Ignoring intermolecular exchange (setting $J = 0$) in analysing the magnetic data of **1** gives poorer agreement between experiment and theory, indicating the presence of weak antiferromagnetic exchange, mediated by the H-bonding network. Of relevance here are previous studies on some monometallic tetrakis(pyridine) nickel(II) complexes (20) that showed very similar magnetic properties to those seen for **1**. In fact, the D, zJ, and g parameter values obtained for $Ni(py)_4Cl_2$ (20), a complex known to have a monometallic *trans*-octahedral structure (21), are, within experimental uncertainty, the same as those obtained in the present work for **1**. We conclude that the intermolecular H-bonding network, present in **1** but absent in the pyridine complex, provides a pathway for exchange that, however, is not measurably better than that provided by normal non-bonding contacts.

Crystals of $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (**2**) have the same stoichiometry and belong to the same space group as **1**. Compound **2**, however, is not isostructural with **1**. The structure of **2** with the atom numbering scheme is shown in Fig. 4. In this structure, each copper is *trans*-coordinated by two chelating $pyzdcH^-$ ligands to form planar $Cu(pyzdcH)_2$ units as in **1**. In **2**, however, the axial positions are not occupied by water molecules but instead are occupied by the non-protonated oxygen atoms O(4) of protonated carboxylate substituents on neighbouring $Cu(pyzdcH)_2$ units. This results in extended chains of copper ions linked by double-bridging $pyzdcH^-$ groups. The lattice water molecules link chains in a three-dimensional H-bonded network, part of which is shown in Fig. 5.

Since the $Cu(pyzdcH)_2$ units in **2** are connected in chains by conventional coordinative interactions the potential for magnetic exchange is greater than in **1**. In spite of this, the magnetic moment of **2** is relatively constant down to about 4 K. For **2** we extended the measurements to 2 K and observed a decrease in moment at the low temperatures indicative of very weak antiferromagnetic exchange (Fig. 3). Anticipating that intrachain coupling would be significantly stronger than interchain coupling via the H-bonding network, we analysed the magnetic susceptibilities of **2** (over the full temperature range studied) according to the Weng linear chain model with the coefficients generated by Hiller *et al.* (22) for $S = 1/2$. The best fit to the data was obtained with the parameters $g = 2.14$ and $J = -0.11$ cm^{-1} ($F = 0.016$) and the line calculated with these parameter values is shown in Fig. 3. Although this analysis confirms antiferromagnetic exchange in **2**, it is clearly very weak. This is probably a consequence of the fact that the $Cu(pyzdcH)_2$ units in **2** are linked via long, axial, Cu—O bonds (2.405(2) Å) combined with the fact that the plane of the CO_2 group is almost orthogonal to the plane of the pyrazine ring, thus eliminating a delocalized π-electron pathway for exchange. Finally, it should be noted that in an earlier study (11) of a 2:1 copper complex of composition $Cu(pyzdcH)_2 \cdot 3H_2O$ the authors found no evidence for exchange in measurements to 6 K. It is possible that the compound studied in the earlier work has the same linear chain structure as **2** with an additional water of hydration.

1:1 complexes

$[Co(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**3**) and the nickel (**4**) and copper

[4] Here and elsewhere in this work the uncertainties in the magnetic parameters are estimated to be approximately 2% in g and 10% in the other parameters.

Fig. 4. Stereoscopic view of the structure of part of the chain in $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (**2**) with atom numbering scheme; 33% probability thermal elipsoids are shown.

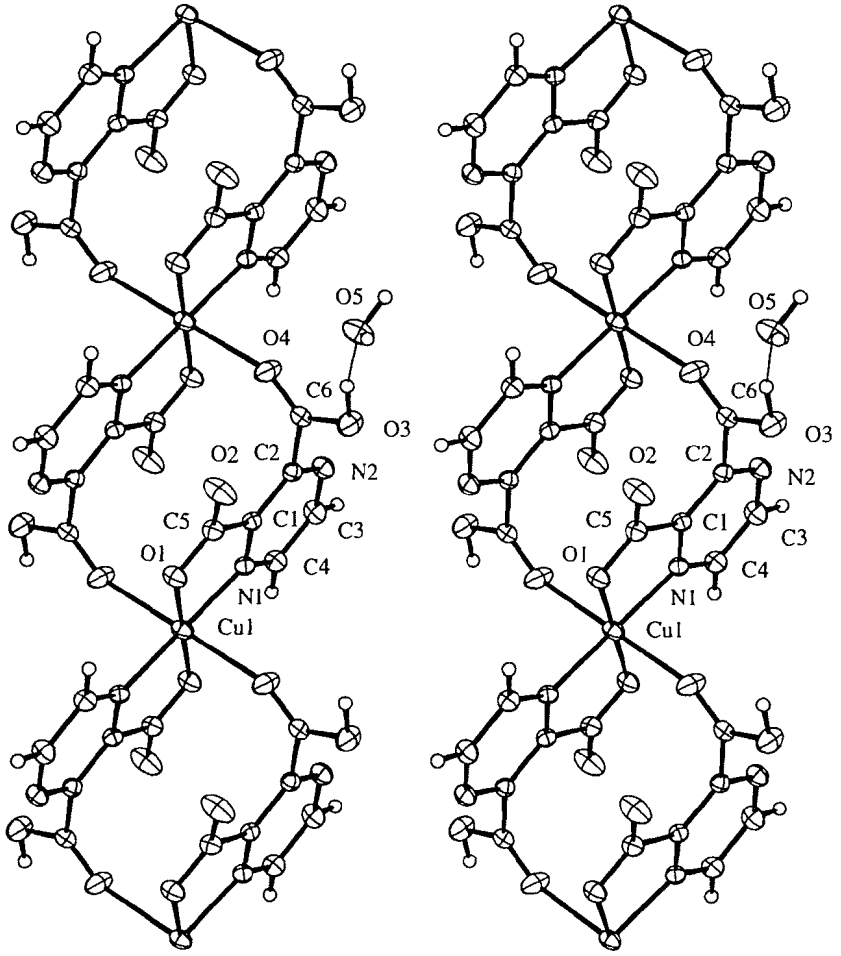

Fig. 5. Stereoscopic view showing part of the H-bonding network in $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (**2**).

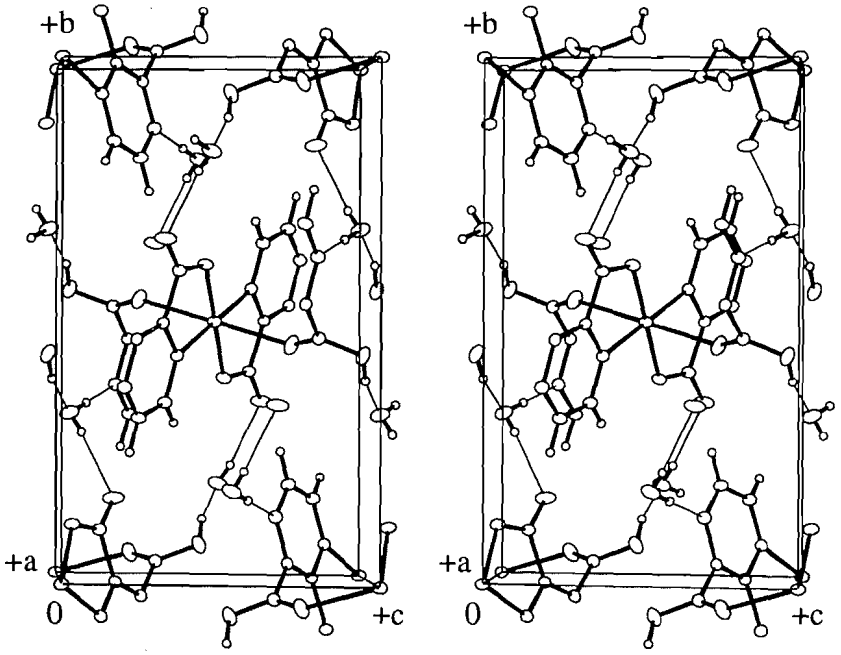

Fig. 6. The structure of part of the chain in $[Co(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**3**) with atom numbering scheme; 33% probability thermal elipsoids are shown.

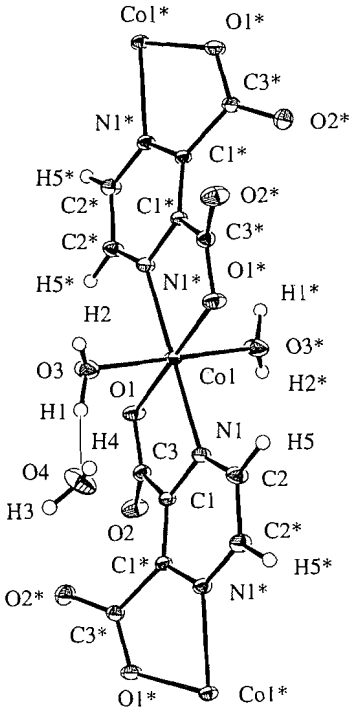

(**5**) analogues are isomorphous; they have structures in which $pyzdc^{2-}$ ligands bridge metal ions to form extended linear chains.The structure of **3** with the atom numbering scheme is shown in Fig. 6. In this structure the $pyzdc^{2-}$ ligand coordinates to two metal centers via chelate interactions involving each nitrogen N(1) and an oxygen O(1) from the adjacent carboxylate substituent. Six coordination on each metal is completed by oxygens O(3) of axially coordinated water molecules and two additional water molecules are present in the lattice. As shown in Fig. 7, the chains in **3** are linked in a three-dimensional array by H-bonding interactions involving all water molecules. The H-bonding network in **4** is the same as in **3** but it differs in **5**. In the latter, as shown in Fig. 8, the lattice water hydrogen H(3) H-bonds to O(1) as in **3** and **4** but forms an additional H bond to noncoordinating carboxylate oxygens O(2). The other lattice water hydrogen H(4) does not H-bond to O(1) as in **3** and **4** but, instead, H-bonds to the coordinated water oxygen O(3).

The crystal structure of a 1:1 complex of composition $Co(pyzdc)\cdot 2H_2O$ was previously reported (8). This compound, which belongs to the space group *Pcca*, has the same linear chain structure as **3**, with axially bonded waters but no lattice water. This lack of lattice waters and the associated H-bonding interactions has a measurable effect on the bond parameters in the immediate environment of the metal. In $Co(pyzdc)\cdot 2H_2O$ the CoN_2O_4 chromophore is non-centrosymmetric. The bond angles show greater deviation from regular octahedral angles than is observed here for **3**. The two Co—O (coordinated water) distances are shorter (2.069(4) and 2.033(4) Å) than the corresponding distance (2.094(1) Å) in **3**. The two Co—O(carboxylate) bond distances (2.069(4) and 2.037(4) Å) bracket the corresponding distance (2.0555(9) Å) in **3** but the average (2.053(4) Å) is the same within error. The Co—N distances (2.173(4) and 2.135(4) Å) also bracket the corresponding distance (2.1458(9) Å) in **3**; however, in this case the average distance (2.154(4) Å) is slightly greater. In view of these structural differences involving what is likely to be the dominant exchange pathways in **3** and $Co(pyzdc)\cdot 2H_2O$, the magnetic properties of the latter could be measurably different from those reported here for **3**.

Compounds **3**, **4**, and **5** all have the same extended chain structures involving chelate supported 1,4-diazine links between metal centers. Although the chains are connected via H-bonded networks, results obtained on compounds such as **1** indicate that interchain exchange via these pathways will likely be very weak. Magnetic studies on these compounds, then, should permit an evaluation of intrachain exchange via the supported diazine links and its dependence on d-electron configuration.

The analysis of magnetic data for cobalt(II) complexes in distorted octahedral environments as seen in $[Co(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**3**) is complicated by the fact that, in addition to possible magnetic exchange effects, single ion effects such as electron delocalization, spin-orbit coupling, distortions from regular stereochemistry, and crystal field mixing of excited states into the ground state affect the magnetic properties (23). The problem is simplified if it is assumed that the distortion from O_h symmetry is strong enough to leave a well-isolated orbital singlet as the ground state (24). Under this assumption the magnetic susceptibilities of **3** were analysed (over the full temperature range studied) according to the Weng model with the coefficients generated by Hiller et al. (22) for $S = 3/2$. The solid line in Fig. 3 shows the best fit ($g = 2.17$ and $J = -0.380$ cm^{-1}, $F = 0.072$) that could be obtained with this model and it is clearly poor. An alternative approach to the problem is to consider the fact that spin-orbit coupling leads to a Kramers doublet as the lowest level and, assuming that at low temperatures this is the only thermally occupied level, the magnetic susceptibilities in the low temperature region (31–4 K) were analysed using the Weng model for an effective spin $S = 1/2$. Attempts to fit the data employing g, J, and Temperature Independent Paramagnetism (TIP) as variable parameters gave good agreement with experiment but an unrealistically high value of TIP (0.017 cm^3 mol^{-1}). We decided instead to fix TIP at 0.006 cm^3 mol^{-1}, the value determined for the very weakly magnetically coupled $[Co(pyzdcH)_2(H_2O)_2]$ by high-precision magnetic measurements at low temperatures (10). Because of the similarities in the metal chromophores of **3** and $[Co(pyzdcH)_2(H_2O)_2]$, the TIP should be much the same in the two compounds. The dotted line in Fig. 3 covering the low temperature region was calculated from theory using the best fit parameters $g = 4.31$ and $J = -0.74$ cm^{-1} ($F = 0.027$). Considering the difficulties in analysing this system, not too much significance should be placed on the actual parameter values; nonetheless, the results do support the presence of measurable exchange in **3.** This should be contrasted with the earlier report that the pyrazine-bridged complexes, $Co(pyz)_2X_2$ (X = Cl or Br), give no evidence for magnetic exchange down to 1.8 K (25). This suggests that in this cobalt system the effect of supporting the diazine bridge through chelate formation is to enhance the exchange.

The magnetic data for $[Ni(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**4**) were

Fig. 7. Stereoscopic view showing part of the H-bonding network in $[Co(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**3**).

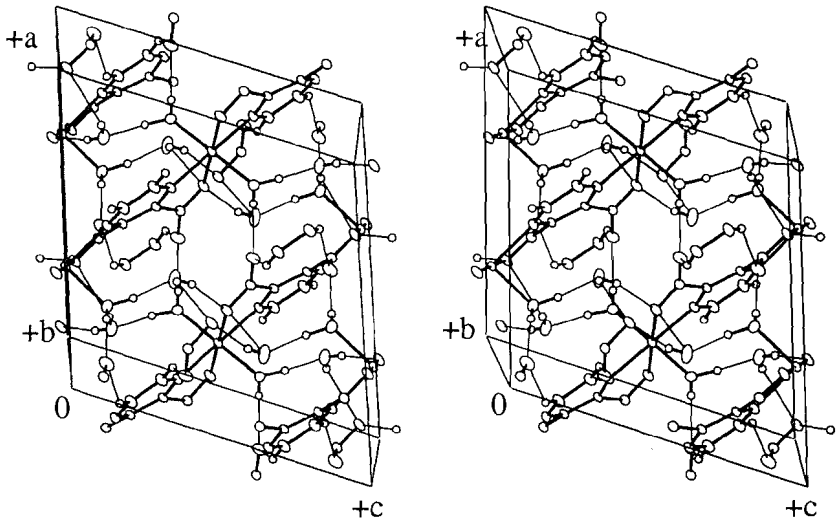

Fig. 8. Stereoscopic view showing part of the H-bonding network in $[Cu(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**5**).

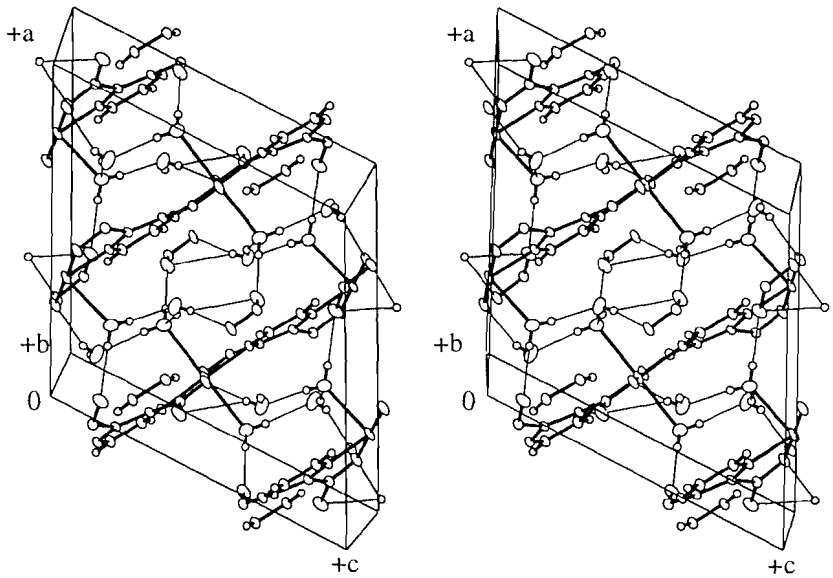

analysed as described above for **1**. Excellent agreement between experiment and theory (Fig. 3) was obtained with the parameters $g = 2.24$, $zJ = -0.098$ cm^{-1}, and $D = 3.3$ cm^{-1} ($F = 0.0029$). Significantly, the D values for **1** and **4** are very similar, consistent with similarities in the metal chromophores of the two compounds, while $-zJ$ is significantly greater for the pyzdc^{2-}-bridged **4**. Since **4** has a linear chain structure, $z = 2$ and therefore $J = -0.049$ cm^{-1}. This value is comparable to the J values determined in earlier work (20) for three complexes assumed to have monopyrazine-bridged structures ($-J$ in the range 0.018 to 0.047 cm^{-1}). The earlier work concluded that pyrazine is significantly poorer at mediating magnetic exchange between nickel centers than, for example, between copper or iron centers (20) and it appears that pyzdc^{2-} is not significantly better, in spite of the presence of the chelate-supported bridges. It was suggested previously (20) that a factor in accounting for weaker exchange in nickel versus copper pyrazine complexes is longer metal–N bond lengths in the Ni complexes, an effect not countered, as it is in Fe complexes, by the presence of additional pathways for exchange involving t_{2g} unpaired electron density. This relative order of bond lengths (Ni—N = 2.074(1), Cu—N = 1.996(2) Å; Table 5) is observed for **4** and **5**, supporting the notion that the relatively long metal–N bond distance is contributing to the weakness of the exchange in both pyz- and pyzdc^{2-}-bridged complexes of nickel.

Due to its instability in air, we were unable to study the magnetic properties of $[Cu(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (**5**); however, the anhydrous derivative, Cu(pyzdc) (**6**), was investigated (Fig. 3). This compound was previously studied at high temperatures (2) and our low temperature results mesh very well with the earlier work. The magnetic susceptibilities (80 – 4 K) were analysed using the Weng model for $S = 1/2$ and excellent agreement between experiment and theory was

obtained with the parameters $g = 2.10$ and $J = -1.14$ cm^{-1} ($F = 0.0087$). It seems likely that the basic chain structure of **5** is retained in **6** with the axially coordinated water molecules replaced by weak coordinative interactions involving carboxylate oxygens from neighbouring chains. Magnetic exchange interactions via these long Cu—O bonds are likely to be very weak (as seen for **2**); considering this and the fact that the experimental susceptibilities show excellent agreement with values calculated from theory for linear chains, we conclude the exchange observed in **6** is mediated primarily by the pyzdc^{2-} ligands. The pathway provided by these ligands in **6** is clearly better at mediating exchange than that provided by the pyzdcH$^-$ ligands in **2** ($-J$ values of 1.14 and 0.11 cm^{-1}, respectively); however, considering that $-J$ values as large as 16.8 cm^{-1} have been observed in extended chain compounds of copper(II) in which the metals are bridged by pyrazine itself (25), the magnitude of the coupling in **6** is still rather weak. An explanation for this comes from a consideration of the probable structure of **6** as inferred from the X-ray determined structure of **5**. The pyrazine ligand is bound in the equatorial plane of the copper chromophore and, as a result of the chelate interaction, the plane of the pyrazine ring is forced to be nearly coplanar with the equatorial plane.[5] Earlier studies (26) have shown that under such structural conditions magnetic exchange interactions in copper pyrazine complexes is likely to be weak. This is because the magnitude of the exchange is determined from the overlap of the $d_{x^2-y^2}$ magnetic orbital and the pyrazine π-system, which becomes significant only when the pyrazine ring is canted out of the xy-plane. In $Cu(pyz)(NO_3)_2$, for example (27, 28), where the canting angle is about 50°, the exchange interaction ($-J = 3.7$ cm^{-1}) is significantly greater than that observed here for **6**.

Summary and conclusions

Of the six compounds studied in this work, all have extended chain structures with the exception of $[Ni(pyzdcH)_2(H_2O)_2]$ (**1**). The monometallic units in **1** are linked in a three-dimensional array by H-bonding interactions, which are shown to provide pathways for intermolecular exchange that are no better than would be expected for non-bonding contacts. In $[Cu(pyzdcH)_2]_x \cdot 2xH_2O$ (**2**) the pyzdcH$^-$ ligands exhibit a form of coordination not previously reported for this group. Although the metals are doubly bridged by these ligands, the links involve weak axial Cu—O bonds and a ligand geometry that prevents π-electron delocalization throughout the bridge. This leads to only very weak antiferromagnetic exchange in **2**.

The compounds $[M(pyzdc)(H_2O)_2]_x \cdot 2xH_2O$ (M = Co, Ni, and Cu ; **3**, **4**, and **5**, respectively) all have linear chain structures with pyzdc^{2-} ligands forming chelate-supported 1,4-diazine links between metal centers. Magnetic studies on **3**, **4**, and **6** (Cu(pyzdc), the anhydrous form of **5**) reveal intrachain antiferromagnetic interactions mediated by the bridging ligands. While the analysis of the magnetic data indicates that the magnitude of the exchange in the Ni and Cu compounds (**4** and **6**) is not greatly different from that observed in analogous systems involving unsupported pyrazine bridges, this appears not to be the case for the Co system (**3**). The presence of the chelate interactions in the pyzdc^{2-} bridge imposes a geometrical constraint on the bridge and in the case of copper(II), in particular, this limits the potential for exchange. Such geometrical constraints may not be so important in the case of metals with unpaired t_{2g} electron density, as in cobalt(II) compounds, and with this in mind we are attempting to prepare and study complexes of iron(II) and manganese(II) that are isostructural with **3**.

[5] The dihedral angle between these planes is approximately 13.3° in **5**.

Structural studies of organoboron compounds LXIV.[1] Boron chelate formation with glycolohydroxamic acids, and the crystal and molecular structure of 5-(1-hydroxycyclohexyl)-2,2-diphenyl-1,3-dioxa-4-azonia-2-borata-4-cyclopentane

Wolfgang Kliegel, Ute Schumacher, Steven J. Rettig, and James Trotter

Abstract: The syntheses of representative diphenyl- and difluoroboron chelates of 2-hydroxycarbohydroxamic acids (glycolohydroxamic acids) are reported. Crystals of 5-(1-hydroxycyclohexyl)-2,2-diphenyl-1,3-dioxa-4-azonia-2-borata-4-cyclopentene, **2***a*, are triclinic, a = 11.5717(5), b = 11.7262(4), c = 14.3529(5) Å, α = 90.277(6)°, β = 110.497(5)°, γ = 96.814(5)°, Z = 4, space group $P\bar{1}$. The structure was solved by direct methods and refined by full-matrix least-squares procedures to R = 0.042 and R_w = 0.056 for 5318 reflections with $I \geq 3\sigma(F^2)$. Compound **2***a* is the first *N*-unsubstituted hydroxamatoborate derivative to be structurally characterized by an X-ray crystallographic analysis. The solid state structure of **2***a* consists of centrosymmetric, hydrogen-bonded tetrameric units that also feature intermolecular O—H···π(aromatic) interactions. Bond lengths include: B—O(N) = 1.557(2) and 1.553(2) Å, B—O(C) = 1.558(2) and 1.566(2) Å, B—C(phenyl) = 1.592(3)–1.601(3) Å.

Key words: hydroxamatoborate, organoboron compound, crystal structure.

Résumé : On a effectué la synthèse de chélates représentatifs diphényl- et difluorobore des acides 2-hydroxycarbohydroxamiques (acides glycolohydroxamiques). Les cristaux du 5-(1-hydroxycyclohexyl)-2,2-diphényl-1,3-dioxa-4-azonia-2-boratacyclopent-4-ène, **2***a*, sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 11,5717(5), b = 11,7262(4) et c = 14,3529(5) Å, α = 90,277(6)°, β = 110,497(5)° et γ = 96,814(5)°, Z = 4. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés, matrice complète, jusqu'à des valeurs de R = 0,042 et R_w = 0,056 pour 5318 réflexions avec $I \geq 3\sigma(F^2)$. Le composé **2***a* est le premier dérivé hydroxamatoborate *N*-non-substitué à être caractérisé par diffraction des rayons X. La structure du composé **2***a* à l'état solide consiste en des unités tétramères centrosymétriques réunies par des liaisons hydrogènes qui comportent aussi des interactions O—H···π(aromatique). Les longueurs des liaisons incluent : B—O(N) = 1,557(2) et 1,553(2) Å, B—O(C) = 1,558(2) et 1,566(2) Å, B—C(phényle) = 1,592(3)–1,601(3) Å.

Mots clés : hydroxamatoborate, composés orbanoborés, structures cristallines.

Introduction

2- and 3-Hydroxycarbohydroxamic acids and their chelating abilities are of interest in drug research on the anti-inflammatory and analgesic activities of hydroxamic acids (1). In the course of our investigations of hydroxamic acids as bi- or polydentate ligands in the formation of boron chelates (2–15) we chose two different 2-hydroxycarbohydroxamic acids (glycolohydroxamic acids), the 2,2-dialkyl derivative **1***a* and a 2,2-diaryl derivative, the benzilohydroxamic acid **1***b*, for the reaction with diphenylborenium (Ph_2B^+) and difluoroborenium (F_2B^+) ion-delivering reagents. Because of the presence of four different (nucleophilic) ligand functions within a compound of type **1**, various chelating modes could be expected. Furthermore, no in-depth structural descriptions of *N-un*substituted hydroxamato–borate complexes have yet been reported.

Experimental

5-(1-Hydroxycyclohexyl)-2,2-diphenyl-1,3-dioxa-4-azonia-2-borata-4-cyclopentene, 2*a*

1-Hydroxy-1-cyclohexanecarbohydroxamic acid (16) (0.32 g, 2.0 mmol) and oxybis(diphenylborane) (0.35 g, 1.0 mmol) are refluxed in 50 mL of benzene for 10 min using a Dean–Stark

trap for continuous removal of water. The solution is evaporated in vacuo to a residue of 2–4 mL. After addition of petroleum ether and cooling, colorless crystals are obtained. Yield: 0.14 g (22%); mp 137–139°C (from ethanol – petroleum ether). Infrared (KBr): 3520, 3140 (O-H/N-H), 1600 (C=O/C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS); δ (ppm): 0.80–2.10 (m, -$(CH_2)_5$-), 3.85 (s, v br, exchangeable, OH), 6.95–7.65 (m, 10 aromatic H), 11.8 (s, v br, exchangeable, NH). Anal. calcd. for $C_{19}H_{22}BNO_3$: C 70.61, H 6.86, N 4.33; found: C 70.52, H 6.93, N 4.34. The substance gives a deep blue color reaction with diphenylcarbazone in methanolic solution, indicating the presence of the diphenylboron moiety (17).

Crystals suitable for X-ray analysis were obtained by slow crystallization from absolute ethanol – petroleum ether: mp 136°C.

5-(1-Hydroxy-1,1-diphenylmethyl)-2,2-diphenyl-1,3-dioxa-4-azonia-2-borata-4-cyclopentene, 2*b*

2-Hydroxy-2,2-diphenylacetohydroxamic acid (benzilohydroxamic acid) (16) (0.73 g, 3.0 mmol) and oxybis(diphenylborane) (0.52 g, 1.5 mmol) are reacted as described for **2***a*. Yield: 0.72 g (59%) of colorless crystals; mp 106–108°C (from ethanol). Infrared (KBr): 3450, 3250 (O-H/N-H), 1600 (C=O/C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS); δ (ppm): 3.7 (s, v br, exchangeable, OH), 6.93–7.70 (m, 20 aromatic H), 11.2 (s, v br, exchangeable, NH). Anal. calcd. for $C_{26}H_{22}BNO_3$: C 76.68, H 5.44, N 3.44; found: C 76.46, H 5.41, N 3.50. The substance gives a deep blue color reaction with diphenylcarbazone in methanolic solution, indicating the presence of the diphenylboron moiety (17).

2,2-Difluoro-5-(1-hydroxycyclohexyl)-1,3-dioxa-4-azonia-2-borata-4-cyclopentene, 3*a*

1-Hydroxy-1-cyclohexanecarbohydroxamic acid (16) (0.32 g, 2.0 mmol) is mixed with 30 mL of dried diethyl ether and 2.0 mmol of dimethyl ether – trifluoroboron complex. After the addition of freshly regenerated molecular sieve (4 Å, 1.5 g) the solution is stored at room temperature for 12 h. The molecular sieve is removed, and the solution evaporated in vacuo. Crystallization starts spontaneously or after the addition of petroleum ether. Yield: 0.13 g (31%) of a white powder; mp 121–124°C (from CH_2Cl_2 – petroleum ether). Infrared (KBr): 3470, 3230 (O-H/N-H), 1625 (C=O/C=N) cm^{-1}; ^1H nmr (90 MHz, $CDCl_3$–TMS); δ (ppm): 1.10–2.35 (m, -$(CH_2)_5$-), 5.8 (s, v br, exchangeable, OH and NH). Anal. calcd. for $C_7H_{12}BF_2NO_3$: C 40.62, H 5.84, N 6.77; found: C 40.78, H 5.96, N 6.57.

X-ray crystallographic analysis of 2*a*

Crystallographic data for **2***a* appear in Table 1. The final unit-cell parameters were obtained by least squares on 2 sin θ/λ values for 25 reflections with 2θ = 40.4°–48.0°. The intensities of three standard reflections, measured every hour of X-ray exposure time throughout the data collection showed only small random fluctuations. The data were processed[3], corrected for Lorentz and polarization effects, but not for absorption in view of the low value of μ.

The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an *E*-map or from subsequent difference Fourier syntheses. The structure analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the *E*-statistics, this choice being confirmed by the subsequent successful solution and refinement of the structure. The asymmetric unit contains two crystallographically independent molecules of **2***a*. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were refined with isotropic thermal parameters. A correction for secondary extinction was applied, the final value of the extinction coefficient being $1.20(10) \times 10^5$ (Hamilton isotropic type I). Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (18). The largest peak on the final difference map (0.62

Results and discussion

The colorless crystalline products resulting from the reactions of **1** with the boron reagents show elemental analyses consistent with the expected 1:1 diphenyl- and difluoroboron chelates, in accordance with the infrared and ^{1}H nmr spectroscopic data. Furthermore, an intact chelated diphenylboron moiety is detected by the blue color reaction with diphenylcarbazone (17) in the case of the reaction of **1** with oxybis(diphenylborane). Unfortunately neither the infrared absorption in the region of N-H/O-H stretching frequencies between 3200 and 3500 cm^{-1}, the broad NH/OH proton signals in the ^{1}H nmr spectra, nor the other spectral features are sufficient to estab-

Fig. 1. Stereoviews of the two independent molecules of **2***a*; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

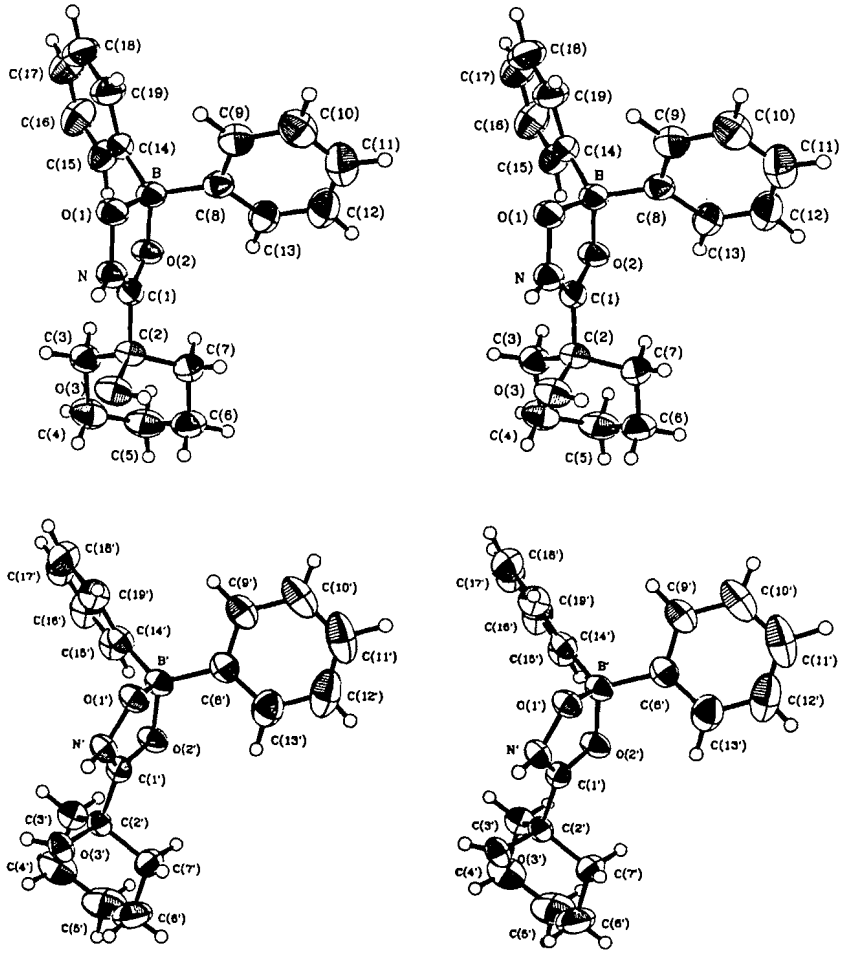

Fig. 2. Stereoview of the packing arrangement of **2***a*; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Broken lines indicate hydrogen bonds.

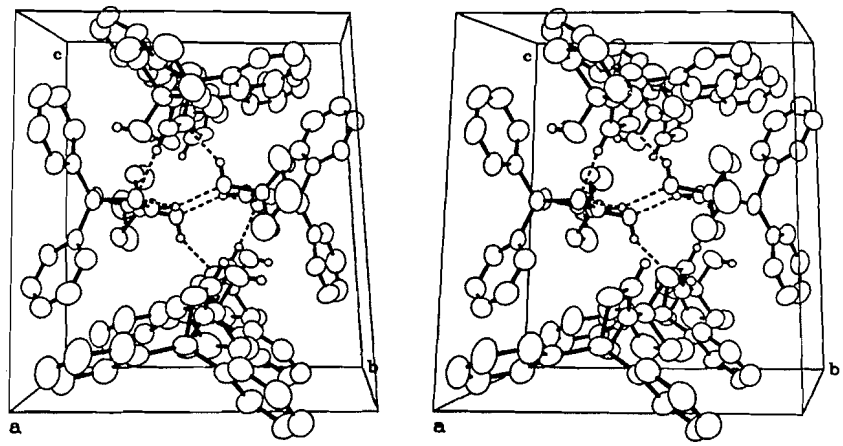
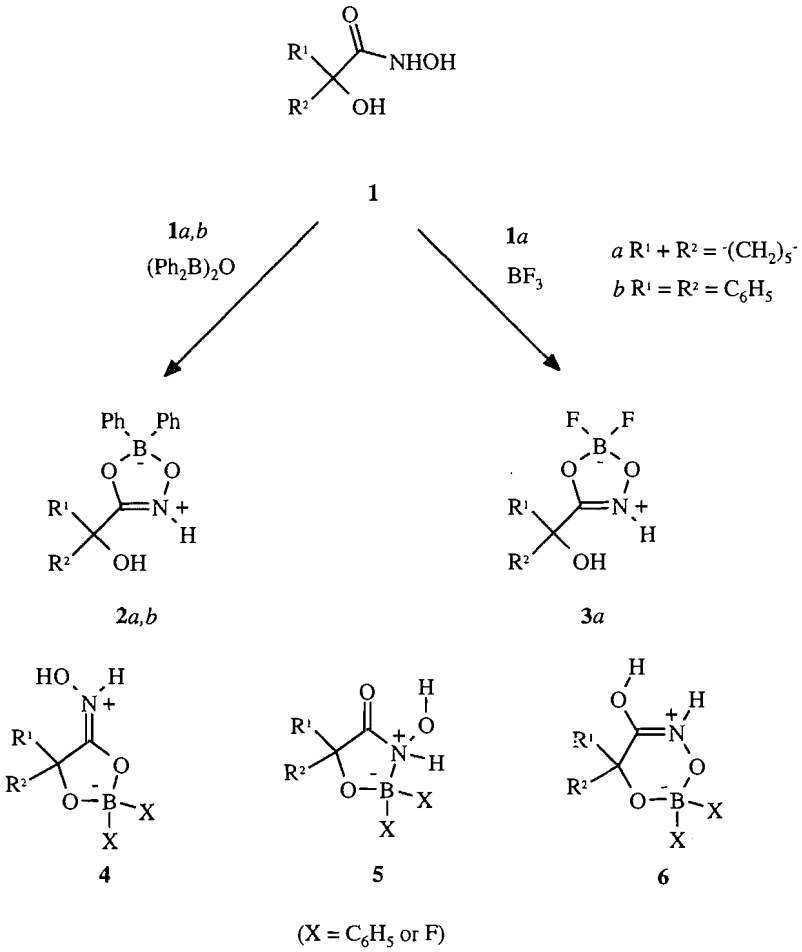
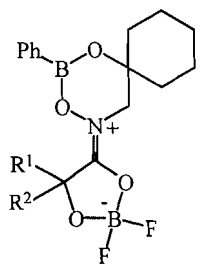


lish unambiguously the expected regular five-membered hydroxamatoborate ring structures **2** and **3** that correspond to the established ring systems of diphenyl- and difluoroboron chelates of various *N*-substituted hydroxamic acid derivatives (2, 3, 6, 9–11).

The observed spectroscopic data could also be assigned to

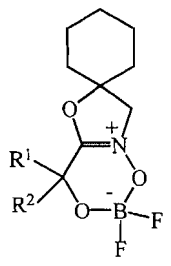


alternative five-membered chelate ring systems, **4** and **5**, or to the six-membered ring isomer **6**.[5] Structure **4** would involve the alkanol and the carbonyl groups as chelating ligands, as found in the five-membered difluoroboron chelate moiety of compound **7**, the molecular structure of which has been determined by an X-ray crystallographic analysis (14). The five-membered isomer **5**, which would have to be formed by a very weak N→B donor bond from the amide nitrogen atom to the boron atom, seems quite improbable. In the six-membered ring skeleton of the isomeric boron chelate **6**, however, the alkanol and the *N*-hydroxy groups would serve as coordinating ligands, as observed in the difluoroboron chelate ring portion



7

($R^1 = R^2 = 4\text{-}CH_3OC_6H_4$)



8

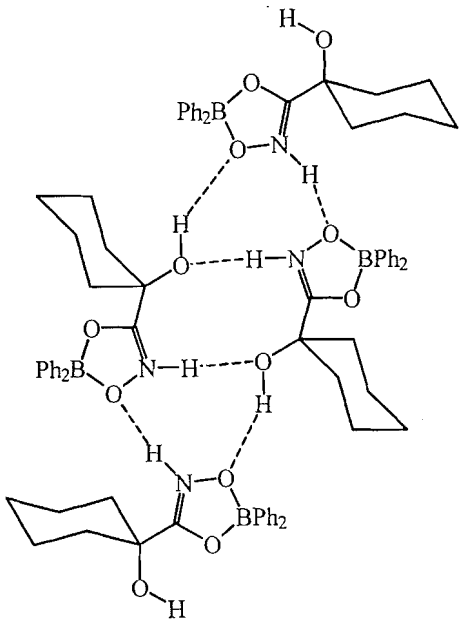
($R^1 = R^2 = C_6H_5$)

of the fully characterized compound **8** (12). To exclude the possible alternative chelate ring structures (**4** and **6** in particular) an X-ray crystallographic analysis of compound **2***a*, which gave the best crystals, was carried out.

The X-ray crystallographic analysis established the five-membered chelate ring structure (Fig. 1) analogous to those of the boron chelates of *N*-substituted hydroxamic acids (2, 3, 6, 9–11). In **2***a*, as in the *N*-substituted hydroxamatoborates, the hydroxamic acid serves as a "normal" *O,O*-bidentate ligand and forms the expected five-membered BONCO ring. This ring skeleton can also be ascribed, with a high degree of probability, to the other diphenylboron derivative (**2***b*) and to the difluoroboron derivative (**3***a*). To the best of our knowledge, **2***a* is the first structurally characterized example of an *N*-unsubstituted hydroxamatoborate complex in the literature. The crystallographic analysis is an especially important aspect of this work in view of the additional alternative modes of chelate formation offered by the α-hydroxy group neighboring the hydroxamic acid function.

In the crystal the chelate rings of **2***a* are further stabilized by intermolecular O—H···O and N—H···O hydrogen bonds that form centrosymmetric tetrameric units (**2***a*-tetramer, Fig. 2). Hydrogen bond geometry is as follows: O(3′)—H(O3′)···O(1)($-x$, $1-y$, $1-z$), O—H = 0.85(3) Å, O···H = 1.96(3) Å, O···O = 2.708(2) Å, O—H···O = 146(2)°; N—H(N)···O(1′)($-1+x$, y, z), N—H = 0.90(2) Å, N···H = 1.94(2) Å, N···O = 2.806(2) Å, N—H···O = 161(2)°; and N′-H(N′)···O(3′)(1–x, 1–y, 1–z), N—H = 0.97(2) Å, N···H =

[5] The formulae **2–6** depict only one important form out of the many possible resonance structures for each of the molecules.



2*a* - tetramer

1.96(2) Å, N···O = 2.788(2) Å, N—H···O = 159(2)°. The tetrameric assembly can be described as a centrosymmetric dimer composed of "primed" molecules that features a central 10-membered ring containing two N—H···O bonds. The central ring is flanked by two "unprimed" molecules via one N—H···O and one O—H···O hydrogen bond each, forming eight-membered rings as shown in formula **2*a***-tetramer. The tetramers thus consist of two of each type of molecule (denoted by primed and unprimed atom labels) present in the solid state. Involved in the hydrogen bonding are the acidic hydroxamic acid N-H groups (the acidity of which is enhanced by the boron chelate formation) of all four molecules and the alcoholic O-H groups of the two primed molecules that function both as H-bond acceptors and donors as depicted in **2*a***-tetramer. All four hydroxamic N-O oxygen atoms act as H-bond acceptors, indicating higher electron density at these oxygen atoms than at the carbonyl oxygen atoms. The second pair of alcoholate O-H groups (unprimed molecules) are involved in intermolecular, intra-tetramer O—H···π(aromatic) interactions with the C(8′-13′) phenyl rings, further stabilizing the tetrameric unit (see Fig. 2). The H(O3)···C(phenyl) distances range from 2.65(3) Å for C(9′) to 3.33 Å for C(12′) (average 3.00 Å), and H(O3) is displaced 2.56(3) Å from the mean plane of the phenyl ring. All distances between the tetramers correspond to van der Waals interactions.

The short C=N distances (1.292(2) and 1.293(2) Å) show considerable double bond character, similar to that observed in the *N*-substituted hydroxamatoborates (2, 3, 6, 9–11). Plots of π-bond order vs. C—N bond length (19) and calculation (20) indicate that the C=N bonds have a π-bond order of about 0.85. The π-bond order of the C(1)—O(2) bonds (1.289(2) and 1.284(2) Å) is estimated to be about 0.56 from a plot of C—O distance vs. MO-π-bond order (21) and about 0.58 from calculation (20). These data fully support the *B,N*-betaine formulation of the chelates **2** and **3**, displaying the partial double bond character of the C—N bond and the weakened double bond character of the C=O bond of the hydroxamate ligands. This tendency is distinctly pronounced in the boron chelates compared to the average bond distances found in hydroxamic acids and their metal complexes (22). The average C-N, C—O, and N-O bond lengths for the boron chelate **2*a*** are 1.293, 1.287, and 1.391 Å, respectively. The corresponding values for metal chelates are 1.312, 1.269, and 1.376 Å (22); and those for hydroxamic acids are 1.325, 1.247, and 1.394 Å (22). The mean C-B/mean O-B bond length ratio of 1.025 is similar to those reported for other hydroxamato borates and is slightly less than the average value of 1.035 for "Ph_2BO_2" complexes having five-membered chelate rings (9, 10, 23), indicative of weak-to-intermediate binding strength of the *O,O*-chelating ligand to the "Ph_2B^+" moiety.

The hydroxamate group and the cyclohexane ring are oriented roughly perpendicular to one another, with the hydroxamate occupying an equatorial position, in both of the crystallographically independent molecules of **2*a***. Thus the N—H and C(2)—O(3) bonds are approximately coplanar, favoring the formation of the 10-membered hydrogen-bridged ring that is the central feature of the tetrameric associate of **2*a*** (see above). The five-membered BONCO chelate rings in both of the independent molecules have flattened and slightly distorted *B*-envelope conformations while the cyclohexane rings have nearly ideal chair conformations (see Table 5).

COMMUNICATION

Use of ^{19}F NMR as a direct probe of Δ^9 desaturase cryptoregiochemistry: a feasibility study

Peter Buist, Dale Marecak, Brian Dawson, and Bruce Black

Abstract: ^{19}F NMR can be used to monitor the relative efficiency with which various fluorinated aromatic sulfides are oxidized by the Δ9 desaturating system of *Saccharomyces cerevisiae*. Thus the sulfoxy acids produced from methyl *S*-(4-(trifluoromethyl)benzyl)-8-mercaptooctanoate (**3***d*), methyl *S*-(4-(trifluoromethyl)phenyl-2-ethyl))-8-mercaptooctanoate (**3***e*), and methyl *S*-(4-(trifluoromethyl)benzyl)-9-mercaptononanoate (**4***c*) were observed in the supernatant of *S. cerevisiae* cultures at concentrations of ~140, ~45, and ~10 μM, respectively. This paper lays the methodological basis for a novel, in vitro "thia test" of cryptoregiochemistry and provides further experimental evidence that the yeast Δ9 desaturase initiates oxidation of stearoyl CoA at C-9.

Key words: ^{19}F NMR, desaturase, chiral sulfoxidation, hydrocarbon activation.

Résumé : On a utilisé la RMN du ^{19}F pour évaluer l'efficacité relative de l'oxydation de divers sulfures aromatiques fluorés par le système désaturant Δ9 du *Saccharomyces cerevisiae*. On a ainsi observé les sulfoxyacides produit à partir du *S*-(4-(trifluorométhyl)benzyl)-8-mercaptooctanoate de méthyle (**3***d*), du *S*-(4-(trifluorométhyl)phényl-2-éthyl)-8-mercaptooctanoate de méthyle (**3***e*) et du *S*-(4-(trifluorométhyl)benzyl)-9-mercaptononanoate de méthyle (**4***c*) qui se retrouvaient dans le liquide surnageant les cultures de *S. cerevisiae* à des concentrations respectives d'environ 140, 45 et 10 μM. Cette publication décrit les bases méthodologiques d'un nouveau "thia test" in vitro de cryptorégiochimie et elle fournit des données expérimentales qui suggèrent que le levure Δ9 désaturase initie l'oxydation du stéaroylCoA en C-9.

Mots clés : RMN du ^{19}F, désaturase, sulfoxydation chirale, activation d'hydrocarbures.

[Traduit par la rédaction]

The biological *syn*-dehydrogenation (desaturation) of fatty acids as exemplified by the Δ9 desaturase-mediated transformation of stearoyl CoA (**1**) to give oleyl CoA (**2**) is a remarkable example of enzymic selectivity (1). A possible mechanism (2, 3) for this process involves regioselective hydrogen abstraction by an iron oxo species, followed by carbocation formation and subsequent proton elimination (Scheme 1). We have devised a simple "thia test" for determining the site of initial oxidation (cryptoregiochemistry) that consists of comparing the relative efficiency of oxo transfer to 9- vs. 10-thia substrate analogues (Scheme 1). Using a whole cell *Saccharomyces cerevisiae* Δ9 desaturating system, we have determined (4) that the yield of sulfoxide products obtained upon incubation of 9-thia fatty acids, such as **3***a–c*, is consistently higher than yields obtained with the corresponding 10-thia analogues (**4***a,b*) (Scheme 2). We have interpreted this data to mean that yeast Δ9 desaturation is initiated at C-9 of the parent stearoyl substrate. Renewed interest in the mechanism of fatty acid desaturation has arisen recently with the isolation and characterization of the soluble, plant Δ9 desaturases (5). Unlike the membrane-bound, non-heme monoiron Δ9 desaturases of which the *S. cerevisiae* and rat liver enzymes are prototypical examples (6), the plant enzymes are soluble and contain a carboxylate-bridged, non-heme diiron center. It would be of considerable interest to compare the mechanisms of these two classes of desaturases and thus there is an urgent need to modify our "thia test" so that it can be used with enzyme preparations and micromolar amounts of substrate. In this communication, we wish to report a possible solution to this problem.

It occurred to us that if our thia analogues were labelled with an appropriately situated fluorine substituent, the desaturase-mediated sulfoxidation could be monitored directly by ^{19}F NMR spectroscopy (7). Thus 4-(trifluoromethyl)phenyl substituted sulfides (**3***d,e*, **4***c*) were synthesized in good yield

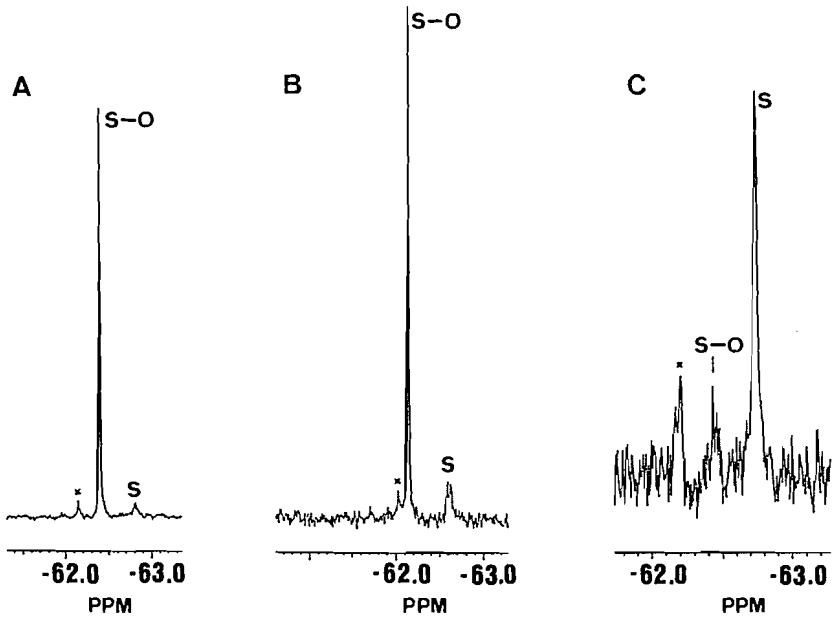
via selective S-alkylation of the appropriate ω-mercaptoalkanoic acids using previously published procedures (8). Commercially available 4-(trifluoromethyl)benzyl bromide was used as the alkylating agent in the synthesis of **3***d* and **4***c*. The preparation of **3***e* required the use of 4-(trifluoromethyl)phenyl-2-ethyl bromide (synthesized from 4-(trifluoromethyl)phenylacetic acid via a reduction ($LiAlH_4$) – bromination (PBr_3) sequence). Racemic sulfoxide reference standards (**5***d*,

Fig. 1. ^{1}H-decoupled ^{19}F NMR (376.5 MHz) spectra of cell-free supernatants containing micromolar amounts of sulfoxides (S-O) produced by oxidation of the corresponding sulfides (S) via the Δ9 desaturase of *S. cerevisiae*. (*A*): sulfoxide (**5***d*) produced from sulfide **3***d*: (*B*): sulfoxide **5***e* produced from sulfide **3***e*; and (*C*): trace sulfoxide **6***c* produced from sulfide **4***c*. An asterisk is used to designate an unknown trace impurity in the starting material.



e, **6***c*) were prepared by oxidation of the corresponding sulfide methyl ester using one equivalent of *m*-chloroperoxybenzoic acid–CH_2Cl_2 (4) followed by hydrolysis using 2 N ethanolic KOH. All structural assignments were confirmed by ^{1}H NMR, MS, and elemental analyses.

Each fluorinated substrate methyl ester (160 μmol) was administered as 5% w/v ethanolic solutions to growing cultures (300 mL) of *S. cerevisiae* as previously described (4, 9). After growth, the yeast cells were allowed to settle and 500 μL aliquots of the resultant clear supernatants were examined by ^{1}H-decoupled ^{19}F NMR.[2] The partial NMR spectra obtained in each experiment are displayed in Fig. 1. We were gratified to see that the spectra were "clean" and exhibited two signals that we were able to assign to substrate and product with the help of synthetic standards. (We did not see any fragmentation products arising from oxidative cleavage α to sulfur in accordance with results of previous experiments (9)). In each spectrum, the ^{19}F resonance of the sulfoxy acid products[3] appeared at lower field (Δδ = 0.3 –0.5 ppm) than the signal due to the corresponding sulfide (Table 1).[4] By adding a known quantity of an internal standard (4-(trifluoromethyl)benzyl alcohol) after incubation, the concentration of sulfoxide produced in each experiment was determined as follows: **5***d*, ~140 μM (26%[5] conversion of sulfide); **5***e*, ~45 μM (8% conversion); **6***c*, ~10 μM (~ 2% conversion). These values for % conversion can be

[2] D_2O (50 μL) was added to each aliquot to provide a spectral lock. Use of ^{1}H decoupling eliminates unresolved, long-range coupling to neighbouring aromatic protons and results in a ca. twofold increase in sensitivity. All ^{19}F NMR spectra were obtained on a Bruker AM 400 (9.4 T) spectrometer operating at 376.50 MHz with a dedicated 5 mm ^{19}F/^{1}H probe and ^{19}F-specific preamplifier. A Bruker 400 MHz band-pass filter and a 376.5-MHz band-stop filter were used in the proton decoupler channel, and a 376.5 MHz band-pass filter and a 400 MHz band-stop channel were used in the fluorine observe channel for all acquisitions. Proton decoupling was achieved by using low power (composite phase decoupling). Chemical shifts are reported relative to external trichlorofluoromethane ($CFCl_3$) at 0.00 ppm. Spectra were acquired with 32 K data points and processed with ca. 2 Hz line broadening after zero-filling to 64 K. Other instrumental parameters include: T = 300 K, PW = 5.3 ms (90 deg), RD = 3.0 s. Acquisition time: 15 min.

[3] It should be noted that the sulfoxide product is produced in hydrolyzed form because the sulfide methyl ester must be converted to the corresponding CoA thioester in the yeast cell before attempted desaturation (= oxygenation) can take place. The sulfoxide CoA product is hydrolyzed to the free carboxylate form upon its excretion into the culture medium (pH 7). As would be expected, the difference in ^{19}F NMR chemical shifts for the free carboxylate and methyl ester forms of the sulfoxides is very small and ranges from 0.00 to ca. 0.03 ppm at pH 7.

[4] Only a small amount of sulfide is seen in the supernatants since these compounds associate with and are taken up by the yeast cells. Indeed, ^{19}F NMR spectra of the cell slurry in each experiment showed a broad ($w_{1/2}$ = 0.2 ppm) signal corresponding to that of the starting material.

[5] An independent check of the validity of this value was accomplished by extracting **5***d* from the acidified culture medium using CH_2Cl_2, followed by methylating the carboxylic acid group with diazomethane (4). A 26% yield of sulfoxide was obtained, in good agreement with the value estimated by ^{19}F NMR. The stereochemistry of this material was also assessed by ^{1}H NMR analysis using our newly developed (10) chiral shift reagent, (*S*)-(+)-α-methoxyphenylacetic acid. This allowed us to assign the "*S*" configuration to the major enantiomer (>96% ee), a result matching that obtained previously (4) for the corresponding nonfluorinated compound (**5***b*).

Table 1. ^{19}F NMR chemical shift data for trifluoromethyl aromatic fatty acid sulfides and the corresponding sulfoxides.

^{19}F Chemical Shift (ppm)[a]				
Substrates[c]		Products[c]		Δδ (ppm)[b]
3*d*	−62.81 ± 0.04	**5***d*	−62.40 ± 0.02	0.41 ± 0.05
3*e*	−62.64 ± 0.04	**5***e*	−62.14 ± 0.02	0.50 ± 0.05
4*c*	−62.74 ± 0.04	**6***c*	−62.43 ± 0.02	0.31 ± 0.05

[a]The uncertainty in the chemical shift values is based on data from at least five ^{19}F NMR spectra.

[b]Δδ = δ(sulfoxide)−δ(sulfide). It is somewhat surprising that the Δδ for **3***e*, **5***e* is greater than the Δδ for **3***d*, **5***d* despite the fact that the CF_3 group in **3***e*, **5***e* is one methylene group further removed from the sulfur atom. It is possible that premicellar aggregate formation is influencing the ^{19}F chemical shifts although we find that the chemical shifts of both sulfoxides and sulfides do not vary appreciably over a concentration range of 5–150 μM in biological media.

[c]Detection limits are typically 10 μM using 15 min acquisition times.

compared to the isolated yields obtained in previous experiments for the corresponding nortrifluoromethyl thiasubstrates: **5***b* (49%, ref. 4), **5***d* (17%, unpublished data), **6***b* (6%, ref. 4). Thus it is clear that each of the fluorinated sulfides is less efficiently oxidized, by a factor of ca. 2–3, than its nortrifluoromethyl analogue. This is an important result since it implies that the trifluoromethyl group is far enough away from the sulfur atom so that it would not dramatically bias the outcome of a "thia test" involving the two fluorinated sulfides with equivalent chain lengths: **3***e* and **4***c*. The cryptoregiochemistry of various Δ9 desaturases could be assessed in vitro by monitoring the appearance of ^{19}F NMR signals due to the corresponding sulfoxide products, **5***e* and **6***c*.[6] An additional advantage of this approach is that the ^{19}F chemicals shifts of the two sulfoxides are sufficiently different (0.29 ppm, see Table 1) to allow the "thia test" to be conveniently carried out as a direct competition experiment.

In summary, we have illustrated how some of the characteristics of ^{19}F NMR methodology (high sensitivity, lack of interferences, wide chemical shift range) can be used to develop a novel probe for the mechanistic study of a long-neglected biological reaction.

[6] It is reasonable to expect that the difference in ^{19}F NMR chemical shift of the CoA or ACP thioester derivatives of sulfoxides **5***e* and **6***c* would be similar to the observed chemical shift difference of the free carboxylate forms of **5***e* and **6***c* (See footnote 4).

1995 R.U. Lemieux Award Lecture
Ketenes and bisketenes: organic chemistry in microcosm[1]

Annette D. Allen, Jim D. Colomvakos, Ian Egle, Ronghua Liu, Jihai Ma, Romeo M. Marra, Michael A. McAllister, and Thomas T. Tidwell

Abstract: Silyl substituents stabilize ketenes, and permit the preparation of persistent bisketenes, which show characteristic ^{13}C, ^{17}O, and ^{29}Si NMR chemical shifts. The structures and conformations of bisketenes have been examined, as well as their interconversion with cyclobutenediones. A tetraketene has been prepared, and the hydration reactivity of carbon suboxide has been measured.

Key words: bisketenes, structures and conformations; cyclobutenedione interconversion.

Résumé : Les substituants silyle stabilisent les cétènes et ils rendent possible la préparation de biscétènes persistants qui présentent des déplacements chimiques caractéristiques en RMN du ^{13}C, du ^{17}O et du ^{29}Si. On a étudié les structures et les conformations des biscétènes ainsi que celles de leurs produits d'interconversion en cyclobutènediones. On a préparé un tétracétène et on a mesuré la réactivité d'hydratation du sous-oxyde de carbone.

Mots clés : biscétènes, structures et conformations; interconversion en cyclobutènediones.

[Traduit par la rédaction]

The preparation of the first bisketene, carbon suboxide (**1**), by the dehydration of malonic acid, was reported in 1906 by Diels and Wolf (*1a*) and it was soon found by Staudinger and Bereza (*1b*) that the same bisketene could be obtained by a bisdehalogenation (eq. [1]).

[1] $$HO_2CCH_2CO_2H \xrightarrow{P_2O_5} \underset{\mathbf{1}}{O{=}C{=}C{=}C{=}O} \xleftarrow{Zn} ClOCCBr_2COCl$$

Staudinger and Anthes (*2a*) attempted to prepare the simplest bisketene, carbon monoxide dimer **2**, by an analogous dehalogenation route, but this was unsuccessful, and gave only carbon monoxide (eq. [2]). Despite strenuous efforts **2** is still unknown (*2b–d*), although the most recent calculations predict that this molecule is an energy minimum (*2e*). Other investigations have succeeded in the preparation of some higher carbon oxides, including C_4O_2 (*2f,g*) and C_5O_2 (*2h,i*), under gas phase or matrix conditions.

Other bisketenes that Staudinger et al. attempted unsuccessfully to prepare include 1,2-bisketene (**3**) and 1,4-quinoketene (**4**) (*3a,b*). Ketene **3** and a number of derivatives have subsequently been prepared and observed under matrix isolation

[2]

conditions, or in solution by fast UV or IR measurement techniques (*3c–h*) as reviewed elsewhere (4). The benzannulated analogue of **3**, namely, **5**, which is isomeric to **4**, has also been studied (*3i–k*). Evidence has been obtained for the formation and polymerization of **4** by the reductive dehalogenation of terephthalyl chloride (**4***a*) with alkali metals (*3n*), and this species has been directly observed, with an IR band at 2082 cm^{-1}, by photolysis of [2.2]paracyclophane-1,10-dione in an Ar matrix at 10 K (*3o*).

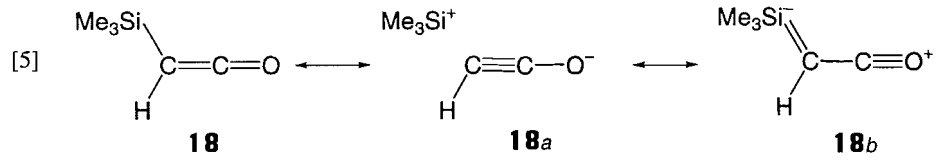
Several bisketenes in which the ketenyl groups are not directly bonded to one another have been prepared and directly observed, and examples **6–13** are shown (5*a–h*). These have been prepared by zinc dehalogenation of α-bromo acyl halides (**6, 7, 10, 12**), bis(dehydrohalogenation) (**8**), photochemical ring opening (**9**), and double Wolff rearrangement (**13**). Other reactions involving the conversion of two functional groups such as diazoketone (5*i*), dioxinone (5*j*), and isopropenyl ether (5*k*) to ketenyl groups in molecules may have occurred successively so that bisketenes were never present.

Investigations in our laboratory have focused on the influence of silyl substituents in the stabilization of ketenes and bisketenes (6, 7). Molecular orbital calculations at the MP2/6-31G*//MP2/6-31G* level for the isodesmic reaction of eq. [3] indicate that the SiH_3 substituent is 11.5 kcal/mol more stabilizing for ketene than is CH_3 compared to the effect on alkenes (6*d*,*e*). The ring opening of the cyclobutenedione **14** to the bisketene **15** is calculated (6*g*) to be exothermic by 4.9 kcal/mol (eq. [4]). These bisketenes are calculated to have the twisted conformation shown, as discussed in more detail below.

Experimentally, the ring opening of **16** to **17** proceeds quantitatively on heating, and there is good agreement between the calculated E_{act} for ring opening of **14** of 27.2 kcal/mol and the experimental $\Delta H^{\ddagger}$ of 29.4 kcal/mol for **16** (6*g*, 7*a*). This confirmation of the predictive power of ab initio molecular orbital calculations of the stabilities of ketenes and analogous molecules has encouraged us to extend these studies, and useful results have also been obtained for isocyanates (7*d*), diazo compounds, allenes, diazirines, and cyclopropenes, as well as for a variety of ketenes (6*d*,*e*), and the magnitude of the stabilization is related to the coefficient of the cumulene LUMO (7*d*).

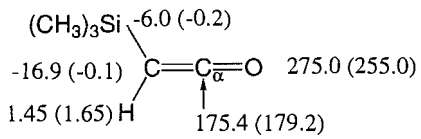
The origin of the stabilization of ketenes by silyl substituents has been of interest since the first preparation of $Me_3SiCH{=}C{=}O$ (6*a*), when it was found that this ketene had no tendency to dimerize, in contrast to all other aldoketenes known at that time. Calculations predict that all of the cumulenes are stabilized by electropositive substituents (6*d*,*e*, 7*d*) but so far this effect has been most extensively investigated experimentally with ketenes. Two specific descriptive expla-

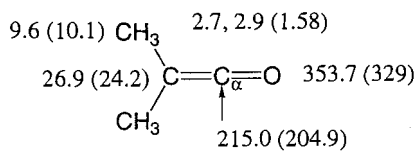


nations that have been advanced for this phenomenon are overlap of the C—Si σ bond with the in-plane π bond of the carbonyl as shown in eq. [5] (6*b*), and also p_π–d_π donation of electrons from the electron-rich β-carbon of the ketene to silicon as in **18***b* (6*c*). Molecular orbital calculations (6*d*,*e*) gave a quantitative measure of the stabilizing effect of silicon (eq. [3]), but the calculated structure of $SiH_3CH{=}C{=}O$ was inconclusive regarding any strong structural evidence for the type of overlap shown in eq. [5]. The alternative of p_π–d_π overlap is regarded as unimportant in other contexts (4*a*, 6*f*).

Study of the ^{13}C, ^{17}O, and ^{29}Si NMR spectra of silylketenes and bisketenes (8*a*) provides evidence for the type of "neutral hyperconjugation" shown in **18***a* (8*b*). Thus the ^{13}C and ^{17}O resonances of silylketenes are shifted upfield by 18.7–26.4 and 59–85 ppm, respectively, compared to other ketenes, while the ^{29}Si resonance is shifted downfield by 4–12 ppm in comparison to silylalkenes (Table 1). This is the effect expected if there is increased negative charge density on the carbonyl carbon and oxygen, and increased positive charge on the silicon, whereas just the opposite effects would be expected if there were charge donation to the silicon, as in **18***b*. Chemical shifts are affected by a variety of factors besides atomic charges, and so the use of such shifts to evaluate "neutral hyperconjugation" must be used with caution (8*b*), but nevertheless charges exert a major influence and the consistent results for three different nuclei and a variety of substrates are highly supportive of the phenomenon shown in **18***a*.

Calculations of the chemical shifts of $Me_3SiCH{=}C{=}O$ and $(CH_3)_2C{=}C{=}O$ using the IGLO method, basis set II, with MP2/6–31G* optimized geometries gave the results shown below, with experimental values in parentheses for comparison (8*a*).

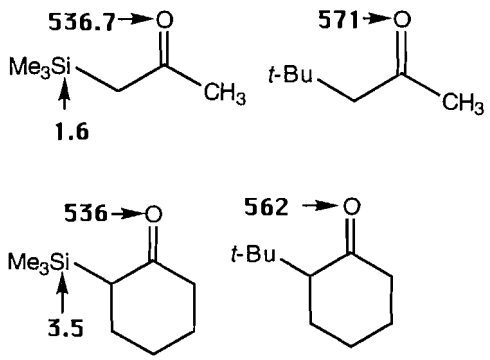




The calculated values are in reasonable but not exact agreement with the experimental values but, most importantly, the calculations reproduce the large effects of Si substitution on chemical shifts for $^{13}C_\alpha$ (Δδ calcd. 39.6, obsd. 25.7 ppm) and ^{17}O (Δδ calcd. 78.7, obsd. 74 ppm). Some of the differences between the calculated and experimental chemical shifts may arise from factors such as solvent effects, but for the analysis of trends these calculated values appear to be quite useful.

Other factors besides electronic charge distributions as shown in eq. [5] undoubtedly affect the chemical shifts, but nevertheless the fact that the observed shifts are consistent in all cases with the effects expected from electron donation from the C—Si bond to the carbonyl group, and opposite from the effects expected for electron donation toward Si, provide a powerful argument for the importance of the former effect as opposed to the latter.

Similar behavior is also observed in α-silylated ketones, in which downfield shifts in the ^{29}Si NMR of the silyl groups are observed relative to $(CH_3)_4Si$ and upfield shifts in the ^{17}O NMR are shown relative to non-silylated model compounds (8*a*).



For the parent bisketene **3** the HF/6-31G*//HF/6-31G* calculated relative energies of the twisted, *anti*, and *syn* conformations are 0.0, 2.4, and 4.0 kcal/mol, respectively (6*g*). The difference of 1.6 kcal/mol between the *syn* and *anti* conformers may be due to a repulsion between the electron-deficient C_α carbons. For the $SiMe_3$ substituted bisketenes **17** the difference between the *syn* and *anti* conformers is 8.2 kcal/mol (6*h*) and the larger difference of 6.6 kcal/mol evidently reflects a steric effect.

The twisted conformation **17**, with a dihedral angle of 105° between the ketenyl units, is calculated to be 2.8 and 11.0 kcal/mol, respectively, more stable than the *anti* and *syn* conformations corresponding to **17***a* and **17***b* (6*h*). A major population of the *anti* conformation **17***a* is also ruled out by the measured dipole moment of 2.7 D for the bis(trimethylsilyl) analogue **17**, compared to a measured dipole moment of 1.7 D for $Me_3SiCH{=}C{=}O$ (6*h*). The *syn* rotamer **17***b* can be excluded from consideration because of the apparent large steric interactions and calculated low stability of this conformation.

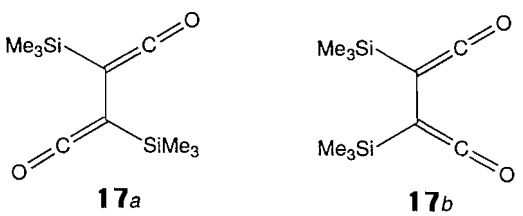


Table 1. NMR chemical shifts in $CDCl_3$ of ketenes and reference compounds (8*a*).

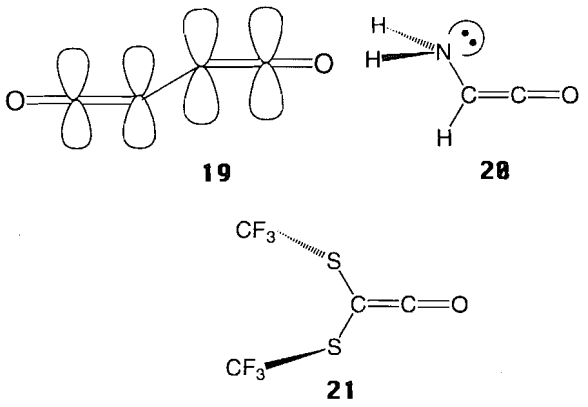
Ketene	$\delta^{13}C$ (C_α)	$\delta^{17}O$	$\delta^{29}Si$
$Me_2C{=}C{=}O$	204.9	329	
t-$Bu_2C{=}C{=}O$	203.4	330.6 (331.5)[a]	
$PhCMe{=}C{=}O$	205.6		
$Ph_2C{=}C{=}O$	201.3	340[a]	
$Me_3SiCH{=}C{=}O$	179.2	255.0	−0.2
$Me_3SiCPh{=}C{=}O$	182.5		−0.6
$(Me_3SiC{=}C{=}O)_2$	181.8	269.2 (269.0)[a]	3.2
$(t\text{-}BuMe_2SiC{=}C{=}O)_2$	182.2	270.5	10.6
$Me_3SiCH_2CO_2H$			3.8
$Me_3SiCH_2CO_2Et$			3.2
$Me_3SiCH_2COCH_3$	206.8	536.7	1.6
	202.0	499.1	−8.4
	202.1		0.4
CH_3COCH_3	206.5	565.3 (571)[a]	
$Me_3SiCH{=}CH_2$			−6.6
$Me_3SiC_6H_5$			−4.5

[a] CH_3CN solvent

We have suggested that a major reason that the bisketenes **15** and **17** are not coplanar is because of the repulsion between the electrons in the *p* orbitals at C_β of the ketenes (6*g*,*h*). These carbons carry a high negative charge density, as evidenced by the remarkably high-field ^{13}C NMR chemical shift of C_β in **17** of δ 4.5, and, to avoid the π–π repulsion in a coplanar array as in **19**, the dienyl units twist out of planarity. The phenomenon of unfavorable π–π interactions with electron-rich groups at C_β of ketenes has also been found in the computed geometries of ketenes substituted with the lone pair containing substituents OH, SH, NH_2, and PH_2, which are predicted (6*d*,*e*) to have conformations in which the lone pairs are twisted out of conjugation with the C=C π bond, as illustrated for NH_2 (**20**). This behavior has been confirmed experimentally for the ketene $(CF_3S)_2C{=}C{=}O$, for which the twisted conformation **21** with the S—CF_3 bond almost perpendicular to the molecular plane was found to be favored, using electron diffraction (9).

The *ortho* isomer **5** of "quinoketene" **4** (3*i*–*k*) has been generated in CH_3CN solution at 23 ± 2°C by laser flash photolyis of benzocyclobutadienedione **22** (10*a*), and directly observed by time-resolved infrared spectroscopy (TRIR). The rate constant for ring closure was measured as 1.9×10^4 s^{-1} both from the disappearance of the ketene band at 2128 cm^{-1} of **5**, and from the reappearance of the ketone band at 1781 cm^{-1} of **22** (10*a*). This reclosure is calculated at the MP2/6-31G*//MP2//6-31G* level to be exothermic by 38.2 kcal/mol and, based on the observed rate constants and the assumption that $\Delta S^{\ddagger} = 0$ for this process, the barrier to ring closure is 6 kcal/mol (10*a*).



