)]$ are displayed in Fig. 2. For $[(CuCl_2)_2(L1)]$, the shape of the χT versus T curve and the values of χT and μ_{eff} (1.77 B.M.) at room temperature indicate only very weak antiferromagnetic coupling (32) between the Cu(II) atoms. The best fit of the data to the Friedberg magnetization expression (32, 33) obtained by using g, $-2J$ (the intradimer coupling), and J' (the interdimer coupling) as parameters gives $g = 2.041(4)$, $-2J = 2.5(3)$ cm^{-1}, and $J' = -1.99(5)$ cm^{-1} (assuming four nearest-neighbour dimers in the solid). This value of g (2.041) obtained by the fitting process compares reasonably with that obtained by ESR (2.075) and gives some confidence in the values of $-2J$ and J' also obtained by curve fitting.

For $[(CuCl_2)_2(L2)]$, the shape of the χT versus T curve is consistent with very weak ferromagnetic interactions between Cu(II) atoms. In fact, the shape of this curve is quite unusual throughout the higher temperature region where most χT values are larger than normal for a Curie Law or a Curie–Weiss Law Cu(II) system with weak coupling and decrease with temperature instead of remaining constant. In its low-temperature region, there is clear indication of very weak ferromagnetic interactions in the sample. Due to the weakness of these interactions, a plot of χ versus T appears normal for a magnetically dilute system. A plot of $1/\chi$ versus T (Fig. 3), however, reveals both the weakness of the ferromagnetic interactions (a

nearly zero intercept) and a curious increasing deviation from linearity as the temperature is raised. Both effects are reflected in the slightly higher than usual value at room temperature for μ_{eff} (1.86 B.M.). We believe that the high temperature effects are due to spin-orbit coupling since other explanations based on alternating chains of dimers or one dimensional chains with inter-chain interactions fail to give acceptable fits of the data to known models (34). This hypothesis is the subject of an

ongoing theoretical study. The ferromagnetic interactions detected at low temperature in $[(CuCl_2)_2(L2)]$ that appear instead as antiferromagnetic in $[(CuCl_2)_2(L1)]$ are believed to arise from a small change in the Cu-Cl-Cu bridge angle between the two complexes. This change could be caused by differences in environmental strain on the Cu_2Cl_2 rings in the two complexes originating from the extra CH_2 groups in L2 compared to L1. As a result, the bridge angle just barely provides weak antiferromagnetic coupling via super-exchange in $[(CuCl_2)_2(L1)]$ but provides accidental orthogonality of the magnetic orbitals in the bridge of $[(CuCl_2)_2(L2)]$. This would eliminate antiferromagnetic coupling from $[(CuCl_2)_2(L2)]$ and leave only weak ferromagnetic coupling as observed.

The ^{1}H NMR spectra of $\{[(\eta\text{-}C_3H_5)Pd]_2(L1)\}\{PF_6\}_2$ and $\{[(\eta\text{-}C_3H_5)Pd]_2(L2)\}\{PF_6\}_2$ were examined in a variety of solvents as a function of temperature. The purpose of this examination was to search for differences between the L1 and L2 complexes that could be explained on the basis of structural variation. Any such differences found would provide support for the hypothesis presented above to explain the differing magnetic behaviour of the copper(II) complexes of these two ligands. The results are in Table 6 and the important conclusions are that the complexes exhibit stereochemical nonrigidity and that the L2 complex does so at lower temperature than that of L1. Stereochemical nonrigidity of palladium–thioether complexes is now well documented (17, 18,

35–37) and may involve dissociative equilibria, inversions at coordinated sulfur, or sigmatropic rearrangements of the metal atom over several heteroatom binding sites in a ligand. Precisely which are involved in the present cases is not immediately obvious but it is clear that the L1 complex, $\{[(\eta\text{-}C_3H_5)Pd]_2(L1)\}\{PF_6\}_2$, undergoes the processes with greater difficulty than its L2 counterpart. This is evident from the fact that, in CD_3NO_2 at room temperature, the spectrum of $\{[(\eta\text{-}C_3H_5)Pd]_2(L1)\}\{PF_6\}_2$ is only beginning to show broadening of its peaks due to the onset of the processes whereas the spectrum of $\{[(\eta\text{-}C_3H_5)Pd]_2(L2)\}\{PF_6\}_2$ is already indicating discrimination between two types of thiophene hydrogens, two kinds of allyl groups, and two different three-carbon bridges in the macrocyclic ring. In other words, the greater flexibility of L2 proposed above to account for the Cu(II) magnetic phenomena is apparent in the Pd(II) NMR spectra also.

Conclusions

IR, ESR, and electronic spectroscopic evidence and an X-ray diffraction study of the analogous Cu(I) species all indicate that the Cu(II) coordination spheres of the dinuclear complexes described herein are probably distorted square pyramids linked apex-to-base and apex-to-base by two Cl bridges. Together with their macrocyclic ligands, these dinuclear units would give a two-dimensional polymeric sheet, and the sheets when stacked in a staggered array would give the isolated three-dimensional solids. Although the coordination spheres in the Cu(II) L1 and L2 complexes are similar, the evidence indicates their dimensions are probably slightly different due to influences arising from skeletal changes in remote portions of the ligands. Electronic spectroscopic, electrochemical, and ESR evidence indicate dissolving is accompanied by solvolysis, the extent of which is controlled by structural details outside the coordination sphere. Thus, the nature of the ligand framework outside the coordination sphere influences magnetic properties in the solid state, and in solution it influences the extent of solvolysis, which in turn affects the degree of dissociation, stereochemistry of the coordination sphere, and electrochemistry. The same ligand framework differences affect the stereochemical nonrigidity of palladium complexes of these ligands as well.

Acknowledgements

The assistance of Dr. E.J. Gabe (National Research Council) and Dr. L.K. Thompson (Memorial University of Newfoundland) (X-ray and variable temperature magnetic susceptibility data collection, respectively) is gratefully acknowledged as is that of Ms. M. Baggs and Dr. B. Gregory with collection of the FAB and EI mass spectral data. Financial support was provided by the Natural Sciences and Engineering Research Council of Canada and Memorial University of Newfoundland.

Polycarbon ligands: synthesis and characterization of the phosphinodiynes $Ph_2PC{\equiv}C\text{-}C{\equiv}CR$ (R = Bu^t, Ph, $SiMe_3$), the $\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}$-butadiynyl complexes $Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CR)$, and the molecular structure of a cobalt carbonyl derivative $Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{:-}\mu\text{-}\eta^2,\eta^2_{\gamma,\delta}\text{-}C{\equiv}C\text{-}C{\equiv}CBu^t)Co_2(CO)_6$

Peter Blenkiron, John F. Corrigan, Didier Pilette, Nicholas J. Taylor, and Arthur J. Carty

Abstract: The phosphino-diynes ($PPh_2C{\equiv}C\text{-}C{\equiv}CR$) (R = Bu^t, Ph, $SiMe_3$) are obtained in excellent yield from the corresponding diyne anions $RC{\equiv}C\text{-}C{\equiv}C^-$ by quenching with PPh_2Cl. Monosubstitution on $Ru_3(CO)_{12}$ yields the trinuclear clusters $Ru_3(CO)_{11}(PPh_2C{\equiv}C\text{-}C{\equiv}CR)$, which upon thermolysis afford the butadiynyl complexes $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$ (R = Bu^t, **7***a*; R = Ph, **7***b*; R = $SiMe_3$, **7***c*) as the major products. The full characterization of the series of compounds (**7***a–c*) $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$ is reported including an X-ray diffraction study of **7***a*. Crystals of **7***a* are monoclinic, a = 9.849(2), b = 9.886(2), c = 28.368(9) Å, β = 95.18(2)°, space group $P2_1/n$, and Z = 4; refinement converged to R = 0.0243 (R_w = 0.0253). The structure shows that the tetracarbon chain is bonded to the first metal atom by a simple M—C σ bond and to the second via a dative π interaction leaving an outer alkyne unit uncoordinated. In the reaction between **7***a* and cobalt carbonyl, a $Co_2(CO)_6$ moiety becomes attached to the $\text{-}C_\gamma{\equiv}C_\delta\text{-}$ bond in a tetrahedral arrangement to give the tetranuclear mixed-metal species $Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{:}\mu\text{-}\eta^2,\eta^2_{\gamma,\delta}\text{-}C{\equiv}C\text{-}C{\equiv}CBu^t)Co_2(CO)_6$ **8**, as confirmed by X-ray crystallography: triclinic, a = 9.9969(9), b = 11.3018(9), c = 17.268(1) Å, α = 90.653(6)°, β = 100.911(6)°, γ = 110.465(5)°, space group $P\bar{1}$ and Z = 2; refinement converged to R = 0.0222 (R_w = 0.0264).

Key words: diruthenium complexes, butadiynyl, synthesis, structure.

Résumé : On a obtenu les phosphino-diynes ($PPh_2C{\equiv}C\text{-}C{\equiv}CR$) (R = Bu^t, Ph, $SiMe_3$), avec un excellent rendement, par désactivation des anions diynes correspondants $RC{\equiv}C\text{-}C{\equiv}C^-$ avec le PPh_2Cl. La monosubstitution sur le composé $Ru_3(CO)_{12}$ donne les clusters trinucléaires $Ru_3(CO)_{11}(PPh_2C{\equiv}C\text{-}C{\equiv}CR)$ qui, sur thermolyse, donnent les complexes butadiynls $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$ (R = Bu^t, **7***a*; R = Ph, **7***b*; R = $SiMe_3$, **7***c*) comme produits majoritaires. On rapporte la caractérisation complète de la série de composés (**7***a–c*) $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$ en incluant les études de diffraction de rayons X du composé **7***a*. Les cristaux du composé **7***a* appartiennent au groupe d'espace monoclinique $P2_1/n$ avec a = 9,849(2), b = 9,886(2), c = 28,368(9) Å, β = 95,18(2)°, et Z = 4; l'affinement converge vers des valeurs de R = 0,0243 (R_w = 0,0253). La structure montre que la chaîne tétracarbonée est liée au premier atome métallique par une liaison σ simple M—C et au second via une interaction dative π laissant l'unité alcyne externe non coordonnée. Dans l'interaction entre le composé **7***a* et le cobalt carbonyle, l'unité $Co_2(CO)_6$ devient attachée à la liaison $\text{-}C_\gamma{\equiv}C_\delta\text{-}$ selon un arrangement tétraédrique pour donner l'espèce métallique mixte tétranucléaire $Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{:}\mu\text{-}\eta^2,\eta^2_{\gamma,\delta}\text{-}C{\equiv}C\text{-}$

carbon single (M—C_{sp}) (e.g., **2**) and double (M=C_{sp}) (e.g., **4**) bonds or three-dimensional arrays by using both the σ and π electrons of the polycarbon fragment. Much attention has focussed on linear bis(acetylide)-based metal complexes due to the interesting nonlinear optical and liquid crystalline properties of rodlike oligomers and polymers derived from these building blocks (see, for example, ref. 1). Metal fragment terminated polyyne-diyls L_nM-$(C{\equiv}C)_x$-ML_n (2) are also being examined in detail in an effort to prepare materials known as molecular wires where the potential for electronic communication along an extended unsaturated C_n chain can be explored (3). Monometallic and bimetallic cumulenes such as the pentatetraenylidene ruthenium complex [Ru=C=C=C=C=CPh_2(Cl)$(DPPE)_2$][PF_6] (4) and the butatrienebis(ylidene) rhenium compounds [Re]=C=C=C=C=[Re] ([Re] = Cp*(NO)$(PPh_3)^+$) (3*c*) have also been synthesized to probe the materials, and the electronic and chemical properties of these linear polyunsaturated metal complexes. Yet another unsaturated unit for assembling rodlike materials is the polyynylalkylidyne **5** where metal fragments terminate a chain via M≡C_{sp} or M—C_{sp} bonds.[2] There are now many examples of organometallic complexes built from the structural entities represented by **1**–**5**. The polyyne bis(alkylidyne) **6** represents another potential building block. In each of these ligands, the polyunsaturated carbon chains, as well as the metal–carbon multiple bonds in **3**–**6**, are potential sites for further metal complexation and these additional π-bonding capabilities offer enormous scope for the development of new classes of metal-adorned polycarbon materials. Yet to date, few attempts have been made to exploit this carbon–carbon unsaturation to build new polymetallic compounds (5*c*,*d*, 6).

[2] Examples of polyynylalkylidynes are known. See for example, ref. 5.

As an extension of our detailed investigations on the chemistry of bi- and polynuclear compounds bearing μ-η-bound acetylides (7) we have initiated a program to synthesize polymetallic complexes with diynyl -$(C{\equiv}C)_2$-R and diyne-diyl -$(C{\equiv}C)_2$- ligands where one or both C—C multiple bonds are bound in η-fashion to metal fragments. We have found that the phosphino-diynes ($PPh_2C{\equiv}C$-C≡CR) (R = Bu^t, Ph, $SiMe_3$) provide convenient entry to this area of chemistry, undergoing facile P—C bond cleavage in the metal coordination sphere to access complexes containing the butadiynyl ligand. In this paper, we describe the synthesis of these phosphinodiynes and the generation of the first series of binuclear compounds with μ-η^1,η^2 diynyl ligands, namely $Ru_2(CO)_6$(μ-η^1,$\eta^2_{\alpha,\beta}$-C≡C-C≡CR)(μ-PPh_2) (R = Bu^t, **7***a*; R = Ph, **7***b*; R = $SiMe_3$, **7***c*). In this series of compounds, in addition to a metal–C_{sp} bond to one metal, one of the two carbon–carbon triple bonds of the diynyl ligand is attached in η^2 fashion to a second metal atom via a π interaction. The remaining triple bond is free. A further incentive for the study of molecules of type **7** is the opportunity to compare reactivity patterns for coordinated vs. free triple bonds in the same molecule and we report here the reactivity of **7***a* towards $Co_2(CO)_8$. To our knowledge, such a comparison has not been made for alkyne triple bonds.

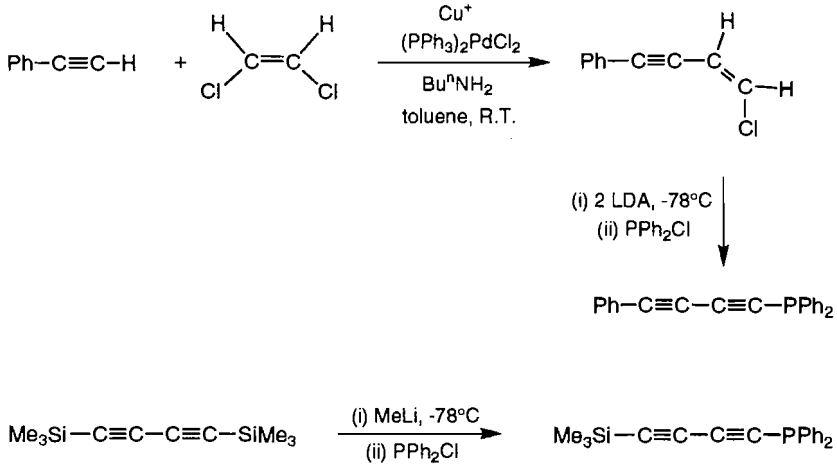
c, R = $SiMe_3$

Results and discussion

Synthesis and characterization of $PPh_2C{\equiv}C$-C≡CR (R = Bu^t, Ph, $SiMe_3$)

The phosphinodiynes $PPh_2C{\equiv}C$-C≡CR (R = Bu^t, Ph) were obtained in good yields from the corresponding terminal butadiyne by low-temperature deprotonation followed by addition of PPh_2Cl. The diynes Bu^{t}C≡C-C≡CH and PhC≡C-C≡CH were prepared according to a literature procedure involving the Cadiot–Chodkiewicz coupling of an

Scheme 1.



appropriately substituted 1-bromoalkyne and the alkynol $HC{\equiv}CCMe_2OH$ (8). This method, however, is a multistep process that provides the diynes in low to moderate overall yield and is particularly unreliable in the case of R = Ph because of a facile polymerization pathway. We have found that a relatively simple two-step route can give direct access to $PPh_2C{\equiv}C\text{-}C{\equiv}CPh$, thus avoiding the necessity of isolating the parent diyne. As shown in Scheme 1, the Pd-catalyzed coupling of *cis*-1,2-dichloroethylene and $PhC{\equiv}CH$ gives the chloro-enyne (9), which is then treated with two equivalents of base to give the diyne anion. Quenching of this solution with PPh_2Cl affords the desired acetylenic phosphine in much improved yield (56%) compared with the Cadiot–Chodkiewicz route (17%). The attempted coupling of $Bu^tC{\equiv}CH$ and $HClC{=}CHCl$ under identical conditions proved unsuccessful, however. A GC–MS analysis of the reaction mixture gave a strong signal corresponding to $Bu^tC{\equiv}CC{\equiv}CBu^t$ and, while reductive elimination of the alkynyl ligands in first-formed $(PPh_3)_2Pd(C{\equiv}CR)_2$ followed by C–C coupling is thought to be the first stage in the catalytic process (10), it seems that subsequent oxidative addition of more alkyne is favoured over addition of $HClC{=}CHCl$.

The $SiMe_3$-substituted phosphinodiyne was prepared in almost quantitative yield (92%) by monodesilylation of $Me_3SiC{\equiv}C\text{-}C{\equiv}CSiMe_3$ using MeLi to give the diyne anion $Me_3SiC{\equiv}C\text{-}C{\equiv}C^-$ (11). Subsequent in situ treatment with PPh_2Cl afforded the desired $PPh_2C{\equiv}C\text{-}C{\equiv}CSiMe_3$ quantitatively and this was isolated as a pale yellow powdery solid.

The series of phosphinodiynes has been characterized by elemental analysis and by IR, NMR, and mass spectroscopies. The latter show the molecular ion at the expected mass and in addition each gives a strong signal corresponding to a PPh_2C_4 fragment. ^{31}P spectra exhibit the expected high-field resonance at $\sim \delta -30$ while ^1H data are in accord with expectation. All four butadiynyl carbons ($PPh_2C_\alpha{\equiv}C_\beta\text{-}C_\gamma{\equiv}C_\delta\text{-}R$) are observed in the ^{13}C spectra and, in common with previously reported alkynylphosphines $PR_2C{\equiv}CR'$ (12), C_β resonates downfield of C_α. Assignment of the ^{13}C signals was achieved on the basis of the magnitude of the J_{PC} coupling constant and by comparing $C\{^1H\}$ and proton-coupled spectra. Thus distinct doublets are observed for C_α (J_{PC} = 9–15 Hz) and C_β (J_{PC} = ~ 6 Hz) (cf. J_{PC} = 15.8 and 5.2 Hz for C_α and C_β, respectively, in the bisphosphine $PPh_2\text{-}C_\alpha{\equiv}C_\beta\text{-}C{\equiv}C\text{-}PPh_2$ (13)) while C_γ and C_δ appear as singlets in the $C\{^1H\}$ spectra. For $PPh_2C{\equiv}C\text{-}C{\equiv}CPh$, C_γ is considerably broadened and this effect may be due to communication along the unsaturated carbon chain. Identification of C_δ is readily apparent in the proton-coupled ^{13}C spectra, occurring either as a multiplet (R = Bu^t, Ph) or as a broadened singlet (R = $SiMe_3$). The remaining quaternary carbon resonance is thus ascribed to C_γ.

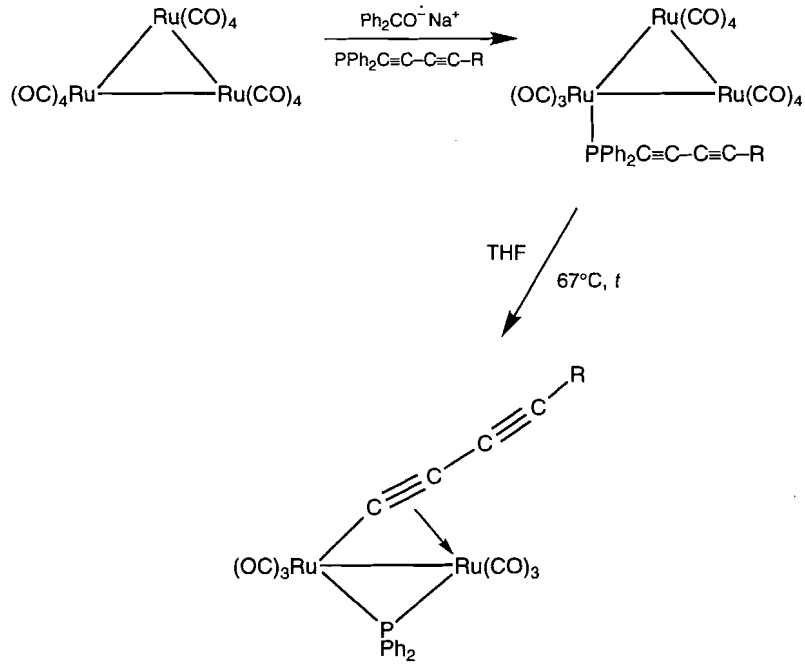
Synthesis and chemistry of $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$ (R = Bu^t, Ph, $SiMe_3$)

Addition of a few drops of sodium benzophenone ketyl catalyst to a room temperature THF solution of $Ru_3(CO)_{12}$ and a slight excess of $PPh_2C{\equiv}C\text{-}C{\equiv}CR$ allows rapid and quantitative conversion to the monosubstituted product $Ru_3(CO)_{11}(PPh_2C{\equiv}C\text{-}C{\equiv}CR)$. Thermolysis of this solution effects P—C bond cleavage and cluster fragmentation (Scheme 2) to afford the yellow dinuclear σ–π complexes $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$ in reasonable yield (R = Bu^t, 31%, **7***a*; R = Ph, 24%, **7***b*; R = $SiMe_3$, 20%, **7***c*) after work-up.

The spectroscopic properties of the series **7** are entirely in accord with expectation and correlate closely with those observed in the acetylide analogue $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$ (**A**). Thus six ν(CO) bands are found in the IR spectrum. These appear at slightly higher wave numbers than in their acetylide counterparts and presumably reflect the electron-withdrawing effect of the outer alkyne group.

The ^{31}P NMR spectra show the expected single peak in the chemical shift range 122.0 – 124.6 with frequencies typical of phosphido-bridged Ru—Ru bonds (14). In the corresponding acetylides $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$ (R = Bu^t, Ph) $\delta^{31}P$ values are 125.2 and 130.5 ppm, respectively (15). As was observed in the case of the acetylides (**A**), **7***a–c* show dynamic behaviour in solution and thus exhibit only three CO resonances in the ^{13}C NMR spectrum. This occurs as a result of σ–π interconversion in which the coordinated C_4R ligand undergoes rapid exchange between the two metal sites, via the well-known windshield wiper fluxional process. All three CO resonances are phosphorus-coupled and consist of a characteristically large J_{PC} coupling for the CO *trans* to the phosphido bridge (J_{PC} ~ 72 Hz) and two smaller *cis* couplings (J_{PC} ~ 12

Scheme 2.



7

a, R = Bu^t, t = 4 h
b, R = Ph, t = 2.5 h
c, R = SiMe$_3$, t = 2 h

Hz, *trans* to M—C_β bond; J_{PC} ~ 5 Hz, *trans* to M—M bond) (16). The four *sp* diyne carbon resonances of **7***a–c* were all located and lie in the range δ 74–109. Chemical shifts for C_α–C_δ were assigned on the basis of their J_{PC} coupling constants.[3] Thus in each case C_α appears as a doublet with a coupling to phosphorus of ~28 Hz and is found downfield of the other quaternary carbons, consistent with its unique coordination to both metal centres. The signal ascribed to C_β shows a J_{PC} of ~8 Hz and these couplings match almost exactly those observed in $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2\text{-}C{\equiv}CR)(\mu\text{-}PPh_2)$. In the latter compounds the chemical shift of C_α and C_β is dependent on the nature of the R group; for the archetypal electron-withdrawing group R = Ph, C_α is downfield of C_β while for the electron-donating Bu^t and Pr^i substituents the positions of the signals are reversed. This picture is consistent with our observation that in **7***a–c*, C_α occurs at lower field than C_β due to the presence of an electronegative outer alkynyl functionality.

Whereas in **7***a* and **7***c* P–C coupling extends only to C_γ, the resonance of C_δ in the ^{13}C spectrum of **7***b* appears as a doublet with $^5J_{PC}$ = 3 Hz. It is tempting to attribute this to increased communication along the C_4 chain when the terminal group is a phenyl substituent attached to C_δ via an sp^2 Ph_{ipso} carbon atom. A paucity of ^{13}C NMR data for butadiynyl complexes prevents any assessment of the generality of this phenomenon; however, it is worth noting that in the η^1-butadiynyl species $Rh(C{\equiv}CC{\equiv}CPh)(CO)(PPr^i_3)_2$, P–C coupling also extends to the C_δ carbon (6*a*). In contrast, for the diynyl complexes $Cp^*Re(NO)(PPh_3)C_4R$ (R = H, Me, $SiMe_3$), P–C coupling to C_δ is absent (5*a*). Long-range, six-bond P–H coupling in the terminal butadiynyl compounds *trans*-$Ru(CO)_2(PEt_3)_2(C{\equiv}CC{\equiv}CH)_2$ has also been cited as evidence of electronic communication along a C_4 chain (1*f*). In the free ligands $PPh_2C{\equiv}CC{\equiv}CR$, J_{PC} coupling extends only to C_β, with C_γ and C_δ resonating as singlets, although in the case of R = Ph, the signal corresponding with C_γ is considerably broadened. Thus it appears that the binding of the C_4 ligand to the metal enhances electronic communication between the phosphorus atom and the butadiynyl carbons.

Since **7***a–c* represent the first known $\mu\text{-}\eta^1,\eta^2$-butadiynyl complexes, it was of interest to determine precise details of the structure for comparison with the acetylide analogues. Thus an X-ray diffraction study of $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2{}_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CBu^t)(\mu\text{-}PPh_2)$ **7***a* was undertaken and the molecular structure is shown in Fig. 1. In the dinuclear molecule two $Ru(CO)_3$ units are bonded via a short (Ru(1)-Ru(2) 2.769(1) Å) bond and are bridged by a symmetrical phosphido group (Ru(1)-P-Ru(2) 71.9(1)°) and a butadiynyl ligand. The tetracarbon fragment is attached to the diruthenium unit via the inner C_α—C_β triple bond, leaving the outer alkyne group unattached. The bonding mode is thus constituted from a σ interaction between Ru(1) and C(7) (2.031(3) Å) and a π-type coordination of the C(7)—C(8) triple bond to Ru(2) (Ru(2)—C(7) 2.284(3) Å, Ru(2)—C(8) 2.408(3) Å). The C(7)—C(8)

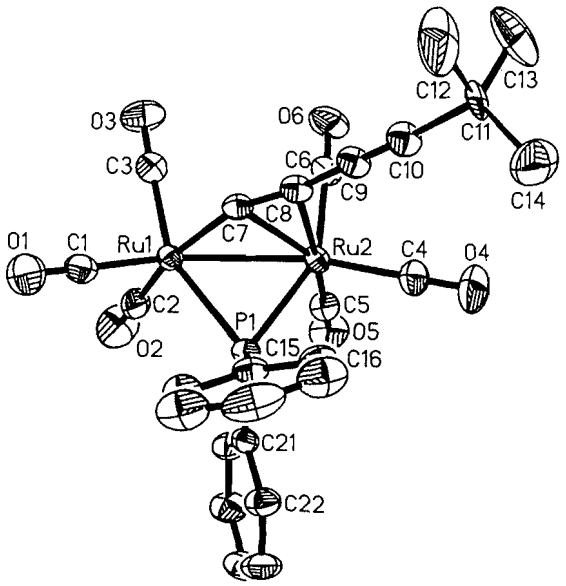
Fig. 1. The molecular structure of $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CBu^t)(\mu\text{-}PPh_2)$ **7***a* showing the atomic numbering scheme. Hydrogen atoms are omitted for clarity.



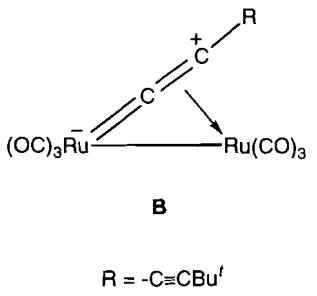


Fig. 2. Key bond lengths and angles in the Ru-C≡C-C≡C fragment of **7***a*.

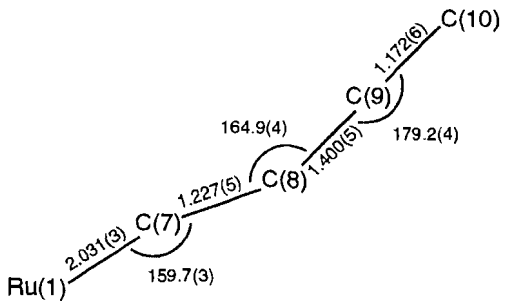


distance of 1.227(5) Å in **7***a* compares favourably with that found in the corresponding acetylide $Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2\text{-}C{\equiv}CBu^t)(\mu\text{-}PPh_2)$ (1.218(4) Å) but is significantly longer than values normally found for C≡C bond lengths in metal-alkynyl complexes where the triple bond is uncoordinated. Indeed, transition metal-alkynyl C≡C bond lengths fall into a relatively narrow range of values and show only small structural perturbations across a wide array of chemical and electronic environments. A recent compilation by Manna et al. revealed that two-thirds of the C≡C distances recorded fall in the range 1.190–1.214 Å (mean value 1.201(16) Å (17). Thus the influence of $\mu\text{-}\eta^1,\eta^2$ coordination is to effect a small but noticeable elongation of the C≡C triple bond with respect to free acetylene (1.2033(2) Å) and in metal η^1-alkynyl complexes. It is interesting that in the molecules *trans*-$Ru(CO)_2(PEt_3)_2(C{\equiv}CC{\equiv}CSiMe_3)_2$ where the butadiynyl ligands are terminal, the C_α—C_β bond length of 1.226(2) Å is essentially identical to that in **7***a*. In this case -C≡C- bond lengthening was attributed to greater delocalization along the $RuC{\equiv}CC{\equiv}CSiMe_3$ chain in the Me_3Si-substituted diynyl complex. This can be represented by a contribution of the type $^-Ru{=}C{=}C{=}C{=}SiMe_3^+$ to the ground state and implies both Ru*d*π–C*p*π* and Si*d*π–polyyne π interactions.

A comparison of the Ru(1)—C(7) distance (2.031(3) Å) in **7***a* with Ru—C_{sp} bond lengths in ruthenium η^1-ynyls and diynyls (*trans*-$Ru(CO)_2(PEt_3)_2(C{\equiv}CPh)_2$, Ru(1)—$C_{sp}$ 2.074(3) Å; *trans*-$Ru(CO)_2(PEt_3)_2(C{\equiv}CSiMe_3)_2$, Ru(1)—$C_{sp}$ 2.062(2) Å; *trans*-$Ru(CO)_2(PEt_3)_2(C{\equiv}CC{\equiv}CSiMe_3)_2$, Ru(1)—$C_{sp}$ 2.057(2) Å) (1*f*) indicates significant Ru—C_α bond shortening in **7***a* consistent with some degree of Ru—C_α multiple bonding as represented by the vinylidene-like structure **B**.

This shortening of the formal single bond between the σ-bound metal atom and C_α of an acetylide coordinated in $\mu\text{-}\eta^1,\eta^2$- fashion at a dinuclear centre becomes even more apparent in trinuclear acetylides. Thus, for example, in $Ru_3(CO)_9$ $(\mu_3\text{-}\eta^1,\eta^2,\eta^2\text{-}C{\equiv}CPr^i)(\mu\text{-}PPh_2)$ the Ru(2)—C(10) *sp* bond length is 1.960(6) Å (18) and in $\{Ru_3(CO)_9(\mu\text{-}PPh_2)\}_2(\mu_6\text{-}C_4)$ where a diyne-diyl unit is bonded in $\mu_3\text{-}\eta^1,\eta^2,\eta^2$- fashion to two separate Ru_3 centres the formal Ru—C_{sp} σ bonds are of length 1.936(6) Å (19). These latter values approach the Ru—CO distances. The presence of partial metal–carbon multiple bonding in the vinylidene-like resonance form **B** has implications for the chemistry of these ruthenium diynyl complexes towards unsaturated metal fragments, as will be described in a forthcoming communication.

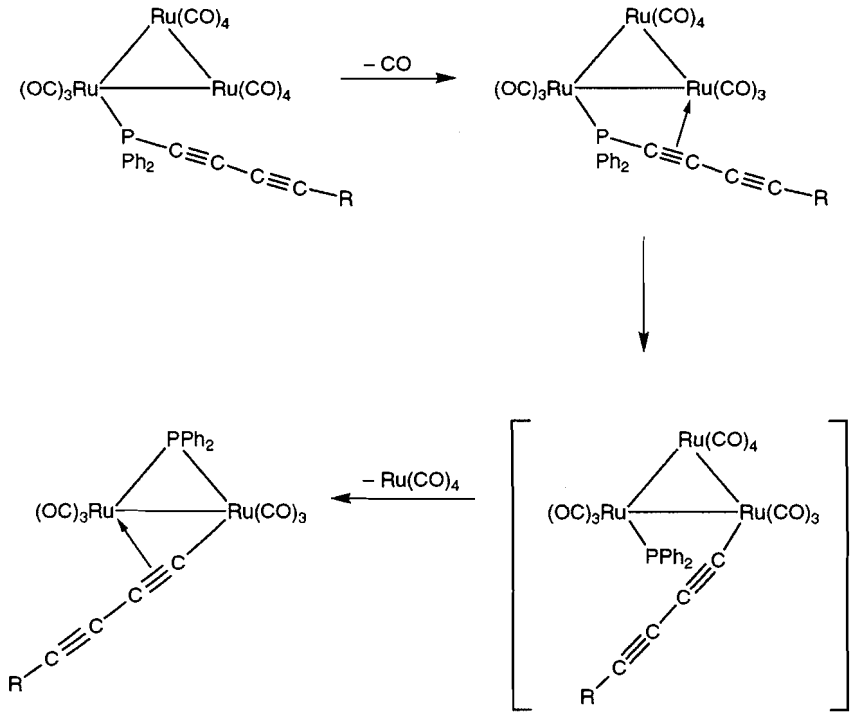
The uncoordinated alkyne -C≡C- bond of **7***a* is very short (C(9)—C(10) 1.172(6) Å and in the normal range for free alkynes (cf. HC≡CH 1.2033(2) Å). Thus it appears that the outer, uncoordinated alkyne in **7***a* serves as an electronegative substituent on the $\mu\text{-}\eta^1,\eta^2$-ynyl fragment, enhancing Ru*d*π—C*p*π* backbonding, shortening Ru—C_α, and elongating the -C≡C- triple bond of the π-coordinated ynyl group.

As expected, there is a marked deviation from linearity in the butadiynyl group on coordination, as shown schematically in Fig. 2, with a C(7)-C(8)-C(9) angle of 164.9(4)°, indicative of some carbon atom rehybridization. This compares closely with corresponding angles in the related tetrairon butadiynediyl complex $\{Fe_2(CO)_6(\mu\text{-}PPh_2)\}_2(\mu_4\text{-}C_4)$ reported by Bruce and co-workers (164.2(4), 165.8(5)°) (19) and approaches those recorded for π-coordinated substituted butadiyne complexes (2*c*, 6*a*, 20). The Ru(1)-C(7)-C(8)-C(9) fragment is *trans* bent as opposed to the normal *cis* bending of an alkyne on η^2 coordination.

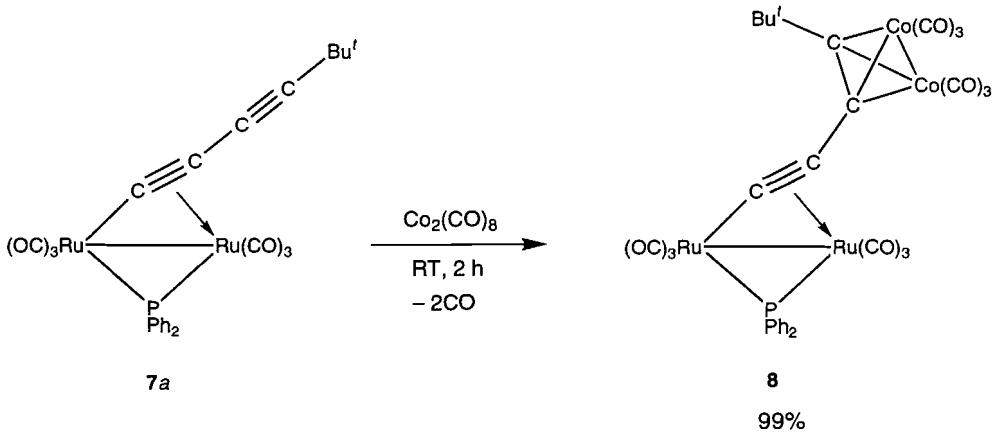
The C(8)—C(9) (1.400(5) Å) bond linking the two alkyne units is shorter than its formal single designation would suggest and is evidence for a certain amount of electronic delocalization along the C_4 fragment. This effect has been noted in structural studies of organic diynes (21) as well as in other transition metal butadiynyl complexes (1*f*, 2*c*,*d*, 3*a*, 22).

A rational mechanism for the formation of **7***a–c* involves

Scheme 3.



Scheme 4.

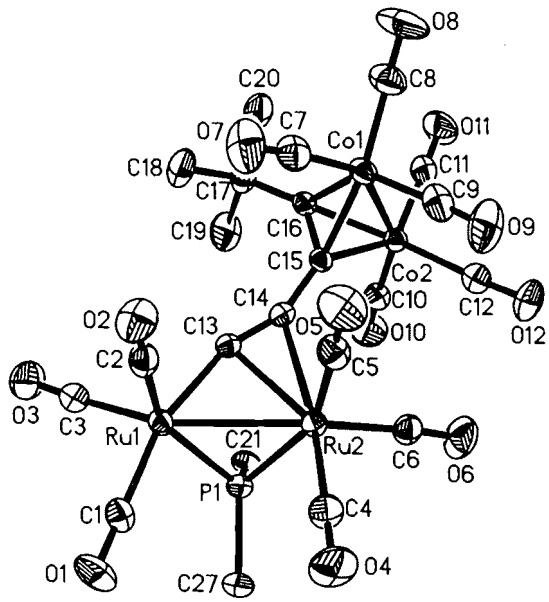


initial attachment of the phosphinobutadiyne via phosphorus to an $Ru_3(CO)_{11}$ moiety followed by intra- (Scheme 3) or intermolecular π coordination of one triple bond, subsequent P—C bond scission, and formation of μ-phosphido and μ-η-alkynyl groups. This mechanism allows the generation of both dinuclear μ-η^1,η^2- and trinuclear alkynyl complexes.

We were interested in exploring the chemical behaviour of the butadiynyl ligand in **7** and as an initial test of its reactivity we investigated the reaction with dicobalt octacarbonyl, $Co_2(CO)_8$ (Scheme 4). From the crystal structure of ***7a*** it appears that the outer alkyne unit is fairly accessible and so it seemed possible that a $Co_2(CO)_6$ group might coordinate perpendicular to the triple bond to furnish the well-known tetrahedral Co_2C_2 arrangement. Thus addition of $Co_2(CO)_8$ to ***7a*** at room temperature gave smooth and quantitative conversion to a single red-brown product after 2 h. A single crystal X-ray diffraction study confirmed the coordination of a $[Co_2(CO)_6]$ unit to the alkyne function to give the mixed-metal tetranuclear compound $Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{:}\mu\text{-}\eta^2,\eta^2_{\gamma,\delta}\text{-}C{\equiv}C\text{-}C{\equiv}CBu^t)Co_2(CO)_6$ **8**. The molecular structure of **8** is shown in Fig. 3.

The structural parameters of the Co_2C_2 tetrahedrane unit in which the alkyne acts as a bridging μ_2 ligand to the dicobalt system are consistent with those reported for other compounds containing this fragment. Thus the Co(1)—Co(2) and C(15)—C(16) separations of 2.462(1) and 1.365(4) Å, respectively, compare with the ranges 2.453(4)–2.477(2) and 1.32(4)–1.36(3) Å found for five other $Co_2(CO)_6(\mu$-diyne) complexes (13, 23). Similarly, the Co—C distances in the Co_2C_2 core fall in the ranges found for these same compounds. The structure provides an interesting comparison of the effect of a three-electron donor σ–π alkynyl group versus a four-electron

Fig. 3. The molecular structure of $Ru_2(CO)_6(\mu\text{-}PPh_2)$-$(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{:}\mu\text{-}\eta^2,\eta^2_{\gamma,\delta}\text{-}C{\equiv}C\text{-}C{\equiv}CBu^t)Co_2(CO)_6$ **8** showing the atomic numbering scheme. For clarity, only the *ipso* carbons of the phenyl rings are drawn and the hydrogen atoms are omitted.



donor 2π acetylene functionality. The effect is most apparent in the C≡C bond lengths of the two alkyne units with the 2π-bonded moiety giving a greater separation (C(15)—C(16) 1.365(4) Å) than that seen in the σ–π-bound unit (C(13)—C(14) 1.241(3) Å). The Co_2 axis in **8** is bound essentially symmetrically to the C≡C bond (Co(1)—C(15) 1.971(2), Co(1)—C(16) 1.968(3), Co(2)—C(15) 1.963(2), Co(2)—C(16) 1.960(3) Å) with the C–C and Co–Co vectors lying perpendicular to one another. Addition of the dicobalt moiety produces a bending back of the outer alkyne substituents (C(14)-C(15)-C(16) 135.0(2)°, C(15)-C(16)-C(17) 136.8(2)°) and an increase in the *trans*-bending of the inner Ru_2-coordinated alkyne, C(13)-C(14)-C(15) 158.2(3)° (vs. 164.9(4)° in **7***a*). The *cis*-bending in the C(14)-C(15)-C(16)-C(17) fragment is slightly greater than normal (e.g., 138.9(6)° and 144.6(6)° in $\{Co_2(CO)_6\}PhC{\equiv}C\text{-}C{\equiv}CPh$ (**23***b*)) and may be caused by the steric constraints of the Bu^t and $Ru_2(CO)_6(PPh_2)(C_2)$ substituents.

The complexes **7***a–c* provide a unique opportunity to compare directly the reactivity of free and coordinated alkyne units and to assess the impact of a second alkynyl group. It is clear from initial studies that **7** exhibits distinctly different reactivity patterns in comparison with its monoynyl counterpart (24). Further investigations in this area are currently underway.

Experimental section

General procedures

All manipulations and reactions were carried out under an atmosphere of dinitrogen using standard Schlenk-line techniques or in a dry-box. Solvents for reactions, chromatography, and crystallizations were distilled under nitrogen from appropriate drying agents prior to use. Reactions were monitored by thin-layer chromatography (Baker-flex IB2-F) and infrared spectroscopy (carbonyl region). Purification of products was performed by column chromatography using oven-dried (150°C, 24 h) silica gel (70–230 mesh) on a dry-packed column or by thin-layer chromatography (TLC). Triruthenium dodecacarbonyl, dicobalt octacarbonyl, and chlorodiphenylphosphine were purchased from Strem, *cis*-1,2-dichloroethylene, 3-3-dimethyl-1-butyne, and 1,4-bis(trimethylsilyl)-1,3-butadiyne from Aldrich and were used without further purification. 5,5-Dimethyl-hexa-1,3-diyne was prepared according to the literature procedure (8).

IR spectra were recorded on Nicolet 520 FTIR and Bio-Rad FTS-40A instruments, using sodium chloride cells of 0.5 mm path length for solution spectra (*n*-hexane) or as KBr pellets. NMR spectra were recorded on Bruker AC 200, AM 200 (^{1}H, 200 MHz; $^{31}P\{^1H\}$ 81.0 MHz; $^{13}C\{^1H\}$ 50.3 MHz) and MSL 300 (^{1}H, 300 MHz; $^{31}P\{^1H\}$ 121.5 MHz) instruments. The $^{31}P\{^1H\}$ spectra are referenced externally to 85% H_3PO_4 and ^{1}H, ^{13}C to solvent sources. Mass spectrometric data were obtained by GC–MS on a Hewlett–Packard 5790A GC with a Hewlett–Packard 5970A mass selective detector (EI, 70 eV). Elemental analyses were performed by M-H-W Laboratories, Phoenix, Arizona, and by the Microanalysis Service of the Institute for Biological Sciences, NRC, Ottawa.

Syntheses

$PPh_2C{\equiv}C\text{-}C{\equiv}C\text{-}Bu^t$

A two-necked round-bottomed flask (250 mL) was charged with Bu^{t}C≡C-C≡C-H (3.60 g, 33.9 mmol) and diethyl ether (25 mL) and cooled to −78°C. To this was added a slight excess of 1.6 M Bu^{n}Li (22.0 mL, 35.2 mmol) over 20 min using a dropping funnel and the solution allowed to stir for 1 h before the addition of PPh_2Cl (6.2 mL, 34.5 mmol) in ether (10 mL). After warming to room temperature and further stirring for 1 h the solvent was partially removed and benzene added. The resulting white precipitate (LiCl) was filtered off to yield a pale yellow oil on drying. Addition of *n*-hexane precipitated an off-white microcrystalline solid. Yield = 6.90 g, 70%; mp 72°C.

$PPh_2C{\equiv}C\text{-}C{\equiv}C\text{-}Bu^t$: IR ν(C≡C)/cm^{-1}, (C_6H_{14}): 2249 vs, 2208 s, 2102 s; (KBr): 2250 m, 2207 s, 2100 w. ^{1}H NMR ($CDCl_3$) δ: 7.53–7.22 (m, 10H, Ph), 1.17 (s, 9H, Bu^t). $^{13}C\{^1H\}$ NMR ($CDCl_3$) δ: 135.3 (d, J_{PC} 5.9 Hz, PC_{ipso}), 132.7–128.6 (m, Ph), 92.0 (d, J_{PC} 6.0 Hz, C_β), 91.74 (s, C_δ), 74.3 (d, J_{PC} 8.8 Hz, C_α), 64.2 (s, C_γ), 30.4 (s, CMe_3), 28.2 (s, CMe_3). Proton-coupled ^{13}C NMR ($CDCl_3$) δ: 135.4–127.0 (m, Ph), 92.0 (d, J_{PC} 5.8 Hz, C_β), 91.7 (m, C_δ), 74.3 (d, J_{PC} 12.5 Hz, C_α), 64.2 (s, C_γ), 30.4 (virtual qt, CMe_3), 28.2 (m, CMe_3). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: −31.4 (s). $PPh_2C{\equiv}C\text{-}C{\equiv}C\text{-}Ph$

Synthesis of $PhC{\equiv}C\text{-}CH{=}CHCl$:[4] Phenylacetylene (5.90 mL, 53.7 mmol), and 2.5 molar equivalents of *cis*-1,2-dichloroethylene (13.0 g, 134 mmol) were placed in a 250 mL round-

[4] This synthesis is based on the method reported by Kende and Smith (9*a*). We found that use of *trans*-$Pd(PPh_3)_2Cl_2$ gave slightly better yields than $Pd(PPh_3)_4$ (90% vs. 75%).

bottomed flask along with n-butylamine (25 mL, 253 mmol), copper iodide (0.30 g, 1.58 mmol) and *trans*-$Pd(PPh_3)_2Cl_2$ (0.30 g, 0.43 mmol). The solution was stirred for 16 h after which the solvent was removed under reduced pressure to afford a red-brown oil. Column chromatography on SiO_2 yielded a pale yellow oil identified by GC–MS as the chloro-enyne PhC≡C-CH=CHCl (7.90 g, 90%).

Synthesis of $PPh_2C{\equiv}C\text{-}C{\equiv}C\text{-}Ph$: The enyne PhC≡C-CH=CHCl (5.80 g, 35.7 mmol) was dissolved in THF (150 mL) and cooled to −78°C. Addition of two molar equivalents of LDA gave an orange-brown solution, which was stirred at low temperature for 3 h before treating with PPh_2Cl (7.0 mL, 39.0 mmol). After 20 min the low-temperature bath was removed and the solution stirred for a further 2 h after temperature equilibration. Partial evaporation of the solvent, filtration, and then drying yielded a brown oil, which was chromatographed on silica. Elution with dichloromethane–n-hexane (3:10) and evaporation of the solvent gave $PPh_2C{\equiv}C\text{-}C{\equiv}C$-Ph as a pale yellow powdery solid. Yield 6.90 g, 62%, mp 54°C.

$PPh_2C{\equiv}C\text{-}C{\equiv}C$-Ph: IR ν(C≡C)/cm^{-1}, (C_6H_{14}): 2205 vs, 2208 s, 2111 m; (KBr): 2201 s, 2104 w. ^{1}H NMR ($CDCl_3$) δ: 7.64–7.27 (m, Ph). $^{13}C\{^1H\}$ NNMR ($CDCl_3$) δ: 134.9 (d, J_{PC} 6.1 Hz, PC_{ipso}), 132.7–128.5 (m, Ph), 121.1 (s, Ph_{ipso}), 91.4 (d, J_{PC} 6.2 Hz, C_β), 81.0 (s, C_δ), 80.9 (d, J_{PC} 12.8 Hz, C_α), 74.1 (s, br, C_γ). Proton-coupled ^{13}C NMR ($CDCl_3$) δ: 134.9–126.7 (m, Ph), 121.1 (m, Ph_{ipso}), 91.4 (d, J_{PC} 5.9 Hz, C_β), 81.0 (m, C_δ), 80.9 (d, J_{PC} 14.4 Hz, C_α), 74.1 (s, br, C_γ). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: −30.0 (s). MS: 310 $(M)^+$, 233 $(M - Ph)^+$. Anal. calcd. for $C_{22}H_{15}P$: C 85.15, H 4.87; found: C 85.24; H 4.57.

$PPh_2C{\equiv}C\text{-}C{\equiv}C\text{-}SiMe_3$

A solution of $Me_3SiC{\equiv}C\text{-}C{\equiv}CSiMe_3$ (4.0 g, 20.6 mmol) in THF (90 mL) was cooled to −78°C and treated with a slight excess of MeLi (16.0 mL, 22.4 mmol). After a few minutes a fine off-white precipitate had formed. Stirring at −78°C was continued for 2 h before allowing the solution to warm to −40°C for 30 min. On cooling to −78°C, PPh_2Cl (4.0 mL, 22.3 mmol) was added. After 30 min, the cooling bath was removed and the solution was allowed to warm to room temperature. Removal of the solvent under reduced pressure produced a brown oil, which was chromatographed on silica. Elution with dichloromethane–*n*-hexane (1:1) yielded a single colourless band that afforded $PPh_2C{\equiv}C\text{-}C{\equiv}C\text{-}SiMe_3$ as a pale yellow solid on evaporation of the solvent. Yield 5.78 g (92%); mp 32°C.

$PPh_2C{\equiv}C\text{-}C{\equiv}C\text{-}SiMe_3$: IR ν(C≡C)/cm^{-1}, (C_6H_{14}): 2228 vw, 2165 w, 2073 s. ^{1}H NMR ($CDCl_3$) δ: 7.61–7.33 (m, 10H, Ph), 0.21 (s, 9H, $SiMe_3$). $^{13}C\{^1H\}$ NNMR ($CDCl_3$) δ: 135.6 (d, J_{PC} 6.1 Hz, PC_{ipso}), 133.4–129.5 (m, Ph), 92.5 (d, J_{PC} 6.4 Hz, C_β), 91.5 (s, C_δ), 88.3 (s, C_γ), 77.0 (d, J_{PC} 14.9 Hz, C_α), 0.03 (s, $SiMe_3$). Proton-coupled ^{13}C NMR ($CDCl_3$) δ: 135.5–127.9 (m, Ph), 92.5 (d, J_{PC} 5.9 Hz, C_β), 91.5 (s, br, C_δ), 88.3 (s, C_γ), 77.0 (d, J_{PC} 15.2 Hz, C_α), 0.0 (q, J_{CH} 120 Hz, $SiMe_3$). $^{31}P\{^1H\}$ NMR ($CDCl_3$) δ: −31.7 (s). MS: 306 $(M)^+$, 233 $(M - SiMe_3)^+$, 73 $(SiMe_3)^+$. Anal. calcd. for $C_{19}H_{19}PSi$: C 74.48, H 6.25; found: C 74.25. H 6.39.

$Ru_2(CO)_6(\mu\text{-}\eta^1,\eta^2_{\alpha,\beta}\text{-}C{\equiv}C\text{-}C{\equiv}CBu^t)(\mu\text{-}PPh_2)$ **7**a

Triruthenium dodecacarbonyl (2.50 g, 3.91 mmol) was dissolved in tetrahydrofuran (300 mL, three freeze–pump–thaw cycles) and treated with a slight excess of $PPh_2C{\equiv}C\text{-}C{\equiv}CBu^t$ (1.20 g, 4.13 mmol). A few drops of sodium benzophenone ketyl catalyst in THF were added, causing an immediate colour change to deep red. After stirring for 10 min an IR (2098 w, 2047 s, 2031 ms, 2016 s cm^{-1}) indicated the complete consumption of $Ru_3(CO)_{12}$ while a spot TLC showed a single red-orange band that we assign as the monosubstituted species $Ru_3(CO)_{11}(PPh_2C{\equiv}C\text{-}C{\equiv}CBu^t)$. The solution was then heated to reflux for 4 h, causing considerable darkening. On cooling, the solvent was partially evaporated in vacuo and the residue absorbed onto a small amount of silica gel. Column chromatography on silica yielded a minor band of $Ru_3(CO)_{12}$ (identified by IR) using *n*-hexane as eluant. With dichloromethane–*n*-hexane (1:49), a broad band of pale yellow **7***a* was then removed. Reducing the volume to ~5 mL and overnight cooling to −10°C yielded 0.805 g (31%) of a yellow crystalline solid; mp 119°C.

$Ru_2(CO)_6(\mu\text{-}PPh_2)(\mu\text{-}\eta\text{-}C{\equiv}C\text{-}C{\equiv}CBu^t)Co_2(CO)_6$ **8**

Compound **7***a* (0.20 g, 0.30 mmol) was dissolved in toluene (20 mL) and treated with an excess of $Co_2(CO)_8$ (0.15 g, 0.44 mmol). A darkening of the solution was evident after a few minutes and an IR spectrum recorded after 2 h stirring showed complete consumption of **7***a*. The solvent was removed under reduced pressure and the resulting brown residue loaded onto TLC plates. Elution with dichloromethane–*n*-hexane (1:4) gave a red-brown band as the major product (crude yield 0.284 g, 99%). Crystallization from *n*-hexane at −10°C produced

Crystal structure determination of complex 7*a*

Yellow crystals of **7***a* were grown from a saturated *n*-hexane solution at −10°C. Data were collected at 295 K on a Siemens R3m/V diffractometer. Background measurements using the stationary crystal, stationary counter method were made at the beginning and end of each scan, each for 25.0% of the total scan time. Two standard reflections were monitored every 100 measurements; no significant decay was detected over the time of data collection. Data were corrected for Lorentz and polarization effects and absorption corrections were applied using the face-indexed numerical method. Relevant crystal and data collection parameters for the present study are given in Table 1.

The structure was solved by Patterson and Fourier methods and refined by full-matrix least squares, first with isotropic thermal parameters and then with anisotropic thermal parameters for all non-hydrogen atoms. A difference Fourier map revealed the positions of the hydrogen atoms, which were

included in calculated positions. The hydrogen atoms were treated using the riding model method with refined isotropic thermal parameters for phenyl hydrogens and fixed isotropic thermal parameters for the methyl hydrogen atoms. Atoms C(11A), C(13A), and C(14A) arise from a disorder about the *tert*-butyl group. A satisfactory model was refined with an occupancy of 60:40 (C:C(A)) for these three atoms. Atom C(12) was refined with full occupancy. In the final cycles of refinement a weighting scheme, $w = [s^2(F_o)]^{-1}$ was used. The function minimized in the least-squares refinement was $\Sigma w(|F_o| - |F_c|)^2$. The weighted R value, R_w, is defined as $[\Sigma w(|F_o|—|F_c|)^2/\Sigma w|F_o|^2]^{1/2}$, where the weights, w, are optimized on moderate intensities. The atomic scattering factors, corrected for the real and imaginary parts of anomalous dispersions, were taken from ref. 25; for hydrogen, those of Stewart et al. were used (26). Programs used are described elsewhere (27). Final atomic coordinates for the non-hydrogen atoms and equivalent isotropic displacement coefficients are presented in Table 2 (equivalent isotropic U (U_{eq} = 1/3 × orthogonalized U_{ij} tensor). Bond lengths and angles are presented in Tables 3 and 4, respectively. Anisotropic displacement coefficients and hydrogen atom parameters have been deposited as supplementary material.[5]

Crystal structure determination of complex 8

Red-brown crystals of **8** were grown from a saturated *n*-hexane solution at −10°C. Data were collected at 200 K on a Siemens P4 diffractometer. Background measurements using the stationary crystal, stationary counter method were made at the beginning and end of each scan, each for 25.0% of the total scan time. Three standard reflections were monitored every 100 measurements; no significant decay was detected over the time of data collection. Data were corrected for Lorentz and polarization effects and absorption corrections were applied using the face-indexed numerical method. Relevant crystal and data collection parameters are given in Table 1.

The structure was solved and refined as for **7***a*. Final atomic coordinates for the non-hydrogen atoms and equivalent isotropic displacement coefficients are presented in Table 5. Bond lengths and angles are presented in Tables 6 and 7, respectively. Anisotropic displacement coefficients and hydrogen atom parameters have been deposited as supplementary material.[5]

[5] This supplementary data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Complete crystallographic data for **7***a* have been deposited at the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, UK. Lists of structure factors are available from the authors.

A density functional study of the bonding in tertiary phosphine chalcogenides and related molecules

Nicole Sandblom, Tom Ziegler, and Tristram Chivers

Abstract: The nature of the phosphorus–tellurium bond in tertiary phosphine tellurides is not well understood. There is also controversy over the nature of multiple bonding in the lighter chalcogenides and the related ylides and imides. Density functional theory (DFT) was used to investigate the interactions in the molecule, Me_3PE (E = O, S, Se, Te, BH_3, CH_2, NH). The calculated PE bond energies and orbital populations reveal contributions from both σ donation from the phosphine and π back-donation to the phosphine in all of the above cases. Down the group from oxygen to tellurium, the PE bond weakens from 544 kJ mol^{-1} to 184 kJ mol^{-1}, but multiple bonding becomes more significant with respect to the single bond. For E = BH_3, the PB bond energy is 166 kJ mol^{-1}. Trimethylphosphine ylide was found to have a π-bond order of 0.5, while that of trimethylphosphine imine is 0.6. For comparison, the oxides of trimethylamine and trimethylarsine were also calculated to examine the pnictogen–oxygen bond; Me_3N does not participate in multiple bonding with oxygen, while the π-bond orders for Me_3PO and Me_3AsO were calculated as 0.7 and 0.6, respectively.

Key words: phosphine chalcogenides, phosphine ylides, phosphine imides, DFT calculations

Résumé : La nature de la liaison phosphore–tellure dans les tellurures de phosphine tertiaires n'est pas très bien comprise. Il ya a également une controverse relativement à la nature de la liaison multiple dans les chalcogénures plus légères et dans les ylures et imides apparentés. On a fait appel à la théorie de la densité fonctionnelle (TDF) pour étudier les interactions dans la molécule de Me_3PE (E = O, S, Se, BH_3, CH_2, NH). Les énergies de liaison PE calculées et les populations des orbitales révèlent des contributions à la fois du transfert σ à partir de la phosphine et du transfert en retour π vers la phosphine dans tous les cas ci-dessus. La liaison PE s'affaiblit lorsqu'on descend dans la famille de l'oxygène vers le tellure, elle passe de 544 kJ mol^{-1} à 184 kJ mol^{-1}, mais la liaison multiple devient plus significative par rapport à la liaison simple. Pour E = BH_3, l'énergie de la liaison PB est de 166 kJ mol^{-1}. On a trouvé que l'ylure de la triméthylphosphine a une liaison π de l'ordre de 0,5, tandis que pour l'imine de la triméthylphosphine l'ordre est de 0,6. Pour fins de comparaison, on a également calculé les oxydes de la triméthylamine et de la triméthylarsine, pour examiner la liaison oxygène–azote; Le Me_3N ne participe pas à la liaison multiple avec l'oxygène, alors que calcul des ordres de la liaison π pour le Me_3PO et le Me_3AsO donnent 0,7 e 0,6 respectivement.

Mots clés : chalcogénures de phosphine, ylure de phosphore, imides de phosphine, calculs de TDF.

[Traduit par la rédaction]

1. Introduction

The useful electrical properties of certain metal tellurides have sparked research into developing single-source precursors for these semiconductors (1, 2). Many research groups now routinely use trialkylphosphine tellurides, R_3PTe, as tellurium transfer agents; for example, the reaction of Et_3PTe with low-valent transition-metal compounds generates metal-tellurium clusters that can be subsequently pyrolyzed to binary metal tellurides (3). Other important applications of R_3PTe reagents as a source of reactive tellurium include the preparation of terminal metal tellurides (4), chalcogen exchange reactions (5), insertions into metal–carbon (6) and metal–metal (7) bonds, and in the titanium-mediated heterohydrocoupling of Te and Bu_3SnH (8).

Relatively little is known about the bonding in phosphine tellurides. The three crystallographically characterized structures suggest that the phosphorus–tellurium bond has an order of about 1.5, where PTe is 2.368 Å for $^tBu_3PTe$ (9), 2.365 Å in the case of $^iPr_3PTe$ (10), and 2.371 Å in $^tBu_2[NH(C_6H_{11})]PTe$ (11). ^{125}Te solution NMR spectroscopy at room temperature and ^{125}Te Mössbauer spectroscopy at 4.2 K provide results that have been interpreted as inconsistent with the presence of π bonding (12). The controversy is not confined to tellurium. Although phosphine oxides are commonly described as $R_3P{=}O$, there is still debate over the nature of the PO bond in these molecules (13). The possible resonance contributors range from a single to triple bond (Fig. 1). Several experimental observations, e.g. bond energies of oxides and sulfides,

Received March 12, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

bond lengths, dipole moments, NMR shifts and coupling constants when E = Se, and infrared stretching frequencies of the P—E bond in the oxides, sulfides, and selenides, suggest multiple bonding (14). However, in a recent paper, Power (15) studied the chemical shift tensors of Me_3PO and related molecules, and concluded that the phosphorus–oxygen bond is dative.

Ab initio studies of phosphine chalcogenides have been limited to oxygen and sulfur, and the most extensive work focuses on H_3PO (14). Given the proven ability of density functional theory (DFT) to predict geometries and energies accurately (16), we decided to study the orbital interactions involved in the trimethylphosphine chalcogenide bond. For comparison purposes, trimethylphosphine-borane, trimethylphosphine ylide, and trimethylphosphine imide, and the oxides of trimethylamine and trimethylarsine were also considered.

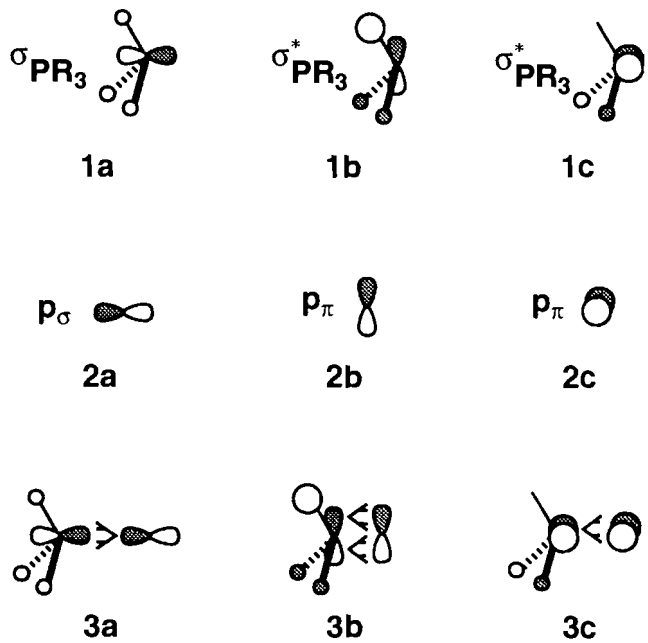
2. Computational details

All calculations were based on approximate density functional theory within the local density approximation (17), LDA, in the parameterization by Vosko et al. (18). In addition, we used Becke's (19) nonlocal exchange correction as well as inhomogenous gradient corrections for correlation due to Perdew (20), NL-SCF. The reported calculations were performed utilizing the vectorized version of the ADF program system developed by Baerends et al. (21, 22) and vectorized by Ravenek (23). The numerical integration procedure applied for the calculations was developed by te Velde and co-workers (24). All molecules were optimized with C_{3v} symmetry with the following exceptions: borane (D_{3h}), methylene (C_{2v}), trimethylphosphine ylide (C_s), imine (C_{2v}), trimethylphosphine imide (C_s). The geometry optimization procedure was based on the method developed by Versluis and Ziegler (25). A double ζ-STO basis set (25) was employed for the *ns* and *np* shells of the main group elements. The basis set was augmented by a single *3d* STO function except for hydrogen, where a *2p* STO was used as polarization. Electrons in lower shells were considered as core and treated according to the procedure due to Baerends and co-workers. (26). An auxiliary (27) set of *s*, *p*, *d*, *f*, and *g* STO functions, centered on all nuclei, was used in order to fit the molecular density and present Coulomb and exchange potentials accurately in each SCF cycle. All structures were optimized at the LDA level of theory. The calculated bond energies include nonlocal corrections evaluated from LDA densities.

3. Results and discussion

General bonding scheme in Me_3PE and related systems

The PE bond in trimethylphosphine chalcogenides (Me_3PE) can be analysed by considering the frontier orbitals on the two fragments Me_3P and E. The orbitals of interest on Me_3P are the occupied σ-type HOMO, **1a**, of a_1 symmetry, and the empty e_1 pair, **1b** and **1c**. The three *p* orbitals on the chalcogens (E) are shown as **2a**, **2b**, and **2c**. The σ component of the P—E bond involves donation of charge from the occupied orbital **1a** on Me_3P to the empty orbital **2a** on the chalcogen. This process is illustrated in **3a**. The π interactions are represented by donation from the filled π-type *p* orbitals, **2b** and **2c**, on E to the empty σ* orbitals on Me_3P. This type of donation, as shown in **3b** and **3c**, has been termed negative hyperconjugation (28). We note further that each of the orbitals **3b** and **3c** has π symmetry with respect to the PE bond. Interaction **3a** represents the singly bonded σ-resonance structure I of Fig. 1, whereas **3b** and **3c** each represent the π-resonance structure II of Fig. 1.



A number of fragments have frontier orbitals analogous to the chalcogens. They are, in the terminology of Hoffmann (29), isolobal with the chalcogens and form similar bonds with tertiary phosphines. Thus the transition metal fragment, $Cr(CO)_5$, with the frontier orbitals, **4a–c**, is isolobal with the chalcogens; its bonding to R_3P has been studied previously (30). Other isolobal fragments are borane, **5a–c**, methylene, **6a–c**, and imine, **7a–c**. The frontier orbital energies of the chalcogens as well as those of BH_3, CH_2, and NH are compared to those of Me_3N, Me_3P, and Me_3As in Fig. 2.

General bond energy decomposition scheme

In general, the molecules under consideration are of the form

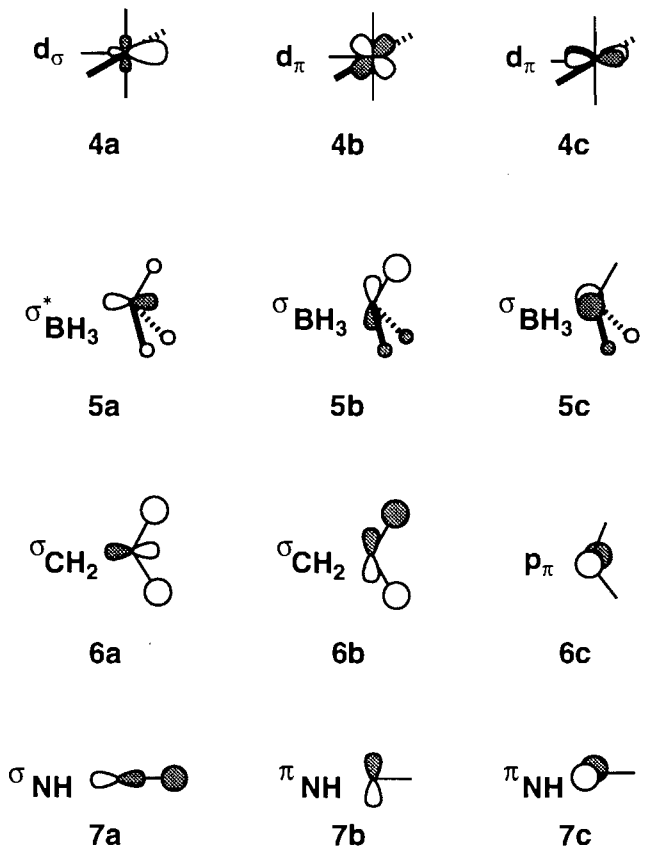


Fig. 2. Orbital energies for the frontier orbitals of the Me_3X and E fragments.

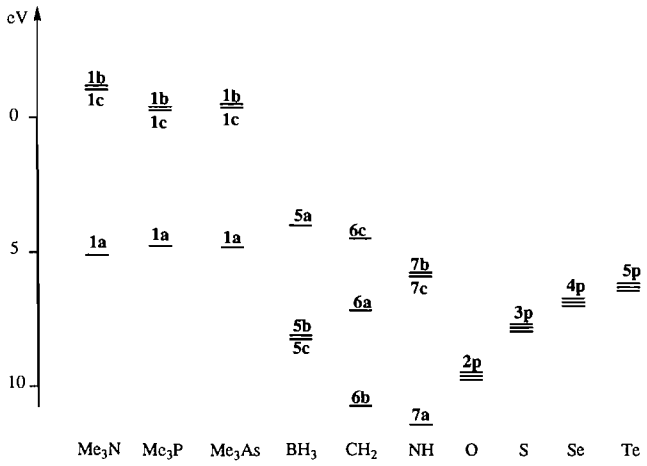

Me_3XE where X = N, P, As and E = O, S, Se, Te, BH_3, CH_2, NH. Using the generalized transition state method (31), we are able to separate steric and electronic contributions to the XE bond energy:

[1] $\Delta H_{XE} = E(E) + E(Me_3X) - E(Me_3XE)$

according to

[2] $\Delta H_{XE} = -[\Delta E_{prep} + \Delta E^0 + \Delta E_{el}]$

[a]Experimental values are given in parentheses.
[b]For $^tBu_3PTe$.

Here ΔE_{prep} is the energy required to alter the Me_3X and E fragments from their ground state conformation to the geometry they adopt in the combined complex. The term ΔE_{prep} in the fragments E = O, S, Se, Te, CH_2, and NH also contains a promotion energy from the electronic ground state to a valence state suitable for σ donation and π back-donation with Me_3X, as explained in detail later.

The term ΔE^0 represents the steric interaction energy between Me_3X and E. It includes the stabilizing electrostatic interaction between the two fragments and the exchange repulsion component resulting from the destabilizing interactions between occupied orbitals on E and Me_3X. The steric interaction energy, ΔE^0, is obtained as ΔH_{XE} of eq. [1] from a calculation of Me_3XE and E(Me_3XE) in which only the occupied orbitals of E and Me_3X are used as basis functions.

Finally, ΔE_{el} of eq. [2] accounts for the stabilizing interactions between occupied and empty fragment orbitals. The stabilizing electronic interaction energy ΔE_{el} is further decomposed into

$$[3] \quad \Delta E_{el} = \Delta E_{don} + \Delta E_{bdon} + \Delta E_{syn} + \Delta E_{res}$$

Here ΔE_{don} represents the stabilizing contribution to ΔH_{XE} due to σ donation, **3a**, of charge from the σ-donor orbital, **1a**, on Me_3X to an empty σ-acceptor orbital (**2a**, **5a**, **6a**, or **7a**) on E. It is obtained as the additional energy gained by adding one of the σ-acceptor orbitals (**2a**, **5a**, **6a**, or **7a**) on E to the basis of occupied E and Me_3X fragment orbitals in a calculation of Me_3XE. The orbital population, e_{don}, shows how many electrons the orbital on E (**2a**, **5a**, **6a**, or **7a**) accepts in this calculation. The term ΔE_{bdon} is due to the π donations, **3b** and **3c**, in which charge is transferred to **1b** and **1c** on Me_3X from two occupied π-donor orbitals on E such as **2b** and **2c**. The term is obtained in a way similar to ΔE_{don}, except that the added virtual orbitals now are **1b** and **1c**. Similarly, the orbital population, e_{bdon}, now refers to the electrons accepted by **1b** and **1c**. The third contribution, ΔE_{syn}, is a measure of the synergic effect, the degree to which donation, **3a**, and back-donation, **3b** + **3c**, reinforce each other. It is the extra stabilization of the XE bond gained by including the virtual fragment orbitals, **1b** and **1c**, as well as **2a**, or its equivalent, at the same time. This calculation gives the synergic orbital populations, e_{don} and e_{bdon}, which represent the number of electrons in the σ-acceptor orbital on E (**2a**, **5a**, **6a**, or **7a**) and in the σ*-acceptor orbitals on Me_3X (**1b** and **1c**), respectively. Finally, ΔE_{res} measures the additional stabilization gained by including the remaining virtual fragment orbitals in the calculation. It is often combined with the steric interaction energy since it stems from interactions that serve to reduce the exchange repulsion.

Trimethylphosphine chalcogenides

Table 1 describes the bond energy decomposition and orbital populations of the trimethylphosphine chalcogenides. The preparation energy of trimethylphosphine is due to a slight geometric distortion from the free phosphine; it is relatively small for all of the chalcogens. The preparation energy for the chalcogens is electronic. It represents a promotion of the chalcogen from its ^3P ground state to the $(2p_\sigma)^0(2p_\pi)^4$ valence configuration. The promotion energy is due to the loss of exchange stabilization as two electrons of parallel spin in the ^3P ground state are given opposite spin orientations in the $(2p_\sigma)^0\ (2p_\pi)^4$ valence configuration. This requires much more energy for oxygen, 276 kJ mol^{-1}, with contracted p orbitals and high exchange stabilization, than for tellurium, 132 kJ mol^{-1}, with the most diffuse p orbitals and the smallest exchange stabilization.

The combined steric interaction energy, $\Delta E^0 + \Delta E_{res}$, is dominated by destabilizing overlaps between occupied orbitals on the Me_3P and E fragments (Table 1). It is most repulsive, 771 kJ mol^{-1}, for Me_3PO with the shortest distance between the two fragments and decreases gradually from Me_3PS, 178 kJ mol^{-1}, to Me_3PTe, 53 kJ mol^{-1}, as the PE distance increases.

The stabilization, $-\Delta E_{don}$, due to the σ donation is largest for E = O with $-\Delta E_{don}$ = 1210 kJ mol^{-1}, and decreases gradually from Me_3PS, 497 kJ mol^{-1}, to Me_3PTe, 243 kJ mol^{-1}. The trend is understandable, when we observe that the donation from the occupied σ orbital on Me_3P, **1a**, to the empty p_σ orbital on E is most favorable for oxygen with the p_σ orbital of lowest energy (Fig. 2). The gain in stabilization decreases gradually from E = S to E = Te as the energy of the p_σ orbital approaches that of **1a**. The actual charge transfered is 1.0 e for Me_3PO with a drop from 0.7 e in Me_3PS to 0.5 e in Me_3PTe (Table 1).

The contribution, $-\Delta E_{bdon}$, from the back-donations, **3b** and **3c**, is not very large. This is not surprising since the p_π donor orbitals on E are of much lower energy than the π-acceptor orbitals **1b** and **1c** on Me_3P, Fig. 2. This is especially true in the case of oxygen where the back-donation amounts to 0.1 e and $-\Delta E_{bdon}$ = 37 kJ mol^{-1}. For the remaining chalcogens, the energy gap is reduced and the back-donation somewhat larger at 0.2 e with $-\Delta E_{bdon}$ = 50 kJ mol^{-1}.

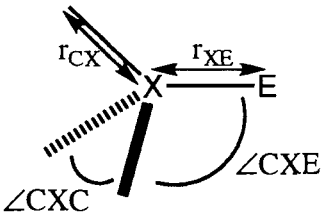
Fig. 3. Bond lengths and angles in Me_3XE.



The synergic effect substantially increases the multiple bonding character of the PE linkage. Thus the back-donation for oxygen is increased by 0.6 *e* to a total of 0.7 *e* (Table 1). Now the PO bond has the most pronounced π components, **3b** and **3c**. By equating the total π-bond order with the electron charge back-donated we get an order of 0.7 for the PO linkage. The corresponding π-bond orders for E = S, Se, and Te are 0.6, 0.5, and 0.5, respectively.

The σ component of the PE bond, **3a**, is also enhanced by the synergic effect. For the PO bond, 1.4 *e* is donated to oxygen. (Table 1) For the other chalcogens, the σ donations are 1.0 *e* (S), 0.9 *e* (Se), and 0.7 *e* (Te), respectively.

It is clear that both the σ and π components are important for the PE linkage after the synergic effect has been taken into account. Both σ and π bonding have the largest contributions for oxygen. Their contributions decrease from sulfur to tellurium, and σ bonding is always more pronounced than π bonding. However, in relative terms, the two bonding modes become more comparable in importance upon descending Group 16 from oxygen towards tellurium.

The synergic contribution to the PE bond, $-\Delta E_{syn,}$ is substantial, starting at 365 kJ mol^{-1} for E = O and decreasing to 90 kJ mol^{-1} for E = Te (Table 1). The calculated PE bond energies for oxygen and sulfur compare well with the experimental estimates obtained for Me_3PO (32), and Pr_3PS (32), respectively. The overall phosphorus–chalcogen bond energy is predicted to decrease down the group (Table 1).

Table 2 contains calculated bond lengths and angles (as defined in Fig. 3) for the Me_3PE systems. The optimized structures are in good agreement with the experimentally observed data. The deviation is largest in the case of tellurium, because the experimental data are those of the tri-*tert*-butylphosphine telluride. This molecule has bulkier substituents than trimethylphosphine telluride, so it is not surprising that the ∠CPC angle is larger and the PC distance longer in tri-*tert*-butylphosphine telluride as the result of the steric interaction between the *tert*-butyl groups. Indeed, the PTe bond length in tri-*tert*-butylphosphine telluride has been described as anomalous and suspiciously long (14). Therefore, the calculated bond length of 2.303 Å is probably a more realistic value.

The PH_3 molecule has a ∠HPH angle of 93°. Thus, electronically, the optimal ∠CPC angle for phosphines should be close to 90°. However, the bulk of the R groups attached to phosphorus tends to increase the ∠CPC angle, and PC distance, in order to relieve the steric repulsion. The ∠HPH bond angle in PH_4^+ is 109°. Thus the ∠CPC angle in R_3PE should open up towards 109° if, to a first approximation, we consider the chalcogenides as pure electrophiles with a σ-acceptor orbital, **3a**, but without any π-donation ability, **3b** and **3c**. We see, in fact, that the ∠CPC angles in R_3PE are larger than in

Table 4. Optimized bond lengths (Å) and angles (°) for Me_3P, E, and Me_3PE[a] (E = BH_3, CH_2, NH).

[a]Experimental values are given in parentheses.
[b]For $^tBu_3PNH$.

R_3P, both experimentally and theoretically. Further, the PC distance is somewhat shorter in R_3PE as the larger ∠CPC angle allows the R groups to move closer to the phosphorus atom for the same amount of steric repulsion as in R_3P. The effect of π donation, **3b** and **3c**, would be to increase the PC distance and close the ∠CPC angle as the σ* orbitals, **1b** and **1c**, accept electron density. Obviously, the PE σ bonding in R_3PE is dictating the changes of the R_3P framework. However, the degree of increase in the ∠CPC angle and decrease in the PC distance is likely modified by the opposing trends from the π back-donation, **3b** and **3c**. This balance between the σ and π effects on geometry is evident in the trend down the group. The telluride has the longest PC bonds, and has the most π character relative to the σ contribution.

Me_3PBH_3, Me_3PCH_2, and Me_3PNH

Table 3 contains the bond energies and orbital populations of the isoelectronic series, Me_3PE (E = BH_3, CH_2, and NH), and compares them to those of the oxide. The preparation energies of the phosphine are due to a slight distortion of geometry and are fairly small in these cases. The preparation of borane distorts it from a planar to a pyramidal conformation, and ΔE_{prep} is only 54 kJ mol^{-1}. We shall explain the reason for the distortion of BH_3 as well as the NH and CH_2 fragments later (Table 4). For imine, the preparation involves shortening the NH bond and promoting electrons from the $^3\Sigma^-$ ($\mathbf{7a}^2\mathbf{7b}^1\mathbf{7c}^1$) ground state to a paired $\mathbf{7a}^0\mathbf{7b}^2\mathbf{7c}^2$ valence state. The preparation of NH requires the most energy, 970 kJ mol^{-1}. The preparation of methylene is both electronic and geometric; the ∠HCH angle opens up and the $^3B1$ ($\mathbf{6a}^1\mathbf{6b}^2\mathbf{6c}^1$) ground state is promoted to a $\mathbf{6a}^0\mathbf{6b}^2\mathbf{6c}^2$ valence state . The preparation of CH_2 takes substantially less energy, 343 kJ mol^{-1}, than NH because it only involves the promotion of one electron out of a bonding orbital to pair up with another electron in the nonbonding $2p_C$ π orbital, **6c**.

Across the row from boron to oxygen, the combined steric interaction energy, $\Delta E^0 + \Delta E_{res}$, increases from 80 to 771 kJ mol^{-1}. This trend can be explained in terms of the distance between the two fragments. The PE distance decreases from left to right across the row, giving rise to a more and more repulsive interaction between occupied orbitals on the two fragments.

The relative energies of **5a**, **6a**, and **7a** (Fig. 2), explain the differences in stabilization due to σ donation, $-\Delta E_{don}$. It is greatest for E = NH, $-\Delta E_{don}$ = 1724 kJ mol^{-1}, which has the lowest energy acceptor orbital, **7a**. For E = CH_2 and BH_3, $-\Delta E_{don}$ equals 600 and 256 kJ mol^{-1}, respectively; this trend is expected since the orbital energies decrease by **7a** < **6a** < **5a**. The charge transferred by σ bonding decreases from 1.8 *e* for the imine to 0.6 *e* for the borane.

Back-donation in the borane is not very favourable because of the large gap between the donor orbitals, **5b** and **5c**, and the back-donation acceptor orbitals, **1b** and **1c** (Fig. 2). The stabilization is quite small in this case, $-\Delta E_{bdon}$ = 24 kJ mol^{-1}. The imine donor orbitals, **7b** and **7c**, are higher in energy; the stabilization is greater here, $-\Delta E_{bdon}$ = 272 kJ mol^{-1}. There is some back-donation in the case of the methylene fragment, and almost all of the stabilization, $-\Delta E_{bdon}$ = 69 kJ mol^{-1}, comes from the higher energy orbital, **6c**. While **6b** has the proper symmetry to be involved as a donor, its overlap with **1b** is very small, and there is a wide energy gap between these two orbitals. The trimethylphosphine ylide does not have equal contributions in the two back-donation interactions, and can be represented by the resonance structure III in Fig. 1 with only one σ and one π bond.

There is a synergic effect for all of the isoelectronic analogues, but none is as substantial as that for E = O. For the borane and imine adducts, the stabilization is quite small, $-\Delta E_{syn}$ = 36 and 51 kJ mol^{-1}, respectively. For methylene, the stabilization, 172 kJ mol^{-1}, is still not as large as the synergic effect for oxygen, 365 kJ mol^{-1}. However, all of these compounds have some multiple bonding. The π-bond order for borane is 0.3 *e*, for methylene, 0.5 *e*, and for imine, 0.6 *e*. The overall bond energy for PE decreases from −333 kJ mol^{-1} for E = NH, to −166 kJ mol^{-1} for E = BH_3.

The optimized geometries for this series are described in Table 4 along with some experimental comparisons; in the case of Me_3PNH, no experimental data are available; instead, the data for $^tBu_3PNH$ are given. For the C_s optimized molecules, Me_3PCH_2 and Me_3PNH, average PC bond lengths and ∠CPC are shown. The experimental electron diffraction study of Me_3PCH_2 assumed C_3 symmetry for the Me_3P fragment, so in this case the calculated numbers may be more realistic (13*a*). As observed for the trimethylphosphine chalcogenides, the PC bonds in Me_3PBH_3, Me_3PCH_2, and Me_3PNH are slightly shorter than those in trimethylphosphine and the CPC

[k]XO bond energy.
[l]Experimental energy for Me_3PO from ref. 32.

angle also opens up. The changes here are not as significant as the change to Me_3PO, but are on the order of the changes observed for the heavier chalcogens. As mentioned above, this is indicative of the σ-bonding interaction dominating the geometry. The π-bonding effects of PC bond lengthening and ∠CPC decreasing must also play a part, but are overshadowed. For E = BH_3, the PC bond is the shortest for this isoelectronic series; while the σ-donation energy is not the largest, it has the smallest back-donation energy, so the shortening effect (σ) is not significantly cancelled by the lengthening effect (π). Trimethylphosphine imine has both the largest $-\Delta E_{don}$ and largest $-\Delta E_{bdon}$ for this series; a balance between these two factors leads to an overall shortening of the PC bond.

In these molecules, the fragments bonded to Me_3P also change geometry. The boron–hydrogen bonds in the phosphine adduct are longer than those in borane. The σ interaction populates **5a**, which is nonbonding in the planar ground state of BH_3 and becomes B—H bonding in the pyramidal BH_3 fragment, while the π interactions depopulate the BH bonding orbitals **5b** and **5c**. The geometry at boron becomes pyramidal in order to stabilize the now populated **5a** by allowing bonding overlaps between $2p_B$ and $1s$ on each hydrogen, **5a**.

The carbon–hydrogen bonds in methylene stay approximately the same. This is understandable because the ground state methylene has one electron in the bonding orbital **6a**, which is also the population of **6a** in coordinated CH_2. The π interaction involves back-donation from a nonbonding orbital, **6c**, which holds 1.5 *e* in the ylide compound. The main change in the methylene fragment is the decrease in ∠HCH from 138.0° in free CH_2 to 119.5° in the ylide. The decrease in the ∠HCH angle stabilizes the **6a** acceptor orbital by enhancing the bonding overlap. Steric factors might also decrease the ∠HCH angle in the ylide compound.

The **7a** orbital of NH is a slightly anti-bonding combination between an *sp* lobe on nitrogen and $1s$ on hydrogen. It is thus understandable that the NH bond in coordinated imine shortens, since **7a** holds 1.6 *e* in complexed NH, compared to 2.0 *e* in free NH (Table 3). The optimized structure of Me_3PNH has ∠PNH of 118.9°; this structure is 39 kJ mol^{-1} lower in energy than a structure with a linear PNH.

Me_3NO, Me_3PO, and Me_3AsO

Table 5 gives the bond energy decomposition for the oxides of the second-, third-, and fourth-row pnictogens. We shall show that in the case of the trimethylpnictogen oxides there is a balance between a favourable steric arrangement with a long Me_3X—O distance and optimal orbital interactions between Me_3X and O. The optimized bond lengths and angles of the trimethylpnictogens and the oxides are shown in Table 6.

The preparation energy for Me_3N is the most substantial (70 kJ mol^{-1}), compared to the relatively small preparations for Me_3P and Me_3As (21 and 22 kJ mol^{-1}, respectively). The amine must distort significantly by expanding the length of the CN bonds in order to reduce crowding, as it is smaller than the heavier pnictogens. Trimethylarsine oxide slightly distorts in a manner similar to trimethylphosphine oxide. While both σ donation and π back-donation affect the geometry, the dominant σ contribution leads to slightly longer CAs bonds and an opening of ∠CAsC.

Because of the small size of nitrogen and the closer contacts

Table 6. Optimized bond lengths (Å) and angles (°) for Me_3X and Me_3XO[a] (X = N, P, As).

	r_{XO}	r_{CX}	∠CXO	∠CXC	Ref.
Me_3N		1.433(1.451)		110.8(110.9)	37
Me_3NO	1.337(1.388)	1.521(1.479)	109.1(109.9)	109.8(109.1)	40
Me_3P		1.857(1.847)		100.2(98.6)	33
Me_3PO	1.497(1.476)	1.816(1.809)	112.8(114.4)	106.0(104.1)	34
Me_3As		1.996(1.964)		97.1(96.0)	35
Me_3AsO	1.666(1.631)	1.960(1.967)	112.6(112.6)	106.2	34

[a]Experimental values are given in parentheses.

in Me_3NO, one might expect Me_3NO to have a larger steric contribution, $\Delta E^0 + \Delta E_{res}$, than either Me_3PO or Me_3AsO, but this is not the case. In fact, trimethylamine oxide has the lowest contribution, 318 kJ mol^{-1}, compared to 771 kJ mol^{-1} for trimethylphosphine oxide and 555 kJ mol^{-1} for trimethylarsine oxide. We shall comment on this shortly.

The donation stabilization for Me_3N is smaller, $-\Delta E_{don}$ = 859 kJ mol^{-1}, than those of Me_3P and Me_3As, where $-\Delta E_{don}$ = 1210 and 918 kJ mol^{-1}, respectively. The energies of the donation orbitals are all about the same, **1a**, and the overlap between this orbital and **2a** is similar in all three pnictogens. When Me_3XO forms, the energy of **1a** will drop as it donates electrons and forms a bond. This drop in energy is more drastic in the case of amine, which makes further donation more difficult, and only 0.7 *e* is donated, as compared to the phosphine (1.0 *e*) and the arsine (0.9 *e*).

Figure 2 shows that the back-donation acceptor orbitals, **1b** and **1c**, of the amine are much higher in energy than the phosphine and arsine orbitals, and thus are less likely to interact with the full orbitals on oxygen, **2b** and **2c**. There is virtually no stabilization from back-donation for Me_3N, $-\Delta E_{bdon}$ = 1 kJ mol^{-1}, whereas both Me_3P and Me_3As have contributions due to back-donation. The energy of **1b** and **1c** is slightly lower and the overlap with **2b** and **2c** is slightly better for Me_3P than for Me_3As, and $-\Delta E_{bdon}$ reflects this with 37 kJ mol^{-1} (Me_3P) compared to 18 kJ mol^{-1} (Me_3As).

The synergic effect is considerable for the heavier pnictogens and nonexistent for nitrogen. As mentioned earlier, the π-bond order of X = P increases to 0.7 due to the synergic effect; for X = As, there are similar effects and the π-bond order is 0.6. The different pnictogen–oxygen bonds vary in strength in the order phosphorus (−544 kJ mol^{-1}) > arsenic (−343 kJ mol^{-1}) > nitrogen (−197 kJ mol^{-1}).

Me_3NO could have acquired stronger σ and π interactions by decreasing the NO distance at the expense of enhancing the steric repulsion as well. Apparently, the potential gain in σ and π bonding from shortening the NO bond is offset by higher steric crowding.

4. Conclusions

DFT calculations were used to study the nature of the trimethylphosphine chalcogenide bond. All of the chalcogens participate in π back-donation to a pair of low-lying PC σ* orbitals with *e* symmetry in the C_{3v} point group. The π-bond order was found to decrease down Group 16 from 0.7 for oxygen to 0.5 for tellurium. The phosphorus–oxygen bond is strongest, ΔH_{PO} = −544 kJ mol^{-1}. Other elements bonded to trimethylphosphine were also considered in terms of the isoelectronic series, BH_3, CH_2, and NH. The trimethylphosphine imine had the strongest bonding with ΔH_{PN} = −333 kJ mol^{-1}. Trimethylphosphine ylide was found to bond by σ donation from the phosphine and one π back-donation interaction from the nonbonding *p* orbital of methylene. The borane adduct participated in σ bonding and also had a π-bond order of 0.3. Further comparison of bonding in trimethylpnictogen oxides revealed no multiple bonding in Me_3NO, but a π-bond order of 0.6 for Me_3AsO. The inability of Me_3N to π-bond to O affects the geometry of Me_3NO. Compared to Me_3N, the CN bonds are longer in trimethylamine oxide, due to the steric crowding around nitrogen.

An unusually large value of $^1J(^{31}P,^{31}P)$ for a solid triphenylphosphine phosphadiazonium cationic complex: determination of the sign of *J* from 2D spin-echo experiments

Klaus Eichele, Roderick E. Wasylishen, Robert W. Schurko, Neil Burford, and W. Alex Whitla

Abstract: Phosphorus-31 NMR spectra of a solid triphenylphosphine phosphadiazonium salt, [Mes*NP-PPh_3][SO_3CF_3], have been acquired at 4.7 and 9.4 T. Analysis of the spectra obtained with magic-angle spinning indicates that the two phosphorus nuclei are strongly spin–spin coupled, $|^1J(^{31}P,^{31}P)| = 405(5)$ Hz, despite the unusually long P—P separation, $r_{P,P} = 2.625$ Å. Two-dimensional spin-echo spectra provide convincing evidence that $^1J(^{31}P,^{31}P)$ is negative. Semi-empirical molecular orbital calculations at the INDO level support the negative sign for $^1J(^{31}P,^{31}P)$. A large span, 576 ppm, is observed for the chemical shift tensor of the two-coordinate phosphorus centre ($\delta_{11} = 307$ ppm, $\delta_{22} = 174$ ppm, $\delta_{33} = -269$ ppm), which is very similar to the value previously reported for the non-coordinated phosphorus centre in the free Lewis acid, [Mes*NP][$AlCl_4$]. The principal components and orientations of the phosphorus shielding tensors of these compounds are compared with those calculated for $[HNP]^+$ and its phosphine adduct using the ab initio Gauge-Including Atomic Orbitals method. The phosphorus chemical shift tensor of the triphenylphosphine moiety has a relatively small span of 33 ppm.

Key words: spin–spin coupling constants, solid-state NMR, ^{31}P NMR, MO calculations, phosphadiazonium cation, P—P bonds.

Résumé : Les spectres de la RMN du phosphore-31 du sel de phosphadiazonium de la triphénylphosphine, [Mes*NP-PPh_3][SO_3CF_3] ont été enregistré à 4,7 et 9,4 T. L'analyse des spectres obtenus avec la rotation de l'angle-magique indiquent que les deux noyaux de phosphore ont un couplage spin–spin très fort, $|^1J(^{31}P,^{31}P)| = 405(5)$ Hz, en dépit de la longue distance de séparation inhabituelle P—P, $r_{P,P} = 2{,}65$ Å. Les spectres en deux dimensions spin-écho fournissent une preuve convaincante de la valeur négative de $^1J(^{31}P,^{31}P)$. Les calculs d'orbitale moléculaire semi empirique au niveau INDO confirment le signe négatif de $^1J(^{31}P,^{31}P)$. On a observé un graqnd étalement, 576 ppm, pour le déplacement chimique du tenseur des deux centre phosphore coordonnés $\delta_{11} = 307$ ppm, $\delta_{22} = 174$ ppm, $\delta_{33} = -269$ ppm, ce quei est très voisin des valeurs rapportées antérieurement pour les centres phosphore non coordonnées dans les acides de Lewis libres [Mes*NP][$AlCl_4$]. On a comparé les composantes principales et les orientations du tenseur de blindage du phosphore avec celles calculées pour le $[HNP]^+$ et ses adduits phosphine en utilisant les calculs ab initio de Gauge incluant la méthode de l'orbitale atomique. Le déplacement chimique du tenseur phosphore de l'unité triphénylphosphine s'étale relativement peu 33 ppm.

Mots clés : constantes de couplage spin–spin, RMN à l'état solide, RMN du ^{31}P, calculs de OM, cation phosphadiazonium, liaison P—P.

[Traduit par la rédaction]

Introduction

The magnitudes of $^{31}P,^{31}P$ spin–spin coupling constants between directly bonded phosphorus nuclei, $^1J(^{31}P,^{31}P)$, have been reported for numerous compounds (1–5). Although the sign of $^1J(^{31}P,^{31}P)$ has been determined for very few compounds, some general patterns have emerged. Values of $^1J(^{31}P,^{31}P)$ can be of either sign and vary from at least +766 Hz (6) to −451 Hz (7). The largest positive values have been observed for tetracoordinate–hexacoordinate adducts such as R_3P–PF_5, $J \approx +723$ Hz (8), pentacoordinate–pentacoordinate compounds, $J \approx +750$ Hz (9), and hypodiphosphate anions such as $[FO_2P$–$PO_2F]^{2-}$, $J \approx +766$ Hz (6). In each case, one or both of the phosphorus nuclei are bonded to several electronegative substituents. On the other hand, negative values of $^1J(^{31}P,^{31}P)$ seem to be associated with systems containing low-coordinate phosphorus nuclei, e.g., systems such as H_2P–PH_2 and $(t\text{-Bu})_2P$–$P(t\text{-Bu})_2$, where $^1J(^{31}P,^{31}P)$ is −108 Hz (10) and −451 Hz (7), respectively. Similarly, values of $^1J(^{31}P,^{31}P)$ involving a dicoordinate centre bound to a di-, tri-, or tetracoordinate centre are thought to be negative (4, 5), but these have not been confirmed experimentally. Interestingly, the lat-

ter couplings cover a wide range, (−)232 Hz to (−)684 Hz, and it has been suggested that $^1J(^{31}P,^{31}P)$ in these systems increases (i.e., becomes more negative) with increasing phosphorus–phosphorus bond order (4, 5, 11).

The purpose of this communication is to demonstrate the power of solid-state ^{31}P NMR experiments in determining the absolute sign and magnitude of $^1J(^{31}P,^{31}P)$ for an adduct composed of a phosphadiazonium cation, [Mes*NP]$^+$ (Mes* = 2,4,6-tri-*tert*-butylphenyl), and triphenylphosphine, bound by an unusually long P—P bond of 2.625 Å (12). The results of this study clearly demonstrate that there is no simple, general relationship between $^1J(^{31}P,^{31}P)$ and P—P bond order. Finally, information concerning the phosphorus shielding tensors is also derived.

Experimental

Materials

The preparation of [Mes*NP-PPh_3][SO_3CF_3] from its precursor [Mes*NP][SO_3CF_3] has been previously reported (12).

Solid-state ^{31}P NMR experiments

Solid-state ^{31}P NMR experiments were carried out using Bruker MSL-200 (B_0 = 4.7 T) and AMX-400 (B_0 = 9.4 T) spectrometers. Phosphorus-31 NMR spectra obtained with cross-polarization and magic-angle spinning (CP/MAS) were acquired using Bruker double-bearing MAS probes, with 3.5 μs proton pulse widths and recycle delays of 4–10 s. Chemical shifts were referenced with respect to external 85% aqueous H_3PO_4 by setting the peak of external solid [NH_4][H_2PO_4] to 0.8 ppm.

The 2D spin-echo spectrum of [Mes*-NP-PPh_3][SO_3CF_3] was obtained at 4.7 T. A standard spin-echo pulse sequence was used under CP and high-power ^1H decoupling conditions (14). For each t_1 increment, 32 transients were collected. A total of 64 t_1 increments were acquired. After zero-filling once in each dimension, the data size for 2D FT was 512 × 128. Gaussian window-functions were applied to FIDs in both dimensions prior to 2D FT, and the final 2D spectrum was displayed in magnitude mode.

Calculations of the spectra due to static powder samples or samples spinning at the magic angle were performed using a 80586 microprocessor. The program WSolids, written in the C++ language and developed in our laboratory, was used for all calculations.

Quantum mechanical calculations

The ab initio Gauge-Including Atomic Orbitals (GIAO) calculations of phosphorus chemical shieldings were performed using a 6-311G basis set, augmented with two sets of polarization functions on all atoms. Absolute chemical shieldings were converted to chemical shifts using the absolute chemical shielding of 85% aqueous H_3PO_4, σ = 328.35 ppm. All calculations were performed using an IBM RS6000/580 workstation.

Semiempirical molecular orbital calculations of $^1J(^{31}P,^{31}P)$ were carried out using the self-consistent field finite-perturbation approach of Pople and Beveridge (17). The Fermi contact contribution was calculated using the Intermediate Neglect of Differential Overlap (INDO) approximation (17). Values of the one-centre exchange integrals *G*1 and *F*2 were taken as 0.276 and 0.190, respectively.[2] The phosphorus *s*-orbital density, $1s|0|^2$, was taken as 5.6251 (19).

Results and discussion

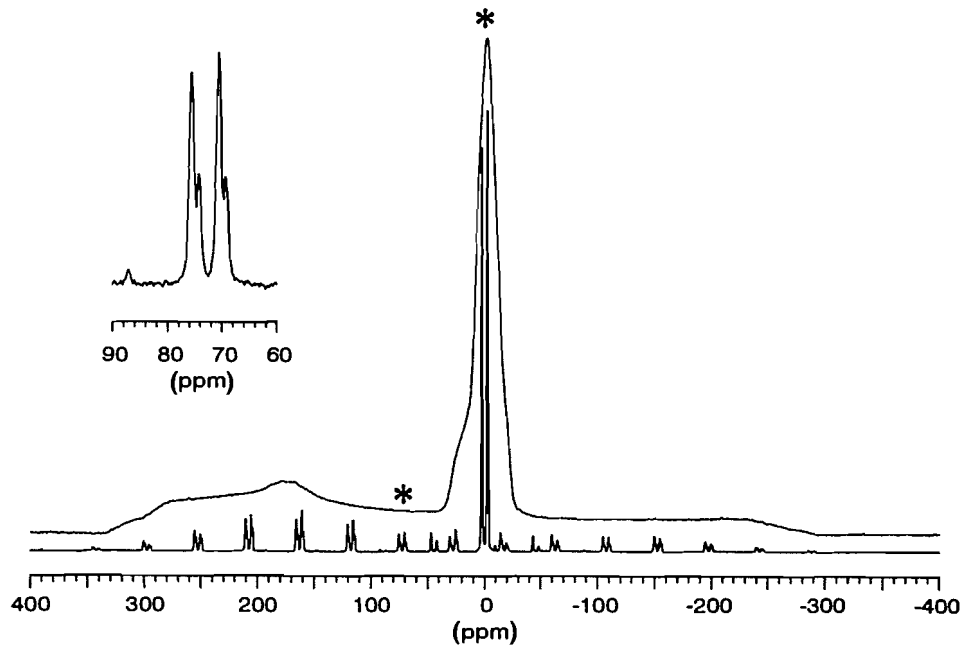
Phosphorus-31 NMR spectra of a polycrystalline powder sample of [Mes*NP-PPh_3][SO_3CF_3] are shown in Fig. 1. The lower spectrum, obtained with magic-angle spinning (MAS), shows two doublets and associated spinning side bands. One of the phosphorus centres has a relatively large chemical shift anisotropy, indicated by the numerous spinning side bands, and is assigned to the dicoordinate phosphorus centre. The magnitude of the indirect homonuclear spin–spin coupling constant $^1J(^{31}P,^{31}P)$ determined from the doublets is 405(5) Hz. Identical splittings, 405(5) Hz, were observed in ^{31}P NMR spectra obtained at 9.4 T, thereby ruling out crystallographic nonequivalence as the origin of the splittings. The doublets arising from the phosphorus centre, which is directly bonded to nitrogen, show additional asymmetric splittings of 100 Hz due to residual dipolar coupling with the quadrupolar ^{14}N nucleus (see insert, Fig. 1). This phenomenon is well documented (20). Since the C-N-P bond angle is approximately linear, 169.5°, it is reasonable to assume that the electric field gradient at the nitrogen centre will be nearly axially symmetric, with the largest component along the formal PN triple bond. From the known internuclear separation, $r_{P,N}$ = 1.486(4) Å (12), the dipolar coupling constant, $R(I,S) = (\mu_0/4\pi)(\gamma_I\gamma_S/r_{I,S}^3)(\hbar/2\pi)$, can be calculated, 1070 Hz. With these values, analysis of the asymmetric doublets yields an upper limit for $|^1J(^{31}P,^{14}N)|$ of 25 Hz and a nitrogen nuclear quadrupolar coupling constant, $\chi(^{14}N)$, of −1.7(2) MHz. This relatively small value of $\chi(^{14}N)$ is reasonable, given that in typical isonitriles (21), N-bonded thiocyanates (22), and the central nitrogen nucleus of hydrazoic acid (23), HN_3, values of $\chi(^{14}N)$ between −0.3 and −2.0 MHz have been reported.

The ^{31}P NMR spectrum of the stationary powder sample is also depicted in Fig. 1. In contrast to the MAS spectrum, in which all homo- and heteronuclear spin–spin interactions anticipated for the three-spin system (^{31}P–^{31}P–^{14}N) are resolved, no clear evidence for couplings is apparent from the spectrum of the static sample. The only exception is a distinct splitting of 2.6 kHz observed in the high-frequency region of the spectrum, corresponding to δ_{11} of the chemical shift tensor for the dicoordinate phosphorus centre. To obtain more detailed information about the homonuclear spin–spin interactions, a two-dimensional spin-echo experiment was performed. This experiment is analogous to the *J*-resolved experiment in high-resolution NMR spectroscopy, with the exception that homonuclear direct dipolar coupling and anisotropy in the indirect spin–spin coupling also contribute to the line shape. The experimental 2D spin-echo experiment, together with the F_1 projection, is shown in Fig. 2. Small separate "islands" in the contour plot confirm that the large splitting at 307 ppm is indeed due to homonuclear $^{31}P,^{31}P$ spin–spin interactions.

From the internuclear separation, $r_{P,P}$ = 2.625 Å, the direct dipolar coupling constant $R(^{31}P,^{31}P)$ is calculated as 1090 Hz.

[2] R. Sebastian and T. Schaefer, private communication; obtained by extrapolation of the values given by Galasso (18).

