REVIEW / SYNTHÈSE

Électrons en excès dans les milieux polaires homogènes et hétérogènes

Annette Bernas, Christiane Ferradini et Jean-Paul Jay-Gerin

Résumé : Une synthèse des connaissances actuelles concernant la solvatation des électrons en excès ($e^-_{exc} \rightarrow e^-_{solv}$) produits par photoionisation ou par radiolyse dans les milieux polaires a été tentée. Sont successivement envisagées les diverses propriétés de l'espèce alors formée : les mécanismes proposés pour sa solvatation, sa structure, ses caractéristiques physico-chimiques. En dépit de certaines analogies entre les anions halogénure solvatés et e^-_{solv}, celui-ci ne paraît pas pouvoir en constituer le prototype. Le comportement de e^-_{exc} dans des systèmes hétérogènes modèles, tels que solutions micellaires et agrégats moléculaires, est également abordé et corrélé aux résultats relatifs aux solutions homogènes.

Mots clés : électrons en excès, milieux polaires homogènes et hétérogènes, photoionisation, radiolyse, solvatation, transfert de charge au solvant, propriétés de l'électron solvaté, solutions micellaires, agrégats moléculaires, comparaison avec la solvatation des anions.

Abstract: A review of our present knowledge concerning the solvation of excess electrons ($e^-_{exc} \rightarrow e^-_{solv}$) produced by photoionization or radiolysis in polar media has been attempted. Various properties of the solvated electron (proposed solvation mechanisms, structure, physicochemical characteristics) are considered. In spite of some similarities, e^-_{solv} does not seem to be a good prototype for solvated halide anions. The behavior of e^-_{exc} in heterogeneous model systems, such as micellar solutions and molecular clusters, is described and correlated with that observed in homogeneous media.

Key words: excess electrons, homogeneous and heterogeneous polar media, photoionization, radiolysis, solvation, charge transfer to solvent, properties of the solvated electron, micellar solutions, molecular clusters, comparison with the solvation of anions.

I. Introduction

L'électron solvaté (e^-_{solv}), c'est-à-dire l'électron «en excès» (e^-_{exc}) stabilisé par interaction avec les dipôles de molécules solvant, présente les caractéristiques d'une véritable entité chimique; ses propriétés thermodynamiques et cinétiques peuvent être définies et déterminées.

La couleur bleue stable des solutions de métaux alcalins dans l'ammoniac liquide avait été observée dès la fin du siècle dernier (1), mais c'est Kraus (2) qui, le premier, a associé couleur et conductivité ionique de telles solutions à la présence d'*electrons surrounded with an envelope of ammonia.* C'est seulement en 1960 que l'avènement de la radiolyse pulsée a permis à Gilbert et al. (3) et à Keene (4) de mettre en évidence une forte absorption transitoire dans l'eau irradiée, absorption que Hart et Boag (5) ont confirmée et attribuée à l'électron hydraté (e^-_{aq}).

Depuis il a été bien établi que e^-_{solv} constitue un intermédiaire important, notamment en chimie sous rayonnement, photochimie et électrochimie. Le radical anion e^-_{aq} est apparu comme un réducteur efficace. Par ailleurs, e^-_{solv} et son précurseur non relaxé peuvent constituer des microsondes de la structure du milieu et de la dynamique de sa réorganisation.

Ces dernières années, un regain d'intérêt et d'activité s'est manifesté concernant l'électron solvaté (voir, par exemple, réfs. 6–11), et ceci grâce à de nouvelles approches tant expérimentales que théoriques. Entre autres, il faut citer, d'une part, l'utilisation de montages de spectroscopie laser femtoseconde et, d'autre part, l'avènement des techniques de simulation numérique. L'interaction entre expérience et théorie s'est avérée particulièrement bénéfique pour le développement de nos connaissances. Néanmoins, nous le verrons, beaucoup de problèmes subsistent.

Dans un tel contexte, nous avons tenté ici une mise au point sur l'ensemble de ces questions en prenant en compte les résultats les plus marquants obtenus, mais en tâchant autant que possible de rendre cet ensemble facilement accessible au non-spécialiste.

Ce travail, de nature surtout physico-chimique, est organisé de la façon suivante. Nous rappelons d'abord les données les plus significatives concernant la caractérisation, la dynamique et le mécanisme de solvatation de e^-_{exc} en solutions liquides homogènes. L'accent est mis sur les aspects de ce mécanisme qui restent controversés. La spécificité de e^-_{aq} est ensuite discutée. Enfin, à partir des propriétés de e^-_{solv} et plus particulièrement de e^-_{aq}, nous nous proposons de : (*i*) comparer les caractéristiques de la solvatation des électrons en excès à celles des ions halogénure X^-; (*ii*) confronter les informations relatives à e^-_{solv} en solutions homogènes, en solutions micellaires ou lié à des agrégats de molécules polaires.

II. Électrons en excès en solutions polaires homogènes

A. Techniques de production et d'analyse de e^-_{solv}

1. Techniques de production

L'énergie nécessaire à la formation de l'électron solvaté peut être apportée par différentes voies :

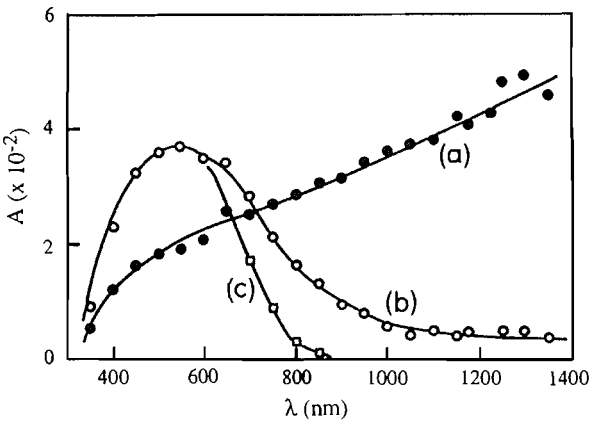
(*i*) *Chimique* : La formation de e^-_{solv} par dissolution de métaux alcalins dans l'ammoniac liquide ou dans l'eau présente surtout un intérêt historique (2). Notons néanmoins l'apparition de e^-_{aq} par réaction acido-basique des atomes H à pH élevé (pH > 11) (12).

(*ii*) *Électrochimique* : Des électrons solvatés peuvent être produits à la cathode pour des potentiels électriques suffisamment élevés ou être photoinjectés dans la solution électrolytique à partir d'électrodes métalliques ou semiconductrices. Les études photoélectrochimiques, largement développées depuis une trentaine d'années (13), ont permis en particulier d'estimer les distances de thermalisation de e^-_{exc} et l'énergie fondamentale de l'électron quasi-libre (e^-_{qf}) dans quelques liquides polaires (voir, par exemple, réf. 14).

(*iii*) *Photochimique* : Des processus d'ionisation peuvent aussi être engendrés par voie photochimique (photons d'énergie supérieure à quelques eV) (voir, par exemple, réf. 15). Ils concernent soit des molécules neutres, solvants purs ou solutés, soit des anions, tels que Cl^-, OH^-,... Suivant les conditions expérimentales, ces photoionisations peuvent être mono- ou multiphotoniques. Des avancées technologiques récentes ont permis d'obtenir des impulsions laser ultra-courtes (16). Les temps de résolution pouvant dorénavant atteindre couramment la centaine de femtosecondes ont ouvert la voie à de nombreux travaux permettant de suivre la dynamique de formation de e^-_{aq}.

(*iv*) *Radiolytique* : Les sources d'irradiation employées sont, soit des faisceaux d'électrons accélérés et le plus souvent pulsés (de 1 à 10 MeV), soit des rayons γ de l'ordre du MeV, soit plus rarement des ions lourds accélérés. Pour les impulsions d'électrons, les temps de résolution les plus courts restent supérieurs à environ 10 ps, soit de deux à trois ordres de grandeur plus élevés que ceux mentionnés plus haut. En revanche, la radiolyse pulsée s'est avérée particulièrement appropriée pour analyser quantitativement les mécanismes réactionnels des espèces transitoires, en particulier ceux impliquant des électrons solvatés (voir, par exemple, réf. 17).

Fig. 1. Spectres d'absorption du propanol-1 irradié à −121°C par des impulsions d'électrons de 5 ns : (*a*) à la fin de l'impulsion, (*b*) 200 ns après la fin de l'impulsion et (*c*) 1 μs après la fin de l'impulsion (d'après Baxendale et Wardman (19)).



2. Méthodes analytiques

Une interception chimique de e^-_{solv} a été souvent utilisée dans le cas d'irradiations continues, les principaux capteurs préconisés étant N_2O, SF_6, Cd^{2+}, NO_3^-,...

Les techniques physiques les plus adaptées sont la conductimétrie, la résonance paramagnétique électronique (RPE) et surtout la spectroscopie d'absorption optique. La luminescence associée à la recombinaison des charges a également été analysée en intensité et en composition spectrale.

B. Dynamique et mécanisme(s) de solvatation

Tous les liquides polaires ne conduisent pas à la formation d'électrons solvatés. En effet, dans certains cas, la solvatation entre en compétition avec un processus d'attachement électronique. Ce dernier l'emporte, par exemple, pour l'acétonitrile, le formamide, la diméthylcétone (18).

Les premières études relatives à la solvatation de e^-_{exc} ont concerné divers alcools liquides à basses températures, ce qui permettait d'ajuster les temps de solvatation alors observés aux temps de résolution expérimentalement accessibles.

1. Dynamique de solvatation dans les alcools liquides

L'irradiation du propanol-1 à −121°C, c'est-à-dire à 6° au-dessus de son point de fusion, par des impulsions d'électrons de 5 ns (19) a conduit aux spectres reportés sur la figure 1. Une absorption dans l'infra-rouge, attribuée à une espèce transitoire e^-_{ir} et présente dès la fin de l'impulsion, disparaît en même temps que croît la bande centrée vers 550 nm correspondant à l'électron solvaté. À partir de la figure 1, les constatations suivantes ont été soulignées : (*i*) environ 50% de l'absorption correspondant à l'état relaxé e^-_{solv} sont déjà présents à la fin de l'impulsion (spectre *a*); (*ii*) le passage du spectre *b* au spectre *c* montre une diminution d'absorption dans le proche infra-rouge sans augmentation corrélative de la bande visible, ce qui suggère que le rappel de e^-_{ir} vers l'ion positif entre en compétition avec la solvatation.

Soulignons qu'une évolution similaire du spectre de e^-_{exc} a aussi été enregistrée dans le cas du propanol-1 vitreux à 77 (20) et 4 K (21) pour des échelles de temps évidemment beaucoup plus longues.

Des études dans le domaine picoseconde par radiolyse pulsée (22–24) et impulsions laser (24, 25) ont ensuite élargi le domaine de température et porté sur une série d'alcools aliphatiques de C_1 à C_{10}. Ces expériences ont pleinement confirmé l'existence de e^-_{ir} précurseur de e^-_{solv}. Kenney-Wallace et Jonah (23, 24) ont observé que l'évolution cinétique de l'absorbance à une longueur d'onde donnée (entre 450 et 750 nm) montre en effet un signal rapide qui apparaît dans le temps de résolution de l'appareil (<10 ps) et un signal lent (10–300 ps), indépendant de la longueur d'onde, décrit par une exponentielle (figure 2).

Les temps de solvatation de $e^-_{exc}(\tau_s)$, pris comme les inverses des constantes de vitesse exponentielles, augmentent régulièrement avec la longueur de la chaîne des alcools (voir tableau 1). Ceux-ci ont d'autre part été comparés aux différents temps de relaxation diélectrique τ_1, τ_2 et τ_3 qui correspondent respectivement (26, 27) : (*i*) au temps requis pour la rupture de liaisons hydrogène suivie de la réorientation moléculaire; (*ii*) au temps de rotation de molécules monomères et (ou) de petits multimères «libres» (c'est-à-dire, non liés par des liaisons hydrogène); (*iii*) au temps de réorientation des dipoles OH autour de la liaison C—O. Le tableau 1 met en évidence une bonne correspondance entre les valeurs τ_s et τ_2. Ceci suggère que la rotation moléculaire réglerait, pour une large part, la dynamique de solvatation de l'électron dans les alcools, laquelle procéderait en deux étapes successives, à savoir, localisation et solvatation.

La photoionisation de divers solutés en solutions alcooliques par impulsions laser de 6–10 ps a aussi été étudiée (28–30). Examinant à différentes longueurs d'onde l'évolution des spectres transitoires de e^-_{exc}, Hirata et al. (30) observent un déplacement continu vers le bleu de la bande d'absorption de l'électron et suggèrent que le processus global de solvatation impliquerait l'existence d'un état supplémentaire entre e^-_{ir} et e^-_{solv} (voir sect. II-B.3).

Les expériences de spectroscopie laser femtoseconde de Pépin et al. (32) utilisant des impulsions de ~300 fs très intenses à 620 nm (2 eV), ont par ailleurs mis en évidence une ionisation du méthanol liquide à la temperature ambiante par un processus d'absorption impliquant au moins trois photons. Ces auteurs observent dans le spectre de e^-_{exc} une transition discrète entre e^-_{ir} et une espèce transitoire apparaissant avec un temps caractéristique de 6,1 ± 0,6 ps. Simultanément, un déplacement spectral continu vers le bleu est observé pour l'une et l'autre de ces espèces. Pour l'espèce transitoire, ce déplacement est exponentiel avec un temps caractéristique de 13,6 ± 0,6 ps, en bon accord avec la valeur de 10,7 ± 1,7 ps déterminée par Hirata et al. (30). Des résultats analogues ont été obtenus récemment par Shi et al. (33) en utilisant des impulsions laser de ~150 fs à 312,5 nm (4 eV/photon), pour le méthanol, l'éthanol et le butanol-1 à 21°C (voir tableau 1). De plus, une évolution continue de l'espèce transitoire vers l'état relaxé e^-_{solv} a également été mise en évidence par Walhout et al. (34) pour les quatre alcools légers C_1 à C_4 à la température ambiante, lors d'expériences de spectroscopie d'absorption transitoire pompe-test de e^-_{solv} (vide infra), mettant en jeu trois impulsions laser consécutives.

Ces divers résultats montrent ainsi l'insuffisance d'un modèle de solvatation de l'électron n'impliquant que deux

Fig. 2. (*a*) Évolutions cinétiques de l'absorbance de e^-_{solv} à $\lambda = 514$ nm pour divers alcools aliphatiques de C_1 à C_{10} liquides à 295 K, normalisée à temps infini à l'absorbance maximale pour le méthanol. (*b*) Tracés semi-logarithmiques de l'absorbance en fonction du temps, à partir desquels les valeurs des temps de solvatation de e^-_{exc} (τ_s) sont calculées (voir texte). i-C_3 correspond à l'isopropanol ou propanol-2 (d'après Kenney-Wallace et Jonah (23)).

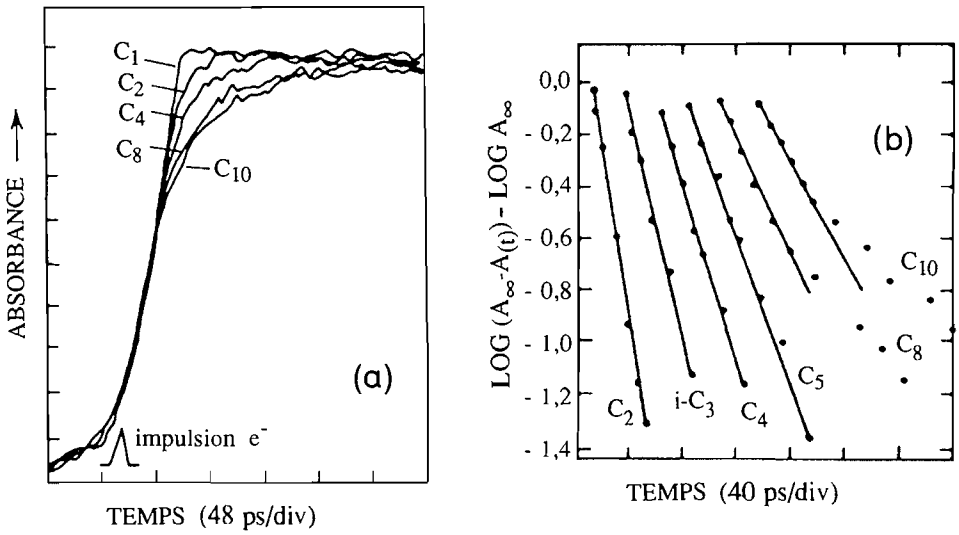


Tableau 1. Temps de solvatation τ_s de e^-_{exc} et temps de relaxation diélectrique τ_2 pour divers alcools à ~295 K.

Alcool	τ_s (ps)	τ_2 (ps)
Méthanol	10,7 ± 1 (22), 11 ± 1 (24), 17 ± 3 (28), < 10 (30), 9,5 ± 2 (31), 6,1 ± 0,6 (32), 7,1 ± 0,3 (33)	7,09,[a] 12,6[b]
Éthanol	23 ± 2 (22), 18 ± 2 (23, 24), 26 ± 5 (28), < 20 (29), 11 (30), ~21 (31), 15,2 ± 1 (33)	8,97,[a] 16,4[b]
Propanol-1	34 ± 3 (22), 25 ± 3 (23, 24), ~20 (29), 21 (30)	15,1,[a] 21,9[c]
Propanol-2	24 ± 3 (23, 24), 22 (30), ~20 (29)	14,5[a]

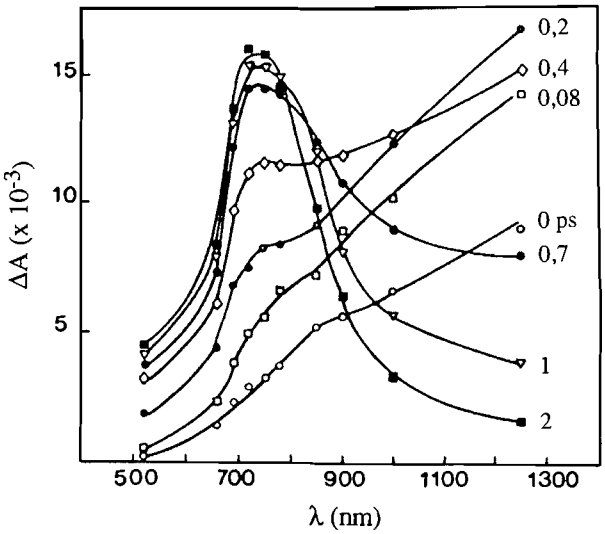
[c]D'après Garg et Smyth (26).

états. Soulignons qu'une telle conclusion n'est pas contredite par les données antérieures relatives à la dynamique de solvatation de l'électron dans les alcools liquides à basse température (19, 35, 36). En effet, celles-ci ne mettent pas clairement en évidence un point isobeste (voir, par exemple, réf. 37). Or, l'existence de celui-ci aurait témoigné de la seule participation de deux états électroniques distincts et de la relaxation exclusive du premier état vers le deuxième.

Fig. 3. Spectres d'absorption de e^-_{exc} mesurés à différents délais (entre 0 et 2 ps) après photoionisation selon un processus biphotonique (4 eV/photon) de l'eau liquide à 21°C (d'après Gauduel et al. (38)).



2. Dynamique de solvatation dans l'eau liquide pure

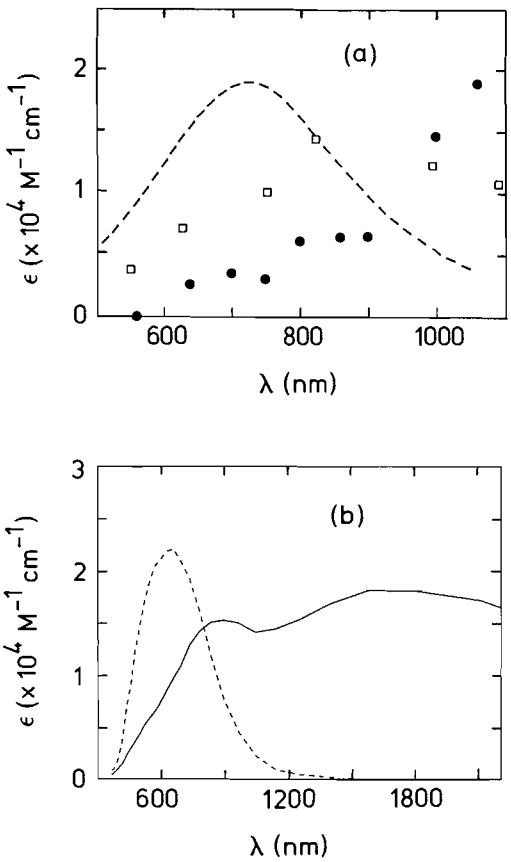
L'existence d'un précurseur de l'électron solvaté, déjà établie dans le cas des alcools, a été démontrée directement pour la première fois par Gauduel et al. (38) par photoionisation à deux photons de l'eau pure sous impulsions laser de ~100 fs à 310 nm (figure 3). Ces auteurs ont ainsi pu déterminer : un temps de montée de e^-_{ir}, $T_1 = 110 \pm 30$ fs, et un temps de relaxation $e^-_{ir} \rightarrow e^-_{aq}$, $T_2 = 240 \pm 40$ fs, cette relaxation suivant une loi cinétique du premier ordre. Le déclin de e^-_{ir} et la montée de e^-_{aq} apparaissent concomitants, mais on n'observe pas de transformation spectrale continue $e^-_{ir} \rightarrow e^-_{aq}$. La transition impliquerait donc, pour l'essentiel de la relaxation, deux états électroniques distincts.

Utilisant des techniques semblables de spectroscopie laser femtoseconde, Long et al. (39) ont conclu à l'existence d'un point isobeste à 820 nm. L'identification d'un tel point, qui corroborerait ainsi la conclusion que le passage $e^-_{ir} \rightarrow e^-_{aq}$ se fait selon une «vraie» transition entre deux états distincts, n'a cependant pas été retrouvée ni par Gauduel et al. (38, 40, 41) et ni, plus récemment, par Barbara et coll. (42). Il a d'autre part été noté que l'observation d'un point isobeste pourrait dépendre des conditions expérimentales, et en particulier de l'intensité du faisceau laser incident (38, 43).

Par ailleurs, Long et al. (39) ont noté une certaine similitude entre le spectre d'absorption trouvé pour e^-_{ir} et celui de e^-_{aq} (figure 4*a*), et considèrent que e^-_{ir} serait un état excité de l'état relaxé e^-_{aq} (voir sect. II-B.3). D'après ces auteurs, le temps de formation de e^-_{ir} serait de 180 ± 40 fs, alors que la relaxation $e^-_{ir} \rightarrow e^-_{aq}$ s'effectuerait en 540 ± 50 fs, durée comparable au temps de vie moyen des liaisons hydrogène dans l'eau liquide (44).

Plus récemment, les expériences de spectroscopie laser femtoseconde de Houde et collaborateurs (45, 46), utilisant des impulsions de ~150 fs à 620 nm (2 eV/photon), ont permis d'ioniser l'eau liquide via un processus d'absorption multiphotonique résonant mettant en jeu au moins quatre photons.

Fig. 4. (*a*) Spectres d'absorption de e^-_{ir} dans l'eau : d'après Long et al. (39) (□) et d'après Kimura et al. (42) (•). La courbe en tirets représente le spectre d'absorption de e^-_{aq} à titre de comparaison. (*b*) Coefficients d'extinction molaire, exprimés en M^{-1} cm^{-1}, de e^-_{aq} (courbe en tirets) et de e^-_{ir} (courbe en trait plein) calculés par Rossky et al. (81, 84; voir aussi réf. 10). À noter que le maximum théorique du spectre de e^-_{aq} est décalé de ~0,7 eV vers les hautes énergies par rapport au maximum expérimental.



Les temps T_1 et T_2, estimés par ces auteurs, sont respectivement de 130 ± 40 et 620 ± 60 fs à 1100 nm (46).

Une autre méthode originale où e^-_{ir} est formé non pas à partir de l'électron quasi-libre mais à partir de l'électron déjà relaxé e^-_{aq}, utilise, ainsi qu'il a été cité précédemment, trois types d'impulsions laser consécutives (42). La première produit e^-_{aq}; après un retard de quelques nanosecondes, la deuxième, centrée à 780 nm (~1,6 eV) et d'une durée de 130 fs, blanchit e^-_{aq}; la troisième enfin sonde l'évolution temporelle de e^-_{ir} dans la gamme spectrale 540–1060 nm. Le temps de relaxation T_2 moyenné sur toutes les longueurs d'onde est trouvé égal à 310 ± 80 fs. Il faut néanmoins tenir compte du fait que la transition correspondant à T_2 n'implique pas ici l'état pleinement relaxé de l'électron. En effet, dans ces expériences, il a été mis en évidence, en apparente contradiction avec les résultats de Gauduel et al. (38), un déplacement continu du spectre intermédiaire vers le bleu avec un temps caractéristique relativement long (1,1 ± 0,2 ps). Comme nous le verrons plus loin, la dynamique complexe observée a amené

ces auteurs à compléter le modèle cinétique n'impliquant que deux états électroniques. Le spectre de e^-_{ir} obtenu en développant le modèle précédent est reporté sur la figure 4*a*.

Autres espèces formées parallèlement dans l'eau pure ou certaines solutions aqueuses : Il s'agit en particulier d'espèces formées par transfert de proton. C'est ainsi qu'en radiolyse, comme en photolyse de solvants associés, l'ionisation primaire conduisant au cation est accompagnée du transfert d'un proton quasi-instantané vers une molécule voisine, soit pour l'eau :

$$H_2O^+ + H_2O \rightarrow OH + H_3O^+ \ (\sim 10^{-14}\ s \text{ (voir, par exemple, réf. 47)})$$

Signalons toutefois que l'évolution de l'absorption due à l'hydratation de l'électron et mesurée par spectroscopie laser femtoseconde, soit à 625 nm (39), soit dans la gamme 410–460 nm (48), montre une composante à très courte durée de vie (~50–100 fs) qui pourrait être assignée au cation H_2O^+.

Par ailleurs, il a été avancé qu'un transfert de proton pouvait s'effectuer très rapidement à partir de H_2O neutre électroniquement excitée (49–52). En effet, en phase gazeuse, un tel transfert a été inféré de données de spectrométrie de masse (53). De plus, l'affinité protonique de H_2O est élevée : de 7,2 eV pour la molécule isolée, elle augmente de façon continue avec la taille des agrégats pour atteindre environ 10,5 eV pour des agrégats de 40 à 50 molécules (54).

Outre H, OH, H_2O^+ et H_3O^+, d'autres espèces intermédiaires peuvent apparaître très précocement : il s'agirait de paires hydratées $[H_3O^+{:}e^-{:}OH]_{nH_2O}$, de très faible durée de vie, formées par couplage transitoire de l'électron non relaxé avec la sphère d'hydratation du proton (40, 41). L'existence de ces paires de rencontre a été suggérée pour expliquer les résultats concernant la photoionisation de solutions aqueuses concentrées d'acide chlorhydrique (11 M en HCl) où toutes les molécules d'eau sont impliquées dans l'hydratation de H_3O^+ et de son contre-ion Cl^- (55). En effet, une bande d'absorption a été observée dans le proche infra-rouge, centrée à 920 nm, et un recours à D_2O permet, d'après les auteurs, de discriminer entre ces états électroniques hybrides et e^-_{ir}. À l'inverse de la formation et de la relaxation de e^-_{ir}, l'apparition et la durée de vie des paires mesurées dans la région infra-rouge sont influencées de façon importante par la substitution isotopique H/D. De plus, la relaxation des paires dans H_2O et D_2O est trouvée plus longue que la durée de vie de e^-_{ir} et la probabilité de former e^-_{aq} à partir de leur neutralisation apparaît très faible à température ambiante (41).

Dans le cas de solutions aqueuses de chlorure de sodium (1 ou 6 M), l'existence de paires de contact $[e^-{:}Cl]_{nH_2O}$ a également été postulée pour expliquer l'évolution de l'absorption dans le proche infra-rouge (820–1000 nm) (56). La disparition de ces paires se produirait, soit par reformation de Cl^-, soit par formation de e^-_{aq}, les temps caractéristiques correspondants étant respectivement de 330 et 750 fs. Toutefois, signalons que Long et al. (57) expliquent le destin du photoélectron dans des solutions aqueuses d'halogénures alcalins ou de NaOH sans invoquer la formation de paires de contact.

3. Mécanisme(s) de solvatation et définitions

Il est clair que, comme les ions solvatés, e^-_{solv} résulte d'un équilibre entre les puits de potentiel attractifs qui se développent quand les molécules solvant sont polarisées par l'électron en excès et l'énergie cinétique de ce dernier qui, à elle seule, conduirait à un état délocalisé.

On considère généralement que la solvatation procède en plusieurs étapes, selon la séquence suivante :

$$e^-_{qf} \rightarrow e^-_{th} \rightarrow e^-_{ir} \rightarrow e^-_{solv}$$

e^-_{qf} désigne un électron quasi-libre, tel que, par exemple, un électron de subexcitation (58, 59) dont l'énergie cinétique est typiquement de l'ordre de quelques électron-volts; e^-_{th} désigne un électron quasi-libre thermalisé, se trouvant donc, à l'énergie thermique près, au bas de la bande de conduction du liquide; la fonction d'onde associée à e^-_{th}, comme à e^-_{qf}, s'étend sur de nombreux diamètres moléculaires; e^-_{ir} désigne un électron localisé, incomplètement relaxé, dont la fonction d'onde ne s'étend que sur quelques diamètres moléculaires; e^-_{solv} désigne l'électron solvaté, c'est-à-dire un électron localisé, complètement relaxé, en équilibre avec le solvant; e^-_{exc} ou électron «en excès», recouvre l'ensemble des dénominations précédentes.

Les résultats de Hirata et al. (30) pour les alcools ont été mentionnés plus haut. Dans leur interprétation concernant la solvatation de e^-_{exc}, ces auteurs considèrent une espèce intermédiaire entre e^-_{ir} (dénoté e^-_{loc} ou e^-_t) et e^-_{solv} correspondant à un état «partiellement solvaté» (e^-_{ps}) :

$$e^-_{qf} \longrightarrow e^-_{th} \longrightarrow e^-_{loc}(e^-_t) \xrightarrow{[i]} e^-_{ps} \xrightarrow{[ii]} e^-_{solv}$$

L'étape [i], discrète, serait corrélée, nous l'avons vu, au temps de relaxation diélectrique τ_2 de l'alcool, en accord avec les interprétations de Chase et Hunt (22) et de Kenney-Wallace et Jonah (23, 24). La vitesse de l'étape [ii], plus lente et continue, serait, elle, assimilable à l'inverse du temps de relaxation diélectrique longitudinale $\tau_{L1} = (\varepsilon_\infty/\varepsilon_s)\tau_1$, où ε_s et ε_∞ sont les constantes diélectriques statique et à fréquence infinie du solvant. La solvatation de e^-_{exc} s'interpréterait donc, d'après Hirata et al. (30), par la réorientation initiale d'un petit nombre de molécules d'alcool «libres» dans la première couche de solvatation, suivie d'une stabilisation plus poussée due à la réorganisation de molécules de solvant plus éloignées, nécessitant la rupture de liaisons hydrogène. Il est intéressant de noter ici que cette succession temporelle est opposée à celle décrite par Onsager (dans réf. 60, voir Discussion p. 1819) dans l'approximation du continuum diélectrique, qui considère que la solvatation de e^-_{exc} procèderait d'abord des couches éloignées pour gagner ensuite les couches les plus proches de la charge (61).

Nous avons vu plus haut que, grâce à une résolution temporelle bien inférieure aux temps caractéristiques des phénomènes mis en jeu, des expériences de spectroscopie laser femtoseconde ont permis à Pépin et al. (32) d'étudier la solvatation de e^-_{exc} dans le méthanol liquide pur. Ces auteurs ont montré, en particulier, la coexistence de deux mécanismes de relaxation de l'espèce transitoire e^-_{ir}, l'un discret et l'autre continu. Le modèle hybride ainsi proposé implique deux états électroniques, l'un et l'autre relaxant via un déplacement continu vers le bleu et entre lesquels existe un mécanisme discret de transfert. Un tel modèle pourrait être en mesure de concilier certaines données apparemment contradictoires concernant la

solvatation de e^-_{exc}, non seulement dans les alcools mais également dans l'eau (32).

En ce qui concerne l'eau pure, nous avons évoqué précédemment que le recours à trois impulsions laser consécutives a permis à Barbara et coll. (42) d'apporter de nouvelles informations concernant la transition non radiative de l'état précurseur e^-_{ir}, considéré comme un état excité de e^-_{aq} (dénoté $e^-_{état\ p}$), vers l'état fondamental ($e^-_{état\ s}$). Ces auteurs ont ainsi été amenés à examiner la dynamique de solvatation d'un état intermédiaire $e^{-*}_{état\ s}$, dynamique qu'ils associent à une élévation locale de température. Cet état intermédiaire se relaxe de façon continue vers e^-_{aq}. Le schéma global peut être écrit :

$$e^-_{état\ p} \xrightarrow{310\ fs} e^{-*}_{état\ s} \xrightarrow[\text{déplacement continu}]{1,1\ ps} e^-_{état\ s}\ (e^-_{aq})$$

Remarquons qu'un tel schéma présente une grande ressemblance avec les mécanismes évoqués plus haut pour la solvatation de e^-_{exc} dans divers alcools (30, 32–34). Une telle analogie est toutefois restreinte par le fait que les échelles de temps mises en jeu pour décrire les phénomènes sont bien supérieures pour les alcools que pour l'eau.

Le mécanisme de solvatation de l'électron dans les alcools et l'eau apparaît ainsi plus complexe qu'il ne semblait *a priori*. Pour rendre son interprétation plus quantitative, bien des points restent à élucider; un certain nombre d'entre eux sont évoqués ci-dessous.

La formation de e^-_{qf} est-elle une étape obligée de la solvatation? Cette question concernerait en particulier le domaine d'énergie des photons proche du seuil d'ionisation du solvant et situé au-dessous du bas de la bande de conduction de celui-ci. Elle s'appliquerait notamment aux expériences de spectroscopie laser femtoseconde de l'eau liquide pour lesquelles l'énergie d'excitation est de 8 eV lors d'un processus biphotonique (λ_{exc} = 310 nm) (38, 39), les énergies du seuil d'ionisation et du bas de la bande de conduction, dans ce cas, étant respectivement de 6,5 ± 0,5 eV (62) et de ~8,9 (63) ou 10–12 eV (52).

Des données de photoélectrochimie avaient suggéré que les électrons en excès pouvaient être directement localisés dans des pièges préexistants de la solution électrolytique (64).

Nous avons récemment proposé une interprétation analogue pour la photoionisation de l'eau pure et des solutions aqueuses diluées (63). Il a ainsi été noté que les courbes exprimant la variation du rendement d'ionisation (ϕ_e) en fonction de l'énergie (E_{ph}) des photons incidents dans la région du seuil étaient exponentielles. De telles lois exponentielles sont également caractéristiques des bandes d'Urbach (65), traduisant l'existence d'états électroniques localisés dans la bande d'énergie interdite de divers solides amorphes ou désordonnés, ces états localisés étant corrélés au désordre du milieu.

Ces remarques suggèrent que lors de la photoionisation de l'eau liquide, pour E_{ph} voisin du seuil, les états électroniques finals pourraient se situer, non pas dans la bande de conduction, mais dans une bande d'états localisés s'étendant au-dessous de celle-ci; la variation de ϕ_e avec E_{ph} traduirait alors la distribution énergétique des états localisés dans la bande d'Urbach.

L'existence de telles bandes d'états localisés dans les liquides a été utilisée par Houée-Levin et Jay-Gerin (66) pour interpréter les spectres d'absorption optique des électrons e^-_{ir} dans l'eau à 21°C et dans certains alcools liquides à basse température, et a été confirmée pour l'eau (67–69) et le méthanol (70) liquides à température ambiante par des calculs de simulation de dynamique moléculaire.

Une localisation initiale des e^-_{exc} dans la bande d'Urbach a conduit également à envisager le dépiégeage possible de certains d'entre eux, faiblement liés, sous l'action du champ coulombien du cation parent (71). Les électrons ainsi libérés pourraient soit se recombiner avec l'ion positif géminé, soit se piéger à nouveau. Globalement, les pièges peu profonds se videraient au profit des pièges plus profonds, entraînant une diminution de la partie infra-rouge du spectre d'absorption de e^-_{ir}, spectre qui devrait donc présenter un maximum. Celui-ci n'a cependant pas encore été déterminé expérimentalement sans équivoque (pour le cas de l'eau, voir figure 4*a*).

Les pièges préexistants dans les liquides sont-ils nécessaires à la localisation de e^-_{exc}? Thermalisation et piégeage sont-ils concomitants? Les expériences de spectroscopie femtoseconde ne permettent pas de trancher le dilemme suivant : l'électron crée-t-il son propre puits de potentiel (autopiégeage ou *self-trapping*) ou se fixe-t-il dans des sites de piégeage préexistants, sites dus à des fluctuations de densité électronique ou d'orientation des molécules du solvant?

Les calculs de simulation de Schnitker et al. (67), mentionnés précédemment, ont conclu à l'existence, dans l'eau liquide, de sites préexistants favorables énergétiquement au piégeage de e^-_{exc}, de par leur dimension et leur profondeur. D'après ces auteurs, la distribution énergétique de ces sites s'étend jusqu'à environ 1,4 eV en-dessous du bas de la bande de conduction pour le site de localisation le plus favorable. On peut remarquer qu'une telle valeur est voisine de l'enthalpie libre d'hydratation de l'électron $\Delta G^0_{hyd} \sim -1{,}68$ eV/molécule (voir sect. II-D), indiquant ainsi l'existence de sites de piégeage préexistants de e^-_{exc} ayant une structure proche de celle correspondant à e^-_{aq}. Les calculs de simulation les plus récents de ces mêmes auteurs (69), également pour l'eau liquide, ont indiqué une concentration relativement élevée (~0,01 M) de l'ensemble des pièges préexistants, comparable aux valeurs minimales estimées par ailleurs par Mozumder (72).

Cependant, un modèle, pour lequel la paire «électron (d'énergie inférieure à ~1 eV) – ion positif» dans un milieu polaire est traitée comme un atome d'hydrogène plongé dans un continuum diélectrique qui se relaxe, conclut à la possibilité d'une localisation instantanée par auto-piégeage, localisation qui précéderait ainsi la thermalisation (73). Les pièges préexistants dans le liquide ne seraient alors pas nécessaires à la localisation de l'électron en excès.

Notons enfin que d'après le schéma précédemment décrit pour la photoionisation de l'eau pure et des solutions aqueuses diluées (63), les électrons photoéjectés ne seraient pas initialement dans un état quasi-libre, mais se localiseraient directement à partir d'états excitoniques, de type Mott–Wannier, du liquide (74) : thermalisation et piégeage seraient alors des processus quasi-synchrones.

La transition $e^-_{ir} \rightarrow e^-_{solv}$ est-elle ou non continue? En ce qui

concerne l'*eau liquide*, les premières études de spectroscopie laser femtoseconde ont abouti à la conclusion que le processus prédominant d'hydratation de e^-_{exc} n'était pas associé à la relaxation progressive des molécules de solvant entourant la charge, mais correspondait plutôt à un processus impliquant deux états électroniques distincts de e^-_{exc} (38, 39).

En revanche, divers calculs de simulation de dynamique «adiabatique»,[3] utilisant la méthode des intégrales de chemin et traitant le solvant–eau de manière classique (75, 76), ont indiqué un déplacement continu, allant de l'infra-rouge vers le visible, du maximum du spectre d'absorption de e^-_{exc}. De plus, selon ces mêmes calculs, la majeure partie du processus d'hydratation aurait lieu sur une échelle de temps de l'ordre de 80–100 fs. Ces désaccords avec l'expérience ont amené Rossky et Schnitker (75) à postuler que l'état responsable de l'absorption infra-rouge est un état «excité» de e^-_{aq} et que sa relaxation s'effectue de manière non adiabatique vers l'état fondamental. Selon ces auteurs (75, 77), le spectre de e^-_{aq} serait ainsi dominé par des transitions électroniques à partir d'un état fondamental (de type *s*) vers trois états excités, localisés (de type *p*), non dégénérés. À ceci s'ajouterait, à plus haute énergie, une composante spectrale moins intense comprenant des excitations vers un continuum d'états délocalisés. Dans un tel schéma, l'étape limitante dans la dynamique de solvatation de e^-_{exc} serait donc déterminée par la conversion interne de l'état excité de e^-_{aq}. Le spectre ainsi calculé par Rossky et al. (75, 77) a son maximum d'absorption situé à ~2,4 eV et une largeur à mi-hauteur de ~1,1 eV, alors que les valeurs expérimentales correspondantes sont respectivement de 1,73 et 0,85 eV (voir sect. II-C.2-a).

Un tel modèle, consistant à considérer e^-_{ir} comme un état excité de e^-_{aq}, a également été avancé par Long et al. (39) pour interpréter leurs résultats. Par ailleurs, soulignons que Messmer et Simon (78) n'ont pu reproduire qualitativement les données expérimentales de Gauduel et al. (38) qu'en prenant en compte une population d'électrons subissant une transition non adiabatique. Dans ce cas, l'analyse phénoménologique mènerait à la répartition suivante des électrons qui donnent lieu à la solvatation : 55% subiraient une transition non adiabatique, 20% conduiraient quasi-instantanément à e^-_{aq} et 25% s'hydrateraient de façon continue.

Des calculs de simulation de dynamique «non adiabatique» directe ou des simulations de dynamique moléculaire mettant en oeuvre diverses variantes de ces calculs, ont tenté d'explorer, dans une étape ultérieure, la validité du modèle d'hydratation en deux étapes (79–85), sans toutefois qu'une interprétation quantitative puisse être établie. Quelques remarques méritent, en particulier, d'être évoquées ici. Il est apparu, par exemple, que les vibrations des molécules d'eau jouaient un rôle substantiel dans la cinétique de disparition de l'intermédiaire mis en jeu. En effet, Webster et al. (79) ont trouvé une durée de vie de ~1 ps pour l'état e^-_{ir} en utilisant un modèle d'eau rigide. Si, au contraire, la flexibilité de la molécule d'eau est prise en compte, la valeur correspondante obtenue est ~160 fs (81), inférieure à celles données par l'expérience (240–620 fs, selon les auteurs; voir sect. II-B.2).

[3] Dans l'hypothèse d'une évolution «adiabatique», l'électron est astreint à rester dans l'état fondamental de la cavité où il s'est piégé, état déterminé par la configuration microscopique instantanée du solvant.

Par ailleurs, Neria et al. (80) ont mis en évidence un désaccord entre calcul et expérience concernant la durée de vie de e^-_{ir} dans H_2O et D_2O : le calcul à 300 K donne T_2 = 220 fs pour H_2O et 800 fs pour D_2O avec une marge d'erreur estimée à ~30%; cet effet isotopique est bien supérieur à celui trouvé expérimentalement ($(T_2)_{D_2O}/(T_2)_{H_2O}$ = 1,04 (86) ou ~1,35 (87)). Citons enfin un point abordé récemment par Rossky et coll. (81, 84) : des calculs du type de ceux évoqués ci-dessus font en effet apparaître un spectre d'absorption qui serait caractéristique de l'électron initialement «quasi-libre». Le maximum en serait situé vers 1400 nm avec un coefficient d'extinction molaire de $\sim 2{,}3 \times 10^4$ M^{-1} cm^{-1}. Cette dernière estimation traduit une interaction spectrale importante si l'on se réfère à la valeur correspondante pour e^-_{aq} ($1{,}9 \times 10^4$ M^{-1} cm^{-1} à ~300 K; voir réf. 88 et sect. II-C.2-a). L'origine d'une telle interaction demanderait à être examinée. Ces mêmes calculs (81, 84; voir aussi réf. 10) conduisent corrélativement pour e^-_{ir} au spectre donné figure 4*b* à titre de comparaison avec les valeurs expérimentales (figure 4*a*).

Les insuffisances des calculs actuels de simulation pour interpréter quantitativement l'hydratation de l'électron nous paraissent provenir de différentes causes, parfois déjà mentionnées. La première est l'emploi de pseudopotentiels très simplifiés pour décrire l'interaction électron–eau. Il nous paraîtrait souhaitable que ces pseudopotentiels soient préalablement validés, par exemple, en calculant à faible énergie les sections efficaces correspondantes en phase gazeuse et en comparant les résultats ainsi obtenus avec l'expérience. La deuxième cause concerne le fait que les pseudopotentiels utilisés sont construits afin de décrire l'état fondamental de l'électron, alors qu'ils sont également appliqués à la description des états «excités». Enfin, troisième cause, le traitement classique du solvant pose problème. Un traitement quantique est clairement souhaitable. Toutefois, la mise en oeuvre pratique des calculs palliant les insuffisances précédentes présente, pour le moment, de nombreux défis.

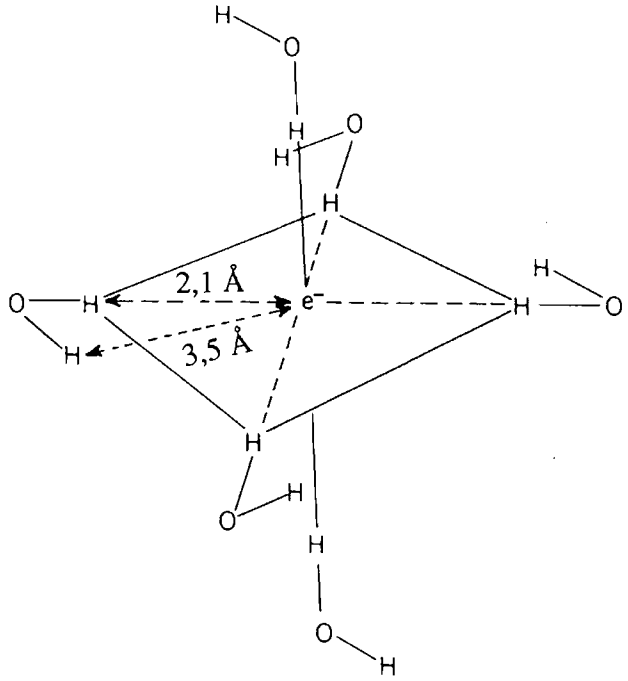
La situation a rebondi récemment, ainsi que nous l'avons déjà mentionné (voir sects. II-B.2 et II-B.3), par suite des expériences de Barbara et coll. (42) qui montrent que, pour l'eau liquide, l'état fondamental impliqué dans le processus d'hydratation se relaxe de façon continue vers e^-_{aq}, le temps caractéristique de ce déplacement spectral étant relativement long (1,1 ± 0,2 ps). Il faut souligner que l'existence, dans ce milieu, d'une telle relaxation continue n'avait pas jusqu'alors été mise en évidence.

Pour les *alcools liquides*, les premières études de dynamique de solvatation, exclusivement expérimentales, concluaient à un processus en deux étapes (localisation et solvatation), comme pour l'eau. Les travaux ultérieurs de Lewis et Jonah (89), concernant l'éthanol et le propanol-1, ont permis de mettre en évidence deux voies possibles de solvatation, l'une directe et rapide et l'autre, plus lente, impliquant l'électron piégé comme intermédiaire. D'après les études citées plus haut (30, 32–34), il semble actuellement qu'il faille envisager pour les alcools liquides, non seulement un déplacement continu vers le bleu de la bande visible du spectre, mais également la coexistence de deux mécanismes de relaxation de l'espèce transitoire e^-_{ir}, l'un discret et l'autre continu (32).

C. Propriétés physico-chimiques de e^-_{solv}

On considérera successivement structure, spectres d'absorp-

Fig. 5. Structure de e^-_{aq} obtenue par modulation d'écho de spin d'électrons piégés dans des matrices alcalines vitreuses irradiées par rayons γ à 77 K (d'après Kevan (94)).



tion optique et de RPE, et mobilité de e^-_{solv}. Les propriétés de cette espèce, et surtout de e^-_{aq}, ont été abondamment étudiées durant les dernières décennies. En particulier, la structure de e^-_{aq} et les caractéristiques du spectre d'absorption optique ont permis la confrontation des modèles théoriques avec les données expérimentales.

Les récentes tentatives de modélisation physique d'un électron en excès dans un liquide ont utilisé deux approches principales : l'une est basée sur l'intégration numérique de l'équation de Schrödinger dépendante du temps pour une particule quantique se déplaçant dans un fluide classique (90), et l'autre sur la formulation de Feynman de la mécanique statistique quantique utilisant les intégrales de chemin (91, 92). En fait, la plupart des traitements théoriques proposés pour l'étude des propriétés de e^-_{solv} font usage de la seconde voie, associée aux techniques de simulation Monte Carlo ou de dynamique moléculaire. Ces traitements diffèrent cependant, soit dans le modèle choisi pour le solvant, soit dans le choix des potentiels qui décrivent l'interaction e^-_{exc}–solvant (voir, par exemple, réf. 93).

1. Structure de e^-_{solv}

Peu de données expérimentales sont disponibles au sujet de la structure de e^-_{solv}. En ce qui concerne les résultats se rapportant à e^-_{aq}, ceux-ci ont été principalement obtenus à 77 K par Kevan et coll. (94) en utilisant la technique de modulation d'écho de spin d'électrons piégés dans des matrices alcalines vitreuses irradiées par rayons γ. Ces résultats ont conduit à proposer la structure représentée figure 5 où l'électron est entouré de six molécules d'eau. Une liaison O—H de chacune de ces molécules d'eau étant orientée vers l'électron, l'ensemble présente une structure octaédrique. Il a été suggéré (95) qu'une telle géométrie pouvait constituer une représentation réaliste de e^-_{aq} dans l'eau liquide.

Les récents résultats de simulations paraissent en assez bon accord avec cette suggestion. Un nombre de coordination voisin de 6 est en effet obtenu à 300 K pour une distance électron–oxygène qui est statistiquement égale à 3,7 (96) ou 3,3 Å (75), à comparer à 3,1 Å, valeur déterminée expérimentalement par Kevan et coll. (94). Toutefois, un nombre de coordination de 4 (93, 97) ou entre 5 et 6 (98, 99) a aussi été proposé. En fait, les écarts trouvés pour ce nombre sont probablement liés aux très grandes fluctuations des dimensions de la cage de solvatation de e^-_{aq} (75, 77, 100). À titre de comparaison, on peut signaler que des calculs analogues conduisent à un nombre de coordination d'environ 7–8 pour les ions chlorure hydratés (Cl^-_{aq}) (101–103).

De plus, une étude de l'état fondamental de e^-_{aq} dans la gamme 77–300 K, basée sur un modèle de semi-continuum prenant en compte, non seulement la structure géométrique proposée par Kevan et coll. (94), mais également l'influence de la deuxième couche d'hydratation, a amené Pommeret et Gauduel (104) à conclure qu'il n'existe pas de différence structurale fondamentale entre l'électron piégé dans la glace ou hydraté dans l'eau liquide.

Notons, enfin, que la technique de modulation d'écho de spin a été également appliquée au cas de l'électron dans d'autres solides vitreux et en particulier dans le méthanol et l'éthanol (94). Les résultats obtenus pour ces deux alcools indiquent que la première couche de solvatation de e^-_{solv} se compose de quatre molécules approximativement équivalentes et disposées de façon tétraédrique. À l'inverse de l'eau, ce sont les dipoles moléculaires, et non pas les liaisons O—H, qui pointent vers l'électron. L'hydrogène le plus proche de l'électron (2,3 Å pour le méthanol) est celui du groupement hydroxyle. Pour l'éthanol, la valeur correspondante est 2,2 Å.

2. Propriétés spectroscopiques

(a) Spectres optiques

Caractéristiques générales : Le spectre d'absorption optique — pierre de touche du mécanisme de solvatation — est probablement la plus étudiée des propriétés de l'électron solvaté. Il permet à la fois d'identifier celui-ci et de tester la validité des traitements théoriques proposés.

Ce spectre est caractérisé essentiellement par une bande large (la largeur à mi-hauteur $W_{1/2}$ = 0,85 eV pour e^-_{aq} à 300 K, contre environ 0,3 eV pour l'électron piégé à 77 K dans la glace cristalline) sans structure, asymétrique avec une traîne vers le bleu (voir, par exemple, réfs. 7 et 105).

Tandis que la longueur d'onde correspondant au maximum d'absorption[4] (λ_{max}) est située dans le proche infra-rouge pour l'électron solvaté dans les solvants peu polaires tels que les éthers, les amines, etc., elle se situe dans le rouge pour l'électron hydraté ou solvaté dans les alcools à la température ambiante (pour e^-_{aq}, λ_{max} = 715 nm ou E_{max} = 1,73 eV; voir réf. 88 pour une compilation récente des propriétés spectrales de e^-_{solv} dans les liquides polaires).

[4] On sait que λ_{max} est reliée à l'énergie E_{max} associée au maximum d'absorption de e^-_{solv} par $E_{max} = 1240/\lambda_{max}$, où E_{max} est exprimée en eV et λ_{max} en nm.

Le coefficient d'extinction molaire au maximum d'absorption (ε_{max}) se révèle être une fonction linéaire de $1/W_{1/2}$; ceci découle du fait que la force d'oscillateur (f) correspondant au spectre d'absorption de e^-_{solv} varie peu d'un solvant à l'autre ($f \sim 0{,}6$) (106). Les valeurs de ε_{max} varient également de façon exponentielle avec E_{max}, relation qui permet, connaissant λ_{max} pour un solvant donné, de calculer ε_{max}, et donc de déduire du spectre de e^-_{solv} une estimation du rendement en électrons solvatés dans ce solvant (106; voir aussi réf. 7).

Notons enfin qu'une bande d'absorption de e^-_{solv} a été observée dans l'ultra-violet, avec un seuil situé vers 200 nm pour l'électron hydraté (107) et 240 nm pour l'électron ammonié (18, 108). D'après l'interprétation proposée, il s'agirait d'un déplacement vers le rouge de la première bande d'absorption du solvant, déplacement induit par la perturbation due à la présence de e^-_{solv} des transitions électroniques des molécules formant les premières couches de solvatation.

Effets de température et de pression : L'effet de température sur le spectre d'absorption de e^-_{aq} a été examiné par divers auteurs (109–113). Dans la gamme de −4 à 390°C, les travaux de Michael et al. (110) et de Christensen et Sehested (113) ont montré que l'allure générale de la bande d'absorption n'est pas sensiblement modifiée. En revanche, de −4 à 175°C, E_{max} se déplace de −0,003 eV/deg. Au-dessus de 175°C, le maximum d'absorption continue à se déplacer vers les énergies plus faibles, avec un coefficient de température moindre; cette variation se poursuit jusqu'à la température critique de l'eau (371°C pour D_2O), et même au-delà. Ce déplacement pourrait être attribué à la modification des pièges due à la rupture progressive des liaisons hydrogène et au changement de la structure associative de l'eau liquide. Miura et Hirata (114) ont développé, dans ce cadre, un modèle théorique de la stabilité de e^-_{aq} et ont pu prévoir le sens de cette influence. Notons, en revanche, qu'un tel déplacement n'a pas été retrouvé entre 300 et 373 K par l'application de méthodes de simulation Monte Carlo et d'intégrales de chemin (96). Le piégeage d'électrons à des températures supercritiques où l'eau serait à l'état monomérique à plus de 95% indiquerait, d'après Michael et al. (110), que la préexistence de pièges n'est pas une condition nécessaire à la solvatation.

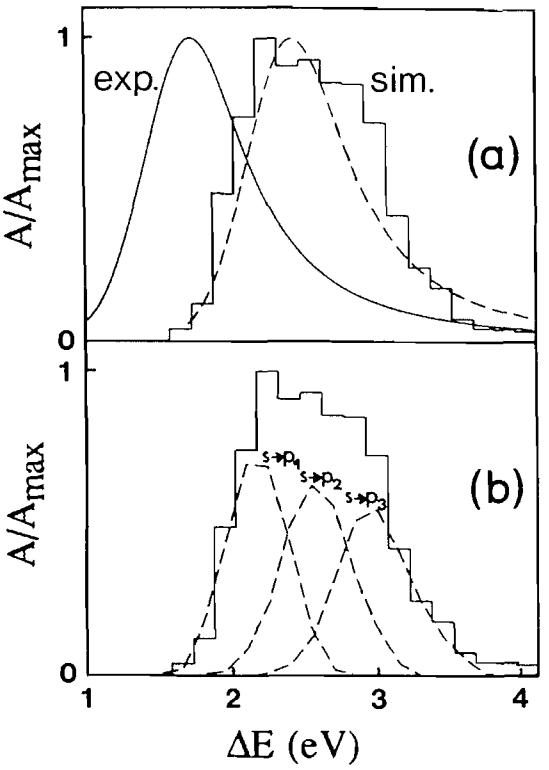
Pour la glace cristalline, comme pour l'eau liquide, la valeur de E_{max} est décalée vers le bleu quand la température décroît et on n'observe pas de discontinuité à la température de fusion de la glace (115).

Par ailleurs, Elliot et Ouellette (116) rapportent, pour l'électron hydraté et pour des températures allant jusqu'à 200°C, une décroissance sensiblement linéaire de ε_{max} en fonction de la température, qui conduit à la valeur $\varepsilon_{max} \sim 1{,}6 \times 10^4$ M^{-1} cm^{-1} à 200°C.

L'influence de la pression, comme celle de la température, ne modifie que faiblement l'allure générale du spectre d'absorption de e^-_{aq}. Toutefois, quand la pression est augmentée, le maximum du spectre se déplace vers le bleu; pour des pressions allant jusqu'à 2 kbar et à 27°C, Jou et Freeman (117) ont ainsi observé pour e^-_{aq} une variation linéaire de E_{max} de +0,065 eV/kbar. Le sens d'un tel déplacement peut être attribué à la diminution des dimensions des cavités pièges pour l'électron.

Type de transition impliquée et largeur de bande : La nature

Fig. 6. (*a*) Comparaison des spectres d'absorption de l'électron hydraté expérimental et simulé (voir aussi figure 4). La ligne en tirets est obtenue par déplacement du spectre expérimental de ~0,7 eV vers les hautes énergies. (*b*) Sous-bandes *s–p* individuelles contribuant au spectre d'absorption simulé (d'après Rossky et Schnitker (75)).



des transitions responsables du spectre d'absorption de e^-_{aq} a fait l'objet de nombreux travaux théoriques et expérimentaux qui relèvent principalement de deux interprétations (voir, par exemple, réfs. 118 et 119) : l'une d'entre d'elles considère que les transitions mises en jeu s'effectuent entre un état lié et le continuum, et l'autre envisage surtout des transitions entre états liés. C'est ainsi que Jortner et al. (120) ont proposé une interprétation basée sur une transition d'un état fondamental de type 1*s* vers un état excité lié de type 2*p* du solvant polarisé. Cependant, l'invariance de la forme de la bande d'absorption quand la température ou la pression varie a été considérée comme l'indice d'une prépondérance de transitions vers les états délocalisés de la bande de conduction du solvant (121), l'état fondamental e^-_{aq} n'étant pas de type *s* pur (et donc s'écartant d'une symétrie purement sphérique) (122). En revanche, les récents résultats de simulation de dynamique moléculaire ou Monte Carlo, utilisant les intégrales de chemin, semblent indiquer que la bande d'absorption de e^-_{aq} traduirait la transition fortement permise $1s \rightarrow 2p$ (75, 77, 85, 96, 100, 123). Ces derniers auteurs estiment ainsi que la bande peut être représentée par l'enveloppe de trois sous-bandes correspondant aux transitions de l'état 1*s* vers les trois états excités liés p_1, p_2, p_3 non dégénérés, et que la traîne d'absorption vers le bleu résulterait, elle, de transitions vers des états délocalisés (figure 6). La non-dégénérescence des trois états *p* serait due à l'anisotropie locale de l'interaction de e^-_{exc} avec le

solvant et leur séparation en énergie s'élèverait, selon les auteurs, à 0,8 (77, 83) ou 0,3 (85) eV. Notons qu'une résolution de la bande d'absorption expérimentale en plusieurs sous-bandes de forme gaussienne avait déjà conduit à une décomposition analogue (124).

La largeur inusitée de la bande d'absorption de e^-_{solv} est actuellement interprétée théoriquement comme étant due aux fluctuations en forme et en dimensions des cavités pièges (75, 77, 100; voir aussi sect. II-C.1). D'utiles informations à ce sujet peuvent être obtenues expérimentalement grâce à la méthode de dynamique de blanchiment (*spectral hole burning*) qui permet de sonder directement les caractéristiques spectrales différentielles de la bande d'absorption (voir, par exemple, réf. 125). En ce qui concerne e^-_{aq}, des résultats théoriques (76, 83, 125, 126) et expérimentaux (42, 127) ont été obtenus récemment par cette méthode (voir sects. II-B.2 et II-B.3). Soulignons, en particulier, les travaux réalisés par Schwartz et Rossky (126) et par Reid et al. (127) qui utilisent la lumière polarisée, l'électron hydraté étant alors une sonde de l'anisotropie locale de la cavité solvant. Selon ces derniers auteurs, une telle anisotropie s'établirait de manière simultanée avec l'excitation et décroîtrait en ~3 ps, montrant ainsi que des fluctuations anisotropes lentes du solvant pourraient intervenir dans la dynamique d'hydratation de e^-_{exc}.

Pour les alcools légers, soit vitreux à basse température, soit liquides à ~300 K, une autre méthode d'étude, basée sur le couplage entre e^-_{exc} et les modes vibrationnels intramoléculaires du solvant, a été proposée par Abramczyk et al. (128; voir aussi réf. 9) pour déterminer le profil des bandes d'absorption infra-rouge et visible de e^-_{exc}. Les résultats, obtenus dans le cadre d'une théorie de réponse linéaire, conduisent à la conclusion qu'il y aurait deux types d'électrons piégés : ceux absorbant dans le visible qui seraient associés aux groupements hydroxyle (couplage avec les modes d'élongation C–O ou de flexion O–H), et ceux absorbant dans l'infrarouge qui seraient piégés par les groupes alkyle (couplage avec les modes d'élongation C–H). La situation serait différente pour l'eau et les verres aqueux qui n'offriraient à e^-_{exc} qu'un seul type de piège. Selon les auteurs, une telle représentation pourrait rendre compte de la différence apparente des propriétés spectroscopiques de e^-_{exc} dans l'eau et les alcools. Toutefois, vu la valeur extrêmement élevée du champ électrique au voisinage de l'électron (jusqu'à 10^7 V/cm), on peut s'interroger sur la pertinence de l'emploi de la théorie de réponse linéaire utilisée par Abramczyk et collaborateurs, théorie qui suppose une perturbation faible du solvant par e^-_{exc}; il pourrait, en effet, être indispensable de prendre en compte l'intervention de phénomènes non linéaires (129).

(b) Spectres de RPE

Les spectres de RPE de l'électron piégé (e^-_p) sont généralement obtenus à partir de matrices vitreuses irradiées à basse température. Dans le cas de la glace (H_2O) cristalline aucun signal RPE de e^-_p n'est observé, le signal du radical OH masquant celui de l'électron. Toutefois, pour D_2O cristalline, un recuit préalable à la mesure facilite la disparition du radical OD et permet ainsi la mise en évidence d'un signal RPE de e^-_p (130). La raie unique caractéristique de e^-_p est en revanche directement observable dans des glaces vitreuses alcalines à 77 K, où le rendement en e^-_p peut atteindre des valeurs élevées (1,9 molécule/100 eV) pour des concentrations suffisantes en ions OH^- (131). Le facteur g ainsi mesuré est égal à 2,0008 (132) ou 2,0006 (133), valeurs proches de celle correspondant à un électron non lié (2,002 32).

Dans le cas des alcools vitreux, le blanchiment de e^-_p par la lumière visible substitue quantitativement le signal des radicaux $\dot{C}H_2OH$, $CH_3\dot{C}HOH$,..., dont la formation est initiée par la recombinaison des charges, à la raie unique relative à e^-_p (131).

Diverses expériences de RPE de e^-_{solv} ont été effectuées pour l'eau, le méthanol ou l'éthanol en phase liquide en utilisant soit la radiolyse pulsée (134–136), soit une photolyse continue (137). Cette dernière méthode donne pour e^-_{aq} une valeur du facteur g de 2,000 43 à 23,3°C (137), tandis que la radiolyse pulsée conduit respectivement à g = 2,002 05 et 2,001 97 pour e^-_{solv} dans le méthanol et l'éthanol à 22°C (136).

L'interprétation des résultats obtenus par RPE concernant e^-_{solv} reste encore difficile actuellement.

(c) Spectres d'absorption de e^-_{solv} et spectres CTTS des ions halogénure

De nombreux anions en solution, tout particulièrement les ions halogénure, présentent dans l'ultra-violet un spectre d'absorption intense immédiatement suivie par une production de e^-_{solv} dans le solvant. Franck et Scheibe (138) ont été les premiers à interpréter cette absorption comme l'indication d'un mécanisme de transfert de charge au solvant (*charge transfer to solvent* ou CTTS). La libération de l'électron, dans ce cas, n'est pas due à une photoionisation au sens classique, mais implique un état excité électronique intermédiaire de l'ion parent. L'électron concerné occupe une orbitale qui, quoique centrée sur l'atome d'halogène, recouvre la première couche de solvatation de l'anion. L'ensemble de la configuration de solvatation peut donc être considéré comme l'«accepteur» dans une transition de CTTS (139). L'énergie E_{max} au maximum d'absorption des bandes CTTS a été ensuite exprimée dans le cadre de divers formalismes (voir, par exemple, réfs. 15 et 140).

Le développement des techniques de spectroscopie femtoseconde a rendu accessibles les aspects dynamiques relatifs au CTTS. Divers résultats expérimentaux concernant principalement les ions iodure et chlorure (56, 57, 141) en solution aqueuse ont été publiés récemment.

Pour des solutions 1 M en NaI ou KI, Long et al. (57, 141) ont constaté l'existence d'un état lié CTTS dans lequel l'électron «piégé» serait un précurseur de l'espèce intermédiaire e^-_{ir}. Les temps caractéristiques de solvatation de l'électron dans ces conditions ont pu être mesurés. Dans le cas de I^-, Long et al. (141) ont obtenu $T_2 = 600 \pm 40$ fs; ce temps est peu différent de celui mesuré par photoionisation de l'eau pure (540 ± 40 fs; voir sect. II-B.2). En revanche, la formation de e^-_{ir} a été trouvée sensiblement plus lente ($T_1 = 400 \pm 40$ fs; voir réf. 141) que dans le cas de l'eau pure (180 ± 40 fs; voir sect. II-B.2). L'existence d'un point isobeste à 850 nm a été avancée pour le passage $e^-_{ir} \rightarrow e^-_{aq}$ et la transition correspondante serait discontinue (57, 141). Cependant, dans des travaux plus récents, Long et al. (141) ont suggéré que seule une faible fraction des électrons hydratés présents seraient produits selon le mécanisme CTTS précédemment décrit. D'après les auteurs, en effet, une fraction importante de ces e^-_{aq} seraient formés via un processus de photoionisation à trois photons (4 eV/photon), plutôt qu'à partir de l'excitation CTTS

à 8 eV. Ces auteurs (141) ont, de plus, indiqué que l'état CTTS initial évoluerait, pour une large part, vers l'état CTTS de plus basse énergie. Ce dernier état, dont le temps de formation serait inférieure à 50 fs (mesure limitée par le temps de résolution de l'appareil), se relaxerait ensuite en 80 ± 40 fs vers l'état fondamental de I^-.

Gauduel et al. (56), quant à eux, ont interprété leurs résultats concernant des solutions aqueuses de chlorure de sodium (1 ou 6 M) en supposant la formation non diffusionnelle de paires de contact électron–atome $[e^-{:}Cl]_{nH_2O}$, formation qui a été déjà évoquée plus haut (voir sect. II-B.2). D'après ces derniers auteurs, deux populations de paires électron–atome seraient formées, l'une se relaxant directement, en 330 fs, vers l'état fondamental de Cl^-, et l'autre conduisant en 750 fs à e^-_{aq}, via un processus de photodétachement électronique.

Afin de présenter une description moléculaire des états électroniques et des spectres CTTS précédemment cités, différents auteurs (84, 85, 142, 143) ont développé, parallèlement, des travaux de simulation. Les plus récents d'entre eux mettent en oeuvre des calculs de dynamique non adiabatique (84, 143; voir aussi réf. 10). Ceux-ci ont révélé l'existence de deux voies de relaxation électronique de l'état initialement créé par une photoexcitation de l'ion halogénure de 8 eV : l'une, mineure, conduirait au transfert direct, non adiabatique, de l'électron vers une des cavités pièges préexistantes du solvant, et l'autre, dominante, impliquerait, sur une échelle de temps inférieure à ~50 fs, une transition vers l'état le plus bas en énergie de la bande CTTS, suivie du détachement adiabatique de l'électron et d'une recombinaison géminée non diffusionnelle ultrarapide des paires électron – atome d'halogène alors formées. Ces résultats sont compatibles avec l'allure générale des phénomènes expérimentaux déjà décrits (56, 57, 141).

Par ailleurs, dès 1954, Platzman et Franck (144) ont suggéré une corrélation possible entre les valeurs de E_{max} correspondant aux maxima des spectres d'absorption de e^-_{solv} et des ions iodure solvatés. Une relation linéaire empirique a effectivement été établie dans ce cas par Fox et Hayon (145) pour toute une série de solvants. En dépit de l'analogie suggérée par une telle relation, un certain nombre de dissemblances ont été récemment soulignées (6), si bien que e^-_{solv} ne semble pas pouvoir être considéré comme le prototype d'un anion monoatomique X^- solvaté.

3. Mobilité de e^-_{solv}

La détermination de la mobilité (μ_e) de e^-_{solv} dans des solvants de diverses polarités et sa variation avec certains paramètres caractérisant soit e^-_{solv} lui-même, soit le solvant, permettent de mieux cerner le mécanisme de la migration d'un électron en excès dans ces milieux. Les valeurs de μ_e mesurées sont intermédiaires entre celles des anions solvatés et celles des conducteurs métalliques. Ceci résulte du fait que la mobilité électronique peut être de type ionique, c'est-à-dire, $\mu_e \sim 10^{-2}$–10^{-4} $cm^2\ V^{-1}\ s^{-1}$ (88, 146; voir aussi réf. 7), lorsque l'électron est solvaté et se déplace avec une cage de solvatation, ou voisine de celle de e^-_{qf}, c'est-à-dire, $\mu_e > 1$–10 $cm^2\ V^{-1}\ s^{-1}$ (voir, par exemple, réfs. 146 et 147), dans le cas où l'électron migre hors des sites de piégeage, ou encore une combinaison de ces deux mécanismes.

(a) Variation de μ_e avec E_{max}

Une relation simple ne peut être établie; cependant, si on porte E_{max} en fonction de μ_e pour différents solvants polaires, on peut distinguer deux régions : l'une pour $\mu_e < (2\text{–}3) \times 10^{-3}$ $cm^2\ V^{-1}\ s^{-1}$ où E_{max} augmente quand μ_e diminue, l'autre pour $\mu_e > 3 \times 10^{-3}$ $cm^2\ V^{-1}\ s^{-1}$ où E_{max} reste à peu près constante (~0,5 eV). On peut penser que le domaine des faibles valeurs de μ_e correspondrait à des liquides présentant des pièges profonds où l'électron serait en permanence stabilisé par les couches de molécules solvatantes. Au contraire, dans le domaine des valeurs de μ_e plus élevées, l'électron serait en interaction faible avec le solvant et sa migration facilitée (148–150; voir aussi réf. 7).

(b) Variation de μ_e avec la viscosité η du solvant

D'après les données de la littérature concernant les solvants polaires, la variation de μ_e en fonction de η peut être représentée, à la température ambiante, par une relation de la forme

$$\mu_e = C\eta^{-n}$$

où l'intervalle de confiance à 99% de l'exposant inclut la valeur $n = 1$. Une telle variation est en faveur d'un mécanisme de diffusion pour la migration de e^-_{solv} (151; voir aussi réf. 7), conclusion qui est d'ailleurs elle-même en accord avec les résultats de calculs de simulation obtenus pour e^-_{aq} (152–154) et pour l'électron ammonié (155).

4. Déclin de l'électron relaxé

Le déclin initial de e^-_{aq} a été mesuré pour des temps allant jusqu'à plusieurs centaines de picosecondes, ceci après photoionisation de l'eau pure et spectroscopie laser femtoseconde (31, 43, 45, 46, 48, 52, 57, 86, 87, 156–158). On observe des cinétiques de déclin analogues (50–60% des e^-_{aq} ayant disparu au bout d'environ 60–80 ps) dans les expériences de Lu et al. (156) et de Gauduel et al. (157), pour des photons de 4 eV et un processus supposé biphotonique (figure 7). Dans les conditions expérimentales de Houde et al. (45, 46), pour lesquelles l'excitation met en jeu au moins quatre photons de 2 eV, le déclin est plus lent (~20% pendant les 17 premières picosecondes). De même, la décroissance trouvée par Sander et al. (31, 52), pour un processus biphotonique impliquant des photons de 5 eV, est également lente (~30% à 180 ps). En revanche, McGowen et al. (158), se réclamant d'un processus à 3 photons (3,2 eV/photon), ne décèlent aucune évolution notable (≤5%) de l'absorption de e^-_{aq} pour des temps allant jusqu'à 700 ps.

Ces différentes vitesses de déclin ont été attribuées à une variation du nombre de photons absorbés simultanément selon les conditions expérimentales de chaque montage, entraînant donc une variation de la recombinaison géminée avec l'intensité de l'impulsion excitatrice (43). Suivant l'énergie absorbée, l'électron libéré se trouve plus ou moins éloigné de l'ion positif parent et son déclin serait d'autant plus lent qu'il serait plus éloigné. Malheureusement, il est difficile de comparer précisément, à ce point de vue, les techniques expérimentales, ce qui rend actuellement cette hypothèse difficilement vérifiable.

Nous avons vu plus haut (voir sect. II-B.2) que les espèces H_3O^+ et OH étaient formées avant l'hydratation de l'électron; ce sont elles qui, par les réactions géminées qu'elles entraînent, seraient responsables du déclin de e^-_{aq} à temps courts.

Fig. 7. Variation en fonction du temps de l'absorbance des électrons hydratés après photoionisation de l'eau pure à 21°C, pour des photons de 4 eV et un processus supposé biphotonique : (*a*) d'après Lu et al. (156), pour λ_{test} = 700 nm; (*b*) d'après Gauduel et al. (157), pour λ_{test} = 720 nm.

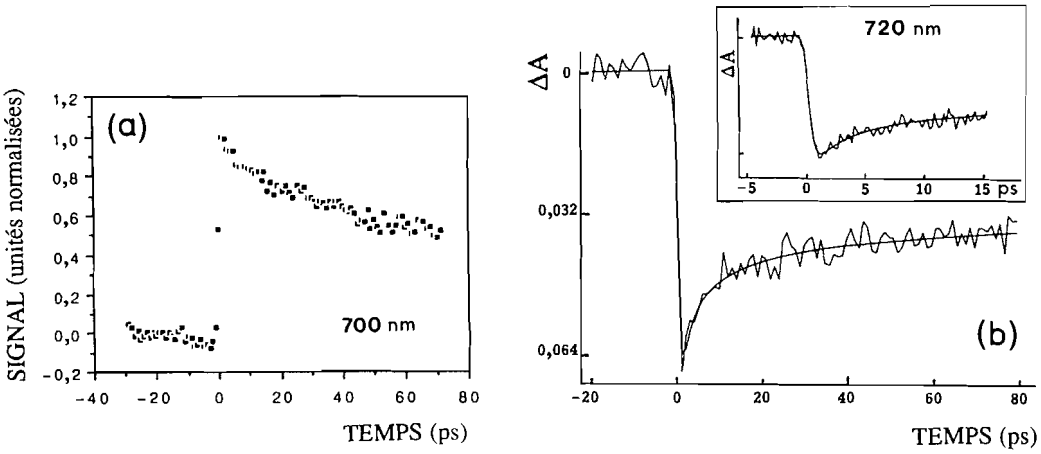


Tableau 2. Propriétés thermodynamiques de e^-_{aq} à 298 K.[a]

	Jortner et Noyes (162)	Hickel et Sehested (164 et 167)	Han et Bartels (165)	Schwarz (166)
ΔG^0_{hyd}	−157		−161 ± 14	
ΔH^0_{hyd}	−159	−142 ± 7	−126 ± 11	−142
ΔS^0_{hyd}	−7,9	49 ± 23	118 ± 20	67

[a]Valeurs exprimées en kilojoules par mole pour l'enthalpie libre et l'enthalpie, et en joules par mole et par degré pour l'entropie (1 kJ/mol = 1,0364 × 10^{-2} eV/molécule).

Ces réactions de recombinaison ont été récemment analysées par simulation; les résultats obtenus permettent de conclure (159, 160) que l'attraction par H_3O^+ limite la diffusion de e^-_{aq}, augmentant ainsi l'efficacité de la réaction de celui-ci avec OH : sur l'échelle de temps 0–80 ps, cette dernière serait ~7 fois plus probable que la recombinaison avec H_3O^+ (160).

Des expériences de déclin (8 eV, processus biphotonique) ont été également effectuées sur des solutions aqueuses 1 M en OH^- (57), Cl^- (56, 57) ou I^- (57). Selon Long et al. (57), la disparition de e^-_{aq} est plus lente que dans le cas de l'eau pure. Ainsi, après 70 ps, ces auteurs obtiennent respectivement pour les trois anions cités, 30, 20 et 11% d'électrons hydratés disparus. Les différences observées avec l'eau pure (50–60%) sont attribuées au fait que, dans ce dernier cas, e^-_{aq} se recombine avec un cation, alors qu'il se recombine avec une espèce neutre dans le cas des solutions anioniques. Par ailleurs, l'évolution cinétique complexe intervenant pour de telles solutions à des temps très courts (inférieurs à quelques picosecondes) a été étudiée, ainsi que son interprétation, par Long et al. (57, 141) et Gauduel et coll. (56); ces travaux ont été mentionnés ci-dessus, dans la section II-C.2-c.

Le déclin picoseconde de l'électron relaxé a, de plus, été mesuré dans D_2O par spectroscopie laser femtoseconde mettant en jeu un processus biphotonique (4 eV/photon). Un effet isotopique est constaté : 38% des électrons hydratés ont disparu au bout de 165 ps, contre 46% dans le cas de H_2O (87); d'autres auteurs (86; voir aussi réf. 11) rapportent les valeurs correspondantes suivantes, à ~100 ps : 49% pour D_2O et 55% pour H_2O. L'hypothèse avancée pour expliquer un tel effet repose sur le fait que D_2O est un liquide plus ordonné que H_2O, et que par conséquent la concentration des pièges d'électron y est plus faible (52). La distance moyenne séparant l'électron libéré de son cation parent est donc plus grande dans D_2O que dans H_2O; dans le premier cas, la recombinaison géminée de e^-_{aq} se trouve ainsi défavorisée.

D. Données thermodynamiques

Baxendale (161) le premier a considéré à la fois l'équilibre en solution aqueuse

$$e^-_{aq} + H_2O \rightleftarrows H_{aq} + OH^-_{aq}$$

et le cycle thermodynamique

$$e^-_{aq} + H^+_{aq} \rightarrow 1/2\ (H_2)_{aq}$$

$$e^-_g + H^+_g \rightarrow (H)_g \rightarrow 1/2\ (H_2)_g$$

ce qui conduit à la valeur de l'enthalpie libre d'hydratation de l'électron $\Delta G^0_{hyd} = -167$ kJ/mol.

À partir d'un cycle thermodynamique analogue et en supposant que les équations qui relient ΔG^0_{solv} et ΔS^0_{solv} au rayon d'un anion solvaté puissent être appliquées à e^-_{aq}, les termes enthalpique ΔH^0_{hyd} et entropique ΔS^0_{hyd} ont été évalués pour l'électron hydraté (162, 163).

Des études plus récentes et plus approfondies, s'appuyant soit sur l'équilibre $e^-_{aq} + H_2O \rightleftarrows H_{aq} + OH^-_{aq}$ (164, 165), soit sur l'équilibre $e^-_{aq} + (NH_4^+)_{aq} \rightleftarrows H_{aq} + (NH_3)_{aq}$ (166), ont conduit aux valeurs de ΔG^0_{hyd}, ΔH^0_{hyd} et ΔS^0_{hyd} rassemblées dans le tableau 2, valeurs exprimées en kilojoules par mole pour

l'enthalpie libre et l'enthalpie, et en joules par mole et par degré pour l'entropie. Ce tableau appelle un certain nombre de commentaires.

(*i*) Au vu des larges marges d'erreurs estimées par les différents auteurs, les valeurs précédentes montrent un accord raisonnable si l'on excepte celle de ΔS^0_{hyd} donnée par Jortner et Noyes (162).

(*ii*) La valeur absolue de ΔH^0_{hyd} est plus faible pour e^-_{aq} que pour les anions monoatomiques X^-_{aq}. Citons, par exemple : pour I^-, $\Delta H^0_{hyd} = -257$ kJ/mol et pour Cl^-, $\Delta H^0_{hyd} = -318$ kJ/mol (168). En d'autres termes, et comme on pouvait s'y attendre, e^-_{aq} est moins lié que les ions X^-_{aq}.

(*iii*) L'entropie d'hydratation relative à l'électron est positive, alors que tous les anions monoatomiques X^- sont caractérisés par une valeur de ΔS^0_{hyd} négative. Citons, par exemple : pour I^-, $\Delta S^0_{hyd} = -11{,}4$ J mol^{-1} deg^{-1} et pour Cl^-, $\Delta S^0_{hyd} = -49{,}4$ J mol^{-1} deg^{-1} (169). Les électrons hydratés apparaissent ainsi comme d'efficaces *structure breakers* dans l'eau (169, 170). Ce résultat serait explicable par le fait que la distribution radiale des molécules d'eau autour de l'électron est beaucoup plus diffuse qu'autour des anions classiques (voir, par exemple, réfs. 99 et 103).

Notons enfin que cette disparité entre les signes de ΔS^0_{hyd} pour e^-_{aq} d'une part et les ions X^-_{aq} d'autre part ne semble pas en faveur de l'interprétation de Robinson et coll. (171) qui assimilent l'électron hydraté à un complexe $(OH^-...H_3O)_{aq}$ en s'appuyant sur une certaine similitude entre les rôles joués par e^-_{aq} et les ions OH^-_{aq} ou H^+_{aq} vis-à-vis de l'organisation structurale des molécules d'eau voisines.

III. Électrons en excès en solutions micellaires

Les milieux microhétérogènes, dits «milieux organisés», qui sont des agrégats de molécules amphiphiles, naturelles ou synthétiques, neutres ou ioniques, ont fait l'objet de multiples études au cours des dernières décennies (voir, par exemple, réfs. 172–176). Nous ne considérerons ici que les *milieux organisés clos* (MOC), c'est-à-dire des globules lipidiques en solution aqueuse : micelles (Mi) directes et vésicules (Ve) ou des globules aqueux en solution hydrocarbonée (micelles inverses). Les caractéristiques spécifiques de ces systèmes dont on peut tirer profit sont principalement : (*i*) une aire interfaciale considérable si bien que les réactions en surface peuvent se substituer à des réactions en volume; (*ii*) l'existence fréquente d'un potentiel électrique interfacial qui peut être modulé expérimentalement et calculé de façon approximative; (*iii*) la compartimentation dans deux phases distinctes des réactifs et (ou) des espèces transitoires suivant leur caractère hydrophile ou hydrophobe, situation qui peut augmenter très notablement la durée de vie de ces dernières. Comme pour les solutions homogènes, les électrons en excès peuvent être produits soit par radiolyse, soit par photoionisation de chromophores appropriés. Dans le cas des Mi directes, les plus étudiées, les solutions micellaires sont généralement peu concentrées, de l'ordre de 10^{-4}–10^{-3} M. Les électrons produits par voie radiolytique sont ainsi formés dans la phase aqueuse, sans effet direct sur les agrégats micellaires. Dans ces conditions, l'objectif est essentiellement d'examiner le pouvoir catalytique des Mi ou Ve sur la réactivité des e^-_{aq} vis-à-vis des molécules de surfactant ou d'additifs micellisés. Les réactions obéissent à des lois complexes de cinétique non homogène (177). Cet aspect ne sera pas traité ici. En revanche, des expériences de photoionisation de composés micellisés peuvent apporter des informations intéressantes sur la dynamique et l'énergétique de la production de e^-_{exc} (176).

A. Dynamique de formation de e^-_{aq} en micelles directes ou inverses

La production de e^-_{aq} par ionisation biphotonique (4 eV/photon) de phénothiazine a été suivie, comme pour l'eau pure, sous excitation laser femtoseconde et spectroscopie d'absorption résolue dans le temps (178–180). Un état présolvaté absorbant dans l'infra-rouge, précurseur de e^-_{aq}, a été mis en évidence dans ce cas également. Le temps T_1 de montée de l'absorption infra-rouge est trouvé égal à 250 ± 20 fs pour les Mi directes (micelles cationiques Mi^+ ou anioniques Mi^-) et à 140 ± 10 fs pour les Mi inverses. Cette dernière valeur est proche de celle déterminée pour l'eau pure (110 ± 30 fs; voir sect. II-B.2); en revanche, la présence de micelles $Mi^\pm$ paraît retarder la formation de e^-_{ir}. Pour les Mi directes, la dynamique des étapes primaires de la photoionisation : séparation intramicellaire des charges et diffusion de e^-_{exc} vers la phase aqueuse, est trouvée la même pour Mi^+ et Mi^-.

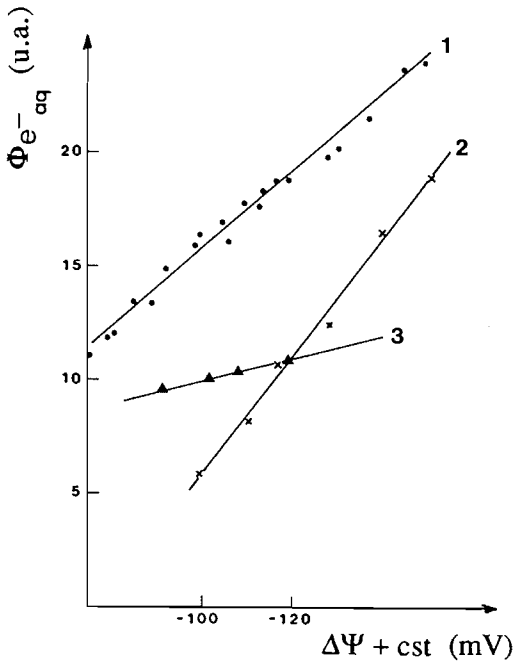
Pour les systèmes micellaires cités ci-dessus, comme dans le cas de l'eau pure ($T_2 = 240 \pm 40$ fs; voir sect. II-B.2), e^-_{ir} relaxe vers l'état hydraté avec une seule constante de temps : $T_2 = 270 \pm 20$ fs (179, 180). Ceci suggère que la localisation initiale de e^-_{exc} et sa solvatation complète s'effectuent à une distance de l'interface micellaire pour laquelle la constante diélectrique et la force ionique sont celles relatives à l'eau en masse.

B. Énergies seuil d'ionisation et rendements en e^-_{aq} en micelles et vésicules

La photoionisation monophotonique du pérylène et de la tétraméthylbenzidine (TMB) incorporés dans des micelles directes anioniques, neutres (Mi^0) ou cationiques a été étudiée en fonction de la longueur d'onde d'excitation λ_{exc} et du potentiel électrique interfacial $\Delta\Psi$ (181, 182). Plusieurs conclusions peuvent être dégagées : (*i*) les courbes de rendement de photoionisation $\Phi_{e^-_{aq}}$ (λ_{exc}) sont décalées vers le rouge par rapport aux courbes de rendement relatives à des solutions organiques homogènes. Cette plus faible valeur de l'énergie seuil d'ionisation (E_i) répercute la variation de l'énergie fondamentale V_0 de l'électron quasi-libre avec le solvant considéré : eau liquide par comparaison avec un solvant organique. (*ii*) Pour un chromophore donné, la valeur de E_i n'est pas sensible à une variation du potentiel électrique interfacial. Ceci traduit le fait que $\Delta\Psi$ est au moins d'un ordre de grandeur inférieur aux autres facteurs qui contrôlent E_i, notamment V_0. (*iii*) les formes différentes des courbes $\Phi_{e^-_{aq}}$ (λ_{exc}) obtenues pour Mi^- d'une part, et pour Mi^0 et des solutions homogènes d'autre part, peuvent refléter une plus grande probabilité pour l'électron d'échapper à une recombinaison géminée dans le cas des micelles négatives.

L'effet du potentiel $\Delta\Psi$ sur le rendement de photoionisation a ensuite été précisé en modulant $\Delta\Psi$ par addition de différents sels à une solution micellaire de Mi^- (183, 184). On trouve ainsi par photoionisation du pérylène et de la TMB en Mi^- ou Ve^- que le rendement $\Phi_{e^-_{aq}}$ est une fonction linéaire de

Fig. 8. Rendements de photoionisation $\Phi_{e^-_{aq}}$ en Mi^- de SDS (*sodium dodecyl sulfate*) et en Ve^- de DHP (*dihexadecyl phosphate*) en fonction du potentiel électrique interfacial $\Delta\Psi$: (1) pérylène dans Mi^- SDS, (2) TMB dans Mi^- SDS et (3) TMB dans Ve^- DHP (d'après Bernas et al. (184)).



$\Delta\Psi$ (figure 8). Le potentiel négatif, répulsif pour e^-_{exc}, ou bien facilite l'éjection de l'électron à partir d'états de Rydberg s'étendant au-delà de l'interface micelle–eau, ou bien (et) oppose une barrière au retour de e^-_{aq} vers le cation qui reste micellisé.

C. Micelles inverses : Rendements en e^-_{aq} et organisation de l'eau

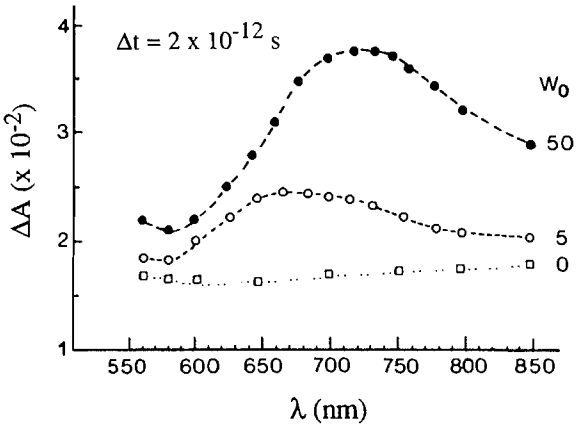
En micelles inverses, e^-_{aq} peut résulter de la photoionisation de chromophores hydrophiles ou hydrophobes, ou de la radiolyse du solvant hydrocarboné suivie de la localisation des e^-_{exc} dans le coeur aqueux des micelles. Des diverses études publiées, il est possible de dégager les conclusions suivantes.

(*i*) Dans les expériences de radiolyse picoseconde de Bakale et al. (185), l'efficacité de capture des électrons en excès par l'eau micellisée dans le système H_2O/AOT/isooctane[5] augmente avec le rapport des concentrations molaires $w_0 = [H_2O]/[AOT]$ qui caractérise le volume du coeur aqueux. Les microgouttes H_2O/AOT n'offriraient pas de pièges suffisamment profonds pour qu'il y ait attachement d'électron à chaque collision jusqu'à ce qu'au moins 30 molécules d'eau soient associées à chaque molécule de surfactant ($w_0 \geq 30$).

(*ii*) Excitation et spectroscopie laser femtoseconde ont de plus permis la caractérisation directe des étapes primaires du piégeage de e^-_{exc} dans l'eau micellisée. Ainsi, pour $w_0 = [H_2O]/[AOT] = 50$, Gauduel et al. (180) ont montré que la photoionisation d'un composé hydrophobe (phénothiazine) localisé à la périphérie micellaire donne naissance à deux

[5] AOT désigne le surfactant : di(2-éthylhexyl)sulfosuccinate de sodium.

Fig. 9. Spectre d'absorption transitoire de e^-_{aq} à 2 ps en micelles inverses de AOT pour trois valeurs du rapport des concentrations molaires $w_0 = [H_2O]/[AOT] = 50$, 5 et 0 (d'après Gauduel et al. (180)).



populations d'électrons. Les uns se piègent dans le solvant hydrocarboné (dans ce cas, le *n*-heptane) en 90 ± 10 fs, les autres s'hydratent en deux étapes : les e^-_{ir} apparaissant en 140 fs et relaxant vers l'état totalement hydraté en 270 fs. Comme mentionné plus haut, la similitude de ces temps caractéristiques avec ceux relatifs à l'eau pure suggère que localisation et solvatation s'effectuent alors au coeur de la poche aqueuse où aucune structure particulière n'est imposée par l'interface.

Pour $w_0 = 5$, où l'eau micellisée présente un temps de corrélation rotationnelle nettement plus élevé que l'eau en masse (186), la constante de temps T_2 correspondant à la formation de e^-_{aq} atteint 500 fs, alors que la composante rapide de piégeage de e^-_{exc} dans le *n*-heptane reste inchangée (90 fs) (180).

(*iii*) L'efficacité d'attachement de e^-_{exc} dans les micelles inverses H_2O/AOT dépend par ailleurs du solvant utilisé : elle est plus faible pour un solvant où la mobilité de e^-_{exc} est plus élevée (187). Ainsi, pour des micelles de taille comparable, la capture de e^-_{exc} a été trouvée, selon la valeur du rayon micellaire, de 5 à 20 fois plus efficace pour l'isooctane ($\mu_e = 6{,}5$ cm^2 V^{-1} s^{-1}) que pour le tétraméthylsilane ($\mu_e = 103$ cm^2 V^{-1} s^{-1}; voir, par exemple, réf. 147).

(*iv*) Pour $w_0 \geq 30$, le spectre d'absorption optique de e^-_{aq} est identique à celui obtenu dans l'eau pure. En abaissant w_0, on observe un déplacement vers le bleu du maximum d'absorption (figure 9), déplacement qui peut être associé à la forte concentration locale des contre-ions Na^+ à l'intérieur du coeur micellaire (180, 188–191); cette concentration atteindrait ~6 M pour $w_0 = 5$ et un degré de dissociation des molécules AOT de 0,5. L'existence d'une interface chargée se traduit donc par un gradient de concentration de e^-_{aq}, et de plus, les propriétés spectroscopiques de ce dernier dépendent de l'état d'organisation de l'eau dans la région interfaciale.

(*v*) La largeur de la bande d'absorption de e^-_{aq} diminue avec w_0 (188, 191, 192) et aussi avec la température. Ces observations ont été considérées comme l'indice d'un environnement plus ordonné, la bande d'absorption de e^-_{aq} présentant dans ces conditions une certaine analogie avec celle de l'électron piégé dans la glace à −194°C (192). Par ailleurs, Gębicki et al. (191) ont indiqué récemment que la forme de la bande

d'absorption de e^-_{aq} dépendrait, non seulement de w_0, mais également du type de solvant hydrocarboné utilisé.

(*vi*) e^-_{aq} n'est pas observé en-dessous d'une certaine taille critique de la poche d'eau correspondant à $w_0 \leq 5$ (180, 188, 189), ce qui pourrait signifier que toutes les molécules d'eau sont alors préférentiellement engagées dans les couches de solvatation des contre-ions Na^+. Une telle interprétation est confortée par de récents résultats de spectroscopies Raman et infra-rouge qui permettent de distinguer les contributions respectives de l'eau liée, dont la structure serait imposée par le surfactant, et de l'eau «libre», la contribution de cette dernière s'annulant justement pour $w_0 \sim 4$–6 (193, 194). En revanche, pour le système H_2O/AOT/isooctane, Jain et al. (195) distinguent trois types d'eau coexistant dans le volume du coeur micellaire : eau libre, eau liée et eau piégée à l'interface micellaire. Par spectroscopie infra-rouge et déconvolution en plusieurs gaussiennes du spectre dans la région d'élongation de O–H, ces auteurs estiment que, pour $w_0 = 5$, le nombre de molécules d'eau libres rapporté à une molécule de surfactant serait de 3. Pour un nombre d'agrégation moyen de 40 (196), correspondant à un rayon de coeur aqueux micellisé de ~12 Å, environ 120 molécules d'eau resteraient à l'état libre dans chaque micelle. La solvatation de e^-_{exc} pourrait cependant être trop lente pour entrer en compétition avec la diffusion de celui-ci. Soulignons enfin que la valeur seuil d'observabilité de e^-_{exc} peut dépendre de la mobilité de e^-_{exc}, c'est-à-dire de la nature du solvant hydrocarboné utilisé (187).

En résumé, l'ensemble des résultats présentés ci-dessus illustrent bien l'effet de l'état d'organisation des molécules d'eau dans les MOC. Ils soulignent également l'influence du potentiel électrique interfacial sur les rendements en électrons hydratés et sur leur distribution au voisinage de l'interface. Ces conclusions, valables pour des milieux organisés synthétiques, devraient pouvoir être étendues aux membranes naturelles qui impliquent une interface chargée stable, ainsi qu'aux poches aqueuses des bioagrégats.

IV. Agrégats négativement chargés

D'une façon générale, les expériences conduites depuis une à deux décennies sur les agrégats moléculaires ont évidemment tenté d'établir une transition entre la phase gazeuse et les phases condensées. Plus particulièrement, l'étude du processus d'attachement d'un électron en excès a été largement motivée par la possibilité d'assimiler les agrégats gazeux $(H_2O)_n^-$ et $(NH_3)_n^-$ à des modèles d'électrons solvatés dans le liquide correspondant.

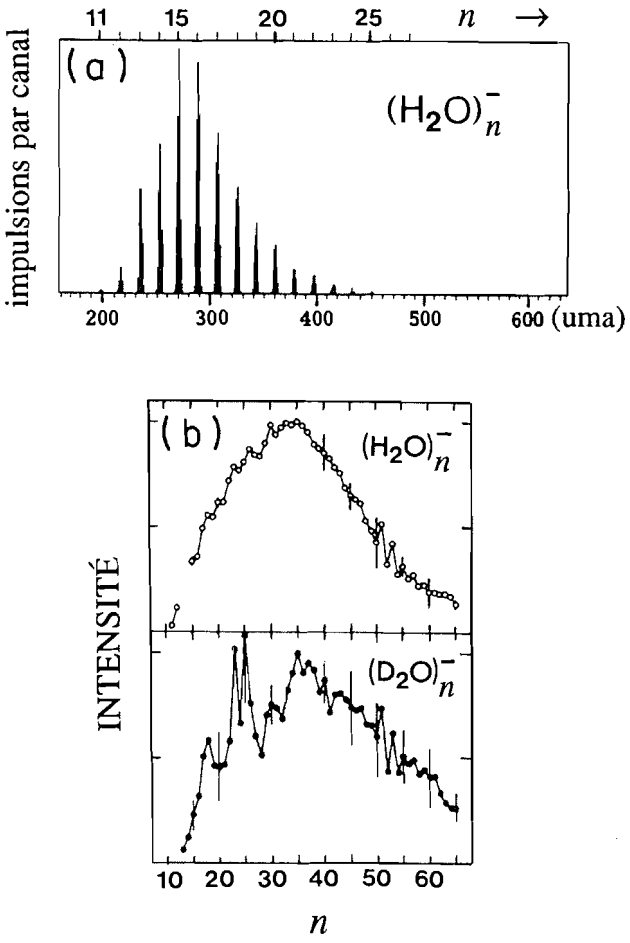
Après la suggestion initiale (197) que des agrégats gazeux de dimensions suffisantes seraient susceptibles d'attacher un électron, on a été amené à examiner la formation, l'état et les propriétés de e^-_{exc} en fonction de n. Les résultats, tant expérimentaux que théoriques, ont alors permis de préciser la nature des forces de stabilisation de e^-_{exc} en milieu condensé.

A. Données expérimentales

1. Méthodes de production

Les premières évidences (198) d'agrégats négativement chargés $(H_2O)_n^-$ ont été obtenues à partir de jets supersoniques de vapeur d'eau (100–1000 Torr; 1 Torr = 133.3 Pa), à ~400 K, irradiée par les rayons β^- d'une source radioactive. Les

Fig. 10. Spectres de masse d'agrégats d'eau négativement chargés $(H_2O)_n^-$ et $(D_2O)_n^-$: (*a*) d'après Haberland et al. (199); (*b*) d'après Kondow et al. (202).



électrons émis sont rapidement thermalisés et une analyse par spectrométrie de masse à temps de vol montre un pic principal à la masse 198 ($n = 11$) avec un seuil à $n = 8$. Un montage amélioré (199, 200), où des photoélectrons d'énergie cinétique inférieure à 0,5–2 eV sont injectés dans un jet supersonique de vapeur d'eau en expansion, a permis de minimiser l'effet des impuretés, les seuls pics enregistrés étant alors ceux correspondant à $(H_2O)_n^-$ (figure 10*a*).

L'attachement d'électrons a également été réalisé sur des agrégats libres, préformés et froids, les électrons incidents ayant dans ce cas une énergie quasi-nulle (201). La formation d'anions $(H_2O)_n^-$ est observée pour $n \geq 11$ (ou $n \geq 12$ pour l'eau deutérée), en accord avec la distribution des valeurs de n trouvée par Haberland et coll. (198–200).

Les deux mécanismes suivants de déclin interviennent :

$$(H_2O)_n^- \rightarrow (H_2O)_m^- + (n - m)\, H_2O$$

$$(H_2O)_n^- \rightarrow (H_2O)_n + e^-$$

et c'est le deuxième qui apparaît comme le plus efficace. La probabilité de celui-ci décroît quand n augmente, ce qui atteste d'une augmentation parallèle de l'affinité électronique adiabatique d'un agrégat d'eau avec ses dimensions. Knapp et al.

(201) suggèrent qu'un piège peu profond pourrait être associé à un état de surface ne présentant pas de barrière de potentiel à l'électron. En revanche, ils notent qu'on ne peut trancher sur l'origine de la brusque montée de la section efficace de formation de $(H_2O)_n^-$ observée pour $n \geq 11$: s'agit-il d'une prélocalisation qui devient plus efficace ou d'une stabilité accrue de l'agrégat négatif relaxé?

Une toute autre approche a été mise en oeuvre par Kondow et coll. (202). Ces auteurs forment $(H_2O)_n^-$ et $(D_2O)_n^-$ par collision d'agrégats neutres avec des atomes de gaz rares excités dans des états de Rydberg élevés :

$$(H_2O)_n + Kr^{**} \rightarrow (H_2O)_n^- + Kr^+$$

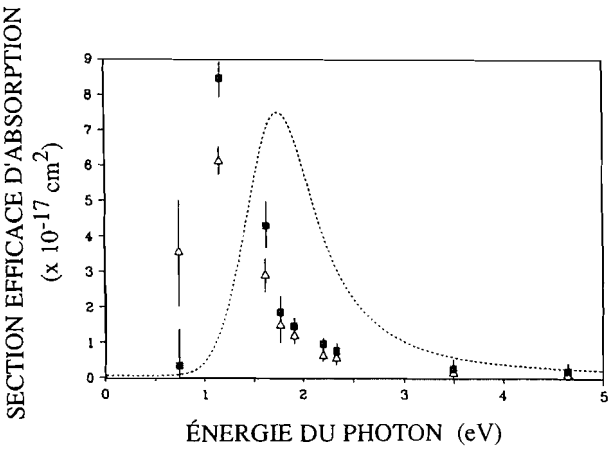
l'électron transféré ayant alors une énergie de quelques dizaines de meV avec une distribution en énergie du même ordre. Dans ces conditions, il n'y aurait pas d'évaporation concomitante de molécule monomère après l'attachement de l'électron de Rydberg. Cette technique conduit, de nouveau, aux seuils d'attachement $n = 11$ pour H_2O et $n = 13$ pour D_2O (figure 10*b*). Si, de plus, les atomes de gaz rares sont excités par un laser accordable, l'énergie des électrons de Rydberg peut varier — entre environ 5 et 300 meV (203, 204). Ainsi, pour des valeurs élevées de cette énergie (≥50 meV) et en présence d'hélium comme gaz porteur des agrégats neutres, les anions $(H_2O)_2^-$, $(H_2O)_6^-$ et $(H_2O)_7^-$ ont pu être observés, conformément aux résultats antérieurs de Haberland et al. (200). Il a été montré aussi que l'énergie seuil d'observabilité de l'anion dimère dépend de la nature du gaz porteur utilisé (203). Enfin, sous des conditions expérimentales très spécifiques, cette même approche mettant en jeu des collisions d'atomes excités Xe** avec des agrégats mixtes eau–ammoniac a donné lieu à la formation d'anions $[(H_2O)_p(NH_3)_q]^-$ avec les nombres «magiques» $n = p + q = 2, 5, 6, 7, 9$ et au-dessus (205); les auteurs ont souligné que la production de l'anion dimère mixte $(H_2O...NH_3)^-$ constitue un test pour la théorie de l'attachement d'un électron à un dipôle.

2. Photodétachement et photofragmentation

Les spectres de photoélectrons (photodétachement) obtenus à partir d'agrégats $(H_2O)_n^-$ (n = 2–69) à l'aide de photons visibles consistent, pour $n \geq 11$, en des bandes uniques, larges et asymétriques (206). Les énergies correspondant aux maxima de ces spectres représentent les énergies verticales de détachement de l'électron; celles-ci augmentent régulièrement de 0,75 à 1,92 eV quand n passe de 11 à 69. Leur variation avec $n^{-1/3}$ est linéaire, avec une extrapolation à l'origine ($n \rightarrow \infty$) de 3,3 eV qui équivaudrait, d'après ces auteurs, au seuil photoélectrique (~3,2 eV) de e^-_{aq} dans la glace.

Parallèlement au photodétachement, on observe une photofragmentation; les rendements relatifs de ces deux processus compétitifs ont été déterminés pour $15 \leq n \leq 40$ en détectant simultanément les intensités des ions parents et fragments sous excitation par un faisceau laser pulsé d'énergie supérieure au seuil de photodétachement (0,8 eV) (207). Le rendement quantique de photofragmentation (ϕ_n) croît, à partir de zéro, pour n variant de 15 à 20, et atteint un palier égal à 0,56 ± 0,10 pour $n > 20$. Cette variation de ϕ_n avec la taille de l'agrégat est semblable à la distribution des ions parents $(H_2O)_n^-$ en fonction de n, les parents les plus abondants se fragmentant donc plus efficacement. Une telle corrélation indique que la dynamique de la réaction d'attachement de l'électron serait analogue à celle de son photodétachement au voisinage du seuil.

Fig. 11. Spectres de photodestruction d'agrégats d'eau $(H_2O)_n^-$, pour n = 18 (△) et 30 (■), et pour des photons variant entre 0,75 et 4,66 eV. La ligne en pointillés représente, à titre de comparaison, le spectre d'absorption de e^-_{aq} à 298 K (d'après Campagnola et al. (208)).



Compte tenu de ces deux processus compétitifs, c'est la photodestruction des ions parents, plutôt que le spectre d'action du photofragment, qui permet d'atteindre indirectement le spectre d'absorption de l'agrégat négatif. La figure 11 reproduit les résultats obtenus sur la photodestruction de $(H_2O)_n^-$ pour n = 18 et 30, et pour des photons variant entre 0,75 et 4,66 eV (208, 209). La section efficace de photodestruction pour $n = 30$, qui apparaît décalée vers le rouge (~0,5 eV) par rapport au spectre d'absorption de e^-_{aq} à 298 K, présente une certaine analogie avec ce dernier, en ce qui concerne notamment la force d'oscillateur et la traîne vers le bleu.

Ainsi, il apparaît que les paramètres qui contrôlent la forme du spectre de e^-_{aq} interviendraient aussi dans le cas des microagrégats chargés négativement. L'état «excité» de $(H_2O)_n^-$ peut être testé en examinant les conséquences de l'absorption : une transition état lié → continuum se traduirait par l'éjection de l'électron en excès (photodétachement), tandis qu'une transition état lié → état lié aboutirait, après conversion interne de l'énergie électronique vers des niveaux vibrationnellement excités de l'état fondamental, à une photofragmentation. Campagnola et coll. (209) ont ainsi pu déconvoluer le spectre d'absorption obtenu pour $(H_2O)_{30}^-$ en deux composantes distinctes représentant respectivement ces deux types de transitions, la traîne d'absorption vers les grandes énergies étant principalement due à la photoéjection.

3. Réactions de $(H_2O)_n^-$

L'étude des réactions de $(H_2O)_n^-$ avec différents capteurs d'électrons (O_2, CO_2, NO, N_2O, Br_2 et CH_3Br) a montré qu'il ne s'agissait pas de simples transferts de charge (210). La réaction globale observée serait du type suivant :

$$(H_2O)_n^- + X \rightarrow X^-(H_2O)_m + (n - m)\, H_2O$$

X désignant le capteur.

En effet, la perte de molécules d'eau neutres ($n - m$) impliquée dans de tels processus a été mise en évidence par un

déplacement de la courbe de distribution en masse de l'ion parent $(H_2O)_n^-$. Cette évaporation peut, d'autre part, être corrélée avec l'exothermicité évaluée pour le transfert de charge vers X de l'électron lié à l'agrégat, transfert suivi de l'hydratation de l'ion résultant.

On aurait ainsi provoqué dans un agrégat gazeux l'équivalent d'une «chimie en microsolution» (210).

B. Traitements théoriques

Des calculs de simulation employant la méthode Monte Carlo et les intégrales de chemin révèlent que deux molécules d'eau peuvent fixer un électron; il en est de même pour le trimère dans une configuration linéaire (93, 211). Cependant, les énergies de liaison de e^-_{exc} ainsi évaluées sont très faibles : 3–6 meV pour le dimère et 4–9 meV pour le trimère. Expérimentalement, $(H_2O)_2^-$ ou $(H_2O)_3^-$ ne sont observés qu'en présence d'un gaz rare (He, Ar ou Xe) porteur (199, 200, 203, 205).

Des agrégats plus volumineux $(H_2O)_n^-$ (n = 8–128) ont ensuite été étudiés, pour une large gamme de température (79–300 K), par Barnett et coll. (212–215), au moyen de simulations de dynamique moléculaire utilisant les intégrales de chemin. Ces auteurs ont ainsi trouvé que l'affinité électronique adiabatique[6] favorise la formation d'états de surface pour $8 \lesssim n < 32$. Pour des agrégats de plus grandes dimensions ($32 < n < 64$), une transition graduelle s'effectuerait vers un mode de localisation interne, mode qui prévaudrait ensuite pour $n \gtrsim 64$. Les calculs de Barnett et al. (123, 217) indiquent par ailleurs l'existence d'états excités liés pour l'un et l'autre mode de localisation de e^-_{exc}; les énergies d'excitation associées aux états de surface seraient, selon ces auteurs, environ moitié de celles relatives aux états internes stables pour des agrégats plus grands. De plus, d'après ces calculs, le spectre d'excitation correspondant au mode de localisation interne de e^-_{exc} ne dépendrait que très faiblement de la taille de l'agrégat, pour n compris entre 64 et 256 (217). Il est intéressant de souligner que cet état interne de e^-_{exc} pourrait être considéré comme un précurseur de e^-_{aq}. Les interactions attractives de polarisation à longue distance, dont l'importance a par ailleurs été soulignée récemment dans ce contexte (216), joueraient ainsi un rôle prédominant dans l'hydratation de l'électron dans l'eau liquide.

Notons toutefois que la zone de transition présumée (n = 32–64) entre états de surface et modes internes de localisation de e^-_{exc} n'apparaît pas dans les spectres mesurés de photoélectrons (photodétachement) de $(H_2O)_n^-$, où l'énergie verticale de détachement de l'électron varie de façon régulière dans la gamme $11 < n < 69$ (206).

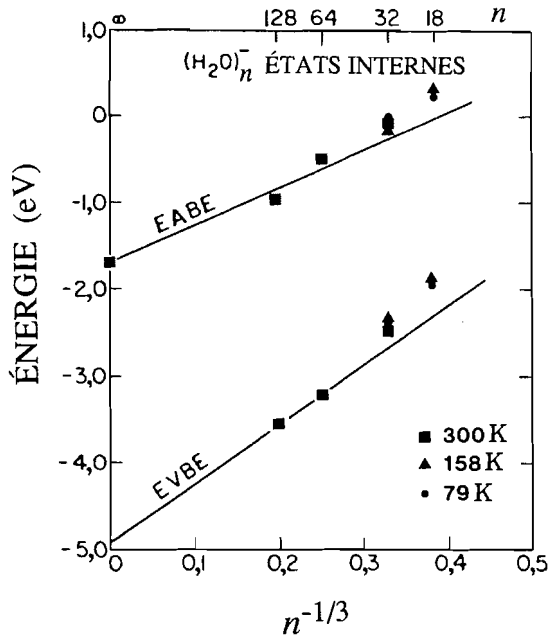
Dans le cas de l'ammoniac, les calculs de simulation de Barnett et al. (214) et de Marchi et al. (218) ont indiqué que les agrégats chargés négativement $(NH_3)_n^-$ n'apparaissaient respectivement que pour $n \geq 32$ ou 36, en bon accord avec l'expérience (199, 200, 205, 219) et en contraste marqué avec les résultats trouvés pour $(H_2O)_n^-$ ($n \geq 11$). Cette dernière différence traduirait, selon les auteurs, une interaction électron–molécule plus faible pour l'ammoniac que pour l'eau. Signalons toutefois que ces calculs n'ont pas pu s'accorder sur le fait de savoir si la formation de $(NH_3)_n^-$ impliquait des états de surface ou des modes internes de localisation de e^-_{exc} (218).

Pour les agrégats d'eau $(H_2O)_n^-$, Barnett et coll. (212, 214, 215) ont de plus calculé les énergies de liaison, verticales (EVBE) ou adiabatiques (EABE), des états internes de e^-_{exc} et montré qu'elles variaient linéairement avec $n^{-1/3}$ (figure 12). D'autre part, une extrapolation vers $n \rightarrow \infty$ des EABE fournit une valeur (−1,7 eV) en bon accord avec l'enthalpie de solution ou d'hydratation (ΔH^0_{hyd}) de e^-_{aq} (voir sect. II-D et tableau 2). La variation avec n des EVBE et des EABE calculées pour les états internes de e^-_{exc} permet ainsi d'établir «une transition continue entre les effets microscopiques de solvatation dans des systèmes finis et dans des fluides polaires macroscopiques» (215).

Enfin, l'évolution de e^-_{exc} en interaction avec un agrégat d'eau a été analysée par simulation adiabatique de la transformation dynamique, en temps réel, du système électron–agrégat (220–222). Pour $(H_2O)_n^-$ où n = 256, à 300 K, les résultats indiquent que l'électron initialement dans un état de surface évolue en moins de 2 ps vers un état interne solvaté. La migration de e^-_{exc} accompagnant le passage de l'état de surface vers l'état interne serait caractérisée par un mécanisme de transfert de nature polaronique, sans «sauts» entre sites de localisation successifs, ni entraînement de molécules d'eau (221).

En résumé, les résultats tant théoriques qu'expérimentaux ont révélé la formation d'agrégats gazeux négativement chargés relativement stables pour $(H_2O)_n$ où $n \geq 11$. De plus, les calculs relatifs à $(H_2O)_n^-$ montrent que, pour n assez grand, un mode de localisation interne supplante la formation d'états de surface, si bien que ces agrégats chargés volumineux seraient assimilables à des précurseurs de l'électron hydraté en phase liquide.

Fig. 12. Énergies de liaison, verticale (EVBE) et adiabatique (EABE), de l'état de localisation interne d'un électron en excès dans des agrégats d'eau $(H_2O)_n^-$ à 79, 158 et 300 K, en fonction de $n^{-1/3}$ (d'après Barnett et al. (213, 215)).



[6] Celle-ci, on le sait, prend en compte les énergies d'interaction de e^-_{exc} avec l'agrégat et de réorganisation moléculaire de ce dernier consécutive à la localisation de l'électron (voir, par exemple, réf. 216).

V. Conclusions

La solvatation des électrons en excès ($e^-_{exc} \rightarrow e^-_{solv}$) produits par radiolyse ou photoionisation a été étudiée principalement dans le cas de l'eau, des alcools liquides purs et de l'ammoniac.

En ce qui concerne les propriétés de e^-_{solv}, les nombres de coordination se sont avérés très voisins pour l'électron hydraté et l'anion Cl^-_{aq}, et le déplacement de la bande d'absorption de e^-_{solv} avec le solvant est trouvé analogue à celui observé pour les ions halogénure. En revanche, les données thermodynamiques et les traitements théoriques attestent d'une distribution de charge plus étalée pour e^-_{aq} que pour Cl^-_{aq}, ainsi que de grandes fluctuations dans la configuration de la cage de solvatation de l'électron hydraté.

Les avancées récentes réalisées dans la production d'impulsions laser ultracourtes et dans les calculs de simulation utilisant les méthodes de dynamique moléculaire et (ou) Monte Carlo associées aux intégrales de chemin, ont permis de mieux cerner le mécanisme séquentiel et la dynamique du processus de solvatation de e^-_{exc}. Pour l'eau liquide notamment, on a pu déterminer la cinétique d'apparition (temps caractéristique : $T_1 \sim$ 110–180 fs) et de relaxation (temps caractéristique : $T_2 \sim$ 240–620 fs) du précurseur de l'électron hydraté. La plupart des auteurs privilégient un modèle de solvatation, simple ou plus élaboré, mettant essentiellement en jeu deux états électroniques. Toutefois, la nature et le(s) mode(s) de déclin du précurseur de e^-_{aq} restent l'objet de controverses et l'existence d'un état intermédiaire entre e^-_{ir} et e^-_{aq} a été suggérée. La formation et le déclin ultra-rapides de paires hydratées $[H_3O^+:e^-:OH]_{nH_2O}$ (ou $[e^-:Cl]_{nH_2O}$ dans le cas de solutions aqueuses de chlorure de sodium) ont été analysés par spectroscopie femtoseconde. Une fraction des e^-_{exc} produits ne s'hydrate pas, mais disparaîtrait alors par un mécanisme de recombinaison non diffusionnel. Enfin, le caractère protique de l'eau et des alcools a été souligné, et l'intervention de transferts de protons, soit au stade de la formation de e^-_{exc}, soit au stade des recombinaisons géminées, a été invoquée.

Quant au méthanol, les expériences récentes de photoionisation multiphotonique du liquide pur ou de solutés en solution méthanolique montrent clairement l'insuffisance d'un modèle de solvatation n'impliquant que deux états.

Les conditions de formation de e^-_{solv} ont également été précisées par le recours à des systèmes modèles, tels que solutions micellaires et agrégats de molécules polaires. L'irradiation de solutions micellaires a clairement mis en évidence l'influence, sur les rendements et les propriétés spectroscopiques de e^-_{aq}, des interfaces ou interphases micellaires et de poches aqueuses modulables en taille. Pour les agrégats gazeux $(H_2O)_n^-$ ($n \sim$ 8–32), les calculs suggèrent que l'attachement de l'électron en excès se ferait dans un état de surface; en revanche, pour des agrégats suffisamment volumineux ($n \geq 64$), e^-_{exc}, initialement localisé en surface, évoluerait en quelques picosecondes vers un état interne, précurseur de l'électron hydraté dans l'eau liquide.

En conclusion, le caractère collectif, coopératif non seulement de la solvatation des électrons en excès, mais également des actes primaires d'excitation électronique et de séparation des charges, a été mis en relief, compliquant la description du mécanisme global de solvatation. En revanche, la coordination des résultats obtenus suivant les différentes approches évoquées, tant expérimentales que théoriques, devrait pouvoir conduire à une compréhension plus affinée de la formation de e^-_{solv}.

Enfin, il apparaîtrait souhaitable que les études de spectroscopie femtoseconde concernant l'électron solvaté soient étendues à une plus large gamme de solvants (alcools supérieurs, solvants polaires non protiques, par exemple) et étendues également vers l'infra-rouge plus lointain. L'observation simultanée à temps courts de l'évolution des électrons et des radicaux libres corrélés pourrait aussi apporter des informations précieuses et permettre une appréhension plus complète, et éventuellement plus générale, du processus de solvatation dans les milieux polaires.

Remerciements

Nos remerciements s'adressent à D. Grand et D. Solgadi qui ont bien voulu faire une lecture critique de certaines des pages de ce mémoire. C.F. et J.-P. J.-G. sont reconnaissants de l'aide financière que leur a apportée le Programme de coopération franco-québécoise en recherche médicale, le Programme de chercheurs invités du Fonds de la Recherche en Santé du Québec (FRSQ) et le Programme de subventions à la recherche en coopération de l'OTAN (Subvention n° 91/0996). J.-P. J.-G. remercie également le Conseil de Recherches Médicales du Canada pour son support financier, ainsi que le Programme d'échanges INSERM–FRSQ en recherche en santé pour lui avoir permis d'effectuer un stage de trois mois au Laboratoire de Chimie-Physique de l'Université Paris V.

Irreversible inhibition of 3-hydroxy-3-methylglutaryl-coenzyme A synthase from yeast by F-244 and (*RS*)-β-butyrolactone

Karen Bell, Endang Saepudin, and Paul Harrison

Abstract: The inhibition of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) synthase from yeast was compared for both F-244 (**1**) and (*RS*)-β-butyrolactone (**5**). F-244 exhibits irreversible inhibition with an IC_{50} of 8 nM, similar to that reported for the rat liver enzyme, while the binding constant ($1/K_I$) and inactivation rate constant (k_{inact}) are similar to values reported for the human cytoplasmic enzyme. (*RS*)-β-Butyrolactone (**5**) also irreversibly inhibits the enzyme, but with much lower efficiency (IC_{50} 2 mM). The values for K_I (9 mM) and k_{inact} (0.0078 s^{-1}) for **5** were determined. The results show that k_{inact} for **5** and **1** differ by a factor of only 2.5, while K_I for **5** is higher by a factor of 1.8×10^5. Hence, the β-lactone ring is shown to be the sole essential structural feature in **1** for irreversible inactivation of HMG-CoA synthase; however, the remaining functionality enhances the binding of **1** to the enzyme relative to **5**.

Key words: HMG-CoA synthase, F-244, butyrolactone, irreversible, inhibitor.

Résumé : On a comparé l'inhibition de la synthase 3-hydroxy-3-méthylglutaryl coenzyme A (HMG-CoA) vis-à-vis le composé F-244 (**1**) anisi que de la (*RS*)-β-butyrolactone (**5**). Le composé F-244 présente une inhibition irréversible avec un IC_{50} de 8 nM, semblable à celle rapportée pour l'enzyme du foie de rat, alors que la constante de fixation ($1/K_I$) et la constante de la vitesse d'inactivation (k_{inact}) sont toutes les deux semblables aux valeurs rapportées pour l'enzyme cytoplasmique humain. La(*RS*)-β-butyrolactone (**5**) inhibe aussi l'enzyme d'une façon irréversible, mais son efficacité est beaucoup plus faible (IC_{50} de 2 nM). On a déterminé les valeurs de K_I (9 mM) et de k_{inact} (0,0078 s^{-1}) du composé **5**. Les résultats montrent que les valeurs de k_{inact} des composés **1** et **5** diffèrent par un facteur de 2,5 alors que la valeur de K_I du composé **5** est $1{,}8 \times 10^5$ fois plus élevée que celle du composé **1**. On montre donc que le noyau β-lactone est la seule caractéristique structurale essentielle du composé **1** pour l'inactivation irréversible de la synthase HMG-CoA; toutefois, par comparaison avec le composé **5**, les autres fonctions augmentent la fixation du composé **1** à l'enzyme.

Mots clés : synthase HMG-CoA, F-244, butyrolactone, irréversible, inhibiteur.

[Traduit par la rédaction]

Introduction

The antibiotic F-244 (**1**) (Fig. 1) is a member of a small but growing number of natural products containing the β-lactone moiety. F-244 was first isolated from *Cephalosporium* sp. ACC 1233 as antibiotic 1233A (1, 2), and subsequently from *Scopulariopsis* species as F-244 (3–5) and from *Fusarium* species as L-659,699 (3, 6). The biological activity of **1**, revealed through studies on both microorganisms (4) and plants (7), has been shown by experiments both in vivo (5, 6, 8–10) and in vitro (3–6, 11, 12) to arise from specific and potent inhibition of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) synthase, a key enzyme in the sterol biosynthetic pathway. Early reports by Greenspan et al. (6) describing reversible inhibition have since been corrected (8); it is now clear that F-244 is an irreversible inhibitor of the rat liver HMG-CoA synthase (12). Several syntheses of F-244 and related analogues have been reported (13–19), and a number of inhibition studies (17–21) have started to reveal structure–activity correlations.

Due to interest in developing F-244 and analogues as anti-hypercholesterolemic drugs, the structure–activity correlations have focused on compounds that are similar to F-244 in chemical structure: all have an extended hydrophobic chain at C-4, in most cases terminated with carboxylic acid or carboxymethyl groups, and all but one of the analogues reported to date have a substituent at C-3, usually either hydroxymethyl or alkoxymethyl. In the C-3 unsubstituted example of Mayer et al. (12), 3-(2′-(*ortho*-biphenyl)ethyl)oxetanone (**2**) was shown to be a reversible inhibitor of the rat liver enzyme; however, the analogue **3** is irreversible. Further, due to the high affinity of F-244 for HMG-CoA synthase, classical analysis of irreversible inhibition by F-244 using double-reciprocal plots shows that the enzyme does not saturate, so that only a lower limit could be placed on K_I (the equilibrium constant for enzyme–inhibitor dissociation) and k_{inact} (the inactivation rate constant for the second step) (12). Recently, K_I (53.7 nM) and k_{inact} (0.018 s^{-1}) for F-244 were determined using nonlinear regression to solve the substrate concentration vs. time profiles of mixtures of enzyme, substrates (acetyl- and ace-

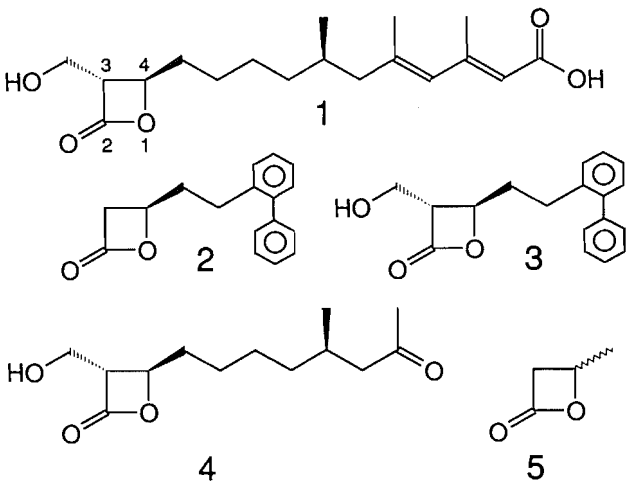
Fig. 1.



toacetyl-CoA), and inhibitor at various concentrations (22). For **4**, Mayer et al. (12) measured K_I (120 μM) and k_{inact} (0.14 s^{-1}). In other cases, the data have been presented as IC_{50} values, in order to draw comparisons between the efficacy of F-244 and analogues.

Our interest in the inhibition process led us to investigate simple β-lactones as inhibitors of HMG-CoA synthase and to evaluate K_I and k_{inact}. Herein, we describe the inhibition of HMG-CoA synthase by the simple inhibitor (*RS*)-β-butyrolactone (**5**), which forms the basis for further analysis of the influence of substituents on the fundamental inactivation parameters.

Experimental section

General

(*RS*)-β-Butyrolactone was purchased from Aldrich Chemical Co., and distilled prior to use. F-244 was prepared by incubation of *Fusarium* sp. ATCC 20788 by a modification of the procedure of Chabala et al. (23), and extracted and purified by column chromatography as described elsewhere (24). Yeast, coenzyme A esters, and all other biochemical reagents were purchased from Sigma and used as supplied.

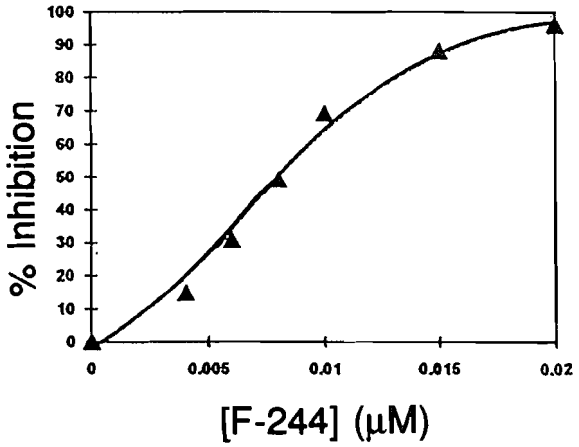
Enzyme assay

The assay for HMG-CoA synthase was performed as described by Miller et al. (25).

3-Hydroxy-3-methylglutaryl-coenzyme A synthase

Freeze-dried yeast (*Saccharomyces cerevisiae*, cat. no. YSC-1, 100 g) was autolysed in 0.2 M Tris base/HCl buffer (pH 8.2, 400 mL) at 38°C for 4 h. Centrifugation gave a yellow supernatant preparation containing a total activity of 16 units of HMG-CoA synthase with a specific activity of 3–7 units/g. The enzyme was partially purified by a modification of the ethanol fractionation procedure of Middleton and Tubbs (26) (25–30% pellet, 5-fold purification), followed by an ammonium sulphate precipitation (35–55% pellet, 2-fold purification) and hydroxylapatite chromatography (potassium hydrogen phosphate/HCl buffer, 0.01 to 0.2 M, pH 6.8, 5-fold purification). The final preparation had a specific activity of 0.14 units/mg protein.

Fig. 2. Percentage inhibition of HMG-CoA synthase as a function of F-244 concentration. HMG-CoA synthase was incubated for 5 min with F-244, then assayed for activity relative to a control without F-244.



Inhibition with F-244

Method A

Volumes of a solution of F-244 in DMSO (150 μM) and DMSO to a total of 150 μL were added to 50 μL aliquots of the partially purified enzyme in 0.2 M Tris (pH 8.2, total volume 3 mL) to give final concentrations of 0, 4, 6, 8, 10, 15, and 20 nM in **1**. The mixtures were incubated 5 min at 30°C. Aliquots of the resulting solutions were withdrawn and assayed for activity. Dilutions of the enzyme–inhibitor complex to test for reversibility of inhibition were performed according to the method of Greenspan (6).

Method B

The partially purified enzyme was added to a mixture of F-244 (0, 0.1, 0.5, and 1 μM) and substrates acetoacetyl-CoA (7 μM) and acetyl-CoA (150 μM) in 0.1 M Tris (pH 8.0) containing $MgCl_2$ (20 mM) and EDTA (0.2 mM), according to the procedure of Rokosz et al. (22). The change in absorbance of acetoacetyl-CoA at 303 nm was monitored as a function of time. The data were solved for K_I and k_{inact} according to the equations derived by this group.

Inhibition with (*RS*)-β-butyrolactone

Volumes of a solution of **5** in DMSO (100 mM) and DMSO to a total of 120 μL were added to 30 μL aliquots of the partially purified enzyme in 0.2 M Tris (pH 8.2, total volume 3 mL) to give final concentrations of 0, 1, 2, 4, and 8 mM in **5**. Each of these mixtures was incubated at 30°C for 5 min. Aliquots of the resulting solutions were withdrawn after 0, 2, 4, 8, and 10 min, and assayed for enzyme activity.

Results and discussion

Antibiotic F-244 inhibits yeast HMG-CoA synthase in a concentration-dependent manner (Fig. 2) when the time of preincubation of **1** with the enzyme is kept constant at 5 min. The IC_{50} value is approximately 8 nM under these conditions, close to the value reported for the rat liver enzyme (9 nM) (12) for identical preincubation times. Time-dependent inhibition was established by comparing assays (method A) of enzyme–

Table 1. Time-dependent inhibition of yeast HMG-CoA synthase by F-244.

[F-244] (μM)	% Inhibition (no preincubation)	% Inhibition (5 min preincubation)
0.004	12	100
0.008	48	100
0.020	95	100
0.040	100	100

Note: HMG-CoA synthase and F-244 at the specified concentration were mixed. Aliquots were removed immediately, or after 5 min, added directly into the assay cell, and assayed immediately.

F-244 mixtures both immediately after, and 5 min after mixing (Table 1). The %inhibition observed increased with longer preincubation times. The method developed by Rokosz (method B) was used to determine K_I (50 nM) and k_{inact} (0.02 s^{-1}) for F-244 with yeast enzyme. The results obtained were similar to values reported for the human enzyme.

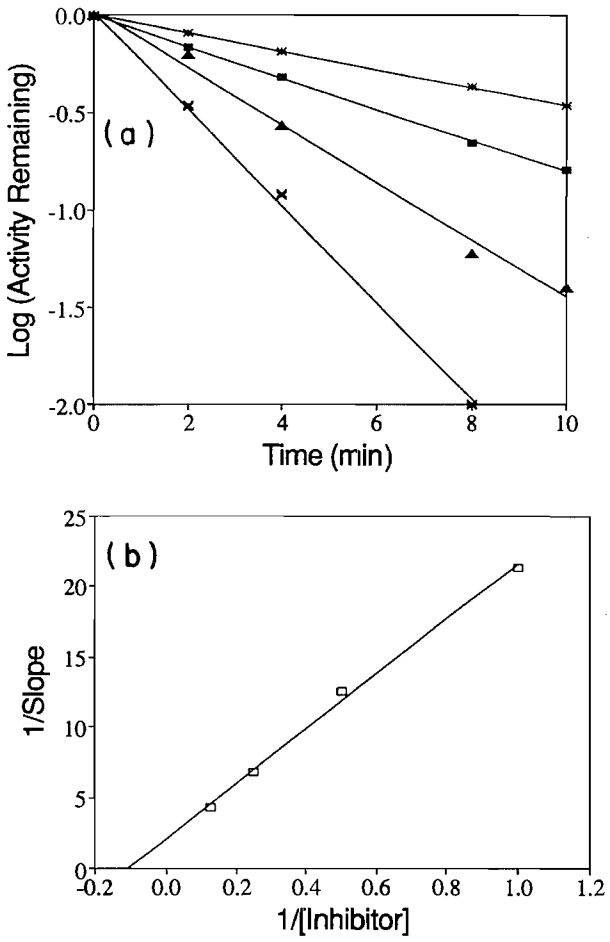
These observations show that the characteristics of inhibition by F-244 are very similar for yeast, rat liver, and human cytoplasmic enzymes. Indeed, a cysteine residue at the active site, which is involved in covalent thioester formation with the substrate acetyl-CoA in the first step of the catalytic cycle, has been strongly implicated in the yeast protein (26–28) and demonstrated to be present in the avian liver (29–31) and human cytoplasmic (22) enzymes. While these results are not surprising, it is interesting to note that cerulenin has been shown to inhibit the yeast enzyme (32), but not that of avian liver (5).

Inhibition of the same enzyme sample was studied with **5**, as a function of both concentration and time of preincubation (Fig. 3*a*). A double reciprocal plot of the data (Fig. 3*b*) gives a linear correlation ($R^2 = 0.9978$) and values of $K_I = 9$ mM and $k_{inact} = 0.0078$ s^{-1}. As is the case for **1**, dilution of inhibited enzyme under a variety of conditions failed to restore activity, while significant protection of the enzyme by the substrates occurred.

The data show that the mechanism of inhibition by **5** is qualitatively similar to that for **1**, i.e., time dependent and irreversible, demonstrating unambiguously that the β-lactone ring is the key component for irreversible inhibition. These results are in accord with previous studies, which show that hydrolysis of the β-lactone moiety results in inactive compounds (5, 6, 12). However, the results contrast with the observation that inhibition by **2** is reversible, but inactivation by **3** is irreversible, which had cast doubt on the hypothesis that the β-lactone is the only moiety responsible for irreversibility (12). It thus appears that the differences between **5** and **2** are attributable to structural differences in the enzyme–inhibitor complexes, as is also suggested by the 12 to 13-fold increase in k_{inact} for **2** relative to **1**. The value of k_{inact} for **5** is reduced relative to that for **1** by a factor of only 2.6, while K_I is increased for **5** by more than 10^5. Therefore, the substituents on the β-lactone ring play an important role in influencing the rate constant of the inactivation step.

It should be noted that the findings in the current study refer to racemic β-lactone **5**; in the absence of other effects, $K_I = 4.5$ mM if only one enantiomer is active. We are currently examining the individual enantiomers of **5**. The nature of the structural contributions to both K_I and k_{inact} is also being evaluated through systematic extension of the C-3 and C-4 substituents on the β-lactone ring. These results will be communicated in due course.

Fig. 3. (*a*) Plot of % activity remaining as a function of time during inhibition of HMG-CoA synthase by various concentrations of (*RS*)-β-butyrolactone; (*b*) double reciprocal re-plot of the data from (*a*). Concentrations: *, 1 mM; ■, 2 mM; ▲, 4 mM; X, 8 mM.



Conclusion

Examination of inhibition of yeast HMG-CoA synthase by F-244 (**1**) has shown that the characteristics of the irreversible inhibition are essentially the same as for the rat liver and human cytoplasmic enzymes. The simple analogue (*RS*)-β-butyrolactone (**5**) inhibits the yeast enzyme by an apparently identical mechanism. The results show that k_{inact} for **5** is only marginally lower than that for **1**, while K_I is much higher. Hence, the β-lactone ring is shown to be the essential structural feature in **1** for irreversible enzyme inactivation; however, the remaining functionality plays a role in enhancing the binding of **1** to the enzyme relative to **5**.

Near-infrared and visible luminescence and absorption spectroscopy of low-coordinate organometallic rhenium compounds

Carole Savoie and Christian Reber

Abstract: Low-temperature absorption and luminescence spectra of four organorhenium compounds were measured in the visible and near-infrared spectral regions. Effects of the temperature, formal oxidation state, and the oxo-, bromo-, and organic ligands on the metal center are reported. The emission maxima of the four compounds show a large variation between 9000 and 14 200 cm^{-1}. Stokes shifts show a smaller variation from 3700 to 4200 cm^{-1}. Luminescence intensities are used to qualitatively characterize nonradiative relaxation processes.

Key words: luminescence spectra, absorption spectra, organorhenium compounds.

Résumé : Les spectres d'absorption et de luminescence à basse température de quatre complexes organométalliques du rhénium(III) et du rhénium(V) ont été mesurés dans les régions du visible et du proche infrarouge. Les effets apportés par la variation de la température, du degré d'oxydation et du nombre et caractère des ligands oxo, bromo et organiques sur le centre métallique ont été étudiés. Les énergies des maxima d'émission varient entre 9000 et 14 200 cm^{-1}. Les déplacements de Stokes montrent une variation plus faible de 3700 à 4200 cm^{-1}. Les résultats spectroscopiques nous renseignent sur les processus de relaxation impliqués lors des transitions.

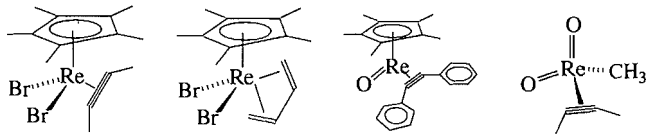
Mots clés : spectroscopie de luminescence, spectroscopie d'absorption, composés organométalliques du rhénium.

1. Introduction

Rhenium shows a very rich organometallic chemistry with a wide variety of oxidation states and many different coordination geometries that have been explored over the past decade (1–3). The main emphasis of the work reported in the literature is on the synthesis, structure determination, and NMR spectroscopic properties of organorhenium compounds.

These systems offer a unique opportunity to examine a variety of coordination geometries, oxidation states, and ligand environments for the same transition metal center with electronic spectroscopic techniques. We present emission spectra of a series of organorhenium compounds with oxo and bromo ligands in the near-infrared and visible regions. The molecules studied are $ReBr_2(C_5(CH_3)_5)(CH_3C{\equiv}CCH_3)$ (A), $ReBr_2(C_5(CH_3)_5)(CH_2{=}CH\text{-}CH{=}CH_2)$ (B), $ReO(C_5(CH_3)_5)(C_6H_5C{\equiv}CC_6H_5)$ (C), and $ReO_2(CH_3)(CH_3C{\equiv}CCH_3)$ (D), presented in Scheme 1. They share low coordination numbers and an approximate C_s symmetry and were chosen for this study based on their varying ligand environments and metal oxidation states: compounds A–C in Scheme 1 have Re(III) metal centers ([Xe]$5d^4$ electron configuration), whereas compound D has a Re(V) metal center ([Xe]$5d^2$). The large spectroscopic differences between these molecules

Scheme 1.



A B C D

indicate exceptionally large tuning ranges for properties such as the emitting state energy, an important quantity for selective photochemical and photocatalytical applications. Up to now, organometallic compounds of the heavy transition elements were only rarely studied from this perspective.

We present low-temperature absorption and luminescence spectra and establish a qualitative correlation between band energies and the nature of the ligands of compounds A–D. The near-infrared spectral region is of crucial importance for these studies, in contrast to traditional coordination compounds of the third-row transition metals, where the lowest energy excited states are often observed in the visible or ultraviolet regions, at significantly higher energies than for the organorhenium compounds studied in this work (4).

2. Experimental

The syntheses and crystal structures of compounds A–D are described in refs. 5–7. Compounds A (black), B (purple), and C (red-brown) were obtained in solid form from Dr. Roland A. Fischer. Compound D and its acetylene analogue (both yellow) were synthesized using the methods described in refs. 7 and 8, using trioxomethylrhenium(VII) as a starting material and mild, selective deoxidation with polymer-bound triphenylphosphine in order to obtain the Re(V) dioxo compound D.

The purity of our samples was checked by comparing ^{1}H NMR and IR spectra to the literature data (5–8). Thin crystalline samples suitable for spectroscopy were obtained either by slow evaporation of saturated solutions in dry methanol on quartz plates at room temperature or by cleaving thin samples from larger crystals. All solutions must be kept under an inert atmosphere to prevent decomposition of the molecules. The optical quality of the sample crystals was examined under a microscope between crossed polarizers, and extinction directions were determined. Only unpolarized spectra are reported in the following because the polarization direction had no significant effect on band intensities and positions, most likely due to the low crystal symmetries with multiple inequivalent sites for the chromophores in the crystal, leading to molecular units with different orientations relative to the polarization directions (5–8). The crystals, with typical areas of 0.5 mm^2, were mounted in a helium cryostat (Oxford Instruments CF 1204). All absorption spectra were measured with a Varian Cary 5E spectrophotometer. The instrumentation used for luminescence measurements is described in detail elsewhere (9). Both broadband UV light and the 514.5 nm line from an Ar^+ ion laser were used as excitation sources. Weak luminescence was found for compounds B–D; no luminescence was detectable for compound A. Emission at wavelengths longer than 1000 nm was detected with a Ge detector (ADC 403L, cooled to 77 K) and a lock-in amplifier. All spectra are corrected for system response (9, 10), but no smoothing or noise-removal routines were applied to experimental data.

3. Spectroscopic results

Emission was observed from three of the compounds in Scheme 1 between 600 and 1500 nm. The luminescence spectra of compounds B–D are shown in Fig. 1. The energy of the emission band maxima varies between 9000 and 14 200 cm^{-1}, an exceptionally large variation for a series of organometallic compounds of the same metal. The acetylene analogue of compound D shows a luminescence spectrum with a similar bandwidth and a higher energy band maximum (14 500 cm^{-1} at 20 K) than compound D. This comparison illustrates the small influence of the nature of the substituents on the alkyne ligands on the energy and properties of the emitting state. No emission was observed from compound A at wavelengths shorter than 2000 nm, most likely due to efficient nonradiative relaxation processes from its very low-energy first excited state. The luminescence intensities for all compounds decrease rapidly with increasing temperature, as illustrated in Fig. 1 with two selected temperatures. Figure 2 shows integrated band intensities as a function of temperature. Band maxima and bandwidths at low temperature are summarized in Table 1 for the compounds in Scheme 1.

The solid-state absorption spectra of all four molecules are shown in Fig. 3. The dibromo compounds A and B show onsets of their first absorption bands in the near-infrared region, in contrast to the oxo compounds C and D, where these onsets are in the visible. The energies of the first absorption bands show a variation similar to that of the luminescence band maxima. Transition energies were determined from the spectra in Figs. 2 and 3 and are summarized for all the compounds in Table 1. Absorption intensities and band positions show no large change with temperature, as expected for low-

Fig. 1. Low-temperature luminescence spectra of the organometallic rhenium compounds B (circle), C (square), and D (triangle) in Scheme 1.

symmetry systems and similar to the experimental results for a series of organometallic mono-oxo rhenium compounds (11). The lowest energy absorption bands of compounds B–D in dichloromethane solution at room temperature are not as easily discernible as the corresponding bands in the low-temperature, solid-state spectra in Fig. 3. We determine extinction coefficients of 5, 33, and <1 M^{-1} cm^{-1} for the first absorption bands of compounds B–D, respectively. The higher energy visible bands in solution correspond well to the solid state spectra. Wavelengths (extinction coefficients) are as follows: A: 700 nm (365), 510 nm (1134), 340 nm (4713); B: 520 nm (62), 360 nm (124); C: 500 nm (200), 420 nm (450); D: 360 nm (193).

4. Discussion

The organorhenium compounds investigated in this work show a very large variation of their lowest excited state energies. This large tuning range is possible because of the unique,

Table 1. Absorption and luminescence band maxima and luminescence bandwidths.

Compound	Absorption max., cm^{-1}	Emission max., cm^{-1}	Bandwidth, cm^{-1}	Stokes shift, cm^{-1}
$ReBr_2(C_5(CH_3)_5)(CH_3C{\equiv}CCH_3)$ (A)	7 000[a]	—	—	—

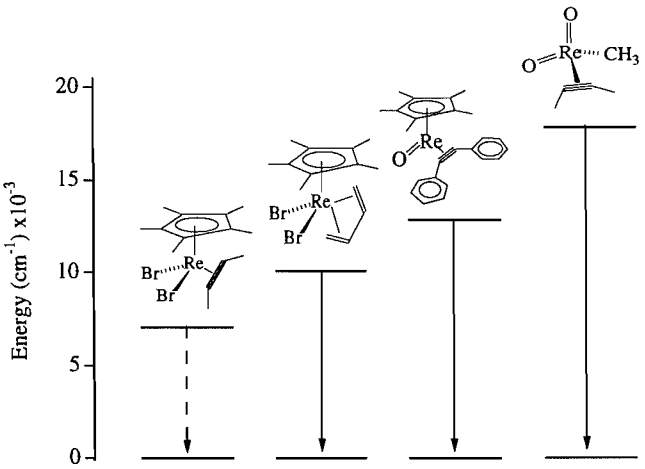
very rich organometallic chemistry of rhenium. We qualitatively examine some spectroscopic trends observed for compounds A–D and relate the emitting state energies to the nature of the ligands. The weak low-energy absorption bands for the luminescent compounds B–D are indicative of d-d transitions, an assignment supported by the low extinction coefficients observed in the solution spectra. This proposed assignment is further supported by the molecular orbital calculations for mono-oxo systems reported in ref 2. We notice that the absence of luminescence from compound A might not be caused exclusively by the low energy of its first excited state, but might be caused in part by a qualitatively different nature of this state. Large structural distortions are common to occur in charge-transfer excited states and would lead to more efficient nonradiative relaxation processes than for d-d emitting states with smaller distortions.

It was shown for an extended series of cyclopentadienyl compounds of nickel(II) that the d-d absorption band energies follow the standard spectrochemical series for common anionic ligands such as halides or the oxide ion (12). Based on these correlations, established for Ni(II), we expect the bromo compounds A and B to have lower energy excited states than the oxo systems C and D, corresponding to the observations in Figs. 1 and 3 and in qualitative agreement with our d-d assignment. Furthermore, the emitting state for compound C with only one oxo ligand is observed at lower energy than for compound D with two oxo ligands, again in agreement with the spectrochemical series. The rhenium–oxygen bond lengths are 1.709 Å for C and 1.74 Å for D, shorter than in *trans*-ReO_2 complexes, but longer than found for the majority of the known Re≡O organometallic compounds (13). The emitting state energy for the dioxo compound D varies by less than 1000 cm^{-1} from the band maxima obtained for Re≡O systems with a shorter rhenium–oxygen bond (11). This comparison illustrates the limited applicability of ligand-field concepts to our series of organometallic compounds. Transition energies appear to depend less strongly on metal–ligand bond length than expected from ligand-field theory. We note that the formal oxidation state of the metal center does not appear to be the main determinant of the emitting state energy, as illustrated by very similar emission band maxima for the Re(V) compound D and the Re(III) compounds in ref. 11. The energies of the first excited states obtained from the electronic spectra are summarized for compounds A–D in Fig. 4.

The higher energy absorption bands for compounds C and D in Fig. 3b are more intense than the first band, likely corresponding to the spin-allowed d-d transitions expected at higher energy than the spin-forbidden first bands (11). Compound B shows a series of bands with comparable intensities throughout the visible region, a different spectrum from those for compounds C and D, reflecting the different coordination geometries. A possible reason for the sequence of intense absorption bands of compound B throughout the visible spectral region could be low-energy intra- or intermolecular electron transfer transitions. Despite these large variations between the absorption spectra, the lowest energy excited state has some common characteristics for compounds B–D, illustrated by the similar luminescence bandwidths and the low extinction coefficients in the solution absorption spectra, qualitatively supporting our proposed d–d assignment.

The luminescence intensities decrease with increasing temperature, similar to those reported in ref. 11, where it was shown that luminescence lifetimes decrease in parallel with the intensities. The quantum yields of these luminescences are low and the lifetimes are expected to be much shorter than those expected for purely radiative transitions (11). Their use

Fig. 4. Energies of the lowest excited states for the series of organometallic rhenium compounds in Scheme 1. The energies are determined from the luminescence and absorption spectra in Figs. 1 and 3, respectively. Solid arrows denote observed luminescence transitions; the broken arrow for compound A indicates efficient nonradiative relaxation processes.



for the characterization of the emitting state is limited, and we made no attempt to measure them for compounds B–D. The decrease in luminescence intensity with temperature can be correlated with the number of oxo ligands: the most pronounced decrease is observed for compound D, which contains two high-frequency rhenium-oxo oscillators. A distinction between compounds B and C is not possible, illustrating that other high-frequency vibrations, most likely C-H oscillators, play an important role in the relaxation dynamics. This conclusion is in agreement with ref. 11, where a qualitative correlation between the decrease of both the luminescence intensity and lifetime with the number of C-H oscillators was established. Such qualitative arguments neglect the importance of intermolecular energy transfer processes to impurities, shown to be important in some organometallic solids (9, 10), and therefore a more quantitative analysis of the temperature dependence of the luminescence intensities is not possible from our data.

The Stokes shifts for compounds B–D are included in Table 1. Their large values indicate significant structural changes between the ground and lowest energy excited states. In contrast to the emitting state energies, there is no systematic variation of the Stokes shift for compounds B–D, and similar Stokes shifts between 3400 and 3700 cm^{-1} were obtained for the rhenium–oxo compounds in ref. 11. The lack of vibronic structure does not allow us to determine individual bond length changes, but the similar luminescence and absorption bandwidths of our compounds and those reported in ref. 11 indicate similar excited state distortions.

This work illustrates the large variation of the emitting state energy of organometallic rhenium compounds, establishing these molecules as new near-infrared chromophores with a very large tuning range. Excited-state energies and transition intensities reflect the nature of the ligands and the coordination geometry and indicate a potential for photochemical applications of these molecules.

Acknowledgments

We thank Dr. Roland A. Fischer (Technische Universität München, Germany) for the gift of some of the compounds used in this study. Mechanistic variations in the formation of benzocyclooctatetraene from benzobicyclo[4.2.0]octa-2,4,7-triene

Christopher Owen Bender

Abstract: Benzocyclooctatetraene (i.e., COT, **2**) is the major product from the thermolysis and direct photolysis of 2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (i.e., triene **1**). It is also a minor product from the sensitized irradiation of **1**. The mechanism of the reaction **1**→**2** was investigated using deuterium-labelled triene (i.e., **1***a/b*), which was prepared in a two-step procedure from a known triene mixture (**1***a*) containing deuterium at both C-4 (43%) and C-5 (97%): the thermolysis of **1***a* led to labelled COT **2***a*, which upon direct irradiation ($\lambda \geq 310$ nm) gave the deuterated triene mixture **1***a/b* in good chemical yield (61%) but in low quantum efficiency ($\Phi \approx 0.0001$). The COT produced from the direct irradiation (Corex filter) of **1***a/b* possessed different deuterium distributions than when generated thermally or from triplet sensitization (*p*-dimethylaminobenzophenone), as determined by ^{1}H NMR integration. The observed deuterium-labelling patterns are in accord with a Zimmerman di-π-methane rearrangement being involved in formation of the COT from S_1 of triene **1**, while a mechanism proceeding by initial cleavage of the cyclobutene C_1—C_6 bond appears to operate during the thermal or sensitized (T_1) generations of **2**.

Key words: mechanisms, rearrangements, photochemistry, di-π-methane.

Résumé : Le benzocyclooctatétraène (soit, le COT, **2**) est le principal produit soit lorsqu'on chauffe des solutions du composé 2,3-benzobicyclo[4.2.0]octa-2,4,7-triène (**1**), ou lorsqu'on le photolyse directement. Le composé COT **2** est aussi un produit mineur des irradiations sensibilisées du triène **1**. Le mécanisme pour la réaction **1**→**2** a été étudié à l'aide du triène marqué au deutérium (**1***a/b*). On a préparé le mélange **1***a/b* en deux étapes à partir du triène **1***a* contenant des atomes de deutérium à C-4 (43%) et à C-5 (97%) : la thermolyse du triène **1***a* conduit au COT **2***a* qui ensuite se transforme en **1***a/b* par irradiation directe, en bon rendement (61%) mais faible efficacité ($\Phi \approx 0{,}0001$). Les distributions de deutérium dans le COT obtenu par irradiation directe (filtre de Corex), par thermolyse ou par irradiation sensibilisée (*p*-diméthylaminobenzophénone), du **1***a/b* sont différentes. Des études de marquage suggèrent qu'une transposition di-π-méthane de Zimmerman est le mécanisme qui produit le COT à partir du S_1 du triène **1**, tandis que la voie suivie pendant la thermolyse ou l'irradiation sensibilisée (T_1) est une ouverture de la liaison C_1—C_6 du composé **1**.

Mots clés : mécanismes, transpositions, photochimie, di-π-méthane.

Introduction

There is current interest in the synthesis of benzocyclooctenes due to their demonstrated potential for conversion, via Birch reduction, to derivatives of the anti-cancer drug Taxol (1). Recently, we reported (2) that unsubstituted benzocyclooctatetraene (**2**) is the major product from both the thermolysis and the direct photolysis of 2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**1**). It is also a very minor product from sensitized irradiations of the triene. Details of the ground and excited-state products of triene **1** are summarized in Scheme 1. It was noted that a simple $2\sigma_s+2\pi_s$ electrocyclic opening (3) of the cyclobutene ring of triene **1** could account for the COT formation in each case, and experiments using deuterium-labelled starting material (**1**-d_2) gave results consistent with this mechanistic view, viz **1**-d_2→**2**-d_2 (Scheme 1). We now report further results based on a new labelling pattern that indicate that the pathways used in the formation of COT **2** from triene **1** involve different carbon reorganizations when formed from the singlet excited state than when generated from sensitization (T_1) or from thermolysis.

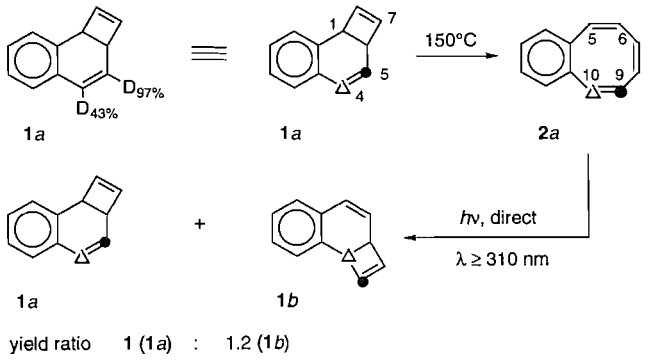
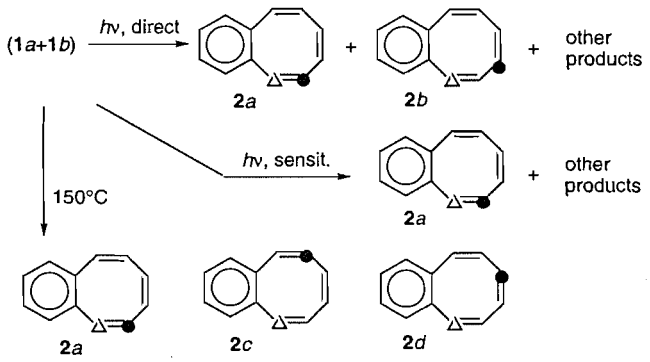
[a]In each case the aromatic multiplet at δ 6.93–6.99 was set as the normalized integration standard of 2.00H; the other aromatic multiplet at δ 7.17–7.24 gave integral values within the range 2.00–2.04H.

Scheme 2. Preparation of deuterium-labeled triene mixture.



Scheme 3. Observed and possible label locations in COT product from triene thermolyses and photolyses.



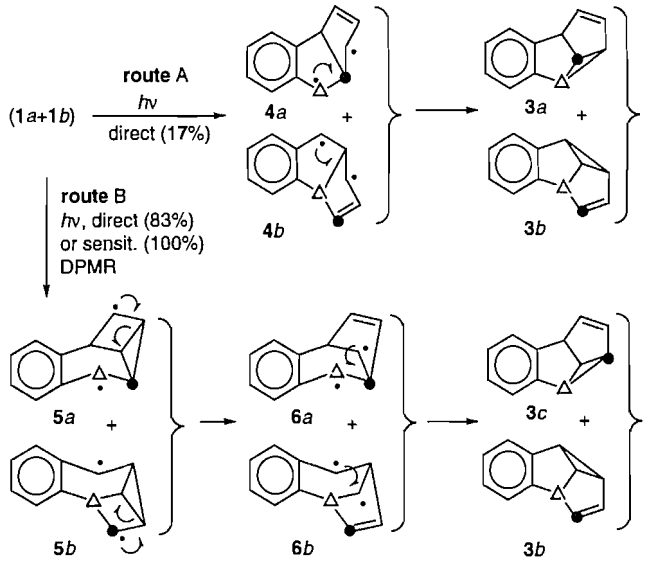
prepared in a two-step procedure from the known (2) triene mixture **1***a*, which contained deuterium at both C-4 (43%) and C-5 (97%) (Scheme 2). Thus, the thermolysis of **1***a* led to the labelled COT **2***a* (see Table 1, entry 1, for the ^{1}H NMR integrations of the aliphatic hydrogens), which upon direct irradiation (λ ≥ 310 nm) gave the deuterated triene mixture **1***a* and **1***b* in good chemical yield (61%, based on 35% conversion), but in low quantum efficiency (Φ ≈ 0.0001). The inefficiency of the rearrangement may provide an explanation for a previous report that found COT **2** to be unreactive (4). The label distributions in the isotopic triene mixture **1***a,b* were determined by proton NMR analysis (see Experimental); a small isotope effect ($k_{1b}/k_{1a} \leq 1.2$) in favour of the formation of **1***b* was observed in the 2π + 2π photoclosure step.

A solution of the mixture **1***a,b* in *n*-nonane, when heated to reflux (150°C) for 12 h, gave a 75% yield of COT product, which showed no deuterium attachment to C-7 and C-8 (i.e., the γ carbons) and corresponded uniquely to the presence of the mixture **2***a* (note Scheme 3). The observed and calculated ^{1}H NMR integration values are listed in Table 1 (see entries 3 and 2, respectively). Although in principle the isotopic mixture **2***c* (note structure in Scheme 3) would also lead to the same overall proton integrations as **2***a*, we were able to rule out the formation of **2***c* on the basis of the NMR peak ratios of the two types of signal (a singlet and a doublet)[2] observed for the COT α hydrogens (i.e., for H-5 and H-10), and also those found for the β hydrogens (i.e., H-6 and H-9). If **2***c* were present, the anticipated ratio of the singlet to doublet peaks would then be 1(s):0.6(d) for the α hydrogens, and 0.7(s):1.0(d) for the β hydrogens (see entry 4, Table 1). The observed ratios were 1(s):1.9(d) and <0.02(s):1.0(d), respectively, which agrees with the ratios required for **2***a* (see entry 2, Table 1).

In the case of the COT product isolated from the direct irradiation of the triene mixture **1***a,b*, the NMR hydrogen distributions were distinctly different from those found for the

[2] There are two types of signal observed for the α hydrogens: besides the doublet centred at δ6.55 ($J_{5(10),6(9)}$ = 12 Hz) there is a singlet at δ 6.55 that results from the absence of coupling when a β carbon is partially deuterated. The integration ratio of the singlet to doublet signals indicates the relative amount of deuterium at the β positions. The situation is similar for the β hydrogens, which occur as a doublet of triplets centred at δ 6.03 ($J_{6(9),5(10)}$ = 12 Hz, $J_{6(9),7(8)} = J_{6(9),8(7)}$ = 2 Hz), and which are accompanied by a broad singlet at δ6.03 when an α carbon is partially deuterated.

Scheme 4. Mechanisms that operate in semibullvalene photoformation.



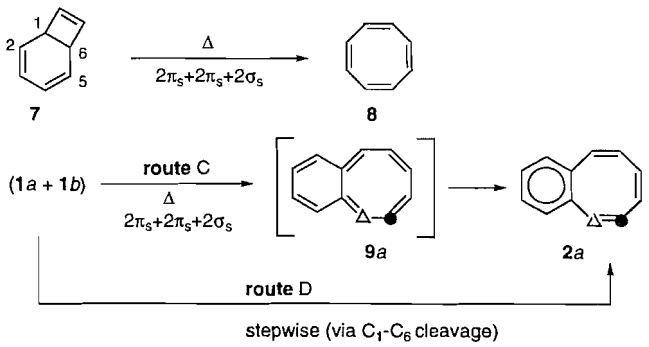
thermally generated COT.[3] Importantly, the integrations for the β hydrogens were heavy, while those for the γ hydrogens were light (note entry 6, Table 1), and accord well with a composite of 72.5% **2***a* and 27.5% **2***b* (note entry 7, Table 1). Although the formation of mixture **2***c* in place of **2***a* can be discounted, since this would have led to significantly different s:d ratios for the α and for the β hydrogen signals (see entry 8, Table 1), we are not able to eliminate the possibility that isotope mixture **2***d* (see structure in Scheme 3) forms part of the COT product in place of **2***b*: both **2***b* and **2***d* would give the same gross proton integrations and also the same s:d ratios for the α and for the β signal peaks (see entry 7, Table 1). Similar difficulties in interpretation of the proton distributions for related deuterated benzocyclooctatetraenes were encountered by Zimmerman, Givens, and Pagni (4), and arise from the C_{2v} symmetry of the benzo-COT system.

In contrast to the direct irradiation results, the COT material obtained from the sensitized irradiation of the triene mixture **1***a,b* showed NMR spectral details that were the same as those observed for the thermally generated COT **2***a* product (cf. Table 1, entries 5 and 3, respectively).[3]

The direct and sensitized photolyses of the deuterated triene also gave the labelled semibullvalenes (i.e., SB) **3***a–c*. The observed SB deuterium distributions (see Experimental) depend on the mode of excitation and fully confirm conclusions from a previous report (2) that the semibullvalene product from direct irradiation derives from two reaction pathways (note Scheme 4, route A (17%) and route B (83%)), whereas that from triplet senistization is provided uniquely by a Zimmerman di-π-methane (DPM) rearrangement (5) (Scheme 4, route B).

[3] To minimize complications due to possible kinetic isotope effects in the photolyses of triene mixture **1***a,b*, the runs were carried out to almost complete conversion of the starting material: ≥97% in the direct irradiation, and 96% in the case of sensitization.

Scheme 5. Mechanisms that account for COT formation from triene thermolysis and sensitized irradiation.



Discussion

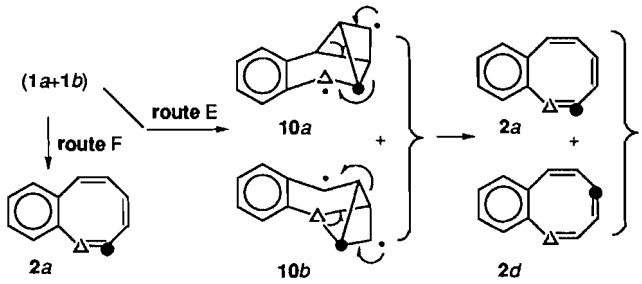
The thermal rearrangement of the parent aliphatic triene **7** to COT **8** (Scheme 5) is a facile reaction (6) that is formally a $2\pi_s + 2\pi_s + 2\sigma_s$ electrocyclic opening of the six-membered ring (3). The concerted process, however, would be expected to be more demanding in the case of the benzo derivative **1** since the initial loss of aromaticity (note route C and structure **9***a*, Scheme 5) is required before bond reorganization can occur to give the boat structure of COT **2***a*. It is therefore not surprising that benzo-triene **1** has a half-life of ca. 1 h at 150°C whereas the parent triene **7** has a $t_{1/2}$ of 14 min at 0°C (6). An alternative explanation for the thermal rearrangement of triene **1** to COT **2** is that the reaction proceeds via a stepwise process (route D, Scheme 5) involving the initial cleavage of the strained C_1—C_6 bond of **1***a,b*. The observed deuterium labelling in **2***a* is in accord with operation of either route C or route D (Scheme 5).

The photochemical generation of COT from triene **1** is more complex. The previous study (2) of the excited-state reactivity of **1** showed that ≥98% of the COT produced from the direct irradiation originates from the S_1 state of the triene; the COT from sensitized runs is triplet derived (T_1). The present results now reveal that S_1 and T_1 engage different pathways when forming the COT. In the case of T_1, the observed COT deuterium-labelling pattern (entry 5, Table 1) is consistent with a process that proceeds with a simple opening of the cyclobutene ring of triene **1**, similar to the stepwise thermal pathway to COT **2***a* (cf. route D, Scheme 5).

The COT formed from S_1, on the other hand, must involve another mechanism, at least in part, since deuterium occurs also at the γ carbon(s) (note entry 6, Table 1). One possible rationale that does account for the observed label distribution involves the formation of the COT products **2***a* and **2***d*[4] via a 1:1 competition between the pathways depicted in Scheme 6 (routes E and F): **2***a* may derive in part (50%) from the $2\sigma_s + 2\pi_s$ electrocyclic process (route F) or stepwise, whereas **2***d* (27.5%) and additional **2***a* (22.5%) may arise from the initial C_5–C_8 diagonal bridging shown as route E. However, a point of concern with this rationale is that the latter mechanism has not been reported in derivatives of bicyclo[4.2.0]octatriene,

[4] We are unable to differentiate between isomer mixture **2***d* and **2***b* with the NMR data at hand, vide supra.

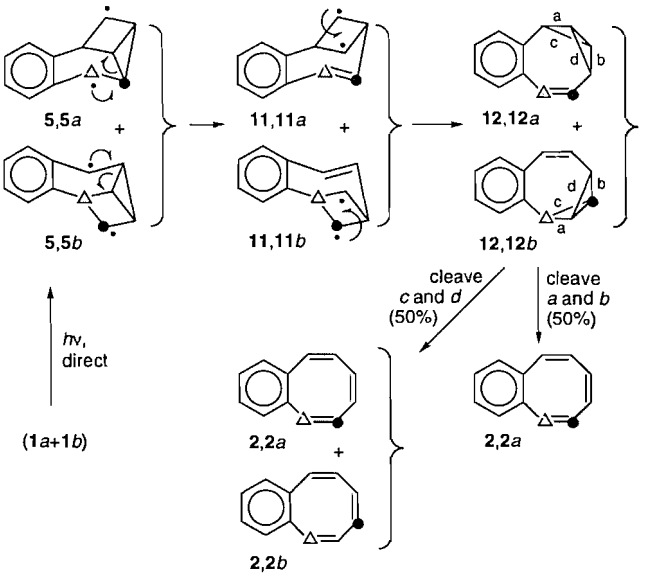
Scheme 6. Possible mechanism for COT formation from direct irradiation of triene.



and diagonal bridging of this kind is unknown in other di-π-methane systems.[5]

A more simple explanation of the labelling results, and one that has literature precedence, involves the coformation of the COTs **2***a* and **2***b* from a single mechanistic pathway. This pathway proceeds by Zimmerman DPM rearrangement (5) of triene **1** and entails the initial formation and subsequent thermal reorganization of the symmetrical octavalene intermediate **12** (note Scheme 7). The final step is assumed to occur with equal facility via rupture of alternate pairs of allylic (*b* and *d*) and benzylic (*a* and *c*) bonds of **12**, i.e., 50% by cleavage of bonds *a* and *b*, and 50% by cleavage of bonds *c* and *d*. A similar mechanism was previously invoked by us (7) to account for the photochemical conversion of the 8-cyano triene **13** to equal amounts of the labelled cyano COTs **17** and **18** (see route G, Scheme 8). Interestingly, and as required by the present proposal for **1**, in the case of 8-cyano triene **13** the $2\sigma_s + 2\pi_s$ electrocyclic opening (route H, Scheme 8) was totally avoided, i.e., COT **19** was not detected. We have not obtained physical evidence for the formation of the octavalene **12** during the direct photolysis of **1**, but this may be due to the rate of rearrangement of **12**→**2** being much higher than the rate of formation of the octavalene at the photolysis temperature employed (ca. 20°C). The 1,4-diradical **5** is thus viewed to be a common species on the pathways to the major products observed in the photochemistry of triene **1**, and rearranges to give alternative vinylcyclopropanes, i.e., SB **3***b,c* (route B, Scheme 4) and the thermally unstable octavalene **12** (Scheme 7).

Scheme 7. Suggested mechanism for COT formation from direct irradiation of triene.



Structures denoted by "a" and "b" represent compounds labelled with deuterium at the positions marked by △ and ● . For structures denoted by a number only (e.g.,12) △ and ● = H.

Lastly, we note that the proposed pathway in Scheme 7 is attributed to S_1 of **1**. Although the occurrence of a DPM rearrangement from S_1 is uncommon in rigid molecules (5), it has precedent in other benzobicyclo[4.2.0]octa-2,4,7-trienes (8), e.g., **13** gives **17** and **18** (7).

Experimental

Instrumentation and materials

The ^1H spectra were recorded in $CDCl_3$ solvent at 250 MHz; the chemical shifts are in δ units and the coupling constants (*J*) in Hz. The abbreviations br, s, d, t, q, and m refer to broad, singlet, doublet, triplet, quartet, and multiplet, respectively. Cyclohexane solvent for photolyses was prepared by scrub-

[5] A referee has suggested an additional route that might account for the label distributions in the COT product obtained from the triene direct irradiation, viz. rearrangement of **1***a,b* to benzobarrelene (a photochemically allowed 1,3-shift), which then undergoes the well-known singlet-mediated transformation to COT (4). Evidence against this proposal exists from a previous study (2) based on the labelled triene **1**-d_2 (note structure in Scheme 1). If the benzobarrelene **20** (note Fig. 1 below) were formed from **1**-d_2 its subsequent photolysis would have led to the COT mixture **2***a,b*-d_2 through a pathway that involves initial 2π +2π bridging, mainly (94 ± 3%) between the benzo-vinyl portions of **20** (4). The NMR spectrum of the COT product therefore would have revealed a low hydrogen integration for the γ hydrogens. The reported (2) integration value was 1.97H, which indicates that within experimental error no deuterium was attached to the COT C-7 or C-8 positions. Hence the COT **2***a*-d_2 is not formed, and consequently (assuming reasonable isotope effects) the pathway depicted in Fig. 1 does not operate. Furthermore, careful monitoring of the photolysates of the direct irradiation of triene **1** revealed no trace of benzobarrelene (by NMR and GC analyses).

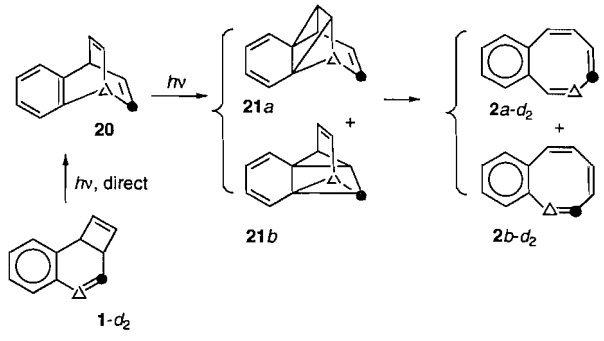
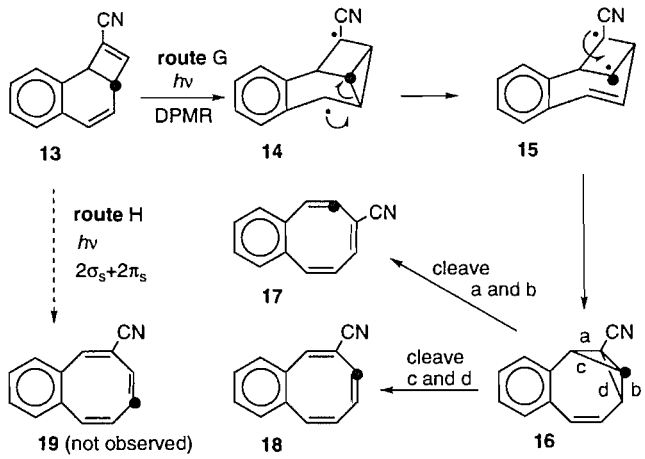


Scheme 8. Label locations in COT product from direct irradiation of 8-cyano triene.



bing with 20% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Column chromatography was carried out on Silica Gel 60 (Merck; 230–400 mesh), or Lobar columns (Merck; size B, LiChroprep Si 60), or on Silica Gel 60/$AgNO_3$ columns (10:1, by weight). The GC analyses were determined by FID on a DB-23 fused silica capillary column (30 m × 0.25 mm; J&W Scientific).

General procedures for preparative photolyses

The apparatus consisted of a 450-W Hanovia medium-pressure mercury arc surrounded by a water-cooled quartz immersion well. Unless otherwise stated, the light was filtered through either a cylindrical sleeve of Pyrex, or Corex, or an aqueous lead nitrate solution (1 g of $Pb(NO_3)_2$ and 100 g of NaBr in 1 L of water; transmittance was 0% below 318 nm) contained in a concentric filter jacket (10 mm path length). Three types of sample cell were used. Cell A (200 mL sample volume) consisted of a cylindrical collar (Pyrex) that surrounded the aqueous filter jacket. Cell A was fitted with gas inlet and exit ports, and sample solutions were purged with argon prior to and during irradiations. Cell B (40 mL sample volume) and Cell C (3.5 mL) were a quartz test-tube-like vessel and a quartz cuvette, respectively; sample solutions contained therein were deoxygenated by flushing with argon and sealed under a positive pressure; the solutions were magnetically stirred throughout the course of the irradiations.

Deuterium-labelled triene **1**a

Deuterated triene **1***a* (97%-d_1 labelled at C-5 and 43%-d_1 labelled at C-4) was obtained as previously described (2); ^{1}H NMR: 7.00–7.17 (m, 4.35H, aromatics and residual $CHCl_3$), 6.26 (br s, 0.57H, H-4), 6.13 (d, 1.02H, H-7, $J_{8,7}$ = 2.7), 6.02 (dd, 0.98H, H-8, $J_{7,8}$ = 2.7, $J_{7,6}$ = 0.9), 5.88 (dd, 0.03H, H-5, $J_{5,4} = J_{5,6}$ = 4.5), 4.11 (d, 1.02H, H-1, $J_{1,6}$ = 4.5), and 3.64 (d, 1.00H, H-6, $J_{6,1}$ = 4.5).

Thermolysis of deuterium labelled triene **1**a

A solution of 186.6 mg (1.21 mmol) of triene **1***a* in 4 mL of *n*-nonane was refluxed (ca. 150°C) for 10 h. The thermolysis product was chromatographed on Silica Gel 60 (0.9 cm × 10 cm; hexane), to give 162.7 mg (87%) of COT **2***a*; mp 47–49°C (lit. (4) mp 48–50°C); ^{1}H NMR: 7.17–7.24 (m, 2.03H, aromatics), 6.93–6.99 (m, 2.00H, aromatics), 6.55 (d + br s, 1.56H, H-10 and H-5, $J_{10,9}$ = 11.8), 6.03 (dm, 1.04H, H-6 + H-9, $J_{9,10}$ = 11.5), and 5.88 (d, 2.01H, H-7 and H-8, J = 1.8); the ratio of the s:d at δ6.55 is given in entry 1, Table 1.

Formation of mixture **1**a,b *from direct irradiation of COT* **2**a

A solution of 162.0 mg (1.05 mmol) of **2***a* in 200 mL of cyclohexane was irradiated at >318 nm for 91 h in Cell A (ca. 35% conversion by GC). The photolysate was concentrated and chromatographed on a Silica Gel/$AgNO_3$ column (1 cm × 11 cm; 0.1% ethyl acetate – hexane). Two bands were observed. The first band contained 34.4 mg (21%) of the triene mixture **1***a,b*; ^{1}H NMR: 7.00–7.17 (m, 4.15H, aromatics and residual $CHCl_3$), 6.26 (d + br s, 0.81H, H-4), 6.13 (br s, 1.02H, H-7), 6.02 (br d, 0.46H, H-8, $J_{8,7}$ = 2.7), 5.88 (dd, 0.55H, H-5, $J_{5,4} = J_{5,6}$ = 4.5), 4.11 (d, 0.76H, H-1, $J_{1,6}$ = 4.5), and 3.64 (br d, 1.00H, H-6, $J_{6,1}$ = 4.5); the calculated integrations for a mixture of 55% **1***a* and 45% **1***b* are: 0.81 H-4, 1.00 H-7, 0.47 H-8, 0.56 H-5, 0.76 H-1, and 1.00 H-6. The second band off the column gave 105.8 mg (65%) of recovered COT **2***a*; ^{1}H NMR: 7.17–7.24 (m, 2.02H, aromatics), 6.93–6.99 (m, 2.00H, aromatics), 6.55 (d + br s, 1.60H, H-10 and H-5, $J_{10,9}$ = 11.8), 6.03 (dm, 1.01H, H-6 + H-9, $J_{9,10}$ = 11.5), and 5.88 (d, 1.98H, H-7 and H-8, J = 1.8).

Thermolysis of deuterium-labelled triene **1**a,b

A solution of 4.0 mg (0.026 mmol) of triene **1***a,b* in 1 mL of *n*-nonane was refluxed (ca. 150°C) for 12 h. The thermolysis product was chromatographed on Silica Gel 60 (0.9 cm × 10 cm; hexane), to give 3.0 mg (75%) of COT **2***a*; note Table 1, entry 3 for details of the ^{1}H NMR spectrum.

Direct irradiation of labelled triene mixture **1**a,b

A solution of 39.4 mg (0.26 mmol) of **1***a,b* and ca. 40 mg of dodecane (GC standard) in 40 mL of cyclohexane was irradiated (Corex filter) for 30 min in Cell B (97% conversion by GC). The photolysate was chromatographed, first on Silica Gel 60 (0.9 cm × 10 cm; 100 mL hexane) to remove polymeric materials, and then on a Lobar column with hexane solvent. The first band gave ca. 2 mg (5%) of naphthalene (identified by GC comparison with an authentic sample). The last band (i.e., third) gave 7.5 mg (19%) of deuterated 3,4-benzotricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene (i.e., SB mixture **3***a-c*) as a colourless oil (GC purity >98%), which was identified by comparison of the chemical shifts and coupling constants of the ^{1}H NMR spectrum with that reported for authentic SB **3** (4); ^{1}H NMR: 7.31–7.35 (m, 1.00H, aromatic), 7.04–7.18 (m, 3.20H, aromatics), 5.60 (dd, 0.47H, H-6, $J_{6,7}$ = 5, $J_{6,5}$ = 2.3), 5.21 (m, 0.99H, H-7), 3.90 (dd, 0.77H, H-5, $J_{5,1}$ = 6.3, $J_{5,6}$ = 2), 3.29 (m, 0.94H, H-1), 3.04 (t, 0.81H, H-2, $J_{2,1} = J_{2,8}$ = 6.3), and 2.70–2.76 (m, 0.67H, H-8); the calculated integrations for a mixture of 7.7% **3***a*, 55% **3***b*, and 37.4% **3***c* (as required by 17% utilization of route A and 83% of route B, Scheme 4) are 0.47 H-6, 1.00 H-7, 0.76 H-5, 0.93 H-1, 0.81 H-2, and 0.64 H-8.

The contents of the second band from the Lobar chromatography were rechromatographed on a Silica Gel 60/$AgNO_3$ column (1 cm × 11 cm; 0.1% ethyl acetate – hexane). Two bands were observed. The first band contained 1.0 mg (2.5%) of recovered triene mixture **1***a/b*; ^{1}H NMR: 7.00–7.17 (m,

4.15H, aromatics and residual $CHCl_3$), 6.26 (d + br s, 0.84H, H-4), 6.13 (br s, 1.00H, H-7), 6.02 (br d, 0.38H, H-8, $J_{8,7}$ = 2.7), 5.88 (dd, 0.63H, H-5, $J_{5,4} = J_{5,6} = 4.5$), 4.11 (d, 0.71H, H-1, $J_{1,6} = 4.5$), and 3.64 (br d, 1.00H, H-6, $J_{6,1} = 4.5$). The second band off the column gave 11.8 mg (30%) of COT **2***a,b* (or perhaps **2***a,d*); note Table 1, entry 6 for details of the ^{1}H NMR spectrum.

Sensitized irradiation of labelled triene mixture ***1***a,b

A solution containing 12.9 mg (0.058 mmol) of *p*-dimethylaminobenzophenone, 43.5 mg (0.28 mmol) of **1***a,b*, and 29.3 mg of dodecane (GC standard) in 40 mL of cyclohexane was irradiated for 40 min in Cell B, with light filtered through a Pyrex and WG 345 glass (Schott) filter (95% conversion by GC). The photolysate was concentrated, chromatographed on Silica Gel 60 (0.9 cm × 10 cm; 100 mL hexane) to remove polymeric materials and sensitizer, and then rechromatographed on a Lobar column (hexane). The first band contained a trace of naphthalene (identified by GC comparison with an authentic sample). The second band gave 1.6 mg (4%) residual triene mixture **1***a/b*, ^{1}H NMR: 7.00–7.17 (m, 4.26H, aromatics and residual $CHCl_3$), 6.26 (d + br s, 0.81H, H-4), 6.13 (br s, 1.00H, H-7), 6.02 (br d, 0.43H, H-8, $J_{8,7}$ = 2.7), 5.88 (dd, 0.60H, H-5, $J_{5,4} = J_{5,6} = 4.5$), 4.11 (d, 0.74H, H-1, $J_{1,6} = 4.5$), and 3.64 (br d, 1.01H, H-6, $J_{6,1} = 4.5$). The third band gave ca. 1.0 mg (2%) of COT **2***a*: note Table 1, entry 5, for details of the ^{1}H NMR spectrum.

The final band gave 24.1 mg (55%) of SB mixture **3***b,c* (GC purity >98%); ^{1}H NMR: 7.31–7.35 (m, 1.00H, aromatic), 7.04–7.18 (m, 3.29H, aromatics), 5.60 (dd, 0.46H, H-6, $J_{6,7}$ = 5, $J_{6,5}$ = 2.3), 5.21 (m, 1.00H, H-7), 3.90 (dd, 0.76H, H-5, $J_{5,1}$ = 6.3, $J_{5,6}$ = 2), 3.29 (m, 1.01H, H-1), 3.04 (t, 0.80H, H-2, $J_{2,1} = J_{2,8}$ = 6.3), and 2.70–2.76 (m, 0.59H, H-8); the calculated integrations for a mixture of 55% **3***b*, and 45% **3***c* (as required by 100% utilization of route B Scheme 4) are 0.47 H-6, 1.00 H-7, 0.76 H-5, 1.00 H-1, 0.81 H-2, and 0.56 H-8.

Quantum efficiencies

The quantum yield for the conversion of COT **1**→**2** was performed on an apparatus previously described (9), which includes an optical bench arranged for beam splitting into a potassium ferrioxalate actinometer (10). Cyclohexane solutions (in Cell C, 3.5 mL) of COT **2** (8×10^{-3} M) were deoxygenated prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations carried out with light of wavelength 313 nm. The quantum yield of 0.0001 was obtained from two runs extrapolated to zero conversion. Product analyses were determined by GC (internal dodecane standard).

Influence of vanadium(V) complexes on the catalytic activity of ribonuclease A. The role of vanadate complexes as transition state analogues to reactions at phosphate[1]

Chui Har Leon-Lai, Michael J. Gresser, and Alan S. Tracey

Abstract: The interactions of vanadate and its complexes of uridine, 5,6-dihydrouridine, and methyl β-D-ribofuranoside with bovine pancreatic ribonuclease A (RNase A) (EC 3.1.27.5) were studied by ^{51}V NMR spectroscopy and enzyme kinetics. From kinetic studies, it was found that neither inorganic vanadate nor the methyl β-D-ribofuranoside–vanadate complex significantly inhibited the RNase A catalyzed hydrolysis of uridine 2′,3′-cyclic monophosphate. The NMR binding studies were in full agreement with the kinetics studies and showed that neither inorganic vanadate nor the methyl β-D-ribofuranoside–vanadate complex was bound tightly by the enzyme. Approximate binding constants were $(5.0 \pm 1.0) \times 10^{-7}$ M and $(3.0 \pm 0.6) \times 10^{-6}$ M for the uridine– and 5,6-dihydrouridine–vanadate complexes, respectively. An induced-fit mechanism is suggested, in which the pyrimidine subsite of the active site of RNase A must be fully occupied for the enzyme to be able to tightly bind the transition state or transition state analog. Calculation of the binding energies of vanadate complexes in ribonuclease, phosphoglycerate mutase, and phosphoglucomutase revealed an excess of binding energy over the analogous phosphate derivative of about 25 kJ/mol for all enzymes, even though the binding constants themselves varied by about six orders of magnitude. This energy represents about 40% of that expected to be available for a trigonal-bipyramidal transition state and requires a reassessment of the role of vanadate as a transition state analogue for phosphate transfer.

Key words: vanadate, ribonuclease, transition state, binding constants, phosphate analogues, kinetics.

Résumé : Faisant appel à la spectrscopie RMN du ^{51}V et de la cinétique des enzymes, on a étudié les interactions entre le vanadate et ses complexes de l'uridine, de la 5,6-dihydrouridine et du β-D-ribofuranoside de méthyle avec la ribunucléase A du pancréas de boeuf (RNase A) (EC 3.1.27.5). Sur la base des études cinétiques, on a trouvé que, vis-à-vis de l'hydrolyse du monophosphate 2′,3′-cyclique de l'uridine de la RNase A, ni le vanadate inorganique ni le complexe du β-D-ribofuranoside de méthyle–vanadate n'inhibent cette réaction d'une façon significative. Les études par RMN ont montré qu'il ne se produit aucune fixation entre ces matériaux et elles étaient en parfait accord avec les études cinétiques; elles montrent aussi que ni le vanadate inorganique ni le complexe du β-D-ribofuranoside de méthyle–vanadate ne se complexent fortement avec l'enzyme. Les constantes apparentes de fixation ont respectivement de $(5{,}0 \pm 1{,}0) \times 10^{-7}$ M et $(3{,}0 \pm 0{,}6) \times 10^{-6}$ M pour les complexes de l'uridine et du 5,6-dihydrouridine avec le vanadate. On propose un mécanisme induit d'ajustement dans lequel il est important que tout le sous site de la pyrimidine du site actif de la RNase A soit occupé pour que l'enzyme soit capable de bien fixer l'état de transition ou son analogue. Des calculs d'énergie de fixation des complexes du vanadate dans la ribonucléase, la phosphoglycératemutase ou la phosphoglucomutase ont révélé que, pour chacun de ces enzymes, ces valeurs sont environs 25 kJ mol^{-1} supérieures à celle du dérivé analogue du phosphate, même si les constantes de fixation elles-mêmes varient par un facteur d'environ un million. Cette énergie représente environ 40% de toute l'énergie qui devrait être disponible pour un état de transition trigonal bipyramidal et elle nécessite une réévaluation du rôle du vanadate comme analogue de l'état de transition pour le transfert du phosphate.

Mots clés : vanadate, ribonucléase, état de transition, constante de fixation, analogue du phosphate, cinétique.

Introduction

Ribonuclease A (RNase A) (EC 3.1.27.5) is a bovine pancreatic enzyme with a molecular weight of 13 700 (1).[4] It catalyzes the hydrolysis of ribonucleic acid (RNA), with the formation and decomposition of an intermediate cyclic 2′,3′-nucleotide (2). Inhibition exerted by a vanadate–uridine complex on the catalytic activity of RNase A was the first reported example of the influence of vanadium on an enzyme (3). An inhibition constant (K_i) value of 1.2×10^{-5} M was reported (3) from this early work.

Vanadate, in the presence of uridine or other nucleosides, gives rise to a number of complexes. The predominant products are dimeric in nature and their formation constants are large compared to those of the monomeric precursors. Recent work (4, 5) has evaluated the formation constant for the 2:2 complex and has also provided a value for the formation constant of the monomeric (1:1) complex. The nature of this equilibration process was not appreciated at the time of the original inhibition studies.

Questions concerning the mechanism of action of this enzyme have arisen over the past few years with the suggestion that the reaction proceeds via a triester intermediate instead of the generally accepted classical acid–base catalyzed mechanism (6, 7). The evidence seems to favour the classical mechanism for ribonuclease A (8). However, a steadily increasing number of ribonucleases have been discovered so it is important to fully understand the mechanism, or mechanisms, by which these enzymes operate. This problem has, to an extent, been recently addressed by extensive theoretical calculations (9–11) that have included interactions with the uracil base (10). Because of the affinity of ribonuclease A for vanadate-derived analogues to the cyclic phosphate substrate, additional possibilities for investigating the role of the uracil ring in the catalytic process have arisen.

A reevaluation of the binding of uridine–vanadate complex by ribonuclease is also of general interest since this provides information on the role that the vanadium centre in complexes of vanadate plays as an analogue to phosphate in this enzyme. It is also necessary if comparisons are to be drawn with other enzymic systems. Unfortunately, only a very few other systems have been studied in detail. However, a picture of the role of vanadate as a phosphate analogue begins to emerge from these studies that is inconsistent with the general picture of the role of vanadate as a transition state analogue to phosphate.

In this study, ^{51}V NMR spectroscopy has been utilized to study the binding of vanadate complexes of uridine, 5,6-dihydrouridine, and methyl β-D-ribofuranoside to ribonuclease. Enzyme kinetics studies have also been carried out in conjunction with these NMR studies. The results obtained here have been compared with those reported for phosphoglycerate mutase (12) and for phosphoglucomutase (13, 14).

Materials and methods

Bovine pancreatic ribonuclease A (lyophilized powder) was purchased from Boehringer Mannheim. All reagents used were of reagent grade. Both enzyme and reagents were used without any further purification. Vanadium(V) oxide, 99.99% (gold label) was purchased from Aldrich Chemical Co. Uridine 2′,3′-cyclic monophosphate (sodium salt), uridine, 5,6-dihydrouridine, and methyl β-D-ribofuranoside (crystalline) were purchased from Sigma Chemical Company. Tris buffer (tris(hydroxymethyl)aminomethane hydrochloride or tris(hydroxymethyl)aminomethane) was from either Boehringer Mannheim or Sigma Chemical Company. KCl and HCl (1 N) were from BDH Chemicals. NaOH (1 N) was from Anachemia Chemicals Inc. and Fisher Scientific. Reference buffer solutions (pH 4, 7, and 10) were from Canlab.

Solutions

Preparation of the vanadate stock solutions

For ^{51}V NMR studies: Stock solutions of sodium vanadate (NaH_2VO_4) were prepared by dissolving 0.5 mol equivalent of vanadium pentoxide (V_2O_5) in 1 equivalent of 1.0 M NaOH. The mixture was stirred until the orange color disappeared, generally overnight, to give a colourless solution. It was then combined with enough KCl and diluted with sufficient deionized distilled water to give a final concentration of 0.1 M NaH_2VO_4 and 0.35 M KCl.

For kinetics studies: Stock solutions of 1.0 mM sodium vanadate (0.35 M KCl) were prepared by dilution of the above 100 mM solution of vanadate. The dilution was made into 5.0 mM Tris/0.35 M KCl to near the desired final volume. The pH was adjusted to 7.0 with small aliquots of 0.1 N NaOH before diluting to the final volume.

Preparation of the ligand stock solutions

Stock solutions of uridine, 5,6-dihydrouridine, and methyl β-D-ribofuranoside were prepared by dissolving each of them in 0.35 M KCl/5.0 mM Tris buffer at a pH near 7.0. Subsequently, the pH was adjusted to 7.0 by the addition of appropriate quantities of 0.1 N HCl or 0.1 N NaOH. The concentration of the Tris buffer was low enough to avoid the formation of a significant amount of vanadate–Tris complexes (15) during the sample preparation. The concentration of uridine was determined by UV spectrophotometry (ε_{260} = 9.9 mM^{-1} cm^{-1}).

Preparation of the substrate

A solution of uridine-2′,3′-cyclic phosphate (U-2′,3′-P), in 0.35 M KCl/5.0 mM Tris buffer, pH 7.0, was prepared fresh on the day of use, prior to the kinetics experiments, and kept on ice. The concentration of substrate was determined spectrophotometrically (ε_{258} = 9.57 mM^{-1} cm^{-1}).

Preparation of the RNase A samples

For ^{51}V NMR spectroscopy: The enzyme samples were prepared by dissolving the lyophilized powder in a solution of 5.0 mM Tris buffer and 0.35 M KCl, the pH was adjusted to about 7 with small aliquots of 0.05 N NaOH, and vanadate was added to give a final concentration of 1.0 mM. The pH was adjusted again to 7.0 before bringing the solution to the final volume. It was done this way to avoid the formation of decavanadate which is an oligomer that hydrolyzes very slowly at neutral pH.

[4] List of abbreviations: U-2′;3′-P =uridine 2′:3′-cyclic monophosphate. U-3′-P =uridine 3′-monophosphate. RNase A = bovine pancreatic ribonuclease A. Tris = tris(hydroxymethyl)aminomethane.

Before the addition of vanadate to the enzyme sample, a small aliquot was withdrawn from the sample in order to determine the concentration of protein by reading the absorbance at 280 nm ($\varepsilon^{1\%}_{280}$ = 7.3, MW = 13 700 (1)). This procedure avoided the interference by vanadate, which also has a significant absorbance at this wavelength; 2.0 mL samples were used for the NMR spectroscopy.

For kinetics studies: Two enzyme stock solutions were prepared by dissolving the lyophilized powder in sufficient 5.0 mM Tris buffer solution to give a volume close to that desired. This was followed by adjustment of the pH to 7.0 using 0.05 N NaOH, then adding distilled water to give the desired final volume. The concentrations were 1.59 and 1.46 mg/mL.

The uridine–vanadate samples for the kinetics experiments were prepared by mixing the appropriate amounts of the ligand and vanadate stock solutions to obtain the desired final concentrations of reactants. These solutions were allowed to equilibrate approximately 1 h before combining with the ribonuclease. The assay conditions were 5.0 mM Tris, 0.35 M KCl, 14–16 μg/mL RNase A at pH 7.0, and 25°C.

NMR spectroscopy

^{51}V NMR spectra were obtained at 105 MHz on a Bruker WM-400 spectrometer. All spectra were obtained in the unlocked mode. Acquisition parameters were 0.05 s acquisition times, 50 kHz sweep widths, and 50° pulse widths. Each spectrum was obtained from 20 000 scans. All the spectra were zero filled from 4 K to 8 K and a line-broadening factor of 50 Hz was used before transformation to the frequency domain. The Fourier transform was done in the absolute intensity mode to allow signal intensities from different spectra to be compared. $VOCl_3$ was used as the external reference standard, and its signal was assigned as 0 ppm. When the Fourier transform was done in the relative intensity mode, the external/internal reference was a complex of V(V)–H_2O_2 contained in a concentric capillary tube within the standard NMR tube. The vanadium-51 signals from this solution occur at −765 and −625 ppm. This chemical shift reference was chosen because its signals do not interfere with the signals of the vanadate species of interest. Spectra were obtained at room temperature. A baseline correction was carried out before measurement of any signal intensities. The instrument manufacturer's software was used for all NMR measurements and manipulations.

UV–visible spectrophotometry

Reaction rates were obtained by monitoring the change in absorbance at 286 nm on a Hewlett Packard 8452A diode array spectrophotometer. UV cells (3 mL) with cylindrical stir bars were used for all experiments. The signal averaging time was 10 s, the scanning interval was 35 s, and the reaction rates were followed for 10 min. The rate of hydrolysis of uridine-2′,3′-cyclic phosphate was followed at 286 nm, using $\Delta\varepsilon_{286}$ = 600 M^{-1} cm^{-1} (1).

Equilibrium studies of vanadate plus ligands

Complex formation with uridine, 5,6-dihydrouridine, and methyl β-D-ribofuranoside was studied. The equilibrium constants for formation of the complexes were determined using standard techniques (5) under the conditions of 5.0 mM Tris buffer, 0.35 M ionic strength with added KCl and 1.0 mM vanadate, pH 7.0. The ligand concentration was varied from 0 to 21 mM for each of the various studies.

Binding of vanadate–ligand complexes to RNase A

Solutions were prepared by successive additions of small volumes of the stock ligand (uridine, 5,6-dihydrouridine, or β-methyl riboside) solution to 2.0 mL of a (1:1) enzyme–vanadate solution. The concentration of the ligand was varied from 0 to 60 mM and the binding of the vanadium–ligand complex to ribonuclease was monitored by ^{51}V NMR spectroscopy. The ribonuclease concentration for all studies was close to 1.0 mM.

Inhibition of RNase A by vanadate–uridine and vanadate–dihydrouridine complexes

Reaction solutions were prepared at 295 K by mixing the appropriate quantities of the ligand–vanadate stock solution with the uridine 2′,3′-cyclic phosphate solution. The reaction was then started by addition of 20 μL of enzyme solution to 2.0 mL of the reaction solutions. For uridine–vanadate the concentrations were 1.0 mM uridine or 1.0 mM uridine + 0.1 mM vanadate with 5.0 mM Tris buffer, 0.35 M KCl, pH 7.0, and 14–16 μg/mL of ribonuclease. The conditions were similar for the dihydrouridine experiments except that this nucleoside concentration was 39.6 mM. The rate measurements were made at 295 K and were started 1.5 min after the addition of ribonuclease and followed for 10 min. Except for the higher concentrations of substrate, the changes in the absorbance were linear with time throughout the entire 10 min, indicating that product inhibition was insignificant. The first 3 min of all runs were used for the determination of initial rates. In separate experiments it was confirmed that the initial rates were proportional to the enzyme concentration.

Results

Uridine, 5,6-dihydrouridine, and methyl β-D-ribofuranoside plus vanadate

The interactions of vanadate with nucleosides (4, 16–20) and β-methylriboside (5) have been studied by a number of workers. These studies have clearly shown that, under conditions of a few millimolar concentrations of vanadate with equivalent amounts of ligand at neutral pH, the major product of the reaction is a binuclear bisligand product. Early studies proposed that the coordination about the vanadium in this type of product was trigonal bipyramidal (21), although there has been some controversy over the details of the structure (5, 16, 18). A recent X-ray structure of an adenosine–vanadate dimer showed a slightly distorted square-pyramidal coordination about each of the vanadium nuclei of the dimer in the crystalline material (22). NMR studies strongly suggest that the square-pyramidal structure is retained in solution (22). It should, however, be noted that a trigonal-bipyramidal coordination has been proposed for similar compounds in aqueous solution (23).

The details of determining the formation constants for the products in solution have been discussed in detail elsewhere (4, 5) and that work has shown that the formation constant for the major product of the reaction of vanadate with nucleosides is about 5×10^7 M^{-3} (4). For the conditions of this study, the formation constants measured for the compounds of interest

here (uridine, (5.3 ± 0.2) × 10^7 M^{-3}; 5,6-dihydrouridine, (4.8 ± 0.4) × 10^7 M^{-3}; methyl β-D-ribofuranoside, (2.1 ± 0.1) × 10^7 M^{-3}) are close to the above value. Unfortunately, this formation constant for the dimer is not the one that is of most interest although the value is useful for comparative purposes. Signals corresponding to these products occur near −520 ppm, as can be seen in the relevant spectra of Fig. 1.

The formation constants of primary interest for this work is that of the tetrahedrally coordinated cyclic ester (VL) formed between the 2′ and 3′ hydroxyl groups of the ribose ring. Detailed investigation of a number of nucleosides has revealed the formation of a complex that is thought to correspond to such a product (4). From those studies, a formation constant of about 3 M^{-1} was obtained for each of the different nucleoside complexes. Such a detailed study has not been carried out here but, since the overall formation constants for the various dimers are not much different from the values obtained in the study mentioned above, a value of 3 M^{-1} has been assumed for this work. There is no reason to expect significant changes in formation constants since the reaction conditions for the two studies are similar.

NMR binding studies

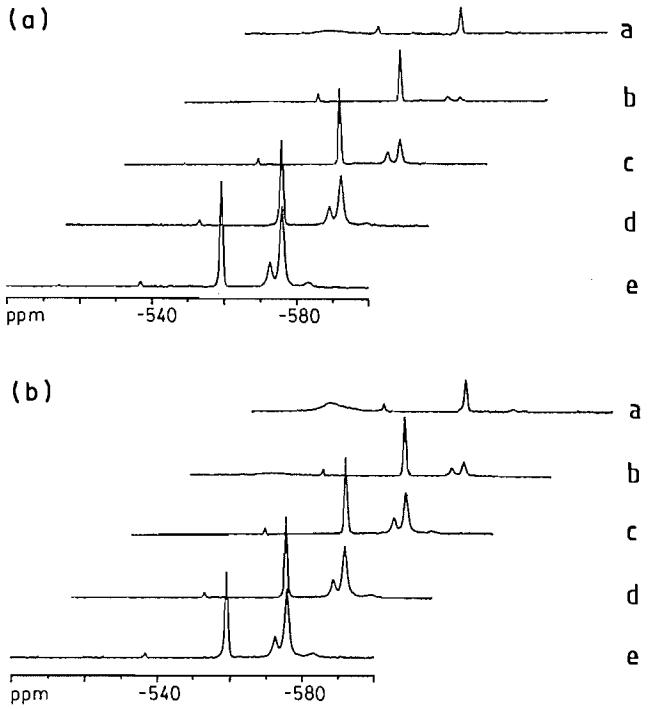
Vanadium-51 is a quadrupolar nucleus and the linewidths of the V-51 NMR signal are determined by the efficiency of the quadrupole-induced nuclear relaxation. For vanadium attached to proteins of the size of ribonuclease, the quadrupolar induced relaxation is very efficient and the vanadium signal from bound vanadium is so broad that it is effectively lost in the baseline of the spectrum. As a consequence, the observed spectrum corresponds to the various species that are not bound. Because of this effect, the incorporation of vanadium into ribonuclease is readily quantitated.

Initial ^{51}V NMR experiments were carried out to determine the extent of the binding of vanadate itself to ribonuclease. Under the reaction conditions of this study, there was not enough vanadate being bound to be observable, that is, less than 10% of the vanadate in a 1.0 mM vanadate–1.0 mM ribonuclease solution. However, an X-ray study showing a single vanadate attached to ribonuclease T has been reported (24), so clearly vanadate can be bound.

Figure 1*a* shows the result of adding uridine, in a progressive manner, to a solution of 1.0 mM vanadate in the presence of 1.1 mM ribonuclease. There very clearly is a loss of observable vanadium signal intensity. The more rapid loss of signal intensity of the vanadate oligomers, compared to monovanadate itself, is expected for a system that is in equilibrium. Figure 1*b* shows similar behaviour for dihydrouridine. Tables 1 and 2 give the amounts of free and bound vanadium for the two studies. A similar procedure using methyl β-D-ribofuranoside provided no evidence for other than a possible weak binding of the ribofuranoside–vanadate complex.

To interpret the results of the binding studies it is necessary to account for all the equilibrations that vanadate undergoes while in the presence of the nucleoside, including self-condensation reactions. In addition, in the presence of ribonuclease there are additional equilibria that must be considered: the formation of the vanadate–nucleoside–ribonuclease (E·VL) complex and a nucleoside–ribonuclease (E·L) complex. It seems clear that any binding of vanadate itself or its oligomers to ribonuclease A is weak because no binding was observed in any of

Fig. 1. ^{51}V NMR spectra showing the loss of vanadium signal intensity as uridine (Fig. 1*a*) or 5,6-dihydrouridine (Fig. 1*b*) is added to a solution of vanadate (1 mM) in the presence of ribonuclease A (1.06 mM). The vanadium signals correspond to: −560 ppm, monovanadate; −572 ppm, divanadate; −572 ppm, tetravanadate; −583 ppm, pentavanadate. Conditions of the experiments: 5.0 mmol Tris buffer; pH 7.0; 0.35 M KCl and, for Fig. 1*a*, 0, 0.3, 1.0, 4.0, and 11.7 mM added uridine for traces e, d, c, b, and a, respectively; Fig. 1*b*, 0, 0.3, 1.1, 4.4, and 12.8 mM added dihydrouridine for traces e, d, c, b, and a, respectively.



the studies carried out here. Assuming a minimum observable quantity of vanadate being bound as 10% of the total utilized in the binding study (vanadate to ribonuclease, 1:1), a lower limit of 0.01 M was estimated for a possible dissociation constant. The value would have to be much smaller than this before it would have a significant effect on the analysis of the binding studies. In agreement with the binding studies, kinetics studies showed no inhibition by vanadate. The kinetics result allowed a lower limit of 3.0 mM to be calculated for the inhibition constant of vanadate (3). This value is about a factor of 3 from the lower limit value estimated from the binding study.

Kinetics studies have clearly shown that free uridine is a reasonably efficient inhibitor of the function of ribonuclease A, its K_i being about 2 mM (see Table 3). This value is not much different from the lower limit value estimated for the dissociation of vanadate. However, nucleoside concentrations in this study range up to about two orders of magnitude larger than the free monomeric vanadate concentration, and the corresponding dissociation constant therefore influences the analysis of the results.

$$[1]\quad \frac{[V_b]}{[E_t]} = \frac{[V_i](K_7 + K_1K_6[L])}{1 + K_5[L] + [V_i](K_7 + K_1K_6[L])}$$

Equation [1] describes the proportion of bound vanadium as a function of the concentration of free uridine and free vana-

Table 1. Distribution of vanadium between free vanadate species and vanadate bound to ribonuclease A, determined in the presence of added uridine.[a,b]

[Uridine]	$[V_i]$	$[V_{vis}]$	$[V_b]$
0.0	0.36	1.00	0.00
0.2	0.35	0.90	0.10
0.3	0.31	0.76	0.24
0.4	0.32	0.74	0.26
0.6	0.29	0.63	0.37
1.0	0.27	0.51	0.49
2.0	0.23	0.37	0.63
4.0	0.17	0.26	0.74
6.9	0.14	0.24	0.76
7.9	0.12	0.20	0.80
12.0	0.09	0.22	0.78

[a]All concentrations are reported as mmol/L and, for vanadium, represent vanadium atom concentrations. V_i corresponds to monomeric vanadate while V_{vis} represents all vanadate species, including the monomer, oligomers, and uridine–vanadate complexes, that are observed in the NMR spectrum. V_b represents the enzyme-bound vanadium.

[b]Conditions for the experiments: total vanadate, 1.0 mM; RNase, 1.06 mM; Tris buffer, 5.0 mM; pH, 7.0; KCl, 0.35 M; total uridine, as indicated in table.

Table 2. Distribution of vanadium between vanadate bound to ribonuclease A and free vanadate species in the presence of 5,6-dihydrouridine.[a,b]

[Dihydrouridine]	$[V_i]$	$[V_{vis}]$	$[V_b]$
0.0	0.36	1.00	0.00
0.2	0.36	0.95	0.05
0.3	0.34	0.89	0.11
0.4	0.32	0.84	0.16
0.7	0.34	0.84	0.16
1.1	0.32	0.75	0.25
2.2	0.29	0.58	0.42
3.4	0.27	0.55	0.45
4.4	0.26	0.50	0.50
6.6	0.21	0.47	0.53
8.7	0.18	0.42	0.58
13.0	0.12	0.38	0.62

[a]All concentrations are reported as mmol/L and, for vanadium, represent vanadium atom concentrations. V_i corresponds to monomeric vanadate while V_{vis} represents all vanadate species, including the monomer, oligomers, and dihydrouridine–vanadate complexes, that are observed in the NMR spectrum. V_b represents the enzyme-bound vanadium.

[b]Conditions for the experiments: total vanadate, 1.0 mM; RNase A, 1.06 mM; Tris buffer, 5.0 mM; pH, 7.0; KCl, 0.35 M; total dihydrouridine, as indicated in table.

date in the equilibrated solution. The derivation of this equation is described in the Appendix. The binding curve, as described by eq. [1], contains terms for binding of the nucleoside, K_5, for binding of vanadate, K_7 ($1/K_7 = 0.01$ M), and for binding of the nucleoside–vanadate complex, K_6. In fact this latter value enters as the product K_1K_6, where K_1 is the formation constant for the nucleoside–vanadate complex. K_1 has a value close to 3 M^{-1} (4).

Fig. 2. A representation of the proportion of vanadate bound to ribonuclease A as a function of the amount of added uridine. The points present the experimental data while the curves were calculated as described in the Appendix. The best-fit curve was obtained using the parameters $K_1K_6 = 6 \times 10^6$ M^{-2}, $K_5 = 125$ M^{-1}, and $K_7 = 100$ M^{-1}, as required for eq. [1]. Conditions for the experiments: 1.06 mM RNase A, 1.0 mM vanadate, 5.0 mM Tris buffer, pH 7.0, 0.35 M KCl, and the indicated amounts of added uridine.

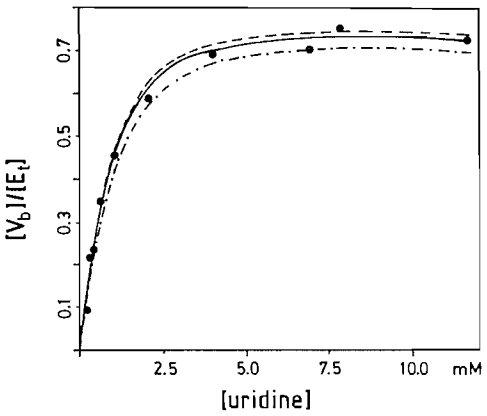


Fig. 3. The proportion of vanadate bound to ribonuclease A as a function of the amount of added 5,6-dihydrouridine is shown. The points present the experimental data while the curves were calculated as described in the Appendix. The best-fit curve was obtained using the parameters $K_1K_6 = 1 \times 10^6$ M^{-2}, $K_5 = 28$ M^{-1}, and $K_7 = 100$ M^{-1}, as required for eq. [1]. Conditions for the experiments: 1.06 mM RNase A, 1.0 mM vanadate, 5.0 mM Tris buffer, pH 7.0, 0.35 M KCl, and the indicated amounts of added dihydrouridine.

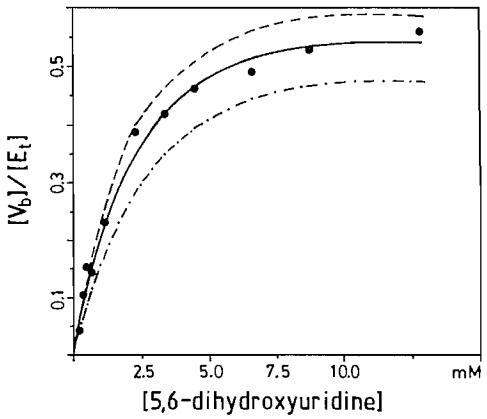

Figure 2 shows the proportion of vanadate bound by ribonuclease as a function of added uridine and also calculated curves that bracket the experimental values. The curve that best describes the experimental results has the values of $(6 \pm 1) \times 10^6$ M^{-2} for K_1K_6 with a value of 1.3×10^2 M^{-1} for K_5. If the inhibition constant for uridine is a true dissociation constant, then $1/K_5 = 8 \times 10^{-3}$ M should be equal to the inhibition constant reported for uridine from kinetics studies (3, 25). The two values are the same to within the errors of the experiments. The interaction constant, K_1K_6, gives a value of $(5 \pm 1) \times 10^{-7}$ M for the dissociation of VL from E·VL ($= 1/K_6$) when K_1 ($= 3$ M^{-1}) is factored out.

Table 3. Binding and inhibition of ribonuclease A by nucleosides and nucleoside/vanadate complexes.[a]

Inhibitor	Binding constant	Inhibition constant	Reference[b]
Uridine	7.7 mM	1.7 mM	A
		8.0 mM	B
		2.3 mM	C
Dihydrouridine	36 mM	41 mM	A
2′-Deoxyuridine		45 mM	B
Vanadate	>10 mM		A
		>0.3 mM	B
Uridine–vanadate	0.50 μM	0.45 μM	A
		0.49 μM	D
Dihydrouridine–vanadate	3.0 μM	1.1 μM	A
β-Methylriboside–vanadate	>0.2 mM		A

[a]Binding constants were determined from NMR studies; inhibition constants from kinetics experiments.
[b]References correspond to the following: A, this work; B, ref. 3; C, ref. 25; D, recalculated from Fig. 3 of ref. 3.

Dihydrouridine, in the presence of vanadate, also undergoes strong binding interactions with ribonuclease A. The results of the binding study and the corresponding calculated binding curves are shown in Fig. 3. The constants describing the best-fit curve are $K_1K_6 = (1.0 \pm 0.2) \times 10^6$ M^{-2} and $K_5 = 28 \pm 5$ M^{-1}. These values correspond to $(3.0 \pm 0.6) \times 10^{-6}$ M and $(3.6 \pm 0.7) \times 10^{-2}$ M for $1/K_6$ and $1/K_5$, respectively.

No binding of the methyl β-D-ribofuranoside–vanadate complex to the enzyme was found for any of the concentrations utilized. An apparent disappearance of less than 5% of the total vanadate signal intensities was observed when the concentration of the methyl riboside was increased from 15 to 60 mM. However, because of the uncertainty in the integration of the vanadium(V) signals, it is not clear that this can be ascribed to binding of the riboside–vanadate complex to the enzyme. However, a lower limit for the dissociation constant ($1/K_6 = 2 \times 10^{-4}$ M)) was estimated by assuming that no more than 5% of the enzyme was bound when the concentration of the ligand was 60 mM. This value is two to three orders of magnitude larger than those for the tightly bound complexes formed with uridine or 5,6-dihydrouridine (see above). From these results, it seems evident that a nonreacting portion of the substrate, the uracil group, is essential for the tight binding of the vanadate–nucleoside complex to ribonuclease A.

During the ligand titration experiments, it was found that after addition of uridine and 5,6-dihydrouridine, the pH of the enzyme-vanadate mixture increased. This observation is similar to that reported for phosphate-containing compounds (26) and it indicates that protons are required for the binding of these complexes to RNase A.

Kinetics studies

Independent kinetics experiments were also carried out for the two inhibitors. The procedure for analysis of the kinetics results was similar to that employed by Lindquist et al. (3) except that the inhibiting species was assumed to be only the uridine–vanadate monomeric complex, as supported by the crystal structure studies (27). It was necessary to use the formation constants K_1 and K_3 in eqs. [2] and [3] and the conservation equation, eq. [4], where cV_t corresponds to the total amount of vanadate in solution. For the analysis, it was not necessary to use the full eq. [4] because the concentrations of VUr and E·VUr together represent less than 1% of the total vanadate concentration. Therefore, using a simplified conservation equation and eq. [3], eq. [5] is obtained. Because of the low relative amount of vanadate used in these studies, at no time is the total amount of uridine, cUr_t, significantly different from the true concentration, [Ur], so the conservation equation for uridine is not required. Therefore, $[V_i]$ was calculated from eq. [5] using $[Ur] = cUr_t$. This value of $[V_i]$ was then used to calculate the concentrations of V_2Ur_2 and VUr. For the conditions used in this study (0.1 mM total vanadate and 1.0 mM total uridine) with $K_3 = 5.3 \times 10^7$ M^{-3}, [Ur] = 0.30 μM and $[V_2Ur_2] = 0.52$ μM. Similar calculations for dihydrouridine (0.1 mM total vanadate and 39.6 mM total dihydrouridine with $K_3 = 4.8 \times 10^7$ M^{-3}) gave the corresponding concentrations, $[V(H_2Ur)] = 2.7$ μM and $[V_2(H_2Ur)_2] = 37.5$ μM.

$$[2] \quad V_i + Ur \overset{K_1}{\rightleftharpoons} VUr, \qquad [V_i][Ur]K_1 = [VUr]$$

$$[3] \quad 2V_i + 2Ur \overset{K_3}{\rightleftharpoons} V_2Ur_2, \qquad [V_i]^2[Ur]^2K_3 = [V_2Ur_2]$$

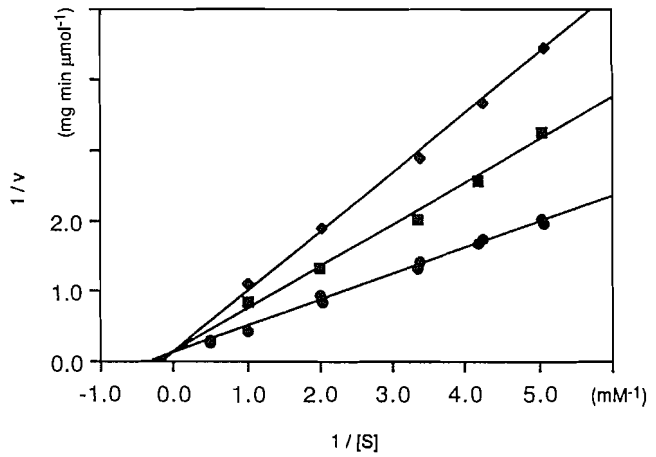
$$[4] \quad cV_t = [V_i] + [VUr] + 2[V_2Ur_2] + [E{\cdot}VUr]$$

$$[5] \quad 2K_3[Ur]^2[V_i]^2 + [V_i] - cV_t = 0$$

Figure 4 shows the results of a kinetics study of the uridine–vanadate–ribonuclease A system. As can be seen from this figure and is well known for this system (3, 25), uridine is an inhibitor, and this is in keeping with the observation of uridine binding in the NMR study. The initial reaction velocity (v) of the kinetics equation then requires terms for inhibition by uridine and by the VUr complex as defined by eq. [6] where V_{max} is the maximum reaction velocity, [S] is the substrate concentration, K_m is the Michaelis constant, and the K_i are the inhibition constants.

$$[6] \quad \frac{1}{v} = \frac{K_m}{V_{max}}\left(1 + \frac{[Ur]}{K_{i;Ur}} + \frac{[VUr]}{K_{i;VUr}}\right)\frac{1}{[S]} + \frac{1}{V_{max}}$$

Fig. 4. The inverse rate of hydrolysis of cyclic 2′,3′-uridine monophosphate catalyzed by ribonuclease A is shown as a function of the inverse substrate concentration. Ribonuclease inhibitors: (●) no inhibitor added; (■) 1 mM uridine; (◆) 1 mM added uridine plus 0.1 mM vanadate. Conditions of the experiments: 14–16 μg/mL ribonuclease A; 5.0 mM Tris buffer; 0.35 M KCl; pH 7.0; 298 K. Each experimental point is the average of two independent determinations.



The bottom trace of Fig. 4 shows the results of the rate measurements in the absence of inhibitor so that the intercept gives $1/V_{max}$ and the slope K_m/V_{max}. The values, 0.09 ± 0.02 mg min μmol^{-1} and 380 ± 30 mg min for the intercept and slope, respectively, provided a value of 4.2 ± 1.5 mM for the K_m of 2′,3′-uridine monophosphate. This value of the Michaelis constant is close to that previously reported, about 9 mM (3, 28) and almost identical to the value determined here from the independent dihydrouridine study, $K_m = 3.7 \pm 1.6$ mM.

The centre trace of Fig. 4 was obtained when the reaction solution contained 1.0 mM uridine. The inhibition constant obtained was $K_{i;Ur} = 1.7 \pm 0.2$ mM, a value close to that previously reported, 2.3 mM (25). The corresponding value for dihydrouridine was 41 ± 6 mM.

The upper trace of Fig. 4 shows the influence of the uridine–vanadate complex on the rate measurements. The $K_{i;VUr}$ value determined for this complex was $(4.5 \pm 0.6) \times 10^{-7}$ M on the basis of the concentration of VUr obtained above. This value compares very favorably with the dissociation constant measured from the NMR binding experiments, $(5.0 \pm 0.4) \times 10^{-7}$ M. Reanalysis of the results of Lindquist et al. (Fig. 3 of ref. 3), with the correction for the occurrence of V_2Ur_2 in the reaction solution, yielded a value of 4.9×10^{-7} M for $K_{i;VUr}$. This value is in excellent agreement with that of the present study. The inhibition constant determined for dihydrouridine–vanadate was $(1.1 \pm 0.2) \times 10^{-6}$ M, a value quite close to that of the corresponding uridine complex. Table 3 summarizes the values for the binding constants obtained from the NMR measurements and the inhibition constants obtained from kinetics experiments.

Discussion

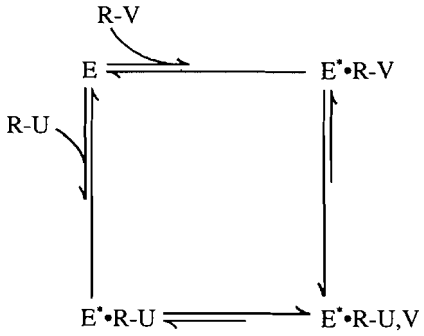
RNase A is potently inhibited by uridine 2′,3′-cyclic monovanadate and 5,6-dihydrouridine 2′,3′-cyclic monovanadate. The association constant for the binding of these complexes to the enzyme at pH 7.0 is 10^3 to 10^4 times larger than the estimated association constant for the uridine 2′,3′-cyclic monophosphate. There is little reason to suspect that tetrahedral vanadate will be bound much more strongly than tetrahedral phosphate in a ground state structure. In fact, tetrahedral vanadate esters are thought to be responsible for the activation of certain enzymes that normally require a phosphate ester for their function (29–31). The tight binding therefore suggests that, in the present case, the role of the vanadate complexes is that of transition state analogs. This is supported by the crystallographic structure for the complex between ribonuclease and uridine 2′,3′-cyclic monovanadate (27) that revealed that the amine group of Lys-41 and the imidazole rings of His-12 and His-119 are hydrogen bonded to the oxygens of a pentacoordinate vanadium(V). This coordination closely approximates the transition state structure originally proposed for the hydrolysis of pyrimidine 2′,3′-cyclic monophosphates catalyzed by RNase A (3). A recent crystallographic study of vanadate incorporated into rat acid phosphatase also revealed a similar coordination about the vanadium centre (32). However, recent NMR studies have suggested that there is a structural change in the ribonuclease on going from the crystalline material to its solution counterpart and that this change modifies the binding interactions of one of the histidines to the phosphate group (33).

From the binding studies and the kinetics results obtained here, it appears that there is a synergistic interaction involving the pyrimidine and the vanadate groups. The degree of this synergism was increased with the replacement of uridine by 5,6-dihydrouridine while replacement of the pyrimidyl group by a β-methoxy group caused a large loss in affinity of the enzyme for the riboside–vanadate complex. This suggests that, without the pyrimidine group, there can not be tight binding of the ribose–vanadate moiety to the enzyme and this emphasizes the importance of the amino acid residues, Thr-45, Phe-120, and Val-43, which interact with the base. The presence of strong interactions with the base is also supported by molecular dynamics simulations (10).

In the induced-fit mechanism of enzyme action (34), the catalytic groups at the active site of the free enzyme are not in optimal positions to exert effective catalytic activity. A substrate must have the minimal structural features to force a conformational change of the enzyme to the active form, so that a reaction can occur. The ^{51}V NMR binding studies and the kinetic inhibition studies of this work are consistent with this mechanism of action for RNase A but certainly do not require it. Other support for this possible mode of action is provided from alternate sources.

Evidence that a conformational change can occur in the active site of RNase A is available. X-ray data on the binding of cytidylic acid (2′-CMP) (35) and cytidine-N(3)-oxide 2′ phosphate (O(3)-2′-CMP) (35, 36) to RNase A have revealed different modes of binding and some significant displacements of side-chain atoms in the active site (Lys-41 and His-119). Also, it was found that Lys-7 and Lys-66 occupied different positions in the absence and presence of inhibitors at the active site (35, 36). Competitive inhibition studies using cytidine 2′-monophosphate and cytidine 3′-monophosphate have shown a conformational change due to the binding process (37). It was also concluded from temperature-dependence studies of ribonuclease-catalyzed opening of the cytidine cyclic 2′,3′-phosphate that conformational changes occur dur-

Scheme 1. E: ribonuclease in its receptive form. E*: ribonuclease in its activated state. R-V: vanadate component of the inhibitor complex. R-U: uracil component of the inhibitor complex. R-U,V: both components of the uridine–vanadate inhibitor.



ing the catalytic cycle (38). Furthermore, X-ray analysis has shown that the free enzyme exists in two different conformations for which the imidazole ring of His-119 occupies two different sites (39) and evidence suporting this is available from NMR studies (33). Taken together, this evidence provides strong support for the existence of at least two different conformations available to RNase A.

The results obtained here can be explained by suggesting there are two interconvertible conformations of RNase A that differ in their affinity toward the various inhibitor complexes of vanadate. The low-affinity or inactive form of ribonuclease A (E) is complementary to the substrate, while the high-affinity or active form (E*) has a structure complementary to that of the transition state. In the absence of either the pyrimidyl group or the vanadate group, the low-affinity form of the enzyme predominates. The binding of either of these groups, in isolation, to their respective RNase subdomains is unfavorable. In the presence of both groups, the equilibrium between the two RNase A species is shifted towards the high-affinity form. Either subdomain, once it is occupied by its corresponding group, promotes a change in conformation of the RNase so that both groups of the ligand are fully accommodated. This leads to an overall energetically favorable interaction with the substrate. A reaction sequence that is consistent with the observed results is shown in Scheme 1.

When both the pyrimidyl and ribose-phosphate subsites of the active site are occupied, the reactive groups are brought together so that the full binding of the unstable five-coordinate phosphate can be achieved. The transition state energy required for forming the intermediate phosphate is high and some of the energy required is provided by binding of the pyrimidine group. Protein engineering studies on tyrosyl-tRNA synthetase (40) have provided direct evidence of transition state stabilization in enzyme catalysis. Taking at face value the fact that the β-methylriboside–vanadate complex is only weakly bound, it then appears that binding interactions to the ribose ring and the attached pentacoordinate vanadate are sufficient to approximately balance the energy requirements of ribonuclease for its active state. To the extent that the pentacoordinate vanadate in the enzyme complex is a good mimic of the phosphate transition state, this means that the additional energy required to achieve the transition state of phosphorus is matched by that available from the interactions of the uracil group of the nucleoside with the active-site threonine, valine, and phenylalanine that were identified in the X-ray work (35). Unfortunately, such considerations are complicated by entropic factors that must be taken into account when comparing the binding of the nucleoside–vanadate complex to the individual binding of riboside–vanadate and of the free nucleoside (41, 42). The energy of binding of the nucleoside–vanadate complex will be greater than the sum of the energies available from the binding of ribose–vanadate and the binding of the free nucleoside.

It is instructive to examine the role of vanadate and its complexes as transition state analogues a little more closely. If the K_m for 2′,3′-cyclic phosphouridine, as defined by eq. [6], is taken to approximately correspond to a true dissociation constant, then binding of this substrate occurs with an energy of about -14 kJ/mol (from $\Delta G = -RT \ln K$). This compares with −36 kJ/mol for the binding of the cyclic vanadiouridine complex. A similar comparison can be drawn for phosphoglycerate mutase. In this case, the specific cofactor, 2,3-bisphosphoglycerate, has a K_m of 3.3×10^{-7} M (43) while 2-vanadio-3-phosphoglycerate has a dissociation constant of 1×10^{-11} M (12). These two parameters correspond to −37 and −62 kJ/mol, respectively, for the association energy. Values close to this are also found for phosphoglucomutase where the K_m for 1,6-bisphosphoglucose is equal to 4.8×10^{-8} M while K_i for 6-vanadio-glucose-1-phosphate is 2×10^{-12} M (13). These constants correspond to $\Delta G = -41$ and −66 kJ/mol, respectively.

From these three examples it can be seen that the excess binding energy deriving from the replacement of a single phosphate by a vanadate in the enzyme complex falls within the range of 22 – 25 kJ/mol, this despite a range of about 10^6 in the values of the dissociation constants. This excess energy of binding might be considered to be dependent on two major factors: the energy required to generate the phosphate transition state and that required for the corresponding state with vanadate. To the extent that vanadate is a good substitute for phosphate, the excess energy of binding the enzyme complex is equal to the difference between these two binding energies.

It is possible to compare the transition and ground state energies by obtaining the values of the rate constant for catalyzed hydrolysis, k_{cat}, and the rate constant, k_{hyd}, for the noncatalyzed reaction. The ratio of these two values, k_{cat}/k_{hyd}, should roughly correspond to $K_m/K_{i;VUr}$ if the vanadate complex provides a good transition state analogue to the phosphate reaction. From the known hydrolysis rates of uridine cyclic phosphate, 4×10^{-9} s^{-1} at 298 K (44) and $k_{cat} = 4$ s^{-1}, the ratio obtained here for k_{cat}/k_{hyd} is 1×10^9, to be compared to $K_m/K_{i,VUr} = 1.6 \times 10^4$. (In ref. 44 the rate enhancement for the enzymic reaction is given as 7×10^9 for the analogous cytidine hydrolysis.) In energy terms, $RT \ln(K_m/K_{i,VUr}) = 22$ kJ/mol while $RT \ln(k_{cat}/k_{hyd}) = 54$ kJ/mol. These values are quite significantly different from each other and suggest that the reaction with pentacoordinate vanadate goes only about 40% of the way to a transition state structure in the ribonuclease reaction.

An approach to this problem that would provide valuable information would be to directly compare the activation energies for hydrolysis of the cyclic phosphate to the corresponding cyclic vanadate. Unfortunately, the rate of hydrolysis of the appropriate vanadate derivative is not known. However, if it is assumed that the transition state structure about phosphate

in the enzyme-catalyzed reaction is similar to that for ester hydrolysis, it is possible to estimate in an independent manner the excess energy available to vanadate. At 373 K, the energy of activation to hydrolysis, ΔE, for the methyl phosphate, glycerol-1-phosphate, and glucose-1-phosphate monoanions is close to 126 kJ/mol for all compounds with corresponding preexponential factors, A, (for $k = A \exp \Delta E/RT$), of 6.5×10^{12} s^{-1}, 4.3×10^{12} s^{-1}, and 5.0×10^{12} s^{-1} (45). For methyl phosphate the rate constant for hydrolysis is 8.2×10^{-6} s^{-1} compared to 6.1×10^{-6} s^{-1} for ethyl phosphate. Other closely related esters have similar rate constants. It can, therefore, reasonably be assumed that the preexponential factor for ethyl phosphate is close to 5×10^{12} s^{-1}. This, together with the rate of 6.1×10^{-6} s^{-1}, corresponds to a ΔE of 128 kJ/mol. This value is not exact but small errors are not significant. This calculated value for ethyl phosphate is the same as the value reported for methyl phosphate, 128 kJ/mol (45). Assuming these values of ΔE and A, a rate constant of 2.0×10^{-8} s^{-1} is calculated for the hydrolysis of ethyl phosphate at 328 K.

The rate constant for the hydrolysis of ethyl vanadate at 328 K is 1.2×10^{3} s^{-1} (46). If the preexponential factors for ethyl phosphate and ethyl vanadate are not exceedingly different, the difference in activation energies for hydrolysis between these two compounds can be estimated from the ratio of the two rate constants. On this basis, the energies required to obtain the pentacoordinate transition state structures are different by about 68 kJ/mol or ΔE_V = 60 kJ/mol and ΔE_P = 128 kJ/mol.

Since the excess binding energies of the vanadate complexes in the three enzyme–vanadate systems mentioned previously are about 25 kJ/mol, this analysis suggests there is a shortfall of about 40 kJ/mol in the excess binding energy available to these three enzymic reactions. Put another way, in all three enzymes, the enzyme–vanadate complex goes only about 40% of the way towards a transition state structure. This agrees with our analysis above for the studies carried out here with ribonuclease A. A different set of arguments has been advanced for phosphoglucomutase, suggesting that the reaction with vanadate proceeds about 45% of the way to the transition state in that particular system (14).

Some of this shortfall in energy may arise because the V—O bond lengths are slightly longer than P—O bond lengths, by about 0.15 Å, or about 10% of the bond length (47). It does not seem that this offers a reasonable explanation for other than a small proportion of the energy shortfall. However, there are some indications that the oxygens of pentacoordinate vanadate may not be as good hydrogen bond acceptors as those of the corresponding phosphate (47). It also does not seem likely that this will account for the large energy shortfall since, at least in ribonuclease, hydrogen bonding will still be present (47).

A plausible explanation for the observations of this work is that vanadate does not provide as good a transition state analogue as might be expected simply because the geometry about vanadium in the enzyme complex is not a good representation of the transition state actually utilized during the phosphate transfer step of either of these three enzymes. Indeed, the complexities inherent in phosphate ester hydrolysis have been examined and no clear answer is available (9, 11). Whatever the details of the structures of the transition states for phosphate, it seems that the incremental binding energies arising from the presence of the vanadium in these three different ligand–vanadium complexes in the different enyme systems are almost identical. This suggests that there is a structure associated with the phosphate reaction that is not mimicked well by vanadate and that costs about 40 kJ/mol of binding energy. Since it is reasonable to expect that pentacoordinate vanadate can assume a trigonal-bipyramidal structure with minimal costs in energy, this suggests that there are significant deviations from this structure in the phosphate reactions. Presumably, this structure will be similar for RNase A, phosphoglycerate mutase, phosphoglucomutase, and, possibly, other phosphate-transferring enzymes.

Appendix

Calculation of the binding curve

The following conservation equations were taken into account:

[A.1] $[E_t] = [E] + [E{\cdot}L] + [E{\cdot}VL] + [E{\cdot}V_i]$

[A.2] $[V_t] = [V_i] + 2[V_2] + 4[V_4] + 2[V_2L_2] + [VL] + [E{\cdot}V_i] + [E{\cdot}VL]$

[A.3] $[L_t] = [L] + [VL] + 2[V_2L_2] + [E{\cdot}VL] + [E{\cdot}L]$

where $[E_t]$ = total RNase A concentration; $[E]$ = free RNase A concentration; $[E{\cdot}L]$ = RNase A–ligand complex concentration; $[E{\cdot}VL]$ = RNase A–vanadate–ligand complex concentration; $[E{\cdot}V_i]$ = RNase A–vanadate complex concentration, assuming that

[A.4] $[V_b] = [E{\cdot}VL] + [E{\cdot}V_i]$

and including the following equilibria

[A.5] $2\,V_i \overset{K_2}{\rightleftharpoons} V_2, \qquad K_2 = \dfrac{[V_2]}{[V_i]^2}$

[A.6] $4\,V_i \overset{K_4}{\rightleftharpoons} V_4, \qquad K_4 = \dfrac{[V_4]}{[V_i]^4}$

[A.7] $V_i + L \overset{K_1}{\rightleftharpoons} VL, \qquad K_1 = \dfrac{[VL]}{[V_i][L]}$

[A.8] $2\,V_i + 2L \overset{K_3}{\rightleftharpoons} V_2L_2, \quad K_3 = \dfrac{[V_2L_2]}{[V_i]^2[L]^2}$

[A.9] $E + L \overset{K_5}{\rightleftharpoons} E{\cdot}L, \qquad K_5 = \dfrac{[E{\cdot}L]}{[E][L]}$

[A.10] $E + VL \overset{K_6}{\rightleftharpoons} E{\cdot}VL, \quad K_6 = \dfrac{[E{\cdot}VL]}{[E][VL]}$

[A.11] $E + V_i \overset{K_7}{\rightleftharpoons} E{\cdot}V_i, \quad K_7 = \dfrac{[E{\cdot}V_i]}{[E][V_i]}$

The inhibition constant K_{iVL} is the dissociation constant of VL from E·VL and so is equal to $1/K_6$.

By making the appropriate rearrangements and substitutions into eqs. [A.3], [A.2], and [A.1], the following expressions are obtained:

[A.12] $[L]^2 2K_3 [V_i]^2 + [L] (1 + K_1[V_i] + K_5 [E] + K_1K_6 [E] [V_i]) - L_t = 0$

[A.13] $[V_i]^4 4K_4 + [V_i]^2 2(K_2 + K_3[L]^2) + [V_i](1 + K_1[L] + K_7[E] + K_1K_6[E][L]) - V_t - 0$

[A.14] $$[E] = \frac{[E_t]}{1 + K_5[L] + K_1K_6[L][V_i] + K_7[V_i]}$$

The fraction of total enzyme that is bound by vanadate (as a vanadate–ligand complex and (or) vanadate by itself) is

[A.15] $$\frac{[V_b]}{[E_t]} = \frac{[E{\cdot}VL] + [E{\cdot}V_i]}{[E_t]}$$

By making the appropriate substitutions into eq. [A.15], the final equation is obtained:

[A.16] $$\frac{[V_b]}{[E_t]} = \frac{[V_i](K_7 + K_1K_6[L])_t]}{1 + K_5[L] + [V_i](K_7 + K_1K_6[L])}$$

To obtain values of $[V_b]/[E_t]$ to construct a family of calculated curves, an iterative approach was used. Values for the equilibrium constants used for the iterative calculations were $K_2 = 470\ M^{-1}$, $K_4 = 6.3 \times 10^9\ M^{-3}$, and $K_7 = 0\ M^{-1}$. A value of 0 was assigned for K_7, since no binding of vanadate by RNase A was detected in any experiment. Values for K_1K_6 were assumed in order to calculate the ratio $[V_b]/[E_t]$ as a function of total ligand concentration and assumed K_5. The values assumed for K_1K_6 and K_5 were then varied until the values that best fit the experimental results were obtained. Since K_1 is known ($K_1 = 3.0\ M^{-1}$), K_6 is explicitly specified by this process and $1/K_6$ is the dissociation constant for the dissociation of uridine–vanadate from the enzyme complex. K_1K_6, in conjuncition with K_5, defines the shape of the binding curve.

The iterative procedure utilized is described as follows.

Step 1: Assume a value for K_1K_6 and for K_5. Use the closest experimental value for $[V_i]$ for the total ligand concentration and assume a reasonable value for [L], the free ligand concentration.

Step 2: Calculate [E] from eq. [A.14], then calculate [L] from eq. [A.12]. Use this new value of [L] to recalculate [E]. Repeat this procedure until [E] and [L] are constant.

Step 3: Use the values of [E] and [L] obtained above along with the assumed $[V_i]$ to calculate the left side of eq. [A.13]. If this value is not 0 to within 0.001 mM, adjust $[V_i]$ appropriately and repeat step 2.

Step 4: Repeat steps 2 and 3 until both the left sides of eq. [A.12] and [A.13] are satisfied to within 0.001 mM. Use these values of $[V_i]$ and [L] to calculate $[V_b]/[E_t]$ from eq. [A.16] for the assumed values of K_1K_6 and K_5.

A kinetic study on singlet molecular oxygen ($O_2(^1\Delta_g)$) generation and quenching by dihydroxynaphthalenes

Marta Luiz, Arnaldo T. Soltermann, Alicia Biasutti, and Norman A. Garcia

Abstract: A kinetic study on the aerobic ($O_2(^1\Delta_g)$-mediated) photooxidation of a series of dihydroxynaphthalenes was carried out. Members of this family of compounds include important environmental contaminants. The interaction with $O_2(^1\Delta_g)$, determined by both time-resolved phosphorescence and static methods, yields a quenching rate constant in the range of 10^5–10^9 M^{-1} s^{-1}, depending on the solvent polarity, pH, and substitution pattern of the dihydroxynaphthalene. According to experimental evidence, the mechanism of the interaction seems to be mediated by an encounter complex with a considerable charge transfer component. From a mechanistic point of view this characteristic of DHN indicates a behaviour very similar to that of simple substituted phenols and dihydroxybenzenes. Quantum yields for DHN photooxidation (Φ_r) indicate that these substrates are excellent candidates for $O_2(^1\Delta_g)$-mediated degradation under environment conditions. Furthermore, these compounds proved to be good self-sensitizers upon irradiation at 337 nm. Quantum yields (Φ_Δ) for the production of $O_2(^1\Delta_g)$ were determined to be on the order of 0.25 in benzene.

Key words: dihydroxynaphthalenes, photooxidation, quenching, sensitization.