19 **20** **21**

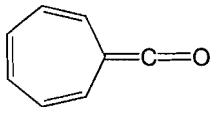
[6] 
22 **5**

The 38.2 kcal/mol greater stability calculated for **22** relative to **5** is remarkably high, for, even though **22** possesses an aromatic benzene ring, this is fused to a strained cyclobutenedione ring. However, this latter ring system may possess some aromatic stability itself, and furthermore the 1,2-bisketene unit of **5** is destabilized relative to an ordinary diene, as shown by the isodesmic energy change of eq. [7] (6*d*). The ketenyl groups of **5** are calculated to be twisted out of planarity with a dihedral angle of 34.2°, and thus **5** resembles other bisketenes such as **15** and **17** in this respect. In the case of a coplanar conformation of **5** there would be not only π-electron repulsion at C_β, but also repulsion of the positively charged C_α carbonyl carbons. Antiaromaticity of **5** due to a high electron density at the two C_β ketenyl carbons giving 8π electron character similar to that proposed for heptafulvenone **23** (10*b*) may also contribute to the high preference for **22** relative to **5**.

A variety of long-lived 1,2-bisketenes **24** substituted with stabilizing silyl groups ($R_3{}^1Si$ = Me_3Si, *t*-$BuMe_2Si$, i-Pr_3Si) have been prepared from photolysis or thermolysis of the corresponding cyclobutenediones (**25**), as shown in eq. [8] (7). When these bisketenes have two silyl substituents they are thermodynamically stable relative to the cyclobutenedione precursors (7*a*), but in examples substituted with one Me_3Si group and either Ph (**26**) or Me (**27**) the bisketene is rather long lived at room temperature, but reverts to the more stable cyclobutenedione at measurable rates at higher temperatures (7*b*,*c*).

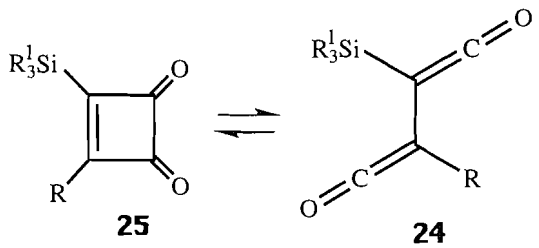
[7] $(CH{=}C{=}O)_2 + 2CH_2{=}CH_2 \xrightarrow[-11.9\ kcal/mol]{\Delta E =} (CH{=}CH_2)_2 + 2CH_2{=}C{=}O$

3

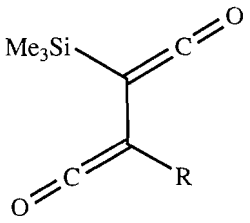


23

[8]



25 **24**

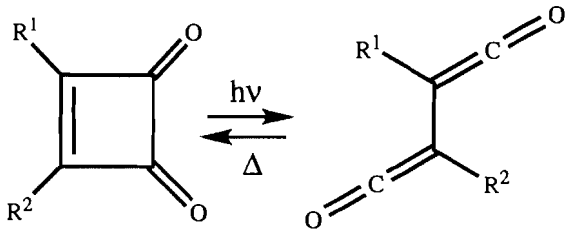


26 (R = Ph)
27 (R = Me)

Using flash photolysis and time-resolved infrared detection, a number of rather unstable 1,2-bisketenes have been generated and directly observed (10*a*). The examples **26** and **27** bearing a single Me_3Si are quite long lived at room temperature and their ring closure to the thermodynamically more stable cyclobutenediones was only observed at elevated temperatures. Surprisingly, for the long-known examples **28***a* (R^1 = Ph, R^2 = H) and **28***b* ($R^1 = R^2$ = Ph) conventional photolysis and UV detection were sufficient for observation of the bisketenes, which were found to have half-lives of 1 h and 18 s, respectively, at 25°C. Summarizing the examples that have been observed, the scale of reactivities is as shown. The observed difference between **26** and **5** is a factor of 10^{10} and, based on the measured rate of ring opening of **16** to **17** and the equilibrium constant for this process estimated by the calculated energy difference of the process for R = SiH_3 of 4.9 kcal/mol (eq. [4]), the rate of ring closure of **17** may be estimated as less than that of **26** by a factor of 10^5, giving a total span in reactivity of 10^{15}.

As noted above, bisketenes **4** and **6–13** where the ketenyl groups are non-adjacent have been prepared and directly observed (5). Poly(ketenes) have also been generated (11) by photolysis of poly(cyclobutenediones) in a matrix at 30 K, as in the conversion of **29** to form hexa(ketene) **30**, which displayed an IR band at 2115 cm^{-1} (eq. [10]). Further photolysis led to decarbonylation and possible formation of cyclooctadecanonyne (C_{18}).

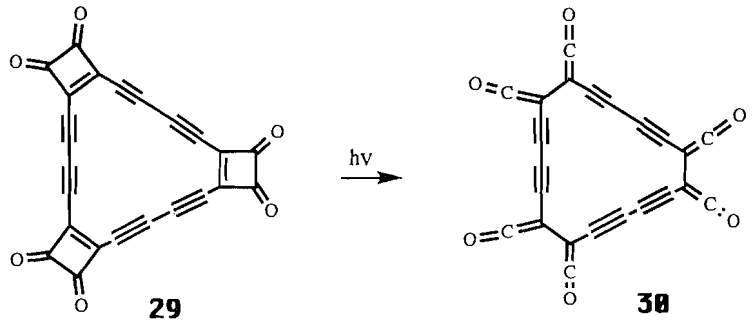
[9]



Relative rates of cyclobutenedione formation from bisketenes:

R^1,R^2	Me_3Si, Me_3Si **17**	Me_3Si, Ph **26**	Me_3Si, Me **27**	Ph, H **28***a*	Ph, Ph **28***b*	**5**
k_{rel}	~10^{-5}	1.0	2	84	2×10^4	10^{10}

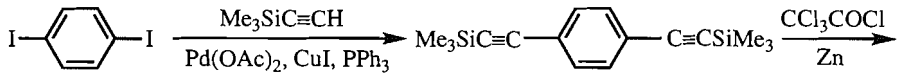
[10]

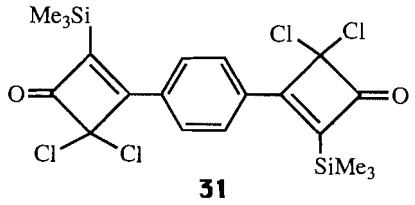


29 **30**

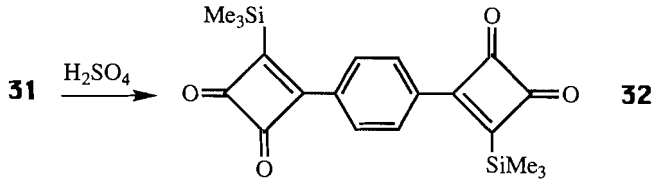
Using the route shown in Scheme 1 we have prepared the bis(cyclobutenedione) precursor **32** for a long-lived tetraketene **33** stabilized by Me_3Si groups, and studied its reactivity (12). Photolysis of **32** with 350 nm light led to the formation of a new species with λ_{max} 280 nm and an ^1H NMR spectrum ascribed to the tetraketene structure **33**, formed by photochemical ring opening of **32**, probably by a stepwise process via the bisketene **34** (eq. [11]). Evidence for the structure of **33** includes the ketenyl IR band observed at 2086 cm^{-1}, which is comparable to that at 2093 cm^{-1} for bis(ketene) **26** (7*b*,*c*), and the very distinctive signals in the ^{13}C NMR spectrum at δ 6.9 and 32.8 for the Me_3Si and aryl-substituted ketenyl carbons, as compared to the values for the corresponding carbons of **26** at δ 7.9 and 33.5, respectively. Upon heating of **33** with monitoring of the UV absorption the initial conversion of **33** to **34**, and then a slower conversion of **34** to **32** could be observed.

Scheme 1.

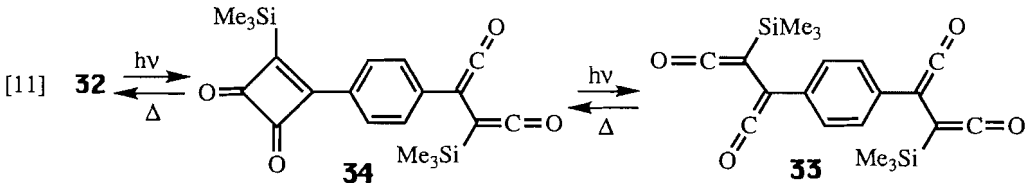




31



32



We have also been attracted (13) to the study of reactivity of carbon suboxide, the first bisketene (1), which despite its long history has seldom been the object of mechanistic examination (14, 15). In particular, the hydration reactivity of C_3O_2 was of interest both for comparison to other ketenes (16, 17), and also because of a recent proposal (14*a*) that C_3O_2 is present on comet Halley, which is largely composed of water ice (14*a*). Carbon suboxide is known to react with water to form $CH_2(CO_2H)_2$, with alcohols ROH to form esters $CH_2(CO_2R)_2$, and with HCl to form $CH_2(COCl)_2$ (15*c*). As shown in eq. [12] for alcohol addition, acylketenes **35** have been implicated as intermediates in these reactions (15*d*) but these have not been well characterized when formed from this source because their reactivity toward nucleophiles appears comparable to that of C_3O_2.

[12] $O{=}C{=}C{=}C{=}O \xrightarrow{ROH} RO_2CCH{=}C{=}O \xrightarrow{ROH} CH_2(CO_2R)_2$

1 **35**

Experimentally the hydration reactivity of C_3O_2 is less than that of $CH_2{=}C{=}O$ in both the acid-catalyzed and neutral reactions, by factors of 5.2×10^4 and 2.5×10^3, respectively, in water at 25°C. Only a single rate process was observed in each case, and this is assigned to the initial reaction of carbon suboxide.

As a guide to understanding this behavior and to test possible mechanistic proposals, the structures and energies (Table 2) of some of the species involved in these reactions were calculated by ab initio methods at the MP2/6-31G* + ZPVE// MP2/6-31G* level, as has been done previously for other ketenes (6*d*,*e*,*g*, 16).

The mechanism of ketene hydration has been interpreted (4*a*, 17) as involving an initial nucleophilic attack by H_2O at the carbonyl carbon to give a rather polar transition state resembling **36** that is also solvated by additional water molecules. This forms an intermediate enediol **37**, or the corresponding enolate, and then is rapidly converted to acetic acid (eq. [13]). This mechanism is favored even though the addition of water to the C=C bond to form acetic acid directly is more favorable, but the calculated barrier via **36** is lower than that for addition to the C=C bond, which involves rehybridization of both carbon atoms.

[13] $CH_2{=}C{=}O \xrightarrow{H_2O}$  $\longrightarrow$ 
36

37

The analogous addition of H_2O to C_3O_2 could occur by 1,2-addition to the C=O bond to produce as the first intermediate the geminal diol **38**, which could then isomerize to the ketenyl carboxylic acid **39** (eq. [14]). Just as for $CH_2{=}C{=}O$ (16), the direct addition of H_2O to the C=C bond of C_3O_2 to form **39** is calculated to be of lower energy than is formation of **38** but,

although the barriers for the formation of **38** and **39** have not been calculated, formation of the geminal diol is relatively more favorable for C_3O_2 compared to $CH_2{=}C{=}O$, and so this route (eq. [14]) appears plausible for C_3O_2 as well.

[14] 
For the reaction of C_3O_2 in dilute HCl, the linear dependence on $[H^+]$ of the rate and the isotope effect ($k_H{}^+/k_D{}^+$ = 1.21), are both consistent with a mechanism involving rate-limiting proton transfer to C_β (eq. [15]), as has been proposed for other ketenes (4*a*, 6*f*, 17). Protonation at C_β in C_3O_2 would be favored by the high negative charge density at this carbon, as indicated by the ^{13}C NMR chemical shift of δ −14.6 (15*e*), and by the favorable bisacylium-type resonance expected for this species, as shown in **40**. Whether or not **40** would have a sufficient lifetime under the conditions to exist as a genuine intermediate is a question that cannot be answered at present.

[15] 
comet Halley is composed mainly of water ice, which is warmed significantly during the passages of the comet near the Sun, raises the question of whether any C_3O_2 ever present on comet Halley could survive during the long existence of this celestial body. Uncertainties as to the actual proximity of the putative C_3O_2 and the water ice, and the temperature, preclude a definitive judgment. Experiments to test the reactivity of C_3O_2 in an ice matrix may be informative in this regard.

Table 2. MP2/6-31G* + ZPVE//MP2/6-31G* calculated energies (kcal/mol) for reactions of carbon suboxide and ketene.

Reaction	ΔE (kcal/mol)
$O{=}C{=}C{=}C{=}O + H^+ \rightarrow O{=}C{=}CH{-}\overset{+}{C}{=}O$	−182.9
$CH_2{=}C{=}O + H^+ \rightarrow CH_3\overset{+}{C}{=}O$	−199.2
$O{=}C{=}C{=}C{=}O + H_2O \rightarrow (HO)_2C{=}C{=}C{=}O$	9.9
$O{=}C{=}C{=}C{=}O + H_2O \rightarrow HO{-}C{\equiv}C{-}CO_2H$	19.6
$O{=}C{=}C{=}C{=}O + H_2O \rightarrow HO_2CCH{=}C{=}O$	−23.5
$(HO)_2C{=}C{=}C{=}O \rightarrow HO_2CCH{=}C{=}O$	−33.4
$HO{-}C{\equiv}C{-}CO_2H \rightarrow HO_2CCH{=}C{=}O$	−43.0
$HO_2CCH{=}C{=}O + H_2O \rightarrow HO_2CCH{=}C(OH)_2$	−20.2
$CH_2{=}C{=}O + H_2O \rightarrow CH_2{=}C(OH)_2$	−6.0
$CH_2{=}C(OH)_2 \rightarrow CH_3CO_2H$	−35.4
$HO_2CCH{=}C(OH)_2 \rightarrow CH_2(CO_2H)_2$	−12.3
$O{=}C{=}C{=}C{=}O + OH^- \rightarrow {}^-O{-}C{\equiv}C{-}CO_2H$	−62.2
${}^-O{-}C{\equiv}C{-}CO_2H \rightarrow HO{-}C{\equiv}C{-}CO_2^-$	31.5
${}^-O{-}C{\equiv}C{-}CO_2H \rightarrow O{=}C{=}CH{-}CO_2^-$	−11.2
$CH_2{=}C{=}O + OH^- \rightarrow CH_2{=}C(OH)O^-$	−75.6
$CH_2{=}C(OH)O^- \rightarrow CH_3CO_2^-$	−30.7

The calculated results in Table 2 indicate that the gas phase protonations of both C_3O_2 and $CH_2{=}C{=}O$ are favored to occur at carbon rather than at oxygen, and that protonation is predicted to be more favorable for ketene than for C_3O_2, by 16.3 kcal/mol, in agreement with the experimental results.

As noted above there is a recent proposal (14*a*) that the source of atomic carbon in the coma and nucleus material of comet Halley could be C_3O_2. In particular it was envisaged (14*a*) that photolysis of C_3O_2 to produce atomic carbon (14*b*) could give rise to the carbon observed. However the appreciable reactivity of C_3O_2 with liquid water, and the fact that

In summary, our studies of bisketenes, which have been underway since 1992, and some of which are described here, have involved organic synthesis, kinetic and theoretical studies, flash photolysis, spectroscopy, stereochemistry, and photochemistry. Further studies in polymer and organometallic chemistry are underway. Thus ketenes provide a view in microcosm of much of the field of organic chemistry. Each new advance has revealed even more opportunities in this area, and we look forward to the new discoveries that will appear in the last decade of the first century of bisketene chemistry.

Quinone methides: relevant intermediates in organic chemistry[1]

Peter Wan, Beverly Barker, Li Diao, Maike Fischer, Yijian Shi, and Cheng Yang

Abstract: *ortho* and *para*-Quinone methides (2-methylene-3,5-cyclohexadien-1-one and 4-methylene-2,5-cyclohexadien-1-one, respectively) are intermediates in a variety of important chemical systems. In particular, *o*-quinone methides are useful in synthesis for the construction of chroman ring systems. A brief account of the relevance of quinone methide chemistry will be provided. This is followed by a review of recent studies from our laboratory on efficient methods for the photogeneration of quinone methides, concentrating on the use of hydroxy-substituted benzyl alcohols in aqueous media. It is shown that this method is general since it provides access to *o*-, *m*-, and *p*-quinone methide isomers. When appropriately substituted, all of these quinone methide isomers have been spectroscopically characterized by laser flash photolysis, making this technique the one of choice for studying the dynamics of these reactive intermediates. The mechanism of photochemical generation from hydroxybenzyl alcohols and extensions of the reaction to photogeneration of fluorenyl and biphenyl quinone methides will also be presented.

Key words: quinone methide, biphenyl quinone methide, carbocation, photosolvolysis, photodehydroxylation, hetero-Diels–Alder reaction.

Résumé : Les méthides d'*o*- et *p*-quinones (respectivement 2-méthylènecyclohexa-3,5-dièn-1-one et 4-méthylènecyclohexa-2,5-dièn-1-one) sont des intermédiaires dans une variété de systèmes chimiques importants. En particulier, les méthides d'*o*-quinones sont utiles en synthèse pour la construction de systèmes incorporant le noyau chromane. On fournit un bref résumé de l'importance de la chimie des méthides de quinone. On présente ensuite une revue des études récentes réalisées dans notre laboratoire sur des méthodes efficaces de photogénération des méthides de quinone, en se concentrant sur l'utilisation, en milieux aqueux, d'alcools benzyliques substitués par des groupes hydroxyles. On montre que cette méthode est générale puisqu'elle permet d'obtenir facilement les isomères *ortho*, *méta* et *para* des méthides de quinone. Lorsqu'ils sont substitués d'une façon adéquate, tous ces isomères de méthides de quinone ont pu être caractérisés d'un façon spectroscopique par photolyse éclair au laser qui en fait une technique de choix pour l'étude dynamique de ces intermédiaires réactifs. On présente aussi le mécanisme de la génération photochimique à partir des alcools hydroxybenzyliques et des extensions de la réaction à la photogénération des méthides de quinones dérivés du fluorényle et du biphényle.

Mots clés : méthide de quinone, méthide de quinone du biphényle, carbocation, photosolvolyse, photodéshydroxylation, réaction d'hétéro-Diels–Alder.

[Traduit par la rédaction]

Introduction

Quinone methides (QMs) (1, 2) are structurally related to both benzoquinones (BQs) and quinone dimethides (QDMs, also known as *o*-xylylenes). As is the case for BQs and QDMs, two isomers of QMs are well known (*ortho* and *para* isomers **1** and **2**) with the *meta* isomer **3** being of theoretical interest (3). Unlike BQs and QDMs, QMs are highly polarized and hence are reactive under both nucleophilic and electrophilic condi-

tions (1, 2). Since reaction generally gives an aromatic phenol ring, the driving force inherent in this transformation makes QMs highly reactive intermediates.

ortho-Quinone methides are widely used in organic synthesis for carrying out "reverse electron demand" Diels–Alder [4+2] cycloadditions with electron-rich alkenes, to give chroman derivatives (1, 2, 4). Because of this utility, various thermal methods for generating *o*-QMs have been developed during the last two decades, including methods involving Ag_2O oxidation of phenols (5), high-temperature dehydration of *o*-hydroxybenzyl alcohols (6), fluoride-induced desilylation of silyl ethers (7), and thermal extrusion of small molecules (8). Generation of *o*-QMs from the extrusion of phenyl boronic acid from 1,3,2-benzodioxaborins has been reported by Lau and Defresne and co-workers (9) as a simple and general method for making *o*-QMs for synthesis (Scheme 1). The required 1,3,2-benzodioxaborins are readily made by condensation of phenylboronic acid with phenol and the required aldehyde. The *o*-QMs obtained from this method were trapped using a variety of standard agents such as ethyl vinyl ether and a ketene acetal. The cycloaddition of an *o*-QM with an electron-rich alkene has been employed as a key step in total syntheses, some representative examples are carpanone (10), hexahydrocannabinol (7), and thielocin A1β (11).

para-Quinone methides have also been used in synthesis, notably by Angle et al. (12). In these systems, *p*-QMs were generated, via Ag_2O oxidation of the corresponding *p*-substituted phenol, that subsequently react via (*a*) formal [3+2] cycloaddition with an alkene, to give indanes or (*b*) undergo intramolecular cyclization to give a variety of *p*-hydroxyphenyl-substituted ring systems.

p-QMs are believed to be crucial intermediates in the biosynthesis and subsequent chemistry of lignin (13). The polymerization of coniferyl alcohol, the predominant *p*-coumaryl alcohol of softwood lignins, is believed to involve initial coupling of two coniferyl alcohol phenoxyl radicals, to give various *p*-QM structural isomers, which subsequently react further in the polymerization process to yield lignin. The aging of lignin can also involve formation of transient *p*-QMs in the chemistry.

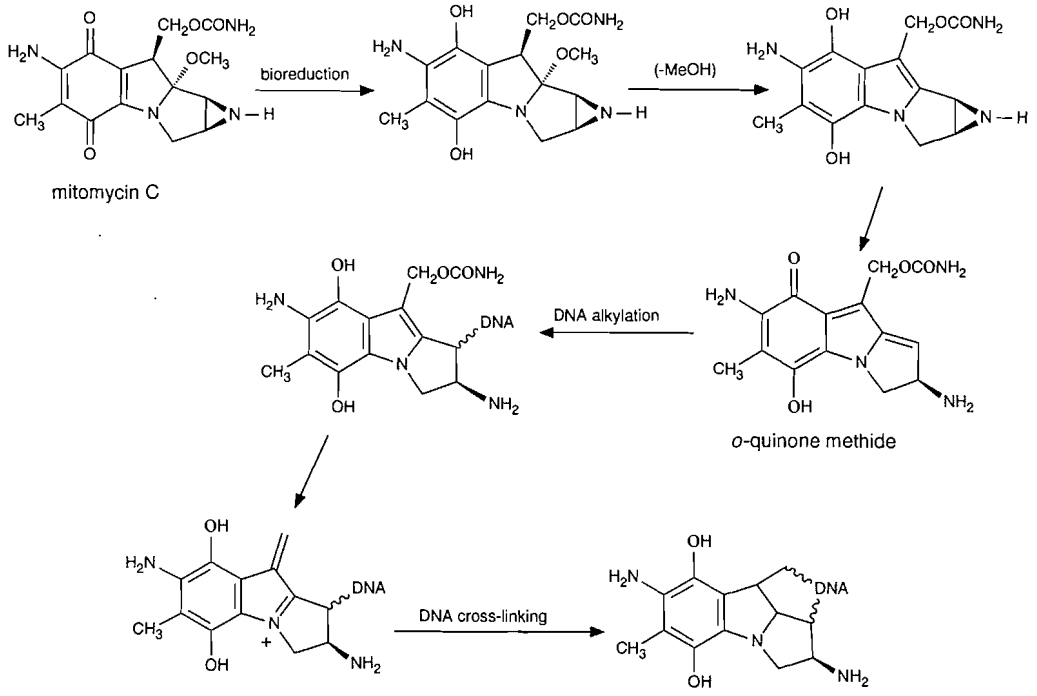
p-QMs have been proposed to be the key intermediates in the known toxicity of common phenols found in spices, flavouring agents, and food preservatives such as BHT (butylated hydroxytoluene) (14). These phenols are oxidized during the metabolic process to their corresponding *p*-QMs, which are believed to be responsible for their toxicity, due to their ability to alkylate cellular macromolecules such as proteins and DNA. The highly electrophilic character of QMs also makes them useful as the critical intermediate of several antitumour/antibiotic drugs (14*a*). For example, the mode of action of mitomycin C (a clinically used anticancer drug) involves a bioreductive step (Scheme 2) followed by loss of CH_3OH and opening of the aziridine ring, to generate an *o*-QM, which alkylates DNA (14*a*, 15). Due to the relevance of DNA alkylation by QMs, studies have been directed at sequence-specific alkylation of DNA using both thermally and photochemically generated QMs (16).

In view of the widespread relevance of QMs in organic and biological chemistry, it would be desirable to devise a general photochemical method for forming QMs since this would allow one to study their reaction dynamics without the encumbrance associated with thermal methods. During our studies of photosolvolysis of benzyl alcohols, we were fortunate enough to recognize that a simple and general photochemical method is indeed available using readily available substrates. Moreover, the method is capable of generating *m*-QMs, in addition to the more common *ortho* and *para* isomers. The rest of this review summarizes our work on QM photogeneration carried out during the last decade.

Photosolvolysis of hydroxybenzyl alcohols: parent quinone methides

For many years, our interest was focused on photochemical reactions of aromatic substrates that could be thought to arise

Scheme 2.



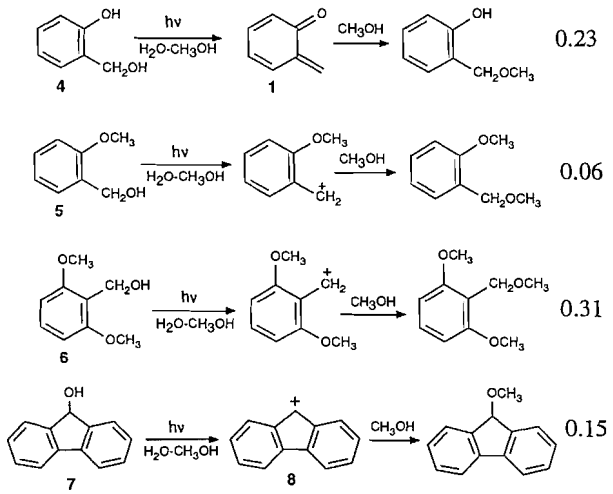
from a change in acidity or basicity of an attached functional group on excitation to the excited singlet state (S_1) (17). Much of the pioneering work in this area is attributable to Wan and Yates (18) who in the early 1980s first studied in mechanistic detail the photohydration of aromatic alkenes and alkynes via S_1, in neutral or moderately acid aqueous solution, conditions under which thermal hydration was nonexistent. The rationale for the more efficient *photo*hydration of these substrates was believed to be due to the enhanced basicity of the alkene or alkyne moiety in S_1 (17, 18), arising from significant charge delocalization from the benzene ring to the unsaturated moiety.

At about the same time, Wan, Yates, Turro, and co-workers (19, 20) showed that certain benzyl alcohols efficiently photosolvolyzed by formal loss of hydroxide ion (photodehydroxylations) to give the corresponding carbocation intermediates. These reactions could also be thought of as arising from a change in excited pK_a. That is, the benzyl alcohol becomes a stronger pseudo base in S_1 (or the corresponding benzyl cation becomes a weaker pseudo acid in S_1) (eq. [1]) (17). Using this

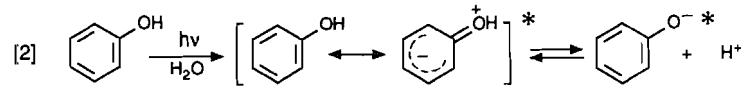
$$[1] \qquad ArCH_2OH^{*} \rightleftharpoons ArCH_2^{+\bullet} + {}^{-}OH$$

simple idea, we investigated the possible photodehydroxylation of a wide variety of benzyl alcohols (17, 20) and discovered several interesting systems that showed particularly efficient reaction, some of which are summarized in Chart 1. Two of the most reactive systems were 2,6-dimethoxybenzyl alcohol (**6**) and 9-fluorenol (**7**), both reacting via initial C—OH bond heterolysis to give the corresponding carbocation intermediate. When only one *o*-methoxy group was used (*o*-methoxybenzyl alcohol (**5**)), the quantum yield for methyl ether formation (Φ) was reduced significantly. However, *o*-hydroxybenzyl alcohol (**4**) reacted with a Φ value approaching that of **6** and we proposed at the time a mechanism involving assistance of the *o*-hydroxyl group and that, instead of a benzyl carbocation intermediate as required for **5**–**7**, **4** reacted via *o*-QM **1**.

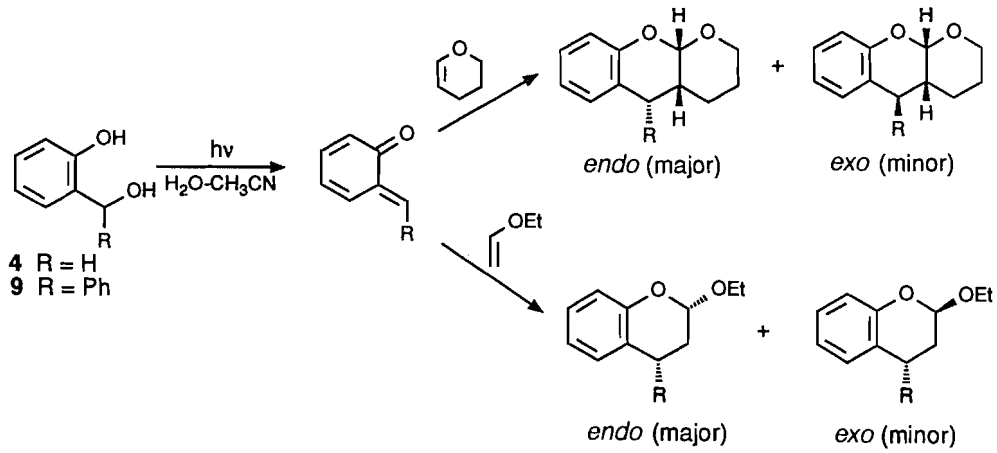
Chart 1.



Phenols and hydroxyaromatics are known to be much stronger acids in S_1 (17, 21) with $pK_a(S_1)$ values generally in the 1–4 range, 6–9 orders of magnitude more acidic than in the ground state. The enhanced electron-donating power of the oxygen substituent in S_1 is responsible for the increased acidity of the phenolic hydroxyl group (eq. [2]). Yates and coworkers (22) have shown that use of an *o*-hydroxyl group results in more efficient photohydration of styrene and phenylacetylene. They proposed that a fast intramolecular proton transfer from the more acidic ArOH to the alkyne or alkene moiety is responsible for the enhanced reactivity. A similar



Scheme 3.



mechanism could be envisioned for the reaction of **4** in which loss of hydroxide ion is concerted with deprotonation of the phenolic proton, giving rise to *o*-QM **1**, resulting in a more efficient photosolvolysis reaction. Additional evidence for formation of **1** from **4** came from the discovery of a photocondensation reaction to form phenol-formaldehyde resins on photolysis of **4** in basic aqueous solution (23). In the initial step of this process, photochemically generated **1** is alkylated at the benzylic carbon by the substrate (via the *ortho* position of the phenol), which is sufficiently nucleophilic in the phenolate form. This step gives rise to a "dimer" of **4** that on subsequent photoreaction gives rise to phenol–formaldehyde oligomers.

Prior to our investigations of QM photogeneration, occasional reports of photochemical methods for their generation have appeared in the literature. Some of these methods have involved (*i*) decarbonylation of lactones (24); (*ii*) photolysis of *o*-hydroxybenzyl derivatives (25); (*iii*) photoisomerization of chromenes (26); and (*iv*) photolysis of benzoquinones and Vitamin K derivatives (27). None of these methods could be considered to be general since only selected *o*-QMs were photogenerated. We decided to investigate the full potential of using hydroxybenzyl alcohols as photochemical precursors of QMs since all three isomers (*ortho*, *meta*, and *para*) of the substrate were readily available and there was potential that all three isomers might react to give the corresponding QM. We discovered that this was indeed the case (28).

Product studies provided the initial evidence for a general method of QM photogeneration (28). For example, photolysis of *o*-hydroxybenzyl alcohols **4** and **9** in aqueous CH_3CN in the presence of ethyl vinyl ether or dihydropyran gave the corresponding [4+2] cycloaddition products (Scheme 3) in > 80% yield. Photolysis of **4**, **9**, and the corresponding *meta* and *para* isomers **10–13** in aqueous methanol gave the corresponding methyl ethers with quantum yields in the order $o > m \gg p$. The corresponding methoxy derivatives of these compounds, e.g., **15**, showed much less or no reaction, confirming the requirement of a hydroxy group and hence consistent with a mechanism involving a QM in the reaction of the hydroxy-substituted benzyl alcohols. Product studies of photosolvolysis of *o*-aminobenzyl alcohol in CH_3OH–H_2O are consistent with formation of an *o*-quinone methide imine intermediate

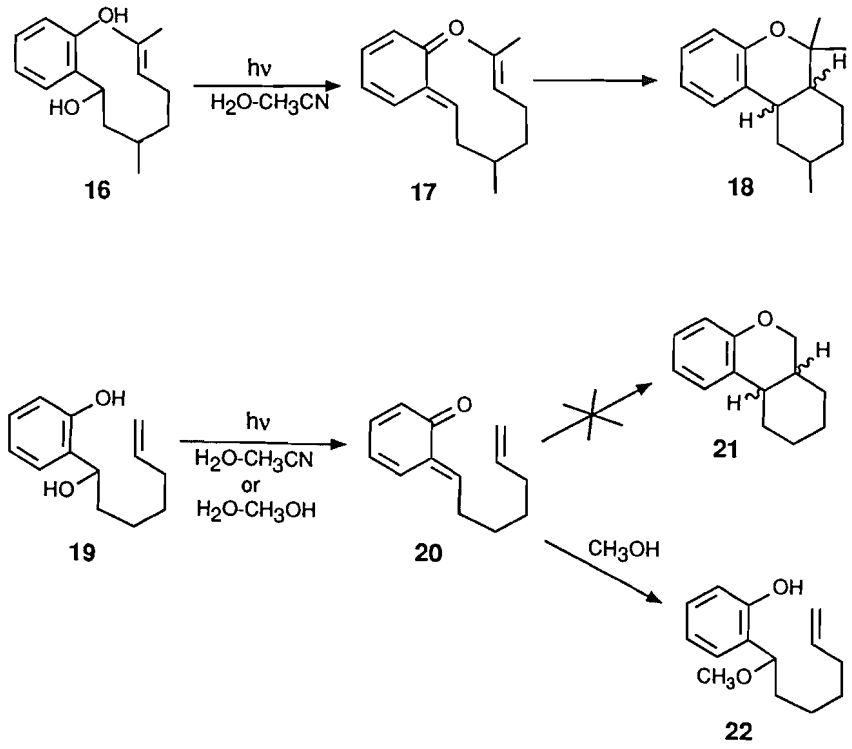
(29) although such intermediates are not readily trapped with dienophiles.

We have also shown that intramolecular trapping of a photogenerated *o*-QM can be readily accomplished using *o*-hydroxybenzyl alcohol **16** (Scheme 4).[3] Photolysis of **16** in aqueous CH_3CN resulted in high yields of the expected tetrahydrocannabinol derivative **18** via **17**. Interestingly, under the same conditions, *o*-hydroxybenzyl alcohol **19** gave no reaction. However, photolysis of **19** in 1:1 CH_3OH–H_2O resulted in high yields of methyl ether **22**, indicative of formation of *o*-QM **20**. The failure of *o*-QM **20** to undergo [4+2]

[3] B. Barker and P. Wan. Unpublished results.

Scheme 4.



cycloaddition to give **21** is simply due to the fact that the terminal alkene used as the "dienophile" in this reaction is not sufficiently electron rich to compete with nucleophilic quenching of **20**, which gives back substrate when H_2O is the only nucleophile.

Direct evidence for QM photogeneration came from nanosecond laser flash photolysis (LFP) studies of α-phenyl-substituted hydroxybenzyl alcohols **9**, **11**, **13**, and **14** and some of their corresponding methoxy-substituted derivatives (28). LFP experiments were carried out at 20°C using a YAG laser at 266 nm of flowing solutions to avoid complications arising from product photolysis and long-lived species. LFP of each of **9**, **11**, **13**, and **14** gave strongly absorbing transients all of which were unaffected by oxygen and which could be quenched by adding ethanolamine as nucleophile. Shown in Fig. 1 are the spectra observed for **9** and **13**, which we have assigned to their corresponding QM. LFP of their methoxy-substituted derivatives (on the benzene ring) failed to give any signal consistent with QM formation from **9** and **13**. The transients in Fig. 1 showed no observable decay in neutral pH (up to 2 ms, the longest time window of the detection equipment used). Indeed, LFP is unnecessary for **9** and **13** since we found that when solutions were photolyzed in a cuvette and UV–vis spectra taken quickly, it was possible to observe the clean decay (to base line) of the same transients, with lifetimes in the order of 5–40 s depending on the proportion of water used.

Transients observed on LFP of **11** and **14** were also strong but much shorter lived (30 ns and 10 μs, respectively) (Fig. 2). The λ_{max} and bandshape of these spectra are essentially identical to the corresponding diaryl and triarylmethyl cations photogenerated by McClelland et al. (30) using photoheterolysis of appropriate arylmethyl substrates. Although McClelland et al. (30) did not photogenerate *m*-hydroxy-substituted arylmethyl cations, the lifetimes of those that were reported are informative. For example, diarylmethyl cations without strongly stabilizing substituents have lifetimes of less than 10 ns in aqueous solution and are not detectable by standard nanosecond LFP; τ was estimated to be 1 and 6 ns for the diphenylmethyl and the (*p*-methylphenyl)phenylmethyl cations, respectively. The lifetimes of the parent trityl (triphenylmethyl) cation and the (*m*-methoxyphenyl)diphenylmethyl cation were measured to be 7 and 6 μs, respectively. It is clear that the transients observed from **11** and **14** are arylmethyl carbocations, but their lifetimes are too long to be simply the corresponding *m*-hydroxy-substituted species. The rationale is as follows. The deprotonated hydroxy group (O^-) is an electron-donating group on the benzene ring, at either the *meta* or *para* position ($\sigma_m = -0.47$; $\sigma_p = -0.81$) (31), unlike the simple hydroxy group, which is actually electron withdrawing at the *meta* position ($\sigma_m = +0.12$) (31). If the transient from **11** were simply the (*m*-hydroxyphenyl)phenylmethyl carbocation, its expected lifetime in aqueous solution, using data from McClelland et al. (30), would be *less* than 1 ns and hence not observable using our LFP system. Its much longer observed lifetime (30 ns) is consistent with a deprotonated hydroxyl group. Additional evidence that the transients observed in Fig. 2 are not simple arylmethyl cations is the fact that the corresponding 3-methoxy derivative of **14** did not give any observable transient by LFP. Moreover, **11** and **14** (and not their corresponding 3-methoxy derivatives) gave high yields (>50%) of the corresponding methyl ether products on photolysis at 254 nm in 1:1 MeOH–H_2O. We thus assign the transients in Fig. 2 as *m*-QMs **25** and **26**, from **11** and **14**, respectively. *m*-QMs and *m*-xylyl systems in particular have

Fig. 1. Spectra observed on LFP of hydroxybenzyl alcohols **9** and **13** in aqueous CH_3CN. These transients showed no observable decay within the 2 ms time scale, the longest available using the detection system employed (reprinted with permission from the American Chemical Society).

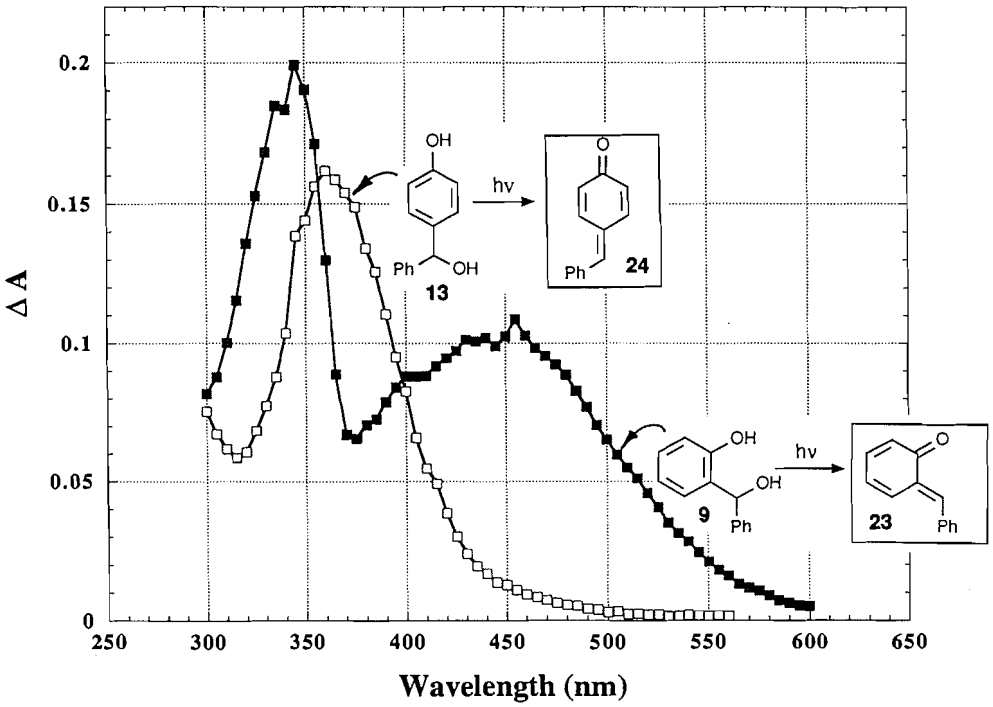


Fig. 2. Transient spectra observed on LFP of **11** and **14** in aqueous CH_3CN. Inset: clean first-order decay of **26** with a lifetime of 10 μs. The lifetime of **25** was 30 ns (reprinted with permission from the American Chemical Society).

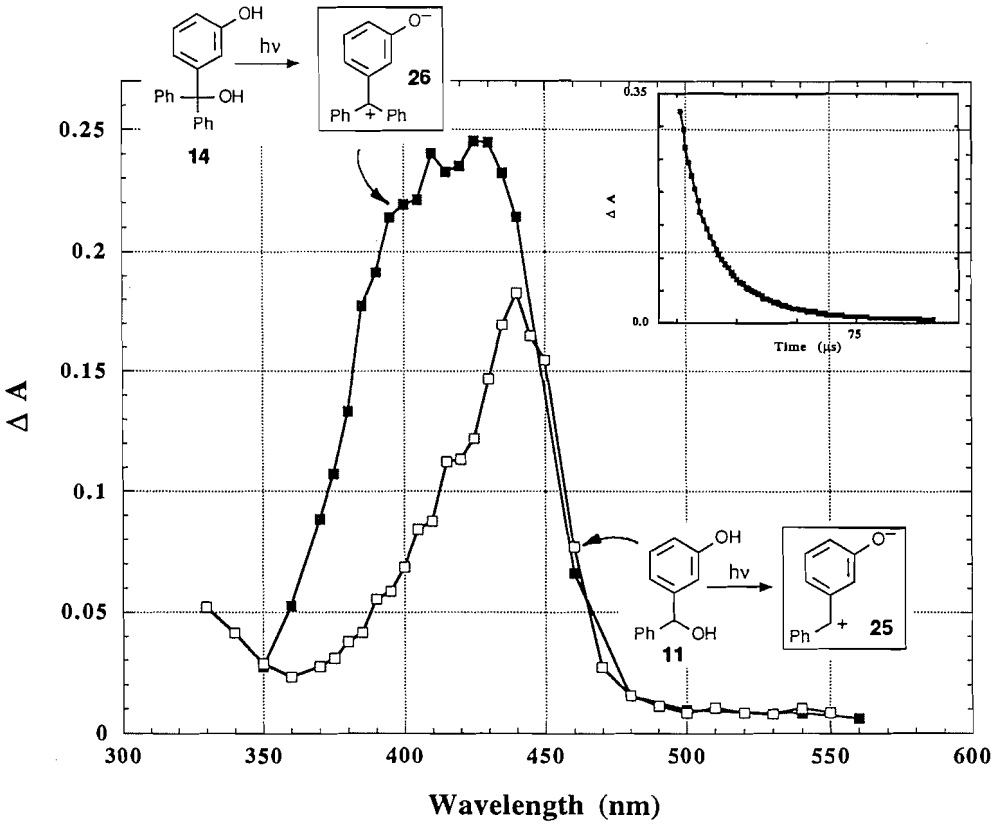

Fig. 3. Plot of relative quantum yield for formation of **23** from **9** vs. pH, as measured by ΔA at λ_{max} = 450 nm using LFP.

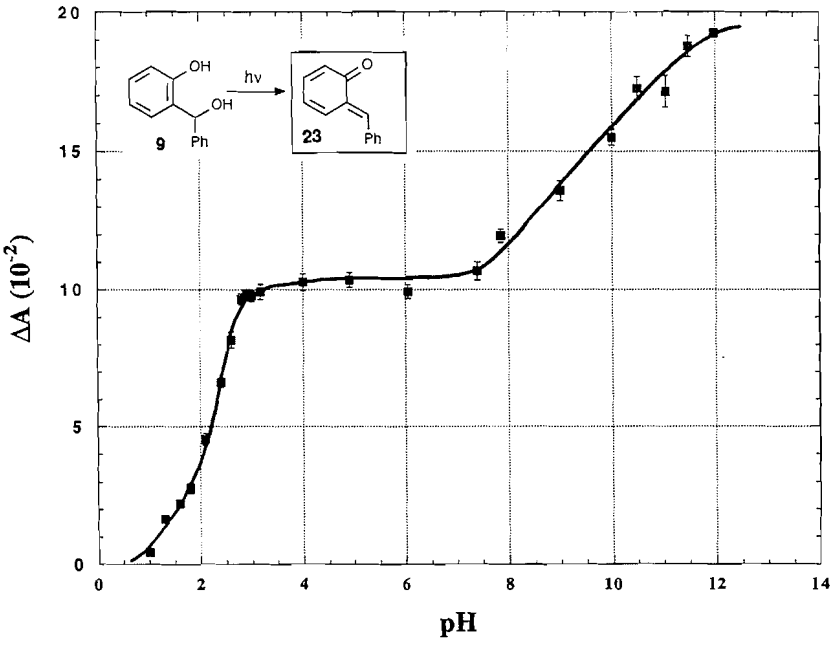
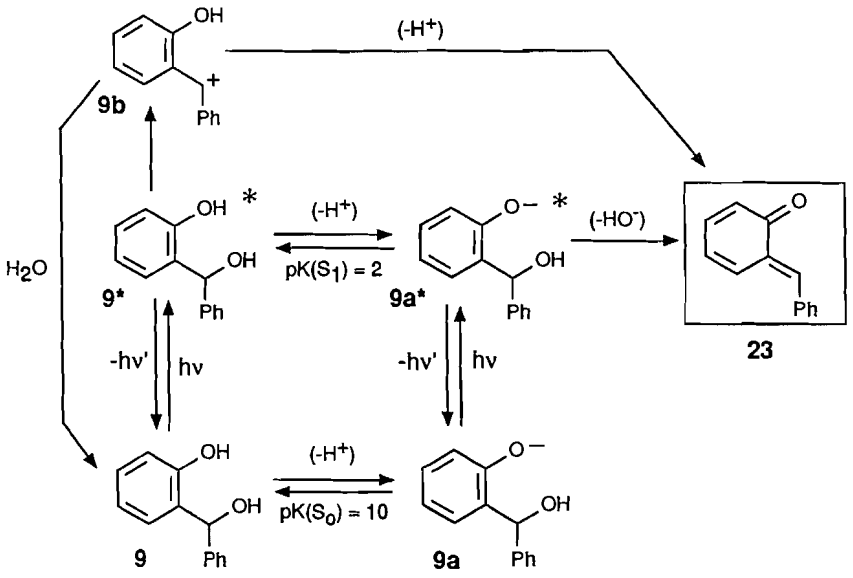


Scheme 5.

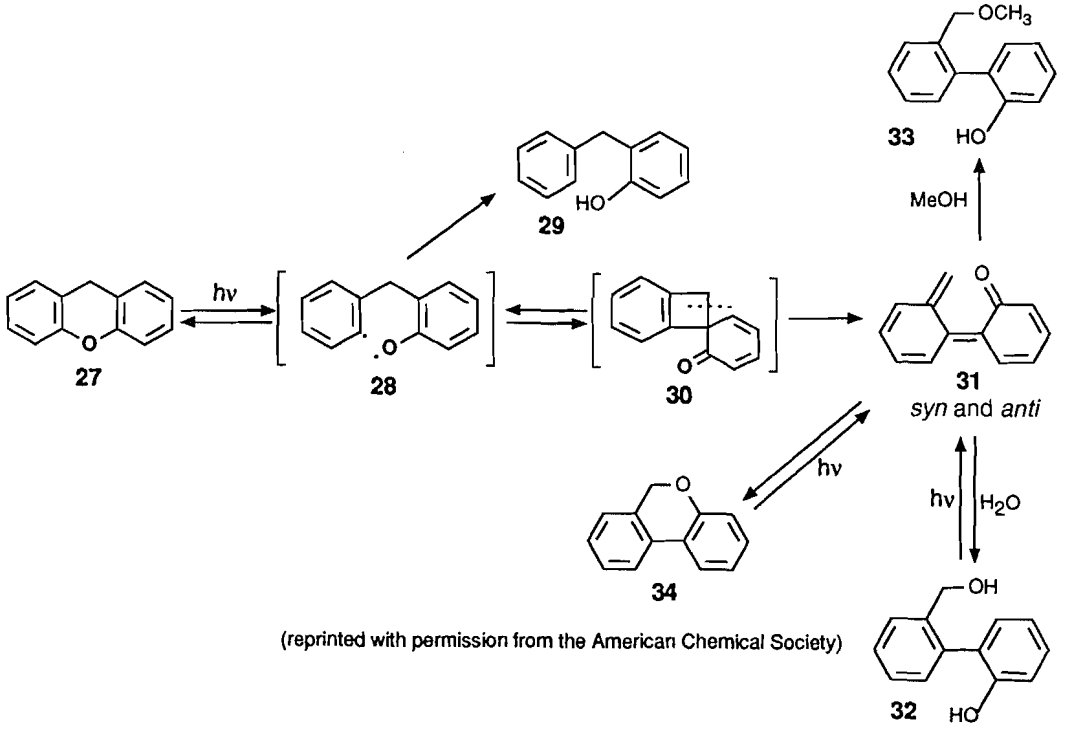


received considerable theoretical and experimental study (3). The present method offers a simple and efficient way for photogenerating *m*-QMs in their zwitterionic singlet states.

A particularly informative measurement available from LFP studies is the measurement of relative quantum yield for QM formation as a function of pH or in different solvents. Such relative quantum yields are readily measured by recording the absorbance change (ΔA) at the wavelength of interest (λ_{max} of transient) on photolysis at a particular pH (or solvent) and taking the average of several runs, keeping the absorbance at λ_{excit} (266 nm) constant. A plot of relative quantum yield for formation of **23** from **9** versus pH is shown in Fig. 3.[4] The sharp increase in the yield of **23** between pH 1 and 3 indicates that excited state dissociation to the electronically excited phenolate ion is a required step in the mechanism. This plot is essentially a titration curve with an estimated $pK_a(S_1) \approx 2.5$ for this compound. Direct excitation of the ground state phenolate ion also results in higher yields of **23**, as indicated by another titration curve with $pK_a(S_0) \approx 9.8$. These observations may be rationalized with a mechanism shown in Scheme 5. The prod-

[4] L. Diao and P. Wan. Unpublished results.

Scheme 6.



uct-forming step is loss of hydroxide ion of the excited state phenolate ion **9a***. Excitation of **9** at pH <8 results in **9***, which dissociates to **9a***. Since the yield of **23** is lower at these pHs, it implies that this equilibrium is not fully established, which is reasonable since fluorescence, intersystem crossing, and internal conversion are competing deactivational modes still available for **9*** (and **9a***). The possibility of a contributing pathway to **23** via carbocation **9b** cannot be excluded although the fraction reacting via this route is probably small since the corresponding methoxy derivative **15** is significantly less reactive in photosolvolysis than **9.**

Recent LFP studies of the parent *o*-hydroxybenzyl alcohol **4** and related compounds show that the parent *o*-QM chromophore (e.g., **1**, **17**, and **20**) absorbs with $\lambda_{max} \approx 390$ nm with lifetimes in aqueous solution that are considerably shorter than those of **23** and **24**.[4] LFP experiments of these simpler systems are complicated by observation of the corresponding radical cations, which absorb in the same region but have much shorter lifetimes. We have also extended the above method for QM photogeneration to a variety of other systems that formally have an *o*-hydroxybenzyl alcohol moiety. For example, photolysis of Vitamin B_6 in the presence of ethyl vinyl ether[4] gave the expected [4+2] adduct, implying that a variety of related *o*-QMs based on the pyridine ring system will be photogenerable. Additional examples are described individually in the sections that follow.

Biphenyl quinone methides

It was our venture into diaryl ether photochemistry that led to the discovery of a method for photogenerating biphenyl quinone methides. We observed that curious rearrangements were occurring on photolysis of xanthene (**27**) (32*a*) and *o*-phenoxybenzyl alcohol (32*b*) in aqueous solution. The mechanism for xanthene (**27**) to 5*H*-dibenzo[*b*,*d*]pyran (**34**) photoisomerization is shown in Scheme 6. Photolysis of **27** results in the expected homolysis of the aryl-O bond, to give biradical **28**, which can be trapped with 2-propanol to give **29**. In aqueous solution, however, *ipso* attack of the phenyl radical at the *ortho* position of the other ring results in the spiro ketone **30**, which subsequently gives *o*,*o*′-biphenyl quinone methide **31**. Electrocyclic ring closure gives the major product **34**. Nucleophilic trapping of **31** by water and by CH_3OH, if used as a cosolvent, gives **32** and **33**, respectively.

Scheme 6 posed the question of whether **31** could be photogenerated by photolysis of **32** or **34**. These questions have been addressed in a detailed mechanistic study of the photocyclization of 2-(2′hydroxyphenyl)benzyl alcohol (**32**) and related compounds (33), the mechanism of which is shown in Scheme 7. Evidence for reaction from an electronically excited phenolate ion **32a*** was obtained from a plot of quantum yield for formation of **34** as a function of pH, which showed two sigmoidal curves at pH $\approx$1 ($pK_a(S_1)$ and at pH $\approx$10 ($pK_a(S_0)$). Since ground state **32** is highly twisted (dihedral angle of 72° in the *syn* geometry by X-ray crystallography; its solution structure may differ to some extent due to solvation) whereas product **34** is essentially planar, the mechanism shown in Scheme 7 also involves twisting of the bond joining the two benzene rings on the S_1 surface. This twisting motion probably takes place before or concerted with deprotonation of S_1, either process of which is believed to be very fast. LFP experiments have been carried out in an attempt to detect **31** but have so far failed, which suggests that such QMs are very short lived (<5 ns). Although it was not possible to rule out formation of *anti*-**31**, the lack of any observable visible transient in LFP experiments would suggest it is not formed in

Scheme 7.

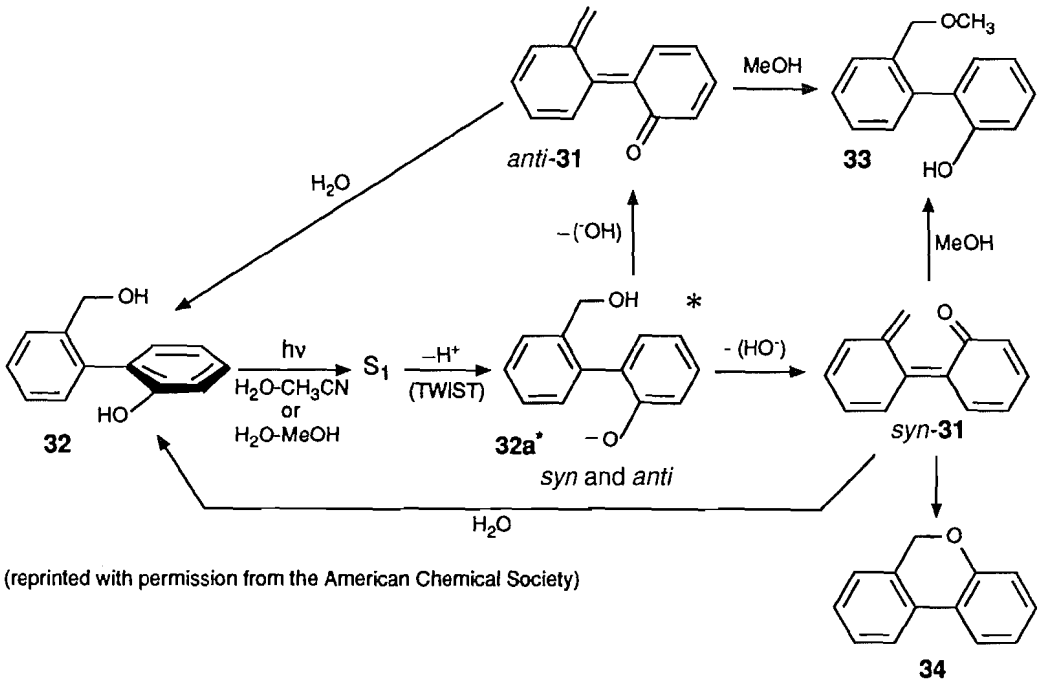


Chart 2.

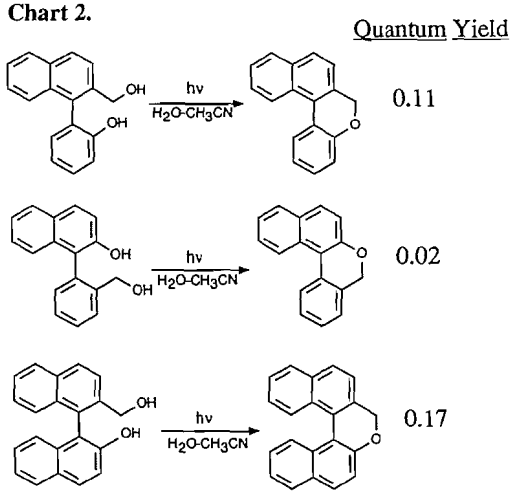

any significant amount. Such an intermediate cannot close to give **34** and hence should be sufficiently long lived to be detectable with nanosecond LFP. The fact that **32** exists only in the *syn* geometry in the X-ray structure might suggest that it is also the major conformation in aqueous solution, which would tend to give mostly *syn*-**31** on photolysis.

We have extended the photocyclization of **32** to a variety of other biaryls to test the generality of this reaction.[5] As shown in Chart 2, we have found that biaryls incorporating a naphthalene ring undergo the photocyclization and in most cases with high quantum efficiency. Indeed, the highly twisted binaphthyl system (dihedral angle ≈ 90°) reacts with the highest quantum efficiency, to yield a binaphthyl pyran that is much less twisted (dihedral angle ≈ 35°). These results are consistent with the well-known tendency of biaryls to twist to a more planar geometry on electronic excitation (33). With appropriately substituted *o,o'*-substituents, this inherent twisting motion results in net chemistry.

To obtain direct spectroscopic evidence for photogeneration of biphenyl quinone methides, we required biphenyl derivatives that on reaction (loss of water) would give biphenyl quinone methides that cannot cyclize, and hence extend their lifetime in aqueous solution. Such substrates are biphenyl alcohols **35** and **37** (34) (Fig. 4). LFP of these alcohols gave very long wavelength transients (λ_{max} = 570 and 530 nm, respectively) assigned to the corresponding biphenyl quinone methides **36** and **38**, with lifetimes of 0.47 and 67 μs, respectively (Fig. 4). Photolysis in CH_3OH–H_2O gave the expected methyl ether substitution products. Biphenyl quinone methides have much shorter lifetimes than to the *o*- and *p*-QMs discussed earlier. This is probably due to the fact that biphenyl quinone methides can gain two benzene rings on nucleophilic addition at the benzylic carbon, which is a very significant driving force.

Fluorenyl quinone methides

We first reported the facile photogeneration of the 9-fluorenyl cation (**8**) from 9-fluorenol (**7**) in aqueous solution (Chart 1) (35). This carbocation is unique amongst those we have photogenerated in that it is formally antiaromatic in the ground state. Indeed, it is one of the more elusive diarylmethyl carbocations in physical organic chemistry. Its facile photogeneration (35) has now opened up a method for studying the chemistry and dynamics of 9-fluorenyl cations in aqueous solution (17). We wondered whether it would be possible to photogenerate a fluorenyl quinone methide using the obvious substrate, 1-hydroxy-9-fluorenol (**39**). LFP of **39** in aqueous solution produced a long-lived ($\tau > 2$ ms) and strongly absorb-

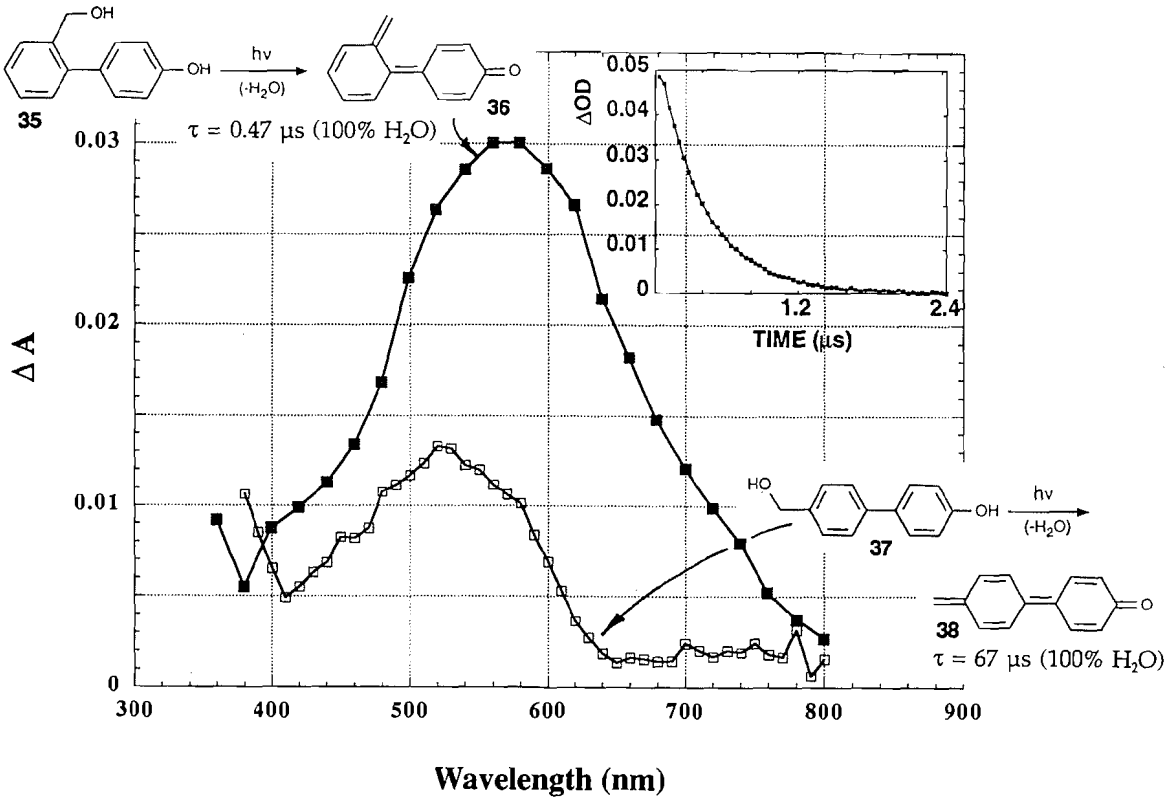
Fig. 4. Transient spectra observed on LFP of **35** and **37** in aqueous CH_3CN, to give biphenyl quinone methides **36** and **38**, respectively. Inset: first-order decay of **36** in H_2O (τ = 0.47 μs) (reprinted with permission from the Journal of the Chemical Society, Chemical Communications).



ing transient with λ_{max} = 450 nm, consistent with formation of fluorenyl quinone methide **40**[6] (eq. [3]). This was confirmed with trapping studies using CH_3OH and ethyl vinyl ether,

[3] 
which gave high yields of the expected products. The long lifetime (>2 ms) of **40** (**8** itself has a lifetime in the ps range (17)) is consistent with a quinone methide structure that effectively removes much of the antiaromatic character of the 9-fluorenyl cation. We are currently investigating the photochemical behaviour of other isomers of this system.

Summary

We have shown that all the QM isomers can be photogenerated readily, with high efficiency for the *ortho* and *meta* isomers, by photolysis of the corresponding hydroxybenzyl alcohols in aqueous solution. The method appears sufficiently general for the photogeneration of a wide variety of these intermediates and this is shown by extension of the method to biphenyl, fluorenyl, and heteroaromatic systems. It is possible to characterize photogenerated QMs spectrophotometrically, and that *m*-QMs react as zwitterions in aqueous solution. The utility of the photochemical method of QM generation in preparative chemistry and detailed kinetic and mechanistic studies of QM chemistry are continuing in our laboratory.

Acknowledgements

I am grateful to all of my present and former students for their contributions in increasing our understanding of the mechanistic photochemistry of aromatic molecules. Without their hard work and dedication, none of the above work and our other contributions would have been made. Dr. Cornelia Bohne provided invaluable help in laser flash photolysis experiments. We thank Dr. Victor Snieckus for a sample of 1-hydroxy-9-fluorenone. The continuing support of the Natural Sciences and Engineering Research Council (NSERC) of Canada is gratefully acknowledged. Partial funding came from the University of Victoria, the Petroleum Research Fund, administered by the American Chemical Society, and a starter grant from the Research Corporation.

Wavelength dependence and solvent effects on the ligand field photochemistry: the ring closure process in the excited $[Fe(CN)_5(tn)]^{3-}$ complex

Jailson Farias de Lima and Neyde Yukie Murakami Iha

Abstract: The solvent composition and wavelength effects on the quantum yield of the photoinduced ring closure process of the $[Fe(CN)_5(tn)]^{3-}$ complex (tn = 1,3-diaminopropane) were investigated. The reactivity was shown to be controlled by the macroscopic properties of water–glycerol mixtures. A sharp decrease in quantum yields with increasing medium viscosity was observed for all the irradiation wavelengths employed (313, 334, 365, 404, and 434 nm). The observed quantum yields ranged from 0.24 (λ_{irr} = 313 nm, 66.48 wt.% of acetonitrile) to 0.010 (λ_{irr} = 404 or 434 nm, 61.85 wt.% of glycerol). The overall efficiency is a complex function of the dynamics of radical recombination and dissociation pathways. The proposed cage model for the deactivation dynamics of the excited states illustrates that the decrease in medium viscosity favors a diffusional escape of the cyanide from the solvent cage.

Key words: photochemistry, pentacyanoferrate(II) complexes, solvent effect, wavelength effect.

Résumé : L'effet de la composition du solvant et de la longueur d'onde de l'excitation dans le rendement quantique du processus photoinduit de fermeture d'anneau du complexe $[Fe(CN)_5(tn)]^{3-}$ (tn = 1,3-diamineпropane) a été etudié. La reactivité semble être controlée par les proprietés macroscopiques des mélanges de solvant eau–glycerol. Une décroissance abrupte dans le rendement quantique est observée avec la variation de la viscosité du milieu, pour tous les longueurs d'onde d'irradiation employées (313, 334, 365, 404 et 434 nm). Le rendement quantique observé varie de 0,24 (λ_{irr} = 313 nm; 66,48% poids acétonitrile) à 0,010 (λ_{irr} = 404 ou 434 nm; 61,85% poids glycerol). L'efficacité totale est une fonction complexe de la dynamique des étapes de dissociation et de recombinasion radicale. Le modéle cage proposé pour la dynamique de deactivation des états excités montre que la décroissance dans la viscosité du milieu favorise la sortie de la cyanide de la cage du solvant.

Mots clés : photochimie, complexes de pentacyanoferrate(II), effet du solvant, effet de la longueur d'onde de l'excitation.

Introduction

Wavelength dependence and solvent effects on photoinduced reactions have been reported for a large number of transition metal complexes (1–11). Most of the literature addresses the analysis of the influence of solvent on intra- and intermolecular electron transfer processes (11–17) in which the reaction rate is controlled by solvent movements. Solvent mixtures in different proportions have been employed in order to change those properties of the medium that can be quite easily adjusted.

Wavelength-dependent photolabilization reactions constitute another class in which the solvent plays an important role in determining quantum yields. Particular emphasis has been placed on complexes of d^6 transition metal ions, and among them Co(III) complexes have historically been used as attractive model systems for such studies (2–9). The classical approach to this phenomenon is concerned with the competition between geminate recombination and solvent cage escape. When this competition can be related to properties of the solvent, one has an indication that the species will react on time scales sufficiently long to reach an equilibrium with the solvent environment. Despite its simplicity, this model has been shown to be consistent with a significant number of the available experimental results, although the data from some particular systems do not fit within its conceptual framework (3, 10, 11, 17).

During the last few years we have been studying the photochemical behavior of pentacyanoferrate(II) complexes, $[Fe(CN)_5L]^{3-}$. The investigated photoreactions include the labilization of either L (18–20) or a cyanide ligand (19, 21–23). The cyanide photolabilization was found to be strongly wavelength dependent. For the 365 nm irradiations, it was also observed that quantum yields of the process decreased with increasing glycerol concentration in the aqueous solution of the complex (23). The previously reported results allowed us to postulate a solvent cage mechanism for the reactive deactivation of the excited states of these complexes.

Following these studies, we now report the effect of glycerol concentration on quantum yields for the 313, 334, 404, and 434 nm irradiations. To analyze the solvent effect in further detail, experiments were performed with water–acetonitrile mixtures, including the 365 nm irradiation. The latter system has quite different properties then the water–glycerol mixtures.

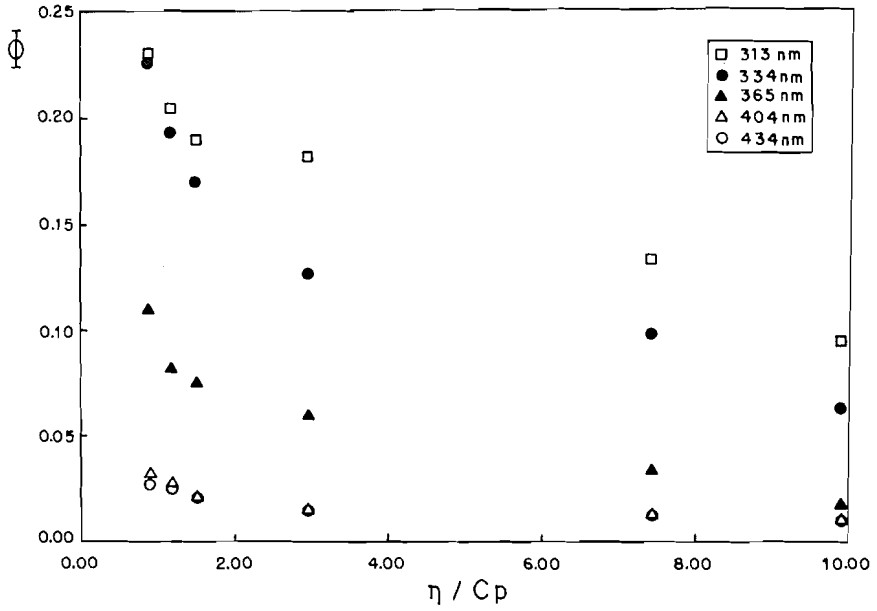
Fig. 1. Quantum yield for the ring closure reaction vs. viscosity of the water–glycerol mixtures.



Experimental

Materials

The $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ salt was synthesized according to slight modifications of a published procedure (24). The pentacyanoferrate(II) complex with 1,3-diaminopropane was always freshly prepared in the mixed aqueous solution by direct reaction of $Na_3[Fe(CN)_5NH_3]$ with a severalfold excess of the ligand. The ligand was purified by distillation under reduced pressure. Glycerol (Sigma Grade) and chromatographic grade acetonitrile (Merck) were used as supplied. The potassium tris(oxalate)ferrate(III) salt was prepared and purified according to literature procedure (25). *N*-Methylpyrazinium iodide was synthesized and recrystallized according to a procedure adapted from that described by Bahner and Norton (26).

Physical measurements and procedures

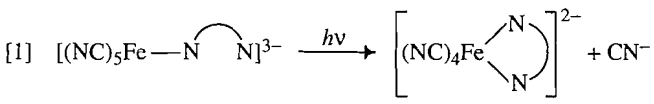
The continuous photolyses were performed using an Oriel 200 W Hg(Xe) arc lamp model 6291. Monochromatic irradiations were obtained by using Oriel interference filters to isolate the 313, 334, 365, 404, or 434 nm Hg line. The photolysis system is described in detail elsewhere (22, 23). The starting complex, $[Fe(CN)_5(tn)]^{3-}$, and the photoproduct, $[Fe(CN)_4(tn)]^{2-}$, absorb at the same wavelength with similar absorption coefficients. For this reason, direct spectrophotometric analysis is unsuitable for quantitative determinations. The analytical method involves the conversion of the starting complex, $[Fe(CN)_5(tn)]^{3-}$, to a highly absorbing species. The tetracyanoferrate(II) is inert toward substitution and can be isolated and further characterized. The light intensity at each wavelength was determined by tris(oxalate)ferrate(III) actinometry (25) carried out before and after each photolysis run. All absorption spectra were recorded on a Beckman DU 70 spectrophotometer at 25.0°C.

The concentration of the starting complex ranged from 3.2 to 6.0 mM depending on the irradiation wavelength employed.