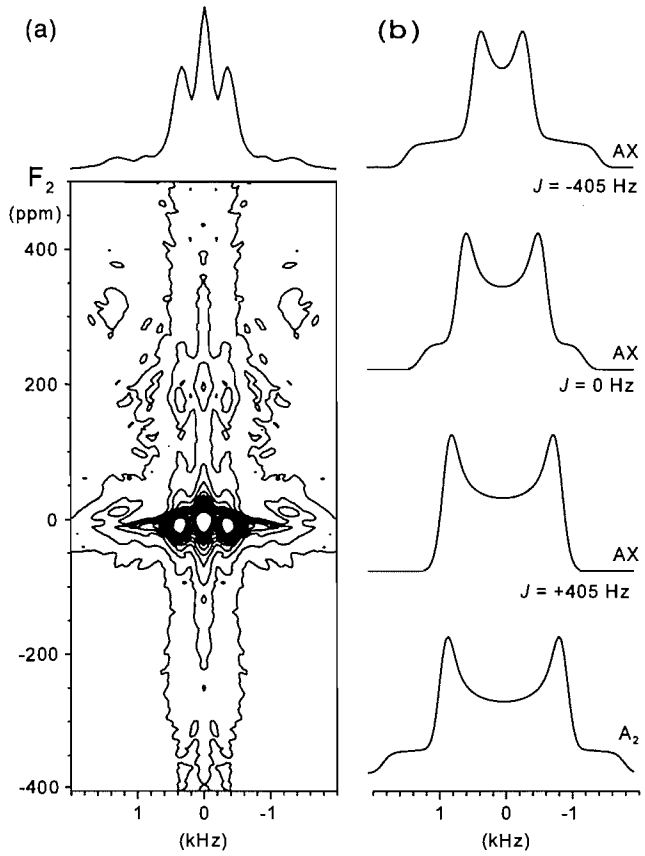
Fig. 1. Solid-state ^{31}P NMR spectra of [Mes*NP-PPh_3][SO_3CF_3] obtained at 4.7 T. The bottom trace shows the MAS spectrum for a sample spinning at 3.6 kHz (360 scans), the upper trace was obtained for the stationary sample (14 086 scans). Asterisks denote the isotropic peaks. The expansion shows the isotropic multiplet of the dicoordinate phosphorus centre, with the large splitting due to $^1J(^{31}P,^{31}P)$. The smaller asymmetric splitting is due to $^{31}P,^{14}N$ spin–spin interactions.



Thus, considering only the direct dipolar interaction for an AX spin system, one would anticipate a Pake doublet for the F_1 projection with a maximum splitting of $2R$, or 2.2 kHz. The experimental observation of 2.6 kHz for the maximum splitting indicates that the indirect spin–spin coupling cannot be neglected in this case. Idealized Pake-like powder patterns for $^1J(^{31}P,^{31}P) = -405$, 0 and +405 Hz are shown in Fig. 2*b*. Also included is the Pake doublet arising from an A_2 spin system (in which case J is not an observable). The F_1 projection will be a mixture arising from the sum of A_2, AB, and AX type coupling patterns (24); however, given the significant differences in chemical shift anisotropies for the two phosphorus nuclei, the AX-type coupling is expected to dominate. Indeed, a comparison between calculated and observed projections reveals that the AX-type couplings prevail in this spin system (the small features at ± 800 Hz might be attributed to contributions from A_2-type spectra). The comparison further shows that the sign of $^1J(^{31}P,^{31}P)$ is opposite to that of the dipolar coupling constant, $R(^{31}P,^{31}P)$. In principle, the direct dipolar coupling may contain contributions from the anisotropy in the indirect spin–spin coupling, ΔJ (25). Therefore, ambiguity arises as to the absolute sign of the effective dipolar coupling constant, $R_{eff} = R - \Delta J/3$, which cannot be resolved at room temperature. However, in the case of a negative effective dipolar coupling constant, ΔJ would be required to be 6.54 kHz, while the alternative results in $\Delta J = 0$ Hz. Given that the isotropic value of $|^1J(^{31}P,^{31}P)|$ is 405 Hz, anisotropies on the order of 6.54 kHz seem unreasonably large. Therefore, our results indicate that the absolute sign of $^1J(^{31}P,^{31}P)$ is negative.

Having obtained this information about the homonuclear spin–spin interactions, the lineshape of the static powder pattern can be simulated to extract information about the phosphorus shift tensors. This line shape depends on the relative orientations of the chemical shift and dipolar coupling tensors (26). For the dicoordinate phosphorus centre, the occurrence of the maximum dipolar splitting at 307 ppm indicates that the P—P vector is close to the direction of δ_{11}. That is, δ_{11} is approximately perpendicular to the NP bond axis, since the NPP bond angle is 109.8(2)°. Similar orientations of the phosphorus chemical shift tensor have also been established for related systems containing the $[Mes*NP]^+$ (27) and Mes*CP (28) fragments. Interestingly, for the triphenylphosphine ligand the direction of least shielding also appears to be along the direction of the P—P bond. The field dependence of the NMR spectrum arising from the triphenylphosphine ligand is illustrated in Fig. 3. The results for the principal components of the phosphorus chemical shift tensors and their orientations are summarized in Table 1 and compared to experimental values reported for [Mes*NP][$AlCl_4$] (27). Surprisingly, the chemical shift tensors of $[Mes*NP]^+$ and its triphenylphosphine adduct are very similar; it appears that the short N—P bond in the adduct still dominates the shielding characteristics of the dicoordinate phosphorus in this compound and is hardly affected by the coordination of PPh_3. To confirm this notion, we have carried out ab initio molecular orbital (MO) calculations of phosphorus chemical shieldings on the simple model compound $[HNP]^+$ and its phosphine adduct, $[HNP–PH_3]^+$, using the GIAO method (15). The results of these calculations are included in Table 1. The calculations are successful in that they qualitatively predict the span of the phosphorus chemical

Fig. 2. The left side shows the experimental solid-state ^{31}P 2D spin-echo experiment on a stationary sample of $[Mes^*NP\text{-}PPh_3][SO_3CF_3]$ obtained at 4.7 T. The right-hand side displays several Pake-like doublets calculated for AX and A_2 spin systems using the values of J indicated. In each case, R was kept at 1090 Hz.



shift tensor for the two-coordinate phosphorus to be much greater than that of the four-coordinate phosphorus. Furthermore, the calculated phosphorus chemical shift tensor of the two-coordinate phosphorus is only marginally perturbed by the PH_3 ligand. However, for the geometries indicated, the calculations predict an increase in shielding of the dicoordinate phosphorus upon coordination that is greater than observed experimentally for $[Mes^*NP]^+$ and $[Mes^*NP\text{-}PPh_3]^+$. Given the simplicity of our model compounds, this is not unexpected. Finally, the calculated orientation of the phosphorus chemical shift tensor of the dicoordinate centre corroborates our experimental finding that the direction of least shielding is close to the internuclear vector.

The minor change of the phosphorus chemical shift tensor of the dicoordinate centre upon formation of the adduct can be rationalized in terms of a weak P-P interaction consistent with the long P–P distance. However, the observation of a relatively large indirect $^{31}P,^{31}P$ spin–spin coupling for this compound is counterintuitive, indicating that there is, nevertheless, a strong communication of nuclear spins via the electronic framework. For comparison, in the donor-stabilized methylenediylphosphenium cation $[R_2C{=}P\text{-}PPh_3]^+$, the $|^1J(^{31}P,^{31}P)|$ has been reported as 450.5 Hz; however, the P—P separation is about

2.267(2) Å (19). The negative value of $^1J(^{31}P,^{31}P)$ for $[Mes^*NP\text{-}PPh_3][SO_3CF_3]$ provides further evidence that $^1J(^{31}P,^{31}P)$ is negative in compounds with phosphorus in low coordination environments (2, 4, 5).

In spite of the large amount of experimental data available for $^1J(^{31}P,^{31}P)$, such couplings are not well understood. Several researchers have suggested that in systems containing formal phosphorus lone-pairs, the orientations of these electron lone pairs are of paramount importance (30, 31). However, other than qualitatively recognizing that the lone pairs reduce $^1J(^{31}P,^{31}P)$, the reasons behind this are not obvious. For many years it was assumed that mechanisms other than the Fermi contact must be important even in systems containing single P—P bonds because large anisotropies in $^1J(^{31}P,^{31}P)$ were reported for $R_2(S)P\text{–}P(S)R_2$ (32). Reinvestigation of one of these compounds indicates that ΔJ is in fact small (25), thus there may be no need to suppose that mechanisms other than the Fermi contact are important for these systems. In systems containing formal phosphorus–phosphorus double bonds, theoretical calculations predict mechanisms other than the Fermi contact to be important (33); however, the reliability of these theoretical calculations has not been established. While some workers have indicated that a clear relationship exists between the magnitude of $^1J(^{31}P,^{31}P)$ and the P—P bond order for some systems (4, 5, 11), the generality of such claims must be limited. For the system under examination in the present study, the phosphorus–phosphorus separation is well beyond values typical of P—P "single-bond" lengths (≈2.2 Å), yet the value of $^1J(^{31}P,^{31}P)$ is −405 Hz. The lability of the P—P interaction

Fig. 3. Expansion of the ^{31}P NMR spectra of static samples obtained at 4.7 (14 086 scans) and 9.4 T (10 000 scans), showing the field dependence of the lineshape due to contributions by the triphenylphosphine ligand. The top depicts the experimental spectra, the bottom shows spectra calculated using the values listed in Table 1. The detailed lineshape depends upon both the phosphorus chemical shift tensor and the $^{31}P,^{31}P$ spin-spin interactions.

in [Mes*NP-PPh$_3$][SO_3CF_3] is further highlighted by its dissociation in solution: no evidence of $^1J(^{31}P,^{31}P)$ is observed by solution ^{31}P NMR spectroscopy at 190 K.

Semiempirical molecular orbital calculations have been successful in reproducing many experimental trends in spin–spin coupling constants involving first-row elements (17, 34); therefore, it is of interest to calculate $^1J(^{31}P,^{31}P)$ as a function of $r_{P,P}$ in a simple model compound, $[HNP\text{-}PH_3]^+$. The orientation of the PH_3 group relative to the linear $[HNP]^+$ moiety was fixed to mimic that found experimentally for [Mes*NP-PPh$_3$][SO_3CF_3]. The results of the INDO calculations are summarized in Table 2. A negative sign is calculated for $^1J(^{31}P,^{31}P)$, and the value is of the correct magnitude. Negative values of $^1J(^{31}P,^{31}P)$ are also calculated for the related cations, $[H_2C{=}P\text{-}PH_3]^+$ and $[HP{=}P\text{-}PH_3]^+$. Only the Fermi contact interaction is considered in these calculations. To check the reliability of the INDO method for calculating $^1J(^{31}P,^{31}P)$, additional calculations have been carried out for model compounds related to systems where the sign of $^1J(^{31}P,^{31}P)$ is experimentally known. While the calculations correctly predict large and positive values for $^1J(^{31}P,^{31}P)$ in $H_3P\text{–}PF_5$ (8) and the difluorohypodiphosphate anion (6), the magnitude of $^1J(^{31}P,^{31}P)$ is overestimated. Calculations on $H_2P\text{–}PH_2$ indicate that $^1J(^{31}P,^{31}P)$ is very sensitive to molecular conformation, in agreement with previous semiempirical (35–37) and ab initio calculations (38). A negative value of $^1J(^{31}P,^{31}P)$ is also calculated for the *gauche* conformation in agreement with previous INDO calculations (36, 37) and experiment (10). For *trans*-diphosphene, $^1J(^{31}P,^{31}P)$ is predicted to be positive. As already mentioned, it has been suggested that this value is negative (2–5). Ab initio calculations of $^1J(^{31}P,^{31}P)$ in *trans*-diphosphene indicate that the orbital mechanism dominates and that its contribution is large and negative (33). Similar arguments have been used to rationalize the negative value of $^1J(^{15}N,^{15}N)$ in a *trans*-diazene, where the Fermi contact con-

tribution is positive on the basis of INDO calculations (39), while ab initio calculations predict a small but negative Fermi contact contribution (33). Clearly, much more research will be required before an understanding of $^1J(^{31}P,^{31}P)$ values is realized. Further measurements of the sign of $^1J(^{31}P,^{31}P)$ in systems containing low-coordinate phosphorus nuclei would be helpful. Also, solid-state NMR measurements that might shed light on the anisotropy of $^1J(^{31}P,^{31}P)$ tensors would be desirable. Finally, we hope that this work will stimulate further theoretical interest in $^1J(^{31}P,^{31}P)$ tensors. Clearly, the semi-empirical approaches such as the INDO method used in this study are qualitative at best and consequently of limited value.

In summary, we have observed a large $^{31}P-^{31}P$ spin–spin coupling constant between two phosphorus nuclei that are separated by more than 2.6 Å! Clearly, there is no simple relationship between $^1J(^{31}P,^{31}P)$ and bond order or bond length. To our knowledge, this is the first example where the absolute sign of J has been determined using the 2D spin-echo experiment. It also appears to be the first sign determination of $^1J(^{31}P,^{31}P)$ where one of the phosphorus nuclei is associated with a low-coordinate phosphorus centre.

Synthesis and characterization of phosphinimine-substituted trifluoro- or trichloro-*p*-benzoquinones and their cationic Rh(I) complexes. The crystal and molecular structure of 3,5,6-trichloro-2-(triphenylphosphinimino)-*p*-benzoquinone

Jin Li, Kattesh V. Katti, A. Alan Pinkerton, Herbert Nar, and Ronald G. Cavell

Abstract: Reaction of tetrafluoro- or tetrachloro-*p*-benzoquinone with silylated phosphoranimines $R_2R'P{=}NSiMe_3$ (R = Ph, Me) yields very highly colored monosubstituted derivatives of the *p*-quinone that act as two-electron acceptors showing clean, reversible CV traces. The molar absorptivity values are typical of dyes. These ligands also form chelate complexes with Rh(I) precursors using the quinone oxygen and the imine nitrogen donor sites. One of the quinone derivatives, 3,5,6-trichloro-2-(triphenylphosphinimino)-*p*-benzoquinone, has been structurally characterized. The iminated quinone shows a normal P═N bond length (1.597(2) Å) and P-N-C angle (P-N-C(3) 132.7(2)°). The N—C(3) bond, 1.327(3) Å, is a little shorter as is expected for the establishment of a conjugated structure between the phosphinimine substituent and the quinone ring. Some steric crowding pushes the Cl and N substituents on the quinone ring out of the plane of the ring.

Key words: quinones, phosphinimines, fluorine, chlorine, rhodium.

Résumé : La réaction de la tétrafluoro- ou de la tétrachloro-*p*-benzoquinone avec des phosphoranimines silylées $R_2R'P{=}NSiMe_3$ (R = Ph, Me) fournit des dérivés monosubstitués fortement colorés de la *p*-quinone qui agissent comme des accepteurs de deux électrons et qui présentent de courbes de CV réversibles propres. Les valeurs d'absorption molaire sont typiques des colorants. Ces coordinats forment aussi des chélates complexes avec des précurseurs Rh(I); ils utilisent l'oxygène de la quinone et l'azote de l'imine comme sites donneurs. On a caractérisé la structure de l'un des dérivés de la quinone, la 3,5,6-trichloro-2-(triphénylphosphinimino)-*p*-benzoquinone. Pour la quinone iminée la longueur de la liaison P═N (1,597(2) Å) et l'angles P-N-C (P-N-C(3), 132,7(2)°) sont normaux. La liaison N—C(3), 1,327(3) Å, est un peu plus courte que celle à laquelle on pourrait s'attendre pour une structure conjuguée entre le substituant phosphinimine et le noyau quinone. Un encombrement stérique force les substituants Cl et N attachés au noyau quinone à adopter des positions hors-plan.

Mots clés : quinones, phosphinimines, fluorure, chlorure, rhodium.

Introduction

The quinone–hydroquinone system is a well-known redox couple widely used synthetically as an oxidant or as a dehydrogenating agent. In the context of the present study it is also notable that there is a fairly extensive phosphorus chemistry (1, 2) although not by any means as large as that of the general organic derivatives. Several important biochemicals (for example, Vitamins E and K) belong to the quinone system and such species have been implicated in photosynthesis and respiration processes (3–6). Benzoquinone is also an efficient oxidant for metallocenes (7, 8). Many quinone derivatives are very highly coloured and so find applications as dyes and pigments (9–11). Some benzoquinone, anthraquinone, and naphthoquinone derivatives absorb light above 700 nm and thus find use as laser filters (12–14).

The first examples of phosphinimine derivatized *p*-quinones (15) were obtained from the reaction of azido-*p*-benzoquinone with phosphines (eq. [1]). It was claimed that these compounds would be useful as dyestuffs, insecticides, and synthetic intermediates.

An alternate route (16) to such compounds was provided by the reaction of phosphorus pentachloride with 1-aminoanthraquinone to first form *N*-tetrachlorophosphoranyl-1-aminoanthraquinone, which was then converted into the trichlorophosphazoanthraquinone by treatment with tertiary bases (B) (eq. [2]).

Although the *o*-benzoquinones are known to be good chelating agents, forming numerous stable transition-metal compounds (17–20), there are only a few examples of σ-coordinated *p*-benzoquinones. These systems typically form bridged complexes and most of the systems studied have yielded polymeric products. Less condensed examples are the dimeric products obtained from the reaction of *p*-benzoquinone with the pentacyanocobaltate anion (21) or Schiff's base metal complexes; for example, $Co^{(II)}$(salen) (eq. [3]) yields the pyridine-stabilized Co^{III}[*N*,*N*′-ethylenebis(salicylideneiminato) product. In these latter examples, however, only the parent quinone reacted in this way. Tetrachloro-*p*-benzoquinone did not react with the $Co^{(II)}$ precursor (22).

If these *o*-quinone ligands are combined with metal salts in a 1:1 ratio, polymeric products are obtained (23, 24). Formation of polymeric products can be prevented by blocking the coordination positions with other polydentate ligands. In such cases dimetallic complexes are obtained. The Fe(III) quinone complex (23) contains both bridging and terminal dihydroxybenzoquinone ligands. Dimetallic complexes of Ni and Cu are known, with several structurally characterized examples being reported (25–27). Recently, Calvo et al. reported the crystal structure of a dimetallic complex of Rh(I) (28). Related is 2,5-bis(arylamino)-*p*-benzoquinone, obtained from the reaction of phenylamine with *p*-benzoquinone, which combines with the first-row transition metals to form polymeric metal complexes (29). Unfortunately, the ligands themselves generally have very poor solubility and the resultant polymeric materials are also generally insoluble.

Recent interest in the design of new charge transfer complexes of quinones using a selection of donor groups (30)[2] has been sparked by the metal-like electrical conductivity of single crystals of the tetrathiafulvalene–tetracyanoquinodimethane (TTF–TCNQ) charge transfer complex (32). Although many different substituents have been attached to the quinone framework to supply electron density, there has been little use of electron-rich inorganic functionalities such as phosphazenes or thiazenes for such purposes. Monophosphazenes of the type $RPh_2P{=}NR'$ are themselves versatile one-, two-, or four-electron donors to transition and actinide metals (33–36) and this property suggested that such functionalities might provide suitable electron donor sources for the quinone framework while simultaneously conferring unique reactivity, high thermal stability, and structural diversity beyond that available with strictly organic substituents. In addition, the proximity of the N and O ligating centers that can be developed with phosphazene-substituted *p*-quinones suggested that chelate complexes could be readily formed with transition metals. These metals might have interesting electrical and optical properties. Therefore, as part of a study of iminophosphorane substitutional chemistry, we have explored the attachment of iminophosphoranes to halogenated quinones and herein report the formation and characterization of chloro- and fluoro-*p*-quinones derivatized with one iminophosphorane substituent. These species are notably highly colored and also act as complexing agents toward metals.

Results and discussion

Synthesis and properties of the ligands

Derivatization of the halogenated quinones is readily achieved by extension of the process in which an activated halogenoaromatic reacts with a silyliminophosphorane to eliminate trimethylsilylhalide, binding the imine center to the aromatic (34–36). In the present case, reaction of tetrafluoro- or tetrachloro-*p*-benzoquinone with one equivalent of trimethylsilylphosphinimines in CH_2Cl_2 proceeded smoothly in the same fashion as the activated aromatics (34–36), giving the corresponding monosubstituted *p*-benzoquinone derivatives **1–5** in good yield (eq. [4]). The elimination of trimethylsilylchloride, which was not previously demonstrated in the developments of our system of substituted ligands (34–36), is as effective as the elimination of trimethylsilyl fluoride.

The monosubstituted phosphoraniminequinones are very highly colored, air-stable, solids that are soluble in most common organic solvents. The solid compounds appear black. Upon dissolution, intense purple or blue solutions are obtained. The large values of their UV–visible molar extinction coefficients place them in the category of dye molecules (Table 1). The composition and structure of each of the compounds has been determined from the analytical data, mass spectra, and ^1H, ^{31}P, and ^{19}F NMR spectroscopy. Molecular ions for each of the compounds have been observed in the mass spectra. Phosphorus-31 NMR data are also given in Table 1.

We have structurally characterized 3,5,6-trichloro-2-(triphenylphosphinimino)-*p*-benzoquinone (**3**) and the structure is illustrated in Fig. 1. Crystallographic experimental details are given in Table 2, the positional parameters in Table 3, and selected important bond angles and lengths are given in Table

[2] For leading references of quinones with extended π-systems see ref. 31.

[4]

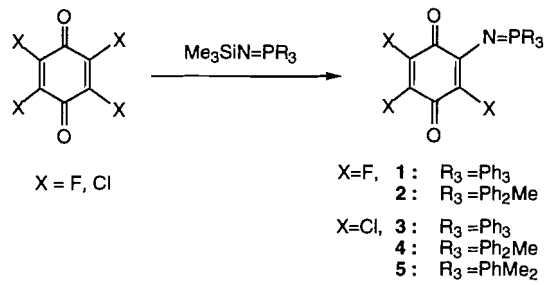

Fig. 1. ORTEP drawing of **3** with 30% probability ellipsoids for all non-hydrogen atoms.

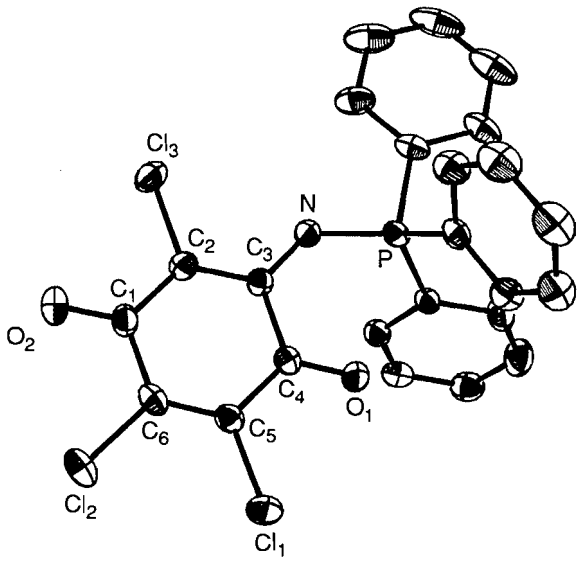

4. The P=N bond length of 1.597(2) Å is comparable to those we observed earlier (36) for iminophosphoranophosphines and is not exceptionally short, but the N—C(3) distance, 1.327(3) Å, is short compared to those in previously evaluated systems (36). This shortening suggests stronger binding between the quinone framework and the phosphinimine. The angle subtended at the imine nitrogen, P-N-C(3), 132.7(2)°, is comparable to those observed for fluoroaromatic iminophosphinimines (36). The environment around the quinone ring is quite crowded. This leads to a distortion in which Cl(1) and Cl(2) are pushed to opposite sides of the aromatic plane (+0.067 and −0.087 Å, respectively, with respect to the aromatic plane defined by the framework carbons C(1) thru C(6)) and, similarly, Cl(3) and N are also pushed out of the plane (+0.099 and −0.119 Å, respectively).[3]

Complexation reaction of the ligands with [Rh(cod)Cl]$_2$

Reactions of **1** or **4** with 1/2[Rh(cod)Cl]$_2$ and $AgClO_4$ in acetone at 25°C proceed smoothly to give complexes **6** and **7** in high yield (see eq. [5]).

The monocation for each of the cationic complexes is observed in the mass spectra (FAB). The ^{31}P NMR chemical shift of complex **6** shows a single peak at 39.2 ppm, which is 23.9 ppm downfield from the signal for the corresponding uncoordinated ligand **1**. The ^{19}F NMR of complex **6** showed three signals: at −140.4 ppm (a doublet of doublets with splittings of 1.5 and 4.9 Hz), which is due to the fluorine *meta* to the phosphinimine, at −148.3 ppm (a doublet with a splitting of 4.9 Hz), which is due to the fluorine *para* to the phosphinimine, and at −158.8 ppm (a singlet) due to the fluorine that is *ortho* to the phosphinimine. In comparison, the uncoordinated ligand **1** shows corresponding ^{19}F NMR chemical shift signals at −141.92 ppm (d, 7.5 Hz) for the *meta* fluorine, −148.4 ppm (dd, 3.8 and 7.5 Hz) for the *para* fluorine, and −152.6 ppm (d, 3.8 Hz) for the *ortho* fluorine. Comparing the complex and the ligand ^{19}F NMR spectra reveals that the signal at −140.4 ppm showed only a small (1.5 ppm) downfield shift and there is no significant shift for the signal at −148.3 ppm. However, the third signal (at −158.8 ppm), which belongs to the fluorine closest to the phosphinimine, shows a 6 ppm upfield shift compared to the uncoordinated ligand. These data are consistent with a structure in which the imine nitrogen is coordinated to the Rh(I) center. There is no evidence for Rh—F coupling, which has been observed in some similar compounds (37). The infrared spectrum of complex **6** showed two quinone carbonyl stretching bands at 1692 and 1664 cm^{-1} compared with bands at 1709 and 1685 cm^{-1} for the corresponding free ligand (**1**). These changes in frequency can be attributed to π backdonation from the Rh center to the C=O π^* orbital. All of the spectral evidence suggests that complex **6** contains rhodium(I) coordinated by the ligand via both an oxygen and an imine nitrogen, as illustrated in eq. [5].[4]

The ^{31}P NMR spectrum for complex **7** showed a single peak at 31.2 ppm, 16 ppm downfield from the value for the corresponding uncoordinated ligand **4**. The quinone carbonyl infrared stretching frequencies for complex **7** are 1681 and 1629 cm^{-1}, which are to be compared with the corresponding bands at 1725 and 1679 cm^{-1} for the free ligand **4**. The IR and NMR evidence suggests that **7** has the same structure as **6** with the small numerical differences in the spectral parameters arising from and in accord with the differences between the nature of the halogenated quinones. The chloroquinone more readily allows electron density to flow toward the metal center upon coordination, resulting in larger coordination shifts than for the fluoroquinone.

[3] Details of the crystal structure determination of **3** including crystal and data collection parameters, temperature factor expressions (U's), and positional parameters and their estimated standard deviations (14 pages) are available as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. With the exception of the temperature factor expressions, these data have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

[4] One referee suggested that the Rh(I) center was oxidized either by Ag^+ or by the quinone to yield Rh(III) complexes. The evidence that no oxidation occurs in these preparations is provided by independent reactions of ligand **3** with [Rh(cod)Cl]$_2$ and KPF_6 to give a Rh(I) complex of **3** with ^{31}P NMR parameters very similar to those of **6** and **7**. Reaction of this product with dppe displaces the quinone ligands and generates the well-known $Rh(dppe)_2^+$ cation (38), thus the Rh(I) center is not oxidized by the quinone ligands or reagents used in the formation of the Rh(I) precursor from the original source dimer.

Electrochemistry of phosphinimine-*p*-benzoquinone derivatives

The electrochemical data for the mono-phosphinimine derivatives of the chloro- and fluoroquinones show that they reversibly accept two electrons as do the parent quinones. The CV traces are clean and well shaped, showing the classic "duck-bill" shape and a pair of reverse sweep peaks that match the forward, reduction sweep. Numerical data for the potentials and the differences between peak positions in the forward and the reverse sweeps (ΔE) are given in Table 5. The CV trace of 3,5,6-trichloro-2-(triphenylphosphinimino)-*p*-benzoquinone (**3**) showed, on occasion, extra features that appear to be due to hydrolysis of the compound. The fluoroquinones **1** and **2** and the related chloroquinones **4** and **5** did not appear to be so susceptible nor do a number of related chloro-cyano-phosphinimine quinones that we have investigated (37).

Conclusions

Halogenated quinones can be readily substituted with phosphinimine moieties and the resultant compounds are highly colored species with potential for dye applications. These quinones demonstrate reversible two-electron redox behaviour and they also readily form complexes with transition metals. There would appear to be considerable potential for the utilization of the properties shown by these new ligands.

Experimental

All experimental manipulations were performed under an atmosphere of dry argon using Schlenk techniques. Solvents were dried and distilled under argon prior to use: CH_2Cl_2, CH_3CN, THF, and toluene were distilled from P_2O_5, P_2O_5–CaH_2, Na–benzophenone, and Na, respectively. The deuterated solvent, $CDCl_3$, was distilled and stored under argon before use. Commercial (Aldrich) supplies of dppm, Me_3SiN_3, 1,4-tetrachloro- and 1,4-tetrafluoro-quinones were used as obtained. $Ph_3P{=}NSiMe_3$, $(CH_3)Ph_2P{=}NSiMe_3$, and $Ph(CH_3)_2P{=}NSiMe_3$ were prepared from the reaction of the appropriate phosphine with Me_3SiN_3 as previously described (39). Nuclear magnetic resonance spectra were recorded on Bruker WH-200 and 400 spectrometers using as the reference the deuterium signal of the solvent employed (respective operating frequencies: ^1H = 200.133 and 400.135 MHz, ^{13}C = 50.323 and 100.614 MHz, ^{31}P = 81.015 and 161.977 MHz, ^{19}F = 188.313 and 376.503 MHz). The ^1H chemical shifts are reported in ppm from external Me_4Si, the ^{31}P NMR spectra are reported in ppm from external 85% H_3PO_4, and the ^{19}F NMR spectra are reported in ppm from external $CFCl_3$. Positive values are shifts downfield. Low-resolution mass spectra (Electron Impact, EI) were recorded at 16 or 70 eV on an AEI MS50 spectrometer. Positive ion fast atom bombardment mass spectra (FAB-MS) were obtained by using Xe fast atoms on a customized AEI MS9 spectrometer. Infrared spectra were recorded using a Nicolet 7199 infrared spectrometer. UV–visible spectra were recorded using a Hewlett Packard 8450A diode array spectrophotometer. Elemental analyses were performed by the Microanalytical Services Laboratory at the University of Alberta. Melting points were ascertained by visual methods in unsealed capillaries. Osmometry measurements were made in CH_2Br_2 or *o*-dichlorobenzene solutions using a Corona Wescan vapor pressure osmometer operated by the University of Alberta Microanalytical Services Laboratory. The crystal structure was determined at the University of Toledo. Details are given in Tables 2–4.

benzoquinone (**1**): To a solution of 1,4-tetrafluorobenzoquinone (1.00 g, 5.55 mmol) in CH_2Cl_2 (40 mL), maintained at 0°C using an ice–water bath, was added dropwise a solution of $Me_3SiN{=}PPh_3$ (1.941 g, 5.55 mmol), also in CH_2Cl_2 (20 mL). A purple color formed immediately. The reaction mixture was stirred at 0°C for about 1 h, then at room temperature for 12 h. The solution was taken to dryness in vacuum and the resultant purple solids were washed with hexane (20 ml × 3)

Synthesis of 3,5,6-trifluoro-2-(methyldiphenylphosphinimino)-*p*-benzoquinone (**2**): To a solution of 1,4-tetrafluorobenzoquinone (1.00 g, 5.55 mmol) in CH_2Cl_2 (40 mL), maintained at 0°C using an ice–water bath, was added dropwise a solution of Me_3SiN=PPh_2Me (1.560 g, 5.55 mmol), also in CH_2Cl_2 (20 mL). A purple color formed immediately. The reaction mixture was stirred at 0°C for about 1 h, then at room temperature for 12 h. The solution was taken to dryness in vacuum and the resultant purple solids were washed with hexane (20 mL × 3) and dried in vacuum (yield 1.10 g; 56%; purple powder). ^{19}F NMR ($CDCl_3$): δ(F_1 (*ortho* to N=PPh_3)) −154.30 (s, 1F), δ(F_2 (*para* to N=PPh_3)) −141.00 (d, 1F, $^3J_{F_2-F_3}$ = 3.8 Hz), δ(F_3 (*meta* to N=PPh_3)) −148.90 (d, 1F, $^3J_{F_2-F_3}$ = 3.8 Hz). ^{1}H NMR ($CDCl_3$): phenyl rings δ 7.45, 7.80 (m, 10H), methyl group δ 2.30 (d, 3H, $^2J_{P-H}$ = 16.0 Hz). MS (EI, *m/z*): 475 (M^+, 100%). Anal. calcd. for $C_{19}H_{13}NF_3O_2P$: C 60.81, H 3.49, N 3.73; found: C 59.67, H 3.31, N 4.33.

Synthesis of 3,5,6-trichloro-2-(triphenylphosphinimino)-*p*-benzoquinone (**3**): To a solution of 1,4-tetrachlorobenzoquinone (2.500 g, 10.17 mmol) in THF (80 mL) at room temperature (RT) was added dropwise a solution of Me_3SiN=PPh_3 (3.554 g, 10.17 mmol), also in THF (20 mL). The reaction mixture was refluxed for 12 h. The deep blue solution was taken to dryness in vacuum and the resultant solids were washed with hexane (20 mL × 3) and dried in vacuum (yield 4.25 g; 88%; blue powder; mp 227–229°C). ^{1}H NMR ($CDCl_3$): phenyl rings δ 7.55, 7.70 (m, 15H). MS (EI, *m/z*): 487 (M^+, 100%). Anal. calcd. for $C_{24}H_{15}NCl_3O_2P$: C 59.23, H 3.11, N 2.88, Cl 21.85; found: C 59.19, H 3.09, N 2.86, Cl 21.80.

Synthesis of 3,5,6-trichloro-2-(methyldiphenylphosphinimino)-*p*-benzoquinone (**4**): To a solution of 1,4-tetrachlorobenzoquinone (2.567 g, 10.44 mmol) in THF (40 mL) at RT was added dropwise a solution of Me_3SiN=PPh_2Me (3.00 g, 10.44 mmol), also in THF (10 mL). The reaction mixture was refluxed for 12 h. The deep blue solution was taken to dryness in vacuum and the resultant solids were washed with hexane (20 mL × 3) and dried in vacuum (yield 2.30 g; 52%; blue powder; mp 208–210°C). ^{1}H NMR ($CDCl_3$): phenyl rings δ 7.55, 7.85 (m, 10H), methyl group δ 2.35 (d, 3H, $^2J_{P-H}$ = 16.0 Hz). MS (EI, *m/z*): 425 (M^+, 100%). Anal. calcd. for $C_{19}H_{13}NCl_3O_2P$: C 53.74, H 3.09, N 3.30, Cl 25.05; found: C 53.73, H 3.17, N 3.54, Cl 23.82.

Synthesis of 3,5,6-trichloro-2-(dimethylphenylphosphinimino)-*p*-benzoquinone (**5**): To a solution of 1,4-tetrachlorobenzoquinone (0.436 g, 1.78 mmol) in THF (25 mL) at room temperature was added dropwise a solution of Me_3SiN=$PPhMe_2$ (0.400 g, 1.78 mmol), also in THF (10 mL). The reaction mixture was refluxed for 12 h. The deep blue solution was taken to dryness in vacuum and the resultant solids were washed with hexane (20 mL × 3) and dried in vac-

Table 5. Reduction potential ($E^{0'}$) data for monosubstituted quinone derivatives and selected reference systems.

[a]Literature: $E^{0'}$ = −0.15 and −0.81 V (vs. Ag/AgCl in DMF at 19°C with [*n*-Bu_4N]ClO_4 (0.1 M) as electrolyte) (3).
[b]Literature: $E^{0'}$ = +0.35 and −0.43 V (vs. Ag/AgI in CH_2Cl_2 at 25°C with [*n*-Bu_4N]ClO_4 (0.5 M) as electrolyte) (3).

uum to obtain (**5**) (yield 0.52 g; 81%; blue powder). ^{1}H NMR ($CDCl_3$): phenyl rings δ 7.55, 7.80 (m, 5H), methyl groups δ 2.02 (d, 3H, $^2J_{P-H}$ =16.0 Hz). MS (EI, *m/z*): 361 (M^+, 100%). Anal. calcd. for $C_{14}H_{11}NCl_3O_2P$: C 46.38, H 3.06, N 3.86, Cl 29.33; found: C 44.07, H 2.76, N 3.85, Cl 30.83.

Synthesis of rhodium (I) complexes

Synthesis of [(3,5,6-trifluoro-2-(triphenylphosphinimino)-*p*-benzoquinone){σ-O,N}Rh(cod)](ClO_4) (**6**): To a 100 mL Schlenk flask were added [(cod)RhCl]$_2$ (0.049 g, 0.100 mmol), $AgClO_4$ (0.042 g, 0.20 mmol), and acetone (15 mL). The mixture was stirred for 15 min whereupon a light yellow solution and a white precipitate formed. This solution was filtered into a purple solution of **1** (0.088 g, 0.200 mmol), also in acetone (15 mL), and the mixed solutions were stirred for 1 h. The solution was taken to near dryness; then hexane (10 mL) was added, whereupon a precipitate formed. The product was filtered and washed with hexane (10 mL × 2) and dried in vacuum. Recrystallization from CH_2Cl_2 gave the one-eighth dichloromethane solvate of **6** (yield: 0.11 g; 73%; brown powder). ^{19}F NMR ($CDCl_3$): δ −140.43 ppm (dd, 1F, coupling constant: 1.5 Hz and 4.9 Hz), δ −148.33 ppm (d, 1F, coupling constant: 4.9 Hz), δ −158.76 ppm (s, 1F). ^{1}H NMR ($CDCl_3$): phenyl rings: δ 7.55, 7.65 ppm (m, 15H), cod groups: δ 4.20 ppm (s, 4H, HC═), δ 2.45 ppm (m, 4H, H_2C), δ 1.65 ppm (broad, 4H, H_2C). MS (FAB): 648 (monocation). Anal. calcd. for $C_{32}H_{27}NClF_3O_6PRh \cdot 1/8CH_2Cl_2$: C 50.87, H 3.62, N 1.85, Cl 5.84; found: C 49.06, H 3.63, N 1.87, Cl 5.65.

A similar procedure to that described above was used to prepare [3,5,6-trichloro-2-(methyldiphenylphosphinimino)-*p*-benzoquinone){σ-O,N}Rh(cod)](ClO_4) (**7**) from [(cod)RhCl]$_2$, $AgClO_4$, and **4**, again in acetone (yield: 0.102 g; 69%; brown powder). ^{1}H NMR ($CDCl_3$): phenyl rings: δ 7.60, 7.80 ppm (m, 10H), cod groups: δ 4.23 ppm (s, 4H, HC═), δ 2.50 ppm (m, 4H, H_2C), δ 1.70 ppm (broad, 4H, H_2C). Methyl group: δ 2.80 ppm (d, $^2J_{P-H}$ = 12 Hz). MS (FAB): 636 (monocation). Mol. Wt.: 511.4 (solvent: CH_2Br_2). Anal. calcd. for $C_{27}H_{25}NCl_4O_6PRh$: C 44.11, H 3.43, N 1.91, Cl 19.29; found: C 44.08, H 3.49, N 1.93, Cl 17.96.

Electrochemistry

An electrochemical cell was constructed to provide a small-volume (ca. 10 mL) inert-gas-blanketted environment for the measurements. Three electrodes were introduced through a sealed glass cap extending to the base of the tube where they projected into the solution volume. A gas inlet was provided as well as a rotatable bent side arm on the cell to hold the solid sample ready for addition. The procedure was as follows: first, the sample was put in the sidearm tube and solvent was added to the cell. A blank cyclovoltammetric scan was done. Then the sample tube was turned to drop the sample into the solvent. The sample was allowed to dissolve completely, and then the CV scan of the solution was taken. The working electrode was a small (1 mm diameter) Pt bead sealed in soft glass. A coiled Pt wire (15 cm in length) was used as the auxiliary electrode. The compartment for the Ag/AgCl quasi-reference electrode was separated from the working electrode compartment by a fine frit. The support electrode was [*n*-Bu_4N]BF_4. The solvent (dichloromethane, Spectrograde, BDH) was degassed and dried over alumina (ICN Biomedical, neutral, W200 Super 1). The working electrode was cleaned by placing the electrode tip over boiling HNO_3 (reagent grade) for 0.5 h, rinsing with distilled water (2 L), and soaking in a saturated ferrous ammonium sulphate solution (made up in 1 M H_2SO_4) for 0.5 h. Finally, it was rinsed with distilled water (2 L) and reagent acetone (1 L), and dried with a hot air gun immediately before

use. The potential was supplied by a EG&G model 273 potentiostat, and the resulting cyclic voltammograms were recorded using a Hewlett Packard 7015B X-Y recorder. The solutions employed during cyclic voltammetry were typically (5–7) × 10^{-4} M in organometallic complex and 0.1 M in [n-Bu_4N]BF_4. These experiments were carried out at ambient temperatures (about 23°C). The formal oxidation or reduction potential, $E^{0'}$, for reversible couples is defined as the average of the anodic ($E_{p,a}$) and cathodic ($E_{p,c}$) peak potentials. The separation of the cathodic and anodic potentials is ΔE, $|E_{p,c} - E_{p,a}|$. The cathodic to anodic peak current ratio is defined as $i_{p,c}/i_{p,a}$ (40). The oxidation of ferrocene is reported to be highly reversible in many solvents (41) and was used as an internal reference (under our experimental conditions, $E^{0'}$ = +0.47 V vs. Ag/AgCl, $i_{p,c}/i_{p,a}$ = 1.0, ΔE = 100 mV) (42). A scan rate of 0.1 V s^{-1} was used for all the compounds measured. The ratio $i_{p,c}/i_{p,a}$ was used to establish chemical reversibility for the compounds studied.

$Mo_2(OCH_2{}^tBu)_6(Cp)Na(DME)$. Preparation, structure, and solution behavior

Theodore A. Budzichowski, Malcolm H. Chisholm, and William E. Streib

Abstract: From the reaction between $Mo_2(OCH_2{}^tBu)_6$ and NaCp (Cp = C_5H_5) in THF the title complex was obtained as a crystalline product in the presence of DME (DME = dimethoxyethane). Crystal data for $Mo_2(OCH_2{}^tBu)_6(Cp)Na(DME)$ at −167°C: a = 11.885(2) Å, b = 19.240(1) Å, c = 11.562(2) Å, α = 102.73(1)°, β = 106.95(1)°, γ = 98.55(1)°, Z = 2 and space group of $P\bar{1}$. In the solid state there is an unbridged Mo≡Mo bond of distance 2.276(1) Å. One Mo atom is bonded to four alkoxides, two of which are also bonded to Na^+ while the other is η^5-bonded to the Cp ligand, with Mo—C distances ranging from 2.34 to 2.66 Å, and to two OR groups, one of which is bound to the Na^+ ion. In addition to the coordination to three OR groups the Na^+ ion binds one DME molecule via both of its ether oxygen atoms. The Mo—O distances fall in the range 1.91–2.01 Å with the longer distances being associated with those groups that are also bonded to the Na^+ ion. In polar solvents the title complex dissociates to give $Mo_2(OCH_2{}^tBu)_6$ and Na^+ Cp^-.

Key words: molybdenum, alkoxide, cyclopentadienyl, metal–metal triple bonds.

Résumé : On a obtenu le composé mentionné dans le titre sous forme cristalline à partir de la réaction entre le $Mo_2(OCH_2{}^tBu)_6$ et le NaCp (Cp = C_2H_5) dans le THF. Les données cristallines pour le composé $Mo_2(OCH_2{}^tBu)_6(CP)Na(DME)$ à −167°C sont les suivantes : a = 11,885(2) Å, b = 19,240(1) Å, c = 11,562(2) Å, α = 102,73(1)°, β = 106,95(1)°, γ = 98,55(1)°, Z = 2 et groupe d'espace $P\bar{1}$. À l'état solide il y a une distance de liaison Mo≡Mo non ponté de 2,276(1) Å. Un atome de Mo est lié à quatre groupes alcoolates, dont deux sont également liés à l'ion Na^+ tandis que l'autre est lié par une liaison η^5 au ligand Cp avec des distances de liaison allant de 2,34 à 2,066 Å et à deux groupes OR dont l'un est lié à l'ion Na^+. En plus de la coordiantion aux trois groupes OR, l'ion Na^+ est lié à une molécule de DME par l'intermédiaire de ses deux atomes d'oxygène. Les distances Mo—O se situent dans un intervalle de 1,91 à 2,01 Å, la plus grande distance étant associée aux groupes qui sont également liés à l'ion Na^+. Dans les solvants polaires, le composé mentionné dans le titre se dissocie pour donner le complexe $Mo_2(OCH_2{}^tBu)_6$ et Na^+Cp^-.

Mots clés : molybdène, alcoolate, cyclopentadiényle, triple liaison métal–métal.

[Traduit par la rédaction]

Introduction

We have for some time been exploring the chemistry associated with dinuclear complexes of the formula $M_2(OR)_6$ where M = Mo and W (1). These are members of a class of so-called ethane-like dimers having a cylindrical M—M triple bond of electronic configuration $\sigma^2\pi^4$. The metal atoms are weakly Lewis acidic since the metal d_{xy}, $d_{x^2-y^2}$ orbitals are vacant and are only weakly involved in π-bonding to the alkoxide oxygen p_π orbitals. This allows for substrate uptake and often subsequent activation at the dinuclear center (2). Recently we have been examining the uptake of anionic ligands such as CN^- (3*a*) and OR^- (3*b*), which may bind reversibly according to eqs. [1] and [2].

[1] $M_2(OR)_6 + X^- \rightleftharpoons [M_2(OR)_6X]^-$

[2] $[M_2(OR)_6X]^- + X^- \rightleftharpoons [M_2(OR)_6(X)_2]^{2-}$

The position of the equilibria in eqs. [1] and [2] is sensitive to the steric properties of R and the metal. For given systems the $\Delta H°$ value is more negative by ca. 3 kcal/mol for M = W relative to M = Mo and weak nucleophiles such as halides and NCS^- do not bind to the $M_2(OR)_6$ complexes.

We describe here our studies of the binding of the cyclopentadienyl ligand, which was of interest to us in part because earlier studies of $M_2(NMe_2)_4Cp_2$ complexes were inconclusive concerning the mode of coordination of the C_5H_5 moiety to the $Mo_2{}^{6+}$ center (4).

Results and discussion

Syntheses and solution behavior

The reaction between NaCp and $Mo_2(OCH_2{}^tBu)_6$ proceeds quickly in THF, based on the rapid color change from yellow to deep purple that occurs when the two are mixed at room temperature. The product may be obtained by simply evaporating the solvent in vacuo (0.01 Torr, 25°C; 1 Torr = 133.3 Pa) and retains at least two equivalents of THF (depending on the drying time) based on ^1H NMR spectroscopic analysis. Surprisingly, the spectrum is quite simple and belies the color

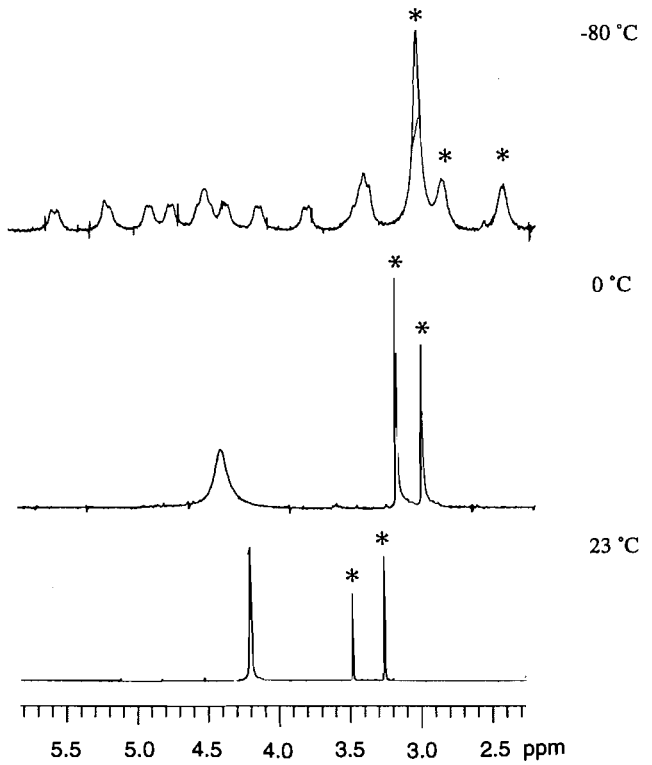
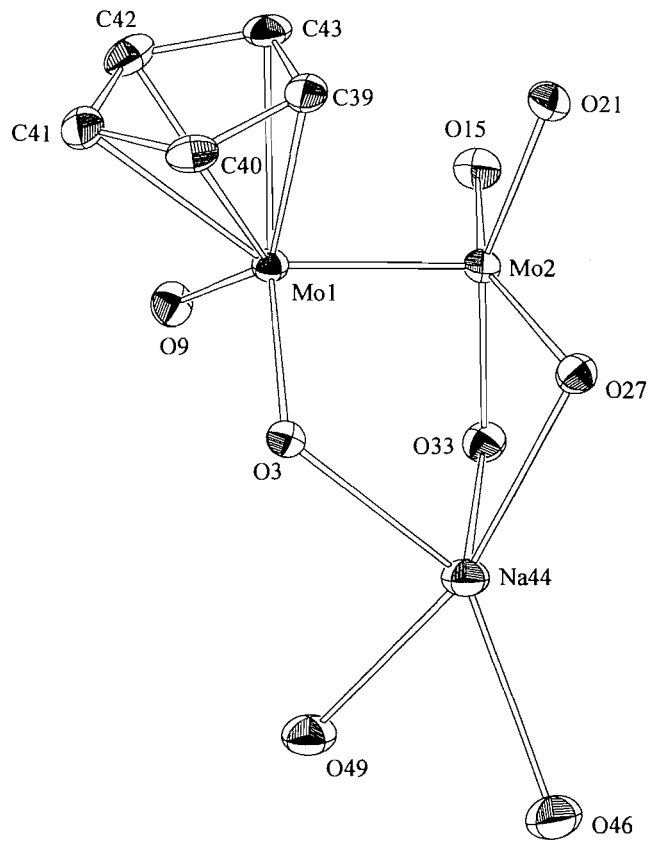
Fig. 1. Stacked plot of ^{1}H NMR spectra (-CH_2- region, toluene-d_8, 300 MHz, 23°C to –80°C) showing the changes that occur upon cooling. Resonances marked with an asterisk are due to DME.



of the material since the chemical shifts of the alkoxide resonances are only slightly altered from those of pure $Mo_2(OCH_2{}^tBu)_6$, but are significantly broadened. When DME is added, however, the product crystallizes nicely from cold THF solution (−34°C) as large purple parallelopipeds. The ^{1}H NMR spectrum is similarly straightforward and consists of single resonances for the –$OCH_2{}^tBu$ (both methylene and methyl) groups, DME (both methyl and methylene groups), and cyclopentadienyl moieties. The normalized ratio of these resonances (alkoxide:DME:Cp) is 6:1:1, consistent with the analytical data and the solid state structure observed by single-crystal X-ray diffraction (vide infra).

Once again, the neopentoxide resonances are only slightly shifted and broadened from those of $Mo_2(OCH_2{}^tBu)_6$ at room temperature (23°C, toluene-d_8), which is consistent with fluxional behavior and *dissociation* of the cyclopentadienyl moiety from the dimolybdenum center. Upon cooling, the spectrum becomes quite complex and at very low temperature (–80°C, toluene-d_8) it is clear that the solid state structure is maintained in solution: the molecule is asymmetric, possessing six different alkoxide groups. These give rise to 6 ^{t}Bu resonances and 12 doublets (6 doublets of doublets) for the methylene groups, which are all diastereotopic. Furthermore, the methylene groups of the DME are split into two broad resonances, but the signal for the methyl groups of this moiety is only broadened. Apparently, the process that equilibrates these groups of the DME is not completely frozen out at –80°C since one would anticipate two resonances, and two doublets of doublets for the methylene groups, based on the observed molecular structure in the solid state.

Fig. 2. ORTEP plot of the core atoms for Na(DME)Mo_2-$(OCH_2tBu)_2(\eta^5$-$C_5H_5)$ with ellipsoids at the 50% probability level. This view is roughly perpendicular to the Mo≡Mo axis.

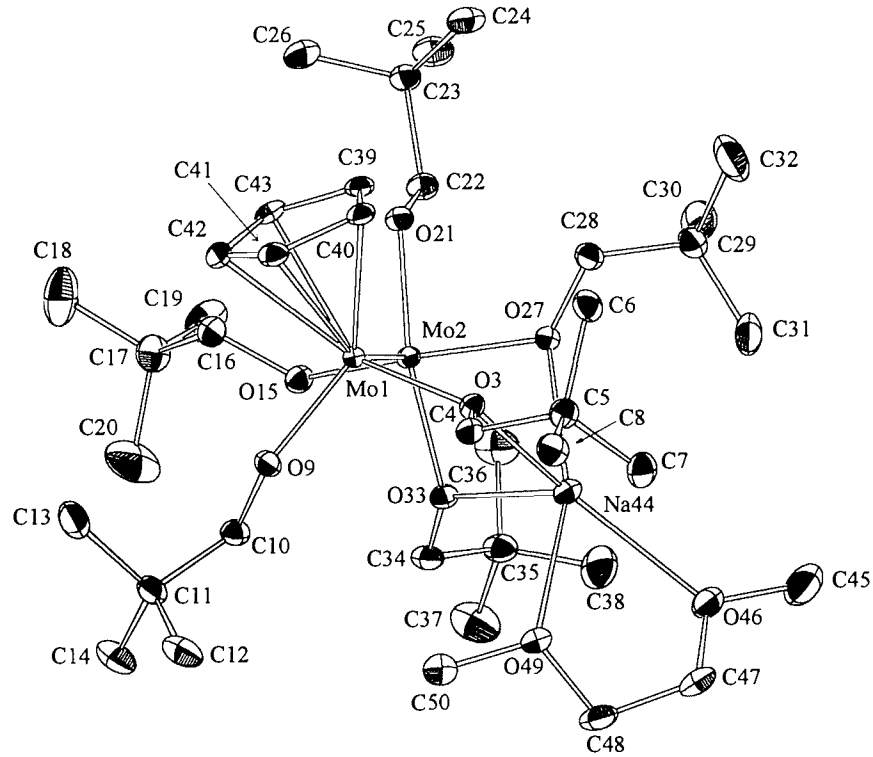


In contrast, warming a solution of the complex briefly (60°C, 2–3 min) in toluene-d_8 produces sharper resonances (for free $Mo_2(OCH_2{}^tBu)_6$) and a distinctive color change to yellow that may be readily observed prior to decomposition. The process is reversible and cooling causes reassociation. Unfortunately, because of the fluxionality of the adduct, (DME)$NaMo_2(OCH_2{}^tBu)_6(\eta^5$-$C_5H_5)$, data could not be obtained with the precision necessary for computation of $\Delta H°$ and $\Delta S°$ for the equilibrium. These changes are shown in Fig. 1.

It was clear at this point that the enthalpy of η^5-C_5H_5 association is only modestly favorable and is balanced with the unfavorable loss in entropy that occurs when NaCp, $Mo_2(OCH_2{}^tBu)_6$, and the molecule of DME are brought together in the adduct. With this in mind, 18-crown-6 was introduced as a potential complexing agent for the sodium cation. Unfortunately, no appreciable changes could be observed spectroscopically, and recrystallization from DME:THF produced (DME)$NaMo_2(OCH_2{}^tBu)_6(\eta^5$-$C_5H_5)$, not a charge-separated complex such as $[Na(18\text{-crown-}6)]^+[Mo_2(OCH_2{}^tBu)_6$-$(\eta^5$-$C_5H_5)]^-$. Addition of pyridine to solutions of (DME)$NaMo_2(OCH_2{}^tBu)_6(\eta^5$-$C_5H_5)$ resulted in the formation of $Mo_2(OCH_2{}^tBu)_6(py)_2$, NaCp, and DME. This is an unusual result in the sense that the sodium cations, which are bound to alkoxide ligands in the adduct, dissociate along with the cyclopentadienyl moiety.

Metathesis of alkoxide for Cp might otherwise have been

Fig. 3. ORTEP plot of $Na(DME)Mo_2(OCH_2{}^tBu)_6(\eta^5\text{-}C_5H_5)$ showing all non-hydrogen atoms at the 40% probability level (for clarity). The view is roughly parallel to the Mo≡Mo axis and highlights the staggered and asymmetric arrangement of the ligands.



anticipated based on hard–soft acid–base principles. Numerous complexes are known that contain η^5-cyclopentadienyl ligands and metal–ligand multiple bonds (e.g., $[(\eta^5\text{-}C_5Me_5)Ta(\equiv N)(Me)]_3$ (5). Given the isolobal analogy between triply-bonded ligands (such as nitride) and the $\eta^5\text{-}C_5H_5$ ligand it is somewhat perplexing that a formation of $CpMo(OR)_2(\equiv Mo(OR)_3)$ would be energetically unfavorable relative to $Mo_2(OR)_6(py)_2$.

Solid-state structure

A view of the central $CpO_6Mo_2NaO_2$ skeleton giving the atom number scheme is given in Fig. 2 and an ORTEP view of the complex is given in Fig. 3. A listing of atomic coordinates is given in Table 1, selected bond distances and bond angles are given in Tables 2 and 3, and a summary of structural data is given in Table 4.

The Mo—Mo distance of 2.276 Å is typical of that for a triple bond. One molybdenum atom Mo(1) is coordinated to two $OCH_2{}^tBu$ groups and the Cp ligand, which may be considered as $\eta^5\text{-}C_5H_5$, with Mo(1)—C distances spanning a relatively narrow range 2.34–2.66 Å. There are two short, 2.34 and 2.36 Å, and three longer, 2.51, 2.54, and 2.66 Å, Mo(1) to C distances. These distances do not lend themselves to either the η^1 or $\eta^3\text{-}C_5H_5$ bonding pattern. The other Mo atom is bonded to four $OCH_2{}^tBu$ groups. Of the six $OCH_2{}^tBu$ ligands, three are bonded to both Mo and the Na ion, one from Mo(1) and two from Mo(2), and coordination to the Na ion results in a slight lengthening of the Mo—O distance from 1.98 to 2.01 Å. The coordination of the Na ion is completed by the η^2-DME ligand such that Na is five coordinate. The Na—O distances span a narrow range 2.31–2.51Å.

Experimental section

All synthetic procedures were performed under an inert atmosphere utilizing standard procedures in conjunction with a Vacuum Atmospheres Corporation Dri-Lab. The solvents used were dried by standard procedures and stored over 4 Å molecular sieves prior to use. $Mo_2(OCH_2{}^tBu)_6$ was prepared as described in the literature (7) and was recrystallized from cold hexanes and dried in vacuo prior to use. Sodium cyclopentadienide was prepared from freshly cracked cyclopentadiene (Aldrich) and sodium hydride (Aldrich) in THF. The soluble portion was collected by filtration, and the volatile components were removed in vacuo (25°C, 0.01 Torr) to afford NaCp as a pure white powder. The crown ether (18-crown-6) was purchased from Aldrich and was purified by repeated sublimation (100°C, 0.001 Torr) prior to use. NMR spectra were recorded on Varian XL-300 (300.1 MHz) and Bruker AM-500 (500.0 MHz) spectrometers and were referenced to residual protio impurities of the deuterated solvents.

Synthesis of $Na(DME)Mo_2(OCH_2{}^tBu)_6(\eta^5\text{-}C_5H_5)$

Yellow crystalline $Mo_2(OCH_2{}^tBu)_6$ (800 mg, 1.12 mmol) and NaCp (110 mg, 1.24 mmol) were weighed into a 30 mL

Schlenk flask equipped with a Teflon-coated magnetic stirring bar in the dry box. THF (~15 mL) was added via cannula under N_2 outside the box resulting in the formation of a deep purple solution, which was stirred for 2 h. After this time the volatile components were evaporated in vacuo (0.01 Torr, 25°C) and the purple foamy residue dried for 2 h. Despite numerous attempts, crystalline material could not be obtained from Et_2O or THF (even in the presence of 18-crown-6) by the addition of hexanes or pentane in which the product is insoluble. However, the addition of DME dramatically improves the crystallinity of the product, which vigorously retains one equivalent of this chelating ether and is easily isolated as large crystals from 2:1 THF:DME (5 mL total volume, 0°C). One of these was eventually used for the single-crystal X-ray diffraction experiment. The product was reasonably soluble in benzene-d_6 and toluene-d_8 and analyzed satisfactorily for $Na(DME)Mo_2(OCH_2{}^tBu)_6(\eta^5\text{-}C_5H_5)$. For $Na(DME)Mo_2(OCH_2{}^tBu)_6(\eta^5\text{-}C_5H_5)$: ^1H NMR (toluene-d_8, 0°C); δ: 6.62 (s, 5H), 4.20 (s, 12H), 3.14 (s, 6H), 3.01 (s, 4H), 1.11 (br s, 54H). ^1H NMR (toluene-d_8, −80°C), δ: 6.71 (s, 5H), 5.49, 5.12, 4.87, 4.72, 4.51, 4.47, 4.36, 4.13, 3.72 (d, 1H each for $-CH_2$), 3.43 (m, 3 overlapping d, 3H total for $-CH_2$), 3.08 (br s, 6H, $CH_3OCH_2CH_2OCH_3$), 2.91 (br s, 2H, $CH_3OCH_2CH_2OCH_3$), 2.52 (br s, 2H, $CH_3OCH_2CH_2OCH_3$), 1.57, 1.48, 1.29, 1.25, 1.00, 0.85 (s, 9H each for $-CH_2C(CH_3)_3$. Single crystal X-ray study

General operating procedures and listings of programs have been given previously (8).

An irregular crystal of suitable size was obtained by cleaving a large piece of the sample in a nitrogen atmosphere filled glove bag. The crystal was mounted using silicone grease and it was then transferred to a goniostat where it was cooled to −167°C for characterization and data collection. A systematic

search of a limited hemisphere of reciprocal space revealed no symmetry among the observed intensities. An initial choice of space group $P\bar{1}$ was later proven correct by the successful solution of the structure. Following complete data collection, data processing gave a residual of 0.023 for the averaging of 6291 unique intensities that had been observed more than once. Four standards measured every 400 data showed no significant trends. No correction was made for absorption.

The structure was solved by using a combination of direct methods (MULTAN78) and Fourier techniques. The positions of the molybdenum atoms were determined from an initial E-map. The positions of the remaining non-hydrogen atoms were obtained from subsequent iterations of least-squares refinement and difference Fourier calculation. Only a few of the hydrogens were observed. Hydrogens were included in fixed calculated positions with thermal parameters fixed at one plus the isotropic thermal parameter of the atom to which they were bonded.

In the final cycles of refinement, the non-hydrogen atoms were varied with anisotropic thermal parameters to a final $R(F) = 0.021$. The final difference map was featureless, the largest peak being 0.328 e/Å^3 and the deepest hole being −0.331 e/Å^3.

The nonbonded Mo—Na distances, not shown in the tables, are: Mo(1)—Na(44), 3.646(1) Å, and Mo(2)—Na(44), 3.201(1) Å.

COMMUNICATION

Synthesis and spectroscopic characterization of bis(trifluorophosphinyl)-gold(I) undecafluorodiantimonate(V) $[Au(PF_3)_2][Sb_2F_{11}]$

B. Bley, M. Bodenbinder, G. Balzer, H. Willner, G. Hägele, F. Mistry, and F. Aubke

Abstract: The synthesis of $[Au(PF_3)_2][Sb_2F_{11}]$, the first example of a linear, thermally stable metal bis(trifluorophosphine) complex is achieved by CO substitution of $[Au(CO)_2][Sb_2F_{11}]$ by PF_3. The $[Au(PF_3)_2]^+$ cation can also be generated by reductive phosphorylation by an excess of PF_3 in fluorosulfuric acid. Spectroscopic characterization involves ^{19}F and ^{31}P NMR in HSO_3F and SO_2 solution including spectral simulation by the WIN-DAISY method and FT-IR and Raman spectra. Spectroscopic evidence suggests that the metal–ligand bond involves predominantly σ-bonding with drastically reduced π-back-donation.

Key words: gold(I) complex, linear; gold(I) PF_3 complex; ^{31}P NMR; ^{19}F NMR; vibrational spectra.

Résumé : On a réalisé la synthèse du $[Au(PF_3)_2][Sb_2F_{11}]$, le premier exemple d'un complexe de bis(trifluorophosphine) d'un métal, linéaire et thermiquement stable, en substituant le groupe CO du composé $[Au(CO)_2][Sb_2F_{11}]$ par le groupe PF_3. Le cation $[Au(PF_3)_2]^+$ peut également être généré par phosphorylation réductrice avec un excès de PF_3 dans l'acide fluorosulfurique. Les caractérisations par spectroscopie impliquent la RMN du ^{19}F et du ^{31}P en solution dans du HSO_3F et du SO_2 incluant la simulation spectrale par la méthode du WIN-DAISY et des spectres FT-IR et Raman. Les preuves spectroscopiques suggèrent que la liaison ligand–métal implique de façon prédominante une liaison σ qui réduit drastiquement le transfert en retour π.

Mots clés : complexe d'or(I), linéaire; complexe de PF_3 or(I); RMN du ^{31}P; RMN du ^{19}F; spectres vibrationnels.

[Traduit par la rédaction]

While a substantial number of transition metal complexes with trifluorophosphine, PF_3, have become known (1–3), compounds containing homoleptic metal–PF_3 cations are rare. The known examples involve $[M(PF_3)]^+$ complexes of d^{10} metal ions like Ag^+ (4), Cu^+ (5), and Hg_2^{2+} (4) with $[AsF_6]^-$ as anion (4, 5). The salts are frequently thermally unstable (4) and incompletely characterized. We want to report here the synthesis of $[Au(PF_3)_2][Sb_2F_{11}]$ and the spectroscopic characterization of the linear $[Au(PF_3)_2]^+$ cation by IR, Raman, and ^{19}F and ^{31}P NMR spectroscopy. Two earlier publications by us form the basis for the synthesis of $[Au(PF_3)_2][Sb_2F_{11}]$. The recently reported compound $[Au(CO)_2][Sb_2F_{11}]$ (6) provides a convenient starting material and the molecular structure determination of $[Hg(CO)_2][Sb_2F_{11}]$ (7) demonstrates why the very weakly basic $[Sb_2F_{11}]^-$ anion is so eminently suited to stabilize unusual, highly electrophilic cations by weak, secondary interionic SbF--CO contacts. Moreover, additional homoleptic metal carbonyl cations like $[M(CO)_4]^{2+}$ (8), M = Pd and Pt, and $[M(CO)_6]^{2+}$ (9), M = Ru or Os, have $[Sb_2F_{11}]^-$ as counter anion.

The synthesis of $[Au(PF_3)_2][Sb_2F_{11}]$ is readily accomplished by the displacement of CO by PF_3 using a slight excess of gaseous PF_3 according to:

$$[1]\quad [Au(CO)_2][Sb_2F_{11}]_{(s)} + 2\,PF_{3\,(g)} \xrightarrow{25°C} [Au(PF_3)_2][Sb_2F_{11}] + 2\,CO_{(g)}$$

Received March 13, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

The white, moisture-sensitive product decomposes at 105°C in a N_2 atmosphere. The composition is established by the mass balance of the reaction, by PF_3 uptake measurements, and by the identification of CO by IR in the gas phase after displacement. The substitution of CO by CH_3CN to give $[Au(CH_3CN)_2][SbF_6]$ (6) provides a precedent. In $[Au(CO)_2]^+$, where CO is predominantly a σ-donor ligand, displacement by a better σ-donor is possible. Hence substitution of CO by PF_3 suggests that PF_3 is a better σ-donor towards univalent gold then is CO. An alternative approach starts from $Au(SO_3F)_3$ dissolved in HSO_3F and allows the in situ generation of the $[Au(PF_3)_2]^+$ cation according to:

$$[2]\quad Au(SO_3F)_3 + 3\ PF_3 \xrightarrow{HSO_3F,25°C} [Au(PF_3)_2]^+_{(solv)} + OPF_3 + S_2O_5F_2 + SO_3F^-_{(solv)}$$

The cation and the products of the reduction, OPF_3 and $S_2O_5F_2$, are detected in the ^{19}F and ^{31}P NMR spectra. The volatile compounds OPF_3 and $S_2O_5F_2$ are also detected by gas phase IR. Hence the formation of solvated $[Au(PF_3)_2]^+$ in HSO_3F proceeds in complete analogy to the reported reductive carbonylation of $Au(SO_3F)_3$ to produce $[Au(CO)_2]^+_{(solv)}$ (10).

The observed vibrational bands of $[Au(PF_3)_2][Sb_2F_{11}]$ are listed in Table 1, together with estimated intensities, an approximate description of the vibrational modes, and the previously reported fundamentals for free PF_3 (11). Bands attributed to the $[Sb_2F_{11}]^-$ anion are observed in similar positions in both IR and Raman spectra, as was reported for $[Au(CO)_2][Sb_2F_{11}]$ (6).

For $[Au(PF_3)_2]^+$ the partial coincidence of bands in the IR and Raman spectrum, most noticeable in the P–F stretching range at 963–974 cm^{-1}, would suggest a linear cation with eclipsed PF_3 groups (point group D_{3h}) rather than D_{3d} where the PF_3 groups are staggered. A clear distinction between both possibilities cannot be made using vibrational data. A complete assignment of bands will have to await a molecular structure determination and successful depolarization measurements on $[Au(PF_3)_2]^+_{(solv)}$.

The $\bar{\nu}$ (PF_3) modes are clearly separated from bands due to the anion and are easily identified. In $[Au(PF_3)_2]^+$, $\bar{\nu}$ (PF_3) vibrations are shifted to higher wave numbers relative to free PF_3 (11). This shift, previously attributed to reduced M to PF_3 π-back-bonding (4, 5), is even more pronounced than in $[Ag(PF_3)]^+$ (4), $[Hg_2(PF_3)_n]^{2+}$, $n = 1$ or 2 (4), or in $[Cu(PF_3)]^+$ (5), all with $[AsF_6]^-$ as anion. Since in metal–PF_3 complexes the π-acceptor orbital on the ligand has some antibonding character (3), a reduction in π-back-bonding results in increased P—F bond strength. The implication for $[Au(PF_3)_2]^+$ is that metal–ligand bonding as in $[Au(CO)_2]^+$ (6) involves predominantly σ-bonds. The ability of univalent gold to form strong covalent σ-bonds, resulting largely in linear complexes, is well documented (12), and seemingly aided by relativistic effects (13).

For NMR measurements in solution, two different samples are employed. In sample 1, solid $[Au(PF_3)_2][Sb_2F_{11}]$ is dissolved in SO_2. In sample 2 the $[Au(PF_3)_2]^+$ cation is generated in HSO_3F by reduction of $Au(SO_3F)_3$ with PF_3. In the second sample, HSO_3F together with SO_3F^- (14), uncoordinated PF_3 (4), and the reduction products $S_2O_5F_2$ (14) and OPF_3 (15) are identified by comparison to published precedents. Broad resonances in the ^{19}F spectrum of sample 1 at −90.6 (F br.), −110.1 (F eq.), and −132.0 ppm (F ax.) are attributed to the $[Sb_2F_{11}]^-$ anion (15).

Since ^{19}F and ^{31}P NMR spectra at room temperature exhibit rather broad, poorly resolved peaks, ^{19}F spectra are recorded at 215 K and ^{31}P NMR spectra at 225 K. The results are compiled in Table 2, together with the parameters obtained by automated analysis and spectral simulations, using the WIN-DAISY (16) method. Experimental and simulated ^{19}F and ^{31}P NMR spectra are shown in Figs. 1 and 2. The spectra of the species present in SO_2 and HSO_3F solution are identical and the species is clearly identified as $[Au(PF_3)_2]^+_{(solv)}$. The observed splitting pattern is consistent with a $[AX_3]_2$ spin system. The coupling constant $^1J_{PF}$ is with −1414.6 Hz (at 215 K) slightly larger than in free PF_3 in SO_2 solution (−1403 Hz). This suggests, according to observations reported for $[Ag(PF_3)]^+$ and $[Hg_2(PF_3)]^{2+}$ (4), reduced metal to PF_3 π-back-donation. In neutral metal PF_3 compounds $^1J_{PF}$ values are smaller and fall between −1230 and −1350 Hz (3). Finally, the rather large $^2J_{PP}$ value of 922.7 Hz (at 215 K) is consistent with a *trans* geometry in $[Au(PF_3)_2]^+$, because *cis* complexes such as, for example, $Mo(CO)_4(PF_3)_2$ have much smaller values of 55 Hz (17). It is interesting to note that the long-range coupling constant $^4J_{FF}$, which has significant influence on the spectral theory of $[AX_3]_2$ systems, is not zero but between −1.8 Hz (from ^{19}F NMR) and −0.7 Hz (from ^{31}P NMR), respectively.

In summary, $[Au(PF_3)_2]^+$, the first example of a linear, ther-

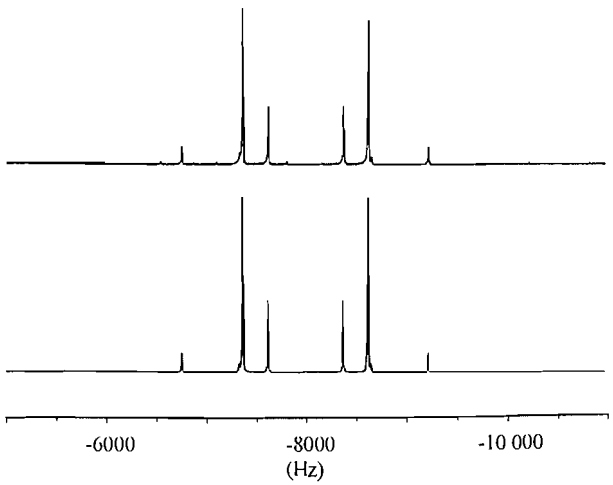
Fig. 1. 188.3 MHz ^{19}F NMR spectrum of $[Au(PF_3)_2]^+$, dissolved in HSO_3F, at 215 K. Upper: experimental, lower: simulated spectrum. Resonance frequencies (Hz) referenced vs. ext. $CFCl_3$ in $CDCl_3$.



mally stable metal–bis(PF_3) complex, is obtained either in HSO_3F or SO_2 solution, or as solid material in $[Au(PF_3)_2][Sb_2F_{11}]$. As in $[Au(CO)_2]^+$ (6, 10), the metal–ligand bonds in $[Au(PF_3)_2]^+$ are predominantly σ-bonds. Both cations are 14-e$^-$ species and violate the noble gas formalism. The formation of $[Au(PF_3)_2]^+_{(solv)}$ in HSO_3F by reduction of $Au(SO_3F)_3$ with PF_3 is unusual and proceeds in analogy to the formation of $[Au(CO)_2]_{(solv)}$, with PF_3 replacing CO both as reducing agent and as ligand. It is hoped that $[Au(PF_3)_2]^+$ will be the first member of a new class of thermally stable, homoleptic $[M(PF_3)_n]^{m+}$ cations.

Aminoacyl ethyl phosphates. Biomimetically activated amino acids[1]

Ronald Kluger, Xianfeng Li, and Richard W. Loo

Abstract: Aminoacyl ethyl phosphates are functional analogues of aminoacyl adenylates, the activated intermediates formed by ribosomal enzymes from the reaction of amino acids with ATP. The aminoacyl ethyl phosphates are prepared by DCC-mediated coupling of a tetraalkylammonium salt of ethyl phosphate and an *N*-*t*-Boc-amino acid, followed by deprotection. The efficiency of the synthesis and the solubility properties of the product depend on the alkyl group in the ammonium counterion of the phosphate. *N*-Protected and free aminoacyl ethyl phosphates hydrolyze slowly ($t_{1/2}$ in neutral solution, 25°C, ~100 h). These materials are potentially useful in biomimetic peptide synthesis, protein modification, and aminoacylation of RNA.

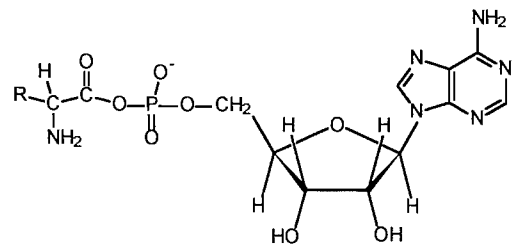
Key words: amino acids, acyl phosphates, aminoacyl phosphates, biomimetic aminoacylation.

Résumé : Les éthylphosphates d'aminoacyles sont des analogues fonctionnels des adénylates d'aminoacyles, les intermédiaires activés formés par les enzymes ribosomaux par réaction des acides aminés avec l'ATP. Les éthylphosphates d'aminoacyle se préparent par le couplage, sous l'action du DCC, d'un sel tétraalkylammonium de l'éthylphosphate et d'un acide *N*-*t*-Boc-aminé, suivi d'une déprotection. L'efficacité de la synthèse et la solubilité du produit dépendent de la nature du groupe alkyle du contreion ammonium du phosphate. Les éthylphosphates portant des groupes aminoacyles libres ou *N*-protégés s'hydrolysent lentement ($t_{1/2}$, en solution neutre, 25°C, est d'environ 100 h). Ces produits présentent un intérêt potentiel dans les synthèses biomimétiques des peptides, dans la modification des protéines ainsi que dans l'aminoacétylation de l'ARN.

Mots clés : acides aminés, phosphates d'acyles, phosphates d'aminoacyles, aminoacétylation biomimétique.

The formation of peptides and proteins from amino acids is a central biosynthetic process in all living systems. Each amino acid that is added to the growing peptide does so against inherently large thermodynamic and kinetic barriers, following the sequence specified by the bases of DNA. In this process, the carboxyl portion of the amino acid is chemically activated, overcoming the thermodynamic barrier and kinetic pathway by formation of a suitable intermediate (1). In most organisms, including all eukaryotes, this is accomplished in reactions promoted by aminoacyl *t*-RNA synthetases (one for each of the types of amino acid) (1, 2). The specific amino acid is added to the appropriate *t*-RNA to form a 3′-terminal ester, providing the amino acid with a nucleic acid-coded "tag."

The initial step in the process catalyzed by the synthetase is activation of the specified amino acid by reaction with ATP to form the aminoacyl adenylate. ATP undergoes a substitution reaction at its α-phosphorus to produce the 5′-adenosyl ester of the acyl phosphate of amino acid, an aminoacyl adenylate, along with inorganic pyrophosphate. The aminoacyl adenylates are enzymic reaction intermediates, reacting on the same enzyme with the appropriate tRNA to form an aminoacyl *t*RNA (1).



Aminoacyl adenylate

Aminoacyl adenylates are acyl phosphate monoesters and their reactions occur at the acyl phosphate functional site. The adenosine portion of the molecule adds chemical complexity and is a direct result of the enzymic reaction of ATP with the amino acid. Since the aminoacyl adenylates are intermediates in the enzymic reaction and do not accumulate, chemical characterization required their synthesis. The presence of the adenosyl group caused considerable difficulty and resulted in impure materials (3–6). However, the general properties and their validity as intermediates were established by these studies.

As mixed anhydrides of amino acids and phosphate esters, the materials are of interest for chemical study. They are acti-

Received August 8, 1996.

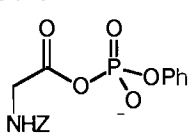
[1] This paper expands upon a portion of the Alfred Bader Award Lecture presented by Ronald Kluger at the Annual Conference of the Canadian Society for Chemistry in St. John's, Newfoundland, June 1996.

[2] Author to whom correspondence may be addressed. Telephone and Fax: (416) 978-3582. E-mail: rkluger@alchemy.chem.utoronto.ca

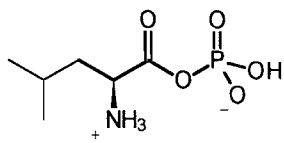
vated amino acids, presenting the possibility of aminoacylating various acceptors under conditions that are compatible with biochemical materials. However, the complexity arising from the adenosine portion has made their synthesis inefficient. While this group has many sites for binding to a protein, the inherent reactions it undergoes should be found in materials with less complex alkyl groups. Based on these considerations, we reasoned that simpler monoesters of aminoacyl phosphates might retain the potentially chemically useful properties of aminoacyl adenylates while avoiding the complexity that arises from the adenosyl group.

The reported syntheses of aminoacyl adenylates utilize the reaction of 5′-adenylic acid with acyl chlorides, mixed carboxylic anhydrides, or DCC-activated amino acids (4, 6, 7). Berg's pioneering synthesis used free amino acids (3), giving the product in very low yield. The use of *N*-protected amino acids gives improved yields (4, 6).

We found no reports of the isolation of simple aminoacyl alkyl phosphates. In an early study, Chantrenne proposed that *Z*-glycyl phenyl phosphate was present in the reaction of *Z*-glycyl chloride and disilver phenyl phosphate (8).

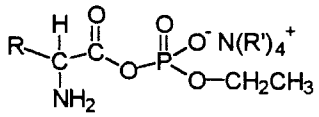


Katchalsky and Paecht (9) used an extension of Lynen's acyl phosphate synthesis (10) to make an aminoacyl aryl phosphate. They reacted the silver salt of *Z*-leucine with dibenzyl phosphorochloridate and removed the protecting groups with HBr. The resulting leucyl phosphate contained benzyl bromide that could not be removed without destroying the acyl phosphate.



Leucyl phosphate

Based on the reaction patterns of acyl phosphate esters (11, 12) and properties of amino protecting groups (13) we have now achieved a convenient synthesis of aminoacyl ethyl phosphates. We made a diverse group of examples and assessed their properties. The general structure is shown below. Variation occurs in the "R" group that defines the amino acid and the "R"' group of the tetralkylammonium ion.



Aminoacyl ethyl phosphate

Experimental section

Synthesis of aminoacyl ethyl phosphates

These were prepared as a variety of tetralkylammonium salts whose properties were assessed. The materials are in general hygroscopic and give inconsistent results in elemental analysis. However, they are readily analyzed by a combination of NMR (^{1}H, ^{31}P), mass spectrometry, and HPLC. NMR chemical shifts are reported relative to tetramethyl silane (^{1}H) and 85% phosphoric acid (^{31}P).

Bis(tetraalkylammonium) ethyl phosphates

Ethyl dichlorophosphate (5.9 mL, 50 mmol) was added (over 10 min) to 20 mL of water in an ice-cooled round-bottom flask and stirred for 1 h. The water was removed on a rotary evaporator. To the residue was added two equivalents of a tetraalkylammonium hydroxide solution. After titration to pH 7.0 with hydrochloric acid, the resulting solution was lyophilized to yield a white paste that was used for coupling reactions without further purification. ^{31}P NMR spectra indicated that only a single compound was present.

Bis(tetramethylammonium) ethyl phosphate: ^{1}H NMR (D_2O) δ: 3.70 (2H, m), 3.00 (24H, s), 1.04 (2H, t); ^{31}P NMR (D_2O) δ: 1.68. *Bis(tetraethylammonium) ethyl phosphate:* ^{1}H NMR (D_2O) δ: 3.74 (2H, m), 2.98 (16H, t), 1.07 (3H, t), 0.74 (24H, t); ^{31}P NMR (D_2O) δ: 1.68. *Bis(tetrapropylammonium) ethyl phosphate:* ^{1}H NMR (D_2O) δ: 3.74 (2H, m), 2.98 (16H, t), 1.55 (16H, m), 1.07 (3H, t), 0.74 (24H, t); ^{31}P NMR (D_2O) δ: 1.68. *Bis(tetrabutylammonium) ethyl phosphate:* ^{1}H NMR (D_2O) δ: 3.63 (2H, m), 2.97 (16H, t), 1.42 (16H, m), 1.13 (16H, m), 1.00 (3H, t), 0.72 (24H, t); ^{31}P NMR (D_2O) δ:1.68.

Synthesis of tetraethylammonium salts of *N*-protected aminoacyl ethyl phosphates

Dicyclohexylcarbodiimide (1.0 mmol) was added to a stirred solution of an *N*-protected amino acid (1.2 mmol) in dry dichloromethane (20 mL). The resulting solution (cloudy) was stirred for 5 min, then bis(tetraethylammonium) ethyl phosphate (1 mmol), dissolved in 5 mL of dichloromethane, was added. ^{31}P NMR was used to follow the reaction. Upon completion, the resulting white suspension was collected by filtration and washed with 10 mL dichloromethane. The clear dichloromethane solution was then washed twice with water and the aqueous phase was collected, frozen, and lyophilized overnight to give a white paste. The paste was dissolved in acetone (5 mL) and the mixture was passed through a silica Sep-pak cartridge to remove inorganic salts. The eluent was evaporated to give the *N*-protected aminoacyl ethyl phosphate as a glassy material. The following compounds were prepared from the reaction of an *N*-protected amino acid and bis(tetraethylammonium) ethyl phosphate. Each product gave a single peak in reverse phase HPLC analysis as well as appropriate NMR and mass spectral results. The first example contains full details.

Tetraethylammonium N-t-*Boc phenylalanyl ethyl phosphate*

To a stirred solution of *N*-(*tert*-butoxycarbonyl)-L-phenylalanine (318 mg, 1.2 mmol) in dry dichloromethane (20 mL) was added DCC (247 mg, 1.2 mmol). The resulting white cloudy solution was stirred for 5 min and tetraethylammonium ethyl phosphate (385 mg, 1.0 mmol) dissolved in 5 mL of dichloromethane was added. The reaction was stirred at room temperature for 1 h. After the reaction was complete, the resulting white suspension was filtered and washed with 10 mL of dichloromethane. The clear dichloromethane solution was then washed twice with water and the aqueous phase was collected. The aqueous solution was frozen and lyophilized over-

night to give a white solid. The solid was dissolved in 5 mL of acetone and the mixture was passed through a silica Sep-pak cartridge to remove inorganic salts. The eluent was evaporated to give *N-t*-Boc phenylalanyl ethyl phosphate as a glassy material (453 mg, 87%). ^{1}H NMR ($CDCl_3$) δ: 7.23 (5H, m), 5.03 (1H, d), 4.56 (1H, m), 4.03 (2H, m), 3.37 (8H, q), 3.20 (2H, m), 1.38 (9H, s), 1.30 (12H, t), 1.24 (3H, t); ^{31}P NMR ($CDCl_3$) δ: −6.8; FAB mass spectrum (–, glycerol): 125 (100, $EtHPO_4^-$), 372 (51.4, M). Other derivatives were made by the same general procedure.

Tetraethylammonium N-t-*Boc alanyl ethyl phosphate:* (73% yield) ^{1}H NMR ($CDCl_3$) δ: 5.17 (1H, d), 4.24 (1H, m), 4.00 (2H, m), 3.38 (8H, q), 1.40 (9H, s), 1.36 (3H, d), 1.32 (12H, t), 1.22 (3H, t); ^{31}P NMR ($CDCl_3$) δ: −6.8; FAB mass spectrum (–, glycerol): 296 (100, M).

Tetraethylammonium N-t-*Boc*-O-*Bn serinyl ethyl phosphate:* (58% yield) ^{1}H NMR ($CDCl_3$) δ: 7.30 (5H, m), 5.42 (1H, d), 4.52 (2H, s), 4.42 (1H, m), 3.98 (2H, m), 3.80 (2H, m), 3.35 (8H, q), 1.41 (9H, s), 1.28 (12H, t), 1.18 (3H, t); ^{31}P NMR ($CDCl_3$) δ: −7.1; FAB MS (–, glycerol): 402 (95.5, M).

Tetraethylammonium N-t-*Boc*-S-B*n cysteinyl ethyl phosphate:* (76% yield) ^{1}H NMR ($CDCl_3$) δ: 7.28 (5H, m), 5.40 (1H, d), 4.52 (1H, m), 4.02 (2H, m), 3.78 (2H, s), 3.38 (8H, q), 2.93 (2H, m), 1.42 (9H, s), 1.30 (12H, t), 1.25 (3H, t); ^{31}P NMR ($CDCl_3$) δ: −6.9; FAB mass spectrum (–, glycerol): 418 (100, M).

Tetraethylammonium N-t-*Boc valyl ethyl phosphate:* (72% yield) ^{1}H NMR ($CDCl_3$) δ: 5.14 (1H, d), 4.17 (1H, m), 4.00 (2H, m), 3.38 (8H, q), 2.18 (1H, m), 1.40 (9H, s), 1.32 (12H, t), 1.22 (3H, t), 0.91 (6H, dd); ^{31}P NMR ($CDCl_3$) δ: −7.7; FAB mass spectrum (–, glycerol): 324 (100, M).

Tetraethylammonium N-t-*Boc tryptophanyl ethyl phosphate:* (85% yield) ^{1}H NMR ($CDCl_3$) δ: 6.90–7.60 (6H, m), 5.01 (1H, d), 4.62 (1H, m), 4.08 (2H, m), 3.36 (2H, m), 3.05 (8H, q), 1.39 (9H, s), 1.29 (3H, t), 1.10 (12H, t); ^{31}P NMR ($CDCl_3$) δ: −7.7; FAB mass spectrum (–, glycerol): 411 (100, M).

Hydrolysis

The rate of hydrolysis of *N-t*-Boc phenylalanyl ethyl phosphate was measured using ^{31}P NMR. *N-t*-Boc phenylalanyl ethyl phosphate (0.04 M) was incubated in 1 mL of 0.5 M 3-(*N*-morpholino])propanesulfonate (MOPS) pH 7.0, at 25.0°C. The hydrolysis was followed by integrating signals for the aminoacyl phosphate ester (δ −6.6 ppm) and the product, ethyl phosphate (δ 2.8 ppm). The hydrolysis was monitored to 90% completion.

General procedure for the deprotection of *N-t*-Boc protected aminoacyl phosphates

The *N-t*-Boc protected aminoacyl alkyl phosphate was dissolved in a minimum amount of trifluoroacetic acid (TFA). After the dissipation of gases, the TFA was removed by rotary evaporation (30°C) and vacuum pumping. The resulting oil was dissolved in acetone or diethyl ether. The resulting precipitate was then collected by vacuum filtration and washed several times with acetone or diethyl ether. After air drying for 10 min aminoacyl alkyl phosphate was isolated.

[b]Determined from ^{31}P NMR spectra of an aqueous extract of the reaction mixture.

Detection of racemization

The retention of chiral integrity in the aminoacyl phosphate during the coupling reaction was determined by first removing the protecting group and then hydrolyzing the resulting aminoacyl phosphate. The resulting amino acid was treated with Mosher's acid chloride (14). The ^{19}F and ^{1}H NMR spectra of the amides were compared with pure standards.

Results

The preparation of aminoacyl ethyl phosphates is readily accomplished by coupling an amino-protected amino acid with a salt of ethyl phosphate, followed by removal of the protecting group. The removal is done under conditions that do not affect the acyl phosphate. Both natural L α-amino acids and "unnatural" amino acids were converted. Since acyl phosphates are unstable in base, the protecting group should be selected to permit removal in acidic solutions, principally carbobenzyloxy (Cbz) and the more readily removed *tert*-butyloxycarbonyl (*t*-Boc). Thus, we chose *t*-Boc as the protecting group for our studies.

The activation of the amino acid for formation of the acyl phosphate is best accomplished under conditions that do not lead to racemization. Reaction with *N,N'*-dicyclohexylcarbodiimide (DCC) fulfills these requirements (13). This dehydrating–coupling reagent functions most efficiently in organic solvents such as dichloromethane (15). Since phosphate salts are not normally soluble in dichloromethane, we utilized tetraalkylammonium salts of phosphates (16, 17). These dissolve in organic solvents and the phosphate oxygens are highly nucleophilic. (Scheme 1).

Results from the reaction of *N-t*-Boc-phenylalanine and various bis(tetraalkylammonium) ethyl phosphates are shown in Table 1. Except for the case of bis(tetramethylammonium) ethyl phosphate, all coupling reactions went to completion in 1 h. The reaction with bis(tetramethylammonium) phosphate gave the product in 55% yield in 3 h due to its poor solubility in dichloromethane.

The solubility of these aminoacyl phosphates depends critically upon the nature of their counterions. A longer alkyl chain increases solubility in nonpolar solvents while a shorter chain improves aqueous solubility. The effect of the nature of alkyammonium is useful for the separation and purification of the product. For bis(tetrabutylammonium) ethyl phosphate salts, the product is isolated from the organic phase while unreacted starting material is removed by an aqueous wash. *N,N'*-Dicyclohexylurea (DCU) is the by-product from DCC. For products isolated in an organic phase, most of the DCU is removed by precipitation in acetonitrile, but the product inevitably contains some DCU. Further purification of the *N*-protected aminoacyl phosphate was attempted by silica and ion exchange chromatography. However, both treatments led to some hydrolysis.

The product from the reaction of an amino acid and bis (tetrapropylammonium) ethyl phosphate partitions into both water and dichloromethane. This also gives mixtures that are difficult to purify. With tetramethylammonium or tetraethylammonium ethyl phosphates, the resulting aminoacyl phosphate is preferentially soluble in water. Therefore, a slight excess of amino acid can be used to ensure the complete conversion of the phosphate. The product is collected in the aqueous layer and isolated by freeze-drying. In this case, after removal of inorganic salts, the protected aminoacyl phosphate is obtained without contamination by DCU.

The tetraethylammonium salts of a diverse group of amino acids were efficiently converted to the corresponding tetraethylammonium salt of aminoacyl phosphates by this method (Table 2). As a test of the generality of the method, different *N*-protection groups were used, including *tert*-butyloxycarbonyl (*t*-Boc), carbobenzyloxy (Cbz), 9-fluorenylmethoxycarbonyl (Fmoc), and *N-o*-nitrophenyl sulfenyl (Nps). Completion of the reaction was checked by ^{31}P NMR of the reaction mixture. The coupling reaction was complete in 1–12 h, giving aminoacyl phosphates in 58–88% isolated yields. The *N*-Fmoc aminoacyl phosphates could not be isolated in the same way, presumably due to the hydrophobic nature of Fmoc group. We have developed alternative methods for the preparation of *N*-Fmoc aminoacyl phosphate esters (unpublished work of Z. Huang and N. Branda). However, since the protecting group is designed for removal in base, conditions

Table 2. Aminoacyl phosphates synthesized from *N*-protected amino acids and bis(tetraethylammonium) ethyl phosphate.

[b]Product not isolated, estimate from ^{31}P NMR.

that also cleave acyl phosphate, we did not generalize the development of this class.

The aminoacyl ethyl phosphates have appropriate ^1H, ^{13}C, and ^{31}P NMR spectra as well as mass spectra for the parent peak (FAB (−) with glycerol). Although carboxyl-activated amino acids are prone to racemization, we observed that the aminoacyl ethyl phosphates retain their stereochemical integrity using NMR analysis of diastereomeric amides derived from Mosher's acid (14). This is consistent with the optical activity we observe.

Stability toward hydrolysis

The utility of *N*-protected aminoacyl ethyl phosphates depends on reactions with nucleophiles proceeding more rapidly than reactions with water. *N*-*t*-Boc-phenylalanyl ethyl phosphate (0.04 M) was incubated in 1 mL of 0.5 M MOPS, pH 7.0, at 25 0°C. The reaction was followed by integrating signals for the disappearance of the starting material and the formation of ethyl phosphate in the ^{31}P NMR. The hydrolysis is slow with an observed first-order rate constant of 2×10^{-6} s^{-1}, corresponding to a half-life of about 100 h.

Removal of the *N*-*t*-Boc group from *N*-*t*-Boc-aminoacyl ethyl phosphates is readily achieved with trifluoroacetic acid under conditions that do not cleave the acyl phosphate. The resulting aminoacyl ethyl phosphate is sufficiently resistant to hydrolysis to be useful for reaction with the amino group of a free amino acid or the *N*-terminus of a growing peptide chain. The hydrolysis of phenylalanyl ethyl phosphate follows first-order kinetics, $k_{obsd} = 1.9 \times 10^{-6}$ s^{-1}. The half-life is over 100 h, indicating that these reagents do not hydrolyze rapidly in neutral solution, even if the protecting group is removed.

Acylation reactions

The biosynthesis of proteins involves the formation of the 3′-terminus ester of *t*RNA and the approproiate amino acid. Direct reaction of aminoacyl ethyl phosphate and *t*RNA in the absence of an enzyme requires that alcohols react readily with aminoacyl ethyl phosphates. Combination of isopropanol, a model for the secondary alcohol in *t*RNA, and aminoacyl ethyl phosphates gave no reaction. In fact, isopropanol is a good solvent for other reactions. Extended reaction in methanol produces the amino acid methyl ester.

We are in the process of developing catalytic systems that will enhance the reaction of alcohols with aminoacyl ethyl phosphates. We have found that divalent metal ions promote the reaction (18). In another study we found that amino-alcohols, such as triethanolamine, react at their hydroxyl centre with monoesters of acyl phosphates (19). This information may provide the basis for the development of a route to aminoacylation of RNA. We have assessed the utility of aminoacyl ethyl phosphates as activated aminoacids for the chemical synthesis of peptides in water (19). The reaction occurs efficiently and will be reported in detail in a separate paper. Preliminary studies also indicate that the reagents can serve as site-directed inactivators of enzymes that promote reactions of amino acids (Y. Song, unpublished). Such inactivation is consistent with the report that aminoacyl adenylates react with lysines in enzymes (20).

Conclusions

N-*t*-Boc-protected aminoacyl ethyl phosphates are readily prepared as their tetralkylammonium salts by DCC-mediated coupling. The reaction efficiency depends on the choice of solvent in relation to the alkyl group of the tetralkylammonium ion. Deprotection is readily achieved with trifluoroacetic acid, conditions that leave the acyl phosphate intact. The convenient preparation, hydrolytic stability, and retention of chiral integrity make these aminoacyl ethyl phosphates a new class of activated amino acids that function in aqueous solution.

Dihydrofurans from α-diazoketones due to facile ring opening – cyclization of donor–acceptor cyclopropane intermediates

Elizabeth A. Lund, Isaac A. Kennedy, and Alex G. Fallis

Abstract: A series of α-diazoketones, **8**, **25**, **28**, **31**, and **34**, have been synthesized and their reaction with ethyl vinyl ether examined under various reaction conditions. In the presence of metal salts ($Rh_2(OAc)_4$, $Pd(OAc)_2$, CuCl) the ethoxydihydrofurans **12**, **37**, **39**, **41**, and **43** are produced. Sensitized irradiation of the α-diazoketone **8** afforded the dihydrofuran **12** plus cyclobutanone **7**, while direct photolysis of α-diazoketones **8**, **25**, **28**, **31**, and **34** gave the cyclobutanones **7**, **38**, **40**, **42**, and **44**, respectively. A sample of the cyclopropylketone **45** was isolated from the rhodium(II) acetate mediated reaction of **34** and its facile rearrangement to dihydrofuran **43** demonstrated. Collectively, these results indicate that the initial product from the reaction of an α-diazoketone with an electron-rich alkene such as ethyl vinyl ether is a cyclopropylketone. The donnor–acceptor substitution pattern of this intermediate results in spontaneous rearrangement to a dihydrofuran. Thus a direct dipolar cycloaddition mechanism is not involved when α-diazoketones react with enol ethers under metal-mediated conditions. Instead, these reactions follow a cyclopropanation rearrangement or, more accurately, cyclopropanation – ring opening – cyclization pathway.

Key words: diazoketone, rhodium acetate, dihydrofuran, cyclopropylketone, vinyl ether.

Résumé : On a synthétisé une série d'α-diazocétones **8**, **25**, **28**, **31** et **34** et on a étudié, dans différentes conditions, leur réaction avec l'éther éthylvinylique. En présence de sels métalliques ($RH_2(OAc)_4$, $Pd(OAC)_2$, CuCl) on obtient les éthoxydihydrofurannes **12**, **37**, **39**, **41** et **43**. L'irradiation sensibilisée de l'α-diazocétones **8** produit le dihydrofuranne **12** et la cyclobutanone **7**, tandis que la photolyse directe des α-diazocétones **8**, **25**, **28**, **31** et **34** donne les cyclobutanones **7**, **38**, **40**, **42** et **44** respectivement. On a isolé un échantillon de cyclopropylcétone **45** de la réaction du composé **34** en présence de l'acétate de rhodium et on démontre sa transposition facile en dihydrofuranne **43**. Collectivement, ces résultats indiquent que le produit initial de la réaction d'une α-diazocétone avec un alcène riche en électrons tel l'éther éthylvinylique est une cyclopropylcétone. Le modèle de substitution donneur–accepteur de cet intermédiaire provient d'une transposition spontanée en dihydrofuranne. Ainsi un mécanisme de cycloaddition dipolaire directe n'est pas impliqué lorsque une α-diazocétone réagit avec des éthers énoliques en présence d'un métal. Au lieu de cela ces réactions suivent une transposition cyclopropanique ou plus précisément un processus de cyclopropanation, d'ouverture du cycle du cyclopropane et de cyclisation.

Mots clés : diazocétone, acétate de rhodium, dihydrofuranne, cyclopropylcétone, éther vinylique.

Introduction

Motivated by our interest in the total synthesis of the potent anti-tumor agent paclitaxel (Taxol®) (1) we initially envisaged a strategy that depended upon the successful application of an α-cyclopropyl radical ring opening – conjugate addition sequence (**1**–**3**, Scheme 1) for the construction of the congested tricyclo[9.3.1.$0^{3,8}$]pentadecene nucleus. This ring opening should install both the bridgehead double bond at C_{11}—C_{12} and generate a radical center in a relatively flat precursor suitably disposed to add in an 8-*endo* fashion to a ring C enone (2). We therefore required precursors that would give rise to a radical intermediate of type **A** (Scheme 2) in order to examine this strategy.

Initial results

A variety of standard Simmons–Smith based methods for cyclopropanation of appropriately substituted olefins to generate systems related to **A** were unsuccessful. Thus a different approach was investigated. The α-diazoketone **8** was synthesized from the cyclohexenone **4** (1*d*) as follows. Conjugate addition of lithium dimethylcuprate generated the enolate, which reacted in situ with ethyl formate to provide the ketone **5**. Diazo transfer was effected with tosylazide and triethylamine followed by treatment with potassium hydroxide to generate the α-diazoketone **8**. It was anticipated that treatment of this material with rhodium(II) acetate in the presence of ethyl vinyl ether would afford the requisite spiro cyclopropyl system **9**. However, treatment of **8** with $Rh_2(OAc)_4$ (2 mol %, 21°C) in the presence of excess ethyl vinyl ether afforded neither the expected cyclopropylcyclohexanone **9** nor the cyclobutanone **7** that would have arisen from Wolff rearrangement of **8** to the ketene **10** followed by conventional [2+2] cycloaddition. Instead, a new compound was isolated, whose spectra

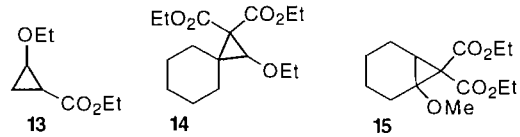
suggested the presence of two tertiary vinyl carbons (^{13}C NMR δ 102.4, 148.3 ppm) and an acetal carbon (δ 104.6 ppm) with an attached proton (^1H NMR δ 5.45 ppm). These features were consistent with both the oxetane structure **11** and the dihydrofuran system **12**. The oxetane could arise from the formal [2+2] addition of ethyl vinyl ether to the carbonyl group of the ketene **10**, while the dihydrofuran **12** could have been formed directly from a dipolar cycloaddition to ethyl vinyl ether or alternatively could have arisen from a ring opening – rearrangement – ring closure of the intermediate cyclopropyl ketone **9**. In spite of the visual difference between these two ring systems, various NMR experiments were inconclusive.

In addition, standard acid hydrolysis and oxidative cleavage

Scheme 3. Carbonyl-ether substituted cyclopropanes.



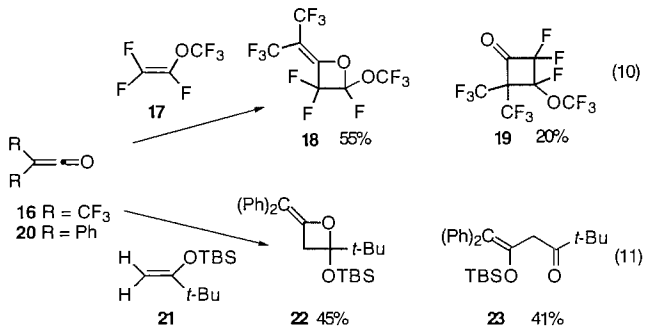
reactions (ozone, RuO_4) gave mixtures that did not permit a definitive structural assignment with only one compound available. As described below, the structures of **12** and related dihydrofurans were ultimately established by acid-catalyzed hydrolysis and in situ trapping to form a new keto-acetal. However, based on additional studies with related α-diazoketone systems, it is now clear that with electron-rich olefins such as ethyl vinyl ether, cyclopropylketones are formed initially but do not survive the standard reaction work-up at room temperature (21°C), and rapidly rearrange to dihydrofurans related to **12**. Thus, in contrast to literature examples that invoke dipolar cycloaddition mechanisms to rationalize dihydrofuran formation, with cyclopropanes containing both electron-donating and -withdrawing substituents the normal mechanism involves cyclopropanation followed by rearrangement (ring opening – cyclization) to afford the cyclic ethers (3).

Background

Donor–acceptor (push–pull) cyclopropanes have received considerable attention (4). Generally cyclopropanes with a single electron-donating and an electron-withdrawing group (e.g., 1-ethoxy-2-carboethoxycyclopropane, **13**) are stable at room temperature and require more forcing conditions for rearrangement to a dihydrofuran acetal, although cyclopropyl β-amino acids ring open readily, indicating the donating ability of the donor is a key feature (Scheme 3). Thus, for oxygen-substituted systems direct rearrangement usually requires either two donor or two acceptor groups. The ease with which the initial cyclopropane undergoes a 1,3-sigmatropic shift is therefore both substituent and substrate dependent (4). For example, the spirosystem **14** may be isolated, but the related cyclopropane **15** was not detected when dimethyl diazomalonate reacted in the presence of copper with 1-methoxycyclohexene (5). Other methoxy cyclopropanes also rearranged more readily than the corresponding ethoxy-substituted derivatives (6). However, the reaction conditions markedly influence the course of diazocarbonyl rearrangements, particularly solvent polarity (pentane versus CH_2Cl_2) (7) and the catalyst ($Rh_2(OAc)_4$ versus $Rh_2(OPiv)_4$) (8). Cyclopropanes were the presumed intermediates generated from cyclic β-diazodiketones in the presence of furans and rhodium carboxylate salts (9).

Discrete ketene carbonyl cycloadditions are rare and have received limited attention. The two previously reported cases involved strong electron-withdrawing groups in the ketene. One case involved the reaction of bis(trifluoromethyl)ketene (**16**) with vinyl ether **17** to give a mixture of the oxetane **18** and the expected [2+2] cycloaddition product **19** (Scheme 4) (10). A related example employed the sterically hindered silyl enol ether of *tert*-butyl methyl ketone (**21**) with diphenylketene (**20**) to provide the oxetane **22** and the ketone **23** from ring opening of the initial cyclobutanone adduct followed by silyl

Scheme 4. Ketene carbonyl cycloadditions.



migration (11). In addition, ab initio molecular orbital calculations have demonstrated that alkene addition to the ketene carbonyl is usually energetically disfavoured relative to cyclobutanone formation (12).

Results

Is the dihydrofuran structure **12** correct, or do the methyl groups in the ketene **10**, derived from Wolff rearrangement of **8**, provide sufficient steric hindrance to alter the normal [2+2] cycloaddition reaction to give the oxetane **11** rather than the cyclobutanone **7**?