Résumé : On a réalisé une étude cinétique de la photooxydation aérobique (avec médiation par le $O_2(^1\Delta_g)$) d'une série de dihydroxynaphtalènes. Les membres de cette famille sont des contaminants environnementaux importants. L'interaction avec le $O_2(^1\Delta_g)$ a été déterminée par des méthodes statiques ainsi que par phosphorescence résolue en fonction du temps et elle conduit à une constante de vitesse de désactivation de l'ordre de 10^5 à 10^9 M^{-1} s^{-1}, suivant la polarité du solvant, le pH et le patron de substitution du dihydroxynaphtalène. Sur la base des données expérimentales obtenues, il semble que le mécanisme de l'interaction soit l'objet d'une médiation de la part d'un complexe de rencontre qui implique une composante importante de transfert de charge. D'un point de vue mécanistique, cette caractéristique du DHN indique un comportement très semblable à celui des phénols et des dihydroxybenzènes simples, substitués. Les rendements quantiques pour la photooxydation du DHN (Φ_r) indiquent que ces substrats sont d'excellents candidats pour des dégradations avec médiation du $O_2(^1\Delta_g)$ dans des conditions environnementales naturelles. De plus, lorsqu'on les a irradiés à 337 nm, ces composés ont montré d'excellentes propriétés comme autosensibilisateurs. On a déterminé que les rendements quantiques (Φ_Δ) pour la production du $O_2(^1\Delta_g)$ sont de l'ordre de 0,25, dans le benzène.

Mots clés : dihydroxynaphtalènes, photoxydation, désactivation, sensibilisation.

[Traduit par la rédaction]

Introduction

Over the last few years we have focussed our investigation of the kinetic and mechanistic aspects of dye-sensitized photooxidations of different types of pollutants on those containing hydroxy-aromatic groups such as phenols (1–9), hydroxybiphenyls (10), and polyhydroxybenzenes (11). In the present contribution we examine this kind of photorreaction and, more specifically, singlet molecular oxygen [$O_2(^1\Delta_g)$]-mediated processes, in relation to dihydroxynaphthalenes (DHN). This family of polycyclic aromatic hydrocarbons constitutes a group of contaminants widespread in the environment. These compounds are released into natural aquatic media from diverse sources, industrial wastes and petroleum spills providing two massive contributions (12, 13).

A crucial objective of research in this area is to establish possible relationships between substrate and susceptibility to photooxidative degradation. The fraction of $O_2(^1\Delta_g)$-quenching events leading to effective photooxidation of the substrate, and the conditions favouring this process, are

two important points to be elucidated. In this context, the characteristics of the reaction medium (solvent polarity and pH) frequently play decisive roles from a kinetic point of view. These aspects have been carefully examined in the present contribution, to establish the feasibility of environmental degradation of dihydroxynaphthalenes through an aerobic photosensitized process. As well, the potential role of DHN as $O_2(^1\Delta_g)$ generators, upon direct irradiation, was also explored by determination of their quantum yields (Φ_Δ) of $O_2(^1\Delta_g)$ production.

Experimental

Chemicals

Rubrene (Rub); Rose Bengal (RB); 1,3-dihydroxynaphthalene (1,3-DHN); 1,5-dihydroxynaphthalene (1,5-DHN); 2,3-dihydroxynaphthalene (2,3-DHN) and 2,7-dihydroxynaphthalene (2,7-DHN); 4,5-dihydroxynaphthalene 2,7-disulfonic acid (4,5-DHN-2,7 DS); 3,5-dihydroxynaphthalene 2,7-disulfonic acid (3,5-DHN-2,7 DS); 3,6-dihydroxynaphthalene 2,7-disulfonic acid (3,6-DHN-2,7 DS); 2-methoxynaphthalene; 9,10-dimethylanthracene (DMA), furfurylalcohol (FFA), 1,4-diazabicyclo[2.2.2]octane (DABCO), and sodium azide were purchased from Aldrich. The naphthalenes and DMA were purified by sublimation, except for the sulfonated derivatives, which were recrystallized from MeOH. The solvents benzene (Bz), toluene (Tol), and methanol (MeOH) were of the highest available purity. Water was triply distilled. All measurements were made on freshly prepared solutions. A Na_2HPO–NaOH buffer was employed to adjust aqueous solutions to pH 12. At this pH, only the ionized form of the substituted naphthalenes was spectrophotometrically detected.

Methods

Ground state absorption spectra were recorded employing a Hewlett Packard 8452A diode array spectrophotometer.

The irradiation setup, including the specific oxygen electrode (Orion 97-08) was described earlier (14). The temperature was kept at 22 ± 2°C throughout.

The kinetic laser spectrophotometer for time-resolved phosphorescence detection (TRPD) of $O_2(^1\Delta_g)$ was previously described (14). In the present case RB was the sensitizer. Typically, an absorbance of the dye of ca. 0.3 at 337 nm was employed. The decay kinetics were first order in all cases.

The $O_2(^1\Delta_g)$ lifetimes were evaluated in the absence (τ^0) and in the presence (τ) of the quencher, and their ratio plotted as a function of quencher concentration [DHN], according to a simple Stern–Volmer treatment (eq. [1]), as shown in Fig. 1 for 1,5-DHN.

$$[1] \qquad \tau^0/\tau = 1 + k_t\tau^0[\mathrm{DHN}]$$

In Bz–MeOH, k_t was mainly determined according to Carlsson et al. (15) on the basis of self-sensitized photooxidation of rubrene, provided that the results employing this simple methodology were coincident with those obtained by TRPD. The ratio of initial rates of rubrene photooxidation in the absence (V_0) and in the presence (V) of different concentrations of the DHN was plotted against the DHN concentration, and k_t was calculated from eq. [2]

$$[2] \qquad V_0/V = 1 + k_t[\mathrm{DHN}]/(k_d + k_{rRub}[\mathrm{Rub}])$$

In the present case $k_{rRub}[\mathrm{Rub}] \sim 370\ s^{-1}$ (assuming $k_{rRub} = 4.4 \times 10^7\ M^{-1}\ s^{-1}$, see ref. 16). Under these conditions the denominator of eq. [2] can be practically taken as equal to k_d. The value for $1/k_d$ employed in the calculations was 23 μs obtained from TRPD experiments.

For aqueous solutions, k_t was calculated from eq. [3] (graphical method) (16) by using RB as dye sensitizer and assuming reaction [9] to be the only source of oxygen uptake.

$$[3] \qquad \mathrm{rate}^{-1} = (I_a\Phi_\Delta)^{-1}\{(k_t/k_r) + k_d/k_r[\mathrm{DHN}]\}$$

where rate and I_a denote the velocity of substrate consumption and the intensity of light absorbed by the sensitizer, respectively. For experimental reasons we measured the rate of O_2 uptake (employing the selective oxygen electrode) instead of rate of substrate consumption (reaction [9]). This replacement is only valid for cases in which the stoichiometry of reaction [9] is 1:1 (see Results and discussion). A k_d value of $2.5 \times 10^5\ s^{-1}$ was employed in the calculations (17).

The k_r values obtained for DHN in both aqueous solutions and organic solvents were determined by the method of Foote and Ching (18), eq. [4],

$$[4] \qquad k_r = k_{rR}\ \mathrm{slope}_{DHN}/\mathrm{slope}_R$$

which compares the slopes of the first-order plots for substrate and reference uptake (slope_{DHN} and slope_R, respectively) against the irradiation time for the oxidizable substrate or a reference of known k_{rR}. The reference used were DMA (in organic media) and FFA (in water). The k_{rR} values employed for the hydrocarbon and the alcohol were $1.2 \times 10^7\ M^{-1}\ s^{-1}$ (16) and $1.2 \times 10^8\ M^{-1}\ s^{-1}$ (19), respectively.

The rate of DHN photooxidation in organic media was determined spectrophotometrically. In water, the oxygen uptake was measured instead of the DHN uptake. The accuracy of this methodology for substituted phenols has been discussed elsewhere (9).

The modus operandi for obtaining the Φ_Δ values by means of TRPD was as follows: the traces for individual luminiscence decay from DHN and the reference compound 2-methoxynaphthalene (for both sample and reference Abs_{337} = 0.1, 0.2, and 0.5) were fitted with monoexponential functions to yield the initial intensity I^0 at time $t = 0$. In all cases the linearity between laser pulse energy (typically 1 mJ per pulse) and I^0 was ensured. The respective I^0 values were plotted against the fraction of absorbed light, yielding linear plots. The slopes of these plots were compared with the slope of the reference 2-methoxynaphthalene ($\Phi_\Delta = 0.34$ in Bz (20)) to obtain the absolute values for DHN.

Results and discussion

The TRPD signal of $O_2(^1\Delta_g)$ generated by aerobic irradiation of the dye sensitizer (RB) was inhibited by the presence of DHN. The interaction can be kinetically depicted as follows:

$$[5] \qquad S + h\nu \longrightarrow {}^*S^1 \xrightarrow{k_{ISC}} {}^*S^3$$

$$[6] \qquad {}^*S^3 + O_2(^3\Sigma_g^-) \xrightarrow{k_{ET}} S + O_2(^1\Delta_g)$$

$$[7] \qquad O_2(^1\Delta_g) \xrightarrow{k_d} O_2(^3\Sigma_g^-)$$

$$[8] \qquad O_2(^1\Delta_g) + Q \xrightarrow{k_q} O_2(^3\Sigma_g^-) + Q$$

$$[9] \qquad O_2(^1\Delta_g) + Q \xrightarrow{k_r} \mathrm{Products}$$

Fig. 1. Stern–Volmer plots, according to eq. [2], for the quenching of $O_2(^1\Delta_g)$ by DHN in Tol–MeOH 4:1 (v/v). For 1,5-DHN the circles represent the τ^0/τ ratio, according to eq. [1], obtained through TRPD methodology.

[d]Calculated in this work.

The sensitizer (S) absorbs convenient light and generates electronically excited singlet and triplet states (reaction [5]). From the excited triplet state an energy transfer reaction to ground-state triplet molecular oxygen [$O_2(^3\Sigma_g^-)$] can take place, producing the excited oxygen species $O_2(^1\Delta_g)$ (reaction [6]). It can decay by collision with surrounding molecules (typically the solvent, reaction [7]) or interact physically (reaction [8]) or chemically (reaction [9]) with an eventual quencher Q. Reactions [7] and (or) [8] are responsible for the already mentioned inhibition of the TRPD signal. In kinetic terms the addition k_q+k_r is known as k_t, the rate constant for the overall process of $O_2(^1\Delta_g)$ quenching.

Overall rate constants for $O_2(^1\Delta_g)$ quenching in Tol–MeOH were determined as described in the experimental section. Excellent agreement was found between the k_t values obtained using the time-resolved $O_2(^1\Delta_g)$ emission technique and the independent technique based on the autoperoxidation of rubrene (see Figs. 1 and 2 for typical cases of k_t determination in organic and aqueous solutions). The respective k_t values are listed in Table 1.

The absorption spectra of air-equilibrated solutions of DHN were strongly modified upon sensitized irradiation in both normal and alkalinized solvents, employing RB as a dye sensitizer. In Fig. 3 are shown, as typical examples, the results for 1,3-DHN and 4,5-DHN-2,7 DS in water. No spectral modifications were observed in the presence of quenchers frequently employed as $O_2(^1\Delta_g)$ testers (16) (either 1 mM sodium azide, in aqueous solution, or 60 mM DABCO, in Tol–MeOH). The same was true when Ar-saturated solutions of the DHN–RB mixtures were photolyzed.

Even when the TRPD experiments unambiguously demonstrate the existence of an important $O_2(^1\Delta_g)$ quenching by all the DHN assayed, the above-mentioned experiments indicate, according to currently accepted criteria (21), that the dye-sensitized *photooxidation* occurs via an $O_2(^1\Delta_g)$-mediated process.

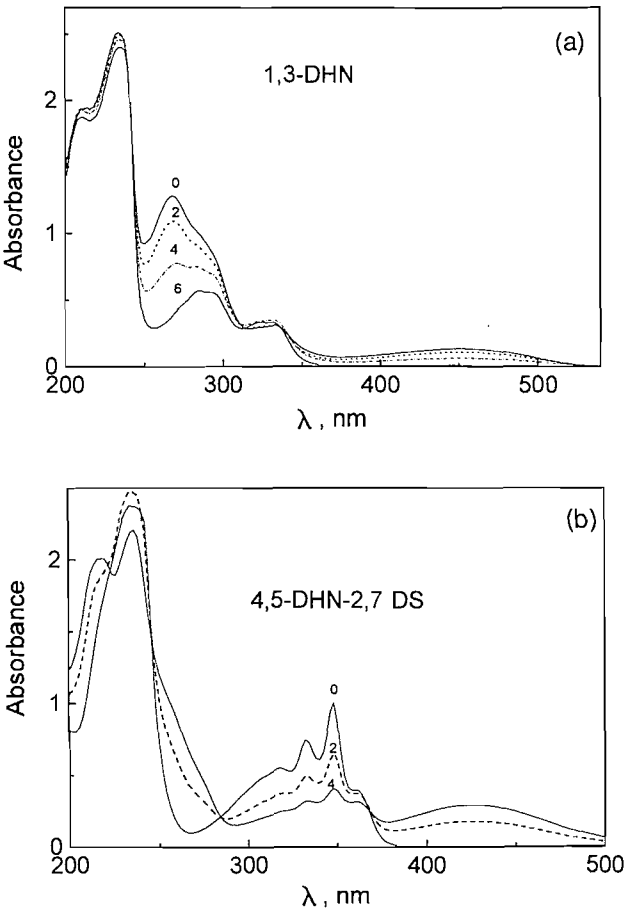
The ability of DHN to act as $O_2(^1\Delta_g)$ quenchers, as determined by the experimental methods employed in this work, does not provide any information about the nature of the quenching mechanism. Distinction between the chemical and physical contributions to the overall rate constant was possible by employing an actinometric method, as described in the experimental section. The fourth column on Table 1 exhibits k_r values for DHN that were obtained employing FFA as a sacrificial reference compond (see Methods). This compound is a very convenient reference for $O_2(^1\Delta_g)$ reactions since its k_r value is independent of pH (19). An illustration of typical results is given in Fig. 4.

It should be stressed once more (8, 9) that for an $O_2(^1\Delta_g)$-mediated photooxidation process, neither the reactive rate constant nor the overall rate constant provide information in themselves about the efficiency of the real photodegradation for a given substrate. The knowledge of its actual significance, as extracted from the kinetic data, is only given by the photooxidation quantum yield (Φ_r) (eq. [10]).

$$[10] \qquad \Phi_r = \Phi_\Delta k_r[DHN]/(k_d + k_r[DHN])$$

Upper limits of Φ_r values for DHN at concentration 1 mM were calculated by means of eq. [10] (they are shown in Table 1). The value $\Phi_\Delta = 1$, corresponding to an ideal photosensitizer, was employed in the calculations. In these conditions

Fig. 3. Spectral evolution of DHN in water, upon sensitized irradiation. Sensitizer: RB, $Abs_{560} = 0.5$. Numbers on the spectra indicate irradiation time (min): (*a*) 1,3-DHN; (*b*) 4,5-DHN-2,7 DS.

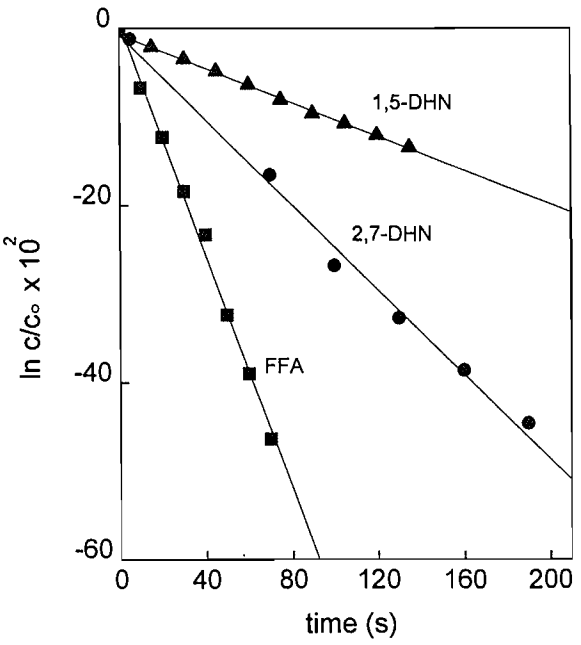


the Φ_r values indicate a moderate to high susceptibility of DHN to photosensitized degradation via an $O_2(^1\Delta_g)$-mediated process.

To evaluate the influence of the ionization of the -OH groups of DHN on the kinetics of the photooxidation process, both k_t and k_r were determined, where possible, at different pH values. Different solvent polarities were also explored. As follows from the data in Table 1, both pH and, expecially, solvent polarity affect the kinetics of the DHN–$O_2(^1\Delta_g)$ interaction. In extreme cases, differences higher than two orders of magnitude can be observed in k_t on going from water to a Tol–MeOH (4:1, *v*/*v*) mixture as solvent. Due to solubility problems in the 2,7-subsituted disulfonic acid derivatives, only the 4,5-DHN was assayed in the organic solvent mixture MeOH–Bz (10:1) (*v*/*v*). Also in this case a difference of two orders of magnitude between k_t in water and organic solvent was observed.

The ionization of the -OH groups in DHN (see Table 1) has a variable influence on the photooxidation process: depending on the particular substitution pattern the oscillations in k_t varied within a factor of ca. 8 (3,6-DHN-2,7 DS) to quasi insensitivity (4,5-DHN-2,7 DS) due to changes in the pH of the solution.

Fig. 4. First-order plots for oxygen uptake by 1,5-DHN, 2,7-DHN, and FFA (reference compound) in water. All substrates were 0.2 mM. Sensitizer: RB, Abs_{560} = 0.5.



Finally, in Table 1 are listed the Φ_Δ values for the Bz-soluble DHN. This solvent was chosen in order to compare our results with the Φ_Δ values reported in the literature, for related substituted naphthalene derivatives (20).

The only published data on the $O_2(^1\Delta_g)$-mediated photooxidation of DHN belongs to Croux et al. (22). These authors reported kinetic information for a series of DHN substituted on both aromatic rings (the DHN derivatives in common with our work are 2,7 DHN and 1,5 DHN) employing methanol as a solvent. The reported k_t values varied between 53 and 2 $\times$ 10^6 M^{-1} s^{-1}, and the respective k_r values between 30 and 7 $\times$ 10^6 M^{-1} s^{-1}. The determination of photooxidation products indicates that DHN subsituted in position 1 yields a monohydroxy 1,4-naphthoquinone, whereas other DHN of the series (such as 2,6- and 2,7-DHN) react slowly with $O_2(^1\Delta_g)$ and do not give the quinone derivative (see Scheme 1).

The main conclusion is that the kinetic parameters of the reactivity of DHN with $O_2(^1\Delta_g)$ depend markedly on the substitution pattern given by the relative position of the two hydroxyl groups. Similar behaviour can be observed in our present results: 2,7-DHN and the disulfonated derivatives 3,5- and 3,6-DHN exhibit markedly lower values for the rate constants of both the overall and the reactive interactions with $O_2(^1\Delta_g)$.

Croux et al. (22) suggest that the photoreaction (Scheme 1), consisting of a concerted [2 + 4] cycloaddition reaction as an initial step, could be influenced by solvent polarity. This assumption is largely corroborated by our present results. Turning again to the data in Table 1, the strong solvent effect on k_t immediately suggests the intermediacy of a polar encounter complex $[O_2(^1\Delta_g)$–DHN]. The stabilization of the transition state by solvation could be explained by the contribution of an electron transfer component. The mechanism is schematically represented in eq. [12]:

Scheme 1.

[1] 
$$O_2(^1\Delta_g) + DHN \underset{k_{-D}}{\overset{k_D}{\rightleftharpoons}} [O_2(^1\Delta_g)\text{–DHN}] \xrightarrow{k_p} \text{Products}$$

[12] $\Big\downarrow k_{ISC}$

$$[O_2(^3\Sigma_g^-)\text{–DHN}] \longrightarrow O_2(^3\Sigma_g^-) + DHN$$

where k_D denotes the diffusion-dependent rate constant for the encounter pair formation. Events within the $[O_2(^1\Delta_g)$–DHN] encounter pair would subsequently result either in intersystem crossing to yield ground-state triplet oxygen or photooxidation products. This mechanism has been postulated to account for the bimolecular reactions of $O_2(^1\Delta_g)$ with indoles, amines, sulfides, phenols, and dihydroxybenzenes, among other families of compounds (4, 10, 23–26). On structural grounds, one can expect a certain similarity in the photooxidative kinetic behaviour of DHN to that of phenols and dihydroxybenzenes. For the last two families of compounds two neat characteristics for the rate constant for reaction with $O_2(^1\Delta_g)$ can be observed (9): (*a*) they are highly favoured by increasing the solvent polarity and (*b*) the k_t values for the ionized species (ionization of the -OH groups) exceed those of the non-ionized forms *at least* by one order of magnitude. As already pointed out, the first point is a common attribute for all DHN in Table 1. This fact constitutes a strong argument in favour of a charge transfer mechanism for the $O_2(^1\Delta_g)$-DHN interaction.

Regarding the ionization of the -OH groups in DHN, only for 3,5- and 3,6-DHN (disodium salts) does the pH effect on k_t parallel that reported for phenols. For the remaining DHN derivatives, k_t values are either similar or slightly lower than those for the non-ionized species. Nevertheless, the Φ_r values in aqueous alkaline solution are, without exception, much higher than those determined in any other solvent. In fact, even when in some cases the overall quenching process is more effective for the non-ionized DHN species, its low chemical reactivity largely prevails. This means that the fraction of product-yielding encounter complexes (irreversible electron transfer process) increases for the better electron-donor naphtholate species. Nevertheless, the characteristic parameter for the evaluation of the tendency to photooxidation of the DHN derivatives would be the oxidation potentials, unfortunately not available in the literature for any of these compounds.

Dihydroxynaphthalenes are excellent photosensitizers for the generation of $O_2(^1\Delta_g)$ by direct irradiation. The Φ_Δ values in Bz are in the range 0.21–0.29.

The quantum yield for singlet oxygen formation is given by the sum of contributions from oxygen quenching of the lowest singlet (S) and triplet (T) excited states of DHN.

[12] $\Phi_\Delta = \Phi_\Delta(S) + \Phi_\Delta(T)$

For air-saturated solutions (oxygen concentration in 1.91 mM Bz (27)) the contribution from the DHN excited singlet state can be neglected. Hence, the expression for the quantum yield of $O_2(^1\Delta_g)$ formation is reduced to:

[13] $$\Phi_\Delta = S_\Delta \Phi_T$$

where S_Δ represents the proportion of triplet DHN–$O_2(^3\Sigma_g^-)$ that leads to the formation of $O_2(^1\Delta_g)$ and Φ_T is the quantum yield for excited triplet state generation. On this basis, although no data have been reported on DHN excited triplet properties, our present determination of Φ_Δ constitutes an upper limit for Φ_T.

Recently McGarvey et al. (20) determined the Φ_Δ values for a series of monosubstituted naphthalenes. The efficiency of $O_2(^1\Delta_g)$ generation ranges from 0.83 for 1-nitronaphthalene to 0.34 for 1-methoxynaphthalene, Φ_Δ being 0.62 for the non-substituted hydrocarbon. These authors found an inverse correlation between the ionization potential of the sensitizer and the Φ_Δ value. Assuming that this dependency holds in the case of DHN, the lack of correlation between the estimated ionization potential and reactivity towards $O_2(^1\Delta_g)$ could be an indication, as above postulated, that the charge transfer interaction is not the only component in the photooxidative mechanism of DHN.

Concluding remarks

The strong solvent effect observed on the overall rate constant for the interaction of DHN with $O_2(^1\Delta_g)$ resembles the photooxidative kinetic behaviour of substituted phenols and dihydroxybenzenes. The interaction DHN–$O_2(^1\Delta_g)$ seems to be mainly driven by a charge transfer mediated mechanism, but in this case in conjunction with structural factors. Nevertheless, the rate constants for overall and reactive interactions do not depend on pH in the same manner as those of phenols. Even so, DHN are highly reactive towards $O_2(^1\Delta_g)$ when the -OH groups are ionized, as indicated by the Φ_r values.

Dihydroxynaphthalenes efficiently produce $O_2(^1\Delta_g)$ upon direct irradiation in Bz, with quantum yields near 0.25.

Both Φ_r and Φ_Δ values indicate that DHN-like contaminants are good candidates for an environmental $O_2(^1\Delta_g)$-mediated photooxidation. The photodegradative process is favoured in the alkaline range of pH and by solvents of high polarity.

Electrochemically induced chain reactions: the addition of fluorene and indene to aromatic aldehydes initiated by electrochemical reduction

J.C. Gard, B. Hanquet, L. Roullier, Y. Mugnier, and J. Lessard

Abstract: The electrochemical reduction at −30°C of 2,6-dichlorobenzaldehyde (**1***a*), benzaldehyde (**1***b*), and terephthalaldehyde (**2**) in tetrahydrofuran with tetrabutylammonium perchlorate as supporting electrolyte, under an argon atmosphere and in the presence of fluorene or indene, gives carbinols resulting from the addition of fluorene or indene and requires only a catalytic amount of electricity. The chain reaction is initiated by proton abstraction from fluorene or indene by a base electrogenerated by reduction of the aldehyde and the propagation involves the addition of the carbanion to the aldehyde followed by regeneration of the nucleophile by proton transfer from the proton donor to the alkoxide anion (base-catalyzed addition). The voltammetric behavior of the aldehydes in the absence and in the presence of fluorene or indene is also presented.

Key words: electrochemical reduction, aromatic aldehydes, addition of fluorene (indene), base catalysis, chain reaction.

Résumé : La réduction électrochimique à −30°C des 2,6-dichlorobenzaldehyde (**1***a*), benzaldehyde (**1***b*) et terephtalaldehyde (**2**) dans le tetrahydrofurane contenant du perchlorate de tetrabutylammonium comme électrolyte support, sous atmosphère d'argon et en présence de fluorène ou d'indène, donne des carbinols provenant de l'addition basique du fluorène ou de l'indène et ne nécessite qu'une quantité catalytique d'électrons. La réaction en chaîne est initiée par l'arrachement d'un proton du fluorène ou de l'indène par une base électrogénérée par réduction de l'aldéhyde et les étapes de propagation sont l'addition du carbanion à l'aldéhyde suivie de la regénération du nucléophile par transfert de proton du donneur de proton à l'ion alkoxyde. Le comportement en voltamétrie des aldéhydes, en absence et en présence du fluorène ou d'indène, est également discuté.

Mots clés : réduction électrochimique, aldéhydes aromatiques, addition du fluorène (indene), catalyse basique, réaction en chaîne.

Introduction

Studies on electrochemically induced chain reactions have received considerable attention. Some representative examples are as follows: $S_{RN}1$ aromatic substitutions initiated by the electroreduction of an aryl halide (1), *cis–trans* isomerization of functionalized olefins (2), oxidation of alcoholates to aldehydes and ketones by aryl halides (3), electrooxidative initiation of triphenyltin hydride promoted radical reactions (4), ligand substitution of organometallic complexes (5), addition of chloroform to aldehydes (6), Michael reactions (7), and addition of fluorene and indene to nitrosobenzene (8). In the last two examples, the initiation step involves the generation of the nucleophile by hydrogen abstraction from a proton donor by a base generated by electroreduction of the electrophile or acceptor.

In this paper, we present a new example of a chain process involving the addition of a nucleophile initiated by electrochemical reduction of the electrophile: the reaction between a proton donor such as fluorene (FlH_2) or indene (InH_2) and an aromatic aldehyde (ArCHO), induced by the electroreduction of the latter in tetrahydrofuran (THF) with n-Bu_4NClO_4 as the supporting electrolyte. We describe the results with 2,6-dichlorobenzaldehyde (**1***a*),[2] benzaldehyde (**1***b*), and terephthalaldehyde (**2**).

Results and discussion

Voltammetric reduction

The cyclic voltammogram of 2,6-dichlorobenzaldehyde (**1***a*) at −30°C in THF containing $(n\text{-Bu})_4NClO_4$ as supporting electrolyte and on a vitreous carbon electrode (Figs. 1a and 2a) shows two reduction peaks A_1 ($E_p = -1.55$ V vs. SCE) and A_2 ($E_p = -1.70$ V), and several oxidation peaks. In the presence of FlH_2 (Figs. 1b–1d) or InH_2 (Figs. 2b–2d), the voltammogram at the same sweep rate is modified: both peaks A_1 and A_2 decrease, and peak A_2 more so than peak A_1. With two to three equivalents of proton donor AH_2 (Figs. 1c and 2c), peak A_2 has disappeared. For peak A_1, the rapid drop of the current after the peak potential, resulting in a sharp, narrow, and symmetric peak (Figs. 1b–1d and Figs. 2b and 2c), is characteristic

[2] Preliminary results on the electroreduction of **1***a* in the presence of fluorene have been reported (9).

Fig. 1. Cyclic voltammogram of 2,6 dichlorobenzaldehyde (**1***a*) on a vitreous carbon electrode in THF–$(n\text{-Bu})_4NClO_4$ (0.2 M) at −30°C: (a) **1***a* alone; (b), (c), and (d), in the presence of 1, 2, and 10 equivalents of FlH_2 respectively. Starting potential: +0.3 V. Sweep rate: 0.02 V s^{-1}.

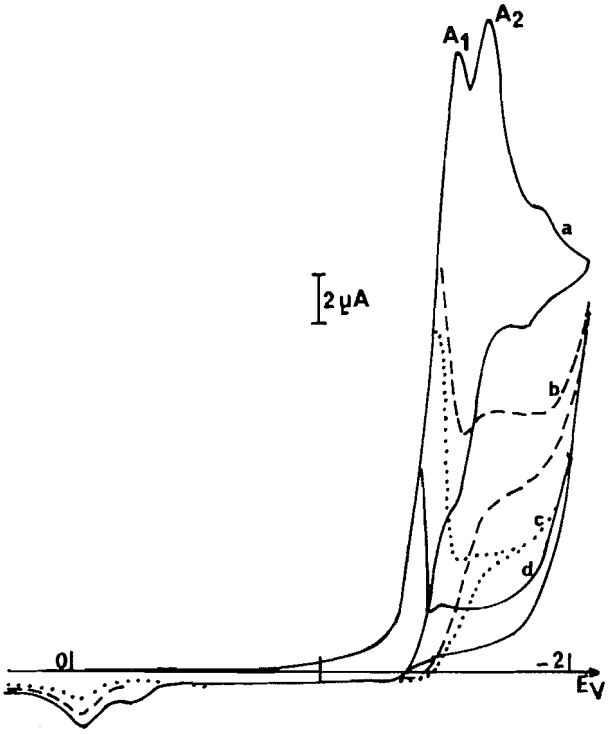

Fig. 2. Cyclic voltammogram of 2,6 dichlorobenzaldehyde (**1***a*) on a vitreous carbon electrode in THF–$(n\text{-Bu})_4NClO_4$ (0.2 M) at −30°C: (a) **1***a* alone; (b), (c), in the presence of 1, and 10 equivalents of InH_2, respectively. Starting potential: +1 V. Sweep rate: 0.02 V s^{-1}.

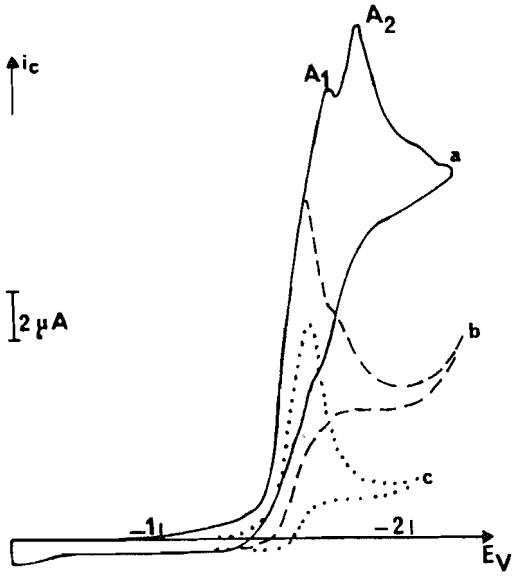
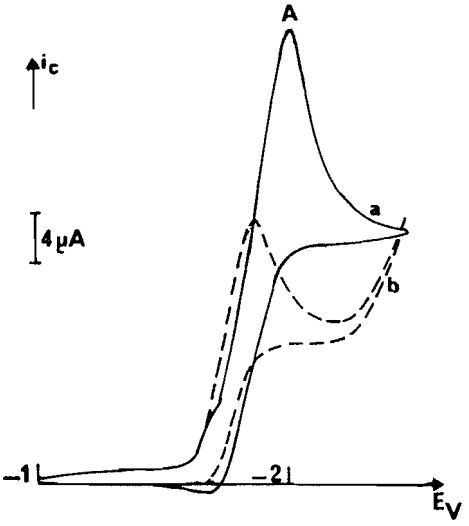


of a catalytic reaction occurring outside the diffusion layer (8, 10). This is further confirmed (*i*) by the fact that when the sweep rate is decreased, peak A_1 becomes smaller, and (*ii*) by the consumption of a catalytic amount of electrons in the controlled potential electrolysis performed on mercury, at −30°C,

Fig. 3. Cyclic voltammogram of benzaldehyde (**1***b*) on a vitreous carbon electrode in THF–$(n\text{-Bu})_4NClO_4$ (0.2 M) at −30°C: (a) **1***b* alone; (b) in the presence of 10 equivalents of FlH_2. Starting potential: −1 V. Sweep rate: 0.02 V s^{-1}.



at the potential of peak A_1 and in the presence of 10 equivalents of AH_2 (ca. 0.03 and 0.02 mole of electrons per mole of **1***a* for FlH_2 and InH_2, respectively, see below). The voltammetric behavior of benzaldehyde (**1***b*) in the presence of proton donor AH_2 is similar to that of **1***a* as shown by the cyclic voltammograms of Fig. 3: a decrease of peak A (E_p = −2.0 V vs. SCE) and a change of its morphology in the presence of 10 equivalents of FlH_2 (Fig. 3b), characteristic of a catalytic process. And indeed, the electrolysis of **1***b* at −30°C, on mercury, in the presence of 20 equivalents of FlH_2 and at the potential of peak A, also consumed a catalytic amount of electron (ca. 0.25 and 0.2 mole of electrons per mole of **1***b* for FlH_2 and InH_2, respectively, see below). Peak A_1 in the cyclic voltammogram of 2,6-dichlorobenzaldehyde (**1***a*) (Figs. 1a and 2a) and peak A in the voltammogram of benzaldehyde (**1***b*) correspond to the reduction of the aromatic aldehyde to the radical anion (eq. [1]). This electrogenerated base, in the presence of proton donor AH_2, abstracts a proton from it to form the anion AH^- and a neutral radical (eq. [2]). The latter probably disappears in subsequent fast reactions. Reactions [1] and [2] constitute the initiation step of a chain reaction involving, as propagation steps, the nucleophilic addition of AH^- to the carbonyl (eq. [3]) followed by protonation of the resulting anions (bases) by AH_2 (eq. [4]) to regenerate the nucleophile AH^- and give a carbinol that has been isolated from the preparative electrolyses (see below). In the case of **1***a*, the radical anion can be converted to 2-chlorobenzaldehyde (see eqs. [5] and [6]), which is most probably responsible for peak A_2 (eq. [7]) in the voltammograms of **1***a* (Figs. 1 and 2). In the presence of AH_2, the elimination of chloride ion from **1***a* (eq. [5]) competes with its protonation (eq. [2]), leading to the chain process (eqs. [3] and [4]) outside the diffusion layer, and the formation of 2-chlorobenzaldehyde is completely suppressed with two (FlH_2) to three (InH_2) equivalents of proton donor (see Figs. 1c and 2c).

The voltammogram of terephthalaldehyde (**2**) (Fig. 4), recorded under the same conditions as those of **1***a* and **1***b*, differs from the latter in showing two redox systems, giving rise to peaks A/A′ and B/B′ that correspond to the formation of the

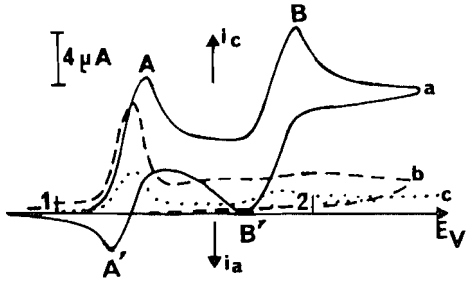
peak A_2 (Figs. 1a and 2a)

Fig. 4. Cyclic voltammogram of terephthaladehyde (**2**) on a vitreous carbon electrode in THF–$(n\text{-Bu})_4NClO_4$ (0.2 M) at −30°C: (a) **2** alone; (b) and (c) in the presence of 5 and 20 equivalents of InH_2, respectively. Starting potential: 0 V. Sweep rate: 0.02 V s^{-1}.



radical anion (eq. [8]) and the dianion (eq. [9]), respectively. In the presence of a proton donor (InH_2, Figs. 4b and 4f), the radical anion is protonated, the oxidation peak A′ and the system B/B′ disappear accordingly, and the reduction peak A behaves as peak A_1 in the voltammogram of **1***a* (see Figs. 1b–1d) and peak A in the voltammogram of **1***b* (see Figs. 1b and 2c): its height decreases with the concentration of AH_2 and its shape is characteristic of a catalytic reduction (see eqs. [1]–[4]). The same behavior was observed with FlH_2 as proton donor. And indeed, the controlled potential electrolysis of **2** at −30°C, on mercury, in the presence of 20 equivalents of FlH_2 and at the potential of peak A (−1.2 V) consumed 0.06–0.12 mole of electrons per mole of **2** and gave products resulting from the addition of FlH_2 to the carbonyl group (see below).

Controlled potential electroreductions

The controlled potential reductions of aldehydes **1***a*, **1***b*, and **2** were carried out at −30°C, on a mercury pool electrode, in

[8] 
System A/A′

[9] 
System B/B′

THF–$(n\text{-Bu})_4NClO_4$ (0.2 M), in the presence of an excess (10–20 equivalents) of proton donor (AH_2), under an atmosphere of argon and at a potential corresponding to the formation of the radical anion (peak A_1 in Figs. 1 and 2, peak A in Figs. 3 and 4). The solution became colored (see Table 1) and, after the current had dropped to zero, there was no reduction peak in the voltammogram of the electrolyzed solution from 0 to −1.8 V.[3] The electrolyzed solution was extracted after the current dropped to zero. The results are reported in Table 1. In the case of 2,6-dichlorobenzaldehyde (**1***a*) (Table 1, entries 1 and 2), the carbinols **3** (Scheme 1) were isolated in very good to excellent yields (74–93%). As already mentioned, the carbinols result from the nucleophilic addition of AH^- to the aldehyde (eq. [3]) followed by protonation of the resulting anion by AH_2 regenerating AH^- (eq. [4]), the chain process being initiated by the electrochemical generation of AH^- (eqs. [1] and [2]). In the case of benzaldehyde (**1***b*) (entries 3 and 4), the yields of isolated carbinols were much lower (14–28%) and the number of moles of electrons per mole of aldehyde consumed was larger (ca. 0.2 for **1***b* as compared to ca. 0.02 for **1***a*). The yields reflect the higher reactivity of **1***a* compared to that of **1***b* (fewer side products such as glycols and alcohols formed in the case of **1***a*), most probably due to the electron-withdrawing effect of the two chlorine atoms at the *ortho* positions of the carbonyl group in **1***a*.

With terephthalaldehyde (**2**) and fluorene (Table 1, entry 5), dehydration of the carbinol **4** occurred to a small extent during the electrolysis and (or) during the work-up to give the alkene **6** (1%) (Scheme 2). The total yield of isolated addition products was 33%. The controlled potential electrolysis in the presence of InH_2 was not performed because of the large number of isomeric carbinols possible.

It has long been known that FlH_2 can be added to aldehydes, mainly aromatic aldehydes, in the presence of a basic catalyst (e.g., potassium hydroxide) in refluxing ethanol to form dibenzofulvenes (11). By carrying out the reaction between FlH_2 and benzaldehyde (**1***b*), at room temperature and in sodium ethoxide – ethanol, the carbinol **3***b*$_1$ was isolated in a 23% yield (12). A dibenzofulvene was obtained in a 45% yield by reaction of benzaldehyde (**1***b*) with InH_2 in refluxing methanolic potassium hydroxide (13). Both FlH_2 and InH_2 were condensed with benzaldehyde (**1***b*) using $KF–Al_2O_3$ as the basic catalyst at room temperature (14). With FlH_2, a mixture of carbinol **3***b*$_1$ (32%) and a dibenzofulvene (63%) was obtained (14). With InH_2, a benzofulvene (66%) was isolated together with a product (14%) resulting from the addition of the 3-(α-hydroxyphenyl)-indene to another molecule of benzaldehyde followed by loss of one molecule of water (14). The complex $(InH)_2\,Ca{\cdot}NH_3{\cdot}THF$ was reported to react with ben-

[3] There was no reaction between FlH_2 and InH_2 and any of the aldehydes in the absence of an electron source (no potential applied).

zaldehyde (15) in liquid ammonia to give the carbinol **3***b*$_2$ in a 50–55% yield (16). The reaction of terephthalaldehyde (**2**) with excess FlH_2 in ethanol, with sodium ethoxide as the base and at 60–70°C, was reported to afford a di-(dibenzofulvene) in an 11% yield (15). Finally, Ghera and Spinsak (11) observed that the condensation of FlH_2 and InH_2 with aliphatic aldehydes in pyridine at 0°C, using benzyltrimethylammonium hydroxide (Triton B) as base, gave the corresponding carbinols in substantial yields. At 25°C, in the same medium, the 9-(α-hydroxylalkyl)-fluorenes underwent dehydration to the corresponding bibenzofulvenes, which, in the presence of

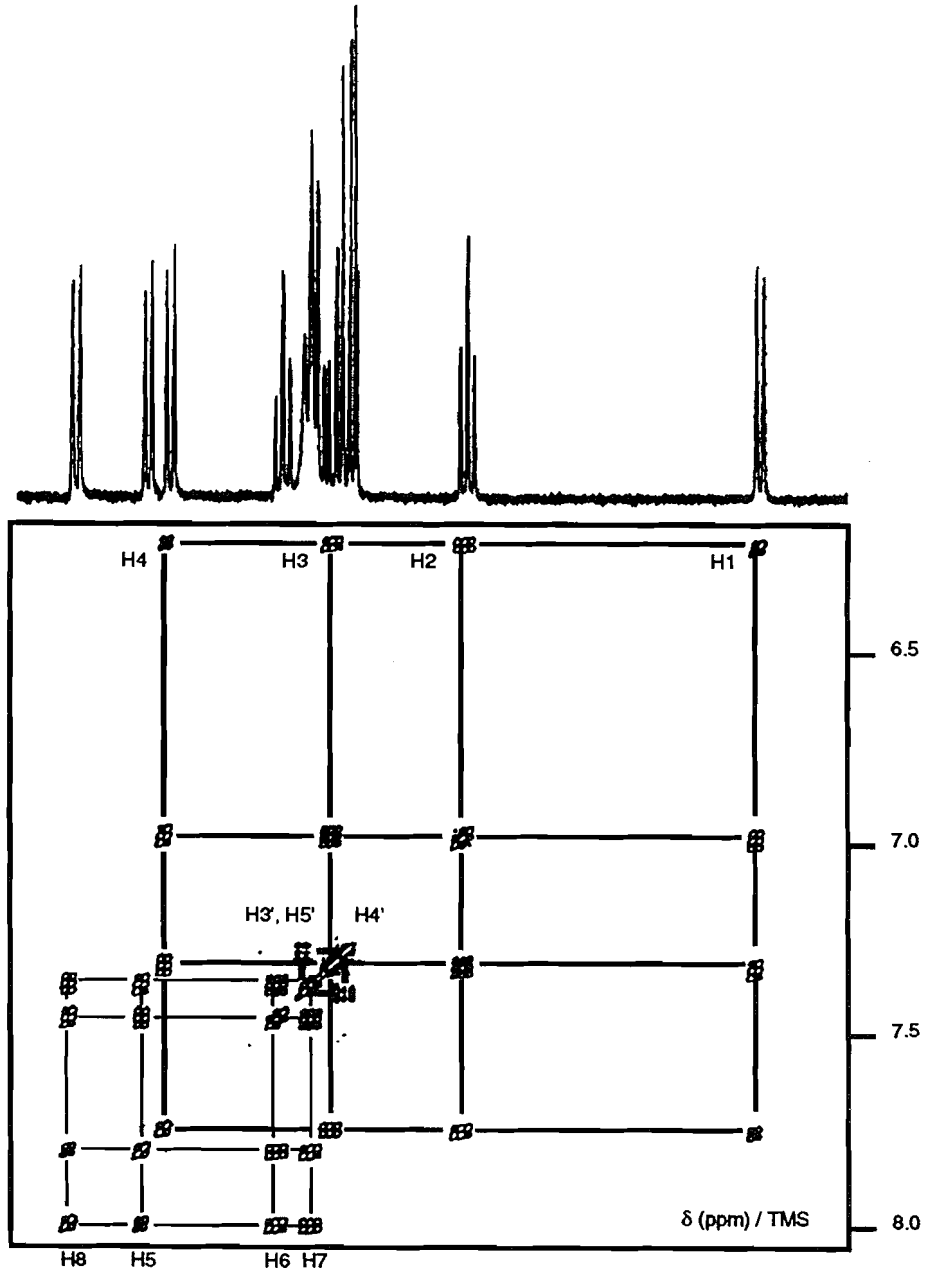
an excess of FlH_2, afforded the corresponding 1,1-bis-(9-fluorenyl)-alkanes (11).

Structure of products

All compounds were characterized by mass spectrometry (Table 2). The crystalline compounds $3b_1$ and $3b_2$ are known and had melting points close to those reported in the literature (Table 3). Microanalytical data were obtained for all new crystalline compounds (Table 3). The structure of alcohol $3a_1$ was determined by ^1H and ^{13}C NMR spectroscopy and that of alcohols $3a_2$ by ^1H NMR spectroscopy. They are shown below.

The complete attribution of the protons of $3a_1$ was made

Fig. 5. (^{1}H–^{1}H) COSY spectrum of alcohol $3a_1$.



using COSY and NOE differential spectroscopy. Alcohol $3a_1$ exhibits a (^{1}H–^{1}H) COSY spectrum (Fig. 5) with three sets of protons. The first and the second set (four protons each) concern the fluorene backbone and the third set (three protons), the aryl group. Protons H3′ and H5′ and H4′ appear, respectively, as a broad doublet centered at 7.38 ppm and as a sharp triplet (7.27 ppm). This result indicates a restricted motion around the C1′—C4′ axis. Assignment of proton H8 is given by the NOE enhancement observed on this proton by presaturation of the OH. Consequently the set H8, H7, H6, and H5 (ring B) is easily deduced. It should be noticed that the chemical shifts observed for these protons are very similar whereas the important chemical shift difference for the second set of four protons (H1–H4) (ring A) indicates a preferred conformation of the dichlorophenyl ring almost perpendicular to the fluorene moiety, leaving H1 *inside* the shielding cone, hence the assignments of H1, H2, H3, and H4. The {^{1}H}–^{13}C NMR spectrum displays 18 individual resonances for the 20 carbon atoms (C2′, C6′ and C3′ and C5′ are broad resonances). The final attribution is made using the (^{1}H–^{13}C) COSY spectrum (see Fig. 6). The ^{1}H and ^{13}C NMR data parameters are given in the experimental part.

The stereochemistry of the two diastereoisomeric alcohols $3a_2$ (*RR* + *SS*) and $3a_2$ (*RS* + *SR*) was proven by NMR spectroscopy experiments, including homonuclear COSY and NOE differential spectroscopy. From comparison of the normal proton spectra of the two alcohols, it appears that the coupling constants between H_a and H_b are very similar (9.3 and 10.5 Hz), indicating an antiperiplanar orientation of the H_a-C-C-H_b system in both alcohols. The NMR spectra of Fig. 7

Fig. 6. (^{1}H–^{13}H) COSY spectrum of alcohol $3a_1$.

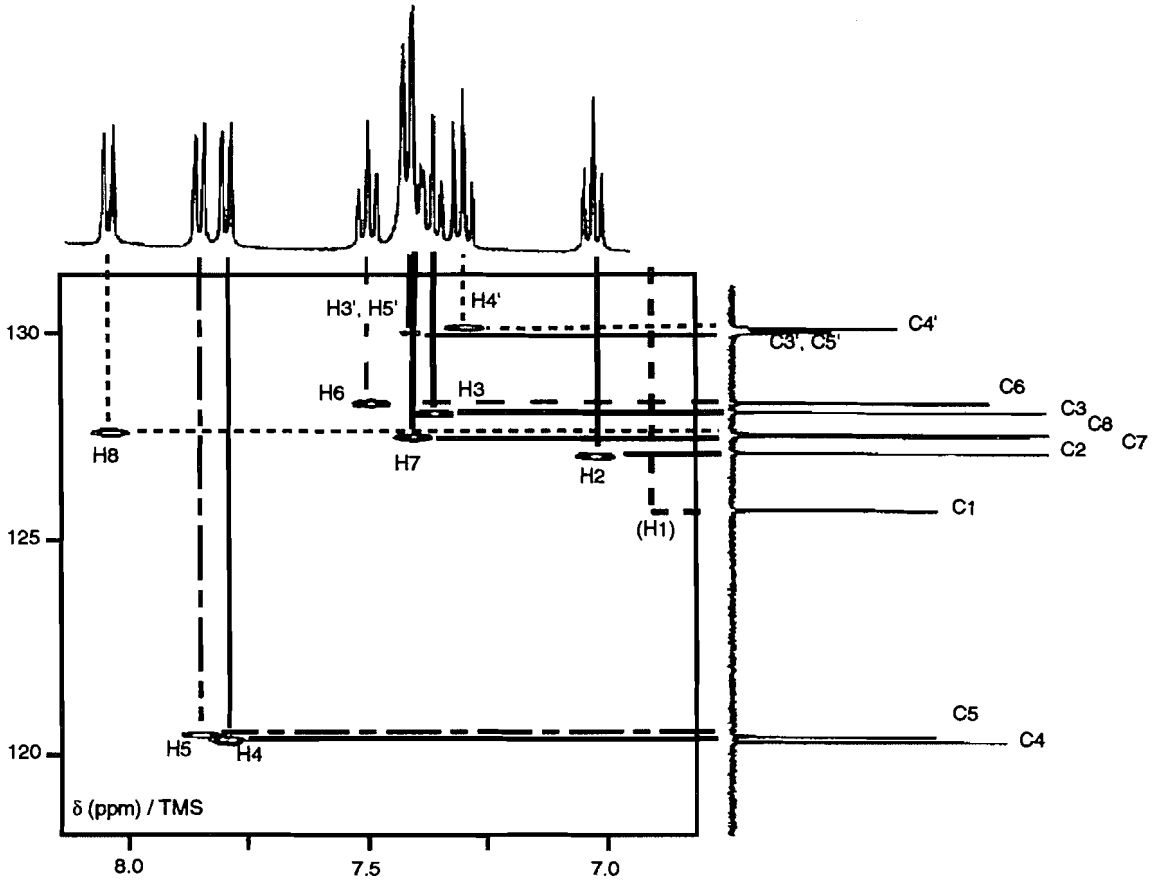


Fig. 7. ^{1}H NMR spectra of $3a_2$ (*RR* + *SS*) and $3a_2$ (*RS* + *SR*).

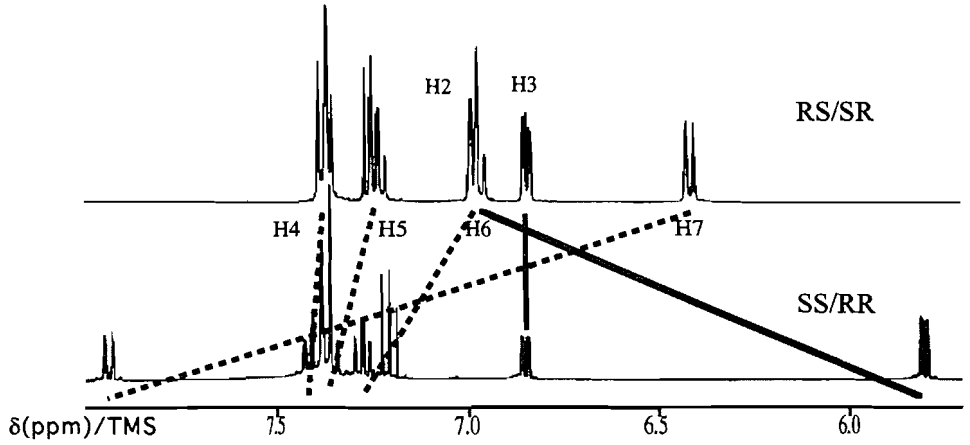

show clearly that the dichlorophenyl ring has a different position in the diastereoisomeric alcohols, as illustrated in the structures. The protons on the benzene ring B of the *RR* + *SS* diastereoisomer are in a location analogous to those of the protons of the ring B of alcohol $3a_1$ and the protons of ring A of the *RS* + *SR* diastereoisomer are in a similar location to those of ring A of alcohol $3a_1$. Indeed, proton H2 of the *RR* + *SS*, being in the shielding cone of the dichlorophenyl group, is strongly shielded with respect to proton H2 of the *RS* + *SR* isomer (Fig. 7). For the same reason, protons H7 and H6 of the *RS* + *SR* isomer are shielded with respect to these same protons of the *RR* + *SS* isomer (Fig. 7) but the shielding is smaller for proton H6 because it is further away from the dichlorophenyl group in the *RS* + *SR* isomer. Thus, the stereochemistry *RR* + *SS* and *RS* + *SR* was attributed respectively to the major (47%) and minor (27%) diastereoisomer of alcohol $3a_2$. The chemical shifts and coupling constants for alcohols $3a_2$ (*RR* + *SS*) and $3a_2$ (*RS* + *SR*) are given in the experimental part. Interest-

ingly, carbinol $3a_2$ exists as the α form. No sigmatropic rearrangement (17, 18) or base-catalyzed rearrangement (19) to the γ-form was observed (eq. [10]).

[10] 
3 (α-form) 3 (γ-form)

Experimental part

Reagents

Tetrahydrofuran was purified by distillation under argon from sodium benzophenone ketyl. The supporting electrolyte was tetrabutylammonium perchlorate (0.2 M) in all cases. Fluorene, indene, 2,6 dichlorobenzaldehyde (**1***a*), benzaldehyde (**1***b*), and terephthalaldehyde (**2**) were all commercial products.

Apparatus and general procedures

All experiments were carried out under an argon atmosphere. In voltammetry, the working electrode was a vitreous carbon disc (diameter 1.2 mm) and, for the controlled potential electrolyses, a mercury electrode. In all cases, the reference electrode was a saturated calomel electrode (SCE) separated from the solution by a sintered glass disc. The auxiliary electrode was a platinum wire. All reagents in solution in THF were added, with a syringe previously purged with argon, to the THF–$(n\text{-Bu})_4NClO_4$ solution in the cell. The cyclic voltammetry experiments were conducted with a Tacussel PJT 24-1 potentiostat. The controlled potential electrolyses were carried out with an Amel 552 potentiostat equipped with a Tacussel IG5 integrator. For the experiments carried out at −30°C, the cell was placed in a cooling bath (acetone – liquid nitrogen). Melting points were determined on a Kofler apparatus and are uncorrected. The ^1H (400 MHz) and ^{13}C (100 MHz) NMR spectra were recorded from $CDCl_3$ solutions on a WM400 Bruker NMR spectrometer at the CSMUB (Centre de spectrométrie moléculaire de l'Université de Bourgogne). The chemical shifts (δ) are given in ppm (downfield from TMS) and the coupling constants (*J*) in hertz. The multiplicities are as follows: s, singlet; d, doublet; t, triplet. Mass spectra were taken on Kratos Concepts spectrometer. Silica gel Merck (280–400 mesh) was used for flash column chromatography and silica gel Merck BOF_{254} for thin-layer chromatography. Eluents for chromatographic separation, solvents for recrystallization, melting points, and microanalytical data are recorded in Table 3. The mass spectral and microanalytical data are given in Tables 2 and 3, respectively.

Typical electrolysis procedure

2,6-Dichlorobenzaldehyde (**1***a*) (152.7 mg, 0.87 mmol) was electrolyzed on a mercury electrode at −1.6 V vs. SCE with indene (1 mL, 10 mmol) at −30°C in THF (20 mL) containing $(n\text{-Bu})_4NClO_4$ (0.2 M). The electrolysis was stopped when the current dropped to zero (0.0015 electron per molecule of **1***a*). The orange-yellow solution was immediately poured into water and extracted with ether. Chromatography on silica gel with hexane–ether (4:1) as eluent gave two diastereoisomeric 3-[α-hydroxy-(2′,6′-dichloro-phenyl)]-indenes ($3a_2$). The less polar *RR* + *SS* isomer was isolated as an oil (119 mg, 47%). The more polar *RS* + *SR* isomer was recrystallized from pentane, mp 98°C (68 mg, 27%).

Novel experimental findings in the B–Z system employing mixed substrates

V. Jayalakshmi and R. Ramaswamy

Abstract: Certain novel features of the Belousov–Zhabotinsky (B–Z) system employing different mixed substrates and Mn(II) as the catalyst are presented. Malic acid is the common substrate together with one of malonic, citric, cyanoacetic, maleic, acetic, oxalic, or tartaric acid as the second substrate. The correlation of the oscillatory behaviour with values of exchange current density establishes the oscillatory control by the redox couple, namely, Mn(III)/Mn(II) and (or) Br_2/Br^-. Each substrate when used alone gives rise to an oscillatory behaviour with characteristic features that can be compared with the system containing mixed substrate. The combination of substrates provides different modes of oscillatory behaviour such as entrainment, independent, partial inhibition, or complete inhibition. These observations are rationalized in terms of relevant steps involved in the mechanism of the reaction.

Key words: mixed substrate, exchange current density, entrainment, independent, inhibition.

Résumé : On présente certaines caractéristiques nouvelles du système de Belousov–Zhabotinsky (B–Z) dans lesquelles on utilise des substrats mixtes et du Mn(II) comme catalyseur. L'acide malique est un substrat courant avec l'un ou l'autre des acides malonique, citrique, cyanoacétique, maléique, acétique, oxalique ou tartrique comme deuxième substrat. La corrélation du comportement oscillatoire avec les valeurs de la densité du courant d'échange permet d'établir que le contrôle oscillatoire dérive du couple redox, Mn(III)/Mn(II) et (ou) Br_2/Br^-. Lorsqu'on utilise les substrats seuls, ils donnent lieu à un comportement oscillatoire dont les caractéristiques particulières peuvent se comparer à celles d'un système contenant un substrat mixte. Les combinaisons de substrats conduisent à des modes différents de comportement tels qu'entraînement, indépendant, inhibition partielle ou inhibition complète. On peut rationaliser ces observations en fonction d'étapes appropriées impliquées dans le mécanisme de la réaction.

Mots clés : substrat mixte, densité du courant d'échange, entraînement, indépendant, inhibition.

Introduction

Oscillatory reactions in the Belousov–Zhabotinsky (B–Z) and Briggs–Rauscher (B–R) systems have been investigated by employing a variety of organic substrates in aqueous as well as aqueous–organic mixed media (1–3). Oscillatory reactions with mixed organic substrates (4–6) have also received considerable attention. The present paper deals with certain novel experimental findings in the B–Z system employing mixed substrates with malic acid as the common substrate.

Experimental

The constituents of the experimental solution, with the exception of potassium bromate, were kept well stirred and thermostated in a polythene beaker. The addition of the last constituent ($KBrO_3$) triggered off the oscillations. The EMF oscillatory profile between a platinum indicator electrode and a saturated calomel (SCE) reference electrode was continously recorded. Different substrates were employed for the study, either individually or in combination with malic acid as the common substrate. The structures of the substrates employed have been tabulated for convenient reference.

Structures of different substrates employed.

S.No.	Substrate	Structure
1.	Malic acid	HOOC—CH_2—CH(OH)—COOH
2.	Citric acid	CH_2—COOH | C(OH)—COOH | CH_2—COOH
3.	Malonic acid	HOOC—CH_2—COOH
4.	Cyanoacetic acid	NC—CH_2—COOH
5.	Maleic acid	HOOC—CH=CH—COOH
6.	Acetic acid	CH_3—COOH
7.	Tartaric acid	CH(OH)—COOH | CH(OH)—COOH
8.	Oxalic acid	COOH | COOH

Results and discussion

(i) Malic acid and citric acid

The oscillatory profile of the malic acid – citric acid mixed substrate system under the concentration conditions indicated

Received March 29, 1995.

citric acid	0.025	1–30	0.590	0.820	0.230	0.50	15
	+						
	0.025	31–54				1.66	40

[a][$KBrO_3$] = 0.05 M; [H_2SO_4] = 2.0 M; [$MnSO_4$] = 0.005 M; temperature = 30 ± 0.1°C.

in Table 1 is presented in Fig. 1*b*. Each substrate when used alone in the B–Z reaction gives rise to characteristic features that permit identification of its oscillatory behaviour in the system with mixed substrates. The oscillatory reactions with the individual substrate under the concentration conditions indicated in Table 1 are presented in Figs. 1*a* and 2. The potential developed at the platinum indicator electrode is determined by the relative values of the exchange current density and (or) the relative concentrations of the redox couples involved. The values of the exchange current density for Pt/Mn(III), Mn(II), and that of Pt/Br_2, Br^- are comparable (10^{-5} A/cm^2). Therefore the potential range of oscillation can be decided by the relative concentration of Mn(III)/Mn(II) and Br_2/Br^-. The potential range of oscillation with malic acid as the substrate is 0.775–1.05 V (vs. SCE). The peak potential is as high as 1.05 V, indicative of the predominant potential control by the Mn(III)/Mn(II) redox couple. The standard potentials (vs. SHE) of the Mn(III)/Mn(II) and Br_2/Br^- redox systems are 1.488 and 1.066 V, respectively. However, the prevailing concentrations of the different species are much smaller. Thus the malic acid oscillatory profile is predominantly controlled by the Mn(III)/Mn(II) redox couple due to the nominal reactivity of the substrate towards bromination.

On the other hand, the potential range of oscillation in the citric acid system is 0.60–0.825 V (vs. SCE), which is indicative of mixed control of potential by both redox couples, namely, Mn(III)/Mn(II) and Br_2/Br^-. This is presumably due to the high reactivity of the substrate towards bromination, leading to considerable production and consumption of bromine.

This can be well understood in terms of the relevant steps involved in the FKN mechanism.

[1] $HOBr + Br^- + H^+ \rightleftharpoons Br_2 + H_2O$

[2] $BrO_2^{\bullet} + M^{n+} + H^+ \rightleftharpoons HBrO_2 + M^{(n+1)+}$

These steps lead to the formation of bromine and the oxidized form of metal ion. In addition, the reaction involving the substrate would lead to the consumption of bromine as well as the oxidized form of the metal ion according to the following steps:

[3] $S + Br_2 \rightleftharpoons Br{\cdot}S + Br^- + H^+$

[4] $S + M^{(n+1)+} \rightleftharpoons M^{n+} + \text{product}$

Steps [3] and [1] are more favoured in the citric acid system because of its high reactivity towards bromination. Enhancement in the production and consumption of bromine in the citric acid system is also reflected in the smaller time per oscillation (0.5 min) compared to that of malic acid (1.0 min) as indicated in Table 1. Thus the high reactivity of the substrate contributes considerably to the high frequency and mixed control of potential by both redox couples, namely, Mn(III)/Mn(II) and Br_2/Br^-.

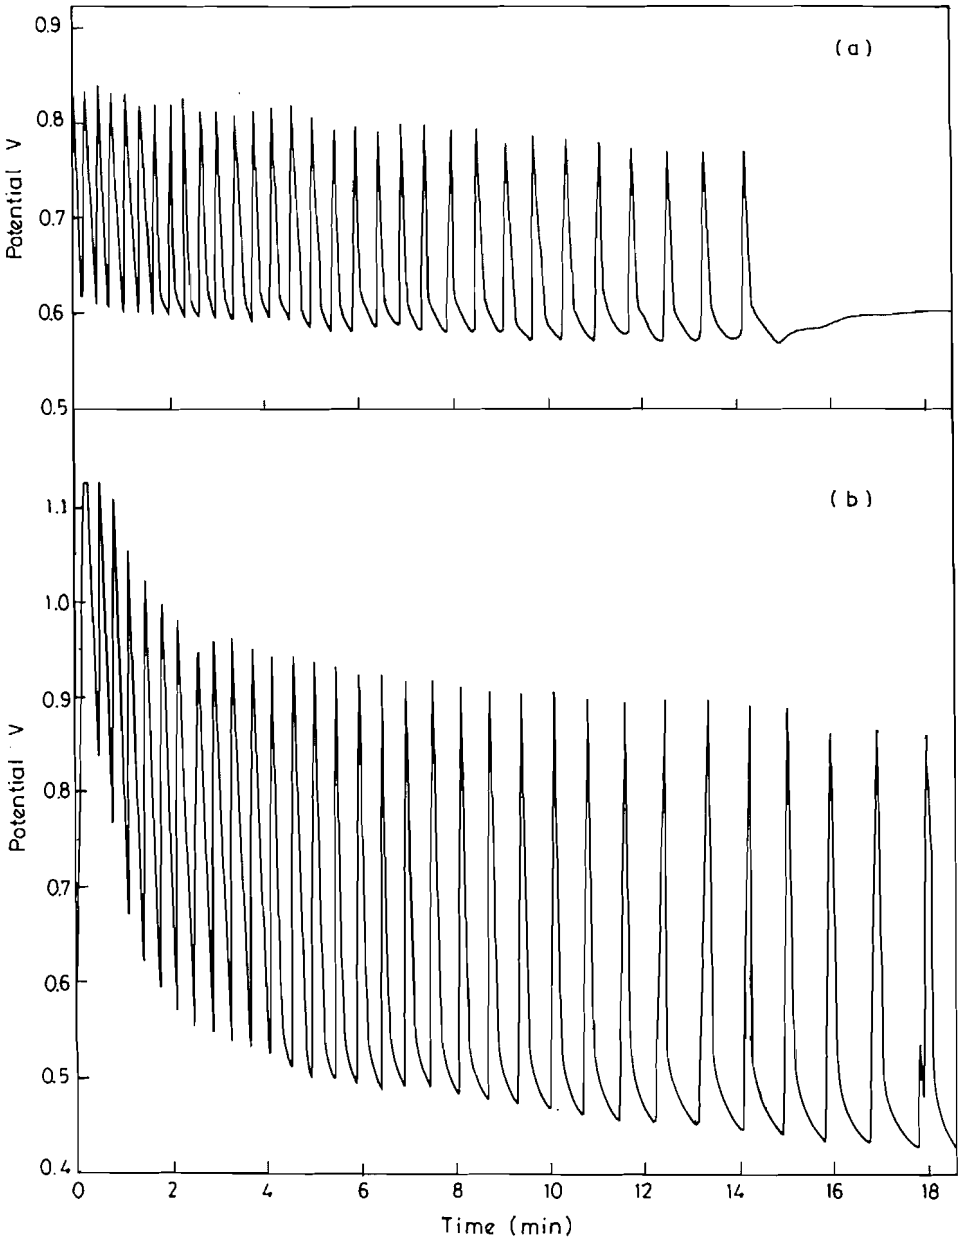
The oscillatory profile observed in this mixed substrate system is almost identical to the oscillatory parameters with citric acid except for the increase in the amplitude of oscillations. The wave form, potential range, and the oscillatory period also clearly indicate that the oscillations are of the citric acid type and the role of malic acid is just to increase the amplitude of oscillations to the extent of 225 mV. Thus the system investigated here is an example of entrainment oscillations, in which citric acid is responsible for oscillations and the presence of malic acid increases the amplitude of oscillations.

The oscillatory behaviour of the system with 0.1 M of the individual substrate (malic acid or citric acid) leads to an increase in the frequency of oscillations due to an enhancement in the formation and consumption of bromine as well as of Mn(III). The solution containing a total concentration of 0.05 M of malic and citric acid (0.025 M each) gives an oscillatory behaviour that is identical with that of citric acid (0.05 M) for a duration of 15 min followed by an additional 24 oscillations in 40 min. Such an oscillatory behaviour can be termed as independent and persistent.

(ii) Malic acid and malonic acid

The oscillatory behaviour of this system under the concentration conditions indicated in Table 2 is presented in Fig. 3. The oscillatory profile observed with mixed substrate is identical to that of malonic acid in almost all aspects of the wave form, namely, potential range, frequency, and the alternation between a pink and a colourless solution. This clearly indi-

Fig. 1. Oscillatory behaviour of bromate–Mn(II) system at 30 ± 0.1°C. Concentration conditions: $[H_2SO_4]$ = 2.0 M; $[MnSO_4]$ = 0.005 M; $[KBrO_3]$ = 0.05 M. (*a*) Citric acid (0.05 M); (*b*) malic acid (0.05 M) + citric acid (0.05 M).



cates that the oscillations are of malonic acid type. The only difference between these two systems is in the number of oscillations. The presence of malic acid decreases the number of oscillations of the malonic acid system. Here, though the oscillations are controlled predominantly by malonic acid as the substrate, malic acid also participates in the reaction under the concentration conditions employed. This results in a decrease in the concentration of bromate, leading to an unfavourable concentration ratio of bromate to substrate at 9.5 min duration and a premature termination of oscillations. These observations can be substantiated on the basis of the relevant steps of the overall reaction involving the formation of Mn(III) and bromine (steps [1] and [2]) as well as their consumption (steps [3] and [4]). The unfavourable ratio of bromate to substrate disfavours steps [1] and [2], which would otherwise have resulted in the up reaction. This is further supported by the restart of oscillation by the addition of bromate at the 9.5 min mark. Thus this system represents an example of interrupted independent oscillations, where malonic acid mainly controls the nature of oscillations and the interruption is due to an effective decrease in the relative concentration of bromate.

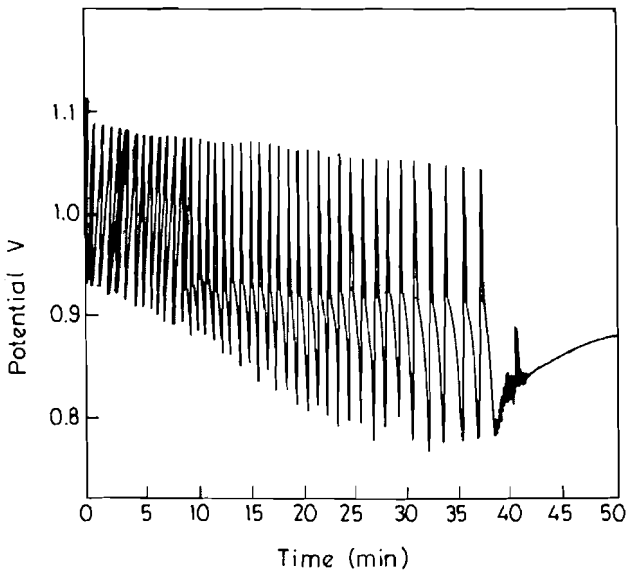
The oscillatory behaviour of the system with 0.1 M malonic acid alone is characterized by a smaller time per oscillation due to an enhancement in the formation and consumption of bromine as well as of Mn(III). The solution containing 0.05 M

Table 2. Oscillatory characteristics with malic acid and malonic acid.[a]

Substrate	[S] M	Number of oscillations	Potential (V vs. SCE) Base value	Potential (V vs. SCE) Peak value	Amplitude (V)	Time per oscillation (min)	Duration (min)
Malic acid	0.05	40	0.775	1.050	0.275	1.00	40.0
Malonic acid	0.05	39	0.825	1.010	0.185	0.45	17.5
Malic acid + malonic acid	0.05 + 0.05	22	0.825	1.010	0.185	0.45	9.5
	0.025 + 0.025	39	0.825	1.020	0.195	0.45	17.5

[a][$KBrO_3$] = 0.05 M; [H_2SO_4] = 2 M; [$MnSO_4$] = 0.005 M; temperature = 30 ± 0.1°C.

Fig. 2. Oscillatory behaviour of bromate–Mn(II) system at 30 ± 0.1°C. Concentration conditions: [Malic acid] = 0.05 M; [$KBrO_3$] = 0.05 M; [$MnSO_4$] = 0.005 M; [H_2SO_4] = 2.0 M.



of the mixed substrate (0.025 M each) leads to an oscillatory behaviour identical with that of 0.05 M malonic acid alone. This behaviour can be termed as independent. The system behaves as if it contains only malonic acid.

(iii) Malic acid and cyanoacetic acid/maleic acid/acetic acid

In this set of experiments the second constituent, unlike malic acid, does not act as a substrate under the concentration conditions indicated in Table 3 and presented in Fig. 4. In all three systems the presence of the second substrate introduces an induction period, and decreases the duration and the number of oscillations. The second constituent is presumably involved in the following steps of the overall reaction.

[5] $BrO_3^- + HBrO_2 + H^+ \rightleftharpoons 2BrO_2^\bullet + H_2O$

[6] $BrO_2^\bullet + S \rightleftharpoons HBrO_2 + S_{ox}$

(S = substrate or added constituent; S_{ox} = oxidized product)

The course of the reaction involves steps [1]–[4] when malic acid is a single substrate. The inclusion of any one of the second constituents leads to a predominance of step [6] over steps [3] and [4]. This leads to a delay in the onset of oscillations and is manifest as an increase in the induction time as well as a decrease in the number of oscillations and in duration, resulting in partial inhibition. The reaction involving the second substrate in step [6] leads to a depletion in the bromate concentration in a non-oscillatory reaction as a result of which there is premature cessation of oscillations with smaller number and duration. This is confirmed by the restart of oscillation on addition of potassium bromate after the oscillations cease.

The system employing 0.1 M of the second substrate does not show oscillatory behaviour as with 0.05 M. Further, the system containing 0.05 M of the mixed substrate (0.025 M each) does not exhibit oscillatory behaviour. This is presumably due to high concentration of potassium bromate leading to consumption of substrate in a non-oscillatory reaction. This is substantiated by the fact that the system oscillates when the concentration of potassium bromate is reduced to 0.025 M.

(iv) Malic acid and tartaric acid/oxalic acid

The addition of either tartaric or oxalic acid to malic acid results in a total inhibition of oscillations. The potential remains constant at 1.01 V (vs. SCE) corresponding to the peak potential region. In these instances step [6], involving the consumption of substrate/added constituent, is totally overwhelming. The extent of reactions [3] and [4] is quite insignificant under these conditions, resulting in complete inhibition of oscillations.

It is interesting to note that the system exhibits oscillatory behaviour in a solution containing 0.05 M potassium bromate and 0.05 M mixed substrate (0.025 M each). The system changes from one of complete inhibition at 0.1 M mixed substrate to one of partial inhibition at a concentration of 0.05 M of mixed substrate resulting from a favourable concentration ratio of bromate to substrate.

Conclusion

A study of the B–Z reaction with mixed substrates provides valuable information regarding the key role of the substrate in the overall reaction. Different combinations of the substrates,

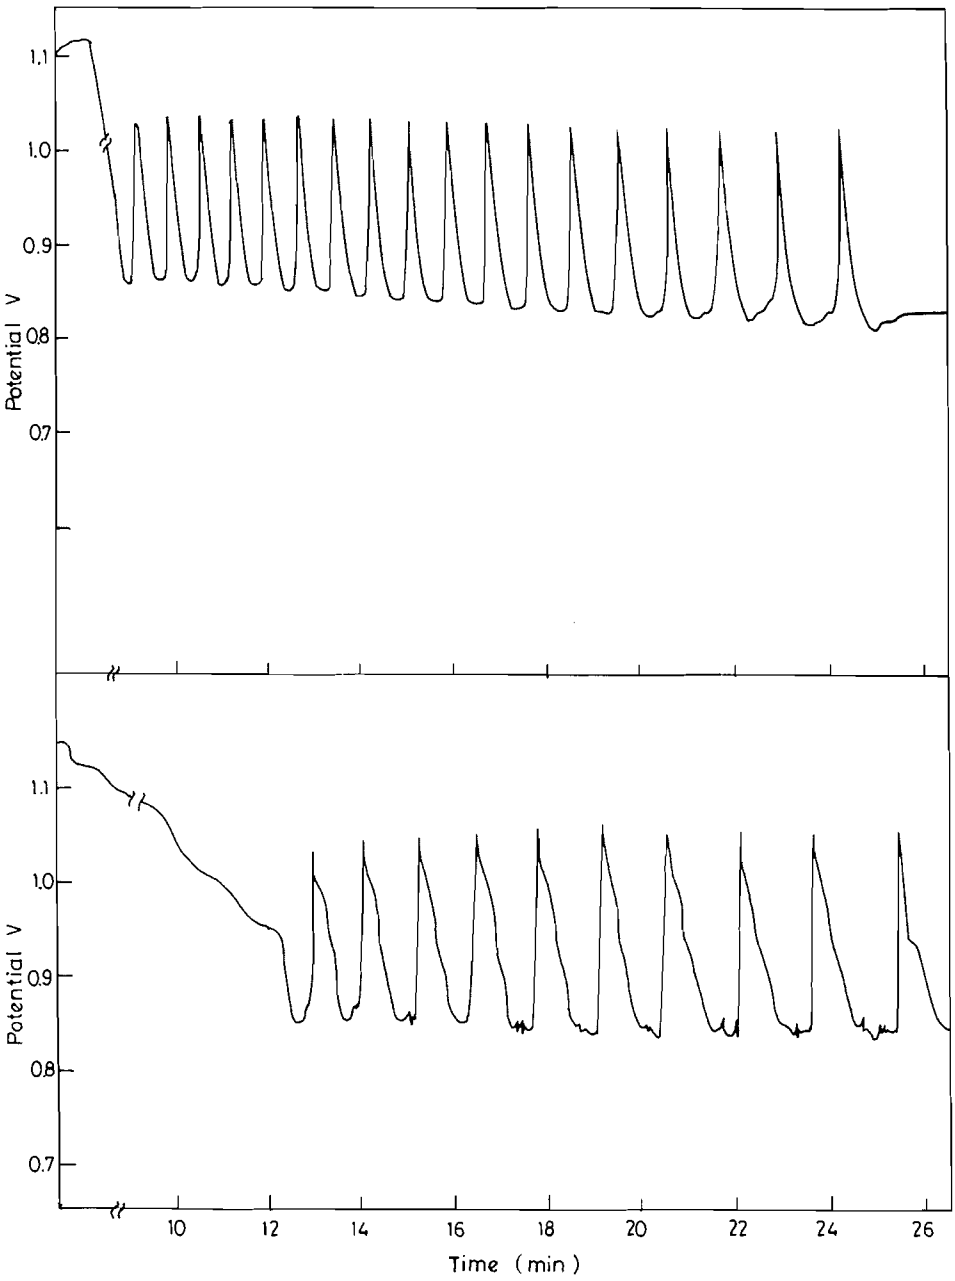
Fig. 4. Oscillatory behaviour of bromate–Mn(II) system at 30 ± 0.1°C. Concentration conditions: $[H_2SO_4]$ = 2.0 M; $[MnSO_4]$ = 0.005 M; $[KBrO_3]$ = 0.05 M. (*a*) Malic acid (0.05 M) + cyano acetic acid (0.05 M); (*b*) malic acid (0.05 M) + maleic acid (0.05 M).



malic acid being common, provide different types of oscillatory behaviour of the system. The resultant pattern of behaviour is mainly governed by the reactivity of the second substrate in relation to malic acid. The behaviour of these systems can be well understood in the light of the relevant steps involved in the overall reaction.

SCF-MO computational analysis of the geometric conformation and charge distribution in picric acid and alkali picrate salts

Zbigniew Zimpel, Barbara R. Nelson, and John A. Weil

Abstract: SCF-MO computations were employed in a study of picric acid, the −1 picrate ion, and Li, Na, and K picrates. Atomic coordinates from crystallographic structural analyses were used as initial parameters in the computation of the minimum-energy conformations of each free molecule at the 6-31G level. The Mulliken charge numbers for each atom in the optimized model molecules were calculated at the 6-31G** level. The induction and resonance effects of the OX group (X = H, Li, Na, K) on the trinitrophenyl ring are discussed. It is demonstrated that molecular (electron) isodensity surfaces (MIDCOs) describe charge-density results nicely compatible with the point Mulliken charge numbers.

Key words: picrates, SCF-MO, charge distribution.

Résumé : On a utilisé des calculs d'OM en champ auto-cohérent pour étudier l'acide picrique, l'ion picrate et les picrates de Li, Na et K. On a utilisé des coordonnées atomiques provenant d'analyses cristallographiques de structures comme paramètres initiaux dans les calculs des conformations d'énergies minimales de chacune des molécules libres au niveau 6-31G. Opérant au niveau 6-31G**, on a calculé les nombres de charge de Mulliken des molécules modèles optimisées. On discute des effets d'induction et de résonance des groupes OX (X = H, Li, Na, K) sur le noyau trinitrophényle. On a démontré que les surfaces d'isodensité électronique au niveau moléculaire décrivent bien l'adéquation entre les résultats de densité de charge et les nombres de charge de Mulliken.

Mots clés : picrates, OM en champ auto-cohérent, distribution de charge.

[Traduit par la rédaction]

Introduction

1-R substituted 2,4,6-trinitrobenzene derivatives (1-R-TNB) undergo nucleophilic aromatic substitution reactions that proceed via the two-step S_NAr addition–elimination mechanism shown in eqs. [1] and [2]. In the first step the nucleophile Nu^- attacks the electron-deficient ring and forms the σ-bonded species **1** (a σ adduct) in which $C_{(1)}$ is rehybridized from sp^2 to sp^3. The nucleophile can attack either at $C_{(1)}$ to produce a 1,1-bonded anion or at $C_{(3)}$ ($C_{(5)}$) to give a 1,3-bonded anion.[3] In the second step the aromatic ring is restored by expulsion either of R^- to yield the substitution product **2** (eq. [2]) or of Nu^- to regenerate the starting material (1).

The presence of the three electron-withdrawing nitro groups situated *meta* to each other on the phenyl ring is believed to promote the formation of **1** in two ways. First, replacement of hydrogen atoms by such groups enhances the rate of nucleophilic attack on the aromatic carbon ring of the molecule by withdrawing electron density from the originally electron-rich ring, via induction and resonance. Second, it increases the stability of **1** by delocalizing the −1 charge initially on the attacked aromatic ring into the three nitro groups. The increase in stability of **1** decreases the rate of decomposition of the σ adduct, back to the reactants or to product **2**. The stabilizing effect of the nitro groups, coupled with the use of 1-R-TNBs in which R^- is a poor leaving group, enables discrete and relatively stable σ adducts to form.

Figure 1 shows what are believed to be the most significant

types of resonance structures in 1-R-TNB for activation of the ring toward nucleophilic substitution. Note that the shifted electron density is concentrated on the nitro oxygens and that electron density is withdrawn primarily from carbons at positions 1, 3, and 5. It is evident from resonance structure **2** that, if R is electron withdrawing, $C_{(1)}$ will be further activated to nucleophilic attack.

In our experimental research on the formation and reactions of σ adducts of 1-R-2,4,6-trinitrobenzenes,[4] we were curious about the quantitative extent to which the benzene ring is activated by the nitro groups and by R, and how the identity of R affects this activation. One 1-R-TNB compound in which we are specifically interested is picric acid. As is strongly indicated in both our experimental studies and in the literature (3, 4), it is the picrate –1 anion,[5] and not the picric acid molecule, that is attacked by the nucleophile to form the σ adduct. One commonly asked question regarding this reaction is: why does a negatively charged nucleophile attack the negatively charged picrate anion? The generally given qualitative answer is that the –1 charge on the picrate anion is withdrawn into the three nitro groups to such an extent that the ring remains activated (π-electron deficient), albeit somewhat less so than in the neutral picric acid molecule.

To obtain a more quantitative measure of ring activation in the picrate anion and to determine the charge distribution in the molecule, we performed self-consistent-field molecular orbital (SCF-MO) computations on picric acid, on the isolated picrate anion, and on three alkali picrates (Li, Na, and K). The three different picrate salts were studied to determine what effect(s) the identity of the cation has on the geometric conformation of and charge distribution in the anion.

As will be shown quantitatively, the presence of electron-withdrawing groups (such as NO_2 and OX (X = H, Li, Na, K)) results in considerable withdrawal of π-electron density from the phenyl ring in the molecules studied. Such withdrawal is expected to increase the susceptibility of the ring to nucleophilic attack, as is observed experimentally.

Methods and results

SCF-MO computations using the Gaussian-92 package (6) were employed in the study of picric acid and its derivatives, namely the picrate anion and the alkali picrates, respectively, represented by $C_6H_2O(NO_2)_3^-$ and $C_6H_2O(NO_2)_3X$ with X = H, Li, Na, or K. The optimization of nuclear configuration (i.e., nuclear geometry defined in terms of internuclear distances, angles, and dihedral angles) was generally performed using the 6-31G split-valence basis set of atomic orbitals. In the geometry optimization of potassium picrate, the single-valence (SV) basis set of contracted AOs {63311/53680} of the ^2S ground state of potassium energy, described by Schäfer et al. (7), was employed. As was pointed out in ref. 7, the expansion of the SV basis set to a double-zeta (DZ) basis set does not result in a significant improvement of the atom energy. A triple-zeta-type basis (which leads to a slightly more accurate value of the ground-state potassium atom) is far too large for our computational capabilities.

The atom-numbering scheme for the substituted trinitrobenzene molecule is shown in Fig. 2. The crystallographic atomic coordinates were used as the initial parameters in calculating the minimum-energy conformations of model picric acid (8) and potassium picrate (9). The coordinates for potas-

[4] Our experimental research is primarily concerned with: (*i*) identifying the products (usually σ adducts but not necessarily so (2)) formed in the reaction between 1-R-TNBs and the acetone enolate and (*ii*) the reaction of these products with protons in acidic peroxide solution (B.R. Nelson and J.A. Weil, to be published). We found that the identity of the product(s) formed in these two reactions depends on the identity of R. Some of the properties of R that appear to determine the reaction path include size, electronegativity, hydrogen-bonding ability, and acidity.

[5] With a pK_a of 0.3 (5), picric acid is assumed to be 100% dissociated in the aqueous basic solutions necessary for the formation of the σ adduct. The picrate ion is the only trinitrophenyl species observed in the room-temperature ^1H NMR (300 MHz) spectrum of the initial reaction mixture.

Table 1. The definition of the symbols representing the structural parameters listed in Tables 2–5. The symbols r, r', and d are bond lengths, α and α' bond angles, and β, β', β_1, ..., $\beta_{6'}$ dihedral angles. Symbols $A_{(i)}$ (i = 1, 2, ...) represent the sequentially bonded atoms. The symbol X represents H, Li, Na, or K.

sium picrate were used as the initial structural data in the optimization of both lithium and sodium picrate, for which no crystallographic diffraction data are reported in the literature.[6] The optimized geometry of the picrate anion was derived starting from the data for the potassium salt.

The relative position of each atom in the studied molecules is reported in standard internal molecular coordinates (bond lengths, bond angles, and dihedral angles[7]). These parameters are defined in Table 1 and include the definition of the position with respect to the rest of the molecule of X and $O_{(1)}$, as well as the rotation angles with respect to the carbon-ring plane of the three nitro groups. The relevant initial crystallographic structural parameters are given in Table 2. The calculated values for the 6-31G/6-31G** optimized structural parameters for picric acid, the picrate ion, and the alkali picrates are given in the upper part of Table 3. The calculated values for picric acid and lithium picrate from all three levels of optimization are given in Tables 4 and 5, respectively.

Whereas the geometry was optimized at the 6-31G level, polarization functions (p and d orbitals) were added to this basis to compute the Mulliken charges on individual atoms.

[6] No references for lithium picrate or sodium picrate were found in the Cambridge Structural Database.

[7] The internuclear dihedral angle Δ for the atoms A_a, A_b, A_c, and A_d is defined as the angle between the planes defined by atoms A_a, A_b, A_c, and atoms A_b, A_c, A_d, with atoms A_b and A_c sharing the planes ($-180° \leq \Delta \leq 180°$). The sign is positive if the movement of the vector $A_b \rightarrow A_a$ towards the vector $A_c \rightarrow A_d$ is a right-handed screw motion. The various dihedral angles in the molecules discussed herein are designated β, β', β_1, β_2, $\beta_{2'}$,...., $\beta_{6'}$

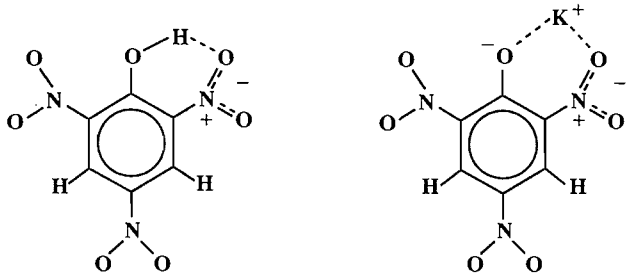
Fig. 3. Chemical structures showing: (*a*) hydrogen bonding in picric acid, and (*b*) ionic bonding in potassium picrate.



(a) (b)

This level of computation will be referred to as the 6-31G/6-31G** level. The 3*p* polarization function computed by Wachters (10) was also added to the SV set of AOs for potassium (7). It is widely agreed that while the molecular geometry is relatively less sensitive to the choice of an appropriate basis set of AOs, the calculated energy and charges are strongly dependent on this basis. This is demonstrated in Tables 4 and 5, where the structural data and charge numbers of the picric acid and lithium picrate molecules, obtained at the 6-31G**, 6-31G/6-31G**, 6-31G, and STO-3G levels, are shown. One can see that the structural parameters obtained at the 6-31G** and 6-31G levels are very similar. However, the atomic charges computed at the 6-31G** level are significantly different from those obtained at the 6-31G level. Because the computations performed at the 6-31G/6-31G** level for picric

acid and lithium picrate produce results very similar to those obtained at the pure 6-31G** level, and because full optimization of the geometry of sodium and potassium picrates at the 6-31G** level would be extremely time consuming, performing the computations at the 6-31G/6-31G** level is justified.

The electrical charge distribution[8] for each molecule in the optimized configuration is given in the lower part of Tables 3–5. Consideration both of structural parameters and of charge distribution allows address of such topics as the competition between the inductive effects of the nitro groups and of the oxygen atom at $C_{(1)}$, the relationship between the molecular conformation and the charge distribution on the molecule, the correlation between the charge on the carbon ring and the reactivity of the ring to nucleophilic attack, and the nature of the chemical bond between the alkali cation and the picrate anion.

To better understand how the presence and position of one or more nitro groups on the benzene ring affect the charge distribution in the molecule, model benzene, chlorobenzene, nitrobenzene, and TNB molecules were also optimized (6-31G/6-31G**) using typical bond lengths (11) rather than crystallographic data as initial input data. Optimization of these model molecules yielded planar conformations to within computational accuracy, with all bond angles close to 120°. Semi-empirical MO calculations on nitrobenzene by Matsunaga et al. (12) also indicate that the planar conformation is the most stable. The nitrobenzene model molecule with the nitro group arbitrarily fixed in an orientation perpendicular to the phenyl plane was also optimized to investigate the influence of the rotation of a nitro group on the relative magnitudes of the inductive and resonance effects. The charge distributions for benzene, the two nitrobenzene molecules, and TNB are depicted in Fig. 4.

Another type of analysis of the configuration of nuclei and the electron charge-density distribution can be carried out using charge-density maps. Such a display utilizes partially integrated electron probability densities derived from our SCF MO wave functions (13). The maps provide for visual techniques demonstrating the main features of the molecular geometry and its electron charge distribution. In the present contribution, we have produced molecular isodensity surfaces (MIDCOs) (14, 15) of the electron charge-density maps for picric acid (Fig. 5) and potassium picrate (Fig. 6). These maps were computed using the RHOCALC computer program (16).

Discussion

Part A. Mulliken point charges

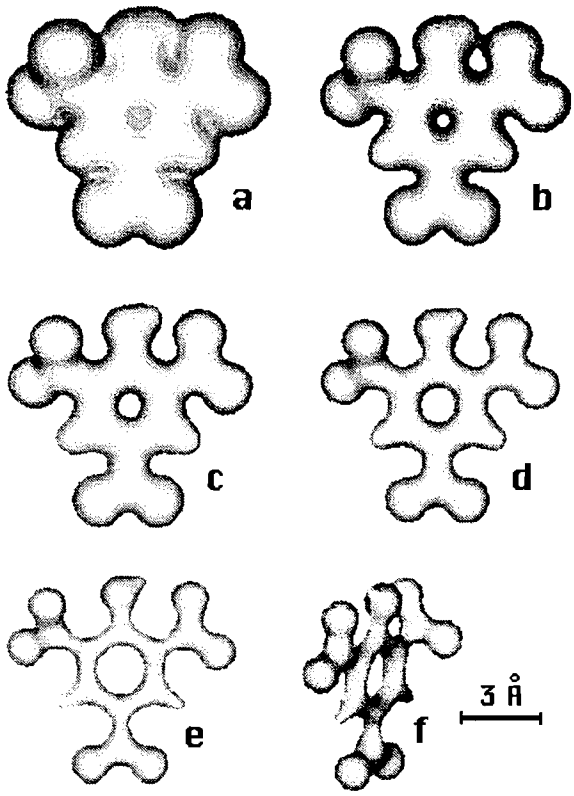
The following discussion of the optimized 1-R-TNB molecules is primarily concerned with the conformational geometry of, and the charge distribution in, each molecule. As will be shown, the two primary structural factors that influence both of these properties are: (*i*) the identity of the atom X, and (*ii*) the orientation and position of the nitro groups relative to X and to each other. There are three interrelated properties of X that are important: (*i*) its size, (*ii*) its ability to form intramolecular bonds, and (*iii*) its electron-withdrawing properties.

As noted above, the optimized configuration of the TNB molecule is planar, i.e., the ring is planar and the three nitro groups are coplanar with the ring. A functional group R substituted for one of the protons in TNB may interact with the two adjacent nitro groups, causing these adjacent nitro groups to rotate so that they are no longer coplanar with the ring. The degree to which rotation occurs is related to the size of R, the charge on R, and possibly other relevant factors such as intramolecular hydrogen bonding.

The presence at $C_{(1)}$ of groups such as OH that can hydrogen-bond with oxygens on the adjacent nitro groups tends to restrict rotation of the bonded nitro group. For example, even though one would expect rotation of both *ortho* nitro groups due to electrostatic repulsion between $O_{(1)}$ and the nitro oxy-

[8] The electrical charge on each atom is derived using Mulliken population analysis. The charge is presented as a "charge number," a unitless value calculated by dividing the electrostatic charge on the atom by the absolute value of the charge on an electron. Although the concept of a point atomic charge never exactly represents reality, it provides a quick and computationally inexpensive insight into molecular electronic charge-density distribution.

Fig. 5. Five top views and one side view of MIDCOs for picric acid at ρ_0 equal to (a) 0.01, (b) 0.03, (c) 0.05, (d) 0.1, (e) and (f) 0.2. The boundary density ρ_0 is expressed in $Å^{-3}$.



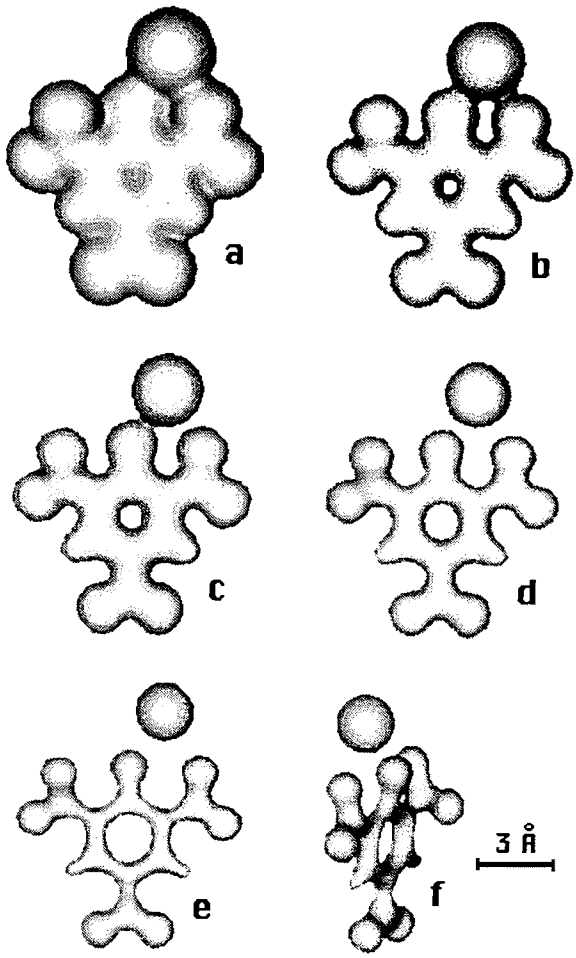
gens, the formation of the hydrogen bond between $H_{(1)}$ and $O_{(2)}$ in the picric acid molecule (Fig. 3*a*) forces the $N_{(2)}$ nitro group to be coplanar with the ring. Only the $N_{(6)}$ nitro group is rotated. Similarly, the picrate salts would be expected to form intramolecular ionic bonds between the cation X^+ and $O_{(1)}$ and $O_{(2)}$ (Fig. 3*b*), which would result in similar restricted rotation of the $N_{(2)}$ nitro group.

The charge distribution in 1-R-TNB compounds is significantly influenced by the inductive and resonance effects of the three nitro groups, by the electron-withdrawing (inductive) and (or) the electron-donating properties of R, and by the extent of nitro group rotation due to steric and electrostatic effects and intramolecular hydrogen bonding or ionic bonding. The effects on the molecular charge distribution of the number of nitro groups attached to the ring, their relative position on the ring, and their rotation angle with respect to the ring plane are illustrated by comparing the computed charge distributions in the benzene, nitrobenzene, and TNB molecules, shown in Fig. 4.

In benzene, which has D_{6h} ground-state symmetry, the charge number for each carbon atom is −0.148 and for each hydrogen atom +0.148. The ring charge number, Q_{ring},[9] is −0.888, as shown in Fig. 4. Replacing one ring hydrogen with a nitro group to form nitrobenzene results in the withdrawal of electron density from the phenyl ring to the nitro group via

[9] $Q_{ring} = \sum_{i=1}^{6} Q_{C_{(i)}}$ is the charge number of the carbon ring for the 1-R-2,4,6-trinitrobenzenes.

Fig. 6. Five top views and one side view of MIDCOs for potassium picrate at ρ_0 equal to (a) 0.01, (b) 0.03, (c) 0.05, (d) 0.1, (e) and (f) 0.2. The boundary density ρ_0 is expressed in $Å^{-3}$.



both induction and resonance. Maximum resonance withdrawal occurs when the nitrogen *p* orbital containing the lone pair of electrons is parallel with the π-*p* orbital of the attached ring carbon so that maximum overlap can occur. Resonance withdrawal of electron density in nitrobenzene occurs primarily at the *ortho* and *para* positions.

If the nitro group is coplanar with the ring (the angle β_1 of rotation of the nitro group equals 0°), charge can be visualized to be withdrawn by both induction and resonance. Comparison of the charge (Q_ϕ = +0.445)[10] on the C_6H_5 group in planar nitrobenzene (Fig. 4) with that (Q_ϕ = −0.148) on the phenyl group in benzene indicates the extent of electron withdrawal by the nitro group *via* both induction and resonance (Fig. 4). All the ring carbons experience a decrease in electron density, with $C_{(1)}$ showing the greatest change (from −0.148 to +0.140). The carbons *ortho* and *para* to the nitro group experience the next largest withdrawal.

If, however, the plane of the nitro group is perpendicular to the plane of the ring (β_1 = 90°), one expects electron withdrawal primarily via induction, since then there is no effective *p* orbital overlap. Figure 4 gives the charge distribution for the

[10] Q_ϕ is the sum of the charge numbers for the six carbons plus those of the five hydrogens.

Table 6. The charge number Q_{ring} for the carbon ring in picric acid, the picrate −1 ion, the picrate salts, and 2,4,6-trinitrobenzene.

	Picric acid	Picrate −1 ion	Li picrate	Na picrate	K picrate	Trinitrobenzene
Q_{ring}	+0.829	+0.548	+0.811	+0.761	+0.720	+0.297

nitrobenzene model molecule in which $\beta_1 = 90°$ and Q_ϕ = +0.431. The data show that electron withdrawal is primarily from $C_{(1)}$. Also the $C_{(4)}$ carbon atom "attracts" some electron density, increasing the electronic charge gradient on the phenyl ring. From the comparison of the charge distribution on the C_6H_5 portion of each nitrobenzene molecule, one can see that rotation of nitro group primarily modulates the inductive effect while the resonance effect varies relatively little.[11] Similar results were obtained by Hehre et al. (17) using the STO-3G basis set.

In TNB, where three nitro groups are *meta* to each other, resonance withdrawal of electron density is reinforced at $C_{(2)}$, $C_{(4)}$, and $C_{(6)}$, since each of these carbon atoms is *ortho* to two nitro groups and *para* to one. The charge number on each of these carbons is +0.103, as compared to −0.100 in nitrobenzene ($\beta_1 = 0°$) and −0.148 in benzene. The total charge number Q_{ring} on the carbon ring in TNB is +0.297, as compared to −0.511 in nitrobenzene and −0.888 in benzene. Thus the presence of three nitro groups on the phenyl ring activates the ring to nucleophilic substitution by withdrawing electron density from the carbon ring, giving it a positive charge.[12]

In picric acid the intramolecular hydrogen bond between $H_{(1)}$ and $O_{(2)}$ causes the $N_{(2)}$ nitro group to be coplanar with the phenyl ring. The $N_{(6)}$ nitro group is twisted ~38° out of plane.[13] The difference in the calculated charge numbers at $C_{(2)}$ (+0.077) and $C_{(6)}$ (+0.097) is the direct result of the difference in the rotation of the $N_{(2)}$ and $N_{(6)}$ nitro groups. As was shown in Fig. 4, rotation of the nitro group resulted in an increase in positive charge on the attached ring carbon. It is postulated that this increase is the result of the loss of back-bonding of the unshared electron pair on the nitro nitrogen when the nitro group is rotated.

Optimization of the model picrate −1 ion was performed for use as a reference structure for comparison with picric acid and the alkali picrates. It is recognized that the picrate anion without the presence of the counter-cation does not represent an "actual" species. It does, however, provide a starting point for discussions regarding the effects of the presence of the proton or cation on the conformation of, and the charge distribution in, the neutral molecule and the picrate salts.

In the picrate anion there are two interrelated effects that can cause rotation of the *ortho* nitro groups. These are the steric and electrostatic repulsion between $O_{(1)}$, which exhibits a negative charge number of −0.599, and $O_{(2)}$ and $O_{(6)}$, both of which are at −0.445 (Table 3). The fact that the magnitudes of the charges on $O_{(2)}$ and on $O_{(6)}$ are less than those on the other four nitro oxygens can be interpreted in terms of a stabilizing withdrawal of electron density to these other oxygens, to minimize the electrostatic repulsion. The combination of the steric and electrostatic repulsion results in a 30° twist[14] of the *ortho* nitro groups. Both the *ortho*-nitro groups are twisted to the same side of the planar ring (with $O_{(1)}$ and $O_{(6')}$ above the ring plane) and $O_{(1)}$ lies 10° out of the ring plane on the opposite side ("behind" the ring plane). Thus, the picrate anion has C_s symmetry, with $C_{(1)}$, $C_{(4)}$, and $O_{(1)}$ lying in the reflection plane situated perpendicular to the carbon ring. In picric acid and the picrate salts this symmetry is absent because the proton and alkali cations are not in the symmetry plane.

In the alkali picrates, intramolecular bonding between the cation X^+ and $O_{(1)}$ and $O_{(2)}$ influences the rotation angle of the $N_{(2)}$ nitro group, with the magnitude of this angle directly related to the size of the cation. The lithium ion, the smallest of the alkali cations, is the least distant (0.005 Å) from the $C_{(1)}$-$C_{(2)}$-$C_{(3)}$ plane and is approximately equidistant from $O_{(1)}$ and $O_{(2)}$. The interatomic distances r [Li···$O_{(1)}$] and d [Li···$O_{(2)}$] are 1.763 and 1.842 Å, respectively. These distances are less than the sum of the ionic radii of Li(+1) (0.68 Å (20)) and O(−2) (1.32 Å (20)), indicating an intramolecular bonding. With the larger Na^+ and K^+, the cations are positioned, respectively, 0.133 and 0.334 Å above the $C_{(1)}$-$C_{(2)}$-$C_{(3)}$ plane. To maintain the proper interatomic distances for ionic bonding of each cation to $O_{(1)}$ and $O_{(2)}$, the $N_{(2)}$ nitro group rotates ~10° for Na^+ and ~17° for K^+. As a consequence of this rotation, the dihedral angle β (Table 3) also increases, with the angle of rotation increasing with the size of the cation.

The deviations of the optimized molecular coordinates (particularly r, d, α, β, β_2, and $\beta_{6'}$) from those of the crystallographic data for picric acid and potassium picrate are primarily the result of intermolecular interactions that exist within the crystal but are absent in the free molecule. For example, in the potassium picrate crystal, the K^+ cation is coordinated with eight oxygen atoms (two $O_{(1)}$, four $O_{(2)}$ and two $O_{(4)}$) from four neighboring molecules (9). Similarly, intermolecular hydrogen bonding in picric acid results in a deviation of the optimized molecular configuration from the x-ray determined configuration. However, this interaction

[11] The optimized molecular conformation and the intramolecular rotational barrier of the nitro group in nitrobenzene have been calculated and compared with experimental data by Head-Gordon and Pople (18), who compared the results from 11 *ab initio* Hartree–Fock theoretical models, and also by Matsunaga et al. (12), who found that the semi-empirical (AM1) computations give good agreement.

[12] The π-electron charges for the atoms in TNB were calculated by Wennerström and Wennerström (19) using a modified SCF-MO-PPP (Pariser, Parr, Pople) method.

[13] The fact that the differences between dihedral angles β_2 and $\beta_{2'}$, β_4 and $\beta_{4'}$, and β_6 and $\beta_{6'}$ are not exactly 180° (Tables 3 and 4) is the result of the two oxygens in each nitro group being allowed to rotate independently about their respective C—N bonds during the conformational optimizations.

[14] The 2–4° differences between dihedral angles β_2 and β_6 and angles $\beta_{2'}$ and $\beta_{6'}$ are the result of the small deviations from planarity of the carbon ring.

does not influence the orientation of the nitro group at $C_{(2)}$, which proves that the intramolecular hydrogen bonding between the $H_{(19)}$ and $O_{(2)}$ is much stronger than any intermolecular interaction.

As shown by the data in Table 3, ~ -0.4 of the nominal -1 charge on $O_{(1)}$ of the model picrate anion has been drawn into and redistributed over the trinitrophenyl ring. Comparison of the charge numbers for picric acid and for the picrate ion show that the charge is redistributed primarily to the carbon atoms $C_{(2)}$ and $C_{(6)}$, and to the six nitro oxygens. Introduction of the lithium, sodium, or potassium cation to form the picrate salt shifts the electron density in the isolated picrate anion toward $O_{(1)}$ and $O_{(2)}$, due primarily to the electrostatic attraction of the cation. The electron densities on the other five nitro oxygens in the three picrate salts are less than those on the corresponding oxygens of the picrate anion. The magnitude of the positive charge on the cations confirms the presence of ionic bonding between the cation and $O_{(1)}$ and $O_{(2)}$, in agreement with the interpretation of the crystallographic data reported by Maartmann-Moe (9).

As shown in Table 6, withdrawal of electron density from the carbon ring is significantly greater for picric acid and the alkali picrates than for trinitrobenzene. This is due primarily to the presence of the electronegative oxygen atom $O_{(1)}$ in the former molecules. As expected, as the size of X increases, the magnitude of the positive charge on the carbon ring decreases, i.e., X withdraws less electron density from the ring. This is consistent with the corresponding increase in the magnitude of the charge numbers for X, as shown in Table 3.

Part B. Electron charge densities

In the second part of this paper we demonstrate that the electronic charge densities yield useful information about the character and strength of chemical bonds, and the configuration of atomic nuclei. Gratifyingly, this information can easily be graphically displayed, allowing conclusions to be derived from the pictorial representation of the electron charge distribution. Since the charge density is a function on a 3-dimensional space, it cannot be shown as a functional (4-dimensional) graph. The best way to plot a charge-density map is by using the molecular isodensity surfaces (MIDCOs). The topological features of these surfaces can then be interpreted in terms of the character and strength of chemical bonds. In general, there is a strong covalent bond between two atoms if they remain inside a connected isodensity surface, even at relatively high electron density thresholds. Otherwise, if an isodensity surface splits into two disconnected pieces each containing an atom, the covalent bond between these atoms is considered weak. The more electron charge is concentrated on a molecular group or individual atom, the larger are the connected components of isodensity surfaces surrounding this atom as compared to other groups or atoms. This powerful and very elegant method of analysis, based on the topological features of "Density Domains," was recently proposed and developed by Mezey (14, 15).

In Figs. 5 and 6, sets of six MIDCOs for the picric acid and potassium picrate molecule are presented. The electron charge-density function $\rho(\boldsymbol{r})$ is defined as the fractional number of electrons within a small volume element δV at $\boldsymbol{r}$ divided by δV (in $Å^3$). We are concerned with isodensity surfaces for given values ρ_0 of ρ. At low density ($\rho_0 = 0.01$) there is one connected surface with no holes for each molecule. However, even at this low density threshold one can see that the characters of the $O_{(1)}$—X and the $O_{(2)}$—X bonds are very different in picric acid while both bonds are more or less equivalent in potassium picrate. This can be observed in every picture in Figs. 5 and 6. In picric acid the first of these bonds is strongly covalent and the second bond is a hydrogen bond. In potassium picrate both bonds are much less covalent and the surface surrounding the potassium atom becomes disconnected below $\rho_0 = 0.1$. This fact and the spherical shape of the surface surrounding the potassium atom suggest that the bond type for both discussed bonds is ionic. The $O_{(1)}$—K bond is slightly more covalent than the $O_{(2)}$—K bond but the difference is only quantitative and not very significant. The size of the hydrogen atom and the intramolecular hydrogen bond explain why the nitro group at $C_{(2)}$ is coplanar with the phenyl ring. The much larger potassium ion repulses the two oxygen atoms $O_{(1)}$ and $O_{(2)}$ out of the phenyl ring plane. However, it appears quite likely that there is some interaction between the potassium atom and the oxygen atom $O_{(6)}$, resulting in a decrease of the angle by which the nitro group at $C_{(6)}$ is twisted about the $C_{(6)}$—$N_{(6)}$ bond.

Conclusions

It is evident from the data that the presence of electron-withdrawing groups such as NO_2 and OX (X = H, Li, Na, K) results in inductive and resonance withdrawal of the π-electron density from the phenyl ring into these electron-withdrawing groups. This shift in electron-charge distribution results in positive charge numbers Q_{ring} on the phenyl ring of TNB, picric acid, and the alkali picrate salts (Table 6). This means that the phenyl ring becomes more susceptible to nucleophilic attack.

The alkali-metal – picrate-group bonds are shown to be highly ionic with the picrate anion exhibiting a negative total charge number (< -0.8: Table 3). Therefore, as was suggested by the x-ray study of the potassium picrate crystal (9), one can treat the picrate group in alkali picrates as an independent species, the picrate anion. The computations carried out for a model free picrate anion give results that are reasonably close to those obtained for the alkali-metal salts. This fact additionally supports the conclusion about the ionic character of the alkali-metal – picrate-group bond.

Comparison of the charge numbers on the phenyl ring for the alkali picrates and for picric acid shows that the ionic character of the O—X bond in alkali picrates, resulting in more electron withdrawal onto the picrate group, does not significantly alter their Q_{ring} values as compared to that of picric acid. This is attributed to the stabilizing effect of the nitro groups, which have enough capacity to withdraw the excess electron charge from the phenyl ring. Similarly, the identity of the alkali–metal ion in the alkali picrates has only a moderate effect on the molecular configuration and charge distribution, which thus do not lead to any substantial redistribution of charges on the carbons of the phenyl ring (Table 3). Therefore, the identity of the atom X should not markedly influence the susceptibility of the phenyl rings to nucleophilic attack.

In situ preparation of cyclopropanones with the bicyclo[3.1.0]hexan-6-one skeleton (substituted examples of the Loftfield intermediate). Confirmation of a very facile intramolecular alkyl cyclopropanone – dienol rearrangement

T. S. Sorensen and F. Sun

Abstract: Four substituted bicyclo[3.1.0]hexan-6-ones (cyclopropanones) were prepared *in situ*, starting from the corresponding 2,6-dibromocyclohexanone and reductively removing the bromine atoms with the organometallic salt $PPN^+Cr(CO)_4NO^-$. The reaction is essentially instantaneous at −78 or −100°C, and can be conveniently carried out in an NMR tube for easy characterization of the products by low-temperature ^1H and ^{13}C NMR spectroscopy. The 1,5-di-*tert*-butyl and 1-*tert*-butyl analogs were thermally stable to ca. 0°C, but the 1-*tert*-butyl-5-methyl and 1-*tert*-butyl-5-ethyl derivatives were extremely labile, rearranging at ca. −80°C into a cross-conjugated enol, where the methyl (or ethyl) substituent was converted into an exomethylene group. These enols were also characterized as *in situ* species using ^1H and ^{13}C NMR spectroscopy, and by allowing the enol → α,β-unsaturated ketone rearrangement to take place at about 25°C. The mechanism of the enol formation was investigated using a 1-*tert*-butyl-5-CD_3 analog, and the k_H/k_D ratio for enol formation was determined to be 6 ± 2. From this, the rate-determining step in the enol formation was postulated as a C-H → H-O transfer of a hydrogen atom in a cyclohexyl oxyallyl intermediate. The 1,5-di-*tert*-butylbicyclohexanone shows dynamic ^1H NMR line broadening, the origin of which is also proposed to involve a cyclohexyl oxyallyl intermediate.

Key words: cyclopropanone, oxyallyl, bicyclo[3.1.0]hexan-6-one, dienol, sigmatropic rearrangement.

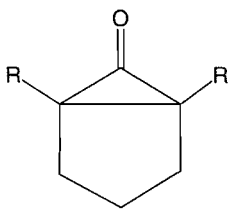
Résumé : On a préparé quatre bicyclo[3.1.0]hexan-6-ones (cyclopropanones) substituées *in situ* à partir des 2,6-dibromocyclohexanones correspondantes, en procédant à l'élimination réductrice des atomes de brome par le sel organométallique $PPN^+Cr(CO)_4NO^-$. La réaction est essentiellement instantanée à −78 ou à −100°C et on peut facilement l'effectuer dans un tube à RMN pour une caractérisation facile des produits par spectroscopie RMN du ^1H et ^{13}C à basse température. Les analogues 1,5-di-*tert*-butyle et 1-*tert*-butyle sont thermiquement stables jusqu'à environ 0°C, mais les dérivés 1-*tert*-butyl-5-méthyle et 1-*tert*-butyl-5-éthyle sont extrêmement labiles qui se réarrangent à environ −80°C pour conduire aux énols à conjugaison croisée dans lesquels les groupes méthyle (ou éthyle) ont été transformés en groupes éxométhylène. On a aussi caractérisé ces énols sous la forme d'espèces *in situ* en faisant appel à la spectroscopie RMN du ^1H et du ^{13}C et en permettant au réarrangement énol → cétone α,β-insaturée de se produire à environ 25°C. On a étudié le mecanisme de formation de l'énol en utilisant un analogue 1-*tert*-butyl-5-CD_3: on a déterminé que la k_H/k_D pour le formation de l'énol est de 6 ± 2. Sur cette base, on en déduit que l'étape qui détermine la vitesse de formation de l'énol doit être un transfert C-H → H-O d'un atome d'hydrogène dans un intermédiaire cyclohexyl oxyallyle. Dans le spectre RMN du ^1H de la 1,5-di-*tert*-butylbicyclohexanone, on observe un élargissement dynamique de la raie dont l'origine implique probablement un intermédiaire cyclohexyl oxyallyle.

Mots clés : cyclopropanone, oxyallyle, bicyclo[3.1.0]hexan-6-one, diénol, réarrangement sigmatropique.

[Traduit par la rédaction]

Introduction

In a classic study involving the early use of a ^{14}C label in studying organic reaction mechanisms, Loftfield (1) discovered in 1950 that the Favorski rearrangement of 2-chlorocyclohexanone proceeded by way of a symmetrical intermediate, postulated to be the cyclopropanone **1** (R=H) (bicyclo-[3.1.0]hexan-6-one).



1 R=H
2 R=CH_3

To date there has been no direct observation of **1**. In a previous study (2), we attempted without success to prepare the 1,5-dimethyl analog **2** by the debromination of **3** at −78°C

Received August 4, 1995.

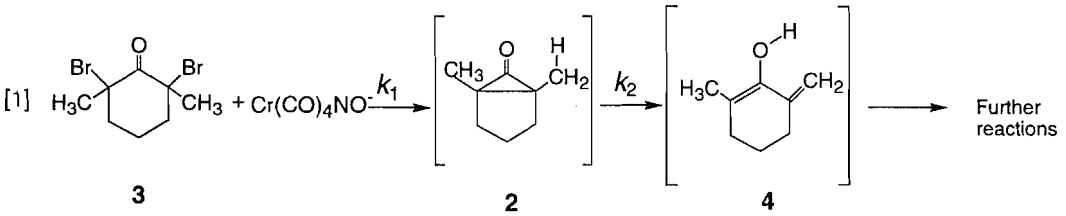
with the reagent $PPN^+Cr(CO)_4NO^-$, a reaction type that worked well with larger rings and with various acyclic systems to produce near-quantitative *in situ* yields of the corresponding cyclopropanones.

In the case of the failed reaction **3** —X→ observable **2**, it was postulated that the cyclopropanone **2** was being formed, but that it was rearranging to a dienol **4** faster than it was being formed in the reaction of the organometallic anion with the dibromide **3**, as shown in eq. [1], where $k_2 > k_1$.



3 **2** **4**

Since **4** (acidic hydrogen) would also be expected to readily react with the $Cr(CO)_4NO^-$ reagent, the actual course and stoichiometry of the reaction was complex. The end result of all this, in terms of reaction products, has been published (2). However, it should be kept in mind that the evidence for **2** was circumstantial since this species was not directly observed.

In retrospect, and assuming that the fast rearrangement of **2** → **4** was taking place, it was apparent that the methyl groups in **2** vs. **1**, far from providing "steric protection" for the molecule, were in fact an Achilles heel allowing for the very facile rearrangement of **2** into the dienol **4** by the C → O shift of a methyl hydrogen. This same process has now been observed by us for a number of cyclopropanones and, although unexplored until recently, is one of the key reasons why cyclopropanones are such reactive molecules.

The obvious solution to the rearrangement problem is to use either tertiary substituents or hydrogen. In this paper, we show that this approach allows one to finally prepare and characterize *in situ* solutions of bicyclo[3.1.0]hexan-6-ones, but it should be emphasized that we have removed only the most urgent of the rearrangement routes available to these molecules and they remain too unstable to isolate in any conventional way.

Nevertheless, an analysis of the NMR spectra of these cyclopropanones does provide considerable structural information and, in addition, dynamic NMR observations with the 2,5-di-*tert*-butyl analog of **1** show that reversible ring opening to the presumed oxyallyl valence bond isomer is a very facile process.

As an added bonus, we have also been able to prepare and characterize *in situ* solutions of bicyclo[3.1.0]hexan-6-ones with one "reactive" substituent (CH_3 or CH_3CH_2) and one tertiary substituent. As expected, these are very labile, rearranging quite cleanly to the corresponding dienol, which can also be completely characterized by NMR spectroscopy as an *in situ* solution species. Using one of these examples (*t*Bu, CH_3) also allowed us to directly measure the large kinetic isotope effect associated with the rearrangement of the cyclopropanone to the dienol.

Results and discussion

In each case, the cyclopropanones **10–13** were generated *in situ* at low temperature in NMR tubes and characterized by both ^1H and ^{13}C NMR, using a procedure previously described (2, 3). The overall reaction is shown in eq. [2]. The starting dibromo ketones **5–9** were easily prepared by direct bromination, and the ketones themselves are either known or accessible by alkylation of 2-*tert*-Bu-cyclohexanone.

All attempts to convert dibromo ketone **9** into a characterizable cyclopropanone were unsuccessful. Some of the cyclopropanone may indeed be formed but, unless the product formation is clean, it is difficult to definitively interpret the experimental *in situ* NMR spectrum. Previously we had attempted[2] to prepare the parent bicyclo[3.1.0]hexan-6–one from 2,6-dibromocyclohexanone, again without success.

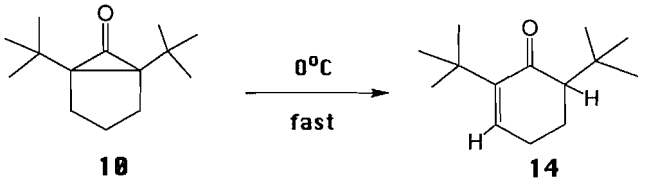
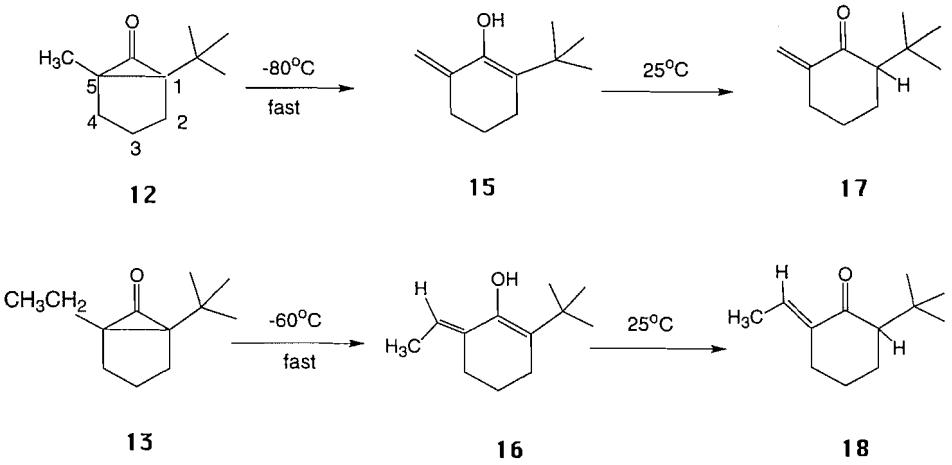
Qualitative stability comparisons of the bicyclo[3.1.0]hexan-6-ones 10–13

Cyclopropanone **10** could be prepared at −78°C in methylene chloride (or CD_2Cl_2) solution. NMR spectra were obtained at intervals from −80 to −10°C, where a clean rearrangement to α, β-unsaturated ketone **14** (4) became rapid. Cyclopropanone **11** solutions were slightly more stable than those of **10**, but **11** rapidly decomposes at 20°C without forming a characterizable rearrangement product, i.e., no single dominant product was formed.



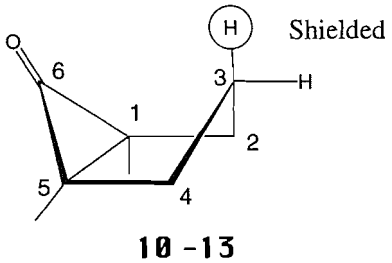
In contrast to **10** and **11**, and as mentioned in the Introduction, cyclopropanones **12** and **13** were very labile. Solutions of **12** in a $CDCl_2F$–CD_2Cl_2 mixture could be prepared at *ca.* −100 to −110°C, and NMR spectra were collected at −95°C. Even under these conditions there was a small amount of the rearrangement dienol formed during a 1 h ^{13}C NMR collection. Cyclopropanone **12** rearranges rapidly at −80°C to give a new species, identified by NMR spectroscopy as the aforementioned dienol **15** (a cross-conjugated enol). Cyclopropanone **13** is slightly more stable than **12**, but also cleanly rearranges to a dienol, in this case the stereoselective formation of **16**.



At about 25°C, dienols **15** and **16** are slowly rearranged to the α,β-unsaturated ketones **17** and **18**, respectively. These stable compounds can of course be isolated and characterized in the normal way. The key advantage of the systems **12** and **13** in probing the overall mechanism of the cyclopropanone rearrangement is that the intermediate dienols are formed at a much faster rate than that of their subsequent ketonization, so that definitive NMR characterization of a "clean" dienol product is possible.

NMR characterization of the cyclopropanones

In the *in situ* reactions corresponding to eq. [2], one first sees that the starting material (dibromo ketone) peaks have completely disappeared and are replaced by those we assign to the cyclopropanone. Since the latter are all alkyl-type hydrogens, the ^1H NMR spectra are not particularly distinctive, although in all cases the H-3 methylene hydrogens of the cyclopentane ring have distinctly different chemical shifts, one appearing at δ 1.78, and the other at 1.05 in **10** (δ 1.85 and 1.18 in **11**; 1.76 and 1.12 in **12**). The unusually high-field position of one of these signals (ranging from δ 1.05 to 1.18) is indicative of a shielding contribution from the carbonyl π bond, which in turn implies a boatlike conformation, as shown below:

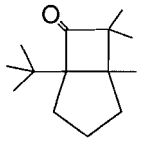


Simple bicyclo[3.1.0]hexanes also have a boat conformation (5). Further evidence for this boat conformation in **10–13** comes from a detailed analysis of the vicinal coupling constants in the cyclopentane ring (see Experimental).

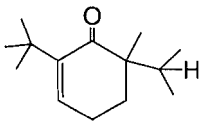
The ^{13}C NMR results are more diagnostic in that the $^{13}C{=}O$ peak is quite deshielded, ca. δ 225–226 ppm in **11–13**. A similar result was previously observed with simple methyl-substituted cyclopropanones (2). Compound **10** is unusual in this series in having a more shielded ^{13}C carbonyl peak (δ 217.0).

Comparison of $Fe_2(CO)_9$ and $Cr(CO)_4NO^-$ for the debromination of α, α′-dibromo ketones

2,6-Dibromo-2,6-di-*tert*-butylcyclohexanone **5** reactions offer a direct comparison between the Noyori reaction (4) for the debromination of α,α′-dibromo ketones and that employed in our work. In benzene solvent, the major product of the $Fe_2(CO)_9$ reaction is compound **19** (80%), with smaller amounts of **20** (3%) and **14** (15%). With $Cr(CO)_4NO^-$, the bicyclohexanone **10** is formed, this rearranging below room temperature to **14**. The $Fe_2(CO)_9$ reaction clearly induces Wagner–Meerwein shifts, which Noyori has attributed to an oxyallyl-O-FeLn$^+$ intermediate (allyl cation character).



19



20

In contrast, we believe that the reactions using $Cr(CO)_4NO^-$ involve a very transitory "free" oxyallyl (see later discussion), which shows no tendency for Wagner–Meerwein rearrangements.

Rearrangement reaction of bicyclo[3.1.0]hexan-6-ones 12 and 13 into dienols 15 and 16

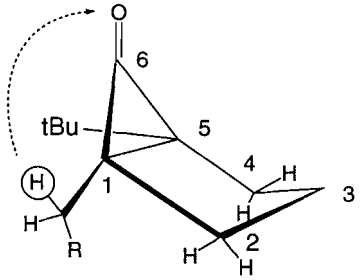
As briefly mentioned, bicyclo[3.1.0]hexan-6-ones **12** and **13** rearrange rapidly at low temperatures to give the dienols **15** and **16**, respectively. The characterization of these dienols involves: (*a*) *in situ* ^1H and ^{13}C NMR spectra that agree well with those expected for these structures. In particular, the exocyclic methylene hydrogens in the ^1H NMR and the alkene carbons, and absence of carbonyl carbon, in the ^{13}C NMR are diagnostic. The -OH is also located as a broad, temperature-dependent chemical-shift peak. These NMR data are given in the experimental section. (*b*) at 25°C, the *in situ* dienols are observed by NMR to rearrange to the corresponding α,β-unsaturated ketones **17** and **18**, respectively, which can be obtained on work-up.

Many simple enols and dienols have been previously characterized as *in situ* species (6, 7). In addition, NMR parameters for our dienols can be compared to those obtained from silyl enol ethers and related silyl dienol ethers (2).

An alkylcyclopropanone → dienol rearrangement, as far as we are aware, represents a previously unrecognized preparative method for obtaining cross-conjugated dienols.

Mechanism of the rearrangement reaction

The rearrangements **12** → **15** and of **13** → **16** formally involve a hydrogen transfer from the α-carbon of the alkyl substituent to the carbonyl oxygen. As sketched below, this hydrogen is not close in space to the carbonyl oxygen in **12** or **13**, and it would therefore seem unlikely that **12** or **13** is directly involved in the hydrogen transfer. One also observes that there are hydrogens on the ring carbons 2 and 4, which have a similar orientation to the carbonyl oxygen, but these ring hydrogens are *not observed* to be involved in dienol formation.



12 R=H

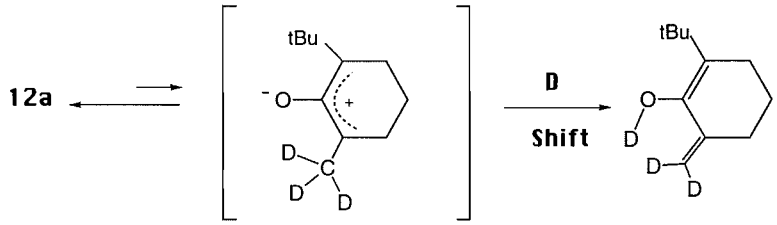
13 R=CH_3

There is considerable indirect evidence that cyclopropanones can interconvert with an oxyallyl by a disrotatory ring opening. In general, these oxyallyl valence-bond isomers are energetically less stable than cyclopropanones, but they can certainly serve as reactive intermediates. The rearrangement reaction, using solutions tenfold different in initial bicyclohexanone concentration, has the same rate within experimental error, showing that the reaction is not bimolecular in either the bicyclohexanone or an oxyallyl intermediate. If the latter is indeed present in very low concentrations, then a bimolecular reaction would be very unlikely. Accordingly, the overall reaction of **12** to **15** can be proposed to proceed as shown in eq. [3], where oxyallyl **19** is the intermediate in which the direct hydrogen transfer from C to O takes place. Note that in the disrotatory formation of the intermediate **19**, the alkyl substituent must end up *syn* to the oxyallyl oxygen atom since the opposite disrotatory mode is sterically impossible. This places the hydrogen on the α-carbon of the alkyl substituent in reasonably close proximity to the oxygen atom, compared to the situation in **12**. Conversely, the ring hydrogens are moved even further away.

[3] 
12 **19** **15**

In the eq. [3] mechanism, either the oxyallyl formation or the H transfer could be rate determining, although the latter possibility seemed much more likely since it was believed that the oxyallyl **19** was actually the first-formed species in the eq. [1] reaction (which "instantly" cyclizes to the cyclopropanone rather than rearranging to the dienol). In previous work (2), it had also been shown that H was preferred over D migration in a system where a competition between these two routes was set up. However, this observation would be expected regardless of whether k_1 or k_2 were rate-determining.

To clear up any doubts, we decided to carry out a k_H/k_D determination, and the rearrangement of **12** to **15** appeared to be ideally suited for this measurement, the rate comparison being between compounds **12** and **12a**. Since NMR spectroscopy was the tool being used to monitor the rearrangement, we prepared solutions in which both **12** and **12a** were present in the same NMR tube. These experiments involved allowing the rearrangement to proceed for a short time at −60 to −80°C and then quickly carrying out a reactant–product analysis at −95°C, where both reaction sets are essentially "quenched." Compounds **12** and **15** were monitored using ^{1}H NMR, and ^{2}H NMR was used for **12a** and **15a** (see Experimental for details). The data can be analyzed (8) to give k_H/k_D even though neither k_H or k_D is directly measured. In practice one obtains multiple values of k_H/k_D for each run by allowing the reaction to proceed and stop several times. The average of all these results gives a k_H/k_D ratio of 6 ± 2.



19a **15a**

The product analysis method being used here is actually better suited for determining smaller k_H/k_D ratios. For example, at the point where 50% of **12** has rearranged, only 11% of **12a** has reacted. Nevertheless, it would be even more difficult to attempt to accurately measure separate k_H and k_D rates, where the individual errors would be magnified in the k_H/k_D ratio.

Isotope effects of the size being observed here can only come from a primary isotope effect where the rate-determining step is the transfer of the hydrogen from carbon to oxygen, i.e., k_2 in eq. [3].

This rearrangement reaction can be considered, under the Woodward–Hoffmann rules (9), as an allowed, thermal, suprafacial sigmatropic rearrangement; i.e., in the Ψ_3 HOMO, both the original carbon terminus and the new oxygen site have in-phase coefficients, as shown in Fig. 1.

Approximate rearrangement kinetics were also determined for the first-order **12** → **15** reaction, k ca. 1×10^{-4} s^{-1}, $\Delta G^{\neq} = 13.5 \pm 1$ kcal/mol at −95°C.

We end this discussion with a minor caveat concerning our mechanism studies. The *in situ* solutions of the bicyclohexanones reported here also contain $Cr(CO)_4NOBr$ (a '"saturated" 18e$^-$ species) and the salt PPN^+Br^-, although some of the latter usually forms a precipitate at the bottom of the NMR tube at the low temperatures being used. It is not feasible to separate the very reactive bicyclohexanones (**12** and **13**) from the by-products, but with other more stable cyclopropanones we have done comparison studies between *in situ* samples containing by-products and solutions without these, and have noted no differences in the reaction rates, for example, the reversible ring-opening reaction of *cis*-di-*tert*-amylcyclopropanone to the corresponding oxyallyl has the same rate in both cases (10). In conclusion, we think it unlikely that either $Cr(CO)_4NOBr$ or PPN^+Br^- could somehow act as a catalyst in the dienol forming reaction.

Dynamic NMR observations involving bicyclo[3.1.0]hexan-6-one 10. Independent evidence for a cyclohexyl oxyallyl intermediate

In principle, a bicyclo[3.1.0]hexan-6-one → cyclohexyl oxyallyl equilibrium reaction could be probed by dynamic NMR techniques. The geminal hydrogen pairs in the cyclopentane ring of our bicyclohexanones are nonequivalent, and this is independent of whether the ring is a boat (preferred) or a chair conformer (in practice these nonequivalent hydrogens also mostly show separate ^{1}H NMR chemical shifts). However, if the bicyclic ring is opened to a cyclohexyl oxyallyl, then a ring conformer flip in this oxyallyl will interconvert geminal CH_2 pairs and result in a single averaged position for these, as illustrated in eq. [4]. for the C2 geminal pair.

[4] 
The reactive bicyclohexanones **12** and **13** do not show any dynamic NMR line-broadening, because they rearrange at quite low temperatures. Analogs **10** and **11** are better possibilities, and **10** does indeed show line-broadening coalescence of a type that agrees perfectly with that expected for the eq. [4] process. The actual line-broadening results, at temperatures −40 to −20°C, are somewhat ephemeral since **10** is irreversibly rearranging at −20°C (see earlier section).

The coalescence temperature for the averaging of the geminal C2–C4 methylene proton peaks in **10** (eq. [4], R = R^1 = *t*Bu) was ca. −20°C, giving $k = 250\ s^{-1}$, $\Delta G^{\neq} = 11.6$ kcal/mol.

To provide further verification of this degenerate exchange in **10**, spin-inversion transfer experiments were carried out, again using the C2–C4 geminal proton peaks (δ 2.50 (dt) and 2.25 (dd)). Experiments were conducted by inverting one or the other of these peaks and then measuring the response to this inversion using the modified Hoffman–Forsén procedure (11). Rate constants of 23 and 8 s^{-1} were obtained at temperatures of −54 and −64°C, $\Delta G^{\neq} = 11.4$ kcal/mol, in good agreement with the line-broadening data.

Cyclopropanone **11** does not show any ^{1}H NMR line broadening up to the decomposition temperature of +20°C ($\Delta G^{\neq}$ > ca. 15 kcal/mol). The large difference between **10** and **11** in the rate of the degenerate process shown in eq. [4] could arise from two factors: (*i*) nonbonded repulsions in **10** between the *tert*-butyl groups result in a destabilization of the cyclopropanone relative to the oxyallyl (at least compared to the situation in **11**) and (*ii*) oxyallyls appear to be stabilized by alkyl substituents (12), there being an extra *tert*-butyl substituent in the oxyallyl from **10**.

Other indirect evidence for a cyclohexyl oxyallyl intermediate

In a previous study (2) it was found that a bicyclo[4.1.0]heptan-7-one and a bicyclo[5.1.0]octan-8-one were considerably slower in undergoing the dienol rearrangement, compared to the (then unseen) bicyclo[3.1.0]hexan-6-one (see Introduction). These observations can be rationalized in terms of relative ring-strain effects. In each case, a strained cyclopropanone moiety is present, but the other ring is cyclopentyl, cyclohexyl, and cycloheptyl in this series. The corresponding oxyallyl (if indeed involved) would be, respectively, cyclohexyl, cycloheptyl, and cyclooctyl. In the bicyclo[3.1.0] case, a slightly strained cyclopentane ring opens to the optimal six-membered oxyallyl while, in comparison, in the bicyclo[4.1.0] situation a stable cyclohexane ring is being opened to a strained cycloheptyl oxyallyl. These opposing effects can rather nicely rationalize the observed behavior, and this provides yet further evidence for the oxyallyl intermediate as a key species in rationalizing the mechanism of the rearrangement.

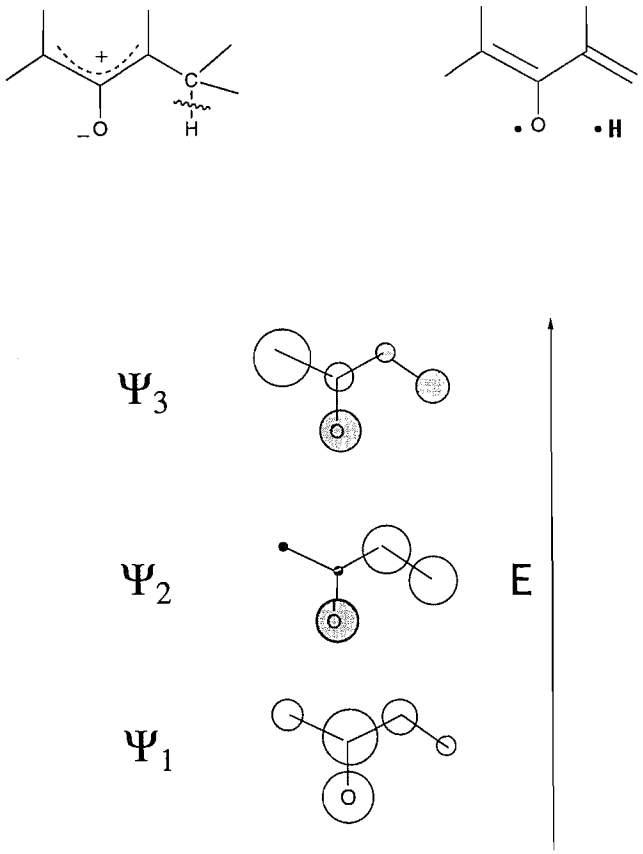
To conclude this section, we have shown that an alkylcyclopropanone→cross-conjugated dienol rearrangement is a very facile process. The evidence indicates that an oxyallyl is the key reactive intermediate in this reaction and that the hydrogen transfer occurs only from a *syn*-substituent on this oxyallyl (obviously at least one hydrogen must be present on the α-carbon of this substituent). The rate-determining step is the hydrogen transfer itself and the kinetic data show that this is an extraordinarily facile shift, considering that a C—H bond is being broken. We hope in the future to model this reaction computationally.

Mechanism of the bicyclohexanone formation

The elegant ^{14}C labelling studies of Loftfield (1) established that the Favorski rearrangement of 2-chlorocyclohexanone proceeded by way of an unseen symmetrical intermediate, postulated by him to be bicyclo[3.1.0]hexan-6-one. However, Loftfield pictured this bicyclohexanone formation as a direct displacement of chloride by the enolate carbon. A few years later, Burr and Dewar (13) pointed out that the first symmetrical species must in fact be the corresponding zwitterionic structure (subsequently known as an oxyallyl) because the cyclohexanone enolate geometry did not permit an internal S_N2 displacement.

In our reactions, we assume that we produce the same initial halo-enolate as is postulated in the Favorski reaction (eq. [5])

[5] 
Fig. 1. Simple Hückel MOs for the 2-oxobuta-1,3-dienyl radical (occupied orbitals only). For the HOMO Ψ_3 orbital, the oxygen and C4 carbon have an in-phase relationship, a condition for an allowed suprafacial sigmatropic shift of the hydrogen atom from carbon to oxygen.



and that this intermediate follows the Dewar proposal to lose halide ion and first give the transient cyclohexyl oxyallyl, the bicyclohexanone forming from the latter by way of an extremely facile ring closure. Thus, in our case, the cyclohexyl oxyallyl is *both* the first-formed dehalogenated intermediate and, ultimately, the source of the bicyclohexanone instability because of a minute equilibrium concentration of this very reactive species.

Our success in preparing and characterizing observable bicyclo[3.1.0]hexan-6-ones stems from several factors:

(*i*) The methodology is very applicable to *in situ* low-temperature NMR determinations. Part of this success lies in the almost instantaneous reaction rate, even at quite low temperatures.

(*ii*) The $Cr(CO)_4NOBr$ by-product shows no interaction with the oxyallyl (or cyclopropanone) oxygen, in contrast to the by-products of some reducing metals (e.g., Zn (14)) or metal carbonyl (e.g., $Fe_2(CO)_9$ (4)) debrominations.

(*iii*) Favorski reaction deprotonation bases (or solvents) are generally nucleophilic towards either the carbonyl group of the cyclopropanone or a terminal carbon of an oxyallyl. In contrast, the anion $Cr(CO)_4NO^-$ appears to be unreactive.

However, we have not yet been successful in preparing the parent ketone **1** using this methodology.

Experimental

GC–MS measurements were performed on a Hewlett–Packard model 5890 gas chromatograph equipped with a 5971A mass selective detector. Split injection was used, employing a 12 m × 0.2 mm i.d. OV-101 column. High-resolution mass spectra were obtained on a Kratos MS-80. NMR spectroscopy was carried out on Bruker ACE-200, AMX-300, and AM-400 instruments (J in Hz, s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet, b = broad. For $^{13}C\{^1H\}$ NMR, multiplicities were determined from DEPT 90 and 135 spectra. 2D NOESY and COSY spectra employed standard pulse sequences.

In situ NMR experiments

The operating procedure has been described in several earlier publications (2, 3). In the present work, cyclopropanones **12**, **12a**, and **13** required a preparation temperature of ca. −100 to −110°C (ethanol–N_2 slush bath at ca. −115°C with occasional short-duration removal of the NMR tube from the bath). After complete mixing the NMR tube was frozen in liquid N_2 prior to insertion into the precooled magnet. $CDFCl_2$ was used as the main solvent, with a few drops of CD_2Cl_2 being used to help dissolve the bromo ketone prior to addition to the organometallic salt.

Dibromo ketones

Ketones **5** (4), **6** (15), and **9** (16) were previously reported.

2,6-Dibromo-2-(1,1-dimethylethyl)-6-methylcyclohexanone 7

A solution of bromine (0.86 mL) and the ketone (1.28 g, 7.6 mmol) in 15 mL CCl_4 was sealed in a glass tube and heated for ca. 16 h at 80°C. The cooled reaction mixture was diluted with 20 mL CH_2Cl_2, washed successively with H_2O, 10% $NaHSO_3$, and brine, dried over anhydrous $MgSO_4$, and the solvent removed to give 2.3 g (93%) of the crude dibromo ketone (ca. 9:1 mixture of *cis* and *trans* isomers, by GLC or NMR). The major isomer could be crystallized from CH_3OH in a freezer, mp <30°C; ^1H NMR (major): 1.28 (s, 9H); 1.88–2.03 (m, 2H); 1.95 (s, 3H); 2.35–2.45(m, 2H); 2.60–2.88 (m, 2H). ^{13}C NMR: 16.6 (CH_3); 27.5 (CH_3); 29.8 (CH_2); 30.0 (CH_2); 35.7 (CH_2); 38.9 (Cq); 63.4 (Cq); 75.8 (Cq); 196.4 (Cq). MS: 326 (2), 270 (9) and 191, 189 (100); HRMS calcd. for $C_{11}H_{18}O^{79}Br^{81}Br$: 325.9705; found: 325.9710.

2,6-Dibromo-2-(1,1-dimethylethyl)-6-ethylcyclohexanone 8

2-(1,1-Dimethylethyl)cyclohexanone (0.77 g, 5.0 mmol) in 2 mL dry THF was added to an LDA solution (diisopropylamine, 0.85 mL, *n*-butyllithium, 2.2 mL of 2.5 M, in 10 mL of dry THF under nitrogen) at −25°C. After 20 min, the reaction mixture was cooled to −78°C and iodoethane (0.8 mL, 10 mmol) in THF (1 mL) was added. The solution was allowed to warm to room temperature and kept overnight. The reaction mixture was quenched with saturated NH_4Cl solution, and extracted with diethyl ether (3 × 25 mL). The organic solution was washed with water and brine, dried over anhydrous $MgSO_4$, and the solvent evaporated to give 0.77 g (93%) of crude product that is a mixture of *cis* and *trans* (ca. 40:60 by GLC and NMR). ^1H NMR (200 MHz): 0.88 (t, J = 7, 3H); 0.99, 1.00 (s, 9H) individual *t*Bu peaks; 1.10–2.30 (complex mult.). GC–MS (very similar for both isomers): 182 (M^+, 15), 167 (23), 126 (50), 98 (42), 41 (100). This crude compound in

CCl_4 (10 mL) and bromine (0.5 mL) was stirred overnight, diluted with 20 mL CH_2Cl_2, washed with water, 10% $NaHSO_3$, and brine, dried with anhydrous $MgSO_4$, and the solvent evaporated to give 1.40 g of an oily liquid, crude yield 98%. This material is a ca. 10:1 mixture of isomers by ^1H NMR. ^1H NMR (major): 1.00 (t, $J = 7$, 3H);1.29 (s, 9H); 1.80–2.90 (complex mult.). ^{13}C NMR: 9.8 (CH_3); 16.5 (CH_2); 27.5 (CH_3); 29.6 (CH_2); 31.5 (CH_2); 34.1 (CH_2); 39.0 (Cq); 69.4 (Cq); 76.4 (Cq); 195.1 (Cq). GC–MS: 340 (M^+, 1), 284 (5), 205, 203 (40), 57 (100); HRMS calcd. for $C_{12}H_{20}O^{79}Br^{81}Br$: 339.9862; found: 339.9828. The crude product was sufficiently pure to be used in the next step.

Conformation of the bicyclo[3.1.0]hexan-6-one ring

In addition to the chemical shift discussion in the Results section, a boatlike conformation is also consistent with the detailed ^1H NMR data: (*a*) the H5 proton in **11** is a doublet of 5 Hz, indicating coupling to only one of the H4 hydrogens (one dihedral is ca. 90° in a boat structure). In a chair structure, two couplings would be expected; (*b*) in **10** (and in the others), the high-field hydrogen on C3 couples to both of the C2–C4 pairs of methylene hydrogens, with the largest coupling indicative of the expected vicinal diaxial interaction with the pair *anti* to the cyclopropanone ring.

Kinetic isotope studies

A solution of ca. equal concentrations of **12** and **12a** was prepared as described for **12**. For **12**, the reactant–product ratios were obtained in several ways using ^1H NMR: (*a*) the *t*Bu peak of **12** and **15** differs by ca. 0.16 ppm and the peak height ratios of these can be used, although the H3 (prow) peak of **12** is also overlapping in this region; (*b*) the decrease of the peak at δ 2.41 in **12** can be compared to a fixed reference peak area (the CH_2 of diethyl ether at δ 3.4). For **12a**, ^2H NMR was used. The conversion of **12a** to **15a** is still relatively small in those cases where the **12**→**15** conversion is already substantial. The **12a** → **15a** conversion was monitored using the total ^2H area in the δ 4.25–5 ppm region (two peaks, $=C^2H_2$), relative to the area of the remaining $-C^2H_3$ peak at ca. 1.25. When the **12a** → **15a** reaction is allowed to proceed to completion there is a broad residual ^2H peak remaining in the δ 1–2 region, which we attribute to side reactions. Fortunately, at low conversions the error resulting from this is not a large factor. Based on the ^1H NMR results for $-O-^1H$ in **15** at low temperatures, the $-O-^2H$ peak is expected to be broadened into the baseline.

2-(1,1-Dimethylethyl)-6-methylenecyclohexanone ***17:*** ^1H NMR ($CDCl_3$): 5.64 and 5.03 (poorly resolved mult, 1H each) $=CH_2$; 2.35–2.75 (m, 2H) C5 hydrogens; 1.50–2.30 (mult); 1.02 (s, 9H). ^{13}C NMR (CD_2Cl_2): 213.6 (C=O), 148.8 (Cq); 117.7 ($=CH_2$), 58.5 (C6), 33.2 (C of *t*Bu); 28.0 (CH_3 of *t*Bu); 33.0, 26.4, 24.0 (C3,4,5). GC–MS: 166 (M^+), 110 (100), 95 (55), 82 (20), 81 (20). HRMS calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1343.

E-*2-(1,1-Dimethylethyl)-6-ethylidenecyclohexanone* ***18***: ^1H NMR ($CDCl_3$): 6.46 (qt, $J = 7$, 2, 1H)=CH-; 2.58 (bd, $J = 16$, 1H) H5; 2.33 (complex mult, 1H) H5; 2.15 (dd, $J = 11$, 7, 1H) H2; 2.05 (m, 1H) H3; 1.89 (m, 1H) H4; 1.45–1.65 (m, 2H) H3, H4); 1.69 (dt, $J = 7$, 2, 3H) CH_3; 0.99 (s, 9H). Stereochemical assignment: a NOESY spectrum shows a weak cross peak between the ethylidene CH_3 peak and the broad doublet at δ 2.58, which is assigned to the equatorial H5 hydrogen. In addi-

tion, comparisons with literature data on *cisoid* α,β-unsaturated ketones support the present assignment. ^{13}C NMR: 204.5 (C=O); 140.4 (C6); 131.6 (=CH); 57.2 (C2), 33.8 (C of *t*Bu); 28.1 (CH_3 of *t*Bu), 26.6, 25.7, 22.3 (C3, 4, 5); 14.1 (CH_3). GC–MS: 180 (M^+, 2), 165 (3), 109 (25), 95 (10). HRMS calcd. for $C_{12}H_{20}O$: 180.1514; found: 180.1485.

The asymmetric synthesis of aryltetralin lignans: (–)-isolariciresinol dimethyl ether and (–)-deoxysikkimotoxin

Don M. Coltart and James L. Charlton

Abstract: The total asymmetric syntheses of (−)-isolariciresinol dimethyl ether (**6**) and (−)-deoxysikkimotoxin (**7**) have been carried out, in an attempt to exploit a synthetic strategy recently developed for the synthesis of (−)-deoxypodophyllotoxin (**1**, R^1 = -CH_2-, Ar = 3,4,5-trimethoxyphenyl). In so doing, a generalized method for the synthesis of aryltetralin lignans has been developed that should be applicable to a variety of substitution patterns and stereochemistries. A one-pot, 100% regio-selective reduction–lactonization procedure has been developed for the conversion of the ester **18***b* to (−)-deoxysikkimotoxin, which gave 93% isolated yield in that step.

Key words: *ortho*-quinodimethanes, lignans, Diels–Alder, asymmetric, mandelate.

Résumé : Dans le but d'exploiter une stratégie de synthèse développée récemment pour la synthèse de la (−)-désoxypodophyllotoxine (**1**, R^1 = -CH_2-, Ar = 3,4,5-triméthoxyphényle), on a réalisé la synthèse totale asymétrique de l'éther diméthylique (**6**) de (−)-isolaricirésinol et de la (−)-désoxysikkimotoxine (**7**). On a ainsi développé une méthode généralisée de synthèse des lignanes aryltétralines que l'on devrait pouvoir appliquer à une variété de stéréochimies et de patrons de substitutions. On a développé une méthode unipot, 100% régiosélective, de réduction–lactonisation qui permet d'effectuer la conversion de l'ester **18***b* en (−)-désoxysikkimotoxine; pour cette étape, le rendement en produit isolé est de 93%.

Mots clés : *ortho*-quinodiméthanes, lignanes, Diels–Alder, asymétrique, mandélate.

[Traduit par la rédaction]

Introduction

The aryltetralin lignans make up a particular subclass of natural products collectively referred to as lignans. The occurrence of lignans in nature is widespread and they have been shown to possess considerable diversity in their biological activity (1). As such, there is a substantial interest in these compounds and their synthesis.

In a recent asymmetric synthesis of the aryltetralin lignan (−)-deoxypodophyllotoxin (**1**, R^1 = -CH_2-, Ar = 3,4,5-trimethoxyphenyl), a synthetic strategy was developed, shown retrosynthetically in Scheme 1, which gave the desired compound optically pure, in 6% isolated yield (2). As a key reaction, the synthesis relied on an asymmetric [4 + 2] cycloaddition occurring between the fumarate of methyl (*S*)-mandelate (**3**), and an appropriately substituted *ortho*-quinodimethane (**4**), to give the *endo* cycloadduct **2** (Scheme 1).

The *ortho*-quinodimethane in question was obtained via thermolysis of its corresponding α-hydroxy-α-aryl-benzocyclobutenol **5**. The synthetic route to the benzocyclobutenol, and the synthetic route by which the cycloadduct was elaborated to the target molecule, were sufficiently general that it was considered possible that variation of functional groups and stereochemistry of the resulting aryltetralin lignan might be achieved without adversely affecting the synthetic strategy. Hence, to broaden the scope of the synthetic strategy in question, and consequently develop a generalized method for the synthesis of aryltetralin lignans, an attempt was made to apply the method to the total asymmetric syntheses of (−)-isolariciresinol dimethyl ether (**6**) and (−)-deoxysikkimotoxin (**7**) (Scheme 2).

An asymmetric synthesis of deoxysikkimotoxin, the 6,7-dimethoxy analogue of deoxypodophyllotoxin, has not previously been reported in the literature. To date, only two total syntheses of optically pure isolariciresinol dimethyl ether have appeared in the literature (3, 4).

Results and discussion

Benzocyclobutenol **15***a* required for the synthesis of (−)-isolariciresinol dimethyl ether was obtained as outlined in Schemes 3 and 4, following, in part, earlier work carried out by Aidhen and Narasimhan (5). The monobromination of 3,4-dimethoxybenzaldehyde (**8***a*) was carried out using bromine and acetic acid, according to a modified literature procedure (6). Recrystallization of the crude product gave pure 2-bromo-4,5-dimethoxybenzaldehyde (**9**) in 86% yield. Aldehyde **9** was protected as its ethylene glycol acetal, and then subjected to halogen exchange by exposing it to *n*-butyllithium followed by iodine. Hydrolysis of the acetal protecting group gave, in 94% yield, 2-iodo-4,5-dimethoxybenzaldehyde (**10**) (7, 8). Conversion of **10** to benzyl alcohol **11** was carried out in 96%

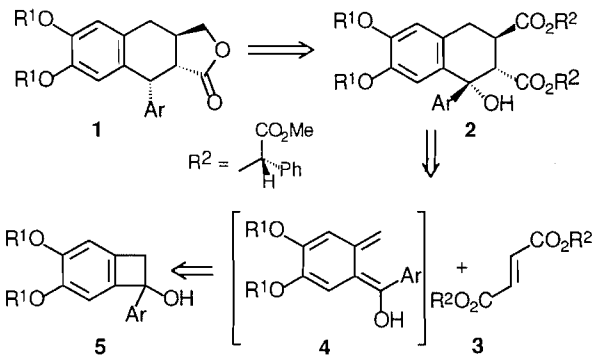
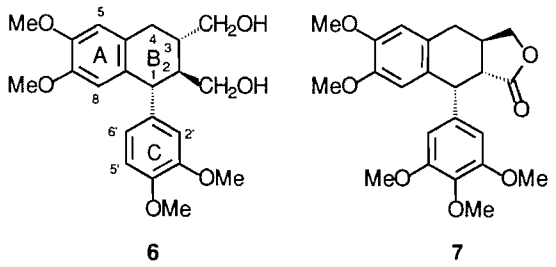


Scheme 2.

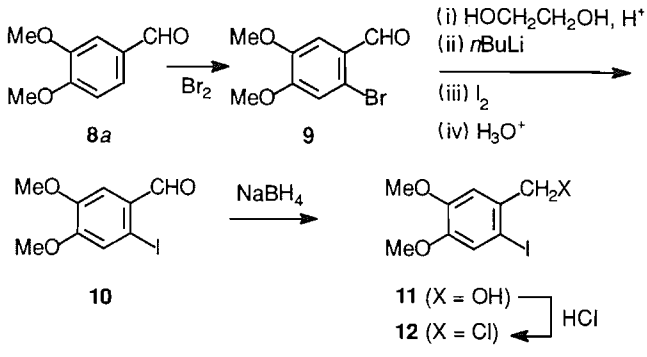


yield via sodium borohydride reduction. Exposure of **11** to hydrochloric acid afforded 2-iodo-4,5-dimethoxybenzyl chloride (**12**) in 76% overall yield from 3,4-dimethoxybenzaldehyde.

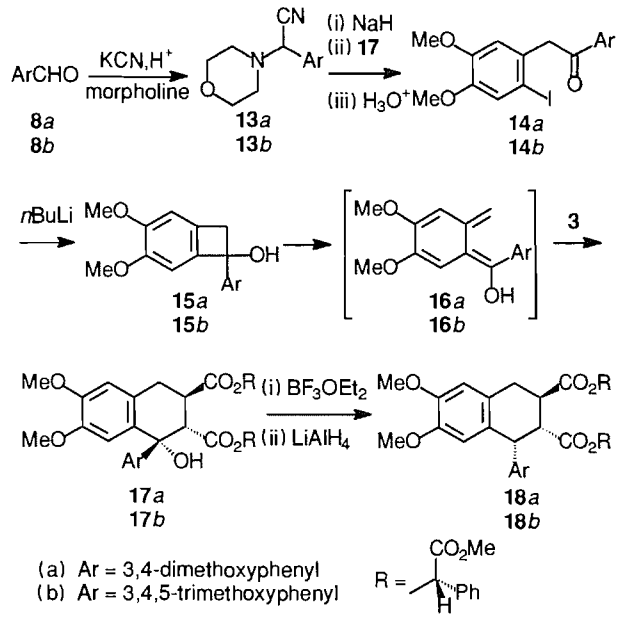
α-Aminonitrile **13***a* (Scheme 4), required for condensation with benzyl chloride **12**, was obtained using a modified Strecker synthesis (9). The reaction was originally carried out in methanol, but under these conditions it was found to give a mixture of the desired α-aminonitrile and a compound whose proton NMR spectrum corresponded to that of 3,4-dimethoxybenzaldehyde dimethyl acetal. The ratio of α-aminonitrile to acetal was 1.0 to 2.4. When carried out in ethanol, the analogous reaction gave a mixture of compound **13***a* and a compound that, based on its proton NMR spectrum, was assumed to be 3,4-dimethoxybenzaldehyde diethyl acetal, in a 2.0 to 1.1 ratio. The same reaction, using 2-propanol as the solvent, gave almost exclusive formation of the desired α-aminonitrile, with a very slight trace (less than 2%) of 3,4-dimethoxybenzaldehyde present. Presumably, the absence of acetal formation in the latter case was due to the use of a sterically hindered alcohol, a situation known to be unfavorable for acetal formation (10).

The coupling of benzyl chloride **12** and α-aminonitrile **13***a* was initiated by treating **13***a* with sodium hydride in *N*,*N*-dimethyl formamide, in order to generate its resonance-stabilized carbanion, followed by the addition of compound **12**. After acid-catalyzed hydrolysis, aryliodoketone **14***a* was obtained in 94% yield. Compound **14***a* was cyclized following the procedure of Aidhen and Narasimhan (5) by treating it with *n*-butyllithium, giving the desired benzocyclobutenol **15***a* in 74% isolated yield. It appears that metal halogen exchange with *n*-butyllithium is much faster than H abstraction or addition of *n*-butyllithium to the carbonyl group as has been noted

Scheme 3.



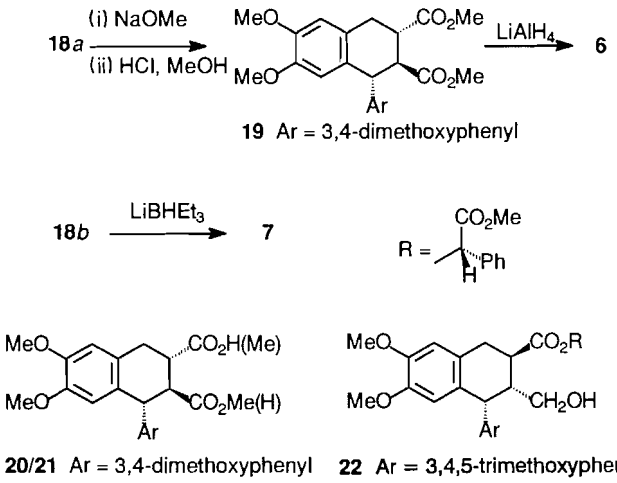
Scheme 4.



previously (refs. 5, 11, and references cited). The bromo compound analogous to **14***a* (I = Br) did not give the benzocyclobutenol **15***a* when treated with *n*-butyllithium, but gave instead material apparently derived from addition of *n*-butyllithium to the carbonyl group. This observation also parallels that of Aiden and Narasimhan (5).

Following a procedure used previously (12, 13), *ortho*-quinodimethane **16***a* was generated in refluxing toluene and trapped in situ with the fumarate of methyl (*S*)-mandelate, resulting in a 51% isolated yield of cycloadduct **17***a* after chromatography (Scheme 4). Justification for the geometry of the *ortho*-quinodimethane and the stereochemistry of the major cycloadduct has been given in an earlier publications (2, 13). Reductive removal of the C1 hydroxyl substituent from compound **17***a* was achieved according to the method of Bogucki and Charlton (2), and resulted in the formation of ester **18***a*. This gave the absolute stereochemistry at C1 required for (−)-isolariciresinol dimethyl ether. To establish the correct stereochemistry at C2 and C3, however, it was necessary to epimerize both centers. Concurrent epimerization and transesterification using sodium methoxide, followed by

Scheme 5.



work-up with dilute acid, gave a compound presumed to be either the half ester **20** or **21** (Scheme 5), which, when treated with 3% hydrochloric acid in methanol, gave the all-*trans* dimethyl ester **19** in 83% isolated yield from **18***a*. (−)-Isolariciresinol dimethyl ether was obtained from compound **19** in 96% isolated yield by reduction with lithium aluminum hydride (3).

Given that the aromatic ring A of (−)-deoxysikkimotoxin possesses the same substitution pattern as that of (−)-isolariciresinol dimethyl ether, the benzyl chloride required for the α-aminonitrile coupling reaction of the (−)-deoxysikkimotoxin synthesis was the same as that for the synthesis of (−)-isolariciresinol dimethyl ether, namely compound **12** (Scheme 3). The aromatic ring C of (−)-deoxysikkimotoxin, however, bears methoxy substituents at the 3′, 4′, and 5′ positions and, as such, the α-aminonitrile **13***b* (Scheme 4) was required for its synthesis. Compound **13***b* was obtained according to a procedure previously reported (2). The coupling of benzyl chloride **12** and α-aminonitrile **13***b* was carried out in a manner analogous to that used for the coupling of compounds **12** and **13***a*. The product of this particular reaction, aryliodoketone **14***b*, was obtained in 91% isolated yield, and was readily cyclized to benzocyclobutenol **15***b* by treatment with *n*-butyllithium. Benzocyclobutenol **15***b* was thermolyzed to *ortho*-quinodimethane **16***b* in the presence of the fumarate of methyl (*S*)-mandelate. The proton NMR spectrum of the crude reaction product showed signals consistent with those expected for cycloadduct **17***b*, and did not indicate the presence of any other cycloadducts. The cycloadduct was obtained in 57% yield after chromatography. Reductive removal of the C1 hydroxyl substituent from this compound gave the ester **18***b* in a manner analogous to that used for the formation of compound **18***a*.

Given that compound **18***b* possessed the correct absolute stereochemistry required for (−)-deoxysikkimotoxin, **7**, the possibility of obtaining the target molecule directly, via the regioselective reduction of the ester substituent at C3 followed by lactonization, was explored. The conditions that were employed initially involved the use of three equivalents of lithium triethylborohydride at room temperature. This gave a mixture consisting of (−)-deoxysikkimotoxin and starting compound **18***b* in a ratio of approximately 1 to 1, as well as a trace amount of a compound presumed to be the γ-hydroxyester **22**. When the reaction conditions were altered such that six equivalents of lithium triethylborohydride were used, no starting material could be detected, but the reaction product was still a mixture consisting of (−)-deoxysikkimotoxin and the presumed γ-hydroxyester, in a ratio favoring (−)-deoxysikkimotoxin. In an attempt to increase the regioselectivity of the reduction reaction, the temperature of the reaction was lowered to 0°C. Proton NMR analysis of the crude product in this case indicated that all of the starting material had been consumed and showed the exclusive formation of (−)-deoxysikkimotoxin. Chromatography of the crude product afforded (−)-deoxysikkimotoxin in 93% isolated yield from compound **18***b*.

Conclusion

(−)-Isolariciresinol dimethyl ether and (−)-deoxysikkimotoxin were each synthesized in an asymmetric fashion with reasonable overall yields. The overall yield of (−)-isolariciresinol dimethyl ether was 9% from 3,4-dimethoxybenzaldehyde, and the overall yield of (−)-deoxysikkimotoxin was 11% from 3,4-dimethoxybenzaldehyde. This is the first total asymmetric synthesis of deoxysikkimotoxin that has been reported.

By achieving the aforementioned syntheses, the scope of the synthetic strategy developed by Bogucki and Charlton has been broadened to allow for different substitution patterns, functionality, and stereochemistry, thereby providing a generalized procedure for the synthesis of aryltetralin lignans. In particular, it was demonstrated that the methylenedioxy substituent of aromatic ring A can be replaced without adversely affecting the reaction sequence. It was also shown that removal of the 5′ methoxy substituent of aromatic ring C does not impede the synthetic strategy in any way. As well, it was established that the functionality and stereochemistry at carbons two and three of the aryltetralin lignan could be altered by epimerization during the final steps of the strategy.

The conversion of the reduction product **18***b* to (−)-deoxysikkimotoxin was achieved in one step with an overall yield of 93%, via a reduction–lactonization reaction that proceeded with unexpectedly high regioselectivity. This represents a substantial synthetic improvement in comparison to the synthesis of (−)-deoxypodophyllotoxin carried out by Bogucki and Charlton (2). Given the similarity of these compounds to one another, it seems reasonable to conclude that a corresponding improvement in the synthesis of (−)-deoxypodophyllotoxin could also be achieved.

Experimental

The analytical instruments employed have been described in a previous publication (14).

2-Bromo-3,4-dimethoxybenzaldehyde 9

Compound **9** was synthesized by adapting a literature procedure (6). To a round-bottom flask, equipped with a mechanical stirring apparatus, was added 3,4-dimethoxybenzaldehyde (20.09 g, 120.9 mmol) and glacial acetic acid (145 mL). The resulting suspension was stirred at room temperature and, once all of the 3,4-dimethoxybenzaldehyde

had dissolved, bromine (2 equivalents, 12.5 mL, 243 mmol) was added and stirring was continued for an additional 4 h. At that point, the mixture was diluted with ice-cold water (145 mL) and allowed to stand in a refrigerator at 5°C overnight. The mixture was then filtered and the resulting solid washed with ice-cold water (100 mL), and then refiltered. The solid was then recrystallized from 80/20 (v/v) methanol–water and dried in an oven overnight at 50°C. The process yielded a light beige crystalline compound (25.6 g, 104 mmol, 86%); mp 148–150°C; IR (CH_2Cl_2): 1682 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.92 (s, 3H), 3.96 (s, 3H), 7.05 (s, 1H), 7.40 (s, 1H), 10.17 (s, 1H); ^{13}C NMR ($CDCl_3$) δ: 56.1 (CH_3), 56.4 (CH_3), 110.4 (CH), 115.4 (CH), 120.3 (C), 126.5 (C), 148.8 (C), 154.4 (C), 190.6 (CO); MS *m/e* (relative %): 246 (100), 245 (58), 244 (M^+, 99), 243 (53), 231 (17), 229 (16), 94 (45); HRMS calcd. for $C_9H_9{}^{79}BrO_3$: 243.9735; found: 243.9800.

2-Iodo-3,4-dimethoxybenzaldehyde 10

To a round-bottom flask was added 6-bromo-3,4-dimethoxybenzaldehyde (20.2 g, 82.3 mmol), benzene (300 mL), ethylene glycol (9.5 mL, 170.4 mmol), and *p*-toluenesulfonic acid hydrate (0.10 g, 0.53 mmol). The flask was attached to a Dean–Stark trap and refluxed for 5 h. The benzene was then evaporated to give a light yellow viscous liquid, which was filtered through silica gel (10 cm) with 50/50 (v/v) ethyl acetate/hexanes. The filtrate was evaporated to give a colorless crystalline compound. The crystals were dissolved in THF (150 mL) in a round bottom flask that was sealed with a rubber septum, flushed with nitrogen, and placed in a Dry Ice – acetone bath. At that point, *n*-butyllithium (44 mL of a 2.03 M solution in hexanes, 89 mmol) was added and the resulting solution was stirred for 15 min. Iodine (25.0 g, 98.5 mmol), dissolved in THF (80 mL), was then added and the mixture was stirred for 15 min, removed from the Dry Ice – acetone bath, and stirred for an additional 60 min. Saturated aqueous sodium bisulphite (10 mL) was added to dissipate the dark color caused by the iodine, leaving the solution light yellow. The THF portion was removed and the aqueous portion was extracted three times with ethyl acetate. The organic portions were combined and evaporated to give an oily residue. The residue was dissolved in methanol (50 mL) and to this was added 10% $HCl_{(aq)}$ (10 mL). The resulting solution was allowed to stir for 20 h at room temperature, by which time a colourless precipitate had formed. The product was extracted into CH_2Cl_2 and then evaporated to give a light colored oil. The oil was taken up in 50/50 (v/v) ethyl acetate/hexanes and filtered through silica gel (10 cm). Evaporation of the solvent gave colorless crystals (22.48 g, 77.0 mmol, 94%); mp 134–136°C; IR (CH_2Cl_2): 1695 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.92 (s, 3H), 3.96 (s, 3H), 7.31 (s, 1H), 7.41 (s, 1H), 9.86 (s, 1H); ^{13}C NMR ($CDCl_3$) δ: 56.1 (CH_3), 56.5 (CH_3), 92.7 (C), 111.1 (CH), 121.8 (CH), 128.4 (C), 149.7 (C), 154.4 (C), 194.8 (CO); MS *m/e* (relative %): 292 (M^+, 100), 291 (31), 277 (5), 164 (10), 136 (10); HRMS calcd. for $C_9H_9IO_3$: 291.9596; found: 291.9629.

2-Iodo-4,5-dimethoxybenzyl alcohol 11

6-Iodo-3,4-dimethoxybenzaldehyde (1.52 g, 5.20 mmol) was dissolved in 2–propanol (40 mL). $NaBH_4$ (0.232 g, 6.14 mmol) was then added and the mixture was refluxed for 12 h. The resulting solution was made just acidic by the addition of 10% $HCl_{(aq)}$ and then evaporated to a minimum volume, after which it was taken up in dichloromethane and washed with water. The aqueous portion was saturated with NaCl and extracted three times with dichloromethane. The organic portions were combined, dried with $MgSO_4$, and evaporated to give off-white crystals (1.47 g, 5.00 mmol, 96%); mp 94–96°C; IR (CH_2Cl_2): 3605 (OH) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.77 (bs, 1H), 3.84 (s, 6H), 4.56 (s, 2H), 6.98 (s, 1H), 7.19 (s, 1H); ^{13}C NMR ($CDCl_3$) δ: 55.8 (CH_3), 56.1 (CH_3), 68.7 (CH_2), 85.1 (C), 111.3 (CH), 121.3 (CH), 135.1 (C), 148.6 (C), 149.2 (C); MS *m/e* (relative %): 294 (M^+, 33), 166 (28), 71 (28), 69 (100), 57 (59); HRMS calcd. for $C_9H_{11}IO_3$: 293.9753; found: 293.9757.

2-Iodo-4,5-dimethoxybenzyl chloride 12

2-Iodo-4,5-dimethoxybenzyl alcohol (0.764 g, 2.60 mmol) was dissolved in dichloromethane (20 mL) and to that mixture was added glacial acetic acid (20 mL). HCl gas was passed through the resulting solution at a rate of approximately one bubble per second for 30 min. At that point, water (40 mL) was added to the solution and the organic portion was removed via a separatory funnel. The aqueous portion was then extracted twice with dichloromethane. The organic portions were combined and then washed with 10% $NaHCO_{3(aq)}$. The organic phase was removed, dried with $MgSO_4$, and evaporated to give off-white crystals (0.793 g, 2.55 mmol, 98%); mp 83–85°C; ^1H NMR ($CDCl_3$) δ: 3.85 (s, 3H), 3.86 (s, 3H), 4.63 (s, 2H), 6.96 (s, 1H), 7.22 (s, 1H); ^{13}C NMR ($CDCl_3$) δ: 51.2 (CH_2), 55.8 (CH_3), 56.1 (CH_3), 87.8 (C), 112.6 (CH), 121.5 (CH), 132.0 (C), 149.3 (C), 149.4 (C); MS *m/e* (relative %): 314 (M^+, 13) 312 (M^+, 36), 278 (23), 277 (100), 151 (15), 107 (18); HRMS calcd. for $C_9H_{10}{}^{35}ClIO_2$: 311.9414; found: 311.9426.

1-(3,4-Dimethoxyphenyl)-1-*N*-morpholinoacetonitrile 13*a*

3,4-Dimethoxybenzaldehyde (9.99 g, 60.1 mmol) was dissolved in 2-propanol (100 mL), in a round-bottom flask. In a separate flask KCN (3.93 g, 60.3 mmol) was dissolved in water (5 mL) and then morpholine (5.27 mL, 5.26 g, 60.4 mmol) was added with stirring, and the resulting mixture was cooled in an ice bath. At that point, concentrated HCl (4.96 mL, ca. 5.24 g, ca. 60 mmol) was added dropwise with stirring. The resulting suspension was then added all at once to the 3,4-dimethoxybenzaldehyde solution, and the final mixture was allowed to stir at room temperature for 7 days. The suspension that formed was filtered off and the filtrate was evaporated to a minimum volume, giving a viscous oil. The oil was taken up in ethyl acetate and washed with water, and the aqueous portion was subsequently extracted with ethyl acetate. The organic portions were combined, dried with $MgSO_4$, and evaporated to give a colorless crystalline compound (13.2 g, 50.3 mmol, 84%); mp 64–66°C; IR (CH_2Cl_2): 2305 (CN) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.57 (m, 4H), 3.72 (m, 4H), 3.89 (s, 3H), 3.91 (s, 3H), 4.76 (s, 1H), 6.87 (d, 1H, J = 8.3), 7.01 (d, 1H, J = 2.0), 7.10 (dd, 1H, J = 2.0, 8.3); ^{13}C NMR ($CDCl_3$) δ: 49.9 (CH_2), 56.0_0 (CH_3), 56.0_2 (CH_3), 62.1 (CH), 66.6 (CH_2), 110.8 (CH), 110.9 (CH), 115.3 (C), 120.4 (CH), 124.8 (C), 149. 2 (C), 149.6 (C); MS *m/e* (relative %): 262 (M^+, 9), 177 (23), 176 (100), 151 (27), 111 (18), 97 (34), 83 (44), 69 (73), 57 (95); HRMS: calcd. for $C_{14}H_{18}N_2O_3$: 262.1317; found: 262.1361.

Aryliodoketone 14*a*

An NaH/oil mixture (50/50, w/w, 0.457 g, 9.53 mmol with respect to NaH) was combined with DMF (10 mL) in a round-bottom flask, which was subsequently sealed with a rubber septum and flushed with nitrogen. The α-aminonitrile **13*a*** (1.66 g, 6.33 mmol), dissolved in DMF (15 mL), was then added dropwise to the suspension over a period of 5 min. Once addition was complete, the benzyl chloride **12** (1.98 g, 6.33 mmol), dissolved in DMF (15 mL), was added dropwise to the suspension over a period of 5 min, and the resulting mixture was allowed to stir at room temperature for 1 h. At that point, 10% $HCl_{(aq)}$ (10 mL) was added to the suspension and the mixture was allowed to stir for 16 h at 65°C, causing the formation of a precipitate. The precipitate was isolated from the solution and washed with cold methanol, leaving a colorless crystalline compound (2.64 g, 5.96 mmol, 94%); mp 170–172°C; IR (CH_2Cl_2): 1682 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.81 (s, 3H), 3.86 (s, 3H), 3.94 (s, 3H), 3.95 (s, 3H), 4.35 (s, 2H), 6.76 (s, 1H), 6.91 (d, 1H, J = 8.4), 7.26 (s, 1H), 7.57 (d, 1H, J = 2.0), 7.72 (dd, 1H, J = 2.0, 8.4); ^{13}C NMR ($CDCl_3$) δ: 49.6 (CH_2), 55.9 (CH_3), 56.0 (CH_3), 56.1_0 (CH_3), 56.1_5 (CH_3), 89.1 (C), 110.1 (CH), 110.6 (CH), 113.2 (CH), 121.6 (CH), 123.1 (CH), 129.8 (C), 131.0 (C), 148.5 (C), 149.0 (C), 149.4 (C), 153.4 (C), 195.4 (CO); MS *m/e* (relative %): 442 (M^+, 1), 315 (26), 165 (100); HRMS calcd. for $C_{18}H_{19}O_5$ (M − I): 315.1232; found: 315.1255.

Benzocyclobutenol 15*a*

The aryliodoketone (1.64 g, 3.71 mmol) was dissolved in THF (40 mL) under a nitrogen atmosphere, and cooled in a Dry Ice – acetone bath. *n*BuLi (2.5 M in hexanes, 3.0 mL, 7.5 mmol) was then added and the mixture was allowed to stir at low temperature for 30 min. At that point, 10% $NH_4Cl_{(aq)}$ (10 mL) was added and the mixture was allowed to stir while warming to room temperature. The THF portion was removed and the aqueous portion was extracted three times with dichloromethane. The organic portions were combined, dried with $MgSO_4$, and evaporated to give a yellow semisolid that, when chromatographed on silica gel using 60/40 (v/v) ethyl acetate/hexanes, gave a colorless crystalline compound (0.869 g, 2.75 mmol, 74%); mp 136–138°C; IR (CH_2Cl_2): 3583 (OH) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.88 (bs, 1H), 3.44 (d, 1H, J = 13.4), 3.49 (d, 1H, J = 13.4), 3.84 (s, 3H), 3.85 (s, 3H), 3.86 (s, 3H), 3.88 (s, 3H), 6.78 (d, 1H, J = 8.3), 6.79 (s, 1H), 6.81 (s, 1H), 6.90 (dd, 1H, J = 2.0, 8.3), 7.06 (d, 1H, J = 2.0); ^{13}C NMR ($CDCl_3$) δ: 49.8 (CH_2), 55.9_0 (CH_3), 55.9_1 (CH_3), 56.2_0 (CH_3), 56.2_4 (CH_3), 80.5 (C), 105.3 (CH), 107.8 (CH), 109.1 (CH), 110.7 (CH), 117.8 (CH), 133.5 (C), 136.7 (C), 140.3 (C), 148.2 (C), 148.8 (C), 150.0 (C), 151.4 (C); MS *m/e* (relative %): 316 (M^+, 35), 315 (41), 301 (19), 286 (19), 285 (100), 179 (19), 165 (64), 69 (63), 55 (79); HRMS calcd. for $C_{18}H_{20}O_5$: 316.1311; found: 316.1283. Spectral data were identical to those reported for material prepared by an alternate route (12).

Cycloadduct 17*a*

This compound was prepared with slight modifications to a previously described method for the enantiomer (13). The fumarate of methyl (*S*)-mandelate (0.453 g, 1.10 mmol) was dissolved in toluene (5 mL) and heated to 98°C in an oil bath. The benzocyclobutenol **15*a*** (0.140 g, 0.44 mmol), dissolved in dichloromethane (4 mL), was then added and the mixture was allowed to boil, open to the atmosphere, until the dichloromethane had evaporated. At that point, a condenser was attached to the reaction flask and the mixture was refluxed for 48 h. The contents of the flask were then evaporated under reduced pressure, leaving a reddish-brown oil. Chromatography of the oil on silica gel with 40/60 (v/v) ethyl acetate/hexanes gave a colorless solid (0.164 g, 0.22 mmol, 51%); $[\alpha]_D^{20}$ 127.4 (*c* 0.31 g/100 mL in $CHCl_3$); IR (CH_2Cl_2): 3443 (OH), 1751 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.17 (dd, 1H, J = 11.7, 16.5), 3.44 (dd, 1H, J = 4.6, 16.5), 3.61 (s, 3H), 3.63 (s, 3H), 3.73 (s, 3H), 3.82 (s, 3H), 3.87 (s, 3H), 3.92 (s, 3H), (H2 and H3 under the methoxyl signals), 5.74 (s, 1H), 5.90 (s, 1H), 6.45 (s, 1H), 6.66 (s, 1H), 6.87 (m, 2H), 6.99 (dd, 1H, J = 2.1, 8.4), 7.12 (d, 1H, J = 2.1), 7.17–7.27 (m, 3H), 7.36–7.42 (m, 3H), 7.44–7.47 (m, 2H); ^{13}C NMR ($CDCl_3$) δ: 32.4 (CH_2), 39.7 (CH), 52.6 (CH_3), 52.8 (CH_3), 54.9 (CH), 55.7 (CH_3), 55.8 (CH_3), 55.9 (CH_3), 56.0 (CH_3), 74.7 (CH), 74.9 (CH), 76.1 (C), 110.1 (2 × CH), 110.7 (CH), 112.1 (CH), 118.9 (CH), 125.7 (C), 127.1 (2 × CH), 127.6 (2 × CH), 128.4 (2 × CH), 128.7 (2 × CH), 129.0 (CH), 129.2 (CH), 132.4 (C), 132.8 (C), 133.2 (C), 139.2 (C), 147.9_0 (C), 147.9_3 (C), 148.5 (C), 148.7 (C), 169.3 (CO), 169.6 (CO), 171.5 (CO), 174.2 (CO); MS *m/e* (relative %): 710 (M^+ − H_2O, 29), 351 (64), 324 (40), 165 (21), 149 (64), 121 (100); HRMS calcd. for $C_{40}H_{38}O_{12}$ (M - H_2O): 710.2363; found: 710.2347. Spectral details were consistent with those reported for the enantiomer (13).

Ester 18*a*

The cycloadduct **17*a*** (0.0869 g, 0.12 mmol) was dissolved in dichloromethane (20 mL) under nitrogen, and cooled to −20°C. BF_3OEt_2 (0.10 mL, 0.80 mmol) was then added, causing the solution to turn dark blue. The mixture was cooled to −55°C and $LiAlH_4$ (0.37 M in diethyl ether, approximately 1.0 mL, approximately 0.37 mmol) was added dropwise until all of the blue had dissipated, followed by the dropwise addition of 50/50 (v/v) methanol/water (10 mL). The resulting solution was stirred for 20 min at −55°C and was then allowed to warm to room temperature. At that point, 10% $HCl_{(aq)}$ (1 mL) was added and the organic portion was separated from the aqueous portion. The aqueous portion was extracted three times with dichloromethane and the original organic portion was washed with 10% $HCl_{(aq)}$. The organic portions were combined, dried with $MgSO_4$, and evaporated to give an amorphous solid, which was chromatographed on silica gel with 30/70 (v/v) ethyl acetate/hexanes to give a colorless solid (0.0356 g, 0.05 mmol, 42%); $[\alpha]_D^{20}$ −54.3 (*c* 0.28 g/100 mL in $CHCl_3$); IR (CH_2Cl_2): 1746 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.04 (m, 1H), 3.38 (m, 2H), 3.52 (m, 1H), 3.64 (s, 3H), 3.68 (s, 3H), 3.69 (s, 3H), 3.70 (s, 3H), 3.73 (s, 3H), 3.87 (s, 3H), 4.56 (d, 1H, J = 5.5, H1), 5.67 (s, 1H), 6.07 (s, 1H), 6.32 (dd, 1H, J = 1.9, 8.3), 6.39 (s, 1H), 6.43 (d, 1H, J = 8.3), 6.50 (d, 1H, J = 1.9), 6.69 (s, 1H), 6.99 (d, 2H, J = 7.3), 7.08 (t, 2H, J = 7.6), 7.16–7.36 (m, 4H), 7.44–7.47 (m, 2H); ^{13}C NMR ($CDCl_3$) δ: 31.8 (CH_2), 37.1 (CH), 45.7 (CH), 48.2 (CH), 52.4 (CH_3), 52.5 (CH_3), 55.4 (CH_3), 55.8 (3 × CH_3), 73.9 (CH), 74.6 (CH), 110.4 (2 × CH), 112.2 (CH), 112.8 (CH), 121.8 (CH), 125.6 (C), 127.0 (2 × CH), 127.9 (2 × CH), 128.2 (2 × CH), 128.6 (C), 128.7 (2 × CH), 129.2 (CH), 133.4 (C), 133.6 (C), 133.9 (C), 147.8 (C), 147.9 (C), 148.0 (C), 148.1 (C), 168.8 (CO), 169.5 (CO), 171.1 (CO), 174.2 (CO) ; MS *m/e* (relative %):

712 (M^+, 20), 563 (6), 518 (10), 485 (7), 398 (22), 397 (36), 351 (47), 325 (55), 149 (63), 121 (100); HRMS calcd. for $C_{40}H_{40}O_{12}$: 712.2520; found: 712.2502. Spectral data were consistent with those reported for the enantiomer prepared by another method (12).

Ester 19

Ester **18***a* (0.050 g, 7.02×10^{-2} mmol) was dissolved in dry methanol (10 mL) and sodium metal (0.240 g, 10.4 mmol) was added under nitrogen. The solution was stirred at reflux for 23 h. The mixture was acidified with 10% $HCl_{(aq)}$ and extracted three times with dichloromethane. The organic portions were combined, dried with $MgSO_4$, and evaporated to give a soft crystalline compound. The compound was dissolved in 3% HCl–methanol (10 mL) and stirred for 12 h. The resulting solution was extracted three times with dichloromethane and the organic portions were combined, dried with $MgSO_4$, and evaporated to give a soft crystalline compound. The compound was subsequently chromatographed on silica gel using 30/70 (v/v) ethyl acetate/hexanes to give a colourless solid (0.026 g, 5.85×10^{-2} mmol, 83%); mp 126–127°C; $[\alpha]_D^{20}$ −23.2 (*c* 0.21 g/100 mL in $CHCl_3$); ^{13}C NMR ($CDCl_3$) δ: 31.8 (CH_2), 43.3 (CH), 48.8 (CH), 51.6_7 (CH), 51.6_9 (CH_3), 52.1 (CH_3), 55.8 (CH_3), 55.9_0 ($2 \times CH_3$), 55.9_2 (CH_3), 110.7 (CH), 110.9 (CH), 111.7 (CH), 112.1 (CH), 121.5 (CH), 126.0 (C), 129.6 (C), 135.4 (C), 147.6 (C), 147.7 (C), 148.0 (C), 148.9 (C), 174.1 (CO), 174.5 (CO). Compound **19** had ^1H NMR, IR, and mass spectral properties identical to those previously reported (3).

Isolariciresinol dimethyl ether 6

The reduction of dimethyl ester **19** was carried out using the previously described procedure (3). The dimethyl ester **19** (0.0118 g, 0.027 mmol) was dissolved in dry THF (5 mL) under nitrogen and added dropwise to a suspension of $LiAlH_4$ (0.0012 g, 0.032 mmol) in THF (5 mL) under nitrogen. The mixture was allowed to reflux for 2 h. At that point, water (2 drops) and 10% $HCl_{(aq)}$ (0.5 mL) were added and then the mixture was dried with $MgSO_4$ and evaporated to give a solid. The solid was recrystallized from ethyl acetate – hexanes to give colorless crystals (0.0102 g, 0.026 mmol, 96%); mp 150–152°C; $[\alpha]_D^{20}$ −15.3 (*c* 0.49 g/100 mL in $CHCl_3$); ^{13}C NMR ($CDCl_3$), δ: 33.2 (CH_2), 39.9 (CH), 48.0 (CH), 48.2 (CH), 53.4 (CH_3), 55.8 ($2 \times CH_3$), 56.0 (CH_3), 62.8 (CH_2), 66.5 (CH_2), 110.8 (CH), 111.1 (CH), 112.0 (CH), 113.0 (CH), 121.9 (CH), 128.2 (C), 131.8 (C), 137.7 (C), 147.1 ($2 \times C$), 147.6 (C), 149.1 (C). Compound **6** had ^1H NMR, IR, and mass spectral properties identical to those previously reported (3).

Aryliodoketone 14*b*

An NaH/oil mixture (50/50, w/w, 0.367 g, 7.65 mmol with respect to NaH) was combined with DMF (10 mL) in a round-bottom flask, which was subsequently sealed with a rubber septum and flushed with nitrogen. The α-aminonitrile **13*b*** (1.04 g, 3.57 mmol), dissolved in DMF (15 mL), was then added dropwise to the suspension over a period of 5 min. Once addition was complete, the benzyl chloride **12** (1.13 g, 3.61 mmol), dissolved in DMF (15 mL), was added dropwise to the suspension over a period of 5 min, and the resulting mixture was allowed to stir at room temperature for 1 h. At that point, 10% $HCl_{(aq)}$ (10 mL) and water (10 mL) were added to the suspension and the mixture was allowed to stir for 16 h at 65°C, causing the formation of a precipitate. The precipitate was isolated from the solution and washed with cold methanol, leaving a colorless crystalline compound (1.53 g, 3.25 mmol, 91%); mp 147–150°C; IR (CH_2Cl_2): 1684 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.81 (s, 3H), 3.86 (s, 3H), 3.92 (s, 3H), 3.93 (s, 6H), 4.35 (s, 2H), 6.76 (s, 1H), 7.26 (s, 1H), 7.29 (s, 2H); ^{13}C NMR ($CDCl_3$) δ: 49.8 (CH_2), 55.8 (CH_3), 56.1 (CH_3), 56.3 (CH_3), 60.8 (CH_3), 89.0 (C), 106.0 (CH), 112.8 (CH), 121.5 (CH), 130.7 (C), 131.5 (C), 142.6 (C), 148.5 (C), 149.4 (C), 152.9 (C), 195.6 (CO); MS *m/e* (relative %): 472 (M^+, 1), 344 (73), 329 (64), 195 (100); HRMS calcd. for $C_{19}H_{21}IO_6$: 472.0383; found: 472.0366.

Benzocyclobutenol 15*b*

The aryliodoketone **14*b*** (2.01 g, 4.25 mmol) was dissolved in THF (40 mL) under nitrogen, and cooled in a Dry Ice – acetone bath. *n*BuLi (2.5 M in hexanes, 3.6 mL, 9.00 mmol) was then added and the mixture was allowed to stir at low temperature for 30 min. At that point, 10% $NH_4Cl_{(aq)}$ (10 mL) was added and the mixture was allowed to stir while warming to room temperature. The THF portion was removed and the aqueous portion was extracted three times with dichloromethane. The organic portions were combined, dried with $MgSO_4$, and evaporated to give a yellow semisolid that, when chromatographed on silica gel using 50/50 (v/v) ethyl acetate/hexanes, gave a colorless crystalline compound (1.06 g, 3.05 mmol, 72%); mp 121–123°C; IR (CH_2Cl_2): 3588 (OH) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.66 (s, 1H), 3.45 (d, 1H, J = 13.4), 3.52 (d, 1H, J = 13.4), 3.81 (s, 6H), 3.83 (s, 3H), 3.86 (s, 3H), 3.90 (s, 3H), 6.67 (s, 2H), 6.81 (s, 1H), 6.82 (s, 1H); ^{13}C NMR ($CDCl_3$) δ: 50.0 (CH_2), 56.1 (CH_3), 56.2 (CH_3), 56.3 (CH_3), 60.8 (CH_3), 80.8 (C), 102.8 (CH), 105.1 (CH), 107.8 (CH), 133.7 (C), 137.2 (C), 139.6 (C), 140.0 (C), 150.1 (C), 151.6 (C), 153.0 (C); MS *m/e* (relative %): 346 (M^+, 5), 315 (7), 195 (3), 88 (10), 86 (64), 84 (100); HRMS calcd. for $C_{19}H_{22}O_6$: 346.1416; found: 346.1431.

Cycloadduct 17*b*

The fumarate of methyl (*S*)-mandelate (1.94 g, 4.70 mmol) was dissolved in toluene (10 mL) and heated in an oil bath to 98°C. The benzocyclobutenol **15*b*** (0.623 g, 1.80 mmol), dissolved in dichloromethane (4 mL), was then added and the mixture was allowed to boil, open to the atmosphere, until the dichloromethane had evaporated. At that point, a condenser was attached to the reaction flask and the mixture was refluxed for 48 h. The contents of the flask were then evaporated under reduced pressure leaving a reddish-brown oil. Chromatography of the oil on silica gel with 40/60 (v/v) ethyl acetate/hexanes gave a colorless, crystalline compound (0.779 g, 1.03 mmol, 57%), mp 82–85°C; $[\alpha]_D^{20}$ +136 (*c* 0.30 g/100 mL in $CHCl_3$); IR (CH_2Cl_2): 3475 (OH), 1741 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.17 (dd, 1H, J = 11.4, 16.4), 3.45 (dd, 1H, J = 4.3, 16.4), 3.59–3.92 (m, 2H), 3.63 (s, 6H), 3.73 (s, 3H), 3.79 (s, 6H), 3.87 (s, 3H), 3.90 (s, 3H), 5.75 (s, 1H), 5.90 (s, 1H), 6.46 (s, 1H), 6.66 (s, 1H), 6.73 (s, 2H), 6.95 (m, 2H), 7.20–7.28 (m, 2H), 7.36–7.40 (m, 4H), 7.44–7.48 (m, 2H); ^{13}C NMR ($CDCl_3$) δ: 32.3 (CH_2), 39.8 (CH), 52.6 (CH_3), 52.8 (CH_3), 54.8 (CH), 55.8 ($2 \times CH_3$; methoxy substituents on the 1,2,4,5 substituted aromatic ring), 56.2 ($2 \times CH_3$), 60.9 (CH_3), 74.7 (CH), 75.0 (CH), 76.3 (C), 104.1 ($2 \times CH$), 110.1 (CH), 112.1

(CH), 125.7 (C), 127.1 (CH), 127.6 (CH), 128.5 (CH), 128.7 (CH), 129.1 (CH), 129.3 (CH), 132.1 (C), 132.8 (C), 133.2 (C), 137.0 (C), 142.1 (C), 148.0 (C), 148.8 (C), 152.8 (C), 169.3 (CO), 169.5 (CO), 171.7 (CO), 174.1 (CO); MS *m/e* (relative %): 758 (M^+, 8), 740 (39), 548 (36), 381 (66), 355 (72), 107 (100); HRMS calcd. for $C_{41}H_{40}O_{13}$ (M − H_2O): 740.2469; found: 740.2457.

Ester 18*b*

The cycloadduct **17*b*** (0.0767 g, 0.10 mmol) was dissolved in dichloromethane (20 mL) under nitrogen, and cooled to −12°C. BF_3OEt_2 (0.10 mL, 0.81 mmol) was then added, causing the solution to turn dark blue. The mixture was cooled to −55°C and $LiAlH_4$ (0.37 M in diethyl ether, ca. 1.5 mL, ca. 0.56 mmol) was added dropwise until all of the blue had dissipated, followed by the addition of 50/50 (v/v) methanol/water (10 mL) dropwise. The resulting solution was stirred for 20 min at −55°C and was then allowed to warm to room temperature. At that point, 10% $HCl_{(aq)}$ (1 mL) was added and the organic portion was separated from the aqueous portion. The aqueous portion was extracted three times with dichloromethane and the original organic portion was washed with 10% $HCl_{(aq)}$. The organic portions were combined, dried with $MgSO_4$, and evaporated to give an off-white crystalline mass. Chromatography using silica gel and 30/70 (v/v) ethyl acetate/hexanes gave pure **18*b*** (0.0312 g, 0.043 mmol, 40%); $[\alpha]_D^{20}$ −43.0 (*c* 0.40 g/100 mL in $CHCl_3$); IR (CH_2Cl_2): 1744 (CO) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.05 (m, 1H), 3.39 (5-line m, 2H), 3.52 (6 line m, 2H), 3.58 (s, 3H), 3.63 (s, 6H), 3.69 (s, 3H), 3.73 (s, 3H), 3.74 (s, 3H), 3.87 (s, 3H), 4.57 (d, 1H, J = 5.5), 5.70 (s, 1H), 6.04 (s, 1H), 6.12 (s, 2H), 6.42 (s, 1H), 6.70 (s, 1H), 7.10–7.45 (m, 10H); ^{13}C NMR ($CDCl_3$) δ: 31.8 (CH_2), 37.3 (CH), 46.2 (CH), 48.1 (CH), 52.5_0 (CH_3), 52.5_4 (CH_3), 55.8 (CH_3), 55.9 (CH_3), 56.2 (CH_3), 60.6 (CH_3), 74.1 (CH), 74.7 (CH), 107.2 (CH), 110.4 (CH), 112.2 (CH), 125.6 (C), 126.8, (CH), 127.9 (CH), 128.3 (C), 128.4 (CH), 128.7 (CH), 128.8 (CH), 129.2 (CH), 133.3 (C), 133.5 (C), 136.9 (C), 137.2 (C), 147.9 (C), 148.2 (C), 152.6 (C), 168.8 (CO), 169.4 (CO), 171.2 (CO), 174.1 (CO); MS *m/e* (relative %): 742 (M^+, 21), 578 (7), 548 (7), 515 (8), 427 (27), 381 (22), 355 (41), 149 (74), 121 (97), 107 (93), 91 (61), 77 (100); HRMS calcd. for $C_{41}H_{42}O_{13}$: 742.2625; found: 742.2575.

Deoxysikkimotoxin 7

Ester **18*b*** (0.0236 g, 3.17×10^{-5} mol) was dissolved in THF (5 mL), under nitrogen. Lithium triethylborohydride (191 μL of a 1 M solution in THF, 1.91×10^{-4} mol, 6 equivalents) was then added at 0°C, and the mixture was allowed to stir for 2 h. 10% $HCl_{(aq)}$ (5 mL) was added and the resulting solution was stirred overnight. The mixture was diluted with water and extracted three times with dichloromethane. The organic portions were combined, dried with $MgSO_4$, and evaporated to give a clear, amorphous solid that was chromatographed on silica gel using 40/60 (v/v) ethyl acetate/hexanes to give pure (−)-deoxysikkimotoxin (0.0122 g, 2.94×10^{-5} mol, 93%); $[\alpha]_D^{20}$ −85.8 (*c* 3.3 g/100 mL in $CHCl_3$); ^{13}C NMR ($CDCl_3$) δ: 32.8_0 (CH_2), 32.8_4 (CH), 43.4 (CH), 47.7 (CH), 55.9 (CH_3), 56.0 (CH_3), 56.2 (CH_3), 60.8 (CH_3), 72.1 (CH_2), 77.2 (C), 108.3 (CH), 111.4 (CH), 113.3 (CH), 127.1 (C), 129.4 (C), 136.4 (C), 148.0 (C), 148.2 (C), 152.5 (C), 175.0 (CO); MS *m/e* (relative %): 414 (M^+, 100), 246 (13), 181 (30); HRMS calcd. for $C_{23}H_{26}O_7$: 414.1679; found: 414.1649. Compound **7** had ^1H NMR and IR spectral properties identical to those previously reported (15).

Electrochemical investigation of reduction of mercury complexes of 2-aminocyclopentene-1-dithiocarboxylic acid and some of its derivatives at mercury electrodes

A. Safavi and M.B. Gholivand

Abstract: Electrochemical techniques of polarography, cyclic voltammetry, and controlled potential electrolysis at mercury electrodes have permitted a detailed investigation of the reduction reactions associated with mercury 2-aminocyclopentene dithiocarboxylate complexes, $Hg(ACD)_2$, in dimethyl sulphoxide (DMSO). As a complementary study, the electrochemistry of the ligands themselves was investigated in DMSO solutions and at mercury electrodes. The lability of mercury(II) complexes and their rapid interaction with elemental mercury strongly influence the nature of the redox processes observed at mercury electrodes. Reduction of $Hg(ACD)_2$ at a mercury electrode occurs in an overall two-electron step as:

$$Hg(ACD)_2 + 2e^- \rightleftharpoons Hg + 2\ ACD^-$$

although mercury(I) is implicated as an intermediate.

Key words: reduction, electrochemical techniques, mercury complexes.

Résumé : Faisant appel à des techniques électrochimiques de polarographie, de voltampérométrie cyclique et d'électrolyse à potentiel contrôlé à des électrodes de mercure, on a réalisé une étude détaillée des réactions de réduction associées aux complexes du 2-aminocyclopentènedithiocarboxylate de mercure, $Hg(ACD)_2$, dans le diméthylsulfoxyde (DMSO). Comme étude complémentaire, on a aussi étudié l'électrochimie des coordinats eux-mêmes en solutions dans la DMSO et à des électrodes de mercure. La labilité des complexes du mercure(II) et leur interaction rapide avec le mercure élémentaire influencent fortement la nature des processus rédox observés aux électrodes de mercure. La réduction du $Hg(ACD)_2$ à l'électrode de mercure se produit par un processus global à deux électrons de la forme :

$$Hg(ACD)_2 + 2e^- \rightleftharpoons Hg + 2\ ACD^-$$

même si le mercure(I) est impliqué comme intermédiaire.

Mots clés : réduction, techniques électrochimiques, complexe du mercure.

Introduction

Much interest in transition element – sulphur systems has been generated by organic, inorganic, and physical chemists over the past 10 years (1–3). The redox behaviour of dithiocarbamates and their metal complexes has been extensively studied (4–8) and is noteworthy for the stabilization of unusually high oxidation states of transition metals in metal dithiocarbamate complexes. In contrast, the electrochemistry of dithiocarboxylates has barely been investigated.

2-Aminocyclopentene-1-dithiocarboxylic acid, its derivatives, and their complexes have important applications, especially as fungicides (9, 10) and as models of sulphur–metal proteins (11). The electroanalytical behaviour of some of the above ligands at mercury electrodes and in aqueous media has recently been studied (12, 13). The anodic waves observed for these ligands in aqueous or aqueous–ethanolic media were attributed to mercury complex formation (12, 13). Detailed electroanalytical studies on the above ligands revealed an E_qC_i mechanism (quasi-revsersible electron transfer process followed by an irreversible chemical reaction), as follows, for oxidation of mercury in the presence of these ligands in aqueous or aqueous ethanolic solutions.

$$[1]\quad HG + ACD \rightleftharpoons Hg^{(I)}(ACD) + e^-$$

$$[2]\quad 2Hg^{(I)}(ACD) \rightarrow Hg^{(II)}(ACD)_2 + Hg^0$$

where ACD represents the 2-aminocyclopentene-1-dithiocarboxylate anion.

As part of a continuing study into the electrochemistry of

transition metal complexes of these ligands in nonaqueous solvents such as dimethyl sulphoxide (DMSO), it became necessary to first examine the electrochemical behaviour of the ligands in nonaqueous media, since a knowledge of the electrochemistry of the free ligand is a necessary prerequisite for understanding the redox behaviour of coordinated dithiochelates. DMSO was chosen as the most suitable solvent because the mercury complexes of ACD^- and its derivatives (e.g., $Hg(ACD)_2$) are completely insoluble in water and DMSO was found to be the best solvent for these complexes. Because the electrochemical behaviour of a redox couple can be changed dramatically when water is replaced by a nonaqueous solvent (14), and to aid in the interpretation of the electrochemical behaviour of the complexes, the ligands themselves as well as their complexes seemed to warrant an electrochemical investigation.

Experimental

Instrumentation

The electrochemical measurements were performed with a Princeton Applied Research (PAR) electrochemical system (Princeton, N.J.), model 170 polarographic analyzer. A dropping mercury working electrode (drop time = 2 s), an SCE reference electrode, and a platinum wire auxiliary electrode were used for all polarographic measurements. All measurements were made at 25 ± 0.2°C in DMSO containing 0.5 M $KClO_4$. Controlled potential electrolysis experiments were performed at a mercury pool electrode. The auxiliary and reference electrodes were identical with those used for polarographic measurements. Mercury used as dropping mercury electrode and mercury pool was supplied from Merck (Suprapur) and used without further purification.

Cyclic voltammograms were recorded with the PAR electrochemical system at a Metrohm hanging mercury drop electrode (HMDE). All solutions were thoroughly degassed with

pure argon and a continuous stream of argon was passed over the solutions while measurements were being performed.

Materials

ACDA, its ammonium salt, and its derivatives were prepared according to the procedure described by Takeshima and Yokoyama (15) and Bordas et al. (10). Stock solutions (4×10^{-3} M) of the above ligands were prepared in DMSO (Fluka).

The mercury(II) complexes of ACDA and its derivatives were prepared by the reaction of methanolic solutions of the appropriate ligand with mercury(II) nitrate in a 2:1 molar ratio, drying, and then recrystallizing (16).

Because of its hygroscopic nature and the expense of obtaining strictly anhydrous DMSO (17) and because it is well known that solution properties can change significantly when small amounts of water are added to nonaqueous solvents (14), experiments were conducted to determine the effect of traces of water in DMSO on our results. The experiments undertaken in the presence of alumina and deliberately added water (up to 1%) demonstrated that electrochemical measurements of ligands are insensitive to the presence of small amounts of water in DMSO.

Results and discussion

Electrochemistry of acid derivative ligands of ACDA

The ligands that were studied can be categorized into two groups: the acid derivatives of ACDA that differ from each other by the substitution on nitrogen (Scheme 1; **1**–**4**) and the ester derivatives of ACDA (Scheme 1; **5**, **6**) in which the hydrogen on the dithiocarboxylic acid group is substituted with an alkyl group. The electroanalytical behaviour of the acid derivatives is discussed first.

The polarogram of ACDA illustrated in Fig. 1 is typical of all the acid derivatives examined. The two oxidation waves are characteristic of ACDA and its acid derivatives. The second anodic wave occurred close to the anodic potential limit and is either due to oxidation of the Hg(I) complex or formation of mercury-rich cationic forms of the Hg(II) complex as is suggested for other Hg(II) dithiocarbamate complexes (7). Further work on this is in progress to characterize the oxidation wave II. However, most of the interest in relation to the anodic waves of the acid derivatives lies in the wave near −0.35 V (wave I), which we will consider in detail. Table 1 lists the half-wave potentials of wave I for various derivatives of ACDA at a concentration of 9×10^{-4} M in DMSO. The height of wave I is proportional to the square root of the column height ($h^{1/2}$) and concentration, showing the diffusion character of this wave. Voltammograms of ACDA at a rotat-

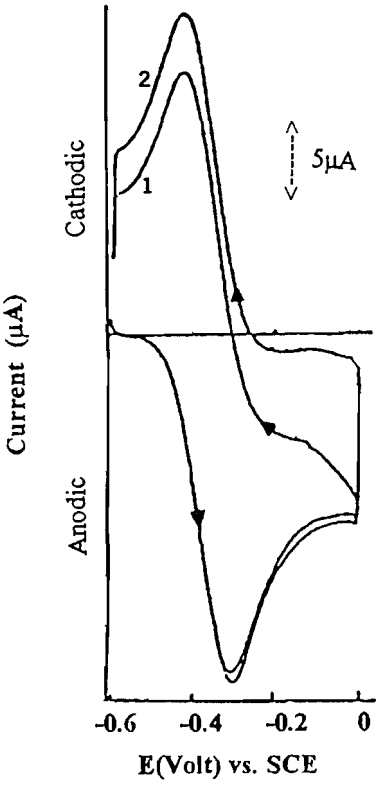
ing platinum working electrode showed no anodic wave at a potential range of −1 to zero. This indicates that wave I is due to the oxidation of mercury in the presence of the above ligands. With increasing concentration, half-wave potentials were essentially constant for the acid derivatives, which is an indication of a 1:1 (ligand:metal) mercury complex formation (18). Controlled potential coulometry at a potential on the plateau of wave I showed a one-electron oxidation process. Plots of E vs. log $(i_d - i)/i$ and $E_{1/4} - E_{3/4}$ data are also consistent with $n = 1$ (Table 1).

For further elucidation of the electrode mechanism associated with wave I, a solution of mercurous nitrate in DMSO was added to the polarographic cell containing ACDA, and its polarogram was recorded. A composite cathodic–anodic wave was obtained, as is illustrated in Fig. 2. By increasing the concentration of mercurous nitrate, the participation of the cathodic part was increased while the anodic current was decreased. By addition of a solution of mercuric nitrate in DMSO to a DMSO solution of ACDA, a cathodic wave was observed at wave I and a composite cathodic–anodic wave was observed at wave II. The height of the cathodic part of wave II was time dependent and decreased with time, while the height of the cathodic wave I increased. All these findings illustrate that wave I is due to Hg(I) compound formation and oxidation wave II is due either to the oxidation of the Hg(I) complex or to oxidation of the mercury electrode in the presence of the Hg(II) complex to form a mercury-rich compound. Later it was found that the oxidation wave II appears also as an anodic wave in the polarograms of synthetically prepared Hg(II) complexes and occurs at the same potential. The appearance of a composite cathodic–anodic wave upon addition of mercurous nitrate can normally be taken as evidence of the reversibility of the electrode process. However, other data obtained suggest that a quasi-reversible assignment is more appropriate.

Cyclic voltammetry was also used to study the mechanism of the electrode process on mercury. The diagnostic criteria used to interpret the cyclic voltammograms were those developed by Nicholson and Shain (19, 20) and Matsuda and Ayabe (21) as summarized by Bard and Faulkner (22) and Brown and Large (23). Directly measured parameters are (22, 23) the anodic and cathodic peak potentials, $E_{p,a}$ and $E_{p,c}$, peak currents $i_{p,a}$ and $i_{p,c}$, half peak potentials (i.e., the potentials at $i = 0.5i_p$), $E_{p,a/2}$, and $E_{p,c/2}$, and the scan rate, v. Derived terms are peak separation $E_{pp} = E_{p,a} - E_{p,c}$, the normalized peak currents $i_{p,c}/v^{1/2}$, $i_{p,a}/v^{1/2}$, the peak current ratio $i_{p,c}/i_{p,a}$, $E_{p,c/2} - E_{p,c}$, and $E_{p,a/2} - E_{p,a}$. Full experimental results are given elsewhere (13), but briefly, taking ACDA as an example, in a solution containing 1.5 mM of ACDA, an increase in scan rate from 0.01 to 0.20 V s^{-1} resulted in an increase in E_{pp} from 75 to 125 mV, with the cathodic and anodic peak potentials both shifting

Fig. 3. Cyclic voltammogram of 10^{-4} M ACDA Switching potential was held for (1) 0 s, (2) 15 s; scan rate, 0.2 V s^{-1}.



about 25 mV. $E_{p,c/2} - E_{p,c}$ increased by 20 mV, and also $E_{p,a/2} - E_{p,a}$ increased by 20 mV. The values of $i_{p,a}/v^{1/2}$ decreased from 47.5 to 43.5 and $i_{p,c}/v^{1/2}$ decreased from 46 to 43.5 with increase in scan rate. The ratio of $i_{p,c}/i_{p,a}$ was approximately constant at 0.97 ± 0.03. An experiment was conducted in which the switching potential was held for 15 s. No change in cyclic voltammetry parameters was observed by holding the switching potential for 15 s (Fig. 3). Although these results are consistent with a quasi-reversible electron transfer process without any coupled chemical reactions, the possibility of a fast disproportionation reaction such as

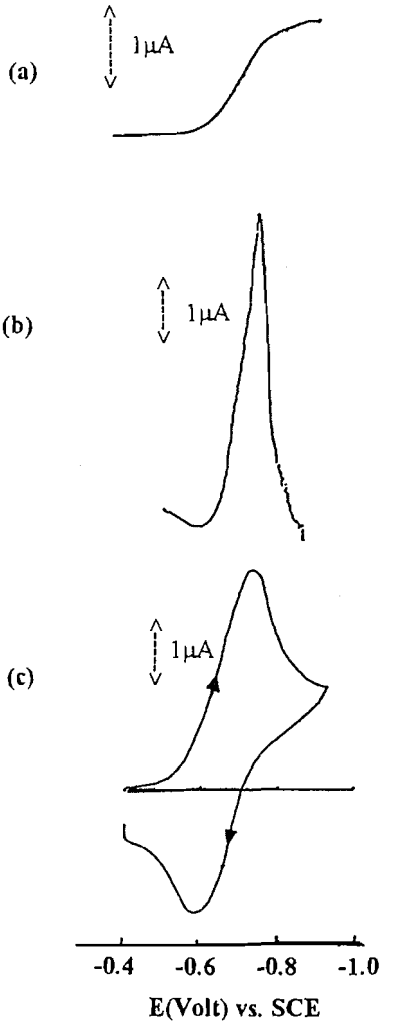
[3] $2Hg(ACDA) \quad Hg^0 + Hg(ACDA)_2$

cannot be ruled out.

Reduction of mercury(II) complexes of ACDA and its acid derivatives

Preliminary polarographic analysis indicated that each mercury complex of ACDA or its derivatives undergoes reduction in one step. The reduction wave appears at about −0.70 V for complexes of ACDA and its acid derivatives. In each case, the graphical plot of limiting current vs. the square root of the column height of mercury ($h^{1/2}$) was linear and passed through the origin. This is taken as evidence that the limiting currents are diffusion controlled. Figure 4 shows a dc polarogram, differential pulse polarogram, and cyclic voltammogram for reduction of $Hg^{II}(ACD)_2$ in a DMSO solution. Controlled-potential coulometry at the mercury pool electrode at a potential on the

Fig. 4. Reduction of $Hg(ACD)_2$ at the mercury electrode in DMSO (0.5 M $KClO_4$) at 25°C; (a) dc polarogram; (b) differential pulse polarogram; (c) cyclic voltammogram.



plateau of the reduction wave gave n values of 2 ± 0.1 for all the complexes. These data provide convincing evidence that, in DMSO, the overall electrode process is as follows.

[4] $HgL_2 + 2e^- \quad Hg + 2L^-$

If the above direct two-electron reduction step is accurate, the plot of E vs. log $(i_d - i)/i^2$ should be linear with a slope of 29 mV. Experimentally determined slopes are much greater than this for all the mercury complexes (Table 2). Table 2 also shows that $E_{1/4} - E_{3/4}$ values are close to that expected for a one-electron process. Therefore, while the overall electrode process was previously characterized by eq. [4], the reaction pathway in DMSO has yet to be considered.

The data in Table 2 suggest that a reversible one-electron transfer mechanism appears to be more accurate in describing the reduction process than a two-electron charge transfer step. Since coulometric data gave $n = 2$, it appears that the presence of a chemical reaction is prevalent in this reduction step. Thus, it is assumed that the reduction occurs via species other than the mercuric complex. The decomposition of mercuric com-

plexes seems feasible, as will be described later. This may take place via one of the following mechanisms.

[5] $Hg^{II}L_2 \ll Hg^0 + L_2$

[6] $2Hg^{II}L_2 \ll 2Hg^{I}L + L_2$

[7] $Hg^{II}L_2 + Hg^0 \ll 2Hg^{I}L$

If one of the above prechemical processes is taking place, the reduction wave may be due either to the reduction of the dimer (L_2) or of $Hg^{I}L$. If mechanism [5] applies, the product of the chemical reaction is the dimer (L_2) and thus the reduction wave is due to the reduction of this entity. The reduction of the dimer is a two-electron process with the slope of the plot of E vs. log $(i_d - i)/i$ nearly equal to 29 mV (13, 24). However, the slopes of the plots of E vs. log $(i_d - i)/i$ obtained for reduction waves in this study were much higher than this value (Table 2). Moreover, it was later proved (13, 24) that the dimer is converted to $Hg^{I}L$ in the presence of elemental mercury. Therefore, the reaction denoted by eq. [5] is ruled out.

Further investigation revealed that the polarogram of the ammonium salt of ACDA showed an oxidation wave with an $E_{1/2}$ value similar to that found for the reduction of the $Hg(ACD)_2$ complex. Also, when a DMSO solution of the ammonium salt of ACDA (denoted by ACD^-) was added to a solution of $Hg^{II}(ACD)_2$ in DMSO, a composite cathodic–anodic wave was obtained. In a similar manner the polarogram of each anion of the acid derivatives of ACDA showed an oxidation wave with $E_{1/2}$ value similar to that found for the reduction of the corresponding mercury complex in DMSO. Moreover, when the cyclic voltammogram of the ammonium salt of ACDA (ACD^-), in DMSO, was compared with that of $Hg(ACD)_2$ at HMDE, similar cyclic voltammograms were obtained (Fig. 5). It was discussed before that the anodic wave of ACDA and its acid derivatives in DMSO solutions is due to the formation of mercury(I) complex. Therefore, the reduction wave obtained in the case of these complexes is due to the reduction of $Hg^{I}L$. This means that the reduction of each mercuric complex occurs via a mercurous intermediate produced according to either eq. [6] or [7].

If eq. [6] is responsible for the prechemical step occurring before the reduction process, the coulometric analysis at the potential of the cathodic wave must yield $n = 1$, since each mole of Hg(II) complex yields only one mole of Hg(I) complex, which can undergo reduction at the electrode surface. The actual value of n obtained experimentally was equal to 2. Therefore, formation of $Hg^{I}L$ is most probably taking place via eq. [7]. If this reaction is correct, for each mole of $Hg^{II}L$ complex, two moles of $Hg^{I}L$ complex are produced that can then undergo reduction at the electrode surface. This is consistent with the coulometric data of $n = 2$ and also with the slopes of the linear plots of E vs. log $(i_d - i)/i$ and $E_{1/4} - E_{3/4}$ values, which show a one-electron cathodic process. Thus, the following mechanism is suggested for reduction of the mercuric complexes of ACDA and its acid derivatives on the mercury electrodes and in DMSO.

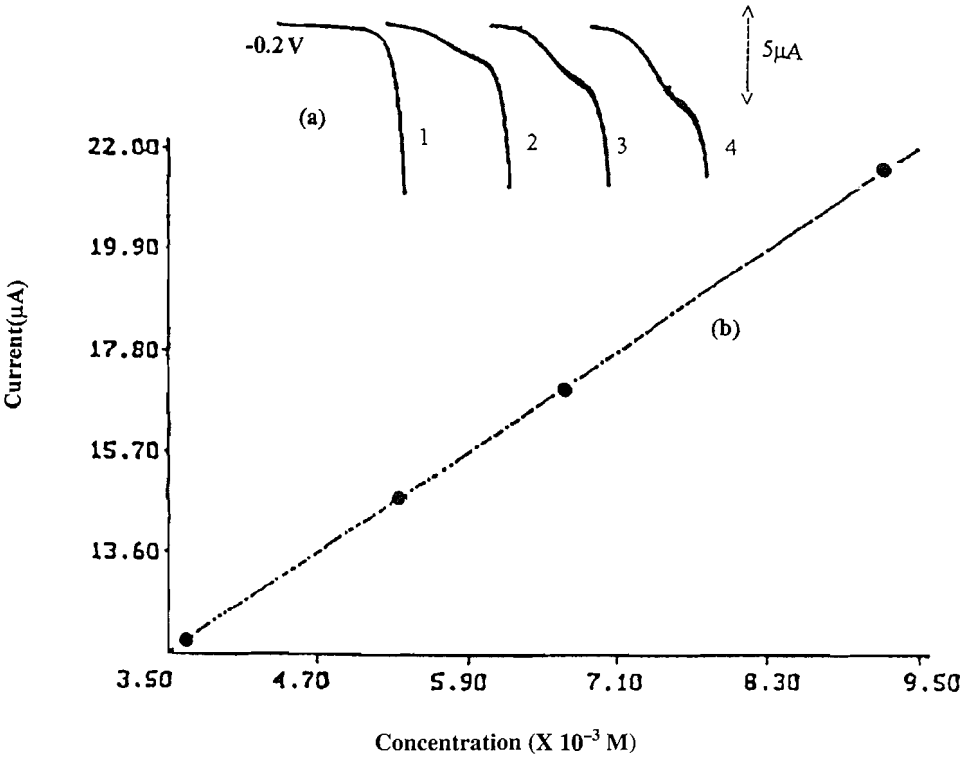
[7] $Hg^{II}L_2 + Hg^0 \ll 2Hg^{I}L$

[8] $2Hg^{I}L + 2e^- \quad 2Hg^0 + 2L^-$

The mercuric complexes of the ligands **3** and **4** all showed exactly the same electroanalytical behaviour and therefore the reduction mechanisms for these complexes all obey the above pattern. A similar mechanism has been suggested for mercury(II) dithiocarbamates (25–27).

For further elucidation of the electrode process, the cyclic voltammograms were analyzed. Full experimental data on individual complexes are given elsewhere (13) but, as an example, consider the cyclic voltammograms of 1.1 mM $Hg^{II}(ACD)$. As the scan rate increases from 0.02 to 0.2 V s^{-1}, the following observations in the cyclic voltammetry parame-

Fig. 6. (a) Polarograms of compound **5** at concentration (1) 0, (2) 1.67, (3) 2.86, and (4) 3.75 ($\times 10^{-4}$ M). Polarograms were recorded from −0.2 V vs. SCE towards more positive potentials. (b) The dependence of anodic wave current of compound **6** on its concentration.

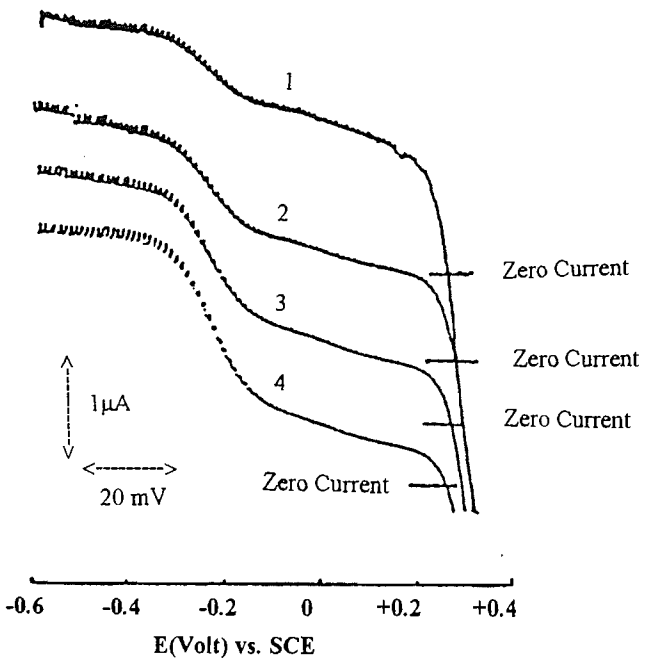


ters are obtained. The peak-to-peak separations E_{pp}, $E_{p,c/2} - E_{p,c}$, and $E_{p,a/2} - E_{p,a}$ were approximately constant at 80, 80, and 75 mV, respectively, and the ratio $i_{p,a}/i_{p,c}$ was constant at about 0.67. The values of $i_{p,c}/v^{1/2} = 0.41 \pm 0.02$ and $i_{p,a}/v^{1/2} = 0.62 \pm 0.03$ also remained effectively constant. An experiment was also conducted in which the switching potential was held for some time. No change in CV parameters was observed by holding the switching potential for 15 s. According to the diagnostic criteria (22, 23), these results are consistent with a quasi-reversible electron transfer process without any coupled chemical reaction. However, polarographic data show that the electrode reduction of the mercuric complex of ACDA and its acidic derivatives is accompanied by a prechemical reaction. It is reported (22) that the effect of the coupled prechemical reaction on the electrode reaction depends on the magnitudes of both the forward and backward rate constants, K_f and K_b (s^{-1}), and the equilibrium constant k. When k is large, the equilibrium lies so far to the right that most of the material is already in the form of the electroactive substance. The preceding reaction then has little effect on the electrochemical response, which appears as unperturbed Nernstian behaviour. This situation exists for mercuric complexes of ACDA and its acid derivatives.

Electrochemistry of ester derivative ligands of ACDA

The dc polarographic study of the esters of ACDA (compounds **5** and **6**) showed one anodic wave at about +0.24 V (Table 1 and Fig. 6*a*). The height of the wave was proportional to $h^{1/2}$ and concentration, showing the diffusion behaviour of this wave (Fig. 6*b*). The height of the polarographic wave of a solution at a given concentration of ester was about twice the height of the polarographic wave obtained in the case of the acid derivatives. The log plot analyses of the anodic wave of the esters together with $E_{1/4} - E_{3/4}$ data were consistent with $n = 2$ (Table 1), while coulometric analysis at a potential on the plateau of the anodic wave of each of the esters gave $n = 1$. Furthermore, no anodic wave was observed for esters in the potential range of −1 to +0.5 V on a rotating platinum electrode. It is therefore concluded that the anodic wave obtained for esters of ACDA arises from oxidation of mercury and formation of the mercury(II) complex. The fact that the half-wave potential of the anodic wave of esters is concentration dependent shows that the mercury complex is not 1:1 (ligand:metal) as in the case of the mercury(I) complex of the acid derivatives. For further illustration of the anodic wave of esters, to a solution of compound **6** in a polarographic cell was added a solution of mercurous nitrate in DMSO, and its polarogram was recorded; a new cathodic peak was observed at about −0.26 V. By increasing the concentration of mercurous nitrate the height of the cathodic wave at −0.26 V was increased, while addition of a DMSO solution of mercuric nitrate to a solution of one of the esters resulted in a cathodic wave at −0.26 V and a composite cathodic–anodic wave at about +0.24 V, as illustrated in Fig. 7. The height of the composite wave was time dependent. The participation of the cathodic part of the composite wave was decreased while the height of the cathodic part at −0.26 V was increased by time. These findings clearly indicate that the anodic wave obtained

Fig. 7. Polarograms of (1) 10^{-3} M of compound **6** plus 5.7×10^{-4} M $Hg(NO_3)_2$; (2) solution (1) after 10 min; (3) solution (1) after 20 min; (4) solution (1) after 30 min. Polarograms were recorded from −0.6 V vs. SCE towards more positive potentials.



in the case of esters is due to Hg(II) rather than Hg(I) complex formation.

Cyclic voltammetry of solutions of esters individually at HMDE reflects the dc polarographic pattern of each ligand. One oxidation peak was obtained in each case and a cathodic peak was observed in the reverse scan. The diffusion behaviour of the anodic peak was also confirmed by its linear dependence on $v^{1/2}$ and on concentration.

In DMSO containing 5 mM of compound **5**, an increase in scan rate, v, from 0.02 to 0.2 V s^{-1} resulted in the following changes to the usual cyclic voltammetry parameters (22, 23): (*i*) an increase of the peak-to-peak separation, from 48 to 90 mV, with the cathodic potential, $E_{p,c}$, shifting more (27 mV) than the anodic peak potential, $E_{p,a}$ (15 mV); (*ii*) $E_{p,c/2} - E_{p,c}$ increased by 20 mV whereas $E_{p,a/2} - E_{p,a}$ increased by only 10 mV. Similarly, the values of $i_{p,c}/v^{1/2}$ and $i_{p,a}/v^{1/2}$ were about constant with scan rates at 1.57 ± 0.05 and 1.66 ± 0.06, respectively. The ratio $i_{p,c}/i_{p,a}$ increases slightly and approaches unity with increase in scan rate.

The above results are consistent with a quasi-reversible electron transfer process. The presence of a coupled chemical reaction can be deduced from the asymmetry of the cyclic voltammograms of esters, arising from the increasingly drawn-out nature of the cathodic branch with increasing scan rate, whereas changes in the anodic wave are smaller. However, changes in the cyclic voltammetry parameters with scan rate are not so distinct. The most likely reason is that the chemical reaction accompanying the electron transfer process is either too slow or too fast (22) with respect to the cyclic voltammetry time scale, so that its effect is not easily distinguished from cyclic voltammetry parameters. These results are in accordance with polarographic results that, as mentioned before, proved the presence of a chemical reaction coupled with the electron transfer process, i.e., conversion of Hg(II) complex to Hg(I) complex (the reverse of the disproportionation reaction). This conversion was relatively slow with respect to the cyclic voltammetry time scale. Thus, it is not surprising that the effect of the coupled reaction on the cyclic voltammograms is not so pronounced. The most probable mechanism associated with the oxidation of esters of ACDA on a mercury electrode is an EC process as follows.

[9] $Hg + 2L^- \rightleftharpoons Hg^{(II)}L_2 + 2e^-$

[10] $HgL_2 + Hg \rightleftharpoons 2Hg^{(I)}L$

This mechanism agrees well with the coulometric data for $n = 1$ and the slope of the plot of E vs. log $(i_d - i)/i^2$, together with $E_{1/4} - E_{3/4}$ data that showed a two-electron process.

Reduction of mercury complexes of the ester derivatives

Polarographic analysis of the mercuric complexes of the esters of ACDA (ligands **5** and **6**) indicated that these mercuric complexes undergo reduction in one step. The reduction wave that appears at about −0.25 V is diffusion controlled as its height is directly proportional to $h^{1/2}$ and concentration of the ligand. Cyclic voltammograms at mercury electrodes are those expected for a chemically reversible electrode process. Controlled potential coulometry of each of the complexes at a mercury pool electrode gave $n = 2$. A plot of E against log $(i_d - i)/i$ for each complex gave linear plots ($r = 0.998$) with slopes of 76 and 65 mV for mercury complexes of ligands **5** and **6**, respectively. $E_{1/4} - E_{3/4}$ values from dc polarograms are close to that expected for a one-electron charge-transfer step for the above complexes (Table 2).

It was proved before that, while in DMSO solutions ACDA and its acid derivatives undergo a one-electron anodic process at a mercury electrode, the ester derivatives of ACDA react at a mercury electrode via a two-electron oxidation process, giving the $Hg^{(II)}L_2$ complex. The wave due to the anodic oxidation of mercury in the presence of ester derivatives of ACDA occurred at about +0.24 V, which, as proved, is due to $Hg^{(II)}L_2$ formation. However, when a solution of synthetically prepared $Hg^{(II)}L_2$ is electrolyzed at a mercury electrode it is reduced to elemental mercury and L^- via a $Hg^{(I)}L$ intermediate. In fact, in this case the $Hg^{(I)}L$ complex undergoes reduction at about −0.25 V. That is why the half-wave potential of the reduction of the $Hg^{(II)}L_2$ complex (−0.25 V) is different (cf. Tables 1 and 2) from the half-wave potential of the anodic wave of the free ligand (+0.24 V). The $Hg^{(I)}L$ complex can then undergo reduction at about −0.25 V. All these findings show that although the overall electrode process is again

[11] $HgL_2 + 2e^- \rightleftharpoons Hg + 2L^-$

the data support the idea that, in DMSO solution, reduction of mercuric complexes of the ester derivatives occurs via a mercury(I) intermediate, as was suggested for mercuric complexes of the acid derivatives of ACDA.

It seems clear from the above discussion that, at mercury electrodes and in DMSO solutions and in the presence of the

above ligands, mercury(II) complexes reduce to elemental mercury via a mercury(I) intermediate.

Radiation-induced dissolution of chromium oxide in aqueous solutions

Luis García Rodenas, Mauricio Chocrón, Pedro J. Morando, and Miguel A. Blesa

Abstract: Gamma irradiation of suspensions of a commercial sample of α-Cr_2O_3 in the presence of $KBrO_3$ in the concentration range $0.1 \leq [BrO_3^-] \leq 0.4$ mol dm^{-3}, at pH 4 and 25°C brings about oxidative dissolution. Release of Cr(VI) to the solution proceeds at a constant rate that increases with bromate concentration, even in conditions of quantitative e_{aq}^- scavenging. A mechanism of reactions is proposed in which OH and BrO_2 radicals oxidize surface Cr(III) to Cr(IV), and ionic release is achieved by oxidation of surface Cr(IV) by bromate. The corresponding set of equations was solved by a rigid method for the integration of ordinary differential equations, using these two heterogeneous rate constants as adjustable parameters. The calculated profiles are in close agreement with the experimental data.

Key words: chromium oxides, radiation-induced dissolution, oxidation dissolution.

Résumé : L'irradiation γ d'un échantillon commercial d'α-Cr_2O_3, en présence de $KBrO_3$, à des concentrations de BrO_3^- allant de 0,1 à 0,4 mol dm^{-3}, à un pH de 4 et à 25°C, provoque une dissolution oxydante. L'apparition de Cr(VI) dans la solution se produit à une vitesse constante qui augmente avec la concentration de bromate, même dans des conditions de piégeage quantitatif de e_{aq}^-. On propose un mécanisme des réactions dans lequel les radicaux OH et BrO_2 oxydent la surface du Cr(III) en Cr(IV) qui est par la suite oxydé par le bromate pour provoquer une apparition de chrome ionique. L'ensemble correspondant des équations a été résolu par une rude méthode pour l'intégration des équations différentielles ordinaires qui utilise ces deux constantes de vitesse hétérogènes comme paramètres ajustables. Les profils calculés sont en bon accord avec les données expérimentales.

Mots clés : oxydes de chrome, dissolution induite par les radiations, dissolution oxydante.

[Traduit par la rédaction]

Introduction

The interaction of chromium(III) oxides is governed by the chemical inertia of the d^3 Cr(III) ion. Substitution reactions on octahedral Cr(III) complexes in solution are slow, and can be accelerated only by severe distortions from the octahedral coordination (1) or by electron transfer to generate either Cr(II) or Cr(IV). Phase transfer of Cr(III) as involved in α-Cr_2O_3 can also be accelerated by oxidation (2, 3) or reduction,[2] as accomplished by heterogeneous electron transfer. Acid attack (4) is only effective in dissolving hydrous oxides.

Comparison of the behavior of the chromium(III) and iron(III) oxides is interesting for both fundamental and applied reasons. Iron(III) oxides are easily dissolved by reductive attack (5–9), whereas oxidation to Fe(VI) is only possible in strongly alkaline and (or) oxidative media (10). The reverse is true for chromium(III) oxides. As both oxides are present in the layers grown on stainless steel by corrosion, the sensitivity to aqueous attack is influenced by this contrasting behavior. In particular, whenever it is necessary to remove the oxide layers, a two-stage cleaning process is almost mandatory: an oxidative step to remove chromium oxides and a reductive stage to dissolve iron oxides (11). Cleaning of stainless steel surfaces is an important problem in nuclear technology, associated with the need to remove the radioactive oxides to decrease the radiation fields in the critical components of the heat transport circuit (chemical decontamination).

The dissolution of these oxides is influenced by radiation fields in two ways. First, the defect structure of the oxides is heavily influenced by the annealing effect of the radiation, and eventually by the creation of defects by neutron irradiation (for in-core components). Secondly, the radiolysis of the aqueous medium generates both oxidizing and reducing species, especially OH and e_{aq}^-.

The first effect has been explored in previous papers (12).[3] Concerning the influence of solvent radiolysis, Buxton et al. (13) have shown that colloidal haematite (α-Fe_2O_3) and magnetite (Fe_3O_4) dissolve following attack by one-electron reducing free radicals generated by the radiolysis aqueous solutions of propan-2-ol saturated with nitrous oxide. Also, Mulvaney et al. (14) reported the reductive dissolution of suspensions of manganese oxides (α-, δ-, and γ-MnO_2 and Mn_5O_8) under steady γ-irradiation of aqueous solutions of propan-2-ol saturated with nitrous oxide.

Whereas the reductive dissolution of Fe(III) oxides in media containing OH scavengers is well known, the possibility of oxidative dissolution of chromium(III) oxides in media containing e_{aq}^- scavengers has not been explored. In neutral aqueous solution, Patnaik et al. (15) reported the homogeneous radiolytic oxidation of chromium(III) sulfate in the presence of BrO_3^-.

In the present paper we report a kinetic study of the radiolytic dissolution of suspensions of α-Cr_2O_3 in the presence of $KBrO_3$ at pH 4 and 25°C.

Experimental

α-Cr_2O_3 was a commercial sample (Puratronic). It was characterized by chemical analysis: the assay of Cr was 68.40 wt.% measured by atomic absorption spectrometry (AAS) using a Varian AAR 5 spectrophotometer. The powder X-ray diffractogram obtained in a Philips X-ray PW 1130 demonstrated the product to be α-Cr_2O_3; its surface BET area was measured in a Micromeritics Accusorb 2100 E to be 1.73 $m^2\ g^{-1}$.

The dissolution experiments were performed in a cylindrical beaker, under continuous magnetic stirring. In a typical experiment 20 mg α-Cr_2O_3 was suspended in 50 cm^3 $KBrO_3$ solution of appropriate concentration at pH 4.0 and 25.0 ± 0.1°C. The reaction was started by placing the test tube in a standarized position in a ^{60}Co γ-irradiation facility (Ezeiza Atomic Center); the γ-dose rate in the tube position was 10.12 krad min^{-1}. Previous tests demonstrated that the thermally activated dissolution reaction was negligible during the whole time span of the irradiation experiments. The reaction progress was followed by periodically withdrawing samples with a syringe and filtering them through a 0.45-μm Nuclepore membrane; the concentration of Cr(VI) in the filtrate was determined spectrophotometrically using diphenylcarbazide (16). In some samples, total chromium was measured by AAS.

Results and discussion

Figure 1 shows the concentration of Cr(VI) dissolved from α-Cr_2O_3 as a function of time for different $KBrO_3$ concentrations. Thermal data (no irradiation) and total chromium concentration data are also shown. The oxide dissolves as Cr(VI) at a constant rate that is a function of the oxidant concentration.

The primary processes occurring during the radiolysis of water have been studied extensively (17). In particular, in aqueous $KBrO_3$ solutions, the hydrated electron reacts with BrO_3^- yielding BrO_2, which was postulated to readily oxidize dissolved Cr(III) (15). Therefore we propose the following mechanism for the radiation-induced dissolution of α-Cr_2O_3 in aqueous solutions of $KBrO_3$, reactions [1]–[9]:

[1] $H_2O \rightarrow e_{aq}^-, OH, H, H_2O_2, H_2$

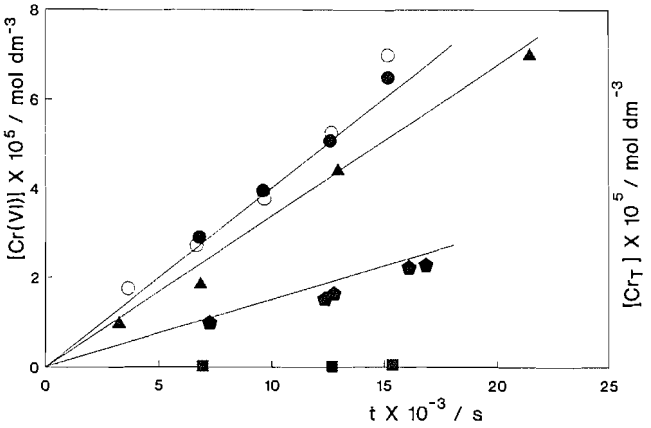
[2] $BrO_3^- + e_{aq}^- + H_2O \rightarrow BrO_2 + 2\ OH^-$

[3] $\equiv Cr^{3+} + BrO_2 \rightarrow \equiv Cr^{4+} + \text{products}$

[4] $Cr_T + \equiv Cr^{4+} + BrO_3^- \rightarrow Cr(VI)_{aq} + \equiv Cr^{3+} + \text{products}$

[5] $\equiv Cr^{4+} + e_{aq}^- \rightarrow \equiv Cr^{3+}$

Fig. 1. Concentrations of Cr(VI) and total chromium (Cr_T) as a function of time from radiation-induced dissolution of Cr_2O_3 in aqueous solution of $KBrO_3$ at 25°C and pH 4.0. Experimental values: ⬟, 0.1; ▲, 0.3, and ○, 0.4 mol dm^{-3} $KBrO_3$ as [Cr(VI)] and ●, 0.4 mol dm^{-3} $KBrO_3$ as [Cr total]; ■, 0.4 mol dm^{-3} $KBrO_3$, no irradiation.
Calculated values: (_____).



[6] $\equiv Cr^{3+} + OH \rightarrow \equiv Cr^{4+} + OH^-$

[7] $BrO_2 + BrO_2 \rightarrow Br_2O_4 + H_2O \rightarrow BrO_2^- + BrO_3^- + 2H^+$

[8] $OH + OH \rightarrow H_2O_2$

[9] $BrO_2^- + OH \rightarrow BrO_2 + OH^-$

In these equations, $\equiv Cr^{3+}$ and $\equiv Cr^{4+}$ represent surface chromium ions. To normalize the kinetic equations, the corresponding surface concentrations (in mol m^{-2}) were transformed into equivalent bulk concentrations (in mol dm^{-3}) using eq. [10]

[10] $[\equiv Cr^{3+}] = N_s S_e w / V$

where N_s = number of active sites per unit area, S_e = specific surface area, w = mass of oxide, and V = volume of solution. The N_s value was estimated to be 5 sites nm^{-2} (18). The value of instantaneous surface ($S = S_e w$) can be considered invariable throughout the experiment because the fraction of dissolved chromium is only about 2%. From eq. [10], the value $[\equiv Cr^{3+}] = 5.3 \times 10^{-6}$ mol dm^{-3} was obtained.