Results and discussion

The $[Fe(CN)_5(tn)]^{3-}$ complex exhibits a low-intensity absorption band (λ_o = 395 nm, $\varepsilon_o = 4.5 \times 10^2$ M^{-1} cm^{-1}), which is assigned to the ligand field transition $^1A_1 \rightarrow {}^1E(1)$, under C_{4v} symmetry (27). An additional high-intensity band, with the maximum absorption located around 250 nm, is ascribed to a charge transfer transition from iron(II) to the cyanide ligands (27).

The continuous photolysis of aqueous or mixed aqueous solutions of $[Fe(CN)_5(tn)]^{3-}$ in the presence of a large excess of 1,3-diaminopropane yields the chelated tetracyanoferrate(II) complex as the only photoproduct (21–23) according to eq. [1].



Quantum yields for the ring closure process at different excitation wavelengths and glycerol content in the mixed solvent are shown in Table 1. The observed pattern for the 313, 334, 404, and 434 nm irradiations aligns with that previously reported for the 365 nm excitation (23). Figure 1 shows the role of solvent viscosity, whose decrease clearly favors a diffusional escape of the cyanide ion from the solvent cage. For the 404 and 434 nm excitations, the quantum yield, 0.010, was the lowest value determined in this work. The reduction in photoconversion was less pronounced for the 313 nm irradiation (0.230 to 0.095), indicating a more efficient escape from the solvent cage.

An extrapolation of the data in Fig. 1 to zero viscosity indicates primary quantum yields of bond cleavage around 0.4 (313 or 334 nm), 0.2 (365 nm), and 0.06 (404 or 434 nm).

A good correlation between quantum yields and the reciprocal of the dielectric constant values can be seen from the data of Table 1 for different solvent compositions. This behav-

ior is somehow unexpected since the parameters of the elementary electrostatic theory, such as dipole moment, polarizability, and dielectric constant, are usually found to be unsuitable for the description of solvent effects (28). Double reciprocal plots ($1/\Phi$ vs. $1/\eta$ and $1/\Phi$ vs. $1/\varepsilon$) do not present better correlations.

Water and glycerol are very much alike. They exhibit a strong tendency to form intermolecular hydrogen bonds (29, 30), and keep the solvent structure from changing due to preferential solvation. Specific interactions, such as hydrogen bonding, have been recognized for a long time to be more important than dispersion forces, depending on polarizabilities, in accounting for solvent effects (28, 30). The magnitude of the bulk solution properties for water–glycerol mixtures can be considered close to that for the coordination sphere. It is possible to correlate each set of variations of quantum yield with viscosity as an index of the microstructure, and dielectric constant as a measure of solvent polarity. A similar pattern for viscosity was reported by Scandola et al. for some isoelectronic cyanocobaltate(III) complexes (2, 4) and by Langford and Malkhasian (8) for amine complexes of Co(III).

Glycerol solutions are one of the best systems for analyzing the effect of viscosity on quantum yields without a great variation of dielectric constant. On the other hand, a remarkable change in dielectric constant values can be obtained using acetonitrile as the water cosolvent. Table 2 shows quantum yield values of the ring closure process for different excitation energies and water–acetonitrile compositions. One can see that the dielectric constant value decreases by roughly one third on going from aqueous solutions to 66.48 wt.% of acetonitrile. The quantum yield variation for the 313 or 334 nm irradiation presents a similar trend with viscosity as that observed for the water–glycerol system. The 365, 404, and 434 nm irradiation data do not align with the former ones.

As previously discussed (23), the 313 nm excitation populates exclusively the $Fe \rightarrow CN^-$ charge transfer state, namely ^1CT. According to one of our proposed mechanisms, in this condition, an excess of energy allows an efficient escape of the cyanide ion from the solvent cage. The quantum yield of aqueous solutions for this irradiation wavelength is around 0.23, while a higher value was obtained for 66.48 wt. % of acetonitrile. At this excitation energy the generation of the primary radical pair has the highest efficiency, and the difference in quantum yields reflects changes in the diffusional escape of the cyanide ion, which can be attributed to the 30% reduction in bulk solvent viscosity.

The reduction in viscosity, on going from aqueous solution to 66.48 wt.% acetonitrile, is expected to lead to higher efficiencies. This trend has not been observed for the 365 nm irradiations because the lowest limit to populating the ^1CT state with reasonable efficiency should be around this energy. The absence of the extra energy, which allows the cyanide to escape from the cage, makes the yields markedly lower when compared to those obtained for aqueous solutions.

For the 404 or 434 nm excitation, which populates exclusively the ^1LF state, little change was observed upon the increase of acetonitrile content in the medium. In this case the photoreactive channel is expected to be from the ^3LF state whereas an increasing participation of the ^1LF reactive channel is obtained at higher excitation energies.

According to the so-called mechanical cage effect, it is likely that the rate of vibrational energy transfer to the solvent medium can limit the rate of thermal equilibrium of the excited states. Their deactivations can be altered according to

the solvent composition. Since the cosolvents employed, water and acetonitrile, differ in their hydrogen bond properties (31), coupling differences between the metal complex and the solvent can lead to solvent-dependent rates of nonradiative deactivation to the ground state. Due to the lack of a systematic correlation such as those obtained for water–glycerol systems, the data can reflect the existence of preferential solvation by water. If the composition of the first solvation shell differs significantly from the bulk solution, solvation structures change considerably within small areas around the solute particles. Thus, in this case, macroscopic properties of the solvent are not good parameters for correlations.

The higher quantum yields obtained for the 313 nm excitation represent a pronounced break in the general trend for the water–acetonitrile series. They indicate the existence of an electronic perturbation caused by the solvent due to the higher nucleophilicity of acetonitrile in comparison to water (32–34). It is difficult to analyze the role of dielectric constant in the photochemical behavior of this complex since the quantum yield variation is dominated by the effect of viscosity.

The cage effect mechanism is a simple model to explain photochemical behavior that presents wavelength-dependent reactions. Recently, flash photolysis experiments showed that the solvent mixture not only changes the macroscopic properties of the solvent but also alters the efficiency of primary radical formation. Langford and co-workers (11) also pointed out the importance of the so-called thermal solvent cage, where the dynamics are controlled by the rate at which the energy is dissipated from the excited species to the solvent. For the $W(CO)_5py$ system (35), the quantum yields for pyridine substitution depend mainly on the "mechanical" cage effect at the highest excess excitation energy, while the thermal effect is pronounced at an intermediate excess excitation energy.

The solvent can also play a role in dictating the orbital population of the Frank–Condon excited state for charge transfer transitions (7). Considering that there are no noticeable changes in the position or shape of the absorption spectrum bands for water–glycerol mixtures, it can be concluded that, in this case, the quantum yield variation results not from the solvent-induced perturbation of electronic states but from variation in the kinetic parameters that govern excited state deactivation. This factor can be important to the water–acetonitrile system where the direct ^1CT population may be altered due to solvent composition in the coordination sphere. The absence of direct measurement of the intermediates in a fast time domain for such complexes precludes a determination of the mechanism. However, the two proposals are both consistent with the reported data but not mutually exclusive.

In fact, these two approaches are complementary in the sense that the medium property parameters are related to the dynamics of deactivation for formation of the final photoproduct. On the other hand, the wavelength dependence accounts for different efficiencies of primary radical formation in the very first step achieved before the deactivation process takes place. The overall quantum yield reflects the balance between solvent and irradiation wavelength effects. This work shows that for a determined excitation energy, the characteristics of the medium can shift the balance from one mode to another, tuning the efficiency of the photochemical process. The results point out that wavelength energy is as important as solvent properties in determining the overall quantum yield. For high energy excitations, the observed data reflect limitations imposed by the medium.

Synthèse et analyse structurale de nouvelles *méso*-arylporphyrines glycosylées en vue de l'application en photothérapie des cancers

Olivier Gaud, Robert Granet, Mourad Kaouadji, Pierre Krausz, Jean Claude Blais et Gerard Bolbach

Résumé : Nous décrivons la synthèse de 13 nouvelles *méso*-glycosylarylporphyrines pour lesquelles la partie glucidique est séparée du substituant aryle par l'intermédiare d'un bras espaceur. Ces composés sont synthétisés par différentes méthodes : glycosylation des *ortho*- et *para*-hydroxyalkyloxyarylporphyrines, condensation d'aldéhydes glycosylés avec du pyrrole ou du *méso*-(*p*-tolyl)dipyrrométhane. Dans une seconde étape la partie glucidique est déprotégée en milieu basique. Dans tous les cas, les glucides *O*-liés présentent une configuration β. Ces composés sont caractérisés par différentes méthodes spectrales. Une étude détaillée de la RMN permet d'attribuer tant en ^{1}H qu'en ^{13}C les différents signaux aux noyaux tolyles, aryles, pyrroles, alkyles et glycosyles. Nous discutons de l'allure des spectres obtenus en spectrométrie UV–visible et enfin nous présentons les résultats de spectrométrie de masse obtenus par une nouvelle méthode de désorption laser adaptée à ces molécules de haut poids moléculaire. Par leur pouvoir sensibilisateur, ces molécules constituent de bons candidats pour la thérapie photodynamique.

Mots clés : porphyrines, glycosylations, photothérapie, cancer.

Abstract: The synthesis of 13 novel *meso*-glycosylarylporphyrins where the carbohydrate moiety is separated from the aryl substituent by a spacer arm is described. These compounds were synthesized by different methods, either by direct glycosylation of the *ortho*- or *para*-hydroxyalkoxyarylporphyrin or by condensation of glycosylated aldehyde with pyrrole or *meso*-(*p*-tolyl)dipyrromethane. In all cases, a β configuration was observed. Deprotection of the sugar then followed in a basic medium. The compounds were characterized by a variety of means. A detailed ^{1}H and ^{13}C NMR study allowed complete structural determination. The UV–visible and laser desorption mass spectra are presented. Due to their sensitizing abilities, these resultant compounds are of considerable interest for photodynamic therapy.

Key words: porphyrins, glycosylations, phototherapy, cancer.

Depuis la première publication de Mironov et al. (1), l'étude des porphyrines glycosylées (2) a pris une importance sans cesse croissante en raison de son impact, en particulier en thérapie photodynamique (PDT). Plusieurs travaux effectués ces dernières années ont montré que les porphyrines solubles dans l'eau tendent à se concentrer davantage dans les tumeurs que dans les tissus sains. Ainsi, une tumeur enrichie en porphyrines peut être sélectivement détruite par irradiation sans toucher aux tissus non atteints (3). Après un travail préliminaire (4), nous présentons la synthèse de 13 nouvelles porphyrines glycosylées (figure 1) du type *méso*-arylporphyrine, dont la partie saccharidique est séparée du macrocycle tétrapyrrolique par un bras espaceur. Nous avons, en particulier, fait varier la position du bras sur le groupement phényle (*ortho* ou *para*), la nature du glucide représenté par un monosaccharide (glucosyle ou ribosyle) ou un disaccharide (maltosyle ou lactosyle) ainsi que le nombre d'entités osidiques fixées sur le macrocycle tétrapyrrolique (une à quatre en série glucosyle). De telles structures nous semblent être de bons candidats pour la PDT. En effet, le bras espaceur devrait accroître le caractère amphiphile de ces composés en permettant de disposer de molécules à la fois solubles dans l'eau et capables de s'intégrer facilement aux membranes phospholipidiques. Par ailleurs, il est maintenant admis que la présence d'unités glucidiques peut améliorer le ciblage de ces substrats vis-à-vis de certaines tumeurs (5).

Synthèse

Monoglycosylporphyrines 1a,b–4a,b

Deux méthodologies sont utilisées. La première (voie A, schéma 1) part des *ortho*- ou *para*-5-hydroxyphényl-10,15,20-tritolylporphyrines **10a,b** synthétisées selon la méthode de Little et al. (6). Ces porphyrines sont alkylées en milieu DMF-K_2CO_3 par le 3-bromopropan-1-ol pour mener, avec des rendements quasi-quantitatifs, aux 5-hydroxypropyloxyphényl-10,15,20-tritolylporphyrines **11a,b**, (7). Ces derniers composés sont ensuite glycosylés par des dérivés *per*acétylés du glucose, du maltose ou du lactose ou par le 1-*O*-acétyl 2,3,5-tribenzoate-β-D-ribose par le système $SnCl_4$–CH_2Cl_2 à température ambiante. En fin de réactions, l'analyse des pro-

duits formés montre, outre les produits attendus **12a,b–15a,b**, des glucides de départ, des produits de dégradation de ces derniers ainsi que des traces des porphyrines **11a** ou **11b** et de leur dérivé acétylé au niveau du groupement hydroxyle (*o*- et *p*-(acétyloxypropyloxy)phényltritolylporphyrine). Comme attendu dans ce type de glycosylation, on note l'absence de porphyrines α-glycosylées. Les produits obtenus, **12a,b–15a,b,** sont purifiés par chromatographie préparative sur couche mince de gel

de silice. Tous présentent, comme le montrent les constantes de couplage des protons anomériques, une configuration β (tableau 2-3, réf. 8). Les rendements de réaction varient de 20 à 70%. Ils sont maximaux pour les dérivés monosaccharidiques *para*-substitués. Nous avons également obtenu les composés **12a,b** et **14b** par une deuxième méthode (voie B, schéma 2). Celle-ci nécessite la synthèse préalable, en deux étapes, des précurseurs aldéhydiques glycosylés **17a,b** et **18b**. La première consiste à faire réagir l'*ortho*- ou le *para*-hydroxybenzaldéhyde sur le 3-bromopropan-1-ol en milieu K_2CO_3–DMF. Elle conduit aux intermédiaires **16a,b** qui sont purifiés par chromatographie sur colonne de silice avec des rendements acceptables (Rdt 65–75%). Dans une deuxième étape, ces dérivés sont glycosylés par le glucose ou le maltose *per*acétylé avec le système $SnCl_4$–CH_2Cl_2. Les β glycosides obtenus, **17a,b** et **18b**, sont isolés par chromatographie et (ou) cristallisation avec des rendements de 20 à 35%. Ces précurseurs glycosylés sont alors condensés sous reflux dans l'acide propionique, sur des quantités stoechiométriques de *para*-tolualdéhyde (3 equiv.) et de pyrrole (4 équiv.). Ces conditions expérimentales mènent aux porphyrines **12a,b** et **14b** avec des rendements de l'ordre de 10%. Cette deuxième voie de synthèse permet d'accéder plus rapidement aux monoglycosylporphyrines avec des rendements comparables à ceux de la voie A. Elle implique par contre, la formation de quantités importantes de précurseurs glycosylés qui ne se prêtent pas toujours à des purifications aisées. Les porphyrines glycosylées synthétisées par les deux voies, sont ensuite déprotégées par le méthylate de sodium en milieu CH_2Cl_2–MeOH. Les réactions sont totales en 1 h et les porphyrines obtenues sont isolées après purification sur colonne de Sephadex LH20 avec des rendements de l'ordre de 80%. Elles sont toutes peu solubles dans l'eau, mais cette solubilité augmente lorsqu'on passe d'un mono à un disaccharide ou encore par passage d'une substitution *para* à une substitution *ortho*.

Tétraglycosylporphyrines 5,6

Ces deux composés sont synthétisés selon le schéma 2. Les condensations des précurseurs glycosylés **17b** et **18b** sur le pyrrole sont effectuées par la méthode de Lindsey et al. (9) en milieu CH_2Cl_2 et en présence d'acide trifluoroacétique (TFA). Les porphyrinogènes formés en 1 h pour le composé glucosylé et en 4 h pour le composé maltosylé sont ensuite oxydés par addition de *p*-chloranile. Les porphyrines **19** et **20** sont alors purifiées par chromatographie sur colonne de silice et isolées avec des rendements respectifs de 36 et 16%. Ces deux composés sont désacétylés par le méthylate de sodium dans des conditions similaires à celles précédemment employées. Les porphyrines déprotégées **5** et **6** présentent toutes les deux une bonne solubilité dans l'eau.

Di- et triglycosylporphyrines 7–9

Tout comme la monoglycosylporphyrine **12b**, les di- et triglycosylporphyrines **22**, **23**, **21**, sont synthétisées selon le schéma

Schéma 2.

Les protons benzoïques du composé **13a** sont enregistrés à δ pm : ca. 7,90, ca. 7,83 et ca. 7,76, t él. (3 × 2H, J = 7,1 Hz, H-2,6), ca. 7,57, ca. 7,55 et ca. 7,53 t él. (3 × 1H, H-4), ca. 7,40, ca. 7,26 et ca. 7,12 t él. (3 × 2H, J = 7,7 Hz, H-3,5). Les protons benzoïques du composé **13b** sont enregistrés à δ ppm : 8,12, 8,06 et 7,92, dd (3 × 2H, J = 8,5-1,4 Hz, H-2,6), ca. 7,50 m (3H, H-4), ca. 7,45 m (2H, H-3,5), 7,33 et 7,20 t (2 × 2H, J = 8,5 Hz, H-3,5).

[a]Composé dont l'attribution des signaux est vérifiée par COSY.

[b–d]Les attribution affectées du même exposant dans une même colonne sont réversibles.

[e]Attribution déterminée par irraditions sélectives.

2 en adaptant la stoechiométrie des réactifs. Ces synthèses sont cependant peu sélectives et donnent lieu à la formation d'un mélange de porphyrines, de chlorines et de produits de polymérisation. Dans ces conditions, nous obtenons le composé **21** avec un rendement de 4%. Par contre la synthèse des diglycosylporphyrines substituées sur les positions 5,10 (composé *cis*) **22** ou 5,15 (composé *trans*) **23** du macrocycle donne des résultats moins satisfaisants (Rdt < 2%). Dans ce dernier cas, nous avons cherché à adapter une troisième voie de synthèse de façon à limiter la formation des composés parasites (voie c, Schéma 3). Parmi les différentes voies qui permettent d'accéder à un cycle porphyrinique, la condensation d'unités dipyrrométhane avec un aldéhyde représente une méthode importante. En imposant la géométrie d'une partie de la molécule, elle permet de limiter la formation d'isomères. Cette méthode a récemment été utilisée pour la synthèse de *méso*-arylporphyrines disubstituées (10–15) ou tétrasubstituées (16–19). Pour notre part nous avons réalisé cette synthèse selon la procédure développée par Lee et Lindsey (19). L'unité dipyrrométhane (**24**) est préparée en faisant réagir le *para*-tolualdéhyde sur un excès de pyrrole en absence de solvant. Après évaporation du pyrrole, le composé **24** est chromatographié sur silice par élution au toluène en présence de 1% de triéthylamine. Dans une deuxième étape, ce composé est mis à réagir en présence de $BF_3{\cdot}Et_2O$ sur le précurseur **17b** en milieu CH_2Cl_2 sous atmosphère inerte. Le porphyrinogène formé est ensuite oxydé par addition de *p*-chloranile. Dans les conditions décrites par Lindsey, cette réaction conduit par acidolyse du dipyrrométhane, puis par recombinaison des unités libérées à la formation d'un mélange de porphyrines. Dans une deuxième série d'essais nous avons réalisé ces condensations dans l'acide propionique, mais ce système ne s'est pas révélé efficace. En effet dans ces conditions, la complexité du mélange obtenu reste identique et les rendements de réaction diminuent. Pour améliorer les premiers résultats obtenus dans le système CH_2Cl_2–$BF_3{\cdot}Et_2O$, nous avons anticipé l'addition du *p*-chloranile et ramené la température d'oxydation à celle du milieu ambiant. Dans ces conditions nous avons sensiblement augmenté la proportion du composé **23** par rapport aux autres glycoporphyrines **12b**, **21**, et **22**. Par la voie C, nous avons donc isolé par chromatographie sur silice la monoglycosylporphyrine **12b** (Rdt 16%), les *cis* et *trans* diglycosylporphyrines **22** et **23** (Rdt 5%, Rdt 9%) et la triglycosylporphyrine **21** (Rdt 2%). Les isomères **22** et **23** de R_f très voisins, n'ont pu être séparés qu'à la suite d'une triple élution sur plaques de gel de silice. Comme attendu, le composé **22** est le plus polaire. Tout comme les mono- et tétraglycosylporphyrines les porphyrines **21**, **22**, **23** sont déprotégées par le méthylate de sodium et mènent après purification sur colonne de Sephadex LH20 aux composés **7**, **8**, **9** avec de bons rendements (Rdt > 80%). Ces composés présentent une solubilité dans l'eau, intermédiaire entre celles des monoglycosylporphyrines et celles des tétraglucosylporphyrines.

Analyses spectroscopiques

Spectrométrie UV–visible

Tous les spectres d'absorption UV–visible des porphyrines lipophiles **11**–**21** sont mesurés dans le dichlorométhane (tableau 1). L'analyse des résultats montre la bande de Soret vers 420 nm ainsi que les quatre bandes, I, II, III et IV de moindre intensité généralement attendues pour ce type de porphyrines (20). La plupart de ces spectres sont de type *étio* ($\epsilon_{IV} > \epsilon_{III} > \epsilon_{II} > \epsilon_I$). En passant cependant des spectres des composés *ortho*- à ceux des composés *para*-substitués on note une diminution relative de l'intensité de la bande II par rapport à celle de la bande I. Cette variation conduit pour les composés **20**, **21** et **22** à des spectres atypiques présentant un coefficient d'absorption ϵ_I supérieur à ϵ_{II}. Nous avons réalisé les spectres des composés amphiphiles **1**–**9** dans le mélange mixte tétrahydrofurane/eau 8:2 (tableau 1). Dans ce milieu, nous retrouvons des spectres d'allure similaire à ceux précédemment décrits. Tout comme leurs homologues acétylés ou benzoylés, ces composés présentent des variations des bandes I et II par passage d'une substitution *ortho* à une substitution *para* du *méso*-phényle. Par contre, lorsque ces spectres sont réalisés dans l'eau pure, ils présentent des variations importantes; ils montrent ainsi un élargissement ou un dédoublement de la bande de Soret avec une diminution du coefficient d'absorption. Ce phénomène est réversible après addition de THF. Par analogie aux résultats observés par Fuhrhop et al. (21) ces comportements spectraux peuvent être interprétés par la formation d'agrégats.

Spectrométrie de masse

En raison de la non volatilité des porphyrines, les méthodes classiques de spectrométrie de masse (IE, IC) se révélent inadaptées. Les spectres de massse sont par conséquent effectués avec les modes d'ionisation SIMS ou MALDI. Les monoglycosylporphyrines protégées 12a,b–15a,b sont analysées en mode SIMS. Comme nous l'avons déjà montré sur des composés de ce type (22), les spectres obtenus en mode positif présentent les pics moléculaires $(M+H)^+$. De plus, on observe dans tous les cas, un pic de fragmentation correspondant au départ du propyloxyglucosyle. Les autres porphyrines sont analysées en mode MALDI. Le pic moléculaire est toujours présent avec ce mode d'ionisation et on note en général l'absence d'ions fragments.

RMN ^{1}H

Les spectres de résonance magnétique nucléaire du proton des composés glycosylés sont enregistrés à 200 MHz dans $CDCl_3$. Les attributions détaillées des signaux sont rassemblées dans les tableaux 2 et 3. Elles reposent sur l'intégration, le découplage sélectif homonucléaire mais également sur les spectres 2D de corrélation homonucléaire ^{1}H–^{1}H (COSY). Les spectres de RMN ^{1}H des précurseurs ainsi que ceux des octaacétylmaltose et lactose sont utilisés comme références. La RMN du proton de ces composés présente sept groupes de signaux : (*i*) les protons β pyrroliques vers 9 ppm; (*ii*) les signaux des *méso*-substituants aromatiques entre 8,2 et 7,2 ppm; (*iii*) les protons osidiques entre 5 et 3 ppm dans le cas des composés substitués en position *para* et entre 5 et 2 ppm pour celui des composés *ortho*-substitués; (*iv*) les protons de la chaîne hydrocarbonée entre 4 et 1,5 ppm qui sont souvent confondus avec certains protons glucidiques; (*v*) les signaux CH_3 tolyles à 2,7 ppm; (*vi*) les protons des groupements acétyles vers 2 ppm; (*vii*) les protons NH pyrroliques vers –2,7 ppm. L'analyse fine de la zone β pyrrolique permet d'appréhender la symétrie de ces molécules (figure 2). Alors que les protons β pyrroliques des composés **19** et **20** (un seul type de substituant) résonnent sous la forme d'un singulet, ceux des composés mixtes (tolyle et aryloxypropyloxyglucosyle) se présentent sous la forme de figures plus com-

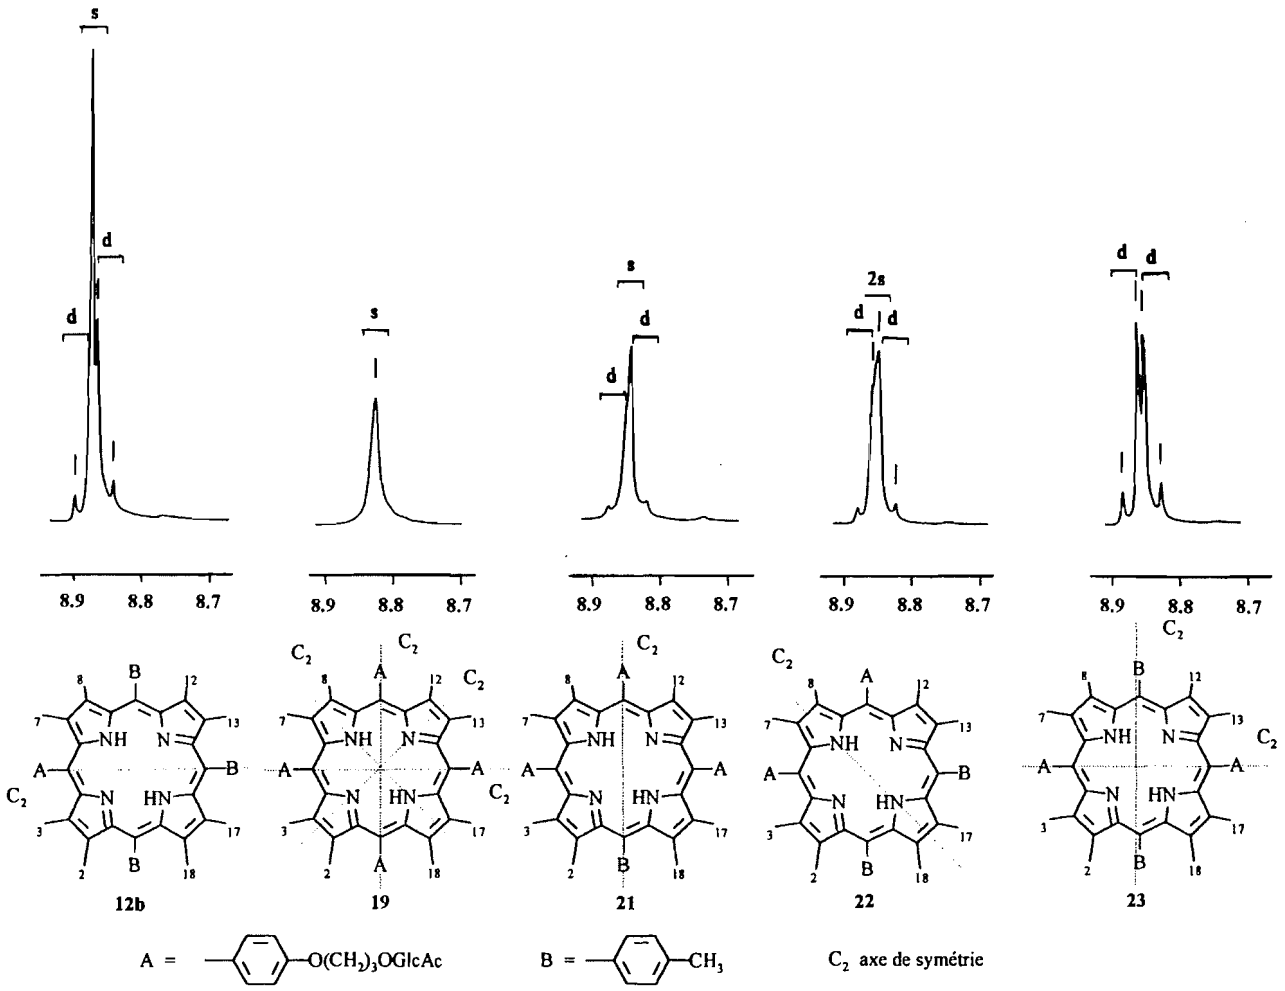
[a,b]Les attributions affectées du même exposant dans une même colonne sont réversibles.

plexes. Bien que dans la plupart des cas il y ait chevauchement des signaux et donc dégénérescence des figures, on peut cependant différencier les figures des protons β pyrroliques de ces composés diversement substitués. Comme attendu, les signaux des protons β pyrroliques des composés **12**b et **21** s'apparentent à deux doublets et un singulet. Ceux du composé **22** s'apparentent à deux doublets et deux singulets. Par contre les signaux des protons β pyrroliques du composé **23** apparaissent nettement sous la forme de deux doublets; ils confirment la symétrie double de ce type de composé. Le passage des porphyrines substituées en position *para* du *méso*-phényle à celles substituées en position *ortho* entraîne des changements significatifs dans la résonance de l'ensemble des noyaux. La substitution d'un glycosyloxypropyloxy en position *ortho* induit une perte

Fig. 2. Comportement des protons β pyrroliques (δ 8,7–9,0) dans les composés **19**, **12b**, **21**, **22** et **23** dans $CDCl_3$ à 30°C.

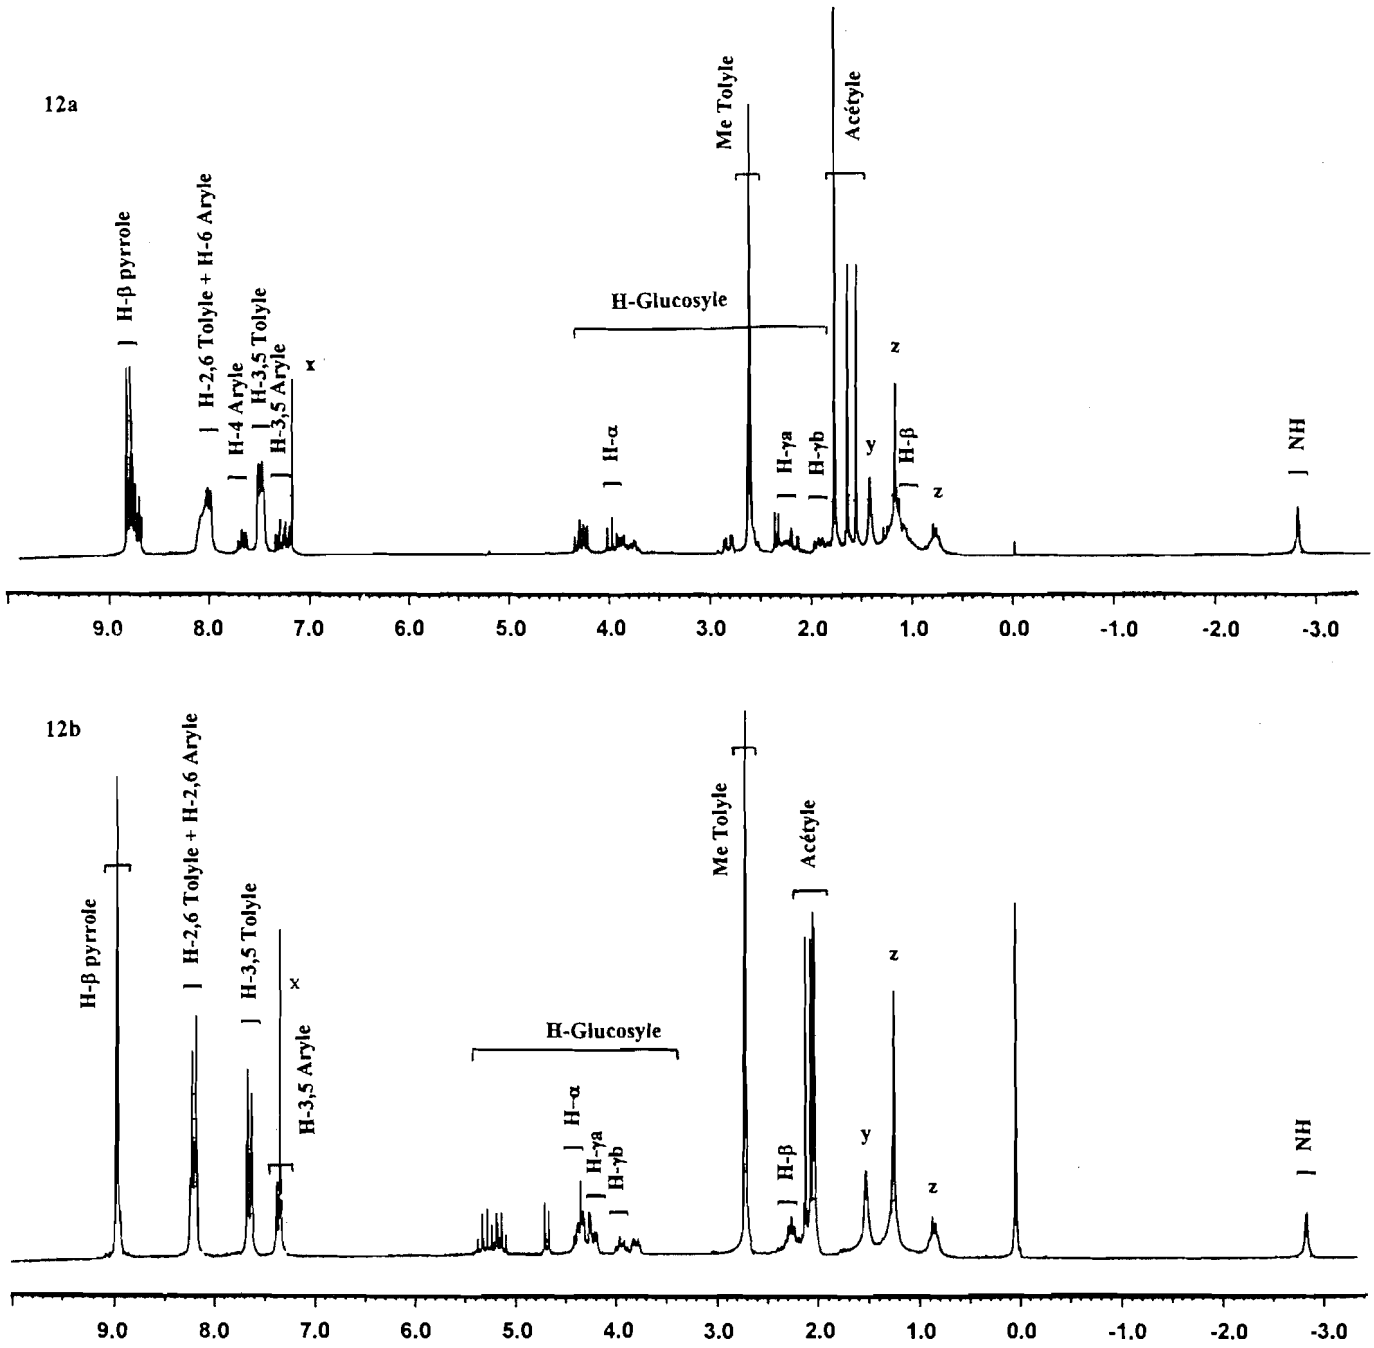


de symétrie et provoque du fait de la non équivalence des noyaux, un élargissement des signaux aromatiques des tolyles. Elle conduit également à la multiplication des signaux β pyrroliques. Comme le montrent les exemples de la figure 3, les protons β pyrroliques des monoglucosylporphyrines se présentent sous la forme de deux doublets et un singulet dans le cas du composé *para*-substitué **12b** et quatre doublets et deux singulets dans celui du composé *ortho* **12a**. Les protons alkyles (α–γ), également affectés par le changement de substitution, présentent un blindage significatif par rapport à la série *para* (tableau 2). Celui-ci augmente lorsque l'on s'éloigne du groupement *méso*-aryle ($\Delta\delta$ Hγ > $\Delta\delta$ Hβ > $\Delta\delta$ Hα). L'unité glycosyle en série *ortho* est également blindée par rapport à son analogue *para*. Si par exemple on compare les résultats des porphyrines glucosylées **12a** et **12b** on observe un blindage significatif de tous les protons osidiques et en particulier des protons H-1 ($\Delta\delta$ 2 ppm), H-5 ($\Delta\delta$ 2,66 ppm) et H-$6_{a,b}$ (1,32 < $\Delta\delta$ < 1,92 ppm). Les protons acétyles glycosidiques sont par contre moins affectés (0,1 < $\Delta\delta$ < 0,2). En série *ortho*, le remplacement du glucose acétylé par un autre glucide (ribose benzoylé, maltose ou lactose acétylé) transforme sensiblement certaines régions spectrales. Les figures des protons β pyrroliques et tolyles sont modifiées et, de plus, le blindage des protons glycosyloxypropyloxy est variable. En série *para*, de telles variations ne sont pas observées. Dans les dérivés *ortho*, la proximité de l'enchaînement propyloxyglycosyle du macrocycle porphyrinique engendre par compression stérique la déformation de celui-ci et l'inclusion de l'alkyloxyglycosyle dans la cavité qui en résulte. Cette situation permet d'expliquer le blindage des protons aliphatiques situés dans le cône d'anisotropie du macrocycle (23).

RMN ^{13}C

Pour confirmer les structures de ces nouvelles glycoporphyrines acétylées ou benzoylées nous avons également réalisé les spectres de RMN du ^{13}C. Les résultats sont rassemblés dans les tableaux 4 et 5. La discrimination entre certains carbones quaternaires éthyléniques et certains carbones tertiaires éthyléniques est basée sur l'utilisation de la séquence DEPT 135. Elles sont vérifiées dans le cas du composé **13b** par une expérience de couplage hétéronucléaire longue distance (COLOC). Les carbones primaires, secondaires et tertiaires sont confirmés grâce aux spectres 2D de corrélation hétéronucléaire directe ^{1}H–^{13}C (XHCORR). En série homologue polyglucosylées (composés **12b**, **19**, **21**, **22** et **23**) l'intégration relative des noyaux confirme les structures attendues. En série monoglycosylée, le changement de la nature de l'unité glucidique des composés *para*-substitués **12b**–**15b** ne modifie pas l'allure des spectres obtenus. Par contre par passage d'une substitution *para* à une substitution *ortho*, on retrouve les

Fig. 3. RMN ^{1}H des composés **12a** et **12b** dans $CDCl_3$: x = $CHCl_3$, y = HOD, z = hydrocarbures.



variations de déplacements chimiques observées en RMN ^{1}H. Les porphyrines **12a–15a** présentent toutes un blindage de l'unité glycosyloxypropyloxy qui augmente lorsqu'on s'éloigne des *méso*-substituants aryles. Ces variations s'accompagnent également de dédoublements des signaux C aryle et C tolyle, ce qui traduit une perte de symétrie de la molécule et donc une déformation du macrocycle porphyrinique.

Conclusion

Dans cet article, nous avons décrit la synthèse et la caractérisation d'une nouvelle classe de porphyrines glycosylées pour laquelle la ou les parties glucidiques sont séparées de la partie porphyrinique par l'intermédiaire d'un bras espaceur. Ces composés possèdent des propriétés amphiphiles différentes. Ils présentent sous leur forme déprotégées des solubilités dans l'eau qui varient avec le nombre et la taille des unités glucidiques fixées mais également avec l'orientation de la substitution. Une étude détaillée de spectroscopie RMN de ces composés sous leur forme protégée nous a permis de mettre en évidence, pour les dérivés *ortho*-substitués, l'existence d'un repliement de la partie osidique sur le macrocycle. Nous pensons qu'une telle conformation, si elle persiste après désacétylation, assure une protection du macrocycle et favorise sa

Les carbones benzoiques de **13a** sont enregistrés à δ ppm : 165,8 165,2 et 165,0 (3 × 1C, C-7), 133,2 (2C, C-4), 132,8 (1C, C-4), 129,7 (4C, C-2,6), 129,5 (2C, C-2,6) 129,0 et 129,2 (3C, C-1), 128,4, 128,3 128,1 (3 × 2C, C-3,5).

Les carbones benzoïques de **13b** sont enregistrés à δ ppm : 166,2 165,4 et 165,3 (3 × 1C, C-7), 134,4 (2C, C-4), 133,1 (1C, C-4), 129,6 (6C, C-2,6), 129,0 (3C, C-1), 128,5 128,4 128,2 (3 × 2C, C-3,5).

[a]Composé dont l'attribution des signaux est vérifiée par XHCORR.

[b]Composé dont l'attribution des signaux est vérifiée par COLOC.

[c]Les signaux correspondant aux C pyrroliques α et β se présentent sous la forme de figures élargies du fait de la tautomérie.

solubilisation dans l'eau. Des essais biologiques sont actuellement en cours afin de déterminer l'incorporation, la rétention et la phototoxicité vis à vis de lignées de cellules cancéreuses.

Partie expérimentale

Méthodes générales

Les spectres UV–visible sont réalisés sur un spectrophotomètre UV–visible à barrette de diodes Hewlett Packard 8452 A. Tous les spectres sont effectués dans des cellules en quartz de 1 ou 0,1 cm de trajet optique à une concentration de l'ordre de 10^{-6} M. Les pouvoirs rotatoires $[\alpha]_D$ sont mesurés à 22°C au polarimètre Jasco DIP-370 pour la raie D du sodium, dans une cuve de 1 dm de longueur. Les températures de fusion sont mesurées sur un banc Kofler ou en tube capillaire sur un appareil de Thomas Hoover et ne sont pas corrigées. Les spectres de RMN du proton et du carbone 13 sont réalisés en solution dans $CDCl_3$ sur un appareil Bruker AC-200 (200 MHz pour ^1H et 50 MHz pour ^{13}C). Les déplacements chimiques (δ) sont donnés en ppm par rapport au tétraméthylsilane (TMS). Les constantes de couplage J sont mesurées en hertz (Hz). Les spectres de masse par impact électronique (IE) sont effectués au Laboratoire départemental d'analyse de Limoges sur un appareil Shimadzu QP 100. Les spectres de masse SIMS (Secondary Ion Mass Spectrometry) et MALDI-TOF MS (Matrice Assisted Laser Desorption Ionisation Time of Flight Mass Spectrometry) sont réalisés au Laboratoire de chimie structurale organique et biologique de l'Université Pierre et Marie Curie. L'analyse élémentaire est réalisée au Service régional de microanalyse à l'Université Pierre et Marie Curie de Paris.

Réactifs et solvants

Tous les solvants ou réactifs de qualité RP proviennent de chez Aldrich, Prolabo ou Janssen. Le pyrrole est distillé sur CaH_2 sous pression réduite juste avant son utilisation. Le dichlorométhane est distillé sur P_2O_5 puis sur CaH_2; le carbonate de potassium est stocké à 120°C.

Chromatographie

Les chromatographies analytiques sur couche mince (CCM) sont réalisées sur plaques de gel de silice ($60F_{254}$ Merck). Les composés non colorés sont révélés sous irradiation UV et (ou) pulvérisation d'une solution de H_2SO_4 2 N suivie d'un chauffage à 150°C durant 2 min; le dipyrrométhane est révélé par exposition aux vapeurs de brome. Les chromatographies sur colonne sont réalisées sur silice (60AAC, 15–40 μm, Merck), sur polyamide (Macherey–Nagel) ou sur Sephadex LH20 (Pharmacia). Les éluants utilisés sont les suivants : toluène/acétate d'ethyle 95:5 (A), toluène/acétate d'éthyle 60:40 (B), toluène/acétone 98:2 (C), toluène/acétone 85:15 (D), toluène/acétone 80:20 (E), toluène/acétone 70:30 (F), toluène/acétone/méthanol 70:15:15 (G), toluène/éther de pétrole 80:20 (H), toluène/triéthylamine 99:1 (I), méthanol/$CHCl_3$/acétone 6:2:2 (J), CH_2Cl_2/éthanol 90:10 (K), CH_2Cl_2/éthanol 85:15 (L), CH_2Cl_2-éthanol 80:20 (M), CH_2Cl_2/éthanol/H_2O 4:6:2 (N), THF/H_2O 80:20 (O).

Synthèses

*5-[2-(3-Hydroxypropyloxyphényl)]-10,15,20-tritolylporphyrine (**11a**)*

Dans un ballon surmonté d'un réfrigérant, coiffé par une garde à $CaCl_2$, on introduit a l'abri de la lumière, 50 mg d'*ortho*-hydroxyphényltritolylporphyrine (**10a**) (0,07 mmol, 1 équiv.), 200 mg de carbonate de potassium (1,50 mmol, 20 équiv.) et 4 mL de DMF fraîchement distillé. À ce milieu hétérogène porté 15 min à 60°C, on ajoute 0,067 mL de 3-bromopropan-1-ol (0,74 mmol, 10 équiv.). L'ensemble est porté à léger reflux et la réaction est suivie par CCM. Après 2 h de réaction, le DMF est évaporé sous pression réduite. Le solide obtenu est dissous dans 10 mL de CH_2Cl_2 et la phase organique est lavée à l'eau distillée (3 × 10 mL), séchée sur sulfate de magnésium, filtrée, puis évaporée. Le mélange obtenu est purifié par chromatographie préparative sur plaques de gel de silice (éluant D). On isole ainsi 42 mg du composé **11a** (Rdt 80%). R_f 0,35 (éluant D). RMN ^1H, δ : 8,9 (s él., 8H, H β pyr.), 8,1 (d él., 6H, J = 7,2 Hz, H-2,6 Tol), 7,9 (d él., 1H, H-6 Ar), 7,7 (m, 1H, H-4 Ar), 7,5 (d, 2H, J = 7,2 Hz, H-3,5 Tol), 7,3 (m, 2H, H-3,5 Ar), 4.2 (t él., 2H, J = 6,0 Hz, H-α), 3,8 (t él., 2H, J = 6,0 Hz, H-γ), 2,7 (s, 9H, CH_3 Tol), 2, 1 (quint él., 2H, J = 6,0 Hz, H-β), –2,7 (s él., 2H, NH), UV–visible (tableau 1). SM (MALDI); *m/z* : 730, 8 $(M+H)^+$.

*5-[4-(3-Hydroxypropyloxyphényl)]-10,15,20-tritolylporphyrine (**11b**)*

Ce composé est synthétisé à partir de la *para*-hydroxyphényl-

[a]Les attributions des carbones osidiques des composés **19–23** sont réalisées par analogie avec celles des composés **12b** et **14b**. L'intégration relative de chacun des noyaux aryles par rapport aux tolyles confirme la structure attendue de ces composés.

[b]Les signaux correspondant aux C pyrroliques α et β se présentent sous la forme de figures élargies du fait de la tautomérie.

tritolylporphyrine selon la méthode décrite pour le composé **11a**. En partant des mêmes quantités, on isole après 1 h de réaction, traitement et purification 50 mg du composé **11b** (Rdt 95%). R_f 0,40 (éluant D). RMN ^{1}H, δ: 8,9 (s él., 8H, H β pyr.), 8,1 (d él., 6H, J = 7,2 Hz, H-2,6 Tol), 8,1 (d él., 2H, J = 7,2 Hz, H-2,6 Ar), 7,5 (d él., 6H, J = 7,2 Hz, H-3,5 Tol), 7,1 (d él., 2H, J = 7,2 Hz, H-3,5 Ar), 4.2 (t él., 2H, J = 6,0 Hz, H-α), 3,7 (t él., 2H, J = 6,0 Hz, H-γ), 2,7 (s, 9H, CH_3, Tol), 2,1 (quint. él., 2H, J = 6,0 Hz, H-β), –2,7 (s él., 2H, NH). UV–visible (tableau 1). SM (MALDI); m/z : 730, 8 $(M+H)^+$.

*2-(3-Hydroxypropyloxy)benzaldéhyde (**16a**)*

Dans un ballon surmonté d'un réfrigérant, et d'une garde à $CaCl_2$, on dissout 6,1 g d'*ortho*-hydroxybenzaldéhyde (50 mmol, 1 équiv.), en présence de 10,3 g de carbonate de potassium (1,5 équiv.) dans 30 mL de DMF. L'ensemble est porté 15 min à reflux puis 6 mL de 3-bromopropanol (1,5 équiv.) sont ajoutés au milieu. La réaction est poursuivie 8 h sous reflux. Le DMF est alors éliminé par évaporation sous vide et le résidu obtenu est dissous dans 50 mL de CH_2Cl_2, celui-ci est lavé par une solution de soude à 5% (3 × 100 mL), rincé par de l'eau distillée (2 × 100 mL) et séché sur sulfate de magnésium. Après filtration, le solvant est évaporé sous pression réduite et l'huile résultante est chromatographiée sur colonne de silice (éluant acétate d'éthyle/éther de pétrole 4:6 à 6:4). Après évaporation du solvant, on obtient 4,5 g du composé **16a** sous la forme d'une huile incolore (Rdt 50%). R_f 0,23 (éluant B). RMN ^{1}H, δ: 10,37 (s 1H, CHO), 7,79 (dd, 1H, J = 7,5; 1,8 Hz, H-6), 7,53 (ddd, 1H, J = 9,2; 7,5; 1,8 Hz, H-4), 7,03 (t él., 1H, J = 9,2 Hz, H-5), 7,00 (d, 1H, J = 8,4 Hz, H-3), 4.23 (t, 2H, J = 6,0 Hz, H-α), 3,89 (t, 1H, J = 5,8 Hz, H-γ), 2,11 (quint., 2H, J = 5,8 Hz, H-β). RMN ^{13}C; δ : 190,0 (CHO), 160,7 (C-2), 135,9 (C-6), 130,1 (C-4), 124,6 (C-1), 120,7 (C-5), 112,4 (C-3), 66,1 (C-α), 59,7 (C-γ), 31,6 (C-β). Analyse élémentaire calc. pour $C_{10}H_{12}O_3$ (180,20 g mol^{-1}): C 66,65; H 6,71; trouvée : C 66,37; H 6,63.

*4-(3-Hydroxypropyloxy)benzaldéhyde (**16b**)*

Les conditions opératoires sont les mêmes que celles décrite pour le composé **16a**. Après 4 h de reflux et purification on obtient 5,4 g du produit **16b** sous la forme d'une huile translucide (Rdt 60%). R_f 0,28 (éluant B). RMN ^{1}H; δ : 9,86 (s, 1H, CHO), 7,83 (d, 2H, J = 8,8 Hz, H-2,6), 7,00 (d, 2H, J = 8,8 Hz, H-3,5), 4.19 (t, 2H, J = 6,0 Hz, H-α), 3,86 (t, 2H, J = 5,8 Hz, H-γ), 2,07 (quint., 2H, J = 6,0 Hz, H-β). RMN ^{13}C; δ : 190,9 (CHO), 163,9 (C-4), 132,0 (C-2,6), 129,9 (C-1), 114,7 (C-3,5), 65,5 (C-α), 59,6 (C-γ), 31,6 (C-β). Analyse élémentaire calc. pour $C_{10}H_{12}O_3$ (180,20 g mol^{-1}) : C 66,65; H 6,71; trouvée : C 66,45; H 6,62.

Procédure générale de glycosylation des ortho- *et* para-*hydroxybenzaldéhydes*

Dans un bicol surmonté d'une garde à $CaCl_2$ contenant le glucide *per*acétylé (5,4 mmol, 1,2 équiv.) en solution dans 25 mL de dichlorométhane, on introduit sous courant d'argon et à 0°C, 0,7 mL de tétrachlorure d'étain (5,4 mmol, 1,2 équiv.). Après 15 min d'agitation, 0,8 g du composé **16a** ou **16b** (4,5 mmol, 1 équiv.) en solution dans 2 mL de CH_2Cl_2 sont ajoutés à ce mélange. La température du milieu est ramenée à température ambiante et la réaction est poursuivie durant 8 h. Le mélange réactionnel est alors neutralisé par addition d'une solution glacée, saturée en hydrogénocarbonate de sodium jusqu'à la neutralité. La phase organique est lavée par de l'eau distillée (3 × 20 mL), séchée sur sulfate de magnésium, filtrée puis évaporée sous vide.

*2-[3-(2,3,4,6-Tétra-*O*-acétyl-β-*D*-glucosyloxy)propyloxy)benzaldéhyde (**17a**)*

En partant de 2,1 g de 1,2,3,4,6-penta-*O*-acétyl β-D-glucopyranose on obtient après réaction et traitement, une huile qui est purifiée par chromatographie sur colonne de silice (éluant B). On isole ainsi 600 mg d'une huile incolore qui cristallise au bout de quelques jours à 4°C (Rdt 25%). F 40–45°C. R_f 0,41 (éluant B). $[\alpha]_D$ +7,40 (c 0,21, $CHCl_3$). RMN ^{1}H; δ : 9,50 (s, 1H, CHO), 7,82 (dd, 1H, J = 7,7; 1,8 Hz, H-6), 7,54 (ddd, 1H, J = 8,5; 7,5; 1,8 Hz, H-4), 7,02 (t él., 1H, J = 7,5 Hz, H-5), 6,97 (d él., 1H, J = 8,5 Hz, H-3), 5,19 (t, 1H, J = 9,3 Hz, H-3 Glc), 5,08 (t, 1H, J = 9,3 Hz, H-4 Glc), 4,98 (dd, 1H, J = 9,4; 7,8 Hz, H-2 Glc), 4,52 (d, 1H, J = 7,8 Hz, H-1 Glc), 4,24 (dd, 1H, J = 12,4; 4,8 Hz, H-6_a Glc), 4,15 (m, 1H, H-6_b Glc), 4.15 (m, 2H, H-α), 4,07 (m, 1H, H-γ_a), 3,76 (m, 1H, H-γ_b), 3,72 (m, 1H, H-5 Glc), 2, 10 (m, 2H, H-β); quatre singulets à 2,07 (3H), 2,02 (3H), 1,99 (3H), 1,89 (3H) (CH_3CO). RMN^{13} C; δ : 189,5 (CHO), 170,6, 170,2, 169,4, 169,2 (4, C, CH_3**CO**), 161,3 (C-2), 135,9 (C-4), 128,5 (C-6), 124,9 (C-1), 120,8 (C-5), 112,5 (C-3), 100,9 (C-1 Glc), 72,7 (C-5 Glc), 71,6 (C-3 Glc), 71,3 (C-2), 68,4 (C-4), 66,1 (C-γ), 64,5 (C-α), 61,7 (C-6 Glc), 29,3 (C-β); 20,5 (4C, **CH$_3$**CO). Analyse élémentaire calc. pour $C_{24}H_{30}O_{12}$ (510,49 g mol^{-1}) : C 56,46; H 5,92; trouvée : C 56,39; H 6,01.

*4-[3-(2,3,4,6-Tétra-*O*-acétyl-β-*D*-glucosyloxy)propyloxy)benzaldéhyde (**17b**)*

Ce composé est synthétisé à partir du dérivé **16b**. On isole après réaction et purification par recristallisation dans un mélange diéthyléther/éther de pétrole (4:1), 800 mg de cristaux blancs (Rdt 35%). F 120–122°C. R_f 0,42 (éluant B). $[\alpha]_D$ -6,87 (c 4,5; $CHCl_3$). Synthèse des porphyrines monoglycosylées

Voie A (schéma 1)

*Procédure générale de glycosylation des 5-(hydroxypropyl-oxyphényl)-10,15,20-tritolylporphyrines (**12a,b–15a,b**)*

En milieu rigoureusement anhydre, sous argon, dans un bicol surmonté d'un réfrigérant, le glucide acétylé ou benzoylé est mis en solution dans 10 mL de CH_2Cl_2. À cette solution refroidie à 0°C, on introduit le tétrachlorure d'étain. Après 15 min d'agitation, le composé **11a** ou **11b** en solution dans 2 mL de CH_2Cl_2 sec est ajouté au milieu. La réaction controlée par CCM est alors poursuivie à température ambiante. En fin de période de réaction, le milieu est neutralisé par addition d'une solution glacée saturée en hydrogénocarbonate de sodium. La phase organique est extraite par le dichlorométhane (2 × 15 mL), lavée à l'eau distillée (3 × 15 mL) puis séchée sur sulfate de magnésium. Après filtration, le solvant est évaporé et résidu est chromatographié.

*5-[2-[3-(2,3,4,6-Tétra-*O*-acétyl-β-D-glucosyloxy)propyl-oxy)]-10,15,20-tritolylporphyrine (**12a**)*

En partant de 40 mg de **11a** (0,054 mmol, 1 équiv.), 110 mg de 1,2,3,4,6-penta-*O*-acétyl β-D-glucopyranose (0,27 mmol, 5 équiv.) et 0,025 mL de tétrachlorure d'étain (0,27 mmol, 5 équiv.), on obtient après 18 h de réaction, traitement et purification sur plaques de gel de silice (éluant D) 20 mg du composé **12a** (Rdt 35%). R_f 0,67 (éluant D). RMN ^1H (tableau 2). RMN ^{13}C (tableau 4). UV–visible (tableau 1). SM (SIMS); m/z : 1063,1 $(M + H)^+$, 672,8 $[M - (CH_2)_3\text{-O-GlcAc}]^+$.

*5-[4-[3-(2,3,4,6-Tétra-*O*-acétyl-β-D-glucosyloxy)propyl-oxy)]phényl]-10,15,20-tritolylporphyrine (**12b**)*

En partant de 30 mg de **11b** (0,04 mmol, 1 équiv.), 80 mg de 1,2,3,4,6-penta-*O*-acétyl β-D-glucopyranose (0,20 mmol, 5 équiv.) et 0,023 mL de tétrachlorure d'étain (0,20 mmol, 5 équiv.), on obtient après 2 h de réaction, traitement et purification sur plaques de gel de silice (éluant D) 25 mg du composé **12b** (Rdt 60%). R_f 0,55 (éluant D). RMN ^1H (tableau 2). RMN ^{13}C (tableau 4). UV–visible (tableau 1). SM (SIMS); m/z : 1063,1 $(M + H)^+$, 672,8 $[M - (CH_2)_3\text{-O-GlcAc}]^+$.

*5-[2-[3-(2,3,5-Tri-*O*-benzoyl-β-D-ribosyloxy)propyl-oxy)]phényl]-10,15,20-tritolylporphyrine (**13a**)*

O-Acétyl-2,3,5 tribenzoate-β-D-ribofuranose (100 mg, 0,20 mmol, 5 équiv.) et 30 mg de composé **11a** (0,04 mmol, 1 équiv.) sont mis à réagir en présence de 0,025 mL de $SnCl_4$ (0,20 mmol, 5 équiv.). Après 16 h de réaction, on isole par traitement puis par chromatographie sur plaques de silice (éluant A) 27 mg du composé **13a** (Rdt 60%). R_f 0,75 (éluant A.). RMN ^1H (tableau 2). RMN ^{13}C (tableau 4). UV–visible (tableau 1). SM (SIMS); m/z : 1175,9 (M^+), 672,8 $[M - (CH_2)_3\text{-O-RbBz}]^+$.

*5-[4-[3-(2,3,5-Tri-*O*-benzoyl-β-D-ribosyloxy)propyl-oxy)]phényl]-10,15,20-tritolylporphyrine (**13b**)*

Le composé **13b** est synthétisé à partir de **11b**. En partant des mêmes quantités que celle utilisées pour **13a**, on isole après 2 h de réaction, traitement et purification sur plaques de gel de silice 35 mg du composé désiré (Rdt 75%). Ce composé se dégradant partiellement sur silice nous en avons repurifié 25 mg par chromatographie moyenne pression sur polyamide (éluant H) afin d'obtenir un échantillon analytique. R_f 0,60 (éluant A). RMN ^1H (tableau 2). RMN ^{13}C (tableau 4). UV–visible (tableau 1). SM (SIMS); m/z : 1176,2 $(M + H)^+$, 672,8 $[M - (CH_2)_3\text{-O-RbBz}]^+$.

*5-[2-[3-(2,3,6,2,3,4,5,6-Hepta-*O*-acétyl-β-D-maltosyl-oxy)propyloxy)]phényl]-10,15,20-tritolylporphyrine (**14a**)*

En partant de 50 mg de **11a** (0,06 mmol, 1 équiv.), 200 mg de β-D-maltose *per*acétate (0,30 mmol, 5 équiv.) en présence de 0,045 mL de tétrachlorure d'étain (0,30 mmol, 5 équiv.), on isole après 24 h de réaction, traitement et purification sur plaques de gel de silice (éluant E) 20 mg d'un mélange de deux porphyrines glucosylées difficilement séparables. Afin d'obtenir un échantillon analytique nous avons chromatographié ce mélange sur plaques de silice par cinq migrations successives (éluant C). On isole ainsi 10 mg de **14a** (Rdt 12%) et 5 mg d'impureté non identifiée. R_f 0,54 (éluant E). RMN ^1H (tableau 2). RMN ^{13}C (tableau 4). UV–visible (tableau 1). SM (SIMS); m/z : 1350,4 $(M+M)^+$, 672,8 $[M - (CH_2)_3\text{-O-MalAc}]^+$.

*5-[4-[3-(2,3,6,2,3,4,5,6-Hepta-*O*-acétyl-β-D-maltosyl-oxy)propyloxy)]phényl]-10,15,20-tritolylporphyrine (**14b**)*

Ce composé est synthétisé à partir de **11b**. En partant des mêmes quantités que celles utilisées pour **14a**, on obtient après 6 h de réaction, traitement et purification sur plaques de gel de silice (éluant E) 30 mg du composé **14b** (Rdt 38%). R_f 0,54 (éluant E). RMN ^1H (tableau 2). RMN ^{13}C (tableau 4). UV–visible (tableau 1). SM (SIMS); m/z : 1350,4 $(M+M)^+$, 672,8 $[M - (CH_2)_3\text{-O-MalAc}]^+$.

*5-[2-[3-(2,3,6,2,3,4,5,6-Hepta-*O*-acétyl-β-D-lactosyloxy)propyloxy)]phényl]-10,15,20-tritolylporphyrine (**15a**)*

β-D-Lactose *per*acétate (200 mg, 0,30 mmol, 5 équiv.) additionné à 50 mg de composé **11a** (0,06 mmol, 1 equiv.) en présence de 0,035 mL de $SnCl_4$ (0,30 mmol, 5 équiv.) donnent après 24 h de réaction, traitement puis purification sur plaques de gel silice (éluant E) 17 mg du composé **15a** (Rdt 21%). R_f

0,54 (éluant E). RMN ^{1}H (tableau 2). RMN ^{13}C (tableau 4). UV–visible (tableau 1). SM (SIMS); *m/z* : 1350,4 $(M+H)^+$, 672,8 $(M - (CH_2)_3\text{-O-LacAc})^+$.

*5-[4-[3-(2,3,6,2,3,4,5,6-Hepta-*O*-acétyl-*β*-D-lactosyloxy)propyloxy)]phényl]-10,15,20-tritolylporphyrine (**15b**)*

La synthèse du composé **15b** est réalisée à partir du composé **11b**. En partant des quantités utilisées pour **15a** on obtient après 6 h de réaction, traitement et purification sur plaques de gel de silice (éluant E) 34 mg du composé **15b** (Rdt 42%). R_f 0,50 (éluant E). RMN ^{1}C (tableau 2). RMN ^{13}C (tableau 4). UV–visible (tableau 1). SM (SIMS); *m/z* : 1350,4 $(M+H)^+$, 672,8 $(M - (CH_2)_3\text{-O-LacAc})^+$.

Voie B (schéma 2)

Méthode générale

Dans un bicol surmonté d'un réfrigérant et d'une garde à $CaCl_2$, le précurseur glycosylé **17a,b** ou **18b** et le *para*-tolualdéhyde sont dissous dans l'acide propionique. Le mélange est porté à léger reflux et le pyrrole est ajouté à l'aide d'une seringue. La réaction est alors poursuivie durant 45 min à reflux. Après refroidissement du milieu, l'acide propionique est éliminé par évaporation à la pompe à palette. Le solide noir obtenu est fractionné par passage sur colonne de silice (2.5 cm × 20 cm, éluant CH_2Cl_2/EtOH 100/0 à 97/3). Le premier produit élué, la tétratolylporphyrine, est suivie dans l'ordre par la porphyrine monoglycosylée, les diglycosylporphyrines, la triglucosylporphyrine puis finalement par le tétraglucosylporphyrine. Les deux dernières porphyrines sont mal séparées, elles sont accompagnées de goudrons. Les proportions de chacun des composés sont fonction des proportions des réactifs employés. Dans chaque cas, les porphyrines brutes sont soumises à une purification ultérieure.

*5-[2-[3-(2,3,4,6-Tétra-*O*-acétyl-*β*-D-glucosyloxy)propyloxy)]phényl]-10,15,20-tritolylporphyrine (**12a**)*

Par réaction de 115 mg de *para*-tolualdéhyde (1,2 mmol, 3 équiv.), 160 mg de précurseur glycosylé **17a** (0,4 mmol, 1 équiv.) et 0,090 mL de pyrrole (1.6 mmol, 4 équiv.) en solution dans 25 mL d'acide propionique, on isole après fractionnement puis purification sur plaques de gel de silice (éluant D) 32 mg du composé **12a** (Rdt 8%).

*5-[4-[3-(2,3,4,6-Tétra-*O*-acétyl-*β*-D-glucosyloxy)propyloxy)]phényl]-10,15,20-tritolylporphyrine (**12b**)*

Le composé **12b** est synthétisé à partir du précurseur **17b**. En partant des mêmes quantités que celles employées pour **12a**, on isole après fractionnement et chromatographie sur plaques de gel de silice 36 mg du composé désiré (Rdt 9%).

*Méthode générale de synthèse des tétraglycosylporphrines (**19**, **20**)*

À l'obscurité, dans un bicol muni d'un réfrigérant et d'une garde à $CaCl_2$, 0,035 mL de pyrrole (0,5 mmol, 1 équiv.) et 0,5 mmol de précurseur **17b** ou **18b** (1 equiv.) sont dissous sous courant d'argon dans 50 mL de CH_2Cl_2. Ce mélange est agité pendant 15 min à température ambiante puis 0,040 mL d'acide trifluoroacétique (0,5 mmol, 1 équiv.) sont ajoutés au milieu. La réaction est poursuivie sous agitation durant 1–4 h. Au terme de la réaction, 90 mg de *p*-chloranile (0,38 mmol) sont alors ajoutés au milieu et l'ensemble est porté à léger reflux durant 1 h. Le solvant est évaporé sous vide et le résidu obtenu est purifié par passage sur colonne de silice (12 cm × 2 cm, éluant CH_2Cl_2/éthanol 100:0 à 95:5) puis par chromatographie sur plaques de gel de silice (éluant G).

*5,10,15,20-Tétra[4-[3-(2,3,4,6-Tétra-*O*-acétyl-*β*-D-glucosyloxy)propyloxy)]phénylporphyrine (**19**)*

À partir de 250 mg de composé **17b** (0,5 mmol, 1 équiv.) et 0,035 mL de pyrrole (0,5 mmol, 1 équiv.) on isole après 1 h de réaction et oxydation, 100 mg du composé **19** (Rdt 36%). R_f 0,46 (éluant G). RMN ^{1}H (tableau 3). RMN ^{13}C (tableau 5). UV–visible (tableau 1). SM (MALDI); *m/z* : 2232 $(M + H)^+$.

*5,10,15,20-Tétra[4-[3-(2,3,4,6-Tétra-*O*-acétyl-*β*-D-maltosyloxy)propyloxy)]phényl]porphyrine (**20**)*

À partir de 400 mg de composé **18b** (0,5 mmol, 1 équiv.) et 0,035 mL de pyrrole (0,5 mmol, 1 équiv.) on isole après 4 h de réaction puis oxydation, 70 mg du composé **20** (Rdt 16%). R_f 0,55 (éluant G). RMN ^{1}H (tableau 3). RMN ^{13}C (tableau 5). UV–visible (tableau 1). MS (MALDI); *m/z* : 3386 $(M+H)^+$.

*Poly-[(2,3,4,6-tétra-*O*-acétyl)glycosyloxypropyloxy]tolylporphyrine (**21**, **22**, **23**)*

Par réaction de 1,0 g de précurseur glycosylé **17b** (2,0 mmol, 3 équiv.), 80 mg de para-tolualdéhyde (0,65 mmol, 1 équiv.) et 0,175 mL de pyrrole (2,65 mmol, 4 équiv.) en solution dans 25 mL d'acide propionique on obtient après fractionnement la mono (**12b**), les di- (**22**, **23**) et la triglucosylporphyrine (**21**). Chacune de ces porphyrines est alors purifiée par chromatographie. Les composés **22** et **23** sont séparées par une triple élution sur plaque de silice (éluant D). Le composé **21** est purifié par passages successifs sur colonne de polyamide (éluant H) puis sur colonne de Sephadex LH20 (éluant J) et **12b** est isolé comme précédemment. On récupère ainsi 20 mg de **12b** (Rdt 2,8%), 2 × 7 mg de **22** et **23** (Rdt 1,5%), 36 mg de **21** (Rdt 3,0%). **21**: R_f 0,36 (éluant F). RMN ^{1}H (tableau 3). RMN ^{13}C (tableau 5). UV–visible (tableau 1). MS (MALDI); m/z : 1841 $(M+H)^+$.

Voie C (schéma 3)

méso-*(p-Tolyl)dipyrrométhane (**24**)*

Dans un ballon, 0,5 mL de *para*-tolualdéhyde (4,1 mmol, 1 équiv.) sont mélangés à 11,2 mL de pyrrole (0,16 mol, 40 équiv.). À cette solution, dégazée par barbotage d'argon durant 10 min, on ajoute 0,032 mL d'acide trifluoroacétique (0,4 mmol, 0,1 équiv.). Le mélange est agité 15 min à température ambiante jusqu'à disparition totale de l'aldéhyde. Il est ensuite dilué par addition de 50 mL de dichlorométhane, neutralisé par une solution aqueuse d'hydroxyde de sodium 0,1 N, rincé à l'eau distillée puis séché sur sulfate de magnésium. Après évaporation du pyrrole à température ambiante, le produit est porté sous vide (1 Torr (133.3 Pa)) durant 1 h. On obtient ainsi un solide brunâtre qui est chromatographié sur colonne de silice (éluant I). Après évaporation du solvant on récupère 650 mg de solide verdâtre (Rdt 66%). *F* 114°C (litt. (19) *F* 111–112°C). R_f 0,24 (éluant I). IR (KBr) ν (cm^{-1}) : 3415 (N-H), 1690, 1640 (C—O). Analyse élémentaire calc. : pour $C_{16}H_{16}N_2$ (236,13 g mol) : C 81,38; H 6,83; N 11,86; trouvé : C 81, 53; H 6,82; N 12,17.

5,10-Bis[(2,3,4,6-tétra-O-*acétyl)glyosyloxypropyloxy]-15,20-ditolylporphyrine* (**22**, *et 5,15-bis[(2,3,4,6-tétra*-O-*acétyl)glyosyloxypropyloxy]-10,20-ditolylporphyrine* (**23**)

Dans un ballon 130 mg de précurseur glycosidique **17b** (0,25 mmol, 1 équiv.) et 60 mg de dipyrrométhane **24** (0,25 mmol, 1 équiv.) sont mis en solution dans 25 mL de CH_2Cl_2. À ce milieu protégé de la lumière et purgé 15 min par barbotage d'argon, on ajoute 0,033 mL d'une solution 2,5 M de $BF_3{\cdot}Et_2O$. Après 10 min d'agitation, 50 mg de *p*-chloranile (0,2 mmol) sont additionnés au milieu et la réaction est poursuivie à température ambiante durant 1 h 30. Le solvant est évaporé sous vide et la résidu obtenu est fractionné par chromatographie sur colonne de silice (éluant CH_2Cl_2/éthanol 100:0 à 98:2). Après évaporation des différentes fractions, on récupère 20 mg de monoglycosylporphyrine (16%), 30 mg du mélange des diglycosylporphyrines et 5 mg de la triglycosylporphyrine. Le mélange des deux isomères de la diglucosylporphyrine est séparé par chromatographie sur plaques de gel de silice par une triple élution (éluant C). Le composé **22** substitué sur les carbones *méso*-adjacents (*cis*) est le plus retenu. On isole ainsi 9 mg du composé **22** (Rdt 5%) et 16 mg du composé **23** (Rdt 9%). **22** : R_f 0,43 (éluant E). RMN ^1H (tableau 3). RMN ^{13}C (tableau 5). UV–visible (tableau 1). SM (MALDI); *m/z* : 1453 $(M+H)^+$. **23** : R_f 0,46 (éluant E). RMN ^1H (tableau 3). RMN ^{13}C (tableau 5). UV–visible (tableau 1). SM (MALDI); *m/z* : 1453 $(M+H)^+$.

Procédure générale de déprotection

À 25 mg de porphyrine en solution dans 1 mL de CH_2Cl_2/MeOH (80:20), on ajoute 1,5 équivalent de méthylate de sodium (solution 1 M dans le méthanol) par groupement protecteur acétylé ou benzoylé. Le milieu réactionnel est agité à température ambiante durant 1 h puis la porphyrine est précipitée par addition d'éther de pétrole. Après filtration, lavage à l'éther de pétrole, la porphyrine isolée est purifiée par chromatographie sur colonne de Sephadex LH20 (éluant O).

Energétique des liaisons inter et intramoléculaires dans les trois isomères de l'aminophénol

Raphaël Sabbah et Meriem Gouali

Résumé : Le présent travail porte sur l'étude thermodynamique des trois isomères de l'aminophénol de formule générale : C_6H_7NO. Il a été réalisé en utilisant quatre techniques : la calorimétrie de combustion de faibles quantités de substance (quelques milligrammes par essai), la calorimétrie de sublimation, l'analyse thermique différentielle et la mesure de capacités calorifiques. Cette étude nous a permis : de déterminer les enthalpies de combustion, de sublimation et de fusion de ces composés; de préciser la stabilité relative des trois isomères; de déterminer les énergies de conjugaison expérimentales et de les comparer aux valeurs théoriques; de déterminer qualitativement et quantitativement les interactions intermoléculaires; de déterminer les enthalpies d'atomisation des trois composés et de vérifier qu'elles sont compatibles aux valeurs calculées à partir des contributions énergétiques précédemment déterminées au laboratoire; de discuter de l'existence d'une liaison hydrogène intramoléculaire dans l'isomère *ortho*.