To learn more about the reactivity of the α-diazoketone **8**, other metal salts ($Pd(OAc)_2$, CuCl) were examined as well as its photolytic behaviour. In addition, other diazo ketones **25**, **28**, **31**, and **34** with various substitution patterns were synthesized (Scheme 5) and subjected to a parallel set of conditions. The initial enolate, derived from the conjugate addition of lithium dimethylcuprate to **4**, underwent rapid proton transfer to the sterically less hindered enolate when allowed to warm to 21°C, so that condensation with ethyl formate afforded the keto-aldehyde **24** directly. Diazo transfer as above generated the α-diazoketone **25**. Parallel reactions afforded **28** from **26**, while **31** was synthesized by treatment of acyl chloride **30** with diazomethane. The diphenyl system **34** (azibenzil, 2-diazo-1,2-diphenyl-1-ethanone) was prepared by silver oxide oxidation of **33** (13).

The results of the catalytic reactions and the irradiation experiments are summarized in Table 1. In the case of **8**, the major product from the metal-catalyzed reaction with ethyl vinyl ether was the dihydrofuran **12**, although the yield varied with the catalyst selected. Thus the reactions with $Pd(OAc)_2$ or CuCl afforded **12** in isolated yields of 72% and 30%, respectively. However, when standard alkenes, rather than electron-rich olefins, were used, the dihydrofuran products were not observed. Instead, cyclopropylketone **35** was isolated in 25% yield in the rhodium(II) acetate catalyzed reaction with 2,5-dihydrofuran in place of ethyl vinyl ether (Scheme 6). In a similar manner, addition to cyclohexene afforded **36** (25%). Clearly the methyl groups are not a major factor as the other α-diazoketones listed in Table 1 also afforded acetal products. In all cases direct irradiation generated the [2+2] cycloaddition products illustrated, which arise from Wolff rearrangement to the ketene followed by conventional cycloaddition.

The dihydrofuran-acetal structures observed above in the metal-catalyzed reactions of the various α-diazoketones

require additional experimental data to establish their structures unambiguously. To ascertain the decomposition pathways of these systems, the model system azibenzil (**34**) was examined in detail, particularly its behaviour with ethyl vinyl ether and rhodium(II) acetate. Direct pathways to the dihydrofuran **43** or the oxetane **48** from the α-diazoketone **34** (Scheme 7) are feasible after initial reaction of the carbenoid intermediate. Both of these products may arise from zwitterionic intermediates such as **46** or **47** that possess both enolate and oxacarbenium ion character. Surprisingly, the acetal product from the reaction could not be established from its spectral data. High-resolution mass spectroscopy confirmed the molecular formula ($C_{18}H_{18}O_2$). Both structures contain an equal number of CH, CH_2, CH_3, and quaternary carbons plus one methine attached directly to two ether oxygens, two methylene groups, and the methyl group of an ethoxy substituent. Unfortunately two-dimensional ^1H–^1H COSY, ^1H–^1H ROESY, and ^1H–^{13}C HETCOR experiments were inconclusive. A ^{13}C–^{13}C coupling INADEQUATE experiment should have allowed differentiation of the two different olefin substitution patterns, but the olefin carbon atoms had long relaxation

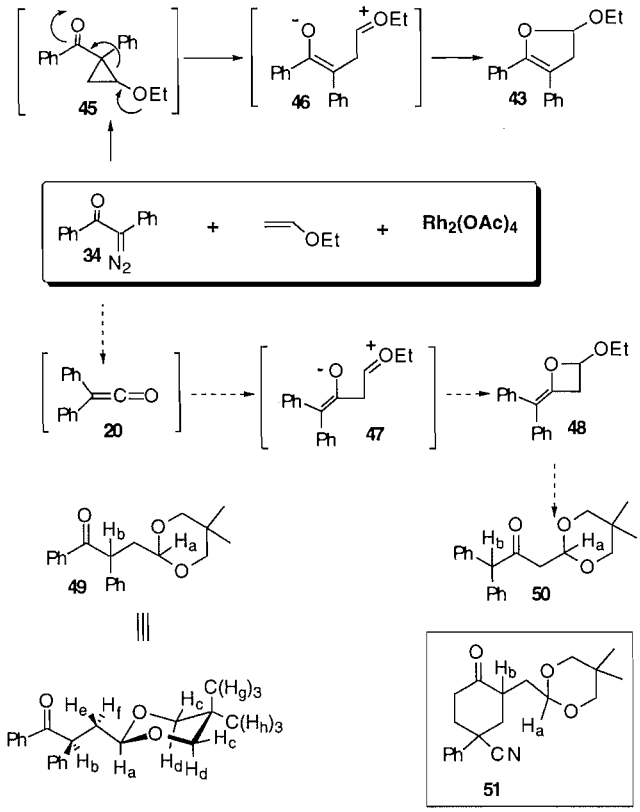
times (approximately 10 s), making it impossible to resolve the structural differences.

To establish the structure unambiguously the acetal product was subjected to acid-catalyzed hydrolysis with in situ trapping of the resulting keto-aldehyde with 2,2-dimethyl-1,3-propanediol. These experiments confirmed the upper pathway was followed (Scheme 7), since treatment of the presumed acetal **43** with *p*-toluenesulfonic acid in the presence of 3,3-dimethyl-1,3-propanediol afforded ketone **49** (68% yield), which could be distinguished from **50** by its ^1H NMR spectrum. The spectrum exhibited a characteristic one-proton doublet of doublets at δ 4.91 ppm (J = 7.8, 7.0 Hz) that was assigned to the acetal proton H_a coupled with each of the diastereotopic methylene protons. A second one-proton doublet of doublets at δ 4.31 ppm (J = 4.9, 5.6 Hz) was assigned to the methine proton H_b adjacent to the carbonyl group. The splitting pattern seen with this signal also arises from independent couplings with each of the diastereotopic methylene protons H_e and H_f. This type of coupling is only possible in structure **49**. Proton H_b in structure **50** has no adjacent carbons bearing protons and would therefore be expected to appear as a singlet in the ^1H NMR spectrum. In a similar manner the dihydrofuran **39** derived from diazoketone **28** afforded the keto-acetal **51** and thus established that the dihydrofurans are the final products of these α-diazoketones upon treatment with various metal catalysts in the presence of ethyl vinyl ether.

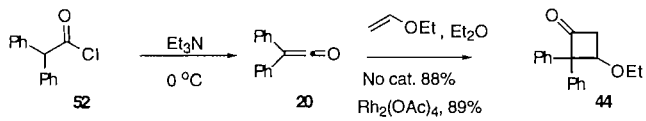
Diphenyl ketene, the putative Wolff rearrangement product from azibenzil (**34**) is relatively stable. It was synthesized independently to determine its reactivity with ethyl vinyl ether and its behaviour in the presence of rhodium(II) acetate and to establish with certainty that neither dihydrofuran **43** nor oxetane **48** were formed from the ketene. Diphenylketene (**20**) was prepared from acid chloride **52** upon treatment with triethylamine (Scheme 8) (14). For the thermal reaction a solution of diphenyl ketene (**20**) and ethyl vinyl ether in freshly distilled ether was stirred overnight under argon. Cyclobutanone **44** was obtained in 88% yield (IR, 1779 cm^{-1}). A metal-ketene intermediate, if formed, does not appear to alter the course of the reaction, as only the cyclobutanone **44** was isolated (89%) in the presence of $Rh_2(OAc)_4$.

The use of benzophenone as a triplet sensitizer during the photolysis of α-diazoketones is known to promote cyclopropane formation (15), although a large excess of sensitizer is required (16). It was anticipated that these conditions would allow detection of the cyclopropane. However, benzophenone (10 equiv.) sensitized photolysis of **8** failed to provide the cyclopropane **9**. A mixture of cyclobutanone **7** (30%) and dihydrofuran **12** (25%) was formed instead (Table 1). This

Scheme 7. Rearrangement pathways for α-diazoketone **34**.



Scheme 8. Diphenylketene cycloadditions.



result was unexpected since Wolff rearrangement is considered to arise only from the singlet carbene (16, 17). Upon direct irradiation, no acetal products could be detected and clean conversion to the cyclobutanone **7** from [2+2] cycloaddition to the ketene double bond was observed. As mentioned above, this same pattern was observed with the other α-diazoketones **25**, **28**, **31**, and **34** to give **38**, **40**, **42**, and **44**, respectively. Decomposition of **8** under various conditions that are known to promote cyclopropanation ($Rh_2(OAc)_4$, pentane/ethyl vinyl ether, 30:1, 0°C; $Rh_2(OPiv)_4$, pentane/ethyl vinyl ether, 30:1, 0°C) (7, 8) also afforded **12** as the major product. A similar result was obtained with $Rh_2(OAc)_4$ in ethyl vinyl ether at −78°C, although immediate GC–MS analysis indicated the presence of a minor component (~10%) consistent with cyclopropylketone **9.**

A final attempt was made to prepare a sample related to **9**, the methoxy cyclopropane **B**, by addition of dimethyloxosulfonium methylide (18) to the enol ether ketone **6**. It was anticipated that conjugate addition would occur in accord with literature precedent (18, 19) to generate the methoxy cyclopropanone **B**. However, the product was a new methoxydihydrofuran system that differed from the dihydrofuran **12** by more than the substitution pattern. The ^1H NMR signal at δ 5.55 and

Table 2. NMR data for dihydrofurans.

Compound	δ H5 (ppm)	δ C2 (ppm)	δ C3 (ppm)
 43	5.62 (dd, J = 7.2, 2.6 Hz)	148.2	102.6
 12	5.45 (m)	148.3	102.4
 37	5.45 (m)	147.3	102.4
 59	5.55	148.2	113.2

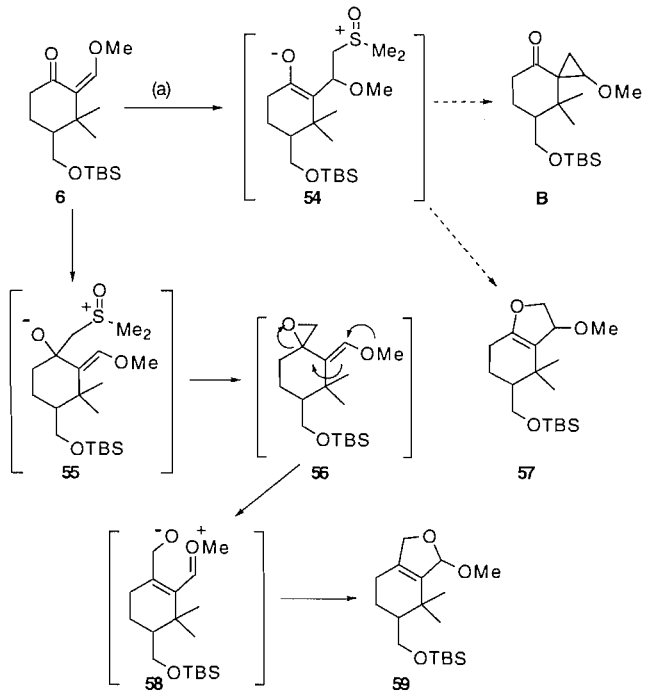
the olefinic carbon signals at δ 113.2 and 148.0 did not fit the chemical shift pattern observed for the other isomers, as tabulated in Table 2. In addition, it was not the product **57** from closure of the oxygen anion on the sulfinyl bearing carbon. In contrast to literature examples, the ylide adds preferentially to the carbonyl group, possibly as a consequence of the steric interference of the geminal dimethyl groups. Closure of **55** should afford the epoxide **56**, but this material was not detected. Instead it opens in a similar manner to the cyclopropanes to generate a dipolar zwitterionic species **58**, which collapses to give the observed product **59** (Scheme 9).

Discussion

The experiments above have established that the major product isolated from the reaction of structurally diverse α-diazoketones in the presence of rhodium(II) acetate and related catalysts with an electron-rich olefin such as ethyl vinyl ether is a dihydrofuran. There are two possible mechanisms for this process. The dihydrofuran may arise from a concerted or stepwise dipolar cycloaddition to the enol ether or, alternatively, the ethoxy-substituted cyclopropylketone is a true intermediate that undergoes rapid fragmentation and subsequent ring closure to the dihydrofuran.

Doyle et al. (20) have examined cyclopropanations with ethyl diazoacetate. The regio- and stereochemical control in catalytic cyclopropanation reactions is derived from the transition metal, its associated ligands, the diazo compound, and the olefin. The influence of the olefin is the weakest, while the electronic influence of the transition metal provides the dominant regio- and stereochemical control. Studies with chiral catalysts confirmed (21–24) that the transition metal is directly involved in the product-forming step. The more stable *trans* cyclopropanes usually predominate and the stereoselec-

Scheme 9. Attempted synthesis of cyclopropylketone **B**.

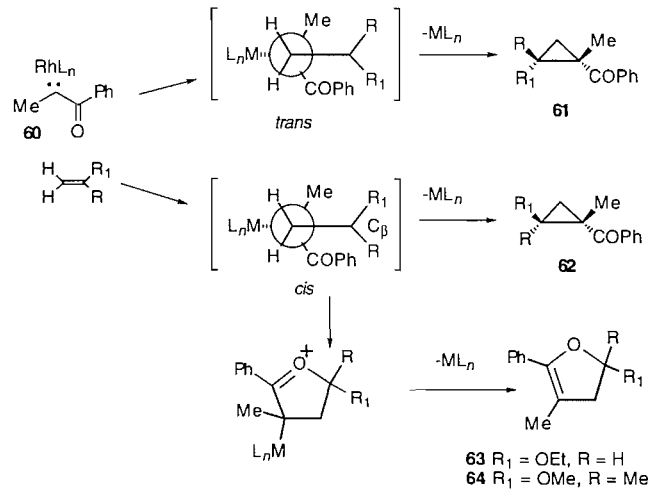


(a) Me_2SOCH_3I, NaH, DMF, 21 °C, 2h, 40%

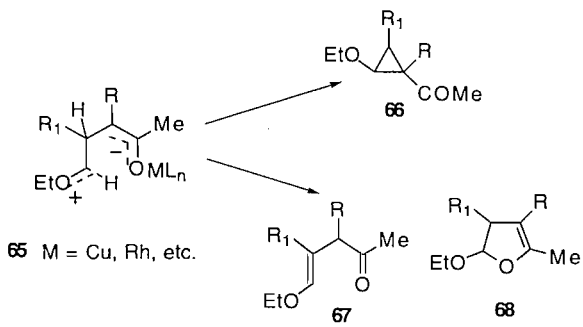
tivities are not altered by the catalyst concentration, the rate of addition of the diazo compound, or the molar ratio of olefin to diazo compound. The cyclopropanation process was proposed by Doyle et al. (6, 20, 25) to occur through an initial interaction between the olefinic π bond and the electrophilic centre of the metal carbenoid, followed by σ-bond formation with backside displacement of the catalyst (Scheme 10). As the reaction proceeds the π-complexed olefin may rotate around the electrophilic centre to place the C—C bond of the olefin parallel to the metal–carbon bond. Thus the substituted carbon of the olefin is oriented *anti* to the metal. Two transition states, *trans* and *cis*, are possible in which the energy difference due to the interactions between R/R_1 and COPh determines the predominant isomer **61** or **62**. A study by Noels, Hubert, and co-workers supports the existence of a free carbene–carbenoid equilibrium (26).

The product distribution is influenced by an increase in the nucleophilicity of the carbonyl oxygen and (or) the electrophilicity of the β-carbon in the metaloid complex. This favours the dihydrofuran products as a consequence of the increased stabilization provided by both the carbonyl group and the developing electrophilic centre on the vinyl ether (Scheme 10). Due to the absence of an ether oxygen this stabilization is less with a standard olefin. This influence is usually only observed with α-diazoketones, as α-diazoesters are less nucleophilic. Dihydrofurans have also been obtained from copper-catalyzed reactions of diazomalonates and related diazoketones with various vinyl ethers (27, 28). These subtle effects are illustrated by the finding that dihydrofuran **63** (9%) was the minor product (cyclopropane 83%) in the $Rh_2(OAc)_4$ catalyzed reaction of α-diazopropiophenone (**60**) with ethyl vinyl ether, but **64** was the major product (40%) with 2-methoxypropene (6).

Scheme 10. Possible combined cyclopropanation–dihydrofuran mechanism.



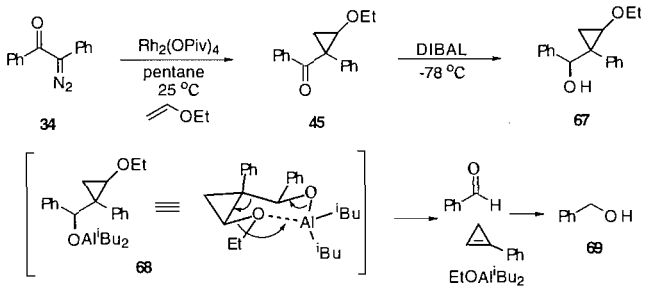
Scheme 11. Possible dipolar mechanism for dihydrofuran formation.



Alonso et al. (27) suggested a direct dipolar mechanism to explain the formation of dihydrofuran and acyclic products from various cyclopropanation reactions (Scheme 11) (27, 29). The dipolar intermediate **65** was proposed as the precursor to both the acyclic **67** and dihydrofuran **68** products. In this case, 1,3 ring closure to **66** is disfavoured with respect to the 1,5 ring closure. The stabilization of the dipolar intermediate is consistent with Doyle's mechanism where an increase in the nucleophilicity of the enolate oxygen increases the ease of 1,5-cyclization compared to 1,3-cyclization (6).

Variation of the catalyst ligands and solvent polarity has a significant effect on the outcome of rhodium(II) carboxylate catalyzed cyclopropanation reactions (7, 8, 30). Padwa, Doyle, and co-workers have established that the products that may arise from a dipolar mechanism are inhibited in pentane relative to dichloromethane (30). Competition experiments between cyclopropanation and bond insertion (tertiary C—H) provided a 44:56 product ratio with $Rh_2(OAc)_4$. More electrophilic metal carbenoids (perfluoroborate ligands) resulted in hydrogen insertion exclusively. In contrast, only cyclopropanation products were obtained with the less electrophilic rhodium(II) caprolactamate catalyst, which suppresses the carbene insertion into the C—H bond. Cyclopropanation is enhanced relative to dihydrofuran formation with rhodium(II) pivalate as catalyst (31, 32). Thus azibenzil (**34**) and ethyl vinyl ether

Scheme 12. Reduction of cyclopropylketone **45**.



were treated with $Rh_2(OAc)_4$ in ether and pentane in separate experiments to provide the dihydrofuran **43** in yields of 97% and 91%. However, unexpectedly, the use of rhodium pivalate also gave the same product **43** (93%) in each case.

Dowd et al. (33) found that $Rh_2(OAc)_4$ catalyzed reactions of ketene acetals with methyl diazoacetate yielded unstable cyclopropyl esters that were reacted in situ with lithium aluminum hydride, albeit in low yield. They concluded that with diazoacetone the cyclopropylketone was too reactive to be isolated and probably rearranged through a dipolar intermediate to yield a small amount of a dihydrofuran product.

It is standard practice to purify reaction products prior to spectroscopy by filtration and chromatography. To discern the influence of the work-up conditions on the presumed cyclopropylketone intermediates the following experiments were conducted. Reactions with **34** were conducted separately with $Rh_2(OAc)_4$–ether and $Rh_2(OPiv)_4$–pentane, excess solvent was evaporated under a stream of argon, and the crude material was dissolved in $CDCl_3$ (which had been passed through basic alumina immediately prior to use). The ^1H NMR spectrum of this material displayed the characteristic cyclopropane signals expected at δ 0.6–0.9 ppm and a ^{13}C NMR signal at δ 194.5 ppm. In addition, an IR absorption at 1675 cm^{-1} was consistent with the cyclopropyl ketone **45**. Storage at −15°C (24 h) or further purification resulted in complete conversion to dihydrofuran **43**. A further attempt was made to detect the cyclopropylketone by in situ reduction with DIBAL at −78°C (Scheme 12). GC–MS analysis of the red reaction solution indicated a new compound (23%) had been formed with a mass corresponding to that of cyclopropanol **67** (*m/z* 268). Aqueous work-up and chromatography afforded dihydrofuran **43** plus benzyl alcohol (**69**), which appears to result from a Grob-type fragmentation (34) to generate benzaldehyde from the intermediate aluminate **68** followed by further reduction (Scheme 12).

Conclusions

The results of the acetal hydrolysis trapping experiments, together with the spectroscopic evidence for the formation of cyclopropane **45**, indicate that dihydrofuran **43** is not formed by either a direct concerted or a stepwise mechanistic pathway involving a dipolar cycloaddition. Rather the dihydrofuran arises from a facile rearrangement of the initially formed cyclopropane due to its donor–acceptor substitution pattern. This conclusion finds support in related metal-catalyzed systems (27) in which cyclopropanation of enol ethers or ketene acetals is followed by rearrangement as the preferred pathway (6, 35, 36). In addition, mild oxidation of 1-hydroxymethyl-2-ethoxycyclopropane to the corresponding ethoxy-aldehyde resulted in spontaneous rearrangement to a dihydrofuran (37). In the case of vinyl diazoester addition to vinyl ethers ($Rh_2(OAc_4)$, the initial vinyl cyclopropanes undergo a Et_2AlCl catalyzed rearrangement to cyclopentenes (36). Over 35 years ago D'Yakonov and Komendantov concluded that furans arose from copper-catalyzed cyclopropanations with ethyl diazoacetate and acetylenes by rearrangement of the initial cyclopropene (38). By analogy, the same conclusion can be extended to the other α-diazoketones in this study with ethyl vinyl ether. Indeed the majority of alkene–diazocarbonyl combinations produce cyclopropanes in good yields with standard alkenes. Only when the "electronics" of both the reacting partners are "tuned" to stabilize a dipolar intermediate due to their donor–acceptor or push–pull properties, are appreciable amounts of dihydrofuran formed (6, 8, 31, 33, 37).

Thus, in keeping with current knowledge, it is reasonable to suggest that the α-diazoketone initially forms a metal carbenoid intermediate, which adds to the olefin to form an α-cyclopropylketone. In the majority of cases with a standard olefin, the stable cyclopropane product is isolated. However, with electron-rich enol ethers the electronic substitution pattern precipitates further rearrangement, resulting in ring opening and subsequent cyclization to afford the observed dihydrofurans. In these cases, exposure to most purification conditions (filtration through a plug of Celite®, TLC, or standing at −10 to −15°C, ~24 h) assists the rearrangement. Variation in the polarity of the reaction medium has no significant effect on the outcome of the reaction, and it is therefore unlikely that a dipolar-type mechanism, as illustrated in Schemes 10 and 11, is involved. Thus, we favour the intermediacy of the cyclopropane in the majority of literature examples that involve electron-rich alkenes. Therefore, a common mechanism should be applied to most metal-catalyzed α-diazoketone cyclopropanations with all olefins. The product distribution reflects, in large measure, the relative stability of the three-membered ring system and its substitution pattern. Consistent with this conclusion, the literature experimental data are (naturally) not reported on crude reaction products before the dihydrofurans are formed but after purification, by which time, in most cases, the primary donor–acceptor substituted cyclopropanes have rearranged by ring opening and subsequent cyclization (Scheme 7). This implies that much of the mechanistic work and corresponding conclusions compiled to date concerned with cyclopropanation – dihydrofuran formation would benefit from further study under controlled, neutral conditions.

In summary, spontaneous dihydrofuran formation from α-diazoketones usually requires diactivated cyclopropyl carbonyl systems. This mild route from cyclic α-diazoketones via monoactivated cyclopropyl ketones provides an attractive sequence to generate compounds for further synthetic manipulation in view of the widespread occurrence of five-membered oxygen-containing heterocyclic ring systems in nature (39).[2]

Finally, it would be beneficial to have a standard, recognized nomenclature to describe this rhodium(II) mediated cyclopropanation–rearrangement process to afford dihydro-

[2] For a spiro-dihydrobenzofuran system see ref. 39*c*.

furans. This conversion has a formal resemblance to a dipolar cycloaddition. For example, in a nice synthesis of aflatoxin B_2, the intermolecular addition of an α-diazodiketone to 2,3-dihydrofuran via a cyclopropanation–rearrangement sequence is described as a "rhodium carbenoid dipolar cycloaddition", a "rhodium-mediated dipolar cycloaddition", or "the formal dipolar cycloaddition of cyclic diazodicarbonyl compounds with vinyl ethers mediated by dirhodium catalysts" (40). Clearly a cycloaddition is an addition reaction that forms a ring; however, this term also has mechanistic implications implying the reaction is either of a pericyclic or dipolar nature. In the present context these dihydrofuran-forming reactions may be characterized as a sequence involving a metal carbenoid or metal-mediated cyclopropanation – ring opening – cyclization pathway in which the cyclopropane cleavage step is similar to a Grob-type fragmentation,[3] which affords a dipolar intermediate that closes to the dihydrofuran.

Experimental (see ref. 1*d* for general procedures)

2-Formyl-3,3-dimethyl-4-*tert*-butyldimethylsilyloxymethylcyclohexanone (5)

Copper(I) iodide (3.80 g, 20 mmol) suspended in ether (200 mL) was cooled to 0°C and methyllithium (28.6 mL, 40 mmol) was added to the stirred suspension. After stirring for 15 min, an ether solution of the enone **4** (1*d*) (2.56 g, 20 mmol) was added dropwise over 10 min. After 90 min, ethyl formate (9 mL) was added and, after a further 20 min at 0°C, the reaction was poured into aqueous 10% NH_4Cl solution (150 mL). The organic layer was washed (3×) with dilute aqueous 1% HCl solution, dried, and concentrated. Chromatography (ethyl acetate/petroleum ether; 1:20) gave **5** (0.64 g, 20%). ^{1}H NMR (200 MHz) δ: 0.03 (s, 6H), 0.90 (s, 9H), 1.11 (s, 3H), 1.30 (s, 3H), 1.55 (m, 2H), 1.95 (m, 1H), 2.40 (m, 2H), 3.42 (dd, 1H, J = 8.4, 5.3 Hz), 3.83 (dd, 1H, J = 4.3, 8.7 Hz), 8.90 (d, 1H, J = 3.2 Hz), 15.22 (d, 1H, J = 3.2 Hz); ^{13}C (50.3 MHz) δ: 188.3, 185.6, 117.9, 62.5, 46.0, 33.3, 30.2, 29.0, 25.6, 19.9, 18.0, −5.7; HRMS calcd. for $C_{12}H_{21}O_3Si$ ($M^+ - C_4H_9$): 241.1259; found: 241.1252.

2-Formyl-5,5-dimethyl-4-*tert*-butyldimethylsilyloxymethylcyclohexanone (24)

This compound was a component of the reaction above and was prepared selectively when the reaction was allowed to warm to 21°C prior to adding the ethyl formate. After a further 4 h, work-up as above afforded **24** (2.5 g, 78%). ^{1}H NMR (200 MHz) δ: 0.02 (s, 6H), 0.85 (s, 12H), 0.98 (s, 3H), 1.55 (m, 1H), 2.09 (d, 2H, J = 11.4 Hz), 2.51 (dd, 1H, J = 5.8, 15.7 Hz), 3.41 (dd, 1H, J = 8.4, 5.3 Hz), 3.75 (dd, 1H, J = 4.3, 8.7 Hz), 8.73 (d, 1H, J = 1.6 Hz), 15.0 (d, 1H, J = 1.6 Hz); ^{13}C (50.3 MHz) δ: 188.3, 185.6, 117.9, 62.5, 46.0, 33.3, 30.2, 29.0, 25.6, 19.9, 18.0, −5.7. HRMS calcd. for $C_{12}H_{21}O_3Si$ ($M^+ - C_4H_9$): 241.1259; found: 241.1254.

2-(Methoxymethylidene)-3,3-dimethyl-4-*tert*-butyldimethylsilyloxymethylcyclohexanone (6)

Treatment of **5** (200 mg, 0.067 mmol) in ether (1 mL) at 22°C with excess diazomethane (prepared from *N*-nitrosomethylurea) in ether afforded **6** directly. Concentration followed by chromatography (20% acetone – petroleum ether) gave the product **6** (174 mg, 83%). ^{1}H NMR (acetone-d_6) (200 MHz) δ: 0.08 (s, 6H), 0.90 (s, 9H), 1.11 (s, 3H), 1.34 (s, 3H), 1.56–2.32 (m, 5H), 3.50 (dd, 1H, J = 8.15, 10 Hz), 3.85–3.92 (m, 4H), 7.22 (s, 1H); ^{13}C (50.3 MHz) δ: 201.8, 160.6, 123.5, 62.7, 61.9, 47.8, 37.1, 36, 26.9, 25.8, 21.1, 20.7, 18.2, −5.4; HRMS calcd. for $C_{13}H_{23}O_3$ ($M^+ - C_4H_9$): 255.1416; found: 255.1409.

2-Diazo-3,3-dimethyl-4-*tert*-butyldimethylsilyloxymethylcyclohexanone (8)

Standard diazo transfer procedure

2-Formyl-3,3-dimethyl-4-*tert*-butyldimethylsilyloxymethylcyclohexanone (**5**) (3.6 g, 12 mmol) was dissolved in dichloromethane (25 mL) and freshly distilled triethylamine (3.37 mL, 0.024 mmol) was added. The solution was cooled in an external ice–salt bath (−10°C) and *p*-toluenesulfonyl azide (1.8 g, 10 mmol, prepared from *p*-toluenesulfonyl chloride and sodium azide) was added with vigorous stirring over a period of approximately 1 h. Stirring was continued for an additional 2 h as temperature rose to 0°C. A solution of KOH (0.672 g, 12 mmol) in water (25 mL) was added and the mixture was stirred at 21°C for 15 min. The resulting emulsion was placed in a separatory funnel (100 mL), the dichloromethane layer separated, and the aqueous layer extracted twice with dichloromethane (5 mL). The combined dichloromethane extracts were washed with aqueous KOH solution (0.05 g in 15 mL water), water, and dried. Concentration and chromatography (5% ethyl acetate – petroleum ether) gave the product in 20% yield from **4**. IR (neat): 2100, 1740 cm^{-1}; ^{1}H NMR (200 MHz) δ: 3.85 (dd, 1H, J = 10.0, 4.4 Hz) 3.54 (dd, 1H, J = 10.0, 7.5 Hz), 2.41 (m, 2H), 2.1 (m, 1H), 1.71 (m, 2H), 1.39 (s, 3H), 11.17 (s, 3H), 0.93 (s, 9H), 0.1 (s, 6H); ^{13}C (50.3 MHz) δ: 193.9, 62.5, 62.2, 51.4, 44.2, 32.6, 28.4, 25.6, 22.3, 17.9, −5.8; HRMS calcd. for $C_{15}H_{28}O_2Si$: 268.1858; found: 268.1865.

2-Diazo-4-(*tert*-butyldimethylsilyloxy)methyl-5,5-dimethylcyclohexanone (25)

70% yield from **24**. IR (neat): 2100, 1740 cm^{-1}; ^{1}H NMR (200 MHz) δ: 3.82 (dd, 1H, J = 10.0, 4.4 Hz), 3.5 (dd, 1H, J = 10.0, 7.5 Hz), 2.85 (m, 1H), 2.60 (m, 1H) 2.08 (s, 2H), 1.68 (m, 1H,), 0.97 (s, 3H), 0.89 (s, 3H), 0.85 (s, 9H), 0.15 (s, 6H); ^{13}C (50.3 MHz) δ: 193.9, 62.5, 62.2, 51.4, 44.2, 32.6, 28.4, 25.6, 22.5, 17.9, −5.8; HRMS calcd. for $C_{15}H_{28}O_2Si$: 268.1858; found: 268.1865.

2-Diazo-4-cyano-4-phenylcyclohexanone (28)

40% yield from the parent ketone **26**. IR (CCl_4) 2238, 2110, 1727 cm^{-1}; ^{1}H NMR (200 MHz) δ: 2.34 (dd, 2 H, J = 8.1, 4.2 Hz), 2.57 (dt, 1 H, J = 18.4, 4.1 Hz), 2.80 (dt, 1 H, J = 18.4, 9.5 Hz), 3.22 (s, 2 H), 7.42 (m, 5 H); ^{13}C (50.3 MHz) δ: 190.4, 137.7, 129.5, 129.0, 125.5, 120.8, 62.5 (C-2), 41.2, 34.3, 33.7, 32.2; MS *m/z*: 225, 197, 168, 154, 141, 129.

2-Diazo-1-cyclohexyl-1-oxoethane (31)

Oxalyl chloride (4.8 mL, 54.6 mmol) was added dropwise to a stirred solution of cyclohexanecarboxylic acid (1 g, 7.8 mmol)

[3] For a Grob-type fragmentation in cyclopropanone acetals see ref. 41.

in benzene (40 mL). Concentration gave the acid chloride (97%), which was reacted directly with an ethereal solution of diazomethane to generate the diazoketone **31** (95%). IR (neat): 2104, 1636 cm^{-1}; ^1H NMR (200 MHz) δ: 1.25 (m, 6H), 1.71 (m, 4H), 5.22 (s, 1H), 2.10 (br, 1H); ^{13}C (50 MHz) δ: 198.5, 29.1, 25.6; HRMS calcd. for $C_8H_{12}N_2O$: 152.0950; found: 152.0942.

2-Diazo-1,2-diphenyl-1-ethanone (34)

A suspension of benzil monohydrazone **33** (2.0 g, 8.92 mmol) in THF (200 mL) was heated at reflux until the mixture became homogeneous. Powdered Ag_2O (2.26 g, 9.75 mmol) was added in small portions over 15 min and the resulting mixture was heated at reflux for 5 h with vigorous stirring. The silver residue was removed by hot filtration (gravity, over Celite®) and washed with two 5 mL portions of THF. The filtrate was concentrated to give ~2 g of oily orange crystals. Recrystallization from pentane yielded 1.66 g (84%) of azibenzil **34** as bright orange crystals, mp 66–67°C (lit. (13*b*) mp 67–67.5°C); IR (KBr pellet): 3051, 2075,1605 cm^{-1}; ^{13}C NMR (50.3 MHz): δ: 182.5, 132.0, 125.9, 125.7, 123.4, 123.1, 122.6, 122.1, 121.5, 120.1 ppm.

2-Formyl-4-cyano-4-phenylcyclohexanone (27)

A stirred mixture of sodium hydride (0.376 g, 12.5 mmol, 80% in mineral oil, Aldrich), anhydrous ether (100 mL), and ethyl alcohol (0.25 mL) was cooled (0°C) and a solution of ketone **26** (2.5 g, 12.5 mmol) and redistilled ethyl formate (1.52 mL, 18.8 mmol) was added dropwise over 1 h. After 66 h, ethanol (1 mL) and water (10 mL) were added and the mixture was poured into a separatory funnel (500 mL). The organic layer was separated, washed with water (5 mL), and the combined aqueous extract was washed with ether (100 mL). The aqueous layer was acidified with 6 N HCl (4 mL) and the mixture extracted twice with ether (30 mL). The combined ether solutions were washed with brine (25 mL), dried, filtered, and concentrated to give the product **27** (2.5 g), which was used directly in the diazo transfer step.

2,2-Dimethyl-3-*tert*-butyldimethylsilyloxymethyl-7-oxa-8-ethoxybicyclo[4.3.0]non-1,6-ene (12)

Standard catalytic procedure

An anhydrous diethyl ether (1.5 mL) solution of α-diazoketone **8** (100 mg, 0.34 mmol) was added over 4 h by syringe pump (Sage model 341A) to a stirred solution (dichloromethane, anhydrous ether, pentane, or benzene) of the catalyst ((1 mg, 4.5 mmol, palladium(II) acetate) or (0.7 mg, 1.7 mmol, rhodium(II) acetate or rhodium(II) pivalate) or (1.7 mg, 16.8 mmol, cuprous chloride)) and excess alkene (1 mL) at room temperature (21°C). The needle of the syringe was placed just below the surface of the reaction solution. Once the addition was complete, the mixture was concentrated, flushed through a small amount of silica gel (70–230 mesh) or Celite®, and reconcentrated. The product was purified by chromatography (5% ethyl acetate – petroleum ether) to give **12** in 70% yield (rhodium(II) acetate). IR (neat): 1100 cm^{-1}; ^1H NMR (200 MHz) δ: 0.15 (s, 6H), 0.85 (s, 9H), 1.05 (s, 3H), 1.24 (t, 3H, J = 7.1 Hz), 1.27 (s, 3H), 1.71–2.80 (m, 7H), 3.35 (m, 1H), 3.50 (m, 1H), 3.75 (m, 2H), 5.45 (m, 1H); ^{13}C (50.3 MHz) δ: 148.3, 104.6, 102.4, 63.4, 63.2, 45.7, 39.5, 39.4, 32.6, 28.8, 25.7, 23.8, 23.0, 18.0, 15.0, −5.7; DEPT (50.3 MHz) δ: 104.6 (CH), 63.4 (CH_2), 63.2 (CH_2), 45.7 (CH), 39.5 (CH_2), 38.4 (CH_2), 28.8 (CH_3), 25.7 (CH_3), 23.8 (CH_2), 23.0 (CH_3), 15.0 (CH_3), −5.7 (CH_3); HRMS calcd. for $C_{19}H_{36}O_3Si$: 340.2433; found: 340.2433.

4,4-Dimethyl-3-*tert*-butyldimethylsiloxymethyl-7-oxa-8-ethoxybicyclo[4.3.0]non-1,6-ene (37)

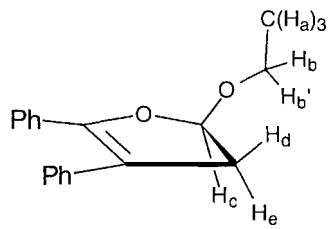
75% yield from diazoketone **25** with rhodium(II) acetate catalyst. IR (neat): 1100 (vs, C-O) cm^{-1}; ^1H NMR (200 MHz) δ: 0.14 (s, 6H), 0.85 (s, 9H), 0.86 (s, 3H), 0.96 (s, 3H), 1.19 (t, 3H, J = 7.1 Hz), 1.70–2.60 (m, 7H), 3.35 (m, 1H), 3.53 (m, 1H), 3.75 (m, 2H), 5.50 (m, 1H); ^{13}C (50.3 MHz) δ: 147.3, 105.0, 102.4, 63.6, 63.2, 45.5, 39.4, 39.2, 31.6, 28.6, 25.5, 23.8, 22.9, 18.0, 15.1, −5.6; HRMS calcd. for $C_{19}H_{36}O_3Si$: 340.2433; found: 340.2425.

3-Cyano-3-phenyl-7-oxa-8-ethoxybicyclo[4.3.0]non-1,6-ene (39)

40% yield from cyclohexanone **27** with rhodium(II) acetate catalyst. IR (CCl_4): 1098, 2241 cm^{-1}; ^1H NMR (200 MHz) δ: 1.23 (t, 3H, J = 7.1 Hz), 2.40 (m, 8H), 3.71 (m, 2H), 5.55 (m, 1H), 7.33 (m, 5H); ^{13}C (50.3 MHz) δ: 149.3, 139.9, 129.0, 102.0, 64.0, 39.3, 35.9, 32.8, 21.2, 14.9; HRMS calcd. for $C_{17}H_{19}NO$: 269.1411; found: 269.1382.

2,3-Diphenyl-5-ethoxy-4,5-dihydrofuran (43)

The $Rh_2(OAc)_4$ catalyzed addition of ethyl vinyl ether to **34** (21°C) (500 mg, 2.25 mmol) followed the general method described above. The ^1H NMR spectrum of the crude product showed no remaining starting material and GC–MS analysis indicated a 97% conversion to the dihydrofuran **43**. Analysis (TLC, silica gel, 20:1 petroleum ether/ethyl acetate) indicated rapid decomposition of the acetal. Dihydrofuran **43** was decomposed on exposure to $CDCl_3$ that had not been passed through basic alumina immediately prior to use. A purified sample was obtained by flash chromatography (20:1, hexanes/ether) to give **43** (68%) as a pale yellow oil.



43

43: IR (film, NaCl): 1011, 760, 694 cm^{-1}; ^1H NMR (200 MHz) δ: 7.53–7.10 (m, 10H, aromatic protons), 5.62 (dd, H_c, $J_{c,e}$ = 7.2 Hz, $J_{c,d}$ = 2.6 Hz), 3.97 (dq, H_b, $J_{b,a}$ = 9.6 Hz, $J_{b,b'}$ = 7.1 Hz), 3.66 (dq, $H_{b'}$, $J_{b',a}$ = 9.6 Hz, $J_{b',b}$ = 7.1 Hz), 3.41 (dd, H_e, $J_{e,d}$ = 16.4 Hz, $J_{e,c}$ = 7.2 Hz), 2.93 (dd, H_d, $J_{d,e}$ = 16.4 Hz, $J_{d,c}$ = 2.6 Hz), 1.06 (dd, 3H_a, $J_{a,b}$ = $J_{a,b'}$ = 9.6 Hz); ^{13}C NMR (50.3 MHz, DEPT) δ: 148.2 (s, Ph(O)*C*=C), 135.1 and 131.7 (s, phenyl *ipso* C), 128.5, 128.2, 128.1, 127.9, 127.5, 126.1 (d, phenyl *C*H), 109.3 (s, C=*C*Ph(CH_2)), 102.6 (d, O*C*HO), 63.7 (t, CCH_2CH(O)(O)), 42.3 (t, OCH_2CH_3), 15.3 (q, CH_2CH_3) ppm; HRMS calcd. for $C_{18}H_{18}O_2$: 266.1307; found: 266.1331.

3,3-Dimethyl-4-*tert*-butyldimethylsilyloxymethyl-2-(spiro-3-oxabicyclo[3.1.0]hexyl)cyclohexanone (35)

The standard reaction with **8** and rhodium(II) acetate with 2,5-dihydrofuran afforded the cyclopropyl product **35** (25%). IR (neat): 1710 cm^{-1}; ^1H NMR (200 MHz) δ: 0.0 (s, 6H), 0.81 (s, 3H), 0.87 (s, 9H), 1.21 (s, 3H), 1.23–1.50 (m, 2H), 1.9 (m, 1H), 2.1–2.7 (m, 4H), 3.31–3.60 (m, 2H), 3.70–3.85 (m, 2H), 4.21 (m, 1H), 4.70 (m, 1H); ^{13}C (50.3 MHz) δ: 210.2, 75.0, 62.7, 54.0, 46.0, 38.5, 36.1, 33.0, 29.5, 26.0, 21.2, 18.0, −6.4; HRMS calcd. for $C_{19}H_{34}O_3Si$ ($M^+ - H_2O$): 320.2099; found: 320.2097.

3,3-Dimethyl-4-*tert*-butyldimethylsilyloxymethyl-2-(spiro[4.1.0]heptanyl)cyclohexanone (36)

The standard reaction with rhodium(II) acetate and **8** plus cyclohexene gave the product **36** in 25% yield. IR (neat): 1710 1093 cm^{-1}; ^1H NMR (200 MHz) δ: 0.04 (s, 6H), 0.88 (s, 12H), 1.03 (s, 3H), 1.06–2.31 (m, 15H), 3.84 (m, 1H); HRMS calcd. for $C_{21}H_{38}O_2Si$: 350.2641; found: 350.2661.

Diphenylketene (20) (ref. 14)

A Schlenk flask (100 mL) containing a solution of diphenyl acyl chloride **52** (4.2 g, 5.64 mmol) in Et_2O (50 mL) was cooled to 0°C. Triethylamine (2.36 mL, 16.9 mmol, 3 equiv.) was added dropwise over 5 min to give a canary-yellow solution. The flask was sealed under argon and placed in the fridge overnight to precipitate $Et_3N{\cdot}HCl$. The salt was removed by filtration through a medium glass frit under an atmosphere of argon. Concentration under vacuum followed by flash vacuum distillation gave **20** as a thick yellow oil (0.91 g, 83%), bp 120–122°C at 0.15 Torr (1 Torr = 133.3 Pa). The distillation must be done rapidly to avoid formation of the ketene dimer. IR (KBr): 1762 cm^{-1}; IR (film, NaCl): 2097 (s) cm^{-1}; ^1H NMR (200 MHz) δ: 7.1–7.8 (m, 10H).

2,2-Diphenyl-3-ethoxycyclobutanone (44)

Standard photolysis procedure

A solution of α-diazoketone **34** (100 mg, 0.45 mmol) in ethyl vinyl ether (5 mL, 52.3 mmol) was placed in an oven-dried quartz tube (15 mm × 120 mm) that had been cooled under a stream of argon. The solution was degassed with dry deoxygenated argon (20 min) and irradiated with a medium-pressure Hanovia mercury lamp for 2.5 h until TLC analysis indicated that the starting material was consumed. Concentration and chromatography (11:1 petroleum ether/ethyl acetate) gave the cyclobutanone **44** (103 mg, 87%). IR (film): 1779 cm^{-1}; ^1H NMR (200 MHz) δ: 7.5–7.1 (m, 10H, aromatic protons), 4.82 (m, 1H), 3.6–3.11 (m, 4H), 1.06 (t, 3H); HRMS calcd. for $C_{18}H_{18}O_2$: 266.1307; found: 266.1316.

*Sensitized photolysis of α-diazoketone **34** with ethyl vinyl ether*

The procedure above was modified by the addition of benzophenone (0.813 g, 4.46 mmol, 10 equiv.) to the solution of α-diazoketone **34** (100 mg, 0.446 mmol) and ethyl vinyl ether (5 mL, 52.3 mmol). The mixture was degassed and irradiated (4.5 h). Concentration and chromatography (11:1 petroleum ether/ethyl acetate) gave 63 mg of cyclobutanone **44** and 8 mg of crude dihydrofuran **43** (7%)). Further radial chromatography (silica gel, 4 mm plates, 20:1 petroleum ether/ethyl acetate) afforded cyclobutanone **44** (52 mg, 44%).

Thermal reaction, no catalyst: Ethyl vinyl ether (246 μL, 2.57 mmol), diphenylketene **20** (200 mg, 1.03 mmol), and freshly distilled ether (25 mL) were placed in a 5 mL round-bottom flask and stirred under argon overnight. The IR of the reaction mixture contained no diphenylketene absorption (2096 cm^{-1}). Excess ethyl vinyl ether was removed under vacuum and the last traces of the ether were removed under a stream of argon. Chromatography (silica gel, 5:1 petroleum ether/ethyl acetate) gave **44** (241 mg (88%) as a bright yellow oil. The less polar product was the dimer of diphenylketene (IR (neat): 1814 (s) cm^{-1}; ^1H NMR (200 MHz) δ: 7.84–7.72 (m, 1.5H), 7.62–7.38 (m, 2H), 7.3–7.1 (m, 1.5H) 7.84–7.10 (m, aromatic protons)).

With catalyst: A solution of diphenylketene **20** (200 mg, 1.03 mmol) and freshly distilled ether (9 mL) was added by syringe pump to a mixture of ethyl vinyl ether (~1 mL, excess) and $Rh_2(OAc)_4$ (9 mg, 2 mol %) over a period of 7 h. The reaction mixture, after column chromatography (silica gel, 5:1 petroleum ether/ethyl acetate), yielded cyclobutanone **44** (206 mg, 89%).

5,5-Dimethyl-3-ethoxy-6-*tert*-butyldimethylsilyloxymethylspiro[3.4]heptan-1-one (7)

Direct photolysis of **8** in ethyl vinyl ether gave **7** in 88% yield. IR (neat): 1780, 1100 cm^{-1}; ^1H NMR (200 MHz) δ: 0.15 (s, 6H), 0.85 (s, 12H), 1.05 (s, 3H), 1.20 (m, 3H), 1.71 (m, 4H), 2.11 (m, 1H), 3.02 (m, 2H), 3.45 (m, 4H), 3.87 (m, 1H); HRMS calcd. for $C_{19}H_{36}O_3Si$: 283.1734; found: 283.1715.

6-Phenyl-6-cyano-3-ethoxyspiro[3.4]heptan-1-one (40)

Direct photolysis of **28** in ethyl vinyl ether gave **40** in 60% yield. IR (CCl_4): 2234, 1779 cm^{-1}; ^1H NMR (200 MHz) δ: 1.23 (m, 3H), 2.52 (m, 6H), 3.19 (m, 2H), 3.63 (m, 2H), 4.11 (m, 1H), 7.34 (m, 5H); HRMS calcd. for $C_{17}H_{19}O_2N$: 269.1411; found: 269.1411.

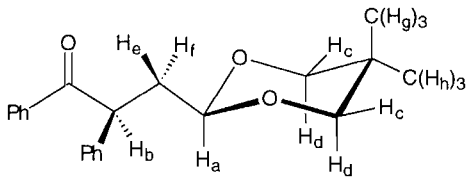
2-Cyclohexyl-3-ethoxycyclobutanone (42)

Direct photolysis of **31** in ethyl vinyl ether gave **42** in 80% yield. IR (neat): 1780 cm^{-1}; ^1H NMR (200 MHz) δ: 1.00 (m, 9H), 1.83 (m, 5H), 2.91 (m, 3H), 3.45 (m, 2H), 4.15 (m, 1H); MS *m/z*: 197, 196, 168, 154, 150, 132, 122, 108, 80, 67.

3,4-Diphenylbutan-4-oxo-(2,2-dimethylpropylenedioxy) acetal (49)

Dihydrofuran **43** (17 mg, 0.064 mmol) and 2,2-dimethyl-1,3-propanediol (20 mg, 0.192 mmol, 3 equiv.) were dissolved in dry benzene (10 mL) and a single crystal of PPTS was added. The mixture was stirred at room temperature until there was no remaining dihydrofuran by TLC analysis. The crude reaction mixture was concentrated and chromatographed (5:1 petroleum ether/ethyl acetate) to give acetal **49** (14 mg, 68%). ^1H NMR (500 MHz, COSY) δ: 8.00–7.98 (m), 7.97–7.20 (m) (10H, phenyl protons), 4.91 (dd, H_a, J = 7.8, 7.0 Hz), 4.31 (dd, H_b, J = 5.6, 4.9 Hz), 3.38 (ddd, $2H_c$, J = 18.8, 10.9, 2.7 Hz), 3.29 (dd, $2H_d$, J = 17.2, 11.0 Hz), 2.60 (ddd, H_e, J = 13.8, 7.9, 5.8 Hz), 2.15 (ddd, H_f, J = 13.8, 6.8, 4.8 Hz), 1.14 (s, $3H_g$), 0.67 (s, $3H_h$); ^{13}C NMR (125 MHz, DEPT) δ: 199.2 (s, C=O),

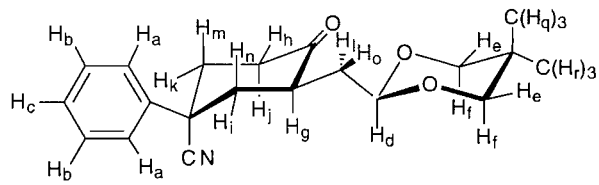
139.0 (s), 136.6 (s), 134.8 (d), 132.7 (d), 129.8 (d), 128.9 (d), 128.9 (d), 128.6 (d), 128.3 (d), 128.2 (d), 127.0 (d), 100.0 (d, C_a), 77.71 (t, $C_{c,d}$), 48.1 (d, C_b), 38.5 (t, $C_{e,f}$), 30.0 (s, $C(CH_3)_2$), 22.9 (q, C_g), 21.7 (q, C_h) ppm; HRMS calcd. for $C_{21}H_{24}O_3$: 324.1726; found: 324.1741.



49

Ethan-2-(4-cyano-4-phenyl-2-ethyl-1-oxocyclohexyl)-2,2-dimethylpropylenedioxy acetal (51)

Compound **39** (18 mg, 0.067 mmol) and 2,2-dimethyl-1,3-propanediol (35 mg, 0.33 mmol, 5 equiv.) were dissolved in anhydrous benzene (4 mL). A single crystal of PPTS was added and the solution was stirred at 21°C for 13 h. Chromatography (5:1 petroleum ether/ethyl acetate) provided **51** (12.3 mg, 56%).



51

51: ^{1}H NMR (500 MHz, COSY) δ: 7.50–7.48 (m, 2H_a), 7.42–7.39 (m, 2H_b), 7.36–7.34 (m, H_c), 4.58 (dd, H_d, J = 5.9, 3.9 Hz), 3.56 (dm, 2H, J = 11.3 Hz, H_e), 3.40 (d, 1H, J = 11.3 Hz, H_f), 3.37 (d, 1H, J = 11.3 Hz, H_f'), 3.24 (m, H_g), 2.97 (m, H_h), 2.67 (ddd, H_i, J = 13.6, 5.4, 3.7 Hz), 2.57 (ddd, H_j, J = 14.3, 4.2, 2.5 Hz), 2.450 (m, H_k), 2.32 (ddd, H_l, J = 3.91, 6.14, 14.31 Hz), 2.25 (ddd, H_m, J = 14.0, 14.0, 4.2 Hz), 1.98 (ddd, H_n, J = 13.6, 13.6, 13.6 Hz), 1.45 (ddd, H_o, J = 5.9, 5.9, 14.3 Hz), 1.16 (s, 3H_q), 0.69 (s, 3H_r). In ^{1}H–^{1}H decoupling experiments, irradiation of the methine proton at δ 3.24 (H_g) caused the collapse of the following signals: δ 2.67 (H_i) to a dd, J = 13.6, 3.7 Hz; δ 2.32 (H_l) to a dd, J = 14.3, 3.9 Hz; δ 1.98 (H_n) to a dd, J = 13.6, 13.6 Hz; and δ 1.45 (H_o) to a dd, J = 14.3, 5.9 Hz. Irradiation of the acetal methine proton at δ 4.58 (H_d) caused the collapse of the signal at δ 2.32 (H_l) to a dd, J = 14.3, 6.1 Hz and the signal at δ 1.45 (H_o) to a dd, J = 14.3, 5.9 Hz; ^{13}C NMR (125 MHz, DEPT) δ: 208.4 (s, *C*=O), 138.7 (s, phenyl=*C*(C)(C)), 129.2 (d, C_b), 128.5 (d, C_c), 125.5 (d, C_a), 121.6 (s, *C*N), 100.1 (d, C_d), 77.2 (t, $C_{e,f}$), 76.7 (t, $C_{l,o}$), 44.6 (s, *C*-CN), 42.9 (d, C_g), 39.0 (t, $C_{k,m}$), 38.0 (t, $C_{n,l}$), 33.5 (t, $C_{h,j}$), 30.1 (s, $C(CH_3)(CH_3)$), 23.0 (q, C_q), 21.8 (q, C_r); MS (EI) *m/z*: 326 (M−1, 1.0%), 283 (M−44, 8.1%), 197 (20.3%), 149 (74%), 129 (43%), 115 (37%), 105 ($C_6H_5C{=}O^+$, 16%), 77 (22%, $C_6H_5^+$), 57 (base peak), 41(81%); HRMS calcd. for $C_{20}H_{24}NO_3$ (M^+ −H): 326.1834; found: 326.1801.

9-Methoxy-2,2-dimethyl-3-*tert*-butyldimethylsilyloxymethyl-8-oxabicyclo[4.3.0]non-1,6-ene (59)

Trimethyloxosulfonium iodide (38.2 mg, 0.17 mmol) in DMF (0.5 mL) was added to a suspension of NaH (4 mg) in DMF (1 mL) at 21°C. After stirring for 20 min, a solution of **6** (53 mg, 0.17 mmol) in DMF (0.5 mL) was added in one portion and stirring was continued for 2 h. Cold water was added and the reaction mixture was extracted several times with ether. The combined ether extracts were washed with water and brine, dried, and chromatographed (5% Et_2O – petroleum ether) to give **59** (22 mg, 40%). ^{1}H NMR (300 MHz) δ: 0.02 (s, 6H), 0.86 (s, 3H), 0.87 (s, 9H), 1.1 (s, 3H), 1.43–1.50 (m, 2H), 1.90–1.96 (m, 1H), 2.04–2.09 (m, 2H), 2.38–2.35 (m, 1H), 2.64–2.68 (m, 1H), 3.40 (dd, 1H, J = 8.8, 10 Hz), 3.42 (s, 3H), 3.75 (dd, 1H, J = 3.6, 10 Hz), 5.34 (dd, 1H, J = 2.6, 7.2 Hz); ^{13}C (75 MHz) δ: 148.2, 113.2, 105.6, 63.5, 55.4, 47, 35.4, 26.9, 25.9, 22.4, 22.18, 22, 21.8, −5.3; DEPT (75 MHz) δ: 105.6 (CH), 63.5 (CH_2), 55.4 (CH_3), 47 (CH), 35.4 (CH_2), 26.9 (CH_3), 25.9 (CH_3), 22.4 (CH_2), 22.2 (CH_2), 22 (CH_3), −5.3 (CH_3); HRMS calcd. for $C_{18}H_{34}O_3$: 326.2276; found: 326.2285.

1-Phenacyl-1-phenyl-2-ethoxycyclopropane (45)

Trapping experiment with DIBAL

Diazo compound **34** (0.050 g, 0.223 mmol) in pentane (30 mL) with $Rh_2(OPiv)_4$ (2 mol%) as the catalyst was reacted as above. After the addition of **34** was complete the lime-green reaction mixture was cooled to −78°C and DIBAL (1.5 M in toluene, 300 μL, 0.446 mmol) added in one portion. The solution immediately turned bright red. This mixture was allowed to stir at −78°C for 15 min. GC–MS analysis indicated the presence of a new peak (23% of the mixture) with a mass corresponding to the α-cyclopropyl alcohol **67**. The reaction was quenched with a saturated aqueous solution of sodium potassium tartrate (5 mL). This mixture was extracted with ether (3 × 10 mL). The combined extracts were washed with brine, filtered, dried, and concentrated to give 54 mg of crude product as a thick red-brown oil. Chromatography (5:1 petroleum ether/ethyl acetate) afforded benzyl alcohol (6 mg) and the cyclopropyl alcohol **67** (10 mg).

The standard reaction rhodium(II) acetate reaction was conducted with ethyl vinyl ether and **34** but filtration was bypassed and the lime-green crude solution was concentrated directly under a stream of argon. It was dissolved in $CDCl_3$ that had been passed through basic alumina immediately prior to use. The ^{1}H and ^{13}C NMR and IR spectra of this opaque suspension were recorded immediately. The sample was stored in the freezer, without solvent, under an atmosphere of argon. Attempts to purify cyclopropane **45**, other than by filtration under an inert atmosphere, resulted in either partial or complete conversion to dihydrofuran **43**. Slow conversion of **45** to **43** occurred on storage (−10–15°C) in a sealed flask under an inert atmosphere. Compound **45**: IR (film, NaCl): 3062, 1722 cm^{-1}; ^{1}H NMR (200 MHz) δ: 7.92–7.78 (m, 5H), 7.62–6.90 (m, 5H), 3.38 (q, 2H), 1.41–0.90 (m, 5H, overlapping t at 1.12), 0.90–0.62 (m, 1H) ppm; ^{13}C NMR (50.3 MHz) δ: 194.5, 134.8, 132.9, 129.9, 129.1, 129.0, 128.7, 128.6, 128.2, 128.1, 128.0, 65.8, 32.4, 29.7, 23.2, 15.3 ppm.

Extended chain 2,3-pyrazinedicarboxylate complexes of manganese(II) and cadmium(II); synthesis and structure and magnetic properties

Long Mao, Steven J. Rettig, Robert C. Thompson, James Trotter, and Shihua Xia

Abstract: Manganese and cadmium complexes of singly and doubly deprotonated 2,3-pyrazinedicarboxylic acid ($pyzdcH_2$) have been prepared and studied. Crystal data: $[H_3O]_{2x}[Mn(pyzdc)_2]_x$, **1**, monoclinic, $C2/c$ (no. 15), a = 14.472(1) Å, b = 8.475(2) Å, c = 13.0771(9) Å, β = 114.753(4)°, Z = 4; $[H_3O]_{2x}[Cd(pyzdc)_2]_x$, **2**, monoclinic, $C2/c$ (no. 15), a = 14.4857(9) Å, b = 8.502(1) Å, c = 14.9803(7) Å, β = 126.951(2)°, Z = 4; $[Mn(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **3**, monoclinic, $P2_1/c$ (no. 14), a = 6.5523(7) Å, b = 7.6702(7) Å, c = 20.5815(6) Å, β = 93.605(5)°, Z = 4; $[Cd(pyzdc)(H_2O)_3]_x \cdot xH_2O$, **4**, monoclinic, Cc (no. 9), a = 6.088(1) Å, b = 11.5410(9) Å, c = 15.0624(7) Å, β = 96.532(8)°, Z = 4. The structures were solved by Patterson (**1**, **4**) or direct (**2**, **3**) methods and were refined by full-matrix least-squares procedures to R = 0.036, 0.025, 0.034, and 0.022 (R_w = 0.032, 0.025, 0.036, and 0.023) for 2825, 4961, 1672, and 2641 reflections with $I \geq 3\sigma(F^2)$, respectively. The structures of **1** and **2** consist of extended anionic chains of metal ions that are linked by double-bridging $pyzdc^{2-}$ groups, with electrical neutrality maintained by the presence of H_3O^+ cations in the lattice. In **3** double chains of manganese ions are cross-linked by $pyzdc^{2-}$ ligands forming a "ladder-like" motif. The structure of **4** consists of extended chains of cadmium ions in which single $pyzdc^{2-}$ groups bridge metal centres. Magnetic susceptibility studies indicate, at most, only weak antiferromagnetic exchange in **1** but moderately strong antiferromagnetic interactions in **3**, mediated by bridging carboxylate groups ($J = -0.27$ cm^{-1}).

Key words: extended chains, manganese, cadmium, 2,3-pyrazinedicarboxylates, X-ray structures, antiferromagnetism.

Résumé : On a préparé et on a étudié des complexes de manganèse et de cadmium de l'acide pyrazinedicarboxylique ($pyzdcH_2$) déprotoné et doublement déprotoné. Les données cristallines sont les suivantes : $[H_3O]_{2x}[Mn(pyzdc)_2]_x$, **1**, monoclinique, $C2/c$ (no. 15), a = 14,472(1) Å, b = 8,475(2) Å, c = 13,0771(9) Å, β = 114,753(4)°, Z = 4; $[H_3O]_{2x}[Cd(pyzdc)_2]_x$, **2**, monoclinique, $C2/c$ (no. 15), a = 14,4857(9) Å, b = 8,502(1) Å, c = 14,9803(7) Å, β = 126,951(2)°, Z = 4; $[Mn(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **3**, monoclinique, $P2_1/c$ (no. 14), a = 6,5523(7) Å, b = 7,6702(7) Å, c = 20,5815(6) Å, β = 93,605(5)°, Z = 4; $[Cd(pyzdc)(H_2O)_3]_x \cdot xH_2O$, **4**, monoclinique, Cc (no. 9), a = 6,088(1) Å, b = 11,5410(9) Å, c = 15,0624(7) Å, β = 96,532(8)°, Z = 4. On a résolu les structures par la méthode de Patterson (**1**, **4**) ou la méthode directe (**2**, **3**) et on les a affinées par la méthode des moindres carrés matrice complète jusqu'à des valeurs de R = 0,036, 0,025, 0,034, et 0,022 (R_w = 0,032, 0,025, 0,036 et 0,023) pour 2825, 4961, 1672 et 2641 réflexions avec $I \geq 3\sigma(F^2)$, respectivement. Les structures des composés **1** et **2** consistent en des chaînes anioniques allongées d'ions métalliques qui sont liées par des groupes $pyzdc^{2-}$ doublement pontés, avec la neutralité électrique maintenue par la présence de cations H_3O^+ dans le réseau. Dans le composé **3** des chaînes doubles d'ions manganèse sont réticulées par les ligands $pyzdc^{2-}$ formant un motif en forme d'échelle. La structure du composé **4** consiste en des chaînes allongées d'ions cadmium dans lesquelles un seul groupe $pyzdc^{2-}$ forme un pont entre les centres métalliques. Les études de susceptibilité magnétique indiquent, tout au plus, uniquement un faible échange ferromagnétique dans le composé **1** mais des interactions antiferromagnétiques modérément fortes dans le composé **3** au moyen du groupe carboxylate en position de pont ($J = -0,27$ cm^{-1}).

Mots clés : chaînes allongées, manganèse, cadmium, 2,3-pyrazinedicarboxylates, structures aux rayons X, antiferromagnétisme.

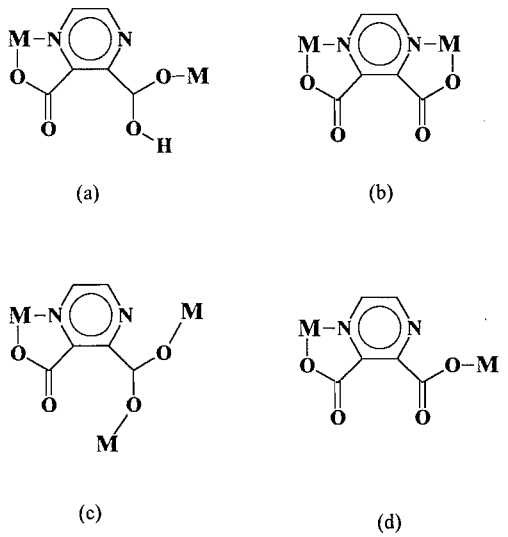
Fig. 1. 2,3-Pyrazinedicarboxylate bridging modes



Introduction

The ligands formed by the single and double deprotonation of 2,3-pyrazinedicarboxylic acid ($pyzdcH_2$) can, by virtue of their six donor atoms, bind to metal ions in a variety of ways, including bridging, the latter generating extended polymeric materials. Pyrazine itself (1,4-diazine) has attracted considerable attention as a linear bridge between metals in extended covalent network solids (1–3) and the pyrazinedicarboxylate ligands under consideration here have the added characteristic of potentially forming chelate-supported bridges. Such structural features have been observed in the compound $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (4), for example, which has extended chains of copper ions linked by double-bridging $pyzdcH^-$ groups. The bridging mode, depicted in Fig. 1(a), involves chelate interactions to one metal and bonding through single carboxylate oxygens to the second metal. $[M(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (where M = Co, Ni, or Cu) (4) and $[Co(pyzdc)(H_2O)_2]_x$ (5), on the other hand, have extended chain structures in which single $pyzdc^{2-}$ ligands bridge the metals by 1,4-diazine links that are supported by chelate formation to both metals (Fig. 1(b)). The compound $Zn(pyzdc) \cdot 3H_2O$ exhibits a different type of structure (6), one in which double chains of metal ions are cross-linked by $pyzdc^{2-}$ groups. The ligands in this structure chelate to a metal in one chain and bridge two metals in the second chain by O-C-O links involving the second carboxylate group (Fig.1(c)).

The dependence of structural type on the nature of the metal in 2,3-pyrazinedicarboxylate complexes has prompted us to extend our detailed structural investigations of this class of compound to complexes of other metals, specifically those of manganese(II) and cadmium(II). By employing dilute aqueous solutions to obtain products, as described previously (4), polymer formation is slow and as a result all four compounds reported here were obtained in crystalline form suitable for single crystal X-ray diffraction studies.

A second interest in studying these complexes concerns the potential of pyrazinedicarboxylate ligands to mediate magnetic exchange interactions in poly- or oligo-metallic complexes. Previous studies revealed only weak antiferromagnetic interactions in polymetallic Co(II), Ni(II), and Cu(II) complexes of these ligands (4) and it was suggested that stronger interactions might be found in systems such as those of manganese(II) in which the metals incorporate unpaired electron density in t_{2g} orbitals. The magnetic properties of two manganese complexes are examined here.

There have been earlier reports on 2,3-pyrazinedicarboxylates of manganese(II) that focused mainly on syntheses and characterization by thermochemical and spectroscopic means (7, 8). No crystal structure determinations or detailed cryomagnetic studies on these systems have been published prior to the present work.

Experimental

Syntheses

Chemicals of at least reagent grade quality were used without further purification. All products are air stable.

*Oxonium poly-bis-μ-(2,3-pyrazinedicarboxylato)manganate(II), $[H_3O]_{2x}[Mn(pyzdc)_2]_x$, **1***

2,3-Pyrazinedicarboxylic acid (0.42 g, 2.5 mmol) was dissolved in 100 mL water and slowly added to a 60 mL aqueous solution of $MnCl_2 \cdot 4H_2O$ (0.25 g, 1.25 mmol). After standing for ~48 h, the solution yielded yellow crystals. After selecting suitable crystals for X-ray analysis, the rest of the product was collected by filtration, washed with water, and dried in vacuo at room temperature for 24 h. Anal. calcd. for $C_{12}H_{10}MnN_4O_{10}$: C 33.90, H 2.37, N 13.18; found: C 33.96, H 2.42, N 13.15.

*Oxonium poly-bis-μ-(2,3-pyrazinedicarboxylato)-cadmiumate(II), $[H_3O]_{2x}[Cd(pyzdc)_2]_x$, **2***

Procedure was as described above for **1**, employing 1.25 mmol $CdCl_2 \cdot 2.5H_2O$ in 60 mL water and 2.5 mmol $pyzdcH_2$ in 70 mL water. Crystals of $[H_3O]_{2x}[Cd(pyzdc)_2]_x$ are colourless. Anal. calcd. for $C_{12}H_{10}CdN_4O_{10}$: C 29.86, H 2.09, N 11.61; found: C 29.89, H 2.08, N 11.81.

*Poly-diaqua-μ-2,3-pyrazinedicarboxylatomanganese(II) dihydrate, $[Mn(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **3***

2,3-Pyrazinedicarboxylic acid (0.42 g, 2.5 mmol) was dissolved in 120 mL water and the solution was adjusted to pH = 5 with 1.0 M aqueous NaOH. This solution was added slowly to a 60 mL aqueous solution of $MnCl_2 \cdot 4H_2O$ (0.50 g, 2.5 mmol). Pale yellow, very thin, crystals deposited after the solution was left standing for ~12 h. Crystal growth was allowed to continue for ~2 weeks, then crystals suitable for X-ray diffraction studies were selected. The remainder of the crystals were separated by filtration, washed with water, and dried in vacuo at room temperature for 24 h. Anal. calcd. for $C_6H_{10}MnN_2O_8$: C 24.58, H 3.44, N 9.56; found: C 24.65, H 3.47, N 9.42.

*Poly-triaqua-μ-2,3-pyrazinedicarboxylatocadmium(II) monohydrate, $[Cd(pyzdc)(H_2O)_3]_x \cdot xH_2O$, **4***

Procedure was as described above for **3**, employing 2.5 mmol $CdCl_2 \cdot 2.5H_2O$ in 60 mL water and 2.5 mmol $pyzdcH_2$ in 85 mL water. Colourless crystals deposited after the solution was left standing for ~48 h. Crystals suitable for X-ray diffraction studies were selected and the remainder were separated by filtration, washed with water, and dried in vacuo at room temper-

X-ray crystallographic analyses of 1–4

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 37.7°–44.7° for **1**, 61.9°–73.7° for **2**, 102.9°–110.3° for **3**, and 45.0°-51.2° for **4**. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random fluctuations for all four compounds. The data were processed and corrected for Lorentz and polarization effects, and absorption (empirical, based on azimuthal scans).[2]

The structures were solved by Patterson (**1**, **4**) or direct (**2**, **3**) methods. The structural analyses of **1** and **2** were initiated in the centrosymmetric space group *C*2/*c* and that of **4** in the non-centrosymmetric space group *Cc* on the basis of the E-statistics. These choices were confirmed by subsequent calculations. The metal atoms in **1** and **2** are situated on crystallographic C_2 axes. It should be noted that **1** and **2** are *not* isostructural even though they are nearly isomorphous and the polymeric chains in the two structures are very similar.

All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms of **1**, **2**, and **3** were refined with isotropic thermal parameters and those of **4** were fixed in calculated positions (O—H = 0.88 Å, C—H = 0.98 Å, $B_H = 1.2\ B_{bonded\ atom}$, O—H hydrogen orientations based on difference map peak positions). Secondary extinction corrections were applied for **1**, **2**, and **3**, the final values of the extinction coefficients being $1.7(2) \times 10^{-7}$, $4.07(9) \times 10^{-7}$, and $2.02(5) \times 10^{-5}$, respectively. Neutral atom scattering factors for all atoms (9) and anomalous dispersion corrections for the non-hydrogen

complete tables of bond lengths and bond angles, torsion angles, intermolecular contacts, and least-squares planes are included as supplementary material.[3]

Physical measurements

Thermal Gravimetric Analysis (TGA) was performed on powdered samples using a TA Instruments TGA 51 thermogravimetric analyzer. Samples of 5–20 mg were heated at 10°C min^{-1} in an atmosphere of dry nitrogen at a flow rate of 100 mL min^{-1}. Magnetic susceptibilities over the temperature range ~4–82 K were measured at applied fields of 7 501 Oe using a P.A.R. model 155 vibrating sample magnetometer as previously described (11). Samples were held in Kel-F capsules and corrections were made for background signal over the entire temperature range studied. Magnetic susceptibilities were corrected for diamagnetism of all atoms (manganese, −14; $pyzdc^{2-}$ −68; H_2O, −12 (all corrections in units of 10^{-6} cm^3 mol^{-1})). Complete magnetic data have been deposited as supplementary material. Carbon, hydrogen, and nitrogen analyses were performed by P. Borda of this department.

Results and discussion

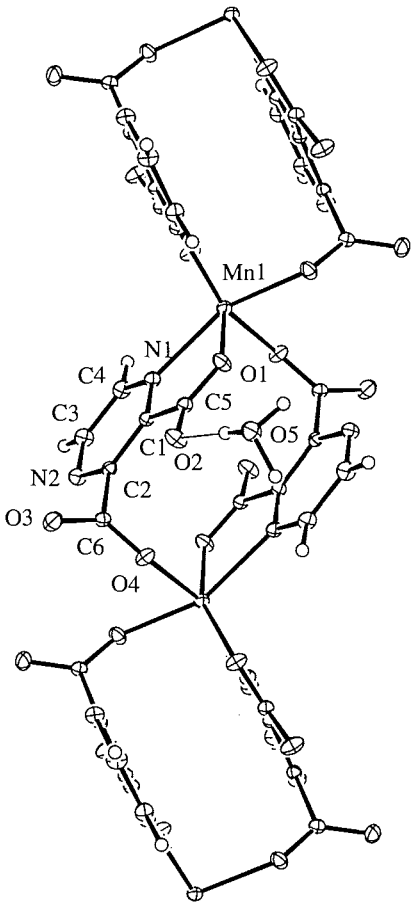
$[H_3O]_{2x}[M(pyzdc)_2]_x$, 1 (M = Mn), 2 (M = Cd)

Single crystal X-ray diffraction studies reveal that although **1** and **2** have similar unit-cell dimensions and crystallize in the same space group, the two materials are neither isomorphous nor isostructural. The extended chain structures of **1** and **2** (see below), however, are essentially superimposable. Part of the structure of **1**, with the atom numbering scheme, is shown in Fig. 2. In this structure each metal ion is *cis*-coordinated by chelation interactions (involving a ring nitrogen, N(1), and an adjacent carboxylate oxygen, O(1)) to two ligands forming $M(pyzdc)_2^{2-}$ units. The other two *cis* positions are occupied by oxygen atoms, O(4), from carboxylate groups not involved in chelation on two neighbouring units. This results in extended chains of metal ions double-bridged by $pyzdc^{2-}$ ligands, each ligand coordinating in the manner depicted in Fig. 1(d). Electrical neutrality is maintained by the presence of H_3O^+ ions in the lattice. In all four structures described in this work hydrogen-bonding interactions involving the lattice entities H_3O^+ (**1** and **2**) or H_2O (**3** and **4**) link chains in a 3-dimensional network. As an example, part of the network is shown for **1** in Fig. 3.

The stoichiometry of **1** and **2** is the same as that of the previously characterized $[Co(pyzdcH)_2(H_2O)_2]$ (12), $[Ni(pyzdcH)_2(H_2O)_2]$ (4), and $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (4), yet the five compounds encompass three very distinct structures. Structurally, **1** and **2** are more closely related to the copper compound, which has a chain structure with double-bridging $pyzdcH^-$ ligands (Fig 1(a)). This contrasts structurally with the cobalt and nickel complexes which are monometallic. Whereas $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ has H_2O molecules in the lattice, in **1** and **2** the lattice entity is H_3O^+. In effect, the hydroxyl protons of the $pyzdcH^-$ ligands, which are H-bonded to the lattice waters in the copper compound, are transferred to the lattice waters in **1** and **2**, thus forming the H_3O^+ ions. Evidence for this "transfer" comes from the X-ray analyses in which the hydrogen atoms in both structures were located and refined, clearly indicating the presence of H_3O^+ entities. In considering

[3] Supplementary material mentioned in the text may be purchased from: The Depository of Unpubliahed Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada K1A 0S2. Tables of hydrogen atom coordinates and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

Fig. 2. The structure of $[H_3O]_{2x}[Mn(pyzdc)_2]_x$ (**1**), with atom numbering scheme; 33% probability thermal elipsoids are shown.



why the ligand proton should be "transferred" from the hydroxyl group in the Mn and Cd compounds but not in the Cu compound, we note that in the latter the oxygen, O(4), of the carboxylic acid group is only weakly coordinated to a metal ion (Cu—O(4) distance 2.405(2) Å versus 1.948(1) Å for the distance involving the chelating oxygens, O(1)). Hence the acidity of the hydroxyl proton is not greatly enhanced by electron polarization effects of the metal ion and the proton remains bonded to O(3). In both **1** and **2**, however, each ligand has one oxygen from each of its carboxylate groups involved in comparable and relatively strong coordination to a metal (Mn—O(1) = 2.1486(9) Å, Mn—O(4) = 2.136(1) Å, Cd—O(1) = 2.2611(8) Å, and Cd—O(4) = 2.2716(8) Å); thus, the other carboxylate oxygens on each ligand, O(2) and O(3), are rendered weakly basic and the hydroxyl protons are transferred to water molecules, forming H_3O^+ entities. The weak Cu—O(4) interaction is a consequence of the preference of Cu(II) for distorted geometries, a factor not relevant for Mn(II) or Cd(II).

Interestingly the thermal properties of these compounds clearly reflect the difference in the lattice units. Whereas $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ undergoes dehydration with relative ease, losing the lattice water over the temperature range 50–160°C (4), **1** and **2** are thermally stable to significantly higher temperatures. Thermogravimetric analysis, TGA, of **1** shows it to be stable to about 150°C, decomposing with loss of two moles of H_2O and two moles of CO_2 over the range 150–265°C. This is in good agreement with an earlier thermal study on a structurally uncharacterized compound of the same stoichiometry as **1** (8). TGA studies on **2** show the compound to be stable to 165°C, decomposing with loss of two moles of H_2O and one mole of CO over the range 165–268°C.

Octahedral complexes of manganese(II), by virtue of their high unpaired spin density and orbitally non-degenerate ground state ($^6A_{1g}$ in O_h), are ideally suited for studies on magnetic exchange interactions. The possibility of magnetic exchange interactions mediated by the bridging $pydzdc^{2-}$ ligands in **1** was investigated by examining the magnetic prop-

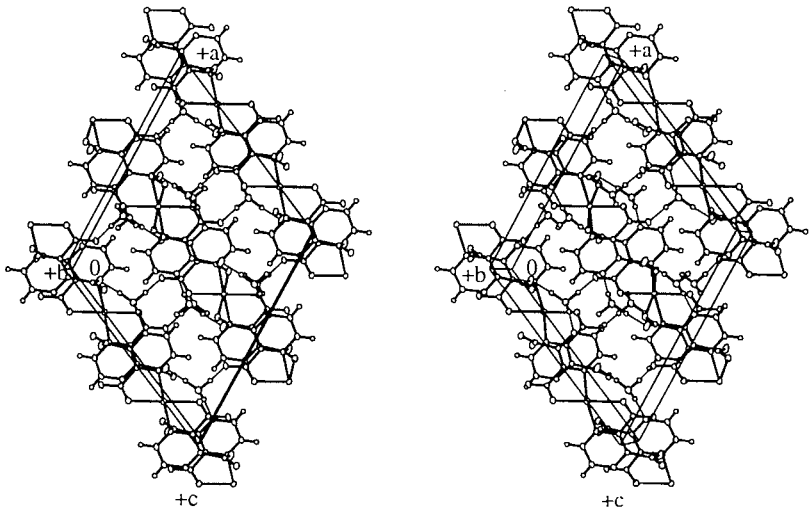
Fig. 3. Stereoscopic view showing part of the H-bonding network in $[H_3O]_{2x}[Mn(pyzdc)_2]_x$ (**1**).



erties of a powdered sample of the compound at low temperatures. The magnetic moment of **1** is 5.90 μ_B at 82 K and decreases only slightly to 5.70 μ_B at 4.4 K. In view of the known structure of the compound, the magnetic susceptibilities were analysed according to the Weng Heisenberg model for antiferromagnetically coupled linear chains of metal ions with the coefficients generated by Hiller et al. (13) for $S = 5/2$. Accordingly

$$[1] \quad \chi_M = [Ng^2\beta^2/kT]\,[A + BX^2]\,[1 + CX + DX^3]^{-1}$$

where for $S = 5/2$, $A = 2.9167$, $B = 208.04$, $C = 15.543$, $D = 2707.2$, and $X = |J|/kT$. Fits of the experimental data to the model were made using a nonlinear least-squares procedure with the following function minimized:

$$[2] \quad F = \left[\frac{1}{n}\sum_{i=1}^{n}\left(\frac{\chi^i_{calc} - \chi^i_{obs}}{\chi^i_{obs}}\right)^2\right]^{1/2}$$

where n is the number of data points. F provides a measure of the goodness of fit between theory and experiment. In the fitting procedure g was fixed at 2.00 and J, the exchange coupling constant, was allowed to vary. The best agreement between experiment and theory was obtained with $J = -0.017$ cm^{-1} ($F = 0.0094$).[4] The experimental magnetic moments as well as the line calculated using the best fit value of J are shown in Fig. 4. The magnitude of J is small and, particularly since zero field splitting effects can account for minor decreases in moment at low temperatures (14), not too much quantitative significance should be attached to it. Clearly though, the results place an upper limit of 0.017 cm^{-1} on the magnitude of the exchange coupling constant in **1** and show that antiferromagnetic exchange in the compound, if it exists at all, is very weak. It is of interest to compare the results for **1** with those reported earlier for the structurally related $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$. To compare complexes with different d^n configurations it is appropriate to compare values of $4S^2J$ (where S is the total spin) rather than J (15). The upper limit of this parameter for **1** is 0.43 cm^{-1}, comparable to, though greater than, the value 0.11 cm^{-1} for $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (4). A structural feature of the $pyzdc^{2-}$ bridge in **1** that is not seen in the depiction in Fig. 1(d) but is seen in the detailed representation in Fig. 2 concerns the CO_2 group engaged in the non-chelate metal binding; the plane of this group is almost orthogonal to the plane of the heterocyclic ring. This feature was noted previously in the case of the $pyzdcH^-$ bridging ligands in $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (4) and, as discussed there, such a situation would not favor magnetic exchange interactions as it eliminates a delocalized π-electron pathway for exchange.

[4] Here and elsewhere in this work the uncertainty in J is estimated to be approximately 10%.

$[Mn(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, 3, and $[Cd(pyzdc)(H_2O)_3]_x \cdot xH_2O$, 4

Compounds **3** and **4** have the same stoichiometry as that of the previously studied complexes of composition $[M(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (M = Co, Ni, or Cu) (4). Structurally though, **3** and **4** are different from one another and each has different structures from the other three. The Co, Ni, and Cu compounds are isomorphous (4) and have structures involving extended chains of metal ions linked by $pyzdc^{2-}$ ligands coordinated to two metal centres via chelate interactions as depicted in Fig. 1(b). Part of the structure of **3** with the atom numbering scheme is shown in Fig. 5. This structure consists of double chains of manganese ions in which $pyzdc^{2-}$ ligands provide O(3)-C(6)-O(4) bridges between metals in each chain and, through chelate interactions with metals in the other chain (involving a ring nitrogen, N(1), and a carboxylate oxygen, O(1) of the second carboxylate group), cross-link the chains forming a "ladder-like" motif. A similar double chain structure was reported earlier for $Zn(pyzdc) \cdot 3H_2O$ (6) and a simplified representation of the $pyzdc^{2-}$ bridging mode in **3** and in the zinc compound is shown in Fig. 1(c). There are, in addition, two *cis*-coordinated and two lattice water molecules per metal in **3**. We note that the metal – ligand chromophore in **3** is MNO_5 while in the analogous Co, Ni, and Cu complexes the chromophore is MN_2O_4. Manganese(II) often shows a prefer-

ence for O over N donors and this may, in part at least, account for the different structure adopted by **3**.

Consistent with the presence of lattice water in **3**, the compound undergoes decomposition at fairly low temperatures. TGA analysis revealed loss of water in two distinct steps involving loss of three moles over the range 50–175°C and a fourth water from 175 to 320°C. This is in good agreement with thermal studies reported previously (7) on a structurally uncharacterized compound of the same stoichiometry as **3**. The inconsistency of the pattern of

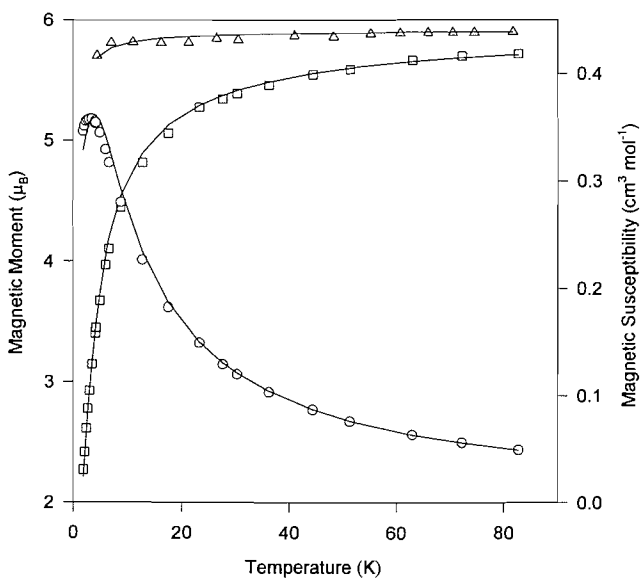
Fig. 4. Magnetic moment and magnetic susceptibility versus temperature plots: triangles and squares are moment data for **1** and **3**, respectively; circles are susceptibility data for **3**; lines are calculated from theory as described in the text.



water loss in relation to the structure of the original compound (two lattice and two coordinated water molecules) suggests that considerable structural rearrangement occurs during dehydration.

Cryomagnetic studies on **3** show the magnetic moment to decrease from 5.71 μ_B at 82 K to 2.27 μ_B at 1.9 K. Such behaviour indicates the presence of significant antiferromag-

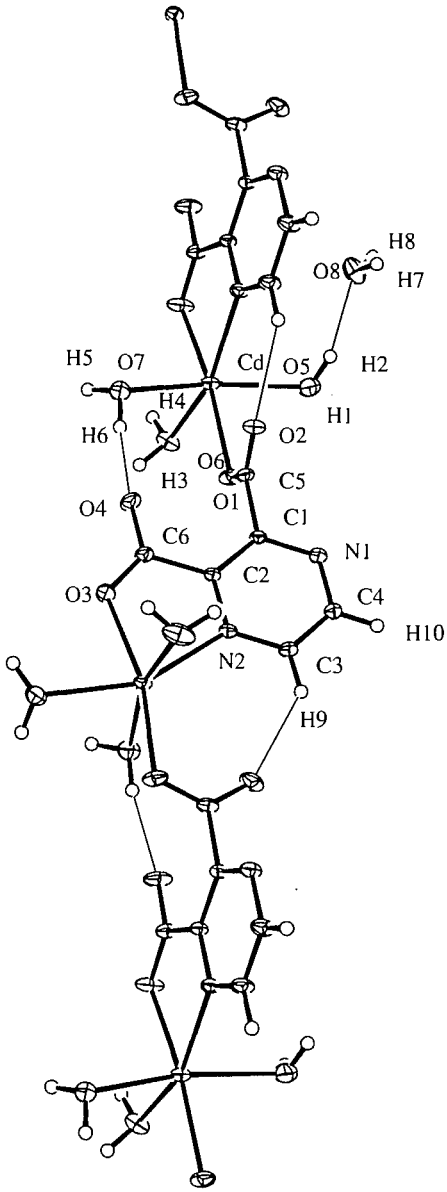
netic exchange, a fact confirmed by the observation of a maximum in the susceptibility versus temperature plot at about 3 K (Fig. 4). The structure of **3** shows each metal bonded to two nearest neighbours via O-C-O bridges and to a third nearest neighbour metal in the attached chain by the heterocyclic ring. This suggests the possibility of a fairly complex coupling scheme with at least two J's needed to characterize the system. However, in view of our results for **1** it seems likely that exchange mediated by the ligands between the chains will be very weak and, to a good approximation, may be ignored. The behaviour under such circumstances should follow that expected for isolated chains. Under this assumption, we examined fits of the magnetic susceptibility to the Weng linear chain model as described above and obtained a satisfactory best fit for $J = -0.27$ cm^{-1} with g fixed at 2.00 (F = 0.027). The experimental magnetic moments and susceptibilities as well as the lines calculated using the best fit value of J are shown in Fig. 4. In a classic paper on linear chain antiferromagnetism (16) Wagner and Friedberg determined that in $Mn(HCO_2)_2 \cdot 2H_2O$ chains of manganese(II) ions, linked by double-bridging carboxylate groups, are antiferromagnetically coupled with $J = -0.56$ cm^{-1}, while manganese ions linked by single-bridging carboxylates in the same structure are more weakly antiferromagnetically coupled. Consistent with these early results, our analysis shows that in **3** the single carboxylate-bridged manganese(II) ions are coupled antiferromagnetically with the magnitude of the exchange coupling constant approximately half that observed for the double carboxylate-bridged manganese chains in the formate compound.

Figure 6 shows part of the structure of **4** along with the atom numbering scheme. This structure consists of extended chains of cadmium ions in which single bridging $pyzdc^{2-}$ groups bind to metal centres as in **1** and **2** (Fig. 1(d)) and six-coordination about each metal is achieved with three water molecules coordinating in a *mer* fashion. There is one lattice water per metal in this structure and, consistent with this, the compound is thermally unstable above 60°C. TGA studies reveal loss of four H_2O over the temperature range 60–270°C. There are no other known examples of pyrazinedicarboxylates with the structure exhibited by **4**.

Summary and conclusions

All four of the compounds studied in this work have extended

Fig. 6. The structure of $[Cd(pyzdc)(H_2O)_3]_x \cdot xH_2O$ (**4**), with atom numbering scheme; 33% probability thermal elipsoids are shown.



chain structures. The novel "ladder-like" double chain structure of **3** is known to occur in one other pyrazinedicarboxylate structure, $Zn(pydc) \cdot 3H_2O$ (6), while the structural types exhibited by **1**, **2**, and **4** have not been reported previously. Cryomagnetic studies on **1** reveal, at best, only weak antiferromagnetic interactions and confirm an earlier observation that 2,3-pyrazinedicarboxylate ligands are not strong mediators of magnetic exchange when the π-pathway for exchange is disrupted. In **3**, moderate antiferromagnetic coupling occurs between magnetic centres where the pathway for exchange does not involve the heterocyclic part of the ligand but involves single O-C-O bridges. The magnitude of the exchange is consistent with that observed previously for carboxylate-bridged chains of manganese(II) ions.

Ryanoids and related compounds. Identification of five new ryanoids from the plant *Ryania speciosa* Vahl. Formal total syntheses of 3-deoxyryanodol (cinnzeylanol), 10-*O*-acetyl-3-deoxyryanodol (cinnzeylanine), 2-deoxyryanodol, 2-deoxy-2-epiryanodol, 2,3-dideoxy-2,3-dihydroryanodol, 2-deoxy-3-epiryanodol, and 2-deoxy-3-epiryanodine[1]

Luc Ruest and Marco Dodier

Abstract: In the course of a preliminary investigation on the relationships between the chemical structure of ryanoids and their affinity to the ryanodine binding site, we have isolated, from the plant *Ryania speciosa* Vahl, four new members of this family of natural insecticidal compounds (ryanoids **3**, **4**, **5**, and **6**) and corrected the reported structure of a fifth one (ryanoid **7**). In addition, we have synthesized, from anhydroryanodol (**10**), new members of this family having fewer hydroxyl groups in ring A: cinnzeylanol (**14**) and cinnzeylanine (**15**), 2,3-dideoxy-2,3-dihydroryanodol (**16**), 2-deoxy-3-epiryanodol (**18**), and 2-deoxy-3-epiryanodine (**19**), 2-deoxyryanodol (**20**), and 2-deoxy-2-epiryanodol (**21**).

Key words: ryanoids synthesis, cinnzeylanine, 2-deoxyryanodols, 2-deoxy-3-epiryanodine.

Résumé : Dans le cadre d'une étude préliminaire des relations structures chimiques – activité biologique des ryanoïdes et de leur affinité au site récepteur de la ryanodine, nous avons isolé de la plante *Ryania speciosa* Vahl, quatre nouveaux membres de cette famille d'insecticides naturels (les ryanoïdes **3**, **4**, **5** et **6**) et corrigé la structure déjà rapportée d'un cinquième (le ryanoïde **7**). Par ailleurs, à partir de l'anhydroryanodol (**10**), nous avons synthétisé quelques membres de cette famille, moins oxygénés au cycle A : le cinnzeylanol (**14**) et la cinnzeylanine (**15**), le 2,3-didéoxy-2,3-dihydroryanodol (**16**), le 2-déoxy-3-épiryanodol (**18**) et la 2-déoxy-3-épiryanodine (**19**), le 2-déoxyryanodol (**20**) et le 2-déoxy-2-épiryanodol (**21**).

Mots clés : synthèse de ryanoïdes, cinnzeylanine, 2-déoxyryanodols, 2-déoxy-3-épiryanodine.

Introduction

Ryanodine (**1**) (Fig. 1) (1–3) is an interesting and important calcium release channel modulator in mammalian muscles (4).[3] In a search to identify the structural features that are necessary to maintain biological activity, we (5–7) and others (8–14) have recently focused on the characterization of new ryanoids from the plant *Ryania speciosa* Vahl, and also on skeleton and functional group modifications (5, 6, 8, 10, 15–24) in order to obtain more information on their eventual role in the affinity of these molecules to the ryanodine binding site.

[3] A recent review on ryanodine will appear shortly in Pharmacological Reviews.

Recently, we have identified four new ryanoids (**3**–**6**) (Fig. 1) and corrected the structure of a fifth one (**7**) reported earlier (10). We have also modified the oxidation level of ring A of the ryanodine skeleton, which resulted in the syntheses of two natural diterpenes, cinnzeylanol (**14**) and cinnzeylanine (**15**) (25, 26), and of several other compounds (**16**, **18**–**20**, **21**).

Results and discussion

New natural ryanoids

The new natural ryanoids were obtained by chromatographic separation of the crude extracts of powdered *Ryania speciosa* wood after removal of the most abundant ryanoids (5, 8, 12, 13). We noted that simple crystallization of column-purified ryanodine left, in the mother liquors, an enriched mixture of ryanodine (**1**), 9,21-didehydroryanodine (**2**), and two new compounds: 9α,21-epoxyryanodine (**3**) and 3-*O*-benzoyl-18-hydroxyryanodol (**5**). The epoxide **3** was obtained in pure form via HPLC. Epoxide **3** has been synthesized previously by epoxidation of 9,21-didehydroryanodine (**2**) (10, 19, 23).

Benzoate **5** and ryanodine (**1**) have the same HPLC reten-

tion time and were first obtained as a 1:5 mixture. Fractional crystallization of ryanodine from this mixture gave mother liquors enriched in benzoate (ca. 40%). The resulting mixture was reacted with ozone (10), which cleaved the pyrrole moiety of ryanodine but left benzoate unaltered. A final TLC purification of the ozonolysis mixture gave pure compound **5**. The location of the hydroxyl group in **5** at position 18 follows the discussion below, which combines both NMR and X-ray diffraction analyses and offers the possibility of discriminating between 18- and 19-hydroxylated ryanoids when an aromatic ring is present at position 3.

From the group of ryanoids more polar than 9,21-dehydroryanodine (**2**), we isolated three other compounds, **4**, **7**, and **6** (in order of increasing polarity), hydroxylated at the isopropyl group, and fortunately crystallized the one that showed the same NMR data as a ryanoid reported previously (10). X-ray analysis of that ryanoid (see **7**, Fig. 2) (27), showed that the isopropylic hydroxyl group is located at position 19, close to the shielding area of the pyrrole ring attached as a pyrrole-2-carboxylate at C3. The remaining protons at C19 appear as an ABX pattern centered at about 3.6 ppm while the C18 methyl group occurs as a doublet at about 1.27 ppm. For the other isomer **4**,[4] which carries the OH at C18, the unshielded ABX pattern and shielded methyl doublet are found at 3.9 and 0.9 ppm, respectively. The same concordant arguments have been applied to the new 9,21-didehydroryanodine **6**, hydroxylated at position 18, and also to benzoate **5**, which both show an ABX pattern close to 3.9 ppm and a shielded methyl doublet at 0.89 ppm.

Synthetic achievements

The ryanodine molecule has been derivatized extensively, first by Wiesner and co-workers (2, 28) to elucidate its structure and subsequently by several groups to establish the structural features important for biological activity and to make experimentally useful analogs. Since 1984, most of the modifications done by us and others have involved ryanodine (**1**), 9,21-didehydroryanodine (**2**), and ryanodol (**8**). Several modifications were made at positions 8, 9, 10, and 21 in ring C (10, 15, 16, 18, 29–24). Various nucleophiles have recently been introduced at C4 and C12 (17). Some years ago, we described (18) the epimerization of ryanodine at position 3 and we wish now to report other modifications in ring A that led us to the syntheses of the title compounds.

Syntheses of cinnzeylanol (14) and cinnzeylanine (15) from anhydroryanodol (10)

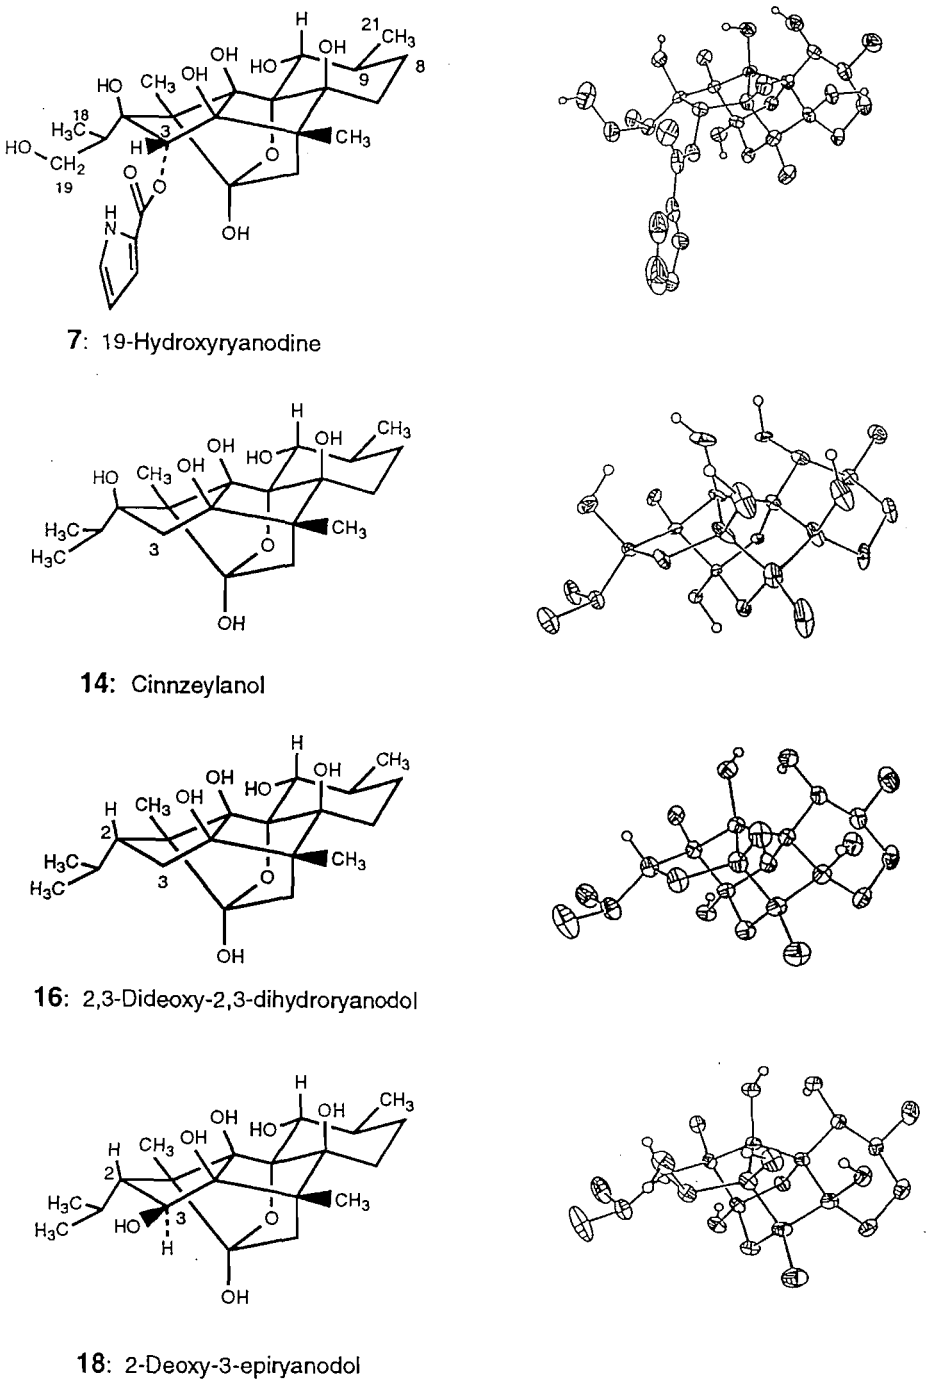
Cinnzeylanol (**14**) and cinnzelanine (**15**) (Scheme 1) were isolated from *Cinnamomi Cortex* by Nohara et al. (25). Very recently, compounds of this family were also isolated from *Persea indica* by Fraga and co-workers (26). These natural diterpenes are closely related to ryanodol (**8**), being its 3-deoxy analogs. Synthetically, the specific removal of the 3-*endo* hydroxyl group from the ryanodol molecule appears not a trivial operation. Previously (18), we showed (Scheme 2) how either ryanodine (**1**) or ryanodol (**8**) can lead to olefin **11** through anhydroryanodine (**9**) or anhydroryanodol (**10**). Based on the conversion of ryanodine (**1**) to anhydroryanodine (**9**) (2, 28), we proceeded to the treatment of the olefin **11** (Scheme 1) with strong acid, which resulted in the formation (89%) of anhydrocinnzelanol (**12**) by C1—C15 bond cleavage, promoted by protonation of the C2—C3 double bond. Compound **12** was oxidized (18) to epoxide **13**, which underwent a transannular cyclization to give cinnzeylanol (**14**), in 75% yield, under the reductive action of lithium in ammonia. This intramolecular cyclization had been used in the total syntheses of ryanodol (29, 30) and of 3-epiryanodol (18). The structure of compound **14** was confirmed by X-ray diffraction analysis (see Fig. 2) (27). Acetylation of **14** gave cinnzeylanine (**15**).

Synthesis of 2,3-dideoxy-2,3-dihydroryanodol (16)

Removal of a second oxygen atom (the one at C2) from the

[4] This ryanoid, 18-hydroxyryanodine (**4**), was also observed recently by Prof. H.R. Besch, Jr. and Dr K.R. Bidasee, Department of Pharmacology and Toxicology, Indiana University School of Medicine, Indianapolis, Indiana 46202, U.S.A. (personal communication, 1995).

Fig. 2. ORTEP perspective view of crystalline **7**, **14**, **16**, and **18**: 30% probability thermal ellipsoids are shown for the non-hydrogen atoms.



ryanodol molecule also became possible by submitting anhydrocinnzeylanol (**12**) (Scheme 3) directly to the reducing action of lithium in ammonia. Thus was obtained, in 92% yield, compound **16**, which has no hydroxyl group in ring A aside from those common with ring B at positions 4 and 12. The stereochemistry at position 2 of that compound was clearly established by X-ray diffraction (see Fig. 2) (27). We did not observe the presence of the possible epimer at that position. An attack (see Fig. 3, path a) of the unactivated C1—C2 double bond by the proximate radical anion, first developed at the lactone carbonyl group (see **12A**), has to be invoked as a possible mechanistic explanation (18, 31–33). Subsequent fast reduction of this radical species would give a highly basic alkyl anion at C2 (see **12B**) that would be protonated immediately in this medium from the "*exo*" face of the molecule, to give **16**.

Scheme 1.

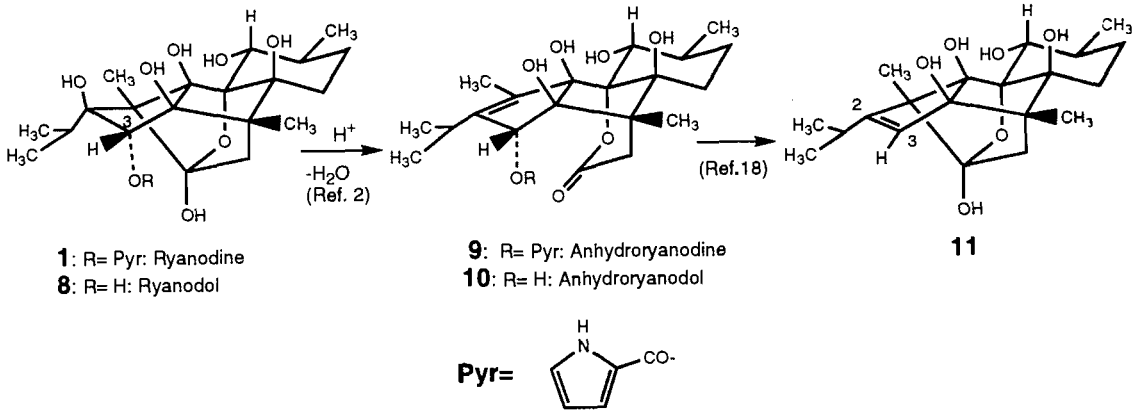
Scheme 2.