In eq. [4] $[Cr_T] = 1$ was introduced as a procedure to keep $[\equiv Cr^{3+}] + [\equiv Cr^{4+}]$ constant throughout the reaction. The rate is therefore given by

[11] $R = k_4\ [BrO_3^-]\ [\equiv Cr^{4+}]$

where k_4 is given in $mol^{-1}\ dm^3\ s^{-1}$.

Most of the rate constants involved in eqs. [2]–[9] are available from the literature. Equation [6] represents the heterogeneous attack of OH on ≡Cr(III). The equivalent homogeneous process has been studied, and the reported rate constant is $3.1 \times 10^8\ M^{-1}\ s^{-1}$ (19). In principle, it is possible to calculate the ratio of collisional frequencies of the heterogeneous to homogeneous reactions; see, for example, refs. 20 and 21. We

Table 1. Rate constants for reactions [2]–[9].

Reaction	Constant/M^{-1} s^{-1}	Reference
[2]	4.1×10^9	24
[3]	4.3×10^4	This work
[4]	3.8×10^{-3}	This work
[5]	1.3×10^{11}	Upper limit; see text
[6]	3.1×10^8	19
[7]	1.4×10^9	24
[8]	5.5×10^9	17
[9]	1.9×10^9	24

found, however, that the rate calculated using the homogeneous rate constant and the equivalent homogeneous concentration (eq. [10]) was similar to that calculated from the above-mentioned ratio. Furthermore, the values of k_3 and k_4 (our most important parameters, see below) are highly insensitive to large changes in k_6.

Using these literature data, only the heterogeneous rate constants for reactions, [3], [4], and [5] must be derived from our results. In fact, reaction [5] does not contribute to the dissolution behavior; even a diffusion-limited value cannot compete with the scavenging of e_{aq}^- by BrO_3^-, reaction [2], at the concentrations used in this work. A value $k_5 = 1.3 \times 10^{11}$ M^{-1} s^{-1} was nominally included in the calculations.

The set of reactions [1]–[9] implies that dissolution is achieved in two heterogeneous stages: (*a*) the oxidation of ≡Cr(III) to ≡Cr(IV) through the action of both BrO_2 and OH (reactions [3] and [6]); (*b*) the oxidation of ≡Cr(IV) to eventually yield dissolved Cr(VI) through the action of bromate (eq. [4]). Equations [7] and [8] represent the alternative pathways of BrO_2 and OH consumption through dimerization; the contribution of reaction [8] is negligible as compared to reaction [6] whereas, in the steady state, reaction [7] is the main pathway of BrO_2 disappearance. The buildup of BrO_2^- through eq. [7] in turn triggers the alternative OH consumption pathway, eq. [9].

The scheme of reactions leads to a limiting constant dissolution rate when $[\equiv Cr^{4+}]$ achieves a steady state value, given by:

$$[12] \quad R_{ss} = k_4 [BrO_3^-] [\equiv Cr^{4+}]_{ss}$$

The heterogeneous scheme, eqs. [1]–[9], bears resemblances to and dissimilarities with the scheme proposed by Patnaik et al. (15) for the homogeneous radiolytic oxidation of Cr(III) in bromate media. Patnaik et al. proposed homogeneous reactions equivalent to [3] and [6]; due to the higher [Cr(III)], the only fate for BrO_2 in his scheme is the reaction with Cr(III), at variance with the heterogeneous case. The second difference is the fate of Cr(IV); in homogeneous media, it disproportionates rapidly:

$$[13] \quad 3\ Cr(IV) \rightarrow 2\ Cr(III) + Cr(VI)$$

whereas on the surface of the solid, it survives long enough to accumulate. Its removal takes place as a rather slow chemical oxidation by bromate (eq. [4]).

The whole set of rate equations corresponding to the reaction scheme [1]–[9] was solved by a rigid method for the integration of ordinary differential equations (22), using standard G values for e_{aq}^- and OH of 2.8 molecules per 100 eV of absorbed energy. Table 1 shows the rate constants used in the optimized calculations. The results are in agreement with the qualitative analysis given above.

Fig. 2. Concentrations of ≡Cr(IV) as a function of time for different concentrations of $KBrO_3$.

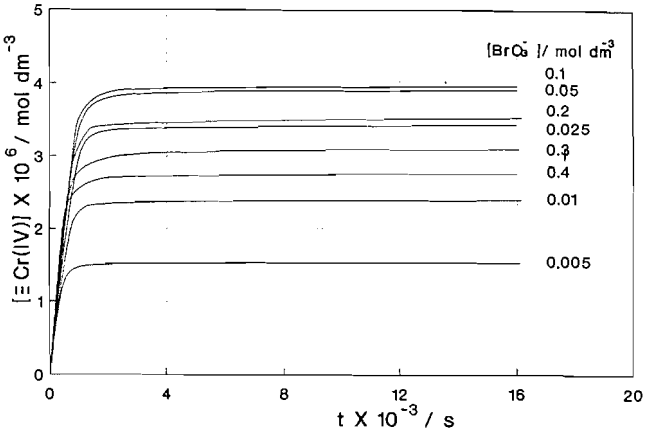


Fig. 3. Calculated steady state concentration of ≡Cr(IV) as a function of $KBrO_3$.

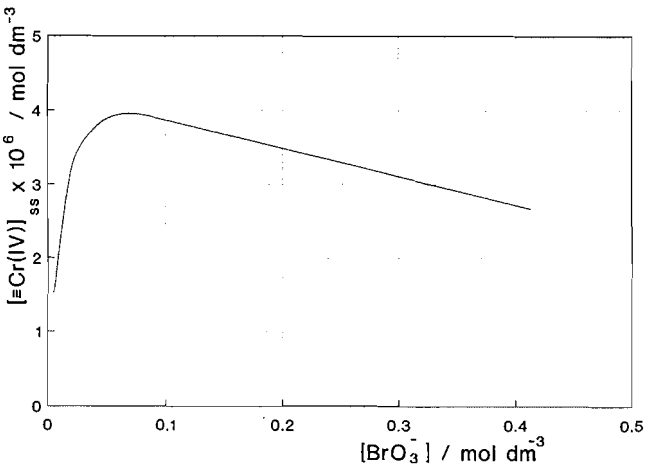
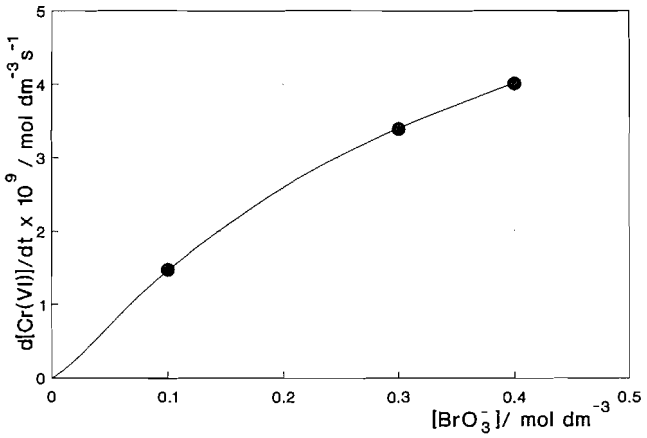


The calculated shapes of the dissolution profiles, expressed as Cr(VI) vs time, are in very good agreement with the experimental data, as shown in Fig. 1. The reaction scheme predicts that steady state concentrations of ≡Cr(IV) are reached at rather short times. These steady state values depend on the $KBrO_3$ concentration, as seen in Fig. 2. The data from Fig. 2 indicate a decrease in $[\equiv Cr^{4+}]_{ss}$ as the BrO_3^- concentration increases, within the explored range ($[BrO_3^-] \geq 0.1$ mol dm^{-3}). This effect is due to the increased rate of removal from the surface (eq. [12]). The rate of generation of $\equiv Cr^{4+}$ according to eq. [3] is insensitive to $[BrO_3^-]$ because the BrO_3^- ion is a very effective scavenger of e_{aq}^- (eq. [2]) and the rate of generation of BrO_2 radicals remains the same for the different bromate concentrations studied. Figure 3 shows the expected relationship between $[\equiv Cr^{4+}]_{ss}$ and $[BrO_3^-]$; the initial rise is completed for $[BrO_3^-] \cong 0.1$ mol dm^{-3}.

Radiation-induced dissolution is seen to be severely lim-

Fig. 4. Calculated effect of bromate concentration on the dissolution of α-Cr_2O_3. ●: experimental points.



ited. In the absence of e_{aq}^- or OH scavengers, as in an operating reactor, recombination is much faster than any possible attack on iron or chromium oxides, and only the molecular products (H_2, H_2O_2) are of importance. Hydrogen influences the kinetics and increases the solubility of iron oxides in high temperature water, but it exerts little or no influence on chromium oxides, because of the low redox potential of the Cr(III)/Cr(II) couple. The influence of the other molecular product, hydrogen peroxide, is also negligible. Unless a very strongly alkaline medium is generated, dissolution does not take place. A kinetic study of the dissolution of Cr_2O_3 in hydrothermal media has shown that oxidation does not enhance the rate of basic dissolution that put $Cr(OH)_4^-$ into solution, although in this medium this species is readily oxidized in solution (23). Thus, water radiolysis per se is not efficient to bring about dissolution. Scavengers for e^- are required; in these conditions, reaction [6] in principle may lead to dissolution, but the sluggishness of the removal of $\equiv Cr^{4+}$ from the surface (reaction [4]) severely limits the dissolution rate. When BrO_3^- is the e^- scavenger, BrO_2 may also oxidize surface $\equiv$Cr(III), but in this case dimerization (eq. [7]) severely limits the dissolution rate. The rate is given by eq. [12]; from the data in Fig. 3, it is possible to calculate the rates at any given $[BrO_3^-]$. The maximum value, for $[BrO_3^-] = 0.4$ mol dm^{-3}, is $R \cong 4 \times 10^{-9}$ mol dm^{-3} s^{-1}, which is equivalent to 6×10^{-3} μmol m^{-2} s^{-1}.

The calculated rate vs. $[BrO_3^-]$ curve is shown in Fig. 4, together with experimental rate values. The model curve includes a sigmoidal behavior at low $[BrO_3^-]$ (< 0.05 mol dm^{-3}), outside the explored range, and a deviation from linearity, observed at high $[BrO_3^-]$, that is well accounted for as due to the decrease in $[\equiv Cr^{4+}]$ (see eq. [11]).

The sigmoidal trace at low $[BrO_3^-]$ is due to incomplete scavenging of e_{aq}^- by BrO_3^- (eq. [2]), and the operation of reaction [5]. In these conditions, other possible reactions, e.g., $e^-_{aq} + OH \rightarrow OH^-$, should also be included; the lack of experimental data does not warrant a detailed analysis of this region.

The selective complexation of adamantane nitriles by tungsten pentacarbonyl

Valerie J. Jefford, Melbourne J. Schriver, and Michael J. Zaworotko

Abstract: Adamantyl-1,3,4-oxathiazol-2-one is usually prepared as a mixture with 1-adamantanecarbonitrile. To separate these two compounds the mixture is reacted with thf·$W(CO)_5$, which selectively forms a complex with the nitrile. The resulting mixture can then be readily separated into pure compounds by sublimation. Characterization data are presented, including the X-ray crystal structure of the nitrile complex, which can be prepared directly from the reaction of the adamantyl nitrile and thf·$W(CO)_5$. (Crystal data for $C_{16}H_{15}NO_5W$: orthorhombic, space group *Pmcn*, a = 10.5869(19) Å, b = 14.0622(22) Å, c = 23.342(4) Å, V = 3475.0(11) Å^3, Z = 8, R = 0.042.) The nitrile can be recovered from the complex by reaction with $P(C_6H_5)_3$ followed with separation by sublimation. The reaction of the related 1-cyano-3-(1,3,4-oxathiazol-2-on-5-yl)-adamantane with thf·$W(CO)_5$ yields a complex in which the site of coordination is shown spectroscopically to be the nitrile moiety. Semi-empirical calculations at the PM3 level indicate that the oxathiazolone heterocycle may be a poor ligand due to the influence of the exo- and endo-cyclic oxygen atoms.

Key words: oxathiazolone, nitrile, tungsten, complexation, selectivity, adamantane.

Résumé : L'adamantyl-1,3,4-oxathiazol-2-one est généralement préparée sous la forme d'un mélange avec l'adamantane-1-carbonitrile. Pour séparer ces deux composés, on fait réagir le mélange avec du thf·$W(CO)_5$ qui forme sélectivement un complexe avec le nitrile. Le mélange qui en résulte peut alors être séparé facilement en composés purs par sublimation. On présente des données de caractérisation, y compris la structure cristalline par diffraction des rayons X du complexe avec le nitrile qui peut être préparé directement par réaction de l'adamantylnitrile avec du thf·$W(CO)_5$. Les données cristallines pour $C_{16}H_{15}NO_5W$: orthorhombique, groupe d'espace *Pmcn*, a = 10,5869(19), b = 14,0622(22) et c = 23,342(4) Å, V = 3475,0(11) Å^3, Z = 8, R = 0,042. On peut récupérer le nitrile du complexe en faisant réagir ce dernier avec du $P(C_6H_5)_3$ et en procédant ensuite à une sublimation. La réaction du 1-cyano-3-(1,3,4-oxathiazol-2-on-5-yl)-adamantane apparenté avec du thf·$W(CO)_5$ fournit un complexe dans lequel il a été démontré par spectroscopie que le site de coordination est la portion nitrile. Des calculs semi-empiriques au niveau PM3 indiquent que l'hétérocycle oxathiazolone est probablement un mauvais coordinat à cause de l'influence des atomes d'oxygène exo- et endo-cycliques.

Mots clés : oxathiazolone, nitrile, tungstène, complexation, sélectivité, adamantane.

[Traduit par la rédaction)

Introduction

The 1,3-dipole cycloaddition reaction is an important synthetic route to a number of heterocyclic systems (1, 2). The nitrile sulphides **1** are a family of 1,3-dipoles that contain a sulphur–nitrogen π bond and have been the subject of several recent reviews (3, 4). They are typically generated in situ from precursor oxathiazolone heterocycles such as **2** in the presence of a dipolarophile to give five-membered ring heterocycles. We have reported the first systematic X-ray crystallographic analysis of the precursor ring and the cycloadducts from the reaction of adamantane – nitrile sulphide with the alkyne and thiazyl triple bonds and explored the chemistry of the first bis(nitrile sulfide) (5).

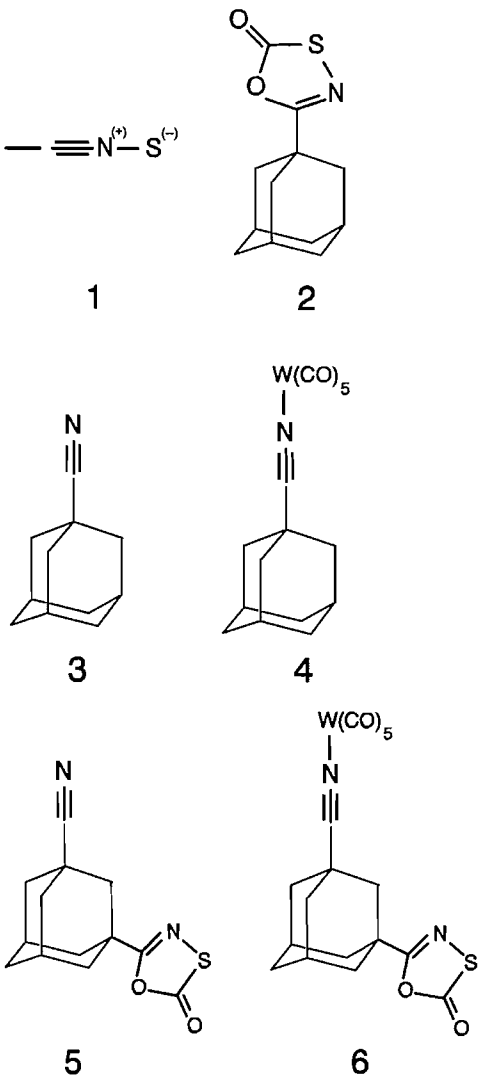
The nitrile sulphides have been shown to readily decompose to the corresponding nitriles and elemental sulphur. In previous reports the preparation of the precursor oxathiazolone heterocycle has suffered from the premature generation of the 1,3-dipole, leading to significant loss of product and the generation of mixtures of heterocycles and nitriles. Indeed, we reported that the separation of adamantane oxathiazolone **2** from adamantane nitrile **3** was laborious and gave low yields of pure material (5).

In this work we report the separation of the nitrile **3** from an impure sample of **2** by selective complexation with tungsten pentacarbonyl. The preparation and the solid state structure of the nitrile complex **4** is described and compared with the structures of other nitrile·$W(CO)_5$ complexes. The selectivity of the complexation is confirmed by reaction with the bifunctional molecule 1-cyano-3-(1,3,4-oxathiazol-2-on-5-yl)-adamantane **5** and the site of complexation is shown spectroscopically to be the nitrile moiety, giving **6**.

Experimental

General procedures

Reagents used in synthesis ($W(CO)_6$ and $P(C_6H_5)_3$) were purchased from Aldrich and used as received. The pure com-



pounds and mixtures of $C_{10}H_{15}$-$\overline{COC(O)NS}$ and $C_{10}H_{15}$-CN were prepared from the literature procedures (5). The thf·$W(CO)_5$ was prepared as described in ref. 6 and was handled under a nitrogen atmosphere. Solvents were refluxed with the appropriate drying agent (C_6H_5Cl (CaH_2), C_4H_8O (Na), CH_2Cl_2 (CaH_2)) and distilled under nitrogen prior to use. Melting points were determined on a Mel-Temp II melting point apparatus and are uncorrected. Elemental analyses were carried out at Canadian Microanalytical Service Ltd., Delta, British Columbia, Canada. IR spectra were recorded from Nujol mulls on KBr plates using a Mattson Polaris FT-IR instrument or as solutions using a Perkin Elmer 283 instrument. NMR spectra were recorded on a General Electric 300 MHz instrument (^1H, ^{13}C). Chemical shifts are reported in ppm (high-frequency positive) relative to internal standards (^1H, ^{13}C: TMS). Mass spectra were recorded on a VG Micromass 7070HS double focusing spectrometer. Molecular orbital calculations were made using the HyperChem (version III) suite of semi-empirical programs from Autodesk operating on a 80486-based IBM compatible computer. Molecules were subjected to a full geometry optimization (Polak-Ribiere conjugate gradient) prior to single point calculation of the molecular orbitals.

Preparation and characterization data

$C_{10}H_{15}$-CN·$W(CO)_5$

Tungsten hexacarbonyl ($W(CO)_6$, 2.6 g, 7.4 mmol) was dissolved in approximately 250 mL of dry THF and irradiated (UV) under nitrogen for ~16 h. Adamantane nitrile (0.6 g, 3.7 mmol) was added, the reaction mixture was stirred for 48 h, and a yellow solution was obtained after filtration through Celite. A yellow solid (2.4 g) was recovered by the removal of solvent with a rotary evaporator and was transferred to a sublimation apparatus. The sublimation proceeded at room temperature (10^{-3} Torr; 1 Torr = 133.3 Pa) for 24 h and gave large, colourless crystals of excess $W(CO)_6$. The non-sublimed, yellow powder remaining was shown to be $C_{10}H_{15}C{\equiv}N{\cdot}W(CO)_5$ (1.1 g, 2.27 mmol, 60%). Crystals suitable for X-ray crystallographic analysis were grown from a hot hexanes solution. The relevant infrared and ^{13}C NMR data are given in Tables 1 and 2, respectively. Characterization data for $C_{10}H_{15}$-$C{\equiv}N{\cdot}W(CO)_5$: mp > 300°C. ^1H NMR, δ: 2.08 (9H), 1.76 (6H). Mass spectrum (IE, 70 eV) *m/z* (%, assign.): 483* (8, $C_{10}H_{15}$-CN-$W(CO)_5$, M^+), 455* (2, M^+-CO), 329 (56,M^+-2CO), 399 (11,M^+-3CO), 371 (10, M^+-4CO), 161 (80, $C_{10}H_{15}-CN^+$), 134 (100, $C_{10}H_{14}^+$) (* indicates that the peak is the strongest peak in an isotopic distribution pattern consistent with the presence of tungsten). Anal. calcd. (obsd.): C 39.61(39.39), H 3.12(3.19), N 2.89(2.76).

Reaction of $C_{10}H_{15}$-$\overline{COC(O)SN}$/$C_{10}H_{15}$-C≡N with thf·$W(CO)_5$

Tungsten hexacarbonyl ($W(CO)_6$, 11.9 g, 33.8 mmol) was dissolved in dry THF and irradiated (UV) under nitrogen for ~16 h. A mixture of adamantane nitrile and adamantane-oxathiazol-2-one (4.0 g) was added and the solution stirred for 48 h to give a brown solution from which a clear yellow solution was obtained after filtration through Celite. A yellow solid (9.2 g) was recovered by the removal of the solvent under vacuum. Sublimation of this solid at room temperature for 24 h (10^{-3} Torr) gave large, colourless crystals of excess $W(CO)_6$ (5.1 g). Pure adamantane-oxathiazol-2-one sublimed at 55°C over a period of 24 h (3.4 g, 13.1 mmol) . The non-sublimed, bright yellow residue was recrystallized from hot hexanes to give clear, yellow, needle-shaped crystals of $C_{10}H_{15}C{\equiv}N$-$W(CO)_5$ (0.7 g, 1.7 mmol).

Reaction of $\overline{NSC(O)OC}$-$C_{10}H_{14}$-C≡N with thf·$W(CO)_5$

Tungsten hexacarbonyl ($W(CO)_6$, 2.15 g, 6.10 mmol) was dissolved in approximately 250 mL of dry THF and irradiated (UV) under nitrogen for ~9 h. 1-Cyano-3-(1,3,4-oxathiazol-2-on-5-yl)-adamantane $\overline{NSC(O)OC}$-$C_{10}H_{14}$-C≡N (0.75 g, 3.05 mmol) was added and the reaction mixture was stirred for 48 h to give a yellow-brown solution from which a yellow solution was obtained after filtration through Celite. A sticky rust-brown solid was recovered by evaporation over several days and was washed with hot hexanes to give a dry khaki-coloured powder (1.46 g), which was transferred to a sublimation apparatus. The sublimation proceeded at 65°C (10^{-3} Torr) for 24 h and gave large, colourless crystals of $W(CO)_6$. The non-sublimed, khaki powder remaining was shown to be $\overline{NSC(O)OC}$-$C_{10}H_{14}$-C≡N·$W(CO)_5$ (0.54 g, 0.92 mmol, 30%). The relevant infrared and ^{13}C NMR data are given in

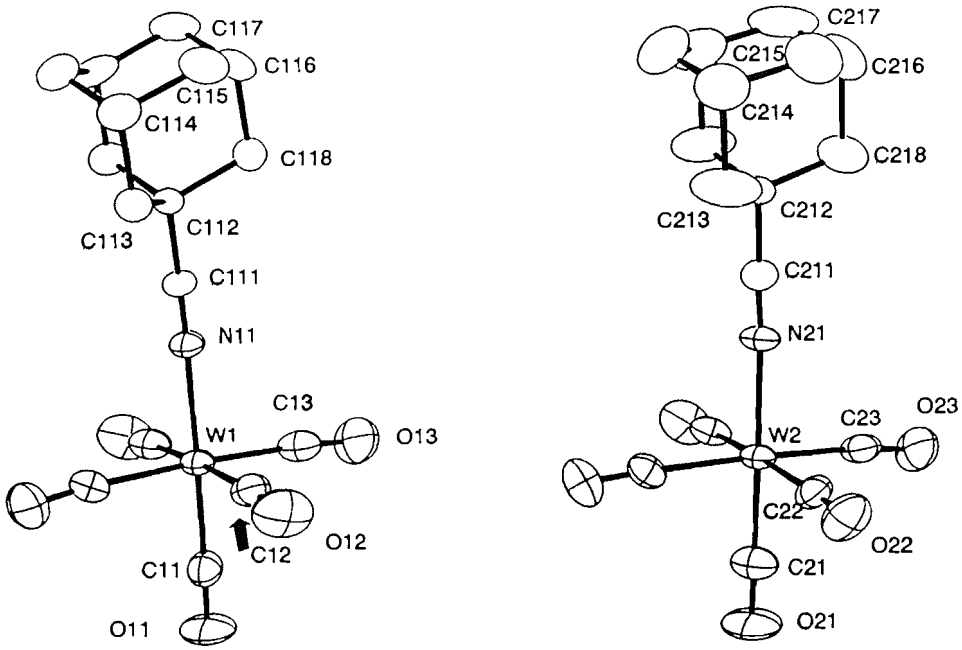
Reaction of $C_{10}H_{15}$-C≡N·W(CO)$_5$ with $P(C_6H_5)_3$

A mixture of $C_{10}H_{15}$-CN·W(CO)$_5$ (0.787 g, 1.62 mmol) and $P(C_6H_5)_3$ (0.426 g, 1.62 mmol) was dissolved in approximately 100 mL of thf. The reaction mixture was stirred while heating at 50°C for 19 h to give a green-yellow solution over a white solid. The solvent and volatile materials were removed by evacuation to give a khaki solid (1.26 g). The khaki solid was transferred to a sublimation apparatus and was heated to 50°C (10^{-3} Torr) for 24 h to give a sublimed white solid ($C_{10}H_{15}$-CN, 0.194 g, 1.20 mmol, 74%) and a non-sublimed khaki solid (($C_6H_5)_3$P-W(CO)$_5$, 0.96 g).

X-ray data collection, solution, and refinement for $C_{10}H_{15}$-C≡N·W(CO)$_5$

All pertinent crystallographic data are summarized in Table 3. Data were collected at room temperature (17 ± 1°C) on an Enraf–Nonius CAD-4 diffractometer (MoK_α, λ = 0.70930 Å, graphite monochromator) using the ω scan mode. Unit cell parameters were obtained from 24 reflections with 2θ angle in the range of 35.00°–41.00°. The choice of space group was based on systematically absent reflections. Data were corrected for Lorentz and polarization effects. Scattering factors were taken from the International tables for X-ray crystallography (7). An empirical absorption correction was made based on a series of ψ scans that resulted in minimum and maximum transmission factors of 0.712 and 0.998, respectively. The structure was solved via direct methods that revealed the presence of two independent molecules of **4**, both of which lie around crystallographic mirror planes. Hydrogen atoms were treated as follows: methylene hydrogen atoms were placed in calculated positions with D_{C-H} = 1.08 Å; methyne hydrogen atoms were located via difference Fourier map inspection. Hydrogen atoms were given temperature factors based on the

Fig. 1. ORTEP (16) views of the two independent molecules of $C_{10}H_{15}$-CN·W(CO)$_5$. (Selected bond distances (Å) and angles (deg): C111—C112 = 1.448(19), C211—C212 = 1.461(22), C111—N11 = 1.098 (18), C211—N11 = 1.132(20), N11—W1 = 2.227(12), N21—W2 = 2.204(12); C112-C111-N11 = 177.7(16), C212-C211-N21 = 178.6(16), C111-N11-W1 = 174.1(12), C211-N21-W2 = 174.9(12.)



carbon atoms to which they are bonded and fixed during least-squares refinement. All crystallographic calculations were effected with the PC version of NRCVAX (8) implemented on a 80486-based IBM compatible computer. Fractional atomic coordinates and isotropic thermal parameters are given in Table 4 and selected bond distances and angles are given in the caption of Fig. 1. Supplementary material (anisotropic thermal parameters and structure factors) is available.[3]

Results and discussion

Preparation, characterization, and structure of adamantane-based nitrile tungsten pentacarbonyl complexes

Nitrile complexes of the Group VIA metal pentacarbonyls (M = Cr, Mo, W) are well known (6, 9, 10). In general, nitrile·metal pentacarbonyl complexes are useful intermediates in ligand substitution reactions due to the relative weakness of the metal–ligand bond. Complexes have been reported for a number of R-C≡N·W(CO)$_5$ compounds where the nitrile substituent can be alkyl, aromatic, or π-delocalized vinyl or acyl groups. However, such compounds have not been reported for any adamantane-based nitrile. Only one X-ray structure has been reported for R-C≡N·W(CO)$_5$ (R = CH_2COOH (10)). Metal carbonyl complexes with a higher order of nitrile substitution (M(CO)$_{6-n}$(RCN)$_n$ $n > 1$) have also been reported (11).

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

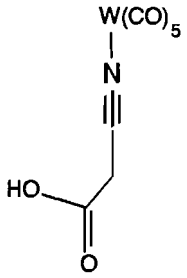
The preparation of R-C≡N·$W(CO)_5$ has been reported using a number of synthetic procedures. Photolytic generation of a thf·$W(CO)_5$ intermediate that reacts *in situ* with a nitrile has been successfully used to prepare a number of alkyl nitrile complexes (6). Thus the preparation of $C_{10}H_{15}$-C≡N·$W(CO)_5$ **4** and NSC(O)OC-$C_{10}H_{15}$-C≡N·$W(CO)_5$ **6** following this procedure gave reasonable yields as described in the literature. The elemental analyses for **6** revealed that the isolated compound was not analytically pure. The near absence of unassigned bands, resonances, or peaks in the spectra of **6** suggest that the impurities must be present in small amounts and (or) highly related to **6** in structure (i.e., $C_{10}H_{14}(CN)_2$·nW$(CO)_5$, n = 0, 1, 2).

The identity of **2** was established unequivocally by X-ray crystallography. The analysis of the spectroscopic data of **2** provides a framework for the determination of the mode of complexation in **6**. The infrared spectra of both compounds **2** and **6** are given in Table 1 and compared with the free ligands. Both compounds show bands assignable to the carbonyl and metal–carbon bonds expected in $W(CO)_5$ moieties (12). The infrared of **6** additionally indicates that the bands assignable to the heterocycle are essentially unaffected by complexation while the band assigned to the nitrile bond in the free ligand is not found in the spectrum of the complex. These observations are consistent with complexation of the free ligand **5** via the nitrile group. The mass spectra of **2** and **6** confirm the presence of tungsten carbonyls and the expected nitriles in the compounds.

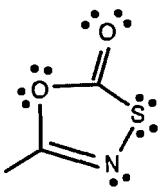
The strongest evidence for the mode of complexation in the complex **6** is derived from the ^{13}C NMR spectral data. The ^{13}C NMR data for the free ligands and the complexes **4** and **6** are given in Table 2. The data clearly indicate the presence of $W(CO)_5$ in the compounds **4** and **6** with resonances assignable to the *trans* (**4**, 200.0 ppm; **6**, 199.7 ppm) and *cis* (**4**, 196.5 ppm, **6**, 196.3 ppm) carbonyl carbon atoms as described in the literature (9, 10). It has also been reported that the complexation of alkyl chalcogenonitriles (R-Ch-C≡N; Ch = S, Se (13)) and cyanoacetic acid (10) with $W(CO)_5$ results in a downfield shift of the nitrile carbon by 8.1 ± 0.9 ppm. Similar complexation with $Cr(CO)_5$ leads to a shift of +10.5 ± 0.3 ppm (10). In compounds **4** and **6** the nitrile carbon atoms resonate 5.8 and 6.0 ppm downfield from the corresponding carbon atoms in the free ligands. The smaller shift observed in the adamantane

nitriles may be a reflection of the nature of the substituent groups on the nitrile moiety. The resonances assigned to the carbon atoms in the adamantane moieties of **4** and **6** and the heterocycle in **6** are essentially unchanged by complexation, consistent with nitrile coordination in both compounds.

The crystallographic data relating to the structure of **4** are given in Tables 3 and 4 and Fig. 1. The structure of the adamantane moiety in **4** is not significantly ($\delta D > 3\sigma$, D is bond distance) different than the distances and angles observed in other mono-substituted adamantane compounds (5). The nitrile–metal bond gives an essentially linear W-N-C unit with bond angles at the carbon (177.7(16)°/178.6(16)°) and the nitrogen (174.1° (12)/174.9 (12)°) atoms not significantly different from the related angles in **7** (10). The W—N distance in **4** (2.227(12)/2.204(12) Å) is longer than that observed in **7** (2.178(7) Å) while the C—N distance is shorter (**4** 1.098(18)/1.132(20) Å; **7** 1.15(1)). This would indicate that the metal–



7



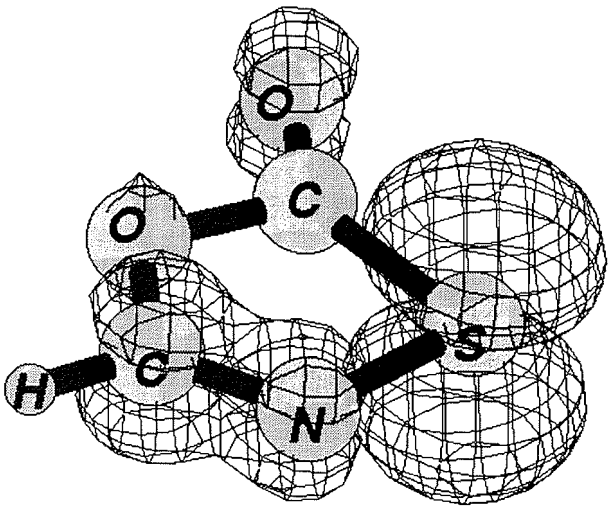
8

ligand interaction is weaker in **4** and the nitrile π bond is relatively stronger. The C—O bond distance in the *trans* carbonyl in **4** is shorter than in the *cis* carbonyls, as expected, but the difference is not as significant as that observed in other nitrile complexes (9, 10). The relative weakness of the metal–ligand bond in **4** that was indicated spectroscopically above is consistent with this observation and suggests that **3** has a relatively weak *trans* effect in metal carbonyl complexes.

Selective complexation of nitriles from nitrile–oxathiazolone mixtures

As stated above, we were interested in separating adamantyl oxathiazolone derivatives from the related nitriles by selectively changing the properties of one of the molecules. The protocols for the formation of metal pentacarbonyl complexes from the substitution reactions of thf·$M(CO)_5$ are well known so the mixture of **2** and **3** was reacted with thf·$W(CO)_5$ in thf at room temperature in the hope that a complex would form with only one of the molecules. This was indeed found to be true and subsequent work-up revealed that the reaction product was a mixture of a colourless white solid that sublimed readily at room temperature (shown to be excess $W(CO)_6$), a colourless white solid that sublimed at 60°C (shown to be pure **2**), and a non-sublimed yellow solid (shown to be pure **4**). Thus we have determined that we can purify samples of **2** that are contaminated with **3** by selective complexation of the nitrile with $W(CO)_5$. It is likely that this technique would be of general utility in the resolution of nitrile–oxathiazolone mixtures where the standard techniques of solubility, distillation or chromatography fail to give the desired separation. The nitrile

Fig. 2. View of the HOMO of H-COC (O) SN (ChemPlus / HyperChem).

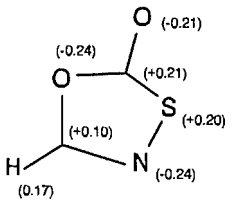


2 itself can be recovered as a pure compound by substitution in solution with triphenyl phosphine followed by sublimation.

If one considers a typical Lewis structure of an oxathiazolone heterocycle such as **8** it is observed that the ring bears multiple lone pairs that would be potential sites for coordination. On the other hand, the nitrile group is well known as a ligand that forms weak metal–ligand bonds and is easily displaced in substitution reactions (14). The reaction of thf·$W(CO)_5$ with a mixture of **2** and **3** gives a complex exclusively to the nitrile. There were no indications at any time that coordination to the heterocycle occurred. Reaction of thf·$W(CO)_5$ with pure **2** yielded only pure **2** and tungsten hexacarbonyl. The relative ligand ability of these moieties was dramatically demonstrated by the reaction of thf·$W(CO)_5$ with **5**, which was shown to form a complex exclusively via the nitrile moiety.

The simplest explanation of why coordination selectively occurs to the nitrile is that it must be a better ligand than the heterocycle for this metal system. The nitrile moiety, while recognised as giving weak metal–ligand bonds, is a π acid analogue of CO and is therefore a preferred ligand for $W(CO)_5$. The heterocycle, on the other hand, features lone pairs on both a π-bonded nitrogen and a sulfur atom, which should be reasonable sites for coordination by a medium soft Lewis acid such as $W(CO)_5$. It can be argued, however, by using simple electronegativity concepts, that the endocyclic and exocyclic oxygen atoms in the heterocycle must draw significant electron density away from the nitrogen and sulfur atoms. This process renders these atoms such poor Lewis bases that they do not form coordinate covalent bonds to the metal. These arguments are supported by semiempirical PM3 molecular orbital calculations on the parent oxathiazolone ring.[4] The calculated HOMO of this molecule is shown in Fig. 2 and the calculated atomic charges are given in **9**. A simple FMO (Frontier Molecular Orbital) analysis of the interaction

[4] A copy of the HyperChem PM3 logfile (matrix, eigenvalues, eigenvectors, and atomic charges) has been included with the supplementary material.



9

of Lewis acids and bases predicts that the atom that makes the greatest contribution to the acid LUMO should preferentially form a bond to the atom that makes the greatest contribution to the HOMO of the base (15). From Fig. 2 it is clear that the sulfur and nitrogen atoms do make significant contributions to the HOMO but the atom charges indicate that the atoms are electron deficient and are coulombically unsuited for coordination to the metal. The oxygen atoms are electron rich but are likely too hard to form a stable adduct to $W(CO)_5$. The complexation of this heterocycle could probably be accomplished with harder metal centers, such as the lighter, early transition metals. The formation of coordination complexes of oxathiazolone derivatives may provide information on the generation of the 1,3-dipoles from this heterocyclic family and will be the object of future investigations.

AM1 semiempirical study of benzopyrroles as dienes for Diels-Alder reaction

Branko S. Jursic

Abstract: A qualitative approach for quick evaluation of the reactivity of dienes such as cyclopentadiene, furan, pyrrole, indole, and isoindole for Diels–Alder reactions was applied. As qualitative methods, the frontier molecular orbital (FMO) energy gap and the Hammond postulate through bond orders and energy of the reaction were evaluated for such dienophiles as ethylene, 1,3-dioxa-4-cyclopentene, and maleic anhydride. It was demonstrated that pyrrole and benzopyrroles are poor dienes in comparison with cyclopentadiene and furan. Because the reaction is controlled by the HOMO of the diene there are special cases when isoindole can react as a diene, while the loss of indole aromaticity in the course of the reaction precludes the cycloaddition. Geometries of transition structures and the accompanying activation energies were calculated for pyrrole, indole, and isoindole as dienes. The stereoselectivity of the reaction is discussed and compared with experimental results.

Key words: benzopyrroles as dienes, Diels–Alder cycloaddition, Hammond postulate.

Résumé : On a appliqué une approche qualitative pour effectuer une évaluation rapide de la réactivité des dièenes, comme le cyclopentadiène, le furane, le pyrrole l'indole et l'isoindole dans des réactions de Diels–Alder. Les méthodes qualitative examinées pour des réactions avec des diénophiles comme l'éthylène, le 1,3-dioxacyclopent-4-ène et l'anhydride maléique comporte les méthodes qualitatives suivantes : la différence d'énergie des orbitales moléculaires frontières (OMF), le postulat de Hammond par le biais des ordres de liaison et l'énergie de la réaction. Il a été démontré que le pyrrole et les benzopyrroles sont de mauvais dièenes par comparaison avec le cyclopentadiène et le furane. Compte tenu du fait que la réaction est contrôlée par l'OM haute occupée du diène, il existe certains cas dans lesquels l'isoindole peut réagir comme un diène alors que la perte de l'aromaticité de l'indole au cours de la réaction empêche la cycloaddition de se produire. On a calculé les géométries des structures de transition et les énergies d'activation apparentées pour les cas du pyrrole, de l'indole et de l'isoindole comme dièenes. On discute de la stéréosélectivité de la réaction et on la compare avec les résultats expérimentaux.

Mots clés : benzopyrroles comme dièenes, cycloaddition Diels–Alder, postulat de Hammond.

[Traduit par la rédaction]

Introduction

Five-membered heterocyclic aromatic compounds are, from the theoretical standpoint, capable of acting like dienes in cycloaddition reactions. Nevertheless, there are not very many heterocycles that undergo cycloaddition reactions.[2] Usually, for these reactions to succeed, special activation of a heterocyclic compound or a very reactive dienophile is necessary. Most of the problems arise from the fact that, in the course of the reaction, the aromaticity of the heterocyclic ring is destroyed. If the reaction is accomplished, a Diels–Alder adduct can be one of the key intermediates on the long road to natural product synthesis (for selected publications, see ref. 2).

It is generally accepted that Diels–Alder reactions are concerted cycloadditions (3), although other mechanisms have also been proposed (4). For the all-carbon Diels–Alder reactions there is an enormous body of theoretical work (for a review see ref. 5); however, hetero Diels–Alder reactions are considerably under-investigated (6). From a synthetic point of view, it is probably the most important method for the preparation of heterocyclic and natural product compounds (7). This can be highlighted with five-membered heterocyclic compounds as dienes for Diels–Alder reactions (8).

We recently studied theoretically the suitability of pyrrole as diene for the Diels–Alder reaction for the cycloaddition reaction (9). The predicted activation energies are too high even for the Diels–Alder reaction in the case of pyrrole acting as diene. This is similar to an observation made for a cycloaddition reaction with cyclopentadiene as diene (10). The AM1 semiempirical method has proven to be very useful in determining the reactivity of benzothiophene and thiophenes in cycloaddition reactions with different dienophiles (11). Here we would like to present our theoretical results on dienophile addition to indole and isoindole.

Methodology

All calculations were performed on a DEC 7620 computer. Chem-3D Plus on a Macintosh IIfx was used as a graphical interface for drawing and visualizing all structures and for preparing input files for MOPAC (12). The transition states were located, optimized, and verified as explained in our previous

work.[3,4] Vibrational and thermal analyses were performed on all optimized structures.

Results and discussion

Qualitative evaluation of reactivity of cyclopentadiene, furan, pyrrole, indole, and isoindole

Three dienophiles: 1,3-dioxa-4-cyclopentene, ethylene, and maleic anhydride, were used for qualitative evaluation of the reactivity of pyrrole. Frontier molecular orbital (FMO) theory can be used to determine relative reactivity of reactants that are engaged in similar reactions (15). This involves the basis of the theory of maximal orbital overlap between frontier orbitals of reactants. Better molecular orbital overlap will be obtained between frontier orbitals that are similar in energies. The frontier orbital energy gaps (eV) between ethylene, 3,5-dioxa-4-cyclopentene, and maleic anhydride as dienophiles and cyclopentadiene, furan, pyrrole, indole, and isoindole as dienes are presented in Table 1. All of these compounds have been carefully chosen: ethylene as middle, maleic anhydride as electron-deficient, and 3,5-dioxa-4-cyclopentene as electron-rich dienophiles for Diels–Alder reactions. Two dienes, cyclopentadiene and furan, as aromatic dienes are used for determining the influence of aromaticity on the Diels–Alder reaction. Ethylene and maleic anhydride addition to cyclopentadiene is predicted to be a LUMO dienophile controlled reaction while, as expected, addition of electron-rich 3,5-dioxa-4-cyclopentene is HOMO dienophile controlled. A low energy gap is predicted for maleic anhydride and is in agreement with experimental observations (16). Furan as aromatic diene is predicted to have lower reactivity than cyclopentadiene, as is well documented in the literature (16, 17). Pyrrole is predicted to be more reactive then furan and the addition is LUMO dienophile controlled with electron-rich dienophiles such as 3,5-dioxa-4-cyclopentene. This finding is somewhat surprising because experimental results favor furan over pyrrole (18). Both benzopyrroles are predicted to be more reactive than cyclopentadiene, furan, and pyrrole as dienes. The most reactive is isoindole with a predicted FMO energy gap with maleic anhydride of only 6.18 eV.

One can argue that the frontier orbital approach to studying the reactivity is not reliable. There are many disadvantages; one major problem is that the energies of the frontier orbitals are computed separately. Consequently the steric and electronic interactions between reactants during the course of the

[3] For a detailed explanation of input files and key words for transition state computation by mopac see ref. 13.

[4] The transition state has to have only one imaginary frequency and that has become the major criterion for proving the transition state. For perspectives of transition state theory see refs. 14*a*–14*c*.

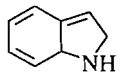
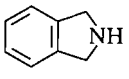
[a]Heat of formations are −55.12 for 1,3-dioxa-4-cyclopentene, 16.47 kcal/mol for ethylene, and −76.35 kcal/mol for maleic anhydride.

reaction are totally neglected. Although indole is predicted to be more reactive than furan, for example, there is not a single literature report using indole as diene for a Diels–Alder reaction. There is an abundance of reports using furan in Diels–Alder reactions (17). To explore the energy change caused by the transformation of dienes into products, we have determined the heat of hydrogenation of two benzopyrroles. The hydrogen atoms are put in position where new CC bonds will be formed (structures **A** and **B**). According to AM1 calcula-



A



B

tions structure **A** is 9.53 kcal/mol above structure **B** in energy. These results are not surprising and can be explained by consideration of aromaticity. The heat of formation of isoindole is 6.57 kcal/mol above that of indole. All of this undoubtedly predicts that isoindole should be a much better diene than indole for Diels–Alder reactions.

If we consider only the energies of the reactants and products without performing time-consuming calculations of transition state structures, the qualitative reactivity can be estimated by applying Hammond's postulate (19). It seems reasonable that the reactants for an exothermic reaction will undergo a small change in geometry by reaching the transition state. The opposite is true for an endothermic reaction, which requires a quite considerable reorganization of geometry in the reactants. In other words, the more exothermic the reaction, the smaller the reaction barrier, contrary to the more endothermic reaction, where a higher reaction barrier results. Calculated exothermicity of the Diels–Alder reaction for ethylene and maleic anhydride is presented in Table 2. Although different values are obtained with different dienophiles, all calculations agree in general reactivity.

Table 3. Sum of bond orders of new forming CC bond of dienes with ethylene.

Cyclopentadiene	Furan	Pyrrole	Indole	Isoindole
0.821	0.874	0.956	0.933	0.874

The cycloaddition reaction with cyclopentadiene will be the most exothermic and, with indole, the most endothermic. If the Hammond principle is applied, indole should have the highest activation energy, followed by pyrrole and isoindole. The reactivity of isoindole is predicted to be somewhat similar to that of furan. This finding is different than that obtained with FMO, which predicts increasing reactivity in the following order: cyclopentadiene, furan, pyrrole, indole, and isoindole (Table 1). The qualitative order of reactivity for pyrrole and benzopyrrole agrees with experimental evidence (8).

The position of the transition structure with regard to reactants and products can be determined by the bond orders in its structure. The same results can be obtained by following any bond distance that undergoes change during the course of the reaction. For the sake of simplicity we will consider the sum of the bond orders for two CC bonds in formation between the dienes and dienophiles (Table 3). The lower bond order determines a transition structure closer to the reactants and consequently a lower activation barrier. The reactivity is predicted to be similar in general to that based on the Hammond postulate, except for indole. Again, this diene deviates from the other dienes. Further studies were carried out by estimation of activation energies for the cycloaddition reaction.

Transition state structures

Qualitative results presented here can be obtained in a short time period with modest computational power. We have demonstrated the shortcomings of these methods for reliable prediction of the reactivity. For example, pyrrole is predicted to be more reactive than both cyclopentadiene and furan, and isoindole is predicted, according to FMO, to be more reactive than all of the dienes studied. Nevertheless, this approach can sometimes be applied for very similar systems. To obtain a more accurate scale of reactivity of the benzopyrroles, the transition structures for ethylene, 1,3-dioxa-4-cyclopentene, and maleic acid anhydride addition to pyrrole, indole, and isoindole must be determined.

There are three transition state structures with ethylene as dienophile (Fig. 1). Transition state structures **1** and **3** have a bisecting plane of symmetry corresponding to a synchronous concerted mechanism for the cycloaddition reaction. Indole does not have a plane of symmetry separating the two CC double bonds that are considered in the Diels–Alder reaction. Consequently, all transition structures for a concerted Diels–Alder reaction with indole as dienophile must be asynchronous. Structure **2** demonstrates this effect.

For addition of both 1,3-dioxa-4-cyclopentene (Fig. 2) and maleic anhydride (Fig. 3) to pyrrole dienes, two stereoisomers

Fig. 1. Transition state structure for ethylene addition.

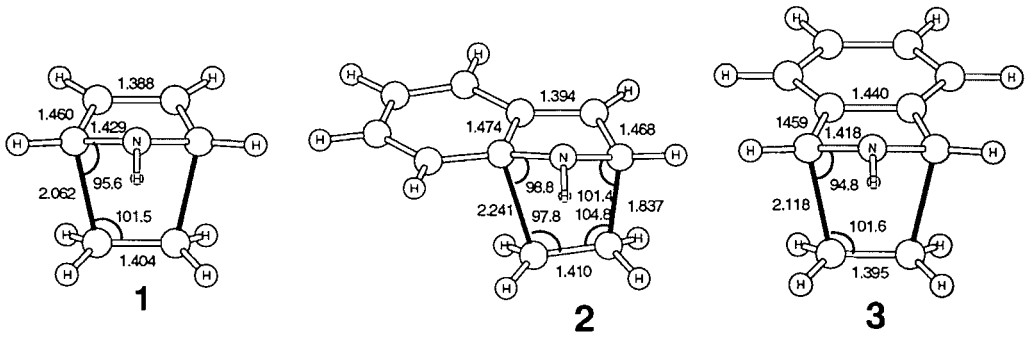


Fig. 2. Transition state structures for 1,3-dioxane-4-cyclopentene.

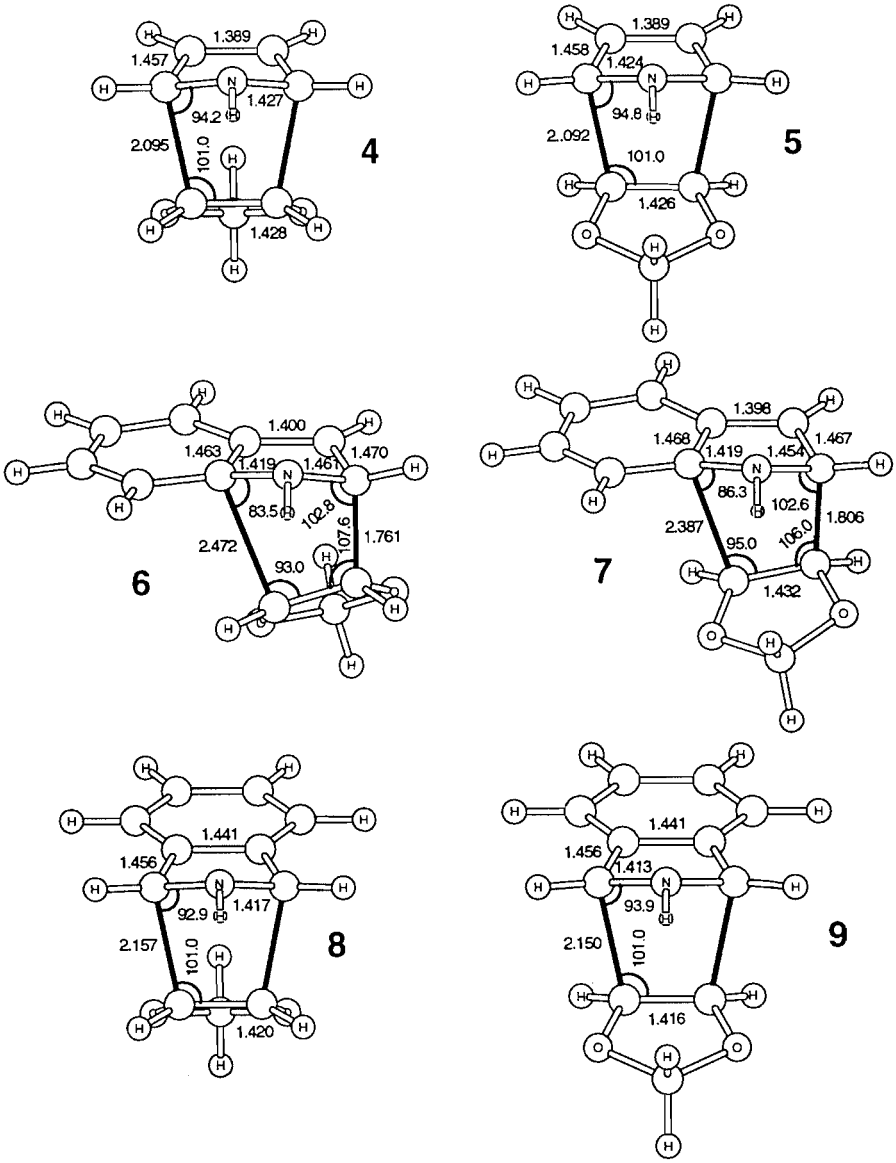

are possible. AM1 calculations of 1,3-dioxa-4-cyclopentene addition to pyrrole and isoindole produce transition structures (Fig. 2) that point to a synchronous concerted mechanism of Diels–Alder reactions. The transition state structures **6** and **7** for 1,3-dioxa-4-cyclopentene addition to indole indicate an asynchronous concerted cycloaddition. There should be considerable repulsion interaction between the oxygen lone pair of the dienophiles and the π orbitals of the indole benzene

Fig. 3. Transition state structures for maleic anhydride addition.

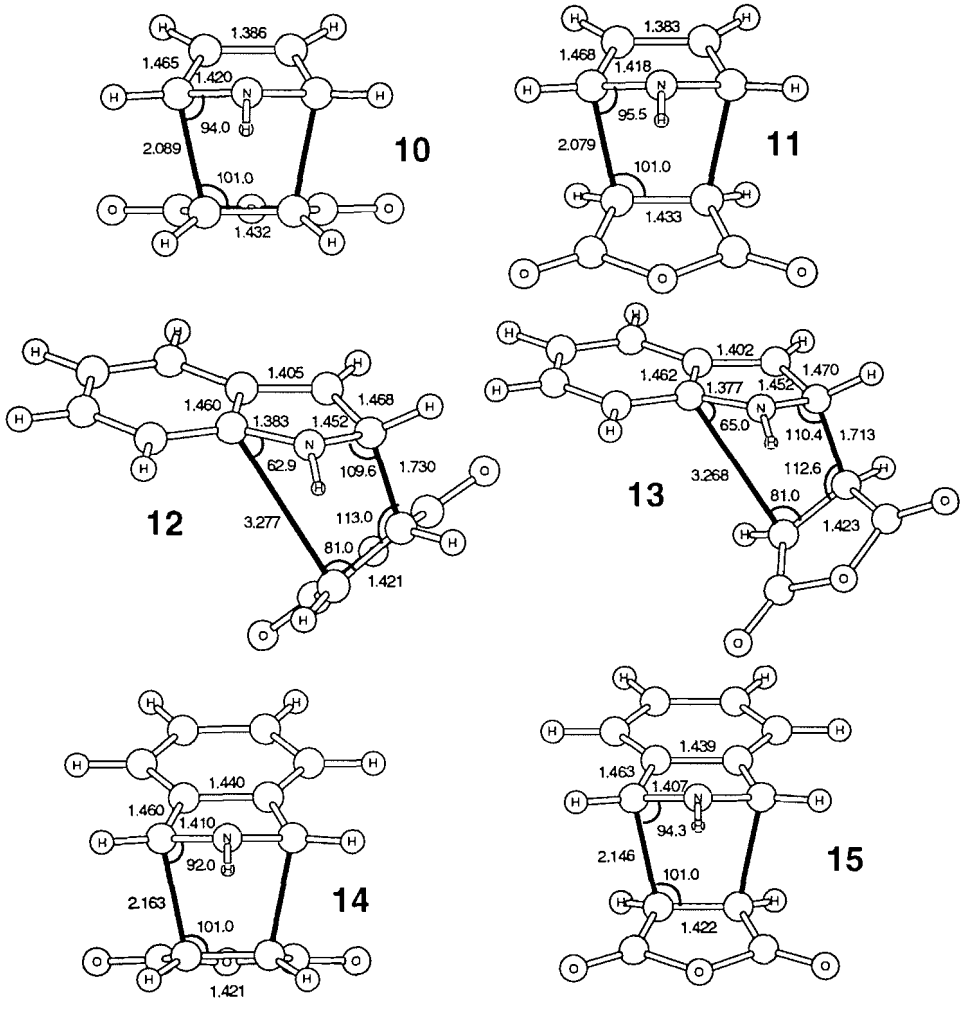

Table 4. AM1 estimated activation energies (kcal/mol).

Transition structure	ΔE	ΔE + ZPVE
1	33.54	34.70

13	34.89	34.92
14	25.22	25.10
15	18.81	18.62

ring. We assume that the electronic repulsion might be responsible for the high (0.581 Å) asynchronicity of transition structure **7**. For *endo* isomer **6** additional steric repulsions make this value even higher (0.761 Å).

Similar observations can be noted for the maleic anhydride addition (Fig. 3). Transition state structures with pyrrole and isoindole as diene were generated for a synchronous concerted Diels–Alder reaction. Here again, the longer new forming bond distance is in *endo* transition structures and again can be explained by repulsion interactions between diene and dienophile. There is considerable asynchronicity for transition structures **12** and **13** and, in fact, might represent the first transition structure in a two-step mechanism. Since one of the new forming bonds is longer than 3 Å, there should be reduced repulsion interaction with benzene π orbitals on oxygen n orbitals. Therefore, the asynchronicity of *endo* and *exo* isomers is almost identical (1.547 Å for **12** and 1.555 Å for **13**). The higher asynchronicity of these transition state structures can be explained by the fact that maleic anhydride is capable of stabilizing the negative charge while at the same time indole, bearing a partially positive charge, retains some aromaticity. Our results support this explanation.

Estimation of activation energies

The activation energies for these cycloaddition reactions are presented in Table 4. As expected on the basis of the Hammond postulate, indole showed a comparatively high activa-

tion barrier. For each dienophile, the order of reactivity is predicted to be isoindole, pyrrole, and indole.

The highest reactivity, as demonstrated by the FMO energy, is obtained for isoindole with maleic anhydride, demonstrating the HOMO character of indole for this reaction. Based on the values of predicted activation energies, with 18.62 kcal/mol for maleic anhydride addition to isoindole, the reaction should be experimentally feasible. The energy difference between the *exo* and *endo* isomers is 6.48 kcal/mol and favors exclusive formation of the *exo* isomer. On the other hand, for the same reaction with indole the predicted activation energy is 34.92 kcal/mol, too high to be experimentally achievable. Since the reaction is HOMO diene controlled, with electron-rich dienophiles the reaction will have a higher barrier. That was demonstrated by using 1,3-dioxa-4-cyclopentene as dienophile. Now the activation barriers for *exo* addition to indole and isoindole are 41.86 and 25.10 kcal/mol, respectively.

There are experimental results that fully support our AM1 calculations. Both indoles and pyrroles generally react with electron-deficient alkenes to give Michael addition product rather than the expected Diels–Alder cycloadducts (20). Isoindoles react with maleic anhydride to produce the Diels–Alder adduct. The reaction is reversible and, if formed, *endo* isomers can be converted readily into the *exo* isomers (21). Experimental evidence for indole as the diene for Diels–Alder reactions is not available.

Conclusions

It is demonstrated that the semiempirical AM1 method is useful for determining the reactivity of benzopyrroles as dienes for Diels–Alder reactions. The frontier molecular orbital (FMO) energy gap predicts higher reactivity of indole in comparison with pyrrole. This finding is contradictory to results obtained using both the Hammond postulate and the experimental data. The reaction is predicted to be HOMO diene controlled based on the frontier orbital correlation. It is suggested that the lower reactivity of indole is caused by loss of aromaticity in the course of the cycloaddition reaction, while with isoindole the aromaticity of the benzene ring is preserved. The predicted activation energy favors isoindole as diene in reactions with strong electron-deficient dienophiles. This finding is fully supported by the experimental data.

Molar excess volumes of binary liquid mixtures: 2-pyrrolidinone with C_6–C_{10} *n*-alkanols

Begoña García, Francisco J. Hoyuelos, Rafael Alcalde, and José M. Leal

Abstract: The excess volumes V^E of the binary mixtures 2-pyrrolidinone – (C_6–C_{10}) *n*-alkanols have been calculated from density measurements over the whole composition range and the 298.15–318.15 K temperature range. The excess volumes were independent of temperature, but changed noticeably with the chain length of the alkanol. The V^E values were only positive starting from heptanol, with the maximum value, 0.239 cm^3 mol^{-1}, for equimolar decanol. The observed changeover V^E <0 to V^E >0 suggests that the steric effect is primarily responsible for the positive contributions to V^E. The thermal expansion coefficients α were evaluated from the variation of densities with temperature.

Key words: excess volumes, 2-pyrrolidinone, *n*-alkanols, liquid mixtures, hydrogen bonding.

Résumé : Utilisant des mesures de densités obtenues pour l'ensemble des compositions et à des températures allant de 298,15 à 318,15 K, on a calculé les volumes en excès, V^E, de 2-pyrrolidinone – (C_6–C_{10}) *n*-alcanols. Les volumes en excès sont indépendants de la température, mais ils varient d'une façon importante avec la longueur de l'alcanol. Les valeurs de V^E ne sont positives pour toutes les compositions qu'à partir de l'heptanol, avec la valeur maximale, 0,239 cm^3 mol^{-1}, pour le décanol équimolaire. La position du changement de V^E <0 à V^E >0 suggère que l'effet stérique est la cause principale des contributions positives au V^E. On a évalué les coefficients d'expansion thermique, α, à partir des variations des densités avec la température.

Mots clés : volumes en excès, 2-pyrrolidinone, *n*-alcanols, mélanges liquides, liaison hydrogène.

Introduction

Despite the large number of studies on alcohol liquid mixtures, very few data are available for alcohol mixtures with 2-pyrrolidinone, a cyclic amide (lactam) with both basic (-CO) and acidic (-NH) groups of the peptide bond -NH-CO-. Owing to its high dipole moment (μ = 3.55 D), 2-pyrrolidinone is self-associated, forming dimers in dilute solutions and higher oligomers in concentrated solutions, as demonstrated by different techniques (1). This compound serves as a model for hydrogen bonding of bases of nucleic acids, and is useful in studying the interaction between alkanols and the carbonylamide group (2).

The state of aggregation of alkanols varies from the pure state to solution, and it depends on the nature of the other cosolvent. In the pure state *n*-alkanols are self-associated, forming both open and cyclic aggregates; the probability of the latter increases for smaller alkanols (3), but in nonpolar solvents is independent of the chain length (4). Based upon the excess volumes of pyridine–alkanol binary mixtures, Dewan et al. (5) reported that C_6–C_{10} alkanols in the pure state remain as 1:1 monomer – open dimer mixtures and C_1–C_5 alkanols as dimers, with ethanol as trimer.

In a previous paper on 2-pyrrolidinone – (C_1–C_5) alkanol mixtures (6), we reported negative V^E values over the whole composition range, and suggested a balance between dispersion forces and the specific interactions responsible for heteroassociations. We report here excess volumes and thermal expansion coefficients of 2-pyrrolidinone – (C_6–C_{10}) alkanol mixtures, calculated from density values measured at five different temperatures.

Experimental

The pure liquids, commercially available from Fluka and Aldrich (stated purity >99% GC), were used without further purification but, prior to measurements, they were degassed for several days with ultrasound and stored over freshly activated Fluka AG 3A molecular sieves. The binary mixtures were fully miscible over the entire composition range; the solutions were prepared by weighing the cosolvents with a Mettler AT 261 Delta Range balance (±0.01 mg) and syringing them into stoppered bottles. The error in the mole fraction of the samples was estimated at 10^{-5}. The purity of the chemicals was assessed by measuring their densities, with close agreement between the experimental and literature values (Table 1).

Densities were measured with an Anton Paar DMA 58 vibrating-tube digital densimeter (±10^{-5} g dm^{-3}), equipped with a Peltier element that ensures thermostatization and a resistance thermometer for electrical control of temperature (±0.01 K); the apparatus was calibrated at the working temperatures with *n*-nonane and doubly distilled and degassed

Fig. 1. Experimental molar excess volumes V^E vs. X_1 at 298.15 K of (X_1) 2-pyrrolidinone + (1–X_1) *n*-alkanols: (◇) hexanol, (☆) heptanol, (★) octanol, (▲) nonanol, and (✱) decanol.

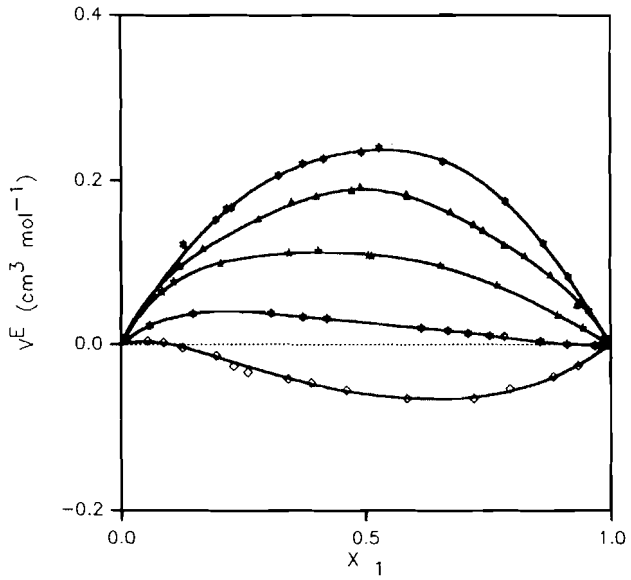

Fig. 2. Plot of molar excess volumes V^E of mixtures: (*a*) (0.5) 2-pyrrolidinone + (0.5) *n*-alkanol at 298.15 K (data for methanol to pentanol from ref. 6) and (*b*) pyridine + *n*-alkanol (data from ref. 5).

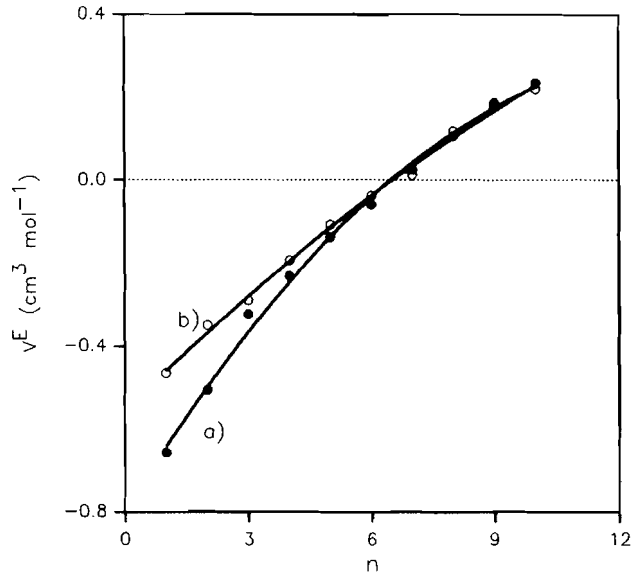

water as calibration standards. Only a small sample size is required for measurements (0.7 mL). To prevent the samples from preferential evaporation new solutions were made up at each temperature.

Results and discussion

Molar excess volumes V^E at different temperatures covering the whole composition range were calculated from the measured densities of the mixtures by means of the equation:

$$[1] \quad V^E = X_1M_1(\rho^{-1} - \rho_1^{-1}) + X_2M_2(\rho^{-1} - \rho_2^{-1})$$

where subscript 1 refers to 2-pyrrolidinone, M_i and ρ_i stand for the molar masses and densities of the pure components, and ρ is the density of the mixtures. The polynomial function [2] was fitted to the variation ρ vs. X_1:

$$[2] \quad \rho = \sum_{k=0}^{n} b_k X_1^k$$

the optimum number of coefficients b_k (Table 2)[2] was ascertained for each mixture with standard deviation σ and linear correlation coefficient r_{xy} as a criterion of goodness of fit. The Redlich–Kister equation [3] was fitted to the calculated V^E values as a function of X_1 (Table 3):

$$[3] \quad V^E = X_1X_2 \sum_{k=0}^{n} [a_k(2X_1 - 1)^k]$$

the a_k coefficients being ascertained with the standard deviation and χ^2 (Table 4).[2]

The excess volumes were independent of temperature, but changed with the alcohol size. Figure 1 shows the isothermal variation V^E vs. X_1 for all the five systems; the curves were sigmoid for hexanol (with positive values at lower X_1) and heptanol (with negative values at higher X_1) and positive for octanol to decanol. These results are consistent with those previously reported for 2-pyrrolidinone – (C_1–C_5) alkanol mixtures (6); the excess volumes were negative at all temperatures and compositions, and became smaller as the chain length of the alcohol increased. Figure 2 shows the equimolar excess volumes V^E vs. chain length of the alcohol. For comparison purposes the results reported by Dewan et al. (5) for (C_1–C_{10}) alkanol – pyridine (μ = 2.37 D) mixtures are also plotted; the two excess volume series differ noticeably for the smaller alkanols (V^E <0), but they gradually converge with increasing chain length and full agreement is reached in the hexanol to decanol (positive V^E) range.

Molar excess volumes of liquid mixtures reflect the result of different contributions arising from the structural changes undergone by the pure cosolvents. It is expected that positive contributions arise from the breakup interactions between like molecules, namely, the rupture of the hydrogen-bonded chains of alcohols and the loosening of the dipolar interactions between 2-pyrrolidinone (or pyridine) molecules (21, 22). The transition V^E <0 to V^E >0 from methanol to decanol suggests a steric effect that increases the mixture volume.

The most important source of negative contributions should be the different shape and size of the two components. Given that 2-pyrrolidinone is a poor proton acceptor and alkanols are relatively poor proton donors (23), it is reasonable to assume that heteroassociations (site–site interactions) do not contribute sufficiently to override the positive contributions. Steric effects and proton-accepting abilities increase as the alkanol chain length increases (24), with a net increase in the positive contributions to V^E. Figure 2 supports such an assumption.

[2] Table 2, containing coefficients for the least-squares fitting of eq. [2], and Table 4, containing the least-squares fitting of the results of eq. [3], have been deposited, and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6.

Table 3. Molar excess volumes of (x_1) 2-pyrrolidinone + ($1-x_1$) (C_6–C_{10}) *n*-alkanol at different temperatures.

Thermal expansion coefficients, α, for each mixture were calculated from the experimental densities at different temperatures as:

$$[4] \quad \alpha = -\rho^{-1}(\Delta\rho/\Delta T)_P$$

Table 5 lists the α values of the mixtures calculated with eq. [4]. Figure 3 shows the plot α of the pure components vs. number of carbon atoms; as the variation with temperature is small, this permits calculation of an averaged $\bar{\alpha}$ value at each temperature. These averaged values are consistent with those reported using other types of functions (7). The fact that interactions between like molecules are stronger than between unlike molecules (25) explains why the positive contributions to excess volume depend on the alcohol chain length, but not on its dipole moment. Figure 4 shows the variation of α with the number of alkanol carbon atoms at different compositions of the mixtures. These values decrease with increasing X_1, and the difference in α at different concentrations decreases as the number of carbon atoms increases, which reveals that the role played by the chain length of the alcohol is even more important than the interactions between donor–acceptor groups of unlike molecules.

Transannular Diels–Alder cyclization of substituted 13-membered trienes. An approach to the B.C.D.[6.6.5] rings of the 14β-hydroxysteroids

Pascal Langlois, Pierre Soucy, Yves L. Dory, and Pierre Deslongchamps

Abstract: The transannular Diels–Alder strategy has been applied to three 13-membered macrocyclic trienes whose characteristics are: a *cis-trans* diene and a *cis* methoxymethyl enol ether as the dienophile. The successful trials led to three 6.6.5 tricyles having a *trans-syn-cis* geometry exactly as in the B.C.D. rings of the 14β-hydroxysteroids.

Key words: transannular, Diels–Alder, 14β-hydroxysteroids, 13-membered rings.

Résumé : La stratégie de Diels–Alder transannulaire a été appliquée sur trois trièmes macrocycliques à 15 membres dont les caractéristiques sont : un diène *cis-trans* et un éther d'énol méthoxyméthyle *cis* comme diénophile. Les essais positifs ont conduit à trois tricycles 6.6.5 ayant une géométrie *trans-syn-cis* exactement comme les cycles B.C.D. des 14β-hydroxystéroïdes.

Mots clés : transannulaire, Diels–Alder, 14β-hydroxystéroïdes, cycles à 13 membres.

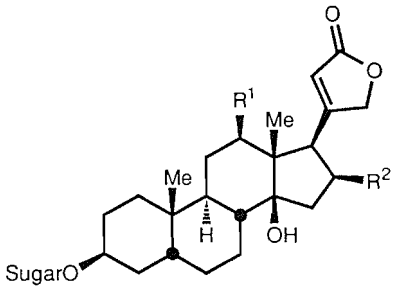
Introduction

We have already demonstrated that 13-membered macrocyclic trienes can be nicely used in the synthesis of the A.B.C.[6.6.5] ring system of the Veratrum alkaloid family (1). We wish now to report on a similar approach towards the B.C.D.[6.6.5] ring skeleton of the 14β-hydroxysteroids. This class of compounds, the 14β-hydroxysteroids, may be divided into 2 subclasses: the 5α,14β-hydroxysteroids and the 5β,15β-hydroxysteroids, the latter groups being the more numerous as well as the most important with regards to therapeutic potency. The aglycones of the cardiac glycosides, digitoxin **1** (2), digoxin **2** (3), digitalin **3** (4), and diginatin **4** (5) (Scheme 1), belong to this family of compounds.

All the reported syntheses (6) of these compounds begin with already elaborated starting materials obtained by degradation of steroids. But the major common snag to the existing approaches is the tedious introduction of the 14β-hydroxyl group. As a consequence the different syntheses that have so far been designed lack versatility and do not allow the design of substituted analogues related to these important natural products.

Since we had recognized that the B.C.D.[6.6.5] ring system, common to all these compounds, could well be obtained via a transannular Diels–Alder reaction (Scheme 2), we carried out a preliminary model study aimed ultimately at the synthesis of 14β-hydroxysteroids. The B.C.D. framework possesses the

Scheme 1.



1 $R^1 = R^2 = H$ = digitoxin (aglycone: digitoxigenin)
2 $R^1 = OH$, $R^2 = H$ = digoxin (aglycone: digoxigenin)
3 $R^1 = H$, $R^2 = OH$ = digitalin (aglycone: gitoxigenin)
4 $R^1 = R^2 = OH$ = diginatin (aglycone: diginatigenin)

trans-syn-cis (TSC) geometry at the ring junctions; therefore the corresponding Diels–Alder adduct **6** requires the 13-membered TCC (*trans-cis-cis*) macrocyclic triene **7** as the precursor. Two models have been devised (Scheme 3) whose goals are, firstly, to check the feasibility of such an approach (model 1) and, secondly, to tackle the introduction of chirality in our systems (model 2). The latter concern, of particular importance, relies on the synthesis of chiral aldols (7) at the macrocyclic level, which could then transmit their chirality to the four stereogenic centres created during the transannular Diels–Alder reactions.

Results and discussion

Synthesis of the macrocycles

Model 1 (Schemes 4 and 6)
The monoprotected diol **8** (8) was oxidized using Swern's

conditions (9) to the aldehyde **9**, which was then subsequently transformed into the enol ether **10** by the Horner–Emmons approach (10, 11) and in 54% yield from **8**; the unwanted geometrical isomer of **10** (11% of the mixture) was easily removed by flash chromatography. The alcohol **11** was obtained by diisobutyl aluminium hydride reduction (12) of the ester **10** in 69% yield. The allylic chloride **12** prepared from **11** using Meyer's conditions (13) (yield: 86%) was treated with di-*tert*-butyl sodiomalonate to give the monosubstituted malonate **13** in 72% yield. Deprotection of the silyl ether **13** by means of tetrabutylammonium fluoride afforded the alcohol **14** in 87% yield that was then protected as its benzoate ester **15** (14) in 79% yield.

The alcohol **16** (9) was oxidized to the aldehyde **17** by means of pyridinium chlorochromate (15) in 48% yield. The dienic ester **18** was then obtained by Horner–Emmons condensation (16) in 100% yield. The allylic chloride **20** was made from **18** by the same two-step procedure used to synthesize **12** from **10** (59% overall yield). The allylic chloride **20** was coupled with the malonate anion of **15** to yield the triene **21** in 88% yield. Mild basic hydrolysis of the benzoate **21** gave the corresponding alcohol **22** (83% yield), which was then converted to the mesylate **23** (100% yield) prior to coupling with dimethyl sodiomalonate to afford the tetraester **24** (79% yield). The silyl ether **24** was deprotected to the alcohol **25** (85% yield). Using Meyer's conditions (13) the alcohol **25** was subsequently transformed into the chloride **26** in 86% yield.

Several attempts to macrocyclize the allylic chloride **26** with cesium carbonate under high dilution conditions either in *N*,*N*-dimethylformamide or in acetonitrile proved unsuccessful, giving mostly the macrocyclic ketone **30** and very little cyclic enol **29** (Scheme 6). The alcohol **25** was then transformed into the corresponding acetate **27** (96% yield) and pivaloate **28** (80% yield). The macrocyclization step was carried out on both esters **27** and **28** via their π allyl palladium complexes (17) to yield the desired macrocycle **29** in 23 and 79% yields, respectively.

Model 2 (Schemes 5 and 6)

The allylic chloride **12** was transformed into the monosubstituted methyl malonate **31** by the same method used to prepare **13** from the same starting chloride **12** in 74% yield. The ester **32** was obtained by decarboxylation of **31** in 67% yield (18). Subsequent removal of the silyl protecting group (14) afforded the alcohol **33** (97% yield), which was transformed into the malonate **35** by the same two-step procedure that was followed to prepare **24** from **22** (75% overall yield). The alcohol **19** was oxidized under Swern's conditions (9) to the aldehyde **36** in 86% yield. Aldol condensation (19) between the dianion of the tetraester **35** and the aldehyde **36** produced the two aldols **37** and **38**, in 59% total yield (*erythro* isomer **37**: 42% of the mixture; *threo* isomer **38**: 58% of the mixture). The structures of the two aldols were assigned according to the NMR chemical shifts of the methoxy groups of the aldol ester moieties (3.53 ppm: *erythro* isomer; 3.69 ppm: *threo* isomer); it has long been observed in our laboratories (19) that similar aldol products displayed NMR spectra where the *erythro* methoxy signals were consistently upfield from their *threo* counterparts by 0.1–0.2 ppm. The silyl ether **37** was cleaved (8) to yield the diol **39** (80% yield), which was then selectively monoprotected as the primary benzoate ester **41** (15) in 72% yield. The remaining alcohol group of the *erythro* aldol **41** was protected as its silyl ether **43** (8) in 100% yield. The alcohol **45** obtained by hydrolysis of the benzoate **43** (76% yield) was transformed into the corresponding allylic chloride **47** (13) (96% yield), which was subsequently cyclized with cesium carbonate under high dilution conditions to give the macrocycle **49** in 59% yield. The same six-step procedure (**37** to **49**) was applied to the *threo* aldol **38** to synthesize the macrocycle **50** in 33% overall yield.

Diels–Alder reactions (Schemes 6, 7, and 8)

The Diels–Alder cycloaddition reactions were carried out on

Scheme 4.

the macrocyclic trienes **29**, **49**, and **50** in toluene at 180°C, 230°C, and 200°C, respectively (Scheme 6).

Model 1

The tetraester **29** led to the formation of three tricycles **51**, **52**, and **53** (78%, 11%, and 11% of the mixture, respectively; total yield: 66%). The triesters **52** and **53** were the result of the thermic decarboxylation of one *tert*-butyl ester either on the macrocycle **29** before Diels–Alder reaction or on the tricycle **51**. The structures of the adducts **51**, **52**, and **53** were assessed by the following chemical path (Scheme 7): the methoxymethyl ethers were cleaved by means of hydrochloric acid to give the corresponding alcohols **58**, **59**, and **60** (89%, 89%, and 80% yield). The alcohol **58** underwent *tert*-butyl ester hydrolysis and lactonization under acidic conditions; then treatment with diazomethane gave the lactone **61** (90% yield) whose structure was confirmed by X ray analysis (20). Acidic treatment of the alcohol **59** led to the lactone **62** in 81% yield. The alcohol **60** was treated in the same way as **58** to afford the unconjugated alkene-ester **63** (78% yield), thus proving the *anti* geometry of the *tert*-butyl ester with regard to the methoxymethyl ether in the Diels–Alder adduct **53**.

Scheme 5.

Model 2

The macrocycle *syn* **49** (*erythro* series) led to only one Diels–Alder adduct **54** (57% yield), the structure of which was proved chemically (Scheme 8). The methoxymethyl ether **54** was cleaved by means of dimethylboron bromide (21) to yield quantitatively the alcohol **64**, which then lactonized under acidic conditions to give the compound **66**. When treated under similar conditions the macrocycle *anti* **50** (*threo* series) also gave only one Diels–Alder adduct, **56** (94% yield), which did not afford a lactone as above, but rather the diol ester **67**, proving implicitly the *anti* geometry of the methoxymethyl ether and the ring D ester in the adduct **56**.

Geometry of the transition states (Scheme 9)

The transition state A en route from the macrocycle **29** to the adduct **51** is obviously in competition with no other transition state; therefore, no other adduct results from the Diels–Alder reaction of **29**. On the contrary, two transition states B and C may be considered to be issued from the tricycle **49**; C, however, displays a very severe steric interaction between the silyl ether and an external dienic proton (E side). As a consequence of this effect no corresponding adduct **55** is experimentally observed; the tricycle **54**, obtained through the steric-interaction-free transition state B, is the only reaction product. Regarding the Diels–Alder reaction from the macrocycle **50**, the outcome is the same: the only observed adduct **56** is issued from the transition state D displaying no major steric-disfavoring interaction, whereas the other possible isomeric adduct **57** is not obtained since it would arise from the hindered transition state E, which is sterically similar to C.

Conclusion

We have shown that the B.C.D. rings framework of the 14β-steroids could be obtained in a straightforward manner by means of the transannular Diels–Alder strategy from easily built macrocyclic trienes. Furthermore, the racemic Diels–Alder adducts with aldol moieties in the D ring have the same relative geometry at centres 8, 9, 13, 14, and 17 (steroid

nomenclature) thus proving that the silyl ether (position 17) is responsible on its own for the stereochemical fate of the Diels–Alder reactions, the aldol ester group stereochemistry having no effect. Therefore, stereochemical control of the alcohol group (position 17) should provide easy access to enantiomerically pure 14β-steroids.

We are currently investigating this route, together with the introduction of the A ring, which will end the synthesis.

Experimental section

Melting points were recorded on a Rinco M-50 apparatus and are uncorrected. MS data were determined at 70 eV on a VG Micromass ZAB-1F spectrometer. IR absorption spectra were measured on a Perkin Elmer 681. Proton (^{1}H) NMR spectra were recorded on a Bruker WM-250. Chemical shifts are reported relative to TMS (δ 0.00) with residual $CHCl_3$ as internal standard (δ 7.26) or residual C_6H_6 (δ 7.21).

All reactions were conducted in oven-dried (120°C) or flame-dried glassware under an atmosphere of dry argon, unless otherwise stated.

Aldehyde ***9***

To a solution of oxalyl chloride (4.46 mL, 51.1 mmol) in dichloromethane (112 mL) at −55°C was added a solution of dimethyl sulfoxide (7.59 mL, 106.9 mmol) in dichloromethane (23 mL). The mixture was added to a solution of the alcohol **8** (8) (14.0 g, 45.0 mmol) in dichloromethane (22 mL) over a 5 min period. The mixture was stirred for 45 min, then *N,N*-diisopropylethylamine (38.8 mL, 222.7 mmol) was added. The solution was allowed to warm up, then water was added at −10°C. The mixture was extracted with dichloromethane and washed with brine. Drying ($MgSO_4$) and removal of solvent afforded the title compound (14.0 g, 100%), which was used in the next step without further purification; ir (film): 3080–3005, 2960–2840, 1730, 1430, 1115 cm^{-1}; ^{1}H nmr ($CDCl_3$, δ ppm): 1.06 (9H, s, t-*Bu*), 2.62 (2H, td, *J* = 6 Hz, 2 Hz, CH_2CHO), 4.04 (2H, t, *J* = 6 Hz, CH_2OSi), 7.35–7.45 (6H, m, Ph), 7.65–7.75 (4H, m, Ph), 9.83 (1H, t, *J* = 2 Hz, *CH*O); ^{13}C nmr ($CDCl_3$, δ ppm): 19.10, 26.72, 46.33, 58.25, 127.74, 129.79, 133.21, 135.51, 201.89; ms *m/e*: 255 (M^+ − *t*-Bu).

Ester ***10***

A solution of 2-methoxymethyloxytrimethylphosphonoacetate (21.54 g, 89 mmol) (11) in tetrahydrofuran (30 mL) was treated at 0°C with *n*-butyllithium (1.65 M in hexane) (51.2 mL, 84 mmol) for 10 min. A solution of the aldehyde **9** (13.89 g, 45 mmol) in tetrahydrofuran (50 mL) was added at −78°C and the resulting mixture was stirred for 5 min at −78°C; then saturated aqueous ammonium chloride was added and the reaction mixture extracted with dichloromethane. Drying ($MgSO_4$) and removal of solvent afforded an oil that was purified by flash chromatography on silica gel (ethyl acetate – hexane, 5:95) to give the desire *E* olefin **10** (10.34 g, 54%) and its *Z* isomer (1.37 g, 7%).

General procedure for the preparation of benzoates

Method A

Benzoate ***15***

To a solution of the alcohol **14** (2.46 g, 6.85 mmol) in anhydrous pyridine (12.0 mL) at 0°C was added benzoyl chloride (1.75 mL, 14.95 mmol). The mixture was stirred at room temperature for 3 h. The reaction mixture was extracted with dichloromethane and the organic layer was washed with saturated aqueous sodium bicarbonate. Drying ($MgSO_4$) and removal of the solvent gave an oily residue that was purified by flash chromatography (hexane – ethyl acetate, 4:1) to give the title compound (2.50 g, 79%); ir (CH_2Cl_2): 1725, 1670 cm^{-1}; ^1H nmr ($CDCl_3$δ ppm): 1.45 (18H, s, t-*Bu*CO_2), 2.51 (2H, q, *J* = 7.0 Hz, OCH_2CH_2), 2.73 (2H, d, *J* = 7.5 Hz, CH_2CH(CO_2t-Bu)$_2$), 3.39 (3H, s, CH_2OMe), 3.52 (1H, t, *J* = 7.5 Hz, C*H*(CO_2t-Bu)$_2$), 4.27 (2H, t, *J* = 7.0 Hz, BzOCH_2), 4.82 (1H, t, *J* = 7.5 Hz, C*H*=COMOM), 4.89 (2H, s, OCH_2O), 7.25–7.55 (3H, m, *Ph*), 8.03 (2H, m, *Ph*).

Method B

Benzoate ***41***

To a solution of the diol **39** (101 mg, 0.22 mmol) and pyridine (358 μL, 4.42 mmol) in dichloromethane (0.5 mL) at 0°C was added benzoyl chloride (27 μL, 0.23 mmol). The mixture was stirred at 0°C for 2 h, then treated with saturated aqueous sodium bicarbonate and extracted with dichloromethane. The organic extract was dried ($MgSO_4$) and the solvent was removed under reduced pressure. The crude product was purified by chromatography on silica gel (hexane – ethyl acetate, 4:1 to pure ethyl acetate) to afford the title compound (90 mg, 72%); ir (CH_2Cl_2): 1735, 1665, 1437 cm^{-1}; ^1H nmr ($CDCl_3$, δ ppm): 1.83 (3H, s, *Me*C=C), 1.90–2.10 (4H, m, (CH_2)$_2$), 2.38 (1H, d, *J* = 4.5 Hz, O*H*), 2.57 (1H, dd, *J* = 14.0 Hz, 10.5 Hz, C=C(OMOM)C*H*H), 2.70 (1H, dd, *J* = 14.0 Hz, 4.0 Hz, C=C(OMOM)CH*H*), 2.88 (1H, ddd, *J* = 10.0 Hz, 9.0 Hz, 4.0 Hz, C*H*CO_2Me), 3.37 (3H, s, CH_2OMe), 3.39 (1H, t, *J* = 7.0 Hz, C*H*(CO_2Me)$_2$), 3.54 (3H, s, CHCO_2Me), 3.74 (6H, s, CH(CO_2Me)$_2$), 4.70 (1H, t, *J* = 7.0 Hz, C*H*=COMOM), 4.79 (1H, dd, *J* = 9.5 Hz, 4.0 Hz, C*H*OH), 4.84 and 4.86 (2H, d, *J* = 6.5 Hz, OCH_2O), 4.85 (2H, d, 6.5 Hz, CH_2OBz), 5.79 (1H, dt, *J* = 15.0 Hz, 6.5 Hz, C*H*=CHCH=CMe), 5.95 (1H, d, *J* = 11.0 Hz, C*H*=CMe), 6.68 (1H, dd, *J* = 15.0 Hz, 11.0 Hz, CH=C*H*CH=CMe), 7.44 (2H, m, *Ph*), 7.56 (1H, m, *Ph*), 8.03 (2H, m, *Ph*); ^{13}C nmr ($CDCl_3$, δ ppm): 17.87, 24.28, 29.31, 29.50, 49.32, 50.82, 51.32, 52.38, 55.73, 65.24, 70.35, 93.48, 101.14, 126.36, 127.25, 128.22, 129.39, 132.84, 138.53, 152.54, 166.21, 169.74, 172.85; ms *m/e*: 530 (M^+ − MeOH). General procedure for the preparation of mesylates

Mesylate 23

To a stirred solution of the alcohol **22** (2.51 g, 3.54 mmol) and pyridine (2.20 mL, 16.02 mmol) in dichloromethane (60 mL) at 0°C was added methanesulfonyl chloride (0.28 mL, 3.70 mmol). The mixture was stirred for 30 min, then quenched with ice and extracted with dichloromethane. Drying ($MgSO_4$) and removal of solvent afforded the crude product, which was filtered on Florisil (ethyl acetate – hexane, 3:7) to give the title compound (2.78 g, 100%), which was used in the next step without further purification; ir (CH_2Cl_2): 1725, 1660 cm^{-1}; ^{1}H nmr ($CDCl_3$, δ ppm): 1.05 (9H, s, t-*Bu*Si), 1.44 (18H, s, t-*Bu*CO_2), 1.76 (3H, s, *Me*C=C), 2.34 (2H, q, *J* = 7.5 Hz, MsOCH$_2$C*H*$_2$), 2.79 (4H, d, *J* = 6.5 Hz, C*H*$_2$C(CO$_2$*t*-Bu)$_2$C*H*$_2$), 2.94 (3H, s, *Ms*), 3.29 (3H, s, CH$_2$O*Me*), 4.09 (2H, t, *J* = 8.0 Hz, MsOC*H*$_2$), 4.20 (2H, d, *J* = 5.0 Hz, SiOC*H*$_2$), 4.65 (1H, t, *J* = 7.5 Hz, C*H*=COMOM), 4.77 (2H, s, OC*H*$_2$O), 5.63 (1H, dt, *J* = 15.0 Hz, 5.0 Hz, C*H*=CMe), 5.87 (1H, d, *J* = 11.0 Hz, C*H*=CHCH=CMe), 6.41 (1H, dd, *J* = 15.0 Hz, 10.0 Hz (CH=C*H*CH=CMe), 7.35–7.45 (6H, m, *Ph*), 7.65–7.75 (4H, m, *Ph*).

Mesylate 34: Yield 99%; ^{1}H nmr ($CDCl_3$, δ ppm): 2.48 (6H, m, C*H*$_2$CH=C(OMOM)(C*H*$_2$)$_2$), 2.99 (3H, s, *Ms*), 3.36 (3H, s, CH$_2$O*Me*), 3.66 (3H, s, CO$_2$*Me*), 4.16 (2H, t, *J* = 7.0 Hz, MsOC*H*$_2$), 4.65 (1H, t, *J* = 7.5 Hz, C*H*=COMOM), 4.88 (2H, s, OC*H*$_2$O).

Acetate 27

To a solution of the alcohol **25** (42 mg, 72 μmol) in pyridine (20 mL) was added acetic anhydride (1.0 mL). The mixture was stirred at 0°C for 24 h. The solvent was evaporated and the residue purified by flash chromatography (ethyl acetate – hexane, 3:17) to give the title compound (43 mg, 96%); ir (CH_2Cl_2): 1735, 1660 cm^{-1}; ^{1}H nmr ($CDCl_3$, δ ppm): 1.44 (18H, s, t-*Bu*CO_2), 1.75 (3H, s, *Me*C=C), 1.9–2.0 (4H, m, (C*H*$_2$)$_2$CH(CO$_2$Me)$_2$), 2.05 (3H, s, *Ac*), 2.78 (4H, d, *J* = 14.0 Hz, C*H*$_2$C(CO$_2$*t*-Bu)$_2$C*H*$_2$), 3.36 (1H, t, *J* = 7.5 Hz, C*H*(CO$_2$Me)$_2$), 3.40 (3H, s, CH$_2$O*Me*), 3.74 (6H, s, CO$_2$*Me*), 4.57 (2H, d, *J* = 7.0 Hz, AcOC*H*$_2$), 4.66 (1H, t, *J* = 7.5 Hz, C*H*=COMOM), 4.83 (2H, s, OC*H*$_2$O), 5.58 (1H, dt, *J* = 15.0 Hz, 7.0 Hz, C*H*=CMe), 5.85 (1H, d, *J* = 10.0 Hz, C*H*=CHCH=CMe), 6.51 (1H, dd, *J* = 15.0 Hz, 11.0 Hz, CH=C*H*CH=CMe).

Pivaloate 28

To a solution of the alcohol **25** (0.80 g, 1.40 mmol) in dichloromethane (5.5 mL) at 0°C were added pyridine (3.31 mL, 6.87 mmol) and trimethylacetylchloride (251 μL, 1.80 mmol). The mixture was stirred at room temperature for 3 h, then washed with satured aqueous ammonium chloride. Drying ($MgSO_4$) and removal of solvent under reduced pressure gave the crude product, which was purified by flash chromatography on silica gel (ethyl acetate – hexane, 3:7) to give the title compound (0.74 g, 80%); ir (CH_2Cl_2): 1735, 1660 cm^{-1}; ^{1}H nmr ($CDCl_3$, δ ppm): 1.19 (9H, s, *piv*), 1.43 (18H, s, t-*Bu*CO_2), 1.76 (3H, s, *Me*C=C), 1.85–2.00 (4H, m, (C*H*$_2$)$_2$ CH(CO$_2$Me)$_2$), 2.79 (4H, d, *J* = 14.0 Hz, C*H*$_2$C(CO$_2$*t*-Bu)$_2$C*H*$_2$), 3.37 (1H, t, *J* = 6.5 Hz, C*H*(CO$_2$Me)$_2$), 3.39 (3H, s, CH$_2$O*Me*), 3.74 (6H, s, CO$_2$*Me*), 4.56 (2H, d, *J* = 7.0 Hz, C*H*$_2$O piv), 4.68 (1H, t, *J* = 6.5 Hz, C*H*=COMOM), 4.82 (2H, s, OC*H*$_2$O), 5.59 (1H, dt, *J* = 15.0 Hz, 5.0 Hz, C*H*=CMe), 5.86 (1H, d, *J* = 11.0 Hz, C*H*=CHCH=CMe), 6.51 (1H, dd, *J* = 15.0 Hz, 10.0 Hz, CH=C*H*CH=CMe).

Ester 32

To a solution of the malonate **31** (2.8 g, 5.4 mmol) in dimethyl sulfoxide (55 mL) was added sodium cyanide (530 mg, 10.8 mmol). The mixture was stirred for 64 h at 90°C, then extracted with hexane and ether (1:1). The combined organic extract was dried ($MgSO_4$), solvent was removed under reduced pressure, and the residue was purified by flash column chromatography (hexane – ethyl acetate, 19:1) to yield the title compound (2.6 g, 67%); ir (film): 3055, 2950–2860, 1740, 1670 cm^{-1}; ^{1}H nmr ($CDCl_3$, δ ppm): 1.11 (9H, s, Si*t*-Bu), 2.30 (2H, dt, *J* = 7.5 Hz, 7.0 Hz, SiOCH$_2$C*H*$_2$), 2.48 (4H, m, *J* = 7.5 Hz, (C*H*$_2$)$_2$CO$_2$Me), 3.39 (3H, s, CH$_2$O*Me*), 3.65 (2H, t, *J* = 7.0 Hz, SiOC*H*$_2$), 3.67 (3H, s, CO$_2$*Me*), 4.72 (1H, t, *J* = 7.5 Hz, C*H*=COMOM), 4.87 (2H, s, OC*H*$_2$O), 7.35–7.50 (6H, m, *Ph*), 7.70–7.80 (4H, m, *Ph*); ^{13}C nmr ($CDCl_3$, δ ppm): 18.97, 25.34, 26.53, 30.11, 31.99, 51.52, 55.85, 64.16, 93.42, 98.13, 127.66, 129.59, 133.89, 135.56, 153.23, 173.54; ms *m/e*: 425 (M^+ − MeO), 411 (M^+ − MOM), 399 (M^+ − *t*-Bu). HRMS (M^+ − *t*-Bu): 399.1628; found: 399.1618.

Aldehyde 36

To a solution of the alcohol **19** (558 mg, 1.52 mmol) in dichloromethane (4 mL) and pentane (16 mL) at room temperature was added manganese dioxide (199 mg, 22.84 mmol). The resulting mixture was stirred for 2 h, then more manganese dioxide (662 mg, 76.13 mmol) was added. The mixture was stirred for another 2 h, then filtered on Celite. Solvent was removed under reduced pressure and the residue was purified by chromatography on silica gel (hexane – ethyl acetate, 24:1) to give the title compound (478 mg, 86%); ^{1}H nmr ($CDCl_3$, δ ppm): 1.09 (9H, s, t-*Bu*Si), 1.86 (3H, s, *Me*C=C), 4.36 (2H, d, *J* = 5.0 Hz, C*H*$_2$OSi), 6.06 (1H, dt, *J* = 15.0 Hz, 5.0 Hz, SiOCH$_2$C*H*=CH), 6.96 (1H, d, *J* = 11.0 Hz, C*H*=CMeCHO), 7.25–7.45 (7H, m, *Ph*, SiOCH$_2$CH=C*H*), 7.65–7.70 (4H, m, *Ph*), 10.28 (1H, s, C*H*O); ms *m/e*: 307 (M^+ − *t*-Bu).

Aldols 37 and 38

To a solution of diisopropylamine (0.25 mL, 1.80 mmol) in tetrahydrofuran (1.5 mL) at −78°C was added *n*-butyllithium (1.6 M in tetrahydrofuran, 1.1 mL, 1.74 mmol). The solution was stirred at 0°C for 20 min, then cooled to −78°C. The triester **35** (232 mg, 0.70 mmol) in tetrahydrofuran (0.5 mL) was added, and the reaction mixture stirred for 30 min at −78°C. The aldehyde **36** (509 mg, 1.40 mmol) in tetrahydrofuran was added and the reaction mixture stirred for another 30 min at −78°C. The reaction was quenched with saturated aqueous ammonium chloride, and extracted 3 times with dichlo-

romethane. The organic extract was dried ($MgSO_4$) and the solvent was removed under reduced pressure. The crude product was purified by chromatography on silica gel (hexane – ethyl acetate, 17:3 to 3:1) to afford the title compounds (overall yield: 286 mg, 59%; *erythro* isomer **37**: 42% of the mixture, *threo* isomer **38**: 58% of the mixture).

Alternative method used to prepare the macrocyclic enol ether ***29***

O,N-Bis(trimethylsilyl)acetamide (570 μL, 2.27 mmol) was added to a stirred solution of the pivaloate **28** (0.74 g, 1.10 mmol) in tetrahydrofuran (15 mL) at room temperature. The reaction mixture was refluxed for 5 h, cooled down to room temperature, then added over 14 h by means of a syringe pump to a refluxed solution of palladium(0) tetrakis(triphenylphosphine) (270 mg, 0.22 mmol) and 1,3 bis(diphenylphosphino) propane (97 mg, 0.23 mmol) in tetrahydrofuran (535 mL). The resulting mixture was refluxed for another 20 h. The solvent was removed under reduced pressure. The crude product was purified by flash chromatography (hexane – ethyl acetate, 24:1) to give the title compound (0.49 g, 79%).

The same method applied to the acetate **27** afforded the title compound in 23% yield.

General procedure for the Diels–Alder reactions

Tricycles ***51, 52, and 53***

A solution of the macrocycle **29** (351 mg, 0.62 mmol) in toluene (600 μL) was heated in a quartz tube (sealed under vacuum) at 185°C for 4 h. The resulting solution was concentrated under reduced pressure and the residue was purified by flash chromatography (hexane – acetone, 24:1) to give the pure tricycle **53** (25 mg) and a mixture of **51** and **52**. The mixture was purified by preparative thick-layer chromatography (hexane – ethyl acetate, 17:3; four elutions) to yield the tricycles **51** (171 mg) and **52** (26 mg). The overall yield of the reaction was 66% (**51**: 78% of the mixture, **52**: 11%, **53**: 11%).

Procedure use for the lactonization attempts

Alcohol ***61***

A solution of the alcohol **58** (35 mg, 67 μmol) and paratoluenesulfonic acid monohydrate (1 mg) in benzene (1 mL) was refluxed for 4 h. The solvent was removed under reduced pressure, and the residue dissolved in either (2 mL). Diazomethane (ether solution, 1 mL) was added and the resulting mixture

was stirred for 1 h at room temperature. Removal of solvent under reduced pressure gave a solid residue that was crystallized from dichloromethane and ether to give the title compound (24 mg, 90%); mp 156–158°C; ir (CH_2Cl_2): 1790, 1740 cm^{-1}; ^1H nmr (C_6D_6, δ ppm): 0.87 (3H, s, CMe), 0.97 (1H, m, $H_{ax}C13$), 1.35–1.65 (4H, m, HC1, $H_{ax}C10$, $H_{ax}C5$, $H_{ax}C12$), 1.65–1.95 (4H, m, HC9), $H_{eq}C13$, H_2C3), 2.12 (1H, dd, $H_{eq}C5$), 2.40–2.62 (2H, m, $H_{eq}C12$, $H_{eq}C10$), 3.27 (3H, s, CO_2Me), 3.40 (3H, s, CO_2Me), 3.78 (3H, s, CO_2Me), 4.89 (2H, dd, J = 10.0 Hz, 1.5 Hz, HC7), 5.05 (2H, dd, J = 10.0 Hz, 2.5 Hz, HC8) (see Scheme 2 for atom numbers: **6**); ^{13}C nmr (C_6D_6, δ ppm): 22.9, 23.3, 30.9, 36.7, 37.3, 37.9, 40.8, 41.3, 52.1, 45.3, 52.2, 55.2, 57.3, 92.3, 126.6, 135.7, 171.1, 171.8, 172.7; ms m/e: 406 (M^+); HRMS (M^+): 406.1628; found: 406.1641.

Synthesis and study of Pt(II)–nitrile complexes. Multinuclear NMR spectra and crystal structures of compounds of the types $[Pt(R\text{-}CN)Cl_3]^-$ and *cis* and *trans*-$Pt(R\text{-}CN)_2Cl_2$

Fernande D. Rochon, Robert Melanson, Eryk Thouin, André L. Beauchamp, and Corinne Bensimon

Abstract: Complexes of the type $[Pt(R\text{-}CN)Cl_3]^-$ were synthesized and studied by ^1H, ^{13}C, and ^{195}Pt NMR spectroscopies. The $^2J(^{195}Pt\text{-}^{13}C)$ coupling constants are about 240 Hz. The signals due to the cyano carbon atoms of the coordinated ligands were observed at higher fields than those of the free ligands. The shielding on the cyano carbon increases as the alkyl chain lengthens and also when the branching increases. The ^{195}Pt signals of all the complexes were observed around −2000 ppm. The crystal structures of $(NMe_4)[Pt(C_3H_7\text{-}CN)Cl_3]$ (**1**) and $(NMe_4)[Pt(p\text{-}HO\text{-}C_6H_4\text{-}CN)Cl_3]$ (**2**) were determined. Compound **1** is monoclinic, $P2_1/c$, $a = 8.384(5)$, $b = 15.336(19)$, $c = 11.759(9)$ Å, $\beta = 99.52(6)°$, $Z = 4$, $R = 0.054$, and $wR = 0.051$. Crystal **2** is tetragonal with $a = 16.222(6)$, $c = 12.052(5)$ Å, $Z = 8$, $R = 0.059$, and $wR = 0.044$. The Pt—Cl bond *trans* to the nitrile ligand is shorter than normal (2.276(3) Å for **1** and 2.264(7) Å for **2**) while the two other bonds are normal (2.293(4), 2.287(3) Å for **1** and 2.320(7), 2.275(8) Å for **2**). The Pt—N bonds are 1.97(1) Å (**1**) and 1.92(2) Å (**2**) and the segments Pt-N≡C-C are linear. Disubstituted compounds were also synthesized and studied by multinuclear NMR. The ^{195}Pt signals of the *cis* isomers were observed at lower fields than those of the *trans* isomers ($\Delta \approx 65$ ppm), while the ^{13}C signals of the cyano carbons of the *trans* isomers were observed at lower fields than those of the *cis* compounds ($\Delta \approx 0.6$ ppm). The *cis* complexes isomerize to the *trans* compounds upon heating. The crystal structures of *cis*-(**3**) and *trans*-$Pt(C_2H_5\text{-}CN)_2Cl_2$ (**4**) and also of *cis*-$Pt(p\text{-}HO\text{-}C_6H_4\text{-}CN)_2Cl_2$ (**5**) were determined. Crystal **3** is monoclinic, $P2_1/c$, $a = 7.506(5)$, $b = 9.539(5)$, $c = 14.823(7)$ Å, $\beta = 92.31(4)°$, $Z = 4$, $R = 0.050$, and $wR = 0.042$. The *trans* isomer **4** is monoclinic with the Pt atom on an inversion centre, $P2_1/c$, $a = 5.149(4)$, $b = 9.394(8)$, $c = 10.944(10)$ Å, $\beta = 97.84(7)°$, $Z = 4$, $R = 0.017$ and $wR = 0.020$. Finally, compound **5** is triclinic, $P\text{-}1$, $a = 7.464(3)$, $b = 10.712(6)$, $c = 12.291(5)$ Å, $\alpha = 75.63(4)°$, $\beta = 75.63(4)°$, $\gamma = 80.32(4)°$, $Z = 2$, $R = 0.045$, and $wR = 0.056$. The Pt—Cl bond distances for the *cis* isomers are 2.269(5), 2.270(4) Å for **3** and 2.274(2), 2.279(3) Å for **5** while they are 2.289(3) Å for the *trans* isomer (**4**). The Pt—N bonds are 1.962(14), 1.988(11) Å (**3**), 1.972(7), 1.976(7) Å (**5**) and 1.969(5) Å for **4**.

Key words: platinum, nitrile, NMR, isomerization, crystal structure.

Résumé : Des complexes de type $[Pt(R\text{-}CN)Cl_3]^-$ ont été synthétisés et étudiés par résonance magnétique nucléaire protonique, carbon-13 et platine-195. Les constantes de couplage $^2J(^{195}Pt\text{–}^{13}C)$ sont environ 240 Hz. La résonance des carbones cyano des ligands coordinés a été observée à un champ plus fort que celle des ligands libres. Ce blindage augmente lorsque la chaîne alkyle s'allonge et aussi lorsque le branchement augmente. Les signaux ^{195}Pt de tous les complexes ont été observés autour de −2000 ppm. Les structures cristallines des composés $(NMe_4)[Pt(C_3H_7\text{-}CN)Cl_3]$ (**1**) et $(NMe_4)[Pt(p\text{-}HO\text{-}C_6H_4\text{-}CN)Cl_3]$ (**2**) ont été déterminées. Le composé **1** est monoclinique, $P2_1/c$, $a = 8{,}384(5)$, $b = 15{,}336(19)$, $c = 11{,}759(9)$ Å, $\beta = 99{,}52(6)°$, $Z = 4$, $R = 0{,}054$ et $wR = 0{,}051$. Le cristal **2** est tétragonal avec $a = 16{,}222(6)$, $c = 12{,}052(5)$ Å. $Z = 8$, $R = 0{,}059$ et $wR = 0{,}044$. Le lien Pt—Cl en position *trans* du ligand nitrile est plus court qu'un lien normal (2,276(3) pour **1** et 2,264(7) Å pour **2**) tandis que les deux autres liens sont normaux (2,293(4), 2,287(3) Å pour **1** et 2,320(7), 2,275(8) Å pour **2**). Les liaisons Pt—N sont 1,97(1) Å (**1**) et 1.92(2) Å (**2**) et le segment Pt-N≡C-C est linéaire. Des complexes disubstitués ont également été synthétisés et étudiés par résonance magnétique multinucléaire. Les signaux ^{195}Pt des isomères *cis* ont été observés à des champs plus faibles que ceux des complexes *trans* ($\Delta \approx 65$ ppm), tandis que les résonances des carbones cyano des isomères *cis* ont été observées à des champs plus forts que celles des composés *trans* ($\Delta \approx 0.6$ ppm). Les complexes *cis* s'isomèrisent en isomères *trans* sous l'effet de la chaleur. Les structures cristallines de *cis*-(**3**) et *trans*-$Pt(C_2H_5\text{-}CN)_2Cl_2$ (**4**) et de *cis*-$Pt(p\text{-}HO\text{-}C_6H_4\text{-}CN)_2Cl_2$ (**5**) ont été déterminées. Le crystal **3** est monoclinique, $P2_1/c$, $a = 7{,}506(5)$, $b = 9{,}539(5)$, $c = 14{,}823(7)$ Å, $\beta = 92{,}31(4)°$, $Z = 4$, $R = 0{,}050$ et $wR = 0{,}042$. L'isomère *trans* (**4**) est monoclinique avec l'atome de Pt sur un centre d'inversion, $P2_1/c$, $a = 5{,}149(4)$, $b =$

Mots clés : platine, nitrile, RMN, isomérisation, structure cristalline.

Introduction

Although several disubstituted nitrile–Pt(II) complexes, mostly with acetonitrile and benzonitrile, have been reported (1–7), few mononitrile complexes have been studied (8–10). The synthesis of these compounds is important as starting material for the preparation of mixed-ligand complexes.

The nature of the Pt–nitrile bond is not very well known. IR data and X-ray diffraction of a few acetonitrile complexes have shown that CH_3CN is bonded through its lone pair of electrons on the nitrogen atom (2, 8, 10, 11) and the segment Pt-N≡C-C is linear. Acetonitrile is expected to accept electron density from the metal, much like CO, because of its empty π* orbitals. Therefore it was expected that its *trans* effect should be fairly large but this hypothesis has not been confirmed.

Disubstituted nitrile compounds are usually the *cis* isomers. It was expected that the *trans* isomers would be formed first and would then isomerize to the *cis* compounds, similarly to the sulfoxide complexes (12–15). In the latter compounds, the $(d–d)\pi$ bonding is much more efficient in the *cis* configuration than in the *trans* isomers. But recent studies on disubstituted complexes with acetonitrile, and dibenzonitrile seem to indicate that the *cis* compound is the first product formed, and isomerization then occurs (3, 16). The nature of the back-donation in Pt–nitrile compounds (d–π*) is quite different from that in Pt–sulfoxide (d–d) complexes. Bond lengths usually give information on the presence of multiple bonding but this is not always obvious. Multinuclear NMR spectroscopy can also give some indication on the strength of the Pt–ligand bond. The σ bond will cause a deshielding effect on the ligand and a shielding effect on the metal, while back-donation from the metal to the ligand should produce the opposite effect. We have measured the proton, carbon-13, and platinum-195 NMR spectra of several complexes of the types $[Pt(R\text{-}CN)Cl_3]^-$ and $Pt(R\text{-}CN)_2Cl_2$ in order to obtain information about the Pt–nitrile bond. To study disubstituted compounds, it is important to know exactly the nature of these compounds. A study was undertaken to determine the configuration of such compounds, which were also studied by IR spectroscopy and a few by X-ray diffraction. The potassium mononitrile complexes are not very stable and decompose quite readily. To stabilize the compounds, a larger cation was used. The tetramethylammonium salts proved much more stable and several complexes of the type $N(CH_3)_4[Pt(nitrile)Cl_3]$ were isolated and characterized. The compounds with butyronitrile and p-hydroxybenzonitrile gave crystals suitable for X-ray diffraction and their structures were determined. The crystal structures of the disubstituted complexes with propionitrile (*cis* and *trans*) and p-hydroxybenzonitrile were also studied. *trans*-$Pt(C_2H_5CN)_2Cl_2$ is the first example of this type of compound to be analyzed by X-ray diffraction methods. The results of these studies are described below.

Experimental

The ^{195}Pt NMR spectra were measured either on a Bruker WH-400 (85.83 MHz) or a Varian-300 (64.507 MHz) spectrometer. The proton and ^{13}C NMR spectra were obtained on the same instruments and occasionally (for ^1H) on a EM-360L (60 MHz) equipped with a signal averager (Varian V-2048) in order to measure the $J(^{195}Pt–^1H)$ couplings. The monosubstituted complexes were measured in D_2O, while the disubstituted complexes were measured in $CDCl_3$. The comparison with the free ligands is made with identical solvents, unless another solvent is specified. The external standard for the ^{195}Pt spectra was $[Pt(H_2O)_6]^{4+}$ (δ = 0 ppm). The IR spectra were measured on either a FTIR Bio-Rad 600 (resolution 1 cm^{-1}) or a P.E. 783. The decomposition points were measured on a Fisher–Johns instrument. The ligands were obtained from Aldrich and K_2PtCl_4 from Johnson Matthey and Co. The latter was recrystallized from water before use.

$(N(CH_3)_4)_2[PtCl_4]$ was prepared either by passing an aqueous solution of K_2PtCl_4 through a cation ($N(CH_3)_4^+$) exchange resin or by mixing directly an aqueous solution of K_2PtCl_4 with tetramethylammonium chloride. The yield is quantitative; mp 260–262°C (dec.); IR: ν(Pt–Cl): 318 and 303 cm^{-1}; ^1H NMR in D_2O, δ: 3.2 ppm.

$(N(CH_3)_4)[Pt(R\text{-}CN)Cl_3]$

The nitrile (1 mmol) was added to 5 mL of an aqueous solution containing 1 mmol of $(N(CH_3)_4)_2[PtCl_4]$. The solution was stirred until it became yellow (about 10 days). The mixture was filtered and the filtrate was evaporated to dryness. The residue was dissolved in a small quantity of acetone and the mixture was filtered to remove KCl and unreacted K_2PtCl_4. The filtrate was evaporated to dryness and dried under vacuum. $(N(CH_3)_4)[Pt(CH_3CN)Cl_3]$: Yield: quantitative; mp 150–158°C (dec.); IR (cm^{-1}): 2300 ν(C≡N), 2333 (δ(CH_3) + ν(C-C)), 345, 332, 310 (ν(Pt-Cl)); ^1H NMR, δ(ppm): 3.19 ($(CH_3)_4N^+$), 2.54s + d (CH_3), and $^4J(^{195}Pt–^1H)$ = 14.5 Hz. $(N(CH_3)_4)[Pt(C_2H_5CN)Cl_3]$: Yield: 40%; dec. mp 167-185°C (dec.); IR (cm^{-1}): 2295 ν(C≡N), 333, 323, 318 (ν(Pt-Cl)); ^1H NMR, δ(ppm): 3.19 ($(CH_3)_4N^+$), 1.41t(CH_3), 2.80q(CH_2), and $^4J(^{195}Pt–^1H)$ = 14 Hz. $(N(CH_3)_4)$ $[Pt(C_3H_7CN)Cl_3]$: Yield: 40%; mp 172–180°C (dec.); IR (cm^{-1}): 2290 ν(C≡N), 2342 (δ(CH_3) + ν(C-C)), 345, 333, 318 (ν(Pt-Cl)); ^1H NMR, δ(ppm): 3.20 ($(CH_3)_4N^+$), 1.03t(CH_3), 1.78m(CH_2), 2.97t(CH_2), and $^4J(^{195}Pt–^1H)$ = 15 Hz. $(N(CH_3)_4)[Pt(PhCN)Cl_3]$: Yield: 20%; mp 165–172°C (dec.); IR (cm^{-1}): 2285 ν(C≡N), 345, 339, 321 (ν(Pt-Cl)); ^1H NMR, δ(ppm): 3.19 ($(CH_3)_4N^+$), 7.75m (Ph).

$K[Pt(R\text{-}CN)Cl_3]$

The CH_3CN complex was prepared as already reported (8). The other complexes were synthesized in a similar way. The reaction time varied from 1 day to 1 week depending on the

ligand. The mixture was stirred on a cooling plate and evaporation was done below 30°C to avoid decomposition. $K[Pt(CH_3CN)Cl_3$: ^{13}C NMR, δ(ppm): 3.84, 117.39 (ligand: 1.72, 119.81). $K[Pt(C_2H_5CN)Cl_3$: IR (cm^{-1}): 2310 ν(C≡N) (ligand 2250), 342, 338, 333 ν(Pt-Cl). NMR, δ(ppm): ^1H, 1.27t, 2.90q (ligand: 1.22t, 2.44q); ^{13}C, 9.87, 12.99, 121.16 (ligand: 10.45, 11.10, 123.83). $K[Pt(C_3H_7CN)Cl_3$: IR (cm^{-1}): 2303 ν(C≡N) (ligand 2250), 328 (br) ν(Pt-Cl). NMR δ(ppm): ^1H, 1.02t, 1.72m, 2.90t (ligand: 1.01t, 1.66m, 2.44t); ^{13}C, 13.38, 19.05, 20.75, 120.21 (ligand: 13.38, 19.08, 19.27, 122.99). $K[Pt(C_4H_9CN)Cl_3$: IR (cm^{-1}): 2310 (ligand 2250) ν(C≡N), 345, 338, 325 ν(Pt-Cl). $K[Pt(CH_3)_2CHCN)Cl_3$: ^{13}C NMR, δ(ppm): 19.21, 22.11, 123.65 (ligand: 19.75, 20.29, 126.68). $K[Pt((CH_3)_3CCN)Cl_3$: IR (cm^{-1}): 2300 ν(C≡N) (ligand 2235), 343, 328, 310 ν(Pt-Cl). $Pt(R\text{-}CN)_2Cl_2$

These complexes can be prepared from the aqueous reaction of K_2PtCl_4 with an excess of the nitrile at room temperature as already reported for acetonitrile (1). $(N(CH_3)_4)_2[PtCl_4]$ can also be used as starting material and the yields are quantitative. $Pt(C_2H_5CN)_2Cl_2$: Yield: 85%; mp 155–163°C (dec.); IR (cm^{-1}): 2315 ν(C≡N), 351, 345 (ν(Pt-Cl)); ^1H NMR, δ(ppm): 1.42t (CH_3), 2.92q (CH_2), and $^4J(^{195}Pt\text{-}^1H)$ = 14 Hz. $Pt(C_3H_7CN)_2Cl_2$: Yield: 85%; mp 215–250°C (dec.); IR (cm^{-1}): 2304 ν(C≡N), 2343 δ(CH_3) + ν(C-C), 355, 348 (ν(Pt-Cl)); ^1H NMR, δ(ppm): 1.12t (CH_3), 2.95t (CH_2), 1.87m (CH_2), and $^4J(^{195}Pt\text{-}^1H)$ = 15 Hz. $Pt(C_4H_9CN)_2Cl_2$: Yield: 80%; IR (cm^{-1}): 2309 ν(C≡N), 359, 348 (ν(Pt-Cl)). $Pt(CH(CH_3)_2CN)_2Cl_2$: Yield: 80%; IR (cm^{-1}): 2303 ν(C≡N), 358, 352 (ν(Pt-Cl)). $Pt(C(CH_3)_3CN)_2Cl_2$: Yield: 80%; IR (cm^{-1}): 2301 ν(C≡N), 353(br) (ν(Pt-Cl)); ^1H NMR, δ(ppm): 1.43s. $Pt(PhCN)_2Cl_2$: Yield: 85%; mp 210–218°C (dec.); IR (cm^{-1}): 2290 ν(C≡N), 360, 345 (ν(Pt-Cl)); ^1H NMR, δ(ppm): 7.75m (Ph). $Pt(p\text{-}OH\text{-}C_6H_4\text{-}CN)_2Cl_2$: Yield: 75%; IR ($cm^{-1}$): 2290 ν(C≡N), 353, 340 (ν(Pt-Cl)). $Pt(p\text{-}CH_3O\text{-}C_6H_4\text{-}CN)_2Cl_2$: Yield: 75%; IR ($cm^{-1}$): 2280 ν(C≡N), 352 (br) (ν(Pt-Cl)); ^1H NMR, δ(ppm): 3.92s (CH_3), 7.65d, 7.06d.

The data collections (2θ/θ) were made at room temperature, either on a Syntex $P\bar{1}$ diffractometer (**1**, **5**) or a Siemens P4 (**2**, **3**, **4**), with graphite-monochromatized MoKα radiation (0.71069 Å). The cell parameters were calculated from the refined angles of 15–30 centered reflections. The experimental details of the crystallographic studies are shown in Table 1. The scan rate varied between 1° and 29° min^{-1}. An absorption correction based on the equations of the crystal faces was applied and the data were corrected for Lorenz and polarization effects. The calculations were done on a Siemens SHELXTL system, PC-plus version.

Results and discussion

$[Pt(R\text{-}CN)Cl_3]^-$ complexes

The complexes $K[Pt(R\text{-}CN)Cl_3]$ were synthesized from the aqueous reaction of K_2PtCl_4 with the nitrile in a mole to mole ratio of 1:1.5. In a 1:2 proportion, only the disubstituted compound is formed, while in a 1:1 ratio the reaction is slow and decomposition can occur. The monoacetonitrile compound is fairly stable and can be obtained overnight, but the complexes with other ligands are more slowly formed (1 day to 1 week) and are less stable. It is therefore important to cool the reaction medium during their synthesis. The crystals were too unstable in air for X-ray diffraction studies. Therefore the larger cation $N(CH_3)_4^+$ was used. The complexes were prepared from the aqueous reaction of $(N(CH_3)_4)_2[PtCl_4]$ with the nitrile (1:1 ratio) at room temperature. The reaction time was between 7 and 10 days. The compounds with butyronitrile and *p*-hydroxybenzonitrile were studied by X-ray diffraction.

The IR spectra of the $N(CH_3)_4^+$ complexes have shown that the ν(C≡N) vibration is observed at higher frequency in the coordinated ligand (Δ = 43–50 cm^{-1}), while Δ is slightly larger (55–65 cm^{-1}) for the K^+ compounds. This absorption at higher energy than in the free ligands is well known and has been discussed in detail for *cis*-$Pt(CH_3CN)_2Cl_2$ (11). The spectra showed three ν(Pt-Cl) ($2A_1$ and B_2) expected for a C_{2v} symmetry, between 345 and 310 cm^{-1}. The ^1H NMR spectra, measured on a low-field instrument, showed $^4J(^{195}Pt\text{-}^1H)$ coupling constants of 14–15 Hz.

The refined atomic parameters of the two complexes $N(CH_3)_4^+$ $[Pt(R\text{-}CN)Cl_3]$ where R = C_3H_7 and *p*-OH-C_6H_4, are listed in Table 2. Labelled diagrams of the molecules are shown in Figs. 1 and 2. As expected, the coordination around Pt(II) is square planar and the angles around Pt are close to 90 and 180°. The nitrile ligand is bonded through its lone pair of electrons on the N atom.

Some selected bond distances and angles are listed in Table 3. For each structure, the Pt—Cl bond in *trans* position to the nitrile ligand is shorter (2.276(3) Å for **1** and 2.264(7) Å for **2**) than the other two Pt—Cl bonds, which are normal (2.293(4), 2.287(3) Å for **1** and 2.320(7), 2.275(8) Å for **2**). Shorter Pt— Cl bonds located in *trans* position to CH_3CN (2.263(3)–2.277(5) Å) (11) and 2.266(2) Å (10)) have also been reported. The differences are not very large, but they are very consistent. The *trans* influence of nitriles seems therefore to be smaller than that of sulfoxides, halides, and amines. The short bond distances might also be due to the multiple nature of the Pt—N bonds located in *trans* position to the short Pt—Cl bonds. These results have shown that Pt—Cl bonds located in *trans* positions to nitrile ligands are definitely shorter than normal, and we suggest that the presence of multiple bonding in the *trans* bond is responsible for the bond shortening.

The Pt—N bonds are 1.97(1) Å for **1** and 1.92(2) Å for **2**. These values are similar to the reported values (10, 11), and are shorter than those observed for Pt–amine or Pt–pyridine bonds. The shortening might be ascribed to the presence of electron back-donation from the metal to the ligand. The segment Pt-N≡C-C is linear with angles Pt-N-C = 174(1)°, 171(2)° and N-C-C = 178(1)°, 176(3)° and

Fig. 1. Labelled diagram of $N(CH_3)_4[Pt(C_3H_7\text{-}CN)Cl_3]$ (**1**).

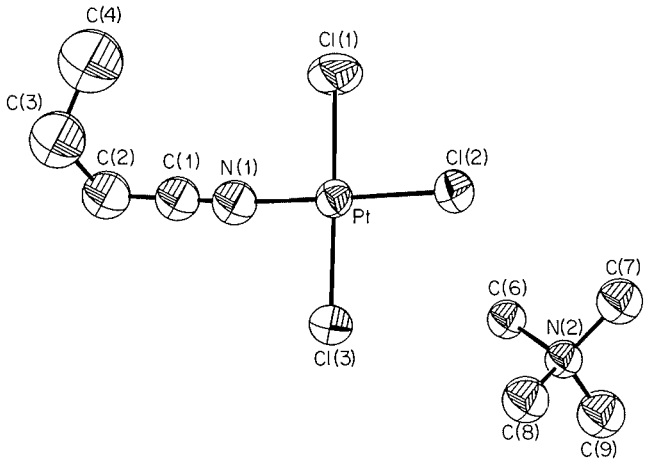

Fig. 2. Labelled diagram of the ion $[Pt(p\text{-}OH\text{-}C_6H_4\text{-}CN)Cl_3]^-$ (**2**).

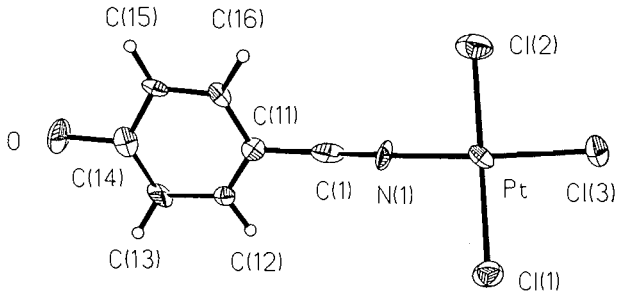

the N≡C bond distances are 1.13(2) and 1.13(4) Å for **1** and **2**, respectively.

The crystal $N(CH_3)_4[Pt(p\text{-}OH\text{-}C_6H_4\text{-}CN)Cl_3]$ is stabilized by intermolecular hydrogen bonding between the hydroxy group and Cl(3), located in *trans* position to the nitrile ligand. This hydrogen bond does not seem to affect the Pt—Cl(3) bond length. The distance O···Cl(3) is 3.271 Å. A packing diagram of the molecules has been prepared and is part of the supplementary material.[2]

[2] The following tables and figures have been deposited: anisotropic thermal factors (S1), H coordinates (S2), bond distances and angles (S3), weighted best planes (S4), and packing diagrams of crystal **2** (Fig. S1) and of crystal **5** (Fig. S2). This material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6. With the exception of Tables S1 and S4, the above have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

The ^{195}Pt NMR spectra of the complexes were measured in D_2O and the results are shown in Table 4. The signals were observed between −1997 and −2020 ppm. The chemical shifts seem almost independent of the R substituent on the ligand. Pregosin (17) had observed a downfield shift when the ligand became sterically larger. Due to the linear nature of the Pt-N≡C-C segment, the binding site in nitriles is far from the R substituent, resulting in almost constant chemical shifts. The signals are observed at higher fields than those reported for $[Pt(amine)Cl_3]^-$ (−1822 to −1865 in DMF, −1855 to −1875 ppm in acetone (18)) and for $[Pt(pyridine)Cl_3]^-$ complexes (−1763 to −1897 ppm in D_2O (19)). The shielding observed for the mononitrile complexes (compared to amine complexes) might be attributed to the special nature of the Pt–nitrile bond. Nitrile ligands might be good π-donors in addition to their σ-donor ability.

The ^{13}C NMR spectra of the complexes were also measured in D_2O. The positions of the cyano carbons are listed in Table 4, along with Δ (complex–ligand) in order to evaluate the influence of the R substituents. The two ligands *p*-CH_3O-C_6H_4-CN and *p*-HO-C_6H_4-CN are not soluble in water, therefore their spectra were measured in $CDCl_3$. For comparison, Ph-CN was also measured in $CDCl_3$. The chemical shifts of the cyano carbon atoms are shifted towards higher field upon coordination. Most of the other C atoms are deshielded when compared to those of the ligands. The substituent effects on the ^{13}C chemical shifts in free nitriles were studied and it was found that the cyano carbon resonance shifts to higher field

with increasing electronegativity of the substituent R (20). The correlation was explained in terms of the π-bond polarization, which is caused by the electric field of the substituent. The chemical shifts are linearly dependent on the π-electron density on the nucleus and a change on the cyano carbon atom is caused by the variation of the π-bond polarization (20). The complexation of the nitrile ligand to platinum will increase the polarization of the bond. It can be observed from Table 4 that, upon complexation, the cyano carbon atoms become more shielded as the number of methyl groups increase (Δ(complex–ligand) = −2.4 for R = CH_3 to −3.4 ppm for R = $C(CH_3)_3$). There are at least three factors that could affect the electron density on the complexed ligand: the π-bond polarization effect as discussed above, which should increase the electron density on the cyano carbons as the number of methyl groups in the substituent R increases, the σ-bond, which should reduce the electron density on the nitrile ligand; and finally the π-back-donation, which should increase the electronic density of the ligand. Therefore, it is not easy to interpret the results of such studies. When the alkyl groups on the nitriles are replaced by phenyl groups, the shielding on the cyano carbon is slightly reduced (Table 4). The formation of complexes with these derivatives is favored by the mesomeric effect on the ligand, which increases the polarization of the C≡N π-bond.

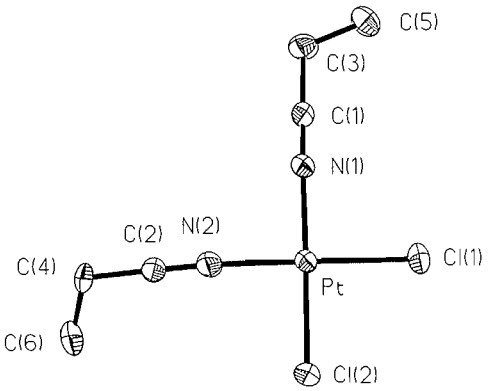
The $^2J(^{195}Pt\text{–}^{13}C)$ were difficult to measure for several reasons: the low intensity of quaternary cyano carbon atoms, the high field of the instrument (a 400 MHz was used, since on lower field instruments, the compounds decomposed after several hours of accumulation) that causes low intensities for the satellites' couplings, and finally the close environment of a ^{14}N atom with a spin $I > ½$ that increases the relaxation time of the cyano carbon atom. The ^2J couplings vary from 223 to 257 Hz, but the values are not very precise. The couplings are quite high because of the large *s* character of the cyano carbon atoms.

$Pt(R\text{-}CN)_2Cl_2$ complexes

Some of these complexes are known in the literature, but their ^{195}Pt NMR spectra and their crystal structures (except for *cis*-$Pt(CH_3CN)_2Cl_2$) have not been reported. When the reactions were done at room temperature, only *cis*-$Pt(RCN)_2Cl_2$ was formed (or >95%), since only one peak was observed in ^{195}Pt NMR spectroscopy. These results are different from those published by Fraccarollo et al. (7), who reported that most of their products at room temperature were *cis–trans* mixtures containing between 7 and 15% of *trans* compounds, except for trimethylacetonitrile, which produced 80% of *trans* isomers after 4 days. But their experimental procedures were different. They used a much larger excess of nitrile ligands. The mixture was treated with dichloromethane and the isomers were separated by crystallization in organic solvents such as hot benzene, *n*-hexane, ether, and petroleum ether. We believe that the *trans* isomers were probably formed when dichloromethane was added to the mixture to extract the complexes. The *cis–trans* isomerization of these complexes in chloroform is discussed below.

The ^{195}Pt signals for all the *cis* complexes (Table 5) were observed at very similar fields (−2276 to −2288 ppm) except for *cis*-$Pt(p\text{-}CH_3O\text{-}C_6H_4\text{-}CN)_2Cl_2$, which was observed at slightly lower field (−2239 ppm). These values are at a

Fig. 3. Labelled diagram of *cis*-$Pt(C_2H_5\text{-}CN)_2Cl_2$ (**3**).



slightly higher field than those reported for the *cis* complexes of several primary amines (≈−2230 ppm), and the corresponding complexes with secondary amines (≈−2180 ppm) (18). These observations are in agreement with the results observed by Pregosin (17), who reported a ^{195}Pt downfield shift when the ligand became more sterically demanding close to the binding site. Nitriles are never bulky around the binding atom, resulting in slightly more shielded ^{195}Pt signals. As already mentioned for mononitrile complexes, nitriles might be good π-donors in addition to their σ-donor ability. The IR spectra of these complexes showed two ν(Pt-Cl) bands (or a large band) around 345 and 355 cm^{-1} as expected for C_{2v} symmetry and as already reported (2, 3, 7, 11).

The crystal structures of the *cis* complexes with C_2H_5-CN (**3**) and *p*-HO-C_6H_4-CN (**5**) were determined. The refined atomic parameters of the complexes are listed in Table 2. Labelled diagrams of the molecules are shown in Figs. 3 and 4. Some selected bond distances and angles are listed in Table 3. The Pt—Cl bonds are again shorter than normal (2.269(5), 2.270(4) Å for **3** and 2.274(2), 2.279(3) Å for **5**) as observed for the Pt(II)–mononitrile complexes discussed above and as reported for *cis*-$Pt(CH_3CN)_2Cl_2$ (11), confirming the small *trans* influence of nitriles. Again, we believe that the presence of multiple bonding in the *trans* bond is responsible for these bond shortenings.

The Pt—N bonds are 1.962(14), 1.988(11) Å for **3** and 1.976(7), 1.972(7) Å for **5**. These values are similar to those observed for *cis*-$Pt(CH_3CN)_2Cl_2$ (11), and are shorter than those usually reported for Pt–amine or Pt–pyridine bonds. The shortening might be due to the presence of electron back-donation from the metal to the ligand or (and) to the presence of π-donation from the ligand. The segments Pt-N≡C-C are linear with angles Pt-N-C = 175(1)°, 176(1)°; 177.7(7)°, 175.9(7)° and N-C-C = 174(1)°, 178(1)°; 175.3(9)°, 177(1)° for **3** and **5**, respectively. The nitrile bonds are 1.09(2), 1.14(2) Å for **3** and 1.15(1), 1.16(1) Å for **5**. The crystal *cis*-Pt(*p*-OH-C_6H_4-$CN)_2Cl_2$ is stabilized by intermolecular hydrogen bonds between the hydroxy groups and the chloro ligands. The distances O(1) ··· Cl(1) and O(2) ··· Cl(2) are 3.417(6) and 3.161(8) Å and the angles C-O ··· Cl are reasonable, 101.5(6)° and 111.3(6)°, respectively.

When the *cis* isomers were heated for a few hours at about 50°C in $CHCl_3$, they partly isomerized to the *trans* compounds. The ^{195}Pt NMR spectra showed a new signal at lower field than that of the *cis* isomers (Δ = 65 Hz). The isomerization was not complete. For the complex $Pt(C_2H_5CN)_2Cl_2$, the proportion of each isomer was about 50%. The mixture was

chromatographed on a silica gel column using CH_2Cl_2–CH_3OH as eluant. The separation was almost complete. The first compound to be eluted was the *trans* isomer, which was shown by ^{195}Pt NMR to contain about 5% of the *cis* isomer. The IR spectrum of the purified *trans* compound showed a single sharp ν(Pt-Cl) band at 347 cm^{-1}. These results are similar to those reported on *cis*-$Pt(R\text{-}CN)_2Cl_2$ (R = CH_3 and Ph), which were found to isomerize in the solid state, to the *trans* isomers with partial decomposition. In solution, a mixture of *cis* and *trans* isomers were obtained (4, 16).

These observations suggest that, at room temperature, the first compound formed in these reactions is the *cis* isomer, which then isomerizes to the *trans* compound upon heating. The *trans* effect of nitriles seems therefore to be smaller than that of chlorides. This result might appear surprising because of the presence of multiple bonding in the nitrile ligands. But the nature of the Pt–nitrile bond is very different from that with ligands having a high *trans* effect. Ligands which have a high *trans* effect can form π-bonds with the metal either through a $(d–d)\pi$ bond like sulfoxides or phosphines, or through the multiple bond of the ligand as observed for alkenes or alkynes, where the multiple bond of the ligand is perpendicular to the platinum plane. With nitriles, the segment Pt-N≡C-C is linear and therefore the triple bond of the nitrile is in the Pt square plane.

In ^{13}C NMR spectroscopy, the cyano carbon atoms of the *cis* isomers are more shielded (0.6–1.5 ppm) than those of the *trans* compounds (Table 5). The ^{195}Pt NMR spectra have shown that the *trans* isomers are more shielded (≈65 ppm), as expected from the results of ^{13}C NMR spectroscopy. The back-donation of electron density from the metal to the ligand is less effective in the *trans* isomer than in the *cis* isomer, which has very effective $\pi(d–\pi^*)$ bonding. The $^2J(^{195}Pt–^{13}C)$ coupling constants for the *trans* isomers (286 Hz) are larger than those for the *cis* compounds (231 Hz), as was observed by Fraccarollo et al. (7).

The crystal structure of *trans*-$Pt(C_2H_5CN)_2Cl_2$ (**4**) was determined. This is the first crystal structure report on a *trans* compound. The labelled diagram of the molecule is shown in Fig. 5. The Pt atom lies on an inversion centre. The Pt—Cl distances are 2.289(3) Å, very similar to the distances observed for the bonds located in *cis* positions to the nitrile in $[Pt(R\text{-}CN)Cl_3]^-$, in agreement with the hypotheses described above regarding short Pt—Cl bonds located in *trans* positions to nitrile ligands. The Pt—N bonds are 1.969(5) Å, identical to the values obtained in the crystals described above. The N-C

bond is 1.124(7) Å, and the Pt-N-C(1) and N-C(1)-C(2) angles are 179.3(4)° and 178.1(5)°, respectively.

Some thermodynamic and transport properties of lithium salts in mixed aprotic solvents and the effect of water on such properties

Lorraine Couture, Jacques E. Desnoyers, and Gérald Perron

Abstract: In a continuing study on the optimization of the electrolyte medium for high-energy lithium batteries, volumes, heat capacities, and specific conductivities of $LiClO_4$ and LiBr were measured in mixtures of γ-butyrolactone (BUTY) and 1,2-dimethoxyethane (DME) and of propylene carbonate (PC) and BUTY. These results are compared with those of the electrolytes in the pure solvents. Phase diagrams are also reported when appropriate. The effect of addition of water to these binary and ternary systems was investigated with the same techniques. The mixtures DME–BUTY, PC–DME, DME–H_2O, and BUTY–H_2O are typical of mixtures of aprotic solvents and mixtures of aprotic solvents and water. The electrolytes at high concentrations in aprotic solvents of low dielectric constants are largely associated. The medium still conducts electrolytically since the ion pairs are in a state that resembles to a large extent that of a molten salt. With some systems at high concentration, stable solvates persist in the solution medium, as evidenced mostly by heat capacities, and are in equilibrium with either the excess solvent or unsolvated molten salts. In mixed solvents, the properties of electrolytes can largely be predicted from the binary systems and by the coexistence of these solvates. The properties of water in DME, BUTY, or mixtures of the two solvents are modified significantly in the presence of LiBr but only slightly with $LiClO_4$. These specific interactions, which affect the heat capacities much more than the volumes and which are especially large with the system LiBr–DME, could be responsible for the decrease in reactivity of water with lithium metal in an aprotic medium in the presence of certain electrolytes.

Key words: $LiClO_4$, LiBr, γ-butyrolactone, dimethoxyethane, propylene carbonate, lithium battery, aprotic solvent, water, association, solvates, solid–liquid phase diagrams, volumes, heat capacities, specific conductivities.

Résumé : Dans le cadre d'une étude sur l'optimisation du milieu électrolytique pour les piles au lithium à haute densité d'énergie, les volumes, capacités calorifiques et conductivités spécifiques du $LiClO_4$ et du LiBr ont été mesurés dans des mélanges de γ-butyrolactone (BUTY) et de 1,2-diméthoxyéthane (DME) et dans des mélanges de carbonate de propylene (PC) et de BUTY. Ces résultats ont été comparés aux propriétés équivalentes des électrolytes dans les solvants purs. Les diagrammes d'état sont aussi présentés pour plusieurs systèmes. L'effet d'addition d'eau à ces systèmes binaires et ternaires a aussi été étudié par les mêmes techniques. Les mélanges DME–BUTY, PC–DME, DME–H_2O et BUTY–H_2O sont typiques des mélanges de solvants aprotiques et de solvants aprotiques dans l'eau. Les électrolytes à forte concentration dans les solvants aprotiques de faible constante diélectrique sont fortement associés. Le milieu est quand même conducteur puisque les paires d'ions sont dans un état similaire à celui d'un sel fondu. Dans certains systèmes à forte concentration, des solvates stables existent en solution, tel que mis en évidence par les capacités calorifiques, et sont en équilibre avec soit un excès de solvant ou un excès de sel fondu non solvaté. Dans les solvants mixtes, les propriétés peuvent en grande partie être prédites par les systèmes binaires et par la coexistence de tels solvates. Les propriétés de l'eau dans le DME, le BUTY et le mélange des deux solvants sont modifiées de façon appréciable en présence de LiBr mais légèrement en présence de $LiClO_4$. Ces interactions spécifiques, qui affectent beaucoup plus les capacités calorifiques que les volumes, peuvent être responsables de la grande atténuation de la réactivité de l'eau au lithium en présence de LiBr.

Mots clés : $LiClO_4$, LiBr, γ-butyrolactone, diméthoxyéthane, carbonate de propylène, batterie au lithium, solvant aprotique, eau, association, solvates, diagrammes de phase solide–liquide, volumes, capacités calorifiques, conductivités spécifiques.

Introduction

Lithium batteries are often considered future leaders in the battery industry, mainly because of their high capacity for energy storage and low environmental impact. The relatively low solubility and conductivity of lithium salts in aprotic solvents and the reactivity of the solvents with lithium metal often limits the efficiency of such batteries. For these reasons, mixed aprotic solvents are often envisaged in optimization studies. For example, acetonitrile (AN) reacts slowly with lithium metal but mixtures of acetonitrile with propylene carbonate (PC) are quite stable (1). It is also interesting to note that the reactivity of the solvent with lithium is often altered significantly in the presence of an electrolyte (2). For example, while both SO_2 and AN react with lithium, the formation of a complex between LiBr and SO_2 decreases the reactivity with lithium (3, 4).

Water is often one of the main impurities of the electrolyte medium since the solvents and the lithium salts are hygroscopic. The reaction of water with lithium metal forms a hydroxide or oxide that passivates the anode and generates hydrogen gas. This makes the battery unsafe for commercial use. To reduce the manufacturing cost of lithium batteries, it is desirable to reduce the need for highly dried solvents. This can be achieved by controlling the reactivity of water with lithium rather than trying to eliminate it completely from the electrolyte system. There are various ways of controlling this reactivity. Any physical process that hinders the adsorption of water should decrease the extent of reaction with lithium. This can be achieved by the formation of a protective film on the surface of lithium or by complexing or reacting water with additives or hygroscopic components in the aprotic solvent medium.

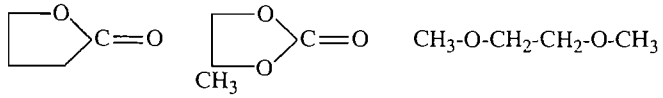
Most recent fundamental studies on the reactivity of water with lithium are concerned with the identification of the in situ film formed on the surface of the lithium metal exposed to various solutions and to the effect of water on the electrochemical rechargeability of the battery. Analytical techniques such as FTIR in external reflectance mode (5), XPS (6, 7), Raman spectroscopy (8), and electrochemical corrosion potential (9–11) have been used for this purpose. Indirect information on films can also be deduced from the investigation of chemical reactions involving lithium. In particular, Dey et al. (2) studied the reactivity of AN with lithium by differential scanning calorimetry and Holding and Fletcher (11) used the reaction of lithium with bromobenzene to study film formation on lithium foil. All these studies show that film formation is fast, even when experiments are performed in an argon dry box. A surface film will be formed with lithium in practically all batteries constructed with lithium foil and this will have some effect on the initial discharge curve or on the recycling.

The second approach in the control of the reactivity of water is to complex or react it with an additive in the solution. Investigations in our laboratory show that the presence of LiBr, and to a lesser extent $LiClO_4$, in γ-butyrolactone (BUTY) and 1,2-dimethoxyethane (DME) containing water significantly hinders the reactivity of the water with lithium metal. For example, the total time needed to completely consume a lithium pellet (0.014 mol) by reaction with 1 mol kg^{-1} of water is increased 150-fold in the presence of 1.5 mol kg^{-1} of LiBr in BUTY.

Relatively little is known about the properties of concentrated electrolytes in aprotic solvents. At very low concentration, the free ions are highly solvated and the concentration dependence will be governed by long-range Coulombic forces as predicted by the Debye–Hückel theory. As the concentration increases, association takes place and the ion pairs could also interact with the solvent. At still higher concentration, the properties of the electrolyte must approach those of a molten salt. The nature of the interactions becomes even more complex if mixed solvents or mixed electrolytes are used or if additives or contaminants such as water are present.

The present investigation is part of a continuing study on the characterization of the electrolyte medium for high-energy batteries through thermodynamic and transport properties. The volumes, heat capacities, and, to a lesser extent, compressibilities of electrolytes were measured in AN (12), PC (13, 14), and BUTY and DME (15). Transport properties were also measured with some systems (15). A simple association model has been proposed for the interpretation of the thermodynamic properties of electrolytes in acetonitrile (16) and work under way (17) shows that the Bjerrum association model can account quantitatively for the low concentration dependence of the partial molar volumes of electrolytes in aprotic solvents. It was also observed that stable solvates, which are identified in the solid–liquid phase diagrams, often persist in the solution above the melting point of the solvate and seem to affect the thermodynamic and transport properties of the solutions (18).

In this paper we report the properties of lithium salts in mixed aprotic solvents. The electrolytes chosen are $LiClO_4$ and LiBr and the mixed aprotic solvents are BUTY–DME and PC–DME. Only $LiClO_4$ was investigated in the mixture PC–DME. These solvents, which are used in commercial batteries, have many of the required characteristics for the electrolyte medium of lithium batteries (19) while having vastly different structures; BUTY and PC are cyclic molecules while DME is a linear one. DME is also an analog of polyethylene oxide, which is used in solid electrolyte lithium batteries (20).



BUTY PC DME

In a second set of experiments, the effect of the presence of water on the thermodynamic and transport properties was investigated. The purpose of these investigations was to evaluate the importance of the interactions between water and the electrolytes and to understand the impact of such interactions on the reactivity of water with the lithium electrode. In particular, it is hoped that such investigations will explain the effectiveness of electrolytes such as LiBr in reducing the reactivity of traces of water in aprotic solvents with lithium metal.

The properties investigated are solid–liquid phase diagrams, volumes, heat capacities, and specific conductivities. In the case of the ternary system DME–H_2O–LiBr, the liquid–liquid phase diagram was also determined.

Experimental

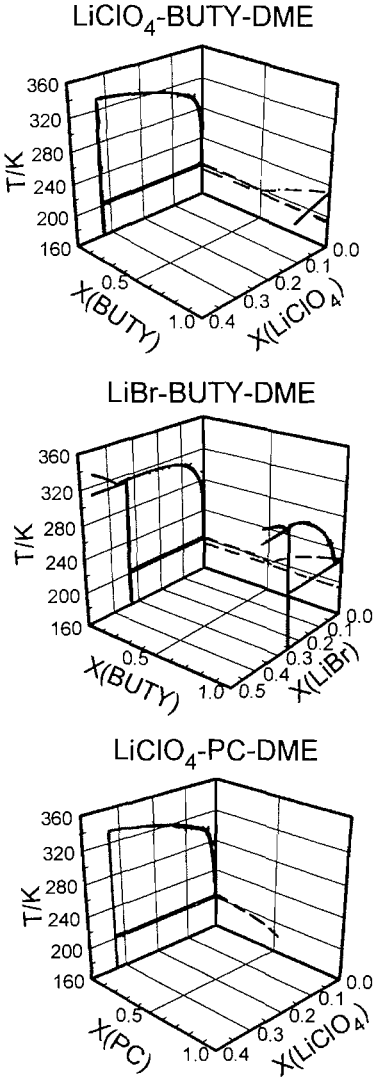
The techniques for the determination of the thermal analyses, densities (d), heat capacities per unit volume (σ), and specific conductivities (k_{SP}) were the same as in previous studies (14). The ternary phase diagram LiBr–H_2O–DME was determined with the cloud point technique. The specific heat capacities were calculated from σ and d by the relation

$$[1] \quad c_p/c_{p_0} = [1 + (\sigma - \sigma_0)/\sigma_0](d_0/d)$$

where the subscript (0) refers to the pure solvent (binary systems) or reference mixed solvent (ternary system).

The origin and purity of the chemicals are the following. $LiClO_4$: Omega Chemical Products, dried at 205°C under vacuum. LiBr: Aldrich, dried under vacuum at 200°C. DME: American Chemicals, anhydrous, distilled in glass. BUTY: Omega Chemical Products, dried over molecular sieves, redistilled under vacuum. PC: Aldrich, 99.7% anhydrous, used as such.

Fig. 1. Solid–liquid phase diagrams of the systems $LiClO_4$–BUTY–DME, $LiClO_4$–PC–DME, and LiBr–BUTY–DME. Data are taken from Perron et al. (14).



Results and discussion

The densities and heat capacities were used to calculate apparent molar quantities of components 1 or 2, $Y_{1,\varphi}$ and $Y_{2,\varphi}$, or excess thermodynamic quantities, V^{ex} or C^{ex}.

$$[2]\quad V_{2,\varphi} = (M_2/d) - 1000(d - d_0)/m_2 dd_0 = (M_2/d) - M_1(1 - X_2)(d - d_0)/X_{2d}dd_0$$

$$[3]\quad C_{p,2,\varphi} = (M_2c_p) + 1000(c_p - c_{p0})/m_2 = (M_2c_p) + M_1(1 - X_2)(c_p - c_{p0})/X_2$$

where M_1 and M_2 are the molecular mass of the solvent 1 and solute 2, respectively, m_2 is the molality (moles per kg of solvent or mixed solvent) of the solute, X_2 the mole fraction of the solute, and the subscript 0 refers to the reference system (pure solvent or mixed solvent).

$$[4]\quad Y^{ex} = Y - X_1Y_2^* - X_2Y_2^*$$

where Y is the overall property (volume or heat capacity) per total number of moles, the superscript (*) refers to the molar properties of the pure liquids, and X_i is the mole fraction of component i. The reduced excess properties are directly related to the apparent molar quantities (18),

$$[5]\quad Y^{ex}/X_1X_2 = (Y_{2,\varphi} - Y_2^*)/X_1 = (Y_{1,\varphi} - Y_1^*)/X_2$$

At infinite dilution (X_1 or $X_2 \rightarrow 0$), Y^{ex}/X_1X_2 will tend to $Y_2^\circ - Y_2^*$ and to $Y_1^\circ - Y_1^*$, where Y_2° and Y_1° are the standard infinite dilution partial molar quantities of the two components.

The original data on the mixtures of aprotic solvents and on the mixtures of aprotic solvents with water are given in Table 1. The parameters required to fit the reduced excess quantities of mixtures of aprotic solvents are given in Table 2. It is possible to measure $Y_2^\circ - Y_2^*$ more precisely than the absolute Y_2°, since it is not always easy to measure precisely Y_2° of the solvent. For example, with a flow instrument, a heat capacity cannot be measured to better than 0.5% and often the absolute error can be of the order of 1–2% (proper references, presence of impurities, etc). Also, as noted previously (15, 21), the calibration constants of some flow densimeters are slightly different for aqueous and nonaqueous systems. While this source of error hardly affects the reduced excess volumes of aqueous–organic mixtures, it affects systematically the absolute values of $V_{2,\varphi}$ by about 0.07 $cm^3\ mol^{-1}$ with the densimeter used. The Y_2° of the binary solvent systems are given in Table 3 along with the values of Y_2^* used for the calculations.

The original data for the ternary systems and for the phase diagrams are available as supplementary material[2] and only the trends will be shown graphically.

Since our aim is to compare the properties of the electrolytes in the solvents with those in the mixed solvents, we have chosen, when appropriate, to plot the data in three-dimensional graphs. Essentially, these graphs combine three two-dimensional graphs, e.g., the property of an electrolyte in solvent 1, in solvent 2, and in the mixed solvent at a fixed electrolyte concentration.

Solid–liquid phase diagrams

The solid–liquid phase diagrams for all the binary systems of the components DME, BUTY, PC, $LiClO_4$, and LiBr were taken from the literature or determined from thermal analysis and are shown in Fig. 1. The system DME–BUTY forms a simple eutectic and is close to being ideal since the phase diagram can be largely accounted for through the enthalpies of fusion assuming ideal solubilities. The mixture DME–PC forms a glass in the PC-rich zone and only a glass-transition temperature T_g is observed. No eutectic temperatures are observed. Still, in the DME-rich zone, the trends of the liquid–solid equilibria are those predicted from ideal solubilities. The phase diagram is possibly of the solid solution type. The solid–liquid phase diagram of $LiClO_4$–DME indicates that $LiClO_4$ forms a 1:2 complex with DME that melts at about 335 K. In BUTY, only the dilute region could be investigated since a T_g is present at higher concentrations. LiBr forms a 1:3 solvate in BUTY (mp 301 K) and a 1:2 solvate (mp 315 K) in

DME. $LiClO_4$ forms a glass in PC and the phase diagram could not be determined.

Specific conductivities, volumes and heat capacities of binary and ternary systems

The reduced excess volumes and heat capacities for the binary systems BUTY–DME and PC–DME are shown in Fig. 2. This representation is more informative than the usual method of plotting excess thermodynamic functions, and the near linearity of these reduced functions shows that the nonideality of these mixtures of aprotic solvents can be defined nearly entirely by two functions, $Y_2° - Y_2^*$ and $Y_1° - Y_1^*$. These trends are typical of mixtures of aprotic solvents. The interactions are stronger for PC and BUTY surrounded by DME (more positive excess partial molar heat capacity and more negative excess partial molar volume) than for DME surrounded by the other aprotic solvent. The difference in the solvation of the two solvents is larger for the system PC–DME than for BUTY–DME. These values are comparable to those of PC in aromatic liquids (22).

At very low concentrations, electrolytes in aprotic solvents must be completely dissociated and the limiting trends in thermodynamic properties should be those expected from the Debye–Hückel theory. Similarly, the transport properties should be those of typical electrolytes The properties should thus vary with the square root of the molality or molarity. However, they behave as strongly associated electrolytes in aprotic solvents of low dielectric constant in the concentration range presently studied, which represents the working electrolyte concentrations of lithium batteries. At these concentrations, the systems resemble mixtures of polar liquids more

than electrolyte solutions. We therefore felt that it would be preferable to express all concentrations in terms of mole fractions to compare the trends in the properties.

The specific conductivities (k_{sp}) at 25°C are shown in Fig. 3. When the electrolytes are sufficiently soluble in the aprotic solvents, k_{sp} of the binary systems generally goes through a maximum; with the two present solvents the maximum is at about 0.7 mol kg^{-1}. For the ternary systems, the concentrations of the electrolyte were kept constant at 0.1 and 0.7 mol kg^{-1} and the mole fraction of the mixed solvent was changed from 0 to 1. The trends are the same for both electrolyte concentrations but are more pronounced at the higher concentration. Therefore, only the trends of $LiClO_4$ and LiBr at 0.7 mol kg^{-1}, corresponding to approximately 0.06 mole fraction, are shown in Fig. 3. As for the binary systems, k_{sp} of the ternary systems also goes through a maximum, as observed by many authors (1, 23). With both solvent mixtures, there is a gain in conductivity when a mixed solvent is used. This gain is particularly important with the system $LiClO_4$–PC–DME.

The trends in $V_{2,\varphi}$ and $C_{p,2,\varphi}$ of the two electrolytes in the mixed solvents are compared with the binary systems in Figs. 4 and 5. The results for LiBr in DME are for supercooled solutions. It has been shown (15), however, that these trends are quite similar to those at 45°C. For the ternary systems, the

Fig. 3. Specific conductivities $LiClO_4$–BUTY–DME, $LiClO_4$–PC–DME and LiBr–BUTY–DME. Data for the binary systems are from Perron et al. (14) and for the ternary system $LiClO_4$ in PC–DME are from Gores and Barthel (23). The open circles are for the electrolytes in each solvent and the closed circles are for the electrolyte in the mixed solvent.

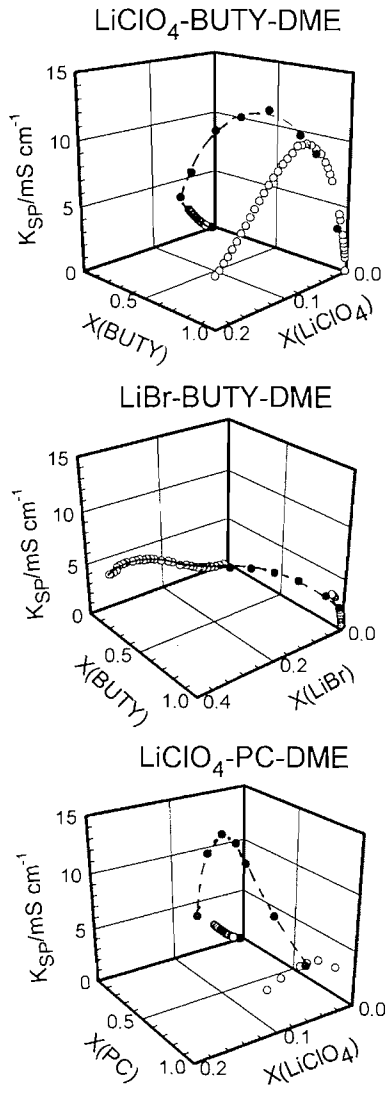

Fig. 4. Apparent molar volumes of the electrolytes in the systems $LiClO_4$–BUTY–DME, $LiClO_4$–PC–DME, and LiBr–BUTY–DME. Data for the binary systems are from Perron et al. (14). The open circles are for the electrolytes in each solvent and the closed circles are for the electrolyte in the mixed solvent.

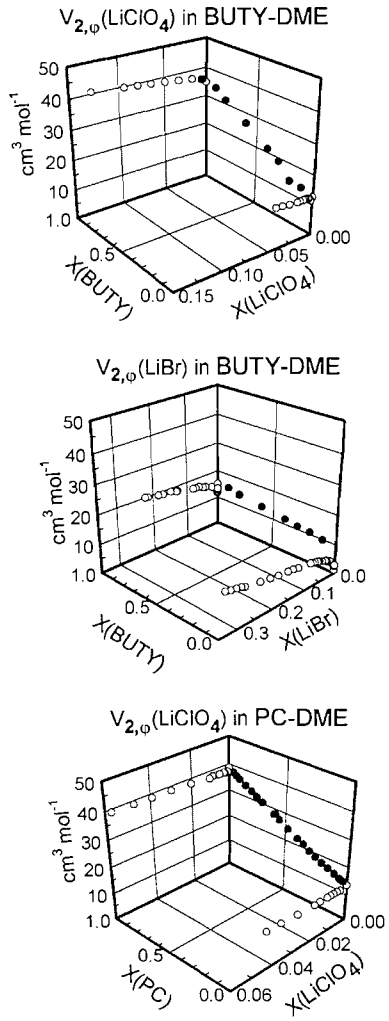

Fig. 5. Apparent molar heat capacities of the electrolytes in the systems $LiClO_4$–BUTY–DME, $LiClO_4$–PC–DME, and LiBr–BUTY–DME. Data for the binary systems are from Perron et al. (14). The open circles are for the electrolytes in each solvent and the closed circles are for the electrolyte in the mixed solvent.

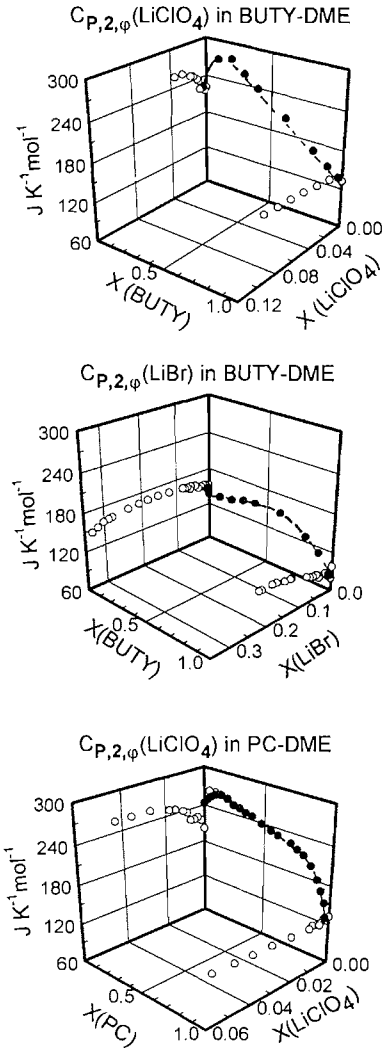

electrolyte concentrations were fixed at 0.1 mol kg^{-1}, which is less than 0.01 for the associated electrolyte on a mole fraction scale. It should be recognized that below 0.1 mol kg^{-1} the thermodynamic properties would undergo further changes due to the increasing presence of free ions. These trends at low concentration could be predicted if the association constant of the electrolyte and the variation of the dielectric constant with pressure and temperature are known (17).

The $V_{2,\varphi}$ of $LiClO_4$ in Fig. 4, in the concentration range investigated, are much larger in BUTY and PC than in DME and vary nearly linearly with the salt mole fraction in the binary systems and also vary linearly with the mole fraction of the mixed solvent. It is therefore expected that the $V_{2,\varphi}$ of $LiClO_4$ would also vary nearly linearly with the mole fraction of the mixed solvent at other salt concentrations. This of course would not be true if measurements could be made at very low concentrations where the electrolytes would be dissociated (15). $V_{2,\varphi}$ of LiBr varies nearly linearly in BUTY but decreases significantly at low concentration in DME. The trend in the mixed solvent BUTY–DME is also linear up to $X_{DME} = 0.9$ and then dips to a lower value as for the binary system.

As shown in Fig. 5, the $C_{p,2,\varphi}$ of the two electrolytes shows important nonlinear concentration dependences in DME. $LiClO_4$ varies nearly linearly with mole fraction in PC and shows only a small deviation from linearity at low concentration in BUTY. LiBr has a significant concentration dependence in BUTY and DME. $C_{p,2,\varphi}$ shows also a large deviation from linearity when the mole fraction of the mixed solvents is changed with all systems, expecially in the DME–rich region.

Electrolytes are largely associated at these concentrations. Association in these systems must be understood in the sense of Bjerrum; ion pairs are not necessarily in physical contact but are under the influence of strong Coulombic forces. This state resembles in many aspects that of a molten salt. For

example, it was shown (16) that when an associated electrolyte forms a nearly ideal solution with an aprotic solvent up to the molten salt (simple eutectic phase diagram), such as the system ethylammonium nitrate – acetonitrile, the thermodynamic properties of the associated electrolyte are approximately those of the molten salt. However, when stable complexes are formed in the solid state, as evidenced from the solid–liquid phase diagram, such solvates often persist in solution and the heat capacities of the associated electrolyte tend to those of the molten solvates (18). These heat capacities can be significantly different from those of the pure molten salt. Investigations under way in our laboratory on lithium bis-trifluoromethylsulfonylimide (LiTFSI) in DME definitely support the presence of stable solvates in solution.[3] In such cases, the association complex probably has a definite structure involving one or more solvent molecules. Therefore, at high mole fractions, the properties of such electrolytes are essentially those of solvated ion pairs in a molten salt.

The equivalent conductance Λ of unsolvated molten salts at 25°C, as in the case of ethylammonium nitrate (16), is quite low. However, in systems where stable solvates seem to exist in solution, Λ generally goes through a maximum at high concentrations. The conductance mechanism of such solutions is probably much closer to that of molten salts modified by the presence of a solvent than to the type of ionic conductance that is observed at very low concentrations. Unfortunately, thermodynamics and transport data do not give any insight into the structure of such species in solution. Still, the presence of solvated molten salts may offer an alternative avenue to triple ion formation (24, 25) to explain the high-concentration conductance. A model for such solvated ion pairs has been proposed by Blomgren (1).

It is important to note that the changes observed in heat capacities of electrolytes in aprotic solvents are often less evident with volumes. There are many examples of phenomena that are evident with heat capacities but not with volumes, e.g., post-micellar transitions and critical demixing. Being related to the second derivative of the chemical potential, properties such as heat capacities are more sensitive to second-order transitions than are volumes or enthalpies. This therefore suggests that the transitions that seem to be related to the formation of stable solvates in solution are probably second order in nature.

As shown in Fig. 1, LiBr forms stable solvates in both DME and BUTY while $LiClO_4$ can form such a complex only in DME. The solid–liquid phase diagrams of electrolytes in PC could not be measured. If the observed maxima in heat capacity can be attributed to the existence of similar complexes is solution, then the maximum in $C_{p,2,\varphi}$ for the electrolytes in BUTY–DME and two breaks for $LiClO_4$ in PC–DME (Fig. 5) could well be related to changes in the structure of such solvates. With volumes (Fig. 4), the changes in $V_{2,\varphi}$, when going from one solvent to another, are large and small changes in slopes are not evident.

There is a qualitative similarity between the trends in k_{sp} and $C_{p,2,\varphi}$ in mixed solvents. At 0.7 mol kg^{-1} in a low dielectric constant solvent like DME, the electrolytes are essentially fully associated. Yet, k_{sp} is larger in the mixed solvent than in pure PC, which has a high dielectic constant (Fig. 3).

Effect of the presence of water

In the preceding section, it was suggested that the trends in the properties of electrolytes at high concentration in aprotic and mixed aprotic solvents were related to the presence of stable solvates in an excess of solvent or molten salt. Since $LiClO_4$ also forms stable 3:1 and 1:1 hydrates with water (26) and LiBr forms many unstable hydrates and one stable 1:1 hydrate (27), our hypothesis was that the presence of these hydrates may account for the large decrease in reactivity of traces of water with lithium metal in the presence of some electrolytes. To investigate this possibility, the addition of water to the binary and ternary systems of $LiClO_4$ or LiBr in BUTY and DME was investigated.

The phase diagrams of the mixtures BUTY–H_2O and DME–H_2O are shown in Fig. 6. With both systems, a simple eutectic is formed, but the melting points of BUTY and DME nearly coincide with the eutectic concentrations. There is therefore no evidence from phase diagrams of strong interactions in concentrated solutions.

The reduced excess volumes and heat capacities of the mixtures H_2O–BUTY and DME–H_2O are shown in Fig. 7. The volumes of the mixture H_2O–BUTY are in excellent agreement with those (not shown) of Abdullah et al. (28) except in the water-rich region. These authors expressed their data in the traditional way of excess quantities and missed the small changes at low BUTY concentrations. In the mixed solvent, the water concentration was kept at 1 mol kg^{-1}. Therefore the values of $Y_{2,\varphi} - Y_2^*$ are approximately equivalent to Y^{ex}/X_1X_2 at infinite dilution of H_2O and are shown in Fig. 7.

The trends of the binary systems are typical of most aprotic solvents with water. In the water-rich region, where the structural effects of water are important, the volumes go through a minimum (large with DME and small with BUTY) and the heat capacities decrease sharply. This is typical of all hydrophobic solutes in water, which show no tendency to autoassociate. The minimum in volume simply reflects the complexity of the effect of hydrophobic hydration on volumetric properties. In the transfer of a hydrophobic solute from the pure liquid state to infinite dilution in water, there is an increase in the "ice-likeness" of water (positive contribution to the volume) but at the same time a decrease in volume due to the occupation of free space by the solute in the water structure. At low concentration, the solute–solute interactions primarily reflect the decrease in hydrophobic hydration (negative second virial coefficient). At higher concentration, more and more contact pairs are formed between two hydrophobic solutes and there is a reappearance of free space (positive contribution to volume). With heat capacities, interactions between two hydrophobic solutes primarily reflect the reduction in hydrophobic hydration (negative second virial coefficient) whether or not the solutes come in contact.

The changes are much more important with DME than with BUTY since DME is more hydrophobic than BUTY (DME has four extra H atoms). On the other hand, in the organic-rich region that is of interest here, the reduced excess functions have the same sign as in the water-rich region but their magnitudes are much smaller. The changes for volumes are nearly linear with mole fraction. There is a small decrease in the reduced excess heat capacities as the mole fraction of the aprotic solvent tends to 1. The interactions are stronger for DME in the water-rich region and they are also stronger in the organic-

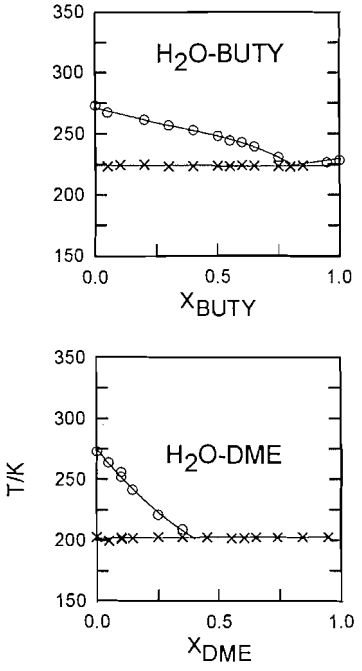

Fig. 7. Reduced excess volumes and heat capacities of H_2O in the systems H_2O–BUTY–DME at 25°C. The open circles are for the electrolytes in each solvent and the closed circles are for the electrolyte in the mixed solvent.

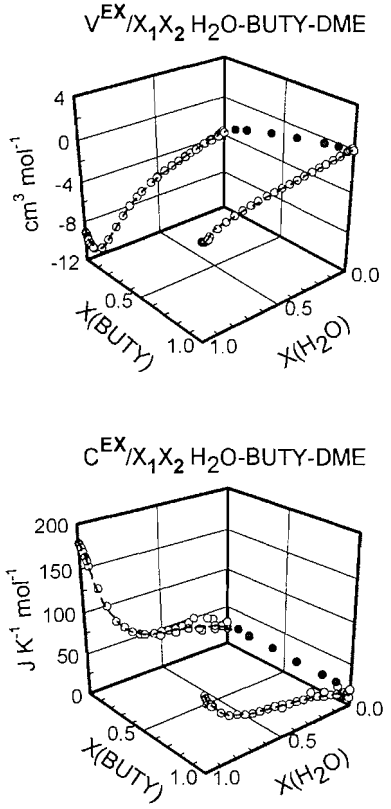

Fig. 8. Effect of the addition of LiBr and $LiClO_4$ on the apparent molar volume and heat capacity of H_2O in DME at 25°C.

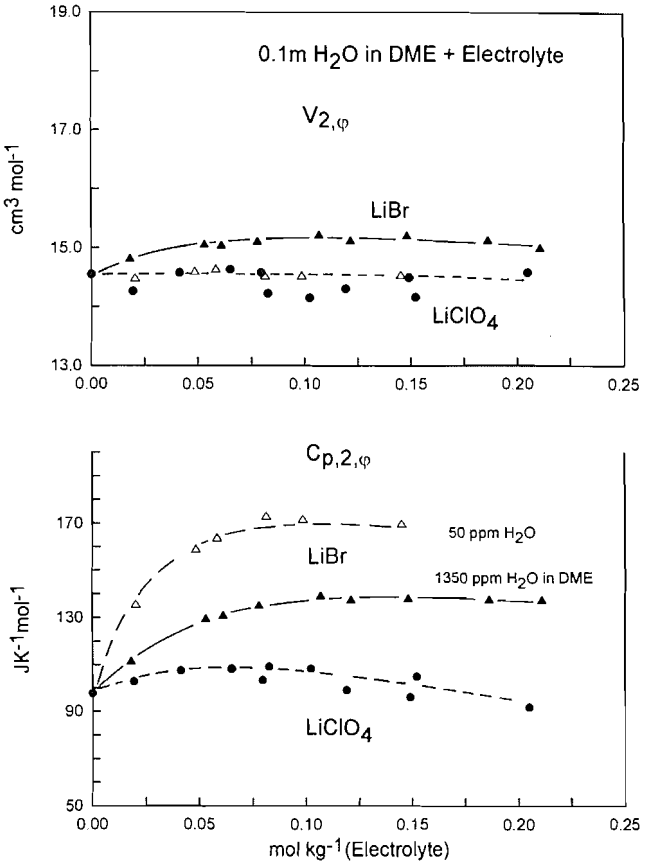


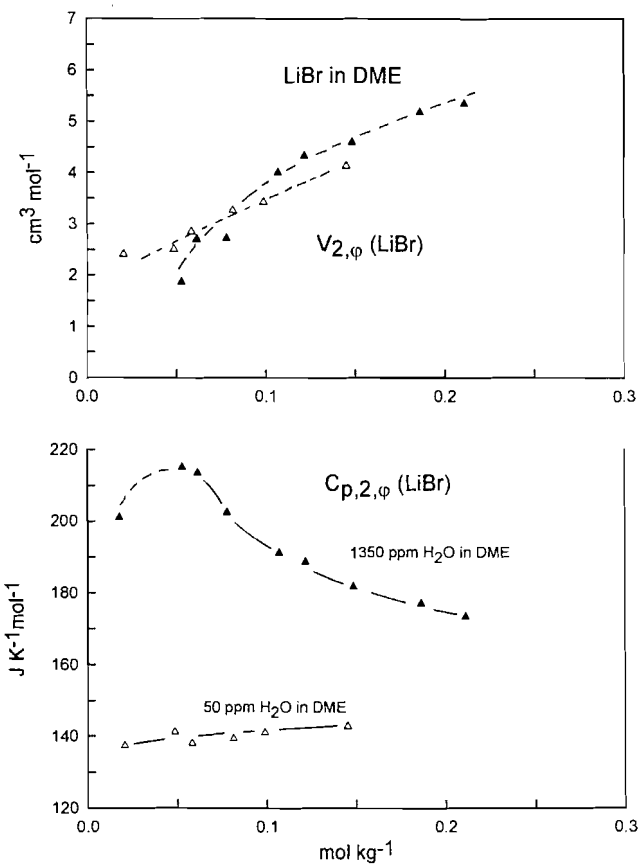
rich region. No anomalies are observed with the reduced excess volumes and heat capacities in the mixed solvent in the sense that they vary linearly from one solvent to the other.

Costas and Patterson (29) made a systematic study of the heat capacity of water in non-aqueous solvents and showed that the interactions in the organic-rich region of water–organic mixtures are related to the proton-acceptor nature of the solvent. The properties of water resemble to a large extent the properties of methanol in a proton acceptor. The high heat capacity is related to the formation of hydrogen-bonded complexes between water molecules and between water and the solvent molecules. The thermodynamic and spectroscopy studies of DeGrandpré et al. (30) confirm this.

The effect of addition of an electrolyte on the volume and heat capacity of water in DME is shown in Fig. 8. The concentration of water was kept at 0.1 mol kg^{-1} and the electrolyte concentration was varied up to about 0.2 mol kg^{-1}. In the presence of $LiClO_4$, both $V_{2,\varphi}$ and $C_{p,2,\varphi}$ of water are essentially constant in DME. In a previous study (12) it was observed that the effect of water was also negligible for $LiClO_4$ in AN.

It is difficult to eliminate water completely from DME. In the case of LiBr, experiments were therefore made with DME containing different initial quantities of water. The properties when H_2O is present increase with electrolyte concentration but seem to level off when the concentration of the electrolyte is equal to or larger than that of H_2O. Changes are more important with heat capacities than with volumes and the increase in properties is attenuated significantly when there is already

Fig. 9. Effect of H_2O on the apparent molar volume and heat capacity of LiBr in DME at 25°C.

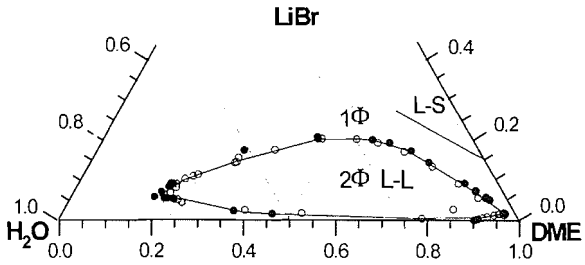


water in the solvent. It should be mentioned that work under way with LiTFSI[3] shows that this electrolyte *decreases* the heat capacity of water in DME. It is known that the NMR chemical shifts of Li^7 in aprotic solvents are largely affected by the presence of water and the effect is larger for LiBr than $LiClO_4$ (31, 32).

The strong interactions of LiBr with H_2O can also be illustrated from the effect of H_2O on the heat capacity of LiBr in DME. The above data were used to calculate $V_{2,\varphi}$ and $C_{p,2,\varphi}$ of LiBr in DME. The DME used for most of our studies contained less than 50 ppm of water while the addition of 0.0723 mol kg^{-1} of H_2O corresponds to the presence of 1300 ppm of water. New measurements were made with a sample containing less than 20 ppm. These data are compared in Fig. 9. While the presence of water does not have much effect on volumes, its effect on heat capacities is much more important; the heat capacities at low concentration can vary by a factor of 2 depending on the quantity of water present. Similar trends were observed for $C_{p,2,\varphi}$ of LiBr in acetonitrile containing small quantities of water (12) and seem to be present in all the aprotic solvents we studied.

The properties of LiBr in aprotic solvents are often anomalous when water is present. For example, dry LiBr is nearly insoluble in PC, while in the presence of a small quantity of water it is quite soluble. The reactivity towards lithium metal of traces of water in an aprotic solvent is largely decreased in the presence of LiBr. DME is completely miscible with water and LiBr is reasonably soluble in DME. However, the ternary

Fig. 10. Ternary phase diagram of the system LiBr–DME–H_2O at 25°C. The open circles are for the passage of the one-phase to the two-phase system and the filled circles are for the passage from the two-phase to the one-phase system.



system H_2O–DME–LiBr separates into two liquid phases in the low-salt region. This phase diagram, determined with the cloud point technique, is shown in Fig. 10. The solid–liquid equilibrium was determined in the DME region only. The two-phase liquid region increases significantly with temperature (not shown). The binary solutions H_2O–DME and anhydrous LiBr–DME are colourless. However, when a small quantity of LiBr is added to DME containing water ($m(H_2O) > m(LiBr)$), the solution becomes yellowish and a small precipitate is formed after a few hours. When the LiBr concentration is equal to or larger than that of H_2O, the solution remains clear. This phenomenon occurs in the right-hand corner of the ternary phase diagram (Fig. 10).

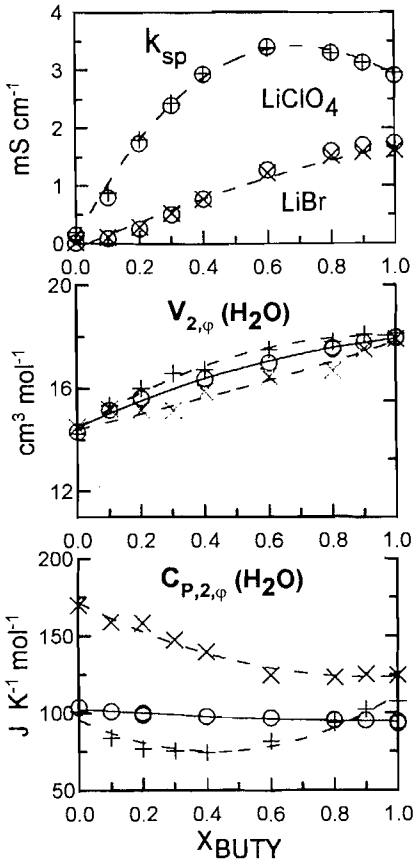
There are therefore specific interactions between LiBr and H_2O in aprotic solvents that have major effects on the properties of these solutions. These specific interactions cannot be related simply to the hydration of Li^+ or to the presence of a stable hydrated ion pair since they depend significantly on the nature of the anion and all these lithium salts form stable hydrates. A clue to the role of LiBr may come throngh a comparison with the system LiBr–SO_2–AN. There is spectroscopic evidence to show that a complex is formed between halide anions and SO_2 (3) and these interactions lower the apparent association constant of LiBr in AN (4). There is possibly a similar interaction between H_2O and Br^- in some aprotic solvents and this influences the properties of H_2O.

The effect of adding an equimolar quantity of $LiClO_4$ or LiBr on the specific conductivities, apparent molar volumes, and heat capacities of water in the mixed solvent is shown in Fig. 11. In these new experiments, the concentrations of both H_2O and of the electrolytes were kept at 0.1 mol kg^{-1}. The addition of equimolar quantities of water has no effect on the specific conductivity of 0.1 mol kg^{-1} of electrolyte. The specific conductivity does not seem to be affected by the presence of water, presumably because we are not looking at a property of water in this case. The influence of electrolytes on the volumes and heat capacities of water in mixed solvents is consistent with Fig. 8. The presence of an electrolyte has only a small effect on the volumes of H_2O but a larger one on heat capacities and the changes are much larger with LiBr than with $LiClO_4$.

Conclusions

Electrolytes in mixed aprotic solvents and water in aprotic electrolyte solutions are complex systems. Still, some general

Fig. 11. Effect of the addition of an electrolyte on the specific conductivity, apparent molar volume, and apparent molar heat capacity of H_2O in the mixed solvent BUTY–DME at 25°C. For conductivities, ○ is for the electrolyte systems (0.1 mol kg^{-1}) without water in the mixed solvent and + and × are for the same systems with 0.1 mol kg^{-1} of water; for volumes and heat capacities, ○ is for the properties of 0.1 mol kg^{-1} of H_2O in the mixed solvent, + and × are for the same properties in the presence of 0.1 mol kg^{-1} $LiClO_4$ and LiBr.



rules seem to apply to the interactions between the various components.

1. The phase diagrams and reduced excess thermodynamic properties of mixed aprotic solvents show no strong nonideality. There are no stable new species formed and the interactions change nearly linearly over the whole mole fraction range.

2. The phase diagrams of mixtures of water and aprotic solvents are also quite simple and the interactions of DME and BUTY with water are typical of those of other aprotic solvents. In the water-rich end, hydrophobic hydration predominates, while in the aprotic-rich end the interactions are typical of strong donor–acceptor molecules.

3. The ternary system DME–BUTY–H_2O is also quite simple in the organic end and can be predicted from the binary systems.

4. The electrolytes at high concentrations in aprotic solvents are largely associated in the Bjerrum sense and the heat capacity data suggest that these ion pairs exist as stable solvates in equilibrium with an excess of solvent or of unsolvated molten salt. In mixed solvents, the properties will be affected by the coexistence of these solvates.

5. The presence of water has only a small effect on the properties of $LiClO_4$ but a large effect on those of LiBr. In particular, the LiBr-DME–H_2O system demixes and, when H_2O is in excess of LiBr, the solution becomes yellowish. The strong interactions involving LiBr and H_2O in aprotic solvents are also evident in the quaternary system electrolyte–H_2O–DME–BUTY.

6. The specific conductivities, which generally go through a maximum when the electrolyte concentration increases and also when mixed solvents are used, are similar to those of molten salts at high concentration. The presence of traces of water, on the other hand, has little effect on this property.

7. The specific interactions between water and electrolytes in aprotic solvents are probably responsible for the large reduction in reactivity of water with lithium metal in aprotic solvents.

Peptaibol metabolites of *Tolypocladium geodes*

Youla S. Tsantrizos, Sotiria Pischos, Françoise Sauriol, and Paul Widden

Abstract: Three antibiotic peptides, LP237-F8 (**1**), F5 (**2**), and F7 (**3**), were isolated from the liquid culture of the fungus *Tolypocladium geodes*. Chemical shift assignments of the ^{1}H and ^{13}C NMR resonances and sequencing of these metabolites were achieved by extensive high-field 2D NMR spectroscopy. The N-terminal of peptides **1** and **2** is protected with an octanoyl (Oc) fatty acid unit, whereas that of peptide **3** is protected with a decanoyl (Dec) unit. The C-terminal of all three peptides is protected with the amino alcohol leucinol (Lol). All three metabolites contain the common amino acids Ala, Phe or Tyr, Pro, and Gln, as well as the unusual amino acid α-aminoisobutyric acid (Aib). In addition, peptides **1** and **2** contain the amino acid α-amino-α-ethyl-*n*-pentanoic acid (α-ethylnorvaline, EtNor), which has not been previously reported as a constituent of a natural product. Metabolites **1**, **2**, and **3** are new members of the class of natural products known as peptaibols.

Key words: *Tolypocladium geodes*, peptaibols, leucinol, α-amino-α-ethyl-*n*-pentanoic acid.

Résumé : On a isolé trois peptides antibiotiques, LP237-F8 (**1**), F5 (**2**) et F7 (**3**) à partir de milieux de culture liquides du champignon *Tolypocladium geodes*. On a attribué les déplacements chimiques des spectres RMN du ^{1}H et du ^{13}C ainsi que la séquence de ces métabolites en faisant un usage extensif de la spectroscopie RMN 2D à haut champ. Le groupe N-terminal des peptides **1** et **2** est protégé par une unité d'acide gras octanoyle (Oc) alors que celui du peptide **3** est protégé par une unité décanoyle (Dec.) Le groupe C-terminal de chacun de ces trois peptides est protégé par l'alcool aminé leucinol (Lol). Les trois métabolites contiennent les acides aminés usuels Ala, Phé ou Tyr, Pro et Gin ainsi que l'acide α-aminoisobutyrique (Aib), un acide aminé inhabituel. De plus, les peptides **1** et **2** contiennent l'acide aminé, α-amino-α-éthyl-*n*-pentanoïque (α-éthylnorvaline, EtNor), dont on n'a jamais rapporté la présence comme constituant d'un produit naturel. Les métabolites **1**, **2** et **3** sont de nouveaux membres de la classe des produits naturels connus comme des peptaïbols.

Most clés : *Tolypocladium geodes*, peptaïbols, leucinol, acide α-amino-α-éthyl-*n*-pentanoïque.

[Traduit par la rédaction]

Introduction

The *Tolypocladium geodes* isolate LP237 was originally found in soil samples collected at the Pennine mountains of England at an altitude of 600 meters.[2] Fungi of the *Tolypocladium* genus are commonly found in cold climates and include the well-known species *T. cylindrosporum* and *T. niveum*. *Tolypocladium geodes* is a much more rare organism and it is the species that is most sensitive to warm temperatures (2). In the past, the metabolites of several *Tolypocladium* fungi have been investigated (1, 3) and a number of biologically active peptides have been reported. These include the cyclosporins (for a review, see ref. 4), which are immunosuppressing cyclic undecapeptides of important pharmacological value, and two families of antibiotic peptides, the efrapeptins (5) and elvapeptins (6).

In the course of our screening program for novel fungal metabolites exhibiting potent antitumor activity, a mixture of cytotoxic peptides was isolated from the liquid cultures of *T. geodes* LP237. High levels of cytotoxicity were observed in assays using P388D1 murine leukemia cells (IC_{50} = ~0.5 μg/mL) and a number of human carcinoma cell lines (lung A549, ovarian OVCAR3, colon SW620, and breast MCF7, IC_{50} = 0.2–0.5 μg/mL). The structure of the main component in this mixture of peptides, antibiotic LP237-F8 (**1**), was recently reported (7). This paper describes the details on the isolation of several cytotoxic peptides from the liquid culture of *T. geodes* LP237 and the structure elucidation of two new metabolites, LP237-F5 (**2**) and F7 (**3**). The complete ^{1}H and ^{13}C chemical shift assignments were achieved by extensive high-field 1D and 2D NMR spectroscopy.

Metabolites **2** and **3** are structurally related to metabolite **1** (7). All three peptides (**1**, **2**, and **3**) have both the N- and C-terminals protected with a short fatty acid unit and the amino alcohol leucinol (Lol), respectively. They contain common amino acids such as Ala, Phe or Tyr, Pro, and Gln and the unusual amino acid α-aminoisobutyric acid (Aib), commonly found in peptaibols. Peptides **1** and **2** also contain the amino

LP237-F8 (1), R^1 = Et, R^2 = *n*Pr (EtNor), R^3 = H (Phe), *n* = 4 (Oc)

LP237-F5 (2), R^1 = Et, R^2 = *n*Pr (EtNor), R^3 = OH (Tyr), *n* = 4 (Oc)

LP237-F7 (3), R^1 = R^2 = Me (Aib), R^3 = H (Phe), *n* = 6 (Dec)

acid α-amino-α-ethyl-*n*-pentanoic acid (α-ethylnorvaline, EtNor), which has not been previously reported as a constituent of a natural product. Metabolites LP237-F5 (**1**), F7 (**2**), and F8 (**3**) are novel linear peptides belonging to the family of natural products known as peptaibols.

Results and discussion

Isolation and purification of peptides

Liquid culture medium of 2% malt extract was inoculated with actively growing mycelium plugs of *T. geodes* and was incubated at 20°C on a rotary shaker for a period of 7 days. A bioassay-guided purification scheme was developed for the isolation of the extracellular cytotoxic metabolites of *T. geodes* produced under these fermentation conditions. The presence of active metabolites in fractions collected from each purification step was identified using the SOS Chromotest, a bacterial colorimetric assay that is widely used as a reliable test for the detection of genotoxic compounds (DNA-damaging compounds) (reviewed in ref. 8).

The fermentation broth was initially absorbed onto a column of Diaion HP 20 resin, which was eluted with a linear solvent gradient from H_2O to MeOH and then to acetone. The cytotoxic metabolites eluted from the column with aqueous MeOH (75–100%) and were further partitioned by size exclusion chromatography (Sephadex LH-20). Reverse-phase flash column chromatography (9) led to the isolation of a strongly cytotoxic and genotoxic mixture of peptides, exhibiting an IC_{50} value in the range of 5–10 ng/mL with P388D1 murine leukemia cells and a positive SOS Chromotest.

Mass spectral analysis of the cytotoxic mixture of peptides, by MALDI and ESI MS, indicated the presence of many different compounds ranging in molecular weight from *m/z* 1300 to 2000. Separation of these metabolites by C18 reverse-phase semi-preparative HPLC, using a solvent mixture of MeOH:H_2O:MeCN (70:20:10 with 0.1% TFA in all solvents) allowed the isolation of five peptides. At a flow rate of 4 mL/min, metabolites LP237-F5 (**2**), F6, F7 (**3**), F8 (**1**), and F9 eluted from the HPLC column with retention times of 16.4, 17.2, 20.7, 23.6, and 26.0 min, respectively. Each component was further purified by HPLC in order to obtain the pure peptides as white amorphous solids. At the present time, the structural assignments of the three main components, metabolites **1**, **2**, and **3**, have been completed (Fig. 1) and those of peptides LP237-F6 and F9 are in progress.

Structure determination of metabolite LP237-F5 (2)

Both MALDI and FAB MS of metabolite **2** suggested a molecular formula of $C_{65}H_{108}N_{14}O_{16}$ (MALDI MS (2,5-dihydroxy benzoic acid + NaCl or NaLi matrix) *m/z*: 1365.1 $(MCH_3+Na)^+$ and 1347.8 $(M+Li)^+$, FAB MS (NBA+NaCl matrix) *m/z*: 1363.5 $(M+Na)^+$; calculated mass for $C_{65}H_{108}N_{14}O_{16}Na$ = 1363.8).

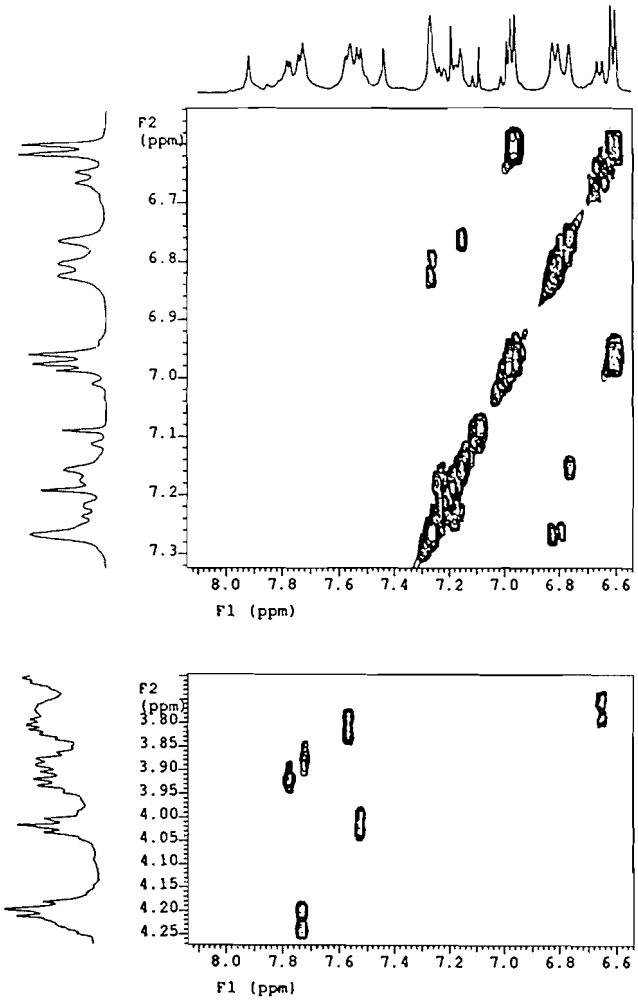
The NMR spectral data of metabolite LP237-F5 (**2**) were very similar to those of the previously assigned peptaibol LP237-F8 (**1**) (7). However, metabolite **2** could easily be methylated with diazomethane (MALDI MS (2,5-dihydroxy benzoic acid + LiCl matrix) *m/z*: 1362.5 $(M+Li)^+$) whereas metabolite **1** was resistant to methylation under the same reaction conditions. Based on the NMR data, the difference in reactivity towards CH_2N_2 observed between **1** and **2** was attributed to the presence of a Tyr unit in **2** as opposed to a Phe unit in **1.** Complete acid hydrolysis of peptide **2** and amino acid analysis comfirmed the presence of the amino acid Tyr, in addition to Ala, Pro, and Glx in a ratio of 1:1:1:3 (10).

The ^{1}H NMR spectrum (500 MHz in DMSO-d_6) of **2** showed the presence of 21 resonances in the downfield region (Table 1, Fig. 2). The two doublets at δ 6.60 and 6.96 (J = 8.3 Hz, 2 × 2H) and the singlet at δ 9.18 (OH) were assigned to the Tyr unit. All of the remaining downfield protons could be exchanged in CD_3OD and they were assigned to 16 NH protons. The COSY NMR of **2** showed coupling between the NH resonances at δ 6.76, 6.80, 6.82 and those at 7.16, 7.27, 7.27, respectively (Fig. 2). Thus, these signals were assigned to three ε-NH_2 groups of Gln. From the combined ^{1}H and COSY NMR data (Table 1, Fig. 2), the α-H and the backbone NH protons could easily be assigned for the Tyr (δ 4.22, 7.73), Ala (δ 4.01, 7.52), ^{6}Gln (δ 3.92, 7.78), ^{7}Gln (δ 3.89, 7.73), ^{3}Gln (δ 3.81, 7.57), and Lol (δ 3.76, 6.65) units.

The remaining chemical shifts of each amino acid were assigned based on the combined ^{1}H, COSY, HMQC, HMBC, and NOESY NMR data (Tables 1 and 2). For example, coupling between the NH (δ 6.65) of Lol, the α-H resonance (δ 3.76), and the two non-equivalent -CH_2OH protons (δ 3.23 and 3.14) was clearly observed in the COSY NMR spectrum of metabolite **2**. The chemical shifts of the corresponding carbons were assigned from the HMQC spectrum at δ 48.77 (α-C) and 64.38 (-CH_2OH).[3] Furthermore, coupling between the α-H resonance and the two β-H (δ ~ 1.30), as well as between the two δ-CH_3 groups (δ ~ 0.78), the β-H (δ ~1.30), and the γ-H (δ ~1.58), was also observed in the COSY spectrum of **2**. The ^{13}C chemical shifts of the β-CH_2 (δ 40.15) and the γ-CH (δ ~ 25.4) were obtained from the HMQC data, whereas the ^{13}C shifts for the two δ-CH_3 groups (δ 23.6 and 21.9) were obtained from the HMBC spectrum.[3]

The order of the amino acid sequence of peptide **2** was based primarily on the NOESY NMR data. Strong NOE effects were observed between the backbone amide protons and the α-protons of neighboring residues and also between amide protons and the side chains of the neighboring amino acids. The most relevant NOE data for the sequence assignment (peptide backbone) are given in Table 2.

Fig. 2. Partial expansion of the COSY NMR spectrum (NH and αH regions) of LP237-F5 (500 MHz, DMSO).



Structure determination of metabolite LP237-F7 (3)

FAB MS of metabolite **3** suggested a molecular formula of $C_{64}H_{106}N_{14}O_{15}$ ((NBA+NaCl matrix) *m/z*: 1333.8 $(M+Na)^+$; calculated mass for $C_{64}H_{106}N_{14}O_{15}Na$ = 1333.7859). Amino acid analysis of **3** indicated the presence of the same common amino acid units as in metabolite **1**, Phe, Ala, Pro, and Glx in a ratio of 1:1:1:3. Metabolite **3** was also resistant to methylation with diazomethane, suggesting the absence of free carboxyl or phenolic functionalities.

The ^{1}H NMR spectrum of LP237-F7 (**3**) was distinctly different from that of metabolite **1** in the upfield methyl region; a total of three methyl signals was observed at δ 0.7–0.9 in **3** as opposed to five in metabolite **1**. The two overlapping doublets observed (δ 0.887 and 0.893) were assigned to the two δCH_3 of Lol, and a triplet (δ 0.863) was assigned to the terminal methyl of the fatty acid unit. Thus, it was assumed that metabolite **3** did not contain the unusual amino acid EtNor, which was found in **1** and **2**. This assumption was further supported by the absence of the expected correlations in the COSY spectrum of **3** between the methyl region and the methylene region for the EtNor unit, as had been observed previously in the COSY spectum of metabolite **1**. Furthermore, a total of eight singlets due to methyls of Aib units (δ 2 × 1.409, 1.458, 1.470, 1.474, 1.535, 1.539, and 1.604) was observed in the ^{1}H spectrum of **3**. To account for (*a*) the similarities in the spectral data between **1** and **3**, (*b*) the difference in mass of 14 units, (*c*) the loss of the EtNor unit ($C_7H_{13}NO$, MW = 127), and (*d*) the addition of a fourth Aib unit (C_4H_7NO, MW = 85), it was proposed that peptide **3** contains a decanoyl (Dec) fatty acid instead of the Oc unit found in peptides **1** and **2**. The overlapping of many -CH_2- resonances in the ^{1}H NMR spectum of **3** did not permit exact chemical shift assignments for the Dec unit to be made; however, the presence of this unit was confirmed from the ^{13}C and HMQC NMR data of this metabolite. The remaining amino acid units of peptide **3** were identical to those of peptide **1**, and their chemical shift assignments (Table 3) were consistent with the NMR data; the combined NMR data from the ^{1}H, ^{13}C, COSY, HMQC, HMBC, TOCSY, ROESY, and NOESY spectra were used to confirm the proposed structural assignment (Fig. 1).

[3] Due to the very small amount of available material of metabolite **2** (~2 mg) a directly observed ^{13}C NMR spectrum was not obtained. However, the ^{1}H, COSY, HMQC, HMBC, and NOESY NMR data of **2** were similar to those of metabolite **1** and consistent with the proposed structure.

Table 1. ^{1}H (500 MHz) and ^{13}C (125 MHz) NMR data of **2** in DMSO-d_6.

Conclusion

Linear peptides containing a C-terminal amino alcohol, Lol (11), Phol (phenylalaninol) (12), or Trpol (tryptophanol) (13), and a high proportion of the unusual amino acid Aib (14) belong to the class of natural products known as peptaibols. The *Trichoderma* metabolites trichorzianine A (13), trichosporin B (12*b*,*c*,*d*), tricholongin BI and BII (11*a*), trichogin A IV (11*b*), trichodecenins-I and -II (11*d*), and the alamethicins (12*f*) are among the best known peptaibols. The zervamicins (15), emerimicins (12*a*, 15), and hypelcin A (11*c*,*e*) represent examples of peptaibols produced by a few other fungi. The N-terminal amino acid of peptaibols is usually protected by an acetyl group; however, in trichogin A IV (11*b*) and the trichodecenins-I and -II (11*d*) it is protected with an octanoyl and a *cis*-4-decenoyl group, respectively. In peptides **1**, **2**, and **3**, the N-terminal amino acid is also protected with an octanoyl or decanoyl fatty acid unit, whereas the C-terminal is protected with a Lol unit. In addition to the common amino acids, Ala, Phe or Tyr, Pro, and Gln, these peptides contain several Aib units. Metabolites **1** and **2** also contain the novel amino acid α-amino-α-ethyl-*n*-pentanoic acid (α-ethylnorvaline, EtNor); to our knowledge, this amino acid has not been previously reported as a component of a natural product. However, EtNor has been found in extraterrestrial sediments such as the Murchison meteorite (16). EtNor has also been synthesized and shown to act as a competitive inhibitor of methionine (17).

The novel peptides LP237-F8 (**1**), LP237-F5 (**2**), and LP237-F7 (**3**) are the first peptaibols to be isolated from the *Tolypocladium* genus. Peptaibols are known to exhibit many unique biological activities, including the formation of voltage-gated ion channels in lipid bilayer membranes (18, 11*b*), induction of catecholamine secretion from adrenal chromaffin cells (19), uncoupling of oxidative phosphorylation in mitochondria (20), and the inhibition of cell multiplication in amoebae (21). The cytotoxicity of metabolites **1** (IC_{50} = ~30 μg/mL), **2** (IC_{50} = ~10 μg/mL), and **3** (IC_{50} = ~40 μg/mL) towards P388D1 murine leukemia cells was much lower than the mixture of peptides. Therefore, it is reasonable to assume that the most potent component of the mixture remains to be identified or that there is a synergistic effect associated with the antitumor activity of the mixture. The biological activities of the *T. geodes* metabolites are currently under further investigation.

Experimental

Spectral data

NMR spectra were obtained at 20–22°C using a Varian Unity-500 spectrometer (operating at 499.84 MHz for ^{1}H and 125.7 MHz for ^{13}C) or a Bruker AMX-600 spectrometer (operating at 600.13 MHz for ^{1}H and 150.9 MHz for ^{13}C). ^{1}H and ^{13}C- NMR chemical shifts are quoted in ppm and are referenced to the internal deuterated solvent downfield from tetramethylsilane (TMS). NOESY experiments performed on the Varian Unity-500 spectrometer (hypercomplex phase mode) were obtained using a mixing time of 400 ms with Varian's standard pulse program and 256 increments in *t*1.

Table 3. ^{1}H (600 MHz) and ^{13}C (150 MHz) NMR data of **3** in DMSO-d_6.

	Assignment	^{13}C (δ)	^{1}H (δ)	intensity mult., J (Hz)

[a]Chemical shift assignment could be interchanged.

[b]Although all of the expected carbonyl resonances (a total of 14 signals) were clearly observed in the ^{13}C NMR spectrum of metabolite **3**, the exact chemical shift of each amino acid unit could not be assigned due to extensive overlapping of the correlation signals in the HMBC spectrum.

[c]Exact chemical shifts could not be determined due overlapping resonances in ^{1}H NMR spectrum.

[d]Chemical shift assignment was based on the HMQC NMR spectrum.

Zero-filling in the evolution domain and linear prediction to lengthen the evolution domain were used to obtain the final data size of the 2048 × 2048 complex matrix. The HMQC experiments with a preceding BIRD nulling period were used with hypercomplex phase mode, and ^{13}C broadband waltz decoupling was applied during acquisition of the proton spectra. The HMBC experiment was acquired using similar conditions (without the null period and ^{13}C decoupling) and the τ delay was set to 100 ms for long-range coupling. NOESY experiments performed on the Bruker AMX-600 spectrometer were obtained using a mixing time of 300 ms and Bruker's standard pulse program, 256 increments in $t1$, and a 2048 × 2048 complex matrix. The HMQC and HMBC NMR spectra were acquired using Bruker's standard pulse programs for these experiments.

Mass spectra were obtained using a ZAB-E4F instrument for FAB MS, a Finnigan SSQ 700 instrument for the ESI MS, and a Kratos Kompact MALDI 3 V 4.0 instrument for MALDI MS. Ultraviolet spectra were recorded on a Hewlett Packard 8452A diode array spectrophotometer. Optical rotations were measured using a JASCO DIP-140 Digital polarimeter.

Chromatography

Reverse-phase flash column chromatography was carried out on silica gel (Silica Gel 60, 70–230 mesh) reacted with *n*-octadecyltrichlorosilane. C_{18} reverse-phase silica gel was prepared following literature procedures (9). All chromatographic solvents were fractionally distilled prior to use with the exception of HPLC grade solvents. Doubly distilled H_2O was filtered through a 0.45 mm filter membrane and HPLC grade MeOH and MeCN were filtered through a 0.5 mm filter membrane (Millipore Corp., Mississauga, Ont.) before they were used in HPLC. Analysis and purification were carried out on a semi-preparative reverse-phase C_{18} column: Waters NOVA-PAK (25 mm × 100 mm, 6 μm, 60 Å) using a Waters instrument (pump model W600EP), UV/VIS detector wavelength set to 210 nm (model M486P), Rheodyne injector. All retention times were automatically recorded from the time of injection.

General extraction of active metabolites

Stock cultures of *T. geodes* were maintained on 2% malt extract (Difco) plus 1.5% agar in slant tubes at 4°C. A small amount of mycelium was used to inoculate 2% malt extract agar plates, which were then incubated in the dark, at room temperature, for a period of 14 days. Plugs (~15 plugs/flask) of actively growing mycelium were used to inoculate 2% malt extract liquid medium (6 × 500 mL culture in 3 L flasks). The fermentation flasks were then incubated at 20°C on a rotary shaker at 120 rpm for 7 days. The mycelium was removed by filtration, and the resulting filtrate was absorbed onto a Diaion HP 20 column (60 mm × 25 cm), which was eluted with a linear gradient from 100% H_2O to 100% MeOH to 100% acetone, at a flow rate of 10 mL/min. The cytotoxic fractions that eluted from ~75% aqueous MeOH to 100% MeOH, were combined and evaporated to dryness to give ~1.5 g of a brown gum. The active crude (IC_{50} = 0.5 μg/mL on P388D1 murine leukemia cells) was subsequently dissolved in 2–5 mL of MeOH, loaded on a Sephadex LH-20 column (25 mm × 100 cm), and partitioned into 90 fractions (~8 mL each) by eluting with degassed MeOH at a flow rate of 0.7 mL/min.. Fractions 22–30 exhibited strong cytotoxic activity (IC_{50} = 52 ng/mL) and gave a strong positive SOS Chromotest. These fractions were combined, evaporated to dryness (~230 mg), and further purified by flash column chromatography on a C_{18} reverse-phase column (20 mm × 15 cm), using a linear solvent gradient from 100% H_2O to 100% MeOH to 100% CH_2Cl_2 at a flow rate of 2 mL/min. The cytotoxic metabolites eluted in the fractions collected from ~85% aqueous MeOH to ~95% aqueous MeOH; some of these fractions exhibited IC_{50} values in the 3–5 ng/mL range. However, each fraction contained a very small

amount of material that was still a mixture of several components. Therefore, the active fractions were combined and evaporated to dryness to obtain ~40 mg of cytotoxic crude, which was further analyzed by semi-preparative C_{18} reverse-phase HPLC. HPLC purification of the above cytotoxic crude, using a solvent mixture of MeOH:H_2O:MeCN (70:20:10, with 0.1% TFA in all solvents), allowed the isolation of five biologically active peptides; two of these metabolites, LP237-F6 and F9, are currently under investigation. At a flow rate of 4 mL/min, metabolites **1**, **2**, and **3** had a retention time of 23.6, 16.4, and 20.7 min respectively. All three peptides were purified by HPLC for a second time, using the same conditions, in order to isolate the pure compounds as amorphous white solids (~3.8 mg of **1**, ~1.2 mg of **2**, and ~6.2 mg of **3**). *Metabolite 2*: UV (MeOH, nm): max 226, min 276. $[\alpha]_D$ +9.50 (*c* 0.0027, MeOH). NMR data given in Table 1. *Metabolite 3*: UV (MeOH, nm): max 226, min 258. $[\alpha]_D$ +0.21 (c 0.0102, MeOH). NMR data given in Table 2. MS data for both metabolites reported in the discussion.

Acknowledgments

This work was supported by grants from the Natural Sciences and Engineering Research Council of Canada and le Fonds pour la Formation de Chercheurs et l'Aide à la Recherche du Québec. We are grateful to Dr. Theresa M. Allen's research group (Department of Pharmacology, University of Alberta) for performing the cytotoxicity bioassays on the P388D1 murine leukemia cells and Dr. Brian Leyland-Jones' group (Oncology Department, Faculty of Medicine, McGill University) for the bioassays on human carcinoma cell lines. We wish to thank Mr. Bernard Gibbs, Biotechnology Research Institute, National Research Council Canada, for the amino acid analysis of peptides **1**, **2**, and **3**. We also thank Dr. Orvil A. Mamer of the Biomedical Mass Spectrometry Unit for recording the FAB MS spectra, Mr. George Tsaprailis (Department of Chemistry and Biochemistry, Concordia University) for recording the ESI MS spectra, and Mr. Gerry Barbiero (Chemistry Department, McGill University) for recording the MALDI MS spectra. We also wish to thank Dr. M.T. Phan Viet, Laboratoire Régional de RMN, Université de Montréal, for recording all of the 600 MHz (^{1}H) NMR spectra.

Conformational analysis and 2D NMR assignment strategies for lignin model compounds. The structure of acetoguaiacyl-dehydro-diisoeugenol methyl ether

Theodore M. Garver, Karen Joy Maa, and Kirk Marat

Abstract: The resolved ^{1}H and ^{13}C chemical shifts for the lignin model trimer acetoguaiacyl-dehydro-diisoeugenol methyl ether have been completely assigned using one- and two-dimensional NMR techniques. Identification of spin families and assignments within the spin families were made using routine one-dimensional experiments for chemical shifts and multiplicities, and COSY and heteronuclear correlation experiments to determine connectivities. NOESY, HOESY, and long-range heteronuclear correlation experiments were then used to determine the juxtaposition of the assigned groups and to provide a confirmation of assignments. Steady state NOE difference and time-dependent NOESY and HOESY experiments were then used to provide experimental measures of the trimer conformation. Semiempirical molecular orbital methods were used to calculate minimum energy structures and energy barriers for bond rotations within the molecule. We have found that for the trimer-size molecule the NOE experiments provide a less detailed picture of the molecular conformation than the molecular orbital results. A comparison of NOE and MO results with crystal structures from the literature indicates the extent to which side-chain and methoxyl torsion angles may be estimated using each method. The correlation between NOE and MO predictions for interatomic distances apparently is related to the narrow minima for β-O-4 torsion angles for which the different results confirm each other. Broad minima or low-energy barriers for torsion angle rotations may yield minimized structures by computational methods that are not experimentally justified.

Key words: semiempirical molecular orbital calculation, 2D NMR, conformation, lignin model, nuclear Overhauser effect.

Résumé : On a attribué tous les déplacements chimiques ^{1}H et ^{13}C du modèle de la lignine, le trimère acétoguaïacyl-déhydro-diisoeugénol-oxyde de méthyle, en faisant à des techniques de RMN mono- et bi-dimensionnelles. On a fait l'identification et les attributions des familles de spin en faisant appel à des expériences de routine en une dimension pour les déplacements chimiques et les multiplicités et des expériences COSY et de corrélation hétéronucléaires pour déterminer les connectivités. On a alors utilisé des expériences de corrélation NOESY, HOESY et de corrélation hétéronucléaire à longue distance pour déterminer la juxtaposition des groupes attribués et pour servir de confirmation aux attributions. On a alors utilisé des expériences de différences d'eOn à l'état stationnaire et de NOESY et d'HOESY en fonction du temps pour obtenir des mesures expérimentales de la conformation du trimère. On a utilisé des méthodes semiempiriques d'orbitales moléculaires pour calculer les structures d'énergie minimale et les barrières d'énergie aux rotations de liaison dans la molécule. On a trouvé que pour la molécule de la grosseur d'un trimère, les expériences d'eOn fournissent une représentation moins détaillée de la conformation de la molécule que les résultats d'orbitales moléculaires. Une comparaison des résultats des eOn et des calculs d'OM avec les structures cristallines obtenues à partir de la littérature indiquent que l'on peut évaluer les angles de torsion entre la chaîne latérale et le méthoxyle. La corrélation entre les prédictions faites sur la base des eOn et des calculs d'OM pour les distances interatomiques est apparemment reliée au fait que les minima pour les angles de torsion du β-O-4 pour lesquels les différents résultats se confirment mutuellement sont étroits. Des barrières aux rotations des angles de torsion qui seraient larges ou faibles peuvent conduire à des structures minimisées par des méthodes de calculs qui ne sont pas justifiées expérimentalement.

Mots clés : calculs semiempiriques d'orbitales moléculaires, RMN 2D, conformation, modèle pour la lignine, effet Overhauser nucléaire.

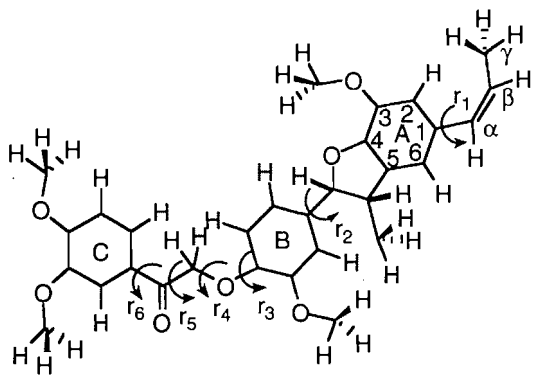
Fig. 1. Structure of acetoguaiacyl-dehydro-diisoeugenol methyl ether or **1** with labels for ring and side-chain carbons and rotations about side-chain torsion angles.



Introduction

Nuclear magnetic resonance analysis of the structure of lignin and lignin model compounds has focused on the identification of carbons and the side-chain protons (1). The assignment of aromatic protons and the further analysis of conformation normally have been excluded from the analysis. The application of 2D NMR to the study of macromolecular lignin has been limited (2–4) because lignin poses special problems related to short $T1$ and $T2$ relaxation times. Long correlation times found for the lignin macromolecule (5) lead to broad line widths (>10 Hz), which limit the resolution or detection of protons with small coupling constants. In NOE-type experiments, spin diffusion, resulting from long correlation times, will lead to a loss of the spatial dependence of the NOE peak intensity (6).

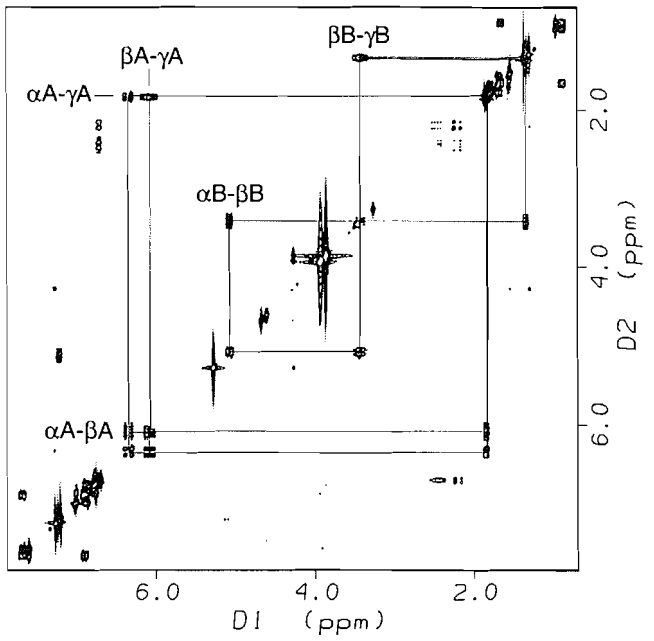
When all protons in a molecule have been assigned, NOE measurements between aromatic protons, side-chain protons, and methoxyl groups may assist in quantifying distances between protons and providing constraints for analyses of the three-dimensional structure. The difficulties in assigning aromatic proton resonances in lignin include the very small differences in chemical shift, the high spin multiplicities, and the relatively short relaxation times. Furthermore, the side chains, methoxyls, and aromatic groups constitute separated spin systems, which then must be linked together over three or four bonds and one or two quaternary carbons.

Acetoguaiacyl-dehydro-diisoeugenol methyl ether, or **1**, is a lignin model compound consisting of three guaiacyl-type units joined together by phenylcoumaran and β-O-4 type linkages as shown in Fig. 1. There is a vinylic side chain and a carbonyl group at the α carbon on the β-O-4 linked side chain. In addition there are three guaiacyl methoxyl groups at the aromatic 3 position. A fourth methoxyl exists as a methylated phenolic group. Overall, there are 19 different proton peaks and 30 different carbon peaks expected. Of these, seven protons and seven carbons are aliphatic, one carbon is carbonyl, four groups of 12 protons and four carbons are methoxyl, and eight protons and 18 carbons are aromatic.

Assignment strategies

The overall assignment scheme is to first identify different spin families or the directly coupled spins and then piece together the connectivities for the different spin groups. The

Fig. 2. COSY spectrum of **1** at 200 MHz with cross-peak connectivities drawn for two side-chain spin groups.



proton spin families may be identified using COSY (COrrelated SpectroscopY) spectra to group together aromatic protons and side-chain protons. The initial COSY spectra normally allow the assignment of the side-chain protons and will separate most of the aromatic protons into groups attached to the same rings. Single-bond carbon–proton connectivities are readily identified using standard single-quantum heteronuclear correlation type experiments. Heteronuclear correlation optimized for long-range couplings (7) provides an efficient method for connecting the side chains with the adjacent aromatic groups. NOESY (6, 8) HOESY (Heteronuclear Overhauser Enhancement SpectroscopY) (9, 10), HMQC (Heteronuclear correlation through Multiple Quantum Coherence) (8, 11), and HMBC (1H detected Multiple-Bond heteronuclear multiple-quantum Coherence) (8, 12) all provide complementary information, which may be used to knit the isolated spin groups into a coherent structure. Although some long-range couplings may be present in a COSY spectra, these normally may be used only for making preliminary assignments for aromatic side-chain connectivities. Methoxyl groups are assigned using a combination of HMBC, HOESY, and NOESY spectra, with confirmation of assignments with NOE difference spectra. Chemical shifts, spin multiplicities, and coupling patterns are required to make the assignments for the side-chain protons within the spin family. A comprehensive review of the carbon chemical shifts of lignin models by Kringstad and Mörck provides a reasonable starting point for assigning carbon chemical shifts (13, 14).

Identification of spin families

The three side-chain spin families can be readily identified from the COSY spectrum. These groups are illustrated by the lines connecting the protons within two side-chain spin families in the COSY spectrum as presented in Fig. 2. The third spin group is the singlet at 5.28 ppm. Integration and analysis

Table 1. Chemical shift assignments and coupling constants measured in $CDCl_3$ at 27°C on a 500 MHz (^1H) Bruker AMX spectrometer.

of the chemical shifts, multiplicities, and integrals readily lead to the assignments presented in Table 1. The coupling constants for α and β protons on the vinylic side chain are consistent with a *trans* configuration (15). The four methoxyl peaks at ~3.9 ppm are the only remaining unassigned proton resonances in the aliphatic region.

Resolution and assignment of aromatic ring protons

The eight aromatic protons present additional complications due to the difficulty of resolving multiplets from the overlapping peaks in the aromatic region. Furthermore, the observed position of the peaks changes with magnetic field strength because of the tight coupling between protons. The 500 MHz instrument used with resolution enhancement via a Lorentz to Gauss transformation significantly improves the resolution of these peaks (16). Peak integrals and a knowledge of the coupling patterns for substituted aromatic units (17) greatly assist in the identification of coupled aromatic protons (18). Protons on carbons 5 and 6 are normally AX doublets with about 8 Hz splitting. The proton on carbon 6 is normally split again with 2 Hz coupling to the *meta* proton at carbon 2; depending on chemical shift differences this coupling results in ABC, AMX, or ABX coupling. Examination of Fig. 3 clearly shows these coupling patterns in the distinct region between 7.5 and 8.0 ppm. The doublet at 7.59 and two doublets at 7.67 each belong to a single proton. The peaks between 6.75 and 6.95 ppm are much more difficult to resolve into the component peaks. As shown in Fig. 3*b*, this region consists of two groups with a total of five protons. Moreover, in this region the coupling constants (8.2–8.5 Hz) are sufficiently close to the differences in chemical shifts (0.9 ppm or 45 Hz at 500 MHz and 18 Hz at 200 ppm) that the AB character in the 200 MHz experiment becomes more an AX character in the 500 MHz experiment (19). Comparison of Figs. 3*a* and 3*b* shows how the field independence of the spin–spin coupling changes the observed chemical shift of these peaks. The single-quantum H/C correlation of this region, shown in Fig. 4, clearly resolves three doublets with couplings of about 8 Hz and two singlets. The H/C correlation also facilitated the assignment of the carbons adjacent to protons. These are reported with coupling constants in Table 1.

Protons were assigned to individual rings using a variety of long-range and nuclear Overhauser enhancement experiments. Consider the protons with chemical shifts centered at

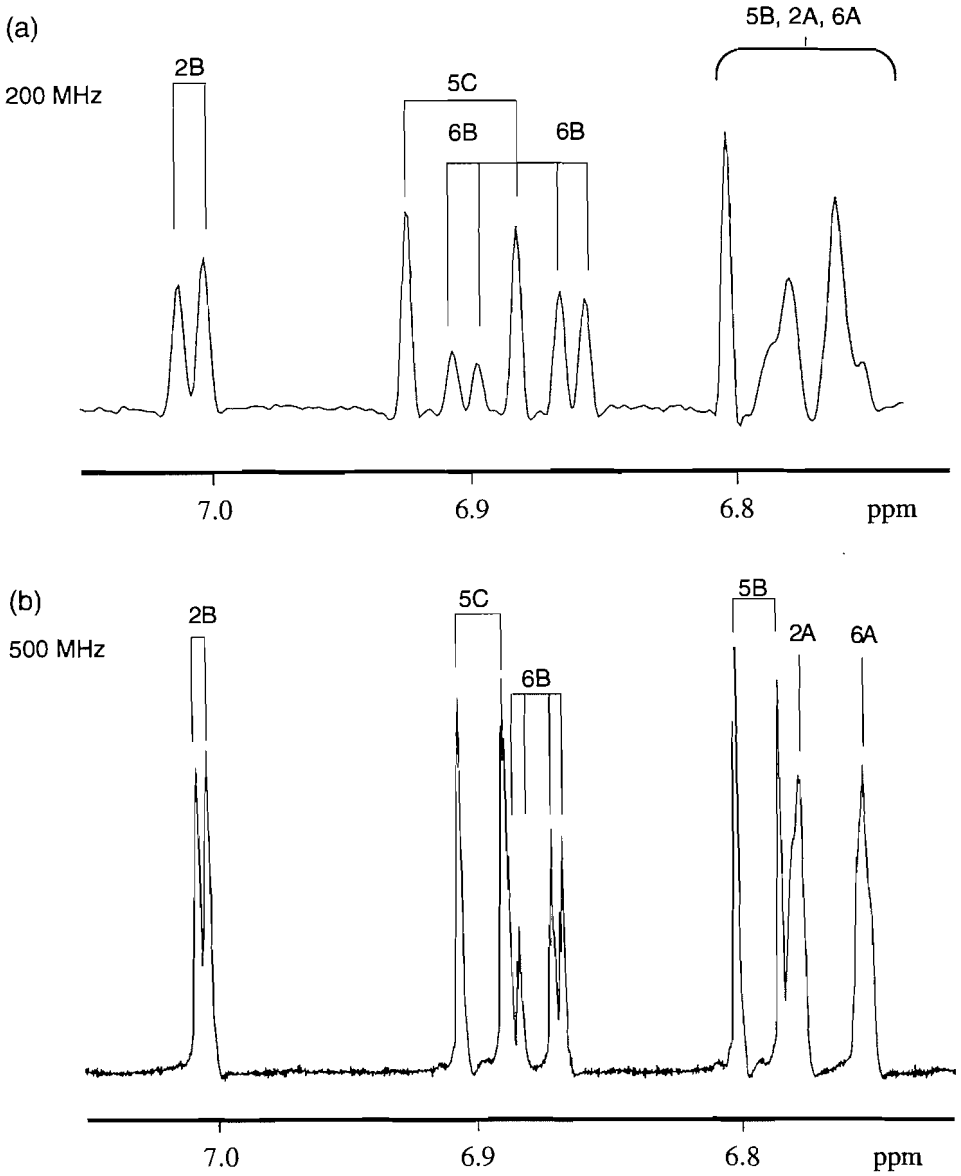
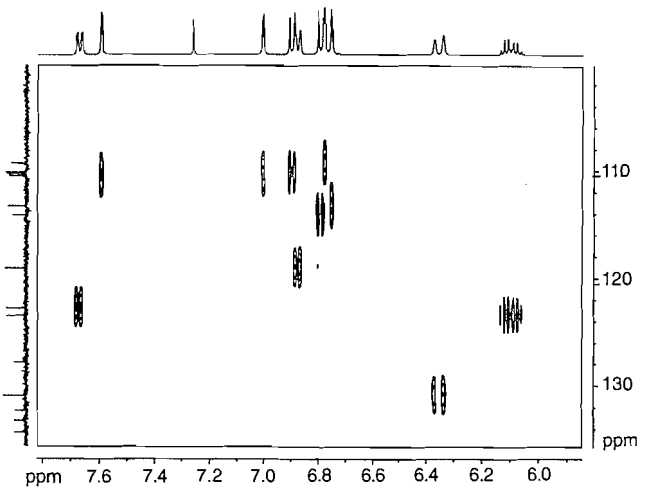
Fig. 3. Proton NMR of the crowded portion of the aromatic region between 6.75 and 7.05 ppm at 200 MHz (*a*) and 500 MHz (*b*). In this area coupling, which may be described as AB in the 200 MHz spectrum, has more AX character in the 500 MHz spectra. Furthermore, the separation and relative positions of the peaks have changed.



7.67, 7.59, and 6.90 ppm that have been identified as a group using COSY spectra and coupling constants. Long-range heteronuclear correlation data (Table 2) established connections from the α carbonyl carbon (193.1 ppm) to the protons at 7.67 and 7.59 ppm. NOESY spectra (Table 3) and NOE difference spectra (Table 3) have peaks between the side-chain proton $H_{\beta C}$ (5.28 ppm) and the protons 7.67 and 7.59 ppm. The carbonyl carbon is adjacent to ring C, therefore 7.67, 7.59, and 6.90 ppm are most likely on ring C. The positions of the ring protons were then deduced from coupling constants and con-

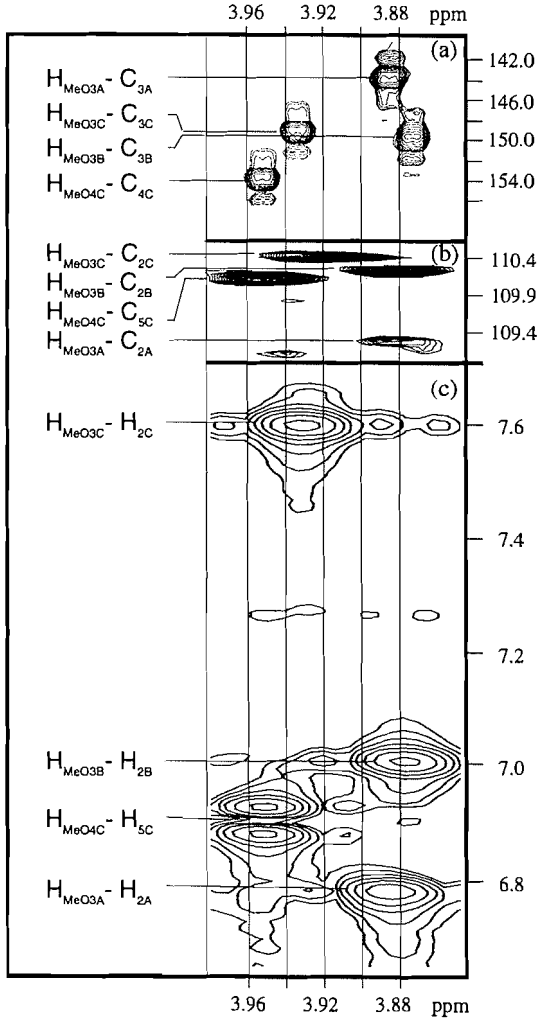
Fig. 4. Heteronuclear CH correlation (HMQC) experiment of the aromatic and vinylic regions of **1** at 500 MHz.



firmed by long-range experiments. In the ring C proton group there was ~8Hz coupling between the *ortho* protons at 7.67 and 6.90 ppm, ~2 Hz coupling between *meta* protons at 7.67 and 7.59 ppm, and the absence of coupling between *para* protons at 7.59 and 6.90 ppm. Hence the proton assignments for the ring protons are 7.67 for H_{6C}, 7.59 for H_{2C}, and 6.90 for H_{5C}. The long-range heteronuclear correlation between the carbonyl carbon at 193.1 ppm and the protons at 7.67 and 7.59 confirms that these are the protons on carbons 6 and 2. A similar analysis was used to establish the assignments given in Table 1 for the protons in the other rings. Carbon-13 chemical shifts were determined using 2D heteronuclear experiments (HOESY and HMBC) and articles by Kringstad and Mörck (13, 14).

Similarities in chemical shifts for the protons at certain ring positions were evident when our results were compared to other model compounds with similar side-chain structures and ring substitution (20–22). The protons at the 2 and 6 positions in rings with an adjacent carbonyl group were normally always shifted downfield to the region between 7.5 and 7.85 ppm. Given that all other aromatic protons are normally upfield from 7.05 ppm, the region between 7.5 and 7.85 may be used to obtain an estimate of the quantity of α carbonyl groups. This may potentially be applied to the analysis of the spectra of lignin derivative or lignin model compounds. The consistency of the reported chemical shifts in the literature also suggests that there is no significant change in the chemical shifts between monomer- and trimer-size lignin models.

Fig. 5. Spectra showing spin exchange with the methoxyl protons. Long-range heteronuclear correlation (HMBC) at 500 MHz (a) shows the spin–spin coupling to the methoxyl-substituted ring carbons. The heteronuclear NOE experiment (HOESY) for the same region (b) shows the incoherent spin exchange between the methoxyl protons and the carbons adjacent to the methoxyl-substituted carbon. NOESY spectra of the aromatic region (c) indicate spin exchange between the methoxyl protons and the protons attached to the carbons adjacent to the methoxyl-substituted ring carbon; these same peaks were also observed on COSY spectra.



Assignment of methoxyl protons

Peaks on the proton spectrum corresponding to the methoxyl protons consisted of four peaks of equal height in a chemical shift range of 0.08 ppm. Both NOE and long-range spin–spin couplings were used to assign these difficult methoxyl protons. Cross peaks between the methoxyl protons and the methoxyl-substituted ring carbon as shown in Fig. 5*a* were observed in the long-range heteronuclear correlation experiment. Nuclear Overhauser effects observed using HOESY and NOESY spectra established dipolar spin exchange between the methoxyl protons and the proton and carbon adjacent to the methoxyl-substituted ring carbon (Fig. 5 and Table 2). The HOESY cross peaks for the methoxyl region shown in Fig. 5*b* indicate that the methoxyl protons are spatially closer to the carbons at position 2 than they are to any other ring carbon. NOESY spectra between C2 protons and methoxyl protons shown in Fig. 5*c* also confirm this spatial proximity. The proton NOE difference spectra also show cross relaxation between the methoxyl protons and the proton at C2.

NOE and molecular orbital analysis of conformation

We have compared semiempirical molecular orbital analysis with NOE analysis of the conformation of **1**. This molecule provides a reasonable model to study the limitations of these

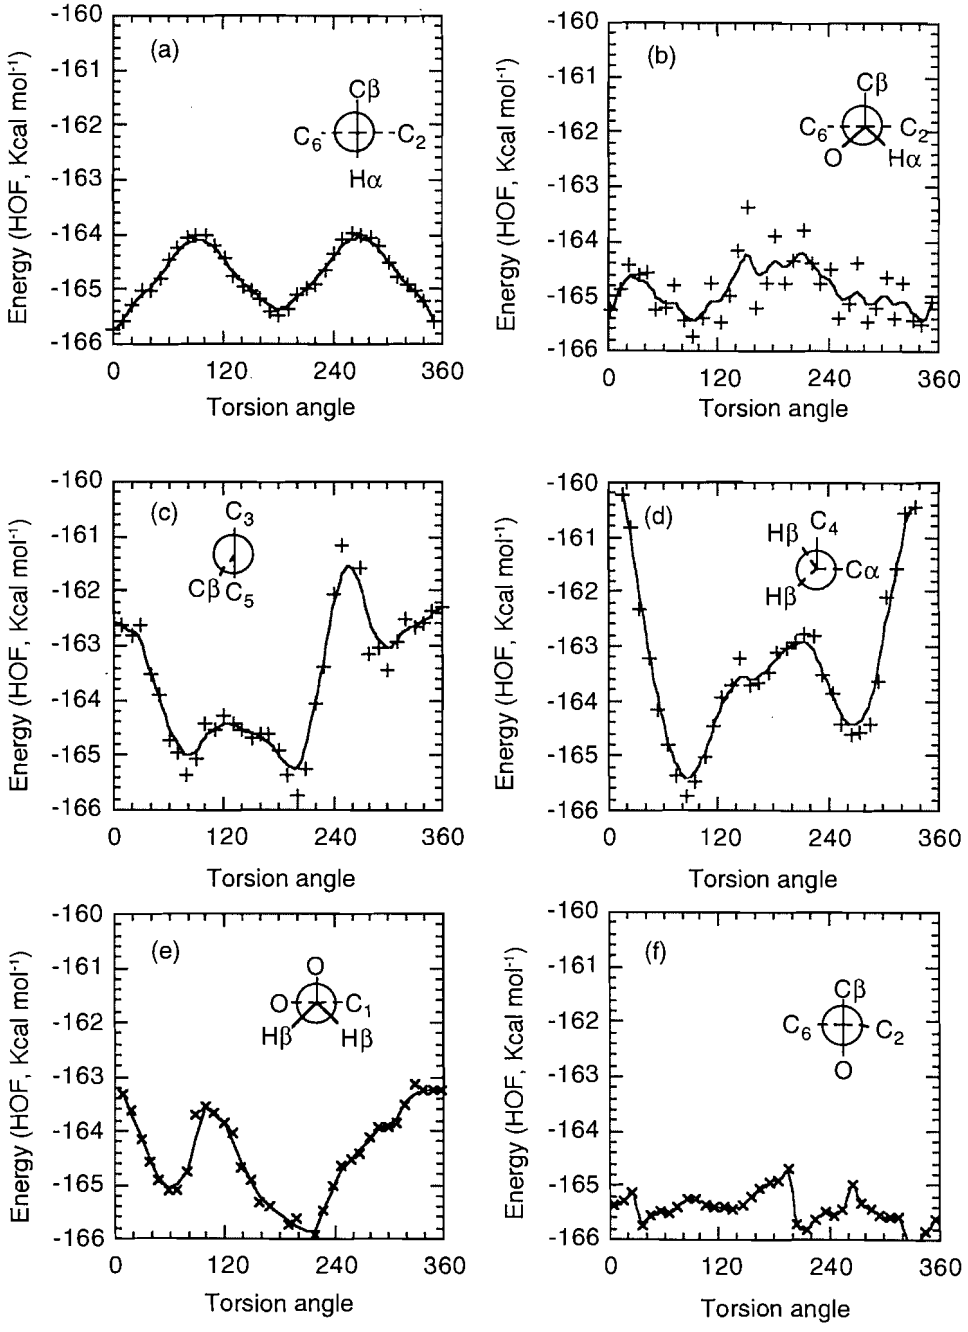
methods of conformational analysis for lignin oligomers. Among the significant conformational variables that have been addressed are the side-chain dihedral bond rotation and the methoxyl bond dihedral rotation. Different conformational energies for model compound **1** have been calculated by rotation of the side-chain dihedral angles r_1–r_6 as shown in Fig. 1.

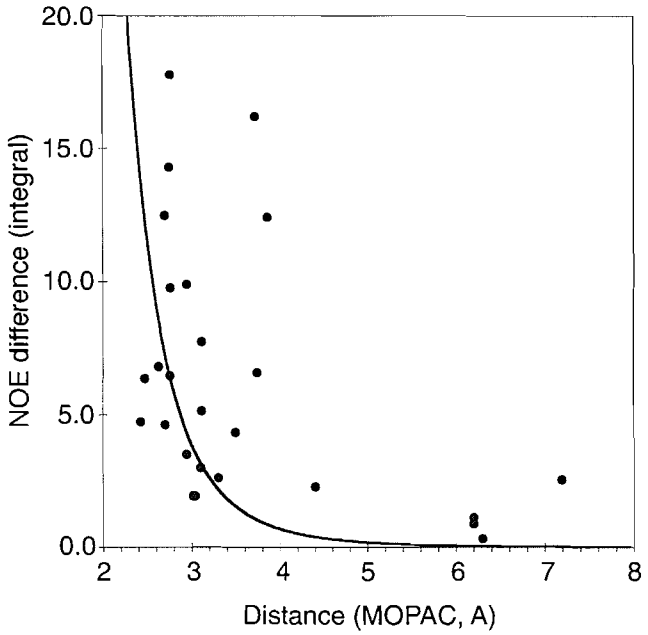
Fig. 6. Heat of formation energies calculated using MNDO-PM3 semiempirical methods for torsion-angle bond rotations shown in Fig. 1 (r_1–r_6). Fisher projections shown on each graph correspond to minima or maxima for the conformational energies. For rotation 1, defined by $C_{\beta A}$-$C_{\alpha A}$-O_{1A}-C_{2A} (*a*), the projection at the local maximum at 90° is shown. The minimum at 90° for the rotation of $C_{\beta B}$-$C_{\alpha B}$-O_{1B}-C_{2A} (r_2) is shown in (*b*). Global minima at 200° and at 90° are shown for C_{3B}-C_{4C}-$O_{\beta C}$-$C_{\beta C}$ (*c*) and C_{4C}-$O_{\beta C}$-$C_{\beta C}$-$C_{\alpha C}$ (*d*). Local maxima at 90° are shown for $O_{\beta C}$-$C_{\beta C}$-$C_{\alpha C}$-C_{1C} (*e*) and $C_{\beta C}$-$C_{\alpha C}$-C_{1C}-C_{6C} (*f*).



Our results may be compared to other NMR results (23), other molecular orbital or molecular mechanics results (24), and X-ray crystal structures (25–28).

We used the 1D NOE 1H difference and 2D NOESY and HOESY experiments for conformational analysis. Steady state NOE is obtained from the NOE difference experiment whereas NOEs from NOESY experiments are measured by transient effects (29). Internuclear distances obtained from the 1D experiment rely on the observation that NOE transfer rates are proportional to the inverse sixth power of the distance between dipolar nuclei (30). Distances from NOESY and HOESY experiments are estimated from the initial buildup rates of the NOE (29). Errors involved in estimating distances using NOE data include problems with measurement and accounting for competing relaxation pathways. In contrast, the errors for distance estimation with semiempirical calculations

Fig. 7. Steady state NOE difference intensities plotted against interatomic distances calculated from a structure (shown in Fig. 8) minimized using MNDO-PM3 semiempirical methods.



are due to the accuracy of the computational model, the differences between solution state and gas state geometries, and the possibility that the minimized structure is a local minima.

Conformations with the lowest overall energy and side-chain bond rotation energies were calculated using semiempirical molecular orbital methods on the MOPAC 93 program (31) installed on a SUN IPX computer. We have used the MNDO-PM3 method (Modified Neglect of Diatomic Overlap (32), Parametric Method 3 (33)), which neglects diatomic overlap in the secular equation. In this method the excessive repulsive energy arising from the MNDO method is empirically reduced using Gaussian attractive functions in calculating the nuclear energies (34). The full atomic parameter set has been optimized for calculating the heat of formation from the electron–electron and nuclear–nuclear interactions and the heats of formation of the constituent atoms (33). The SYMMETRY function was used for methyl proton bond lengths and angles, and all parameters except individual rotation bond angles were relaxed for these calculations. Bond rotation energies shown in Fig. 6 were obtained by calculating the energies of minimized structures for the rotamers at 10° torsion angle intervals. Optimization parameters SCFCRT and GNORM were set to 1.0×10^{-7} and 0.01, respectively. Given the computational power available on today's computers, this semiempirical MO approach provides a good compromise between computational economy and theoretical accuracy for conformational studies of molecules of this size. It should be noted that these semiempirical results correspond to gas phase heats of formation, which do not take into account the sometimes substantial effects of solvation.