Mots clés : thermodynamique; thermochimie; calorimétrie; analyse thermique différentielle; 2-aminophénol ou *ortho*-aminophénol; 3-aminophénol ou *méta*-aminophénol; 4-aminophénol ou *para*-aminophénol; enthalpie de combustion, de sublimation, de fusion, d'atomisation, enthalpies des liaisons inter et intramoléculaires; liaison hydrogène; énergie de conjugaison; température du point triple.

Abstract: The present work is concerned with a thermodynamic study of the three aminophenol isomers (general formula: C_6H_7NO). It was achieved using four techniques: combustion calorimetry of small amounts of substance (a few milligrams), sublimation calorimetry, differential thermal analysis, and heat capacity measurements. From this study, it was possible: to determine the enthalpies of combustion, sublimation, and fusion of these compounds; to discuss the relative stability of the three molecules; to determine the intermolecular enthalpy bonds; to determine the experimental resonance energies and to compare them with the theoretical values; to determine the atomization enthalpies and to compare them with the values calculated from the energetical contributions previously determined in our laboratory; to consider the existence of an intramolecular hydrogen bond in the *ortho* isomer.

Key words: thermodynamics; thermochemistry; calorimetry; differential thermal analysis; 2-aminophenol or *ortho*-aminophenol; 3-aminophenol or *meta*-aminophenol; 4-aminophenol or *para*-aminophenol; enthalpy of combustion, of sublimation, of fusion, of atomization, enthalpy of inter and intramolecular bonds; hydrogen bond; resonance energy; triple point temperature.

I. Introduction

Les aminophénols possèdent de nombreuses applications industrielles. Ils servent à la coloration des fourrures et le 4-aminophénol est utilisé comme révélateur photographique et comme intermédiaire dans la synthèse du paracétamol. Le 2-aminophénol est utilisé dans la fabrication d'un insecticide : le phosalone (1).

Très peu d'études thermodynamiques ont été réalisées sur les aminophénols. La plus récente concerne les travaux de Nuñez et al; elle a constitué pratiquement la seule référence pour la plupart des résultats de notre étude (2).

Ce travail a pour but de mettre en évidence le lien existant entre les grandeurs énergétiques et la structure des aminophénols, d'interpréter et de discuter l'importance relative des forces de cohésion cristalline. Il trouve ses applications dans l'industrie mais également dans l'environnement avec les problèmes liés à l'élimination et au stockage des déchets.

Reçu le 31 octobre, 1995.

II. Partie expérimentale

II.1. Produits utilisés

Les trois substances étudiées sont des produits Aldrich de pureté supérieure ou égale à 98%, repurifiées par trois sublimations successives sous une pression résiduelle de 1,3 Pa à 373 K pour le 3-aminophénol et le 4-aminophénol. Le 2-aminophénol a été préalablement recristallisé dans du méthanol absolu avant de subir le même traitement que les deux autres isomères (2).

À l'état pur, les aminophénols sont incolores. Exposés à l'air, ils s'oxydent en brunissant. Nous avons pu vérifier que la lumière est responsable de cette oxydation et que l'humidité est un facteur secondaire favorisant ce phénomène. Ce sont des substances instables qui se décomposent souvent à des températures inférieures à leur point de fusion. C'est pourquoi, après leur purification, nous les avons stockées dans des flacons en verre brun, maintenus sous vide dans un dessiccateur en présence de soude.

La réactivité des aminophénols avec l'oxygène a été étudiée en fonction de divers paramètres dans les références 3, 4, et 5. Dans sa thèse (6), Perrin étudie les phénols d'une façon plus générale et montre que ces composés, à l'état pur et maintenus dans l'obscurité, ne se colorent pas à l'air et n'absorbent pas d'oxygène. Nous avons pu vérifier cette propriété avec les aminophénols.

Ce sont également des substances nocives par inhalation, par contact avec la peau et par ingestion. Leur toxicité a fait l'objet de quelques études (7, 8). C'est pourquoi, nous avons travaillé sous hotte en nous munissant de masque et de gants toutes les fois qu'il s'agissait de manipuler d'importantes quantités de produits pendant des temps relativement longs.

II.2. Appareillages, techniques et modes opératoires

II.2.1. Analyse thermique différentielle

Nous avons utilisé la version moyenne température de l'analyseur thermique différentiel et les cellules expérimentales en verre décrites dans la référence 9.

Dans toutes nos expériences: (*i*) la vitesse de montée en température du four a été de 0,2 K min^{-1}; (*ii*) la masse de substance utilisée a été d'environ 100 mg, déterminée par double pesée à l'aide d'une balance Mettler, type M5, sensible au μg et dont l'inexactitude des pesées est de ±2 μg; (*iii*) la préparation des échantillons et leur mise en container ont été conduites de la façon décrite dans la référence 9.

La mesure des températures a été faite à l'aide de deux thermocouples (thermocoax, type 2ABI 15), l'un est solidaire de l'échantillon, l'autre de la référence (alumine-α). La différence entre les fem délivrées par ces deux thermocouples est amplifiée par un microvoltmètre AOIP, type EVA, sensibilité 300 μV pleine échelle. Le signal ainsi amplifié est envoyé simutanément à un enregistreur Sefram, type Gépérac, pour le visualiser, et à un multimètre Keithley, modèle 175, pour le digitaliser. Un autre multimètre Keithley modèle 196, sensibilité 300 μV (résolution 100 nV) est utilisé pour mesurer la fem correspondant à la température de l'échantillon. Les données issues de ces deux multimètres sont envoyées vers un ordinateur en vue de leur traitement à l'aide d'un programme écrit et mis au point au laboratoire. En appliquant l'équation de Clausius-Clapeyron à l'équilibre solide ⇔ liquide et la loi de Raoult, ce programme permet de déterminer la pureté de l'échantillon, son enthalpie de fusion ainsi que la température de son point triple.

Comme indiqué dans la référence 9, l'étalonnage (*i*) en température de notre analyseur thermique a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque, diphénylacétique et anisique, de carbazole et d'anthraquinone, dont la température de leur point triple est bien connue dans la littérature; celle-ci est comprise entre 353 et 558 K; (*ii*) en énergie a été réalisé à partir d'échantillons rigoureusement purs de naphtalène, de fluorène, d'acides benzoïque et diphénylacétique, dont l'enthalpie de fusion est bien connue dans la littérature.

II.2.2. Calorimétrie de combustion

Les enthalpies de combustion de nos composés ont été déterminées en utilisant un calorimètre monopile basculant CRMT (sensibilité : 0,0623 V W^{-1}) équipé d'une microbombe en acier inoxydable (Superimphy 625) de volume interne égal à 42 cm^3 à la température ambiante.

Le signal issu du calorimètre est amplifié par un microvoltmètre électronique AOIP, modèle EVA, sensibilité 30 mV pleine échelle, avant son envoi simultané sur un intégrateur éléctronique, conçu, réalisé et mis au point au laboratoire, qui détermine l'aire des thermogrammes $dQ/dt=f(t)$ et sur un enregistreur potentiométrique (Sefram, modèle Servotrace) qui le visualise.

La rotation du calorimètre suivant plusieurs plans permet à toutes les génératrices de la bombe d'être lavées par l'eau déminéralisée placée en son fond (1 cm^3).

Comme indiqué dans la référence 10, les substances à étudier sont mises sous forme de pastilles. À cet effet, nous avons utilisé un ensemble piston-moule façonné dans un acier trempé, ce qui a pour effet d'éviter l'entraînement dans les pastilles de traces de métal et d'augmenter ainsi la qualité des résultats.

Les pesées ont été effectuées sur une microbalance Mettler, modèle UM3, équipée d'un jeu de poids étalonnés par le N.I.S.T. Sa portée est de 3 g et sa sensibilité de 0,1 μg. L'erreur commise avec cette balance sur une pesée de quelques milligrammes est de l'ordre de ±0,2 μg. Dans toutes nos pesées, nous avons tenu compte des corrections de poussée de l'air pour calculer les masses réelles.

Une fois garnie, la bombe est remplie d'oxygène sous une pression de 3,04 MPa. L'oxygène utilisé à cet effet, provient de l'Air Liquide et son degré de pureté est supérieur à 99,995% (fraction molaire d'azote < 10^{-5}). La durée d'une expérience a toujours été de 120 min à partir du moment de la mise de feu.

Après chaque expérience, nous avons déterminé, dans la phase aqueuse, les concentrations d'acide nitrique par titrage acido-basique en présence de phénolphtaléine avec une solution de soude préalablement titrée à l'aide d'une solution d'acide oxalique de concentration connue; et vérifié, à l'aide des tubes de Dräger, l'absence d'oxyde de carbone et d'oxydes d'azote (NO, NO_2) dans la phase gazeuse.

Des tests préliminaires ont été effectués dans le but de déterminer les meilleures conditions expérimentales. Afin de mettre en évidence, dans ces conditions, l'oxydation éventuelle de nos substances sous 3,04 MPa d'oxygène, des pastilles de chacun des trois isomères ont été placées dans la bombe et abandonnées pendant 1,5 h (temps nécessaire pour atteindre l'équilibre thermique dans nos expériences). Nous avons ainsi pu vérifier que : (*i*) l'aspect de nos pastilles restait inchangé (pas de coloration jaune, violette ou brune caractéristique de l'oxydation à l'air de nos substances); (*ii*) la masse avant et après chaque expérience restait invariable.

Nous en avons conclu qu'il n'y avait pas d'oxydation de la substance restée à l'abri de la lumière ou de réaction détectable dans nos conditions expérimentales, ce qui confirme les conclusions de Perrin (6).

II.2.3. Calorimétrie de sublimation

Nous avons utilisé un calorimètre Tian-Calvet (sensibilité 0,0185 V W^{-1}) associé à un montage différentiel doté de cellules d'effusion de Knudsen pour déterminer les enthalpies de sublimation de nos composés. L'étalonnage de notre système calorimétrique a été réalisé par effet Joule avant et après chaque série d'expériences. Le mode opératoire a été décrit dans la référence 11. Précisons que :

le signal issu du calorimètre est amplifié par un nanovoltmètre Keithley modèle 147, sensibilité 30 μV pleine échelle,

Tableau 1. Grandeurs physiques à 298,15 K des substances étudiées.

Substance	Formule brute	M^a (mol g^{-1})	ρ (g cm^3)	$-(\delta U/\delta P)_T$ (J g^{-1} MPa^{-1})
Acide benzoïque	$C_7H_6O_2$	122,1234	1,32 (14)	0,12
Coton	$CH_{1,791}O_{0,850}$	27,4157	1,50 (14)	0,29
2-Aminophénol	C_6H_7NO	109,1277	1,328 (2)	0,1 (2)
3-Aminophénol	C_6H_7NO	109,1277	1,328 (2)	0,1 (2)
4-Aminophénol	C_6H_7NO	109,1277	1,328 (2)	0,1 (2)

[a]Calculées à partir du tableau des masses atomiques de 1993 (13).

Tableau 2. Degrés de pureté, températures du point triple et enthalpies de fusion des aminophénols.

	Pureté (mol%)	$T^a_{p.t.}$ (K)	$\Delta_{fus}H_m$ (kJ mol^{-1})
2-Aminophénol	99,96 ± 0,01	449,23 ± 0,02	25,4 ± 0,5
3-Aminophénol	99,95 ± 0,01	394,83 ± 0,02	19,6 ± 1,4
4-Aminophénol	99,81 ± 0,03	462,50 ± 0,12	26 ± 2

[a]Définies par rapport à l'échelle EIT-90 (15).

puis digitalisé par un multimètre numérique Keithley modèle 175 et enregistré sur un enregistreur potentiométrique, Sefram, modèle Servotrace;

le diamètre des trous d'effusion pratiqués dans des joints en Téflon de 0,2 mm d'épaisseur est de 0,7, 0,8 et 1,5 ou 2 mm, respectivement, dans le cas du 2-aminophénol, 3-aminophénol et 4-aminophénol;

l'ouverture et la fermeture de l'orifice d'effusion des cellules sont pilotées par l'ordinateur;

toutes les pesées ont été effectuées à l'aide d'une balance Mettler, type UM3.

L'acquisition et le traitement des données sont réalisés à l'aide d'un ordinateur et d'un programme conçu et mis au point au laboratoire. Il permet, entre autres, de déterminer l'aire des thermogrammes et, à partir du coefficient d'étalonnage, l'enthalpie de sublimation de nos composés à la température de l'expérience $\Delta_{sub}H_m(T)$.

Des tests préliminaires sont nécessaires pour la détermination des conditions expérimentales précisées ci-dessus et dans le tableau 6: diamètre du trou d'effusion, température du calorimètre, sensibilité de l'amplificateur Keithley, quantité de substance à utiliser.

La faible pression de vapeur saturante de nos composés à 298,15 K nous a obligés à travailler entre 332 et 337 K. De plus, nous avons admis l'identité :

$$\Delta_{sub}H_m(T) \equiv \Delta_{sub}H^\circ_m(T)$$

II.2.4. Mesure des capacités calorifiques

Pour calculer $\Delta_{sub}H^\circ_m$ (298,15 K) à partir de $\Delta_{sub}H^\circ_m$ (T), il est nécessaire de connaître :

le comportement thermique de nos substances entre 298,15 K et T. Nous nous sommes donc assurés que nos substances ne présentaient aucun changement de phase dans cet intervalle;

la capacité calorifique à pression constante des phases condensée et gazeuse des substances étudiées à 298,15 K et T de façon à pouvoir appliquer la relation suivante :

$$\Delta_{sub}H_m^\circ(298{,}15\ \text{K}) = \Delta_{sub}H^\circ_m(T) + \int_T^{298{,}15\ \text{K}} [C^\circ_{p,m}(g) - C^\circ_{p,m}(s)]\, dT$$

La différence enthalpique $H^\circ_m(T) - H^\circ_m(298{,}15\ \text{K})$ à l'état solide a été déterminée par la méthode de chute à l'aide d'un calorimètre Tian-Calvet et d'un four maintenus respectivement à 298,15 K et T. Le calorimètre a été préalablement étalonné en utilisant des échantillons d'alumine-α.

Quant aux valeurs des capacités calorifiques à l'état gazeux $C^\circ_{p,m}(g)$ aux températures 298,15 K et T, elles ont été déterminées à partir d'une méthode incrémentale en utilisant les capacités calorifiques à l'état gazeux des molécules de benzène, de phénol et d'aniline (12).

Les différents calorimètres et analyseur thermique, leurs périphériques ainsi que les balances sont placés dans des salles thermorégulées à (19,0 ± 0,2)°C.

III. Résultats

Les constantes physiques de nos composés sont résumées dans le tableau 1.

III.1. Analyse thermique différentielle

Cette étude nous a posé quelques difficultés dues essentiellement à la décomposition des aminophénols au moment de leur fusion. C'est la raison pour laquelle pour chaque échantillon, seuls ont été retenus les résultats issus de la première fusion minimisant ainsi les risques d'erreurs dus au phénomène de décomposition. Nous consignons dans le tableau 2 les principaux résultats obtenus. Les valeurs de la température du point triple sont compatibles avec celles de la littérature. Quant aux enthalpies de fusion, aucune comparaison n'est possible par manque, à notre connaissance, de valeurs publiées.

III.2. Calorimétrie de combustion

L'équivalent énergétique du système calorimétrique (U_{calor}) a été déterminé à partir de six combustions d'acide benzoïque, échantillon 39i du N.I.S.T. pour lequel $\Delta u°_c$(s, 298,15 K) = (−26 414 ± 3) J g^{-1} (16). Dans chaque expérience, nous avons utilisé environ 5 mg d'acide et 0,2 mg de coton (dont l'énergie de combustion, préalablement déterminée au laboratoire, a pour valeur $\Delta u°_c$(s, 298,15 K) = (−16 399 ± 23) J g^{-1} (17)). Nous avons trouvé U_{calor} = (16,056 ± 0,007) J V^{-1} s^{-1}.

Les enthalpies standard de combustion de nos composés (tableaux 3–5) concernent la réaction suivante :

$$C_6H_7NO(s) + 29/4\ O_2(g) \rightarrow 6\ CO_2(g) + 7/2\ H_2O(l) + 1/2\ N_2(g)$$

et sont calculées à l'aide d'un ordinateur et d'un programme écrit et mis au point au laboratoire, à partir de nos valeurs expérimentales en tenant compte des corrections dites de Washburn.

Nos valeurs expérimentales sont inférieures aux valeurs de Nuñez *et al* (2) d'environ 0,3%, 0,2% et 0,1% respectivement, pour les isomères *ortho*, *méta* et *para*. N'ayant pas rencontré de difficultés particulières en calorimétrie de combustion des aminophénols qui seraient dues à leur volatilité, à leur hygroscopicité et (ou) à leur oxydation (à condition d'éviter l'exposition prolongée des pastilles à la lumière), nous pensons que la masse de substance brûlée, déterminée à partir de nos pesées initiales, est plus fiable que celle qui est calculée à partir de la quantité de CO_2 issue de la combustion comme l'ont fait Nuñez *et al*. Par ailleurs, signalons l'absence dans leur travail de toute indication relative à la pureté des substances étudiées.

III.3. Calorimétrie de sublimation et mesures des capacités calorifiques

Les enthalpies de sublimation de nos substances sont consignées dans le tableau 6. Comme on peut le constater (tableau 7), nos résultats à 298,15 K sont plus faibles que les valeurs de Nuñez et al. (2).

Si l'on se réfère à la méthode expérimentale, utilisée par ces auteurs pour la détermination des enthalpies de sublimation ou de vaporisation, décrite dans la référence 18, on se rend compte que le signal endothermique mesuré par le microcalorimètre correspond à une énergie de sublimation à une température T et non pas à une enthalpie puisque la pression n'est pas constante tout au long du changement d'état. Une correction relative à la différence $\Delta_{sub}H_m(T) - \Delta_{sub}U_m(T)$, égale à RT, avec T = 414 K (température à laquelle ont été réalisées les mesures), ne peut pas expliquer, à elle seule, l'écart observé entre nos valeurs et celles de ces auteurs. A noter que cette différence est aussi constatée si l'on compare les valeurs des enthalpies de sublimation des trois isomères de l'acide chlorobenzoïque obtenues au laboratoire (19) avec celles qui ont été mesurées par Adedeji et al. (18) en utilisant la même méthode.

Par ailleurs, signalons que Dunn (20) a déterminé l'enthalpie de sublimation du 4-aminophénol dans l'intervalle de température (403 < T/K < 430) et a trouvé 92 kJ mol^{-1}. Ramenée à 298,15 K, cette valeur, égale à 98,2 kJ mol^{-1}, s'écarte davantage de la valeur de Nuñez et al. (Δ = 10,9 kJ mol^{-1}) que de la nôtre (Δ = 5,5 kJ mol^{-1}).

En utilisant les résultats expérimentaux obtenus par calorimétrie de combustion et de sublimation, nous avons calculé l'enthalpie molaire standard de formation à l'état gazeux de chacun des trois isomères (tableau 7).

III.4. Enthalpie d'atomisation

À une température donnée, la réaction d'atomisation des aminophénols s'écrit :

$$C_6H_7NO\ (g) \rightarrow 6\ C(g) + 7\ H(g) + N(g) + O(g)$$

En conséquence, l'enthalpie liée à cette réaction est égale à :

$$\Delta_{a,exp}H°_m = 6\ \Delta_f H°_m\,[C(g)] + 7\ \Delta_f H°_m\,[H(g)] + \Delta_f H°_m\,[N(g)] + \Delta_f H°_m\,[O(g)] - \Delta_f H°_m\,[C_6H_7NO(g)]$$

Les valeurs de $\Delta_{a,exp}H°_m$ de nos substances (tableau 7) ont

été calculées en utilisant les valeurs de $\Delta_f H°_m$(g, 298,15 K) de C, H, N et O consignées dans la référence 22.

Dans le présent travail, l'incertitude qui accompagne les résultats expérimentaux représente l'écart moyen, $\sigma_m = \pm \{(x - x_0)^2/n(n-1)\}^{1/2}$, x étant chacune des n valeurs entrant dans le calcul de la moyenne x_0. Lorsque la valeur expérimentale est fonction de plusieurs variables, l'incertitude calculée tient compte de l'erreur sur chacune de ces variables.

IV. Discussion

IV.1. Énergie de conjugaison

L'énergie de conjugaison est la différence entre l'énergie réelle de la molécule et l'énergie qu'elle aurait si les divers systèmes insaturés qu'elle comporte étaient indépendants. Sur le plan pratique, pour la déterminer, il suffit d'utiliser les enthalpies standard de combustion à l'état gazeux de la molécule réelle et de la molécule fictive non conjuguée. La première de ces grandeurs s'obtient expérimentalement et la seconde nécessite le recours aux systématiques. En ce qui nous concerne, nous avons utilisé celle de Klages qui est consignée dans la référence 23.

Nous avons également calculé l'énergie de conjugaison théorique à l'aide de la méthode de calcul indiquée dans la référence 24 et ce, en utilisant les paramètres suivants : $\alpha_O = \alpha + 2{,}500\ \beta_0$; $\alpha_N = \alpha + 2{,}250\ \beta_0$; $\beta_{(C\text{-}O)} = 0{,}750\ \beta_0$; $\beta_{(C\text{-}N)} = 0{,}750\ \beta_0$ (β_0 est l'intégrale de recouvrement de la molécule de benzène; elle est égale à 131,7 kJ mol^{-1}).

Les valeurs de l'énergie de conjugaison expérimentale et théorique (tableau 8) ainsi obtenues sont compatibles. De plus et comme on peut le constater, l'énergie de conjugaison du 2-aminophénol étant la plus élevée laisse supposer que cet isomère serait le plus stable.

IV.2. Liaisons intramoléculaires dans les aminophénols

Par définition, l'enthalpie d'atomisation d'une molécule est égale à la somme des liaisons intramoléculaires compte tenu des facteurs de stabilisation et de déstabilisation. Pour retrouver, par le calcul, l'enthalpie d'atomisation de nos composés, nous avons tenu compte du principe de la transférabilité et avons utilisé les valeurs énergétiques des différentes liaisons intramoléculaires préalablement déterminées au laboratoire à partir d'autres molécules.

Pour ce qui est des liaisons C_b—C_b du cycle benzénique, nous avons utilisé le procédé de calcul consigné dans la référence 10. Celui-ci fait intervenir un paramètre lié à la géométrie de la molécule, l'indice de liaison l_{rs} entre deux atomes directement liés r et s, obtenu à partir du calcul

6632,7 kJ mol^{-1} respectivement, pour l'isomère *ortho*, *méta* et *para* et sont en parfait accord avec les résultats expérimentaux consignés dans le tableau 7.

IV.3. Liaisons intermoléculaires dans les aminophénols

L'enthalpie de sublimation d'une substance organique est liée aux interactions intermoléculaires. Dans le cas des aminophénols, ces interactions sont du type van der Waals et concernent les forces de dispersion et d'interactions dipolaires. À côté de ces interactions, il existe aussi des liaisons hydrogène intermoléculaires. Il nous a donc paru intéressant de déterminer la part énergétique de chacune d'elles. Pour ce faire, nous avons appliqué un procédé de calcul déjà utilisé au laboratoire (26–31). Il consiste, dans notre cas, à déterminer la contribution énergétique des forces de dispersion (London) en considérant qu'elle est égale à l'enthalpie de sublimation des diméthylbenzènes, composés isoélectroniques des aminophénols.

À une température donnée (ici 298,15 K), la différence D_1 des enthalpies de sublimation des aminophénols et des diméthylbenzènes correspondants représente la somme des énergies d'interaction dipolaire et des liaisons hydrogène intermoléculaires (tableau 9).

Afin de déterminer la contribution énergétique des interactions dipolaires D_2, nous avons comparé les enthalpies de sublimation des dichlorobenzènes, composés isoélectroniques des aminophénols et des diméthylbenzènes, qui présentent un moment dipolaire mais ne forment pas de liaisons hydrogène intermoléculaires, à celles des diméthylbenzènes correspondants. Comme on peut le constater, celle-ci est faible.

La différence $D_1 - D_2$, soit 38,5 kJ mol^{-1}, représente la part énergétique pouvant être attribuée à la somme des liaisons hydrogène intermoléculaires mises en évidence par des études cristallographiques (32–35). Celles-ci ont montré l'existence de deux types de liaisons hydrogène intermoléculaires dans les molécules d'aminophénols: N—H···O et O—H···N. Ces liaisons forment, dans le cas du 2-aminophénol (32, 33), des feuillets liés entre eux par de faibles forces de van der Waals.

La liaison O—H···N est plus forte que N—H···O. En effet, l'électronégativité de O étant plus importante que celle de N,

Tableau 9. Comparaison des enthalpies de sublimation des aminophénols, des diméthylbenzènes et des dichlorobenzènes.

	$\Delta_{sub}H°_m$(298,15 K) (kJ mol^{-1})		
	ortho	*méta*	*para*
OH, $NH_2 \rightarrow$ A	96,90	101,58	103,63
Cl, Cl $\rightarrow$ B	64,35	62,78	65,15
CH_3, $CH_3 \rightarrow$ C	59,82	58,26	60,18
D_1 = A − C	37,08	43,32	43,45
D_2 = B − C	4,53	4,52	4,97
$D_1 - D_2$	32,55	38,80	38,48

la liaison O—H est plus polarisée et la charge δ^+ portée par l'hydrogène est plus importante, induisant ainsi une liaison H···N plus forte. La longueur de la liaison O···N est d'ailleurs plus petite dans le cas de O—H···N (2,780 Å (33), 2,764 Å (32)) que dans celui de N—H···O (3,113 Å (33), 3,114 Å (32)).

On sait que la force d'une liaison est inversement proportionnelle à sa longueur. Afin de déterminer la contribution enthalpique de chacun de ces deux types de liaisons hydrogène intermoléculaires à partir de l'enthalpie attribuée à leur ensemble, soit 38,5 kJ mol^{-1}, nous avons, dans un premier temps, utilisé la relation donnée par Jaskólski (36) pour calculer le taux de raccourcissement de la distance interatomique entre deux atomes H et X liés par une liaison hydrogène intramoléculaire et admis que nous pouvions confondre liaison hydrogène intra et intermoléculaire.

Cette relation s'écrit :

$$\Delta(HX) = [W(H) + W(X) - R(H\cdots X)] / [W(H) + W(X)]$$

$\Delta(HX)$ représente le raccourcissement de la liaison H···X, $W(H)$ et $W(X)$ représentent respectivement les rayons de van der Waals des atomes H et X; $R(H\cdots X)$ représente la distance réelle entre les atomes H et X.

Appliquée dans notre cas avec X = N ou O, la relation précédente nous permet de calculer $\Delta(HN)$ et $\Delta(HO)$. Les valeurs de $W(H)$ = 1,00 Å; $W(O)$ = 1,52 Å et $W(N)$ = 1,55 Å ont été empruntées à la référence 37.

À défaut de trouver dans la référence 34 les distances interatomiques du 4-aminophénol qui présente l'avantage de ne pas contracter de liaisons hydrogène intramoléculaires, nous avons adopté pour les distances $R(H\cdots N)$ et $R(H\cdots O)$ respectivement les valeurs 1,77 et 2,22 Å données avec la structure cristalline du 2-aminophénol (33). Le rapport $\Delta(HN)/\Delta(HO)$ est égal à 2,6.

La seule étude cristallographique sur le 4-aminophénol a été réalisée par Brown (34). Cet auteur propose trois liaisons hydrogène intermoléculaires par molécule de 4-aminophénol. La troisième liaison nous paraît être contestable si l'on se réfère à la valeur de la distance (N—H···O = 3,18 Å) qui est relativement élevée comparée à celles des liaisons de même type. Toutes les autres études cristallographiques, réalisées sur l'isomère *ortho* ou *méta* (32, 33, 35), montrent l'existence de deux liaisons hydrogène par molécule d'aminophénol, l'une de type N—H···O et l'autre de type O—H···N. En conséquence, nous avons supposé qu'il en était de même pour le 4-aminophénol, ce qui nous a permis, à partir de la valeur du rapport $\Delta(HN)$ / $\Delta(HO)$, d'attribuer une énergie d'environ

10,7 kJ mol^{-1} pour la liaison N—H···O et 27,8 kJ mol^{-1} pour la liaison O—H···N. Dans son ouvrage (38), Julg propose une énergie variant de 8,4 à 12,6 kJ mol^{-1} pour la liaison N—H···O dans les oximes et de 16,7 à 29,3 kJ mol^{-1} pour la liaison O—H···N, ce qui est tout à fait compatible avec nos résultats.

IV.4. Liaison hydrogène intramoléculaire dans l'isomère *ortho*

À la suite de leurs études cristallographiques sur le 2-aminophénol, Ashfaquzzaman et Pant (32), d'une part, et Korp et al. (33), d'autre part, proposent une structure en feuillets formés par des molécules liées entre elles par des liaisons hydrogène intermoléculaires de type N—H···O et O—H···N.

Cette organisation engendre des cavités dans lesquelles peuvent s'infiltrer d'autres molécules permettant ainsi aux molécules du 2-aminophénol de jouer le rôle de composés d'insertion ou clathrates. L'existence d'un hydrogène libre de la fonction NH_2 pourrait partiellement expliquer le fait que des molécules comme l'eau et l'éthanol soient attirées préférentiellement à l'intérieur de ces cavités.

En conséquence, si l'on admet les conclusions tirées par Ashfaquzzaman et Pant et Korp et al., il n'y aurait pas de place pour une liaison hydrogène intramoléculaire dans l'isomère *ortho*. Pourtant, quelques observations faites sur les propriétés physico-chimiques des aminophénols tendraient à attribuer la différence entre les valeurs de l'enthalpie de sublimation des isomères *ortho* et *para*, soit 6,73 kJ mol^{-1}, à une liaison hydrogène intramoléculaire :

1. La pression de vapeur saturante à 335 K de l'isomère *ortho* (0,5 Pa) est plus forte que celle des deux autres isomères : *méta* (0,4 Pa) et *para* (0,06 Pa), évaluées à partir de nos résultats expérimentaux d'après la méthode de calcul indiquée dans la référence 25.

2. La température du point triple (ou de fusion), qui renseigne sur la force des liaisons intermoléculaires, est plus élevée dans le cas de l'isomère *para* que dans celui de l'isomère *ortho*. Il en est de même pour l'enthalpie de fusion (tableau 2).

Enfin précisons que, même si elle existe, cette liaison hydrogène intramoléculaire serait faible et du même ordre de grandeur que celle que l'on pourrait rencontrer dans le cas du 1,2-dihydroxybenzène (6,63 kJ mol^{-1}) (26), composé ayant, par ailleurs, une structure cristalline analogue à celle du 2-aminophénol (39). Toutefois, une autre explication peut être envisagée pour interpréter la différence entre les enthalpies de sublimation des isomères *ortho* et *para* aussi bien dans le cas de l'aminophénol que dans celui du dihydroxybenzène sans qu'elle ne soit en contradiction avec les structures cristallines respectives de ces composés. Elle consiste à supposer que les liaisons hydrogène intermoléculaires, qui associent les molécules par deux dans les isomères *ortho*, soient suffisamment fortes pour qu'un certain nombre de ces molécules passe de l'état solide à l'état gazeux sous forme de dimères. Dans ce cas, l'enthalpie de sublimation ne tiendrait pas compte de toutes les liaisons hydrogène intermoléculaires et serait inférieure à l'enthalpie de sublimation de l'isomère *para* pour lequel seules des molécules monomères existent en phase gazeuse.

Remerciements

L'un de nous (M.G.) remercie les gouvernements Algérien et Français pour l'octroi d'une bourse d'études lui ayant permis de préparer une thèse de doctorat dont ce travail constitue une partie.

Substituted tetra-2,3-pyrazinoporphyrazines. Part I. Angular annelation of tetra-2,3-quinoxalinoporphyrazine

Svetlana V. Kudrevich, Maria G. Galpern, Evgeny A. Luk'yanets, and Johan E. van Lier

Abstract: Several derivatives of 2,3-dicyanopyrazine were prepared via the condensation of *o*-quinones with diaminomaleodinitrile. Benzo[*f*]quinoxaline-2,3-dinitrile was obtained from 1,2-naphthoquinone, and a series of isomeric, di-*tert*-butyl substituted 5,6-(9,10-phenanthro)-2,3-dicyanopyrazines were prepared from the corresponding di-*tert*-butyl-9,10-phenanthrenequinones. Complexation of benzo[*f*]quinoxaline-2,3-dinitrile, and unsubstituted 5,6-(9,10-phenanthro)-2,3-dicyanopyrazine, with an appropriate metal salt yielded metal complexes of tetra-2,3-(benzo[*f*]quinoxalino)porphyrazine and tetra-2,3-[5,6-(9,10-phenanthro)]porphyrazine, respectively. Metal-free tetra-2,3-[5,6-(9,10-phenanthro)porphyrazine was obtained from the dilithium derivative by demetallation in HCl. These compounds have limited solubility in organic solvents, such as quinoline, and are aggregated in solutions. To eliminate the aggregation phenomenon and to determine the spectral properties of angularly annelated naphthalocyanine aza analogs, we prepared several isomeric tetra-2,3-[5,6-(di-*tert*-butyl-9,10-phenanthro)pyrazino]porphyrazines. These octa(*tert*-butyl) substituted complexes were synthesized via complexation of di-*tert*-butyl substituted 5,6-(9,10-phenanthro)-2,3-dicyanopyrazines with metal salts in the presence of urea, quinoline, and tri(*n*-butyl)amine, and purified by silica gel chromatography. They are soluble in chloroform and substantially monomerized in solutions. A hypsochromic shift of the Q-band of octaaza naphthalocyanines versus their carbocyclic analogs was observed for all aza analogs, with the extent of the shift depending on the composition of the aromatic macrocycle. Thus, the first angularly annelated benzo ring addition causes a hypsochromic shift (~25 nm) of the Q-band of tetra-2,3-quinoxalinoporphyrazine, whereas addition of a second condensed benzo ring has little effect.

Key words: phthalocyanine, aza analog, tetra-2,3-quinoxalinoporphyrazine, angular annelation.

Résumé : Plusieurs dérivés de 2,3-dicyanopyrazine ont été préparés via la condensation de *o*-quinones avec le diaminomaleodinitrile. Le benzo[*f*]quinoxaline-2,3-dinitrile a été obtenu de la 1,2-naphthoquinone et plusieurs isomères de di-*tert*-butyl-5,6-(9,10-phenanthro)-2,3-dicyanopyrazines ont été préparés à partir des di-*tert*-butyl-9,10-phenanthrenequinones correspondants. La condensation de benzo[*f*]quinoxaline-2,3-dinitrile et de 5,6-(9,10-phenanthro)-2,3-dicyanopyrazine non substitué avec un sel du métal approprié a produit des complexes métalliques de tetra-2,3-(benzo[*f*]quinoxalino)porphyrazine et de tetra-2,3-[5,6-(9,10-phenanthro]porphyrazine, respectivement. La tetra-2,3-[5,6-(9,10-phenanthro)porphyrazine sans métal a été obtenu du dérivé de dilithium par la démétallisation dans HCl. Ces composés ont une solubilité limitée dans les solvants organiques tels que la quinoline et sont agrégés dans les solutions. Afin d'éliminer le phénomène d'agrégation et pour déterminer les propriétés spectrales des azaanalogues de naphthalocyanine avec d'anneaux angulaires condensés, nous avons préparé plusieurs isomères de tetra-2,3-[5,6-(di-*tert*-butyl-9,10-phenanthro)pyrazino]porphyrazines. Ces complexes substitués d'octa(*tert*-butyl) ont été synthétisés via la complexation de di-*tert*-butyl substitué 5,6-(9,10-phenanthro)-2,3-dicyanopyrazines avec des sels du métal en présence d'urée, de quinoline et d'amine tri-*n*-butylique, et purifiés par la chromatographie sur gel de silice. Ils sont solubles dans le chloroforme et sont monomérisés substantiellement en solutions. Un déplacement hypsochromique de la bande Q des octaaza naphthalocyanines versus leurs analogues carbocycliques a été observé pour tous les azaanalogues, avec la grandeur du déplacement relié à la composition du macrocycle aromatique. Par conséquent, l'addition d'un premier anneau benzo angulaire produit un déplacement hypsochromique (~25 nm) de la bande Q du tetra-2,3-quinoxalinoporphyrazine, alors que l'addition d'un deuxième anneau benzo condensé a peu d'effet.

Mots clés : phtalocyanine, azaanalogue, tetra-2,3-quinoxalinoporphyrazine, annélation angulaire.

Introduction

The potential use of aza analogs of phthalocyanine (AzaPc) and naphthalocyanine (AzaNc) as electrocatalysts for oxygen reduction (1, 2), materials for electrochromic displays (3–5), media for optical data storage with a large-capacity memory (6–8), and photosensitizers for photodynamic therapy of cancer (9, 10) has been extensively investigated in the past decade. We previously reported on the synthesis and properties of an AzaPc series differing in the number and position of nitrogen atoms in the macrocycle, as well as in the number of attached linearly condensed benzo rings. The main changes in the UV–VIS spectra of Pc and Nc, resulting from linear annelation and aza substitution in the macrocycles, were readily explained by quantum chemical calculations (11–14). Subsequently we investigated the effect of aryl substitution on the UV–VIS spectra in a series of octaaza Pcs and tetraaza Ncs (15). As an extension of this work we studied the influence of *angular* annelation on the electronic spectra of AzaPc. We now report on the synthesis and spectral properties of angularly annelated derivatives of the tetra(2,3-quinoxalino)porphyrazine, i.e., metal complexes of tetra-2,3-(benzo[*f*]quinoxalino)porphyrazine, tetra-2,3-[5,6-(9,10-phenanthro)]porphyrazine, and the *tert*-butyl substituted analogs.

Results and discussion

Precursors

The dinitriles of heterocyclic *o*-dicarboxylic acids are the best precursors for the synthesis of AzaPcs. Unlike syntheses with other derivatives of *o*-dicarboxylic acids, the use of *o*-dinitriles affords pure AzaPcs in high yields. Several derivatives of 2,3-dicyanopyrazine (**1**) were prepared via the condensation of *o*-quinones with diaminomaleodinitrile (**2**) (16). Thus, 5,6-(9,10-phenanthro)-2,3-dicyanopyrazine (**5**) (16) was obtained by condensation of phenanthrenequinone and compound **2** with 80% yield.

In contrast to phenanthrenequinone, the condensation of 1,2-naphthoquinone (**3**) and compound **2** proceeds with low yield (10%), affording benzo[*f*]-quinoxaline-2,3-dinitrile (**4**) along with the oxidation products of **2** (Scheme 1). Varying reaction conditions, such as temperature, quantities of reagents, or the use of an inert atmosphere, did not improve the yield of the desired dinitrile.

Di-*tert*-butyl substituted (9,10-phenanthro)-2,3-dicyanopyrazines (**10***a–c*) were obtained from the reaction of **2** with the appropriate di-*tert*-butyl-9,10-phenanthrenequinones (**9***a–c*) (Scheme 2). The latter compounds were prepared using a modified oxidation procedure of the isomeric polyalkylated phenanthrenes (17). Chromatographic separation on silica gel using a mixture of chloroform–hexane as eluant gave three isomeric products. Based on ^{1}H NMR spectroscopy data, these isomers were assigned as 2,7- (**9***a*), 2,6- (**9***b*), and 3,6-di-*tert*-butyl-9,10-phenanthrenequinone (**9***c*), produced in a 1:2:1 ratio. This ratio is in accordance with substitution of H atoms in the phenanthrene molecule at the sterically accessible positions, assuming an equal reactivity for those positions. The main patterns of the ^{1}H NMR spectra of *o*-dinitriles **10***a–c* resemble those of the parent *o*-quinones, which allowed us to assign the isomers (Table 1).

Substituted Nc octaaza analogs: synthesis, purification, and spectral properties

The metal complexes of tetra-2,3-(benzo[*f*]quinoxalino)porphyrazine (**6***a,b*) and tetra-2,3-[5,6-(9,10-phenanthro)]porphyrazine (**7***b–g*) were obtained from the dinitriles **5** and **4** and the appropriate metal salts upon heating in the presence of urea and quinoline. We previously found these conditions optimal for the synthesis of Pc and Nc aza analogs (10, 14, 15). Metal-free tetra-2,3-[5,6-(9,10-phenanthro)]porphyrazine **7***a* was obtained by demetallation in HCl of the dilithium derivative, which in turn was prepared by treatment of compound **5** with metallic Li in amyl alcohol (Scheme 3) (18).

Compounds **6***a,b*, **7***a–g* were obtained as dark green solids. Unlike Pcs, they cannot be sublimated in high vacuum and they are only slightly soluble in organic solvents such as DMF, DMSO, and quinoline.

All Nc octaaza analogs were purified by extensive washing of the reaction mixtures with dilute HCl, hot water, and organic solvents followed by multiple reprecipitation from concentrated sulfuric acid, drying, and continuous extraction of impurities with hot methanol–acetone in a Soxlet apparatus until the intensity ratio between the absorption bands in the UV–VIS spectra remained constant. It is known that Pc hetero analogs are prone to form hydrates (14, 19). Accordingly, we dehydrated the analytical samples of complexes **6***a,b* and **7***a–g* by heating in acetic anhydride. The results of elemental analysis are compared to values calculated for anhydrous compounds (Table 2). The symmetry of the annelated AzaNc is evident from their structural drawings; complexes **7** retain the symmetry of tetra-(2,3-quinoxalino)porphyrazine whereas **6** may exist as a mixture of type isomers, one of which is shown in Scheme 3.

The metal complexes **6***a,b* and **7***b–g* are only slightly soluble in quinoline ($\sim 10^{-6}$ M) and at this concentration they are extensively aggregated. Nevertheless, we can draw some preliminary conclusions concerning the effects of aza substitution and angular annelation on the UV–VIS absorption maxima of Nc octaaza analogs. Thus, vanadyl tetra-4,5-(9,10-phenanthro)Pc (20) has an absorption maximum at 776 nm in quinoline (shoulder due to strong aggregation), whereas its octaaza analog **7***b* shows a peak at 700 nm. Comparison of the spectra of quinoline solutions of PcVO (21) vs. vanadyl tetra-2,3-pyrazinoporphyrazine (11) (λ_{max} 695 nm vs. 635 nm, shift of −60 nm), NcVO (22) vs. vanadyl tetra-2,3-quinoxalinoporphyrazine (11) (λ_{max} 819 nm vs. 725 nm (shift of −94 nm), and vanadyl anthracyanine (22) vs. vanadyl tetra-2,3-benzo[*g*]quinoxalinoporphyrazine (14) (λ_{max} 932 nm vs. 830 nm, shift of −102 nm) shows, in all cases, hypsochromic shifts of the Q-band of AzaPc and AzaNc as compared to their carbocyclic analogs, with the extent of the shift depending on the structure of the aromatic macrocycle.

The UV–VIS spectral properties of linearly annelated AzaPc have previously been reported (11–14). Thus, for octaaza Pcs each additional benzo ring causes a strong batho-

chromic shift of the Q-band (80–100 nm). This displacement of absorption maxima with sequential annelation, which does not change the symmetry of the molecule, is due to the extension of the aromatic system of the macrocycle. This correlation was first noticed in the series of Pc aza analogs; it was also observed in the sequence porphyrazine – Pc – 2,3–Nc (23) – anthracyanine (24) and recognized as a common feature of Pc related compounds.

How does the *angular* annelation affect the spectral properties of the aza analogs? The absorption maximum of the

ii: MX, urea, quinoline

vanadyl tetra-2,3-(benzo[*f*]quinoxalino)porphyrazine (**6***a*) is located at 700 nm, whereas the vanadyl tetra-2,3-[5,6-(9,10-phenanthro)]porphyrazine (**7***b*) shows a maximum at 706 nm, and vanadyl tetra-2,3-quinoxalinoporphyrazine at 725 nm (all spectra in quinoline). Therefore, the first angularly annelated benzo ring causes a *hypsochromic* shift of the Q-band, and the second annelated benzo ring hardly affects the absorption maximum. Furthermore, aggregation of Pc molecules in solutions affects the position of the long-wave absorption maxima and in general increases with the size of the molecule (25). Thus, to perform an accurate study of the spectral properties of the angularly annelated Nc aza analogs, we required a

series of more soluble derivatives that were less prone to aggregation.

Alkyl substitution is known to increase solubility and several synthetic routes for the preparation of alkyl-substituted AzaPcs have been reported (12, 13, 15, 26, 27). Based on prior experience, we selected *tert*-butyl substitution onto the benzene rings of the macrocycle and synthesized the isomeric tetra-2,3-[5,6-(di-*tert*-butyl-9,10-phenanthro)pyrazino]porphyrazines (**11***a–f*) by complexation of the corresponding dinitriles **10***a–c* with the metal salts in the presence of urea (Scheme 4). Among all solvents (neutral and basic) tested for this reaction, a 1:1 (v/v) mixture of quinoline and tri(*n*-butyl)amine was found to be the most suitable. The isomeric precursors differ in reactivity: under comparable conditions the 2,6-substituted dinitrile is the most reactive, whereas the 3,6-substituted isomer is the least reactive. Compounds **11***a–f* were purified by chromatography on silica gel. Chloroaluminium complex **11***d* was eluted with acetone, whereas the hydroxyaluminium derivative, obtained by reprecipitation of **11***d* from concentrated H_2SO_4, remained absorbed to the silica and was impossible to eluate even with pyridine. Complexes **11***a–f* were characterized by MS, UV–VIS spectral data, and combustion analysis (Table 3). The symmetry of the isomeric octa(*tert*-butyl) substituted AzaNcs **11***b* and **11***c* does not change as compared to their unsubstituted analog **7***e*, whereas compounds **11***a,d–f* represent a mixture of type isomers. The UV–VIS spectrum of the compound **11***d* (in chloroform) is presented in Fig. 1. The intense peak at 690 nm is indicative of substantial monomerization, confirming the effect of *tert*-butyl substitution on the solubility of the dye. The Q-band is narrow with resolved vibrational structure, whereas the position of the main absorption maximum remains the same as observed for the complex **7***d* (in quinoline). This spectrum shows that double angular annelation of octaaza Ncs causes a hypsochromic shift of the Q-band of about 25 nm. It should be noted that low solubility and strong aggregation of the unsubstituted carbocyclic analogs did not permit measurement of their absorption maxima (21), whereas substituted or any other soluble derivatives of tetra(9,10-phenanthro)Pc are unknown.

Finally we prepared a series of angularly annelated derivatives of the tetra-2,3-quinoxalinoporphyrazine, both unsubstituted and featuring the *tert*-butyl moieties on the benzo rings of the macrocycle. The spectral properties of these novel compounds are described and the influence of octaaza substitution and angular annelation on the position of the long-wave absorption maxima is presented.

We are currently using these data to develop Pc-related structures with "tuned" absorption maxima and selected solubility. Such compounds, containing at least one benzo[*f*]-quinoxaline or 9,10-phenanthropyrazine ring per molecule, could find application as photosensitizers in medicine or as agents for the preparation of Langmuir–Blodgett films.

Experimental

Materials and methods

FAB-MS were obtained on an LG Autospec Q mass spectrometer from the Department of Chemistry, Université de Montréal. High-resolution Direct Inlet Probe (DIP) mass spectra (HR-MS) were obtained on a V9 Micro-mass model ZAB-1F apparatus at 70 eV ionization voltage. 1H NMR spectra were taken on a Bruker AC-300 (300 MHz) spectrometer. UV–VIS

spectra were recorded with a Hitachi U-2000 spectrophotometer. Melting points were determined on a Fisher–Johns apparatus and are uncorrected. Preparative chromatography was conducted on 70–230 mesh silica gel (Aldrich, U.S.A.). TLC was performed on 0.25 mm thick Polygram SIL G/UV^{254} plates (Macherey–Nagel, Germany).

Diaminomaleodinitrile, 1,2-naphthoquinone, and phenanthrene were obtained from a commercial source (Aldrich). All solvents were HPLC grade and were used without further purification unless otherwise stated.

5,6-Phenanthro-2,3-dicyanopyrazine (**5**) was prepared by a published method (16).

*2,7-Di-*tert*-butyl-9,10-phenanthrenequinone (**9**a), 2,6-di-*tert*-butyl-9,10-phenanthrenequinone (**9**b), and 3,6-di-*tert*-butyl-9,10-phenanthrenequinone (**9**c) (Scheme 2)*

These compounds were prepared using a modified procedure of Petrova et al. (17). *tert*-Butyl chloride (25 mL) was added gradually to the stirred mixture of phenanthrene (10 g, 0.056 M) and anhydrous $AlCl_3$ (0.4 g) in dry CCl_4 (40 mL). After evolution of HCl had ceased, the dark blue mixture was heated to 60°C and maintained at this temperature for 5 h. Then 3 mL of water was added and the solvent was evaporated. The residue (brown slurry) was dissolved in 60 mL of glacial acetic acid. A solution of 16.8 g CrO_3 in 50 mL of 50% aqueous acetic acid was added gradually and the mixture was heated to 110°C, stirred at this temperature for 1 h, cooled to room temperature, and poured into 0.5 L of cold water. Chloroform (250 mL) was added to extract the precipitated orange slurry, phases were separated, and the aqueous phase was extracted repeatedly with chloroform. All extracts were combined, dried with anhydrous Na_2SO_4, chloroform was evaporated, and the residue was chromatographed on silica gel with chloroform–hexane (3:2) to yield **9***a* (2.06 g, 11.5% based on phenanthrene), **9***b* (4.3 g, 24%), and **9***c* (2.5 g, 14%).

2,3-Dicyano-benzo[f]*quinoxaline (**4**) (Scheme 1), 5,6-[2,7-di-*tert*-butyl-(9,10-phenanthro)]-2,3-dicyanopyrazine (**10***a*), 5,6-[2,6-di-*tert*-butyl-(9,10-phenanthro)]-2,3-dicyanopyrazine (**10**b), and 5,6-[3,6-di-*tert*-butyl-(9,10-phenanthro)]-2,3-dicyanopyrazine (**10**c) (Table 1, Scheme 2)*

These compounds were prepared by condensation of **2** with the appropriate *o*-quinones **3**, **9***a*, **9***b*, or **9***c* (16).

Compound **4** was purified on silica gel using CH_2Cl_2 as eluant (R_f 0.6). Slightly yellow crystals, 10%, mp 207°C. ^{1}H NMR, δ, ppm (in $CDCl_3$): 9.25–9.22 (m, 1H), 8.33 (d, 1H, J = 9.2 Hz), 8.08–7.92 (m, 4H). HR-MS *m/e*: calcd. 230.0592; found: 230.0602. Anal. calcd. for $C_{14}H_6N_4$: C 73.04, H 2.63, N 24.34; found: C 73.02, H 2.61, N 24.02.

Compounds **10***a*, **10***b*, and **10***c* were obtained as yellow powders after recrystallization from ethanol.

10*a*: Yield 62%, decomp. >340°C. HR-MS *m/e*: calcd. 392.2001; found: 392.1997. DIP-MS *m/e*: 392 (M^+, 31), 377 ($M^+ - CH_3$, 100). Anal. calcd. for $C_{26}H_{24}N_4$: C 79.56, H 6.16, N 14.27; found: C 79.67, H 6.16. N 14.20.

10*b*: Yield 70%, decomp. >300°C. HR-MS *m/e*: calcd. 392.2001; found: 392.2004. DIP-MS *m/e*: 392 (M^+, 20), 377 ($M^+ - CH_3$, 100). Anal. calcd. for $C_{26}H_{24}N_4$: C 79.56, H 6.16, N 14.27; found: C 79.51, H 6.08, N 14.07.

10*c*: Yield 78%, mp 275–276°C. HR-MS *m/e*: calcd: 392.2001; found: 392.1994. DIP-MS *m/e*: 392 (M^+, 30), 377 ($M^+ - CH_3$, 100) Anal. calcd. for $C_{26}H_{24}N_4$: C 79.56, H 6.16, N 14.27; found: C 79.24, H 6.20, N 14.09.

Metal complexes of tetra-2,3-(benzo[f]*quinoxalino)-porphyrazine* ***6***a *and* ***6***b *(Scheme 3, Table 2).*

A mixture of 0.230 g (1 mmol) of the dinitrile **4** and 1 mmol of salt (VCl_3 or CuCl) was heated at 250°C for 2 h. The dark green cake obtained was finely ground, washed with dilute HCl, hot water, methanol, and acetone, air dried, then reprecipitated from H_2SO_4 until the UV–VIS spectrum remained constant. The analytical samples were further extracted (Soxlet) with acetone for 24–72 h. Finally, the dark green solid remaining in the Soxlet thimble was dehydrated by refluxing with acetic anhydride for 2 h and drying at 100°C, 1 Torr (133.3 Pa) for 4 h.

*Tetra-2,3-[5,6-(9,10-phenanthro)pyrazino]porphyrazine (***7***a) (Scheme 3, Table 2)*

Metallic lithium (0.01 g, 1.43 mmol) was dissolved in freshly distilled isoamyl alcohol (1 mL) at 60°C, and the solution was allowed to cool to room temperature. The dinitrile **5** (0.14 g, 0.5 mmol) was added in small portions and the temperature of the stirred mixture was brought to 110°C over a 20–30 min period. Heating was discontinued after the mixture turned an intense dark green colour. The resulting solution was allowed to cool to room temperature, then diluted with 15 mL of ethanol. The precipitate was collected by centrifugation, then washed with 1 N HCl, water, ethanol, and acetone. An analytical sample of compound **7***a* was prepared as described for complexes **6***a,b*. Compound **7***a* is insoluble in organic solvents, including quinoline.

*Metal complexes of tetra-2,3-[5,6-(9,10-phenanthro)-pyrazino]-porphyrazine (***7***b–g) (Scheme 3, Table 2). General procedure*

A mixture of dinitrile **5**, metal salt (in molar ratio 1:1), urea (500 mg per 100 mg of dinitrile), and quinoline (1 mL per 100 mg of dinitrile) was heated to 300–320°C for 3–4 h. The solvent was removed by washing the mixture with methanol and acetone on a glass filter. Further purification was performed as described for compounds **6***a,b*.

*Metal complexes of isomeric tetra-2,3-[5,6-(di-*tert*-butyl-9,10–phenanthro)pyrazino]porphyrazines (***11***a–f) (Scheme 4, Table 3). General procedure*

A mixture of the dinitrile **10***a–c*, metal salt (in molar ratio 1:1), urea (500 mg per 100 mg of dinitrile), quinoline, and tri(*n*-butyl)amine (0.5 mL each per 100 mg of nitrile) was heated to 300°C for 1–2 h, then allowed to cool to room temperature and extracted with chloroform. The combined extracts were dried and concentrated, the complexes were precipitated upon addition of hexane, filtered, redissolved in chloroform, and chromatographed on silica gel (eluant: chloroform for compounds **11***a–c*, **11***e*, **11***f*, acetone for **11***d*). Precipitation from chloroform–hexane mixtures afforded compounds **11***a–f* as dark olive-green solids.

The reactions of $O(^3P)$ with some carboxylic acids and esters

P. Caravan, Suzanne M. Budge, and John M. Roscoe

Abstract: The reactions of $O(^3P)$ with formic acid, acetic acid, methyl acetate, ethyl acetate, *n*-propyl acetate, and isopropyl acetate have been studied kinetically as a function of temperature. The rate constants were measured in a discharge-flow system under pseudo-first-order conditions with a large excess of the organic reagent. No reaction could be found between $O(^3P)$ and either formic acid or acetic acid in the temperature range 300–420 K. The acetate esters, on the other hand, reacted with $O(^3P)$ at readily measurable rates over the same temperature range. The temperature dependence of the rate constants for these reactions in the temperature range 300–580 K is given, in the units L mol^{-1} s^{-1}, by:

O + methyl acetate: $\ln k = (19.46 \pm 0.24) - (1740 \pm 170)/T$
O + ethyl acetate: $\ln k = (20.30 \pm 0.35) - (1750 \pm 310)/T$
O + *n*-propyl acetate: $\ln k = (21.80 \pm 0.41) - (1920 \pm 400)/T$
O + isopropyl acetate: $\ln k = (19.91 \pm 0.36) - (1430 \pm 250)/T$

The lack of measurable reaction with the carboxylic acids, the systematic increase in the preexponential factor with increasing size of the ester group, and the observation of a significant yield of acetic acid among the products of the reactions with the esters indicate that attack by $O(^3P)$ is predominantly at the ester function. Linear free energy correlations are used to compare the results for the esters with those for reactions of $O(^3P)$ with other organic compounds containing oxygen.

Key words: kinetics, mechanism, reactions of $O(^3P)$ with esters.

Résumé : On a étudié la cinétique, en fonction de la température, des réactions du $O(^3P)$ avec les acides formique et acétique, les acétates de méthyle, d'éthyle, de *n*-propyle et d'isopropyle. On a mesuré les constantes de vitesse dans un système d'écoulement à décharge sous des conditions de pseudo premier ordre, en présence d'un grand excès du réactif organique. On n'a pas pu détecter de réaction entre le $O(^3P)$ et les acides formique et acétique pour la plage de température allant de 300 à 420 K. Par ailleurs, pour les mêmes températures, les esters acétiques réagissent avec le $O(^3P)$ à des vitesses qui peuvent être mesurées. La relation entre les constantes de vitesse et la température pour ces réactions dans la plage de température allant de 300 à 580 K est donnée par les équations suivantes, en unités L mol^{-1} s^{-1} :

O + acétate de méthyle : $\ln k = (19{,}46 \pm 0{,}24) - (1740 \pm 170)/T$
O + acétate d'éthyle : $\ln k = (20{,}30 \pm 0{,}35) - (1750 \pm 310)/T$
O + acétate de *n*-propyle : $\ln k = (21{,}80 \pm 0{,}41) - (1920 \pm 400)/T$
O + acétate d'isopropyle : $\ln k = (19{,}91 \pm 0{,}36) - (1430 \pm 250)/T$

Le fait qu'il ne se produise pas de réactions à des vitesses mesurables avec les acides carboxyliques, qu'il y a une augmentation systématique dans le facteur préexponentiel avec l'augmentation du groupe ester et que l'on observe la formation d'acide acétique avec un rendement significatif parmi les produits des réactions avec les esters indique que l'attaque par $O(^3P)$ se fait surtout au niveau de la fonction ester. On a utilisé des corrélations linéaires d'énergie libre pour comparer les résultats pour les esters avec ceux pour des réactions de $O(^3P)$ avec d'autres composés organiques contenant de l'oxygène.

Mots clés : cinétique, mécanisme, réactions du $O(^3P)$ avec les esters.

Introduction

In earlier work from this laboratory, we compared the reactivity of a series of alcohols and a series of ketones with $O(^3P)$ (1). While the activation energies for the reactions of $O(^3P)$ with the ketones were comparable to those for the reactions with the alcohols and showed a similar trend with increasing chain length, the preexponential factors for the reactions with the ketones were some 5–10 times smaller than those for the reactions with the alcohols. The Taft reaction parameter was also significantly more negative for the reactions of $O(^3P)$ with the ketones than for the reactions with the alcohols. We report here the results of kinetic experiments on the reactions of $O(^3P)$ with formic acid, acetic acid, and a series of acetate esters. This extends the measurements made with the ketones to further examine the role of substituents, and the effect of accumulation of polarizable atoms such as oxygen, on the reactivity of organic compounds toward $O(^3P)$.

Examination of the literature failed to reveal any previous work on the reactions of $O(^3P)$ with carboxylic acids. How-

ever, the reactions of some acetate and formate esters have been studied from approximately 300 to 420 K by measuring the rate of loss of the organic reagent under conditions of excess $O(^3P)$ in a flow system (2). In that work, the Arrhenius preexponential factors were approximately an order of magnitude larger than those for the reactions with ketones and the activation energies were significantly larger than those for the reactions of $O(^3P)$ with either ketones or alcohols (e.g., refs. 1, 3–8). We report here experiments made under conditions of large excess of the esters that complement the earlier work by employing conditions in which secondary reactions of $O(^3P)$ are less likely to be important. Our measurements also cover a somewhat larger temperature range than the earlier work and the series of acetate esters has been expanded to include isopropyl acetate.

Experimental

The reactions were studied in a conventional discharge-flow system operated at a pressure of approximately 1 Torr (133.3 Pa) (1, 3, 5, 7). Gas flow velocities in the cylindrical reaction vessel ranged from approximately 700 to 1100 cm s^{-1}. The excess reactant entered the reaction vessel through a moveable inlet and the $O(^3P)$ concentration was monitored at a fixed point at the downstream end of the reaction vessel as the inlet was moved along the axis of the reaction vessel. The reaction vessel was heated electrically and the temperature was measured with a calibrated iron–constantan thermocouple located in the tip of the moveable reactant inlet. This made it possible to also determine the uniformity of the temperature within the heated part of the reaction vessel. At the highest temperatures used, the variation in temperature was no more than ±2°C over the part of the reaction vessel used for the kinetic measurements and this variation decreased at lower temperatures.

Atomic oxygen was prepared by titrating $N(^4S)$ atoms, formed in a microwave-powered discharge in N_2, with NO. This avoids possible interference from O_2, which has been found to alter the secondary reactions in some reactions of $O(^3P)$ (3). The concentration of $O(^3P)$ was controlled and kept small by allowing only a very small part of the total N_2 flow to pass through the discharge. The rest of the N_2 mixed with the discharge products before entering the reaction vessel. This arrangement made it possible to achieve as much as a 1000-fold excess of the organic reagent over $O(^3P)$, thereby minimizing the effects of secondary reactions of atomic oxygen with intermediates such as OH radicals. The concentration of $O(^3P)$ was monitored by observing the NO_2 chemiluminescence produced by adding a small (a few percent) excess of NO beyond the titration end point. The initial concentration of $O(^3P)$ was determined from the flow rate of NO at the titration end point in the absence of the organic reagent. The rate constants were independent of the excess amount of NO used.

The flow rate of N_2 was measured with a calibrated capillary flowmeter. Flow rates of the other stable species were measured by determining the rate of increase of pressure in an initially evacuated vessel of known volume. Flow rates of formic acid and acetic acid were calibrated periodically by trapping the material, at a flow rate measured as above, for a known period of time at the temperature of liquid nitrogen. The collected material was then titrated with standard NaOH solution.

Formic acid (MacArthur, 88% min.) was analysed by gas chromatography and found to contain no detectable organic impurities. The sample contained 92% formic acid and 8% water, which is necessary for stability. The formic acid was used without drying since it has been found that dry formic acid gives erratic kinetic results (9). Acetic acid (BDH 99.7%), acetone (Anachemia, toxigraphic, distilled in glass), methyl acetate (Aldrich, anhyd., 99%+), ethyl acetate (Aldrich, anhyd., 99.8%), *n*-propyl acetate (Aldrich, 99%), and isopropyl acetate (Aldrich, 99%) were analysed by gas chromatography and contained no detectable organic impurities. All these reagents were thoroughly degassed before use. A few kinetic measurements were made periodically on the reaction of $O(^3P)$ with acetone, which has been well characterized under conditions similar to those used in this work (1, 4), to verify that the entire apparatus was functioning reliably. Gas chromatographic analysis was done on an 8 ft × 1/4 in. column packed with Porapak Q. Both flame ionization and thermal conductivity detectors were used, the latter being required for water analyses. Product analysis was done by collecting the condensable material leaving the reaction vessel in two traps cooled with liquid nitrogen. The samples were then removed for chromatographic analysis. The organic reactant was always present in sufficient excess that it could be used as an internal standard in these analyses. The traps were located sufficiently far from the end of the reaction vessel to ensure that all reaction intermediates were consumed before the sample was collected for analysis.

The pseudo-first-order loss of $O(^3P)$ was analysed by the Guggenheim method (10). The advantages of this approach were described in a recent publication (11). Briefly, the data are divided into two sets with pairs of points in the sets separated by a constant time interval Δt. If the signals due to $O(^3P)$ in the two sets are S_1 and S_2 and the signal decays as a single exponential with a constant background, it may be shown that

$$\ln(S_1 - S_2) = -k_{obs}t_1 + \ln[S_0(1 - \exp(-k_{obs}\Delta t))]$$

where t_1 is the time corresponding to signal S_1. Since the signal at "zero time", S_0, and Δt are constants, a plot of $\ln(S_1 - S_2)$ against t_1 will be linear with slope $-k_{obs}$, the "observed" overall pseudo-first-order rate constant. Typical Guggenheim plots are found in Fig. 1. These plots typically had correlation coefficients of 0.99 or better and the pseudo-first-order rate constants calculated from them had standard deviations of less than ±5%.

It is often the case that the first-order heterogeneous loss of atomic species upstream from the tip of the moveable inlet differs appreciably from that downstream from the inlet tip where the surface/volume ratio is smaller and the adsorption of reactants and products can also alter the behaviour of the surface. We have adopted the practice of calculating second-order rate constants by obtaining the slope of a plot of the pseudo-first-order rate constants against the concentration of the excess reactant (1, 7, 11). Such plots have the form

$$k_{obs} = k_0 + k_R[\text{Reactant}]$$

where k_{obs} is the pseudo-first-order rate constant, k_R is the second-order rate constant, and k_0 is the intercept, which represents the difference in first-order atom loss, in the absence of

Fig. 1. Representative Guggenheim analysis plots for first-order rate constants; (○) methyl acetate, 584 K, [O] = 1.05×10^{-8} mol L^{-1}, [CH_3OAc] = 4.83×10^{-6} mol L^{-1}; (●) ethyl acetate, 488 K, [O] = 1.26×10^{-8} mol L^{-1}, [C_2H_5OAc] = 4.34×10^{-6} mol L^{-1}; (□) isopropyl acetate, 510 K, [O] = 1.38×10^{-8} mol L^{-1}, [C_3H_7OAc] = 9.36×10^{-7} mol L^{-1}; (■) *n*-propyl acetate, 335 K, [O] = 1.53×10^{-8} mol L^{-1}, [C_3H_7OAc] = 3.22×10^{-6} mol L^{-1}.

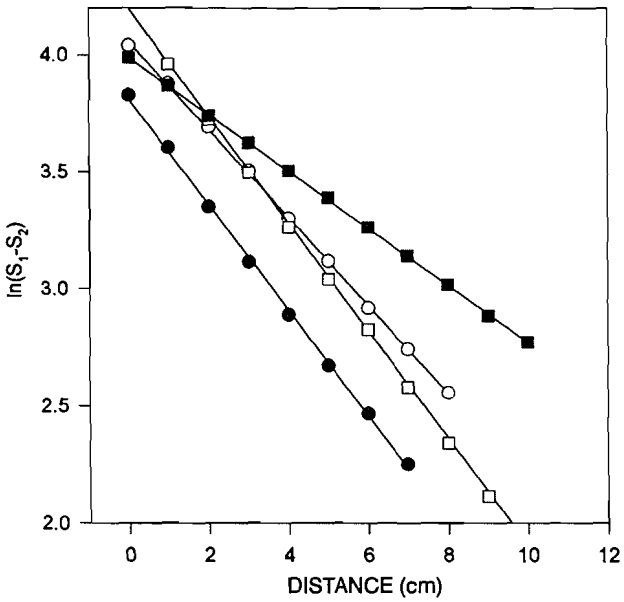

Fig. 2. Representative concentration dependence of pseudo-first-order rate constants; (○) methyl acetate, 506 K; (Δ) ethyl acetate, 488 K; (□) isopropyl acetate, 350 K; (▽) *n*-propyl acetate, 430 K.

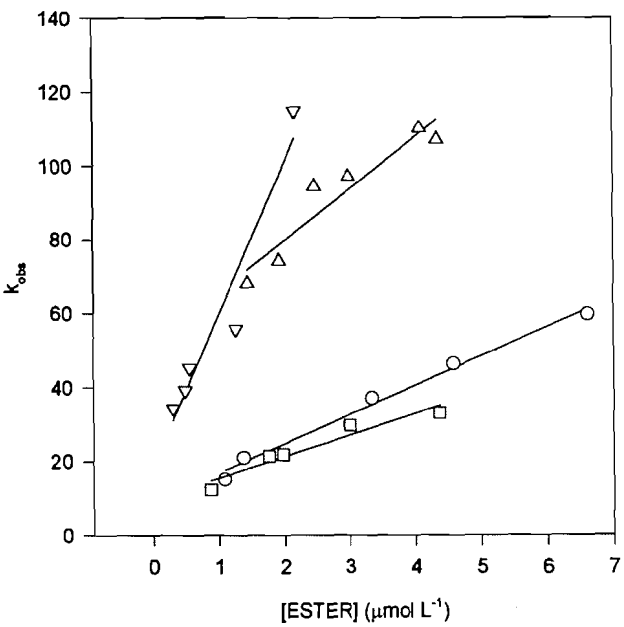

reactant, upstream and downstream from the tip of the moveable reactant inlet. Interpretation of the value of k_0 is difficult at best since it can be either positive or negative depending on the relative effectiveness of heterogeneous atom loss upstream and downstream from the tip of the moveable inlet. Some typical plots are found in Fig. 2. The quality of these plots was not as good as that of the Guggenheim plots, due in part to the smaller number of data points and to the larger number of variable parameters from one run to another. However, the correlation coefficients were better than 0.90 and in many cases better than 0.95.

Results and discussion

Reactions of $O(^3P)$ with carboxylic acids

Thirty kinetic experiments with formic acid and eleven with acetic acid at temperatures from 300 K to 420 K did not result in measurable consumption of $O(^3P)$. It has been found that (9, 12, 13), in the reactions of OH with formic acid and acetic acid, the monomeric form of the acid is much more reactive than the dimer. The possibility that the apparent lack of reactivity might be due to dimerization of the acid was tested by calculating the monomer/dimer concentration ratios for our experiments using the equilibrium data reported by Büttner and Maurer (14). In the experiments with formic acid, the monomer/dimer ratio ranged from 40 to 5.8×10^4 while in the experiments with acetic acid the ratio ranged from 20 to 1.3×10^4. It is clear that, in all our experiments, by far the dominant form of the carboxylic acid was the monomer.

Experiments to measure the rate constant for the reaction of $O(^3P)$ with acetone were used periodically to verify the correct functioning of the apparatus, as described in the experimental section. The reaction conditions used in these experiments were the same as those used to examine the behaviour of the carboxylic acids. In all cases, the results with acetone were in excellent agreement with those in the literature (1, 4). It is clear from these results that the lack of reaction of formic acid and acetic acid with $O(^3P)$ in our experiments was a real effect and not an experimental artifact.

The rate constants for reactions of $O(^3P)$ with organic compounds have been found to correlate well with those for the reactions of OH radicals with the same compounds (15, 16). Figure 3 shows such a correlation for the reactions of $O(^3P)$ and OH with a selection of aldehydes, ketones, ethers, and alcohols (9, 12, 13). The intersections of the vertical lines with the regression line indicate the rate constants to be expected for the reactions of $O(^3P)$ with formic acid and acetic acid if the mechanisms of their reactions were consistent with the rest of the correlation. On this basis, the rate constant at room temperature for the reaction of $O(^3P)$ with formic acid would be estimated to be approximately 1×10^6 L mol^{-1} s^{-1} while the rate constant for the reaction of $O(^3P)$ with acetic acid under the same conditions is estimated to be 2×10^6 L mol^{-1} s^{-1}. The lower limit of reliable measurement of second-order rate constants in our apparatus is approximately 1×10^5 L mol^{-1} s^{-1}, so the predicted magnitudes of the rate constants for the reactions of $O(^3P)$ with formic acid and acetic acid are well within the accessible range of our experiments. The other reactions in the correlation proceed by hydrogen abstraction, so we may conclude that, if $O(^3P)$ does react with formic acid and acetic acid at a rate that is too slow for us to measure, the reaction is unlikely to proceed by the same kind of hydrogen abstraction process as that followed by the other reactions in the correlation.

The reactions of $O(^3P)$ with acetate esters

Kinetic data

The four acetate esters examined all consumed $O(^3P)$ at

Fig. 3. 482	33 ± 9	576	40 ± 10

readily measurable rates. The kinetic data are summarized in Table 1 and the temperature dependence is presented in Fig. 4. In general, the results obtained in this work were comparable to those reported by Mix et al. (2), which are also plotted in Fig. 4 for comparison. While the agreement is good for the reaction of $O(^3P)$ with *n*-propyl acetate, our results for methyl acetate and ethyl acetate are progressively lower than theirs as the temperature increases. The source of this disagreement is unclear. However, the earlier work measured the rate of loss of the organic reactant in the presence of a large (typically less than 100-fold at the higher temperatures) excess of atomic oxygen. It is possible that, at the higher temperatures, reactions of atomic hydrogen formed by the reaction of $O(^3P)$ with OH might have consumed enough of the organic reagent to lead to a larger rate constant than would be measured in our experiments. This effect would be least important for the reaction of $O(^3P)$ with *n*-propyl acetate since the rate constants for this reaction are the largest and competition from reactions of atomic hydrogen might be expected to be the least efficient.