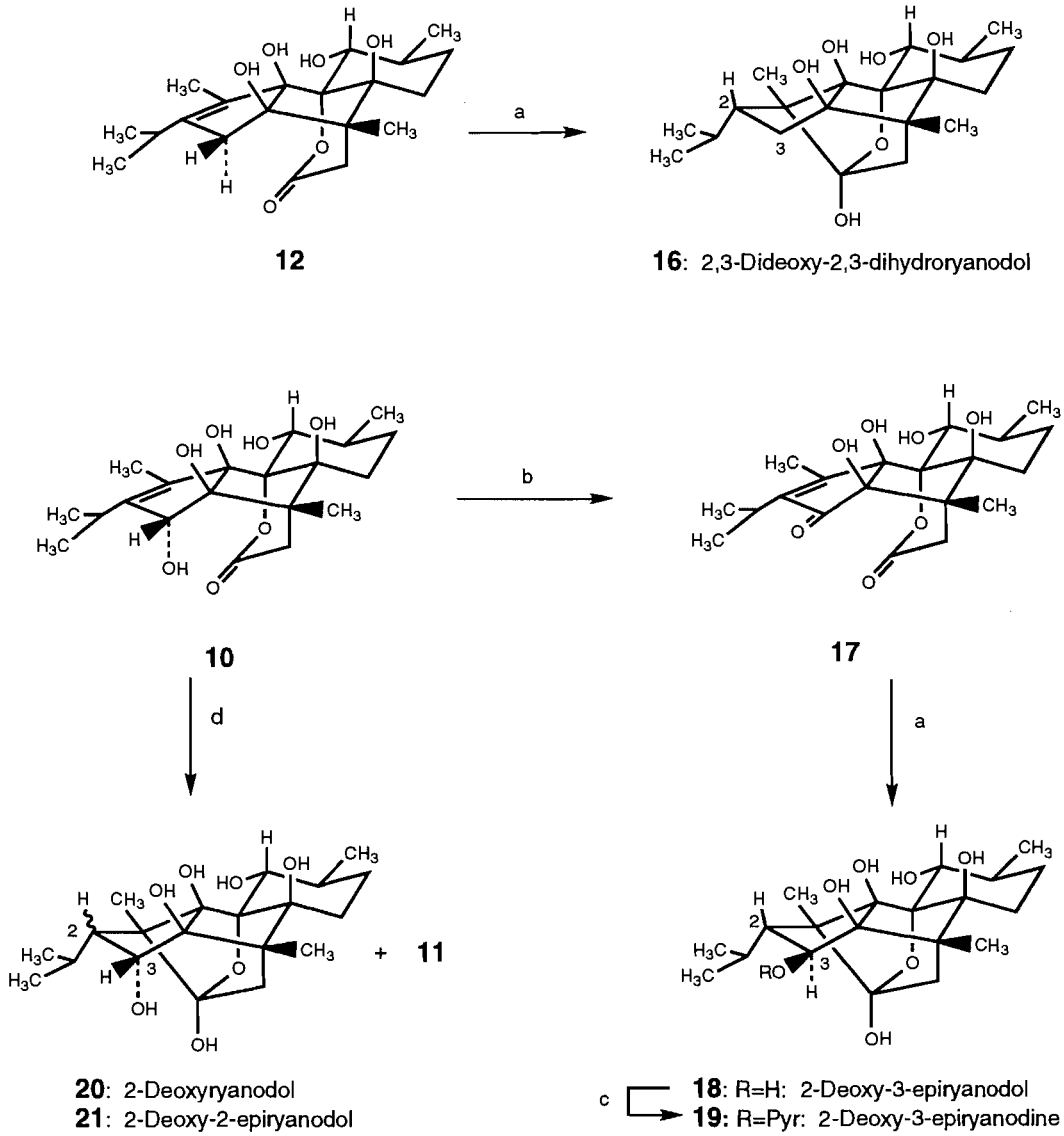
Synthesis of 2-deoxy-3-epiryanodol (18) and 2-deoxy-3-epiryanodine (19)

Oxidation of anhydroryanodol (**10**) with manganese dioxide (30) gave enone **17**, which was submitted to lithium in ammonia and furnished 2-deoxy-3-epiryanodol (**18**) in 69% yield. The stereochemistry at position 2 was clearly established by X-ray diffraction analysis (see Fig. 2) (27). A possible mechanistic explanation (see Fig. 3, path b) involves a dianion (or a radical anion) formed in the enone moiety that could attack, from C1, the lactone carbonyl (or, respectively, a lactone radical anion), thus forming the C1—C15 bond. Rapid *exo*-protonation at C2 of the resulting enolate **17A** would then give cyclopentanone **17B**, which would be reduced by lithium and protonated to give the most stable 3-*exo* hydroxyl group, with "*anti*" substituents at positions 2 and 3. Selective acylation of the 3-*epi*-hydroxyl group of **18** with 2-pyrrolecarboxylic acid (34) furnished 2-deoxy-3-epiryanodine (**19**).

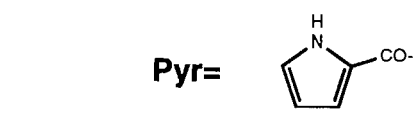
Synthesis of 2-deoxyryanodol (20) and 2-deoxy-2-epiryanodol (21)

Anhydroryanodol (**10**), when first submitted (Scheme 3) to the action of a strong base, then transferred into the usual lithium–ammonia reducing medium, furnished a mixture of 2-deoxy epimers (24%) of ryanodol **20** and **21** together with the already known alkene **11** (54%). The basic treatment was used to deprotonate (see Fig. 3, path c) the 3-*endo* hydroxyl group, thus removing its reactivity as a leaving group (which, otherwise, gives alkene **11**). This alkoxide **10A** would be reduced to

Scheme 3.



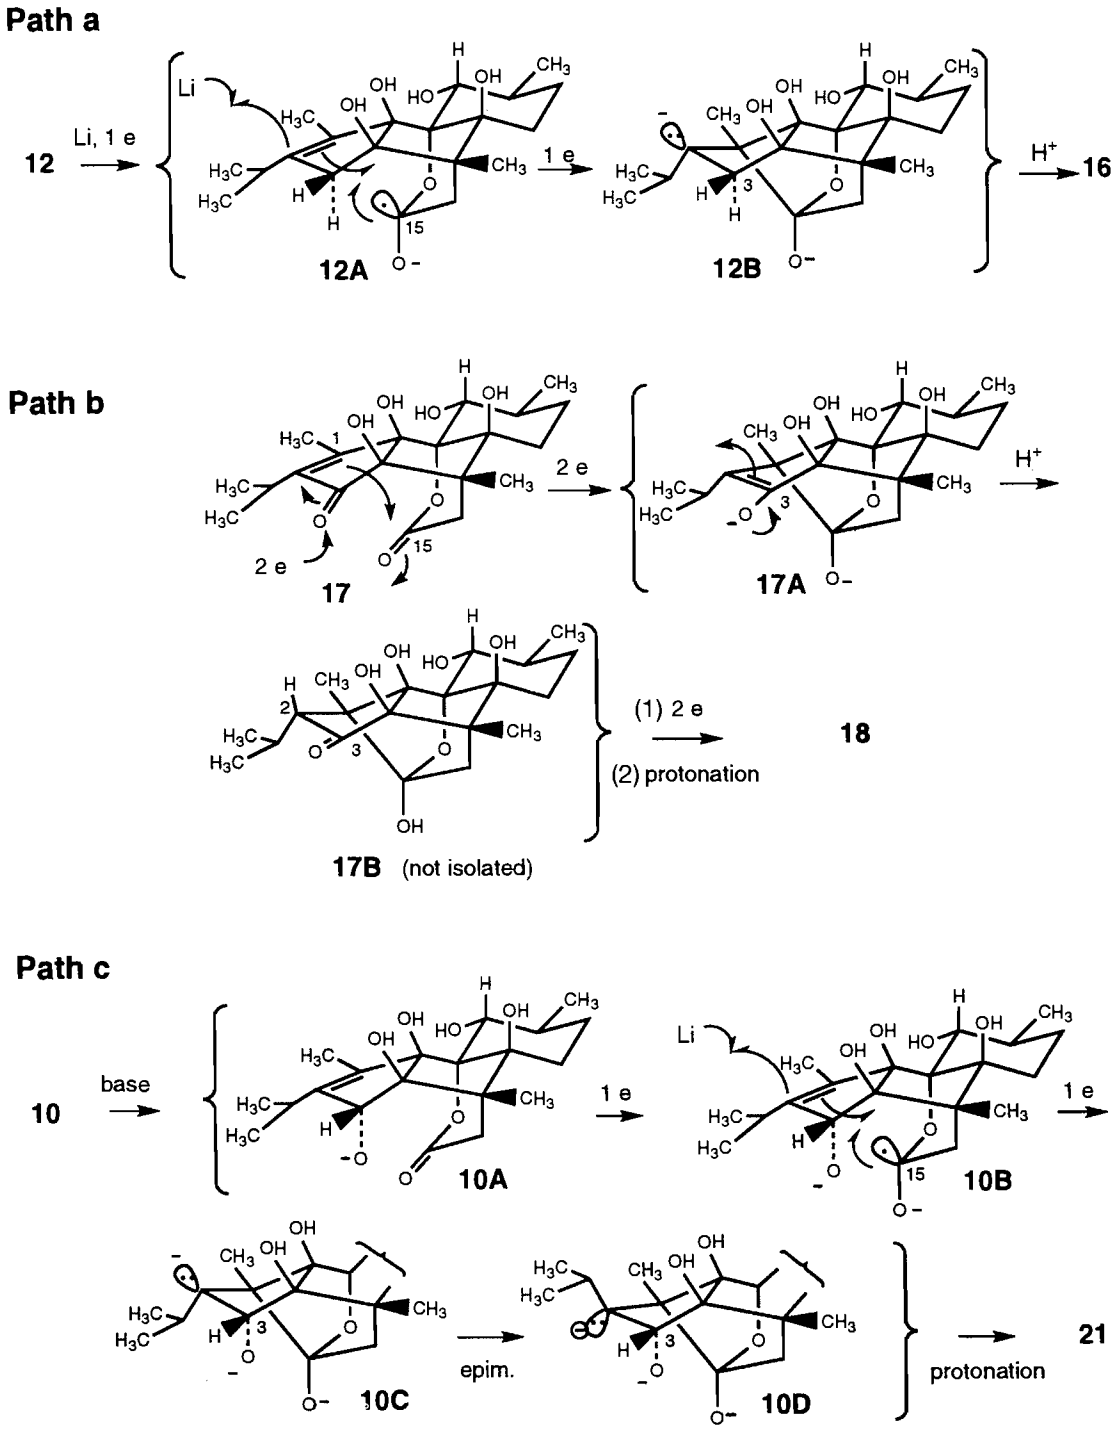
Reaction conditions: a: Li, NH_3, THF, 92% in **16**; 69% in **18**; b: MnO_2, $CHCl_3$, 69%; c: Pyrrole-2-carboxylic acid, Diphenylphosphorylazide (DPPA), Et_3N, DMF, 13%; d: LDA, THF then condition a, 24% in **20** and **21**; 54% in **11**.



10B and the usual C1—C15 reductive cyclization previously described would occur and lead to an anion (see **10C**) located at C2. Based on steric arguments this species should normally invert at C2 towards "*anti*" mutual orientation of the isopropyl and hydroxyl groups (see **10D**), leading to compound **21** after protonation. By calculation (see **20**, **21A**, and **21B**, Fig. 4), isomer **21** should be sterically favored by more than ~2.0 kcal/mol over the "*syn*" isomer. On the other hand, stereoelectronic arguments (delocalization of the anion at C2 in the antibonding orbital of the C3—O bond; n–σ^* interaction) (35), suggest an enhanced stability of the "*syn*" stereochemistry that would allow a protonation of **10C** from the *exo* face to yield compound **20**. The presence of a 1:1 mixture (see experimental) of these 2-epimers (besides favoring **21** by >95:5) suggests that stereoelectronic effects indeed play a significant role in the stabilization of anion **10C**.

In conclusion, we identified five new minor ryanoids in the extracts of *Ryania speciosa*. In a preliminary attempt to relate the structure of ryanoids to their affinity to the ryanodine receptor, we have focused on ring A and showed that positions

Fig. 3.



2 and 3 of these molecules can be specifically deoxygenated, leading to hydrophobic ring A. The impact of the reported modifications on affinity is currently under analysis[5] through measurements of the affinities of a number of specific derivatives of each of these compounds and the results of this analysis will be reported elsewhere. Access to other positions of the ryanodine molecule are currently under investigation.

Experimental section

Melting points were recorded on a Reichert hot stage apparatus and are uncorrected Mass spectra (ms) and peak matching (HRMS) data were determined at 70 eV on a VG Micromass

ZAB-1F spectrometer. Infrared absorption spectra were measured on a FT-IR Perkin–Elmer 1600 spectrophotometer. The ^1H (300 MHz) and ^{13}C (75 MHz) NMR spectra were recorded on a Bruker AC-300 instrument (with CHD_2OD as internal standard centered at 3.30 or 49.15δ). Some ^{13}C peaks are obscured by the strong solvent signal at ~49δ. The usual standard abbreviations have been used to indicate the multiplicity of the proton signals. Analytical and preparative thin-layer chromatography were carried out on glass plates 0.25 or 0.5 mm precoated with silica gel 60F-250 (Merck). Column chromatography was performed with Merck silica gel (200–400 mesh). HPLC utilized a Waters model 510 instrument equipped with a Vydac C18 reverse-phase preparative column (15 μm, 2.5 × 25 cm) and a Waters 484 tunable UV detector set at 254 nm. A typical solvent for HPLC preparative separation was a mixture of 40% methanol in water. All reactions were performed under argon atmosphere and in solvents purified by standard methods. Reaction mixtures were extracted with at least five portions of distilled ethyl acetate. Solutions in organic solvents were washed with brine, dried over anhydrous magnesium sulfate or anhydrous sodium sulfate, filtered, and then stripped of solvents with a rotatory evaporator connected to a water aspirator. Molecular modelling was performed using the MOPAC program by means of semiempirical AM1 methods.

Isolation of the new ryanoids

Extraction of powdered Ryania wood was done as previously described in the literature (1, 5, 13) but over a longer period of time (average 11 compared to 3–4 days). The crude extract was partitioned into three main fractions by column chromatography: in the fraction less polar than ryanodine we did not observe the presence of any new ryanoid other than the ones already described. The intermediate main fraction containing ryanodine–dehydroryanodine mixture was thoroughly crystallized from acetone–hexane to give the usual crystalline mixture of ryanodine (**1**) and dehydroryanodine (**2**) and leave the mother liquors, enriched in two new compounds: epoxide **3** and benzoate **5**. A sample of this mixture was purified by HPLC under the general conditions described above and gave (in order of decreasing polarity) pure epoxide **3**, pure dehydroryanodine (**2**), and a ~5:1 mixture of ryanodine (**1**) and benzoate **5**, along with small quantities of other known ryanoids. By further crystallization (acetone–hexane) of ryanodine from this new mixture, the proportion became ~3:2. Treatment with ozone of a sample of this mixture following a known procedure (10) gave a mixture of several compounds from which unaltered benzoate **5** was easily purified by plate chromatography (0.5 mm, 10% methanol in chloroform). The third fraction, more polar than the main one, furnished compounds **4**, **7**, and **6** (in order of increasing polarity) by HPLC separation, along with other known polar ryanoids already reported (7, 11, 13, 14).

0.75 (d, 6.4 Hz, 3H, CH_3C13); ms *m/e*: 507 (M^+, weak); HRMS calcd. for $C_{25}H_{33}O_{10}N$: 507.2104 (M^+); found: 507.2097.

18-Hydroxy-3-O-benzoylryanodol (5): ^1H NMR (CD_3OD, δ ppm): 8.06 (2H), 7.66 (1H) and 7.53 (2H) (3 m for Ar-H), 5.72 (s, 1H, HC3), 3.91 (app. d, 4.8 Hz, 2H, 2H, H_2C18), 3.79 (d, 10.1 Hz, HC10), 2.51 (d, 13.7 Hz, 1H, H_AC14), 2.25 (m, 1H, HC13), 2.10 (m, 1H, $H_{ax}C7$), 1.98 (d, 13.7 Hz, 1H, H_BC14), 1.85 (m, 1H, HC9), 1.50 (m, 2H, $H_{ax}C8$, $H_{eq}C7$), 1.42 (s, 3H, CH_3C1), 1.22 (m, 1H, $H_{eq}C8$), 1.01 (d, 6.5 Hz, 3H, CH_3C9), 0.88 (d, 6.5 Hz, 3H, CH_3C13), 0.82 (s, 3H, CH_3C5); ms *m/e*: 502 ($M^+ - H_2O$); HRMS calcd. for $C_{27}H_{34}O_9$ ($M^+ - H_2O$): 502.2203; found: 502.2198.

18-Hydroxyryanodine (4): ^1H NMR (CD_3OD, δ ppm): 7.03, 6.87, and 6.23 (3 m for pyrrole hydrogens), 5.59 (s, 1H, HC3), 3.94 (dd, 10.3 and 5.4 Hz, 1H, H_AC18), 3.85 (dd, 10.3 and 3.9 Hz, H_BC18), 3.79 (d, 10.2 Hz, 1H, HC10), 2.50 (d, 13.8 Hz, 1H, H_AC14), 2.21 (m, 1H, H_XC13), 2.09 (m, 1H, $H_{ax}C7$), 1.94 (d, 13.8 Hz, 1H, H_BC14), 1.89 (m, 1H, HC9), 1.50 (m, 2H, $H_{eq}C7$, $H_{ax}C8$), 1.41 (s, 3H, CH_3C1), 1.23 (m, 1H, $H_{eq}C8$), 1.00 (d, 6.4 Hz, CH_3C9), 0.90 (d, 7.3 Hz, CH_3C13), 0.88 (s, 3H, CH_3C5); ms *m/e*: 491 ($M^+ - H_2O$); HRMS calcd. for $C_{25}H_{33}O_9N$ ($M^+ - H_2O$): 491.2155; found: 491.2148.

19-Hydroxyryanodine (7): NMR data of this ryanoid in CD_3OD are slightly different from those reported in a mixture of $CDCl_3$ and CD_3OD (10). We confirmed that addition of $CDCl_3$ to a solution of **7** in CD_3OD almost removes these differences; mp 153–155°C (CH_3OH); ^1H NMR (CD_3OD, δ ppm): 6.98, 6.91, and 6.21 (3 m for pyrrole hydrogens), 5.55 (s, 1H, HC3), 3.78 (d, 10.2 Hz, 1H, HC10), 3.54 (dd, 10.8 and 4.6 Hz, 1H, H_AC19), 3.46 (dd, 10.8 and 2.4 Hz, 1H, H_BC19), 2.33 (d, 13.8 Hz, 1H, H_AC14), 2.18 (m, 1H, H_XC13), 1.98 (m, 1H, $H_{ax}C7$), 1.87 (d, 13.8 Hz, 1H, H_BC14), 1.77 (m, 1H, HC9), 1.50–1.35 (m, 2H, $H_{eq}C7$, $H_{ax}C8$), 1.34 (s, 3H, CH_3C1), 1.27 (d, 6.8 Hz, 3H, CH_3C13), 1.23 (m, 1H, $H_{eq}C8$), 0.97 (d, 6.5 Hz, CH_3C9), 0.81 (s, 3H, CH_3C5); ms *m/e*: 491 ($M^+ - H_2O$); HRMS calcd. for $C_{25}H_{33}O_8N$ ($M^+ - H_2O$): 491.2155; found: 491.2148.

18-Hydroxy-9,21-dehydroryanodine (6): ^1H NMR (CD_3OD, δ ppm): 7.03, 6.88, and 6.23 (3 m for pyrrole hydrogens), 5.61 (s, 1H, HC3), 5.05 and 4.86 (2 br s, 1H each, H_2C21), 4.74 (br s, 1H, HC10), 3.94 (dd, 10.4 and 5.3 Hz, 1H, H_AC18), 3.89 (dd, 10.4 and 3.8 Hz, 1H, H_BC18), 2.49 (d, 13.8 Hz, 1H, H_AC14), 2.29–2.07 (m, 3H, HC13, HC7, HC8), 1.92 (d, 13.8 Hz, 1H, H_BC14), 1.42 (s, 3H, CH_3C1), 1.38–1.26 (m, 2H, HC7, HC8), 0.91 (s, 3H, CH_3C5), 0.90 (d, 6.4 Hz, 1H, CH_3C13); ms *m/e*: 489 ($M^+ - H_2O$); HRMS calcd. for $C_{25}H_{31}O_9N$ ($M^+ - H_2O$): 489.1999; found: 489.2010.

Synthesis of 3-deoxyryanodol (cinnzeylanol) (14) and cinnzeylanine (15)

Anhydrocinnzeylanol (3-deoxyanhydroryanodol) (12)
Concentrated sulfuric acid (0.1 mL) was added, at 25°C, to a solution of olefin **11** (26 mg, 0.074 mmol) in methanol (10 mL) and the mixture refluxed for 40 h. The cooled mixture was transferred into aqueous sodium bicarbonate (5%) and extracted with ethyl acetate. The crude product was chromatographed on silica plate (0.5 mm, 10% methanol in chloroform) to give pure **12** (23 mg, 89%); mp 110–112°C (MeOH); IR (film, ν cm^{-1}): 3389, 2922, 1732, 1461; ^1H NMR (CD_3OD, δ ppm): 4.02 (d, 10.0 Hz, 1H, HC10), 2.70 (m, 1H, HC13), 2.61 (dq, 17.5 and 1.7 Hz, 1H, H_AC3), 2.45 (d, 19.5 Hz, 1H, H_AC14), 2.36 (d, 19.5 Hz, 1H, H_BC14), 2.10 (dq, 17.5 and 2.6 Hz, H_BC3), 1.80 (m, 1H, HC9), 1.72 (br s, 3H, CH_3C1), 1.63–1.48 (m, 4H, H_2C7), 1.07 (d, 6.4 Hz, 3H, CH_3C9), 1.02 (s, 3H, CH_3C5), 1.00 (d, 7.0 Hz, 3H, CH_3C13), 0.94 (d, 7.0 Hz, 3H, CH_3C13); ^{13}C NMR (CD_3OD, δ ppm): 174.2, 148.6, 137.6, 87.1, 75.6, 75.4, 43.3, 39.9, 37.6, 31.4, 30.9, 29.3, 23.3, 23.0, 21.4, 16.1, 14.5; ms *m/e*: 349 ($M^+ - H_2O$); HRMS calcd. for $C_{20}H_{29}O_5$ ($M^+ - H_2O$): 349.2015; found: 349.2008.

1,2-Epoxyanhydrocinnzeylanol (13)
At ambient temperature, solid sodium bicarbonate (2 mg) was added to a solution of anhydrocinnzeylanol (**12**) (27 mg, 0.074 mmol) in a mixture of 1,2-dichloroethane (2 mL) and acetonitrile (1 mL). To this mixture was added a solution of trifluoroperacetic acid (1 N, 120 μL) in 1,2-dichloroethane. After 20 h at room temperature and addition of aqueous sodium thiosulfate (0.1 N, 2 mL), the mixture was extracted with ethyl acetate and the crude product was chromatographed (flash, 5–10% methanol in chloroform) to give epoxide **13** (19 mg, 71%); mp 182–184°C (MeOH); IR (film, ν cm^{-1}): 3426, 2968, 1731; ^1H NMR (CD_3OD δ ppm): 4.04 (d, 10.5 Hz, 1H, HC10), 2.78 (d, 20.0 Hz, 1H, H_AC3), 2.63 (d, 20.0 Hz, 1H, H_BC3), 2.25 (d, 15.6 Hz, 1H, H_AC14), 1.75 (m, 1H, HC9), 1.60 (d, 15.6 Hz, 1H, H_BC14), 1.65–1.50 (m, 4H, H_2C7, H_2C8), 1.54 (s, 3H, CH_3C1), 1.06 (d, 6.3 Hz, 3H, CH_3C9), 1.00 (d, 6.9 Hz, 3H, CH_3C13), 0.96 (d, 5.9 Hz, CH_3C13), 0.94 (s, 3H, CH_3C5); ^{13}C NMR (CD_3OD, δ ppm): 173.2, 95.4, 87.5, 80.6, 78.9, 75.4, 43.8, 38.1, 37.4, 33.1, 29.4, 21.2, 20.7, 17.3, 16.4; ms *m/e*: 382 (M^+); HRMS calcd. for $C_{20}H_{30}O_7$: 382.1991; found: 382.1989.

Cinnzeylanol (3-deoxyryanodol) (14)
A solution of epoxide **13** (29 mg, 0.076 mmol) in tetrahydrofuran (THF) (3 mL) was transferred (cannula) into a blue solution of lithium (50 mg) in ammonia (10 mL, −78°C). The mixture was stirred for 30 min, then treated with solid ammonium chloride (100 mg) and stirred until discoloration (~5 min). Ammonia was allowed to escape while raising the temperature to 25°C and the residue was dissolved in water and extracted with ethyl acetate. Pure cinnzeylanol (**14**) (22 mg, 75%) was obtained from the crude product by flash chromatography (10% methanol in chloroform); mp 140–141°C (MeOH) (lit (26) mp 140–141°C (25) 139–142°C); IR (film, ν cm^{-1}): 3366, 2937, 1469, 1017; ^1H NMR (CD_3OD, δ ppm): 3.79 (d, 10.2 Hz, 1H, HC10), 2.41 (d, 15.5 Hz, 1H, H_AC3), 2.10 (app td, 12.5 and 5.8 Hz, $H_{ax}C7$), 1.92 (m, 1H, HC13), 1.84 (d, 13.6 Hz, H_AC14), 1.80 (m, 1H, HC9) 1.76 (d, 15.5 Hz, 1H, H_BC3), 1.73 (d, 13.6 Hz, 1H, H_BC14), 1.60–1.40 (m, 2H, $H_{ax}C8$, $H_{eq}C7$), 1.31 (s, 3H, CH_3C1), 1.28 (m, 1H, $H_{eq}C8$), 1.00 (d, 6.4 Hz, 3H, CH_3C9), 0.99 (d, 6.7 Hz, 3H, CH_3C13), 0.95 (d, 6.7 Hz, 3H, CH_3C13), 0.86 (s, 3H, CH_3C5); ^{13}C NMR (CD_3OD, δ ppm): 102.4, 98.3, 90.2, 87.3, 86.3, 72.8 (2), 43.4, 35.3, 34.2, 29.5, 27.3, 19.1, 18.9, 18.8, 11.1, 9.7; ms *m/e*: 366 ($M^+ - H_2O$); HRMS calcd. for $C_{20}H_{30}O_6$ ($M^+ - H_2O$): 366.2042; found: 366.2050.

Cinnzeylanine (10-O-acetyl-3-deoxyryanodol) (15)

To a solution of alcohol **14** (25 mg, 0.065 mmol) in THF (10 mL) was successively added triethylamine (19 μL, 0.14 mmol), acetic anhydride (1.0 mL of a 0.1 M solution in THF, 0.10 mmol), and 4-dimethylaminopyridine (DMAP) (3 mg). After 48 h at room temperature, the mixture was poured onto aqueous sodium bicarbonate (5%) and extracted with ethyl acetate. The crude product was chromatographed on two silica plates (0.5 mm, 10% methanol in chloroform) to furnish cinnzeylanine (**15**) (4.9 mg, 18%), anhydrocinnzeylanol (**12**) (2.9 mg), and anhydrocinnzeylanine (2.4 mg), along with unchanged starting material **14** (11 mg); this yield was not optimized; ^{1}H NMR (CD_3OD, δ ppm): 5.26 (d, 10.7 Hz, 1H, HC10), 2.39 (d, 15.5 Hz, 1H, H_AC3), 2.12 (m, 1H, HC9), 2.05 (s, 3H, CH_3CO), 1.92 (app td, 13.5 and 6.6 Hz, 1H, $H_{ax}C7$), 1.89 (m, 1H, HC13), 1.85 (d, 13.7 Hz, 1H, H_AC14), 1.74 (d, 13.7 Hz, 1H, H_BC14), 1.72 (d, 15.5 Hz, 1H, H_BC3), 1.56 (m, 2H, $H_{ax}C8$, $H_{eq}C7$), 1.34 (m, 1H, $H_{eq}C8$), 1.33 (s, 3H, CH_3C1), 1.00 (d, 6.6 Hz, 3H, CH_3C9), 0.94 (d, 6.9 Hz, 3H, CH_3C13), 0.87 (s, 3H, CH_3C5), 0.84 (d, 6.6 Hz, 3H, CH_3C13); ms *m/e*: 426 (M^+, weak), 408 ($M^+ - H_2O$); HRMS calcd. for $C_{22}H_{32}O_7$ ($M^+ - H_2O$): 408.2148; found: 408.2142.

Synthesis of 2,3-dideoxy-2,3-dihydroryanodol (16)

A solution of anhydrocinnzeylanol (**12**) (18 mg, 0.049 mmol) in THF (2 mL) was transferred (cannula) into a cold (−78°C) blue solution of lithium (20 mg) in ammonia (10 mL). After 30 min of stirring and addition of solid ammonium chloride (100 mg), the discolored mixture was allowed to warm to room temperature (evaporation of ammonia). The solid residue was dissolved in water and extracted with ethyl acetate to give pure compound **16** (17 mg, 92%); this compound was recrystallized (MeOH) for monocrystal X-ray diffraction analysis: mp 217–220°C; IR (film, ν cm^{-1}): 3282, 2944, 1459, 1005; ^{1}H NMR (CD_3OD, δ ppm): 3.80 (d, 10.2 Hz, 1H, HC10), 2.13 (app td, 12.3 and 5.9 Hz, 1H, $H_{ax}C7$), 1.90–1.70 (m, 7H, HC13, HC9, H_2C14, H_2C3, HC2), 1.55–1.43 (m, 2H, $H_{ax}C8$, $H_{eq}C7$), 1.28 (m, 1H, $H_{eq}C8$), 1.21 (s, 3H, CH_3C1), 1.03 (d, 5.7 Hz, 3H, CH_3C13), 1.00 (d, 6.5 Hz, 3H, CH_3C9), 0.90 (d, 5.7 Hz, 3H, CH_3C13), 0.86 (s, 3H, CH_3C5); ^{13}C NMR (CD_3OD, δ ppm): 103.5, 97.5, 90.8, 87.2, 73.1, 61.9, 50.9, 43.4, 39.0, 35.4, 30.4, 29.5, 27.4, 24.1, 23.7, 18.9, 11.2; ms *m/e*: 368 (M^+); HRMS calcd. for $C_{20}H_{32}O_6$: 368.2199; found: 368.2192.

Syntheses of 2-deoxy-3-epiryanodol (18) and 2-deoxy-3-epiryanodine (19)

3-Oxoanhydroryanodol (17)

Following a slightly modified procedure (30), a solution of anhydroryanodol (**10**) (17 mg, 0.044 mmol) in chloroform (10 mL) was reacted with activated manganese dioxide (25 mg) at 25°C for 3 h. Filtration (cotton, Celite) of the mixture and evaporation of the solvent left a residue that was purified by flash chromatography (5% methanol in chloroform) to give pure enone **17** (11 mg, 66%); IR (film, ν cm^{-1}): 3439, 2966, 1745, 1691, 1622, 1021; ^{1}H NMR (CD_3OD, δ ppm): 4.04 (d, 10.4 Hz, 1H, HC10), 2.75 (heptuplet, 7.0 Hz, 1H, HC13), 2.58 (d, 19.8 Hz, 1H, H_AC14), 2.23 (d, 19.8 Hz, 1H, H_BC14), 2.21 (s, 3H, CH_3C1), 1.76 (m, 1H, HC9), 1.61–1.46 (m, 4H, H_2C8), 1.15, 1.13, and 1.08 (3 d, 7.0 Hz, 3H each, 3 CH_3CH), 1.09 (s, 3H, CH_3C5); ms *m/e*: 380 (M^+); HRMS calcd. for $C_{20}H_{28}O_7$: 380.1835; found: 380.1826.

2-Deoxy-3-epiryanodol (18)

A solution of enone **17** (50 mg, 0.131 mmol) in THF (5 mL) was transferred into a blue solution (−78°C) of lithium (25 mg) in ammonia (10 mL). After 30 min, extraction was performed as described above. Flash chromatography of the crude product gave compound **18** (34.8 mg, 69%); mp 304–308°C (MeOH); IR (film, ν cm^{-1}): 3396, 2929, 1634, 1453; ^{1}H NMR (CD_3OD, δ ppm): 3.81 (d, 10.0 Hz, 1H, HC10), 3.59 (d, 5.2 Hz, 1H, HC3), 2.15–2.00 (m, 1H, $H_{ax}C7$), 1.95 (m, 1H, HC13), 1.83 (m, 1H, HC9), 1.81 (d, 13.7 Hz, 1H, H_AC14), 1.58 (d, 13.7 Hz, 1H, H_BC14), 1.55–1.43 (m, 3H, HC2, $H_{ax}C8$, $H_{eq}C7$), 1.24 (s, 3H, CH_3C1), 1.08 (d, 6.4 Hz, 3H, CH_3C13), 1.07 (d, 6.6 Hz, 3H, 3H, CH_3C13), 1.00 (d, 3H, 6.4 Hz, 3H, CH_3C9), 0.87 (s, 3H, CH_3C5); ^{13}C NMR (CD_3OD, δ ppm): 103.0, 87.6, 86.2, 75.3, 61.8, 42.1, 35.4, 29.6, 27.1, 24.3, 23.7, 18.9, 14.9, 11.3; ms *m/e*: 384 (M^+); HRMS calcd. for $C_{20}H_{32}O_7$: 384.2148; found: 384.2139.

2-Deoxy-3-epiryanodine (19)

Following a modified method form the literature (34), a solution of alcohol **18** (18 mg, 0.046 mmol) and 2-pyrrolecarboxylic acid (7.6 mg, 0.069 mmol) in dimethylformamide (DMF) (1.5 mL) was treated with diphenylphosphorylazide (DPPA) (20 μL, 0.092 mmol) and triethylamine (39 mL, 0.276 mmol) and stirred for 64 h at room temperature. The mixture was transferred into aqueous sodium bicarbonate and extracted with ethyl acetate. The crude product was chromatographed on silica plate (0.5 mm, 10% methanol in chloroform) to give unreacted starting material (15 mg) along with compound **19** (3 mg, 13%). No attempt was made to increase this yield; IR (film, ν cm^{-1}): 3391, 2935, 1693, 1412, 1324, 1148; ^{1}H NMR (CD_3OD, δ ppm): 6.95, 6.90, and 6.18 (3 m for pyrrole hydrogens), 5.16 (d, 5.7 Hz, 1H, HC3), 3.79 (d, 10.2 Hz, 1H, HC10), 2.13 (app td, 12.5 and 6.1 Hz, $H_{ax}C7$), 2.04 (m, 1H, HC13), 1.94 (dd, 10.6 and 5.7 Hz, 1H, HC2), 1.92 (d, 14.2 Hz, 1H, H_AC14), 1.84 (m, 1H, HC9), 1.74 (d, 14.2 Hz, 1H, H_BC14), 1.52 (m, 2H, $H_{ax}C8$, $H_{eq}C7$), 1.32 (s, 3H, CH_3C1), 1.23 (m, 1H, $H_{eq}C8$), 1.07 (d, 6.2 Hz, 3H, CH_3C13), 1.01 (s, 3H, CH_3C5), 1.00 (d, 6.1 Hz, 3H, CH_3C9), 0.91 (d, 6.4 Hz, 3H, CH_3C13); ms *m/e*: 477 (M^+); HRMS calcd. for $C_{25}H_{35}O_8N$: 477.2362; found: 477.2365.

Synthesis of 2-deoxyryanodol (20) and 2-deoxy-2-epiryanodol (21)

To a cold (−78°C) solution of anhydroryanodol (13 mg, 0.034 mmol) in THF (3 mL) was added a solution of lithium diisopropylamide (100 μL, ~2 M in THF). After 30 min of stirring at −78°C, this preparation was transferred (cannula) to a cold (−78°C) blue solution of lithium (~50 mg) in ammonia (10 mL) and the mixture was stirred for 1 h. After the addition of solid ammonium chloride (100 mg) and warming to 25°C (evaporation of ammonia), the residue was dissolved in water and extracted with ethyl acetate. The crude extract was chromatographed on silica plate (0.5 mm, 10% methanol in chloroform) to give the known olefin **11** (6.7 mg, 54%) (18) and a 1:1 mixture (by NMR evidence) of 2-deoxyryanodol (**20**) and 2-deoxy-2-epiryanodol (**21**) (3.1 mg, 24%). In our hands, these epimers were inseparable by the usual silica plate chromatography. Fortunately, fractional crystallization (methanol) of their mixture furnished pure compound **20**. Stereochemistry at C2 was revealed by X-ray diffraction analysis (see Fig. 4) (27).

2-Deoxyryanodol (20): mp 243°C (dec.) (MeOH); ^{1}H NMR (CD_3OD, δ ppm): 4.34 (d, 11.4 Hz, 1H, HC3), 3.78 (d, 10.2 Hz, 1H, HC10), 2.52 (d, 13.2 Hz, 1H, H_AC14), 2.14–2.00 (m, 2H, $H_{ax}C7$, HC9), 1.83 (m, 1H, HC13), 1.81 (app t, 11.4 Hz, 1H, HC2), 1.72 (d, 13.2 Hz, 1H, H_BC14), 1.58–1.40 (m, 2H, $H_{eq}C7$, $H_{ax}C8$), 1.24 (m, 1H, $H_{eq}C8$), 1.20 (s, 3H, CH_3C1), 1.12 (s, 3H, CH_3C5), 1.09 (d, 6.6 Hz, 1H, CH_3C9), 1.01 (d, 5.2 Hz, 3H, CH_3C13), 0.99 (d, 5.8 Hz, 3H, CH_3C13); ms *m/e*: 384 (M^+); HRMS calcd. for $C_{20}H_{32}O_7$: 384.2148; found: 384.2143.

A revised structure for the piperidine alkaloid andrachamine

Sibel Mill and Claude Hootelé

Abstract: A new method for the synthesis of *trans*-2,6-disubstituted piperidine derivatives is described. The transformation of cyclic α-methoxycarbamates **5** and **6** affords *trans* ketones **17** and **18**. The synthesis of diols **1–4** from **17** and **18** has shown that the structure proposed in the literature for the piperidine alkaloid andrachamine is incorrect. A reexamination of the original spectral data of this alkaloid suggested that it is a *meso* 2,6-disubstituted piperidine derivative. Unambiguous syntheses of **23** and **24** and comparison with a sample of andrachamine have established that this alkaloid possesses structure **23**.

Key words: *N*-acyliminium, piperidine, alkaloid, andrachamine.

Résumé : Une nouvelle méthode de synthèse de dérivés pipéridiniques *trans*-2,6-disubstitués est décrite. La transformation des carbamates cycliques α-méthoxylés **5** et **6** conduit aux cétones *trans* **17** et **18**. La synthèse des diols **1–4** au départ de **17** et **18** a montré que la structure proposée dans la littérature pour l'alcaloïde pipéridinique andrachamine est erronée. Un réexamen des propriétés spectrales de cet alcaloïde a permis de conclure qu'il s'agit d'un dérivé pipéridinique 2,6-disubstitué *méso*. Des synthèses non ambiguës des dérivés **23** et **24** et la comparaison avec un échantillon d'andrachamine ont établi que cet alcaloïde possède la structure **23**.

Mots clés : *N*-acyliminium, piperidine, alcaloïde, andrachamine.

In 1986, the isolation of a new piperidine alkaloid from extracts of the shrub *Andrachne aspera* (Euphorbiaceae), collected near Karachi, was reported (1). The new base was called andrachamine. A second piperidine derivative, andrachcine, was described shortly afterwards from the same species (2). Structure **1** was proposed for andrachamine, based mainly upon spectroscopic studies. Of particular importance for the structural attribution was the assignment to C4 of a signal appearing at 18.7 ppm in the ^{13}C NMR spectrum of andrachamine; comparison of this value with ^{13}C values reported in the literature for C4 in *cis*- and *trans*-2,6-disubstituted piperidine derivatives led to the assignment of the *trans* configuration to the alkaloid (1).

More recently, an unambiguous nitrone-based synthesis of the aminodiol (±)**1** was published (3). No direct comparison was possible but the authors claimed the correspondence, based on the alleged agreement of the spectroscopic properties, between their synthetic compound and andrachamine. Indeed, although the ^{13}C chemical shift for C4 (19.12 ppm) in (±)**1** is close to the value reported for andrachamine, some of the other ^{13}C values reported for (±)**1** do *not* agree with those reported for the alkaloid: the chemical shifts of C2 and C6 for instance differ by more than 10 ppm between the two spectra. An examination of the evidence accumulated convinced us that the structure of andrachamine could not be **1**. As the presence of the C4 signal at 18.7 ppm in the ^{13}C NMR spectrum of andrachamine appeared as a definite argument in favour of a *trans*-disubstituted piperidine structure, we decided to synthesize the four racemic *trans* diastereomers **1–4** and to compare their spectral properties with those of the alkaloid.

4

The stereoselective synthesis of *trans*-2,6-disubstituted piperidines is generally more difficult than the synthesis of the corresponding *cis* derivatives. Recent work from our laboratory has shown that the sequence: anodic methoxylation – elimination – nucleophilic addition provides an efficient route for the synthesis of *cis*-2,6-disubstituted piperidine derivatives from 2-substituted compounds (4). The high stereoselectivity observed in favour of the *cis* compounds results from the stereoelectronically preferred axial attack of the nucleophile (5, 6) on the *N*-acyliminium intermediate whose favoured conformation has a pseudoaxial alkyl group at C2 (Fig. 1*a*) (7, 8). On the basis of the above model we reasoned that the presence of a cyclic 6-membered carbamate would force the C2 side chain in a pseudoequatorial orientation in the *N*-acyliminium ion and that the preferred axial attack of an incoming nucleophile should therefore lead to a *trans*-2,6-disubstituted derivative (Fig. 1*b*). One related example was reported in the literature (9) and a few more appeared after the present work was complete (10).

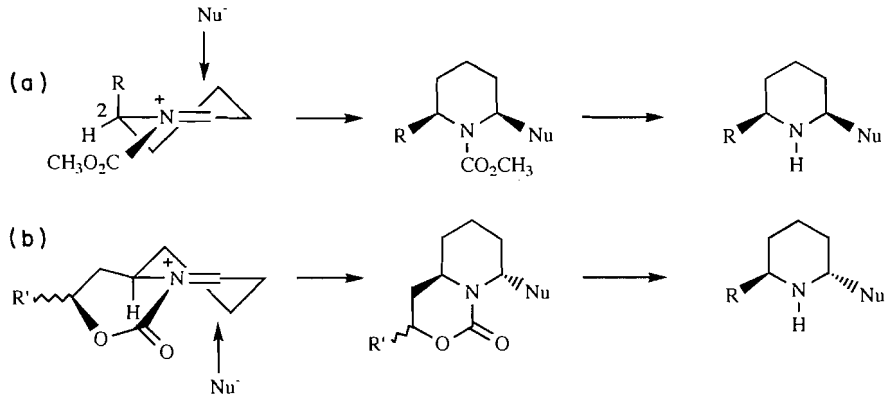
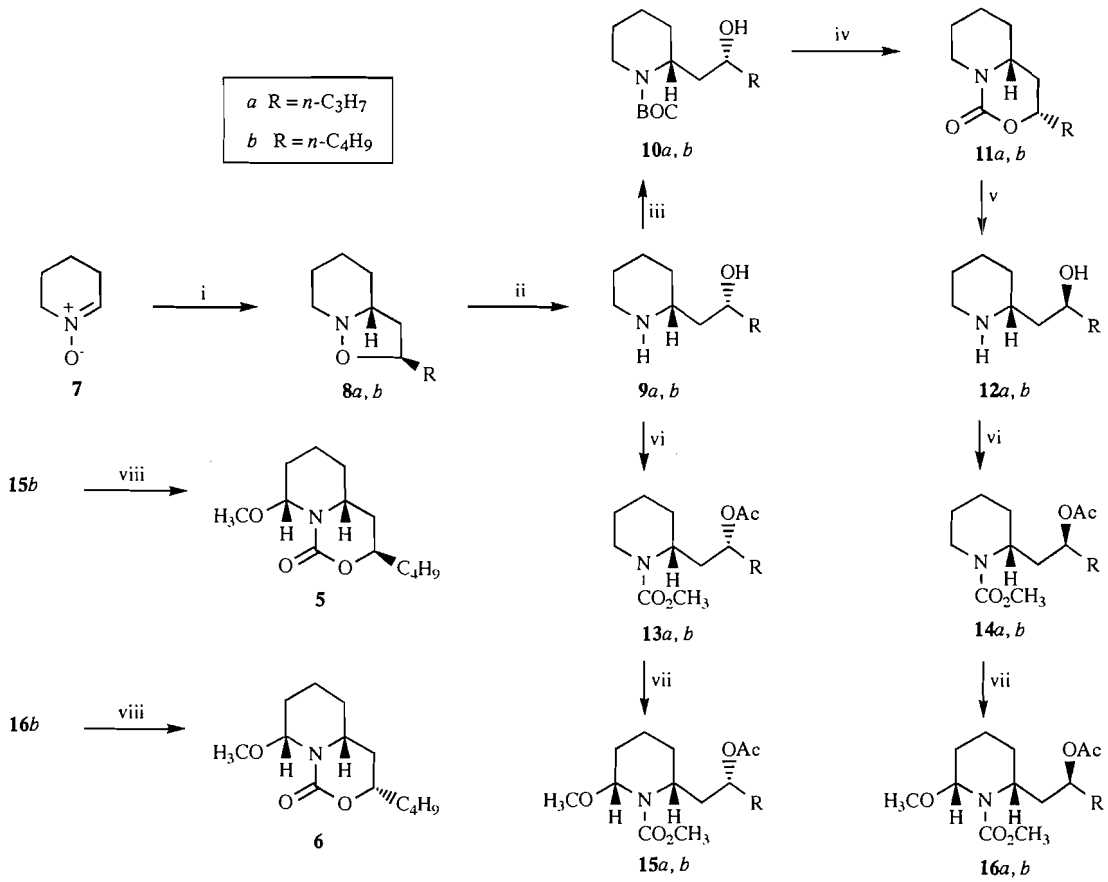


Scheme 1.



i: $CHCl_3$:EtOH (1:1), sealed tube (*a*: 1-pentene, 50°C, 90 h, 87%; *b*: 1-hexene, 60°C, 70 h; 93%); ii: Ni/Al, 1 M aqueous KOH solution, MeOH, r.t., 17 h (*a*: 98%; *b*: 95%); iii: BOC_2O, THF, r.t., 3 h (*a*: 80%; *b*: 95%); iv: MesCl, pyridine, r.t., 24 h, (*a*: 96%; *b*: 91%); v: 2 M ethanolic KOH, r.t., 17 h + 1 h reflux (*a*: quant.; *b*: 94%); vi: (*a*) $ClCO_2CH_3$, K_2CO_3, H_2O, r.t., 3 h; (*b*) Ac_2O, pyridine, r.t., 17 h (**13***a*: 79%; **13***b*: 91%; **14***a*: 69%; **14***b*: 86%); vii: −2e, Et_4NOTs, MeOH, 8 V; 8 F/mol (**15***a*: 99%; **15***b*: 99%; **16***a*: 92%; **16***b*: 83%); viii: *t*BuOK, THF, r.t., 1 h (**5**: 97%; **6**: 97%).

Indeed, we established that access to *trans*-2,6-piperidine derivatives through cyclic 6-membered carbamates was possible and a pathway was developed in which cyclic α-methoxycarbamates **5** and **6** serve as precursors of diastereomers **1**–**4** (see Scheme 2).

The synthesis of carbamates **5** and **6** is outlined in Scheme 1. Cycloadditions between nitrones and terminal alkenes are known to be highly regio- and diastereoselective (11–13). *exo* Addition of nitrone **7** to 1-hexene gave 93% of isoxazolidine **8***b*; the isolated *exo*/*endo* ratio was found to be 99/1. i: $TiCl_4$, CH_2Cl_2, 0°C, 5 min, then −45°C, $CH_2{=}CH\text{-}(OSiMe_3)CH_2CH_3$, 2 h (**17**: 58%; **18**: 55%); ii: $NaBH_4$, MeOH, r.t., 25–50 min, (**19**: 38%; **20**: 51%; **21**: 54%; **22**: 34%); iii: 2 M ethanolic KOH, reflux 1–18 h (**1**: quant.; **3**: 95%; **4**: 91%).

tive cleavage of the N—O bond of **8***b* with Ni/Al alloy and KOH in aqueous methanol afforded γ-aminoalcohol **9***b* in 95% yield. The epimeric alcohol **12***b* was obtained from **9***b* after a three-step sequence: protection of **9***b* as the N-BOC derivative **10***b* followed by treatment with mesyl chloride afforded the corresponding cyclic carbamate **11***b* with inversion at carbon 8; hydrolysis and decarboxylation of this carbamate led to γ-aminoalcohol **12***b* in 81% overall yield. The two epimeric γ-aminoalcohols **9***b* and **12***b* were then submitted to the same reaction sequence; after protection of the amine and alcohol functions, anodic oxidation of the resulting carbamates **13***b* and **14***b* was performed in the conditions described previously (4). The cyclic carbamates **5** and **6** were obtained by treatment of α-methoxycarbamates **15***b* and **16***b* with *t*BuOK in THF.

The synthesis of aminodiols **1**–**4** from **5** and **6** is outlined in Scheme 2.

The nucleophilic displacement of the methoxy group of **5** and **6** was performed by treatment with an excess of 2-(trimethylsilyloxy)but-1-ene (14) in the presence of $TiCl_4$ at low temperature to give the expected *trans*-2,6-piperidine derivatives **17** and **18** with yields of 58 and 55%, respectively. No *cis* product was detected. The desired *trans* aminodiols **1**–**4** were obtained by subsequent $NaBH_4$ reduction of the ketone function of **17** and **18**, separation of the resulting diastereomeric alcohols, and finally cleavage of the carbamate function under basic conditions.

The ^{13}C chemical shifts of the aminodiols **1**–**4** are given in Table 1.

These values deserve some comments. The *trans*-2,6 configuration of the four diastereomers is confirmed by the chemical shifts of C4: they range from 19.8 to 20.6 ppm, in agreement with typical values reported for *trans*-2,6-disubstituted piperidine models (15). Comparison of the ^1H and ^{13}C NMR properties of **1** and its *N*-benzyl derivative with those published (3) clearly shows the identity of Carruthers' compound with ours. The complete relative configurations of **1** and **2** (**2** only differs from **1** at C10) are therefore established. On this basis, examination of the C2, C6, C8, and C10 chemical shifts through the series and comparison with mono- and disubstituted piperidine derivatives of established configuration (16)[2] allow the unambiguous determination of the relative configurations of **3** and **4**.

Comparison of the ^{13}C chemical shifts of the four aminodiols **1**–**4** with the values published for andrachamine clearly establishes that none of them is identical with andrachamine. *The structure of andrachamine has therefore been misassigned.* When this work was complete, it came to our knowledge that the same conclusion had been reached independently in another laboratory (17). As an authentic specimen of the alkaloid was no longer available, a reexamination of the spectral properties of andrachamine appeared necessary. The original ^1H and ^{13}C NMR spectra were kindly supplied by Professor Ahmad; their study revealed that the alkaloid was not isolated as a pure compound as indicated inter alia by the relative intensities of the signals in the ^{13}C NMR spectrum. Indeed, on a given spectrum, signals corresponding to equally substituted carbon atoms are expected to display nearly equal intensities. However, on the original ^{13}C spectrum of andrachamine the intensities associated with the 73.6/71.0 (assigned to C10 and C8) and 9.9/13.9 (assigned to C12 and C16) signal pairs for instance appear in a 1/3 ratio. In a similar way, the low intensities of the signals at 31.0 and 39.6 ppm did not match those of the other major signals of the spectrum. It therefore appears that the signals at 73.6, 39.6, 31.0, and 9.9 ppm are due to the presence of impurities and that only the eight following ^{13}C signals are attributable to the major constituent: δ 71.0, 59.1, 40.3, 40.1, 29.4, 23.0, 18.7, and 13.9 ppm (Table 2). The signal at 23.0 ppm being only attributable to C4, a C_2 symmetric *trans*-2,6-disubstituted derivative can be ruled out. It is likely therefore that the alkaloid is a *meso* 2,6-disubstituted piperidine derivative corresponding either to structure **23** or to structure **24**.

*, **, ***These values may be interchanged.

The synthesis of the two *meso* isomers **23** and **24** was achieved as outlined in Scheme 3.

Carbamates **15***a* and **16***a* were obtained by the same cycloaddition, C8 inversion, and anodic methoxylation pathway as described above for the synthesis of **15***b* and **16***b* (Scheme 1). The elimination – nucleophilic addition, respectively, yielded the two *cis* ketones **26** and **27**. Methanolysis of the ester function of **26** followed by $NaBH_4$ reduction yielded a mixture of diols **28** and **29**; they were separated on alumina and transformed under basic conditions into the aminodiols **24** and **25**. The relative configurations of **24** and **25** rest on the analysis of their ^{13}C NMR spectra. On the other hand, **23** was obtained after stereoselective reduction of the ketone **27** followed by basic hydrolysis of **30**. The complete analysis of the ^1H and ^{13}C NMR spectra of **23**, **24**, and **25** could be achieved using COSY and HMQC experiments.

Unexpectedly, we observed that the ^{13}C chemical shifts of neither **23** nor **24** were identical with the eight values retained for andrachamine (Table 2). However, significant differences only affect the α and β positions relative to the nitrogen atom and suggest that the values reported for andrachamine do not refer to the free base but to a salt of the alkaloid (18). Indeed,

Table 3. ^{13}C (90.6 MHz) chemical shifts (ppm) of andrachamine from *Andrachne aspera* and its trifluoroacetate.

Attribution	Andrachamine from *A. aspera*	Andrachamine·CF_3COOH
C8	71.7	72.9
C2	57.0	58.8
C7	43.7	40.3*
C9	40.7	40.1*
C3	33.5	29.9
C4	24.7	23.0
C10	18.9	18.6
C11	14.4	14.0

*These values may be interchanged.

the chemical shift values observed after protonation of **23** (by addition of one equivalent of trifluoroacetic acid) are in complete accordance with the retained values while the ^{13}C spectrum of **24** after protonation is quite different (Table 2). The values of the ^1H NMR spectrum of **23**·CF_3COOH (i.a. δ(H2): 3.13 ppm, δ(H8): 3.77 ppm) are in perfect agreement with the published ones (1); in the free base, however, H2 occurs at 2.72 ppm.

From the evidence accumulated above, it appears that the alkaloid andrachamine is correctly depicted by structure **23**. To obtain a definite confirmation of this attribution a sample of andrachamine was reisolated from *Andrachne aspera* and compared with synthetic **23**; the two samples appeared identical. Moreover, after protonation, our sample of andrachamine exhibited eight ^{13}C signals corresponding to the eight major signals appearing on the original spectrum of Professor Ahmad (Table 3).

Experimental

Mass spectral data were obtained on a Micromass 7070 or a Fisons Autospec spectrometer (high-resolution measurements). NMR spectra were recorded on a Bruker WM 250 (^1H: 250 MHz, ^{13}C: 62.8 MHz), an AMX 400 (^1H: 360 MHz, ^{13}C: 90.6 MHz), or a Varian Unity 600 (^1H: 600 MHz, ^{13}C: 150.7 MHz) spectrometer in $CDCl_3$ with TMS as internal standard. IR spectral data were recorded on a Brucker IFS 25 spectrometer, as liquid films unless otherwise stated.

Analytical thin-layer chromatography was performed on Polygram Sil G/UV254 plates and on Merck aluminium sheets, aluminium oxide 60 F 254 neutral, type E. Visualization was accomplished either by ethanolic phosphomolybdic acid solution followed by heating or by iodine followed by Dragendorff's reagent.

General procedure for the cycloaddition reactions

To a stirred solution of 1-hydroxypiperidine (0.023 mol) in dichloromethane (20 mL) at 0°C, yellow mercuric oxide (0.047 mol) is slowly added. The solution is then allowed to warm up to room temperature, stirred until the hydroxylamine has disappeared (TLC), and then filtered through Celite. After evaporation of the solvent under reduced pressure, the residue is mixed with the terminal alkene (0.159 mol), ethanol (20 mL), and chloroform (20 mL) in a sealed tube. After 70–90 h at 50–60°C, the solvent is evaporated under reduced pressure; after one or two successive flash chromatographies (Kieselgel 60 Merck; ether:hexane 2:3), the pure *exo* isoxazolidine is isolated.

The ^1H NMR spectra of **8***a* and **8***b* indicate a "slow" nitrogen inversion process at room temperature: all signals are enlarged, due to interconversion between the *trans* conformer (*t*, ca. 89%) and the *cis* pair (*c*).

Isoxazolidine **8**a, *87%*: ^1H NMR, δ ppm: 4.35 (m, H8(*c*)), 4.04 (m, H8(*t*)), 3.5–3.4 (m, H6e(*t*) + H2(*c*)), 3.02 (m, H6e(*c*)), 2.73 (m, H6a(*c*)), 2.46 (m, H6a(*t*)), 1.18–2.40 (13H, m), 0.93 (3H, m); ^{13}C NMR, δ ppm: 76.3 (C8), 66.9 (C2), 55.6 (C6), 40.6, 38.0, 30.0, 25.3, 24.4, 19.6, 14.5 (CH_3); MS *m/z*: 169 ($M^{+\cdot}$ 15%), 168 (10) (calcd. for $C_{10}H_{18}NO$ ($M^{+\cdot}$ −H): 168.1388; found: 168.1386), 126 (4), 100 (100), 84 (21).

Isoxazolidine **8**b, *93%*: ^1H NMR, δ ppm: 4.33 (m, H8(*c*)), 4.02 (m, H8(*t*)), 3.5–3.4 (m, H6e(*t*) + H2(*c*)), 3.02 (m, H6e(*c*)), 2.66 (m, H6a(*c*)), 2.44 (m, H6a(*t*)), 1.14–2.32 (15H, m), 0.90 (3H, m); ^{13}C NMR, δ ppm: 76.6 (C8), 66.9 (C2), 55.7 (C6), 40.6, 35.6, 30.0, 28.6, 25.3, 24.5, 23.2, 14.5 (CH_3); MS *m/z*: 183 ($M^{+\cdot}$, 24%), 182 (8) (calcd. for $C_{11}H_{20}NO$ ($M^{+\cdot}$ −H): 182.1545; found: 182.1547), 126 (5), 100 (100), 84 (37).

General procedure for the hydrogenolysis of isoxazolidines 8 *a*, *b*

A 1 M aqueous KOH solution (10 mL) is added to a stirred solution of the isoxazolidine (1.48 mmol) in methanol, (10 mL). The Ni/Al alloy (twice the weight of isoxazolidine) is slowly added. The reaction mixture is left overnight and then filtered through Celite and rinsed with methanol (200 mL). After evaporation of the methanol under reduced pressure, aqueous NaOH (30 mL) is added to the residue and the aqueous phase is extracted with chloroform (3 × 40 mL). Removal of the solvent under reduced pressure gives the pure γ-aminoalcohol.

9a, (±/−)-halosaline, 97%: IR (CCl_4 solution), cm^{-1}: 3350, 2956, 2932, 2872; ^1H NMR, δ ppm: 3.88 (1H, m, H8), 3.17 (2H, m, OH, NH), 3.05 (1H, dd, J = 11 and 2 Hz, H2), 2.86 (1H, m, H6e), 2.56 (1H, dt, J = 12 and 3 Hz, H6a), 1.26–1.80 (12H, m), 0.92 (3H, t, J = 7 Hz); ^{13}H NMR, δ ppm: 69.1 (C8), 55.1 (C2), 47.3, 42.6 (C6, C7), 40.4 (C9), 32.0, 26.5 (C3, C5), 25.1, 19.3 (C10, C4), 14.4 (CH_3); MS *m/z*: 171 ($M^{+\cdot}$, 36%) (calcd. for $C_{10}H_{21}NO$: 171.1623; found: 171.1620), 154 (17), 128 (100), 98 (68).

9b, *95%*: IR (CCl_4 solution), cm^{-1}: 3326, 2933, 2859; ^1H NMR, δ ppm: 3.86 (1H, m, H8), 3.29 (2H, m, OH, NH), 3.04 (1H, m), 2.86 (1H, m), 2.56 (1H, dt, J = 12 and 3 Hz, H6a), 1.23–1.81 (14H, m), 0.90 (3H, t, J = 7 Hz); ^{13}C NMR, δ ppm: 69.3 (C8), 55.0 (C2), 47.2, 42.5 (C6, C7), 37.8 (C9), 31.9, 28.3, 26.5 (C3, C5, C10); 25.1, 23.0 (C4, C11), 14.3 (CH_3); MS *m/z*: 185 ($M^{+\cdot}$, 5%) (calcd. for $C_{11}H_{23}NO$: 185.1780; found: 185.1783), 128 (13), 112 (6), 98 (11), 84 (100).

General procedure for the synthesis of *N*-carbomethoxy derivatives of 9 *a*, *b* and 12*a*, *b*

K_2CO_3 (7.87 mmol) and methyl chloroformate (5.30 mmol) are successively added to a stirred solution of γ-aminoalcohol (1.06 mmol) in water. After 3 h at room temperature, NH_4OH is added and the basic solution is extracted with $CHCl_3$ (3 × 20 mL). The combined $CHCl_3$ phases are evaporated under reduced pressure and the residue is filtered through a short column of alumina to afford the corresponding *N*-carbomethoxy derivative.

N-*Carbomethoxy derivative of* ***9***a, *95.5%*: IR (CCl_4 solution), cm^{-1}: 3346, 2942, 2872, 1682; ^1H NMR, δ ppm: 4.50 (1H, m, H2), 3.98 (2H, m, H6e and OH), 3.72 (3H, s, NCO_2CH_3), 3.36 (1H, m, H8), 2.74 (1H, dt, J = 13 and 2Hz, H6a), 2.00 (1H, dt, J = 14 and 2Hz), 1.16–1.76 (11H, m), 0.91 (3H, t, J = 7 Hz); ^{13}C NMR, δ ppm: 157.9, 67.7 (C2), 53.4 (NCO_2CH_3), 47.9 (C8), 39.7, 39.6, 38.1, 30.0, 26.0, 19.7, 14.6 (CH_3); MS *m/z*: 229 ($M^{+\cdot}$, 2%) (calcd. for $C_{12}H_{23}NO_3$: 229.1678; found: 229.1686), 186 (2), 170 (1), 168 (1), 142 (100).

General procedure for anodic methoxylations and preparation of 15*a*, *b* and 16*a*, *b*

The anodic methoxylations are carried out at room temperature in methanol (analytical grade) containing Et_4NOTs as a supporting electrolyte, in an undivided cell equipped with two vitreous carbon electrodes, an exit tube (containing $CaCl_2$) for venting purposes, and a magnetic stirring bar. The carbon electrodes (3 mm in diameter, immersed 3.5 cm in the solution) are 1.0 cm apart. The potentiostat is a homemade apparatus.

The carbamate (0.52 mmol), Et_4NOTs (0.13 mmol), and methanol (15 mL) are placed in the electrolysis cell. The solution is stirred for 10 min and then a constant potential of 8.00 V is applied. After 8 F/mol of electricity is passed, a few drops of NH_4OH are added to the solution and the solvent is evaporated. The residue is then dissolved in water (200 mL), basified with NH_4OH, and extracted with $CHCl_3$ (3 × 50 mL). The combined $CHCl_3$ phases are evaporated and the residue is filtered ($CHCl_3$) through a short column of alumina to afford the 6-methoxy derivative.

Nucleophilic displacement of the methoxy group of 5 and 6

To a stirred solution of $TiCl_4$ (1.18 mmol) in dichloromethane (1 mL) at 0°C under a nitrogen atmosphere is added a solution of the methoxy derivative (0.67 mmol); after 5 min under stirring at 0°C, the temperature is lowered to −45°C and trimethylsilyloxybut-1-ene (contaminated with ca. 20% of trimethylsilyloxybut-2-ene) (4.44 mmol) is added. The resulting mixture is left at −45°C for 2 h. Water (20 mL) is then added, the mixture extracted with $CHCl_3$ (3×20 mL), the organic phase evaporated, and the residue submitted to a flash chromatography (Kieselgel 60 Merck; acetone:hexane 1:5), to afford the pure ketone.

Preparation of 1, 2, 3, and 4 from 19, 20, 21, and 22

Cyclic carbamate (0.024 mmol) is mixed with a 2 M ethanolic solution of potassium hydroxide. After 1–18 h at reflux, the solvent is evaporated under reduced pressure. The residue is diluted with water (10 mL) and the aqueous phase is extracted with $CHCl_3$ (3 × 10 mL). Evaporation of the chloroform yields the pure aminodiol.

1, quant.: IR (CCl_4 solution), cm^{-1}: 3382, 2958, 2933, 2873; ^1H NMR, δ ppm: 3.67–3.82 (2H, m, H8 and H10), 3.44 (3H, br, NH and 2 OH), 3.27 (2H, m, H2 and H6), 1.26–1.88 (18H, m), 0.91 (6H, 2t, J = 7 Hz); MS *m/z*: 257 ($M^{+\cdot}$, 2%) (calcd. for $C_{15}H_{31}NO_2$: 257.2355; found: 257.2353), 228 (8), 200 (14), 184 (93), 156 (100), 138 (16), 84 (14), 82 (21).

Transformation of 26 into 28 and 29

K_2CO_3 (1.29 mmol) is added to a stirred methanolic (6 mL) solution of **26** (2.15×10^{-4} mol). After 23 h at room temperature, the methanol is evaporated under reduced pressure and the residue is taken up in water (15 mL). The aqueous phase is extracted with $CHCl_3$ (3 × 15 mL), the chloroform evaporated, and the corresponding alcohol is obtained in 84% yield. This derivative is immediately submitted to reduction with $NaBH_4$ (same procedure as above, r.t. for 30 min). The diastereomeric alcohols **28** and **29** are separated by chromatography on alumina (ethyl acetate:hexane 1:2).

28, 10%: ^1H NMR, δ ppm: 3.77 (3H, s, NCO_2CH_3), 2–4.5 (6H, m), 1.28–1.82 (18H, m), 0.92 (6H, t, J = 7 Hz); ^{13}C NMR, δ ppm: 158.5, 68.7 (C2), 53.7 (NCO_2CH_3), 48.2 (C8), 43.9, 39.8, 30.7, 19.5, 15.3, 14.6 (CH_3); MS *m/z*: 315 ($M^{+\cdot}$, 1%) (calcd. for $C_{17}H_{33}NO_4$: 315.2410; found: 315.2415), 272 (2), 256 (14), 228 (45), 10 (23), 156 (8), 142 (100), 140 (60).

29, 62%: ^1H NMR, δ ppm: 4.40 (3H, br m, H2, H6, and OH), 3.74 (3H, s, NCO_2CH_3), 3.49 (2H, br m), 3–4 (1H, OH), 1.25–1.92 (18H, m), 0.92 (6H, 2t, J = 7 Hz); ^{13}C NMR, δ ppm: 158.3, 69.9, 68.2 (C2, C6), 53.6 (NCO_2CH_3), 48.2, 47.8, 43.5, 43.5, 40.7, 39.7, 30.5, 28.2, 19.5, 19.3, 14.8, 14.6 (CH_3), 14.5 (CH_3); MS *m/z*: 315 ($M^{+\cdot}$, <1%) (calcd. for $C_{17}H_{33}NO_4$: 315.2410; found: 315.2408), 256 (17), 228 (47), 210 (24), 156 (8), 142 (100), 140 (71).

Reduction of 27 into 30

To a stirred solution of ketone **27** (3.77×10^{-4} mol) in THF (13 mL) is added $LiHAl(OtBu)_3$ (1.53 mmol) at 0°C. After 1 h, a few drops of water are added and the mixture is filtered through Celite. The solvent is then evaporated under reduced pressure and the residue is chromatographed on alumina (ethyl acetate:hexane 2:1) to afford the alcohol **30** in 84% yield.

30: ^1H NMR, δ ppm: 4.88 (1H, m, H8), 4.27 (1H, m), 4.17 (1H, m, H10), 3.69 (3H, s, NCO_2CH_3), 3.54 (1H, m), 2.06 (3H, s, $OCOCH_3$), 1.24–1.83 (19H, m), 0.92 (6H, 2t, J = 7 Hz); ^{13}C NMR, δ ppm: 171.2, 157.0, 72.1, 70.0, 52.9 (NCO_2CH_3), 48.3, 47.6, 44.3, 40.3, 40.2, 39.4, 37.0, 29.0, 27.8, 22.5, 21.4 ($OCOCH_3$), 19.1, 18.9, 14.3 (CH_3), 14.2 (CH_3); MS *m/z*: 357 ($M^{+\cdot}$, <1%) (calcd. for $C_{19}H_{35}NO_5$: 357.2515; found: 357.2499), 298 (30), 270 (11), 238 (9), 228 (20), 210 (50), 142 (48), 140 (100).

General procedure for the basic hydrolysis of carbamates 28, 29, and 30

The carbamate (0.182 mmol) is mixed with a 1–2 M ethanolic solution of potassium hydroxide. After 1–5 h at reflux, the solvent is evaporated under reduced pressure. After 1–5 h at reflux, the solvent is evaporated under reduced pressure. The residue is diluted with water (20 mL) and the aqueous phase is extracted with $CHCl_3$ (3 × 20 mL). Evaporation of the chloroform yields the pure aminodiol.

23 (synthetic andrachamine), 95%: ^1H NMR (600 MHz), δ ppm: 3.79 (2H, m, H8), 2.72 (2H, m, H2), 1.84 (1H, dqn, J = 13 and 3.5 Hz, H4e), 1.71 (2H, dq, J = 13 and 3 Hz, H3e), 1.54 (1H, qt, J = 13 and 4 Hz, H4a), 1.48 (2H, dt, J = 14 and 4 Hz, H7e), 1.46–1.32 (13H, m), 0.97 (2H, qd, J = 13 and 4 Hz, H3a), 0.92 (6H, t, J = 7 Hz, H11; MS *m/z*: 257 ($M^{+\cdot}$, 3%) (calcd. for $C_{15}H_{31}NO_2$: 257.2355; found: 257.2369), 240 (2), 228 (2), 214 (11), 184 (2), 170 (100).

24, quant.: ^1H NMR (600 MHz), δ ppm: 3.85 (2H, m, H8), 2.88 (2H, m, H2), 1.83 (2H, m, H4), 1.21–1.59 (19H, m), 0.92 (6H, t, J = 7 Hz, H11); MS *m/z*: 257 ($M^{+\cdot}$, 4%) (calcd. for $C_{15}H_{31}NO_2$: 257.2355; found: 257.2342), 240 (3), 228 (2), 214 (16), 184 (2), 170 (100).

25, 99%: ^1H NMR (600 MHz), δ ppm: 3.87 (1H, m, H8), 3.82 (1H, m, H8′), 2.85 (1H, m, H2), 2.73 (1H, m, H6), 1.84 (1H, m, H4e), 1.64 (3H, H3e, H5e, OH), 1.22–1.56 (15H, m), 1.10

(1H, m, H5a), 1.01 (1H, m, H3a), 0.92 (3H, t, J = 7 Hz), 0.91 (3H, t, J = 7 Hz); ^{13}C NMR, δ ppm: 72.4, 68.0, 57.8 (C6), 53.6 (C2), 43.9, 43.3, 40.6, 40.5, 33.7, 33.0 (C3, C5), 24.8 (C4), 18.9, 18.7, 14.2 (CH_3), 14.1 (CH_3); MS *m/z*: 257 ($M^{+\cdot}$, 4%) (calcd. for $C_{15}H_{31}NO_2$: 257.2355; found: 257.2342), 240 (2), 228 (2), 214 (16), 184 (3), 170 (100).

Isolation of andrachamine from *Andrachne aspera*

Dried plants of *Andrachne aspera* (870 g) collected near Karachi (Pakistan) were immersed in methanol (3 L) for 4 days. Methanol was filtered and the process repeated three times. The combined MeOH phases were evaporated under reduced pressure and the residue was digested overnight with 2% aqueous HCl (100 mL). The solution was filtered through Celite, basified with NaOH, and extracted with $CHCl_3$ (3 × 1 L). The organic phase was then washed with water (50 mL), concentrated to ca. 20 mL, and extracted with 2% aqueous HCl (3 × 25 mL). The aqueous phase was basified (NaOH) and extracted with $CHCl_3$ (3 × 100 mL). The combined organic phases were washed with water (25 mL) and evaporated under reduced pressure to give 1.22 g of crude alkaloids (0.14% dry weight).

The crude extract (254 mg) was submitted to two successive chromatographies (Kieselgel 60 Merck; $CHCl_3$:isopropylamine 50:1) to give crystalline andrachamine **23** (3.5 mg). The alkaloid was found identical with synthetic **23** (TLC, MS, ^{1}H and ^{13}C NMR).

Natural andrachamine: ^{1}H NMR, δ ppm: 3.80 (2H, m, H8), 2.76 (2H, m, H2), 1.26–1.88 (20H, m), 1.01 (1H, m, H3a), 0.92 (6H, t, J = 7 Hz, H11); MS *m/z*: 257 ($M^{+\cdot}$, 2%) (calcd. for $C_{15}H_{31}NO_2$: 257.2355; found: 257.2357), 240 (2), 228 (2), 214 (13), 184 (5), 170 (100).

Synthesis of β-hydroxypiperidine alkaloids by anodic oxidation of carbamates and hydroboration

Mark Plehiers and Claude Hootelé

Abstract: The β-hydroxypiperidine alkaloids (±)-pseudoconhydrine, (±)-*N*-methylpseudoconhydrine, (−)-5-hydroxysedamine, and (+)-sedacryptine were synthesized. Successive functionalization of the piperidine ring via anodic methoxylation allowed the regio- and stereoselective introduction of the substituents. The α and α′ substituents were introduced by application of the sequence elimination – nucleophilic addition from 2- or 2,5-substituted 6-methoxycarbamates. Hydroboration – oxidation of enecarbamates, obtained by elimination of methanol from α-methoxycarbamates, allowed the introduction of the β-hydroxy function.

Key words: alkaloid, Sedum, *N*-acyliminium, enecarbamate.

Résumé : La synthèse des alcaloïdes pipéridiniques β-hydroxylés tels que la (±)-pseudoconhydrine, la (±)-*N*-méthylpseudoconhydrine, la (−)-5-hydroxysédamine et la (+)-sédacryptine est décrite. L'oxydation anodique de carbamates permet l'introduction successive, de manière régio- et stéréosélective, des substituants sur le cycle pipéridinique. Les substituants α et α′ sont introduits par application de la séquence élimination–addition nucléophile aux carbamates 6-méthoxylés, 2- ou 2,5-substitués. La fonction β-hydroxy est aménagée par hydroboration–oxydation d'ènecarbamates obtenus, au départ d'α-méthoxycarbamates, par élimination de méthanol.

Mots clés : alcaloïde, Sedum, *N*-acyliminium, ènecarbamate.

Development of efficient methods for the elaboration of polysubstituted piperidine compounds is an important goal in the area of natural product synthesis. Indeed, the increasing interest observed in this field is related to the search for new strategies for the synthesis of potentially bioactive compounds and was stimulated recently, among others, by the glycosidase inhibitory properties of polyhydroxylated piperidine derivatives (1). While numerous methods are known for the introduction of a substituent α to the nitrogen atom of the piperidine nucleus, functionalization of β and (or) γ positions has seldom been described in the literature.

The anodic methoxylation of carbamates followed by elimination and nucleophilic substitution now emerges as a powerful method for the synthesis of 2- and 2,6-substituted piperidine derivatives (2–4); the success of this method rests on the highly regioselective preparation of intermediate α-methoxycarbamates from the parent heterocycles. These intermediates are protected forms of reactive *N*-acyliminium cations that can be generated by treatment with Lewis acids and can add a number of nucleophiles. On the other hand, treatment of α-methoxycarbamates in acidic or thermolytic conditions leads to the formation of enecarbamates; these enamine-type compounds allow the introduction of electrophiles at the β position on the piperidine ring (5, 6).

In this paper, we wish to report a new route for the synthesis of β-hydroxy α- and α,α′-substituted piperidine derivatives based on successive functionalizations via anodic oxidation. As an illustration, norsedamine **10** was efficiently functionalized at position 5 (via hydroboration of the enecarbamate **12**) to yield 5-hydroxysedamine **20**; the immediate precursor of ent-**20** was substituted at position 6 to furnish (+)-sedacryptine **28** after functional group transformations.

Results and discussion

Synthesis of β-hydroxypiperidine derivatives

In a preceding communication (6), we briefly reported that hydroboration–oxidation of piperidine enecarbamates constitutes an efficient procedure for the preparation of β-hydroxypiperidine derivatives; the reaction proceeds with good yields to furnish *trans*/*cis* isomers in ratios ranging from 2/1 (20°C) to 6/1 (−78°C to −10°C). Although the last ratio was recently questioned (7), it appears reproducible in our hands. The stereoselectivity observed in favour of the *trans* compound results from a preferential attack of borane from the less hindered side of the enecarbamate **A** (Scheme 1).

Enecarbamate hydroboration was first applied to the model derivative ***3a*** and then exploited to realize short syntheses of pseudoconhydrine **8** (8) and *N*-methylpseudoconhydrine **9** (9), which have a 2,5-*trans* relative stereochemistry (Scheme 1).

On the other hand, we established that alcohols possessing a 2,5-*cis* relative stereochemistry can be efficiently obtained by stereoselective reduction of the corresponding ketone. The method is illustrated by the synthesis of (−)-5-hydroxysedamine **20**.

(2*S*,8*S*)-Norsedamine **10** was prepared in optically pure form, protected, and anodically oxidized in methanol to give

chromatography. Attribution of the 2,5 relative stereochemistry of alcohols **13** and **14** rests on the analysis of the ^{1}H (coupling connectivity by 2D-COSY) and ^{13}C NMR spectra of the corresponding diacetyl derivatives **15** and **16** and comparison with those of the model compounds **6***a* and **7***a*. In all these compounds, $A^{(1,3)}$ interactions between the N-acyl moiety and the C2 substituent force this last one in an axial orientation (10). Selected diagnostical values from the ^{1}H NMR spectra are reported in Table 1.

Attempts to prepare ketone **17** by oxidation of the intermediate boranes only proceeded with low yield but we observed that this unstable ketone was readily obtained by oxidation of the alcohol **13** or the mixture of **13** and **14** (Scheme 3). Swern oxidation (11) was found to give higher and more reproducible yields of **17** than PCC (12).

Reduction of the keto function of **17** with $NaBH_4$ yielded a 1/8 ratio of the alcohols **13** and **14**. Use of lithium tri-*tert*-butoxyaluminium hydride resulted in the formation of the *cis* alcohol **14** only, with concomitant deacetylation (88% global yield of *cis* derivatives **14** and **18**).

The procedure described above provides the 2,5-*cis* alcohol **14** in a global yield of 60% from the enecarbamate **12**.

Lithium aluminium hydride reduction of the carbamates **14** and **13** furnished (−)-5-hydroxysedamine **20** and its C5 epimer **19**. Spectral and specific rotation values of synthetic and natural **20** (13) are in perfect agreement.

The preferred solution conformation of sedamine was established previously (14): the hydroxyl function at C8 is involved in an intramolecular hydrogen bonding with the nitrogen lone pair and the base exists predominantly in a *cis*-fused conformation. The ^{1}H NMR spectra of **19** and **20** indicate that the hydroxyl function at C5 and the phenyl group are both equatorial in the two diols; the C2 side chain is therefore equatorial in **19** and axial in 5-hydroxysedamine **20**. On the other hand, the diacetyl derivatives (13) obtained from **19** and **20** present a chair conformation in which the C2 substituent has an equatorial orientation and the acetoxy at C5 occupies, respectively, an equatorial and an axial orientation.

Synthesis of 2,5,6-trisubstituted piperidine compounds

To our knowledge, no example of transformation of a 2,5-disubstituted piperidine into a 2,5,6-trisubstituted derivative by anodic methoxylation has been described in the literature. The anodic oxidations of piperidine carbamates we described previously were generally carried out in MeOH containing $Et_4N^+OTs^-$ as supporting electrolyte in an undivided cell equipped with two vitreous carbon electrodes (3, 4) and the electrolysis was performed by application of a constant potential of 8 V between the electrodes. Before undertaking the oxidation of compound ent-**16**, precursor of (+)-sedacryptine **28**, we studied the influence of the supporting electrolyte ($Et_4N^+OTs^-$ and $Bu_4N^+BF_4^-$) and of the electrode (carbon and platinum) on the oxidation of the model compound **7***a*. Some significant results are given in Table 2.

It appeared that the anodic oxidation performed under our usual conditions (3, 4) (entry 1) furnished the methoxy compound **21** with a moderate yield. The replacement of the carbon rod anode by a platinum foil allowed a substantial

Table 2. Anodic oxidation of acetate 7*a*.

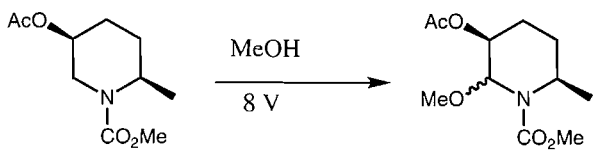
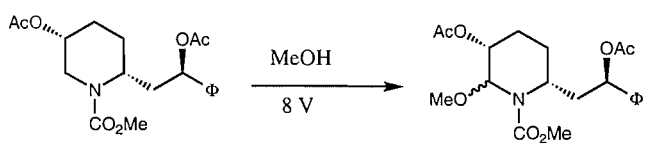
increase of the yield (entry 3). During our systematic study we observed that in the case of $Et_4N^+OTs^-$ as electrolyte the best yields were obtained when the electrolyte/carbamate molar ratio was kept below a 0.1 value; on the other hand, in the case of $Bu_4N^+BF_4^-$, electrolyte/carbamate ratios ranging from 0.1 to 1 gave comparable yields. Of course, a high relative concentration of the electrolyte is suitable in that it allows shorter reaction times.



7*a* **21**

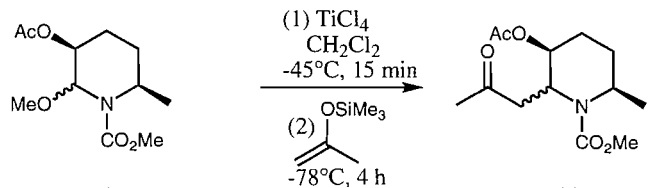
Application to the diacetoxy derivative ent-**16** (2*R*,5*R*,8*R*) of the best conditions found for the oxidation of 7*a* appeared disappointing as a yield of less than 50% of **23** was obtained. A new series of experiments was therefore undertaken and the results are reported in Table 3.

For the anodic oxidation of ent-**16**, the highest yield of the methoxy derivative **23** was achieved using $Et_4N^+OTs^-$ as supporting electrolyte and a vitreous carbon rod as anode. In all cases the reaction appeared incomplete and a substantial amount of starting material could be recovered. It was observed that an increase in the number of Faraday did not improve the yield (entry 4) but led to the formation of degradation products. The α-methoxycarbamates **21** and **23** were found to be stable compounds and they can be stored for months without noticeable degradation.



ent-**16** **23**

The elimination – nucleophilic addition sequence was first performed on the model compound **21**. The iminium cation was formed at −45°C with $TiCl_4$ as a Lewis acid and reacted with 2-trimethylsilyloxypropene at −78°C to yield a 76/24 mixture of the expected ketones **22** in 73% yield.



21 **22** (*c*+*t*)

The same sequence was applied to the methoxy derivative **23**. The reaction was first conducted at low temperature (−78°C to −45°C, 4 h), furnishing a mixture in which the expected *cis* and *trans* compounds **24** were present in low yield (ca. 25%); the other major constituents were identified as the starting material (ca. 50%) and a 6-hydroxy derivative **25** (ca. 25%) originating from the addition of water to the iminium cation during the work-up. These observations indicate that the formation of the iminium cation was not complete under these conditions. When the two steps were conducted at 0°C a 77/23 mixture of the two expected diastereoisomers was isolated in 60% yield. The *cis* relative stereochemistry is attributed to the major compound on the basis of our previous results on related compounds.

Simple functional group transformations of **24** allowed the synthesis of (+)-sedacryptine **28** (Scheme 4).

After protection of the keto group of the *cis* and *trans*

28 **29**

i: ethylene glycol, $TsOH \cdot H_2O$, benzene, reflux; ii: $LiAlH_4$, THF, reflux, 67% from **24**; iii: 0.1 N HCl, reflux.

trisubstituted compounds **24**, reduction of the carbamate and acetate functions furnished the corresponding amino alcohols **27** in 67% yield without modification of the diastereoisomeric ratio. Deprotection of the acetal function was performed in boiling 0.1 N aqueous hydrogen chloride, providing, after neutralization, a mixture of (+)-sedacryptine **28** and its C6-epimer **29** in a 60/40 ratio.

Compounds possessing a β-amino ketone moiety are able to epimerize under a variety of conditions (4, 15). We observed that pure sedacryptine as well as the above 60/40 mixture epimerizes in methanol at room temperature affording a 80/20 mixture of **28** and **29**. On the other hand, this last ratio shifted to >95/5 in cyclohexane. Spectral properties of our synthetic (+)-sedacryptine **28** were identical with those of the natural compound; the optical rotations of both samples were identical in magnitude but of opposite sign. The above synthesis confirms the absolute configuration (2*S*,5*S*,6*S*,8*S*,10*S*) previously attributed to the alkaloid (16).

Experimental

Mass spectral data were obtained on a Micromass 7070 spectrometer or a Fisons Autospec spectrometer. Unless otherwise stated, NMR spectra were recorded on a Bruker WM 250 spectrometer in $CDCl_3$ with TMS as internal standard. IR spectral data were recorded on a Brucker IFS 25 spectrometer. Analytical thin-layer chromatography was performed on Polygram Sil G/UV254 plates and on Merck aluminium sheets, aluminium oxide 60 F_{254} neutral, type E. Visualization was accomplished either by ethanolic phosphomolybdic acid solution followed by heating or by iodine followed by spraying Dragendorff reagent.

Anodic methoxylations were carried out at room temperature in methanol (analytical grade) containing the supporting electrolyte, in an undivided cell equipped with two vitreous carbon electrodes (unless otherwise stated) and a magnetic stirring bar. The carbon electrodes (0.3 cm diameter, immersed 3.5 cm into the solution) were placed 1.0 cm apart. The platinum foil anode (0.3 × 4 cm) was immersed 2 cm into the solution at 1 cm of the carbon cathode. The potentiostat was a homemade apparatus; the potential between the electrodes was fixed at 8 V.

Anodic oxidation of 1*a*

The carbamate **1***a* (521 mg, 3.3 mmol), $Et_4N^+OTs^-$ (50 mg, 0.16 mmol), and 15 mL of methanol were introduced into the electrolysis cell. The solution was stirred for 10 min and then a constant potential of 8 V was applied. After 2.6 F/mol of electricity was passed, some drops of NH_4OH were added to the solution and the solvent was evaporated; the residue was dissolved in water (30 mL), basified with NH_4OH, and extracted with $CHCl_3$ (2 × 30 mL). The combined $CHCl_3$ layers were evaporated and the residue was filtered through a short column of silica gel (ethyl acetate/hexane 1:2) to afford the 6-methoxy derivative **2***a* (oil, 476 mg, 2.54 mmol, 77%): ^1H NMR δ: 5.39 (1H, m, H6), 4.33 (1H, m, H2), 3.72 (3H, s, NCO_2CH_3), 3.26 (3H, broad s, CH_3O), 1.2–2.1 (6H, m), 1.28 (3H, d, J = 7 Hz, CH_3); ^{13}C NMR δ: 82.6, 55.3, 52.9, 47.0, 30.8, 30.5, 19.9, 14.0; MS, *m/z*: 187 ($M^{+\bullet}$, 3%), 186 (5), 172 (33), 156 (100), 142 (76), 71 (86).

Preparation of the enecarbamate 3*a* from 2*a*

The 6-methoxy derivative **2***a* (100 mg, 0.53 mmol) was dissolved in dry benzene (10 mL); $TsOH \cdot H_2O$ (10 mg, 0.052

mmol) was added and the reaction mixture was stirred at room temperature. After 1.5 h, some drops of NH_4OH were added to the reaction mixture and the solvent was evaporated; the residue was dissolved in water (30 mL) and the solution extracted with $CHCl_3$ (2 × 30 mL). The combined organic layers were evaporated and the residue was filtered through a short column of alumina to afford the enecarbamate **3***a* (65 mg, 0.42 mmol, 80%) as a colourless oil: ^{1}H NMR δ: 6.69 (1H, m, H6), 4.86 (1H, m, H2), 4.40 (1H, m, H5), 3.75 (3H, s, NCO_2CH_3), 1.7–2.2 (4H, m), 1.12 (3H, d, J = 7 Hz, CH_3); ^{13}C NMR δ: 124.1, 105.8, 53.1, 46.7, 26.9, 17.6, 17.1; MS, *m/z*: 155 ($M^{+\bullet}$, 36%), 140 (100).

Synthesis of *N*-carbomethoxyconiine 1*b*

N-Carbomethoxypiperidine (5.04 g, 35 mmol), $Et_4N^+OTs^-$ (550 mg, 1.8 mmol), and 50 mL of methanol were introduced into the electrolysis cell. The solution was stirred for 10 min and a constant potential of 8 V was applied. After 2.7 F/mol of electricity was passed, some drops of NH_4OH were added to the solution and the solvent was evaporated; the residue was dissolved in water (400 mL), basified with NH_4OH, and extracted with $CHCl_3$ (3 × 400 mL). The combined $CHCl_3$ layers were evaporated and the residue was filtered through a short column of silica gel (ethyl acetate/hexane 1:2) to afford 2-methoxy-*N*-carbomethoxypiperidine (6 g, 34 mmol).

To a solution of $TiCl_4$ (7.2 g, 38 mmol) in CH_2Cl_2 at −78°C, under an atmosphere of nitrogen, was added dropwise a solution of allyltrimethylsilane (9.5 g, 59 mmol) and 2-methoxy-*N*-carbomethoxypiperidine (6 g) in 40 mL of CH_2Cl_2. After 1 h at −78°C, the reaction mixture was poured into 400 mL of water and extracted with 2 × 400 mL of CH_2Cl_2. The combined CH_2Cl_2 layers were evaporated to dryness. Distillation of the residue under reduced pressure afforded the substitution derivative (4.98 g, 27.2 mmol, 77% global yield) as a colourless oil, bp 94–98°C (3 Torr;): ^{1}H NMR δ: 5.7 (1H, ddt, J = 17, 10 and 7 Hz), 5.01 (1H, dd, J = 17 and 2 Hz), 4.98 (1H, dt, J = 2 and 10 Hz), 4.28 (1H, m, H2), 3.96 (1H, broad d, J = 14 Hz, H6e), 3.64 (3H, s, NCO_2CH_3), 2.79 (1H, td, J = 2 and 14 Hz, H6a), 2.35 (1H, dt, J = 14 and 7 Hz), 2.26 (1H, dt, J = 14 and 7 Hz), 1.3–1.6 (6H, m); ^{13}C NMR δ: 156.6, 135.7, 117.1, 52.8, 50.8, 39.7, 34.8, 28.0, 25.9, 19.2; MS, *m/z*: 182 ($M^{+\bullet}$ − 1, 4%), 142 (100).

The above derivative (4.5 g, 24.5 mmol) in 300 mL of ethanol containing 10% Pd/C (0.5 g) was hydrogenated (1 atm (101.3 kPa)). After filtration through Celite and evaporation of the solvent, a distillation under reduced pressure of the residue furnished *N*-carbomethoxyconiine **1***b* (3.7 g, 20 mmol, 81%), bp 92–96°C (2 Torr; 1 Torr = 133.3 Pa): ^{1}H NMR δ: 4.24 (1H, m, H2), 3.98 (1H, broad d, J = 13 Hz, H6e), 3.67 (3H, s, NCO_2CH_3), 2.80 (1H, td, J = 13 and 3 Hz, H6a), 1.2–1.7 (10H, m), 0.91 (3H, t, J = 7 Hz); ^{13}C NMR δ: 156.7, 52.8, 51.0, 39.5, 32.3, 28.8, 26.1, 19.9, 19.4, 14.4; MS, *m/z*: 185 ($M^{+\bullet}$, 2%), 142 (100).

Preparation of the enecarbamate 3*b* from 1*b*

The carbamate **1***b* (2.52 g, 13 mmol), $Et_4N^+OTs^-$ (250 mg, 0.83 mmol), and 50 mL of methanol were introduced into the electrolysis cell. The solution was stirred for 10 min and a constant potential of 8 V was applied. After 3F/mol of electricity was passed, some drops of NH_4OH were added to the solution and the solvent was evaporated; the residue was dissolved in water (400 mL), basified with NH_4OH, and extracted with $CHCl_3$ (3 × 400 mL). The combined $CHCl_3$ layers were evaporated to dryness to afford the 6-methoxy derivative **2***b* (2.8 g, 13 mmol): ^{1}H NMR δ: 5.45 (1H, m, H6), 4.14 (1H, m, H2), 3.71 (3H, s, NCO_2CH_3), 3.28 (3H, s, OCH_3), 1.2–1.9 (10H, m), 0.92 (3H, t, J = 7 Hz); ^{13}C NMR δ: 82.9, 55.8, 53.0, 51.3, 36.3, 31.1, 27.9, 20.9, 14.4, 14.2; MS, *m/z*: 215 ($M^{+\bullet}$, <1%), 200 (4), 184 (32), 172 (64), 142 (22), 140 (20), 71 (100).

The crude 6-methoxy derivative **2***b* was dissolved in dry benzene (200 mL); $TsOH{\cdot}H_2O$ (300 mg, 1.57 mmol) was added and the reaction mixture was stirred at room temperature. After 1 h, some drops of NH_4OH were added to the reaction mixture and the solvent was evaporated. The residue was dissolved in 30 mL of dilute NH_4OH and extracted with 2 × 30 mL of $CHCl_3$. The combined $CHCl_3$ layers were evaporated to dryness and the residue was filtered through a short column of alumina ($CHCl_3$) to afford the enecarbamate **3***b* (2.18 g, 11.9 mmol, 91% from **1***b*): ^{1}H NMR δ: 6.75 (1H, m, H6), 4.8 (1H, m, H2), 4.3 (1H, m, H5), 3.74 (3H, s, NCO_2CH_3), 1.2–2.1 (8H, m), 0.92 (3H, t, J = 7 Hz); ^{13}C NMR δ: 124.2, 106.4, 53.2, 50.7, 33.2, 24.5, 19.6, 18.0, 14.4; MS, *m/z*: 183 ($M^{+\bullet}$, 12%), 140 (100).

General procedure for the acetylation reactions

The alcohol was treated with a mixture of pyridine and acetic anhydride for 1 night at room temperature. After addition of ethanol and chloroform, the solvents were evaporated and the residue was filtered through a short column of alumina to yield the corresponding O-acetyl derivative.

General procedure for the hydroboration of enecarbamates

All the glassware was dried in an oven, assembled hot, and cooled under a stream of dry nitrogen. THF was distillated from lithium aluminium hydride, into the reaction flask containing the enecarbamate; the flask was then equipped with a rubber septum and a positive pressure of nitrogen was maintained. The hydroboration was carried out by adding a 2 M solution of borane in THF (Aldrich) through the septum via a hypodermic syringe previously flushed with dry nitrogen. After the reaction was complete, the reaction flask was immersed in a cooling bath at 0°C, and the excess of borane was destroyed by adding some drops of water. The oxidation step was carried out under magnetic stirring at room temperature by adding the proper amounts of aqueous NaOH and hydrogen peroxide.

Hydroboration of the enecarbamate 3*a*

The enecarbamate **3***a* (267 mg, 1.72 mmol) was subjected to hydroboration, according to the general procedure described above, in 25 mL of THF with addition of a 2 M $BH_3{\cdot}SMe_2$ solution (0.86 mL, 1.72 mmol). After 3 h, the reaction was stopped and the oxidation was performed by adding 1 mL of 3 M NaOH and 1 mL of H_2O_2 (35% w/w). After 2 h at room temperature, the reaction mixture was basified by addition of 100 mL of dilute NH_4OH and extracted with $CHCl_3$ (3 × 100 mL). The combined $CHCl_3$ layers were evaporated to dryness and the residue was submitted to flash chromatography (silica gel, ethyl acetate/hexane 1:1) to furnish successively the *cis* alcohol **5***a* (69 mg, 0.39 mmol, 22%), and the *trans* alcohol **4***a* (148 mg, 0.85 mmol, 49%); **4***a*: ^{1}H NMR δ: 4.44 (1H, m, H2),

4.02 (1H, broad d, J = 14 Hz, H6e), 3.93 (1H, m, H5), 3.69 (3H, s, NCO_2CH_3), 3.06 (1H, dd, J = 14 and 2 Hz, H6a), 1.3–2.1 (4H, m), 1.15 (3H, d, J = 7 Hz, CH_3); ^{13}C NMR δ: 157.4, 64.8, 53.0, 46.7, 45.1, 25.6, 24.1, 15.8; MS, *m/z*: 173 ($M^{+\bullet}$, 10%), 158 (100), 140 (48), 125.9 (m*), 124.0 (m*), 114 (16), 102 (11), 88 (11); **5***a*: ^{1}H NMR δ: 4.36 (1H, m, H2), 4.12 (1H, ddd, J = 13, 5 and 1 Hz, H6e), 3.68 (3H, s, NCO_2CH_3), 3.57 (1H, tt, J = 5 and 11 Hz, H5), 2.66 (1H, dd, J = 11 and 13 Hz, H6a), 1.5–1.8 (4H, m), 1.15 (3H, d, J = 7 Hz, CH_3); ^{13}C NMR δ: 156.4, 67.7, 53.1, 45.9, 45.7, 28.9, 28.5, 16.0; MS, *m/z*: 173 ($M^{+\bullet}$, 28%), 158 (100), 140 (69), 126 (17), 116 (32), 114 (16), 102 (24), 88 (22).

The O-acetyl derivatives **6***a* and **7***a* were prepared according to the procedure described above; **6***a*: ^{1}H NMR δ: 4.87 (1H, m, H5), 4.47 (1H, m, H2), 4.13 (1H, broad d, J = 15 Hz, H6e), 3.67 (3H, s, NCO_2CH_3), 3.03 (1H, dd, J = 15 and 2 Hz, H6a), 1.2–2 (4H, m), 2.01 (3H, s, OAc), 1.15 (3H, d, J = 7 Hz, CH_3); ^{13}C NMR δ: 170.8, 156.8, 67.5, 52.9, 46.3, 42.2, 24.7, 23.2, 21.5, 15.9; MS, *m/z*: 215 ($M^{+\bullet}$, <1%), 200 (3; calcd. for $C_9H_{14}NO_4$: 200.0922; found: 200.0927), 155 (66), 140 (100), 126.4 (m*). **7***a*: ^{1}H NMR δ: 4.64 (1H, tt, J = 5 and 11 Hz, H5), 4.39 (1H, m, H2), 4.14 (1H, ddd, J = 13, 5, and 2 Hz, H6e), 3.68 (3H, s, NCO_2CH_3), 2.76 (1H, dd, J = 13 and 11 Hz, H6a), 2.03 (3H, s, OAc), 1.5–1.9 (4H, m), 1.15 (3H, d, J = 7 Hz, CH_3); ^{13}C NMR δ: 170.4, 156.2, 69.6, 53.0, 45.9, 42.3, 28.5, 25.2, 21.5, 15.9; MS, *m/z*: 215 ($M^{+\bullet}$, <1%), 200 (2; calcd. for $C_9H_{14}NO_4$: 200.0922; found: 200.0920), 155 (66), 140 (100), 126.4 (m*).

Hydroboration of the enecarbamate 3*b*

The enecarbamate **3***b* (108 mg, 0.59 mmol) was submitted to hydroboration, according to the general procedure described above, in 5 mL of THF with the addition, at −78°C, of a 2 M $BH_3{\cdot}SMe_2$ solution (0.3 mL, 0.59 mmol). Once the addition was complete, the reaction mixture was maintained at −10°C for 20 h; the reaction was then stopped and the oxidation was performed by adding 0.5 mL of 3 M NaOH and 0.5 mL of H_2O_2 (35% w/w). After 2 h at room temperature, the reaction mixture was poured into 20 mL of dilute NH_4OH and extracted with $CHCl_3$ (3 × 20 mL). The combined $CHCl_3$ layers were evaporated to dryness and the residue was submitted to flash chromatography (silica gel, ethyl acetate/hexane 1:1) to furnish successively the *cis* alcohol **5***b* (11 mg, 0.054 mmol, 9%) and the *trans* alcohol **4***b* (74 mg, 0.36 mmol, 62%). **4***b*: ^{1}H NMR δ: 4.27 (1H, m, H2), 4.05 (1H, broad d, J = 14 Hz, H6e), 3.91 (1H, m, H5), 3.69 (3H, s, NCO_2CH_3), 3.0 (1H, dd, J = 14 and 2 Hz, H6a), 1.1–2.1 (8H, m), 0.92 (3H, t, J = 7 Hz, CH_3); ^{13}C NMR δ: 64.6, 52.6, 50.4, 44.8, 31.3, 25.5, 22.1, 19.5, 13.9; MS, *m/z*: 201 ($M^{+\bullet}$, 3%), 170 (3), 158 (100), 140 (50); **5***b*: ^{1}H NMR δ: 4.1 (2H, m, H2 and H6e), 3.66 (3H, s, NCO_2CH_3), 3.55 (1H, tt, J = 10.5 and 5 Hz, H5), 2.58 (1H, dd, J = 13 and 10.5 Hz, H6a), 1.2–1.9 (8H, m), 0.89 (3H, t, J = 7 Hz, CH_3); ^{13}C NMR δ: 67.2, 52.6, 49.5, 45.4, 31.5, 28.5, 26.8, 19.4, 13.9; MS, *m/z*: 201 ($M^{+\bullet}$, 3%), 170 (3), 158 (100), 140 (51).

The O-acetyl derivatives **6***b* and **7***b* were prepared according to the procedure described above; **6***b*: ^{1}H NMR δ: 4.86 (1H, m, H5), 4.33 (1H, m, H2), 4.18 (1H, broad d, J = 15 Hz, H6e), 3.68 (3H, s, NCO_2CH_3), 2.97 (1H, dd, J = 15 and 2 Hz, H6a), 2.02 (3H, s, OAc), 1.2–2.0 (8H, m), 0.92 (3H, t, J= 7 Hz, CH_3); ^{13}C NMR δ: 170.9, 157.2, 67.5, 52.9, 50.4, 42.2, 31.8, 23.6, 23.2, 21.5, 19.9, 14.3; MS, *m/z*: 243 ($M^{+\bullet}$, 2%), 212 (2), 200 (42; calcd. for $C_9H_{14}NO_4$: 200.0922; found: 200.0922), 183 (15), 158 (6), 140 (100); **7***b*: ^{1}H NMR δ: 4.67 (1H, tt, J = 5 and 11 Hz, H5), 4.2 (2H, m, H2 and H6e), 3.71 (3H, s, NCO_2CH_3), 2.74 (1H, dd, J = 11 and 13 Hz, H6a), 2.06 (3H, s, OAc), 1.2–1.9 (8H, m), 0.95 (3H, t, J = 7Hz, CH_3); ^{13}C NMR δ: 170.4, 156.8, 69.5, 53.1, 50.1, 42.4, 31.9, 26.9, 25.6, 21.5, 19.9, 14.4; MS, *m/z*: 242 ($M^{+\bullet}$, <1%), 212 (1), 200 (30; calcd. for $C_9H_{14}NO_4$: 200.0922; found: 200.0926), 183 (28), 158 (13), 140 (100).

Hydroboration of the enecarbamate 12

The enecarbamate **12** (252 mg, 0.83 mmol) was subjected to hydroboration, according to the general procedure described above, in 20 mL of THF with addition of a 2 M $BH_3{\cdot}SMe_2$ solution (0.45 mL, 0.91 mmol). After 1.5 h, the reaction was stopped and the oxidation was performed by adding 1 mL of 3 M NaOH and 1 mL of H_2O_2 (35% w/w). After 2 h at room temperature, the reaction mixture was basified with 50 mL of dilute NH_4OH and extracted with $CHCl_3$ (3 × 50 mL). The combined $CHCl_3$ layers were evaporated to dryness and the residue was submitted to flash chromatography (silica gel, ethyl acetate/hexane 9:1) to furnish successively the *cis* alcohol **14** (49 mg, 0.15 mmol, 18%) and the *trans* alcohol **13** (154 mg, 0.47 mmol, 57%). **13**: ^{1}H NMR δ: 7.3 (5H, m), 5.71 (1H, dd, J = 6 and 7 Hz, H8), 4.32 (1H, m, H2), 4.12 (1H, m H6e), 3.95 (1H, m, H5), 3.66 (3H, s, NCO_2CH_3), 3.15 (1H, dd, J = 2 and 14 Hz, H6a), 2.05 (3H, s, OAc), 1.2–2.4 (7H, m); ^{13}C NMR δ: 157.1, 140.2, 128.5, 128.2, 126.7, 74.4, 64.4, 52.7, 48.3, 45.1, 36.1, 25.6, 22.5, 21.3; MS, *m/z*: 321 ($M^{+\bullet}$, 1%), 261 (25), 202 (15), 158 (100), 156.3 (m*), 140 (41), 124.0 (m*). **14**: ^{1}H NMR δ: 7.3 (5H, m), 5.7 (1H, dd, J = 5 and 8 Hz, H8), 4.17 (2H, m, H2 and H6e), 3.66 (3H, s, NCO_2CH_3), 3.58 (1H, m, H5), 2.73 (1H, dd, J = 11 and 13 Hz, H6a), 2.04 (3H, s, OAc), 1.4–2.4 (7H, m); ^{13}C NMR δ: 170.6, 156.3, 140.7, 128.9, 128.5, 127.0, 74.7, 67.4, 53.2, 47.9, 46.1, 36.7, 28.9, 27.6, 21.6; MS, *m/z*: 321 ($M^{+\bullet}$, <1%), 278 (6), 261 (55), 202 (35), 158 (100), 140 (50).