Comparison of NOE results with molecular orbital minimized structures

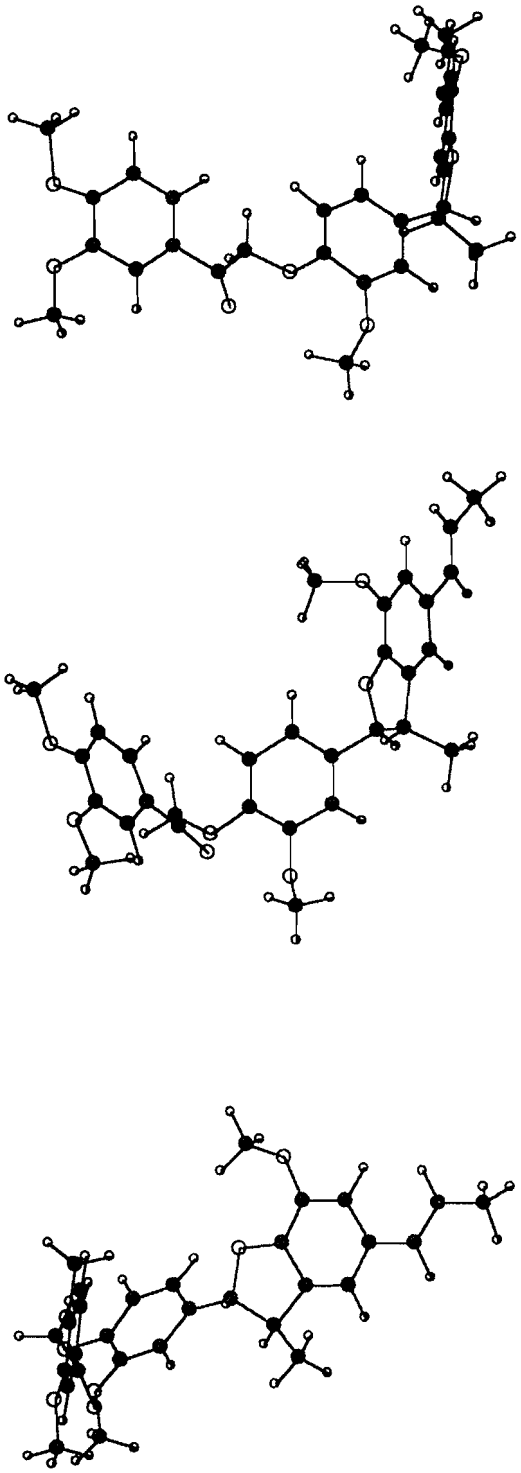
NOE values that serve as experimental measures of the approximate distances between atoms may be compared to interatomic distances calculated using MO methods. In addition, the likelihood of a single conformation dominating the relationship between any two atoms may be addressed by examining bond torsion-angle rotation energy barriers. In the first approximation, when one considers dipole–dipole interaction between two nuclei, the rate of spin exchange by the nuclear Overhauser effect (cross relaxation) will be proportional to r^{-6} (35). In practice, our system with multiple spins that have both dipolar interactions and spin–spin coupling between many atoms is significantly more complicated (29). In Fig. 7 the steady state NOE values are plotted against the distances from the minimized structures. The fitted line in Fig. 7 shows the best fit of the steady state NOE intensity to a r^{-6} dependence.

Rotation at bonds conjugated to ring structures

At room temperature it appears that there is free rotation about the benzylic bond of the vinyl structure (Fig. 1, r_1). NOESY and NOE difference intensities between side-chain protons $H_{\alpha A}$ and $H_{\beta A}$ to the ring protons H_{2A} and H_{6A} are similar in magnitude. This indicates that similar populations of these two rotamers exist. Indeed, the NOE results conform to results from molecular orbital calculations for different rotamer conformations (Fig. 6*a*) that indicate that the energy difference is 0.22 kcal mol^{-1} between the two rotamers with the α–β conjugated double bond in plane with the aromatic ring. This energy difference corresponds to an equilibrium constant at room temperature of about 0.7. In addition, there is a 1.7 kcal mol^{-1} activation energy for rotation about the benzylic vinyl bond. The torsion-angle bond rotation about the benzylic bond at ring A is rapid compared to the chemical shift difference that may exist due to the chemical exchange ($\tau < 1/20$ Hz). It is also fast compared to the NOE buildup ($\tau << 1/1$ Hz). The NOE data corresponding to rotation at the benzylic bond on ring B (r_2 in Fig. 1, (b) in Fig. 6), however, clearly indicate a favored conformation in which the single benzylic proton is closer to the proton at the 2 ring position than the proton at the 6 ring position. This is difficult to see in the minimized structures shown in Fig. 8, but the calculated distances for the minimized structure are 2.82 Å and 3.45 Å for H_α to H_{C2} and H_{C6}. The steady state NOE (Table 3) and the NOESY buildup experiments (Table 4) both indicate that $H_{\alpha B}$—H_{6B} is farther apart than $H_{\alpha B}$—H_{2B}. The dominant conformation has $H_{\alpha B}$ and H_{2B} close together as shown in our calculated structure in Fig. 7. The calculation for the rotation about this bond showed some instabilities (Fig. 6*b*), but the favored conformation and a relatively low barrier to rotation are evident.

A priori one expects that conjugation of α carbonyl with ring C will restrict rotation about the benzylic bond defined by the torsion angle C_2-C_1-C_α-C_β. Our NOE results correspond well with this prediction, but the calculated results for this bond rotation showed some instabilities and an unexpectedly low-energy barrier for rotation. The relative intensities for the steady state NOE difference spectra between protons $H_{\beta C}$ and H_{6C} or H_{2C} are 6.37 and 2.29, respectively. This corresponds to distances of about 2.6 for the $H_{\beta C}$—H_{6C} interaction and 3.2 Å for the $H_{\beta C}$—H_{2C} interaction estimated from the empirical fit between all of the NOE difference data and the PM3 minimum structures as shown in Fig. 8.

Fig. 8. Perspective view of acetoguaiacyl-dehydro-diisoeugenol methyl ether minimized structure rotated to show the view with each aromatic ring in the plane.



Rotation at the β-O-4 bond

The two torsion angles at the β-O-4 bond between rings B and C have the greatest rotation barriers as shown by the results presented in Figs. 6*c* and 6*d* for the rotamers calculated by the MNDO-PM3 method. For rotation about the torsion angle defined by C_{3B}-C_{4C}-$O_{\beta C}$-$C_{\beta C}$ (Fig. 6*c*) the principle constraints appear to be interaction of the β proton with the methoxyl and H_{5C} protons. The small rotation barrier at angles between 120° and 180° corresponds to interaction between the β protons and the C_5 hydrogen. The larger barriers between −120° (240°) and 90° correspond to interaction between the β protons and the methoxyl protons. The absence of NOE exchange between the β (ring C) protons and the methoxyl protons as well as the strong NOE between the β protons and the C5 proton indicates that the 200° torsion angle conformation is probably dominant in solution. Unfortunately, no HOESY peaks were observed between the 3 and 5 aromatic carbons and the β protons. The crystal structure for similar molecules with a γ CH_2OH substituent (26) showed a C_β-O-C_4-C_3 torsion angle of 172.3° corresponding to nearly the same conformation as we have found experimentally and by MNDO-PM3 calculations. The substantial energy barrier of about 5 kcal mol^{-1} for the rotation about the torsion angle C_4-O-C_β-C_α corresponds to the geometry in which the C_α and the carbonyl oxygen are in the plane of the aromatic ring B (a torsion angle of 0° as shown in Fig. 6*d*). The minimum for rotation about this axis is at ~82° and corresponds to the lowest steric interactions energy. This geometry is again similar to the 68.5° torsion angle found by Stomberg and Lundquist for a similar α-carbonyl β-O-4 structure (26).

Steric interactions between aromatic rings will restrict rotation about the α–β bond defined by $O_{\beta C}$-$C_{\beta C}$-$C_{\alpha C}$-C_{1C} as shown by the broad barrier to rotation between −120° and 40°. The minima for this bond rotation place the β-ether oxygen at a 60° angle to the aromatic plane of ring C as shown in Figs. 7 and 5*e*. Crystal structures for β-O-4 model compounds indicate that the minima at about −160° (−152.4°) is favored for α-carbonyl-containing compounds while the α-hydroxylated compounds crystallize with torsion angles in the minima between 50° and 65°.

Methoxyl rotation

In our experience the observed NOE values may not be used to distinguish the C_{MeO}-O_{MeO}-C_3-C_2 dihedral angles precisely with respect to the plane of the aromatic ring. However, NOESY and HOESY peaks and the NOE values were always consistent with a close proximity between the methoxyl protons and the aromatic C2 protons. Close examination of Tables 3 and 4 reveals that there is general agreement between the NOE and MO data with respect to determining the juxtaposition of the methoxyl protons relative to the ring protons. In Table 3 there are several steady state NOE peaks listed between methoxyl protons and protons on adjacent aromatic rings where the MOPAC calculated distance is over 10 Å. We did not see strong evidence of corresponding peaks in the NOESY spectra and we believe these peaks are artifacts of the steady state experiment. Also there are negative NOE peaks listed in Table 3 that we attribute to multi-spin effects. Crystal structures have shown that syringyl-type groups have methoxyl torsion angles of ±20° to the ring for one group and at about 85° for the second methoxyl group (27). Molecular mechanics (36) and molecular orbital studies (37) also have found similar dihedral angles for the methoxyl groups. For the three C3 methoxyls we have calculated minimum torsion angles (C_{MeO}-O_{MeO}-C_3-C_2) of 107° (ring A), 85° (ring B), and 167° (ring C). The methoxyl on the C4 position on ring C is in the ring plane

Table 4. Initial rates, selected NOESY peak intensities.

		Mixing Time (ms)		
		100	200	400
Peak (ppm)	Assignment	Intensity		
1.37–3.44	γB–βB	4.79	4.55	4.19
3.87–7.00	OMe3B–2B	1.98	3.58	6.39
3.89–6.78	OMe3A–2A	1.72	3.08	5.24
3.93–7.59	OMe3C–2C	1.84	3.19	5.70
3.95–6.90	OMe4C–5C	2.22	3.73	6.62
5.10–3.44	αB–βB	3.06	1.42	1.25

7.67–6.90	6C–5C	8.04	4.70	3.39

with a 0° angle to C5. Values for the energy barrier for methoxyl rotation have been estimated to be between 1.6 and 3.4 kcal mol^{-1} (37). We have calculated rotational energy barriers of between 1.3 and 2.0 kcal mol^{-1} for methoxyl rotation for this lignin model.

Experimental section

Acetoguaiacyl-dehydro-diisoeugenol methyl ether was kindly donated by Dr. Jerzy Arct at Lakehead University in Thunder Bay, Ontario. Spectra were obtained on a 200 MHz Bruker AC-E spectrometer at Lakehead University and a 500 MHz Bruker AMX spectrometer at the High-Field NMR facilities at the Prairie Regional NMR Centre, Winnipeg, Manitoba. Spectra were obtained at 300 K from samples dissolved in $CDCl_3$ (99.8%, Cambridge Isotope Laboratories) with TMS as internal standard. Carbon-13 spectra were obtained with two-level decoupling. The 200 MHz COSY pulse sequence was based on articles by Aue et al. (38) and Nagayama et al. (39). The COSY spectrum presented in Fig. 2 was obtained with 1K data points in *F*2, a sweep width of 1600 Hz, 256 *F*1 increments with 32 acquisitions each, and a relaxation delay between acquisitions of 5 s. Standard NOESY experiments (29) were performed at 200 MHz with 32 acquisitions for 256 increments in *F*1 and 1024 data points in *F*2 (Fig. 5*c*). The spectral width in both dimensions was 1602 Hz at 200.14 MHz. Phase-sensitive TPPI NOESY spectra were obtained at 500 MHz (D_1–90–D_0–90–D_9–90–FID) with mixing times of 0.1, 0.2, 0.4, 0.8, and 1.2 s, a 5 s relaxation delay, 16 acquisitions for 512 points with a spectral width of 7.631 ppm in *F*1, and 1024 points with a spectral width of 3816.79 Hz in *F*2 (Table 4). Heteronuclear Overhauser experiments using a standard carbon-detected HOESY pulse sequence were executed on the 200 and 500 MHz instruments (10, 40, 41). At 500 MHz the HOESY spectra (Fig. 5) were 4K in *F*2 with a sweep width of 23 809.52 Hz, 128 spectra with 64 acquisitions each in *F*1 at 500.14 MHz, and a mixing time of 2 s and the relaxation delay of 3.5 s. A 5.0 s saturation time was used for the steady state NOE difference method (42). Inverse-detected long-range H/C correlations via zero and double-quantum coherence (HMBC) (12) were optimized for long-range couplings of 5–10 Hz ($1/2J_{CH}$ delay = 0.070 s) with a low-pass *J* filter, *F*1 = 128 points, 198.776 ppm at 125.7699 MHz; *F*2 = 4096 points, 7.24 ppm at 500.136 MHz. Inverse-detected H/C correlations optimized for single bond couplings (HMQC) (11) (delay = 0.001 78 s for $(1/4)J$, $J_{CH} \sim 140$ Hz) were obtained at 500.1376 MHz with 128 points and a spectral width of 159.029 ppm in *F*1 (125.7699 MHz), and 4096 points over a 7.24 ppm (500.136 MHz) spectral width in *F*2.

Properties of atoms in molecules: nuclear magnetic shielding

T.A. Keith and R.F.W. Bader

Abstract: This paper analyzes the nuclear magnetic shielding tensors underlying the chemical shift in NMR spectroscopy in terms of the field generated at the nucleus by the current $\boldsymbol{J}^{(1)}(\boldsymbol{r})$ induced by an external magnetic field. The magnetic field at nucleus $\mathcal{N}$ resulting from an element of the induced current density at a distance $r_{\mathcal{N}}$ is proportional to $\boldsymbol{r}_{\mathcal{N}} \times \boldsymbol{J}^{(1)}(\boldsymbol{r})/r_{\mathcal{N}}^3$, which defines the shielding density $\sigma_{\mathcal{N}}(\boldsymbol{r})$. The magnetic shielding of a nucleus is fundamentally an atomic property, a feature brought to the fore by using the theory of atoms in molecules, and the integration of $\sigma_{\mathcal{N}}(\boldsymbol{r})$ over the individual atomic basins relates the shielding tensor $\sigma_{\mathcal{N}}$ to a sum of atomic contributions. The shielding of nucleus $\mathcal{N}$ is primarily determined by the flow of current within the basin of atom $\mathcal{N}$, a contribution that varies from the approximate diamagnetic limit, given by the atomic Lamb value for the atom in the molecule, to values that are greatly reduced by the presence of paramagnetic current flows associated with particular bonding effects. Whether the contribution of a neighbouring atom is shielding or deshielding is readily understood by relating the form of the current flow within its basin to the magnetization density $\boldsymbol{r}_{\mathcal{N}} \times \boldsymbol{J}^{(1)}(\boldsymbol{r})$. A study of the currents induced in benzene shows that the extent to which a proton, bonded to a ring of atoms, is deshielded by the field exerted by its bonded neighbour provides a direct diagnostic test for a ring current and an accurate relative measure of its strength. The theory of atoms in molecules isolates transferable atomic properties, and because of this ability one finds, in addition to the anticipated result that a given functional group contributes identical amounts to the isotropic shielding $\bar{\sigma}_{\mathcal{N}}$ of a nucleus external to it through a series of molecules, the more remarkable result that the whole of the variation in $\bar{\sigma}_{\mathcal{N}}$ can have its origin in the basin of atom $\mathcal{N}$, the contribution from external groups remaining constant. For example, the external contribution to $\bar{\sigma}_{\mathcal{N}}$ for a carbon nucleus in a normal hydrocarbon is independent of chain length and position of $\mathcal{N}$ within the chain, the methyl group in ethane contributing the same shielding to a methyl carbon as does the butyl group in pentane. This constancy in external contributions to the shielding is also found for N, O, and F nuclei in substituted, saturated hydrocarbons.

Key words: NMR, magnetic shielding, current density, magnetic shielding density.

Résumé : Dans ce travail, on analyse les tenseurs du blindage magnétique nucléaire sous-jacents au déplacement chimique en spectroscopie RMN en fonction du champ généré au niveau du noyau par le courant $\boldsymbol{J}^{(1)}(\boldsymbol{r})$ induit par un champ magnétique externe. Le champ magnétique au niveau du noyau $\mathcal{N}$ qui résulte d'un élément de la densité du courant induit à une distance $r_{\mathcal{N}}$ est proportionnel à $\boldsymbol{r}_{\mathcal{N}} \times \boldsymbol{J}^{(1)}(\boldsymbol{r})/r_{\mathcal{N}}^3$ qui définit la densité de blindage $\sigma_{\mathcal{N}}(\boldsymbol{r})$. Le blindage magnétique d'un noyau est fondamentalement une propriété atomique, une caractéristique mise de l'avant par l'utilisation de la théorie des atomes dans les molécules, et l'intégration de $\sigma_{\mathcal{N}}(\boldsymbol{r})$ sur les basins atomiques individuels permet d'établir une relation entre le tenseur de blindage $\sigma_{\mathcal{N}}$ avec une somme de contributions atomiques. L'écoulement du courant dans le basin de l'atome $\mathcal{N}$, une contribution que diffère de la limite diamagnétique approximative donnée par la valeur atomique de Lamb pour l'atome de la molécule, limite le blindage du noyau $\mathcal{N}$ à des valeurs qui sont grandement réduites par la présence des écoulements de courant paramagnétique associés avec des effets de liaison particuliers. On peut facilement comprendre que la contribution d'un atome avoisinant est blindante ou déblindante en établissant une relation entre la forme de l'écoulement du courant dans son basin et la densité de magnétisation $\boldsymbol{r}_{\mathcal{N}} \times \boldsymbol{J}^{(1)}(\boldsymbol{r})$. Une étude des courants induits dans le benzène montre que, pour un proton par ailleurs lié à un cycle d'atomes, le degré de déblindage causé par le voisin qui lui est lié fournit une méthode directe de diagnostique pour un courant de cycle et une mesure relative correcte de sa force. La théorie des atomes dans les molécules permet d'isoler les propriétés atomiques transférables; à cause de cette caractéristique, il est possible d'observer, en plus du résultat anticipé selon lequel un groupe fonctionnel donné contribue des quantités égales au blindage isotrope, $\bar{\sigma}_{\mathcal{N}}$, d'un noyau qui lui est externe par une série de molécules, un résultat encore plus remarquable, à savoir que l'ensemble de la variation du $\bar{\sigma}_{\mathcal{N}}$ trouve son origine dans le basin de l'atome $\mathcal{N}$ et que la contribution des groupes externes reste constante. Par exemple, la contribution externe au $\bar{\sigma}_{\mathcal{N}}$ pour un noyau de carbone dans un hydrocarbure normal est indépendante de la longueur de la chaîne et de la position de l'atome $\mathcal{N}$ dans la chaîne; le groupe méthyle de l'éthane fait la même contribution à un atome de carbone que le groupe butyle du

Atomic basis of the chemical shift

Nuclei of chemically inequivalent atoms of the same element give rise to distinct resonance signals in an NMR experiment, the chemical shift. The ability to distinguish between the atoms of a given element in a molecule makes the chemical shift the most important parameter to be derived from an NMR spectrum (1). The shift in signal relative to the bare nucleus is called the "nuclear magnetic shielding" and is the result of the external magnetic field inducing an electronic current within the molecule whose associated magnetic field at the nucleus partially shields or deshields it from the applied field. The nuclear magnetic shielding, like the magnetic susceptibility, is determined by the first-order current distribution induced by a uniform external magnetic field. The current density is the expectation value of the current operator (2), the product of the observables for the electron density and velocity, and for a field applied along the β Cartesian axis the first-order induced current density, $\boldsymbol{J}_\beta^{(1)}(\boldsymbol{r})$, is given by

$$\boldsymbol{J}_\beta^{(1)}(\boldsymbol{r}) = -(e/m)\sum_i \{\langle\psi^{(0)}|\hat{\delta}(\boldsymbol{r}_i - \boldsymbol{r})\hat{\boldsymbol{p}}_i|\psi_\beta^{(1)}\rangle + \langle\psi_\beta^{(1)}|\hat{\delta}(\boldsymbol{r}_i - \boldsymbol{r})\hat{\boldsymbol{p}}_i|\psi^{(0)}\rangle + (e/c)\langle\psi^{(0)}|\hat{\delta}(\boldsymbol{r}_i - \boldsymbol{r})\boldsymbol{A}_{\beta i}|\psi^{(0)}\rangle\} \quad [1]$$

where $\psi_\beta^{(1)}$ is the corresponding first-order correction to the wave function and $\boldsymbol{A}_{\beta i} = (1/2)\boldsymbol{B}_\beta \times (\boldsymbol{r}_i - \boldsymbol{r}_0)$ is the vector potential for an applied field $\boldsymbol{B}_\beta$ with gauge origin $\boldsymbol{r}_0$. The magnetic shielding of a given nucleus is basically an atomic property. Understanding the dependence of the shielding of a nucleus of a given atom on its chemical environment is predicated upon understanding the atomic contributions to the shielding in terms of the current density distribution, a step that is accomplished using the theory of atoms in molecules (3). This theory identifies an atom with a bounded region of real space whose properties, including those induced by an external field, are defined by the quantum action principle (4).

In the case of magnetic properties, the theory enables one to go beyond the definition of the atomic contributions, by leading to a method for their determination, one that takes advantage of the known result that the nucleus serves as the natural gauge origin for the calculation of the current in an isolated atom. The use of a separate nuclear-centred gauge origin for each atom in a molecule, termed the method of Individual Gauges for Atoms in Molecules (IGAIM) (5), enables one to calculate first-order magnetic response properties that are in relatively good agreement with experiment, using standard basis sets of moderate size. The properties are calculated directly from the wave functions obtained in conventional CPHF calculations. IGAIM, by assigning multiple gauge origins in real space, thus differs from GIAO (6) or IGLO (7, 8), which assign different gauges to individual atomic-centred basis functions or to localized molecular orbitals, respectively.

The theory also leads to a method for the relatively accurate and continuous determination of the first-order induced current density $\boldsymbol{J}^{(1)}(\boldsymbol{r})$, by extending the idea of the set of multiple real-space gauge origins used in IGAIM to the limit of a continuous set of gauge origins (9). In this method, the current is determined through the definition of a continuous set of gauge transformations (CSGT), a separate gauge origin to calculate the current $\boldsymbol{J}^{(1)}(\boldsymbol{r})$ at each point $\boldsymbol{r}$ in real space, yielding the following expression for the induced current distribution:

$$\boldsymbol{J}_\beta^{(1)'}(\boldsymbol{r}) = \boldsymbol{J}_\beta^{(1)}(\boldsymbol{r}) - (e/m)\sum_i \{\langle\psi^{(0)}|\hat{\delta}(\boldsymbol{r}_i - \boldsymbol{r})\hat{\boldsymbol{p}}_i|\psi_\beta^{(1)'}\rangle + \langle\psi_\beta^{(1)'}|\hat{\delta}(\boldsymbol{r}_i - \boldsymbol{r})\hat{\boldsymbol{p}}_i|\psi^{(0)}\rangle + (e/c)\langle\psi^{(0)}|\hat{\delta}(\boldsymbol{r}_i - \boldsymbol{r})\boldsymbol{A}'_{\beta i}|\psi^{(0)}\rangle\} \quad [2]$$

$\psi_\beta^{(1)'}$ is the additional first-order correction arising from the changed vector potential $\boldsymbol{A}'_{\beta i} = (1/2)\boldsymbol{B}_\beta \times \boldsymbol{d}(\boldsymbol{r})$, wherein $\boldsymbol{d}(\boldsymbol{r})$, the shift in gauge origin, is defined to be a continuous function of $\boldsymbol{r}$, the position vector in real space. The vector currents determined using the form of this method termed CSDGT (9) satisfy the local current conservation requirement that $\nabla\cdot\boldsymbol{J}^{(1)}(\boldsymbol{r}) = 0$ with relatively high numerical accuracy, enabling one to obtain faithful displays of the current and determine its topology for the first time (2, 9).

The atomic current theorem obtained from the theory of atoms in molcules enables one to define the atomic contributions to the magnetic susceptibility and relate them to the form of the current density (10). The resulting atomic contributions have been shown to recover Pascal's group increments for the magnetic susceptibilities of hydrocarbons, thus adding magnetic properties to the list of the measurable additive group contributions that are predicted by the theory, a list that includes heats of formation, populations, volumes, and electric polarizabilities.

The induced current that generates the field shielding a nucleus corresponds to a divergence-free flow of electron density. The electron density and the current are the expectation values of quantum observables that, according to Schrödinger (11), underlie the elucidation of the electric and magnetic properties of matter. The theory of atoms in molecules uses these two fields to obtain an atomic partitioning of the space of a molecule and of its magnetic properties, to obtain thereby a physical understanding of magnetic properties at the atomic level.

Computational methods

The nuclear magnetic shielding results reported here were calculated at the CPHF level using IGAIM (5). The CPHF

first-order wave functions were obtained from a locally modified version of CADPAC 4.0 (12), while the atomic integrations were done using AIMPAC.[2] The 6–311++G(2*d*,2*p*) Gaussian basis sets of Pople et al. (14) were used in all calculations. For consistency, all geometries were fully optimized at the HF level using the same basis set. All vector current maps were calculated using CSGT (9). Jameson (15) has reviewed the theoretical and physical aspects of nuclear shielding, including methods for its calculation and interpretation.

Magnetic shielding density and its relation to the induced current

Definition of atomic contribution to nuclear magnetic shielding

Jameson and Buckingham (16) have shown how properties induced by electric and magnetic fields can be expressed as integrals of corresponding property densities defined in real space in terms of the electronic charge and current distributions. In particular, the first-order magnetic dipole induced in a molecule by an external field $\boldsymbol{B}$ is related to the magnetization density in terms of the first-order induced current, as $(1/2c)\boldsymbol{r}\times\boldsymbol{J}^{(1)}(\boldsymbol{r})$. This is the density that determines the magnetic susceptibility of a molecule (10, 16). This same density, with origin located specifically at nucleus $\mathcal{N}$ and divided by $r_{\mathcal{N}}^3$, determines the local contribution that the induced current makes to the magnetic field at the position of nucleus $\mathcal{N}$. Specifically, the nuclear magnetic shielding tensor density for nucleus $\mathcal{N}$, $\sigma_{\mathcal{N}}(\boldsymbol{r})$, is defined in eq. [3] (16, 17):

$$[3]\qquad \sigma_{\mathcal{N}}(\boldsymbol{r})\cdot\boldsymbol{B} = (-1/c)\boldsymbol{r}_{\mathcal{N}}\times\boldsymbol{J}^{(1)}(\boldsymbol{r})/r_{\mathcal{N}}^3$$

The α,β component of the nuclear magnetic shielding tensor $\sigma_{\mathcal{N}}^{\alpha,\beta}$ is obtained by integration of the corresponding component of this density over the space of the molecule, an atom Ω at a time,

$$[4]\qquad \sigma_{\mathcal{N}}^{\alpha,\beta} = (-1/Bc)\sum_{\Omega}\int_{\Omega} d\boldsymbol{r}_{\mathcal{N}}\{\boldsymbol{r}_{\mathcal{N}}\times\boldsymbol{J}_{\beta}^{(1)}(\boldsymbol{r})/r_{\mathcal{N}}^3\}_{\alpha} = (-1/Bc)\sum_{\Omega}\sigma_{\mathcal{N}}^{\alpha,\beta}(\Omega)$$

The magnetic shielding, like all atomic properties, is additive. Because of the overall dependence of $\sigma_{\mathcal{N}}(\boldsymbol{r})$ on the inverse square of $r_{\mathcal{N}}$, the dominant contribution to $\sigma_{\mathcal{N}}$ is that arising from the basin of the atom containing nucleus $\mathcal{N}$, that is, $\sigma_{\mathcal{N}}(\mathcal{N})$. This quantity is referred to as the internal contribution, with the external contribution $\sigma_{\mathcal{N}}(\text{ext})$ equaling $\sigma_{\mathcal{N}} - \sigma_{\mathcal{N}}(\mathcal{N})$, that is, all atomic contributions other than that from atom $\mathcal{N}$. The nuclear magnetic shielding tensor is dimensionless and is generally reported in parts per million (ppm). The isotropic shielding, one-third of the trace of the tensor $\sigma_{\mathcal{N}}$, is labelled $\bar{\sigma}_{\mathcal{N}}$.

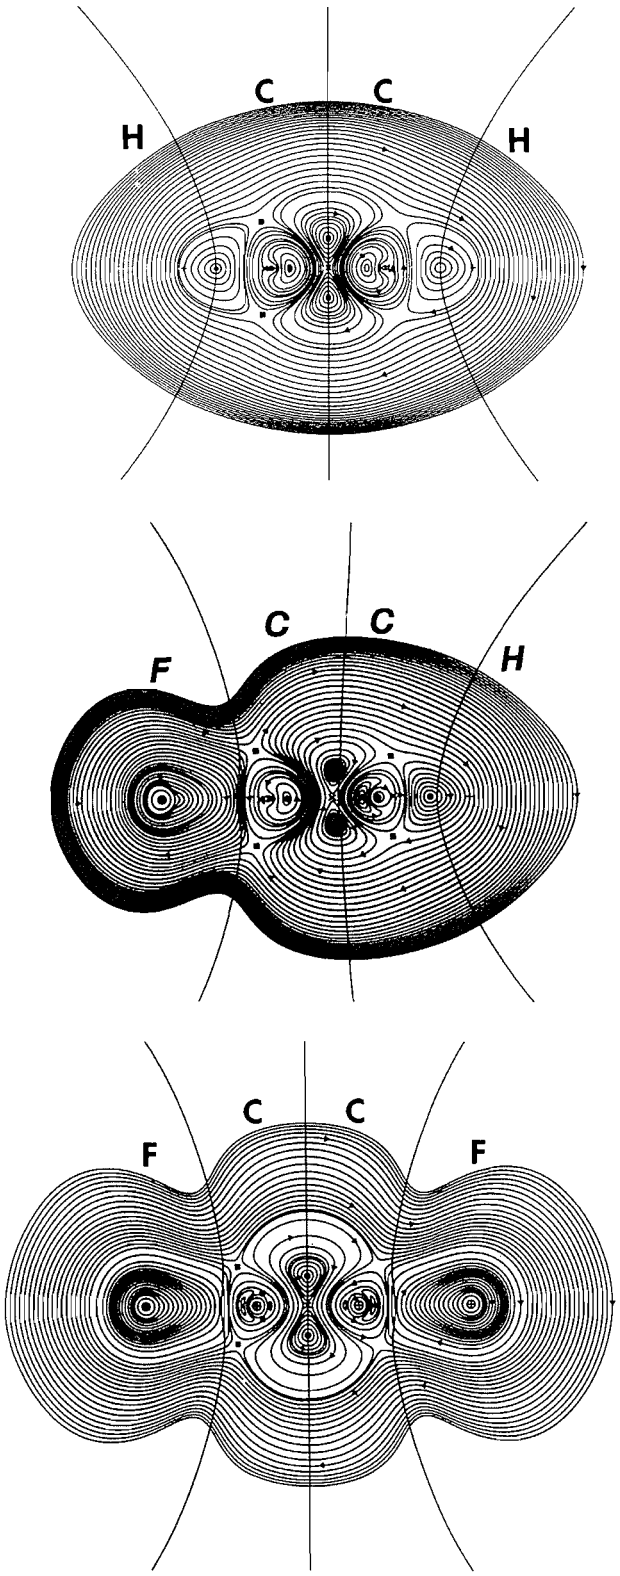
The expression for the first-order current calculated from perturbation theory, eq. [1], is expressed as a part depending on the first-order correction to the wave function, the "paramagnetic" part, and a part depending on the unperturbed electron density, the "diamagnetic" part (8, 10). Each can be considered to make a corresponding contribution to magnetic properties (1), as in Van Vleck's expression for magnetic susceptibility (18) or in Ramsey's corresponding expression for nuclear shielding (19), and references in the older literature (1) to such contributions generally refer to this breakdown of the current. While the total current is in principle independent of the gauge origin chosen for its calculation, this particular partitioning into para- and dia-magnetic contributions is not unique and is gauge origin dependent. Nonetheless, the total current exhibits regions in which the current flow is such as to generate a field internal to the region that is either opposed to the applied field or acts in concert with it, flows that are termed diamagnetic or paramagnetic, respectively. This characterization of the total current is both useful and valid, as is illustrated next.

Figure 1 displays the current density distribution for acetylene and its mono- and di-substituted fluoro compounds, for a field applied perpendicular to the molecular axis.[3] The regions of clockwise current flow enveloping the entire molecule and those confined within the basins of the fluorine atoms are termed diamagnetic because the interior magnetic field they generate is opposed to the applied field. It is these induced currents that are responsible for the diamagnetic nature of the susceptibility observed for most closed-shell molecules. However, within the basins of the carbon atoms one sees regions of current flow in the counterclockwise direction; the internal fields they generate reinforce the applied field and they are termed paramagnetic. The presence of paramagnetic currents reduces the value of the diamagnetic susceptibility and, in some molecules such as BH that possess a low-lying excited state of Π symmetry, can lead to a paramagnetic susceptibility for the molecule and to a net deshielding of a nucleus relative to the bare nucleus. The presence of both diamagnetic and paramagnetic current

[2] AIMPAC v is the most recent version of the program, described in ref. 13, and is available from R.F.W.B.

[3] Displays of the total induced current $\boldsymbol{J}^{(1)}(\boldsymbol{r})$ have been given previously for some diatomic (8) and polyatomic (20) molecules. In the former (8), trajectories representing the vector field are indicated by a succession of arrows. They are incapable of showing complex current patterns, for example (2), those in the vincities of linked spiral critical points found in ethylene and water and those in the immediate vicinity of nuclei. The reader may compare their current map for HF with the trajectory map given here (see Fig. 5). The polyatomic maps (20), obtained in single gauge origin calculations, have been demonstrated (2, 9) to seriously violate the criterion of current conservation, the condition that $\nabla\cdot\boldsymbol{J}^{(1)}(\boldsymbol{r}) = 0\forall\boldsymbol{r}$. Because of this, these maps (20) do not display behaviour consistent with that demanded of a divergenceless three-dimensional vector field (2, 21) and their topology is wrong. Only current maps obtained from the CSDGT method have been demonstrated to closely satisfy current conservation. The interested reader is invited to compare previous maps (8, 20) with those obtained using the CSDGT method presented here and elsewhere (2, 5, 9, 10). Specific failures in the prediction of the form of $\boldsymbol{J}^{(1)}(\boldsymbol{r})$ and in its critical points in previous maps (20) have been previously discussed (2, 22). Authors (23) of the single gauge origin approach (20) now advocate the CSGT method (9) for the determination of the current, since its use eliminates the unphysical features obtained in their previous maps, features that result from the failure to meet the demand of current conservation.

Fig. 1. Displays of the vector current density in HCCH, FCCH, and FCCF induced by an applied field directed out of and perpendicular to the indicated plane. The directions of the current flow are indicated by arrows. The maps in this and the remaining figures are overlaid with interatomic surfaces. Note the presence of paramagnetic (counterclockwise) flows in the basins of the carbon atoms.



flows is real and is not an artifact of the calculation or dependent upon the choice of gauge origin (2, 9). While a special method using a continuous set of gauge transformations is required to obtain such maps in calculations employing a finite basis set (9), the obtained currents reflect the property of the true current as being an observable, independent of gauge origin.

While the overall effect of diamagnetic and paramagnetic currents is to make opposing contributions to the magnetic susceptibility of a molecule, the contribution from either type of current to the magnetic field exerted at the position of a particular nucleus within the molecule can be shielding or deshielding. The diamagnetic current flow about the position of a fluorine nucleus in both HCCF and FCCF, Fig. 1, generates a field at this nucleus strongly shielding it from the applied field. This same current flow can, however, as illustrated below, contribute to a relatively small shielding or deshielding of a neighbouring carbon nucleus. The presence of a paramagnetic current flow that is contained within the basin of a given atom will generally lead to a deshielding of its nucleus. Thus the carbon nuclei in these molecules will be relatively less shielded than the fluorine nuclei, because of the presence of the paramagnetic currents contained within their basins. The current distributions illustrated in Fig. 1 will be used to illustrate the contributions that the possible patterns of current flow make to the shielding of contained and distant nuclei.

A useful reference for determining the extent of shielding or deshielding of a nucleus in a molecule is given by the so-called Lamb shift (24) σ_L, which is the magnetic shielding density in eq. [3] integrated over the free atom. In this case, the shielding density is proportional to the atomic average of $1/r_{\mathcal{N}}$ as given in eq. [5]

$$[5] \qquad \bar{\sigma}_{L,\mathcal{N}} = (e^2/3mc^2) \int d\boldsymbol{r}\, \rho(\boldsymbol{r})/r_{\mathcal{N}}$$

This expression is exact for a free closed-shell atom where the current flow consists entirely of diamagnetic circular flows centred on the nucleus. Consequently, the Lamb shift represents an approximate upper limit to the diamagnetic shielding of a given nucleus arising from the flow of current within its own basin. In general, the shielding of a nucleus in a molecule is observed to be less than $\bar{\sigma}_{L,\mathcal{N}}$ because of the disruption of the atomic nature of the current flow and, in particular, because of the creation of paramagnetic currents that are frequently localized within the basin of a single atom, as seen in Fig. 1 for the carbon atoms. The average of $1/r_{\mathcal{N}}$ is readily determined for atom $\mathcal{N}$ in a molecule and the quantity

$$[6] \qquad \bar{\sigma}_L(\mathcal{N}) = (e^2/3mc^2) \int_{\mathcal{N}} d\boldsymbol{r}\, \rho(\boldsymbol{r})/r_{\mathcal{N}}$$

called the atomic Lamb shift, when compared with $\bar{\sigma}_{\mathcal{N}}(\mathcal{N})$, the internal contribution to $\bar{\sigma}_{\mathcal{N}}$, provides a useful measure of the effectiveness of the currents generated within the atomic basin of atom $\mathcal{N}$ in shielding its own nucleus. The value of the atomic Lamb shift for a fluorine atom in difluoroacetylene, for example, is 481 ppm, very similar to the value of 485 ppm obtained for $\bar{\sigma}_F(F)$, while for a carbon atom in the same molecule the two corresponding values are very different, equalling 256 and 132 ppm, respectively.

In the IGAIM method of calculating the atomic contribution to a magnetic property, the nucleus of the atom is chosen as the gauge origin for calculating the current within the atom. This choice uniquely determines the paramagnetic and diamagnetic contributions to the current in eq. [1]. Within this formalism, the atomic Lamb shift defined in eq. [6] is exactly the diamagnetic contrbution to $\bar{\sigma}_{\mathcal{N}}(\mathcal{N})$, the internal magnetic shielding of nucleus $\mathcal{N}$, while the difference $\bar{\sigma}_{\mathcal{N}}(\mathcal{N}) - \bar{\sigma}_{\mathrm{L}}(\mathcal{N})$ equals the paramagnetic contribution. For the examples given above, this difference equals 4 ppm for F and 124 ppm for C in FCCF. The atomic average of $1/r_{\mathcal{N}}$ for a bound atom is a physically measurable quantity and, thus, so is the diamagnetic contribution to the magnetic shielding of an atom in a molecule.

Essential topological characteristics of the induced current flows

The types of current flows induced in a molecule by an external magnetic field are described in terms of the seven possible critical points exhibited by the vector field $\boldsymbol{J}^{(1)}(\boldsymbol{r})$ (2). Only those topological features of $\boldsymbol{J}^{(1)}$ essential to the understanding of the diamagnetic and paramagnetic contributions to σ will be discussed here. The reader wishing a full account of the topology of $\boldsymbol{J}^{(1)}$ is referred to the earlier work (2, 22). The critical points are classified in terms of their rank and signature (r, s), as determined by the 3×3 coefficient matrix of $\nabla \boldsymbol{J}^{(1)}$. The current generated in a free closed-shell atom for any field direction or for a linear molecule in a field applied parallel to the molecular axis is planar and consists of a set of circular current loops centered on a $(2,0)$ critical point whose two roots are imaginary. This pattern of flow extends into the third dimension about an axis defined by the stagnation path, the line consisting of the continuous set of non-isolated $(2,0)$ critical points. Such a critical point is called a centre point and its associated set of flow lines is ubiquitous in the currents induced in molecules. Chemical bonding, however, frequently disrupts the centre point flows to give patterns associated with other critical points. The current distribution in acetylene (21) is described to illustrate the manner in which paramagnetic currents can be generated within a molecule.

The current distribution induced by a perpendicular field in acetylene, Fig. 1 (top), exhibits nine $(2,0)$ critical points lying along its internuclear axis and a central critical point that is a saddle point, a $(2,0)$ critical point with real eigenvalues. The name derives from its phase portrait being of the same form as for the gradient vector field derived from a scalar field that exhibits a saddle in two dimensions, as observed for a two-dimensional display of $\rho(\boldsymbol{r})$ in an internuclear region, for example. There is a $(2,0)$ centre point on each C—H bond path that coincides almost exactly with the position of the corresponding bond critical point. They serve as centres for diamagnetic current flows. There are two more centre points in each carbon basin, both of which lie relatively close to the carbon nucleus, one on either side. That on the hydrogen side serves as the locus for a small diamagnetic flow while the other serves as the centre of a much larger region of paramagnetic flow localized within the carbon basin. These two regions of flow are separated by trajectories originating and terminating at a saddle point that lies along the C—H bond path, close to the diamagnetic centre point. There are six off-axis critical points. The two lying along the C_2 axis serve as centre points for diamagnetic current flows, whose corresponding regions are separated by trajectories originating and terminating at the central saddle point. The remaining four off-axis critical points consist of two linked pairs of surface critical points, a pair of $(3, \pm 1)$ critical points, one pair for each C—H group. The surface each pair defines encompasses the C—H bonded current flow, as well as the flow about the two centre points within the carbon basin. The surfaces separate these regions from the diamagnetic flow about the entire molecule, as well as the diamagnetic flows about the C_2 symmetry axis.

Nuclear shielding in acetylenic molecules

The contributions to the shielding of the nuclei in the linear acetylenic molecules for a field applied parallel to the internuclear axis, $\sigma_{\|}$, arise from simple circular diamagnetic current flows about a $(2,0)$ stagnation path coincident with the molecular axis. One can compare the internal contributions $\sigma_{\|\mathcal{N}}(\mathcal{N})$ with the corresponding diamagnetic atomic Lamb shielding and, through a further comparison of the Lamb values with those obtained for perpendicular fields, $\sigma_{\perp}$, determine the deshielding resulting from the disruption of the atomic flows induced in the atomic basins by the bonding effects of neighbouring atoms.

The atomic contributions to the magnetic shielding of the nucleus indicated by a star are listed in Tables 1–3. Where known, experimental gas phase values or their shifts δ relative to a standard compound are indicated in the tables. The agreement between the calculated and experimental values is quite good for the C and H nuclei in the hydrocarbons. In all cases the trends predicted in the calculated values are in agreement with experiment, agreement that would improve if the calculations were carried out at the experimental rather than at the optimized geometries (8). In all cases, the remaining error is primarily in the internal contribution $\sigma_{\mathcal{N}}(\mathcal{N})$, the values listed under the starred atom.

The first observation concerns the basic atomic nature of $\bar{\sigma}_{\mathcal{N}}$, its dominant contribution arising from the current induced within the atomic basin containing nucleus $\mathcal{N}$, an observation true, but to a lesser extent, even for a proton. The principal internal contribution is from the atomic-like diamagnetic current induced by a field parallel to the molecular axis and this value differs, in general, from the atomic Lamb value by less than 1%. Atomic charges determined by the atomic populations are also listed in the tables. There is a small variation in the value of the atomic Lamb shielding, which, in general, parallels the population. Note that in HCCF, the largest positive charge is on the carbon once removed from F, the mobile electron density in the triple bond responding to the transfer of density to F from C_α by a shift of 0.17 au in the C|C interatomic surface towards C_β.

There are no paramagnetic currents induced in the basins of the fluorine atoms by a perpendicular field, the current maps in Fig. 1 showing diamagnetic flows about a single centre point situated at the position of the nucleus in the basin of each of the fluorine atoms in both the mono- and di-substituted molecules, the flow in the difluoro molecule being more regular than that in the monofluoro molecule.

Table 1. Atomic contributions to carbon shielding in acetylene molecules in ppm.[a]

Acetylene	$\bar{\sigma}_C = 118.1\,(117.2)^b$		$\bar{\sigma}_L(C) = 266.1$

$\bar{\sigma}$	5.24	132.26	8.98	0.95	15.17	147.44

[a] $\sigma_\perp$ and $\sigma_\parallel$ denote the contributions to the shielding tensor from the indicated atom for a field applied parallel and perpendicular to the molecular axis, respectively. $\bar{\sigma}_L(C)$ is the atomic Lamb contribution, eq. [6].

[b] Numbers in parentheses are experimental values from ref. 27.

Table 2. Atomic contributions to fluorine shielding in acetylene molecules.

Fluoroacetylene	$\bar{\sigma}_F = 439.4$		$\bar{\sigma}_L(F) = 480.90$			
	H————	C————	C————F*		External $\sum$	Total
$q(\Omega)$	+0.142	+0.566	+0.044	−0.752		
$\sigma_\perp$	0.53	1.85	−1.28	412.91	1.10	414.01
$\sigma_\parallel$	0.08	1.43	6.52	482.14	8.03	490.17
$\bar{\sigma}$	0.38	1.71	1.32	435.99	3.41	439.40
Difluoroacetylene	$\bar{\sigma}_F = 488.8$		$\bar{\sigma}_L(F) = 480.75$			
	F————	C————	C————F*		External $\sum$	Total
$q(\Omega)$	−0.743	+0.743	+0.743	−0.743		
$\sigma_\perp$	0.89	1.81	−0.77	485.89	1.93	487.82
$\sigma_\parallel$	0.62	1.79	6.02	482.25	8.43	490.68
$\bar{\sigma}$	0.80	1.80	1.49	484.68	4.09	488.78

Correspondingly, the internal contributions to $\bar{\sigma}_F$ are very similar to the atomic Lamb values.

The presence of paramagnetic flows in the basins of the carbon atoms in all of the acetylene molecules greatly decreases the internal contributions to the magnetic shielding of the carbon nuclei for fields applied perpendicular to the axis, relative to their purely diamagnetic values found for the parallel field that are close to the limiting atomic Lamb values. This effect is most pronounced for the carbon adjacent to fluorine in HCCF where the internal contribution is reduced to 3 ppm. The value of this internal contribution to $\bar{\sigma}_C$ increases with the decreasing extent of the paramagnetic current flow in the basin of the carbon atom.

No paramagnetic flows are found with the basins of the hydrogen atoms, a general observation. The net charge on the hydrogen atom is relatively small in both HCCH and HCCF and the basin contributions are similar to the atomic Lamb values, being slightly greater for the atom with the larger population. The decrease in the perpendicular contribution is partly a result of the centre point for its diamagnetic flow

Table 3. Atomic contributions to hydrogen shielding in acetylene molecules.

being displaced off the proton to the position of the bond critical point on the interatomic surface.

The total external contribution to the shielding is less than 1% for a fluorine nucleus, around 12% for a carbon nucleus, and around 40% for a proton. Contributions from atoms twice or thrice removed from the nucleus in question are nearly independent of their chemical nature, β hydrogens contributing essentially equal amounts to the shielding of a carbon nucleus as does a β fluorine. γ Hydrogen and fluorine atoms contribute nearly equal amounts to the shielding of a proton and $\bar{\sigma}_H$ is the same for both HCCH and HCCF. The external contributions for a parallel field, which are purely diamagnetic, decay rapidly in value with an increase in distance from $\mathcal{N}$. The same atom in different molecules, even when neighbouring the atom in question, contributes nearly the same shielding to a given $\mathcal{N}$. However, the contributions from neighbouring atoms for perpendicular fields are greatly reduced from the parallel field result, and are frequently smaller than those from the next nearest neighbour. In some cases their contribution is negative, corresponding to a deshielding of the nucleus. Their behaviour is best understood in terms of the properties of the shielding density, first displayed by Jameson and Buckingham for the hydrogen atom, the fluoride ion, and the hydrogen fluoride molecule (16).

Properties of the shielding density

Contour maps of the shielding density defined in eq. [3] and displayed in Fig. 2 provide a visual understanding of the local contribution made by $\boldsymbol{J}^{(1)}(\boldsymbol{r})$ to the magnetic shielding of a given nucleus. The shielding density for a nucleus $\mathcal{N}$ attains its maximum value in the region of the nucleus and decays rapidly away from this point. For a fluorine atom, the current induced by a perpendicular field consists of simple diamagnetic loops flowing about a single centre point located at the nucleus, Fig. 1. The shielding density displayed in Fig. 2a for F in FCCF is correspondingly simple and similar in form, resulting in positive contributions to the shielding from all points within the atomic basin. However, the same fluorine shielding density in Fig. 2a exhibits both positive and negative contributions over the basin of the neighbouring carbon atom and the net contribution from this atom to the shielding of the F nucleus is small and deshielding, Table 2.

To understand this behaviour, consider first the contribution to the shielding density of a carbon nucleus resulting from the simple diamagnetic flow around the nucleus of a neighbouring F atom in FCCF, whose contribution to $\bar{\sigma}_C$ is again vanishingly small and is actually negative in the molecule HCCF. The display of the shielding density for C in FCCF, Fig. 2b, shows that the shielding density within the basin of the fluorine atom makes both positive and negative contributions to the shielding of the C nucleus. This behaviour is easily understood in terms of the $\boldsymbol{r} \times \boldsymbol{J}^{(1)}$ component of the shielding density operator: the upwardly directed flow of the trajectories on the bonded side of the F nucleus makes negative contributions to $\sigma(\boldsymbol{r})$, while their downwardly directed flow in the nonbonded region makes positive contributions. The resulting near cancellation of the two contributions to the shielding is more pronounced the less distorted the current flow in the basin of the neighbouring atom. Thus the smallest shielding contributions to C are from neighbouring fluorines.

The shielding density for a perpendicular field arising from a neighbouring carbon is more complex because of the presence of paramagnetic current flows. Thus the shielding of a F nucleus from the density that lies within the basin of the neighbouring carbon atom, Fig. 2a, shows an inner pair of competing contributions arising from the innermost diamagnetic flow about the carbon nucleus (and similar to that noted above for the whole of a neighbouring F basin) that are encompassed by a pair of outer regions of opposite sign, arising from the paramagnetic current flow. The net result is once again a near cancellation, leading to a small negative contribution to the shielding of a F nucleus from a neighbouring carbon atom in both FCCF and HCCF. The same inner and outer counter polarizations of the shielding density are observed for the basin of the carbon neighbouring the C nucleus serving as origin in Fig. 2b. The map also makes clear the deshielding effect that the paramagnetic currents generated within the carbon basin has on its own nucleus. The shielding density for C in FCCF, Fig. 2b, shows a positive peak encompassing the nucleus surrounded by a region of deshielding density and thus the internal contribution to the shielding for a perpendicular field is much reduced from the parallel one.

All of these features of the shielding density are of a general nature as can be seen from the remaining displays of the

Fig. 2. Displays of the shielding density for acetylenic molecules. The quantity plotted is the diagonal element of the shielding tensor corresponding to the direction of the applied field for unit field strength and unit nuclear magnetic moment, the quantity $\{\boldsymbol{r}_{\supset\mathcal{N}} \times \boldsymbol{J}_{\alpha}^{(1)}(\boldsymbol{r})/r_{\supset\mathcal{N}}^{3}\}_{\alpha}$. Solid (dashed) contours denote positive (negative) values. The contour values range from 0.01 to 800 ppm, as generated by the set $\pm 1, \pm 2, \pm 4, \pm 8 \times 10^{n}$ with n beginning at -2 and increasing in steps of unity to 2. The shielding densities are for F and C in FCCF, (a) and (b), respectively, for C_{α} and C_{β} in FCCH, (c) and (d), respectively, for F and H in FCCH, (e) and (f), respectively and for C and H in HCCH, (g) and (h), respectively. Only the nucleus serving as origin for the shielding density is labelled. The density exhibits the highest contour value of 800 au in the immediate vicinity of each shielded nucleus.

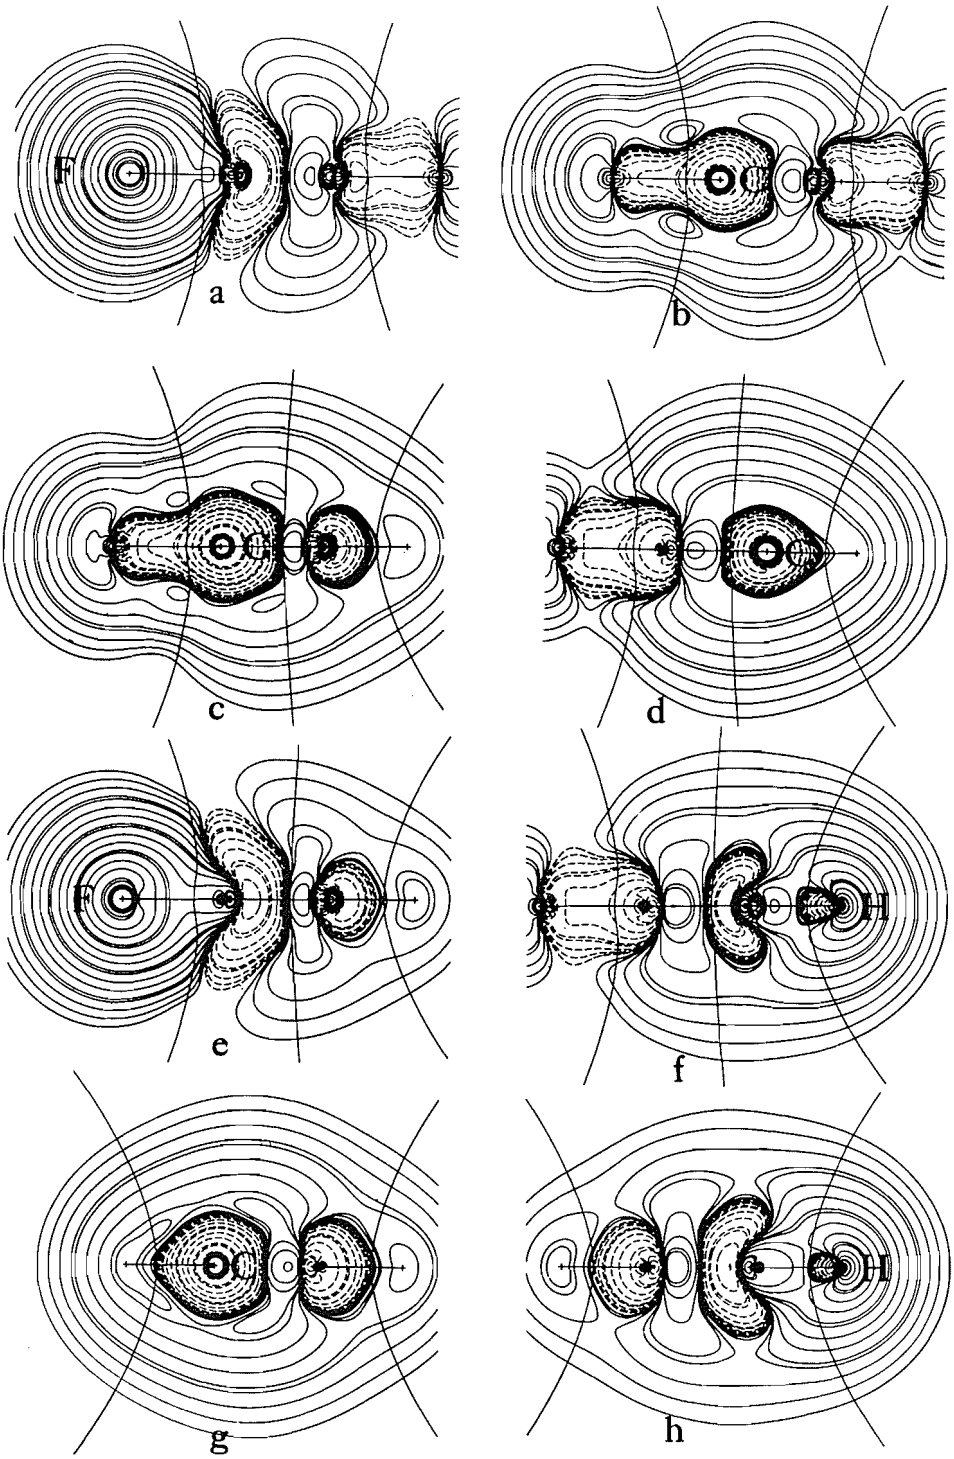

Table 4. Atomic contributions to proton shielding in hydrides in ppm.[a]

AH_n	q(H)	$\bar{\sigma}_L$(H)	$\bar{\sigma}_H$(H)	$\bar{\sigma}_H$(ex)[b]	$\sigma_{\parallel H}$	$\sigma_{\perp H}$	$\bar{\sigma}_H$	δ[c]

shielding densities given in Fig. 2. The differing internal contributions to the shielding densities, $\sigma_\perp(\boldsymbol{r})$, for the C_α and C_β nuclei in FCCH, Figs. 2c and 2d, are noteworthy. While C_α has a larger electron population than does C_β, as reflected in its larger atomic Lamb value and its correspondingly larger value for $\sigma_\parallel$(C), its overall shielding is less. Figure 2 shows this to be the result of a relative increase in the positive over the negative contributions to the shielding density $\sigma_\perp(\boldsymbol{r})$ within the basin of C_β compared to that found in the basin of C_α, changes that are reflected in the decrease in the value of $\sigma_\perp$(C) from 108 for C_β to 3 ppm for C_α. The behaviour of the internal shielding density for carbon in acetylene, Fig. 2g, is intermediate between that for C_β and C_α, as is its value of $\bar{\sigma}_C$ and its internal contribution $\sigma_\perp$(C). The shielding maps for a proton, Figs. 2f and 2h, exhibit a small negative region on its bonded side, a feature that, as illustrated below, is characteristic of the proton shielding density in non-ionic bonds.

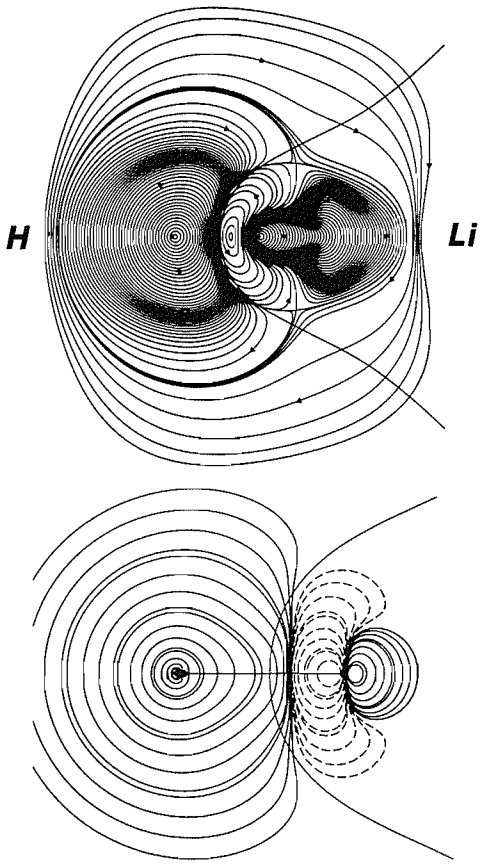
Proton shielding

In hydride molecules AH_n

The variation in the shielding of the proton and its atomic contributions through the series H_2 to HF are given in Table 4 and the current and shielding density plots for representative members shown in Figs. 3, 4, and 5. The shielding is a one-electron property and can be equated to a sum of orbital contributions, and the proton shielding in this set of molecules has been so discussed using localized molecular orbitals (8). The associated orbital current densities, which determine the orbital contributions to σ, are, however, not divergenceless and they do not meet the requirement of conservation of the current, as demanded of the real, physical current flow $\boldsymbol{J}^{(1)}(\boldsymbol{r})$ that is used here in the definition of the shielding density.

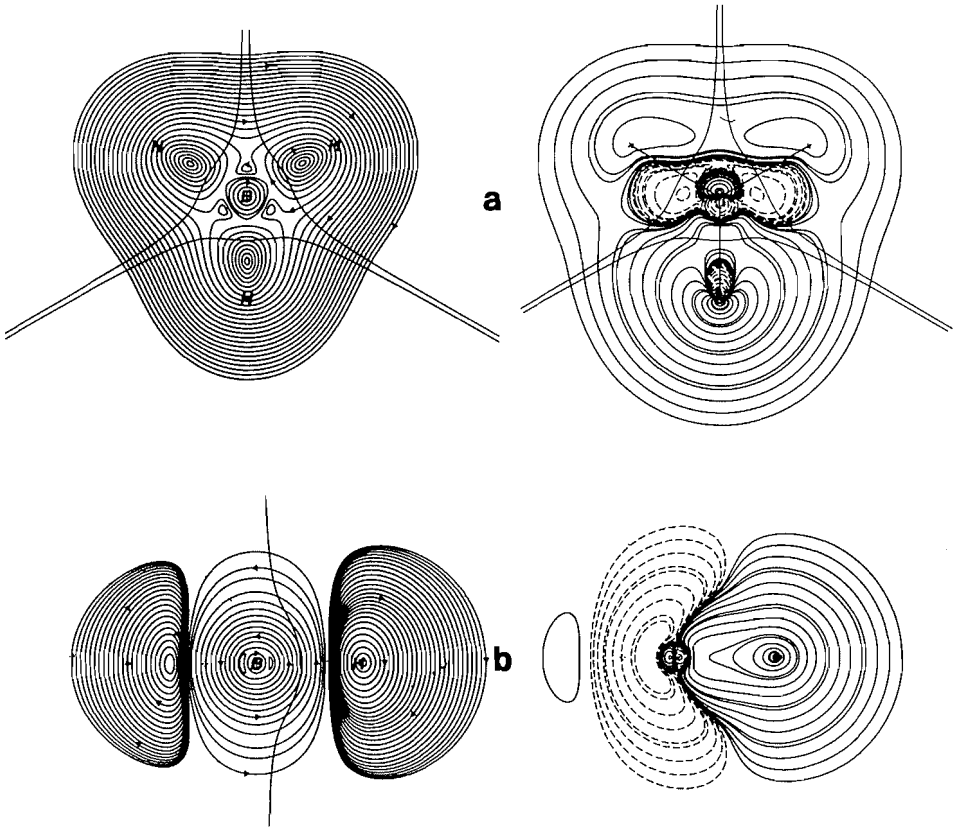
The currents in LiH, Fig. 3, and in BeH_2 given previously (2) are typical of ionic systems (see Table 4 for atomic charges). The currents for a $\perp$ field are, like the electron density, strongly localized within the individual atomic basins with circular diamagnetic currents flowing about a centre point in a hydride ion and a paramagnetic flow about a centre point localized within the cationic basin. The form of the

Fig. 3. Displays of the current and proton shielding densities in LiH for a field applied perpendicular to the internuclear axis. The shielding map is drawn to a slightly larger scale. Note the deshielding of the proton resulting from the paramagnetic current flow in the basin of the lithium atom.



shielding density for the proton in LiH, for a perpendicular field, is similar to and readily related to the form of the induced current, Fig. 3. The simple diamagnetic current flow in the hydrogen basin gives rise to a corresponding pattern of positive contributions to $\sigma_\perp(\boldsymbol{r})$. Since the current for a parallel field is perforce diamagnetic, the two field directions

Fig. 4. Displays of the current, on LHS, and proton shielding densities for the BH_3 molecule for a field applied perpendicular to the plane of the nuclei in (a) and for one parallel to this plane in (b). The lower proton serves as origin in the shielding density in (a). Note the deshielding contribution arising from the paramagnetic current flow in the basin of the boron atom for the parallel field. The B–H interatomic surface is shown only for the current map in (b).



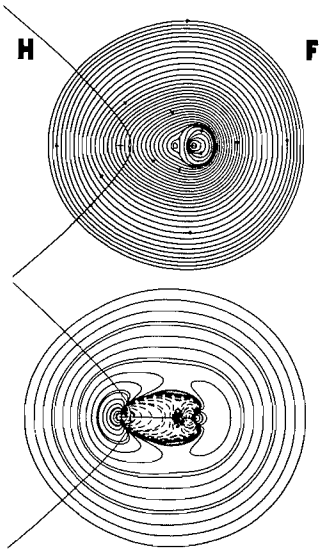
lead to nearly equal internal contributions and, because of their atomic nature, to values that closely bracket the atomic Lamb values. There is a one-to-one correspondence in the form of the paramagnetic and diamagnetic current regions with the deshielding and shielding regions of $\sigma_\perp(r)$ within the cationic basin, Fig. 3, and the resulting net deshielding contribution to $\sigma_\perp(r)$ effectively cancels the external contribution to $\bar{\sigma}_H$ resulting from the parallel field, a result that holds true for BeH_2 as well. Thus the $\bar{\sigma}_H$ values for the ionic systems LiH and BeH_2 are determined by the internal atomic contributions and are close to the corresponding atomic Lamb values.

A similar cancellation of the external contribution to $\bar{\sigma}_H$ occurs in BH_3, where a large paramagnetic flow for a field parallel to the plane of the nuclei and primarily confined to the basin of the boron atom, Fig. 4b, contributes to a net deshielding of the proton in the amount of −0.9 ppm. The reduced hydridic nature of BH_3, $q(H) = -0.7\ e$, is reflected in the movement of the centre point away from the position of the proton in the current induced by a field perpendicular to the molecular plane, leading to the formation of "bonded" current loops that are shared with the boron atom, Fig. 4a. Thus the internal shielding contributions are reduced by ≈5 ppm from the atomic Lamb value, as is the value of $\bar{\sigma}_H$. A considerable anisotropy in σ_H is predicted for this molecule, a result of the deshielding effect of the external contributions arising from the paramagnetic flow about the boron nucleus for a field applied parallel to the plane of the nuclei, as evidenced by the deshielding displayed in Fig. 4b.

The atomic contributions to the magnetic susceptibility $\bar{\chi}$ for LiH, BeH_2, and BH_3 mirror the same dominant properties of the current distributions. An atomic contribution to $\bar{\chi}$ is the sum of a basin contribution, determined by the atomic average of the magnetization density within the boundaries of the atom, and a surface contribution arising from the flux in the current through the interatomic surfaces bounding the atom (10). The atomic nature of the current in these ionic molecules results in near-vanishing contributions to $\bar{\chi}(\Omega)$ from the interatomic surface fluxes and the susceptibility is determined by the basin contributions $\bar{\chi}_b(\Omega)$. The value of $\bar{\chi}_b(A)$ is near zero for Li and *positive* for Be and B, a result of the magnetic dipole moment associated with the paramagnetic currents within the basins of these atoms being aligned parallel to the applied field, an effect that leads to large anisotropies in χ and to its relatively small values in these molecules.

In the remaining molecules, hydrogen is bonded to A in a covalent or polar manner and thus the external contribution to $\bar{\sigma}_H$ increases. The current for a perpendicular field in H_2 consists of a single set of elliptically shaped diamagnetic

Fig. 5. Displays of the current and proton shielding densities for the HF molecule for a field applied perpendicular to the internuclear axis.



flow lines about a single centre point situated at the bond midpoint (22). This flow is not dissimilar to the diamagnetic flow induced by a field parallel to the internuclear axis and the anisotropy in σ_H is less than 10%. Thus the internal contributions $\bar{\sigma}_H(H)$ for both field directions bracket the atomic Lamb value and the external contributions, which contribute 22%, are nearly isotropic. The general form of the current distribution for the parallel field in BH_3, Fig. 4, is typical of those induced for corresponding fields applied along a threefold axis in CH_4 and NH_3 and for one applied perpendicular to the plane of the nuclei in H_2O (2). The bonded flows in BH_3 are replaced by spiral pairs that become increasingly contracted towards the A nucleus across the row, reaching a limiting form in HF where the whole of the current for a $\perp$ field is dominated by the flow about a centre point located at the fluorine nucleus, Fig. 5. The small oval-shaped region of negative shielding density found on the bonded side of the proton in BH_3, Fig. 4a, and in the acetylenic molecules, Fig. 2, is also found in H_2 and is characteristic of the remaining molecules in this series. In the hydrides of N, O, and F it is contiguous with a deshielding region in the core of the heavy nucleus, as found for the proton in HF, Fig. 5. The paramagnetic currents generated by any field direction become increasingly smaller in methane, ammonia, and water and are absent in hydrogen fluoride. Correspondingly, there is a decrease in the negative regions of the shielding density from methane through to HF, as illustrated in Fig. 5 for HF. The result is a sharp increase in the external contributions to $\bar{\sigma}_H$, one that arises primarily from the current flows in the basins of the A atoms. The particularly large shielding of the proton in HF for a parallel field, Table 4, is primarily a result of the shielding density within the basin of the fluorine atom generated by the circular diamagnetic current flow induced about the molecular axis, a neighbouring carbon in acetylene having a similar effect in increasing the shielding of a proton. Jameson and Buckingham (16) also comment on the sizable contributions to the proton shielding arising from the shielding density in the region around the F nucleus.

The decreasing hydrogen population across the row is accompanied by a decrease in the internal shielding contribution that, with the exception of HF, differs by no more than 2 ppm from the atomic Lamb value. This decrease in shielding is offset by the accompanying increase in the external shielding from A, two effects that are almost equally balanced in CH_4, NH_3, and H_2O, accounting thereby for the near equality in their $\bar{\sigma}_H$ values.

In hydrocarbon molecules

The relative degree of shielding of the proton in ethane, ethene, benzene, and ethyne was the subject of much early speculation in the attempts to relate observed chemical shifts to electronic structure (1). The values of $\bar{\sigma}_H$ and its separate contributions for the principal field directions for these molecules are given in Table 5, together with their atomic contributions. An argument based on changing hybridization would suggest a deshielding of the proton through the series corresponding to the transfer of charge from hydrogen to carbon that accompanies the change in hybridization on carbon from sp^3 to sp^2 to sp. These charge transfers are indeed borne out by the populations given in the table but the shielding does not follow the anticipated trend. The question arises as to why the proton in acetylene is nearly as shielded as it is in ethane and why it is more deshielded in benzene than it is in ethene. Pople et al. (1) have provided qualitative explanations of these apparent exceptions and the atomic contributions for the parallel and perpendicular fields given in Table 5 bear out their arguments and place them on a quantitative level.

The internal contributions to the isotropic shielding of the proton, $\bar{\sigma}_H(H)$, do parallel the atomic Lamb values $\sigma_L(H)$ and hence the trend predicted on the basis of the hybridization arguments, with the shielding of the proton being largest in methane and ethane, nearly identical in ethene and benzene, and least for acetylene where the hydrogen bears a net positive charge, and is, indeed, acidic. However, when the external contributions to $\bar{\sigma}_H$ are taken into account, this trend is lost — the external contribution is too small for benzene and too large for acetylene — and, as discussed below, this is primarily the result of the contributions from the neighbouring carbon atom for a field parallel to the principal symmetry axis.

The largest shielding contribution from a neighbouring carbon occurs in acetylene, and its value for a parallel field, equal to 16.8 ppm, is five times larger than for a perpendicular field. The large shielding contribution for a parallel field is, as discussed above, a result of the unhindered diamagnetic current flow induced about the internuclear axis in this case. In ethane and ethene, on the other hand, the contributions from C_α for the two field directions are nearly equal and both are smaller in magnitude than $\sigma_{\|H}(C_\alpha)$ by ~13 ppm.

The contributions of C_α to the shielding of the proton in ethene and benzene differ by only 0.7 ppm for a field parallel to the plane containing the nuclei. However, for the field perpendicular to this plane, the contribution from C_α in benzene, the *ipso* carbon, is deshielding, equal to −4.2 ppm, while in ethene its value is nearly isotropic, decreasing by only 0.2 ppm from its value of 2.8 ppm for a parallel field. As

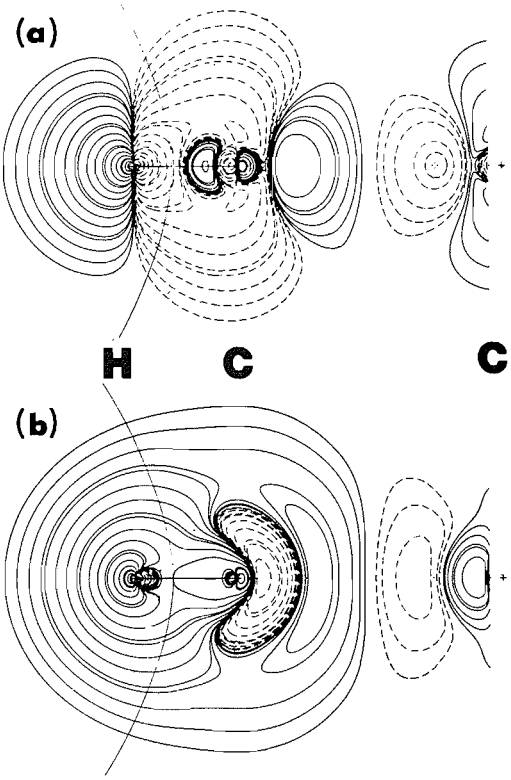
Fig. 6. Displays of shielding density for the proton indicated in each diagram in a σ_v symmetry plane containing the *ipso* and *para* carbon atoms. The *ipso* carbon is on the LHS and only a portion of the density over the basin of the *para* carbon is shown. (a) The applied field is perpendicular to the molecular plane. (b) The field is applied parallel to the molecular plane. The deshielding of the proton resulting from the density in the basin of the *ipso* carbon atom shown in (a) is generated by the ring current characteristic of an aromatic system. The bond path linking H to the *ipso* carbon is indicated along with the associated interactomic surface. The surface between the *ipso* and *para* carbons is planar and nearly coincident with the central positive and negative regions of the maps.



a result, the *ipso* carbon in benzene makes a zero contribution to the isotropic shielding of the proton compared to a value of 2.8 ppm from C_α in ethene.

This deshielding in benzene is a result of the substantial ring current induced on each side of the ring of carbon atoms by a perpendicular field, a current whose presence has been established by its accurate calculation and display (10), the most direct manner of demonstrating its existence. The negative contribution to the shielding density for the proton from within the basin of the *ipso* carbon atom in a perpendicular field, Fig. 6a, demonstrates that the magnetic field associated with the flow of the ring current through the basin of the *ipso* carbon atom reinforces the applied field over its basin, the effect responsible for the deshielding contribution of −4.2 ppm. Its form, with the large negative (deshielding) density in the basin of *ipso* carbon, is to be contrasted with that shown in Fig. 6b, the shielding density for a proton obtained for a field applied parallel to the plane of the ring. This latter density contributes +2.1 ppm to the shielding of the proton.

Waugh and Fesenden (25) modeled the effect of a ring current in terms of the field generated by a circular current of appropriate radius and obtained a value of −6.6 ppm for the deshielding, compared to the contribution of −4.2 ppm found here from the *ipso* carbon atom. The contributions to the shielding of a proton from the *ortho*, *meta*, and *para* carbons for an in-plane field exhibit a simple decay with increasing distance from the proton. However, for the perpendicular field, the contribution from the *ortho* carbon is zero, as opposed to *meta* and *para* contributions of 1.1 ppm. Thus there is a net deshielding of the proton resulting from the currents in the *ipso* carbon and a complete cancellation of the shielding and deshielding effects from those in the *ortho* carbon atoms.

Anisotropy in the proton shielding generally arises from the external contributions, as noted in the AH_n series, and in these molecules is predicted to be significant only in acetylene and benzene where $\Delta\bar{\sigma}_H = \sigma_{H\parallel} - \sigma_{H\perp} = 16.5$ and −5.6 ppm, respectively, the negative anisotropy in benzene being the result of the ring current. The ring current is also manifested in the nature of the atomic contributions to the magnetic susceptibility $\bar{\chi}$ for benzene, its large observed anisotropy being a result of the anisotropy in the C—C surface flux contributions, as opposed to an anisotropy in the basin contributions (10). Fleischer et al. (26), in studying LMO contributions to the proton shielding in benzene, find a π contribution of −3.2 ppm, which they ascribe to a ring current effect.

shielding constants $\bar{\sigma}_C$ for the first five members of the homologous series of normal hydrocarbons are presented in Table 6. The calculated shifts in shielding, relative to the value in methane, are in good agreement with experimental gas phase values. A comparison of the internal and external contributions to $\bar{\sigma}_C$ exhibits a remarkable feature: the whole of the variation in the shielding of a carbon nucleus arises from the basin contribution of the atom containing the nucleus in question, the external contribution to the shielding remaining essentially constant throughout the series, being independent of chain length and of the positioning of the nucleus within the chain.

The internal contribution is greatest for a primary carbon and increases with chain length. The external contributions are remarkably constant for equivalent atoms or functional groups, excluding methane. The contribution from a hydrogen bonded directly to the atom containing nucleus C, a contribution labelled $\bar{\sigma}_C(H_\alpha)$, exhibits characteristic values equal to 4.2 ppm when bonded to a methyl carbon and to 4.0 ppm when bonded to a methylene carbon. Similarly, contributions from methyl and methylene groups bonded directly to the carbon in question and denoted by $\bar{\sigma}_C(G_\alpha)$ both exhibit equally constant values as do the same groups once removed, contributions denoted by $\bar{\sigma}_C(G_\beta)$. Thus, replacing the neighbouring methyl group in ethane by a succession of three methylenes and a methyl group to obtain pentane, yields external contributions of 3.7, 0.6, and 0.3 from the methylene groups and 0.2 ppm from the terminal methyl. These values sum to yield 4.8 ppm, identical to the shielding contribution from the single methyl group in ethane.

This behaviour is not unique to the parent hydrocarbons but applies equally to their derivatives, as illustrated by the corresponding data for the normal alcohols given in Table 7. If one differentiates between the shielding of a carbon nucleus adjacent to the OH group and one once removed, one then recovers nearly constant external group contributions that sum to the same total value, with the exception of methanol. The OH group, for example, contributes 4.7 ppm to the shielding of an adjacent carbon nucleus, the same as the average shielding provided by a neighbouring methyl group. The methyl and methylene group contributions are the same, to within a few tenths of a part ppm, as those found in the parent hydrocarbons. These results indicate the possibility of assigning a set of group contributions to the shielding of a given nucleus in homologous series of molecules, the value depending upon the group's position relative to the nucleus in question. Equally useful is the knowledge that the external contribution is fixed for a carbon nucleus in a given homologous series of molecules, $\bar{\sigma}_C$(ext) equaling 17.7 ppm for a hydrocarbon and 17.4 ppm for a carbon in a normal alcohol not bearing the OH group and 15.6 ppm for the carbon that does.

The internal contribution to the shielding of the carbon nucleus in both series of alcohols is not constant and, as

found for the hydrocarbons, it is the change in the internal contribution that is responsible for the substituent effect on the shielding $\bar{\sigma}_C$.

Shielding of nitrogen, oxygen, and fluorine nuclei

The behaviour found for the internal shielding of carbon nuclei is general. Table 8 lists the isotropic shielding tensors for nitrogen in the amino group, oxygen in the hydroxyl group, and fluorine nuclei in their methyl, ethyl, and propyl derivatives and in the series obtained by linking these same groups to the fragment YCH_2CH_2- with Y = CH_3, NH_2, OH, or F. We have previously illustrated how the contributions from a X = OH or F group to the population energy, volume, and magnetic susceptibility in the homologous series $CH_3(CH_2)_n$-X, assume essentially constant values when $n = 1$ or more. With the exception of methyl amine, the net charges on N, O, and F, $q(\Omega)$, and their contributions to the magnetic susceptibility, $\bar{\chi}(\Omega)$, are remarkably constant throughout both sets of molecules for the N, O, and F atoms. The same is not true of the shielding of their nuclei, however, and nearly the whole of the variation has its origin in the current flow within the basin of the atom containing the nucleus in question, the quantity $\bar{\sigma}_{\mathcal{N}}(\mathcal{N}) = \bar{\sigma}_{\mathcal{N}}(\text{int})$, as found above for the carbon nucleus. The external contributions throughout the series of molecules for all three nuclei exhibit only small variations. The individual contributions from chemically equivalent atoms, such as the hydrogens bonded to N and O or a methylene group bonded to N, O, or F or once removed, also exhibit only small variations. An NH_2, OH, or F group, bonded to a β carbon, makes a nearly constant contribution to the shielding of all three nuclei throughout all three series of molecules.

Thus substituent effects on the shielding of C, N, O, and F nuclei in these saturated systems are the result of small perturbations in the shielding density transmitted to the basin of the atom containing nucleus $\mathcal{N}$. What is remarkable is that these same substitutions and their accompanying perturbations leave the shielding contribution from the remainder of

the molecule unchanged. Clearly, the division of the magnetization density $\boldsymbol{r}_{\mathcal{N}} \times \boldsymbol{J}^{(1)}(\boldsymbol{r})$ by $r_{\mathcal{N}}^{-3}$, as found in the shielding density, causes the result that any perturbation of the current is most pronounced in the basin of nucleus $\mathcal{N}$ and, in the examples of saturated systems presented here, the effect is restricted to just this single contribution to within ±0.1 ppm. Even for unsaturated systems such as the acetylenes, the external contributions to the variations in nuclear shielding are small relatively and absolutely, contributing 2 or 3% to $\bar{\sigma}_C$ and less than 1% to $\bar{\sigma}_F$. While LMO contributions to σ predict essentially constant isotropic contributions from atomic core orbitals (8), this does not imply that the substituent-related perturbations of the shielding density do not occur close to nucleus $\mathcal{N}$, the opposite being evident for the carbons in Fig. 2. The result implies only that core orbitals are not appreciably mixed in by the angular momentum perturbation operator. In general, even LMO's removed from atom $\mathcal{N}$ will have tails that contribute to the shielding density in the basin of atom $\mathcal{N}$.

Conclusions

This paper provides a theoretical basis for the atomic nature of the magnetic shielding of nuclei. It does so by relating the shielding to the magnetic field exerted at a nucleus generated by the induced current, the primary contribution arising from the flow of current within its own atomic basin. An electronegative atom such as fluorine in a polar bond, or hydrogen in a hydridic molecule, exhibits an atomic-like diamagnetic current flow within its basin for all field directions and the internal contribution to $\bar{\sigma}_{\mathcal{N}}$ approaches the atomic Lamb value, $\bar{\sigma}_L(\mathcal{N})$. There is a correlation of the internal contribution to the shielding of a proton with the electron population of H that can, in some instances, carry over to $\bar{\sigma}_{\mathcal{N}}$ itself. However, in general, the effect of bonding on other atoms is to generate paramagnetic current flows of increasing extent within their basins and the internal contribution to the shielding is correspondingly reduced relative to $\bar{\sigma}_L(\mathcal{N})$. Because of this effect, there is, in general, no correlation of $\bar{\sigma}_{\mathcal{N}}$ with the electron population of atom $\mathcal{N}$.

A neighbouring atom X shields nucleus $\mathcal{N}$ from a field applied parallel to the X—$\mathcal{N}$ bond, but its shielding for a field perpendicular to the X—$\mathcal{N}$ bond is greatly reduced and may be deshielding, a direct consequence of the dependence of the shielding density on the appropriate components of $\boldsymbol{r}_{\mathcal{N}} \times \boldsymbol{J}^{(1)}(\boldsymbol{r})$. The most important observation concerning the contribution of neighbouring groups to the shielding of a nucleus, however, is its near constancy in many systems. As shown here, essentially all of the variations in the shielding of C, N, O, and F nuclei in different series of saturated molecules originate within the basin of the atom containing $\mathcal{N}$, the nucleus in question, the contribution from the groups making up the remainder of the molecule being independent of their number and, if sufficiently removed from $\mathcal{N}$, even of their chemical nature. This constancy in the external shielding contribution is obtained whether $\mathcal{N}$ is a terminal or an interior atom. Thus the external contribution to the shielding of a carbon nucleus at any position within a hydrocarbon containing two or more carbons is 17.6 ± 0.1 ppm.

The essential observation to be made is that the difference in chemical shifts observed for nucleus $\mathcal{N}$ in different environments is primarily determined by changes to the shielding density occurring within the basin of the atom $\mathcal{N}$. For example, the external contribution to the shielding of a carbon nucleus in a wide variety of bonding situations is found to vary by less than 10 ppm for $\bar{\sigma}_C$ values that range from 63 to 217 ppm, a value that is reduced to 6 ppm if one excludes molecules with two or more fluorines bonded to carbon. The averaging of the shielding density over the region of the molecule external to atom $\mathcal{N}$ exhibits a remarkable insensitivity to the size of the system and even to the chemical nature of groups twice removed from the atom in question. In addition, chemically equivalent groups are found to contribute characteristic, identical amounts to the external shielding. It appears that the external contribution to $\bar{\sigma}_{\mathcal{N}}$ increases with a decrease in the electronegativity of $\mathcal{N}$, as evidenced by the external contributions to the shielding of the C, N, O, and F nuclei decreasing in the order 17.6, 10.6, 5.5, and 3.3 ppm, respectively, found here. All of these observations, which bring to the fore the essential atomic nature of the magnetic shielding of a nucleus in a molecule, are obtained as a consequence of averaging the shielding density over the individual atomic basins defined by the zero-flux surface condition of a proper open system (3).

Crystal chemistry of tetraradial species. Part 8. Mix and match: cation geometry, ion packing, hydrogen bonding, and π–π interactions in *cis*-2,2′-bipyridinium(1+) and 1,10-phenanthrolinium(1+) tetraphenylborates — and what about proton sponges?[1]

Pradip K. Bakshi, T. Stanley Cameron, and Osvald Knop

Abstract: The crystal structures at −20°C of *cis*-2,2′-bipyridinium(1+) (BPTB, $P2_1/n$, $a = 9.249(3)$, $b = 14.093(7)$, $c = 20.285(3)$ Å, $\beta = 92.86(2)°$, $Z = 4$) and 1,10-phenanthrolinium(1+) (PTB, $P2_1/c$, $a = 11.194(2)$, $b = 13.837(3)$, $c = 18.303(3)$ Å, $\beta = 107.82(1)°$, $Z = 4$) tetraphenylborates have been determined. Inasmuch as 1,10-phenanthroline is an aromatically bridged *cis*-2,2′-bipyridine, monoprotonation results, in both systems, in the formation of an intra-cation N—H...N′ hydrogen bond, the geometric and spectroscopic properties of which we have investigated. The cation skeleton in PTB is planar to 0.03(2) Å; in BPTB the dihedral angle between the two cation ring planes is 5.2°. In the pale yellow PTB there are significant π–π stacking interactions that persist into solution. The effect of protonation on the geometry of the 2,2′-bipyridine and 1,10-phenanthroline systems is examined in considerable detail and compared with the corresponding effects in the paraquat(2+) and similar cations. On both geometric and spectroscopic (infrared spectra between 10 and 295 K) evidence, the N—H...N′ hydrogen-bonding interaction is stronger in BPTB; in PTB this interaction is among the weakest reported in crystals, the ν(NH) stretching frequency at 10 K being as high as 3279 cm^{-1}. A detailed comparison of the geometries of the intra-cation N—H...N′ bonds in BPTB and PTB with those in classical and modified proton-sponge cations has led to the formulation of criteria useful in predicting the occurrence of proton-sponge-like properties.

Key words: bipyridinium ions, hydrogen bonding, phenanthrolinium ions, proton sponges, tetraphenylborates.

Résumé : Opérant à −20°C, on a déterminé les structures cristallines des tétraphénylborates du *cis*-2,2′-bipyridinium(1+) (BPTB, $P2_1/n$, $a = 9,249(3)$, $b = 14,093(7)$ et $c = 20,285(3)$ Å, $\beta = 92,86°$, $Z = 4$) et du 1,10-phénanthrolinium(1+), (PTB, $P2_1/c$, $a = 11,194(2)$, $b = 13,837(3)$ et $c = 18,303(3)$ Å, $\beta = 107,82°$, $Z = 4$). Comme la 1,10-phénanthroline est une *cis*-2,2′-bipyridine aromatiquement pontée, la monoprotonation de ces deux systèmes conduit à la formation d'une liaison hydrogène intramoléculaire N—H...N′ intra-cation dont on a étudié les propriétés géométriques et spectroscopiques. Le squelette du cation du PTB est plan à 0,03(2) Å près; dans le BPTB, l'angle dièdre entre les plans des deux cycles du cation est de 5,2°. Dans le PTB qui est jaune pâle, il existe des interactions d'empilement π–π importantes qui persistent même en solution. On a étudié en détail l'effet de la protonation sur la géométrie des systèmes de la 2,2′-bipyridine et de la 1,10-phénanthroline et on le compare avec les effets correspondants dans le paraquat(2+) et dans des cations similaires. Sur la base des données tant géométriques que spectroscopiques (spectres IR entre 10 et 295 K), l'interaction de la liaison hydrogène N—H...N′ est plus forte dans le BPTB; dans le PTB, cette interaction est l'une des plus faibles rapportés dans les cristaux, la fréquence d'élongation ν(NH) à 10 K ayant une valeur aussi élevée que 3279 cm^{-1}. Une comparaison détaillée des géométries des liaisons N—H...N′ intra-cation dans le BPTB et le PTB avec celles observées dans des cations classiques ou modifiés comme éponges à proton a conduit à la formulation de critères utiles pour prédire l'apparition de propriétés ressemblant à celles des éponges à proton.

Mots clés : ions bipyridinium, liaison hydrogène, ions phénanthrolinium, éponges à proton, tétraphénylborates.

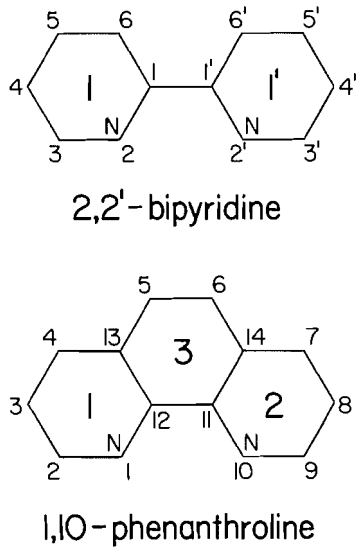
Fig. 1. Correlated numbering scheme for cation skeletons.



As part of our exploration of hydrogen bonding to aromatic π systems in crystals (2–5) we set out to investigate the nature of secondary bonding interactions in 2,2′-bipyridinium (BP) tetraphenylborate. Unaware at the time of the results of a preparative and ir study of BP salts of other anions (cf. below, refs. 6–8), we were not sure what stoichiometry and BP cation conformation to expect in a tetraphenylborate crystal, although the ionization constant of 2,2′-bipyridine (9) and the necessity of using strong acids to stabilize the BP^{2+} cation (10) pointed to the likelihood of a 1:1 rather than 1:2 stoichiometry. The 1:1 ratio eventually turned out to be the correct one, giving a product of the composition $(C_{10}H_9N_2)BPh_4$ (= BPTB), with the BP^+ cation in a very nearly planar *cis* conformation.[5] Since the near-planarity of the *cis* rotamer imparts aromatic character to the BP system, the BP^+ ion may be regarded as a subsystem of the aromatic, intrinsically planar 1,10-phenanthrolinium(1+) (= $phenH^+$) cation (Fig. 1). It therefore seemed of interest to see how differences between the two cations manifest themselves in the crystal structures of their tetraphenylborates, in which cation distortions resulting from cation–anion interaction could be expected to be small. Secondly, to the best of our knowledge no systematic investigation had previously been published of the effect of the dihedral angle ψ between the two phenyl ring planes on the C(1)—C(1′) and other bond lengths and angles in BP^+. While in BPTB ψ is only ~5°, angles of up to 19° have been reported in other BP^+ salts (cf. below). The present investigation thus seemed to offer an opportunity for assessing the effect of ψ from a statistical analysis of the observed variations in BP^+ geometry in crystals.

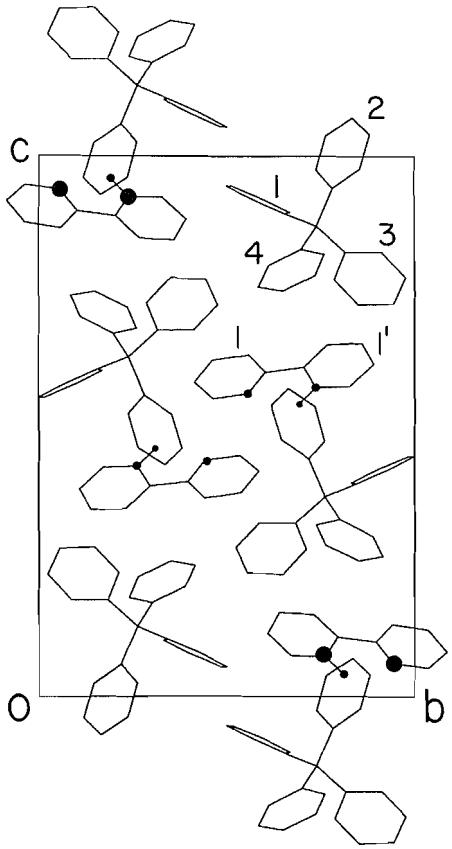
Crystals of $phenH^+$ tetraphenylborate (PTB) were, in contrast to the colourless BPTB, pale yellow. The appearance of colour was suggestive of charge-transfer interactions arising from π–π stacking, possibly of the kind observed in *N*,*N*′-Me_2-4,4′-bipyridinium(2+) (= paraquat, PQ^{2+}) tetraphenylborate (PQTB, ref. 11), and prompted an ^1H nmr investigation of PTB in solution. Furthermore, the comparison of the intra-cation hydrogen bonding in BPTB and PTB and other relevant structures, which was supplemented by a study of the ir spectra of the two solids at temperatures between 10 K and ambient, has led to an extensive comparison of these cations with proton sponges (an important class of proton-sequestering agents in which a captured proton is strongly held between two closely spaced N atoms of a rigid planar cation system, cf. below), and to formulation of geometric criteria useful in predicting the occurrence of proton-sponge-like properties.

The crystal data of BPTB and PTB at −20°C appear in Table 1. The positional parameters of the nonhydrogen (Table A) and hydrogen (Table B) atoms, the anisotropic thermal parameters of the nonhydrogen atoms (Table C), interatomic distances and bond angles (Table D), deviations from the best planes through the ring skeletons (Table E), correlated mean bond lengths and angles in *cis*-BP^+ and in phen systems (Table

[5] *Housekeeping note:* (*1*) All the 2,2′-bipyridinium(1+) cations discussed in this paper are *cisoid* rather than *cis* (i.e., of C_s symmetry). However, to avoid clumsiness, they will be referred to as *cis* throughout, with the dihedral angle ψ clearly specified. A similar practice will be followed for *trans* and *transoid* conformations. (*2*) Crystallographic esd's are quoted in parentheses. Standard deviations of means of bond lengths and angles etc. are quoted in square brackets. The means were computed with unit weights and their standard deviations do not take account of the esd's of the individual component values. (*3*) *Literature structures:* Atom numbering schemes other than those in Fig. 1 have been converted to match. Bond lengths and angles not quoted in the original papers have been calculated from the available information.

Fig. 2. Projection of the unit cell of BPTB on (100). Large circles, N atoms; small circles, H(N2′) atoms.



F), and summaries of bond lengths and angles in *cis*-BP^+ (Table G), $phenH^+$ (Table H), BP^{2+} (Table J), and 4,4′-BP^{2+} and PQ^{2+} Table K) salts have been deposited.[6]

Results and discussion

Crystal structures

Although the BPTB and PTB structures (Figs. 2 and 3) have the same space-group symmetry, they are not similar. However, the ion packing in the two must be of comparable efficacy, as the difference between the volume per formula unit is 24.1 Å^3, in agreement with the volume increment expected for the insertion of two aromatic ring carbons into BP^+, 25.4 Å^3 (12). Both structures are completely ordered.

The BP^+ cation has a *cis* conformation. Ring skeleton 1 is planar to 0.003[1] Å, ring skeleton 1′ to 0.002[1] Å, and ψ is only 5.2° (Table E). If the cation is treated as planar, the mean deviation of the nonhydrogen atoms from the best plane is 0.041[16] Å and the angles of the ring planes R1 and R1′ with the cation plane are ~2.6°. The bond lengths and angles in the cation are listed in Table 2. The thermal motion of the cation is satisfactorily described on the rigid-body-motion model (see Experimental).

The bond lengths and angles in the $phenH^+$ cation of PTB are listed in Table 2. The cation skeleton is planar to 0.029[17] Å; the individual rings R1, R2, and R3 are planar to 0.010[4], 0.011[5], and 0.007[4] Å, respectively, with the dihedral angles R2/R1 = 3.7°, R3/R1 = 1.2°, and R3/R2 = 2.6° (Table E), which indicates a slight departure from the ideal C_s conformation. The cations are confined to slabs ∥(100) which are cleanly separated by regions formed entirely by anion C—H bonds (Fig. 3, *left*). The PTB structure is unusual in that it consists of a bc packing of centrosymmetric (anion–cation–cation–anion) units arranged in such a way that the phenyl-2

Tables A, B, D, and G–K have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, CCDC, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

Fig. 3. Projections of portions of the PTB structure on (010) (*left*) and (100) (*right*).

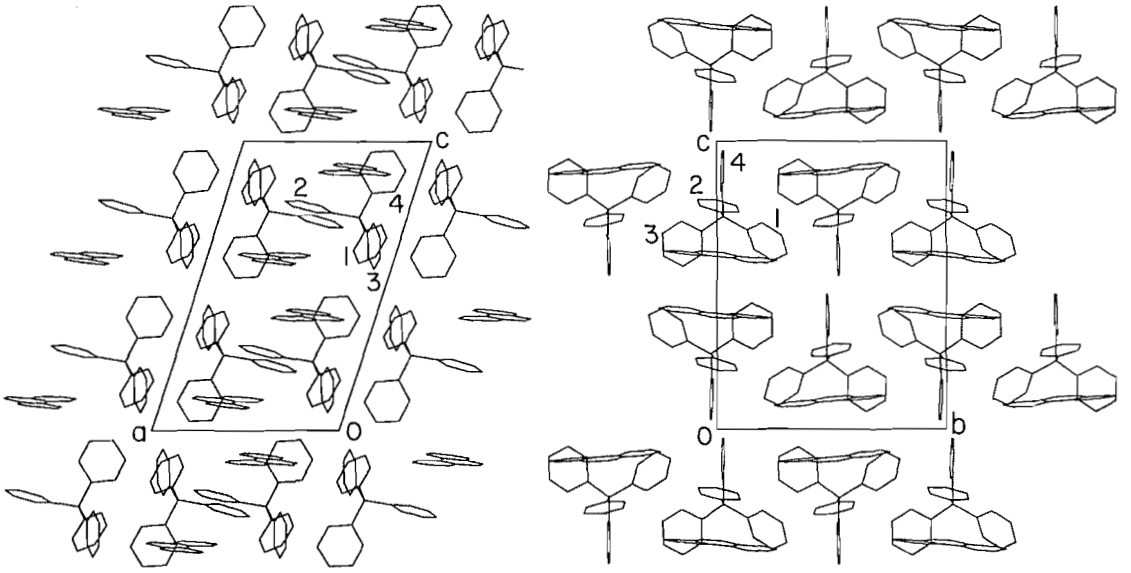

Fig. 4. π–π stacking in PTB. (*A*) Projection of the four-stack perpendicular to its pair of cation planes to display ring overlap. (*B*) Projection of the four-stack parallel to its cation planes to display spacing between ring planes. The features drawn in broken lines are related by inversion to those in solid lines. H(N10) atoms are indicated by black dots. Anion ring numbering as in Table A.

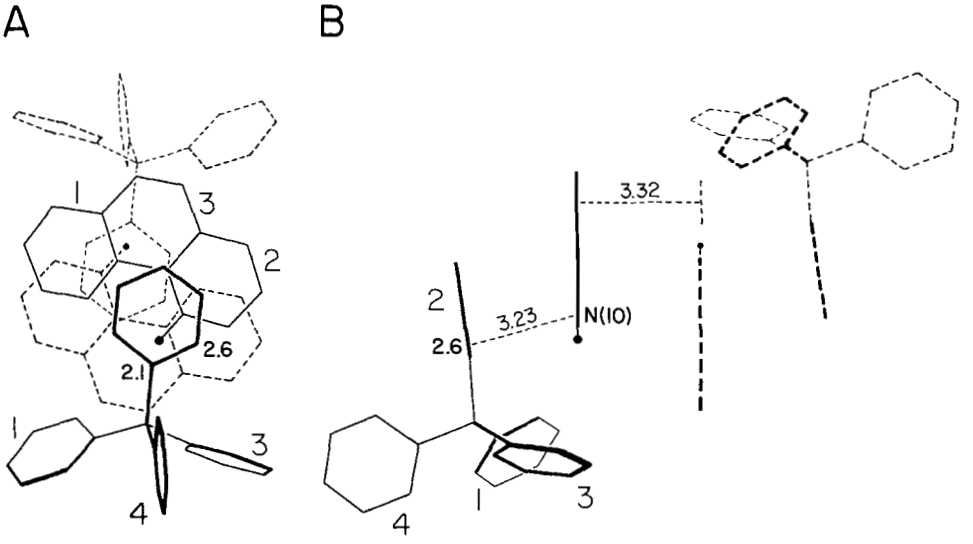
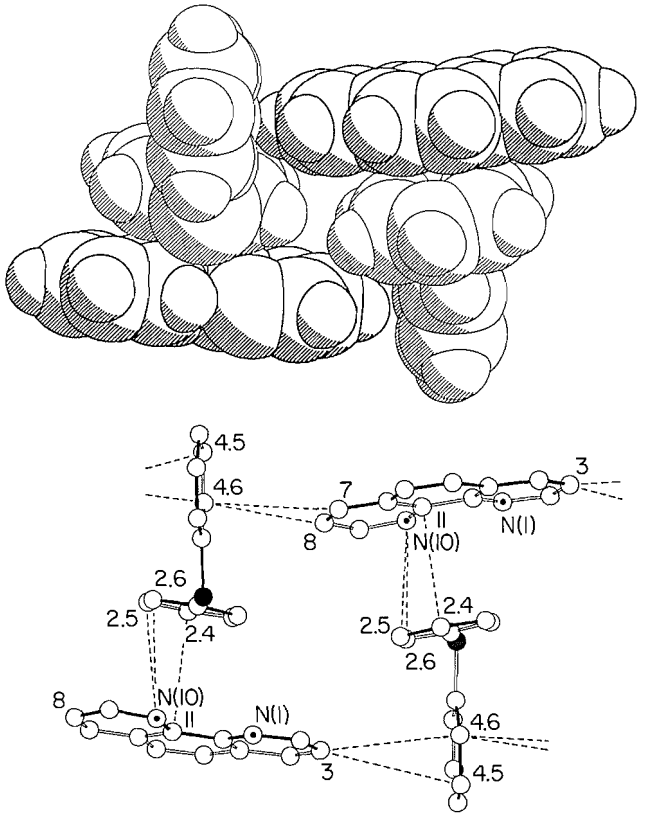


rings of the two anions are roughly parallel to the cation planes; the angle between the phenyl-2 and the cation planes is 9.8°. These four-stacks are clearly identifiable in Fig. 3 (*right*). Viewed perpendicular to the cation planes (Fig. 4*A*), adjacent phenyl-2 and phenH^+ rings are seen to overlap, as are the rings of the cation pairs. The perpendicular spacing between the cation ring planes is 3.32 Å (Fig. 4*B*). The shortest distances, in the region of overlap, between the carbons of phenyl-2- and the skeleton atoms of cation ring 2 are shown in Fig. 5. The perpendicular distances of N(10), C(11), and C(12) from the phenyl-2 plane are 3.15, 3.38, and 3.33 Å, respectively, i.e., ~3.3 Å on the average. As another interesting feature of the structure, the cation planes are nearly perpendicular (85°) to phenyl-4 rings in adjacent four-stacks, at ring-centre separations π_c(cat 1)...π_c(phenyl-4) and π_c(cat 2)...π_c(phenyl 4′) of 5.35 and 5.32 Å, respectively, and at the shortest C(cat)...C(an) distances illustrated in Fig. 5. These T-shaped edge-to-face orientations of cat–an pairs are thought to contribute to lowering of the crystal energy (cf. ref. 11 and below).

The arrangement of phenyl and cation rings in the four-stacks is indeed reminiscent of the π–π stacking in the red (deep yellow in acetone solution) PQTB, in which the centrosymmetric planar cation is sandwiched between two phenyl rings, one from each anion, at ψ(phenyl/cat) = 10°, and which also contains edge-to-face ring contacts (11). The PQTB structure is compared to PTB in more detail further on.

The H(N) atoms in BPTB and PTB were clearly visible in the respective difference maps (Fig. 6), at 1.10 Å from N(2′) in BPTB and 1.11 Å from N(10) in PTB. The protonation is associated with an increase in the CNC angle, in consequence of the strong σ-electron-withdrawing effect of the proton (1), and in

Fig. 5. π(cat)–π(an) stacking and edge-to-face inter-ion relations in PTB. (*Bottom*) Projection of two cat–an pairs in neighbouring four-stacks approximately on (100). A 2_1 axis relating the two pairs is roughly horizontal in the page. Only the relevant phenyl-2 and phenyl-4 rings are shown. Filled circles, B atoms; circles with dots, N atoms. Hydrogen atoms are not shown. (*Top*) Corresponding space-filling representation, slightly rotated for better visibility and with the H atoms included. Cations are drawn in heavier lines. Shortest cat–an distances in Å (broken lines): N(10)...C(2.5), 3.43; N(10)...C(2.6), 3.23; C(11)...C(2.4), 3.44; C(3)...C(4.5), 3.97; C(3)...C(4.6), 3.85; C(7)...C(4.6), 3.67; C(8)...C(4.6), 3.60.

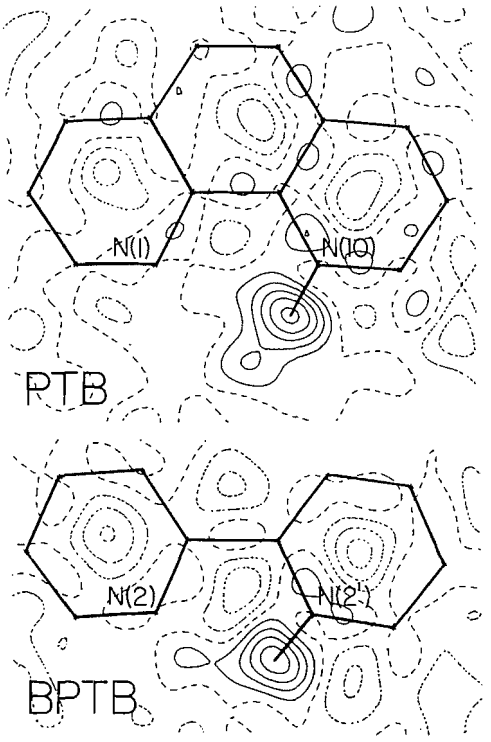


complete agreement with the analogous angle expansion in other BP^+ and $phenH^+$ salts (Tables 3 and G–K). The CNC angle at the protonated N atom, ~124°, can be compared with the 123.0° angle in the fully protonated BP^{2+}, and that at the unprotonated N with the 117.7° angle in 1,10-phenanthroline (= $phen^0$) (10, 19, 28; Table F). The H(N10)...N(1) distances and N(10)-H(N10)-N(1) angles in PTB are similar to those in the $phenH^+$ salts of the oxyacids (Table 3), in all of which there is a well-defined, strongly bent H-bond to an anion acceptor.[7]

The anion geometry in BPTB and PTB (Tables D and E) closely approximates the mean tetraphenylborate geometry described in ref. 3, except that in BPTB the symmetry of the $BC(\alpha)_4$ tetrahedron, though low, is recognizably related to S_4, whereas that of the distorted tetrahedral $BC(\alpha)_4$ core in PTB is not.

[7] Recently (21) a similar situation has been reported in the structure of **14** where the N-H-N angle corresponding to N(10)-H(10)-N(1) is only 97° and the H(N)...N distance is 2.56 Å (Table 3); cf. also ref. 23 and **ak** in Table 4).

Fig. 6. Difference Fourier maps revealing the positions of the H(N) atoms in the N(2)-C(1)-C(1′) cation plane of BPTB and the N(1)-N(10)-C(5) cation plane of PTB. Contour interval, 0.05 e/Å^3.



Cation geometry in BPTB and PTB

Among the correlated interatomic distances and bond angles in Table 2 the only ones that differ by more than 3σ are those affected by the relationship of ring 1 to ring 1′ in BP^+ and of ring 1 to ring 2 in $phenH^+$, viz. the bond pairs C(1)—C(1′)|C(11)—C(12), N(2)...N(2′)|N(1)...N(10), and C(6)—C(6′)|C(13)—C(14), and the bond-angle pairs C(1)-C(1′)-C(6′)|C(12)-C(11)-C(14), C(1′)-C(1)-C(6)|C(11)-C(12)-C(13), and C(1′)-C(1)-N(2)|C(11)-C(12)-N(1) (in BP^+ the angles involved are all exocyclic). The 3σ intervals in all the other bond-length and bond-angle pairs overlap. This indicates that the main difference between BP^+ and $phenH^+$ is in the extent of the in-plane inclination of the essentially rigid C_5N rings to the central C—C bond. This in-plane bending is almost certainly a consequence of the formation of an intra-cation N—H...N′ bond, the latter of course being the reason for the existence of the *cis* conformation to begin with: no *trans*-BP^+ cation has been reported to date. In BP^+ the bending takes place in such a way that the N atoms come closer together, while at the same time the C(6)...C(6′) separation increases, with attendant changes in the exocyclic C-C-C angles at C(1) and C(1′) but not in the endocyclic angles. In $phenH^+$ the bending is restrained by the presence of ring 3: the normalized ratio of the separation (N(1)...N(10)):(C(11)—C(12)):(C(13)...C(14)) is 1.89(1):1:1.99(2) compared to the corresponding ratio (N(2)...N(2′)):(C(1)—C(1′)):(C(6)...C(6′)) of 1.76(1):1:2.07(1) in BP^+.

Interestingly, a paired *t* statistic (t_p) for matching pairs of bond lengths in the C_5N rings of BPTB and PTB shows (two-tailed *t* test at the 0.01 and 0.05 significance levels) that the bond lengths in the two cations come from the same population: $t_p = -1.62$, $t_{11,0.01} = 3.11$, $t_{11,0.05} = 2.20$. A corresponding test shows this even more strongly for the matching endocy-

clic angles: $t_p = 0.02$ for the same number of degrees of freedom. There is thus no fundamental difference in the geometric properties of the respective C_5N rings in BPTB and PTB. A similar comparison for pairs of bond lengths (but not angles) in the left-hand and the right-hand halves of each cation leads to the conclusion that in this respect rings 1 and 1′ in BP^+ are statistically equivalent, as are rings 1 and 2 in $phenH^+$.

Cation geometry: statistical treatment

It may be validly argued that the conclusions for BPTB and PTB alone are of limited significance. We have therefore compiled the geometric parameters of BP^+ and $phenH^+$ in a number of structures of acceptable quality (Tables 3, G, and H): eight sets for BP^+ (BPTB, **5–11**), four sets for $phenH^+$ (PTB, **1–3**);[8] both are of a reasonable size for statistical scrutiny. The results of the statistical comparisons are as follows.

(a) Bond lengths and angles in BP^+ compared to those in $phenH^+$ (Fig. 7)

The central C—C bond is significantly longer in BP^+ than in $phenH^+$, 1.476[9] as against 1.431[3] Å, and the angles flanking this bond (exocyclic in BP^+) are significantly different in the two cations. The C(5)-C(6)-C(1)|C(4)-C(13)-C(12) and C(5′)-C(6′)-C(1′)|C(7)-C(14)-C(6) angles (endocyclic in BP^+) also are significantly affected by the in-plane bending, as is the endocyclic N(2′)-C(1′)-C(6′) angle. The angles in the right half of the cation are affected more than those in the left, unprotonated half.

(b) Right half vs. left half (Figs. 7A, C)

The matching bond lengths in the two halves of $phenH^+$ are statistically equivalent at both the 0.01 and 0.05 significance levels; in BP^+ the lengths in the C(1)—N(2)|C(1′)—N(2′) and C(4)—C(5)|C(4′)—C(5′) bond pairs are weakly differentiated. Protonation thus introduces little left/right asymmetry

[8] The mean (uncorrected) bond lengths and angles in these two sets as well as in $phen^0$ (24), $(phen_2H^+)ClO_4^-$ (25), and $(phenH_2^{2+})(ClO_4)_2 \cdot H_2O$ (26) are listed in Table F. The bond lengths and angles in BPTB and PTB at −20°C and room temperature differ only within their stated esd's (results not presented here). The cation geometries in **4** and **12** are not sufficiently accurate to be combined with the others.

Fig. 7. Statistical comparison of matching experimental bond lengths and angles in the *cis*-BP^+ and $phenH^+$ systems. (*A*) Left half of the BP^+ cation compared to the right half. (*B*) BP^+ compared to $phenH^+$. (*C*) Left half of the $phenH^+$ cation compared to the right half. Orientations as in Fig. 1. Thin lines and unfilled angles: sample means of the matched pairs *not* different at the 0.01 (1%) or 0.05 (5%) significance levels. Heavy lines and filled angles: sample means different at the 0.01 or 0.05 significance levels.

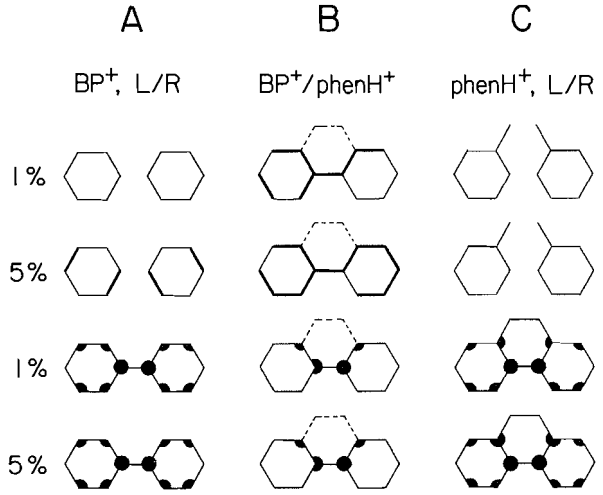

Fig. 8. Effect of protonation on experimental bond lengths and angles in the phen system (cf. caption of Fig. 7). (*A*) $phen^0$ compared with $phenH^+$. (*B*) $phenH^+$ compared with $phenH_2^{2+}$. (*C*) $phen^0$ compared with $phenH_2^{2+}$. Dotted lines: sample means of N(1)...N(10) distances, and of C(13)...C(14) distances, different at the 0.01 or 0.05 significance levels (large dots), or not different (small dots).

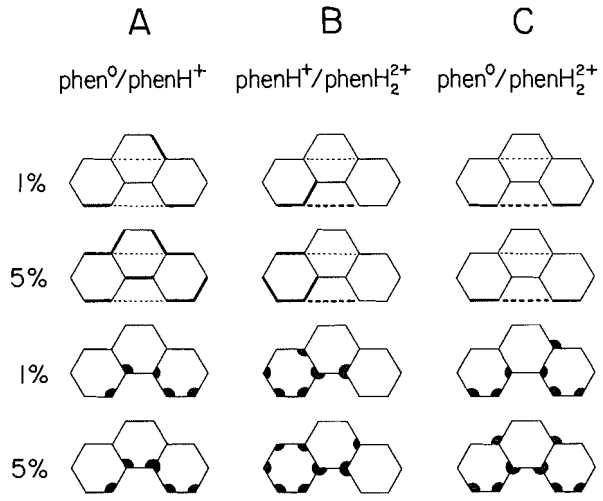
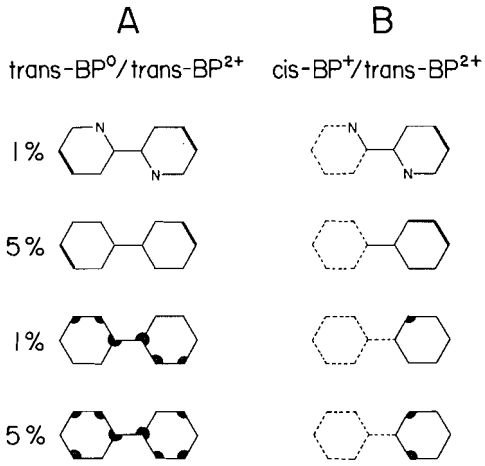


into the bond lengths of the BP^+ and $phenH^+$ ring systems (C(1)—C(1′), C(5)...C(6), and C(11)—C(12) are not testable). However, with the exception of C(3)-C(4)-C(5)IC(3′)-C(4′)-C(5′), *all* the *angles* in the two halves of BP^+ are statistically nonequivalent. A similar situation exists in $phenH^+$ (the peripheral angles in ring 3 are affected only weakly by protonation). The compensation for the increase in the endocyclic *ipso* angle on protonation is thus much more pervasive than for any change in the bond lengths.

Fig. 9. Effect of protonation on the geometry of the BP system (cf. caption of Fig. 7). (*A*) *trans*-BP^0 compared with *trans*-BP^{2+}. (*B*) Protonated ring 1′ of *cis*-BP^+ compared with one half of the *trans*-BP^{2+} cation.



(c) Effect of successive protonation on the geometry of the phen and BP systems (Figs. 8A–C, Table F)

The changes for phen are most simply described by comparing the [N(1)...N(10)]:[C(11)—C(12)]:[C(13)...C(14)] ratios normalized to C(11)—C(12): $phen^0$, 1.87(1):1:1.95(2); $phenH^+$, 1.90(1):1:1.99(2); $phenH_2^{2+}$, 2.02(1):1:1.98(1). On second protonation the repulsion between the two N-hydrogens considerably lengthens the N(1)...N(10) distance, by ~8% from 2.722[9] to 2.873[4] Å, and that in spite of the increased positive charge on the ion and the engagement of the two H(N) atoms in inter-ion H-bonds to the same anion oxygen (26).

Although protonation of BP^+ converts the cation conformation from *cisoid* to *transoid*,[9] one can still trace its effect on the ring geometry by comparing the lengths and angles in the protonated ring 1′ with those in the BP^{2+} rings (Fig. 9*B*). From the Cl^- (28), SO_3F^- (10), and $B_{10}H_{10}^{2-}$ (19) salts, for which the cation geometry is adequately defined (Table J), one finds that the effect of the protonation on the ring bond lengths and endocyclic angles in BP^+ is quite limited and that the lengths of the central C—C bond in BP^+ and BP^{2+} are statistically equivalent ($t_9 = 1.03$, $t_{9,0.01} = 3.25$, $t_{9,0.05} = 2.26$).

(d) The effect of ψ on BP geometry

The effect of the loss of aromatic character attendant on loss of cation planarity is difficult to establish. On the one hand, the central C—C bond would be expected to lengthen; on the other hand, the effect of *ortho* repulsions will be reduced. From the present data there is no evidence of it in *cis*-BP^+, where the reported ψ_{cis} angles range from 1.3° to 19.0° (Table G), nor is there any indication of a ψ-dependent trend in *trans*-

[9] The range of ψ (in a planar *trans* conformation, $\psi_{trans} = 0°$) in the BP^{2+} cation is considerable: $(BP^{2+})Cl_2$ (28), 18.9°; $(BP^{2+})Br_2$ (29), 21.2°; $(BP^{2+})(SO_3F)_2$ (10), 31.5°; $(BP^{2+})(SeOCl_4)$ (52), 35.1° and 35.9°; $(BP^{2+})(B_{10}H_{10})$ (19), 44.4°; $(BP^{2+})I_6$ (30), 48.9°. No BP^{2+} planar by symmetry appears to have been reported to date. The distortion of these *transoid* BP^{2+} cations from planarity has been attributed (10) to the presence of N—H(N)...X bonds, X = O, Cl, etc., but see the next section.

BP^{2+}, as shown by analysis of variance for the available three sets of bond length and angles ($18.9° \leq \psi_{trans} \leq 44.4°$, Table J). This is consistent with a similar finding for the two forms of 4,4′-bipyridinium(2+) nitrate (31, 32), in one of which ψ_{trans} = 0° and in the other, ψ_{trans} = 39.0°; the mean length of the central C—C bond is 1.484[4] Å (Table K).

(e) Length of the central C—C bond

This length is in fact codetermined by a number of factors, the separate effects of which may be difficult or impossible to evaluate from experiment. Examination of the means for this bond length (uncorrected, in Å; Table F), with the PQ systems included,[10]

$phen^0$	1.454[6]	$phenH^+$	1.431[3]	$phenH_2^{2+}$	1.421[7]
BP^0	1.490[3]	BP^+	1.476[9]	BP^{2+}	1.469[9]
PQ^0	1.367[4]	$phen_2H^+$	1.434[7]	4,4-BP^{2+}	1.484[4]
		$PQ^{\cdot+}$	1.422[22]	PQ^{2+}	1.477[21][11]

shows that unless obvious chemistry is at work (loss of ring aromaticity in PQ^0 and formation of a C=C bond, cf. ref. 36), statistically supportable conclusions about differences in this bond length in the above biphenyl-like systems cannot be made on the crystallographic evidence available at present. The overall mean of these means is 1.456[25] Å.

Cation geometry: calculation vs. crystallography

No ab initio calculations on the uncomplexed phen systems appear to be available, but a number of semiempirical and ab initio (STO-3G) calculations on the uncomplexed bipyridines and their cations have been reported (37–47). The main conclusions are as follows:

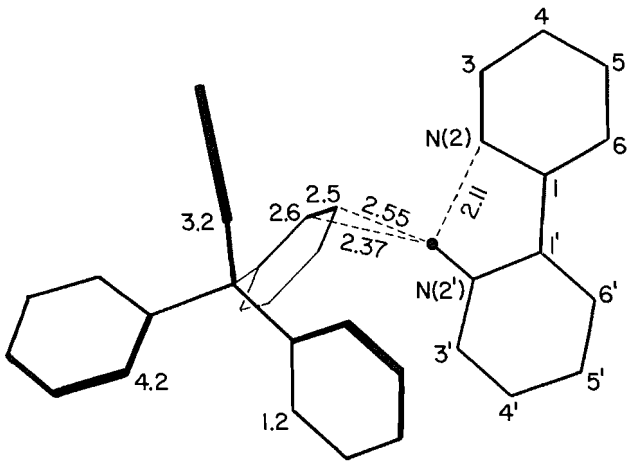
1. The energy minimum found in a semiempirical calculation for BP^+ (37, 38, 48) was at ψ_{cis} = 0°, with an indication of a small H(N2′)...N(2) interaction.
2. The ground-state conformation of BP^{2+} is *transoid*, ψ_{trans} = 41.9°, with a higher-energy *cisoid* conformation, ψ_{cis} = 54.3° (41, 43).
3. The ground-state conformation of BP^0 is planar *trans*, with a subsidiary energy minimum at $\psi_{cis} \sim 50°$ (38–40, 44–49). The C(1)—C(1′) bond length varies between only 1.512 and 1.518 Å from planar *trans* to planar *cis* and at equilibrium is close to the uncorrected experimental value of 1.490(3) Å (27).
4. The ground-state conformation of $phen^0$ is not C_{2v} but C_2; the barrier for interconversion is only 4.7 kcal/mol (47, 49). The CNDO/2 calculation for $phenH^+$ (50) points to a situation similar to that found for BP^+ (37).

These limited results (*i*) confirm that the effect of ψ on the C(1)—C(1′) bond length in BP^+ can be expected to be small and that on the ring bond lengths even smaller and thus likely to be masked by fortuitous effects in a crystal. (*ii*) The conversion of *trans*-BP^0 to *cis*-BP^+ on protonation is coincident with the formation of an intra-cation N(2′)—H(N2′)...N(2) bond, as observed (cf. below). (*iii*) The optimized ψ_{trans} of free BP^{2+} being ~42°, the observed substantial deviations of the cation from *trans* planarity (ψ_{trans} = 19–49°, Table J) cannot be claimed (10) as arising from inter-ion H-bonding interactions with the anion, though the latter probably are at least in part responsible for the observed departures of ψ_{trans} from the optimized value.

[10] The cation bond lengths and angles in $(PQ^{2+})Cl_2$ (33), $(PQ^{2+})Cl_2 \cdot 2H_2O$ (34), $(PQ^{2+})Br_2$ (33), $(PQ^{2+})I_2$ (33), $(PQ^{2+})[CuCl_4]$ (35), and $(PQ^{2+})(BPh_4)_2$ (11) are compared in Table K. This table also contains relevant details for PQ^0 and $(PQ^{\cdot+})PF_6$ (36).

[11] 1.468[9] Å if the 1.521[7] Å value for $(PQ^{2+})(BPh_4)_2$ (11) is not included.

Fig. 10. Cation geometry and hydrogen bonding in BPTB. Projection on cation planes; distances in Å. Putative H-bonds are indicated by broken lines. Filled circle, H(N2′). Ring carbons are identified by appropriate numbers (Table A).

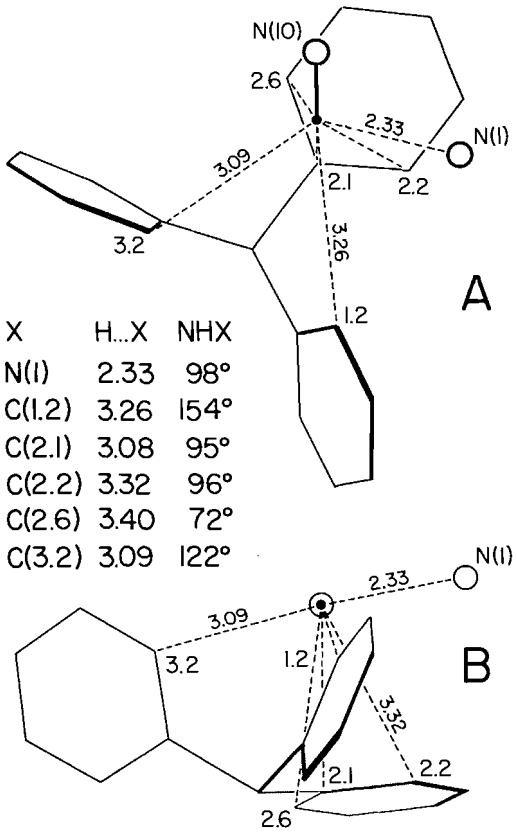


Hydrogen bonding: geometry

In BPTB only three interatomic distances qualify for possible H(N2′)...acc bonds: H(N2′)...N(2) = 2.11 Å, H(N2′)...C(2.6) = 2.37 Å, and H(N2′)...C(2.5) = 2.55 Å (Fig. 10). All the other H(N2′)...C(an) distances are at least 3.27 Å (Table D) and thus unlikely to give rise to effective H-bonding interactions (3). Although the N(2′)-H(N2′)-N(2) angle of 105° looks unfavourable even for a branched H-bond, the intra-cation H(N2′)...N(2) interaction must be significant: not only has the cation been forced into a *cis* conformation, but the N(2′)...N(2) separation, 2.610(5) Å, is 4% shorter than the corresponding mean N(1)...N(10) distance in $phenH^+$, 2.722[9] Å, and the C(6)...C(6′) separation, 3.078(8) Å, is 8% longer than the corresponding mean C(13)...C(14) distance in $phenH^+$, 2.846[24] Å (Table F). The H(N2′)...N(2) interaction must thus be strong enough to bend the *cis*-BP^+ ion in its plane and thus reduce the N(2′)...N(2) distance.

The N(2′)-H(N2′)-C(2.6) and N(2′)-H(N2′)-C(2.5) angles are 142° and 123°, respectively (Table 3). The distances of H(N2′) and N(2′) from the centre $\pi_c(2)$ of phenyl-2 of the nearest anion, 3.07 and 3.71 Å, respectively, and the corresponding mean distances $\bar{d}$[H(N2′)...C] and $\bar{d}$[N(2′)...C], 3.31[67] and 3.93[51] Å, respectively, are entirely consistent with the statistics of the branched H(N)...phenyl bonds in tetraphenylborates (Fig. 12 of ref. 3). Similarly, points for the differences Δ[H(N2′)...C] = $[H(N2')...C]_{max} - [H(N2')...C]_{min}$ and Δ[N(2′)...C] = $[N(2')...C]_{max} - [N(2')...C]_{min}$ for the C atoms of phenyl-2 fall within the distributions in Fig. 13 of ref. 3, where the Δ for a large number of N—H(N)...phenyl bonds are plotted against d[H(N)...π_c] and d[N...π_c], respectively, even though the Δ[H(N2′)...C] point is at the margin of the reference population. The N(2′)—H(N2′)...acc bond in Fig. 10 may thus be regarded as bifurcated, with an intra-cation com-

Fig. 11. Potential H-bonding acceptors X in PTB.
(*A*) N(10)—H(N10) bond and the cation plane are in the page.
(*B*) N(10)—H(N10) bond and the cation plane are perpendicular to the page, with H(N10) on top of N(10). Black dot, H(N10); 1.2 stands for C(1.2) in phenyl-1, etc. H(N10)...X distances are indicated by broken lines; NHX = N(10)-H(N10)-X. The fourth phenyl ring of the anion has been omitted.



ponent engaging the lone pair on N(2) and an inter-ion component pointing at phenyl-2 of the nearest anion at an angle of 93° between N(2′)—H(N2′) and the ring plane.

Support for this interpretation comes from the existence of similar bifurcated N(2′)—H(N2′)...acc bonds in other BP^+ cations (Table 3). For example, in **11** H(N2′)...Cl(1A) = 2.52(3) Å, N(2′)...Cl(1A) = 3.310 Å, and N(2′)-H(N2′)-Cl(1A) = 147°.[12] This clearly corresponds to an N—H(N)...Cl branch of a bifurcated N—H(N)...Cl, X bond, with characteristics very similar to those observed for the stronger component of the bifurcated N—H(N)...2Cl bond in, for example, $(Et_3NH)_2SnCl_6$ (53) and $(Et_2NH_2)_2\ SnCl_6$ (54).

We now turn to PTB, in which the potential H-bond acceptor environment is represented in Fig. 11. The shortest interatomic H(N10)...acc approach is H(N10)...N(1) = 2.33 Å, N(10)-H(N10)-N(1) = 98°. This situation looks even less favourable for an effective H-bonding interaction than that in BPTB. Furthermore, because the N(1)...N(10) distances in $phen^0$ and $phenH^+$ are statistically indistinguishable, and ditto for C(13)...C(14) (cf. above and Tables 2 and F), it cannot be argued that the $phenH^+$ ion in PTB is significantly distorted by in-plane bending as a result of an H(N10)...N(1) interaction, in contrast to the *cis*-BP^+ cation.

[12] [*x*, *y*, *z*] of Cl(1A) = [−*x*, −*y*, −*z*] of Cl(1) in ref. 20.

The shortest H(N10)...C(an) distances in reasonable directions are H(N10)...C(3.2) = 3.09 Å (N(10)-H(N10)-C(3.2) = 122°) and H(N10)...C(1.2) = 3.26 Å (N(10)-H(N10)-C(1.2) = 154°), the corresponding H(N10)—C vectors being more or less in the extended cation plane (Fig. 11). These distances are substantially longer than similar distances in BPTB. While for phenyl-3 the N(10)...π_c(3) = 4.35 Å, H(N10)...π_c(3) = 3.94 Å, $\bar{d}$[N(10)...C] = 4.54 Å, $\bar{d}$[H(N10)...C] = 4.12 Å, Δ[N(10)...C] = 1.44 Å, and Δ[H(N10)...C] = 1.95 Å distances, though long, still fall within the respective plots for the bifurcated N—H(N)...π bonds of ref. 3, the corresponding distances for phenyl-1 are all well outside the populations of these plots.[13] It is therefore reasonable to view the geometry at H(N10) as corresponding to a very weak bifurcated N(10)—H(N10)...N(1),phenyl-3 bond with the H(N10)...N(1) branch as the stronger component. However, if the H(N10)...C(3.2) distance of 3.09 Å is admitted as a component of a bifurcated H-bond at an N(10)-H(N10)-C(3.2) angle of 122°, then the H(N10)...C(2.1) and H(N10)...C(2.2) distances of 3.08 and 3.32 Å, respectively, cannot be ignored, even though the corresponding N-H(N)-C angles are only ~95°, i.e., with the N(10)—H(N10) bond close to parallel to the phenyl-2 plane (Figs. 4*B* and 11*B*). So little is known about such H-bonding interactions that judgment must be reserved, for the present, as to the significance and importance of the participation of phenyl-2 in the H-bonding, but if the latter *is* claimed to be involved, then H(N10) will be described as bonded to N(1), phenyl-3, and phenyl-2, i.e., forming a branched H-bond of a type not provided for in the classification of ref. 3.

Hydrogen bonding: infrared spectra

As a supplement to crystallography we examined FT-ir spectra of fluorocarbon mulls of BPTB and PTB in the 3700–2700 cm^{-1} region between 10 and 295 K. In the 10 K spectrum of PTB a single sharp, unsplit ν(NH) peak was observed at 3278.7 cm^{-1}, well resolved from the ν(CH) absorptions, and of a height comparable to that of the strongest ν(CH) peak (Fig. 12). With increasing temperature this peak shifted progressively and smoothly to slightly lower frequencies (Fig. 13). The frequency lowering between 10 and 295 K amounted to 6.5 cm^{-1} (8.2 cm^{-1} when ν(NH) is referred to the strongest ν(CH) absorption, the frequency of which increased somewhat with temperature). There was no indication of a thermally induced phase transition in this spectral region.

The ν(NH) absorption in the 10 K spectrum of BPTB (Fig. 12) consisted of a prominent peak at 3147.2 cm^{-1}, of approximately twice the height of the strongest ν(CH) absorption. The peak showed incipient splitting, and there was no clean separation between it and the ν(CH) absorptions. In addition, it was flanked on the high-frequency side by small, well-resolved satellite peaks at 3199.3, 3183.2, and 3170.3 cm^{-1}, and on the low-frequency side by a subsidiary peak at 3125.1 cm^{-1}. The main peak and the subsidiary peak were replicated, on weak deuteration, at 2358.0 and 2344 cm^{-1}, respectively, confirming the correctness of the ν(NH) assignment (ν(NH)/

[13] The distance H(N10)...C(1.2) = 3.26 Å would correspond to an edge-on H-bond, i.e., almost an H(N10)...H(1.2) bond, unlikely to qualify for a π interaction, cf. Fig. 10 of ref. 3.

Fig. 12. The ν(NH) and ν(CH) region of the FT-ir spectra of BPTB and PTB in fluorocarbon mulls at 10 K. The principal ν(NH) stretching absorptions are indicated by blacks dots (see text).

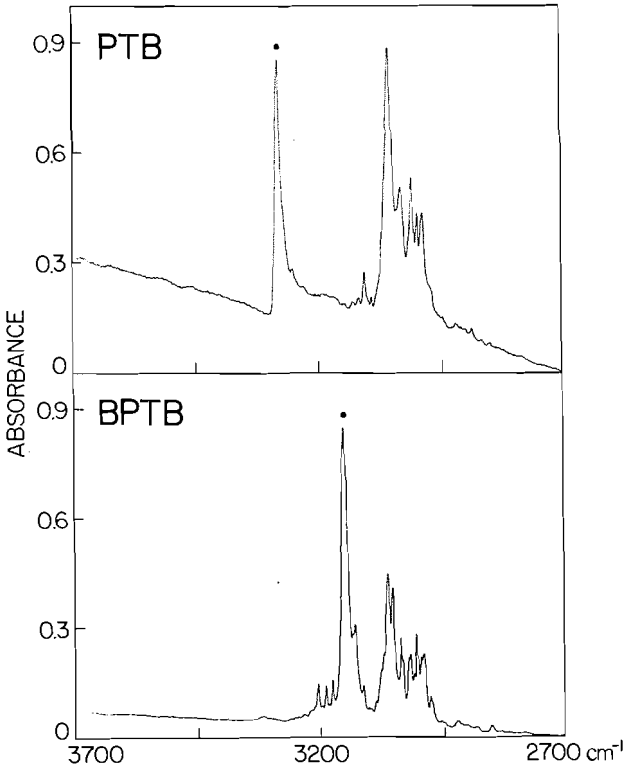


Fig. 13. Variation of the ν(NH) stretching frequency in BPTB and PTB with temperature. The quadratic regression of ν(NH) on T is represented by the solid line. Open circles: ν(NH) lowering referred to the frequency of the highest ν(CH) peak (see text). The broken line is to guide the eye only.

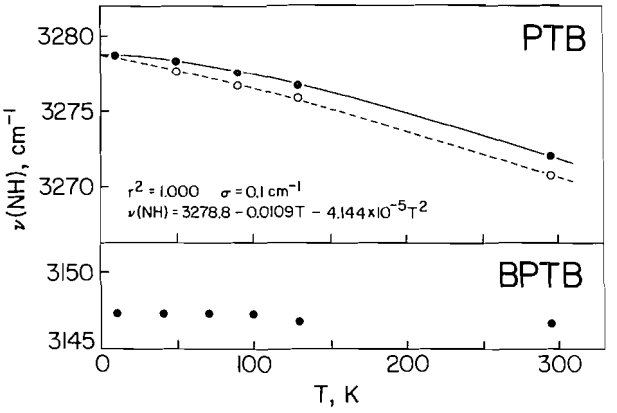


ν(ND) = 1.333). It was not possible to say with certainty whether or not the satellites were present also in the ν(ND) region; their origin and the origin of the splitting of the main peak were not investigated further.[14] The frequency of the ν(NH) absorption remained practically unchanged with temperature (Fig. 13).

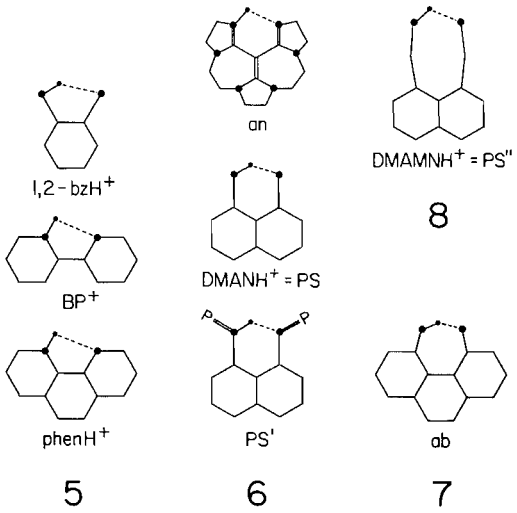
The high frequency of the ν(NH) peak in the PTB spectrum is indicative of very weak H-bonding,[15] while the negative $d\nu/dT$ coefficient is consistent with the strengthening of a branched or highly bent N—H...acc bond with increasing temperature (58). To understand the nature of the H-bonding in PTB let us consider the following. The room-temperature ν(NH) frequencies reported in ref. 22 are in the range 3300–3100 cm^{-1} for the anhydrous ClO_4, BF_4, and I salts of $phenH^+$, but between 2950 and 2600 cm^{-1} for the hydrated Cl and Br salts, as confirmed by deuteration and having assigned the ν(OH) absorptions between 3430 and 3250 cm^{-1}. The crystal structure of $(phenH^+)ClO_4$ contains an H(N10)...$OClO_3$ = 2.25 Å bond; the H(N10)...OH_2 distance in the hydrated chloride is 1.91 Å, as are the H(N10)...O(an) distances in the anhydrous NO_3 and HSO_4 salts (Table 3). It thus seems that in those $phenH^+$ salts in which H(N10) is bonded to the oxygen of a water molecule or of a strongly H-bonding anion the ν(NH) frequency is in the 2950–2600 cm^{-1} range, whereas in the salts containing the weakly H-bonding ClO_4^-, BF_4^-, and I^- anions it is in the 3300–3100 cm^{-1} range. On this premise, and keeping in mind that on geometric evidence the H-bond involving H(N10) is bifurcated, we suggest that ν(NH) frequencies in the 3300–3100 cm^{-1} range result from N(10)–H(N10)...N(1) dominated H-bonds, whereas the 2950–2600 cm^{-1} frequencies correspond to bonds dominated by inter-ion N(10)—H(N10)...X interactions. Consequently the 3279 cm^{-1} absorption observed in the 10 K spectrum of PTB originates in a bifurcated H-bond dominated by the N(10)—H(10)...N(1) intra-cation interaction and, being well defined and "isolated," its frequency can be adopted as a standard for this type of H-bond. The effect of the increasing amplitude of thermal motion on the H(N10) atom will then be to bring this atom, dynamically, closer to the N(1) acceptor, increase the N(10)-H(N10)-N(1) angle, and thus strengthen the H-bonding interaction, as manifested in the observed lowering of the ν(NH) with increasing temperature.

In BPTB the frequency of the principal ν(NH) absorption at 10 K, 3147 cm^{-1}, is about 130 cm^{-1} lower than that in PTB, pointing to a stronger H-bonding interaction. The increased strength of the bifurcated N(1′)—H(N2′)...N(2),phenyl-2 bond in BPTB is consistent with the shorter intra-cation H(N2′)...N(2) distance and with the shortest H(N2′)...C(an) distances, H(N2′)...C(2.6) = 2.37 Å and H(N2′)...C(2.5) = 2.55 Å, both much shorter than similar distances in PTB (Fig. 10). The almost zero temperature dependence of ν(NH) in BPTB can arise from several conceivable causes and no definite scenario can be offered at present. For comparison, the frequency

[14] The room-temperature ν(NH) absorptions reported in ref. 6 for anhydrous BP^+BF_4, BP^+ClO_4, and BP^+SbCl_6 were also composite. Since the cation conformation in those salts is almost certainly similar to that in BPTB regardless of the nature of the *purely inorganic* counter-anion, the complexity of the ν(NH) absorption appears to arise either from vibrational interactions within the cation or from the existence of multiple potential energy minima associated with alternative orientations of the N—H bond. A detailed spectroscopic study seems indicated.

[15] The ν(NH) frequency of the solitary, bifurcated N—H...2 Cl bond in $(Et_3NH)_2SnCl_6$ (53) is 3117.8 cm^{-1} at 10 K and 3109.7 cm^{-1} at 293 K; in $(Me_3NH)_2SnCl_6$ (55) at 10 K it is 3187 cm^{-1} (mean). In contrast to these weak N—H...Cl bonds the ν(NH) frequencies in the strongly H-bonded Et_3NHX (56) at 10 K are 2740, 2685, and 2611 cm^{-1} (centroids) for X = I, Br, and Cl, respectively. The mean frequency of the ir-active $\nu_3(NH_4^+)$ fundamental in the very weakly H-bonded NH_4BPh_4 (57) at 10 K is 3236[30] cm^{-1}, the highest-frequency component being at 3284.5(5) cm^{-1} and thus comparable to ν(NH) in PTB.

Fig. 14. Schematic representation of 5- to 8-membered rings closed by the formation of an N—H...N′ bond (cf. Table 4). PS, cations **a–hh**; PS′, cations **pp–ww**; PS″, cations **jj–nn**; 1,2-bzH$^+$, cations **ac–ah**. Large circles, N atoms; small circles, H(N) atoms.



of the principal ν(NH) absorption in anhydrous BP^+BF_4 has been reported (6) as 3185 cm^{-1} (2390 cm^{-1} on deuteration), and those in anhydrous BP^+ClO_4 and BP^+SbCl_6 can be estimated from Fig. 3 of ref. 6 as 3190 and 3165 cm^{-1}, respectively.[16]

Proton sponges: essential geometry

In classical $DMANH^+$ and modified proton-sponge cations (Table 4, Fig. 14; refs. 59–99) the local geometry involving the N—H...N′ group is constrained by the rigidity of the naphthalene skeleton in much the same way as that in $phenH^+$ is constrained by the rigidity of the phen skeleton, and that in BP^+ by the *cisoid* conformation of the BP system. It is thus of interest to see what differences there are in the consequences of the N—H...N′ bond formation in these and similar systems.

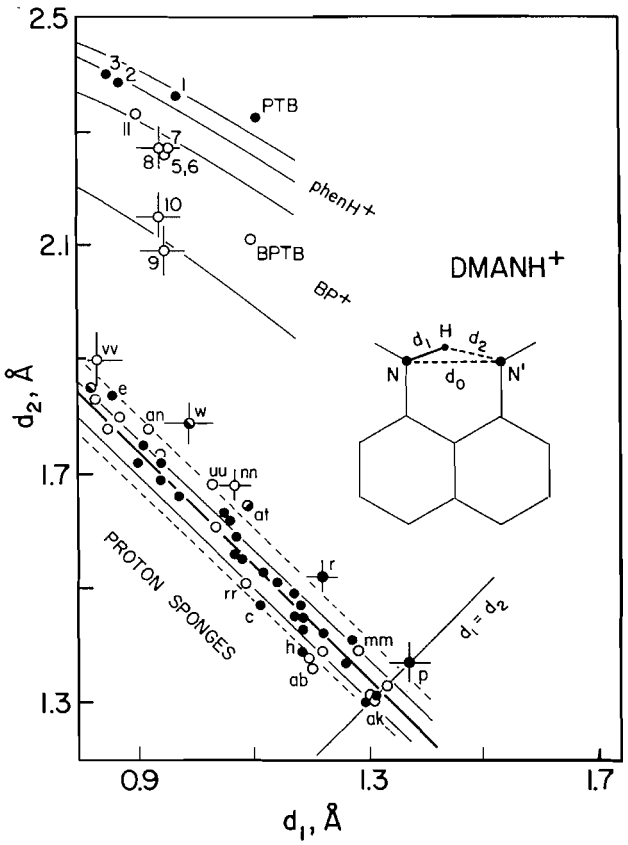
The $d_1 = d$(N −H) and $d_2 = d$(H...N′) distances ($d_2 \geq d_1$) in the $DMANH^+$ proton sponges are related by

$$[1] \quad d_2 = d_1 \cos\alpha + [d_1^2(\cos^2\alpha - 1) + d_0^2]^{1/2}$$

where $d_0 = d$(N...N′) and α = NHN′ (Fig. 15). Inspection of Table 4 reveals that d_0 and α are relatively constant: the means for **a–hh** are $\bar{d}_0 = 2.583[21]$ Å and $\bar{\alpha} = 154.2[72]°$, i.e., $\sigma(\alpha)$ is of the order of the stated experimental esd of α and $\sigma(\bar{d}_0)$ is about four times the average experimental esd of d_0. Most of the 32 $DMANH^+$ points in the d_2 vs. d_1 plot of Fig. 15 fall within the limits calculated from eq. [1] for the two combinations that produce the largest effects in d_1,d_2, viz. $d_0 = \bar{d}_0 \pm \sigma(\bar{d}_0)$, $\alpha = \bar{\alpha} \mp \sigma(\bar{\alpha})$. With four exceptions, *all* the points are accommodated inside the $2\sigma(\bar{d}_0)$,$2\sigma(\bar{\alpha})$ band.

[16] References 6–8 and 22, which came to our attention only when the present investigation was well under way, contain ir spectra of a number of BP^+ and $phenH^+$ salts (*not* BPTB or PTB). Like the present paper, these references aim explicitly at interpreting the spectra in terms of the intra-cation bond. However, owing to the lack of crystallographic information at the time, their conclusions, while generally similar to ours, are supported by spectroscopic evidence alone.

Fig. 15. Variation of $d_2 = d$(H...N′) with $d_1 = d$(N—H) in proton-sponge, *cis*-BP^+, and $phenH^+$ cations (cf, Tables 3 and 4). Heavy line, regression of d_2 on d_1. Thin lines, $\pm1\sigma(\bar{d}_0)$, $\mp1\sigma(\bar{\alpha})$ limits; thin broken lines, $\pm2\sigma(\bar{d}_0)$, $\mp2\sigma(\bar{\alpha})$ limits (see text). Proton sponges: full circles, $DMANH^+$ cations; open circles, other cations of Table 4; **w**, **gg**, [N—H...N′]$^-$ bonds; **at**, ab initio value for $[N_2H_7]^+$.



With the above values of $\bar{d}_0$ and $\bar{\alpha}$, eq. [1] closely approximates linear variation. Using the above 32 experimental points to regress d_2 on d_1 yields $d_2 = 2.656(55) - 1.017(49)d_1$, $r^2 = 0.97$, $\sigma = 0.03$ Å, i.e., statistically the slope is not different from −1. Thus within the experimental accuracy of the present sample, $d_1 + d_2 = 2.66$ Å, which in turn implies that the approximate locus of the H(N) position is a segment of an ellipse with N and N′ as the foci and a major axis of 1.33 Å, d_1 and d_2 being the focal radius vectors of the proton.

If Fig. 15 is a reasonable approximation to the actual gross behaviour of d_1 and d_2 in $DMANH^+$, with d_2/d_1 ranging from 1 to ~2, what is responsible for the wide variation in the asymmetry of the N-H-N′ in the first place? The ab initio calculation for free $[H_3N\text{-}H\text{-}NH_3]^+$ (**at**, $d_2/d_1 \sim 1.5$) indicates that, for N...N′ separations that are not extremely short, an *asymmetric* N-H-N′ bond is the ground-state norm.[17] The effect, in crystals, of a *second* acceptor X, which would generate a bifurcated N—H...N′,X bond, is not clear. In general, a short H...X separation would be expected to correspond to a lengthened N—H bond and probably to an increased $d_1 + d_2$, and possibly to an increased N-H-N′ bond symmetry. However, this is not

[17] For a recent account of ab initio studies of N-H-N′ interactions see ref. 99.

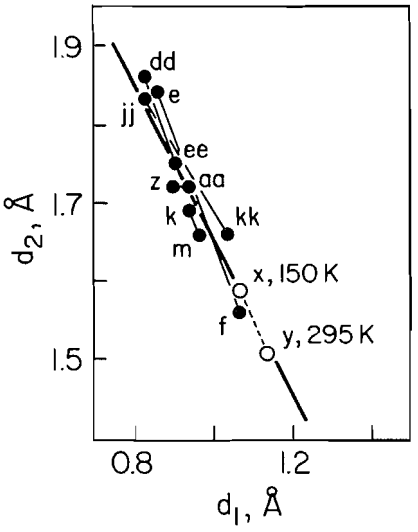
borne out unambiguously, if at all, by the present sample. Thus in **cc**, **ee**, and **hh** there appears to be no eligible second acceptor, yet d_1 in these cations ranges from 0.91(5) to 1.18(3) Å. In **x** and **aa** the resolved d_1 distances are 0.90(6) and 0.94(3) Å, with H...O = 2.58 and 2.50 Å, respectively; in **r**, d_1 = 1.22(3) Å, but H...O = 2.60(6) Å (all N—H...O bonds strongly bent). It would therefore seem imprudent to make definitive statements on the probable causes of the observed N—H...N′ asymmetry in crystals at this time. It is worth noting (Fig. 16) that in the five cations in Table 4 for which resolved twofold disorder of the H(N) atom has been reported, the alternative H(N) positions in each case conform closely (and certainly within their stated individual esd's) to the $DMANH^+$ regression line of Fig. 15.

Fig. 16. Relationship between the positions of the H(N) atoms in resolved positional disorder in proton-sponge crystals (full circles; **e–f, k–m, z–aa, dd–ee, jj–kk**, cf. Table 4), and the effect of temperature on the position of H(N) (open circles, **x–y**). Heavy line: d_2 on d_1 regression for proton sponges in Fig. 15.



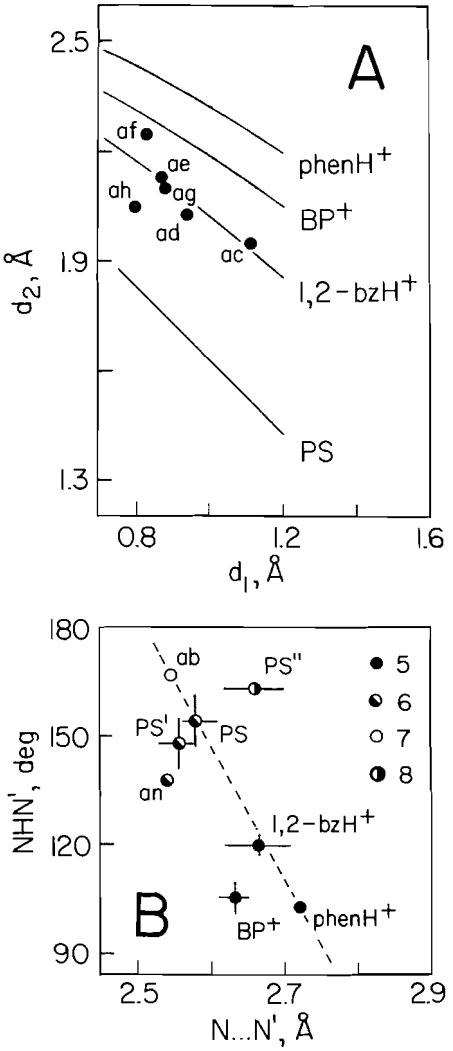
The $2\sigma(\bar{d}_0)$,$2\sigma\bar{\alpha}$) band also accommodates the d_1,d_2 points for cations other than $DMANH^+$, even though the local stereochemistries at their N—H...N′ bonds differ from that in $DMANH^+$ (the exceptions are **nn, pp, uu, vv, ab**).[18] Thus **xx, yy**, and **zz** are fused-ring variations on $DMANH^+$ with probably pseudosymmetric N-H-N′ bonds, and **jj** is a CH_2-expanded version of $DMANH^+$, with the two N atoms brought into a *syn* relationship by the H-bond. The cations in **ab** and **ar** are of particular interest in that in **ar** the centrosymmetric N-H-N′ group forms spontaneously on crystallization, without apparent constraint and yet with a d_0 value within 1σ of the above d_0 value for $DMANH^+$. In **ak**, even more interestingly, the monoprotonated saturated 1,6-Me_2-1,6-diazacyclodecane ring in the crystal spontaneously assumes a conformation that contains an intra-annular N-H-N′ bond with $d_0 = 2.60$ Å.

Proton sponges: comparison with BPTB and PTB

What distinguishes, geometrically, BP^+ and $phen^+$ from the proton sponges and their analogs, and where is the dividing line between the former and the cations that exhibit proton-sponge properties?[19]

The parameters considered here are d_0, d_1, d_2, and α, any one of which can be expressed in terms of the other three. Using only d_1 and d_2 (Figs. 15 and 17*A*), we see immediately that the points for the planar, non-proton-sponge BP^+, $phenH^+$, and 1,2-bzH^+ systems fall in a region of the plot with much larger d_2 distances. They also conform reasonably closely to the lines calculated from eq. [1] using the appropriate $\bar{d}_0$ and $\bar{\alpha}$

Fig. 17. (*A*) Correlation of d_1 and d_2 (cf. Fig. 14). Full circles, cations **ac–ah** of Table 4. The lines refer to $\bar{d}_0$ and $\bar{\alpha}$ in each group (see text); the line for PS is the d_2 on d_1 regression line of Fig. 14. (*B*) Variation of NHN′ = $\bar{\alpha}$ with N...N′ = $\bar{d}_0$ in the rings of Fig. 14; for **ab** and **an** only one d_0,α pair each is available. The broken line passes through the points corresponding to (essentially) planar, rigid ring systems.



means for each cation class from Table 5.[20] These lines are well separated from the regression line for the proton sponges. This separation and the importance of the size of the ring closed by the N—H...N′ bond are evident in Fig. 17*B*, in which $\bar{\alpha}$ is plotted against $\bar{d}_0$ for several classes of cations. While this may be fortuitous, the points for the planar, rigid $phenH^+$, 1,2-bzH^+, and $DMANH^+$ systems are seen to lie on a straight line. This line accommodates even the point for **ab**, in which cation the steric crowding at the N atom is so severe as to produce a helical twist of 23° between the outer rings about the central C—C bond of the phenanthrene system (77, 78). The Me groups on the nitrogens apparently are so locked in place that they make the system rigid in spite of its nonplanarity.

[18] In the (N-H-N)-containing $TFAN^-$ *anion* (**w** in Table 4) the d_0 distance, 2.608(4) Å, is close to the above $\bar{d}_0$ mean but the NHN′ angle, 138(3)°, is significantly smaller than $\bar{\alpha}$.

[19] Normally as judged by the basicity of the cation, but for our present purposes by the ν(NH) stretching frequency in the crystal (see above), which in true proton sponges is depressed to values below 1000 cm^{-1}.

[20] The scatter of the points for BP^+ may in part be attributed to the *cisoid* rather than *cis* conformation of the cation (see above), and that of the 1,2-bzH^+ points may be due to the bulk of the Ph_3P group(s) on the N atom(s).

Table 5. Means of N...N′ distances and NHN′ angles (Fig. 17*B*).[a]

Cation	$\bar{d}_0$, Å	$\bar{\alpha}$, deg	Ring size	d_2/d_1 range	$\langle d_2/d_1 \rangle$
ab[b]	2.545(4)	167(1)	7	1.13(4)	1.13(4)
PS″	2.662[38]	163.7[13]	8	1.09(5)–2.20(22)	1.40[22][d]
PS[c]	2.583[21]	154.2[72]	6	1–2.14(26)	1.43[26][e]
PS′	2.557[29]	148.1[74]	6	1.15(13)–2.29(20)	1.60[39]
an[b]	2.541(5)	138	5	1.93(7)	1.93(7)
1,2-bzH$^+$	2.665[45]	119.6[27]	5	1.76(17)–2.39(18)	2.34[31]
BP$^+$	2.635[22]	105.6[41]	5	1.92(1)–2.59(12)	2.32[18]

[a]See Table 4 and Fig. 16. Ring size, number of atoms in the ring; $\langle d_2/d_1 \rangle$, mean d_2/d_1 value. The 7-membered rings in **zz**, **yy**, **xx**, and **aj** (d_0 = 2.573(3), 2.587(3), 2.626(2), 2.650(6) Å, respectively; α = 175(2)°, 173(1)°, 177(7)°, 185(2)°, respectively, the last-named value corresponding to a re-entrant angle) are not included in the table and Fig. 17*B*. Their N—H...N′ bond lengths are reported as symmetric, but the H(N) position may be disordered.

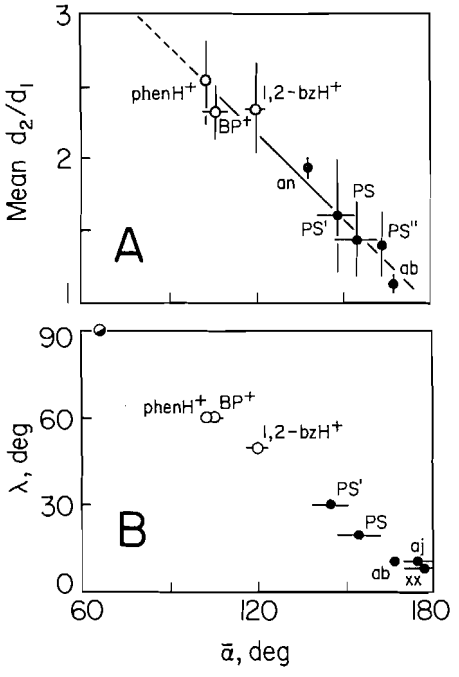
[b]Single values.

[c]N—H—N′ bonds reported as symmetric are not included in the means.

[d]Not including **jj**.

[e]Not including **e** and **dd**.

Fig. 18. (*A*) Correlation of the mean d_2/d_1 ratio with the mean NHN′ angle $\bar{\alpha}$. Full circles, proton-sponge cations; open circles, non-proton-sponge cations (cf. caption of Fig. 14). (*B*) Correlation of the mean NHN′ angle $\bar{\alpha}$ with the angle λ between the N...N′ vector and the idealized direction of the axis of the lone electron pair on N. Half-filled circle, estimate (from the correlation) of α for 1,8-naphthyridinium(1+) cation.



A comparison that includes the eight cations of Fig. 14 and takes account of three of the four parameters is presented in Fig. 18*A*. The unmistakable visual correlation of the mean d_2/d_1 values and $\bar{\alpha}$ (Table 5) can be approximated by a linear regression of $\langle d_2/d_1 \rangle$ on $\bar{\alpha}$: $\langle d_2/d_1 \rangle = 4.582 - 0.0200\bar{\alpha}$ ($r^2 = 0.96$, $\sigma = 0.09$ ~6% of range). The proton-sponge character is lost when simultaneously (*i*) $\langle d_2/d_1 \rangle$ is large, i.e., when the N—H...N′ bond is highly asymmetric and H(N) is close to N′; (*ii*) $\bar{\alpha}$ decreases, i.e., the N—H...N′ bond is highly bent. The dividing line between the proton-sponge and non-proton-sponge regimes appears to be at $\langle d_2/d_1 \rangle \sim 2$ and $\bar{\alpha} \sim 130°$. For $\langle d_2/d_1 \rangle > 2$ and $\bar{\alpha} < 130°$ the N—H...N′ configuration ceases to function as an effective two-centre force field.

To introduce the N...N′ separation explicitly, eq. [1] can be recast as

$$[2] \quad d_2/d_1 = \cos\alpha + [\cos^2\alpha + (d_0/d_1)^2 - 1]^{1/2}$$

for use with the individual cations. For the class parameters of Table 5,

$$[3] \quad \langle d_2/d_1 \rangle = 2.667 - 0.0190(\bar{\alpha} - 90) + 0.577(\bar{d}_0 - 2.5)$$

($r^2 = 0.96$, $\sigma = 0.07$). In this form the empirical correlation reveals the relative importances of changes in $\bar{\alpha}$ and $\bar{d}_0$: the range of $\bar{\alpha}$ being ~80° and that of $\bar{d}_0$, ~0.2 Å, it is clear that changes in $\bar{d}_0$ produce only a minor effect on $\langle d_2/d_1 \rangle$ and that $\bar{\alpha}$ is the major factor responsible for the proton-sponge properties. This is consistent with the smallness of the improvement that results when $\bar{d}_0$ is included in the regression.

The $\bar{\alpha}$ values are strongly correlated with the angle λ formed by the idealized direction of the axis of the lone pair on the N atom and the N...N′ vector (Fig. 18*B*). This correlation may proved helpful in estimating α in cations the structures of which have not yet been determined or in which H(N) is difficult to locate. Thus, for example, on monoprotonating 1,8-naphthyridine (100), quino[7,8-*h*]quinoline (101), and 1,14-diaza[5]helicene (102), the idealized λ angles in the cations are expected to be 90°, 30°, and perhaps ~0° respectively. From Fig. 18 the corresponding NHN′ angles would be estimated as ~66°, ~140°, and ~180°, i.e., the 1,8-naphthyridinium(1+) ion would not have proton-sponge characteristics.[21]

[21] Contrary to ref. 103, where a symmetric N-H-N′ bond has been proposed (cf. also ref. 100). The unprotonated quino[7,8-*h*]quinoline molecule is planar (101) and likely to remain so on protonation. The helical twist in the 1,14-diaza[5]-helicene molecule (102) renders estimation of λ uncertain.

π–π stacking in PTB: geometry

As pointed out earlier, some of the features of the PTB structure (face-to-face cat/an ring stacking, edge-to-face cat/an orientations) parallel similar features in the structure of PQTB, where they have been attributed to π–π interactions (11). Accounting for these features in these terms does not seem to contradict the set of rules announced in a position paper on the nature of π–π interactions (104), to the extent to which the rules are applicable to cat/an systems as complex as PQTB (cf. also ref. 105). A similar rationalization can therefore be adopted in describing the PTB structure.[22] However, PTB contains additional features, the quasi-discrete four-stacks (cf. above), which to our knowledge have not been reported previously but which, too, it is tempting to associate with π–π interactions, even though explicit support from current theory may be lacking.[23]

Each four-stack consists of a centrosymmetric pair of planar phenH$^+$ cations. Their perpendicular separation, 3.32 Å (Fig. 4*B*), is small enough to suggest attractive interaction, the like charges on the cations notwithstanding. Each cation in turn is flanked by the phenyl-2 ring of an anion, at a plane-to-plane angle of ~9°, i.e., about the same as the corresponding cat/phenyl angle in PQTB.[22] The shortest C(an)...N(an) distance, *d*[C(2.4)...N(10)], is 3.23 Å. The two cations in a pair thus constitute a cofacial $[cat_2]^{2+}$ dimer. Because of the inversion centre their relative orientation is such that the protonated N(10) atom of one cation is roughly above the unprotonated N(1) atom of the other, and the N(10) atom of the second cation is roughly below the N(1) cation of the first (Fig. 4*A*). The phenyl-2-ring and the cation in a pair are offset, roughly parallel to the cation plane. The overlap (Fig. 4*A*) between the cation ring 2 and the phenyl-2 ring is not substantial, but it brings the N(10)—H(N10) bond under (or above) the phenyl-2 ring. Thus, while the ion charges on the cations have the same sign, the atom charges and the electron densities at the vertically related N(1) and N(10)′ atoms are not the same. This difference may well generate an attractive interaction and thus reinforce the cofacial π–π interaction between the cation and the phenyl-2 ring in the four-stack. Each four-stack would then contain three cofacial interactions (phenyl-2/cat, cat/cat′, cat′/phenyl-2′) plus four edge-to-face cat/phenyl-4 interactions. The phenyl-4 groups involved in the T-geometry interactions mediate between adjacent four-stacks by organizing them into slabs parallel to (001) (Fig. 3).

[22] Consistent with the 1:2 stoichiometry of PQTB, the centrosymmetric PQ^{2+} cation is sandwiched between two anions to form discrete [an-cat-an] aggregates (11). Each cation ring is engaged by an anion in a simultaneous face-to-face and edge-to-face interaction, whereas in PTB the face-to-face and the edge-to-face anion ring partners of a cation are from different anions. In PQTB the cat/phenyl angle is 10° (9° in PTB), and the shortest edge-to-face $\pi_c...\pi_c$ distance between the cation and anion rings is 5.0 Å (5.32 and 5.35 Å in PTB). The shortest distances, in the region of face-to-face overlap, are C(cat)...phenyl plane = 3.27 Å and C(phenyl)...cation plane = 3.28 Å.

[23] On this point we paraphrase the apt comment made in ref. 104: where ab initio treatments are available, they reproduce experimental results well (106), but they do not explain the basic mechanisms of π–π interactions in a way that is helpful or predictive for the practical chemist (cf. also ref. 107). Besides, in situations believed to be governed by π–π interactions, there may be other determining factors at work.

π–π interactions: PTB in solution

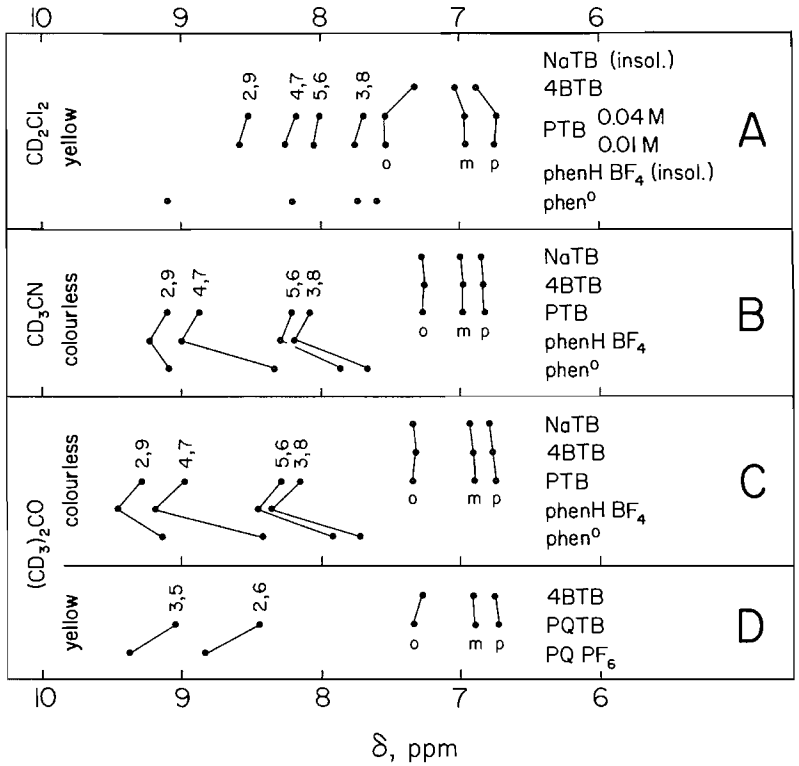
The presence of charge-transfer interactions in the PTB crystal is betrayed by the pale yellow colour. The colour persists in solution but only in some solvents. Fresh solutions in acetone, MeCN, and DMSO appear colourless, at high concentrations slightly yellowish, but solutions in CH_2Cl_2, THF, and pyridine (less so in $CHCl_3$ and $MeNO_2$) are yellow. The uv–visible spectra of 6 mM solutions of PTB in CH_2Cl_2 and acetone are quite different. The spectrum of the CH_2Cl_2 solution contains a broad double absorption ($\Delta\lambda_{1/2}$ ~ 160 nm) extending from below 190 to about 480 nm (hence the yellow colour), with the maxima at 260 and 330 nm (ε ~ 300). On a hundredfold dilution this broad absorption resolves into a narrower band ($\Delta\lambda_{1/2}$ ~ 60 nm), with a maximum at 270 nm, and a small shoulder on the long-wavelength side. In contrast, the spectrum of the acetone solution has a single narrow absorption ($\Delta\lambda_{1/2}$ ~ 40 nm) between 280 and 460 nm, with a maximum at 340 nm (ε ~ 550). The BPh_4^- anion ($NaBPh_4$ in acetone) shows no significant absorption between 190 and 800 nm, while phen^0 in acetone has a sharp band at 330 nm (ε ~ 240); a sharp maximum at the same wavelength is observed also in the spectrum of a saturated solution of phenH$^+$Cl$^-$ in acetone.

Room-temperature ^{1}H nmr spectra of PTB solutions depend markedly on the solvent. To find out why the CH_2Cl_2 solutions are yellow but those in acetone and MeCN at comparable concentrations almost colourless, we obtained spectra of PTB, phen^0, and (*n*-Bu_4N)BPh_4 (= 4BTB) in the three deuterated solvents. The PTB solution in CD_2Cl_2 was examined at two concentrations, 0.01 and 0.04 M. For comparison, spectra were also obtained of $NaBPh_4$ (= NaTB) and phenH$^+BF_4^-$ in $(CD_3)_2CO$ and CD_3CN; unfortunately, these two salts are not sufficiently soluble in CD_2Cl_2, and phenH$^+BF_4^-$ is insoluble also in THF, hence the corresponding spectra are not available. The results are summarized in Fig. 19 (phen proton assignments as in ref. 108).

The phen^0 frequencies in the three solvents are quite similar. In the colourless PTB solutions in acetone and MeCN these frequencies are shifted downfield by more or less similar amounts, ranging from $\Delta\delta_{2,9}$ ~ 0.14 to $\Delta\delta_{4,7}$ ~ 0.55 ppm in acetone, and from $\Delta\delta_{2,9}$ ~ 0 to $\Delta\delta_{4,7}$ ~ 0.55 ppm in MeCN, i.e., in the direction expected for cation formation. The anion proton frequencies in the PTB solutions in acetone and MeCN show only very minor shifts relative to NaTB and 4BTB. In the yellow PTB solutions in CD_2Cl_2, however, the spectral changes are strikingly different. The H(3,8), H(4, 7), and H(5,6) frequencies in the 0.01 M solution again are shifted downfield relative to phen^0, $\Delta\delta$ ~ 0.06–0.31 ppm, but the H(2,9) frequency is shifted *upfield* by ~0.50 ppm. On increasing the concentration to 0.04 M all the cation H(C) frequencies shift upfield by amounts not exceeding 0.1 ppm, making the total upfield shift $\Delta\delta_{2,9}$ ~ −0.56 ppm relative to phen^0. At the same time, the *ortho* frequency of the anion undergoes a *downfield* shift of ~0.2 ppm relative to 4BTB, while the *meta* and *para* proton frequencies are shifted upfield by ca. −0.08 and ca. −0.15 ppm, respectively; these anion proton shifts are practically independent of the concentration.

The direction and magnitude of the shifts in the PTB solution spectra relative to the phen^0 and BPh_4^- reference spectra demonstrate the persistence of a vestigial, dynamic, short-range cation–anion structure in the CD_2Cl_2 solution (and probably also in the other coloured solutions) and its absence in the

Fig. 19. The ^{1}H nmr spectra of PTB and reference compounds in different solvents (*A–C*; centroid frequencies, TMS as reference). The spectra of PQTB and $PQ(PF_6)_2$ in $(CD_3)_2CO$ (ref. 11; $(CHD_2)_2CO$ in $(CD_3)_2CO$ as reference) are shown in *D*; note that, relative to the N position, H(3) and H(2), respectively, in the PQ system correspond to H(2) and H(3) in the phen system.



colourless acetone and MeCN solutions. The large upfield shift of proton H(2,9) on the carbon adjacent to the N atom and the downfield shift of the anion *ortho* protons both support the simultaneous existence of cofacial and T-shape interactions in the CD_2Cl_2 solutions. In this respect PTB in CD_2Cl_2 resembles PQTB in the deep-yellow acetone solution (Fig. 19*D*), for which similar but somewhat smaller shifts have been observed (11). The additional upfield shifts of all four PTB cation protons with increased concentration may arise from an overall reduction of dilution and thus from a higher probability of ion–ion encounter, but they would not be inconsistent with incipient formation of four-stack-like aggregates in the solution, especially since the anion proton shifts do not appear to vary with concentration. A detailed study of the concentration dependence of the shifts (also in the other yellow PTB solutions) would not be amiss.

Conclusions

Monoprotonation of BP^0 and phen^0 results in the formation of an intra-cation N—H...N′ H-bond that is strong enough to convert *trans*-BP^0 to a *cisoid* BP^+ and bend this cation in its plane so as to decrease the N...N′ separation. In BPTB the dihedral angle ψ between the two cation rings is 5.2°, but angles up to 19° are on record for other BP^+ salts. In $phenH^+$ an in-plane distortion is prevented by the rigidity of the fused ring system: N...N′ is 2.61 Å in BPTB but 2.71 Å in PTB. More generally, the N...N′ mean is 2.635[22] Å in a sample of eight BP^+ salts and 2.722[9] Å in a sample of four $phenH^+$ salts. The difference of ~0.09 Å is statistically significant, the observed variation in ψ notwithstanding.

The H-bond in BPTB and PTB is a bifurcated N—H...N′,phenyl bond in which the intra-cation H...N′ component dominates the inter-ion H...phenyl component. However, in PTB even the former is very weak: ν(NH) = 3299 cm^{-1} at 10 K, H...N′ = 2.33 Å. In BPTB, H...N′ = 2.11 Å and ν(NH) at 10 K is about 130 cm^{-1} lower than in PTB, i.e., the H-bond in BPTB is stronger, consistent also with the significantly shorter H...C(an) distances.

The crystal structure of PTB contains features characteristic of π–π interactions, the presence of which is manifested in the pale yellow colour of the solid and the well-developed yellow colour of its solutions in some nonaqueous solvents, e.g., CH_2Cl_2, $CHCl_3$, THF. The structure contains partially offset, nearly parallel (~9°) cofacial arrangements of phenyl(an)–cat–cat–phenyl(an) aggregates, with approximate vertical plane separations of 3.2–3.4 Å. In addition, it contains T-shaped, edge-to-face, cat/phenyl(an) pairs, with the two planes almost at right angles. In containing parallel as well as perpendicular π–π system arrangements, the PTB structure is reminiscent of the structure of paraquat(2+) tetraphenylborate (11), but the cofacial π–π four-stacks appear to be a novel feature.

Cation geometry

The correlated cation bond lengths and angles in a number of BP^+ and $phenH^+$ salts have been examined in detail, statistically, for geometric equivalence of rings 1 and 1′ in BP^+ and of rings 1 and 2 in $phenH^+$, for equivalence of the BP^+ and

phenH$^+$ ring systems, and for differential effects of protonation on the ring geometry of the phen system (Figs. 7–9). The results are highly informative and provide insight into the limits of usefulness of crystallographic evidence for detecting the consequences of N-protonation, the twist angle ψ, and the BP $\rightarrow$ phen ring closure for the geometries of the BP and phen ring systems. Among the more conspicuous results the following merit mention.

1. The mean CNC angle at the unprotonated N atom in *trans*-BP^0, *cis*-BP$^+$, phen^0, and phenH$^+$ is 117.1[5]°. On N-protonation the mean *ipso* angle in *cis*-BP$^+$, *trans*-BP^{2+}, phenH$^+$, and phenH$_2^{2+}$ is 123.2[3]°, i.e., protonation increases the angle consistently by ~6°, regardless of the degree of rigidity of the ring system.
2. The central C—C bond length and the ring geometry in the BP systems do not appear to correlate with the twist angle ψ.
3. With the exception of the phenH$^+$|phenH$_2^{2+}$ pair (Fig. 8*B*), the endocyclic C-C-C angles at carbons 4|4′ in the BP and carbons 3|8 in the phen systems (i.e., *para* to the central C—C bond) remain undifferentiated on *N*-protonation or BP $\rightarrow$ phen ring closure or both.
4. The correlated bond lengths in rings 1 and 2 of phenH$^+$, statistically, are not differentiated but all the endocyclic angles *are*, with the exception of those at carbons 3|8 (see point 3) and the peripheral carbons 5|6 (Fig. 7*C*). Similarly, the bond angles in ring 1 of BP$^+$, statistically, are all differentiated from the corresponding angles in ring 1′, with the exception of the angles at carbons 4|4′ (Fig. 7*A*).
5. The endocyclic angles at the peripheral carbons 5|6 and the C(5)—C(6) bond length in the phen system are insensitive to N-protonation (Figs. 8*A*, *C*).
6. The left/right ring symmetry in BP$^+$ and phenH$^+$, statistically, is much more pronounced in the bond angles than in the bond lengths (Figs. 7*A*, *C*), while the opposite is true of the BP$^+$|phenH$^+$ pair (Fig. 7*B*), where the endocyclic angles affected are those at carbons 13|14 (involved in the BP $\rightarrow$ phen ring closure) and the endocyclic angle at C(11).
7. The effect of protonating *trans*-BP^0 to *trans*-BP^{2+} on the ring bond lengths is remarkably selective, affecting only the bond length between the carbons *meta* and *para* to the N atom (Fig. 8*A*).
8. *N*-Protonation in one ring leads to a readjustment and differentiation of the bond angles in *both* rings except as under point 3 (Figs. 7*A*, *C*).

Although the available ab initio calculations on the BP and phen systems are not sufficiently detailed, where they exist they confirm the BP^0, BP$^+$, and BP^{2+} conformations observed in crystals. They also indicate that variations in the ring geometry on protonation may be too small to be established with confidence by crystallography, and the same may be true of the effect of the twist angle ψ on ring bond lengths and angles.

Proton sponges

A detailed survey of relevant crystal structures (Table 4) shows that the difference between the intra-cation N—H...N′ bond geometry in the BP$^+$ and phenH$^+$ cations and that in the proton sponges (typically 1,8-(Me$_2$N)$_2$-naphthalene-H(1+) = DMANH$^+$) is one of degree, not of kind. In planar or approximately planar cations containing intra-ion N—H...N′ bonds the parameters $d_0 = d$(N...N′), $d_1 = d$(N—H), $d_2 = d$(H...N′), and α = NHN′ are related by eq. [1]. When such cations are grouped by type (Table 5) and the group means $\bar{d}_0$ and $\bar{\alpha}$ are computed, the range of the $\bar{d}_0$ values is found to be relatively narrow, ~0.2 Å or ~7% of the overall $\bar{d}$(N...N′) mean, while the $\bar{\alpha}$ range is very substantial, ~65°. The mean ratio $\langle d_2/d_1 \rangle$ for each cation group can be taken as a geometric indicator of proton-sponge behaviour. If $\bar{d}_0$ is taken as essentially constant, the ratio can be approximated by $\langle d_2/d_1 \rangle = 4.582 - 0.0200\bar{\alpha}$ ($r^2 = 0.96$, $\sigma = 0.09$ Å ~6% of range) for BP^{2+}, phenH$^+$, and the cations of Table 5. The boundary between cations that have proton-sponge properties (high pK_a, low ν(NH) stretching frequency) and those that do not appears to fall at $\langle d_2/d_1 \rangle \sim 2$ and $\bar{\alpha} \sim 130°$ (Fig. 18*A*). For $\langle d_2/d_1 \rangle > 2$ and $\bar{\alpha} < 130°$ the N—H...N′ configuration ceases to function as an effective two-centre force field and loses its proton-sponge character. When $\bar{d}_0$ is introduced explicitly, the ratio can be approximated as $\langle d_2/d_1 \rangle = 2.667 - 0.0190(\bar{\alpha} - 90) + 0.577(\bar{d}_0 - 2.5)$ ($r^2 = 0.96$, $\sigma = 0.07$), i.e., changes in the N...N′ distances are relatively much less important in determining the proton-sponge character than changes in the NHN′ angle. The angle λ between the N...N′ vector and the axis of the lone electron pair on the protonated N atom is another important diagnostic parameter (Fig. 18*B*). To the best of our knowledge no clear evidence for the existence of statically symmetric ordered (i.e., single-well potential) N-H-N bonds has been provided by crystallography to date, in agreement with expectation from theoretical treatments.

Experimental

The free base was dissolved in dilute HCl and the resulting solution was added to an aqueous solution of NaBPh$_4$. The precipitate, which formed immediately, was washed with water and air-dried. Crystals suitable for X-ray work were obtained by recrystallizing the products from aqueous acetone by slow evaporation at room temperature.

Crystallography

The crystallographic information is summarized in Table 1. We wish to reiterate that, in general, organoammonium tetraphenylborate crystals are weak and fickle scatterers. As pointed out previously (3), significant reflections are seldom observed above a (sin θ)/λ limit of 0.48 Å^{-1} ($\theta = 20°$ for Mo radiation). Since in this laboratory X-ray data collection routinely extends to a limit of 0.55 Å^{-1} ($\theta = 23°$), the ratio of observed reflections to total measured unique reflections never exceeds 50%, as in the present case.

The TEXSAN package (109) was used in the data reduction, structure solution by direct methods, and structure refinement, with PLUTO (110) for special graphics. The anisotropic temperature factor is defined as $\exp[-2\pi^2(U_{11}h^2a^{*2} + ... + 2U_{23}klb^*c^* + ...)]$. The H(C) atoms, though seen in the difference maps, were placed geometrically (C—H, 1.08 Å, U_{iso}(H) = $1.2U_{eq}$(C) of the attached C atom) and not refined. The positions of the H(N) atoms were obtained from the difference maps and kept fixed during the final refinement (U_{iso}(H) = $1.2U_{eq}$(N) of the attached N).

A test of the cation in BPTB for conformity to rigid-body-motion behaviour (TLS analysis) resulted in $R(U_{ij}) = 6.1\%$ and rms(U_{ij}) = 0.0030 Å^2 compared to rms[esd(U_{ij})] = 0.0030 Å^2, i.e., the U_{ij} (Table C) are satisfactorily accounted for on the rigid-body-motion model. The largest mean librational ampli-

tude, 6.8°, is about a principal axis roughly parallel to the long cation axis, the mean amplitudes about the other two principal axes being 2.9° and 3.3°, respectively. The corresponding screw pitches do not exceed 0.02 Å/deg. The thermal corrections to the lengths of the bonds parallel to the long cation axis are ~0.004 Å; those to the lengths of the bonds inclined to the long cation axis are ~0.010 Å. Corrections to the bond angles are all less than |0.3|°.

Infrared spectra

The FT-ir spectra, at 2 cm^{-1} resolution, of fluorocarbon mulls supported on CaF_2 plates were obtained with a Boumem DA3.02 spectrometer fitted with a closed-cycle He refrigerator.

The ^1H nmr spectra

The room-temperature ^1H spectra of PTB solutions were obtained with a Bruker AC250F spectrometer operating at 251 MHz.

Acknowledgments

We thank Dr. S.V. Sereda for assistance with some of the X-ray diffraction work, Dr. M. Falk and Mr. Ping Seto for obtaining the FT-ir spectra, and Professor D.L. Hooper for obtaining the nmr spectra. This investigation was supported by grants from the Natural Sciences and Engineering Research Council of Canada to O.K. and T.S.C.

Acyl cyanides as carbonyl heterodienophiles: application to the synthesis of naphthols, isoquinolones, and isocoumarins

Richard Connors, Elisabeth Tran, and Tony Durst

Abstract: Irradiation of 2-methylbenzoyl cyanide (**3***a*) in acetonitrile solution results in the formation of its dimer, which upon loss of HCN gives rise to the cycloadduct **7***a*. The dimerization also proceeds efficiently with derivatives of **3***a* giving adducts **7***b* and **7***c*. When 2-methylaroyl cyanides are photolyzed in the presence of a more reactive acyl cyanide the mixed adducts **8***a–e* are obtained in excellent yields. The cycloadducts **7***a–c* and **8***a–e* react with carbon and nitrogen nucleophiles by a tandem addition–cyclization sequence furnishing substituted naphthols (**10***a* and **10***b*) and isoquinolones (**11***a–d*), respectively. Isocoumarins **12***a* and **12***b* were prepared from the adducts **8***a* and **8***e* by treatment with potassium *tert*-butoxide in THF.

Key words: naphthols, isoquinolones, isocoumarins, synthesis of; acyl cyanides; hetero Diels–Alder.

Résumé : L'irradiation du cyanure de 2-méthylbenzoyle (**3***a*) en solution dans l'acétonitrile conduit à la formation de son dimère qui, par perte de HCN, fournit le cycloadduit **7***a*. La dimérisation se produit aussi d'une façon efficace avec les dérivés du composé **3***a*; elle conduit alors aux composés **7***b* et **7***c*. Lorsqu'on effectue la photolyse des cyanures de 2-méthylaroyle en présence d'un cyanure d'acyle plus réactif, on obtient alors les produits mixtes **8***a–e* avec d'excellents rendements. Les cycloadduits **7***a–c* et **8***a–e* réagissent avec les nucléophiles carbonés et azotés par une séquence de réactions d'addition–cyclisation en tandem qui fournissent respectivement des naphtols (**10***a* et **10***b*) et des isoquinoléines (**11***a–d*) substitués. Par réaction des adduits **8***a* et **8***e* avec du *tert*-butylate de potassium dans le THF, on a préparé les isocoumarines **12***a* et **12***b*.

Mots clés : naphtols, isoquinoléines, isocoumarines, synthèse; cyanures d'acyle; hétéro Diels–Alder.

[Traduit par la rédaction]

Introduction

o-Quinodimethanes (OQDM) have seen extensive application in the synthesis of natural products (1). Diels–Alder reactions of these intermediates have been studied with both alkene- and heterodienophiles. Oppolzer (2) and Kametani et al. (3) have demonstrated that imines, nitriles, and aldehydes can serve as both inter- and intramolecular dienophiles with *o*-quinodimethanes generated via ring openings of benzocyclobutenes. Sammes and co-workers (4) reported that the dienol generated photochemically from 2-methylbenzaldehyde reacted efficiently with ground state aldehydes in a cycloaddition reaction. Other carbonyl-containing functional groups have not been observed as dienophiles in Diels–Alder reactions with *o*-quinodimethanes. Highly reactive ketones, such as ketomalonates, have received limited attention as dienophiles (5); there is only one report of the carbonyl group of an ester participating in a Diels–Alder reaction (6).

Our report (7) of the cycloaddition of both thermally and photochemically generated *o*-quinodimethanes with benzoyl and acetyl cyanide (see Scheme 2), represents the first example in which an acyl cyanide acts in such a capacity. The recent publication by Kessar et al. which describes the synthesis of various 3-aryl-3,4-dihydroisocoumarins and protoberberines involving fluorodesilylation of 2-((trimethylsilyl)-methyl) benzoyl chlorides, **1**, in the presence of aromatic aldehydes and 3,4-dihydroisoquinolium salts (8), is closely related to our work. This group also describes a "dimerization" of the chloride **1** to the isocoumarin **2** when the fluoride treatment was carried out in the absence of other trapping agents (Scheme 1).

In this paper we present a more detailed account of our earlier report including additional reactions involving several new dienes and dienophiles. In addition, considerable synthetic utility of the cycloadducts has also been demonstrated by their use as intermediates in the synthesis of highly functionalized naphthols, isoquinolones, and isocoumarins.

Discussion and results

At the outset of this study, we postulated that photoenolization of 2-methylbenzoyl cyanide (**3***a*) and, especially, some of the more crowded analogs such as 2-methoxy-6-methylbenzoyl cyanide **3***b* might lead to a benzocyclobutenone such as **6**, by electrocyclization of the intermediate dienol **4** to **5** followed by HCN loss (Scheme 3). Sammes and co-workers demon-

strated that photoenolization of **3***a*, in the presence of maleic anhydride, yields the expected cycloaddition product, confirming the intermediacy of **4** (9). Wagner (10) showed that substitution of the aldehydic hydrogen of 2-methylbenzaldehyde with either an alkyl or aryl group enhances benzocyclobutenol formation, presumably because of a greater propensity for cyclization by the sterically more crowded photoenol. Based on the possibility of a similar effect, we decided to reinvestigate the photochemsitry of **3***a*.

As was described in our preliminary communication (8), irradiation of 0.1–1.0 M acetonitrile solutions of **3***a* furnished an 80% yield of purified **7***a* (Scheme 2). Attempts to isolate the cyanohydrin **5** or the ketone **6** were unsuccessful, suggesting that **4** was not sterically crowded enough to facilitate benzocyclobutenol formation. The formation of **7***a* was interpreted as having resulted from the cycloaddition of **3***a* to photochemically generated **4**, followed by HCN loss.

The presence of the methoxy group in 2-methoxy-6-methylbenzaldehyde, while increasing steric crowding, is known to stabilize its photoenol by intramolecular hydrogen bonding, thus inhibiting benzocyclobutenol formation (11). Irradiation of compounds **3***b* and **3***c* in acetonitrile solution afforded the cycloadducts **7***b* and **7***c*, respectively, in excellent yields (Scheme 3). Photolysis of the *p*-methoxy analog **3***d* produced an intractable mixture. This was not altogether surprising since the similarly substituted aldehyde exhibits little useful photoactivity (12).

Compounds **3***b*–**3***d* were prepared from the appropriately substituted aldehydes (13) via a two-step sequence involving conversion to the TMS cyanohydrins (trimethylsilyl cyanide, ZnI_2), followed by oxidation (pyridinium dichromate) to the aroyl cyanides. The sequence was amenable to a one-pot procedure and afforded the desired compounds in approximately 60% overall yields from the requisite aldehydes.

The reaction between mixed aroyl cyanide pairs was also investigated. It was anticipated that benzoyl cyanide, being less sterically congested, should compete well with **3***a* as a

dienophile. Indeed, irradiation of an acetonitrile solution of **3***a*, in the presence of two equivalents of benzoyl cyanide, gave the cycloadduct **8***a* in 83% yield (Scheme 4); no trace of **7***a* was detected, even when only one equivalent of benzoyl cyanide was used. The aroyl cyanides **3***b* and **3***c* exhibited similar behavior when irradiated in the presence of benzoyl cyanide, furnishing the adducts **8***b* and **8***c* in excellent yield. Finally, the highly substituted cycloadduct **8***d* was prepared in 95% yield by irradiation of an acetonitrile solution of the 2,6-disubstituted benzoyl cyanide **3***b* in the presence of one equivalent of 2-methoxy-4-methylbenzoyl cyanide.

Cycloaddition between the cyanohydrin OQDMs and alkanoyl-substituted acylcyanides was also found to be highly efficient. For example, irradiation of 2-methylbenzoyl cyanide in the presence of 2 equivalents of acetyl cyanide afforded 50% of adduct **8***e*.

The cycloadducts **7** and **8** contain an interesting combination of functional groups, with the internally acylated cyanohydrin representing a masked carbonyl function that would be revealed by loss of HCN following ester cleavage (Scheme 5). Such a process would generate the intermediate **9**, which, depending on the nature of the nucleophile, would be able to undergo cyclization to a fused ring system. This process has been realized with nucleophiles such as methyllithium and various amines and resulted in the synthesis of highly functionalized 3-arylnaphthols and 3-substituted isoquinolones, respectively. Finally, treatment of the adducts **7** and **8** with strong bases afforded isocoumarins.

Preparation of 3-aryl-1-naphthols

Treatment of a THF solution of **7***a* with 2 equivalents of methyllithium at −78°C and slowly warming the reaction mixture to room temperature gave the naphthol **10***a* in 60% yield (Scheme 6). Compound **7***b* was similarly converted, in 78% yield, into the naphthol **10***b*, which was readily characterized by its ^1H NMR spectrum showing the methyl group at δ = 2.30, singlets at δ = 6.78 and 7.36 ppm due to the C2 and C4 hydrogens on the naphthol ring, seven additional aromatic

hydrogens, and a broad exchangeable singlet at 5.53 ppm corresponding to the phenolic hydrogen. Analysis of the ^1H NMR spectrum of the crude product indicated that complex mixtures consisting of a methyl ketone (compound **9**, NuH=CH_3, Scheme 5) and permethylated by-products were obtained when the same methodology was attempted with **7***c* and **7***d*. Presumably, the steric crowding in the 2,6-disubstituted biaryl adducts is sufficient to inhibit facile cyclization to the naphthols from the intermediate methyl ketones.

Isoquinolones and isocoumarins

In addition to the naphthols, the cycloadducts provided a facile route to various isoquinolones. The isoquinolone (1-oxo-1,2-dihydroisoquinoline) ring system is of interest owing to its presence in numerous alkaloids, in addition to its utility as a synthetic intermediate (14).

Compound **8***a* (Scheme 7), when refluxed with 1.5 equivalents of benzylamine in dry cyclohexane, yielded a viscous yellow oil that gave a complex proton NMR spectrum and exhibited a strong infrared absorbance at 1650 cm^{-1}. This material was readily converted to **11***a* (86%) upon further refluxing in 50% aqueous acetic acid. Compound **11***a* exhibited a strong infrared absorbance at 1652 cm^{-1}, confirming the presence of the amide functionality, as well as characteristic signals in the proton NMR spectrum at 5.23 and 6.43 ppm due to the benzyl and alkene hydrogens, respectively. The same methodology was applied to the synthesis of compounds **11***b–d* from **8***a* or **8***e* with yields ranging from 60 to 80%.

Finally, the potential for an isocoumarin synthesis was briefly investigated. The cycloadducts **8***a–e* are essentially masked isocoumarins that, it may be envisioned, have undergone addition of HCN across the 3,4 double bond. It follows that the isocoumarins should be accessible by base-catalyzed elimination of HCN. Initial attempts employing DBU or DBN, known to catalyze efficient dehydrohalogenation (15), gave unsatisfactory results with **8***a–e*. Potassium *tert*-butoxide proved to be the reagent of choice as treatment of an ice-cooled THF solution of compound **8***a* (Scheme 8) with 1.5 equivalents of the base yielded the known isocoumarin **12***a* (16) in 50% yield. Similarly, isocoumarin **12***b* (17) was prepared from **8***e* in 66% yield.

Experimental section

General

Melting points were determined by use of a Gallenkamp digital melting point apparatus and are uncorrected. IR spectra were recorded as chloroform solutions on a Bomem–Michelson MB-100 spectrophotometer. ^1H and ^{13}C NMR spectra were obtained as $CHCl_3$ solutions on either a Varian XL-300 or a Gemini-200 spectrometer with the chemical shifts reported in ppm relative to TMS. Solvents for the extractions and chromatographic purifications (ethyl acetate = EA, and hexane = H) were routinely distilled prior to use. Reagent grade acetonitrile was used as received. Silica gel, 230–400 mesh, was used for flash chromatography.

2-Methylbenzoyl cyanide (*3a*) (**9**)

A mixture of 20 g (0.13 mol) of 2-methylbenzoyl chloride, 6.3 g (0.13 mol) sodium cyanide, and 0.1 g (0.36 mmol) of tetrabutylammonium chloride in 140 mL of 5:1 CH_2Cl_2–water was vigorously stirred at room temperature for 12 h, after which time IR analysis indicated complete reaction. After filtration of the solids the organic phase was separated, dried over magnesium sulfate, and concentrated in vacuo, giving 19.6 g of a yellow oil. Vacuum distillation furnished 11.3 g (60%) of a colorless liquid (bp 75–80°C/10 Torr; 1 Torr = 133.3 Pa) that solidified on standing. IR: 2222, 1680 cm^{-1}; ^1H NMR δ: 2.61 (s, 3H), 7.35 (d, 1H, J=7.5 Hz), 7.44 (dd, 1H, J = 7.5, 7.8 Hz), 7.60 (t, 1H, J = 7.5 Hz), 8.20 (d, 1H, J = 7.8 Hz); MS (EI) *m/z*: 145 (M^+), 118, 90.

2-Methoxy-6-methylbenzoyl cyanide (*3b*)

To an ice-cooled stirred solution of 5.0 g (33.3 mmol) of 2-methoxy-6-methylbenzaldehyde and 100 mg of zinc iodide (0.3 mmol) in 75 mL CH_2Cl_2 was added 3.6 g (4.9 mL, 36.7 mmol) of trimethylsilyl cyanide via syringe under nitrogen atmosphere. The mixture was allowed to warm to room temperature and TLC analysis (H/EA, 3:1) indicated complete conversion after 1 h after warming. The solvent was removed on a rotovap at 40°C and the concentrate passed through 20 g of 70–230 mesh silica gel with 150 mL of CH_2Cl_2. The CH_2Cl_2 solution of the TMS cyanohydrin was transferred to a

250 mL round-bottomed flask, cooled to 0°C under nitrogen atmosphere, and 18.8 g (50.0 mmol) of pyridinium dichromate was introduced, with efficient stirring, over 5 min. The mixture was stirred at room temperature for 12 h after which time the solvent was removed on a rotovap at 20°C. The residue was triturated with ether and the solution was filtered through 20 g 70–230 mesh silica gel. Concentration of the ether solution produced 4.2 g of crude **3***b*, which furnished 3.5 g (60%) of purified **3***b* as yellow needles after flash chromatography (3:1 H/EA); mp 55.3–56.1°C (CH_2Cl_2–hexane); IR: 2220, 1670 cm^{-1}; ^1H NMR δ: 2.39 (s, 3H), 3.96 (s, 3H), 6.86 (d, 1H, J = 7.5 Hz), 6.87 (d, 1H, J = 8.3 Hz), 7.43 (t, 1H, J = 8.4 Hz); ^{13}C NMR δ: 20.7, 56.1, 109.7, 114.8, 123.2, 124.2, 135.5, 142.2, 161.1, 167.6; MS (EI) *m/z*: 175 (M^+), 160, 148; HRMS calcd. for $C_{10}H_9NO_2$: 175.0633; found: 175.0635.

2-Methoxy-4,6-dimethylbenzoyl cyanide (3*c*)

A solution of 5.0 g (33.3 mmol) of 2-methoxy-4,6-dimethylbenzaldehyde in 75 mL of CH_2Cl_2 was treated as described for **3***b*. Concentration of the product mixture followed by trituration with ether and filtration of the solution through a silica gel plug gave 5.6 g of a tan-brown solid. The crude aroyl cyanide was readily crystallized from CH_2Cl_2–hexane, furnishing 4.6 g (79%) of pure **3***c* as yellow crystals, mp 71.8–72.5°C. IR: 2219, 1608 cm^{-1}; ^1H NMR δ: 2.34 (s, 3H), 2.35 (s, 3H), 3.93 (s, 3H), 6.65 (s, 1H), 6.66 (s, 1H); ^{13}C NMR δ: 21.0, 22.2 55.9, 110.4, 115.0, 120.6, 125.4, 142.6, 147.5, 161.5, 166.8; MS (EI) *m/z*: 189 (M^+), 174, 162; HRMS calcd. for $C_{11}H_{11}NO_2$: 189.0790; found: 189.0802.

2-Methyl-4-methoxybenzoyl cyanide (3*d*)

A solution of 5.0 g (33.3 mmol) of 2-methyl-4-methoxybenzaldehyde in 75 mL of CH_2Cl_2 was treated as described for **3***b*. Concentration of the product mixture followed by trituration with ether and filtration of the solution through a silica gel plug gave 5.1 g of a yellow solid. The crude aroyl cyanide crystallized from ether–hexane, furnishing 4.5 g (78%) of pure **3***d* as colorless needles, mp 62.0–62.8°C. IR: 2219, 1667 cm^{-1}; ^1H NMR δ: 2.59 (s, 3H), 3.90 (s, 3H), 6.79 (d, 1H, J = 2.0 Hz), 6.88 (dd, 1H, J = 2.0, 8.8 Hz), 8.15 (d, 1H, J = 8.8 Hz) ^{13}C NMR δ: 22.4, 55.7, 111.7, 113.6, 118.5, 124.9, 138.15, 146.0, 165.2, 166.6; MS (EI) *m/z*: 175 (M^+), 163, 148; HRMS calcd. for $C_{10}H_9NO_2$: 175.0633; found: 175.0648.

2-Methoxy-4-methylbenzoyl cyanide (3*e*)

A solution of 5.0 g (33.3 mmol) of 2-methoxy-4-methylbenzaldehyde in 75 mL of CH_2Cl_2 was treated as described for **3***b*. Flash chromatography (5:1 H/EA) gave 3.8 g (65%) **3***e* as a yellow oil, which solidified on storage at 0°C (mp 68.2–69.0°C). IR: 2221, 1608 cm^{-1}; ^1H NMR δ: 2.42 (s, 3H), 3.96 (s, 3H), 6.81 (s, 1H), 6.87 (d, 1H, J = 8.1 Hz), 7.84 (d, 1H, J = 8.1 Hz); ^{13}C NMR δ: 22.5, 55.9, 112.9, 114.3, 120.2, 122.1, 132.9, 150.5, 161.3, 164.7; MS (EI) *m/z*: 175 (M^+), 158, 149; HRMS calcd. for $C_{10}H_9NO_2$: 175.0633; found: 175.0646.

3,4-Dihydro-3-cyano-3-(2-methylphenyl)-1*H*-2-benzopyran-1-one (7*a*)

A solution of 300 mg (2.1 mmol) of 2-methylbenzoyl cyanide in 2.0 mL of acetonitrile (1.0 M), contained in a quartz test tube, was suspended 10 cm from a Hanovia medium-pressure mercury lamp and irradiated until TLC analysis indicated complete conversion of the starting material (5–6 h). Concentration of the solvent on a rotovap at 40°C followed by flash chromatography (5:1 H/EA) of the crude adduct gave 220 mg (81%) of **7***a* as white needles, mp 126.5–127.5°C (CH_2Cl_2–hexane); IR: 1747 cm^{-1}; ^1H NMR δ: 2.68 (s, 3H), 3.64 (d, 1H, J = 16.5 Hz), 3.75 (d, 1H, J = 16.5 Hz), 7.23–7.40 (m, 4H), 7.46–7.70 (m, 3H), 8.16 (d, 1H, J = 7.7 Hz); ^{13}C NMR δ: 20.9, 37.4, 77.4, 117.5, 123.7, 125.6, 126.4, 127.9, 129.0, 130.8, 130.8, 132.4, 133.1, 135.0, 135.6, 136.8, 162.0; MS (EI) *m/z*: 262 $(M-1)^+$, 245, 218; HRMS calcd. for $C_{17}H_{13}NO_2$: 263.0946; found: 263.0935.

3,4-Dihydro-3-cyano-8-methoxy-3-(2-methoxy-6-methylphenyl)-1*H*-2-benzopyran-1-one (7*b*)

A solution of 300 mg (1.7 mmol) of 2-methoxy-6-methylbenzoyl cyanide in 2.0 mL of acetonitrile, contained in a quartz test tube, was irradiated as described for **7***a* until TLC analysis (H/EA acetate 2:1) indicated complete conversion of the starting material (12 h). Concentration of the solvent on a rotvap at 40°C followed by flash chromatography (CH_2Cl_2) of the crude adduct gave 249 mg (90%) of **7***b* as a white solid. Recrystallization from CH_2Cl_2-hexane afforded colorless crystals, mp 145.3–146.0°C. IR: 1744 cm^{-1}; ^1H NMR δ: 2.61 (s, 3H), 3.46 (d, 1H, J = 16.9 Hz), 3.66 (d, 1H, J = 16.9 Hz), 3.87 (s, 3H), 3.94 (s, 3H), 6.85 (m, 3H), 6.98 (d, 1H, J = 8.3 Hz), 7.22 (dd, 1H, J = 7.8, 5.36 Hz), 7.53 (dd, 1H, J = 7.8, 8.3 Hz); ^{13}C NMR δ: 23.2, 38.2, 56.1, 56.2, 77.0 110.5, 111.9, 112.2, 118.2, 119.6, 122.4, 126.4, 130.0, 135.6, 138.2, 138.6, 156.4, 158.6, 161.4; MS (EI) *m/z*: 322 $(M-1)^+$, 278, 263; HRMS calcd. for $C_{19}H_{17}NO_4$: 323.1158; found: 323.1160.

3,4-Dihydro-3-cyano-8-methoxy-6-methyl-3-(2-methoxy-4,6-dimethylphenyl)-1*H*-2-benzopyran-1-one (7*c*)

A solution of 300 mg (1.6 mmol) of 2-methoxy-4,6-dimethylbenzoyl cyanide in 2.0 mL of acetonitrile was irradiated as above until TLC analysis indicated complete conversion of the starting material (16 h). Concentration of the solvent at 40°C followed by flash chromatography (2:1 H/EA) gave 140 mg (50%) of **7***c* (colorless crystals from CH_2Cl_2–hexane), mp 202.5–203.0°C. IR: 1741 cm^{-1}; ^1H NMR δ: 2.28 (s, 3H), 2.38 (s, 3H), 2.56 (s, 3H), 3.40 (d, 1H, J = 16.6 Hz), 3.58 (d, 1H, J = 16.6 Hz), 3.85 (s, 3H), 3.93 (s, 3H), 6.65 (s, 2H), 6.67 (s, 1H), 6.76 (s, 1H); ^{13}C NMR δ: 21.2, 22.2, 23.0, 38.4, 56.1, 56.1, 77.4, 109.7, 111.3, 112.6, 118.4, 119.7, 120.5, 127.2, 137.9, 138.6, 140.1, 147.0, 156.4, 158.9, 161.4; MS (EI) *m/z*: 351 (M^+), 350, 306; HRMS calcd. for $C_{21}H_{21}NO_4$: 351.1471; found 351.1466.

3,4-dihydro-3-cyano-3-phenyl-1*H*-2-benzopyran-1-one (8*a*)

A solution of 300 mg (2.1 mmol) of 2-methylbenzoyl cyanide and 550 mg (4.1 mmol) of benzoyl cyanide in 2.0 mL of acetonitrile was irradiated as described above for 6 h. Concentration of the solvent on a rotovap at 40°C followed by flash chromatography (5:1 H/EA) of the crude adduct gave 385 mg (75%) of **8***a*, colorless plates, mp 144.6–146.1°C, from ether–hexane. IR: 1748 cm^{-1}; ^1H NMR δ: 3.48 (d, 1H, J = 16.7 Hz), 3.60 d, 1H, J = 16.7 Hz), 7.34 (d, 1H, J = 7.5 Hz), 7.45–7.55 (m, 4H), 7.61–7.71 (m, 3H), 8.19 (d, 1H, J = s7.7 Hz); ^{13}C NMR δ: 40.8, 78.2, 117.8, 123.6, 125.1, 127.7, 129.0, 129.2,

130.1, 130.9, 135.0, 135.5, 135.7, 162.2; MS (EI) *m/z*: 249 (M^+), 203, 190; HRMS calcd. for $C_{16}H_{11}NO_2$: 249.07900; found: 249.0809.

3,4-Dihydro-3-cyano-8-methoxy-3-phenyl-1*H*-2-benzopyran-1-one (8*b*)

A solution of 300 mg (1.7 mmol) of 2-methoxy-6-methylbenzoyl cyanide and 450 mg (3.4 mmol) of benzoyl cyanide in 2.0 mL of acetonitrile was irradiated as above for 6 h. Concentration of the solvent followed by flash chromatography (3:1 H/EA) of the crude adduct gave 420 mg (88%) of **8*b*** as a white solid, mp 146.0–147.0°C. IR: 1748 cm^{-1}; ^1H NMR δ: 3.40 (d, 1H, J = 16.4 Hz), 3.46 (d, 1H, J = 16.4 Hz), 3.98 (s, 3H), 6.87 (d, 1H, J = 7.6 Hz), 7.02 (d, 1H, J = 8.6 Hz), 7.40–7.50 (m, 3H), 7.57 (t, 1H, J = 7.6 Hz), 7.65–7.75 (m, 2H); ^{13}C NMR δ: 41.2, 56.3, 77.5, 112.0, 112.3, 117.8, 119.6, 125.1, 129.1, 130.0, 135.7, 135.9, 138.0, 158.8, 161.6; MS (EI) *m/z*: 279 (M^+), 249, 220; HRMS calcd. for $C_{17}H_{13}NO_3$: 279.0895; found: 279.0888.

3,4-Dihydro-3-cyano-8-methoxy-6-methyl-3-phenyl-1*H*-2-benzopyran-1-one (8*c*)

A solution of 300 mg (1.6 mmol) of 2-methoxy-4,6-dimethylbenzoyl cyanide and 420 mg (3.2 mmol) of benzoyl cyanide in 2.0 mL of acetonitrile was irradiated as above for 6 h. Concentration of the solvent followed by flash chromatography (5:1 H/EA) gave 363 mg (78%) of **8*c***, white solid, mp 166.0–167.0°C. IR: 1746 cm^{-1}; ^1H NMR δ: 2.41 (s, 3H), 3.33 (d, 1H, J = 16.1 Hz), 3.47 (d, 1H, J = 16.1 Hz), 3.97 (s, 3H), 6.69 (s, 1H), 6.82 (s, 1H), 7.50 (m, 3H), 7.70 (m, 2H); ^{13}C NMR δ: 22.3, 41.2, 56.2, 77.4, 109.4, 112.9, 117.9, 120.4, 125.1 129.0, 129.9, 135.8 137.8, 147.6 159.0, 161.8; MS (EI) *m/z*: 293 (M^+), 263, 247; HRMS calcd. for $C_{18}H_{15}NO_3$: 293.1052; found: 293.1055.

3,4-Dihydro-3-cyano-8-methoxy-3-(2-methoxy-4-methylphenyl)-1*H*-2-benzopyran-1-one (8*d*)

A solution of 300 mg (1.7 mmol) of 2-methoxy-6-methylbenzoyl cyanide and 300 mg (1.7 mmol) of 2-methoxy-4-methylbenzoyl cyanide in 2.0 mL of acetonitrile contained in a quartz test tube was irradiated for 6 h after which time TLC analysis indicated complete conversion of the starting materials. Concentration of the solvent at 40°C followed by flash chromatography (2:1 H/EA acetate) of the crude adduct gave 526 mg (95 %) of **8*d*** as a yellow solid, mp 176.5–177.5°C. IR: 1745 cm^{-1}; ^1H NMR δ: 2.36 (s, 3H), 3.34 (d, 1H, J = 16.3 Hz), 3.78 (d, 1H, J = 16.3 Hz), 3.91 (s, 3H), 3.96 (s, 3H), 6.84 (m, 3H), 6.98 (d, 1H, J = 8.5 Hz), 7.53 (dd, 1H, J = 7.8, 7.6), 7.60 (d, 1H, J = 7.9 Hz); ^{13}C NMR δ: 21.5, 38.2, 55.9, 56.2, 77.4, 111.9, 112.3, 112.9, 117.6, 119.7, 121.0, 121.7, 126.1, 135.7, 138.6, 141.5, 155.8, 159.1, 161.4; MS (EI) *m/z*: 323 (M^+), 293, 278; HRMS calcd. for $C_{19}H_{17}NO_4$: 323.1158; found: 323.1161.

3,4-Dihydro-3-cyano-3-methyl-1*H*-2-benzopyran-1-one (8*e*)

A solution of 300 mg (2.1 mmol) of 2-methylbenzoyl cyanide and 285 mg (4.1 mmol) of acetyl cyanide in 2.0 mL of acetonitrile was irradiated as described above until TLC analysis indicated complete conversion of the starting material (12 h). Concentration of the solvent followed by flash chromatography (3:1 H/EA) gave 192 mg (50%) of **8*e*** as a white solid, mp 98.0–100.0°C. IR: 1746 cm^{-1}; ^1H NMR δ: 1.94 (s, 3H), 3.26 (d, 1H, J = 16.6 Hz), 3.32 (d, 1H, J = 16.6 Hz) 7.29 (d, 1H, J = 6.8 Hz), 7.48 (t, 1H, J = 6.4 Hz), 7.63 (dt, 1H, J = 1.4, 7.5 Hz), 8.12 (dd, 1H, J = 14, 7.5 Hz); ^{13}C NMR δ: 26.6, 38.26 (t), 77.4, 118.8, 123.34 (s), 127.6, 128.9, 130.89, 134.89, 135.4, 162.3; MS (EI) *m/z*: 187 (M^+), 172, 144; HRMS calcd. for $C_{11}H_9NO_2$: 187.0633; found: 187.0646

3-(2-Methylphenyl)-1-naphthol (10*a*)

To a stirred THF solution of 600 mg (2.3 mmol) of 3,4-dihydro-3-cyano-3-(2-methylphenyl)-1*H*-2-benzopyran-1-one (**8*a***), cooled to −78°C under nitrogen atmosphere, was added via syringe 1.8 mL (2.5 mmol) of MeLi (1.4 M in ether). The mixture was maintained at −78°C for 30 min before a second 1.8 mL aliquot of MeLi was administered. The reaction mixture was then warmed to room temperature over 30 min and left stirring overnight (15 h). The yellow solution was quenched by dropwise addition of 10% aqueous HCl and the resulting phases were separated. The aqueous layer was extracted with ether and the combined organic phases were washed with brine. The resulting ether solution was dried over $MgSO_4$ and concentrated on a rotvap, giving 412 mg of a brown oil. Flash chromatography (1:2 H/CH_2Cl_2) furnished 320 mg (60%) of **10*a*** as a brown oil. IR: 3577 cm^{-1}; ^1H NMR δ: 2.30 (s, 3H), 5.53 (s, 1H), 6.78 (s, 1H), 7.28 (s, 4H), 7.36 (s, 1H), 7.50 (m, 2H), 7.82 (m, 1H), 8.20 (m, 1H); ^{13}C NMR δ: 20.6, 110.9, 120.6, 121.5, 123.3, 125.1, 125.7, 126.7, 127.3, 127.7, 129.77 (d), 130.3, 134.5, 135.5, 139.7, 141.7, 151.0; MS (EI) *m/z*: 234 (M^+), 215, 202; HRMS calcd. for $C_{17}H_{14}O$: 234.1045; found: 234.1043.

8-Methoxy-3-(2-methoxy-4-methylphenyl)-naphthol (10*b*)

3,4-Dihydro-3-cyano-8-methoxy-3-(2-methoxy-4-methylphenyl)-1*H*-2-benzopyran-1-one (**8*d***) (100 mg; 0.3 mmol) was treated as described above for **10*a***, giving 108 mg of a brown oil. Flash chromatography (3:1 H/EA) furnished 78 mg (86%) of **10*b*** as a yellow oil. IR: 3404 cm^{-1}; ^1H NMR δ: 2.40 (s, 3H), 3.80 (s, 3H), 4.04 (s, 3H), 6.73 (d, 1H, J = 7.7 Hz), 6.81 (s, 1H), 6.85 (d, 1H, J = 8.4 Hz), 7.10 (d, 1H, J = 1.5 Hz), 7.27 (t, 2H, J = 7.6 Hz), 7.40 (d, 1H, J = 6.2 Hz), 7.42 (d, 1H, J = 1.6 Hz), 9.27 (s, 1H); ^{13}C NMR δ: 21.5, 55.5, 56.1, 103.7, 112.2, 112.4, 113.9, 119.3, 121.4, 122.1, 125.5, 127.4, 130.7, 136.6, 138.2, 138.9, 153.6, 156.0, 156.4; MS (EI) *m/z*: 294 (M^+), 267, 234; HRMS calcd. for $C_{19}H_{18}O_3$: 294.1256; found: 294.1264.

1-Oxo-3-phenyl-2-phenylmethyl-1,2-dihydroisoquinoline (11*a*)

A solution of 200 mg (0.8 mmol) of 3,4-dihydro-3-cyano-3-phenyl-1*H*-2-benzopyran-1-one (**8*a***) and 130 mg (1.2 mmol) benzylamine in 10 mL cyclohexane was heated to reflux for 15 h after which time TLC analysis indicated complete conversion of the starting materials. The solvent was removed on a rotovap, the concentrate dissolved in 10 mL 50% aqueous acetic acid, and the mixture heated to reflux for an additional 3 h. After cooling to room temperature, the product mixture was diluted with 20 mL water and extracted with three 15 mL portions of CH_2C1_2. The combined organic phases were dried over $MgSO_4$, filtered, and concentrated, giving a yellow oil that after flash chromatography (3:1 H/EA) furnished 217 mg (86%) of **11*a***. IR: 1652 cm^{-1}; ^1H NMR δ: 5.23 (s, 2H), 6.43 (s, 1H), 6.88 (m, 2H), 7.14–7.70 (m, 11H), 8.48 (d, 1H, J = 8.0

Hz); ^{13}C NMR δ: 48.5, 108.0, 125.2, 125.8, 126.7, 126.8, 126.9, 128.2, 128.2, 128.3, 128.8, 129.1, 132.5, 135.8, 136.4, 137.6, 143.8, 163.1; MS (EI) *m/z*: 310 $(M-1)^+$, 232, 205; HRMS calcd. for $C_{22}H_{17}NO$: 311.1310; found: 311.1287.

2-Butyl-1-oxo-3-phenyl-1,2-dihydroisoquinoline (11*b*)
A solution of 275 mg (1.1 mmol) of 3,4-dihydro-3-cyano-3-phenyl-1*H*-2-benzopyran-1-one (**8***a*) and 120 mg (1.7 mmol) of *n*-butylamine in 15 mL cyclohexane was treated as described for **11***a*. Flash chromatography (3:1 H/EA) gave 236 mg (77%) of **11***b* IR: 1648 cm^{-1}; ^1H NMR δ: 0.70 (t, 3H, $J = 7.4$ Hz), 1.11 (m, 2H), 1.52 (m, 2H), 3.92 (t, 2H, $J = 7.7$ Hz), 6.37 (s, 1H), 7.40 (m, 7H), 7.60 (t, 1H, $J = 7.4$ Hz); ^{13}C NMR δ: 13.4, 19.9, 30.7, 45.3, 107.7, 125.2, 125.6, 126.5, 127.9, 128.3, 128.8, 129.0, 132.2, 136.2, 136.2, 143.6, 162.7; MS (EI) *m/z*: 277 (M^+), 260, 234, 221; HRMS calcd. for $C_{19}H_{19}NO$: 277.1426; found: 277.1446.

1-Oxo-3-methyl-2-phenylmethyl-1,2-dihydroisoquinoline (11*c*)
A solution of 217 mg (1.2 mmol) of 3,4-dihydro-3-cyano-3-methyl-1*H*-2-benzopyran-1-one (**8***e*) and 200 mg (1.8 mmol) benzylamine in 15 mL cyclohexane was treated as described for **11***a*. Flash chromatography (4:1 H/EA) gave 165 mg (57%) of **11***c*: IR: 1657 cm^{-1}; ^1H NMR δ: 2.30 (s, 3H), 5.40 (s, 2H), 6.34 (s, 1H), 7.13 (d, 2H, $J = 7.6$ Hz), 7.23 (m, 3H), 7.41 (m, 2H), 7.59 (t, 1H, $J = 7.5$ Hz), 8.41 (d, 1H, $J = 8.1$ Hz); ^{13}C NMR δ: 20.6, 47.0, 106.1, 124.4, 125.0, 125.9, 126.3, 127.1, 128.2, 128.7, 132.3, 136.8, 137.6, 139.5, 163.4; MS (EI) *m/z*: 249 (M^+), 232, 172, 158; HRMS calcd. for $C_{17}H_{15}NO$: 249.1154; found: 249.1161.

2-Butyl-1-oxo-3-methyl-1,2-dihydroisoquinoline (11*d*)
A solution of 289 mg (1.5 mmol) of 3,4-dihydro-3-cyano-3-methyl-1*H*-2-benzopyran-1-one (**8***e*) and 210 mg (2.3 mmol) of *n*-butylamine in 15 mL cyclohexane was treated as described for **11***a*. Flash chromatography (4:1 H/EA) gave 281 mg (85%) of **11***d*: IR: 1651 cm^{-1}; ^1H NMR δ: 0.92 (t, 3H, $J = 7.2$ Hz), 1.41 (m, 2H), 1.64 (m, 2H), 2.35 (s, 3H), 2.35 (s, 3H), 4.01 (t, 2H, $J = 7.7$ Hz), 6.25 (s, 1H), 7.33 (m, 2H), 7.50 (t, 1H, $J = 8.3$ Hz), 8.31 (d, 1H, $J = 8.1$ Hz); ^{13}C NMR δ: 13.7, 20.3, 20.4, 30.9, 44.1, 105.9, 124.5, 124.8, 125.7, 127.8, 132.0., 136.6, 138.9, 162; MS (EI) *m/z*: 215 (M^+), 198, 186, 173; HRMS calcd. for $C_{14}H_{17}NO$: 215.1310; found: 215.1298.

3-Phenyl-1*H*-2-benzopyran-1-one (12*a*)
To a stirred solution of 100 mg (0.4 mmol) of 3,4-dihydro-3-cyano-3-phenyl-1*H*-2-benzopyran-1-one (**8***a*) in 15 mL of dry THF, cooled to 0°C, was added 70 mg (0.6 mmol) of potassium *tert*-butoxide under nitrogen atmosphere. The mixture was warmed to room temperature and stirred for 15 h after which time TLC analysis indicated complete conversion of the starting material. The reaction was quenched by dropwise addition of 6.0 mL 10% aqueous HCL followed by extraction with three 15 mL aliquots of CH_2C1_2. After drying over $MgSO_4$ and concentrating the solvent, the crude isocoumarin was purified by flash cohromatography (4:1 H/EA) to give 45 mg (50%) of **12***a*, mp 89–90°C. The spectral properties agreed with the literature values (16).

3-Methyl-1*H*-2-benzopyran-1-one (12*b*)
A stirred solution of 100 mg (0.5 mmol) of 3,4-dihydro-3-cyano-3-methyl-1*H*-2-benzopyran-1-one (**8***e*) in 15 mL dry THF was treated as described above and gave 57 mg (66%) of purified **12***b*, mp 74°C, after flash chromatography (CH_2Cl_2). The melting point and spectral characteristics agreed with the literature values (17).

Decomposition of tosylhydrazones of benzoin, benzoin acetate, and benzoin benzoate with alkali and metal complex hydrides

Tsukasa Iwadare, Yoshiyuki Ichinohe, and Kazuhiko Orito

Abstract: Treatment of tosylhydrazones of benzoin, benzoin acetate, and benzoin benzoate with alkali under protic and aprotic conditions yielded diphenyl acetylene together with desoxybenzoin. An increase in leaving aptitude of the adjacent group enhanced the formation of diphenyl acetylene. By treatment with $LiAlH_4$ and with $NaBH_4$, the tosylhydrazones gave stilbenes in good yields. Selective formation of *cis*- or *trans*-stilbene was observed in some cases.

Key words: tosylhydrazone, benzoin derivatives, decomposition, metal complex hydrides.

Résumé : Le traitement des tosylhydrazones de la benzoïne, de l'acétate de benzoïne et du benzoate de benzoïne par des alcalis dans des conditions tant protiques qu'aprotiques fournit du diphénylacétylène et de la désoxybenzoïne. Une augmentation du pouvoir migratoire du groupe adjacent tend à provoquer une formation accrue de diphénylacétylène. Par traitement avec du $LiAlH_4$ et du $NaBH_4$, les tosylhydrazones conduisent aux stilbènes avec de bons rendements. Dans certains cas, des formation sélectives de *cis*- ou *trans*- stilbène ont été observées.

Mots clés : tosylhydrazone, dérivés de la benzoïne, décomposition, hydrures métalliques complexes.

Introduction

Since the report of Bamford and Stevens (1), a number of papers have been published (2, 3) on the decomposition of tosylhydrazones. The reaction developed by Shapiro and Heath (4) was particularly significant for progress in the synthesis of substituted alkenes. In recent years, there have been many studies on photolysis (5–7) and pyrolysis (8–13) of metal salts of tosylhydrazones via a carbene intermediate. Reductive decomposition of tosylhydrazones with $LiAlH_4$ and with $NaBH_4$ to alkane or alkene was reported by Caglioti and Magi (14–16). The reaction has been modified by using $NaBH_3CN$ (17) to give reduction products in excellent yields. However, there have been only a few reports (18–20) on the reaction of tosylhydrazones containing a leaving group on the adjacent carbon. In this paper, we report the reactions of such a tosylhydrazone.

Bamford and Stevens (1) reported that the tosylhydrazone (**1**) of benzoin gave desoxybenzoin (**2**) in 65% yield by decomposition in a protic solvent (Na, $HOCH_2CH_2OH$). Although they did not refer to the formation of diphenylacetylene (**3**), the reaction is expected to give **3** according to the reaction sequence shown (Scheme 1). The study by Hassner and Reuss (21) on the reaction of nitrooxazolidines with NaOMe, providing **3** through the same intermediate, gives supportive evidence for the reaction pathway to **3** assumed in Scheme 1.

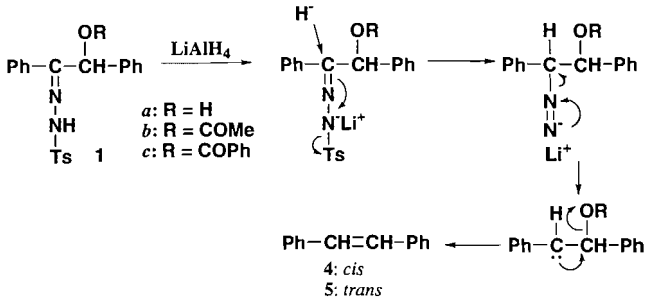
verted into the respective tosylhydrazones (**1***a*,*b*,*c*) by the usual method, and treated with alkali under protic and aprotic conditions. The product mixtures were separated by preparative TLC and analyzed by GLC. As shown in Table 1, the anticipated triple bond formation took place under both protic and aprotic conditions. Also, it was revealed that an increase in the leaving aptitude of the OR group (R = H, COMe, COPh) results in facile formation of **3**. Freedman and Schechter (22) have proven that decomposition of tosylhydrazones proceeds via a carbene intermediate under aprotic conditions. If elimination of the adjacent group does not take place a carbene intermediate (route a) is formed, and gives **2** via the enolate. However, an alternative pathway via protonation (route b) must also be considered for entries 1, 2, 3, and 4. The results revealed that the elimination (route c) of the acetoxyl and benzoyloxyl groups of **1***b* and **1***c* under aprotic conditions strongly predominates over the formation of **2**.

Djerassi and co-workers (23) showed that the reductive decomposition of tosylhydrazones with $LiAlH_4$ proceeds via a carbanion intermediate, which incorporates proton in the course of work-up leading to products. However, it seems reasonable to assume that alkene formation would be strongly favored in the presence of a suitable leaving group on the carbon adjacent to the incipient carbanion. Thus **1***a*, **1***b*, and **1***c* would be expected to give stilbenes (*cis*: **4**, *trans*: **5**) by decomposition with $LiAlH_4$ via the sequence shown in Scheme 2. Accordingly, **1***a*, **1***b*, and **1***c* were treated with $LiAlH_4$ in ethyl ether, THF, and dioxane, and the products were analyzed by GLC. While **4** and **5** were obtained in good yields in each case, stereoselectivity in the formation of stilbene isomers was observed only when ethyl ether was employed as a solvent

Scheme 2.



(entries 1, 2, 3), as shown in Table 2. Desoxybenzoin (**2**) and 1,2-diphenylethanol, which may form through protonation of the carbanion intermediate, were not detected at all.

Djerassi and co-workers demonstrated (23) that tosylhydrazones are decomposed to alkane or alkene by treatment with $NaBH_4$ through an alkyl diimide intermediate. In our experiments, if a similar carbanion intermediate is formed via the diimide by treatment of tosylhydrazones (**1***a*,*b*,*c*) with $NaBH_4$, stilbene must be produced. Thus **1***a*, **1***b*, and **1***c* were treated with $NaBH_4$ in dioxane, and the products were analyzed by GLC. As shown in Table 3, stilbenes (**4**, **5**) were formed in good yields. The results support the above assumption. Formation of **5** was selective only when **1***b* was the substrate (entry 2), and **1***c* afforded predominantly **4** (entry 3). However, a reasonable explanation of these differences in stereoselectivity cannot be given at the present point.

On the basis of the results, we conclude that (*i*) decomposition with alkali of tosylhydrazones containing a leaving group on the adjacent carbon gives rise to triple bond formation

through the sequential pathway, as shown in Scheme 1 (route c), and (*ii*) treatment with metal complex hydrides yields alkenes resulting form 1,2-elimination between the incipient carbanion and the leaving group (Schemes and 2 and 3).

Experimental

Melting points were uncorrected. GLC analysis was carried out using a Hitachi 263-50 gas chromatograph and D-7500 integrator (Quadrex bonded fused silica capillary column methyl silicone (0.53 mm i.d. × 10 m × 3.0 mm) at 205°C; injector temperature, 180°C; detector temperature, 220°C; carrier gas, N_2; flow rate, 13.0 mL/min) for *cis*-stilbene (**4**) (retention time, 2.54 min), diphenylacetylene (**3**) (retention time, 3.78 min), *trans*-stilbene (**5**) (retention time, 4.34 min), desoxybenzoin (**2**) (retention time 4.51 min), and benzoin (retention time 5.63 min). Preparative TLC was performed on Merck silica gel 60 PF_{254}, being developed with a 1:1 mixture of benzene and hexane for **2** (R_f 0.33) and **3** (R_f 0.92), and also with hexane for **4** (R_f 0.53) and **5** (R_f 0.42). The products were identified by direct comparison with authentic samples prepared by the usual methods.

Preparation of tosylhydrazones (1*a*,*b*,*c*)

A solution of benzoin (2.5 g, 11.80 mmol) and tosylhydrazine (2.2 g, 11.81 mmol) in EtOH (30 mL) was refluxed for 4 h. EtOH was evaporated under reduced pressure, and the residue crystallized after standing overnight. Recrystallization from MeOH gave colorless needles of **1***a*, mp 145–145.5°C. Tosylhydrazones of benzoin acetate (**1***b*, mp 127–129°C) and benzoin benzoate (**1***c*, mp 153–154.5°C) were prepared in the same manner.

Decomposition of tosylhydrazones (1*a*,*b*,*c*) with sodium ethylene glycolate in ethylene glycol

Tosylhydrazone (**1***a*, **1***b*, or **1***c*, 2.6 mmol) was added to a solution of Na metal (60 mg, 2.61 mmol) in ethylene glycol (10 mL), and the solution was refluxed for 40 min. The cooled reaction mixture was diluted with water (50 mL), extracted with ether (50 mL), and the ethereal layer was washed successively with saturated brine (10 mL), water (10 mL), and then dried over anhydrous Na_2SO_4. After evaporation of the solvent, the residue was subjected to GLC analysis and to preparative TLC for isolation and identification of the products.

Decomposition of tosylhydrazones with NaOMe in diethyleneglycol diethyl ether

A solution of NaOMe (141 mg, 2.51 mmol) and tosylhydrazone (**1***a*, **1***b*, or **1***c*, 2.61 mmol) in diethyleneglycol diethyl ether (10 mL) was refluxed for 40 min. The reaction mixture was cooled, diluted with water (50 mL), and extracted with ether (50 mL). The extract was washed with water (5 × 10 mL), dried over anhydrous Na_2SO_4, and the solvent was evaporated. The residue was subjected to GLC analysis and to preparative TLC for isolation and identification of the products.

Decomposition of tosylhydrazones with $LiAlH_4$

A suspension of tosylhydrazone (**1***a*, **1***b*, or **1***c*, 2.61 mmol) and $LiAlH_4$ (100 mg, 2.64 mmol) in an appropriate solvent (30 mL) was stirred at room temperature for 1 h and then refluxed for 1 h. The excess $LiAlH_4$ was decomposed (24) by the successive addition of water (1 mL), 15% NaOH solution (1 mL), and water (3 mL). The precipitate that formed was filtered off, and the filtrate was extracted with ether (50 mL). The ethereal extract was washed with water (10 mL), dried over anhydrous Na_2SO_4, and the ether was evaporated. The residue was subjected to GLC analysis and to preparative TLC for isolation and identification of the products.

Samples of **4** and **5** were recovered unchanged after being subjected to the above reaction conditions.

Decomposition of tosylhydrazones with $NaBH_4$

A solution of tosylhydrazone (**1***a*, **1***b*, or **1***c*, 2.61 mmol) and $NaBH_4$ (100 mg, 2.65 mmol) in dioxane (30 mL) was stirred at room temperature for 1 h and then refluxed for an additional 2 h. The excess reagent was decomposed with acetic acid. The reaction mixture was made alkaline with 5% Na_2CO_3 solution, and then extracted with ether (50 mL). The ethereal layer was washed with water (10 mL), and then dried over anhydrous Na_2SO_4. The solvent was evaporated and the residue was subjected to GLC analysis and to preparative TLC.

Samples of **4** and **5** were recovered unchanged after being subjected to the above experimental conditions.

Kraft pulp bleaching using dimethyldioxirane: stability of the oxidants

J. Bouchard, C. Maine, R.M. Berry, and D.S. Argyropoulos

Abstract: Dimethyldioxirane (DMD) is a cyclic peroxide made by oxidizing acetone with peroxymonosulfate (PMS) in water buffered at pH 7.5 using sodium bicarbonate. It has been shown that DMD generation can be achieved in situ within a pulp suspension allowing very selective TCF bleaching of kraft pulp. This process involves simultaneous generation of DMD, reaction of PMS and DMD with residual lignin, and spontaneous decomposition of both oxidants. The first part of this work is a kinetics study of the decomposition of PMS and DMD as a function of pH under conditions similar to those for in situ bleaching. The effect of chelation as well as the effect of transition metal ions on decomposition rate was also investigated. DMD is very sensitive to pH and its half-life is very short under alkaline conditions. The presence of any transition metal ion that can be involved in a one-electron transfer is detrimental to DMD stability. However, fast reaction of DMD with pulp almost counteracts the effect of metal ions.

Key words: bleaching, peroxymonosulphate, dimethyldioxirane, metal ions, kinetics, decomposition, kraft pulp.

Résumé : Le diméthyldioxirane (DMD) est un peroxyde cyclique obtenu par oxydation de l'acétone avec le peroxymonosulfate (PMS) en milieu aqueux tamponné à pH 7,5 à l'aide du bicarbonate de sodium. La synthèse du DMD, lorsque réalisée in situ dans une suspension de pâte kraft, représente un procédé de blanchiment sans chlore très sélectif. Au cours de ce procédé, la synthèse du DMD, l'attaque de la lignine résiduelle par le DMD et le PMS ainsi que la décomposition naturelle de ces deux oxydants se produisent simultanément. Le première partie de ce travail consiste en une étude cinétique de la décomposition du DMD et du PMS en fonction du pH dans des conditions similaires à celle du procédé de blanchiment in situ. L'effet de la chelation ainsi que la présence d'ions métalliques ont également été étudiés. La décomposition du DMD est très sensible au pH et des demi-vies très courtes sont observées en milieu basique. La présence de métaux de transition pouvant échanger un électron s'avère néfaste à la stabilité du DMD mais la vitesse de réaction du DMD diminue grandement cet effet négatif.

Mots clés : blanchiment, peroxymonosulfate, diméthyldioxirane, ions métalliques, cinétique, décomposition, pâte kraft.

Introduction

The development of a totally chlorine-free (TCF) sequence for kraft pulp bleaching has focused on using molecular oxygen, hydrogen peroxide, and ozone. Recently, Lee, Hunt, and Murray have shown that dimethyldioxirane (DMD), a member of the cyclic peroxide family, can be used as a novel and selective non-chlorine bleaching agent (1–4). Effective bleaching of kraft pulp using DMD in either an isolated (1) or an in situ generated form (2) has been demonstrated.

Dimethyldioxirane is a stereospecific electrophilic oxygen transfer agent that allows epoxidation of unsaturated centres at room temperature. It is formed during the acetone-catalyzed decomposition of peroxymonosulfuric acid (H_2SO_5) as shown by Edwards et al. (5) and can be isolated as an azeotrope with acetone (6). Reviews on DMD chemistry have been published (7, 8), and new applications of this chemical routinely appear in the literature.

The specific reactions of DMD with lignin model compounds have been studied by Argyropoulos et al. (9) who have shown that DMD oxidizes the aromatic ring of both etherified and non-etherified (phenolic) lignin model compounds. DMD appears to be more reactive toward etherified structures than ClO_2, O_2, and H_2O_2. This higher reactivity partially explains the superiority of DMD because the etherified aromatic units are the majority in almost all residual lignins.

It has been assumed in these initial evaluations that DMD and the oxidant used in its preparation are relatively stable and that any decomposition has limited consequences on the progress of the required oxidation reactions. It is this assumption that is being more fully evaluated in this report.

Bleaching of kraft pulp by in situ generation of DMD

To generate DMD in situ, a method was demonstrated by Lee et al. (3, 4), whereby pulp is mixed with acetone, peroxymonosulphuric acid (PMS), and bicarbonate. This system is complex in that it involves the simultaneous in situ generation of DMD, the decomposition of oxidants, and the delignification of the pulp (Fig. 1).

Both DMD and PMS react with lignin but both oxidants are relatively unstable and undergo spontaneous decomposition that generates oxygen. As well, DMD is decomposed by reacting with PMS (5). To add to this complexity is the possible effect of interaction with water. While the decomposition of isolated DMD in nonaqueous media has been discussed previously (6), the stability of DMD as a function of the pH in aqueous solutions has not.

DMD stability (in a nonaqueous medium)

Isolated solutions of DMD can be kept for months at −20°C (10); however, at room temperature they decompose comparatively quickly with reported lifetimes ranging from a few hours (11) to 24 h (12). While it has been reported that DMD decomposition follows a complex rate law (11, 12), Singh and Murray (10) have shown that first-order kinetics can be obtained at low DMD concentrations (0.03 M). They also showed that autodecomposition of DMD at room temperature leads almost stoichiometrically to methyl acetate. No evidence was found for the formation of acetone diperoxide, acetol, or acetolacetate.

As previously mentioned, the effects of water and pH on DMD stability in aqueous solutions have not yet been addressed. Since the in situ DMD bleaching of kraft pulp requires a buffered aqueous solution, the effects of water and pH are particularly relevant and are addresed in this study.

Peroxymonosulfuric acid (PMS) stability

This inorganic peracid ($HOSO_2OOH$) has two ionization constants. The acidic proton has a $pK_{a_1} < 0$ while the peroxide proton is weakly acidic ($pK_{a_2} \approx 9.4$) (13). Ball and Edwards (14) studied the kinetics of spontaneous PMS decomposition as a function of pH and found that spontaneous decomposition is the sole mechanism when trace-metal catalysis is suppressed by chelation.

$$2\ HSO_5^- \rightarrow 2\ H^+ + 2\ SO_4^{-2} + O_2$$

In the pH range from 6 to 8 where HSO_5^- is the major species, Ball and Edwards proposed a rate law (eq. [1]) based on second-order kinetics.

$$[1] \quad -\frac{d\,[HSO_5^-]}{dt} = k_a \frac{[HSO_5^-]^2}{[H^+]}$$

They also reported that the log of the rate of decomposition, as a function of the pH, shows a typical bell-shaped profile with the maximum located at pK_{a2}. The slopes of the straight lines from both sides of the bell-shaped curve indicate first-order kinetics in both the peracid and its anion.

It should be remembered that in the Ball and Edwards study solutions of PMS have an active oxygen (AO) concentration of the order of 0.02 M. However, the AO concentration Lee et al. (3) found necessary for pulp bleaching was about one order of magnitude higher. Since commercial preparations of PMS have only recently become available in a solid state salt form, Ball and Edwards used a solution they prepared themselves that was roughly composed of half PMS and half sulphuric acid and also contained hydrogen peroxide. In recent work, hydrogen peroxide-free commercial preparations of PMS (2 $KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) have been used to generate DMD in situ. For this reason and due to differences between the earlier work of Ball and Edwards and the more recent work of Lee et al. (3), it was considered appropriate to determine whether the commercially produced PMS was comparable in terms of stability with the preparations tested by Ball and Edwards.

Stability of oxidants in presence of metal ions

Recently, Francis et al. (15) have shown that PMS is quite insensitive to the presence of transition metal ions (Mn, Fe, Cu, Ni, V, Co) except in the case of copper under alkaline conditions and cobalt at concentrations much higher than normally found in pulps. However, no work has been published on determining the effect of metal ions on DMD stability. The present study evaluates this significant parameter.

Experimental

DMD synthesis

Pure dimethyldioxirane was prepared according to general literature procedures (11, 16). Solutions in acetone were assayed for dioxirane content by iodometric titration, and only those solutions with molarity 0.06 M or higher were used. These solutions were stored over 5 Å molecular sieves at −20°C until required.