Mechanisms and products

The reactions to be considered under our experimental conditions are

[1] $O + RHOAc \rightarrow OH + ROAc$

[2] $O + OH \rightarrow O_2 + H$

[3] $OH + RHOAc \rightarrow H_2O + ROAc$

[4] $O + ROAc \rightarrow$ Products

In writing reaction [1], we have assumed that the oxygen atom abstracts a hydrogen atom from the -OR part of the molecule. The lack of reactivity of acetic acid suggests that the CH_3CO_2 part of the molecule is unreactive. The observation that the Arrhenius preexponential factors increase systematically with increasing size of the -OR group also supports this assumption. The rate constants for reactions [2] and [3] are known from previous work (8, 17) and, with the results of our experiments, permit estimation of the relative importance of reactions [1]–[3]. In all our experiments, the rate of reaction [3] was at least a factor of four larger than the rate of reaction [2], so the dominant fate of OH was reaction with the ester rather than reaction with $O(^3P)$. This is borne out by measurements of the yields of water in the reaction of $O(^3P)$ with methyl acetate, presented in Table 2, in which the water yields were nearly equal to the amount of $O(^3P)$ consumed. The rate constant for reaction [4] is not known. However, the measured yields of water in Table 2 would be inconsistent with a large rate constant for reaction [4] and we conclude that this reaction does not play a major role in the reaction of $O(^3P)$ with methyl acetate. The rate constants for the reaction of $O(^3P)$ with methyl acetate were the smallest, at a given temperature, of any of the esters studied so it seems reasonable to generalize this conclusion to the other three reactions as well. This is supported by the limited analytical data in Table 2 for the reaction of $O(^3P)$ with ethyl acetate in which the yields of water were comparable to those in the reaction with methyl acetate.

Acetic acid was identified as a reaction product by spiking samples of the reaction products with known amounts of ace-

tic acid. The peak in the chromatograms of these samples, which increased in size in proportion to the amount of the spike, was attributed to acetic acid. Similar experiments in which samples of products from the reactions of $O(^3P)$ with methyl acetate and ethyl acetate were spiked with methanol and ethanol resulted in the appearance of new peaks in the gas chromatograms. This suggests that appreciable amounts of methanol and ethanol were not present in the reaction products. If the -OR group of the ester survived the reaction with $O(^3P)$ one might expect OR radicals to be present and to produce the parent alcohol by hydrogen abstraction from the ester. These chromatographic results support our postulate that the oxygen atom attacks the -OR part of the ester molecule and that the CH_3CO_2 unit survives unchanged. The observation of comparatively small yields of acetic acid may reflect a relatively facile decarboxylation of the CH_3CO_2 radical in competition with the reactions leading to formation of acetic acid.

Arrhenius parameters

The Arrhenius parameters for the reactions studied here are summarized in Table 3. Also shown for comparison are the results of ref. 2 and the parameters for the reactions of $O(^3P)$ with a series of ketones. The rate constants at 298 K for the reactions of the esters, calculated from the data of both sources, are also plotted in Fig. 3. The rate constants at 298 K required for Fig. 3 are found in Table 4, which summarizes the data used in the Taft analysis to be discussed later. While our Arrhenius preexponential factors and activation energies are

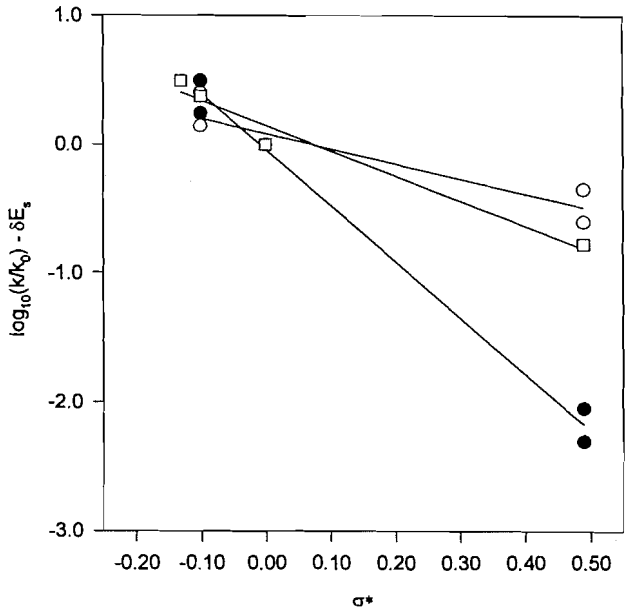
3-Pentanone	$2.9 \times 10^{8} \pm 32\%$	$8.6 \pm 50\%$	1

smaller than those in ref. 2, the rate constants calculated at 298 K from the Arrhenius parameters of the two studies are in reasonable agreement, presumably because the effect of the larger activation energies in ref. 2 tends to be qualitatively the same as that of the comparatively small preexponential factors calculated from our results. The difference in the Arrhenius parameters in the two studies may be partly due to the somewhat narrower temperature range used in ref. 2. The spread in their data would have resulted in a somewhat steeper Arrhenius plot and the somewhat longer extrapolation of this steeper plot to obtain the preexponential factor would have led to much larger values of the preexponential factors than those obtained with our data. The preexponential factors obtained in our experiments are comparable to those obtained for the reactions of $O(^3P)$ with ketones (1, 4) but are roughly an order of magnitude smaller than those found for the reactions of $O(^3P)$ with alcohols (7, 8). The activation energies obtained from our data are also comparable to those found for the reactions of $O(^3P)$ with ketones (1, 4) and with primary alcohols (7, 8).

Fig. 5. Taft plots for the reactions of $O(^3P)$ and OH with acetate esters. (○) $O(^3P)$ correlated with polar substituent parameters only ($\delta = 0$); (●) $O(^3P)$ correlated using both the polar substituent parameters and the steric substituent parameters; (□) OH correlated using both the polar substituent parameters and the steric substituent parameters.



Linear free energy correlations

Figure 3 indicates that both the results of this work and those of ref. 2 are well correlated with the rate constants for the reactions of OH with the same esters. However, in both cases the rate constant for the reaction of $O(^3P)$ with methyl acetate falls on the correlation with the other organic compounds while the points for the remaining esters fall significantly below the main correlation. This implies a smaller reactivity of $O(^3P)$ toward the esters than toward the other compounds in the correlation. In ref. 2, this would be attributed to a comparatively large activation energy while in our work it is attributed to an abnormally small Arrhenius preexponential factor.

Table 4 provides data for a Taft linear free energy analysis (18) of the reactions of $O(^3P)$ and OH with acetate esters. The relevant plots are presented in Fig. 5. The data are fitted to the equation

$$\log_{10}(k/k_0) = \rho^*\sigma^* + \delta E_s$$

The value of ρ^* measures the sensitivity of the reaction to transmission of polar effects to the reaction centre while the value of δ reflects the sensitivity of the reaction to steric effects. Implicit in the use of this analysis in the present case is the assumption that the oxygen atom preferentially, but probably not exclusively, abstracts the hydrogen atom α to the ester oxygen. This is consistent with the behaviour found in the reactions of $O(^3P)$ with alcohols (7). The open circles in Fig. 5 present the data with δ set to zero. The filled circles in that figure represent the data fitted to allow for both polar and steric effects. The sum of squares of relative y-deviations for the results calculated with the inclusion of steric effects (2.8) is slightly smaller than that neglecting steric effects (3.2), suggesting that the data may be better correlated when both effects are included. The values of

Table 4. Summary of data for Taft correlations.[a]

Reaction	k_{298} (L mol^{-1} s^{-1})	σ*	E_s	Reference
O + methyl acetate	8.23×10^5	0.49	1.24	This work
O + methyl acetate	8.15×10^5	0.49	1.24	2
O + ethyl acetate	1.84×10^6	0.00	0.00	This work
O + ethyl acetate	3.29×10^6	0.00	0.00	2
O + *n*-propyl acetate	4.67×10^6	−0.10	−0.07	This work
O + *n*-propyl acetate	4.60×10^6	−0.10	−0.07	2
OH + methyl acetate	2.09×10^8	0.49	1.24	17
OH + ethyl acetate	8.96×10^8	0.00	0.00	17
OH + *n*-propyl acetate	2.08×10^9	−0.10	−0.07	17
OH + *n*-butyl acetate	2.50×10^9	−0.115	−0.36	17

[a]In all cases, the reference compound is the one for which σ* = E_s = 0.00 by definition. Values of σ* and E_s were taken from ref. 18.

Table 5. Summary of Taft parameters for reactions of $O(^3P)$.

Reaction	Taft ρ*	Taft δ	Standard deviation	Reference
O + acetate esters	−4.36	1.38	0.13	This work
OH + acetate esters	−1.96	0.12	0.13	17
O + alcohols	−2.37	0.01	0.17	7
OH + alcohols	−1.31	0.01	0.06	7
O + alkanes	−4.48	0.37	0.00	7
OH + alkanes	−4.55	0.55	0.00	7
O + aldehydes	−1.29	0.01	0.08	7
OH + aldehydes	−0.82	0.01	0.09	7

ρ* and δ obtained from the latter plot are −4.36 and +1.38, respectively. The comparatively large negative value of ρ* suggests that, as expected, $O(^3P)$ is an electrophile and the reaction is significantly facilitated by inductive transfer of electron density to the reaction centre.

Table 5 provides a summary of the Taft parameters determined for the reactions of $O(^3P)$ and OH with a variety of organic compounds. The reactions of $O(^3P)$ and OH consistently have negative values of ρ*, indicating that both are electrophilic, with $O(^3P)$ generally being the more electrophilic reagent. The difference between $O(^3P)$ and OH is much greater for the compounds containing oxygen than for the alkanes, where both reagents have approximately the same sensitivity to transmission of polar effects. Among the compounds containing oxygen, the order of sensitivity to polar effects for the reactions of both $O(^3P)$ and OH is acetate esters > alcohols > aldehydes. The effect of the electronegative ester oxygen may be moderated somewhat by the adjacent carbonyl, making the sensitivity greater to polar effects originating in the alkyl group than is the case in the alcohols. In the aldehydes, the carbonyl presumably dominates the polar effects to such an extent that residual polar effects originating in the alkyl group are much less significant, leading to a comparatively small value of ρ*. Of the compounds examined, only the alkanes and esters have appreciable sensitivity to steric effects. In the case of the esters, both OH and $O(^3P)$ show significant sensitivity to steric effects, with the $O(^3P)$ reactions being the more sensitive. This would be consistent with the picture of a reaction resulting from an addition complex formed between the oxygen atom and the ester, followed by rearrangement and formation of products in competition with simple decomposition back to reactants.

An AM1 calculational study of the protonation and reactions of 3,4-dihydro-2-oxo-1,4-ethanoquinoline, 3,4-dihydro-2-oxo-1,4-propanoquinoline, 3,3,4,5-tetrahydro-2-oxo-1,5-ethanobenzazepine, 3,3,4,5-tetrahydro-2-oxo-1,5-propanobenzazepine, and *N*-methyl-4-bromo-2-methylacetanilide

N.H. Werstiuk, R.S. Brown, and Q. Wang

Abstract: The gas phase N- and O-protonation of distorted amides 3,4-dihydro-2-oxo-1,4-ethanoquinoline (**1***a*), 3,4-dihydro-2-oxo-1,4-propanoquinoline (**1***b*), 3,3,4,5-tetrahydro-2-oxo-1,5-ethanobenzazepine (**1***c*), and 3,3,4,5-tetrahydro-2-oxo-1,5-propanobenzazepine (**1***d*) and normal amides 4-bromo-2,*N*-dimethylacetanilide (**5***a*) and 2,*N*-dimethylacetanilide (**5***b*), along with the N-protonation of benzoquinuclidine (**7**), has been studied calculationally at the semiempirical level of theory with AM1. Calculated enthalpies of N- and O-protonation (proton affinities) indicate that **1***a*, **1***b*, and **1***c* should protonate on nitrogen and **1***d*, **5***a*, and **5***b* on oxygen. A satisfactory straight-line relationship between the calculated proton affinities of **1***a*, **1***b*, **1***c*, and **7** with experimental solution pK_a's is used to estimate the solution pK_a of **1***d*. Results of a calculational study on the gas phase N- and O-methylation of **1***b*, **1***c*, and **1***d* are nicely in accord with the findings of an experimental solution phase study of the methylation–hydrolysis of **1***b* and **1***d*: while **1***b* methylates on nitrogen, **1***d* methylates on oxygen. A calculational study of possible pathways of hydrolysis of the N-protonated amides indicates that solvolysis of the hydrates of these species represents a viable route for their conversion to ring-opened products.

Key words: protonation, methylation, reactions, distorted amides, AM1 calculations.

Résumé : Faisant appel à des calculs AM1 au niveau semiempirique, on a étudié les N- et O-protonations d'amides déformés (3,4-dihydro-2-oxo-1,4-éthanoquinoléine (**1***a*), 3,4-dihydro-2-oxo-1,4-propanoquinoléine (**1***b*), 3,3,4,5-tétrahydro-2-oxo-1,5-éthanobenzazépine (**1***c*) et 3,3,4,5-tétrahydro-2-oxo-1,5-propanobenzazépine (**1***d*)) et d'amides normaux (4-bromo-2,*N*-diméthylacétanilide (**5***a*) et 2,*N*-diméthylacétanilide (**5***b*)) ainsi que la protonation de la benzoquinuclidine (**7**). Les enthalpies calculées pour les N- et O-protonations (affinités protoniques) indiquent que les composés **1***a*, **1***b* et **1***c* devraient se protoner sur l'azote alors que les composés **1***d*, **5***a* et **5***b* devraient se protoner sur l'oxygène. Une relation linéaire satisfaisante entre les affinités protoniques calculées des composés **1***a*, **1***b*, **1***c* et **7** avec les valeurs expérimentales des pK_a en solution a été utlisée pour évaluer le pK_a en solution du composé **1***d*. Les résultats des calculs sur les N- et O-méthylations en phase gazeuse des composés **1***b*, **1***c* et **1***d* sont en bon accord avec les observations d'une étude expérimentale en solution de la méthylation–hydrolyse des composés **1***b* et **1***d* : alors que le composé **1***b* se méthyle sur l'azote, le composé **1***d* se méthyle sur l'oxygène. Une étude par calculs des diverses voies possibles pour l'hydrolyse d'amides N-protonés indique que la solvolyse des hydrates de ces espèces représente une route viable pour leurs conversions en produits résultants d'ouvertures de cycles.

Mots cles : protonation, méthylation, réactions, amides déformés, calculus AM1.

[Traduit par la rédaction]

Introduction

By studying a group of benzo-substituted bicyclic amides Brown and co-workers showed that distorting the amide linkage away from planarity leads to a dramatic change in the basicity of the amides and their reactivities in H_2O (1, 2). The kinetics of hydrolysis of distorted amides 3,4-dihydro-2-oxo-1,4-ethanoquinoline (**1***a*), 3,4-dihydro-2-oxo-1,4-propanoquinoline (**1***b*), 3,3,4,5-tetrahydro-2-oxo-1,5-ethanobenzazepine (**1***c*), 3,3,4,5-tetrahydro-2-oxo-1,5-propanobenzazepine (**1***d*), and N-methyl-4-bromo-2-methylacetanilide (**5***a*) were studied as a function of pH and the general hydrolytic mechanism shown in Scheme 1 was used to account for the pH–rate profiles. It was suggested that in going from **1***d* to **1***a* the site of protonation changes from oxygen to nitrogen giving rise to N-

protonated amides as reactive intermediates in the case of **1***a*, **1***b*, and **1***c*. This change was reflected in the nature of the pH–rate profiles; plateaus are seen at progressively lower pH in going from **1***a* to **1***c*. Using the rate data fitted to the appropriate kinetic expression for Scheme 1, Brown and co-workers determined kinetic pK_a's for **1***a*, **1***b*, and **1***c*. Table 1 shows the observed rate constants and the kinetic pK_a's for **1***a*, **1***b*, and **1***c*. A kinetic pK_a could not be determined for **1***d*, the least reactive amide, because it does not exhibit a plateau between pH 0.0 and 3.0. The availability of the structural and kinetic data for these amides prompted us to undertake a computational study of **1***a*–**1***d*, **5***a*, and *N*-methyl-*o*-methylacetanilide (**5***b*), (*a*) to calculate the geometries and relative energies of the N- and O-protonated species, (*b*) to provide support for the postulated changes in basicity, and (*c*) to gain insight into possible mechanisms of ring opening of the protonated species in H_2O. This paper documents the results of our study.

Experimental

I. Calculational method

The geometrical structures of the amides and their N- and O-protonated analogues were generated and optimized with MMX of PCMODEL (3) or MM+ of HYPERCHEM (4) and used as input for AM1 calculations with AMPAC (5), MOPAC (6), or HYPERCHEM. In the case of the AM1 calculations, the keyword PRECISE was used to tighten the convergence criteria. For the HYPERCHEM calculations, the optimizations were terminated when the RMS of the gradient dropped below 0.1 kcal/mol. In the case of the additions of H_2O to the N-protonated amides, the geometrical structures of the solvated substrates and the hydrates were generated with PCMODEL, optimized, and then used as input for the semiempirical calculations. In some cases, the locations of the H_2O molecules were adjusted prior to the optimization calculations by making appropriate changes in the input Z-matrix. Transition structures were calculated by refining the geometries at the maxima of the potential energy surfaces obtained for stretching the amide N—C bonds or shortening the H_2O...C=O internuclear distances for nucleophilic addition of H_2O in 0.1 Å increments with SIGMA or NLLSQ calculations.[3]

II. Methylation of 3,4-dihydro-2-oxo-1,4-propanoquinoline (**1***b*) and 2,3,4,5-tetrahydro-2-oxo-1,5-propanobenzazepine (**1***d*)

(a) **1***b*

Amide **1***b* (15.16 mg, 0.081 mmol) was dissolved in 0.5 mL of CD_2Cl_2 in an NMR tube. In a dry box flushed with argon, methyl trifluoromethanesulfonate (9.17 μL, 0.081 mmol) was injected into the solution. The reaction mixture was monitored periodically by ^1H NMR over a period of 90 h. ^1H NMR of **1***b* (200 MHz, CD_2Cl_2); δ: 7.12–7.45 (4 H, m), 3.75–3.91 (1 H, m), 3.04–3.22 (2 H, m), 2.62 (2 H, d, $J = 2$ Hz), 1.12–2.12 (4 H, m); the CH_3 protons of methyl triflate appear as a singlet at δ 4.21 ppm. During the reaction, a new peak appears at δ 3.65.

The reaction was terminated at 90 h by the addition of 2 mL of H_2O and the mixture extracted with 3×20 mL of CH_2Cl_2. The combined organic extracts were dried ($MgSO_4$) and the volatiles removed to yield a residue that was directly analyzed by ^1H NMR and MS. ^1H NMR (200 MHz, $CDCl_3$), δ: 6.92–7.22 (4 H, m), 3.45–4.00 (2 H, m), 2.88 (3 H, m), 2.82 (3 H, s), 1.48–1.95 (4 H, m). *m/z* (relative intensity): 219 (M^+ 69%), 174 ($M^+ - CO_2$ 38%), 160 ($M^+ - CH_2CO_2H$ 38%), 146 (16%), 132 (31%). Exact Mass calcd. for $C_{13}H_{17}NO_2$: 219.1259; found: 219.1255.

(b) Authentic N*-methyl-5-(2-hydroxycarbonylmethyl)-2,3,4,5-tetrahydrobenzazepine (**8**)*

To a flask was added NaH (60% dispersion, 0.546 g, 13.6 mmol, washed with hexane 3 times), 5-(hydroxycarbonylmethyl)-2,3,4,5-tetrahydrobenzazepine (0.30 g, 1.46 mmol), and 20 mL of dry THF. To this was added CH_3I (0.23 mL, 3.7 mmol) after which the mixture was heated at reflux overnight. The reaction mixture was worked up by the addition of 20 mL of H_2O, and extracted with 3×25 mL of $CHCl_3$. The combined extracts were dried ($MgSO_4$) and the volatiles removed to yield a crude product that was purified by column chromatography (SiO_2, ethyl acetate). The final product was a light yellow oil. ^1H NMR (200 MHz, $CDCl_3$), δ: 6.84–7.20 (4 H, m), 3.45–3.82 (2 H, m), 2.90 (3 H, m), 2.82 (3 H, s), 1.52–1.90 (4 H, m). *m/z* (relative intensity): 219 (M^+ 66%), 174 ($M^+ - CO_2$ 32%), 160 ($M^+ - CH_2CO_2H$ 100%), 146 (20%), 132 (38%). Exact Mass calcd. for $C_{13}H_{17}NO_2$: 219.1259; found: 219.1257.

*(c) Methylation of 2,3,4,5-tetrahydro-2-oxo-1,5-propanobenzazepine (**1**d)*

In a dry box, 5.90 μL of methyl trifluoromethanesulfonate (0.052 mmol) was injected into a solution of amide **1***d* (10.46 mg, 0.052 mmol) in 0.5 mL of CD_2Cl_2. The reaction mixture was monitored by ^1H NMR over a period of 9 days. At time zero, ^1H NMR (200 MHz, CD_2Cl_2), δ: 7.25–7.38 (2 H, m), 7.12–7.24 (2 H, m), 4.36–4.52 (1 H, m), 3.08–3.21 (1 H, m), 2.81–2.94 (1 H, m), 2.02–2.32 (3 H, m), 1.20–1.68 (3 H, m).

[3] The keyword SIGMA invokes the McIver–Komornicki gradient norm minimization routines. The keyword NLLSQ invokes Bartel's nonlinear least-squares gradient norm minimization method.

Over the course of the reaction, the ratios of the CH_3OTf and the other generated CH_3 singlets at δ 4.45, δ 4.21, and δ 3.50 were 21:1:7.

The mixture was worked up as above for the methylation of **1***b* and the crude mixture directly analyzed by ^1H NMR and MS. ^1H NMR (200 MHz, $CDCl_3$), δ: 6.68–7.09 (4 H, m), 3.65 (3 H, s), 3.18–3.32 (1 H, m), 2.72–2.88 (2 H, m), 1.58–2.38 (8 H, m). *m/z* (relative intensity): 233 (M^+ 41%), 202 ($M^+ - OCH_3$ 12%), 174 ($M^+ - CO_2CH_3$ 5%), 160 ($M^+ - CH_2CO_2Me$ 76%), 146 ($M^+ - CH_2CH_2CO_2Me$ 100%), 132 (11%). Exact Mass calcd. for $C_{14}H_{19}NO_2$: 233.1416; found: 233.1414.

Since the new peak at δ 3.50 in the reaction mixture might be attributed to the N-methylated acid corresponding to **8**, the remaining aqueous layer was neutralized with dilute HCl to pH 4.0 and extracted with CH_2Cl_2. There was no material isolated so we speculate that the δ 3.50 peak was from CH_3OH formed from the reaction of CH_3OTf with adventitious H_2O.

*(d) Authentic 5-(2-methoxycarbonylethyl)-2,3,4,5-tetrahydrobenzazepine (**9**)*

HCl gas was bubbled through a solution of the corresponding amino acid (0.0734 g, 0.33 mmol) in 10 mL of CH_3OH for 30

min. The solution was then heated to reflux overnight. The solvent was removed by rotary evaporation and 5 mL of H_2O was then added to the residue. The pH of the solution was adjusted to pH 10 (NaOH dropwise) and the mixture extracted with 3 × 10 mL of CH_2Cl_2). The organic layers were washed with H_2O and dried (Na_2SO_4). The crude product (~50 mg) was purified by chromatography (SiO_2, petroleum ether – ethyl acetate; 75:15). Further purification was effected by dissolving the product in ether and bubbling HCl through the solution. After refrigeration, the HCl salt of **9** formed as white crystals. These were dissolved in 10 mL of saturated Na_2CO_3 and the free amine was extracted with 3 × 20 mL of CH_2Cl_2. The combined organic layers were dried (Na_2SO_4) and evaporated to yield a solid that was analyzed by ^1H NMR and MS. ^1H NMR (200 MHz, $CDCl_3$), δ: 6.62–7.08 (4 H, m), 3.65 (3 H, s), 3.18 (1 H, m), 2.72–2.90 (2 H, m), 1.58–2.38 (8 H, m). *m/z* (relative intensity): 233 (M^+ 46%), 202 ($M^+ - OCH_3$ 12%), 174 ($M^+ - CO_2Me$ 2%), 160 ($M^+ - CH_2CO_2Me$ 75%), 146 ($M^+ - CH_2CH_2CO_2Me$ 100%), 132 (9%). Results and Discussion

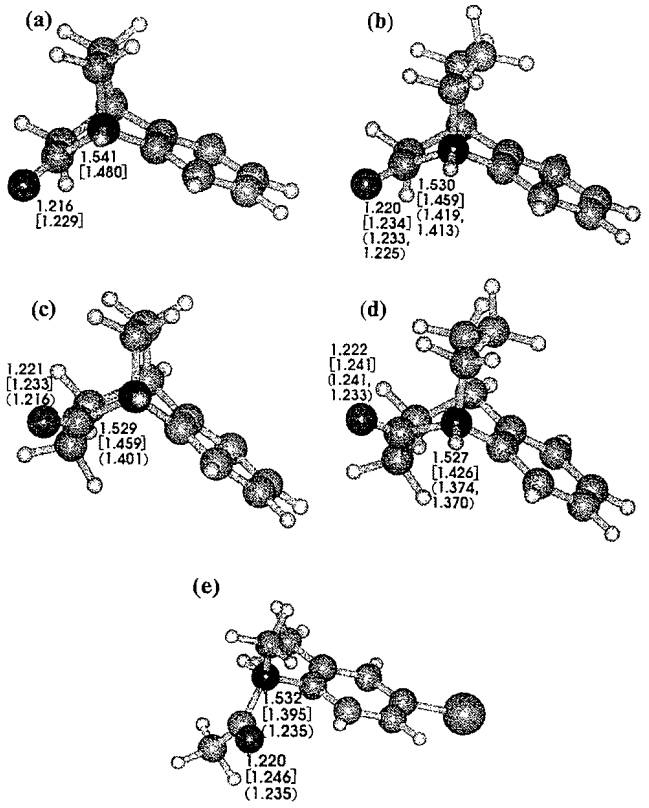
Calculated geometries and heats of formation of N- and O-protonated amides

The optimized equilibrium geometries of **1***b*–**1***d* and **5***a* (structural formulas not shown) calculated with AM1 correspond closely to the molecular structures of **1***b*–**1***d* and **5***a* obtained by X-ray diffraction (1, 7). Although the X-ray structure of **1***a* has not been reported, the AM1 computed geometry is probably accurate, based on the close similarity of the computed and experimental geometries for the other members of the series. The seven-membered ring of **1***c* adopts a chair conformation, while the eight-membered ring of **1***d* adopts a crown conformation. The torsional angle between the planar amide group and the plane of the phenyl ring of acetanilide **5***a* is 73.3°. Figure 1 shows the optimized geometrical structures of the N-protonated amides **2***a*–**2***d* and **6***a* labelled with selected geometrical parameters obtained with AM1. In the case of **6***a* and **6***b* (not shown), the most stable geometrical structure has the N—H bond *cis* to the methyl group at C2 of the phenyl ring. The values in brackets correspond to the values calculated for the unprotonated amides **1***a*–**1***d* and **5***a*; the values in parentheses are the bond lengths of the starting materials obtained by X-ray diffraction. There is a progressive decrease in the calculated N—C(O) bond lengths in going from **1***a* to **5***a*: **1***a* 1.480 Å, **1***b* 1.459 Å, **1***c* 1.459 Å, **1***d* 1.426 Å, and **5***a* 1.395 Å. These results are in accord with the expectation that the resonance interaction increases in going from **1***a* to **1***d*. While the anticipated shortening of the N—C(O) bonds through the series **1***a*–**1***d* seen in the X-ray diffraction data (parentheses) is reproduced with the AM1 calculations, the computed bond lengths (brackets) are around 0.05 Å longer than those obtained experimentally. That the N—C(O) bond of **1***d* is longer than the N—C(O) bond of **5***a* suggests that the interaction of the former's lone pair with the carbonyl group does not occur to the same extent as in **5***a* even though **1***d* has two 3-carbon bridges. As found experimentally with X-ray crystallography (7) and expected on the basis of ab initio calculations (8, 9), the C=O bond lengths calculated with AM1 increase only to a small degree through the series **1***a*–**1***d* and **5***a* (Fig. 1).

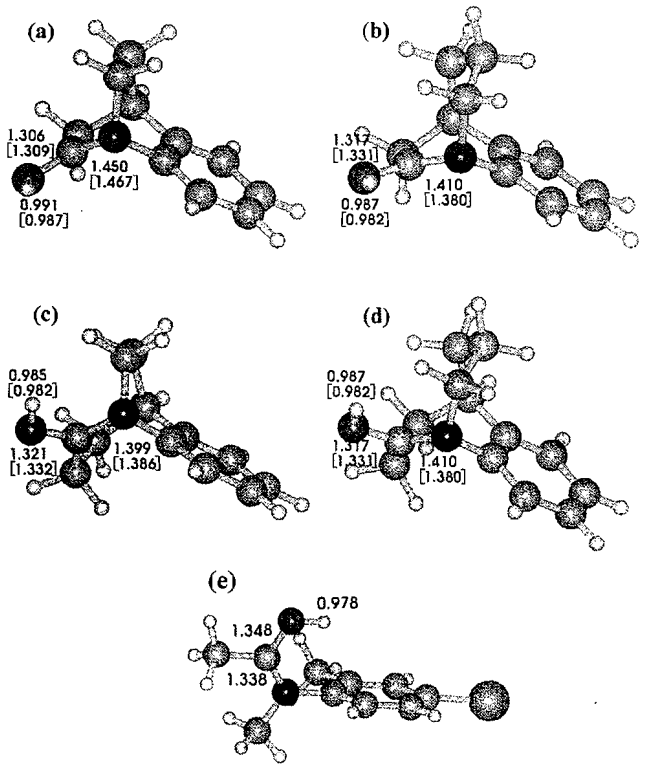
Fig. 1. Displays of the AM1 optimized geometrical structures of N-protonated amides ((*a*) **2***a*; (*b*) **2***b*; (*c*) **2***c*; (*d*) **2***d*; (*e*) **6***a*) and selected structural parameters of these species. The values shown in brackets are the AM1 calculated bond lengths of the corresponding amides; the experimental values are shown in parentheses.



Protonation of the nitrogen results in a large increase in the N—C(O) bond lengths (see Fig. 1), 0.061 Å for **1***a*, 0.071 Å for **1***b*, 0.070 Å for **1***c*, 0.101 Å for **1***d*, and 0.137 Å for **5***a*, but the C=O bonds shorten only slightly: 0.013, 0.014, 0.012, 0.019, and 0.026 Å for **1***a*, **1***b*, **1***c*, and **5***a*, respectively. In the case of **1***b*, **1***c*, **1***d*, and **5***a*, these changes undoubtedly arise predominantly from a loss of the resonance interaction upon formation of the N—H bond. Because there is little interaction of the lone pair with the carbonyl group,[4] the source of the unusual lengthening of the N—C(O) bond of **1***a* in going to **2***a* is presently unknown. But, it is possible that our AIMPAC studies[4] will provide information on this point. The other bonds to nitrogen also lengthen upon protonation (Ar-N- by

[4] Using the theory of atoms in molecules, specifically the AIMPAC computational package (10), we have undertaken a study of the topology of the charge density of amides **1***a*–**1***d* and **5***b*, in large part to characterize the nonbonded charge concentrations (lone pairs) on nitrogen. The Laplacians of ρ at the (3, −3) critical points of benzoquinuclidine (**7**) and **1***a* are virtually identical. This finding and the fact that the torsional angle between the (3,−3) critical point of the nonbonded charge concentration and the C=O group of **1***a* is 4.5° indicate that there is no interaction between the nitrogen lone pair and the π system of the carbonyl group.

Fig. 2. Displays of the AM1 optimized geometrical structures of the *cis*-O-protonated amides ((*a*) **3***a*; (*b*) **3***b*; (*c*) **3***c*; (*d*) **3***d*; (*e*) O-protonated **5***a*) and selected structural parameters of these species; those of the *trans* diastereomers are shown in square brackets.



0.016 and -CH_2-N- by 0.036 Å, respectively), but not to the same degree. These increases in the N—C(O) bond lengths calculated with AM1 are in accord with the results of an ab initio calculational study we have undertaken on **1***a*–**1***d* and **2***a*–**2***d* (at the HF/6-31G** level of theory) and with data reported on N-protonation of 1-azabicyclo[2.2.2]octan-2-one (the N—C(O) bond length increased by 0.071 Å) and 1-azabicyclo[3.3.1]nonan-2-one (the bond lengthened by 0.137 Å) obtained at the 6-31G* level of theory (11). In going from **2***a* to **2***d*, there is a progressive increase in the O-C-N^+-H torsional angle (**2***a*, 1.4°; **2***b*, 16.5°; **2***c*, 22.5°; **2***d*, 53.9°). Up to the present time, there have been no reports of X-ray crystallographic structure determinations of N-protonated amides.

The geometrical structures of the *cis*-O-protonated amides **3***a*–**3***d* and the most stable conformer of the O-protonated **5***a* are shown in Fig. 2 along with selected geometrical parameters. Values for the *trans*-O-protonated isomers **4***a*–**4***d* are shown in square brackets. That there is an increase in the resonance interaction involving the nitrogen lone pair in going from **1***a* to **1***d* is seen in the elongation of the C=O bond that accompanies O-protonation (**3***a* 0.077 Å, **3***b* 0.083 Å, **3***c* 0.088 Å, **3***d* 0.096) and a shortening of the C—N bond (**3***a* 0.030 Å, **3***b* 0.049 Å, **3***c* 0.060 Å, **3***d* 0.167 Å) relative to neutral amides and the N-protonated analogues is seen from the data in Fig. 1. In the case of O-protonated **5***a*, where full interaction of the nitrogen lone pair and C=O is possible, the C=O bond length increases by 0.175 Å and the N—C(O) bond shortens by 0.057 Å relative to the neutral amide. The H-O-C-N torsional angles of the O-protonated amides **3***a*, **3***b*, **3***c*, and **3***d*, respectively, are 179.2°, 175.5°, 175.4°, 172.5°.

The calculated heats of formation of amides **1***a*–**1***d*, **5***a*, and **5***b*, and the N-protonated compounds **2***a*–**2***d*, **6***a* and **6***b*, along with the calculated proton affinities (PA's, the negatives of the enthalpies of N-protonation) are given in Table 2. Also included in Table 2 are the AM1 calculated heats of formation of the O-protonated species **3***a*–**3***d* (the =O^+-H bonds are *cis* to the bridgehead nitrogen) and **4***a*–**4***d* (the =O^+-H bonds are *trans* to the bridgehead nitrogen) along with the PA's. It is seen that the nitrogen PA's of **1***a*–**1***c* range from 216.8 to 214.9. The accuracy of these values is unknown at present because the gas phase PA's of distorted amides have not been measured. In this connection, the PA's for N-protonation of 1-azabicyclo[2.2.2]octan-2-one and 1-azabicyclo[3.3.1]nonan-2-one calculated with AM1 are 214.1 and 211.7 kcal/mol, respectively. These values are smaller than the values (238.8 and 228.8 kcal/mol) at the HF/6-31G*//6-31G* levels of theory (11). It is noteworthy that the AM1 calculated PA for O-protonation of formamide (198.4 kcal/mol) is identical to the experimental value of 198.41 kcal/mol (12). On the other hand, *ab initio* calculations at the MP2/6-31G*//4-31G level of theory provided a PA of 203.7 kcal/mol for O-protonation, 5.3 kcal/mol higher than the experimental value (13). On the basis of the calculated enthalpies of formation, **1***a*–**1***c* should undergo equilibrium protonation preferentially on nitrogen, **1***d* should protonate on both oxygen and nitrogen, and **5***a* and **5***b* should protonate preferentially on oxygen. The reason for the difference in the gas phase stabilities of the *cis*- and *trans*-O-protonated species (Table 2) is unknown, although intramolecular hydrogen bonding to the nitrogen and (or) hyperconjugation of the oxygen lone pair with the C—N bond may give rise to the difference in stability of the diastereomers. We also calculated the enthalpies of formation of 3,4-dihydro-2,5-ethanoquinoline (benzoquinuclidine) (**7**) and the corresponding N-protonated species, and those data, along with the calculated enthalpy of protonation (PA), and available experimental pK_a's (2, 14) are given in Table 2.

A plot of PA (N-protonated) vs. the observed solution pK_a gives the satisfactory straight-line relationship in eq. [1], r^2= 0.98. Some sort of relationship is anticipated although one must be mindful that the solution pK_a's depend heavily on

$$[1] \quad \text{PA (N-protonated)} = 0.50\ \text{p}K_a + 215.3$$

solvation, which may be reflected in differential ΔS values in the various solution equilibria, but cannot be accounted for in the gas phase enthalpy calculations. Nevertheless, if we extrapolate the line to estimate the solution pK_a for N-protonated **2***d*, a value of −11.7 is obtained. As far as we are aware, there are no directly measured solution pK_a's of N-protonated amides. Even though our estimated value falls outside the range of the pK_a's (−7.22 to −8.38) of five noncyclic N-protonated amides estimated from rates of acid-catalyzed N–H exchange by Williams (15), it is possible that the relief of angle strain as seen in the case of the solvolysis of 1-chlorobicyclo[3.3.3]undecane (16) is the source of the higher than expected acidity of **2***d*. The results of our study suggest that AM1 calculations might be useful for predicting the pK_a's of N-protonated amides.

Table 2. Calculated enthalpies of formation and proton affinities.

Amide or amine	ΔH_f[a]	ΔH_f N-protonated	ΔH_f *cis*-O-protonated	ΔH_f *trans*-O-protonated	PA[b] N-protonated	pK_a	PA *cis*-O-protonated	PA *trans*-O-protonated

Methylation of 3,4-dihydro-2-oxo-1,4-propanoquinoline (1*b*), 3,3,4,5-tetrahydro-2-oxo-1,5-ethanobenzazepine (1*c*), and 3,3,4,5-tetrahydro-2-oxo-1,5-propanobenzazepine (1*d*)

We also studied the methylation of **1***b*, **1***c* and **1***d* by calculating the enthalpies of formation of N- and O-methylated compounds **2***e*–**2***g*, **3***e*–**3***g*, and **4***e*–**4***g* (Table 3). The N-methylated compounds derived from **1***b* and **1***c* are more stable than the *cis*- and trans-*O*-methyl species. In the case of **1***d*, the O-methyl diastereomers are calculationally more stable (*cis* 5.3 kcal/mol and *trans* 4.9 kcal/mol) than the N-methyl compound. Yet the N-protonated species **2***d* and the *cis*-O-protonated isomer **3***d* are nearly identical in energy (Table 2). Why the methylation of **1**d differs from the protonation is not evident at this time. If the relative energies of the methylated amides are important in determining the rates of the methylation, then **1***b* and **1**c will kinetically methylate on nitrogen and **1***d* will yield the O-methylated *trans* isomer.

This question was experimentally addressed as follows (17). Methylation of each of **1***b* and **1***d* by $CH_3OSO_2CF_3$ in CD_2Cl_2 was monitored by ^1H NMR over a 96 h period. During this time, in the case of **1***b* the peak attributable to $CH_3OSO_2CF_3$ at δ 4.21 diminished in intensity concomitant with the growth of a new singlet at δ 3.65. In the case of **1***d* the loss of the $CH_3OSO_3CF_3$ singlet gave rise to one at δ 4.45. In each case, the reaction mixture was quenched by the addition of H_2O, and worked up to yield products that were immediately subjected to exact mass and ^1H NMR analysis. The spectra of the respective materials proved to be identical with authentic N-methylated ring-opened **8** (in the case of **1***b*) and authentic methyl ester **9** (in the case of **1***d*). Overall, the processes are depicted in eqs. [2] and [3]. The above kinetic methylation studies give results for the position of methylation that are in full accord with what is expected on the basis of AM1 calculations, which show that **1***b* should methylate on nitrogen and **1***d* should methylate on oxygen.

Hydrolysis of N-protonated amides

A series of calculations was also undertaken to provide information about the mechanism of hydrolysis of the N-protonated amides. In the first study, **2***a* and **2***c* were converted to the N-protonated hydrates, **10***a* and **10***b*, which are found to be

[a]In kcal/mol.

roughly 16 and 13 kcal/mol, respectively, more stable than their corresponding N-protonated amides and one isolated H_2O molecule (Table 4). We next looked at heterolysis of the N-protonated hydrates in the presence of zero, one, and two associated H_2O molecules to determine the effects of solvating the hydrates. The HN^+—$C(OH)_2$ bonds of **10***a* and **10***b* were stretched in 0.1 Å increments with full geometry optimization (including the associated H_2O molecules) to calculate the potential energy profiles and transition structures for the heterolysis of the unsolvated and solvated hydrates into the corresponding dihydroxy carbenium ions. The associated enthalpies of formation for the hydrates and transition structures are given in Table 5. The calculated $\Delta H^{\neq}$'s shown in Table 5 (8.0–10.0 kcal/mol) fall in the range of the experimental values (Table 1), but the magnitudes are reversed. While the rate-determining steps for the hydrolyses of **1***a*, **1***b*, and **1***c* are not known with certainty, the work of Guthrie et al. — the calculated $\Delta G^{\neq}$ for heterolysis of the HN^+—$C(OH)_2$ bond of the N-protonated hydrate of *N*-methylformanilide where relief of strain is not an important factor is 12.4 kcal/mol — provides support for the calculational results (18). The computed potential energy profile for heterolysis of **10***a*·$2H_2O$ is displayed in Fig. 3. Figures 4*a* and 4*b* show the transition structures for heterolysis of **10***a*·$2H_2O$ and **10***c*·$2H_2O$ labelled with the N—$C(OH)_2$ bond lengths and showing the location of the two solvating waters. The dihydroxy carbenium ion in reality is probably not the final product of the heterolysis, which should be the N-protonated carboxylic acid. In support of this, we have calculated the ΔH_f for the N-protonated amino acids resulting from N—C cleavage of **10***a* and **10***c* with one associated water, the values being 6.67 and 3.59 kcal/mol. With two associated waters, the ΔH_f values are −64.13 and −68.85 kcal/mol, respectively, for the N-protonated amino acids derived from **10***a*·$2H_2O$ and **10***c*·$2H_2O$. These values are substantially lower than the corresponding dihydroxy carbenium ions (carbenium ion derived from **10***a*·$1H_2O$, 19.37; **10***a*·$2H_2O$, −50.41 kcal/mol; **10***c*·$1H_2O$, −55.26 kcal/mol), but we have not explored theoretically the possible routes for the required $C^+(OH)_2 \rightarrow$ N proton transfer. The important result of the calculated enthalpies for heterolysis is the apparent insensitivity of the $\Delta H^{\neq}$ to the presence of the solvating waters. This result is in accord with heats of hydration of NH_4^+ in the presence of one, two, or three water molecules obtained experimentally in the gas phase and with AM1 calculations. The experimental gas phase heats of hydration of NH_4^+ in the presence of one, two, and three water molecules are −17.3, −14.7, and −13.4 kcal/mol, respectively (19); AM1 calculations give values of −15.3, −13.1, and −14.9 kcal/mol, respectively (20). Importantly, the low activation energy for cleavage suggests that the N-protonated hydrates, once formed, easily proceed to products through low-energy pathways involving simple N—$C(OH)_2$ cleavage, followed by rapid proton transfers to yield the N-protonated carboxylic acids as the final products.

In a second study, N-protonated amides **2***a* and **2***b* were solvated with two and three water molecules and subjected to HN^+—C(O) stretches of 0.1 Å to ring open to the corresponding acylium ion. The ΔH_f values for the processes are given in Table 6 while the transition structures are displayed in Figs. 4*c* and 4*d*. Two points are of note. First, the computed ΔH_f values for the geometry-optimized N-protonated amides with associated water molecules are higher than for the corresponding hydrates (e.g., ΔH_f (**2***a*·$2H_2O$) − ΔH_f (**10***a*·$1H_2O$) = 8.2 kcal/mol; ΔH_f (**2***a*·$3H_2O$) − ΔH_f (**10***a*·$2H_2O$) = 9.0 kcal/mol), confirming that solvation does not alter the relative stabilities of the N-protonated amides and corresponding hydrates. Second, the heterolysis of **2***a* → acylium ion in the presence of two or three H_2O molecules proceeds with a $\Delta H^{\neq}$ of 17.9 or 19.2 kcal/mol: the corresponding $\Delta H^{\neq}$ values for the similar heterolysis of **2***c* are 20.8 and 28.8 kcal/mol. These high barriers render N—C cleavage of **2***a,c* to the acylium ions far less likely than the pathways involving hydrate formation followed by N—$C(OH)_2$ cleavage.

[b]Attempts to refine the transition structure at the maximum of the potential energy surface with SIGMA or NLLSQ calculations failed.

Fig. 3. AM1 potential energy profile for the heterolysis of hydrate **10a** solvated with two water molecules.

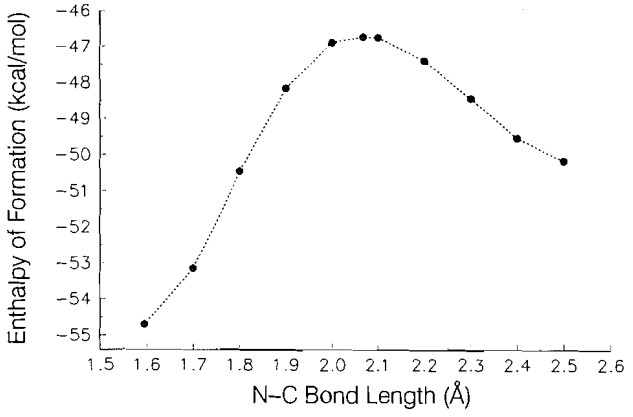

Fig. 4. Displays of the transition structures and the C—N bond lengths (Å) for the heterolysis of N-protonated hydrates and N-protonated amides solvated with two H_2O molecules: (*a*) **10***a*; (*b*) **10***c*; (*c*) **2***a*; (*d*) **2***c*.

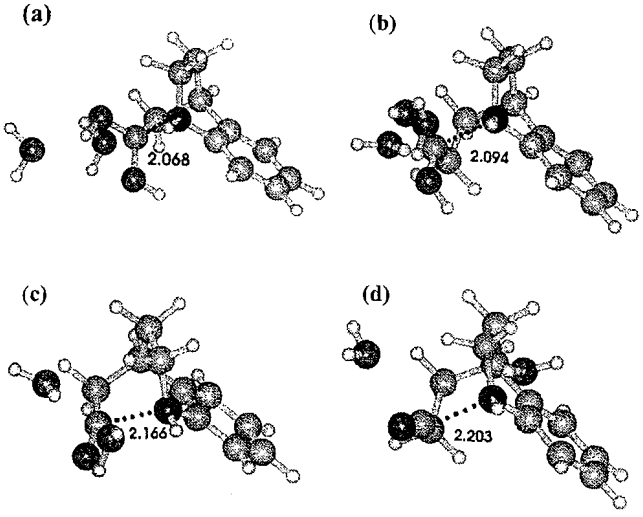
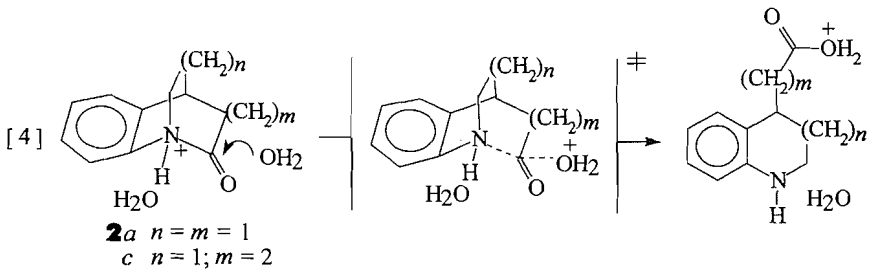


As a final check on the viability of other N—C bond cleavage pathways, a water molecule of the above solvated amides (**2***a*,*c*) was allowed to attack the C=O group. This was done by selecting the H_2O best aligned for nucleophilic attack, and decreasing the H_2O...C=O distance in 0.1 Å increments. The ΔH_f values of the solvated N-protonated amides, the transition structures, and the $\Delta H^{\neq}$'s are given in Table 7. It is seen that the $\Delta H^{\neq}$'s for the nucleophilic reaction of **2***a* and **2***c* with H_2O



2*a* $n = m = 1$
c $n = 1; m = 2$

are very much larger than the $\Delta H^{\ddagger}$'s found calculationally for the solvolysis of the N-protonated hydrates and amides as well as the values found experimentally. The calculated process is depicted in eq. [4] and leads to the corresponding O-protonated carboxylic acids. Because the O-protonated carboxylic acid is a very strong acid, proton transfer, possibly occurring simultaneously with ring opening, to a solvating water molecule would be fast. The neutral amino acid with the hydronium ion bonded with the carbonyl group would, in a fast process in the solvent cage, transform into the N-protonated amino acid. We have not investigated possible routes for the proton transfers calculationally. Nevertheless, this study suggests that the N-protonated distorted amides do not hydrolyse via the nucleophilic ring-opening reaction depicted in eq. [4].

Synthesis and characterization of polymer-bound selenium coronands: enhancing the stability of reactive dications by restricting intermolecular interactions

Ivan Cordova-Reyes, Hanbin Hu, Jian-Hua Gu, Elizabeth VandenHoven, Ali Mohammed, Steven Holdcroft, and B. Mario Pinto

Abstract: The stepwise synthesis of 1,5,9,13-tetraselenacyclohexadecan-3-ol **7** from the reaction of sodium propane-1,3-bisselenolate-2-ol with 4,8-diselenaundecan-1,11-di-*p*-toluenesulfonate **5** in THF and ethanol in 62% yield is described. Compound **5** is obtained from the corresponding diol **3**, which is obtained, in turn, from the reaction of sodium propane-1,3-bisselenolate with two equivalents of 3-chloropropanol. 1,5-Diselenacyclooctan-3-ol **9** and 1,5,9,13-tetraselenacyclohexadecan-3,11-diol **10** are obtained in yields of 43% and 11%, respectively, from the one-step reaction of sodium propane-1,3-bisselenolate-2-ol with 1,3-dibromopropane. Polymers with pendant selenium coronands, 1,5-diselenacyclooctane (8Se2) and 1,5,9,13-tetraselenacyclohexadecane (16Se4), have been prepared by free radical polymerization of the corresponding selenium coronands **9** and **7**, derivatized as their acryloyl esters **11** and **12**. Copolymers of methyl acrylate and 3,7-diselenacyclooctyl acrylate **11** have also been prepared in analogous fashion. The polymers have been characterized by ^{1}H and ^{13}C NMR, IR, and UV–visible spectroscopy. The redox chemistry of polymer-bound selenium coronands in solution, and in the form of thin films coated on electrodes, has been determined by electrochemical methods. Selenium coronands attached to the polymer chain exhibit enhanced oxidative stability compared to monomeric analogues, presumably because restrictive motion of polymer-bound moieties inhibits inter- and intra-molecular degradation reactions. Electroactivity of polymer-modified electrodes is restricted to a few monolayers close to the electrode surface. Spatial separation of coronands along the chain, achieved by copolymerization with electro-inert methyl acrylate, gave copolymer-modified electrodes that possessed even greater redox stability than their corresponding homopolymers. Furthermore, by blending electro-inert poly(methyl acrylate) with electroactive selenium coronand copolymers, polymer-modified electrodes that possessed superior electrochemical stability were obtained.

Key words: selenium coronands, polymers, electrochemistry, dications.

Résumé : On décrit la synthèse par étape (rendement de 62%) du 1,5,9,13-tétrasélénacyclohexadécan-3-ol, **7**, réalisée par réactions par étapes du propane-1,3-bissélénolate-2-ol de sodium avec le di-*p*-toluènesulfonate de 4,8-disélénundécan-1,11-diyle, **5**, dans le THF et l'éthanol. On obtient le composé **5** à partir du diol **3** correspondant qui est obtenu, à son tour, par la réaction du propane-1,3-bissélénolate de sodium avec deux équivalents de 3-chloropropanol. Les 1,5-disélénacyclooctan-3-ol, **9**, et 1,5,9,13-tétrasélénacyclohexadécan-3,11-diol, **10**, ont été obtenus avec des rendements respectifs de 43% et de 11% par des réactions en une étape du propane-1,3-bissélénolate-2-ol de sodium avec le 1,3-dibromopropane. On a préparé des polymères portant des pendants de coronands de sélénium, 1,5-disélénacyclooctane (8Se2) et 1,5,9,13-tétrasélénacyclohexadécane (16Se4), en procédant à la polymérisation des coronands séléniés correspondants, **9** et **7**, transformés en dérivés sous la forme de leurs esters acryloyles, **11** et **12**. Opérant d'une façon analogue, on a aussi préparé les copolymères de l'acrylate de méthyle et l'acrylate de 3,7-disélénacyclooctyle, **11**. On a caractérisé les polymères par leurs spectres RMN du ^{1}H et du ^{13}C ainsi que par leurs spectres IR et UV–visible. Faisant appel à des méthodes électrochimiques, on a déterminé la chimie rédox des coronands du sélénium liés à ces polymères, en solution ainsi que sous la forme de films minces sur des électrodes. Les coronands du sélénium attachés au polymère présentent une stabilité oxydative qui est augmentée par rapport aux analogues monomériques, probablement à cause des restrictions aux mouvements des portions attachées au polymère qui inhibent les réactions de dégradations inter- et intramoléculaires. L'électroactivité des électrodes modifiées par le polymère est restreinte à quelques monocouches proches de la surface de l'électrode. La séparation spatiale des coronands le long de la chaîne, qui est réalisée par une copolymérisation avec de l'acrylate de méthyle électro-inerte, fournit des électrodes modifiées par le copolymère qui possèdent une stabilité rédox encore plus grande que celle des homopolymères correspondants. De plus, en mélangeant du

[Traduit par la rédaction]

Introduction

We recently reported the synthesis of a novel class of compounds, the selenium coronands (1–3). Of interest to us was the comparison of properties between the selenium coronands and the lighter sulfur congeners, in particular, the preferential stabilization of transition metal ions by these macrocycles, the effect of ligand conformation on chelation, and the propensity for electron transfer reactions in the free ligands as well as in the metal-ion complexes. Towards this end, we have reported the conformational analysis of the free ligands (1, 2), their metal-ion complexation properties (4–6), and the unusual electron transfer reaction of a Cu(II)–selenium coronand complex (4). Although the metal-ion complementarity and structural features of the complexes are similar to those of the sulfur congeners (4–8), the observed differences in electron transfer chemistry (4) were not anticipated and were linked to the propensity for transannular stabilization in the ligands.

We now report the synthesis of functionalized selenium coronands for incorporation into polymers or for the ready attachment of aliphatic or functionalized chains. The latter compounds are of interest for the development of transition-metal ion-selective electrodes and membrane transport systems or for the generation of water soluble or micellar transition-metal ion transport systems. We also report the synthesis of the first polymer-bound selenium coronands for investigation as new materials together with their characterization by spectroscopic and electrochemical techniques. We describe the electrochemistry of polymers in solution and in the form of polymer-modified electrodes, and illustrate how spatial control of the coronands leads to stabilization of their oxidized state.

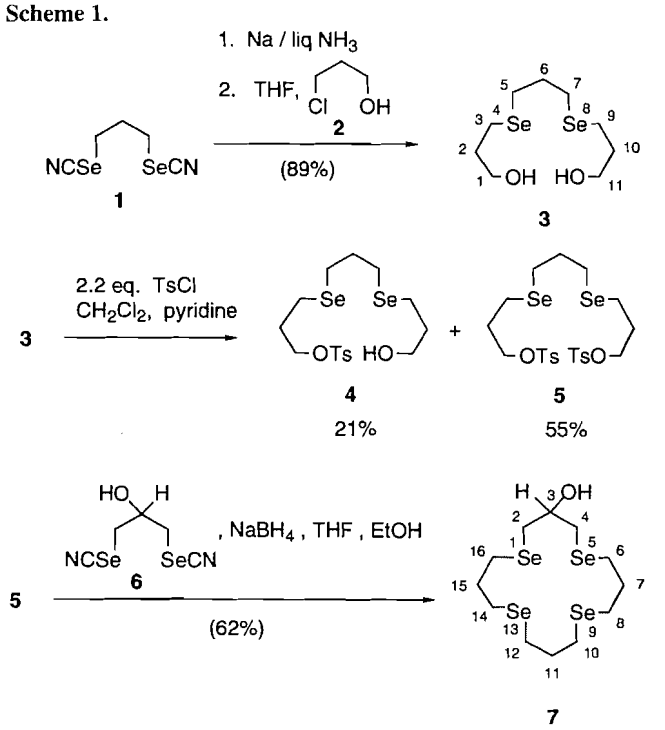
Results and discussion

Synthesis

The strategy for the synthesis of the polymeric selenium coronands involved the synthesis of a selenium coronand bearing a hydroxyl functional group, which could be used subsequently to tether the selenium coronands to a second functional group to form a reactive monomer. An acrylate ester was chosen as the latter functional group and radical-initiated vinyl polymerization as the method of polymerization. The route is general in that it can be adapted to yield different polymers by choice of the vinyl group attached to the coronand or the selenium coronand itself. The strategy is illustrated here for the case of two selenium coronands, as their acrylate esters. In addition, copolymers have been synthesized from the selenium coronand-containing monomers and other reactive monomers.

The monomers were synthesized as follows. Reaction of the bisselenolate anion, derived from propane-1,3-bisselenocyanate **1** (9) by sodium metal reduction in liquid ammonia, with 2 equivalents of 3-chloropropanol **2** afforded the acyclic diol containing two selenium atoms, namely 4,8-diselenaundecane-1,11-diol **3** in 89 % yield (Scheme 1). Tosylation of the diol **3** gave a mixture of the monotosylate **4** (21%) and the

Scheme 1.

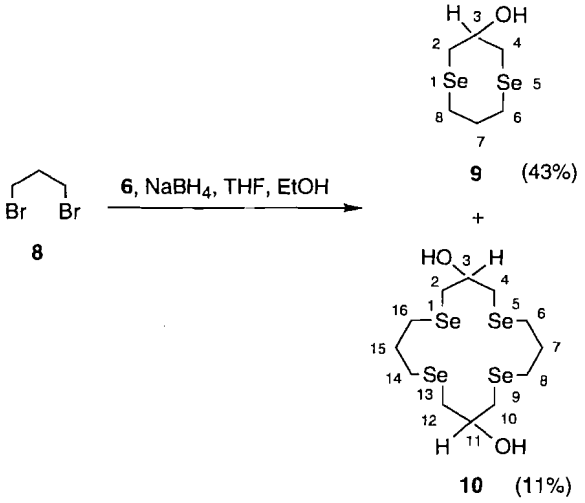


desired ditosylate **5** (55%). Conversion of the ditosylate to the functionalized coronand was effected by treatment with the bisselenolate anion derived from 1,3-bisselenocyanatopropan-2-ol **6**. Compound **6** was obtained, in turn, from the nucleophilic displacement of 1,3-diiodo-2-propanol with potassium selenocyanate in acetone. The optimum conditions for the cyclization reaction consisted of the simultaneous addition of the ditosylate **5** and the bisselenocyanate **6** to a suspension of sodium borohydride in a mixture of THF and ethanol over a period of 10 h. The target 16-membered selenium coronand containing four selenium atoms and a hydroxyl moiety **7** was obtained in a yield of 62%.

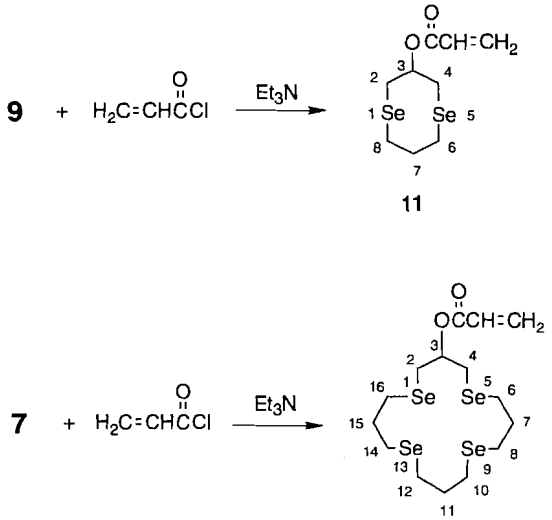
The synthesis of the mono-functionalized 8-membered coronand and the difunctionalized 16-membered coronand was a one-step synthesis that consisted of the reaction of the bisselenolate anion derived from **6** and 1,3-dibromopropane **8** (Scheme 2). 1,5-Diselenacyclooctan-3-ol **9** and 1,5,9,13-tetraselenacyclohexadecan-3,11-diol **10** were obtained in yields of 43% and 11%, respectively.

Reaction of 1,5-diselenacyclooctan-3-ol **9** with acryloyl chloride in THF and dichloromethane containing triethylamine afforded the acrylate ester **11** in 87% yield (Scheme 3). Similarly, 1,5,9,13-tetraselenacyclohexadecan-3-ol **7** was converted to its acrylate ester **12** in 75% yield. The monomer **11** was polymerized in oxygen-free benzene containing AIBN as a radical initiator to give poly(1,5-diselenacyclooctyl acrylate) (poly(8Se2)) **13** in 90% yield (Scheme 4). An analogous reaction of the monomer **12** afforded poly(1,5,9,13-tetraselenacyclohexadecyl acrylate) (poly(16Se4)) **14** in 95% yield.

Scheme 2.



Scheme 3.



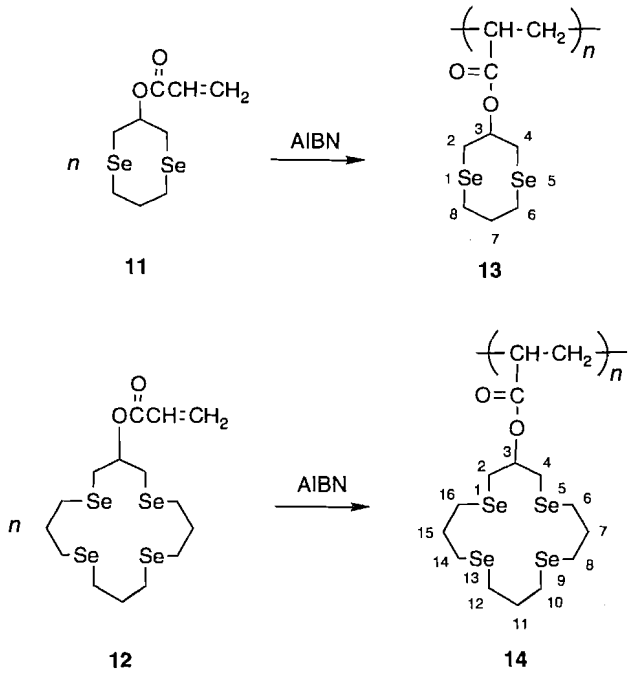
Copolymers consisting of 1,5-diselenacyclooctyl acrylate units and methyl acrylate units were prepared with mixtures of methyl acrylate **15** and 1,5-diselenacyclooctyl acrylate **11** in analogous fashion to that described above (Scheme 5). A starting ratio of **11**:**15** of 1:1 yielded a copolymer **16** with a ratio of diselenacyclooctyl acrylate:methyl acrylate units of 1.4:1, as determined by integration of the peaks for H_3 and OCH_3 in the ^{1}H NMR spectrum. A separate experiment with a starting ratio of **11**:**15** of 1:2 yielded a copolymer **16** with a ratio of diselenacyclooctyl acrylate:methyl acrylate units of 0.75:1.

The microanalysis for **13** was calculated based on a degree of polymerization of 8 and on the assumption that chain termination had occurred via disproportionation, to give one $(CH_3)_2CHC(CN)H$ unit per molecule. In the case of **14**, a molecular weight determination was not possible but a degree of polymerization of 8 was found to be consistent with the analytical data.

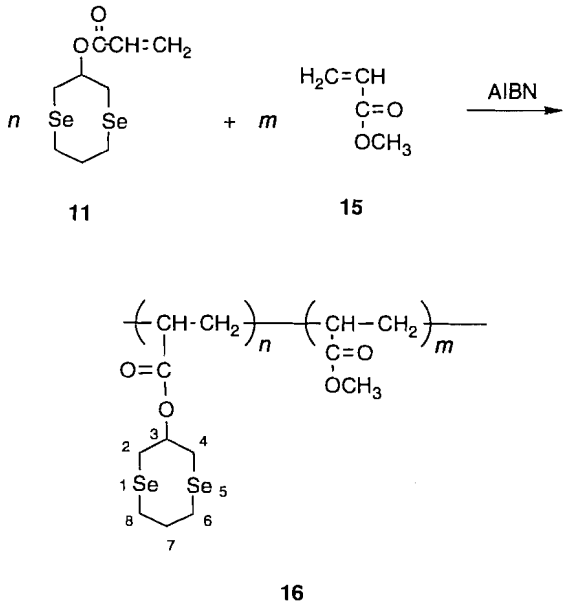
^{1}H NMR spectra

The ^{1}H NMR spectra of poly(8Se2) **13** and mono 8Se2 **11** (Fig. 1) clearly show that the vinyl hydrogens of mono 8Se2 (5.70 ppm to 6.50 ppm) disappear after the polymerization.

Scheme 4.



Scheme 5.



Several new signals, associated with backbone hydrogens of the polymer chain, appear in the region 1.40–2.30 ppm. For poly(8Se2), the peak at 2.27 ppm is assigned to -CO-C*H*-CH_2- of the polymer backbone and the peaks at 1.46, 1.64, and 1.88 ppm to the two diastereotopic methylene protons (-CO-CH-CH_2). The complexity of these signals indicates that the structure of the poly(8Se2) is an atactic polymer. Comparison of the spectra of mono 16Se4 **12** and poly(16Se4) **14** indicates similar features to those of the lower homologues, mono 8Se2 **11** and poly(8Se2) **13** (Fig. 2).

Electrochemistry of selenium coronands

Selenium coronands 8Se2 and 16Se4 were electrochemically

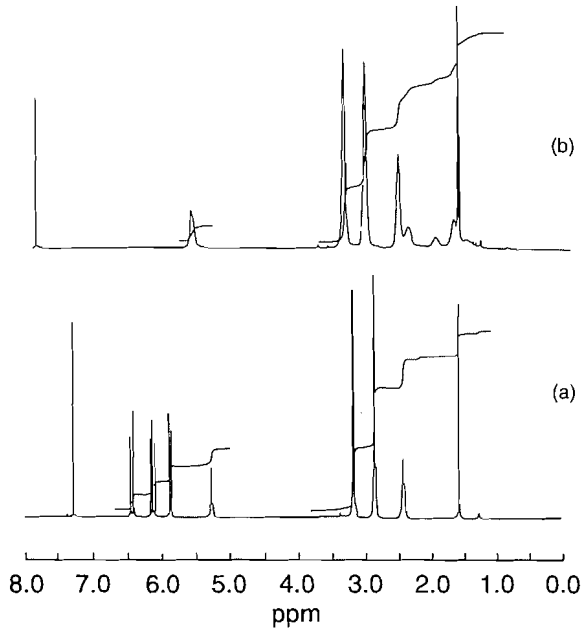

Fig. 2. ^{1}H NMR spectra of (*a*) mono 16Se4 **12** and (*b*) poly(16Se4) **14**.

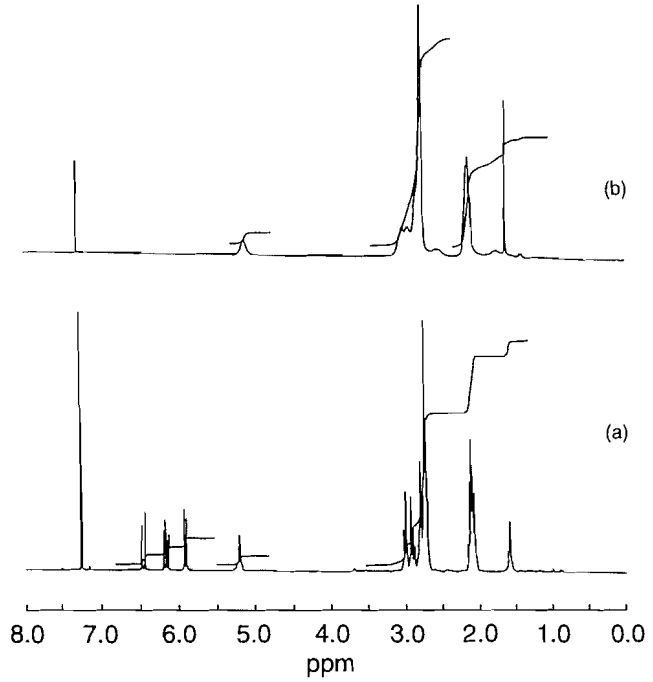
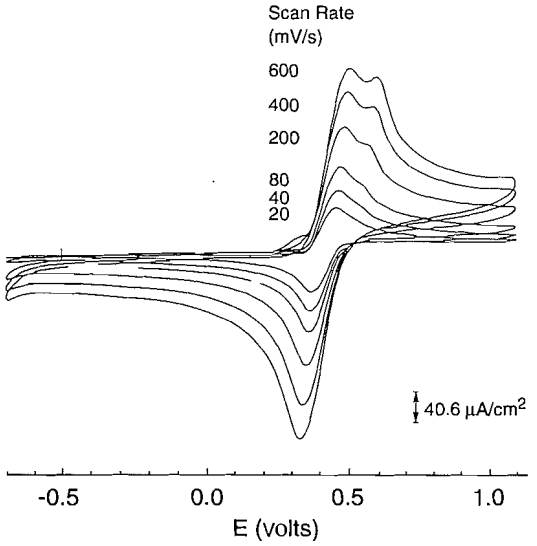


oxidized at carbon electrodes. The redox processes are complex due to subsequent chemical reactions following electron transfer. Previous studies on the electrochemistry of 16Se4 in dichloromethane–TEAP electrolyte revealed that radical cation and dication intermediates undergo rapid chemical rearrangement via one of two paths (6, 10). The first path is intermolecular in nature, in which oxidized species react with neutral ligands, as shown below; L represents the selenium coronand and subscripts refer to different selenium coronands. The second pathway occurs intramolecularly via transannular

Fig. 3. Scan rate dependence on cyclic voltammograms of 1×10^{-3} M 1,5-diselenacylcyclooctane (8Se2) in 0.1 M TEAP – CH_3CN. Reference electrode, Ag/AgCl.



stabilization (4,6,10). The scheme is analogous to that proposed by Asmus and Musker for the oxidation of 1,5-dithiacyclooctane (11).

$$[1] \quad L_1 \xrightarrow{-e^-} L_1^{+\cdot} \xrightarrow{L_2} [L_1 - L]^{+\cdot}$$

In the present study, the electrochemistry of free and polymer-bound selenium coronands was investigated in acetonitrile and dichloromethane, respectively; polymer-modified electrodes were studied in acetonitrile. Cyclic voltammograms of 8Se2 in acetonitrile–TEAP were found to be quasi-reversible. Previous studies in CH_2Cl_2 established that the oxidation proceeded by a two-electron transfer process (6, 10, 12). In acetonitrile solvent, a single oxidation peak was observed at slow voltage sweep rates (<20 mV/s) whereas two oxidation peaks were observed at faster sweep rates (Fig. 3). These results are consistent with previous electrochemical studies of selenium coranands (6, 10, 12) and sulfur coronands (11). Thus, by drawing upon previous reports, the electrochemistry can be explained in the following manner (Scheme 6). Following oxidation of 8Se2 to form a radical cation, either a second electron is removed to form a diradical cation with subsequent formation of a transannular bond or, alternatively, the radical cation undergoes transannular stabilization prior to losing a second electron. Under the fast scan rate regime, two oxidation peaks are observed due to two one-electron transfer steps. We suggest the occurrence of a "slow" transannular reaction of the intermediates. The oxidation process is designated an EEC (electrochemical–electrochemical–chemical) process. At slow scan rate, e.g., <20 mV/s, transannular stabilization occurs on the time scale of the experiment so that only one two-electron oxidation peak is observed. This pathway represents an ECE process.

We and others have previously established that the opportunity exists for inter-coronand reactions between oxidized and neutral species during the electrochemical process (eq. [1]) (6, 10, 11). Thus, the concentration of the coronand is expected to play an important role. Indeed, as the concentration of the selenium coronand is increased from 10^{-3} M to 10^{-2} M, inter-

Scheme 6.

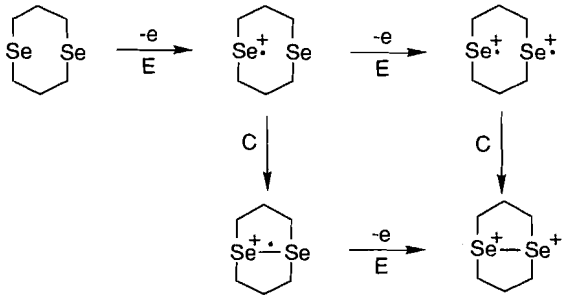


Fig. 4. Concentration dependence of cyclic voltammograms of 1,5-diselenacylcyclooctane (8Se2) in 0.1 M TEAP – CH_3CN: (*a*) 1×10^{-3} M, (*b*) 1×10^{-2} M. Reference electrode, Ag/AgCl; scan rate, 20 mV/s.

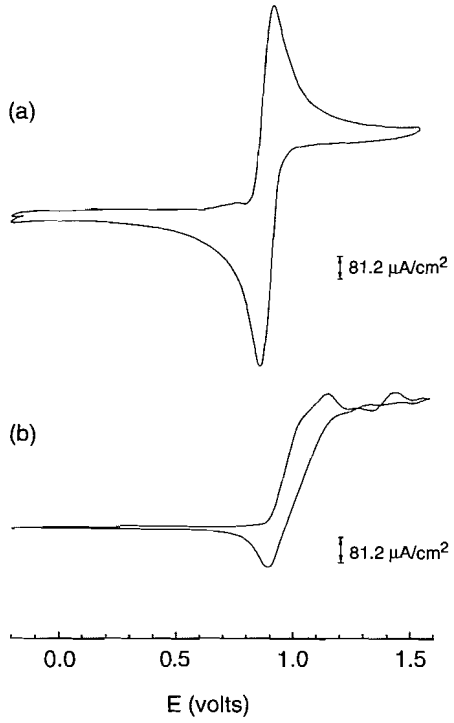

molecular reactions between oxidized products and neutral selenium coronand are more pronounced, and it becomes difficult to observe the corresponding re-reduction peak, as observed in Fig. 4. In addition, at higher concentrations, a red/brown precipitate (elemental selenium) is formed near the electrode surface upon oxidation.