The O-acetyl derivatives **15** and **16** were prepared according to the procedure described above. **15**: ^{1}H NMR δ: 7.3 (5H, m), 5.72 (1H, dd, J = 6 and 8 Hz, H8), 4.87 (1H, m, H5), 4.37 (1H, m, H2), 4.23 (1H, broad d, J = 15 Hz, H6e), 3.66 (3H, s, NCO_2CH_3), 3.11 (1H, dd, J = 15 and 2 Hz, H6a), 2.04 (3H, s, OAc), 2.01 (3H, s, OAc), 1.3–2.4 (6H, m); ^{13}C NMR δ: 170.8, 170.5, 156.9, 140.6, 128.9, 128.5, 127.0, 74.6, 67.2, 53.0, 48.2, 42.5, 36.5, 23.6, 23.4, 21.5; MS, *m/z*: 363 ($M^{+\bullet}$, <1%; calcd. for $C_{19}H_{25}NO_6$: 363.1681; found: 363.1688), 320 (2), 303 (17), 252.9 (m*), 244 (12), 243 (9), 200 (40), 194.8 (m*), 158 (10), 156 (10), 140 (100), 110.2 (m*), 98 (m*); **16**: ^{1}H NMR δ: 7.3 (5H, m), 5.72 (1H, dd, J = 6 and 8 Hz, H8), 4.65 (1H, tt, J = 5 and 11 Hz, H5), 4.2 (2H, m, H2 and H6e), 3.67 (3H, s, NCO_2CH_3), 2.84 (1H, dd, J = 11 and 13 Hz, H6a), 2.04 (3H, s, OAc), 2.05 (3H, s, OAc), 1.2–2.4 (6H, m); ^{13}C NMR δ: 170.1, 169.9, 155.8, 140.2, 128.5, 128.2, 126.6, 74.2, 68.9, 52.8, 47.4, 42.3, 36.3, 26.7 25.2, 21.2, 21.1; MS, *m/z*: 363 ($M^{+\bullet}$, <1%; calcd. for $C_{19}H_{25}NO_6$: 363.1681; found: 363.1687), 304 (4), 303 (7), 260 (4), 244 (10), 243 (8), 200 (37), 140 (100), 110.2 (m*), 98 (m*).

Preparation of pseudoconhydrine 8

To a solution of **4***b* (46 mg, 0.22 mmol) in 5 mL of CH_2Cl_2 was added TMSI (0.32 mL, 2.28 mmol) distilled over copper pow-

der just before use. The reaction mixture was refluxed for 1 h and after addition of some drops of MeOH was allowed to stand at room temperature during 10 min. The solvent was evaporated to dryness and the residue was dissolved in dilute NH_4OH and extracted with $CHCl_3$ (3 × 15 mL). Evaporation of the $CHCl_3$ layers furnished **8** as a colourless oil (28 mg, 0.19 mmol, 89 %). Mass and ^1H NMR spectra were identical with those reported in the literature (17).

Preparation of *N*-methylpseudoconhydrine 9

To a solution of **4***b* (30 mg, 0.15 mmol) in THF (10 mL) was added $LiAlH_4$ (50 mg). The mixture was refluxed for 2.5 h. Some drops of water were added at room temperature, the mixture was filtered through Celite, and the solvent was evaporated to dryness. The residue was dissolved into 10 mL of $CHCl_3$ and extracted with 0.1 N HCl (2 × 10 mL). The organic phase was discarded and the aqueous phase basified with NH_4OH and extracted with $CHCl_3$ (2 × 100 mL). The combined $CHCl_3$ layers were evaporated to dryness and the residue was filtered through a short column of alumina ($CHCl_3$/MeOH 9:1) to afford **9** (20 mg, 0.12 mmol, 80%). Mass and ^1H NMR spectra were identical with those reported in the literature (18).

Swern oxidation of alcohol 13

DMSO (102 μL, 1.45 mmol) was added to a stirred solution of oxalyl chloride (126 μL, 1.45 mmol) in 2 mL of CH_2Cl_2 at −78°C under a nitrogen atmosphere. After 10 min, alcohol **13** (156 mg, 0.48 mmol) dissolved in 1 mL of CH_2Cl_2 was added; the reaction flask was then cooled at −40°C and after 10 min at −78°C triethylamine (1 mL) was added dropwise. The reaction mixture was allowed to reach room temperature and after 15 min poured into 30 mL of water. After neutralization with concentrated HCl and extraction with CH_2Cl_2 (30 mL), the organic phase was washed with dilute NH_4OH, dried, evaporated, and filtered through a short column of silica gel (ethyl acetate/hexane 4:1) to give the ketone **17** (142 mg, 0.44 mmol, 92%). IR: (CCl_4 solution) cm^{-1}: 2955, 1739, 1708, 1450, 1234; ^1H NMR δ: 7.3 (5H, m), 5.83 (1H, dd, J = 5 and 9 Hz, H8), 4.3 (2H, m, H2 and H6e), 3.71 (3H, s, NCO_2CH_3), 3.62 (1H, d, J = 19Hz, H6a), 2.07 (3H, s, OAc), 1.6–2.4 (6H, m); ^{13}C NMR δ: 206.8, 170.6, 156.2, 140.5, 129.0, 128.7, 126.9, 73.8, 53.5, 50.9, 48.8, 39.7, 36.0, 26.7, 21.6; MS, *m/z*: 319 ($M^{+\bullet}$, 1%), 291 (2), 275 (15), 260 (11), 156 (100),128 (32).

PCC oxidation of the alcohol 13

PCC adsorbed on alumina (1 g, 0.9 mmol) was added under stirring to a solution of **13** (73 mg, 0.22 mol) in 10 mL of CH_2Cl_2. The mixture was refluxed and stirred for 1 h, cooled, and then filtered through a column of Florisil (CH_2Cl_2, then AcOEt). The combined organic layers were evaporated to dryness and the residue was filtered through a short column of silica gel (AcOEt). Evaporation of the solvent furnished the ketone **17** as a colourless oil (50 mg, 0.15 mmol, 71%).

Reduction of ketone 17 with $NaBH_4$

$NaBH_4$ (60 mg, 1.6 mmol) was added to a solution of ketone **17** (103 mg, 0.32 mmol) in 5 mL of absolute ethanol at 0°C. After 15 min some drops of water were added and the solvent was evaporated to dryness. The residue was dissolved in 10 mL of dilute NH_4OH and extracted with CH_2Cl_2 (3 × 10 mL). The combined CH_2Cl_2 layers were evaporated and the residue was submitted to flash chromatography (silica gel, ethyl acetate/hexane 4:1) to furnish successively the alcohols **14** (84 mg, 0.26 mmol, 81%) and **13** (10 mg, 0.031 mmol, 10%).

Reduction of ketone 17 with $LiAl(O\text{-}t\text{Bu})_3H$

$(t\text{BuO})_3AlLiH$ (24 mg, 0.094 mmol) was added to a solution of ketone **17** (20 mg, 0.062 mmol) in THF (2 mL) at 0°C. After 2 h some drops of water were added and the mixture was filtered through Celite. After evaporation of the solvent, dilute NH_4OH was added to the residue and the solution was extracted with $CHCl_3$. Evaporation of the solvent followed by a flash chromatography (silica gel, AcOEt/hexane 1:9) furnished the *cis* acetate **14** (12 mg, 0.037 mmol, 60%) and the *cis* diol **18** (5 mg, 0.017 mmol, 28%). **18**: ^1H NMR δ: 7.3 (5H, m), 4.73 (1H, m, H8), 4.36 (1H, m, H2), 4.07 (H, m, H6e), 3.66 (3H, s, NCO_2CH_3), 3.58 (1H, m, H5), 2.61 (1H, dd, J = 11 and 12 Hz, H6a), 1.4–2.2 (8H, m); MS, *m/z*: 279 ($M^{+\bullet}$, 3%), 261 (4), 244 (m*), 202 (4), 186 (4), 173 (3), 158 (100), 140 (78), 124.0 (m*).

Preparation of alcohol 19

To a solution of the carbamate **13** (33 mg, 0.1 mmol) in THF (5 mL) was added $LiAlH_4$ (35 mg). The mixture was then refluxed for 3.5 h. After addition of some drops of water the mixture was filtered through Celite and the solvent was evaporated to dryness. The residue was filtered through a short column of alumina ($CHCl_3$, MeOH 5%, NH_4OH) to give **19** as a colourless oil (15 mg, 0.063 mmol, 63%): $[\alpha]_D^{20}$ −80.5 (c = 0.9, MeOH); ^1H NMR δ: 7.34 (5H, m), 4.82 (1H, dd, J = 3 and 10 Hz, H8), 3.79 (1H, tt, J = 4 and 8 Hz, H5), 2.99 (1H, ddd, J = 12, 4, and 1 Hz, H6e), 2.56 (1H, m, H2), 2.40 (3H, s, NCH_3), 2.26 (1H, dd, J = 8 and 12 Hz, H6a), 1.36–2.08 (6H, m); ^{13}C NMR δ: 128.8, 127.7, 125.9, 73.5, 65.7, 61.2, 60.3, 41.4, 39.9, 32.5, 25.9; MS, *m/z*: 235 ($M^{+\bullet}$, 3%), 128 (3), 114 (100), 96 (10).

Preparation of (−)-5-hydroxysedamine 20

The alcohol **14** (18 mg, 0.056 mmol) was reduced with $LiAlH_4$ (20 mg) in THF (5 mL) as described for **13** to afford alcohol **20** as a colourless oil (10 mg, 0.045 mmol, 80%). The mass, ^1H, and ^{13}C spectra were identical with those reported in the literature (13); $[\alpha]_D^{20}$ −53 (c = 0.3, MeOH).

Anodic oxidation of carbamate 7*a*

The carbamate **7***a* (59 mg, 0.27 mmol), $Bu_4N^+BF_4^-$ (22 mg, 0.068 mmol), and 5 mL of methanol were introduced into the electrolysis cell equipped with a platinum anode and a vitreous carbon cathode. A constant potential of 8 V was applied. After 5F/mol of electricity was passed, the usual work-up was applied; the crude fraction (68 mg) was flash chromatographed (silica gel, AcOEt/hexane 1:2) to give **21** (47 mg, 0.19 mmol, 71%): ^1H NMR δ: 5.5 (1H, m, H6), 4.70 (1H, dt, J ≈ 4 and 12 Hz, H5), 4.3 (1H, m, H2), 3.73 (3H, s, NCO_2CH_3), 3.33 (3H, broad s, OCH_3), 2.10 (3H, s, OAc), 1.64–2.14 (4H, m), 1.29 (3H, d, J = 7 Hz, CH_3); ^{13}C NMR δ: 170.7, 156.3, 82.9, 72.2, 55.8, 53.2, 46.2, 29.1, 21.5, 19.8; MS, *m/z*: 245 ($M^{+\bullet}$, <1%), 214 (8), 202 (4), 198 (5), 185 (23), 172 (11), 170.4 (m*), 170 (7), 142 (25), 140 (11), 118 (100).

Preparation of 22 from 21

To a solution of $TiCl_4$ (21 μL, 0.19 mmol) in 0.2 mL of

CH_2Cl_2 at −45°C, under an atmosphere of nitrogen, was added a solution of **21** (32 mg, 0.13 mmol) in 0.6 mL of CH_2Cl_2. After 15 min the solution was cooled to −78°C and 2-trimethylsilyloxypropene (112 mg, 0.65 mmol) contaminated by ca. 25% of $(CH_3)_3SiOSi(CH_3)_3$ was added. After 4 h at −78°C, the solution was poured into 10 mL of water and NaCl was added; extraction with CH_2Cl_2 (2 × 10 mL), evaporation to dryness, and two successive flash chromatographies (silica gel, ethyl acetate/hexane 1:1) furnished **22** as a 76:24 mixture of diastereoisomers (26 mg, 0.096 mmol, 73%): MS, *m/z* (*c* + *t*): 271 ($M^{+\bullet}$, <1%), 256 (2), 240 (2), 214 (14), 211 (100), 198 (16), 196 (17), 172 (50), 171 (46), 169 (65), 168 (54), 156 (28), 154 (47), 152 (30), 140 (64), 102 (75), 85 (86). The following NMR values were extracted from the spectra of the mixture: major constituent: ^{1}H NMR δ: 4.8–5.07 (2H, m, H5 and H6), 4.35 (1H, m, H2), 3.69 (3H, s, NCO_2CH_3), 2.99 (1H, dd, *J* = 16 and 9 Hz, H7), 2.35 (1H, dd, *J* = 16 and 3 Hz, H7′), 2.19 (3H, s, CH_3), 1.95 (3H, s, OAc), 1.6–1.8 (4H, m), 1.18 (3H, d, *J* = 7 Hz, CH_3); ^{13}C NMR δ: 205.4, 169.7, 156.1, 70.4, 53.0, 48.6, 45.6, 45.4, 30.0, 28.3, 21.0, 20.2, 20.1; minor constituent: ^{1}H NMR δ: 4.78 (1H, m), 4.27 (1H, m), 4.01 (1H, m), 3.64 (3H, s, NCO_2CH_3), 3.12 (1H, dd, *J* = 16 and 8 Hz, H7), 2.60 (1H, dd, *J* = 16 and 7 Hz, H7′), 2.19 (3H, s, CH_3), 2.03 (3H, s, OAc), 1.3–1.9 (4H, m), 1.33 (3H, d, *J* = 7 Hz, CH_3); ^{13}C NMR δ: 205.8, 169.7, 156.2, 70.9, 52.4, 51.4, 49.0, 44.9, 30.0, 26.9, 24.8, 21.3, 18.4.

Anodic oxidation of ent-16

(+)-ent-**16** (93 mg, 0.25 mmol), $Et_4N^+OTs^-$ (8 mg, 0.026 mmol), and 5 mL of methanol were introduced into the electrolysis cell. The solution was stirred for 10 min and a constant potential of 8 V was applied. After 8F/mol of electricity was passed, some drops of NH_4OH, were added to the solution and the solvent was evaporated; the residue was dissolved in water (50 mL), basified with NH_4OH, and extracted with $CHCl_3$ (2 × 50 mL). The combined $CHCl_3$ layers were evaporated and the residue was filtered through a short column of silica gel (ethyl acetate/hexane 1:1) to afford a mixture of **23** and unreacted ent-**16**. This mixture was submitted to column chromatography on alumina (ethanol-free $CHCl_3$) to furnish the mixture of the diastereomeric methoxy compounds **23** (57 mg, 0.145 mmol, 58%): MS, *m/z* (*cis* and *trans*): 362 ($M^{+\bullet}-CH_3O^\bullet$, 3%), 333 (17), 319 (20), 259 (27), 231 (41), 230 (20), 202 (23), 198 (100), 170.4 (m*), 170 (18), 156 (61). The following NMR values were extracted from the spectra of the mixture: major constituent: ^{1}H NMR δ: (330 K): 7.31 (5H, m), 5.79 (1H, dd, *J* = 7 Hz, H8), 5.5 (1H, m, H6), 4.67 (1H, dt, *J* = 12 and 4 Hz, H5), 4.24 (1H, m, H2), 3.72 (3H, s, NCO_2CH_3), 3.35 (3H, s, OCH_3), 2.28 (m, 2H), 2.06 (6H, s, OAc), 1.6–1.94 (4H); ^{13}C NMR δ: (330 K): 170.7, 156.9, 141.2, 129.0, 128.5, 127.0, 83.5, 74.2, 72.2, 57.0, 53.3, 47.8, 40.5, 26.6, 21.4, 20.0; minor constituent: ^{1}H NMR δ (330K): 7.3 (5H, m), 5.8 (1H, m, H8), 5.19 (1H, d, *J* = 2 Hz, H6), 4.91 (1H, dt, *J* = 6 and 3 Hz, H5), 3.70 (3H, s, NCO_2CH_3), 3.60 (1H, m, H2), 3.28 (3H, s, OCH_3), 2.58 (1H, ddd, *J* = 5, 9, and 14 Hz, H7), 2.25 (1H, m, H7′), 2.04 (3H, s, OAc), 1.96 (3H, s, OAc), 1.6–1.9 (4H, m); ^{13}C NMR δ (330 K): 170.7, 170.3, 157.7, 141.2, 129.0, 128.5, 127.1, 85.8, 74.5, 69.2, 56.0, 52.6, 49.2, 39.8, 23.7, 23.4, 21.3, 21.2.

Nucleophilic displacement of the methoxy group of 23

To a stirred solution of $TiCl_4$ (43 μL, 0.39 mmol) in 1 mL of CH_2Cl_2 at 0°C, under an atmosphere of nitrogen, was added a solution of **23** (139 mg, 0.35 mmol) in 3 mL of CH_2Cl_2 and 2-trimethylsilyloxypropene (303 mg, 1.75 mmol) contaminated by ca. 25% of $(CH_3)_3SiOSi(CH_3)_3$. The solution was stirred for 2 h at 0°C, then poured into 50 mL of water and, after addition of NaCl, extracted with CH_2Cl_2 (4 × 50 mL). The combined CH_2Cl_2 layers were evaporated to dryness and the residue was submitted to two successive flash chromatographies (silica gel ethyl acetate/hexane 1:1) to furnish **24** as a 77/23 mixture of *c/t* diastereoisomers (88 mg, 0.21 mmol, 60%): MS, *m/z* (*cis* + *trans*): 419 ($M^{+\bullet}$, <1%; calcd. for $C_{22}H_{29}NO_7$: 419.1944; found: 419.1938), 362 (2), 359 (38), 316 (6), 299 (61), 298 (21), 270 (6), 256 (64), 249.0 (m*), 198 (70), 197 (27), 196 (37), 195 (50), 194 (35), 156 (61), 154 (60), 153.1 (m*), 150.0 (m*), 138 (40), 114 (100). The following NMR values were extracted from the spectra of the mixture: major constituent: ^{1}H NMR δ: 7.35 (5H, m), 5.76 (1H, dd, *J* = 10 and 4 Hz, H8), 5.07 and 4.93 (2H, m, H5 and H6), 4.29 (1H, m, H2), 3.69 (3H, s, NCO_2CH_3), 2.92 (1H, dd, *J* = 16 and 9 Hz, H9), 2.39 (1H, dd, *J* = 16 and 3 Hz, H9′), 2.17 (3H, s, CH_3), 2.09 (3H, s, OAc), 1.93 (3H, s, OAc), 1.9–2.2 (2H, m, H7), 1.2–1.7 (4H, m); ^{13}C NMR δ: 205.4, 170.5, 169.7, 156.1, 140.4, 128.8, 128.4, 126.6, 73.7, 70.1, 53.2, 48.5, 46.9, 45.2, 40.9, 30.1, 25.8, 21.8, 21.4, 20.3; minor constituent: ^{1}H NMR δ (characteristic values): 5.87 (1H, dd, *J* = 8 and 6 Hz, H8), 4.73 (1H, m), 4.2 (1H, m), 3.8 (1H, m), 3.58 (3H, s, NCO_2CH_3), 3.10 (1H, dd, *J* = 17 and 8 Hz, H9), 2.58 (2H, m), 2.17 (3H, s, CH_3), 2.06 (3H, s, OAc), 2.00 (3H, s, OAc), 1.6–2.1 (5H, m).

25: ^{1}H NMR δ: 7.3 (5H, m), 5.90 (1H, broad s, H6), 5.78 (1H, dd, *J* = 5 and 9 Hz, H8), 4.72 (1H, dt, *J* = 12 and 4 Hz, H5), 4.23(1H, m, H2), 3.72 (3H, s, NCO_2CH_3), 2.98 (1H, m, OH), 1.79 (1H, m, H7), 2.09 and 2.07 (6H, 2s, 2 × OAc), 1.7–2.1 (5H, m); MS, *m/z*: 379 ($M^{+\bullet}$, <1%), 319 (9), 318 (5), 301 (5), 259 (16), 241 (6), 231 (11), 216 (8), 198 (33), 156 (100), 121 (73).

Preparation of 27

A solution of **24** (68 mg, 0.16 mmol), ethylene glycol (17 mg, 3.2 mmol), and $TsOH{\cdot}H_2O$ (7 mg) in 20 mL of benzene was refluxed for 3 h in a Dean–Stark apparatus. After evaporation of the solvent, the residue was dissolved in dilute NH_4OH and extracted with CH_2Cl_2 (3 × 15 mL). The combined organic layers were evaporated to dryness to furnish **26** as a colourless oil (70 mg).

To a solution of the crude acetal **26** in THF (15 mL) was added $LiAlH_4$ (116 mg). The mixture was heated under reflux for 3 h. Some drops of water were added and the mixture was filtered through Celite and evaporated to dryness. The combined CH_2Cl_2 layers were evaporated and a chromatography on alumina of the residue furnished the diol **27** as a *c/t* mixture (36 mg, 1.1 mmol, 67% from **24**). The following NMR values (major constituent) were extracted from the spectra of the mixture: ^{1}H NMR δ: 7.3 (5H, m), 4.90 (1H, dd, *J* = 3 and 11 Hz, H8), 3.96 (4H, m, -OCH_2CH_2O-), 3.92 (1H, m, H5), 3.04 (1H, m), 2.91 (1H, td, *J* = 5 and 2 Hz, H6), 2.49 (3H, s, NCH_3), 1.2–2.1 (10H, m), 1.35 (3H, s, CH_3); ^{13}C NMR δ: 145.6, 128.6, 127.4, 125.9, 109.6, 75.9, 68.2, 65.0, 64.7, 64.2, 61.1, 40.8, 39.1, 32.4, 32.3, 24.4, 20.7; MS, *m/z*: 335 ($M^{+\bullet}$, 8%), 320 (2), 292 (6), 234 (14), 214 (97), 112 (29), 87 (100), 58.6 (m*).

Preparation of sedacryptine 28 from 27

A solution of the acetal **27** (36 mg, 1.1 mmol) in 0.1 N aqueous HCl (5 mL) was heated under reflux for 30 min. The mixture was then cooled, basified with NH_4OH, and extracted with CH_2Cl_2 (3 × 15 mL). The combined CH_2Cl_2 layers were evaporated to dryness to furnish a mixture of sedacryptine **28** and **29** in a 60/40 ratio (25 mg, 0.086 mmol, 80 %). After epimerization in MeOH the diastereoisomeric ratio moved to 80/20. Crystallization from cyclohexane furnished pure (+)-sedacryptine **28** as colourless crystals, mp 122–123°C; $[\alpha]_D^{20}$ +14 (c = 0.54, $CHCl_3$); ^1H NMR δ (360 MHz): 7.34 (5H, m), 4.85 (1H, dd, J = 10 and 3 Hz, H8), 4.07 (1H, q, J = 3 Hz, H5), 2.69 (1H, t, J = 3 Hz, H6), 2.31 (1H, m, H2), 2.28 (3H, s, NCH_3), 2.24 (1H, d, J = 13 Hz, H9), 2.20 (1H, m, H7), 2.09 (1H, ddt, J = 14, 3 and 3 Hz, H4e), 1.91 (1H, dd, J =13 and 4 Hz, H9′), 1.83 (1H, m, H3e), 1.54–1.65 (3H, m, H3a, H4a, H7′), 1.5–1.9 (2H, OH), 1.48 (3H, s, CH_3); MS, m/z: 291 ($M^{+\bullet}$, 4%), 273 (12), 234 (2), 230 (4), 170 (100), 152 (83), 135.9 (m*), 112 (44), 95 (75).

Study of the coordinated system Pb(II) – neutral valine – valinate ion

Teresa María Borges Miquel, Mercedes Lemus Sánchez, Josefa Castro Macías, and Jesús César Rodríguez Placeres

Abstract: The polarographic method has been applied to the study of the mixed-coordinated system (Pb(II) – neutral valine – valinate ion, in aqueous medium, I = 1.0 mol L^{-1} ($NaClO_4$) and 25 ± 0.1°C. The stabilization of the following complexes: $[Pb(HV)]^{2+}$ (β_{10} = 9.7), $[Pb(HV)_2]^{2+}$ (β_{20} = 28), $[Pb(HV)(V)]^{+}$ ($\beta_{11} = 3.3 \times 10^4$), $[Pb(V)]^{+}$ ($\beta_{01} = 3.7 \times 10^4$), and $[Pb(V)_2]$ ($\beta_{02} = 2.8 \times 10^7$) was observed.

Key words: polarography, Pb(II), valine, speciation.

Résumé : On a appliqué la méthode polarographique à l'étude du système coordiné mixte Pb(II) – valine neutre – ion valinate, en solution aqueuse, I = 1,0 mol L^{-1} ($NaClO_4$), à 25 ± 0,1°C. On a observé la stabilisation des complexes suivants : $[Pb(HV)]^{2+}$ (β_{10} = 9,7), $[Pb(HV)_2]^{2+}$ (β_{20} = 28), $[Pb(HV)(V)]^{+}$ ($\beta_{11} = 3{,}3 \times 10^4$), $[Pb(V)]^{+}$ ($\beta_{01} = 3{,}7 \times 10^4$), et $[Pb(V)_2]$ ($\beta_{02} = 2{,}8 \times 10^7$).

Mots clés : polarographie, Pb(II), valine, espéciation.

Introduction

The study of the coordinated systems metal ion – amino acids has become increasingly important in recent times, and from different points of view. Increasing worldwide interest was confirmed in 1991, when EC countries selected "Biocoordination Chemistry" as one of seven priority research fields.

One of the most interesting procedures currently followed to investigate the structures and functions of complex macromolecules consists in the analysis of simple molecules that present properties similar to those characteristic of macromolecules. The model compounds are, generally, easier to study and the information obtained has frequently been successfully extrapolated to macromolecules. Thus, for example, Freeman (1) has shown the utility of the information obtained in the study of some simple complexes for understanding the structure of the active sites of carboxypeptidase.

Likewise, diverse observations have led to the study of the formation of metal ion complexes of small molecular weight since this is the way in which metal ions are mobilized during prolonged periods of nutrition. The reliability of the stability constant values of both simple and mixed complexes with simple amino acids is also of importance since they represent the main form of administration in the nutritive mixture or the form of excretion. Thus, the reinvestigation of the coordinated system Zn(II)–cysteinate–hystidinate (2) led to a reduction of the initial estimate of the daily dosage of zinc from 38 mg to 32 mg in some nutritive mixtures studied.

On the other hand, studies of the coordinated systems metallic ion – amino acid have generally taken into account only the anion is ligand, disregarding the complexing nature of the neutral species. It was therefore thought worthwhile to undertake a systematic analysis of these systems from the wider standpoint of considering the complexation of the metallic ion by both species.

Lastly, the fact must be pointed out that the majority of studies of coordinated metallic ion – amino acid systems have been carried out by adjusting the ionic strength with weakly complexing electrolytes. We have shown and verified experimentally (3) that the constants determined under these conditions do not in fact respond to true stability constants but rather to defined arrangements of formation constants of simple and mixed species existing in the medium. The importance of this particular results became evident on finding that the use of this type of electrolyte was generalized, and it provided a solid basis for questioning the greater part of the data previously reported in the literature on coordination chemistry.

In this work we report on the analysis of the mixed coordinated system Pb(II) – neutral valine – valinate ion, which has been studied (4,5), Table 1, but never at the standard temperature of 25°C. Only the formation of two complexes with the valinate ion; $[Pb(V)]^{+}$ and $[Pb(V)_2]$, has been described. The scatter of the results is quite remarkable and requires experimental revision. No stabilization of any complex with neutral valine has been detected.

Theoretical

If the molecule of neutral valine (HV), the zwitterion form of

4	6.12	2–18	$(6.438–56.56) \times 10^{-6}$	1.990–17.89
5	6.52	2–18	$(1.008–14.20) \times 10^{-5}$	1.966–17.88
6	6.53	3–18	$(2.422–14.25) \times 10^{-5}$	2.980–17.94
7	6.58	2–18	$(1.865–16.68) \times 10^{-5}$	1.998–17.88
8	6.77	2–18	$(2.782–25.30) \times 10^{-5}$	1.969–17.91
9	6.95	2–18	$(4.252–38.04) \times 10^{-5}$	1.989–17.79
10	7.33	2–18	$(1.035–8.903) \times 10^{-4}$	1.990–17.76

which widely predominates, and the valinate ion (V) are considered to be possible ligands of Pb(II) and we admit that, as occurs in the studies of alanine (6), leucine (7), and isoleucine (7), only two ligands can be coordinated, the F_{00} function of Schaap and McMasters (8) will be developed as follows:

$$[1] \quad F_{00} = \{1 + \beta_{10}[HV] + \beta_{20}[HV]^2\} + \{\beta_{01} + \beta_{11}[HV]\}[V] + \{\beta_{02}\}[V]^2$$

It is evident that at sufficiently high values of pH the complexes with the anion will predominate since their concentration will be significative and their stability constants must be much greater than those of the neutral form.

At sufficiently low values of pH it is to be expected that the high concentration of the neutral species with respect to that of the anionic species compensates greatly for its much lower stability constant and its complexes with the metallic cation under study can be determined.

Between the limits mentioned, determination of the constants of the mixed coordinated species will be possible.

In any case, it is understood that if the pH required is very low, the concentration of the protonated form may be high, appreciably modifying the ionic strength. This effect can be minimized by decreasing the total concentration of amino acid.

Likewise, in every case it will be necessary to work with the concentration of complexing forms of amino acid such that their complexation will prevail appreciably over the formation of hydroxo-complexes.

The studies were carried out at constant pH but modifying the total concentration of amino acid, such that [HV] and [V] vary with V_T.

With regard to the expression $K_{a2} = [V][H^+]/[HV]$, eq. [1] transforms to:

$$[2] \quad F_{00} = 1 + \{\beta_{10} + \beta_{01}(K_{a2}/[H^+])\}[HV] + \{\beta_{20} + \beta_{11}(K_{a2}/[H^+]) + \beta_{02}(K_{a2}/[H^+])^2\}[HV]^2$$

a relationship that at constant pH will reduce to

$$[3] \quad F_{00} = 1 + B[HV] + C[HV]^2$$

where, if $m = [H^+]/K_{a2}$, the B and C coefficients will be defined by:

$$[4] \quad B = \beta_{10} + \beta_{01} m^{-1}$$

$$[5] \quad C = \beta_{20} + \beta_{11} m^{-1} + \beta_{02} m^{-2}$$

and can be calculated in the usual manner.

The knowledge of an appropriate number of values of the B and C coefficients would allow us to determine the stability constants of the coordinated species present in the medium.

If substitution is made in terms of [V] the expressions would be analogous

$$[6] \quad F_{00} = 1 + \{\beta_{01} + \beta_{10}([H^+]/K_{a2})\}[V] + \{\beta_{02} + \beta_{11}([H^+]/K_{a2}) + \beta_{20}([H^+]/K_{a2})^2\}[V]^2$$

$$[7] \quad F_{00} = 1 + B'[V] + C'[V]^2$$

where:

$$[8] \quad B' = \beta_{01} + \beta_{10} m$$

$$[9] \quad C' = \beta_{02} + \beta_{11} m + \beta_{20} m^2$$

Experimental

Each of the i vs. E curves was plotted with an Inelecsa PDC1212 electrochemistry system. An Ag/ClAg/NaCl sat. Metrohm EA427 electrode and a Pt (EA285) electrode were employed as reference and auxiliary electrode, respectively. The temperature was always 25 ± 0.1°C and the drop time was set at 3 s. The ionic strength was maintained constant at I = 1.0 mol L^{-1} by addition of $NaClO_4$. The pH measurements were carried out with a pHM84 digital pH-meter (± 0.002) and a Radiometer GK2401C combination electrode. The lead perchlorate, Merck p.a., was prepared by weight and it was standardized complexometrically. Sodium perchlorate was also Merck p.a. and the L-valine was from Sigma p.a. The values of the acidity constants (9) were pK_{a1} = 2.35 ± 0.01 and pK_{a2} = 9.62 ± 0.01.

Procedures

The studies were carried out at constant pH, varying the concentration of total valine between the limits indicated in Table 2. In every case, the plots in absence of ligand were made at low pH (2.00 – 3.00) and $[Pb^{2+}] \simeq 1.0 \times 10^{-4}$ M.

All adjustments were carried out utilizing Sigma Plot 5.01.

Results

In all the solutions studied the polarograms show good symmetry and a regular outline. The plot of log $[i_d–i/i]$ vs. E shows that the discharges occurred by a reversible bielectronic pro-

Fig. 1. Plot of the functions F_{00} and F_{10} vs. [HV] at pH 4.16.

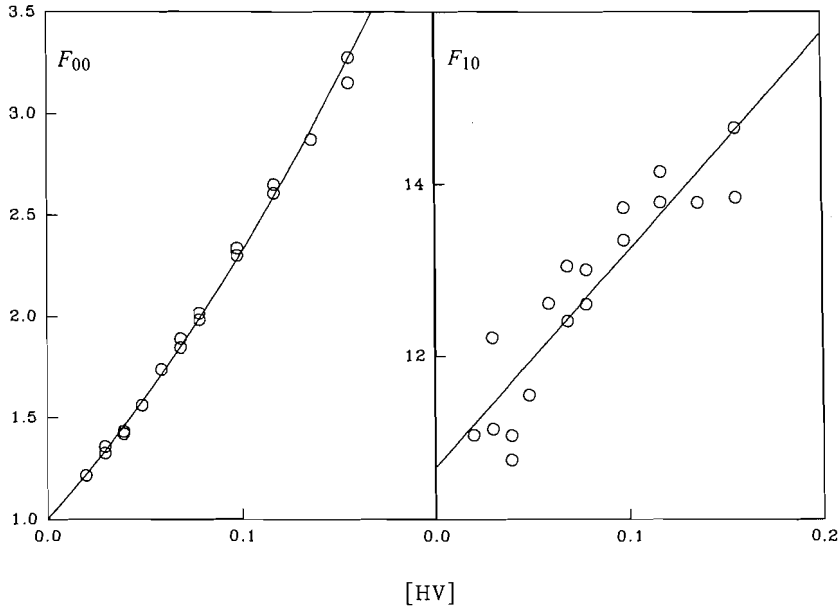

Fig. 2. Plot of the functions F_{00} and F_{10} vs. [HV] at pH 6.95.

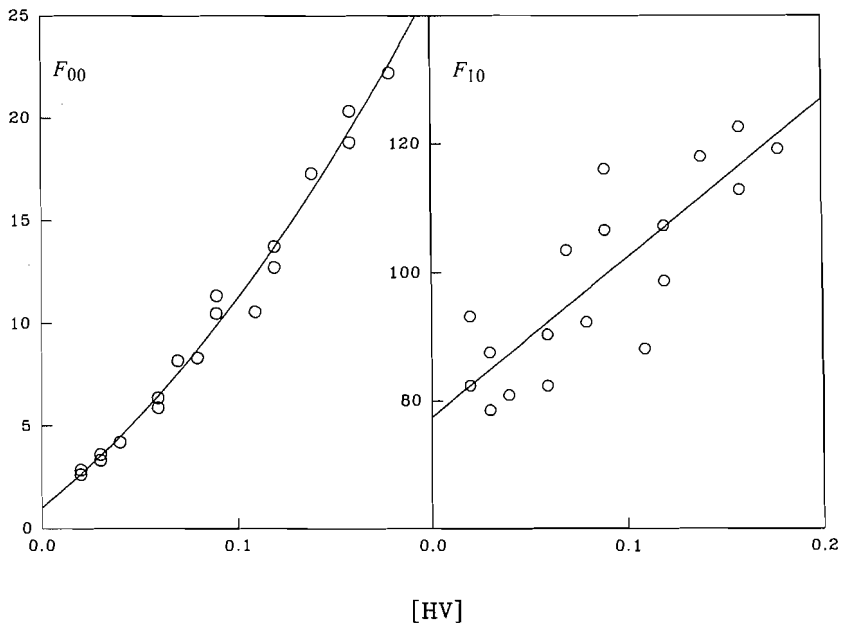

cess. The values for the reversible half-wave potentials were obtained directly from those plots. With few exceptions, the accuracy was better than ± 0.5 mV.

Figures 1–3 present the plots of the F_{i0} functions vs. the concentration of the ligand indicated. In each case, eq.[3] is confirmed. Adjusting by least squares provides the values of B and C given in Table 3.

The studies performed were planned such that studies 1–3 correspond to low values of pH, in which the complexes with neutral valine should prevail. The sets carried out at higher values of pH (4–10) allow the determination of the simple and mixed complexes with the anionic form.

Determination of the β_{10} and β_{20} constants

It will be shown that in eqs. [4] and [5] the summands other than β_{10} and β_{20} are negligible with respect to the corresponding coefficients, B and C, which leads us to propose the following values of the formation constants of the complexes $[Pb(HV)]^{2+}$ and $[Pb(HV)_2]^{2+}$: $\beta_{10} = 9.7 \pm 1.3$ and $\beta_{20} = 28 \pm 7$.

Determination of the β_{01} constant

Equation [4] indicates that a plot of the coefficient B vs. m^{-1} must be a straight line. By fitting to the previously determined ordinate, $\beta_{10} = 9.7$, from the slope of the said plot, Fig. 4, the

Fig. 3. Plot of the functions F_{00} vs. [HV] at pH 7.33.

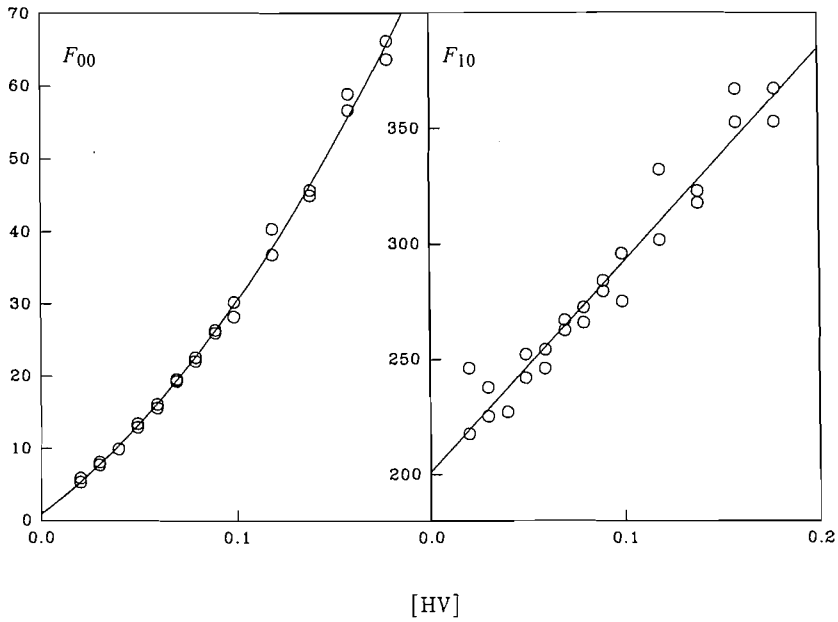

Fig. 4. Plot of B vs. m^{-1}.

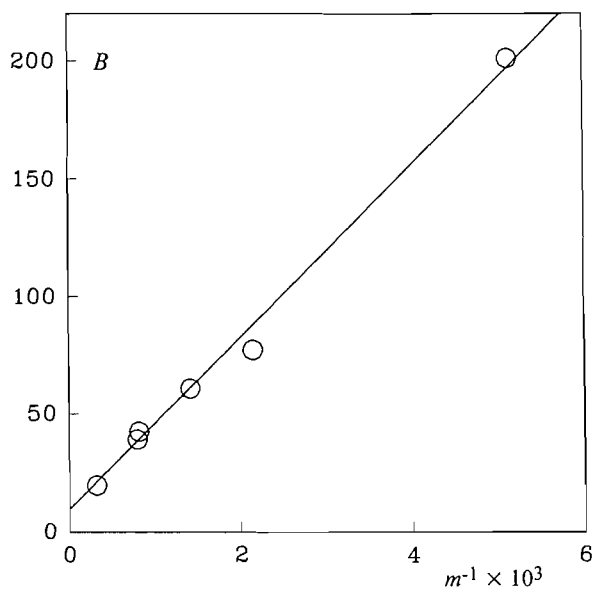

Fig. 5. Plot of $(C - \beta_{20})/m^{-1}$ vs. m^{-1}.

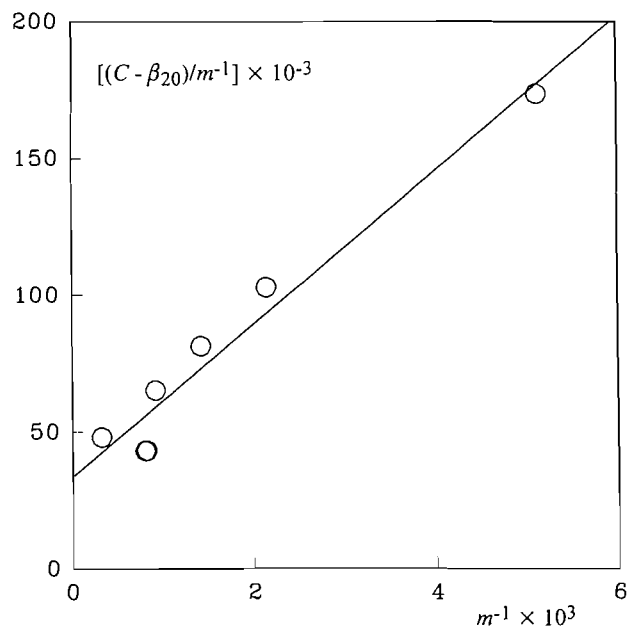

value of the stability constant of the complex $[Pb(V)]^+$ will be obtained:

$$\beta_{01} = (3.7 \pm 0.2) \times 10^4$$

Determination of the β_{02} and β_{11} constants

Taking into account that β_{20} is known, and that the coefficient C is defined by

$$C = \beta_{20} + \beta_{11}\, m^{-1} + \beta_{02}\, m^{-2}$$

the plot of the function $(C - \beta_{20})/m^{-1}$ vs. m^{-1} will determine a straight line with the ordinate in the origin β_{11} and the slope β_{02}.

Figure 5 shows the above-mentioned dependence, which by least squares allows the formation constant of the complexes $[Pb(V)_2]$ and $[Pb(HV)(V)]^+$ to be determined as: $\beta_{02} = (2.8 \pm 0.3) \times 10^7$ and $\beta_{11} = (3.3 \pm 0.6) \times 10^4$.

Discussion

This is the first experimental confirmation of the stabilization of the complexes $[Pb(HV)]^{2+}$, $[Pb(HV)_2]^{2+}$, and $[Pb(HV)(V)]^+$.

Fig. 6. Distribution curves of the lead–valine complexes as a function of pH.

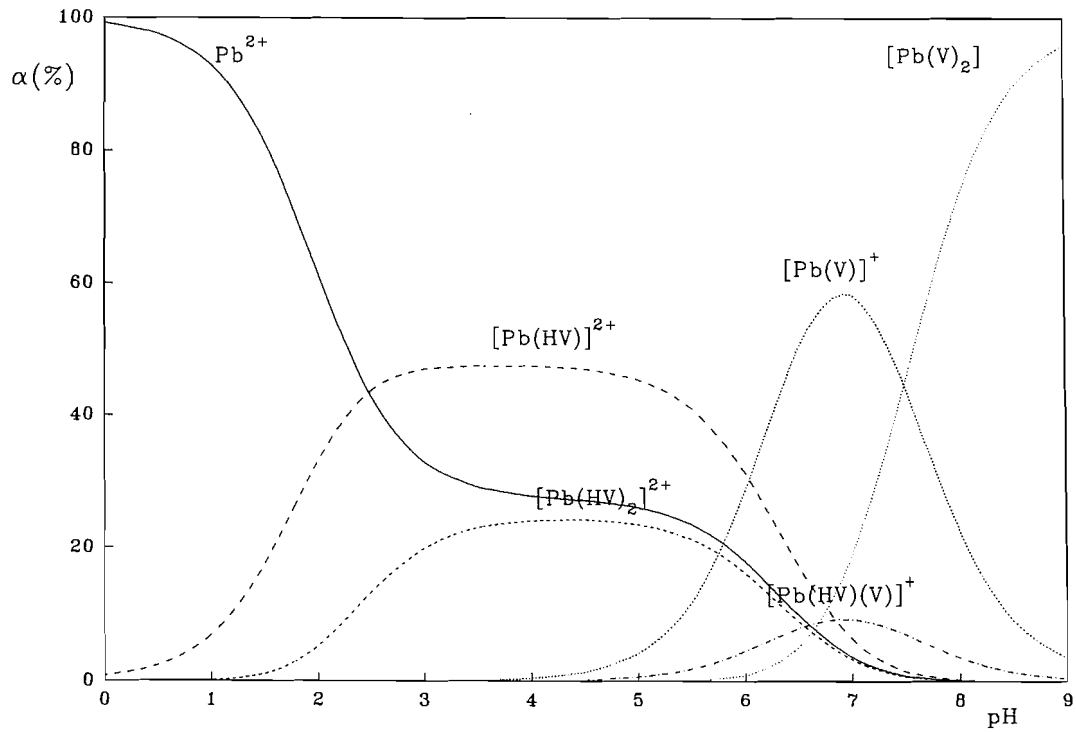

Table 3. Coefficients of the polynomial $F_{00} = 1 + B[HV] + C[HV]^2$.

Set	pH	$m^{-1} \times 10^6$	B	C
1	4.16	3.467	10.70 ± 0.3	25.26 ± 3
2	4.17	3.548	8.446 ± 0.2	35.13 ± 3
3	4.22	3.981	9.807 ± 0.4	22.68 ± 4
4	6.12	316.2	19.72 ± 1	42.92 ± 14
5	6.52	794.8	39.18 ± 2	62.01 ± 16
6	6.53	812.8	42.64 ± 2	62.86 ± 16
7	6.58	912.0	78.35 ± 5	87.27 ± 44
8	6.77	1413	61.04 ± 3	142.9 ± 24
9	6.95	2138	77.43 ± 3	248.1 ± 34
10	7.33	5122	201.2 ± 5	916.4 ± 45

A comparison is only possible with the theoretical value from the equations of Watters and Dewitt (10) using the constants of the simple complexes and from purely statistical considerations: $\beta_{11} = 2\ \beta_{20}^{1/2} \cdot \beta_{02}^{1/2} = 2.8 \times 10^4$. This is in remarkable agreement with the experimental value, $\beta_{11} = 3.3 \times 10^4$.

In relation to the stability constants of the species with one and two valinate ligands, $\beta_{01} = 3.7 \times 10^4$ and $\beta_{02} = 2.8 \times 10^7$, they are of the order of those obtained by Rao and Subrahmanya (4): $\beta_{01} = 1.58 \times 10^4$ and $\beta_{02} = 7.8 \times 10^7$.

In Table 4, the constants obtained in this work are compared with those previously determined for the coordinated system Pb(II)–alanine – alaninate ion (6). A marked parallelism can be observed in the stability of the complexes $[Pb(HX)]^{2+}$, $[Pb(HX)_2]^{2+}$, and $[Pb(X)]^+$, a little higher for those of alanine than the others.

Table 4. Stability constants of Pb(II)–alanine and Pb(II)–valine systems.

System	β_{10}	β_{20}	$\beta_{01} \times 10^{-4}$	$\beta_{02} \times 10^{-7}$	$\beta_{11} \times 10^{-4}$
Pb(II)–alanine	13	25	3.8	6.7	10
Pb(II)–valine	9.7	28	3.7	2.8	3.3

Figure 6 shows the distribution in percentages as a function of the pH for the solution: ($C_{Pb} = 1.0 \times 10^{-4}$ M; $A_T = 0.18$ M).

Quantitative elemental and structural analysis of dissolved organic carbon fractions from lakes near Sudbury, Ontario

Roy Carl Boerschke, Elizabeth Ann Gallie, Nelson Belzile, Richard Neville Gedye, and James Robert Morris

Abstract: Dissolved organic carbon (DOC) was quantitatively isolated as five separate fractions from two Sudbury area lakes (Ontario, Canada) using the tandem XAD-8/XAD-4 resin technique. Fulvic acids made up ≈48% of the total, humic acids ≈8%, hydrophobic neutrals ≈8%, XAD-4 acids ≈11%, and XAD-4 acetonitrile extracts ≈13%. Hydrophobic:hydrophilic ratios were about 65:35. Solid-state CPMAS ^{13}C NMR indicated a primarily aliphatic nature in all fractions. Percent aromaticity was in the order humic acids > fulvic acids > XAD-4 acetonitrile extracts ≈ XAD-4 acids ≈ hydrophobic neutrals. Titration analysis showed that the ^{13}C NMR peaks of fulvic acids, humic acids, and XAD-4 acids from 160–190 ppm were primarily carboxyl in nature. The XAD-4 acids were the most acidic, suggesting that they may be important geochemical agents. ^{13}C NMR indicated that polysaccharides formed <20% of any fraction. The two neutral fractions (hydrophobic neutrals and XAD-4 acetonitrile extracts) had relatively high N contents, possibly due to the acetonitrile used to extract them. However, the ^{13}C NMR spectra did not show significant quantities of acetonitrile. The elemental and structural composition covaries in the three acid fractions, such that if one acid is enriched or depleted, so are the others. This suggests that the humic and non-humic acids form a continuum in which all fractions are affected by the same formative processes. Compared to published data for other freshwater samples, the three acid fractions from the Sudbury area lakes have low or very low aromaticity. This may indicate that the acid and metal loadings in the Sudbury area have affected the structure of the organic acids, despite the circumneutral character of the study lakes. These are the first quantitative ^{13}C NMR results published for the hydrophobic neutrals and XAD-4 acetonitrile extracts, so comparisons are not possible.

Key words: aquatic DOC, organic acids, ^{13}C NMR, humic substances, non-humic substances.

Résumé : Le carbone organique dissous a été isolé de façon quantitative en cinq fractions distinctes à partir de deux lacs de la région de Sudbury (Ontario, Canada), en utilisant le tandem de résines XAD-8/XAD-4. Les acides fulviques forment ≈48% du total, les acides humiques ≈8%, les hydrophobiques neutres ≈8%, les acides XAD-4 ≈11% et l'extrait acétonitrile de résine XAD-4 ≈13%. Les rapports hydrophobiques:hydrophiliques sont respectivement de 65:35 et 62:38 pour les lacs Ramsey et Nepewassi. Les analyses RMN ^{13}C CPMAS montrent que toutes les fractions ont une nature principalement aliphatique. Les pourcentages d'aromaticité se situent dans l'ordre suivant : acides humiques > acides fulviques > extrait acétonitrile XAD-4 ≈ acides XAD-8 ≈ hydrophobiques neutres. L'analyse par titrage a démontré que les pics RMN ^{13}C des acides fulviques, humiques et XAD-4 de la région 160–190 ppm sont principalement carboxyliques. Les acides XAD-4 étaient les plus acides ce qui suggère qu'ils puissent être des agents géochimiques importants. L'étude RMN ^{13}C indique aussi que les polysaccharides forment <20% de toutes les fractions isolées. Les deux fractions neutres (les hydrophobiques neutres et l'extrait acétonitrile de résine XAD-4) ont montré des contenus en azote relativement élevés possiblement reliés à l'acétonitrile utilisé pour les extraire. Cependant, les spectres RMN ^{13}C n'ont montré aucune quantité significative de ce produit. Les compositions élémentaire et structurelle covarient dans les trois fractions acides de telle sorte que si un des acides est enrichi ou déficient, les autres le sont aussi. Cela suggère que les acides humiques et non-humiques forment un continuum dans lequel toutes les fractions se trouvent affectées par les mêmes processus de formation. En comparant avec les données publiées sur d'autres échantillons d'eau douce, on constate que les trois fractions acides des lacs de la région de Sudbury affichent de basses ou très basses aromaticités. Cela pourrait indiquer que les déversements d'acide et de métaux dans cette région ont pu affecter la structure des acides organiques et ce, malgré le caractère neutre des lacs étudiés. Puisque les résultats sur l'analyse quantitative RMN ^{13}C sur les hydrophobiques neutres et l'extrait acétonitrile XAD-4 sont les premiers à être publiés, la comparaison avec d'autres milieux n'est pas possible.

Mots clés : carbone organique dissous, acides organiques, RMN ^{13}C, matières humiques, matières non-humiques.

Introduction

Dissolved organic carbon (DOC) is an ubiquitous and pivotal component of aquatic ecosystems. Recognized as a major reservoir of carbon, DOC plays an important role in many physical, chemical, and metabolic processes occurring in water. Whether acting as a food source for bacteria and microorganisms (1), providing mechanisms for the mobilization of metals and organic pollutants and mediating their effects (2–5), or performing a number of other biological or geochemical functions (6), DOC has been identified as a major player in natural processes.

To understand the role DOC plays in aquatic environments, it is necessary to be concerned with the character of its component molecules. DOC in aquatic environments can range from simple compounds such as CH_4 to high molecular weight polymers, and may contain functional groups ranging from hydrocarbons to complex multifunctional compounds (7). However, DOC consists primarily of a complex mixture of organic acids, along with small amounts of bases and neutral compounds (8).

In general, DOC can be divided into six fractions: hydrophilic acids, bases, and neutrals; and hydrophobic acids, bases, and neutrals (9). The hydrophobic acids, which are composed of fulvic and humic acids, make up the humic substances. All other fractions are considered non-humic. Humic substances have been intensively studied. Forming the largest fraction of the DOC, humic substances have been reported to constitute from 40 to 60% (10) to as high as 60–80% (2) of total carbon present.

Many studies on the characterization of aquatic humic substances involve degradative and non-degradative techniques. Degradative methods, including oxidative and reductive degradations (11, 12), hydrolysis (13), and pyrolysis (14, 15) have all been used with some success to elucidate the molecular structure of humic substances. Non-degradative methods such as fluorescence and ultraviolet spectroscopy (16) and infrared spectroscopy (17) have shown limited utility in the determination of humic substance structure. Elemental analysis provides the elemental composition of humic substances, from which the sources of DOC can be inferred from C/H, C/N, and O/C ratios (18). Unfortunately, use of these traditional techniques provides primarily qualitative results concerning the character of humic substances.

Recently, carbon-13 nuclear magnetic resonance (^{13}C NMR) has become a valuable non-degradative approach in the characterization of humic substances. Analysis using ^{13}C NMR has shown that distinct differences in structure exist between humic substances isolated from different environments (19, 20). Furthermore, if determinations employ favourable T_{CP} (cross-polarization time), T_{1P} (proton relaxation time) constants, and repeat times, and if any organic free radicals and (or) inorganic paramagnetic species in the sample are identified, then quantitative evaluation of the spectra is possible (21). The importance of quantitative spectra is that they allow for valuable structural relationships to be determined, from which the origin of the humic fractions can be inferred.

The study of non-humic DOC has not been as extensive. Although some work has been done on the fractional distribution of DOC (22–24), little information concerning the structural characterization of the non-humic DOC is available.

Table 1. Physical and chemical characteristics for Ramsey Lake[a] and Nepawassi Lake (26).

Characteristic	Ramsey Lake	Nepawassi Lake
Area (ha)	795.0	1125.0
Maximum depth (m)	20.5	39.0

Manganese (μg/L)	8.2	29.7

[a]Ontario Ministry of the Environment and Energy, unpublished data, 1993.

Thus the purposes of this study were: (*i*) to isolate DOC quantitatively from two lakes near Sudbury, Ontario, (*ii*) to fractionate the DOC into its major humic and non-humic components, and (*iii*) to characterize all fractions quantitatively using elemental analysis and solid-state cross-polarization magic angle spinning (CPMAS) ^{13}C NMR. This information will broaden the base of data on DOC from different environments, in particular Canadian environments, and will add fundamental structural information for three non-humic fractions on which little has been published.

Materials and methods

Samples for the study were collected from two lakes near Sudbury, Ontario. Both lakes fall within the Sudbury deposition zone, an area of high anthropogenic sulphate loading (25), but they have not been strongly acidified due to local natural buffering. Ramsey Lake (46°29′N, 80°57′W), a mesotrophic lake located in the centre of Sudbury, covers an area of approximately 795 ha. It has a maximum depth of 20.5 m and a pH of 7.5 (Table 1). Ramsey Lake is primarily spring fed. Primary allochthonous sources of DOC are wetland outflow on the southern and eastern ends of the lake. The balance of Ramsey Lake's watershed is urbanized.

Nepewassi Lake (46°22N, 80°38W), a mesotrophic lake located approximately 40 km southeast of Sudbury, covers an area of 1125 ha. It has a maximum depth of 39 m and a pH of 6.9 (Table 1). Nepewassi Lake has one major and several

minor inflowing tributaries. Roughly 20% of the lake is surrounded by wetlands, with the balance of the lake being encompassed by recreational properties and forest.

Bulk water samples were collected over a 2 week period from November 8 to 25, 1993. This period was about 1 month after fall overturn had begun. Water samples were collected from a depth of approximately 1 m using a manual bilge pump. Immediately upon arrival at the lab, samples were filtered using 0.45 μm Gelman Supor 450 membrane filters, and acidified to pH 1.9 using 1.0 M HCl.

Tandem XAD-8/XAD-4 resin setup

Two 5.3 L columns, containing Rohm and Haas XAD-8 and XAD-4 resins, respectively, were set up. The predicted capacity factor for these columns for $k' = 50$ was determined to be 150 L. Columns were eluted and regenerated after passage of each 150 L batch.

The previously filtered, acidified water was pumped first onto XAD-8 resin at a rate of 400 mL/min. The XAD-8 resin adsorbed the fulvic acids, humic acids, and hydrophobic neutrals. Effluent from the XAD-8 resin was collected in a reservoir before being pumped onto the XAD-4 resin at 400 mL/min. The XAD-4 resin adsorbed most of the remaining DOC (XAD-4 acids and XAD-4 acetonitrile extracts). Hydrophobic and hydrophilic bases, and some hydrophilic neutrals passed through both the XAD-8 and XAD-4 resins and were discarded.

The humic and fulvic acids were eluted from the XAD-8 resin, and the XAD-4 acids from the XAD-4 resin, with dilute 0.1 M NaOH. Humic and fulvic acids were separated by acidification to pH 1 followed by centrifugation. All three fractions were then protonated by cation exchange, vacuum-concentrated, and freeze-dried. Following this, the hydrophobic neutrals were extracted from the XAD-8 resin, and the XAD-4 acetronitrile extracts from the XAD-4 resin, by processing each resin separately with acetonitrile and water in a Soxhlet apparatus for 2 days. These two fractions were also vacuum-concentrated and freeze-dried. All the detailed steps and recommendations of previous researchers were followed (10, 24).

DOC analysis

For each 150 L batch, samples of the filtered unacidified and filtered acidified water were taken to determine initial DOC values. Samples of the effluent from both the XAD-8 and the XAD-4 resins were taken at 25 L intervals from 0 L to 150 L to determine quantitatively the DOC adsorbed by each resin. The ratio of hydrophobic:hydrophilic DOC was also determined through adsorption on the XAD-8 resin, with hydrophobic DOC considered to be the fraction that was adsorbed to the XAD-8 resin.

Following the cation exchange phase for the humic acids, fulvic acids, and XAD-4 acids, samples of each fraction (for all batches combined) were taken to quantitatively determine the relative percentage of each DOC fraction. The relative percentage of each DOC fraction was also calculated after freeze-drying to determine losses incurred during isolation.

DOC analysis was done using an automated Oceanographic International Carbon Analyzer. The carbon analyzer was standardized for a range of 0.1 to 10.0 mgC/L, with sample accuracy ±0.03 mgC/L using potassium acid phthalate and fulvic acid standards. Sample precision was ±0.02 mgC/L determined with standards run every tenth sample.

Elemental analysis

Analyses of C, H, O, N, S, P, and ash were conducted by Huffman Laboratories, Inc., Golden, Colorado. All analyses were carried out using direct methods of determination. Carbon and hydrogen were determined through sample combustion at 1000°C in oxygen, producing carbon dioxide (CO_2) and water (H_2O), respectively. CO_2 was measured using a Coulometrics model 5010 detector. H_2O was quantitatively exchanged with CO_2, by passage through 1,1-carbonyldiimidozole, which was then measured using a second coulometer. Nitrogen was ascertained using a Carlo Erba N 1500 analyzer, which employed a Dumas method with thermal conductivity detection (TCD). Oxygen was resolved using a Coulometrics model 5060 oxygen analyzer, utilizing the Unterzaucher method and a Coulometrics model 5010 for detection. Sulphur was measured using a Leco model SC 132 sulphur analyzer. Ash was determined through oxidation of the sample in a furnace until a constant weight was obtained. Phosphorus was measured by Inductively Coupled Plasma–Atomic Emission Spectrometry.

NMR spectra

The solid state CPMAS ^{13}C NMR analyses were performed by the U.S. Geological Survey, Denver, Colorado. Spectrometer frequency for the ^{13}C NMR was 50.30 MHz, 90 degree pulse width of 4.50 s, contact time of 1.00 ms, pulse delay of 1.00 s, sweep width of 30.030 kHz, and 1000 scans were collected for each spectrum. Optimum contact and relaxation times were determined prior to ^{13}C NMR analysis being performed.

The percent carbon in each shift range was determined by planimetering the areas under the curve three times and averaging. Percent aromaticity was determined using (19):

$$[1] \quad fa_1 = \frac{\text{Area of 110–160 ppm}}{\text{Total Area}} \times 100$$

Titrations

Titrations to estimate the concentration of carboxyl groups were performed with an automated Radiometer titrator. Samples were titrated twice and results averaged. The titer to pH 8 was assigned solely to carboxyl groups (27).

Results and discussion

Dissolved organic carbon

Initial DOC values determined immediately after filtration indicated an average of 5.53 mgC/L for Ramsey Lake and 7.84 mgC/L for Nepewassi Lake. Analysis of effluent from the XAD-8 resin indicated that an average of 3.59 mgC/L and 4.86 mgC/L was adsorbed to the resin from Ramsey and Nepewassi lakes, respectively. Because XAD-8 removes all the hydrophobic DOC, the ratio of hydrophobic:hydrophilic was 65:35 in Ramsey Lake and 62:38 in Nepewassi Lake, values that are probably not significantly different. (Hydrophobic bases, which do not sorb to either XAD-8 or XAD-4 resin, usually make up only 1–2% of the total DOC (24).) From the DOC remaining in the XAD-8 effluent, XAD-4 resin adsorbed a further 1.27 mgC/L and 2.27 mgC/L of hydrophilic material from

Ramsey Lake and Nepewassi Lake, respectively. The remaining 12% of the DOC or about 0.67 mgC/L from Ramsey Lake, and 9% or 0.71 mgC/L from Nepewassi Lake, were discarded. The material discarded was assumed to be mostly bases and hydrophilic neutrals, though some acids may have been present (28).

DOC was isolated as five major fractions: fulvic acids, humic acids, hydrophobic neutrals, XAD-4 acids (sometimes called hydrophilic acids or low-molecular-weight acids), and XAD-4 acetonitrile-removed substances (hereafter referred to as XAD-4 ace extracts). Fulvic acids constitute the largest fraction of the DOC in both lakes (48%) (Table 2). The ratio of fulvic acid to humic acid is 6:1 and 7:1 in Ramsey and Nepawassi lakes, respectively. The ratio for an average of about 100 rivers in the United States is 9:1 (10). However, there is a trend to lower ratios as one moves north into more DOC-rich, organically coloured waters (10), and values as low as 2.5:1 are reported for some Scandanavian lakes (24).

Hydrophobic neutrals are one of the smallest fractions of DOC in the study lakes (Table 2). Published data on hydrophobic neutrals are scanty, but may indicate a trend toward a higher proportion in more northerly lakes. The average percentage in 100 U.S. rivers is 6% (10), in the study lakes it is 7–9%, and in Lake Skjervatjern in Norway it is 9–11% (24).

XAD-4 acids commonly make up 20–25% of freshwater DOC (10, 24, 28). However, in the study lakes, XAD-4 acids make up only 10–11%. There are other freshwaters with documented percentages as low or lower (Yakima River, Wash., U.S.A. at 8–12%; two Antarctic lakes at 7–9%), but these waters also all had much lower fulvic acid percentages (23–26%) (28). Until more data are available for comparison, it is difficult to know how to interpret the difference.

The XAD-4 ace extracts made up 13–18% of the DOC in the study lakes, and 9–12% of the DOC was not captured on either resin. Presumably these final two components are largely made up of non-elutable low-molecular-weight acids, hydrophilic neutrals, and bases. Malcolm (10) indicates that hydrophilic neutrals make up 15% and bases 4% of freshwater DOC, on average, in U.S. rivers. In Lake Skjervatjern, the XAD-4 ace extracts and the lost DOC together made up 13–15% of the total. However, there is no information available for the XAD-4 ace extracts alone.

Elemental and ^{13}C NMR analyses

Fulvic Acid

The elemental composition of fulvic acids is similar in both study lakes (Table 2) and is consistent with fulvic acids from other freshwater sources (Table 3). Of the five fractions isolated, fulvic acids have the lowest N content, giving them the highest C/N ratio. They also have the lowest ash content (Table 2).

The ^{13}C NMR spectra for fulvic acids show the four major peaks and three minor peaks common to lake and stream fulvic acids (29) (Fig. 1; Table 4). The largest peak for fulvic acids is aliphatic carbon (0–62 ppm), accounting for approximately 43% of the total carbon. (The main chemical shift assignments used to interpret the ^{13}C NMR spectra are given in Table 5.)

Aliphatic carbons singly bonded to oxygen or nitrogen (62–90 ppm) are considered to be mainly C-O because of the low N content. Polysaccharides, which have major peaks in this region, may account for the majority of the carbon present in this shift. This suggestion is based on the size of the anomeric peak (90–110 ppm), which can be used to estimate roughly the polysaccharide or carbohydrate-like fraction (19, 30). Up to half the anomeric peak is assumed to result from the C_1 anomeric carbon of polysaccharides (R. Malcolm, personal communication). The total carbon due to polysaccharides is then six times this amount, while the C-O carbon due to polysaccharides is five times this amount (29). These calculations suggest that polysaccharides make up <15% of the total carbon in fulvic acids in Ramsey and Nepawassi lakes, and about two-thirds of the C-O carbon. Any remaining carbon in the C-O region is probably a variety of alcohol and ether carbons. A significant contribution from free saccharides is unlikely given the XAD-8 isolation procedure (29).

Titration analysis to pH 8 used 5.8 and 5.5 mequiv./g for

Table 3. Comparison of elemental composition (ash free), atomic ratios, and ash content from Ramsey Lake and Nepewassi Lake with those from other studies.

Lake Fryxell (28)	49.3	4.8	39.2	4.8	1.8	12.0	0.86	0.60	8.9

Ramsey Lake and Nepewassi Lake, respectively. This indicates that carboxyl groups account for about 13% of total carbon and the majority of the carboxyl and ester carbon (160–190 ppm).

The diverse spectra in the ketonic regions (190–230 ppm) is indicative of a variety of aromatic and aliphatic ketones. The ketonic peak is weak but distinct, similar to other lake (29) and stream fulvic acids (19).

Percent aromaticity for the lakes was approximately 15% for fa_1. This falls at the low end of the range of 16–25% for streams (average 21%) (28, 29), and is comparable to data from an alpine oligotrophic lake with fa_1 of 17% (29).

Humic acids

Humic acids from Ramsey and Nepawassi lakes have a similar elemental composition (Table 2), although the Ramsey Lake humic acids have a slightly higher N and P content, possibly related to this urban lake's slightly more productive nature (Table 1). The humic acids are consistent with humic acids from other lakes (Table 3). The humic acids resemble the fulvic acids in many ways. However, the N and ash contents are higher, and the C/N ratio is lower. This is illustrated in Fig. 2 where the points plot above the 1:1 line for %N and ash, and below for the C/N ratio, for both the study lakes and the comparison lakes (16, 21). Figure 2 also illustrates that the elemental composition of fulvic acid covaries with the composition of humic acid. This is not surprising if one accepts that humic and fulvic acids form a continuum, operationally divided into two arbitrary fractions. Thus the processes affecting the composition of one may well affect the composition of the other.

Three significant differences can be seen in the ^{13}C NMR spectra between the humic and fulvic acids (Fig. 1; Table 4). The first difference is the increased resolution in the 0–50 ppm region in humic acids. The sharp peaks at 28 and 40 ppm suggest that terminal methyl and methylene groups in alkyl chains are important compositional features of humic acids.

The second difference is the presence of a methoxyl peak (50–62 ppm). Methoxyl groups appear to be present in all freshwater humic acids (29). They account for about 8% of the carbon present in Ramsey and Nepewassi lake humic acid samples.

The final difference is an increase in the percent aromaticity of humic acids to about 21% (Table 4). This increase is due in part to a pronounced peak for phenolic aromatic carbon (140–160) that is present only as a weak shoulder in the fulvic acids. A phenolic aromatic peak is a signature of stream and lake humic acids (29). In the study lakes, the peak is well resolved, though the total carbon represented (≈5%) is lower than reported for other lakes (29). The overall aromaticity of the Ramsey and Nepawassi humic acids ($fa_1 \approx$ 21%) is much lower than occurs in one alpine oligotrophic lake ($fa_1 \approx$ 37%: (29)) and lower than in rivers where fa_1 averages 34% (range 30–35%) (29). However, there is very little literature published on lakes so it is difficult to know how to interpret the difference.

The ^{13}C NMR spectra for C-O groups (62–90 ppm) and anomeric carbon (90–110 ppm) demonstrate that polysaccharides do not make up a large fraction of humic acids (<15%), though they may account for virtually all of the C-O carbon. The small polysaccharide component is a point of difference from humic acid characterizations based on soil humates (29, 31).

Humic acid titrations to pH 8 used 4.2 and 4.3 mequiv./g for Ramsey and Nepawassi lakes, respectively. This indicates that humic acids are less acidic than fulvic acids, with carboxyl groups accounting for only about 10% of total carbon.

Hydrophobic neutrals

The hydrophobic neutrals differ in elemental composition and atomic ratios from the other fractions, especially with regard to nitrogen and sulphur contents (Table 2). However, they also have high ash contents[3] and, for Nepawassi samples especially, that introduced some uncertainty in the results and interfered with ^{13}C NMR analyses. For this reason, only the hydrophobic neutrals from Ramsey Lake will be discussed.

The hydrophobic neutrals and XAD-4 ace extracts both have relatively high N contents (Table 2). Since both are isolated from their respective resins using acetonitrile, the question arises whether some of the N could be an artifact of the extraction method. This could happen in two ways. First, it is possible that hydrolysis of the acetonitrile during the refluxing step could break some of the C≡N bonds in the acetonitrile and form ammonium ions (NH_4^+). The ammonium ions might then react with functional groups present in the hydrophobic neutrals, increasing nitrogen levels. A second possibility is that some residual acetonitrile remained in the fraction due to inadequate washing of the isolated hydrophobic neutrals with distilled water (32). Both acetonitrile and its breakdown products (acetic acid and acetamide) should reveal themselves in the ^{13}C NMR spectra. The peak where acetonitrile should fall (117 ppm) is very small. It accounts for <1% of total carbon, which if it were due to acetonitrile would correspond to <10% of the N in the hydrophobic neutrals. Peaks for the breakdown products, however, would be masked by other signals (e.g., amides at 173 ppm would be masked by carboxyl and ester carbons). Nevetheless, this suggests that the N in the hydrophobic neutrals may be a natural part of the material.

The sulphur content is more than five times higher in hydrophobic neutrals than in any other fraction (Table 2). The study lakes have elevated sulphate levels (Table 1) due to years of sulphate loading from local smelting operations. Although XAD-8 resins have no affinity for inorganic anions (28), it is possible that sulphates do not have time to diffuse out of the resins during the rapid elution process in which humic substances are removed. Later, during the longer extraction process in which hydrophobic neutrals are removed, sulphates may have time to escape (J.A. Leenheer, personal communication). Further research is needed on the extent to which elevated S is a contaminant or a real characteristic of hydrophobic neutrals in acidified lakes.

The ^{13}C NMR spectra reveal that the non-humic hydrophobic neutrals are quite different from the humic substances (Fig. 1, Table 4). Aliphatic chains play a more important role in hydrophobic neutrals. Related to the higher aliphatic content, the percent aromaticity is the lowest of all five materials examined, about one-half to one-third the aromaticity of the humic substances. The small quantity of anomeric carbon (90–110 ppm) indicates that polysaccharides form the smallest proportion (<10%) of the total carbon of any of the five materials. Equally, polysaccharides appear to account for less than a third of the carbon in the C-O shift (62–90 ppm). The remaining carbon in this shift could be ethers and alcohols, but may also be carbon singly bonded to N, whether such N is a natural com-

[3] The resins were desalted until conductivity fell below 30 μS/cm. Thus it seems unlikely that NaCl was a large component of the ash.

Fig. 1. Solid state CPMAS ^{13}C NMR spectra for humic fractions (fulvic acids, humic acids) and non-humic fractions (hydrophobic neutrals, XAD-4 acids, XAD-4 ace extracts) isolated from (*a*) Ramsey Lake and (*b*) Nepawassi Lake.

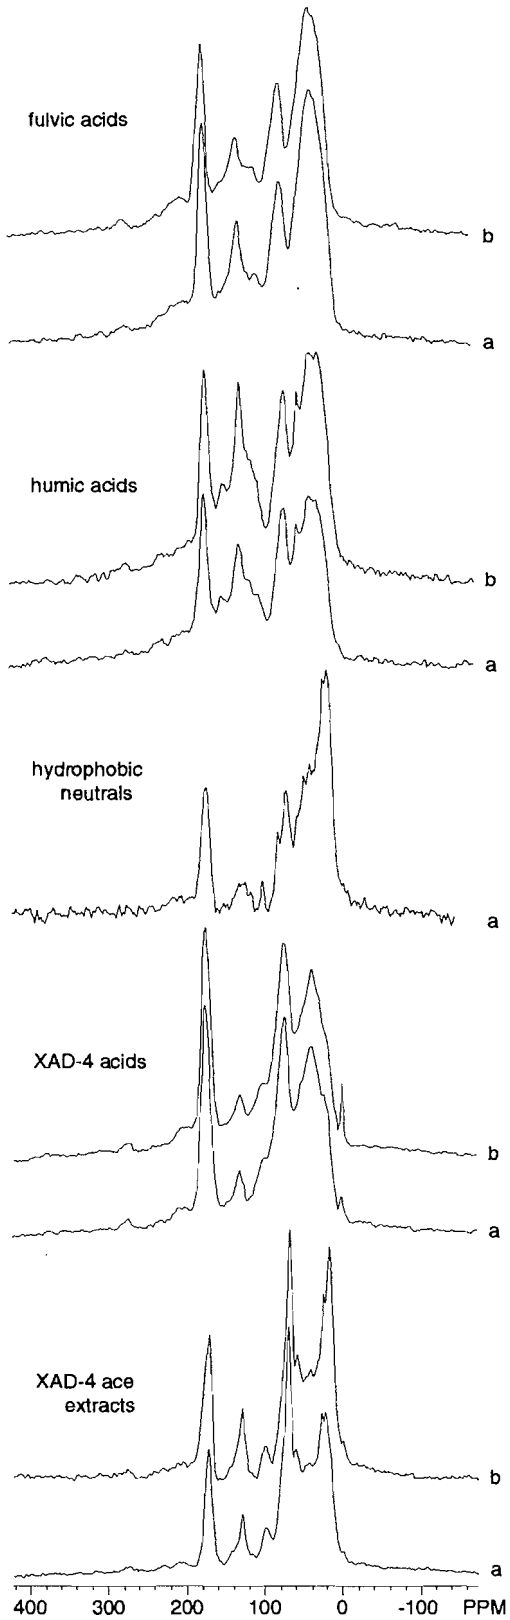

Table 4. Percentage of carbon associated with chemical shifts of ^{13}C NMR for DOC fractions isolated from Ramsey Lake and Nepewassi Lake. Data from Yakima River (28), the only other published data for XAD-4 acids, is included for comparison.

ponent or not. Finally, the carboxyl and ester peak (160–190 ppm) is smaller than for humics, and must be primarily esters since the material has a neutral character.

There are some similarities to humic acids. A weak shoulder from 50–62 ppm is attributed to methoxyl groups, and a very weak phenolic peak is discernable (140–160 ppm). Such features are charactersitic of freshwater humic acids and may characterize freshwater hydrophobic neutrals as well.

The authors are not aware of any published quantitative information on hydrophobic neutrals for comparison.

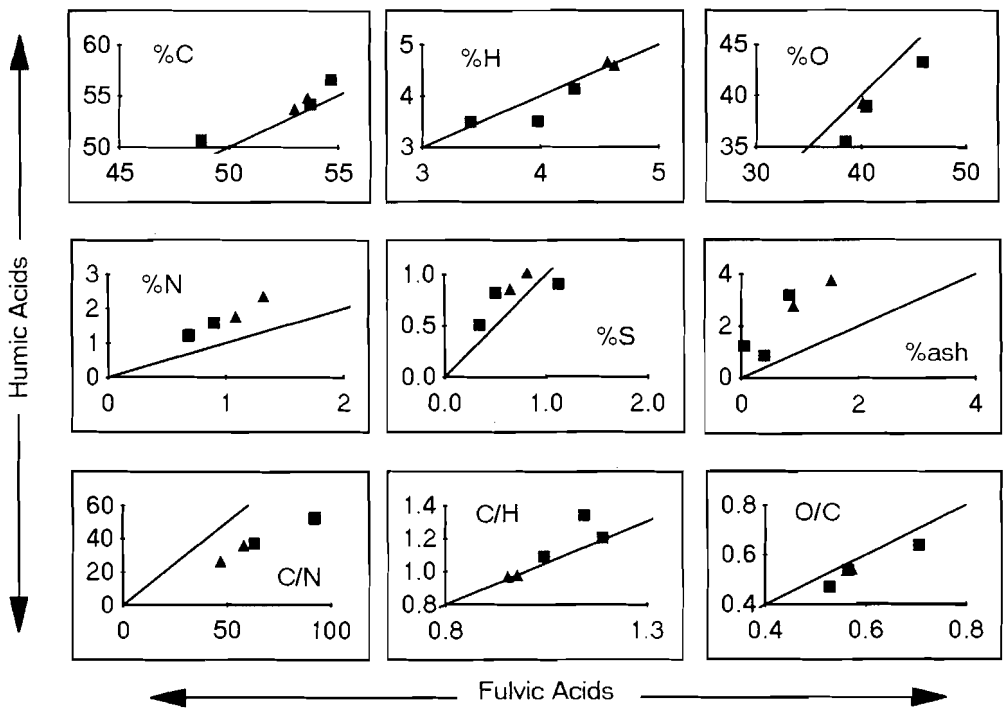
XAD-4 acids

The elemental composition of XAD-4 acids is similar in

Table 5. General chemical shift assignments for the CPMAS ^{13}C NMR spectra (19, 29).

Shift range (ppm)	Assignment
00 – 62	Short-chained and (or) highly branched aliphatic carbon.
00 – 50	Unsubstituted and saturated aliphatic carbon. Individual peaks are taken to indicate terminal methyl groups, and methylene and methine groups in alkyl chains.
50 – 62	Methoxyl (-OCH_3); aliphatic esters and ethers.
62 – 90	Aliphatic carbons singly bonded to oxygen or nitrogen; ring carbons of polysaccharides; alcohols and ether-bonded aliphatic carbon (C-O).
90 – 110	Anomeric carbon (carbon singly bonded to two oxygen atoms); C_1 anomeric carbon in polysaccharides.
110 – 140	Aromatic carbon with protonated functional groups (110–120 ppm) and unsubstituted and alkyl-substituted aromatic carbon (120–140 ppm).
140 – 160	Aromatic carbon substituted by oxygen or nitrogen; phenol.
160 – 190	Carboxyl carbon; ester carbon.
190 – 230	Aromatic and aliphatic ketones (C=O); aldehydes.

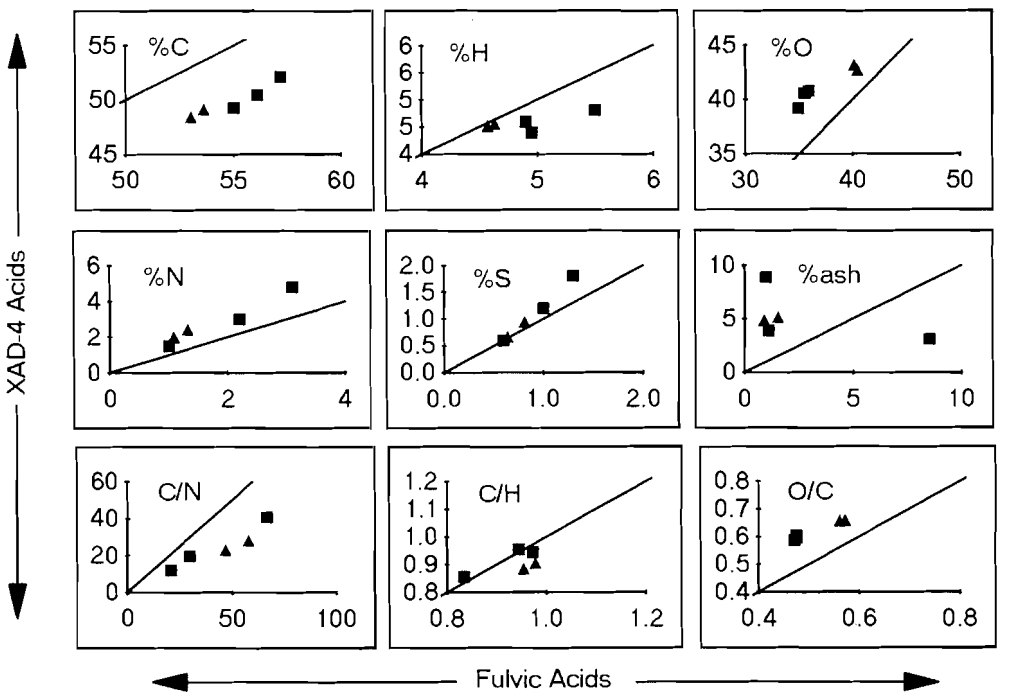
Fig. 2. Comparison of elemental content, ash content, and atomic ratios of fulvic acids vs. humic acids. The line on each graph is the 1:1 line. Triangles represent Ramsey and Nepawassi lakes. Squares represent data for Skjervatjern Lake (21), Suwannee River (16), and IHSS Nordic Reference (16). See Table 3 for more detail.



Nepewassi and Ramsey lakes (Table 2), though the Ramsey Lake acids have a slightly higher N content (again attributed to the slightly more productive conditions in Ramsey). Compared to other freshwater XAD-4 acids, those in the study lakes may have a slightly higher O content, but are similar with regard to other elements (Table 3).

The non-humic XAD-4 acids differ from fulvic acids in several ways. They have less C, and more O, N, and ash, and hence plot below and above the 1:1 line, respectively, in Fig. 3. This gives the XAD-4 acids consistently lower C/N ratios, and higher O/C ratios. The latter may imply either a higher carboxylic or polysaccharide content than in fulvic acids. Aiken et al. (28) is the only source of published data for comparison. Aiken et al. (28) found similar elemental differences between XAD-4 acids and fulvic acids in the Yakima River and Lake Fryxell, with one exception. They concluded that XAD-4 acids were enriched in S in comparison to fulvic acids, but our data do not confirm this (Fig. 3). The data in Fig. 3 also show that there is a strong covariance for most of the

Fig. 3. Comparison of elemental content, ash content, and atomic ratios of fulvic acids vs. XAD-4 acids. The line on each graph is the 1:1 line. Triangles represent Ramsey and Nepawassi lakes. Squares represent data for Yakima River at Kiona and Cle Elum (28) and Lake Fryxell (28). See Table 3 for more detail.



elements in fulvic acids and XAD-4 acids. This suggests that the non-humic components isolated on XAD-4 resin form a continuum with the humic substances, with similar formational processes affecting the composition of all.

The XAD-4 acids distinguish themselves in several ways in the ^{13}C NMR spectra (Fig. 1, Table 4). The anomeric region (90–110 ppm) is larger than in any of the other four fractions. Thus, polysaccharides probably form more of the total carbon (<20%) than in other fractions. In comparison to humic and fulvic acids, the fa_1 aromaticity is low, as with the other non-humic fractions. The carboxyl and ester region (110–160 ppm) is larger than in any other fraction. Titration analysis to pH 8 required 5.9 and 6.0 mequiv./g for Ramsey and Nepawassi lakes, respectively, indicating that approximately 15% of the total carbon and the major part of the carboxyl and ester carbon (110–160 ppm) were carboxyl in nature. Thus, the elevated O/C ratio mentioned above probably indicates both a higher saccharide and higher acidic content. Finally, the XAD-4 acids produce a distinct ketonic (190–230 ppm) peak, similar to fulvic acids.

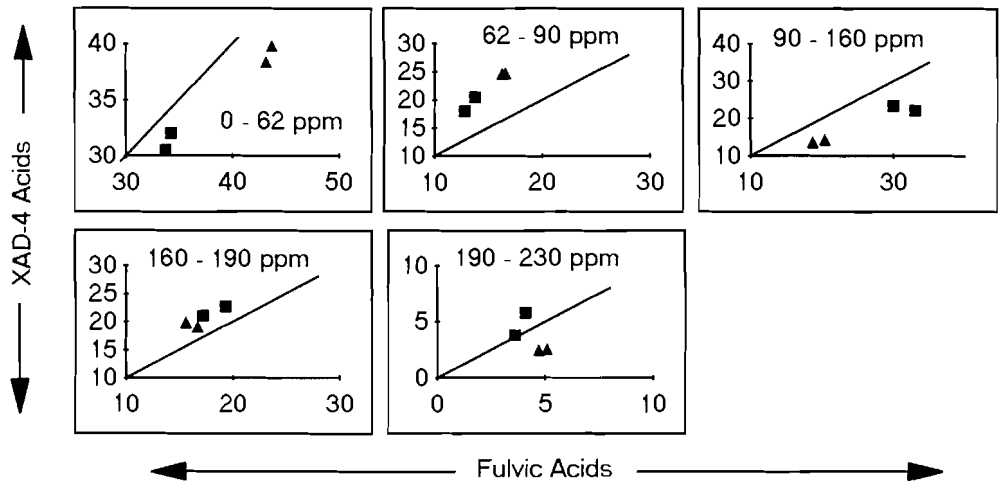
The only published quantitative ^{13}C NMR spectra for XAD-4 acids are solution-state spectra for two samples from the Yakima River (28) (Table 4). The aromaticity of these samples is reported for the 90–160 ppm shift rather than as fa_1. The Ramsey and Nepawassi samples have much less carbon (about 14% vs. 23%) in the aromatic shift so defined. Thus it appears that all three acids from the study lakes are less aromatic than other freshwater samples. The decrease in aromaticity is offset by an increase in aliphatic carbon, and to a lesser extent heteroaliphatic (C-O) carbon, with little change in the proportion of carboxylic carbon.

Despite the difference described above, the Yakima River samples show the same structural differences between XAD-4 acids and fulvic acids as our data. That is, XAD-4 acids are less aromatic and aliphatic, but more heteroaliphatic (C-O) and carboxylic than fulvic acids from the same body of water (Fig. 4). Given that XAD-4 acids can compose up to 25% of the DOC (28), the acidic component is especially significant, and may contribute to an important geochemical role in weathering, metal interactions, and other environmental processes (28). The same covariance as is noted in elemental composition is present for some structural groups (Fig. 4); that is, where fulvic acids are enriched or depleted in aliphatic, heteroaliphatic, or aromatic components, and possibly carboxylic components, so are the XAD-4 acids. There are few data points on the graphs and one should interpret them with caution, but the covariance again reinforces the sense that the non-humic and humic components form a continuum, in which all fractions are affected by similar formative processes.

XAD-4 acetonitrile extract

XAD-4 ace extracts from both study lakes are alike elementally (Table 2). As with the hydrophobic neutrals that are also extracted with acetonitrile, N content is high, and it is uncertain whether this is an artifact of the isolation procedure or represents a natural component of the extracts. There is virtually no peak at 117 ppm in the ^{13}C NMR spectra, however, which suggests that the N is not due to acetonitrile contamination. The O/C ratio is the lowest of the five fractions. This suggests a less acidic nature, particularly when examined in context with the low to moderate C/H ratio.

Fig. 4. Comparison of ^{13}C NMR functional group content in fulvic acids vs. XAD-4 acids. The line on each graph is the 1:1 line. Triangles represent Ramsey and Nepawassi lakes. Squares represent data for Yakima River at Kiona and Cle Elum (28). 0–62 ppm is aliphatic carbon; 62–90 ppm is C-O; 90–160 ppm is primarily aromatic; 160–190 ppm is carboxyl or ester carbon; and 190–230 ppm is ketonic carbon. The ketonic peak for the Yakima samples was integrated from 190–220 ppm. See Table 4 for more detail.



The ^{13}C NMR spectra (Fig. 1; Table 4) show that the XAD-4 ace extracts have low aromaticity, in common with the other non-humic fractions. The C-O region is large, as with the XAD-4 acids, but the anomeric peak indicates that polysaccharides account for <10–15% of the total carbon, and less than half of the C-O carbons. It is possible that some of the remaining C-O carbons are in fact carbon singly bonded to N. The carboxyl and ester region is small, as with the hydrophobic neutrals, and presumably represents primarily esters since the material did not elute with NaOH. The low O/C and C/H ratios also suggest the predominance of esters. Finally, the XAD-4 ace extracts have a higher methoxyl peak (50–62 ppm) than either the humic acids or hydrophobic neutrals. There are no other published ^{13}C NMR results for XAD-4 ace extracts for comparison.

Conclusions

Quantitative elemental and structural analyses were carried out on five DOC fractions isolated from two circumneutral freshwater lakes within the zone of influence of the large mining and smelting industry at Sudbury, Ontario. The isolated fractions were as follows: humic acids and fulvic acids, which have been extensively studied by others, and hydrophobic neutrals, XAD-4 acids (hydrophilic acids), and XAD-4 acetonitrile extracts, which to date have not been well described in the literature.

The ratio of hydrophobic (XAD-8) to hydrophilic (XAD-4) DOC is approximately 65:35. The fulvic acids constitute the largest fraction of the total DOC in both lakes at 48%, with a fulvic acid:humic acid ratio of 6:1 and 7:1 in Ramsey and Nepawassi lakes, respectively. The remaining fractions each make up from ≈7 to 18% of the total DOC.

The key factor distinguishing the humic substances from the non-humic is aromaticity. The former have fa_1 = 14–22% whereas the three non-humic components have fa_1 = 7–9%. Making up for the low aromaticity, the non-humic components are more aliphatic or heteroaliphatic, though, for all five fractions, aliphatic carbon is the single largest carbon group.

Although the humic components are often thought of as the prime source of organic acidity, the XAD-4 acids were found to have a slightly higher carboxylic content. This was seen in the size of the carboxyl shift, and confirmed by titration analysis. The XAD-4 acids in the study lakes make up just less than 20% of the organic acids (10% of DOC). Given their more intense acidity, and the fact that they compose a higher percentage of the DOC in other lakes (28), it is clear that they may be a significant geochemical agent. To date, they have been largely ignored, but with the relative ease of the XAD-8/XAD-4 tandem extraction, their role in weathering, metal transport, and other environmental processes (28) should be investigated.

Both primarily neutral fractions, the hydrophobic neutrals and the XAD-4 ace extracts, have a resolvable methoxyl component. In this they resemble the humic acids. Both neutral fractions appear to have a high N content. Since both are extracted with acetonitrile, the N could be a contaminant. However, the ^{13}C NMR spectra suggest that acetonitrile cannot account for more than about 10% of the N. Both neutral fractions share a small carboxylic-ester peak, assumed to be mostly esters, in keeping with their neutral character. Although the interpretation of ^{13}C NMR spectra for polysaccharide content is difficult, it appears that the neutral fractions have the lowest polysaccharide content. The two neutral fractions are, however, not identical. The hydrophobic neutrals are substantially more aliphatic (54% vs. 39%). They also have the highest sulphur of any of the five fractions, though the sulphur is probably a contaminant from the lakewater.

The two hydrophilic fractions isolated on the XAD-4 resin

have C-O shifts that are substantially higher than those found in the hydrophobic fractions. Other than this, however, there is little that distinguishes the fractions isolated on the two different resins.

Compared to samples from other freshwaters, the three acid fractions in Ramsey and Nepawassi lakes do not appear to be unusual with regard to elemental composition. However, there do appear to be some structural differences. All three acids are either at the low end of the normal range for aromaticity, or are much less aromatic than samples from other freshwaters. There are few lakes with which to compare so it is difficult to interpret the results, but they may indicate that DOC and its formative mechanisms have been affected by the acid rain and metal loadings of the Sudbury area (25), despite the circumneutral character of the study lakes. The results also show that several characteristics of the suite of acid fractions covary, such that when one fraction is richer in an element or functional group, so are the others. Some of the covariance could be due to methodological artifacts, such as the operationally defined fractions not being fully separated (28). However, since the full suite of humic and non-humic fractions form in the same environment and are exposed to the same geochemical milieu, it seems reasonable that they share some elemental and structural characteristics.

Labdane diterpenes from the marine pulmonate gastropod *Trimusculus peruvianus*

Aurelio San-Martín, Elías Quezada, Pilar Soto, Yolanda Palacios, and Juana Rovirosa

Abstract: The marine gastropod mollusk *Trimusculus peruvianus* collected on the coast of Central Chile yielded four new labdane metabolites. The structural elucidation of all compounds was accomplished by spectral analysis. One diterpenoid showed modest antimicrobial activity.

Key words: *Trimusculus peruvianus*, labdanes, marine mollusk.

Résumé : Le mollusque gastéropode marine *Trimusculus peruvianus* recueilli sur les côtes du centre du Chili a fourni quatre nouveaux métabolites de la famille du labdane. On a élucidé les caractéristiques structurales de chacun de ces composés par le biais d'analyses spectrales. L'un des diterpénoïdes présente une modeste activité antibactérienne.

Mots clés : *Trimusculus peruvianus*, labdanes, mollusques marins.

[Traduit par la rédaction]

Among marine organisms, the most chemically studied are sponges and mollusks. The chemistry of shell-less marine mollusks (e.g., *Aplysia* and nudibranchs) has attracted much interest, mostly because these organisms obtain metabolites present in defensive secretions directly from dietary sources (algae and sponges, respectively) (1). Other mollusks, such as cone shells, produce peptide toxins to catch prey organisms (2). Intertidal gastropods employs a wide variety of tactics in dealing with predators. In addition to morphological adaptations, both behavioral and chemical defenses are employed. Several compounds have been isolated from pulmonate mollusks that presumably play important ecological roles. Polyproprionate metabolites have been identified in the genera *Onchidium* (3) and *Siphonaria* (4), and labdane diterpenes are present in the genus *Trimusculus* (5). Continuing our interest in the structure of secondary metabolites present in marine organisms from Chilean coasts, we report the chemical study of *Trimusculus peruvianus* (6).

Materials and methods

General experimental procedures

The ir spectra were recorded on a Perkin Elmer System 2000 ft-ir spectrophotometer. Low-resolution mass spectra were recorded on a Hewlett–Packard 5995 mass spectrometer. The ^{1}H and ^{13}C nmr spectra as well as ^{1}H–H COSY, ^{13}C (DEPT), HMQC (optimized for $^1J_{H-C}$ = 140 Hz), HMBC (mixing time of 75 ms), and ROESY (mixing time of 250 ms) data were obtained on a Bruker AM-300 spectrometer. All chemical shifts are reported with respect to TMS (δ = 0). Solvents and chemicals were of analytical grade.

Isolation

Specimens of *T. peruvianus* (dry wt. after extraction ca. 850 g) were collected on intertidal rocks near El Tabo, V Region, Chile, during November 1992. The organisms was identified by Prof. C. Osorio, Universidad de Chile. The voucher specimens are on deposit at the Facultad de Ciencias, Universidad de Chile collection. The extraction was carried out at room temperature using acetone by percolation every 48 h (5 × 6 L). The aqueous acetone was concentrated under reduced pressure and extracted with EtOAc and then the organic solvent was dried over anhydrous $MgSO_4$.

Evaporation of the solvent gave a green gum (35 g), which was chromatographed over Sephadex LH-20 using MeOH as eluant. The fractions obtained were then chromatographed on Silica gel and eluted with petroleum ether – EtOAc (0–100% EtOAc). Further normal phase hplc with 2% isopropanol in hexane yielded diterpenes **1** (0.086 g), **2** (0.162 g), **3** (0.012 g), **4** (0,014 g), and **5** (0.005 g).

6β,7α-Diacetoxylabda-8,13-dien-15-ol (4): Viscous yellow oil; H nmr, see Table 1; ^{13}C nmr, see Table 2; ir (film) ν_{max}: 3450 (m), 2950 (s), 1740 (s), 1660 (w), 1380 (s), 1220 (s), 1100 (s), 760 (s) cm^{-1}; lrms *m/z* (%): 347 (1), 288 (1), 287 (3), 286 (5), 271 (5), 260 (31), 219 (52), 218 (71), 205 (46), 203 (24), 201 (15), 135 (100).

6β-Acetoxylabda-8,13-dien-15-ol (5): Oil, ^{1}H nmr, see Table 1; ^{13}C nmr, see Table 2; ir (film) ν_{max}: 3450 (m), 2950 (s), 1750 (s), 1660 (w), 1280 (s), 1210 (s), 1050 (m); eims (70 eV) *m/z* (rel. int): 348 (2), 306 (1), 270 (3), 202 (5), 187 (36), 133 (44), 119 (100).

Antimicrobial assays

The qualitative assays were performed using an agar well-diffusion assay. Antimicrobial activity was recorded as the diameter (in mm) of the zone of inhibition, measured from the edge of the agar well to the zone edge. The compounds **1**, **2**, **3**, **4**, and **5** were tested at a concentration of 100 μg/mL against *Klebsiella bronchiseptica, Bacillus anthracis, Bacillus pumilus, Bacillus subtilis, Staphylococcus aureus, Staphylococcus epidermidis, Pseudomonas aeruginosa, Bordetella bronchiseptica, Sarcina lutea, Micrococcus flavus, Proteus vulgaris,* and *Escherichia coli.*

Minimum inhibitory concentration (MIC)

The lowest concentration of the test compounds in which no growth occurred was defined as the MIC.

The quantitative assay for determination of MIC was performed using a twofold serial dilution technique (7). Only compound **3** was tested against all eight organisms, which were highly sensitive to it. See Table 3.

Results and discussion

The concentrated acetone extract of *T. peruvianus* was partitioned between EtOAc and H_2O to give a crude organic extract (see Experimental). This extract was repeatedly subjected to Sephadex LH-20 cc, Si gel open and medium-pressure column chromatography, and hplc, to yield the known diterpene **1**, 6β-acetoxylabda-8,13-dien-7-α,15-diol (6) and four new analogs.

The ^{1}H nmr spectrum of the major compound **2** showed one vinyl proton signal at δ 5.36 (1H, t, J = 7.3 Hz). Two vinylic methyl signals at δ 1.82 (3H, bs) and 1.69 (3H, s) together with four signals in the ^{13}C nmr spectra belonging to sp^2 carbons at δ 148.1 (s), 143.1 (s), 121.0 (s), and 118.8 (d) established the presence of two double bonds. The chemical shifts in ^{1}H nmr and ^{13}C nmr spectra of the vinylic methyl (Me-16), olefinic protons (H-14), and C-12, together with the magnitude of the coupling constant (7.3 Hz) are only compatible with a *Z* configuration for the trisubstituted double bond (5, 8–10). The presence of two 3H singlets at δ 2.06 and 2.08 in its ^{1}H nmr spectrum indicated the presence of two acetate ester groups. The carbonyl groups were confirmed by the strong band at 1740 cm^{-1} in the ir spectrum and the signals at δ 171.1 (s) and 170.0 (s) in the ^{13}C nmr spectrum. The nature of the ester groups as primary and secondary was confirmed by the presence of ^{13}C nmr signals at δ 60.8 (t) and 78.0 (d). In addition, the ^{1}H nmr spectrum showed signals at δ 4.56 (2H, d, J = 7.3 Hz), 4.85 (1H, bs), and 4.16 (1H, bs). The ^{1}H–^{1}H COSY spectrum revealed that the two last signals are strongly coupled and the first one has correlations to an olefinic proton and a vinylic methyl group (Me-16). That the secondary hydroxyl was attached to C-6 was shown by ir, ^{13}C nmr, and ^{1}H nmr data: 3500 cm^{-1}, δ 68.7 (d), and δ 4.16 (1H, bs), respectively. Detailed analysis of ^{1}H and ^{13}C nmr spectra plus ^{1}H–^{1}H COSY, HMQC, and HMBC experiments allowed unambiguous assignment of the ^{1}H and ^{13}C signals shown in Tables 1 and 2, respectively, and indicated a labdane skeleton with two vicinal oxygenated groups in a *trans* diaxial disposition that could be placed at C-6 (hydroxyl group) and C-7 (ester group). The other ester group was assigned to C-15. The relative configurations were assigned by comparison with related compounds (5, 6) and ROESY data. The molecular ion peak was not observed in lrms. The highest mass detected was *m/z* 347 [$M^+ - CH_3OO^-$]. The molecular formula was deduced as $C_{24}H_{38}O_5$ from the ^{13}C and ^{1}H nmr spectra. These data showed compound **2** to be 7α,15-diacetoxylabda-8,13-dien-6β-ol. As far as we know, this is a new natural compound.

Compound **3** yielded spectroscopic data similar to **2**. The absence of an alcoholic function was the main difference. Instead, three acetate groups were present. That this compound is the acetylated derivative of the previous one was evident by the signals in the ^{1}H nmr spectrum at δ 5.32 (1H, bs) instead of 4.16 (1H, bs) in **2**. Also, this spectrum showed three acetyl groups at δ 2.09, 2.05, and 2.04. The ^{13}C nmr spectra also showed the presence of these functions (see Table 2). Acetylation of **2** (Ac_2O/Py, room temperature) gave **3**. The ms did not exhibit a molecular ion peak and gave the highest mass peak at *m/z* 328 [$M^+ - 2 \times CH_3COOH$]. The molecular formula was suggested as $C_{26}H_{40}O_6$ from the analysis of it DEPT ^{13}C nmr spectrum, which showed the presence of 26 carbon atoms (see Table 2). Compound **3** is therefore described as 6β,7α,15-triacetoxylabda-18,13-diene. To our knowledge **3** is a novel natural product.

Compound **4** had analogous spectral features to the previous diterpenes **2** and **3**. The ir spectrum displayed absorption bands at 3450 and 1750 cm^{-1}, indicating the presence of hydroxyl and ester functionalities in its molecule. The hydroxyl group was located at C-15, based on the signals at δ 4.05 (2H, d, J = 7.0 Hz) in the ^{1}H nmr. The ^{1}H–^{1}H COSY spectrum revealed that this signal is strongly coupled with one ole-

finic proton (δ 5.34 (1H, t, *J* = 7.0)) and one vinylic methyl (Me-16, δ 1.73 (3H, bs)). The ^{13}C nmr spectrum exhibited signals due to this system (δ 124.7 d, 139.6 s, 23.6 q, and 59.1 t) The ms did not exhibit the molecular ion peak and gave the highest mass peak at *m/z* 347 [M − CH_3COO^-]. Its molecular formula was suggested as $C_{24}H_{38}O_5$ from the analysis of its DEPT ^{13}C nmr spectrum, which showed the presence of 24 carbon atoms (see Table 2). Acetylation of **4** (Ac_2O–Py, rt) gave **3**. The structure of compound **3** is assigned as 6β,7α-diacetoxylabda-8,13-dien-15-ol. To our knowledge this is the first natural occurrence of this compound.

The principal spectroscopic characteristics of compound **5** are similar to the other diterpenes of this animal. It contained a free hydroxyl group, as was evident by the signals at 3450 cm^{-1}, δ 58.4 (t), and 4.00 (2H, d, *J* = 6.7 Hz) in ir, ^{13}C nmr, and ^{1}H nmr spectra, respectively. Only one acetate ester group was present and it was assigned to C-6 by the signals at 1750 cm^{-1} (ir spectrum), δ5.45 (1H, d, *J* = 5.5 Hz) (^{1}H nmr spectra). The ^{13}C nmr spectra exhibited signals for six quaternary carbons (four of them olefinic and one belonging to the carbonyl group), three methine carbons (one of them olefinic), six methyl carbons, (one of them olefinic), six methyl carbons,

Staphylococcus aureus	65
Staphylococcus epidermidis	75
Pseudomonas aeruginosa	80
Bordetella bronchiseptica	85

and seven methylene carbons, consistent with the molecular ion *m/z* 348 in the mass spectrum and with a molecular formula $C_{22}H_{36}O_3$. Compound **5** was thus established to be 6β-acetoxylabda-8,13-dien-15-ol. To the best of our knowledge this compound is new.

All the compounds were evaluated in the agar well diffusion assay for antimicrobial activity against microorganisms, as indicated in the experimental section. Only compound **3** exhibited a modest activity, and its MIC values were determined by the twofold serial macrobroth dilution assay. The results of these assays are summarized in Table 3.

Compound **3** showed a marginal activity against the Gram-positive bacteria *Bacillus anthracis, B. pumilus, B. subtilis*, and Gram-negative *Klebsiella bronchiseptica*. None of the other compounds showed any remarkable activity.

Acknowledgments

This work was supported by grants from Universidad de Chile (D.T.I.) and Fondecyt (No. 1038-92). The mass spectral were provided by the Instituto de Productos Naturales y Agrobiologia de Canarias. The authors thank María Inés Polanco for assistance with the antimicrobial assays.

Theoretical study of the PSi_2 radical

Jose M. Elorza and Jesus M. Ugalde

Abstract: G2 methodology has been used to characterize minima on both doublet and quartet potential energy surfaces of the PSi_2 radical system. We found that for states with doublet spin multiplicity the most stable isomer is the cyclic $^2A_1$. Linear isomers lie more than 24 kcal/mol above in energy. For the quartets the most stable state isomer is the cyclic $^4A_2$, and the most stable linear isomer, i.e., Si-Si-P($^4\Sigma^-$), lies 10.68 kcal/mol higher in energy. The structural features of the various isomers characterized have been rationalized in terms of the bonding features of the molecular orbitals involved.

Key words: ab initio, excited states, radical.

Résumé : On a utilisé la méthodologie G2 pour caractériser les minimums des surfaces d'énergie potentielle tant du doublet que du quadruplet du système radicalaire PSi_2. On a trouvé que, pour les états avec une multiplicité de spin doublet, l'isomère le plus stable est la forme cyclique $^2A_1$. L'énergie des isomères linéaires est plus élevée de 24 kcal/mol. L'état cyclique $^4A_2$ des quadruplets correspond á celle de l'isomére le plus stable; l'énergie de l'isomère linéaire le plus stable, c'est-à-dire Si-Si-P($^4\Sigma^-$) est 10,68 kcal/mol plus élevée. On a rationalisé les caractéristiques structurales des divers isomères étudiés en faisant appel à des caractéristiques de liaison des orbitales moléculaires impliquées.

Mots clés : ab initio, états excités, radicaux.

[Traduit par la rédaction]

1 Introduction

Hypersilicon molecules $Si_nX(n = 3, 2)$ with electronegative X atoms such as oxygen or nitrogen, have been the subject of recent theoretical (1) and experimental (2) studies. In particular, the gas phase experiments of Iraqui et al. (2) have shown that both OSi_2 and NSi_2 radicals have triangular ground state geometries. Both of the linear isomers Si-Si-X and Si-X-Si are higher in energy than these triangular isomers. These species are important in surface science, since they may be viewed as prototypes for the interaction between the X atom and silicon sites in clusters and surfaces (3).