Peroxymonosulfate stability experiments

A series of experiments was done to show the relationship between the stability of commercially prepared PMS (Oxone, Dupont) and pH. Oxone was dissolved in buffered aqueous solution in order to give an active oxygen (AO) concentration of 0.139 mol/L, which corresponds to an AO charge of 2% on oven dried (o.d.) pulp at 10% consistency (1 g of oxone contains 0.045 g of active oxygen). The PMS solutions were buffered using phosphate (pH 5.0 through 8.8), bicarbonate (pH 7.1), or carbonate (pH 9.2) buffers (0.18–0.5 M). In some experiments, metal ions were chelated with EDTA (0.1%). At fixed intervals, 5 mL samples were analyzed iodometrically for residual AO concentration. The formation of HSO_4^- from HSO_5^- caused the pH to fluctuate slightly. As a result, the pH was periodically checked and, if necessary, readjusted to its target value.

A second series of experiments dealing with the effect of PMS concentration on its stability was done using PMS concentrations of 0.296, 0.198, and 0.088 mol/L. These values correspond to AO charges of 3.0, 2.0, and 0.9%, respectively, on o.d. pulp at 13.6% consistency. This work was carried out at pH 7.1 using bicarbonate buffer.

Effect of water or buffered aqueous solutions on DMD stability

Solutions of isolated DMD (0.066 M in acetone) or isolated DMD diluted in water (0.048 M DMD containing 28% water)

Fig. 2. Second-order kinetics of peroxymonosulfate decomposition at different pH. (Q) indicates chelating agent addition, $[PMS]_0$ is the concentration at zero reaction time.

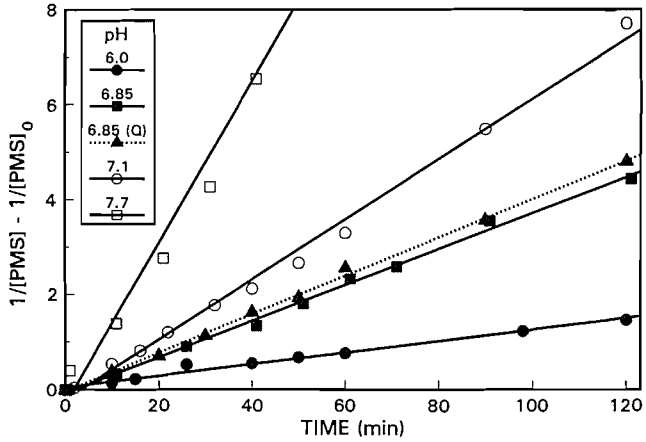

Fig. 3. Log of the PMS decomposition rate constant as a function of the pH in the presence of different buffering agents.

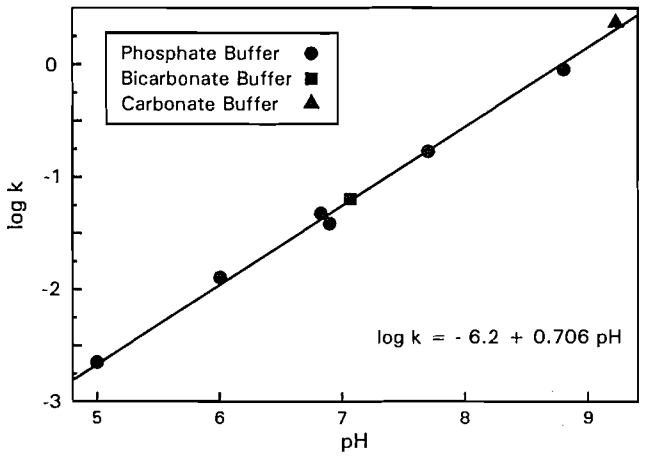


were used in these experiments. Decreases in DMD concentration as a function of time at room temperature were followed using iodometric titration. The solutions were monitored for at least three half-lives.

For monitoring the effect of pH on DMD stability, the procedure was the same as that described in the previous paragraph, except that 20 mL of a phosphate buffer (0.18 or 0.50 M) or bicarbonate buffer (0.1 M) was added to 30 mL of isolated DMD. The pH of the buffers ranged from 5 to 9.

Effect of metal ions on DMD stability

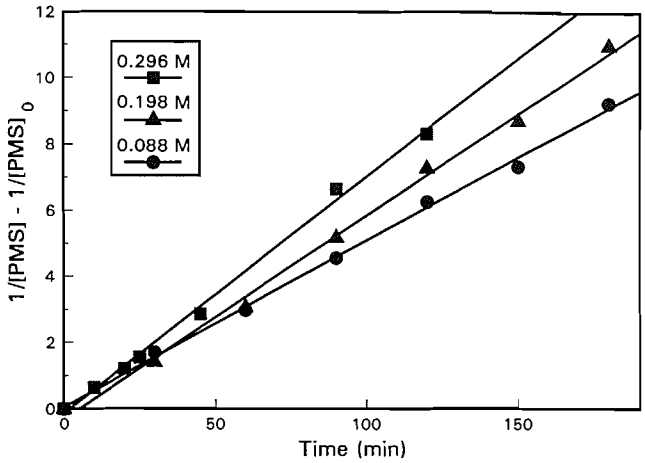
DMD–acetone solution (20 mL; 0.03 M) was added to 10 mL of 0.18 M phosphate buffer containing different metal ions at pH 7.0. The final metal ion concentration was 100 ppm in each case. The metal ions used were Mg^{+2} ($MgSO_4$), Mn^{+2} ($MnCl_2$), Fe^{+2} ($FeCl_2$), and Mn^{+4} (MnO_2). The solutions were monitored for at least three half-lives.

Results and Discussion

Effect of pH on decomposition rate constants of PMS

Figure 2 shows that at a fixed pH and temperature, PMS decomposition follows second-order kinetics and also that the decomposition is accelerated as the pH is varied from 6.0 to 7.7. Adding a chelant to the solution appears to have no effect. This conclusion is made because the two curves at pH 6.85, obtained with and without EDTA, gave very similar rate constants of 0.041 and 0.038 $(mol/L)^{-1}$ min^{-1} respectively. This result indicates that decomposition resulting from trace metal ions present in the buffer or in the commercial preparation of PMS itself is not a concern. Only the mechanism responsible for spontaneous decomposition is significant.

Fig. 4. Second-order kinetics of peroxymonosulfate decomposition at various PMS concentrations.



In Fig. 3, log k is plotted as a function of the pH as was done by Ball and Edwards (14). The slope of the linear relationship indicates that the dependence on the concentration of hydrogen ion is on the order of 0.7 as opposed to the first order measured by Ball and Edwards (14). Goodman and Robson (17) and, more recently, Francis et al. (15) have also used the solid triple potassium salt of PMS to study decomposition. Using their data, we calculated a 0.73 (Goodman and Robson) and 0.62 (Francis et al.) order of reaction with respect to hydrogen ion concentration. Goodman and Robson did not mention the PMS concentration used in their experiments while Francis et al. used 0.033 M. When our results were combined with theirs, the rate law of peroxymonosulphate decomposition becomes:

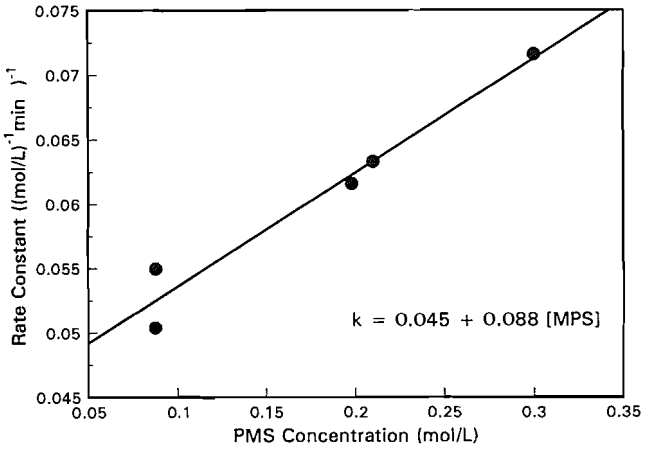
$$[2] \quad -\frac{d\,[HSO_5^-]}{dt} = k_a \frac{[HSO_5^-]^2}{[H^+]^{0.7}}$$

The reason why the triple potassium salt of PMS has a lower order of dependence on the hydrogen ion concentration remains unknown. The effect of PMS concentration on decomposition is shown in Fig. 4. This second-order plot illustrates the degradation at three concentrations of PMS at pH 7.1. These concentrations correspond to the range used for in situ DMD bleaching of pulp. The rate constant of decomposition increases slightly as the PMS concentration is increased. The linear relationship between the rate constants of decomposition and PMS concentration is shown in Fig. 5 and can be described by eq. [3].

$$[3] \quad k_a = 0.045 + 0.088\,[PMS]$$

Greater rates of decomposition of PMS have been reported when the ionic strength of the PMS solution is increased with

Fig. 5. Relationship between the rate constants of decomposition and PMS concentration.



either potassium sulphate (14) or sodium sulphate (17). Since oxone carries a dead load of about 57% potassium sulphate salts, it is not surprising that we also observed higher rates of decomposition when we increased the PMS concentration at the same pH.

Effect of PMS decomposition on pulp bleaching

At present, kraft pulps bleached with PMS and acetone are initially buffered to pH 7.4 with sodium bicarbonate. According to our kinetic results, the half-life of PMS is 22.5 min at pH 7.4 while it is 10 times higher at pH 6.0. This suggests that PMS bleaching of kraft pulp should be done under acidic conditions where PMS has a greater stability. However, preliminary work has shown that the rate of pulp bleaching increases as the pH of the pulp suspension increases. Consequently pulp bleaches faster under alkaline conditions while, at the same time, PMS decomposes more quickly.

Another advantage of higher pH has been indicated by Francis et al. (15) who demonstrated a detrimental effect on pulp viscosity when pulp is bleached at pH below 4. The effect of pH on the kinetics of PMS bleaching will be elaborated in a future publication.

Effect of water and buffered aqueous solution on DMD stability

Decomposition of isolated DMD or DMD in an acetone–water mixture obeys first-order kinetics. Table I gives the observed decomposition rate constants and the half-life of DMD under different conditions. These data indicate that DMD decomposes about three to four times faster in the presence of water than in pure acetone. The natural pH of the water–acetone–DMD solution was 3.8. Bringing this pH close to neutrality (6.8) increases the degradation rate by a factor of about 30. Consequently, the half-life of the DMD, which is approximately 77 h as an acetone solution, drops to 27 h for acetone–water solution, and to 50 min when the pH of the acetone–water solution is brought to neutrality.

Pure DMD solutions were diluted using aqueous buffers to give an acetone/water ratio of 60:40. The decrease of DMD concentration as a function of time is shown in Fig. 6 over the pH range 5–9. The main conclusion from Fig. 6 is that DMD is much more stable in acidic conditions than in neutral or alkaline conditions. All these curves can be described by first-order kinetics. The rate constants as well as the half-life of DMD are presented in Table 2.

Fig. 6. First-order kinetics of dimethyldioxirane decomposition at different pHs.

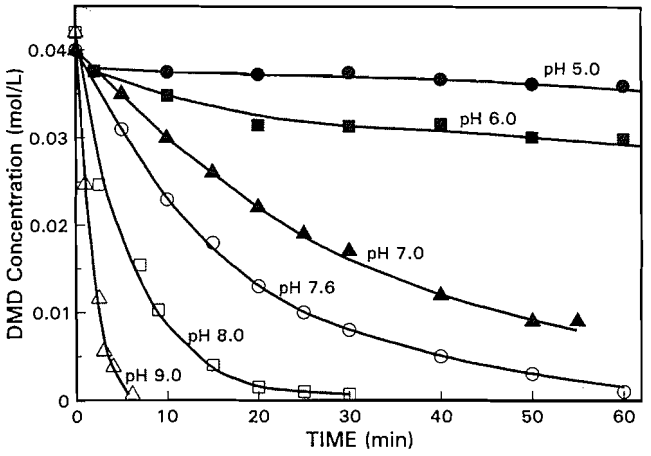


Table 1. First-order rate constants for DMD decomposition in acetone and an acetone–water mixture (70:30).

DMD solvent	DMD conc. (mol/L)	pH	k (min^{-1})	Half-life (min)
Acetone	0.044 – 0.066	—	1.2×10^{-4}	5800
Acetone–H_2O	0.048	3.8	4.2×10^{-4}	1650
Acetone–H_2O	0.040	6.8	1.4×10^{-2}	50

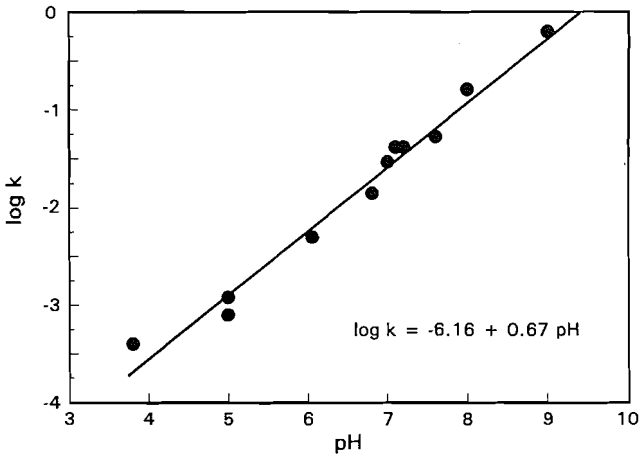
Table 2. First-order rate constants for degradation of DMD in buffered acetone–water solutions at different pHs (PO_4: phosphate buffer).

Buffer	pH	k_{obs} (min^{-1})	Half-life (min)	log k_{obs}
Water	3.8	4.2×10^{-4}	1650	−3.40
PO_4	5.0	1.0×10^{-3}	690	−3.00
PO_4	6.05	5.0×10^{-3}	140	−2.30
Water	6.8	1.4×10^{-2}	50	−1.90
PO_4	7.0	2.9×10^{-2}	24	−1.50
PO_4	7.2	4.2×10^{-2}	17	−1.40
Bicarb	7.6	5.4×10^{-2}	13	−1.30
PO_4	8.0	1.6×10^{-1}	4.3	−0.80
PO_4	9.0	6.2×10^{-1}	1.1	−0.20

DMD is relatively stable at room temperature under acidic conditions. However, under neutral conditions, the half-life of DMD is less than 30 min. Under the conditions used for kraft pulp bleaching (bicarbonate buffer, pH 7–7.5), the half-life of DMD is about 15 min.The last column of Table 2 gives the logarithmic values of k_{obs}.

The plot of log k_{obs} as a function of pH is shown in Fig. 7. The linear relationship between log k_{obs} and pH indicates the sensitivity of DMD to hydroxyl anion (or the stabilizing effect of the hydrogen ion) and is expressed by the following rate law:

Fig. 7. Log of the DMD decomposition rate constant as a function of the pH.



$$[4] \quad -\frac{d\,[DMD]}{dt} = k_{obs}\frac{[DMD]}{[H^+]^{0.7}}$$

Unlike PMS, DMD is not sensitive to the ionic strength or nature of the species used for buffering. For example, pure water, or buffers with concentrations of phosphate or bicarbonate ranging from 0 to 0.5 M, had no effect on the rate of decomposition of DMD.

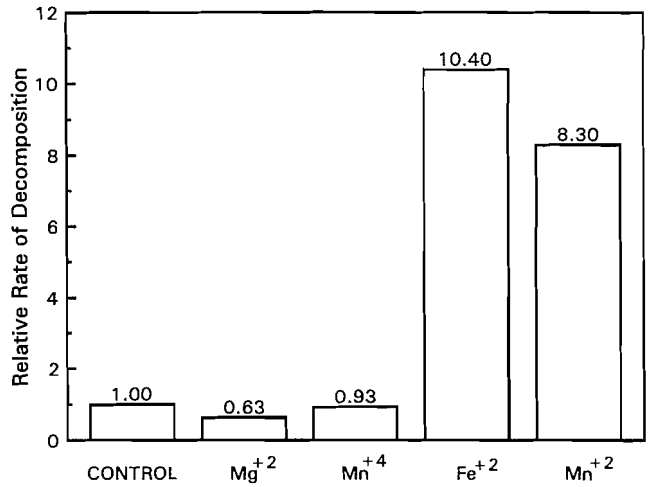
Effect of transition metals on DMD decomposition

The relative rates of decomposition of DMD in buffered aqueous solutions spiked with 100 ppm of metal ions are shown in Fig. 8. The control experiment was given a value of 1 and the others were normalized accordingly. When the metal ions can not be further oxidized by one-electron transfer, e.g., Mg^{+2}, Mn^{+4}, they do not increase the decomposition rate of DMD. Moreover, Mg^{+2} seems to stabilize the cyclic peroxide. When this transfer of one electron is possible, e.g., Fe^{+2}, Mn^{+2}, the rate of decomposition of DMD increases by a factor of 10. This acceleration of decomposition, however, does not have a large impact because of the fast reaction of DMD with pulp. The need for a metal management strategy is therefore less critical. Lee et al. (2) have shown only a slight improvement in selectivity by doing a chelation stage prior to in situ DMD bleaching. If necessary, the removal of metal ions can be done by an acid treatment (18) or a chelation stage (19) followed by a wash step. Further work needs to be done regarding the positive role played by magnesium ion.

Effect of oxidant decomposition on in situ DMD bleaching

Lee et al. (2) have shown that all the oxidants (PMS and DMD) are consumed within 45 min during in situ bleaching of kraft pulp. However, they also observed, when mixing pure DMD solution with kraft pulp at room temperature, that all the DMD is consumed in a very short period of time. They concluded that the reaction rate of DMD with lignin is much faster than the reaction rate of PMS and acetone to yield DMD. Consequently, generation of DMD appears to be the rate determining step of in situ bleaching and therefore decomposition of PMS is likely the main oxidant-loss mechanism. As PMS is insensitive to metal ions, the omission of the chelation stage prior to in situ DMD bleaching has less impact than for a hydrogen peroxide bleaching stage.

Fig. 8. Relative rate of decomposition of DMD in the presence of different metal ions.



Under the conditions used for kraft pulp bleaching (bicarbonate buffer, pH 7–7.5), the half-life of PMS is 22 min and this would significantly affect the overall oxidant concentration. As a result the effective charge of DMD will not be equivalent to the applied charge on pulp.

Conclusions

1. As previously shown, the decomposition of peroxymonosulphate is second order in PMS and the rate of decomposition increases as the pH is increased from 5 to 9. The dependence of the reaction on hydrogen ion concentration was found to be a lower order (0.7) than that previously published in the literature.
2. There is a small dependence of the rate constant of decomposition on the concentration of PMS. The dependence causes an acceleration of decomposition as the PMS concentration is increased.
3. Dimethyldioxirane is quite stable (half-life>25 h) at room temperature in acetone or acetone–water solution as long as the pH is kept below 4.
4. The decomposition of DMD is first order in DMD and is unaffected by the ionic strength of the solution. The dependence of the reaction on hydrogen ion concentration is the same order as that observed in the decomposition of PMS.
5. Under kraft pulp bleaching conditions where the pH is buffered between 7 and 8, the half-life of DMD varies between 24 and 4 minutes while the half-life of PMS varies between 43 and 8.5 min.
6. The decomposition of DMD is accelerated by the presence of transition metal ions such as Fe^{+2} and Mn^{+2} but seems to be protected by the presence of Mg^{+2}. The impact of this acceleration is counteracted by the fast reaction of DMD with lignin in pulp.

Preparation and analysis of some acetosugar esters of abscisic acid and derivatives[1]

J. Balsevich, G. Bishop, S.L. Jacques, L.R. Hogge, D.J.H. Olson, and N. Laganière

Abstract: Racemic abscisic acid (ABA), the *cis* and *trans* 1′, 4′-diols (ABA diols) derived from ABA by reduction of the 4′ ketone, and the corresponding 4′-O-acetates were converted into various acetosugar esters by reaction of their cesium salts with the 1-chloroacetosugars derived from glucose, galactose, lactose, and maltose. Analytical separations of the acetosugar esters using high-performance liquid chromatography (LC) on reverse-phase columns were developed. Continuous flow secondary ion mass spectra (CFSIMS) of the various acetosugar esters were obtained and an LC/CFSIMS protocol employing multiple reaction monitoring was used to detect ABA acetoglucose ester in an acetylated extract obtained from plant cells that had been treated with ABA.

Key words: abscisic acid, acetosugar esters, synthesis, chromatography, mass spectrometry.

Résumé : La réaction des sels de césium de l'acide abscissique (AAB) racémique, des diols-1′, 4′ *cis* et *trans* (diols de l'AAB) obtenus par réduction de la 4′-cétone ainsi que des 4′-O-acétates correspondants avec les 1-chloroacéto sucres dérivés de glucose, galactose, lactose et maltose, a permis de les transformer en esters d'acétosucres. On a développé une méthode analytique qui permet de séparer les esters d'acétosucres par chromatographie liquide (CL) à haute performance sur des colonnes en phase inversées. Pour chacun des esters d'acétosucres, on a obtenu les spectres de masse des ions secondaires en écoulement continue (SMISÉC) et un protocole de CL/SMISÉC faisant appel à un monitoring de réactions multiples a été utilisé pour l'ester acétoglucose ABA dans le produit d'extraction acétylé obtenu à partir de cellules de plantes traitées par du ABA.

Mots clés : acide abscissique, esters d'acétosucres, synthèse, chromatographie, spectrométrie de masse.

[Traduit par la rédaction]

(+)-Abscisic acid (ABA, Fig. 1) is a plant growth regulator that has also been implicated in a variety of stress-related responses (1). Several metabolites of endogenous and exogenously added ABA have been isolated and identified, including the reduction products, *cis* and *trans* ABA 1′, 4′-diols (2–5); the oxidized derivative, phaseic acid (6–8); and the glucose esters (β-D-glucose, C-1-linked) of ABA and the aformentioned compounds (Fig. 1) (9–12). There has also been a report of the detection of a maltose ester of ABA (13).

We were interested in following ABA metabolism, and in developing analytical methods to facilitate our studies; in particular, we sought to extend the utility of liquid chromatography–continuous flow secondary ion mass spectrometry (LC/CFSIMS), which we had earlier used to detect ABA glucose ester in a plant extract (14), to other ABA-derived conjugates, which we felt were potential metabolites. To achieve these objectives, samples of potential metabolites or suitable derivatives thereof were required as standards.

Previously, ABA glucose ester (β anomer) had been prepared by reaction of ABA (cesium or triethyl ammonium salt) with α-bromoacetoglucose followed by deacetylation of the intermediate acetoglucose ester with an enzyme preparation derived from sunflower seeds (*Helianthus annus*) (15, 16). ABA diols had been prepared by sodium borohydride reduction of ABA methyl ester, which yielded a mixture rich in both the 1′, 4′-*cis* and -*trans* diols (17).

To further extend earlier synthetic efforts as well as the use of LC/CFSIMS in analysis of metabolite mixtures, we report here the preparation of various acetosugar derivatives of ABA (and deuterated ABA) and the diols, and acetylated diols of ABA, and the development of LC and LC/CFSIMS protocols using these derivatives. The acetosugar derivatives were easily prepared and possessed good stability. Some deuterated analogs were prepared as an aid in assigning fragments in the mass spectrum and for potential use as internal standards. As an example of the utility of the developed protocol, a sample plant extract was analyzed.

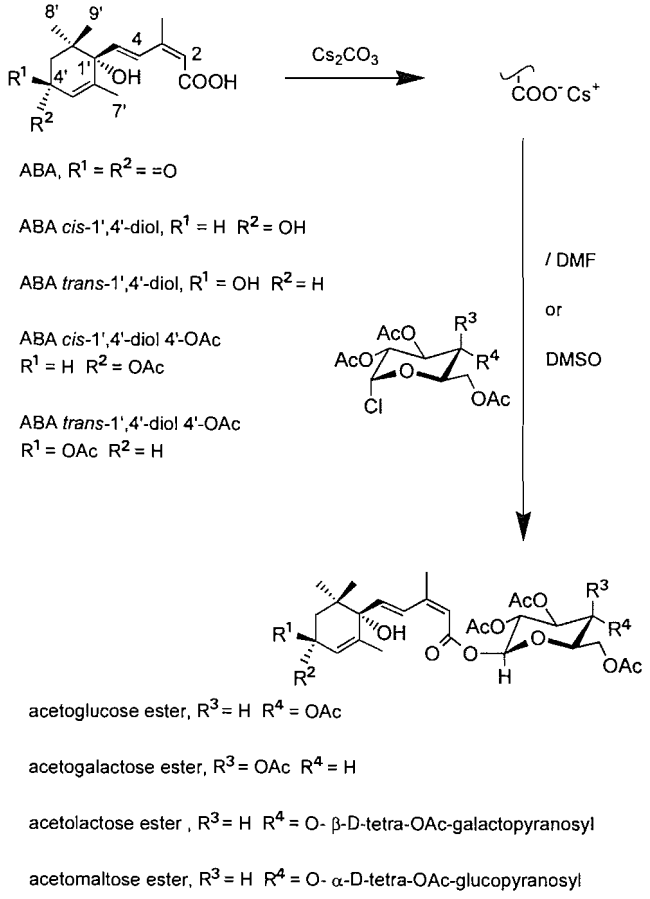
Results and discussion

Selective reduction of ABA

Previous preparations of ABA diols involved reduction of ABA methyl ester with sodium borohydride (2, 17). This method was not selective as the ratio of *cis/trans* 1′, 4′-diols was ca. 2:1 (2). Formation of the sodium salt of ABA in THF followed by reduction with L-Selectride®, however, rapidly led to a very clean product that consisted predominantly of the 1′, 4′-*cis*-diol (*cis/trans* 10:1). Alternatively, reduction of the

Fig. 1. Preparation and structures of various acetosugar esters of ABA, ABA diols, and the 4′-O-acetates. Only the diastereomers derived from (+)-ABA are pictured; however, in the actual preparations racemic ABA was used.



preformed sodium salt of ABA in THF with lithium aluminum hydride led to a product mixture containing predominantly the *trans* diol (*cis*/*trans* <1:20), contaminated with a small amount of conjugate reduction products (< 5%). The *trans* diol could be obtained in pure form via crystallization of either the acetate or methyl ester derivative. Similarly, the *cis* diol could be obtained in pure form via crystallization of the methyl ester.

Formation of acetosugar esters

The preparation of ABA acetoglucose ester was previously achieved by reaction of α-bromoacetoglucose with the cesium salt of ABA in DMF (16). This method had been used for the preparation of esters of amino acids by reaction of their cesium salts with alkyl halides (18). As an extension of these procedures, the cesium salts of ABA, hexadeutero ABA, ABA diols, and the C-4′ O-acetates of the ABA diols were prepared by treatment of the acids with Cs_2CO_3 and found to react effectively with α-chloroacetoglucose, -chloroacetogalactose, -chloroacetolactose, and -chloroacetomaltose in either DMF or DMSO (Fig. 1). β-Chloroacetoglucose did not react as well, providing ABA α-acetoglucose ester in only 21% yield. Attempted reactions with chloroacetomannose and chloroacetoglucosamine were unsuccessful. A summary of the acetosugar esters prepared is outlined in Table 1; the esters were obtained as diastereomeric mixtures, as racemic ABA and its

Table 1. Various acetosugar esters of ABA and derivatives prepared by reaction of acetochlorosugars with appropriate cesium salt.

Compound prepared	Reaction conditions	Isolated yield (%)
(±)-ABA β-D-acetoglucose ester	DMSO, 60°C, 5 h	53
d_6-(±)-ABA α-D-acetoglucose ester	DMF, RT, 4 d	21
(±)-ABA *cis* diol β-D-acetoglucose ester	DMSO, RT, 4 d	59

d_6-(±)-ABA β-D-aceto-galactose ester	DMF, RT, 4 d	49
(±)-ABA β-acetomaltose ester	DMF, 60°C, 5 h	61
(±)-ABA *cis* diol β-aceto-maltose ester	DMF, 60°C, 5 h	53
(±)-ABA *cis* diol C-4′-O-acetate β-acetomaltose ester	DMSO, RT, 4 d	48

diols were used in the preparations. Two sets of resonances were observed for some of the signals in the ^{1}H NMR spectra, but the chemical shifts differed only slightly.

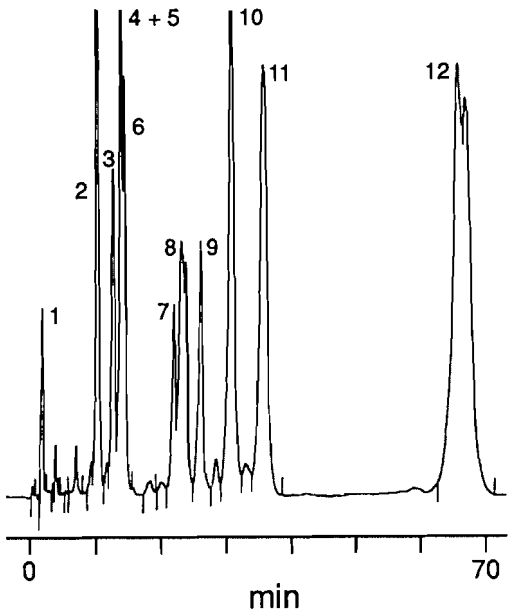
Deacetylation of acetoglucose esters

Deacetylation of the acetoglucose esters of ABA and ABA *cis* diol using a crude enzyme preparation derived from sunflower seeds (15, 16) was successful in our hands; however, the deacetylation of acetolactose and acetomaltose derivatives was problematic, being complicated by solubility problems and incomplete deacetylation. This result led us to consider the use of the acetosugar ester derivatives rather than the sugar esters for development of a general analytical protocol.

LC of acetosugar esters

The LC trace in Fig. 2 shows the separation achieved on a reverse-phase ultrasphere ODS column employing CH_3CN/H_2O (52:48, isocratic) as solvent and 24 (12 pairs of diastereomers) acetosugar derivatives. The disaccharide derivatives, e.g., ABA acetomaltose and acetolactose esters, eluted later than the corresponding monosacharride derivatives and were well separated from each other. Separation of the α and β anomers of the acetoglucose esters of ABA was not achieved; however, separation of ABA β-acetogalactose ester from the acetoglucose esters was. The β-acetoglucose esters of the *cis* and *trans* ABA diols eluted slightly earlier than the ABA monosaccharide derivatives and were well separated from each other. The corresponding *cis* and *trans* acetate derivatives eluted much later, even later than the disaccharide esters of ABA and ABA diols; they were also well separated from

Fig. 2. HPLC separation of acetosugar esters of ABA, ABA diols, and the 4′-O-acetates, on a reverse-phase ultrasphere ODS column using isocratic acetonitrile–H_2O (52/48). Compounds: 1, ABA glucose ester; 2, ABA *trans*-1′, 4′-diol acetoglucose ester; 3, ABA *cis*-1′, 4′-diol acetoglucose ester; 4, ABA acetoglucose ester; 5, d_6-ABA α-acetoglucose ester; 6, d_6-ABA acetogalactose ester; 7, ABA acetolactose ester; 8, ABA *cis*-1′, 4′-diol acetomaltose ester; 9, ABA acetomaltose ester; 10, ABA *trans*-1′, 4′-diol 4′-OAc acetoglucose ester; 11, ABA *cis*-1′, 4′-diol 4′-OAc acetoglucose ester; 12, ABA *cis* 1′, 4′-diol 4′-OAc acetomaltose ester. All esters except 5 have β-D- configuration and are diastereomeric mixtures as racemic ABA was used in their preparation.



each other. The latest eluting compound was the C-4′-O-acetate of the *cis* diol of ABA acetomaltose ester. Diastereomeric pairs were not resolvable to any great extent on this column, although some separation of diastereomers was noted in the cases of the acetomaltose esters of ABA *cis* diol and the corresponding 4′-OAc.

To check on the separation of diastereomeric pairs, an LC analysis of some acetosugar esters was also performed on a Chiralcel OD column. This column, which contains a chiral stationary phase, had previously been used to resolve racemic ABA methyl ester (19). The results are summarized in Table 2. Overall, the best separation observed was between (+)- and (−) ABA-β-D-acetoglucose esters, which, under the conditions employed, were baseline resolved (R_t 11.3 and 16.9 min) with reasonable peak shapes; other ABA acetosugar esters generally eluted later, which resulted in broadened peaks and poorer resolution. The diastereomers of acetosugar esters derived from ABA diols and C-4′-O-acetates were not well separated. By comparison, (+)- and (−)-ABA methyl esters, under the same conditions, were also baseline resolved with retention times of 5.5 and 7.3 min, respectively.

MS of acetosugar esters

The continuous flow secondary ion mass spectra of the acetosugar esters contained strong ions due to the acetosugar fragments at *m/z* 331 for monosaccharides, and 619 and 331 for disaccharides (Table 3). ABA acetosugar esters exhibited weak but discernible M+1 ions as well as an ion at *m/z* 247 (253 for d_6-ABA) due to the loss of the O-acetosugar. Acetosugar esters of the *cis* and *trans* 1′, 4′-ABA-diols and their acetates unfortunately did not afford significant protonated parent (M+1) ions; a significant ion due to the ABA diol portion appeared at *m/z* 231, arising from loss of the O-sugar and either water (in the case of the diols) or acetic acid (in the case of the 4′-O-acetates).

Identification of d_6-ABA acetoglucose ester in an acetylated extract obtained from a maize cell suspension culture treated with d_6-ABA

To test the ability of LC/CFSIMS to detect an acetosugar ester in a plant extract, a maize cell suspension culture, which was known to metabolize ABA efficiently (20), was treated with d_6-ABA and the cells were isolated after 4 days and extracted with methanol. After acetylation, the extract was analyzed by LC/MS/MS. Figure 3 shows the reaction-monitoring chromatogram obtained for the transition *m/z* 601–331. The identity of the derivatized metabolite as the acetoglucose ester of ABA was established from its mass spectrum (Fig. 3) and cochromatography with an authentic sample. No other acetosugar esters were found in this extract.

In conclusion, various acetosugar esters of ABA and ABA derivatives were made readily available for use as reference and (or) internal standards in the analysis of plant extracts. The ability of LC/CFSIMS to detect these derivatives in acetylated extracts was shown, and should prove useful both quantitatively (via use of deuterated internal standards) and qualitatively in the study of ABA metabolism. Finally, the ready formation of various acetosugar derivatives by reaction of α-chloroacetosugars with the cesium salt of an acid would appear to be quite general and may represent a means for the resolution of some racemic acids.

Experimental

General

Solvents and reagents were of reagent grade and were used without further purification. Preparative layer chromatography was performed with 1 mm thick Merck Silica gel 60 F254 20 × 20 cm plates. Racemic abscisic acid was purchased from Aldrich Chemical Company. Deuterium-labeled abscisic acid was prepared by base-catalyzed exchange in D_2O/MeOD according to the procedure of Balsevich et al. (21). Infrared spectra (IR) were recorded using a Perkin–Elmer 257 grating infrared specrophotometer (films on NaCl). Ultraviolet spectra (UV)) were obtained (MeOH) with a Beckman DU-64 spectrophotometer. Proton nuclear magnetic resonance spectra (^{1}H NMR) were obtained with a Bruker AM 360 spectrometer with samples in deuterochloroform unless otherwise noted. An asterisk (*) beside a chemical shift listing denotes that two sets of signals were distinguishable for that resonance due to the two diastereomers. LC/CFSIMS and LC/MS/MS were peformed using a 0.32 × 150 mm Spherisorb 3 μm ODS-2 packed capillary column interfaced with a VG Analytical (Manchester, UK) 70-250 SEQ hybrid mass spectrometer equipped for continuous flow SIMS analysis according to Hogge et al. (14), except for gradient elution using a two-solvent system consisting of A: 2% glycerol and 0.1% trifluoro-

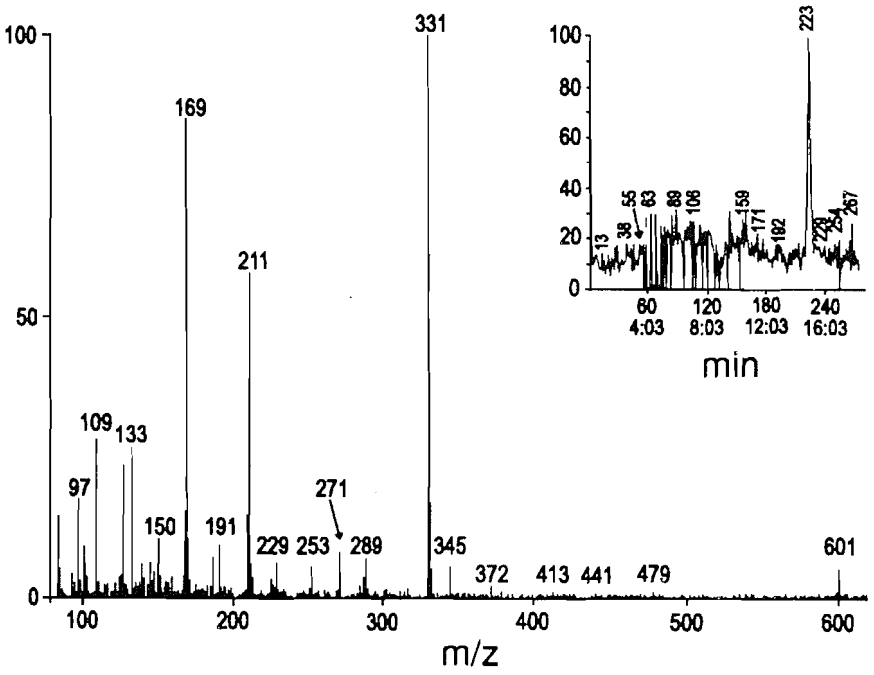
acetic acid in H_2O, and B: 80% CH_3CN, 2% glycerol, and 0.1% trifluoroacetic acid in H_2O. The gradient elution used was 50% A to 10% A in 10 min, which was held for a further 25 min. Analytical LC was performed on a Waters system equipped with a reverse-phase Ultrasphere 5 μm ODS 4.6 mm × 25 cm column using isocratic CH_3CN/H_2O (52:48) at a flow rate of 0.5 mL/min. UV detection at 262 nm was used. Chiral LC was performed with a Chiralcel OD 0.46 × 25 cm coated silica column (Daicel, Los Angeles, Calif.) using isocratic hexane/isopropanol (7:1) at a flow rate of 1 mL/min. Mass spectrometry (MS) was performed with a VG 70-250SEQ double focussing hybrid spectrometer. High-resolution mass spectrometry (HRMS) was performed using fast ion bombardment ionization with the sample in a glycerol matrix.

Reduction of ABA with L-Selectride® — (±)-ABA *cis*-1′, 4′-diol

A solution of ABA (264 mg, 1 mmol) in anhydrous THF (10

Fig. 3. Reaction monitoring chromatogram for the transition *m/z* 601–331 (insert), and the obtained CFSIMS spectrum from analysis of an acetylated plant extract.



mL) was cooled to 0°C, treated with sodium hydride – mineral oil suspension (60%, 44 mg, 1.1 mmol), and stirred for 20 min. A 1 M solution of L-Selectride® (1.1 mL, 1.1 mmol) in THF was added at a dropwise rate over 10 min. The reaction was allowed to warm to ambient temperature and stirred for a further 3 h. Water (100 mL) was cautiously added and the aqueous solution washed with ethyl acetate (3 × 15 mL). The combined ethyl acetate washings were back-extracted with water (2 × 10 mL) and discarded. The aqueous portions were combined, made acidic by the addition of 1 N HCl (3 mL), and extracted with ethyl acetate (3 × 20 mL). The combined ethyl acetate extract was washed with water (2 × 5 mL), dried (Na_2SO_4), and concentrated in vacuo to afford a mixture consisting mainly of the *cis* diol plus ca. 9% of the *trans* diol as a white amorphous solid (260 mg, 0.98 mmol, 98%). The proportions of the two isomers were determined from the ^1H NMR spectrum of the reaction product. The diols were separated by preparative TLC on silica gel using EtOAc as solvent.

cis Diol: UV, λ_{max} (log ε): 262 (4.24); IR; ν_{max} (cm^{-1}): 3400, 2965, 1688, 1631, 1598, 1240; ^1H NMR; δ: 7.70 (1H, d, 16 Hz, C-5), 6.05 (1H, d, 16 Hz, C-4), 5.69 (1H, s, C-2), 5.64 (1H, bs, C-3′), 4.24 (1H, m, C-4′), 2.01 (3H, s, C-6), 1.79 (1H, ABX, 13 and 6 Hz, C-5′α or β), 1.71 (1H, ABX, 13 and 7 Hz, C-5′α or β), 1.65 (3H, s, C-7′), 1.00 (3H, s, C-8′ or 9′), 0.92 (3H, s, C-8′ or C-9′). MS (ammonia CI) *m/z*: 284 ($[M+18]^+$, 9%), 267 ($[M+1]^+$, 38%), 266 (M^+, 69%), 248 (35%), 231 (100%); HRMS, calcd. for $[M+glycerol]^+$ $C_{18}H_{31}O_7$: 359.2070; found: 359.2026.

trans Diol: mp 148–153°C; UV, λ_{max} (log ε): 262 (4.21); IR, ν_{max} (cm^{-1}): 3400, 2962, 1686, 1631, 1598, 1240; ^1H NMR, δ: 7.58 (1H, d, 16 Hz, C-5), 6.05 (1H, d, 16 Hz, C-4), 5.69 (1H, s, C-2), 5.67 (1H, bs, C-3′), 4.22 (1H, m, C-4′), 2.02 (3H, s, C-6), 1.78 (1H, ABX, 13 and 6.5 Hz, C-5′α), 1.64 (3H, s, C-7′), 1.61 (1H, ABX, 13 and 9.5 Hz, C-5′β), 1.02 (3H, s, C-8′ or 9′), 0.89 (3H, s, C-8′ or C-9′). ^1H NMR (D_2O); δ: 7.25 (1H, d, 16 Hz, C-5), 6.11 (1H, d, 16 Hz, C-4), 5.71 (1H, s, C-2), 5.54 (1H, bs, C-3′), 4.22 (1H, m, C-4′), 1.94 (3H, s, C-6), 1.66 (1H, ABX, 13 and 6 Hz, C-5′α), 1.54 (3H, s, C-7′), 1.46 (1H, ABX, 13 and 10 Hz, C-5′β), 0.91 (3H, s, C-8′ or 9′), 0.82 (3H, s, C-8′ or C-9′). MS (ammonia CI) *m/z*: 284 ($[M+18]^+$, 16%), 267 ($[M+1]^+$, 10%), 266 (M^+, 100%), 248 (30%), 231 (61%); HRMS, calcd. for $[M+glycerol]^+$ $C_{18}H_{31}O_7$: 359.2070; found: 359.2108.

The *cis* and *trans* diols were also converted to their methyl esters by treatment with ethereal diazomethane and afforded ^1H NMR spectra comparable to published data [2].

Reduction of ABA with lithium aluminum hydride — (±)-ABA *trans*-1′, 4′-diol

A solution of ABA (264 mg, 1 mmol) in anhydrous THF (10 mL) was cooled to 0°C, treated with sodium hydride–mineral oil suspension (60%, 40 mg, 1 mmol), and stirred for 20 min. $LiAlH_4$ (30 mg, 0.75 mmol) was added in several portions over 10 min. The reaction was allowed to warm to ambient temperature and stirred for a further 4 h. The reaction was poured into cold water (100 mL), washed with hexane (3 × 25 mL), acidified with 1 N HCl (3.5 mL), and extracted with EtOAc (3 × 30 mL). The EtOAc extract was dried (Na_2SO_4), filtered, and concentrated in vacuo to afford a mixture of the *trans* diol contaminated with ca. 5% overreduced products as a white amorphous solid (260 mg). The presence of overreduced products was determined from the ^1H NMR spectrum from signals at δ 3.6–3.9 attributable to saturated alcohols. The main product was the *trans* diol (C-4′ β-OH) identical to the minor product from above; virtually no *cis* diol was observable by NMR.

(±)-ABA *trans*-1′, 4′-diol C-4′-O-acetate

trans ABA diol (260 mg, ca. 0.9 mmol), obtained directly from the $LiAlH_4$ reduction of ABA without further purifica-

tion, was dissolved in a 1:2 (v/v) mixture of acetic anhydride and pyridine (1 mL), and let stand at ambient temperature for 17 h. The mixture was concentrated in vacuo, and the residue was dissolved in EtOAc (ca. 50 mL), washed with 1 N HCl (2×), water (3×), and concentrated in vacuo. The residue was treated with ethyl acetate (ca 1 mL) and stored at 0°C overnight. The resultant crystalline solid was isolated by filtration and the crystals dried in vacuo to afford the acetate as a white crystalline solid (170 mg), mp 185–188°C; UV, λ_{max} (log ε): 258 (4.18); IR, ν_{max} (cm^{-1}): 3400, 2960, 1720sh, 1710, 1680 sh, 1632, 1598, 1245; ^1H NMR ($CDCl_3$/DMSO-d_6, 3:1), δ: 7.61 (1H, d, 16 Hz, C-5), 6.02 (1H, d, 16 Hz, C-4), 5.55 (1H, s, C-2), 5.3 3 (1H, s, C-3′), 5.20 (1H, m, C-4′), 1.94 (3H, s, OAc), 1.91 (3H, s, C-6), 1.71 (1H, *A*BX, 6 and 13 Hz, C-5′β), 1.56 (3H, s, C-7), 0.94 (3H, s, C-8′), 0.81 (3H, s, C-9′). HRMS, calcd. for $[(M-H_2O)+H]^+$ $C_{15}H_{21}O_3$: 249.1491; found: 249.1457.

(±)-ABA *cis*-1′, 4′-diol C-4′-O-acetate

The *cis* diol (130 mg, 0.5 mmol) was treated as above except the crude product was purified by TLC on Silica gel using EtOAc to afford a colorless film (80 mg, 52%); UV, λ_{max} (log ε): 258 (4.20); ^1H NMR, δ: 7.68 (1H, d, 16 Hz, C-5), 5.93 (1H, d, 16 Hz, C-4), 5.68 (1H, s, C- 3′), 5.51 (1H, s, C-2) 5.26 (1H, m, C-4′), 2.01 (3H, s, OAc), 1.93 (3H, s, C-6), 1.80 (1H, ABX, 6 and 14 Hz, C-5′β), 1.72 (1H, ABX, 6 and 14 Hz, C-5′α), 1.62 (3H, s, C-7), 0.97 (3H, s, C-8′), 0.90 (3H, s, C-9′). HRMS, calcd. for $[(M-H_2O)+H]^+$ $C_{15}H_{21}O_3$: 249.1491; found: 249.1507.

Preparation of cesium salts of ABA, ABA diols, and diol acetates

Cesium salts were prepared by treating a solution of racemic ABA, or the ABA diols, or the acetates (1 mmol) in 50% aqueous methanol (10 mL) with cesium carbonate (0.5 mmol) and concentrating the resultant solution in vacuo. The residues were treated with benzene and concentrated in vacuo (2×), and then stored in a vacuum desiccator for 24 h. The cesium salts were obtained as colorless to pale yellow glasses and were used without further purification.

Preparation of α-chloroacetosugars and β-chloroacetoglucose

The α-chloroacetosugars were prepared by reaction of the peracetylated sugars with titanium tetrachloride in refluxing chloroform as outlined in refs. 22 and 23. β-Chloroacetoglucose was prepared by reaction of glucose pentaacetate with aluminum chloride in dichloromethane as outined in ref. 24.

General protocol for preparation of acetosugar esters

A solution of the appropriate cesium salt (1 mmol) in either DMF or DMSO (5 mL) was treated with the appropriate chloroacetosugar (1.1 mmol). After 4 days at ambient temperature or 5 h at 60°C, the reaction was treated with H_2O (30 mL) and extracted with EtOAc (3 × 20 mL). The combined organic extract was washed with 0.1 N NaOH (2 × 10 mL), H_2O (2 ×10 mL), brine (2 × 10 mL), and dried over anhydrous sodium sulfate. Evaporation of the solvent in vacuo afforded an amber oil, which was subjected to TLC on silica, gel using hexane/EtOAc (7:3) as solvent to afford the appropriate acetosugar ester as a colorless glass, generally in about 50% yield (see Table 1). ABA acetosugar esters gave UV spectra having λ_{max} (log ε): 272 (4.29), 240sh (4.07), while the acetosugar esters of ABA diols and C-4′-O-acetates gave λ_{max} (log ε): 272 (4.18). ABA acetosugar esters gave IR spectra having ν_{max} (cm^{-1}): 3500, 2962, 1748, 1663, 1630sh, 1598, 1224, 1070, 1040; acetosugar esters of ABA diols gave ν_{max}: 3515, 2964, 1750, 1633, 1598, 1228, 1070, 1038; acetosugar esters of the C-4′-O-acetates gave ν_{max}: 3510, 2954, 1755, 1735sh, 1633, 1598, 1225, 1070, 1040.

(±)-ABA β-D-*acetoglucose ester:* ^1H NMR (ref. 17), δ: 7.78 (1H, d, 16 Hz, C-5), 6.21, 6.20* (1H, d, 16 Hz, C-4), 5.92 (1H, bs, C-3′), 5.74 (1H, d, 8.6 Hz, sugar C-1), 5.72 (1H, s, C-2), 5.27 (1H, t, 9 Hz, sugar C-3 or 4), 5.20 (1H, t, 8.5 Hz, sugar C-2), 5.13 (1H, t, 9.5 Hz, sugar C-3 or C-4), 4.29 (1H, ABX, 12.5 and 3.4 Hz, sugar C-6), 4.11 (1H, ABX, 12.5 and 2 Hz, sugar C-6), 3.84 (1H, m, sugar C-5), 2.46, 2.44* (1H, AB, 17 Hz, C-5′α or β), 2.30 (1H, AB, 17 Hz, C-5′α or β), 2.06 (3H, s, OAc), 2.02 (3H, s, OAc), 2.01 (3H, bs, C-6), 2.00 (3H, s, OAc), 1.99 (3H, s, OAc), 1.91, 1.90* (3H, s, C-7′), 1.10 (3H, s, C-8′ or 9′), 0.99* (3H, s, C-8′ or 9′). HRMS, calcd. for $[M+H]^+$: $C_{43}H_{59}O_{22}$: 927.3498; found: 927.3491.

Enzymatic deacetylation of ABA *cis* diol- and ABA acetoglucose esters

The acetoglucose esters of ABA and ABA *cis*-1′, 4′-diol were deacetylated using a modification of the procedure of Lehmann et al. (15) as follows. Enzyme preparation: dehusked sunflower seeds (9 g, Super Store) were added to cold (<10°C) pH 7.0 100 mM phosphate buffer (75 mL) and homogenized with an Ultra Turrax homogenizer for 2–3 min. The resulting suspension was centrifuged at 25 000*g* for 30 min. The middle aqueous layer was removed and re-centrifuged. The resulting clear aqueous portion, free of oil droplets, was used for deacetylations.

(±)-ABA cis-*1′, 4′-diol glucose ester*

A solution of the *cis* diol β-acetoglucose ester (230 mg, 0.39 mmol) in EtOH (15 mL) was added to a vigorously stirred solution of 100 mM pH 7.0 phoshate buffer (35 mL), and the sunflower seed enzyme preparation from above (60 mL). A further portion of EtOH (3 mL) was added dropwise over a period of 20 min and the resulting mixture stirred at ambient temperature for 20 h. Isopropanol (100 mL) was added and and the resulting mixture centrifuged at 10 000*g* for 30 min. The supernatant was concentrated in vacuo and the residue was triturated with a further portion of isopropanol (50 mL) and centrifuged again. The supernatant was concentrated in

vacuo and the residue (200 mg) subjected to thin-layer chromatography (silica gel), using CH_3CN/H_2O (93:7) as the solvent system, to yield the *cis* diol glucose ester as a white amorphous solid (75 mg, 0.18 mmol, 46%). ^1H NMR (D_2O), δ: 7.46 (1H, d, 16 Hz, C-5), 6.21 (1H, d, 16 Hz, C-4), 5.76 (1H, s, C-2), 5.59 (1H, bs, C-3), 5.50 (1H, d, 8 Hz, sugar C-1), 4.20 (1H, m, C-4′), 3.9–3.3 (6H, overlapping peaks, sugar C-2 C-6), 2.01 (3H, s, C-6), 1.70 (1H, ABX, 13 and 6 Hz, C-5′α or b), 1.57 (3H, s, C-7′), 1.53 (1H, ABX, 13 and 7 Hz, C-5′α or β), 0.89 (3H, s, C-8′ or 9′), 0.84 (3H, s, C-8′ or C-9′); CFSIMS, *m/z*: 429 (2%, M^++1), 411 (50%, M^++1−H_2O), 393 (28%, M^++1−2H_2O), 249 (44%), 231 (100%). HRMS, calcd. for $[M+H]^+ C_{21}H_{33}O_9$: 429.2125; found: 429.2177.

(±)-ABA glucose ester

A solution of ABA β-acetoglucose ester (230 mg, 0.39 mmol) was treated as above to yield ABA glucose ester as a colorless film (84 mg, 0.2 mmol, 51%) having an ^1H NMR spectrum similar to that reported in the literature (17). ^1H NMR (D_2O), δ: 7.50 (1H, d, 16 Hz, C-5), 6.26 (1H, d, 16 Hz, C-4), 5.97 (1H, bs, C-3′), 5.78 (1H, s, C-2), 5.49 (1H, d, 8 Hz, sugar C-1), 3.9–3.2 (6H, overlapping peaks, sugar C-2–C-6), 2.50 (1H, AB, 17 Hz, C-5′α or β), 2.16 (1H, AB, 17 Hz, C-5′α or β), 1.99 (3H, s, C-6), 1.85 (3H, s, C-7′), 0.9 6 (3H, s, C-8′ or 9′), 0.93 (3H, s, C-8′ or C-9′); CFSIMS, *m/z*: 427 (27%, M^++1), 409 (8%, M^++1−H_2O), 265 (base peak), 247 (77%). HRMS, calcd. for $[M+H]^+ C_{21}H_{31}O_9$: 427.1968; found: 427.1992.

Feeding of d_6-ABA to a maize cell suspension

Suspension cultures of corn (*Zea mays L.* cv Black Mexican Sweet) were maintained on modified Murashige–Skoog medium as described previously (20, 25). d_6-(±)-ABA (0.4 mg) in EtOH (30 μL) was added to the cell suspension (60 mL, ca. 2 g fresh wt. of cells) 24 h after being subcultured. After 4 d cells were separated from medium by filtration and extracted with methanol (100 mL). Cell material was removed by filtration and the methanol extract concentrated in vacuo. The residue was washed with hexane, redissolved in cold methanol/acetonitrile (1:1, 20 mL), filtered, and concentrated in vacuo. The residue was treated with Ac_2O/pyridine (1 mL of a 1:2 mixture, v/v). After 4 h, volatiles were removed in vacuo and the residue dissolved in 50% acetonitrile (aq) and used for the LC/CFSIMS analysis described earlier.

Acknowledgements

We thank Dr Adrian Cutler for supplying the maize cell suspension culture and Dr Suzanne Abrams for helpful discussions.

Single-crystal polarized spectra in the near-infrared region: a local-mode analysis of the spectra of $M_2MnCl_4 \cdot 2X_2O$ (M = Cs, Rb; X = H, D)

Ian M. Walker and Paul J. McCarthy

Abstract: The polarized crystal spectra of $M_2MnCl_4 \cdot 2X_2O$ (M = Cs, Rb; X = H, D) have been measured at 10 K in the near-infrared region. The data have been analyzed using a local-mode model that includes the bending mode. The resulting parameters are related to hydrogen bonding in the crystals. The spectra of partially deuterated species show a large number of bands due to HOD vibrations. The parameters from these spectra are compared to those from the H_2O and D_2O spectra. Arguments as to the importance of Fermi resonance in these spectra are presented.

Key words: near-infrared, single crystal, hydrogen bond, Fermi resonance.

Résumé : Opérant à 10 K, dans la région du proche infrarouge, on a mesuré les spectres cristallins polarisés du $M_2MnCl_4 \cdot 2X_2O$ (M = Cs, Rb; X = H, D). On a analysé les données en utilisant un modèle de mode local qui incorpore le mode de déformation. Les paramètres qui en résultent peuvent être reliés à une liaison hydrogène dans les cristaux. Les spectres des espèces partiellement deutérées présentent un grand nombre de bandes dues à des vibrations HOD. On a comparé les paramètres dérivés de ces spectres avec ceux obtenus à partir des spectres du H_2O et du D_2O. On présente des arguments relatifs à l'importance de la résonance de Fermi dans ces spectres.

Mots clés : proche infrarouge, cristal unique, liaisons hydrogène, résonance de Fermi.

[Traduit par la rédaction]

Introduction

In several recent articles we have studied in detail the near-infrared (nir), low-temperature, polarized spectra of crystals containing H_2O (1–4) or the NH_2 group as found in a series of guanidinium salts (5). The absorptions that appear in this region between about 4000 and 10 000 cm^{-1} are due almost entirely to overtones and combinations of OH or NH stretching vibrations and to combinations of various quanta of stretching vibrations with bending and (or) librational modes. In all cases we used local-mode theory to calculate the energies of the vibrational bands. From the best fit between calculated and observed energies we have obtained a set of local-mode parameters that give the harmonic oscillator frequencies and anharmonicities of the OH or NH stretching vibrations, as well as the extent of coupling between nearby oscillators. Our purpose has been to estimate hydrogen-bond strength from the local-mode parameters obtained from an analysis of the spectra. From this we hope to see if there is any relationship between the estimated hydrogen-bond strength and the interatomic distances and bond angles reported for the crystal. In the long run this requires a large selection of data for OH and NH oscillators lying in diverse crystals on sites of varied symmetry.

Most recently we studied the spectra of $CsMnCl_3 \cdot 2H_2O$ (4). Here we report a study of the related compounds, $Cs_2MnCl_4 \cdot 2H_2O$, $Rb_2MnCl_4 \cdot 2H_2O$, and their deutero analogues. These salts crystallize in space group $P\bar{1}$ (C_i^1, no. 2) with $Z = 1$. A stereoscopic view of the unit cell is shown in Fig. 1, and the unit cell parameters (6) and selected interatomic distances and angles (6–8) are listed in Table 1. The structures consist of discrete *trans*-$\{MnCl_4(H_2O)_2\}$–anions interleaved with alkali cations. All atoms lie on general positions save manganese, which lies on the inversion centre. The water molecules thus occur in symmetry-related pairs, as do the two crystallographically distinct chloride ions (Table 1). Each OH group makes a nearly linear hydrogen bond to a chloride from a neighboring complex ion. As can be seen from Table 1, the two OH oscillators that make up the water molecule experience significantly different environments in the crystals. This is most noticeable in the Rb salt.

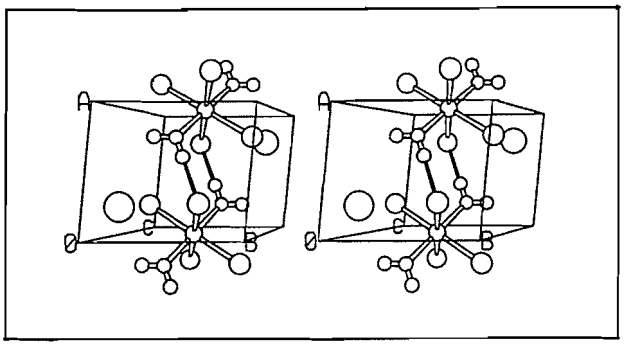
The IR spectra of these compounds have been reported by Stefov et al. (9, 10), who measured the spectra at room temperature and at liquid nitrogen temperature. Adams and Lock (11) had earlier reported the room temperature IR spectra of all these compounds as well as the liquid nitrogen IR and room temperature Raman spectra of some of them.

The crystals to be discussed are notable for the clear resolution of many of the nir bands. This feature has enabled us to give a rather detailed account of the stretch–bend combinations, and also of the energies of many vibrations of the HOD molecule in both lattices.

Local-mode theory

This approach has been found to be well suited to the study of the fundamental and overtone spectra of molecules containing

Fig. 1. Stereoscopic view of the unit cell of $Cs_2MnCl_4 \cdot 2H_2O$, looking down the *c*-axis. Only one hydrogen bond is shown; the other terminates on a chlorine atom in the adjacent unit cell. Hydrogen positions are from ref. 7, the rest are from ref. 6. The circles decrease in size in the order Cs, Cl, Mn, O. The H and O atoms are shown the same size.



the OH, NH, and CH groups. Several reviews of the subject have appeared (12, 13), as well as a number of treatments of the theory for water and other small molecules (14–20). We have outlined elsewhere (2, 3) its application to water on general sites.

The energy level expressions that we chose for the present work are based on the Harmonically Coupled Anharmonic Oscillator (HCAO) model (14, 15) and are an adaptation of the work of Duncan et al. (18) to the case of water on a general site. The simplicity of this formulation is compatible with the small data sets common to crystal systems. The vibrational wave functions are written as products of harmonic oscillator basis functions in the three local coordinates. The two stretches are described by quantum numbers v_1 and v_2 and the bend by quantum number b. Thus for a water molecule the basis ket would be written $|v_1 v_2 b\rangle$. It is often desirable to adjust the energy of the lowest $|000\rangle$ state to zero. The resulting complete expression for the diagonal elements of the secular determinant, in units of cm^{-1}, is:

$$[1]\quad \langle v_1 v_2 b|H/hc|v_1 v_2 b\rangle = \omega_1 v_1 + \omega_2 v_2 + \omega_b b + X_1 v_1(v_1 + 1) + X_2 v_2(v_2 + 1) + X_b b(b + 1) + X_{s1b} v_1 b + X_{s2b} v_2 b$$

The first six terms on the right in eq. [1] are the traditional local-mode terms and are the largest ones energetically. Here, ω_1, ω_2, and ω_b are the harmonic frequencies of the two stretches and the bend, respectively, while X_1, X_2, and X_b represent the corresponding local-mode anharmonicities. Since the X terms are usually negative, states such as $|110\rangle$, which represents a stretch–stretch combination, occur at higher energy than the stretch overtones, $|020\rangle$ and $|200\rangle$. Because of the inequivalence of the O—H bonds in the compounds, the matrices contain a harmonic oscillator frequency and an anharmonicity for each OH oscillator.

The last two terms in eq. [1] represent the diagonal stretch–bend couplings for water on general sites. We find that X_{s1b} and X_{s2b} are small and nearly equal in these crystals, so that little error is introduced into the fitting procedure by combining these into one parameter, X_{sb}.

Allowance for coupling between stretching local modes is made by including off-diagonal elements of the form:

[b]Calculated using hydrogen coordinates from ref. 7. These were computed by the method of Baur (8).

$$[2]\quad \langle v_i + 1, v_j - 1, b|H/hc|v_i v_j b\rangle = \lambda[(v_i + 1)v_j]^{1/2}$$

where λ is a measure of the coupling between the two oscillators.

The λ-coupling term causes the stretch local-mode functions to combine into sum and difference combinations; in the gas phase, these are written $|v00\rangle_+$ and $|v00\rangle_-$, respectively. When the diagonal energies are discernibly different and the λ-term is small, one term in the sum is predominant. Except in those cases where the functions in the sum are present to a nearly equal extent, the final eigenstates are labelled in the tables with the identity of the dominant term.

A vibrational manifold is defined as a collection of vibrational states of like energy. Each product of the form $|v_1 v_2 b\rangle$ can be described (18) by means of a manifold quantum number $V = v_1 + v_2 + b/2$. We make the usual approximation that only coupling within each manifold need be considered. For the sake of clarity, we also use the older notation, e.g., ν, 2ν, $\nu + \delta$, in the body of the text to refer to, for example, the stretch fundamental, overtone, and stretch–bend combinations, respectively.

Experimental

Well-formed crystals suitable for spectroscopy were grown from water by slow evaporation of a solution containing a 2:1 molar ratio of CsCl (or RbCl) and $MnCl_2 \cdot 4H_2O$. Moderately deuterated crystals were obtained from the same starting materials by slow evaporation of a D_2O solution over concentrated H_2SO_4 in a desiccator. More highly deuterated crystals were obtained by using anhydrous $MnCl_2$; water of hydration is removed by heating at about 120°C for a few hours. The materials grow as thin well-formed plates with one extinction direction nearly coincident with one of the edges. While the

indices of this principal face are not known, a pair of angles on opposite corners of the crystals are about 114°. This corresponds nicely to 180° − α as reported by Jensen (6). So it is quite likely that this crystal face represents the *bc* crystal plane. From the crystal data (6) and the calculated parameters of El Saffar (7) one finds that one of the O—H bonds of water lies nearly along the *b*-axis of the crystal. This oscillator should then be excited most strongly by light with *E*||*b*. This may help explain the difference in intensity of the |020⟩, |200⟩, and |110⟩ bands in the different polarizations noted below.

The crystals were mounted in a Displex cryogenic refrigerator and the nir spectra were recorded at 10 K using a Varian-2300 spectrophotometer. Polarized light was obtained by a pair of Glan–Thompson prisms. Spectra were taken with the electric vector of the light parallel to the extinction axes of the crystals.

For all the spectra recorded, the gain was set as low as possible (25.5) in order to maximize the signal-to-noise ratio. The instrument then automatically set the spectral bandwidth at a value that depended on the size and quality of the crystal. When a band appeared to be multiple, other scans were made with higher gain to see if the multiplet could be resolved. In all cases, we chose the largest and clearest crystal available. Without special optics, however, it is difficult to record the spectrum of a crystal smaller than about 1 mm × 0.25 mm. Even if it is of excellent optical quality, such a crystal will yield spectra with a rather low signal-to-noise ratio.

The band positions given in this report are the peak maxima. In the case of unresolved shoulders, no deconvolution was attempted, but the position of the underlying peak was estimated as well as possible.

Our room temperature IR spectra (CsCl pellets) recorded on a Nicolet 5DX FTIR spectrophotometer do not differ significantly from those of Stefov et al. (9, 10). It is their low-temperature data, however, that we use in the discussion below.

Results and discussion

Crystal spectra

The observed spectra in the region 4600–5200 cm^{-1} are shown in Figs. 2 and 3, while the spectra in the region 5700–6900 cm^{-1} are shown in Fig. 4. Figure 5 shows one polarization of the 3ν region of $Cs_2MnCl_4 \cdot 2H_2O$. Since the Cs and Rb salts are isomorphous, it is not surprising that their spectra are quite similar. One polarized spectrum recorded with light incident on the plate-like crystal shows only very weak bands and is much like the *E*||*b* spectrum of $CsMnCl_3 \cdot 2H_2O$ (4). Since in this latter crystal the *b*-axis is nearly perpendicular to the plane of the water molecules, it is quite likely that the weak polarization is largely perpendicular to the H_2O plane in the spectra of the present compounds. The orthogonal polarization contains more detail and has bands of considerably greater intensity. We were able to grow thick crystals of $Cs_2MnCl_4 \cdot 2H_2O$ only, and we recorded spectra on other faces of these crystals also. Most of these spectra appear to be various mixtures of the spectra orthogonal to the weak polarization. A notable feature is the extreme variability of the relative intensities of the |020⟩, |200⟩, and |110⟩ bands in the various orientations. While the band intensities differ in the various orientations, no new bands appear. For this reason we consider that we have recorded all the essential details in the spectra of both substances.

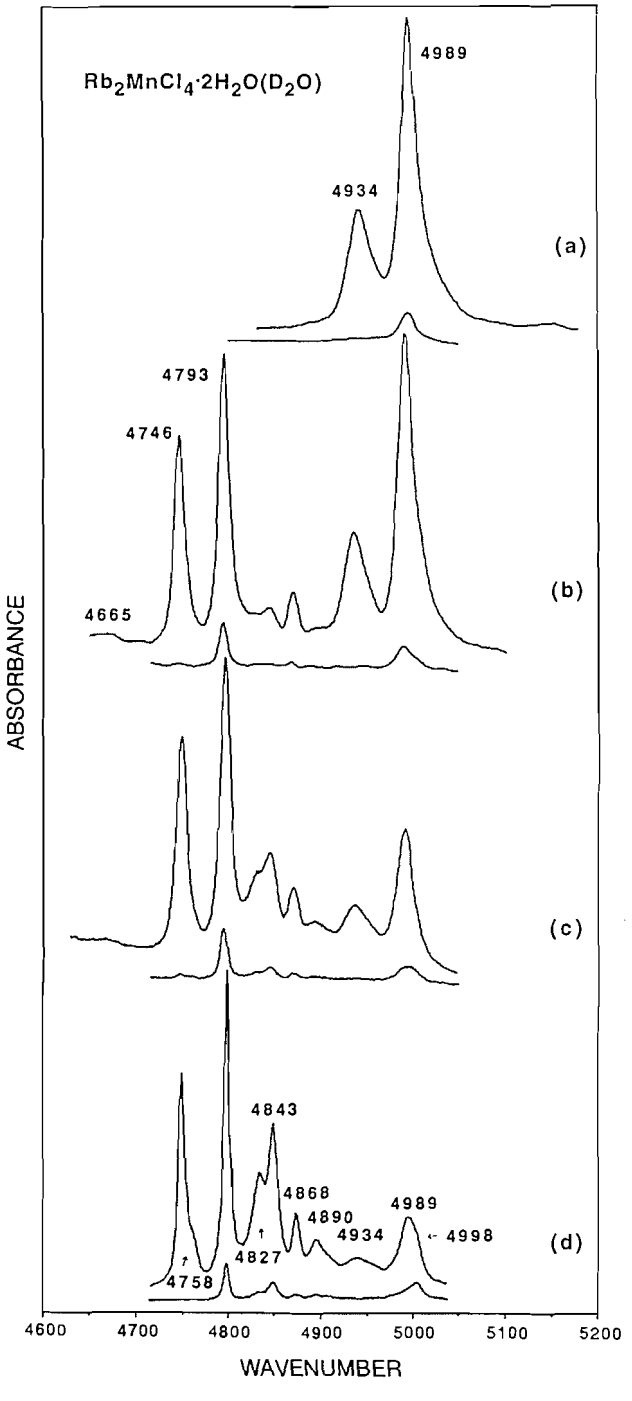
Spectra of HOH in crystals

The principal spectral bands used in the subsequent discussion are found in Table 2.

The two stretch plus bend combination (ν + δ) bands are found at 4924 and 5030 cm^{-1} (Cs) and at 4934 and 4989 cm^{-1} (Rb) (trace (*a*) in Figs. 2 and 3). As expected, the separation between the two bands (106 cm^{-1} (Cs) and 55 cm^{-1} (Rb)) closely matches the separations observed between the two fundamental stretches (104 cm^{-1} (Cs) and 60 cm^{-1} (Rb)).

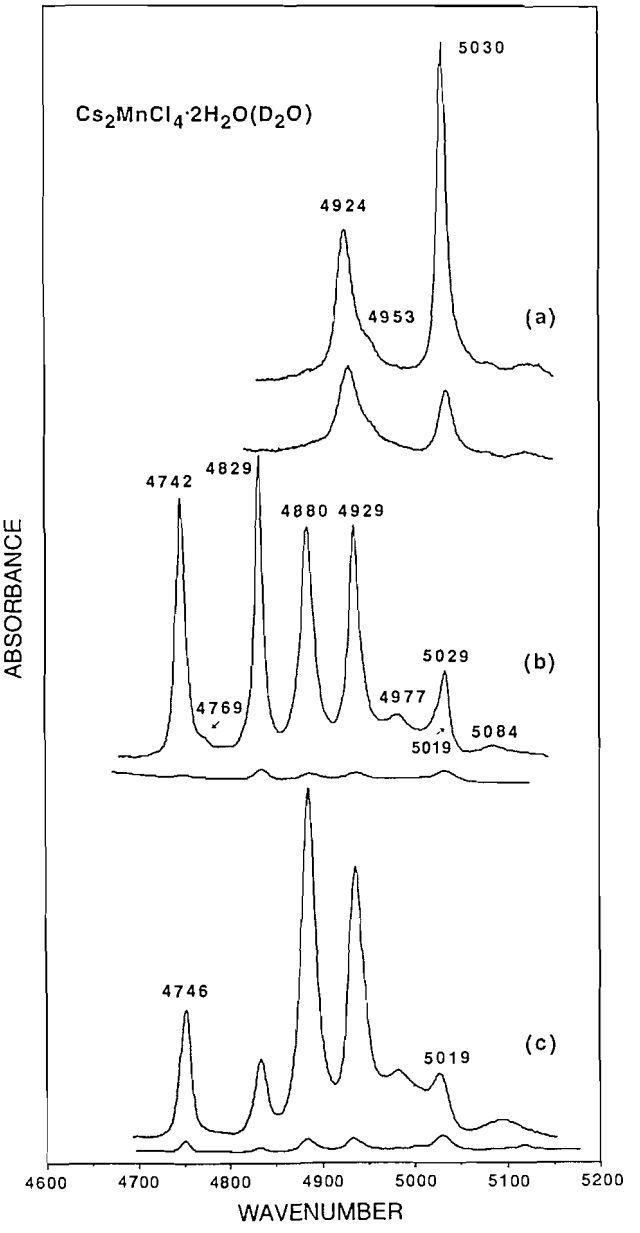
The first stretch overtone (2ν) absorptions lie at 6307, 6555 cm^{-1} (Cs) and 6328, 6469 cm^{-1} (Rb). The band at 6555 cm^{-1} (Cs) shows weak satellite peaks lying about 46, 82, and 104 cm^{-1} to higher energy. Similar, but less well-defined, satellites are found above the 6469 cm^{-1} (Rb) band. These have been assigned (4) to lattice or hydrogen-bonding modes (see Fig. 4). The high-energy |110⟩ combination at 6758 cm^{-1} (Cs) and 6727 cm^{-1} (Rb) is broad and appears to be multiple. The extra features may be due to excitations of single stretch quanta on neighboring water molecules.

Fig. 2. Crystal spectra (4600–5200 cm^{-1}) of the orthogonal polarizations of $Rb_2MnCl_4 \cdot 2X_2O$ (X = H, D) at 10 K; (*a*) contains no D_2O; deuteration increases from (*b*) to the highly deuterated (*d*).



Each compound shows a set of very weak bands (not shown in the figures) in the 7460–8475 cm^{-1} region due mainly to $2\nu + \delta$. Three principal peaks of the Cs spectrum (7869, 8116, and 8320 cm^{-1}) and two of the Rb spectrum (7890 and 8033 cm^{-1}) have been used in the local-mode calculations discussed below. The separation between the principal bands within this manifold closely mirrors the separation between the bands in the stretch overtone manifold.

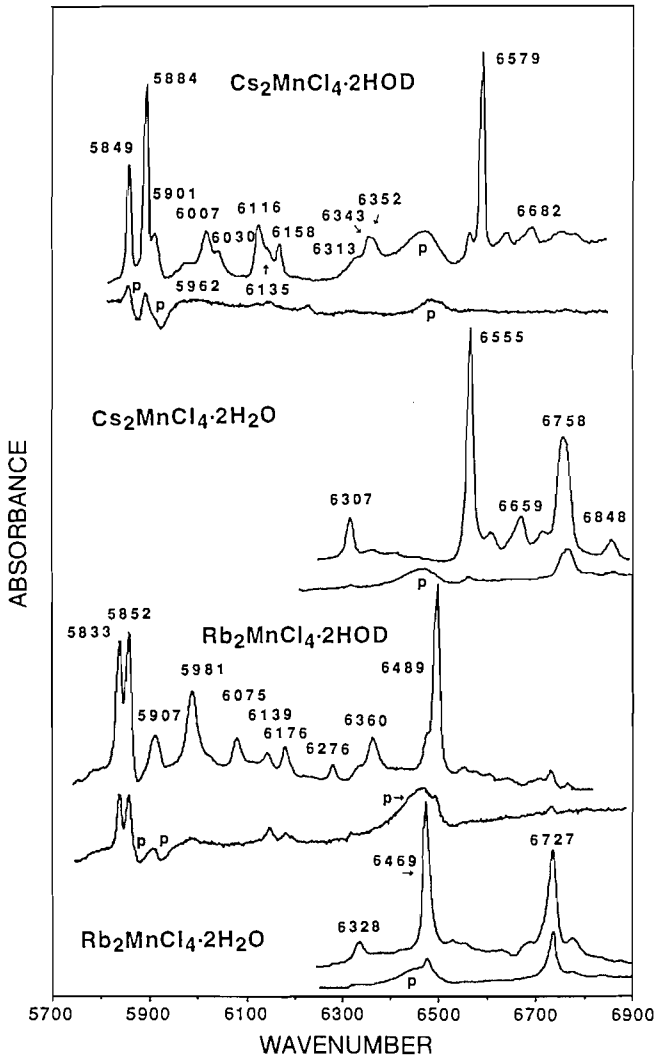
Fig. 3. Crystal spectra (4600–5200 cm^{-1}) of the orthogonal polarizations of $Cs_2MnCl_4 \cdot 2X_2O$ (X = H, D) at 10 K; (*a*) contains no D_2O, (*c*) is highly deuterated, and (*b*) is intermediate.



We were able to observe resolved second overtone (3ν) absorptions only in a 2 mm thick crystal of $Cs_2MnCl_4 \cdot 2H_2O$ (Fig. 5). The spectrum is at most 0.004 as strong as the strongest bands in the 2ν region. One maximum, representing a stretch combination band, corresponds rather well to expectation (see Table 2). The nature of the other two peaks is not clear; one may be the other combination band. The local modes $|300\rangle$ and $|030\rangle$, however, appear to be unobservably weak.

In gas-phase water, within a given manifold, stretch combinations are generally weaker than the stretch overtones. In several crystals that we have examined, the stretch combinations are of comparable intensity to the overtones in certain polarizations (2, 3), and in one case (4) they are more intense

Fig. 4. Crystal spectra (5700–6900 cm^{-1}) of the orthogonal polarizations of $M_2MnCl_4{\cdot}2HOD$ and $M_2MnCl_4{\cdot}2H_2O$ (M = Cs, Rb) at 10 K. The HOD spectra represent an intermediate degree of deuteration. The bands marked **p** are due to the polarizers.



than the overtones. This effect may be attributable to modifications in the dipole moment operator due to hydrogen bonding.

Spectra of HOD and DOD in crystals

The principal maxima of the D_2O molecule are listed in Table 3, while those due to HOD may be found in Table 4. The spectra of the deuterated compounds are quite complex, since the crystals contain some H_2O and HOD in addition to D_2O. Although each of these has a distinct spectrum, bands from different species often lie in the same region and even overlap. In spite of this, however, rather secure assignment of many features is possible. Each assignment has been made on the basis of (*i*) the energy of the band, (*ii*) its change in intensity with increased deuteration, and (*iii*) the relative intensity of the band in the two polarizations.

For water on general sites, replacement of a proton by a deuteron can occur in two physically distinct ways; the two resulting isotopomers, i.e., H_1OD_2 and D_1OH_2, have distinctly

[a]All data in cm^{-1}. Data below 4000 cm^{-1} from ref. 9.

[b]For H_1OD_2, the three digits in the ket give the number of quanta of OH_1, OD_2 stretches and H_1OD_2 bend, respectively. For D_1OH_2, the three digits in the ket give the number of quanta of OD_1, OH_2 stretches and D_1OH_2 bend, respectively.

[c]All parameters in cm^{-1}. Standard deviations in parentheses.

combinations of the type $\nu_{OH} + \rho_{HOD}$. None of these is shown in the figures.

Figure 2 shows the spectra of four crystals of the Rb complex with different D/H ratios. The assignment of most of the bands is given in Tables 3 and 4. The significant band at 4827 cm^{-1} is probably one of the $\nu + 2\delta$ bands of D_2O. We can make no assignment for the features at 4665 and 4890 cm^{-1}.

In Fig. 3 are the spectra of three crystals of the Cs complex with different D/H ratios. Since these spectra contain fewer bands than the analogous Rb spectra, there appears to be more overlapping of bands with resulting multiple assignments. The assignments are given in Tables 3 and 4. While we have assigned the 4929 cm^{-1} band to |200⟩ of D_1OH_2, its intensity appears anomalous, and it may contain $\nu + \delta$ of H_2O. Since it remains very strong in the most deuterated crystal, it probably contains other absorptions as well. We can make no assignments for features at 4953 cm^{-1} (trace (*a*)), 4769 cm^{-1} (trace (*b*)), and 4977 and 5084 cm^{-1} (traces (*b*) and (*c*)).

In the partly deuterated crystals the doublet at 5833, 5852 cm^{-1} (Rb) and 5849, 5884 cm^{-1} (Cs) is due to $\nu_{OH} + \nu_{OD}$ in HOD molecules (see Fig. 4). The spectra do not appear to show any extra bands due to excitations on adjacent HOD units.

In both of the compounds, as H is replaced by D, the |020⟩ and |200⟩ bands of H_2O weaken and are replaced by the corresponding bands in HOD. These uncoupled modes are seen in Fig. 4 at 6352 and 6579 cm^{-1} (Cs) and 6360 and 6489 cm^{-1} (Rb); they lie about 20–45 cm^{-1} higher in energy than the cor-

responding bands in H_2O. The bands at 6579 cm^{-1} (Cs) and 6489 cm^{-1} (Rb) show weak satellites similar to those associated with the coupled modes.

In the 5900–6320 cm^{-1} region most of the remaining bands are assigned to $2\nu + \delta$ of D_2O and $2\nu_{OD} + \delta$ of HOD, as can be seen in Tables 3 and 4. In the Rb spectrum only the band at 6075 cm^{-1} cannot be assigned. In the more complex Cs spectrum, bands at 5962, 6030, 6116, and 6343 cm^{-1} remain unassigned.

Local-mode parameters

The procedures used to obtain the local-mode parameters are well documented (4); the parameter sets for HOH and DOD may be found at the bottom of Tables 2 and 3, respectively. Those for DOD are in general less certain than those for HOH or for HOD (Table 4) due to the much smaller data sets available in these crystals.

A total of 18 parameters is needed in order to describe the spectra of HOD at the level of theory used for H_2O. Questions of physical significance arise when attempting to analyze crystal spectra using such large parameter sets. Some simplification is possible by replacing the small X_{sb} and X_b parameters for each isotopomer by single global fitting parameters. In addition, since the λ-coupling has almost no effect on the computed stretch frequencies in HOD, this parameter was dropped from the treatment entirely. The resulting 12-parameter model gives a good fit to the many observed HOD features (Table 4).

Fermi resonance

Since local-mode parameters are properties of individual chemical bonds, they should not change when oscillators such as OH are transferred from an H_2O to a HOD environment. As a consequence, the average energy (barycentre) of the observed OH stretch fundamentals in H_2O and HOD should be the same. This is very nearly true for water in the gas phase (17, 21), and in crystals such as $K_2SnCl_4{\cdot}H_2O$, where the effects of hydrogen bonding are small (22). Comparison of the IR spectra of the more strongly hydrogen-bonded $BaCl_2{\cdot}2H_2O$ with its HOD analogue indicates, however, that the OH barycentres are on the average 5 cm^{-1} different (2, 3). In $Cs_2MnCl_4{\cdot}2H_2O$ this effect is especially clear; the barycentre of the H_2O stretch fundamentals (3378 cm^{-1}) is considerably increased relative to the HOD barycentre (3364 cm^{-1}).

In addition, the energies of the first overtone bands in $BaCl_2{\cdot}2H_2O$ and $CsMnCl_3{\cdot}2H_2O$ are markedly lower in energy than those of the HOD analogues (2–4). The crystals in this report show similar behaviour. These spectral variations cannot be accounted for by λ-coupling.

By contrast, the OD barycentres in DOD and HOD are usually the same within experimental error in most hydrogen-bonded crystals. This observation is by no means restricted to H_2O. In a study of a series of isotopically substituted ethylenes, substantial Fermi resonance was found in the CH spectra, but none was detectable in the CD spectra (18). An explanation for these phenomena has not been provided, but may lie in the interplay between kinetic and potential energy contributions to the Fermi resonance term.

Preliminary fitting of the HOH spectrum using a single Fermi resonance parameter has been undertaken, using the HOH and HOD data sets for the crystals in this study. Values close to 70 cm^{-1} for this parameter give a very good fit to the observable bands in the stretch fundamental and overtone (V = 1, 2) manifolds. The fit to the V = 3/2 (e.g., $\nu + \delta$), and V = 5/2 (e.g., $2\nu + \delta$) manifolds is, however, not as good.

The issue of Fermi resonance in these and other hydrogen-bonded crystals will be taken up in a future article.

Conclusions

Due to the low symmetry of the space group, we could not correlate the spectral properties of the OH_1 and OH_2 oscillators with the two distinct oscillators from Table 1 on the basis of polarization of the bands. Correlations of local-mode parameters with hydrogen-bond distances may not be meaningful for many crystals, since the O—H···Cl grouping is often not isolated from its neighbours. For example, from our study of $CsMnCl_3{\cdot}2H_2O$, the local-mode parameters are found to be very similar (4), but they do not reflect the very disparate hydrogen-bond distances reported for this compound (7, 23). And in the present instance, the rather large difference in O···Cl distances for $Rb_2MnCl_4{\cdot}2H_2O$ as compared with the relatively small difference in the Cs analogue is not reflected in the "best-fit" local-mode parameters. This is doubtless due in part to the fact that there are 12 distinct configurations of the O··Cl··O group with an angle between 98° and 121° and with the two O··Cl distances less than 4 Å. Any or all of these interactions might influence the spectroscopic parameters to some extent.

A perusal of the local-mode parameters for $M_2MnCl_4{\cdot}2XOY$ (M = Cs, Rb; X, Y = H, D) listed in Tables 2–4 reveals the following relations and trends:

1. In general, the values of the OH stretch anharmonicities show little variation between Cs and Rb salts. The difference between X_1 and X_2 appears to be real. The values reported in Table 2 for the H_2O data set are somewhat more negative than those for HOD in Table 4. All are much larger in absolute size than those computed for gas-phase water (ca. −80 cm^{-1}) (19, 20); this appears to be a consequence of hydrogen bonding. Some modification of the Morse oscillator model, perhaps the inclusion of an attractive potential term that reflects the presence of the negatively charged acceptor ion, could explain these deviations.

2. The value of ω_1 for the OH oscillator in the Cs compound is significantly larger than for ω_2, indicating the presence of a weaker hydrogen bond than is found in the Rb compound. The remaining harmonic stretch frequencies are comparable.

3. The ω values in HOH are larger than those in HOD. The same trends are observed in $BaCl_2{\cdot}2X_2O$(X = H, D) for three of the four distinct OH oscillators (3) as well as in $CsMnCl_3{\cdot}2X_2O$(X = H, D) (4). In this latter case all the values are not given explicitly in the reference but can be calculated from the data presented there.

4. For the HOD species the difference between the two ω_b parameters for the Cs complex is greater than between the two values for the Rb complex. This correlates with the values observed for the bending vibrations for the two complexes.

5. The λ-coupling in the D_2O complexes is smaller than the value calculated for D_2O in the gas phase (ca. −60 cm^{-1}) (19). This was also found for $BaCl_2{\cdot}2X_2O$ (2, 3), and is a consequence of hydrogen bonding.

The value of zero calculated for the λ-coupling in $Cs_2MnCl_4{\cdot}2H_2O$ is a direct consequence of the energy of the

observed |110⟩ state being less than the sum of the |100⟩ and |010⟩ energies. This is in turn a direct consequence of the interaction of the two stretch fundamentals with the first bend overtone (2δ) via Fermi resonance. A similar problem occurs in the Rb salt; the value of λ is artificially low as a result. Obtaining accurate values of λ will be the subject of a future article.

6. The average of the ratios for ω_D/ω_H and X_D/X_H in the complexes of both metals are, respectively, 0.722 ± 0.013 and 0.530 ± 0.058. These are very close to the theoretical values for a Morse oscillator, namely, 0.728 and 0.529.

7. The parameter X_{sb} for the H_2O and D_2O complexes is significantly larger in absolute size (-28 ± 3 cm^{-1}) than is observed in gas-phase water (-17 cm^{-1}) (21). On the other hand, X_{sb} is barely significant (-5 cm^{-1}) in the HOD spectra of $M_2MnCl_4 \cdot 2H_2O$. The physical significance of these trends is not known at present; the effect may be related to hydrogen bonding.

8. Finally, it is worth noting that the detailed study of the combination bands can permit each observed HOD bend mode to be assigned to a specific HOD isotopomer. This requires that the two bend frequencies be quite different in energy, as they are in the Cs salt. Such assignments cannot be made based on fundamental data in the bend region alone.

Spectra in the overtone region seem to be especially sensitive to small changes in the environment of the OH oscillators, even in isomorphous salts. Some possible reasons for the differences in the spectra of the Cs and Rb salts in the fundamental region have already been outlined (9). We note that on replacing Rb with Cs, there is a detectable increase in the unit cell volume. A closer look shows that the *b* and *c* cell edges increases more than the *a* edge, making the lattice expansion effect distinctly anisotropic (Table 1). There is undoubtedly a subtle shift in the relative dispositions of the complex anions to accommodate the larger alkali cation. The spectra indicate that one hydrogen bond, that formed by oscillator no. 1, is weakened as a result of this readjustment. OH_A is almost exactly parallel to the crystal *b*-axis, which joins together the two complex units in adjacent cells. It would be the more sensitive to the forcing apart of these complex ions. An accurate neutron diffraction study of the title compounds would be invaluable in pinning down these subtle changes in hydrogen-bond distances. Quantitative correlations of local-mode parameters with hydrogen-bond geometry, even in isostructural systems, must await the development of a more complete theory for the O—H···Cl hydrogen bond.

The effect of *ortho* and *para* substituents on the formation of the *E* and *Z* isomers of the arylhydrazones obtained from diazonium coupling with methyl 3-aminocrotonate and 3-aminocrotononitrile

Jason V. Jollimore, Marc Vacheresse, Keith Vaughan, and Donald L. Hooper

Abstract: Reaction of arene diazonium salts with 3-aminocrotononitrile or methyl 3-aminocrotonate affords the 2-arylhydrazono-3-oxobutanenitrile (**1** or **3** and **3'**) or the methyl 2-arylhydrazono-3-oxobutanoate (**2** and **2'** or **4** and **4'**). A series of these hydrazones has been prepared with a range of electron-withdrawing and -donating substituents in the *ortho* or *para* position of the aryl moiety. The hydrazones have been characterized by spectroscopic methods, with emphasis on the ^{1}H NMR spectra, which have been used to determine the configuration of the hydrazones as *E* or *Z* or a mixture of the two. The *para*-substituted hydrazononitriles (**1**) are formed as a single species, namely the *Z* isomer, whereas the *ortho* isomers are formed as a mixture of *E* and *Z* configurations (**3** and **3'**). The hydrazonobutanoates (**2** and **2'** or **4** and **4'**) are formed as *E/Z* mixtures regardless of the position of the substituent in the aryl moiety. Complete assignments of all signals in the ^{1}H NMR spectra have been made on the basis of the ability of the various substituents to participate in intramolecular hydrogen bonding and a mechanism is proposed to account for the variations in the proportions of *E* and *Z* isomers and the effect of the nature of the substituent on this ratio. ^{13}C NMR spectra of selected hydrazones have been recorded as an aid to structure assignment.

Key words: hydrazone, diazonium, NMR spectroscopy, *E/Z* isomers, crotonic acid derivatives.

Résumé : La réaction des sels d'arène diazonium avec le 3-aminocrotonitrile ou le 3-aminocrotonate de méthyle conduit au 2-arylhydrazono-3-oxobutanenitrile (**1** ou **3** et **3'**) ou le 2-arylhydrazono-3-oxobutanoate de méthyle (**2** et **2'** ou **4** et **4'**). On a préparé une série de ces hydrazones portant, en positions *ortho* ou *para* de la portion aryle, une variété de substituants ayant des caractères plus ou moins électroattracteurs ou électrodonneurs. On a caractérisé les hydrazones par des méthodes spectroscopiques, en particulier à l'aide de la RMN du ^{1}H qui a été utilisée pour déterminer que la configuration est *E* ou *Z* ou un mélange des deux. Les hydrazononitriles substitués en *para* (**1**) existent principalement sous la forme d'une seule espèce, l'isomère *Z*, alors que les isomères *ortho* forment un mélange des configurations *E* et *Z* (**3** et **3'**). Les hydrazonobutanoates (**2** et **2'** ou **4** et **4'**) conduisent à des mélanges *E/Z* quelle que soit la position du substituant dans la portion aryle. On a pu attribuer tous les signaux des spectres RMN du ^{1}H se basant sur la capacité des divers substituants à participer à des liaisons hydrogènes intramoléculaires et on propose un mécanisme pour expliquer les variations dans les proportions des isomères *E* et *Z* ainsi que l'effet de la nature des substituants sur ces rapports. Afin de faciliter l'attribution des structures, on a aussi enregistré les spectres RMN du ^{13}C d'hydrazones choisies.

Mots clés : hydrazone, diazonium, spectroscopie RMN, isomères *E/Z*, dérivés de l'acide crontonique.

[Traduit par la rédaction]

Introduction

In a previous report (1), the reaction of arene diazonium ions with 3-aminocrotononitrile (**8***a*) or methyl 3-aminocrotonate (**8***b*) was found to afford either the 2-arylhydrazono-3-oxobutanenitriles (**1**) or the methyl 2-arylhydrazono-3-oxobutanoates (**2**), respectively. The hydrazones were produced by diazonium coupling at the C2-vinylic carbon of the αβ-unsaturated ester or nitrile, followed by hydrolysis of the 3-amino substituent to the 3-oxo derivative. All of the examples in the previous study used arenediazonium ions with an electron-withdrawing substituent (NO_2, CN, CO_2R, $CONH_2$, or Br) in the *para* position of the aryl moiety. In the present work, we have extended this study to include electron-donating groups in the aryl moiety and we have also prepared the *ortho* isomers of all the hydrazones in this series. This paper reports the synthesis and characterization of an extended series of *ortho*- and *para*-substituted arylhydrazones, with an analysis of the ^{1}H NMR spectra with respect to the effect of the substituent on

the relative amounts of the *E* and *Z* isomers of the hydrazones produced in the coupling reaction.

Experimental

All reagents were reagent grade materials purchased from the Aldrich Chemical Co. Ltd., and were used without further purification. Melting points were determined on a Reichert hot-stage microscope and are uncorrected. Infrared spectra were obtained using Nujol mulls, unless otherwise indicated, on a Perkin Elmer 299 spectrophotometer. ^1H and ^{13}C NMR spectra were obtained on the Bruker 250 and AMX400 MHz spectrophotometers of the Atlantic Region Magnetic Resonance Centre at Dalhousie University. Chemical shifts are relative to TMS (1%) internal standard.

2-Arylhydrazono-3-oxobutanenitriles (1 and 3) and Methyl 2-arylhydrazono-3-oxobutanoates (2 and 4)

General procedure

These compounds were prepared by the general procedure described previously (1). This procedure was successful in the preparation of the 2-(3′-pyridyl)-hydrazono-3-oxobutanenitrile (**5**) when 3-aminopyridine was used as the arylamine.

Table 1 shows the yields and physical data of the new hydrazones prepared for this study. The yields reported in Table 1 are those of the crude products; the melting points in Table 1 are those measured after recrystallization to constant melting point. Tables 2-6 list the complete spectroscopic data for all the hydrazones in these series, including those reported previously (1) for comparison. The percentages of *E* and *Z* isomers reported in Tables 3 and 4 represent the composition of the crude product as calculated from the relative integrations in the ^1H NMR spectra. In most cases of *E*- and *Z*-hydrazone mixtures, the isomers did not separate on TLC plates and the isomers cocrystallize when recrystallized, as indicated by the essentially unchanged ^1H NMR spectra of the recrystallized materials. The only cases where two spots were evident on TLC plates were the crude products of compounds **4***d*, **4***e*, **4***f*, and **4***g*, but even in those cases recrystallization did not effect a separation of the isomers.

2-(*ortho*-Carbamoylphenylhydrazono)-3-oxobutanenitrile (3*e*)

Modified procedure

Anthranilamide (0.01 mol) was dissolved in 10 M hydrochloric acid (40 mL) and the solution cooled to 0°C. The cold solu-

tion was diazotized with sodium nitrite (0.011 mol) in water and the resulting mixture stirred for 0.5 h. The diazonium salt solution was filtered and treated with a cold solution of 3-aminocrotononitrile (0.011 mol) dissolved in 2 M hydrochloric acid (1 equiv.) After stirring for 1 h in the cold, the solution was made alkaline with aqueous sodium bicarbonate solution, whereupon the yellow product precipitated immediately. The precipitate was filtered, dried, and recrystallized from a mixture of ethyl acetate and ethanol to afford the hydrazone (**3***e*), mp 252-254°C.

Results and discussion

Reaction of the diazonium ion (**7**) with 3-aminocrotononitrile (**8***a*) or methyl 3-aminocrotonate (**8***b*) affords excellent yields of the 2-arylhydrazono-3-oxobutanenitriles (**1** or **3** and **3′**) or the methyl 2-arylhydrazono-3-oxobutanoates (**2** and **2′** or **4** and **4′**). The reaction works equally well with *ortho*- or *para*-substituted arenediazonium ions; slightly lower yields are observed for compounds **2**/**2′***i*, **2′***j*, **4**/**4′***g*, and **4′***h*, which have electron-releasing groups in the aryl moiety. A modified pro-

cedure, derived from the work of Siddiqui and Stevens (2), was used for the preparation of the *ortho*-carbamoylphenyl diazonium ion en route to the 2-(*ortho*-carbamoylphenylhydrazono)-3-oxobutanenitrile (**3**/**3′**e); strongly acid conditions are required to prevent cyclization of the intermediate diazonium ion. The nitrile series was extended to include the 3-pyridylhydrazone (**5**).

Table 1 shows the frequency of the principal bands in the IR spectra of these hydrazones. The *para*-substituted 2-arylhydrazono-3-oxobutane-nitriles (**1**) have a single NH absorption in the range 3180–3220 cm^{-1}, nitrile absorption at 2170–2190 cm^{-1}, and ketone carbonyl at 1640–1660 cm^{-1}. In the *ortho*-substituted isomers (**3** and **3′**) the NH absorption band is shifted slightly to lower frequency; the nitrile and carbonyl absorption bands are largely unchanged. The methyl 2-arylhydrazono-3-oxo-butanoates (**2** and **2′** or **4** and **4′**) have a lower frequency NH absorption and an ester carbonyl band at higher frequency than the ketone carbonyl band. All compounds show the appropriate bands for the functional group present in the aryl substituent (X).

Table 2 shows the ^1H NMR chemical shifts of the *para*-substituted 2-arylhydrazono-3-oxobutanenitriles (**1***a–i*), including data previously reported (1) for comparison. It is immediately obvious that these hydrazones are formed in a single stereochemical form, namely, as the intramolecularly hydrogen-bonded *Z* isomer shown in structure **1**. The evidence for assignment of the *Z* configuration to these products is unequivocal: (*i*) firstly, the intramolecular hydrogen bond provides stabilization compared to the *E* isomer (not shown), which cannot form an intramolecular hydrogen bond; (*ii*) the chemical shift of the NH proton, 12.20–12.55 ppm, is consistent with hydrogen bonding to a ketone-carbonyl oxygen atom (3). In geometric isomers of hydrazones that preclude

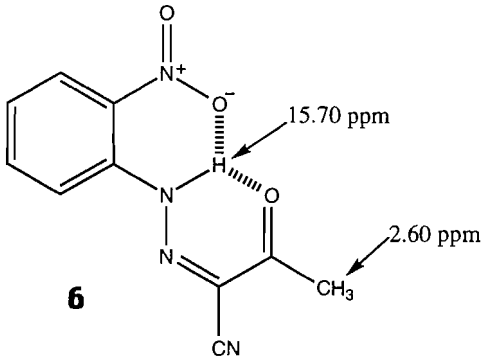
5

(NO_2 in **1***a*) to electron releasing (OMe in **1***i*), accompanied by a shift to lower frequency in the chemical shift of the protons in the methyl ketone moiety.

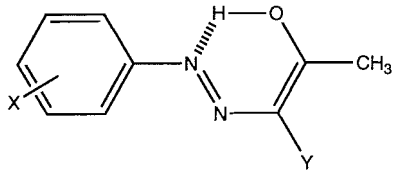
The *ortho*-substituted 2-arylhydrazono-3-oxobutanenitriles (**3***a–i*) are formed as mixtures of *E* and *Z* isomers (**3** and **3'**). The principal evidence for this is the ^{1}H NMR spectrum, which clearly shows the signals from both isomers. Table 3 shows the chemical shift assignments for the *E* and *Z* isomers of hydrazones **3***a–i*. All ^{1}H NMR spectra show two NH signals, the high-frequency NH resonance being assigned to the intramolecularly hydrogen-bonded *Z* isomer (**3**). In most cases, the signals from the acetyl methyl protons are resolved, and most of the aromatic multiplets of the two isomers can be discerned. The chemical shift of the NH proton in the *E* isomer (**3'**) correlates well with the nature of the X substituent, i.e., with its ability to hydrogen bond. When X is not able to form a strong hydrogen bond with the hydrazone NH, i.e., when X = H, Br, Me, or OMe, the chemical shift of the NH proton is at low frequency in the range 9.2–9.7 ppm as expected (3). In contrast, when the X substituent can form a strong intramolecular hydrogen bond, i.e., when X = NO_2, CO_2R, $CONH_2$, or COMe, the chemical shift of the hydrazone NH shifts back to the range 12–13 ppm, which is similar to the observed chemical shift of the NH in the *para*-substituted *Z* isomers (**1***a–i*). An intermediate effect is seen when X is a cyano group, which would not be expected to hydrogen bond, but which might cause a shift of ca. 1 ppm by a field effect.

The high-frequency NH signal in the NMR spectra of **3** is assigned to the *Z* isomer, and this chemical shift is similarly

dependent on the hydrogen-bonding ability of the substituent X. When X can form a strong intramolecular hydrogen bond, e.g., X = NO_2, CO_2R, $CONH_2$, or COMe, the NH chemical shift is found at ca. 15.70 ppm, which is to be expected for the chemical shift of a hydrazone NH proton hydrogen bonded to two potential hydrogen-bonding groups (3) as shown, for example, in structure **6**.[2] In the hydrazones with non-hydrogen



6



15 Y = CN or CO_2Me

bonding *ortho* substituents (X = CN, Br, Me, OMe), the chemical shift of the *Z*-hydrazone NH proton is shifted to higher frequency, ca. 14.8 ppm, which is still at a higher frequency than the chemical shift of the NH proton in the *Z* isomer of the *para*-substituted hydrazones (**1**). Thus, the *ortho* substituent (X) in the *Z*-hydrazone (**3**) may be exerting a steric effect on the alignment of the N-H··O=C hydrogen-bonding groups that brings the hydrogen and oxygen atoms closer together, strengthening the hydrogen bond and causing a shift of the NH proton signal to higher frequency.

Table 3 also shows the percentage of each diastereomer in the crude hydrazone mixtures; the composition has been determined from the relative integration of the signals in the ^1H NMR spectrum, and the percentages averaged from the NH and ketone methyl proton signals, which were in close agreement. In general, the presence of an electron-withdrawing X substituent favours formation of the *E* isomer (**3′**) and electron-releasing groups favour the *Z* isomer (**3**), which might be explained by a substituent effect on the mechanism of hydrazone formation. However, an acceptable mechanism must also be able to account for the change from 100% preference for the *Z* isomer with *para* substituents to the *E/Z* mixtures observed with *ortho* substituents.

A proposed mechanism, which may account for these observations, is shown in Scheme 1. Coupling of the diazonium ion (**7**) with the enamine (**8**) affords the arylazo-iminium ion (**9**), which deprotonates from the α-carbon to give the crucial intermediate arylazo-enamine (**10**). This rotamer (**10**) is ideally set up for an intramolecular proton shift, path (a), to give the 2-arylazo-3-imino derivative (**11**), which undergoes hydrolysis in the reaction mixture to give one isomer of the 2-arlhydrazono-3-oxo derivative (**12**). The alternative pathway leads from the rotamer (**10′**); when Y = CN, this rotamer (**10′**) cannot proceed via intramolecular proton transfer and proceeds by intermolecular proton transfer, path (b), to give the isomeric 2-arylazo-3-imino derivative (**13**), which hydrolyzes to give the other isomer of the 2-arylhydrazono-3-oxo derivative (**14**). The assignment of *E* or *Z* configuration to the products **12** and **14** depends on the nature and position of the substituent Y.

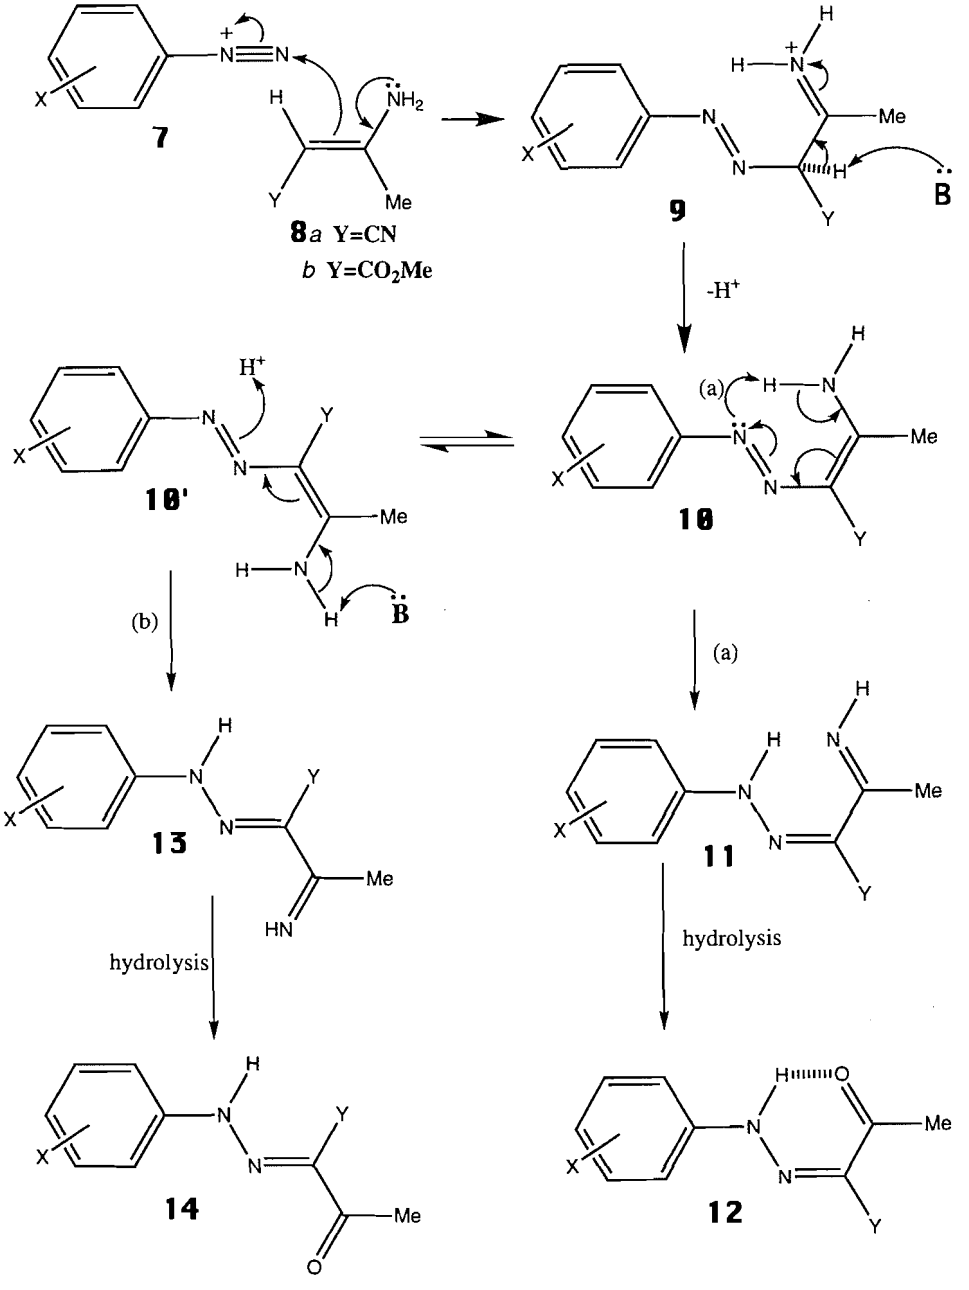
This mechanism seems to explain the observed product distribution. Reaction of the *para*-substituted arenediazonium ion (**7**) with 3-aminocrotononitrile (**8** , Y = CN) proceeds directly through the pathway → **9** → **10** → **11** → **12** to give a single product, the *Z*-2-arylhydrazono-3-oxobutanenitrile (**1**). The formation of a single product is determined by two factors: (i) the favourable entropy factor of the intramolecular process, path (a), over the intermolecular reaction, path (b); and (ii) the stability of the hydrogen-bonded product (**12** ≡ **1**) over the non-hydrogen-bonded product **14**. The presence of the substituent (X) in the *ortho* position of the intermediate **10** interferes sterically with the electron lone pair on the adjacent nitrogen atom, which in turn prevents the efficient abstraction of the N-H proton in the intramolecular process, path (a). This allows time for the conformational change to the rotamer (**10′**), resulting in formation of the isomer **14** in addition to **12**. Thus reaction of the *ortho*-substituted arenediazonium ion (**7**) with 3-aminocrotononitrile affords a mixture of the *E* isomer (**14** ≡ **3′**) and the *Z* isomer (**12** ≡ **3**).

The mechanism in Scheme 1 also explains the substituent effect on the preference for the *E* or *Z* isomer, **3** or **3′**. An electron-withdrawing substituent in the *ortho* position of the intermediate **10** reduces the electron density at the adjacent nitrogen atom and thus slows down path (a), allowing path (b) to become predominant. Thus it appears that a combination of steric and electronic effects determines the relative proportion of products obtained from paths (a) and (b) in Scheme 1.

Diazonium coupling with methyl 3-aminocrotonate (**8**, Y = CO_2Me) affords a mixture of the *E* and *Z* isomers of the methyl 2-arylhydrazono-3-oxobutanoates (**2** and **2′** or **4** and **4′**). The formation of mixtures is evident in almost all cases, whether the substituent is in the *ortho* or *para* position as shown by the data in Table 4, which shows all chemical shift assignments for the protons in these hydrazones. Only two examples, **2′***j* and **4′***h*, show complete preference for one species, which is the *Z* isomer in each case. In general, the product distribution shows similar dependence on the nature of the X substituent as in the nitrile series. In the *para*- substituted series (**2/2′***a–i*), the preferred form is the ketone-carbonyl hydrogen-bonded isomer (**2**, the *E* isomer), but in the *ortho*-

[2] There is an alternative explanation for the extremely high frequency of the NH signals (ca. 15.70 ppm) in many of these hydrazones, one which does not appear to have been expressed in the literature before. Chemical shifts in the range 15–16 ppm have been associated with an enolic proton of such species as acetylacetone and other β-diketones (*5b*), and this suggests that some of these hydrazones may be present as the enolic tautomer such as that shown in structure **15**. Of course, structure **15** is also the azo-tautomer of the hydrazone, and, although it may not be wise to resurrect the old hydrazone vs. azo compound vs. enehydrazine question (6), it seems that we might be negligent in not pointing out the potential of a tautomeric species like **15** as a possible explanation for some of our observations.

Scheme 1.



substituted series (**4**/**4**′*a–h*) there is a switch in the order of preference with electron-releasing groups, which favour the *Z* isomer (**4**′*f*, **4**′*g*, and **4**′*h*); this substituent effect is opposite to that observed in the *ortho*-substituted arylhydrazonocrotononitrile series (**3**/**3**′*a–i*).

Table 4 reveals a similar correlation of the chemical shift of the NH proton with the proximity of potential hydrogen-bonding groups. The *E* isomers of the *para*-substituted series (**2***a–i*) show NH signals at 11.50–12.80 ppm, consistent with hydrogen bonding to the neighbouring ketonic carbonyl function. The *Z* isomers of the same series (**2**′*a–i*) show NH signals shifted to higher frequency, ca. 14.7 ppm, which must reflect the stronger hydrogen bond between the hydrazone NH and the ester carbonyl oxygen. In the *ortho*-substituted series, the *E* isomers (**4***a–g*) display the NH chemical shift at 14.0–14.5 ppm in the presence of an electron-withdrawing group as compared to 13.1 ppm for other *ortho* substituents. The *Z* isomers (**4**′*a–h*) have the NH signal shifted to higher frequency due to the stronger hydrogen-bonding effect of the ester carbonyl oxygen atom.

The formation of both *E* and *Z* isomers (**2** and **2**′ or **4** and **4**′) is consistent with the mechanism in Scheme 1, when Y = CO_2Me. The driving force would appear to be the presence of the intramolecular hydrogen bond in both products (**14** and **13**, Y = CO_2Me), as a stabilizing influence that seems to override the entropy factor of the intramolecular process in path (a).

Table 4. ^{1}H NMR chemical shifts of the *ortho*- and *para*-substituted methyl 2-arylhydrazono-3-oxobutanoates (**2** and **4**).

A selected number of these hydrazones were analysed by ^{13}C NMR spectroscopy to provide additional corroboration of structure. Tables 5 and 6 record the ^{13}C NMR data obtained for these compounds. The pairing of signals seen in the ^1H NMR spectra is not routinely observed in the ^{13}C NMR spectra under standard procedures. The chemical shifts observed in cases where a major species is predominant are those of the major species, which makes unequivocal peak assignment using additivity rules (*5a*) possible. Compounds **2/2′***c* and **2/2′***f* contain two carbonyl groups that cannot be unambiguously assigned by simple inspection of the ^{13}C NMR spectrum. This problem was overcome using the 2-D NMR technique, Heteronuclear Multiple Bond Correlation (HMBC) spectroscopy, which shows the presence of coupling between the substituent carbonyl carbon and the aromatic protons *ortho* to it in the form of a crosspeak.

In the HMBC spectrum of **2/2′***c*, the signal at 165.8 ppm shows long-range coupling to aromatic protons in the form of a cross peak; thus the 165.8 ppm signal is assigned to the ester carbonyl group attached to the aromatic ring and by inference the signal at 162.7 ppm is assigned to the ester carbonyl carbon of the butanoate moiety. Having made these assignments for compound **2/2′***c*, the analogous assignments for compound **4/4′***c* (the *ortho* isomer of **2/2′***c*) followed logically without the necessity for a separate HMBC experiment. In the HMBC spectrum of **2/2′***f*, the signal at 196.4 ppm shows long-range coupling to aromatic protons in the form of a cross peak, thus enabling the assignment of this signal to the carbonyl carbon of the *para*-acetyl substituent and, hence, the assignment of the signal at 193.9 ppm to the carbonyl carbon of the 3-oxo substituent.

The photochemistry of 3,3′,4,4′-tetramethoxy- and 4-hydroxy-3,3′,4′-trimethoxystilbene — models for stilbene chromophores in peroxide-bleached, high-yield wood pulps

William J. Leigh, T. Johnathan Lewis, Vincent Lin, and J. Alberto Postigo

Abstract: The photochemistry of the title compounds has been investigated in ethanol and tetrahydrofuran solution under aerobic and anaerobic conditions. Direct irradiation of *trans*-3,3′,4,4′-tetramethoxystilbene (*trans*-**1**) in deoxygenated ethanol leads to the rapid establishment of a photostationary state with the *cis* isomer, and the slower formation of the ethyl ether corresponding to addition of ethanol across the olefinic C=C bond and cyclobutane dimers. The same products are formed upon photolysis in the presence of oxygen under the same conditions but, in addition, two isomeric tetramethoxyphenanthrenes and 3,4-dimethoxybenzaldehyde are formed. Photolysis of *trans*-**1** in oxygenated tetrahydrofuran leads to the same products in different relative yields. Quantum yields for *cis,trans* photoisomerization, phenanthrene formation, and addition of ethanol have been determined by ferrioxalate actinometry. Direct irradiation of *trans*-4-hydroxy-3,3′,4′-trimethoxystilbene (*trans*-**2**) in ethanol solution also results in rapid *cis–trans* isomerization and the formation of (three) isomeric phenanthrene derivatives in photolyses carried out in the presence of oxygen, although the material balance is low. The various products of photolysis of *trans*-**2** have been independently synthesized by desilylation of the products isolated from photolysis of *trans*-4-*tert*-butyldimethylsiloxy-3,3′,4′-trimethoxystilbene (*trans*-**3**) under similar conditions. Fluorescence-quenching experiments have been carried out to determine the relative rates of quenching of the excited singlet states of *trans*-**1** and *trans*-**2** by alcohols and oxygen. The formation of aldehydes is proposed to arise via reaction of superoxide ion with stilbene radical cations, which are formed by electron-transfer quenching of the stilbene excited singlet state by oxygen.

Key words: stilbenes, lignin, photochemistry, photooxidation.

Résumé : On a étudié la photochimie des composés mentionnés dans le titre en solutions dans l'éthanol et le tétrahydrofurane, dans des conditions tant aérobiques qu'anaérobiques. L'irradiation direct du *trans*-3,3′,4,4′-tétraméthoxystilbène (*trans*-**1**) dans de l'éthanol désoxygéné conduit à la création rapide d'un état photostationnaire avec l'isomère *cis* et à une formation plus lente de l'éther éthylique correspondant à l'addition de l'éthanol sur la double liaison C=C oléfinique ainsi que des dimères cyclobutanes. Les mêmes produits se forment lors de la photolyse dans les mêmes conditions, en présence d'oxygène; toutefois, il se forme de plus deux tétraméthoxyphénanthrènes isomères ainsi que du 3,4-diméthoxybenzaldéhyde. La photolyse du *trans*-**1** dans du tétrahydrofurane oxygéné conduit à la formation des même produits avec des rendements relatifs différents. On a déterminé les rendements quantiques de la photoisomérisation *cis*, *trans*, de la formation du phénanthrène et de l'addition de l'éthanol par actinométrie ferrioxalate. L'irradiation directe du *trans*-4-hydroxy-3,3′,4′-triméthoxystilbène (*trans*-**2**) en solution dans l'éthanol effectuée en présence d'oxygène conduit aussi à une isomérisation *cis–trans* rapide et à la formation de (trois) dérivés phénanthrènes isomères, même si la balance des produits est faible. Les divers produits de photolyse du *trans*-**2** ont été synthétisés par des voies indépendantes par désilylation des produits isolés de la photolyse du *trans*-4-*tert*-butyldiméthylsiloxy-3,3′,4′-triméthoxystilbène (*trans*-**3**) dans des conditions semblables. On a effectué des expériences de désactivation de la fluorescence pour déterminer les vitesses relatives de désactivation des états singulets excités des composés *trans*-**1** et *trans*-**2** par les alcools et l'oxygène. On suggère que la formation des aldéhydes résulte de la réaction de l'ion superoxyde avec les cations radicaux du stilbène qui se forment par une désactivation du transfert d'électron de l'état singulet excité du stilbène par l'oxygène.

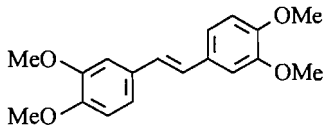
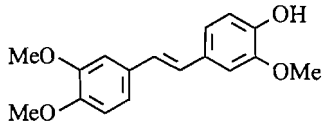
Introduction

The development of an understanding of the mechanisms of the various chemical processes responsible for the photochemical yellowing of lignin-rich pulp and paper products, and discovering ways of inhibiting these processes, is a matter of considerable commercial importance and intense current interest (1). It is generally agreed that oxidative processes involving the conversion of phenoxy radicals to quinonoid species represent the main contributor to photoyellowing, and various mechanisms for the formation of phenoxy radicals from photolysis of the more abundant chromophore types present in lignin, such as α-phenoxycarbonyl and -benzyl alcohol moieties, have been proposed (2–7).

Relatively little attention has yet been paid to the less-abundant chromophores that are present in lignin-rich papers as a result of condensation reactions that take place during alkaline bleaching processes. Castellan et al. have described qualitative results from the irradiation of several model compounds of this general type, stilbenes, benzofurans, biphenyls, diarylmethanes, and alkenylphenols, adsorbed on filter paper and in solution (8). This study was confined to measurements of the rates of photoinduced discolouration of the paper as a function of adsorbate and photolysis time. Interestingly, two of the compounds that proved to be most active under these conditions were *trans*-3,3′,4,4′-tetramethoxystilbene (*trans*-**1**) and *trans*-4-hydroxy-3,3′,4′-trimethoxystilbene (*trans*-**2**).



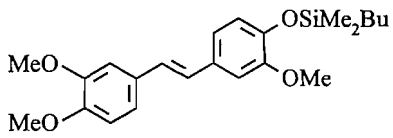
trans-**1**



trans-**2**

Zhang and Gellerstedt have reported the results of a more detailed investigation of the photochemistry of *trans*-**2** on filter paper (9, 10). Using natural sunlight as an excitation source, they verified the substantial photoreactivity of this compound under these conditions, and isolated several dimers and a highly coloured *ortho*-quinonoid compound from the photolysis mixture. Interestingly, no evidence for the formation of the *cis* isomer or phenanthrene derivatives — the normal products expected from irradiation of stilbene derivatives (11–13) — was reported. While other explanations are possible, the "unusual" photoreactivity of **2** under these conditions may be due to the reaction medium being microcrystalline; the [2+2] photodimerization of stilbene and other phenylalkene derivatives in the crystalline solid phase is well documented (14). It remains to be determined whether these results are relevant to the photochemistry of stilbene chromophores in the amorphous molecular environment provided by natural lignin.

As part of a study designed to evaluate the importance of phenolic polyalkoxystilbenes and their photoproducts in contributing to the photoyellowing of lignin-rich materials, we report the results of the direct irradiation of **1**, **2**, and *trans*-4-*tert*-butyldimethylsiloxy-3,3′4′-trimethoxystilbene (*trans*-**3**) in ethanol and tetrahydrofuran solutions in the presence and absence of oxygen. The latter compound was prepared primarily as a synthon to aid in the preparation and isolation of the various phenanthrene derivatives expected from photooxidation of *trans*-**2**. We also report fluorescence-quenching studies



trans-**3**

of *trans*-**1**, *trans*-**2**, and a tetramethoxyphenanthrene derivative derived from the photooxidation of *trans*-**1**, which allows an assessment of the effects of oxygen and proton donors on the photochemistry of these compounds.

Results

Compounds *trans*-**1** and *trans*-**2** were synthesized according to the published procedures, while *trans*-**3** was synthesized by silylation of *trans*-**2** with *tert*-butyldimethylsilyl chloride. The latter compound exhibited spectroscopic and analytical data consistent with its proposed structure (see Experimental section). The ultraviolet absorption spectra of *trans*-**1** and *trans*-**2** exhibit maxima at ~335 nm in tetrahydrofuran (THF) solution. No changes in the spectra could be detected upon saturating the solutions with oxygen.

The three compounds were irradiated as solutions (0.002–0.015 M) in 95% ethanol and dry tetrahydrofuran (THF), under both nitrogen and oxygen atmospheres, with the progress of the reactions monitored by capillary GC, GC–MS, and ^{1}H NMR spectroscopy. Photoproducts were isolated by thick-layer chromatography, after both short and long irradiation times, and identified on the basis of spectroscopic data (vide infra). As expected, establishment of a photostationary state with the corresponding *cis* isomer is substantially more rapid than the formation of other products and, with broadband irradiation through a Pyrex filter, the photostationary states are rich in the *cis* isomer in all cases. Quantitative detection of *cis*-**2** was carried out by ^{1}H NMR spectroscopy in deuterated solvents, as the compound was found to undergo facile thermal isomerization to *trans*-**2** in the GC injector port at the temperatures required for GC analysis of the mixtures.

In nitrogen-saturated ethanol solution, prolonged irradiation of *trans*-**1** and *trans*-**3** led to isolable yields of solvent-addition products, which were identified as **4** and **5**, respectively; the latter consisted of a mixture of two regioisomers, which were not further separated. GC analysis of the photolysates during the very early stages of photolysis verified that the formation of these products accompanies photoisomerization to the *cis* isomers. Cyclobutane dimers **6**–**8** were also isolated; their yields were generally higher in irradiations carried out using the higher stilbene concentrations, but the concentration dependence was not examined in detail. These products could not be detected by GC analysis under the conditions employed, but were readily detectable in the ^{1}H NMR spectra of the crude reaction mixtures. Irradiation of oxygen-saturated ethanol solutions led to the additional formation of phenan-

threne derivatives **9–11**, which were isolated by thick-layer chromatography, and 3,4-dimethoxybenzaldehyde (**12**). Minor yields of **9–11** were also obtained in the nitrogen-atmosphere experiments, but this was shown to be due to diffusion of air into the irradiation cells during the course of the experiment. Irradiation in THF solution under similar sets of conditions afforded the same products, with the exception of **4** and **5**. Prolonged irradiation of both *trans*-**1** and *trans*-**3** resulted in the development of a yellow colour and the formation of several minor products in each case. These could be detected by GC and GC–MS, but could not be isolated owing to their small yields; GC–MS data for some of these compounds are included in the Experimental section. Small amounts of highly coloured fractions containing mixtures of relatively polar minor products were generally obtained from the thick-layer plates, but the amounts were too low to warrant further attempts at separation. The infrared spectra of these mixtures showed them to be rich in carbonyl absorptions.

Prolonged irradiation of oxygen-saturated ethanol or THF solutions of *trans*-**2** led to the development of a deep yellow-brown colour, complex product mixtures, and poor material balances. Phenanthrenes **9***b*–**11***b* were identified as photoproducts on the basis of GC coinjections of authentic samples, which were synthesized by desilylation of **9***c*–**11***c* with tetrabutylammonium fluoride. In addition, a cyclobutane dimer (**8***b*) was isolated in low yield from irradiation in THF solution.

Table 1 summarizes the products obtained from irradiation of the three compounds under the various conditions employed, along with their chemical yields and material balances, as estimated by a combination of GC and ^1H NMR analysis of crude reaction mixtures.

The phenanthrenes **9–11** were identified on the basis of their ^1H and ^{13}C NMR, mass, and UV absorption spectra; NMR was particularly useful for the regiochemical assignments of individual sets of regioisomers. Compound **9***a* could be easily distinguished from **10***a* by NMR, owing to σ_v molecular symmetry. Phenanthrene **9***c* could be readily distinguished from **10***c* and **11***c* from the aromatic proton region in the ^1H NMR spectra, and by comparison to the spectra of **9***a* and **10***a*. Two of the compounds (which, coincidentally, elute together under our GC conditions) show singlets at $\delta \sim 9.2$ (due to the C4 ring proton) and must therefore possess alkoxy substitution at the 5-position of the phenanthrene ring system; by default, the compound without a singlet at $\delta \sim 9.2$ can be assigned to **9***c*. The aromatic region of the ^1H NMR spectrum of this compound compares quite favourably with that in the spectrum of the symmetrical tetramethoxyphenanthrene derivative **9***a*; the spectrum shows single-proton singlets at 7.76 and 7.88 ppm, a two-proton singlet at 7.53 ppm, and single-proton singlets at 7.19 and 7.20 ppm. This should be compared with the spectrum of **9***a*, which shows two-proton singlets at 7.79, 7.55, and 7.21 ppm. ^1H nOe experiments were employed to distinguish between **10***c* and **11***c*. The C7/C8 protons give rise to an AX splitting pattern, with doublets at ca. 7.2 and 7.6 ppm. Irradiation of the *tert*-butyl methyl singlets at ~1.08 ppm results in nOe enhancement of the singlet at 9.2 ppm for the compound assigned as **10***c*, and enhancement of the doublet at δ7.15 for the compound assigned as **11***c*. Irradi-

Table 1. Product yields from irradiation of stilbenes **1–3** in 95% ethanol and THF under various conditions.[a]

Compound	Conditions: Solvent	Conc/M	Conversion (%)	Products: Phenanthrenes	Others	Material balance (%)

	THF–O_2	0.0166	25[c]	**9***c* (5%); **10***c* (4%); **11***c* (11%)	**12** (5%) + unident. (0.25%)	95[e,f]

[a]Determined by GC–MS analysis of crude photolysis mixtures relative to internal standard, with no correction for detector response.
[b]Only those products observed by gas chromatography are reported (dimers **6–8** are undetectable by GC).
[c]The % conversion was determined by GC–MS, and calculated as $100\% \times (100\% - \%(trans\text{-}\mathbf{1} + cis\text{-}\mathbf{1})_{final})/(trans\text{-}\mathbf{1})_{initial}$.
[d]*cis,trans* Isomerization is the only photoprocess observed at the given conversion.
[e]Calculated as $100 \times (\%trans\text{-}\mathbf{1} + cis\text{-}\mathbf{1})_{NMR}/(\%trans\text{-}\mathbf{1} + cis\text{-}\mathbf{1})_{GC\text{-}MS}$.
[f]Most of the deficiency in the material balance was due to formation of cyclobutane dimers.
[g]Calculated as $100\% \times (\%(trans\text{-}\mathbf{1} + cis\text{-}\mathbf{1})_{final})/(trans\text{-}\mathbf{1})_{initial}$.

ation of two of the methoxy singlets in the spectrum of the latter compound results in enhancement of the singlet at 9.2 ppm, thus verifying the assignment. Unfortunately, the methoxy singlets are too closely spaced in the 500 MHz spectrum of **10***c* to allow meaningful information to be gleaned from analogous experiments in this case.

Identification of the cyclobutane dimers **6–8** was made on the basis of their ^{1}H NMR and mass spectra (15, 16). The ^{1}H NMR spectrum of the *trans-syn-trans* dimer **6** shows a multiplet at $\delta \sim 4.4$ ppm, which is characteristic of *trans-syn-trans* stereochemistry in stilbene photodimers (15). The spectra of the all-*trans* dimers **7***a* and **8***a,b* show characteristic resonances at $\delta \sim 3.7$ ppm (16, 17). The identities of the isomers **7***a* and **8***a* were established on the basis of their mass spectral fragmentation patterns (18); that of **8***b* was analogous to that of **8***a*. In most cases, the presence of other regio- and (or) stereoisomeric dimers was evident in the crude irradiation mixtures or in chromatographic fractions, but they could not be characterized owing to either the small amounts obtained or to the fact that they were obtained as mixtures with other minor products. The presence of these products is not evident by GC or GC–MS analyses of the crude irradiation mixtures under the conditions employed.

Prolonged photolysis of **1–3** produced several additional minor products that were detectable by GC–MS, and strongly coloured solutions (particularly in the case of **2**). While all attempts to isolate these products have so far proved unsuccessful, their GC retention times and mass spectra suggest them to be demethylation products of the phenanthrenes; i.e., dimethoxyphenanthrenedione and phenanthrenetetrone derivatives. Our efforts to rigorously identify these products are continuing.

Quantum yields for direct *cis,trans* photoisomerization of *cis*- and *trans*-**1** were determined using 300 nm excitation in deoxygenated ethanol and tetrahydrofuran (THF) solution by electronic actinometry using 0.001 M solutions. In ethanol, $\phi_{t\rightarrow c} = 0.35 \pm 0.04$ and $\phi_{c\rightarrow t} = 0.41 \pm 0.04$ while in THF, $\phi_{t\rightarrow c} = 0.40 \pm 0.04$ and $\phi_{c\rightarrow t} = 0.51 \pm 0.06$. The photostationary state is *cis*-**1** / *trans*-**1** = 1.38 ± 0.05 in ethanol solution for 300 nm excitation. The quantum yields for *cis,trans* isomerization matched the quantum yields for disappearance of the starting isomers in both solvents.

Quantum yields for formation of **4**, **9***a*, **10***a*, and **12** in oxygen-saturated ethanol were estimated relative to $\phi_{t\rightarrow c}$ and $\phi_{c\rightarrow t}$ from the slopes of concentration vs. time plots. The values obtained are $\phi_4 = 0.007 \pm 0.003$, $\phi_{9a} = 0.008 \pm 0.003$, $\phi_{10a} = 0.005 \pm 0.002$, and $\phi_{12} = 0.009 \pm 0.004$.

Irradiation of *trans*-**1** was also carried out in the presence of 2,6-di-*tert*-butylphenol as a free radical scavenger. Thus, a solution of *trans*-**1** (0.0054 M), *n*-hexadecane as internal standard, and 2,6-di-*tert*-butylphenol (0.006 M) in dry tetrahydrofuran was oxygenated with a stream of dry oxygen for 10 min, irradiated for 6 h with 300 nm light, and monitored by GC–MS and TLC at 1 h intervals. The formation of aldehyde **12** was evident in the earliest stages of photolysis, but reached a maximum yield that fell off at long (>8 h) photolysis times. Compounds *cis*-**1**, **9***a*, and **10***a* were isolated and identified by comparison with authentic samples obtained from previous photolysis experiments. The mixture contained enhanced amounts (~5% total) of two of the minor products whose mass spectra are consistent with dimethoxyphenanthrenedione structures (see Experimental section). Significantly, no evidence was obtained for the formation of products of more extensive demethylation, under these conditions.

Direct irradiation (300 nm) of an oxygenated, 0.014 M solution of tetramethoxyphenanthrene **10***a* in THF yielded minute amounts of a single unidentifiable product after several hours of photolysis. Irradiation (254 nm) of an oxygenated THF solution containing **10***a* (0.07 M), *trans*-**1** (0.013 M), and *n*-hexadecane as internal standard (under conditions where **10***a* absorbs >99% of the light) yielded a qualitatively similar product distribution to that obtained from photolysis of

trans-**1** under similar conditions: none of the products was formed in significantly enhanced or reduced yields under these conditions.

Samples of *cis*- and *trans*-**1** adsorbed on filter paper (ca. 0.5% by weight) were irradiated with 300 nm light (in a Rayonet reactor operating at half intensity) under an air atmosphere, extracted into dichloromethane, and analysed by gas chromatography. Photolysis of *trans*-**1** for 1 h under these conditions caused mild yellowing of the paper. GC analysis indicated that ca. 30% of the starting material had been consumed, but only a small amount of *cis*-**1** had formed (~2% of the amount of *trans*-**1** present) and there was no evidence for the formation of phenanthrenes **9***a* and **10***a*. Irradiation of *cis*-**1** under these conditions results in initially rapid conversion to the *trans* isomer, followed by behaviour similar to that observed upon irradiation of the sample of *trans*-**1** as described above.

Fluorescence emission spectra of *trans*-**1**, *trans*-**2**, and 2,3,6,7-tetramethoxyphenanthrene (**9***a*) were recorded in ethanol and THF solution. The spectra were unexceptional; those of *trans*-**1** and *trans*-**2** were indistinguishable from each other and from the spectrum of *trans*-**2** in toluene reported by Zhu and Gray (19), while that of **9***a* is similar to that of phenanthrene itself (20). Attempts were made to determine fluorescence lifetimes for the two stilbene derivatives using the time-correlated single-photon counting technique. In the case of *trans*-**1** in deoxygenated ethanol, fluorescence decay was too fast to be determined accurately with our system. This affixes an upper limit of ca. 0.5 ns for the singlet lifetime of *trans*-**1** in this solvent. In deoxygenated THF solution, fluorescence decay followed single exponential kinetics and exhibited an apparent lifetime of $\tau = 1.2 \pm 0.3$ ns. The lifetime was shortened to 0.9 ns in oxygen-saturated solution. Both values are very close to the limits of reliability of our system, and we do not consider them reliable. Similar results were obtained for *trans*-**2** in deoxygenated THF solution. The fluorescence lifetime of **9***a* was determined to be $\tau = 16.6 \pm 1.8$ ns in nitrogen-saturated THF, and $\tau = 3.5 \pm 0.4$ ns in oxygen-saturated solution under the same conditions.

The steady state fluorescence spectra of *trans*-**1** and *trans*-**2** in THF are quenched upon addition of ethanol, 2,2,2-trifluoroethanol (TFE), 1,1,1,3,3,3-hexafluoroisopropanol (HFIP), or oxygen to the deoxygenated solution. Stern–Volmer quenching experiments led to the $k_q\tau$ values listed in Table 2.

Table 2. Stern–Volmer constants ($k_q\tau/M^{-1}$) for fluorescence quenching of *trans*-**1** and *trans*-**2** by ethanol (EtOH), 2,2,2-trifluoroethanol (TFE), and 1,1,1,3,3,3-hexafluoroisopropanol (HFIP) in deoxygenated THF solution at 23°C.[a]

Alcohol	EtOH	TFE	HFIP	O_2
trans-**1**	0.13 ± 0.02	0.18 ± 0.03	0.27 ± 0.03	29 ± 9
trans-**2**	0.26 ± 0.04	0.36 ± 0.04	0.46 ± 0.03	47 ± 12

[a]Errors in the $k_q\tau$ values are given as twice the standard deviation from least-squares analysis of the Stern–Volmer plot.

Discussion

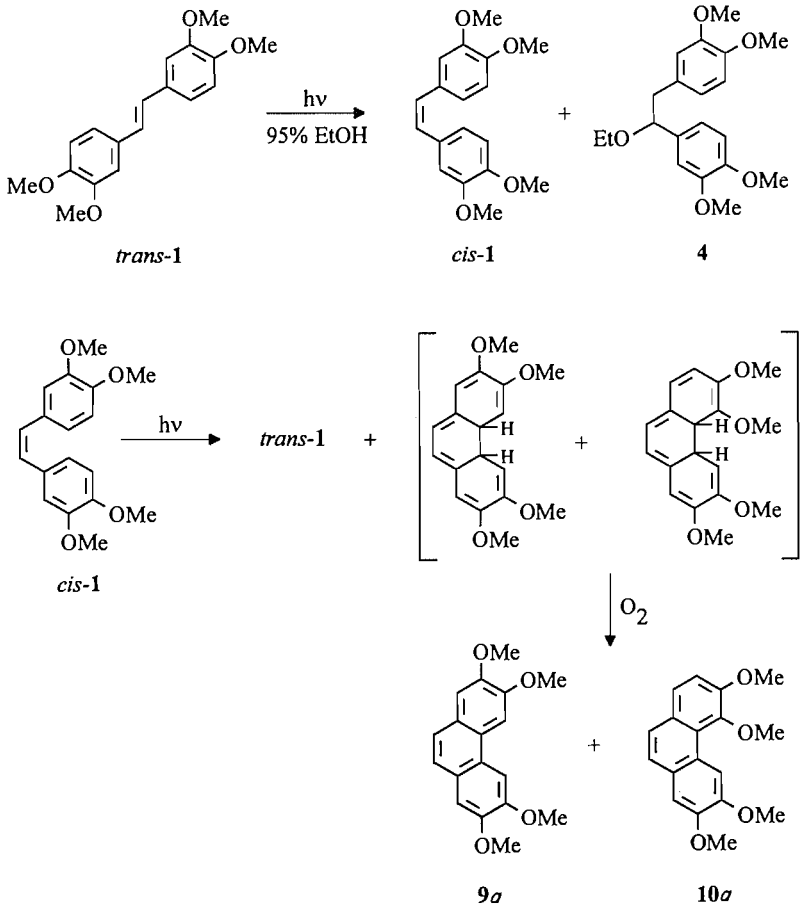
The general features of the photochemistry of *trans*-**1** and *trans*-**3** in solution are typical of the photochemistry of stilbene derivatives (11–13). *cis,trans* Photoisomerization occurs with relatively high efficiency, leading to a photostationary state that is rich in the *cis* isomer for 300 nm excitation; in rigorously deoxygenated, non-protic solvents, *cis,trans* isomerization is the only productive photoprocess detectable at short irradiation times. In the presence of oxygen, *cis,trans* isomerization is accompanied by the formation of 3,4-dimethoxybenzaldehyde (**12**) and phenanthrene derivatives (**9–11**), with efficiencies some two orders of magnitude lower than that of *cis,trans* isomerization. Phenanthrene derivatives are well known to be formed by a mechanism involving oxidation of 4a,4b-dihydrophenanthrene intermediates formed by photoelectrocyclic ring-closure of the *cis* isomer of the stilbene (11, 21). In the absence of oxidizing agents, these intermediates undergo thermal or photochemical cycloreversion to the *cis*-stilbene derivative from which they were formed. Thermal cycloreversion is relatively rapid; at room temperature in fluid solution, their lifetimes range from seconds to a few hours depending on substituent (21). Thus, the direct detection of these compounds in the present cases is not expected to be straightforward with the analytical methods employed in this work. The relevant chemistry is illustrated for *trans*-**1** in Scheme 1.

While compounds identifiable as 3,4,5,6-tetrasubstituted phenanthrene derivatives could not be detected in the irradiation mixtures from **1–3**, there appears to be little regioselectivity in the formation of the 2,3,6,7-tetrasubstituted regioisomer over the 2,3,5,6-isomer(s), at least according to GC analysis. Evidently, this lack of regioselectivity in the photocyclization of *meta*-substituted stilbene derivatives is common (11, 21).

The formation of ethyl ethers **4** (from **1**) and **5** (from **3**) in ethanol is presumably the result of excited singlet state quenching by protonation of the electron-rich stilbene double bond, followed by trapping of the resulting carbenium ion by the solvent. Photoprotonation of phenylalkenes is well documented (22–28), and is known to be enhanced by the presence of electron-donating aromatic substituents. The process occurs with relatively low efficiency (compared to *cis,trans* isomerization) in **1** and **3**, but competes effectively with phenanthrene formation and oxidative cleavage in the presence of oxygen. An upper limit for the rate constant for photoprotonation of *trans*-**1** by ethanol in THF solution is on the order of 5×10^8 M^{-1} s^{-1} (assuming a singlet lifetime of 1 ns), which seems reasonable considering the structure of the molecule compared to those of other phenylalkenes for which quantitative data exist in the literature (22–24, 28). It is interesting to note that the rate constant for this process varies by less than a factor of two for EtOH, TFE, and HFIP for both *trans*-**1** and -**2**, in spite of the fact that the pK_a's of the three alcohols vary substantially. To our knowledge, there are, unfortunately, no data available in the literature with which to compare these results.

The irradiations of *trans*-**1–3** in oxygenated ethanol solutions lead to lower yields of phenanthrenes than those obtained in oxygenated THF solutions at similar concentrations. As discussed above, the formation of ethyl ethers, corresponding to addition of ethanol across the olefinic C=C bond, provides a productive deactivation pathway for the excited states of *trans*-**1–3** that is not available in THF, but this accounts for only a fraction of the differences in the phenan-

Scheme 1.



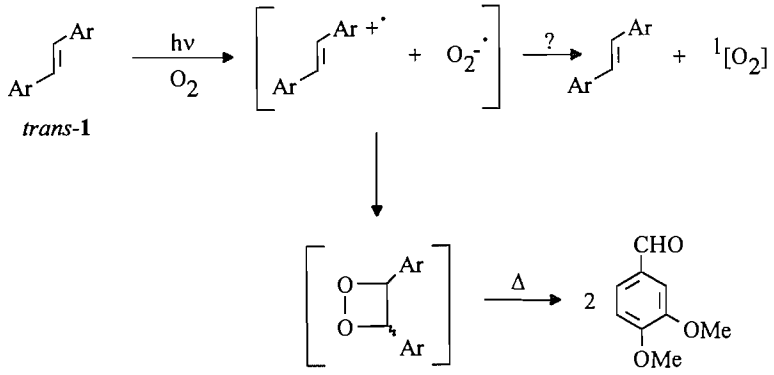
threne yields in the two solvents. The main contributor appears to be a higher propensity for dimer formation in the protic solvent. Similar solvent effects on stilbene photodimerization have been documented previously (18).

The formation of 3,4-dimethoxybenzaldehyde (**12**) as a primary product of photolysis of **1** in oxygen-saturated solution most likely results from the reaction of the olefin radical cation with superoxide ion, formed as a result of electron transfer quenching of the excited singlet state of the stilbene by molecular oxygen. There is a considerable body of evidence that supports this conclusion. First, the sensitized photooxygenation of stilbene derivatives with cyanoaromatics and *some* dye sensitizers (e.g., methylene blue) has been shown to proceed by an electron transfer mechanism (29–31), in which electron transfer quenching of the excited sensitizer by the olefin, followed by reduction of molecular oxygen by the sensitizer radical anion, results in the ultimate formation of oxidative cleavage products through reaction of the olefin radical cation and superoxide ion. The initial product of this reaction is thought to be the corresponding 1,2-dioxetane (29–32), although evidence that an ozonide may be involved in these reactions has also been reported (33). In the present cases, we believe that the mechanism for formation of superoxide and stilbene radical cation is direct electron transfer quenching of the excited singlet state of the stilbene by molecular oxygen. This is supported by fluorescence-quenching experiments (Table 2), which indicate that oxygen quenching of *trans*-**1** and -**2** proceeds at the diffusion-controlled rate (note that the Stern–Volmer constants reported in Table 2 indicate a quenching rate constant of $(2–5) \times 10^{10}$ M^{-1} s^{-1}, assuming singlet lifetimes of 1 ns for the two stilbene derivatives). The oxidation potential of **1** ($E_{1/2}^{ox} = 0.82$ V vs. SCE in acetonitrile;[2] a similar value can be expected for **2**) is clearly low enough that photoinduced electron transfer to molecular oxygen will be strongly exothermic. Once formed, $\mathbf{1}^{\cdot+}$ and $O_2^{\cdot-}$ can react to yield dioxetane **13** directly. This mechanism is related to that proposed for the photooxygenation of electron-rich styrenes and other arenes, which has been shown in some cases to proceed via direct excitation of a charge transfer complex between the arene and molecular oxygen (34, 35). However, no evidence for the formation of analogous charge transfer complexes could be obtained from the UV absorption spectra of *trans*-**1** and -**2** in oxygen-saturated THF or acetonitrile solution.

Another possible mechanism for the formation of **13** might involve generation of singlet oxygen ($^1O_2$) by back-electron-transfer of the initially produced radical ion pair (this should also produce the excited triplet state of **1**), followed by reaction of $^1O_2$ with ground state **1** (9). We believe that this mechanism can be discounted, on the basis that the relative yield of **12** (the product of decomposition of the presumed intermediate **13**) does not appear to be enhanced when the photolysis of

[2] We thank Professor M.S. Workentin for the oxidation potential measurement.

Scheme 2.



12

1 is sensitized by phenanthrene **9***a*. The phenanthrene can be expected to be a much more efficient sensitizer for the formation of superoxide ion (and thus $^1O_2$, by this mechanism) because of its longer singlet lifetime and lower oxidation potential compared to *trans*-**1** (36); fluorescence quenching experiments indicate that the excited singlet state of **9***a* is quenched just as rapidly by molecular oxygen as those of *trans*-**1** and -**2**. Phenanthrene **9***a* also has the potential of producing $^1O_2$ directly by triplet–singlet energy transfer, because intersystem crossing is expected to be efficient (37). In fact, the product distribution obtained in this experiment is similar to that produced in the direct irradiation of *trans*-**1**, suggesting that the dominant mechanism for reaction involves singlet energy transfer from **9***a* to **1**.

Thus, we suggest the tentative mechanism shown in Scheme 2 for the formation of **12** from photolysis of *trans*-**1** in oxygen-saturated solution. Further work is clearly required in order to conclusively identify the reactive oxygen species involved in the reaction, and to fully understand the mechanism(s) by which it is formed.

Of the three lignin-model stilbenes whose photochemistry has been investigated in the present work, **2** is the most relevant to the stilbene chromophores present in lignin-rich materials (10). It is also the most difficult to study because of the large number of minor, unisolable products produced upon its irradiation. Nevertheless, it is clear that UV irradiation of this compound in solution *does* result in the formation of products analogous to those produced from **1** under similar conditions: phenanthrenes derived from photocyclization/oxidation of the *cis* isomer, and products derived from oxidative cleavage of the olefinic double bond. Highly coloured (presumably) quinonoid materials are also formed, but in significantly higher yields than those obtained from photolysis of **1** or **3**.

The irradiation of **2** in solution bears only marginal resemblance to that obtained when the compound is adsorbed on filter paper (9). In the latter case, the main products are cyclobutane dimers and dimethoxybenzaldehyde **12**; minor products are reported to include a dimeric ether from addition of the phenolic OH in **2** across the double bond in a second molecule (which is related to the ethanol-addition products observed in the present work), and a stilbenequinone. In contrast to the solution phase results described here, no phenanthrene derivatives were reported. Furthermore, we observe the formation of only very minor amounts of compounds, tentatively identifiable as stilbenequinones, in the photolysis of **2** in oxygen-saturated solution. On the basis of our results for *trans*-**1**, it seems likely that the absence of phenanthrenes as photoproducts in the irradiation of *trans*-**2** on filter paper is due to the fact that the photostationary state consists of <5% of the *cis* isomer under these conditions. We believe that the extremely low *cis*-**1** content in the photostationary state for the filter paper irradiations is probably due to the reactant existing in a microcrystalline environment in which the *trans* isomer is thermodynamically favoured. The same is likely to be true for **2** under these conditions.

Summary and conclusions

Irradiation of polyalkoxystilbene derivatives in solution in the presence of oxygen leads to *cis,trans* isomerization, polyalkoxyphenanthrene formation, oxidative cleavage of the olefinic double bond, dimerization, and the formation of small amounts of highly coloured, carbonyl-containing compounds. The formation of phenanthrene derivatives is the result of photoelectrocyclization of the corresponding *cis*-stilbene isomer, followed by oxidation, and is a well-known reaction in stilbene photochemistry. For monochromatic 300 nm excitation in solution, the *cis/trans* photostationary state is rich in the *cis* isomer, so that cyclization to yield phenanthrene derivatives occurs with significant efficiency. The photostationary state obtainable with broadband irradiation with >300 nm light is undoubtedly lower in *cis* content, since the UV absorption spectra of the *cis* isomers extend slightly further to the red. However, our experiments show that phenanthrene formation still proceeds readily under these conditions.

Both the stilbenes and their phenanthrene photoproducts are powerful photoreductants, and are potentially capable of initiating oxidative processes involving reaction of superoxide ion and (or) singlet oxygen with *other components* in the natural lignin matrix. Defining the extent to which this might contribute to lignin photoyellowing is the subject of continuing investigation in our laboratory.

Experimental section

^1H NMR spectra were recorded on Bruker AC200, AC300, or AM500 spectrometers in deuteriochloroform solution, while ^{13}C NMR spectra were recorded on the Bruker AC200 or AM500 spectrometers. Spectra reported for new compounds

were recorded on the AM500 spectrometer unless otherwise noted, and are reported in parts per million relative to tetramethylsilane. Infrared spectra were recorded in carbon tetrachloride solution on a Biorad FTS-40 FTIR spectrometer or as the neat samples in the case of liquids. Ultraviolet absorption spectra were recorded on a Perkin Elmer Lambda 9 spectrometer interfaced to an IBM PS/2-286 microcomputer, or on a Hewlett–Packard HP8451 UV spectrometer. Fluorescence emission and excitation spectra and fluorescence lifetimes were recorded on a Photon Technologies Inc. LS-100 spectrofluorometer/single-photon counting system, which is controlled by a 486-33 PC using software provided by the manufacturer. Single-photon counting experiments employed a hydrogen flashlamp.

Gas chromatographic analyses were carried out using a Hewlett–Packard 5890 gas chromatograph equipped with a flame ionization detector, a Hewlett–Packard 3396 integrator, and a DB-1 megabore capillary column (5 m × 0.53 mm; Chromatographic Specialties, Inc.). GC–MS analyses were carried out using a Hewlett–Packard 5890 gas chromatograph equipped with a HP-5971A mass selective detector and a DB-5 microbore capillary column (30 m × 0.2 mm; Chromatographic Specialties, Inc.). Exact Masses were determined on a VGH ZABE mass spectrometer and employed a mass of 12.000 000 for carbon. Thick-layer chromatographic separations employed a Chromatotron (Harrison Research, Inc.) and 2 or 4 mm silica gel 60 (E. Merck) thick-layer plates.

Preparative photolyses were performed using a Hanovia 450 W medium-pressure mercury lamp and a Pyrex immersion well (at 20°C), or a Rayonet reactor equipped with 14 RPR-3000 Å lamps and a 120 mL capacity Pyrex container (at 27°C). Analytical-scale photolyses employed the latter in conjunction with a merry-go-round; samples (ca. 0.5 mL) were contained in 5 × 80 mm Pyrex tubes that were sealed with rubber septa. Experiments carried out using 254 or 419 nm radiation employed the Rayonet reactor equipped with 6 RPR-2537 or 10 RPR-4190 lamps, respectively.

Tetrahydrofuran (Caledon Reagent grade) was dried over sodium metal and distilled prior to use. Benzene (Fisher Reagent) was purified by several extractions with concentrated sulfuric acid, rinsed with dilute sodium bicarbonate solution, predried over sodium sulfate, and distilled from sodium metal. Methanol (Fisher Reagent) was distilled from magnesium. Ethanol (95%) was purchased from Caledon Chemical Co. and distilled prior to use. Absolute ethanol was purchased from BDH and distilled from magnesium. Pentane (BDH Omnisolv) was used as received from the supplier. *N,N*-Dimethylformamide (Caledon) was dried over potassium hydroxide and distilled prior to use. Neutral alumina, dichloromethane, diethyl ether, ethyl acetate, hexanes, potassium carbonate, potassium bicarbonate, anhydrous sodium sulfate, and HPLC-grade water were all used as received from Fisher Chemical Co. Benzophenone, *n*-butyllithium, *tert*-butyldimethylsilyl chloride, 3,4-dimethoxybenzylalcohol, *n*-hexadecane, imidazole, methylene blue, thionyl chloride, triphenylphosphine, and vanillin acetate were all used as received from Aldrich Chemical Co.

trans-3,3′,4,4′-Tetramethoxystilbene (*trans*-**1**) and *trans*-4-hydroxy-3,3′,4′-trimethoxystilbene (*trans*-**2**) were synthesized according to the method of Castellan et al. (8). They exhibited melting points (*trans*-**1**; mp 154.6–155.0°C; *trans*-**2**; mp 129.6–130.1°C) and spectroscopic data that were similar to the reported data in both cases.

trans-4-*tert*-Butyldimethylsiloxy-3,3′,4′-trimethoxystilbene (*trans*-3)

In a 100 mL round-bottom flask equipped with a condenser and magnetic stirrer were placed *trans*-**2** (1.0 g, 0.001 mol), *tert*-butyldimethylsilyl chloride (0.63 g, 0.0042 mol), imidazole (0.60 g, 0.0083 mol), and dry dimethylformamide (7 mL). The mixture was stirred at room temperature for 24 h, with periodic monitoring by thin-layer chromatography on neutral alumina using 15% ethyl acetate in hexane as the eluant. The product mixture was diluted with ether (15 mL), washed with water (2 × 5 mL), dried with anhydrous sodium sulfate, and filtered. Evaporation of the solvent yielded a slightly yellow solid, which was recrystallized from hexane–ethanol to yield colourless crystals of the desired product (1.18 g, 84%; mp 70.0–71.3°C); UV (ethanol) $\lambda_{max}(\varepsilon)$: 203 nm (36 800), 332 nm (39 400); IR: 3030 (s), 2960 (w), 2840 (w), 1601 (w), 1514 (s), 1465 (m), 1251 (s), 1027 (w), 902 (w) 815 (w); ^{1}H NMR, δ: 0.15 (s, 6H), 0.99 (s, 9H), 3.84 (s, 3H), 3.88 (s, 3H), 3.96 (s, 3H), 6.89 (d, 2H), 6.91 (m, 6H); ^{13}C NMR, δ: –4.6, 18.6, 25.7, 55.5, 55.9, 55.9, 108.7, 109.7, 111.3, 119.5(2), 121.0, 126.6, 126.9, 130.8, 131.5, 144.8, 148.7, 149.1, 151.1; MS, *m/e* (*I*): 400 (44), 343 (24), 328 (100), 286 (90), 271 (13), 73 (9). Exact Mass, calcd. for $C_{23}H_{32}SiO_4$: 400.207; found: 400.2076.

Preparation and isolation of photoproducts

(i) From irradiation of trans-***1***

(a) Irradiation of trans-***1*** *in 95% ethanol*

A continuously oxygenated solution of *trans*-**1** (0.30 g, 1.0 mmol) in 95% ethanol (500 mL) was placed in a Pyrex immersion well system and irradiated for 0.5 h with a 450 W medium-pressure mercury lamp. GC analysis of the mixture indicated the presence of five compounds, which were subsequently identified (in order of increasing retention time) as *cis*-**1**, **4**, **10***a*, *trans*-**1**, and **9***a*. The solvent was distilled in vacuo to yield a yellow solid residue, which was placed on the Chromatotron and eluted with a 0–7.5% ethyl acetate – hexane gradient. The five compounds eluted in the order **10***a* < *cis*-**1** < *trans*-**1** < **4** < **9***a* under these conditions. Compounds *cis*-**1**, **9***a*, and **10***a* were isolated in >90% purity as solids, and recrystallized several times from ethyl acetate – hexane mixtures. Compound **4** was isolated in ca. 80% purity after several repeated elutions, and finally isolated as a colourless oil by cyclic medium-pressure column chromatography on a 1 in. × 10 in. Merck Lobar silica gel column using 9% ethyl acetate in dichloromethane as the eluant. The purified yields of the five compounds were: *cis*-**1** (0.045 g), *trans*-**1** (0.055 g), **4** (0.061 g), **9***a* (0.065 g), **10***a* (0.020 g). They were identified on the basis of the following spectroscopic data.

cis-*3,3′4,4′-Tetramethoxystilbene (*cis-***1***)*: 0.045 g, 0.15 mmol, 15%, mp 119.3–120.2°C); UV (ethanol) $\lambda_{max}(\varepsilon)$: 200 nm (33 200), 296 nm (12 700); IR: 3030 (s), 2961 (w), 2839 (w), 1582 (w), 1513 (s), 1464 (m), 1421 (w), 1267 (s), 1140 (m), 1027 (m); ^{1}H NMR (300 MHz), δ: 3.71 (s, 6H), 3.90 (s, 6H), 6.40 (s, 2H), 6.77 (m, 2H), 6.90 (m, 4H); ^{13}C NMR, δ: 55.6, 55.8, 55.9, 108.6, 110.9, 111.3, 111.8, 119.5, 121.8, 126.7,

128.7, 130.2, 130.7, 148.1, 148.4, 148.7, 149.1; MS, *m/e* (*I*): 300 (100), 285 (20), 225 (10), 181 (8), 152 (9), 128 (11). Exact Mass, calcd. for $C_{18}H_{20}O_4$: 300.1374; found: 300.1377.

1-Ethoxy-1,2-bis(3,4-dimethoxyphenyl)ethane (**4**): 0.061 g, 18%. UV (ethanol), $\lambda_{max}(\varepsilon)$: = 202 nm (79 560), 229 nm (19 750), 279 nm (6760); IR: 3059 (w), 2968 (s), 2968 (s), 2836 (s), 1591 (w), 1516 (w), 1262 (w), 1155 (w); ^{1}H NMR (300 MHz), δ: 1.2 (t, 3H), 2.8 (dd, 1H), 3.05 (dd, 1H), 3.75 (s, 3H), 3.80 (s, 6H), 3.85 (s, 3H), 4.3 (t, 1H), 6.5–6.8 (m, 6H); ^{13}C NMR, δ: 14.2, 15.3, 22.5, 44.5, 55.7, 55.8, 61.0, 64.1, 83.2, 109.5, 110.6, 110.8, 133.0, 119.3, 121.4, 131.2, 135.0, 147.4, 148.3, 149.0; MS (NH_3 CI), *m/e* (*I*): 364 (5), 301 (100), 195 (95), 151 (8).

2,3,6,7-Tetramethoxyphenanthrene (**9***a*): 0.065 g, 22%, mp 178.9–179.4°C; UV (ethanol), $\lambda_{max}(\varepsilon)$: 218 nm (26 960), 254 nm (52 430), 285 nm (32 460), 299 nm (20 240); IR: 3011 (s), 2960 (w), 2836 (w), 1512 (s), 1481 (s), 1255 (s), 1197 (s), 1160 (s), 1112 (m), 1041 (w); ^{1}H NMR, δ: 4.02 (s, 6H), 4.12 (s, 6H), 7.21 (s, 2H), 7.55 (s, 2H), 7.79 (s, 2H); ^{13}C NMR, δ: 55.9, 56.1, 102.8, 108.4, 124.3, 126.4, 128.3, 148.8, 149.3; MS, *m/e* (*I*): 298 (100), 283 (5), 255 (10), 240 (12), 225 (10), 212 (7), 169 (8), 139 (5), 126 (6). Exact Mass, calcd. for $C_{18}H_{18}O_4$: 298.1205; found: 298.1225.

2,3,5,6-Tetramethoxyphenanthrene (**10**a): 0.020 g, 7%, mp 98–100°C; UV (ethanol), $\lambda_{max}(\varepsilon)$: 261 nm (65 600), 312 nm (12 590); IR: 3010 (s), 2960 (w), 2839 (w), 1514 (s), 1472 (s), 1422 (w), 1268 (s), 1241 (s), 1137 (w), 1103 (s), 1050 (w); ^{1}H NMR, δ: 3.96 (s, 3H), 4.03 (s, 3H), 4.04 (s, 3H), 4.08 (s, 3H), 7.22 (s, 1H), 7.28 (d, 1H), 7.49 (d, 1H), 7.55 (d, 1H), 7.63 (d, ^{1}H), 9.22 (s, 1H); ^{13}C NMR, δ: 55.5, 56.3, 59.8, 107.8, 108.5, 112.2, 123.6, 124.0, 124.4, 124.7, 125.0, 127.6, 128.2, 145.9, 148.2, 148.5, 150.7; MS, *m/e* (*I*): 298 (100), 283 (25), 255 (20), 240 (30), 225 (15), 197 (20), 169 (10), 139 (13), 126 (18), 87 (8), 63 (8). Exact Mass, calcd. for $C_{18}H_{18}O_4$: 298.1205; found: 298.1225.

(b) Irradiation of trans-**1** *in THF*

A solution of *trans*-**1** (0.19 g, 0.63 mmol) and *n*-hexadecane (5.65 mg, 0.025 mmol) in dry tetrahydrofuran (5 mL) was placed in a Pyrex tube sealed with a rubber septum, oxygenated with a stream of dry oxygen for 10 min, and then irradiated for 4.5 h with 300 nm light (Rayonet reactor, 14 lamps, 27°C), with periodic bubbling of oxygen through the solution. GC analysis of the photolysis mixture indicated that the conversion of the starting material to products was ca. 80%. The photolysate consisted of a mixture of 3,4-dimethoxybenzaldehyde (**12**) (8%), *cis*-**1** (41%), **9***a* (11%), **10***a* (22%), and *trans*-**1** (17%), in order of increasing retention times. *cis*- and *trans*-**1** were found to be thermally stable under the gas chromatographic conditions employed. The identity of **12** was established by GC–MS and after chromatographic isolation from the mixture (vide infra).

After a total of 7.5 h of irradiation (resulting in a deep yellow solution), there was a further enrichment of the product mixture in **9***a*, **10***a*, and **12**, and a concomitant decrease in the concentration of **1**. At this point the material balance accounted for (by GC and GC–MS analyses) was only ca. 80%.

Two minor products were detected by GC–MS analysis after 4.5 h of irradiation; they were also present after 7.5 h of irradiation in higher concentrations (~3% of the total). Their GC retention times were similar to those of **9***a* and **10***a*. The two products exhibit the following GC–MS data, consistent with their having 1,2,6,7- and 2,3,6,7-phenanthrenetetrone structures: *m/e* (*I*): 238 (12), 221 (2), 167 (100), 151 (4), 139 (78), 124 (21), 108 (12), 95 (6), 77 (8), 71 (21), 65 (3), 51 (2); *m/e* (*I*): 238 (13), 220 (0.5), 167 (100), 151 (1), 139 (77), 124 (17), 108 (10), 95 (7), 77 (7), 71 (10), 65 (2), 51 (5).

The ^{1}H NMR spectrum of the crude photolysis mixture (7.5 h irradiation) revealed the presence of unaccounted-for resonances in the δ3.5–4.5 range; with the assumption that these are due to the cyclobutane ring protons of photodimers, integration indicated that they accounted for ca. 15% of the total material.

The solvent was distilled under vacuum, and the yellow oil that remained was chromatographed on the Chromatatron using a 2 mm silica gel plate. Elution with 10% ethyl acetate – hexane afforded **10***a* (0.063 g, 33%), *cis*-**1** (0.013 g, 7%), *trans*-**1** (0.007 g, 4%), **9***a* (0.038 g, 20%). Further elution with 35% ethyl acetate – hexane afforded two additional compounds. 3,4-Dimethoxybenzaldehyde (**12**, 0.004 g, 2%) was identified by comparison to an authentic sample, while cyclobutane dimer **6** was identified on the basis of the following.

cis,trans,trans-*1,2,3,4-Tetra(3,4-dimethoxyphenyl)cyclobutane* (**6**): 0.057 g, 30%. ^{1}H NMR, δ: 3.63 (s, 6H), 3.78 (s, 6H), 4.27 (s, 2H), 6.49 (s, 1H), 6.50 (s, 1H), 6.65–6.90 (cplx m, 4H); ^{13}C NMR, δ: 47.54, 55.81, 55.97, 110.82, 112.09, 118.88, 120.04, 133.64, 147.36; MS, *m/z* (*I*): 601 (1), 300 (100), 285 (9), 151 (5); MS (NH_3 CI), *m/z* (*I*): 618 (100), 301 (45), 300 (54).

(c) Irradiation of trans-**1** *in the presence of 2,6-di*-tert-*butylphenol*

A solution of *trans*-**1** (0.243 g, 0.81 mmol), *n*-hexadecane (16.9 mg, 0.0747 mmol), and 2,6-di-*tert*-butylphenol (0.186 mg, 0.901 mmol) in dry tetrahydrofuran (15.0 mL) was placed in a 20.0 mL Pyrex container, sealed with a rubber septum, oxygenated with a stream of dry oxygen for 10 min, and then irradiated for 6 h with 300 nm light (Rayonet reactor, 12 lamps, 27°C). The reaction was monitored by GC–MS and TLC at 1 h intervals. Compounds *cis*-**1**, **9***a*, **10***a*, and **12** were formed in similar relative yields to those in irradiations in the absence of the phenol at irradiation times of less than 6 h. The yield of **12** was reduced substantially, however, at long irradiation times. Two new minor products, of GC retention times similar to those of **9***a* and **10***a*, were detected in the mixture after short irradiation times. These were tentatively identified on the basis of GC–MS as 5,6-dimethoxyphenanthrene-2,3-dione (*m/z* (*I*): 268 (100), 253 (81), 238 (3), 225 (31), 210 (90), 195 (11), 182 (1), 167 (47), 152 (8), 151 (9), 139 (33), 113 (5), 63 (5)) and 6,7-dimethoxyphenanthrene-2,3-dione (*m/z* (*I*): 268 (100), 253 (21), 225 (33), 210 (41), 195 (7), 182 (36), 167 (6), 152 (14), 139 (38), 75 (2), 63 (1)).

After 5 h of continuous irradiation the mixture showed an intense yellow color. The solvent was distilled under vacuum, and the yellow oil that remained was chromatographed on the Chromatotron using a 2 mm silica gel plate. Elution with 10% ethyl acetate – hexane allowed isolation of **10***a* (0.048 g,

20%), *cis*-**1** (0.041 g, 17%), *trans*-**1** (0.036 g, 15%), and **9***a* (0.029 g, 12%). Continued gradient elution to 30% ethyl acetate afforded **12** (0.024 g, 10%) and two new compounds (0.024 g, 5% each). The FT-IR spectrum of these compounds (CCl_4) showed the presence of carbonyl absorptions in the 1650–1710 cm^{-1} range, but their GC retention times did not match those of the two minor products observed in the crude reaction mixture (vide supra). Continued gradient elution to 50% ethyl acetate afforded **6** (0.007 g, 3%) and a third minor component (0.007 g, 3%) that is presumably an isomer of **6**.

(ii) From irradiation of trans-***3***

(a) Irradiation of trans-***3*** *in 95% ethanol*

A continuously oxygenated solution of *trans*-**3** (1.0 g, 2.5 mmol) in 95% ethanol (500 mL) was irradiated under similar conditions to those described above for *trans*-**1**. A single product, subsequently identified as *cis*-**3** (vide infra), was observed by GC analysis during the first 30 min of photolysis. Continued irradiation resulted in the slower formation of four other compounds that eluted between *cis*- and *trans*-**3** under the GC conditions employed (order of elution: *cis*-**3** < **5** < **11***c* = **10***c* < **9***c* < *trans*-**3**), and the development of a dark yellow colour. The irradiation was stopped after 1 h (ca. 75% conversion of *trans*-**3**), and the solvent was removed on the rotary evaporator to yield a brown oil. The mixture was chromatographed on the Chromatotron using a 4 mm silica gel thick-layer plate that was first deactivated with triethylamine, using an ethyl acetate – hexane gradient (1–8% ethyl acetate). The products eluted in the order **10***c* < *cis*-**3** < **11***c* < **9***c* < **5** < *trans*-**3**. Compounds *cis*-**3** and **10***c* were isolated in pure forms as a colourless oil and a crystalline solid, respectively. Compounds **9***c* and **11***c* initially eluted together, but could be separated with subsequent passes through the plate. Compound **9***c* was obtained as a colourless solid after recrystallization from ethyl acetate – hexane. Compound **11***c* was obtained as a pale yellow, low-melting solid that resisted further attempts at purification by either chromatography or recrystallization. Compound **5** was obtained as a colourless solid after two recrystallizations from hexane. Isolated chemical yields and spectroscopic properties of these materials are listed below. The material balance was typically less than 50% from photolyses in ethanol solution.

cis-*4*–tert-*Butyldimethylsiloxy-3,3′,4′-trimethoxystilbene (*cis-***3***)*: 0.112 g, 0.28 mmol, 11%; mp 53–55°C. UV (ethanol), $\lambda_{max}(\varepsilon)$: 201 nm (52 400), 281 nm (13 900); IR: 3001 (m), 2954 (s), 2932 (s), 2857 (s), 1509 (s), 1465 (s), 1289 (s), 1128 (s), 1031 (s), 899 (s), 839 (s); ^{1}H NMR, δ: 0.11 (s, 6H), 0.97 (s, 9H), 3.60 (s, 3H), 3.63 (s, 3H), 3.84 (s, 3H), 6.43 (s, 2H), 6.75 (m, 6H); ^{13}C NMR, δ: −4.7, 18.5, 25.7, 55.3, 55.5, 55.8, 110.8, 111.7, 112.6, 120.6, 121.8, 128.6, 128.9, 130.2, 131.1, 144.2, 148.1, 148.3, 150.5; MS, *m/e* (*I*): 400 (40), 343 (25), 328 (100), 253 (4), 209 (7),149 (7), 73 (8). Exact Mass, calcd. for $C_{23}H_{32}SiO_4$: 400.2070; found: 400.2069.

*1(2)-Ethoxy-1-(3-(*tert-*butyldimethylsiloxy)-4-methoxyphenyl)-2-(3,4-dimethoxyphenyl)ethane (***5***)*: 0.070 g, 0.16 mmol, 6%, mixture of regioisomers. *Major isomer* (67%): ^{1}H NMR, δ: 0.10 (s, 6H), 0.96 (s, 9H), 1.13 (t, 3H), 2.76 (quint, 1H), 3.04 (dd, 1H), 3.34 (m, 2H), 3.76 (s, 3H), 3.82 (s, 3H), 3.84 (s, 3H), 4.27 (m, 1H), 6.65 (cplx m, 6H); ^{13}C NMR, δ: −4.57, 15.34, 18.47, 25.72, 44.57, 55.35, 55.85, 55.94, 64.11, 83.32, 109.45, 110.61, 113.73, 119.27, 120.34, 121.66, 132.07, 134.97, 143.22, 148.26, 148.93, 150.30. *Minor isomer* (33%): ^{1}H NMR, δ: 0.13 (s, 6H), 0.97 (s, 9H), 1.13 (t, 3H), 2.76 (quint, 1H), 3.04 (dd, 1H), 3.34 (m, 2H), 3.66 (s, 6H), 3.73 (s, 3H), 4.27 (m, 1H), 6.65 (m, 6H). *Mixture*: UV (ethanol) $\lambda_{max}(\varepsilon$: 202 nm (50 900), 286 nm (11 100), 332 nm (19 260); IR (mixture): 3001 (m), 2954 (s), 2932 (s), 2857 (s), 1509 (s), 1465 (s), 1289 (s), 1128 (s), 1031 (s), 899 (s), 839 (s); MS, *m/e* (*I*): 446 (3), 400 (45), 389 (15), 343 (26), 328 (100), 313 (7), 295 (57).

*6-(*tert-*Butyldimethylsiloxy)-2,3,5-trimethoxyphenanthrene (***11***c)*: 0.057 g, 0.14 mmol, 6%; mp 51–53°C; UV (ethanol), $\lambda_{max}(\varepsilon)$: 201 nm (62 800), 260 nm (72 560); IR: 3030 (s), 2959 (m), 2933 (m), 1514 (s), 1470 (s), 1423 (m), 1265 (s), 1239 (s), 1085 (s), 838 (s); ^{1}H NMR (300 MHz), δ: 0.27 (s, 6H), 1.09 (s, 9H), 3.92 (s, 3H), 4.02 (s, 3H), 4.10 (s, 3H), 7.16 (m, 2H), 7.52 (m, 3H), 9.20 (s, 1H); ^{13}C NMR, δ: −4.4, −0.3, 18.3, 25.8, 55.7, 55.8, 59.3, 107.9, 108.7, 120.5, 124.0, 124.6, 124.8, 125.3, 128.3, 128.4, 128.7, 147.3, 148.2, 148.4, 148.6; MS, *m/e* (*I*): 398 (20), 326 (100), 163 (10), 73 (12), 57 (6). Exact Mass, calcd. for $C_{23}H_{30}SiO_4$: 398.1914; found: 398.1910.

*3-(*tert-*Butyldimethylsiloxy)-2,5,6-trimethoxyphenanthrene (***10***c)*: 0.11 g, 0.28 mmol, 11%; mp 95–97°C; UV (ethanol), $\lambda_{max}(\varepsilon)$: 202 nm (17 900), 261 nm (38 400); IR: 3030 (s), 2959 (m), 2934 (m), 1599 (m), 1512 (s), 1469 (s), 1275 (s), 1247 (s), 1103 (s), 1049 (m); ^{1}H NMR (300 MHz), δ: 0.25 (s, 6H), 1.07 (s, 9H), 3.94 (s, 6H), 4.0 (s, 3H), 7.21 (m, 2H), 7.50 (m, 3H), 9.15 (s, 1H); ^{13}C NMR, δ: −4.6, −0.5, 18.5, 25.8, 55.3, 56.4, 59.8, 108.6, 112.2, 118.8, 123.9, 124.3, 124.8, 125.3, 127.7, 129.2, 144.7, 146.3, 150.9, 151.0; MS, *m/e* (*I*): 398 (25), 341 (22), 326 (100), 311 (15), 268 (15), 163 (8), 134 (7), 89 (7), 73 (12), 57 (10). Exact Mass, calcd. for $C_{23}H_{30}SiO_4$: 398.1914; found: 398.1910.

*3-(*tert-*Butyldimethylsiloxy)-2,6,7-trimethoxyphenanthrene (***9***c)*: 0.083 g, 0.21 mmol, 8%; mp 95.0–96.8°C; UV (ethanol), $\lambda_{max}(\varepsilon)$: 255 nm (90 600), 286 nm (38 700); IR: 3030 (s), 2958 (m), 2934 (m), 1509 (s), 1478 (s), 1434 (m), 1272 (s), 1197 (s), 903 (s), 866 (m), 811 (m); ^{1}H NMR (300 MHz), δ: 0.23 (s, 6H), 1.06 (s, 9H), 3.94 (s, 3H), 4.02 (s, 3H), 4.09 (s, 3H), 7.18 (s, 2H), 7.52 (s, 2H), 7.76 (s, 1H), 7.88 (s, 1H); ^{13}C NMR, δ: −4.5, −4.4, −0.01, 0.30, 18.6, 25.8, 55.3, 55.8, 55.9, 103.0, 108.3, 108.7, 112.8, 124.2, 124.6, 126.2, 127.2, 145.3, 148.7, 149.2; MS, *m/e* (*I*): 398 (23), 341 (20), 326 (100), 240 (4), 163 (12), 73 (5). Exact Mass, calcd. for $C_{23}H_{30}SiO_4$: 398.1914; found: 398.1915.

GC analysis of exhaustively irradiated solutions of **3** in oxygenated THF indicate the primary relative phenanthrene yields to be similar to those obtained in ethanol solution. However, irradiation in THF allows isolation of **9***c*–**11***c* in significantly higher chemical yields than are obtained from irradiations in ethanol.

(b) Irradiation of trans-***3*** *in THF*

A solution of *trans*-**3** (1 g, 2.5 mmol) in dry tetrahydrofuran (15.0 mL) was oxygenated with a stream of dry oxygen for 10 min and then irradiated with 300 nm light (Rayonet reactor, 12 lamps, 27°C). The reaction was not monitored, but instead was stopped after 12 h of continuous irradiation. A deep orange

solution was obtained. The solvent from the reaction mixture was evaporated and the remaining dark orange oil was chromatographed using a 2-mm-thick Chromatotron plate that had previously been treated with triethylamine (5 drops in 600 mL of eluent). The less polar fractions (that eluted with 10:90 ethyl acetate:hexanes, containing **9***c*-**11***c*, *cis*-**3** and *trans*-**3**) represented 50% of the photolyzed material.

Continued gradient elution to 35% ethyl acetate afforded four additional fractions, the first and fourth of which consisted of single components. They were identified as the following on the basis of spectral data.

trans-*1,2-Bis(3,4-dimethoxyphenyl)*-cis,trans-*3,4-bis(4*-tert-*butyldimethylsiloxy-3-methoxyphenyl)-cyclobutane (***7***a)*: first fraction (oil), 0.201 g, 20%; ^{1}H NMR, δ: 0.055 (s, 6H), 0.93 (s, 9H), 3.54 (s, 3H), 3.64 (s, 3H), 3.76 (s, 3H), 4.25 (br s, 2H), 6.45 (d, 1H, *J* = 1.83 Hz), 6.52 (d, 1H, *J* = 1.97 Hz), 6.62 (dd, 1H, *J* = 1.87 Hz, *J* = 8.15 Hz), 6.65 (d, 2H, *J* = 8.10 Hz), 6.68 (dd, 1H, *J* = 2.0 Hz, *J* = 8.28 Hz); ^{13}C NMR (125.8 MHz), δ: −4.80, 18.31, 25.62, 47.31, 47.39, 55.34, 55.45, 55.63, 110.31, 112.00, 112.76, 119.92, 120.13, 120.18, 133.67, 134.45, 143.11, 147.16, 148.37, 150.23; MS, *m/z* (*I*): 550 (12), 501 (10), 400 (100), 354 (10), 328 (71), 300 (7), 284 (7), 151 (7); MS (NH_3 CI), *m/z* (*I*): 818 (38), 568 (20), 502 (11), 401 (100), 301 (21), 151 (15).

cis-*1,3-Bis(3,4-dimethoxyphenyl)*-trans,trans-*2,4-bis(4*-tert-*butyldimethylsiloxy-3-methoxyphenyl)-cyclobutane (***8***a)*: 4th fraction (oil), 0.191 g, 19%; ^{1}H NMR, δ: 0.073 (s, 6H), 0.96 (s, 9H), 3.55 (s, 3H), 3.63 (s, 3H), 3.78 (s, 3H), 4.23 (s, 1H), 4.24 (s, 1H), 6.46 (d, 1H, J = 1.99 Hz), 6.50 (d, 1H, *J* = 1.91 Hz), 6.59 (dd, 1H, *J* = 1.99 Hz, *J* = 8.13 Hz), 6.63 (d, 1H, *J* = 8.08 Hz), 6.67 (d, 1H, *J* = 8.28 Hz), 6.71 (dd, 1H, *J* = 1.99 Hz, *J* = 8.25 Hz); ^{13}C NMR, δ: −4.73, 18.36, 25.68, 47.38, 47.58, 55.39, 55.71, 55.76, 110.71, 112.79, 112.03,, 120.14, 120.10, 133.76, 134.44, 143.16, 147.23, 148.45, 150.35; MS, *m/z* (*I*): 501 (3), 400 (100), 343 (22), 328 (57), 310 (3), 286 (12), 195 (10), 73 (8); MS (NH3 CI), *m/z* (*I*): 818 (100), 569 (8), 464 (5), 402 (76), 328 (20).

The second fraction consisted of a mixture of two carbonylic compounds, which were tentatively identified as stilbenequinones on the basis of ^{1}H and ^{13}C NMR spectroscopy of the mixture, but they could not be rigorously identified. The third fraction consisted of a mixture of **12** and dimer **8***a*.

(iii) From irradiation of trans-*2*

(a) Irradiation of trans-*2 in 95% ethanol*

An oxygenated solution of *trans*-**2** (0.50 g, 1.7 mmol) in 95% ethanol (500 mL) was irradiated under similar conditions to those described above. GC and GC–MS analysis of the crude mixture after 15 min irradiation revealed the presence of a single product that was identified as *cis*-**2** (vide infra). Continued irradiation (30 min total) resulted in the solution turning yellow, and GC analysis indicated there to be substantial loss of volatile material with only a slight apparent increase in the yield of *cis*-**2** relative to the amount of *trans*-**2** present. The solvent was distilled from the reaction mixture under vacuum, yielding a dark yellow oily solid (0.49 g). ^{1}H NMR analysis of the crude photolysate indicated a *cis*-**2**/*trans*-**2** ratio of ca. 3:1.

The reaction mixture was chromatographed on a 4 mm silica gel thick-layer plate and eluted with dichloromethane. This allowed recovery of 0.013 g of *trans*-**2**, the first compound to elute. The second fraction consisted of *cis*-**2** (0.018 g) contaminated with a small amount of the *trans* isomer, as determined by ^{1}H NMR spectroscopy. GC analysis of this mixture indicated it to consist of *cis*-**2** and *trans*-**2** in a ~1:1 ratio, but lowering the injector temperature resulted in correspondingly higher amounts of the *cis* isomer in the mixture. ^{1}H NMR analysis of the mixture after storage for 24 h in the dark at room temperature indicated complete thermal isomerization to the *cis* isomer. The remaining material consisted of two dimeric products and **12**; these were isolated from the photolysis of *trans*-**2** in THF (vide infra).

cis-*4-Hydroxy-3,3′,4′-trimethoxystilbene (*cis-***2***)*: mp 131.9–132.3°C; UV (ethanol), $\lambda_{max}(\varepsilon)$: 200 nm (26 150), 303 nm (9780); GC/FTIR: 3564 (br m), 2983 (s), 2939 (m), 1724 (s), 1384 (s), 1325 (m), 1186 (s), 1143 (m), 957 (w), 919 (w); ^{1}H NMR (300 MHz), δ: 3.68 (s, 3H), 3.69 (s, 3H), 3.87 (s, 3H), 5.57 (s, 1H), 6.45 (s, 2H), 6.80 (m, 6H); ^{13}C NMR (AM500), δ: 55.80, 55.82, 55.89, 108.01, 108.56, 111.24, 114.48, 119.43, 120.11, 126.27, 149.08; MS, *m/e* (*I*): 286 (100), 271 (13), 211 (6), 168 (5), 165 (4), 143 (8), 77 (7), 45 (38). Exact Mass, calcd. for $C_{17}H_{18}O_4$: 286.1205; found: 286.1208.

Extended photolysis of **2** in oxygenated ethanol solution resulted in substantial loss of volatile material, the appearance of small amounts of three new products, and the development of a deep orange-brown colour. Attempts to isolate the three new products by thick-layer chromatography were unsuccessful.

Phenanthrenes **9***b*–**11***b* were prepared by desilylation of the corresponding *tert*-butyldimethylsiloxy compound **9***c*–**11***c*. For example, **9***c* (0.05 g, 0.18 mmol), tetra-*n*-butylammonium fluoride (0.066 g, 0.25 mmol), and tetrahydrofuran (0.25 mL) were placed in a 5 mL round-bottom flask and stirred at room temperature for 30 min, with periodic monitoring of the progress of reaction by thin-layer chromatography (silica gel, 15% ethyl acetate in hexane). The solvent was removed under vacuum, saturated aqueous ammonium chloride (5 mL) was added, and the mixture was extracted with anhydrous ether. The combined ether extracts were dried over anhydrous magnesium sulfate, filtered, and stripped of solvent on the rotary evaporator. The resulting yellow oil was chromatographed on a silica gel column, eluting with hexane (~100 mL) to remove unreacted starting material and other silicon-containing compounds, and then a 25% ethyl acetate – hexane mixture. Compound **9***b* was obtained as a colourless solid (0.033 g, 0.16 mmol, 93%) and recrystallized from ethyl acetate – hexanes and ethyl acetate. GC coinjection with crude mixtures from photolysis of **2** verified its presence in the photolysate. A similar procedure was employed for the synthesis of **10***b* and **11***b* from **10***c* and **11***c*, respectively.

*6-Hydroxy-2,3,7-trimethoxyphenanthrene (***9***b)*: mp 155–158°C; UV (ethanol), $\lambda_{max}(\varepsilon)$: 254 (65 800), 286 nm (29 470); IR: 3542 (m), 3030 (s), 1512 (s), 1480 (s), 1436 (m), 1266 (m), 1197 (s), 1159 (s), 1111 (m), 1041 (m), 864 (m); ^{1}H NMR, δ: 4.01 (s, 3H), 4.03 (s, 3H), 4.08 (s, 3H), 5.90 (s, 1H), 7.19 (s, 2H), 7.51 (s, 2H), 7.79 (s, 1H), 7.96 (s, 1H); ^{13}C NMR, δ: 55.90, 55.96, 103.10, 105.99, 107.65, 108.17, 123.96, 124.32,

124.36, 125.14, 126.10, 126.35, 145.60, 146.39, 148.81, 149.18; MS, *m/e* (*I*): 284 (100), 269 (13), 241 (14), 198 (8), 142 (12). Exact Mass, calcd. for $C_{17}H_{16}O_4$: 284.1048; found: 284.1047.

6-Hydroxy-2,3,5-trimethoxyphenanthrene (***11***b): mp 157.3–159.1°C; UV (THF) $\lambda_{max}(\varepsilon)$: 274 nm (20 180), 260 (25 600); IR (KBr): 3363 (br), 1601 (s), 1513 (s), 1474 (s), 1423 (s), 1370 (m), 1254 (s), 1154 (s), 1076 (s), 1042 (s), 860 (s), 779 (s); ^{1}H NMR, δ: 3.81 (s, 3H), 3.96 (s, 3H), 4.00 (s, 3H), 6.05 (br s, 1H), 7.14 (s, 1H), 7.18 (d, 2H, J = 3.8 Hz), 7.20 (s, 1H), 7.46 (m, 2H), 8.82 (s, 1H); ^{13}C NMR, δ: 55.76, 55.83, 60.29, 107.79, 108.06, 115.44, 122.12, 122.87, 124.08, 125.58, 125.94, 127.56, 128.49, 143.01, 147.69, 148.64, 148.94. MS, *m/z* (*I*): 284 (100), 269 (22), 241 (19), 226 (16), 198 (10), 181 (7), 142 (20), 121 (5), 71 (13), 57 (16). Exact Mass, calcd. for $C_{17}H_{16}O_4$: 284.1048; found: 284.1052.

3-Hydroxy-2,5,6-trimethoxyphenanthrene (***10***b): mp 147.4–149.6°C; UV (THF), $\lambda_{max}(\varepsilon)$: 255 nm (88 000), 287 nm (37 500), 301 (21 000); IR (KBr): 3416 (br), 1516 (s), 1474 (s), 1456 (m), 1427 (m), 1370 (m), 1270 (s), 1101 (s), 1053 (m), 818 (m); ^{1}H NMR, δ: 3.90 (s, 3H), 3.95 (s, 3H), 3.98 (s, 3H), 5.74 (br s, 1H), 7.13 (s, 1H), 7.20 (d, 1H, J = 8.7 Hz), 7.39 (d, 1H, J = 8.8 Hz), 7.43 (d, 1H, J = 8.7 Hz), 7.52 (d, 1H, J = 8.7 Hz), 9.09 (s, 1H); ^{13}C NMR, δ: 55.82, 56.68, 59.79, 107.63, 112.27, 112.78, 124.38, 124.54, 124.68, 124.81, 125.03, 127.99, 128.21, 145.07, 146.54, 146.71, 151.16; MS, *m/z* (*I*): 284 (100), 269 (59), 241 (11), 226 (8), 181 (9), 155 (10), 139 (9), 126 (7), 84 (14). Exact Mass, calcd. for $C_{17}H_{16}O_4$: 284.1048; found: 284.1049.

(b) Irradiation in THF

A solution of *trans*-**2** (0.261 g, 0.91 mmol) and *n*-hexadecane (0.169 g, 0.075 mmol) in dry tetrahydrofuran (15.0 mL) was oxygenated with a stream of dry oxygen for 10 min and then irradiated with 300 nm light (Rayonet reactor, 12 lamps, 27°C). The reaction was monitored by GC–MS analysis for 8 h at 1 h intervals. The formation of **9***b*, **10***b*, **11***b*, and **12** was observed to proceed linearly as a function of irradiation time.

After 5 h of irradiation, the solution had turned light yellow; GC analysis of the product mixture indicated it to consist of **12** (14%), **9***b* (19%), *trans*-**2** (12%), and **10***b*+**11***b* (12%). After 8 h of irradiation, the presence of other volatile minor products in the photolysate accounted for 8% of the mixture, as determined by GC–MS analysis. The retention times and mass spectral data of two of these products (ca. 4% each) coincide with those found for the two phenanthrenetetrones detected in the photolysis of *trans*-**1** (vide supra).

The solvent was distilled from the photolysate under vacuum, and the dark orange oil that remained was chromatographed on the Chromatotron using a 2 mm silica gel plate and gradient elution with ethyl acetate – hexane. Compounds *cis*-**2** and *trans*-**2**, **9***b*–**11***b*, and **12** were isolated, as well as one other fraction that contained a mixture of two dimeric compounds. This was followed by a fraction containing a single component, which was tentatively identified as cyclobutane dimer **8***b* on the basis of ^{1}H NMR and MS evidence.

cis-*1,3-Bis(3,4-dimethoxyphenyl)*-trans,trans-*2,4-bis(4-hydroxy-3-methoxyphenyl)-cyclobutane* (***8***a): 4th fraction (oil), 0.191 g, 19%; ^{1}H NMR, δ: 3.64 (s, 6H), 3.74 (s, 3H), 4.69 (s, 2H), 6.36 (s, 1H), 6.37 (s, 1H), 6.71 (cplx m, 4H); MS, *m/e* (*I*): 571 (1), 501 (1), 400 (51), 328 (60), 288 (39), 286 (51), 195 (100), 152 (31), 73 (29).

Irradiation of phenanthrene 10*a* under various conditions

A solution of **10***a* (2.1 mg, 0.007 mmol) in THF (0.5 mL) was placed in a Pyrex tube, sealed with a rubber septum, oxygenated with a stream of dry oxygen for 10 min, and then irradiated for 7 h with 300 nm light (Rayonet reactor, 12 lamps, 25°C), with monitoring of the photolysate at 1 h intervals by GC–MS. After 7 h of irradiation, only a single minor photoproduct could be detected (0.5 %, shorter retention time than **10***a*, M^+ = 330), in addition to remaining **10***a*.

A solution of **10***a* (10.1 mg, 0.034 mmol), *trans*-**1** (2 mg, 0.0066 mmol), and *n*-hexadecane (0.068 mg, 0.0003 mmol) in dry THF (0.5 mL) was placed in a quartz NMR tube, sealed with a rubber septum, and oxygenated with a stream of dry oxygen for 10 min. The solution was irradiated with 254 nm light ($[\varepsilon_6/\varepsilon_{trans\text{-}1}]_{254\ nm}$ = 55), and monitored at 20 min intervals by GC–MS. Compounds *cis*-**1**, **9***a*, and **12** were observed to form in similar relative yields to those produced upon irradiation of *trans*-**1** under similar conditions (vide infra). No new products could be detected in significant yields after photolysis to 50% (total) conversion of **1**.

Photostationary state and quantum yield determinations

Quantum yields were determined using an electronic actinometry system similar to that reported by Leigh and Arnold (38), using 300 nm light from a 100 W xenon lamp attached to a high-intensity monochromator. A Corning CS 7-54 glass filter was employed to remove the higher order spectral lines. The system was calibrated prior to each experiment by ferrioxalate actinometry. Solutions were contained in round Suprasil UV cells (1.0 × 2.54 cm) that were sealed with rubber septa. The samples were deoxygenated with a stream of nitrogen or oxygen for 15 min prior to photolysis, and stirred throughout using a 6 mm Teflon-coated magnetic stirrer. Product formation was followed by GC relative to *n*-eicosane as an internal standard. Relative FID response factors were determined for both *trans*- and *cis*-**1** by construction of working curves. Product yields were determined from plots of product concentration vs. accumulated photon counts. Quantum yields for the formation of **4** (in ethanol) and phenanthrenes **9***a* and **10***a* (in O_2-saturated solution) were estimated from runs ca. 10 times longer than those employed for the determination of quantum yields for *cis,trans* isomerization. The linearity of the system over these longer time scales was not, however, verified.

For photostationary state determinations, 10^{-3} M solutions of *cis*- and *trans*-**1** were purged for 15 min with a stream of nitrogen, and irradiated alternately in the system described above, with periodic monitoring of the course of reaction by GC. The irradiation was continued until the ratios of *cis*-**1**/*trans*-**1** in the two solutions achieved a common value (*cis*-**1**/*trans*-**1** = 1.38 ± 0.07).

Steady state fluorescence quenching experiments

Fluorescence spectra were recorded using ~5×10^{-6} M solutions of the stilbenes or phenanthrenes in dry THF containing various amounts of absolute ethanol, TFE, or HFIP, in 1 × 1

cm Suprasil quartz cuvettes that were sealed with rubber septums. The solutions were deoxygenated prior to recording the spectra by bubbling with a stream of dry nitrogen for a constant period of time. A fresh solution was employed for each spectrum recorded, and fluorescence intensities were estimated from the integrated emission spectra. For oxygen-quenching experiments, aliquots of standard solutions of *trans*-**1** and *trans*-**2** were placed in 10 mL volumetric flasks, and then premixed nitrogen–oxygen mixtures were bubbled through the solutions, topping the flasks up to the mark with fresh solvent when evaporation resulted in some loss. The compositions of the gas mixtures were controlled with a Matheson 73510-600 gas proportioner. Oxygen concentrations were calculated using a value of 0.0101 M for the concentration of oxygen in oxygen-saturated THF at 25°C (39).

Acknowledgments

We wish to thank Dr. D. Hughes for assistance with high-field NMR spectra, the McMaster Regional Centre for Mass Spectrometry for high-resolution mass spectra and Exact Mass determinations, and P. Palermo for technical assistance. The financial support of the Natural Sciences and Engineering Research Council (NSERC) National Centres of Excellence in Mechanical and Chemimechanical Wood Pulps is also gratefully acknowledged.

Chromatographie à contre courant et micelles inverses pour la séparation et l'extraction de cations métalliques[1]

Alain Berthod, Jun Xiang, Serge Alex et Colette Gonnet-Collet

Résumé : La chromatographie à contre courant (CCC) est une technique de séparation dans laquelle la phase stationnaire est un liquide. L'acide diéthylhexyl phosphorique (DEHPA) est capable de former des micelles inverses dans l'heptane. Des cations métalliques localisés dans une phase aqueuse peuvent passer dans la phase heptane par complexation–extraction dans le centre des micelles inverses de DEHPA. Un appareil CCC peut être considéré comme un puissant mélangeur et extracteur avec une efficacité de plusieurs centaines de plateaux. L'association de la technique CCC avec l'extraction par micelles inverses à permis de séparer les ions métalliques La^{3+}, Ce^{3+}, Pr^{3+} et Nd^{3+}. L'utilisation de phases mobiles à différents pH a permis de déterminer les constantes d'extraction et les coefficients de séparation de chaque ion. Les conditions de surcharge sont soulignées. Avec des solutions d'ions Co^{2+} et Ni^{2+}, l'utilisation de l'appareil CCC en mode dit chromatographie frontale a permis de concentrer une quantité maximale d'ion Co^{2+} dans la phase stationnaire heptane + DEHPA. Une partie de la solution a été désionisée, une autre partie ne contenait plus que des ions Ni^{2+}. La méthode permet également de déterminer les constantes d'extraction et les coefficients de séparation. L'utilisation de la technique CCC avec une phase stationnaire extractrice peut être généralisée en tant que filtre à ions pour extraire, concentrer des cations dans un faible volume de phase organique ou pour désioniser des phases aqueuses.

Mots clés : chromatographie à contre courant, CCC; filtration d'ions, extraction d'ions, désionisation, lanthanides, métaux de transition.

Abstract: Countercurrent chromatography (CCC) is a separation technique in which the stationary phase is a liquid. Diethylhexyl phosphoric acid (DEHPA) forms reverse micelles in heptane. Metallic ions, located in an aqueous phase, can be extracted into the aqueous core of the reverse micelles in the heptane phase. A CCC apparatus can be considered as a powerful mixing and extracting machine with efficiency above several hundreds of theoretical plates. La^{3+}, Ce^{3+}, Pr^{3+}, and Nd^{3+} lanthanide cations were separated using CCC with a DEHPA-containing heptane stationary phase. Studying the retention variations with aqueous mobile phase pH, it was possible to determine the lanthanide extraction constants and separation coefficients. Overloading conditions are described. Frontal chromatography was performed using a Co^{2+} and Ni^{2+} solution. The Co^{2+} ions were concentrated in the heptane + DEHPA stationary phase, a part of the solution was deionized, and another part was enriched in only Ni^{2+} ions. This method also produced the extraction constants and separation coefficients. The use of CCC with a complexing stationary phase can be applied to any cation for ion filtering and concentration, or for deionization of aqueous phases.

Key words: countercurrent chromatography, CCC; ion extraction, ion filtering, deionization, lanthanides, transition metals.

Introduction

La chromatographie à contre courant (CCC) est une technique de séparation avec une phase stationnaire et une phase mobile. À la différence des autres techniques de chromatographie, en CCC, la phase stationnaire est un *liquide* sans aucun support solide. La phase mobile, elle aussi liquide, demeure la seule à se déplacer dans la colonne. Il n'y a pas de circulation de liquides à contre courant dans la technique CCC comme son nom semble le laisser croire. L'inventeur de la technique, Yoishiro Ito (1), a publié plus d'une centaine d'articles scientifiques en utilisant le sigle CCC (2–4). Le nom, chromatographie à contre courant, et le sigle, CCC, se sont imposés.[3] Plusieurs dénominations plus adaptées ont été proposées : chromatographie de partage centrifuge ou chromatographie liquide–liquide centrifuge (6).

Les avantages d'une phase stationnaire liquide sont :

(*i*) une grande capacité : les solutés à séparer ont accès au volume de la phase stationnaire et non pas seulement à l'interface solide – phase mobile comme dans les autres techniques chromatographiques. C'est l'avantage principal de la CCC qui

3. Tant que l' International Union for Pure and Applied Chemistry (IUPAC) n'aura pas recommandé une autre dénomination que celle proposée par l'inventeur de la technique, Yoishiro Ito, les termes chromatographie à contre courant et le sigle CCC seront utilisés.

est plutôt utilisée dans la prépurification d'extraits chargés ou la séparation préparative;

(*ii*) un très grand choix de systèmes : les mélanges de solvants qui produisent un système biphasique liquide sont innombrables (7), certains systèmes liquides permettent de faire des gradients de composition (8);

(*iii*) une gamme de sélectivité originale comparée aux sélectivités obtenues en chromatographie liquide classique à phases stationnaires solides (silice nue ou silice greffée alkyle) (9);

(*iv*) l'inversion possible du rôle des phases : la phase mobile peut devenir la phase stationnaire et vice versa. En conséquence, aucun soluté injecté ne peut rester irréversiblement adsorbé dans la colonne CCC. S'il n'est pas élué, dû à sa forte affinité pour la phase stationnaire, on inverse le rôle des phases et le soluté est poussé hors de la colonne (9). Ainsi il y a toujours récupération totale des solutés injectés;

(*v*) la mesure des coefficients de partage liquide–liquide (10).

Un dernier avantage est que la technique CCC utilise tous les éléments périphériques classiques de la chromatographie liquide : pompes, détecteurs, vannes, collecteurs de fractions, intégrateurs. Seule la colonne est différente.

La technique a des inconvénients. Le principal est évident : il faut maintenir la phase stationnaire liquide en place pendant que l'on fait circuler la phase mobile. Une « colonne » CCC ne sera donc pas un simple tube rempli de phase stationnaire comme en chromatographie liquide classique. Des forces centrifuges seront nécessaires pour retenir la phase stationnaire liquide. Tous les appareils CCC modernes, qui ne sont en fait que la colonne CCC, comportent des rotors. Deux types d'appareils CCC sont commercialisés, les appareils à tubes enroulés, dits hydrodynamiques, et les appareils à tubes et canaux, dits hydrostatiques. Ils sont décrits dans de nombreux articles de revue (3, 4, 11).

La technique CCC peut être utilisée pour séparer des cations métalliques par extraction par solvant avec échange d'ions (12–16). Les lanthanides trivalents sont très difficiles à séparer en une seule extraction. Des procédés d'extraction multiples doivent être mis en oeuvre (17). La technique CCC est idéale, elle permet en un processus continu d'effectuer un nombre d'extractions très important. Ce nombre d'extractions correspond au nombre de plateaux théoriques de la colonne CCC. Il peut atteindre plusieurs centaines de plateaux voire plusieurs milliers (13, 15). La grande capacité de charge de la phase stationnaire liquide prend tout son intérêt. Le fait que l'échantillon introduit dans la colonne soit toujours totalement récupéré est également un énorme avantage lorsque des actinides ou autres ions radioactifs sont séparés.

Nous nous proposons dans ce travail de présenter rapidement les paramètres théoriques de la technique CCC. Une seconde étape montre que l'utilisation comme phase stationnaire en CCC d'une solution de micelles inverses dans l'heptane permet de séparer les premiers éléments de la famille des lanthanides. Une micelle inverse est une association de plusieures molécules de tensio-actif de telle sorte que les têtes polaires soient tournées vers l'intérieur de la micelle et les chaînes hydrophobes vers l'exterieur. Le centre polaire de la micelle inverse peut emprisonner des molécules d'eau et des cations métalliques. On montrera qu'on peut ainsi concentrer des métaux dans la phase organique micellaire en utilisant l'appareil CCC non pas en mode séparatif mais comme un filtre à ions. Les métaux de transition seront utilisés comme exemple.

La chromatographie à contre courant (CCC)

Comme il l'a été indiqué dans l'introduction, la CCC est une technique chromatographique dans laquelle la phase stationnaire est un liquide. Les solutés sont retenus par ordre de coefficient de partage croissant. Ils sont séparés par la colonne CCC et sortent sous forme de pics symétriques ou gaussiens. À la différence des autres types de chromatographie, le mécanisme de rétention des solutés est très simple : c'est uniquement le partage entre les deux phases liquides qui discrimine les solutés. Le volume de rétention, V_R, d'un soluté s'exprime par :

$$[1] \quad V_R = V_M + PV_S$$

V_M et V_S sont, respectivement, les volumes de phase mobile et de phase stationnaire dans la colonne. P est le coefficient de partage du soluté exprimé par :

$$[2] \quad P = \frac{[\text{soluté}]_{\text{phase stationnaire}}}{[\text{soluté}]_{\text{phase mobile}}} = \frac{V_R - V_M}{V_S}$$

La somme des volumes des phases, $V_M + V_S$, est égale au volume interne de la colonne, V_C. Le facteur Sf,

$$[3] \quad Sf = V_S / V_C$$

mesure le pourcentage de rétention de phase stationnaire par rapport au volume interne de la colonne CCC utilisé. Il permet de comparer d'un appareil à l'autre la quantité de phase stationnaire retenue.

Le facteur de capacité ou facteur de rétention, k', est très utilisé en chromatographie car il est indépendant du volume de la colonne chromatographique. Il s'exprime par :

$$[4] \quad k' = (V_R - V_M)/V_M$$

En utilisant l'équation [1], on obtient :

$$[5] \quad k' = P\,V_S/V_M$$

L'équation [5] montre qu'il y a une relation directe entre le facteur de rétention d'un soluté et son coefficient de partage dans le système liquide utilisé dans le chromatographe CCC. Si le coefficient de partage est connu ou s'il peut être mesuré, il pourra être utilisé pour prédire exactement le comportement chromatographique du soluté (4, 9, 11). Au contraire, la technique CCC pourra être utilisée pour déterminer avec précision les coefficients de partage dans les systèmes biphasiques liquides (9, 10, 19).

Le domaine utile de coefficient de partage s'étale de 0,05 à 100 (18). Un soluté ayant un coefficient de partage plus faible que 0,05 sera si peu retenu par la phase stationnaire qu'on ne pourra pas le différencier du volume mort V_M. Un soluté avec un coefficient P de 100 aura un volume de rétention supérieure à 100 fois le volume de phase stationnaire (eq. [1]) ce qui peut être prohibitif. D'autre part, un soluté très retenu va être élué de la colonne CCC en un pic étalé qui pourra être interprété comme une dérive de ligne de base.

Les paramètres principaux en CCC sont les volumes de rétention (V_R) des solutés. Ils ne dépendent que de leur coefficient de partage et des volumes de phases mobile (V_M) et stationnaire (V_S) retenus dans l'appareil. On pourra toujours transposer d'un appareil CCC à l'autre un résultat obtenu. Par exemple, l'appareil A, de volume V_C^A = 80 mL est capable de retenir 80% de phase stationnaire soit 64 mL. Le volume de phase mobile est donc de 16 mL (20%). Deux solutés 1 et 2 ont des volumes de rétention V_R^{A1} = 56 mL et V_R^{A2} = 80 mL. On calcule leur coefficient de partage P_1 = 0,5 et P_2 = 1. On veut séparer les deux solutés sur un appareil CCC B de volume V_C^B = 250 mL. Il retient moins bien la phase stationnaire du même système liquide : V_S = 150 mL (Sf = 60%) et V_M = 100 mL. Les volumes de rétention des solutés 1 et 2 sont calculés avec leur coefficient de partage qui ne dépend que du système liquide et non de l'appareil : V_R^{B1} = 100 + (0,5 × 150) = 175 mL et V_R^{B2} = 100 + (1 × 150) = 250 mL. Les chromatogrammes peuvent avoir une allure différente car l'efficacité de l'appareil A peut être différente de celle de l'appareil B. Par contre les volumes de rétention sont prévisibles.

L'efficacité, N, d'un appareil CCC peut atteindre plusieurs centaines de plateaux théoriques. Elle se mesure par la largeur des pics à mi-hauteur, $W_{0,5H}$, ou à 60% de leur hauteur, $W_{0,6H}$:

$$[6] \quad N = 4\left(\frac{V_R^2}{W_{0,6H}}\right) = 5{,}54\left(\frac{V_R^2}{W_{0,5H}}\right)$$

Elle est liée à la cinétique des échanges du soluté entre la phase stationnaire et la phase mobile.

Partie experimentale

Chromatographie à contre courant

Le modèle CPHV 2000 de la Société Française de Chromato-Colonne (Life Sciences-Shandon, Eragny, France) est un appareil de type hydrodynamique avec trois bobines de tubes enroulés connectées en série et portées par un rotor. Son prototype a été décrit par Ito (3). Chaque bobine contient 133 tours de tube Téflon (diamètre interne 1,6 mm) soit 29 m embobinés en 7 couches de 19 tours. Le volume d'une bobine est d'environ 54 mL. Plus d'informations sur l'appareil CCC seront trouvées dans un travail récent (19). Autour de l'appareil CCC ont été utilisés : une pompe Shimadzu LC6–A (Touzart & Matignon, Paris, France) pour pousser les phases, un détecteur évaporatif à diffusion de lumière (DEDL), connu également sous les termes anglais « evaporative light scattering detector » (ELSD), modèle DDL21 (Cunow, Eurosep, Cergy-Pontoise, France); un intégrateur Shimadzu CRC5-A (Touzart & Matignon) et une vanne d'injection Rhéodyne 4125. Le détecteur DEDL nébulise la phase liquide sortant de l'appareil CCC, l'aérosol est chauffé à 100°C, la phase liquide est évaporée, les sels dissous cristallisent et diffusent la lumière de la lampe du détecteur. Le détecteur DEDL permet d'observer sans problème les ions métalliques difficilement détectables par spectrophotométrie UV–visible.

Pour faire une analyse CCC, il faut préparer la « colonne » qui n'existe que lorsque le champ de forces centrifuges est présent, c'est à dire tant que le rotor de l'appareil tourne. L'appareil CCC est d'abord rempli par la phase stationnaire (heptane + complexant) à fort débit (8 mL/min) et sans rotation. Le rotor est mis en mouvement à 800 rotations par minute (rpm) et on commence à pousser la phase mobile (eau + tampon) à 2 mL/min dans le sens tête vers queue (2–4, 11, 14). La phase heptane qui sort de l'appareil CCC, déplacée par la phase aqueuse, est collectée dans une éprouvette graduée. Lorsque la phase aqueuse apparaît à la sortie de l'appareil CCC, deux phases sont observées dans l'éprouvette; la « colonne » est prête. Le volume de phase heptane déplacée est mesuré; il correspond à V_M, le volume de phase mobile dans l'appareil. V_S est calculé par $V_C - V_M$. Les volumes V_M et V_S permettent de calculer les coefficients P des ions ou solutés élués dans l'appareil CCC (eq. [1]).

Réactifs et solutés

L'acide di(2-éthyl hexyl) phosphorique ($C_{16}H_{35}PO_4$, M = 322 g/mol, d = 0,975 (20°C), pK_A = 1,4) est l'extractant utilisé, il sera représenté par le sigle DEHPA. Obtenu de Merck (Schuchardt, Allemagne), il a été utilisé tel que reçu. Le DEHPA est très utilisé en hydrométallurgie parce qu'il est très sélectif, résiste bien à l'hydrolyse et il est presque insoluble dans l'eau (20). En solution dans l'heptane, il forme des micelles dites « inverses » car le coeur de la micelle est polaire avec des molécules d'eau et les têtes phosphates anioniques. Les nitrates de lanthane, cérium, praséodyme et néodyme sont des produits Prolabo (Paris, France) ainsi que les acétates de cobalt, de nickel et de cuivre. L'heptane provient de SDS (Peypin, France).

Spectrométrie d'émission atomique à source plasma

Un spectromètre d'émission à source plasma (ICP-AES) Perkin–Elmer Optima 3000 a été utilisé pour déterminer les concentrations ioniques en métaux de transition (Co, Ni, Cu) lorsqu'ils n'étaient pas complètement séparés par la « colonne » CCC. Cet appareil est équipé d'un détecteur CCD (Charge Coupled Device). Il peut mesurer simultanément l'émission produite par plusieurs éléments. Nous l'avons réglé pour mesurer les trois éléments Co, Ni et Cu, à deux longueurs d'onde différentes pour chaque élément. Le tableau 1 donne les longueurs d'onde utilisées pour suivre les concentrations des trois métaux de transitions étudiés. La sensibilité indiquée est celle de Wohlers (21). Elle a été obtenue expérimentalement comme le rapport signal/fond pour des solutions de concentration 100 mg/L sur un appareil dont les conditions de travail ont été fixées (21). Les raies choisies sont les plus sensibles, libres d'interférence spectrale. L'énergie de la torche était de 1100 W. Le débit de la pompe péristaltique était de 1 mL/min. Les débits d'argon étaient de 1 L/min dans le nébuliseur de type « cross-flow », 1 L/min en circulation auxiliaire et 15 L/min dans la torche elle-même.

Résultats et discussion

Séparation des quatre premiers éléments lanthanides

Il a été montré que les solutions de DEHPA dans l'heptane étaient au moins sous forme de dimères. En présence d'eau, des micelles inverses se forment. Les chaînes diéthylhexyl sont en contact avec les molécules d'heptane, les têtes polaires phosphates anioniques s'assemblent au coeur de la micelle où elles emprisonnent de l'eau. Les protons assurent la neutralité électrique. C'est dans le coeur des micelles que les cations métalliques vont se localiser en remplaçant des protons du DEHPA (12–17, 20). La structure physico-chimique des

micelles inverses et de leurs associations avec les cations métalliques ne sera pas abordée dans ce travail.

Principe

Les composés organométalliques sont d'excellents complexants des ions métalliques qu'ils sont capables d'extraire de la phase aqueuse dans une phase organique selon :

$$[7] \quad M^{n+}_{aq} + n\,HA_{org} \rightleftarrows M(A)_{n,\,org} + n\,H^{+}_{aq}$$

La constante d'équilibre d'une telle réaction s'écrit :

$$[8] \quad K_{ex} = \frac{[MA_n]_{org}[H^+]^n_{aq}}{[M^{n+}]_{aq}[HA]^n_{org}}$$

Cette constante peut être reliée au coefficient de partage ou de distribution, P, obtenue par CCC (eq. [1]) :

$$[9] \quad P = K_{ex}\left(\frac{[HA]^+}{[HA^+]}\right)^n$$

Si deux cations métalliques n'ont pas la même constante d'extraction K_{ex}, ils n'auront pas le même coefficient P. Ils pourront donc être séparés par l'appareil CCC puisqu'ils sont nécessairement confrontés à la même concentration de complexant (même phase stationnaire) et au même pH (même phase mobile). Les rétentions relatives dépendront cependant du pH de la phase mobile et de la concentration en complexant dans la phase organique.

En prenant le logarithme de l'expression [9], on forme :

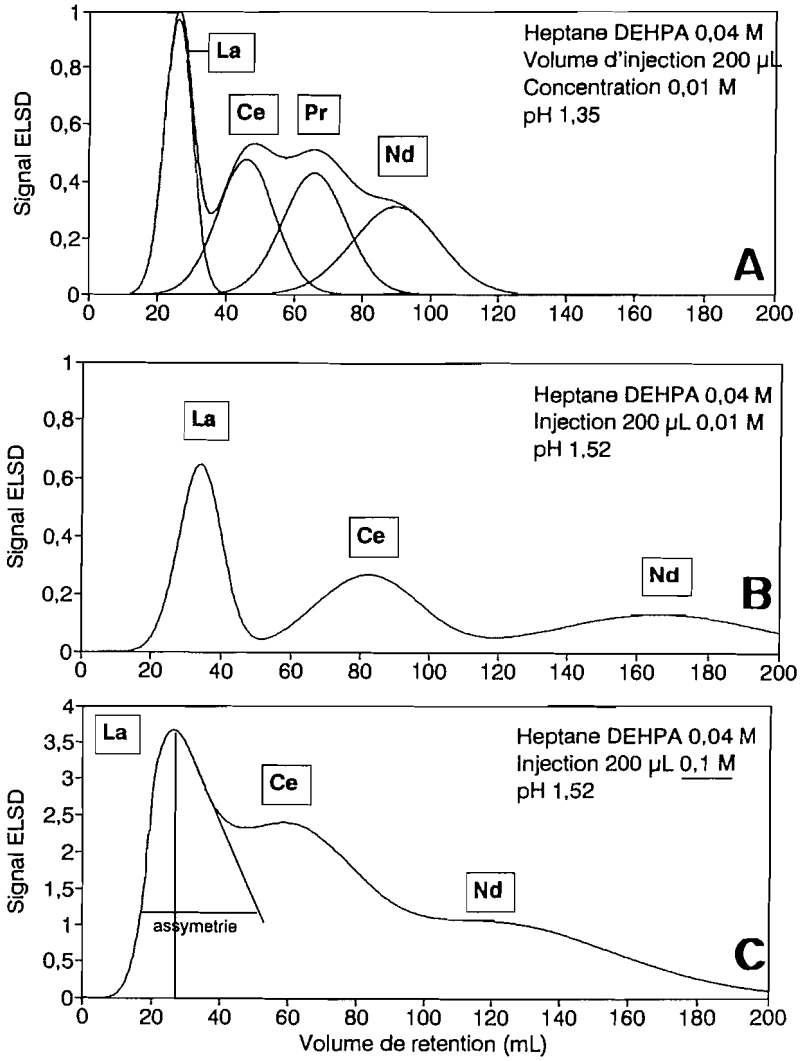
$$[10] \quad \log P = \log K_{ex} + n \log [HA] + n\,pH$$

L'équation (10) montre que le logarithme du coefficient P obtenu par CCC est linéairement relié à la fois au pH et au logarithme de la concentration en complexant. La pente correspond au nombre de molécules de complexant par ion métallique et l'ordonnée à l'origine permet d'estimer log K_{ex}.

Volume de rétention et pH

La figure 1 présente trois chromatogrammes CCC obtenus avec des conditions expérimentales différentes. Le premier chromatogramme montre que seul l'ion La^{3+} est séparé des trois autres, Ce^{3+}, Pr^{3+} et Nd^{3+}, avec une phase mobile acide à pH 1,40 et une concentration en DEHPA 0,04 M dans l'heptane. Chacun des ions lanthanides a été injecté séparément dans la même « colonne » CCC. Les tracés obtenus ont été indiqués sur le chromatogramme. Le deuxième chromatogramme montre l'accroissement des volumes de rétention dû au pH. Une augmentation de 0,12 unité du pH de la phase mobile double les volumes de rétention. Le tableau 2 rassem-

Fig. 1. Séparation des ions lanthanides par CCC. Volume de la colonne : V_C = 53 mL (1 bobine), V_S = 37 mL, rotation 800 rpm, débit de phase mobile aqueuse 2 mL/min, sens tête vers queue, détecteur à diffusion lumineuse, photomultiplicateur : 600 V, unité mV (arbitraire); gaz nébuliseur : air comprimé 1,5 kg/cm^2, température de séchage : 100°C. *A* : pH de la phase mobile = 1,4, chaque espèce cationnique a été injectée séparément et la courbe enveloppe est montrée. *B* : pH = 1,52, l'ion Pr^{3+} a été supprimé pour obtenir une résolution satisfaisante. *C* : pH = 1,52, effet de surcharge.



ble les résultats pour chaque ion qu'il ait été injecté seul ou en mélange avec les autres. Il donne également le nombre de plateaux correspondant à chaque pic. Ce nombre est lié à la cinétique de l'échange entre les phases (22). On note qu'il a tendance à diminuer lorsque le volume de rétention augmente. La cinétique de l'échange semble plus lente lorsque le cation est plus fortement retenu dans la phase organique.

Le troisième chromatogramme (figure 1*C*) montre l'effet d'un accroissement de la masse injectée. Les pics se déforment et deviennent asymétriques et les volumes de rétention diminuent. On a toutes les caractéristiques d'une surcharge de la phase stationnaire. La solution injectée contenait une concentration de 0,1 mol/L pour chacun des cations. Cette concentration est très supérieure à la concentration en complexant DEHPA dans la phase stationnaire (0,04 mol/L). Une partie des cations n'est pas complexée et avance dans la colonne jusqu'à ce qu'elle trouve de la phase stationnaire libre. L'ensemble des cations voit une colonne plus courte. Cela explique les diminutions de temps de rétention et les déformations de pic.

La figure 2 présente graphiquement les valeurs de coefficient *P* obtenues pour les lanthanides à différentes valeurs de pH. On note la forte augmentation de *P* avec le pH, comme l'exprime l'équation [9]. Les valeurs de log *P* ont été portées en fonction du pH selon l'équation [10]. Le tableau 3 donne les valeurs de pente, ordonnée à l'origine et coefficients de régression des droites obtenues. Les constantes K_{ex} sont également indiquées.

La facilité de la séparation de deux cations par extraction liquide–liquide est mesurée par le coefficient α_D, le facteur de

séparation, rapport des constantes d'extraction, K_{ex}, des deux cations considérés. α_D mesure le déplacement d'un cation par un autre. Les valeurs obtenues confirment les observations expérimentales : l'ion lanthane est facile à séparer des autres lanthanides avec un facteur de séparation de 4,2 avec le cérium, 7,9 avec le praséodyme et 11 avec le néodyme. Les autres ions lanthanides ont des facteurs de séparation plus faibles (tableau 3); leur séparation mutuelle sera difficile, mais pourtant possible par CCC (16).

Charge de la colonne

La figure 1*C* montre un effet de surcharge de la colonne CCC lorsqu'une plus grande masse d'ions lanthanides a été injectée. Les pics s'élargissent et les volumes de rétention diminuent. 200 µL de solution 0,1 M en chacun des ions, soit environ 2,8 mg de chaque ion ou 8,4 mg de cations (20 mg de sels nitrates), ont été injectés. La concentration des ions lanthanides en tête de colonne est 9 fois plus élevée que la concentration en complexant DEHPA. La plus grande partie des cations ne peut pas interagir avec la phase stationnaire saturée. Ils sont poussés par la phase mobile jusqu'à ce qu'ils trouvent de la phase stationnaire libre. Les cations sont en contact avec une partie seulement de la phase stationnaire. Ils semblent voir une colonne plus courte, d'où les volumes de rétention réduits, et avec moins de plateaux, d'où l'élargissement des pics.

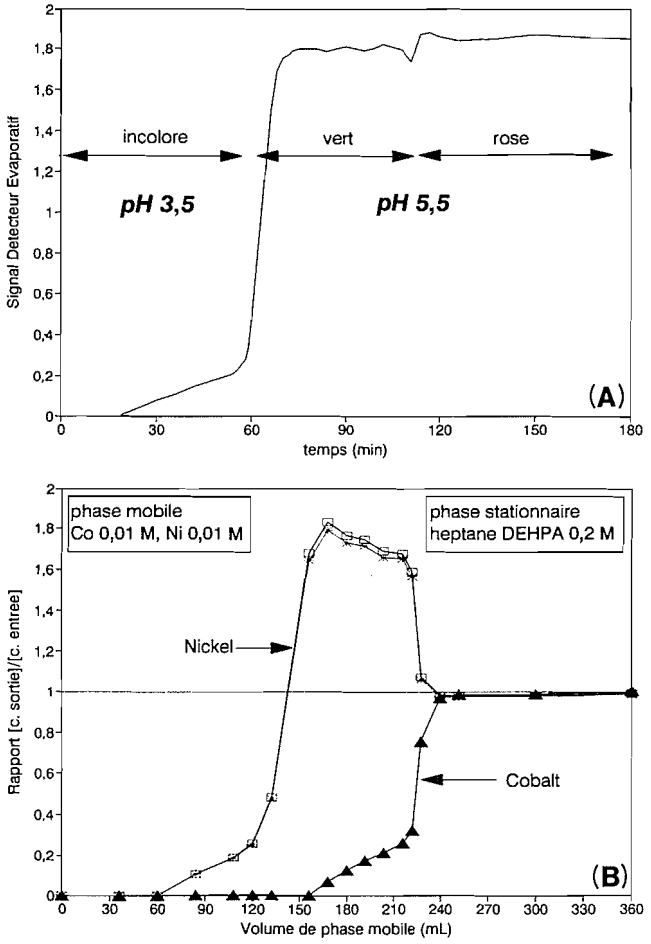
La figure 3 montre que la surcharge de la phase stationnaire commence dès que la concentration en néodyme, injecté seul, dépasse 0,01 M. La concentration en complexant DEHPA est 0,04 M, la concentration maximale en cation dans la phase mobile est 0,04/3 = 0,013 M (eq. [5]). Lorsque plusieurs cations sont injectés ensemble (figure 1*C*), la concentration maximale peut être dépassée en tête de colonne. Les cations se déplaçant à des vitesses différentes dans la colonne et une dilution se produisant (élargissement de bande), la surcharge peut cesser en cours de séparation. Cette surcharge se produit pour les différentes valeurs du pH de la phase mobile. L'efficacité de la colonne CCC diminue rapidement avec la surcharge. Pour le néodyme (figure 3), elle passe de 20 plateaux pour une concentration injectée de 0,005 M à environ 6 plateaux pour la concentration 0,1 M.

Comme il l'a été décrit pour des séparations préparatives (3–5), pour pouvoir séparer de grandes quantités de cations lanthanides sans surcharge de colonne, il faut augmenter la teneur de la phase stationnaire en complexant. Il faudra également travailler à des pH faibles, avec des phases mobiles très acides, pour compenser l'augmentation de volume de rétention qui découle de l'augmentation de la concentration en complexant (eq. [10]). Une autre voie pour séparer de grandes quantités de solutés est la chromatographie frontale ou chromatographie de déplacement (23).

Séparation de métaux de transition

La technique de chromatographie frontale et de déplacement à été mise en oeuvre pour montrer qu'un appareil CCC peut être utilisé comme un filtre à ions pour séparer de grandes quantités d'ions ou pour concentrer dans un très petit volume de

Fig. 4. Chromatogramme frontal obtenu avec une colonne CCC chargée de 20 mL de phase stationnaire heptane + DEHPA 0,2 M. La phase mobile est une solution d'ions cobalt Co^{2+} 0,01 M et nickel Ni^{2+} 0,01 M. Mêmes conditions expérimentales que pour la figure 1. *A* : tracé brut obtenu sur l'enregistreur. Les variations de pH et de coloration sont indiquées. *B* : profil de concentration en ions Co^{2+} et Ni^{2+} reconstruit avec les analyses par ICP-AES faites sur les prélevements de *A*.



phase organique les ions contenus dans un grand volume de solution aqueuse.

Principe

L'appareil CCC est équilibré comme indiqué dans la partie expérimentale avec une phase stationnaire organique et une phase mobile aqueuse ne contenant aucun ion. Un grand volume (1 L) de solution aqueuse d'acétate de nickel, de cobalt ou de cuivre et leur mélange est préparé. Cette solution est poussée dans la colonne CCC en guise de phase mobile. La concentration totale en ions est mesurée en continu à la sortie d'appareil CCC par le détecteur évaporatif à diffusion de la lumière (DEDL).

Résultats

La figure 4*A* montre le tracé obtenu avec le DEDL lorsqu'une solution d'acétate de nickel (0,01 M ou 590 ppm) et de cobalt (0,01 M ou 590 ppm) est utilisée comme phase mobile avec un appareil CCC hydrodynamique de 53 mL de volume de colonne (une seule bobine). Le volume de la phase stationnaire, heptane + 0,2 M DEHPA, a été limité à 20 mL. En début de mesure, des variations de pH ont été notées. Le pH de la phase éluée était initialement de 6. Il descend jusqu'à 3,5 pour remonter à 5,5 lorsque le signal DEDL indique la présence d'ions (figure 4*A*). Puis, lors du développement du chromatogramme frontal, des variations de colorations ont été observées comme indiqué sur la figure 4*A*, sans que le signal DEDL ne change notablement. Des fractions de 5 mL ont été collectées toutes les 6 min. Ces fractions ont été analysées par ICP-AES selon la procédure décrite dans la partie expérimentale. Les teneurs en nickel et cobalt dans la phase éluée sont rapportées aux teneurs de la phase mobile entrant dans la colonne.

La figure 4*B* présente graphiquement les résultats des analyses ICP-AES. En début de chromatogramme, on mesure une très faible teneur en ions Co^{2+} et Ni^{2+}. Correspondant à la montée du signal DEDL, on mesure une concentration en nickel presque double de la concentration d'entrée. Le cobalt est absent. Puis le cobalt apparaît à la sortie de colonne et la concentration en nickel devient égale à la concentration d'entrée. On vide la colonne CCC, la phase stationnaire heptane à une couleur bleu foncé. Mise en présence d'une solution aqueuse très acide, elle se décolore. La solution acide réextrait les ions. Cette solution est également dosée par ICP-AES. Elle contient du cobalt pratiquement pur.

Interprétation

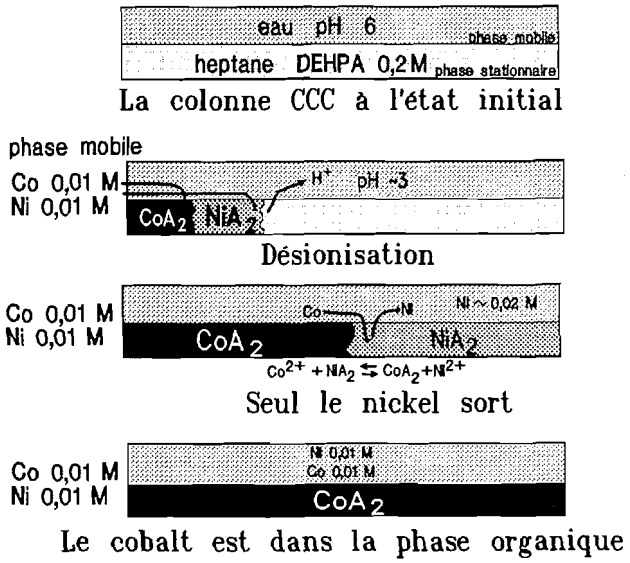
Des résultats similaires à ceux présentés par la figure 4 ont été obtenus avec des mélanges d'ions cuivre, cobalt et nickel. La figure 5 schématise le phénomène observé. À l'état initial, la colonne CCC est équilibrée avec de l'eau permutée comme phase mobile et une solution de DEHPA dans l'heptane comme phase stationnaire.

Lorsque la solution de cobalt et de nickel est introduite dans la colonne, il y a interaction des ions avec l'extractant de la phase stationnaire selon l'équation [7]. Les ions sont remplacés par des protons. Ces protons sont partiellement absorbés par les anions acétates. On mesure, à la sortie de colonne, une diminution du pH à une valeur de l'ordre de 3. Les ions nickel et cobalt sont absents. C'est l'étape de *désionisation*. Les ions cobalt et nickel sont capables de déplacer le proton du complexant DEHPA. Le cobalt a plus d'affinité pour l'extractant que le nickel. Il est capable de déplacer le nickel qui, repassant dans la phase mobile va se fixer plus loin dans la colonne. On observe une bande de phase stationnaire riche en nickel poussée par une bande de phase stationnaire riche en cobalt (figure 5). Cette étape de désionisation dure tant qu'il reste de la phase stationnaire propre (DEHPA) dans la colonne.

Lorsque le nickel atteint la fin de la phase stationnaire, il ne peut plus s'y adsorber, il reste donc dans la phase mobile et sort de la colonne. La concentration en protons n'est plus modifiée. Le pH devient celui de la phase mobile à l'entrée. La concentration en ions nickel est celle de la phase mobile à l'entrée augmentée du nickel déplacé par les ions cobalt. On mesure à la sortie une concentration en nickel supérieure à celle à l'entrée. Le cobalt est absent. Cette étape dure tant que les ions cobalt trouvent de la phase stationnaire contenant des ions nickel à déplacer.

Le processus se termine lorsque la phase stationnaire est

Fig. 5. Principe de la chromatographie frontale. La phase stationnaire comporte des bandes de concentration en une seule espèce ionique. Voir le texte.



saturée en ions cobalt (figure 5). Les concentrations d'ions à l'entrée se retrouvent à la sortie. La phase stationnaire est riche en cobalt. La technique CCC permet (*i*) d'extraire les ions d'une phase aqueuse, (*ii*) de séparer ces ions par concentration d'une espèce dans une partie de la phase aqueuse et de l'autre espèce dans la phase stationnaire.

Volumes filtrés

La figure 6 présente les concentrations en ions et les volumes obtenus au cours des étapes décrites par la figure 5. La colonne CCC de 53 mL contenait 20 mL de phase stationnaire heptane + 0,5 M DEHPA. Les 33 premiers mL sont de l'eau (pH ~6), ils correspondent au volume V_M. Puis le pH diminue jusqu'à ~3,5. Pendant l'élution de 330 mL, la phase aqueuse sortant de la colonne CCC ne contient que des traces (moins de 1 ppm) d'ions nickel et cobalt. Le volume de phase aqueuse qui peut être désionisé par la colonne CCC, V_D, dépend du volume de la phase stationnaire, V_S, de la concentration en extractant, C_E, et de la charge, n_I, et des concentrations en ions, C_I, dans la phase mobile :

$$[11] \quad V_D = \frac{V_S C_E}{\Sigma(n_I C_I)}$$

Une solution enrichie en ions nickel et très appauvrie en ions cobalt sort ensuite. La concentration en nickel est de l'ordre de la concentration totale en ions dans la phase entrant dans la colonne CCC. Le volume de solution enrichie en nickel, V_{Ni}, correspond à :

$$[12] \quad V_{Ni} = \left[\frac{V_S C_E}{n_{Co} C_{Co}}\right] - V_D$$

équation dans laquelle n_{Co} et C_{Co} correspondent respectivement à la charge électrique et à la concentration en ions cobalt. Le volume V_{Ni} est la différence entre le volume de phase aqueuse nécessaire pour saturer la phase stationnaire en cobalt diminué du volume de phase aqueuse désionisée. Dans l'expérience de la figure 6, on a obtenu 165 mL de solution contenant 97,4% d'ions nickel (Ni^{2+} 0,0133 M ou 780 ppm; Co^{2+} 0,00035 M ou 20 ppm). Le rotor a alors été arrêté et la colonne CCC vidée. On a récupéré 20 mL de phase stationnaire heptane fortement colorée en bleu par les ions cobalt. Leur concentration s'élève à 0,285 M (17000 ppm) avec seulement 60 ppm d'ions nickel. La masse d'ions cobalt extraite avec une pureté de 99,3% est de 336 mg. La précision des analyses est de l'ordre de 5%. La précision des analyses par ICP est de l'ordre de 1%. La principale source d'erreur est l'échantillonnage : une partie de la phase stationnaire peut rester dans la machine.

Facteurs de séparation ou constantes de déplacement

Les valeurs de volume données par les équations [11] et [12] correspondent à un déplacement total des ions nickel par les ions cobalt. Ce n'est le cas que tant que les concentrations sont du même ordre de grandeur (figures 4 et 6). Lorsque la concentration en ions nickel est très supérieure à la concentration en ions cobalt, ces derniers ne peuvent pas déplacer complètement les premiers. Les équations [11] et [12] ne peuvent plus être utilisées. La figure 7 présente les résultats obtenus avec une phase contenant à l'entrée de la colonne 10 fois plus d'ions nickel que d'ions cobalt. L'équation [11] donne une valeur de volume désionisé de V_D = 454 mL. Il faut ajouter le volume V_M (33 mL). Les premiers ions nickel ne devraient se présenter qu'après 487 mL. Le signal DEDL change dès que 390 mL ont été élués hors de la colonne. L'équation [12] permet d'estimer le volume de phase ne contenant que du nickel à la concentration théorique de 0,011 M V_{Ni} = 4550 mL. L'expérience montre une montée régulière de la concentration en cobalt dès l'élution de 450 mL (figure 7). Lorsque les concentrations d'entrée sont égales aux concentrations à la sortie, la phase stationnaire est récupérée et analysée. Elle contient les deux espèces d'ions, nickel à la concentration 0,168 M (10 000 ppm) soit un enrichissement de 17 fois par rapport à la phase aqueuse, et cobalt 0,066 M (3900 ppm) correspondant à un enrichissement de 66 fois.

Ces résultats permettent d'estimer le facteur de séparation, α_D, ou la constante de déplacement du nickel par le cobalt, $K_{Co/Ni}$, exprimé par :

$$[13] \quad \alpha_D = K_{Co/Ni} = \frac{[CoA_2]_{org}[Ni^{2+}]_{aq}}{[NiA_2]_{org}[Co^{2+}]_{aq}} = \frac{K_{exCo}}{K_{exNi}}$$

$K_{Co/Ni}$ est voisin de 4. On note que les constantes de déplacement ou les facteurs de séparation ne dépendent pas du pH. Pourtant si la valeur du pH est faible, les ions Co^{2+} ou Ni^{2+} seront faiblement extraits par la phase organique.

Généralisation du procédé

La figure 8 montre la composition à la sortie de colonne CCC obtenue lorsqu'une solution des trois ions Co^{2+}, Ni^{2+} et Cu^{2+} à la même concentration, 0,1 M, entrait continûment dans l'appareil. Le mouvement des bandes de concentration décrit par la figure 5 peut être généralisé. Dans ce cas, c'est l'ion cuivre qui a la plus forte affinité pour la phase stationnaire, il déplace l'ion cobalt qui déplace lui-même l'ion nickel. Au pH de la phase entrante (5,6) et avec les concentrations de 0,1 M, les équations [11] et [12] sont utilisables. On calcule un

Fig. 6. Profil de concentration en ions Co^{2+} et Ni^{2+} reconstruit avec les analyses par ICP-AES. V_S = 20 mL, phase mobile pauvre en nickel. Conditions expérimentales de la figure 1.

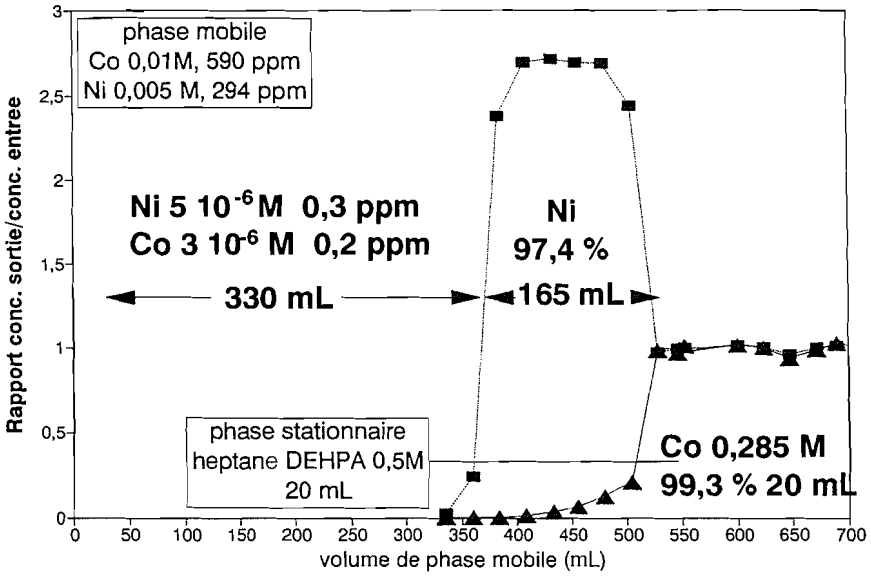


Fig. 7. Profil de concentration en ions Co^{2+} et Ni^{2+} reconstruit avec les analyses par ICP-AES. Phase mobile pauvre en cobalt qui ne peut plus saturer la phase stationnaire. Conditions expérimentales de la figure 1.

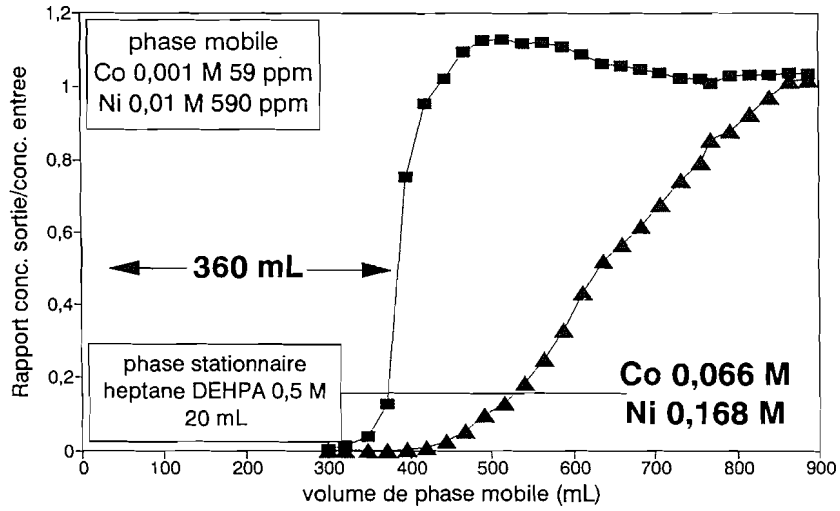

volume de phase désionisée, V_D, de $20 \times 0{,}2/(2 \times 3 \times 0{,}01)$ = 67 mL. Le saut de concentration en nickel est effectivement observé vers 100 mL ($V_D + V_M = 67 + 33$). L'équation [12] permet de calculer le volume de phase ne contenant que du nickel, V_{Ni} = 33 mL. On mesure expérimentalement $V_{Ni} \approx 40$ mL (figure 8).

Le cobalt sort ensuite de la colonne CCC à une concentration supérieure à celle entrante. L'excès est produit par le cobalt déplacé de la phase stationnaire par le cuivre. Mais le nickel est également présent (figure 8). Lorsque l'ion cuivre sort également de la colonne, c'est que la phase stationnaire est saturée. On a alors arrêté le rotor, vidé la colonne et mesuré les concentrations en chacun des ions dans la phase stationnaire. Elle contient majoritairement du cuivre (96,9%) avec des traces de nickel (0,7%) et de cobalt (2,4%).

On peut généraliser le procédé à l'extraction d'ions à faibles concentrations dans de grandes quantités de phase aqueuse. Une colonne CCC est un excellent extracteur et concentrateur qui pourra fonctionner avec une grande variété de phases extractrices. L'importance du pH est illustrée par le tableau 4 qui rassemble les valeurs K_{ex} et les constantes de déplacement des ions Co^{2+}, Ni^{2+} et Cu^{2+} avec les coefficients de distribution P calculés pour deux valeurs de pH.

Le tableau 4 montre que le cuivre déplace facilement le cobalt et le nickel jusqu'à des valeurs de pH aussi faibles que 2. Au-dessous de pH 3, les ions cobalt et nickel n'ont plus une affinité suffisante pour la phase stationnaire pour être extraits en totalité. Dès pH 4, les trois espèces ioniques ont des valeurs de $P > 200$. Elles sont extraites à plus de 99% par la phase stationnaire. Les valeurs de K_{ex} obtenues pour les ions lanthanides (tableau 3) montrent que ces ions pourraient être extraits complètement dès que le pH atteint 1,1.