A cyclic voltammetric study shows that the redox chemistry of 16Se4 in acetonitrile–TEAP (Fig. 5) is slightly different from that of 8Se2. Each oxidation peak corresponds to a one-electron transfer (6, 10). We propose that the radical cation formed, $[16Se4]^{+\cdot}$, rapidly undergoes transannular stabilization, and a new selenium–selenium bond is formed. The proposal is based on the observation of such transannular stabilization in the dication, $[16Se4]^{2+}$, and on the similarity of λ_{max} values (256 nm) for the dication and the radical cation observed in spectroelectrochemical experiments (10). Removal of a second electron prior to transannular stabilization, i.e., the EE process, is not competitive on the time scale of the experiment. Thus, it appears that oxidation of 16Se4 is

Scheme 7.

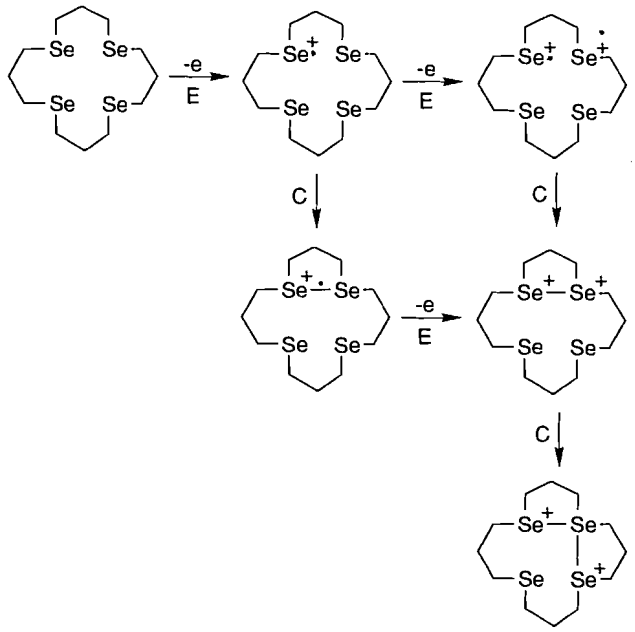

Fig. 5. Concentration dependence of cyclic voltammograms of 1,5,9,13-tetraselenacyclohexadecane (16Se4) in 0.1 M TEAP – CH_3CN: (*a*) 1×10^{-4} M, (*b*) 1×10^{-2} M. Reference electrode, Ag/AgCl; scan rate: 20 mV/s.

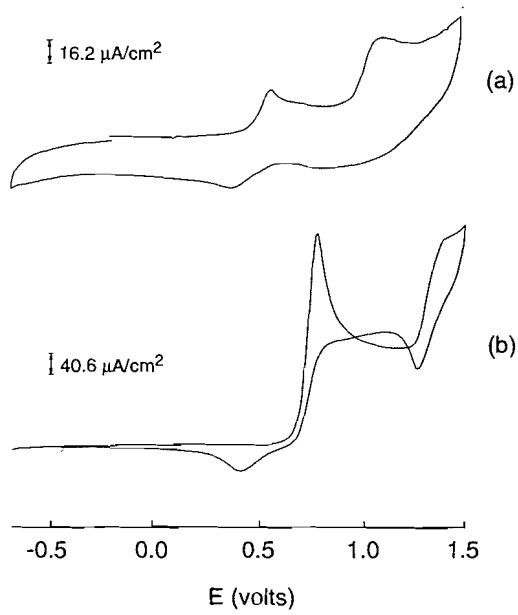

dominated by an ECEC process, as shown in Scheme 7. As a result of rapid transannular stabilization of the radical cation, changing the potential scan rate affects the shapes of cyclic voltammograms to a lesser degree than 8Se2 (not shown); if the redox process had gone through the EECC process as shown in Scheme 7, the ratio of anodic to cathodic peak currents would have exhibited considerable scan rate dependence. As was the case with 8Se2, increasing the concentration of the 16Se4 has a pronounced effect on the voltammograms, as shown in Fig. 5. Cyclic voltammetry obtained with the lowest concentration of 16Se4 shows two

Fig. 6. Cyclic voltammograms of poly(8Se2) **13** in 0.1 M TEAP – CH_3CN: (*a*) 1×10^{-4} M, (*b*) 1×10^{-3} M, (*c*) 1.3×10^{-2} M. Reference electrode, Ag/AgCl; scan rate: 20 mV/s. Concentrations are given with respect to pendant selenium coronands.

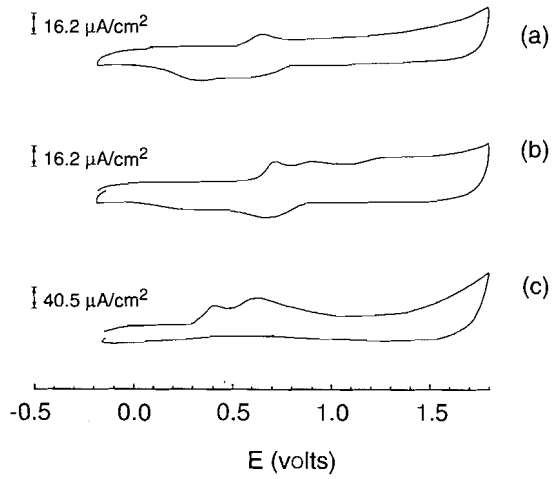

Fig. 7. Cyclic voltammograms of poly(16Se4) **14** in 0.1 M TEAP – CH_2Cl_2: (*a*) 1×10^{-4} M, (*b*) 5×10^{-3} M. Reference electrode, Ag/AgCl; scan rate, 80 mV/s. Concentrations are given with respect to pendant selenium coronands.

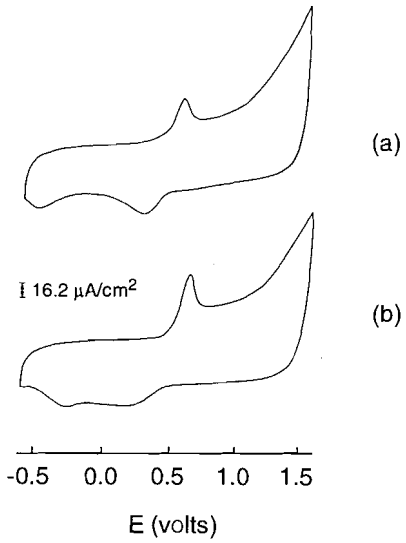


relatively reversible electrochemical oxidations, but as the concentration is increased the voltammetry deviates from Nernstian behaviour and gives rise to irregular voltammetric responses. We attribute this behaviour to the prevalence of intermolecular reactions of the oxidized intermediates with neutral ligand at high concentrations of the reactant. This effect is less pronounced for 16Se4 than for 8Se2, presumably because of the relative stability of $[16Se4]^{2+}$ over $[8Se2]^{2+}$. For both 8Se2 and 16Se4, the oxidation peak current varies linearly with the square root of scan rate, indicating that anodic oxidation is diffusion controlled.

Cyclic voltammetric studies of the monomers 1,5-diselenacyclooctylacrylate (mono8Se2) **11** and 1,5,9,13-tetraselenacyclohexadecyl acrylate (mono16Se4) **12** show that their redox behaviour is similar to that of the corresponding selenium coronands, indicating that the double bond associated with the monomer has no obvious effect on the redox properties of the coronand. We have also synthesized 1,5,9,13-tetraselenacyclohexadecyl propionate, in which the double bond in mono16Se4 **12** is saturated. The cyclic voltammograms of this compound are similar to that of mono16Se4, indicating that the functionality connecting the selenium coronands to the polymer chain has no electronic influence on the electrochemistry of the coronand. The relationship of i_{pa} versus $\upsilon^{1/2}$ for all small molecules evaluated in this study was linear, indicating diffusion-controlled electrochemistry.

Electrochemistry of poly(selenium coronands)

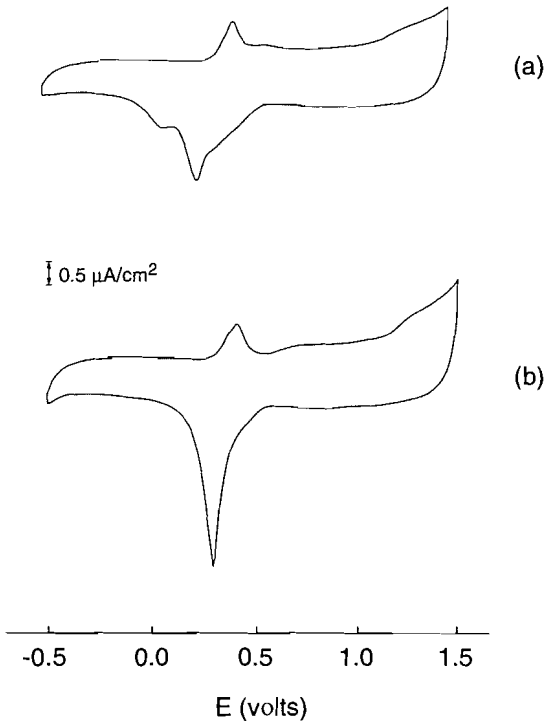
For the poly(selenium coronands), the electroactive pendant funtionalities are sterically crowded by virtue of their covalent attachment to the polymer backbone. As a result, the microscopic concentration of selenium coronands is relatively high both in solution and in the solid state, even though the macroscopic polymer concentration may be low. In principle, the high concentration of coronands might facilitate intermolecular reactions and, therefore, the redox properties of the polymer in the solution would be expected to be irreversible. Alternatively, the close juxtapositioning of electroactive functionality might facilitate electron hopping along, and between, polymer chains. Figures 6 and 7 show cyclic voltammograms of poly(8Se2) **13** and poly(16Se4) **14** in solution for various concentrations of polymer.

The voltammograms of low molar concentrations of the poly(8Se2) **13** ($[8Se2] < 10^{-3}$ M) show a relatively high degree of reversibility. This is surprising since the local concentration of the selenium coronand bound to a polymer chain in a polymer solution is estimated to be 0.1–1 M based on the root-mean-square volume of a polymer coil in a good solvent. Upon increasing the concentration of poly(8Se2), the reduction peaks gradually disappear into the baseline and, as with the oxidation of 8Se2 in solution, new oxidation peaks appear. This is believed to be due to a corresponding increase in intermolecular coupling reactions between oxidized and neutral selenium coronands on different polymer chains.

In contrast, no obvious changes in the shapes of voltammograms with increasing concentration are observed for poly(16Se4) **14** (Fig. 7). The anodic peak current remains constant with increasing concentration, which indicates electroprecipitation of the polymer to form a polymer-modified electrode. It will be shown in a following section that poly(selenium coronands) in the form of thin films on electrodes exhibit enhanced reversibility and stability compared to polymers oxidized in solution.

Copolymers of mono8Se2 and methylacrylate were prepared in which the diluting effect of the methylacrylate group was employed to partially separate 8Se2 selenium coronands on the polymer chains. Thus, electron transfer processes between adjacent selenium coronands should be interrupted and intermolecular reactions inhibited. Figure 8 shows the cyclic voltammograms of two copolymers. Cop8Se2-A possesses a molar 8Se2 to methylacrylate ratio of 1.4:1, and Cop8Se2-B possesses a ratio of 0.75:1. A direct comparison of the behaviour of poly(8Se2) **13**, (Fig. 6) with that of the copolymers at an equivalent coronand concentration of $\sim 10^{-3}$ M confirms that separation of the electroactive units along the chain leads to much greater reversibility upon anodic oxidation. When the concentration of the copolymer in solution is

Fig. 8. Cyclic voltammograms of copolymers in 0.1 M TEAP – CH_2Cl_2: (*a*) Cop8Se2-A **16** (1.0×10^{-3} M), (*b*) Cop8Se2-B **16**, (1.05×10^{-3} M). Reference electrode, Ag/AgCl; scan rate: 20 mV/s. Concentrations are given with respect to pendant selenium coronands.



increased such that the coronand concentration increases from 10^{-4} to 10^{-2} M, a loss in reversibility similar to that observed for poly(8Se2) **13** is observed, indicating that interchain coupling reactions become increasingly important at high concentration.

Polymer modified electrodes

In the previous section, the cyclic voltammetry of polymers in solution has been described. However, for applications of ion-selective and ion-permeable membranes, and for electrocatalysis, it is necessary to understand redox processes occurring in swollen films (13). This was achieved by studying poly(8Se2) polymer-modified electrodes in acetonitrile–TEAP electrolyte. This electrolyte was chosen because acetonitrile swells the polymer, thus allowing electrolyte to access the polymer–electrode interface but not dissolve it. A cyclic voltammogram of polymer-modified electrodes based on poly(8Se2) **13** is shown in Fig. 9*a*. The reverse potential cycle indicates that the redox couple is partially reversible. This is remarkable given that the concentration of 8Se2 in the film is calculated to be ~3 M. We believe that this enhanced stability is due to the physical constraint of the selenium coronands in the film that serves to restrict intra-chain and inter-chain coupling reactions. Polymer-modified electrodes using poly(16Se4) **14** also exhibit quasi-reversible cyclic voltammograms (Fig. 9*b*). The electrochemistry of poly(8Se2) **13** and poly(16Se4) **14** was not completely reversible, and a loss of electroactivity was observed upon repetitive cycling. However, copolymers Cop8Se2-A and Cop8Se2-B were found to be much more stable to repetitive potential cycling than the corresponding

Fig. 9. Cyclic voltammograms of polymer modified electrodes in 0.1 M TEAP – CH_3CN: (*a*) poly(8Se2) **13**, (*b*) poly(16Se4) **14**. Scan rate: 160 mV/s.

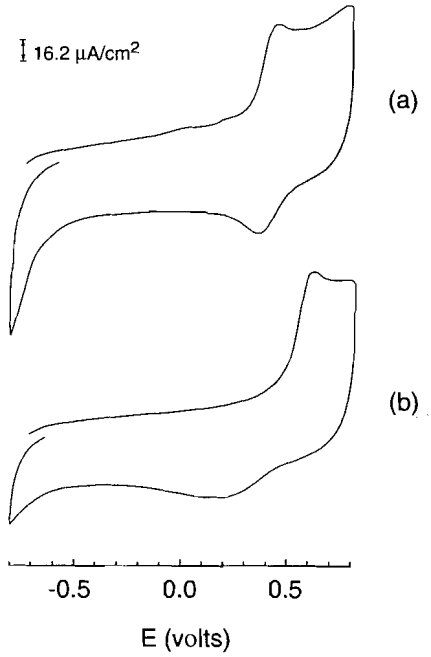


Fig. 10. Ratio of Q_c/Q_a against number of redox cycles for polymer-modified electrodes in 0.1 M TEAP – CH_3CN: (*a*) Cop8Se2-B **16**, (*b*) Cop8Se2-A **16**, (*c*) poly(8Se2) **13**.

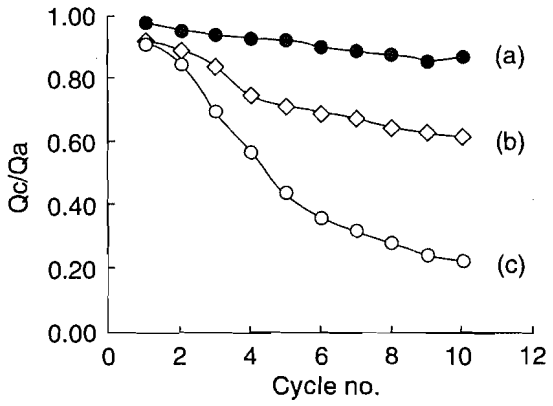

homopolymer. We attribute this behaviour to the spatial separation of coronands and lesser extent of intermolecular coupling reactions in the copolymer samples. A reasonable measure of the electroactive stability was obtained by plotting the cathodic to anodic charge ratio, i.e., charge under the re-reduction peak divided by the charge under the oxidation peak (Q_c/Q_a), against the number of potential cycles. A decreasing Q_c/Q_a ratio with the number of scans indicates instability of the oxidized form. Figure 10 indicates that electrochemical stability increases in the order poly(8Se2) < Cop8Se2-A < Cop8Se2-B, consistent with the decreasing concentration, and increasing spatial separation, of 8Se2 in the polymer films.

In addition to separating coronands along the polymer chain, we attempted to physically separate poly(8Se2) chains from one another by preparing polymer blends in which poly(8Se2) **13**, Cop8Se2-A **16**, and Cop8Se2-B **16** were

Table 1. Characteristics of electrodes modified with films of poly(selenium coronands).

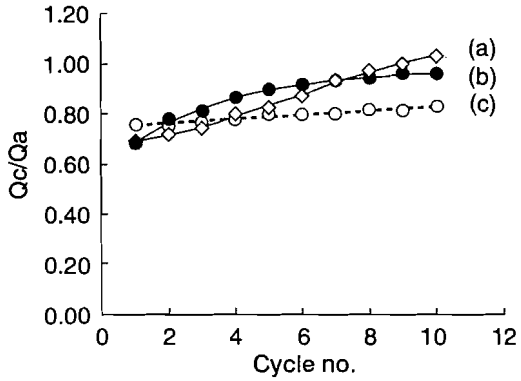
Fig. 11. Ratio of Q_c/Q_a against number of redox cycles for polymer-modified electrodes in 0.1 M TEAP – CH_3CN: (*a*) 1:1 Cop8Se2-A **16**/poly(methylacrylate) blend; (*b*) 1:1 Cop8Se2-B **16**/poly(methylacrylate) blend; (*c*) 1:1 poly(8Se2) **13**/poly(methylacrylate) blend.



mixed, and solution-cast with an inert polymer, poly(methylacrylate) (PMA). Blends of poly(8Se2) with PMA represent polymer systems in which the coronands are juxtaposed to one another along the polymer chain but in which individual chains are diluted in the solid state by inert polymer chains. For blends of the copolymers, the coronands are separated along the chain, in addition to having the polymer chains physically separated from one another. Cyclic voltammograms of the polymer-blend-modified electrodes indicate superior electrochemical stability compared to pure poly(8Se2) **13** and its copolymers, as evidenced from the plot of Q_c/Q_a against the number of scans (Fig. 11). Many of the films showed an increase in Q_c/Q_a with increasing scan number, which can be explained in terms of a break-in period in which swelling of polymer chains is facilitated by oxidation–re-reduction cycles. This is a common phenomenon for polymer-modified electrodes in cases in which the electrolyte is a relatively poor solvent for the polymer.

To determine whether redox activity remained close to the electrode surface or was propagated throughout the films, the extent of oxidation of polymer-modified electrodes was investigated by comparing the charge under the anodic curve with the calculated surface coverage of 8Se2. The number of moles of coronands involved in oxidation processes was calculated from:

$$[2] \quad Q = nF\Gamma_{exp}$$

where Q is the amount of charge passed, n is the number of electrons involved in the redox process, F is Faraday's constant, and Γ_{exp} is the experimentally observed number of moles of coronand on the electrode surface. The results are summarized in Table 1. Γ_{exp} was found to be substantially less than the calculated number of moles in the film, Γ_{calc}. Values of Γ_{exp} are typical of monolayer coverages on electrode surfaces, indicating that oxidation of the polymer films was restricted to only several monolayers at most. Confinement of electroactivity to the electrode is similary attributed to poor electron-transfer kinetics between adjacent redox centres.

Conclusions

The syntheses of the first polymer-bound selenium coronands, poly(8Se2) and poly(16Se4), have been achieved. These poly(selenium coronands) are electroactive polymers. Their redox chemistry is rich, but complex, due to inter- and intramolecular reactions that occur following oxidation. The selenium coronands attached to the polymer chain are sterically crowded and, although the microscopic concentration of selenium coronands is relatively high, intermolecular reactions are reduced compared to analogous concentrations of free coronands in solution. The selenium coronand functionality is even less mobile when the polymers are in the form of thin films; the latter exhibit enhanced stability in their oxidized form compared to polymer-bound selenium coronands in solution. Further separation of the coronands was achieved by their copolymerization or by blending with inert polymers. In both cases, the stability of the oxidized state and redox reversibility of the selenium coronands are enhanced.

These results show that spatial separation of electroactive units along the chain by copolymerization, and dilution of electroactive polymer chains by polymer blending, is a useful strategy for obtaining electrochemically stable polymer-modified electrodes for cases in which intermolecular reaction between electroactive species is a major pathway leading to degradation and loss of electroactivity.

Experimental

Melting points were determined on a Fisher–Johns melting point apparatus and are uncorrected. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker AMX-400 NMR spectrometer at 400.13 and 100.6 MHz, for proton and carbon, respec-

tively. All spectra were recorded in deuterochloroform and chemical shifts are given in ppm downfield from TMS. Chemical shifts and coupling constants were obtained from a first-order analysis of the spectra. Infrared spectra were recorded on a Perkin–Elmer 599B infrared spectrophotometer. UV–visible absorption spectra were carried out on a Perkin–Elmer Lamda 3A UV–visible spectrophotometer. Electron impact mass spectra were measured on a Hewlett–Packard HP-5985 mass spectrometer at 70 eV. Chemical ionization mass spectra were measured on a Hewlett–Packard HP-5985 mass spectrometer with isobutane as the reacting gas. Average molecular weights of polymers were determined by GPC, which included size exclusion chromatography combined with a Spectra-Physics model SP8000 UV–vis spectrophotometer and a Waters model R400 refractive index detector. Electrochemical studies were performed on a Pine RDE4 bipotentiostat and a Hewlett–Packard HP 7046A X-Y recorder.

Analytical thin-layer chromatography (TLC) was performed on aluminum plates precoated with Merck silica gel 60F-254 as the adsorbent. The developed plates were air-dried, exposed to UV light and (or) sprayed with 5% sulfuric acid in ethanol, and heated at 150°C. All compounds were purified by flash chromatography, on Kieselgel 60 (230–400 mesh).

Solvents were distilled before use and were dried, as necessary, by literature procedures. Solvents were evaporated under reduced pressure and below 40°C. Reactions performed under nitrogen were effected by means of standard Schlenk-tube techniques. Microanalyses were performed by M.K. Yang of the Microanalytical Laboratory of Simon Fraser University.

4,8-Diselenaundecan-1,11-diol (3)

To propane-1,3-bisselenocyanate **1** (9) (10.0 g, 39.7 mmol) in liquid ammonia (300 mL) was added Na metal in small pieces until a colourless homogeneous solution was obtained. To the solution was added dry THF (60 mL). A solution of 3-chloro-1-propanol **2** (7.50 g, 79.4 mmol) in dry THF (15 mL + 2 × 5mL rinse) was then added dropwise. The ammonia was allowed to escape and the reaction mixture was diluted with THF (100 mL). The reaction mixture was filtered and evaporated in vacuo to yield a light yellow oil. Purification by silica gel chromatography (hexane:ethyl acetate (1:1)) gave **3** (11.29 g, 89%, R_f 0.34); ^{1}H NMR δ : 1.89 (2H, p, H_6),1.98 (4H, p, H_2, H_{10}), 2.30 (2H, s, OH), 2.64 (8H, t, J = 6.4 Hz, H_3, H_5, H_7, H_9), 3.70 (4H, t, J = 6.1 Hz, H_1, H_{11}); ^{13}C NMR δ : 20.2 (C_6, J_{Se-C} = 30 Hz), 23.6 (C_2, C_{10}, J_{Se-C} = 34 Hz), 30.9 (C_5, C_7), 32.9 (C_3, C_9), 62.1 (C_1, C_{11}); CI MS *m/e*: 321 (M^+ + 1 isotopic cluster). Anal. calcd. for $C_9H_{20}Se_2O_2$: C 33.97, H 6.34; found: C 33.97, H 6.42.

4,8-Diselenaundecan-1,11-bis-*p*-toluenesulfonate (5) and 4,8-diselenaundecan-1-ol-11-*p*-toluenesulfonate (4)

To a solution of **3** (0.50 g, 1.57 mmol) in CH_2Cl_2 (10 mL) was added dropwise a solution of *p*-toluenesulfonyl chloride (0.66 g, 3.46 mmol) in pyridine (0.9 mL, 11.25 mmol). The reaction mixture was stirred at room temperature for 19 h. The reaction mixture was diluted with CH_2Cl_2 (120 mL) and then washed with water (3 × 45 mL), 10% HCl (3 × 45 mL), saturated $NaHCO_3$ (3 × 45 mL), and water (3 × 45 mL). The organic layer was dried ($MgSO_4$), and evaporated in vacuo to give a light yellow oil. Purification by silica gel flash chromatography (hexane:ethyl acetate (3:1); R_f 0.27) gave **5** (0.55 g, 55%) and **4** (R_f 0.08) (0.16 g, 21%).

4: ^{1}H NMR δ: 1.88 (2H, p, H_6), 1.96 (4H, p, H_2, H_{10}), 2.43 (6H, s, Me), 2.52 8H, m, H_3, H_5, H_7, H_9), 4.1 (4H, t, J = 7.3 Hz, H_1, H_{11}), 7.34 (4H, d, J = 8.8 Hz, Ar), 7.77 (4H, d, J = 8.8 Hz, Ar); ^{13}C NMR δ : 19.1 (C_6), 21.6 (C_2, C_{10}), 23.7 (Me), 29.8 (C_5, C_7), 30.8 (C_3, C_9), 69.6 (C_1, C_{11}), 127.9 ($C_{4'}$), 129.9 ($C_{3'}$, $C_{5'}$), 133.1 ($C_{2'}$, $C_{6'}$), 144.8 ($C_{1'}$). Anal. calcd. for $C_{23}H_{32}O_6S_2Se_2$: C 44.09, H 5.15; found: C 43.96, H 5.01.

5: ^{1}H NMR δ : 1.85–1.99 (7H, m, H_2, H_6, H_{10}, OH-11), 2.43 (3H, s, Me), 2.52–2.65 (8H, m, H_3, H_5, H_7, H_9), 3.70 (2H, t, J = 6.6 Hz, H_{11}), 4.1 (2H, t, J = 6.9 Hz, H_1), 7.34 (2H, d, J = 8.7 Hz, Ar), 7.80 (2H, d, J = 8.7 Hz, Ar); ^{13}C NMR δ : 19.6 (C6), 20.3 (C_{10}), 21.6 (C_2), 23.6 (Me), 29.8 (C_5, C_7), 30.9 (C_3), 33.0 (C_9), 62.3 (C_{11}), 69.6 (C_1), 127.9 ($C_{4'}$), 129.9 ($C_{3'}$, $C_{5'}$), 133.1 ($C_{2'}$, $C_{6'}$), 144.8 ($C_{1'}$). Anal. calcd. for $C_{16}H_{26}O_4SSe_2$: C 40.68, H 5.55; found: C 40.64, H 5.42.

1,3-Bisselenocyanatopropan-2-ol (6)

Note: This procedure should be carried out in a well-ventilated fume hood. To a solution of 1,3-diiodo-2-propanol (10.1 g, 32.4 mmol) in reagent grade acetone (150 mL) was added potassium selenocyanate (9.03 g, 62.7 mmol). The reaction mixture was refluxed overnight, filtered, and evaporated in vacuo. Purification of the residue by silica gel flash chromatography (hexane:ethyl acetate (2:1) R_f 0.51) gave **6** as a solid (6.29 g, 75%); ^{1}H NMR δ : 3.20 (2H, dd, J_{gem} = 13.0 Hz, J_{vic} = 7.0 Hz, H_1 and H_3), 3.29 (1H, d, J = 5.0 Hz, OH), 3.39 (2H, dd, J_{gem} = 13.0 Hz, J_{vic} = 4.5 Hz, $H_{1'}$ and $H_{3'}$), 4.35 (1H, m, H_2); ^{13}C NMR δ : 34.6 (C_1, C_3), 69.3 (C_2), 101.5 (SeCN). **Note:** This compound has an extremely pungent odor and was used immediately without further characterization.

1,5,9,13-Tetraselenacyclohexadecan-3-ol (7)

Note: This procedure should be carried out in a well-ventilated fume hood. To a suspension of $NaBH_4$ (0.45 g) in THF (225 mL) and EtOH (25 mL) was added simultaneously, via two separate syringes connected to an automated syringe pump, 1,3-bisselenocyanatopropan-2-ol (**6**) (0.428 g, 1.60 mmol) in EtOH (60 mL) and **5** (0.80 g, 1.60 mmol) in THF (60 mL). The addition time was 10 h and the reaction mixture was allowed to stir at room temperature for 24 h. The reaction mixture was diluted with THF (100 mL) and then washed with water (300 mL). The water layer was then extracted with dichloromethane (5 × 95 mL). The CH_2Cl_2 layer was washed with water (2 × 100 mL), and dried over anhydrous $MgSO_4$. Evaporation of the solvent gave white crystals that required further purification. Flash chromatography (hexane:ethyl acetate (6:1)) gave white crystals **7** (0.400 g, 62%), which were recrystallized from ethyl acetate; mp 54–55°C. FTIR: 3428 cm^{-1} (OH str.); ^{1}H NMR δ : 2.00–2.10 (6H, m, H_7, H_{11}, H_{15}), 2.64–2.79 (12H, m, H_6, H_8, H_{10}, H_{12}, H_{14}, H_{16}), 2.71 (2H, dd, H_2, H_4, J_{gem} = 13.0 Hz, J_{vic} = 7.5 Hz), 2.87 (1H, br s, OH)), 2.90 (2H, dd, $H_{2'}$, $H_{4'}$, J_{gem} = 13.0 Hz, J_{vic} = 5.0 Hz), 3.88 (1H, m, CH(OH)); ^{13}C NMR δ : 23.8 (C_{11}), 24.1 (C_7, C_{15}), 31.2 (C_6, C_8, C_{14}, C_{16}), 31.8 (C_2, C_4), 69.9 (C_3). CI MS *m/e*: 502 (M^++1 isotopic cluster). Anal. calcd. for $C_{12}H_{24}OSe_4$: C 28.82, H 4.84; found: C 28.99, H 4.86.

1,5-Diselenacyclooctane-3-ol (8) and 1,5,9,13-tetraselenacyclohexadecan-3,11-diol (9)

1,3-Propanebisselenocyanate-2-ol (**6**) (2.50 g, 0.093 mol) was dissolved in dry THF (220 mL) and EtOH (25 mL) and put

into a three-necked round-bottom flask. Sodium borohydride (3.5 g, 0.093 mol) was added in small portions at room temperature until the solution became yellowish white. The mixture was stirred for a few minutes. 1,3-Dibromopropane (2.03 g, 0.010 mol) was dissolved in a mixture of THF and EtOH (1:1) (70 mL) and was added dropwise to the reaction flask over 2 h. The reaction mixture was stirred at room temperature for 20 h. All processes were carried out under N_2. The reaction mixture was filtered and the filtrate was placed on the rotary evaporator to remove most of the solvent. Water (100 mL) was added to the residue and extracted with CH_2Cl_2 (3 × 120 mL). The organic layers were combined, washed with water (3 × 100 mL), and dried over $MgSO_4$. Removal of the CH_2Cl_2 gave a crude yellow oil (2.90 g). The products were separated on a silica-gel column with ethyl acetate – hexane (1:3.5) as eluent. The fractions with R_f 0.43 were combined to yield **9** as an oil (1.04 g, 43%) and those with R_f 0.10 were combined to give **10** as a white solid (0.54 g, 11%).

9: ^{1}H NMR δ: 4.00 (1H, m, H_3), 3.16 (2H, dd, $J_{H2,H2'}$ = 13.2 Hz, $J_{H3,H4}$ = 3.2 Hz, H_2, H_4), 2.99 (2H, dd, $J_{H4,H4'}$ = 14 Hz, $J_{H3,H4'}$ = 6.8 Hz, $H_{2'}$, $H_{4'}$), 2.83 (2H, ddd, $J_{H6,H6'}$ = 11.6 Hz, $J_{H6,H7'}$ = 7.6 Hz, $J_{H6,H7}$ = 3.8 Hz, H_6, H_8), 2.71 (2H, ddd, $J_{H6,H6'}$ = 12.0 Hz, $J_{H6',H7}$ = 7.6 Hz, $J_{H6',H7'}$ = 4.2 Hz, $H_{6'}$, $H_{8'}$), 2.33–2.50 (2H, m, H_7, $H_{7'}$), 2.21 (1H, d, OH); ^{13}C NMR δ : 23.9 (C_6, C_8), 30.2 (C_2,C_4), 30.8 (C_7), 69.4 (C_3). Anal. calcd. for $C_6H_{12}OSe_2$: C 27.92, H 4.68; found: C 28.14, H 4.62.

10: mp 79–80°C; IR, cm^{-1}: 3400 (OH str.); ^{1}H NMR δ : 2.72 (4H, p, J = 6.4 Hz, H_7, H_{15}), 2.64–2.90 (18H, m, H_2, H_4, H_6, H_8, H_{10}, H_{12}, H_{14}, H_{16}, OH-3, OH-11), 3.88 (2H, m, H_3, H_{11}); ^{13}C NMR δ : 30.6 (C_3, C_{11}), 35.1 (C_7, C_{15}), 37.8 (C_2, C_4, C_{10}, C_{12}), 77.2 (C_6, C_8, C_{14}, C_{16}). EIMS: 498 (M^+-18). Anal. calcd. for $C_{12}H_{24}O_2Se_4$: C 27.91, H 4.65; found: C 28.07, H 4.56.

1,5-Diselenacyclooctyl acrylate (mono 8Se2) (11)

1,5-Diselenacyclooctan-3-ol (**9**) (0.64 g, 0.002 mol) was dissolved in dry THF (190 mL) and CH_2Cl_2 (10 mL). The solution was cooled in ice and triethylamine (1.52 g, 0.015 mol) was added. Acryloyl chloride (0.24 g, 0.0026 mol) was dissolved in THF (30 mL) and added dropwise with vigorous stirring over 17 min to the reaction mixture. The reaction mixture was stirred overnight at room temperature. The triethylammonium salts were removed by filtration, and the filtrate containing mono 8Se2 was evaporated until most of the solvent was removed. The residue was dissolved in dichloromethane (100 mL). The organic solution was first washed with a mixture of 1 M HCl (15 mL) and H_2O (45 mL), then with a mixture of saturated $NaHCO_3$ (5 mL) and H_2O (45 mL), and finally with H_2O (3 × 150 mL). The organic layer was dried over $MgSO_4$, and removal of the solvent afforded crude mono 8Se2 as a straw-colored oil. The product was chromatographed on a silica-gel column with ethyl acetate – hexane (1:20) as eluent. The fractions containing pure **11** (R_f 0.3) were combined, and the product was isolated as a thick oil (0.67 g, 87%). IR (KBr), cm^{-1}: 1710 (C=O), 1180 (C-O-C); UV, λ_{max} : 234 nm (ε 3.10 × 10^3 cm^{-1} M^{-1}); ^{1}H NMR (400 MHz, $CDCl_3$) δ : 2.40 (2H, m, H_7), 2.83 (4H, m, H_6, H_8), 3.15 (4H, m, H_2, H_4), 5.23 (1H, m, H_3), 5.83 (1H, dd, J_{H-H_Z} = 10.5 Hz, J_{gem} (H_Z,H_E) = 1.5 Hz, -HC=CH_Z), 6.09 (1H, dd, J_{H-H_E} = 17.5 Hz, J_{H-H_Z} = 10.5 Hz, -*H*C=CH_2), 6.39 (1H, dd, J_{gem}(H_Z,H_E) = 1.5 Hz, J_{H-H_E} = 17.5 Hz, -HC=CH_E); ^{13}C NMR (100 MHz, $CDCl_3$) δ : 24.2 (C_7), 26.6 (C_6, C_8), 30.9 (C_2, C_4), 73.8 (C_3), 128.5 (=*C*H$_2$), 130.9 (CO-*C*H=), 165.0 (-*C*=O); MS : 312 (M^+). Anal. calcd. for $C_9H_{14}O_2Se_2$: C 34.65, H 4.52; found: C 34.68, H 4.48.

1,5,9,13-Tetraselenacyclohexadecyl acrylate (mono 16Se4) (12)

1,5,9,13-Tetraselenacyclohexadecan-3-ol (**7**) (0.125g, 0.25 mmol) was dissolved in dry THF (20 mL) and CH_2Cl_2 (10 mL). The solution was cooled in ice and triethylamine (0.030 g, 0.3 mmol) was added. Acryloyl chloride (0.24 g, 0.026 mmol) was dissolved in THF (20 mL) and added dropwise with vigorous stirring over 10 min. The reaction mixture was stirred overnight at room temperature. The triethylammonium salts were removed by filtration, and the filtrate containing mono 16Se4 was evaporated until most of the solvent was removed. The residue was dissolved in dichloromethane (60 mL). The organic solution was first washed with a mixture of 1 M HCl (15 mL) and H_2O (30 mL), then with a mixture of saturated $NaHCO_3$ (5 mL) and H_2O (30 mL), and finally with H_2O (3 × 100 mL). The organic layer was dried with $MgSO_4$, and removal of the solvent afforded crude mono 16Se4 as a straw-colored oil. The product was chromatographed on a silica-gel column with a mixture of ethyl acetate and hexane (1:20). The fractions containing pure **12** (R_f 0.15) were combined, and the product was isolated as a thick oil (0.10 g, 75%). IR (KBr), cm^{-1} : 2925 (C-H), 1718 (C=O), 1180 (C-O-C), 1630 (C=C) ; UV, λ_{max} : 246 nm (ε 4.92 × 10^3 cm^{-1} M^{-1}); ^{1}H NMR (400 MHz, $CDCl_3$) δ : 2.00–2.30 (6H, m, H_7, H_{11}, H_{15}), 2.65–2.85 (12H, m, H_6, H_8, H_{10}, H_{12}, H_{14}, H_{16}), 2.85–3.05 (4H, m, H_2, H_4), 5.15 (1H, m, H_3), 5.86 (1H, dd, J_{H-H_Z} = 10 Hz, J_{gem} (H_Z,H_E) = 2 Hz, -HC=CH_Z), 6.13 (1H, dd, dd, J_{H-H_E} = 17 Hz, J_{H-H_Z} = 10 Hz, -*H*C=CH_E), 6.44 (1H, dd, J_{gem} (H_Z,H_E) = 2 Hz, J_{H-H_E} = 17 Hz, -HC =CH_E); ^{13}C NMR (100 MHz, $CDCl_3$) δ : 23.5 (C_{11}), 23.7 (C_7, C_{15}), 24.7 (C_{10}, C_{12}), 27.1 (C_6, C_8, C_{14}, C_{16}), 31.6 (C_2), 31.8 (C_4), 73.7 (C_3), 128.2 (=CH_2), 132.2 (CO-CH=), 165.4 (C=O); MS: 554 (M^+). Anal. calcd. for $C_{15}H_{28}O_2Se_4$: C 32.51, H 4.73; found: C 32.79, H 4.87.

Poly(1,5-diselenacyclooctyl acrylate) (13)

Mono 8Se2 (**11**) (0.20 g, 0.64 mmol) and AIBN (5% mole ratio to the monomer) were dissolved in benzene (0.80 g, 10.3 mmol). This solution was placed in a glass ampoule and degassed in three freeze–thaw cycles, sealed under vacuum, and heated for 110 h at 60°C. The solution was then poured into MeOH (7 mL) and the polymer was precipitated (0.20 g). The polymers were purified by repeated dissolution–precipitation steps from chloroform–methanol; yield: 0.18 g, 90%; IR (KBr), cm^{-1}: 1705 (C=O), 1155 (C-O-C); UV, λ_{max}: 244 nm (ε 9.00 × 10^3 cm^{-1} M^{-1}); ^{1}H NMR (400 MHz, $CDCl_3$) δ : 1.46, 1.64, 1.88 (2H, br, -CH_2-CH-CO), 2.27 (1H, br, -CH$_2$-C*H*-CO), 2.40 (2H, br, H_7), 2.85 (4H, br, 2 H_6's, 2 H_8's), 3.15 (4H, 2 H_2's, 2 H_4's), 5.16 (1H, br, H_3); ^{13}C NMR (100 MHz, $CDCl_3$) δ : 24.4 (C_4), 26.6, 26.8 (C_6, C_8, CO-CH-*C*H$_2$-), 31.0 (C_2, C_4), 41.5 (CO-*C*H-CH$_2$-), 74.5 (C_3), 173.4 (C=O). Gel permeation chromatography (GPC) gave the average molecular weight of the soluble fraction as 2500. Anal. calcd. for compound **13**: C 36.04, H 4.20; found: C 35.75, H 4.52.

Poly(1,5,9,13-tetraselenacyclohexadecyl acrylate) (14)

Mono16Se4 (**12**) (100 mg, 0.18 mmol) and AIBN (5% mole ratio to the monomer) were dissolved in benzene (0.40 g, 5.1

mmol). This solution was placed in a glass ampoule and degassed in three freeze–thaw cycles, sealed under vacuum, and heated for 110 h at 60°C. The solution was then poured into MeOH (7 mL) and the polymer was precipitated (0.20 g). The polymers were purified by repeated dissolution–precipitation steps from chloroform–methanol; yield: 94.8 mg, 95%; IR (KBr), cm^{-1}: 2923 (C-H), 1728 (C=O), 1156 (C-O-C); UV, λ_{max} : 246 nm (ε 3.90×10^3 cm^{-1} M^{-1}); ^1H NMR (400 MHz, $CDCl_3$) δ : 1.70–2.13 (2H, br, CH_2-CH-CO), 1.95–2.19 (6H, br, 2 H_7's, 2 H_{11}'s, 2 H_{15}'s), 2.50 (1H, br, -CH_2-CH-CO), 2.60–2.80 (12H, br, 2 H_6's, 2 H_8's, 2 H_{10}'s, 2 H_{12}'s, 2 H_{14}'s, 2 H_{16}'s), 2.80–3.20 (4H, br, 2 H_2's, 2 H_4's), 5.10 (1H, br, H_3); ^{13}C NMR (100 MHz, $CDCl_3$) δ : 23.8 (C_7, C_{11}, C_{15}), 24.8 (C_{10}, C_{12}), 27.0 (-CO-CH-CH_2), 27.1 (C_6, C_8, C_{14}, C_{16}), 31.4 (C_2), 31.8 (C_4), 41.5 (CO-CH-CH_2), 73.7 (C_3), 173.5 (C=O). A molecular weight determination was not possible owing to the insolubility of the sample. Anal. calcd. for compound **14**: C 33.14, H 5.14; found: C 32.81, H 4.85.

Copolymer of 1,5-diselenacyclooctyl acrylate and methyl acrylate (16)

Methyl acrylate **15** (25 g, 0.29 mmol) was washed with 1.0 M aqueous NaOH (3 × 20 mL) in order to remove inhibitors such as hydroquinone, and then with water (3 × 30 mL). It was then dried over $CaCl_2$ and fractionally distilled under reduced pressure. The product was stored under nitrogen in the dark until further use. A mixture of methyl acrylate **15** (25.8 mg, 0.3 mmol), 1,5-diselenacyclooctyl acrylate **11** (93.6 mg, 0.3 mmol), and AIBN (4.92 mg, 0.015 mmol) in benzene (0.478 g, 6.1 mmol) was degassed with three freeze–thaw cycles and sealed under vacuum. The mixture was heated at 60°C for 110 h. The mixture was poured into methanol (20 mL) and the polymer was precipitated. The polymer was purified by three dissolution–precipitation steps from chloroform–methanol; yield: 98 mg, 82%. IR (KBr), cm^{-1}: 1706 (C=O), 1165 (C-O-C); UV, λ_{max}: 240 nm (ε 4.50×10^3 cm^{-1} M^{-1}); ^1H NMR δ: 1.46, 1.66, 1.92 (2H, br, -CH_2-CH-CO), 2.28 (1H, br, -CH_2-CH-CO), 2.40 (2H, br, H_7), 2.84 (4H, br, 2 H_6's, 2 H_8's), 3.12 (4H, br, 2 H_2's, 2 H_4's), 3.67 (3H, br, OCH_3), 5.14 (1H, br, H_3). A ratio of diselenacyclooctyl acrylate:methyl acrylate units of 1.4:1 was determined by integration of the peaks for H_3 and OCH_3 in the ^1H NMR spectrum.

In a separate experiment, a mixture of methyl acrylate **15** (34 mg, 0.40 mmol), 1,5-diselenacyclooctyl acrylate **11** (62.4 mg, 0.2 mmol), and AIBN (4.92 mg, 0.015 mmol) in benzene (0.387 g, 5.0 mmol) was treated as described above; yield: 83 mg, 85%. IR (KBr), cm^{-1}: 1708 (C=O), 1167 (C-O-C); UV, λ_{max}: 239 nm (ε 5.00×10^3 cm^{-1} M^{-1}); ^1H NMR δ: 1.46, 1.64, 1.91 (2H, br, -CH_2-CH-CO-), 2.27 (1H, br, -CH_2-CH-CO-), 2.38 (2H, br, H_7), 2.82 (4H, br, 2 H_6's, 2 H_8's), 3.11 (4H, br, 2 H_2's, 2 H_4's), 3.65 (3H, br, OCH_3), 5.14 (1H, br, H_3). A ratio of diselenacyclooctyl acrylate:methyl acrylate units of 0.75:1 was determined by integration of the peaks for H_3 and OCH_3 in the ^1H NMR spectrum.

Chemical oxidation of polymers

Under an N_2 atmosphere, $NOBF_4$ (8 mg) was placed in a UV cell. The cell was sealed by a rubber stopper. Dry CH_2Cl_2 (1 mL) was syringed into the UV cell to dissolve the $NOBF_4$. Polymer solution (3 mL, 10 mg/1 mLCH_2Cl_2) was then added into the cell and a UV–visible measurement was made.

Cyclic voltammetric measurements

A three-electrode system was used for cyclic voltammetry. The working electrode (WE) was a glassy carbon disc electrode polished with 3 μm aluminum oxide powder (Micro Metallurgical Ltd.), and washed with distilled water and acetone prior to each experiment. The counter-electrode (CE) was a Pt wire and the reference electrode (RE) was KCl(saturated)–Ag/AgCl. The electrolyte was 0.1 M TEAP in acetonitrile. The solutions were flushed with N_2 for about 10 min prior to use and measurements were performed at 25°C using a Pine RDE4 bipotentiostat and a Hewlett–Packard HP 7046A X-Y recorder.

Intramolecular 1,2-alkyl shifts in unsymmetric dialkoxycarbenes studied by very low vapour pressure (VLVP) pyrolysis – mass spectrometry

Dennis Suh, David L. Pole, John Warkentin, and Johan K. Terlouw

Abstract: Methoxy-(2,2,2-trifluoroethoxy)carbene radical cations, CH_3O-C-$OCH_2CF_3^{\cdot+}$, $\mathbf{1}^{\cdot+}$, are cleanly generated by the dissociative electron ionization (EI) of 2-methoxy-5,5-dimethyl-2-(2,2,2-trifluoroethoxy)-Δ^3-1,3,4-oxadiazoline **I**. Neutralization–reionization (NR) mass spectrometry of the neutral carbene **1**, generated by one-electron reduction of $\mathbf{1}^{\cdot+}$, shows no recovery ion signal and thus **1** is not a viable species within the μs time scale of the experiment. Very low vapour pressure (VLVP) pyrolysis – mass spectrometry of **I** in conjunction with (multiple) collision experiments shows that **1** completely isomerizes, via a 1,2-trifluoroethyl shift, into methyl 3,3,3-trifluoropropionate, $CF_3CH_2C(=O)OCH_3$, **1a**. This technique was also used to study the related dialkoxycarbenes C_2H_5O-C-OCH_2CF_3, **2**, CH_3O-C-OC_2H_5, **3**, and CH_3O-C-$OCH(CH_3)_2$, **4**, generated from the corresponding 2,2-dialkoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines. The pyrolytically generated carbene **2** behaves analogously to **1** and completely isomerizes to ethyl 3,3,3-trifluoropropionate, **2a**. The neutral carbenes **3** and **4** undergo only a partial isomerization via 1,2-alkyl shifts in which the ethyl and isopropyl groups show a slightly greater migratory aptitude, respectively, than the methyl group. The differences in migratory aptitude are explained in terms of a transition state model similar to that of a 1,2-H shift in carbenes, with development of negative charge in the migrating group. The greater migratory aptitude of CF_3CH_2, as compared to CH_3 and CH_3CH_2, is attributed to the stabilization of negative charge in the transition state by strongly electron-withdrawing β-fluorines whereas the differences in migratory aptitude between the alkyl groups in **3** and **4** are largely due to the greater polarizability of isopropyl and ethyl groups, as compared to the methyl group.

Key words: dialkoxycarbenes, pyrolysis, tandem mass spectrometry.

Résumé : On peut générer proprement les cations radicaux méthoxy-(2,2,2-trifluoroéthoxy)carbènes, CH_3O-C-$OCH_2CF_3^{\cdot+}$, $\mathbf{1}^{\cdot+}$, en procédant à une ionisation électronique (IE) dissociative de la 2-méthoxy-5,5-diméthyl-2-(2,2,2-trifluoroéthoxy)-Δ^3-1,3,4-oxadiazoline, **I**. La spectroscopie par neutralisation–réionisation (NR) du carbène neutre, **1**, généré par une réduction à un électron du $\mathbf{1}^{\cdot+}$, ne présente pas de signal correspondant à de la récupération d'ion et le composé **1** n'est donc pas une espèce appropriée à l'échelle de temps, μs, de l'expérience. La spectrométrie de masse du composé **I** avec pyrolyse à très basse tension de vapeur (VLVP), réalisée de concert avec des expériences de (multiples) collisions ont montré que le composé **1** s'isomérise complètement, par le biais d'un déplacement-1,2 d'un groupe trifluoroéthyle, en un 3,3,3-trifluoropropionate de méthyle, $CF_3CH_2C(=O)OCH_3$, **1a**. On a aussi utilisé cette technique pour étudier des dialkoxycarbènes apparentés : C_2H_5O-C-OCH_2CF_3, **2**, CH_3O-C-OC_2H_5, **3**, et CH_3O-C-$OCH(CH_3)_2$, **4**, générés à parti des 2,2-dialkoxy-5,5-diméthyl-Δ^3-1,3,4-oxadiazolines correspondantes. Le carbène **2** préparé d'une façon pyrolytique se comporte d'une façon analogue à **1** et il s'isomérise complètement en 3,3,3-trifluoropropionate d'éthyle, **2a**. Les carbènes neutres, **3** et **4**, ne subissent que des isomérisations partielles, par les biais de déplacements 1,2 d'alkyles dans lesquels les groupes éthyle et isopropyle présentent respectivement des aptitudes migratoires plus grandes par rapport au groupe méthyle. Les différences dans les aptitudes migratoires peuvent être expliquées en fonction d'une modèle d'état de transition semblable à celui d'un déplacement 1,2 d'hydrogène dans les carbènes, avec le développement de la charge négative dans le groupe qui migre. La plus grande aptitude migratoire du CF_3CH_2 par comparaison avec le CH_3 et le CH_3CH_2 peut être attribué à la stabilisation de la charge négative dans l'état de transition par le caractère très électroaffinitaire des fluors en β alors que les differences dans les aptitudes migratoires entre les groupes dans les composés **3** et **4** sont largement dues à la plus grande polarisabilité des groupes isopropyle et éthyle par comparaison avec celle du groupe méthyle.

Mots clés : dialkyloxycarbènes, pyrolyse, spectrométrie de masse en tandem.

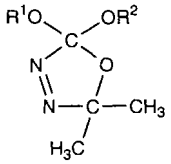
Introduction

The chemistry of carbenes in solution is well documented (1, 2) and methylene, the simplest carbene, is a well-understood compound (3). The electronic and molecular structures of singlet and triplet methylene and the energy difference between these states (ΔE_{ST}) has been determined both experimentally (4) and theoretically (5). Methylene has a triplet ground state whereas other carbenes bearing heteroatomic substituents, like alkoxy groups, have singlet ground states. This is explained by overlap of the lone pairs in heteroatoms with the vacant *p* orbital in the carbene (6).

Although many alkylcarbenes have been spectroscopically characterized under matrix isolation conditions (1, 2), their direct observation in solution is very difficult because they readily undergo 1,2-H migration. However, substituents directly attached to the carbenic carbon can have a dramatic influence on the activation barriers for the 1,2-H shift to this centre (7, 8). Thus, substitution of a methoxy group at the carbenic carbon of an alkylcarbene suppresses the characteristic 1,2-H migration (9) and the direct spectroscopic observation of methylmethoxycarbene in solution has been reported (10).

In view of the high reactivity of most carbenes in addition and insertion reactions, it is very difficult to generate carbenes as stable species in the condensed phase. However, many neutral carbenes have been generated and characterized in the gas phase (11–13) and their reactivity with respect to intramolecular reactions *vis-à-vis* their behaviour in solution can be studied in a collision-free environment. The mass spectrometer provides such an environment for the study of reactive intermediates like carbenes.

In this study, which follows earlier work on dimethoxycarbene (12), the unsymmetric dialkoxycarbene radical cations **1–4** were generated by dissociative electron ionization (EI) of the 2,2-disubstituted-Δ^3-1,3,4-oxadiazolines **I–IV** and the carbene ions were characterized on the basis of their collisional activation (CA) mass spectra (reviews: ref. 14). The advantages of using these precursors, for which an efficient synthetic method has recently been developed (15), are not only that they are stable at room temperature but also that they generate abundant carbene radical cations upon electron impact ionization and undergo thermal decomposition to yield carbenes under relatively mild conditions. These features make them promising precursors for the generation and characterization of these elusive carbenes by the techniques of Neutralization–Reionization (NR) mass spectrometry (reviews: ref. 16) and Very Low Vapour Pressure (VLVP) pyrolysis – mass spectrometry (17) in conjunction with (multiple) collision experiments (18). In particular, the reactivities of neutral dialkoxycarbenes, **1–4**, with respect to intramolecular isomerization via 1,2-alkyl shifts, were studied in detail by VLVP pyrolysis – mass spectrometry.



I $R^1 = CH_3$, $R^2 = CH_2CF_3$ ($m = 228$)
II $R^1 = C_2H_5$, $R^2 = CH_2CF_3$ ($m = 242$)
III $R^1 = CH_3$, $R^2 = CH_2CH_3$ ($m = 174$)
IV $R^1 = CH_3$, $R^2 = CH(CH_3)_2$ ($m = 188$)

1$^{\cdot+}$ $R^1 = CH_3$, $R^2 = CH_2CF_3$ (*m/z* 142)
2$^{\cdot+}$ $R^1 = C_2H_5$, $R^2 = CH_2CF_3$ (*m/z* 156)
3$^{\cdot+}$ $R^1 = CH_3$, $R^2 = CH_2CH_3$ (*m/z* 88)
4$^{\cdot+}$ $R^1 = CH_3$, $R^2 = CH(CH_3)_2$ (*m/z* 102)

Results and discussion

Methoxy-(2,2,2-trifluoroethoxy)carbene ions, 1$^{\cdot+}$: generation and characterization

In an earlier study (12), we reported that dimethoxycarbene (DMC) radical cations, $CH_3O\text{-}C\text{-}OCH_3^{\cdot+}$, are cleanly generated by the dissociative electron ionization (EI) of 2,2-dimethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline. It was further shown, using NR mass spectrometry, that the one-electron reduction of the carbene ion yields the neutral carbene as a stable species in the rarefied gas phase. The neutral carbene was also generated by VLVP mass spectrometry, albeit only in a mixture with its isomer methyl acetate. The methyl acetate was proposed to be formed by intramolecular isomerization of the neutral carbene via a 1,2-CH_3 migration. The reactivity of oxacarbenes, however, can be varied by "tuning" or modifying the electronic properties of the carbenic alkoxy substituent (19). For example, the trifluoroethoxy group, CF_3CH_2O, (σ_R^+ −0,56) is a less effective electron donor than the methoxy group (σ_R^+ −0.66) because of the inductive effect of the CF_3 group. Thus, the methoxy-(2,2,2-trifluoroethoxy)carbene **1** is expected to be somewhat more reactive than DMC. This caused us to examine the stability and reactivity of **1** relative to DMC by both NR and VLVP pyrolysis experiments on **I**.

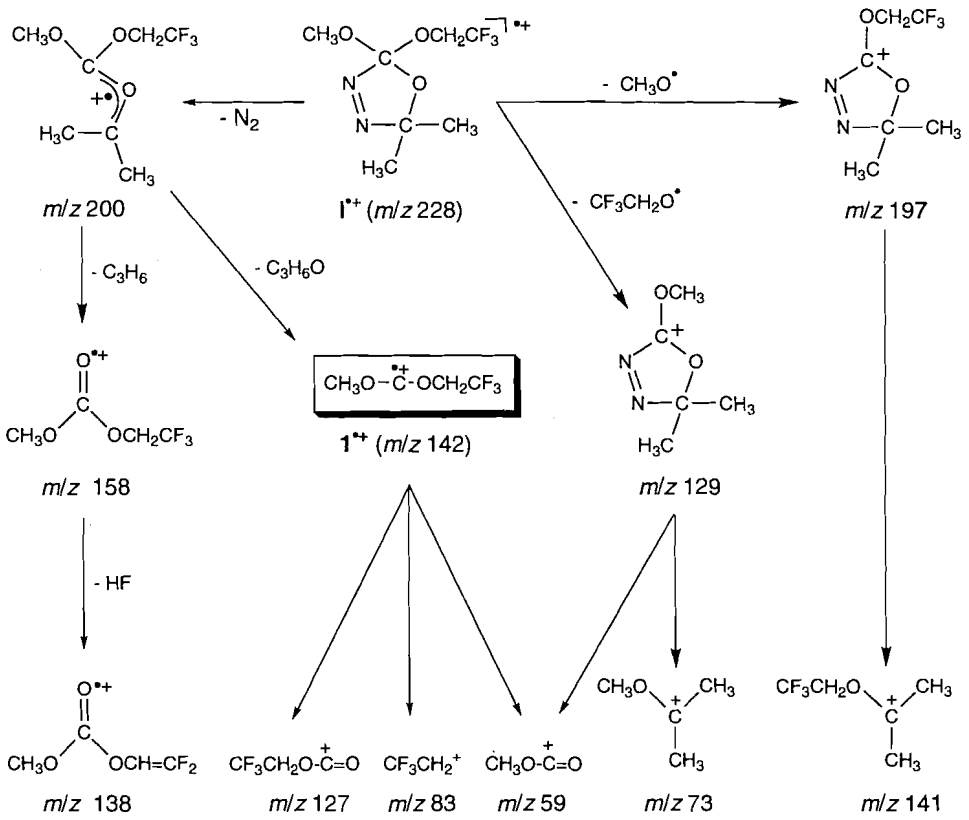
Neutral carbenes can conveniently be studied by NR and VLVP mass spectrometry if the corresponding cations can be distinguished from isomeric structures, particularly those resulting from intramolecular reactions. Therefore, we will first establish the structure of $C_4H_5F_3O_2^{\cdot+}$ radical cations generated by dissociative EI of **I**, on the basis of its collision-induced dissociation characteristics (14).

The 70 eV EI mass spectra of **I** and its deuterium labelled isotopomer **I-*d*$_3$** ($R^1 = CD_3$, $R^2 = CH_2CF_3$) are shown in Table 1. Due to the presence of the orthoester moiety in the precursor molecule, the mass spectra do not show the molecular ions at *m/z* 228 and 231, respectively.

The molecular ion **I**$^{\cdot+}$ undergoes three primary fragmentations to produce product ions at *m/z* 200, 197, and 129, which result from the losses of N_2, $CH_3O^{\cdot}$, and $CF_3CH_2O^{\cdot}$, respectively. The loss of N_2 also occurs under pyrolytic conditions (see below). However, the $[M - N_2]$**I**$^{\cdot+}$ peak observed in the EI mass spectrum is due to the dissociative ionization since the complementary pyrolysis product, ionized acetone (*m/z* 58 in **I** and **I-*d*$_3$**), is absent in the EI mass spectrum.

The major dissociation reactions of **I**$^{\cdot+}$ are shown in Scheme 1*a*. The rationalization is based on the metastable ion (MI) and the collisional activation (CA) mass spectra of the most important fragment ions arising from the fragmentation of **I** and **I-*d*$_3$**. The ion structures proposed in this scheme are based on a comparison of their CA mass spectra with those of reference ions of established structure.

Scheme 1*a*.



The carbene radical cations, *m/z* 142 in $\mathbf{1}^{\cdot+}$ and *m/z* 145 in $\mathbf{1}$-$d_3^{\cdot+}$, are formed via consecutive losses of N_2 and acetone molecules, see Scheme 1*a*.

The CA mass spectrum of $\mathbf{1}^{\cdot+}$, see Fig. 1*a*, is characterized by a peak at *m/z* 59 (CH_3O-C=O^+), which is shifted to *m/z* 62 (CD_3O-C=O^+) in the CA mass spectrum of $\mathbf{1}$-$d_3^{\cdot+}$, and by peaks at *m/z* 83 ($CF_3CH_2^+$) and *m/z* 127 (loss of $CH_3^{\cdot}$). The base peak shown at *m/z* 59 in the CA mass spectrum indicates that the structure of the *m/z* 142 ions is indeed that of $\mathbf{1}^{\cdot+}$ (18). The spectrum also contains weak peaks in the *m/z* 29–33 and 61–69 regions, but these are of limited diagnostic value.

The CA mass spectra of the isomers methyl 3,3,3-trifluoropropionate, $\mathbf{1a}^{\cdot+}$, and 2,2,2-trifluoroethyl acetate, $\mathbf{1b}^{\cdot+}$, are characteristically different from that of $\mathbf{1}^{\cdot+}$, see Figs. 1*c* and 1*d*. The spectra of $\mathbf{1a}^{\cdot+}$ and $\mathbf{1b}^{\cdot+}$ are both dominated by a peak at *m/z* 122 resulting from the unimolecular (metastable) loss of HF. However, the structures of the *m/z* 122 ions generated from $\mathbf{1a}^{\cdot+}$ and $\mathbf{1b}^{\cdot+}$ are not the same: the deuterium-labelled isotopomer $\mathbf{1a}$-$d_3^{\cdot+}$ ($CF_3CH_2C(=O)OCD_3$) shows a specific loss of DF in its CA mass spectrum whereas $\mathbf{1b}$-$d_3^{\cdot+}$ ($CD_3C(=O)OCH_2CF_3$) exclusively eliminate HF. This is corroborated by the different CA mass spectra of the *m/z* 122 $[M - HF]^{\cdot+}$ ions generated from metastable ions $\mathbf{1a}^{\cdot+}$ and $\mathbf{1b}^{\cdot+}$, see Fig. 2: the *m/z* 91 ions, which form the base peak in the spectrum of the former, are not present in the spectrum of the latter. Thus, the base peaks in the "pure" CA mass spectra of $\mathbf{1a}^{\cdot+}$ and $\mathbf{1b}^{\cdot+}$ are formed by the *m/z* 91 and *m/z* 43 ions, respectively. The CA mass spectrum of $\mathbf{1a}^{\cdot+}$ is entirely different from that of $\mathbf{1b}^{\cdot+}$ in that *m/z* 91, which forms the base peak in the spectrum of the former, is absent in the spectrum of the latter. Thus, the carbene ion $\mathbf{1}^{\cdot+}$ and its isomers $\mathbf{1a}^{\cdot+}$ and $\mathbf{1b}^{\cdot+}$ can easily be distinguished on the basis of their CA mass spectra.

Methoxy-(2,2,2-trifluoroethoxy)carbene ions, $\mathbf{1}^{\cdot+}$: NR experiments

The NR spectra of $\mathbf{1}^{\cdot+}$ and the isomeric esters $\mathbf{1a}^{\cdot+}$ and $\mathbf{1b}^{\cdot+}$ are shown in Fig. 3. Unfortunately a recovery signal is absent in these spectra. In the case of the ester ions, where the structure diagnostic *m/z* 91 and *m/z* 43 ions dominate the NR spectra, the absence of the recovery signal could be attributed to failure of the wholly vertical process of collision-induced ionization to regenerate stable ions $\mathbf{1a}^{\cdot+}$ and $\mathbf{1b}^{\cdot+}$ from stable molecules **1a** and **1b** (see ref. 16*e* for a similar case involving CH_3CH_2F). The spectrum of $\mathbf{1}^{\cdot+}$ on the other hand bears little or no resemblance to the CA mass spectrum and in particular the structure diagnostic *m/z* 59 ion $CH_3OC{=}O^+$ is completely absent.

This implies that neutralization leads to dissociation of the incipient neutrals, most likely via $\mathbf{1} \rightarrow CH_3^{\cdot} + CO_2 + CF_3CH_2^{\cdot}$, the dissociation of lowest energy requirement (cf. ref. 12 where the NR spectrum of dimethoxy carbene is discussed in detail). Indeed, the collision-induced dissociative ionization spectrum (CIDI) (16*d*) of the $CF_3CH_2^{\cdot}$ neutrals generated from metastable ions $\mathbf{1}^{\cdot+}$ is closely similar in appearance to the NR mass spectrum of $\mathbf{1}^{\cdot+}$, the only difference being an increased intensity of *m/z* 44 ($CO_2^{\cdot+}$) and *m/z* 15 ($CH_3^{\cdot+}$) in the latter.

Thus NR experiments on **1** using cyclopropane for neutralization do not show it to be a stable species on the μs time scale of the experiment: the incipient neutral carbene appears to completely dissociate and intramolecular isomerization into $\mathbf{1a}^{\cdot+}$ and (or) $\mathbf{1b}^{\cdot+}$ is not observed. The same appears to be true

for the other carbenes investigated in this study, and so these oxacarbenes seem not suitable to be studied by NR mass spectrometry. It is noteworthy, however, that dihydroxy-carbene, HO-C-OH (13*c*, 20), shows an intense recovery signal in its NR spectrum and it was studied in detail using the technique.

Methoxy-(2,2,2-trifluoroethoxy)carbene, 1: pyrolysis experiments

Table 1 shows the 70 eV EI/MS of **I** at a pyrolysis inlet temperature of 430°C, where the pyrolysis is 100% complete. In this spectrum ions at *m/z* 197 and 159, characteristic of the dissociative electron ionization of the intact precursor molecule, see Scheme 1*a*, could no longer be detected. Scheme 1*b* shows the major fragmentations of **I** upon VLVP pyrolysis.

The first step of the pyrolysis involves loss of N_2 to generate the intermediate ylide *m* = 200, which either dissociates into the carbene **1** by loss of an acetone molecule or rearranges via a 1,4-H shift into the orthoester. The orthoester *m* = 200, thus formed, is not expected to show molecular ions upon EI.

The CA mass spectrum of the pyrolytically generated *m/z* 142 ions from **I** appeared to be identical with the spectrum of the ester **1a** shown in Fig. 1*c*. Moreover the CA mass spectrum

Fig. 1. CA mass spectra of *m/z* 142 ions (*a*) $\mathbf{1}^{\cdot+}$ from EI of methoxy-2,2,2-trifluoroethoxycarbene; (*b*) generated after incomplete pyrolysis (350°C, 60–70% conversion, see text) of **I**; (*c*) $\mathbf{1a}^{\cdot+}$ from EI of methyl 3,3,3-trifluoropropionate; and (*d*) $\mathbf{1b}^{\cdot+}$ from EI of 2,2,2-trifluoroethyl acetate.

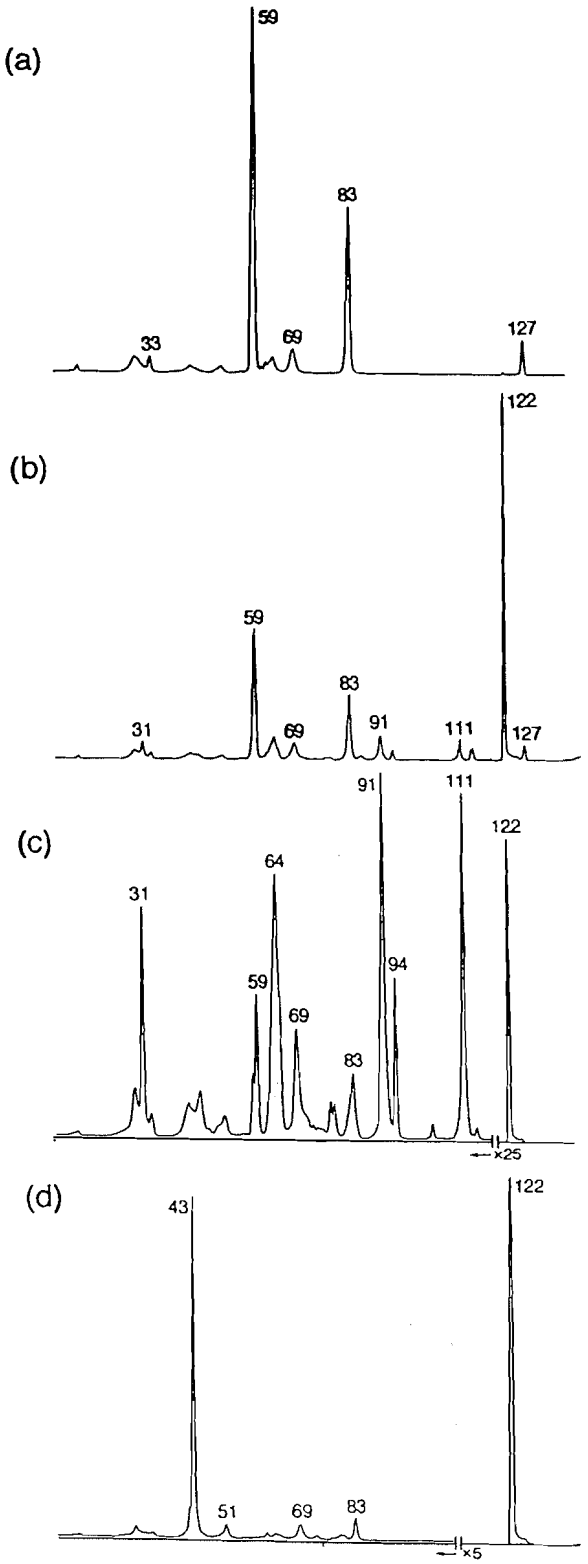

Fig. 2. CA mass spectra of *m/z* 122 ions generated from metastable (*a*) methyl 3,3,3-trifluoropropionate, $\mathbf{1a}^{\cdot+}$and (*b*) 2,2,2-trifluoroethyl acetate, $\mathbf{1b}^{\cdot+}$.

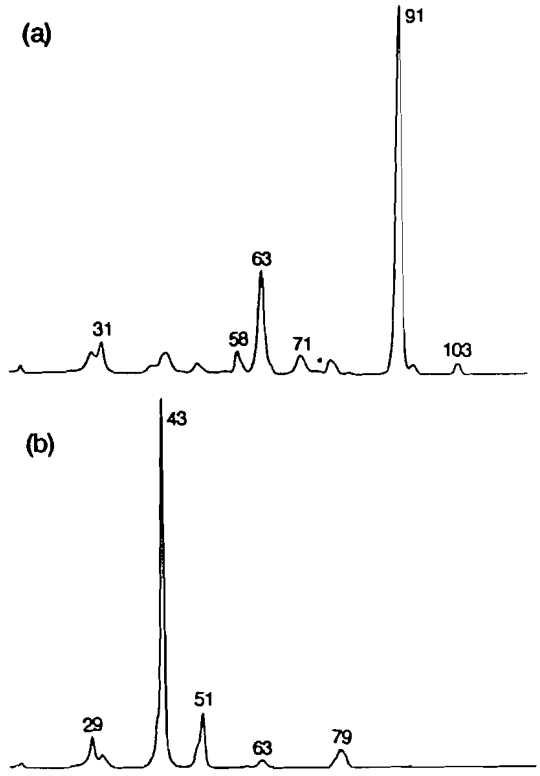

Fig. 3. NR mass spectra of *m/z* 142 ions (*a*) $\mathbf{1}^{\cdot+}$ from EI of methoxy-2,2,2-trifluoroethoxycarbene; (*b*) $\mathbf{1a}^{\cdot+}$ from EI of methyl 3,3,3-trifluoropropionate; and (*c*) $\mathbf{1b}^{\cdot+}$ from EI of 2,2,2-trifluoroethyl acetate.