Recently, theory has predicted (4) a linear geometry for the ground state of the C_2P radical, a species isovalent with the NSi_2 radical. However, contrary to the NSi_2, there exists a cyclic isomer of the C_2P ($^2B_2$ state), which is found to be 6.1 kcal/mol above the C-C-P linear $^2\Pi$ ground state, at the G1 level of theory (4). Notice also that both species are predicted to have large dipole moments, 3.293 D and 2.535 D, respectively, which encourages their experimental detection. On the quartet potential energy surface, the linear C-C-P ($^4\Sigma$) structure is found to be the lowest energy structure, with the cyclic $^4A_2$ state lying 17.2 kcal/mol higher in energy, at the MP4/6-311G(d)//MP2/6-31G(d) level of theory. The C_2P radical, on the other hand, is a species relevant for the chemistry of dense clouds, as pointed out by Millar and Astron (5). Indeed, it should be detectable, provided that it is unreactive with oxygen.

In this paper, we use ab initio molecular orbital theory to investigate the nature of the chemical bonds and determine the energy ordering of the various isomers of the PSi_2 radical system, a species isovalent with the previously studied C_2P and NSi_2 radicals.

2 Methods

All structures were optimized at the MP2/6-31G(d) level of theory (6). Geometries of these species can be found in Figs. 1 and 2. Analytical frequencies at the stationary points were calculated at the MP2/6-31G(d) level of theory and all of them were found to be positive. G2 methodology (7) was used to evaluate the energies. All G2 calculations were performed using the GAUSSIAN 92 code of programs (8). G2 energies with their corresponding corrections to the MP4/6-311G(d,p) base energy can be found in Tables 1 and 2.

Note that we found some spin contamination for some of the structures studied in this paper, as indicated by the expectation values of S^2 given in Tables 1 and 2. However, it is worth mentioning that the G2 procedure, through its quadratic configuration interaction correction term, ΔE^{QCI}, has been shown to be reliable for accurate calculations of energies of small molecules with spin-contaminated single configuration wave functions such as the CN and HCO radicals (8). Therefore, even though we recognize that other approaches, such as multireference configuration interaction (MRCI) with spin-adapted wave functions, would lead to more accurate relative energies, they are considerably more demanding from the computational viewpoint than the G2 method, and would likely not alter substantially the energy ordering of the present calculations, at least for the less spin-contaminated species.

We have explored the bonding characteristics of these

Fig. 1. MP2/6-31G(d) optimized geometries and electronic structure terms and the expectation value of S^2, in parentheses, for the doublet PSi_2 system. Bond lengths are in Å and angles are in degrees.

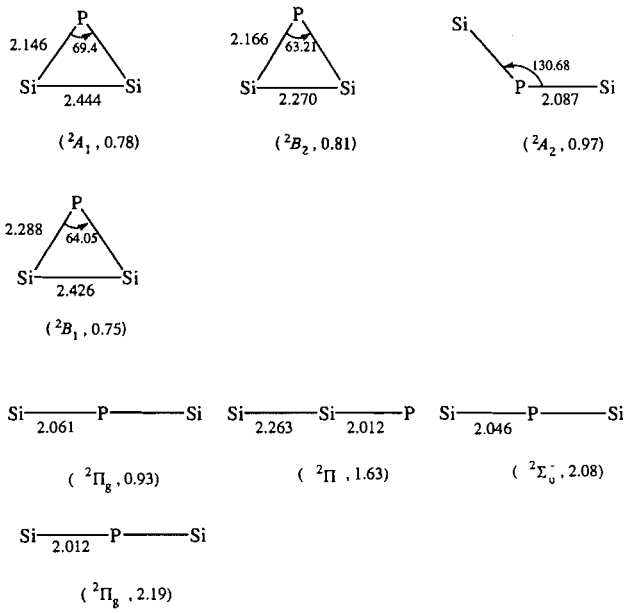

Fig. 2. MP2/6-31G(d) optimized geometries and electronic structure terms and the expectation value of S^2, in parentheses, for the quartet PSi_2 system. Bond lengths are in Å and angles are in degrees.

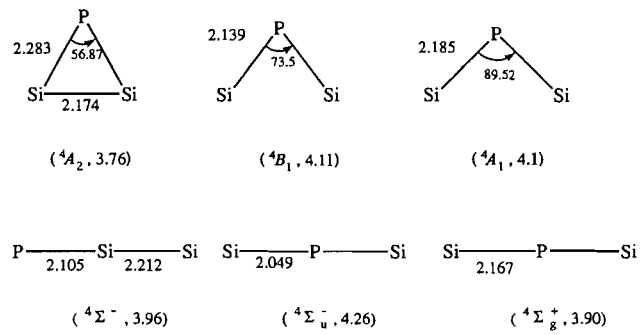

complexes by means of Bader's topological analysis of the electron charge density $\rho(\boldsymbol{r})$ and its associated Laplacian $\nabla^2(\rho\boldsymbol{r})$ (10–13), using the AIMPAC series of programs (14). The MP2/6-31G(d)//MP2/6-31G(d) wave functions were used to build up the electron density. Properties of the bond critical point (r_c), such as $\rho(r_c)$, $\nabla^2\rho(r_c)$, and the value of the energy density $H(r_c)$ have also been calculated. The energy density at the bond critical point indicates a bond to be covalent if $H(r_c) < 0$, and ionic if $H(r_c) > 0$ (11, 12).

3 Results and discussion

The doublet and quartet stable structures, optimized at the MP2/6-31G(d) level of theory, may be found in Figs. 1 and 2, respectively. The energies of the less spin-contaminated structures are shown in Tables 1 (doublets) and 2 (quartets).

3.1 Cyclic doublets

We found four stable triangular PSi_2 structures with the following electronic configurations:

$PSi_2(^2B_2)$ core $8a_1^2\,9a_1^2\,6b_2^2\,10a_1^2\,3b_1^2\,11a_1^2\,7b_2^1$

$PSi_2(^2A_1)$ core $8a_1^2\,9a_1^2\,6b_2^2\,10a_1^2\,3b_1^2\,7b_2^2\,11a_1^1$

$PSi_2(^2A_2)$ core $8a_1^2\,9a_1^2\,6b_2^2\,10a_1^2\,3b_1^2\,7b_2^2\,2a_2^1$

$PSi_2(^2B_1)$ core $8a_1^2\,9a_1^2\,6b_2^2\,10a_1^2\,11a_1^2\,7b_2^2\,3b_1^1$

The structure with the shortest Si—Si bond length belongs to the $^2B_2$ electronic state, which, unlike its isovalent C_2P radical (4), is not the most stable cyclic isomer. Its $8a_1^2$ molecular orbital is mainly composed of the $3s$(P) lone pair with minor contributions from the $3s$ atomic orbitals on the two silicon atoms, the $9a_1$ corresponds to the bonding σ(Si—Si) molecular orbital, the $6b_2$ and the $10a_1$ orbitals correspond to the σ(P—Si) skeletal bonds, and the $3b_1$ and the $11a_1$ are the Si—Si π bonds. The unpaired electron resides on the $7b_2$ orbital, which is Si—Si antibonding and P—Si bonding. Thus, promoting one electron from the doubly occupied $11a_1$ molecular orbital of the $^2B_2$ electronic state to the $7b_2$ orbital yields the most stable cyclic structure, which belongs to the $^2A_1$ electronic state. Note that for the resulting $^2A_1$ structure, the Si—Si bond length has increased and the P—Si bond length has decreased with respect to the $^2B_2$ structure.

The $^2A_2$ electronic state comes from promoting the unpaired $11a_1$ electron, of the $^2A_1$ electronic state, to its virtual $2a_2$ molecular orbital, which is a Si—Si π* antibonding orbital. Accordingly, its Si—Si distance, namely 3.79 Å, is too long to think of an Si—Si bond. The $^2A_2$ electronic state is, therefore, an open triangular structure.

Finally, the $^2B_1$ electronic state, which arises from the $^2A_1$ electronic state by promotion of one electron from the doubly occupied $3b_1$ molecular orbital to the $11a_1$ SOMO, is the least stable of the cyclic PSi_2 doublet structures. Note that this $^2B_1$ structure has the longest P—Si bond length of all the isomers characterized in the study, namely, 2.288 Å.

3.2 Linear doublets

Four stable linear doublet structures have been characterized for the PSi_2 radical system, with the following electronic configurations

Si-P-Si($^2\Pi_g$) core $6\sigma_g^2\,5\sigma_u^2\,7\sigma_g^2\,3\pi_u^4\,6\sigma_u^2\,2\pi_g^1$

Si-P-Si($^2\Sigma^+$) core $6\sigma_g^2\,5\sigma_u^2\,7\sigma_g^2\,3\pi_u^4\,2\pi_g^2\,6\sigma_u^1$

Si-P-Si($^2\Pi_g$) core $6\sigma_g^2\,5\sigma_u^2\,7\sigma_g^2\,3\pi_u^4\,2\pi_g^2\,2\pi_g^1$

Si-Si-P($^2\Pi$) core $10\sigma^2\,11\sigma^2\,12\sigma^2\,4\pi^4\,13\sigma^2\,5\pi^1$

We have also characterized one more linear structure, namely,

Si-P-Si($^2\Pi_u$) core $6\sigma_g^2\,5\sigma_u^2\,7\sigma_g^2\,3\pi_u^4\,6\sigma_u^2\,4\pi_u^1$

which corresponds to the transition state for the inversion of the open PSi_2 ($^2A_2$) isomer, and is 45.12 kcal/mol less stable than the latter, at the G2 level of theory. Hence, such inversion is not accessible at moderate temperatures. Inspection of the optimized Si-P-Si structures shown in Fig. 1 reveals that the Si—P bond length decreases as the instability increases. This behavior can be rationalized in terms of the valence molecular orbitals. Thus, we observed that the population of the $2\pi_g$ MOs increases and the population of the $6\sigma_u$

MO decreases as the bond length decreases. Indeed, the $2\pi_g$ MOs have a node on the central phosphorus atom, while the $6\sigma_u$ has a substantial participation of the $3p_z$ atomic orbital of the phosphorus atom. Hence, populating the $2\pi_g$ MOs at the expense of depopulating the $6\sigma_u$ MO enables the Si—P distance to shrink, so it allows for a better overlap of the atomic orbitals of the bonding $3\pi_u$ MOs. Conversely, as the two degenerate $2\pi_g$ MOs depopulate gradually to populate the $6\sigma_u$ MO, a compromise should be reached for the overall optimum overlap of the atomic orbitals of both the $3\pi_u$ and $6\sigma_u$ MOs, resulting in a steady increase of the Si—P bond length.

The Si-Si-P ($^2\Pi$) structure has one imaginary frequency of $i74.3$ cm^{-1}, on the HF/6-31G(d) potential energy surface, which corresponds to the bending mode. However, reoptimization and subsequent frequency calculation at the MP2/6-31(d) level of theory leads to the stable $^2\Pi$ structure shown in Fig. 1, with all frequencies positive.

3.3 Cyclic quartets

The electronic configurations of the three cyclic quartet structures found on the MP2/6-31G(d,p) potential energy surface are

$PSi_2(^4A_1)$ core $8a_1^2\ 9a_1^2\ 6b_2^2\ 10a_1^2\ 3b_1^2\ 7b_2^1\ 4b_1^1\ 2a_2^1$

$PSi_2(^4A_2)$ core $8a_1^2\ 9a_1^2\ 6b_2^2\ 10a_1^2\ 3b_1^2\ 7b_2^1\ 11a_1^1\ 4b_1^1$

$PSi_2(^4B_1)$ core $8a_1^2\ 9a_1^2\ 6b_2^2\ 10a_1^2\ 3b_1^2\ 7b_2^1\ 11a_1^1\ 2a_2^1$

On the HF/6-31G(d,p) potential energy surface the $^4B_2$ state has an open triangular structure, which collapses to the linear $^4\Sigma_u^-$ state at the MP2/6-31G(d,p) level of theory. The $^4A_1$ state has an Si—Si distance of 3.076 Å at the MP2/6-31G(d,p) level of theory, too long to think of a chemical bond. Indeed further analysis of the electron charge density revealed that no Si—Si bond exists, for no bond critical point was found along the Si—Si path. Therefore, the $^4A_1$ state has an optimum noncyclic triangular structure. The calculated activation energy for the inversion around the phosphorus atom is 9.37 kcal/mol at the G2 level of theory. So, our calculations predict a floppy structure for the $^4A_1$ state, since the calculated activation energy of the inversion process is accessible at moderate temperatures.

The $^4A_2$ state might be thought of as arising from the $^2A_1$ state by promoting one electron from the doubly occupied $7b_2$ orbital to the empty $4b_1$ orbital, the latter being P—Si antibonding and Si—Si bonding. Hence, the P—Si bond length increases and the Si—Si bond length decreases, yielding a SiPSi bond angle even more acute than for the doublets. Concomitantly, replacing the $4b_1$ MO of the $^4A_2$ electronic state by the $2a_2$ MO results in the $^4B_1$ electronic state, whose optimized geometry shows a short P—Si bond length, i.e., 2.139 Å, and a longer Si—Si distance of 2.562 Å, at the MP2/6-31G(d,p) level of theory. Inspection of the gradient paths of the electron charge density, $\rho(r)$, shown in Fig. 3, reveals that there is no bond between the two silicon atoms, though the strain engendered by the bridging phosphorus forces the silicons to lie within the average single bond distance range.

3.4 Linear quartets

The electronic structure of the three stable linear quartets of Fig. 2 are

Si-P-Si($^4\Sigma_u^-$) core $6\sigma_g^2\ 5\sigma_u^2\ 3\pi_u^4\ 7\sigma_g^2\ 6\sigma_u^1\ 2\pi_g^1\ 2\pi_g^1$

Si-P-Si($^4\Sigma_g^+$) core $6\sigma_g^2\ 5\sigma_u^2\ 2\pi_g^4\ 6\sigma_u^2\ 7\sigma_g^1\ 3\pi_u^1\ 3\pi_u^1$

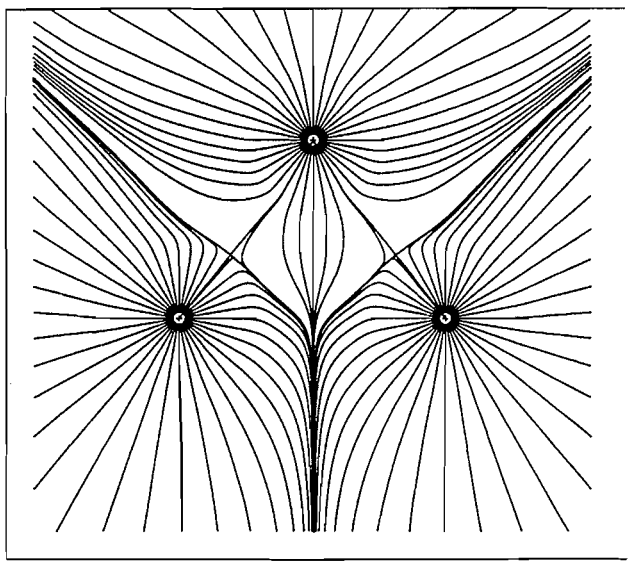
Si-Si-P($^4\Sigma^-$) core $10\sigma^2\ 11\sigma^2\ 12\sigma^2\ 4\pi^4\ 13\sigma^1\ 5\pi^1\ 5\pi^1$

A stable excited state with $^4\Sigma_g^+$ symmetry and the following electronic configuration,

Si-P-Si($^4\Sigma_g^+$) core $6\sigma_g^2\ 5\sigma_u^2\ 3\pi_u^4\ 6\sigma_u^2\ 7\sigma_g^1\ 2\pi_g^1\ 2\pi_g^1$

has also been characterized on the HF/6-31G(d,p) potential

Fig. 3. Gradient map of the electron charge density for the triangular $^4B_1$ state of PSi_2.



energy surface. However, when reoptimized at the MP2/6-31G(d,p) level, the two degenerate bending vibrational modes become imaginary. In fact, on the latter potential energy surface, this linear structure corresponds to the saddle point for the umbrella motion of the $^4B_1$ triangular state. The estimated activation energy at the MP2/6-31G(d,p)//MP2/6-31G(d,p) + ΔZPVE is 56.79 kcal/mol, a barrier too high to overcome at moderate temperatures.

The SiPSi($^4\Sigma_u^-$) arises from the $^2\Pi_g$ state by $2\pi_g \leftarrow 6\sigma_u$ electron promotion. Note that the quartet state results in a shorter Si—P bond length than the doublet, confirming further our earlier remark about the shrinking of the SiP bond length, as a consequence of depopulating the $6\sigma_u$ orbital in favour of the $2\pi_g$ degenerate orbitals. Accordingly, the $^4\Sigma_g^+$ state, which has the $6\sigma_u$ orbital doubly occupied and the $2\pi_g$ orbitals empty, shows the largest Si—P bond length of both the linear doublet and quartet states, namely, 2.167 Å at the MP2/6-31G(d,p) level of theory.

Finally, the $^4\Sigma^-$ state of the Si-Si-P isomer, which originates from the $^2\Pi$ state, by the $5\pi \leftarrow 13\sigma$ electron promotion, has a larger Si—P bond length and a shorter Si—Si bond length than its precursor, as dictated by the bonding features of the 5π and 13σ orbitals; namely, the 13σ is both Si—Si and Si—P σ-bonding, while the 5π is Si—Si π-bonding and Si—P π-antibonding.

3.5 Energies

Energies of the systems with a too large spin contamination will not be discussed, because it is unlikely that ΔE^{QCI} will be able to compensate for the likely poorer behavior of the G2 procedure, with respect to the less spin-contaminated systems. Therefore, we will not comment on the energies of the $^2\Sigma_u^-$ and the first excited $^2\Pi_g$ electronic states of SiPSi, and would also like to add a word of caution about the energies of the linear SiSiP $^2\Pi$ state, for it bears considerably large spin contamination, namely, $\langle S^2 \rangle = 1.63$.

As evidenced by the energies shown in Tables 1 and 2, in general, the cyclic structures of both doublet and quartet spin states are more stable than their corresponding linear isomers. The exceptions are the $^2B_1$ and the $^4A_1$ electronic states, for which the linear $^2\Pi_g$ and $^2\Pi$, and the $^4\Sigma_g^+$ electronic states, respectively, are found to be more stable. Relative energies, however, are not too large. Thus, at the G2 level of theory five quartet states, two cyclic and three linear, are found within a 25 kcal/mol energy range, while on the doublet PES, four states, three with cyclic optimum structure and one with linear optimum structure, are found within this energy range. Therefore, it is only at high temperatures that several isomers with different electronic configurations are predicted to coexist. Note also that the G2 energy ordering is not modified at the less demanding MP4/6-311G(d) level of theory except in one case, namely, for the $^2B_1$ and $^2\Pi$ states. Indeed, at the MP4/6-311G(d) level of theory the cyclic $^2B_1$ state is 0.9 kcal/mol more stable than the $^2\Pi$ state, but the latter is 5.15 kcal/mol more stable at the G2 level. Inspection of Table 1 reveals that the energy correction terms arising from the deficiencies of the basis set of the base level energy (i.e., ΔE^+, which is due to the lack of diffuse function, and ΔE^{2df}, due to the lack of high polarization functions on non-hydrogen atoms) are larger for the cyclic $^2B_1$ state than for the $^2\Pi$. However, they do not compensate for the much larger energy correction term, ΔE^{QCI}, which accounts for the correlation effects beyond the fourth-order perturbation theory. Thus, ΔE^{QCI} is 22.64 mhartree larger for the $^2\Pi$ state than for the $^2B_1$ state, and determines the higher stability of the former electronic state, at the G2 level of theory, as shown in Table 1. Nevertheless, it is worth noting that the relative base level energy differences between various isomers are modified noticeably with respect to the final G2 values. In particular the $^4B_1$ and $^4\Sigma^-$ optimum structures differ by only 0.1 kcal/mol at the MP4/6-311G(d) base level of theory, but by 3.8 kcal/mol at the G2 level. Once again the ΔE^{QCI} correction is found to be crucial for a reliable estimation of the relative energies.

4 Conclusions

An ab initio molecular orbital study has been carried out for the doublet and quartet potential energy surfaces of the PSi_2 radical system. We have found that the ground state of the doublet spin multiplicity species is a cyclic $^2A_1$ state. The most stable Si-P-Si linear structure, with the $^2\Pi_g$ electronic state, lies 24.19 kcal/mol higher in energy. The Si-Si-P $^2\Pi$ isomer lies even higher in energy than the $^2\Pi_g$ one, opposite to the behavior found for its isovalent C_2P system. On the quartet potential energy surface, the $^4A_2$ cyclic state is the most stable of all the isomers. The Si-Si-P ($^4\Sigma^-$) isomer is the most stable linear isomer, 10.68 kcal/mol less stable than the $^4A_2$ state. The symmetrical Si-P-Si linear isomer ($^4\Sigma_u^-$ electronic state) is found to be 9.8 kcal/mol above the Si-Si-P $^4\Sigma^-$ isomer. Structural features have been discussed in terms of the bonding characteristics of the molecular orbitals involved, and for one case, namely, the $^4B_1$, we carried out Bader's topological analysis of the electron charge density, to determine that it is an open triangular structure, with no Si—Si bond.

Solvent and substrate isotope effects on the enolization and carbon-acid ionization of isobutyrophenone

J.R. Keeffe and A.J. Kresge

Abstract: Bromine scavenging was used to measure rates of acid-catalyzed enolization of isobutyrophenone in H_2O and in D_2O solution and of isobutyrophenone-α-*d* in D_2O solution. The results provide the solvent isotope effect $k_{H^+}/k_{D^+} = 0.56$ and the substrate isotope effect $k_H/k_D = 6.2$ on the enolization reaction, both of which are consistent with the generally accepted mechanism for this process. The present results in combination with literature information also provide the solvent isotope effect on the enolization equilibrium, $K_E(H_2O)/K_E(D_2O) = 0.92$, and the solvent isotope effect on the ionization of isobutyrophenone as a carbon acid, $k_a^K(H_2O)/k_a^K(D_2O) = 5.4$, as well as the product of isotopic fractionation factor and medium effect, $\phi\Phi = 0.90$, for isobutyrophenone enol and the medium effect, $\Phi = 0.47$, for its enolate ion. The isotope effect on K_E is the first ever determined for the keto–enol equilibrium of a simple aldehyde or ketone; its near-unit value is consistent with expectation on the basis of fractionation factors for the species involved.

Key words: isobutyrophenone, keto–enol equilibrium, carbon-acid ionization, solvent isotope effects, isotopic fractionation factors.

Résumé : On a utilisé le piégeage par le brome pour mesurer les vitesses d'énolisation acidocatalysées de l'isobutyrophénone en solution dans le H_2O ou le D_2O et de l'α-*d*-isobutyrophénone en solution dans le D_2O. Les résultats permettent de déduire l'effet isotopique du solvant, $k_{H^+}/k_{D^+} = 0{,}56$, ainsi que l'effet isotopique du substrat, $k_H/k_D = 6{,}2$, sur la réaction d'énolisation; ces deux valeurs sont en accord avec le mécanisme généralement accepté pour ce processus. Les résultats obtenus, combinés aux informations disponibles dans la littérature, permettent aussi de déduire l'effet isotopique du solvant sur l'équilibre d'énolisation, $K_E(H_2O)/K_E(D_2O) = 0{,}92$, et l'effet isotopique du solvant sur l'ionisation de l'isobutyrophénone au niveau du carbone acide $k_a^K(H_2O)/k_a^K(D_2O) = 5{,}4$, ainsi que le produit du facteur de fractionnement isotopique et l'effet du solvant, $\phi\Phi = 0{,}90$, pour l'énol de l'isobutyrophénone, et l'effet du milieu, $\Phi = 0{,}47$, pour l'ion énolate. Dans le cas de l'effet isotopique sur K_E, il s'agit de la première mesure de ce genre réalisée sur l'équilibre céto–énolique d'un aldéhyde ou d'une cétone simple; sa valeur, qui est proche de l'unité, est en accord avec celle à laquelle on pourrait sur la base des facteurs de fractionnement des espèces impliquées.

Mots clés : isobutyrophénone, équilibre céto-énolique, ionisation de carbones acides, effets isotopiques du solvant, facteurs de fractionnement isotopiques.

Introduction

The recent developement of methods for generating simple enols in greater than equilibrium amount under conditions where they can be observed directly has produced a renaissance of interest in the chemistry of these unstable substances (see, e.g., ref. 1). Among the wealth of new information that has become available are directly measured rate constants for ketonization of simple enols to their carbonyl tautomers, k_K, and these, in combination with rate constants for enolization, k_E, have led to accurate keto-enol equilibrium constants, K_E, by application of the relationship shown in eq. [1]. Solvent isotope effects have been measured on both k_E and k_K for a

$$[1] \qquad K_E = k_E/k_K$$

number of substrates, but up until the present study, enough information had not been supplied for the same system to determine the solvent isotope effect on K_E. We have now filled this gap using the keto–enol isomerization of isobutyrophenone, eq. [2].[3]

[3] The symbol "L" is used to denote either protium or deuterium, i.e., L = H or D.

We chose isobutyrophenone for this purpose because the keto–enol equilibrium constant for this substance in H_2O, $K_E(H_2O)$, had already been determined (2), and the hydronium-ion catalytic coefficient for ketonization of the enol in D_2O, $(k_K)_{D^+}$, had been measured as well (3); this ketone also has only one enolizable hydrogen, which simplifies matters considerably. The missing piece of information that we have now supplied is the hydronium-ion catalytic coefficient for enolization of the deuterated substrate in D_2O, $(k_E)^D_{D^+}$, eq. [3].

[3] 
We have also in the present study determined hydronium-ion catalytic coefficients for the enolization of the protiated substrate in H_2O, $(k_E)^H_{H^+}$, eq. [4], and in D_2O, $(k_E)^H_{D^+}$, eq. [5]. This additional information has provided solvent and substrate kinetic isotope effects on the enolization of isobutyrophenone. The present results, in combination with other information already in the literature, have also led to the solvent equilibrium isotope effect on the ionization of isobutyrophenone as a carbon acid, and to isotopic fractionation factors for isobutyrophenone enol and enolate ion.

[5] 
Experimental section

Kinetics

Rates of enolization of isobutyrophenone were determined by using bromine to scavenge the enol as it formed. Reactions were conducted in hydrobromic acid solutions under conditions where the bromine is complexed as Br_3^- ion, and changes in absorbance of this species at $\lambda = 310$ nm were used to monitor the reaction; measurements were made with a Cary 118 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.05°C. Initial bromine concentrations were ca. 3×10^{-4} M and initial isobutyrophenone concentrations were $(2–3) \times 10^{-3}$ M. Zero-order initial rates were measured over times corresponding to 0.5–0.8% of the enolization reaction, and observed first-order rate constants were calculated using eq. [6] (4), in which $-dA/dt$ is

$$[6] \qquad k_{obs} = \frac{(-dA/dt\{1 + 1/(K[Br^-])\}}{\varepsilon[S]}$$

the zero-order rate of change of absorbance at $\lambda = 310$ nm, ε is the extinction coefficient of Br_3^- at this wavelength (determined here as 7535 M^{-1} cm^{-1}), [S] is the isobutyrophenone concentration, and K is the equilibrium constant for the $Br_2 + Br^-$ association reaction. Values of K for the conditions employed were interpolated using literature data (5), and [S] was measured spectrophotometrically before each reaction using $\varepsilon = 265$ M^{-1} cm^{-1} for isobutyrophenone at $\lambda = 300$ determined here.

Deuterated isobutyrophenone for the runs with deuterated substrate in D_2O was generated directly in the reaction solutions by first allowing unlabelled substrate to undergo isotope exchange with the solvent via enolization. Since base-catalyzed enolization is much faster than the very slow acid-catalyzed reaction (2), 0.1 M NaOD solutions were used for this purpose. Exchange was allowed to proceed for times judged to be sufficient to effect at least 99.5% deuteration; enough concentrated hydrobromic acid was then added to neutralize the base and produce a final acid concentration of the desired value, and bromination was begun by adding bromine to these acidic solutions. Isobutyrophenone concentration measurements made before and after the exchange process showed no change. Acid concentrations of these and other reaction mixtures were determined by titrating aliquots after the rate measurements had been completed.

Results

The bromine scavenging method of measuring rates of enolization requires enolization to be the rate-determining stage of the bromination process; thus, in the acidic solutions used here, the rate of bromination of the enol, $k_{Br}[Br_2]$, eq. [7], must be

[7] 
much greater than the rate of acid-catalyzed reketonization, $k_{K^+}[L^+]$. This requirement was amply fulfilled under the present experimental conditions. The reaction of enols with bromine is known to be nearly encounter-controlled, with rate constants of the order of 10^9 M^{-1} s^{-1} (6). At the bromine concentrations used here, the rate of the bromination reaction was therefore $k \cong 10^5$ s^{-1}, which is much greater than the $k \cong 1$ s^{-1} that can be estimated for reketonization using the known rate constants for this reaction in H_2O (2) and D_2O (3) solution. It is thus safe to conclude that enolization was indeed the rate-determining stage under the present reaction conditions.

These measurements were made in hydrobromic acid solutions over the concentration range [LBr] = 0.1 – 0.5 M. Three sets of runs were carried out using (*a*) unlabelled isobutyrophenone in H_2O, (*b*) unlabelled isobutyrophenone in D_2O, and (*c*) isobutyrophenone-α-*d* in D_2O. These data are summarized in Table 1.

For the measurements in D_2O, hydrobromic acid was supplied as 48% HBr in H_2O, and these solutions therefore contained small, variable amounts of protium. The rate constants obtained in these solutions were therefore extrapolated to 100% D_2O. A formalism generally applied to rate data in H_2O–D_2O mixtures (7) was used for this purpose, and, because the extrapolations were short, the linear form of this formalism shown as eq. [8] was employed. In this expression k_x is the observed rate constant

$$[8] \qquad k_x/k_H = 1 - x + x\phi$$

determined in the D_2O solution containing some protium, x is

the atom fraction of deuterium of that solution, k_H is the rate constant in H_2O, and ϕ is a fractionation factor. The fractionation factor in this case is equal to the rate constant in 100% D_2O divided by that in H_2O, as shown in eq. [9], which may be obtained from eq. [8] by setting x equal to 1.

$$[9] \qquad k_D/k_H = \phi$$

Elimination of k_H between eqs. [8] and [9] then leads to eq. [10], which may be

$$[10] \qquad k_D = \phi k_x/(1 - x + x\phi)$$

used to convert k_x into k_D.

The value of k_D needed to obtain ϕ for the application of eq. [10] is of course not known before the extrapolation is made, but a first approximation can be obtained by using k_x instead. The extrapolated value of k_D obtained in this way is then used to get a second approximation of ϕ, and the process is repeated until a self-consistent set of results is obtained.

This method was employed in the present case for the runs with unlabelled substrate; good convergence (ϕ changing by less than 0.1%) was reached after only three iterations. The procedure could not be used for the labelled substrate, because the method of introducing the label into this substance (isotopic exchange with the solvent) precluded rate measurements in H_2O, and the value of k_H needed to estimate ϕ was consequently not available. However, solvent isotope effects can be expected to be the same for isotopologs to a very good degree of approximation,[4] and the converged values of ϕ for the unlabelled substrate were consequently used for the labelled material as well.

Least-squares analysis of the relationship between enolization rate constants and acid concentration showed the presence of an "uncatalyzed" as well as an acid-catalyzed pathway. The mechanisms of these two pathways will of course be different and different values of ϕ will apply. Our rate constants were therefore separated into contributions from the two pathways and eq. [10] was applied separately to each. As Fig. 1 illustrates, corrected rate constants proved in all cases to be hardly different from uncorrected values, and both sets were accurately proportional to acid concentration. The results obtained by linear least-squares analysis are listed in Table 1.

One of the hydronium-ion catalytic coefficients determined here, that for enolization of isobutyrophenone-α-*h* in H_2O, had been determined before (2), and the value obtained, $(k_E)^H_{H^+} = (7.02 \pm 0.69) \times 10^{-7}$ M^{-1} s^{-1}, agrees well with the present result, $(k_E)^H_{H^+} = (8.13 \pm 0.45) \times 10^{-7}$ M^{-1} s^{-1}.

The isotope effects provided by the present results plus some related values from the literature are summarized in Table 2.

[4] Any difference would be an isotope effect upon an isotope effect, also known as a departure from the rule of the geometric mean (8). Such departures are produced by coupling of vibrational motions of bonds involving the isotopically substituted atoms; the effects are small even when these bonds are in the same molecule (9), and they will be even smaller, and consequently negligible, in a situation such as the present where one bond is in the substrate and the other is in the solvent.

Discussion

Kinetic isotope effects

The rate measurements made here of the acid-catalyzed enolization of isobutyrophenone-α-*h* in H_2O and D_2O provide the solvent isotope effect $(k_E)^H_{H^+}/(k_E)^H_{D^+} = 0.56$. The inverse direction of this isotope effect ($k_H/k_D < 1$) is consistent with the generally accepted reaction mechanism for the hydronium-ion-catalyzed enolization of simple carbonyl compounds, which consists of rapid and reversible hydronation of the substrate on oxgyen followed by rate-determining removal of a carbon-bound hydron by a molecule of water, eq. [11] (10). The isotope effect is inverse because the hydrogen–oxygen bonds in water are stronger than those in the hydronium ion (11), and the bond tightening that this produces in the pre-equilibrium step is not fully compensated by the bond loosening that occurs as the hydronium ion is regenerated in the transition state of the rate-determining step. The present result is consistent with solvent isotope effects on the enolization of other carbonyl compounds, such as $k_{H^+}/k_{D^+} = 0.46$–0.54 for acetone (12) and $k_{H^+}/k_{D^+} = 0.57$ for acetaldehyde (13).

[11] 
The present rate measurements of the acid-catalzyed enolization of isobutyrophenone-α-*h* and isobutyrophenone-α-*d* in D_2O also provide the substrate isotope effect $(k_E)^H_{D^+}/(k_E)^D_{D^+}$ = 6.2. This is a large, near-maximum, primary effect, which implies a central, symmetrical, rate-determining transition state, with the hydron about half-transferred and the free energy change for the hydron transfer step close to zero (14). This again is consistent with the mechanism of eq. [11], for the acidity of the oxygen-protonated conjugate acid intermediate may be estimated as $pK_a \cong -3.5$ (15), which translates into $\Delta G° = 4.8$ kcal mol^{-1} for the oxygen-hydronation step, and that together with $pK_E = 6.5$ (2), $\Delta G° = 8.8$ kcal mol^{-1}, for the overall reaction, leaves $\Delta G° = 4.0$ kcal mol^{-1} for the hydron transfer step.

Equilibrium isotope effects

A keto–enol equilibrium constant for isobutyrophenone in D_2O solution may be obtained by combining the presently determined acid-catalyzed enolization rate constant for the labelled substrate in D_2O with a literature value of the rate constant for acid-catalyzed ketonization of the enol in D_2O (3): $K_E(D_2O) = (k_E)^D_{D^+}/(k_K)_{D^+} = \{(2.35 \pm 0.09) \times 10^{-7}\}/\{(6.48 \pm 0.07) \times 10^{-1}\} = (3.63 \pm 0.14)\ 10^{-7}$, $pK_E(D_2O) = 6.44 \pm 0.02$.[5] Combination of this result with the value of K_E in H_2O (2) then gives the solvent isotope effect on the keto–enol equilibrium: $K_E(H_2O)/K_E(D_2O) = 0.917 \pm 0.058$.[5] This, as far as we are aware, is the first determination of a solvent isotope effect on the keto–enol isomerization of a simple monofunctional carbonyl compound.

The ionization of a carbonyl compound as a carbon acid may be split formally into two steps, enolization followed by acid ionization of the enol, as shown in eq. [12].

[12] 
The carbon-acid ionization constant, K^K_a, then becomes the product of the keto–enol equilibrium constant and the acidity constant of the enol, $K^K_a = K_E K^E_a$. Since the present work has provided a value of K_E for isobutyrophenone in D_2O and K^E_a for isobutyrophenone enol in D_2O is available from the literature (3), the acidity constant of isobutyrophenone-α-*d* ionizing as a carbon acid in D_2O solution may be determined as $K^K_a(D_2O) = K_E(D_2O)\ K^E_a(D_2O)$: $\{(3.63 \pm 0.14) \times 10^{-7}\}\{(2.83 \pm 0.14) \times 10^{-13}\} = (1.03 \pm 0.05) \times 10^{-19}$ M, $pK^Ka(D_2O) = 18.99 \pm 0.02$.[5,6] Combination of this result with the value for isobutyrophenone-α-*h* in H_2O solution then gives the solvent isotope effect $K^K_a(H_2O)/K^K_a(D_2O) = 5.40 \pm 0.40$.[5] This is a reasonable value for an acid of this strength (16).

Isotopic fractionation factors

It is useful to separate isotope effects into contributions from individual hydrogens by expressing the overall effect in terms of fractionation factors for all of the isotopically substituted sites involved (9). The solvent isotope effect on the keto–enol equilibrium of isobutyrophenone, for example, may be formulated as shown in eq. [13],

$$[13] \quad \frac{K_E(H_2O)}{K_E(D_2O)} = \frac{\phi_K \Phi_K}{\phi_E \Phi_E}$$

where ϕ_K is the fractionation factor for the enolizable hydrogen of the keto form, ϕ_E is the fractionation factor for the hydroxyl group hydrogen of the enol, and Φ_K and Φ_E are medium effects produced by the solvation shells of the keto and enol isomers, respectively. It is likely that ϕ_K will have a value close to unity and consequently make no significant contribution to the overall isotope effect: fractionation factors for hydrogens in sp^3 bonds to carbon are not very different from unity (9), and $\phi = 1.0$ has in fact been determined for the enolizable hydrogen of 3-methylacetylacetone (17). With this assumption and the directly determined medium effect on the keto form, $\Phi_K = 0.827 \pm 0.013$[5] (18), plus the overall isotope effect determined here, the product of fractionation factor and medium effect for the enol may be evaluated as $\phi_E\Phi_E = 0.902 \pm 0.059$.[5] The near-unit value for this product is consistent with the fact that fractionation factors for hydrogens bound to uncharged oxygen, as well as medium effects for neutral solutes, are themselves generally close to unity (9).

A similar analysis of the overall isotope effect on the carbon acid ionization of isobutyrophenone according to eq. [14], in which ℓ {= 0.69 (6809, 19)} is the fractionation factor for the

$$[14] \quad \frac{K^K_a(H_2O)}{K^K_a(D_2O)} = \frac{\phi_K \Phi_K}{\ell^3 \Phi_{E^-}}$$

hydronium ion, gives $\Phi_{E^-} = 0.466 \pm 0.035$[5] for the medium effect on the isobutyrophenone enolate ion. This, again, is a reasonable result inasmuch as enolate ions, like alkoxide ions, can be expected to be strongly solvated by water molecules, to which they are associated by hydrogen bonding, and hydrogen bonding is known to produce low fractionation factors (20). In fact, on the assumption that the solvation shell of the enolate ion consists of three such water molecules, as is the case for the aqueous hydroxide ion, $\phi = 0.78 \pm 0.02$[5] can be calculated for each of the hydrogen-bonded hydrogens; this is not unlike $\phi = 0.7$, which has been deduced for the corresponding hydrogens solvating the hydroxide ion (9, 21).

[5] The error limits cited are statistical uncertainties and do not include possible systematic errors.

[6] This is a *concentration* dissociation constant applicable at ionic strength = 0.10 M.

Folding strain stereocontrol in cyclohexane ring formation by means of an intramolecular ester enolate alkylation reaction

Takashi Tokoroyama and Hisashi Kusaka

Abstract: Diastereoselectivity in the cyclization of ethyl 7-bromo-2-methylheptanoates with an additional substituent at various positions in the chain, by LDA treatment, was investigated in connection with the concept of folding strain stereocontrol. Cyclization of 3-, 4-, and 6-methyl-substituted substrates revealed high selectivity, which demonstrates the prevalence of folding strain stereocontrol and the usefulness of this approach for stereoselective ring construction. In particular, reactions of the latter two substrates resulted in the stereodivergent preparation of diastereomeric 1,3-dimethylcyclohexanecarboxylates. In the case of the 5-methyl-substituted substrate, the selectivity of ring closure was only moderate. ^{1}H and ^{13}C NMR spectroscopic data were useful for determining the conformation of 1-methylcyclohexanecarboxylate derivatives. The origin of the diastereoselectivity was examined through the qualitative comparison of the strain in the diastereomeric folding in the transition state. Various factors that might affect stereoselectivity were examined in the cyclization of 5-substituted substrates to better understand this concept. As predicted, the selectivity increased as the substituent became bulkier: Ph < Me ≈ Et < i-Pr < *t*-Bu. The effects of other factors — solvent, base counter cation, and leaving group — on selectivity agree with results predicted from the reactivity–selectivity relationship.

Key words: folding strain stereocontrol; diastereoselectivity in ring-closure reaction; remote asymmetric induction; ethyl 2-methylcyclohexanecarboxylate derivatives, ^{1}H and ^{13}C NMR; stereoselective synthesis of substituted cyclohexane derivatives.

Résumé : Dans le cadre de travaux sur le concept du stéréocontrôle par le plissement des chaînes, on a étudié la diastéréosélectivité de la cyclisation, sous l'influence du LDA, de 7-bromo-2-méthylheptanoates d'éthyle portant un substituant additionnel dans diverses positions. Les cyclisations des substrats substitués par des groupes méthyles en positions 3, 4 ou 6 se produisent avec une grande sélectivité; ceci met en évidence la prévalence du stéréocontrôle par le plissement de la chaîne et démontre l'utilité de cette approche pour la formation stéréosélective de cycles. Ceci est particulièrement vrai avec les deux derniers substrats qui conduisent à la préparation stéréoconvergente des 1,3-diméthylcyclohexanecarboxylates diastéréomères. Dans le cas du substrat portant un groupe méthyle en position 5, la sélectivité de la formation du cycle n'est que modérée. Les données de la spectroscopie RMN du ^{1}H et du ^{13}C se sont avérées utiles pour la détermination de la conformation des dérivés 1-méthylcyclohexanecarboxylates. On a étudié l'origine de la diastéréosélectivité par le biais d'une comparaison qualitative de la tension dans le plissement diastéréomère dans l'état de transition. Dans le but de mieux comprendre ce concept, on a examiné divers facteurs pouvant affecter la stéréosélectivité lors de la cyclisation de substrats substitués en position 5. Tel qu'on pouvait le prévoir, la sélectivité augmente avec une augmentation de l'encombrement du substituant : Ph < Me ≈ Et < i-Pr < *t*-Bu. Les effets des autres facteurs — solvant, contre-ion basique et le groupe partant — sur la sélectivité sont en accord avec les résultats prédits sur la base de la relation réactivité–sélectivité.

Mots clés : stéréocontrôle par le plissement de la chaîne; diastéréosélectivité lors de réactions de cyclisation; induction asymétrique à distance; RMN ^{1}H et ^{13}C de dérivés du 2-méthylcyclohexanecarboxylate d'éthyle; synthèse stéréosélective de dérivés du cyclohexane substitué.

[Traduit par la rédaction]

Introduction

Diastereoselective cyclization is an efficient approach for the synthesis of ring compounds, with stereoselective installation of substituents on the ring (1). For this reason, cycloaddition reactions, such as the Diels–Alder reaction, are considered a powerful synthetic tool (2). In contrast, diastereocontrol in a simple ring-closure reaction has attracted far less attention. In connection with the stereoselective synthesis of natural products (3), we previously found that the cyclization of 2-(3′,4′-dimethyl-6′-trimethylsilylhex-4′-enyl)cyclohex-2-enone (**1**) proceeded with twofold stereocontrol to give the decalone derivative (**2**) as a single diastereomer (Scheme 1) (4). One of the stereocontrol factors involved the diastereofacial selection based on the conformational preference of the 3′-methyl group with respect to the diastereomeric folding of the acyclic chain in the transition state. We have pointed out the general utility

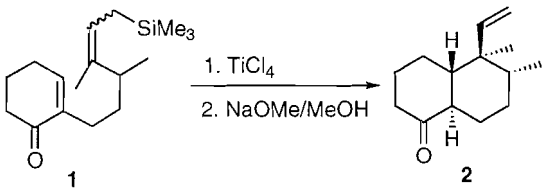
Scheme 1.



of this type of stereoselection for the diastereoselective construction of ring compounds in terms of folding strain stereocontrol (5–7).

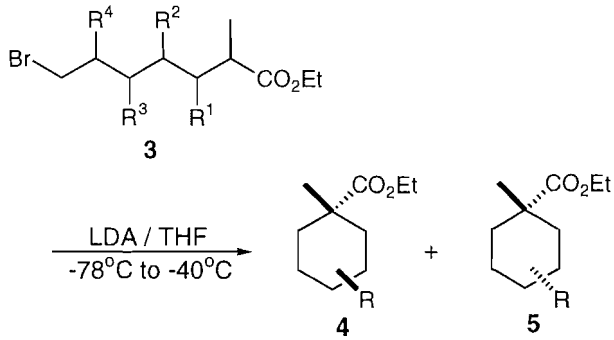
For the intermolecular reaction of acyclic molecules, diastereoselection is generally effective only for 1,2-asymmetric induction without the intervention of chelation or other special conditions. However, for intramolecular reactions, the relative steric strain in the diastereomeric folding of the chain may greatly affect the stereoselectivity, and thus the asymmetric induction, more than a 1,3-relationship to the stereogenic center, could be effective in the folding strain stereocontrol. We believe that the diastereofacial selectivity in a ring-closure reaction is determined by the difference in the total strain energy ($\Delta(SE)_{AB}^{*}$), between the diastereomeric transition states (A,B) and that, even if the stereocenter in the chain is remote from the bond-forming atom, the energy difference could be great enough for the diastereoselection to be effective. Moreover, the design of a stereoselective cyclization may be possible by estimating the strain energy involved. Just as diastereodifferentiation in some acyclic stereocontrols is due to the energy difference between diastereomeric cyclic transition states (e.g., aldol reaction and the Claisen rearrangement) (8), the relative energy of diastereomeric foldings in the transition state determines diastereoselection in the ring-closure reaction. Particularly in carbocyclic six-membered ring formation, the difference in conformational energy between the transition states could be more distinct than that in systems involving many sp^2 carbon atoms and hetero atoms, and a better diastereoselectivity would be reasonably expected. Thus, a high possibility of remote diastereocontrol could be anticipated in carbocyclic ring formation. Although several examples of stereocontrols of this type can be found in the literature, a systematic investigation to demonstrate the underlying concept is lacking (for notable examples, see ref. 9). To further test the feasibility of our concept, we investigated diastereofacial selectivity in the cyclization of ethyl 7-bromo-2-methylheptanoates **3** with a substituent at various positions in the chain to diastereomeric cyclohexanecarboxylates **4** and **5** via an intramolecular ester enolate alkylation reaction (Scheme 2). Kim et al. have used cyclization reactions of this type for the stereoselective synthesis of cyclic natural products (*9f–9n*).

Results and discussion

Synthesis of cyclization substrates

Ethyl 7-bromo-2,3-dimethylheptanoate (**11**) was synthesized by the alkylation of acetoacetate dianion with 3-benzyloxypropyl bromide (**7**) and subsequent successive introduction of methyl groups at the 3 and 2 positions as shown in Scheme 3. To introduce the 3-methyl group, the combination of Nozaki and Weiler methods (10) was used and the resultant trisubstituted olefin was catalytically hydrogenated.

Scheme 2.



Ethyl 7-bromo-2,4-dimethylheptanoate (**15**) was synthesized by homologation of 2-methyl-δ-valerolactone (**12**) using in situ reduction and the Horner–Emmons reaction (11) (Scheme 4). The synthesis of *ethyl 7-bromo-2,5-dimethylheptanoate* (**19**) was achieved in the same way by starting from 3-methyl-δ-valerolactone (**17**) obtained by the NaBH4 reduction (12) of 3-methylglutaric anhydride (**16**) (Scheme 5). Substrates **25** and **26**, which have a 5-ethyl and a 5-isopropyl group, respectively, were synthesized by the introduction of the alkyl groups through the copper-catalyzed conjugate addition (13) of Grignard reagents to 2-penten-5-olide (**20**) and the subsequent transformations were similar to those described above (Scheme 5). To synthesize the *5-phenyl substrate* **30** the requisite 3-phenyl-δ-valerolactone (**28**) was prepared by the $NaBH_4$ reduction of 3-phenylglutaric anhydride (**27**). To synthesize the 5-*tert*-butyl substrate **35**, since the anhydride corresponding to **27** could not be obtained by the Michael reaction of methyl 4,4-dimethyl-2-pentenoate with dimethyl malonate, the other method shown in Scheme 6 was used. *Ethyl 7-bromo-2,6-dimethylheptanoate* (**39**) was synthesized by the homologation of 4-methyl-δ-valerolactone (**37**) (Scheme 7). The substrates **11**, **15**, **19**, **25**, **26**, **30**, **35**, and **39** were all obtained as a mixture of diastereomers, as seen distinctly from their ^{13}C NMR spectra.

Cyclization and stereochemical assignment of the diastereomeric products

Cyclization was performed in THF using three equivalents of LDA at −78°C for 1 h, and moderate to good yields of the cyclization products were generally obtained under these conditions. The isomer ratios were determined by capillary GPC. Stereochemical assignment of the diastereomeric products was carried out effectively by the analysis of 400 MHz ^1H and ^{13}C NMR spectra with reference to those reported in the literature, when available. The results are shown in Tables 1–5.

Ethyl trans-*1,2-dimethylcyclohexanecarboxylate (40)*[3]

The ^1H NMR spectra of the major product in the cyclization of ethyl 7-bromo-2,3-dimethylheptanoate (**11**) agree well with the data reported for the methyl ester corresponding to the *trans* compound **40**, except with regard to the signal due to the

[3] Throughout this paper, the *cis–trans* notation for the relative configuration of substituted cyclohexanecarboxylate derivatives refers to the ester groups.

ester groups (14, 15). When the ^1H NMR spectra of **40** was analyzed using a COSY experiment, the coupling constants between the resonances of the 2-H proton and 3-methylene protons were found to be 3.1 and 10.5 Hz. Therefore, the 2-H proton was concluded to be axial, and the 2-methyl group was considered to assume an equatorial conformation. Moreover, the appearance of the 2-H proton signal at a rather deshielded position (δ 2.01) indicated that the ethoxycarbonyl group is in an equatorial conformation (vide infra).

Ethyl cis- *and* trans-*1,3-dimethylcyclohexanecarboxylates (42 and 43)*

The diastereomers **42** and **43** were obtained as the major products, respectively, in the cyclization of 2,4- and 2,6-dimethyl-7-bromoheptanoic acid esters **15** and **39**. Comparison of the ^1H NMR data with those reported previously (15, 16) suggested that they represented *cis* and *trans* compounds, respectively. The difference between **42** and **43** was more distinct in the ^{13}C NMR spectra in which the signals due to the tertiary methyl groups were observed higher upfield in the former (δ 20.5) than in the latter (δ 28.7). This fact indicates that the former methyl group is axial and the latter is equatorial. Furthermore, in the ^1H NMR spectra, the *trans* ester **43** exhibited signals due to the equatorial C-2 and C-6 protons at deshielded positions (δ 2.13 and 2.16, respectively), while those of the *cis* ester **42** appeared in a normal range, with the ethoxycarbonyl group in **42** and **43** in equatorial and axial orientation, respectively. The ^{13}C resonances of the secondary methyl groups in **42** and **43** were located at a similar field (δ 22.8 and 22.4).

Ethyl trans- *and* cis-*1,4-dimethylcyclohexanecarboxylates (44 and 45)*

The mixture of diastereomers obtained by the cyclization of **19** was separated by flash chromatography, and their conformation was studied by ^1H and ^{13}C NMR spectroscopy. In ^{13}C NMR spectra of the major and minor products, the signals due to tertiary and secondary methyl groups were observed at δ 20.8, 22.7 and δ 28.3, 22.4, respectively. Thus, the former was

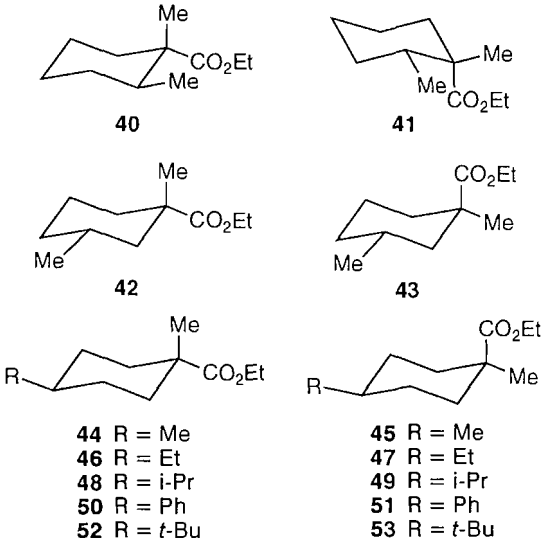
considered to have the *trans* structure (**44**) and the latter the *cis* structure (**45**). This assignment was consistent with the difference in the ^1H NMR spectra for both products. The signals of the 2-H_{eq} (= 6-H_{eq}) and 3-H_{ax} (= 5-H_{ax}) protons for **45** appeared at a deshielded (δ 2.17 vs. 1.58 for **44**) and shielded position (δ 0.96 vs. 1.69 for **44**), respectively, which was ascribed to the axial conformation of an ethoxycarbonyl group in **45**.



Ethyl trans- *and* cis-*4-ethyl-, 4-isopropyl-, 4-phenyl-, or 4-tert-butyl-1-methylcyclohexanecarboxylates (46–53)*

In these compounds C-4 substituents are believed to lock the conformation, in which they are disposed equatorially, even more strictly than in the 4-methyl analogs above. Thus, the configurations of the diastereomeric products were most readily assigned by comparing the chemical shift values of the signals due to 1-methyl groups in ^{13}C NMR spectra; i.e., the compound with the larger δ value was considered to be *cis* and the one with the smaller δ value *trans*. Additional support for these assignments was obtained by analyzing ^1H NMR spectra, as with the 4-methyl analog described above.[4]

Diastereoselectivity in the cyclization of ethyl 7-bromo-2-methylheptanoates with a methyl substituent at various positions in the chain

The ratios of the diastereomeric products observed in the cyclization of substrate **3** with a methyl group at various positions are summarized in Table 1. The reaction shows generally good selectivity, except in the case of 5-methyl-substituted substrate **19**. These results indicate that the remote stereocontrol in a simple ring-closure reaction would have greater potential than is generally thought (1) for the stereoselective synthesis of cyclic compounds, even though the bulkiness of the substituent and the type of the reaction concerned must be taken into account. In the following discussion, the relationship between the degree of diastereoselectivity and the energy difference of the diastereomeric transition states estimated qualitatively from the folding strains is addressed separately for the individual substrates. We have made two assumptions regarding the conformation of the transition state for the sake of simplification.[5] First, we assume that the chair conformation is decidedly preferred over the twist-boat conformation. Second, we assume that the eclipsed (skew) form **54** is favored over the bisected (*gauche*) form **55**, as has been pointed out also by D. Kim et al. (9*g*, 9*k*). The latter assumption is based on the generally accepted view regarding allylic systems, which is supported by the results of computational studies (17, 18). However, these studies have also revealed that the energy difference between the skew and *gauche* forms is much smaller in the model enolate system **56** than in the crotyl analog **57** (1.7 vs. 3.4 kcal/mol) (17). If the presence of the C-2

[4] The ^1H NMR spectral data for the *trans* and *cis* methyl esters corresponding to **52** and **53** were given in ref. 15, but these could not be used to distinguish between the diastereomeric products.

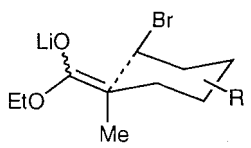
[5] The cyclization is considered to proceed mainly via *E*-enolates (19). The effect of enolate geometry on this issue is unknown, though it is not believed to be very important. A cyclization experiment with the substrates with bulkier ester alkyl groups might be informative in this regard.

Table 1. Remote diastereocontrol in the cyclization of ethyl 7-bromo-2-methylheptanoates with a methyl group at various positions in the chain.[a]

Entry	Subrates	Cyclization products		Diastereomeric ratio (yield)
1	 **11**	 **40**	 **41**	**40** : **41** = 96 : 4 (78%)
2	 **15**	 **42**	 **43**	**42** : **43** = >99 : 4 (83%)
3	 **19**	 **44**	 **45**	**44** : **45** = 79 : 21 (66%)
4	 **39**	 **43**	 **42**	**43** : **42** = 93 : 7 (53%)

[a]The reactions were conducted with 3 equivalents of LDA in THF at −78°C.

methyl group is taken into account, the energy difference between the transition states (TS) **54** and **55** could be considerably less than the former value, since the *gauche* interaction between the 2-methyl group and the C-3—C-4 bond might destabilize TS **54**.



54

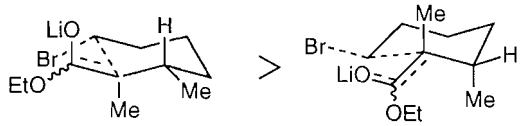
56 R = OMe
57 R = Me

*Cyclization of ethyl 7-bromo-2,3-dimethylheptanoate (**11**)*
In this cyclization, a stereogenic center exists next to the bond-forming carbon atom of an allylic system. Our dually stereocontrolled cyclization reaction mentioned at the outset (Scheme 1) involves this type of stereocontrol. Most of the stereocontrols used by Kim et al. (9) also belong to this category. They have reported an overall selectivity of 98:2 in the cyclization of substrate analogous to **11** (2-butyl and 7-tosyloxy groups instead of 2-methyl and 7-bromo, respectively) (9*f*). The major factors that affect selectivity include the $A^{1,3}$ strain (18, 20) and the additional *gauche* repulsion (quasi-axial vs. quasi-equatorial conformations of the 3-methyl group), both of which make TS **59** unfavorable and lead to the *cis* product through TS **58**.[6] The latter effect is inherent in the



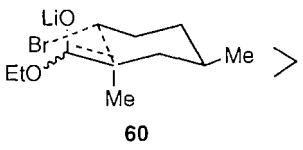
58 > **59**

ring-closure reaction of a carbon chain and should not be neglected (~ 1.8 kcal). In contrast to the models (21, 22) postulated to explain the diastereofacial selectivity in the intermolecular reaction of ester enolates with a β-stereogenic center, where the stereoelectronic effect plays an important role, the steric constraint resulting from the folding of the chain is an additional significant factor in determining the selectivity in the ring-forming reaction. Selectivity in the cyclization of substrates with a substituent remote from the atom on which the bonding occurs largely depends on the extent of the strain energy involved in the chain folding (1,*n*-asymmetric induction, $n \geq 3$).

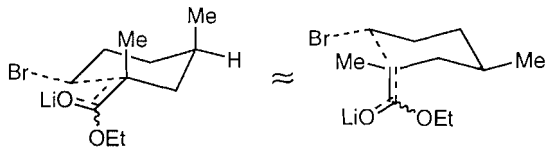
*Cyclization of 7-bromo-2,4-dimethylheptanoate (**15**)*
The diastereoselectivity for the *cis* product **42** was excellent, and formation of the *trans* product **43** was not detected. TS **61**,

[6] The sign of the inequality between formulas for the transition state conformations denotes the energy (or kinetic) preference.

which leads to the *trans* product **43**, is destabilized relative to *cis*-TS **60** by *gauche* repulsion (~1.8 kcal/mol) and 1,3-diaxial dimethyl interaction (3.7 kcal/mol) (23, 24). This energy difference (<5.5 kcal/mol)[7] is sufficient to explain the selectivity of greater than 99%. Incidentally, the *gauche* transition state **62**, which has no destabilization due to severe 1,3-diaxial dimethyl repulsion, must have a strain energy lower than that of **61**, but higher than that of **60**.



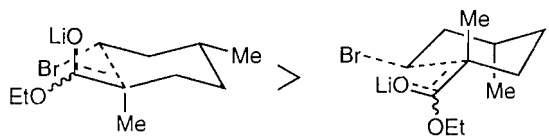
60



61 **62**

Cyclization of ethyl 7-bromo-2,5-dimethylheptanoate (19)

In this cyclization, formation of the *trans* product **44** was preferred to that of the *cis* product **45** by a ratio of 79:21, which corresponds roughly to the energy difference of 0.8 kcal/mol between the diastereomeric transition states. This selectivity is lower than that expected from the conformational energy difference between **63** and **64** (quasi-equatorial vs. quasi-axial methyl groups, ~1.8 kcal/mol). One of the bonds (C-5—C-6) *gauche* to the axial methyl group in TS **64** located at an end is less sterically constrained, provided that the C-1—C-6 bond remains loose and that the ester enolate alkylation reaction involves an early transition state, as generally postulated (19). This situation would account for the lower selectivity.

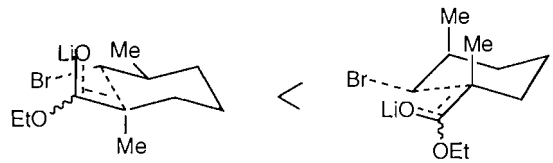


63 **64**

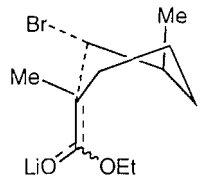
Cyclization of ethyl 7-bromo-2,6-dimethylheptanoate (39)

In this case, the *trans* product **43** was formed predominantly rather than the *cis* isomer **42**, which indicates that TS **66** is preferred to **65**. This fact might be explained by the presence of a severe torsional strain between the 6-methyl and the bromine bonds in TS **65**, which are nearly synperiplanar. While the diastereomeric TS **66** appears to suffer from 1,3-diaxial dimethyl interaction (~3.7 kcal/mol) (23, 24), twist-boat TS **66a** is unlikely since it is doubly disadvantaged (twist-boat form and the *gauche* form). Also, the 1,3-diaxial dimethyl interaction in TS **66** might not be as strong as in a normal cyclohexane ring since the loose C-1—C-6 bond intervenes between the two carbon atoms bearing methyl groups, which differs from the situation in TS **61**. The strong dependence of van der Waals repulsion on the distance between the atoms is well known (25).

[7] The energy difference between the transition states should be less than that estimated for the cyclohexane products, due to the looseness of the emerging bond.



65 **66**



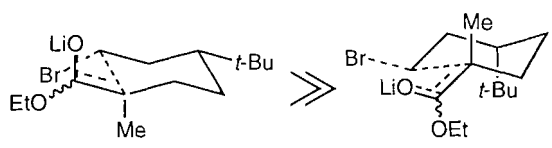
66a

Factors influencing diastereoselectivity

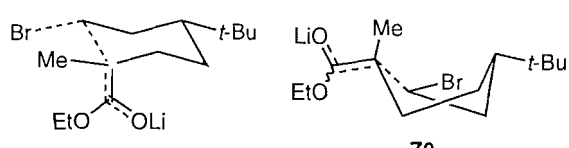
Various parameters that may affect the diastereofacial selectivity, including the size of 5-substituents, were investigated to better understand the parameters governing the cyclization of ethyl 7-bromo-2,5-dimethylheptanoate (**19**), which shows only moderate stereoselectivity.

Relationship between diastereoselectivity and bulkiness of the substituent in the chain

The steric bulkiness of the substituents is believed to greatly affect the energy difference between the diastereomeric transition states, and hence the diastereoselectivity. This subject was investigated in the cyclization of substrate **3**, which carries substituents of various sizes at the 5-position. The results are shown in Table 2 with the relevant conformational free energy (*A*-values) (ref. 24, pp. 433–436, and ref. 26). Generally, selectivity was enhanced as the bulkiness of the 5-substituents increased, as anticipated. However, two points should be mentioned. First, a change in the 5-substituent from methyl to phenyl resulted in a decrease in selectivity, which was contrary to the result predicted from the *A*-values. This result is supported by the fact that in the equilibrium of 1-methyl-1-phenylcyclohexane conformers, the methyl group prefers the equatorial position by 0.3 kcal/mol (27, 28; see also ref. 12). A computational study on a simple allylic system (17) also showed that a phenyl group can be less effective than a methyl group in providing a conformational lock, depending on its disposition. Second, the diastereoselectivity observed for the 5-*tert*-butyl substrate **35** was not as high as expected, considering the ability of the *tert*-butyl group to lock the cyclohexane conformation. This result might indicate the intervention of a *gauche* TS **69** or a twist-boat TS **70** rather than a chair TS **68**, which would definitely be energetically unfavorable.



67 **68**



69 **70**

Table 3. Effect of the solvent on diastereoselectivity in the cyclization of ethyl 7-bromo-2,5-dimethylheptanoate.[a]

Entry	Solvent	Reaction temp. (°C)	Yield (%)	Product ratio *trans*/cis (**44/45**)
1	Et_2O	−20[b]	72.9	73:27
2	THF	−78	66.0	79:21
3	DME	−78	77.5	69:31
4	THF/HMPA[c]	−78	71.9	52:48

[a]The reaction was conducted using 2.5 molar equivalents of LDA.
[b]The reaction did not proceed to completion at −78°C.
[c]HMPA was used in 13.4 molar equivalents.

Effect of the solvent

The effect of the solvent on the diastereoselectivity was examined in the cyclization of the 5-methyl substrate **19** (Table 3). Excluding the reaction in diethyl ether (entry 1), which was conducted at an elevated temperature, selectivity decreased in the order THF > DME > THF/HMPA. This order parallels the well-known increase in enolate reactivity due to the greater dissociation of the enolate cation ion pair and ion aggregate (ref. 26, p. 428). Based on the reactivity–selectivity principle (29), the increase in reactivity should diminish selectivity.

Effect of base counter cation

Kim et al. reported for one of their cyclization reactions that the use of LDA as a base gave better selectivity than potassium hexamethyldisilazide (KHMDS), albeit in poorer yield (9*g*). The results of our investigation in this regard are shown in Table 4. In comparing entries 2 and 4, the selectivity is slightly higher in the reaction with lithium hexamethyldisilazide

Table 4. Effect of the base on diastereoselectivity in the cyclization of ethyl 7-bromo-2,5-dimethylheptanoate.

Entry	Base[a]	Reaction temp. (°C)	Yield (%)	Product ratio *trans*/cis (**44/45**)
1	LDA	−78	66.0	79:21
2	LHMDS	r.t.	72.0	73:27
3	KHMDS	−25	67.6	71:29
4	KHMDS	r.t.	75.0	69:31

[a]Three equivalents were used.

(LHMDS) than with KHMDS. This result is consistent with the trend predicted from the reactivity–selectivity relationship, since the degree of ion-pair dissociation is greater in potassium enolate than in lithium enolate and the former should be more reactive.

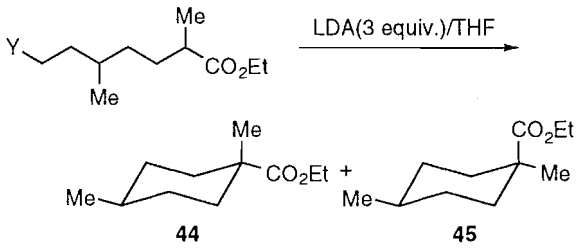
Leaving group effect

In the cyclization reactions described thus far, the observed selectivity is generally lower than that predicted from an estimation of the energy difference between the diastereomeric transition states based on the conformation of the product cyclohexane derivatives. This discrepancy may be largely attributed to the fact that the transition state involves a looser conformation than the product. The extent of the discrepancy should increase as the transition state occurs earlier in the reaction. This influence on selectivity is similar to Hammond–BEP behavior (29). Thus, we can predict that diastereoselectivity should decrease as the ease with which the leaving group dissociates increases. Our results are summarized in Table 5.

Conclusion

Diastereoselectivity in cyclohexane ring formation by the intramolecular ester enolate alkylation reaction has been investigated as a case study of the folding strain stereocontrol concept. In the cyclization of ethyl 7-bromo-2-methylheptanoates (**3**) with a methyl substituent at various positions in the chain under LDA treatment, good to excellent selectivities were obtained, with the exception of the case of 5-methyl, where the selectivity was only moderate. It would be valuable from a synthetic point of view that either of the diastereomeric 1,3-dimethylcyclohexanecarboxylates could be obtained stereoselectively merely by choosing the cyclization substrates. Thus, folding strain control could influence a ring-closure reaction to a greater extent than generally thought, and stereoselective ring construction using this approach would be useful. The direction of the selectivity can be explained by a qualitative consideration of the strain factors in the diastereomeric transition states. In this approach, the location of the bond formed relative to the stereogenic center is extremely important. Noteworthy results in this study include the difference in the degree of diastereoselectivity in cyclization between the 2,5-dimethyl and 2,6-dimethyl substrates **15** and **19**, and the unexpected preference for diastereomer **43** over **42** in the cyclization of substrate **39**. Our assumption requires further support from computational studies. Quantitative estima-

Table 5. Effect of leaving group variation on diastereoselectivity in the cyclization of 7-substituted ethyl 2,5-dimethylheptanoate.



44 45

Entry	Leaving gr. Y	Reaction temp. (°C)	Yield (%)	Product ratio (**44/45**)
1	Cl	–20	60.4	70:30
2	TsO	–78	79.0	81:19
3	Br	–78	66.0	79:21
4	TfO	–78	75.0	73:27
5	I	–78	73.0	69:31

tion of the difference in strain energy between diastereomeric foldings in the transition state is desirable, and future studies should addresss this problem by a combination of MO and force field calculations (30, 31). The effect of bulkiness of the substituent on selectivity was examined in the 5-substituted substrate, and selectivity increased in the order Ph < Me ≈ Et < i-Pr < *t*-Bu, as predicted. The effects of the solvent, the base counter cation, and the leaving group are related to enolate reactivity. A greater reactivity is associated with a lower selectivity, i.e., in accord with the normal reactivity–selectivity relationship. These effects should be taken into account when working with diastereoselective ring contruction.

Experimental

IR spectra were obtained on a JASCO A-100 spectrometer. ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Hitachi R-90-H, a JEOL FX-100, or a JEOL JMN-GX-400 spectrometer. Proton chemical shifts are reported in ppm on the δ scale relative to TMS as an internal reference (0.00), and carbon chemical shifts are reported in ppm relative to the center line of the $CDCl_3$ triplet (77.03). Carbon signal multiplicities were determined by INEPT experiments. The superscript asterisks on chemical shift values denote the observation of signals for the diastereomer at separate positions. MS spectra (EI) were determined on a JEOL JMS D-300 or a JMX AX-500 high-resolution mass spectrometer. GC analyses were performed on a Shimazu GC-9A apparatus using an OV-1 or Shimazu CBP-20-M-25-20 capillary column. TLC was performed on a precoated thin-layer plate (Merck Art 5744 silica gel $60F_{254}$; 0.25 or 0.5 mm). Silica gel (Fuji–Davison BW-820, BW-300, or BW-200) was used for column chromatography. Et_2O, THF, and DME were distilled from sodium benzophenone ketyl under N_2. HMPA, DMSO, Et_3N, and diglyme were distilled from CaH_2. Benzene, CH_2Cl_2, and CCl_4 were distilled from P_2O_5. MeOH and EtOH were dried by distillation from the corresponding magnesium alkoxide. All reactions were conducted in dry glassware under argon or N_2. The organic extracts were dried over $MgSO_4$ prior to solvent removal on a rotary evaporator.

*3-Benzyloxy-1-propanol (**6**) (32)*

A solution of benzaldehyde (20.4 mL, 200 mmol), 1,3-propanediol (17.4 mL, 240 mmol), and $TsOH{\cdot}H_2O$ (1.9 g) in benzene (300 mL) was refluxed overnight. The reaction mixture was cooled to room temperature, washed successively with 1 N NaOH and water, and dried over anhydrous K_2CO_3. After removal of the solvent the product was distilled to give *3-phenyl-1,3-dioxacyclohexane* (31.4 g, 96%) as a colorless oil; ^1H NMR (90 MHz) δ: 1.20–1.80 (m, 2H, $CH_2CH_2CH_2$), 3.81–4.35 (m, 4H, 2 × OCH_2CH_2), 5.48 (s, 1H, CHPh), 7.20–7.50 (m, 5H, Ph). A solution of this product (15.4 mL, 93.9 mmol) in Et_2O (70 mL) was added to the solution prepared by stirring a mixture of $AlCl_3$ (30.7 g, 230 mmol) in Et_2O (80 mL) and $LiAlH_4$ (2.20 g, 57.5 mmol) in Et_2O (40 mL) at 0°C for 30 min and the resulting mixture was refluxed for 4 h. Water was added carefully to the cooled mixture to destroy the excess hydride and then it was acidified by the addition of dilute H_2SO_4. The mixture was extracted with Et_2O and the combined organic layers were washed with aqueous Na_2CO_3 solution and brine. The product, after removal of the solvent, distilled to afford the title compound **6** (11.2 g, 71%) as a colorless oil; 1H NMR (90 MHz) δ: 1.84 (2H, quintet, J = 5.9 Hz, $CH_2CH_2CH_2$), 1.90 (1H, s, OH), 3.63 (2H, t, J = 5.9 Hz, CH_2CH_2OH), 3.74 (2H, t, J = 5.9 Hz, CH_2CH_2OBn), 4.49 (2H, s, OCH_2Ph), 7.30 (5H, s, Ph).

*1-Benzyloxy-3-bromopropane (**7**)*

To a mixture of 3-benzyloxy-1-propanol (**6**) (11.2 g, 66.7 mmol) and Et_3N (14.0 mL, 100 mmol) cooled to 0°C was added $MeSO_2Cl$ (6.2 mL, 80 mmol). The mixture was stirred for 15 min and the reaction was quenched by the addition of NH_4Cl. The product was extracted with Et_2O and the combined organic phases were washed successively with 1 N HCl, aqueous Na_2CO_3, and brine. The solvent was evaporated to afford the crude mesylate; ^1H NMR (90 MHz) δ: 2.02 (2H, quintet, J = 5.9 Hz, $CH_2CH_2CH_2$), 2.92 (3H, s, O*Ms*), 3.58 (2H, t, J = 5.9 Hz, CH_2OBn), 4.34 (2H, t, J = 5.9 Hz, CH_2OMs), 4.50 (2H, s, OCH_2Ph), 7.31 (5H, s, Ph). A solution of the mesylate thus obtained (16.3 g, 66.7 mmol) in acetone (150 mL) was refluxed overnight with LiBr (14.5 g, 167 mmol) with stirring. Et_2O and water were added and the organic phase was washed with water. The crude product obtained by evaporation of the solvent was purified by silica gel chromatography to furnish the title bromide **7** (12.7 g, 83%) as an oil: ^1H NMR (90 MHz) δ: 2.13 (2H, quintet, J = 6.2 Hz, $CH_2CH_2CH_2$), 3.53 (2H, t, J = 6.2 Hz, CH_2CH_2OBn), 3.66 (2H, t, J = 6.2 Hz, CH_2CH_2Br), 4.51 (2H, s), 7.32 (5H, s, Ph); ^{13}C NMR (25 MHz) δ: 128.5, 127.7, 73.2, 67.7, 32.9, 30.7.

*Ethyl 7-benzyloxy-3-oxoheptanoate (**8**)*

To a stirred suspension of NaH (1.9 g, 39.4 mmol) in THF (50 mL) cooled to 0°C was added a solution of ethyl acetoacetate (4.28 mL, 32.8 mmol) in THF (30 mL). After the mixture had been stirred for 15 min, *n*-butyllithium solution (1.6 M in hexane, 22.0 mL, 35.2 mmol) was added and the mixture was stirred for 15 min at 0°C. To the dianion solution thus prepared was added 3-bromo-1-benzyloxypropane (**7**) (7.51 g, 32.8

mmol) in THF (30 mL) and the reaction mixture was stirred at room temperature for 3 h, then quenched by the addition of 1 N HCl. The product was extracted with Et_2O and the combined organic layers were washed with aqueous $NaHCO_3$ and brine. The residue left after evaporation of the solvent was purified by chromatography on a silica gel column to give the title ester **8** (6.47 g, 71%) as a colorless oil: IR (neat): 1740, 1710 cm^{-1}; ^1H NMR (400 MHz) δ: 1.27 (3H, t, J = 7.3 Hz, $MeCH_2O$), 1.60–1.74 (4H, m, CH_2CH_2), 2.56 (2H, t, J = 6.7 Hz, CH_2CH_2CO), 3.41 (2H, s, $COCH_2CO2$), 3.47 (2H, t, J = 6.7 Hz, CH_2OBn), 4.18 (2H, q, J = 7.3 Hz, OCH_2Me), 4.48 (2H, s, OCH_2Ph), 7.33 (5H, m, Ph); ^{13}C NMR (25 MHz) δ: 202.6 (s), 167.2 (s), 138.5 (s), 128.3 (d), 127.6 (d), 72.9 (t), 69.9 (t), 61.3 (t), 49.3 (t), 42.6 (t), 29.0 (t), 20.3 (t), 14.1 (q).

*Ethyl 7-hydroxy-3-methylheptanoate (**9**)*

To a suspension of NaH (1.46 g, 30.5 mmol) in Et_2O was added a solution of ethyl 7-benzyloxy-3-oxoheptanoate (**8**) (7.7 g, 27.7 mmol) in Et_2O (30 mL) at 0°C. After stirring for 15 min, diethyl chlorophosphate (4.42 mL, 30.5 mmol) in Et_2O (30 mL) was introduced dropwise and stirring was continued at room temperature for 2 h. The reaction mixture was quenched by the addition of aqueous NH_4Cl and washed with aqueous $NaHCO_3$. The solvent was evaporated to leave the enol phosphate. A solution of zero valent palladium reagent was prepared in situ from $PdCl_2(PPh)_3$ (0.38 g, 0.55 mmol) in THF (11 mL) and a solution of DIBAL in toluene (2.25 M, 0.49 mL, 1.1 mmol) at 0°C for 10 min and to this was added successively the enol phosphate (11.4 g, 27.5 mmol), obtained above and dissolved in CH_2Cl_2 (55 mL), and a Me_3Al solution (2 M, 42 mL, 82 mmol) in THF (11 mL). The mixture was stirred at room temperature for 5 days. The reaction mixture was diluted with Et_2O and poured into 1 N HCl. The organic layer was separated and washed with saturated $NaHCO_3$ and brine. The chromatographic purification (silica gel) of the residue left after removal of the solvent afforded *ethyl 7-benzyloxy-3-methyl-2-heptenoate* (6.54 g, 86%) as an oil; ^1H NMR (400 MHz) δ: 1.27 (3H, t, J = 7.3 Hz, $MeCH_2O$), 1.50–1.70 (4H, m), 2.14 (3H, s, =CMe), 2.14 (2H, t, J = 6.1 Hz, CH_2CH_2C=), 3.47 (2H, t, J = 6.1 Hz, CH_2CH_2OBn), 4.14 (2H, q, J = 7.3 Hz, OCH_2Me), 4.49 (2H, s, OCH_2Ph), 5.65 (1H, s, CH=C), 7.33 (5H, m, Ph); ^{13}C NMR (100 MHz) δ: 166.8, 159.6, 138.6, 128.4, 127.6, 127.5, 115.8, 72.9, 70.0, 59.4, 40.6, 29.3, 24.1, 18.6, 14.3. Exact Mass calcd. for $C_{17}H_{24}O_3$: 276.1725; found: 276.1716. A portion of the product (2.4 g, 8.8 mmol) was dissolved in EtOH (50 mL) and hydrogenated in the presence of 10% palladium on charcoal (0.2 g) overnight at room temperature. The catalyst was removed by filtration and the filtrate was evaporated to leave a residue that was purified by chromatography on a silica gel column. The product **9** (1.65 g, 100%) was obtained as a colorless oil; ^1H NMR (400 MHz) δ: 0.93 (3H, d, J = 6.2 Hz, $MeCH$), 1.24 (3H, t, J = 7.0 Hz, $MeCH_2O$), 1.00–2.40 (10H, m), 3.64 (2H, t, J = 5.9 Hz, CH_2CH_2OH), 4.13 (2H, q, J = 7.0 Hz, $MeCH_2O$); ^{13}C NMR (25 MHz) δ: 173.3, 62.9, 60.1, 41.8, 36.4, 32.8, 30.3, 23.1, 19.7, 14.2.

*Ethyl 7-hydroxy-2,3-dimethylheptanoate (**10**)*

A mixture of ethyl 7-hydroxy-3-methylheptanoate (**9**) (1.65 g, 8.8 mmol) and diisopropylethylamine (1.99 mL, 11.4 mmol) in CH_2Cl_2 (35 mL) was stirred for a while at 0°C and then chloromethyl methyl ether (0.87 mL, 11.4 mmol) was added. The resulting mixture was allowed to warm slowly to room temperature, where it was stirred for 5 h, then quenched by the addition of 1 N HCl. The product was extracted with Et_2O, and the extract solution was washed with aqueous $NaHCO_3$ and brine. The residue obtained after evaporation of the solvent was purified by chromatography on a silica gel column to afford *ethyl 7-methoxymethoxy-3-methylheptanoate* (1.92 g, 94%) as an oil: ^1H NMR (400 MHz) δ: 0.94 (3H, d, J = 6.1 Hz, $MeCH$), 1.26 (3H, t, J = 7.3 Hz, $MeCH_2O$), 1.18–2.28 (9H, m), 3.36 (3H, s, $MeOCH_2O$), 3.52 (2H, t, J = 6.1 Hz, CH_2CH_2OMOM), 4.13 (2H, q, J = 7.3 Hz, $MeCH_2O$), 4.62 (2H, s, $MeOCH_2O$). The LDA solution, prepared from diisopropylamine (1.4 mL, 10 mmol) in THF (20 mL) and *n*-butyllithium solution in hexane (1.5 M, 6.8 mL, 10.2 mmol), was cooled to −78°C and to this was added, with stirring, a solution of the MOM ether above dissolved in THF (20 mL) and HMPA (7 mL). After stirring for 30 min, iodomethane (0.62 mL, 10 mmol) was introduced. The cooling bath was removed and the reaction mixture was allowed to warm slowly to room temperature. After 3 h it was quenched by the addition of 1 N HCl and the product was extracted with Et_2O. The organic layers were washed with aqueous $NaHCO_3$ and brine. The residue left after evaporation of the solvent was purified by silica gel chromatography to furnish *ethyl 7-methoxymethoxy-2,3-di-methylheptanoate* (1.69 g, 83%) as an oil: ^1H NMR (400 MHz) δ: 0.86, 0.90* (3H, d, J = 6.6 Hz, $MeCH$), 1.06, 1.10* (3H, d, J = 6.8 Hz, $MeCH_2$), 1.25 (3H, t, J = 7.1 Hz, $MeCH_2O$), 1.10–2.00 (8H, m), 3.36 (3H, s, $MeOCH_2O$), 3.52 (2H, t, J = 6.4 Hz, CH_2CH_2OMOM), 4.13 (2H, q, J = 7.1 Hz, $MeCH_2O$), 4.62 (2H, s, $MeOCH_2O$); ^{13}C NMR (25 Hz) δ: 176.5, 96.5, 67.8, 60.0, 55.1, 44.7,* 44.3, 35.4, 34.6, 33.2,* 29.9, 23.9, 23.7,* 17.2,* 15.7, 14.3, 14.0,* 12.4. Demethoxymethylation of the crude product above (2.35 g) was performed by its treatment with 6 N HCl (4 mL) in THF (47 mL) at room temperature overnight. After dilution with water the reaction mixture was extracted with Et_2O and the combined organic layers were washed with aqueous $NaHCO_3$ and brine. Purification of the product by silica gel chromatography afforded a diastereomeric mixture of the title compound (**10**) (1.76 g, 66% from 9) as an oil: IR (neat): 3375, 1720 cm^{-1}; ^1H NMR (400 MHz) δ: 0.86, 0.91* (3H, d, J = 6.7 Hz, $MeCH$), 1.06, 1.10* (3H, d, J = 6.7 Hz, $MeCH_2$), 1.25 (3H, t, J = 7.3 Hz, $MeCH_2O$), 1.14–1.85 (8H, m), 2.35 (1H, quintet, $CHCHMe$), 3.64 (2H, t, J = 6.1 Hz, CH_2CH_2OH), 4.13 (2H, q, J = 6.7 Hz, $MeCH_2O$); ^{13}C NMR (100 MHz) δ: 176.5(s), 62.9(t), 60.1(t), 60.0(t),* 44.7(d),* 44.3(d), 36.0(d),* 35.4(d), 34.5(t), 33.1(t),* 32.9(t), 23.3(t), 23.2(t),* 17.1(t),* 15.7(q), 14.3(q), 13.9(q), 12.4(q). Exact Mass calcd. for $C_{11}H_{22}O_3$: 202.1569; found: 202.1662.

*Ethyl 7-bromo-2,3-dimethylheptanoate (**11**)*

A mixture of the alcohol **10** (0.57 g, 2.8 mmol) and Et_3N (0.59 mL, 4.2 mmol) in CH_2Cl_2 (10 mL) was stirred at 0°C for 5 min and then $MeSO_2Cl$ (0.26 mL, 3.4 mmol) was added. After the reaction mixture had been stirred for 15 min, it was quenched by the addition of aqueous NH_4Cl. The product was extracted with Et_2O and the extract solution was washed successively with 1 N HCl, aqueous Na_2CO_3, and brine. Evaporation of the solvent gave crude *ethyl 7-mesyloxy-2,3-dimethylheptanoate* as an oil: ^1H NMR (90 MHz) δ: 0.87, 0.91* (3H, d, J = 6.8 Hz, $MeCH$), 1.07, 1.10* (3H, d, J = 7.1 Hz, $MeCH_2$), 1.26 (3H, t, J

= 7.1 Hz, *Me*CH_2O), 1.00–2.00 (7H, m), 2.35 (1H, quintet, J = 6.8 Hz, CHC*H*Me), 3.01 (3H, s, O*Ms*), 4.13 (2H, q, J = 7.3 Hz, MeC*H_2*O), 4.22 (2H, t, J = 6.1 Hz, CH_2CH_2OMs). A solution of the mesylate above in acetone (20 mL) was refluxed with LiBr (0.78 g, 8.9 mmol) overnight. After addition of water the product was extracted with Et_2O and the organic layer was washed with water. The evaporation of the solvent and subsequent purification of the residue by silica gel chromatography afforded the title compound (**11**) (0.50 g, 67%); IR (neat) 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.87, 0.89* (3H, d, J = 7.3 Hz, *Me*CH), 1.07, 1.11* (3H, d, J = 7.3 Hz, *Me*CH), 1.26 (3H, t, J = 6.7 Hz, *Me*CH_2O), 1.15–1.58 (4H, m), 1.76–1.87 (3H, m), 2.35 (1H, quintet, J = 6.7 Hz, CHC*H*Me), 3.41 (2H, t, J = 6.7 Hz, CH_2CH_2Br), 4.14 (2H, q, J = 6.7 Hz, CH_2CH_2O); ^{13}C NMR (100 MHz) δ: 176.4(s), 60.1(t), 44.6(d),* 44.3(d), 35.8(d),* 35.2(d), 33.8(t), 33.7(t), 32.9(t), 25.8(t), 25.6(t),* 17.1(q),* 15.7(q), 14.3(q), 13.8(q),*12.5(q). Exact Mass calcd. for $C_{11}H_{21}O_2Br$: 265.0725; found: 265.0820.

*2-Methyl-5-pentanolide (**12**)*

To a solution of LDA prepared from diisopropylamine (11.9 mL, 85 mmol), THF (100 mL), and *n*-butyllithium solution in hexane (1.3 M, 65 mL, 85 mmol) was added δ-valerolactone (4.63 g, 50 mmol) at −78°C under stirring. After the mixture had been stirred for 30 min, iodomethane (9.34 mL, 150 mmol) dissolved in a mixture of HMPA (10.4 mL) and THF (15 mL) was added dropwise (33). The reaction mixture was allowed to warm slowly, by removal of the cooling bath, up to −40°C, where it was quenched by the addition of water. After acidification with 3 N HCl, the product was extracted with Et_2O and the organic layers were washed with aqueous $NaHCO_3$ and brine. Distillation gave the methylated product **12** (3.57 g, 63%) as a colorless oil; IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 1.26 (3H, d, J = 6.7 Hz, *Me*CH), 1.56 (1H, m, 3-H_{ax}), 1.92 (2H, m, 3-H_{eq}, 4-H_{eq}), 2.10 (1H, sextet, J = 6.7 Hz, 4-H_{ax}), 2.59 (1H, dq, J = 11.0, 6.7 Hz, 2-H), 4.32 (2H, m, 5-C$H_{ax}H_{eq}$); ^{13}C NMR (100 MHz) δ: 175.2, 68.5, 34.6, 27.1, 22.0, 16.7. Exact Mass calcd. for $C_6H_{10}O_2$: 114.0681; found: 114.0697.

*Ethyl 7-hydroxy-2,4-dimethyl-2-heptenoate (**13**)*

To a solution of triethyl 2-phosphonopropionate (11.9 mL, 85 mmol) in THF (100 mL) was successively added *n*-butyllithium solution in hexane (1.4 M, 25.4 mL, 33.8 mmol) and 2-methyl-5-pentanolide (**12**) (3 g, 26 mmol) at −78°C. After stirring of the mixture for a short time, addition of DIBAL solution in toluene (1.76 M, 19.3 mL, 33.8 mmol) followed. The resulting mixture was allowed to react overnight after removal of the cooling bath. The reaction mixture was quenched by the cautious addition of aqueous Na_2SO_4 solution. The precipitate was removed by filtration and the solvent was evaporated from the filtrate. The residue was chromatographed on a column of silica gel, giving the title compound **13** (2.7 g, 60%); ^{1}H NMR (100 MHz) δ: 1.02 (3H, d, J = 6.7 Hz, *Me*CH)), 1.29 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.20–1.70 (5H, m), 1.84 (3H, d, J = 1.3 Hz, MeC═), 2.04 (1H, s, OH), 3.60 (2H, t, J = 6.2 Hz, CH_2CH_2OH), 4.19 (2H, q, J = 7.3 Hz, MeC*H_2*O), 6.59 (1H, dq, J = 10.1, 1.3 Hz, CHC*H*═CMe).

*Ethyl 7-hydroxy-2,4-dimethylheptanoate (**14**)*

The unsaturated ester **13** (2.15 g, 10.75 mmol) dissolved in EtOH (30 mL) was hydrogenated in the presence of 10% palladium on charcoal (0.11 g). Removal of the catalyst by filtration through a short column of silica gel and evaporation of the solvent from the filtrate afforded the title compound **14** (2.085 g, 96%) as an oil; IR (neat): 3400, 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.90 (3H, d, J = 6.7 Hz, *Me*CH), 1.14 (3H, d, J = 7.3 Hz, *Me*CH), 1.25 (3H, t, J = 6.7 Hz, *Me*CH_2O), 1.10–1.80 (8H, m), 2.52 (1H, m, CH_2CHMeCO2), 3.62 (2H, t, J = 6.7 Hz, CH_2CH_2OH), 4.12 (2H, q, J = 6.7 Hz, *Me*CH_2O); ^{13}C NMR (100 MHz) δ: 177.0, 63.2, 60.1, 41.4, 41.1,* 37.5, 33.1, 32.8,* 32.7, 30.7, 30.4,* 19.5, 18.1, 17.2,* 14.2. Exact Mass calcd. for $C_{11}H_{22}O_3$: 202.1569; found: 202.1671.

*Ethyl 7-bromo-2,4-dimethylheptanoate (**15**)*

The alcohol **14** (0.98 g, 4.86 mmol) in CH_2Cl_2 (20 mL) was mesylated with $MeSO_2Cl$ (0.46 mL, 5.84 mmol) and Et_3N (1.02 mL, 7.29 mmol) as before, giving crude *ethyl 7-mesyloxy-2,4-dimethylheptanoate* (1.36 g, ~100%); ^{1}H NMR (400 MHz) δ: 0.91 (3H, d, J = 5.7 Hz, *Me*CH), 1.14 (3H, d, J = 6.6 Hz, *Me*CH), 1.25 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.00–1.93 (6H, m), 2.50 (1H, m, CH_2CHMeCO$_2$), 3.00 (3H, s, OMs), 4.12 (2H, q, J = 7.3 Hz, *Me*CH_2O), 4.20 (2H, t, J = 6.2 Hz, CH_2CH_2OMs); ^{13}C NMR (25 MHz) δ: 176.8, 70.3, 60.1, 41.1, 40.7,* 37.3, 32.7, 32.5,* 30.4, 30.2,* 26.6,* 26.5, 19.4, 19.2,* 18.1, 17.2, 14.2. The mesylate (0.72 g, 2.58 mmol) was converted as before with LiBr (0.56 g, 6.45 mmol) in acetone (9 mL) to afford the title bromide **15** (0.63 g, 92%) as an oil, IR (neat): 1735 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.91 (3H, d, J = 6.7 Hz, *Me*CH), 1.15 (3H, d, J = 6.7 Hz, *Me*CH), 1.26 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.44 (4H, m), 1.72 (1H, m), 1.80 (2H, m), 2.51 (1H, m, CH_2CHMeCO$_2$), 3.39 (2H, t, J = 6.7 Hz, CH_2CH_2Br), 4.13 (2H, q, J = 7.3 Hz, *Me*CH_2O); ^{13}C NMR (100 MHz) δ: 177.0,* 176.9, 60.2,* 60.1, 41.2, 40.9,* 37.4,* 37.3, 35.5, 35.4,* 34.1, 30.34, 30.30,* 30.2,* 30.1,* 19.5, 19.35,* 18.1, 17.2, 14.3. Exact Mass calcd. for $C_{11}H_{21}O_2Br$: 264.0725; found: 264.0808.

*Ethyl 3-methyl-5-pentanolide (**17**) (34)*

To a stirred suspension of $NaBH_4$ (2.0 g, 52.9 mmol) in THF (10 mL) cooled in an ice bath was added 3-methylglutaric anhydride (**16**) (5.93 g, 16.3 mmol) dissolved in THF (50 mL). The ice bath was removed and the mixture was allowed to react for 1 h. After addition of EtOH and acidification with 3 N HCl, the mixture was heated on a water bath for 1 h. The cooled mixture was extracted with Et_2O and the organic layer was washed with aqueous $NaHCO_3$ and brine. Distillation of the product afforded the title lactone **17** (4.01 g, 76%) as an oil; IR (neat): 1730 cm^{-1}; 1H NMR (400 MHz) δ: 1.07 (3H, d, J = 6.1 Hz, *Me*CH), 1.54 (1H, m, 3-H), 1.93 (1H, m, 4-H_{eq}), 2.10 (2H, m, 2-H_{ax}, 4-H_{ax}), 2.68 (1H, m, 2-H_{eq}), 4.27 (1H, td, J = 11.6, 3.7 Hz, 5-H_{ax}), 4.42 (1H, dt, J = 11.6, 4.3 Hz, 5-H_{eq}); ^{13}C NMR (100 MHz) δ: 171.3(s), 68.5(d), 38.2(d), 30.6(t), 26.5(d), 21.4(q).

*Ethyl 7-hydroxy-2,5-dimethylheptanoate (**18**)*

3-Methyl-δ-valerolactone (**17**) (3.65 g, 38.4 mmol) was converted to *ethyl 7-hydroxy-2,5-dimethyl-2-heptenoate* in the same way as in the case of the 2-methyl analog using DIBAL solution (1 M in toluene, 38.4 mL, 32 mmol), triethyl 2-phosphophonopropionate (9.02 mL, 38.4 mmol) in THF (10 mL), and *n*-butyllithium solution (1.6 M in hexane, 26.4 mL, 42.23

mmol). The product (4.77 g, 87%) was obtained as an oil; ^{1}H NMR (400 MHZ) δ: 0.95 (3H, d, J = 6.2 Hz, *Me*CH), 1.30 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.84 (3H, s, MeC=), 1.00–2.00 (5H, m), 2.16 (1H, m), 3.70 (2H, t, J = 7.0 Hz, CH_2CH_2OH), 4.19 (2H, q, J = 7.3 Hz, Me*CH*$_2$O), 6.78 (1H, tq, J = 7.3, 1.3 Hz, CH_2CH=CMe). This material (2.33 g, 11.65 mmol) was then hydrogenated with 10% palladium on charcoal (0.31 g) in EtOH (35 mL) to afford the saturated ester **18** (2.48 g, 100%) as an oil; IR (neat): 3450, 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.90 (3H, d, J = 6.7 Hz, *Me*CH), 1.14, 1.15* (3H in total, d, J = 7.3 Hz, *Me*$CHCO_2$), 1.26 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.00–1.80 (6H, m), 2.38 (1H, m, CH_2CHMeCO$_2$), 3.60 (2H, m, CH_2CH_2OH), 4.13 (2H, q, J = 7.3 Hz, Me*CH*$_2$O); ^{13}C NMR (100 MHz) δ: 176.9, 61.1, 61.0,* 60.1, 39.8, 34.5, 34.4,* 34.1, 29.6, 29.4,* 19.6, 17.3, 17.0, 14.3. Exact Mass calcd. for $C_{11}H_{22}O_3$: 202.1569; found: 202.1630.

*Ethyl 7-bromo-2,5-dimethylheptanoate (**19**)*

The hydroxy ester **18** was transformed to *ethyl 7-mesyloxy-2,5-dimethylheptanoate* in the same way as described above. ^{1}H NMR (90 MHz) δ: 0.93 (3H, d, J = 5.7 Hz, *Me*CH), 1.14 (2H, d, J = 6.6 Hz, *Me*CH), 1.25 (3H, t, J = 6.9 Hz, *Me*CH_2O), 1.00–1.80 (8H, m), 2.30 (1H, m, CH_2CHMeCO2), 2.97 (3H, s, OMs), 4.08 (2H, q, J = 7.3 Hz, Me*CH*$_2$O), 4.21 (2H, t, J = 6.2 Hz, C*H*$_2$OMS). Then the mesylate (3.17 g, 11.3 mmol) was treated with LiBr (2.46 g, 28.3 mmol) in acetone (60 mL), refluxing overnight to furnish the title bromide **19** (1.71 g, 57%) as an oil, IR (neat): 1735 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.90 (3H, d, J = 6.7 Hz, *Me*CH), 1.15 (3H, d, J = 7.3 Hz, *Me*CH), 1.26 (3H, t, J = 6.7 Hz, Me*CH*$_2$O), 1.05–1.35 (2H, m), 1.43 (1H, m), 1.65 (3H, m), 1.87 (1H, m), 2.39 (1H, sextet, J = 6.7 Hz, CH_2CHMeCO$_2$), 3.41 (2H, m, CH_2CH_2Br), 4.13 (2H, q, J = 6.7 Hz, Me*CH*$_2$O); ^{13}C NMR (100 MHz) δ: 176.7(s), 60.2(t), 39.8(t) 39.7(d), 33.9(t), 33.8(t),* 31.9(t), 31.6(d), 31.0(t), 30.9(t),* 18.8(q), 17.3(q), 17.0(q), 14.3(q). Exact Mass calcd. for $C_{11}H_{21}O_2Br$: 264.0725; found: 264.0776.

Ethyl 2,5-dimethylheptanoates with various leaving groups at the 7 position

Ethyl 7-chloro-2,5-dimethylheptanoate

A mixture of the hydroxy ester **18** (200 mg, 1.0 mmol), triphenylphosphine (0.63 g, 2.4 mmol), and *N*-chlorosuccinimide (0.37 g, 2.7 mmol) in THF (3 mL) was stirred overnight at room temperature. The usual work-up and chromatographic purification (silica gel) afforded the title chloride (0.17 g, 77%) as an oil; IR (neat) 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.90 (3H, d, J = 6.7 Hz, *Me*CH), 1.15 (3H, d, J = 7.3 Hz, *Me*CH), 1.18 (1H, m), 1.26 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.30 (1H, m), 1.59 (1H, m), 1.64 (2H, m), 1.78 (1H, m), 2.39 (1H, sextet, J = 6.7 Hz, CH_2CHMeCO$_2$), 3.55 (2H, m, CH_2CH_2Cl), 4.13 (2H, q, J = 7.3 Hz); ^{13}C NMR (100 MHz) δ: 176.7, 60.2, 43.1, 39.7,* 39.6, 33.99, 33.96,* 31.01, 30.98,* 30.4, 19.0, 17.3, 17.0, 14.3. Exact Mass calcd. for $C_{11}H_{21}O_2Cl$: 220.1230; found: 220.1292.

Ethyl 7-iodo-2,5-dimethylheptanoate

The mesylate derived from the hydroxy ester **18** (198 mg, 0.97 mmol) was treated with NaI (0.2 g) in acetone (10 mL) under reflux for 1 h and overnight at room temperature. The usual work-up and subsequent chromatographic purification (silica gel) yielded the title iodide (245 mg, 81%) as an oil, IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.88 (3H, d, J = 6.7 Hz, *Me*CH), 1.15 (3H, d, J = 6.7 Hz, *Me*CH), 1.26 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.10–1.74 (7H, m), 1.86 (1H, m), 2.39 (1H, sextet, J = 6.7 Hz, CH_2CHMeCO$_2$), 3.15 (1H, dt, J = 8.1, 7.3 Hz, CH_2CH_2I), 3.23 (1H, dt, J = 8.1, 7.3 Hz, CH_2CH_2I), 4.13 (2H, q, J = 7.3 Hz, 2H, Me*CH*$_2$O); ^{13}C NMR (100 MHz) δ: 176.7, 60.2, 40.7, 39.8,* 39.7, 33.6, 31.0, 30.9,* 18.6, 17.3, 17.0, 14.3. Exact Mass calcd. for $C_{11}H_{21}O_2I$: 312.0586: found: 312.0572.

Ethyl 7-tosyloxy-2,5-dimethylheptanoate

To a mixture of the hydroxy ester **18** (300 mg, 1.5 mmol), pyridine (0.12 mL, 1.59 mmol), and Et_3N (0.21 mL, 1.59 mmol) in CH_2Cl_2 (3 mL) cooled at 0°C was added tosyl chloride (0.42 g, 2.2 mmol) and the mixture was stirred overnight at room temperature. The crude product obtained by the usual work-up was purified by chromatography on a silica gel column, giving the title tosylate (0.42 g, 83%) as an oil; IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.81 (3H, d, J = 6.1 Hz, *Me*CH), 1.11, 1.12* (3H, d, J = 6.7 Hz, *Me*CH), 1.25 (3H, t, J = 7.3 Hz, MeCH_2O), 1.00–1.74 (4H, m), 2.32 (1H, m, CH_2CHMeCO$_2$), 2.45 (3H, s, *Me*Ar), 4.06 (2H, m, CH_2CH_2OTs), 4.12 (2H, q, J = 7.3 Hz, Me*CH*$_2$O), 7.35 (3H, d, J = 8.5 Hz, Ar*H*), 7.79 (2H, d, J = 8.5 Hz, Ar*H*); ^{13}C NMR (100 MHz) δ: 176.6, 144.7, 133.4, 129.8, 127.9, 68.9, 60.2, 39.73, 39.65,* 35.6, 34.1, 31.0, 30.9,* 29.3, 21.6, 19.0, 17.2,* 17.0, 14.3.

Ethyl 7-trifluoromethanesulfonyloxy-2,5-dimethylheptanoate

A stirred solution of Na_2CO_3 (0.11 g, 1.0 mmol) and trifluoromethanesulfonic anhydride (0.26 mL, 1.56 mmol) in CH_2Cl_2 (3 mL) was cooled to 0°C and the hydroxy ester **18** (264 mg, 1.3 mmol) in CH_2Cl_2 (2 mL) was added. After the mixture had been stirred overnight at room temperature, it was quenched by addition of aqueous $NaHCO_3$ and worked up as usual. Chromatographic purification of the product on a silica gel column furnished the title triflate (274 mg, 78%) as an oil; IR (neat): 1730 cm^{-1}; ^{1}H NMR (90 MHz) δ: 0.95 (3H, d, J = 5.9 Hz, *Me*CH), 1.15 (3H, d, J = 6.8 Hz, *Me*CH), 1.25 (3H, t, J = 7.3 Hz, *Me*CH_2O), 0.8–2.0 (7H, m), 2.18 (1H, m, CH_2CHMeCO$_2$), 4.13 (2H, q, J = 7.3 Hz, Me*CH*$_2$O), 4.58 (2H, t, J = 6.8 Hz, CH_2CH_2OTf).

*Ethyl 7-bromo-5-ethyl-2-methylheptanoate (**25**)*

Vinylmagnesium bromide solution prepared from Mg (0.67 g, 27.5 mmol), vinyl bromide (2.14 mL, 30.3 mmol), and THF (40 mL) was added to a stirred suspension of CuI (0.18 g, 0.92 mmol) in THF (20 mL) at −78°C. After stirring at this temperature for 20 min a solution of 5-pent-2-enolide (**20**) (35) (1.8 g, 18.3 mmol) in THF (10 mL) was introduced and the mixture was stirred for 1 h further, then quenched by the addition of aqueous NH_4Cl. The extraction of the product with ether gave *3-vinyl-5-pentanolide* (1.24 g, 54%) as an oil; ^{1}H NMR (100 MHz) δ: 1.50–2.90 (5H, m), 4.20–4.60 (2H, m, 5-$H_{ax}H_{eq}$), 5.09 (1H, dd, J = 12, 1 Hz, CH=CH_2), 5.14 (1H, dd, J = 9, 1 Hz, CH=CH_2), 5.78 (1H, ddd, J = 12,9,1 Hz, $CHCH$=CH_2). This product was hydrogenated in the presence of palladium on charcoal to give *3-ethyl-5-pentanolide* (**21**) (36) as an oil; ^{1}H NMR (400 MHz) δ: 0.87 (3H, t, J = 7.0

Hz, *Me*CH_2CH), 1.33 (2H, quintet, J = 7.0 Hz, MeC*H*$_2$CH), 1.46 (1H, ddt, J = 9.5, 7.4, 5.1 Hz, 3-H), 1.74–1.96 (2H, m, 4-$H_{ax}H_{eq}$), 2.07 (1H, dd, J = 17.2, 10.0 Hz, 2-H_{ax}), 2.62 (1H, ddd, J = 17.4, 6.0, 1.5 Hz, 2-H_{eq}), 4.19 (1H, ddd, J = 11.3, 10.3, 3.5 Hz, 4-H_{ax}), 4.34 (1H, ddd, J = 10.8, 4.8, 4.0, 4-H_{eq}). The lactone **21** (0.69 g, 5.4 mmol) was converted as before by the Takacs procedure (11) to *ethyl 5-ethyl-7-hydroxy-2-methyl-2-heptenoate*, 0.43 g (40%), which on catalytic hydrogenation (10% palladium on charcoal) gave quantitatively *ethyl 5-ethyl-7-hydroxy-2-methylheptanoate* (**23**) as an oil; IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.86 (3H, t, J = 7.3 Hz, *Me*CH_2), 1.15 (3H, d, J = 7.3 Hz, *Me*CH), 1.26 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.20–1.70 (10H, m), 2.39 (1H, sextet, J = 7.3 Hz, CH_2CHMeCO_2), 3.66 (2H, t, J = 6.7 Hz, CH_2CH_2OH), 4.13 (2H, q, J = 7.3 Hz, MeC*H*$_2$O); ^{13}C NMR (100 MHz) δ: 176.9, 61.1, 60.1, 39.9, 36.4, 35.7, 30.7, 30.6, 25.9, 17.1, 14.3, 10.7. Exact Mass calcd. for $C_{12}H_{24}O_3$: 216.1725; found: 216.1810. The hydroxy ester **23** (0.27 g, 1.23 mmol) was transformed as before via a mesylate to the title bromide **25** (0.23 g, 68%). IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.86 (3H, t, J = 7.3 Hz, MeC*H*$_2$), 1.15 (3H, d, J = 6.7 Hz, *Me*CH), 1.26 (3H, t, J = 6.7 Hz, MeC*H*$_2$O), 1.32 (2H, quintet, MeC*H*$_2$CH), 1.20–1.50 (4H, m), 1.63 (1H, m), 1.82 (2H, q, J = 7.3 Hz, CH_2CH_2CH), 2.39 (1H, sextet, J = 6.7 Hz, CH_2CHMeCO_2), 3.41 (2H, t, J = 7.3 Hz, CH_2CH_2Br), 4.13 (2H, q, J = 6.7 Hz, MeC*H*$_2$O); ^{13}C NMR (100 MHz) δ: 176.6, 60.2, 39.8, 37.8, 36.6, 31.9, 30.6, 29.95, 25.3, 17.25, 14.3, 10.5. Exact Mass calcd. for $C_{12}H_{23}O_2$Br: 278.0881; found: 278.0967.