On terminera en soulignant qu'il n'y a pas d'objection théorique pour que la méthode proposée dans cette étude soit

Fig. 8. Chromatographie frontale avec une solution de trois cations, Co^{2+}, Ni^{2+}, et Cu^{2+}. Les bandes successives de concentration sont : Ni^{2+} puis Co^{2+} et Cu^{2+} qui sature la phase stationnaire. Conditions expérimentales de la figure 1.

utilisée avec des effluents réels contenant de nombreuses espèces ioniques. Un classement des cations par ordre de constantes d'extraction croissantes doit être obtenu dans la phase stationnaire heptane. Le problème important est que la technique CCC est au stade du développement. Il n'y a pas encore, en 1995, de compagnies industrielles d'instrumentation qui produisent des appareils CCC en série. L'appareil utilisé pour faire cette étude fait partie d'une présérie de sept exemplaires. La société qui a produit ces appareils a été rachetée par une plus grande compagnie qui ne poursuivra pas les études en CCC. Des prototypes étant à l'étude dans plusieurs pays, il devrait être possible de se procurer une machine CCC fiable et facile d'emploi dans peu de temps.

2-Azabuta-1,3-diene-4-carbonitriles: stereoselective synthesis and nucleophilic substitution at the carbon–nitrogen double bond

Antonio Lorente, Marta Casillas, Pilar Gomez-Sal, and Antonio Manzanero

Abstract: The synthesis of (*E*)-1-methoxy-2-azabuta-1,3-diene-4-carbonitriles was performed by methylation of N-alkenylamides **9** and **11**. The *Z* isomers were obtained by treatment of (*E*)-1-methylthio-2-azabuta-1,3-diene-4,4-dicarbonitriles with sodium methoxide in methanol. We also describe the reactions of (*E*)-1-methylthio-2-azabuta-1,3-diene-4,4-dicarbonitriles with pyrrolidine, which afforded 1-(1-pyrrolidinyl) derivatives **20**, **21**, and **23**. X-ray crystallographic analyses of **21** and **23** established the *E* stereochemistry of the C—N double bond.

Key words: 2-azabuta-1,3-diene-4-carbonitriles: stereoselective synthesis, nucleophilic substitution and X-ray diffraction; N-alkenylamides: methylation.

Résumé : On a effectué la synthèse des (*E*)-1-méthoxy-2-azabuta-1,3-diène-4-carbonitriles en effectuant la méthylation des N-alkénylamides **9** et **11**. On a obtenu les isomères *Z* en traitant les (*E*)-1-méthylthio-2-azabuta-1,3-diène-4,4-dicarbonitriles avec du méthylate de sodium dans le méthanol. On décrit aussi les réactions des (*E*)-1-méthylthio-2-azabuta-1,3-diène-4,4-dicarbonitriles avec la pyrrolidine qui conduisent aux dérivés 1-(1-pyrrolidinyle) **20**, **21** et **23**. On a déterminé la stéréochimie *E* de la double liaison C—N par une analyse cristallographique par diffusion des rayons X.

Mots clés : 2-azabuta-1,3-diène-4-carbonitriles : synthèse stéréosélective, substitution nucléophile, diffraction des rayons X; méthylation de N-alkénylamides.

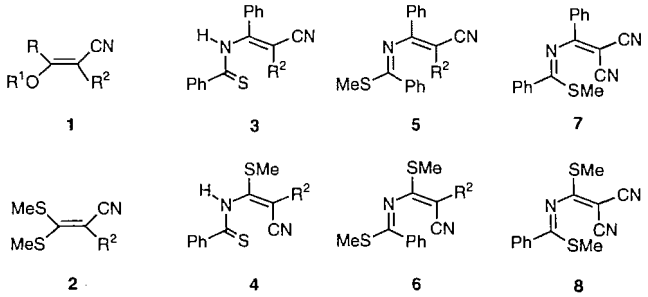
[Traduit par la rédaction]

Introduction

The synthesis of imidates (1–3) or thioimidates (3–5) by alkylation of amides or thioamides is a process that is well documented. In a previous paper (6) we described a stereoselective synthesis of (*E*)-1-methylthio-2-azabuta-1,3-diene-4-carbonitriles (N-alkenyl thioimidates) **5** and **6** by methylation of adducts **3** and **4**, which were formed from addition of thioamides to methoxymethylene compounds **1** or ketene dithioacetals **2**. Treatment of **5***a* and **6***a* with sodium methanethiolate affords *Z* isomers **7** and **8**, respectively.

To gain further insight into the stereoselectivity of these alkylation processes we examined the methylation of adducts **9–11** to afford the 1-methoxy-1-phenyl-2-azabuta-1,3-dienes **12–14**. There are several studies (7–17) on nucleophilic substitutions at the C—N double bond. A nucleophilic addition–elimination mechanism or a pathway involving a nitrilium ion intermediate has been suggested. Herein we describe the reactions of 2-azabuta-1,3-dienes with sodium methoxide or pyrrolidine and their stereochemical results.

Scheme 1.



Results and discussion

The adducts **9–11** were obtained from benzamide and the unsaturated compounds **1** or **2** using NaH as the base. Methylation of adducts **9–11** with diazomethane occurs stereoselectively, affording (*E*)-1-methoxy-1-phenyl-2-azabuta-1,3-dienes **12–14**.

Stereoselective formation of 2-azabuta-1,3-dienes **5** and **6** and **12–14** cannot be explained by assuming an *E* conformation for the adducts because a radiocrystallographic study (18) of **3***b* showed it to have a *Z* conformation. The stereochemical

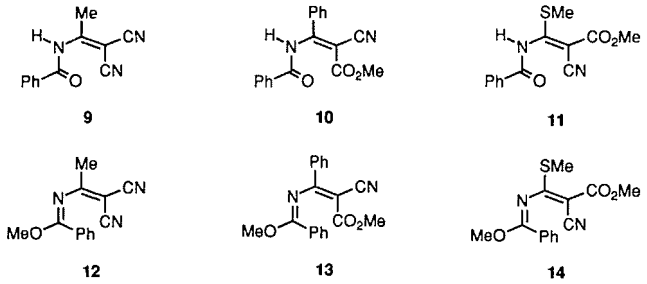
Scheme 2.

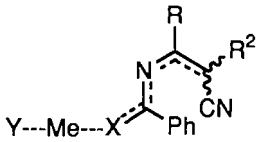


9 **10** **11**

12 **13** **14**

results obtained in the synthesis of these 2-azabuta-1,3-dienes can be accounted for by the lower steric hindrance in the transition state for the formation of the *E* isomers.

Scheme 3.



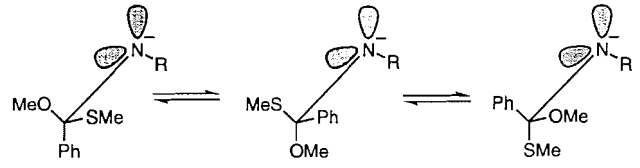
It is well established (19) that the *E* form of imidate or thioimidate esters is more stable than the *Z* form and *E*–*Z* interconvention can proceed by nitrogen inversion or by tautomerization and rotation about the C—N single bond. As we described in a previous paper (6), the 2-azabuta-1,3-dienes **5** and **6** retain their stereochemistry in solution but isomerization of the C—N double bond was achieved by treatment of **5***a* and **6***a* with sodium methanethiolate to afford the *Z* isomers **7** and **8**, respectively. We now report the conversion of (*E*)-1-methylthio-2-azabuta-1,3-diene-4,4-dicarbonitriles **5***a* and **6***a* to (*Z*)-1-methoxyderivatives **15** and **16** by treatment with sodium methoxide in methanol.

Scheme 4.

15 **16**

These results can be rationalized on the basis of the principle of stereoelectronic control. If we assume that an addition–elimination mechanism is followed, the reaction of methoxide ion on **5***a* and **6***a* gives the intermediate **17**, which can rotate to give other conformations with two lone pairs antiperiplanar to SMe, one of which (**18**) gives the *E* product and the other one (**19**) the *Z* product. The fact that only *Z* isomers were obtained can be explained by the greater unfavourable steric hindrance of intermediates **17** and **18**.

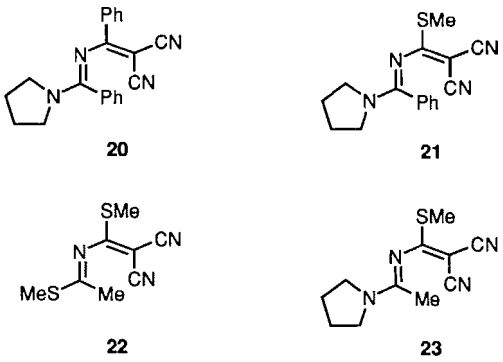
Scheme 5.



18 **17** **19**

The stereochemistry and mechanisms of amine substitution reactions at the C—N double bond have been studied (7–11, 16, 17). In a previous paper (20) were reported the reactions of **5***a* and **6***a* with nitrogen nucleophiles to afford different heterocyclic systems. We describe here the reactions of (*E*)-1-methylthio-2-azabuta-1,3-dienes **5***a* and **6***a* with pyrrolidine in propan-2-ol at room temperature to give (*E*)-1-(1-pyrrolidinyl)-2-azabuta-1,3-dienes **20** and **21**. In a similar manner the reaction of (*E*)-2-azabuta-1,3-diene **22** with pyrrolidine affords (*E*)-1-(1-pyrrolidinyl)-2-azabuta-1,3-diene **23**.

Scheme 6.

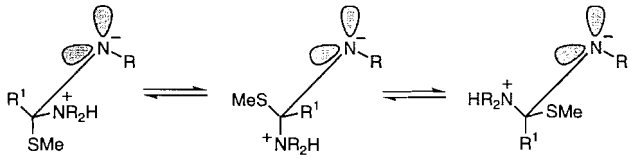


20 **21**

22 **23**

The stereochemical results of these reactions cannot be satisfactorily explained by an addition–elimination pathway because addition of pyrrolidine to **5***a* and **6***a* produces intermediate **24**, which can stereomutate to intermediates **25** and **26**. Both of these have one antiperiplanar electron pair set up for stereoelectronically controlled elimination of methanethiolate ion to afford (*E*)- or (*Z*)-1-(1-pyrrolidinyl)-2-azabuta-1,3-diene, respectively. However, the steric requirements of these intermediates could not account for the stereoselectivity of the reaction.

Scheme 7.



26 **24** **25**

It is possible that the reactions of 1-methylthio-2-azabuta-1,3-dienes with pyrrolidine proceed by an S_N2 or ion-pair (IP) mechanism (21). Additions of nucleophiles to nitrilium ions are known to occur so that the nucleophile and the electron pair on nitrogen are *anti* to each other (22–24), which could account for the observed stereochemical results. Another possibility is the synchronous displacement of the methanethiolate ion without formation of a tetrahedral intermediate (9, 25–27).

Structural study

In previous papers (6, 28) radiocrystallographic studies of 1-methylthio-2-azabuta-1,3-dienes were reported. We describe here the structure of 3-methylthio-1-(1-pyrrolidinyl)-2-azabuta-1,3-diene-4,4-dicarbonitriles **21** and **23**.

Description of the structure of compound ***21***

Positional parameters for non hydrogen atoms are given in Table 1. Figure 1 displays the structural formula with the labelling scheme and Tables 2 and 3 show selected geometric parameters. The azadiene framework deviates from coplanarity (C(1)-N(2)-C(3)-C(4)) but to a lesser extent than that found

in 1-methylthio-2-azabuta-1,3-dienes (6). This allows better conjugation between the pyrrolidine nitrogen and the azadiene framework that produces a shortening of the N(11)—C(1) and N(2)—C(3) bonds and a lengthening of the C(1)—N(2) and C(3)—C(4) double bonds. The phenyl ring is twisted with respect to the plane defined by C(1), N(11), C(11), and N(2) atoms (torsion angle C(12)-C(11)-C(1)-N(2)), which restrains the conjugation. The N(2)-C(3)-C(4) bond angle is expanded whereas S(11)-C(3)-C(4) and S(11)-C(3)-N(2) are correspondingly contracted. These deviations can be considered a consequence of steric effects between the phenyl and dicyanomethylene groups. The stereochemistry of the C(1)—N(2) double bond is *E*. The methylthio group is almost coplanar with the C(3)—C(4) double bond and adopts a *syn* conformation.

Description of the structure of compound ***23***

Positional parameters are given in Table 4 and Fig. 2 displays the structural formula. Tables **5** and **6** show selected geometric parameters, which are similar to those found for compound **21**. The azadiene framework deviates from coplanarity and the stereochemistry of the C(1)—N(2) double bond is *E*. The methylthio group adopts a *syn* conformation.

Structure and stereochemistry of 2-azabuta-1,3-dienes and their precursors

The configuration of the C—C double bond of adduct **10** was established by comparison with the ^1H NMR spectrum of dimethyl 1-benzamido-1-phenylmethylenemalonate (18) taking into account the shielding effect exerted by the phenyl group on the methoxycarbonyl. This configuration can be stabilized by the N-H.....O=C hydrogen bond as in the adduct **3***b* (18). The *Z* geometry of the C—C double bond in compound **11** was deduced from NOE experiments and can be explained by an attractive nonbonded CH_3S.....O=C interaction similar to that found in compound **6***b* (6).

The geometry of the C—N double bond of 2-azabuta-1,3-dienes was established on the basis of chemical shifts (Table 7) of the aromatic hydrogens on C1. The deshielding of the *ortho* hydrogens in compounds **15** and **16** indicates a coplanar arrangement of the phenyl and C—N double bond. This fact is similar to that found in (*Z*)-1-methylthio-2-azabuta-1,3-dienes **7** and **8**. On the contrary, the chemical shifts of the *ortho* aromatic hydrogens of compounds **12–14**, **20**, and **21** are similar to those of the corresponding hydrogens in (*E*)-1-methylthio-2-azabuta-1,3-dienes **5** and **6**. This fact allows us to assign an *E* configuration to the carbon–nitrogen double bond and a twisted conformation for the phenyl ring in solution, as found in the solid state for compound **21**.

Experimental

General

Melting points were determined with a Büchi SMP-20 apparatus and are uncorrected. IR were recorded on a Perkin Elmer 883 spectrophotometer. NMR spectra were obtained on a Varian Unity 300 instrument and mass spectra on a Hewlett Packard HP-5988 at 70 eV. Microanalyses were performed on a Heraeus CHN microanalyser. Flash column chromatography was carried out on silica gel SDS (230–400 mesh). Methoxymethylene compounds (**1**) were prepared using previously reported procedures (29, 30). Ketene dithioacetals (**2**) were prepared according to the procedure described by R. Gompper and W. Töpfl (31). The synthesis of methyl (*Z*)-3-benzamido-2-cyano-3-phenylpropenoate (**10**) was described in a previous paper (18) and methyl (*Z*)-3-benzamido-2-cyano-3-methylthiopropenoate (**11**) was prepared according to the reported procedure (32).

X-Ray diffraction

The crystals were mounted in an Enraf–Nonius CAD-4 automatic four-circle diffractometer, with bisecting geometry and graphite-oriented monochromator, using Mo K_α radiation (λ = 0.7107 Å). Unit cell parameters were calculated by least-squares refinement on diffractometer angles for 25 automatically centered reflections. Crystallographic and experimental details are summarized in Table 8.

[a]All spectra were registered in DMSO-d_6 with the exception of compound **13** ($CDCl_3$).

Data were collected at room temperature, using the $\omega/2\theta$ scan mode. Two check reflections measured every 90 min showed no significant variation. Intensities were corrected for Lorentz and polarization effects in the usual manner. No absorption or extinction corrections were made. The structures were solved by a combination of direct methods and Fourier synthesis and refined by least squares against F^2. All non hydrogen atoms were refined anisotropically. In **21**, the hydrogen atoms were found in the difference Fourier synthesis map and included in further refinement with fixed isotropic temperature factors. In **23** the hydrogen atoms were included from geometrical calculations with thermal parameters equivalent to the carbon to which they were attached. Final R_1 = 0.0664 and wR_2 = 0.1920 were obtained for **21** with a weighting scheme $w = 1/[\sigma^2(F_o^2) + (0.1301P)^2 + 0.6739P]$ and R_1 = 0.0515 and wR_2 = 0.1405 for **23** with a

	In both cases $P = (F_o^2 + 2F_o^2)/3$	

weighting scheme $w = 1/[\sigma^2(F_o)^2 + (0.0761P)^2 + 1.0989P]$ where $P = (F_o^2 + 2F_c^2)/3$ and $R_1 = \Sigma||F_o| - |F_o||/\Sigma|F_o|$ and $wR_2 = [|\Sigma(F_o^2 - F_c^2)^2|/|\Sigma w(F_o^2)^2|]^{1/2}$.

Calculations were performed with SHELXS-90 (33) and SHELXL-93 (34) programs on an Alpha AXP digital workstation.[2]

3-Benzamido-2-cyano-3-methylpropenenitrile 9

To a suspension of 80% NaH (142 mg, 7.3 mmol) in a mixture of dry benzene (15 mL) and dry *N,N*-dimethylacetamide (15 mL), 2-cyano-3-ethoxy-3-methylpropenenitrile (500 mg, 3.6 mmol) and benzamide (445 mg, 3.6 mmol) were added. The mixture was stirred at room temperature for 42 h and then poured into ice-water (50 mL). The aqueous layer was acidified with 10% hydrochloric acid and the precipitate formed was collected and recrystallized from hexane–benzene; 40% yield, mp 120–122°C; ν_{max} (KBr)/cm^{-1}: 3343, 2222, 1713, 1586 and 1476; δ_H (DMSO-d_6) 3.15 (s, 3H, CH_3), 7.54–7.90 (m, 5H, ArH), and 11.16 (s, 1H, NH); *m/z*: 211 (M$^+$, 15%), 106 (58), 105 (100), 77 (97), and 51 (84). Anal. calcd. for $C_{12}H_9N_3O$: C 68.22, H 4.30, N 19.9; found: C 68.05, H 4.41, N 20.01.

(*E*)-1-Methoxy-3-methyl-1-phenyl-2-azabuta-1,3-diene-4,4-dicarbonitrile 12

A solution of **9** (211 mg, 1 mmol) in dry ethyl acetate (20 mL) was methylated at 0°C with diazomethane (generated from Diazald® (750 mg, 3.5 mmol)). The solvent was removed at reduced pressure to afford the crude product, which was purified by flash column chromatography using hexane – ethyl acetate (5:1) as eluent; yield: 7%, mp 34–35°C (from hexane–benzene); ν_{max} (KBr)/cm^{-1}: 2256, 2226, 1658, and 1494; *m/z*: 225 (M$^+$, 44%), 210 (43), 193 (19), 153 (34), 105 (56), and 77 (100). Anal. calcd. for $C_{13}H_{11}N_3O$: C 69.31, H 4.93, N 18.66; found: C 69.10, H 4.89, N 18.91.

(1*E*, 3*Z*)-Methyl 4-cyano-1,3-diphenyl-2-azabuta-1,3-diene-4-carboxylate 13

A solution of **10** (153 mg, 0.5 mmol) in dry ethyl acetate (25 mL) was methylated at 0°C with diazomethane (generated from diazald (375 mg, 1.75 mmol)). The solvent was evapo-

[2] Tables of hydrogen coordinates and of isotropic and anisotropic displacement parameters for **21** and **23** have been deposited and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of hydrogen coordinates have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

rated at reduced pressure and the crude product thus obtained was purified by flash column chromatography using hexane – ethyl acetate (6:1) as eluent; yield: 15%, mp 153–154°C (from propan-2-ol); ν_{max} (Nujol)/cm^{-1}: 2221, 1714, 1687, 1605, 1593, and 1462; *m/z*: 320 (M^+, 4%), 261 (4), 247 (10), 106 (8), 105 (100), 77 (32), and 51 (6). Anal. calcd. for $C_{19}H_{16}N_2O_3$: C 71.24, H 5.03, N 8.74; found: C 71.01, H 5.15, N 8.92.

(1*E*, 3*Z*)-Methyl 4-cyano-1-methoxy-3-methylthio-1-phenyl-2-azabuta-1,3-diene-4-carboxylate 14

A solution of **11** (200 mg, 0.725 mmol) in dry ether (70 mL) was methylated at 0°C with diazomethane (generated from diazald (550 mg, 2.56 mmol)). The solvent was removed at reduced pressure to afford the crude product, which was purified by flash column chromatography using hexane – ethyl acetate, 5:1 and then 3:1, as eluent; yield: 75%, mp 141–142°C (from propan-2-ol); ν_{max} (Nujol)/cm^{-1}: 2216, 1696, and 1644; *m/z*: 290 (M^+, 10%), 249 (15), 118 (5), 105 (100), and 77 (34). Anal. calcd. for $C_{14}H_{14}N_2O_3S$: C 57.92, H 4.86, N 9.65; found: C 57.81, H 4.9, N 9.71.

(*Z*)-1-Methoxy-1,3-diphenyl-2-azabuta-1,3-diene-4,4-dicarbonitrile 15

To a solution of sodium (23 mg, 1 mmol) in dry methanol (40 mL) was added **5***a* (151 mg, 0.5 mmol). The reaction mixture was heated at reflux for 2 h and then the solvent was removed at reduced pressure. The crude product thus obtained was purified by flash column chromatography using hexane – ethyl acetate (7:1) as eluent, affording 48 mg (31% yield) of **7**. With the same eluent 1-methoxy-2-azabuta-1,3-diene (**15**) was obtained; 68% yield, mp 151–152°C (from methanol); ν_{max} (KBr)/cm^{-1}: 2216, 1583, 1554, 1529, 1494, 1468, and 1449; δ_H ($CDCl_3$): 4.29 (s, 3H, OCH_3), 7.50–7.60 (m, 6H, ArH), 8.16–8.19 (m, 2H, ArH), and 8.57–8.60 (m, 2H, ArH); *m/z*: 287 (M^+, 100%), 257 (21), 256 (26), 184 (52), 156 (22), 155 (33), 129 (25), 128 (13), 127 (40), 104 (46), 103 (38) and 77 (39). Anal. calcd. for $C_{18}H_{13}N_3O$: C 75.23, H 4.56, N 14.63; found: C 75.41, H 4.51, N 14.22.

(*Z*)-1,3-Dimethoxy-1-phenyl-2-azabuta-1,3-diene-4,4-dicarbonitrile 16

To a solution of sodium (92 mg, 4 mmol) in dry methanol (25 mL), was added. **6***a* (110 mg, 0.4 mmol). The mixture was stirred at room temperature for 6 h. The solvent was removed at reduced pressure to afford the crude product, which was purified by flash column chromatography using hexane – ethyl acetate (3:1) as eluent; 27% yield, mp 164–165°C (from hexane–methanol); ν_{max} (KBr)/cm^{-1}: 2224, 1583, 1548, and 1461; *m/z*: 241 (M^+, 75%), 214 (27), 196 (26), 186 (27), 170 (18), 118 (53), 104 (100), 92 (69), and 77 (73). Anal. calcd. for $C_{13}H_{11}N_3O_2$: C 64.72, H 4.6, N 17.42; found: C 64.95, H 4.51, N 17.64.

(*E*)-1,3-Diphenyl-1-(1-pyrrolidinyl)-2-azabuta-1,3-diene-4,4-dicarbonitrile 20

To a solution of **5***a* (180 mg, 0.59 mmol) in dry propan-2-ol (20 mL) was added pyrrolidine (74 μL, 0.89 mmol). The mixture was stirred at room temperature for 23 h. The solvent was removed at reduced pressure to afford the crude product, which was washed with hexane and recrystallized from propan-2-ol; 95% yield, mp 170–171°C; ν_{max} (KBr)/cm^{-1}: 2212, 2201, 1581, 1546, 1512, 1486, and 1458; *m/z*: 326 (M^+, 26%), 272 (6), 257 (10), 192 (2), 153 (35), 104 (40), 77 (53), and 70 (100). Anal. calcd. for $C_{21}H_{18}N_4$: C 77.28, H 5.56, N 17.17; found: C 77.41, H 5.62, N 17.11.

(*E*)-3-Methylthio-1-phenyl-1-(1-pyrrolidinyl)-2-azabuta-1,3-diene-4,4-dicarbonitrile 21

To a solution of **6***a* (160 mg, 0.59 mmol) in dry propan-2-ol (20 mL) was added pyrrolidine (74 μL, 0.89 mmol). The mixture was stirred at room temperature for 23 h. The solvent was removed at reduced pressure to afford the crude product, which was washed with hexane and recrystallized from ethyl acetate; 83% yield, mp 138–139°C; ν_{max} (KBr)/cm^{-1}: 2205, 1579, 1453, and 1441; *m/z*: 296 (M^+, 27%), 249 (36), 207 (10), 180 (44), 153 (26), 146 (26), 123 (15), 104 (87), 91 (31), 77 (87), and 70 (100). Anal. calcd. for $C_{16}H_{16}N_4S$: C 64.84, H 5.44, N 18.9; found: C 64.99, H 5.33, N 19.02.

(*E*)-1-Methyl-3-methylthio-1-(1-pyrrolidinyl)-2-azabuta-1,3-diene-4,4-dicarbonitrile 23

To a solution of **22** (32 mg, 0.15 mmol) in dry propan-2-ol (20 mL) was added pyrrolidine (74 μL, 0.89 mmol). The mixture was stirred at room temperature for 22 h. The solvent was removed at reduced pressure to afford the crude product, which was recrystallized from ethyl acetate – hexane; 83% yield, mp 123–124°C; ν_{max} (KBr)/cm^{-1}: 2203, 1567, and 1424; *m/z*: 234 (M^+, 42%), 219 (14), 187 (25), 146 (19), 123 (20), 118 (46), 91 (12), and 70 (100). Anal. calcd. for $C_{11}H_{14}N_4S$: C 56.39, H 6.02, N, 23.91; found: C 56.11, H 6.12, N 24.07.

Effect of concentration, pH, and ionic strength on the viscosity of solutions of a soil fulvic acid

F. Rey, M.A. Ferreira, P. Facal, and A.A.S.C. Machado

Abstract: The influence of pH (3.0–8.0), ionic strength (0.005–0.10 M), and concentration (ca. 50–300 mg L^{-1}) on the viscosimetric behaviour of solutions of a soil fulvic acid has been determined. The results show a complex influence of the concentration on the specific viscosity with maxima at about 80–100 mg L^{-1} and a minimum at 140–160 mg L^{-1}. The viscosity is minimum at pH ca. 6 and decreases when the ionic strength increases. The results are interpreted by a rod-type model from which the dimensions of fulvic acid molecules are calculated.

Key words: soil fulvic acids, viscosity, configurational changes.

Résumé : On a déterminé l'influence du pH (3,0–8,0), de la force ionique (0,005–0,10 M) et de la concentration (environ 30–300 mg L^{-1}) sur le comportement viscosimétrique de solutions d'un acide fulvique de sol. Les résultats démontrent l'existence d'une influence complexe de la concentration sur la viscosité spécifique qui présente un maximum à environ 80–100 mg L^{-1} et un minimum à 140–160 mg L^{-1}. La viscosité est minimale à un pH d'environ 6 et elle diminue avec une augmentation de la force ionique. On interprète les résultats en fonction d'un modèle en forme de bâtonnets à partir duquel on a calculé les dimensions des molécules de l'acide fulvique.

Mots clés : acides fulviques du sol, viscosité, changements configurationnels.

[Traduit par la rédaction]

Introduction

The size and shape of humic substances play an important role in their effects in the environment, for instance in their interaction with the soil particles, their involvement in the binding of trace metals, their biological effects on plants and microorganisms, and their function in surface and groundwater quality. Important information about the size and shape of fulvic acid molecules in solution can be obtained by viscosimetric measurements. Therefore, different authors (1–6) have investigated the behaviour of humic substances by this technique. Although the calculation procedures are well established, the reported data are incomplete and results of most of them are not intercomparable because of differences in extraction and purification techniques (7).

Moreover, the aggregation of humic substances depends on their nature and the solution conditions under which they exist, for example, on the presence of electrolytes and the value of pH. The effect of these configurational changes may have to be considered in transport phenomena involving organic matter and associated metals, in particular for river humic substances. A theoretical explanation of these phenomena based on potentiometric and conductimetric data has recently been reported (8).

Considering these facts, it was decided to include viscosimetric measurements in a collaborative project in progress in our departments to study the behaviour of fulvic acids (FA) in solution (9–12). This work presents the results obtained in a systematic study of the influence of FA concentration (in the range 50–280 mg L^{-1}, which includes lower values than other studies reported in the literature (1–3)), pH (3.0–8.0), and inert electrolyte concentration (0.005–0.10 M) on the viscosimetric properties (at 298 K constant temperature) of low concentration solutions of a soil FA. From the results, the dimensions of FA particles were calculated assuming a rod-type model and their changes with the solution properties are discussed.

Experimental

Reagents and materials

All reagents were p.a. or similar and were used without further purification. Deionized water with resistivity ≥20 MΩ cm was used.

KNO_3 was employed as background electrolyte to adjust the total ionic strength. For pH adjustments, 0.1 M HCl and 0.1 M NaOH were used.

The sample of FA used in the present work (described before (13)) was isolated from a Portuguese forest soil collected at Famalicao (near Oporto, 30 km to the northeast) by the IHSS standard procedure (14, 15). For that a sample of air-dried soil was acidified to pH 2 with 1 M hydrochloric acid solutions and kept for 15 days with occasional agitation. The solid and liquid phases were separated by filtration and the latter was concentrated through an Amberlite XAD-8 resin column. The nonadsorbed fraction was discarded, the column was washed with water until chloride ions (which interfere in the next stages of the process) were absent, and, finally, the column was eluted with 0.1 M NaOH. The liquid extracts recovered (that contain the fulvic acid "molecules") were

transformed to their acidic form by using a cation exchange resin (Merck) and were freeze-dried to get a powder sample. The yield of the process was about 0.5% (W/W).

Equipment

H^+ concentrations (as pH values) were measured with a Crison micro-pH 2002 pH-meter (±0.1 mV) and an Ingold electrode, calibrated at each ionic strength by standard HCl–NaOH titrations (16). Viscosity measurements were done with an Ostwald-type viscometer, having a flow time with distilled water of 345.4 ± 0.2 s at 298.0 K. A flow bath (Tectron 4373200) was used as thermostat (±0.1 K).

Procedure

Each individual sample was prepared by dissolving aliquots of a FA stock solution (about 1000 mg L^{-1}) in water, and the pH and (or) the neutral salt concentration (total ionic strength) were adjusted to the required values. Experiments were made at FA concentrations of 47.0, 62.0, 71.0, 82.0, 94.0 107.0, 118.0, 131.0, 163.0, 189.0, 236.0, and 289.0 mg L^{-1}, total ionic strengths of 0.005, 0.010, 0.030, 0.050, 0.070, and 0.10 M, and pH at 3.0, 4.0, 5.0, 6.0, 7.0, and 8.0. All experiments were repeated at least 20 times with different solutions and the mean values of flow time, obtained after outlier values were rejected using standard statistical tests (17), were used to calculate the viscosity values.

Calculations

Values of relative (η_r), specific (η_{sp}), and reduced (η_z) viscosity were obtained from the experimental absolute viscosity values using their respective definitions (3)

$$\eta_r = \frac{\eta}{\eta_0}$$

$$\eta_{sp} = \frac{\eta - \eta_0}{\eta_0}$$

$$\eta_z = \frac{\eta_{sp}}{c}$$

where η_0 is the absolute viscosity of water and c the concentration of the solutions.

Intrinsic viscosities ([η]) were calculated by extrapolation to zero concentration of the linear part of the reduced viscosity vs. concentration plots.

The viscosity-average molecular weight (M) was calculated using the Staudinger equation, which relates [η] to M

$$[1] \quad [\eta] = KM^{\alpha}$$

where α has a value of 0.67 (3). The value of K (298 K) was calculated using this value and the value of M obtained for the present sample of FA at $I = 0.1$ M by potentiometric measurements (908 g mol^{-1}). Particle (molecular) volumes were calculated by the approach of Chen and Schnitzer (3), using

$$[2] \quad V = \frac{M}{dN_A}$$

where d is the density of FA solutions and N_A is Avogadro's number.

To calculate the dimensions of FA particles, a model of their structure is required, and several different approaches (namely spheres, disks, and rods) have been proposed. Of these, spherical structures can be excluded in the present case because the [η] values obtained are greater than 0.025 (18). On the other hand, if a disk shape is assumed, the calculated thickness values are about 1 Å, not compatible with the postulated general structures of FA molecules (3). Because FA can be considered as a flexible linear colloid (19) a rod model can be used, and the length (a) and thickness (b) of the particles can be related to a $k([\eta])$ dependent factor by

$$[3] \quad k = \frac{(a/b)^2}{15\,(\ln 2a/b - 3/2)} + \frac{3\,(a/b)^2}{15\,(\ln 2a/b - 1/2)} + \frac{14}{15}$$

This equation can be solved by numerical iteration to calculate the a to b ratio. Individual values of a and b can be estimated from this ratio and the expression for the particle volume given as

$$[4] \quad V = \frac{\pi b^2 a}{4}$$

Results and discussion

The results obtained for the viscosimetric parameters of the FA studied are presented in Table 1. As values of the absolute viscosity for 0.1 M ionic strength show no significant differences from pure water viscosities, the values calculated for this ionic strength are not included.

Influence of the concentration of the fulvic acid

Figure 1 shows the variation of the specific viscosity of FA solutions when their concentration changes. For concentrations below of 80–100 mg L^{-1} (depending on pH and ionic strength), a rise in the specific viscosity occurs when the fulvic acid concentration increases. Then, the specific viscosity decreases with increase in the FA concentration up to about 160 mg L^{-1} (also dependent on pH and ionic strength) and after this value a linear increase is obtained. These results are in agreement with those obtained by Reuter (20), who indicated that a concentration of about 100 mg L^{-1} is a "special value" for the behaviour of humic materials. Besides, according to Ghosh and Schnitzer (1), FA presents important conformational changes in the 100–160 mg L^{-1} range when the concentration varies: at concentrations below 100 mg L^{-1} linear colloids prevail, but above 160 mg L^{-1} only spherocolloids exist; conformational changes occur in the range between these values, where both types of structure are present.

Influence of the ionic strength

In Figure 2 the reduced viscosity is plotted versus the FA concentration for different values of ionic strength but constant pH. The plots show a marked decrease in viscosity when the ionic strength increases, suggesting a coiling of fulvic acid molecules (which has been cited in the literature) due to repulsions by the counterions or neutralization by the added salt of the charges on the backbone of the macromolecule (21),

Table 1. Variation of the viscosity (and related parameters) of fulvic acid with ionic strength and pH.

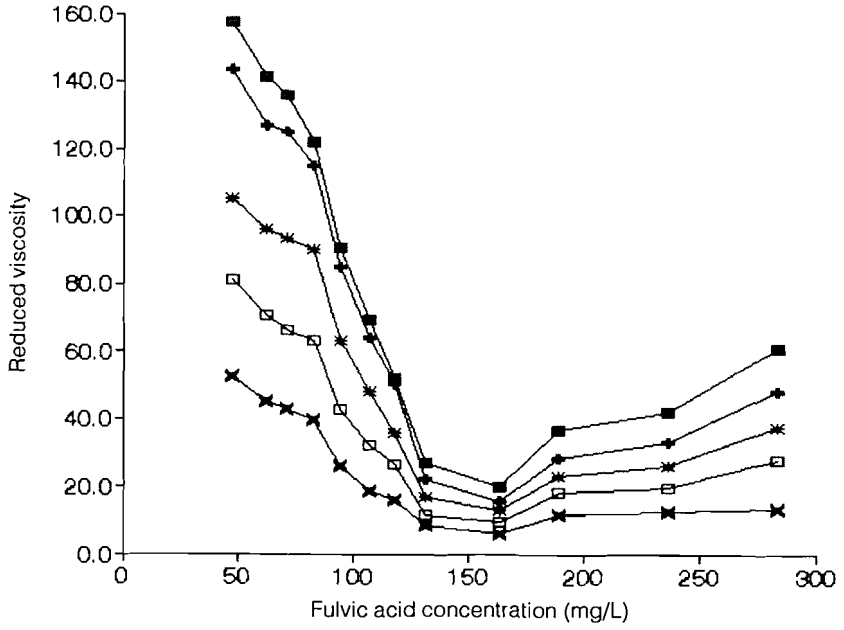

Fig. 3. Variation of the intrinsic viscosity with pH for different ionic strengths: ■ $I = 0.005$; + $I = 0.01$; * $I = 0.03$; □ $I = 0.05$; × $I = 0.07$.

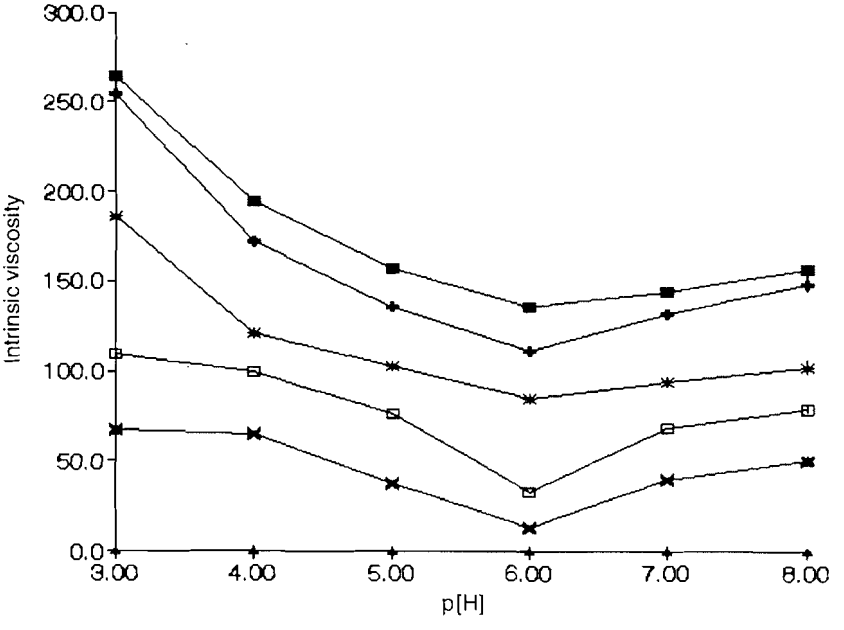

buildup of charges on the macromolecules of the fulvic acid (22), or polidispersity (23). According to Eagland (24), this variation is associated with suppression of the charge atmosphere of the polyelectrolyte molecules, which become less rodlike and hence more flexible.

From these plots, it can be seen that although the viscosity decreases in the presence of the salt, the pattern of the variation with FA concentration is maintained, with a minimum at about 160 mg L^{-1}. Ghosh and Schnitzer (1) concluded that at higher concentrations these polyelectrolytes behaved like uncharged spherocolloids, but the viscosity values suggest that the macromolecules should be considered as tightly coiled and flexible. These results are supported by the behaviour of FA solutions at high ionic strengths described here.

Influence of pH

In addition to polyelectrolyte concentrations and ionic strength, the viscosity of FA solutions varies with pH. Kumada and Kawamura (2) reported a diminution in the reduced viscosity of humic materials when the pH is increased

as the pH approaches 5.0, followed by an increase in the neutral and alkaline pH ranges. Other authors have reported a similar trend but with a minimum at a more acid value of pH (1).

Figure 3 presents the variation of the intrinsic viscosity with pH (for different constant values of ionic strength) for the FA solutions studied in the present work, and shows a minimum in $[\eta]$ between pH 6 and 7. At the lowest pH values, the FA particles remain uncharged, electrostatic repulsions are weak, and the particles present a higher association due to the possible formation of hydrogen bonds, van der Waals forces, and other weak forces (21) (see values of the average molecular weight in Table 1). When the pH increases, the association of the particles is destroyed due to the increase in electrostatic repulsions that are greater than the weak forces, and the aggregates break up because any sort of rearrangement disperses the fully ionized molecules to form small, discrete particles. The viscosity of the fulvic acid decreases until a minimum is reached at pH about 6. At still higher pH values, the intrinsic viscosity increases again, showing a new aggregation due to mineral bridges and intermolecular interactions (25). This behaviour is a common feature for polyelectrolytes of the weak acid type such as FA (26).

The dimensions of the FA aggregates (considered as rod-shaped) are strongly dependent on pH and ionic strength (see *a* and *b* values in Table 1) and present a ×15 variation for *a* values in the range analysed. The values obtained for *a* and *b* are larger than others reported in the literature obtained by viscosimetric measurements at higher FA concentrations (3), perhaps due to the low concentration range analysed in this work in which the molecules are more elongated, but the thickness of the particles is of the same order of magnitude (11.3–4.6 Å) and the values depend strongly on ionic strength but only slightly on pH. The *a* and *b* values suggest that the FA particles are elongated cylinders that change their aggregation states with the external characteristics of solution (namely pH and the presence of counterions).

Conclusions

As can be seen from the results of the present work, viscosimetric measurements of fulvic acids in solution can provide information about the dimensions and modification of the structure of fulvic acid molecules. However, on the other hand, pH plays an important role in the change of these structures, so it is very important to adjust the H^+ concentration when this type of experiment is done. Moreover, the presence of different concentrations of added salt can modify the arrangements of fulvic acid molecules in solution due to the existence of electrostatic interactions between the fulvic acids and the counterions. Because of this it is very important to state clearly the experimental conditions when the results of different experiments are to be compared.

Solvent effects on the reactivity of solvated electrons with organic solutes in 1-butylamine–water mixtures

Yixing Zhao and Gordon R. Freeman

Abstract: The values of the rate constants of the reactions of e_s^- with the efficient scavengers nitrobenzene and acetone are $\geq 2 \times 10^6$ m^3 mol^{-1} s^{-1} in the whole range of 1-butylamine–water mixtures at 298 K; the reaction rates in the mixed solvents vary approximately as the solvent fluidity. In pure butylamine at 298 K, $k_2(e_s^- + \text{nitrobenzene}) = 84 \times 10^6$ m^3 mol^{-1} s^{-1} and $k_2(e_s^- + \text{acetone}) = 7.3 \times 10^6$ m^3 mol^{-1} s^{-1}. The values of the rate constants of the reactions of e_s^- with the inefficient scavengers phenol and toluene are $< 2 \times 10^5$ m^3 mol^{-1} s^{-1} in the whole range of 1-butylamine–water mixtures at 298 K and have a maximum at 50 mol% water and a minimum at 99 mol% water. In pure 1-butylamine at 298 K, $k_2(e_s^- + \text{phenol}) = 1.0 \times 10^4$ m^3 mol^{-1} s^{-1} and $k_2(e_s^- + \text{toluene}) = 0.28 \times 10^4$ m^3 mol^{-1} s^{-1}. The reaction rates with inefficient scavengers show strong dependence on the solvent composition and selective solvation of electron and scavenger. In the amine-rich region (0–30 mol% water), the rate constants increase with the *increase* of viscosity, indicating the chemical participation of solvent molecules in the reaction. In the water-rich region from 50 to 99 mol% water, the decrease of the rate constants indicates the nonhomogeneous solvation of the electrons by water and of the organic solutes by 1-butylamine. From 99 mol% to pure water the rate constant increases rapidly, which we attribute to insufficient 1-butylamine to coat the phenol or toluene molecules. The variation of the activation energies E_2 for the efficient scavengers, 14–27 kJ mol^{-1}, are similar to the variation of E_η in the mixed solvents. The values of E_2 for the inefficient scavengers are from 15 to 38 kJ mol^{-1} for phenol and from 6 to 21 kJ mol^{-1} for toluene. Both k_2 and E_2 for the inefficient scavenger reactions show a correlation with the temperature coefficient $-dE_{Amax}/dT$ of the optical absorption of e_s^- in the mixed solvents, but the reason is obscure.

Résumé : Les constantes de vitesse pour les réactions des e_s^- avec les capteurs efficaces que sont le nitrobenzène et l'acétone sont $\geq 2 \times 10^6$ m^3 mol^{-1} s^{-1} pour l'ensemble des concentrations de la 1-butylamine–eau, à 298 K; la variation des vitesses de réaction dans les solvants mixtes suit approximativement celle de la fluidité du solvant. Dans la butylamine pure, à 298 K, $k_2(e_s^- + \text{nitrobenzène}) = 84 \times 10^6$ m^3 mol^{-1} s^{-1} et $k_2(e_s^- + \text{acétone}) = 7{,}3 \times 10^6$ m^3 mol^{-1} s^{-1}. Les valeurs des constantes de vitesse des réactions des e_s^- avec les capteurs inefficaces que sont le phénol et le toluène sont $< 2 \times 10^5$ m^3 mol^{-1} s^{-1} pour l'ensemble des concentrations de la 1-butylamine–eau à 298 K et elles présentent un maximum à 50 mol% d'eau et un minumum à 99 mol% d'eau. Dans la 1-butylamine pure, à 298 K, $k_2(e_s^- + \text{phénol}) = 1{,}0 \times 10^4$ m^3 mol^{-1} s^{-1} et $k_2(e_s^- + \text{toluène}) = 0{,}28 \times 10^4$ m^3 mol^{-1} s^{-1}. Les vitesses de réaction avec les capteurs inefficaces présentent une forte dépendance sur le composition et une solvation sélective de l'électron et des capteurs. Dans la région riche en amine (0–30 mol% d'eau), les constantes de vitesse augmentent avec une *augmentation* de la viscosité; ce résultat indique qu'il se produit une participation chimique des molécules de solvant dans la réaction. Dans la région riche en eau, de 50 à 90 mol%, la diminution des constantes de vitesse indique qu'il se produit une solvatation non homogène des électrons par l'eau et des solutés organiques par la 1-butylamine. Dans la région de 99–100 mol% d'eau, la constante de vitesse augmente rapidement; on attribue ce résultat au fait qu'il n'y a pas assez de 1-butylamine pour recouvrir les molécules de phénol ou de toluène. Dans les solvants mixtes, les énergies d'activation, E_2, des capteurs efficaces, 14–27 kJ mol^{-1}, ont des variations similaires aux E_η. Les valeurs E_2 des capteurs inefficaces varient de 15 à 38 kJ mol^{-1} pour le phénol et de 6 à 21 kJ mol^{-1} pour le toluène. Les valeurs tant de k_2 que de E_2 des réactions des capteurs inefficaces présentent toutes les deux une corrélation avec le coefficient de température, $-dE_{Amax}/dT$, l'absorption optique des e_s^- dans les solvants mixtes; les raisons sont toutefois obscures.

Mots clés : solvants mixtes 1-butylamine–eau, électrons solvatés, solutés organiques, effets de solvant.

Introduction

The study of solvated electron (e_s^-) reactivity in mixed alcohol–water solvents has been fruitful in elucidating electron behavior in nonhomogeneous fluids (1–10). The reactivity of e_s^- depends on the nature of the coreactant and the structure of the solvent. Some reactions of e_s^- with solutes such as nitrobenzene (1, 4), Ag_s^+ (7), and H_s^+ (7) are diffusion controlled, and some are much slower, as in the case of toluene and phenol (3, 5). Solvent structure implies two aspects. One is the molecular structure, which in some cases affects the chemical participation of solvent molecules in a reaction (11, 12). The other is the solvent molecular packing, such as two- and three-dimensional structures in alcohol–water mixtures (8, 13).

Alcohol, water, and their mixtures are all strongly hydrogen-bonded liquids. It is now of interest to study e_s^- reactivity in mixtures containing a less strongly hydrogen-bonded component. We have chosen 1-butylamine–water, for practical reasons (ease of handling). The optical absorption spectra of e_s^- in these mixed solvents have recently been reported (14). There appears to be less selective solvation of electrons by water in these mixtures than was expected.

Experimental

The method of purification of 1-butylamine was reported in ref. 14. Nitrobenzene (A.C.S. reagent, >99%) and phenol (redistilled, >99%, mp 40–42°C) were obtained from Aldrich. Acetone (HPLC grade, >99.9%) and toluene (HPLC grade, >99.8%) were obtained from Sigma–Aldrich. Nitrobenzene, acetone, and phenol were used without further purification. Toluene was fractionally distilled from sodium under UHP argon (99.999%, Liquid Carbonic Canada) and the middle part was collected and stored in a flask under argon positive pressure.

For the measurement of the rate constant of phenol in pure water, phenol was melted in the bottle by placing the bottle in warm water, and then was pipetted into a volumetric flask and nanopure water was added. For the rest of the measurements of phenol reaction rate, phenol crystals were taken out of the bottle and placed in a watch glass, and then crystals of phenol without any color were scooped into a beaker to weigh. Then solvent was added, and the solution was transferred to a volumetric flask for final dilution.

Techniques of sample solution preparation, irradiation, and optical measurements were the same as described in ref. 9.

Results and discussion

Rate constants

Since the reaction of e_s^- with the solvent amine and water is negligible under our conditions (15), we only consider the following reactions:

[1] $e_s^- + I_S \rightarrow$ Products k_1

[2] $e_s^- + S_S \rightarrow$ Products k_2

where I_S represents residual impurities in the solvent and those produced by the radiation pulse, and S_S is an added solute. The observed first-order decay rate constant $k_{obs} = k_1[I] + k_2[S]$ was measured for the pure solvent and six concentrations of solute S. The value of the second-order rate constant k_2 was obtained from the slope of a plot of k_{obs} against solute concentration.

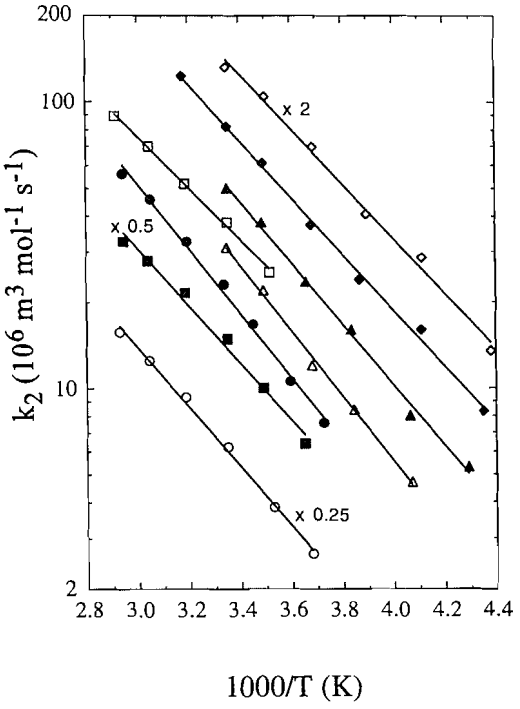

Fig. 1. Arrhenius plots of $k_2(e_s^- + \text{nitrobenzene})$ in 1-butylamine–water mixed solvents. Refer to Table 1 for symbols.

1-Butylamine is completely miscible with water. The rate constants of e_s^- for all solutes were measured in the following compositions in mol% water: 0.0, 10.0, 30.0, 50.0, 70.0, 90.0, 95.0, 97.0, and 100.0. In addition, the rate constants of e_s^- with phenol in 99.0, 99.5, and 99.8 mol% water were measured. The normal freezing point of 1-butylamine is 224 K, and the normal boiling point is 351 K. The values of k_2 for each solvent were measured from about 230 K to 344 K, depending on the freezing and boiling points of each composition.

Arrhenius plots of k_2 for the four organic solutes nitrobenzene, acetone, phenol, and toluene are given in Figs. 1–4; Table 1 contains the symbols for these figures. The rate constants k_2 (10^6 m^3 mol^{-1} s^{-1}) of nitrobenzene, acetone, phenol, and toluene in water at 298 K are 37, 7.2, 0.024, 0.011, which are consistent within experimental uncertainty with values reported by Maham and Freeman (16): 38, 7.7, 0.027, 0.013, and Lai and Freeman (3): 38, 7.7, 0.030, 0.011. Other results reported (15) are 30, 5.9, 0.018, 0.012.

In water, the rate constant $k_2(e_s^- + \text{phenol})$ at 298 K was 2.4×10^4 m^3 mol^{-1} s^{-1}. However, phenol will dissociate somewhat in water:

[3] 

Since the rate constant $k_{H^+}(e_s^- + H_3^+O)$ at 298 K is 2.9×10^7 m^3 mol^{-1} s^{-1} in water at very low ionic strengths

Fig. 2. Arrhenius plots of $k_2(e_s^- + \text{acetone})$ in 1-butylamine–water mixed solvents. Refer to Table 1 for symbols.

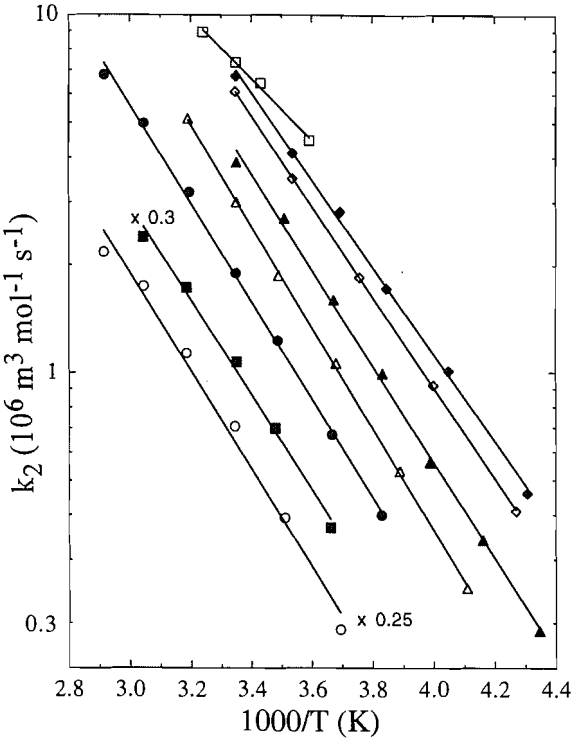

Fig. 3. Arrhenius plots of $k_2(e_s^- + \text{phenol})$ in 1-butylamine–water mixed solvents. Refer to Table 1 for symbols.

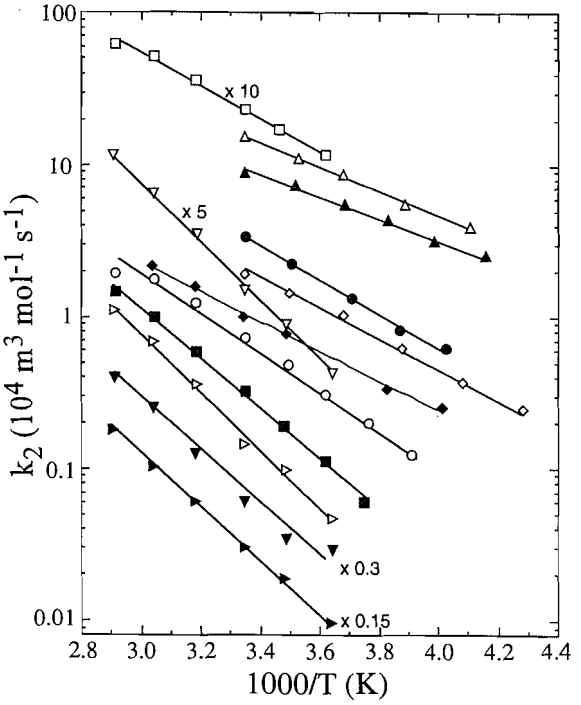

(10), it contributes to k_{obs} in the measurement of $k_2(e_s^- + \text{phenol})$. We used the method in ref. 8 to correct k_2 for phenol alone. That is, $[H_3^+O] = (K_a[\text{phenol}])^{1/2}$ is calculated over the range of [phenol] = 5–30 mol m^{-3} where K_a is the dissociation constant, and at 298 K it is 1.3×10^{-7} mol m^{-3}

Fig. 4. Arrhenius plots of $k2(e_s^- + \text{toluene})$ in 1-butylamine–water mixed solvents. Refer to Table 1 for symbols.

(17). Then the actual value of $k_2(e_s^- + \text{phenol})$ was calculated from the slope of the $(k_{obs} - k_{H^+}[H_3^+])$ against [phenol] plot, and it is 2.1×10^4 m^3 mol^{-1} s^{-1}, which is 13% less than the uncorrected value. Since the values of K_a at other temperatures in water, and in all the other solvents, are not known, we could not make this correction for the other values. For this reason the values in Fig. 3 and Table 2 are uncorrected. Modern studies of the chemical–physical properties of the amine–water mixed solvents and of the phenol solutions would be valuable.

Composition dependence of k_2 at 298 K

Figure 5 shows the solvent composition dependences of $k_2(e_s^- + \text{organic solute})$ in 1-butylamine–water mixed solvents at 298 K. Reaction parameters are listed in Tables 2 and 3. From Fig. 5 we see that the reactions are divided into two groups: (*i*) nitrobenzene and acetone, which have k_2 10^6 m^3 mol^{-1} s^{-1}, and (*ii*) phenol and toluene, most of which have $k_2 < 10^5$ m^3 mol^{-1} s^{-1}. Both the order of magnitude and the patterns of the change of k_2 in the mixtures indicate that these two groups of reactions follow different

reaction mechanisms. While all the reactions involve electron transfer from a potential well in the solvent to a solute molecule, the transfer to toluene and phenol must be secured by a subsequent reaction, which is probably protonation by the solvent (3).

Nitrobenzene and acetone are efficient electron scavengers. The magnitudes of $k_2(e_s^-$ + nitrobenzene) and $k_2(e_s^-$ + ace-

tone) in 1-butylamine–water mixtures are similar to those in methanol–water and ethanol–water mixtures (3), 1-propanol–water mixtures (4), and all isomeric butanol–water mixtures (18). However, the values of $k_2(e_s^- + \text{nitrobenzene})$ and $(e_s^- + \text{acetone})$ in the alcohol-rich region of all alcohol–water mixtures are nearly independent of water content whereas the $k_2(e_s^- + \text{nitrobenzene})$ and $k_2(e_s^- + \text{acetone})$ in the amine-rich region of 1-butylamine–water mixtures decrease as the water content is increased to 70 mol%. These rate constants in 1-butylamine–water mixtures decrease as the viscosity increases (19, 20). The reaction with nitrobenzene is diffusion controlled. The reaction with acetone is an order of magnitude slower and has an approximately 5 kJ mol^{-1} larger activation energy (Table 3), but the rates in the mixed solvents still correlate with solvent fluidity (Fig. 5).

Phenol and toluene are less efficient scavengers. Although the orders of magnitude of $k_2(e_s^- + \text{phenol})$ and $k_2(e_s^- + \text{toluene})$ in 1-butylamine–water mixtures at 298 K are in the same range as in alcohol–water mixtures (3, 4, 17, 21), the pattern of the change in the mixed solvents is quite different from that in alcohol–water mixtures. Instead of having a minimum at 60–70 mol% water as in alcohol–water mixtures, $k_2(e_s^- + \text{phenol})$ and $k_2(e_s^- + \text{toluene})$ have a maximum at 50 mol% water in 1-butylamine, and a sharp minimum at ~99 mol% water (Fig. 5). The values of $k_2(e_s^- + \text{toluene})$ could not be measured in 99.0–99.8 mol% water due to very low rate constants and low solubility of toluene in the solvents. The values of k_2 increase as the values of viscosty and E_{Amax} *increase* in the amine-rich region.

The increase of $k_2(e_s^- + RC_6H_5)$, R = CH_3 or OH, with increasing viscosity η (Fig. 5) is reminiscent of the behavior of $k(e_s^- + NO_{3,s}^-)$ in pure alcohols on increasing the length of the alkyl chain (12, 22). In both cases a transient intermediate reacts with the solvent (3, 12, 16, 21, 22), and the probability of this reaction increases superlinearly with increasing duration τ of the $[e_s^-, S_S]$ encounter pair. For toluene and phenol:

$$[4] \qquad e_s^- + RC_6H_5 \rightleftharpoons [e_s^-, RC_6H_5] \rightleftharpoons [RC_6H_5^-]$$

$$[5] \qquad [RC_6H_5^-] + HNHC_4H_9 \text{ or } HOH \rightarrow R\dot{C}_6H_6 + {}^-NHC_4H_9 \text{ or } {}^-OH$$

In the $(e_s^- + NO_{3,s}^-)$ reaction k_2 increased approximately linearly with η, which means $k_2 \propto \tau^2$, whereas in the RC_6H_5 reaction between zero and 30 mol% water in 1-butylamine k_2 increases approximately as η^3, which means $k_2 \propto \tau^4$. There seems to be an additional effect in the latter reaction, and we suggest it is that water, being a stronger acid than is the amine (17), is a better protonating agent for the phenylide ion in reaction [5].

At water contents >30 mol% the values of $k_2(e_s^- + RC_6H_5)$ increase less rapidly, and from 50 to 99 mol% water they decrease (Fig. 5). The decrease is attributed to nonhomogeneous solvation of the reacting entities: in the water-rich solvents e_s^- is preferentially solvated by the water, while phenol and toluene are selectively solvated by the butylamine. It becomes progressively more difficult for the e_s^- and RC_6H_5 to come within the reaction radius of each other.

The increase of $k_2(e_s^- + RC_6H_5)$ on going from 99.0 to 99.5, 99.8, and 100 mol% water is attributed to the RC_6H_5 being progressively less "coated" by amine molecules, thereby facilitating reactions [4] and [5]. The compressibility of solutions of butylamine in water has a minimum at 98.3 mol% water, which implies optimal packing of the molecules (23). This might be related to the minimum reaction rate, which we observed at our composition closest to 98.3%, namely, 99.0%. The partial molar volume of 1-butylamine has a minimum at 99.1 mol% water (23).

The first-order decay rates in the solvents without added solute showed a solvent composition dependence similar to those of the reactions with phenol and toluene (see $k_1[I_S]$ in Table 2). It therefore appears that the impurities react inefficiently with e_s^-, and are probably olefinic.

Smoluchowski–Stokes–Debye model

In the study of the reactions of e_s^- with organic solutes, the Smoluchowski–Stokes–Debye model has been used (3, 18, 24). The diffusion-controlled rate constant $k_2(e_s^- + S)$ for reaction of e_s^- with a polar solute S is approximately related to the solvent viscosity η by the Smoluchowski–Stokes–Debye equation (3, 8, 10, 25):

$$[6] \qquad k_2 = \frac{N_A k_B T}{1.5\eta}\left(\frac{1}{r_e} + \frac{1}{r_s}\right)(R_e + R_S)\kappa f = \frac{N_A k_B T}{1.5\eta} \cdot \frac{1}{r_d} \cdot f\kappa R_r$$

where N_A is Avogrado's constant, k_B is Boltzmann's constant, T is temperature, r_x and R_x are the effective radii for diffusion and reaction, respectively, κ is the probability that reaction occurs during one encounter, r_d is the effective radius for mutual diffusion of e_s^- and solute, R_r is the average center-to-center reactant separation when reaction occurs, κR_r is considered as an effective reaction radius, and the Debye factor f is given by:

$$[7] \qquad f = \frac{x}{(e^x - 1)}$$

$$[8] \qquad x = -\frac{\mu\xi^2}{4\pi\varepsilon_0\varepsilon R_r k_B T}$$

where x is the ratio of the Coulombic interaction energy of the reactants at R_r to thermal agitation energy $k_B T$, ε is the relative permittivity (26) of the medium between the reactants at separation R_r, and μ is the dipole moment of the solute reactant.

Equation [6] suggests that for diffusion-controlled reactions,

$$[9] \qquad \eta k_2 \approx \text{constant}$$

The solvent composition dependences of ηk_2 are shown in Fig. 6. The relatively efficient reactants nitrobenzene and acetone approximately follow relation [9]. However, the inefficient reactants phenol and toluene do not, as might be expected from the preceding discussion.

Correlation of small values of k_2 with $-dE_{\text{Amax}}/dT$

The temperature coefficient of the optical obsorption energy of e_s^- in these solvents, $-dE_{\text{Amax}}/dT$, has a minimum at 50

Fig. 6. Solvent composition dependence of ηk_2 in 1-butylamine–water mixtures at 298 K. The symbols are as in Fig. 5. ×, relative permittivity ε (26).

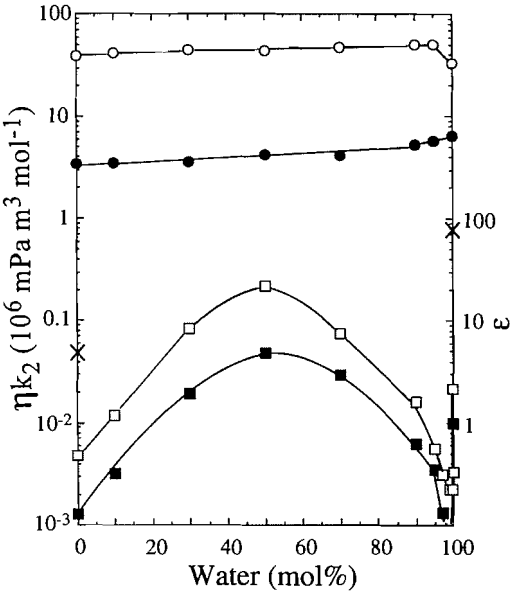

Fig. 7. Correlations of k_2 (phenol and toluene) with $-dE_{Amax}/dT$ (14) in 1-butylamine–water mixtures at 298 K. □, phenol; ■, toluene.

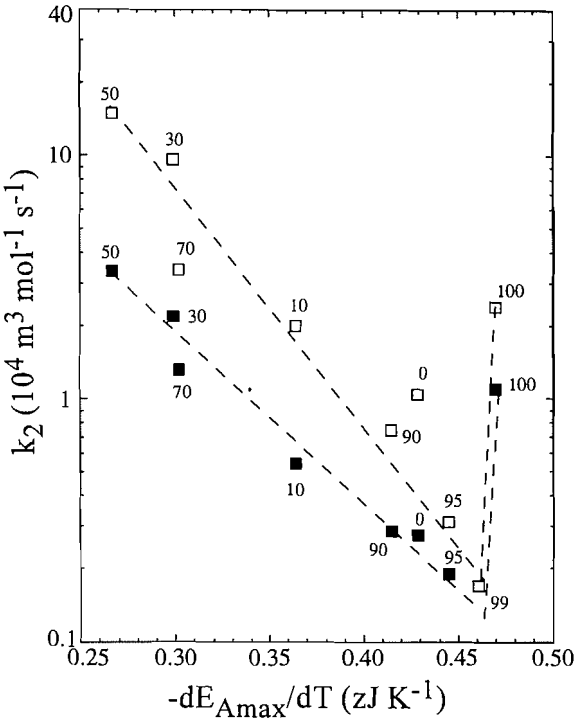
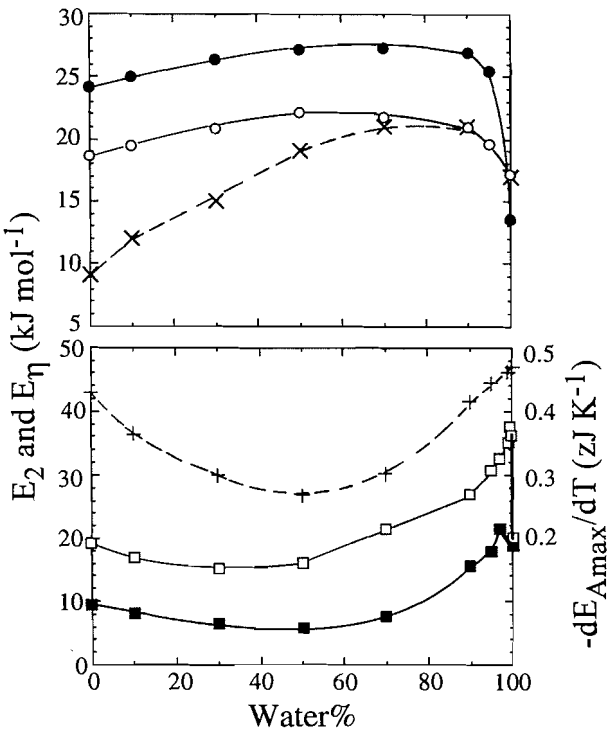


mol% water (14), where $k_2(e_s^- + \text{phenol or toluene})$ has a maximum (Fig. 5). A plot of log k_2 against $-dE_{Amax}/dT$ is roughly linear, with the exception of the 99–100% water zone (Fig. 7). We attributed the two sides of the hump in Fig. 5 to different effects, and we cannot interpret the approximate correlation shown in Fig. 7. We display it as a clue to future interpretation.

Fig. 8. Solvent composition dependence of E_2. Symbols are as in Fig. 5, plus E_η(×) and $-dE_{Amax}/dT$(+) in 1-butylamine–water mixtures.



Activation energies

The solvent dependences of the activation energies of reaction, E_2, are compared with those of viscosity, E_η, and the temperature coefficient $-dE_{Amax}/dT$ (Fig. 8). The variation of E_2 for the efficient reactions of e_s^- with nitrobenzene and acetone is qualitatively similar to that of E_η. The larger values of E_2 compared to E_η in the amine-rich solutions might be attributed to a larger mobility μ and activation energy of mobility E_η of electrons than of molecules in the amine. A similar situation was noted in *tert*-butanol solvent (10).

The variations of E_2 for the inefficient reactions of e_s^- with phenol and toluene are in the opposite direction of those for the efficient reactions, and are in the same direction as those in $-dE_{Amax}/dT$ (Fig. 8). The zone 99–100% water remains an exception. The decrease of E_2 upon adding water to 1-butylamine is attributed to the increased ease of reaction [5]. The increase of E_2 at water contents >50 mol% is attributed to the increased segregation of the reactants by selective solvation in the different components of the solvent, which makes it more difficult for the reactants to encounter each other. The decrease of $E_2(e_s^- + \text{phenol})$ on going from 99.8 to 100.0 mol% water is due to the decrease of that segregation.

The values of both k_2 and E_2 for $(e_s^- + \text{toluene})$ are much smaller than those for $(e_s^- + \text{phenol})$ in all the solvents that contain 1-butylamine (Figs. 5 and 8). Thus the overall entropy of activation of the multi-step reactions is much more negative for the toluene than for the phenol reaction. Phenol is hydrogen bonded to the solvent, whereas toluene is not. In the amine-containing solvents, the ratio of concentrations of amine/toluene was always ≥10, and of amine/phenol was ≥2.

We think the toluene and phenol were always clustered by 1-butylamine. It is possible that the lack of hydrogen bonding of toluene to the solvent, and the presence of it for phenol, affects the relative orientations of the e_s^- and toluene or phenol as they diffuse together in reaction [4], and affects rotatability of the solvent molecules as the protonation reaction [5] occurs.

The reason for the minimum in $-dE_{Amax}/dT$ remains unknown.

The use of bisphthalonitriles in the synthesis of side-strapped 1,11,15,25-tetrasubstituted phthalocyanines

Clifford C. Leznoff and David M. Drew

Abstract: Nucleophilic aromatic substitution reactions of 3-nitrophthalonitrile yield 3-hydroxyphthalonitrile and 3-neopentoxyphthalonitrile, the latter of which condensed to 1,8,15,22-tetraneopentoxyphthalocyanine as a mixture of isomers. Bisphthalonitriles such as 1,3-bis(2′,3′-dicyanophenoxy)-2,2-dipentylpropane, 1,3-bis(2′,3′-dicyanophenoxy)-2,2-diethylpropane, 1,3-bis(2′,3′-dicyanophenoxy)-2,2-dioctylpropane, and 1,3-bis(2′,3′-dicyanophenoxy)-2-methyl-2-trityloxymethylpropane all gave bis-crown-like 1,11,15,25-tetrasubstituted phthalocyanines as pure compounds when treated with lithium octoxide in 1-octanol at 196°C. A host of nine other bisphthalonitriles including 1,5-bis(2′,3′-dicyanophenoxy)-3-oxapentane, 1,1-bis(2′,3′-dicyanophenoxymethyl)cyclohexane, 1,2-bis(2′,3′-dicyanophenoxymethyl)benzene, and 2,5-bis(2′,3′-dicyanophenoxymethyl)furan did not dimerize to mononuclear phthalocynaines. The "*gem* dimethyl" effect was suggested as a reason for the successful macrocyclizations.

Key words: nucleophilic aromatic substitution, phthalonitriles, bisphthalonitriles, 1,11,15,25-tetrasubstituted phthalocyanines.

Résumé : Les réactions de substitutions aromatiques nucléophiles du 3-nitrophtalonitrile conduisent au 3-hydroxyphtalonitrile et au 3-néopentoxyphtalonitrile; ce dernier se condense pour conduire à la 1,8,15,22-tétranéopentoxyphtalocyanine sous la forme d'un mélange d'isomères. Lorsqu'on soumet les bisphtalonitriles, tels que les 1,3-bis(2′,3′-dicyanophénoxy)-2,2-dipentylpropane, 1,3-bis(2′,3′-dicyanophénoxy)-2,2-diéthylpropane, 1,3-bis(2′,3′-dicyanophénoxy)-2,2-dioctylpropane et 1,3-bis(2′,3′-dicyanophénoxy)-2-méthyl-2-trityloxyméthylpropane, à un traitement par de l'octylate de lithium en présence d'octan-1-ol à 196°C on obtient toujours des phtalocyanines 1,11,15,25-tétrasubstituées à l'état pur qui ressemblent à des couronnes doubles. Neuf autres bisnaphtonitriles, y compris les 1,5-bis(2′,3′-dicyanophénoxy)-3-oxapentane, 1,1-bis(2′,3′-dicyanophénoxyméthyl)cyclohexane, 1,2-bis(2′,3′-dicyanophénoxyméthyl)benzène et 2,5-bis(2′,3′-dicyanophénoxyméthyl)-furane, ne se dimérisent pas en phtalocyanines mononucléaires. L'effet «*gem*-diméthyle» a été suggéré pour expliquer le succès des macrocyclisations qui ont réussi.

Mots clés : substitution aromatique nucléophile, phtalonitriles, bisphtalonitriles, phtalocyanines 1,11,15,15-tétrasubstituées.

[Traduit par la rédaction]

Introduction

The synthesis of pure isomers of tetrasubstituted phthalocyanines (Pc) having one substituent in each of the benzene rings remains a difficult problem (1). Single isomers of 2,9,16,23- (2), 2,9,17,24- (3), and 1,8,15,22-tetrasubstituted phthalocyanines (4), and a 1,2-naphthalocyanine (5) have been prepared capitalizing on reactive substrates (2) or electronic (3) or steric constraints (4, 5) but methods towards the synthesis of pure 1,11,15,25-tetrasubstituted phthalocyanines have been only briefly reported by us in a preliminary communication (6). Recently, some specific pure Pc isomers have been separated by chromatography (7). We decided upon a "constrained" approach towards the synthesis of phthalocyanines having substituents in the 1,11,15,25 positions. If we could dimerize bisphthalonitriles with appropriate bridging groups, then 1,11,15,25-tetrasubstituted phthalocyanines containing bridging substituents (side straps) in the 1,25 and 11,15 positions would be obtained. The difficulty in this approach is the fact that polymerization would compete with dimerization. After exploring many different conditions we found that that condensation of bisphthalonitriles under high dilution at high temperatures for short reaction times led in some cases to the desired phthalocyanines as shown below.

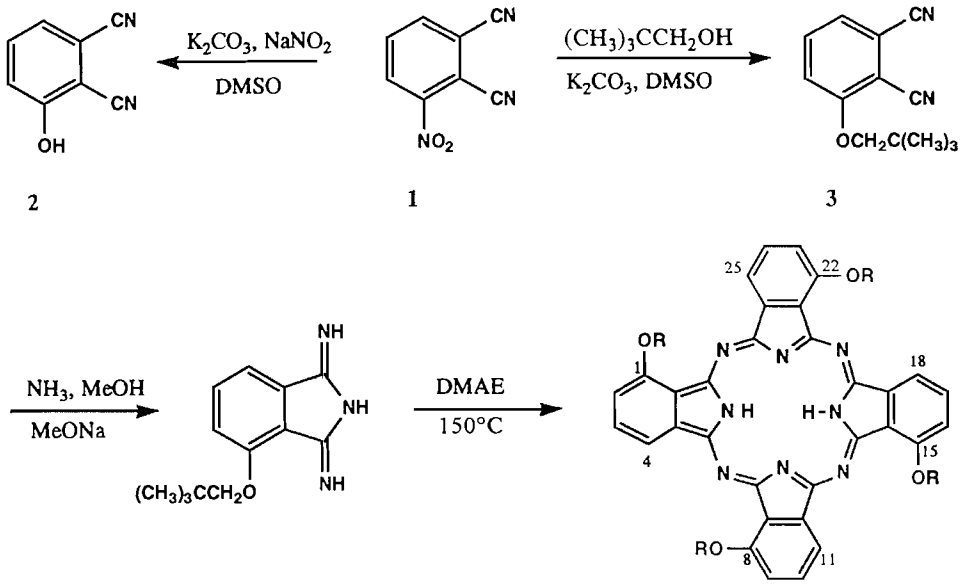
Results and discussion

Nucleophilic aromatic substitution reactions on 3-nitrophthalonitrile (**1**) (9) are not all that common (4, 8, 9) and hence we decided to examine some simple reactions of **1**. Thus treatment of **1** with K_2CO_3 and $NaNO_2$ in DMSO at reflux for 0.5 h, as for the preparation of 4-hydroxyphthalonitrile (10), led to 3-hydroxyphthalonitrile (**2**) in 43% yield. Similarly, treatment of **1** with neopentanol (2,2-dimethyl-1-propanol) and K_2CO_3 in DMSO at room temperature for *6 days* gave 3-neopentoxyphthalonitrile in 63% yield. The long reaction times were necessary to drive the reaction to completion probably due to steric hindrance of the substitution at the 3-position (4, 8) and the bulky alcohol used. Conversion of **3** to its diiminoisoindoline **4** proceeded normally (11, 12). Condensation of **4** at 150°C in 2-*N*,*N*-dimethylaminoethanol (DMAE) (11, 12)

Scheme 1.



gave 1,8,15,22-tetraneopentoxyphthalocyanine (**5**) in 16% yield as a mixture with its 1,8,15,25, 1,8,18,25, and 1,11,15,25 isomers (Scheme 1).

Having established that phthalocyanines containing bulky substituents at positions adjacent to the macrocyclic core are readily prepared, we directed our attention towards the preparation of bisphthalonitriles bridged at the 3-position, for eventual dimerization to 1,11,15,25-tetrasubstituted phthalocyanines. Earlier, we had suggested (12) that β-hydrogens on substituents could lead to β-elimination reactions under the basic conditions of Pc formation and hence we concentrated our attention on bridging groups containing no hydrogens at the β-position, particularly β,β-dialkyl groups. Thus, treatment of **1** with a series of β,β-disubstituted-1,3-propanediols, such as the known 2-methyl-2-trityloxymethyl-1,3-propanediols (**6**) (12), the commercially available 2,2-diethyl-1,3-propanediol (**7**), 2,2-dipentyl-1,3-propanediol (**8**), and 2,2-dioctyl-1,3-propanediol (**9**), and K_2CO_3 in dimethyl sulfoxide (DMSO) at 20°C[2] while evacuated (4, 6) gave the bisphthalonitriles **10–13** in 43–94% yields. Diols **8** and **9** were prepared by lithium aluminum hydride reduction of diethyl 2,2-dipentylmalonate (13) and diethyl 2,2-dioctylmalonate (14), respectively. Dimerization of **10–13** under high-dilution conditions with lithium octoxide in 1-octanol at 196°C for 10 min gave the 1,25:11,15-bis(side-strapped) phthalocyanines **14–17** in 7–21% yields. Pcs **14**, **16**, and **17** were readily metallated to their phthalocyaninato zinc(II) compounds **18–20** in 90% yield by heating with zinc acetate in a 1:1 mixture of pyridine and *N,N*-dimethylformamide for 20 h at reflux conditions (Scheme 2). Attempts at cleavage of the side-strapped Pcs **14**[3] and **19** as examples, using BBr_3 (15, 16) as previously described for 2,9,16,23-tetraneopentoxyphthalocyanine (17), simply gave recovered starting materials, while cleavage with AlI_3 (18) gave decomposition of the phthalocyanine macrocycle.

Phthalocyanines **14** and **18** existed as an unequal mixture of *cis* and *trans* isomers as shown by NMR spectroscopy while Pc **15** was too insoluble for useful studies. Indeed, the insolubility of **15** and the attendant difficulties of purification meant that satisfactory analysis could not be obtained for this compound, although we feel that confirmation of structure is on firm ground with a good HRMS (see Experimental). The problems of working with **15** in fact led to the design of Pcs **16** and **17** having larger alkyl chains generating soluble, more readily characterized Pcs. Pcs **16**, **17**, **18**, and **19** were all sufficiently soluble for easy separation and study. In an attempt to obtain symmetrical hydroxymethyl substituents at the β-position and also to tie back the β-substituents into a ring system so that subsequent cleavage might proceed more readily, 5,5-dihydroxymethyl-2-phenyl-1,3-dioxane (**21**) (19) and 1,1-dihydroxymethylcyclohexane (**22**) (20) were treated as above, but over a 12–16 day period, to give 5,5-bis(2′,3′-dicyanophenoxymethyl)-2-phenyl-1,3-dioxane (**23**) and 1,1-bis(2′,3′-(dicyanophenoxymethyl)cyclohexane (**24**) in 73 and 65% yields, respectively (Scheme 3). Neither **23** nor **24** could be induced to undergo formation of mononuclear phthalocyanines and it appeared that only polymeric pigments were formed.

In attempts to make a larger variety of side-strapped phthalocyanines, including those of crown ethers and benzylic ethers that could be more readily cleaved (4), we treated a host

[2] Side-products at higher temperatures and shorter reaction times included **2**, etherols such as 3-(2′,3′-dicyanophenoxy-2,2-diethylpropan-1-ol, and bis(2,3-dicyanophenyl)ether (BDPE), mp 223–226°C; FT-IR(cm^{-1}): 3087, 3035, 2238 (C≡N), 1565, 1461, 1270, 813; ^1H NMR (acetone-d_6) δ: 702 (m, 4H), 6.78 (d, 2H, J = 8 Hz); ^{13}C NMR (acetone-d_6) δ: 158.29, 136.95, 131.18, 124.76, 118.24, 115.81, 113.02, 108.87; EI-MS for $C_{16}H_6N_4O$, *m/z* (relative intensity): 270 (M^+, 100) 242 (13) 127 (10).

[3] The trityl groups in **14** were removed by BBr_3 to give a mixture in 31% yield of the appropriate *cis* and *trans* diols, as a light blue solid; EI-MS for $C_{42}H_{34}N_8O_6$, *m/z* (relative intensity): 746 (M^+, 100), 716 (20), 355 (18), 281 (22), 207 (37), 119 (39), 73 (42).

of known symmetrical diols such as diethylene glycol (**25**), 1,2-dihydroxymethylbenzene (**26**), 2,2′-bis(hydroxymethyl)biphenyl (**27**) (21), 5-*tert*-butyl-1,3-dihydroxymethylbenzene (**28**) (22), 2,5-dihydroxymethylfuran (**29**), and *cis*-2,5-bis(hydroxymethyl)tetrahydrofuran (**30**) (23) as before to give the new bisphthalonitriles **31–37** in 19–56% yields. Unfortunately, none of **31–37** cyclized to bis side-strapped phthalocyanines under our standard conditions described above.

It is curious that among the 13 symmetrical bisphthalonitriles prepared for this study, only **10–13** underwent dimerization to mononuclear phthalocyanines. With hindsight it is possible to see that perhaps the "*gem* dimethyl (Thorpe–Ingold) effect "(24–26) is operating here as only **10–13** have noncyclic β,β-dialkyl substituents. The *gem* dimethyl effect was originally promulgated to explain favoured cyclization reactions in five- to seven-membered rings containing β,β-dimethyl substituents, but was later expanded to macrocyclic ring systems (27).

Spectroscopic and physical properties

It is well known that electron-donating substituents at the 1, 4, 8, 11, 15, 18, 22, and 25 positions of the phthalocyanine nucleus (cf. **5**) result in an enhanced bathochromic shift of the Q-band in their UV–VIS spectra (1, 7, 28, 29), when compared to similar substitution at the 2, 3, 9, 10, 16, 17, 23, and 24 positions of the Pc nucleus. Thus, **5** shows a typical λ_{max} at 726 nm. Surprisingly, **14–17** exhibit λ_{max} values at 708–711 nm (Fig. 1) rather than the values at ~730 nm exhibited in related pure 1,8,15,22-alkoxy-substituted Pcs (4, 7) and another pure 1,11,15,25-alkoxy-substituted Pc (7). We believe that the nature of the alkoxy substituent constrained in a ring system may cause the lone pair of electrons to lie partially out of conjugation with the benzo groups. Cook et al. (29) noticed that in one of their octaalkoxyphthalocyanines containing additional chloro substituents at the 2, 3, 9, 10, 16, 17, 23, and 24 positions, the λ_{max} is shifted hypsochromically by about 20 nm relative to other octaalkoxyphthalocyanines, and this latter example could be regarded as a partially constrained phthalocyanine. As usual, the Pc zinc(II) derivatives **18–20** (Table 2, Fig. 2) exhibit λ_{max} values of the Q-band having a hypsochromic shift of 20–25 nm compared to their metal-free counterparts.

The UV–VIS spectrum of **19** (Fig. 2) showed a spectral profile consistent with a PcM of D_{4h} symmetry in which a single intense Q-band absorption is found. The single Q-band absorption in the UV–VIS spectrum (suggesting a PcM with D_{4h} symmetry) conflicts somewhat with the actual geometry of **19** in which the 1,25:11,15-bis(side-strapped) PcZn **18** is, on a macromolecular scale, of D_{2h} symmetry. This observation strongly suggests that the peripheral sidestrap substituents do not affect, or only very weakly affect, the Pc macrocycle molecular orbitals involved in the Q-band HOMO–LUMO electron transition. These results are markedly different from other D_{2h} "opposite" Pcs in which Q-band splitting for metallophthalocyanines is observed (30, 31).

The ^1H NMR of ZnPc **18** taken in THF-d_8 clearly showed the ABX splitting pattern generated by the aromatic hydrogens of the Pc macrocycle (doublet–triplet–doublet at 9.02, 7.99, and 7.68 ppm, respectively). As for metal-free **14**, the presence of two possible side strap isomers generated two multiplets at 5.38 and 5.17 ppm for the methylene CH_2 hydro-

Fig. 1. The electronic spectrum for metal-free bis side-strapped Pc (**16**).

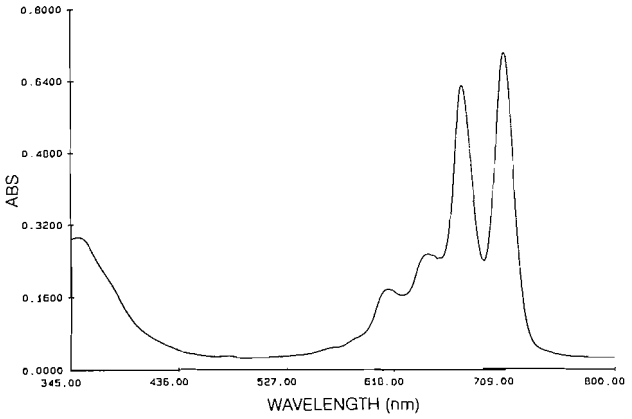

Fig. 2. The electronic spectrum of bis side-strapped zinc (II) Pc (**19**).

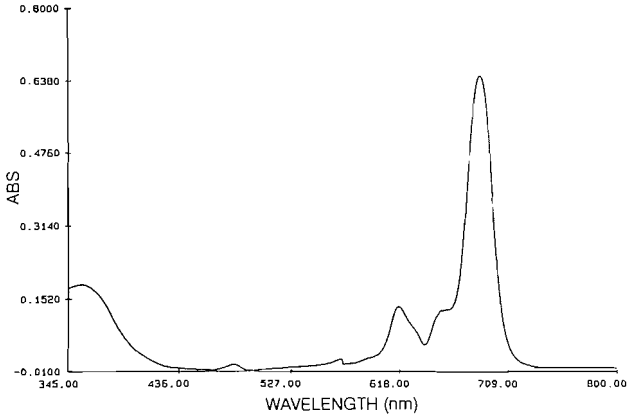

gens of the side-straps in addition to two pairs of singlets that arise from the 2'-methylene CH_2-OTr and 2'-methyl CH_3 hydrogens at 3.66,3.64 and 1.65,1.62 ppm, respectively.

The NMR spectrum of **17** was examined in the most detail as it was the most soluble of the bis side-strapped Pcs. The ^{1}H NMR spectrum of **17** in benzene-d_6 clearly showed the doublet–triplet–doublet signals arising from the ABX-spin-type aromatic hydrogens, and a singlet signal corresponding to the CH_2 hydrogens of the side straps. The internal N-H protons were evident as a broad proton signal shifted upfield to −6 ppm (6). Such a large upfield ^{1}H NMR chemical shift of the N-H hydrogens is typical for Pcs at high concentration or for cofacial binuclear Pcs (12, 32). This upfield chemical shift is a reflection of the strong cone of aromaticity generated by the ring current of the Pc macrocycle (32). At high Pc concentrations, or for Pcs that have a tendency toward cofacial π–π interaction (i.e., Pc aggregates, cofacial binuclear Pcs), the shielding imparted by the Pc macrocycle has profound effects upon the chemical shifts of hydrogens of proximal Pc neighbours.

These shielding effects experienced by the aromatic, side-strap, and internal hydrogens were explored by the acquisition of ^{1}H NMR spectra at varying concentrations of **17** in THF-d_8 (Table 1, Fig. 3 and 4). These data indicate that as the Pc solution concentration increases, Pc aggregation (or π–π stacking)

Table 1. ^{1}H NMR dilution shifts (ppm) of aromatic, side-strap, and internal hydrogens for Pc **17**.

17 (mol/L)	−log **17**	Aryl H-a	Aryl H-b	Aryl H-c	Strap CH_2	N-H
0.0050	2.301	7.75	7.27	6.83	4.32	−5.79
0.0025	2.602	7.91	7.39	6.96	4.45	−5.44
0.0005	3.301	8.32	7.67	7.25	4.74	−4.34

occurs, and results in shifts of Pc macrocycle (and side-strap) hydrogen signals to higher field. The shielding effects imparted by the Pc macrocycle affect the internal N-H hydrogens, the aromatic hydrogens, and the side-strap methylene (CH_2) hydrogens to varying degrees. For instance, the internal N-H hydrogens show the largest changes in chemical shift ($\Delta\delta$ = 1.45 ppm), whereas the change in chemical shift of the side-strap hydrogens is smaller ($\Delta\delta$ = 0.41 ppm). It appears that, in general, the hydrogen atoms closest to the core of the phthalocyanine macrocycle are most strongly influenced by the cone of aromaticity and π–π stacking shielding effects. This information can be used in assigning the signals observed in the ^{1}H NMR spectrum to the three types of Pc ring hydrogens. It would seem plausible that the aromatic hydrogen experiencing the greatest change in chemical shift as a result of changing the Pc concentration would be the aromatic hydrogen closest to the Pc core. In Pc isomers such as **17**, these would be the hydrogens at the 4, 8, 18, and 22 positions of the macrocycle and would be represented by one of the two doublet signals observed in the aromatic region of the ^{1}H NMR spectrum. The furthest downfield doublet signal (i.e., that closest to 8 ppm) exhibited the largest change of chemical shift ($\Delta\delta$ = 0.56 ppm) relative to the doublet found near 7 ppm ($\Delta\delta$ = 0.42 ppm). Even though there was only a one order of magnitude change in the concentration of Pc **17**, the data obtained from this experiment suggest that the 4-, 8-, 18-, and 22-position hydrogens can be assigned to this most downfield doublet signal (H-a in Fig. 3). This allowed an assignment of the highest field aromatic doublet signal (ca. 7 ppm) to the hydrogens at the 2, 10, 16, and 24 positions (H-c, i.e., adjacent to the side strap) and, intuitively, the triplet signal (ca. 7.5 ppm) to the hydrogens at the 2, 9, 16, and 23 positions of the Pc macrocycle. These hydrogen assignments were confirmed upon acquisition of a NOESY-NMR spectrum of **17**. Through-space NOE effects were observed between the side-strap CH_2 and macrocycle H-c hydrogens (i.e., the hydrogens in the position *ortho* to the side-strap), further validating the Pc ring hydrogen assignments determined from the ^{1}H NMR dilution shift experiment.

All new phthalocyanines and phthalonitriles exhibited parent ions in their FAB or EI mass spectra. IR data and good elemental analysis were consistent with the assigned structures. The directed syntheses of phthalocyanines having the unique substitution pattern at the 1,11,15,25 positions have been demonstrated by constraining the substitution pattern with bridges at the 1,25 and 1,11 positions.

Experimental

All organic solvents were dried by appropriate methods and distilled before use. All reagents were freshly distilled, or

Fig. 3. ^{1}H NMR dilution shifts of aromatic, side-strap, and internal hydrogens for Pc **17** taken in THF-d_8.

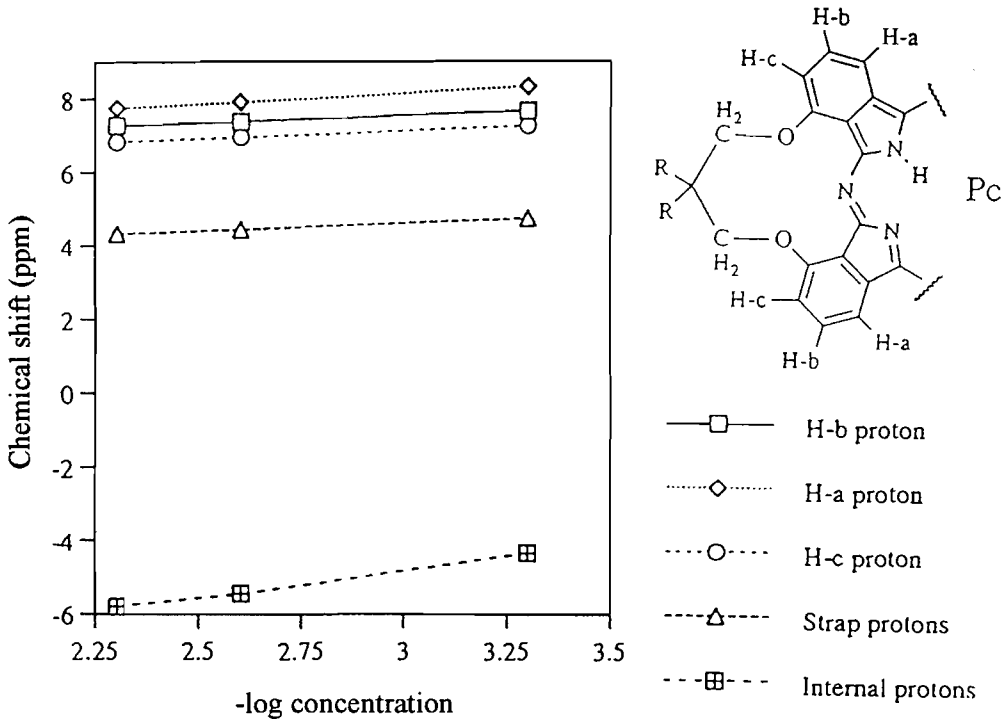

Fig. 4. The ^{1}H NMR spectrum of the downfield region of Pc **17** at 2.5×10^{-4} M in THF.

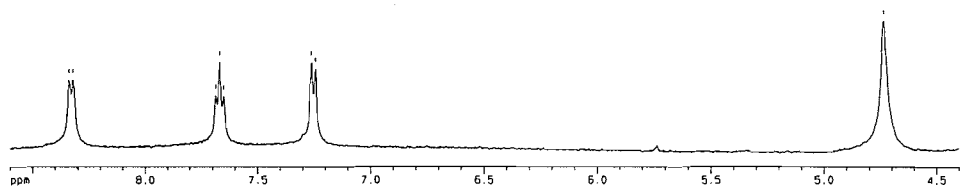

were recrystallized and then dried under reduced pressure, before use. Anhydrous potassium carbonate (K_2CO_3) was finely ground, oven dried at 250°C for 36 h, and then stored in sealed vials. Unless otherwise noted, magnetic stirring methods under an inert atmosphere (Matheson High Purity argon) were utilized during distillation or reaction processes, and round-bottom glass vessels chosen such that the quantity of reagents and solvent did not exceed half of the available volume. Water-cooled condensers were used if reaction processes were held near, or at, reflux conditions. Melting points were determined using a Kofler hot-stage melting point apparatus and are reported uncorrected. Infrared spectroscopy was performed on either a Pye Unicam SP3-200 or a Perkin Elmer 1310 infrared spectrophotometer and FTIR spectroscopy was performed on a Unicam Mattson 3000 FTIR spectrometer using samples prepared as KBr discs unless otherwise noted. Mass spectral analyses were performed by Dr. B. Khouw (York University, North York, Ontario, Canada), Dr. R. Smith (McMaster University, Hamilton, Ontario, Canada), and Dr. R. N. Cerny (Midwest Center for Mass Spectrometry, University of Nebraska–Lincoln, Lincoln, Nebraska, U.S.A.). HRMS were performed by Dr. R. Smith (McMaster University, Hamilton, Ontario, Canada). Nuclear magnetic resonance (NMR) spectroscopy was performed at 295–300 K unless otherwise noted, using either a Bruker Aspect AM3000 or a Bruker ARX 400 high-field Fourier Transform instrument. Chemical shifts are reported in parts per million relative to a tetramethylsilane (TMS) internal standard. Splitting patterns of proton resonances are described as singlets (s), doublets (d), triplets (t), quartets (q), doublets of doublets (dd), multiplets (m), or as broad signals (br). Coupling constants for signals other than singlets and multiplets are reported in hertz. ^{13}C NMR resonances are reported as the proton-decoupled chemical shifts. In addition to one-dimensional (1D) ^{1}H NMR and ^{13}C NMR, compounds requiring absolute structure determination were elucidated using combinations of 2D ^{1}H NMR (COSY and NOESY) and 2D carbon–proton (XH) correlations.

3-Hydroxyphthalonitrile (2)

In a manner similar to that previously described in the preparation of 4-hydroxyphthalonitrile (10), 865 mg (5.00 mmol) of 3-nitrophthalonitrile (**1**) (8, 9) was dissolved in 5 mL of DMSO. K_2CO_3 (760 mg, 5.51 mmol) and $NaNO_2$ (345 mg,

5.00 mmol) were added and the mixture heated at reflux for 30 min. After cooling, the reaction mixture was diluted with 20 mL of H_2O, and the mixture acidified to pH 3 with HCl and then centrifuged. The pellet was collected, resuspended in distilled water, homogenized by sonication, and again centrifuged. The supernatant liquid was discarded and the residue washed with methanol. The highly insoluble orange crude product was purified by column chromatography, using silica gel as the adsorbent and acetone as the eluting solvent. Evaporation of the solvent under reduced pressure gave a yellow solid that was recrystallized from glacial acetic acid to give 312 mg (43%) of **2** as an amorphous pale yellow solid (TLC: 10% CH_3CN–Bz, R_f = 0.03), mp 233–235°C; FT-IR (cm^{-1}): 3228br (O-H), 3072, 2255 (C≡N), 2230 (C≡N), 1584, 1467, 1316, 975, 807; ^1H NMR (DMSO-d_6) δ: 7.62 (t, 1H, J = 8 Hz), 7.39 (d, 1H, J = 8 Hz), 7.29 (d, 1H, J = 8 Hz); ^{13}C NMR (DMSO-d_6) δ: 162.42, 135.09, 123.75, 122.08, 116.16, 114.75, 114.50, 100.68; EI-MS m/z (%): 144 (M^+, 100), 116 (85), 89 (12). Anal. Calcd. for $C_8H_4N_2O$: C 66.67, H 2.78, N 19.44; found: C 66.77, H 2.95, N 18.76.

3-Neopentoxyphthalonitrile (3)

Compound **3** was prepared in similar fashion to 4-neopentoxyphthalonitrile (12) from 2.60 g (15 mmol) of 3-nitrophthalonitrile (**1**), 2.65 g (30 mmol) of neopentanol (3,3-dimethyl-1-propanol), and 5.0 g (36 mmol) of K_2CO_3 in 14 mL of DMF. A drying tube was used to maintain anhydrous conditions over the course of the 6 day reaction period required for complete consumption of **1**. The reaction mixture was poured into 100 mL of ice-cooled water and the organic products extracted with 3 x 30 mL of EtOAc. The EtOAc extracts were combined, washed once with 70 mL of cold water, once with 10 mL of brine, and then dried over $MgSO_4$. The drying agent was removed by filtration and the filtrate evaporated under reduced pressure to give 2.88 g of a crude product. The crude product was purified by column chromatography using 20% EtOAc – petroleum ether as the eluting solvent and then by recrystallization from EtOAc–hexane to give 1.77 g of white crystalline **3** (mp 120–121.5°C). A second crop of **3** was obtained from the mother liquor by addition of hexane followed by cooling to 5°C (0.24 g, mp 119–120.5°C). The combined yield of **3** was 2.01 g (62.6%) (TLC: 20% EtOAc – petroleum ether, R_f = 0.30); IR (cm^{-1}): 3080, 2950, 2220 (C≡N), 1580, 1470, 1300, 1055 (C-O), 790; ^1H NMR ($CDCl_3$) δ: 7.61 (t, 1H, J = 8 Hz), 7.33 (d, 1H, J = 8 Hz), 7.20 (d, 1H, J = 8 Hz), 3.74 (s, 2H), 1.10 (s, 9H); ^{13}C NMR ($CDCl_3$) δ: 161.72, 134.49, 124.84, 116.87, 116.81, 115.34, 112.87, 104.94, 79.51, 32.05, 26.33; EI-MS m/z (%): 214 (M^+, 5.6), 199 (12.5), 116 (5.3), 71 (100), 43 (84). Anal. calcd. for $C_{13}H_{14}N_2O$: C 72.87, H 6.59, N 13.07; found: C 73.20, H 6.60, N 13.23.

4-Neopentoxy-1,3-diiminoisoindoline (4)

Sodium methoxide was prepared from methanol (25 mL) and cleaned sodium metal (35 mg, 1.5 mmol). When methoxide formation was complete, 374.5 mg (1.750 mmol) of **3** was added, the mixture heated to reflux, and gaseous NH_3 bubbled through the solution. After 4.5 h of NH_3 addition the solution colour changed from colourless to light yellow. A small aliquot of the solution was removed and the solvent evaporated under reduced pressure. The absence of a C≡N stretch in the IR spectrum of this sample indicated that the reaction was complete. The reaction mixture was cooled to room temperature (RT) and concentrated to dryness under reduced pressure to give 467.1 mg of crude **4** (TLC: 20% EtOAc – petroleum ether, R_f = 0.01). The yellowish crude product was not further purified and was used immediately in the preparation of PcH_2 **5**; IR (cm^{-1}): 3460–3150br, 3320, 2980, 1605, 1480, 1260, 1055.

1,8,15,22-Tetraneopentoxyphthalocyanine (5)

A solution of 467 mg (1.75 mmol) of diiminoisoindoline **4** in 3 mL of 2-*N,N*-dimethylaminoethanol (DMAE) was heated at 150°C (silicon oil bath) for 36 h. The mixture was cooled to RT and the dark green-black slurry poured into 15 mL of cold water. Cold methanol (30 mL) was added, the mixture homogenized, and the fine precipitate centrifuged and collected in six fractions. The supernatant liquid from each fraction was discarded, and the pellets were resuspended in 5 mL of methanol and centrifuged. This centrifugation procedure was repeated until the supernatant liquid was almost colourless (four cycles). The pellets were combined to give 148 mg of crude material that was purified by flash chromatography using toluene as the eluting solvent. The first product eluted was concentrated under reduced pressure to give 58.6 mg (16%) of PcH_2 **5** as a dark blue, shining solid (TLC: 2% 2-methoxyethanol–toluene, R_f = 0.70), mp > 325°C; UV–VIS (THF) λ_{max} (nm): 318, 354, 630, 664, 696, 726; IR (cm^{-1}): 3280 (N-H), 2950, 1580, 1490, 1330, 1250 (Ar-O-C), 1055, 1035, 1000, 740s; ^1H NMR (THF-d_8) δ: 9.30–7.54 (m, 12H), 4.74–4.23 (m, 8H), 1.64–1.19 (m, 36H), −0.18 (m, 2H); EI-MS m/z (%): 858 (M^+, 100), 578 (17), 205 (30), 71 (18), 28 (29). Anal. calcd. for $C_{52}H_{58}N_8O_4$: C 72.73, H 6.76, N 13.05; found: C 72.56, H 6.60, N 12.87.

General methods of bisphthalonitrile syntheses

Method I (refs. 4, 33)

The distilled or recrystallized diol was placed in a 50 mL round-bottom flask equipped with a magnetic stirrer and distilled DMSO or DMF was added (5 mL/mmol diol) and heated to 50°C. Anhydrous K_2CO_3 (3–4 molar equiv.) and 2.2–2.5 equivalents of 3-nitrophthalonitrile (**1**) (8, 9) were added, the joint was well greased, fitted with a $MgSO_4$ drying tube, and the slurry stirred at rt, producing a pink-red coloured heterogeneous mixture. Two additional 0.25 equivalents of K_2CO_3 were then added at 24 h intervals and the mixture stirred for an additional 3 days or until all of **1** had been consumed. At each 24 h interval, the reaction slurry was briefly homogenized by sonication and the component profile monitored by TLC (10% CH_3CN–Bz).

At the end of the reaction period the mixture was poured into ice-water, the flask rinsed with water, and the rinsings were added to the ice-water. The orange-brown precipitate was collected by centrifugation, washed with 40 mL of 10% $NaHCO_3$ (aq.) (removing red-coloured products and yellow-coloured 3-hydroxyphthalonitrile (**2**)), and then with water. The residue was then washed with methanol, removing yellow coloured materials (mono-reacted diol and any excess **1**). The crude off-white coloured product was analyzed by TLC and recrystallized from either hot ethyl acetate, methanol, acetone, benzene, or acetonitrile. If TLC analysis indicated the presence of impurities (in particular, BDPE[2]) in excess of approx-

imately 15%, the crude product was first purified by column chromatography using silica gel adsorbant and 10% CH_3CN–Bz as the eluting solvent and then recrystallized. The white bisphthalonitrile was dried overnight at 70°C at 10^{-3} Torr (1 Torr = 133.3 Pa).

Method II

The distilled or recrystallized diol was placed in a 50 mL round-bottom flask equipped with a magnetic stirrer and distilled DMSO was added (5 mL/mmol diol). Anhydrous K_2CO_3 (0.54 equiv.) and 0.50 equivalent of **1** were added; the joint was well greased and then fitted with a Quick-Fit stopcock valve. The flask was evacuated to an internal pressure of approximately 20 Torr, the valve closed, and the mixture stirred rapidly at rt, immediately producing a pale pink heterogeneous mixture.

At 24 h intervals, the reaction slurry was briefly homogenized by brief sonication (with swirling) and the component profile monitored by TLC (10% CH_3CN–Bz). The flask was reevacuated and the slurry stirred. If all of **1** had been consumed, additional aliquots of carbonate (0.54 equiv.) and of **1** (0.50 equiv.) were added prior to evacuation and stirring. After the addition of 2.20–2.50 equivalents of **1**, the mixture was stirred for an additional 24 h and then monitored by TLC. Additional K_2CO_3 (0.5–1.5 equiv.) was added if unreacted **1** was present and the mixture then stirred for a further 24 – 96 h. The reaction mixture was then worked up as for Method I.

2,2-Dipentylpropan-1,3-diol (8)

In a manner similar to that previously described (19), a solution of 3.00 g (10.0 mmol) of diethyl 2,2-dipentylmalonate (13) in 4 mL of Et_2O was added dropwise to a stirred 5–10°C suspension of 1.15 g (30.3 mmol) of lithium aluminum hydride ($LiAlH_4$) in 25 mL of Et_2O. After addition of the diester, the mixture was heated at reflux for 2 h and then stirred at RT overnight. Active $LiAlH_4$ was quenched by addition of 2 mL of EtOAc and then 2 mL of 95% EtOH. The inorganic salts were removed by filtration through Celite, washed with Et_2O, and the filtrate was concentrated to dryness under reduced pressure. The oily residue was dissolved in 30 mL of Et_2O and extracted successively with 20 mL portions of 6 M NaOH, 4 M HCl, twice with 40 mL of H_2O, and finally with one 10 mL portion of brine. The organic phase was dried over $MgSO_4$ and then filtered. The filtrate was evaporated under reduced pressure to give 903 mg of a pale yellow oil. Distillation of this oil under reduced pressure gave 800 mg (37%) of diol **8** as a clear, colourless oil, bp 114–117°C/5 × 10^{-3} Torr; ^{1}H NMR ($CDCl_3$) : 3.92 (s, 2H, O*H*), 3.52 (s, 4H, CH_2OH), 1.37–1.24 (m, 16H, 4 × CH_2), 0.90 (t, 6H, J = 7 Hz, CH_3); ^{13}C NMR ($CDCl_3$) δ: 69.45, 41.03, 32.77, 30.80, 22.58, 22.52, 14.04; CI-MS (NH_3) *m/z* (%): 234 ($M^+ + 1 + NH_3$, 100). Hygroscopic **8** was analyzed as its product **12**.

2,2-Dioctylpropan-1,3-diol (9)

In a manner similar to the preparation of diol **8**, a solution of 7.75 g (20.0 mmol) of diethyl 2,2-dioctylmalonate (14) in 30 mL of Et_2O was added dropwise to a stirred 5–10°C suspension of 3.00 g (80.0 mmol) of $LiAlH_4$ in 50 mL of Et_2O. After addition of the diester, the mixture was heated to reflux for 2 h and then stirred at RT overnight. Active $LiAlH_4$ was quenched by addition of 5 mL of EtOAc and then 5 mL of 95% EtOH (aq.). The inorganic salts were removed by filtration through Celite, washed with Et_2O, and the filtrate was concentrated to dryness under reduced pressure. The sticky white residue was dissolved in 60 mL of Et_2O and extracted successively with 40 mL portions of 6 M NaOH, 4 M HCl, twice with 40 mL of H_2O, and finally with one 10 mL portion of brine. The organic phase was dried over $MgSO_4$ and evaporated under reduced pressure to give a yellowish oil. Distillation of the residue under reduced pressure gave 4.13 g (69%) of diol **9** as a colourless viscous oil that slowly solidified to a white wax at RT (23°C), bp 159–162°C/5 × 10^{-3} Torr; IR (cm^{-1}): 3500–3200br (OH), 2950, 2860, 1470, 1380w, 1030, 720; ^{1}H NMR ($CDCl_3$) δ: 3.56 (s, 4H), 1.27–1.22 (br m, 30H), 0.88 (t, 6H, J = 7 Hz); ^{13}C NMR ($CDCl_3$) δ: 69.47 (CH_2OH), 41.00 (4°*C*), 31.88, 30.79, 30.58, 29.55, 29.32, 22.85, 22.66, 14.08 (CH_2CH_3); EI-MS *m/z* (%): 282 (2), 269 (22), 252 (19), 154 (22), 139 (27), 111 (33), 97 (60), 83 (79), 69 (100). Anal. calcd. for $C_{19}H_{40}O_2$: C 76.00, H 13.42; found: C 76.43, H 13.96.

1,3-Bis(2′,3′-dicyanophenoxy)-2-methyl-2-trityloxymethylpropane (10)

Bisphthalonitrile **10** was prepared by Method II from 0.900 g (2.49 mmol) of diol **6** (12), 1.159 g (6.70 mmol) of 3-nitrophthalonitrile (**1**), and 1.460 g (10.6 mmol) of K_2CO_3 in 20 mL of DMSO at RT over a 6 day period. Aqueous work-up and EtOH washing of the crude product gave a pink coloured crude product. Recrystallization of this crude product from EtOAc–hexanes gave 1.44 g (94%) of white crystalline **10** (TLC: 10% CH_3CN–Bz, R_f = 0.85), mp 233–235°C; IR (cm^{-1}): 3090, 2920, 2220 (C≡N), 1580, 1450, 1290, 1060, 790, 700; ^{1}H NMR (CD_3CN) δ: 7.72 (t, 2H, J = 8 Hz), 7.5–7.2 (m, 19H), 4.22 (s, 4H), 3.30 (s, 2H), 1.27 (s, 3H); ^{13}C NMR (acetone-d_6) δ: 162.02, 144.71, 136.30, 129.42, 128.63, 127.84, 126.46, 118.73, 117.00, 116.25, 113.76, 105.07, 87.43, 72.02, 64.50, 41.83, 17.58; EI-MS *m/z* (%): 614 (M^+, 6), 537 (9), 243 (100), 165 (35), 105 (29). Anal. calcd. for $C_{40}H_{30}N_4O_3$: C 78.19, H 4.88, N 9.12; found: C 77.66, H 4.75, N 9.30.

1,3-Bis(2′,3′-dicyanophenoxy)-2,2-diethylpropane (11)

Bisphthalonitrile **11** was prepared by Method II from 692 mg (5.23 mmol) of commercially available 2,2-diethylpropan-1,3-diol (**7**), 2.00 g (11.56 mmol) of **1**, and 3.05 g (22.1 mmol) of K_2CO_3 in 10 mL of DMSO over a 7 day period. The yield of off-white solid **11**, after purification by column chromatography using 10% acetonitrile–benzene as eluting solvent and recrystallization from acetonitrile, was 870 mg (43%) (TLC: 10% CH_3CN–Bz, R_f = 0.79), mp 216–218°C; IR (cm^{-1}): 3080, 2960, 2220 (C≡N), 1580s, 1470, 1450, 1290, 1050 (C-O), 795s; ^{1}H NMR (CD_3CN) δ: 7.67 (t, 2H, J = 8 Hz), 7.35 (d, 2H, J = 8 Hz), 7.34 (d, 2H, J = 8 Hz), 4.11 (s, 4H), 1.63 (q, 4H, J = 15, 7.5 Hz), 0.94 (t, 6H, J = 7.5 Hz); ^{13}C NMR (acetone-d_6) δ: 162.25, 136.34, 126.46, 119.03, 116.96, 116.23, 113.94, 104.99, 71.98, 42.14, 23.69, 7.42; EI-MS *m/z* (%): 384 (M^+, 3), 259 (4), 241 (50), 145 (38), 97 (80), 55 (100). Anal. calcd. for $C_{23}H_{20}O_2N_4$: C 71.88, H 5.21, N 14.58; found: C 72.24, H 4.78, N 14.99.

1,3-Bis(2′,3′-dicyanophenoxy)-2,2-dipentylpropane (12)

Bisphthalonitrile **12** was prepared by Method II from 0.72 g

(3.3 mmol) of 2,2-dipentylpropan-1,3-diol (**8**), 1.40 g (8.1 mmol) of **1**, and 2.1 g (15.2 mmol) of K_2CO_3 in 7 mL of DMSO at RT over a 9 day period. Aqueous work-up and methanol washing of the solid reaction products gave a yellowish crude solid. Recrystallization of the crude product from acetonitrile gave 0.81 g (52%) of white crystalline **12** (TLC: 10% CH_3CN–Bz, R_f = 0.78), mp 173–174°C; IR (cm^{-1}): 3080, 2960, 2210 (C≡N), 1585, 1475, 1285, 1055, 795. ^1H NMR (CD_3CN) δ: 7.71 (t, 2H, J = 8 Hz), 7.45 (m, 4H), 4.13 (s, 4H), 1.54 (m, 4H), 1.3 (m, 12H), 0.86 (t, 6H, J = 7 Hz); ^{13}C NMR (acetone-d_6) δ: 162.27, 136.34, 126.48, 119.08, 116.94, 116.23, 113.95, 104.97, 72.56, 42.05, 33.25, 31.80, 23.05, 22.92, 14.22; EI-MS *m/z* (%): 469 (M^+ + 1, 50), 453 (10), 439 (18), 397 (21), 368 (30), 325 (72), 144 (100). Anal. calcd. for $C_{29}H_{32}N_4O_2$: C 74.36, H 6.84, N 11.97; found: C 74.20, H 6.93, N 12.00.

1,3-Bis(2′,3′-dicyanophenoxy)-2,2-dioctylpropane (13)

Bisphthalonitrile **13** was prepared by Method II from 3.05 g (10.2 mmol) of 2,2-dioctylpropan-1,3-diol (**9**), 3.9 g (22.5 mmol) of **1**, and 7.4 g (54 mmol) of K_2CO_3 in 25 mL of DMSO at RT over an 8 day period. Aqueous work-up and methanol washing of the solid reaction products gave a crude yellowish solid that was recrystallized from acetonitrile. A second recrystallization from ethyl acetate gave 3.17 g (57%) of white crystalline **13** (TLC: 10% CH_3CN–Bz, R_f = 0.80), mp 163–165°C; FT-IR (cm^{-1}): 3083, 2927, 2862, 2225 (C'N), 1518s, 1463, 1294, 1045, 798. ^1H NMR (acetone-d_6) δ: 7.86 (t, 2H, J = 8 Hz), 7.71 (d, 2H, J = 8 Hz), 7.55 (d, 2H, J = 8 Hz), 4.31 (s, 4H), 1.64 (m, 4H), 1.32 (m, 24H), 0.84 (t, 6H, J = 7 Hz); ^{13}C NMR (acetone-d_6) δ: 162.26, 136.35, 126.46, 119.06, 116.95, 116.22, 113.94, 104.99, 72.48, 42.06, 32.54, 31.66, 30.94, 29.88, 23.26, 23.11, 14.30; EI-MS *m/z* (%): 552 (M^+, 4.7), 523 (4.6), 509 (2.8), 495 (2.4), 469 (3.4), 409 (55), 145 (22), 43 (100). Anal. calcd. for $C_{35}H_{44}N_4O_2$: C 76.09, H 7.97, N 10.14; found: C 75.92, H 8.52, N 10.27.

General method of bis side-strapped phthalocyanine synthesis

A solution of the bisphthalonitrile was made using 1-octanol, tetrahydrofuran (THF), or mixtures of 1-octanol and THF. A syringe pump was used to add the bisphthalonitrile dropwise (ca. 0.02 mmol/min) to lithium octoxide in 1-octanol heated at reflux (ca. 196°C) in a modified air-cooled distillation apparatus that allowed rapid removal of cosolvent. In general, 10 mL of 1-octanol containing excess lithium metal was used for every 100 mg of bisphthalonitrile added. Pc formation was usually evident after 20 s of bisphthalonitrile addition. Upon addition of the bisphthalonitrile, the mixture was heated at reflux for an additional 2–10 min and then allowed to cool to RT. Water was then added and the mixture neutralized by addition of HCl (aq.) (ca. pH 7), giving a suspension that was homogenized by ultrasound. The mixture was then concentrated to near dryness under reduced pressure and the crude Pc product purified by centrifugation and chromatographic and recrystallization techniques.

1,25:11,15-Bis(2′-methyl-2′-trityloxymethylpropan-1′,3′-dioxy)phthalocyanine (14)

PcH_2 **14** was prepared, using the general method, by an 18 min dropwise addition of a solution of 300 mg (0.49 mmol) bisphthalonitrile **6** in 7 mL of THF to 30 mL of 1-octanol containing 50 mg (2.2 mmol) of cleaned lithium metal at 200°C. After addition of **6**, the mixture was heated at reflux for an additional 5 min and then cooled to RT. A general method work-up (similar to that of **17**) gave 200 mg of a blue-green crude solid. The solid was dissolved in THF, adsorbed on normal grade silica gel, then purified by flash chromatography (benzene as eluant) to yield a first fraction of almost pure **14** (determined by TLC). PcH_2 **14** was rechromatographed under the same conditions to yield 48 mg (16%) of **14** as a dark blue solid, mp >350°C; IR (cm^{-1}): 3280 (N-H), 3050, 2910, 2860, 1580, 1480, 1250 (Ar-O-C), 1030, 745, 700; UV–VIS (THF) λ_{max} nm log ε: 330 (4.75), 618 (4.45), 656 (4.64), 680 (5.11), 712 (5.13); ^1H NMR (380 K)(pyridine-d_5) δ: 9.07 (m, 4H), 8.06 (m, 16H), 7.84 (d, 4H, J = 6 Hz), 7.57 (m, 14H), 7.40 (t, 4H, J = 7 Hz), 5.41 (m, 4H), 5.21 (m, 4H), 4.00 and 3.99 (2s, 4H), 1.93 and 1.92 (2s, 6H), −1.70 (br s, 2H); +FAB-MS *m/z*: 1231 (M^+ + 1). Anal. calcd. for $C_{80}H_{62}N_8O_6$: C 78.05, H 5.04, N 9.11; found: C 77.93, H 5.21, N 8.88.

1,25:11,15-Bis(2′,2′-diethylpropan-1′,3′-dioxy)phthalocyanine (15)

Cleaned lithium metal (50 mg, 7.1 mmol) and 1-octanol (50 mL) were placed in a 100 mL three-neck flask and the mixture heated to 195–200°C until lithium 1-octoxide formation was complete. The flask was fitted for the modified distillation and a solution of 500 mg (1.3 mmol) of bisphthalonitrile **11** in 30 mL of THF was prepared. A syringe pump was used to add the solution of **11** to the well-stirred alkoxide at 195–200°C over a 20 min period and the evaporated THF was collected. The mixture was then heated for an additional 5 min and then cooled to RT. Water (5 mL) was added and the mixture was concentrated to near dryness under reduced pressure and then neutralized by the addition of dilute HCl (aq.). The solid material was suspended in 15 mL of MeOH and homogenized by ultrasound. The grey-green solid was collected and washed by repeated centrifugation and resuspension in MeOH. Finally, the pellet was dissolved in 5 mL of 50% THF–Bz and purified by silica-gel flash chromatography using benzene as the eluting solvent. A first fraction consisting of a diffuse band of blue pigment was collected. Immobile green and brown materials were not eluted from the column. The solvent of the collected fraction (ca. 300 mL) was removed under reduced pressure to yield 35 mg (7%) of PcH_2 **15** as a blue solid, mp >350°C; IR (cm^{-1}): 3280 (N-H), 2930, 2840, 1590, 1450, 1250 (Ar-O-C), 1040, 810, 750s. UV–VIS (benzene) λ_{max} nm (log ε): 352 (4.75), 614 (4.52), 646 (4.70), 672 (5.11), 708 (5.14). ^1H NMR (CF_3COOD) δ: 9.05 (d, 4H, J = 8 Hz), 8.49 (t, 4H, J = 8 Hz), 8.03 (d, 4H, J = 8 Hz), 5.10 (s, 8H), 2.13 (q, 8H, J = 7 Hz), 1.25 (t, 12H, J = 7 Hz); EI-MS *m/z* (%): 770 (M^+, 35), 211 (10), 145 (31), 55 (100); HRMS required for $C_{46}H_{42}N_8O_4$: 770.33290; found: 770.33220.

1,25:11,15-Bis(2′,2′-dipentylpropan-1′,3′-dioxy)phthalocyanine (16)

PcH_2 **16** was prepared as above from a 3 mL THF/1-octanol (2:1) solution of 150 mg (3.21×10^{-2} mmol) of bisphthalonitrile **12** added over a 5 min period to 15 mL of 1-octanol containing 15 mg (2.2 mmol) of lithium metal at 195–200°C. The mixture was heated for an additional 2 min, cooled to RT and worked up as previously described. PcH_2 **16** was separated

from dimeric and oligomeric Pc products by flash column chromatography (3% Bz–toluene as eluting solvent) as a fast moving blue pigment F1. A slower moving blue-green component was eluted after changing the eluting solvent to 1% THF–toluene. The desired fast moving mononuclear Pc pigment **16** was then treated twice by flash column chromatography (3% Bz–toluene as eluting solvent). This pigment was recrystallized from pyridine to yield 31.5 mg (21%) of PcH_2 **16** as a bright blue solid, mp >350°C; IR (cm^{-1}): 3300 (N-H), 2940, 2850, 1585w, 1460, 1250 (Ar-O-C), 1035, 800w, 745s; UV–VIS (THF) λ_{max} nm (log ϵ): 352.5 (4.76), 614 (4.53), 645 (4.70), 674 (5.10), 709 (5.14); ^{1}H NMR (benzene-d_6) δ: 8.87 (d, 4H, J = 8 Hz), 8.28 (t, 4H, J = 8 Hz), 7.75 (d, 4H, J = 8 Hz), 4.83 (s, 8H), 1.90 (m, 8H), 1.54 (m, 8*h*), 1.32 (m, 16H), 0.80 (m, 12H), −4.5 (s, 2H); +FAB-MS *m/z* (%): 940 (M^+, 2), 869 (1.2), 772 (1), 759 (1), 687 (0.5), 614 (1.5), 460 (5), 307 (34), 154 (100). Anal. calcd. for $C_{58}H_{66}N_8O_4$: C 76.05, H 8.02, N 10.14; found: C 75.92, H 8.52, N 10.27.

1,25:11,15-Bis(2′,2′-dioctylpropan-1′,3′-dioxy)phthalocyanine (17)

PcH_2 **17** was prepared as for **15** from a **20** mL THF/1-octanol (2:1) solution of 1.11 g (2.02 mmol) of bisphthalonitrile **13** added over a 7 min period to 75 mL of 1-octanol containing 85 mg (12.1 mmol) of lithium metal at 195–200°C. The mixture was heated for an additional 5 min, cooled to RT and worked up as previously described. The desired PcH_2 **17** was separated from oligomeric Pc pigments by flash chromatography (benzene as eluting solvent). Flash chromatography of this nearly pure pigment (benzene as eluting solvent) gave 207 mg (19%) of **17** as a dark blue, shining solid, mp >350°C; IR (cm^{-1}): 3290 (N-H), 2930, 2850, 1590w, 1460w, 1255 (Ar-O-C), 1030, 805w, 740s; UV–VIS (THF) λ_{max} nm (log ϵ): 352.5 (4.79), 613 (4.58), 646 (4.73), 675 (5.12), 709 (5.17); ^{1}H NMR (benzene-d_6) δ: 7.92 (d, 4H, J = 7 Hz), 7.25 (t, 4H, J = 7 Hz), 6.88 (d, 4H, J = 7 Hz), 4.44 (s, 8H), 1.58–1.88 (m, 56H), 1.15 (t, 12H, J = 6.8 Hz), −5.99 (s, 2H) (see Table 3); EI-MS *m/z* (%): 1107 (M^+ + 1, 32), 1077 (5), 806 (8), 660 (18), 556 (100). Anal. calcd. for $C_{70}H_{90}N_8O_4$: C 75.91, H 8.19, N 10.12; found: C 75.58, H 8.52, N 9.88.

1,25:11,15-Bis(2′-methyl-2′-trityloxymethylpropan-1′,3′-dioxy)phthalocyaninatozinc(II) (18)

PcZn **18** was prepared from 23 mg (1.87×10^{-2} mmol) of PcH_2 **14** and 50 mg (0.27 mmol) of $Zn(OAc)_2$ in a mixture of 2.5 mL of Py and 2.5 mL of DMF heated at reflux for 20 h. After cooling to RT, the solvents were removed under reduced pressure and the crude product purified by column chromatography using 20% THF–Bz as the eluting solvent. The solvents were removed under reduced pressure to give 22 mg (91%) of PcZn **18**, mp >330°C; UV–VIS (THF) λ_{max} nm (log ϵ): 336 (4.71), 617 (3.92), 654 (4.40), 686 (5.33); ^{1}H NMR (THF-d_8) δ: 9.02 (d, 4H, J = 7.5 Hz), 7.99 (t, 4H, J = 7.5 Hz), 7.77 (m, 12H), 7.68 (d, 4H, J = 7.5 Hz), 7.38 (m, 12H), 7.26 (m, 6H), 5.38 (m, 4H), 5.17 (m, 4H), 3.66 and 3.64 (2s, 4H), 1.65 and 1.62 (2s, 6H); +FAB-MS *m/z*: cluster at 1295 (M+2). Anal. calcd. for $C_{80}H_{60}N_8O_6Zn$: C 74.24, H 4.64, N 8.66; found: C 74.39, H 4.46, N 8.23.

1,25:11,15-Bis(2′,2′-dipentylpropan-1′,3′-dioxy)phthalocyaninato zinc(II) (19)

PcH_2 **16** (50 mg, 5.3×10^{-2} mmol) was dissolved in a mixture of 10 mL of pyridine and 8 mL of DMF. Zinc acetate (0.5 mg, 2.72 mmol) was added and the mixture heated to reflux for 14 h. The mixture was allowed to cool, the solvents were removed under reduced pressure, and the crude product was purified by flash chromatography using THF as eluting solvent. The THF was removed under reduced pressure and the product recrystallized from pyridine to give 47 mg (89%) of PcZn **19** as fine light-blue needles, mp >350°C; UV–VIS (THF) λ_{max} nm (log ϵ): 356 (4.74), 617 (4.62), 655 (4.56), 686 (5.42); ^{1}H NMR (benzene-d_6) δ: 8.87 (d, 4H, J = 8 Hz), 8.28 (t, 4H, J = 8 Hz), 7.74 (d, 4H, J = 8 Hz), 4.83 (s, 8H), 1.91 (m, 8H), 1.54 (m, 8H), 1.27 (m, 16H), 0.80 (t, 12H, J = 6.7); +FAB-MS *m/z* (%): 1002 (M^++1, 100), 932 (10), 821 (18), 640 (29), 634 (27), 610 (23). Anal. calcd. for $C_{58}H_{64}N_8O_4Zn$: C 69.48, H 6.43, N 11.18; found: C 69.51, H 6.50, N 10.92.

1,25:11,15-Bis(2′,2′-dioctylpropan-1′,3′-dioxy)phthalocyaninato zinc(II) (20)

PcH_2 **17** (67.7 mg, 6.12×10^{-2} mmol) was added to a mixture of 20 mL of pyridine and 20 mL of DMF containing 112 mg (0.61 mmol) of $Zn(OAc)_2$. The mixture was heated at reflux overnight and then cooled to RT. The solvents were removed under reduced pressure and the pigment purified by column chromatography (Et_2O as the eluting solvent). After evaporation of the solvent under reduced pressure, 62 mg (87%) of PcZn **20** was obtained, mp >330°C; UV–VIS (THF) λ_{max} nm (log ϵ): 356 (4.63), 480 (3.11), 617 (4.49), 655 (4.46), 685.5 (5.17); ^{1}H NMR (THF-d_8) δ: 8.94 (d, 4H, J = 7 Hz), 7.96 (t, 4H, J = 7 Hz), 7.56 (d, 4H, J = 7 Hz), 5.16 (br s, 8H), 1.96 (m, 8H), 1.89 (m, 8H), 1.60 (m, 40H), 1.00 (t, 12H, J = 7 Hz); +FAB-MS *m/z* (%): 1171 (M^+ + 1, 100), 905 (34), 791 (36), 641 (85), 626 (23), 612 (66). Anal. calcd. for $C_{70}H_{88}N_8O_4Zn$: C 71.81, H 7.58, N 9.57; found: C 71.53, H 7.11, N 9.93.

5,5-Bis(2′,3′-dicyanophenoxymethyl)-2-phenyl-1,3-dioxane (23)

Bisphthalonitrile **23** was prepared by Method II from 1.11 g (5 mmol) of 5,5-dihydroxymethyl-2-phenyl-1,3-dioxane (**21**) (19), 1.75 g (10.1 mmol) of **1**, and 3.1 g (22.5 mmol) of K_2CO_3 in 25 mL of DMSO at RT over a 16 day period. Aqueous work-up and methanol washing of the reaction products gave a pink-coloured solid. Double recrystallization of the pink solid from EtOAc gave 1.83 g (77%) of white crystalline **23** (TLC: 5% CH_3CN–Bz, R_f = 0.43), mp 180–182.5°C; IR (cm^{-1}): 3180, 3100s, 2990, 2880, 2245 (C≡N), 1585s, 1470br, 1395, 1300br, 1115, 1060br, 800s, 740, 700s; ^{1}H NMR (CD_3CN) δ: 7.74 (t, 2H, J = 8 Hz), 7.60 (d, 2H, J = 8 Hz), 7.50–7.36 (m, 7H), 5.59 (s, 1H), 4.70 (s, 2H), 4.55 (d, 2H, J = 12 Hz), 4.19 (s, 2H), 4.12 (d, 2H, J = 12 Hz); ^{13}C NMR (DMSO-d_6)δ: 160.74 and 160.53, 137.95, 136.09 and 136.02, 129.07, 128.19, 126.31, 126.20, 118.94 and 118.69, 115.73 and 115.70, 115.29 and 115.27, 113.48 and 113.39, 103.45 and 113.38, 101.40, 68.85, 68.42, 67.82, 38.36; EI-MS *m/z* (%): 476 (M^+, 63), 475 (23), 399 (5), 197 (60), 157 (25), 105 (100), 77 (22). Anal. calcd. for $C_{28}H_{20}N_4O_4$: C 70.58, H 4.23, N 11.76; found: C 70.25, H 4.66, N 12.00.

1,1-Bis(2′,3′-dicyanophenoxymethyl)cyclohexane (24)

Bisphthalonitrile **24** was prepared by Method II from 0.72 g (5 mmol) of 1,1-dihydroxymethylcyclohexane (**22**) (20), 2.25 g (13 mmol) of **1**, and 2.65 g (19 mmol) of K_2CO_3 in 20 mL of

DMSO over a 12 day period at RT. Aqueous work-up and methanol washing gave a pink coloured crude product. Double recrystallization of the crude product from acetone gave 1.28 g (65%) of bisphthalonitrile **24** as colourless crystals (TLC: 10% CH_3CN–Bz, R_f = 0.63), mp 246–247°C; IR (cm^{-1}): 3080s, 2910, 2850, 2220 (C≡N), 1775s, 1450br, 1290br, 1050, 930, 790s, 730; ^1H NMR (CD_3CN) δ: 7.72 (t, 2H, J = 8 Hz), 7.48 (d, 2H, J = 8 Hz), 7.42 (d, 2H, J = 8 Hz), 4.22 (s, 4H), 1.69–1.53 (m, 10H); ^{13}C NMR (DMSO-d_6) (330 K) δ: 160.84, 135.40, 125.21, 118.60, 115.17, 114.94, 112.90, 103.06, 72.24, 38.02, 28.87, 25.16, 20.32; EI-MS *m/z* (%): 396 (M^+, 32), 252 (100), 157 (77), 144 (87), 127 (93). Anal. calcd. for $C_{24}H_{20}N_4O_2$: C 72.73, H 5.05, N 14.14; found: C 73.03, H 4.77, N 13.78.

1,5-Bis(2′,3′-dicyanophenoxy)-3-oxapentane (31)

Bisphthalonitrile **31** was prepared by Method II from 0.795 g (7.50 mmol) of diethylene glycol (**25**), 2.17 g (18.3 mmol) of **1**, and 3.04 g (22.1 mmol) of K_2CO_3 in 10 mL of DMSO at 50°C over a 6 day period. After work-up by Method I, bisphthalonitrile **31** was obtained from the crude product by column chromatography (15% CH_3CN–Bz as the eluting solvent) as the first fraction collected. After recrystallization from acetonitrile, 509 mg (19%) of **31** was obtained as white needles (TLC: 15% CH_3CN–Bz, R_f = 0.50), mp 223–224°C; IR (cm^{-1}): 3090, 2925, 2220 (C≡N), 1580, 1470, 1300, 1140, 1065, 795; ^1H NMR (CD_3CN) δ: 7.70 (t, 2H, J = 8 Hz), 7.45 (d, 2H, J = 8 Hz), 7.44 (d, 2H, J = 8 Hz), 4.34 (t, 4H, J = 4 Hz), 3.94 (t, 4H, J = 4 Hz); ^{13}C NMR (DMSO-d_6) (330 K) δ: 160.73, 135.21, 125.49, 118.64, 115.25, 115.14, 113.03, 69.35, 68.57; EI-MS *m/z* (%): 358 (M^+, 4.5), 215 (17), 171 (100), 145 (25), 116 (14). Anal. calcd. for $C_{20}H_{14}N_4O_3$: C 67.04, H 3.91, N 15.64; found: C 66.73, H 3.87, N 15.42.

A second fraction eluted from the column consisted of a mixture (by TLC) of BDPE[2] and a monosubstitution product (etherol).

1,2-Bis(2′,3′-dicyanophenoxymethyl)benzene (32)

Bisphthalonitrile **32** was prepared by Method II from 1.068 g (7.5 mmol) of 1,2-dihydroxymethylbenzene (**26**) (Aldrich), 3.0 g (17.3 mmol) of **1**, and 3.0 g (21.7 mmol) of K_2CO_3 in 10 mL of DMSO at RT over a 6 day period. After aqueous work-up and washing with MeOH an off-white crude product was recovered. Recrystallization of the crude product from acetonitrile gave 760 mg (26%) of white **32** as an amorphous solid (TLC: 5% CH_3CN–Bz, R_f = 0.24), mp 254–256°C; FT-IR (cm^{-1}): 3167, 3085, 2924, 2235 (C≡N), 1583s, 1469, 1453, 1272, 1037, 802, 767, 734; ^1H NMR ($CDCl_3$) δ: 7.83 (t, 2H, J = 8 Hz), 7.73 (d, 2H, J = 8 Hz), 7.61 (m, 4H), 7.46 (m, 2H), 5.54 (s, 4H); ^{13}C NMR ($CDCl_3$) δ: 169.24, 135.28, 133.34, 128.66, 128.52, 125.69, 118.64, 115.24, 115.20, 113.09, 103.24, 68.88; EI-MS *m/z* (%): ion signals not observed. Anal. calcd. for $C_{24}H_{14}N_4O_2$: C 73.85, H 3.59, N 14.36; found: C 73.64, H 3.57, N 14.45.

2,2′-Bis(2″,3″-dicyanophenoxymethyl)biphenyl (33)

Bisphthalonitrile **33** was prepared by Method II from 400 mg (1.9 mmol) of 2,2′-dihydroxymethylbiphenyl (**27**) (21), 750 mg (4.34 mmol) of **1**, and 900 mg (6.52 mmol) of K_2CO_3 in 10 mL of DMSO over 4 days at RT. After aqueous work-up and methanol washing, the yellowish crude product was recrystallized twice from benzene to give 370 mg (42%) of bisphthalonitrile **33** as an off-white solid (TLC: 15% CH_3CN–Bz, R_f = 0.80), mp 193–194°C; FT-IR (cm^{-1}): 3085, 3030, 2892, 2229 (C≡N), 1581s, 1470s, 1301, 1286, 1034, 801, 789, 692; ^1H NMR ($CDCl_3$) δ: 7.57 (m, 4H), 7.42 (m, 4H), 7.36 (m, 2H), 7.31 (d, 2H, J = 8 Hz), 7.17 (d, 2H, J = 8 Hz), 4.92 (m, 4H); ^{13}C NMR ($CDCl_3$) δ: 160.77, 139.94, 134.83, 132.19, 130.21, 130.04, 129.06, 128.54, 125.22, 116.98, 116.88, 115.19, 113.14, 104.44, 70.04; EI-MS *m/z* (%): 466 (M^+, 8), 463 (10), 437 (9), 324 (42), 283 (38), 179 (100). Anal. calcd. for $C_{30}H_{18}N_4O_2$: C 77.25, H 3.86, N 12.02; found: C 76.85, H 3.78, N 11.88.

1,3-Bis(2′,3′-dicyanophenoxymethyl)-5-*tert*-butylbenzene (34)

Bisphthalonitrile **34** was prepared by Method II from 388 mg (2.00 mmol) of 3,5-dihydroxymethyl-*tert*-butylbenzene (**28**) (22), 850 mg (4.91 mmol) of **1**, and 1.06 g (7.68 mmol) of K_2CO_3 in 10 mL of DMSO at RT over a 5 day period. Aqueous work-up and methanol washing gave a greyish crude product. Recrystallization of this solid from acetonitrile gave 413 mg (46%) of white crystalline **34** (TLC: 15% CH_3CN–Bz, R_f = 0.76), mp 180-181°C; FT-IR (cm^{-1}): 3089, 2954, 2869, 2234 (C≡N), 1583s, 1471, 1295s, 1083, 795; ^1H NMR (acetone-d_6) δ: 7.86 (t, 2H, J = 8 Hz), 7.73 (d, 2H, J = 8 Hz), 7.67 (s, 2H), 7.59 (d, 2H, J = 8 Hz), 7.48 (s, 1H), 5.47 (s, 4H), 1.36 (s, 9H); ^{13}C NMR (acetone-d_6) δ: 162.03, 153.12, 136.72, 136.16, 126.61, 125.63, 124.77, 119.42, 117.30, 116.32, 114.05, 105.43, 72.23, 35.46, 31.54; EI-MS *m/z* (%): 446 (M^+, 15), 304 (46), 288 (38), 273 (12), 247 (100). Anal. calcd. for $C_{28}H_{22}N_4O_2$: C 75.34, H 4.93, N 12.56; found: C 75.39, H 4.96, N 12.55.

2,5-Bis(2′,3′-dicyanophenoxymethyl)furan (35)

Bisphthalonitrile **35** was prepared by a modification of Method II (using less than 2 equiv. of **1**) from 1.28 g (10.0 mmol) of 2,5-dihydroxymethylfuran **29** (Aldrich), 3.15 g (18.2 mmol) of **1** and 3.4 g (24.6 mmol) of K_2CO_3 in 25 mL of DMSO over a 6 day reaction period at RT. Aqueous work-up and MeOH washing of the reaction product gave a brown solid. Recrystallization of the highly insoluble crude product from 140 mL of acetone gave 1.94 g (56%, **1**) of white crystalline **35** (TLC: 15% CH_3CN–Bz, R_f = 0.57), mp >330°C; FT-IR (cm^{-1}): 3370, 3090, 2920, 2232 (C≡N), 1585s, 1474s, 1275s, 1030s, 809; ^1H NMR (CD_3CN) δ: 7.78 (t, 2H, J = 8 Hz), 7.60 (d, 2H, J = 8 Hz), 7.52 (d, 2H, J = 8 Hz), 6.66 (s, 2H), 5.29 (s, 4H); ^{13}C NMR (DMSO-d_6) (330 K) δ: 159.92, 149.45, 135.17, 125.94, 118.96, 115.35, 115.20, 112.94, 112.11, 103.44, 63.33; EI-MS *m/z* (%): 382 (M^+ + 2, 1.1), 237 (85), 144 (75), 116 (100), 94 (97). Anal. calcd. for $C_{22}H_{12}N_4O_3$: C 69.47, H 3.16, N 14.74; found: C 69.21, H 3.03, N 14.53.

***cis*-2,5-Bis(2′,3′-dicyanophenoxymethyl)tetrahydrofuran (36)**

Bisphthalonitrile **36** was prepared by Method II from 0.66 g (5 mmol) of *cis*-2,5-bis(hydroxymethyl)tetrahydrofuran (**30**) (23), 2.10 g (12.1 mmol) of **1**, and 2.40 g (17.4 mmol) of K_2CO_3 in 10 mL of DMSO at RT over a 10 day period. Work-up and recrystallization from methanol gave 820 mg (43%) of greyish-yellow crystalline **36** (TLC: 15% CH_3CN–Bz, R_f = 0.55), mp 186-188°C; FT-IR (cm^{-1}): 3085, 2977, 2879, 2226 (C≡N), 1563s, 1465s, 1260, 1100, 789; ^1H NMR (acetone-d_6)

δ: 7.81 (t, 2H, J = 8 Hz), 7.62 (d, 2H, J = 8 Hz), 7.53 (d, 2H, J = 8 Hz), 4.39 (m, 2H), 4.34 (m, 2H, J = 4.2 Hz), 4.29 (m, 2H, J = 4.2 Hz), 2.15 (m, 4H); ^{13}C NMR (acetone-d_6) δ: 162.44, 135.12, 126.36, 119.09, 117.11, 116.31, 114.20, 104.90, 78.69, 72.72, 28.30; +FAB-MS *m/z* (%): 385 (M^+ + 1, 100). Anal. calcd. for $C_{22}H_{16}N_4O_3$: C 68.75, H 4.17, N 14.58; found: C 68.65, H 4.16, N 14.24.

Chemical mapping of the active site of the glucoamylase of *Aspergillus niger*

Raymond U. Lemieux, Ulrike Spohr, Mimi Bach, Dale R. Cameron, Torben P. Frandsen, Bjarne B. Stoffer, Birte Svensson, and Monica M. Palcic

Abstract: A recently developed technique for the probing of the combining sites of lectins and antibodies, to establish the structure of the epitope that is involved in the binding of an oligosaccharide, is used to study the binding of methyl α-isomaltoside by the enzyme glucoamylase. The procedure involved the determination of the effects on the kinetics of hydrolysis of both monodeoxygenation and mono-*O*-methylation at each of the seven hydroxyl groups in order to gain an estimate of the differential changes in the free energies of activation, $\Delta\Delta G^{\ddagger}$. As expected, from previous publications, both deoxygenation and *O*-methylation of OH-4 (reducing unit), OH-4′, or OH-6′ strongly hindered hydrolysis, whereas the kinetics were virtually unaffected by either the substitutions at OH-2 or structural changes at C-1. The substitutions at OH-3 caused increases of 2.1 and 1.9 kcal/mol in the $\Delta\Delta G^{\ddagger}$. In contrast, whereas deoxygenation of either OH-2′ or OH-3′ caused much smaller (0.96 and 0.52 kcal/mol) increases in $\Delta\Delta G^{\ddagger}$, the mono-*O*-methylations resulted in severe steric hindrance to the formation of the activated complex. The relatively weak effects of deoxygenation suggest that the hydroxyl groups are replaced by water molecules and thereby participate in the binding by contributing effective complementarity. Methyl α-isomaltoside was docked into the combining site of the X-ray crystal structure at 2.4 Å resolution of the complex with the inhibitor acarbose. A fit free of steric interactions with the protein was found that has the methyl α-glucopyranoside unit in the normal $^4C_1$ conformation and the other glucose unit approaching a half-chair conformation with the interunit fragment defined by the torsion angles $\phi/\psi/\omega$ = 74°/134°/166° (O-5′—C-1′$\overset{\phi}{—}$O-6$\overset{\psi}{—}$C-6$\overset{\omega}{—}$C-5—O-5). The model provides a network of hydrogen bonds that appears to well represent the activated complex formed by the glucoamylase with both maltose and isomaltose since the structures appear to provide a sound rationale for both the specificity and catalysis provided by the enzyme.

Key words: monodeoxy and mono-*O*-methyl derivatives of methyl α-isomaltoside, enzyme binding domain, functioning of glucoamylase, differential changes in free energy of activation, characteristics of hydrogen bonding networks.

Résumé : Dans le but d'étudier la fixation de l'α-isomaltoside de méthyle par l'enzyme glucoamylase, on a fait appel à une technique, développée récemment pour l'examen des sites de fixation des lectines et des anticorps, pour établir la structure de l'épitope impliqué dans la fixation d'un oligosaccharide. La procédure implique la détermination des effets, provoqués sur la cinétique d'hydrolyse, par la monodésoxygénation ainsi que la mono-*O*-méthylation de chacun des sept groupes hydroxyles; on espère ainsi obtenir une évaluation des changements différentiels dans les énergies libres d'activation, $\Delta\Delta G^{\ddagger}$. Tel qu'on peut s'y attendre sur la base des publications antérieures, tant la désoxygénation que la *O*-méthylation des groupes OH-4 (unité réductrice), OH-4′ ou OH-6′ empêchent fortement l'hydrolyse alors que la cinétique n'est virtuellement pas affectée par des substitutions au niveau du OH-2 ou par des changements structuraux en C-1. Les substitutions en OH-3 provoquent des augmentations respectives de 2,1 et de 1,9 kcal mol^{-1} dans le $\Delta\Delta G^{\ddagger}$. Par opposition, alors que la désoxygénation du OH-2′ ou du OH-3′ provoque des augmentations beaucoup plus faibles (0,96 et 0,52 kcal mol^{-1}) du $\Delta\Delta G^{\ddagger}$, les mono-*O*-méthylations provoquent un fort encombrement stérique à la formation du complexe activé. Les effets relativement mineurs de la désoxygénation suggèrent que les groupes hydroxyles sont remplacés par des molécules d'eau et qu'ils participent ainsi à la fixation en apportant une contribution effective à la complémentarité. L'α-isomaltoside de méthyle a été inséré dans le site de combinaison de la structure cristalline de la diffraction des rayons X, à une résolution de 2,4 Å, du complexe avec l'inhibiteur acarbose. On a trouvé un ajustement sans interactions stériques avec la protéine qui possède une unité α-glucopyranoside dans la conformation $^4C_1$ normale et l'autre unité de glucose dont la conformation approche celle d'une demi-chaise pour laquelle le fragment interunitaire est défini par les angles de torsion $\phi/\Psi/\omega$ = 74°/134°/166° (O-5′—C-1′$\overset{\phi}{—}$O-6$\overset{\psi}{—}$C-6$\overset{\omega}{—}$C-5—O-5). Le modèle fournit un réseau de liaisons hydrogènes qui semble bien représenter le complexe activé formé par la glucoamylase avec

[Traduit par la rédaction]

Introduction

It is now well established that the specific binding of oligosaccharides by lectins and antibodies invariably involves the association of complementary polyamphiphilic surfaces (1, 2). The protein combining site is normally a shallow cavity (3, 4) within which several attractive polar interactions are established (5). It was reasonable to expect that the acceptance of an oligosaccharide into the active site of an enzyme is a similar event and that our recently established method (6–8) based on the differential effects on the extent of binding that result from monodeoxygenation and mono-*O*-methylation would shed light on the epitope that is presented to the enzyme for the recognition and binding that provides the catalysis.

The long known (9) industrially highly important amyloglucosidase (EC 3.2.1.3, AMG), referred to herein as glycoamylase, was chosen for this inquiry because the X-ray crystal structures are known for both the native protein (10, 11) and its complexes with inhibitors, namely, 1′-deoxynojirimycin (12) acarbose (13), and D-*gluco*-dihydroacarbose (13, 14). The structures of the complexes with their natural substrates, maltose and isomaltose, remain unknown.

The wild-type glucoamylase used in this study hydrolyzes maltose 30–50 times more rapidly than it does isomaltose (15). In view of the strong demand for the complementarity of the interacting surfaces, the epitopes of the activated complexes are expected to be very similar. Therefore, information gained as to the structure of the complex with isomaltose should apply to that with maltose. Methyl α-isomaltoside (**29**) was chosen as the reference compound for this study because of the much greater ease of the syntheses of all of the monodeoxy and mono-*O*-methyl derivatives. It was anticipated that the results would not only provide useful ancillary information on the mode of action of glucoamylase but also help to assess the use of this chemical probing technique to study the mode of enzyme catalysis when the X-ray crystal structure is not known.

Discussion of results

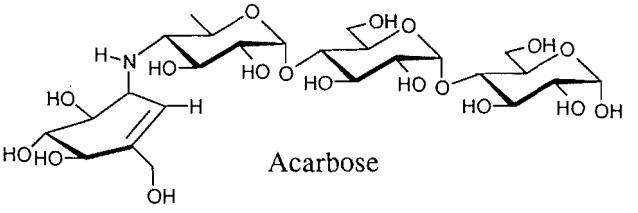
Synthesis

The procedures used to synthesize the target compounds (**29**–**35** and **56**–**62**) listed in Table 1 are outlined in Schemes 1, 2, and 3. These are now conventional and require little discussion. The various intermediates were well characterized by their ^{1}H NMR spectra, which indicated in all cases a high state of purity. The ^{13}C chemical shift data presented in Table 1 are obviously in accord with expectation based on the position of the chemical alteration of the reference methyl α-isomaltoside (**29**). Although some of the assignments are tentative, the conclusions reached as to structure are surely unequivocal.

Although not without precedent (8), the use of fluoride ion to open the stannylene ring formed on reactions of **1** with di-*n*-butyltin oxide is noteworthy. Except for the preparation of **47**, bromide-ion catalyzed glycosylations (16, 17) were used to establish the interunit α-D linkages of the various congeners of methyl α-isomaltoside (**29**). The yields of α-disaccharide were invariably high (>90%) but accompanied by a 5–10% formation of the β isomer. The separation of these isomers was accomplished by column chromatography. In several cases, the overall yields were very low because, in order to achieve high purity, the chromatograms had to be repeated two to three times. Because of the instability of 2-deoxyglycosyl bromides, the blocked 2′-deoxy disaccharide **47** was prepared using the 2-deoxyglucosyl chloride (**39**) and catalyzed by chloride ion. We are not convinced that, for the present purposes, the use of any of the more recently developed and highly vaunted procedures for α-glycosylation (18) are superior in convenience, yield, or cost to that employed herein.

Kinetics

The effects of the various structural changes presented in Table 1 on the kinetics of the hydrolysis of the interunit glycosidic bond of **29** at 318 K are presented in Table 2. The rationalization of these data is reserved for a separate communication (Frandsen et al., in preparation). At this time, attention is restricted to the effects of the structural changes on the free energy of activation ($\Delta\Delta G^{\ddagger}$) (19) using methyl α-isomaltoside (**29**) as the reference substrate. As seen in Table 2 and presented schematically in Fig. 1, the changes in $\Delta\Delta G^{\ddagger}$ spread over 6 kcal/mol. These changes in the energetics of reaction are readily appreciated with reference to the X-ray crystal structure at 2.4 Å resolution recently reported by Aleshin et al. (13) for the complex of the glycoamylase with the inhibitor of the enzyme's activity known as acarbose.



First of all, it is noteworthy that the three-dimensional structure of the native glucoamylase (10) (2.2 Å resolution) and that of its complex with acarbose (13) (2.4 Å resolution) are virtually superimposable and certainly do not differ within experimental certainly (12). The acceptance of methyl α-isomaltoside into the active site must be similar to that for the inhibitor. On this basis, the procedure used to dock methyl α-isomaltoside was to first bring the three key hydroxyl groups (OH-4, OH-4′ and OH-6′) within acceptable hydrogen bonding distances with the same proton-accepting groups for these hydroxyls present in the complex with the inhibitor (13). Since the intent was to model the transition state for the cleavage of the interglucosidic bond, it was decided to flatten the ring of the nonreducing unit to a half-chair conformation in line with

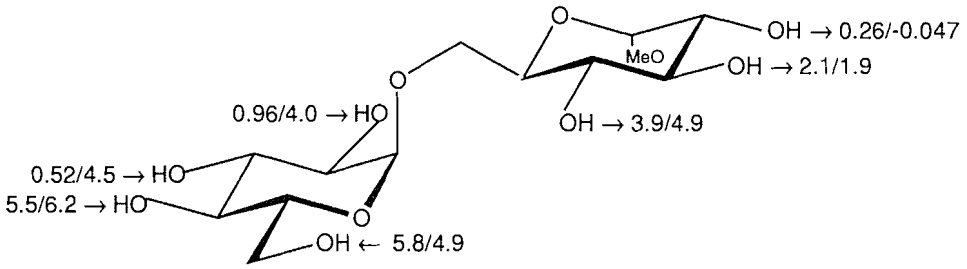
[a] $\Delta\Delta G^{\ddagger} = -RT \ln [(k_{cat}/K_m)_{congener}/(k_{cat}/K_m)_{reference}]$ at $T = 318$ K (19).

Fig. 1. Effects of monodeoxygenations compared to those caused by mono-*O*-methylation presented as $\Delta\Delta G^{\ddagger}$ deoxy/$\Delta\Delta G^{\ddagger}$ O-Me at 318 K (see Table 2).

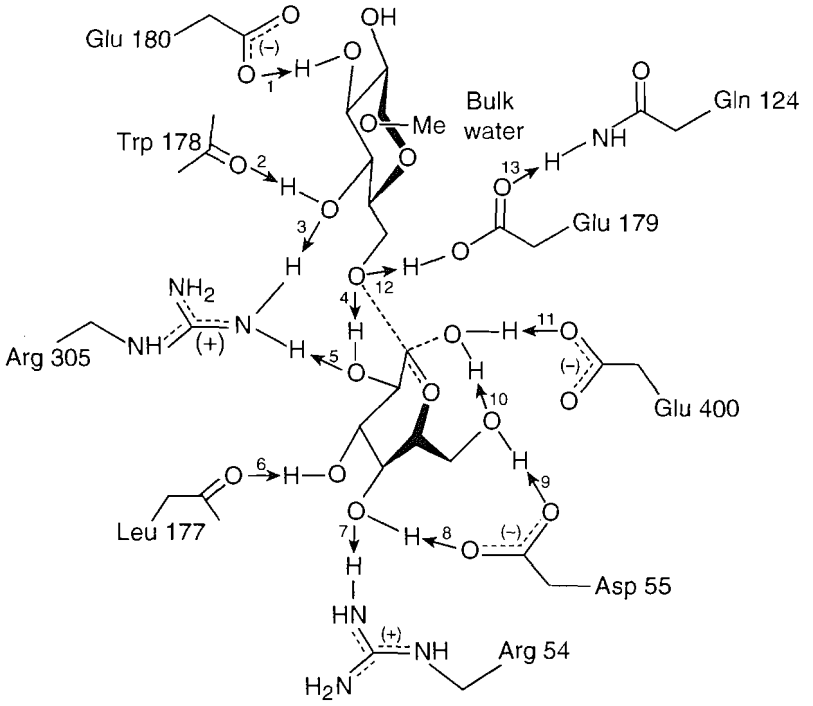


the expectation that the cleavage of the glycosidic bond occurs with participation of the ring oxygen, leading to double bond character for the C-1′—O-5′ bond. Since the cyclohexene ring of the acarbose in its complex with the glucoamylase has such a distortion, the procedure was simply to superimpose the pyranose ring of the nonreducing unit of the isomaltoside and the cyclohexene ring. GEGOP calculations (20) suggest that the distortion results in about 2.8 kcal/mol of strain. Rotations about the three bonds that join the two glucose units were then systematically made to find conformers that would maintain acceptable hydrogen bonding distances of OH-4 with Trp 178 and Arg 305, as depicted in Fig. 2, but which avoided all steric nonbonding interactions with the protein. The conformation that is defined by the ϕ/ψ/ω torsion angles of 74°/134°/166° (O-5′—C-1′$\overset{\phi}{}$O-6$\overset{\psi}{}$C-6$\overset{\omega}{}$C-5—O-5) and schematically depicted in Fig. 2 was found to uniquely meet these criteria. The internuclear distances between O-4, O-4′, and O-6′ of our docked model and O-3, O-4′, and O-6′ of the acarbose in the X-ray structure (13) are 0.21, 0.24, and 0.43 Å, respectively.

The model for the transition state (Fig. 2) provides a remarkable overall network of hydrogen bonding interactions. Clearly, some of the internuclear O-to-O distances are very short and the three O-to-N distances are very long. Nevertheless, the network appears acceptable in view of the 2.4 Å resolution of the crystal structure for the protein which provides the positions of the heavy nuclei to only ± 0.3 Å and that the system is subject to the dynamics of thermal agitation. This conclusion is strongly supported both by the kinds of hydrogen bonds that are formed and by the results of the kinetic investigation. Furthermore, the proposed hydrogen-bond network is also suitable for the formation of the transition state when methyl α-maltoside is the substrate (Fig. 3). This latter partial structure for the transition state is the same as that recently proposed by Coutinho and Reilly (21) except for the participation of Arg 54 as discussed below. The torsion angles for the interunit bonds proposed for the activated methyl α-maltoside of Fig. 3 are ϕ/ψ = 69°/98°, in contrast to the ϕ/ψ = 95°/105° values recently suggested (21) for binding in the ground-state conformation. GEGOP calculation indicates ϕ/ψ = 83°/91° values for the most favorable ground-state conformer. Svensson and co-workers (22–24) have recently reviewed relevant literature.

The differential effects of monodeoxygenation and mono-*O*-methylation listed in Table 2 and presented in Fig. 1 appear to be in agreement with the transition-state complex for methyl α-isomaltoside presented in Fig. 2. The small changes

Fig. 2. Schematic presentation of hydrogen bonding interactions in the transition state for the hydrolysis of methyl α-isomaltoside catalyzed by glucoamylase. The lengths (Å) of the proposed hydrogen bonds are: **1**, 2.60; **2**, 2.65; **3**, 3.44; **4**, 2.76; **5**, 3.39; **6**, 2.75; **7**, 3.27; **8**, 2.56; **9**, 2.62; **10**, 3.16; **11**, 2.65; **12**, 2.46; **13**, 3.04.



in $\Delta\Delta G^{\ddagger}$ that resulted from the substitutions at OH-2 suggest that this hydroxyl group resides in the complex at the periphery of the active site in contact with bulk water. The kinetic data for the hydrolyses of the interglycosidic bond of maltose, isomaltose, and related methyl glycosides are reviewed in Table 3 (25). The slight changes in $\Delta\Delta G^{\ddagger}$ within each group indicate that the substituents at C-1 are also exposed to bulk water, a conclusion in accord with the X-ray structure of the glucoamylase–acarbose complex (12). The small effects caused by the structural changes can be attributed to a change in the water structure about the C-1 substituents (26).

The nearly equal (about 2 kcal/mol) decreases in $\Delta\Delta G^{\ddagger}$ (Table 2) that resulted from the substitutions at OH-3 require that this hydroxyl group become involved in an interaction with the protein. The postulation that this ring interacts with Glu 180 is firmly established (27). That the effect of deoxygenation at position 3 of the isomaltoside is only about one third of that resulting from the same substitutional change for a maltoside (22, 27) is not necessarily surprising because OH-3 of the isomaltoside is in a much different environment near the aqueous phase than is OH-3 of the maltoside. The complex depicted in Fig. 2 has OH-3 well separated from Tyr 311 (not shown) and room appears to exist for an easy insertion of a methyl group on O-3 without rendering the compound essentially inactive as occurs on *O*-methylation of OH-4, OH-4′, or OH-6′. The maintenance of a hydrogen bond with Glu 180 would require the methoxy group to serve as the proton acceptor. In view of the close proximity of OH-3 to water, it is possible that a water molecule fills the space left vacant by the replacement of OH-3 by hydrogen. The filling of such voids by water was first firmly established by Quiocho et al. (28).

As seen from the strong deactivating effects of both kinds of substitutions at positions OH-4 and OH-4′ of the isomaltoside, as previously recognized (29), the interactions of these hydroxyl groups with the protein are highly important to the catalysis. It is to be noted in this regard that the roles played by these hydroxyl groups in achieving the transition state appear reinforced by their functioning cooperatively both as proton donors and proton acceptors. The strong charge delocalization thus provided to the activated complex would surely be of major importance to achievement of the distortion necessary for activation of the anomeric centre.

Since OH-2′ is in *syn*-clinal orientation to O-6, the two oxygen atoms can and may be hydrogen bonded in the transition state. This interaction, reinforced by the simultaneous acceptance of a proton from Arg 305 by O-2′, could well assist the hydrogen bonding of O-6 with Glu 179 to stretch the C-1′ to O-6 glycosidic bond.

As long recognized (13, 14), a water molecule is well positioned in the complex to make a nucleophilic attack at the incipient carbonium ionic centre. As indicated in both Figs. 2 and 3, the water molecule is held in place by hydrogen bonding with both the carboxylate group of Glu 400 and O-6′. The strength of this bond must be reinforced (30) by the hydrogen bonding bond of OH-6′ with the carboxylate group of Asp 55. The increased electron density at the oxygen atom of the water molecule, as the result of the hydrogen bonding of both of its hydrogen atoms, would importantly increase its nucleophilicity (13). Presumably the hydrogen-bond network involving Glu 400, Asp 55, and Arg 54 best accepts the distorted pyranose ring. These charge delocalizations together with the pull of electron charge from the aglyconic O-6 are, in all likeli-

Fig. 3. Schematic presentation of hydrogen bonding interactions in the transition state for the hydrolysis of methyl α-maltoside catalyzed by glucoamylase. The lengths (Å) of the proposed hydrogen bonds are: **1**, 2.99; **2**, 3.07; **3**, 3.00 with the remainder (**4**–**13**) the same as those proposed for the complex with methyl α-isomaltoside as substrate (Fig. 2).

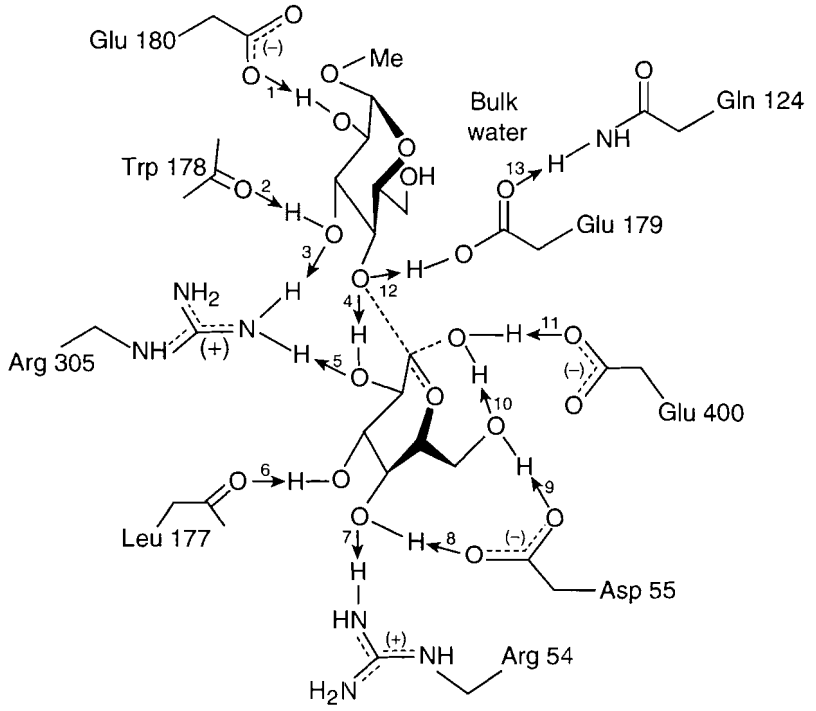


Table 3. Effects of structural changes at C-1 and C-2 on the kinetics of hydrolyses catalyzed by glucoamylase.

hood, at the source of the catalysis provided by glucoamylase for the hydrolysis of both isomaltose and maltose.

The hydrogen bonds formed by OH-2′ and OH-3′ with the protein must surely contribute importantly to the specificity of the catalysis. However, as seen in Table 2, deoxygenation at either one of these positions had relatively modest effects on the rates of hydrolysis. In contrast, the mono-*O*-methylations provided severe hindrance to complex formation. Attempts to place a water molecule into the cavity left by replacement of the hydroxyl groups by hydrogen met with unfavorable non-bonded interactions with the side chain of Arg 305 in the case of the 2′-position and Trp 417 in the case of the 3′-position. Low-energy movements of these side chains could provide sufficient free space to accommodate a water molecule. However, the water molecules could not be involved in attractive hydrogen bonds involving both their hydrogen atoms without movement of the protein-backbone structure. Molecular modelling was not attempted. Perhaps the formation of both hydrogen bonds is not mandatory. Presumably, a decision in this regard could be reached by examining the X-ray crystal structure of acarbose monodeoxygenated at either the 2- or 3-positions of the terminal cyclohexene-derived unit.

Experimental

General methods

The ^1H NMR spectra were measured at 300 MHz and 360 MHz (Bruker AM 300 and WM 360) with tetramethylsilane as internal standard for $CDCl_3$ solutions. The internal reference for D_2O solutions was acetone (2.225 ppm). The ^{13}C NMR

spectra were recorded at 75 MHz with dioxane (67.4 ppm) as reference for D_2O solutions and the $CDCl_3$ signal (77.06 ppm) as reference in $CDCl_3$ solutions. Optical rotations were measured at room temperature (23 ± 1°C) in a 1 dm cell on a Perkin–Elmer 241 polarimeter. Thin-layer chromatography was performed on precoated plates of silica gel (60-F254, E. Merck, Darmstadt) and visualized by spraying with the 5% sulfuric acid in ethanol followed by heating. For column chromatography silica gel 60 (230–400 mesh, E. Merck, Darmstadt) and distilled solvents were used. Solvents and reagents were purified and dried according to standard procedures. Melting points are uncorrected.

Kinetics

Glucoamylase GI was isolated from *Aspergillus niger* by affinity chromatography on an acarbose–Sepharose column (31); glucose diagnostic kits and glucose oxidase were from the Sigma Chemical Co.

Kinetic studies were carried out as previously described by measuring the amount of glucose released from substrates by coupling to glucose oxidase and horseradish peroxidase reactions (32). Incubations were carried out at 45°C in 500 μL microfuge tubes containing substrate and enzyme in 100–150 μL of 50 mM sodium acetate buffer, pH 4.5. Reactions were initiated by the addition of enzyme (8 μg–1.6 mg). At various time intervals ranging from 5 min for good substrates up to 1 h for the slow substrates, 15 μL aliquots were removed from the reaction mixtures and added to 300 μL of quench solution in microtiter plates. The quench solution contained 1.5 units of glucose oxidase, 0.3 units of horseradish peroxidase, and 24 μg of *o*-dianisidine in 1 M Tris·HCl buffer, pH 7.6. For substrates that yielded substituted glucose as a reaction product (compounds **55–62**), the glucose oxidase in the coupling system was increased to 13.5 units. The quenched solutions were covered with foil and color development was allowed to continue at ambient temperature for 1 h or until there was no further increase in absorbance. Standard curves with glucose or substituted glucose were set up in parallel in the microtiter plates. Absorbances were read at 450 nm in a microplate reader and the initial rates of reaction were estimated by linear regression analysis of the glucose released in the enzyme reactions as a function of time. Six to eight substrate concentrations were employed, ranging from 0.2 to 6 times K_m. The kinetic parameters k_{cat} and K_m were obtained by fitting the initial rate data to the Michaelis–Menten equation using the Enzfitter program.

Synthesis

*Methyl 2-*O*-benzyl-(**2**) and methyl 3-*O*-benzyl-4,6-*O*-(p-methoxybenzylidene)-α-*D*-glucopyranoside (**3**)*

A mixture of diol **1** (15 g, 48.0 mmol) (33) and di-*n*-butyltin oxide (12.8 g, 51.4 mmol) in benzene (450 mL) was refluxed with azeotropic removal of water. After 4 h, it was concentrated to 180 mL followed by the addition of tetra-*n*-butylammonium fluoride (18 g, 68.8 mmol), benzyl bromide (33 mL, 277.4 mmol), and 4 Å molecular sieves (45 g). After stirring at room temperature overnight, the solids were removed by filtration and the solvent was evaporated. Column chromatography on silica gel (hexane – ethyl acetate, 4:1, 3:1, 0.1% triethylamine) provided, in the first main fraction, compound **2** as a solid (7.0 g, 36%). $[\alpha]_D$ +29 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.45–7.25 (m, 7H, Ph, *Ph*OMe), 6.88 (d, 2H, *Ph*OMe), 5.47 (s, 1H, C*H*PhOMe), 4.79 and 4.70 (ABq, 2H, $J_{A,B}$ 12.0 Hz, CH_2Ph), 4.60 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.24 (dd, 1H, $J_{6,6'}$ 9.5 Hz, $J_{5,6}$ 4.5 Hz, H-6), 4.14 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.2 Hz, H-3), 3.80 (m, 1H, H-5), 3.79 (s, 3H, CH_3OPh), 3.68 (t, 1H, $J_{6',5}$ 10.0 Hz, H-6'), 3.47 (t, 1H, $J_{4,5}$ 9.5 Hz, H-4), 3.46 (dd, 1H, H-2), 3.37 (s, 3H, CH_3O), 2.45 (bs, 1H, OH). Anal. calcd. for $C_{22}H_{26}O_7$: C 65.66, H 6.51; found: C 65.83, H 6.53. Continued development of the column provided **3** (5.8 g, 30%) as a solid. $[\alpha]_D$ + 71.2 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.45–7.25 (m, 7H, Ph, *Ph*OMe), 6.88 (d, 2H, *Ph*OMe), 5.53 (s, 1H, C*H*Ph), 4.95 and 4.78 (ABq, 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph), 4.28 (dd, 1H, $J_{6,6'}$ 9.5 Hz, $J_{5,6}$ 4.5 Hz, H-6), 3.82 (m, s, 1H, 3H, CH_3OPh, H-5), 3.72 (dd, 1H, $J_{2,3}$ 8.5 Hz, H-2), 3.41 (s, 3H, CH_3O). Anal. calcd. for $C_{22}H_{26}O_7$: C 65.66, H 6.51; found: C 65.62, H 6.56.

*Methyl 3-*O*-benzyl-2-deoxy-4,6-*O*-(p-methoxybenzylidene)-α-*D*-arabino-hexopyranoside (**5**)*

Sodium hydride (~80% suspension, 0.42 g, 14 mmol) was added to a solution of **3** (2.79 g, 6.93 mmol) and imidazole (9 mg) in tetrahydrofuran (23 mL). After stirring for 30 min, carbon disulfide (3.3 mL, 55.9 mmol) was added and, after another 30 min, methyl iodide (0.9 mL, 14.5 mmol). The mixture, kept stirring for 30 min, was diluted with dichloromethane, followed by washing of the organic solution with aqueous saturated sodium hydrogen carbonate and water, prior to drying and evaporation. The residue, crude **4** (6.93 mmol), was taken up in toluene (41 mL) and reduced with tributyltin hydride (4.2 mL, 15.6 mmol) at reflux temperature overnight. The title compound **5** was obtained (1.20 g, 67%) by evaporation and chromatography on a column of silica gel (hexane – ethyl acetate, 3:1, 0.1% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.48–7.25 (m, 7H, Ph, *Ph*OMe), 7.89 (d, 2H, *Ph*OMe), 5.58 (s, 1H, C*H*PhOMe), 4.82 and 4.67 (ABq, 1H, $J_{A,B}$ 12.0 Hz, CH_2Ph), 4.80 (bd, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.24 (m, 1H, $J_{6,6'}$ 9.5 Hz, $J_{5,6}$ 3.5 Hz, H-6), 4.00 (m, 1H, $J_{2ax,3}$ 11.0 Hz, $J_{2eq,3}$ 5.0 Hz, $J_{3,4}$ 8.5 Hz, H-3), 3.81 (s, 3H, CH_3OPh), ~3.78 (m, H-5, H-6'), 3.67 (t, 1H, $J_{4,5}$ 9.0 Hz, H-4), 3.32 (s, 3H, CH_3OPh), 2.26 (ddd, 1H, $J_{2ax,2eq}$ 13.5 Hz, $J_{1,2eq}$ 1.0 Hz, H-2eq), 1.79 (ddd, 1H, H-2ax). Anal. calcd. for $C_{22}H_{26}O_6$: C 68.38, H 6.78; found: C 68.40, H 6.81.

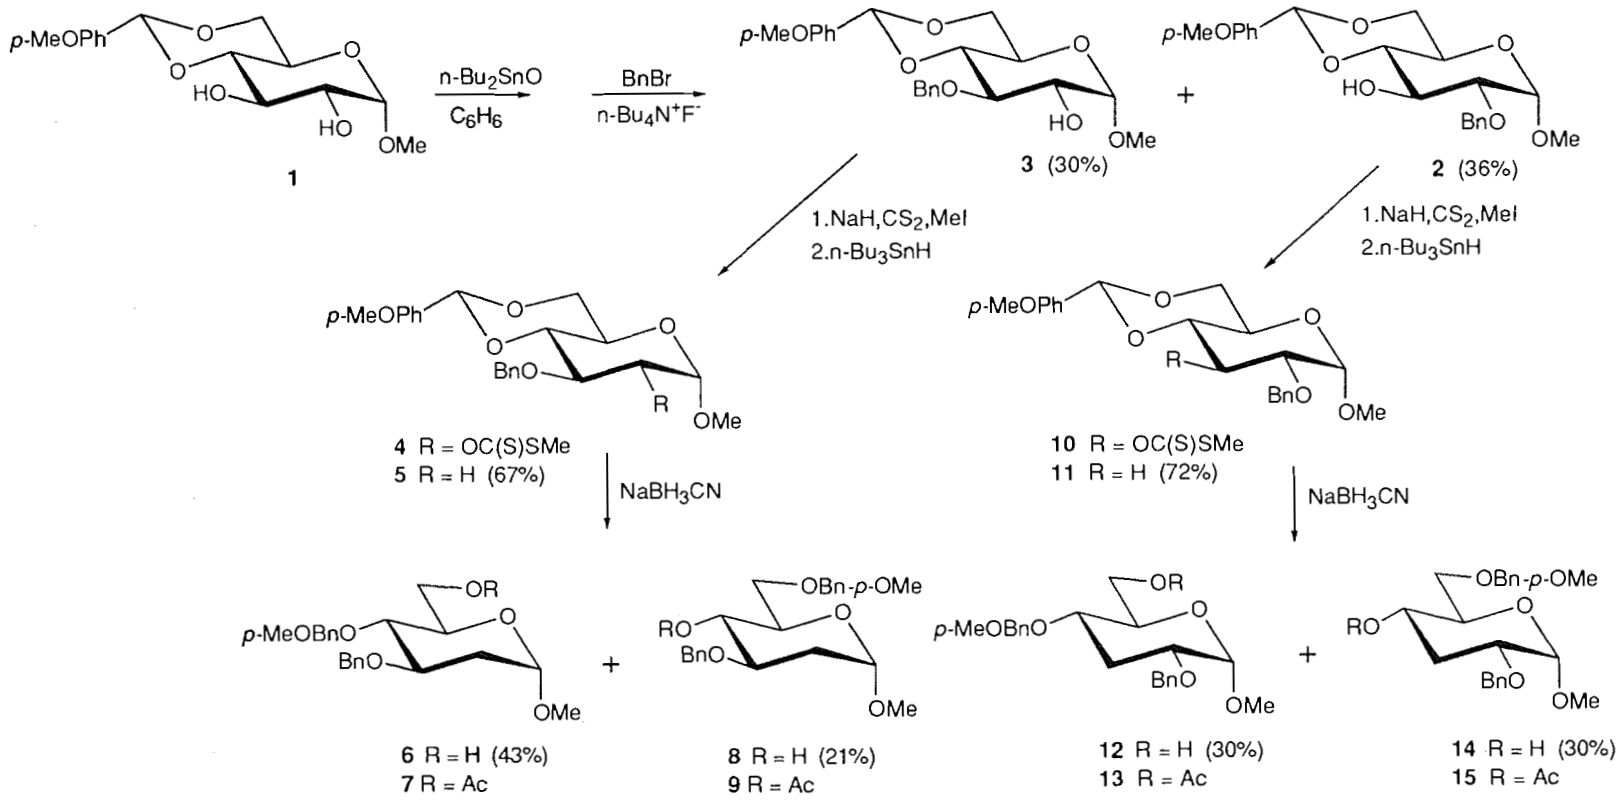
*Methyl 3-*O*-benzyl-4,6-*O*-(p-methoxybenzylidene)-2-*O*-[(methylthio)thiocarbonyl]-α-*D*-glucopyranoside (**4**)*

An analytical sample was obtained by column chromatography of the above crude preparation on silica gel (hexane – ethyl acetate, 3:1) and characterized by ^{1}H NMR spectroscopy. ^{1}H nmr ($CDCl_3$) δ: 7.45–7.25 (m, 7H, Ph, *Ph*OMe), 6.90 (d, 2H, *Ph*OMe), 5.72 (dd, 1H, $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 9.5 Hz, H-2), 5.55 (s, 1H, C*H*Ph), 5.12 (d, 1H, H-1), 4.82 and 4.74 (ABq, 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph), 4.30 (dd, 1H, $J_{6,6'}$ 9.5 Hz, $J_{5,6}$ 4.5 Hz, H-6), 4.20 (t, 1H, $J_{3,4}$ 9.5 Hz, H-3), 3.84 (m, 1H, H-5), 3.82 (s, 3H, CH_3OPh), 3.40 (s, 3H, CH_3O), 2.58 (s, 3H, CH_3S).

*Methyl 3-*O*-benzyl-2-deoxy-4-*O*-(p-methoxybenzyl)-α-*D*-arabino-hexopyranoside (**6**) and methyl 3-*O*-benzyl-2-deoxy-6-*O*-(p-methoxybenzyl)-α-*D*-arabino-hexopyranoside (**8**)*

Trimethylsilyl chloride (3 mL, 23.6 mmol) was added drop-

Scheme 1.



wise to a stirred mixture of **5** (1.53 g, 3.96 mmol), sodium cyanoborohydride (1.5 g, 23.9 mmol), and 4 Å molecular sieves (1.5 g) in acetonitrile (78 mL) at ice-bath temperature. After stirring for 6 h at room temperature (TLC check), it was poured into aqueous saturated sodium hydrogen carbonate and extracted with dichloromethane. The organic solution was washed with water, dried, and evaporated. Subsequent column chromatography (hexane – ethyl acetate, 2:1) provided, in the first main fraction, **8** as a syrup (328 mg, 21%). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.25 (m, 7H, Ph, *Ph*OMe), 6.88 (d, 2H, *Ph*OMe), 4.84 (bd, 1H, $J_{1,2ax}$ 2.8 Hz, H-1), 4.67 and 4.54, 4.56 and 4.51 (2ABq, each 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph, CH_2PhOMe), 3.80 (s, 3H, CH_3OPh), 3.78 (ddd, 1H, $J_{2eq,3}$ 5.0 Hz, $J_{2ax,3}$ 11.5 Hz, $J_{3,4}$ 8.5 Hz, H-3), 3.69 (m, 3H, H_2-6, H-5), 3.63 (m, 1H, H-4), 3.30 (s, 3H, CH_3O), 2.59 (bs, 1H, OH), 2.24 (ddd, 1H, $J_{2eq,2ax}$ 12.5 Hz, $J_{1,2eq}$ ~1 Hz, H-2eq), 1.64 (ddd, 1H, H-2ax). Anal. calcd. for $C_{22}H_{28}O_6$: C 68.02, H 7.26; found: C 67.49, H 7.09. Continued elution of the column provided syrupy **6** (657 mg, 43%). ^{1}H NMR ($CDCl_3$) δ: 7.4–7.2 (m, 7H, Ph, *Ph*OMe), 6.85 (d, 2H, *Ph*OMe), 4.85 and 4.60, 4.67 and 4.63 (2ABq, each 2H, $J_{A,B}$ 10.5, 11.5 Hz, CH_2Ph, CH_2PhOMe), 4.77 (bd, 1H, $J_{1,2ax}$ 3.5 Hz, H-1), 3.96 (ddd, 1H, $J_{2ax,3}$ 11.5 Hz, $J_{2eq,3}$ 4.5 Hz, $J_{3,4}$ 8.5 Hz, H-3), 3.78 and 3.73 (ABX, 2H, $J_{5,6}$ 3.0 Hz, $J_{6,6'}$ 11.5 Hz, $J_{5,6'}$ 5.0 Hz, H-6, H-6′), 3.76 (s, 3H, CH_3OPh), 3.61 (dt, 1H, $J_{4,5}$ 9.5 Hz, H-5), 3.48 (t, 1H, H-4), 3.27 (s, 3H, CH_3O), 2.27 (bdd, 1H, $J_{2ax,2eq}$ 13.0 Hz, $J_{1,2eq}$ ~1 Hz, H-2eq), 2.19 (bs, 1H, OH), 1.63 (ddd, 1H, H-2ax). Anal. calcd. for $C_{22}H_{28}O_6$: C 68.02, H 7.26; found: 68.05, H 7.35.

*Methyl 6-*O*-acetyl-3-*O*-benzyl-2-deoxy-4-*O*-(p-methoxybenzyl)-α-D-*arabino*-hexopyranoside (7)*

The 6-*O*-acetyl derivative of **6** was prepared in the usual manner using acetic anhydride and pyridine, 1:1. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 7H, Ph, *Ph*OMe), 6.85 (d, 2H, *Ph*OMe), 4.85 and 4.54, 4.68 and 4.61 (2ABq, each 2H, $J_{A,B}$ 10.5, 11.5 Hz, CH_2Ph, CH_2PhOMe), 4.80 (bd, 1H, $J_{1,2ax}$ 2.5 Hz, H-1), 4.33 and 4.25 (ABX, 2H, $J_{5,6}$ 4.5 Hz, $J_{6,6'}$ 12.0 Hz, $J_{5,6'}$ 2.5 Hz, H-6, H-6′), 3.99 (ddd, $J_{2eq,3}$ 5.0 Hz, $J_{2ax,3}$ 11.5 Hz, $J_{3,4}$ 8.5 Hz, H-3), 3.78 (ddd, 1H, $J_{4,5}$ 9.0 Hz, H-5), 3.78 (s, 3H, CH_3OPh), 3.43 (t, 1H, H-4), 3.29 (s, 3H, CH_3O), 2.30 (bdd, 1H, $J_{2eq,2ax}$ 13.0 Hz, $J_{1,2eq}$ ~ 1 Hz, H-2eq), 2.06 (s, 3H, CH_3CO), 1.68 (ddd, 1H, H-2ax).

*Methyl 4-*O*-acetyl-3-*O*-benzyl-2-deoxy-6-*O*-(p-methoxybenzyl)-α-D-*arabino*-hexopyranoside (9)*

As for **6**, compound **8** was characterized by acetylation to the title compound. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 7H, Ph, *Ph*OMe), 6.85 (d, 2H, *Ph*OMe), 5.02 (t, 1H, $J_{3,4}$ ~$J_{4,5}$ 9.5 Hz, H-4), 4.83 (bd, 1H, $J_{1,2}$ 2.5 Hz, H-1), 4.61 and 4.45, 4.49 and 4.43 (2ABq, each 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph, CH_2PhOMe), 3.88 (ddd, 1H, $J_{2eq,3}$ 5.0 Hz, $J_{2ax,3}$ 11.5 Hz, $J_{3,4}$ 8.8 Hz, H-3), 3.79 (ddd, 1H, $J_{5,6}$ 3.5 Hz, $J_{5,6'}$ 5.5 Hz, H-5), 3.77 (s, 3H, CH_3OPh), 3.51 and 3.47 (ABX, 2H, $J_{6,6'}$ 10.0 Hz, H-6, H-6′), 3.32 (s, 3H, CH_3O), 2.26 (ddd, 1H, $J_{2eq,2ax}$ 13.0 Hz, $J_{1,2eq}$ ~ 1 Hz, H-2eq), 1.92 (s, 3H, CH_3CO), 1.75 (ddd, 1H, H-2ax).

*Methyl 2-*O*-benzyl-4,6-*O*-(p-methoxybenzylidene)-3-*O*-[(methylthio)thiocarbonyl]-α-D-glucopyranoside (10)*

Alcohol **2** (1.0 g, 2.49 mmol) was converted to the xanthate **10** as described for the preparation of **5**. ^{1}H NMR ($CDCl_3$) δ: 7.4–7.25 (m, 7H, Ph, *Ph*OMe), 6.88 (d, 2H, *Ph*OMe), 6.53 (t, 1H, $J_{2,3}$ ~ $J_{3,4}$ 9.5 Hz, H-3), 5.44 (s, 1H, C*H*Ph), 4.71 and 4.60 (ABq, 2H, $J_{A,B}$ 12.5 Hz, CH_2Ph), 4.69 (overlapped, H-1), 4.26 (dd, 1H, $J_{5,6}$ 4.5 Hz, $J_{6,6'}$ 10.0 Hz, H-6), 3.79, 3.41 (2s, each 3H, 2CH_3O), 2.59 (s, 3H, CH_3S).

*Methyl 2-*O*-benzyl-3-deoxy-4,6-*O*-(p-methoxybenzylidene)-α-D-*ribo*-hexopyranoside (11)*

Reduction of **10** as described above for **4** yielded the title compound (690 mg, 72%) after chromatography on a column of silica gel (hexane – ethyl acetate, 3:1, 0.1% triethylamine). ^{1}H NMR ($CDCl_3$) δ: 7.4–7.25 (m, 7H, Ph, *Ph*OMe), 6.88 (d, 1H, *Ph*OMe), 5.45 (s, 1H, C*H*Ph), 4.68 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.66 and 4.58 (ABq, 2H, $J_{A,B}$ 12.5 Hz, CH_2Ph), 4.22 (dd, 1H, $J_{6,6'}$ 9.5 Hz, $J_{5,6}$ 4.5 Hz, H-6), 3.79 (s, 3H, CH_3OPh), 3.75 (ddd, 1H, $J_{5,6'}$ ~ $J_{4,5}$ 9.5 Hz, H-5), 3.64 (t, 1H, H-6′), 3.60 (dt, 1H, $J_{2,3ax}$ 11.5 Hz, $J_{2,3eq}$ 4.0 Hz, H-2), 3.47 (m, overlapped, H-4), 3.45 (s, 3H, CH_3O), 2.26 (td, 1H, $J_{3eq,4}$ 4.5 Hz, $J_{3eq,3ax}$ 11.5 Hz, H-3eq), 2.04 (q, 1H, $J_{3ax,4}$ 11.5 Hz, H-3ax). Anal. calcd. for $C_{22}H_{26}O_6$: C 68.38, H 6.78; found: C 67.91, H 6.81.

*Methyl 2-*O*-benzyl-3-deoxy-4-*O*-(p-methoxybenzyl)-α-D-ribo-hexopyranoside (12) and methyl 2-*O*-benzyl-3-deoxy-6-*O*-(p-methoxybenzyl)-α-D-*ribo*-hexopyranoside (14)*

Reductive cleavage of **11** (1.12 g, 2.90 mmol) with sodium cyanoborohydride (1.1 g, 17.5 mmol) in the presence of trimethylsilyl chloride (2.2 mL, 17.3 mmol) was performed as described for the preparation of **6**. Column chromatography on silica gel (hexane – ethyl acetate, 3:1) provided an approximately 1:1 mixture of the regio isomers **12** and **14** in 60% yield (672 mg). Repeated column chromatography in the same solvent provided the pure isomers **12** and **14** as syrups. Compound **12**: ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 7H, Ph, *Ph*OMe), 6.87 (d, 2H, *Ph*OMe), 4.64 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.62 and 4.56, 4.56 and 4.38 (2ABq, each 2H, $J_{A,B}$ 11.0 Hz, CH_2Ph, CH_2PhOMe), 3.80 (s, 3H, CH_3OPh), 3.78 and 3.70 (ABX, 2H, $J_{5,6}$ 3.0 Hz, $J_{6,6'}$ 11.5 Hz, $J_{5,6'}$ 4.5 Hz, H-6, H-6′), 3.60 (m, 1H, H-5), 3.44 (ddd, 1H, $J_{2,3eq}$ 4.5 Hz, $J_{2,3ax}$ 11.5 Hz, H-2), 3.40 (s, 3H, CH_3O), 3.40 (overlapped, H-4), 2.32 (td, 1H, $J_{3eq,3ax}$ 11.5 Hz, $J_{3eq,4}$ 4.5 Hz, H-3eq), 1.90 (bs, 1H, OH), 1.86 (q, 1H, $J_{3ax,4}$ 11.5 Hz, H-3ax). Anal. calcd. for $C_{22}H_{28}O_6$: C 68.02, H 7.26; found: C 67.98, 7.28. Compound **14**: ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 7H, Ph, *Ph*OMe), 6.88 (d, 2H, *Ph*OMe), 4.63 (d, 1H, $J_{1,2}$ 3.3 Hz, H-1), 4.63 and 4.55, 4.52 and 4.47 (2ABq, each 2H, $J_{A,B}$ 12.0, 11.5 Hz, CH_2Ph, CH_2PhOMe), 3.80 (3, 3H, CH_3OPh), 3.71–3.53 (m, 4H, H-4, H-5, H_2-6), 3.50 (td, 1H, $J_{2,3eq}$ 4.5 Hz, $J_{2,3ax}$ 11.5 Hz, H-2), 3.40 (s, 3H, CH_3O), 2.19 (td, 1H, $J_{3eq,3ax}$ 11.5 Hz, H-3eq), 1.84 (m, 1H, H-3ax).

*Methyl 6-*O*-acetyl-2-*O*-benzyl-3-deoxy-4-*O*-(p-methoxybenzyl)-α-D-ribo-hexopyranoside (13)*

Compound **12** was further characterized by acetylation to **13**. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 7H, *Ph*OMe), 6.88 (d, 2H, *Ph*OMe), 4.67 (d, 1H, $J_{1,2}$ 3.0 Hz, H-1), 4.63 and 4.57, 4.54 and 4.33 (2ABq, each 2H, $J_{A,B}$ 12.0, 11.0 Hz, CH_2Ph, CH_2PhOMe), 4.24 (d, 2H, $J_{5,6}$ 4.0 Hz, H_2-6), 3.81 (s, 3H, CH_3OPh), 3.77 (dt, 1H, $J_{4,5}$ 9.5 Hz, H-5), 3.48 (ddd, 1H, $J_{2,3ax}$ 11.5 Hz, $J_{2,3eq}$ 4.5 Hz, H-2), 3.41 (s, 3H, CH_3O), 3.34 (dt, 1H, $J_{3ax,4}$ 11.5 Hz, $J_{3eq,4}$ 4.5 Hz, H-4), 2.35 (td, 1H, $J_{3eq,3ax}$ 11.5 Hz, H-3eq), 2.01 (s, 3H, CH_3CO), 1.85 (q, 1H, H-3ax).

*Methyl 4-O-acetyl-2-O-benzyl-3-deoxy-6-O-(p-methoxybenzyl)-α-D-ribo-hexopyranoside (**15**)*

Compound **14** was characterized by acetylation to **15**. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 7H, Ph, *Ph*OMe), 6.88 (d, 2H, *Ph*OMe), 4.81 (dt, 1H, $J_{3ax,4}$ 11.5 Hz, $J_{3eq,4}$ 4.5 Hz, $J_{4,5}$ 10.0 Hz, H-4), 4.68 (d, 1H, $J_{1,2}$ 3.3 Hz, H-1), 4.64 and 4.51, 4.55 and 4.37 (2ABq, each 2H, $J_{A,B}$ 11.5 Hz, CH_2Ph, CH_2PhOMe), 3.81 (s, 3H, CH_3OPh), 3.78 (ddd, 1H, $J_{5,6}$ 2.5 Hz, $J_{5,6'}$ 4.5 Hz, H-5), 3.58 (ddd, 1H, $J_{2,3ax}$ 11.5 Hz, $J_{2,3eq}$ 4.5 Hz, H-2), 3.50 and 3.44 (ABX, 2H, $J_{6,6'}$ 10.0 Hz, H-6, H-6'), 3.43 (s, 3H, CH_3O), 2.33 (dt, 1H, $J_{3eq,3ax}$ 11.5 Hz, H-3eq), 1.91 (s, 3H, CH_3CO) 1.84 (q, 1H, H-3ax).

General procedure for the preparation of substituted α-D-hexopyranosyl bromides

A solution of oxalyl bromide (250 μL, ~2.30 mmol) in dichloromethane (1 mL) was added dropwise to a stirred solution of the substituted hexopyranose (1.6 mmol) in dichloromethane (10 mL) and *N,N*-dimethylformamide (0.6 mL, 8.4 mmol). After 20 min, the mixture was poured into ice-water and the organic solution was washed twice with ice-cold water, dried, and evaporated. These products, which must have contained small equilibrium concentrations of the β anomer, were prepared just prior to use.

General procedure for bromide-ion catalyzed glycosidations

A solution of the substituted hexopyranosyl bromide (2.4 mmol) in dichloromethane (2.5 mL) was added to a stirred mixture of the alcohol (0.8 mmol), tetraethylammonium bromide (2.4 mmol), *N,N*-dimethylformamide (0.53 mL), and 4 Å molecular sieves (powdered, 1 g) in dichloromethane (1 mL). The mixture was stirred under nitrogen for 3 days and then quenched by the addition of methanol (0.3 mL). After stirring for another 30 min, it was diluted with dichloromethane, filtered through a pad of Celite, and the solution washed with saturated aqueous sodium hydrogen carbonate and water, followed by drying and evaporation. The crude product was applied to a silica gel column for purification.

Except for **6** and **12**, the 2,3,4-trisubstituted derivatives of methyl α-D-glucopyranosides (**17–21**), reported in Scheme 2, were prepared as previously reported (8). All of the bromides reported in Scheme 3 were prepared from literature compounds. In all cases, α-glucosylation predominated (~9α:1β); the yields of these mixtures were variable but acceptable for the present purposes. The chief difficulty was to obtain pure α isomers. Often, two or three successive chromatographic separations had to be conducted, normally using mixtures of hexane–dichloromethane – ethyl acetate.

*Methyl 2,3,4-tri-O-benzyl-6-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**22**) (34)*

Obtained as a syrup. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 35H, 7Ph), 4.98 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 4.98–4.39 (m, 14H, 7CH_2Ph), 4.54 (d, overlapped, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.99 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.96 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ 9.5 Hz, H-3'), 3.54 (dd, 1H, overlapped, H-2'), 3.44 (dd, 1H, H-2), 3.35 (s, 3H, CH_3O).

*Methyl 3-O-benzyl-2-deoxy-4-O-(p-methoxybenzyl)-6-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-α-D-arabino-hexopyranoside (**23**)*

The α-glucosylation was conducted following the general procedure except for addition of 1 mol-equiv. of Hünig's base (diisopropylethylamine); mp 92–93°C (ether, hexane); $[\alpha]_D$ +77.6 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.38–7.20 (m, 27H, 5Ph, *Ph*OMe), 6.80 (d, 2H, *Ph*OMe), 5.05 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 4.97–4.40 (m, 12H, 5CH_2Ph, CH_2PhOMe), 4.74 (d, 1H, $J_{1,2ax}$ 3.5 Hz, H-1), 4.00 (t, 1H, $J_{3',4'} \sim J_{2',3'}$ 9.5 Hz, H-3'), 3.95 (m, overlapped, 1H, H-3), 3.74 (s, 3H, CH_3OPh), 3.57 (dd, overlapped, H-2'), 2.22 (ddd, 1H, $J_{2ax,2eq}$ 12.5 Hz, $J_{1,2eq} \sim 1$ Hz, $J_{2eq,3}$ 5.2 Hz, H-2eq), 1.57 (ddd, 1H, $J_{2ax,3}$ 11.5 Hz, H-2ax); ^{13}C NMR ($CDCl_3$) δ: 98.30 (C-1), 97.24 (C-1'), 81.81, 80.20 (C-2', C-3'), 78.14 (C-3), 77.76, 77.69 (C-4, C-4'), 75.52, 74.94, 74.58, 73.46, 72.43, 71.73 (5CH_2Ph, CH_2PhOMe), 70.99, 70.27 (C-5, C-5'), 68.65 (C-6'), 66.41 (C-6), 55.28 (CH_3O-1), 54.58 (CH_3OPh), 35.50 (C-2). Anal. calcd. for $C_{56}H_{62}O_{11}$: C73.82, H 6.86; found: C 73.82, H 6.80.

*Methyl 2-O-benzyl-3-deoxy-4-O-(p-methoxybenzyl)-6-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-α-D-ribo-hexopyranoside (**24**)*

Hünig's base was added as reported for the preparation of **23**. Repeated column chromatography only afforded 12% of pure syrup; $[\alpha]_D$ +80.6 (*c* 0.7, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.35–7.10 (m, 27H, 5Ph, *Ph*OMe), 6.80 (d, 2H, *Ph*OMe), 4.98 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 4.98–4.33 (m, 12H, 5CH_2Ph, CH_2PhOMe), 4.61 (d, overlapped, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.99 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ 9.5 Hz, H-3'), 3.74 (s, 3H, CH_3OPh), 3.65 (overlapped, H-4'), 3.55 (dd, overlapped, H-2'), 3.51 (overlapped, H-4), 3.38 (s, 3H, CH_3O), 3.33 (td, 1H, $J_{2,3eq}$ 4.5 Hz, $J_{2,3ax}$ 12.0 Hz, H-2), 2.25 (td, 1H, $J_{3ax,3eq}$ 12.0 Hz, $J_{3eq,4}$ 4.5 Hz, H-3eq), 1.82 (q, 1H, $J_{3ax,4}$ 11.5 Hz, H-3ax). ^{13}C NMR ($CDCl_3$) δ: 97.07 (C-1'), 97.00 (C-1), 81.88, 80.19 (C-2', C-3'), 77.78 (C-4'), 75.52, 75.00, 73.45, 72.34, 71.11, 70.32 (5CH_2Ph, CH_2PhOMe), 74.11 (C-2), 71.48 (C-4), 70.81, 70.16 (C-5, C-5'), 68.59 (C-6'), 66.06 (C-6), 54.88 (CH_3OPh), 55.28 (CH_3O-1), 30.20 (C-3). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H 6.86; found: C 73.60, H 6.90.

*Methyl 2,3-di-O-benzyl-4-deoxy-6-O-(2,3,4,6-tetra-O-benzyl-α-D-glucopyranosyl)-α-D-xylo-hexopyranoside (**25**)*

Obtained as a syrup (53%), $[\alpha]_D$ +50 (*c* 0.53, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.37–7.10 (m, 30H, 6Ph), 4.98–4.42 (m, 12H, 6CH_2Ph), 4.80 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1'), 4.63 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.96 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ 9.5 Hz, H-3'), ~3.92 (m, 2H, H-3, H-5), 3.82 (ddd, 1H, $J_{4',5'}$ 9.5 Hz, $J_{5',6'a}$ 3.0 Hz, $J_{5',6'b}$ 1.8 Hz, H-5'), 3.70 (dd, 1H, $J_{6'a,6'b}$ 10.5 Hz, H-6'a), 3.55 (dd, 1H, H-2'), 3.43 (dd, 1H, $J_{2,3}$ 9.5 Hz, H-2), 3.41 (dd, 1H, $J_{5,6a}$ 4.5 Hz, $J_{6a,6b}$ 10.5 Hz, H-6a), 3.34 (s, 3H, CH_3O), 2.11 (ddd, 1H, $J_{4ax,4eq}$ 13.0 Hz, $J_{3,4eq}$ 5.0 Hz, $J_{4eq,5}$ 2.0 Hz, H-4eq), 1.47 (q, 1H, $J_{3,4ax} \sim J_{4ax,5}$ 12.0 Hz, H-4ax). ^{13}C NMR ($CDCl_3$) δ: 98.92 (C-1), 97.28 (C-1'), 81.94, 80.61 (C-2', C-3'), 80.05 (C-2), 77.72 (C-4'), 75.36 (C-3), 75.61, 74.97, 73.47, 73.30, 72.99, 72.56 (6CH_2Ph), 70.32 (C-5'), 70.14 (C-6), 68.55 (C-6'), 66.52 (C-5), 55.19 (CH_3O), 34.15 (C-4). Anal. calcd. for $C_{55}H_{60}O_{10}$: C 74.98, H 6.86; found: C 74.68, H 6.84.

*Methyl 3,4-di-*O*-benzyl-2-*O*-methyl-6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**26**)*
Obtained as a syrup (68%), $[\alpha]_D$ +78.4 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 30H, 6Ph), 5.04 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′) 5.00–4.42 (m, 12H, 6CH_2Ph), 4.82 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.00 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ 9.5 Hz, H-3′), 3.93 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.61 (dd, 1H, H-2′), 3.48 and 3.42 (2s, each 3H, 2CH_3O), 3.23 (dd, 1H, H-2). ^{13}C NMR ($CDCl_3$) δ: 97.38 (C-1, C-1′), 82.35, 82.17 (C-2, C-3), 81.74, 80.24 (C-2′, C-3′), 77.65 (C-4, C-4′), 75.52, 75.52, 74.99, 74.91, 73.44, 72.44 (6CH_2Ph), 70.40, 70.32 (C-5, C-5′), 68.55 (C-6′), 66.18 (C-6), 59.19 (CH_3O-2), 55.12 (CH_3O-1). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H 6.86; found: C 73.93, H 6.94.

*Methyl 2,4-di-*O*-benzyl-3-*O*-methyl-6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**27**)*
Obtained pure as a syrup (35%), $[\alpha]_D$ +68 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 30H, 6Ph), 4.98–4.37 (m, 12H, 6CH_2Ph), 4.94 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.52 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.96 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ ~9.5 Hz, H-3′), 3.67 (s, 3H, CH_3O), 3.53 (dd, overlapped, H-2′), 3.35 (dd, overlapped, H-2), 3.33 (s, 3H, CH_3O). ^{13}C NMR ($CDCl_3$) δ: 97.97 (C-1), 97.24 (C-1′), 83.92, 79.95 (C-2, C-3), 81.74, 79.95 (C-2′, C-3′), 77.84, 77.63 (C-4, C-4′), 75.46, 74.86, 74.78, 73.39, 73.28, 72.56 (6CH_2Ph), 70.23, 70.16 (C-5, C-5′), 68.49 (C-6′), 66.19 (C-6), 61.12 (CH_3O-3), 55.08 (CH_3O-1). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H 6.86; found: C 73.57, H 6.74.

*Methyl 2,3-di-*O*-benzyl-4-*O*-methyl-6-*O*-(2,3,4,6-tetra-*O*-benzyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**28**)*
Obtained pure as a solid (45%), mp 78–79.5°C (ether, hexane); $[\alpha]_D$ +55.4 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 30H, 6Ph), 4.98 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.95–4.44 (m, 12H, 6CH_2Ph), 4.53 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.95 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ 9.5 Hz, H-3′), 3.86 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.85 (ddd, overlapped, H-5), 3.62 (dd, overlapped, H-4′), 3.55 (s, 3H, CH_3O), 3.54 (dd, overlapped, H-2′) 3.38 (dd, 1H, H-2), 3.34 (s, 3H, CH_3O), 3.32 (dd, 1H, $J_{4,5}$ 10.0 Hz, H-4). ^{13}C NMR ($CDCl_3$) δ: 98.00 (C-1), 97.32 (C-1′), 82.09, 80.01 (C-2, C-3), 81.75, 80.07 (C-2′, C-3′), 79.69 (C-4), 77.72 (C-4′), 75.63, 75.51, 74.97, 73.46, 73.39, 72.34 (6CH_2Ph), 70.43, 70.32 (C-5, C-5′), 68.65 (C-6′), 66.22 (C-6), 60.85 (CH_3O-4), 55.19 (CH_3O-1). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H 6.86; found: C 73.61, H 6.53.

General procedure for deblocking by hydrogenolysis
The blocked disaccharide (ca. 0.4 g) and 5% palladium-on-carbon (0.4 g) in methanol (22 mL) were hydrogenated in the hydrogen stream for 2–3 h. The catalyst was removed by filtration and the solvent evaporated. Gel filtration on a column of Sephadex LH 20 (ethanol–water, 1:1) provided the disaccharide as a white solid after lyophilization of an aqueous solution. The ^{13}C NMR data are reported in Table 1.

*Methyl 6-*O*-(α-D-glucopyranosyl)-α-D-glucopyranoside (**29**)*
The hydrogenolysis of **22** produced **29** in 96% yield. $[\alpha]_D$ +150.6 (*c* 0.5, water) (lit. (34) $[\alpha]_D^{22}$ +166 (water)). ^{1}H NMR (D_2O) δ: 4.96 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.82 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.99 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{6a,5}$ 4.5 Hz, H-6a), 3.57 (H-2), 3.56 (H-2′), 3.42 (s, 3H, CH_3O).

*Methyl 2-deoxy-6-*O*-(α-D-glucopyranosyl)-α-D-*arabino*-hexopyranoside (**30**)*
The hydrogenolysis of **23** produced **30** in 90% yield. $[\alpha]_D$ +149.6 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 4.96 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.92 (bd, 1H, $J_{1,2ax}$ 3.5 Hz, H-1), 4.03 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.0 Hz, H-6a), 3.56 (dd, 1H, $J_{2',3'}$ 10.0 Hz, H-2′), 3.48, 3.44 (2t, 2H, H-4, H-4′), 3.38 (s, 3H, CH_3O), 2.16 (ddd, 1H, $J_{2eq,2ax}$ 13.5 Hz, $J_{1,2eq}$ 1Hz, $J_{2eq,3}$ 5.5 Hz, H-2eq), 1.74 (ddd, 1H, $J_{2ax,3}$ 11.5 Hz, H-2ax).

*Methyl 3-deoxy-6-*O*-(α-D-glucopyranosyl)-α-D-*ribo*-hexopyranoside (**31**)*
The hydrogenolysis of **24** produced **31** in quantitative yield. $[\alpha]_D$ +150.2 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 4.93 (d, 1H, $J_{1',2'}$ 3.7 Hz, H-1′), 4.71 (d, 1H, $J_{1,2}$ 3.7 Hz, H-1), 3.97 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{6a,5}$ 4.0 Hz, H-6a), 3.83 (H-2), 3.54 (dd, 1H, $J_{2',3'}$ 9.8 Hz, H-2′), 3.45 (s, 3H, CH_3O), 3.43 (t, 1H, $J_{3',4'} \sim J_{4',5'}$ 9.5 Hz, H-4′), 2.17 (td, 1H, $J_{3ax,3eq}$ 12.0 Hz, $J_{2,3eq} \sim J_{3eq,4}$ 4.5 Hz, H-3eq), 1.72 (q, 1H, $J_{2,3ax} \sim J_{3ax,4}$ 11.0 Hz, H-3ax).

*Methyl 4-deoxy-6-*O*-(α-D-glucopyranosyl)-α-D-*xylo*-hexopyranoside (**32**) (29)*
The hydrogenolysis of **25** produced **32** in 95% yield. $[\alpha]_D$ +154 (*c* 0.5 water). ^{1}H NMR (D_2O) δ: 4.91 (d, 1H, $J_{1',2'}$ 3.8 Hz, H-1′), 4.82 (d, 1H, $J_{1,2}$ 4.0 Hz, H-1), 4.09 (m, 1H, $J_{4ax,5}$ 12.0 Hz, H-5), 3.90 (ddd, 1H, $J_{2,3}$ 10.0 Hz, $J_{3,4ax}$ 12.0 Hz, $J_{3,4eq}$ 5.0 Hz, H-3), 3.83 (dd, 1H, $J_{6'a,6'b}$ 12.0 Hz, $J_{5',6'a}$ 2.0 Hz, H-6′a), 3.62 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6b}$ 3.0 Hz, H-6b), 3.53 (dd, 1H, $J_{2',3'}$ 10.0 Hz, H-2′), 3.47 (dd, 1H, H-2), 3.39 (s, 3H, CH_3O), 3.39 (t, overlapped, $J_{4',5'} \sim J_{3',4'}$ 9.5 Hz, H-4′), 2.00 (ddd, 1H, $J_{4eq,4ax}$ 12.8 Hz, $J_{4eq,5}$ 1.8 Hz, H-4eq), 1.57 (q, 1H, H-4ax).

*Methyl 6-*O*-(α-D-glucopyranosyl)-2-*O*-methyl-α-D-glucopyranoside (**33**)*
The hydrogenolysis of **26** produced **33** in quantitative yield. $[\alpha]_D$ +155.2 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 5.07 (d, 1H, $J_{1,2}$ 3.6 Hz, H-1), 4.96 (d, 1H, $J_{1',2'}$ 3.7 Hz, H-1′), 4.00 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.0 Hz, H-6a), 3.68 (t, $J_{3,4} \sim J_{2,3}$ 9.5 Hz, H-3), 3.56 (dd, 1H, $J_{2',3'}$ 9.8 Hz, H-2′), 3.54 (t, 1H, $J_{4,5}$ 9.5 Hz, H-4), 3.49 and 3.44 (2s, each 3H, 2CH_3O), 3.44 (t, overlapped, $J_{4',5'} \sim J_{3',4'}$ 9.5 Hz, H-4′), 3.32 (dd, 1H, H-2).

*Methyl 6-*O*-(α-D-glucopyranosyl)-3-*O*-methyl-α-D-glucopyranoside (**34**)*
The hydrogenolysis of **27** produced **34** in quantitative yield $[\alpha]_D$ +169.8 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 4.94 (d, 1H, $J_{1',2'}$ 3.8 Hz, H-1′), 4.79 (H-1), 3.99 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.0 Hz, H-6a), 3.85 (ddd, overlapped, H-5), 3.84 (dd, 1H, $J_{6'a,6'b}$ 11.0 Hz, $J_{5',6'a}$ 1.8 Hz, H-6′a), 3.62 (dd, overlapped, $J_{2',3'}$ 9.5 Hz, H-2′), 3.60 (s, 3H, CH_3O), 3.58 (t, overlapped, $J_{4,5} \sim J_{3,4}$ 9.5 Hz, H-4), 3.54 (dd, 1H, H-2), 3.42 (5H, s, 2t, CH_3O, H-3, H-4′).

*Methyl 6-*O*-(α-D-glucopyranosyl)-4-*O*-methyl-α-D-glucopyranoside (**35**)*
The hydrogenolysis of **28** produced **35** in 97% yield. $[\alpha]_D$ +174.4 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 4.96 (d, 1H, $J_{1',2'}$ 3.7 Hz, H-1′), 4.78 (d, 1H, $J_{1,2}$ 3.6 Hz, H-1), 3.97 (dd, 1H, $J_{6a,6b}$ 11.5 Hz, $J_{5,6a}$ 4.5 Hz, H-6a), 3.86 (dd, 1H, $J_{5',6'a}$ 2.0 Hz, $J_{6'a,6'b}$ 11.0 Hz, H-6′a), 3.59 (dd, 1H, $J_{2,3}$ 9.2 Hz, H-2), 3.56 (s, 3H, CH_3O), 3.55 (dd, 1H, H-2′), 3.43 (t, 1H, $J_{3',4'} \sim J_{4',5'}$ 9.0 Hz,

H-4′), 3.40 (s, 3H, CH_3O), 3.31 (dd, 1H, $J_{3,4}$ 9.0 Hz, $J_{4,5}$ 10.0 Hz, H-4).

*Allyl 2,3,4-tri-*O*-benzyl-6-*O*-methyl-α-*D*-glucopyranoside (**37**)*

Sodium hydride (80% suspension, 1.7 g, 56.7 mmol) was added to a stirring solution of allyl 2,3,4-tri-*O*-benzyl-α-D-glucopyranoside (**36**) (9.2 g, 18.8 mmol) (36) in *N,N*-dimethylformamide (90 mL) at ice-bath temperature. After 30 min, methyl iodide (3.5 mL, 56.2 mmol) was added and stirring continued at room temperature for 4 h. The excess of hydride was destroyed by the addition of methanol and the product isolated in the usual manner. Chromatography using hexane – ethyl acetate (4:1) provided a pure syrup, $[\alpha]_D$ +29 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.43–7.22 (m, 15H, 3Ph), 5.96 (m, 1H, CH_2=C*H*), 5.34 and 5.24 (2m, 2H, CH_2=CH), 5.06–4.60 (3ABq, each 2H, 3CH_2Ph), 4.82 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.18 and 4.04 (2m, 2H, CH_2=CH-CH_2), 4.04 (t, 1H, $J_{2,3} \sim J_{3,4} \sim$ 9.5 Hz, H-3), 3.80 (ddd, 1H, $J_{5,6}$ 2.5 Hz, $J_{5,6'}$ 4.0 Hz, $J_{4,5}$ 10.0 Hz, H-5), 3.65 (t, overlapped, H-4), 3.64 and 3.55 (ABX, overlapped, 2H, $J_{6,6'}$ 11.0 Hz, H-6, H-6′), 3.58 (overlapped, H-2), 3.33 (s, 3H, CH_3O). Anal. calcd. for $C_{31}H_{36}O_6$: C 73.79, H 7.19; found: C 73.67, H 7.34.

*2,3,4-Tri-*O*-benzyl-6-*O*-methyl-α-*D*-glucopyranose (**38**)*

A mixture of **37** (8.7 g, 17.2 mmol), tris(triphenylphosphine)rhodium(I) chloride (1.2 g, 1.3 mmol), and 1,4-diazabicyclo[2.2.2]octane (0.53 g, 4.7 mmol) in 95% ethanol – toluene–water (7:3:1, 400 mL) was boiled under reflux with stirring for 20 h. The solvent was evaporated and the remainder was taken up in acetone (350 mL) containing mercuric oxide (0.24 g). A solution of mercuric chloride (25 g) in acetone–water (9:1, 175 mL) was added and the mixture stirred for 30 min. After solvent removal, the residue was taken up in dichloromethane, the solution was washed with aqueous saturated potassium bromide and water, and the organic solution concentrated. Purification on a column of silica gel (hexane – ethyl acetate, 3:1) provided an amorphous solid **38** (6.1 g, 76%). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 15H, 3Ph), 5.22 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.95 and 4.87, 4.88 and 4.62, 4.78 and 4.69 (3ABq, each 2H, $J_{A,B}$ 11.0, 11.5 Hz, 3CH_2Ph), 4.00 (m, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 3.5 Hz, $J_{5,6'}$ 2.0 Hz, H-5), 3.96 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.0 Hz, H-3), 3.61 (dd, overlapped, $J_{6,6'}$ 10.0 Hz, H-6), 3.60 (t, 1H, H-4), 3.57 (dd, overlapped, H-2), 3.54 (dd, 1H, H-6′), 3.34 (s, 3H, CH_3O), 2.83 (bs, 1H, OH).

*3,4,6-Tri-*O*-benzyl-2-deoxy-α-*D*-arabino-hexopyranosyl chloride (**39**)*

This reagent (37) was prepared just prior to use. ^{1}H NMR parameters were as previously reported (38).

*2,4,6-Tri-*O*-benzyl-3-deoxy-α-*D*-ribo-hexopyranosyl bromide (**40**)*

Prepared from 2,4,6-tri-*O*-benzyl-3-deoxy-D-*ribo*-hexopyranose (39). ^{1}H NMR ($CDCl_3$) δ: 7.45–7.15 (m, 15H, 3Ph), 6.59 (bd, 1H, $J_{1,2}$ 3.0 Hz, $J_{1,3eq} \sim$ 1 Hz, H-1), 4.65–4.38 (3ABq, 6H, 3CH_2Ph), 3.94 (ddd, 1H, $J_{4,5}$ 9.5 Hz, $J_{5,6}$ 3.0 Hz, $J_{5,6'}$ 2.0 Hz, H-5), 3.79 (dd, 1H, $J_{6,6'}$ 10.5 Hz, H-6), 3.69 (ddd, 1H, $J_{3ax,4}$ 11.0 Hz, $J_{3eq,4}$ 4.5 Hz, H-4), 3.66 (dd, 1H, H-6′), 3.44 (td, 1H, $J_{2,3eq}$ 4.5 Hz, $J_{2,3ax}$ 11.5 Hz, H-2), 2.33 (m, 1H, $J_{3eq,3ax}$ 11.5 Hz, H-3eq), 1.97 (q, 1H, H-3ax).

*2,3,6-Tri-*O*-benzyl-4-deoxy-α-*D*-xylo-hexopyranosyl bromide (**41**)*

Prepared from 2,3,6-tri-*O*-benzyl-4-deoxy-D-*xylo*-hexopyranose (40). ^{1}H NMR ($CDCl_3$) δ: 7.44–7.20 (m, 15H, 3Ph), 6.49 (d, 1H, $J_{1,2}$ 3.5 Hz), 4.77 and 4.68, 4.76 and 4.74, 4.55 and 4.53 (3ABq, each 2H, $J_{A,B}$ 12.0 Hz, 3CH_2Ph), 4.24 (m, 1H, H-5), 4.00 (ddd, 1H, $J_{2,3}$ 9.0 Hz, $J_{3,4ax}$ 12.0 Hz, $J_{3,4eq}$ 5.0 Hz, H-3), 3.52 (d, 2H, $J_{5,6}$ 4.5 Hz, H_2-6), 3.44 (dd, 1H, H-2), 2.13 (ddd, 1H, $J_{4ax,4eq}$ 13.0 Hz, $J_{4eq,5}$ 2.0 Hz, H-4eq), 1.70 (q, 1H, $J_{4ax,5}$ 12.0 Hz, H-4ax).

*2,3,4-Tri-*O*-benzyl-6-deoxy-α-*D*-glucopyranosyl bromide (**42**)*

Prepared from 2,3,4-tri-*O*-benzyl-6-deoxy-D-glucopyranose (41). ^{1}H NMR ($CDCl_3$) δ: 7.45–7.20 (m, 15H, 3Ph), 6.37 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 5.00 and 4.84, 4.93 and 4.66, 4.75 and 4.72 (3ABq, each 2H, $J_{A,B}$ 11.0, 11.5 Hz, 3CH_2Ph), 4.07 (m, 1H, $J_{4,5}$ 9.5 Hz, $J_{5,6}$ 6.5 Hz, H-5), 4.03 (t, 1H, $J_{2,3} \sim J_{3,4} \sim$ 9.5 Hz, H-3), 3.48 (dd, 1H, H-2), 3.21 (t, 1H, H-4), 1.32 (d, 3H, H_3-6).

*3,4,6-Tri-*O*-benzyl-2-*O*-methyl-α-*D*-glucopyranosyl bromide (**43**)*

Prepared from 3,4,6-tri-*O*-benzyl-2-*O*-methyl-D-glucopyranose (42). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 15H, 3Ph), 6.62 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.94 and 4.79, 4.84 and 4.53, 4.58 and 4.47 (3ABq, each 2H, $J_{A,B}$ 11.0 Hz, 3CH_2Ph), 4.06 (m, 1H, $J_{4,5}$ 9.5 Hz, $J_{5,6}$ 2.5 Hz, $J_{5,6'}$ 2.0 Hz, H-5), 3.96 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.80 (dd, overlapped, H-6), 3.78 (t, overlapped, H-4), 3.67 (dd, 1H, $J_{6,6'}$ 11.5 Hz, H-6′), 3.50 (s, 3H, CH_3O), 3.33 (dd, 1H, H-2).

*2,4,6-Tri-*O*-benzyl-3-*O*-methyl-α-*D*-glucopyranosyl bromide (**44**)*

Prepared from 2,4,6-tri-*O*-benzyl-3-*O*-methyl-D-glucopyranose (39). ^{1}H NMR ($CDCl_3$) δ: 7.45–7.20 (m, 15H, 3Ph), 6.38 (d, 1H, $J_{1,2}$ 3.8 Hz, H-1), 4.81 and 4.51, 4.72 and 4.68, 4.57 and 4.46 (3ABq, each 2H, $J_{A,B}$ 11.0, 12.0 Hz, 3CH_2Ph), 4.01 (ddd, 1H, $J_{4,5}$ 9.5 Hz, $J_{5,6}$ 3.0 Hz, $J_{5,6'}$ 2.0 Hz, H-5), 3.76 (dd, 1H, $J_{6,6'}$ 11.0 Hz, H-6), 3.72 (t, overlapped, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.68 (s, 3H, CH_3O), 3.65 (t, overlapped, H-4), 3.63 (dd, 1H, H-6′), 3.42 (dd, 1H, H-2).

*2,3,6-Tri-*O*-benzyl-4-*O*-methyl-α-*D*-glucopyranosyl bromide (**45**)*

Prepared from 2,3,6-tri-*O*-benzyl-4-*O*-methyl-D-glucopyranose (38). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.25 (m, 15H, 3Ph), 6.39 (d, 1H, $J_{1,2}$ 3.8 Hz, H-1), 4.94 and 4.80, 4.60 and 4.50 (2ABq, each 2H, $J_{A,B}$ 11.0, 12.0 Hz, 2CH_2Ph), 4.69 (s, 2H, CH_2Ph), 3.95 (ddd, 1H, $J_{4,5}$ 10.0 Hz, $J_{5,6}$ 3.2 Hz, $J_{5,6'}$ 2.0 Hz, H-5), 3.91 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.0 Hz, H-3), 3.75 (dd, 1H, $J_{6,6'}$ 11.0 Hz, H-6), 3.65 (dd, 1H, H-6′), 3.49 (s, 3H, CH_3O), 3.48 (overlapped, H-4), 3.48 (dd, overlapped, H-2).

*2,3,4-Tri-*O*-benzyl-6-*O*-methyl-α-*D*-glucopyranosyl bromide (**46**)*

Prepared from **38**. ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 15H, 3Ph), 6.39 (d, 1H, $J_{1,2}$ 3.8 Hz, H-1), 4.98 and 4.83, 4.88 and 4.61 (2ABq, each 2H, $J_{A,B}$ 10.5 Hz, 2CH_2Ph), 4.70 (s, 2H, CH_2Ph), 4.03 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 4.02 (overlapped, H-5), 3.72 (t, $J_{4,5}$ 9.5 Hz, H-4), 3.66 (dd, 1H, $J_{6,6'}$ 11.0 Hz, $J_{5,6}$

3.5 Hz, H-6), 3.54 (dd, 1H, $J_{5,6'}$ 2.0 Hz, H-6′), 3.51 (dd, 1H, H-2), 3.32 (s, 3H, CH_3O).

Methyl 2,3,4-tri-O-*benzyl-6*-O-*(3,4,6-tri*-O-*benzyl-2-deoxy*-α-D-arabino-*hexopyranosyl)*-α-D-*glucopyranoside (**47**)*

Freshly prepared chloride **39** (2.19 mmol) (37) was reacted with alcohol **17** (0.85 mmol) in the presence of Hünig's base (2.13 mmol) and tetraethylammonium chloride (5.3 mmol). Subsequent column chromatography (hexane–dichloromethane – ethyl acetate, 4:4:0.5, hexane – ethyl acetate, 3.5:1, 0.1% triethylamine) of the crude product provided **47** in 53% yield; mp 82–83°C (ether, hexane); $[\alpha]_D$ +61.2 (*c* 0.5, dichloromethane). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.12 (m, 30, 6Ph), 5.03 (bd, 1H, $J_{1',2'ax}$ 3.5 Hz, $J_{1',2'eq}$ 1 Hz, H-1′), 5.40–4.00 (m, 12H, 6CH_2Ph), 4.63 (d, 1H, $J_{1,2}$ 3.7 Hz, H-1), 4.02 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.97 (ddd, 1H, $J_{2'ax,3'}$ 11.0 Hz, $J_{2'eq,3'}$ 5.0 Hz, $J_{3',4'}$ 8.5 Hz, H-3′), 3.54 (dd, overlapped, H-2), 3.37 (s, 3H, CH_3O), 2.33 (ddd, 1H, $J_{2'eq,2'ax}$ 13.0 Hz, H-2′eq), 1.72 (ddd, 1H, H-2′ax). ^{13}C NMR ($CDCl_3$) δ: 97.96 (C-1), 97.84 (C-1′), 82.26, 80.05 (C-2, C-3), 78.19 (C-3′), 77.81, 77.26 (C-4, C-4′), 75.81, 74.91, 74.85, 73.43, 73.30, 71.73 (6CH_2Ph), 70.93, 69.80 (C-5, C-5′), 68.75 (C-6′), 65.71 (C-6), 55.13 (CH_3O), 35.31 (C-2). Anal. calcd. for $C_{55}H_{60}O_{10}$: C 74.98, H 6.86; found: C 75.07, H 6.88.

Methyl 2,3,4-tri-O-*benzyl-6*-O-*(2,4,6-tri*-O-*benzyl-3-deoxy*-α-D-ribo-*hexopyranosyl)*-α-D-*glucopyranoside (**48**)*

The bromide **40** (1.53 mmol) was reacted with **17** (0.81 mmol) under the conditions for bromide-ion catalyzed glycosylation. The product was purified by column chromatography (hexane–dichloromethane – ethyl acetate, 4:4:0.5) to provide an anomeric mixture in 64%. Further purification by column chromatography (hexane–chloroform – ethyl acetate, 6:10:0.5) provided pure **48** (14%) as a syrup. $[\alpha]_D$ +79.6 (*c* 0.5). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.23 (m, 30H, 6Ph), 5.05 (d, 1H, $J_{1',2'}$ 3.2 Hz, H-1′), 5.04–4.37 (m, 12H, 6CH_2Ph), 4.60 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 4.04 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.70 (overlapped, H-4), 3.56 (td, 1H, $J_{2',3'ax}$ 12.0 Hz, $J_{2',3'eq}$ 4.5 Hz, H-2′), 3.49 (dd, 1H, H-2), 3.40 (s, 3H, CH_3O), 2.36 (td, 1H, $J_{3'eq,3'ax}$ 12.0 Hz, $J_{3'eq,4'}$ 4.5 Hz, H-3′eq), 1.95 (q, 1H, $J_{3'ax,4'}$ 11.0 Hz, H-3′ax). ^{13}C NMR ($CDCl_3$) δ: 97.97 (C-1), 96.22 (C-1′), 82.18, 80.16 (C-2, C-3), 77.96 (C-4), 75.63, 75.05, 73.43, 73.38, 70.79, 70.49 (6CH_2Ph), 73.77 (C-2′), 71.86 (C-4′), 70.71, 70.39 (C-5, C-5′), 68.69 (C-6′), 65.87 (C-6), 55.11 (CH_3O), 30.34 (C-3′). Anal. calcd. for $C_{55}H_{60}O_{10}$: C 74.98, H 6.86; found: 74.61, H 7.01.

Methyl 2,3,4-tri-O-*benzyl-6*-O-*(2,3,6-tri*-O-*benzyl-4-deoxy*-α-D-xylo-*hexopyranosyl)*-α-D-*glucopyranoside (**49**)*

The bromide **41** (2.30 mmol) was reacted with **17** (0.85 mmol) under the conditions for bromide-ion catalyzed glycosylation. The product was purified by column chromatography (hexane – ethyl acetate, 5.5:1) to provide an anomeric mixture of α:β = 9:1 in 90% yield. Further chromatography (hexane–chloroform – ethyl acetate, 6:12:1) afforded pure **49** (42% yield) as a crystalline solid, mp 74–75°C (ether, hexane); $[\alpha]_D$ +54 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.37–7.16 (m, 30H, 6Ph), 5.00 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.94–4.46 (m, 12H, 6CH_2Ph), 4.54 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.97 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.0 Hz, H-3), ~3.89 (m, H-5′, H-3′), 3.81 (dd, overlapped, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.5 Hz, H-6a), 3.76 (m, H-5), 3.72 (dd, 1H, $J_{5,6b}$ 1 Hz, H-6b), 3.62 (t, 1H, $J_{4,5}$ 9.0 Hz, H-4), 3.46 (dd, 1H, $J_{2',3'}$ 9.5 Hz, H-2′), 3.43 (dd, overlapped, H-2), 3.41 (m, 2H, H_2-6′), 3.30 (s, 3H, CH_3O), 2.02 (ddd, 1H, $J_{4'eq,4'ax}$ 12.5 Hz, $J_{4'eq,5'}$ 2.0 Hz, $J_{4'eq,3'}$ 5.0 Hz, H-4′eq), 1.50 (q, 1H, $J_{4'ax,3'} \sim J_{4'ax,5'} \sim$ 12.0 Hz, H-4′ax). ^{13}C NMR ($CDCl_3$) δ: 98.14 (C-1′), 97.97 (C-1), 82.17, 80.23 (C-2, C-3), 80.74 (C-2′), 78.03 (C-4), 75.70, 74.99, 73.39, 73.34, 72.44, 72.31 (6CH_2Ph), 74.54 (C-3′), 72.20 (C-6′), 70.41 (C-5), 66.92 (C-5′), 66.12 (C-6), 55.06 (CH_3O), 33.93 (C-4′). Anal. calcd. for $C_{55}H_{60}O_{10}$: C 74.98, H 6.86; found: C 74.94, H 6.91.

Methyl 2,3,4-tri-O-*benzyl-6*-O-*(2,3,4-tri*-O-*benzyl-6-deoxy*-α-D-*glucopyranosyl)*-α-D-*glucopyranoside (**50**)*

The bromide **42** (1.53 mmol) was reacted with **17** (0.51 mmol) under the conditions for bromide-ion catalyzed glycosylation. Column chromatography (hexane – ethyl acetate, 5:1) provided an anomeric α:β = 9:1 mixture in 92% yield that was purified by recrystallization from ethanol, mp 124–125°C; $[\alpha]_D$ +50.6 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 30H, 6Ph), 4.99–4.55 (m, 12H, 6CH_2Ph), 4.89 (overlapped, $J_{1',2'}$ 3.5 Hz, H-1′), 4.56 (d, 1H, $J_{1,2}$ 3.8 Hz, H-1), 3.99 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.93 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ 9.5 Hz, H-3′), 3.77 (overlapped, H-5′), 3.67 (t, 1H, $J_{4,5}$ 9.5 Hz, H-4), 3.50 (dd, 1H, H-2′), 3.44 (dd, 1H, H-2), 3.35 (s, 3H, CH_3O), 3.10 (t, 1H, $J_{4',5'}$ 9.5 Hz, H-4′), 1.19 (d, 3H, $J_{5',6'}$ 6.5 Hz, H_3-6′). ^{13}C NMR ($CDCl_3$) δ: 98.04 (C-1), 97.00 (C-1′), 83.85 (C-4′), 82.16, 80.20 (C-2, C-3), 81.43, 80.44 (C-2′, C-3′), 75.70, 75.47, 75.15, 75.03, 73.39, 72.29 (6CH_2Ph), 70.49 (C-5), 66.80 (C-5′), 65.93 (C-6), 55.14 (CH_3O), 17.96 (C-6′). Anal. calcd. for $C_{55}H_{60}O_{10}$: C 74.98, H 6.86; found: C74.54, H 6.82.

Methyl 2,3,4-tri-O-*benzyl-6*-O-*(3,4,6-tri*-O-*benzyl-2*-O-*methyl*-α-D-*glucopyranosyl)*-α-D-*glucopyranoside (**51**)*

Bromide **43** (3.82 mmol) was reacted with **17** (0.64 mmol) under the conditions for bromide-ion catalyzed glycosylation. Column chromatography (hexane – ethyl acetate, 5:1) provided **51** in 73% yield as a solid; mp 96.5–97.5°C (ethanol); $[\alpha]_D$ +56.6 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.10 (m, 30H, 6Ph), 5.06 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 5.00–4.40 (m, 12H, 6CH_2Ph), 4.55 (d, 1H, $J_{1,2}$ 3.8 Hz, H-1), 3.99 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.86 (t, 1H, $J_{2',3'} \sim J_{3',4'}$ 9.5 Hz, H-3′), 3.50 (dd, 1H, H-2), 3.41, 3.36 (2s, each 3H, 2CH_3O), 3.31 (dd, 1H, H-2′). ^{13}C NMR ($CDCl_3$) δ: 97.94 (C-1), 96.64 (C-1′), 82.38, 81.62 (C-2′, C-3′), 82.19, 79.88 (C-2, C-3), 77.89, 77.59 (C-4, C-4′), 75.81, 75.32, 74.90, 74.90, 73.41, 73.33 (6CH_2Ph), 70.30 (C-5, C-5′), 68.58 (C-6′), 66.07 (C-6), 58.41 (CH_3O-2′), 55.14 (CH_3O-1). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H. 6.86; found: C 73.64, H 6.86.

Methyl 2,3,4-tri-O-*benzyl-6*-O-*(2,4,6-tri*-O-*benzyl-3*-O-*methyl*-α-D-*glucopyranosyl)*-α-D-*glucopyranoside (**52**)*

Bromide **44** (1.28 mmol) was reacted with **17** (0.51 mmol) under the conditions for bromide-ion catalyzed glycosylation. Column chromatography (hexane–chloroform – ethyl acetate, 6:10:0.5) of the crude product (89% yield) provided pure **52** in 48% yield. $[\alpha]_D$ +71 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.15 (m, 30H, 6Ph), 4.99–4.39 (m, 12H, 6CH_2Ph), 4.95 (d, 1H, $J_{1',2'}$ 3.6 Hz, H-1′), 4.53 (d, 1H, $J_{1,2}$ 3.7 Hz, H-1), 3.98 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.65 (s, 3H, CH_3O), 3.44 (dd, 1H, $J_{2',3'}$ 9.5 Hz, H-2′), 3.42 (dd, 1H, H-2), 3.34 (s, 3H, CH_3O). ^{13}C NMR ($CDCl_3$) δ: 97.90 (C-1), 97.24 (C-1′), 83.68,

79.73 (C-2′, C-3′), 82.08, 80.14 (C-2, C-3), 77.72, 77.61 (C-4, C-4′), 75.63, 74.87, 74.70, 73.34, 73.29, 72.22 (6*C*H_2Ph), 70.31, 70.06 (C-5, C-5′), 68.43 (C-6′), 66.01 (C-6), 61.02 (CH_3O-3′), 55.06 (CH_3O-1). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H 6.86; found: C 73.64, H 6.86.

Methyl 2,3,4-tri-O-*benzyl-6*-O-*(2,3,6-tri*-O-*benzyl-4*-O-*methyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**53**)*

Bromide **45** (2.46 mmol) was reacted with **17** (0.81 mmol) under the conditions for bromide-ion catalyzed glycosylation. Column chromatography (hexane – ethyl acetate, 5:1) provided an anomeric mixture of α:β = 9:1 in 92% yield, from which pure **53** was isolated by further chromatography (hexane–dichloromethane–acetone, 10:1:0.8) in 62% yield. $[\alpha]_D$ +80.4 (*c* 0.1, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.18 (m, 30H, 6Ph), 4.99–4.42 (m, 12H, 6CH_2Ph), 4.93 (d, 1H, $J_{1',2'}$ 3.8 Hz, H-1′), 4.54 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.98 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.84 (t, $J_{3',4'} \sim J_{2',3'}$ 9.5 Hz, H-3′), 3.70 (overlapped, H-5′), 3.62 (overlapped, H-4), 3.48 (dd, 1H, H-2′), 3.44 (s, 3H, CH_3O), 3.42 (dd, 1H, H-2), 3.35 (s, 3H, CH_3O), 3.33 (t, 1H, $J_{4',5'}$ 9.5 Hz, H-4′). ^{13}C NMR ($CDCl_3$) δ: 97.97 (C-1), 97.26 (C-1′), 82.15, 80.20 (C-2, C-3), 81.59, 79.85, 79.44 (C-2′, C-3′, C-4′), 77.90 (C-4), 75.70, 75.35, 74.99, 73.42, 73.37, 72.42 (6*C*H_2Ph), 70.39, 70.31 (C-5, C-5′), 68.65 (C-6′), 66.12 (C-6), 60.62 (CH_3O-4′), 55.13 (CH_3O-1). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H 6.86; found: 73.89, H 6.82.

Methyl 2,3,4-tri-O-*benzyl-6*-O-*(2,3,4-tri*-O-*benzyl-6*-O-*methyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**54**)*

Bromide **46** (2.30 mmol) was reacted with alcohol **17** (0.81 mmol) under the conditions for bromide-ion catalyzed glycosylation. Column chromatography (hexane – ethyl acetate, 4:1) provided an anomeric mixture (α:β = 95:5) in quantitative yield. Further chromatography (hexane–chloroform – ethyl acetate, 6:10:1) afforded pure crystalline **54** (52% yield), mp 105–106°C (ether, hexane); $[\alpha]_D$ +51 (*c* 0.5, chloroform). ^{1}H NMR ($CDCl_3$) δ: 7.40–7.20 (m, 30H, 6Ph), 5.00–4.55 (m, 12H, 6CH_2Ph), 4.95 (d, 1H, $J_{1',2'}$ 3.5 Hz, H-1′), 4.55 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1), 3.98, 3.95 (2t, 2H, H-3, H-3′), 3.52 (dd, overlapped, $J_{2',3'}$ 9.5 Hz, H-2′), 3.44 (dd, 1H, $J_{2,3}$ 9.5 Hz, H-2), 3.35, 3.29 (2s, each 3H, 2CH_3O). ^{13}C NMR ($CDCl_3$) δ: 97.98 (C-1), 97.36 (C-1), 82.14, 80.18 (C-2, C-3), 81.57, 79.96 (C-2′, C-3′), 77.80, 77.75 (C-4, C-4′), 75.69, 75.40, 74.97, 74.92, 73.36, 72.33 (6*C*H_2Ph), 70.96 (C-6′), 70.38, 70.09 (C-5, C-5′), 66.09 (C-6), 59.09 (CH_3O-6′), 55.13 (CH_3O-1). Anal. calcd. for $C_{56}H_{62}O_{11}$: C 73.82, H 6.86; found: C 74.02, H 6.76.

Methyl 6-O-*(2-deoxy-α-D-*arabino-*hexopyranosyl)-α-D-glucopyranoside (**55**)*

The hydrogenolysis of **47** produced **55** in 95% yield. $[\alpha]_D$ +150 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 5.04 (bd, 1H, $J_{1',2'ax}$ 2.8 Hz, $J_{1',2'eq}$ 1Hz, H-1′), ~4.8 (d, 1H, H-1), 3.94 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.5 Hz, H-6a), 3.93 (dt, overlapped, $J_{2'eq,3'}$ 5.0 Hz, $J_{2'ax,3'}$ 11.5 Hz, H-3′), 3.87 (dd, 1H, $J_{6'a,6'b}$ 11.5 Hz, $J_{5',6'a}$ 2.5 Hz, H-6′a), 3.80 (dd and m, 2H, $J_{6'b,5'}$ 5.0 Hz, H-6′b, H-5), 3.70 (dd and m, 2H, $J_{6b,5}$ 1.8 Hz, H-6b, H-5′), 3.66 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.58 (dd, 1H, $J_{1,2}$ 3.8 Hz, H-2), 3.48 (t, 1H, $J_{4,5}$ 9.5 Hz, H-4), 3.42 (s, 3H, CH_3O), 3.37 (t, 1H, $J_{3',4'} \sim J_{4',5'}$ 9.0 Hz, H-4′), 2.18 (ddd, 1H, $J_{2'ax}$, $J_{2'eq}$ 13.5 Hz, H-2′eq), 1.72 (ddd, 1H, H-2′ax).

Methyl 6-O-*(3-deoxy-α-D-*ribo-*hexopyranosyl)-α-D-glucopyranoside (**56**)*

The hydrogenolysis of **48** produced **56** in quantitative yield. $[\alpha]_D$ +163 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 4.85 (d, 1H, $J_{1',2'}$ 3.6 Hz, H-1′), 4.82 (d, 1H, $J_{1,2}$ 3.8 Hz, H-1), 4.01 (dd, 1H, $J_{6a,6b}$ 11.5 Hz, $J_{5,6a}$ 4.0 Hz, H-6a), 3.58 (dd, 1H, $J_{2,3}$ 9.5 Hz, H-2), 3.55 (t, 1H, $J_{3,4} \sim J_{4,5}$ 9.5 Hz, H-4), 3.44 (s, 3H, CH_3O), 2.18 (td, 1H, $J_{3'eq,3'ax}$ 12.0 Hz, $J_{2',3'eq} \sim J_{3'eq,4'}$ 4.5 Hz, H-3′eq), 1.79 (q, 1H, $J_{2',3'ax} \sim J_{3'ax,4'}$ 11.0 Hz, H-3′ax).