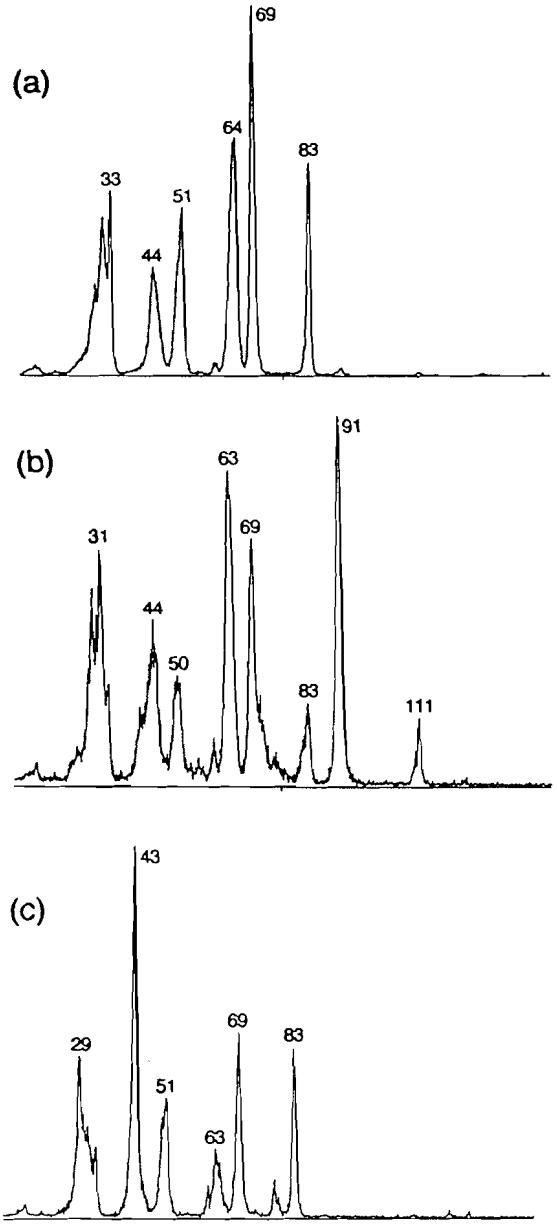


of the *m/z* 145 ions generated upon pyrolysis of the isotopomer **I-d_3** showed a specific loss of DF. These observations clearly indicate that, upon pyrolysis of **I**, the incipient neutral dialkoxycarbene **I** undergoes unimolecular isomerization into **1a**, not **1b**. Moreover, when the pyrolysis is complete, as monitored by the *m/z* 142 : *m/z* 197 peak intensity ratios, no intact carbene could be detected.

Pyrolysis starts at ca. 280°C (10%), reaches ca. 60–70% at 350°C, and is essentially complete at 410°C. At this temperature the CA mass spectrum is essentially that of the ester **1a** and analysis of the spectrum indicates that <5% of the ions $\mathbf{1}^{\cdot+}$ result from the pyrolytically generated neutral carbene. The CA mass spectrum of the *m/z* 142 ions recorded at a pyrolysis temperature of 350°C is shown in Fig. 1*b*. It represents a 1:1 mixture of ions $\mathbf{1}^{\cdot+}$ and $\mathbf{1a}^{\cdot+}$.

Ethoxy-(2,2,2-trifluoroethoxy)carbene, 2: pyrolysis experiments

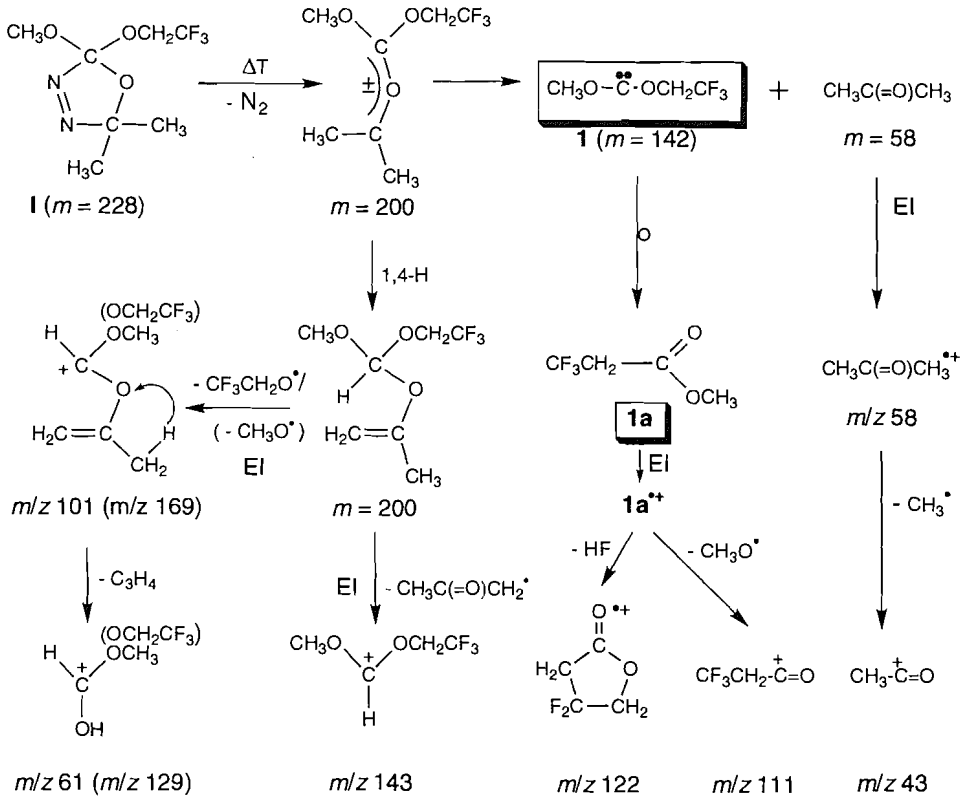
The next precursor molecule studied was 2-ethoxy-5,5-dimethyl-2-(2,2,2-trifluoroethoxy)-Δ^3-1,3,4-oxadiazoline, **II**. Analogous to the methyl analogue **I**, carbene radical cations $\mathbf{2}^{\cdot+}$ are formed by dissociative EI of **II**. However, their intensity is much reduced relative to that of the methyl analogue. This is due to the fact that the molecular ion $\mathbf{II}^{\cdot+}$ undergoes two major primary fragmentations (ca. 97%) to form ions at *m/z* 197 and 143, which results from the losses of $CH_3CH_2O^{\cdot}$ and $CF_3CH_2O^{\cdot}$, respectively. The loss of N_2 also occurs, but to a small extent (ca. 3%).

The CA mass spectrum of $\mathbf{2}^{\cdot+}$ (see Fig. 4*a*) shows characteristic peaks at *m/z* 136 (loss of HF), *m/z* 129 (loss of $C_2H_3^{\cdot}$), *m/z* 83 ($CF_3CH_2^+$), and *m/z* 28 ($C_2H_4^{\cdot+}$) and it is diagnostically different from its isomers, ethyl 3,3,3-trifluoropropionate $\mathbf{2a}^{\cdot+}$ and 2,2,2-trifluoroethyl propionate $\mathbf{2b}^{\cdot+}$ (see Figs. 4*c* and 4*d*). This indicates that indeed the carbene radical cations $\mathbf{2}^{\cdot+}$ are generated by the dissociative EI of **II**.

Upon VLVP pyrolysis, ions at *m/z* 197 and 143, characteristic of the dissociative ionization of the intact precursor molecule, could no longer be detected. Analogous to the methyl analogue **I**, neutral carbenes **2** are generated by consecutive losses of N_2 and acetone molecules.

The CA mass spectrum of the *m/z* 156 ions generated after pyrolysis of **II** at ca. 430°C is shown in Fig. 4*b* and it is characteristically different from that obtained from ions generated by EI of **II**. The intensity of *m/z* 28, which forms the base peak

Scheme 1*b*.



in the spectrum of the latter, is reduced considerably in the spectrum of the former. Moreover, the *m/z* 128 ions form the base peak and the *m/z* 136 ions are barely detectable in the spectrum of the former. This suggests that the neutral carbene **2** generated may have undergone unimolecular isomerization upon VLVP pyrolysis.

To verify this proposal, the CA spectrum of *m/z* 156 ions generated after pyrolysis of **II** at ca. 430°C is compared with that of its isomers **2a** and **2b**. It is seen that the CA mass spectrum of *m/z* 156 generated after pyrolysis of **II** is superimposable upon that of $\mathbf{2a}^{\cdot+}$ and characteristically different from that of $\mathbf{2b}^{\cdot+}$. The *m/z* 136 ions, which form the base peak in the spectrum of $\mathbf{2b}^{\cdot+}$, are hardly present in the spectrum of *m/z* 156 ions generated after pyrolysis of **II**.

These observations indicate that prior to ionization the carbene **2** generated after pyrolysis of **II** has undergone unimolecular isomerization into **2a**, not **2b**. This behaviour parallels that of the methoxy analogue **1** where it also is the trifluorethyl group that migrates. A mechanistic proposal for this intramolecular rearrangement will be discussed below.

Ethoxymethoxycarbene, 3: pyrolysis experiments

Similar to the behaviour of **I** and the dimethoxy analogue of **I**, dissociative EI of **III** yields abundant carbene radical cations $\mathbf{3}^{\cdot+}$ via consecutive losses of N_2 and acetone molecules, see Scheme 2*a*.

The CA mass spectrum of $\mathbf{3}^{\cdot+}$ is shown in Fig. 5*a*. The spectrum is dominated by peaks at *m/z* 61 and 57 and it is characteristically different from that of ionized methyl propionate $\mathbf{3a}^{\cdot+}$ and that of ionized ethyl acetate $\mathbf{3}^{\cdot+}$ (see Figs. 5*c* and 5*d*). Ions at *m/z* 70, which form the base peak in $\mathbf{3b}^{\cdot+}$, are barely detectable in the spectrum of $\mathbf{3}^{\cdot+}$ and *m/z* 61 ions, which are the base peak in $\mathbf{3}^{\cdot+}$, are not present in the CA mass spectrum of $\mathbf{3a}^{\cdot+}$. Thus, the CA mass spectrum of the carbene $\mathbf{3}^{\cdot+}$ is readily distinguishable from that of its isomers $\mathbf{3a}^{\cdot+}$ and $\mathbf{3b}^{\cdot+}$. The peak at *m/z* 57 (loss of $CH_3O^{\cdot}$) in the CA mass spectrum of $\mathbf{3}^{\cdot+}$, however, points to a partial conversion, prior to dissociation, of the carbene radical cations $\mathbf{3}^{\cdot+}$ into the more stable isomer $\mathbf{3a}^{\cdot+}$. This is because the *m/z* 57 ions do not have the structure of the high-energy $C_3H_5O^+$ isomer $CH_3CH_2OC^+$ (21) but rather are $CH_3CH_2C{=}O^{+\cdot}$. This follows from the observation that the CA mass spectrum of the collisionally generated $(M - CH_3O^{\cdot})^+$ ions from $\mathbf{3}^{\cdot+}$ is identical with that from $\mathbf{3}^{\cdot+}$ (spectra not shown), which is known to generate $CH_3CH_2C{=}O^+$.

The major unimolecular reactions of **III** upon VLVP pyrolysis are shown in Scheme 2*b*. The CA mass spectrum of the *m/z* 88 ions from the pyrolysis of **III** at ca. 430°C is characteristically different from that obtained in the EI experiments: compare Fig. 5*b* and 5*a*. The peak at *m/z* 70, which is absent in the CA mass spectrum of $\mathbf{3}^{\cdot+}$, has a significant intensity and the height of *m/z* 57 has increased considerably, such that it becomes the base peak in the CA mass spectrum. The peak at *m/z* 70 in Fig. 5*b* points to a partial isomerization of the neutral carbene **3** into **3b** prior to ionization. This proposal is substantiated by the observation that the CA mass spectrum of the collisionally generated *m/z* $(M - H_2O)^+$ ions in Fig. 5*b* is superimposable upon that from $\mathbf{3b}^{\cdot+}$, see Fig. 6.

In addition, the CA mass spectrum of the collisionally generated *m/z* 61 $(M - C_2H_3^{\cdot})^+$ ions in Fig. 5*b* shows a weak signal at *m/z* 43, see Fig. 7*b*, which forms the base peak in that from **3b**, see Fig. 7*c*. These results indicate that, upon pyroly-

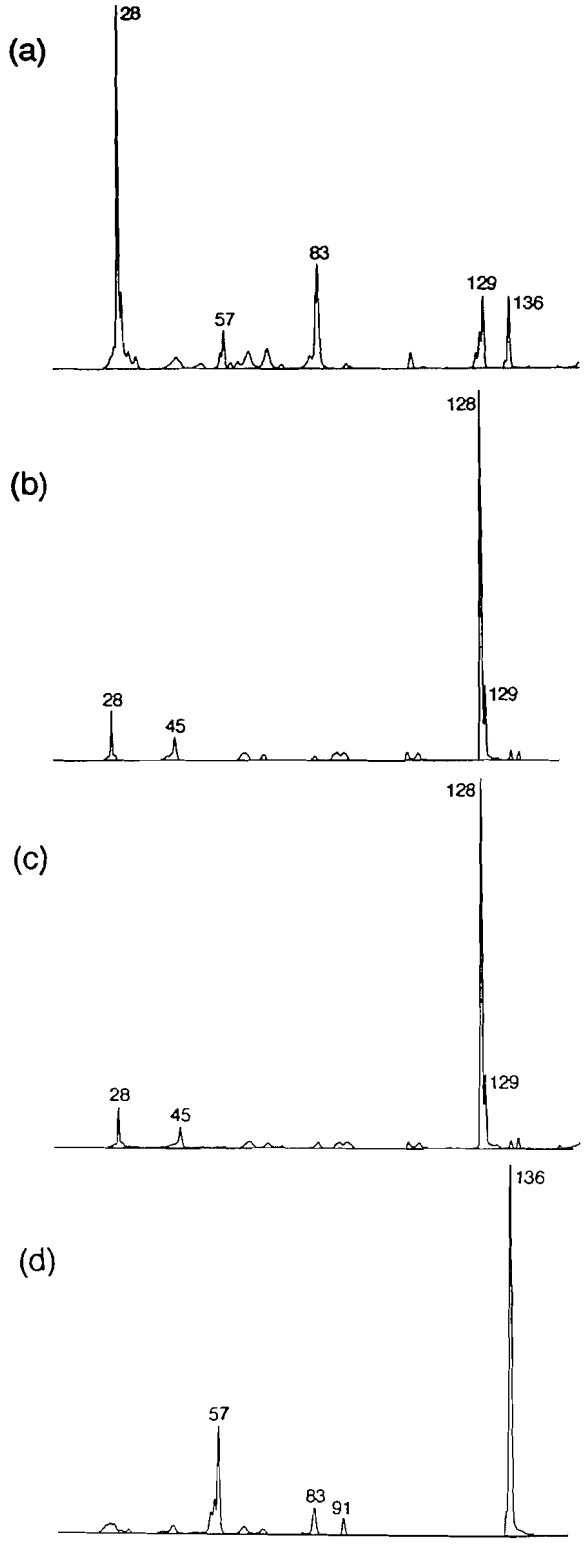

Fig. 5. CA mass spectra of *m/z* 88 ions (*a*) $\mathbf{3}^{\cdot+}$ from EI of ethoxymethoxycarbene; (*b*) generated after pyrolysis of **III**; (*c*) $\mathbf{3b}^{\cdot+}$ from EI of ethyl acetate; and (*d*) $\mathbf{3a}^{\cdot+}$ from EI of methyl propionate.

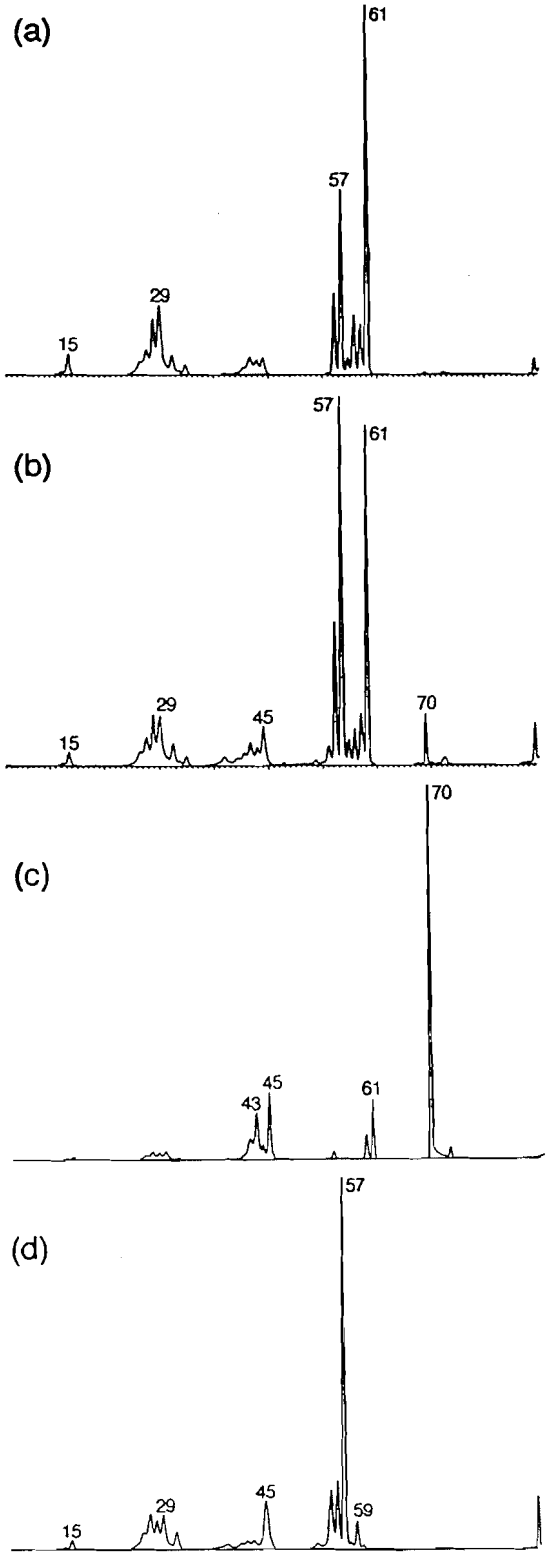

Fig. 6. CA mass spectra of collisionally generated $C_4H_6O^{\cdot+}$ ions from (*a*) *m/z* 88 ions after pyrolysis of **III** and (*b*) ionized ethyl acetate.

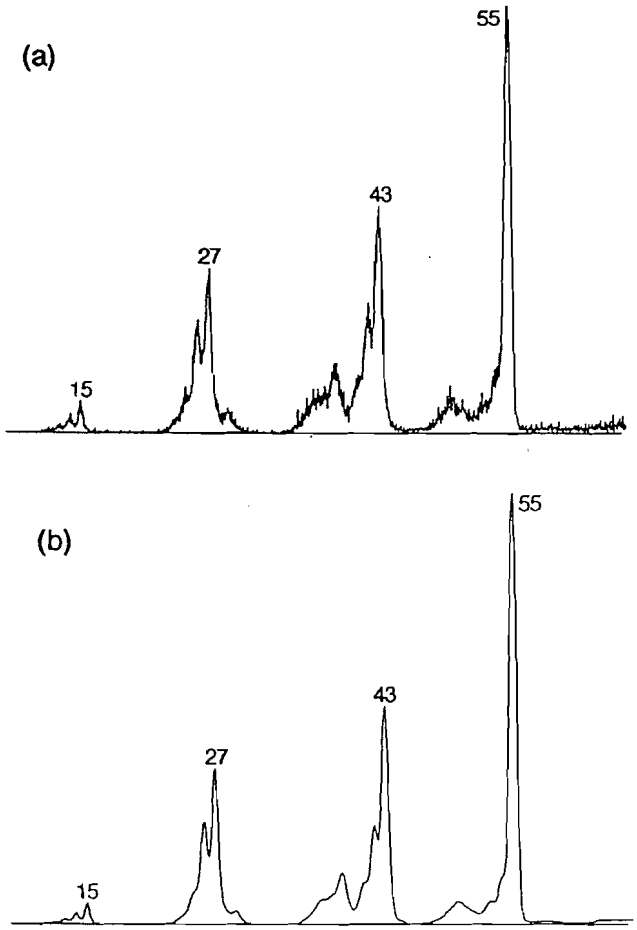

Fig. 7. CA mass spectra of collisionally generated $C_2H_5O_2^{\cdot+}$ ions from (*a*) ionized ethoxymethoxycarbene; (*b*) *m/z* 88 ions after pyrolysis of **III**; and (*c*) ionized ethyl acetate.

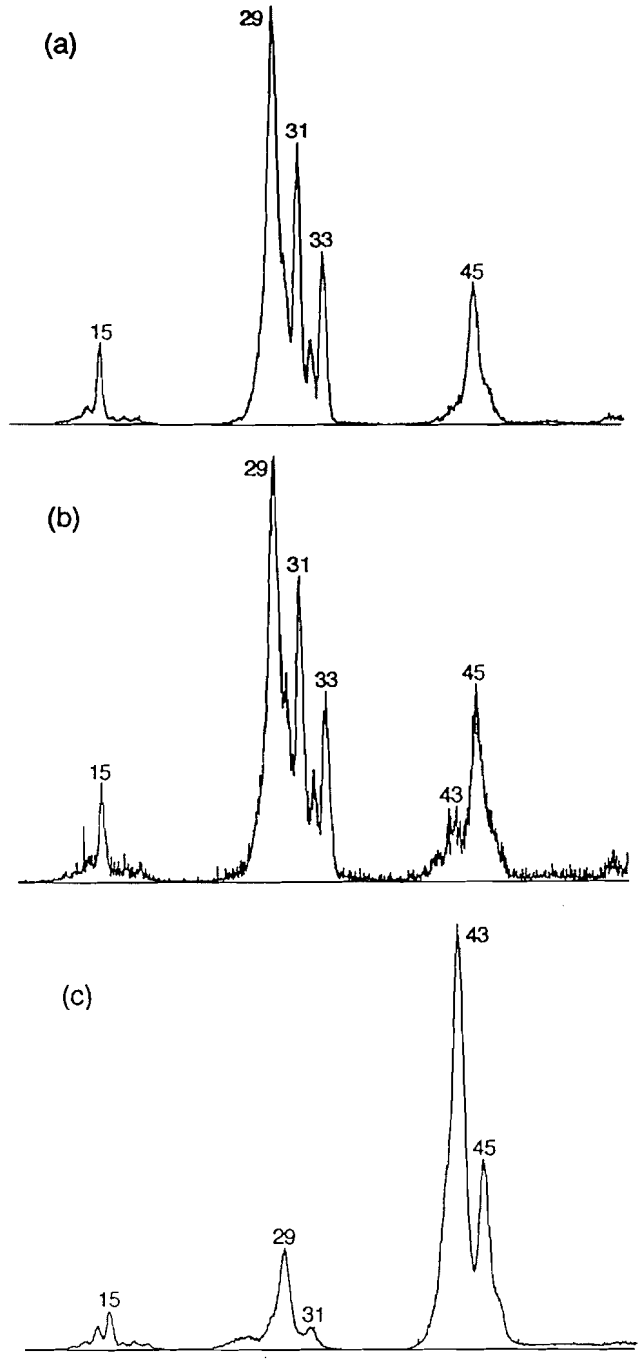


sis, the neutral carbene **3** undergoes a partial unimolecular rearrangement, via a 1,2-methyl shift, to **3b**.

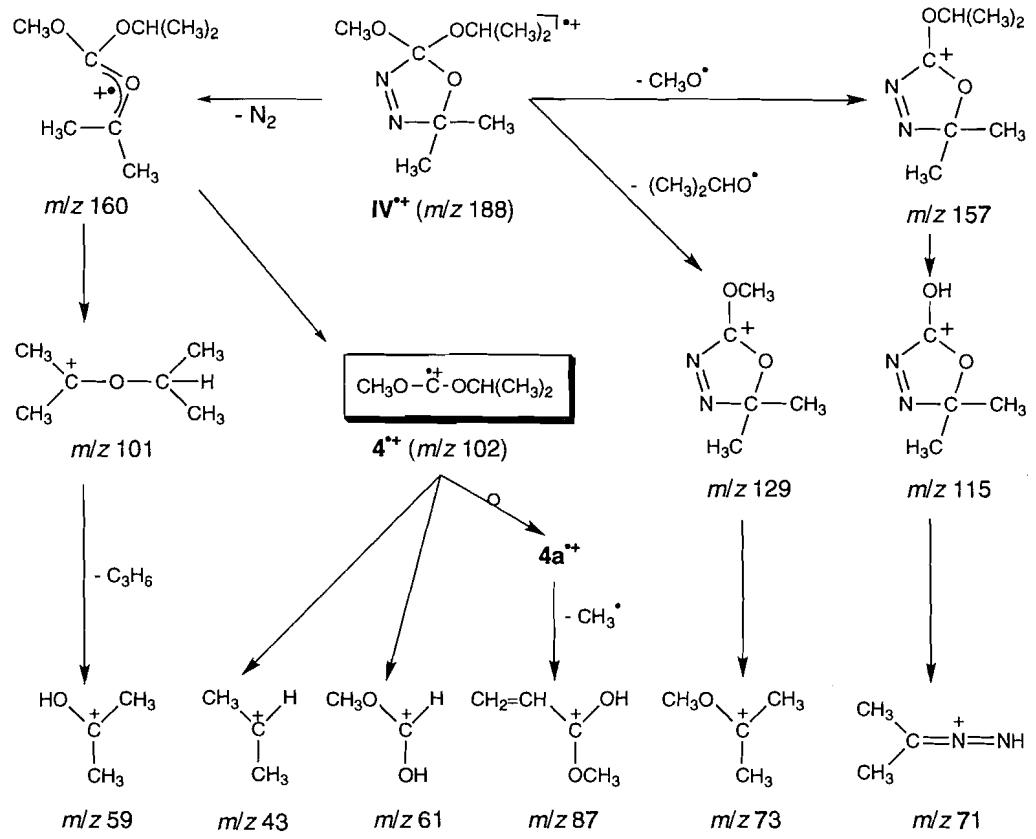
From combined experimental and theoretical studies (22), it appears that the most stable *m/z* 61 $C_2H_5O_2^+$ ions in the gas phase are the conjugatively stabilized carbenium ions $CH_3C(OH)_2^+$, protonated acetic acid, and $HC(OH)(OCH_3)^+$, protonated methyl formate. These $C_2H_5O_2^+$ isomers can readily be distinguished on the basis of their collision-induced dissociation characteristics.

Through comparative collision experiments, the structures of the collisionally generated *m/z* 61 $C_2H_5O_2^+$ ions from $\mathbf{3}^{\cdot+}$ and that from $\mathbf{3b}^{\cdot+}$ were established to be protonated methyl formate and protonated acetic acid, respectively (see Figs. 7*a* and 7*c*). Note, however, from Figs. 7*a* and 7*b*, that the majority of the *m/z* 61 ions in the pyrolysis CA mass spectrum Fig. 5*b* represent protonated methyl formate ions (23) and not protonated acetic acid.

As shown in Fig. 5*b*, the *m/z* 57 ions form the base peak in the CA mass spectrum of *m/z* 88 ions generated by pyrolysis of **III**. The CA mass spectrum of the collisionally generated *m/z* 57 $(M - CH_3O^{\cdot})^+$ ions in Fig. 5*b* appears to be identical with that from **3a** (spectra not shown). This indicates that prior to ionization the neutral carbene **3** undergoes a second partial unimolecular rearrangement, into **3a** via a 1,2-ethyl shift. The above results indicate that the carbene **3** is generated by VLVP pyrolysis but only in admixture with **3a** and **3b**. Isomers **3a** and **3b** are formed from unimolecular rearrangement of the neutral dialkoxycarbene **3** via 1,2-ethyl and 1,2-methyl shifts, respectively.

Based upon analysis of the collision efficiencies of the isomeric ions and the mass spectral characteristics of the esters it follows that Fig. 5*b* represents a mixture of 10% $\mathbf{3}^{\cdot+}$, 80% $\mathbf{3a}^{\cdot+}$, and 10% $\mathbf{3b}^{\cdot+}$ and that the *neutral* esters **3a** and **3b** are formed from **3** in a ratio of 2:1. A mechanism for this intramolecular rearrangement will be discussed below.

Scheme 3*a*.



Isopropoxymethoxycarbene, 4: pyrolysis experiments

Unlike the oxadiazolines discussed above, the molecular ion $\mathbf{IV}^{\cdot+}$ undergoes one major (ca. 90%) primary fragmentation to form ions at *m/z* 129, which results from the loss of $(CH_3)_2CHO^{\cdot}$. Losses of N_2 and $CH_3O^{\cdot}$ also occur, but to a very small extent (ca. 6 and 4%, respectively). The major EI dissociations of **IV** are shown in Scheme 3*a*.

The ylide radical cation (*m/z* 160), formed via loss of N_2, readily dissociates to form ions at *m/z* 101. This process predominates over the formation of the carbene radical cations (*m/z* 102). Note that the intensities of $\mathbf{4}^{\cdot+}$ (*m/z* 102) and that of *m/z* 101 are 2 and 12% of the base peak at *m/z* 59, respectively. Thus, it is expected that a significant fraction of ions $\mathbf{4}^{\cdot+}$ results from the ^{13}C contribution from *m/z* 101.

The CA mass spectrum of $\mathbf{4}^{\cdot+}$ is characterized by peaks at *m/z* 87, 61, and 43 (see Fig. 8*a*) and it is structure-diagnostically different from that of methyl isobutyrate $\mathbf{4a}^{\cdot+}$ and that of isopropyl acetate $\mathbf{4b}^{\cdot+}$ (see Figs. 8*c* and 8*d*). The ions at *m/z* 87 and 61, which result from the dominant collision-induced dissociations in $\mathbf{4}^{\cdot+}$, are not present in the CA mass spectrum of $\mathbf{4b}^{\cdot+}$ and $\mathbf{4a}^{\cdot+}$, respectively. Thus, the carbene radical cation $\mathbf{4}^{\cdot+}$ can easily be distinguished from its isomers $\mathbf{4a}^{\cdot+}$ and $\mathbf{4}^{\cdot+}$ on the basis of its collision induced dissociation characteristics. The peaks at *m/z* 60 and 59 in the CA mass spectrum of $\mathbf{4}^{\cdot+}$ result (largely) from the ^{13}C contribution from *m/z* 101 ($C_5H_9O_2^{\cdot+}$) ions (The CA mass spectrum of *m/z* 101 ions (spectrum not shown) is dominated by a peak at *m/z* 59, i.e., *m/z* 101 $\rightarrow C_2H_3O_2^+ + C_3H_6$).

The peak at *m/z* 87 in the CA mass spectrum of $\mathbf{4}^{\cdot+}$ may originate from a direct bond cleavage in the carbene ion to yield the isopropoxycarbonyl cation, $(CH_3)_2CH\text{-}O\text{-}C{=}O^+$. This proposal was verified by comparing the CA mass spectrum of the collisionally generated $(M - CH_3^{\cdot})^+$ ions from $\mathbf{4}^{\cdot+}$ with that from $\mathbf{4a}^{\cdot+}$. The structure of $(M - CH_3^{\cdot})^+$ ions from $\mathbf{4a}^{\cdot+}$ is established as $CH_2{=}CHC(OH)(OCH_3)^+$ (24), a carbenium ion stabilized by three electron donating groups. Although they are not shown, the two CA mass spectra are superimposable, and thus the carbene radical cation $\mathbf{4}^{\cdot+}$ appears to isomerize partially into its isomer $\mathbf{4a}^{\cdot+}$ prior to dissociation. This is substantiated by the fact that the loss of $CH_3^{\cdot}$ from $\mathbf{4}^{\cdot+}$ is associated with a larger kinetic energy release value than that from $\mathbf{4a}^{\cdot+}$ 95 vs. 85 meV, respectively).

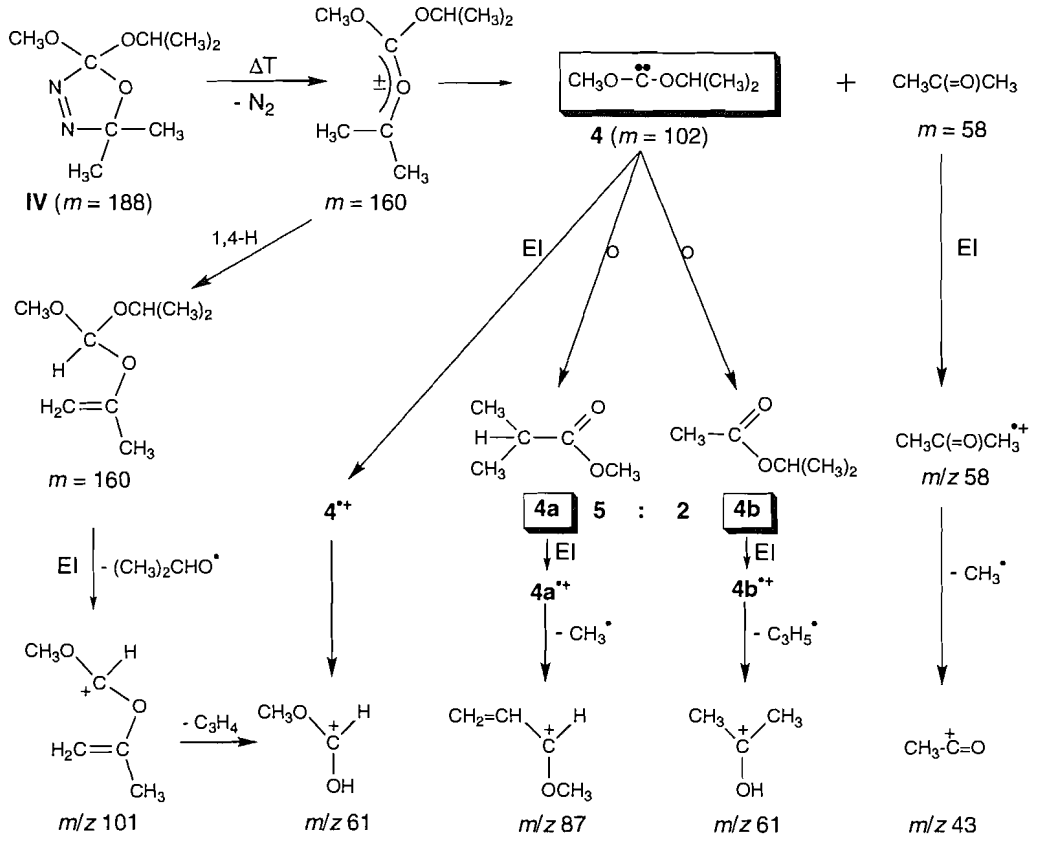
Through comparative collision experiments, the structures of the collisionally generated *m/z* 61 $C_2H_5O_2^+$ ions from $\mathbf{4}^{\cdot+}$ and that from $\mathbf{4b}^{\cdot+}$ were established as protonated methyl formate and protonated acetic acid, respectively. However, a weak signal at *m/z* 43, which forms the base peak in protonated acetic acid, in the CA mass spectrum of the collisionally generated $(M - C_3H_5^{\cdot})^+$ ions from $\mathbf{4}^{\cdot+}$ points to a unimolecular isomerization for a minor fraction of the carbene radical cations into its isomer $\mathbf{4n}^{\cdot+}$ prior to dissociation (see Fig. 7*a* for spectrum of pure protonated methyl formate).

The major fragmentations of **IV** upon VLVP pyrolysis are shown in Scheme 3*b*.

The first step of the pyrolysis involves loss of N_2 molecule to generate the intermediate ylide (*m* = 160). This ylide, in turn, either dissociates into the carbene **4** via loss of acetone molecule or rearranges via a 1,4-H shift into the orthoester. The orthoester *m* = 160, thus formed, is not expected to show molecular ions upon EI.

One of the major primary fragmentations from this orthoester forms ions at *m/z* 101, i.e., by loss of $(CH_3)_2CHO^{\cdot}$. Note

Scheme 3*b*.



that the relative intensity ratio of *m/z* 101 to $\mathbf{4}^{\cdot+}$ (*m/z* 102) is ca. 5:1. Thus, it is expected that a significant amount of $\mathbf{4}^{\cdot+}$ ions results from the ^{13}C contribution from *m/z* ions.

The CA mass spectrum of the *m/z* 102 ions obtained during pyrolysis of **IV** at ca. 430°C, when the pyrolysis is complete, is characteristically different from that generated in the EI experiments (compare Figs. 8*a* and 8*b*). The pyrolysis CA mass spectrum is dominated by a peak at *m/z* 87 and the intensities of the *m/z* 61 and 43 ions are considerably reduced. The peaks at *m/z* 61 and 62 in the spectrum (largely) result form the ^{13}C contribution from *m/z* 101 ions (the CA mass spectrum of *m/z* 101 ions is dominated by a peak at *m/z* 61, i.e., *m/z* 101 → $C_2H_5O_2^+ + C_3H_4$). In addition, the *m/z* 61 ions are now largely $CH_3C(OH)_2^+$, characteristic of ethyl acetate, **4b**. These observations indicate that upon pyrolysis some of the neutral carbene molecules **4** have retained their original structure, as witnessed by the signal at *m/z* 43, but that the majority have isomerized into the isomers **4a** and **4b**, via 1,2-isopropyl and 1,2-methyl shifts, respectively.

Based upon analysis of the collision efficiencies of the isomeric ions and the mass spectral characteristics of the esters it follows that Fig. 8*b* represents a mixture of 30% $\mathbf{4}^{\cdot+}$, 60% $\mathbf{4a}^{\cdot+}$, and 10% $\mathbf{4b}^{\cdot+}$ and that the *neutral* esters **4a** and **4b** are formed from **4** in a ratio of 5:2. A mechanism for this intramolecular rearrangement will be discussed below.

Mechanistic proposal for the intramolecular 1,2-alkyl shifts from dialkoxy carbenes

From the VLVP pyrolysis – mass spectrometry on the various dialkoxy oxadiazolines, it follows that the corresponding neutral dialkoxycarbenes are generated, albeit not free, from the thermodynamically more stable isomers. It is noted that the neutral dialkoxycarbenes **1** and **2**, which have the trifluoroethyl functional group, have completely isomerized to the more stable isomers **1a** and **2a**, respectively, whereas partial isomerization is observed for the other dialkoxycarbenes **3** and **4**.

It has been proposed that the isomerization of dimethoxycarbene (DMC) into its isomer methyl acetate in the gas phase occurs via a reaction akin to a Wolff rearrangement, i.e., by a 1,2-CH_3 shift (25, 26). In the previous study (12), we suggested another possibility, i.e., the bimolecular reaction between CH_3 radicals produced by the thermal decomposition of the carbene and the intact carbene, yielding 1,1-dimethoxyethyl radicals that may subsequently decompose into methyl molecules (eq. [1]):

The mechanism below was tested in this study by the copyrolysis of the precursor molecule with its D-labelled analogue 2,2-bis[trideuteromethoxy]-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline. An increase in the intensity of *m/z* 77, which could be either $CH_3C(=O)OCD_3^{\cdot+}$ and (or) $CD_3C(=O)OCH_3^{\cdot+}$, would

[1]

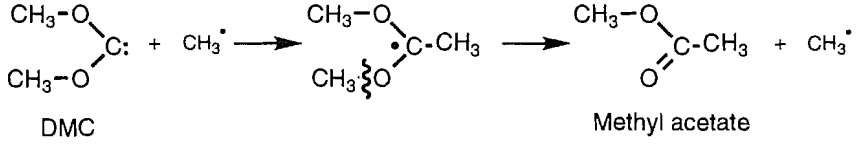


Fig. 8. CA mass spectra of *m/z* 102 ions (*a*) $\mathbf{4}^{\cdot+}$ from EI of isopropoxymethoxycarbene (* indicates the ^{13}C contribution from *m/z* 101 ions); (*b*) generated after pyrolysis of **IV**; (*c*) $\mathbf{4b}^{\cdot+}$ from EI of isopropyl acetate; and (*d*) $\mathbf{4a}^{\cdot+}$ from EI of methyl isobutyrate.

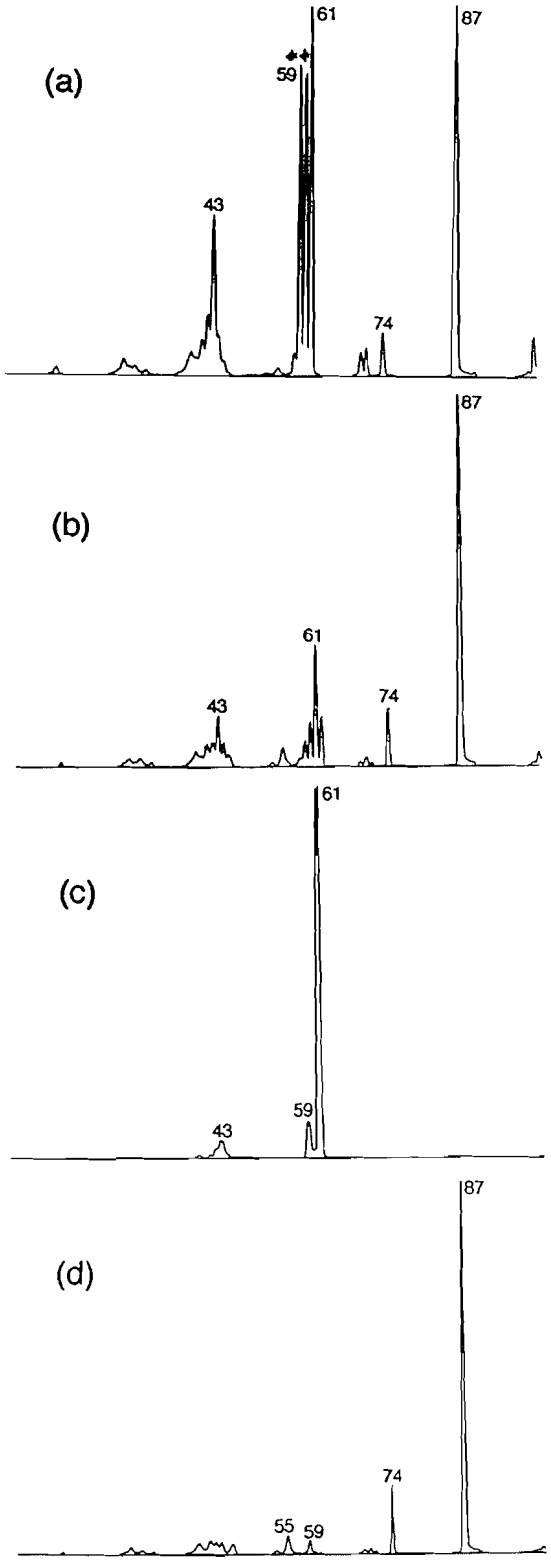


substantiate the proposal. However, the copyrolysis of the labelled and unlabelled precursor molecules in a 1:1 mixture at ca. 440°C does not increase the intensity of *m/z* 77 ions to a significant extent. Thus, the bimolecular mechanism does not add significantly to the unimolecular rearrangement of DMC and this probably also holds true for the carbenes reported in this study.

For DMC there is only one possible isomer, methyl acetate, whereas the ethoxymethoxycarbene **3** could undergo unimolecular isomerization to form two possible isomers, **3a** and **3b**. From the comparative collision experiments, it was concluded that isomer **3a** is formed in larger amount than isomer **3b** (see above). The same trend is found for the isopropoxymethoxycarbene **4**; **4a** is produced in larger amount than **4b**. It seems that the migration of the primary and secondary groups is more favourable than that of the methyl group.

In the case of methoxy- and ethoxy-(2,2,2-trifluoroethoxy)carbenes (**1** and **2**), only the 2,2,2-trifluoroethyl group migrates to form methyl and ethyl 3,3,3-trifluoropropionate **1a** and **2a**, respectively. There is no evidence for methyl and ethyl migration upon VLVP pyrolysis experiments. This indicates that the electron-withdrawing trifluoroethyl group plays a major role in the unimolecular rearrangement because both ethyl and methyl migrations have been observed for the ethoxymethoxycarbene **3**.

There is a body of evidence to suggest that carbene rearrangements progress through a transition state that features the development of negative charge on the migrating group (MG, eq. [2]) and hence these rearrangements are termed hydride shifts (1). For instance, an electron-donating substituent (R^1) at C-2 of a carbene (eq. [2]) greatly facilitates migration, since it stabilizes the development of positive charge at the migration origin (27). Furthermore, the geometries of the transition states calculated for a number of carbene migrations suggest hydride migration to the "vacant" *p*-orbital lying perpendicular to the plane of the carbenic substituents (9). Although these conclusions arise from results on 1,2-H migrations, extrapolations to 1,2-alkyl migrations is reasonable.

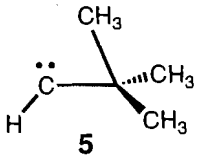
Our results indicate that trifluoroethyl has a large migratory aptitude compared to either methyl or ethyl. There is no doubt that β-fluorines are anion stabilizing; the computed stabilization energy of $CF_3CH_2^-$ relative to $CH_3Ch_2^-$ is 46.0 kcal/mol (28). It follows that trifluoroethyl migrates with development of negative charge in the migrating group as described above. The simplest assumption is that methyl, ethyl, and isopropyl groups migrate by the same mechanism, but with much less negative charge buildup on those migrating groups at the appropriate transition states.

The slightly greater migratory aptitude of ethyl and isopropyl groups, as compared to methyl, is not easy to explain. While there is no doubt that alkyl substituents appear to be electron donating (and base strengthening) in solution (29), there is a body of experimental evidence that shows them to be stabilizing to either cationic or anionic centres in the gas phase. The latter behaviour has been attributed largely to polarizability (30, 31). Combined computational and experimental (28) studies suggest that $CH_3CH_3^-$ and $(CH_3)_2CH^-$ are both somewhat less stable than CH_3^-, although the opposite trend could probably be accommodated without exceeding the error limits of the method.

If the migrating group moves with carbanion character, it

[2] 
[3] 
must be migrating to the electron-deficient site of the singlet carbene. Dialkoxycarbene singlets do not have a "vacant" *p*-orbital at carbon, because of conjugative localization of oxygen lone pairs to provide some π-bonding (eq. [3]). The partial double bond character between the carbene carbon and the oxygen substituents is reflected in the large barrier for rotation about the C—O bond of dihydroxycarbene (ca. 20 kcal/mol) (32).

Dialkoxycarbenes are different from carbenes such as singlet *tert*-butylmethylene, **5**. The computed energy minimum for **5** possesses a bridged structure, with one methyl group eclipsing the *p*-orbital at the carbene centre and populating it by hyperconjugation (33). The ground state is set up geometrically for methyl migration.



5

In contrast, both RO bonds of dioxycarbenes lie in the OCO plane (32, 34), but not necessarily in the sickle conformation drawn (eq. [4]). For migration to the π-system, a twist about a C—OR bond is presumably required, most likely in concert with transfer of R from oxygen to carbon. It is clear that such a rotation would be easier for the ROC—OCH_2CF_3 bond because it would have a lower bond order than the other carbenic C—O bond. Thus, the more facile transfer of CF_3CH_2, as compared to CH_3 or CH_3CH_2, is attributed to the higher ground state energies of **1** and **2** (less π-bonding and consequently easier rotation) and lower transition state energies because of the ability of CF_3CH_2 to migrate with more charge than can be accommodated by ethyl or methyl.

If the migrating group adopts some carbanion character, it is clear that the "stationary" fragment must be cation-like. Thus an extreme representation of the charge separation at the transition states for rearrangements reported here is in terms of an acylium ion – carbanion pair (eq. [5]).

Experimental

The CA and NR mass spectra were measured using the custom-built VG Analytical ZAB-R mass spectrometer (35). The NR mass spectra were obtained using cyclopropane $(Cp)^2$ for neutralization (main beam transmission $T = 80\%$) and oxygen for reionization ($T = 80\%$); oxygen was also used as the collision gas in the CA experiments.

The ZAB-R mass spectrometer is a three-sector BE_1E_2 (B = magnetic sector, E = electric sector) type instrument whose design is based on the standard, nonextended geometry of the ZAB-2F. The instrument is equipped with four collision gas chambers of which the two located in the second field-free region (in front of E_1) were used for the NR experiments. The double collision experiments (18, 22) involved mass (B) and energy (E_1) selected ions generated from collisions in the second field-free region that were analysed by obtaining CA mass spectra in the third field-free region using a scan of E_2. The pyrolysis experiments were also performed on this instrument. The VLVP pyrolysis unit has been described previously (37). Briefly, the pyrolysis oven is constructed of silica and has a high-temperature zone of c. 25 mm length. The exit of the oven into the ion source was situated ca. 10 mm from the ionizing electron beam. The samples were introduced into the pyrolysis unit by evaporation from a small glass bulb kept at room temperature.

Compounds **I**, **III**, and **IV** were synthesized using the method described in ref. 15, and the IE/MS of **III** and **IV** are reported below.

2-Acetoxy-2-ethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline and ethyl 2,3-diaza-4-methylacetoxypent-2-enoate

Acetone (ethoxycarbonyl)hydrazone was prepared by dissolv-

[4] 
(RO bond I to π) (RO bond II to π)

[5] 
[2] For the use of organic neutralization agents, see ref. 36.

ing ethyl carbazate in acetone with $MgSO_4$ added as a desiccant and stirring overnight. Filtration and removal of solvent yielded hydrazone pure enough to use for the next step. Acetone carboethoxyhydrazone (10 g) was dissolved in 250 mL of dichloromethane and cooled with stirring in an ice bath near 0°C. Solid lead tetraacetate (32 g, 1.05 equiv.) was added to the cooled contents of the flask over 5 min. After stirring at ice temperature for 30 min, the bath was removed and the reaction mixture was allowed to warm to room temperature where it was left stirring for about 4 h or until the lead diacetate salts had precipitated as a free-flowing white solid. The mixture was then extracted with sodium bicarbonate solution to remove acetic acid and the lead salts. Drying with $MgSO_4$ and evaporation of the solvent gave product that was found to be a mixture of ca. 66% oxadiazoline and ca. 34% of the acyclic impurity (by NMR).

2-Acetoxy-2-ethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline
^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.24 (t, 3H, ^3J = 7.2 Hz), 1.62 (s, 6H, $C(CH_3)_2$), 2.06 (s, 3H, CH_3CO_2), 3.89 (m, 2H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 15.0, 22.4, 24.1, 24.4, 61.4, 100.4, 133.8, 166.4; EI/MS, *m/z* (%): 143 (5), 71 (4), 59 (29), 43 (100).

Ethyl 2,3-diaza-4-methyl-acetoxypent-2-enoate
^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.37 (t, 3H, ^3J = 7.1 Hz), 1.48 (s, 6H), 2.06 (s, 3H, CH_3CO_2), 4.38 (q, 2H, ^3J = 7.1 Hz); EI/MS, *m/z* (%): 101 (40), 59 (35), 43 (100).

2-Ethoxy-2-(2,2,2-trifluoroethoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline II

2-Acetoxy-2-ethoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (15) (1 equiv., a mixture of oxadiazoline and acyclic impurity) was dissolved in dichloromethane with trifluoroethanol (5 equiv.). Acetic acid (5 mL) was added and the resulting solution was left at room temperature overnight.

Formation of **II** and consumption of acetoxy oxadiazoline can be followed easily by GC. When the exchange was complete, KOH pellets were added to the reaction mixture, which was then stirred at room temperature overnight. Water was added to the reaction mixture and the organic layer was collected and washed with sodium bicarbonate solution. Drying and evaporation of the solvent yielded **II**, which was used without further purification. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.22 (t, 3H, ^3J = 7.0 Hz), 1.48 (s, 3H), 1.54 (s, 3H), 4.127 (q, 1H, $^3J_{HF}$ = 8.4 Hz, OCH_2CF_3), 4.136 (q, 1H, $^3J_{HF}$ = 8.4 Hz, OCH_2CF_3); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 14.8, 23.7, 24.0, 60.9, 61.9 (q, $^2J_{CF}$ = 37 Hz, OCH_2CF_3), 120.4 (C5), 135.7(C2); ^{19}F NMR (471 MHz, $CDCl_3$) δ: −74.553 (t, 1H, $^3J_{HF}$ + 8.5 Hz); EI/MS, *m/z* (%): 214 (1), 197 (27), 173 (3), 172 (17), 156 (9), 145 (23), 143 (10), 141 (16), 136 (1), 135 (1), 129 (3), 128 (3), 127 (6), 125 (20), 113 (2), 87 (13), 83 (47), 71 (17), 70 (5), 69 (2), 64 (5), 63 (2), 61 (17), 60 (5), 59 (100), 58 (4), 57 (13), 56 (7), 45 (11), 44 (3), 43 (39), 42 (56), 41 (35), 40 (7).

2-(Trideuteromethoxy)-2-(2,2,2-trifluoroethoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline I-d_3

2-Acetoxy-2-(trideuteromethoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline was prepared as follows. Methyl carbazate-d_3 was prepared by adding CD_3OD (3 equiv. to 1,1′-carbonyldiimidazole (1 equiv.) in dichloromethane, letting stand for 2 h, and then adding hydrazine monohydrate (10 equiv.) and letting stand overnight. Evaporation of the solvent and removal of excess hydrazine under higher vacuum yielded methyl carbazate-d_3, which was used without further purification. Simply dissolving the carbazate in acetone in the presence of a desiccant ($MgSO_4$) and allowing to stand overnight yielded the labelled (methoxycarbonyl)-hydrazone of acetone. Oxidation and exchange were analogous to the published procedure (15) for the unlabelled molecule. The product was used without further purification. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.49 (s, 3H), 1.55 (s, 3H), 4.13 (q, 1H, $^3J_{HF}$ = 8.4 Hz, OCH_2CF_3), 4.14 (q, 1H, $^3J_{HF}$ = 8.4 Hz, OCH_2CF_3); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 23.7, 24.0, 61.9 (q, $^2J_{CF}$ = 36 Hz, OCH_2CF_3), 120.8, 132.2. (q, $^1J_{CF}$ = 277 Hz), 128; ^{19}F NMR (471 MHz, $CDCl_3$) δ: −74.558 (t, 1H, $^3J_{HF}$ = 8.4 Hz).

2,2-Bis(Trideuteromethoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline

Preparation of 2-acetoxy-2-(trideuteromethoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline was described above. Exchange of this product with methanol-d_4 yielded 2,2-bis(trideuteromethoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline. Acyclic byproduct was hydrolyzed as usual with KOH pellets. Bicarbonate extraction and drying yielded product that was used without further purification.

2-Ethoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline ***III***
EI/MS, *m/z* (%): 146 (5), 144 (3), 143 (24), 130 (5), 129 (45), 105 (7), 104 (24), 89 (5), 88 (41), 87 (14), 77 (39), 73 (34), 71 (28), 70 (7), 61 (20), 60 (23), 59 (100), 58 (9), 57 (25), 56 (23), 45 (22), 44 (14), 43 (51), 42 (43), 41 (33), 40 (9).

2-Ethoxy-2-isopropoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline ***IV***
EI/MS, *m/z* (%): 160 (3),157 (2), 131 (2), 130 (5), 129 (43), 119 (2), 118 (16), 117 (4), 115 (9), 113 (7), 104 (2), 103 (2), 102 (2), 101 (12), 88 (2), 87 (5), 77 (26), 74 (5), 73 (40), 71 (18), 61 (8), 60 (8), 59 (100), 58 (5), 57 (3), 56 (11), 45 (15), 44 (11), 43 (63), 42 (28), 41 (30), 40 (5).

2,2,2-Trifluoroethyl acetate was synthesized by estrerification of acetic anhydride with 2,2,2-trifluoroethanol. Methyl and ethyl 3,3,3-trifluoropropionate were synthesized according to the method described in ref. 38 with some modifications. The experimental details are as follows: A 40 mL autoclave containing 7.4 g (0.056 mol) of oxalacetic acid was cooled with liquid N_2. One third of the SF_4 required was added with liquid N_2 cooling. The autoclave was slowly warmed to ice temperature and then to room temperature. Then the autoclave was again cooled with liquid N_2 and noncondensabile residues were pumped off; this sequence was repeated 2 times. For the third time, the autoclave was slowly warmed to ice temperature and excess HF was removed through vacuum. Then, the mixture in the autoclave was shaken for 12 h using an automatic shaker. The contents were then poured into a Teflon bottle. To a small aliquot was added an excess of CH_3OH–CH_3CH_2OH and the mixture was left in the refrigerator for 1 day. The esters were then purified by preparative GLC.

Methyl 3,3,3-trifluoropropionate ***1a***

Polyhalide anions in crystals. Part 1. Triiodides of the Me_4N^+, Me_4P^+, quinuclidinium, 1-azoniapropellane, and 1,4-diazoniabicyclo[2.2.2]octane ($DabcoH_2^{2+}$) cations, and 1,10-phenanthrolinium(1+) tribromide

Pradip K. Bakshi, Margaret A. James, T. Stanley Cameron, and Osvald Knop

Abstract: Crystal-structure determinations are reported for Me_4NI_3 (4MI3, *Pnnm*, a = 10.107(2), b = 14.141(2), c = 8.252(5) Å, Z = 2), quinuclidinium I_3 (QI3, *Pnnm*, a = 10.290(2), b = 14.011(2), c = 8.813(2) Å, Z = 2), Me_4PI_3 (4MPI3, $P4_2/m$, a = 15.098(4), c = 13.770(4) Å, Z = 10), 1-azoniapropellane I_3 (API3, $P2_1/c$, a = 15.131(7), b = 28.453(6), c = 22.848(8) Å, β = 108.53(3)°, Z = 24), 1,4-diazoniabicyclo[2.2.2]octane $(I_3)_2$ (Da2I3, $P2_1/m$, a = 9.671(6), b = 8.127(2), c = 11.144(3) Å, β = 96.60(3)°, Z = 2), and 1,10-phenanthrolinium(1+) Br_3 (phenBr3, $P\bar{1}$, a = 8.370(2), b = 10.410(4), c = 8.171(2) Å, α = 107.52(2)°, β = 97.35(1)°, γ = 94.84(2)°, Z = 2). The nearly isostructural 4MI3 and QI3 are of a distorted *anti*-NiAs type. The 4MPI3 and API3 structures can be regarded as consisting of distorted CsCl-type coordination cuboids; both are unexpectedly complex, 4MPI3 (not isostructural with 4MI3) containing cations of two and anions of three types, API3 containing cations of six and anions of seven types. API3 thus represents an extreme case of a frustrated CsCl structure. The ion packing in Da2I3 is related to that in CaF_2. The distortion of one of the two nonequivalent I_3^- anions in Da2I3 is one of the largest, if not *the* largest on record (I—I = 2.793(2) and 3.167(2) Å, I-I-I = 172.47(4)°), and attributable to the involvement of the anion in a strong N—H...I bond, H...I = 2.78 Å. The bifurcated H-bond in which the protonated cation nitrogen in phenBr3 is engaged has an intra-cation, N—H(N)...N, branch and an inter-ion branch, N—H(N)...Br.

Key words: crystal structure, hydrogen bond, polyhalide anions, tribromides, triiodides.

Résumé : On a déterminé les structures cristallines du Me_4NI_3 (4MI3, *Pnnm*, a = 10,107(2), b = 14,141(2) et c = 8,252(5) Å, Z = 2), du quinuclidinium I_3 (QI3, *Pnnm*, a = 10,290(2), b = 14,011(2) et c = 8,813(2) Å, Z = 2), du Me_4PI_3 (4MPI3, $P4_2/m$, a = 15,098(4) et c = 13,770(4) Å, Z = 10), du 1-azoniapropellane I_3 (API3, $P2_1/c$, a = 15,131(7), b = 28,453(6) et c = 22,848(8) Å, β = 108,53(3)°, Z = 24), du 1,4-diazoniabicyclo[2.2.2]octane $(I_3)_2$ (Da2I3, $P2_1/m$, a = 9,671(6), b = 8,127(2) et c = 11,144(3) Å, β = 96,60(3)°, Z = 2) et du 1,10-diphénanthrolinium(1+) Br_3 (phenBr3, $P\bar{1}$, a = 8,370(2), b = 10,410(4) et c = 8,171(2) Å, α = 107,52(2)°, β = 97,35(1)° et γ = 94,84(2)°, Z = 2). Les composés 4MI3 et QI3 qui sont pratiquement isostructuraux sont d'un type *anti*-NiAs déformé. Les structures 4MPI3 et API3 peuvent être considérées comme étant formées de cuboïdes de coordination du type CsCl déformé; les deux sont beaucoup plus complexes que prévus avec le 4MPI3 (qui n'est pas isostructural avec le 4MI3) contenant deux types de cations et trois types d'anions alors que l'API3 contient des cations de six types et des anions de sept types. L'API3 représente donc un cas extrême d'une structure de CsCl frustrée. L'empilement ionique dans de Da2I3 est lié à celui du CaF_2. La distortion de l'un des deux anions I_3^- non équivalents dans le Da2I3 est l'une des plus importantes, si non la plus importante, à avoir été rapportée (I—I = 2,793(2) et 3,167(2) Å, I-I-I = 172,47(4)° et on peut l'attribuer à une implication de l'anion dans une forte liaison N—H...I, H...I = 2,78 Å. La liaison hydrogène présentant une bifurcation, dans laquelle le cation protoné de l'azote du $phenBr_3$ est impliqué, présente une branche intracation, N—H(N)...H, et un branche interion, N—H(N)...Br.

Mots clés : structure cristalline, liaison hydrogène, anions polyhalogénés, tribromures; triiodures.

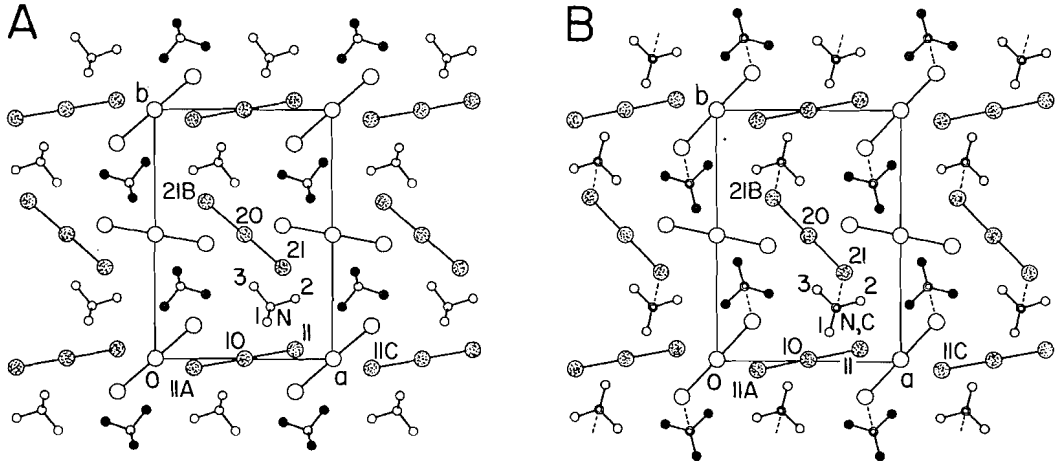
Fig. 1. Projections of the 4MI3 (*A*) and QI3 (*B*) structures on (001). Stippled circles, I atoms at $z = 0$; large open circles, I atoms at $z = \frac{1}{2}$; filled circles, cations with centroids at $z = 0$; small open circles, cations with centroids at $z = \frac{1}{2}$. The cations are disordered (see text); only one orientation is shown in each projection. N—H(N)...I(21) bonds in QI3 are represented by broken lines.



By far the largest number of the many (ideally) linear X_3^- (X = I, Br, Cl) anions in reported crystal structures are homoatomic and triiodides. Because of its size the I_3^- ion is often used as a counter anion of convenience, useful in stabilizing large cations, but its subservient role in preparative chemistry should not conceal certain aspects that make this anion (and Br_3^- and Cl_3^-) interesting.[4] (*i*) I_3^- is not often linear symmetric and, even if it is, by virtue of a crystallographic centre of symmetry at the centre atom, the possibility of a static or dynamic disorder about the inversion centre, resulting in an *averaged* centrosymmetric geometry, may not be ruled out.[5] (*ii*) Even for the centrosymmetric triiodide anions the reported distance between the two outer atoms has a range of ~0.4 Å. This is a dimensional variation of a magnitude not observed with other anions and one that cannot be dismissed, given the accuracy with which the positions of the I atoms in a structure can be determined both by X-ray and neutron diffraction. (*iii*) Last not least, the rodlike character of I_3^- combined with the tendency of a crystal to attain maximum density of packing gives rise to a variety of I_3^- orientations and ion coordinations and hence of space-group symmetries. Analysis of the dependence of the crystal symmetry and packing on the size and shape of the counter cation is a worthwhile and legitimate task for the crystal chemist. Although the nature and properties of the I_3^- anion have received frequent attention over the years, these and other aspects are not yet completely understood, in part because of lack of a systematic approach to the effect of the cation.

Preparatory to our own investigation now in progress we report in the following on our determinations of the crystal structures of five triiodides and a tribromide of the compact, asymmetric title cations. Crystal data of the title compounds are assembled in Table 1 and the positional parameters of anisotropically refined nonhydrogen atoms in Table 2. Details of the determinations are described in the Experimental. The following information has been deposited:[6] positional parameters and isotropic temperature factors of C and N atoms in API3 (Table A); positional parameters and isotropic temperature factors of H atoms (Table B); anisotropic thermal parameters of nonhydrogen atoms (Table C); and interatomic distances and bond angles other than those involving solely the halogen atoms (Table D).[7]

[g]$100R$ on $2\sigma(I)$; $100R_w$ = 26.1% (on F^2), C and N atoms refined isotropically.

[h]Minimum and maximum residual electron density ($e/Å^3$) in final difference map.

orthorhombic compounds are isostructural, with similar unit-cell dimensions (Fig. 1). There are two nonequivalent I_3^- ions in the structures, with their centre atoms I(10) and I(20) at sites of C_{2h} symmetry and with U_{ii} values not suggestive of disorder across the inversion centre. The anions are situated in layers ||(001), each layer also containing the centroids of the cations (cf. below). The *antiferro* arrangement of the anion orientations in each of the two anion systems is consistent with the anions being located on a dichromatic orthorhombic P_I Bravais lattice. The anions are discrete; the inter-anion I...I distances all exceed 4.35 Å (Table 3).

The ion packing is of a distorted *anti*-NiAs type. In an *idealized* hexagonal *anti*-NiAs cell *H* ($P6_3mc$) the anions would be at (0, 0, 0; 0, 0, ½) and the cations at ±(⅓, ⅔, ¼), i.e., forming a layer sequence *AbAc*...; the coordination polyhedron of a cation would be an octahedron of symmetry D_{3d} and that of an anion a trigonal prism of symmetry D_{3h}. This *H* cell can be transformed by

$$\begin{pmatrix} x_O \\ y_O \\ z_O \end{pmatrix} = \begin{pmatrix} -\frac{1}{2} & 0 & \frac{1}{2} \\ 0 & 1 & 0 \\ \frac{1}{2} & 0 & \frac{1}{2} \end{pmatrix} \begin{pmatrix} x_H \\ z_H \\ y_H \end{pmatrix} + \begin{pmatrix} \frac{1}{2} \\ 0 \\ 0 \end{pmatrix}$$

into an orthogonal cell *O* corresponding to the *Pnnm* cell, with an axial ratio $a_O/c_O = \sqrt{3}$. The coordinates of the atoms in the *O* cell would then be (½, 0, 0; ½, ½, 0) for the anions and ±(⅔, ¼, ½) for the cations. The actual fractional coordinates of atoms I(10) and I(20) in 4MI3 and QI3 are (½, 0, 0; ½, ½, 0); those of the N atoms in 4MI3 are ±(0.6434, 0.2105, ½), a_O/c_O = 1.225; and those of the cation centroids in QI3, ±(0.6502, 0.2075, ½), a_O/c_O = 1.168. The ratio $r = c_H/a_H = 2b_O(a_O^2 + c_O^2)^{-1/2}$ (which in a hexagonal close packing of equal spheres would be $(8/3)^{-1/2}$ = 1.633) is 2.19 in 4MI3 and 2.07 in QI3. The larger internal angle in the base of the pseudohexagonal cell corresponding to *Pnnm* is 101.6° in 4MI3 and 98.8° in QI3, both values well below the ideal angle of 120° but leaving no doubt about the packing type.

[a]Parameter values of atoms in special positions are not multiplied by 10^4.

Stoichiometry and symmetry require that in *Pnnm* the cation in 4MI3 and QI3 be located on an element of symmetry, in these two structures on a mirror plane at $z = 0$ or $\frac{1}{2}$. This implies that the cation itself contains a mirror plane. The orientation of the Me_4N^+ cation (Fig. 1; N, C(2), and C(3) in *m*. C(1) duplicated by *m*) satisfies this requirement, i.e., the 4MI3 structure is correctly described in *Pnnm*. However, refinement on this model resulted in unreasonably high values of some of

Fig. 2. Hydrogen bonds in QI3 and Da2I3 viewed approximately perpendicular to the plane of the bond (top) and down the cation axis (bottom); 50% probability thermal ellipsoids on nonhydrogen atoms. In QI3 the probability of the I(21) atom participating in *two* H-bonds is 25% or less (see text), whereas in Da2I3 *both* H(N) atoms of the divalent cation are H-bonded and the cations form *uninterrupted* H-bonded chains ||*b*.

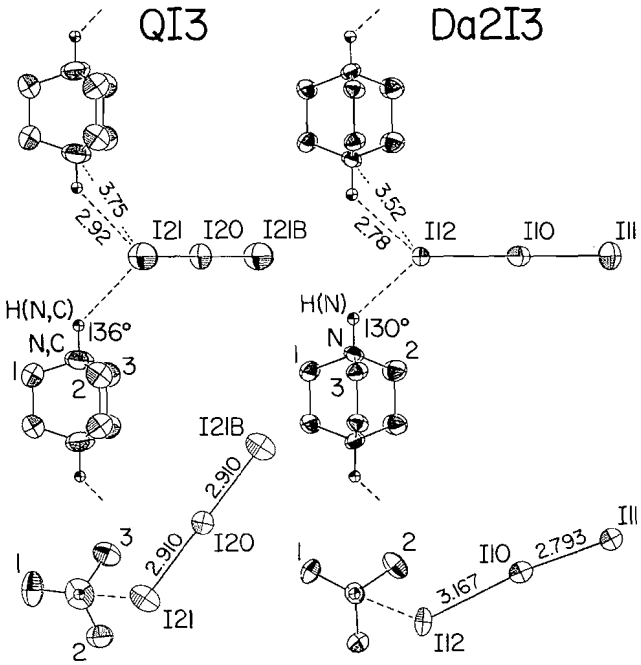

Fig. 3. Projection of the 4MPI3 structure on (001). Filled circles, I atoms at $z = 0$ (except I(31), which coincides with I(30)). All P(1) atoms are at $z \sim \pm \frac{1}{4}$, all P(2) atoms are at $z = \pm \frac{1}{4}$.

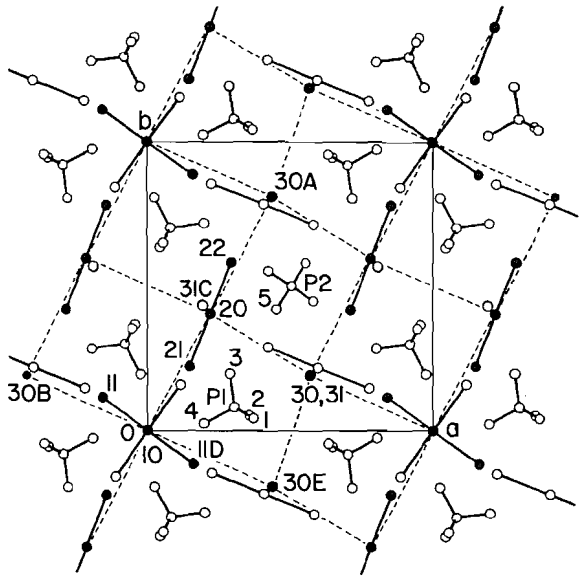
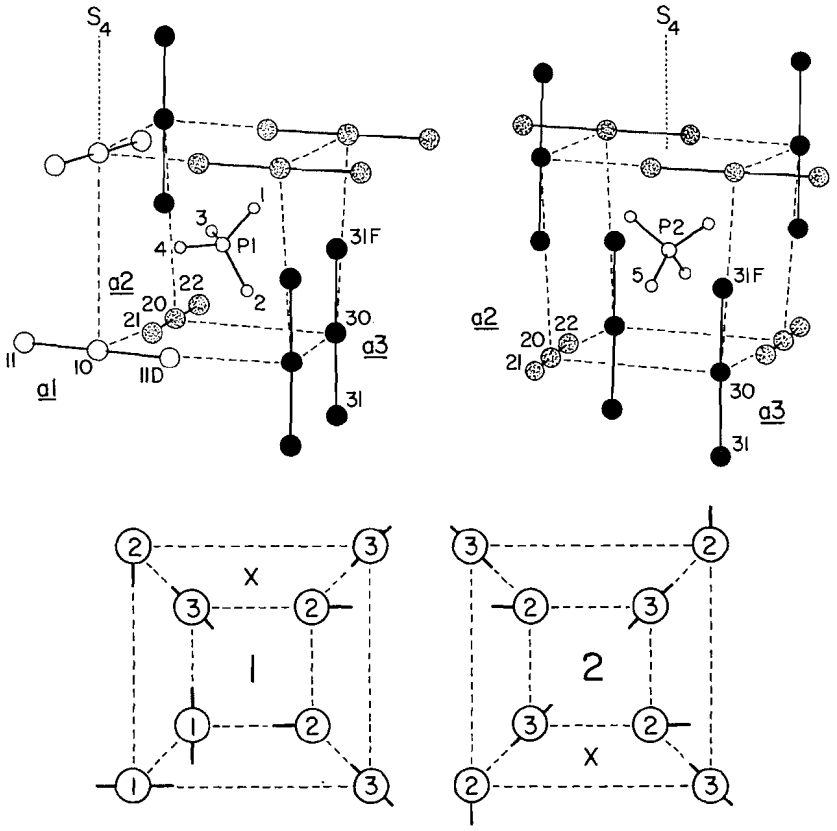


the U_{ii} of C(1) and C(3). An attempt to resolve this problem is described in the Experimental.