*Ethyl 7-bromo-5-isopropyl-2-methylheptanoate (**26**)*

A solution of isopropylmagnesium bromide prepared from isopropyl bromide (1.6 mL, 17 mmol) and Mg (0.38 g, 15.45 mmol) in THF (20 mL) was added to a stirred suspension of CuI (0.1 g, 0.5 mmol) in THF (10 mL) at −78°C. After stirring for 20 min, a solution of 5-pent-2-enolide (**20**) (1.01 g, 10.3 mmol) in THF (5 mL) was introduced and stirring was continued at −78°C for 1 h. Aqueous NH_4Cl was added, and the product was isolated by extraction with Et_2O and was purified by distillation to give *3-isopropyl-5-pentanolide* (**22**) (315 mg, 22%) as an oil; IR (neat): 1720 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.92 (3H, d, J = 6.7 Hz, *Me*CH), 0.93 (3H, d, J = 6.7 Hz, *Me*CH), 1.55 (2H, m, 3-H), 1.75 (1H, m, dq, J = 10.7, 6.1, CHC*H*Me$_2$), 1.92 (1H, dqd, J = 10.4, 4.3, 1.2 Hz, 4-H_{eq}), 2.22 (1H, dd, J = 17.1, 11.0, 2-H_{ax}), 2.66 (1H, ddd, J = 17.1, 4.3, 1.2 Hz, 2-H_{eq}), 4.23 (1H, td, J = 11.0, 3.7 Hz, 5-H_{ax}), 4.41 (1H, dt, J = 11.0, 4.9 Hz, 5-H_{eq}); ^{13}C NMR (100 Hz) δ: 171.9, 68.6, 37.9, 34.1, 32.3, 26.4, 19.3, 19.2. Application of the Takacs procedure (11) on the lactone **22** (314 mg) afforded *ethyl 7-hydroxy-5-isopropyl-2-heptenoate* as an oil, 368 mg (73%). This material was catalytically hydrogenated to give *ethyl 7-hydroxy-5-isopropylheptanoate* as an oil; ^{1}H NMR (400 MHz) δ: 0.84 (3H, d, J = 6.8 Hz, *Me*CH), 0.85 (3H, d, J = 6.8 Hz, *Me*CH), 1.15 (3H, d, J = 7.3 Hz, CH*Me*CO_2), 1.25 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.10–1.80 (8H, m), 2.39 (1H, sextet, J = 6.8 Hz, CH_2CHMeCO2), 3.65 (2H, m, CH_2CH_2OH), 4.13 (3H, q, J = 7.3 Hz, MeC*H*$_2$O); ^{13}C NMR (100 MHz) δ: 176.9, 61.7, 60.2, 40.3, 40.1,* 39.9, 33.7, 33.6,* 31.8, 31.7,* 29.5, 29.4,* 28.3, 19.3, 19.2,* 18.8, 18.7,* 17.2, 14.3. Exact Mass calcd. for $C_{13}H_{26}O_3$: 230.1882; found: 230.1966. The saturated ester (185 mg) was transformed to the bromide as before via a mesylate (163 mg, 71%) giving **26** as an oil; IR (neat) δ: 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.86, 1.16* (3H in total, d, J = 6.7 Hz, *Me*CH), 1.26 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.20–1.40 (4H, m), 1.60–1.80 (3H, m), 1.85 (1H, m), 2.40 (1H, sextet, J = 7.3 Hz, CH_2CHMeCO_2), 3.42 (2H, m, CH_2CH_2Br), 4.13 (1H, q, J = 7.3 Hz, MeC*H*$_2$O); ^{13}C NMR (100 MHz) δ: 176.6, 60.2, 42.6, 39.91, 39.87,* 34.2, 34.1,* 32.7, 31.63, 31.60,* 29.1, 29.0,* 27.7, 27.6,* 19.2, 19.1,* 18.9, 17.2, 14.3. Exact Mass calcd. for $C_{13}H_{25}O_2$Br: 292.1083; found: 292.0879.

*Ethyl 7-bromo-2-methyl-5-phenylheptanoate (**30**)*

To a mixture of NaOEt solution, prepared from Na (1.38 g, 60 mmol) and EtOH (20 mL), and Et_2O (100 mL) was added diethyl malonate (9.1 mL, 60 mmol) and the mixture was stirred for 30 min. Ethyl cinnamate (10.1 mL, 60 mmol) was added and the reaction mixture was refluxed for 5 h. The cooled mixture was acidified with aqueous acetic acid and the product was extracted with Et_2O. Organic layers were washed with aqueous $NaHCO_3$ and brine, and the solvent was removed by evaporation. Distillation of the residue afforded *diethyl 2-ethoxycarbonyl-3-phenylglutarate* (37) (16.14 g, 73%) as an oil; ^{1}H NMR (90 mHz) δ: 0.99 (3H, t, J = 7.0 Hz, *Me*CH_2), 1.07 (3H, t, J = 7.0 Hz, *Me*CH_2), 1.18 (3H, t, J = 7.0 Hz, *Me*CH_2), 2.77 (4H, m), 3.93 (2H, q, J = 2.0 Hz, MeC*H*$_2$O), 3.97 (2H, q, J = 7.0 Hz, MeC*H*$_2$O), 4.21 (2H, q, J = 7.0 Hz, MeC*H*$_2$O), 7.24 (5H, s, Ph). The triester was treated with aqueous KOH (14.7 g, 262 mmol, dissolved in 100 mL of H_2O) under refluxing for 1 day. The hydrolysate solution was evaporated in vacuo to dryness and the residue was mixed with diluted H_2SO_4 (26 g with 100 mL of H_2O), and the mixture was refluxed overnight. After concentration in vacuo, the product was extracted with Et_2O to give crude 3-phenylglutaric acid (9.13 g, 100%); ^{1}H NMR (90 MHz) δ: 2.72 (4H, d, J = 6.7 Hz, 2 × CH_2CH_2CO2), 3.66 (1H, quintet, J = 6.7 Hz, CH_2CHPhCH_2), 7.25 (5H, s), 10.88 (2H, br s, CO2H). This material was heated with Ac_2O under refluxing for 2 h. The reaction mixture was evaporated to dryness in vacuo and the residue was recrystallized from hexane to yield *3-phenylglutaric anhydride* as crystals, 7.73 g (98%). This anhydride (7.73 g, 43.9 mmol) dissolved in THF (50 mL) was added to a solution of $NaBH_4$ (1.7 g, 43.9 mmol) in THF (10 mL) cooled to 0°C. The ice bath was removed and the mixture was allowed to react for 1 h. The reaction mixture was acidified with 3 M HCl, extracted with Et_2O, and the organic layers were washed with aqueous $NaHCO_3$ and brine. Chromatographic purification (silica gel) of the residue left after evaporation of the solvent furnished *3-phenyl-5-pentanolide* (**28**) (38) (1.45 g, 19%) as an oil; IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 2.03 (1H, dtd, J = 14.0, 10.4, 4.9, 4-H_{ax}), 2.18 (1H, dqd, J = 14.0, 3.7, 1.2, 4-H_{eq}), 2.63 (1H, dd, J = 17.7, 10.4, 2-H_{ax}), 2.90 (1H, ddd, J = 17.7, 5.2, 1.2, 2-H_{eq}), 3.24 (1H, tt, J = 10.4 Hz, 3-H), 4.29 (1H, td, J = 11.6, 3.7 Hz, 5-H_{ax}), 4.50 (1H, dt, J = 11.6, 4.9 Hz, 5-H_{eq}), 7.27 (5H, m, Ph); ^{13}C NMR (100 MHz) δ: 170.6, 142.8, 129.0, 127.2, 126.4, 68.6, 37.5, 37.4, 30.3. The lactone **28** was converted as before to *ethyl 7-hydroxy-2-methyl-5-phenyl-2-heptenoate* in 69% yield, this was hydrogenated, giving *ethyl 7-hydroxy-2-methyl-5-phenylheptanoate* (**29**); IR (neat): 3420, 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 1.07, 1.08* (3H, d, J = 7.3 Hz, *Me*CH), 1.22 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.35 (2H, m), 1.48 (1H, m), 1.60 (2H, m), 1.81 (1H, m), 1.92 (1H, m), 2.36 (1H, m), 2.69 (1H, m), 3.45 (1H, m, CH_2CH_2OH), 3.52 (1H, m,

CH_2CH_2OH), 4.09 (2H, q, J = 7.3 Hz, $MeCH_2O$), 7.29 (5H, m, Ph); ^{13}C NMR (100 MHz) δ: 176.7, 144.7, 128.5, 127.6, 126.3, 61.1, 60.1, 42.6, 42.3,* 39.6, 39.5,* 34.4, 34.1,* 31.8, 31.6,* 17.2, 17.0, 14.3. The hydroxy ester **29** (0.34 g) was then transformed via a mesylate to the title bromide **30** in 71% yield. IR (neat): 1730 cm^{-1}; ^1H NMR (400 MHz) δ: 0.88, 1.08* (3H in total, d, J = 7.0 and 6.7 Hz respectively, *Me*CH), 1.23 (3H, t, J = 6.7 Hz, $MeCH_2O$), 1.60 (2H, m), 2.10 (1H, m), 2.35 (1H, m), 2.75 (1H, m), 3.08 (1H, td, J = 6.7, 1.2 Hz, CH_2CH_2Br), 3.26 (1H, td, J = 6.7, 2.4 Hz, CH_2CH_2Br), 4.10 (2H, q, J = 7.3 Hz, $MeCH_2O$), 7.20 (5H, m, Ph); ^{13}C NMR (100 MHz) δ: 176.5, 176.4,* 143.4, 143.3,* 128.6, 127.7, 126.6, 60.1,44.3, 44.1,* 39.7, 39.5,* 34.0, 33.7,* 31.9, 31.7,* 31.6, 31.5,* 22.7, 17.2, 17.1.* Exact Mass calcd. for $C_{16}H_{23}O_2Br$: 326.0881; found: 326.0891.

Ethyl 7-bromo-2-methyl-5-tert-butylheptanoate (35)

A solution of 4-*tert*-butylcyclohexanone (**31**) (15.43 g, 100 mmol), *m*-chloroperbenzoic acid (21.6 g, 125 mmol), and $TsOH{\cdot}H_2O$ (3.5 g) in CH_2Cl_2 (300 mL) was stirred at ambient temperature for 5 h. The precipitate was filtered off and the filtrate was washed successively with aqueous Na_2SO_3, aqueous K_2CO_3, and brine. The residue left after evaporation of the solvent was purified by silica gel chromatography, affording crude *4-tert-butyl-6-hexanolide*, which was used for the next reaction. To the material dissolved in a mixture of THF (120 mL) and Et_2O (80 mL) was added a 1 M methyllithium solution in THF (120 mL, 120 mmol) at −90°C and the mixture was stirred at this temperature for 3 h. After quenching by the addition of aqueous NH_4Cl, the reaction mixture was extracted with Et_2O and the product was purified by chromatography on a silica gel column, giving *6-oxo-3*-tert-*butyl-1-heptanol* (13.82 g, 74% from **31**) as an oil; IR (neat): 3420, 1710 cm^{-1}; ^1H NMR (400 MHz) δ: 0.88 (9H, s, Me3C), 1.28 (2H, m), 1.78 (3H, m), 1.89 (1H, br s, OH), 2.15 (3H, s, MeCO), 2.50 (2H, m, CH_2CH_2CO), 3.65 (2H, t, J = 6.7 Hz, CH_2CH_2OH). A solution of the alcohol (13.8 g, 74.3 mmol), imidazole (12.6 g, 185 mmol), and *tert*-butyldimethylsilyl chloride (13.4 g, 90 mmol) in DMF (30 mL) was stirred at ambient temperature for 1 day, and then the reaction mixture was quenched by the addition of aqueous NH_4Cl. Purification of the product by silica gel chromatography afforded 5-tert-*butyl-7*-tert-*butyldimethylsilyloxy-2-heptanone* (**32**) (12.94 g, 58%) as an oil; IR (neat): 1720 cm^{-1}; ^1H NMR (400 MHz) δ: 0.05 (6H, s, SiMe2), 0.86 (9H, s, $SiBu^t$), 0.90 (9H, s, Me_3C), 1.26 (2H, m), 1.75 (2H, m), 2.12 (3H, s, MeCO), 2.38 (1H, ddd, J = 15.9, 10.3, 6.1 Hz, CH_2CH_2CO), 2.56 (1H, ddd, J = 15.9, 11.0, 5.5 Hz, CH_2CH_2CO), 3.57 (2H, t, J = 6.7 Hz, CH_2CH_2OSi); ^{13}C NMR (100 MHz) δ: 233.9, 63.4, 44.4, 43.7, 34.4, 33.9, 29.9, 27.6, 26.0, 25.4, 18.4. Exact Mass calcd. for $C_{17}H_{36}O_2Si$: 300.2485; found: 300.2556. A solution of the silyl ether **32** (1.4 g, 4.7 mmol) in anhydrous Et_2O was added at −25°C to a solution of methoxymethylenetriphenylphosphorane prepared from methoxymethyltriphenylphosphonium chloride (2.4 g, 7 mmol), 1.6 M *n*-butyllithium solution in hexane (4.4 mL, 7 mmol), and Et_2O (20 mL). The mixture was stirred at −20°C for 1 h and at room temperature for 3 h. After removal of the precipitate by filtration the filtrate was washed with cold water and brine. The crude enol ether obtained by evaporation of the solvent was added to a mixture of 70% aqueous perchloric acid and Et_2O (60 mL), and the mixture was allowed to react at room temperature for 2 h. The reaction mixture was washed successively with water, aqueous $NaHCO_3$, and brine. Evaporation of the solvent gave crude *ethyl 7-hydroxy-2-methyl-5-tert-butylheptanal* (**33**); ^1H NMR (400 MHz) δ: 0.86 (9H, s, Me_3C), 1.10 (3H, d, J = 7.0 Hz, *Me*CH), 0.80–2.00 (9H, m), 3.63 (3H, t, J = 7.3 Hz, CH_2CH_2OH), 9.61 (1H, d, J = 1.2 Hz, CH_2CHO). To a stirred solution of the aldehyde **33** (4.2 g, 21 mmol) in a mixture of *tert*-BuOH (60 mL) and 5% aqueous NaH_2PO_4 was added dropwise 1 M aqueous $KMnO_4$ solution (50 mL, 50 mmol) (39) and stirring was continued at room temperature for 5 h. The reaction mixture was diluted with water and the product was isolated by extraction with Et_2O, giving the corresponding carboxylic acid, which was esterified by refluxing with 3 M HCl, EtOH (15 mL), and toluene (7 mL) for 5 h. Usual work-up afforded *ethyl 7-hydroxy-2-methyl-5*-tert-*butylheptanoate* (**34**). This hydroxy ester was converted via a mesylate to the title bromide **35**; IR (neat): 1730 cm^{-1}; ^1H NMR (400 MHz) δ: 0.87 (9H, s, Me_3C), 1.02 (2H, m), 1.16 (3H, d, J = 6.7 Hz, *Me*CH), 1.26 (3H, t, J = 6.7 Hz, $MeCH_2O$), 1.30–1.80 (4H, m), 2.04 (1H, m), 2.39 (1H, m, $CH_2CHMeCO_2$), 3.38 (1H, dt, J = 8.6, 7.3 Hz, $CH_2CH_aH_bBr$), 3.46 (2H, tdd, J = 9.5, 5.5, 2.4 Hz, $CH_2CH_aH_bBr$), 4.14 (2H, q, J = 6.7 Hz, $MeCH_2O$). Exact Mass calcd. for $C_{14}H_{27}O_2Br$: 306.1194; found: 306.1296.

4-Methyl-5-pentanolide (37)

A mixture of methacrolein (14.8 mL, 143 mmol), dimethyl malonate (14.1 mL, 120 mmol), and Et_3N (16.7 mL, 120 mmol) in MeOH (150 mL) was stirred at 0°C for 17 h (40). The product obtained by Et_2O extraction was distilled, giving *dimethyl 3-formyl-1,1-butanedicarboxylate* (10.1 g, 41%); ^1H NMR (90 MHz) δ: 1.15 (3H, d, J = 7 Hz, $MeCH_2O$), 1.66–2.57 (3H, m), 3.47 (1H, m, $CH_2CH(CO_2Me)_2$), 3.71 (6H, s, 2 × CO_2Me), 9.57 (1H, br s, CH_2CHO). The aldehyde (4.2 g, 20.8 mmol) dissolved in MeOH (10 mL) was treated with a solution of $NaBH_4$ (0.79 g, 20.8 mmol) in MeOH (10 mL) at room temperature for 1.5 h. After addition of 3 M HCl, the mixture was concentrated and then extracted with Et_2O. Evaporation of the solvent afforded crude *dimethyl 4-hydroxy-3-methyl-1,1-butanedicarboxylate* (**36**) (4.0 g, 94%); ^1H NMR (90 MHz) δ: 0.93 (3H, d, J = 7 Hz, *Me*CH), 1.30–2.25 (4H, m), 3.43 (2H, d, J = 6 Hz, $CHCH_2OH$), 3.69 (6H, s, 2 × CO_2Me). The alcohol **36** (3.82 g, 18.7 mmol) was heated under refluxing with NaOH (4.73 g, 84.3 mmol) and water (6 mL) for 3 h. The mixture was diluted with water (6 mL) and concentrated. It was mixed with concentrated H_2SO_4 (5.8 g), diluted with water (7 mL), and the mixture was refluxed for 3 h. Extraction with Et_2O gave the crude title compound **37** (2.03 g, 95%); ^1H NMR (90 MHz) δ: 0.98 (3H, d, J = 6 Hz, *Me*CH), 1.13–2.83 (5H, m), 2.43 (1H, m, 2-H_{eq}), 3.84 (1H, dd, J = 12, 10 Hz, 5-H_{ax}), 4.27 (1H, ddd, J = 12, 5, 2 Hz, 5-H_{eq}).

Ethyl 7-bromo-2,6-dimethylheptanoate (39)

The lactone **37** (1.38 g, 12 mmol) was converted by Takacs' procedure (11) as before to furnish *ethyl 7-hydroxy-2,6-dimethyl-2-heptenoate* (1.62 g, 70%); ^1H NMR (90 MHz) δ: 0.93 (3H, d, J = 6 Hz, *Me*CH), 1.07–1.70 (9H, m), 1.81 (3H, br s, *Me*C=), 3.43 (2H, d, J = 6 Hz, $CHMeCH_2OH$), 4.15 (2H, q, J = 6 Hz, $MeCH_2O$), 6.70 (1H, br t, J = 7 Hz, CH_2CH=). The unsaturated alcohol was catalytically hydrogenated (Pd–C) to

give *7-hydroxy-2,6-dimethylheptanoate* (**38**); ^{1}H NMR (90 MHz) δ: 0.90 (3H, d, J = 6 Hz, *Me*CH), 1.03–2.40 (15H, m), 3.42 (2H, m), 4.17 (2H, q, J = 6 Hz, MeCH_2O). The saturated hydroxy ester **38** was mesylated as before to yield *ethyl 7-mesyloxy-2,6-dimethylheptanoate*; ^{1}H NMR (90 MHz) δ: 0.97 (3H, d, J = 7 Hz, *Me*CH), 1.15–2.60 (14H, m), 2.95 (3H, s, MsO), 4.00 (2H, d, J = 6 Hz, CH_2CH_2OMs), 4.08 (2H, q, J = 7 Hz, MeCH_2O). Treatment of this mesylate with LiBr in acetone afforded the title bromide **39** (51% from mesylate); ^{1}H NMR (90 MHz) δ: 0.97 (3H, d, J = 6 Hz, *Me*CH), 1.23 (3H, t, J = 7 Hz, *Me*CH_2O), 0.78–2.10 (7H, m), 2.40 (1H, sextet, J = 6.0 Hz, CH_2CHMeCO$_2$), 3.30 (2H, d, J = 6 Hz, CHMeCH_2Br), 4.07 (2H, q, J = 7 Hz, MeCH_2O); ^{13}C NMR (25 MHz) δ: 176.5, 60.1, 41.3, 39.4, 35.0, 34.6, 33.8,* 24.4, 18.7, 17.1, 14.3.

*Cyclization of ethyl 7-bromo-2,3-dimethylheptanoate (**11**).*

Typical procedure for cyclization experiments

A mixture of diisopropylamine (0.51 mL, 1.0 mmol) in THF (5 mL) and *n*-butyllithium solution (1.6 M in hexane, 2.0 mL, 3.2 mmol) was stirred at 0°C for 10 min and then the stirring was continued at −78°C for 20 min. To this solution was added a solution of the ester **11** (265 mg, 1.00 mmol) and the mixture was allowed to react at −78°C for 1 h. After quenching by the addition of aqueous NH_4Cl, the reaction mixture was extracted with Et_2O and the combined organic layers were washed with brine. The residue left after evaporation of the solvent was purified by chromatography on a silica gel column, giving the cyclized product (193 mg, 78%), which was a 96:4 mixture of diastereomers (capillary GC). From the reason discussed in the text, the major isomer was identified as *ethyl 1,*t*-2-dimethyl*-r-*1-cyclohexanecarboxylate* (**40**); IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.77 (3H, d, J = 6.7 Hz, *Me*CH), 1.07 (3H, s, *Me*C), 1.25 (3H, t, J = 6.7 Hz, *Me*CH_2O), 1.00–1.60 (6H, m), 2.01 (1H, dqd, J = 10.5, 6.7, 3.1 Hz, 2-H), 4.13 (2H, q, J = 6.7 Hz, *Me*CH_2O); ^{13}C NMR (100 MHz) δ: 178.5(s), 60.1(t), 46.5(d), 36.1(s,t), 29.9(t), 25.4(t), 21.3(t), 17.3(q), 14.3(q), 14.1(q). Exact Mass calcd. for $C_{11}H_{20}O_2$: 184.1463; found: 184.1455.

*Cyclization of ethyl 7-bromo-2,4-dimethylheptanoate (**15**)*

The reaction afforded exclusively *ethyl 1,*c*-3-dimethyl*-r-*1-cyclohexanecarboxylate* (**42**); IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 0.75–0.85 (2H, m), 0.88 (3H, d, J = 6.7 Hz, *Me*CH), 1.00–1.06 (1H, m), 1.20 (3H, t, J = 6.8 Hz, *Me*CH_2O), 1.28–1.90 (6H, m), 4.11 (2H, q, J = 6.8 Hz, MeCH_2O); ^{13}C NMR (100 MHz) δ: 178.9(s), 60.2(t), 42.5(t), 42.4(s), 34.7(t), 33.4(t), 27.4(d), 22.8(q), 21.4(t), 20.5(q), 14.2(q). Exact Mass calcd. for $C_{11}H_{20}O_2$: 184.1463; found: 184.1468.

*Cyclization of ethyl 7-bromo-2,5-dimethylheptanoate (**19**)*

The diasteromeric ratio of the cyclized product was 79:21 and both diastereomers were separated by flash chromatography on a silica gel column for the purpose of the spectroscopic analysis. A *trans* and a *cis* structure was assigned for the major and the minor diastereomers, respectively. *Ethyl 1,*t*-4-dimethyl*-r-*1-cyclohexanecarboxylate* (**44**): ^{1}H NMR (400 MHz) δ: 0.91 (3H, d, J = 6.7 Hz, *Me*CH), 1.10 (2H, td, J = 13.4, 3.6 Hz, 2,6-H_{ax}), 1.18 (3H, s, MeC), 1.24 (3H, t, J = 6.7 Hz, *Me*CH_2O), 1.37 (1H, m, 4-H), 1.58 (4H, m, 2,6-H_{eq}, 3,5-H_{eq}), 1.69 (2H, qd, J = 13.4, 3.7 Hz, 3,5-H_{ax}), 4.11 (2H, q, J = 6.7 Hz, MeCH_2O); ^{13}C NMR (100 MHz) δ: 178.9(s), 60.1(t), 41.6(s), 33.4(t), 31.6(d), 30.0(t), 21.9(q), 20.8(q), 14.2(q). Exact Mass calcd for $C_{11}H_{20}O_2$: 184.1463; found: 184.1474. *Ethyl 1,*c*-4-dimethyl*-r-*1-cyclohexanecarboxylate* (**45**); ^{1}H NMR (400 MHz) δ: 0.85 (3H, d, J = 6.7 Hz, *Me*CH), 0.96 (2H, qd, J = 13.4, 2.5 Hz, 3,5-H_{ax}), 1.12 (2H, td, 2H, J = 13.4, 3.7 Hz, 2,6-H_{ax}), 1.13 (3H, s, MeC), 1.25 (3H, t, J = 6.7 Hz, MeCH_2O), 1.28 (1H, m, 4-H), 1.56 (2H, m, 3,5-H_{eq}), 2.17 (2H, br. d, J = 13.4 Hz, 2,6-H_{eq}), 4.14 (2H, q, J = 6.7 Hz, *Me*CH_2O); ^{13}C NMR (100 MHz) δ: 177.4, 60.0, 43.1, 36.0, 32.5, 32.1, 28.3, 22.4, 14.3. Exact Mass calcd. for $C_{11}H_{20}O_2$: 184.1463; found: 184.1454.

*Cyclization of ethyl 7-bromo-5-ethyl-2-methylheptanoate (**25**)*

The major and the minor products were separated by the flash chromatography and analyzed by spectroscopy to be *trans* and *cis* compounds, respectively. *Ethyl* t*-4-ethyl-1-methyl*-r-*1-cyclohexanecarboxylate* (**46**). ^{1}H NMR (400 MHz) δ: 0.88 (3H, t, J = 7.3 Hz, 4-*Me*CH_2), 1.17 (3H, s, MeC), 1.24 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.06–1.30 (5H, m, 2,6-H_{ax}, 4-H, 4-MeCH_2), 1.63 (6H, m, 2,6-H_{eq}, 3,5-$H_{ax}H_{eq}$), 4.11 (2H, q, J = 7.3 Hz, MeCH_2O); ^{13}C NMR (100 MHz) δ: 178.9(t), 60.1(t), 41.9(s), 38.4(d), 33.4(t), 29.1(t), 27.6(t), 20.7(q), 14.2(q), 11.5(q). Exact Mass calcd for $C_{12}H_{22}O_2$: 198.1620; found: 198.1643. *Ethyl* c*-4-ethyl-1-methyl*-r-*1-cyclohexanecarboxylate* (**47**): ^{1}H NMR (400 MHz) δ: 0.85 (3H, t, J = 7.3 Hz, 4-*Me*CH_2), 0.94 (2H, qd, J = 13.4, 2.5 Hz, 3,5-H_{ax}), 1.06 (1H, m, 4-H), 1.10 (2H, td, J = 12.8, 3.4 Hz, 2,6-H_{ax}), 1.13 (3H, s, MeC), 1.25 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.64 (2H, br d, J = 13.4 Hz, 3,5-H_{eq}), 2.19 (2H, br d, J = 13.4 Hz, 2,6-H_{eq}), 4.13 (2H, q, 2H, J = 7.3 Hz, MeCH_2O); ^{13}C NMR (100 MHz) δ: 177.4(s), 60.0(t), 43.5(s), 38.8(d), 35.9(t), 30.1(t), 29.7(t), 28.3(q), 14.3(q), 11.5(q). Exact Mass calcd. for $C_{12}H_{22}O_2$: 198.1620; found: 198.1646.

*Cyclization of ethyl 7-bromo-5-isopropyl-2-methylheptanoate (**26**)*

Major product: *ethyl* t*-4-isopropyl-1-methyl*-r-*1-cyclohexanecarboxylate* (**48**); ^{1}H NMR (400 MHz) δ: 0.87 (6H, d, J = 6.7 Hz, Me_2CH), 1.02 (1H, m, 4-H), 1.17 (3H, s, MeC), 1.20 (2H, m, 2,6-H_{ax}), 1.24 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.44 (1H, octet, J = 6.7 Hz, Me_2CHCH), 1.57 (2H, dq, J = 12.2, 4.3 Hz, 3,5-H_{eq}), 1.67 (4H, m, 2,6-H_{eq}, 3,5-H_{ax}), 4.11 (2H, q, J = 7.3 Hz, MeCH_2O); ^{13}C NMR (100 MHz) δ: 179.0(s), 60.1(t), 43.5(d), 36.2(t), 32.7(d), 28.4(q), 27.2(t), 24.7(t), 19.9(q), 14.3(q). Exact Mass calcd. for $C_{13}H_{24}O_2$: 212.1776; found: 212.1797. Minor product: *ethyl* c*-4-isopropyl-1-methyl*-r-*1-cyclohexanecarboxylate* (**49**); ^{1}H NMR (400 MHz) δ: 0.83 (6H, d, J = 6.7 Hz, Me_2CH), 0.98–1.12 (5H, m, 2,6-H_{ax}, 3,5-H_{ax}, 4-H), 1.12 (3H, s, MeC), 1.25 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.37 (1H, m, Me_2CH), 1.64 (2H, br, d, J = 6.7 Hz, 3,5-H_{eq}), 2.21 (2H, br d, J = 12.2 Hz, 2,6-H_{eq}), 4.14 (2H, q, J = 7.3 Hz, MeCH_2O); ^{13}C NMR (100 MHz) δ: 177.4(s), 60.0(t), 43.5(d,s), 36.2(t), 32.7(d), 28.4(q), 27.2(t), 24.7(t), 19.9(q), 14.3(q). Exact Mass calcd. for $C_{13}H_{24}O_2$: 212.1776: found 212.1791.

*Cyclization of ethyl 7-bromo-2-methyl-5-phenylheptanoate (**30**)*

Major product: *ethyl 1-methyl*-t*-4-phenyl*-r-*1-cyclohexanecarboxylate* (**50**); IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz)

δ: 1.27 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.29 (3H, s, MeC), 1.68 (2H, qd, J = 12.2, 3.1 Hz, 3,5-H_{ax}), 1.80 (4H, m, 2,6-H_{ax}, 3,5-H_{eq}), 1.84 (2H, td, J = 12.2, 3.7 Hz, 2,6-H_{eq}), 2.50 (1H, tt, J = 12.2, 3.7 Hz, 4-H), 4.15 (2H, q, J = 7.3 Hz, MeC*H*$_2$O), 7.26 (5H, m, Ph); ^{13}C NMR (100 MHz) δ: 178.8, 147.0, 128.4, 126.8, 126.1, 60.3, 43.7, 41.3, 34.1, 29.0, 20.1, 14.2. Exact Mass calcd. for $C_{16}H_{22}O_2$: 246.1620; found: 246.1616. Minor product: *ethyl 1-methyl*-c-*4-pheny*-r-*1-cyclohexanecarboxylate* (**51**); IR (neat): 1730 cm^{-1}; ^{1}H NMR (400 MHz) δ: 1.20 (3H, s, MeC), 1.28 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.30 (2H, m, 2,6-H_{ax}), 1.53 (2H, qd, J = 13.4, 3.1 Hz, 3,5-H_{ax}), 1.80 (2H, br d, J = 13.4 Hz, 3,5-H_{eq}), 2.33 (2H, br d, J = 12.2 Hz, 2,6-H_{eq}), 2.47 (1H, tt, J = 13.4, 3.7 Hz, 4-H), 4.19 (2H, q, J = 7.3 Hz, *Me*CH_2O), 7.26 (5H, m, Ph); ^{13}C NMR (100 MHz) δ: 177.2, 147.2, 128.3, 126.8, 126.0, 60.2, 43.8, 43.1, 36.3, 31.6, 28.4, 14.3. Exact Mass calcd. for $C_{16}H_{22}O_2$: 246.1620; found: 246.1615.

Cyclization of ethyl 7-bromo-2-methyl-5-tert-*butylheptanoate (35)*

Major product: *ethyl 1-methyl*-t-*4*-tert-*butyl*-r-*1-cyclohexanecarboxylate* (**52**); ^{1}H NMR (400 MHz) δ: 0.86 (s, 9H, Me_3C), 0.98 (1H, tt, J = 12.2, 3.1 Hz, 4-H), 1.17 (3H, s, MeC), 1.18 (2H, m, 2-H_{ax}), 1.24 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.59–1.75 (6H, m, 2,6-H_{eq}, 3,5-$H_{ax}H_{eq}$), 4.11 (2H, q, J = 7.3 Hz, MeC*H*$_2$O); ^{13}C NMR (100 MHz) δ: 179.1, 60.1, 47.8, 41.4, 34.4, 32.4, 27.5, 22.2, 19.7, 14.2. Exact Mass calcd. for $C_{14}H_{26}O_2$: 226.1933; found: 226.1905. Minor product: *ethyl 1-methyl*-c-*4*-tert-*butyl-1-cyclohexanecarboxylate* (**53**); ^{1}H NMR (400 MHz) δ: 0.81 (9H, s, Me_3C), 0.90–1.15 (5H, m, 2,6-H_{ax}, 3,5-H_{ax}, 4-H), 1.12 (3H, s, MeC), 1.25 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.64 (2H, m, 3,5-H_{eq}), 2.23 (2H, dt, J = 11.0, 3.2 Hz, 2,6-H_{eq}), 4.15 (2H, q, J = 7.3 Hz, MeC*H*$_2$O); ^{13}C NMR (100 MHz) δ: 177.4, 60.0, 47.6, 43.3, 36.6, 32.4, 28.4, 27.5, 24.8, 14.3. Exact Mass calcd. for $C_{14}H_{26}O_2$: 226.1933; found: 226.1915.

Cyclization of ethyl 7-bromo-2,6-dimethylheptanoate (39)

The reaction yielded the same diastereomeric 1,3-dimethylcyclohexane derivatives as in the case of the bromide **15** but with the reversed predominance — the dominant product was *ethyl 1,* t-*3-dimethyl*-r-*1-cyclohexanecarboxylate* (**43**); ^{1}H NMR (400 MHz) δ: 0.72 (1H, t, J = 12.5 Hz, 2-H_{ax}), 0.79 (1H, qd, J = 13.5, 3.7 Hz. 4-H_{ax}), 0.87 (3H, d, J = 6.7 Hz, *Me*CH), 0.98 (1H, td, J = 13.5, 4.0 Hz, 6-H_{ax}), 1.13 (3H, s, MeC), 1.24 (3H, t, J = 7.3 Hz, *Me*CH_2O), 1.32 (1H, qt, J = 13.5, 3.7 Hz, 5-H_{ax}), 1.41 (1H, m. 3-H), 1.58 (1H, m, 5-H_{eq}), 1.62 (2H, m, 4-H_{eq}), 2.13 (1H, dq, J = 12.5, 2.4 Hz, 2-H_{eq}), 2.16 (1H, br d, J = 13.5 Hz, 6-H_{eq}), 4.13 (2H, q, J = 7.3 Hz, MeC*H*$_2$O); ^{13}C NMR (100 MHz) δ: 177.5, 60.0, 44.8, 43.9, 35.7, 34.5, 29.9, 28.7, 23.8, 22.8, 14.3.

Reflectance infrared and UV–visible spectroelectrochemical studies on a series of $[Ni_3(\mu_3\text{-}L)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3][PF_6]$ (L = CO; CNR, R = alkyl, aryl; dppm = $Ph_2PCH_2PPh_2$) clusters

John Washington and Clifford P. Kubiak

Abstract: The trinuclear nickel clusters $[Ni_3(\mu_3\text{-}L)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3]^+$ (L = CO (**1**); CNR, R = CH_3 (**2**), i-C_3H_7 (**3**), C_6H_{11} (**4**), t-C_4H_9 (**5**), $CH_2C_6H_5$ (**6**), C_6H_5 (**7**), p-C_6H_4I (**8**), p-C_6H_4F (**9**), p-$C_6H_4CH_3$ (**10**), p-$C_6H_4CF_3$ (**11**), p-$C_6H_4OCH_3$ (**12**), p-C_6H_4CN (**13**), 2,6-$(CH_3)_2C_6H_3$ (**14**); dppm = $Ph_2PCH_2PPh_2$) all contain a triply bridging π-acceptor (carbonyl or isocyanide) ligand. Compounds **1–14** all undergo single electron reductions over a relatively narrow range of $E_{1/2}(+/0)$ (−1.08 V to −1.18 V vs. SCE in acetonitrile) and are known electrocatalysts for the reduction of carbon dioxide. Specular reflectance infrared spectroelectrochemical (SEC) measurements on **1–14** indicate that the capping isocyanide or carbonyl ligand remains triply bridging (μ_3,η^1) upon single electron reduction. The magnitude of the ν(C≡O) or ν(C≡N) absorption band shift upon reduction is related to both the electronic and steric properties of the capping π-acceptor ligand. Spectroelectrochemical studies with UV–visible detection revealed a hypsochromic shift upon reduction of the clusters. The SEC cell and spectrometer utilized are extremely versatile and allow for data from 600 to 22 000 cm^{-1} to be acquired without modifying the SEC cell and making only minor configuration changes to the spectrometer.

Key words: nickel, cluster, carbonyl, isocyanide, spectroelectrochemical.

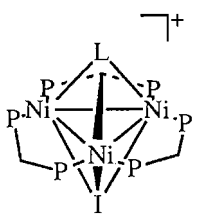
Résumé : Les agrégats trinucléaires du nickel, $[Ni_3(\mu_3\text{-}L)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3]^+$ (L = CO (**1**); CNR, R = CH_3 (**2**), i-C_3H_7 (**3**), C_6H_{11} (**4**), t-C_4H_9 (**5**), $CH_2C_6H_5$ (**6**), C_6H_5 (**7**), p-C_6H_4I (**8**), p-C_6H_4F (**9**), p-$C_6H_4CH_3$ (**10**), p-$C_6H_4CF_3$ (**11**), p-$C_6H_4OCH_3$ (**12**), p-C_6H_4CN (**13**), 2,6-$(CH_3)_2C_6H_3$ (**14**); dppm = $Ph_2PCH_2PPh_2$), comportent tous un coordinat accepteur d'électrons π (carbonyle ou isocyanure) pouvant former trois ponts. Les composés **1–14** subissent tous des réductions impliquant un électron sur une plage relativement restreinte de $E_{1/2}(+/0)$ (−1.08 V à −1.18 V vs. SCE, dans l'acétonitrile) et ils sont reconnus comme électrocatalyseurs pour la réduction du dioxyde de carbone. Des mesures spectroélectrochimiques (SEC) de réflectance infrarouge spéculaire réalisées sur les composés **1–14** indiquent que le coordinat isocyanure ou carbonyle formant le cap maintient le triple pontage (μ_3,η^1) lors de la réduction impliquant un électron. L'amplitude du déplacement de la bande d'absorption ν(C≡O) ou ν(C≡N) lors de la réduction est reliée aux propriétés tant électroniques que stériques du coordinat accepteur d'électrons π qui forme le cap. Des études spectroélectrochimiques avec détection UV–visible révèlent la présence d'un déplacement hypsochrome lors de la réduction des agrégats. La cellule SEC et le spectromètre utilisés sont extrêmement versatiles et permettent d'acquérir des données de 600 à 22 000 cm^{-1} sans modifier la cellule SEC et en ne faisant que des modifications mineures au spectromètre.

Mots clés : nickel, agrégat, carbonyle, isocyanure, spectroélectrochimique.

[Traduit par la rédaction]

Introduction

The synthesis and physical properties of a class of π-acceptor capped trinuclear nickel clusters $[Ni_3(\mu_3\text{-}L)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3]^+$ (L = CO (**1**); CNR, R = CH_3 (**2**), i-C_3H_7 (**3**), C_6H_{11} (**4**), t-C_4H_9 (**5**), $CH_2C_6H_5$ (**6**), C_6H_5 (**7**), p-C_6H_4I (**8**), p-C_6H_4F (**9**), p-$C_6H_4CH_3$ (**10**), p-$C_6H_4CF_3$ (**11**), p-$C_6H_4OCH_3$ (**12**), and p-C_6H_4CN (**13**), 2,6-$(CH_3)_2C_6H_3$ (**14**); dppm = $Ph_2PCH_2PPh_2$) has been recently reported (1–4). Clusters **1–14** all exhibit reversible single electron reductions $E_{1/2}(+/0)$ at ca. −1.1 V vs. SCE.



L = CO (**1**)
= CNR, R = alkyl (**2-6**)
= CNR, R = aryl (**7-14**)

Carbon dioxide reductions in nonaqueous solvents are generally hindered by poor selectivity and high cathodic potentials. However, due to the importance of CO_2 activation, a variety of transition metal catalysts able to effectively catalyze the reduction of CO_2 have been reported (5–18). The methyl isocyanide capped cluster (**2**) is a known electrocatalyst for the reduction and subsequent activation of carbon dioxide in acetonitrile (2). Importantly, **2** is able to reduce carbon dioxide at potentials ca. 1 V anodic of the uncatalyzed reduction potential (2, 19). The cathodic peak in the cyclic voltammogram of **2** in the presence of CO_2 shows significant current enhancement while the return anodic peak has negligible intensity. Clearly, the reduced form of **2** is responsible for the electrocatalytic reduction of carbon dioxide. Additionally, variation of the capping π-acceptor ligand (CO or CNR) in **1–14** gives rise to different activities with respect to the electrocatalytic reduction of CO_2 (4).

Infrared spectroelectrochemistry studies have been carried out on a number of organometallic systems and allow for the in situ monitoring of sensitive electrogenerated species (20–25). The vibrational spectra so obtained allow for structural and electronic changes to be directly monitored. Clusters **1–14** are capped by carbonyl or isocyanide ligands, both of which contain strong IR chromophores (ν(C≡O) or ν(C≡N) bands) and are well suited to study using an infrared spectroelectrochemical (SEC) cell. Spectroelectrochemical studies were carried out on **1–14** to determine the structure of the reduced species involved in the reduction of carbon dioxide. Herein we report the results of these SEC studies carried out on **1–14**. Additionally, the instrumentation utilized can be modified to allow for reflectance UV–visible spectroelectrochemistry; the results of this investigation will also be discussed.

Experimental

Syntheses were performed under an N_2 atmosphere using an inert atmosphere dry-box or Schlenk techniques. The compounds **1–14** were prepared as previously reported (1). Solvents were reagent or HPLC grade and were dried over the appropriate drying agents.

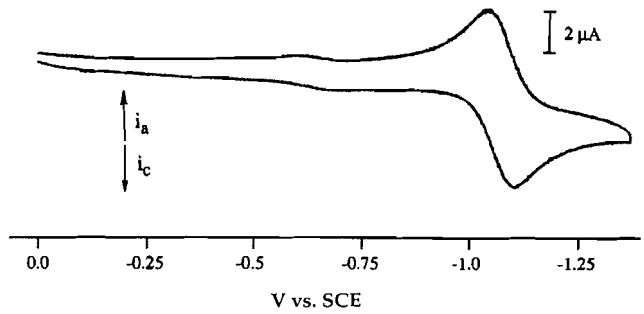
Electrochemistry

Cyclic voltammetry experiments were conducted in CH_3CN with TBAP (tetrabutylammonium hexafluorophosphate) as the supporting electrolyte. A glassy carbon working electrode, a Pt wire counter electrode, and a ferrocene/ferrocinium reference electrode were utilized. The acetonitrile was distilled under nitrogen from CaH_2 just prior to use. The TBAP used in these experiments was purchased from Aldrich, recrystallized from ethanol, dried under vacuum at 120°C for at least 24 h, and stored under nitrogen.

Infrared and UV–visible spectroelectrochemistry

The design of the spectroelectrochemical (SEC) cell used for the nickel trimer studies has been reported previously by our laboratory (25). Infrared spectral changes accompanying thin-layer bulk electrolyses were measured using a flow-through spectroelectrochemical cell. All spectroelectrochemical experiments were carried out in 0.1 M TBAP solutions of freshly distilled THF. All solutions were prepared under an atmosphere of nitrogen and degassed completely before injection into the spectroelectrochemical cell. Blank THF solutions of 0.1 M TBAP were used for the FT-IR and UV–visible solvent subtractions. A PAR model 175 universal programmer with a PAR model 176 current follower were used to effect and monitor thin-layer bulk electrolyses. The IR spectra were acquired using a Mattson Research Series FTIR with an external sampling port and a MCT (mercury–cadmium–telluride) detector. The UV–visible spectra were acquired using a Mattson Research Series FTIR modified with a quartz beamsplitter and a silicon diode detector. No modifications are required to the SEC cell to allow for operation in both the IR and UV–visible ranges as long as a CaF_2 window is utilized.

Fig. 1. Cyclic voltammogram (100 mV/s) of 2 mM solution of $[Ni_3(\mu_3\text{-}CO)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3][PF_6]$ (**1**) in 0.1 M TBAP/CH_3CN.



Results and discussion

Infrared SEC studies on $[Ni_3(\mu_3\text{-}CO)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3]^+$ (1)

As reported previously, the single electron reduction potentials (ca. −1.1 V vs. SCE) for clusters **1–14** (Table 1) are insensitive to the nature of the capping π-acceptor ligand (1). This was attributed to calculations that showed minimal contribution to the LUMO from the capping carbonyl or isocyanide ligand (1, 26). In fact, the LUMO is almost entirely metal based. The cyclic voltammogram of **1** (Fig. 1) shows a reversible one-electron reduction and is representative of the carbonyl and isocyanide clusters **1–14**. The rather large cathodic potentials required for single electron reduction of this class of nickel clusters are consistent with the transformation from a stable 48-electron cluster to a 49-electron radical.

The IR spectra recorded during the bulk reduction of $[Ni_3(\mu_3\text{-}CO)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3]^+$ (**1**) in the SEC cell are shown in Fig. 2. The IR spectrum of **1** in THF solution shows a single ν(C≡O) absorption band at 1730 cm^{-1}, a frequency consistent with a μ_3,η^1 carbonyl ligand (1, 27). The triply bridging carbonyl has also been confirmed using X-ray crystallography (1). Upon reduction, a decrease in the ν(C≡O) band at 1730 cm^{-1} is observed along with a concomitant increase in intensity of a ν(C≡O) band at 1661 cm^{-1}. The reversible nature of the bulk reduction occurring in the SEC cell is evident, as simply reversing the applied potential quantitatively regenerates **1**. The SEC data obtained for **1**· is consonant with the capping carbonyl remaining in its triply bridging form upon reduction of the nickel cluster (eq. [1]). The minimal structural rearrangement upon single electron reduction is also in accord with the highly reversible electrochemistry observed for **1** and the symmetric septet ESR spectrum of **1**·, arising from ^{31}P

Table 1. Electrochemical and infrared spectroelectrochemical data for $[Ni_3(\mu_3\text{-}L)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3][PF_6]$ clusters.

hyperfine coupling to six equivalent dppm phosphorus atoms (1).

[1] 
1 **1·**

The assignment of the band at 1661 cm^{-1} was confirmed using the ^{13}CO labeled cluster (**1***). Specifically, the ν($^{13}C{\equiv}O$) band for **1*** at 1691 cm^{-1} showed the expected shift to 1622 cm^{-1} upon reduction of the nickel cluster. The ν(C≡O) bands for the isolated and reduced forms of **1** and **1*** are listed in Table 1.

Infrared SEC studies on $[Ni_3(\mu_3\text{-}CNR)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3]^+$ (2–14)

A distinguishing feature of the IR spectra for many of the isocyanide capped clusters **2–14** is the appearance of *two* ν(C≡N) absorption bands, both in the solid state and in solution. Isotope labeling experiments confirmed that the appearance of two ν(C≡N) bands was a result of a Fermi resonance between the ν(C≡N) fundamental and the first overtone of the ν(N–C(alkyl)) fundamental (1). A detailed explanation of this phenomenon is available but for the purposes of this study it is important only to realize that the two ν(C≡N) band pattern is an unusual, but characteristic, feature of this class of isocyanide capped trinuclear nickel clusters (1).

The IR spectroelectrochemistry of a 19.0 mM THF solution of **2** was examined under an atmosphere of nitrogen. High concentrations of the alkyl isocyanide capped clusters are required due to the low extinction coefficients for the ν(C≡N) bands. The IR SEC responses (ca. 20 s intervals) for the bulk reduction of **2** are shown in Fig. 3. Upon application of the reduction potential the ν(C≡N) bands for **2** (1914 and 1858 cm^{-1}) decrease in intensity as a single new ν(C≡N) band at 1649 cm^{-1} appears. These changes are also fully reversible. The frequency shift in the ν(C≡N) bands to lower energy is consistent with the capping methyl isocyanide remaining in its original μ_3,η^1 form after reduction of the nickel cluster (eq. [2]) (2, 28).

[2] 
R = alkyl (**2-6**)
= aryl (**7-14**)

Similar results are obtained for the remaining clusters **3–14** and the results of the SEC experiments are listed in Table 1. In each case the ν(C≡N) band(s) in the isolated clusters shift to a *single* ν(C≡N) band of lower energy upon one-electron reduction. The shift to lower frequency for **2–14** indicates that all the isocyanide ligands studied remain triply-bridging upon reduction. This minimal structural rearrangement is consonant with the observed reversible electrochemistry. The appearance of a single ν(C≡N) band in the reduced forms of **2–14** can be readily accounted for using the Fermi resonance model. The decrease in ν(C≡N) frequency upon reduction is large enough to move the ν(C≡N) fundamental out of a Fermi res-

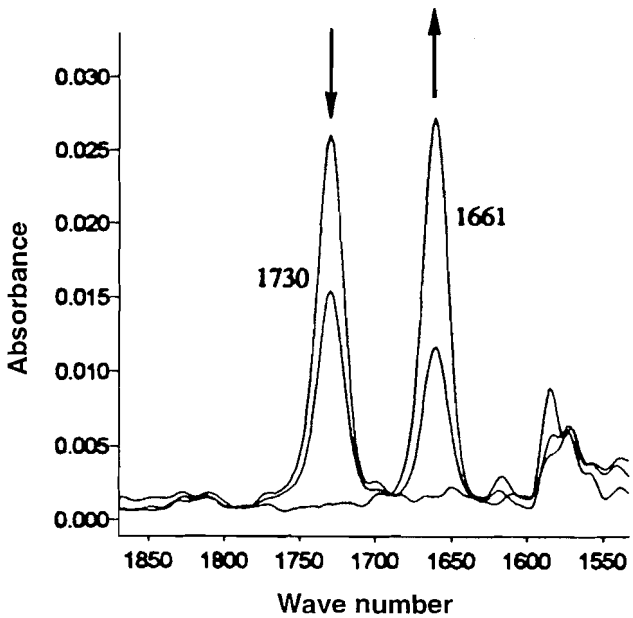

Fig. 3. Plot of the IR spectral changes observed during the spectroelectrochemical reduction of 19.0 mM $[Ni_3(\mu_3\text{-}CNCH_3)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3][PF_6]$ (**2**) in a 0.1 M TBAP/THF solution. Potential held at −1.4 V vs. SCE.

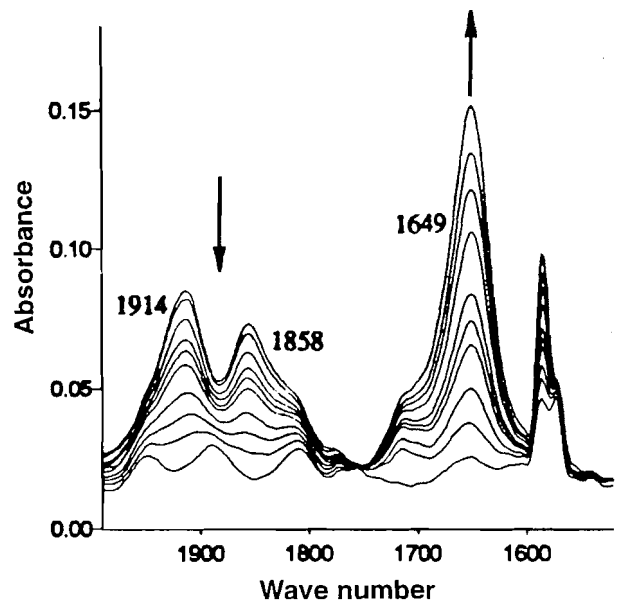
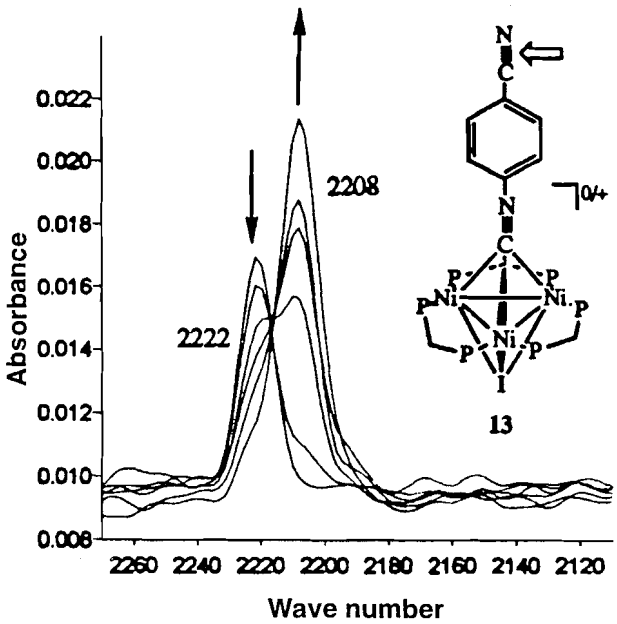


onance condition with the first overtone of the ν(C–N(alkyl)) fundamental (1, 29).

The IR SEC data for **1–14** are collected in Table 1. The differences ($\Delta\nu$, cm^{-1}) in ν(C≡O) or ν(C≡N) frequencies between the isolated and reduced forms of **1–14** are highly dependent on the electronic and steric nature of the capping π-acceptor ligand. For the carbonyl capped cluster **1**, only a 69 cm^{-1} change in ν(C≡O) frequency is observed. In contrast, the magnitude of the shift in ν(C≡N) frequency for the CNR (R = alkyl, aryl) capped clusters is much larger. The greater π-backbonding ability of CO as compared to CNR (R = alkyl, aryl) is well documented (30). From the ν(C≡O) data, significant metal–CO backbonding is present in the isolated state of **1**; which is little altered by reduction of the cluster. Differences in ground state π-acceptor properties also account for the sharp variation in $\Delta\nu$ between the alkyl and aryl isocyanide capped clusters. For the clusters with electron-donating alkyl substituents on the capping isocyanide (CNR; R = CH_3 (**2**), i-C_3H_7 (**3**), C_6H_{11} (**4**)) a decrease in ν(C≡N) frequency of ca. 220 cm^{-1} is observed upon reduction. In contrast, a smaller ν(C≡N) frequency shift ($\Delta\nu$ ca. 170 cm^{-1}) is observed for the aryl isocyanide capped clusters **7–14**. For the isolated clusters **7–14**, the ν(C≡N) bands lie at ca. 100 cm^{-1} lower in energy than those observed for **2–4**. This indicates a stronger isolated state metal–CNR π-backbonding interaction for the aryl isocyanide capped clusters, consonant with aryl isocyanides being better π-acceptors than alkyl isocyanides (31). Thus, upon reduction of the clusters, a larger change in ν(C≡N) is seen for the alkyl isocyanide clusters as the metal-based LUMO is populated and the energies of the nickel *d* orbitals are raised (32). For the benzyl isocyanide capped cluster **6** in the isolated state, the ν(C≡N) band is closer in energy to those for aryl isocyanide (**7–14**), rather than alkyl isocyanide (**2–4**), capped clusters. This indicates significant metal–CNR backbonding present in the ground state. After single electron reduction and subsequent raising of the nickel core *d*-orbital energies, there is a smaller relative difference in the Ni—CNR backbonding interaction for **6** than for **2–4**. Steric effects also influence the magnitude of the shift in ν(C≡N) between the isolated and reduced states of the clusters **2–14**. The most notable example is the 2,6-dimethylphenyl isocyanide capped cluster (**14**) where a value of $\Delta\nu$ = 113 cm^{-1} was observed. The high steric demands of this ligand effectively prevent the approach of the isocyanide to the nickel core and preclude effective Ni—CNR backbonding. This is recognizable in the ground state of **14** where the ν(C≡N) absorption bands are nearly 70 cm^{-1} higher in energy than those for the other aryl isocyanide capped clusters **7–13**. Additionally, even upon reduction, the steric bulk of the 2,6-dimethylphenyl substituent impedes effective metal–CNR π^* overlap and results in only a small change in ν(C≡N) frequency between the isolated and reduced states. A sterically hindered alkyl substituent (R = *tert*-C_4H_9 (**5**)) results in a shift of $\Delta\nu$ = 116 cm^{-1} upon reduction. For **5** in the isolated state, the ν(C≡N) band is at very low energy compared to the related alkyl isocyanide capped species **2–4**. Deviation from a linear μ_3,η^1 bonding mode for the capping *tert*-butyl isocyanide is a plausible explanation for the low-energy ν(C≡N) band of **5**. The reduction of **5** does not cause a large change in ν(C≡N) as the sterically demanding *tert*-butyl substituent hinders the nickel–CNR bond contraction necessary for effective metal–CNR backbonding, as proposed for **13**. Thus, the changes in ν(C≡O) or ν(C≡N) frequency upon reduction are consistent with both the electronic and steric effects of the capping π-acceptor ligand.

The changes in electron density at the capping isocyanide, and hence at the metal core, can also be monitored using ancillary substituents on the isocyanide ligand. The nitrile group on

Fig. 4. Plot of the IR spectral changes observed during the spectroelectrochemical reduction of 6.0 mM $[Ni_3(\mu_3\text{-}CN(p\text{-}C_6H_4CN)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3][PF_6]$ (**13**) in a 0.1 M TBAP/THF solution. Only nitrile region shown; potential held at −1.4 V vs. SCE.

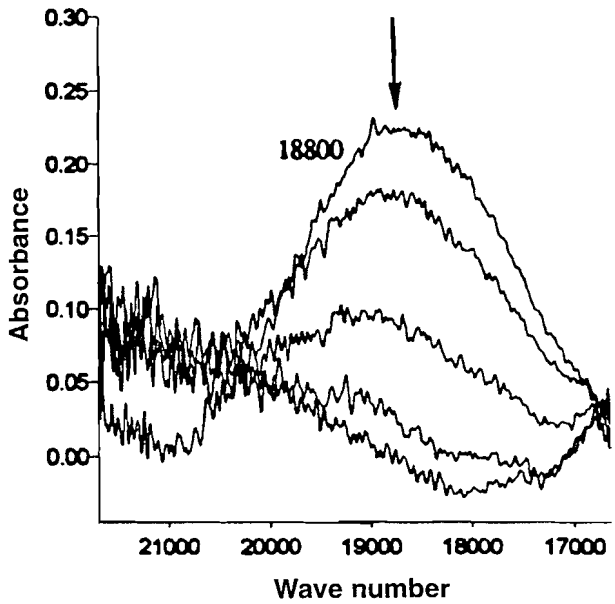


the *p*-cyanophenyl isocyanide capped cluster (**13**) gives rise to a distinctive ν(C≡N) band at 2222 cm^{-1}. Upon reduction of **13** in the SEC cell a new ν(C≡N) nitrile band appears at 2208 cm^{-1} (Fig. 4). This indicates that significant electron density is transferred to the phenyl ring of the capping isocyanide via a Ni—CNR backbonding interaction. This methodology is valuable in cases where overlapping IR bands may obscure the IR signals of primary interest.

UV–visible SEC studies

An important feature of the specular reflectance spectroelectrochemical cell used in this study is its versatility. The SEC cell, equipped with a CaF_2 window, is transparent in both the IR and UV–visible regions while the Mattson spectrometer used in this study can be configured to run in the IR, near-IR, and UV–visible regions. Thus, spectra can be acquired from 600 to 22 000 cm^{-1} using the same SEC cell. The π-acceptor capped clusters **1–14** have intense UV–visible absorptions in the region 520–540 nm ($\varepsilon \sim (2\text{–}4) \times 10^3$ cm^{-1} M^{-1}) (1). The SEC cell was utilized to investigate the UV–visible spectral changes that accompany the single electron reduction of **1–14**. The UV–visible SEC responses (ca. 20 s intervals) for the bulk reduction of the cyclohexyl isocyanide capped cluster (**4**) are shown in Fig. 5. Initially, the absorption band for the isolated state of **4** is observed at 18 800 cm^{-1} (532 nm). As the bulk reduction proceeds this band is bleached while a new, very broad, absorption grows in at ca. 21 000 cm^{-1}. Although the spectrometer can be configured to scan to 27 000 cm^{-1}, the region past 22 000 cm^{-1} is unreliable due to the low power of our visible source. Similar results were obtained for other selected nickel clusters (**3–6**). Methods for increasing the sensitivity of the SEC response past 22 000 cm^{-1} are being pursued. However, as demonstrated, the versatile design of the

Fig. 5. Plot of the UV–visible spectral changes observed during the spectroelectrochemical reduction of 33.0 mM $[Ni_3(\mu_3\text{-}CNC_6H_{11})(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3][PF_6]$ (**4**) in a 0.1 M TBAP/THF solution. Potential held at −1.4 V vs. SCE.



SEC cell utilized in this study allows for detection of in situ electrogenerated intermediates *without* changing the SEC cell or the spectrometer.

Conclusions

The single electron reductions of a class of carbon dioxide reduction electrocatalysts $[Ni_3(\mu_3\text{-}L)(\mu_3\text{-}I)(\mu_2\text{-}dppm)_3]^+$ (L = CO; CNR, R = alkyl, aryl) were investigated using IR and UV–visible spectroelectrochemistry. The IR–SEC studies indicated that the capping carbonyl or isocyanide ligand remained in its original μ_3,η^1 mode upon one-electron reduction. The magnitude of the ν(C≡O) or ν(C≡N) absorption band shift upon reduction is related to both the electronic and steric properties of the capping π-acceptor ligand. Spectroelectrochemical studies with UV–visible detection revealed a hypsochromic shift upon reduction of the clusters. The SEC cell and spectrometer utilized are also extremely versatile as data from 600 to 22 000 cm^{-1} can be acquired without modifying the SEC cell and making only minor configuration changes to the spectrometer.

Photolithography of self-assembled monolayers: optimization of protecting groups by an electroanalytical method

Jamila Jennane, Tanya Boutros, and Richard Giasson

Abstract: Patterned surfaces presenting a high density of chemically reactive functional groups can be prepared through photolithography of self-assembled monolayers (SAM). In this paper, we report the synthesis and the evaluation of three reagents that can be used in SAM-photolithographic applications. These reagents are made up of a triethoxysilylpropylamine moiety in which the amine is temporarily blocked by photolabile protecting groups: NVOC (*o*-nitroveratryloxycarbonyl), ONB (*o*-nitrobenzyl), or DDZ (α,α-dimethyl-3,5-dimethoxybenzyloxycarbonyl). The presence of the triethoxysilyl group allows self-assembled monolayer formation. Release of chemically reactive amino groups is achieved by irradiation of the surface. An electroanalytical method was developed and used to monitor and optimize the three steps of the methodology occurring on surfaces: monolayer formation, photodeprotection, and subsequent functionalization of the released amino groups. Quantitative information on the efficiency of the photodeprotection step was obtained by this method. It was found that the DDZ group is superior to the ONB and NVOC photolabile protecting groups for SAM-photolithographic applications. Percentages of liberated amino groups are generally above 50% with the DDZ group, while they are generally inferior to 25% and 2% for NVOC and ONB, respectively. These differences are attributed to the destruction of some of the released amino groups through a subsequent reaction with the photoproduct, *o*-nitrosobenzaldehyde for ONB and 3,4-dimethoxy-6-nitrosobenzaldehyde for NVOC, and to partial loss or destruction of the monolayer during prolonged irradiations.

Key words: self-assembled monolayers, surface modification, photolithography, photolabile protecting groups, cyclic voltammetry.

Résumé : Des motifs présentant une haute densité de groupes fonctionnels chimiquement réactifs peuvent être préparés sur des surfaces à l'aide de la photolithographie de monocouches auto-assemblées (MAA). Dans cet article, nous relatons la synthèse et l'évaluation de trois réactifs pouvant être utilisés dans des applications de la photolithographie-MAA. Ces réactifs sont constitués d'un fragment triéthoxysilylpropylamine dont la fonction amine est temporairement bloquée par des groupement protecteurs photolabiles : NVOC (*o*-nitrovératryloxycarbonyle), ONB (*o*-nitrobenzyle) ou DDZ (α,α-diméthyl-3,5-diméthoxybenzyloxycarbonyle). La présence du groupe triéthoxysilyle permet la formation de monocouches auto-assemblées. La libération des groupements amines chimiquement réactifs est accomplie par irradiation de la surface. Une méthode électroanalytique a été développée et utilisée pour suivre et optimiser les trois étapes de la méthodologie se produisant à la surface : la formation de la monocouche, la photodéprotection et la fonctionnalisation subséquente des groupes amines libérés. De l'information quantitative sur l'efficacité de l'étape de déprotection a été obtenue par cette méthode. Il a été découvert que le groupe DDZ est supérieur aux groupes protecteurs photolabiles ONB et NVOC en photolithographie-MAA. Le pourcentage de groupes amines libérés est généralement supérieur à 50% avec le groupe DDZ, alors qu'il est généralement inférieur à 25% et 2%, respectivement, pour NVOC et ONB. Ces différences sont attribuées à la reprotection d'une partie des groupes amines libérés suite à une réaction avec un photoproduit, l'*o*-nitrosobenzaldéhyde pour ONB et le 3,4-diméthoxy-6-nitrosobenzaldéhyde pour NVOC, ainsi qu'à la perte ou destruction partielle de la monocouche pendant une irradiation prolongée.

Mots clés : monocouches auto-assemblées, modification de surfaces, photolithographie, groupes protecteurs photolabiles, voltamétrie cyclique.

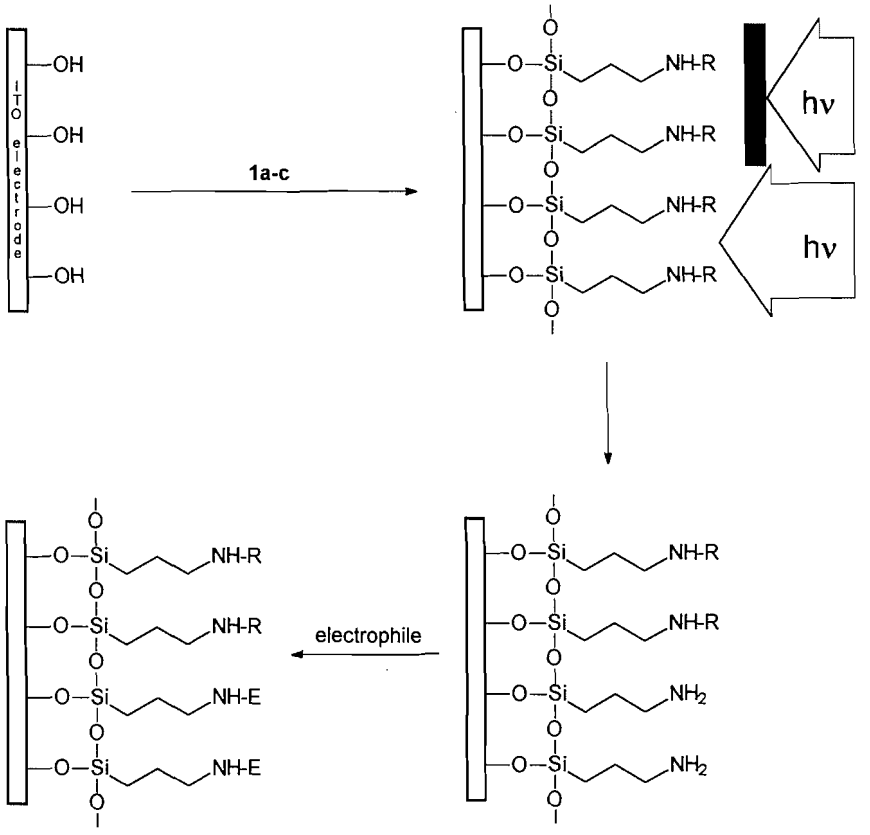
Scheme 1. Schematic representation of the SAM-photolithographic system.



Introduction

Photolithography of self-assembled monolayers (SAM) recently emerged as a powerful method for the preparation of patterned surfaces presenting chemically reactive functional groups. Impressive applications of this new technique have been reported in the chemical literature over the last few years; the technique has been used, namely, for selective adsorption or immobilization of proteins on surfaces (1), controlled adhesion and growth of cells (2), selective electroless metalization of surfaces for microelectronics applications (3), light-directed molecular derivatization of surfaces (4), controlled substitution of self-assembled thiols on gold surfaces (5), and light-directed spatially addressable synthesis of peptides (6). As part of a research program aimed at the development of molecular devices (7), we have developed and optimized a SAM-photolithographic system (Scheme 1) similar to that reported by Fodor et al. (6) for the synthesis of peptides. Features common to both systems are the use of the triethoxysilylpropylamine moiety in the formation of monolayers and the temporary protection of the amino function by photolabile protecting groups. The systems differ, however, in their sequences of reactions (N-protection is performed prior to monolayer formation in our system, while it is achieved after in Fodor's system) and in the nature of the photolabile protecting groups.

In their article, Fodor et al. (6) reported net coupling yields per cycle of ca. 90% including both the photodeprotection and amino acids coupling steps. This yield is based on the hypothesis that illumination conditions used insure >99% photodeprotection. Illumination conditions were determined by measuring the photolysis rate of NVOC-amino acids, but it is not clear whether the amino acids were bound to a surface or in solution. The fact that the rate of photodeprotection may be different for surface-bound species must be taken into consideration in the evaluation of SAM-photolithographic systems. Analytical methods used to evaluate these systems should ideally provide quantitative information on the number of reactive sites present on the surface after irradiation. The number of reactive sites may be influenced not only by the effectiveness of the photocleavage of the protecting group, but also by the partial loss of surface-bound species or subsequent reprotection of reactive groups released during irradiation.

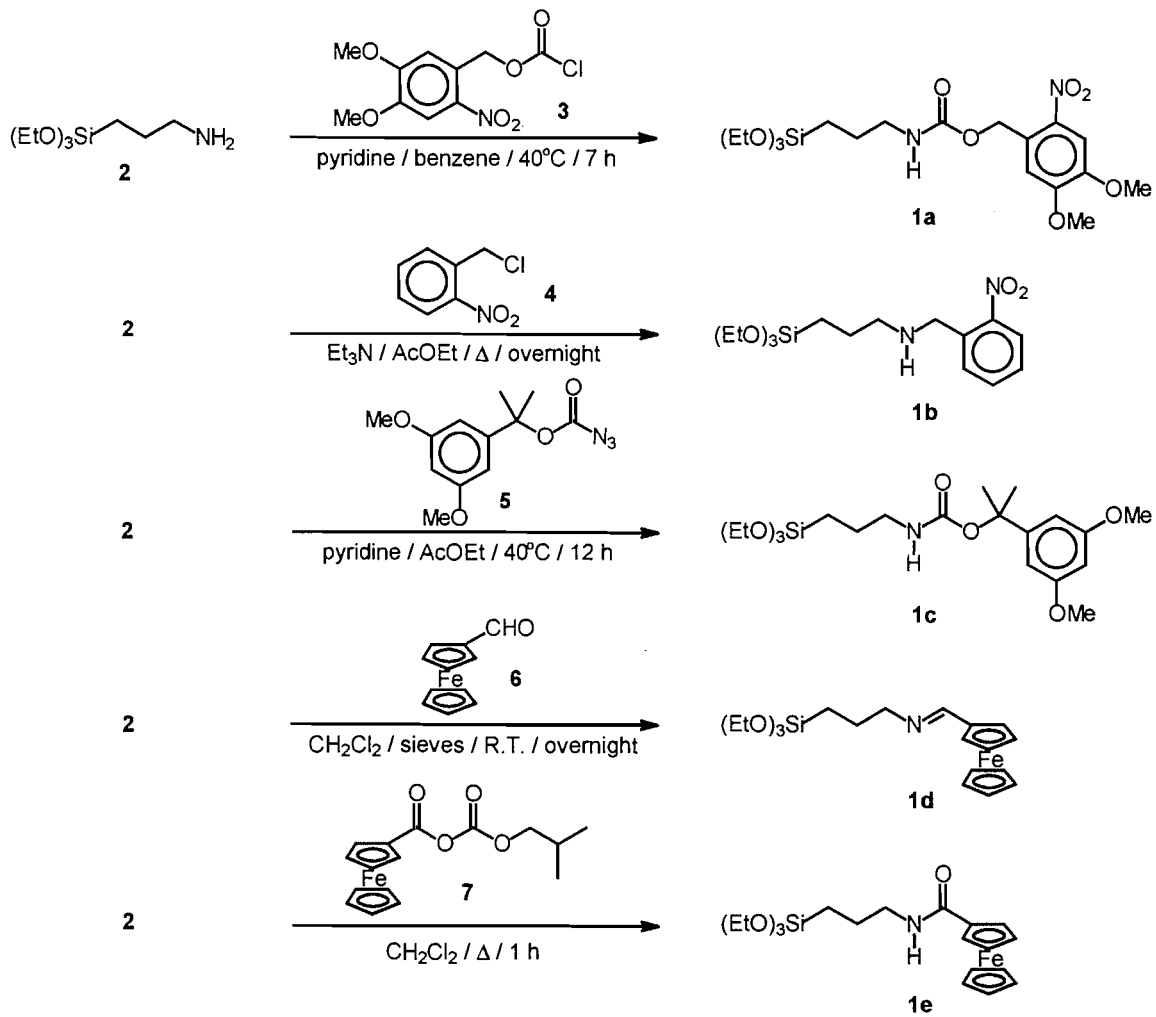
In this paper, we have evaluated the performance of SAM-photolithographic reagents using an electroanalytical technique that provides quantitative information on the number of intact reactive sites present on the surface after irradiation. SAM-photolithographic reagents using three different photolabile protecting groups were tested; the 2-nitroveratryloxycarbonyl (NVOC) (**1a**), the 2-nitrobenzyl (ONB) (**1b**) and the α,α-dimethyl-3,5-dimethoxybenzyloxycarbonyl (DDZ) (**1c**) groups. We found the DDZ group to be superior to the ONB and NVOC photolabile protecting groups for SAM-photolithographic applications. We also found evidence that the deprotection may be complicated by competing photocleavage of the aminopropyl chain bound to the surface.

Results and discussion

Syntheses

Three SAM-photolithographic reagents, **1a**, **1b**, and **1c**, using different protecting groups, were prepared and evaluated in this study (Scheme 2). The first reagent is N-protected with the

Scheme 2. Syntheses of SAM-photolithographic reagents **1a–c** and ferrocene-labeled SAM reagents **1d** and **1e**.



photolabile 6-nitroveratryloxycarbonyl (NVOC) group, one of the most frequently used photolabile protecting groups for amines (8). NVOC-protected reagent **1a** was prepared in 76% yield by the reaction of an excess of 3-aminopropyltriethoxysilane (**2**) with 3,4-dimethoxy-6-nitrobenzyl chloroformate (**3**) in the presence of pyridine in benzene. A second reagent, **1b**, in which the amino group is protected by the 2-nitrobenzyl (ONB) group, was prepared in 70% yield by reacting a 2-fold excess of 3-aminopropyltriethoxysilane (**2**) with 2-nitrobenzyl chloride (**4**) in the presence of triethylamine in refluxing ethyl acetate. While the use of the NVOC photolabile protecting group for the temporary protection of amines is more prevalent, the ONB group has been used before in the N^{im}-protection of histidine (9). The photoremoval of both of these protecting groups is achieved via the same reaction: the light-induced intramolecular rearrangement of 2-nitrobenzylic compounds, the mechanism of which we have studied extensively in solution (10).[3] Finally, the third reagent, **1c**, in which the amino group is protected with the α,α-dimethyl-3,5-dimethoxybenzyloxycarbonyl (DDZ) group, was prepared by reacting a slight excess of 3-aminopropyltriethoxysilane (**2**) with α,α-dimethyl-3,5-dimethoxybenzyloxycarbonylazide (**5**) at 40°C in a mixture of pyridine and ethyl acetate. The DDZ group has been used extensively for the temporary protection of amines and amino acids (9).

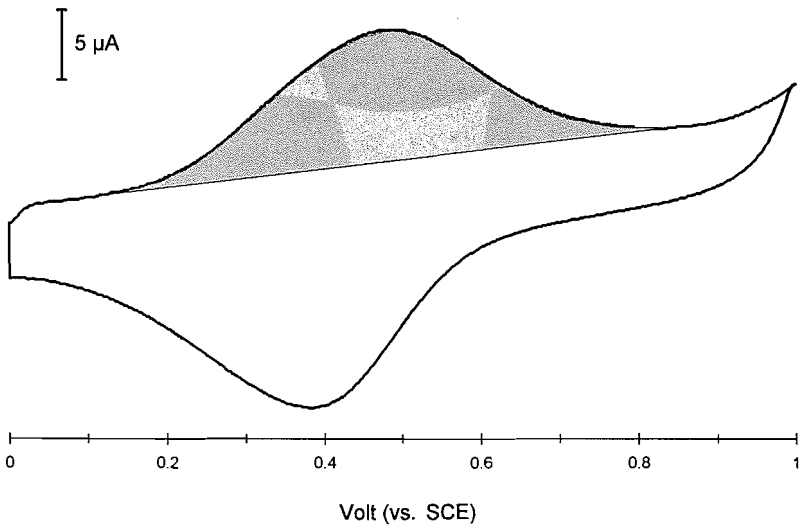
In addition to the three SAM-photolithographic reagents, **1a**, **1b**, and **1c** described above, two SAM-reagents, **1d** and **1e**, labeled with the electroactive ferrocenyl group, were also prepared. These two reagents were used in the electroanalytical method we developed to monitor the progress and optimize the reactions in our methodology. Labeled reagent **1d** was prepared in 80% yield by reacting ferrocenecarboxaldehyde (**6**) with 3-aminopropyltriethoxysilane (**2**) over molecular sieves in dichloromethane. Labeled reagent **1e** was prepared in 70% yield from the reaction of the mixed anhydride **7** with 3-aminopropyltriethoxysilane (**2**) in refluxing dichloromethane. The mixed anhydride **7** used in this reaction is prepared beforehand by reacting ferrocene carboxylic acid with isobutylchloroformate at 0°C in toluene in the presence of triethylamine.

Electroanalytical evaluation and optimization of surface reactions

The sequence of reactions used in the methodology includes

[3] Also, R. Giasson, D. Gravel, and R.W. Yip, unpublished results.

Fig. 1. Cyclic voltammogram of approximately one monolayer of ferrocene bound to the surface of a 1.1 cm^2 ITO electrode. The voltammogram was recorded using 10^{-1} M Bu_4NBF_4 in CH_3CN as electrolyte, a SCE reference electrode and a 200 mV/s sweep rate. The shaded area corresponds to $Q = 1.9 \times 10^{-5}$ C.



the formation of self-assembled monolayers on surfaces, as well as the photochemical deprotection and subsequent functionalization of surface-bound aminopropylsiloxy moieties. Since all of these reactions occur on surfaces, a limited number of techniques could be used to evaluate their efficiency quantitatively and optimize reaction conditions. We adopted an electroanalytical approach because the technique is straightforward, well suited for the study of surface-bound species, and provides quantitative information.

A 1600 Å film of indium – tin oxide (ITO) on a glass support (Applied Film Lab.) was used as substrate for the formation of self-assembled monolayers. This substrate is advantageous because it is electron conducting and, therefore, can serve as working electrode in an electrochemical cell, and because derivatization of ITO with triethoxysilanes is well documented (11, 12). Plates of ITO on glass were cut into 1 cm^2 pieces that were cleaned by sonication in organic solvents and aqueous solutions prior to monolayer formation. The rate of monolayer formation was evaluated by soaking the ITO electrodes in a 2% solution of labeled reagent **1d** or **1e**. Derivatized electrodes were removed from solution at regular intervals over a 30 h period and were freed from unbound species by sonication in organic solvents. Cyclic voltammograms of surface-bound ferrocene were recorded for each electrode. When labeled reagent **1d** was used for monolayer formation, the electrochemical signal observed decreased rapidly and disappeared completely after a few scans. This indicates that the imine linkage used in this case is too labile for this kind of application even when work is carried out under anhydrous conditions. A persistent electrochemical signal was obtained, however, when labeled reagent **1e** was used. The amide linkage is therefore much more suitable and was adopted for our study.

Coverages (Γ) of surface-bound ferrocene were determined by cyclic voltammetry (12). A typical cyclic voltammogram of approximately one monolayer of ferrocene bound to the surface of a 1.1 cm^2 ITO electrode is represented in Fig. 1. The total charge ($Q = 1.9 \times 10^{-5}$ C) for the oxidation of surface-bound ferrocene was calculated by integrating electronically the shaded area of the voltammogram recorded at a sweep rate of 200 mV s^{-1}. A coverage (Γ) of 1.8×10^{-10} mol cm^{-2} was calculated from eq. [1],

$$[1] \qquad \Gamma = Q / n\mathcal{F}A$$

where Γ represents the coverage in mol cm^{-2}, n the number of electrons transferred ($n = 1$ for ferrocene), $\mathcal{F}$ the Faraday constant (9.6485×10^4 C mol^{-1}), and A the area of the electrode in cm^2.

Plotting of coverage as a function of soaking time (Fig. 2) shows that a maximum coverage of 1.9×10^{-10} mol cm^{-2} is reached after 24 h of soaking under our conditions. This coverage is within the range ($(0.8–4) \times 10^{-10}$ mol cm^{-2}) generally observed for approximate noncompacted monolayers obtained with silane reagents (12). It is known, however, that larger than monolayer coverages are sometime obtained with some silanes and under certain conditions, suggesting siloxane polymer formation. Some dimer, trimer, etc., sites are therefore probably scattered among the monomer monolayer population in samples with average coverage in the monolayer range. Formation of globules of siloxane polymer on the surface is, on the other hand, avoidable with proper reaction conditions (12).

To evaluate the yields of photodeprotection of the SAM-photolithographic reagents, we required a method for quantitative labeling of the amino groups liberated during irradiation. Labeling conditions were determined as follows: ITO electrodes (1 cm^2) were soaked in a 2% solution of 3-aminopropyltriethoxysilane (**2**) for 24 h to ensure monolayer formation. The resulting electrodes bearing a monolayer on which every amino group is free were cleaned the usual way and then soaked in a 2% solution of mixed anhydride **7** in toluene. Elec-

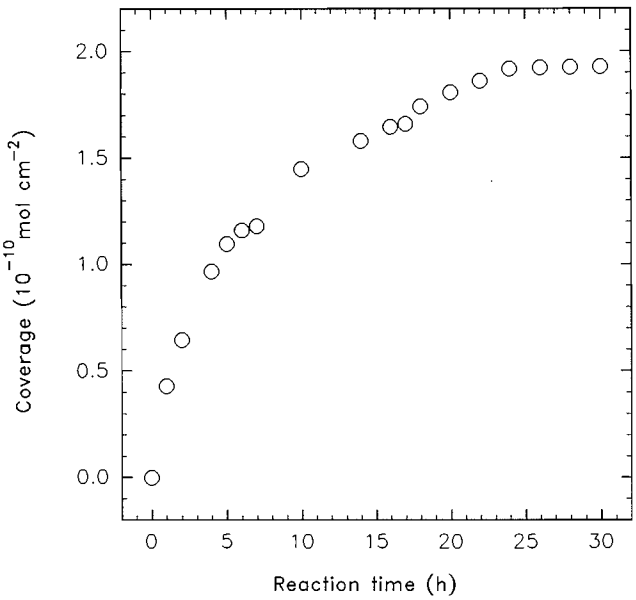

Fig. 3. Coverage (Γ) of surface-bound ferrocene as a function of soaking time of electrodes already modified with SAM reagent **2** in a 2% solution of labeling reagent **7**.

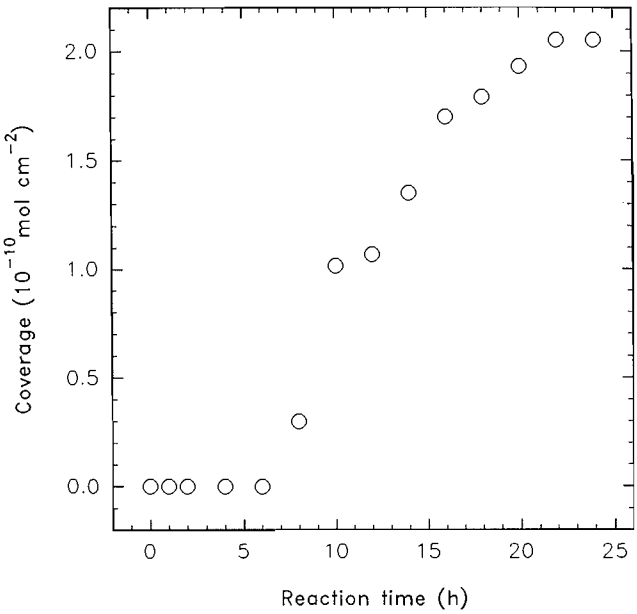
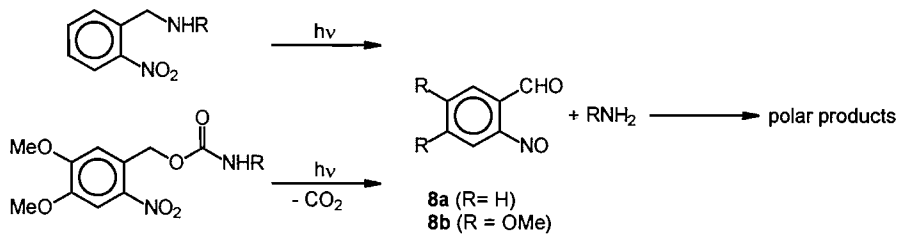


Scheme 3. Products from the photocleavage of ONB and NVOC groups.



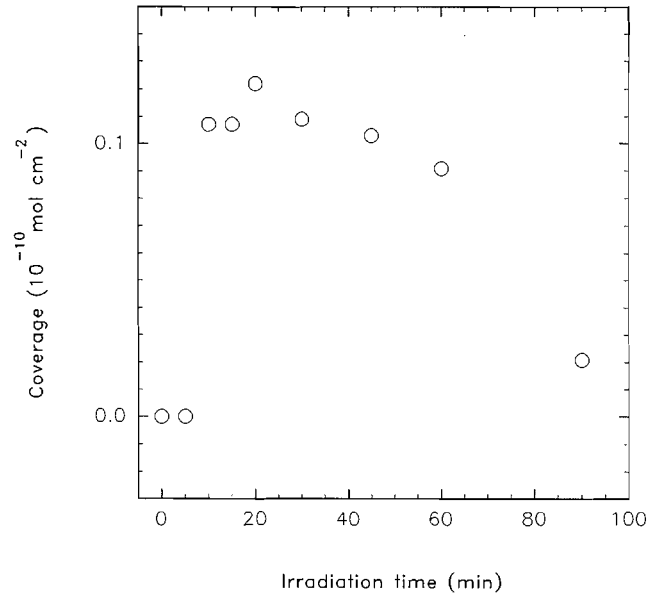
trodes were removed from solution at regular intervals over a 24 h period and freed from unbound species by sonication in organic solvents. Cyclic voltammograms of surface-bound ferrocene were recorded for each electrode. Resulting coverages (Γ) of surface-bound ferrocene were determined and plotted as a function of soaking time (Fig. 3). Coverages (2.1×10^{-10} mol cm^{-2}) as dense as those obtained with complete monolayer formation with labeled reagent **1e** (1.9×10^{-10} mol cm^{-2}) were obtained after 20 h of soaking in mixed anhydride solution.

The efficiency of photoremoval of the protecting groups NVOC, ONB, and DDZ from monolayers of the SAM-photolithographic reagents **1a–c** was estimated as follows. Monolayers were prepared by soaking 1 cm^2 ITO electrodes in 2% solutions of reagents **1a**, **1b**, or **1c** for 24 h. Complete monolayer coverage is assumed in these conditions (vide supra). After appropriate cleaning, the modified electrodes were irradiated to effect deprotection and sonicated in an organic solvent to remove any adsorbed photoproduct. The liberated amino groups on the surface were then labeled by soaking the resulting electrodes for 24 h in a 2% solution of mixed anhydride **7**. Coverages by surface-bound ferrocene were determined as previously. The efficiency of the photodeprotection step was estimated by comparing coverages obtained through this sequence with the value of 2×10^{-10} mol cm^{-2}, corresponding to complete monolayer coverage (vide supra).

Efficiency of photoremoval of the ONB protecting group was first to be estimated with this method. Photoremoval was carried out by irradiating the electrodes at 350 nm for 1 h. Yields of photodeprotection observed for the ONB group were extremely low (best yield: 2%). This disappointing result was not totally unexpected since it is known that the product of this photocleavage, *o*-nitrosobenzaldehyde (**8a**), usually reacts in solution with some of the liberated amine, which leads to the formation of polar products (Scheme 3) (13). This problem is usually minimized by adding aldehyde trapping reagents to the solution, such as hydrazine, hydroxylamine hydrochloride, or semicarbazide hydrochloride. Immersion of the electrodes in a solvent during the photodeprotection in order to dissolve *o*-nitrosobenzaldehyde (**8a**) as it is formed, in the presence or absence of phenylhydrazine, did not, however, improve the yield significantly.

While removal of the NVOC group occurs through the same photorearrangement as that for the ONB group, isolated yields of amine are generally higher with NVOC when the reaction is carried out in solution. This can be explained in part by a lower electrophilicity of the photoproduct, 3,4-dimethoxy-6-nitrosobenzaldehyde (**8b**). We therefore

Fig. 4. Coverage (Γ) of surface-bound ferrocene as a function of irradiation time for electrodes modified with NVOC-protected SAM-photolithographic reagent **1a** after the monolayer formation, photodeprotection, and labeling sequence.



expected the NVOC group to be a superior photolabile group for SAM-photolithographic applications. The efficiency of the photodeprotection step was evaluated, as described above, for electrodes modified with the NVOC-protected SAM-reagent **1a**. A series of modified electrodes were prepared and irradiated at 350 nm over variable periods of time. Resulting coverages (Γ) of surface-bound ferrocene were determined and plotted as a function of irradiation time (Fig. 4). Three conclusions can be drawn from this plot: The population of free amino groups on the electrode surface is maximum after 15–60 min irradiation times. Coverages resulting from 15–60 min irradiation (0.1×10^{-10} mol cm^{-2}) correspond to labeling of approximately 5% of the amino groups. Prolonged irradiation results in lower coverages.

Coverage values obtained through this method correspond to the final yield of a sequence of three reactions. Since the individual yields of each of these reactions can be affected by minute variations in reaction conditions, fluctuation of coverage values was observed when this experiment was repeated. Labeling of less than 25% of the amino group is, however, generally obtained with the NVOC group and this value can be considered as a good estimate of the optimum yield of photodeprotection that can be achieved with this system.

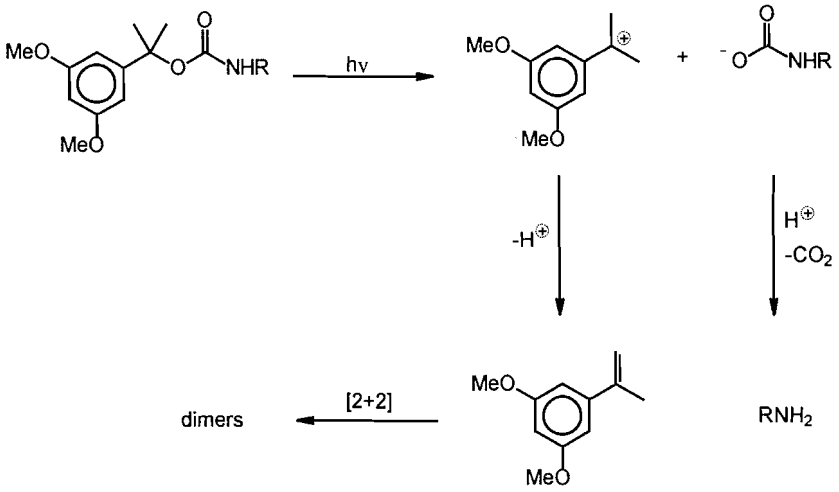
While the NVOC group gives results superior to the ONB group, amino groups are not quantitatively deprotected and kept intact during irradiation. This could be due to subsequent reaction of liberated amino groups with the 3,4-dimethoxy-6-nitrosobenzaldehyde (**8b**) formed during irradiation. However, since observed coverages decrease with prolonged irradiation times, it is also likely that some of the species covalently bound to the electrode surface (free or protected aminopropylsiloxy moieties) are lost or destroyed during irradiation. The rate of the photodeprotection step and, therefore, its quantum yield may be the factor governing the quantity of amino groups that are released and kept intact during irradiation if photodeprotection competes with destruction of the monolayer.

Finally, the DDZ group was also evaluated for SAM-photolithographic applications. This third photolabile protecting group was chosen because it is known that photocleavage intermediates do not react with the liberated amine and that photodeprotection is usually quantitative in solution (Scheme 4) (14). A series of ITO electrodes were modified with SAM-photolithographic reagent **1c** and were irradiated at 254 nm over variable periods of time. Liberated amino groups were labeled and coverages (Γ) were determined as described above. Photocleavage of the DDZ group occurred in a way similar to that of the NVOC group in that maximum population of free amino groups is achieved after 15–60 min of irradiation and that prolonged irradiation resulted in decreased coverage. This latter observation confirms that some of the surface-bound species (free or protected aminopropylsiloxy moieties) are lost or destroyed during irradiation. Maximum coverages obtained after optimal irradiation times are, however, much better with DDZ than with NVOC or ONB. Indeed, coverages varying from a low of 0.3×10^{-10} to more than 2.0×10^{-10} mol cm^{-2} were obtained in different experiments. This corresponds to a density of free amino groups varying between 15% and 100% (generally over 50%). Superior results obtained with this group may be attributed to the fact that photocleavage intermediates do not react with the released amino groups and (or) that photodeprotection of DDZ competes more effectively with destruction of the monolayer.

Conclusion

SAM photolithography represents a powerful method for the preparation of patterned surfaces presenting chemically reactive functional groups. This recently acquired ability to modify the chemical nature and reactivity of a specific area of a surface has already led to impressive applications of this technology. SAM photolithography can be achieved by temporarily blocking a reactive functional group of a SAM reagent with a photolabile protecting group that can later be cleaved. The viability of one such approach, consisting in using NVOC to protect the amino groups of monolayers prepared from the self-assembly of triethoxysilylpropylamine, was first established by Fodor et al. (6). However, prior to our study, questions regarding the efficiency of the photodeprotection step, and whether the use of NVOC as protecting group is optimal, were never addressed. In this paper, we report a straightforward electroanalytical method that can be used to estimate the efficiency of this deprotection step using electrochemical labeling. Using this method, we have evaluated the performance of three different photolabile protecting groups, the NVOC, ONB, and DDZ groups, in SAM-photolithographic reagents. This study clearly demonstrates that ONB and NVOC groups do not perform well in this type of application. Observed yields of photodeprotection were dismal (<2%) for ONB and poor (<25%) for NVOC. These low yields can be explained by a combination of two factors. First, it appears likely that some of the amino groups released during irradiation are reprotected by subsequent reactions with photoproducts **8a** or **8b**. Partial loss or destruction of the monolayer also competes effectively with photodeprotection of the ONB and

Scheme 4. Intermediates and product from the photocleavage of the DDZ group.



NVOC groups. Use of the DDZ group was found to be much more satisfactory. The highest density of free amino groups is achieved between 15 and 60 min of irradiation at 254 nm under our conditions. The density of free amino groups obtained with DDZ was generally superior to 50% and frequently close to 100%. Superior yields obtained with this photolabile group are most probably due to the lack of reactivity of the photointermediates toward the liberated amino groups and a more favorable competition between deprotection and destruction of the monolayer. Use of DDZ is therefore preferable for the protection of amino groups in SAM-photolithographic applications, where a wavelength of irradiation of 254 nm is not detrimental. In other applications, where an irradiation wavelength of 350 nm is preferable, NVOC gives results superior to ONB.

Experimental section

Melting points were determined on a Gallenkamp model 24MF370 melting point apparatus and are reported uncorrected. IR spectra were recorded on a Perkin–Elmer 783 infrared spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ using a Varian VXR-300 (300 and 75 MHz, respectively) spectrometer. Mass spectra were obtained on a V.G. Micromass 12-12 spectrometer, a V.G. Trio-1 quadrupole spectrometer, or a Kratos MS-50 TA spectrometer. Flash column chromatographies were performed using EM Science silica gel 60 (230–400 mesh) using distilled solvents.

Benzene, toluene, and THF were distilled over sodium/benzophenone ketyl. Acetonitrile, dichloromethane, pyridine, and triethylamine were distilled over calcium hydride. Ethyl acetate was distilled over phosphorus pentoxide. 2-Nitrobenzyl chloride (**4**), ferrocenecarboxaldehyde (**6**), and isobutyl chloroformate were purchased from Aldrich™. Isobutyl chloroformate was distilled prior to use. 3-Aminopropyltriethoxysilane (**2**) was purchased from Fluka™ and distilled under reduced pressure prior to use. Ferrocenecarboxylic acid, α,α-dimethyl-3,5-dimethoxybenzyloxycarbonylazide (**5**) and 4,5-dimethoxy-2-nitrobenzyl chloroformate (**3**) were prepared according to published procedures (refs. 15, 14, and 8, respectively). Undesirable light exposure was avoided in every manipulation involving light-sensitive compounds by wrapping glassware in aluminium foil or by working in a dark room.

4,5-Dimethoxy-2-nitro-benzyl [*N*-(3-triethoxysilyl)-propyl]-carbamate (1a)

A solution of 3,4-dimethoxy-6-nitro-benzyl chloroformate (**3**) (0.25 g; 0.94 mmol) and pyridine (1 mL) in benzene (5 mL) was heated to 40°C. After the formation of an orange precipitate, 3-aminopropyltriethoxysilane (**2**) (0.63 g; 2.84 mmol) was added and the resulting mixture was stirred at 40°C for 7 h. The precipitate was removed by decantation and the supernatant evaporated. Purification of the residue by flash chromatography (hexanes/AcOEt/Et_3N 7:3:0.1) afforded the desired product (**1a**) as yellow crystals (0.33 g; 76%): mp 54°C; IR (film) ν_{max}: 3350 (NH), 1695 (C=O), 1515 (NO_2), 1330 (NO_2) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.70 (s, 1H), 7.00 (s, 1H), 5.50 (s, 2H), 5.16 (br t, 1H), 3.97 (s, 3H), 3.95 (s, 3H), 3.81 (q, J = 7.0 Hz, 6H), 3.22 (q, J = 6.6 Hz, 2H), 1.65 (m, 2H), 1.22 (t, J = 7.0 Hz, 9H), 0.64 (m, 2H); ^{13}C NMR (acetone-d_6) δ: 156.6, 154.7, 149.1, 140.5, 129.4, 110.9, 108.9, 63.3, 58.8, 56.6, 56.5, 44.2, 24.2, 18.6, 8.2; HRMS (CI): calcd. for $C_{19}H_{33}O_9N_2Si$ (M+1): 461.1955; found: 461.1941.

(2-Nitrobenzyl)-[3-(triethoxysilyl)-propyl]-amine (1b)

A solution of 3-aminopropyltriethoxysilane (**2**) (2.0 g; 9.0 mmol), 2-nitrobenzyl chloride (**4**) (0.77 g; 4.5 mmol) and triethylamine (1.5 mL; 18 mmol) in ethyl acetate was refluxed for 24 h in a flask under argon atmosphere and protected from light. The precipitate was removed by decantation and the supernatant evaporated in vacuo. The desired product (**1b**) was obtained (1.12 g; 70%) after purification by flash chromatography (hexanes/AcOEt/Et_3N 1:1:0.1). IR (NaCl) ν_{max}: 3360 (NH), 1605 (C=C), 1530 (NO_2), 1350 (NO_2), 1165 (SiO), 1110 (SiO), 1070 (SiO), 950 (SiO), 850 (SiO), and 780 (SiO) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.95 (dd, J = 1.1 and 8.1 Hz, 1H), 7.64 (dd, J = 1.6 and 7.7 Hz, 1H), 7.58 (ddd, J = 1.1, 7.2, and 7.7 Hz, 1H), 7.41 (ddd, J = 1.6, 7.2, and 8.1 Hz, 1H), 4.04 (s, 2H), 3.81 (q, J = 7.0 Hz, 6H), 2.64 (t, J = 7.1 Hz, 2H), 2.18 (br s, 1H), 1.63 (m, 2H), 1.22 (t, J = 7.0 Hz, 9H), 0.65 (m, 2H); ^{13}C NMR ($CDCl_3$) δ: 148.7, 135.5, 132.7, 130.8, 127.4, 124.3, 57.9, 51.9, 50.3, 22.9, 17.9, 7.5; LRMS (CI) *m/z*: 357 (M+1).

α,α-Dimethyl-3,5-dimethoxy-benzyl [*N*-(3-triethoxysilyl)-propyl]-carbamate (1c)

A solution of α,α-dimethyl-3,5-dimethoxybenzyloxycarbonyl-azide (**5**) (0.25 g; 0.94 mmol) in pyridine (2 mL) was added to a solution of 3-aminopropyltriethoxysilane (**2**) (0.31 g; 1.4 mmol) in pyridine (3 mL) and ethyl acetate (3 mL) and the resulting mixture was stirred at 40°C for 12 h. The precipitate was removed by decantation and the supernatant evaporated. Purification of the residue by flash chromatography (hexanes/AcOEt/Et_3N 1:1:0.1) gave the desired product as white crystals (0.30 g; 72%) with a melting point near room temperature. IR (NaCl) ν_{max}: 3370 (NH stretch), 1725 (C=O), 1600 (NH bending), 1150 (SiO), 1100 (SiO), 1085 (SiO), 9.50 (SiO), 8.35 (SiO), 8.15 (SiO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 6.51 (d, J = 2.2 Hz, 2H), 6.34 (t, J = 2.2 Hz, 1H), 4.94 (br q, 1H), 3.81 (q, J = 7.0 Hz, 6H), 3.78 (s, 6H), 3.10 (q, J = 6.5 Hz, 2H), 1.72 (s, 6H), 1.58 (m, 2H), 1.22 (t, J = 7.0 Hz, 9H), 0.61 (m, 2H); ^{13}C NMR ($CDCl_3$) δ: 160.2, 155.0, 149.2, 102.8, 98.0, 80.1, 58.3, 55.1, 43.0, 28.9, 23.2, 18.1, 7.5; HRMS (EI): calcd. for $C_{21}H_{37}O_7NSi$: 443.2339; found: 443.2318.

Ferrocenylmethylene-[3-(triethoxysilyl)-propyl]-amine (1d)

A mixture of ferrocenecarboxaldehyde (**6**) (0.5 g; 2.2 mmol), 3-aminopropyltriethoxysilane (**2**) (0.47 g; 1.9 mmol) and molecular sieves in dichloromethane (25 mL) was stirred for 24 h at room temperature and under argon atmosphere. The mixture was decanted and the supernatant evaporated in vacuo. Bulb-to-bulb distillation of the brown residue gave pure product (**1d**) (0.7 g; 80%). IR (NaCl) ν_{max}: 3090 (CH ferrocene), 1645 (C=N), 1160 (SiO), 1100 (SiO), 1070 (SiO), 950 (SiO), 810 (SiO), 780 (SiO), 720 (SiO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 8.10 (s, 1H), 4.62 (t, J = 1.8 Hz, 2H), 4.34 (t, J = 1.8 Hz, 2H), 4.17 (s, 5H), 3.82 (q, J = 7.0 Hz, 6H), 3.45 (t, J = 7.0 Hz, 2H), 1.77 (m, 2H), 1.22 (t, J = 7.0 Hz, 9H), 0.64 (m, 2H); ^{13}C NMR ($CDCl_3$) δ: 160.6, 80.2, 70.0, 68.9, 68.2, 64.4, 58.2, 24.1, 18.2, 7.9; LRMS (CI) m/z: 417 (M^+), 418 (M+1).

Ferrocenecarboxylic acid 3-(triethoxysilyl)-propylamide (1e)

A solution of carbonic acid ferrocenoyl ester isobutyl ester (**7**) (1.4 g; 4.2 mmol) and 3-aminopropyltriethoxysilane (**2**) (1.3 g; 6.6 mmol) in dichloromethane (15 mL) was refluxed for 1 h. The solvent was evaporated in vacuo and the residue purified by flash chromatography (hexanes/AcOEt/Et_3N 3:2:0.3) to give the desired product (**1e**) as orange needles (1.28 g; 70%): mp 68°C; IR (KBr) ν_{max}: 3300 (NH stretch), 3090 (CH ferrocene), 1620 (C=O), 1540 (NH bending), 1160 (SiO), 1100 (SiO), 1080 (SiO), 950 (SiO), 810 (SiO), 775 (SiO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 5.99 (br t, 1H), 4.66 (t, J = 1.9 Hz, 2H), 4.33 (t, J = 1.9 Hz, 2H), 4.20 (s, 5H), 3.85 (q, J = 7.0 Hz, 6H), 3.39 (br q, J = 6.6 Hz, 2H), 1.72 (m, 2H), 1.25 (t, J = 7.0 Hz, 9H), 0.71 (m, 2H); ^{13}C NMR ($CDCl_3$) δ: 169.9, 76.3, 70.0, 69.5, 67.8, 58.3, 41.6, 23.0, 18.1, 7.5; HRMS (FAB): calcd. for $C_{20}H_{31}NO_4FeSi$: 433.1372; found: 433.1360.