Methyl 6-O-*(4-deoxy-α-D-*xylo-*hexopyranosyl)-α-D-glucopyranoside (**57**)*

The hydrogenolysis of **49** produced **57** in quantitative yield. $[\alpha]_D$ +166.4 (*c* 0.5, water), ^{1}H NMR (D_2O) δ: 4.98 (d, 1H, $J_{1',2'}$ 3.8 Hz, H-1′), 4.82 (d, 1H, H-1), 4.00 (m, 3H, H-5′, H-6a, H-3′), 3.83 (ddd, 1H, $J_{4,5}$ 9.5 Hz, $J_{5,6a}$ 4.5 Hz, $J_{5,6b}$ 2.0 Hz, H-5), 3.73 (dd, 1H, $J_{6a,6b}$ 11.5 Hz, H-6b), 3.58 (dd, 1H, $J_{1,2}$ 3.8 Hz, $J_{2,3}$ 9.5 Hz, H-2), 3.52 (t, 1H, $J_{3,4}$ 9.5 Hz, H-4), 3.48 (dd, 1H, $J_{2',3'}$ 9.5 Hz, H-2′), 3.44 (s, 3H, CH_3O), 2.00 (ddd, 1H, $J_{4'eq,4'ax}$ 12.5 Hz, $J_{4'eq,3'}$ 5.2 Hz, $J_{4'eq,5'}$ 1.8 Hz, H-4′eq), 1.46 (q, 1H, $J_{4'ax,5'} \sim J_{3',4'ax}$ 12.0 Hz, H-4′ax).

Methyl 6-O-*(6-deoxy-α-D-glucopyranosyl)-α-D-glucopyranoside (**58**)*

The hydrogenolysis of **50** produced **58** in quantitative yield. $[\alpha]_D$ +152 (*c* 0.5, water). ^{1}H NMR ($CDCl_3$) δ: 4.88 (d, 1H, $J_{1',2'}$ 3.8 Hz, H-1′), 4.80 (d, 1H, H-1), 3.95 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{6a,5}$ 4.5 Hz, H-6a), 3.80 (m, 2H, H-5, H-5′), 3.72 (dd, 1H, $J_{5,6b}$ 2.0 Hz, H-6b), 3.65 (2t, 2H, H-3, H-3′), 3.56 (2dd, 2H, $J_{2,3} = J_{2',3'}$ 9.5 Hz, $J_{1,2} = J_{1',2'}$ 3.8 Hz, H-2, H-2′), 3.50 (dd, 1H, $J_{3,4}$ 9.0 Hz, $J_{4,5}$ 10.0 Hz, H-4), 3.41 (s, 3H, CH_3O), 3.15 (t, 1H, $J_{3',4'}$ 9.0 Hz, $J_{4',5'}$ 10.0 Hz, H-4′), 1.26 (d, 3H, $J_{5',6'}$ 6.2 Hz, H_3-6′).

Methyl 6-O-*(2*-O-*methyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**59**)*

The hydrogenolysis of **51** produced **59** in quantitative yield. $[\alpha]_D$ +163 (*c* 0.5, water), ^{1}H NMR (D_2O) δ: 5.20 (d, 1H, $J_{1',2'}$ 3.6 Hz, H-1′), 4.81 (d, 1H, H-1), 3.96 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.5 Hz, H-6a), 3.86 (dd, 1H, $J_{6'a,6'b}$ 11.0 Hz, $J_{5',6'a}$ 2.0 Hz, H-6′a), 3.66 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.5 Hz, H-3), 3.57 (dd, 1H, $J_{1,2}$ 3.8 Hz, H-2), 3.50, 3.43 (2s, each 3H, 2CH_3O), 3.50, 3.44 (2t, each 1H, H-4, H-4′), 3.31 (dd, 1H, $J_{2',3'}$ 10.0 Hz, H-2′).

Methyl 6-O-*(3*-O-*methyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**60**)*

The hydrogenolysis of **52** produced **60** in quantitative yield. $[\alpha]_D$ +150.8 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 4.92 (d, 1H, $J_{1',2'}$ 3.6 Hz, H-1′), 4.82 (d, 1H, $J_{1,2}$ 3.6 Hz, H-1), 3.99 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.5 Hz, H-6a), 3.83 (dd, m, 2H, H-6′a, H-5), 3.61, 3.43 (2s, each 3H, 2CH_3O).

Methyl 6-C-*(4*-O-*methyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**61**)*

The hydrogenolysis of **53** produced **61** in 89% yield. $[\alpha]_D$ +167 (*c* 0.5, water), ^{1}H NMR (D_2O) δ: 4.94 (d, 1H, $J_{1',2'}$ 3.6 Hz, H-1′), 4.80 (d, 1H, H-1), 3.96 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.5 Hz, H-6a), 3.65 (t, 1H, $J_{2,3} \sim J_{3,4}$ 9.0 Hz, H-3), 3.56 (s, 2dd, 5H, H-2, H-2′, CH_3O), 3.49 (dd, 1H, $J_{4,5}$ 10.0 Hz, H-4), 3.42 (s, 3H, CH_3O), 3.23 (t, 1H, $J_{3',4'} \sim J_{4',5'}$ 9.5 Hz, H-4′).

*Methyl 6-O-(6-O-methyl-α-D-glucopyranosyl)-α-D-glucopyranoside (**62**)*

The hydrogenolysis of **54** produced **62** in quantitative yield. $[\alpha]_D$ +150 (*c* 0.5, water). ^{1}H NMR (D_2O) δ: 4.93 (d, 1H, $J_{1',2'}$ 3.8 Hz, H-1′), 4.81 (d, 1H, H-1), 3.97 (dd, 1H, $J_{6a,6b}$ 11.0 Hz, $J_{5,6a}$ 4.5 Hz, H-6a), 3.83 (m, 2H, H-5, H-5′), 3.56 (dd, overlapped, $J_{1,2}$ 3.8 Hz, $J_{2,3}$ 10.0 Hz, H-2), 3.54 (dd, overlapped, $J_{2',3'}$ 9.5 Hz, H-2′), 3.51, 3.41 (2t, overlapped, H-4, H-4′), 3.42, 3.39 (2s, each 3H, $2CH_3O$).

Quantum yield of singlet dioxygen and elucidation of the quenching mechanism for the reaction between the doublet excited states of tris(bipyridine)chromium(III) and triplet dioxygen

Acharee Tiyabhorn and K. Omar Zahir

Abstract: The formation of singlet dioxygen ($^1O_2$) in the reaction between the doublet excited states of tris(bipyridine)chromium(III) and triplet dioxygen in deuterium oxide was detected using near-infrared luminescence corresponding to singlet dioxygen decay. In addition, luminescence intensity measurements were used to determine the quantum yield of singlet dioxygen produced. A value of 0.86 ± 0.08 was obtained for the yield of $^1O_2$. Based on these quantum yield measurements, it is proposed that the major quenching mode is energy transfer quenching. However, considering that the $^1O_2$ yield is less than unity and electron transfer quenching is not a viable pathway, it is proposed that, in addition to the energy transfer quenching, physical quenching involving spin-catalyzed deactivation of $Cr(bpy)_3^{3+}$ may also be operative as a minor quenching pathway.

Key words: $Cr(bpy)_3^{3+}$, singlet dioxygen, quenching, quantum yield.

Résumé : Utilisant la luminescence infrarouge correspondant à la désactivation du dioxygène singulet, on a détecté la formation de dioxygène singulet ($^1O_2$) au cours de la réaction des états doublement excités du tris(bipyridine)chrome(III) et du dioxygène triplet dans l'oxyde de deutérium. De plus, on a utilisé des mesures d'intensité de la luminescence pour déterminer le rendement quantique du dioxygène singulet produit. On a obtenu une valeur de 0,86 ± 0,08 pour le rendement de $^1O_2$. Sur la base de ces mesures de rendements quantiques, il est proposé que le mode majeur de désactivation soit un transfert d'énergie. Toutefois, si l'on considère que le rendement en $^1O_2$ est plus petit que un et que la désactivation par un transfert d'électron n'est pas une voie réactionelle viable, il est suggéré que, en plus de la désactivation par transfert d'énergie, la désactivation physique impliquant une désactivation du $Cr(bpy)_3^{3+}$ catalysée par le spin puisse aussi agir comme voie mineure de désactivation.

Mots clés : $Cr(bpy)_3^{3+}$, dioxygène singulet, désactivation, rendement quantique.

Introduction

The quenching of the luminescent excited states of polypyridyl complexes of transition metals, particularly those of Ru(II) and Cr(III), by triplet dioxygen ($^3O_2$) has been a subject of considerable interest for quite some time (1, 2). Such studies have provided useful fundamental information about the nature and reactivity of these excited states (3, 4). Furthermore, such studies also provide a simple method of evaluating new luminescent inorganic photosensitizers and their role in mechanistic inorganic photochemistry (5).

In the case of $^3O_2$ quenching of the $^*RuL_3^{2+}$ excited states, both direct energy transfer (6) and electron transfer (7) processes were initially proposed as the quenching mechanisms. Several reports on the yields of $^1O_2$ production have appeared, and quantum yield values ranging from 0.54 to 1.0 have been reported for a variety of RuL_3^{2+} complexes in various solvents (6, 8–10).

In the case of $(^2E)CrL_3^{3+}$, hereinafter referred to as $^*CrL_3^{3+}$, it has been suggested that the quenching of $^*CrL_3^{3+}$ by $^3O_2$ proceeds by an energy transfer pathway leading to singlet dioxygen formation (3, 4). However, until now, no direct experimental evidence has been presented in support of the proposed mechanism and, to the best our knowledge, no measurements of the $^1O_2$ quantum yields have been made. The only report presenting direct experimental evidence for the production of singlet dioxygen for Cr(III) complexes involves the quenching of the phosphorescent excited state of the complex $Cr(taca)(NCS)_3$ by triplet dioxygen (11). In that study, the detection and yield of singlet dioxygen was determined using chemical means. It should be noted here that the detection of $^1O_2$ and measurement of its quantum yields is a tricky business, and applicability of chemical methods for such studies has recently been questioned (10, 12). Emission intensity measurements are now considered to be the method of choice (10, 12) and should therefore be used for the detection as well as for the determination of the yields of singlet dioxygen (10, 12, 13). In this report, we provide direct spectroscopic evidence for the formation of $^1O_2$ as a result of the quenching of

$^*Cr(bpy)_3^{3+}$, where bpy = 2,2′-bipyridine, by $^3O_2$. In addition, we have used luminescence intensity measurements to determine the quantum yields of $^1O_2$ produced. Such studies on the yields of singlet dioxygen are necessary in order to advance our understanding of the quenching mechanism, and to provide useful fundamental information about the nature of these donor excited states.

Experimental

Materials

Tris(bipyridine)chromium(III) perchlorate was prepared according to the published procedure (3) and the purity was checked by comparison with the reported UV–vis spectra (14). Deuterium oxide (99.9 atom % D) was obtained from Aldrich and was used as received. In all cases, the ionic strength of the solutions was adjusted to 0.1 M using sodium chloride. All solutions, unless specifically mentioned, were prepared using D_2O as the solvent. The desired solution concentrations of dioxygen were obtained by saturation of the solutions with pure dioxygen or air. All measurements were made at ambient temperature.

General instrumentation:

UV–visible absorption measurements were made using a Perkin–Elmer λ14 spectrophotometer. In a few instances when the lifetime of $^*Cr(bpy)_3^{3+}$ was measured, a home-built laser flash photolysis system similar to the one described elsewhere (15, 16) was used. In such studies, the excitation of 52–60 μM $Cr(bpy)_3^{3+}$ solution was carried out using the broadband output of Coumarin 420 dye. The emission decay of $^*Cr(bpy)_3^{3+}$ was monitored at 727 nm.

Near-infrared emission studies:

The detection of singlet dioxygen ($^1O_2$,$^1\Delta_g$) was carried out by observing the infrared luminescence at 1270 nm arising from the first-order decay of $^1O_2$. Our singlet dioxygen detection system was based on the one reported earlier (17–19). Some preliminary studies on $^1O_2$ detection were conducted at the Department of Chemistry, University of California, Los Angeles. All samples used in the luminescence studies were prepared using 420–440 μM $Cr(bpy)_3^{3+}$ in D_2O and were saturated with triplet dioxygen. The solutions were contained in a 1 cm^2 cuvette. The excitation of the samples was carried out using a 200 ns pulse arising from a modified Phase-R model DL-1100 flash lamp pumped dye laser using the appropriate coumarin dye solution. The 1270 nm radiation emerging from the solution was detected at a right angle to the laser beam using a Judson J-16TE2 (5 mm) germanium photodiode. The only element between the cuvette face and diode cover plate was a (2.5 × 2.5 cm) Corning 7–56 infrared long-pass filter that minimized any radiation below 1100 nm. The photodiode output current was amplified with a Judson preamplifier, operating at −20°C to reduce thermal noise. The output from the amplifier was then fed into a Nicolet model 430 digital oscilloscope interfaced to an IBM personal computer. As a control experiment, both Rose Bengal (RB) and tetraphenyl porphrin (TPP), which are known singlet dioxygen sensitizers, were used to produce $^1O_2$ luminescence, which was detected using the instrumentation described above. For quantum yield measurements, the decay kinetics for $^1O_2$ was obtained by the computer average of 20 laser shots. Within a particular set of experiments, the laser intensity was found to be very reproducible. Rose Bengal was used as a reference standard to quantitatively determine the yield of $^1O_2$ for the $Cr(bpy)_3^{3+}$–$^3O_2$ reaction. Both sets of experiments were performed on solutions under identical excitation conditions.

Results and discussion

Irradiation of a $Cr(bpy)_3^{3+}$ solution with visible light will lead to the formation of $^*Cr(bpy)_3^{3+}$. In the absence of triplet dioxygen, the $^*Cr(bpy)_3^{3+}$ will undergo unimolecular decay to the ground state as described in eq. [1].

$$[1]\quad {}^*Cr(bpy)_3^{3+} \xrightarrow{k_1} Cr(bpy)_3^{3+} + h\nu + \Delta$$

Under our experimental conditions, the lifetime of $^*Cr(bpy)_3^{3+}$ was measured in D_2O and was found to be 65 μs. This value is in excellent agreement with the value of 61 μs reported earlier (1) under slightly different conditions. In the presence of triplet dioxygen (aerated or pure dioxygen saturated solutions), the lifetime measurements gave an average value of (2.5 ± 0.4) × 10^7 M^{-1} s^{-1} for k_2, the second order rate constant for the quenching of $^*Cr(bpy)_3^{3+}$ by triplet dioxygen (eq. [2]). Again

$$[2]\quad {}^*Cr(bpy)_3^{3+} + {}^3O_2 \xrightarrow{k_2} Cr(bpy)_3^{3+} + {}^?O_2$$

the value of k_2 obtained in the present study is in very good agreement with the value of 2.9×10^7 M^{-1} s^{-1} in D_2O reported earlier (3) by Brunschwig and Sutin. A good knowledge of k_1 and k_2 is necessary for our subsequent studies involving quantum yield measurements.

Detection of near-infrared luminescence

In the presence of triplet dioxygen, the most commonly proposed quenching pathways for the deactivation of the excited states $^*Cr(bpy)_3^{3+}$ in solution are depicted in Scheme 1. The electron transfer pathways (**B**) (both reductive and (or) oxida-

Scheme 1.

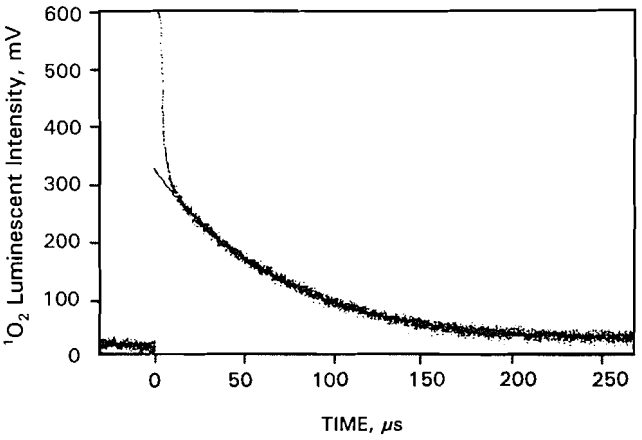

Fig. 2. Decay of near-infrared luminescence of singlet dioxygen obtained from the laser flash photolysis of $^3O_2$-saturated D_2O solution containing $Cr(bpy)_3^{3+}$ as a sensitizer. (Thin line represents the decay curve extrapolated to zero time.)

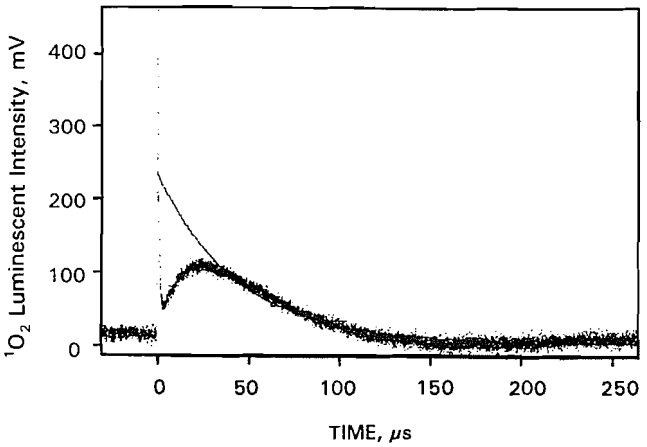


tive quenching) are considered to be endoergonic and have been ruled out (3, 4). If the energy transfer quenching pathway (**A**) is indeed operative, it will lead to the formation of singlet dioxygen. Energy transfer from $^*Cr(bpy)_3^{3+}$ to $^3O_2$ is energetically possible and spin allowed. The $^*Cr(bpy)_3^{3+}$ energy is 40.1 kcal/mol (1), which is enough to allow exothermic energy transfer to triplet dioxygen to give $^1O_2$ ($^1\Delta_g$ = 23 kcal/mol). The singlet dioxygen formed in reaction [2] can then decay to the ground state via eq. [3] and can be detected by observing

$$[3] \quad {}^1O_2 \xrightarrow{k_3} {}^3O_2 + h\nu' + \Delta$$

its near-infrared luminescence at 1270 nm. To validate the detection of singlet dioxygen in these studies, singlet dioxygen was initially generated using Rose Bengal, which is a well-documented sensitizer for singlet dioxygen. Formation and decay of $^1O_2$ produced in a D_2O solution containing Rose Bengal is shown in Fig. 1. The early intense component decayed rapidly and had a time constant of ~10 μs. The slow component is attributed to the 1270 luminescence of $^1O_2$ as it disappeared when triplet dioxygen in the solution was replaced with He gas. With Rose Bengal as a sensitizer, the lifetime of the singlet dioxygen was measured in D_2O and d_6–acetone and was found to be 62 and 710 μs, respectively. These values are in very good agreement with the singlet dioxygen lifetime reported for these two solvents (17–19).

Similarly, if $^1O_2$ luminescence is observed when Rose Bengal is replaced with $Cr(bpy)_3^{3+}$, it will provide direct evidence for the production of $^1O_2$ in reaction [2]. Indeed, when a solution containing 440 μM $Cr(bpy)_3^{3+}$ in D_2O saturated with triplet dioxygen was irradiated with a 420 nm laser pulse, infrared luminescence corresponding to $^1O_2$ production was observed as well. Again, in a control experiment, where all other components were present in the solution but triplet dioxygen was replaced with He gas, no infrared luminescence signal was observed. A profile of $^1O_2$ luminescence intensity vs. time for reaction [2] is shown in Fig. 2. An examination of Fig. 2 shows that, due to slow quenching of the $^*Cr(bpy)_3^{3+}$ by $^3O_2$ ($k_2 = 2.5 \times 10^7$ M^{-1} s^{-1} for $^*Cr(bpy)_3^{3+}$ as compared to 2.7×10^9 M^{-1} s^{-1} for $^*Ru(bpy)_3^{2+}$ and 1.6×10^9 M^{-1} s^{-1} for $^*RB$) (9), the formation of $^1O_2$ is not instantaneous but a rather prolonged process.

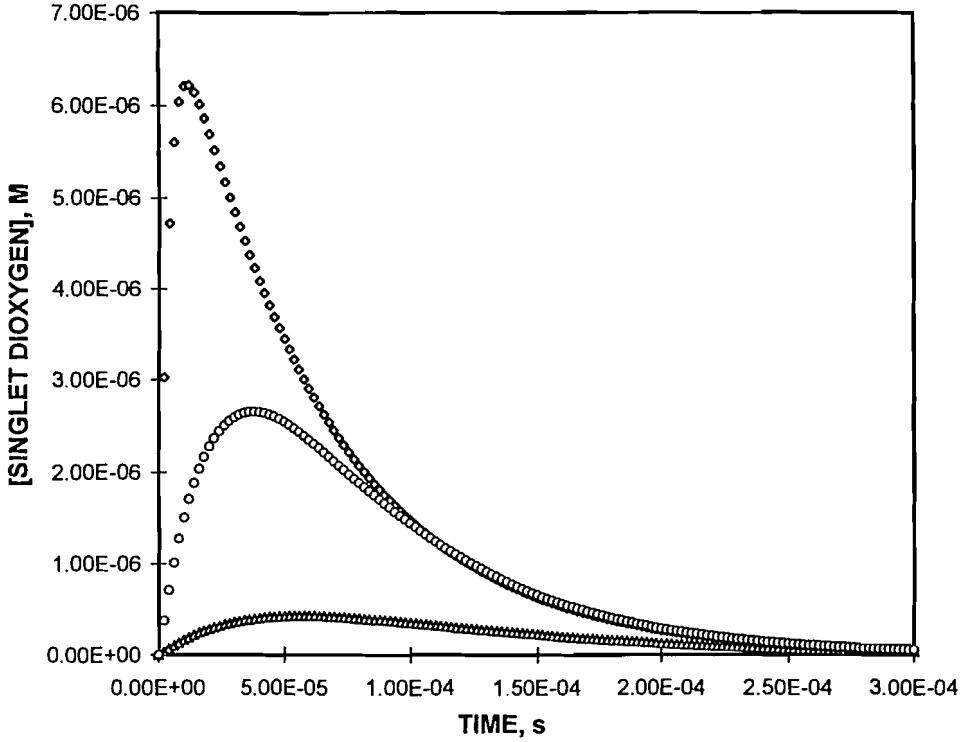
A computer program (KINSIM)[2] was used to simulate the formation and decay of $^1O_2$ using $[^*Cr(bpy)_3^{3+}] = 10$ μM, $k_1 = 1.5 \times 10^4$ s^{-1}, three different values of the quenching rate constant, k_2, as 2.5×10^6, 2.5×10^7, and 2.5×10^8 M^{-1} s^{-1}, and k_3 for the decay of $^1O_2$ as 1.6×10^4 s^{-1}. The profile for the formation and decay of $^1O_2$, obtained from these kinetic simulations, is depicted in Fig. 3. A comparison of the experimental (Fig. 2) and simulated (Fig. 3) plots show that for the k_2 value of 2.5×10^7 M^{-1} s^{-1}, which is the same as the experimentally determined value of the quenching rate constant, the profiles for $^1O_2$ formation and decay are quite similar. Therefore, based on our experimental results and computer simulations, we conclude that $^1O_2$ is indeed produced as a result of quenching of $^*Cr(bpy)_3^{3+}$ by $^3O_2$.

Quantum yield measurements

The magnitude of the infrared luminescence intensity has been used for quantitative determination of the yields of $^1O_2$ produced for a variety of reactions (10, 12, 13). Considering the problems associated with studies involving chemical trapping of $^1O_2$ reported earlier (12), the near-infrared luminescence emission method, which is clean and straightforward, has now become a method of choice. In these studies, the luminescence intensity of $^1O_2$ for a standard, usually Rose Bengal, acridine, or tetraphenyl porphyrin, is determined by extrapolation to zero time and then compared, under identical excitation conditions (i.e., absorbance, laser intensity), with the $^1O_2$ luminescence intensity arising from the reaction of interest. In the present study, the near-infrared luminescent intensity measurements were used to determine the quantum yield of $^1O_2$ formation for reaction [2] in D_2O as described below.

[2] The mechanism used for kinetic simulations was based on reactions [1]–[3]. The concentration of the $^*Cr(bpy)_3^{3+}$ used in the simulations was 8 μM, which was similar to the concentration usually produced under our experimental conditions. The concentration of the excited state can be varied either by changing the initial concentration of $Cr(bpy)_3^{3+}$ or by changing the laser intensity. The kinetic program used for simulation was KINSIM, which was a gift from Professor James Espenson, Iowa State University.

Fig. 3. Profile of singlet dioxygen formation and decay obtained for reactions [1]–[3] using the kinetic simulation program kinsim. The parameters used for simulations are $[^*Cr(bpy)_3^{3+}] = 8\ \mu M$, $k_1 = 1.5 \times 10^4\ s^{-1}$, $k_2 = 2.5 \times 10^6\ M^{-1}\ s^{-1}$ (triangle), $2.5 \times 10^7\ M^{-1}\ s^{-1}$ (circle) $2.5 \times 10^8\ M^{-1}\ s^{-1}$ (diamond), and $k_3 = 1.6 \times 10^4\ s^{-1}$.



The exponentially decaying slow component corresponding to $^1O_2$ luminescence (Fig. 1 for Rose Bengal and Fig. 2 for $Cr(bpy)_3^{3+}$) was extrapolated to zero time. Referring to Figs. 1 and 2, this is the point defined by the intersection between the extrapolated part of the curve and the vertical rise of the luminescence signal. Considering the fact that the instrument response time was approximately 10 μs, and the $^3O_2$ quenching of the $^*Cr(bpy)_3^{3+}$ was rather slow, the decay curve between 40 and 200 μs was used for extrapolation to zero time. Within the same solvent under identical excitation conditions for Rose Bengal and $Cr(bpy)_3^{3+}$, the quantum yield of $^1O_2$ for reaction [2], hereafter referred to as $\Phi_\Delta(CR)$, can be calculated using eq. [4] (10):

$$[4]\quad \frac{I_0(CR)}{I_0(RB)} = \frac{\Phi(^*CR)\Phi_\Delta(CR)f(CR)}{\Phi_\Delta(RB)f(RB)}$$

Here $I_0(CR)$ and $I_0(RB)$ are the luminescence intensities at zero time for $Cr(bpy)_3^{3+}$ and Rose Bengal, respectively. $\Phi(^*CR)$ is the quantum yield for the formation of doublet excited state $^*CrL_3^{3+}$ and is equal to unity (1). $\Phi_\Delta(RB)$ is the quantum yield of $^1O_2$ for the Rose Bengal–$^3O_2$ system and has been determined by others (6, 8, 9, 13) as 0.80. The $f(CR)$ and $f(RB)$ are the fractions of the $Cr(bpy)_3^{3+}$ and Rose Bengal excited states, respectively, that are quenched by triplet dioxygen. The values of $f(CR)$ and $f(RB)$ were calculated using the expression $f = k_q[^3O_2]/k_d + k_q[^3O_2]$. Here k_d is the rate constant for the decay of the sensitizer excited state, and k_q is the second-order rate constant for the quenching of the excited states by triplet dioxygen. The lifetime of the Rose Bengal excited state was determined in the laboratory and was found to be 200 μs. Therefore, using $k_d = 5.0 \times 10^3\ s^{-1}$ and $[^3O_2] = 2.5 \times 10^{-4}$ M, a value of 0.98 was calculated for $f(RB)$. Similarly, using $[^3O_2]$ as 1.2×10^{-3} M, and the experimentally determined values of k_1 and k_2, a value of 0.66 was obtained for $f(CR)$. Using all the necessary data and applying eq. [4], a value of $\Phi_\Delta(CR) = 0.86 \pm 0.08$ was obtained for reaction [2] in D_2O.

Quenching mechanism

This value of 0.86 for the quantum yield of $^1O_2$ suggests that the energy transfer quenching (pathway **A** in Scheme 1) is the major quenching pathway for reaction [2] to occur. However, as the value of $\Phi_\Delta(CR)$ is less than unity, we suspect that, in addition to energy transfer quenching, another pathway, although minor, may also be operative. The electron transfer quenching mode (pathway **B**, reductive or oxidative) is considered to be endoergonic (3, 4). In addition, very little or opposite variation of quenching rate constant with $\Delta^\circ E$ of the reaction was observed (3). Based on these observations and other theoretical considerations, electron transfer quenching has been ruled out (3, 4). To account for the less than unity yield for $^1O_2$ production in reaction [2], we propose that, parallel to the energy transfer quenching, the physical quenching (pathway **C**) may be also operative. It is proposed that once the encounter complex $^*Cr(bpy)_3^{3+}|^3O_2$ is formed, the spin-catalyzed deactivation of the encounter complex will lead to the formation of $Cr(bpy)_3^{3+}|^3O_2$ which then dissociates to give ground state $Cr(bpy)_3^{3+}$ and $^3O_2$. This spin-catalyzed deactiva-

tion of the encounter complex can occur in parallel with the energy transfer mode that initially produces $Cr(bpy)_3^{3+}{}^1O_2$, which upon dissociation gives $Cr(bpy)_3^{3+}$ and $^1O_2$. Nevertheless, any contribution from the spin-catalyzed deactivation pathway (**C**) is expected to be minor.

In the case of $^*RuL_3^{2+}$ complexes, the excited state is a metal to ligand charge transfer excited state and is predominantly triplet in nature (2). Therefore, a triplet–triplet energy transfer process can be operative and was indeed observed for the majority of RuL_3^{2+} complexes with high yields of $^1O_2$ (10). In the case of $^*Cr(bpy)_3^{3+}$–$^3O_2$, however, the excited state $(^2E)Cr(bpy)_3^{3+}$ is metal centered and its deactivation leads to the formation of ground state $(^4A)Cr(bpy)_3^{3+}$. Energy transfer in this case is spin allowed as well, and can be considered similar to the singlet–triplet energy transfer process. The quenching of $^*CrL_3^{3+}$ by $^3O_2$ is observed to be approximately two orders of magnitude slower than the quenching of $^*RuL_3^{2+}$ by $^3O_2$. We propose that, in the case of chromium complexes, slower quenching by triplet dioxygen, is due to the poor overlapping of the donor–accepter orbitals.

Conclusion

Use of the infrared luminescence technique in the present studies clearly establishes that $^1O_2$ is produced as a result of $^3O_2$ quenching of $^*Cr(bpy)_3^{3+}$. From our quantum yield studies, we conclude that the quenching of $^*Cr(bpy)_3^{3+}$ by $^3O_2$ occurs via an energy transfer pathway and that $^1O_2$ can be produced in a high quantum yield. To account for the less than unity value of the $^1O_2$ quantum yield obtained in these studies, we suggest that, in addition to the energy transfer quenching that is the principle mode of quenching, physical quenching may also be operative as a minor quenching mode. We also propose that while elucidating the quenching mechanism for the luminescence excited states of transition metal complexes, in addition to the energy and electron transfer pathways, physical quenching should also be considered when assigning the quenching mechanism.

Acknowledgment

Some preliminary work on $^1O_2$ emission measurements was done at the Department of Chemistry, University of California at Los Angeles. One of the authors (K.O.Z.) is grateful to Professor Chris Foote and Dr. Jim Arbogast for their help with infrared emission studies, and many valuable suggestions. This work was sponsored by the Office of Research and Sponsored Projects, California State University, Northridge.

Modified method of synthesis of N-substituted dithioesters of amino acids and peptides in the Pinner reaction[1]

Witold Neugebauer, Eric Pinet, Munsok Kim, and Paul R. Carey

Abstract: An improved method for the synthesis of dithioesters of amino acids and peptides has been developed. The syntheses have been carried out from the nitriles. The addition of thiol to the nitrile derivative in the Pinner step of dithioester synthesis was activated with hydrogen fluoride. A few examples of dithioester synthesis using liquid HF are described. Some novel dithioesters, which are model compounds for resonance Raman spectroscopic studies of dithioacylpapain intermediates, are described.

Key words: dithioesters, amino acids, Pinner reaction, HF, isotopes.

Résumé : Une méthode améliorée de synthèse de dithioesters d'acides amines et de peptides a été développée. Les synthèses ont été accomplies à partir des nitriles correspondants. L'addition du thiol au dérivé nitrile lors de la synthèse du dithioester, pendant la reaction de Pinner, a été activée par le fluorure d'hydrogène. Nous décrivons plusieurs exemples de synthèse de dithioesters employant du HF liquide, ainsi que plusieurs nouveaux dithioesters,composé-modéles employés dans les études des formes passagères de la dithioacylpapaine par la spectrométrie de résonance de Raman.

Introduction

Dithiocarboxylic acids and esters have recently attracted attention because of their structural and spectroscopic properties (1–5), and their application in organic synthesis (6). Since we have had difficulty in using available procedures for synthesis of dithioesters of N-substituted amino acids or small peptides, modification of the most general procedure seemed to be the best choice. Several methods of synthesis of this class of organo-sulphur compounds have been published (1, 7, 8) and reviewed (9). The most common route for dithioester synthesis is the procedure based on the Pinner reaction (10, 11). Thiols react with nitriles in the presence of hydrogen chloride to give imidothioesters and these are the key intermediates in the synthesis of dithioesters. In the modification reported here, the first step of the synthesis is dissolution of the nitrile in an excess of liquid hydrogen fluoride at a temperature below 0°C to most likely form the $[RCNH]^+HF_2^-$ adduct (eq. [1]) (12). In the presence of the third reaction component, mercaptan, thioimidate hydrofluoride is produced, $[RC(=NH_2)SR']^+HF_2^-$ (eq. [2]). Unlike the classic Pinner reaction with HCl saturated methylene chloride, all nitrile derivatives are completely soluble in the reaction mixture. Excess of hydrogen fluoride and mercaptan are removed under vacuum and the thioimidate hydrofluoride precipitated. It is then used under anhydrous conditions to react with H_2S in dry pyridine, forming the dithioester, eq. [3] (8).

Experimental section

Materials

All solvents used (acetone, chloroform, toluene, diethyl ether, methanol) were of ACS purity and were purchased from BDH. Pyridine was purchased from BDH and distilled over KOH pellets. Ammonium chloride, *p*-halogen benzoyl chlorides, *p*-anisoyl chloride, and ethane thiol were purchased from Aldrich. Sodium cyanide, formaldehyde solution, and acetic acid were purchased from Anachemia Chemicals. Gaseous HF and H_2S were purchased from Matheson Gas, Canada. Anhydrous gas HF operations were undertaken in an HF apparatus (Biosearch). All final products were purified by crystallization and column chromatography on silica gel 60 (E. Merck) with toluene–chloroform—methanol as an eluent on medium pressure glass columns (Michel-Miller) 300 mm, Aldrich. Chromatographic purity of products was checked on TLC (silica gel, aluminium plates, E. Merck) in solvent systems A, chloroform–methanol 4:1, or B, chloroform. The final identity of the synthesized compounds was checked by FAB-MS spectrometry on Jeol, JMS-AX505H with dithiothreitol–dithioerythiol (DTT–DTE) or nitrobenzyl aldehyde (NBA) matrix, and in some cases by NMR spectroscopy.

Synthesis

General procedure of the Pinner reaction (2, 3, 3a, 3b, 3c, 3d, 3e, 3a1, 3a2, 3a3, 3a4, 3a5)

HF gas was liquified at the temperature of liquid nitrogen. N-substituted amino nitrile (10 mmol) and ethanethiol (13 mmol)

[1] $RCN + 2\,HF \longrightarrow [RCNH]^+ HF_2^-$

[2] $[RCNH]^+HF_2^- + R'SH \longrightarrow RC(=NH_2^+)-SR'\ HF_2^-$

[3] $RC(=NH_2^+)-SR'\ HF_2^- + H_2S + \bigcirc N \longrightarrow RC(=S)-SR' + \bigcirc N\cdot HF + NH_4F$

[4] $NH_4Cl + HC(=O)H + NaCN \longrightarrow CH_2{=}NCH_2CN + NaCl + H_2O$

[5] $CH_2{=}NCH_2CN + 2\,C_2H_5OH + H_2SO_4 \longrightarrow H_2NCH_2CN\cdot H_2SO_4 + CH_2(OC_2H_5)_2$

[6] $H_2NCH_2CN\cdot H_2SO_4 + X\text{-}\bigcirc\text{-}C(=O)Cl + 2\,NaOH \longrightarrow$

$X\text{-}\bigcirc\text{-}C(=O)NHCH_2CN + Na_2SO_4 + H_2O$

X= H, F, Cl, Br, I, OCH_3

were placed in a polyethylene reactor with a stirrer, at liquid nitrogen temperature, while HF (3 mL) was added. The reaction vessel was placed in the Biosearch HF apparatus and the reaction was held at 0°C and stirred for 1 h. The excess HF and ethanethiol were then evaporated at room temperature under a water aspirator and finally with an oil pump. The thioimidoester salts produced were precipitated (or solidified) by the addition of anhydrous diethyl ether. They were then decanted from ether, washed, decanted again, and used in the next synthetic step.

Dithiomethyl esters **4** and **6** require the use of liquified CH_3SH (instead of ethanethiol) prepared the same way as liquid HF. Similarly, thiomethyl ester (**1**) requires dry methanol. Dithioesters of dipeptides **5**, **6**, and **7** were formed after coupling of *N*-acetyl or *N*-methoxy phenylalanine to amino acetonitrile with DCC–pentafluorophenol in the standard manner (13).

Dithioesters

Pyridine , dried over KOH pellets, was saturated with dry H_2S at 0°C and thioimido esters were added while stirring and passing dry H_2S for 45 min. $H_2{}^{34}S$ generated from heating ^{34}S in paraffin was used for the isotopically substituted derivative (*3a*5). The coloured solutions (from light yellow to deep orange) were then poured into sufficient amounts of ice-cold 4 N HCl to neutralize the pyridine. The dithioesters were crystallized or precipitated and were collected by filtration and washed with cold water. The precipitates (crystals) were precipitated with water from acetone solution, then dissolved in chloroform and chloroform solution that was dried by rotary evaporation. The crude dithioesters were dissolved in a minimum volume of chloroform (1–3 mL) and purified on a silica gel column that was washed with toluene and solvent exchange under medium pressure from 10% chloroform in toluene (30 min) to 50% and 100% chloroform (65 min each). Finally the column was washed with methanol and toluene for the next purification. TLC identifications in solvent systems A and B were made, and the dithioesters were collected. Their identity was verified by FAB/MS spectrometry using NBA or DTT–DTE as a matrix.

General procedure for Strecker reaction (3a1, 3a2, 3a3, 3a4)

Isotopic substitutions were made using labelled substrates in a Strecker type synthesis; $Na^{13}CN$ (*3a*1), $H^{13}C(=O)H$ (*3a*2), $^{15}NH_4Cl$ (*3a*3), $DC(=O)D$ in D_2O (*3a*4).

NH_4Cl (2.16 g, 0.04) mol was dissolved in 6 mL (0.04 mol) formaldehyde at the ice-bath temperature and, while stirring, 2 g (0.04 mol) NaCN in 6 mL water was added dropwise over 2.5 h. Stirring continued for another 1.5 h and 1.33 mL of acetic acid was added dropwise over 1 h. After 2.5 h, the white precipitate was filtered, washed with cold water, and dried under high vacuum overnight. Yield 1.49 g (59.7%), mp 124–126°C, Schiff base derivative reaction [4].

CH_2NCH_2CN powder (1.49 g, 0.02 mol) was added to 1.3

Table 1. Products obtained in the Pinner reaction with liquid HF.

	Product	M + 1 (FAB/MS)	Yield (%)	Melting point (°C)
1	$CH_3C(=O)NHCH_2C(=S)OCH_3$	148	30	Oil

6	$CH_3O)NHCH(CH_2C_6H_5)C(=O)NHCH_2C(=S)SCH_3$	299	27	130

mL H_2SO_4 in 5.85 mL ethanol and dissolved at room temperature. The solution was then placed in the ice-bath for 2–4 h. The precipitate was filtered, washed with cold ethanol, and dried under high vacuum overnight. The yield of amino acetonitrile sulphate, mp 152–153°C, was 89.7% (reaction [5]).

Amino acetonitrile salt (1.557 g, 0.01 mol) was dissolved in 13 mL of well-stirred 10% NaOH at the ice-bath temperature and, while stirring, 1.5 mL (0.0118 mol) *p*-chloro benzoylchloride in 3.5 mL THF was added over 20 min. The pH of the reaction was maintained at 14 by adding NaOH solution. After 3 h a quantitative amount of amido acetonitrile derivative was filtered and recrystallized from CCl_4. Further purification required dissolution in hot acetone, addition of charcoal, filtration through Celite 454, and precipitation of the final product with water (mp 145°C).

Results and discussion

The Pinner method of dithioester synthesis cannot be considered general for the preparation of this class of compounds, even though many attempts have been made. Using this approach, we tried to synthesize several dithioesters and the resulting yield was unsatisfactory (1), especially for the isotopic derivatives we wanted to make. Low yields in the classic Pinner procedure are a result of the poor solubility of N-substituted amino nitrile substrates in HCl saturated dichloromethane. Some of the N substitutions are not stable under these conditions especially in the presence of a trace amount of water. Use of liquid HF at low temperature gives full and immediate solubility of the N-substituted derivatives in the reaction mixture. This raises the reaction yield to the 70% range, which is a dramatic improvement over the old procedure (1). The final products synthesized by this improved method are summarized in Table 1. As an alternative, simple apparatus can be used: the reaction with HF could be performed in a polyethylene vessel, linked to the HF bottle on one side and a water aspirator on the other. This reactor must be capable of being cooled by liquid nitrogen and of being magnetically stirred. Such a simple arrangement for the reaction vessel could be considered as a general method for the synthesis of dithioesters of N-substituted amino acids and some peptides.

Rheological and interfacial properties of nucleic acid films studied by thickness – shear mode sensor and network analysis

Hongbo Su and Michael Thompson

Abstract: Complete characterization of the thickness – shear mode (TSM) acoustic wave sensor coated with films of nucleic acid and subjected to conductive solution loading is achieved through network analysis of impedance measurements. The responses of coated sensors with respect to series resonant frequency can be separated into two regions. When $0 < \sigma < 0.5\ \Omega^{-1}\ m^{-1}$ the frequencies for sensors with films of single strand (ss) DNA or polycytidylic (5′) (Poly C) in place rise significantly with increasing conductivity. The motional resistances for sensors coated with both species peak at the same value of conductivity where the frequency has the most rapid shift. In the second region ($0.5 < \sigma < 12\ \Omega^{-1}\ m^{-1}$), the frequency response for the ss DNA system exhibits a bell-shaped curve, with a minimum at $\sigma = 4\ \Omega^{-1}\ m^{-1}$. The motional resistances for both nucleic acid layers show reversible behaviour, whereas TSM sensors with bare PdO and Au electrodes yield little change. Models that consider only the bulk properties of solutions fail to explain the observed changes in frequency. On the other hand, an equivalent circuit model incorporating the rheological properties of nucleic acid layers on the sensor surface is successful in explaining the various responses.

Key words: DNA sensor, network analysis, thickness – shear mode sensor, DNA interfacial properties.

Résumé : Faisant appel à une analyse de réseau des mesures d'impédance, on a réalisé une caractérisation complète de senseurs enduits de films d'acide nucléique, opérant en mode de cisaillement de l'épaisseur et soumis à un chargement de solution conductrice. Les réponses des senseurs enduits par rapport à la fréquence de résonance en série ont pu être séparée en deux régions. Lorsque $0 < \sigma < 0{,}5\ \Omega^{-1}\ m^{-1}$, les fréquences des senseurs avec des films d'ADN à simples brins (sb) ou polycytidyliques (5′) (Poly C) en place augmentent beaucoup avec une augmentation de la conductivité. Les résistances au mouvement des senseurs enduits avec les deux espèces atteignent un sommet pour la même valeur de la conductivité alors que la fréquence présente le déplacement le plus rapide. Dans la deuxième région ($0{,}5 < \sigma < 12\ \Omega^{-1}\ m^{-1}$), la fréquence de réponse du système ADN sb présente une courbe en forme de cloche avec un minimum à $\sigma = 4\ \Omega^{-1}\ m^{-1}$. Les résistances au mouvement pour les deux couches d'acides nucléiques présentent dans les deux cas un comportement réversible alors que le senseur MCE avec des électrodes de PdO ou de Au nues ne présentent pratiquement pas de changements. Les modèles qui ne considèrent que les propriétés globales des solutions n'arrivent pas à expliquer les changements observés dans les fréquences. Par ailleurs, un modèle par circuit équivalent incorporant les propriétés rhéologiques des couches d'acide nucléique sur la surface du senseur permet d'expliquer les diverses réponses.

Mots clés : senseur à l'ADN, analyse de réseau, senseur en mode de cisaillement de l'épaisseur, propriétés interfaciales de l'ADN.

Introduction

Technology associated with DNA hybridization has played a major role in the rapid progress of biological research since Watson and Crick deduced the three-dimensional structure of B DNA in 1953 (1, 2). However, the ^{32}P DNA labelling hybridization procedures that are currently employed have the following disadvantages: the effort required for labelling, the requirement for radiochemical facilities, and the laborious nature of studies of hybridization kinetics. There has been recent strong interest in the direct, real-time detection of hybridization in a biosensor format (3, 4). In the DNA biosensor strategy, a single strand nucleic acid attached to the surface of a transducer device can complex the complementary strand in the solution phase to generate a direct signal. Optical (5, 6), electrochemical (7–10), and acoustic wave (11–22) technologies have been dominant in attempts to develop a so-called DNA biosensor based on DNA hybridization.

With respect to acoustic wave sensors, the first report on the direct detection of nucleic acid interactions was provided by Fawcett et al. (11). A polyadenylic acid (5′) (Poly A) probe was covalently linked to a polymer via the pendent carboxylic acid groups. The resonant frequency for a 9-MHz crystal exhibited a 500 Hz decrease upon hybridization of polyuridylic acid (5′) (Poly U) with complementary Poly A. Since this early work, a number of articles have appeared employing similar procedures, resulting in microgravimetric measurements of nucleic acid based on gas-phase responses (12–14). Gold surfaces of a 9-MHz piezoelectric quartz crystal were

Received January 2, 1996.

pretreated by anodic oxidation followed by activation with γ-aminopropyltriethoxysilane. Sheared single stranded (ss) salmon sperm DNA probe was then electro-blotted onto the silanized surface of crystal electrodes and further immobilized on the surface by UV cross-linking. About 0.8 μg ss DNA was immobilized and hybridized to 0.57 μg cDNA, corresponding to 232 and 165 Hz decreases in resonant frequency for gas-phase measurement, respectively (12). Richards and Bach (13) performed an ingenious DNA hybridization experiment in which amplification of mass was obtained using iron oxide microparticles. These entities, bearing one of the reacting pairs, are attracted to the sensor surface by a magnetic field. Recently, Oyama and co-workers (14) reported that λ-phage DNA can be covalently immobilized onto the gold surface of a TSM sensor and that dissociation and hybridization of immobilized DNA can be monitored by impedance analysis in the gas phase. The occurrence of immobilization and hybridization of DNA were then said to be confirmed by a small decrease of f_{Gmax} (the frequency giving the maximum conductance) and increases of motional resistance. It should be emphasized that these various gas-phase microgravimetric measurements suffer from problems with nonspecific adsorption and highly variable hydration of nucleic acid.

The first in situ liquid-phase measurements involved an acoustic plate mode device, which was developed by Lade and co-workers (15). These authors employed the same carbodiimide activation immobilization procedure as described above. The hybridization of short oligomer dA with surface-bound dT was monitored by the frequency and relative phase changes. However, application-oriented DNA samples were not tested with respect to potential interferences in this work. Secondly, avidin was immobilized onto the surfaces of the gold electrode of a TSM sensor by irreversible absorption and the detection of herpes simplex virus nucleic acid through avidin–biotin interaction was demonstrated (16). A gold electrode was also employed to attach a single strand of DNA to a self-assembled monolayer of 11-mercaptoundecanoic acid (17). Calf thymus DNA was bound to the -COOH functional groups of the self-assembled 11-mercaptoundecanoic acid directed outward to the solution side by the carbodiimide activation reaction. A subsequent experiment also demonstrated direct detection of DNA hybridization (involving a conventional mass-based response). Ten-mer deoxynucleotide having a mercaptopropyl group at the 5′-phosphate end was prepared by the phosphoramidite method and then immobilized onto a gold surface via the SH group (18). However, no evidence was presented to confirm the occurrence of hybridization at the sensor–liquid interface.

We have reported in previous papers the in situ detection of polynucleotide (19) and pPT-2 DNA hybridization (20) at the surface of palladium electrodes sputtered onto underlying gold electrodes of TSM sensors. Hybridization of complementary strands of nucleic acid at the device–liquid interface results in series resonant frequency signals that are significantly higher than expected from the conventional Sauerbrey mass response. This effect was attributed to the perturbation of interfacial viscosity associated with the hybridization process.

A particularly important consideration in the development of an acoustic wave biosensor for DNA hybridization is the nature of TSM behaviour and transduction mechanism in liquid (a summary of theoretical approaches employed previously is given in Table 1; symbols are explained in Table 2). A

[9] $R_m = \frac{\eta_Q}{\mu_Q C_1} \left(\frac{\omega}{\omega_s} \right)^2 + \omega_s \frac{L_1}{N\pi} \left(\frac{2\omega\rho_L \eta_L}{\mu_Q \rho_Q} \right)^{1/2}$	Martin and co-workers (31)

[a]A glossary of the symbols used is given in Table 2.

large number of studies have invoked the well-known Sauerbrey equation where changes in resonant frequency are considered to be proportional to added mass on the device surface (eq. [1], Table 1). However, the acoustic wave sensor is also affected by a number of other interfacial properties when it is being operated in the liquid phase. Recent research has centred on the role played by surface free energy, molecular slip, surface roughness, acoustoelectric coupling, and viscoelasticity. The latter property is expected to be crucial if a film of a macromolecular entity is imposed at the sensor–liquid interface. In this respect, correlation of changes in rheological properties of a polymer with the response of theTSM sensor in liquid has recently been examined (27, 28). It has been proposed that a thin film with viscoelastic properties can be regarded as rigid if $T_f << 1/\delta$, where $1/\delta$ is a constant for acoustic waves propagating through a film of thickness T_f, which is in the range of tens of hundreds of nanometers (32). Moreover, it has been demonstrated that the Langmuir–Blodgett multilayer system, as well as polymer films, with a thickness up to 300 nm can be regarded as rigid (33). However, examples of viscoelastic effects in TSM investigations have also been found. Orata and Buttry (34) showed that polyacrylamide films impregnated with hexokinase give much larger changes in frequency values

Table 2. Glossary of symbols used.

A	piezoelectrically active area of a TSM device
μ_Q	elastic constant of quartz (piezoelectrically stiffened)
C_{66}	stiffened elastic constant of the quartz crystal
C_{66}''	effective complex shear modulus of an AT-cut piezoelectric quartz crystal
C_m	motional capacitance
C_m'	motional capacitance for a uncoated TSM device
C_0	electrostatic capacitance
θ	phase angle of impedance
θ_{max}	maximum phase angle
σ	solution conductivity
σ_d	dissipation coefficient of the quartz crystal
τ	viscous relaxation time characteristic of the fluid
ν	parameter related to the distribution of viscous relaxation time
e	thickness of a quartz plate
ε	piezoelectric stress constant
ε_0	permittivity of free space
ε_l	permittivity of liquid
ε_s	permittivity of quartz
ε_{22}	dielectric constants for a quartz crystal
ε_L	dielectric constants for liquid
f_A	anti-resonant frequency
f_R	resonant frequency when the energy dissipation Rm equals zero
f_s	series resonant frequency
f_p	parallel resonant frequency
f_n	frequency at minimum impedance
f_m	frequency at maximum impedance
$f_{\theta max}$	frequency at maximum phase angle
Δf	series resonant frequency change
f_0	fundamental series resonant frequency of a quartz crystal
G	complex modulus of a polymer film
G'	shear storage modulus of a polymer film
G''	shear loss modulus of a polymer film
κ^2	acoustoelectric coupling constant
L_m	motional inductance
L_m'	motional inductance of an uncoated TSM device
Δm	mass change
n	number of faces of a crystal in contact with a liquid
N	harmonic number ($N = 1$ for fundamental mode)
η_L	bulk viscostiy of the liquid
$\dot{\eta}$	dynamic viscosity
ρ_L	bulk density of a liquid
ρ_Q	density of a quartz crystal
ρ_f	polymer density
Q	quality factor, defined as $\omega L_m/R_m$
r	equal to C_0/C_m
R_m	motional resistance
R_m'	motional resistance of an uncoated TSM device
T_α	DNA primary relaxation temperature, which is associated with motions of DNA chain segments. This relaxation is accompanied by large changes in the modulus and viscosity of a polymer
T_β	relaxation associated with the motions of groups attached to the DNA polymer backbone
T_f	thickness of a polymer immobilized on a TSM sensor surface
ω	angular frequency
$\|Z\|$	magnitude of impedance
R	resistance, the real part of Z
X	reactance, the imaginary part of Z
$\|Z\|_{min}$	minimum magnitude of impedance
$\|Z\|_{max}$	maximum magnitude of imedance
δ	loss tangent of a polymer film
δ_L	decay length of acoustic wave propagation, which is in the range of about 1 μm

than expected when glucose binds to the enzyme in the film. This was attributed to changes in the mechanical properties of the polymer film with a corresponding change in the product of the viscosity and density. The viscoelastic effect was also found in the investigation of polymer-coated acoustic wave devices in the gas phase. Grate et al. (35) demonstrated that the polymer-phase swelling can make a significant contribution to the response of polymer-coated surface acoustic wave vapour sensors. The response to this volume increase operates in the same direction as the gravimetric response, effectively multiplying the sensitivity of the sensor. More recently, Martin and Frye (28) characterized the relatively thick polymer-coated TSM sensor in the gas phase by impedance analysis. An equivalent circuit model was derived that relates the near-resonant electrical characteristics of a polymer-coated TSM sensor to the film properties. A different physical model was also proposed by Reed et al. (27) to describe the viscoelasticity of a TSM sensor in viscous liquid.

The ionic environment of an immobilized polynucleotide chain influences its behaviour. Long-range electrostatic repulsions will extend a DNA/RNA polymer beyond the average dimensions expected for an uncharged macromolecule; this effect will be more prominent at lower ionic strength. This expansion will, in turn, influence other properties of a DNA/RNA polymer, such as viscosity and moduli, at the solid–solution interface. Accordingly, the work described in the present paper is concerned with exposure of bare and nucleic acid coated sensors to solutions of varying conductivity and to different temperatures in order to examine such effects. The responses of the sensor, which are characterized by the acoustic wave network analysis technique, are considered in terms of models that invoke added mass effects, bulk solution properties, acoustoelectric coupling, and rheological parameters.

Experimental

Materials

Double strand calf thymus DNA solution (10 mg mL^{-1}) and polycytidylic acid(5′) (Poly C) were purchased from Sigma (St. Louis, Mo.) and used without further purification. All other reagents were analytical grade, and Millipore water (18.2 MΩ m^{-1}) was used. AT-cut quartz piezoelectric crystals (9 MHz) with gold electrodes were supplied by International Crystal Manufacturing, Co. Oklahoma City, Okla. Palladium was sputtered on the gold electrodes using a Perkin–Elmer Ultek 2400-8SA rf sputtering system. Presputtering was performed for 15 min, then about 50 nm of palladium was deposited on the surface. The formation of a surface PdO layer in an $Ar–O_2$ environment was confirmed by X-ray photoelectron

Fig. 1. spectroscopy (XPS). The palladium target was obtained from Pure Tech, Inc. of New York.

Apparatus

The instrument used to characterize the TSM devices was an HP4195A Network/Spectrum Analyzer (Hewlett–Packard). An HP4195A impedance kit was used to make direct measurements of impedance as described previously (20). The values of the equivalent circuit elements of the quartz crystal are calculated internally by the HP 4195A from the measured data. All the data were transferred to an IBM compatible computer through an IEEE-488 bus.

Procedures

Denaturation of double strand DNA into single strand calf thymus DNA (ss CT DNA)

A 40 μL sample of double strand DNA solution was denatured by heating for 5 min at boiling water temperature, followed by rapid chilling in ice-water for at least 5 min. The denatured DNA solution was kept in an ice-water bath before using.

Surface immobilization of nucleic acids on TSMs

A 40 μL sample of a single strand calf thymus DNA solution (1 mg mL^{-1}) was placed on the palladium electrodes of the TSM device. The sensor was rinsed copiously with water and immersed in water at 70°C for 320 min, followed by drying with nitrogen gas. Poly C (1 mg mL^{-1}) was immobilized by the same procedure. The immobilization of nucleic acids was confirmed by XPS and the frequency changes before and after treatment. The sensor surfaces coated with nucleic acids exhibited very low advancing water angles (<10°), indicating a very hydrophilic surface.

Acoustic network analysis

Prior to the network analysis measurements, one face of a TSM sensor was exposured to Millipore water while the other was kept under nitrogen gas. The water was then drained off after stabilization and a 0.005 mM KCl sample solution was injected. The steady-state parameters were measured again after incubating for specific periods of time. Similar procedures were employed for higher concentrations of KCl solution. The measurements were also performed at various temperatures. The impedance responses of uncoated TSM devices agree with published results (36). To ensure reproducibility of the DNA/RNA-immobilized TSM performance, the experiments were repeated at least three times, using a new TSM device for each concentration. The conductivities of the various solutions were calculated from the corresponding solution concentrations.

Data fitting

Fits were performed by a program written in MathCad 4.0. This program uses a modified Neadler–Mead Simplex algorithm to minimize the sum of the squares of the differences between the measured and computed magnitudes of the impedance data.

Results and discussion

Acoustic network analysis

Before discussion of the responses of the nucleic acid coated TSM sensors it is necessary to review briefly the parameters yielded by network analysis of equivalent circuit data. The network analysis method is a passive technique that provides direct measurement of a large number of parameters, in addition to the series resonant frequency. The values of the magnitude and phase of the impedance of the quartz crystal can be determined at each frequency from the voltage and current, and electrical quantities can be found from the magnitude of the impedance–frequency curves (Fig. 1). Definitions of the various terms employed in the network analysis method are collected in Table 3.

Motional resistance R_m represents the dissipation of electrical energy in the quartz crystal. The energy is converted to thermal energy, which flows into the liquid environment in contact with the device in the form of an acoustic wave, including internal dissipation, air damping, surface friction, coating viscoelasticity, and mounting losses. The effects of the energy dissipation on the magnitude and phase angle of the impedance are demonstrated in Fig. 2 by assuming other parameters are constant. R_m is increased from 10 Ω to 1 kΩ and the magnitude of impedance and phase angle versus frequency curves is simulated. Increasing R_m causes the damping of both the |Z|–frequency and phase–frequency curves. The broadening and diminishing of the resonance peaks arises from power dissipation due to increasing R_m. An important

Table 3. Summary of the parameters employed in the network analysis method. (A glossary of the symbols used is given in Table 2.)

	Equations	Parameters
[10]	$\boldsymbol{Z} = \boldsymbol{R} + j\boldsymbol{X}$	Impedance, $\boldsymbol{Z}$ ($\boldsymbol{R}$ and $\boldsymbol{X}$ are resistance and reactance, respectively)
[11]	$\|\boldsymbol{Z}\| = \sqrt{(\boldsymbol{R}^2 + \boldsymbol{X}^2)}$	Magnitude of impedance of quartz, $\|\boldsymbol{Z}\|$
[12]	$\theta = \tan^{-1}(\boldsymbol{X}/\boldsymbol{R})$	Phase angle of impedance, θ
[13]	$f_S = f_S[1 + r/(2Q^2)]$	Series resonanct frequency, f_s
[14]	$f_P = f_R[1 + 1/(2r) - r/(2Q^2)]$	Parallel resonant frequency, f_p
[15]	$f_R = 1/[2\pi\sqrt{L_m C_m}]$	Resonant frequency, f_R
[16]	$f_A = \sqrt{1/(L_m C_m) + 1/(L_m C_0)}/(2\pi)$	Antiresonant frequency, f_A
[17]	$f_n = f_R[1 - r/(2Q^2)]$	Frequency at minimum $\|Z\|$, f_n
[18]	$f_m = f_R[1 + 1/(2r) + r/(2Q^2)]$	Frequency at maximum $\|Z\|$, f_m
[19]	$R_m = e^3\sigma_d/(8A\varepsilon^2)$	Motional resistance R_m for an unperturbed quartz crystal
[20]	$C_m = 8A\varepsilon^2/(\pi^2 e\mu_Q)$	Motional capacitance C_m for an unperturbed quartz crystal
[21]	$C_0 = k\varepsilon_0 A/e$	Electrostatic capacitance C_0

Fig. 2. Effect of the motional resistance R_m on the magnitude and phase of the impedance of a TSM sensor. 1: 10 Ω; 2: 100 Ω; 3: 300 Ω; 4: 600 Ω; 5: 800 Ω; 6: 1000 Ω.

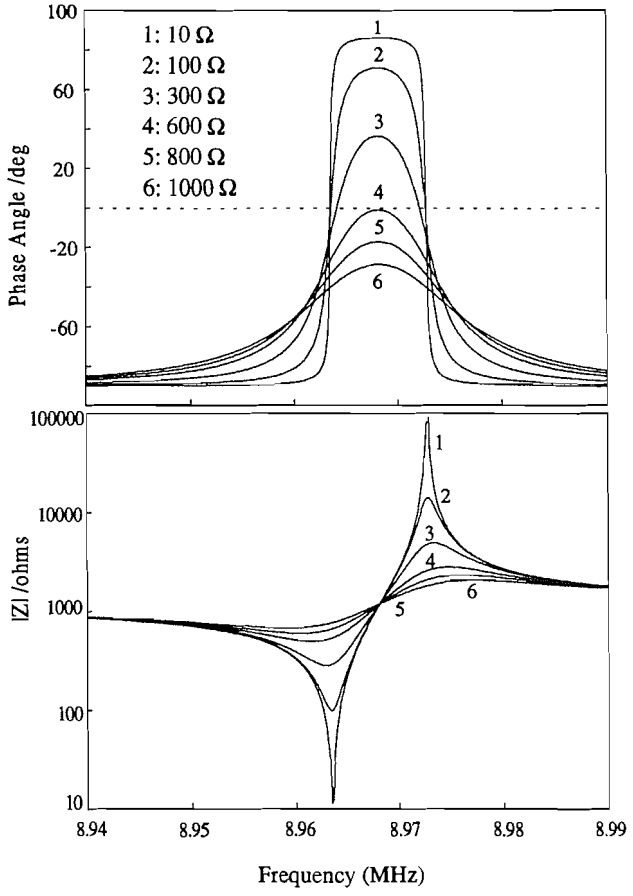

Fig. 3. Effect of the motional resistance R_m on the characteristic frequencies of a TSM sensor. The series and parallel resonant frequencies cease to exist when the maximum phase angle is below zero.

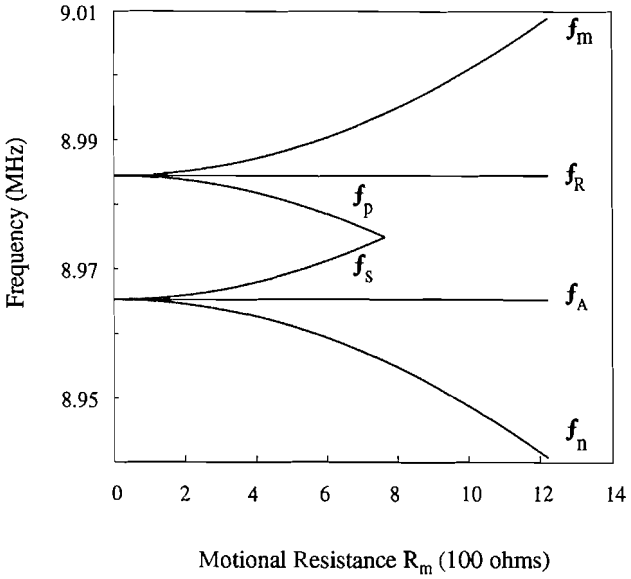

phenomenon is that when R_m reaches a certain value, as in the case where R_m = 800 Ω, the maximum phase angle becomes negative. The consequence is that the frequencies at zero phase angle, f_s and f_p, no longer exist. However, several other quantities can still be measured from the network analysis to describe the behaviour of the quartz resonator under these extreme conditions, including other characteristic frequencies. The effect of the motional resistance on the characteristic frequencies is shown in Fig. 3. With increasing R_m, the series res-

Fig. 4. Effect of the motional inductance L_m on the phase and magnitude of the impedance of a TSM sensor.

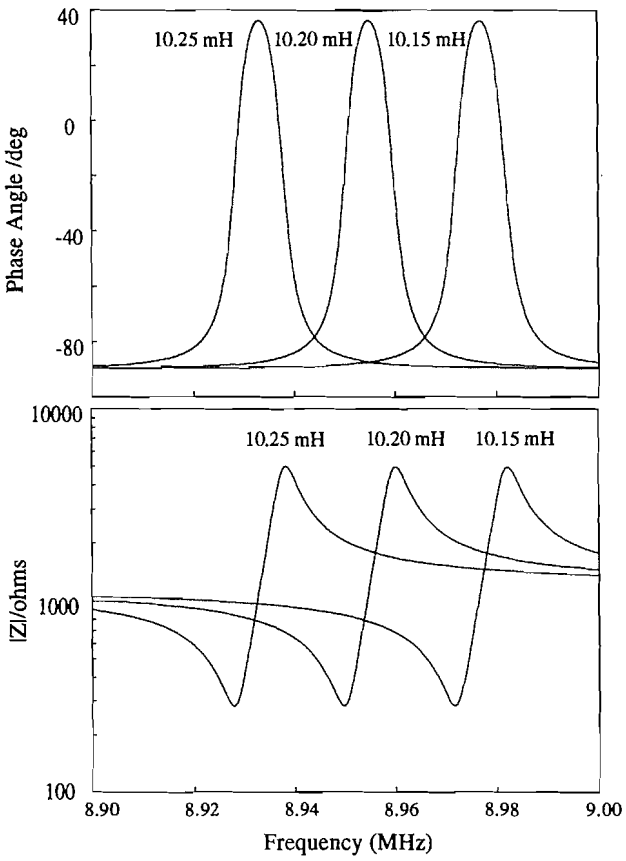

Fig. 5. Effect of the motional capacitance C_m on the phase and magnitude of the impedance of a TSM sensor.

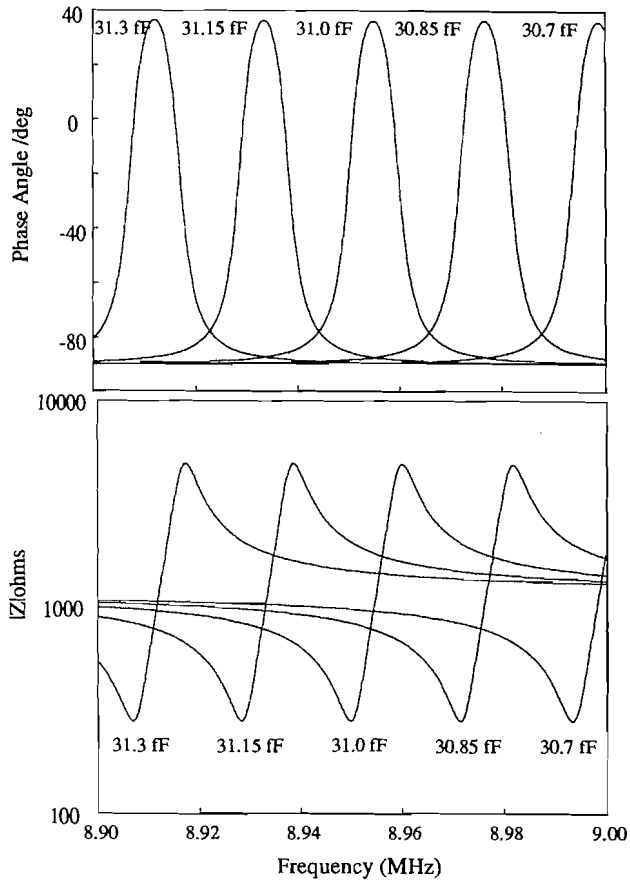

onant frequency and the parallel resonant frequency converge and eventually coincide. On the other hand, with increasing R_m the difference between f_m and f_n increases, reflecting the broadening of the resonance peak. Both f_m and f_n are strongly influenced by R_m and they always exist regardless of the value of R_m. Figure 3 indicates that the series resonant frequency f_s should increase almost linearly 10 kHz as R_m increases from 10 to 800 Ω. However, theoretical and experimental results have shown that f_s should decrease and R_m should increase with $(\rho_L\eta_L)^{1/2}$, as described by eqs. [3] and [9] (Table 1). This kind of discrepancy shows that further theoretical work should be undertaken to relate both series resonant frequency and motional resistance changes to liquid phase properties.

In the solution phase the motional inductance L_m represents the kinetic energy transfer between the TSM resonator and the conducting solution. The efficiency of the interaction depends on the coupling between the shear plane and the solution layer adjacent to the solid. Figure 4 shows the theoretical calculation of the magnitude of the impedance (bottom) and phase (top) as functions of frequency at various L_m. Although it has little effect on the shapes of |Z|–frequency and θ–frequency curves, L_m shifts them down to low frequency. C_m represents the elasticity of the quartz crystal, which corresponds to lattice-restoring forces. The effect of the motional capacitance on the magnitude of impedance and phase vs. frequency curves is illustrated in Fig. 5. Increasing C_m causes the upward movement of both |Z|–frequency and θ–frequency curves, without changing their pattern. In theory, both L_m and C_m have dramatic influences on a uncoated TSM sensor vibrating in a liquid. It would be expected that C_m would become more important when the TSM sensor is in contact with a viscoelastic fluid or a polymer film.

At frequencies far from the resonant frequency, the quartz plate is equivalent to a simple plate capacitor having a capacitance C_0. Figure 6 depicts the calculated results of |Z|–frequency and θ–frequency curves at five different electrostatic capacitances. C_0 is decreased from 25.0 to 10.0 pF and this causes the asymmetric damping of both curves. Furthermore, C_0 dominates the impedance near the condition of parallel resonance and diminishes it near series resonance. Accordingly, the measurement of f_p can be very useful in determining specific properties of the media surrounding the quartz crystal, especially in the case of electrolytes (26). From an equivalent circuit point of view, the formation of an electrical double layer at the TSM electrode – liquid interface can be regarded as an added shunt capacitance in parallel to the sensor. Thus, the measurement of C_0 under conductive solution loading consists of contributions from the quartz substrate as well as from the electrified interface.

Responses of nucleic acid coated sensors in contact with electrolyte

Series resonant frequency (f_s) changes for uncoated and nucleic acid coated resonators in contact with various KCl solutions are shown in Fig. 7(*a*). The changes relative to water are plotted against the solution ion conductivity, σ. The den-

Fig. 6. Effect of the electrostatic capacitance C_0 on the phase and magnitude of the impedance of a TSM sensor.

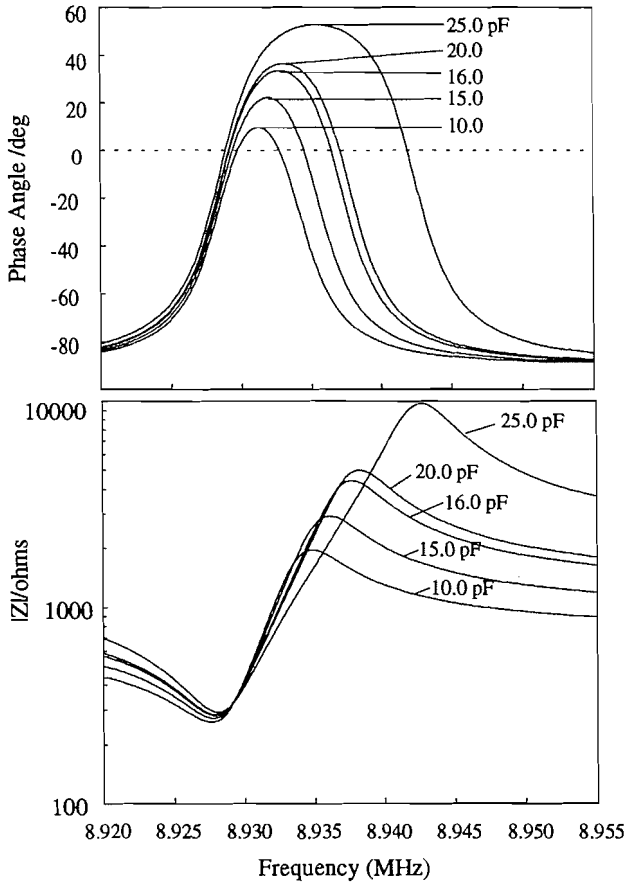

Fig. 7. Responses of the series resonant frequency f_s change (*a*) and the motional resistance R_m (*b*) of TSM sensors with one side in contact with KCl solution.

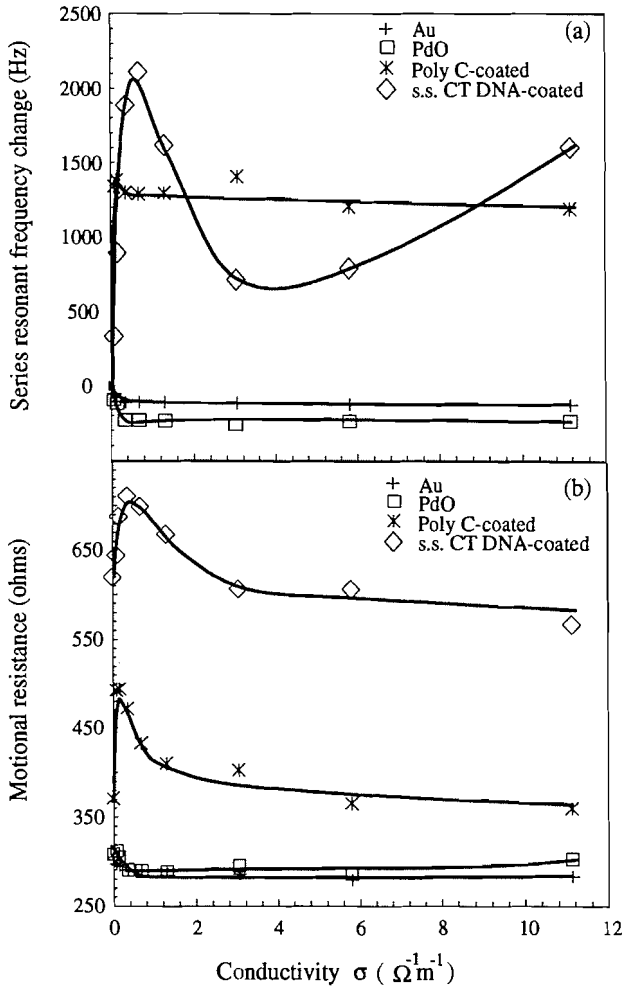
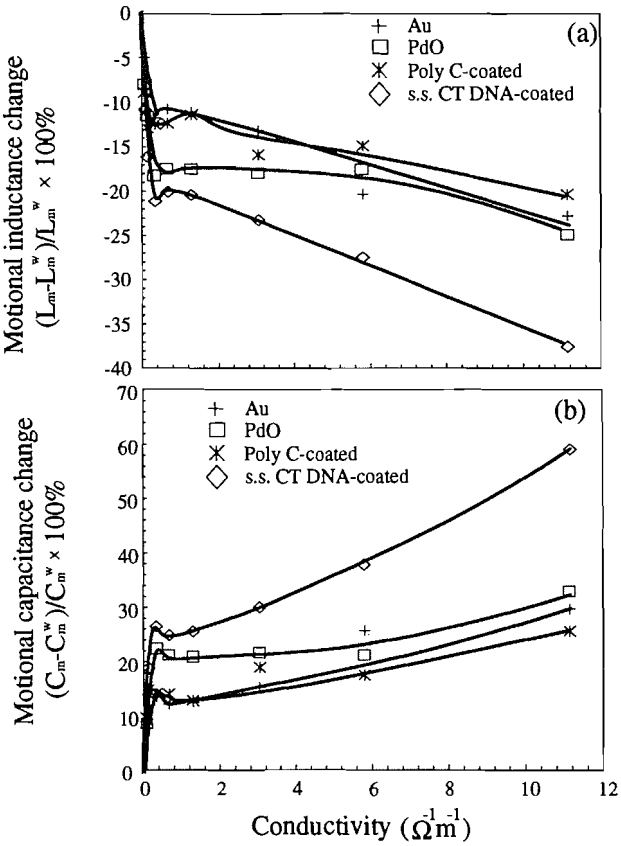


sity and viscosity of the solution are very similar to those of water. Therefore, an increase in ionic concentration does not change the trapped mass component, and thus the series resonant frequency, according to eq. [1] (Table 1). However, the series resonant frequencies of nucleic acid coated TSM sensors did change upon solution loading. Figure 7(*a*) clearly shows that the series resonant frequency responses of nucleic acid coated sensors can be separated into two regions. When $0 < \sigma < 0.5\ \Omega^{-1}\ m^{-1}$ (region I), the series resonant frequencies of ss calf thymus DNA and RNA homopolymer Poly C-coated resonators increase significantly with conductivity by 1400–2100 Hz. In the absence of any nucleic acid coating, however, a decrease of 100–300 Hz was observed, which is attributed to the acoustoelectric coupling effect (36). In region II ($0.5 < \sigma < 12\ \Omega^{-1}\ m^{-1}$), little change in f_s was observed with Poly C coated, bare PdO and Au sensors. However, the frequency response of the ss DNA coated sensor shows a bell-shaped curve with a minimum at $\sigma = 4\ \Omega^{-1}\ m^{-1}$. As mentioned above, motional resistance (R_m) changes will be governed by energy losses arising from propagation of the acoustic wave into the liquid. For solvents not containing electrolyte, it appears that the behaviour of R_m is dominated by the bulk properties of the liquid, expressed as the square root of the density–viscosity product (eq. [9], Table 1). When an electrolyte is involved, acoustoelectric coupling becomes very significant for uncoated TSM sensors. The motional resistance changes obtained for resonators (uncoated and nucleic acid coated) in contact with a series of KCl solutions are plotted against the solution ion conductivity (σ) in Fig. 7(*b*). This clearly shows that the change in R_m for nucleic acid coated sensors can be separated into two regions, in the same way as the changes in series resonant frequency. When $0 < \sigma < 0.5\ \Omega^{-1}\ m^{-1}$ (region I), the R_m of both ss calf thymus DNA and Poly C coated resonators shows significant variation, with a maximum at the same value of conductivity where f_s has the most rapid shift. However, the PdO- and Au-deposited TSM sensors without nucleic acid coatings show a small 20 Ω decrease, which may be caused by energy storage in the electrical double layer (36). In region II ($0.5 < \sigma < 12\ \Omega^{-1}\ m^{-1}$), the motional resistances of both Poly C and ss DNA coated TSM sensors decrease and then return to almost the original points, while the bare PdO and Au TSM sensors show little change.

Figure 8(*a*) shows the responses of the motional inductance of nucleic acid coated and uncoated TSM sensors upon solution loading. L_m decreases up to 15–20% for Au, PdO, and Poly C and 36% for the ss DNA coated sensors. This indicates a change in the decay length of the propagating wave in terms of coupling between the solid and solution. The decay length for a travelling shear wave in a liquid can be written as

Fig. 8. Responses of the motional inductance L_m change (*a*) and motional capacitance C_m (*b*) change of TSM sensors with one side immersed in KCl solutions. $L_m{}^w$ and $C_m{}^w$ are the motional inductance and capacitance upon water loading, respectively.



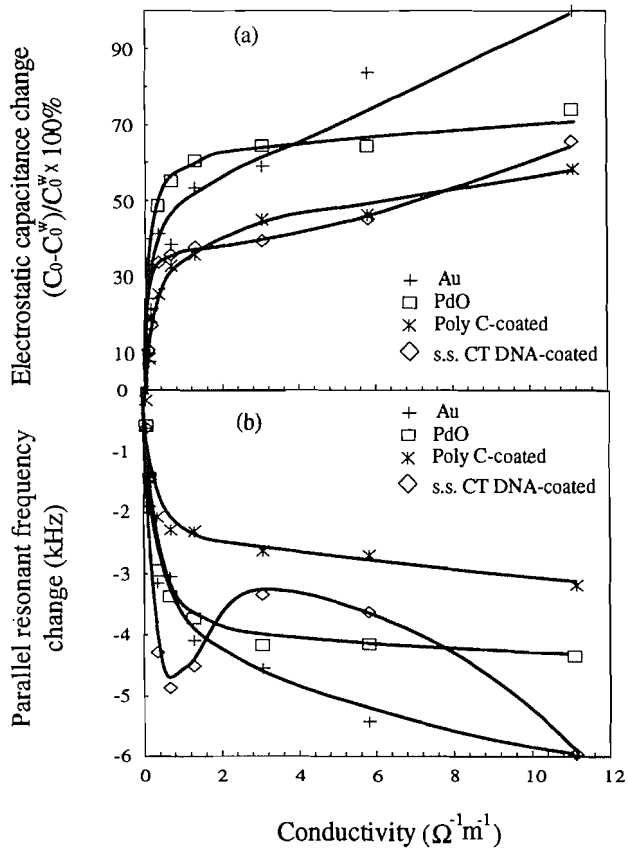
$$[22] \quad \delta_L = \left(\frac{2\eta_L}{\omega\rho_L}\right)^{1/2}$$

For the solution used here, the decay length is ca. 1.0 μm, which is comparable to the length of ss DNA or Poly C molecules. Accordingly, the molecular structure at the solid–solution interface will be critical in determining the coupling of the nucleic acid coated film.

It has been assumed that C_m can be considered a constant under solution loading because a Newtonian liquid does not exhibit any elasticity (37). However, Fig. 8(*b*) shows that C_m does have a 20% increase when the ionic conductivity reaches 10 Ω^{-1} m^{-1} with bare Au and PdO surfaces. This indicates that the KCl solution cannot be treated as a pure Newtonian liquid and the formation of an interfacial liquid structure may change its elastic properties. At the same time, C_m for an ss DNA coated TSM sensor increases 60% and this demonstrates that C_m becomes more important when the TSM sensor is coated with a thin DNA film. Clearly, theoretical (Figs. 4 and 5) and experimental (Fig. 8) results show that the responses of a nucleic acid coated TSM sensor will be significantly altered if C_m and L_m are changed significantly with little mass gain or loss. Accordingly, as mentioned previously, the device not only respond to mass changes at the liquid–solid interface, but to other factors.

The changes in C_0 for solutions of different conductivities

Fig. 9. Responses of the electrostatic capacitance change C_0 (*a*) and parallel resonant frequency f_P change (*b*) of TSM sensors with one side immersed in KCl solutions. $C_0{}^w$ is the electrostatic capacitance upon water loading.



relative to the value for water, $C_0{}^w$, are shown in Fig. 9(*a*). The two distinct regions of C_0 change correspond to the respective Helmholtz–Perrin and Gouy–Chapman capacities of the double layer (37). It is clear that changes in double-layer capacitance result directly in a change in C_0 upon electrolyte solution loading. As shown in Fig. 9(*a*), the responses of C_0 with and without nucleic acid coatings show little difference in their patterns. Accordingly, the shift in electrostatic capacitance is primarily determined by the solution conductivity associated with changes in electrical double layer capacitance.

The shift of the parallel resonant frequency (Δf_p) with the ionic conductivity of the KCl solution is depicted in Fig. 9(*b*). The behaviour of f_p is drastically different from that of f_s: f_p shows a much greater sensitivity towards the conductive properties of the solution with bare PdO and Au TSM sensors. The parallel resonant frequency depends not only on the quartz crystal but also on the associated circuit and all capacitances in parallel with the device (eq. [14], Table 3). The measurement of f_p can be very useful in determining specific properties of the surrounding media such as in the case of electrolytes (26). However, the parallel resonant frequency response of an ss DNA coated TSM sensor shows different behaviour than the uncoated resonator. A dip, which is apparently associated with the changes of motional inductance and capacitance, is observed at a conductivity of 0.5 Ω^{-1} m^{-1} (Fig. 9(*b*)).

Effect of temperature on the responses of nucleic acid coated sensors

Since the series resonant frequency change of a resonator in liquid depends on ρ, μ, η_L, and ρ_L according to eq. [3] and each of these change with temperature, the frequency must also be temperature dependent. For AT-cut quartz crystals, the dependence of $T_c(-nf_o^{2/3}(1/\mu_Q\rho_Q)^{1/2})$ on temperature, from eq. [3], is (25)

$$[23] \quad T_c = -\frac{T_\rho + T_\mu}{2}$$

where $T_\rho = 36.4 \times 10^{-6}$/°C and $T_\mu = 17.8 \times 10^{-6}$/°C. Thus $T_c = 9.8 \times 10^{-6}$/°C, which is relatively small; therefore T_c (20°C) ≈ T_c (60°C) and the temperature factor in eq. [3] can be considered a constant for quartz crystals oscillating in solution over the temperature range studied. Accordingly, the frequency shift observed as the temperature increases is due to changes in the viscosity and density of water in the surface region.

Figure 10(*a*), curve B, shows that the series resonant frequency change (Δf_s) for an uncoated TSM sensor exhibits about a 700 Hz increase and three unusual peaks at 27°C, 38°C, and 52°C, respectively. The frequency remains constant when the solution is kept at a fixed temperature. The rate of temperature increase was very low and did not have a large effect on the frequency change curves. Shifts of only about several hertz were observed and the peak positions were the same. This means that the effect causing these three peaks does not constitute a dynamic process. The surface viscosity (16) and density and compressional wave generation (38) have been attributed to these observed frequency changes. Similar phenomena have also been observed by other researchers. Normura, Watanabe, and West (39) measured a peak near 23°C as the temperature was varied between 15 and 30°C. Muramatsu et al. (40) also found the Δf value at 25°C for water to be larger than that at 30°C; they explained this as due to the water molecules being more closely associated owing to reduced Brownian motion at 25°C.

It is interesting to note in Fig. 10(*a*), curve C, that the f_s of the DNA-coated TSM resonator *decreases* as the temperature increases, which is in the opposite direction to that of an uncoated TSM sensor (curve B). The results again show that the responses of a DNA-coated TSM sensor are not only a function of the properties of the solution contacting the quartz plate, but also of the DNA film. The derivatives of the series resonant frequency as a function of temperature are shown in Fig. 11(*a*). Two large peaks are observed and the correspond-

ing peak temperatures are assigned to the relaxation temperatures. Accordingly, as the temperature increases, the DNA polymer passes through the relaxation temperatures, T_β = 36°C and T_α = 58°C, respectively. α-Relaxation may be referred to as the primary relaxation associated with the motion of DNA chain segments. Relaxation associated with the motions of groups attached to the DNA polymer backbone may occur at temperatures below T_α and is referred to as β-relaxation. The α-relaxation is accompanied by large changes in the modulus and viscosity of a polymer.

The motional resistance R_m can be also calculated from eq. [9]. Figure 10(*b*) (curve A) shows that the theoretically calculated R_m decreases almost linearly with temperature from 580 to 382 Ω as the temperature is varied between 20 and 60°C. This does not follow the results obtained experimentally, as shown in Fig. 10(*b*), curve B. Curve B also shows three peaks corresponding to those for the series resonant frequency. This is reasonable since both R_m and Δf_s are related to the viscosity and density of the solution. For the uncoated TSM sensor, the motional resistance (R_m) change follows the same trend as that predicted but with different magnitude, in comparison with curves A and B in Fig. 10(*b*). The motional resistance (R_m) curves and their derivatives for DNA-coated TSM sensors are shown in Figs. 10(*b*) and 11(*b*) (curve C), respectively. The motional resistance of a DNA-coated TSM device increases rapidly as the temperature reaches T_α, and its derivative (Fig. 11(*b*), curve C) has two peaks near the α- and β-relaxation temperatures.

As demonstrated above (Fig. 5), the motional capacitance C_m, upon loading with electrolyte, becomes more important when the TSM sensor is treated with a thin DNA film. Figure 11(*c*) depicts motional capacitance changes as a function of temperature for the uncoated and DNA-coated TSM sensors. As the temperature rises, there is a small increase in C_m for the uncoated TSM device. For the DNA-coated device, C_m increases rapidly toward T_α and reaches a maximum as the DNA polymer undergoes primary relaxation, indicating a large change of elasticity in the DNA-coated film.

Analysis of sensor responses employing theoretical treatments of TSM behaviour in liquids

Equation [3] (Table 1), developed by Kanazawa, fails to explain the observed TSM signal change in f_s upon conductive solution loading (Fig. 7(*a*)). At 20°C, the viscosity and density values for 0.05 M KCl (ρ = 0.9984, η = 1.0017 cp) and 0.1 M KCl (ρ = 1.0029, η = 0.9996 cp) are very similar to those for water (ρ = 0.9982, η = 1.0020 cp). The series resonant frequency f_s will decrease by only 0.2 and 5 Hz for 0.005 and 0.1 M KCl, respectively. Therefore, the frequency change due to viscosity and density is considered to be negligible in the KCl concentration range employed in this work. Equation [3] also fails to explain the observed change in f_s with temperature (Fig. 10(*a*)). Figure 10(*a*), curve A, shows the series resonant frequency change as a function of temperature, as predicted by eq. [3], without considering the effects of surface viscosity or density, i.e., both of them are the same as the bulk where values of ρ_w and η_w are taken from the literature (41). The frequency shift should increase linearly over about 2000 Hz when the temperature is increased from 20 to 60°C, according to this equation.

The acoustoelectric coupling factor, κ^2, can be obtained by fitting the experimental data (Fig. 7(*a*)) to eq. [4] (Table 1) for sensors with gold and PdO surfaces. The values of κ^2 are 5.4×10^{-3} and 5.2×10^{-3} for gold and PdO surfaces, respectively, indicating that the acoustoelectric interactions are very similar for these two surfaces. Obviously, acoustoelectric coupling (eq. [4]) also fails to explain the responses of nucleic acid coated TSM sensors upon electrolyte solution loading.

The shear vibration of the quartz crystal results in mechanical interactions between the crystal and the nucleic acid film on its surface. The mechanical properties of the DNA/RNA films therefore influence the mechanical properties of the resonator, which results in corresponding changes in the electrical properties of the TSM sensor. When a periodic stress at a particular frequency range is applied to a polymer, periodic strains are induced. If the DNA polymer is above its glass transition temperature, T_g, the strains relax by thermal motion at a rate that is characteristic of the polymer and the temperature. If the characteristic relaxation time is much shorter than the period between stresses, the measured modulus is that of a soft material. If the periodic stresses occur faster than the material can relax, then the measured modulus will be that of a stiff glass.

It is well known that DNA macromolecules undergo viscoelastic changes in solution with increase in ionic conductivity (42). If a single DNA molecule is placed in a "thermodynamically good" solvent, such as water, the DNA segments and water molecules are attracted to one another and the average coil dimensions tend to increase in order to maximize the number of interactions between DNA polymer segments and water molecules. DNA also contains charged groups along the backbone, so additional effects may come into play as well. In pure water, a DNA polymer containing charged groups will tend to extend in order to minimize the repulsion between them. If a simple electrolyte such as KCl is dissolved in the water, the ions of opposite charge to those carried by the DNA polymer can neutralize its charge. Thus, as the ionic strength is increased, the polymer returns to its coiled shape. Accordingly, DNA films will swell greatly in pure water or in electrolyte solutions of low ionic strength; at high electrolyte concentrations, they will shrink. In summary, the structure of DNA is highly dependent on its hydration sheath, and the secondary and tertiary structures are, in part, dependent on the presence of cations in solution to screen the negative charge of the phosphate groups.

The series resonant frequency responses (Fig. 7(*a*)) can therefore be correlated with changes in DNA viscoelasticity upon KCl solution loading. When the ionic conductivity is less than 0.5 Ω^{-1} m^{-1} (region I), the Debye–Hückel screening length is greater than the effective contour distance between charges. Therefore, the charges begin to interact with each other and a stiffening of the chain is expected as σ increases. The series resonant frequency will therefore increase upon the expansion and stiffening of the DNA molecules. At ionic strength greater than 0.5 Ω^{-1} m^{-1} (region II), the Debye–Hückel screening length is less than the effective contour distance between charges on the DNA phosphate backbone after counterion condensation. The charges are therefore effectively screened from one another and so the DNA molecules shrink, resulting in a gradual decrease in f_s. The reason for f_s increasing again at very high ionic conductivity is not clear at the present time, but could be due to motional capacitance and

inductance changes. Furthermore, since the measurements extend only to 1 M KCl solution, the possibility exists that some structural changes may occur in DNA at higher salt concentrations.

The analysis described above provides only a qualitative explanation for the series resonant frequency change for the DNA-coated TSM sensor reported in Fig. 7(*a*). A quantitative analysis, as described below, can be obtained using the equivalent circuit model developed by Martin and Frye (28).

When a TSM sensor is in contact with a viscoelastic fluid or polymer film, the corresponding equivalent circuit can be modified as shown in Fig. 1, where Z_f represents the impedance of the viscoelastic film (eq. [6], Table 1). By fitting the impedance **Z** using eq. [24], the unique storage and loss moduli, G' and G'', can be extracted.

$$[24] \quad \mathbf{Z} = R'_m + j\omega L'_m + \frac{1}{j\omega C'_m} + Z_f$$

The corresponding dynamic viscosity can then be obtained from the following equation:

$$[25] \quad \dot{\eta} = \eta' + j\eta'' \equiv \frac{G''}{\omega} + \frac{jG'}{\omega}$$

As a specific model for this frequency dependence, a three-parameter model recently studied by DeKee et al. (43) is used. The dynamic viscosity $\dot{\eta}$ can be written according to eq. [26].

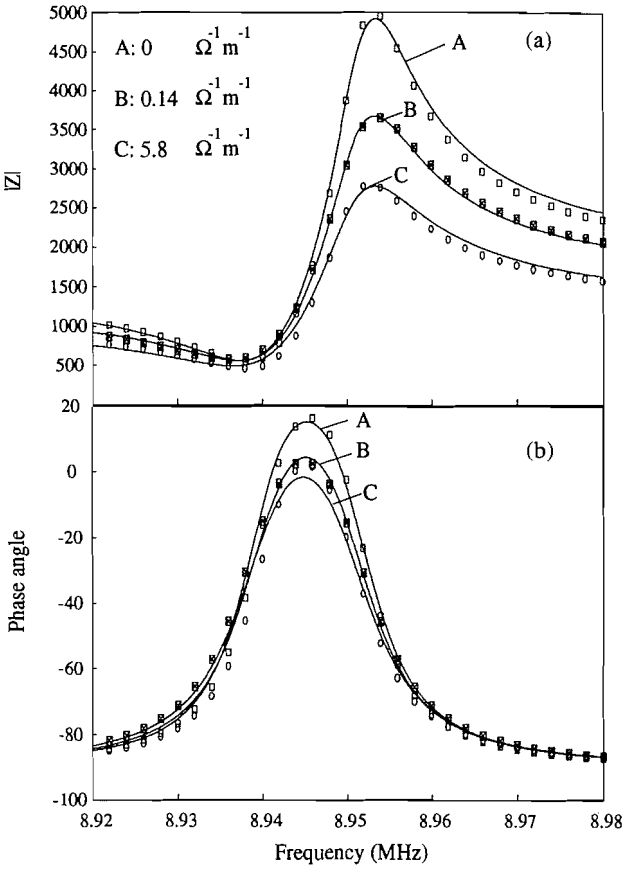
$$[26] \quad \dot{\eta} = \frac{\eta_0}{(1 + j\omega\tau)^{\nu}}$$

This three-parameter model has the advantage that values for two of these three parameters (τ and ν) can be obtained by fitting the data to eq. [26], while the third (η_0) can be obtained from published data for the liquids used here (27).

Very important information on the mechanical properties and nature of polymeric systems in a fluid state can be extracted by this dynamic method of investigation, in which polymers are subjected to cyclic deformation. In dynamic measurements, the energy stored in a polymer is determined. A measure of this energy is the storage modulus of elastic deformation G'. At the same time, the resistance of a polymer to deformation is determined from the dissipation of energy, i.e., conversion of a part of the work of deformation into heat in every cycle. This resistance of a body to deformation is characterized by the loss modulus G''. The ratio G''/G' is known as the mechanical loss tangent, δ, since it is the dissipative losses in each cycle that result in a phase shift of the deformation to the applied stress: as δ increases, the losses become greater.

The total impedance **Z** of a nucleic acid viscoelastic film on a TSM sensor is a function of nucleic acid film thickness, shear modulus and density, and the properties of the liquid contacting the quartz plate. Impedance vs. frequency measurements made for three solution conductivities on the DNA-coated TSM device are shown in Fig. 12. The points are measured directly from the network analyzer and solid lines are calculated from the equivalent circuit model using the best-fit values of G' and G'' from eq. [24] to determine **Z**, along with the

Fig. 12. Magnitude (*a*) and phase (*b*) of impedances measured (points) and calculated from the equivalent circuit model (lines) for a ss CT DNA-coated TSM sensor at three solution conductivities. A: 0; B: 0.14 Ω^{-1} m^{-1}; C: 5.8 Ω^{-1} m^{-1}.

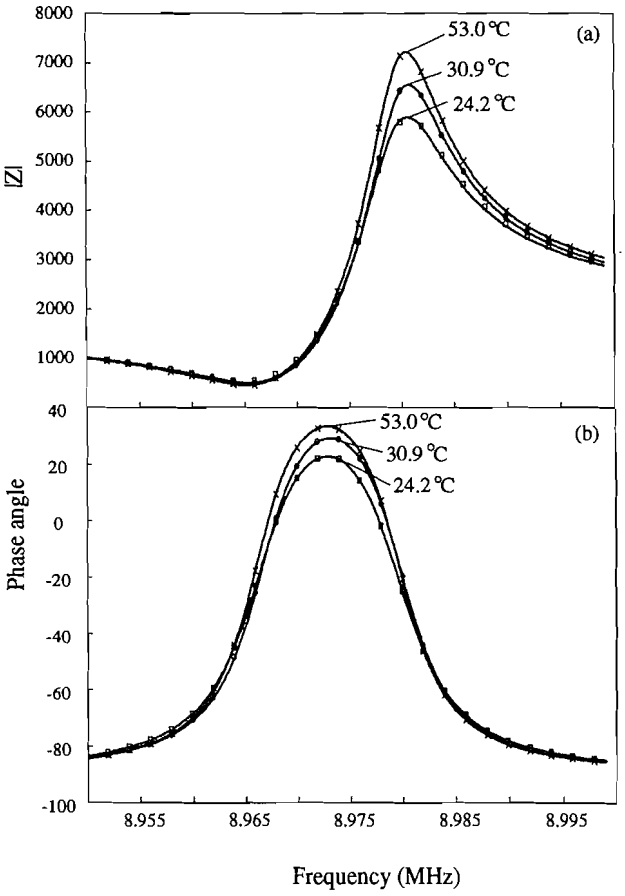


circuit elements determined from the measurements of the uncoated TSM devices. Figure 12 also shows that eq. [24] provides a good fit to each data set (lines), determining a unique combination of G' and G'' for each. It can be noted from Fig. 12 that as solution conductivity increases, the maximum phase angle and $|\mathbf{Z}|$ diminishes, i.e., the resonance is increasingly damped. However, the series resonance frequency does not change monotonically with the solution conductivity.

Figure 13 shows the impedance vs. characteristic frequency measured at three different temperatures (points) with the best-fit data calculated according to eq. [24] (solid lines). A good fit is defined for each data set. Note that increasing temperature causes less damping of both the magnitude–frequency and phase–frequency curves. This results in a decrease in the magnitude of the maximum impedance $|\mathbf{Z}|_{max}$ and the maximum phase angle, θ_{max}. The broadening and diminishing of the parallel resonance peaks arises from power dissipation as modelled by increasing R_m values.

This model can be used to interpret the experimental results obtained for conductive solution loading and temperature change (Figs. 7 and 10). According to eq. [6] (Table 1), the impedance Z_f of a DNA/RNA viscoelastic film on a TSM sensor is a function of device frequency, film thickness, polymer shear modulus, and density. The series resonant frequency response of DNA/RNA-coated TSM devices upon electrolyte solution loading is a complex function affected by all acoustic

Fig. 13. Magnitude (*a*) and phase (*b*) of the impedance measured (points) and calculated from the equivalent circuit mode (lines) for a ss CT DNA-coated TSM sensor at a number of temperatures.



energy transfer and dissipation processes. In water, where the nucleic acid modulus is relatively high and the coil shape of the DNA molecules can be considered as relatively rigid, the entire thickness of the film moves almost synchronously with the device surface in the electrolyte solution. As the ionic conductivity increases, the charges begin to interact with each other, resulting in the expansion and stiffening of the chain. Thus, an increase in f_s is predicted as observed (Fig. 7(*a*)). Continuing decreases in modulus with increasing ionic conductivity increase the phase lag and the strain in the DNA film. When the DNA film's upper surface lags behind the motion at the nucleic acid – solution interface by $\pi/2$, a condition of dynamic DNA resonance is reached. This effect is observed in Fig. 7(*a*) for both ss DNA and Poly C coated TSM sensors. This dynamic resonance phenomena was first observed by Martin and Frye (28) in a study of relatively thick polymer-coated TSM sensors in the gas phase with changing temperature. At temperatures below that of film resonance, the TSM device frequency decreases with increasing temperature as the polymer expands and the modulus decreases. As film resonance is approached, the frequency drops more steeply. But at film resonance, the frequency suddenly increases to values exceeding the initial frequency.

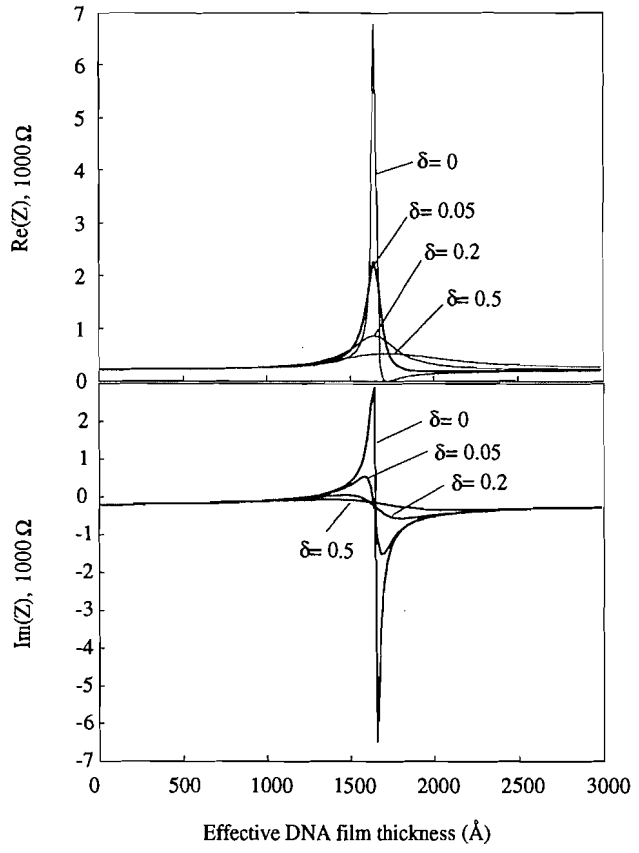
As the ionic conductivity increases further, DNA molecules begin to shrink and the phase lag cannot be $\pi/2$. Accordingly, the series resonant frequency of the ss DNA coated TSM sensor decreases again. The R_m of a nucleic acid coated TSM sensor in pure water is significantly greater than that of the uncoated device, indicating the existence of energy losses other than those due to acoustoelectric coupling (Fig. 7(*b*), when $\sigma = 0$). The DNA film in the solid state is an insulator and exhibits piezoelectricity (44). However, the extent of hydration (water or relative humidity), coupled with the ionic strength, determines the polymorphic character of a DNA duplex. The first hydration shell of duplex DNA is not very permeable to ions. It consists of about 20 water molecules per nucleotide, on average, and does not form an "icelike" structure. The number of water molecules in the secondary hydration shell is not well defined structurally. It is permeable to ions and has some characteristics of bulk water. DNA molecules try to accommodate the varying activity of surrounding water molecules by conformational change, in order to optimize the balance between water–water, water–DNA, and intra-DNA interactions. DNA carries a cloud of counter- and co-ions with it and hydrated samples are ionic conductors, similar to a polyelectrolyte.

In low-ionic-strength electrolyte solutions or pure water, a DNA film will swell enormously. Thus, the corresponding motional resistance R_m increases (Fig. 7(*b*)), indicating more acoustic energy dissipation into the swollen DNA chain as it moves with the quartz plate. At high electrolyte concentrations, DNA molecules will shrink and the corresponding motional resistance decreases, returning close to the original point. This results in DNA molecules moving more easily with the quartz crystal, involving less dissipation of acoustic energy. Another important consideration will be the conductivity over acoustic wave decay length. The reduction in dissipation of acoustic energy with an increase of conductivity associated with mobile positive counterions has also been observed (45).

Equation [6] (Table 1) shows that the effective DNA film thickness T_f plays an important role in determining the magnitude and phase of the impedance of a TSM device. This model is based on the propagation of the acoustic shear wave at the film–air interface, destructive interference being interpreted as giving rise to greater impedance values. It is not strictly applicable to TSM liquid studies and some researchers believe that the presence of a liquid should only modify the absolute values of |**Z**|, the acoustic wave being only partially propagated at the DNA film–solution interface (46). Figure 14 depicts the changes of the real and imaginary parts (Re(**Z**) and Im(**Z**) of the impedance vs. the effective DNA film thickness for different loss tangents. When $T_f \approx 1700$ Å, the changes of Re(**Z**) and Im(**Z**) are much greater than for other thicknesses at various values of the loss tangent. This thickness corresponds to the establishment of destructive interference of the wave in the film when the phase shift is $\pi/2$, the interference attenuation being the greatest for thinner and less lossy films. The Re(**Z**) and Im(**Z**) peaks from Fig. 14 also broaden and diminish as δ increases when the DNA film thickness is ca. 1700 Å.

The effective thickness of a DNA-coated film at a solid–solution interface cannot be determined directly. Some researchers have used the Sauerbrey equation to estimate this, i.e., measurement of the series resonant frequency in the gas phase before and after DNA immobilization followed by calculation of the thickness based on eq. [1] (Table 1). However,

Fig. 14. The calculated real and imaginary parts of the impedance **Z** vs. DNA effective film thickness for a 9-MHz TSM device. δ is the loss tangent.



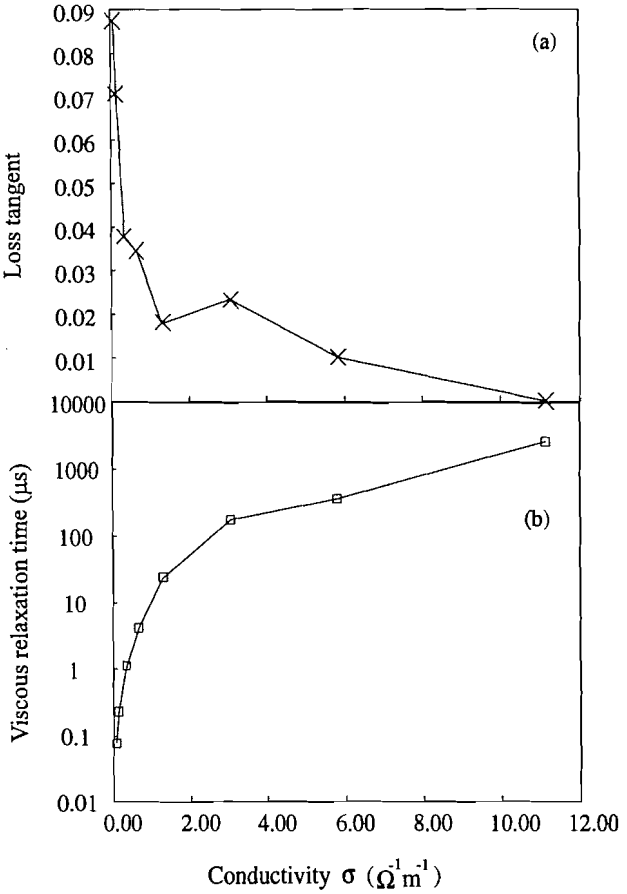
this results in large errors because the coating is assumed to possess the same acoustic properties as that of quartz. As well, the Sauerbrey relationship requires that the deposited film have a uniform thickness across the entire active region of a resonator, whereas the mass sensitivity of the resonator is actually a Gaussian-like distribution (47). Furthermore, the unremoved hydration of DNA will also lead to overestimation of the DNA film thickness. Finally, the DNA film thickness will be changed when the polymer swells upon solution loading.

The coverage of DNA on the surface will also affect the effective film thickness and thus the TSM sensor response. When a surface with low DNA coverage contacts a solution, strong DNA polymer–polymer interactions are replaced by weaker polymer–solvent interactions, and the DNA molecule acts as an isolated chain. The effect of the DNA coating on solvent flow can be predicted on the basis of a simple addition and is the result of inelastic collisions between the Brownian thermal continuum and a polymer chain that obeys Guassian statistics. The connection between the shear viscosity and molecular motion can be described by "normal mode" theories (48). In high-molecular-weight DNA polymers, interactions between elements within the same chain lead to the so-called "excluded-volume" effects. Increasing the DNA surface coverage allows DNA–DNA intermolecular interactions to influence the motion of the DNA polymer. These interactions can be envisaged to be of two types; firstly, because of the relatively close proximity of neighbouring chains, the perturbation of the lamellae flow caused by the polymer has not died down before the next polymer molecule is encountered; and, secondly, the occurrence of intermolecular interactions, which have a similar effect to the intramolecular interactions associated with excluded-volume effects observed for low-surface-coverage regimes. Both effects can be treated theoretically by the interaction of a "hydrodynamic screening" interaction. The moderately covered surface region would be expected to extend from the point where hydrodynamic flow ceases to be lamellar to a point where the DNA polymer completely fills the solution. But this does not lead to a point where the polymer completely fills the surface and effects significant interpenetration of the volume occupied by a neighbouring polymer molecule. At higher concentrations, DNA intercoil contact has been exchanged for dynamic contact as a consequence of coil–coil interpenetration and a pseudo-matrix gel is formed. Gel formation will occur when the time-averaged number of entanglements per chain exceeds a certain value. The probability of chain–chain contacts occurring depends upon the size of the coil and hence on the end-to-end distance for the DNA polymer. Accordingly, the effective DNA film thickness at various solution conductivities employed in the calculation are persistence lengths of DNA macromolecules obtained from the literature (42).

Other important parameters in describing the contribution of a DNA film to the impedance are the storage modulus of elastic deformation, G', and the loss modulus, G'' (or G' and loss tangent δ). The loss tangent has little contribution to the real and imaginary parts of the corresponding impedances for low DNA film thicknesses, and δ becomes dominant as T_f increases. By fitting the **Z** vs. frequency data measured with the DNA-coated TSM device at a number of conductivities, the values of G' and G'' (or δ) were extracted. The typical calculated values of G' and δ were 2×10^5 dyne/cm^2 and 0.02, respectively. Both values are relatively low compared to the DNA modulus in the dry gas phase ($G' = 10^{10}$ dyne/cm^2). The modulus of bulk DNA polymer is a function of the temperature, polymer film properties, and solution components. With DNA biopolymers, a significant change in G' can be obtained by varying the solution composition. G' typically decreases from 10^{10} to 10^7 dynes/cm^2 when the temperature increases from that of glass to rubbery states (44). Although little is known about the viscoelastic properties of a nucleic acid film immobilized on an oscillating TSM sensor surface with solution loading, or for that matter at any interface, it would seem likely that these properties are dynamic and change with the experimental conditions. Nevertheless, the experimental results here demonstrate that the TSM device is sensitive to intrinsic polymer properties. Using a network analyzer to measure admittance as a function of frequency and the equivalent circuit parameters, the DNA polymer elastic shear modulus G' and loss modulus G'' can be extracted.

The loss tangent δ is another important parameter that is dimensionless and conveys no physical magnitude but is a measure of the ratio of energy lost to energy stored in a cyclic deformation. It is a measure of the energy dissipated or lost as heat per cycle of sinusoidal deformation if G' is kept constant. Figure 15(*a*) depicts the loss tangent calculated from the equivalent circuit model vs. solution conductivity. This shows that δ decreases as conductivity increases and approaches a constant value at high conductivity. At low conductivity, the

Fig. 15. The calculated loss tangent δ (*a*) and viscous relaxation time τ (*b*) of TSM sensors with one side immersed in KCl solutions.



behaviour of DNA-immobilized molecules can be modelled by long thin rigid rods with dominant hydrodynamic interactions, giving rise to a high loss tangent. When the solution conductivity is raised, the DNA molecules can change to the flexible random coil structure with small loss tangent. At the same time, entanglement coupling occurs at high solution conductivity. On a molecular basis, this would correspond to the absence of larger molecular or atomic adjustments capable of dissipating energy within the period of deformation.

Figure 15(*b*) shows the calculated viscous relaxation time τ vs. solution conductivity, while the ν is in the range of 0.2–0.3 for all of the solutions studied. When the solution conductivity is not high enough (τ is large) or the period of application of the field is too short (high frequency), i.e., $\tau\omega >> 1$, the orientation moment will not have time to develop and the DNA polyions cannot redistribute fast enough to screen the field. When $\tau\omega << 1$, the orientation moment is fully established at each instant and reaches its maximum static value. On the other hand, for a DNA-coated TSM device upon conductive solution loading, the ionic species at the solid–solution interface can redistribute rapidly in response to an applied surface potential. The formation of an electrical double layer at the solid–solution interface may block the field from penetrating into the bulk solution.

Finally, it should be noted that eq. [24] does not take into account the surface morphology of the quartz crystal, the size of its pores compared to the acoustic wave length, etc. Also, when the "nonslip" condition, a basic assumption in all theories available, is not found to hold, one also expects changes in impedance **Z** to occur. The first detailed study of molecular slip at the solid–liquid interface of an AT-cut TSM sensor was recently reported by Kipling and co-workers (29). A new quantity, called the interfacial slip parameter, is introduced in one of the boundary conditions of the theory of a two-layer model of the TSM sensor in liquid. The interfacial slip parameter is a complex-valued quantity, defined as the displacement of a particle of liquid in contact with the sensor surface divided by the displacement of a particle on the surface of the sensor. The theoretical expression for the impedance of the TSM sensor is derived in terms of the interfacial slip parameter.

The water-advancing contact angles of both ss DNA and Poly C immobilized on TSM sensor surfaces are less than 10°, thus both surfaces are very hydrophilic and are completely wetted by the solutions. Therefore, the propagation of the shear wave into the solution is considered to be continuous. Accordingly, the interfacial free energy change and slippage between the solid–solution molecules have minimal effect on TSM sensor response under these conditions.

Cd(II) complexes with phthalic acid: solution study and crystal structure of cadmium(II) phthalate hydrate

José Luis Lucas Vaz, Gérard Duc, Michelle Petit-Ramel, René Faure, and Olivier Vittori

Abstract: The acid–base properties of phthalic acid (H_2L) have been determined by simultaneous spectroscopic, potentiometric, and polarographic measurements. Stability constants of the complexes $CdHL^+$, CdL, CdL_2^{2-}, CdL_3^{4-}, $CdH_{-2}L_2^{4-}$ and their distribution versus pH were determined at 25°C and ionic strength in 0.1 M $NaNO_3$. The advantages of each method are pointed out in such a way as to describe more precisely the interactions between cadmium and phthalic acid over a wide range of ligand and metal concentrations. The crystal structure of the [CdL] complex has been established by single-crystal X-ray diffraction. $Cd(C_8H_4O_4)\cdot H_2O$ is orthorhombic, space group *Pbca*, $a = 23.463(5)$, $b = 9.293(2)$, $c = 7.730(1)$ Å, $Z = 8$, and $\rho = 2.323$ g cm^{-3}. The structure was refined to a final R value of 0.054 for 3231 unique reflections with $I > 3\sigma(I)$. The crystal is a three-dimensional polymeric network in which the Cd atom is seven-coordinated. The first ligand coordinates in a bidentate carboxylate (O,O′) mode (Cd—O = 2.372(5) and 2.445(5) Å); a second ligand is part of a seven-membered ring formed with its two carboxylate groups (Cd—O = 2.317(5) and 2.341(5) Å); two other phthalic ligands make one coordination bond (Cd—O = 2.255(5) and 2.449(5) Å) while the seventh bond is a water molecule (Cd—O = 2.333(6) Å).

Key words: crystal structure, cadmium complexes, phthalic acid complexes.

Résumé : Les propriétés acido-basiques de l'acide phtalique (H_2L) ont été déterminées par des mesures conjointes de spectrométrie, potentiométrie et de polarographie. Elles donnent accès aux constantes de stabilité des complexes $CdHL^+$, CdL, CdL_2^{2-}, CdL_3^{4-}, $CdH_{-2}L_2^{4-}$, ainsi qu'à leur distribution en fonction du pH à 25°C et pour une force ionique de 0,1 M $NaNO_3$. Les avantages de chaque méthode sont discutés pour cerner les interactions entre le cadmium et l'acide phtalique dans une large gamme de concentrations de ligand et de métal. La structure du complexe [CdL] a été établie par diffraction X. Le composé isolé, de formule $Cd(C_8H_4O_4),H_2O$, cristallise dans le système orthorhombique, groupe *Pbca*, avec $a = 23,463(5)$, $b = 9,293(2)$, $c = 7,730(1)$ Å, $Z = 8$ et $\rho = 2,323$ g.cm^{-3}. L'indice R final vaut 0,054 pour 3231 mesures indépendantes. Le cristal est un enchaînement polymérique tridimensionnel dans lequel l'atome de cadmium est heptacoordiné. Un premier groupe phtalato assure simultanément deux liaisons au moyen d'un groupe carboxylato bidentate (Cd—O = 2,372(5) et 2,445(5) Å); un deuxième coordinat forme un cycle de chélation à sept chaînons au moyen de ses deux groupes carboxylato (Cd—O = 2,317(5) et 2,341(5) Å); deux autres coordinats assurent chacun une seule liaison (Cd—O = 2,255(5) et 2,449(5) Å); le polyèdre de coordination est complété par une molécule d'eau (Cd—O = 2,333(6) Å).

Mots clés : structure cristalline, complexes du cadmium, complexes de l'acide phtalique.

Introduction

The toxic effects of Cd(II) are well established and documented (1). This ion has been found to induce various pathological effects, such as cardiovascular diseases (2, 3) and cancer. Most of the cadmium ion in eco-biological systems is complexed with biological ligands (4, 5). It has been reported that a large number of phthalate derivatives of cadmium demonstrate diverse pathological effects (6).

The aim of this work is to evaluate the composition and stability constants using Differential Pulse Polarography (D.P.P) as a complementary method for potentiometric titrations. As an example of the interactions between cadmium and phthalic acid in the solid state, we report here the X-ray crystal analysis of a cadmium phthalate complex.

Experimental

Reagents

Phthalic acid (99.5%) and Cd(II) nitrate were obtained from Merck and used without further purification. In the potentiometric and polarographic measurements CO_2-free deionized water was used as the solvent. All the potentiometric and polarographic measurements were carried out in 0.1 M $NaNO_3$ as background electrolyte. Potentiometric titrations were performed with a 0.2 M NaOH (Prolabo) solution.

Potentiometric and spectrometric determinations

Equilibrium potentiometric determinations of the ligand pro-

tonation constants and the metal binding constants, in molar ligand to metal ratios of 2/1 and 5/1, were carried out by the glass electrode method at 25.0°C, in 0.1 M $NaNO_3$ solution. The potentiometric assembly consists of a double-walled titration cell under continuous flow of nitrogen, a temperature bath at 25.0°C, a glass electrode (Tacussel C18), a reference electrode (calomel), and a 5 mL capacity Tacussel autoburette monitored by a computer.

The pH-meter was calibrated and the electrode assembly standardized with buffer solutions of 0.05 M potassium hydrogen phthalate (pH = 4.005) and disodium tetraborate (pH = 9.196). The electrodes were calibrated (7) in a thermostated cell and the ionic product of the medium ($K_w = 1.649 \times 10^{-14}$) was calculated from an acid–base titration of HNO_3 by NaOH.

Spectrometric measurements for the protonation constants were made with a Varian 634S UV–VIS spectrometer equipped with 1 mm quartz cells at 25.0°C ($I = 0.1$ M $NaNO_3$). On addition of concentrated NaOH in H_2L solutions in the pH range 2–11, three successive forms appear, leading to three bands corresponding to the species H_2L (278 nm), HL^- (280 nm), and L^{2-} (272 nm).

The log K_{011} and log K_{021} values for the equilibria:

$$[1] \quad H^+ + L^{2-} \rightleftharpoons HL^- \qquad (K_{011})$$

$$[2] \quad H^+ + HL^- \rightleftharpoons H_2L \qquad (K_{021})$$

were calculated from the analytical concentration of the ligand and the log[H^+] values using a BASIC program that determines the equilibrium constants and the molar absorption coefficient necessary to calculate the absorbance values that would best fit the experimental absorbance values for a given spectrometric titration.

According to Beer–Lambert law, the absorbance and concentrations of absorbing species are calculated and then log K_{011} and log K_{021} are determined with the previously described procedure (8).

The complex formation between the metal ion M and the ligand L is described by the general equilibrium :

$$[3] \quad pM + qH + rL \rightleftharpoons M_pH_qL_r$$

The stability of the species $M_pH_qL_r$, labelled by the (pqr) parameters that define the number of metal ions, protons, and deprotonated ligands, respectively, is measured by the stoichiometric stability constant :

$$[4] \quad \beta_{pqr} = \frac{[M_pH_qL_r]}{m^p h^q l^r}$$

where m, h, l, are the free concentrations of Cd(II), proton, and phthalato ligand, respectively.

The state of the system is described by the following set of equations :

$$[5] \quad C_L = l + \Sigma r \times \beta_{pqr} \times m^p \times h^q \times l^r$$

$$[6] \quad C_M = m + \Sigma p \times \beta_{pqr} \times m^p \times h^q \times l^r$$

$$[7] \quad C_H = h - oh + \Sigma q \times \beta_{pqr} \times m^p \times h^q \times l^r$$

where C_L, C_M, C_H are the total concentrations of ligand, metal, and proton, respectively, and oh is the free concentration of OH^-. The experimental data: C_H, E (measured glass electrode potentials in mV) were transformed into standardized variables: $\bar{q}$, log h, $\bar{n}$, log l. where $\bar{q}$ is the number of hydrogen ions bound to a ligand anion and $\bar{n}$ the average number of ligand bound per metal ion.

The graphically estimated stability constants from the Bjerrum method (9) are refined with in-house NEWPRO and NEWSI BASIC programs. These programs are based on minimization of the function U related to the difference between calculated and experimental $\bar{q}$ values:

$$[8] \quad U = \Sigma(\bar{q}_{calc} - \bar{q}_{exp})^2$$

The standard deviation of $\bar{q}$ is given by :

$$[9] \quad \sigma^2(\bar{q}) = U_{min}/(n - m)$$

where n is the number of experimental points and m is the number of calculated constants. These calculations are repeated for several complex compositions, and the set of complexes that is really present will give the lowest values of U_{min} and $\sigma^2(\bar{q})$. The potentiometric method has been widely described elsewhere and more details can be found in ref. 10.

Differential pulse polarography

Pulse polarograms were obtained using a Tacussel PRG5 polarograph. The cell was equipped with a dropping mercury electrode a platinum auxiliary electrode, and a saturated calomel reference electrode. All electrochemical experiments were carried out in a thermostated cell under nitrogen atmosphere, at 25°C, pH 7; an ionic strength of 0.1 M was maintained using $NaNO_3$. Reagent-grade chemicals, deionized water, and hexa-distilled mercury were employed in all cases.

The polarographic half-wave potential was determined in a series of solutions containing a constant amount (4×10^{-5} M) of Cd(II) with phthalic acid concentrations ranging from 0 to 4.4×10^{-2} M.

The computation was performed by the conventional Donald–Deford–Hume method (11) using successive extrapolations, modified by Heath and Hefter for the D.P.P. measurements (12).

Because phthalic acid was in large excess with respect to Cd(II) ions, it was assumed that the presence of the metallic ions did not appreciably affect the free ligand concentration.

Preparation of CdL in solid state

To a stirred solution (50 mL) of 5×10^{-3} M phthalic acid (H_2L) and 5×10^{-3} M $Cd(NO_3)_2 \cdot 4H_2O$, concentrated NaOH was added progressively. At pH 7 some H_2L precipitated and was eliminated. The clear solution was evaporated very slowly at room temperature for 2 weeks. Colorless crystals of CdL appeared and were removed carefully from the bulk. Anal. calcd. for Cd $(C_8O_4H_4) \cdot H_2O$: Cd 38.18, C 32.61, O 27.17, H 2.04%; found: Cd 37.40, C 32.75, H 2.08%.

X-ray structure analysis of $Cd(C_8H_4O_2) \cdot H_2O$

The crystallographic data are given in Table 1. A single crystal ($0.40 \times 0.40 \times 0.15$ mm) was mounted on an Enraf–Nonius CAD4 diffractometer using graphite monochromated MoKα

radiation. Cell constants were obtained from a least-squares refinement using the setting angles of 25 reflections, in the range $12.7 < \theta < 21.3°$. The intensities of three standard reflections, which were measured after every 60 min of X-ray exposure time, drifted by 1.8%. A total of 3699 unique reflections was collected using the θ–2θ scan technique to a maximum 2θ value of 70°. The data were corrected for Lorentz and polarization effects and an empirical absorption correction was made.

The structure was solved by the Patterson method and subsequent Fourier syntheses. The final cycle of the full-matrix least-squares refinement was based on 3231 observed reflections ($I > 3\sigma(I)$) and 127 parameters and converged with R = 0.054, Rw = 0.087. The hydrogen atoms were constrained to idealized positions (C—H = 0.95 Å). Final atomic coordinates and equivalent thermal parameters for the non-hydrogen atoms are given in Table 2.

Selected bond distances and angles are given in Table 3. All computations were performed using the SDP program (13).

Results and discussion

Protonation equilibria

The protonation equilibria H_2L were studied potentiometrically by titrating acidified aqueous solutions (HNO_3) of the ligand (C_L from 10^{-3} to 4×10^{-3} M and ionic strength 0.1 M $NaNO_3$) with 0.2 M NaOH. Protonation constants were obtained from three sets of 20 experimental points in the pH range 2–11. The refined protonation constants are gathered in Table 4.

The protonation constants and molar absorbance were also determined by spectrometric treatment of the protonation equilibria. While protonated and deprotonated forms of phthalic acid absorb at close wavelengths, spectrometric and potentiometric treatments are in good agreement.

ratios of 2/1 to 5/1 (with $C_L = 4 \times 10^{-3}$ M), were titrated with 0.2 M NaOH at ionic strength 0.1 M $NaNO_3$ for studying the formation of the complexes. The titrations were extended to pH 8 before the beginning of precipitation. To avoid any error, all calculations were made only with data recorded before any precipitation (pH < 8).

Besides the two successive complexes CdL and CdL_2^{2-}, the formation of the protonated species $CdHL^+$ and $CdH_{-2}L_2^{4-}$ was determined. The stability constants were fitted by the least squares method from about 120 experimental data according to the pit-mapping procedure previously described (10). The constants that minimized the sums $U = \Sigma(\bar{q}_{cal} - \bar{q}_{exp})^2$ are reported in Table 5.

Polarography

Attention is paid to the fact that the classic potentiometric method for studying complexation in solution uses ligand/metal mole ratios of less than 10, therefore a high degree of coordination is never reached. In the case of a large excess of ligand (ligand/metal ratios of 1 to 1100), the D.P.P. method of complex determination, which allows easy differentiation of free cadmium ion from complexed cadmium at low metallic ion concentration (4×10^{-5} M), is used. In addition, the excess of ligand favors the formation of CdL_2^{2-} and CdL_3^{4-}.

The polarogram of a solution containing Cd(II) (4×10^{-5} M) and $NaNO_3$ (0.1 M) at pH 7 was characterized by an $E_{1/2}$ of –0.568 V/SCE corresponding to the reversible reduction of Cd(II). Addition of phthalic acid was found to shift the $E_{1/2}$ to a more negative value, and to decrease the intensity of the unique peak obtained. This observation is characteristic of the formation of the complexes.

As described previously (11, 12), analysis of the data in the 2×10^{-2} to 4.4×10^{-2} M concentration range of ligand revealed the formation of CdL, CdL_2^{2-}, and CdL_3^{4-} complexes under our experimental conditions. As we can estimate 1 mV as the experimental error in the $\Delta E_{1/2}$ measurements, the constants are then calculated with their error limits (Table 5).

It has to be noted that the graphical method employed here concerns only consecutive complexes of general formula $(CdL_n)^{2-2n}$, whereas other species such as hydroxylated and protonated complexes are omitted. In this way, it is not surprising that D.P.P. and potentiometry are not in accordance for either complex species or stability constants.

The results listed in Table 5 show that potentiometry gives equilibrium constants for CdL, CdL_2^{2-}, and $CdHL^+$. By introducing the CdL_3^{4-} stability constant in the potentiometric refinement, five constants can be refined simultaneously by the pit-mapping method, leading to more accurate values for the constants. These final values, with lower error limits, are listed in Table 5. The goodness of the results is then improved.

Figure 1 shows the distribution of all the species versus pH, in two different molar ligand/metal ratios. We can see that above pH 4 ca. 80% of the Cd(II) is complexed. At pH above 10, further addition of OH^- gave gradual precipitation of cad-

mium phthalate hydroxides. The predominant complexes are $CdHL^+$ and CdL when the ratio ligand/metal is 2 and CdL_3^{4-} for the ratio 100.

In conclusion, the use of potentiometry and D.P.P. permit the investigation of complex formation over a wide range of ligand and metal concentrations, so as to reveal all the complexes.

Crystal structure of $CdL \cdot H_2O$

Figure 2 shows the cadmium environment as a seven-coordinated polyhedron involving four phthalato ligands and one water molecule. A first ligand coordinates the Cd atom in a bidentate carboxylate (O,O′) mode (Cd—$O1^{iii}$ = 2.372(5) Å, Cd—$O2^{iii}$ = 2.445(5) Å). A second ligand is part of a seven-membered ring formed with its two carboxylate groups (Cd—O1 = 2.317(5) Å, Cd — O3 = 2.341(5) Å). Two other phthalic ligands make one coordination bond (Cd—$O4^{i}$ = 2.255(5) Å and Cd—$O3^{ii}$ = 2.449(5) Å). The seventh coordination bond is made through the water molecule (Cd—Ow = 2.333(6) Å).

This structure shows that all the carboxylate oxygen atoms of the deprotonated phthalic ligand are able to form coordination bonds. Thus, in CdL, O1 and O3 form two bonds each, while O2 and O4 form only one bond each. This hexadentate coordination fashion may be due to the conformation of the ligand, showing the two carboxylate groups clearly outside of the phenyl ring plane. The planes of the carboxylate groups make angles of 38.4(4)° and 72.1(2)° with that of the phenyl ring and the angle between them is 89.0(3)°.

The rotation of the carboxylate or carboxylic groups around their C—C bonds is generally found to be similar in most phthalate and hydrogenophthalate compounds, such as the following examples: 32° and 71° in $(NH_4)_2Pht$ (16), 27° and 67° in $Na(HPht) \cdot 1/2\ H_2O$ (17), 28.6° and 63.7° in $Cu(Pht)_2 \cdot 2\ H_2O$ (18), 28° and 71° in $Sr(HPht)_2 2\ H_2O$ (19), 34° and 78° in $Ca(Pht)_2 \cdot H_2O$ (20). However, some compounds show surprising rotation angle values: 88° and 5° in $Mn(HPht)_2 \cdot 2H_2O$ (21), 34.0° and 34.0° in H_2Pht (22). The most unexpected conformation has been found in $Li(HPht)2H_2O$ where the carboxylic and the carboxylate groups lie in the phenyl ring plane (23).

Kinetics and mechanism of covalent addition of S(IV) species to the acridinium cation

Maria P. Ros, Jesus Thomas, Guillermo Crovetto, and Juan Llor

Abstract: The reaction of acridine with S(IV) species ($SO_2 \cdot H_2O$, HSO_3^-, and SO_3^{2-}) to form the adduct acridine–S (IV) has been studied spectrophotometrically throughout the pH range 2.6–8 in aqueous solutions. The observed pseudo-first-order rate constants, k_{obs}, were determined at 25°C and ionic strength $I = 0.11$ M, and the pH profile of the rate reached a maximum at pH $\approx$ 6.1. At constant pH the k_{obs} values were a linear function of the total S(IV) concentration with slopes that increased significantly with pH. These data are consistent with the rate-determining attack of SO_3H^- and SO_3^{2-} upon the C-9 of the acridinium cation. A nonlinear least-squares fitting of the experimental values to the model equation, within the overall pH region studied, yields the pH-independent rate constants $k_1 = 3.7 \pm 0.1$ and $k_2 = (6.24 \pm 0.04) \times 10^4$ M^{-1} s^{-1} for the attack of these two species, respectively. The experimental results agree very well with the kinetic model. Due to the experimental conditions used we did not detect any possible pseudobase formation in the pH range studied. The reactivity of the S(IV) species with acridine follows the order: $SO_3^{2-} \gg HSO_3^- \gg SO_2 \cdot H_2O$. The value obtained for the ratio k_1/k_2 is similar to the results given for other addition reactions of S(IV) species to the double bond of carbonyl compounds such as benzaldehyde and formaldehyde.

Key words: covalent addition, acridine, acridine – S(IV) adducts, kinetics and mechanism.

Résumé : L'acridine réagit avec le S(IV) sous la forme de $SO_2 \cdot H_2O$, HSO_3^- et SO_3^{2-} pour conduire à des adduits que l'on a étudié d'une façon spectrophotométrique à tous les pH allant de 2,6 à 8, en solutions aqueuses. On a déterminé les constantes de vitesse du pseudopremier ordre, k_{obs}, à 25°C et à une force ionique $I = 0,11$ M; les profiles des vitesses en fonction du pH atteignent un maximum à pH $\approx$ 6,1. À des pH constants, les valeurs de k_{obs} sont des fonctions linéaires de la concentration totale en S(IV) avec des pentes qui augmentent d'une façon importante avec le pH. Ces données sont en accord avec une attaque qui déterminerait la vitesse de la réaction du HSO_3^- et du SO_3^{2-} en position C-9 du cation acridinium. Un ajustement non linéaire par la méthode des moindres carrés des valeurs expérimentales obtenues dans la région globale de pH étudiés avec l'équation modèle permet de tirer des constantes de vitesses indépendantes du pH, $k_1 = 3,7 \pm 0,1$ et $k_2 = (6,24 \pm 0,04) \times 10^4$ M^{-1} s^{-1} pour les attaques respectives de ces deux espèces. Les résultats expérimentaux sont en bon accord avec le modèle cinétique. À cause des conditions expérimentales utilisées, on n'a pas pu détecter la formation de pseudobases dans la plage de pH étudiés. La réactivité des espèces S(IV) avec l'acridine est dans l'ordre suivant : $SO_3^{2-} \gg HSO_3^- \gg SO_2 \cdot H_2O$. La valeur obtenue pour le rapport k_1/k_2 est semblable à celle tirée de résultats rapportés pour d'autres réactions d'addition d'espèces S(IV) à des doubles liaisons de composés carbonylés, tels que le benzaldéhyde et le formaldéhyde.

Mots clés : addition covalente, acridine, adduits acridine – S(IV), cinétique et mécanisme.

Introduction

The study of the covalent addition of nucleophilic reagents to N-heteroaromatic molecules is important as this type of reaction may occur in numerous biological process (1).

Acridine is a polynuclear nitrogen heterocycle and as such it belongs to this group of compounds, the derivatives of which are of pharmaceutical use (2) as labels in biological assays (3) and DNA-probe-based assays (4). Thus, equilibrium, kinetic, and thermodynamic data for the addition of several nucleophiles, such as the enolate ion of acetone (5) and the hydroxide ion (6), to the acridine *N*-methyl derivatives have been reported. Very few quantitative data, however, are available concerning the covalent additions of bisulfite and sulfite ions to acridine and its derivatives, although the addition of S(IV) species ($SO_2 \cdot H_2O$, HSO_3^-, and SO_3^{2-}) to derivatives of cytosine (7), uracil (8), pyrimidinium (9), and quinazolinium cations (10) etc. has been extensively studied. Pitmann and Sternson (11) estimated the equilibrium constant of the addition of the sulfite ion to the acridinium cation at 25°C and ionic strength $I = 1.0$ M and Hammond et al. (12) studied the addition of bisulfite to the 9-phenylcarboxylate-10-methylacridinium cation from the equilibrium point of view and describe some aspects of the macroscopic rate of the process. In any case, there is no information about the kinetics, mechanism, or any other factors that might affect the formation of adduct acridine–S(IV).

We have studied the kinetics of the covalent addition of the different S(IV) species to the N-heteroaromatic molecule acridine in water solution at 25°C at different pH values. We propose a mechanism for this reaction and we discuss the relative reactivity of different S(IV) species ($SO_2 \cdot H_2O$, HSO_3^-, and SO_3^{2-}) with acridine.

Experimental

Acridine (Aldrich) was crystallized by sublimation before

being used. Solutions of pH 2 or below were obtained by using hydrochloric acid and for pH 11 or above by using sodium hydroxide. Other pH values were maintained by mixtures of sodium hydroxide and monochloroacetic acid, acetic acid and sodium acetate, citric acid and dibasic sodium phosphate, sodium carbonate and bicarbonate. All the solutions used were prepared with high-purity (18 MΩ cm) deionized water obtained from a Millipore MilliRO-4 MilliQ system, through which oxygen-free argon had been bubbled for 1 h. Ionic strength was held constant at $I = 0.11$ M with KCl. The sodium sulfite (Merck) was used without further purification, and its solutions were freshly prepared and were maintained under an Ar atmosphere. To stabilize the sodium sulfite solution against oxidation we added 1 mL of methanol per 100 mL (13). These S(IV) solutions were standardized by iodometric titration every half hour (14). UV–visible spectra of the mixture of acridine plus S(IV) species at equilibrium were always recorded before the first 15 min of the reaction (see Results) on a Perkin–Elmer spectrophotometer. When the buffered acridine solutions were prepared, a certain time (>10 min) was allowed for the equilibrium of the pseudobase formation to be reached. Ionization equilibrium constants of acridine, K_a^{Acr}, were determined by the general method of Albert and Serjeant (15). pH measurements were made using a PHM64 pH meter equipped with a GK2401C pH electrode.

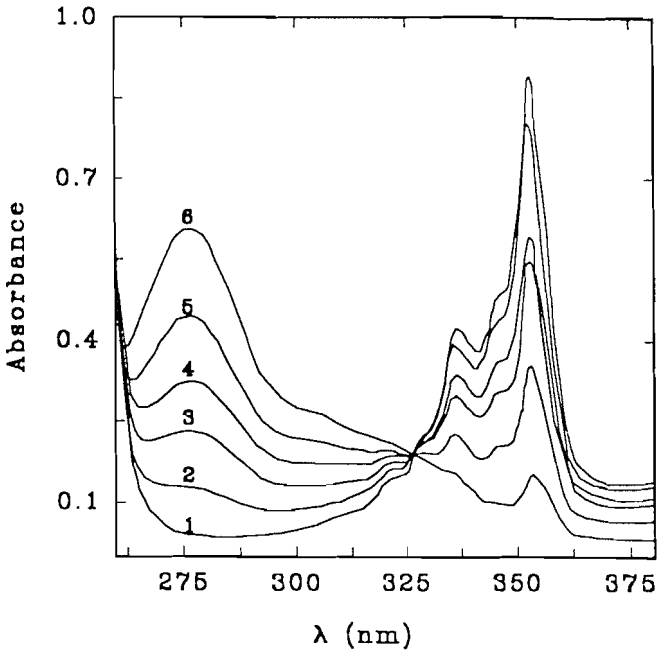
Kinetic measurements were made with a Hi-Tech scientific SF-4 stopped-flow spectrophotometer by mixing the buffered acridine solutions in aqueous media with S(IV) species. The reactions were carried out under anaerobic conditions at different temperatures. The extent of the reaction was followed by monitoring the disappearance of acridine at 354 nm. The pH value of the initial reagent and the resulting solutions (effluents from the stopped-flow aparatus) were measured to confirm that they were constant. Each rate constant value thus obtained was determined as an average of at least three kinetic runs.

Results

We have obtained the UV–visible absorption spectra of buffered solutions ($1 < pH < 12$) of mixtures of acridine with increasing amounts of S(IV). The addition of S(IV) to solutions of acridine produces an adduct that absorbs at 278 nm (see for example Fig. 1, obtained at pH 3.26) and the intensity of this band is a function of the total S(IV) concentration ($[S(IV)]_T$) and pH (Fig. 1).

The addition of increasing concentrations of S(IV) produces a concomitant increase in absorbance in the region of 278 nm, which is accompanied by a decrease in the bands situated in the 320–360 nm range. The increasing absorbance in the 278 nm region is due to two factors: the adduct formation and the absorption band of the $SO_2{\cdot}H_2O$ species. For this reason, at acid pH values we see a significant increase in the absorbance at 278 nm although there is practically no adduct formation, and as a consequence we monitored the reaction at the wavelength of the acridine. The presence of the clear isosbestic point at 327 nm indicates an equilibrium between the acridine and a single acridine–S(IV) adduct as shown in Scheme 1. The structure obtained by the attack of bisulfite (**4**) is identical to that of the sulfite (**5**), due to the low acid pK values for sulfonic acids.

Fig. 1. UV-visible absorption spectra of buffered solutions of acridine ($[Acr]_T = 5 \times 10^{-5}$ M) balanced with different S(IV) concentrations at pH 3.26 and 25°C. $[S(IV)]_T \times 10^3$ M: 1, 0; 2, 0.13; 3, 0.33; 4, 0.67; 5, 1.33; 6, 3.76.



In general, 9,10-dihydroacridines (16) show an intense absorption band with a maximum in the 280 nm region similar to that which we obtained. Pitman and Sternson (11) proposed this structure for the acridine–S(IV) adduct and other authors have proposed similar structures for adducts formed with other acridine derivatives (5, 6, 17).

The percentage of adduct fraction formed as a function of pH has been calculated from the decrease in the absorbance of acridine at 354 nm using eq. [1]:

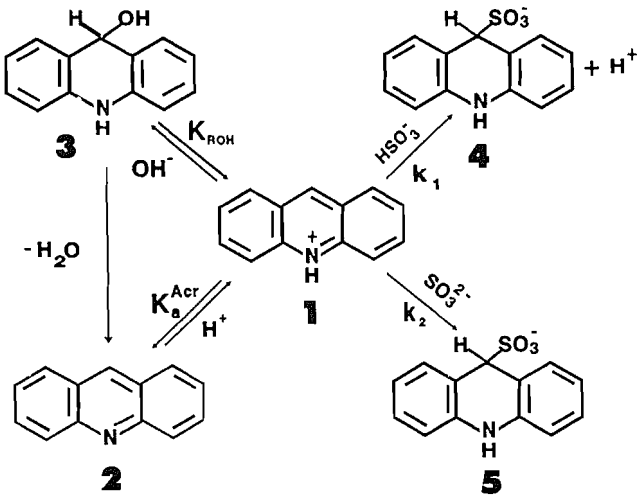
$$[1] \quad ([ADD]_f/[Acr]_0) = (A_0 - A)/A_0 \times 100$$

where A_0 and A are the absorbance of the pure acridine and that at equilibrium, respectively (Fig. 2).

As can be seen in Fig. 2 there is adduct formation in the pH range 2.5–8 and thus we measured rate constants in this pH range. On the other hand, we detected no reaction for $pH < 1$ and $pH > 11$ because there is no change to the acridine band at 354 nm at these pH values. In addition, we observed that the percentage of adduct formation decreases as the ionic strength increases (for example at pH 3.65, from 82.5 to 69% for ionic strength ranging from 6×10^{-3} to 0.6 M) and so this parameter has been carefully adjusted in this study.

The addition of S(IV) to acridine is a fast reaction in the presence of a considerable excess of sulfite species. Thus, pseudo-first-order conditions $[S(IV)]_T \gg [Acr]_T$, the total acridine concentration, were maintained throughout the study with a minimum 70-fold excess of S(IV). We determined the observed pseudo-first-order rate constants (k_{obs}) at 25°C as a function of pH and total S(IV) concentration, from the slope of the plots $\ln(A - A_0)$ vs. time, which were always linear ($r^2 > 0.99$). At constant pH, k_{obs} was a linear function of the total S(IV) concentration:

Scheme 1.



$k_{obs} = k_f [S(IV)]_T + k_d$

where the formation second-order rate constant, k_f, increases significantly with pH and the reverse rate constant, k_d, is very small.

We did not measure rate constants at pH <2.5 because the adduct formation was very small and there was practically no change in the absorbance signal. At 2.5 < pH < 8.0, at 25°C and $I = 0.11$ M, k_{obs} increases with pH; it reaches a maximum at pH 6.1 and then decreases (Table 1). We also studied the temperature effect (10–50°C) on the reaction rate at pH 4.00 and I = 0.15 M (Table 2).

On observing the absorption spectra of the acridine–S(IV) mixture some time after equilibrium has been reached we can see a progressive decrease in the peak corresponding to the adduct (278 nm), and an increase in the peak of acridine (354 nm) vs. time until it finally again reaches the initial spectrum of pure acridine. This behaviour is due to the reaction of O_2 with the S(IV) species. Thus, when the equilibrium for adduct formation is reached, if the S(IV) species concentration is not very high a displacement of the equilibrium towards the left occurs, obtaining acridine again. The pH of the solution always decreases during these processes due to the production of ion sulfate as a result of the oxidation of the S(IV) species (18).

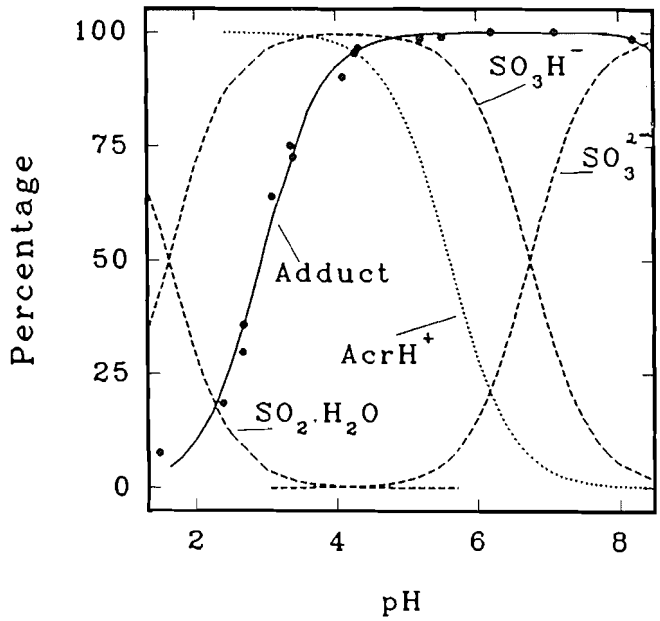
This effect was observed at all the pH values, acridine and S(IV) concentrations, and ionic strengths studied. The stability of the acridine–S(IV) adduct is dependent on ionic strength and it begins to break down depending upon this parameter (from 15 min for $I = 10^{-3}$ M to 120 min for $I = 1$ M). For this reason, and as a precaution, all the measurements for this paper were recorded in time periods of less than 15 min, although we used an ionic strength of 0.11 M.

Discussion

Reagent considerations

Acridine can exist as three different species (Scheme 1) in aqueous solutions (16): acridinium cation (**1**: $AcrH^+$), anhydrous acridine (**2**: Acr), and pseudobase (**3**) depending upon the pH of three medium. In Scheme 1 we suggest the possibility of the formation of an acridine pseudobase (**3**) by adding OH^-.

Fig. 2. pH dependence of the percentage of adduct formation between acridine and S(IV) species at 25°C and $I = 0.11$ M, $[Acr]_T = 2 \times 10^{-4}$ M, $[S(IV)]_T = 4.86 \times 10^{-3}$ M. The broken lines indicate the fractions of S(IV) and acridine species calculated using the ionization equilibrium constant values given in the text.



It is known that many reactions of heteroaromatic molecules in aqueous solutions are initiated by the covalent addition of water, a hydroxide ion, or other nucleophilic reagents across a double bond in the molecule (19–22). For example, Bunting and Meathrel studied the addition of OH^-/H_2O to 2-methyl-4-isoquinolinium, 10-methylacridinium, 10-methyl-9-phenylacridinium (6), and 1-methylquinolinium cations from both the kinetic and equilibrium points of view (23) and reported on the kinetic and activation parameters and the equilibrium constant. On the other hand, there is practically no information about the addition of a hydroxide ion to acridinium cation **1** (Scheme 1). Nevertheless, we detected evidence for the existence of this species in the form of a white precipitate in solutions with high OH^- concentrations (pH > 8) and the presence of a spectral band at 280 nm. The pseudobase is formed very quickly by reaction with the acridinium cation (**1**) but this association cannot be maintained stable in very basic solution. Due to the OH^- ions in the media the pseudobase decomposes to give anhydrous acridine (**2**), until we obtain the characteristic spectrum of the acridine molecule in a basic medium. Due to the presence of pseudobase **3** in our case, some necessary precautions were taken (see experimental procedure).

The S(IV) species in water solution may appear in three different forms: sulfur dioxide, bisulfite, and sulfite. There is some disagreement (24–27) over the values of the ionization equilibrium constants of these forms, K_{a1} and K_{a2}. The values of the equilibrium constants measured by Deveez and Rumpf (27) and Hayon et al. (18) were chosen for the calculations performed in the current study, considering the suggestion put forward by Maahs (28) about the different species of sulfur dioxide in water.

To account for the influence of ionic strength upon the equilibrium of the S(IV) species, and following the recommenda-

tions made by Clarke (29), the thermodynamic equilibrium constants K_{a1} and K_{a2} were corrected using Davies' approximation (30), eq. [2]:

$$[2] \quad \log \gamma = -Az^2 \left(\frac{I^{1/2}}{1 + I^{1/2}} - 0.2I \right)$$

where z is the ionic charge, I the ionic strength, and $A = 1.82 \times 10^6 (\varepsilon T)^{-3/2}$ (ε is the dielectric constant of water).

It is known that if the ion concentration is very high a new S(IV) species, pyrosulfite, may appear (18, 31). We have not considered the presence of $S_2O_5^{2-}$ in the reaction mechanism due to the fact that the total concentrations of S(IV) did not surpass 10^{-3} M.

Mechanism and kinetic analysis

According to all the observations described above, the following reaction mechanism for the adduct formation is proposed (Scheme 1) within the pH range of 2.5–8.0 and at 25°C.

This mechanism involves the nucleophilic addition of bisulfite and sulfite to the C-9 atom of the acridinium cation (**1**). Of the three acridine species, only the acridinium cation **1** reacts and the quaternary ring nitrogen was found to be essential for adduct formation (12), with the resulting loss of ring aromaticity. We did not obtain any kinetic information in basic solutions (pH > 8) due to pseudobase formation and the small value of k_{obs}. Sulphur dioxide is the principal constituent of acid solutions (pH < 2) and therefore no reaction is obtained under these conditions (Fig. 2).

The results obtained for k_{obs} as a function of pH can be explained by two rate-determining steps in the adduct formation, and, taking into account the low value of k_d, the rate law for this reaction scheme would be:

$$[3] \quad v = -\frac{d[Acr]_T}{dt} = k_1[AcrH^+]\,[HSO_3^-] + k_2[AcrH^+]\,[SO_3^{2-}]$$

where

$$[S(IV)]_T = [SO_2{\cdot}H_2O] + [SO_3H^-] + [SO_3^{2-}]$$

$$[Acr]_T = [Acr] + [AcrH^+]$$

and k_1 and k_2 are the pH-independent rate constants of the addition of SO_3H^- and SO_3^{2-} to the acridinium cation, respectively.

k_{obs} for the reaction was obtained under pseudo-first-order conditions in S(IV) and can be related to the k_1 and k_2 values by the equation:

$$[4] \quad k_{obs} = \left(\frac{k_1K_{a1}[H^+] + k_2K_{a1}K_{a2}}{D} \right) \beta[S(IV)]_T$$

where β and D are defined as:

$$\beta = 1/[(K_a^{Acr}/[H^+]) + 1]$$

$$D = [H^+]^2 + K_{a1}\,[H^+] + K_{a1}\,K_{a2}$$

The k_1 and k_2 values can initially be estimated by taking into account that, in the pH range 2.5–4.9, $K_{a1}[H^+] \gg [H^+]^2 + K_{a1}K_{a2}$, and thus eq. [5] can be obtained:

$$[5] \quad k_{obs} = \left(k_1 + \frac{k_2K_{a2}}{[H^+]} \right) \beta[S(IV)]_T$$

A plot of $k_{obs}/\beta[S(IV)]_T$ vs. $[H^+]^{-1}$ over this pH range was linear ($r^2 > 0.999$) and values of $k_1 = 9.07$ and $k_2 = 5.82 \times 10^4$ M^{-1} s^{-1} were obtained. With these initial values and using eq. [4], nonlinear regressions for the experimental values of $(k_{obs}D/[S(IV)]_T)$ vs. β (Fig. 3*A*) in the overall pH region studied yield $k_1 = (3.7 \pm 0.1)$ and $k_2 = (6.24 \pm 0.04) \times 10^4$ M^{-1} s^{-1}. Due to the influence of ionic strength, we used the following values for these calculations: $K_{a1} = 2.44 \times 10^{-2}$ M and $K_{a2} = 1.80 \times 10^{-7}$ M, which were obtained from the thermodynamic values (27, 18) and Davies equation (eq. [2]) and $K_a^{Acr} = 2.5 \times 10^{-6}$ M obtained by us.

For this fitting we used all the experimental data obtained at the different pH values and S(IV) concentrations (74 points). As can be seen in Fig. 3*A*, we obtained a very good fitting of the experimental data to eq. [4], where the standard error for the parameters k_1 (2%) and k_2 (0.6%) was very small. At pH values slightly higher than 4.2 ($\beta < 0.95$) Fig. 3*A* was linear with a slope (eq. [4]) given by $k_2K_{a1}K_{a2}$, due to the fact that $k_1K_{a1}[H^+] \ll k_2K_{a1}K_{a2}$, but at pH < 4.2 ($\beta > 0.95$) the situation changes and the first term is predominant.

In the plot log $(k_{obs}/[S(IV)]_T\beta)$ vs. pH (Fig. 3*B*), within the pH range 3.2–5.9 we obtained a straight line but outside this range the plot was not linear (eq. [4]). The straight line drawn in this figure was calculated with a slope of unity and an intercept of log $(k_2 \cdot K_{a2})$ using the k_2 value obtained above. At pH >6 the term $K_{a1}K_{a2}$ begins to become significant and we must expect k_{obs} values lower than the theoretical straight line, and at pH <3 the term $[H^+]^2$ is significant and the obtained k_{obs} values must be higher than the theoretical ones, as can be seen in Fig. 3*B*.

In Fig. 4 we can see that the theoretical curve fits the experimental points very well. We obtained a dependence with a maximum value of k_{obs} at pH 6.1, which is practically the average of the pK_{a2} and pK_a^{Acr} values. k_{obs} increases in the pH range where the concentration of SO_3^{2-} strongly increases (Fig. 2) and decreases at high pH values where the concentration of the acridinium cation decreases. This plot also confirms agreement of the experimental data with the proposed model and that the values used for the different equilibrium ionization constants of the reagents were correct.

In other kinetic and equilibrium studies (5,6) of related compounds pseudobase formation has sometimes been detected. To obtain information about this point we included the term $(1 + K_{ROH}/[H^+])$ on the right side of eq. [4], where K_{ROH} is the adduct formation equilibrium constant, and we repeated the nonlinear least-squares fitting of $(k_{obs}D/[S(IV)]T)$ vs. β, in the same way as shown in Fig. 3, with K_{ROH} as an additional parameter. We obtained the same value and accuracy for k_2, and an extremely small value for K_{ROH}, indicating that there is no pseudobase formation in the pH range and under the experimental conditions studied. In any case, and as indicated in the experimental section, the precautions taken during the experimental work to avoid interference caused by the formation of a pseudobase in the kinetic results were adequate.

The k_1 and k_2 values obtained in this study reveal the great difference in reactivity with the acridinium ion between HSO_3^- and SO_3^{2-}, with a k_2/k_1 ratio of 1.7×10^4. A similar value for this ratio (3×10^4) has been obtained with benzaldehyde–S(IV) (32) and formaldehyde–S(IV) (33) adducts. If the rate-limiting step of the reaction involves a bimolecular process, then $SO_2 \cdot H_2O$, HSO_3^- and SO_3^{2-} react with $AcrH^+$ at different rates. We obtained results showing that the reactivity of the S(IV) species with acridine follows the order: $SO_3^{2-} \gg HSO_3^- \gg SO_2 \cdot H_2O$. It is well known that the sulfite ion is a much stronger nucleophile than HSO_3^- in reactions with a wide variety of organic and inorganic substrates (34), and the same order of increasing reactivity has been obtained in the reaction of formaldehyde with sulfur dioxide to form hydroxymethanesulfonic acid (33).

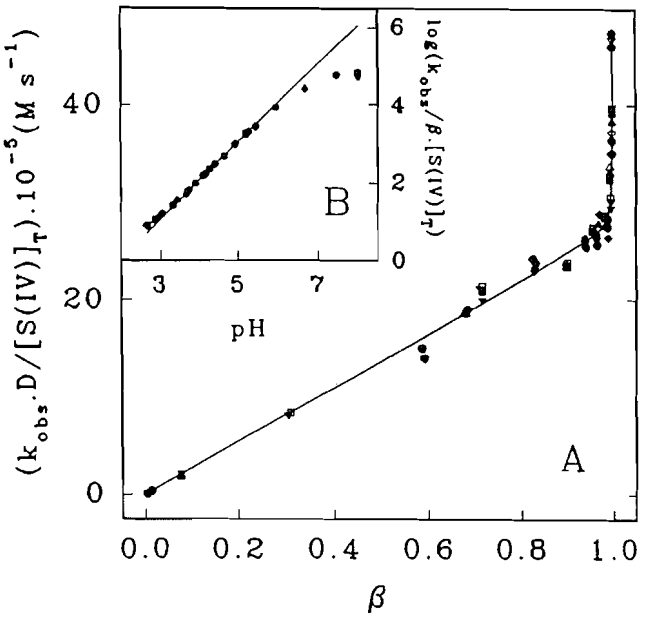

Fig. 3. *A*. Plot of $k_{obs}D/[S(IV)]_T$ vs. β over the pH range studied. The solid line is the theoretical line calculated using eq. [4] and the parameters k_1 and k_2 obtained from a nonlinear least-squares fitting. *B*. Dependence of log $(k_{obs}/\beta[S(IV)]_T)$ vs. pH. The solid line has been drawn with a slope of unity as indicated in the text.

The present mechanism assumes that the formation rates of the reagent species HSO_3^-, SO_3^{2-}, and $AcrH^+$ are very fast in comparison to the other step in the mechanism. Although there is some disagreement about the values of the formation rates of HSO_3^- (25, 35) from $SO_2 \cdot H_2O$, all of these are very high.

The temperature dependence of k_{obs} over the range from 10 to 50°C (at pH 4.0 and ionic strength 0.15 M) is given in Table 2 and Eyring's equation gives the values $\Delta H^{\ddagger} = 27.2$ kJ mol^{-1} and $\Delta S^{\ddagger} = -153.1$ J K^{-1} mol^{-1} for the enthalpy and entropy of activation. The value of the entropy of activation is more negative than we might generally expect for addition reactions of monopositive and mononegative ions. Similar values have been obtained for the addition of bisulfite to formaldehyde ($\Delta S^{\ddagger} = -108.0$ J K^{-1} mol^{-1} (33)), benzaldehyde ($\Delta S^{\ddagger} = -142.35$ J K^{-1} mol^{-1}), and other related compounds (32), and for methylglyoxal ($\Delta S^{\ddagger} = -77.7$ J K^{-1} mol^{-1} (36)). Bunting and Meathrel (6) obtained $\Delta S^{\ddagger} = -71.0$ J K^{-1} mol^{-1} for the reaction between 10-methylacridinium cation and OH^-. Olson et al. (32) have proposed that the transition complex for the addition of bisulfite to benzaldehyde is a cyclic structure formed between the carbonyl and bisulfite groups. In our case it is difficult to establish a possible structure for the transition complex, which would have a high charge separation that would contribute to the low value of $\Delta S^{\ddagger}$.

Fig. 4. Observed pseudo-first-order rate constant (k_{obs}) as a function of pH. The theoretical line has been drawn with the parameters given in the text.

The metabolites of *Trichoderma longibrachiatum*. Part II. The structures of trichodermolide and sorbiquinol

Romano Andrade, William A. Ayer, and Latchezar S. Trifonov

Abstract: *Trichoderma longibrachiatum* Rifai aggr. is a fungus reported to be antagonistic to the fungus *Mycena citricolor*, the causative agent of the American leaf spot disease of coffee. We have investigated the metabolites produced when *T. longibrachiatum* is grown in liquid culture and have isolated several new compounds. The structures of trichodermolide (**2**) and sorbiquinol (**3**) were determined by a combination of spectroscopic techniques, including ^{1}H and ^{13}C NMR, IR, UV, CD, ORD, and mass spectrometry, and by preparation of derivatives.

Key words: *Trichoderma longibrachiatum*, leaf spot disease, coffee, fungal metabolites.

Résumé : Le *Trichoderma longibrachiatum* Rifai aggr. est un champignon qui serait l'antagoniste du champignon *Mycena citricolor*, l'agent qui serait la cause de la maladie des taches sur les feuilles du café américain. On a étudié les métabolites produits lorsqu'on fait une culture liquide du *T. longibrachiatum* et on a isolé plusieurs nouveaux composés. On a déterminé les structures du trichodermolide (**2**) et du sorbiquinol (**3**) par une combinaison de techniques spectroscopiques, y compris la RMN du ^{1}H et du ^{13}C, l'IR, l'UV, le DC, la DRO et la spectrométrie de masse, ainsi qui par la préparation de dérivés.

Mots clés : *Trichoderma longibrachiatum*, maladie des taches sur les feuilles, café, métabolites de champignons.

[Traduit par la rédaction]

Introduction

In part 1 of this series (1), we described the isolation of several metabolites from liquid cultures of *Trichoderma longibrachiatum*, Rifai aggr. The studies leading to the assignment of structure **1** to trichodimerol, an intrinsically interesting natural product that possesses an axis of symmetry, were described. In this article we present evidence for the structural assignment of two other interesting new natural products produced by the fungus, the pale yellow compounds trichodermolide (**2**) and sorbiquinol (**3**).

Results and discussion

Trichodermolide (**2**) is a pale yellow, optically active glass showing maximum ultraviolet (UV) absorption at 280 nm. The molecular formula $C_{24}H_{28}O_5$ was determined by high-resolution mass spectrometry (HREIMS) and the molecular weight was confirmed by chemical ionization mass spectrometry (CIMS). The base peak in the electron impact mass spectrum (*m/z* 95) arises from fragmentation of the sorbyl chains ($H_7C_5CO^+$). The spectrum also shows a $M^+ - 95$ peak and a peak at *m/z* 352 corresponding to the loss of CO_2 (lactone carbon and oxygens). The infrared spectrum (IR) shows absorption at 1781 cm^{-1} (γ-lactone) and at 1687 and 1637 cm^{-1} (α,β-unsaturated ketone).

The ^{1}H NMR spectrum of trichodermolide (**2**) in $CDCl_3$ shows three methyl singlets (δ 1.78, 1.45, and 1.24), and an AB quartet at δ 3.66 (J = 19 Hz) arising from the C-7 methylene group, an isolated three-hydrogen spin system at δ 2.45 (dd, 18.5 and 4 Hz), 3.26 (dd, 18.5 and 6 Hz), and 3.34 (dd, 4 and 6 Hz) for the C-14 methylene hydrogens and the C-5 methine hydrogen, respectively. Signals for the two *E,E*-sorbyl chains are readily apparent. When the spectrum is recorded in benzene the C-7 methylene signals split into clear doublets at δ 3.02 and 3.19 (J = 17 Hz). The large *geminal* coupling constants observed for the C-7 and C-14 methylene hydrogens are consistent with their location α to carbonyl groups (2).

The ^{13}C NMR spectrum of trichodermolide (**2**) (Table 1) shows 24 carbons: 5 methyl carbons, 2 methylene carbons, 1 sp^3 methine carbon (C-5, δ 56.0), 1 sp^3 quaternary carbon (C-4, δ 51.8), a tertiary carbon bearing oxygen (C-6, δ 87.2), 8 sp^2 carbons as doublets, 2 olefinic carbons as singlets, and 4 carbonyl carbons (δ 176.1 (lactone), 191.2, 195.5, and 196.6).

The molecular formula for trichodermolide indicates 11 unsaturations. Two sorbyl chains account for six, the lactone for two, the unsaturated ketone for two, and thus there is only one carbocyclic ring. The functionality described accounts for all five oxygens. A series of NOE experiments (in $CDCl_3$) served to further define structure **2**. The methine hydrogen at C-5 (δ 3.34) shows strong NOE enhancement with the methylene hydrogen at δ 2.45 (one H-14) and the methyls at δ 1.45 and 1.24. The methyl hydrogens at δ 1.24 (H-22) also show NOE enhancement with the methylene hydrogen at δ 3.26 (an H-14) and the methylene at δ 3.66 (H-7). The methylene at δ 3.66 in turn gives reciprocal enhancement with the alkenic methyl (H-21) at δ 1.76 as well as with two hydrogens (δ 6.15 and 7.24) of one of the sorbyl chains. The C-14 methylene

hydrogens (δ 3.26 and 2.45) give strong mutual enhancement as well as enhancement of hydrogens of the other sorbyl chain (δ 6.10 and 7.20).

These data define the constitution of trichodermolide as shown in structure **4** where the starred carbon atoms indicate the points of attachment of the lactone ring. It was now necessary to determine the orientation of the lactone ring, i.e., whether the lactone carbonyl carbon is attached to C-4 or to C-6. The selective INEPT technique (3) was used to locate the carbonyl carbon. The NOE results above indicate that the methyl group at C-4 resonates at δ 1.24, that at C-6 at δ 1.45. Selective Irradiation of the δ 1.24 hydrogens (CH_3 at C-4) gives rise to signals for the carbons at δ 51.8 (C-4), 148.6 (C-3), and the lactone carbonyl carbon (δ 176.1). Irradiation of the methyl hydrogens at δ 1.45 (CH_3 at C-6) gives signals for the carbons at δ 87.2 (C-6) and δ 191.2 (C-1). The carbon at δ 56.0 (C-5) was not enhanced in either experiment although it should be coupled ($^3J_{CH}$) to both methyls. The absence of enhancement may be due to the passive modulation of the carbon by the one-bond C—H coupling (4). Final confirmation of the ring substructure of trichodermolide was obtained from the HMBC spectrum, which showed the correlations (C/H's): 1/21, 23; 2/7, 21; 3/7, 21, 22; 4/7, 14, 22; 5/14, 22, 23; 6/5, 14, 23. The HMBC correlations 8/7, and 15/5, 14 assigned the carbonyl signals at 195.5 and 196.6 to C-8 and C-15, respectively. These results establish structure **2** (other than the stereochemistry at C-5) for trichodermolide.

Additional information on the stereochemistry of trichodermolide was obtained by the preparation of several derivatives. Hydrogenation over palladium on carbon produced an octahydro derivative (**5**), as confirmed by the HREIMS and CIMS. The IR (1782, 1715, and 1688 cm^{-1}) and UV (272 nm) spectra of octahydrotrichodermolide (**5**) indicated that the enone had resisted reduction.

Octahydrotrichodermolide (**5**) was selectively reduced with excess sodium borohydride in methanol for a short time to produce a mixture of epimeric alcohols, **6***a* and **6***b*. These could be separated through careful column chromatography. Neither epimer shows strong absorption in their UV spectra, indicating the enone was reduced. The IR spectra of both epimers show absorption for an alcohol (3460 and 3450 cm^{-1}) while their ^1H NMR spectra show the presence of two hexanoyl side chains.

α-Decahydrotrichodermolide (**6***a*) was acetylated by treatment with acetic anhydride to give the corresponding *O*-acetyl-α-decahydrotrichodermolide (**7***a*). The introduction of an acetyl group in **7***a* caused the expected shifts in its ^1H NMR spectrum when compared to the ^1H NMR spectrum of **6***a*. Comparison of the ^1H NMR chemical shifts reveals that H-1 is shifted downfield from δ 3.71 in **6***a* to δ 5.55 in **7***a*, which is expected for a secondary alcohol (5), and that Me-23 and Me-21 are shifted upfield from δ 1.46 and 1.69 in **6***a* to δ 1.35 and 1.53 in **7***a* (0.11 and 0.16 ppm, respectively). Similarly, β-decahydrotrichodermolide (**6***b*) was acetylated with acetic

anhydride to give *O*-acetyl-β-decahydrotrichodermolide (**7***b*). The introduction of the acetyl group causes shifts similar to the shifts in the ^1H NMR spectrum of **6***a* discussed above. These results are consistent with these methyls being α to the alcohol (for a similar example in aromatic systems, see ref. 6) in **6***a* and **6***b* and show that the enone is reduced selectively.

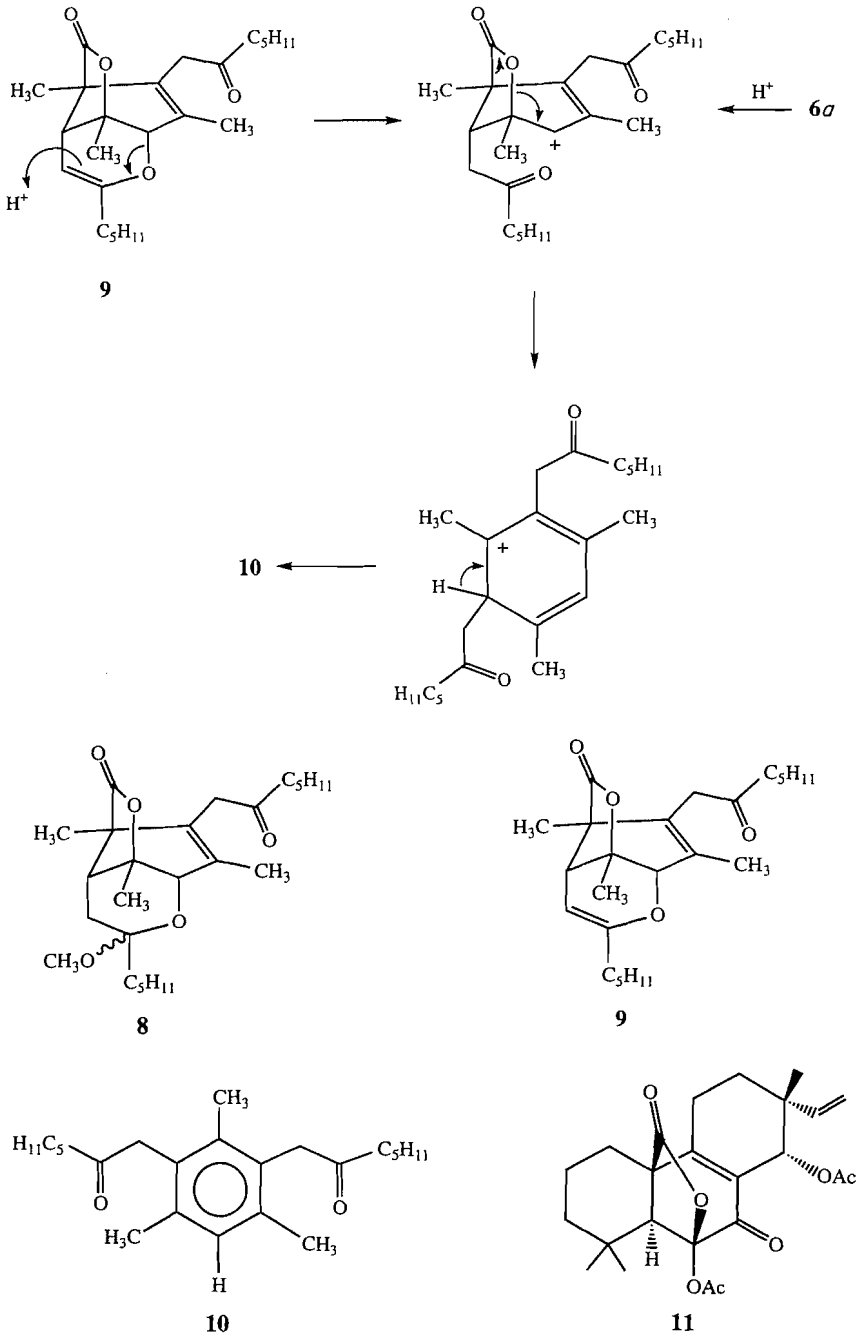
To determine the relative stereochemistry of the two isomers formed we attempted acid-catalyzed formation of the cyclic acetal **8**.

Compound **8** was not produced upon treatment with *p*-toluenesulphonic acid in methanol; instead this resulted in dehydration of the major epimer **6***a*, and simplified the isolation of the minor isomer *6b*, which did not undergo reaction. The dehydration product **9** was easily separated from *6b* by column chromatography. Mass spectrometry (HREIMS and CIMS) confirmed the molecular formula of **9** as $C_{24}H_{36}O_4$. The IR spectrum of **9** shows absorptions corresponding to lactone (1779 cm^{-1}) and ketone (1715 cm^{-1}) but no OH absorption. Comparison of the ^{13}C NMR spectra of anhydro derivative **9** with that of alcohol **6***a* indicates the presence of an additional double bond the alkenic carbons of which form part of an enol ether double bond (Table 1). Further comparison of the ^1H NMR spectra of the compounds shows that the three-hydrogen spin system in **6***a* is absent in **9** and has been replaced by two mutually coupled hydrogens at δ 4.56 and 2.19 ($J = 6$ Hz). The COSY spectrum of anhydrodecahydrotrichodermolide shows the expected correlations Me-21/H-1, H-7; H-5/H-1, H-14; and H-7/H-1, thus confirming the structure as shown in **9**.

The formation of anhydrodecahydrotrichodermolide (**9**) from the major reduction product, α-decahydrotrichodermolide (**6***a*), confirmed the stereochemistry shown and established the relative stereochemistry at C-5 in trichodermolide.

Prolonged exposure of compound **9** or **6***a* to strongly acidic conditions resulted in the formation of the aromatic compound **10**. Mass spectrometry of compound **10** shows a molecular formula $C_{23}H_{36}O_2$. Its IR spectrum shows the presence of a ketone (1704 cm^{-1}) and an aromatic ring (1450, 1418 cm^{-1}). The UV spectrum of compound **10** confirmed the presence of the aromatic group with low-intensity maxima at 205, 210, and 269 nm, indicating that the aromatic ring is unconjugated (7). Compound **10** displays a very simple ^1H NMR spectrum. It shows absorptions for one aromatic hydrogen (δ 6.92), four

Scheme 1.



methylene benzylic hydrogens (δ 3.76), three aromatic methyls as singlets at δ 2.20 (6H) and δ 2.04 (3H), and two equivalent hexanoyl side chains. The simplicity of the ^{1}H NMR spectrum indicates that **10** possesses an element of symmetry.

To establish the relative distribution of the aromatic substituents a series of NOE experiments was performed on **10**. The methyl at δ 2.04 ppm gives NOE enhancement to the methylene hydrogens at δ 3.76, while the latter give enhancement to both aromatic methyls.

The aromatization of anhydrodecahydrotrichlodermolide (**9**) is not surprising since compounds containing similar functional groups are known to aromatize. For example, the acid-catalyzed decarboxylation of gibberellic acid (8) and the aromatization of 2β-hydroxy-19-oxo-4-androstene-3,17-dione to estrone (9) are known to occur in the presence of acid. A possible mechanistic pathway for the formation of **10** is shown in Scheme 1.

The determination of the absolute stereochemistry of trichodermolide (**2**) by analysis of its CD spectrum is complicated since it shows a series of Cotton effects. However the CD spectrum of octahydrotrichodermolide (**5**) is simpler. It displays a split Cotton effect with extrema of opposite sign at 270 and 222 nm (A = +28, positive chirality) due to the inherently dissymmetric α,β-unsaturated ketone chromophore, which shows homoconjugation to the lactone carbonyl (10). Examination of molecular models reveals that the π bond of

the lactone carbonyl of octahydrotrichodimerol is in a favourable position to homoconjugate with the double bond of the α,β-unsaturated ketone.

The UV spectrum of octahydrotrichodermolide displays characteristics in accordance with this assumption. These are: longer absorption wavelength and lower intensity than expected for the charge transfer band (ε = 5600 vs. 10 000, 272 vs. 237 nm) and a stronger n-π^* absorption (ε = 1200 vs. 100). These shifts and intensity changes confirm the homoconjugative effect (11).

Homoconjugation of lactone carbonyls with enones has been documented. Ellestad et al. (12) reported the UV and CD spectra of compound **11**. The UV spectrum of compound **11** shows maxima at longer wavelengths (260-265 nm) than other abietane derivatives with similar structure and a C-10 methyl (13). The CD spectrum of compound **11** shows a split Cotton effect, with extrema at 262 and 230 nm (A = +74.4, positive chirality) and its absolute stereochemistry is known (14). Since octahydrotrichodermolide (**5**) and compound **11** possess virtually the same chromophore and the same chirality in their CD spectra, we assign the absolute stereochemistry of trichodermolide as shown in **2**.

Sorbiquinol was obtained as a pale yellow amorphous solid, $[\alpha]_D$ +234 (MeOH). The molecular formula $C_{28}H_{32}O_7$ is based on HREIMS and CIMS data. The EIMS spectrum of sorbiquinol shows fragment ions at m/z 95 corresponding to a sorbyl side chain and a base peak at m/z 165 corresponding to the substituted benzoyl ion derived from sorbicillin (**12**), also isolated from this fungus (1). The CIMS shows fragment ions at m/z 233 (protonated sorbicillin) and at m/z 249, which could be derived from a sorbicillin o-quinol (**13**). Diels–Alder reaction between **12** and **13** gives rise to the bicyclo[2.2.2] adduct **3**. This structure nicely explains all the properties of sorbiquinol (**3**).

The UV spectrum shows base-induced shifts consistent with the enolic-phenol chromophores (see Experimental). The IR spectrum shows absorption for hydroxyl groups (3450 cm^{-1}), saturated ketone (1730 cm^{-1}), strongly chelated carbonyl (1627 cm^{-1}), and aromatic ring(s) (1606 cm^{-1}).

The ^1H NMR spectrum of sorbiquinol shows methyl singlets (δ 1.20, 1.16), two aromatic methyls (δ 2.26, 2.12), an aromatic methine (δ 7.59), two chelated hydroxyl groups (δ 13.98, 12.58), one E,E-sorbyl chain (δ 5.53, 7.17, 5.93, 6.08, and 1.82), a three-hydrogen spin system (δ 4.28 (dd, 6.5, 1.5), 3.26 (dd, 10, 6.5 Hz), and 3.32 (d, 1.5 Hz)), and an E-1-propenyl (δ 5.45 (dq, 15, 6.5 Hz, 1H), 5.02 (ddq, 15, 10, 1.5 Hz, 1H), and 1.60 (dd, 6.5, 1.5 Hz, 3H)) group. Decoupling experiments carried out in acetone allow us to connect the latter two fragments and build up the fragment H_3C-CH=CH-CH-CH-CH present between C-4 and C-17. The hydrogen at δ 5.02 (H-15) shows *trans* coupling (15 Hz) to the hydrogen at δ 5.45 (H-16) and is also coupled to the hydrogen at δ 3.26 (10 Hz, H-7), which in turn is coupled to the hydrogen at δ 4.28 (6.5 Hz, H-8). The latter hydrogen is also coupled to the methine hydrogen at δ 3.32 (1.5 Hz, H-4).

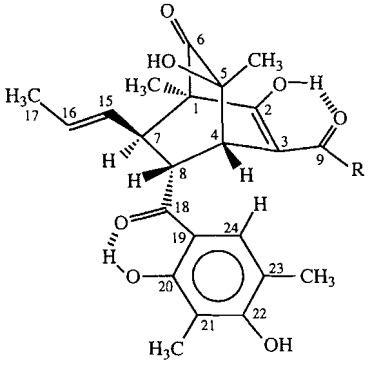
13 R = C_5H_7

16 R = C_5H_{11}



3 R = C_5H_7

14 R = C_5H_{11}

15 R = C_5H_{11}, 15,16-dihydro

The ^{13}C NMR spectrum of sorbiquinol (Table 2) shows 28 carbons. Six signals are assigned to methyl groups, three to aliphatic methines, six to sp^2 methines, one to a tertiary carbon bearing oxygen (δ 75.7), three to carbonyl groups (δ 211.5, 202.1, 198.0), three to oxygen-bearing sp^2 carbons (δ 168.8, 161.9, 159.0) that are not carbonyls, and four to non-hydrogen-bearing sp^2 carbons. A comparison of the ^1H and ^{13}C NMR spectra of sorbiquinol and sorbicillin (**12**) revealed that both compounds have the fragment $(HO)_2(H_3C)_2C_6HCO$. The presence of this fragment is also supported by the mass spectra of sorbiquinol (vide supra). An NOE experiment shows strong enhancement (26%) of the methine hydrogen at δ 4.48 (H-8) and an enhancement of the aromatic methyl at δ 2.24 upon irradiation of the aromatic hydrogen at δ 7.69 (H-24). This information locates the aromatic ring relative to C-8 and is in

Table 2. ^{13}C NMR data of sorbiquinol (**3**), tetrahydrosorbiquinol (**14**), and hexahydrosorbiquinol (**15**).

agreement with the Diels–Alder hypothesis and the resulting structure **3**.

This structure is supported by further NOE experiments, carried out in acetone. The methine hydrogen at C-4 shows NOE with the methyl group on C-5 (δ 1.20). Similarly, the methyl at C-1 (δ 1.07) shows an NOE enhancement to the methine at δ 3.19 (H-7). In addition, the hydrogen at C-4 shows a strong NOE enhancement (25%) with the α-hydrogen of the sorbyl chain (δ 5.82). The NOE experiments proved very useful in determining the relative stereochemistry of sorbiquinol. The hydrogen at C-8 (δ 4.48) shows strong NOE enhancement (14%) with H-15 (δ 5.16), thus establishing that the 1-propenyl group is *cis* to H-8. The absence of enhancement between the methyl at C-5 (δ 1.20) and H-8 suggests that these two groups are in an *anti* arrangement. Conclusive results, however, were obtained from the ^{1}H NMR pyridine solvent shift study. Addition of ca. 20% of pyridine-d_5 to the $CDCl_3$ solution of sorbiquinol results in the signals for H-8 and H-15 being shifted downfield by 0.37 and 0.24 ppm, respectively, indicating that the C-5 hydroxyl group is *syn* to H-8 and H-15. Additional support of this assignment is provided by the relatively high-field signals of the C-5 methyl group (δ 1.20; usually ca. 1.50 ppm), which may be attributed to the shielding effect of the adjacent sorbyl enol system.

Catalytic hydrogenation of sorbiquinol over Pd/C for 1 h afforded the tetrahydro derivative **14** while reduction for 2 days gave the hexahydro derivative **15**. Compound **14** has the molecular formula $C_{28}H_{36}O_7$ as determined by HREIMS. The EIMS shows a hexanoyl chain (*m/z* 99) and a base peak at *m/z* 165, corresponding to $(HO)_2(H_3C)_2C_6HCO^+$. The ^{1}H and ^{13}C NMR spectra confirm that the sorbyl chain is replaced by a hexanoyl chain (Table 2). Under these conditions the C-15, C-16 double bond is not hydrogenated.

Hexahydrosorbiquinol (**15**) has molecular formula $C_{28}H_{38}O_7$ obtained from the HREIMS and confirmed by CIMS. All ^{1}H and ^{13}C NMR signals of compound **15** are similar to those of compound **14**, except those of the *E*-1-propenyl chain, which are replaced by the signals of an *n*-propyl group (Table 2). Similar to the parent compound sorbiquinol, the chemical ionization spectra of the hydrogenated derivatives **14** and **15** show retro-Diels–Alder fragment ions corresponding to sorbicillin (for **14**, at *m/z* 233) or dihydrosorbicillin (for **15**, at *m/z* 235) and tetrahydrosorbicillin-*o*-quinol **16** (for **14** and **15**).

The CD spectra of sorbiquinol, tetrahydrosorbiquinol, and hexahydrosorbiquinol all display a split Cotton effect with positive chirality. The absolute configuration of these compounds, however, cannot be unambiguously deduced from the CD spectra since the direction of the electric transition dipole moment vector of the aromatic chromophore cannot be readily determined. The similarity between the oxygenated sorbicillin subunits present in sorbiquinol, trichodimerol, and the very closely related metabolites of *Verticilliam intertextum* (15) suggests that they all may have the (*S*) configuration of the oxygen-bearing tertiary carbon atom (C-5 in sorbiquinol), present also in the key intermediate **13**.

Both trichodermolide (**2**) and sorbiquinol (**3**) proved to be inactive against *Mycena citricolor*, but they do represent new structural types of natural products.

Experimental

The general experimental section and the isolation and purification of trichodermolide and sorbiquinol are described in the first part of this series (1). The nuclear Overhauser enhancement determinations (NOE) are from difference spectra and are reported as enhanced area over the irradiated signal area in the difference spectrum. Trichodermolide and sorbiquinol showed the following characteristics:

Trichodermolide (2): $[\alpha]_D$ +97 (*c* 0.98, EtOH); FTIR ν_{max} (cm^{-1}): 3015, 2920, 1781, 1687, 1637, 1595, 1375, 1320, 1188, 997; UV (MeOH) λ_{max} nm (log ε): 280 (4.72), 217 (4.15); no change upon addition of NaOH or HCl; CD (EtOH) $\lambda_{extremum}$ nm (Δε): 224 (−15.4), 260 (+5.4), 273 (+2.9), 289 (+9); ORD (EtOH) $\lambda_{extremum}$ nm ([φ]): 240 (−49 000), 278 (−30 000), 300 (+15 000); ^{1}H NMR ($CDCl_3$) δ: 1.24 (s, 3H, H-22), 1.45 (s, 3H, H-23), 1.78 (s, 3H, H-21), 1.87 (d, 6 Hz, 3H, H-13), 1.89 (d, 6 Hz, 3H, H-20), 2.45 (dd, 18.5, 4 Hz, 1H, H-14), 3.26 (dd, 18.5, 6 Hz, 1H, H-14), 3.34 (dd, 6, 4 Hz, 1H, H-5), 3.66 (AB, 19 Hz, 2H, H-7), 6.10 (d, 15.5 Hz, 1H, H-9), 6.15 (d, 15.5 Hz, 1H, H-16), 6.20–6.25 (m, 4H, H-11, 12, 18, 19), 7.20 (dd, 15.5, 9.5 Hz, 1H,

H-17), 7.24 (dd, 15.5, 9.5 Hz, 1H, H-10); NOE δ: [1.24] (H-22): 3.66 (H-7) (4%), 3.34 (H-5) (10%), 3.26 (H-14) (3%); [1.45] (H-23): 2.45 (H-14) (6%), 3.34 (H-5) (9%); [1.78] (H-21): 3.66 (H-7) (7%); [2.45] (H-14): 3.34 (H-5) (8%), 3.26 (H-14) (20%), 6.15 (H-16) (3%), 7.20 (H-17) (3.5%); [3.34] (H-5): 1.24 (H-22) (2%), 1.45 (H-23) (3%), 2.45 (H-14) (10%); [3.66] (H-7): 1.78 (H-21) (11%), 1.24 (H-22) (3%), 6.10 (H-9) (15%), 7.24 (H-10) (19%); [3.26] (H-14): 2.45 (H-14) (27%), 6.15 (H-16) (6%), 7.20 (H-17) (7%); HMBC (C/H's): 1/21, 23; 2/7, 21; 3/7, 21, 22; 4/7, 14, 22; 5/14, 22, 23; 6/5, 14, 23; 8/7; 15/5, 14; ^{13}C NMR spectrum: see Table 1; HREIMS: 396.1936 (calcd. for $C_{24}H_{28}O_5$: 396.1937, 0.7%), 352 ($C_{23}H_{28}O_3$, 0.2%), 340 (0.2), 301 (0.2), 258 (0.3), 257 (0.7), 248 (1), 191 (2.8), 95 (100); CIMS (NH_3): 414 (M + 18, 15%), 397 (M + 1, 100%); TLC: R_f 0.45 (petroleum ether / EtOAc 5:2).

*Sorbiquinol (**3**)*: $[\alpha]_D$ +234 (*c* 0.36, MeOH); FTIR ν_{max} (cm^{-1}): 3450, 3020, 2960, 2920, 2850, 1730, 1627, 1606, 1562, 1380, 1166, 995; UV (MeOH) λ_{max} nm (ε): 292 (23 000), 359 (22 500), 374 (19 500); NaOH: 252 (18 200), 283 (18 300), 352 (27 000); HCl regenerated the original spectrum; CD(MeOH) $\lambda_{extremum}$ nm (Δε): 343 (+25), 296 (−28); *A* = +53; ORD (MeOH) $\lambda_{extremum}$ nm ([φ]): 362 (+38 000), 323 (−85 000), 272 (+73 000), 252 (+85 000); ^{1}H NMR ($CDCl_3$) δ: 1.16 (s, 3H, CH_3-C-1), 1.20 (s, 3H, CH_3-C-5), 1.60 (dd, 6.5, 1.5 Hz, 3H, H-17), 1.82 (dd, 7, 1.5 Hz, 1H, H-14), 2.12 (s, 3H, CH_3-C-21), 2.26 (s, 3H, CH_3-C-23), 3.26 (dd, 10, 6.5 Hz, 1H, H-7), 3.32 (d, 1.5 Hz, 1H, H-4), 4.28 (dd, 6.5, 1.5 Hz, 1H, H-8), 5.02 (ddq, 15, 10, 1.5 Hz, 1H, H-15), 5.45 (dq, 15, 6.5 Hz, 1H, H-16), 5.53 (d, 15 Hz, 1H, H-10), 5.93 (ddq, 15, 10, 1.5 Hz, 1H, H-12), 6.08 (dq, 15, 7 Hz, 1H, H-13), 7.17 (dd, 15, 10.5 Hz, 1H, H-11), 7.59 (s, 1H, H-24), 12.58 (s, 1H, OH-20), 13.98 (s, 1H, OH-2); (acetone-d_6) δ: 1.07 (s, 3H, CH_3-C-1), 1.20 (s, 3H, CH_3-C-5), 1.58 (dd, 7, 1.5 Hz, 3H, H-17), 2.24 (s, 3H, CH_3-C-23), 3.19 (dd, 10, 6.5 Hz, 1H, H-7), 3.50 (d, 1.5 Hz, 1H, H-4), 3.79 (br s, 1H, OH-5), 4.48 (dd, 6.5, 1.5 Hz, 1H, H-8), 5.16 (ddq, 15, 10, 1.5 Hz, 1H, H-15), 5.45 (dq, 15, 7 Hz, 1H, H-16), 5.82 (d, 15 Hz, 1H, H-10), 5.95 (ddq, 15, 10, 1.5 Hz, 1H, H-12), 6.13 (dq, 15, 7 Hz, 1H, H-13), 7.12 (dd, 10, 15 Hz, 1H, H-11), 7.69 (s, 1H, H-24), and 8.05 (br s, 1H, HO-22); NOE (acetone-d_6) δ: [1.07] (CH_3-C-1): 3.19 (H-7) (4%), 5.16 (H-15) (2%); [1.20] (H-27): 3.50 (H-4) (2%), 3.79 (OH-5) (0.7%); [1.58] (H-17): 5.16 (H-15) (2.5%), 5.45 (H-16) (4%); [3.19] (H-7): 4.48 (H-8) (2%), 5.16 (H-15) (2%); [3.50] (H-4): 1.20 (CH_3-C-5) (4%), 4.48 (H-8) (5%), 5.82 (H-10) (25%), 5.95 (H-12) (–2%), 7.69 (H-24) (16%); [4.48] (H-8): 3.19 (H-7) (4%), 3.50 (H-4) (5%), 5.16 (H-15) (14%), 5.45 (H-16) (−2%), 7.69 (H-24) (26%); [5.16] (H-15): 4.48 (H-8) (7%), 3.19 (H-7) (4%), 1.58 (H-17) (6%); [5.45] (H-16): 3.19 (H-7) (9%); [5.82] (H-10): 3.50 (H-4) (19%); [7.12] (H-11): 5.82 (H-10) (2%), 5.95 (H-12) (5%), 6.13 (H-13) (16%); [7.69] (H-24): 2.24 (CH_3-C-23) (9%), 4.48 (H-8) (24%), 3.50 (H-4) (5%), 5.82 (H-10) (-1%), 5.16 (H-15) (−2%), 5.45 (H-16) (−2%); ^{13}C spectrum: see Table 2; HREIMS: 480.2132 (calcd. for $C_{28}H_{32}O_7$: 480.2149, 17%), 452 (2), 434 (1), 248 (2), 233 (18), 232 (32), 217 (22), 191 (8), 165 (100), 95 (31); CIMS: 481 (M + 1, 12%), 249 (24), 233 (100); TLC: R_f 0.28 (2% EtOH – $CHCl_3$), 0.50 (6%).

Preparation of derivatives

Hydrogenation of trichodermolide

Trichodermolide (**2**) (58 mg) in ethyl acetate (10 mL) was hydrogenated over excess 5% palladium on carbon for 1 h at room temperature. The reaction mixture was filtered, concentrated, and purified by column chromatography (silica gel, C_6H_6:Et_2O 3:1, R_f 0.74) to give pure octahydrotrichodermolide (**5**) (30.1 mg, 51% yield): $[\alpha]_D$ +119 (*c* 0.55, $CHCl_3$); FTIR ν_{max} (cm^{-1}): 2956, 2923, 2872, 2850, 1782, 1715, 1688, 1618, 1463, 1379, 1304, 1184, 1052, 920; UV (MeOH) λ_{max} nm (ε): 219 (5600), 272 (5700), 325 (1200), 329 (1200); CD (MeOH) $\lambda_{extremum}$ nm (Δε): 270 (+13), 222 (−15); ORD (MeOH) $\lambda_{extremum}$ nm ([φ]): 288 (+24 000), 242 (−58 000); ^{1}H NMR ($CDCl_3$) δ: 0.89 (t, 7 Hz, 3H, H-13), 0.91 (t, 7 Hz, 3H, H-20), 1.22 (s, 3H, H-22), 1.30 (m, 8H, H-11,12,18,19), 1.46 (s, 3H, H-23), 1.60 (m, 4H, H-10,17), 1.75 (s, 3H, H-21), 2.30 (dd, 19, 3.5 Hz, 1H, H-14), 2.45 (m,[2] 2H, H-16), 2.52 (t, 7 Hz, 2H, H-9), 3.12 (dd, 19, 7.5 Hz, 1H, H-14), 3.24 (dd, 7.5, 3.5 Hz, 1H, H-5), 3.48 (AB, 17.5 Hz, 2H, H-7); NOE ($CDCl_3$) δ: [1.22] (H-22): 3.24 (H-5) (13%), 3.48 (H-7) (8%); [1.46] (H-23): 2.30 (H-14) (8%), 3.24 (H-5) (10%); [1.75] (H-21): 3.48 (H-7) (6%); [3.24] (H-5): 1.22 (H-22) (1%), 1.46 (H-23) (1%), 2.30 (H-14) (3.5%); ^{13}C NMR spectrum: see Table 1; HREIMS: 404.2552 (calcd. for $C_{24}H_{36}O_5$: 404.2564, 0.8%), 262 (33), 163 (19), 99 (100), 85 (20), 71 (79); CIMS: 405 (M + 1, 100%).

*Reduction of octahydrotrichodermolide (**5**)*

Octahydrotrichodermolide (**5**) (22 mg) was dissolved in benzene–ethanol (2 mL), cooled to 0°C, and excess sodium borohydride in ethanol was added. The reaction was quenched after 1.5 min by addition of saturated aqueous ammonium chloride (0.5 mL). The reaction mixture was diluted with water (8 mL), and extracted with ethyl acetate (3 × 15 mL). The ethyl acetate extract was concentrated and purified by column chromatography (silica gel, 2% EtOH – $CHCl_3$ R_f 0.24) to give α-decahydrotrichodermolide (**6***a*) (10.0 mg, 45% yield): FTIR ν_{max} (cm^{-1}): 3460, 2956, 2932, 2872, 2860, 1773, 1756, 1713, 1379, 1043, 925; ^{1}H NMR ($CDCl_3$) δ: 0.87 (t, 7 Hz, 3H, H-20), 0.88 (t, 7 Hz, 3H, H-13), 1.06 (s, 3H, H-22), 1.30 (m, 8H, H-11,12,18,19), 1.46 (s, 3H, H-23), 1.55 (m, 4H, H-10,17), 1.68 (s, 3H, H-21), 2.22 (br, 1H, OH-1), 2.44 (t, 7 Hz, 2H, H-9), 2.50 (m,[3] 2H, H-16), 2.71 (dd, 6.5, 5 Hz, 1H, H-5), 2.83 (dd, 18.5, 5 Hz, 1H, H-14), 2.99 (dd, 18.5, 6.5 Hz, 1H, H-14), 3.27 (s, 2H, H-7), 3.71 (d, 6 Hz, 1H, H-1); NOE ($CDCl_3$) δ: [1.06] (H-22): 2.71 (H-5) (2.3%), 3.27 (H-7) (3.8%); [1.46] (H-23): 2.71 (H-5) (3.1%), 2.83 (H-14) (1%), 3.71 (H-1) (2.7%); [1.68] (H-21): 3.27 (H-7) (1.5%), 3.71 (H-1) (1.5%); [3.27] (H-7): 2.44 (H-9) (5%), 1.68 (H-21) (7%), 1.06 (H-22) (4%); [3.71] (H-1): 2.22 (OH-1) (6%), 1.68 (H-21) (4%), 1.46 (H-23) (4%), 1.06 (H-22) (4%); ^{13}C NMR spectrum: see Table 1; HREIMS: 406.2730 (calcd. for $C_{24}H_{38}O_5$: 406.2720, 0.8%), 150 (19), 149 (22), 147 (37), 133 (28), 121 (50), 99 (100), 71 (70), and traces of starting material.

*Formation of anhydrodecahydrotrichodermolide (**9**)*

Octahydrotrichodermolide (**5**) (21.5 mg) was dissolved in benzene–ethanol (1 mL), and sodium borohydride (14.1 mg) in ethanol (1 mL) was added at 0°C. After 2 min the reaction was quenched by addition of saturated aqueous ammonium

[2] This signal is present as a multiplet, indicating that these hydrogens are diastereotopic and magnetically similar, forming an AA′BB′-like system.

[3] This signal is present as a multiplet, indicating that these hydrogens are diastereotopic (vide supra).

chloride (0.5 mL), diluted with water (5 mL), and extracted with chloroform (3 × 5 mL). The chloroform extract was evaporated, and the crude mixture was treated with *p*-toluenesulphonic acid (10 mg) in methanol (4 mL) for 2 weeks at room temperature. The methanol was removed under reduced pressure and the mixture purified by column chromatography (silica gel, 2% EtOH – $CHCl_3$) to afford β-decahydrotrichodermolide (**6***b*) (2.8 mg): FTIR ν_{max} (cm^{-1}): 3450, 2956, 2929, 2872, 2858, 1770, 1714, 1457, 1379, 1049; UV (MeOH): no absorptions detected; ^1H NMR ($CDCl_3$) δ: 0.89 (t, 7 Hz, 3H, H-20), 0.90 (t, 7 Hz, 3H, H-13), 1.03 (s, 3H, H-22), 1.30 (m, 8H, H-11,12,18,19), 1.49 (s, 3H, H-23), 1.56 (m, 4H, H-10,17), 1.68 (s, 3H, H-21), 2.32 (dd, 18, 3 Hz, 1H, H-14), 2.43 (t, 7 Hz, 2H, H-9), 2.53 (m,[3] 2H, H-16), 2.89 (dd, 7, 3 Hz, 1H, H-5), 3.19 (dd, 18, 7 Hz, 1H, H-14), 3.25 (AB, 18 Hz, 2H, H-7), 3.70 (br s, 1H, H-1); NOE ($CDCl_3$) δ: [1.03] (H-22): 3.25 (H-7) (1%), 2.89 (H-5) (5%); [1.49] (H-23): 3.70 (H-1) (3%), 2.89 (H-5) (3%); [1.68] (H-21): 3.70 (H-1) (2%), 3.25 (H-7) (0.8%); HREIMS: 406.2737 (calcd. for $C_{24}H_{38}O_5$: 406.2720, 0.8%), 361 (29), 248 (19), 245 (22), 149 (54), 147 (26), 133 (20), 121 (38), 99 (100), 71 (66); CIMS: 424 (M + 18, 100%), 407 (M + 1, 12%). Further chromatography with 3% Et_2O – C_6H_6 as eluant afforded aromatic compound **10** (2.6 mg): FTIR ν_{max} (cm^{-1}): 2958, 2928, 2871, 2858, 1704, 1450, 1418; UV (MeOH) λ_{max} nm (ε): 205 (13 000), 210 (15 000), 269 (400); no change upon addition of NaOH or HCl; ^1H NMR ($CDCl_3$) δ: 0.87 (t, 7 Hz, 6H), 1.26 (m, 8H), 1.56 (m, 4H), 2.04 (s, 3H, CH_3Ar), 2.20 (s, 6H, 2 × CH_3Ar), 2.40 (t, 7 Hz, 4H, $COCH_2$), 3.76 (s, 4H, 2 × CH_2Ar), 6.92 (s, 1H, ArH); ^{13}C NMR spectrum: see Table 1; HREIMS: 344.2714 (calcd. for $C_{23}H_{36}O_2$: 344.2715, 5%), 326 (21), 245 ($C_{17}H_{25}O$, 100%), 227 (24), 147 (23), 99 (44); CIMS: 362 (M + 18, 100%), 345 (M + 1, 1%), 245 (7); NOE δ: [2.04] (CH_3Ar): 3.76 (CH_2Ar) (4.3%), 2.20 (CH_3Ar) (−3.2%); [2.20] (CH_3Ar): 3.76 (CH_2Ar) (1.5%), 6.92 (ArH) (3.6%); [3.76] (CH_2Ar): 2.20 (CH_3Ar) (5%), 2.40 ($COCH_2$) (4%), 2.04 (CH_3Ar) (7.3%); [6.92] (ArH): 2.20 (CH_3Ar) (13.5%); and anhydrodecahydrotrichodermolide (**9**) (2.4 mg): FTIR ν_{max} (cm^{-1}): 2955, 2930, 2872, 2859, 1779, 1715, 1687, 1381, 1180, 1070; UV (MeOH) λ_{max} nm (ε): 202 (6000), 232 (2000); no change upon addition of NaOH or HCl; ^1H NMR ($CDCl_3$): 0.86 (t, 7 Hz, 6H, H-13,20), 1.04 (m, 4H, H-18,19), 1.17 (s, 3H, H-22), 1.20 (m, 4H, H-11,12), 1.43 (s, 3H, H-23), 1.43 (m, 2H, H-17), 1.53 (m, 2H, H-10), 1.68 (s, 3H, H-21), 2.04 (m,[3] 2H, H-16), 2.19 (d, 6 Hz, 1H, H-5), 2.37 (m, 2H, H-9), 3.21 (s, 2H, H-7), 4.08 (br s, 1H, H-1), 4.56 (d, 6 Hz, 1H, H-14); COSY ($CDCl_3$): Me-21 (δ 1.68)/H-1 (δ 4.08), H-7 (δ 3.21); H-5 (δ 2.19)/H-1 (δ 4.08), H-14 (δ 4.56); H-7 (δ 3.21)/H-1 (δ 4.08); NOE ($CDCl_3$) δ: [1.17] (H-22): 2.19 (H-5) (3.3%), 3.21 (H-7) (2%), 4.56 (H-14) (1%); [1.43] (H-23): 2.04 (H-16) (1%), 2.19 (H-5) (2.5%), 4.08 (H-1) (3.3%); [1.68] (H-21): 3.21 (H-7) (2%), 4.08 (H-1) (3.5%); [2.19] (H-5): 1.17 (H-22) (6%), 1.43 (H-23) (8%), 4.56 (H-14) (10%); [3.21] (H-7): 1.17 (H-22) (4%), 1.68 (H-21) (5.4%), 2.37 (H-9) (1%); [4.08] (H-1): 1.43 (H-23) (7%), 1.68 (H-21) (5.4%); [4.56] (H-14): 2.04 (H-16) (5%), 2.19 (H-5) (11%), 2.37 (H-9) (1%); ^{13}C NMR spectrum: see Table 1; HREIMS: 388.2611 (calcd. for $C_{24}H_{36}O_4$: 388.2615, 0.6%), 277 ($C_{18}H_{29}O_2$, 100%), 245 (21), 99 (55); CIMS: 406 (M + 18, 100%), 390 (M + 2, 36%).

α-Decahydrotrichodermolide (**6***a*) (4.5 mg) was treated with 1% methanolic *p*-toluenesulphonic acid (2 mL), at room temperature for 2 h. The reaction mixture was concentrated and purified by column chromatography (silica gel, 2% EtOH – $CHCl_3$), to give the enol ether anhydrodecahydrotrichodermolide (**9**) (3.5 mg, R_f 0.71).

α-Decahydrotrichodermolide (**6***a*) (3 mg) was acetylated by overnight reaction with acetic anhydride (1 mL) and pyridine (0.5 mL) at room temperature. The excess pyridine and acetic anhydride were removed azeotropically with toluene to give pure *O*-acetyl-α-decahydrotrichodermolide (**7***a*) (2.5 mg): FTIR ν_{max} (cm^{-1}): 2956, 2928, 2872, 2857, 1780, 1748, 1715, 1457, 1417, 1380, 1371, 1258, 1022, 931, 804; UV (MeOH): no UV absorptions detected; ^1H NMR ($CDCl_3$) δ: 0.89 (t, 7 Hz, 3H, H-20), 0.90 (t, 7 Hz, 3H, H-13), 1.10 (s, 3H, H-22), 1.30 (m, 8H, H-11, 12, 18, 19), 1.35 (s, 3H, H-23), 1.53 (s, 3H, H-21), 1.58 (m, 4H, H-10,17), 2.46 (t, 7 Hz, 2H, H-9), 2.54 (m,[3] 2H, H-16), 2.71 (m, 1H, H-14), 2.73 (1H, H-5), 3.09 (m, 1H, H-14), 3.31 (s, 2H, H-7), 5.29 (br s, 1H, H-1); NOE ($CDCl_3$) δ: [1.10] (H-22): 3.31 (H-7) (3%), 2.73 (H-5) (3%); [1.35] (H-23): 5.29 (H-1) (2.5%), 2.73 (H-5) (1%); [1.53] (H-21): 5.29 (H-1) (2.5%), 3.31 (H-7) (2%); [3.31] (H-7): 1.53 (H-21) (7%), 2.46 (H-9) (4%), 1.10 (H-22) (1%); ^{13}C NMR spectrum: see Table 1; HREIMS: 448.2831 (calcd. for $C_{26}H_{40}O_6$: 448.2826, 0.1%), 404 (M − CO_2, 0.2), 246 (41), 147 (47), 135 (6), 133 (42), 121 (16), 99 (100), 71 (72). Acetylation of β-decahydrotrichodermolide (**6***b*) in a similar way gave *O*-acetyl-β-decahydrotrichodermolide (**7***b*) (1.5 mg): FTIR ν_{max} (cm^{-1}): 2956, 2927, 2873, 2858, 1772, 1742, 1716, 1374, 1231, 1093, 1056, 1028; UV (MeOH): no absorption detected; ^1H NMR ($CDCl_3$) δ: 0.89 (t, 7 Hz, 6H, H-13, 20), 1.04 (s, 3H, H-22), 1.30 (m, 8H, H-11,12,18,19), 1.32 (s, 3H, H-23), 1.49 (s, 3H, H-21), 1.58 (m, 4H, H-10, 17), 2.43 (dd, 18, 3 Hz, 1H, H-14), 2.44 (t, 7 Hz, 2H, H-9), 2.55 (m, 2H, H-16), 2.92 (dd, 8.5, 3 Hz, 1H, H-5), 3.28 (dd, 18, 8.5 Hz, 1H, H-14), 3.29 (AB, 18 Hz, 2H, H-7), 5.40 (br s, 1H, H-1); HREIMS: 448.2817 (calcd. for $C_{26}H_{40}O_6$: 448.2826, 0.1%), 403 (M − CO_2, 8%), 248 (30), 245 (42), 133 (44), 121 (22), 99 (100), 71 (71); CIMS: 466 (M + 18, 100%), 449 (M + 1, 3%).

Aromatization of anhydrodecahydrotrichodermolide (9)

Anhydrodecahydrotrichodermolide (**9**) (8 mg) was refluxed overnight in 1% methanolic *p*-toluenesulphonic acid (2 mL). The reaction mixture was evaporated and purified by column chromatography (3% Et_2O – C_6H_6) to give the aromatic compound **10** (4 mg) and unreacted starting material.

Hydrogenation of sorbiquinol (3)

A mixture (58 mg) containing sorbiquinol and trichodimerol, obtained from the mycelial extract of *T. longibrachiatum* (UAMH 5068), was hydrogenated with excess 5% palladium on carbon in ethyl acetate (4 mL) at room temperature and pressure for 1 h. The reaction mixture was filtered through celite, evaporated, and purified by column chromatography (silica gel, 3% EtOH – $CHCl_3$) to give tetrahyrdosorbiquinol (**14**) (15 mg, 95% pure): $[\alpha]_D$ +86 (*c* 0.23, MeOH); FTIR ν_{max} (cm^{-1}): 3450, 2960, 2870, 2850, 1730, 1625, 1490, 1380, 1292, 1165, 1145; UV (MeOH) ν_{max} nm (ε): 217 (13 800), 232 sh, 290 (19 000); NaOH: 258 (12 400), 309 sh, 344 (29 000);

[4] The chemical shift and multiplicity was obtained from NOE difference spectra since these signals overlap in the reguar ^1H NMR spectrum.

HCl regenerated the original spectrum; ^{1}H NMR ($CDCl_3$) δ: 0.78 (t, 7.5 Hz, 3H, H-14), 1.00 (m, 4H, H-12, 13), 1.16 (s, 3H, CH_3-C-1), 1.23 (s, 3H, CH_3-C-5), 1.45 (m, 2H, H-11), 1.60 (dd, 7, 1.5 Hz, 3H, H-17), 1.96 (t, 8 Hz, 2H, H-10), 2.13 (s, 3H, CH_3-C-21), 2.26 (s, 3H, CH_3-C-23), 2.87 (s, 1H, OH-5), 3.245 (dd,[4] 10, 6.5 Hz, 1H, H-7), 3.247 (d,[4] 1.5 Hz, 1H, H-4), 4.27 (dd, 7, 1.5 Hz, 1H, H-8), 4.99 (ddq, 15, 10, 1.5 Hz, 1H, H-15), 5.44 (dq, 15, 7 Hz, 1 H, H-16), 7.60 (s, 1H, H-24), 12.79 (s, 1H, OH-20), 14.37 (s, 1H, OH-2); NOE ($CDCl_3$) δ: [1.16] (CH_3-C-1): 3.245 (H-7) (2.3%), 4.99 (H-15) (1.1%), 5.44 (H-16) (0.4%); [1.23] (CH_3-C-5): 3.247 (H-4) (2%); [1.96] (H-10): 3.247 (H-4) (7%); [2.26] (CH_3-C-23): 7.60 (H-24) (2%); [4.27] (H-8): 3.245 (H-4, H-7) (7%), 4.99 (H-15) (13%), 7.60 (H-24) (23%); [5.44] (H-16): 3.245 (H-7) (10%), 4.99 (H-15) (2%); [7.60] (H-24): 2.26 (CH_3-C-23) (7%), 3.247 (H-4) (6%), 4.27 (H-8) (22%), 4.99 (H-15) (–2.4%); ^{13}C NMR spectrum: see Table 2; CD (MeOH) $\lambda_{extremum}$ nm (Δε): 318 (+37), 284 (−41); A = +78; HREIMS: 484.2460 (calcd. for $C_{28}H_{36}O_7$: 484.2462, 3.3%), 252 (2), 232 (25), 165 (100), 99 (10), 95 (3); CIMS: 502 (M + 18, 3%), 485 (M + 1, 41%), 253 (32), 233 (100), 106 (82); tlc: R_f 0.26 (2% EtOH – $CHCl_3$), 0.52 (6%); and octahydrotrichodimerol (20 mg).

When the hydrogenation is allowed to proceed for 2 days, work-up of the reaction mixture in a similar way gave hexahydrosorbiquinol (**15**) (6 mg). $[\alpha]_D$ +117 (*c* 0.23, MeOH); FTIR ν_{max} (cm^{-1}): 3480, 2955, 2865, 1732, 1627, 1482, 1450, 1382, 1188, 757; UV (MeOH) λ_{max} nm (ε): 215 (15 900), 230 sh, 290 (19 000); NaOH: 257 (6900), 315 sh, 344 (23 000); HCl regenerated the original spectrum; ^{1}H NMR ($CDCl_3$) δ: 0.79 (m, 6H, H-14,17), 1.1 (m, 8H, H-12, 13, 15, 16), 1.21 (s, 3H, CH_3-C-5), 1.29 (s, 3H, CH_3-C-1), 1.47 (m, 2H, H-11), 1.94 (t, 7 Hz, 2H, H-10), 2.14 (s, 3H, CH_3-C-21), 2.27 (s, 3H, CH_3-C-23), 2.72 (m, 1H, H-7), 2.81 (s, 1H, OH-5), 3.22 (d, 1.5 Hz, 1H, H-4), 4.18 (dd, 7, 1.5 Hz, 1H, H-8), 5.36 (s, 1H, OH-22), 7.64 (s, 1H, H-24), 12.84 (s, 1H, OH-20), 14.38 (s, 1H, OH-2); NOE ($CDCl_3$) δ: [1.21] (CH_3-C-5): 1.47 (H-11) (3%), 2.81 (OH-5) (1%), 3.22 (H-4) (15%); [1.29] (CH_3-C-1): 2.72 (H-7) (2%); [1.94] (H-10): 1.47 (H-11) (10%), 3.22 (H-4) (7%); [3.22] (H-4): 1.21 (CH_3-C-5) (3%), 4.18 (H-8) (4%), 7.64 (H-24) (5%); [7.64] (H-24): 3.22 (H-4) (6%), 4.18 (H-8) (19%); ^{13}C NMR spectrum: see Table 2; CD (MeOH) $\lambda_{extremum}$ nm (Δε): 316 (+29), 285 (−34); *A* = +63; HREIMS: 486.2616 (calcd. for $C_{28}H_{38}O_7$: 486.2618, 17%), 253 (1.4), 235 (28), 191 (28), 165 (100), 99 (5); CIMS: 504 (M + 18, 34), 487 (M + 1, 100), 253 (78), 233 (79), 165 (54); TLC: R_f 0.25 (2% EtOH – $CHCl_3$), 0.56 (6%).

Hydrogen evolution reaction at nickel boride electrodes in aqueous and in aqueous methanolic and ethanolic solutions

Behzad Mahdavi, Danielle Miousse, Joël Fournier, Hugues Ménard, and Jean Lessard

Abstract: The hydrogen evolution reaction (HER) was investigated at nickel boride pressed powder electrodes in aqueous and in aqueous methanolic (ethanolic) alkaline (1 M NaOH) solutions in the presence and the absence of NaCl (0.1 M) and H_3BO_3 (0.1 M) at 25°C by the steady-state polarization and ac impedance techniques. The ac impedance data were analyzed using the constant-phase element (CPE) model. It was found that the electrocatalytic behaviour of a nickel boride electrode for the HER was the same in all the above media and that the HER proceeds via the Volmer–Heyrovsky mechanism. The kinetic parameters of the HER were determined.

Key words: hydrogen evolution reaction, nickel boride electrodes, Tafel curves, ac impedance, kinetic parameters.

Résumé : La réaction de dégagement d'hydrogène (RDH) sur électrodes de borure de nickel faites de poudre pressée a été étudiée en milieu aqueux et aqueux méthanolique (éthanolique) alcalin (1 M NaOH) en présence et en absence de NaCl (0.1 M) et H_3BO_3 (0.1 M) à 25°C par les techniques de polarisation stationnaire et d'impédance ac. Le modèle d'élément de phase constant (EPC) a été utilisé pour l'analyse des données de l'impédance ac. Le comportement électrocatalytique d'une électrode de borure de nickel s'est avéré le même dans les différents milieux étudiés et la RDH fait intervenir un mécanisme Volmer–Heyrovsky. Les paramètres cinétiques de la RDH ont été déterminés.

Mots clés : réaction de dégagement d'hydrogène, électrodes de borure de nickel, courbes de Tafel, impédance ac, paramètres cinétiques.

Introduction

The hydrogen evolution reaction (HER) is of prime importance in the whole range of electrocatalytic processes and has therefore been one of the most studied cathodic reactions (1–5). In the recent past, due to its economic and environmental impact, an increased interest in the practical industrial application of low-overvoltage cathode electrolyses has been noted. Hydrogen has also played a major role in synthetic organic chemistry in the well-known catalytic hydrogenation process by which an unsaturated compound R, adsorbed at the surface of a catalyst M, (M(R)), is reduced by the adsorbed hydrogen M(H) (reactions [1]–[4]) (6).

[1] $H_2 + M = 2\ M(H)$

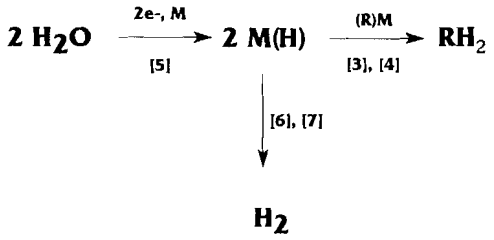
[2] $R + M = M(R)$

[3] $M(R) + 2\ M(H) = M(RH_2) + M$

[4] $M(RH_2) = RH_2 + M$

Such reactions generally require high temperatures and pressures. Another method of hydrogenation of these compounds under much milder conditions is electrocatalytic hydrogenation (**ECH**), in which the adsorbed hydrogen is formed in situ by electrolysis of water (reaction [5]). In this process, the hydrogenation reaction (eqs. [2]–[4]) is in competition with hydrogen evolution (reactions [6] and (or) [7] representing the electrochemical and chemical desorption of hydrogen respectively (Scheme 1)) and the efficiency of the ECH is determined by this competition.

Scheme 1.



[5] $H_2O + e^- + M = (H)M + OH^-$ (Volmer)

[6] $(H)M + H_2O + e^- = H_2 + M + OH^-$ (Heyrovsky)

[7] $(H)M + (H)M = H_2 + M$ (Tafel)

In view of the conjunction of the HER and the ECH reactions, the kinetic and roughness factor parameters obtained from HER studies can clarify the understanding of the ECH process (7). However, the HER is often studied in aqueous alkaline solutions (1 M NaOH) (because the nickel-based electrodes, which are widely used in industrial processes, are stable in this medium) while the electrocatalytic hydrogenation of organic

compounds is often carried out in methanolic or ethanolic solutions containing NaCl (0.1 M) and H_3BO_3 (0.1 M), an acid (8, 9). In fact, the organic solvent permits the dissolution of the organic products, NaCl is used as supporting electrolyte, and H_3BO_3 is used as a buffer to prevent rapid increase of the pH during the electrolysis (reaction [5]). To see if the results obtained in HER studies in aqueous alkaline solutions can be extrapolated to the ECH studies in alcoholic solutions containing NaCl and H_3BO_3, we have investigated HER at nickel boride pressed powder electrodes in aqueous alkaline (1 M NaOH) and in aqueous methanolic (ethanolic) solutions in the presence and in the absence of NaCl (0.1 M) and H_3BO_3 (0.1 M) at 25°C by the steady-state polarization and ac impedance techniques. The results are reported in this paper.

Experimental

Electrodes

Nickel boride (Ni_2B) was obtained as a powder (average particle size of 0.5 μm and specific surface area of 9 $m^2 g^{-1}$) (7) by reduction of nickel acetate with $NaBH_4$ in aqueous NaOH (9). The electrodes were obtained by pressing the particles at $p = 120$ MPa at room temperature. Silver epoxy (EPO-TEK H2OE, Epoxy Tech., Inc) was used to ensure a good electrical contact. One face and the sides of electrodes were coated with Epofix resin (Struers), known for its stability (i.e., no leaching) in alkaline solution (10–12), in order to obtain a projected geometric surface area of 1.1 cm^2 and avoid the effect of the edge plane defects.

Data acquisition

The Tafel plots were measured using an EG&G PAR 273. The potentiostat and an EG&G Lock-in Analyzer (model 5208) connected and controlled by an IBM-compatible microcomputer (by means of a GPIB PC2A interface) were used for the ac impedance measurements.

Electrolyses

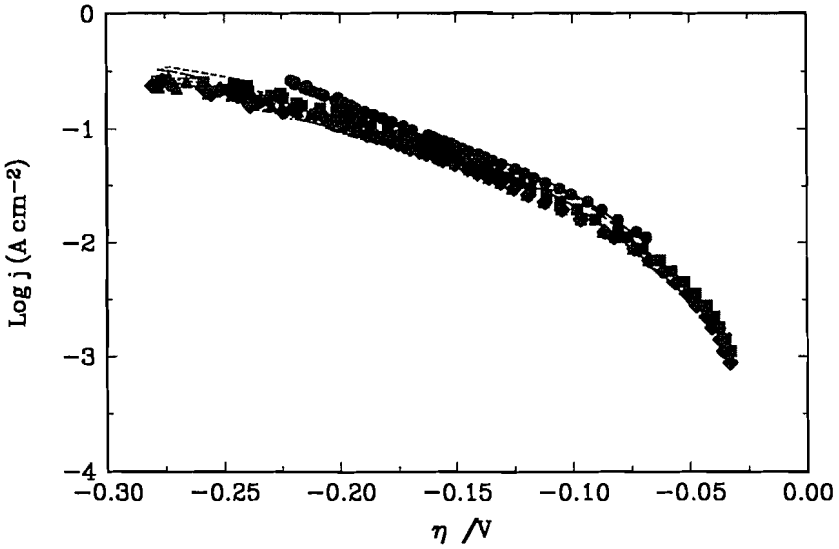
The electrochemical cell (Scheme 2) consisted of two compartments made of Pyrex, separated by a reinforced Nafion cationic membrane (du Pont M-901CATH/MD). A cylindrical platinum grid (length 5.5 cm and diameter 2.5 cm) was used as anode. A Hg/HgO/1 M NaOH reference electrode was connected by a Luggin capillary. Solutions were made with spectrograde NaOH (Aldrich, 99.99%), deionized water ($R = 17.5$ MΩ cm) (Barnstead Nanopure), and commercial methanol(ethanol) (ACP) distilled before use. The equilibrium potential was measured in each solution at a platinized platinum electrode. In all media the value was identical within the experimental error (−920 mV). The electrochemical experiments were performed at 25°C in 1 M NaOH solutions. A reduction current of 100 mA cm^{-2} was applied to the cathode for 12 h prior to the measurements. Tafel curves were recorded galvanostatically in the current range of 300 mA cm^{-2} to 0.1 μA cm^{-2} after a galvanostatic activation of 15 min under a current of 100 mA cm^{-2}. The Tafel parameters were calculated after correction for the ohmic drop. The resistance of the solution was determined by ac impedance spectroscopy. Ten frequencies per decade were thus scanned from 10 kHz to 5 Hz at different dc overpotentials. In the frequency range of 5 – 0.05 Hz, the fast Fourier transform technique was used. The sinusoidal potential superimposed was 10 mV peak to peak.

Theory

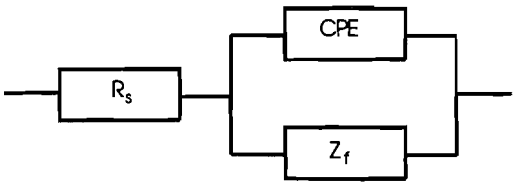
The hydrogen evolution reaction involves the formation of adsorbed hydrogen (reaction [5], Volmer step) and its desorption (reaction [6], Heyrovsky step and (or) reaction [7], Tafel step). The rates of these reactions are given, in units of flux (mol cm^{-2} s^{-1}), by the following expressions (13, 14):

$$[8] \quad v_1 = k_1(1-\theta)\exp(-\beta_1 f\eta) - k_{-1}\theta\exp[(1-\beta_1)f\eta]$$

Fig. 1. Tafel plots obtained at 25°C on a nickel boride electrode in: (●) S_1: 1 M NaOH, (■)S_2: 1 M NaOH/MeOH (50/50)(v/v); (▲)S_3: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl; (◆) S_4: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl +0.1 M H_3BO_3. The points are experimental and lines were calculated from the rate constants shown in Table 3 using the CPE model.



Scheme 3.



[9] $v_2 = k_2\theta \exp(-\beta_2 f\eta) - k_{-2}(1 - \theta) \exp[(1 - \beta_2)f\eta]$

[10] $v_3 = k_3\theta^2 - k_{-3}(1-\theta)^2$

where k_i is the reaction rate constant, which includes the concentrations of OH^- and H_2O, β_1 and β_2 are the symmetry coefficients for the Volmer and Heyrovsky steps, respectively, η is the overpotential, θ is the surface coverage by adsorbed hydrogen, and $f = F/RT$. The electrical equivalent model describing the HER on an ideally smooth electrode consists of the solution resistance, R_s, in series with the parallel connection of the double layer capacitance, C_{dl}, and faradaic impedance, Z_f (Scheme 3). The faradaic impedance, in the case when the mass transport can be neglected, is given by eq. [11]:

[11] $$Y_f = \frac{1}{Z_f} = A + \frac{B}{j\omega + C}$$

where

[12] $$A = -F\left(\frac{\delta r_0}{\delta \eta}\right)_\theta$$

[13] $$B = \frac{-F^2}{\sigma_1}\left(\frac{\delta r_1}{\delta \eta}\right)_\theta\left(\frac{\delta r_0}{\delta \theta}\right)_\eta$$

[14] $$C = -\frac{F}{\sigma_1}\left(\frac{\delta r_1}{\delta \theta}\right)_\eta$$

where $r_0 = v_1 + v_2$, $r_1 = v_1 - v_2 - 2v_3$, and σ_1 is the charge necessary for a monolayer coverage by adsorbed hydrogen. However, on solid electrodes, this model cannot describe adequately the observed impedance data because the nonhomogeneous surface of solid electrodes causes deformation of the complex plane plots. The CPE model was therefore proposed for cases where a depressed semicircle is observed on complex plane plots. In this case, the double layer capacity is substituted by the CPE and its impedance equals (15):

[15] $Z_{CPE} = 1/T(j\omega)^\Phi$

[16] $T = C_{dl}^{\Phi}(R_s^{-1} + A)^{(1-\Phi)}$

where ω is the angular frequency of the ac signal, T is a constant, ϕ is the phase angle related to the surface roughness, and parameter A is equal to $1/R_{ct}$ where R_{ct} is the charge transfer resistance (7, 16–23). For an ideally flat electrode, ϕ is equal to 1 and, thus, T is equal to C_{dl}.

Results and discussion

Nickel boride is a non-magnetic and non-pyrophoric black powder whose catalytic activity in catalytic hydrogenation (24, 25) and in electrocatalytic hydrogenation (7) reactions is similar to that of Raney nickel. Nickel boride electrodes obtained by pressing the powder have a very reproducible surface area (7) since there is no need of an activation method that can modify the surface irregularly as in the case of RaNi electrodes, which are obtained by leaching the pressed Raney alloy (26). However, to ensure that the observations made were due to changes in the solution composition and not to changes on the electrode itself, the same electrode was used during the entire experiment for each solvent.

Fig. 2. Tafel plots obtained at 25°C on a nickel boride electrodes in: (●) S_1: 1 M NaOH; (■)S_5: 1 M NaOH/EtOH (50/50) (v/v). The points are experimental and lines were obtained from the rate constants shown in Table 3 using the CPE model.

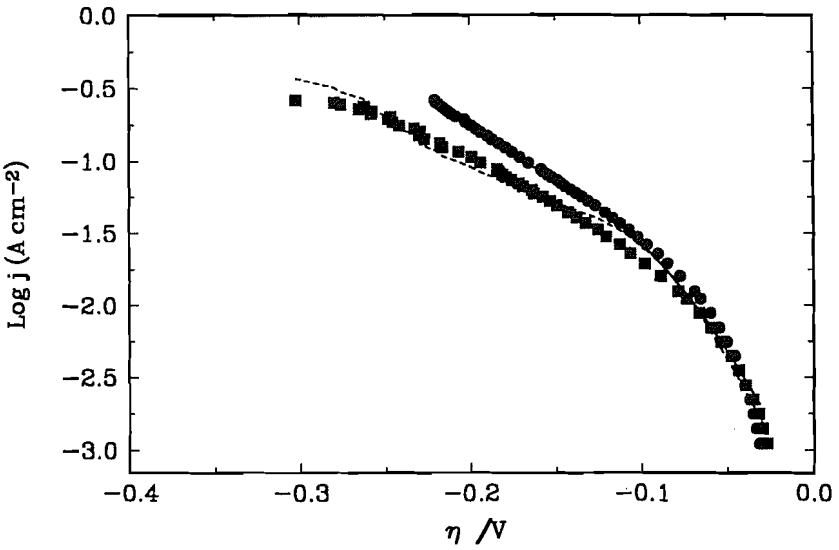


Table 1. Kinetic parameters obtained from the analysis of Tafel curves of nickel boride electrodes[a] at 25°C in aqueous 1 M NaOH: effect of MeOH, NaCl, boric acid, and EtOH.

Entry	Solution	j_0[b] (mA cm^{-2})	b[b] (mV)	r^2	$-\eta_{250}$[c] (mV)
1	S_1: NaOH (1 M)	2.6–3.2[d]	101–107[d]	0.998[d]	200–203[d]
2	S_2: NaOH (1 M) / MeOH (50/50) (v/v)	2.2	100	0.994	204
3	S_3: S_2 + 0.1 M NaCl	1.9	103	0.992	218
4	S_4: S_3 + 0.1 M H_3BO_3	2.4	111	0.994	223
5	S_5: NaOH (1 M) / EtOH (50/50) (v/v)	2.8	112	0.998	219

[a]The nickel boride electrodes were prepared by pressing the Ni_2B powder at p = 120 MPa.
[b]From the Tafel plots.
[c]Experimental value.
[d]Range obtained from two different experiments.

The electrochemical activity was studied by measuring Tafel curves. At potentials more negative than −0.10 V vs. Hg/HgO/1 M NaOH, the Tafel curves became linear (Figs.1 and 2). The linearization was studied by the least-squares method: r^2 values were calculated for the whole polarization curve starting from the most negative potentials and the part of the curve for which the determination coefficient reached a maximum value was considered as linear. The IR-corrected Tafel curves recorded in the different media (S_1: 1 M aqueous NaOH; S_2: 1 M NaOH/MeOH (50/50) (v/v); S_3: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl; S_4: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl +0.1 M H_3BO_3; and S_5: 1 M NaOH/EtOH (50/50) (v/v)) are shown in Figs. 1 and 2 and the corresponding parameters are recorded in Table 1. The values of parameters b, the Tafel slope, j_0, and the exchange current density are practically the same in all media. There is no change of $-\eta_{250}$ (the overpotential at the current density of 250 mA cm^{-2}) upon adding CH_3OH (compare entries 1 and 2) but a slight increase (≃15 mV) upon adding EtOH (entry 5). There is also a slight increase of $-\eta_{250}$ upon adding NaCl to the aqueous methanolic solution (≃15 mV, entry 3). The addition of H_3BO_3 to the aqueous methanolic NaCl solutions has almost no influence (entry 4).These results indicate that the nickel boride electrode is very active for the HER in these media (ECH conditions) and that the electrocatalytic activity is hardly affected by the presence of MeOH, NaCl, boric acid, and EtOH. Kam Cheong et al. (27) have already observed the same behaviour for composite-coated Raney nickel in solutions of methanol and 1 M KOH (%MeOH: 0–100).

The ac impedance technique led to depressed semicircles on the Nyquist complex plane plots over the whole range of overpotentials studied, for all measurements (Fig. 3). The real and the imaginary components were analyzed (18, 28–30) using the complex nonlinear least-squares fitting program (CNLS)

Fig. 3. Complex plane ac impedance spectra obtained on a nickel boride pressed powder electrode at 25°C in (*a*) S_1: 1 M NaOH; (*b*) S_2: 1 M NaOH/MeOH (50/50)(v/v); (*c*) S_3: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl; (*d*) S_4: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl +0.1 M H_3BO_3; (*e*) S_5: 1 M NaOH/EtOH (50/50) (v/v) for various overpotentials: η = 20 mV (●), η = 55 mV (■), and η = 85 mV (▲). written by MacDonald et al. (31) and modified by Rami and Lasia (32). It was previously established (7, 33) that the experimental data of the HER at nickel boride electrodes could be represented by the CPE model (See Experimental). Figures 4 and 5 show the dependence of the double layer capacity, C_{dl}, on the overpotential for nickel boride electrodes in solutions S_1–S_5. A decrease of C_{dl} with η was observed in all media (Figs. 4 and 5). This decrease is due to hydrogen bubbles formed on the surface (7, 32) that block the pores and diminish the active surface area. The roughness factors R, estimated from the mean value of the experimental C_{dl} values measured at different overpotentials (see Figs. 4 and 5) divided by 27.9 μF/cm² (the capacity of a platinum smooth surface (32)), are presented in Table 2. The results of entries 1 and 2 show that the roughness factor is not affected by the presence of methanol, contrary to a report by Kam Cheong et al. (27) of an increase of the roughness factor of composite-coated RaNi electrodes (Raney nickel particles embedded in a nickel matrix) in aqueous methanol compared to water. They attributed this increase of R to a diminution of the surface tension of the methanolic solution (methanol has a lower surface tension than water) and, as a consequence, to a deeper penetration of the methanolic solution into the pores of the electrode surface and (or) to a better access to the smaller pores (then the surface appears to be larger). However, the pores at the surface of the nickel boride electrodes measured by mercury porosimetry (radius = 0.006 μm) are appreciably smaller than those at the surface of the composite RaNi electrodes (radius = 2.3 μm) and it is conceivable that, for much smaller pores, the penetration of methanol in the pores would be the same as that of water. A slight decrease of the roughness factor was observed when NaCl was added to the aqueous solution (from 11 000 in entry 2 to 9 000 in entry 3). This decrease could reflect the adsorption, on the nickel boride surface, of anions that would poison the catalyst. Chloride ions have been reported to poison Raney nickel in the catalytic hydrogenation of styrene (34). However, the decrease of the roughness factor in the presence of NaCl might not be significant since a similar R value of 10 000 was obtained after adding H_3BO_3 (solution S_4, entry 4). Similarly, the small increase of R upon adding ethanol (from 10 000 – 11 000 in

Fig. 4. Dependence of the double layer capacity, C_{dl}, on the overpotential for a nickel boride electrode in: (●) S_1: 1 M NaOH, (■)S_2: 1 M NaOH/MeOH (50/50)(v/v); (▲)S_3: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl; (◆) S_4: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl + 0.1 M H_3BO_3.

entry 1 to 14 000 in entry 5) is probably not significant. In fact, both the active surface area of Ni_2B electrodes and their intrinsic activity for the HER (as measured by the ratio of the exchange current density over the the roughness factor (j_0/R): ($(2.0–2.8) \times 10^{-7}$)) are not affected by the presence of CH_3OH, NaCl, H_3BO_3, and EtOH. If we assume that the active surface area for the ECH process is also not affected by the presence of MeOH or EtOH plus NaCl and H_3BO_3 in water, then the active surface for the HER in aqueous alkali should be proportional to the active surface for ECH, and the active surface for the HER obtained from ac impedance should constitute a good estimate of the active surface for ECH under the conditions used for ECH. It is only an approximate estimation because the hydrogenation step of the ECH process involves the reaction between the adsorbed organic substrate and chemisorbed hydrogen and, thus, the accessibility of the sites is not necessarily the same for the organic substrate and for chemisorbed hydrogen. However, the surface area for the HER obtained from ac impedance measurements in aqueous alkali (roughness factor of 10 000) should be a better estimate of the surface area active in ECH than the surface area measured by BET (specific surface area of 10.7 $m^2\ g^{-1}$) (7). Indeed, BET measurements involve a gas–solid interface whereas ac impedance measurements refer to a solid–solution interface as in the ECH process.

The dependency of $A(=1/R_{ct})$ (Figs. 6 and 7) and current

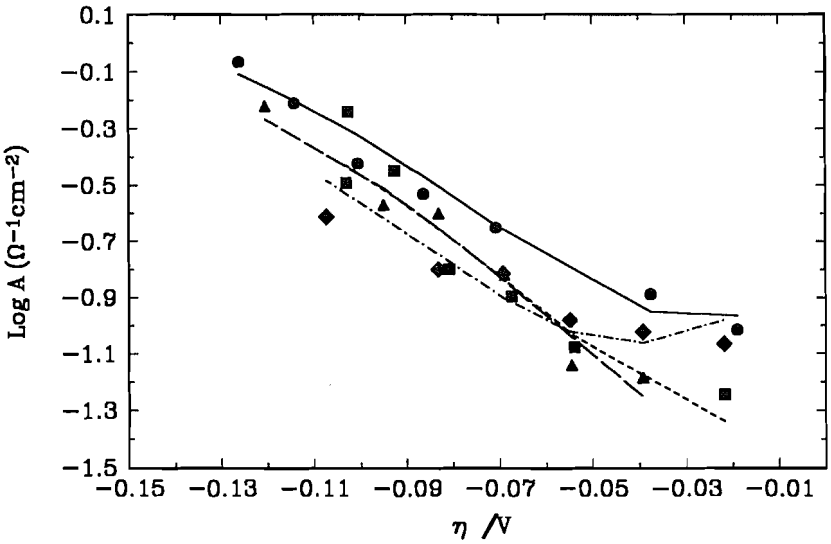
Fig. 6. Variation of the logarithm of parameter $A(=1/R_{ct})$ with the overpotential for a nickel boride electrode: (●) S_1: 1 M NaOH; (■)S_2: 1 M NaOH/MeOH (50/50)(v/v); (▲)S_3: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl; (◆) S_4: 1 M NaOH/MeOH (50/50) (v/v) + 0.1 M NaCl + 0.1 M H_3BO_3. The points were obtained by the use of the CPE model and lines were calculated using the rate constants shown in Table 3.



density j (Figs. 1 and 2) on the overpotential η was used to determine the rate constants k_i of the HER by applying the nonlinear least-squares (NLS) method (18, 28–30) assuming a Volmer–Heyrovsky mechanism. The kinetic results are presented in Table 3. The values of k_i are approximately identical in all media (entries 1 – 5). It means that HER under ECH conditions proceeds via the same mechanism as in an aqueous 1 M NaOH solution. It should be noted that in the case of the Volmer–Heyrovsky mechanism, two equivalent solutions are obtained when the values of k_1 and k_2, k_{-1} and k_{-2}, and α_1 and α_2, are interchanged. This permutation gives the same value for all experimentally accessible parameters (29). Therefore, the rate-determining step could not be determined.

Conclusion

The hydrogen evolution reaction (HER) at nickel boride pressed powder electrodes has been studied under conditions used in the electrocatalytic hydrogenation (ECH) of organic compounds (aqueous methanolic (ethanolic) solution containing 0.1 M NaCl and 0.1 M H_3BO_3). It was shown by steady-state polarization and ac impedance measurements that the electrodes have about the same activity, the same large surface area (roughness factor), and the same intrinsic activity under these conditions as in an aqueous 1 M NaOH solution. The ac impedance results were well approximated by the CPE model, and the parameters obtained were similar and the HER

occurred according to the Volmer–Heyrovsky mechanism in all the media studied. In summary, we have shown that it is possible to extrapolate the results obtained from the HER in aqueous alkali to the media used for the ECH studies.