Carbonic acid ferrocenoyl ester isobutyl ester (7)

Isobutylchloroformate (0.71 g; 5.2 mmol) was added to a solution of ferrocene carboxylic acid (1.0 g; 4.3 mmol) and triethylamine (0.72 mL; 5.2 mmol) in toluene (15 mL) and the resulting mixture was stirred at 0°C for 2 h. The precipitate was removed by decantation and the supernatant evaporated in vacuo to give the desired product (**7**) (1.4 g; 98%). IR (NaCl) ν_{max}: 3110 (CH ferrocene), 1800 (C=O), 1740 (C=O), 1205 (C-O), 1075 (C-O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 4.87 (t, J = 2.0 Hz; 2H), 4.54 (t, J = 2.0 Hz, 2H), 4.32 (s, 5H), 4.11 (d, J = 6.7 Hz, 2H), 2.09 (nona., J = 6.7 Hz, 1H), 1.01 (d, J = 6.7 Hz, 6H); ^{13}C NMR ($CDCl_3$) δ: 166.4, 149.7, 75.2, 72.7, 70.8, 70.2, 67.5, 27.6, 18.7; HRMS (FAB): calcd. for $C_{16}H_{18}O_4Fe$: 330.0555; found: 330.0574.

Preparation and monolayer formation on ITO electrodes

Glass plates (14 in × 14 in) covered with a 1600 Å film of indium – tin oxide (ITO) were purchased from Applied Films Lab Inc. and cut into square pieces of 1 cm^2 area using a diamond cutter. Before derivatization, the surface of the ITO working electrodes was freed from greasy residue by immersion in hexane, followed by rinsing with methanol and distilled water and drying in an oven. The surface was then further cleaned by immersion in 1% aqueous HCl, followed by rinsing with distilled water and methanol and drying at 450°C for 30 min. The electrodes were then placed into a test tube under argon atmosphere containing the reaction solvent and sonicated for 5 min. The solvent was removed and 5 mL of a 2% solution of reagent **1a**, **1b**, **1c**, **1d**, **1e**, or **1f** in benzene or toluene was added with a cannula. After an appropriate reaction time (15 min – 24 h), the electrodes were removed, rinsed with the reaction solvent, and sonicated successively in benzene, dichloromethane, and acetonitrile to remove unbound species.

Irradiation of electrodes

The electrodes were inserted into Pyrex (350 nm) or quartz (254 nm) tubes containing acetonitrile, THF, methanol, or no solvent. The tubes were mounted on a merry-go-round MGR-100 so that the ITO coating of the electrodes was facing the light source and were irradiated for an appropriate time (5 min – 4 h) using a Rayonnet RPR-100 photochemical reactor equipped with 16 RPR-3500 (approximate output power of 24 W) or 16 RPR-2540 (approximate output power of 35 W) lamps with emission centered at 350 nm and 254 nm, respectively. The irradiated electrodes were removed, rinsed with solvent, and sonicated successively in acetonitrile, dichloromethane, and benzene to remove unbound species.

Subsequent functionalization of electrodes

The electrodes were placed into test tubes containing a 2% solution of carbonic acid ferrocenoyl ester isobutyl ester (**7**) in toluene, under argon atmosphere. After an appropriate reaction time (15 min – 24 h), the electrodes were removed, rinsed with benzene or toluene, and sonicated successively in benzene, dichloromethane, and acetonitrile.

Cyclic voltammetry of derivatized electrodes

The cyclic voltammograms of ferrocene bound to the surface of the electrodes were recorded using a EG&G potentiostat/galvanostat model 263 using 0.1 M tetrabutylammonium tetrafluoroborate in acetonitrile as support electrolyte, a platinum coil as counter electrode, and a silver wire (Aldrich™) or a SCE electrode (Fisher Scientific™) as reference electrode. Cyclic voltammograms were recorded using a 200 mV s^{-1} scan rate.

A photochemical retro-Friedel–Crafts alkylation. Rapid rearrangement of cyclohexadienyl cations

Earl MacKnight and Robert A. McClelland

Abstract: This paper reports the use of laser flash photolysis (LFP) techniques to show that cyclohexadienyl cations (σ complexes) of the Friedel–Crafts reaction of 1,3-dimethoxybenzene and the diphenylmethyl cation rearrange on the ns time scale without separating the aromatic compound and the electrophile. This is demonstrated through a study of the photochemical behaviour of 2-diphenylmethyl-1,3-dimethoxybenzene (**4**) in 1,1,1,3,3,3-hexafluoroisopropyl alcohol (HFIP). Derivatives of 1,3-dimethoxybenzene have previously been found to selectively protonate at C2 upon excitation in HFIP, and indeed the principal products with **4** are 1,3-dimethoxybenzene (**6**) and $Ph_2CHOCH(CF_3)_2$ (**7**), the species expected if the cyclohexadienyl cation formed in the C2 protonation cleaved Ph_2CH^+. These products are, however, accompanied by 4-diphenylmethyl-1,3-dimethoxybenzene (**8**), a rearranged isomer of **4**. A portion of this product is explained by the combination of Ph_2CH^+ and 1,3-dimethoxybenzene as the latter accumulates during the irradiation. However, 11.5% of **8** is also seen upon extrapolation to zero time. LFP experiments on the ps time scale reveal that the C2 protonated cation, the 1-diphenylmethyl-2,6-dimethoxybenzenium ion (**5**), is formed within 100–200 ps, and reacts with $k = 9 \times 10^8$ s^{-1}, with absorbance for Ph_2CH^+ growing in as **5** decays. LFP studies on the ns time scale reveal that there is a second quantity of Ph_2CH^+ that grows in, with $k = 5.0 \times 10^5$ s^{-1}. The precursor for this has been identified as the 1-diphenylmethyl-2,4-dimethoxybenzenium ion (**10**), the thermodynamically more stable isomer of **5**. A mechanistic model is proposed in which excited **4** is C2 protonated in HFIP with $k \geq 1 \times 10^{10}$ s^{-1} to form **5**, which loses Ph_2CH^+ with $k = 3 \times 10^8$ s^{-1} in competition with rearrangement to **10** with $k = 6 \times 10^8$ s^{-1}. The cation **10** serves as the second source of Ph_2CH^+, losing Ph_2CH^+ with $k = 4 \times 10^5$ s^{-1}; in competition **10** is deprotonated by HFIP to give **8** with $k = 8 \times 10^4$ s^{-1}. The 11.5% of the rearranged **8** that is observed at zero conversion is thus shown to come from an intramolecular pathway in which the key step is the migration of a diphenylmethyl group without separation: **4** → **4*** → **5** → **10** → **8**.

Key words: cyclohexadienyl, photoprotonation, Friedel–Crafts, diphenylmethyl, 1,3-dimethoxybenzene.

Résumé : Dans ce travail, on présente un rapport sur l'utilisation des techniques de photolyse éclair au laser (« LFP ») pour démontrer que les cations cyclohexadiényles (complexes σ), impliqués dans la réaction de Friedel–Crafts du 1,3-diméthoxybenzène avec le cation diphénylméthyle, se transposent à l'échelle de temps de la ns, sans qu'il se produise de séparation entre le composé aromatique et l'électrophile. Ce résultat a été démontré par le biais d'une étude du comportement photochimique du 2-diphénylméthyl-1,3-diméthoxybenzène (**4**) dans l'alcool 1,1,1,3,3,3-hexafluoroisopropylique (HFIP). Il a été démontré antérieurement que, par excitation dans le HFIP, les dérivés du 1,3-diméthoxybenzène se protonent sélectivement en C2; en fait, les produits principaux obtenus à partir du produit **4** sont les espèces 1,3-diméthoxybenzène (**6**) et $Ph_2CHOCH(CF_3)_2$ (**7**) auxquelles on peut s'attendre si le cation cyclohexadiényle qui se forme par protonation en C2 donne lieu à un clivage de PH_2CH^+. Toutefois, ces produits sont accompagnés par du 4-diphénylméthyl-1,3-diméthoxybenzène (**8**), un isomère de réarrangement du produit **4**. On peut expliquer une partie de ce produit par une combinaison de PH_2CH^+ avec du 1,3-diméthoxybenzène lorsque ce dernier s'accumule au cours de l'irradiation. Toutefois, une extrapolation au temps zéro suggère que 11,5% du produit se forme d'une autre façon. Des expériences de « LFP » réalisées à l'échelle de temps de la ps révèlent que le cation protoné en C2, l'ion 1-diphénylméthyl-2,6-diméthoxybenzénium (**5**), se forme en dedans de 100 à 200 ps et qu'il réagit avec une constante $k = 9 \times 10^8$ s^{-1}, alors que l'absorbance pour PH_2CH^+ augmente tandis que celle du composé **5** diminue. Les études de « LFP » à l'échelle de temps de la ns indiquent qu'une deuxième source de PH_2CH^+ fait croître sa quantité d'après la relation $k = 5.0 \times 10^5$ s^{-1}. On a identifié que le précurseur de cette deuxième source est l'ion 1-diphénylméthyl-2,4-diméthoxybenzénium (**10**), l'isomère thermodynamiquement plus stable du produit **5**. On propose un modèle mécanistique dans lequel, dans le HFIP, le composé **4** excité se protone en C2, avec $k \geq 1 \times 10^{10}$ s^{-1}, pour former du composé **5** qui perd du Ph_2CH^+ avec $k = 3 \times 10^8$ s^{-1} alors que cette perte est en compétition avec un réarrangement en composé **10** pour lequel $k = 6 \times 10^8$ s^{-1}. Le cation **10** sert de deuxième source de Ph_2CH^+, qu'il perd avec $k = 4 \times 10^5$ s^{-1}; au cours d'une réaction compétitive, **10** est déprotoné par HFIP pour conduire au produit **8**, avec $k = 8 \times 10^4$ s^{-1}. On démontre donc que le 11,5% de produit de réarrangement

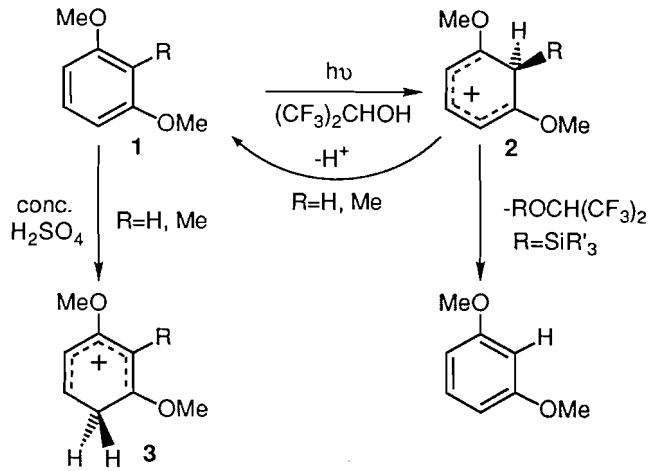
Introduction

The singlet excited states of simple aromatic compounds like benzene and anisole are more basic than the ground state. This enhanced basicity is predicted by Forster-cycle calculations (1, 2) and demonstrated experimentally by the acid quenching of the fluorescence of aromatic compounds, often accompanied by H–D isotope exchange (3–6). This observation of exchange points to a fully protonated intermediate on the reaction pathway — a cyclohexadienyl cation that can lose the proton that was originally attached to the aromatic ring. The presence of such intermediates has recently been conclusively demonstrated through their direct observation with laser flash photolysis (LFP), following irradiation of some relatively electron-rich aromatic compounds in 1,1,1,3,3,3-hexafluoroisopropyl alcohol (HFIP) (7–10) (and in one case 2,2,2-trifluoroethanol (11)). The solvent HFIP has two features that prove especially useful for such LFP experiments. The OH group of this solvent is sufficiently acidic for the excited state protonation to occur with reasonable quantum efficiency without the need for an added stronger acid. At the same time, HFIP is significantly less reactive as a base or a nucleophile when compared to more commonly used solvents such as water and ethanol. Thus transient cations are much longer lived in HFIP.

Excited state protonations often occur with a regioselectivity different from that in the ground state. 1,3-dimethoxybenzene (and derivatives) is a notable example of such behaviour. Irradiation of this compound in HFIP results in selective protonation at C2 resulting in the 2,6-dimethoxybenzenium ion (see Scheme 1, compound **2** with R = H). The regiochemistry here was demonstrated by experiments with deuterated solvent ($(CF_3)_2CHOD$), which showed isotope exchange at C2 of the 1,3-dimethoxybenzene (8). The cation was readily observed with LFP as a relativly long-lived intermediate with a lifetime in HFIP of 0.5 ms (8). Exchange at C2 (accompanied by a small amount of exchange at C5) was also observed upon irradiation in aqueous acids (12). The intermediate cation, however, cannot be detected with ns LFP in these solutions because its lifetime is too short.

In the ground state, protonation occurs selectively at C4 to give the 2,4-dimethoxybenzenium ion (**3**), under conditions of both kinetic control (13) and thermodynamic control (14). The experiments under thermodynamic conditions were carried out in concentrated H_2SO_4 where 1,3-dimethoxybenzene is 100% protonated. The structure of the cation so formed is conclusively demonstrated to be **3** from the characteristic pattern in the ^1H NMR spectrum (8, 14). NMR signals that would correspond to the isomeric **2** are not observed in this experiment, and an estimate of the upper limit for detection suggests that the ratio **3**:**2** must be greater than 20 (8). The different behaviour of the ground state and the excited state is consistent with molecular orbital calculations that show that there is a shift in electron density from C4 to C2 of the aromatic ring upon pro-

Scheme 1.



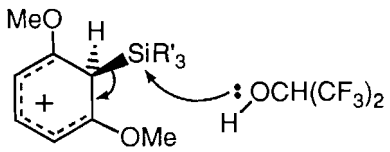
motion of an electron from the HOMO to the LUMO of 1,3-dimethoxybenzene (8, 12, 15).

An important feature from the point of view of the present work is the different UV–visible absorption spectra of the 2,4- and 2,6-dimethoxybenzenium ions **2** and **3**. The 2,4 isomer formed in concentrated acid has a λ_{max} at 315 nm, while the 2,6 isomer observed with LFP in HFIP absorbs almost 100 nm to longer wavelength, at 410 nm (8). Examples of carbocations that have been observed in both strong acids and HFIP — the diphenylmethyl cation (16), the cumyl cation (17), and the 2,4,6-trimethylbenzenium ion (7) — have shown that there is very little dependence of λ_{max} on solvent, at most a 10 nm shift. Thus the difference between the 2,4- and 2,6-dimethoxybenzenium ions is not a solvent effect, but represents an intrinsic difference in the spectra of these two cations.

With 1,3-dimethoxybenzene itself, irradiation in HFIP results in no net photochemistry, other than the proton exchange mentioned above. The 2-methyl derivative cannot undergo this exchange, and shows no photochemical reaction whatsoever (8). This compound, however, still exhibits a strong signal in the LFP experiment in HFIP for the appropriate cyclohexadienyl cation, the 1-methyl-2,6-dimethoxybenzenium ion. Thus a proton does add at C2 upon irradiation in HFIP, but the only fate of the intermediate cation is loss of that same proton.

Derivatives bearing silyl groups (R'_3Si) at C2 do, however, show interesting photochemistry, cleaving the silyl group to form the parent 1,3-dimethoxybenzene and the ether $R'_3SiOCH(CF_3)_2$ upon irradiation in HFIP (9). This reaction involves an initial photoprotonation at C2 to form the intermediate cyclohexadienyl cation (**2**, R = SiR'_3), as demonstrated by the observation of this cation with LFP. The overall photoreaction therefore is a photochemically initiated protodesilylation, the analog of ground state protodesilylations that occur under moderately acidic conditions (18). The intermediate is a

β-silyl-substituted carbocation, and this study represented the first time that such a cation had been observed with LFP (see also ref. 19). Kinetic analysis showed that the cation preferentially cleaved the silyl group over loss of a proton. Moreover, the desilylation was shown to be associative, with solvent (and other nucleophiles) assisting in the cleavage of the C—Si bond.

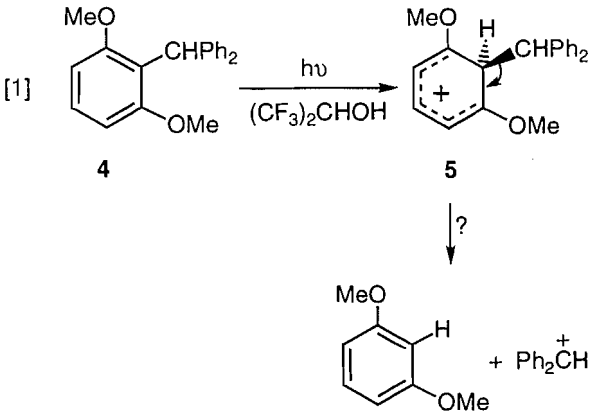


In this paper, we examine the photochemical behavior of 2-diphenylmethyl-1,3-dimethoxybenzene (**4**) in HFIP. We prepared this compound on the expectation that photoprotonation at C2 would lead to the cyclohexadienyl cation **5**, and this would then undergo a dissociative cleavage of the diphenylmethyl cation in competition with deprotonation back to starting material. Such cleavage, if it were to occur, would correspond to the reverse of the step in a Friedel–Crafts alkylation that forms the cyclohexadienyl cation. This cleavage does occur, but to our surprise is accompanied by rearrangement to an isomeric 2,4-dimethoxybenzenium ion. This rearrangement occurs very rapidly, but can be observed with ps LFP. This represents the first example of a system where rearrangement involving two isomeric cyclohexadienyl cations has been observed with LFP. We will also speculate on the possibility that a π-complex is an intermediate in both the cleavage and rearrangement pathways.

Results and discussion

Products

Solutions of the compound **4** in HFIP were irradiated at 254 nm in a Rayonet reactor, and the products were analyzed quantitatively by gas chromatography. Authentic samples were available for comparison and standardization. Three products were obtained: 1,3-dimethoxybenzene (**6**), the ether $Ph_2CHOCH(CF_3)_2$ (**7**), and 4-diphenylmethyl-1,3-dimethoxybenzene (**8**), an isomer of the starting material. The compounds **6** and **7** are consistent with the cleavage of eq. [1], with the ether obviously arising from solvent capture of Ph_2CH^+. As is also consistent with this interpretation, the yields of **6** and **7** were the same, within experimental error, at all irradiation times. As shown in Fig. 1, however, the yield of the rearrangement product **8** increased with increased irradiation time. This was accompanied by a corresponding decrease in the yields of **6** and **7**.

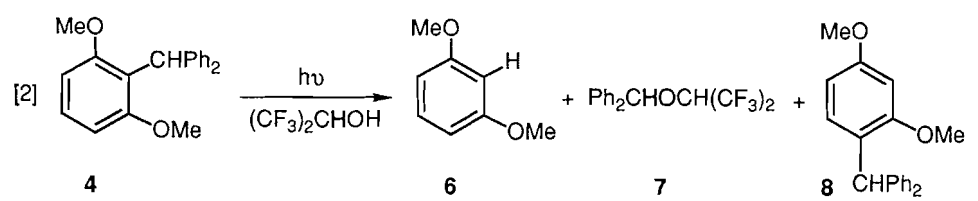


To investigate the origin of this dependence, we first irradiated an equimolar mixture of the products **6** and **7** (0.2 mM in HFIP) for the time corresponding to 25% conversion in Fig. 1. This, however, resulted in no formation of **8**, in fact no change at all. The product **8** was also found to be stable under these same conditions. Thus further photochemistry of the products can be ruled out. 1,3-dimethoxybenzene, and presumably **8**, do absorb the irradiating light, but undergo the reversible C2-photoprotonation, as discussed in the introduction, and there is no overall transformation.

We then carried out two experiments with the same initial concentration of **4** as in Fig. 1 but with 1 mM and 5 mM 1,3-dimethoxybenzene present from the beginning of the irradiation. In each case there was little dependence of product yields on the time of irradiation up to 20% conversion, and **8** had become the major product, 80 ± 3% for 1 mM **6** and 97 ± 2% for 5 mM.

These experiments suggested that the excess 1,3-dimethoxybenzene was reacting with the diphenylmethyl cation forming in the photocleavage, resulting in the high yields of **8**. To investigate this possibility, diphenylmethyl chloride (0.2 mM) was solvolyzed in HFIP in the presence of 5 mM 1,3-dimethoxybenzene (and 0.5 mM triethylamine to remove HCl). This gave a similar result as in the experiment above with 5 mM 1,3-dimethoxybenzene, a 5 ± 1% yield of **7** and 95 ± 2% of **8**. Also noteworthy was that none (less than 0.1%) of the isomer **4** was obtained.

This solvolysis experiment clearly establishes that 1,3-dimethoxybenzene can effectively compete with HFIP for Ph_2CH^+. This result is not surprising in light of similar studies involving the 9-fluorenyl cation in HFIP that also showed efficient trapping by added aromatic compounds, especially electron-rich ones (20, 21). The solvolysis also establishes that the product that forms from 1,3-dimethoxybenzene and Ph_2CH^+ is the 4-substituted isomer **8**, and there is less than 0.1% of the 2-substituted isomer **4**.



Scheme 2.

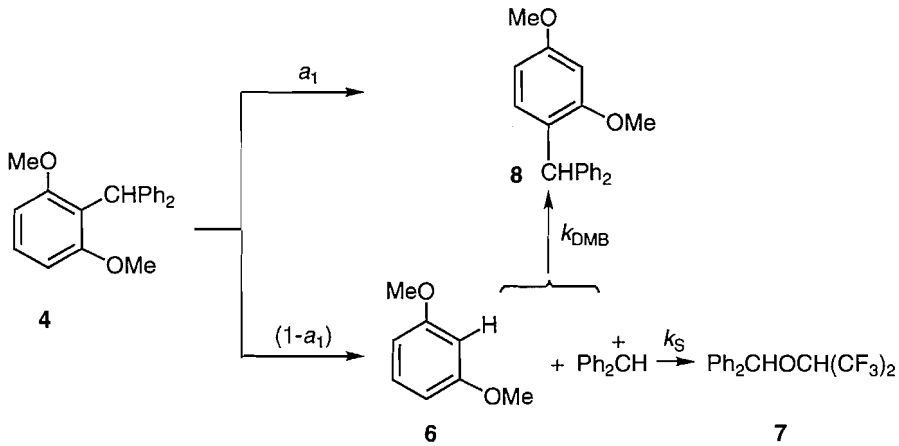


Fig. 1. % Yield of 4-diphenylmethyl-1,3-dimethoxybenzene (**8**) as a function of the % conversion of 2-diphenylmethyl-1,3-dimethoxybenzene (**4**) following irradiation at 254 nm in 1,1,1,3,3,3-hexafluoroisopropyl alcohol. The yields of **8** were based on the total "1,3-dimethoxybenzene" content of the products — $100 \times [\mathbf{8}]:([\mathbf{6}] + [\mathbf{8}])$. The initial concentration of **4** was 8.0×10^{-4} M. The points are experimental; the line has been drawn based upon a kinetic analysis (see text).

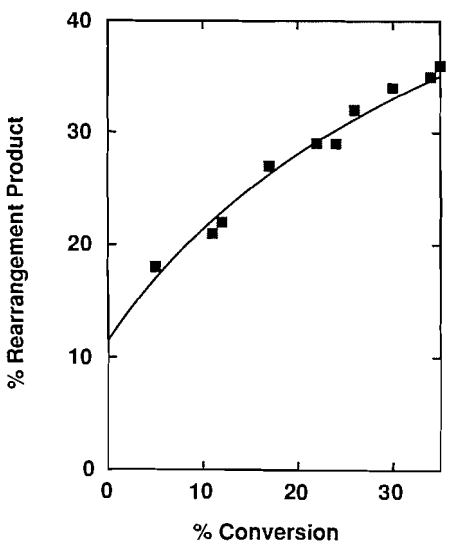


Intermolecular pathway for 4-diphenyl-1,3-dimethoxybenzene

An explanation is now available for the yield dependence when **4** is irradiated alone. In this case, as the reaction proceeds, the diphenylmethyl cation encounters increasing amounts of 1,3-dimethoxybenzene, and is thus more effectively diverted to the product **8** away from the ether **7** derived from solvent trapping.

This situation can be analyzed quantitatively in terms of the model of Scheme 2. In this analysis we define a quantity a_1 that represents the fraction of the precursor **4** that is directly converted to **8** upon irradiation, with $(1 - a_1)$ the fraction that cleaves to 1,3-dimethoxybenzene and the diphenylmethyl cation. A second fraction a_2 is also required, as defined in eq. [3].

$$[3] \quad a_2 = \frac{\left(\frac{k_{DMB}}{k_s}\right)[\mathbf{6}]}{1 + \left(\frac{k_{DMB}}{k_s}\right)[\mathbf{6}]}$$

In this expression k_{DMB} is the second-order rate constant for the reaction of Ph_2CH^+ and 1,3-dimethoxybenzene to form **8**, and k_s is the first-order rate constant for the reaction of the cation with the solvent HFIP. The quantity a_2 represents the fraction of Ph_2CH^+ that reacts at a particular concentration of 1,3-dimethoxybenzene to give **8**; $(1 - a_2)$ is the fraction that proceeds to the ether.

We now define the concentrations of the reagent and the three products at some intermediate stage of the reaction as $[\mathbf{4}]_t$, $[\mathbf{6}]_t$, $[\mathbf{7}]_t$, and $[\mathbf{8}]_t$. If irradiation is carried out for a very short time Δt, so that the concentration of **4** is decreased by a small increment Δ, then the new concentrations are:

$$[\mathbf{4}]_{t+\Delta t} = [\mathbf{4}]_t - \Delta$$
$$[\mathbf{6}]_{t+\Delta t} = [\mathbf{6}]_t + (1 - a_1)\Delta - (1 - a_1)(a_2)\Delta$$
$$= [\mathbf{6}]_t + (1 - a_1)(1 - a_2)\Delta$$
$$[\mathbf{7}]_{t+\Delta t} = [\mathbf{7}]_t + (1 - a_1)(1 - a_2)\Delta$$
$$[\mathbf{8}]_{t+\Delta t} = [\mathbf{8}]_t + a_1\Delta + (1 - a_1)a_2\Delta$$

In the expression for **6**, $(1 - a_1)\Delta$ represents the quantity of **6** that forms during Δt because of the initial cleavage pathway. The same amount $(1 - a_1)\Delta$ of Ph_2CH^+ is also formed, and this accounts for loss of a quantity of **6** equal to $(1 - a_1)a_2\Delta$ because of the reaction forming **8**. This same expression also appears with a positive sign in the equation for **8**, along with the quantity $a_1\Delta$, which represents the amount that forms directly from **4**. Starting at $t = 0$ with initial concentrations $[\mathbf{4}]_0 = [\mathbf{4}]_{initial}$, and $[\mathbf{6}]_0 = 0 = [\mathbf{7}]_0 = [\mathbf{8}]_0$, the concentrations of the three products can be calculated as a function of % conversion through a computer simulation involving a large number of calculations using such small incremental steps. Although the concentration of **6** and the value of the fraction a_2 do change with conversion, the assumption is made that within each increment the changes are so small that these quantities are effectively constant. Our calculations were carried out with $\Delta = 1 \times 10^{-10}$ to ensure that this was the case.

There are two variables in this treatment, the fraction a_1 and

the rate constant ratio $k_{DMB}:k_s$, and we varied these in an iterative procedure until we found the best least-squares fit to the experimental data. This occurred with $a_1 = 0.115$, and $k_{DMB}:k_s = 4.0 \times 10^3\ M^{-1}$. The line drawn in Fig. 1 is based on the incremental computer simulation employing these numbers, and shows the excellent fit of the experimental data to the model. These values of a_1 and $k_{DMB}:k_s$ are also consistent with the results of the experiments carried out with 1,3-dimethoxybenzene present from the beginning. These predict yields of **8** of 82.3% and 95.8% for concentrations of 1 mM and 5 mM 1,3-dimethoxybenzene, respectively, in good agreement with the experimental numbers.

Intramolecular pathway for 4-diphenyl-1,3-dimethoxybenzene

The above analysis requires a finite value for a_1, the parameter representing a pathway that converts **4** directly into **8**. This number expressed as a percentage is also seen as the intercept in the plot of % yield of **8** versus % conversion (Fig. 1); i.e., it is the yield of **8** at zero conversion. This quantity of **8** cannot arise from a mechanism in which a diphenylmethyl cation separates away from 1,3-dimethoxybenzene, and the two later recombine. Under the conditions of very low conversion where the concentration of 1,3-dimethoxybenzene is negligibly small, any Ph_2CH^+ that forms as a free cation must be trapped by solvent.

Consequently, we speculated that the 11.5% of **8** observed at zero conversion was coming from an intramolecular rearrangement, in which the diphenylmethyl group remains attached to its original 1,3-dimethoxybenzene, and the two never separate.

Effect of ethanol

Support for this interpretation was seen in experiments with small concentrations of ethanol added to the solution. If free Ph_2CH^+ were responsible for all of the **8** that formed, the yield of **8** would be expected to decrease because of the additional channel involving reaction with ethanol. Indeed, significant amounts of the ether $Ph_2CHOCH_2CH_3$ were observed in place of the ether **7**. At the same time, however, the yield of **8** actually increased, for example, from a value of 21% at 10% conversion in the absence of ethanol to 36% for the same conversion with 10 mM of ethanol present. The origin of this increase will be discussed later, but it is clearly inconsistent with mechanisms where only Ph_2CH^+ is formed from the initial reaction of **4**.

There is one further important observation involving ethanol, namely that irradiation of **4** in the pure solvent resulted in absolutely no change over an extended period of time. The cleavage products and the fraction of **8** that is due to the intermolecular pathway clearly require photoprotonation, and thus it is not surprising that they are not formed in the weakly acidic ethanol. The failure to observe the intramolecular pathway also implies that this is initiated by photoprotonation.

Nanosecond laser flash photolysis

The most compelling arguments for the occurrence of an intramolecular rearrangement of **4** to **8**, as well as evidence for how this occurs, comes from LFP studies. We start with such studies carried out on the ns time scale, i.e., where transients are observed at the earliest 20 ns after the initiation of the laser pulse. As shown in Fig. 2, two bands are observed at this time, a relatively strong signal with λ_{max} near 440 nm and a weaker signal centered around 340 nm. The 340 nm signal decays, and at the same time there is a further increase in absorbance at the longer wavelengths. These changes occur with identical rate constants ($5.0 \times 10^5\ s^{-1}$), suggesting that they represent a common process. At the end of these changes there is a single strong signal at 440 nm. This eventually does decay, with a rate constant around $10^2\ s^{-1}$ although, because the reaction is so slow, the rate constant is difficult to accurately measure.

The final signal can be clearly identified as the diphenylmethyl cation, since the same spectrum is observed for solutions of this cation obtained under stable ion conditions (16). Moreover, a transient with the identical spectrum and a similar rate constant of decay is obtained on photolyzing diphenylmethyl 4-cyanophenyl ether (**9**) in HFIP. This ether has previously been shown to be a good photochemical precursor for Ph_2CH^+, the cation being generated in a photoheterolysis reaction (22, 23).

Initially we had thought that the initial signal above 400 nm must represent the 2,6-dimethoxybenzenium ion **5**. However, the λ_{max} is slightly longer than those previously observed for this type of cation (8). More importantly, overlaying the spectrum immediately after the laser pulse with the one after 10 microseconds shows that the two exactly superimpose in the region above 400 nm. This is shown in Fig. 3 and suggests that the absorbance at 440 nm immediately after the 20 ns laser pulse is also due to Ph_2CH^+.

Picosecond laser flash photolysis

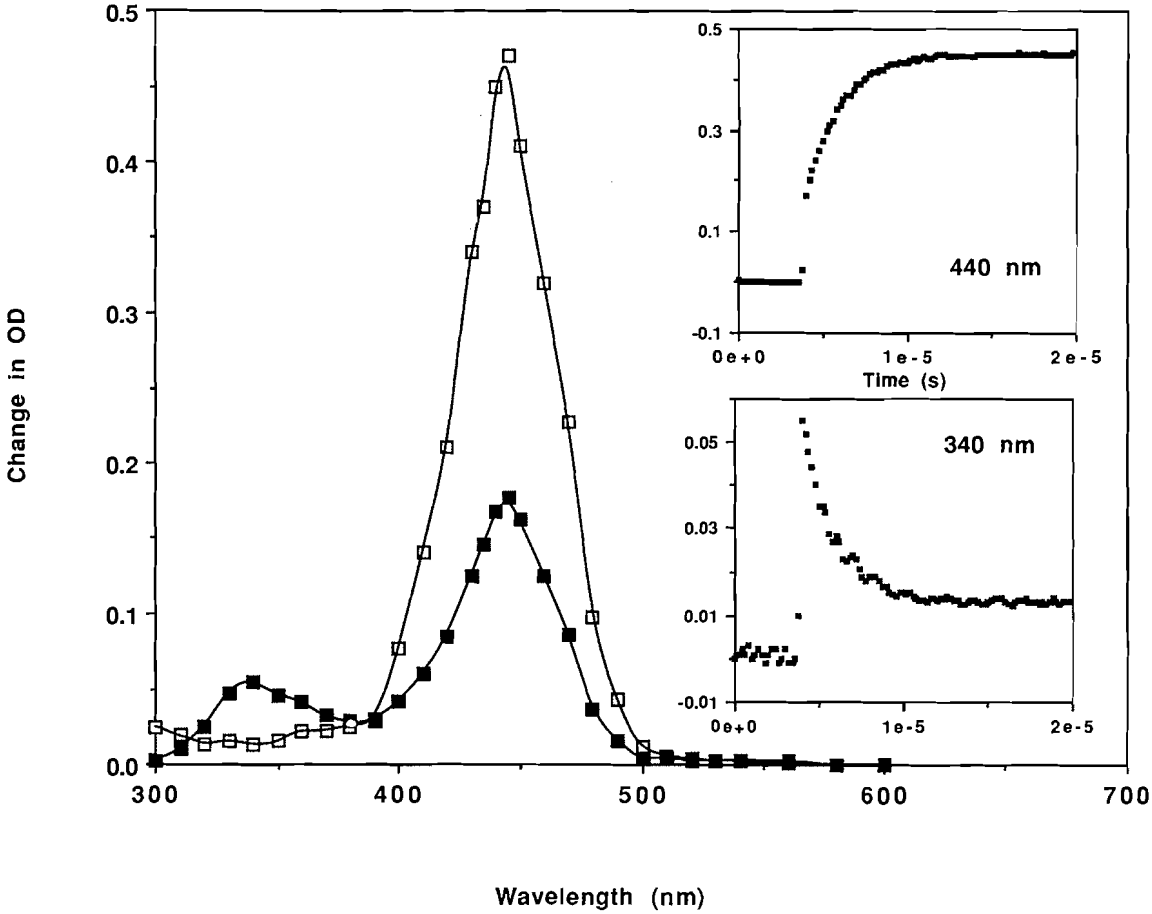
We then turned to a faster time resolution to investigate the possibility that there was a process forming Ph_2CH^+ that had been missed on the ns time scale, and indeed found that this was the case. As shown in Fig. 4, optical density appears above 400 nm even at times as short as 100–200 ps. This has λ_{max} in the region 410–420 nm typical of 2,6-dimethoxybenzenium ions and it is therefore this species that is most reasonably assigned to the cation **5**. There is, however, a rapid change with a rate constant equal to $(9 \pm 1.5) \times 10^8\ s^{-1}$ (Fig. 5), where the λ_{max} shifts to longer wavelengths and the absorbance becomes slightly more intense. The spectrum at the end of this change corresponds to that of Ph_2CH^+; this is the "initial" absorbance above 400 nm in the ns LFP experiment.

Fast and slow processes forming the diphenylmethyl cation

The LFP experiments show that there are two separate processes that form diphenylmethyl cation following irradiation

[4] 
9

Fig. 2. Transient absorption spectra for 248 nm irradiation of 2-diphenylmethyl-1,3-dimethoxybenzene (**4**) in 1,1,1,3,3,3-hexafluoroisopropyl alcohol obtained 50–100 nanoseconds (■) and 9.5–10 microseconds (□) after the laser pulse. The inserts show the kinetic traces at the two selected wavelengths.



of **4** in HFIP, one that occurs on the ps time scale and one that occurs on the ns time scale. The ps study also suggests that the initial photochemical event is C2 protonation by the solvent, producing a 2,6-dimethoxybenzenium ion. This is the result with other 1,3-dimethoxybenzene derivatives (8–10), but the difference with the diphenylmethyl system is that this cyclohexadienyl cation is much less stable. One of its reactions is fragmentation to Ph_2CH^+, and it is this reaction that is observed on the ps time scale. The ns study, however, shows that there is a second growth of Ph_2CH^+. The precursor here must be the 340 nm transient, since this decays at the same rate as the second fraction of Ph_2CH^+ appears. The identity of the 340 nm transient has not yet been discussed, but based on all the evidence the most likely structure is the 1-diphenylmethyl-2,4-dimethoxybenzenium ion (**10**). This cyclohexadienyl cation is obviously also capable of cleavage to Ph_2CH^+, and at the same time its deprotonation provides a route to the product **8**. Moreover, its UV–visible spectrum with a λ_{max} near 340 nm is consistent with a 2,4-dimethoxybenzenium structure, as discussed in the introduction.

Scheme 3 can now be proposed to account for the various experimental observations. Inherent in this model is the assumption that the very fast reaction of the initially formed **5** involves both cleavage and rearrangement. Since the ps apparatus could only monitor above 400 nm, only the cleavage pathway was visible through the formation of Ph_2CH^+. We propose, however, that the cation **10** is also formed in this process. Such a rapid rearrangement followed by deprotonation is consistent with the intramolecular photoisomerization, and also provides a mechanism that converts **4** to **8** without releasing a free diphenylmethyl cation (eq. [5]).

[5] $\mathbf{4} \rightarrow \mathbf{4}^* \rightarrow \mathbf{5} \rightarrow \mathbf{10} \rightarrow \mathbf{8}$.

Also explained is the effect of the addition of a small amount of ethanol. Being more basic than the solvent, the ethanol will increase the overall rate of deprotonation of the cation **10**, but will have no effect on the fragmentation to Ph_2CH^+. This has the effect of increasing the yield of **8** that is formed in the intramolecular process, as observed experimentally.

Quantitative analysis

Scheme 3 also provides rate constants for the various processes. These have been obtained as follows.

The rate constant k_1 refers to the protonation of excited **4**, presumably a singlet, by the solvent. The observation of the cation **5** at very short times in the ps LFP experiment implies that this is a very fast protonation. We estimate a lower limit of 1×10^{10} s^{-1}; anything that was slower would have been observed in the kinetic traces.

Scheme 3.

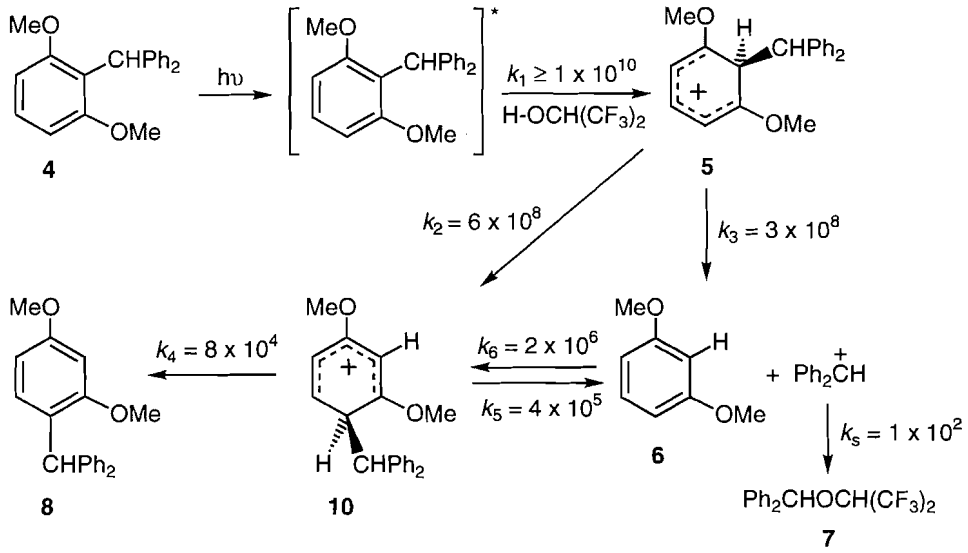


Fig. 3. Overlay of the transient absorption spectra for 2-diphenylmethyl-1,3-dimethoxybenzene in HFIP. The spectrum at 9.5–10 microseconds (□) has been plotted as is. The spectrum at 50–100 nanoseconds (■) has been plotted by multiplying the optical density change by 2.65.

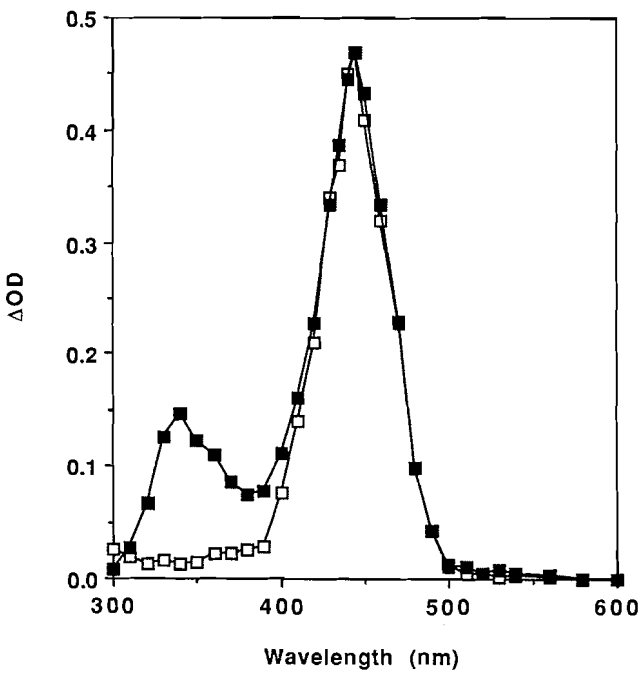

Fig. 4. Transient absorption spectra for 266 nm irradiation of 2-diphenylmethyl-1,3-dimethoxybenzene (**4**) in 1,1,1,3,3,3-hexafluoroisopropyl alcohol obtained at 200 picoseconds and 5000 picoseconds.

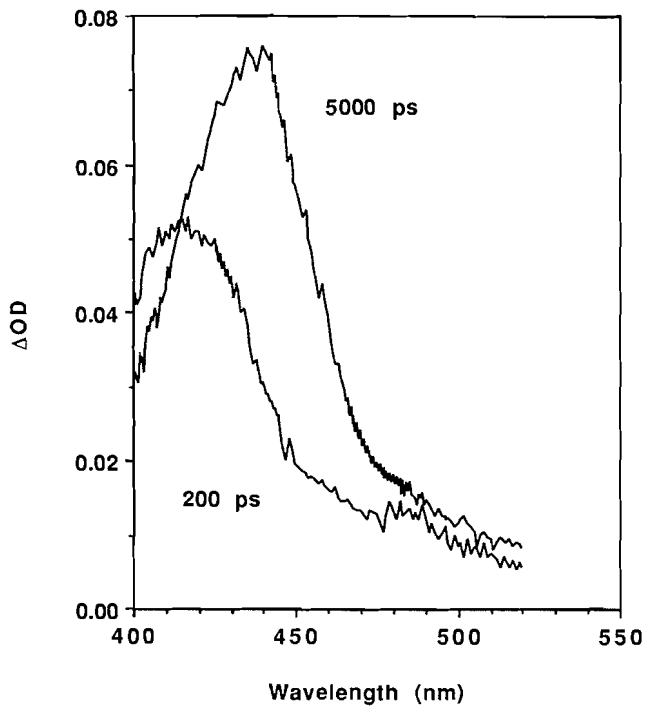

The rate constants k_2 through k_5 are obtained by solving a system of four equations (eqs. [6]–[9]). Equations [6] and [7] refer to the exponential rate constants obtained in the ps and ns LFP studies. The faster of these is the sum of the rearrangement and cleavage processes of **5**; the slower is the sum of the deprotonation and cleavage pathways of **10**. Equation [8] is the expression for the ratio of the amounts of diphenylmethyl cation that are formed in the fast and slow processes. The experimental number has been obtained from the ns LFP study, using the optical density at 440 nm immediately after the completion of the 20 ns laser pulse for the amount that has formed in the ps time range, and the additional optical density that then grows in as the amount formed in the ns time range. The ratio of eq. [9] refers to the total amount of 1,3-dimethoxybenzene (or Ph_2CH^+) relative to the rearrangement product, neglecting any intermolecular recombination. The experimental number is determined from the zero intercept in Fig. 1, the yield of the rearrangement product arising from the intramo-

Scheme 4.

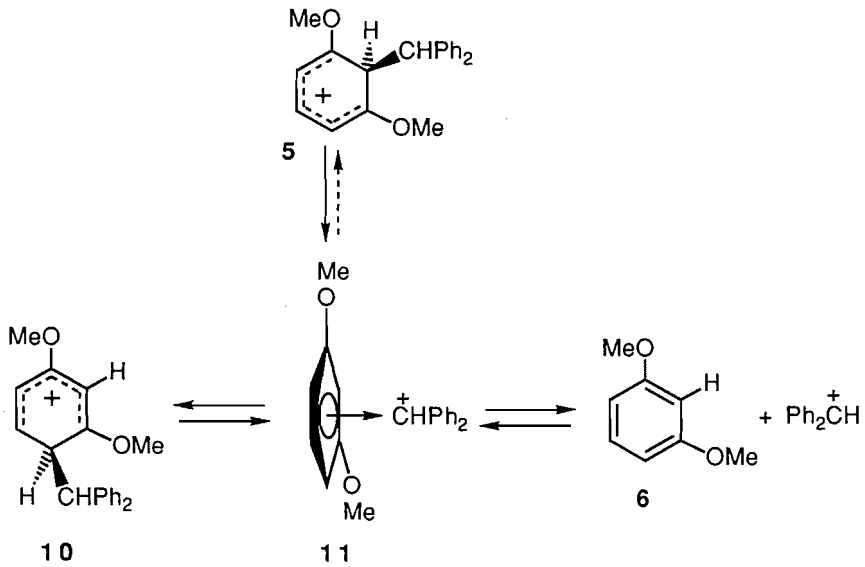

Fig. 5. Increase in 440 nm absorbance on the picosecond time scale following 265 nm irradiation of 2-diphenylmethyl-1,3-dimethoxybenzene (**4**) in 1,1,1,3,3,3-hexafluoroisopropyl alcohol.

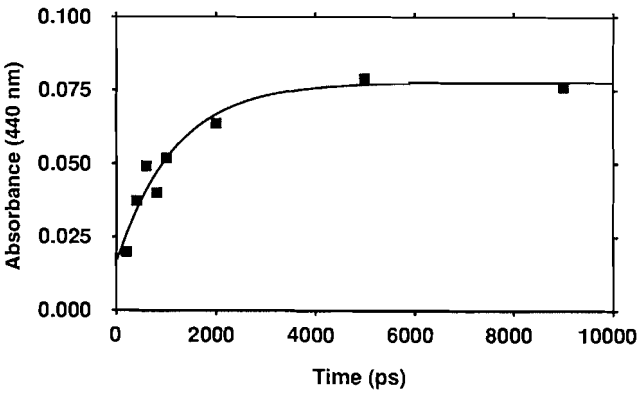

lecular pathway. Equations [8] and [9] are sufficient to provide the partitioning ratios, $k_2:k_3 = 2.0$ and $k_4:k_5 = 0.20$. Substitution of these into eqs. [6] and [7] gives the absolute rate constants.

[6] $k_{ps} = 9 \times 10^8\ s^{-1} = k_2 + k_3$

[7] $k_{ns} = 5.0 \times 10^5\ s^{-1} = k_4 + k_5$

$$[8]\quad \frac{\Delta OD(Ph_2CH^+)_{ps}}{\Delta OD(Ph_2CH^+)_{ns}} = 0.6 = \frac{\left(\left(\frac{k_4}{k_5}\right) + 1\right)}{\left(\frac{k_2}{k_3}\right)}$$

$$[9]\quad \left(\frac{[6]}{[8]}\right)_{\text{zero time}} = \frac{0.885}{0.115} = \frac{\left(\left(\frac{k_2}{k_3}\right) + \left(\frac{k_4}{k_5}\right) + 1\right)}{\left(\frac{k_2}{k_3}\right)\left(\frac{k_4}{k_5}\right)}$$

The constant k_s refers to the reaction of Ph_2CH^+ with HFIP to form **7**. With an absolute value of k_s available, k_{DMB} is then calculated as $4 \times 10^5\ M^{-1}\ s^{-1}$ using the ratio $k_{DMB}:k_S$ obtained in the analysis of Fig. 1. The constant k_{DMB} refers to the overall formation of **8** from 1,3-dimethoxybenzene and Ph_2CH^+, and is equal to $k_6k_4:(k_4 + k_5)$. Since the ratio $k_4:k_5$ is known, the absolute value of k_6 can be obtained. It should be noted that k_s is not well determined, so that any error in that constant will carry over to k_{DMB} and k_6.

An interesting outcome of these calculations is the ratio $k_4:k_5$, which is calculated to be 0.2. This means that in the Friedel–Crafts reaction of 1,3-dimethoxybenzene and Ph_2CH^+ in the solvent HFIP, the formation of the cyclohexadienyl cation **10** is almost reversible, and the rate-limiting step is the deprotonation of the cation. This of course partly reflects the weak basicity of the base doing the deprotonation, and the situation could obviously change if there were stronger bases present.

Mechanism of rearrangement

Perhaps the most interesting feature of these results is the very rapid rate at which the original cyclohexadienyl cation rearranges to its isomer. This is undoubtedly driven by thermodynamics. As discussed in the introduction, the parent 2,4-dimethoxybenzenium ion is thermodynamically more stable than the 2,6 isomer. Because of the bulky Ph_2CH group this should be even more the case with the cations of this study.

One possible mechanism is given in Scheme 4, in which the 2,6-dimethoxybenzenium ion loses Ph_2CH^+ resulting initially in an ion–molecule complex, written in Scheme 4 as the π-complex **11**. This same complex can serve as an intermediate in the interconversion of the 2,4-dimethoxybenzenium ion **10** and 1,3-dimethoxybenzene plus Ph_2CH^+. In the case where it forms from **5**, the complex has the choice of separating Ph_2CH^+ or of collapsing at the 4-position of the 1,3-dimethoxybenzene. The kinetic analysis presented in Scheme 3 suggests that these occur in a 1:2 ratio, respectively. From the failure to detect **4** as a product of the reaction of 1,3-di-

methoxybenzene and Ph_2CH^+ it would also appear as if the complex shows little propensity for collapse at the 2-position to form **5.**

This situation, where a complex collapses to a cyclohexadienyl cation faster than it separates into the aromatic compound and the electrophile, and with high regioselectivity, has previously been suggested as the explanation for very fast nitrations that show little intermolecular selectivity but high intramolecular selectivity (24). The suggestion in this case was that the rate-limiting step is the formation of a complex between NO_2^+ and the aromatic, followed by a rapid and selective collapse to the cyclohexadienyl cation. By demonstrating that σ-complexes can interconvert without separating the electrophile, the present study offers support for such a mechanism.

Experimental section

Flash photolysis experiments were carried out in the standard fashion with ca. 20 ns pulses at 248 nm (ca. 60 mJ per pulse) from a Lumonics excimer laser (KrF emission) and with ca. 25 ps pulses at 266 nm (ca. 4 mJ per pulse) from a Continuum YG-601-C Nd/YAG laser (25). Product analyses were carried out with a Varian 3400 gas chromatograph equipped with a FID detector, using ultra-high-purity helium as the carrier gas. The analyses were performed using a J + W Scientific Inc. Megabore DB1 30 m column with a film thickness of 1.5 μm. The apparatus was calibrated by determining response factors with authentic samples of the products. The identity of the products observed with GC was established by comparison of retention times and by the match in the mass spectra obtained by GC/MS analysis. The steady state photolyses were carried out using a Rayonet photochemical reactor equipped with medium-pressure mercury lamps operating at 254 nm. After various times of irradiation the solutions were directly injected into the GC for quantitative analysis.

The solvent 1,1,1,3,3,3-hexafluoroisopropyl alcohol (Aldrich) was distilled over sodium carbonate, followed by storage over 3A molecular sieves. On the day of use, the solvent was distilled again under an atmosphere of argon over fresh molecular sieves.

2-Diphenylmethyl-1,3-dimethoxybenzene (4)

1,3-Dimethoxybenzene (10 g, 72 mmol) was converted to its 2-lithio derivative (26) by dissolving in 100 mL of dry diethyl ether, adding 30 mL of 2.5 M butyllithium (75 mmol) in hexanes and stirring at room temperature under argon for 40 h. Benzophenone (12.7 g, 70 mmol) dissolved in 50 mL of dry ether was added, and the solution stirred at room temperature for a further 2 days. Standard work-up provided 18 g of 2,6-dimethoxyphenyldiphenylmethanol: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.39 (s, 6H), 6.34 (s, 1H, OH), 6.61 (d, 2H, J = 8.3 Hz), 7.20–7.30 (m, 11H).

The crude alcohol (3 g, 9.4 mmol) was partially dissolved in 190 mL of 95% ethanol, 1 g of 10% palladium on carbon was added, and the mixture was shaken for 2 days under 60 psi (1 psi = 6.9 kPa) of hydrogen. The reaction mixture was shaken with Celite and filtered, followed by removal of the solvent to give a white solid. This was chromatographed using 50:50 hexane:dichloromethane followed by recrystallization from ethanol:water to give 1.7 g (60%) of white needles of 2-diphenylmethyl-1,3-dimethoxybenzene (**4**), mp 91–92°C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.60 (s, 6H), 6.16 (s, 1H), 6.57 (d, 2H, J = 8.3 Hz), 7.12–7.28 (m, 11H). ^{13}C NMR (200 MHz, $CDCl_3$) δ: 45.5, 55.7, 105.1, 121.0, 125.4, 127.5, 128.0, 129.1, 143.8, 158.5. MS (EI) *m/z*: 304.2 (100%), 289.1 (44%), 273.1 (45%), 227.1 (34%), 165.1 (52%), 152.1 (22%), 91.1 (88%). HRMS calcd. for $C_{21}H_{20}O_2$: 304.1463; found: 304.1479. Anal. calcd. for $C_{21}H_{20}O_2$: C 82.85, H 6.63, found: C 82.70, H 6.85.

4-Diphenylmethyl-1,3-dimethoxybenzene (8)

Methyl 2,4-dimethoxybenzoate (5 g, 26 mmol) dissolved in dry benzene was added dropwise to 58.6 mmol of phenylmagnesium bromide in 100 mL of dry ether. After refluxing for 2 h, standard work-up gave 2,4-dimethoxyphenyldiphenylmethanol as a yellow solid. This was purified by steam distillation to remove volatile impurities, followed by chromatography with 100% CH_2Cl_2, and recrystallization from ethanol:water. The product had mp 137–139°C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.64 (s, 3H), 3.79 (s, 3H), 5.14 (s, 1H, OH), 6.31 (dd, 1H, J_1 = 2.3 Hz and J_2 = 8.5 Hz), 6.40 (d, 1H, J = 8.5 Hz), 6.53 (d, 1H, J = 2.3 Hz), 7.20–7.32 (m, 10H).

The alcohol (2 g, 6.2 mmol) was hydrogenated with 10% Pd/C as described above. The white solid so obtained was chromatographed using 50:50 hexane:dichloromethane followed by recrystallization from ethanol:water to give 2.1 g (74%) of 4-diphenylmethyl-1,3-dimethoxybenzene (**8**), mp 122°C. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.72 (s, 3H), 3.82 (s, 3H), 5.87 (s, 1H), 6.40 (dd, 1H, J_1 = 2.5 Hz and J_2 = 8.5 Hz), 6.47 (d, 1H, J = 2.5 Hz), 6.74 (d, 1H, J = 8.5 Hz), 7.05–7.31 (m, 10H). HRMS calcd. for $C_{21}H_{20}O_2$: 304.1463; found: 304.1463.

Diphenylmethyl 1,1,1,3,3,3-hexafluoroisopropyl ether (7)

Diphenylmethanol (1.8 g) was added to 10 mL of 1,1,1,3,3,3-hexafluoroisopropyl alcohol, along with 5 mL of dichloromethane to improve the solubility. One drop of concentrated H_2SO_4 was added, resulting in a deep red solution. An aqueous solution of sodium carbonate was added followed by dichloromethane. The dichloromethane layer was removed, dried over $MgSO_4$, and evaporated. The resulting yellow liquid was chromatographed with 100% CH_2Cl_2, and the ether purified by distillation at 3 Torr, 61°C (1 Torr = 133.3 Pa). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 4.18 (sept, 1H), 5.84 (s, 1H), 7.36 (br s, 10H). HRMS calcd. for $C_{16}H_{12}F_6O$: 334.0792; found: 334.0799.

Solvent effects on nucleophilic substitution reactions. III. The effect of adding an inert salt on the structure of the S_N2 transition state

T.V. Pham and K.C. Westaway

Abstract: The nitrogen and secondary α-hydrogen–deuterium kinetic isotope effects found for the S_N2 reaction between thiophenoxide ion and benzyldimethylphenylammonium ion at different ionic strengths in DMF at 0°C indicate that the structure of the transition state changes markedly with the ionic strength of the reaction mixture. In fact, a more reactant-like, more ionic, transition state is found at the higher ionic strength. This presumably occurs because a more ionic transition state is more stable in the more ionic solvent.

Key words: transition state, ionic strength, secondary α deuterium kinetic isotope effects, nitrogen isotope effects, S_N2.

Résumé : On a déterminé les effets isotopiques cinétiques primaires de l'azote et secondaire des hydrogène/deutérium en α sur la réaction S_N2 des ions thiophénolate et benzyldiméthylphénylammonium, à diverses forces ioniques, dans le DMF, à 0°C; ils suggèrent que la structure de l'état de transition varie d'une façon importante avec la force ionique du mélange réactionnel. En fait, on observe que, à force ionique élevée, l'état de transition est plus ionique et qu'il ressemble aux réactifs. Cette situation existe probablement parce qu'un état de transition plus ionique est plus stable dans le solvant plus ionique.

Mots clés : état de transition, force ionique, effets isotopiques cinétiques secondaires des deutériums en α, effets isotopiques de l'azote, S_N2.

[Traduit par la rédaction]

Introduction

Inert salts are often added to organic reactions where ionic reactants are converted into neutral products so accurate rate constants can be measured. The problem arises because the rate constant "k" for a reaction between two ionic reactants varies with the ionic strength of the medium, eq. [1].

$$[1] \quad \log k = \log k_0 + Z_A Z_B c(\mu / D^3T^3\rho)^{1/2}$$

where "$\log k_0$" is the rate constant at infinite dilution, "Z_A" and "Z_B" are the charges on the reacting ions, c is a constant, "$\mu = 1/2(\Sigma_i c_i Z_i^2)$" is the ionic strength of the solution, "c_i" is the concentration of ion i, "Z_i" is the charge on ion i, "D" is the dielectric constant of the solvent, "T" is the absolute temperature, and "ρ" is the density of the solution (1). In a reaction where two ionic reactants are converted into neutral products (ions are consumed in the reaction), the ionic strength decreases throughout the reaction and the rate constant changes according to eq. [1]. This means that one cannot determine an accurate rate constant for the reaction and, therefore, cannot measure kinetic isotope effects, or any other mechanistic criteria based on kinetic data, to determine the reaction mechanism. In practice, a constant (accurate) rate constant can be obtained for these reactions if the rate constant is determined in solutions containing a high concentration of an inert salt. This is effective because the high concentration of inert salt maintains a high, and effectively constant, ionic strength throughout the reaction so the rate constant does not change significantly. In all the studies where this technique has been used, it is assumed that the added salt only keeps the ionic strength of the medium constant (maintains the rate constant) but does not have any effect on the reaction. The results of this study indicate that an added, inert, salt affects the structure of an S_N2 transition state significantly.

Results and Discussion

The S_N2 reaction between thiophenoxide ion and benzyldimethylphenylammonium ion, eq. [2],

$$[2] \quad Z\text{—}C_6H_4\text{—}S^- + C_6H_5CL_2\text{—}\overset{+}{N}(CH_3)_2C_6H_5 \xrightarrow[NaNO_3]{DMF} Z\text{—}C_6H_4\text{—}S\text{—}CL_2C_6H_5 + (CH_3)_2NC_6H_5$$

L = H, D

has been investigated at 0°C in DMF containing a high concentration of the inert salt, sodium nitrate. The high concentration of sodium nitrate kept the ionic strength virtually constant throughout the reaction, making it possible to determine accurate rate constants.

Table 1. The primary nitrogen (leaving group) and secondary α-hydrogen–deuterium kinetic isotope effects for the S_N2 reaction between sodium thiophenoxide and benzyldimethylphenylammonium nitrate at different ionic strengths in DMF at 0°C.

Ionic strength (M)	k^{14}/k^{15}	$(k_H/k_D)_\alpha$
0.904	1.0166 ± 0.0004[a]	1.215 ± 0.011[b]
0.64	1.0200 ± 0.0007[a]	1.179 ± 0.007[c]

[a]The errors are the standard deviation of the mean of five different measurements.

[b]The error in the isotope effect = $(1/k_D)[(\Delta k_H)^2 + (k_H/k_D)^2 \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively. The Δk_H and Δk_D values were obtained from three rate constants for the undeuterated and three rate constants for the deuterated substrates, respectively, that were measured simultaneously.

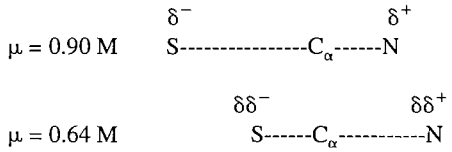
[c]This isotope effect was determined by whole-molecule mass spectrometry. The error is the standard deviation for four separate determinations (2).

The nitrogen (leaving group) and the secondary α-hydrogen–deuterium kinetic isotope effects were measured for this S_N2 reaction at two different ionic strengths to learn whether the added, inert, salt affects the reaction and the structure of its transition state. An examination of the nitrogen (leaving group) and secondary α-hydrogen–deuterium kinetic isotope effects, Table 1, shows that the isotope effects are very different when the reaction is carried out at different ionic strengths. For instance, the nitrogen kinetic isotope effect found at the higher ionic strength (k^{14}/k^{15} = 1.0166 ± 0.0004) is significantly smaller than the k^{14}/k^{15} = 1.0200 ± 0.0007 found for this reaction at the lower ionic strength of 0.64 M (2). The magnitude of a heavy atom (nitrogen (leaving group)) kinetic isotope effect increases linearly with the percent of α-carbon–nitrogen (C_α- - -N) bond rupture in the transition state (2, 3). Therefore, the smaller nitrogen isotope effect found for the reaction at the higher ionic strength indicates that the C_α- - -N bond rupture is much less advanced in the transition state of the high ionic strength reaction.

Recent work has shown that the magnitude of a secondary α-hydrogen–deuterium kinetic isotope effect is determined by the changes that occur in both the C_α—H(D) stretching and the out-of-plane bending vibrations when the reactant is converted into the transition state (4, 5). However, a comparison of the secondary α-hydrogen–deuterium kinetic isotope effects for a series of S_N2 reactions between methyl or ethyl chlorides and fluorides with several different nucleophiles (5) has shown that the magnitude of the isotope effect for a series of S_N2 reactions *with the same leaving group* is determined by the changes that occur in the out-of-plane bending vibrations when the reactant is converted into the transition state (5). This means the magnitude of the secondary α-hydrogen–deuterium kinetic isotope effect for a series of S_N2 reactions *with the same leaving group* is determined by the nucleophile – leaving group distance (the tightness) of the S_N2 transition state (5–7).

The secondary α-hydrogen–deuterium kinetic isotope effect found at the high ionic strength ($(k_H/k_D)_\alpha$ = 1.22 ± 0.01) is significantly larger than the $(k_H/k_D)_\alpha$ = 1.179 ± 0.007 (2) found at an ionic strength of 0.64 M, Table 1. Since the magnitude of a secondary α-hydrogen–deuterium kinetic isotope effect is related to the nucleophile – leaving group distance in the S_N2 transition state (5–7), the larger isotope effect found for the higher ionic strength reaction indicates that the high ionic strength transition state is looser with a greater nucleophile – leaving group distance than the lower ionic strength transition state. If the high ionic strength transition state has a greater nucleophile – leaving group distance but a shorter C_α- - -N bond (vide supra), then the S- - -C_α transition state bond in the high ionic strength reaction must be much longer than the S- - -C_α bond in the transition state of the low ionic strength reaction, Fig. 1.

Fig. 1. The relative transition state structures for the S_N2 reactions between sodium thiophenoxide and benzyldimethylphenylammonium nitrate at different ionic strengths in DMF at 0°C.



Another piece of evidence that suggests the S- - -C_α transition state bond is longer in the higher ionic strength reaction is the Hammett ρ value found by changing the *para* substituent on the nucleophile. A Hammett ρ = −1.62 ± 0.01, Table 2, was observed for the high ionic strength reaction whereas a larger Hammett ρ value of −1.76 ± 0.19 was found for the reaction at an ionic strength of 0.64 M. Since a larger ρ value is observed when the change in charge on going from the reactants to the transition state is larger, i.e., when there is more nucleophile–α-carbon bond formation in the transition state, the reaction at the higher ionic strength (with the larger $(k_H/k_D)_\alpha$) must have the longer S- - -C_α transition state bond.[2] Thus, the ρ values support the conclusion based on the magnitude of the secondary α-hydrogen–deuterium kinetic isotope effects, i.e., that the transition state for the higher ionic strength reaction is looser with a much longer S- - -C_α bond than the transition state for the lower ionic strength reaction. Combining the information obtained from the nitrogen and the secondary α-hydrogen–deuterium kinetic isotope effects with that from the Hammett ρ value suggests that the high ionic strength transition state is earlier (more reactant-like) with a much longer S- - -C_α and a shorter C_α- - -N bond, Fig. 1.

Finally, it is interesting to speculate on why a more reactant-like transition state is found at a higher ionic strength. The earlier transition state in the high ionic strength reaction has both a greater negative and a greater positive charge on the

[2] Hoz et al. (8) used the results of theoretical calculations on homolytic cleavage reactions to question the validity of using Hammett ρ values to determine transition state structure. However, many workers currently use linear free energy relationships such as ρ values to indicate differences in transition state structure (9, 10) and there is no experimental evidence to show which position is correct. The authors believe that ρ values found in closely related systems can be used to indicate transition state structure. Support for this position is that the changes in the structure of the S_N2 transition state suggested by ρ values have been confirmed by isotope effect data (2, 11, 12).

Table 2. The rate constants and Hammett ρ values for the reactions between *para*-substituted sodium thiophenoxides and benzyldimethylphenylammonium nitrate at different ionic strengths in DMF at 0°C.

para-Substituent on the thiophenoxide ion	Rate constant × 10^3 (L M^{-1} s^{-1})	
	Ionic strength μ = 0.904 M	Ionic strength μ = 0.64 M
CH_3O	30.1 ± 0.8[a]	46.2 ± 3.3[a]
H	10.9 ± 0.3	12.8 ± 1.0
Cl	4.67 ± 0.07	6.13 ± 0.65
ρ	−1.62 ± 0.01	−1.76 ± 0.19
Correlation coefficient	1.00	0.994

[a]The errors are the standard deviation of the mean of at least three different measurements.

nucleophilic sulfur and nitrogen atoms, respectively. This means the transition state in the higher ionic strength solvent is more ionic. It is proposed that the more ionic transition state is found at high ionic strength because it is more stable (more highly solvated) in the more ionic solvent.

The significant observation, however, is that inert salts that are used to increase the ionic strength in reactions so that accurate rate constants can be measured, change the structure of the transition state markedly. This is an important discovery because it shows that adding even inert salts changes the reaction from a mechanistic point of view, i.e., the values obtained for any mechanistic criterion will not be for the reaction of interest.

Experimental

Nitrogen kinetic isotope effects for the S_N2 reactions between sodium thiophenoxide and benzyldimethylphenylammonium ion in DMF at 0°C

The procedure used to synthesize the benzyldimethylphenylammonium nitrate and measure the nitrogen kinetic isotope effect has been described (2). The only difference in the two isotope effects was that one was measured at a higher ionic strength. In both experiments, the ionic strength was adjusted by adding sodium nitrate to the solvent.

The secondary α-hydrogen–deuterium kinetic isotope effects for the S_N2 reactions between sodium thiophenoxide and benzyldimethylphenylammonium ion in DMF at 0°C

The preparation of the benzyl-1,1-d_2-dimethylphenylammonium nitrate has been described (2). The procedure used to measure the secondary α-hydrogen–deuterium kinetic isotope effect at the lower ionic strength using whole-molecule mass spectrometry is also described in ref. 2. The secondary α-hydrogen–deuterium kinetic isotope effects at the high ionic strength were obtained by dividing the average second-order rate constant (from three separate kinetic runs done using the same stock solutions and at the same time) for the reaction of the undeuterated substrate with that for the reaction of the deuterated substrate. The least-squares kinetic plots had correlation coefficients of at least 0.999 and the reactions were followed to at least 67% of completion. The procedure used to measure these rate constants is given in refs. 12 and 13. The isotope effects measured with different batches of solvent on different days were identical.

Nitrobenzoxadiazole-labelled polyisoprenoid alcohols

Bruce J. Balcom and Nils O. Petersen

Abstract: We have prepared, isolated, and characterized a series of nitrobenzoxadiazole labelled polyisoprenoid alcohols. The coupling reaction employed was a dicyclohexylcarbodiimide mediated condensation between a carboxylic acid derivative of nitrobenzoxadiazole and the polyisoprenoid alcohols citronellol, solanesol, and dolichol. Upon exposure to visible light, a self-sensitized singlet oxygen "ene" reaction oxidized double bonds in the isoprene moiety. The rate of oxidation is greatly reduced in solvents where singlet oxygen is short-lived.

Key words: nitrobenzoxadiazole, isoprenoid, dolichol, citronellol, solanesol, fluorescence labelling, singlet oxygen, ene reaction.

Résumé : On a préparé, isolé et caractérisé une série d'alcools polyisoprénoïdes dérivés du nitrobenzoxadiazole marqué. La réaction de couplage utilisée implique une condensation, effectuée sous l'influence de la dicyclohexylcarbodiimide, entre un dérivé d'un acide carboxylique du nitrobenzoxadiazole et les alcools polyisoprénoïdes citronellol, solanésol et dolichol. Par exposition à la lumière visible, une réaction "ène" autosensibilisée de l'oxygène singulet permet d'oxyder les doubles liaisons de la portion isoprénique. La vitesse de la réaction est grandement réduite dans les solvants dans lesquels la durée de vie de l'oxygène est réduite.

Mots clés : nitrobenzoxadiazole, isoprénoïde, dolichol, citronellol, solanésol, fluorescence, marquage, oxygène singulet, réaction ène.

[Traduit par la rédaction]

Introduction

We recently examined the size dependence of the lateral diffusion coefficient in model cell membranes using fluorescently labelled probe molecules (1, 2). Our specific intent was to explore the effect of hydrocarbon interactions in the membrane interior as a retardant to lateral diffusion. Systematic exploration of this effect required a homologous series of well-defined hydrophobic polymers derivatized with a fluorophore (3–5) suitable for use in fluorescence photobleaching recovery experiments (6, 7). Based on previous experience (8, 9) we chose nitrobenzoxadiazole (NBD) as the fluorophore. This article describes the synthesis, purification, and characterization of the labelled molecules and also reports an unexpected light-dependent instability of the resulting labelled probes.

Polyisoprenoid alcohols, ubiquitous in nature, are a naturally occurring hydrocarbon polymer with a ready means of derivatization: a terminal hydroxyl function. Short-chain isoprenoid alcohols are most prevalent in plants. Citronellol, nerol, farnesol, and geranyl geraniol are common constituents of fragrant essential oils such as citronella, rose, and musk oil. Solanesol is the major lipid component of tobacco leaves (10). Long-chain polyprenols are more common in mammals. Dolichol in rat liver, for example, is polydisperse with alcohols that range from 14 to 24 isoprenes in length (11). The distribution of dolichols in tissues varies with species. In humans, the mean chain length shifts towards longer chain isoprenoids.

Despite the common linear architecture, two major structural differences occur in these polymers. The extent of unsaturation is variable, as is the double bond stereochemistry. Saturated isoprene subunits typically occur in the α subunit containing the hydroxyl group. This is the case for citronellol and dolichol used in our studies (Scheme 1). Solanesol has an α isoprene subunit that is unsaturated. Solanesol (Scheme 1) also has an all-*trans* stereochemistry about its nine double bonds. Dolichol is poly *cis* with only the three terminal isoprenes possessing *trans* double bonds (12).

Results and discussion

Derivatization

The hydroxyl functional group in the isoprenoid alcohols immediately suggests an esterification as the preferred mode of fluorophore attachment. *N*-Methyl-*N*-(7-nitrobenz-2-oxa-1,3-diazol-4-yl)-6-amino hexanoic acid (NBD-acid) is a carboxylic acid derivative of NBD (inset Fig. 1) designed for labelling alcohols and amines (13). Esters synthesized from NBD-acid are named, in this work, by appending the alcohol name to NBD.

Our chosen esterification reaction was a dicyclohexylcarbodiimide (DCC) mediated acid condensation reaction (14,

Scheme 1. Citronellol and dolichol (top) have $n = 1$ and $n =$ 15–21, respectively. Solanesol (bottom) has $n = 8$.

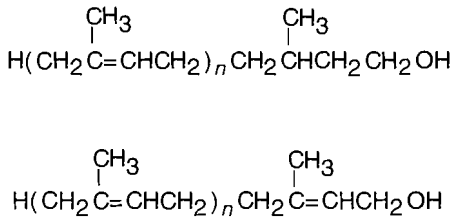

Fig. 1. DCC-mediated NBD-acid esterification reaction. Sample reaction scheme illustrating the labelling reaction. NBD-acid (**1**) combines with DCC to form the anhydride (**2**) and the unwanted *N*-acylurea (**5**). An alkyl aminopyridine catalyst assists the esterification of, in this case, undecanol (**3**). NBD-undecanol (**4**) is the desired product.

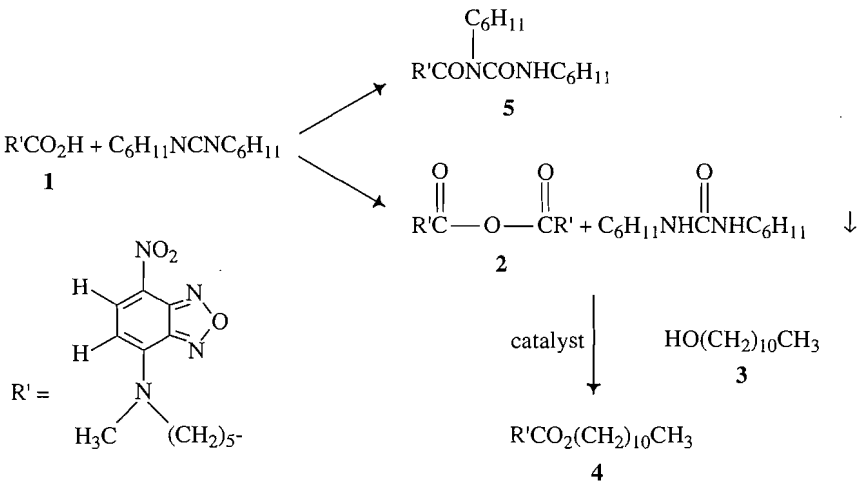


15) with an alkyl aminopyridine catalyst (Fig. 1). This reaction has a significant by-product, *N*-acylurea, production of which is very solvent dependent. Balcom and Petersen (16) showed that solvents that are poor hydrogen bond acceptors are the most efficient in suppressing *N*-acylurea production (an undesirable by-product) in the DCC reaction. Methylene chloride is a poor hydrogen bond acceptor but it also exacerbates the light-induced instability of the product esters. Model esterification reactions were undertaken with undecanol to confirm the reaction products of the NBD labelling reaction and to further explore the unexpected light-induced instability of the labelled isoprenoid alcohols.

HPLC analysis

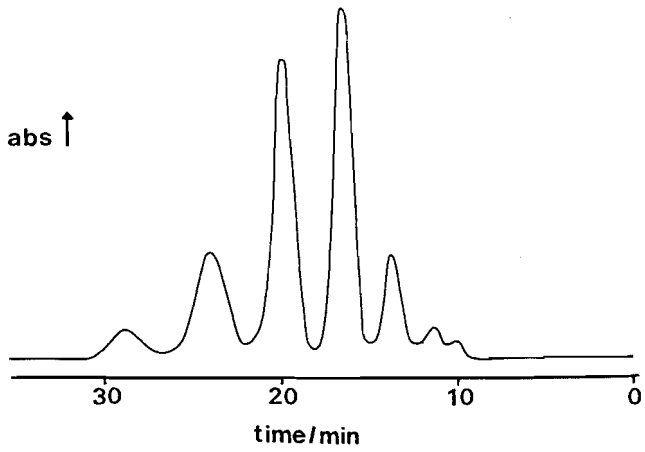
Reverse-phase HPLC was employed to characterize the NBD-labelled alcohols. Unlike chromatography on silica, where the polarity of the NBD group controls the elution, the retention time on a reverse-phase HPLC column is primarily controlled by the hydrocarbon moiety of the labelled alcohols. NBD-undecanol eluted as one peak, retention time 26.7 min. NBD-citronellol, retention time 14.3 min, has a small impurity, less than 5%, which eluted at a shorter time. NBD-solanesol (different mobile phase) also eluted as one peak at 4.0 min.

The dolichol sample was a mixture of individual homologs in the range from 16 to 22 isoprenes. The chain lengths of individual homologs were confirmed by comparison to known dolichol standards. Reverse-phase HPLC resolved the individual labelled (480 nm detection wavelength) dolichol species (Fig. 2). Labelled homologs with 16, 17, 18, 19, 20, 21, and 22 isoprenes had retention times of 10.7, 12.0, 14.4, 17.7, 20.5, 24.2, and 29.5 min, respectively. The same distribution was observed *prior* to labelling, by observation of the isoprene double bond absorption at 210 nm. The unlabelled species (same elution conditions) had shorter retention times. Exposure of NBD-dolichol to light and oxygen in methylene chloride resulted in degradation of the molecule (but not the fluorescent label) and a shift of the distribution back to shorter elution times. Exposure of the NBD-citronellol sample, similar conditions, also resulted in a degradation of the molecule (but again not the fluorescent label), which was observed as a shift in retention time from 14.3 to 4.8 min.

Compound instability

The origin of the solution instability was further investigated because the stability of the probe molecule was of crucial importance with reference to its use as a diffusion tracer. The HPLC results discussed in the previous section showed quantitative conversion of the target ester into the degradation product(s). Silica TLC analysis (NBD-citronellol) showed a change in R_f from 0.87 to 0.75 upon reaction. Less efficient interaction of the degradation product with the HPLC stationary phase, but more efficient interaction with the TLC stationary phase (decreased R_f), suggests the degradation product is more polar than the original NBD-labelled alcohol.

Fig. 2. Reverse-phase HPLC trace of NBD-dolichol sample. Labelled homologs with from 16 to 22 isoprenes are observable. This same distribution was observed for the unlabelled homologs. The NBD-dolichol was detected by the absorbance (480 nm) of the NBD label.



Control experiments (analysis by TLC and HPLC) revealed four additional features of the degradation reaction. (*i*) The degradation was a photochemical reaction involving NBD. NBD-citronellol decayed in both white light and light filtered (via a cutoff filter) to wavelengths greater than 400 nm. (*ii*) Oxygen was required. The decay of NBD-citronellol was quenched, or severely limited, by sparging the solution with nitrogen. Contrarily, saturating the solution with oxygen greatly accelerated the reaction. (*iii*) NBD-undecanol did not degrade. Although it closely resembles NBD-citronellol in size and shape, it does not have a double bond. (*iv*) The decay of NBD-citronellol was solvent dependent. A qualitative comparison of the decay rate in acetone and deuterated acetone, analysis by TLC, showed much faster conversion in the deuterated solvent. The degradation was also observed to proceed rapidly in chlorinated solvents although a direct control experiment, as in the case of the deuterated solvents, was not possible. NBD-citronellol did not degrade in ethanol.

Involvement of the NBD chromophore (λ_{max} = 480 nm), oxygen, and the isoprene double bond in the degradation reaction immediately suggests an NBD sensitized singlet oxygen "ene" reaction (17, 18). Our qualitative observation of a deuterium effect on the degradation kinetics is strong evidence for the singlet oxygen "ene" mechanism; it is often considered diagnostic of a singlet oxygen reaction (19).

Ground state triplet oxygen is known to undergo triplet–triplet annihilation with varied dye sensitizers to produce the reactive singlet oxygen species (20, 21). The isoprene moiety is vulnerable to the "ene" reaction because of the trisubstituted double bond (18, 22). In fact, citronellol is oxidized to rose oxide on an industrial scale by the singlet oxygen "ene" reaction (23). Many different hydroperoxide isomers are produced (22) by this reaction, which made purification and spectroscopic identification of the reaction products impossible. ^{1}H NMR of the crude light-exposed and reacted NBD-citronellol supported the singlet oxygen oxidation mechanism. The ^{1}H NMR spectrum, after light exposure, showed a disruption of the isoprene double bond structure. This is most evident from the disappearance of the terminal methyl singlets (δ = 1.68 and 1.60 ppm) α to the double bond in the original citronellol.

To our knowledge, the NBD chromophore has not previously been identified as a singlet oxygen sensitizer. It is not surprising, however, that it could so function. While the quantum yield of intersystem crossing is unknown for NBD, the low quantum yield of fluorescence, 5% (6), suggests there could be substantial production of triplet state NBD. The singlet oxygen "ene" reaction has a very low activation energy and little direct solvent dependence (18). There is an indirect solvent dependence, however, due to the widely variant lifetimes of singlet oxygen in solution (18, 19). The lifetime is very long in halogenated or deuterated solvents and thus singlet oxygen is very reactive in these environments. For example the lifetime in acetonitrile is 65 μs, while deutero acetonitrile has a singlet oxygen lifetime of 950 μs (24). Similarly, the lifetime in chloroform is 160 μs while a change to deutero chloroform increases the lifetime to 3600 μs (24). Hydroxyl or hydrocarbon solvents yield much shorter singlet oxygen lifetimes (25). The product NBD-esters were stored in ethanol solution, in the dark, under a nitrogen atmosphere prior to use in bilayer diffusion experiments (2). The isoprene double bonds in labelled solanesol and dolichol undergo similar oxidation; however, the problem is more severe because of the greater number of isoprene units in each molecule.

We believe the singlet oxygen "ene" reaction is particularly effective in these systems because the sensitizer and the double bond are in the same molecule. The reaction is thus intramolecular; this is supported by the observation that the reaction rates appear to have no concentration dependence (work in progress).

Conclusion

We have successfully derivatized a series of polyisoprenoid alcohols with a carboxylic acid bearing nitrobenzoxadiazole fluorophore. A self-sensitized singlet oxygen "ene" reaction degrades the polyisoprenoid esters in solution. The "ene" reaction is severe in halogenated and deuterated solvents due to long singlet oxygen lifetimes. Careful storage and handling of the labelled molecules obviates this difficulty. Degradation of the isoprene double bond in a bilayer environment is unlikely to be a severe problem because singlet oxygen lifetimes in water and hydrocarbon media are, in general, very short.

Experimental

General

All solvents and chemicals were BDH analytical grade, unless otherwise noted. Water was doubly distilled and deionized. DCC reactions were run in spectroscopic grade methylene chloride (Caledon). All reactions were carried out at room temperature. NBD-acid was synthesized according to a published procedure (13).

Proton NMR spectra were recorded with a Varian XL-200 or Gemini 200 MHz spectrometer. Carbon-13 NMR spectra were acquired with a Varian XL-300 spectrometer. Tetramethyl silane was used as an internal standard in all cases. Mass spectroscopic analyses were performed on a Finnigan MAT

8230. Melting points, uncorrected, were measured on a Gallenkamp melting point apparatus.

Fluorescently labelled compounds were handled in subdued light. Compounds labelled with NBD-acid were stored, as ethanol solutions under nitrogen, in the dark at 4°C. Optical spectra were recorded using either a Cary 219 or Shidmadzu UV-160. NBD-acid has an extinction coefficient $\varepsilon = 3.4 \times 10^4$ L mol^{-1} cm^{-1} at 476 nm measured in ethanol.

Chromatography

The HPLC system comprised two Waters 510 pumps controlled by a Waters automated gradient controller. Compounds were observed at 480 nm and 210 nm with a Waters 490 multiwavelength detector. HPLC analyses employed a Waters C_{18} reverse phase radial compression column. Elution conditions were 70/30 acetonitrile/water (NBD-undecanol, NBD-citronellol), 65/35 isopropyl alcohol/methanol (NBD-dolichol), 70/30 isopropyl alcohol/methanol (NBD-solanesol) all at 2.0 mL /min.

Silica thin-layer chromatography (TLC) was performed on plastic-backed silica gel 60 uv/254 plates (Merck). Chromatograms were visualized by sample colour. Silica TLC of NBD-acid conjugates employed a solvent system that was 75/25 methylene chloride/ethyl acetate. Mallinckrodt 60–200 mesh silica gel, grade 62 special, was used for column chromatography. NBD labelled alcohols were eluted from a silica gel column with a 75/25 mixture of methylene chloride and ethyl acetate.

NBD-undecanol

NBD-acid (196 mg, 0.64 mmol) and 68 mg (0.33 mmol) DCC (Kodak) were added to 10 mL of methylene chloride. The stirred mixture was allowed to react for 5 h. Orange NBD-acid dissolved gradually as the anhydride was produced. Dicyclohexylurea precipitated as a fluffy white powder. Undecanol (Aldrich) was added to the mixture by syringe (35 μL, 0.17 mmol) along with 10 μL (1.7 μmol) of a stock catalyst solution, 4-pyrrolidinopyridine (Aldrich), in methylene chloride. The reaction vessel was sealed and the mixture left stirring a further 18 h in the dark. Dicyclohexylurea was subsequently removed by filtration.

Silica TLC showed the major products (vide infra) were NBD-undecanol ($R_f = 0.55$) and *N*-acylurea ($R_f = 0.45$). Residual NBD-acid was an orange spot ($R_f = 0.16$). The methylene chloride solution was diluted to 65 mL and extracted twice with 100 mL of pH 8.4 borate buffer to remove residual acid. After extraction with 100 mL of water, the methylene chloride solution was concentrated by rotary evaporation. Column chromatography isolated NBD-undecanol as the first distinct orange band. NBD-undecanol was recrystallized from petroleum ether. Twenty-two milligrams (28% yield based on undecanol) of the chalk-like solid, mp 63–64°C, was recovered. *N*-Acylurea was collected and recrystallized from hot ethanol–water, mp 148–150°C. *N*-Acylurea was confirmed by ^1H and ^{13}C NMR and high-resolution MS (16).

^1H NMR ($CDCl_3$, 200 MHz, δ (ppm)): 8.44 (1H, doublet, ring proton α to nitro group), 6.09 (1H, doublet, ring proton β to nitro group), 4.06 (4H, triplet, CH_2O_2C; unresolved multiplet, CH_2N by analogy to NBD-acid), 3.47 (3H, broad singlet, NCH_3), 2.34 (2H, triplet, O_2CCH_2), 1.9–1.4 (8H, four overlapping partially resolved methylenes, $CH_2CH_2O_2CCH_2CH_2CH_2CH_2$), 1.26 (16H, broad singlet, eight methylenes interior of the undecanol chain), 0.88 (3H, triplet, CH_3). ^{13}C NMR showed that the isolated product incorporated peaks characteristic of the two reactants, NBD-acid and undecanol. High-resolution MS showed a molecular ion *m/e* = 462.2842; expected *m/e* = 462.2842.

NBD-citronellol

NBD-citronellol was prepared using the procedure described for NBD-undecanol. NBD-acid (145 mg, 0.47 mmol) and 108 mg of DCC (0.52 mmol) were reacted with 15 μL of citronellol (Aldrich), 0.082 mmol, in the presence of 25 μmol of the catalyst. NBD-citronellol ($R_f = 0.87$) was isolated by column chromatography as described above. Isolated NBD-citronellol, 35 mg (93% yield based on citronellol), was an orange-red oil.

Exposure of NBD-citronellol to light and oxygen results in oxidation of the isoprene double bond, yielding an oxidized product with $R_f = 0.75$ on silica gel. Chlorinated and deuterated solvents (deutero chloroform) exacerbated the degradation reaction, which made ^1H NMR problematic. Samples submitted for NMR analyses invariably oxidized to some extent before acquisition. ^1H NMR ($CDCl_3$, 200 MHz, δ(ppm)): 8.41 (1H, doublet, ring proton α to nitro group), 6.09 (1H, doublet, ring proton β to nitro group), 5.06 (1H, triplet, CH=C), 4.12 (4H, triplet, CH_2O_2C; unresolved multiplet, CH_2N by analogy to NBD-acid), 3.48 (3H, broad singlet, NCH_3), 2.34 (2H, triplet, O_2CCH_2), 2.00 (2H, unresolved multiplet, $CO_2CH_2CH_2$), 1.80 (3H, singlet, terminal methyl), 1.60 (3H, singlet, terminal methyl), 1.9–1.1 (11H, partially resolved multiplets, three methylenes interior acid chain, two methylenes and one methine interior citronellol chain), 0.91 (3H, doublet, CH_3). High-resolution MS *m/e* = 446.2529; expected *m/e* = 446.2529. NBD-citronellol stored in the dark, under nitrogen, was stable for at least 1 year (HPLC analysis) in ethanol solution.

NBD-solanesol

NBD-solanesol was prepared according to the procedure described for NBD-undecanol. NBD-acid (196 mg, 0.64 mmol) and 68 mg of DCC (0.33 mmol) reacted with 13 mg of crystalline solanesol (Sigma), 0.021mmol, in the presence of 20 μmol of the catalyst. NBD-solanesol ($R_f = 0.87$) was isolated by column chromatography as described above. NBD-solanesol, 9 mg (50% yield based on solanesol), was an orange-red tar. The yield was determined spectroscopically by the absorbance of the NBD chromophore.

NBD-dolichol

NBD-dolichol was prepared according to the procedure described for NBD-undecanol. NBD-acid (71 mg, 0.23 mmol) and 24 mg of DCC (0.12 mmol) reacted with 18 mg of dolichol (0.013 mmol) in the presence of 5 μmol of the catalyst. Dolichol, recovered from human liver upon autopsy, was supplied by Dr. K.K. Carroll. NBD-dolichol ($R_f = 0.91$) was isolated by column chromatography as previously described for NBD-undecanol. NBD-dolichol, 1 mg (6% yield based on dolichol), was an orange-red tar. The yield was determined spectroscopically by the absorbance of the NBD chromophore.

COMMUNICATION

A study of the vacuum pyrolysis of 4-diazoisothiochroman-3-one with HeI ultraviolet photoelectron spectroscopy

N.H. Werstiuk, J. Ma, C.D. Roy, A.J. Kresge, and E.A. Jefferson

Abstract: A newly developed ultraviolet photoelectron spectrometer apparatus that utilizes a tunable 50 W CW CO_2 laser as a directed heat source is used to study the vacuum pyrolysis of 4-diazoisothiochroman-3-one (**1***a*). Analysis of the pyrolysate with ultraviolet photoelectron spectroscopy shows that **1***a* undergoes a facile pyrolysis at a laser power level of less than 26 W, yielding two new compounds: thiaketene **3***a*, the product of a Wolff rearrangement, and benzocyclobutenthione (**6***a*), which can be derived from thiacarbene **4***a*, the decarbonylation product of **3***a*. Activation enthalpies/energies calculated at the AM1 and ab initio levels of theory indicate that, unlike the case of 4-diazoisochroman-3-one (**1***b*), the Wolff rearrangement of the incipient carbene may be concerted with loss of nitrogen from **1***a*. The activation enthalpy/energy calculated for the decarbonylation of **3***a* is significantly higher (AM1, 20.5 kcal/mol; RHF/6-31G(d), 11.7 kcal/mol; MP2(full)//RHF/6-31G(d), 14.3 kcal/mol) than the activation enthalpy/energy for the decarbonylation of **3***b*. This result is in keeping with the fact that we detect **3***a*, but **3***b* is not found in detectable amounts in the pyrolysate of **1***b*.

Key words: vacuum pyrolysis, 4-diazoisothiochroman-3-one, HeI ultraviolet photoelectron spectroscopy, AM1 and ab initio calculations.

Résumé : On a utilisé un spectromètre de photoémission de photoélectrons dans l'ultraviolet récemment mis au point qui utilise un laser ajustable au CO_2 de 50 W CW comme source dirigée de chaleur, pour étudier la pyrolyse sous vide de la 4-diazoisothiochroman-3-one (**1***a*). L'analyse du pyrolysat par la spectroscopie de photoémission de photoélectrons dans l'ultraviolet montre que le composé **1***a* subit facilement la pyrolyse à un niveau de puissance du laser inférieure à 26 W pour donner deux nouveaux composés : la thiacétène **3***a*, le produit d'un réarrangement de Wolff, et la benzocyclobutenthione (**6***a*) qui peut provenir du thiacarbène **4***a*, le produit de décarbonylation du produit **3***a*. Les énergies/enthalpies d'activation calculées aux niveaux théoriques AM1 et ab initio indiquent que, contrairement au cas de la 4-diazoisochroman-3-one (**1***b*), la transposition de Wolff du carbène naissant peut-être concertée avec la perte d'azote à partir de **1***a*. L'énergie/enthalpie d'activation calculée pour la décarbonylation de **3***a* est de façon significative plus élevée (AM1, 20,5 kcal/mol; RHF/6-31G(d), 11,7 kcal/mol; MP2(complet)//RHF/6-31G(d), 14,3 kcal/mol) que l'énergie/enthalpie d'activation pour la décarbonylation de **3***b*. Ce résultat est en accord avec le fait que nous avons détecté le composé **3***a* mais le composé **3***b* n'est pas présent en quantités détectables dans le pyrolysat de **1***b*.

Mots clés : pyrolyse sous vide, 4-diazoisothiochroman-3-one, HeI spectroscopie de photoémission de photoélectrons dans l'ultraviolet, calculs AM1 et ab initio.

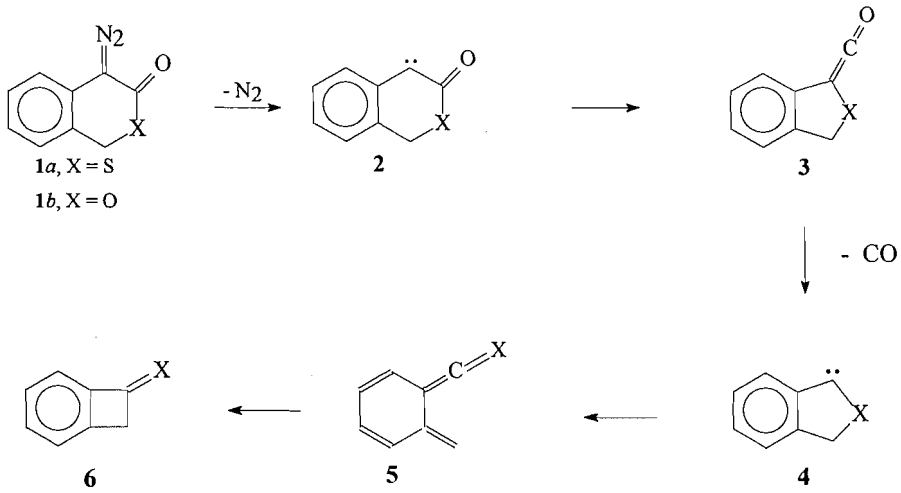
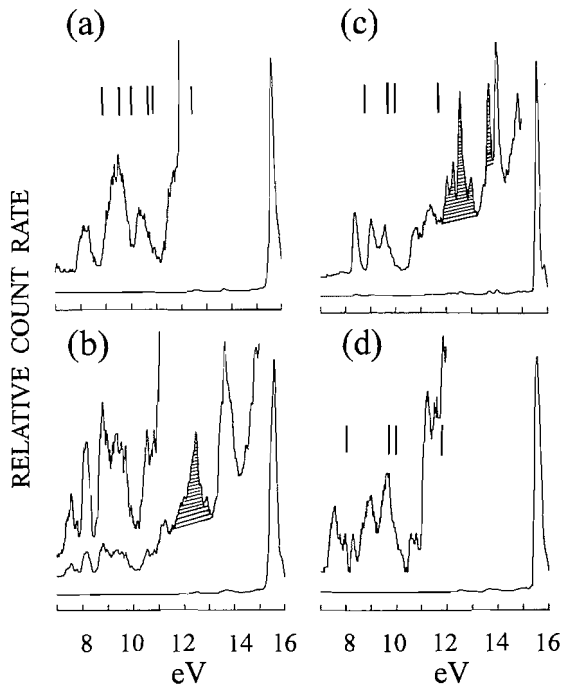
Scheme 1.



To facilitate the preparation and detection of highly reactive transients in the gas phase, we developed an ultraviolet photoelectron (pe) spectrometer – CW CO_2 laser apparatus and used it successfully to study the vacuum pyrolysis of 6,6-dihalobicyclo[3.1.0]hexanes (1), 1,2,3-benzotriazines (2), and 4-diazoisochroman-3-one (**1***b*) (3). To expand our research on transient species, we used this instrument to study the vacuum pyrolysis of 4-diazoisothiochroman-3-one (**1***a*). We anticipated that this study would add new information to the limited amount of data that are available on the vacuum pyrolysis of α-diazocarbonyl compounds in contrast to the large body of work that has been accumulated on the photochemistry of this class of compounds (4–10). Our goals were to compare the chemistries of **1***a* and **1***b* and establish whether two new transients, thiaketene **3***a* and benzocyclobutenthione (**6***a*), that are potential products of the pyrolysis of **1***a* could be characterized with pes. We expected that a pe spectroscopic study of the pyrolysis of **1***a* would provide information about the relative reactivities/stabilities of diazo compounds **1***a* and **1***b* and the corresponding ketenes **3***a* and **3***b*, and yield fundamental information about the electronic structure and bonding of **3***a* and **6***a*. In this communication we document the results of a pes study of the pyrolysis of **1***a* and present semi-empirical AM1 (AMPAC (11) and MOPAC (12)) and ab initio (GAUSSIAN 94 (13)) calculation data for the first three steps of the pyrolysis mechanisms of **1***a* and **1***b* shown in Scheme 1.

Figure 1(*a*) is a display of the partial pe spectrum of **1***a*[2] (obtained with some difficulty because of its low vapor pressure) in the presence of the make-up gas N_2, a procedure that we find useful for obtaining the pe spectra of thermally sensitive materials of low volatility (3). The vertical lines show the negative of the energies of the six highest occupied MOs (8.80, 9.45, 9.96, 10.56, 10.88, 12.22 eV) calculated with AM1 for the optimized equilibrium geometry. Figure 1(*b*) is a display of the pe spectrum of the pyrolysate of **1***a* obtained at a laser power level of 26 W as the beam is chopped by 50% with a cog-wheel rotating disk.[3] It is seen that this spectrum differs substantially — new bands appear at 7.7 and 9.0 eV and the

Fig. 1. (*a*) Partial HeI photoelectron spectrum of 4-diazoisothiochroman-3-one (**1***a*); (*b*) photoelectron spectrum of the pyrolysate of **1***a* obtained at a laser power level of 26 W with the beam reduced in intensity by 50% with a cog-wheel chopper; (*c*) photoelectron spectrum of the pyrolysate of **1***a* obtained at a laser power level of 26 W; (*d*) photoelectron spectrum obtained by subtracting spectrum (*c*) from spectrum (*b*).



[2] The 4-diazoisothiochroman-3-one (**1***a*) (mp 49–50°C) was prepared from 1,4-dihydro-3*H*-benzothiopyran-3-one with the azide exchange method by A.J.K. and E.A.J. The spectroscopic data obtained for **1***a* were entirely consistent with its structure.

[3] Because it is difficult to maintain the power level constant when the laser is tuned to a 10–15 W line, we used a rotating cog-wheel chopper (60 Hz) to reduce the "effective" power level of the 26 W beam by 50%. Measurements with a thermocouple inserted into the tip of the nozzle showed that this technique produces a 350±50°C hot zone 1–1.5 mm in length; at 26 W, the unchopped beam gives a 550±50°C hot zone.

[a]In kcal/mol. Calculated with AM1 with the keyboard PRECISE to tighten the convergence criteria.
[b]In atomic units (hartrees).
[c]In kcal/mol. Calculated from the AM1 heats of formation.
[d]The transition state.
[e]This transition state could not be located.
[f]Not calculated because a transition state could not be located.
[g]Obtained with the IRCMAX method (see footnote 6).
[h]The Becke3LYP functional is used in DFT (density functional theory) calculations; E_T **2***b*: −496.893 07, ts **2***b* → **3***b*: −496.884 81. The transition state exhibits one imaginary frequency.

band at 8.2 eV sharpens considerably — from the spectrum of **1***a*, and CO (the sharp band at 14.0 eV (14)) is detected as a product. Figure 1(*c*) is a display of the pe spectrum of the pyrolysate produced at a laser power level of 26 W (550±50°C). An increase in the power level to 47 W produces little change in this spectrum. The negative values of the AM1 energies of the four highest occupied molecular orbitals (8.70, 9.61, 9.98, 11.69 eV) of benzocyclobutenthione (**6***a*) are shown as vertical lines on spectrum 1(*c*). The HOMO of **6***a* is largely in-plane n_s with some mixing with the cyclobutene C—C bonds, in keeping with the relatively small FWHM of the peak at 8.3 eV; HOMO-1 and HOMO-2 are essentially phenyl π-type MOs mixed to a small extent with π C=S and π CH_2. Figure 1(*d*) is the pe spectrum obtained by subtracting spectrum 1(*c*) from 1(*b*). The vertical bars in spectrum 1(*d*) show the energies of the four highest occupied MOs (7.94, 9.55, 9.86, 11.60 eV) of thiaketene **3***a* calculated with AM1. The HOMO of **3***a* is a π-type MO with the largest coefficients being associated with the C=C bond of the ketene group and the sulfur atom. HOMO-1 and HOMO-2 are essentially phenyl π-type MOs, but in the case of HOMO-1 there is a significant degree of mixing with S_π. HOMO-3 is a highly delocalized, in-plane σ MO with the largest coefficient being associated with the sulfur atom. Thus the experimental and calculational results strongly indicate that **1***a* (like **1***b*, which yields benzocyclobutenone (3)) gives benzocyclobutenthione, a compound that has not been described in the chemical literature as far as we are aware. Because thiones that lack bulky substituents α to C=S trimerize readily (15), benzocyclobutenthione undoubtedly is a transient species. Our work suggests that the vacuum pyrolysis of **1***a* and its substituted analogues may provide a useful general route to **6***a* and substituted benzocyclobutenthiones.

Scheme 1 shows a mechanism for conversion of **1***a* and **1***b* into **6***a* and **6***b*, and the calculational results for the first three steps are collected in Table 1. While a step involving the ring opening of **4***a* to the orthothioquinone methide **5***a* is included in Scheme 1, it is conceivable that **4***a* rearranges directly to **6***a*.

When **1***b* is pyrolyzed under the same conditions as **1***a* with the rotating chopper in place, approximately 50% of the starting material remains. Thus **1***b* is less reactive than **1***a*, in keeping with the activation enthalpies/energies obtained calculationally (Table 1). To provide a reference point for the AM1, RHF/6-31G(d), and MP2/6-31G(d)//RHF/6-31G(d) calculations carried out on **1***a* and **1***b*, we also calculated the activation enthalpy/energies for the conversion of 2-diazocyclohexanone (**7**) (its E_a for pyrolysis in mesitylene is 31±3 kcal/mol (16)) into 2-carbenacyclohexanone (**8**). It is seen that the MP2/6-31G(d)//RHF/6-31G(d) E_a lies closest (+5.2 kcal/mol) to the experimental value: the AM1 $\Delta H^{\ddagger}$ is too high by 16.3 kcal/mol and the RHF/6-31G(d) E_a is 9.9 kcal/mol too low. Frequency calculations on the transition states for the decomposition of **7**, **1***a*, **1***b*, **3***a*, **3***b*, and the rearrangement of **2***b* at the AM1 and RHF/6-31G(d) levels of theory yield one imaginary frequency in each case. In the case of **1***a*, in keeping with orbital symmetry considerations,[4] the imaginary fre-

[4] We thank Professor J. Pincock of Dalhousie University for helpful discussions.

quency corresponds to a vibration — we use PCVIBRATE[5] to animate the normal modes — in which N_2 pivots out from **1***a*: it is not extruded in a linear trajectory. The singlet of **2***a* is found to be a stationary point calculationally, even though potential-energy-scan calculations at the AM1 and RHF/6-31G(d) levels of theory show that a very small pertubation of the S2,C4 distance, in 0.01 Å increments, causes **2***a* to rearrange to **3***a* spontaneously with a barrier of less than 1 kcal/mol. Because the MP2/6-31G(d)//RHF/6-31(d) single point calculations on **2***b* and the transition state for its rearrangement to **3***b* yield a negative E_a while AM1 and RHF/6-31G(d) calculations give large positive values, we also used IRCMAX[6] and DFT (density functional theory) calculations to obtain E_a. As is seen in entry 10 of Table 1, these methods give E_a's of 2.7 and 5.2 kcal/mol, respectively, which, although smaller than the AM1 $\Delta H^{\ddagger}$ (24.0 kcal/mol) and the RHF/6-31G(d) E_a (38.7 kcal/mol), are significantly larger than $\Delta H^{\ddagger}$ and E_a calculated for the rearrangement of **2***a*. Thus our work strongly indicates that in contrast to **1***b*, **1***a* probably decomposes by a process in which the Wolff rearrangement of the incipient carbene is concerted with loss of N_2. That **2***b* is trapped by water or alcohols when **1***b* is decomposed photochemically while **1***a* yields the ester derived from **3***a* supports this conclusion.[8]

Of significance also is our finding that the activation parameters calculated for the decarbonylation of **3***b* at the AM1 and MP2/6-31G(d)//RHF/6-31G(d) levels of theory are lower than the values calculated for the loss of N_2 from **1***b*. The opposite situation is found in the case of **3***a* where, calculationally, $\Delta H^{\ddagger}$ and E_a are higher than $\Delta H^{\ddagger}$ and E_a of **1***a*. These findings are nicely in accord with the experimental results; while **3***a* is detected in the pyrolysate of **1***a*, we find that ketene **3***b* is not found in detectable amounts in the pyrolysate of **1***b* (3). As is seen in the transition states for loss of nitrogen from **7**, **1***a*, and **1***b*, CO pivots out from **3***a* and **3***b* rather than being extruded in a linear trajectory.