Evidence for the role of the α-helix in the xylosylation reactions involving the glycosaminoglycan-bearing serine of decorin/DS-PGII as shown by ^{1}H NMR, CD, and molecular modeling studies

Yunjun Wang, Paul G. Scott, Jan Sejbal, and George Kotovych

Abstract: The conformation of four peptides (N-terminal acetylated and unacetylated 14-mers DEASGIGPEEHFPENH$_2$ and 24-mers AcQKGLFDFMLEDEASGIGPEEHFPENH$_2$ with a normal and an oxidized methionine residue) containing the sequence Asp-Glu-Ala-Ser-Gly-Ile-Gly (DEASGIG), which is known to play an important role in the xylosylation reactions involving the glycosaminoglycan-bearing serine of decorin/DS-PGII, were studied by two-dimensional proton NMR techniques, circular dichroism spectroscopy, and molecular dynamics in a methanol–water mixture. The 14-residue peptide comprises the first (i.e., N-terminal) 14 amino acids of the mature decorin protein and the 24-residue peptide incorporates an additional (N-terminal) sequence of 10 amino acids derived from the procore of decorin. The resonance heterogeneity induced by the isomerization of the two prolines (Pro^8, Pro^{13} in the 14-mer, and Pro^{18}, Pro^{23} in the 24-mer) in the peptides studied was evaluated from TOCSY and NOESY NMR spectra. The *trans-trans*, *trans-cis*, and *cis-trans* isomers exist in approximate 68:25:7 proportions in the methanol–water mixture. The NOE distance constraints were used as input parameters for molecular dynamics and restrained energy minimization calculations. It was demonstrated that the conformation of the DEASGIG fragment was affected by the presence of the 10 amino acids at the N-terminal end of the 24-mer, and that the serine is part of an α-helix. The results indicate that an α-helix is present in the 24-mer beginning at the N-terminal end with Lys^2 and ending at Gly^{15}, and suggest that this could be the signal for the xylosylation of serine Ser^{14}. A type VIb β turn was observed, involving the C-terminal *cis*-proline in the sequence His-Phe-Pro-Glu.

Key words: xylosylation, nascent helix, α-helix, *cis*-proline, type VIb β-turn, molecular dynamics.

Résumé : Faisant appel à des techniques de RMN du proton bidimensionnelles, à la spectroscopie du dichroïsme circulaire et à de la dynamique moléculaire dans un mélange méthanol–eau, on a étudié la conformation de quatre peptides (les 14-mères DEASGIGPEEHFPENH$_2$ non acétylé et acétylé sur le N-terminal et les 24-mères AcQKGLFDFMLEDEASGIGPEEHFPENH$_2$ portant une méthionine normale et une oxydée) qui comportent la séquence Asp-Glu-Ala-Ser-Gly-Ile-Gly (DEASGIG) qui est connue pour jouer un rôle important dans les réactions de xylosylation impliquant la sérine de la décorine/DS PGII portant un glycosaminoglycane. Le peptide à 14 résidus comporte les 14 premiers (c'est-à-dire, N-terminal) acides aminés de la protéine décorine mature et le peptide à 24 résidus incorpore une séquence additionnelle (N-terminale) de 10 acides aminés dérivée du procore de la décorine. L'hétérogénéité de la résonance induite par l'isomérisation des deux prolines (Pro^8, Pro^{13} dans le 14-mère et Pro^{18}, Pro^{23} dans le 24-mère) des peptides étudiés a été évaluée par des spectres RMN TOCSY et NEOSY. Les isomères *trans-trans*, *trans-cis* et *cis-trans* existent dans les proportions approximatives de 68 : 25 : 7 dans le mélange méthanol–eau. Les contraintes de distance des EON ont été utilisés comme paramètres connus pour les calculs de dynamique moléculaire et de minimisation de l'énergie restreinte. Il a été démontré que la conformation du fragment DEASGIG est affectée par la présence des 10 acides aminés de l'extrémité N-terminale du 24-mère et que la sérine fait partie d'une hélice α. Les résultats indiquent qu'il existe une hélice α dans le 24-mère, qu'elle commence à l'extrémité N-terminale avec la Lys^2, qu'elle se termine avec le Gly^{15} et ils suggèrent que ceci pourrait être le signal pour la xylosylation de la sérine, Ser^{14}. On a observé un virage de type VIb β impliquant la *cis*-proline C-terminale dans la séquence His-Phé-Pro-Glu.

Mots clés : xylosylation, hélice naissante, hélice α, *cis*-proline, virage de type VIb β, dynamique moléculaire.

Introduction

Proteoglycans (PGs) are extracellular macromolecules that are present in, and profoundly influence physical properties (e.g., resilience and distensibility) of, connective tissues. In non-cartilaginous soft connective tissues such as skin, tendon, ligament, etc., the predominant PGs are decorin and biglycan, which consist of highly homologous protein cores of about 35 kDa (1) to which are attached glycosaminoglycan (GAG) chains of dermatan (DS) or chondroitin sulphate: one in decorin (2) and two in biglycan (3), close to the amino terminus. The GAGs are polyanionic and dominate the properties of the PGs carrying them. The small PGs may affect collagen fibril morphology and (or) the organization of collagen fibrils into fibres and fibre bundles (4). Failure to efficiently synthesize GAG chains on the skin decorin protein core has been linked to the connective tissue derangements seen in progeroid syndrome (5).

Biosynthesis of GAG chains is initiated, probably in the rough endoplasmic reticulum, by the enzyme xylosyltransferase, which transfers xylose from uridine diphosphate (UDP) to certain serines in the protein cores (6). The specificity of xylosyltransferase is incompletely defined, but it is known that a xylosylated serine is immediately N-terminal to glycine (most often) or to alanine (occasionally). Additional recognition factors must be important, however, because the sequences of both decorin and biglycan include several non-glycosylated Ser-Gly and Ser-Ala sequences. Similar uncertainty surrounds the control of O-glycosylation in glycoproteins (7). It has been suggested, on the basis of predictions of secondary structure rather than on direct physical evidence, that serine should be in a β turn in order to be a candidate for glycosylation (8). The earliest sequence information on decorin was used to predict that residues 2–5 (Glu-Ala-Ser-Gly) would adopt a β turn (9). It was subsequently shown (2) that the single dermatan sulfate chain of skin decorin (then called "proteodermatan sulfate") was located on Ser^4. A preliminary circular dichroism study did not detect a β turn in a peptide comprising the amino-terminal 21 residues of bovine skin decorin (10) but, in view of the evidence for proteolytic processing of the protein core subsequent to translation (11), this negative finding cannot be considered a valid test of the hypothesis. This is because the procore of decorin, the probable substrate for xylosyltransferase (11), carries an additional 14 amino acids between the suggested scissile bond for signal peptidase (12) and the N-terminus, and could adopt a distinct secondary structure in this sequence.

In this paper we report a study by NMR and circular dichroism spectroscopy of four peptides. The first peptide comprises the N-terminal 14 amino acids of the mature decorin protein. The second has this same sequence extended in the N-terminal direction by the incorporation of an additional 10 amino acids derived from the procore of decorin. An additional 24-mer in which the methionine was oxidized to the sulfoxide was also studied. The fourth peptide was the 14-mer with an acetyl group at the N-terminal end. This was included in an attempt to differentiate the effect of blocking the N-terminus from the effect of the additional N-terminal sequence in the 24-mer. The results indicate that an α-helix is present and suggest that this could be a signal for xylosylation of serine in this small PG.

Experimental

Sample preparation

The 24 amino acid peptide $CH_3COQKGLFDFMLEDEASGIGPEEHFPENH_2$ was synthesized by the Alberta Peptide Institute. The 14-mer $DEASGIGPEEHFPENH_2$, the acetylated 14-mer $CH_3CODEASGIGPEEHFPENH_2$, and the oxidized 24-mer $CH_3COQKGLFDFM(O)LEDEASGIGPEEHFPENH_2$ were synthesized on a Biolynx™ 4175 manual peptide synthesizer using FMOC amino acid derivatives (Pharmacia Canada Inc., Baie d'Urfe, Quebec). The peptides were purified by reverse-phase high-performance liquid chromatography on a Beckman model 200 HPLC using a Vydac TP218 column (The Separations Group, Hesperia, Calif.). The purification was carried out using a linear gradient of 0–50% acetonitrile in 0.1% (v/v) trifluoroacetic acid. Purity was assessed by amino acid analysis and mass spectrometry. There were no impurity peaks seen in the NMR. These four samples, 24-mer and oxidized 24-mer, 14-mer, and acetylated 14-mer, are abbreviated as NQ24, OQ24, D14, and AD14, respectively, in the following discussion.

Samples for CD experiments were prepared by dissolving purified peptides in water, and the pH was adjusted to 5.5 or 7.0 by adding 50 mM sodium phosphate buffer at that pH. The required volume of methanol was then added.

The samples used for ^1H NMR experiments were prepared by dissolving peptides in H_2O. The pH was then adjusted to 5.5 by adding diluted NaOH or HCl, followed by CD_3OH to make the solvent at 60/40 methanol/water mixture. Before the NMR experiments, the sample was degassed with argon. After 2D experiments, an aliquot of the OQ24 and AD14 samples was diluted tenfold with 60/40 CD_3OH/H_2O for 1D experiments. These dilution experiments indicated that there was no aggregation.

Circular dichroism spectroscopy

The CD spectra were recorded at room temperature on a Jasco JA20 spectropolarimeter with a thermostated cell holder. Mean residue ellipticities, $[\theta]_{mrw}$ (deg cm^2 $dmol^{-1}$), were calculated in the usual fashion using a mean residue weight of 108.1 for the 14-mer and 110.6 for the 24-mer, calculated from the composition of the peptides. Each spectrum is the average of 16 or 32 scans.

NMR spectroscopy

All experiments were carried out on the Varian Unity 500 NMR spectrometer using a proton-selective 5 mm probe with a 90° proton pulse length of about 9.0 μs at normal power levels. During the experiments the temperature was always controlled to ±0.1°C. For data collection and processing, VNMR software (versions 3.2 and 4.1) was used on the Sun Sparc 4/330 and Sparc 4/470 workstations, respectively. 2D spectra were acquired non-spinning, whereas for one-dimensional experiments the spinner was turned on. All chemical shifts are measured relative to the undeuterated fraction of the methyl group of CD_3OH at 3.30 ppm. All two-dimensional NMR experiments (13) were carried out in the phase-sensitive mode by using the hypercomplex technique (States–Haberkorn–Ruben method) (14). The decoupler and transmitter offsets were always set equal, a sweep width of 5000 Hz was used in

both dimensions, and typically 2K (zero filling to 4K) data points in t_2 and 256 points (zero filling to 1K) experiments in t_1 were acquired. All two-dimensional experiments were preceded by 8 dummy scans but none were applied between individual t_1 increments. The preacquisition delay alfa[2] was carefully and individually adjusted for every 2D experiment. First point distortions caused by analog filters (15) were empirically determined values. No further correction routines were necessary.

The TOCSY (16) experiments were carried out using the basic pulse sequence proposed by Bax and Davies (17). Water suppression was achieved by solvent presaturation during the relaxation period. A 2 ms trim pulse preceded the 80 ms MLEV-17 spin-lock (field strength 7.0 kHz). The NOESY (18, 19) experiments were carried out with the 90°–$t1$–90°–t_m–90°–FID pulse sequence and 1.5 s solvent presaturation. For data processing, approximately 90° shifted squared sine bell weighting functions were used in both dimensions.

Distances were calculated from NOESY spectra with a mixing time of 250 ms for all non-trivial cross peaks by integration of their 3D volumes in the following way: (*a*) cross peaks were integrated and carefully checked for contribution from baseline distortions; whenever possible, the volume was measured in both cross peaks, above and below the diagonal, and the two values were averaged to minimize slight phase imperfections; (*b*) where applicable, the volume was normalized for the contributions of more than two protons to the cross peak by a factor $(2N_aN_b)/(N_a + N_b)$, where N_a and N_b are the number of protons responsible for the diagonal peaks a and b, respectively (20); (*c*) the ββ′ interaction of the His and Phe protons was used as reference at 1.8 Å; and (*d*) corrections for isomers arising from *cis*-proline were made. The internuclear distance r was then calculated since the NOESY cross-peak volume is proportional to $1/r^6$ (21).

Molecular modeling

The program BIOGRAF (Version 3.2.1, Molecular Simulations, Inc. Burlington, Mass., U.S.A.) on the Sun SPARC 470 Workstation (Sun OS 4.1.3 operating system) was used for all calculations. The program Hyperchem (Release 2, Autodesk, Inc.) was used for plotting the stereo structures. The Dreiding II force field was used for all calculations. For all energy minimizations, the conjugate-gradient method was used; 400–800 steps were typically needed for convergence (less than 0.1 kcal mol^{-1} RMS force). Distribution of charges was calculated by the Gasteiger method (22). All simulations were carried out for the molecule with all hydrogen atoms. The dielectric constant of a vacuum ($\epsilon = 1$) was used for all calculations. The molecular dynamic runs were performed with 1 fs steps at 300 K, unless another temperature is mentioned. The list of nonbonded interactions and hydrogen bonds was updated every 0.1 ps during the dynamic runs and every 50 steps during energy minimizations. Cutoff distance for this list was 9 Å. In the Monte Carlo searches, all dihedral angles were set to random values except angles in rings and ω dihedral angles in the backbone.

The acetylated 14-mer (AD14) and acetylated 24-mer with nonoxidized methionine residues (NQ24) were built and subjected to molecular modeling. Where applicable, the constraints used for the first structure were those listed in Table 1 for the *trans*(Pro[8])-*cis*(Pro[13]) (TC) isomer of AD14. For the second structure, constraints used are listed in Table 2 for the *trans*(Pro[18])-*trans*(Pro[23]) isomer (TT). These constraints were calculated from the NOESY spectra of OQ24 since these spectra were better resolved in comparison with that of NQ24, where heterogeneity caused by the *cis* prolines produced more overlap.

Both structures were subjected to the Monte Carlo search: 50 conformers were generated and minimized without solvent shell. All atoms were set movable and all NOESY restraints were applied with a maximum force of 1000 kcal $Å^{-1}$ mol^{-1}. For both structures, the coordinates of the areas of interest (residues 11–14 for the 14-mer and 3–11 for the 24-mer) in the three lowest energy conformers were matched. Resulting structures were averaged and minimized with constraints. Minimized structures were solvated with water (diamond grid, 2.8 Å distance between solvent molecules, 2.6 Å inner cutoff of shell from peptide, 6.6 Å outer cutoff) and the whole system was minimized again. The unsolvated 24-mer and solvated 14-mer and 24-mer were subjected to 100 ps dynamic runs. The first 80 ps were constrained, the last 20 ps were unconstrained. Every 1 ps the structure was written to the trajectory. Coordinates of 20 conformers from the last 20 ps were averaged (peptide only), resolvated where dynamic runs were performed with the solvent shell, and minimized. Backbone dihedral angles of the resulting structures are given in Table 3.

The structure of the nascent helix was also tested by the following procedure: The N-terminal part of the 14-mer (residues 1–10) was folded into an α-helix with backbone torsion angles $\phi = -57°$, $\psi = -47°$, and $\omega = 180°$ and the resulting structure was subjected to constrained minimization. Then a constrained dynamic run of overall length 20 ps was performed. Every 1 ps the structure was minimized without constraints and written to the trajectory file.

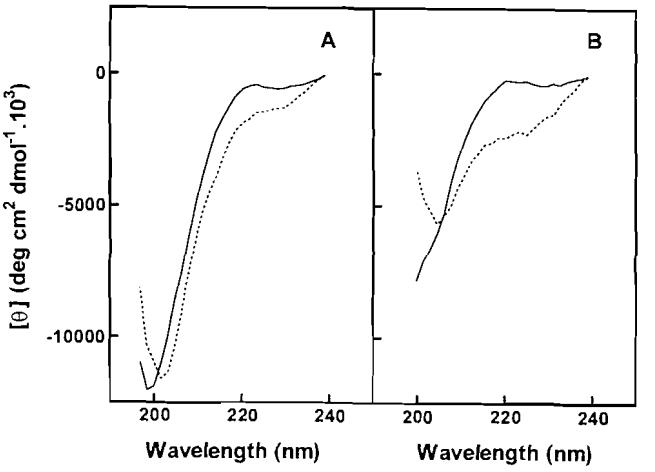

Fig. 1. Circular dichroism spectra of unacetylated 14-mer (*A*) and acetylated 24-mer (*B*) in 0.05 M sodium phosphate buffer (—) pH 5.5 or in 60% methanol/40% sodium phosphate buffer (----). See text for other details.

Results

Circular dichroism spectroscopy

The spectra in Fig. 1 show that both the unacetylated 14-mer

[a]The residue numbers are from 1 to 14.

and the acetylated 24-mer possessed little, if any, regular secondary structure in a purely aqueous solvent. Including methanol at 60 or 70% (v/v), however, induced some secondary structure, more marked in the 24-mer than the 14-mer. Replacing the methanol with an equal volume of trifluoroethanol gave identical spectra, as did altering the pH from 5.5 to 7 (data not shown).

NMR spectroscopy

The resonance assignments (Table 4) of the peptides studied are based on TOCSY experiments and sequential NOEs of the type $\alpha(i)$-NH(i + 1), NH(i)-NH(i + 1) and $\beta(i)$-NH(i + 1) (21). The *trans* isomers of the two prolines predominate but assignment problems arose from the presence of the *cis* isomers. The *cis* form allows much closer contacts between αCH(i) and αCH(i + 1) and between NH(i) and αCH(i + 1), whereas the *trans* form favors short distances between αCH(i) and $\delta CH_2(i$ + 1) and between NH(i) and $\delta CH_2(i$ + 1). The presence of *cis* isomers for the two prolines was unequivocally shown by diagnostic NOESY cross peaks (see Fig. 2*a*). The strong cross peaks between αCH of Phe^{12} and δCH_2 of Pro^{13}, between αCH of Gly^7 and δCH_2 of Pro^8, between δCH_2 of Pro^{13} and NH of Glu^{14}, and between δCH_2 of Pro^8 and NH of Glu^9, show that these two prolines are mainly in the *trans* conformation. The two weaker sets of cross peaks between αCH of Phe^{12} and αCH of Pro^{13} and between αCH of Pro^{13} and NH of Glu^{14} show the presence of the *cis* form of the Pro^{13}. The small proportion of *cis* isomer to Pro^8 was demonstrated by the weak interactions between αCH_2 of Gly^7 and αCH of Pro^8 (see Fig. 2*a*). Weak intra-residue interactions between αCH_2 and NH of Gly^7 could also be observed (see Fig. 5); however, the low population precluded obtaining further NOE interaction patterns for this *cis* isomer. No further interactions of the α protons between Gly^7 and Pro^8 and between Phe^{12} and Pro^{13} were detected, so three isomers arising from *cis* proline were found. They were: *trans*(Pro^8)-*trans*(Pro^{13}) (TT); (TC); and *cis*(Pro^8)-*trans*(Pro^{13}) (CT). Resonance heterogeneity arising from *cis* Pro^8 and *cis* Pro^{13} can be found in the region of I^6-G^7-P^8-E^9-E^{10}-H^{11}-F^{12}-P^{13}-E^{14}-NH_2 and in the region of E^9-E^{10}-H^{11}-F^{12}-P^{13}-E^{14}-NH_2, respectively. Selected regions of the spectra are shown in Fig. 2*b* and Fig. 2*c*. The observed resonance heterogeneity, illustrating these effects, is summarized in Fig. 3.

By comparing the integration of the terminal NH in one-dimensional spectra, the TT, TC, and CT isomers were found at a ratio of about 68:25:7 for AD14. The observed NOEs for the TT and TC isomers are summarized schematically in Fig. 4. An observed medium-range NOE between αCH of Phe^{12} and NH of Glu^{14} (Fig. 5) suggests the presence of a turn, and molecular modeling shows a type VIb β turn, where Pro^{13} would be in the i = 2 position in the turn. No further medium- or long-distance NOEs were detected for the CT isomer due to its low abundance. The three isomers discussed above exist in the same proportion in all peptides studied.

Part of the NOESY spectrum of AD14 is shown in Fig. 5. Similar NOE patterns were observed for the peptides AD14

Table 4. ^{1}H NMR resonance assignments[a] and NH temperature coefficients[b] of the peptides studied: (*a*) AD14[c] and D14[d], (*b*) NQ24[e], and (*c*) OQ 24[f].

[a]Chemical shifts are reported in ppm relative to the methyl group of CD_3OH at 3.30 ppm downfield from tetramethylsilane (TMS). Only parts of data are shown here.

[b]The temperature coefficients are the result of a linear regression analysis of the chemical shifts measured from TOCSY spectra at 5°C intervals from 5°C to 30°C.

[c]The data were recorded at 500 MHz in CD_3OH/H_2O (60/40 v/v%) at a concentration of 2.3 mM. The pH was 5.5 in water, and the temperature was 10 ± 0.1°C.

[d]The NH temperature coefficients of peptide D14 are shown in parentheses. The data were recorded at 500 MHz in CD_3OH/H_2O (60/40 v/v%) at a concentration of 1.6 mM, the pH was 5.5 in water.

[e]The data were recorded at 500 MHz in CD_3OH/H_2O (60/40 v/v%) at a concentration of 1.7 mM. The pH was 7.0 in 25 mM buffer, and the temperature was 15 ± 0.1°C. Only the data for the TT isomer are shown here. The NH temperature coefficients of peptide OQ24 are shown in parentheses. The data were recorded at 500 MHz in CD_3OH/H_2O (60/40 v/v%) at a concentration of 2.0 mM, the pH was 5.5 in water.

[f]A doubling of peaks is due to equal amounts of *R* and *S* sulfoxides.

[g]Average value of the data in Table 4*c*.

[h]Assignments may be interchanged and are ambiguous due to spectral overlap.

and D14: continuous dNN(i,i + 1) connectivities, consecutive weak dαN(i,i + 2) connectivities, and the lack of i,i + 3 medium-range NOEs show that these two peptides have a similar conformation, that is, a nascent helix (23), which is characterized by an ensemble of turnlike structures in the early stages of helix formation (24). There are close connections between chemical shifts and the local secondary structure (25, 26). The net structural shifts obtained by comparing the chemical shift with the random structure (22) for the peptides studied are shown schematically in Fig. 6. The closely similar net shift patterns indicate similar structures for D14 and AD14. The more negative value of D1 of peptide D14 is attributed to the effect of the positive charge at the N-terminus. The NH temperature coefficients (see Table 4) also confirm a similar structure for each pair of peptides. This agrees with the CD results, which were identical for D14 (Fig. 1) and AD14 (not shown).

The presence of the sulfoxide in the Met residue in peptide OQ24 splits the peaks of M^8 into two signals of equal intensity, indicating that equal amounts of sulfoxides with *R* and *S* configuration were formed (27). The NH peaks of Leu^9 and Glu^{10} were also doubled (Table 4*c*). However, the NMR studies show that the sulfoxide group has no effect on the OQ24 peptide conformation. The peptides NQ24 and OQ24 have the same conformation. The medium-range (i)–(i + 3) NOEs (part of data is presented in Fig. 7), low temperature coefficients (see Table 4), and the α-proton shifts (25, 26) (see Fig. 6) indicate that the peptides OQ24 and NQ24 adopt an α-helical

Fig. 2. The contour plots of the two-dimensional 500 MHz NMR spectra of peptide AD14. The concentration was 2.3 mM at pH 5.5 (measured in H_2O) in CD_3OH/H_2O (60/40 v/v%), temperature 10 ± 0.1°C. (*a*) The αH-βH region of the NOESY spectrum, mixing time 250 ms. (*b*) Part of αH-NH region of the TOCSY spectrum. (*c*) Part of NH-βH region of the TOCSY spectrum.

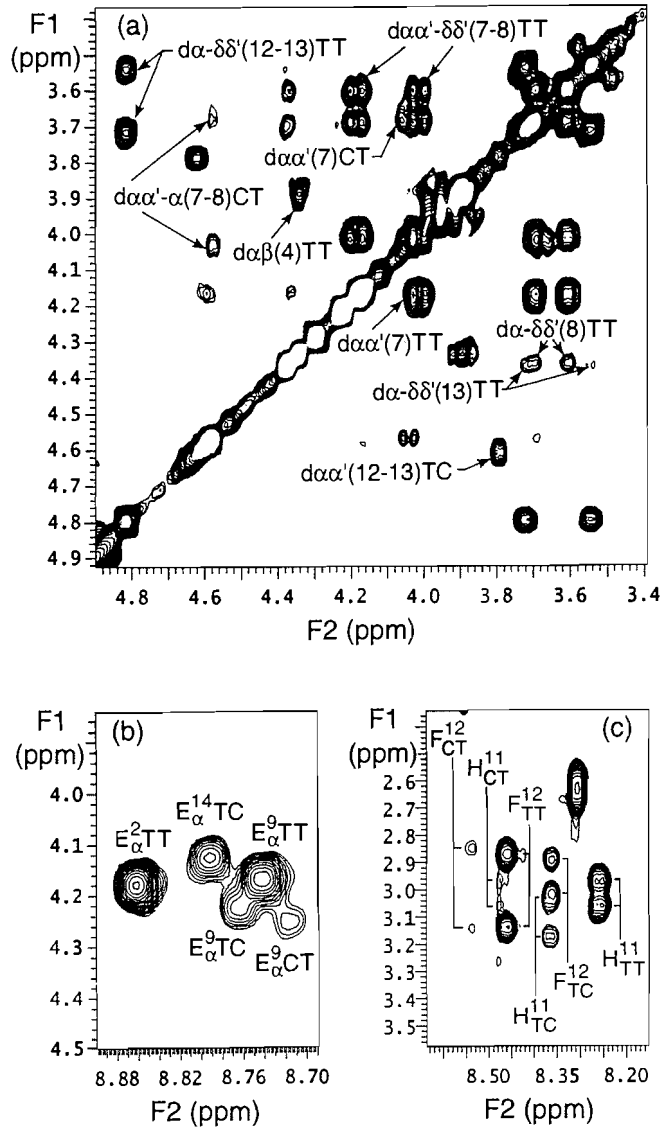

Fig. 3. The observed resonance heterogeneity caused by *cis–trans* isomerization of the prolines in AD14.

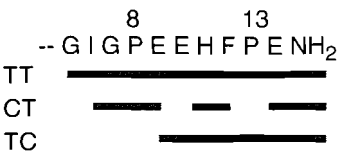
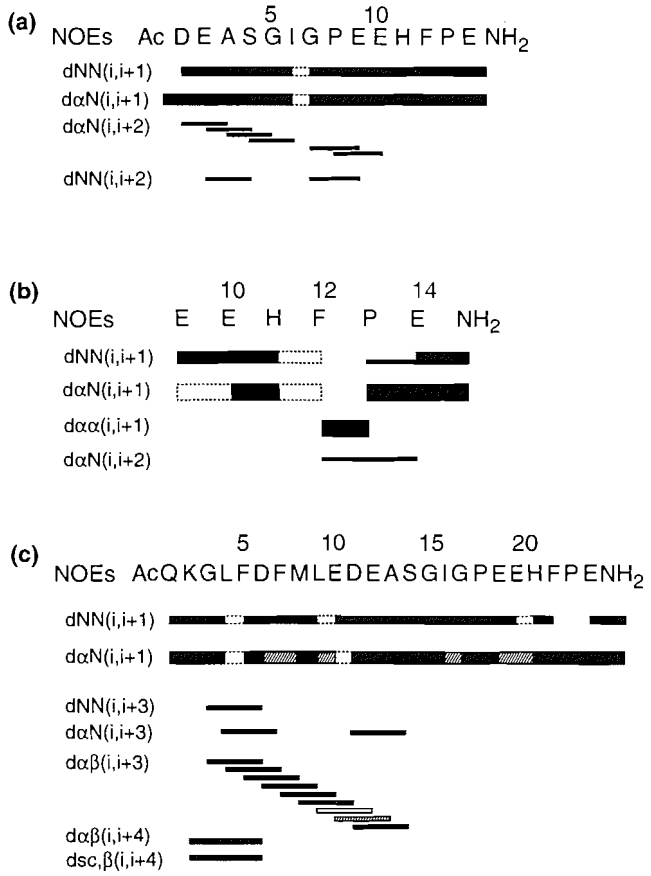


structure from the N-terminus to around Gly^{15}. The low temperature coefficients from Asp^6 to Gly^{15} indicate that the NH protons are protected from solvent and probably hydrogen-bonded.

All of the above data have been correlated with the molecular modeling. As was mentioned above, both 14-mers measured give the similar set of NOESY cross speaks useful for the calculation of distance constraints; in the case of the 24-mers, the situation is similar. Furthermore, the C-terminal part of all peptides shows the same NMR patterns (NOESY, chemical shifts, temperature dependencies, *cis–trans* isomerization); therefore, the proposal that the C-terminus of all peptides has the same conformation is reasonable. Two structures were built for evaluation by molecular modeling: (*i*) AD14 with a *cis* bond between Phe^{12} and Pro^{13} for the evaluation of the nascent helix in the N-terminal part of the peptide and the nature of the turn at the C-terminus: nascent helix is present in both 14-mers, and the C-terminal turn is present in all peptides with a *cis* proline in position 13 for the 14-mers or position 23 for the 24-mers; (*ii*) acetylated 24-mer (NQ24) with all peptide bonds *trans* for the determination of the structure of the α-helix at the N-terminus of both 24-mers.

Fig. 4. Survey of NOE effects recorded for the peptides studied: (*a*) AD14, (*b*) part of AD14 for TC conformation, (*c*) OQ24. For the proline, δ protons are used instead of the NH proton. Solid lines (■) indicate unambiguous NOEs, hatched lines (////) indicate NOEs that are ambiguous due to spectral overlap, and blank spaces ( ) indicate that an NOE was not observed because of overlapping chemical shifts. The thickness of the bars indicates the strength of the NOE.



The NOESY spectra for the N-terminal part of AD14 show a series of $i,i+2$ connectivities. In this part of the peptide, low temperature dependencies for the NH protons are also observed. Similar sequences of $i,i+2$ NOE connectivities were observed by Dyson et al. for some short peptides (23, 24,

Fig. 5. The αH-NH region of the 500 MHz phase-sensitive NOESY spectra of AD14. The experimental conditions were the same as outlined in Fig. 2*a* and interesting NOEs are labelled.

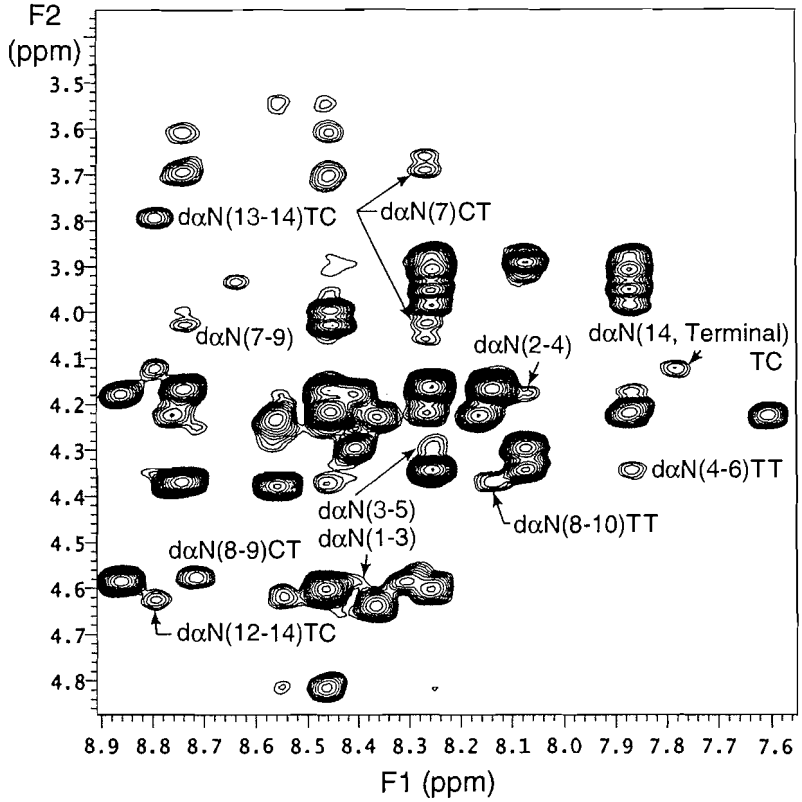


Fig. 6. Net structural shifts of the α proton (□) for peptides (*a*) AD14, (*b*) D14, (*c*) OQ24, and (*d*) NQ24. (■) α′ proton for Gly. For Gly[15] in OQ24 and NQ24, the chemical shifts of the αα′ protons are very similar, hence the average value is used.

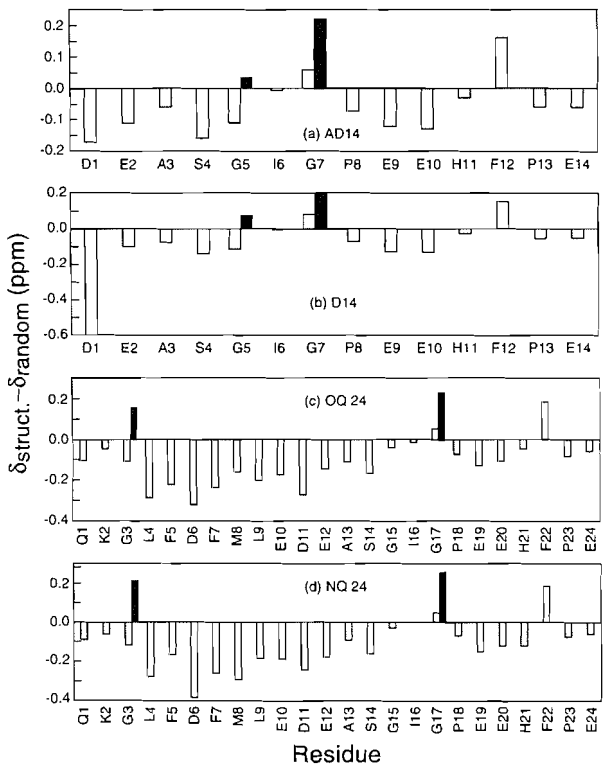
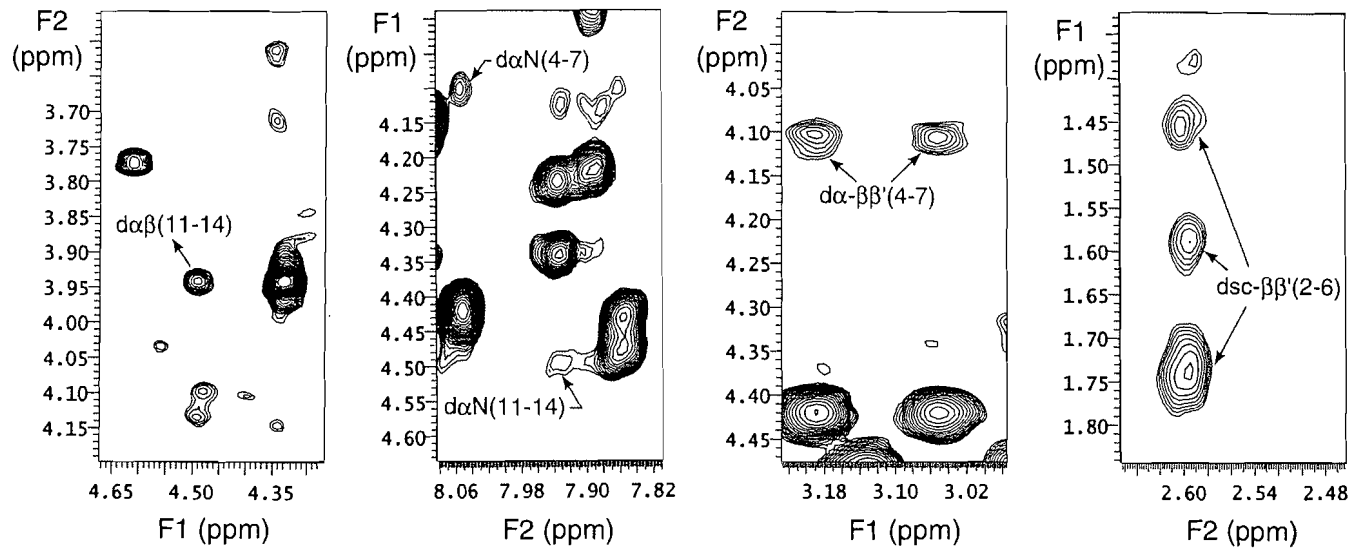


28). This structural element was named the "nascent helix" and it was assumed to consist of rapidly interconverting turns. Recently the term "nascent helix" was also used for small populations of the helical structure in solution (29). Our nascent helix in the 14-mer is a typical case of rapidly interconverting turns. No $i,i+3$ connectivities characteristic for an α-helix were found and the absence of helical fragments is also seen in the CD spectra. Our modeling study started with constrained minimization of randomly generated conformers. Some helical structures were obtained, but these structures quickly unfold when constraints are removed. Unfolding leads to structures with most $i,i+2$ distances observed in the NOESY spectra between 4 and 7 Å. Also, a dynamic run starting from the α-helix (see Experimental) shows an instability of the whole system. From 20 conformers, 11 relax after removing the constraints to the fragments of an α-helix, and 9 relax to structures containing one or two ideal or nonideal turns, mainly type II β-turns. These calculations are in agreement with Dyson et al. (23, 24, 28), namely, that no stable structure is characterized by consecutive $i,i+2$ NOE connectivities, and these connectivities arise from random structures containing some population of turn in various positions. Table 3, column A, gives the backbone dihedral angles for the averaged structure from the last 20 ps of the 100 ps dynamic run (see Experimental). It is seen that this structure relaxes to a random coil with a nonideal type I β-turn in positions Ser[4] to Gly[7].

The same modeling of the AD14 reveals the nature of the C-terminal turn in the conformations containing the *cis*-peptide

Fig. 7. Parts of the contour plot of the two-dimensional 500 MHz NMR NOESY spectrum of peptide OQ24, mixing time 250 ms. The concentration was 2.0 mM at pH 5.5 (measured in H_2O) in CD_3OH/H_2O (60/40 v/v%), temperature 15 ± 0.1°C.



bond between Phe[12] and Pro[13]. Because of the low population of *cis* peptide, no additional constraints to the basic *i,i* + 2 were available, and the Monte Carlo search with constrained minimization led to various turns. The average of the dynamic run starting from the three best conformers led to the nonideal type VIb β-turn (30) (see Table 3, under (A)) as the most probable or most populated conformation for the C-terminus for our peptides containing *cis*-proline. Figure 8*A* shows the averaged minimized structure for the 14-mer with *cis*-proline in position 13; the stereo view of the same structure is in Fig. 9. Figure 8*B* represents the match of the last 20 conformers from the 100 ps dynamic run.

The average conformer from the Monte Carlo search of the 24-mer was subjected to dynamic runs without solvent as well as in the solvent (water) shell. Figure 8*C* shows the averaged minimized structure for the 24-mer with all bonds *trans* modeled without solvent; the backbone data for this structure are listed in Table 3, under (B). Figure 8*D* shows a match of the last 20 conformers from the dynamic run. Figure 10 represents the stereo view of the average minimized structure of the peptide after modeling with the shell of solvent. Backbone data for this structure are in Table 3, under (C). Both structures exhibit a helical structure from Lys[2] to Gly[15]. Analysis of the chemical shifts of the α protons and NOE connectivities shows a continuous helical structure; the temperature dependencies of the NH protons suggest possible disruptions of helix at residues 8 and 11. The structure modeled without solvent shell exhibited disruption of the helical structure at residue 13. This is probably caused by an over-estimation of repulsion between charges in the preceding residues during the calculation "in vacuo." When the dynamic run is performed with peptide in the water shell, the structure of the helix is improved (see data in Table 3, compare data under (B) and (C)). Finally, dihedral angles at the C terminal end of the helix (involving residues 14–17) are similar to those for a type I β-turn.

Discussion

A comparison of the data for the acetylated 14-mer (AD14) with the unacetylated 14-mer (D14) indicates a nascent helix in both peptides. This is consistent with the N-terminal capping preferences for amino acids (31) in α-helical peptides. For example, for the acetyl group the helix fraction is 0.578, whereas when the charged Asp is the N-terminal amino acid with a charged NH_3^+ N-terminus, the fraction of helix for the same control peptide is 0.527 (31).

At the C-terminal end of the peptides, the temperature coefficients and α-proton shifts show that the sequence Ile-Gly-Pro-Glu-Glu-His-Phe-Pro-Glu is of the same conformation in all four peptides studied. The overlap of the spectra and the resonance heterogeneity caused by the prolines prevent further conclusions. The unique ability of the proline to form *cis* peptide bonds and undergo *cis–trans* isomerization (32, 33) is well known. The significance of the study of the isomerization of the proline is twofold: first, the isomerization of proline induces resonance heterogeneity for amino acids adjacent to it; on the other hand, the *cis* and *trans* isomerization forms differ in their solution conformation and are of biological significance (33). In this paper, the peptides have two proline residues and, statistically, four possible isomers could be produced, but in fact three were found.

The addition of the N-terminal 10 amino acids in the 24-mers forms a complete helix ranging from the N-terminal end Lys[2] to Gly[15]. Consequently, the region of interest D^{11}-E^{12}-A^{13}-S^{14}-G^{15} is part of the α-helix, and the N-terminal 10 amino acids promote the α-helix character for this region of the peptide that contains the S that is xylosylated in decorin. Bourdon et al. (34) carried out a kinetic analysis of the xylose-acceptor efficiencies (V_{max}/K_m) of two peptides: FMLE-DEASGIGP and CDEASGIGPEVPDDRD related to human decorin and several variants of these. Both peptides were

acceptors, indicating that they contain the minimum recognition sequence for xylosyltransferase activity, which may be SGXG (34). The N-terminal cysteine in CDEASGIGPEVPDDRD (which is not present in decorin) may be analogous to the N-acetyl group in the 14-mer studied here. It would be of interest to study the solution conformations of these peptides to determine whether they adopt the (nascent) helical structures described here.

While the adoption of an α-helical conformation by the N-terminal segment of the 24-mer could have been predicted from the amino acid sequence by the method of Chou and Fasman (35), the conclusion of the first 5 amino acids (DEASG) of the mature proteoglycan in this helix is somewhat unexpected because this segment was originally predicted to adopt a type I β-turn (9), and these are usually considered to disrupt helices (35). In either a β-turn or an α-helix, the serine (S^{14}), which in decorin becomes xylosylated, would be exposed on the outside of a turn. This may be one structural factor controlling glycosylation enzyme activity (8).

The N-terminal portion of the helix in the 24-mer shows a peak of hydrophobicity and amphipathicity, detected by the sequence helical hydrophobic moment method of Eisenberg (36; data not shown), centered around F^5. Amphipathic helices are found on the surfaces of globular proteins and are common in α/β proteins, the structural class to which decorin and the other small proteoglycans almost certainly belong (10). This helix could thus serve to position the consensus xylosylation sequence for accessibility to xylosyltransferase.

Conclusions

Asp^1-Glu^2-Ala^3-Ser^4-Gly^5 (DEASG) at the N-terminal end of the 14-mer peptide forms a nascent helical structure. Acetylation of the N-terminus has no effect on the structure. The addition of a further 10 amino acids to the N-terminus forms a helical structure that begins at the N-terminus Lys^2 and ends at Gly^{15}. A type VIb β-turn has been observed, involving the C-terminal *cis*-proline in the sequence His^{11}-Phe^{12}-Pro^{13}-Glu^{14} based on the observed NOE spectra and the modeling of the AD14.

Calculation of phase diagrams and thermodynamic properties of 18 binary common-ion systems of Na,K,Ba//F,MoO_4,WO_4

James Malcolm Sangster

Abstract: Phase diagram and thermodynamic data of 18 binary common-ion molten salt systems in Na,K,Ba//F,MoO_4,WO_4 were optimized by computer algorithm. The phase diagram data as well as single-salt data were retrieved from an extensive critical literature search. Expressions for the excess properties of solution phases and thermodynamic properties of intermediate compounds were thereby obtained. These data were used to generate a "best" phase diagram for each binary system considered.

Key words: molten salts, phase diagrams, thermodynamic properties.

Résumé : On a fait un lissage par ordinateur des données thermodynamiques et des diagrammes de phases de 18 systèmes de sels fondus d'ions communs représentés par Na,K,Ba//F,MoO_4,WO_4. Les données de diagramme de phases et des sels purs ont été obtenues à moyen d'une recherche critique bibliographique assez complète. On a donc obtenu des expressions analytiques pour les propriétés en excès des solutions ainsi que les propriétés thermodynamiques des composés intermédiaires. Ces expressions ont été utilisées dans le calcul du diagramme de phases de chaque système.

Mots clés : sels fondus, diagrammes de phases, propriétés thermodynamiques.

[Traduit par la rédaction]

Introduction

The thermodynamic basis for the calculation and interpretation of phase diagrams is well known (1). Once the thermodynamic properties of simple and solution phases are known, a computer can be used to carry out the iterative process involved in calculating the phase boundaries at equilibrium (2). This is a general approach, which can and has been adapted successfully to the calculation of binary and ternary phase diagrams of alloy systems (3, 4), common-ion and reciprocal ternary molten salt systems (5–8), and organic systems (9–11). In this article, this type of calculation is applied to binary molten salt systems containing cations Na,K,Ba and anions F,MoO_4,WO_4.

Critical analysis of thermodynamic/phase diagram data for binary common-ion molten salt systems

A critical analysis of the phase diagram and thermodynamic data of 18 binary common-ion molten salt systems was accomplished with the use of a computer-assisted technique already used for 70 binary alkali halide systems (12). The method is described in some detail in the previous work (12) and is summarized here. An exhaustive literature search was made for phase diagram and thermodynamic data for each system; all references are included here. These data were optimized simultaneously with the use of the computer algorithm to yield analytical expressions that best represent the thermodynamic properties of the solution and intermediate phases. These expressions were then used to generate the phase diagrams (13). The interactive computer programs used (13) are available on-line, as well as in personal computer version on diskette, available from the author. Such phase diagrams automatically incorporate necessary thermodynamic constraints, such as the Gibbs–Duhem relation, the phase rule, the correct limiting liquidus slopes, etc. As in the previous work (12), data not tabulated in original publications were read off published phase diagrams.

Properties of the pure components

The calculational procedure outlined above requires expressions for the Gibbs energy of transition and fusion of the solid components involved. These thermodynamic properties, which were used in the calculation of the final phase diagrams, are summarized in Table 1. These data were based on information from standard sources (14–18). For some salts involved in the present work, these sources differed significantly among themselves, and some necessary data were missing and hence had to be estimated. The choice of data finally adopted for each salt is discussed in the Appendix.

Common anion systems

KF (A) – NaF (B)

This system was examined in a previous publication (12) and no new data have since appeared to necessitate a revision. It is a simple eutectic system with a limited solid solution based on KF. The results (12) are summarized here. The excess enthalpy of the liquid

[a]Sufficient significant figures are given to enable accurate reproduction of phase diagrams.

[1] $H^E(l) = -355x_Ax_B$ J mol^{-1}

was measured calorimetrically and the excess entropy was

[2] $S^E(l) = -2.541$ J mol^{-1} K^{-1}

The solid solution was represented by a Henrian activity coefficient

[3] $RT \ln \gamma_B = 24\,770$ J mol^{-1}

which was assumed to be temperature independent. The calculated eutectic was 719°C, $x_B = 0.400$ and there was 5 mol% solubility of NaF in KF at the eutectic temperature. An uncertainty of ±5°C was assigned to this calculated phase diagram (12).

BaF_2 (A) – KF (B)

Phase diagram data were obtained by the visual-polythermal method (19) and thermal analysis (20). Neither work mentions the BaF_2 transition at 1207°C. A eutectic summary is given in Table 2. The excess enthalpy of the liquid was determined at 1081°C by solid–liquid mixing calorimetry (21), and the result is

[4] $H^E(l) = x_Ax_B(-14\,700 - 1580x_A - 1240x_A^2)$ J mol^{-1}

The liquidus data of Pushin and Bashov (20) are obviously faulty near $x_B = 0$. For the optimization, only liquidus data at $x_B > 0.4$ were used, together with eq. [4], to deduce one excess entropy coefficient:

Table 2. Reported eutectic data for BaF_2 (A) – KF (B).

T (°C)	x_B	Ref.
750	0.70	20
729	0.73	19
729	0.74	22

[5] $S^E(l) = -15.224x_Ax_B$ J mol^{-1} K^{-1}

The phase diagram, Fig. 1, was calculated with the use of eqs. [4] and [5] and shows a calculated eutectic at 745°C, $x_B = 0.711$. A much more strongly composition-dependent excess entropy would allow the calculated liquidus to better approximate the liquidus data of ref. 19, but it would then show a marked inflection on the LHS; the behaviour shown in Fig. 1 was judged to be more probable. The BaF_2 transition appears on the calculated liquidus at $x_B = 0.184$. An uncertainty of ±20°C may be assigned to the calculated diagram.

BaF_2 (A) – NaF (B)

Phase diagram data were obtained by thermal analysis (23) and by the visual-polythermal method (24). A eutectic summary is given in Table 3. The excess enthalpy of the liquid was determined at 1081°C by solid–liquid mixing colorimetry (21) and the result is

Fig. 1. The system BaF_2 (A) – KF (B). ×: ref. 19; ●: ref. 20.

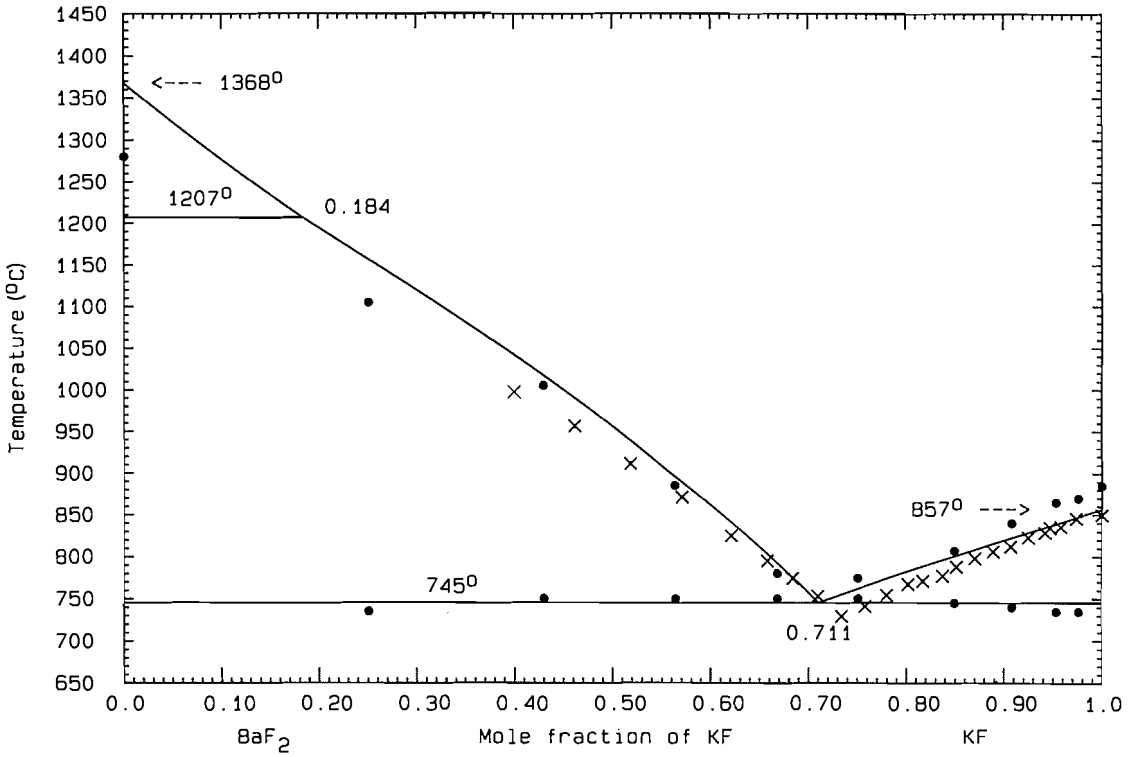

Table 3. Reported eutectic data for BaF_2 (A) – NaF (B).

T (°C)	x_B	Ref.
812	0.63	24
823	0.56	23
820	0.63	25

Table 4. Reported invariant points for $BaMoO_4$ (A) – K_2MoO_4 (B) from ref. 26.

	T (°C)	x_B
Eutectic	924	0.91
Peritectic	1067	0.51
Maximum	936	0.97
Eutectoid	455	0.95

[6] $H^E(l) = x_A x_B(-2670 - 105x_A - 1160x_A^2)$ J mol^{-1}

The BaF_2 transition at 1207°C is not mentioned in either investigation (23, 24) and the liquidus data of Grube (23) on the LHS are clearly in error. In the optimization, the excess enthalpy, eq. [6], was used together with the liquidus data of Grube (23) at $x_B > 0.6$ and all the data of the other report (24), to give one excess entropy coefficient

[7] $S^E(l) = -1.7211x_A x_B$ J mol^{-1} K^{-1}

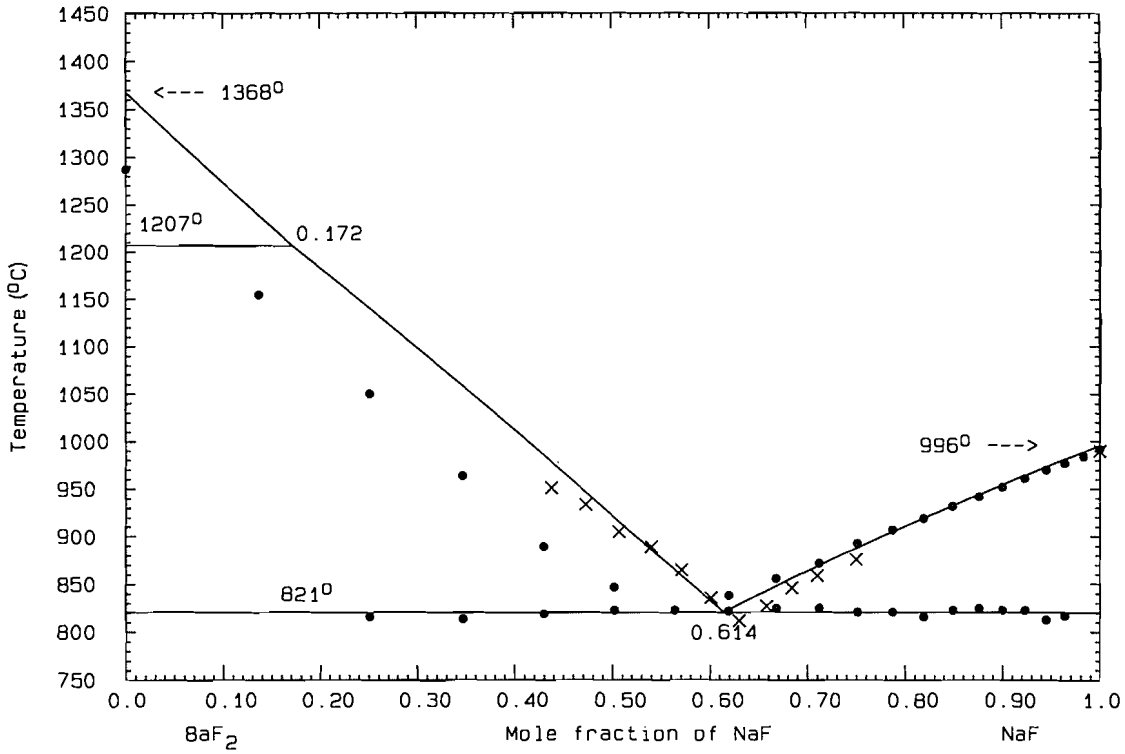
The phase diagram was calculated with the use of eqs. [6] and [7] and is shown in Fig. 2. The calculated eutectic is 821°C, $x_B = 0.614$ and the calculated liquidus agrees well with the selected liquidus data. The BaF_2 transition appears on the calculated liquidus at $x_B = 0.172$. An uncertainty of ±10°C may be assigned to the calculated diagram.

$BaMoO_4$ (A) – K_2MoO_4 (B)

The phase diagram was investigated by the visual-polythermal method, thermal analysis, and X-ray diffraction (26). The reported invariant points are summarized in Table 4. The X-ray diffraction data of the compound were indexed according to trigonal symmetry for the 1:1 stoichiometry $K_2Ba(MoO_4)_2$ (a = 0.606 nm, c = 2.134 nm, Z = 3, space group $R3m$), isostructural with $K_2Pb(SO_4)_2$ (palmerite). The local maximum at $x_B = 0.97$, apparently well established by thermal analysis (26), is an unusual feature not often observed in molten salt systems. Similar maxima apparently occur in the systems Na,Ca//CO_3 (27), Na,Ba//SO_4 (28), an Na,Ca//SO_4 (29). Such a maximum, very close to the pure salt composition, has puzzled investigators; it is apparently not due to the presence of a compound. It has been suggested (30) that in these cases the multiply charged cation enters the sublattice of the singly charged cation, thereby creating vacancies and stabilizing the structure (30). Whatever the explanation, this effect is very difficult, if not impossible, to reproduce with the use of simple thermodynamic models. For present purposes, the maximum was ignored and a solid solution was included to reproduce the observed eutectic. The limited number of liquidus data (none above 1109°C) could be well accounted for by an excess Gibbs energy of the liquid

[8] $G^E(l) = -10\,000x_A x_B$ J mol^{-1}

Fig. 2. The system BaF_2 (A) – NaF (B). ●: ref. 23; ×: ref. 24.



and properties for the 1:1 compound, $(K_2MoO_4 \cdot BaMoO_4)/2$, as follows:

[9] $\Delta_{fus}G^0 = 61\,333 - 45.7628T$ J mol^{-1}

[10] $\Delta_fG^0 = -63\,833 + 40.0000T$ J mol^{-1}

The solid solution was represented by a Henrian activity coefficient

[11] $RT \ln \gamma_A = 7000$ J mol^{-1}

assumed to be temperature independent. The phase diagram, Fig. 3, was calculated with the use of eqs. [8], [10], and [11]. The calculated eutectic is 922°C, $x_B = 0.900$, and the calculated peritectic is 1067°C, $x_B = 0.513$. The solid solution extends practically to the eutectic composition. The calculated eutectoid is 470°C, $x_B = 0.966$. The reported eutectoid (26) is not thermodynamically consistent with the limited extent of solid solution observed (26). An uncertainty of ±20°C may be assigned to the calculated phase diagram.

$BaMoO_4$ (A) – Na_2MoO_4 (B)

Data for this system were obtained by thermal analysis (31, 32) and the visual-polythermal method (32). The reported eutectic (32) was 685°C, $x_B = 0.92$ or (31) 678°C, $x_B = 0.90$. The existence of a solid solution based on Na_2MoO_4 was claimed (31), together with a local maximum at 694°C, $x_B = 0.96$. No such solid solution was mentioned in the other report (32), although the liquidus data near $x_B = 1$ of these authors (32) could be interpreted as evidence for a maximum. As explained in the analysis for the analogous $BaMoO_4$–K_2MoO_4 above, such a maximum might exist. Again, as in the analogous system, this possible maximum was ignored and a limited solid solution was included in the calculated phase diagram since the experimental limiting liquidus slope (32) definitely indicates the presence of such a solid solution.

The liquidus data of Petrosyan et al. (32) show an inflection point, unusual curvature, and abrupt descent to the eutectic; such behaviour is rather unlikely for a simple eutectic system. The liquidus data of Posypaiko et al. (31) were therefore optimized, with the result

[12] $G^E(l) = x_Ax_B(-16\,300 + 24\,212x_B - 7723x_B^2)$ J mol^{-1}

The solid solution was represented by a Henrian activity coefficient

[13] $RT \ln \gamma_A = 20\,000$ J mol^{-1}

assumed to be independent of temperature. The phase diagram Fig. 4, was calculated with the use of eqs. [12] and [13] and shows a calculated eutectic of 686°C, $x_B = 0.900$, with 8.1 mol% solid solubility of $BaMoO_4$ in Na_2MoO_4 at the eutectic temperature. There is a calculated eutectoid at 593°C, $x_B = 0.938$. An uncertainty of ±10°C may be assigned to Fig. 4.

$BaWO_4$ (A) – K_2WO_4 (B)

Scanty liquidus data were obtained by the visual-polythermal method (31); these data were read off the limiting binary edge of a ternary phase diagram. These authors reported a eutectic at 924°C, $x_B = 0.62$, together with "restricted solid solutions." No subsolidus data are available. The stoichiometry of the intermediate compound was established (31) by X-ray analysis (data not reported) to be 1:1. The compound $K_2Ba(WO_4)_2$ is apparently isostructural with $K_2Ba(MoO_4)_2$ and hence with

Fig. 3. The system $BaMoO_4$ (A) – K_2MoO_4 (B). ●: ref. 26.

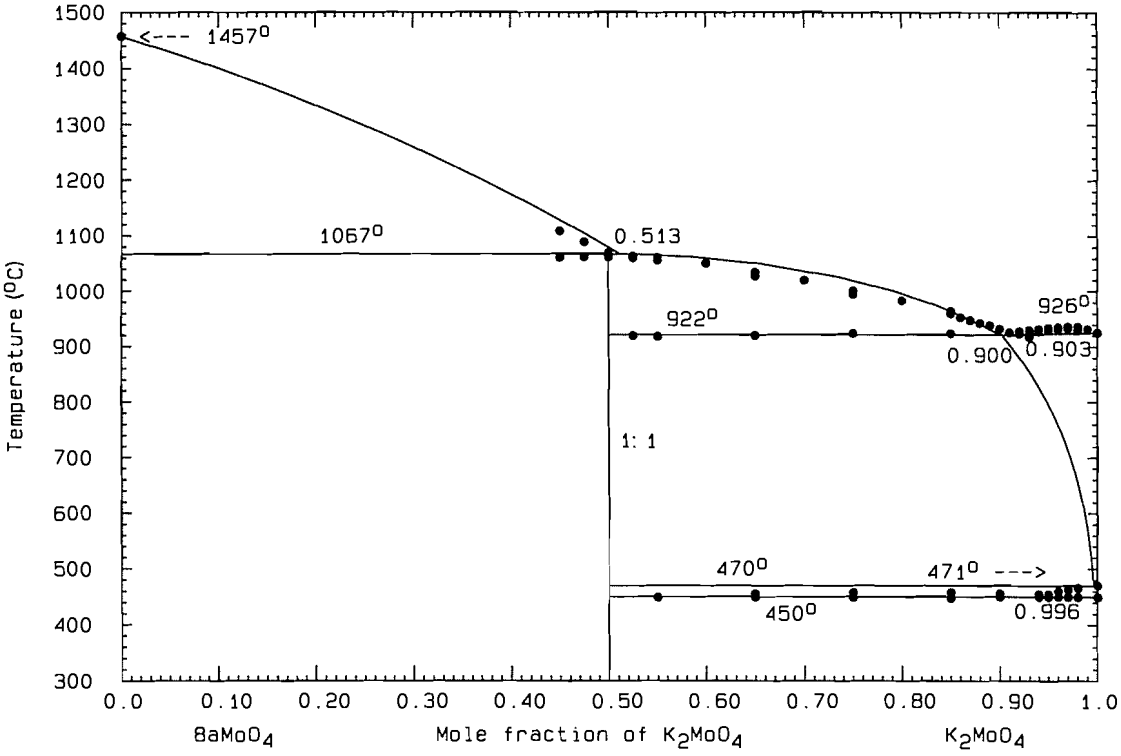


Fig. 4. The system $BaMoO_4$ (A) – Na_2MoO_4 (B). ●: ref. 46; ×: ref. 32.

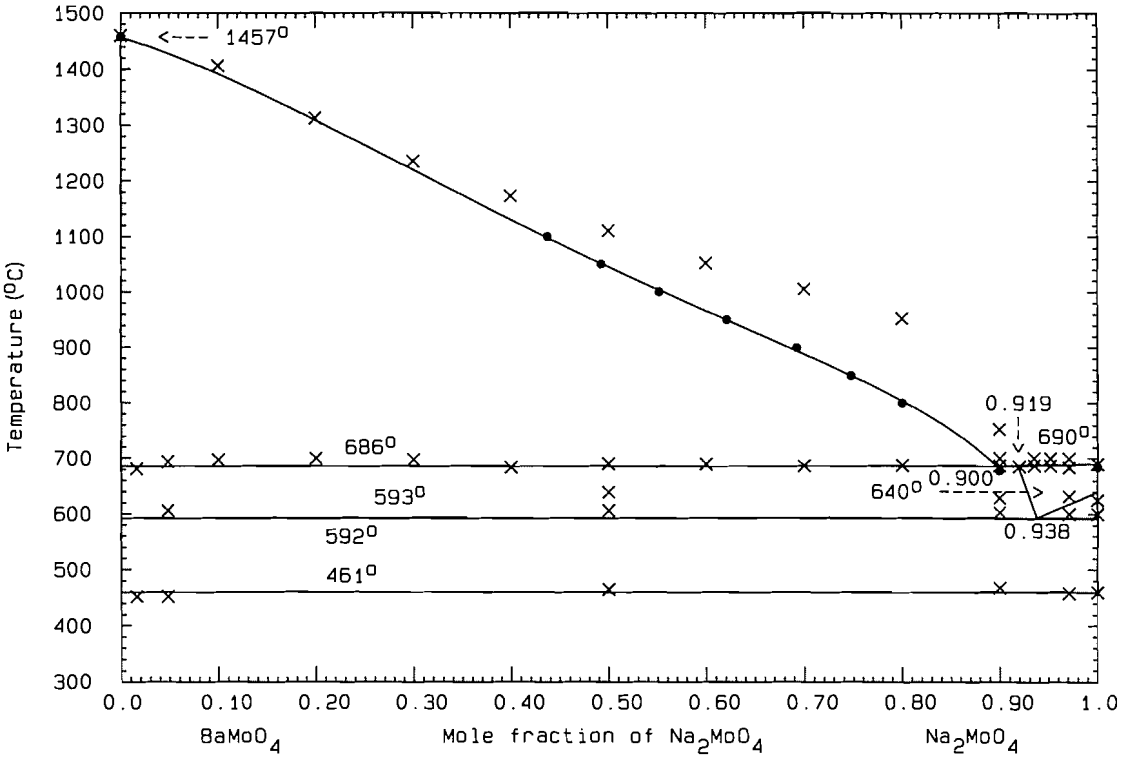
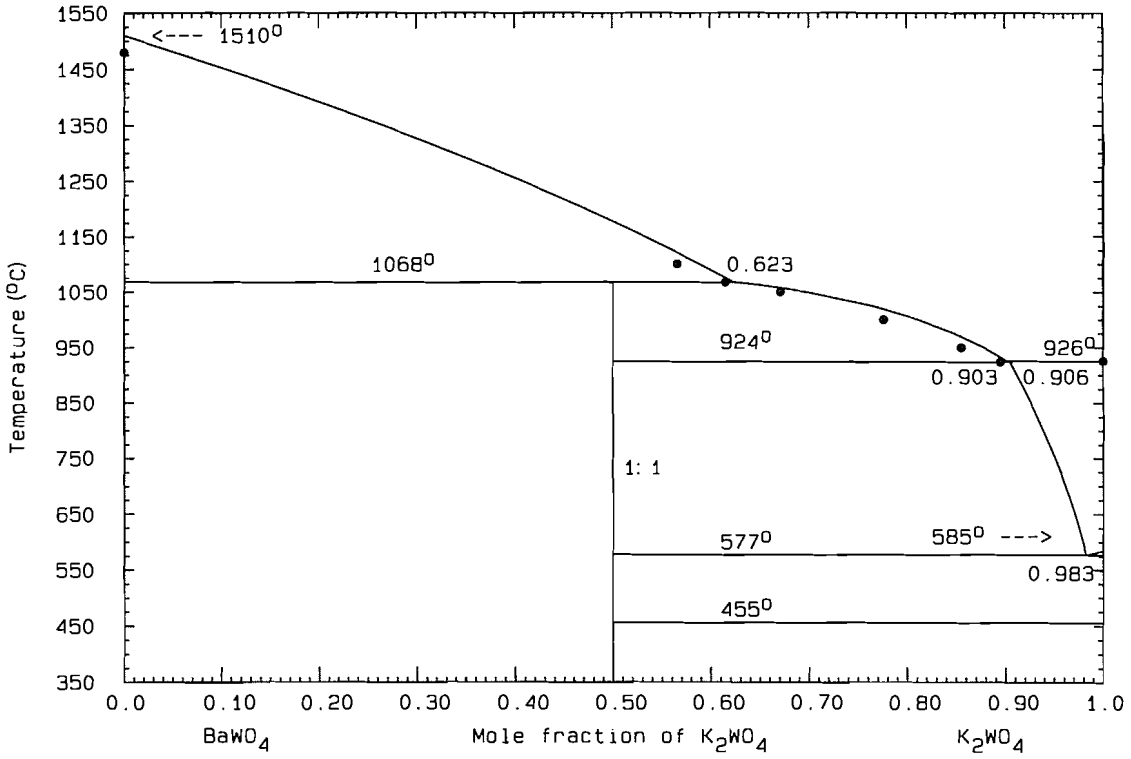


$K_2Pb(SO_4)_2$ (26, 31). The authors (31) also reported a "maximum" temperature in the liquidus near $x_B = 1$, but gave no further information. The limiting liquidus slope (31) at $x_B = 1$ clearly indicates the presence of solid solution based on K_2WO_4. Since the liquidus data are so sparse, no computer optimization was possible; instead, the phase diagram was constructed by trial and error, starting with reasonable estimates of the required thermodynamic data. The phase diagram, Fig. 5, was calculated with the use of eq. [14] for the liquid

Fig. 5. The system $BaWO_4$ (A) – K_2WO_4 (B). ●: ref. 31.



[14] $G^E(l) = -2000x_Ax_B$ J mol^{-1}

and for the 1:1 compound, as $(BaWO_4{\cdot}K_2WO_4)/2$,

[15] $\Delta_{fus}G^0 = 48\,338 - 35.7628T$ J mol^{-1}

[16] $\Delta_fG^0 = -48\,838 + 30.0000T$ J mol^{-1}

where the quantities in eqs. [15] and [16] are, respectively, the Gibbs energy of fusion and formation (from the pure liquids). The solid solution was represented by a Henrian activity coefficient

[17] $RT \ln \gamma_A = 13\,750$ J mol^{-1}

assumed to be temperature independent. The phase diagram, Fig. 5, was calculated with the use of eqs. [14], [16], and [17] and the calculated eutectic is 924°C, $x_B = 0.903$, agreeing with experiment (32). The calculated peritectic is 1068°C, x_B = 0.623, also agreeing with experiment. There is a calculated eutectoid at 577°C, $x_B = 0.983$. The solid solution extends to a maximum of 9.4 mol% at the eutectic temperature. Since the experimental liquidus data are so sparse, no uncertainty can be reliably assigned to the calculated phase diagram.

$BaWO_4$ (A) – Na_2WO_4 (B)

The phase diagram was investigated by thermal analysis, the visual-polythermal method, and X-ray analysis (33). These authors reported a eutectic of 680°C, $x_B = 0.96$; another report (25) gave 678°C, $x_B = 0.94$. The liquidus data (33) were optimized to give an excess Gibbs energy of the liquid

[18] $G^E(l) = x_Ax_B(-2153 + 8285x_B)$ J mol^{-1}

and the phase diagram calculated with the use of this expression is shown in Fig. 6. The calculated eutectic is 681°C, x_B = 0.958. A maximum uncertainty of ±20°C may be assigned to the calculated phase diagram.

K_2MoO_4 (A) – Na_2MoO_4(B)

The phase diagram was investigated by thermal analysis (34) and by the visual-polythermal method (35–37). There is disagreement concerning the subsolidus behaviour in this system. A continuous solid solution across the whole composition range was claimed (34, 38), whereas other investigators (35–37) postulate the existence of two incongruently melting compounds. A summary of invariant points is given in Table 5. Amadori (34) does not state a minimum liquidus temperature, but from his tabulated data it is approximately 661°C, $x_B = 0.8$. The situation is extraordinarily confused, as the existence of compounds is postulated only on the basis of breaks in the liquidus curve (35, 36, 39, 40). From the limiting liquidus slopes at both ends of the phase diagram, it is evident that extensive solid solutions exist at both locations. In preliminary calculations, it was found that, if complete solid solution were assumed at the liquidus temperature, the separation between liquidus and solidus on the LHS would be as much as 60°C at a given composition; on the RHS the separation is only a few degrees. The only investigator to use thermal analysis (34) did not report separate liquidus and solidus thermal arrests, and it is implicit that the liquidus and solidus are very close together over the whole composition range. For present purposes, it was decided to construct a phase diagram with terminal solid solutions and with two compounds (35–37). The liquid was assumed to be ideal

[19] $G^E(l) = 0$

Fig. 6. The system $BaWO_4$ (A) – Na_2WO_4 (B). ●: ref. 33.

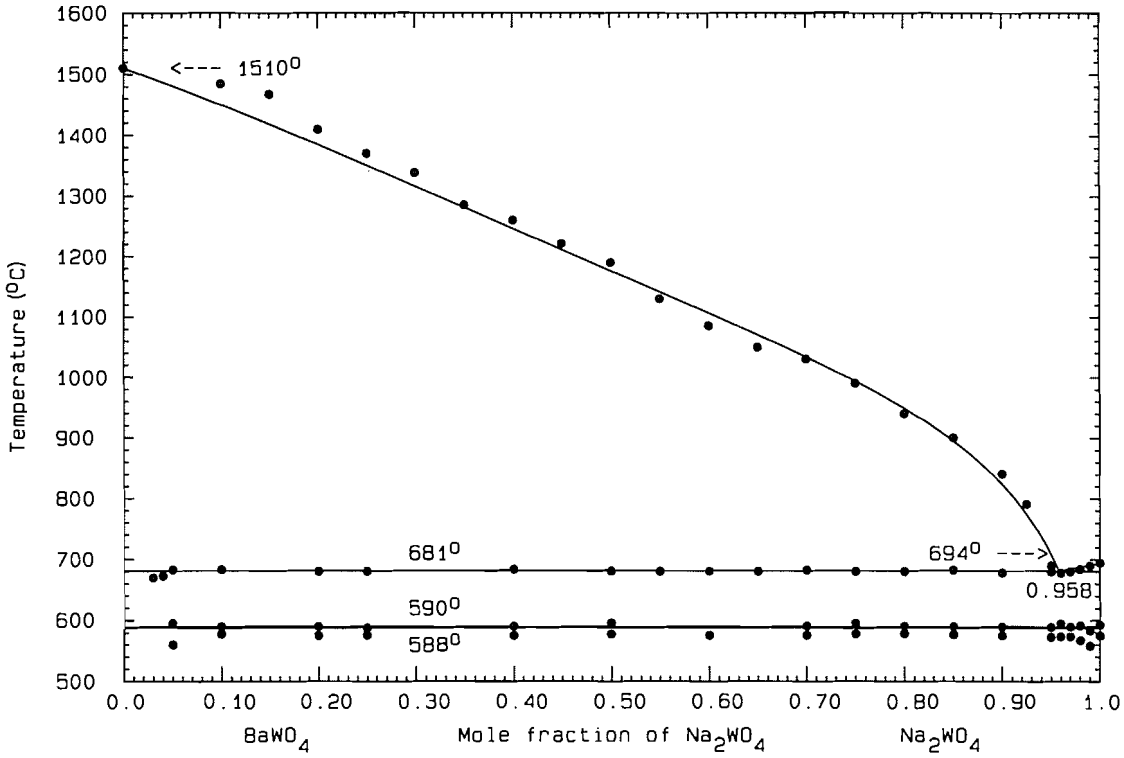


Table 5. Reported invariant points for K_2MoO_4 (A) – Na_2MoO_4 (B).

	T (°C)	x_B	Refs.
Peritectic	736	0.46	36, 39
	743	0.50	41
	737	0.54	35
Peritectic	683	0.63	36, 39
	682	0.64	41
	686	0.63	35

	663	0.81	41
Minimum	656	≈0.8	38

and thermodynamic properties of other phases chosen in order to reproduce the observed liquidus (34–36) as closely as possible. Thus, the two end solid solutions were represented by two Henrian activity coefficients

[20] $RT \ln \gamma_B = 9000$ J per mole of Na_2MoO_4

[21] $RT \ln \gamma_A = 9600$ J per mole of K_2MoO_4

For the compound $(K_2MoO_4 \cdot Na_2MoO_4)/2$,

[22] $\Delta_{fus}G^0 = 78\,900 - 81.5256T$ J mol^{-1}

[23] $\Delta_f G^0 = -78\,900 + 70.0000T$ J mol^{-1}

and for $(Na_2MoO_4 \cdot 2K_2MoO_4)/3$,

[24] $\Delta_{fus}G^0 = 61\,710 - 60.5840T$ J mol^{-1}

[25] $\Delta_f G^0 = -61\,710 + 70.0000T$ J mol^{-1}

The phase diagram, Fig. 7, calculated from eqs. [19]–[21], [23], and [25], shows a calculated eutectic of 664°C, $x_B = 0.760$ and calculated peritectics 682°C, $x_B = 0.673$ and 736°C, $x_B = 0.462$. The solid solutions extend to 25.3 and 21.1 mol% at the peritectic and eutectic temperatures, respectively. There are two calculated eutectoids, at 461°C, $x_B = 0.015$ and 552°C, $x_B = 0.932$. The calculated fusion properties of the compounds, eqs. [22] and [24], are very different from the fusion properties of the pure salts and hence the quantities of eqs. [23] and [25] are to be considered as fitting parameters only and are not to be interpreted as actual suggested properties of these compounds. The entire subsolidus is conjectural. An uncertainty of ±20°C may be assigned to the calculated liquidus.

K_2WO_4 (A) – Na_2WO_4 (B)

The phase diagram was investigated by thermal analysis (34, 44, 42) and by the visual-polythermal method (42–44). The data of Amadori (34) are reproduced exactly by later authors (42). Like the previous system, this system is not well characterized. A summary of invariant points is given in Table 6. As in the previous analogous system, Amadori (34) postulated complete solid solubility with a 1:1 compound decomposing in the subsolidus, whereas other investigators proposed the existence of two compounds (42–44). The two systems K,Na//MoO_4 and K,Na//WO_4 are almost identical with respect to the liquidus, and the same approach to the calculation of the phase diagram was adopted here. For the liquid, again

Fig. 7. The system K_2MoO_4 (A) – Na_2MoO_4 (B). ○: ref. 34; ●: ref. 36; ×: refs. 35, 37. The subsolidus is conjectural.

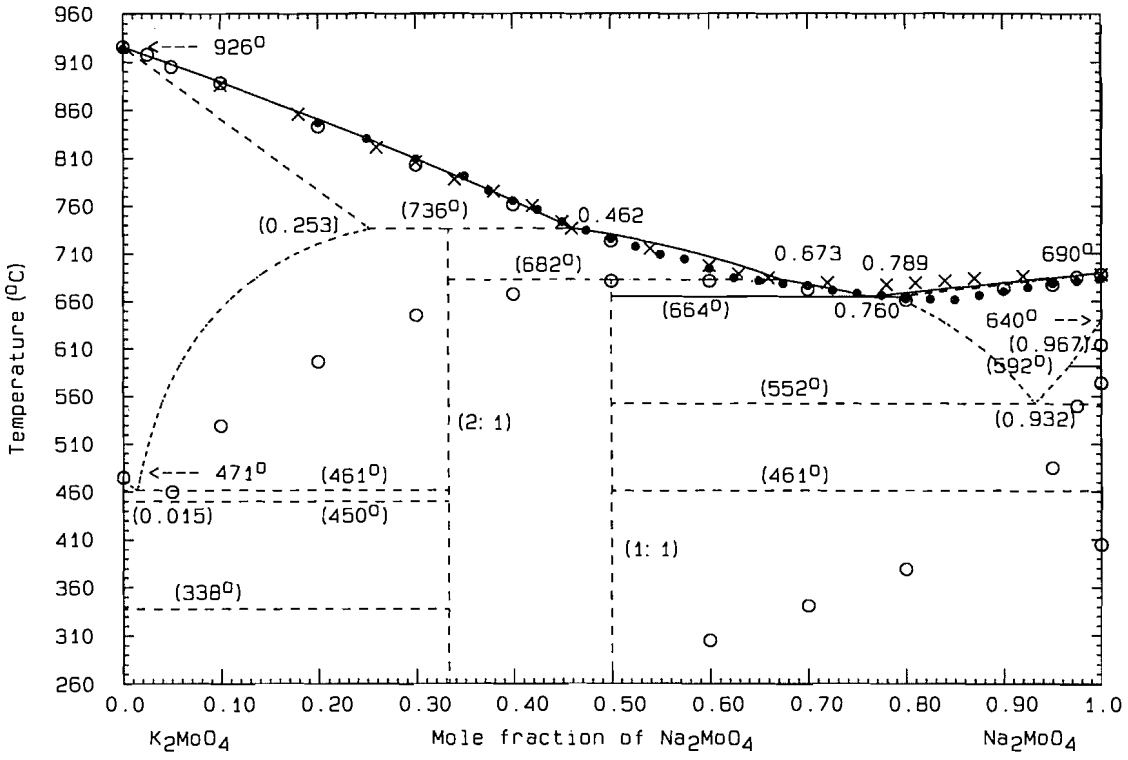

Table 6. Reported invariant points for K_2WO_4 (A) – Na_2WO_4 (B).

	T (°C)	X_B	Refs.
Minimum	636	0.81	34, 42
	≈646	≈0.82	41
Peritectic	678	0.60	43
	689	0.55	44
Peritectic	646	0.76	43
Eutectic	642	0.84	43
	≈645	≈0.86	44
Eutectoid	327	≈0.97	42

[26] $G^E(l) = 0$

and for the two end solid solutions

[27] $RT \ln \gamma_A = 12\,000$ J per mole of K_2WO_4

[28] $RT \ln \gamma_B = 12\,000$ J per mole of Na_2WO_4

being two Henrian activity coefficients assumed to be independent of temperature. For the compound $(Na_2WO_4 \cdot K_2WO_4)/2$ the expressions

[29] $\Delta_{fus}G^0 = 43\,146 - 45.7628T$ J mol^{-1}

[30] $\Delta_f G^0 = -43\,146 + 40.0000T$ J mol^{-1}

were deduced, and for $(Na_2WO_4 \cdot 2K_2WO_4)/3$,

[31] $\Delta_{fus}G^0 = 44\,200 - 45.2920T$ J mol^{-1}

[32] $\Delta_f G^0 = -44\,200 + 40.0000T$ J mol^{-1}

As in the analogous molybdate system, eqs. [29] and [31] represent thermodynamic properties very different from those of the pure salts and hence are to be regarded only as fitting parameters. The phase diagram, Fig. 8, was calculated with the use of eqs. [26], [27], [28], [30], and [32]. The calculated eutectic is 644°C, $x_B = 0.759$ and the calculated eutectoids are 565°C, $x_B = 0.023$ and 561°C, $x_B = 0.924$. The calculated peritectics are 690°C, $x_B = 0.524$ and 656°C, $x_B = 0.694$. The two solid solutions extend to 26.7 and 17.7 mol% at the peritectic and eutectic temperatures, respectively. An uncertainty of ±25°C may be assigned to the calculated liquidus. The entire calculated subsolidus is conjectural.

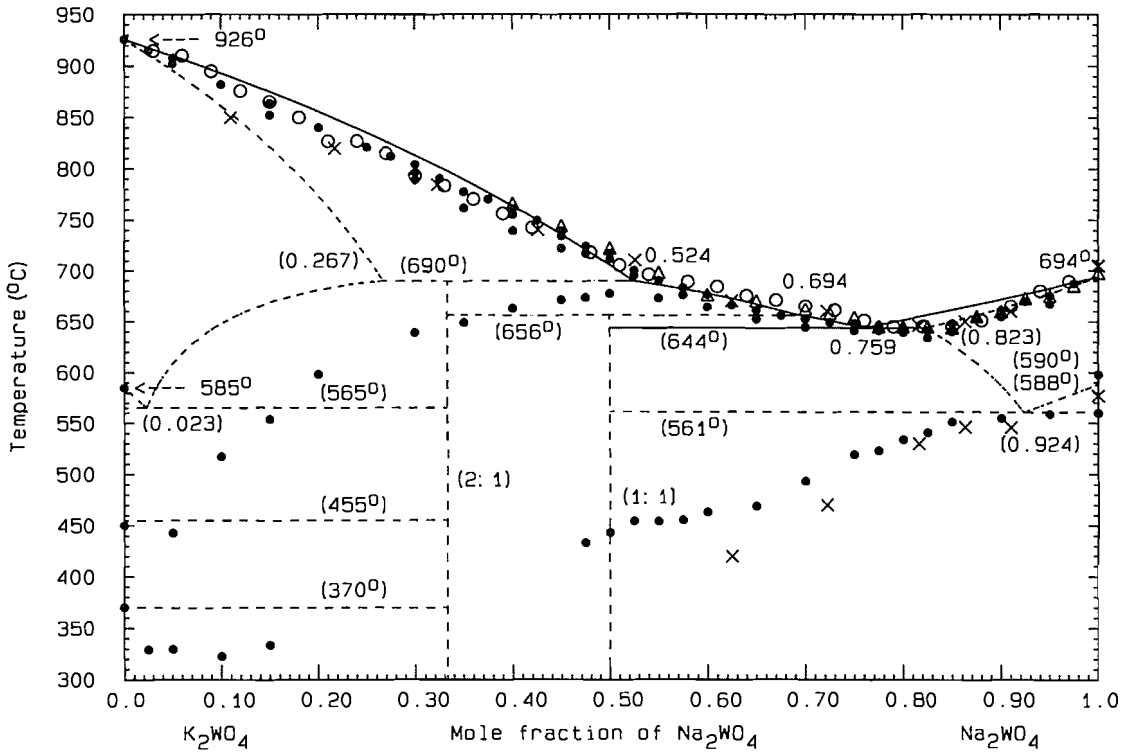
Common cation systems

BaF_2 (A) – $BaMoO_4$ (B)

A few liquidus data were reported (45) from visual-polythermal measurements. The reported eutectic (45) is 958°C, x_B = 0.37. The same eutectic temperature is mentioned in a later report (46). The experimental (45) melting point of BaF_2 is grossly erroneous, and hence the LHS liquidus data are also probably more or less in error. For calculation of the phase diagram, however, a eutectic temperature of 958°C was taken as guide, and a eutectic composition $0.3 < x_B < 0.4$ was assumed. The phase diagram was calculated with the use of eq. [33]

[33] $G^E(l) = x_A x_B(-8300 - 3000x_B)$ J mol^{-1}

Fig. 8. The system K_2WO_4 (A) – Na_2WO_4 (B). ×: ref. 41; ●: ref. 42; △: ref. 43; ○: ref. 44. The subsolidus is conjectural.



and is shown in Fig. 9. The calculated eutectic is 960°C, x_B = 0.380 and the BaF_2 transition appears on the calculated liquidus at x_B = 0.155. Since the experimental liquidus data (45) are so sparse and suspect, there is a large uncertainty (±20°C) in Fig. 9.

BaF_2 (A) – $BaWO_4$ (B)

Only one datum is available for this system, a eutectic report (25) of 988°C, x_B = 0.33. Since there are no liquidus data for optimization, an approximate excess Gibbs energy of the liquid

[34] $G^E(l) = x_A x_B(-10\,000 + 1600x_B)$ J mol^{-1}

was used to calculate the phase diagram, Fig. 10. The calculated eutectic is 988°C, x_B = 0.377 and the BaF_2 transition appears on the calculated liquidus at x_B = 0.159.

$BaMoO_4$ (A) – $BaWO_4$ (B)

There are no phase diagram data available for this system, as the liquidus lies at very high temperatures. From limited thermal analysis, X-ray diffraction, and electrical conductivity data at lower temperatures (47), it is reasonable to assume that there is complete solid solubility at the liquidus temperature and that both solid and liquid solutions are close to ideal (31). The phase diagram, Fig. 11, was calculated with the use of the quantities

[35] $G^E(l) = 0$

[36] $G^E(s) = 0$

and the calculated phase diagram shows no minimum. The phase diagram is necessarily conjectural.

KF (A) – K_2MoO_4 (B)

The phase diagram was investigated by thermal analysis (48, 49) and the visual-polythermal method (37). A summary of invariant points is given in Table 7. The reported melting point of the compound is (37, 48–50) 752, 752, 754, and 752°C, respectively. The compound was characterized by X-ray diffraction (48) and its heat of fusion, measured calorimetrically (50), is 58 kJ per mole of KF·K_2MoO_4. There is good agreement (±5°C) concerning the liquidus on the LHS, but some scatter on the RHS. The excess enthalpy of the liquid was measured by direct calorimetry at 1000°C, and the result (49) is used here:

[37] $H^E(l) = x_A x_B(894 + 9x_A)$ J mol^{-1}

All the liquidus data (37, 48, 49) were optimized together with eq. [37] to give two excess entropy coefficients

[38] $S^E(l) = x_A x_B(4.2765 - 5.9481x_B)$ J mol^{-1} K^{-1}

and the calculated properties of the compound (KF·K_2MoO_4)/2 are

[39] $\Delta_{fus}G^0 = 27\,502 - 26.8262T$ J mol^{-1}

[40] $\Delta_f G^0 = -27\,611 + 21.0634T$ J mol^{-1}

The phase diagram was calculated with the use of eqs. [37], [38], and [40] and is shown in Fig. 12. The calculated eutectics are 720°C, x_B = 0.295 and 748°C, x_B = 0.579. The compound melts congruently at 752°C. An uncertainty of ±5°C may be assigned to the calculated LHS liquidus.

Fig. 9. The system BaF_2 (A) – $BaMoO_4$ (B). ●: ref. 45.

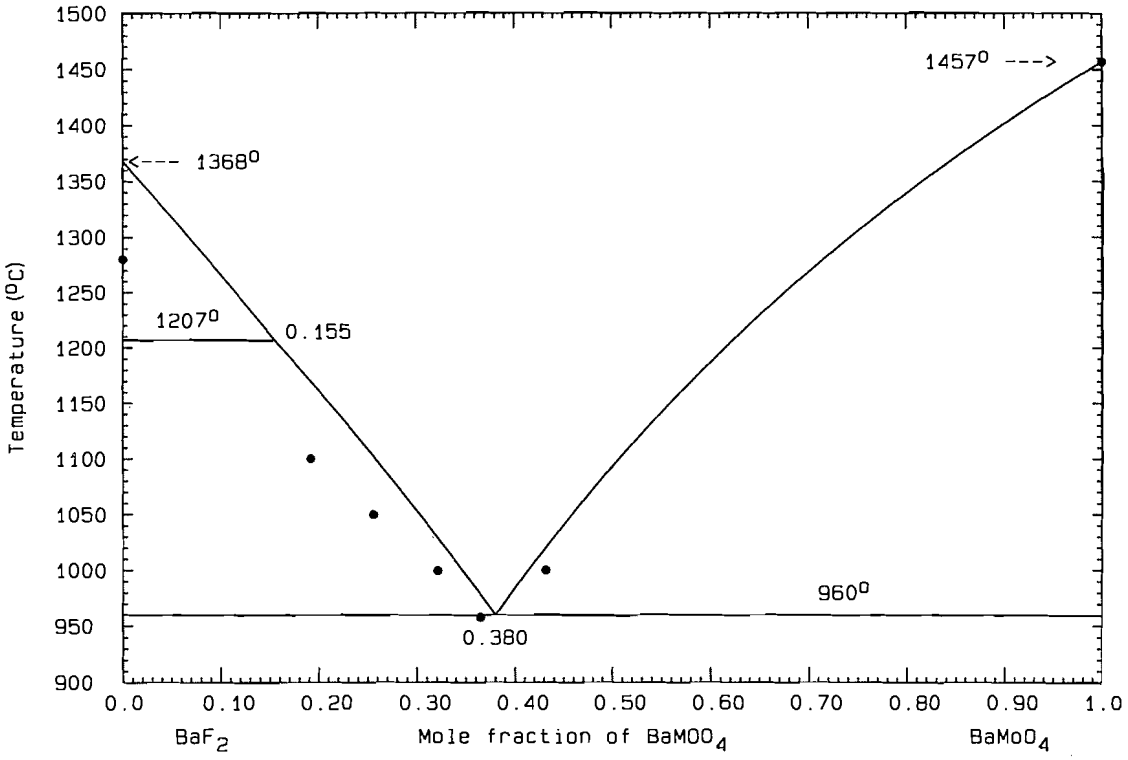


Fig. 10. The system BaF_2 (A) – $BaWO_4$ (B). ●: ref. 25. The diagram is conjectural.

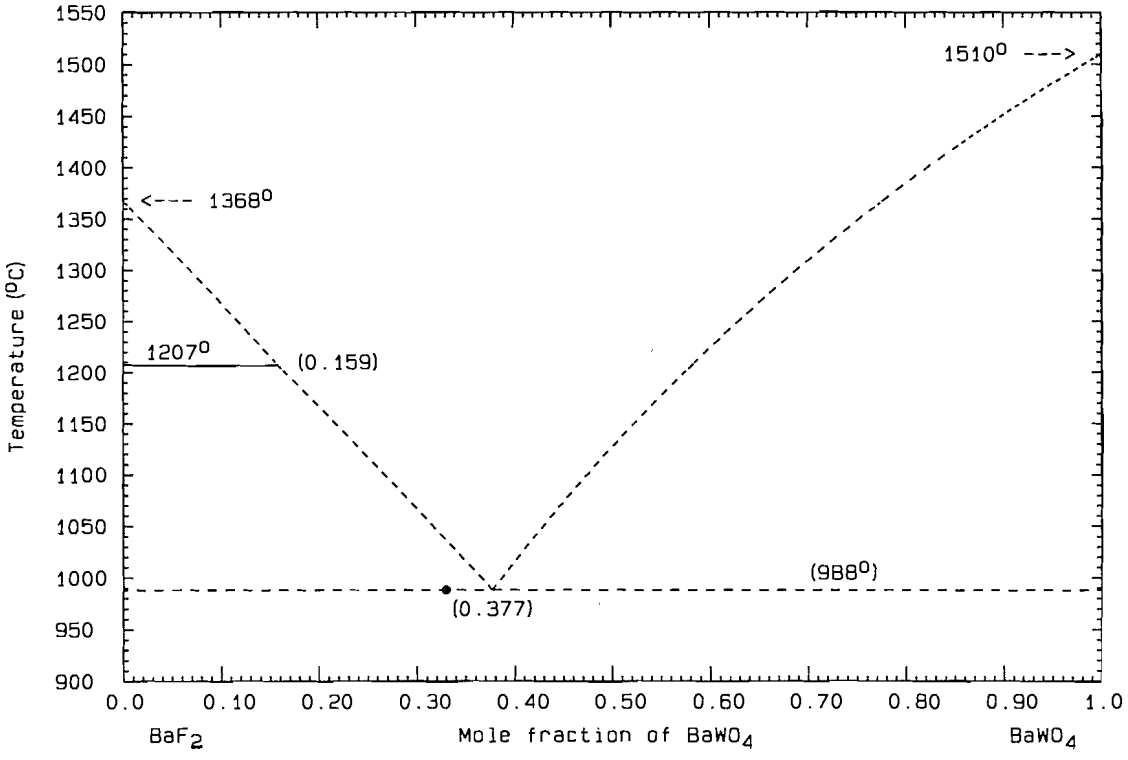

KF (A) – K_2WO_4 (B)

The phase diagram was investigated by thermal analysis (48, 49) and by the visual-polythermal method (51, 52). An invariant point summary is given in Table 8. All investigators (44, 45, 48, 49, 51–53) report the presence of a congruently melting 1:1 compound at temperatures 761, 759, and 764°C, respectively. The excess enthalpy of the liquid was measured at 1000°C by direct calorimetry (49) and the result is used here:

[41] $H^E(l) = x_A x_B(660 + 25x_A)$ J mol^{-1}

Fig. 11. The system $BaMoO_4$ (A) – $BaWO_4$ (B). The diagram is conjectural.

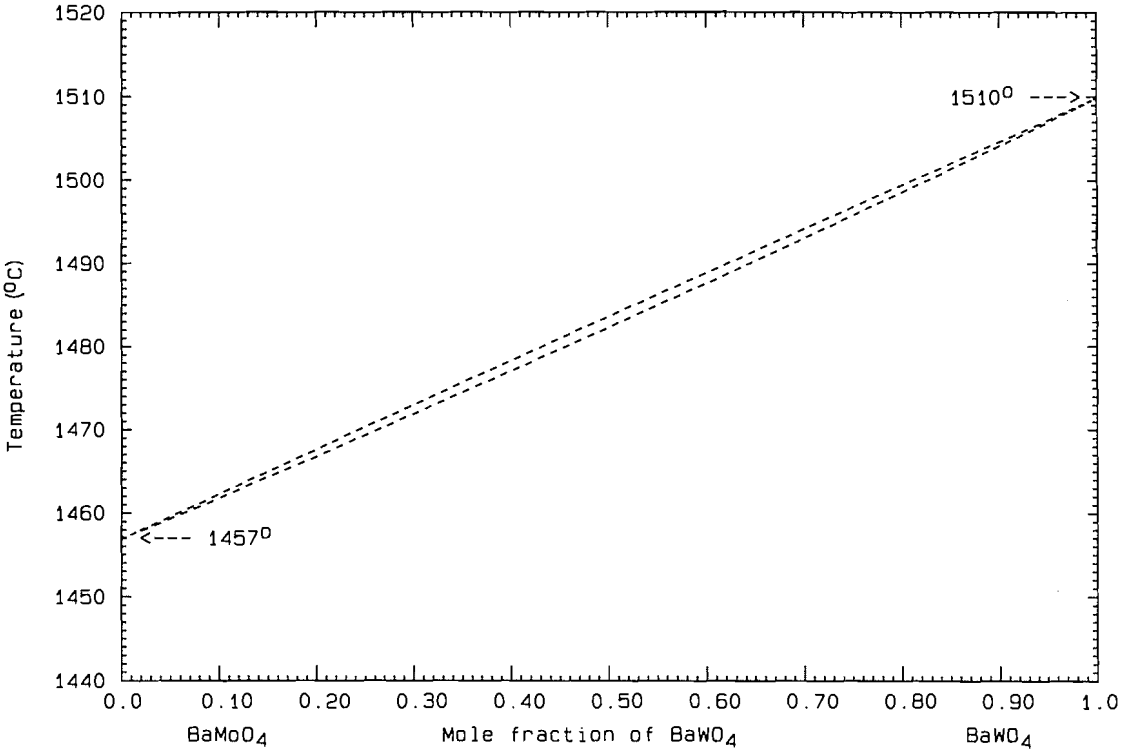

Fig. 12. The system KF (A) – K_2MoO_4 (B). ●: ref. 48; ○: ref. 49; ×: ref. 37.

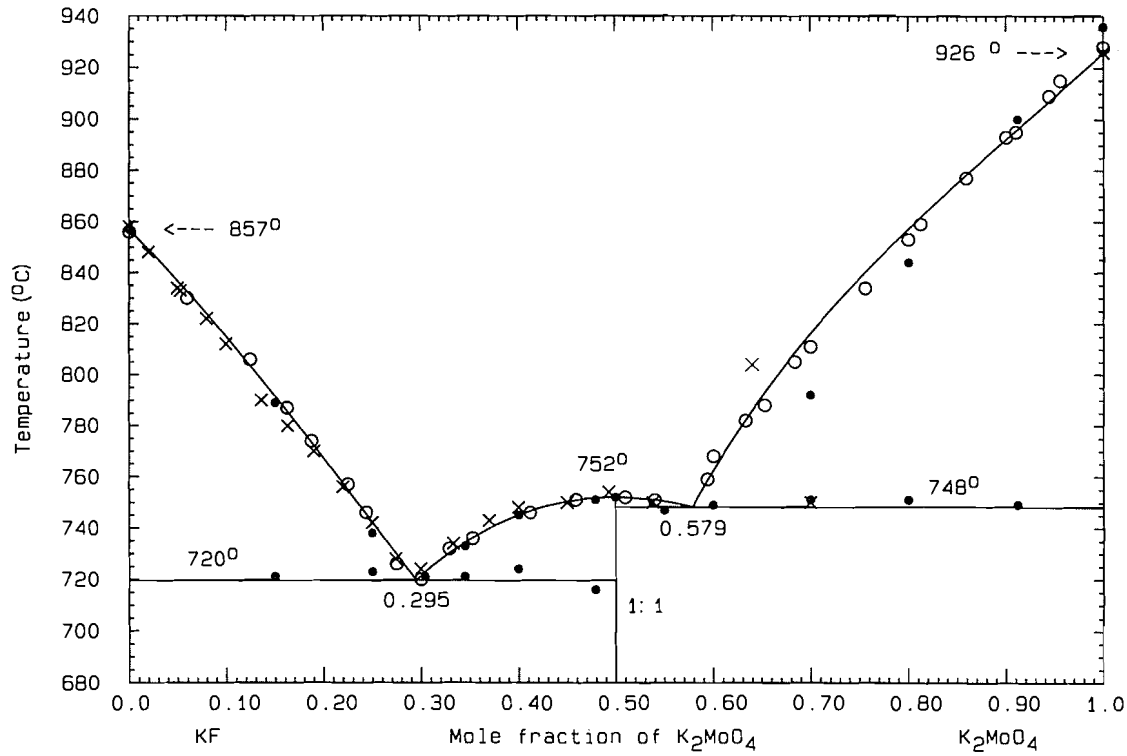

Reported liquidus data (48, 49, 51, 52) agree better in the central region of the phase diagram than elsewhere, where there is up to 30°C difference at a given composition. All liquidus data were optimized together with eq. [41] to give two excess entropy coefficients

$$[42] \quad S^{E}(l) = x_A x_B(8.6300 - 4.2726x_B) \quad \text{J mol}^{-1}\ \text{K}^{-1}$$

The phase diagram, Fig. 13, was calculated with the use of eqs. [41] and [42] and shows calculated eutectics of 724°C, x_B =

Fig. 13. The system KF (A) – K_2WO_4 (B). ●: ref. 48; ×: ref. 49; ○: ref. 51; △: ref. 52.

	748	0.57	37
	748	0.56	49
1:1	752		48
	754		37
	752		49

Table 8. Reported invariant points for KF (A) – K_2WO_4 (B).

	T (°C)	x_B	Refs.
Eutectic	757	0.60	48
	752	0.60	49
	760	0.56	51–53
Eutectic	729	0.28	48
	724	0.27	49
	728	0.27	51–53

0.286 and 757°C, $x_B = 0.602$. The compound $(KF{\cdot}K_2WO_4)/2$ is represented by the properties

[43] $\Delta_{fus}G^0 = 38\,932 - 37.5982T$ J mol^{-1}

[44] $\Delta_fG^0 = -38\,736 + 30.2136T$ J mol^{-1}

and its calculated melting point is 762°C. An uncertainty of ±20°C may be assigned to the calculated phase diagram.

K_2MoO_4 (A) – K_2WO_4 (B)

This system was studied by thermal analysis (cooling mode, ref. 54) and by the visual-polythermal method (43, 55). Amadori (54) does not report a minimum in the liquidus, since his melting point for K_2WO_4 is 32°C lower than the accepted value. According to Mateiko and Bukhalova (43), the liquidus is flat at 920°C over most of the composition range. Like the previous analogous system with Na as cation, the solution phases are almost ideal (43, 55). For the calculation of the phase diagram, the following quantities were used:

[45] $G^E(l) = 0$

[46] $G^E(s, \delta) = 650x_Ax_B$ J mol^{-1}

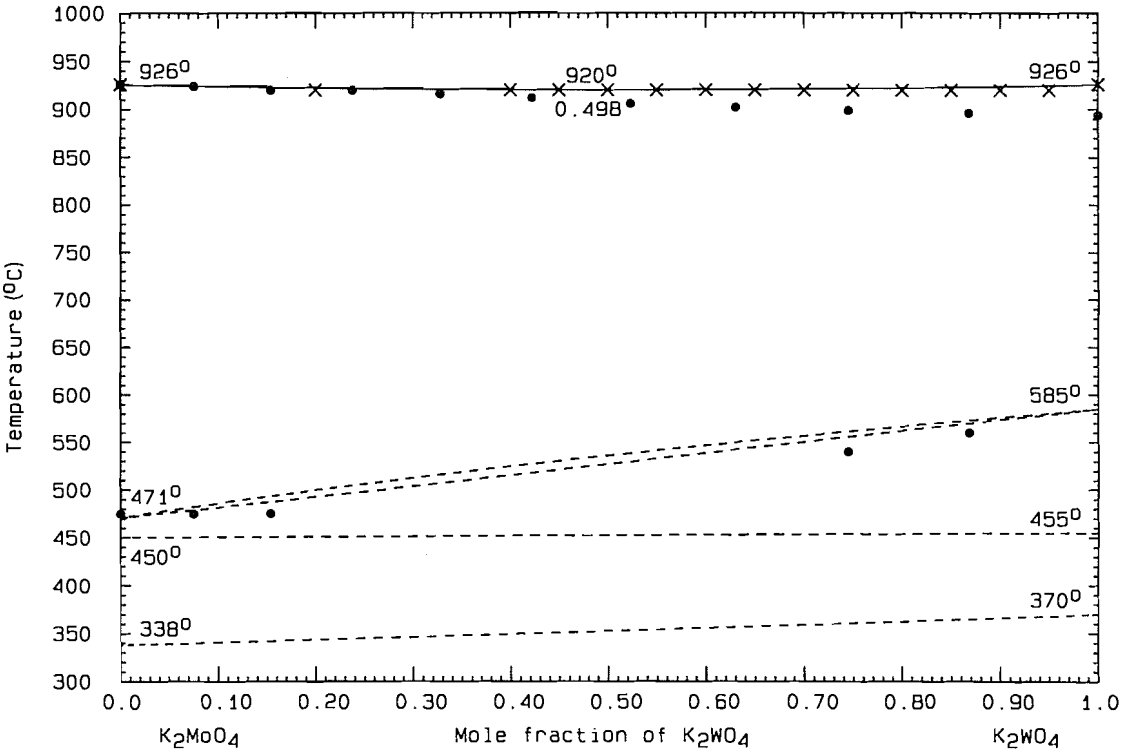
[47] $G^E(s, \gamma) = 100x_Ax_B$ J mol^{-1}

[48] $G^E(s, \beta) = 100x_Ax_B$ J mol^{-1}

[49] $G^E(s, \alpha) = 100x_Ax_B$ J mol^{-1}

The calculated phase diagram, Fig. 14, was constructed with the use of eqs. [45]–[49]. The calculated minimum is 920°C,

Fig. 14. The system K_2MoO_4 (A) – K_2WO_4 (B). ●: ref. 54; ×: refs. 43, 55. The subsolidus is conjectural.



x_B = 0.498. The two-phase regions are all very narrow and there are no minima or maxima in the subsolidus. The calculated subsolidus is conjectural. The uncertainty in the calculated liquidus may be assigned at ±3°C.

NaF (A) – Na_2MoO_4 (B)

The phase diagram was investigated by thermal analysis (37, 48, 49) and the visual-polythermal method (45). There is fairly good agreement on the liquidus among these reports (about ±10°C). A summary of invariant points is given in Table 9. The compound was identified by X-ray diffraction (45, 48), the stoichiometry being 1:1 or 2:1, respectively. The 1:1 stoichiometry was chosen as the more probable, in view of the identity of compounds in analogous systems reviewed in the present work. The excess enthalpy of the liquid was measured by direct calorimetry at 1000°C, and the result (49) is used here:

[50] $H^E(l) = x_A x_B(3067 - 1601x_A + 6801x_A^2)$ J mol^{-1}

It was found that one excess entropy coefficient

[51] $S^E(l) = 8.0000x_A x_B$ J mol^{-1} K^{-1}

permitted a good fit to the liquidus to be made; the properties of the compound (NaF·Na_2MoO_4)/2 were

[52] $\Delta_{fus}G^0 = 36\,792 - 39.3519T$ J mol^{-1}

[53] $\Delta_f G^0 = -35\,800 + 31.5907T$ J mol^{-1}

The phase diagram was calculated with the use of eqs. [50], [51], and [53] and is shown in Fig. 15. The calculated eutectic is 618°C, x_B = 0.805 and the calculated peritectic is 664°C, x_B = 0.633. An uncertainty of ±10°C may be assigned to the calculated phase diagram.

Table 9. Reported invariant points for NaF (A) – Na_2MoO_4 (B).

	660	0.65	37
	660	0.65	45
	665	0.65	49

NaF (A) – Na_2WO_4 (B)

The phase diagram was investigated by thermal analysis (25, 48, 49) and the visual-polythermal method (25, 51). A summary of invariant points is given in Table 10. The liquidus data of Mateiko and Bukhalova (51) are evidently erroneous, while those of the other investigators (25, 48, 49) agree to within 20°C. The stoichiometry of the compound was given as 1:1 by Schmitz-Dumont and Weeg (48), based on X-ray diffraction. This stoichiometry was assumed by later workers (51). The other authors (25) assumed a 2:1 stoichiometry. The excess enthalpy of the liquid was measured at 1000°C by direct calorimetry and the result (49)

Fig. 15. The system NaF (A) – Na_2MoO_4 (B). ●: ref. 48; △: ref. 49; ×: ref. 37; ○: ref. 45.

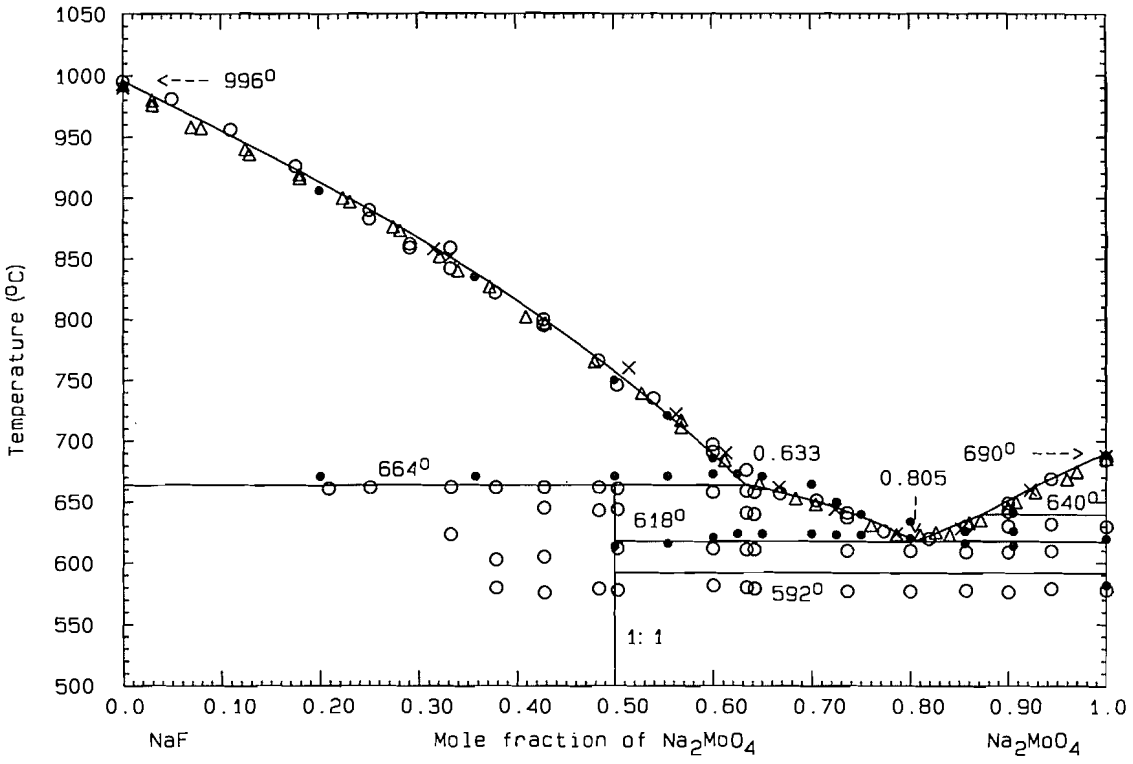

Table 10. Reported invariant points for NaF (A) – Na_2WO_4 (B).

	T (°C)	x_B	Refs.
Eutectic	635	0.80	48
	638	0.82	49
	650	0.88	51
	632	0.81	25
Peritectic	693	≈0.63	48
	691	0.60	49
	716	0.67	51
	690	0.57	25

[54] $H^E(l) = x_A x_B(2483 - 121x_A + 5554x_A^2)$ J mol^{-1}

was used here. The liquidus data (25, 48, 49) were optimized together with eq. [54] to give two excess entropy coefficients

[55] $S^E(l) = x_A x_B(8.1390 - 7.0541x_B)$ J mol^{-1} K^{-1}

and the calculated properties of the compound $(KF{\cdot}K_2WO_4)/2$ are

[56] $\Delta_{fus}G^0 = 25\,513 - 26.2550T$ J mol^{-1}

[57] $\Delta_f G^0 = -24\,560 + 19.3409T$ J mol^{-1}

The phase diagram, Fig. 16, was calculated with the use of eqs. [54], [55], and [57] and has a calculated eutectic of 633°C, x_B = 0.804. The calculated peritectic for the 1:1 compound is 693°C, x_B = 0.587. If the liquidus data of Mateiko and Bukhalova (51) are disregarded, an uncertainty of ±10°C may be assigned to the calculated phase diagram.

Na_2MoO_4 (A) – Na_2WO_4 (B)

The phase diagram was investigated by thermal analysis (cooling mode, ref. 56 (heating mode, ref. 57) and by the visual-polythermal method (43). A minimum liquidus temperature at 676°C, x_B = 0.60 was reported (43). The phase diagram had been calculated previously by a method similar to the present one (58), but the authors were apparently unaware of the work of Bottelberghs and van Buren (57), which is by far the most complete and reliable study of this system to date. These authors (57) also used X-ray diffraction and electrical conductivity measurements to establish the subsolidus. The calculations in the present work were based on the results of these workers (57). The liquid was assumed to be ideal

[58] $G^E(l) = 0$

and all the solid solutions were taken to be regular, as previously suggested (57). For the highest-temperature solid solution (δ), the hypothetical Gibbs energy of fusion of Na_2WO_4(δ) was set at $2000 - 2.058T$ J mol^{-1} (the exact value of this quantity is not crucial for the reproduction of the phase boundaries in the final phase diagram). The excess Gibbs energy of this solid solution turned out to be

[59] $G^E(s, \delta) = 350x_A x_B$ J mol^{-1}

In the earlier calculation (58), this quantity was $120x_A x_B$ J mol^{-1}. For the other solid solutions

[60] $G^E(s, \gamma) = -300x_A x_B$ J mol^{-1}

Fig. 16. The system NaF (A) – Na_2WO_4 (B). △: ref. 25; ●: ref. 48; ×: ref. 49; ○: ref. 51.

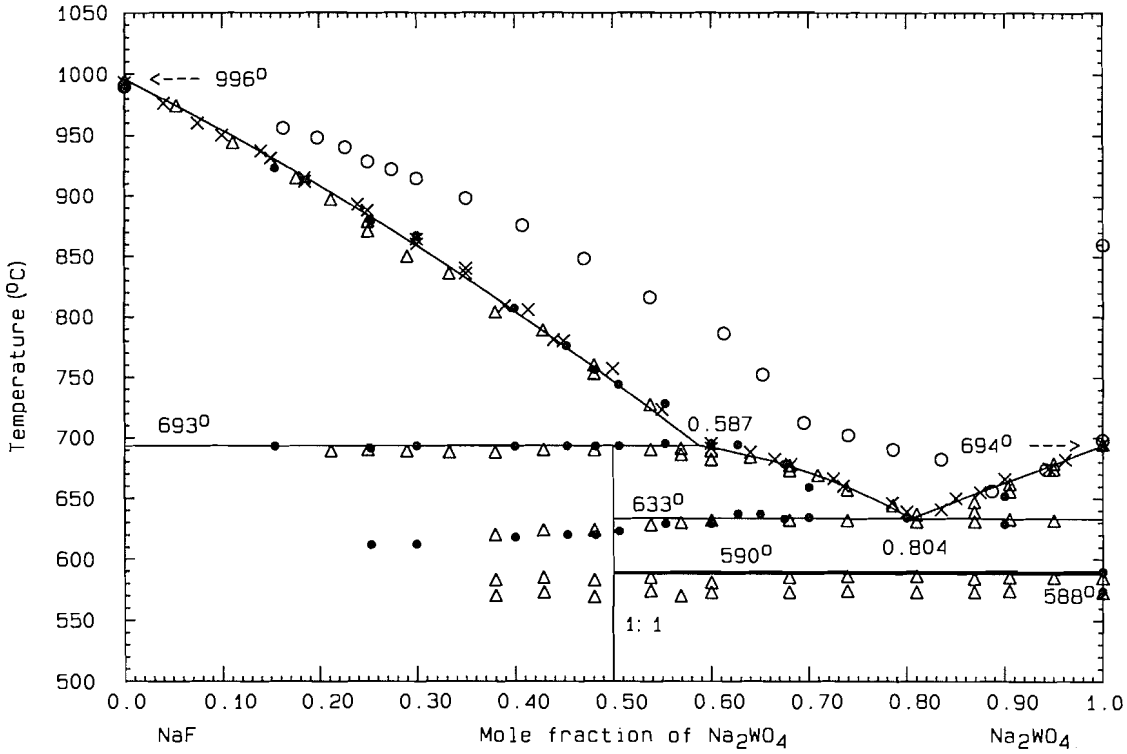

Fig. 17. The system Na_2MoO_4 (A) – Na_2WO_4 (B). ○: ref. 43; ×: ref. 56; ●: ref. 57.

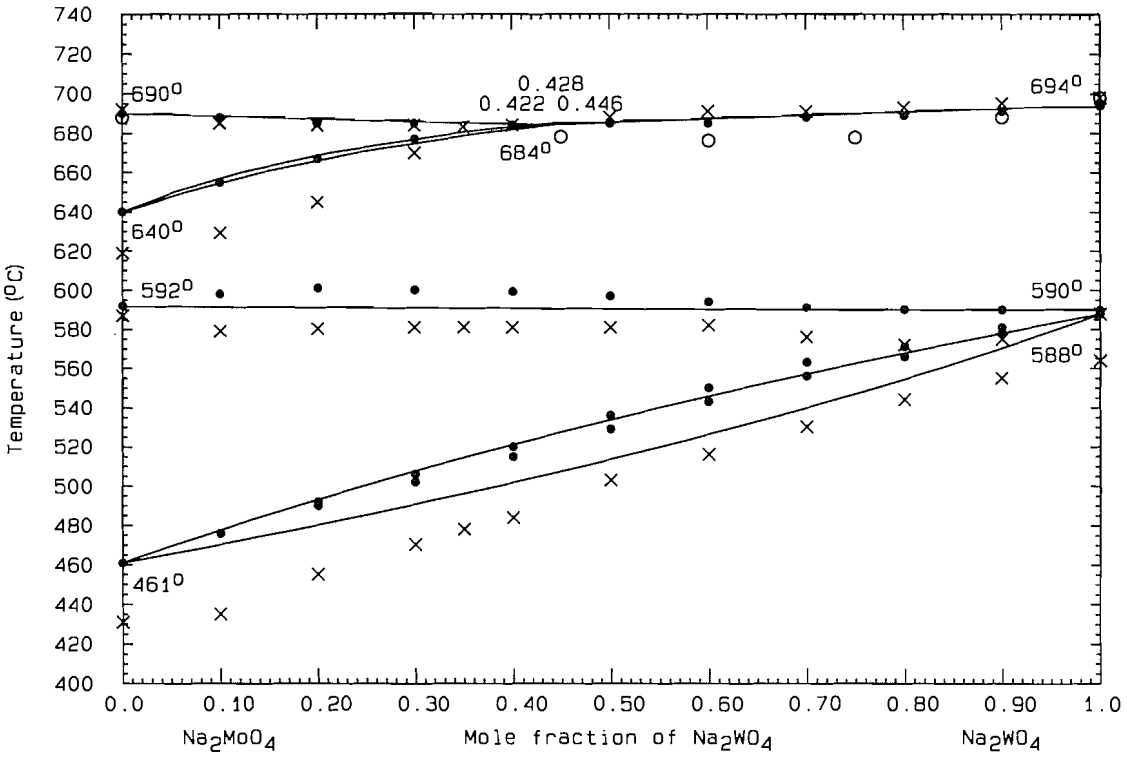

[61] $G^E(s, \beta) = -295.5x_Ax_B$ J mol^{-1}

[62] $G^E(s, \alpha) = 200x_Ax_B$ J mol^{-1}

For purposes of comparison, the previous calculation (58) used the expression $x_Ax_B(-683 - 227x_B)$ J mol^{-1} for $G^E(s, \delta)$, and $G^E(s, \beta)$ was approximately $-113x_Ax_B$ J mol^{-1}, according to Bottelberghs and van Buren (57). The calculated phase diagram, Fig. 17, was calculated with the use of eqs. [58]–[62], and the calculated eutectic is 684°C, $x_B = 0.423$. There are no

maxima or minima in the subsolidus. The two-phase regions are all quite narrow, except for the $\alpha \rightarrow \beta$ transition, where the enthalpies of transition are relatively large. An uncertainty of $\pm 5°C$ may be assigned to the calculated liquidus.

Appendix

Thermodynamic properties of the pure salts

NaF, KF

The C_p and fusion data were taken from a standard source (16). These data are almost identical to those in later compilations (14, 15, 17).

BaF_2

Previous reports on the melting point (16, 20, 23, 45, 46) indicated 1287 or 1290°C; a higher value of 1368°C (15, 17) was adopted here. The heat of fusion is 28 450 J mol^{-1} (16) or 23 359 J mol^{-1} (15, 17); the latter value is used here. There is a transition at 967°C, apparently second order (zero enthalpy change) (15, 17); this was ignored in favour of the transition at 1207°C, $\Delta_{trs}H = 2674$ J mol^{-1} (15, 17). The C_p data were taken from the older compilation (16).

Na_2WO_4

The melting point is given as 694–696°C (15–17, 49, 57, 59) and the heat of fusion 23 800–30 380 J mol^{-1} (15–17, 57, 59). The data of Bottelberghs and van Buren (57) have been adopted here. The α-solid is cubic *Fd3m*, while the β-solid is orthorhombic $Pbn2_1$. This is distinguished from another (γ-solid) orthorhombic variety *Fddd* (57). The enthalpies of fusion and transition were taken from ref. 15. The C_p of the α-solid was taken from ref. 15, while those of the other solids and liquid were assigned a constant value of 209.2 J mol^{-1} K^{-1} (15, 17).

Na_2MoO_4

The melting point is 686–690°C (16, 17, 32, 49, 57, 59, 60) and the heat of fusion 19 240–22 426 J mol^{-1} (16, 17, 57, 59, 60). Three transitions have been reported (16, 17, 32, 49, 57, 59) at temperatures between 445 and 461°C (21 760– 24 230 J mol^{-1}), between 585 and 600°C (1880–2090 J mol^{-1}), and between 625 and 642°C (7680–9121 J mol^{-1}). The chosen data were from refs. 17 and 57. The α, β, γ, and δ solids are, respectively, cubic *Fd3m*, orthorhombic $Pbn2_1$, orthorhombic *Fddd*, and hexagonal $P6_3/mmc$ (57). The C_p of solids and liquid were taken from ref. 17.

K_2WO_4

This salt is not very well characterized. The compilations (14–17) contain no information on fusion or transition. Phase diagram and other reports (31, 43, 44, 48, 49, 59, 60) indicate a melting point in the range 910–926°C. The heat of fusion, according to calorimetric measurements, is (60) 44 350 or (59) 35 140 J mol^{-1}. There are transitions at 370°C (42, 48), 450 or 455°C (61), and at 575 or 585°C (34, 42). It was decided to include all three transitions, making K_2WO_4 and K_2MoO_4 similar to Na_2MoO_4. The form at room temperature (α), is monoclinic *C2/m* (62). Since experimental transition enthalpies could not be found, these were given nominal values (α → β, 35 140 J mol^{-1}; β → γ, 5000 J mol^{-1}; γ → δ, 14 380 J mol^{-1}). K_2MoO_4 was used as a guide for the assignment of the relative magnitudes of these enthalpies. The exact values of these transition enthalpies do not critically affect the calculation of the phase diagrams reported in the present work. The C_p of all solids were set at $136 + 0.0622T$ J mol^{-1} K^{-1}, which is a simple additive result from $K_2O + WO_3$ (17). The C_p of the liquid was set at 211 J mol^{-1} K^{-1}, i.e., the value of the solid at the melting point.

K_2MoO_4

There is no information on fusion or transition properties (14–17). Its melting behaviour is very similar to that of K_2WO_4; phase diagram and other sources give a melting point in the range 891–938°C (26, 43, 48, 49, 60, 63, 64) and 926°C was chosen as the best value. The heat of fusion, from calorimetry, is (60) 45 190 or (49) 34 700 J mol^{-1}. At least three transitions have been reported. The lowest is 315–338°C (26, 48, 61, 63–65). The other two chosen here are 435–465°C (26, 48, 61, 63, 64) and 471–480°C (26, 34, 48, 61, 65). The γ → δ transition enthalpy (14 380 J mol^{-1}) was estimated from the subsolidus part of a phase diagram (26). The other two transition enthalpies were nominally assigned in the same manner as K_2WO_4. Again, the exact value of these enthalpies is not crucial for calculating phase diagrams. The α-solid is monoclinic *C2/m*, and it is suggested (66) that the β-solid is orthorhombic, and the γ-solid, simple hexagonal. The C_p of all solids was set at $133.8 + 0.068T$ J mol^{-1} K^{-1}, a simple additive result from $K_2O + MoO_3$ (17). The C_p of the liquid was set at 215 J mol^{-1} K^{-1}, i.e., the value for the solid at the melting point.

$BaMoO_4$

No fusion properties are found in the compilations (14–17). From phase diagram reports (26, 45, 46, 67), a temperature of 1457°C was adopted. The heat of fusion was estimated from the limiting liquidus slope of a phase diagram at pure $BaMoO_4$ (67); a similar type of estimation (32) yielded the value 53.6 kJ mol^{-1}. A transition at 1259°C (32) is not found in any compilation (14–17) and hence was disregarded. The C_p of the solid was taken from Barin's compilations (16, 17). The C_p of the liquid was taken to be 182 J mol^{-} K^{-1}, i.e., that of the solid at the melting point.

$BaWO_4$

No fusion properties are found in the compilations (14–17). The melting point, from phase diagram and other reports, is in the range 1475–1510°C (31, 33, 45 68–70). The heat of fusion was estimated from the limiting liquidus slope at pure $BaWO_4$ of a phase diagram (33). The C_p of the solid was taken from Barin's compilations (16, 17) and the C_p of the liquid was put equal to that of the solid at the melting point.

Expedient synthesis of unsaturated amide alkaloids from *Piper* spp: Exploring the scope of recent methodology

George M. Strunz and Heather J. Finlay

Abstract: The Sakai aryl aldehyde – cyclic ketone aldol – Grob fragmentation sequence was extended to cinnamaldehyde and cyclohexanone, and the product was elaborated to analogues of the alkaloid piperstachine. The effects of substituents on the reaction involving cinnamaldehyde were studied. The aldol-fragmentation sequence failed with benzaldehyde when cyclooctanone or cyclobutanone was substituted for cyclohexanone or cyclopentanone, and the reasons for this failure were examined. Four-carbon Wittig homologation of the piperonal–cyclobutanone aldol-fragmentation product, a hypothetical route to alkaloids such as retrofractamide A, was thus not viable. Instead, three-carbon homologation of the readily available piperonal–cyclopentanone product, using alkyne chemistry recently disclosed by Lu and Trost, afforded these alkaloids in excellent overall yield. The alkyne isomerization was also used to effect efficient syntheses of pellitorine and several other non-aromatic 2*E*,4*E*-dienoic *Piper* amide alkaloids.

Key words: *Piper*, amides, alkaloids, insecticides, aldol, fragmentation, cinnamaldehydes, alkyne, redox, isomerization.

Résumé : La séquence de Sakai, qui peut consister en une réaction d'aldol entre un aldéhyde et une cétone cyclique suivie d'une fragmentation de Grob, fut utilisée pour préparer des analogues de l'alcaloïde piperstachine à partir du cinnamaldéhyde et de la cyclohexanone. L'influence des substituants sur la réaction du cinnamaldéhyde furent également étudiées. La séquence aldol fragmentation entre le benzaldéhyde et la cyclooctanone ou la cyclobutanone ne fonctionne pas malgré que la cyclopentanone et la cyclohexanone produisent le résultat anticipé. Ce résultat fut étudié en détail. Le produit obtenu à paritr de la cyclobutanone, suite à une homologation de Wittig de quatre carbones, aurait ainsi donné accès aux alcaloïdes tels la réfractamide A. Cependant, une homologation de trois carbones sur le produit de la séquence de Sakai entre le pipéronal et la cyclopentanone fournit ces alcaloïdes en d'excellents rendements en utilisant la chimie acétylenique développé récemment par Lu et Trost. L'isomérisation acétylenique fut aussi employée pour la synthèse de la péllitorine et plusieurs autres alcaloïds amidiques non-aromatiques 2*E*,4*E*-dienoiques des espèces *Piper*.

Mots clés : *Piper*, amides, alcaloïdes, insecticides, aldol, fragmentation, cinnamaldéhydes, alkyne, redox, isomérization.

Introduction

Problems associated with the continued widespread use of synthetic broad-spectrum pesticides, including development of resistance and impact on non-target organisms, have provided impetus for the development of alternative control agents and measures. In this context, plant-derived substances, used as botanical pesticides from antiquity, have increasingly been revisited as being more likely to meet present-day needs for environmental compatibility. The insecticidal and other biological properties of some unsaturated amides, e.g., pipercide **1**, isolated from *Piper* spp. have generated renewed interest in the study of these compounds (1, 2).

A semisystematic nomenclature for *Piper* amides has been advocated by Tsuda and co-workers (3) that, although not in general use, offers some advantages in terms of clarity and brevity and will be adopted in this paper. In Tsuda's system, compounds possessing an aromatic ring and an amide group are assigned the general name "piperamide." Where the aromatic nucleus bears a methylenedioxy group, the alkaloids are designated piperamide A, B, or C *m*:*n* with A, B, and C representing piperidine, *N*-isobutyl, or pyrrolidine amide, respectively, *m* indicating the number of carbons between the nitrogen and the aromatic nucleus, and *n* the number of double bonds in the chain. The position and geometry of the double bonds are indicated in parentheses.

We recently developed efficient methodology for the concise stereoselective synthesis of some *Piper* amides, including pipercide, **1** (piperamide-B11:3(2*E*,4*E*,10*E*)), piperolein A, **2** (piperamide A7:1(6*E*)), and **3**, (piperamide-C7:2(2*E*,6*E*))[2] (6, 7). This approach (Scheme 1) was based on an aldol condensation – Grob-type fragmentation sequence, originally disclosed by Sakai and co-workers (8). Thus, cyclohexanone was first condensed with piperonal under catalysis by boron triflu-

oride. Addition of a glycol (preferably 1,3-propane diol (6)) then produced an acetal **II** ($x = 4$), which underwent fragmentation affording the glycol ester intermediate **III** ($x = 4$), with exclusively *E* geometry about the double bond. The methodology has proved to be eminently suitable for the synthesis of *Piper* amides such as **2** and **3** ($m = 7$), which were prepared via direct amidation of the versatile intermediate **III** ($x = 4$). Alternatively, the latter was readily reducible to an aldehyde, **IV** ($x = 4$, R′ = H), which could be homologated by 4C Wadsworth–Emmons (phosphonocrotonate) reaction affording entry to pipercide, **1** ($m = 11$).

The corresponding nor-piperamides ($m = 6$ or 10) are accessible, if cyclopentanone is substituted for the six-membered ketone (6). The susceptibility of the processes occurring in the course of the aldol condensation – fragmentation sequence to subtle steric and stereoelectronic effects raises interesting questions about the scope of the methodology, e.g., when other sized cyclic ketones (cylobutanone, cycloheptanone etc.) are used.

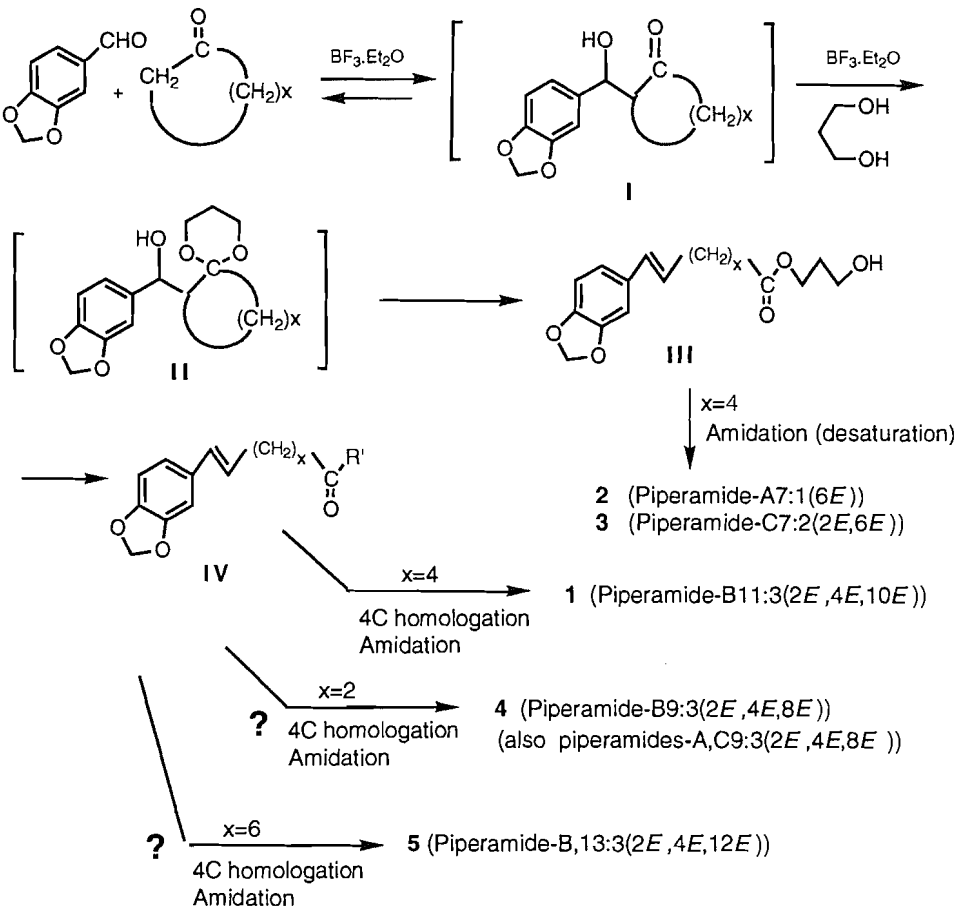
10

An aldol condensation – fragmentation sequence involving cyclobutanone and piperonal (if feasible) could, for instance, with subsequent 4C homologation, lead to facile syntheses of compounds like retrofractamide A, **4** (piperamide-B9:3(2*E*,4*E*,8*E*) from *Piper refractum* (9), piperamide-A9:3(2*E*,4*E*,8*E*) from *P. longum* (10) and piperamide-C9:3(2*E*,4*E*,8*E*) from *P. nigrum* (3) (Scheme 1). On the other hand, synthesis of guineensine **5** (piperamide-B13:3(2*E*,4*E*,12*E*)) from *P. guineense* (11) or piperolein B (piperamide-A9:1(8*E*)) from *P. nigrum* (12) dictates an aldol condensation – fragmentation involving cyclooctanone and piperonal.

If the aldol condensation – fragmentation sequence could be conducted with a homologue of piperonal, 3′,4′-methylenedioxycinnamaldehyde, and cyclohexanone, then reduction, Wadsworth–Emmons (2C) homologation, and amidation would constitute a facile synthesis of piperstachine **6** (piperamide-B11:3(2*E*, 8*E*, 10*E*), an alkaloid from *P. trichostachyon* (13) (Scheme 2).

This paper discloses our observation that the Sakai aldol

Scheme 1.



condensation – fragmentation sequence can be satisfactorily extended to *cinnamaldehyde* (but not so readily to 3′,4′-methylenedioxycinnamaldehyde) and cyclohexanone, opening the way to a short synthesis of a "demethylenedioxy" analogue of piperstachine **6**, and related compounds. We report also on our unsuccessful attempts to effect the condensation–fragmentation process using cyclobutanone or cyclooctanone with piperonal to give **III** (and **IV**) (x = 2 and x = 6, respectively). Alternative, efficient methodology to gain access to **4** and the other 9:3(2*E*,4*E*,8*E*) amide alkaloids is described, in which 3C homologation of the readily available **IV** (x = 3) (6), exploiting recently disclosed alkyne chemistry (14, 15), replaces 4C homologation of the elusive **IV** (x = 2).

Results

(a) Condensation–fragmentation with cyclohexanone and cinnamaldehydes: synthesis of piperstachine (11:3(2*E*,8*E*,10*E*)) analogue and related compounds

The condensation–fragmentation process proceeded readily with cyclohexanone when cinnamaldehyde was substituted for benzaldehyde or piperonal, and the ester **VI** (R,R′ = H), was obtained in 59% yield. Four-carbon (phosphonocrotonate) Wadsworth–Emmons homologation of the aldehyde from **VI** (R,R′ = H) and subsequent amidation by appropriate methodology allowed the synthesis of the model compounds **7** and **8** in overall yields of 22 and 36%, respectively. Similarly, the aldehyde from **VI** (R,R′ = H) was converted, via 2C (phosphonoacetate) Wadsworth–Emmons homologation and amidation to "desmethylenedioxypiperstachine" **9**, (overall yield from cinnamaldehyde ~33%) (Scheme 2). (The corresponding piperidyl amide **10** was also prepared in similar yield.) Exploitation of this concise strategy for the synthesis of piperstachine requires 3′,4′-methylenedioxycinnamaldehyde as starting material but, perhaps not surprisingly, the presence of the ether functionality in the aromatic ring had a detrimental effect on the condensation–fragmentation process, and **VI** (R = 3′,4′-methylenedioxy) was obtained in only ~14% yield (Table 1), deemed insufficient to make this route competitive with the previous synthesis (13).

In view of the effect of the methylenedioxy aromatic substituent on the yield of the condensation–fragmentation process, the effects of other substituents were briefly examined using readily available substituted cinnamaldehydes. The influences of substituents R and R′ on the course of the reaction (Table 1) are in general as expected based on their electron-donating or withdrawing properties (and steric effects of R′), and are consistent with Sakai's observations for substituted benzaldehydes (8).

(b) Attempted piperonal–cyclooctanone condensation–fragmentation

As mentioned in the Introduction and indicated in Scheme 1, the product **III** (x = 6), *if it could be prepared from piperonal and cyclooctanone*, would be readily transformed to the *P. guineense* alkaloid guineensine **5** (piperamide-B13:3(2*E*,4*E*,12*E*) via 4C-(crotonate) Wadsworth–Emmons

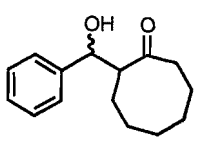
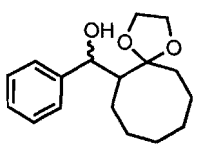
homologation of **IV** (x = 6) and amidation) as well as piperolein B (piperamide-A9:1(8*E*)) from *P. nigrum* (by direct amidation). Attempts to effect the condensation–fragmentation under a variety of conditions were, however, to no avail and resulted in a complex mixture of products that appeared to contain some aldol **I** (x = 6), but no glycol ester **III** (x = 6). To investigate factors contributing to this different behaviour exhibited by the larger ring homologue, models **11** and **12** of the putative intermediates **I** and **II** (x = 6; Scheme 1), were independently prepared by alternative routes, and their behavior under "fragmentation conditions" was observed. Aldol **11**



11



12

was made using Mukaiyama methodology (16), as a mixture of epimers (*anti*:syn~ 65:35). The purified *anti* epimer was immediately treated with propylene glycol and BF_3-etherate. Chromatography afforded the dehydrated product 2-benzylidinecyclooctanone in 40% yield and ~46% of an inseparable (1:1) mixture of cyclooctanone and the propylene glycol acetal of benzaldehyde: no cyclooctanone acetal was observed.

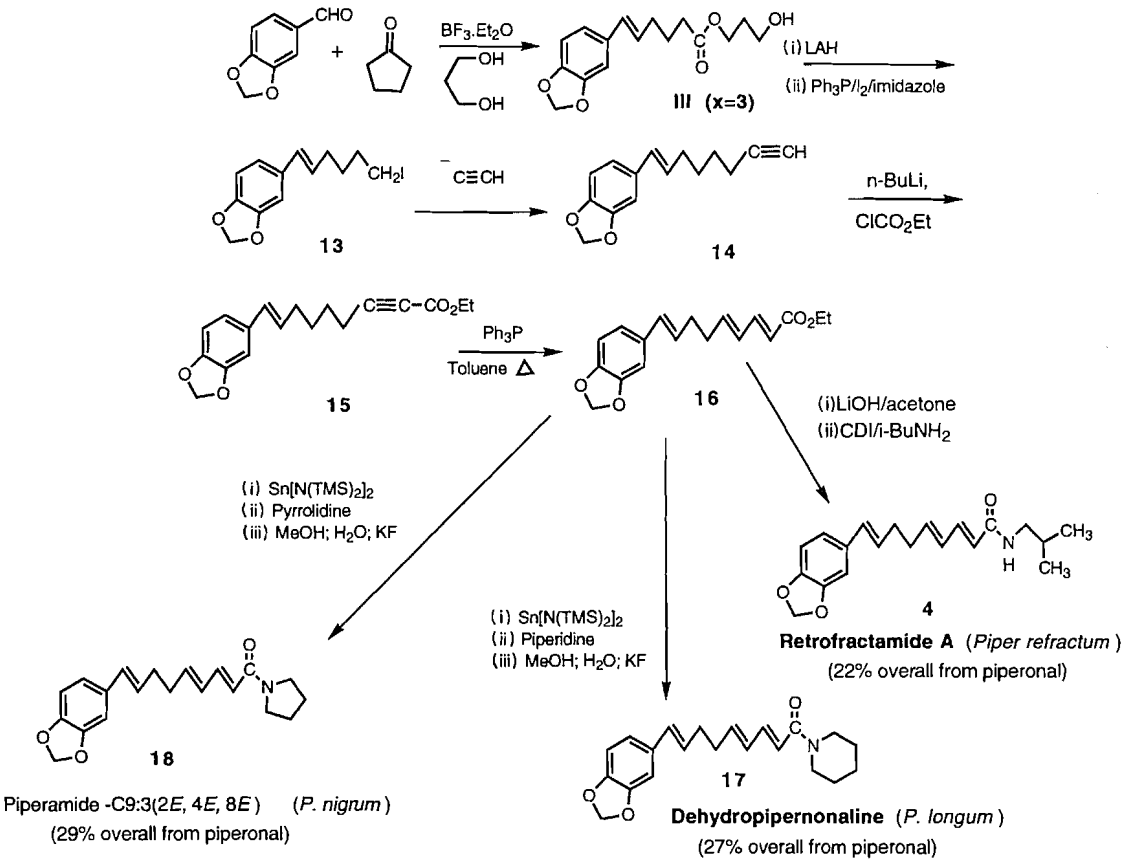
Preparation of **12** was accomplished in low yield by acetalization (slow!) of 2-ethoxycarbonyl cyclooctanone with ethylene glycol, reduction/oxidation (LAH/Swern) to the 2-formyl derivative of the acetal, and, finally, reaction of this (very unstable) material with phenyllithium. Treatment of **12**, in THF solution with BF_3-etherate under anhydrous conditions, resulted in the isolation, after bicarbonate quench and work-up, only of benzaldehyde and cyclooctanone.

It seems clear that the major factor militating against the fragmentation process in the cyclooctanone–piperonal case is the slow rate of acetalization of the initially formed aldol intermediate, which allows alternative pathways to take precedence. (The extensively enolized carbonyl group of cyclooctanone itself is known to be very unreactive towards nucleophilic attack (17).) The observation that **12** (*even if it were* formed from **11** in a Lewis acid – glycol mixture) fails to undergo Grob-type fragmentation, yielding instead products of a retroaldol-type cleavage, could possibly be due to stereoelectronic effects (cf. ref. 6) or to the Lewis acid complexing with an acetal oxygen rather than the hydroxyl group.

(c) 9:3(2*E*,4*E*,8*E*) (or 5:1(4*E*)) Amides formally accessible via piperonal–cyclobutanone condensation–fragmentation

Attempts to effect the condensation–fragmentation sequence using cyclobutanone, piperonal, and 1,3-dihydroxypropane under BF_3 catalysis led to almost quantitative recovery of the

Scheme 3.



piperonal – propylene glycol acetal, suggesting that the essential initial aldol condensation is an unfavorable process.

In lieu of *four-carbon* (crotonate) Wadsworth – Emmons homologation of the elusive **IV** (x = 2, R′ = H), followed by amidation, the 9:3(2*E*,4*E*,8*E*) amides (3, 9, 10) could be prepared via a suitable *three-carbon* homologation of **III** (x = 3), readily available from cyclopentanone and piperonal as described above. Methodology recently developed by Ma and Lu (14) and Trost and Kazmaier (15), involving transition metal or triphenylphosphine-catalyzed isomerization of an activated alkyne, proved to be ideally suited to effect the desired 3C homologation at the appropriate oxidation level. Thus the alkaloids retrofractamide A, **4** (piperamide-B9:3(2*E*,4*E*,8*E*)) (9), dehydropipernonaline **17** (piperamide-A9:3(2*E*,4*E*,8*E*)) (10), and **18** (piperamide-C9:3(2*E*,4*E*,8*E*) (3) were readily synthesized in good yield as follows, by a short stereoselective route exploiting the two recently developed methodologies aldol condensation – fragmentation (8) and alkyne isomerization (14, 15)) (Scheme 3): Lithium acetylide – ethylene diamine complex was alkylated with iodide **13**, simply prepared in two steps from glycol ester **III** (x = 3). The anion of the resulting alkyne, **14**, reacted with ethyl chloroformate affording alkyne ester **15**. As alkynoic amides are less reactive substrates for the internal redox process than the corresponding esters (14, 15), amidation was postponed until after the isomerization. Accordingly, **15** was heated under reflux with Ph_3P in toluene (15), giving the 2*E*,4*E*,8*E* ester **16** in excellent yield. Amidation was effected in one pot by the Roskamp procedure (18) for the piperidine and pyrrolidine amides, and by hydrolysis and carbonyldiimidazole-induced coupling for the isobutylamide. Retrofractamide A (**4**) from *P. refractum* (9) was obtained in an overall yield of 22% from piperonal, dehydropipernonaline (**17**) from *P. longum* (10) in 27% overall yield, and piperamide-C9:3(2*E*,4*E*,8*E*) (**18**) (3) in 29% overall yield.

(d) General route to non-aromatic 2*E*,4*E* dienoic amide alkaloids

The efficacy of our route to retrofractamide A and the other 9:3(2*E*,4*E*,8*E*) piperamides prompted us to turn our attention to the simpler non-aromatic 2*E*,4*E*, dienoic *Piper* amides, some of which, including **19** and **21**, were synthesized earlier by Ma and Lu (14). The key reaction in Lu's route to the dienoic amides was rearrangement of the corresponding 2-ynoic amides under catalysis by ruthenium or iridium complexes of Ph_3P. The alkynoic amide precursors were prepared by classical methodology via carboxylation of the appropriate terminal alkynes (19) and suitable elaboration of the resulting carboxylic acids. We have developed a simple, efficient general stereoselective synthesis of these alkaloids that, while running essentially parallel to Lu's sequence, differs in some important details that, we suggest, may confer on it some advantages in terms of convenience and yield. The new route is exemplified by the synthesis of pellitorine (**19**) (2, 4) in five steps from propiolic acid with overall yield 52% (Scheme 4). Application of this general synthetic route afforded **20** (from *P. nigrum* (3)) in 61% overall yield from propiolic acid; **21**, achillia amide (20) in 66% yield; **22** and **23** (from *P. guineense* (11)) in 39% and 50% yield, respectively; and **24** (from *P. trichostachyon* (21)) in 50% overall yield.

As a result of the present study and previous work (6, 7), more than a dozen unsaturated amides, mostly alkaloids from various *Piper* spp., are readily accessible and several are presently being assayed for insecticidal activity against such economically important insect pests as spruce budworm (*Choristoneura fumiferana*), gypsy moth (*Lymantria dispar*), and forest tent caterpillar (*Malacosoma disstria*).

Experimental

Details concerning instrumentation may be found in ref. 6.

9-Phenyl-6*E*,8*E*-nonadienoic acid propylene glycol ester, VI (R = R′ = H)

Boron trifluoride etherate (5.3 mL, 42 mmol) was added dropwise under argon to a solution of cinnamaldehyde (0.75 mL, 5.9 mmol) in dry freshly distilled THF (15 mL) at 0°C. The solution was stirred for 10 min, after which cyclohexanone (0.61 mL, 5.9 mmol) dissolved in dry THF (10 mL) was added dropwise with stirring over a 20 min period. The ice bath was removed and the mixture allowed to attain ambient temperature during 70 min. To the resulting dark green mixture was added propane-1,3-diol (2.2 g, 31 mmol) and the stirred (now purple) reaction mixture was set aside at ambient temperature for 14 h. The product was worked up by addition of the mixture to a saturated aqueous solution of $NaHCO_3$ (ca. 200 mL) and extraction with ether (3 × 50 mL). The combined organic extracts were washed successively with saturated $NaHCO_3$ (2 × 20 mL) and saturated brine (2 × 20 mL) and, after being dried over $MgSO_4$, were evaporated to dryness under reduced pressure. The resulting crude red oil was subjected to chromatography on a column of silica gel with hexane – EtOAc (3:2) as eluent, to furnish 1.016 g (59%) of ester **VI** (R = R′ = H) as a relatively polar pale yellow oil. This product was rather unstable and, in order to avoid decomposition, was either reduced directly or stored frozen in benzene. It displayed the following spectroscopic characteristics: IR ($CHCl_3$): 3600, 3440, 1720, 1640, 1595, 1460, 1040, 985, and 880 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.35–1.55 (2H, m), 1.55–1.75 (2H, m), 1.86 (2H, pent, J = 6.0 Hz), 2.16 (2H, q, J = 7.2 Hz), 2.34 (2H, t, J = 7.2 Hz), 3.68 (2H, t, J = 6.0 Hz), 4.23 (2H, t, J = 6.0 Hz), 5.79 (1H, dt, J = 7.0 and 15.2 Hz), 6.21 (1H, dd, J = 10.2 and 15.4 Hz), 6.44 (1H, d, J = 15.8 Hz), 6.74 (1H, dd, J = 10.2 and 15.8 Hz), 7.20–7.45 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 288.1723 (33) (M^+) (calcd. for $C_{18}H_{24}O_3$: 288.1725), 212 (36) ($M^+ - C_3H_6(OH)_2$), 169 (13) ($C_{13}H_{13}$), 156 (72) ($C_{12}H_{12}$), 143 (65) ($C_{11}H_{11}$), 131 (86) (C_9H_7O), 128 (100) ($C_{10}H_8$), 115 (52) (C_9H_7), 113 (28) ($C_6H_9O_2$), 103 (53) (C_8H_7) 91 (80) (C_7H_7) 84 (26) (C_5H_8O), 77 (57) (C_6H_5).

9-(3′,4′-Methylenedioxyphenyl)-6*E*,8*E*-nonadienoic acid propylene glycol ester, VI (R = 3′,4′-methylenedioxy, R′ = H)

Boron trifluoride etherate (2.5 mL, 20 mmol) was added dropwise under argon to a solution of 3′,4′-methylenedioxycinnamaldehyde[3] (0.491 g, 2.79 mmol) in dry freshly distilled THF (15 mL) at 0°C. The solution was stirred for 10 min, after which cyclohexanone (0.28 mL, 2.7 mmol) dissolved in dry THF was added slowly dropwise with stirring. The ice bath was removed and the mixture was set aside with stirring for 7.5 h, after which propane-1,3-diol (1.1 g, 14 mmol) was added and stirring resumed at ambient temperature for 14 h. The product was worked up as above and purified by flash chromatography on silica gel with hexane–EtOAc (3:2) as eluent. The chromatographically pure ester **VI** (R = 3′,4′-methylenedioxy, R′ = H) (131 mg, 14%) was a yellow oil: IR ($CHCl_3$): 3675, 3600, 3500, 2945, 2900, 1720, 1600, 1485, 1440, 1040, 990, and 930 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.40–1.55 (2H, m), 1.55–1.75 (2H, m), 1.85 (2H, pent, J = 6.0 Hz), 2.13 (2H, q, J = 7.0 Hz), 2.32 (2H, t, J = 7.2 Hz), 3.67 (2H, q, J = 5.4 Hz), 4.22 (2H, t, J = 6.2 Hz), 5.72 (1H, dt, J = 7.2 and 14.8 Hz), 5.92 (2H, s), 6.15 (1H, dd, J = 10.0 and 15.0 Hz), 6.33 (1H, d, J = 15.6 Hz), 6.56 (1H, dd, J = 10.0 and 15.6 Hz), 6.73 (1H, s), 6.76 (1H, d, J = 1.4 Hz), 6.90 (1H, d, J = 1.4 Hz), HREIMS, *m/z* (relative intensity) (ion): 332.1624 (73) (M^+) (calcd. for $C_{19}H_{24}O_5$: 332.1624), 257 (11) (M − $O(CH_2)_3OH$), 228 (11) M^+ − $CO_2(CH_2)_3OH$), 187 (64) ($C_{12}H_{11}O_2$), 176 (64) ($C_{10}H_8O_3$), 173 (100) ($C_{11}H_9O_2$), 167 (19) ($C_8H_7O_4$), 159 (31) ($C_{10}H_7O_2$), 157 (40) ($C_{11}H_9O$), 149 (76) ($C_8H_5O_3$), 147 (29) ($C_9H_7O_2$), 143 (18) ($C_{10}H_7O$), 135 (54) ($C_8H_7O_2$), 128 (32) ($C_{10}H_8$), 122 (17) ($C_7H_6O_2$), 113 (30) ($C_6H_9O_2$), 95 (18) (C_7H_{11}), 89 (26) (C_5H_7), 87 (16) ($C_4H_7O_2$).

Substituted 9-phenylnona-6*E*,8*E*-dienoic acid propylene glycol esters, VI

The procedure for the preparation of **VI** (R = H, R′ = CH_3) and **VI** (R = 2′-OCH_3) (Entries 6 and 7, Table 1), was essentially as for **VI** (R = R′ = H), using the appropriate substituted (commercially available) cinnamaldehydes. The former displayed IR ($CHCl_3$): 3600, 3500, 2940, 2870, 1725, 1600, 1490, 1460, 1440, 1390, 1380, 1150, 1080, 1050, 970, 920, and 870 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.50 (2H, m), 1.69 (2H, m), 1.88 (2H, sept, J = 6.2 Hz), 1.99 (3H, d, J = 1.2 Hz), 2.20 (2H, dt, J = 7.0 and 6.4 Hz), 2.36 (2H, t, J = 7.2 Hz), 3.70 (2H, br t, J = 4.6 Hz), 4.26 (2H, t, J = 6.0 Hz), 5.77 (1H dt, J = 15.4 and 7.0 Hz), 6.26 (1H, dd, J = 15.8 and 0.8 Hz), 6.44 (1H, br s) 7.25–7.40 (5H, m). HREIMS, *m/z* (relative intensity) (ion): 302.1888 (19) (M^+) (calcd. for $C_{19}H_{26}O_3$: 302.1882), 226 (9) (M^+ − $(CH_2)_3(OH)_2$), 183 (13) ($C_{14}H_{15}$), 155 (25) ($C_{12}H_{11}$), 143 (100) ($C_{11}H_{11}$), 129 (44) ($C_{10}H_9$), 115 (18) (C_9H_7), 91 (30) (C_7H_7).

The latter showed IR ($CHCl_3$): 3600, 3500, 2940, 2850, 1720, 1595, 1485, 1460, 1440, 1395, 1050, 1035, 995, and 915 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.40–1.55 (2H, m), 1.50–1.75 (2H, m), 1.85 (2H, sept, J = 6.4 Hz), 2.14 (2H, dt, J = 7.4 and 7.0 Hz), 2.32 (2H, t, J = 7.2 Hz), 3.67 (2H, m), 3.83 (3H, s), 4.22 (2H, t, J = 6.2 Hz), 5.75 (1H, dt, J = 15.2 and 7.0 Hz), 6.21 (1H, m), 6.74 (1H, d, J = 1.4 Hz), 6.75–6.95 (3H, m), 7.18 (1H, dd, J = 15.2 and 7.4 Hz), 7.42 (1H, d, J = 7.6 Hz); HREIMS, *m/z* (relative intensity) (ion): 318.1822 (86) (M^+) (calcd. for $C_{19}H_{26}O_4$: 318.1831), 242 (21) (M^+ − $(CH_2)_3(OH)_2$), 214 (14) (M^+ − $HCO_2(CH_2)_3OH$), 200 (14) ($C_{14}H_{16}O$), 186 (62) ($C_{13}H_{14}O$), 173 (59) ($C_{12}H_{13}O$), 159 (52) ($C_{11}H_{11}O$), 145 (40) ($C_{10}H_9O$), 131 (73) (C_9H_7O), 128 (24) ($C_{10}H_8$), 121 (100) (C_8H_9O), 119 (18) (C_8H_7O), 115 (35) (C_9H_7), 91 (65) (C_7H_7), 79 (15) (C_6H_7).

9-Phenylnona-6*E*,8*E*-dienal

A solution of glycol ester **VI** (R = R′ = H) (0.901 g, 3.13 mmol) in dry THF (10 mL) was added dropwise at 0°C to a slurry of LAH (0.179 g, 4.84 mmol) in dry THF (40 mL). After the initial evolution of hydrogen, the stirred mixture was allowed to attain ambient temperature during 3.5 h, when TLC analysis showed the reaction to be complete. After cautious sequential addition of water (0.1 equiv.), NaOH (15% aqueous) (0.1 equiv.), and water (0.3 equiv.), the mixture was stirred for 20 min. Magnesium sulfate was then added, the slurry was filtered through Celite and evaporated to dryness under reduced pressure. The resulting alcohol, 9-phenyl-6*E*,8*E*-nonadien-1-ol (642 mg, 95%) was sufficiently pure to be subjected directly to Swern oxidation. It displayed the following spectroscopic characteristics: IR ($CHCl_3$): 3600, 3425, 2930, 2850, 1640, 1595, and 990 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.35–1.50 (4H, m), 1.50–1.65 (2H, m), 2.10–2.25 (2H, m), 3.65 (2H, t, J = 6.4 Hz), 5.82 (1H, dt, J = 7.0 and 15.2 Hz), 6.21 (1H, dd, J = 10.3 and 15.2 Hz), 6.44 (1H, d, J = 15.4 Hz), 6.75 (1H, dd, J = 10.2 and 15.6 Hz), 7.20–7.45 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 216.1517 (84) (M^+) (calcd. for $C_{15}H_{20}O$: 216.1512), 155 (24) ($C_{12}H_{11}$), 143 (97) ($C_{11}H_{11}$), 130 (90) ($C_{10}H_{10}$), 115 (77) (C_9H_7), 111 (8) ($C_7H_{11}O$), 104 (48) (C_8H_8), 91 (100) (C_7H_7), 77 (23) (C_6H_5).

Swern oxidation (22) of the alcohol (642 mg, 2.97 mmol) yielded the desired aldehyde, 9-phenyl-6*E*,8*E*-nonadienal (611 mg, 96%) as a pale yellow oil. This product was sufficiently pure to be used directly in the subsequent Horner–Emmons reaction. A sample after preparative thin-layer chromatography displayed the following spectroscopic characteristics: IR ($CHCl_3$): 2940, 2860, 2740, 1720, 1640, 1595, 1490, 1450, and 990 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.40–1.60 (2H, m), 1.60–1.75 (2H, m), 2.17 (2H, q, J = 6.6 Hz), 2.45 (2H, dt, J = 1.8 and 7.0 Hz), 5.79 (1H, dt, J = 7.0 and 15.0 Hz), 6.21 (1H, ddt, J = 10.0, 15.4, and 1.0 Hz), 6.44 (1H, d, J = 15.8 Hz), 6.74 (1H, dd, J = 10.0 and 15.4 Hz), 7.20–7.40 (5H, m), 9.77 (1H, t, J = 1.8 Hz); HREIMS, *m/z* (relative intensity) (ion): 214.1356 (67) (M^+) (calcd. for $C_{15}H_{18}O$: 214.1357), 155 (13) ($C_{12}H_{11}$), 143 (80) ($C_{11}H_{11}$), 128 (100) ($C_{10}H_8$), 115 (52) (C_9H_7), 104 (72) (C_8H_8), 91 (67) (C_7H_7), 77 (20) (C_6H_5).

Ethyl 13-phenyltrideca-2*E*,4*E*,10*E*,12*E*-tetraenoate

n-Butyllithium (0.78 mL of 2.5 M solution in hexane, 1.95 mmol) was added dropwise by syringe to a stirred solution of triethyl 4-phosphonocrotonate (486 mg, 1.95 mmol) in dry THF (15 mL) at –78°C under argon. Stirring was continued for 20 min, and a solution of the aldehyde prepared above (378 mg, 1.77 mmol) in dry THF (5 mL) was then added dropwise. The pale yellow mixture was stirred at –78°C for a further 10 min, and was then allowed to attain ambient temperature during 1.5 h before the reaction was quenched by cautious addi-

[3] Prepared by reduction of the methyl ester of commercially available 3′,4′-methylenedioxycinnamic acid with sodium bis(2-methoxyethoxy)aluminium hydride, and Swern oxidation of the resulting alcohol.

tion of 1% NH_4Cl (ca. 10 mL). The mixture was extracted with ether (3 × 20 mL) and the extracts were washed with water (2 × 10 mL), dried over $MgSO_4$, and evaporated to dryness under reduced pressure. The crude ester product was passed through a short column of silica gel with hexane–EtOAc (6:1) as eluent, affording chromatographically pure ethyl 13-phenyltrideca-2*E*,4*E*,10*E*,12*E*-tetraenoate (406 mg, 74%) as a colorless oil: IR ($CHCl_3$): 2995, 2940, 2860, 1700, 1640, 1620, 1600, 1450, 1375, 1300, 1140, 1040, 1000, and 990 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.23 (3H, t, J = 7.0 Hz), 1.40 (4H, pent, J = 3.4 Hz), 2.12 (4H, m) 4.14 (2H, q, J = 7.2 Hz), 5.73 (1H, d, J = 15.2 Hz), 5.75 (1H, dt, J = 7.0 and 15.2 Hz), 6.04–6.24 (3H, m), 6.39 (1H, d, J = 15.5 Hz), 6.70 (1H, dd, J = 10.2 and 15.6 Hz), 7.15–7.40 (6H, m); HREIMS *m/z* (relative intensity) (ion): 310.1929 (11) (M^+) (calcd. for $C_{21}H_{26}O_2$; 310.1933), 237 (22) ($M^+ - CO_2C_2H_5$), 219 (10) ($C_{14}H_{19}O_2$), 206 (15) ($C_{13}H_{18}O_2$), 197 (12) ($C_{15}H_{17}$), 169 (14) ($C_{13}H_{13}$), 158 (39) ($C_{12}H_{14}$), 143 (50) ($C_{11}H_{11}$), 128 (77) ($C_{10}H_8$), 117 (78) (C_9H_9), 91 (100) (C_7H_7), 79 (23) (C_6H_7).

13-Phenyltrideca-2*E*,4*E*,10*E*,12*E*-tetraenoic acid

The ethyl ester (406 mg, 1.31 mmol) was heated under reflux for 1.5 h in acetone containing LiOH (3 mL of 1.0 M aqueous solution). The mixture was evaporated to near dryness under reduced pressure, and was then made acidic by addition of 2 M HCl and extracted with EtOAc (3 × 50 mL). The carboxylic acid was extracted from the organic phase into saturated $NaHCO_3$ (4 × 50 mL). The aqueous phase was made acidic by addition of 2 M HCl and the organic acid was reextracted with EtOAc (3 × 50 mL). The extracts, after being dried over $MgSO_4$ and evaporated to dryness, afforded 305 mg (83%) of colorless crystalline 13-phenyl-2*E*,4*E*,10*E*,12*E*-tridecatetraenoic acid, sufficiently pure to be used directly in the subsequent amidation step. A pure specimen melted at 99.5–101°C, and displayed IR absorption ($CHCl_3$) at 3200–2500, 2950, 2930, 2860, 1680, 1640, 1615, 1300, 1110, 1000, 990, and 910 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.46 (4H, t, J = 3.4 Hz), 2.17 (4H, m), 5.79 (1H, d, J = 15.4 Hz), 5.79 (1H, dt, J = 10.0 and 15.4 Hz), 6.12–6.30 (3H, m), 6.44 (1H, d, J = 15.8 Hz), 6.75 (1H, dd, J = 10.2 and 15.6 Hz), 7.15–7.45 (6H, m); HREIMS, *m/z* (relative intensity) (ion): 282.1615 (20) (M^+) (calcd. for $C_{19}H_{22}O_2$: 282.1620), 191 (17) ($C_{12}H_{15}O_2$), 178 (19) ($C_{11}H_{14}O_2$), 169 (17) ($C_{13}H_{13}$), 158 (44) ($C_{12}H_{14}$), 128 (87) ($C_{10}H_8$), 120 (16) ($C_7H_4O_2$), 117 (66) (C_9H_9), 91 (100) (C_7H_7), 79 (24) (C_6H_7).

13-Phenyltrideca-2*E*,4*E*,10*E*,12*E*-tetraenoic acid isobutylamide, 7

The carboxylic acid prepared above (305 mg, 1.08 mmol) in CH_2Cl_2 was stirred with 1,1′-carbonyldiimidazole (210 mg, 1.30 mmol) at 0°C under argon. After 45 min, a solution of isobutylamine (119 mg, 1.62 mmol) in CH_2Cl_2 (1 mL) was added and the reaction mixture was set aside with stirring for 14 h. After addition of water (ca. 10 mL) the product was taken up in CH_2Cl_2 and the organic solution was washed successively with $NaHCO_3$ (2 × 20 mL) and water (2 × 20 mL). The organic solution was dried ($MgSO_4$) and the product obtained on removal of solvent was purified by chromatography on silica gel with hexane–EtOAc (3:2) as eluent, to give pure amide **7** as a colorless solid: mp 87.5–92°C, IR ($CHCl_3$): 3450, 2960, 2870, 1660, 1635, 1620, 1510, and 995 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.93 (6H, d, J = 6.6 Hz), 1.45 (4H, pent, J = 3.4 Hz), 1.78 (1H, sept, J = 6.8 Hz) 2.18 (4H, m), 3.16 (2H, t; J = 6.4 Hz), 5.45 (1H, br s), 5.75 (1H, d, J = 15.0 Hz), 5.80 (1H, dt, J = 7.0 and 15.2 Hz), 6.04–6.16 (1H, m), 6.21 (1H, dd, J = 10.8 and 15.2 Hz), 6.44 (1H, d, J = 15.6 Hz), 6.75 (1H, dd, J = 10.2 and 15.4 Hz), 7.15–7.45 (6H, m); HREIMS, *m/z* (relative intensity) (ion): 337.2387 (56) (M^+) (calcd. for $C_{23}H_{31}NO$: 337.2406), 246 (29) ($C_{16}H_{24}NO$), 217 (26) ($C_{14}H_{19}NO$), 180 (14) ($C_{11}H_{18}NO$), 155 (15) ($C_{12}H_{11}$), 152 (31) ($C_9H_{14}NO$), 147 (20) ($C_{11}H_{15}$), 137 (18) ($C_{10}H_{17}$), 128 (60) ($C_{10}H_8$), 117 (59) (C_9H_9), 105 (24) (C_8H_9), 91 (90) (C_7H_7), 79 (24) (C_6H_7), 69 (100) (C_5H_9).

13-Phenyltrideca-2*E*,4*E*,10*E*,12*E*-tetraenoic acid piperidylamide, 8

The ester ethyl 13-phenyltrideca-2*E*,4*E*,10*E*,12*E*-tetraenoate (65 mg, 0.23 mmol) was treated with the Roskamp (18) reagent $Sn[N(TMS)_2]_2$ (0.28 mmol) and piperidine (27 mg, 0.34 mmol) in hexane. The mixture was set aside with stirring at ambient temperature for 12 h. Chromatography on a preparative silica gel plate (hexane–EtOAc (2:1)) of the product obtained on work-up (18) furnished 27 mg of unreacted ethyl 13-phenyltrideca-2*E*,4*E*,10*E*,12*E*-tetraenoate and 50 mg of the amide **8**, as a colorless oil that solidified on storage in the refrigerator (92% based on consumed starting material). IR ($CHCl_3$): 3000, 2940, 2860, 1645, 1620, 1590, 1440, 1140, 1120, 990, and 850 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.43 (4H, pent, J = 3.6 Hz), 1.50–1.70 (6H, m), 2.15 (4H, m), 3.53 (4H, br s), 5.78 (1H, dt, J = 7.0 and 14.8 Hz), 6.02 (1H, dt, J = 6.4 and 15.0 Hz), 6.10–6.24 (2H, m), 6.24 (1H, d, J = 14.6 Hz), 6.42 (1H, d, J = 15.6 Hz), 6.73 (1H, dd, J = 10.2 and 15.6 Hz), 7.15–7.40 (6H, m); HREIMS, *m/z* (relative intensity) (ion): 349.2392 (63) (M^+) (calcd. for $C_{24}H_{31}NO$: 349.2405), 229 (28) ($C_{15}H_{19}NO$), 192 (20) ($C_{12}H_{18}NO$), 164 (52) ($C_{10}H_{14}NO$), 143 (24) ($C_{11}H_{11}$), 138 (12) ($C_8H_{12}NO$), 132 (12) (C_9H_8O), 128 (53) ($C_{10}H_8$), 127 (31) ($C_7H_{13}NO$), 117 (57) (C_9H_9), 112 (100) ($C_6H_{10}NO$), 91 (79) (C_7H_7), 84 (61) ($C_5H_{10}N$), 77 (28) (C_6H_5).

Ethyl 11-phenylundeca-2*E*,8*E*,10*E* trienoate

n-Butyllithium (1.0 mL of 2.5 M solution in hexane, 2.5 mmol) was added dropwise by syringe to a stirred solution of triethyl phosphonoacetate (572 mg, 2.46 mmol) in dry THF (15 mL) at –78°C under argon. Stirring was continued for 20 min, and a solution of the aldehyde prepared above (438 mg, 2.05 mmol) in dry THF (5 mL) was then added dropwise. The pale yellow mixture was stirred at –78°C for a further 10 min, and was then allowed to attain ambient temperature over 1.5 h before the reaction was quenched by cautious addition of 1% NH_4Cl (ca. 10 mL). The crude ester product obtained on conventional work-up was passed through a short column of silica gel with hexane–EtOAc (6:1) as eluent, affording chromatographically pure ethyl 11-phenyl-(2*E*,8*E*,10*E*) undecatrienoate (421 mg, 73%) as a colorless oil: IR ($CHCl_3$): 2995, 2940, 2860, 1705, 1660, 1600, 1450, 1370, 1040 and 990 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) : 1.28 (3H, t, J = 7.2 Hz), 1.47 (4H, pent, J = 3.4 Hz), 2.19 (4H, m) 4.18 (2H, q, J = 7.2 Hz), 5.79 (1H, dt, J = 7.0 and 15.2 Hz), 5.81 (1H, d, J = 15.8 Hz), 6.20 (1H, dd, J = 10.2 and 15.2 Hz), 6.43 (1H, d, J = 15.6 Hz), 6.74 (1H, dd, J = 10.2 and 15.6 Hz), 6.96 (1H, dt, J = 7.0 and 15.6 Hz), 7.20–7.45 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 284.1792 (13) (M^+) (calcd. for $C_{19}H_{24}O_2$:

284.1776), 210 (38) ($C_{16}H_{18}$), 202 (17) ($C_{13}H_{14}O_2$), 193 (29) ($C_{12}H_{17}O_2$), 155 (19) ($C_{12}H_{11}$), 141 (38) ($C_{11}H_9$), 128 (100) ($C_{10}H_8$), 119 (51) (C_9H_{11}), 91 (77) (C_7H_7), 77 (13) (C_6H_5).

11-Phenylundeca-2*E*,8*E*,10*E*-trienoic acid

Hydrolysis of the above ethyl ester (294 mg, 1.04 mmol), accomplished using the same procedure as for its homologue, afforded 265 mg (96%) of colorless crystalline 1-phenyl-2*E*,8*E*,10*E* undecatrienoic acid, sufficiently pure to be used directly in the subsequent amidation step. A pure specimen melted at 105.5–107°C, and displayed IR absorption ($CHCl_3$) at 3200–2600, 2940, 2860, 1695, 1650, 1600, and 990 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.47 (4H, m), 2.10–2.35 (4H, m), 5.77 (1H, dt, J = 7.0 and 15.0 Hz), 5.82 (1H, d, J = 15.6 Hz), 6.19 (1H, dd, J = 10.2 and 14.8 Hz), 6.43 (1H, d, J = 15.8 Hz), 6.73 (1H, dd, J = 10.0 and 15.6 Hz), 7.06 (1H, dt, J = 7.0 and 15.6 Hz), 7.20–7.40 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 256.1456 (41) (M^+) (calcd. for $C_{17}H_{20}O_2$: 256.1463), 211 (22) ($M^+ - CO_2H$), 165 (24) ($C_{10}H_{13}O_2$), 158 (15) ($C_{12}H_{14}$), 143 (78) ($C_{11}H_{11}$), 128 (100) ($C_{10}H_8$), 115 (44) (C_9H_7), 104 (29) (C_8H_8), 91 (65) (C_7H_7), 77 (15) (C_6H_5), 69 (61) (C_5H_9).

11-Phenylundeca-2*E*,8*E*,10*E*-trienoic acid isobutylamide, 9

The carboxylic acid (191 mg, 0.746 mmol) afforded the corresponding isobutylamide **9** (206 mg, 89%) using the 1,1′-carbonyldiimidazole coupling procedure described for the homologue **7**. Amide **9** was a colorless solid, mp 119–127°C, IR ($CHCl_3$): 3450, 2960, 2930, 2860, 1670, 1640, 1510, and 990 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.88 (6H, d, J = 6.4 Hz), 1.48 (4H, t, J = 3.2 Hz), 1.78 (1H, sept, J = 6.6 Hz) 2.18 (4H, m), 3.14 (2H, t, J = 6.8 Hz), 5.45 (1H, br s), 5.75 (1H, d, J = 15.4 Hz), 5.79 (1H, dt, J = 6.6 and 15.2 Hz), 6.19 (1H, dd, J = 10.2 and 15.0 Hz), 6.43 (1H, d, J = 15.8 Hz), 6.74 (1H, dd, J = 10.2 and 15.6 Hz), 6.82 (1H, dt, J = 6.8 and 15.4 Hz), 7.25–7.45 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 311.2245 (62) (M^+) (calcd. for $C_{21}H_{29}NO$: 311.2249), 220 (53) ($C_{14}H_{22}NO$), 211 (48) ($C_{16}H_{19}$), 196 (20) ($C_{15}H_{16}$), 194 (22) ($C_{12}H_{20}NO$), 154 (62) ($C_9H_{16}NO$), 143 (50) ($C_{11}H_{11}$), 141 (43) (C_8H_5NO), 128 (84) ($C_{10}H_8$), 121 (73) (C_9H_{13}), 115 (44) (C_9H_7), 105 (14) (C_7H_5O), 91 (100) (C_7H_7), 81 (19) (C_6H_9), 77 (17) (C_6H_5), 74 (8) ($C_4H_{12}N$).

11-Phenylundeca-2*E*,8*E*,10*E*-trienoic acid piperidylamide, 10

The ester, ethyl 11-phenyl-2*E*,8*E*,10*E*-undecatrienoate, furnished the amide **10** directly in 86% yield via the Roskamp procedure (18). IR ($CHCl_3$): 3000, 2940, 2860, 1655, 1600, 1440, and 990 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.46 (4H, m), 1.54 (4H, m), 2.17 (4H, q, J = 6.0 Hz), 3.51 (4H, br s), 5.78 (1H, dt, J = 7.0 and 15.0 Hz), 6.10–6.25 (1H, m), 6.23 (1H, br d, J = 15.0 Hz), 6.42 (1H, d, J = 15.6 Hz), 6.73 (1H, dd, J = 10.8 and 15.8 Hz), 6.81 (1H, dt, J = 7.0 and 15.0 Hz), 7.15–7.40 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 323.2237 (48) (M^+) (calcd. for $C_{22}H_{29}NO$: 323.2248), 232 (34) ($C_{15}H_{22}NO$), 206 (15) ($C_{13}H_{20}NO$), 166 (69) ($C_{10}H_{16}NO$), 153 (22) ($C_9H_{15}NO$), 138 (100) ($C_8H_{12}NO$), 131 (95) (C_9H_7O), 127 (32) ($C_7H_{13}NO$), 115 (21) (C_9H_7), 112 (61) ($C_6H_{10}NO$), 103 (42) (C_8H_7), 91 (40) (C_7H_7), 84 (77) ($C_5H_{10}N$), 77 (38) (C_6H_5).

syn- and *anti*- Cyclooctanone-benzaldehyde aldol products, 11 (cf. ref. 16)

n-Butyllithium (2.5 M in hexane, 4.0 mL, 10 mmol) was added dropwise under argon to a solution of diisopropylamine (1.40 mL, 10.0 mmol) in dry THF at –78°C. The solution was stirred at –78°C for 30 min, and a solution of cyclooctanone (1.260 g, 10.0 mmol) in dry THF (5 mL) was then added dropwise by syringe. Stirring was continued at –78°C for a further 30 min, when trimethylsilyl chloride (1.27 mL, 10.1 mmol) was slowly added. The stirred mixture was set aside at –78°C for 1 h. Dilution with ether (70 mL) resulted in precipitation of a white salt that was removed by filtration (2×) through a bed of Celite, and evaporation of solvents in vacuo then furnished a pale yellow oil. The product was chromatographed on a column of silica gel with hexane as eluent to give 1.527 g (77%) of cyclooctanone TMS enol ether. ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.19 (9H, s), 1.50 (8H, br s), 2.01 (2H, br m), 2.18 (2H, br m), 4.74 (1H, t, J = 8.2 Hz).

$TiCl_4$ (0.32 mL, 2.75 mmol) was added dropwise with stirring to a solution of benzaldehyde (0.292 g, 2.75 mmol) in freshly distilled CH_2Cl_2 (20 mL) at –78°C under an atmosphere of argon. Addition of the cyclooctanone TMS enol ether in CH_2Cl_2 (10 mL) followed by stirring for 1 h afforded a dark orange-colored solution. Water (ca. 20 mL) was cautiously added, and the mixture was extracted with ether (3 × 20 mL). The extracts were dried over $MgSO_4$ and the solvent removed under reduced pressure to produce a colorless oil. The isomeric products were separated by flash chromatography on silica gel with hexane–EtOAc (7:1) as eluent. The overall yield was 51%, with *anti* and *syn* products in a ratio of 64:36.

anti *Isomer*: IR ($CHCl_3$): 3600, 3450, 2930, 2860, 1685, 1600, 1450, and 1260 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.55–1.85 (10H, m), 2.33 (2H, m), 3.14 (1H, m), 4.83 (1H, m), 7.30–7.40 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 232.1453 (9) (M^+) (calcd. for $C_{15}H_{20}O_2$: 232.1463), 214 (32) ($M^+ - H_2O$), 175 (31) ($C_{11}H_{11}O_2$), 157 (11) ($C_{11}H_9O$), 147 (11) ($C_9H_7O_2$), 126 (83) ($C_8H_{14}O$) 117 (19) (C_9H_9), 112 (15) ($C_7H_{12}O$), 107 (76) (C_7H_7O), 98 (100) ($C_6H_{10}O$), 91 (25) (C_7H_7), 84 (51) (C_5H_8O), 77 (88) (C_6H_6).

syn *Isomer*: IR ($CHCl_3$): 3600, 3450, 2930, 2860, 1685, 1600, 1450, and 1260 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.15–2.05 (10H, m), 2.25 (2H, m), 3.03 (1H, dt, J = 4.8 and 11.6 Hz), 4.95 (1H, d, J = 4.8 Hz), 7.25–7.40 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 232.1470 (3) (M^+) (calcd. for $C_{15}H_{20}O_2$: 232.1463), 214 (12) ($M^+ - H_2O$), 175 (11) ($C_{11}H_{11}O_2$), 126 (74) ($C_8H_{14}O$), 117 (16) (C_9H_9), 107 (42) (C_7H_7O), 98 (100) ($C_6H_{10}O$), 91 (13) (C_7H_7), 84 (25) (C_5H_8O), 77 (34) (C_6H_5).

Attempted fragmentation of *anti* aldol 11

Boron trifluoride etherate (0.24 mL, 2.0 mmol) was added dropwise by syringe under argon to a stirred solution of **11** (*anti* isomer) (64 mg, 0.27 mmol) in dry THF at 0°C. Propane-1,3-diol (100 mg, 1.32 mmol) was added immediately and the stirred solution allowed to attain ambient temperature during 14 h. The mixture was poured into saturated $NaHCO_3$ and the products were extracted with ether (3 × 50 mL). The extracts were washed successively with saturated brine (30 mL) and

water (30 mL), dried over $MgSO_4$, and evaporated under reduced pressure. The resulting pale yellow oil was subjected to flash chromatography on silica gel (hexane–EtOAc, 4:1) affording, in the early eluates, the styrene 2-benzylidinecyclooctanone (24 mg, 40%). IR ($CHCl_3$): 2925, 2860, 1670, 1595, 1490, 1445, 1345, 1320, 1280, 1160, 1120, 1080, 990, and 870 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.50–1.90 (8H, m), 2.72 (2H, t, J = 6.4 Hz), 2.82 (2H, t, J = 6.2 Hz), 7.30–7.40 (5H, m), 7.48 (1H, s); MS, *m/z* (relative intensity) (ion): 214 (100) (M^+, $C_{15}H_{18}O$), 159 (18) ($C_{11}H_{11}O$), 130 (37) (C_9H_6O), 115 (32) (C_9H_7), 104 (27) (C_8H_8), 91 (29) (C_7H_7).

Further elution produced an unresolved mixture of cyclooctanone and the acetal (1,3-dioxane) of benzaldehyde (37 mg, ratio 1:1 by NMR).

Putative hydroxy-acetal intermediate 12

To a refluxing slurry of KH (35% dispersion in mineral oil, 1.25 g, 11.0 mmol) in benzene (15 mL) was added rapidly a mixture of cyclooctanone (630 mg, 5.00 mmol) and diethyl carbonate (1.33 g, 7.50 mmol) under argon (24). The mixture was heated under reflux for 30 min. Standard work-up (24) yielded a pale yellow oily product, that, after passage through a short column of silica gel (hexane–EtOAc, 4:1), furnished *2-ethoxycarbonylcyclooctanone* (964 mg, 97%) as a colorless oil: IR ($CHCl_3$): 2925, 2860, 1740, 1700, 1640, 1470, 1400, 1380, 1320, and 1100 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) (keto form, 63%) δ: 1.19 (3H, t, J = 7.0 Hz), 1.35–1.95 (10H, m), 2.00–2.15 (2H, m), 3.53 (1H, dd, J = 6.0 and 9.0 Hz), 4.10 (2H, q, J = 7.0 Hz); (enol form, 37%) δ: 1.26 (3H, t, J = 7.0 Hz), 1.35–1.95 (8H, m) 2.30–2.55 (4H, m), 4.16 (2H, q, J = 7.0 Hz); HREIMS, *m/z* (relative intensity) (ion): 198.1266 (100) (M^+) (calcd. for $C_{11}H_{18}O_3$: 198.1256), 170 (45) ($M^+ - C_2H_4$), 152 (82) ($M^+ - C_2H_6O$), 143 (27) ($C_7H_{11}O_3$), 130 (25) ($C_6H_{10}O_3$), 124 (40) ($C_8H_{12}O$), 109 (35) ($C_6H_5O_2$), 96 (36) (C_6H_8O), 84 (14) (C_5H_8O).

A solution of 2-ethoxycarbonylcyclooctanone (964 mg, 4.87 mmol) in benzene (50 mL) containing ethylene glycol (3.0 mL) and pTSA (ca 5 mg) was heated under reflux with azeotropic removal of water using a Dean Stark apparatus. After 4 days, the reaction mixture was diluted with ether (50 mL) and the solution poured into 10% aqueous $NaHCO_3$. The organic phase was washed with saturated brine, dried over $MgSO_4$, and evaporated to dryness in vacuo. The resulting pale yellow oil (2.15 g) was subjected to flash chromatography on silica gel (hexane–EtOAc, 4:1) affording the pure *acetal (dioxolane) of 2-ethoxycarbonylcyclooctanone* (730 mg, 60%) as a colorless oil: IR ($CHCl_3$): 2930, 1720, 1460, 1440, 1380, 1160, 1040, 975, and 950 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.23 (3H, t, J = 7.2 Hz), 1.50–1.80 (8H, m), 1.80–2.00 (4H, m), 2.95 (1H, dd, J = 2.6 and 9.0 Hz), 3.90–4.00 (4H, m), 4.11 (2H, q, J = 7.2 Hz); HREIMS, *m/z* (relative intensity) (ion): 242.1525 (20) (M^+) (calcd. for $C_{13}H_{22}O_4$: 242.1518), 213 (22) ($M^+ - C_2H_5$), 197 (66) ($M^+ - C_2H_5O$), 171 (100) ($C_8H_{11}O_4$), 169 (23) ($M^+ - C_3H_5O_2$), 141 (16) ($C_8H_{13}O_2$), 127 (25) ($C_7H_{11}O_2$), 99 (75) ($C_5H_7O_2$), 86 (39) ($C_4H_6O_2$).

The ester-acetal (46 mg, 0.19 mmol) dissolved in dry THF (1.0 mL) was added under an inert atmosphere to a stirred slurry of LAH (11 mg, 0.30 mmol) in THF 0°C. The stirred mixture was allowed to attain ambient temperature over 1 h, and work-up as described for a previous LAH reduction (vide supra) furnished a quantitative yield (38 mg) of the *2-hydroxymethyl derivative of cyclooctanone dioxolane*, sufficiently pure to be used directly for the subsequent Swern oxidation. IR ($CHCl_3$): 3500, 2930, 1460, 1440, 1410, 1150, 1080, 1025, and 950 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.45–1.90 (12H, m), 2.12 (1H, sept, J = 3.4 Hz), 3.05 (1H, br s), 3.50–3.75 (2H, m), 3.85–4.00 (4H, m); HREIMS, *m/z* (relative intensity) (ion): 200.1410 (11) (M^+) (calcd. for $C_{11}H_{20}O_3$: 200.1412), 183 (29) ($M^+ - OH$), 169 (32) ($M^+ - CH_3O$), 141 (17) ($C_8H_{13}O_2$), 129 (100) ($C_6H_9O_3$), 116 (38) ($C_5H_8O_3$), 99 (88) ($C_5H_7O_2$), 86 (14) ($C_4H_6O_2$).

Swern oxidation (22) produced the *2-formyl derivative of cyclooctanone dioxolane*: IR ($CHCl_3$): 2925, 2875, 1720, 1465, 1440, 1160, 1080, and 950 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.50–1.95 (10H, m), 2.00–2.15 (2H, m), 2.75 (1H, dt, J = 1.8 and 8.2 Hz), 3.80–4.05 (4H, m), 9.72 (1H, d, J = 1.8 Hz). This very unstable product (22 mg, 0.11 mmol) was immediately dissolved in dry THF (1.0 mL) and, at –78°C with stirring under an argon atmosphere, was treated with phenyllithium (0.068 mL of 1.8 M solution in cyclohexane–ether, 0.13 mmol). The reaction mixture was stirred at –78°C for 1.5 h, and then aqueous NH_4Cl (1%, 1.0 mL) was added, and the mixture was extracted with ether (3 × 10 mL). Solvent was removed from the dried extracts in vacuo, and chromatography of the residue on a preparative silica gel plate afforded the desired *hydroxy-acetal* ***12*** (6.0 mg). ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.40–1.95 (12H, m), 2.36 (1H, m), 4.00–4.15 (4H, m), 4.74 (1H, d, J = 9.4 Hz), 5.06 (1H, s), 7.25–7.45 (5H, m); HREIMS, *m/z* (relative intensity) (ion): 276.1762 (4) (M^+) (calcd. for ($C_{17}H_{24}O_3$: 276.1761), 259 (6) ($M^+ - H_2O$), 192 (12) ($C_{11}H_{12}O_3$), 175 (10) ($C_{11}H_{11}O_2$), 170 (41) ($C_{10}H_{18}O_2$), 149 (12) ($C_8H_5O_3$), 142 (22) ($C_8H_{14}O_2$), 127 (14) ($C_8H_{15}O$), 120 (13) (C_8H_8O), 115 (29) ($C_6H_{11}O_2$), 105 (34) (C_7H_5O), 99 (100) ($C_5H_7O_2$), 86 (32) ($C_4H_6O_2$), 77 (23) (C_6H_5).

Attempted fragmentation of 12

Boron trifluoride etherate (0.011 mL, 0.089 mmol) was added by syringe under argon to a stirred solution of the hydroxy-acetal **12** (6.0 mg, 0.022 mmol) in dry THF (3.5 mL) at 0°C. The mixture was allowed to attain ambient temperature and was stirred for 14 h, when it was poured into saturated $NaHCO_3$ (ca. 5 mL). The mixture was extracted with ether (3 × 10 mL) and the extracts were dried over $MgSO_4$ and evaporated under reduced pressure. Analysis of the crude product by TLC and NMR revealed that fragmentation had not occurred, and the only identifiable products were benzaldehyde and cyclooctanone.

1-Iodo-6-(3′,4′-methylenedioxyphenyl)-5*E*-hexene, 13

To a solution of triphenylphosphine (2.96 g, 11.3 mmol) in ether:acetonitrile (3:1) (20 mL) was added imidazole (840 mg, 12.4 mmol) and iodine (2.61 g, 10.2 mmol). The slurry was stirred at ambient temperature for 5 min and a solution of the alcohol (754 mg, 3.43 mmol) (6) derived from **III** (x = 3) in the same solvent mixture (15 mL) was then added. The resulting yellow slurry was set aside with stirring for 14 h, then diluted with hexane (ca. 100 mL) and filtered through a short column of silica gel. Chromatography on a column of silica gel (hexane–EtOAc, 20:1) afforded the pure iodide **13** (1.13 g, 91%) as a colorless oil that solidified on standing: IR ($CHCl_3$): 3000, 2940, 2900, 2860, 1605, 1485, 1440, 1360, 1125, 1100, 1040, 970, 940, 915, and 860 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ:

1.59 (2H, q, J = 7.0 Hz), 1.81–1.92 (2H, m), 2.22 (2H, dt, J = 7.0 and 7.2 Hz), 3.22 (2H, t, J = 6.8 Hz), 5.94 (2H, s), 6.02 (1H, dt, J = 6.8 and 15.8 Hz), 6.31 (1H, d, J = 15.8 Hz), 6.75 (2H, s), 6.90 (1H, s).

8-(3′,4′-Methylenedioxyphenyl)-oct-7*E*-en-1-yne, 14

A solution of iodide **13** (303 mg, 0.918 mmol) in dry DMSO (1.5 mL) was added slowly under argon during 1 h to a slurry of lithium acetylide – ethylenediamine complex (141 mg, 1.53 mmol) in DMSO (1.5 mL) at 8–10°C. Stirring was continued for a further 1 h, whereupon conventional work-up afforded the alkyne **14** (195 mg, 93%) as a colorless oil, sufficiently pure to be used directly in the subsequent step. IR ($CHCl_3$): 3300, 2930, 2860, 2125, 1605, 1485, 1440, 1360, 1130, 1100, 1040, 965, 940, and 865 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.56 (4H, pent, J = 3.4 Hz), 1.93 (1H, t, J = 2.6 Hz), 2.15–2.25 (4H, m), 5.91 (2H, s), 6.01 (1H, dt, J = 6.8 and 15.6 Hz), 6.28 (1H, d, J = 15.8 Hz), 6.72 (2H, s), 6.87 (1H, s).

Ethyl 9-(3′,4′-methylenedioxyphenyl)-non-8*E*-en-2-ynoate, 15

n-Butyllithium (2.5 M in hexane, 0.41 mL, 1.0 mmol) was added dropwise under argon to a stirred solution of **14** (195 mg, 0.855 mmol) in dry THF at 0°C. The mixture was stirred at 0°C for 30 min and ethyl chloroformate (11 mg, 1.03 mmol) was then added dropwise. Stirring was continued for a further 1 h at 0°C and the mixture then allowed to attain ambient temperature during an additional 1 h. Water (10 mL) was added and the product extracted with ether (3 × 30 mL). The oil obtained after washing and drying of the extracts and removal of solvent in vacuo was subjected to flash chromatography on silica gel. Elution with hexane–EtOAc afforded 42 mg of unreacted starting material and 160 mg of the alkyne ester, **15** (79% based on starting material consumed). IR ($CHCl_3$): 2995, 2950, 2910, 2225, 1700, 1600, 1490, 1445, 1370, 1250, 1080, 1040, 970, and 865 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.28 (3H, t, J = 7.0 Hz) 1.50–1.60 (4H, m), 2.17 (2H, dt, J = 6.6 Hz and 6.8 Hz), 2.33 (2H, t, J = 5.2 Hz), 4.19 (2H, q, J = 7.0 Hz), 5.91 (2H, s), 5.98 (1H, dt, J = 6.8 and 15.8 Hz), 6.27 (1H, d, J = 16.0 Hz), 6.71 (2H, s), 6.86 (1H, s).

Ethyl 9-(3′,4′-methylenedioxyphenyl)-nona-2*E*,4*E*,8*E*-trienoate, 16

Alkyne ester **15** (118 mg, 0.395 mmol) in dry toluene (3.0 mL) containing glacial acetic acid (3 drops) and triphenylphosphine (33 mg, 0.13 mmol) was heated under vigorous reflux for 48 h. The residue obtained on concentration of the mixture in vacuo was subjected to flash chromatography on silica gel. Elution with hexane–EtOAc (8:1) furnished trienoate **16** (99 mg, 84%) as a colorless oil: IR ($CHCl_3$): 2980, 2930, 2900, 2890, 1695, 1640, 1620, 1490, 1440, 1370, 1305, 1160, 1140, 1100, 1040, 1005, 965, 940, and 865 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.27 (3H, t, J = 7.0 Hz), 2.31 (4H, m), 4.18 (2H, q, J = 7.0 Hz), 5.78 (1H, d, J = 15.4 Hz), 5.91 (2H, s), 5.90–6.20 (3H, m), 6.30 (1H, d, J = 15.6 Hz), 6.72 (2H, s), 6.86 (1H, s), 7.24 (1H, dd, J = 10.2 and 15.4 Hz).

9-(3′,4′-Methylenedioxyphenyl)-nona-2*E*,4*E*,8*E*-trienoic acid isobutylamide: retrofractamide A, 4

9-(3′,4′-Methylenedioxyphenyl)-nona-2*E*,4*E*,8*E*-trienoic acid was obtained in quantitative yield by hydrolysis of the ester using aqueous LiOH in acetone as described above. The pure acid melted at 161–163°C; IR ($CHCl_3$): 3500–2400, 2995, 1690, 1640, 1620, 1490, 1445, 1045, 1005, 970, and 940 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 2.33 (4H, m), 5.78 (1H, d, J = 15.2 Hz), 5.92 (2H, s), 5.95–6.25 (3H, m), 6.31 (1H, d, J = 15.8 Hz), 6.73 (2H, s), 6.86 (1H, s), 7.33 (1H, br dd, J = 10.2 and 15.2 Hz).

Coupling of the carboxylic acid with isobutylamine through the agency of 1,1′-carbonyldiimidazole (vide supra) afforded, after preparative layer chromatography on a silica gel plate (hexane: EtOAc, 3:2), a 72% yield of retrofractamide A, **4**. A recrystallized sample melted at 130–132°C (lit. (9) mp 129°C). IR ($CHCl_3$): 3450, 2950, 2925, 2875, 1660, 1630, 1615, 1490, 1440, 1100, 1040, 1000, 970, and 870 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.90 (6H, d, J = 6.6 Hz), 1.78 (1H, sept, J = 6.8 Hz), 2.29 (4H, m), 3.14 (2H, t, J = 6.8 Hz), 5.51 (1H, br s), 5.75 (1H, d, J = 15.0 Hz), 5.91 (2H, s), 5.95–6.20 (3H, m), 6.29 (1H, d, J = 15.8 Hz), 6.72 (2H, s), 6.86 (1H, s), 7.17 (1H, dd, J = 10.0 and 15.0 Hz); HREIMS, *m/z* (relative intensity) (ion): 327.1837 (9) (M^+) (calcd. for $C_{20}H_{25}NO_3$: 327.1834), 161 (88) ($C_{10}H_9O_2$), 131 (100) (C_9H_7O), 103 (32) (C_8H_7), 77 (6) (C_6H_5).

9-(3′,4′-methylenedioxyphenyl)-nona-2*E*-4*E*,8*E*-trienoic acid piperidylamide: dehydropipernonaline, 17

Ethyl 9-(3′,4′-methylenedioxyphenyl)-nona-2*E*,4*E*,8*E*-trienoate, **16**, was transformed directly in 88% yield to the piperidyl amide, **17**, dehydropipernonaline, using the Roskamp procedure as described above (18). The synthetic alkaloid melted at 97–98°C (with softening at 86°C) (lit. (10) mp 98–99°C). IR ($CHCl_3$): 3400, 2990, 2945, 2860, 1645, 1620, 1590, 1490, 1440, 1360, 1140, 1120, 1100, 1040, 1020, 970, 930, 910, and 860 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.50–1.70 (6H, m), 2.30 (4H, m), 3.47 (2H, br s), 3.57 (2H, br s), 5.91 (2H, s), 5.95–6.20 (3H, m), 6.25 (1H, d, J = 15.0 Hz), 6.29 (1H, d, J = 15.0 Hz), 6.72 (2H, s), 6.86 (1H, s), 7.22 (1H, dd, J = 10.2 and 14.8 Hz); HREIMS, *m/z* (relative intensity) (ion): 339.1838 (13) (M^+) (calcd. for $C_{21}H_{25}NO_3$: 339.1834), 161 (100) ($C_{10}H_9O_2$), 131 (78) (C_9H_7O), 103 (21) (C_8H_7), 84 (4) ($C_5H_{10}N$).

9-(3′,4′-Methylenedioxyphenyl)-nona-2*E*,4*E*,8*E*-trienoic acid pyrrolidylamide

This alkaloid, **18**, was similarly prepared from ethyl 9-(3′,4′-methylenedioxyphenyl)-nona-2*E*,4*E*,8*E*-trienoate, **16**, in 94% yield by the Roskamp method (18). Melting point 99°C (with softening at 90°C) (lit. (3) mp 105–106°C); IR ($CHCl_3$): 3400, 2970, 2890, 1650, 1620, 1590, 1490, 1430, 1360, 1100, 1040, 1000, 970, 940, 920, and 865 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 1.80–2.00 (4H, m), 2.30 (2H, m), 3.51 (4H, q, J = 4.8 Hz), 5.91 (2H, s), 5.95–6.20 (4H, m), 6.29 (1H, d, J = 15.8 Hz), 6.72 (2H, s), 6.86 (1H, s), 7.25 (1H, dd, J = 10.0 and 15.6 Hz); HREIMS, *m/z* (relative intensity) (ion): 325.1665 (13) (M^+) (calcd. for $C_{20}H_{23}NO_3$: 325.1678), 161 (100) ($C_{10}H_9O_2$), 131 (99) (C_9H_7O), 103 (29) (C_8H_7), 98 (5) (C_5H_9NO),77 (10) (C_6H_5).

Ethyl 2*E*,4*E*-decadienoate

The dianion of propiolic acid (0.46 mL, 7.5 mmol), generated using the procedure of Danheiser and co-workers (23), was alkylated with iodoheptane (1.23 mL, 7.50 mmol) to furnish

1.15 g (91%) of *2-decynoic acid*. The latter, without purification, was converted directly (K_2CO_3/EtI) to the ethyl ester (22). The ester, *ethyl 2-decynoate*, (1.17 g, 87%), after filtration through a short column of silica gel required no further purification. Ethyl 2-decynoate (96.4 mg, 0.492 mmol) in dry toluene (1.0 mL) containing glacial acetic acid (2 drops) and triphenylphosphine (28 mg, 0.11 mmol) was heated under reflux for 3.5 h (17). The residue obtained after removal of solvent under reduced pressure was chromatographed on a preparative silica gel plate (hexane–EtOAc, 20:1) affording 87 mg (90%) of the desired ester, ethyl 2*E*,4*E*-decadienoate. These compounds were characterized on the basis of their spectra as follows:

Alkynoic acid: IR ($CHCl_3$): 3400–2400, 2925, 2860, 2225, 1700, 1690, 1460, 1275, and 1040 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.82 (3H, t, J = 6.5 Hz), 1.20–1.30 (8H, m), 1.57 (2H, pent, J = 7.2 Hz), 2.32 (2H, t, J = 7.0 Hz), 10.4 (1H, br s).

Alkynoic ester: IR ($CHCl_3$): 2930, 2860, 2225, 1700, 1460, 1370, 1260, and 1080 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.5 Hz), 1.20–1.35 (8H, m), 1.28 (3H, t, J = 7.2 Hz), 1.56 (2H, m), 2.30 (2H, t, J = 7.0 Hz), 4.19 (2H, q, J = 7.2 Hz).

Dienoic ester: IR ($CHCl_3$): 2950, 2930, 2860, 1700, 1640, 1620, 1460, 1375, 1300, 1260, 1140, 1035, 1000, and 980 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.88 (3H, t, J = 6.8 Hz), 1.28 (3H, t, J = 7.2 Hz), 1.26–1.29 (4H, m), 1.42 (2H, m), 2.15 (2H, q, J = 5.6 Hz), 4.19 (2H, q, J = 7.0 Hz), 5.77 (1H, d, J = 15.4 Hz), 6.10–6.16 (2H, m), 7.25 (1H, m).

2*E*,4*E*-Decadienoic acid isobutyl amide: pellitorine, 19 (refs. 2, 4)

2*E*,4*E*-Decadienoic acid was obtained in 83% yield by hydrolysis of the ester using aqueous LiOH in acetone as described above. IR ($CHCl_3$): 3400–2400, 2960, 2940, 2860, 1700, 1640, 1620, 1420, 1280, and 1005 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.87 (3H, t, J = 6.4 Hz), 1.27 (4H, m), 1.42 (2H, m), 2.16 (2H, m), 5.63 (1H, d, J = 15.4 Hz), 6.15–6.20 (2H, m), 7.24–7.39 (1H, m).

Coupling of the carboxylic acid with isobutylamine through the agency of 1,1′-carbonyldiimidazole (vide supra) afforded, after preparative layer chromatography on a silica gel plate (hexane: EtOAc, 3:2), an 82% yield of pellitorine, **19**. A sample melted at 70°C (lit. (4) mp 66–68°C): IR ($CHCl_3$): 3450, 2965, 2935, 2880, 2865, 1665, 1635, 1620, 1510, 1470, 1160, and 1000 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.8 Hz), 0.90 (6H, d, J = 6.6 Hz), 1.20–1.30 (4H, m), 1.35 (2H, pent, J = 7.2 Hz), 1.77 (1H, sept, J = 6.8 Hz), 2.13 (2H, q, J = 6.6 Hz), 3.14 (2H, t, J = 6.6 Hz), 5.74 (1H, d, J = 15.6 Hz), 5.76 (1H, m), 6.04 (1H, dt, J = 6.4 and 15.2 Hz), 6.11 (1H, dd, J = 9.9 and 15.6 Hz), 7.17 (1H, dd, J = 9.9 and 15.0 Hz); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.0 20.1 22.5, 28.5, 28.6, 31.3, 32.9, 46.9, 121.7, 128.2, 141.2, 143.2, 166.4; HREIMS, *m/z* (relative intensity) (ion): 223.1943 (36) (M^+) (calcd. for $C_{14}H_{25}NO$: 223.1937), 208 (8) ($C_{13}H_{22}NO$), 152 (32) ($C_9H_{14}NO$), 151 (100) ($C_{10}H_{15}O$), 110 (10) (C_8H_8NO), 96 (32) (C_5H_6NO), 81 (22) (C_5H_5O).

2*E*,4*E*-Decadienoic acid pyrrolidyl amide, 20 (ref. 3)

Ethyl 2*E*,4*E*-decadienoate was transformed directly in 85% yield to the pyrrolidyl amide alkaloid **20**, using the Roskamp procedure as described above (18). IR ($CHCl_3$): 3400, 2955, 2935, 2875, 1645, 1620, 1590, 1430, 1340, and 1000 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.89 (3H, t, J = 6.8 Hz), 1.30 (4H, m), 1.43 (2H, m), 1.87 (2H, t, J = 6.6 Hz), 1.96 (2H, t, J = 6.6 Hz), 2.15 (2H, q, J = 6.8 Hz), 3.52 (2H, t, J = 6.6 Hz), 3.54 (2H, t, J = 6.4 Hz), 6.09 (1H, dt, J = 9.6 and 15.0 Hz), 6.09 (1H, d, 15.0 Hz), 6.19 (1H, dd, J = 9.6 and 15.2 Hz), 7.27 (1H, dd, J = 9.8 and 15.0 Hz); HREIMS, *m/z* (relative intensity) (ion): 221.1782 (39) (M^+) (calcd. for $C_{14}H_{23}NO$: 221.1779), 192 (38) ($C_{12}H_{18}NO$), 178 (31) ($C_{11}H_{16}NO$), 164 (41) ($C_{10}H_{14}NO$), 150 (100) ($C_9H_{12}NO$), 137 (15) ($C_8H_{11}NO$), 113 (16) ($C_6H_{11}NO$), 98 (35) (C_5H_8NO), 95 (16) (C_6H_7O), 81 (49) (C_5H_5O), 70 (52) (C_4H_8N).

2*E*,4*E*-Decadienoic acid piperidyl amide, Achillea amide, 21 (ref. 20)

Ethyl 2*E*,4*E*-decadienoate was similarly transformed directly in 93% yield to the piperidyl amide alkaloid **20**, using the Roskamp procedure as described above (18). IR ($CHCl_3$): 3400, 2995, 2930, 2860, 1645, 1620, 1585, 1440, 1260, 1140, 1020, 1000, and 860 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.6 Hz), 1.27 (4H, m), 1.39 (2H, m), 1.50–1.70 (6H, m), 2.12 (2H, dt, J = 6.4 and 7.4 Hz), 3.47 (2H, br s), 3.58 (2H, br s), 6.02 (1H, dt, J = 6.4 and 15.0 Hz), 6.16 (1H, dd, J = 10.0 and 15.2 Hz), 6.23 (1H, d, J = 15.0 Hz), 7.21 (1H, dd, J = 10.0 and 14.8 Hz); HREIMS, *m/z* (relative intensity) (ion): 235.1945 (18) (M^+) (calcd. for $C_{15}H_{25}NO$): 235.1936), 192 (21) ($C_{12}H_{18}NO$), 164 (75) ($C_{10}H_{14}NO$), 138 (27) ($C_8H_{12}NO$), 112 (12) ($C_6H_{10}NO$), 95 (15) (C_6H_7O), 84 (100) ($C_5H_{10}N$), 69 (23) (C_5H_9).

2*E*,4*E*-Hexadecadienoic acid isobutyl amide, 22

The synthesis of this alkaloid (from *Piper guineense*) (11) was accomplished in overall yield 39%, via a route analogous to that employed for synthesis of pellitorine (vide supra) but with bromotridecane used in lieu of iodoheptane for alkylation of propiolic acid.

2-Hexadecynoic acid: IR ($CHCl_3$): 3400–2400, 2930, 2225, 1700, 1460, and 1270 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.4 Hz), 1.24 (20 H, br s), 150–1.60 (2H, m), 2.33 (2H, t, J = 7.0 Hz).

Ethyl 2-hexadecynoate: IR ($CHCl_3$): 2925, 2850, 2220, 1700, 1460, 1370, 1255, and 1080 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.2 Hz), 1.23 (20 H, br s), 1.28 (3H, t, J = 7.2 Hz), 1.56 (2H, m), 2.30 (2H, t, J = 7.0 Hz), 4.19 (2H, q, J = 7.2 Hz).

Ethyl 2E,4E-hexadecadienoate: IR ($CHCl_3$): 2930, 2860, 1700, 1640, 1620, 1460, 1375, 1305, 1270, 1140, 1040, 1000, and 975 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.88 (3H, t, J = 6.4 Hz), 1.26 (18 H, br s), 1.29 (3H, t, J = 7.2 Hz), 2.20 (2H, m), 4.19 (2H, q, J = 7.0 Hz), 5.78 (1H, d, J = 15.4 Hz), 6.11–6.17 (2H, m), 7.27 (1H, m).

2E,4E-Hexadecadienoic acid: IR ($CHCl_3$): 3600–2400, 2935, 2860, 1690, 1640, 1620, 1460, 1440, 1420, 1380, 1260, 1110, and 1005 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.88 (3H, t, J = 6.4 Hz), 1.21 (2H, m), 1.26 (16H, br s), 2.17 (2H, m), 4.60 (1H, br s), 5.79 (1H, d, J = 15.4 Hz) 6.17–6.22 (2H, m), 7.25–7.30 (1H, m).

2E,4E-Hexadecadienoic acid isobutylamide, ***22***: mp 78.5–84°C; IR ($CHCl_3$): 3450, 2965, 2935, 2860, 1660, 1635, 1620, 1510, 1465, and 1000 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.6 Hz), 0.90 (6H, d, J = 6.8 Hz), 1.24 (16 H, br s), 1.39 (2H, m), 1.78 (1H, sept, J = 6.8 Hz), 2.11 (2H, q, J = 6.8 Hz), 3.14 (2H, t, J = 6.6 Hz), 5.52 (1H, br s), 5.73 (1H, d, J = 14.8 Hz), 6.04 (1H, dt, J = 6.4 and 15.0 Hz), 6.11 (1H, dd, J = 9.9 and 15.4 Hz), 7.17 (1H, dd, J = 9.9 and 15.0 Hz); HREIMS, *m/z* (relative intensity) (ion): 307.2875 (16) (M^+) (calcd. for $C_{20}H_{37}NO$: 307.2875), 235 (35) ($C_{16}H_{27}O$), 223 (32) ($C_{14}H_{25}NO$), 152 (43) ($C_9H_{14}NO$), 151 (100) ($C_{10}H_{15}O$), 110 (13) ($C_6H_{18}NO$), 96 (46) (C_5H_6NO), 81 (42) (C_5H_5O), 67 (22) (C_5H_7), 57 (19) (C_4H_9).

2*E*,4*E*-Octadecadienoic acid isobutyl amide, 23

The synthesis of this alkaloid (from *Piper guineense*) (11) was accomplished in overall yield 50%, via a route analogous to the above but with bromopentadecane used for alkylation of propiolic acid.

2-Octadecynoic acid: IR ($CHCl_3$): 3600–2400, 2925, 2860, 2225, 1700, 1460, and 1260 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.4 Hz), 1.24 (24 H, br s), 1.55 (2H, m), 2.33 (2H, t, J = 7.0 Hz).

Ethyl 2-octadecynoate: IR ($CHCl_3$): 2930, 2860, 2225, 1700, 1465, 1375, 1260, and 1080 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.85 (3H, t, J = 6.2 Hz), 1.23 (24 H, br s), 1.28 (3H, t, J = 7.2 Hz), 1.45–1.60 (2H, m), 2.30 (2H, t, J = 7.0 Hz), 4.19 (2H, q, J = 7.2 Hz).

Ethyl 2E,4E-octadecadienoate: IR ($CHCl_3$): 2930, 2855, 1700, 1640, 1620, 1460, 1375, 1305, 1140, 1035, 1000, 910, and 875 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.80 (3H, t, J = 6.2 Hz), 1.18 (18 H, br s), 1.21 (3H, t, J = 7.2 Hz), 1.30–1.40 (2H, m), 2.05–2.15 (2H, m) 4.12 (2H, q, J = 7.2 Hz), 5.70 (1H, d, J = 15.6 Hz), 5.95–6.20 (2H, m), 7.10–7.30 (1H, m).

2E,4E-Hexadecadienoic acid: mp 59–61°C; IR ($CHCl_3$): 3400–2400, 2925, 2860, 1685, 1640, 1620, 1460, 1420, 1305, 1270, 1150, and 1005 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.88 (3H, t, J = 6.4 Hz), 1.26 (20H, br s), 1.38 (2H, m), 2.18 (2H, m), 5.78 (1H, d, J = 15.6 Hz), 6.10–6.30 (2H, m), 7.31 (1H, br dd, J = 10.0 and 14.8 Hz), 9.00 (1H, br s).

2E,4E-Octadecadienoic acid isobutylamide, ***23***: mp 92–94°C; IR ($CHCl_3$): 3450, 2960, 2930, 2860, 1660, 1635, 1615, 1510, 1465, and 1000 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.6 Hz), 0.90 (6H, d, J = 6.6 Hz), 1.23 (20 H, br s), 1.30–1.40 (2H, m) 1.80 (1H, m), 2.12 (2H, q, J = 6.2 Hz), 3.14 (2H, t, J = 6.2 Hz), 5.44 (1H, m), 5.72 (1H, d, J = 15.0 Hz), 6.00–6.20 (2H, m), 7.28 (1H, ddd, J = 1.8, 9.2, and 15.0 Hz); HREIMS, *m/z* (relative intensity) (ion): 335.3181 (38) (M^+) (calcd. for $C_{22}H_{41}NO$: 335.3187), 263 (75) ($C_{18}H_{31}O$), 152 (50) ($C_9H_{14}NO$), 131 (100) (C_9H_7O), 119 (24) (C_8H_7O), 96 (31) (C_5H_6NO), 91 (41) (C_7H_7), 84 (28) (C_5H_8O), 81 (33) (C_5H_5O), 77 (30) (C_6H_5).

2*E*,4*E*-Eicosadienoic acid pyrrolidyl amide, 24

The synthesis of this alkaloid (from *Piper trichostachyon*) (21) was accomplished via a route analogous to the above but with bromoheptadecane used for alkylation of propiolic acid.

2-Eicosynoic acid: IR ($CHCl_3$): 3500–2400, 2925, 2855, 2225, 1700, 1460, and 1260 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.5 Hz), 1.24 (26 H, br s), 1.37 (2H, m) 2.33 (2H, t, J = 7.2 Hz).

Ethyl 2-eicosynoate: IR ($CHCl_3$): 2925, 2855, 2225, 1700, 1600, 1465, 1375, 1260, and 1080 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.86 (3H, t, J = 6.4 Hz), 1.23 (28 H, br s), 1.28 (3H, t, J = 7.2 Hz), 1.56 (2H, m), 2.30 (2H, t, J = 7.0 Hz), 4.19 (2H, q, J = 7.2 Hz).

Ethyl 2E, 4E-eicosadienoate: IR ($CHCl_3$): 2930, 2860, 1700, 1640, 1620, 1460, 1375, 1305, 1260, 1145, 1005, and 915 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.87 (3H, t, J = 6.4 Hz), 1.25 (24H, br s), 1.36 (2H, m), 2.15 (2H, q, J = 5.8 Hz), 4.19 (2H, q, J = 7.2 Hz), 5.77 (1H, d, J = 15.2 Hz), 6.15–6.20 (2H, m), 7.25 (1H, dd, J = 9.4 and 15.2 Hz).

2E,4E-Eicosadienoic acid pyrrolidylamide, ***24***: mp 78–79°C (lit. (21) mp 65–67°C); IR ($CHCl_3$): 3400, 2930, 2860, 1650, 1620, 1590, 1430, 1345, 1005, 915, and 870 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ: 0.85 (3H, t, J = 6.4 Hz), 1.23 (24 H, br s), 1.36 (2H, m), 1.80–2.00 (4H, m), 2.12 (2H, q, J = 6.6 Hz), 3.50 (4H, q, J = 5.4 Hz), 6.00–6.25 (3H, m), 7.25 (1H, dd, J = 10.2 and 14.8 Hz); HREIMS, *m/z* (relative intensity (ion): 361.3326 (37) (M^+) (calcd. for $(C_{24}H_{43}NO)$: 361.3345), 318 (67) ($C_{22}H_{24}NO$), 186 (30) ($C_{13}H_{14}O$), 173 (30) ($C_{12}H_{13}O$), 159 (25) ($C_{11}H_{11}O$), 150 (63) ($C_9H_{12}NO$), 131 (100) (C_9H_7O), 121 (56) (C_8H_9O), 98 (14) (C_5H_8O), 91 (51) (C_7H_7), 84 (28) (C_5H_8O), 77 (23) (C_6H_5), 55 (32) (C_4H_7).

2,3-Pyrazinedicarboxylates of cobalt(II), nickel(II), and copper(II); magnetic properties and crystal structures

Long Mao, Steven J. Rettig, Robert C. Thompson, James Trotter, and Shihua Xia

Abstract: Complexes of singly and doubly deprotonated 2,3-pyrazinedicarboxylic acid ($pyzdcH_2$) have been prepared and studied. Crystal data: $[Ni(pyzdcH)_2(H_2O)_2]$, **1**, monoclinic, $P2_1/n$, $a = 9.2897(8)$ Å, $b = 7.6931(8)$ Å, $c = 10.1044(9)$ Å, $\beta = 93.378(7)°$, $Z = 2$; $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$, **2**, monoclinic, $P2_1/n$, $a = 6.598(1)$ Å, $b = 14.198(2)$ Å, $c = 8.586(2)$ Å, $\beta = 97.65(2)°$, $Z = 2$;. $[Co(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **3**, monoclinic, $C2/c$, $a = 12.5777(9)$ Å, $b = 7.5191(9)$ Å, $c = 11.839(1)$ Å, $\beta = 110.754(4)°$, $Z = 4$; $[Ni(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **4**, monoclinic, $C2/c$, $a = 12.4772(7)$ Å, $b = 7.452(1)$ Å, $c = 11.9166(5)$ Å, $\beta = 112.302(2)°$, $Z = 4$; $[Cu(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **5**, monoclinic, $C2/c$, $a = 12.784(2)$ Å, $b = 7.527(2)$ Å, $c = 12.323(2)$ Å, $\beta = 116.150(2)°$, $Z = 4$. The structures were solved by Patterson (**1**), direct (**2**, **3**), or isomorphous replacement methods (**4** and **5** are isomorphous with **3**) and were refined by full-matrix least-squares procedures to $R = 0.028$, 0.030, 0.029, 0.030, and 0.030 ($R_w = 0.026$, 0.029, 0.027, 0.025, and 0.027) for 1894, 1694, 2476, 1867, and 1412 reflections with $I \geq 3\sigma(F^2)$, respectively. The structure of **1** consists of monometallic $[Ni(pyzdcH)_2(H_2O)_2]$ units linked by hydrogen-bonding interactions in a three-dimensional network. In **2** extended chains of copper ions are linked by double-bridging $pyzdcH^-$ groups while **3**, **4**, and **5** have structures in which $pyzdc^{2-}$ ligands bridge metal centers to form extended linear chains. Magnetic susceptibility studies reveal antiferromagnetic interactions in **1**, **2**, **3**, **4**, and **6** (**6** is Cu(pyzdc)). The magnitude of exchange ($-zJ = 0.033$ cm^{-1} for **1** and $-J = 0.11$, 0.74, 0.049, and 1.14 cm^{-1} for **2**, **3**, **4**, and **6**, respectively) is discussed in terms of the structures and d-electron configurations involved.

Key words: metal 2,3-pyrazinedicarboxylates, synthesis, X-ray structure, antiferromagnetism.

Résumé : On a préparé et étudié des complexes déprotonés et di-déprotonés de l'acide pyrazine-2,3-dicarboxylique ($pyzdcH_2$). Données cristallines : $[Ni(pyzdcH)_2(H_2O)_2$, **1**, monoclinique, $P2_1/n$, $a = 9,2897(8)$, $b = 7,6931(8)$ et $c = 10,1044(9)$ Å, $\beta = 93,378(7)°$, $Z = 2$; $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$, **2**, monoclinique, $P2_1/n$, $a = 6,598(1)$, $b = 14,198(2)$ et $c = 8,586(2)$ Å, $\beta = 97,65(2)°$, $Z = 2$; $[Co(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **3**, monoclinique, $C2/c$, $a = 12,5777(9)$, $b = 7,5191(9)$ et $c = 11,839(1)$ Å, $\beta = 110,754(4)°$, $Z = 4$; $[Ni(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **4**, monoclinique, $C2/c$, $a = 12,4772(7)$, b, $= 7, 452(1)$ et $c = 11,9166(5)$ Å, $\beta = 112,302(2)°$, $Z = 4$; $[Cu(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$, **5**, monoclinique, $C2/c$, $a = 12,784(2)$, $b = 7,527(2)$ et $c = 12,323(2)$ Å, $\beta = 116,150(2)°$, $Z = 4$. On a résolu les structures par les méthodes de Patterson (**1**), directe (**2**, **3**) et de remplacement isomorphe (**4** et **5** sont isomorphes par rapport à **3**) et on les a affinées par les méthodes des moindres carrés, matrice complète, jusqu'à des valeurs de $R = 0,028$, 0,030, 0,029, 0,030 et 0,030 ($R_w = 0,026$, 0,029, 0,027, 0,025 et 0,027) pour respectivement 1894, 1694, 2476, 1867 et 1412 réflexions avec $I \geq 3\sigma(F^2)$. La structure du composé **1** consiste d'unités monométalliques $[Ni(pyzdcH)_2(H_2O)_2]$ reliées par des interactions de liaisons hydrogènes dans un arrangement tridimensionnel. Dans le composé **2**, des chaînes allongées d'ions de cuivre sont reliées par des groupes $pyzdcH^-$ qui créent des doubles ponts alors que les composés **3**, **4** et **5** comportent des structures dans lesquelles des coordinats $pyzdc^{2-}$ servent de ponts entre des centres métalliques pour former de longues chaînes linéaires. Des études de susceptibilité magnétique révèlent l'existence d'interactions antiferromagnétiques dans les composés **1**, **2**, **3**, **4** et **6** (dans le **6** il s'agit du Cu(pyzdc)). On discute de l'amplitude de l'échange ($-J = 0,033$ cm^{-1} pour **1** et $-zJ = 0,11$, 0,74, 0,049 et 1,14 cm^{-1} pour respectivement les composés **2**, **3**, **4** et **6**) en termes des structures et des configurations des électrons d'impliquées.

Mots clés : pyrazine-2,3-dicarboxylates métalliques, synthèse, structure par diffraction des rayons X, antiferromagnétisme.

Introduction

2,3-Pyrazinedicarboxylic acid ($pyzdcH_2$) has six donor atoms for coordination and, deprotonated, readily forms metal complexes (1–11). Our interest in these compounds stems from the variety of ways the $pyzdc^{2-}$ and $pyzdcH^-$ ligands can potentially bridge metal centers forming polymetallic compounds. The compound $Co(pyzdc) \cdot 2H_2O$, for example, has an extended chain structure in which the metals are bridged by 1,4-diazine links that are supported by chelate formation involving carboxylate substituents adjacent to the ring nitrogens (8). Numerous studies on complexes of pyrazine itself (12) have shown that, in many instances, the unsupported 1,4-

diazine link provides a relatively efficient pathway for magnetic exchange; comparisons of the magnetic properties of compounds such as $Co(pyzdc)\cdot 2H_2O$ with those of related pyrazine systems should permit an evaluation of the effects of the chelate support on the mediation of exchange.

Previous studies involving divalent Mn, Fe, Co, Ni, Cu, and Zn, and which focussed mainly on the synthesis of complexes and on their characterization by spectroscopic and thermochemical methods (1–7), identified so-called 2:1 and 1:1 complexes of composition $M(pyzdcH)_2\cdot xH_2O$ and $M(pyzdc)\cdot xH_2O$. Only limited crystallographic information is reported on these systems. X-ray studies have shown $Co(pyzdc)\cdot 2H_2O$ and $Zn(pyzdc)\cdot 3H_2O$ to have polymetallic chain structures (8, 9) and $Co(pyzdcH)_2\cdot 2H_2O$ to be monometallic (10). Magnetic susceptibility studies on this group of compounds have involved some room temperature measurements on the 1:1 complexes (5), variable temperature measurements in the high temperature range (300–80 K) on Cu(pyzdc), $Co(pyzdcH)_2\cdot 2H_2O$, and $Ni(pyzdcH)_2\cdot 2H_2O$ (2), and measurements to low temperatures on $Co(pyzdcH)_2\cdot 2H_2O$ (10) and $Cu(pyzdcH)_2\cdot 3H_2O$ (11).

In view of the limited studies available we decided to systematically investigate these systems with emphasis on X-ray determined structures and magnetic measurements to cryogenic temperatures. This paper describes work on the 2:1 complexes $[Ni(pyzdcH)_2(H_2O)_2]$ (**1**) (the cobalt analogue has been structurally and magnetically well characterized (10)) and $[Cu(pyzdcH)_2]_x\cdot 2xH_2O$ (**2**) and the 1:1 complexes $[M(pyzdc)(H_2O)_2]_x\cdot 2xH_2O$ (where M = Co, Ni, and Cu; compounds **3**, **4**, and **5**, respectively) and Cu(pyzdc), **6**. We report the crystal structures of **1** through **5** as well as magnetic susceptibility measurements to 4 K on all compounds except **5**.

Experimental

Syntheses

All chemicals were at least reagent grade quality and were used without further purification. All products, with the exception of **5**, are air stable.

*Diaquabis(hydrogen-2,3-pyrazinedicarboxylato(1⁻))-nickel(II), $[Ni(pyzdcH)_2(H_2O)_2]$, **1***

2,3-Pyrazinedicarboxylic acid (0.42 g, 2.5 mmol) was dissolved in 60 mL water and slowly added to a 60 mL aqueous solution of $Ni(NO_3)_2\cdot 6H_2O$ (0.36 g, 1.25 mmol). After standing for 2–3 weeks, the solution yielded green crystals. After selecting suitable crystals for X-ray analysis, the rest of the product was collected by filtration, washed with water, and dried in vacuo at room temperature for 24 h. Anal. calcd. for $C_{12}H_{10}N_4NiO_{10}$: C 33.60, H 2.35, N 13.06; found: C 33.86, H 2.46, N 13.02.

*Poly-bis-μ-(hydrogen-2,3-pyrazinedicarboxylato(1⁻))-copper(II) dihydrate, $[Cu(pyzdcH)_2]_x\cdot 2xH_2O$, **2***

Prepared as above employing 1.25 mmol of copper(II) acetate monohydrate in 60 mL water and 2.5 mmol $pyzdcH_2$ in 100 mL water. On standing overnight the solution produced a precipitate as a blue powder. This was collected by filtration, washed with water, and dried in vacuo at room temperature for 24 h. Analytical data showed this material to be a hemihydrate. The dihydrate, **2**, was obtained as crystalline material suitable for X-ray analysis by recrystallization from water followed by drying in air. The crystals are air stable and samples were ground to a powder for elemental analysis and subsequent studies. Anal. calcd. for $C_{12}H_{10}CuN_4O_{10}$: C 33.22, H 2.32, N 12.92; found: C 33.17, H 2.33, N 12.94.

*Poly-diaqua-μ-2,3-pyrazinedicarboxylatocobalt(II) dihydrate, $[Co(pyzdc)(H_2O)_2]_x\cdot 2xH_2O$, **3***

2,3-Pyrazinedicarboxylic acid (0.42 g, 2.5 mmol) was dissolved in 100 mL water and the solution was adjusted to pH 5 with 1.0 M aqueous NaOH. This solution was added slowly to a 60 mL aqueous solution of $Co(NO_3)_2\cdot 6H_2O$ (0.76 g, 2.5 mmol). Orange crystals deposited after the solution was left standing for about 2 d. Crystals suitable for X-ray diffraction studies were selected, then the remainder were separated by filtration, washed with water, and dried in vacuo at room temperature for 24 h. Anal. calcd. for $C_6H_{10}CoN_2O_8$: C 24.26, H 3.39, N 9.43; found: C 24.21, H 3.39, N 9.31.

*Poly-diaqua-μ-2,3-pyrazinedicarboxylatonickel(II) dihydrate, $[Ni(pyzdc)(H_2O)_2]_x\cdot 2xH_2O$, **4***

Prepared from $Ni(NO_3)_2\cdot 6H_2O$ by the procedure described above for **3**. In this case, however, it took several months before green crystals appeared. Anal. calcd. for $C_6H_{10}N_2NiO_8$: C 24.28, H 3.39, N 9.44; found: C 24.02, H 3.35, N 9.32.

*Poly-diaqua-μ-2,3-pyrazinedicarboxylatocopper(II) dihydrate, $[Cu(pyzdc)(H_2O)_2]_x\cdot 2xH_2O$, **5***

Crystals of **5** were obtained from $Cu(NO_3)_2\cdot 3H_2O$ by the procedure used to obtain crystalline **3**. Green crystals appeared in the solution after 2 d. X-ray analysis of a freshly isolated crystal, mounted wet in a capillary and then sealed, showed it to be **5**. The crystals of **5**, however, rapidly decompose in air with loss of water from the lattice, making it impossible to obtain microanalytical data or to carry out subsequent studies on the compound.

*2,3-Pyrazinedicarboxylatocopper(II), Cu(pyzdc), **6***

Crystals of **5** were removed by filtration from the solution described above, washed with water, and dried in vacuo at room temperature for 24 h. Anal. calcd. for $C_6H_2CuN_2O_4$: C 31.38, H 0.88, N 12.20; found: C 31.57, H 1.02, N 11.90.

X-ray crystallographic analyses of 1–5

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 24.6°–45.9° for **1**, 29.9°–38.8° for **2**, 50.0°–66.0° for **3**, 26.0°–39.6° for **4**, and 33.2°–42.5° for **5**. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random fluctuations. The data were processed,[2] corrected for Lorentz and polarization effects, and for absorption (based on azimuthal scans for three reflections).

The structures were solved by Patterson (**1**) or direct (**2**, **3**) methods. The structure analysis of **3** was initiated in the centrosymmetric space group *C*2/*c* on the basis of the *E*-statistics, this choice being confirmed by the subsequent successful solution and refinement of the structure. Compounds **4** and **5**

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Mo K_α radiation (λ = 0.71069 Å), graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts (scan/background time ratio 2:1), $\sigma^2(F^2) = [S^2(C + 4B)]/Lp^2$ (S = scan speed, C = scan count, B = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(F^2)$.

are isomorphous with **3**. Compounds **3** and **4** are also isostructural, but because of the longer M–OH_2 distances in **5** the hydrogen-bonding in this complex differs from that in **3** and **4** (see below). In all five complexes the asymmetric unit contains half the formula unit, the metal atoms all lying on crystallographic inversion centres. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were refined with isotropic thermal parameters. A correction for secondary extinction was applied for **3**, the final value of the extinction coefficient being 1.13(3) × 10^{-6} (Zachariasen isotropic type 2). Neutral atom scattering factors for all atoms (13) and anomalous dispersion corrections for the non-hydrogen atoms (14) were taken from the *International tables for X-ray crystallography*. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and hydrogen-bonding parameters appear in Tables 2–7. Hydrogen atom parameters, anisotropic thermal parameters, and torsion angles have been deposited as supplementary material.[3]

Physical measurements

Thermal Gravimetric Analysis (TGA) was performed on powdered samples using a TA Instruments TGA 51 thermogravimetric analyzer. Samples of 5–20 mg were heated at 10°C/min in an atmosphere of dry nitrogen at a flow rate of 100 mL

[3] Supplementary material mentioned in the text may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Tables of bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

min^{-1}. Magnetic susceptibilities over the temperature range ~4 to ~82 K were measured at applied fields of 7 501 or 9 225 Oe using a P.A.R. model 155 vibrating sample magnetometer as previously described (15). Samples were held in Kel-F capsules and corrections were made for background signal over the entire temperature range studied. Magnetic susceptibilities were corrected for diamagnetism of all atoms (cobalt, −12; nickel, −11; copper, −11; $pyzdc^{2-}$ and $pyzdcH^-$, -68; H_2O, −12) and temperature independent paramagnetism of nickel and copper, 200 and 60, respectively. All corrections are in units of 10^{-6} cm^3 mol^{-1}. Complete magnetic data have been deposited as supplementary material. Carbon, hydrogen, and nitrogen analyses were performed by P. Borda of this department.

Results and discussion

Synthesis and thermoanalysis

2:1 complexes

$[Ni(pyzdcH)_2(H_2O)_2]$, **1**, was prepared under conditions similar to those described previously (2) with the main difference being that the solutions were some 20 times more dilute, result-

Table 3. Bond lengths (Å) with estimated standard deviations in parentheses for **1** and **2**.

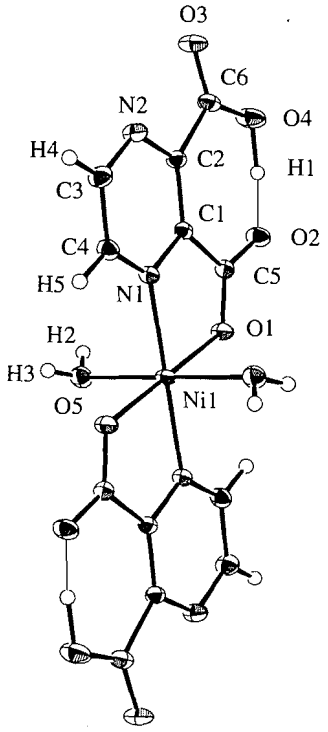
ing in the deposition of crystals suitable for X-ray studies. The presence of two molecules of water per metal was shown by microanalysis and TGA, which confirmed the earlier result (7) that the compound is thermally stable to about 150°C and decomposes with the loss of two moles of H_2O and two moles of CO_2 over the range 150–277°C. While the 2:1 complexes are generally reported as dihydrates (2), the one report of the copper derivative is as a trihydrate (11). We do not observe this formulation; however, compound **2**, like the 2:1 complexes of other metals, contains two water molecules. TGA studies show that **2** loses both molecules of water over the temperature range 50–160°C. The explanation for the relative ease of dehydration of **2** compared to the situation for **1** comes from structural studies which reveal that the water molecules are coordinated to the metal in **1** but are not coordinated in **2** (see below).

1:1 complexes

Previous work has revealed significant variations in the degree of hydration of the 1:1 complexes. Those of Mn, Fe, Co, and Ni have been reported both as tetrahydrates (5), and as dihydrates (7), that of Cu as anhydrous (2, 6), a hemihydrate (5), and a monohydrate (7) and that of Zn as a tetrahydrate (5), a dihydrate (7), and a trihydrate (9). This variation in degree of hydration was commented on earlier (5). Our synthetic method, which yields crystalline samples from dilute solutions, gave, for Co, Ni, and Cu (**3**, **4**, and **5**), complexes that have four water molecules per metal, two coordinated and two lattice, as shown by subsequent X-ray analysis. For **3** and **4** TGA showed the loss of four molecules of water over the ranges 40–300°C and 40–324°C, respectively, in agreement with earlier studies on the tetrahydrates (5). The copper compound, **5**, readily loses water under ambient conditions and

Fig. 1. The structure of $[Ni(pyzdcH)_2(H_2O)_2]$ (**1**), with atom numbering scheme; 33% probability thermal elipsoids are shown.



could not be characterized further. TGA studies of **6** confirmed the anhydrous nature of the compound and showed it to be thermally stable to 240°C.

Structural and magnetic studies

2:1 complexes

Crystals of $[Ni(pyzdcH)_2(H_2O)_2]$ (**1**) are isomorphous with those of the cobalt analogue (10). The structure of **1** with the atom numbering scheme is shown in Fig.1. In the monometallic $[Ni(pyzdcH)_2(H_2O)_2]$ unit the metal is *trans*-coordinated by two $pyzdcH^-$ ligands via chelate interactions involving nitrogen N(1) adjacent to the deprotonated carboxylate and oxygen O(1) of that group. The other nitrogen and the protonated carboxylate on each ligand are not coordinated to the metal. There is a strong intramolecular hydrogen bond involving the carboxylate hydrogen and oxygen O(2). Six coordination about the metal is completed by two axially coordinated water molecules. Hydrogen-bonding interactions involving the water hydrogens and the carboxylate noncoordinated oxygens O(3) on neighbouring molecules generates a three-dimensional network, a portion of which is shown in Fig. 2.

Although $[Co(pyzdcH)_2(H_2O)_2]$ (isostructural with **1**) is a monometallic complex, O'Connor and Sinn (10) pointed out that the hydrogen-bonding network provided by the water molecules can provide a pathway for magnetic exchange. By careful analysis of the low temperature magnetic data these authors were able to show the presence of weak antiferromagnetism in the cobalt complex. The magnetic moments measured for the nickel analogue **1** at the higher temperatures studied are relatively independent of temperature (Fig. 3) and of a magnitude expected for magnetically dilute nickel(II) complexes (16). The observed decrease in magnetic moment

[h] $1/2 - x, 1/2 + y, 3/2 - z$.

Fig. 2. Stereoscopic view showing part of the H-bonding network in $[Ni(pyzdcH)_2(H_2O_2]$ (**1**).

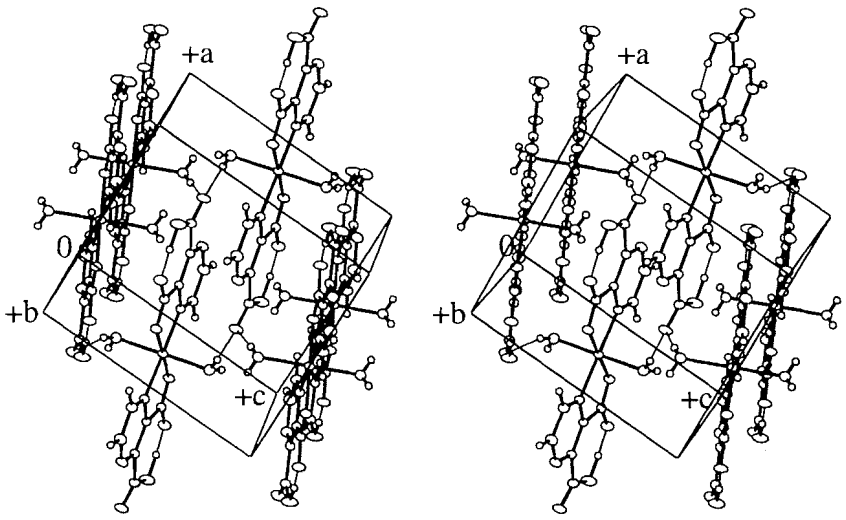

Fig. 3. Magnetic moment versus temperature plots.
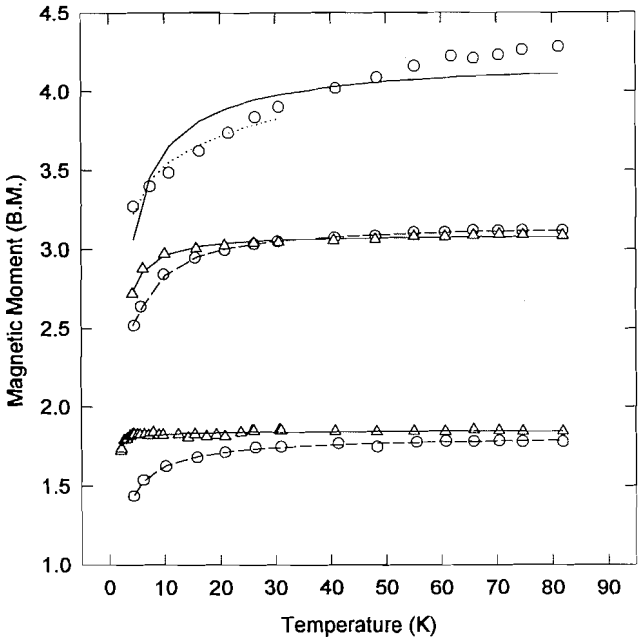
Experimental data: circles at the top, middle, and bottom are for $[Co(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**3**), $[Ni(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**4**), and Cu(pyzdc) (**6**), respectively; triangles at middle and bottom are for $[Ni(pyzdcH)_2(H_2O)_2]$ (**1**) and $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (**2**), respectively. Lines are calculated from theory as described in the text.



at low temperatures is caused by the effects of Zero Field Splitting, ZFS (17), accompanied possibly by very weak exchange effects. Accordingly, we examined fits of the magnetic susceptibility data over the temperature range ~80 to ~4 K employing the previously published equation for the susceptibility, χ_m, of an $S = 1$ system including ZFS (18), with χ_m modified by the molecular field approximation to include the effects of weak spin interactions (19). The equation employed for the exchange-corrected susceptibility, χ_m', is:

$$[1] \quad \chi_m' = (\chi_m/[1 - (2zJ/Ng^2\mu_B^2)\chi_m])$$

where J is the exchange coupling constant, z is the number of interacting nearest neighbours, and the remaining terms have their usual meaning. In the fitting procedure D (the zero-field splitting parameter), g, and zJ were employed as variable parameters. Fits of experimental data to the model were made using a nonlinear least-squares procedure with the following function minimized:

$$[2] \quad F = \left[\frac{1}{n}\sum_{i=1}^{n}\left(\frac{\chi^i_{calc} - \chi^i_{obs}}{\chi^i_{obs}}\right)^2\right]^{1/2}$$

where n is the number of data points. F provides a measure of the goodness of fit between theory and experiment. The parameter values giving the best agreement between experiment and theory are $D = 4.0$ cm^{-1}, $zJ = -0.033$ cm^{-1}, and $g = 2.19$ ($F = 0.0074$).[4] The experimental magnetic moments as well as the line calculated using the best fit parameters are shown in Fig. 3. The fit gives $|D| \gg |zJ|$, a necessary requirement for applying the molecular field approximation (17).