In QI3 the C–N axis of the cation is polar, hence placing the cation in a mirror plane averages the cation orientation ||*c*. The structure can thus be described as correctly assigned in *Pnnm* but with the cation in twofold orientational disorder about the

Fig. 4. (Top) The coordination cuboids of cations 1 and 2 in 4MPI3. Open circles, anion a1; stippled, a2; filled, a3. The top and bottom of the two subcells are in mirror planes ($z = \frac{1}{2}, 0$). (Bottom) The corresponding idealized Schlegel diagrams (down *c*). Large squares, $z = 0$; small squares, $z = \frac{1}{2}$. Anion numbers appear inside the circles. Orientations of the anions are indicated by the line segments attached to the circles. X identifies the face common to the two cuboids.



mirror plane. Alternatively, an attempt can be made to refine the structure as fully ordered in an orthorhombic subgroup of *Pnnm*. For reasons explained in the Experimental we have adopted the solution of the structure in the centrosymmetric group, i.e., the disordered *Pnnm* model.

The shortest (N, C)...I and H(N, C)...I distances in the disordered QI3 are to I(21), 3.75(1) and 2.92(2) Å, respectively, (N, C)-H(N, C)-I(21) = 136(3)°; and to I(11), 4.13(1) and 3.39(2) Å, respectively, (N, C)-H(N, C)-I(11) = 129(3)° (all values based on (N, C)—H(N, C) = 1.05 Å). Although these N-H-I angles seem unfavourable for hydrogen bonding, comparison with a similar situation in Da2I3 (Fig. 2, cf. below) supports the view that (N, C)—H(N, C)...I(21) at least must be considered as a legitimate though highly bent hydrogen bond. In the disordered structure the majority of the I(21) atoms would be, statistically, the recipients of one N—H...I(21) bond only, in contrast to the Da2I3 salt.

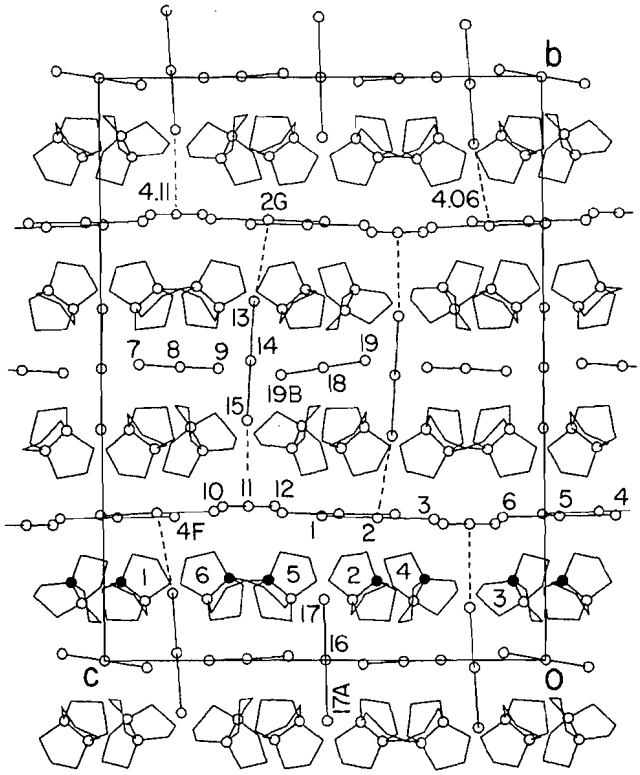
4MPI3

Surprisingly, this compound is not isostructural with 4MI3. It has a lower density than the latter: on replacing N by P the volume V_I per formula unit increases by ~6% while the corresponding increase in mass is only ~4%. The packing arrangement is thus less compact in 4MPI3 than in 4MI3.

For its simple chemistry 4MPI3 has an unexpectedly complex structure. The unit cell, of relatively high tetragonal symmetry, contains two I_3^- anions a1 = I(11)-I(10)-I(11D) ||(001) of symmetry C_{2h}, four anions a2 = I(21)-I(20)-I(22) ||(001) of symmetry C_s, and four anions a3 = I(31)-I(30)-I(31F)||*c*, also of symmetry C_s. Anion a2 is *in* a crystallographic mirror plane, whereas anion a3 is halved by it (Fig. 3). There are eight $Me_4P(1)^+$ cations c1 of symmetry C_1 and two $Me_4P(2)^+$ cations c2 of symmetry S_4 in the unit cell. Each cation is inside a cuboid cell of ~6.9 Å edge length, formed by the centre atoms of anions (Fig. 4), with the CH_3 groups oriented to avoid static interference with the anions. The anions defining a coordination cuboid are approximately located in horizontal (i.e., ||(001)) or vertical (i.e., ||*c*) edges of the cuboid. These cuboids thus tesselate the 4MPI3 structure in such a way that the overall packing can be described as of a distorted 8:8 CsCl type.

The anions are segregated in layers ||(001) at $z = 0, \frac{1}{2}$ and the cations in layers ||(001) at $z \sim \pm \frac{1}{4}$. However, while a1 and a2 are wholly in the $z = 0, \frac{1}{2}$ layers, a3 is perpendicular to them, with the result that the I(31) atoms of a3 are almost in the cation layers. The shortest inter-anion I...I distances below 4.5 Å are, within a layer ||(001), I(10)...I(21) = 3.993 Å, I(22)...I(30A) = 4.085 Å, and I(11)...I(30B) = 4.315 Å; between layers, I(20)...I(31C) = 3.999 Å (Table 3, Fig. 3). The I atoms involved form, within a layer, a quasi-linear I(10)...I(21)-I(20)-I(22)...I(30A) chain terminated perpendic-

Fig. 5. Projection of the API3 anion substructure on (100). Broken lines: shortest inter-anion I...I distances (Å) between anion layers, I(2)...I(13) and I(11)...I(15). The N atoms in cations 1–6 are black.



ularly at I(10) by a1 and at I(30A) by a3. Similarly, a3 forms a quasi-linear I(20K)...I(31)-I(30)-I(31F)...I(20J) chain perpendicularly terminated by a2 anions. These I...I ≥ 4 Å separations are too long for effective bonding interaction, hence the anions in 4MPI3 are regarded as discrete.

The cation geometry is unexceptional (Table D).

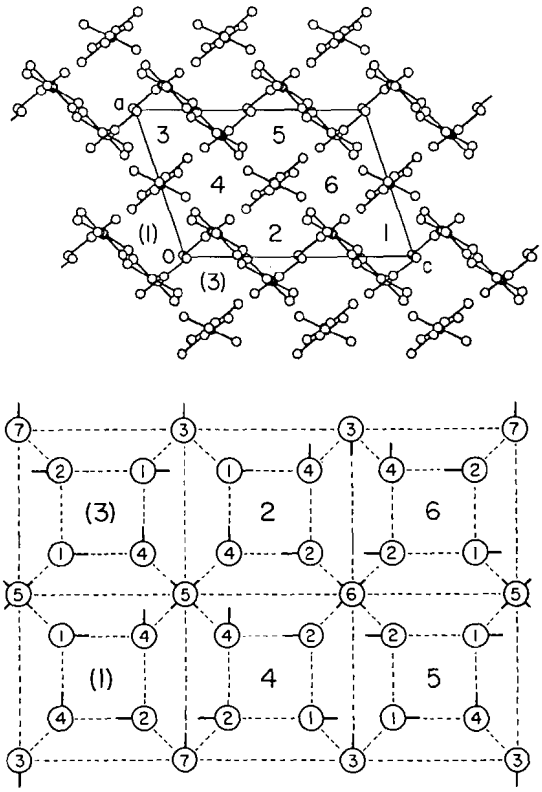
API3

Even more so than 4MPI3, this structure is surprisingly complex for a cation as compact as 1-azoniapropellane. Its large monoclinic cell contains 24 formula units: six sets of nonequivalent C_1 cations, two sets of centrosymmetric I_3^- anions a6 and a7, and five sets of nonequivalent slightly distorted anions a1–a5 (Tables 2 and 3).[8] The anions are arranged in layers ||(010), at approximate heights $y = 0, \pm \frac{1}{4}, \frac{1}{2}$. The atoms of a1, a2 and a4, in the $y \sim \pm \frac{1}{4}$ layers, are almost coplanar; anions a3 and a5, in the $y \sim 0, \frac{1}{2}$ layers, are almost parallel to (010), while anions a6 and a7 are perpendicular to (010). The layers of cations ||(010) are sandwiched between the anion layers, with the cation centroids roughly at $y = \pm \frac{1}{8}, \pm \frac{3}{8}$ (Fig. 5).

The ion packing in API3 is seen in the projection of the anions on (010) (Fig. 6). In addition to the anion layers ||(010) two other such systems are present: one ||($\bar{1}$01) and the other approximately ||(102). These three anion systems tesselate the structure into CsCl-type cuboids of approximate edge length of 7.3 Å, similar to those in 4MPI3 (Figs. 3 and 4). The vertices of these cuboids are formed by the centre atoms of the anions, with the

[8] Anion a1, I(1) to I(3); a2, I(4) to I(6); a3, I(7) to I(9); a4, I(10) to I(12); a5, I(13) to I(15); a6, I(17)-I(16)-I(17A); a7, I(19)-I(18)-I(19B).

Fig. 6. (Top) API3 anion substructure projected on (010). Numbers indicate cation positions (in parentheses, positions *equivalent* to those in Table 2). (Bottom) Schlegel diagrams (down *b*) of the corresponding idealized (cat)(an)$_8$ coordination cuboids in the approximate $0 \leq y \leq \frac{1}{4}$ slab of the API3 structure. Large squares, $y \sim 0$; small squares, $y \sim \frac{1}{4}$; cation centroids at $y \sim \frac{1}{8}$. The anions a1 to a4 and a7 are located in horizontal (i.e., ||(010)) and anions a5 and a6 in vertical (i.e., ||*b*) edges of the cuboids. See also Fig. 4.



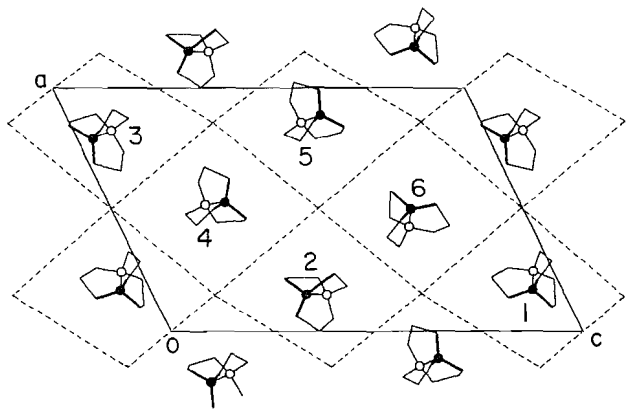
anions aligned in the edges of the cuboids in such a way that a1–a4 and a7 are in edges ||(010), and a5 and a6 in edges ||*b*. The orientations of the anions in a translation motif of adjacent cuboids are displayed in the Schlegel diagrams of Fig. 6.

The shortest inter-anion I...I distances below 4 Å are I(3)...I(6) = 3.632 Å, I(1)...I(11) = 3.877 Å, and I(4)...I(11B) = 3.895 Å (Table 3), all within an anion layer ||(010). The atoms involved form a quasi-linear I(11E)...I(4)-I(5)-I(6)...I(3)-I(2)-I(1)...I(11) chain, which is terminated at each end (at atoms I(11) and I(11E)) by an a4 anion perpendicular to the chain. The shortest I...I distances *between* neighbouring anion layers ||(010) are I(2G)...I(13) = 4.057 Å, i.e., between a1 and a5, and I(11)...I(15) = 4.113 Å, i.e., between a4 and a5. These distances involve the terminal atoms of anion a5, which thus provides a perpendicular link between the centre atoms of a1 and a4 in neighbouring anion layers: I(2G)...I(13)-I(14)-I(15)...I(11).

The positions and orientations adopted by the cations[9] inside their respective coordination cuboids are all different (Fig. 7). In spite of this the vertical (i.e., ||*b*) heights of the cation *centroids* in a cation layer ||(010) are remarkably constant: the mean *y*(centroid) in Figs. 5 and 7 is 0.1201(25) (ideally, $\frac{1}{8}$), corresponding to a standard deviation of only 0.07 Å verti-

[9] For comparison of cation geometry see 1-azoniapropellane tetraphenylborate (6).

Fig. 7. Cations in an approximate $0 \leq y \leq \frac{1}{4}$ slab of the API3 structure (see Fig. 6). The only symmetry operations relating these cations are unit-cell translations (cations in other slabs are of course related by $P2_1/c$ symmetry operations). Filled circles, N atoms; open circles, C(n0) (n = 1–6) atoms. Broken lines represent approximate boundaries of the coordination cuboids.



cally. None of the cation N–C axes is oriented ||b. This may be due to the presence, in each cuboid, of the terminal atoms I(13) and I(15) of a5 or I(17) of a6 or both, which protrude about 2.8 Å vertically into the space between the iodine layers, i.e., are roughly at the same vertical height as the cation centroids and thus sterically interfere with the cation hydrogens (Fig. 5). Regardless of the precise orientation of a cation, the N atoms in a cation layer are all ~0.5 Å in the same direction from the cation centroid, i.e., all the N atoms in the structure face the iodine layers at $y \sim \pm \frac{1}{2}$ rather than those at $y \sim 0$, $\frac{1}{2}$ (Fig. 5).

Da2I3

In this monoclinic layer structure (Fig. 8*A*) all the I atoms and the centroids of the 1,4-diazoniabicyclo[2.2.2]octane cations are located on mirror planes ||(001), at $y = \pm \frac{1}{4}$. The cations and the two nonequivalent I_3^- anions have therefore C_s symmetry. If the cation centroids were shifted from $y = \pm \frac{1}{4}$ to $y = 0$, $\frac{1}{2}$ (i.e., by about 2 Å ||b), the domain D outlined in Fig. 8B, which is related to a doubled B-centred cell (**a** + **c**, **b**, – **a** + **c**), would constitute a projection of a distorted CaF_2-type ion packing, somewhat reminiscent of the packing in the cubic $(N_2H_6)Cl_2$ (7). The alternating orientations of the ions are most simply described by regarding the ions as being located on distorted orthorhombic, dichromatic Bravais B_A lattices.

Anion a1 = I(11)-I(10)-I(12) is noticeably bent, whereas anion a2 = I(21)-I(20)-I(22) is almost linear (Table 3). The distortion of a1 from centrosymmetry (I(10)—I(11) = 2.793 Å, I(10)—I(12) = 3.167 Å, I-I-I = 172.5°) is even larger than in NH_4I_3 (2.797 Å, 3.113 Å, 178.6°; ref. 8) and (1-Me-cytosinium)I_3 (2.794 Å, 3.123 Å, 177.6°; ref. 9); significantly, both these structures contain inter-ion hydrogen bonds (cf. below). The I-I-I angle in a1 in fact appears to be the smallest on record in a triiodide anion.[10]

The shortest interanion I...I distances occur within the layers ||(001): I(11)...I(22B) = 3.673 Å, I(11)...I(21A) = 3.775 Å. Both are appreciably shorter than such distances in 4MI3 and QI3, >4.35 Å (Table 3), but they are comparable to similar distances in other triiodides, e.g., 3.651 Å in $[Pd(en)_2](I_3)_2$ (cited in ref. 8), 3.755 Å in (1-Me-cytosinium)I_3 (9), and 3.770 Å in TlI_3 (11).[11] If these two distances are regarded as corresponding to weak bonding interactions, then a2 anions in a layer are seen to be joined by I(11) atoms of a1 to form zigzag chains ||a, with pendant -I(10)-I(12) segments: ...I(22)-I(20)-I(21)...I(11)[-I(10)-I(12)]... (Fig. 8*B*). In these chains a1 and a2 are roughly orthogonal: I(10)-I(11)-I(21A) = 97.6°, I(21A)-I(11)-I(22B) = 80.2°, I(11)-I(22B)-I(20B) = 78.2°.

Although the crystallographic symmetry of the cation is only C_s, its refined geometry is close to D_{3h}. The three shortest N...I distances are 3.524(7) Å to I(12), 3.881(7) Å to I(21), and 3.884(7) Å to I(22C); the corresponding distances from the placed N(H) atom are 2.78, 3.21, and 3.24 Å, respectively (Table D). The smallest of the three, 3.524 and 2.78 Å, respectively, are each about 0.2 Å shorter than the corresponding N...I and H(N)...I distances in QI3 (Fig. 2), in which the cation has a similar local geometry, and also shorter than the smallest (freely refined) N...I and H(N)...I distances in NH_4I_3, 3.69(1) and 2.82(3) Å, respectively, N-H(N)-I = 168(2)° (8). The H(N) atom is thus clearly involved in a hydrogen bond to I(12),[12] in spite of the smallness of the N-H(N)-I(12) = 130° angle, with I(12) being the recipient of two such m-related bonds (Fig. 2). The N—H(N)...I(12) bonds link the cations into uninterrupted cat...I(12)...cat... chains ||b.

The simultaneous, symmetric engagement of I(12) in two H-bonds would be expected to affect the I(10)—I(12) bond length. Indeed, this bond is lengthened to 3.167 Å, which in turn produces an appreciable shortening (cf. ref. 13) of the conjugate I(10)—I(11) bond, 2.793 Å, and reduces the atom charge on I(11). The resulting induced polarity of a1 is probably responsible for the short I(11)...I(22B) = 3.673 Å contact and thus for a weak bonding interaction with a2 anions in the zigzag chain. This view is supported by the near orthogonality at I(11) of the a1 and a2 anions in a chain, which is consistent with the existence of 90° p–p interactions such as are commonly observed in higher polyiodide anions in crystals.[13] The participation of a1, with its I(12) atom H-bonded and its I(11) atom joining the a2 anions in the chain, is thus different from a2, but neither anion can be regarded as discrete. A similar situation is observed, for much the same reason, in NH_4I_3 (8), where atom I(1) of the anion is H-bonded to three cations and atom I(2′) of another anion is almost collinear with the first anion, I(3)...I(2′) = 3.881 Å.

The validity of the claim that H-bonding indeed causes sig-

[10] An I-I-I angle of 172.7(1)° has been reported for I_3^- in $[L_2Mn^{III}{}_2(\mu\text{-}O)(\mu\text{-}OAc)_2](I_3)I\cdot H_2O$, L = 1,4,7-triazacyclononane (10), but the bond-length disproportionation in this anion is smaller than that in a1 of Da2I3, 2.851 Å and 3.112 Å, respectively.

[11] The corresponding distances in NH_4I_3 (8), RbI_3 (11), and CsI_3 (12) (all three isostructural with TlI_3) are 3.881, 3.921, and 3.972 Å, respectively.

[12] There were indications, in the difference map, of the placed H(N) atom being broadly displaced in the direction of I(12). These are not presented here, as the closeness of I(12) to the presumed H(N) features may have distorted the map. It may also be noted (Fig. 8*B*) that it is the displacement of the cations toward the I(12) atoms that differentiates the shape of domain D (broken edges !) from that of a translated doubled B-cell referred to above, i.e., the distortion of the quasi-CaF_2 packing in Da2I3 is partially attributable to the hydrogen bonding.

[13] Orthogonal p–p bonding interactions in polyiodide structures will be discussed in detail in a sequel in this series.

Fig. 8. Projection of the Da2I3 structure on (010). Stippled circles, I atoms at $y = \frac{1}{2}$; large open circles, I atoms at $y = \frac{1}{2}$; filled circles, cations with centroids at $y = \frac{1}{4}$; small open circles, cations with centroids at $y = \frac{3}{4}$. (*A*) Principal axes of cation libration L_1 and L_2 are in the page, L_3 is perpendicular to the page and coincident with the N–N′ axis. H(N)...I(12) H-bonds are represented by broken lines. (*B*) Solid outline: domain *D* related to ion packing (see text). Dashed lines, anion zigzag chains in $y = \pm \frac{1}{4}$ layers. See Table 3 for I...I distances and I-I-I angles.

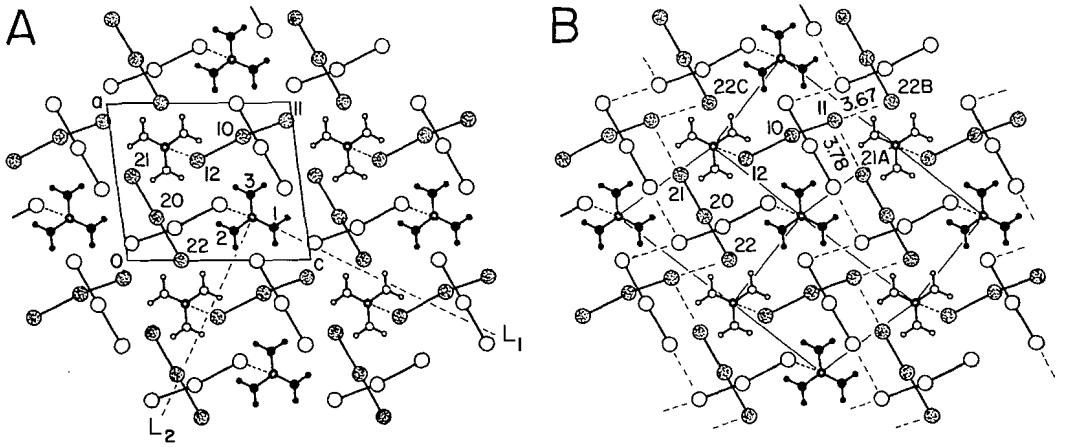


Fig. 9. The phenBr3 structure projected on (100) (left) and on (001) (right). Large circles, Br atoms; smallest circles, H(N10) atoms. The bifurcated N(10)—H(N10)...Br(3), N(1) bonds are represented by broken lines. The quasi-coplanar Br(1) atoms (left) define the pseudo-hexagonal channels ||*a* containing the cation stacks.

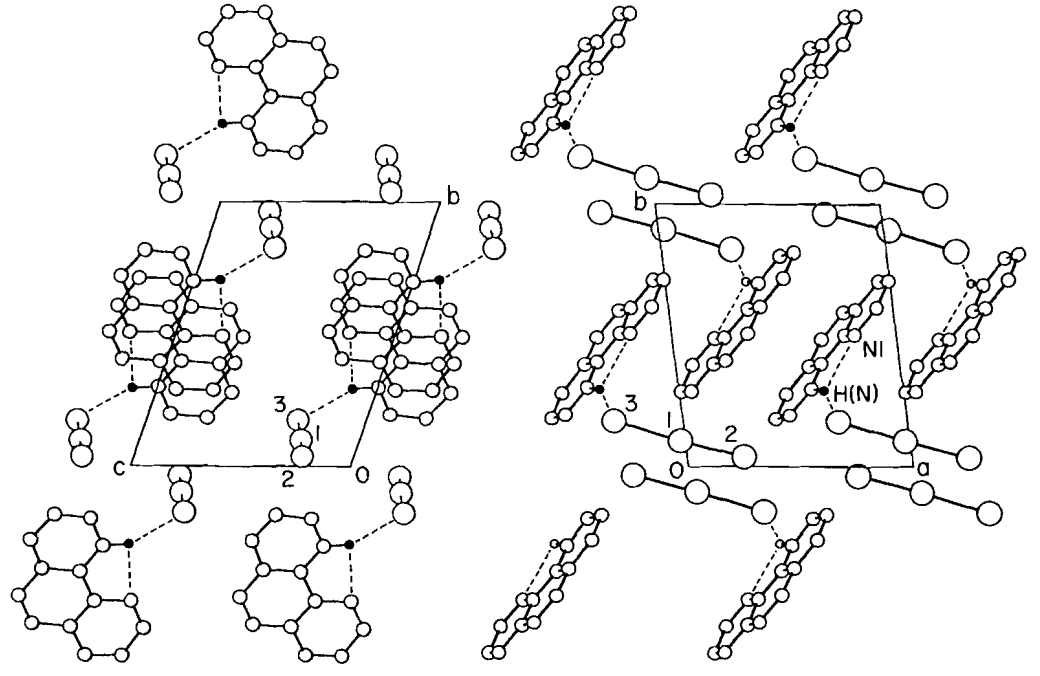


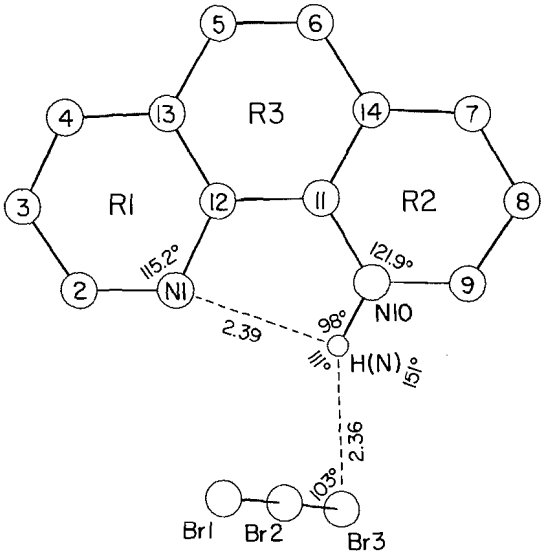
nificant asymmetry of the I_3^- anion and in turn a decrease in inter-anion I...I distances is discussed in more detail in Conclusions.

phenBr3

The phenH^+ cations are obliquely stacked inside pseudo-hexagonal channels ||*a* and defined by the Br(1) atoms (Fig. 9, left). The perpendicular spacing between the parallel neighbouring cation planes in the stacks is 3.46(2) Å, probably too long for an effective π–π stacking interaction. The Br_3^- anion is asymmetric, Br(2)-Br(1)-Br(3) = 177.6° (Table 3). The anion is discrete, although the shortest inter-anion Br...Br distance, 3.713 Å, appears to be at the van der Waals limit.

The cation (Fig. 10) is planar. The mean deviation of the non-hydrogen atoms from the best plane through these atoms is 0.005[2] Å in ring R1, 0.007[4] Å in R2, 0.004[2] Å in R3; and 0.012[9] Å in the cation as a whole. The angles between the best planes are R2/R1 = 1.2°, R3/R1 = 0.1°, R3/R2 = 1.4°, cation/R1 = 0.3°, cation/R2 = 1.0°, and cation/R3 = 0.4°. The protonated N atom was identified unambiguously as N(10), on clear evidence from both a difference Fourier map and the endocyclic C-N-C angle, which is 115.2(8)° for C(2)-N(1)-C(12) but

Fig. 10. Cation atom and ring numbering, and the bifurcated H-bond in phenBr3.



121.9(7)° for C(9)-N(10)-C(11), consistent with expectation (means in $phenH^+$ ions, 116.4[3]° at the unprotonated and 123.2[3]° at the protonated N atom, cf. ref. 14). The H(N) atom is engaged in a bifurcated H-bond, with an inter-ion branch to Br(3) and an intra-cation branch to N(1) (Fig. 10).

The geometry of the cation (Table D) matches closely that of other reported $phenH^+$ cations and is also essentially identical with that of the neutral $phen^0$ molecule (14):

Distance, Å	phenBr3	⟨$phenH^+$⟩	⟨$phen^0$⟩
N(1)...N(10)	2.731(10)	2.722[9]	2.724[2]
C(11)...C(12)	1.440(12)	1.431[3]	1.454[6]
C(13)...C(14)	2.840(12)	2.846[24]	2.841[11]
C(5)—C(6)	1.349(13)	1.339[6]	1.331[9]

The geometry of the intra-cation H-bond resembles the corresponding mean geometry in the $phenH^+$ cation: H(N)...N(1) = 2.39 Å, N(10)-H(N)-N(1) = 98°, (N(10)—H(N) taken as 1.02 Å), compared to the means 2.38[3] Å and 101.6[21]° respectively (14). The H(N)...Br separation is 2.36 Å and the N(10)-H(N)-Br(3) and H(N)-Br(3)-Br(2) angles are 151° and 103°, respectively.

Discussion

The structures of all five title triiodides are of the layer type; the phenBr3 structure can be described as consisting of parallel anion channels that contain oblique cation stacks.

Layer structures are frequently encountered in triiodides. The layer occupancy can be mixed, i.e., each layer contains cations *and* anions, or the cations and the anions can be segregated in separate layers.[14] Which arrangement will prevail depends on the ion-packing type. For 6:6 ion coordination the most common is the distorted (sometimes strongly) NaCl type, characteristic of mixed layers. This type is observed, for example, in the isostructural *Pnma* MI_3 (M = Tl, Rb, Cs, NH_4; layers ||(010) at $y = \pm \frac{1}{4}$; refs. 8, 11, 12) and also in a number of trihalides with heteroatomic anions. However, in 4MI3 and QI3 the alternative 6:6 *anti*-NiAs arrangement (*Pnnm*, layers ||(001), $z = 0, \frac{1}{2}$) is observed instead. Segregation of the cations and anions into separate layers is characteristic of the CsCl-type packing, e.g., in the Et_4NI_3 dimorphs (*Cmca*, layers ||(100), $x_{cat} = \pm \frac{1}{4}$, $x_{an} = 0, \frac{1}{2}$; *Pnma*, layers ||(010), $y_{cat} \sim 0, \frac{1}{2}$, $y_{an} = \pm \frac{1}{4}$, ref. 15) or in 1-Me-hexamethyleneammonium(1+) I_3 ($P2_1/c$, layers ||(100), $x_{cat} \sim \pm 0.21$, $x_{an} = 0, \frac{1}{2}$, ref. 5). Two of the title triiodides fall in this category: in 4MPI3 the layers are ||(001), $z_{cat} \sim \pm \frac{1}{4}$, $z_{an} = 0, \frac{1}{2}$; in API3 the layers are ||(010), $y_{cat} \sim \pm\frac{1}{8}, \pm\frac{3}{8}$, $y_{an} \sim 0, \pm\frac{1}{4}, \frac{1}{2}$ (Fig. 5). The monohydrate of KI_3 (*Pc*, ref. 16) also is of this type: layers ||(100), $x[K^+ + H_2O] \sim 0.86$, $x_{an} \sim 0.37$. Although the 1:2 compound Da2I3 is of a distorted 4:8 fluorite type, all the ions are in *mixed* layers ||(010), at $y = \pm\frac{1}{4}$.

Ion packing

The *anti*-NiAs-type packing found in 4MI3 and QI3 is relatively uncommon in organoammonium compounds. In $(Et_4N)[MX_4]$ (M = Ga, Fe, In, Tl; X = Hal)[15] it is undistorted *hexagonal* ($P6_3mc$), as in the aristotype. However, in $(Et_4N)[GaI_3Cl]$ (I and Cl disordered) and $(Et_4N)[FeI_4]$(*II*), which have the same *Pnnm* space-group symmetry as 4MI3 and QI3, the cation and anion positions are reversed, i.e., the packing is of the *NiAs* type. In these two structures a_O/c_O = 1.80 and 1.79, respectively; r = 1.255 and 1.254, respectively (cf. above). The volumes V_1 per formula unit of the 6:6 $(Et_4N)[FeI_4]$(*II*) and its NaCl-type $(Et_4N)[FeI_4]$(*I*) isomorphs are closely similar, 452 as against 458 Å^3.

In the simplest cases of the *CsCl-type* structures an I_3^- anion of one type only would be sufficient to generate the $[cat][an]_8$ coordination cuboid. This is seen in, for example, $[K(H_2O)]I_3$ (cf. above) and also in the two tetragonal ($P\bar{4}2_1m$) heteroatom trihalides $(PCl_4)[ICl_2]$ (18) and $(Me_4N)[ICl_2]$ (19). As the size of the cation and its complexity increase or its shape varies, I_3^- anions of a single type may not be able to coordinate the cation in a manner that would result in a 3-dimensional 8:8 crystal. Two or more types of anion may then be required to accomplish this. Thus in each of the *Cmca* and *Pnma* dimorphs of Et_4NI_3 (15) two types of I_3^- generate the coordination cuboid, while in the tetragonal 4MPI3 three and in the unusual case of API3 as many as seven types of I_3^- anions are required. The projections of the 4MPI3 and API3 structures in Figs. 3 and 6 show that, in spite of the increase in the number of nonequivalent anions, the 8:8 coordination geometry is closely satisfied: the edges and vertices of the cuboid cells defined by the projected anions are immediately recognized. It thus appears that the increase in the number of anion types and the adjustment of the space-group symmetry provide the compromise required to achieve and maintain the essentially spatially homogeneous CsCl-type packing in triiodide structures that qualify, by their (unspecified) cation/anion size ratio, for 8:8 coordination. The API3 structure thus represents an extreme variety of a frustrated CsCl-type packing.

Alternative descriptions

It should be noted that some of the reported triiodide structures can alternatively be described as, for example, channel structures. Thus the triclinic $(n\text{-}Bu_4N)I_3$ (20) has been described as

[14] In this context anion means the entire anion or its centre atom; cation refers to the cation centroid.

[15] For these and related structures see ref. 17.

consisting of cation channels ||*c* with the I_3^- ions approximately in the channel axes and with the interleaved, fully extended cations in planes approximately ||(001). This is a natural description of this structure and one that suited the authors' purposes. However, the structure can as well be described as a layer structure consisting of separate cation and anion layers ||(010) ($y_{cat} \sim \pm\frac{1}{4}$, $y_{an} \sim 0, \frac{1}{2}$) or as a distorted CsCl-type structure. Similarly, the 4MPI3 structure can be described as one consisting of channels ||*c* (Fig. 3), the API3 structure as one with channels ||*b*, and Da2I3 as one with channels ||*b*.

Hydrogen bonding

The distance from the placed H(N) atom to I(12) in Da2I3, 2.78 Å, is significantly shorter than the corresponding distance in QI3, 2.92 Å (Fig. 2). The H(N)...I(12) distance will be even shorter, and the N-H(N)-I(12) angle larger, if account is taken of the (undetermined) lengthening of the N—H(N) bond and of the displacement of the H(N) atom toward I(12), both expected consequence of H-bond formation.[12] Similar short H(N)...I distances (with located hydrogens) have been reported in 1-Me-cytosinium (MCI3, ref. 9) and ammonium (8) triiodides. Schematic comparison of the three structures leaves no doubt that the asymmetry of the anion, in particular the lengthening of the proximal I—I bond, is associated with the presence of the short H(N)...I bond (atom numbering as in original):

Da2I3

(1.02)	2.78	3.167(2)	2.793(2)	3.673(2)	
N—H(N).....	I(12)	—I(10)	—I(11)	.....	I(22B)
130°		178.6°	178°		

MCI3

[1.035]	*d*	3.123(1)	2.794(1)	3.755(1)	
2 N— 2 H(N).....	I(1)	—I(2)	—I(3)	.....	I(1')
α		177.6°	166.6°		83°

NH_4I_3

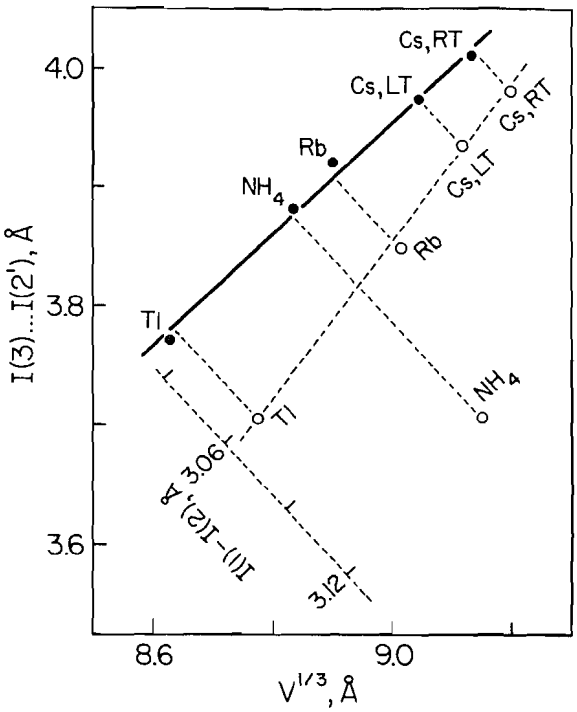
[0.88[4]]	*d*	3.114(2)	2.797(1)	3.881(2)	
4 N— 4 H(N).....	I(1)	—I(2)	—I(3)	.....	I(2')
α		178.6°	172.4°		

(MCI3, *d*, α: 2.67 Å, 152°; 2.66 Å, 149°. NH_4I_3, *d*, α: 2.81(4) Å, 158(4)°; 2.82(3) Å, 167(3)°; 2.87(2) Å, 168(2)°, 2×). Unlike in Da2I3, where there is only one H(N)-donor, in MCI3 the I(1) atom is the recipient of two H-bonds from one cation, and in NH_4I_3 I(1) is the recipient of four H-bonds from four cations. These examples illustrate extremes of deformability of the I_3^- anion under the influence of crystal environment, and of the particular efficacy of short H-bonds in this regard. The fact that the lengthening of the I—I bond is more substantial in Da2I3 than in the other two structures, despite the presence of multiple H-bond donors in the latter, is probably attributable to the double charge on the cation.

A short N—H(N)...I bond would be expected (cf. under Da2I3 above) to produce, apart from the lengthening of the I—I bond in the associated anion, a reduction in the shortest inter-anion I...I distances at the other end of the anion. The I(11)...I(22B) distance in Da2I3 and the I(3)...I(1′) distance in MCI3, both to terminal atoms of anions in the planar zigzag anion chains (Fig. 8; cf. Fig. 3 of ref. 9), are indeed quite short and suggestive of weak I...I bonding interactions; in NH_4I_3 the corresponding I(3)...I(2′) distance is ~0.2 Å longer than in Da2I3 and to the *centre* atom of an anion in the planar herringbone anion pattern (Fig. 1 of ref. 8). The large asymmetry of the H-bonded anion and the shortness of the I(11)...I(22B) distance in Da2I3 strongly suggest that both are the effects of the H-bonding in this structure, and similarly in MCI3, i.e., H-bonding is an active participant significantly co-responsible for the overall structural features of Da2I3 and MCI3. This does not appear to be the case in NH_4I_3. This triiodide is isostructural with TlI_3, RbI_3, and CsI_3. When the I(3)...I(2′) distances in these four compounds (8, 11, 12, 21) are plotted against $V^{1/3}$ (V = unit-cell volume; Fig. 11), the four points fall on a straight line ($r^2 = 0.990$), i.e., the I(3)...I(2′) distance in NH_4I_3 is consistent with those in the other compounds and depends on the gross variable V. However, while the I(1)—I(2) bond lengths in the other triiodides vary linearly with $V^{1/3}$, that in NH_4I_3 is a striking misfit. The short H-bonds to NH_4I_3 thus affect the anion asymmetry but their effect does not appear to extend beyond the other end of the anion and the I(3)...I(2′) distance is not shortened by the agency of the H-bond. The difference in the atom charges on the centre and terminal atoms of the I_3^- anions is of course also a factor.[16]

In contrast to the above structures the H-bonding in QI3 does not produce asymmetry in anion a2, with its centre atom I(20) at an inversion centre: the U_{ii}[I(20)], if anything, are somewhat smaller than those of the other I atoms in the Q3 structure (Table C). Then again, the H-bonds to the two terminal atoms of a2 are longer than the H-bonds in the above struc-

Fig. 11. Thick line, filled circles: variation of the shortest inter-anion distance I(3)...I(2′) in the isostructural MI_3 (M = Tl, Rb, Cs, NH_4; *Pnma*; Cs, LT, 113 K; Cs, RT, room temperature) with $V^{1/3}$ (see text). Broken lines, open circles: variation of the longer I—I bond length in the I_3^- anion with I(3)...I(2′) and $V^{1/3}$.



[16] The existence of a relationship between the lengthening of the proximal I—I bond and the shortening of the distal inter-anion I...I distance in H-bonded triiodides is being investigated, as is the variation of the H(X)-I-I angle in X-H(X)...I-I-I groupings, both in literature structures and in a number of newly determined structures (to be reported shortly).

tures and, by virtue of the crystallographic centrosymmetry of a2, (statistically) balanced about the inversion centre. Moreover, as crystallographically centrosymmetric I_3^- anions go, the I—I bond length in a2, 2.910(2) Å, and the total length of the anion, 5.820(2) Å, are at the low end of the range for such anions (cf. Table 2 of ref. 8).

Conclusions

The five title triiodides have structures of the layer type. The ion packing in 4MI3 and QI3 is of an orthorhombically distorted 6:6 *anti*-NiAs type; in 4MPI3 and API3 it is of the CsCl type; and in the 1:2 compound Da2I3 it is of a monoclinically distorted fluorite type, with the cations and anions in mixed layers. In the phenBr3 structure, obliquely stacked cations are accommodated inside parallel anion channels. The following features of the structures merit emphasis:

1. The asymmetry of one of the two I_3^- anions in Da2I3 appears to be the largest on record: I(11)—I(10) = 2.797 Å, I(10)—I(12) = 3.167 Å, I(11)-I(10)-I(12) = 172.5°. This asymmetry is associated with the short N—H(N)...I(12) bond (N...I(12) = 3.524 Å, H(N)...I(12) = 2.78 Å) and demonstrates clearly the extent to which H-bonding is able to distort the I_3^- anion in a crystal. The charge displacement the distortion produces in the anion has further repercussions in the structure, in that it shortens the inter-anion I...I distance at the non-H-bonded end of the anions and leads indirectly to formation of planar zigzag anion chains in the crystal.

2. The crystal structures of 4MPI3 and API3 are unexpectedly complex. 4MPI3, which is not isostructural with 4MI3, contains cations of two and anions of three types; API3, with its very large unit cell for its chemical simplicity, contains cations of six and anions of seven types. The complexity of these structures appears to be the result of a compromise between a tendency to maintain an 8:8 coordination and an unfavourable cation/anion ratio, which in these two cases possibly is at the boundaries separating different packing regimes:[17]

Compound	V_I, Å^3	Type	cat/an
TlI_3 (11)	160	[NaCl]	1/1
NH_4I_3 (8)	172	[NaCl]	1/1
RbI_3 (11)	176	[NaCl]	1/1
CsI_3 (12, 21)	190	[NaCl]	1/1
2MI3	232	NaCl	1/1
4MI3	295	*anti*-NiAs	1/2
4MPI3	314	CsCl	2/3
QI3	318	*anti*-NiAs	1/2
TrI_3	341	*anti*-NiAs	1/1
MHMTI3 (5)	354	CsCl	1/2
Et_4NI_3(*I*) (15)	380	CsCl	1/2
Et_4NI_3(*II*) (15)	383	CsCl	1/2
API3	389	CsCl	6/7
$MeEt_2PhNI_3$ (22)	410	CsCl	1/2

[17] V_I, volume per formula unit; cat/an, number of nonequivalent cations to number of nonequivalent anions. 2MI3 = $Me_2NH_2I_3$, TrI_3 = tropanium I_3 (K.N. Robertson, T.S. Cameron, and O. Knop, to be published). MHMTI3 = 1-Me-hexamethylenetetrammonium(1+) I_3, 1-Me-1,3,5,7-tetraazaadamantan-1-ium I_3. Brackets indicate strong departure from aristotype.

Unfortunately, because of present paucity of structural information on triiodides of compact, quasi-spherical cations with $V_I > 400$ Å^3 it is not clear what general packing arrangements to expect beyond API3. Below TlI_3 hydrated species appear to prevail, e.g., $KI_3 \cdot H_2O$ (16) and the structurally unexplored hydrates of LiI_3 and NaI_3.

Experimental

The title compounds were prepared by combining a solution of the appropriate halide in a suitable solvent (mostly MeOH) with a stoichiometric amount of an MeOH solution of iodine or bromine, and allowing the resulting solution to crystallize by controlled evaporation at room temperature. Deviations from this procedure are noted under the individual compounds below. The trihalides were recrystallized if required. However, controlling the size and quality of the crystals was not without problems, as large crystals had to be sectioned, not always with entirely gratifying results.

Diffraction intensities were measured at 20(2)°C using a Rigaku AFC5R system with either a sealed 2.4 kW Mo-anode tube (4MI3, QI3, API3, Da2I3, phenBr3) or a rotating-anode tube (4MPI3) (graphite monochromator, λ(Mo Kα) = 0.71069 Å). All intensities were corrected for Lorentz, polarization, absorption (ψ-scans), and secondary extinction as well as for time-decay effects where appropriate. The anisotropic temperature factor is defined as $\exp[-2\pi^2(U_{11}h^2a^{*2} + ... + 2U_{23}klb^*c^* + ...)]$. The structures were solved by direct methods (23) and refined using the TEXSAN-TEXRAY crystallographic software package (24) except for 4MI3 and API3, where the SHELXL-93 system (25) was used, for 4MI3 to model the disorder and for API3 because of the complexity of the structure. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, with unit weights except for 4MI3 and API3. Since the H atoms were placed geometrically (C—H, 1.08 Å, N—H, 1.02 Å) and not refined (U_{iso}(H) = 1.2U_{eq}(C, N) of the attached atom), no esd's are quoted on distances and angles involving H atoms. The residual electron-density maxima were all close to the halogen atom. Tables of structure factors are available from the authors.

4MI3

Straightforward refinement in *Pnnm* (I(10) in 2(*d*), I(20) in 2(*b*), I(11) and I(21) in 4(*g*), all other atoms in 8(*h*)) gave an acceptable structure but some of the U_{ii} of C(1) and C(3) were unreasonably high. Examination of the thermal ellipsoids of the cation atoms revealed that the cation undergoes large-amplitude librational motion essentially about its N–C(2) axis. Splitting the undifferentiated C(1) and C(3) positions (SHELXL-93, $w^{-1} = \sigma^2F_o^2 + (0.0506p)^2 + 5.35p$, $p = [(F_o^2)_{max} + 2F_c^2]/3$) significantly reduced the contentious U_{ii} values, although they still remained high (Table C). This twofold splitting is probably too simple to account for the observed U_{ii} values. Since no additional clues were available, no further attempts were made to improve the agreement.[18]

QI3

As stated above, this structure can be correctly refined in

[18] The existence of diffuse scattering in 4MI3 (as well as in $(Me_4N)IC1_2$ and $(Et_4N)I_3$(*I*)) attributed to orientational disorder of the anion in the unit cell has been reported in ref. 26.

Pnnm but with the cation in twofold orientational disorder across the mirror plane. A fully ordered structure would require refinement in an orthorhombic subgroup of *Pnnm*. Of the three possible subgroups of index 2, $P2_12_12$, *Pnn*2, and $Pmn2_1$ (in two settings, $Pn2_1m$ and $P2_1nm$), the last-named is not applicable because it does not remove the mirror plane perpendicular to the cation C–N axis. However, the difference between refining the disordered structure in *Pnnm* and the fully ordered structure in a noncentrosymmetric subgroup rests on the difference of the scattering powers of an averaged $\frac{1}{2}$(C + N) atom and a C or N atom, i.e., only 0.23% of $F(000)$, in a unit cell the scattering power in which is dominated by the iodine atoms at $z = 0, \frac{1}{2}$. Lacking confidence in the soundness of a subgroup refinement in these circumstances, we present the disordered structure as the one supportable by the data set.

TLS analysis of the anisotropic thermal parameters in the disordered structure showed that the U_{ij} values of the nonhydrogen cation atoms cannot be accounted for satisfactorily on a rigid-body-motion model: $R(U_{ij}) = 13.9\%$, $R_w(U_{ij}) = 14.0\%$, $\text{rms}(U_{ij}) = 0.0071$ Å^2, $\text{rms}[\text{esd}(U_{ij})] = 0.0062$ Å^2. However, the analysis indicated a mean amplitude of libration about a principal axis $\parallel c$ of ~6°.

API3

Because of the large number of nonequivalent cation atoms (60 C, 6 N, 108 H) in the presence of 19 nonequivalent iodine atoms in the unit cell, the N and C atoms were refined only isotropically, with constraint on the C—C and C—N bond lengths, using SHELXL-93. To judge by the large U_{ii} values of some of the I atoms (Table C), the structure at room temperature is quite mobile.[19]

Da2I3

The small black crystals that were deposited within a few hours on mixing stoichiometric amounts of Dabco iodide and iodine solutions in MeOH were not of a quality suitable for single-crystal X-ray diffraction. A sample of the crystals was therefore sealed in contact with dry MeCN, placed in a temperature-cycling recrystallization apparatus, and the temperature was cycled between 26 and 40°C (cycle time of about an hour) for 3 months. During this period a number of chunky crystals had grown on the sides of the container; these were of a size and quality suitable for data collection.

The thermal motion of the cation is consistent with the rigid-body-motion model: TLS analysis of the anisotropic thermal parameters of the C and N atoms gave an $\text{rms}(U_{ij})$ of 0.0029 Å^2 compared to $\text{rms}[\text{esd}(U_{ij})] = 0.0042$ Å^2. The mean amplitudes about the principal axes of libration L were 2.8° about L_1 (= line of intersection of the mirror plane halving the cation with the N-C(1)-C(1′)-N′ plane), 3.9° about L_2 (through the cation centroid and perpendicular to L_1), and 6.3° about $L_3 \parallel b$ (= the N-N′ axis). The geometry of these librational motions is consistent with the cation orientation relative to the I(12) atom, to which the cation is H-bonded (Fig. 8*A*). The mean components of the translational motion along the crystallographic axes were ~0.17, ~0.17, and ~0.14 Å, respectively.

phenBr3

TLS analysis of U_{ij}(C, N) gave $R(U_{ij}) = 10.2\%$, $R_w(U_{ij}) = 10.7\%$, $\text{rms}(U_{ij}) = 0.034$ Å^2 compared to $\text{rms}[\text{esd}(U_{ij})] = 0.0047$ Å^2, with the maximum mean amplitude about a principal libration axis of 4.4°. Librational corrections to bond lengths calculated on the rigid-body-motion model were between 0.002 and 0.006 Å, with a mean of 0.0043 Å. The largest differences between the calculated and observed U_{ii} values were for C(7) and C(8). They are probably attributable to the close proximity of H(7) and H(8) to the nearest Br(2) and Br(3) atoms: H(8)...Br(3D) = 2.92 Å, H(7)...Br(2) = 2.95 Å, H(7)...Br(3B) = 3.04 Å, all below or at the limit of the sum of Pauling's van der Waals radii, ~3.15 Å.

[19] As pointed out by a referee, the axes of the $P2_1/c$ cell (Table 1) can be transformed by (1,0,0/-1,0,-2/0,1,0) to yield a *C*-centred pseudo-orthorhombic cell, $a = 15.131$, $b = 43.330$, $c = 28.453$ Å, 90°, 90°, 89.2°. Examination of the diffraction intensities, however, leads to a clear rejection of a *C*-centred cell, i.e., there is no significance to the transformation.

Acknowledgments

This investigation was supported by research grants from the Natural Sciences and Engineering Research Council of Canada to T.S.C. and O.K., and from the Mount Saint Vincent University Research Fund to M.A.J.

*N*10-(2′-Mercaptoethanoyl)-2,2,5,5-tetramethyl-3,4-diathia-7,10-diazabicyclo[5.3.0]decane and its reaction with oxotrichlorobis(triphenylphosphine)-rhenium(V)

H. Alarabi, R.A. Bell, H.E. Howard-Lock, J. Kowanetz, and C.J.L. Lock

Abstract: The ligand molecule *N*10-(2′-mercaptoethanoyl)-2,2,5,5-tetramethyl-3,4-dithia-7,10-diazabicyclo[5.3.0]decane has been prepared and characterized by ^{1}H and ^{13}C NMR spectroscopy and by mass spectrometry. The protected analogue, *N*10-[(2′-triphenylmethylthio)ethanoyl]2,2,5,5-tetramethyl-3,4-dithia-7,10-diazabicyclo[5.3.0]decane dimethanol hemihydrate, was examined by the same techniques and also by X-ray crystallography. Crystals were triclinic, *P*-1, a = 11.125(2), b = 11.986(2), c = 13.562(3) Å, α = 103.54(3)°, β = 90.29(3)°, γ = 107.11(3)°, and Z = 2. The crystal was unstable in air at room temperature, so measurements were made on a crystal sealed in a tube that contained methanol vapour. Intensities were measured with a Rigaku AFC6R diffractometer and monochromated CuKα radiation (λ = 1.54178 Å). The structure was solved by direct methods and refined to R = 0.1497, wR = 0.0655 based on 5000 independent reflections. The high residuals were caused by solvent disorder. Bond lengths and angles were normal. The reaction of the ligand with oxotrichlorobis(triphenylphosphine) rhenium(V) yielded an unexpected asymmetric complex, oxo(1,1-dimethyl-1,8-dimercapto-3,6-diazaoctan-7-onato-N^3,N^6,S^1,S^8) rhenium(V). Crystals were monoclinic, $P2_1/n$, a = 10.633(2), b = 11.221(2), c = 11.678(1) Å, β = 116.10(1)°, Z = 4. Intensities were measured with a Siemens P4 diffractometer and monochromated MoKα radiation (λ = 0.71073 Å). The structure was solved by the heavy atom method and refined to R = 0.0471, wR = 0.0340 based on 2866 unique reflections. Most bond lengths and angles were normal. The Re≡O distance of 1.681(5) Å was longer than normal. It is postulated that this was caused by competitive π bonding between the deprotonated amidic nitrogen atom and the rhenium atom, as shown by the short Re—N distance (1.997(6) Å) compared to the equivalent distance for the amine nitrogen atom (Re—N, 2.151(4) Å).

Key words: N_2S_2 ligands, rhenium, crystal structure.

Résumé : On a préparé la molécule du coordinat *N*10-(2′-mercaptoéthanoyl)-2,2,5,5-(tétraméthyl-3,4-dithia-7,10-diazabicyclo[5.3.0]décane et on l'a caractérisée par spectroscopie RMN du ^{1}H et ^{13}C ainsi que par spectrométrie de masse. On a étudié l'analogue protégé, l'hémihydrate du *N*10-[(2′-triphénylméthylthio)éthanoyl]-2,2,5,5-tétraméthyl-3,4-diathia-7,10-diazabicyclo[5.3.0]décane diméthanol, par les mêmes techniques ainsi que par cristallographie aux rayons X. Les cristaux sont tricliniques, *P*-1, a = 11,125(2), b = 11,986(2) et c = 13,562(3) Å, α = 103,54(3)°, β = 90,29(3)° et γ = 107,11(3)° et Z = 2. Les cristaux sont instables à l'air à la température ambiante; les mesures ont donc dû être faites sur un cristal scellé dans un tube contenant des vapeurs de méthanol. Les intensités ont été mesurées sur un diffractomètre Rigaku AFC6R à l'aide d'un rayonnement monochromatique CuKα (λ = 1,54178 Å). On a résolu la structure par des méthodes directes et on l'a affinée jusqu'à des valeurs de R = 0,1497 et R_w = 0,0655 sur la base de 5000 réflexions indépendantes. Les hautes valeurs des résidus sont causées par un désordre du solvant. Les longueurs et les angles de liaison sont normaux. La réaction du coordinat avec l'oxotrichlorobis(triphénylphosphine)rhénium(V) conduit à la formation d'un complexe asymétrique inattendu, l'oxo(1,1-diméthyl-1,8-dimercapto-3,6-diazaoctan-7-onato-N^3,N^6,S^1,S^8)rhénium(V). Les cristaux sont monocliniques, $P2_1/n$, a = 10,633(2), b = 11,221(2) et c = 11,678(1) Å, β = 116,10(1)° et Z = 4. Les intensités ont été mesurées avec un diffractomètre Siemens P4 en utilisant un rayonnement monochromatique MoKα (λ = 0,71073 Å). La structure a été résolue par la méthode aux atomes lourds et affinée jusqu'à des valeurs de R = 0,0471 et R_w = 0,0340 pour 2866 réflexions uniques. La plupart des longueurs et des angles de liaisons sont normaux. La distance R≡O à 1,681(5) Å est plus longue que la normale. On suggère que ceci est causé par une liaison π compétitive entre l'atome d'azote amidique déprotoné et l'atome de rhénium, tel que montré par

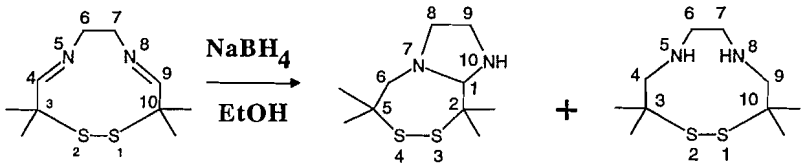
Scheme 1. The reduction of 3,3,10,10-tetramethyl-1,2-dithia-5,8-diazacyclodeca-4,8-diene.



3 **4** **5**

Introduction

In a previous paper we reported that an attempt to prepare the ligand, *N*-(2′-mercaptoethyl)-*N*,*N*′-bis(2-methyl-2-mercaptopropyl)ethylenediamine), **1**, gave instead 2,2,5,5,-tetramethyl-3,4,13-trithia-7,10-diazabicyclo[8.3.0]-tridecane, **2** (1). This was because, as Joshua et al. (2) had shown, the major product of the reduction of 3,3,10,10-tetramethyl-1,2-dithia-5,8-diazacyclodeca-4,8-diene, **3**, was 2,2,5,5-tetramethyl-3,4-dithia-7,10-diazabicyclo[5.3.0]decane, **4**, rather than 3,3,10,10-tetramethyl-1,2-dithia-5,8-diazacyclodecane, **5**, as had been reported previously (3) (Scheme 1). The reaction of **4** with ethylene sulphide was extremely slow and led to the formation of **2**. This prevented the added 2-mercaptoethyl group from binding to the metal.

This paper describes further investigation of the addition of a 2-mercaptoethanoyl group to **4**. The interaction of the resultant ligand with a rhenium complex was studied subsequently.

Experiments

All commercially available chemicals were purchased and used without any further purification. Bulk organic solvents were obtained from Caledon Laboratories, Georgetown, Ont., specialist organic chemicals from Aldrich Chemical Co., Milwaukee, Wis., inorganic acids and solid chemicals from Fisher Scientific, Nepean, Ont. or BDH Chemicals, Toronto, Ont., and $CDCl_3$ from Cambridge Isotope Laboratories, Andover, Mass. Infrared spectra were recorded on Perkin Elmer 283 or Bio Rad FTS-40 spectrometers. Samples were ground with KBr (1–5% w/w) and pressed into pellets. Spectra were calibrated with a polystyrene standard. Raman spectra were recorded on a Jobin Yvon Mole S-3000 1 m spectrometer. It was equipped with 1800 grooves/mm holographic gratings, and Lexel 3500 krypton (λ = 647.1 nm) and Stabilite 2106 argon (λ = 514.5 nm) lasers were used to generate the exciting lines. The spectrometer was equipped with a 1-in. CCD detector. ^1H and ^{13}C NMR spectra were obtained on Bruker AC-200, AC-300, and AM-500 Fourier spectrometers equipped with 5 mm dual frequency ^1H–^{13}C probes. Samples were dissolved in appropriate deuterated solvents and sealed in 507-PP thin-wall 5 mm NMR tubes. Tetramethylsilane was used as an internal standard. Instruments were deuterium-locked to the deuterated solvent. The ^1H spectra were acquired at 200.13, 300.13, or 500.14 MHz in 8 scans in 16K data points. The free induction decays were processed with exponential multiplication (line broadening 0.3 Hz) and were zero-filled to 32K before Fourier transformation. The ^{13}C spectra were acquired at 50.324 MHz (AC-200) or 125.76 MHz (AM-500). Sweep widths were 2500.00 Hz for ^1H and 12 195.122 Hz for ^{13}C. Chemical ionization (CI) and electron impact (EI) mass spectra were recorded on a VG Analytical ZAB-E double focussing mass spectrometer. Low-resolution spectra were recorded for routine sample analysis. Typical experimental conditions were as follows: resolution = 1000, electron energy = 70 eV, source temperature 200°C, source pressure = 2×10^{-6} mbar for EI and 4×10^{-5} mbar for CI (1 bar = 100 kPa). Analytical thin-layer chromatography (TLC) was performed on DC-Alufolien Kieselgel $60F_{254}$ silica-coated aluminium sheets with a stationary phase layer thickness of 0.2 mm. Compounds were developed with iodine vapour. Preparative chromatographic separations were carried out with the use of columns (2 cm × 50 cm) packed with chromatographic silica gel (100–200 mesh).

2-(Triphenylmethylthio)ethanoic acid, 6

This compound was synthesized according to the published procedure (4). Glacial acetic acid (20.0 mL), mercaptoethanoic acid (2.09 g, 1.6 mL, 22.7 mmol), and triphenylmethanol (6.00 g, 23.0 mmol) were mixed and kept warm at 70°C until the reactants dissolved (≈ 5 min). Boron trifluoride etherate (5.0 mL) was added and the heat source was removed. The resulting yellow solution was stirred magnetically at room temperature until a white precipitate had formed (≈ 45 min). The reaction mixture was poured into 50.0 mL of ice-cold distilled water, and deposited a white solid that was removed by filtration and washed thoroughly with water. The product was then recrystallized from toluene; yield: 5.38 g (16.1 mmol, 71%); mp 159–161°C (lit. (4) mp 158.5–160.0°C); TLC; R_f = 0.33 (CH_2Cl_2–CH_3OH, 9:1); IR (KBr pellet), ν_{max} cm^{-1} (relative intensity): 3000 br (62, ν_{OH}), 1709 (82, $\nu_{C=O}$), 1595 (32), 1487 (54), 1445 (51), 1410 (43), 1385 (33), 1292 (67), 1227 (21), 1180 (21), 1152 (48), 1082 (30), 1030 (32), 995 (18), 905 br (34), 843 (20), 768 (44), 745 (95), 709 (74), 699 (100), 625 (19), 618 (50); ^1H NMR ($CDCl_3$), δ: 2.95 (s, 2H, S-CH_2), 7.30 (m, 15H, aryl), 10.20 (s, 1H, CO_2H); ^{13}C NMR ($CDCl_3$), δ: 34.68 (S-CH_2), 67.46 (C-Ph_3), 126.9 (*para* aryl), 128.10 (*meta*

aryl), 129.42 (*ortho* aryl), 144.11 (ipso aryl), 175.79 (CO_2H); MS (DEI), *m/z* (relative intensity): 243 (100, CPh_3^+), 215 (9), 165 (88, $CPh_3^+ - C_6H_6^{\cdot}$), 115 (7); MS (DCI): 352 (4, $M^{\cdot} + NH_4^+$), 243 (100, CPh_3^+), 165 (6, $CPh_3^+ - C_6H_6^{\cdot}$).[2]

N10-[(2-Triphenylmethylthio)ethanoyl]-2,2,5,5-tetramethyl-3,4-dithia-7,10-diazabicyclo[5.3.0]-decane dimethanol hemihydrate, 7

Two methods were used in the synthesis of **7**. Method A involved the use of *N,N'*-carbonyldiimidazole (CDIM) (5, 6) and method B involved the use of 1,3-dicyclohexylcarbodiimide (DCC).

Method A

Compound **6** (3.60 g, 10.8 mmol) was dissolved in tetrahydrofuran (THF) (15.0 mL). To this solution, *N,N'*-carbonyldiimidazole (1.77 g, 10.9 mmol) was added and the mixture was stirred for 3 h under a nitrogen atmosphere at room temperature. Compound **3** (2.50 g, 10.8 mmol) was then added to the solution and the mixture was stirred under nitrogen for another 24 h. The THF was evaporated under reduced pressure and the residue was partitioned between methylene chloride (25.0 mL) and 0.1 M HCl solution (25.0 mL). The aqueous layer was washed with methylene chloride (3 × 15.0 mL). The methylene chloride portions were combined, and washed successively with 0.1 M HCl solution (15.0 mL), 5% sodium bicarbonate solution (15.0 mL), and water (3 × 15.0 mL). The methylene chloride solution was dried over anhydrous sodium sulphate and the solvent removed by evaporation under reduced pressure. This resulted in the isolation of a colourless oil, which solidified to give a colourless solid, **7**, upon addition of methanol (10.0 mL). The solid was collected by vacuum filtration and washed with methanol (3 × 10.0 mL). Yield = 4.16 g (7.6 mmol, 70%).

Method B

Compound **6** (4.00 g, 12.0 mmol) was dissolved in methylene chloride (25.0 mL) and 1,3-dicyclohexylcarbodiimide (DCC) (2.52 g, 12.2 mmol) was added to the resulting solution. The mixture was stirred at room temperature for 1 h under a nitrogen atmosphere. Compound **4** (2.79 g, 12.0 mmol) was added, and the mixture was stirred for another 18 h. The colourless precipitate that formed, dicyclohexylurea (DCU), was removed by filtration and washed with methylene chloride (2 × 20.0 mL). The filtrate was extracted with 0.5 M HCl solution (20.0 mL), 5% sodium bicarbonate solution (20.0 mL), and water (3 × 20.0 mL). Additional precipitate that formed in the methylene chloride layer, DCU, was removed by filtration. The solution was dried with anhydrous sodium sulphate and the methylene chloride was removed by evaporation under reduced pressure. Methanol (10.0 mL) was added to the remaining oil. This resulted in the formation of a colourless precipitate, **7**, that was collected by filtration and washed with methanol (3 × 10.0 mL). Yield = 4.93 g (9.0 mmol, 75%).

Compound **7** showed the following: mp 166–168°C; TLC, $R_f = 0.68$ (chloroform); IR (KBr): 1661 cm^{-1}, $\nu_{C=O}$; ^1H NMR ($CDCl_3$), δ: 1.22 (s, 6H, 2 × CH_3), 1.24 (s, 3H, CH_3), 1.27 (s, 3H, CH_3), 2.51 (d, J = 14.7 Hz, 1H), 2.67 (m, 1H), 2.90 (d, J = 2.4 Hz, 2H), 2.97–3.32 (complex multiplet, 4H), 4.65 (s, 1H), 7.27 (m, 9H, aryl), 7.44 (m, 6H, aryl); ^{13}C NMR ($CDCl_3$), 16 signals were observed: δ 20.03 (CH_3), 25.00 (CH_3), 26.72 (CH_3), 28.14 (CH_3), 36.50 (SCH_2), 47.92 (CH_2N), 53.74 (2 × $C(CH_3)_2$), 54.75 (CH_2N), 66.05 ($CH_2C(CH_3)_2$), 67.21 (CPh_3), 86.23 (CHN), 126.90 (*para* aryl), 128.06 (*meta* aryl), 129.42 (*ortho* aryl), 143.91 (ipso aryl), 167.70 ($C{=}O$); MS (DCI) *m/z* (relative intensity): 549 (1, $M^{\cdot+} + 1$), 307 (47, $M^{\cdot+} - C(Ph)_3^{\cdot} + 2H$), 275 (9, $M^{\cdot+} - SC(Ph)_3 + 2H$), 243 (100, $C(Ph)_3^+$), 231 (14, $M^{\cdot+} - COCH_2SC(Ph)_3$), 199 (10, 231 − S), 157 (14, 231 − $SC(CH_3)_2$), 125(10, 231 − $SSC(CH_3)_2$); MS (DEI): 549 (1, $M^{\cdot+} + 1$), 474 (12, $M^{\cdot+} - SC(CH_3)_2$), 243 (78, $C(Ph)_3^+$), 231 (100, $M^{\cdot+} - C{\cdot}O{\cdot}CH_2SC(Ph)_3$), 165 (19, $C(Ph)_3^+ - C_6H_6^{\cdot}$).

N10-(2-Mercaptoethanoyl)-2,2,5,5-tetramethyl-3,4-dithia-7,10-diazabicyclo[5.3.0]decane, 8

The use of trifluoroacetic acid for the removal of trityl groups was reported by Brenner et al. (7). The trityl-protected compound **7** (1.00 g, 1.8 mmol) was dissolved in 5.0 mL of trifluoroacetic acid. Triethylsilane (0.31 mL, 2.0 mmol) was added to the orange solution. The solution turned colourless and a colourless precipitate formed immediately. The mixture was transferred into a separatory funnel and partitioned between hexanes (10 mL) and water (10 mL). The aqueous phase was filtered through Celite, washed with hexanes (3 × 10 mL), and the water was removed under reduced pressure. The product, **8**, was recovered from the aqueous phase as a colourless oil. Yield: 0.28 g (0.91 mmol, 51%); ^1H NMR ($CDCl_3$), δ: 1.24 (s, 6H, 2 × CH_3), 1.28 (s, 3H, CH_3), 1.35 (s, 3H, CH_3), 2.07 (t, 1H, exchangeable SH), 2.58 (d, J = 15.1, 1H), 3.00 (m, 1H), 3.31 (m, 5H), 3.69 (m, 1H), 4.72 (s, 1H); MS (DEI), *m/z* (relative intensity): 307 (15, $M^{\cdot+} + 1$), 232 (100, $M^{\cdot+} - COCH_2SH$), 217 (4, $M^{\cdot+} - HSCH_2C{\cdot}O{\cdot}N$), 199 (42, 231 − S), 157 (63, 231 − $SC(CH_3)_2$), 125 (14, 231 − $SSC(CH_3)_2$), 83 (6, $C_4H_7N_2^+$); MS (DCI): 307 (100, $M^{\cdot+} + 1$), 275 (6, $M^{\cdot+} + 1$ − S), 233 (25, $M^{\cdot+} + 1 - COCH_2SH$), 199 (6, 231 − S), 157 (7, 231 − $SC(CH_3)_2$).

Oxo(1,1-dimethyl-1,8-dimercapto-3,6-diazaoctan-7-onato-N^3,N^6,S^1,S^8)rhenium(V), 9

$ReO(P(Ph)_3)_2Cl_3$ (150.0 mg, 0.18 mmol) (8) was dissolved in chloroform (100 mL) to give a light green solution. Upon addition of **8** (80 mg, 0.26 mmol), the solution turned dark red. Triethylamine (0.5 mL) was added to the mixture and the solution was stirred for 24 h. The chloroform was removed under reduced pressure. The remaining residue was washed with diethyl ether (3 × 15 mL), dried, redissolved in chloroform (3.0 mL), and passed through a chromatography silica gel column. Elution with a chloroform–methanol mixture (80:20) led to the isolation of the product **9**. Yield: 27 mg (0.064 mmol,

[2] Tables of anisotropic displacement coefficients, bond lengths and angles for the phenyl groups in **7**, hydrogen atom coordinates and isotropic displacement coefficients, vibrational spectral data, and figures showing the cellular packing have been deposited and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of bond lengths and angles, hydrogen atom coordinates, and figures showing the cellular packing have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

X-ray crystallography

Single crystals of **7** were obtained by the addition of methanol (2.0 mL) to a solution of the compound (100 mg) in chloroform (5.0 mL). Crystals separated when the solution was left to evaporate slowly at −15°C. The crystals were unstable and turned to powder when left dry for 3 h. Consequently, the crystal chosen for the data collection was sealed into a capillary tube that was saturated with methanol vapour. Single crystals of **9** were obtained by allowing a solution of the compound in dimethylformamide to evaporate at room temperature. The density was measured by suspending the crystals in a mixture of bromoform and carbon tetrachloride.

For **7**, automatic unit cell determination and data collection were performed on a Rigaku AFC6R diffractometer with the use of CuKα (λ = 1.54178 Å) radiation. Unit cell parameters were refined by least-squares fit of positional parameters for 21 reflections (50.83° ≤ 2θ ≤ 73.78°). Temperature factors for non-hydrogen atoms were refined anisotropically. Details of crystal data and solution refinement are listed in Table 1. Table 2 lists the atomic coordinates. The asymmetric unit contained half a water and two methanol molecules. The position of the methanol molecules could not be clearly defined. They were highly disordered. Attempts to refine the positional parameters were unsuccessful. Atoms moved away from the position in which they were first located and the temperature factors increased to $U > 0.6$ $Å^2$. At the same time peaks appeared in the difference map where the atom had been originally. Eventually the atoms in the methanol molecules were fixed at the points where they were first detected in the difference map. Occupancies were varied to make the temperature factors of atoms of a given type in a given molecule approximately the same. The carbon and oxygen atoms were chosen by considering atoms within 2.9 Å that might be involved in hydrogen bonding. Thus, the first methanol molecule was made up of three fractional oxygen atoms, O(50), O(51), O(52), and C(50) and the second was made up of two fractional oxygen atoms, O(53) and O(54), and C(51). The occupancy of the water molecule site, O(55), was arbitrarily set at 0.5. It could not be greater than 0.5 since two water molecule sites were only 1.8 Å apart. Other close interactions with oxygen atoms from the methanol molecules suggested a similar upper limit. The relatively high residuals ($R = 0.1497$, $R_w = 0.0655$, $S = 1.88$) are partly caused by this disorder and also by the large number of weak reflections with $F < \sigma_F$ (2582). For **9** the crystal was glued to the end of a glass fibre. Automatic unit cell determination and data collection were performed on a Siemens P4 diffractometer with the use of MoKα (λ = 0.71073 Å) radiation. Unit cell parameters were refined by least-squares fit of positional parameters for 23 reflections (7.28° ≤ 2θ ≤ 24.73°). Temperature factors of the non-hydrogen atoms were refined anisotropically. Details of crystal data and solution refinement are listed in Table 1 and Table 3 lists the atomic coordinates.

Results and discussion

Reaction Scheme 2 summarizes the syntheses described here. Unlike the reaction of **4** with ethylene sulphide, which required a period of 1 week and a large excess of ethylene sulphide before any appreciable product could be recovered, the coupling of 2-(triphenylmethylthio)ethanoic acid, **6**, with **4** in

[a]Equivalent isotropic *U* defined as one third of the trace of the orthogonalized U_{ij} tensor.

the presence of *N,N'*-carbonyldiimidazole (CDIM) or 1,3-dicyclohexylcarbodiimide (DCC) required only 24 h of stirring at room temperature and resulted in a high yielding reaction (75%). The product, **7**, was recovered in high purity as a colourless solid. It was characterized by electron impact and chemical ionization mass spectroscopy, ^1H and ^{13}C NMR spectroscopy, and X-ray crystallography. The NMR spectrum was assigned by comparison with the NMR spectra of **4**. Further confirmation of this assignment was achieved with the use of a $^{13}C/^1H$ correlation NMR spectrum.

The next step in the synthesis involved the deprotection of the sulphur atom in compound **7** by removal of the trityl group with trifluoroacetic acid and triethylsilane. This led to the isolation of **8** in 51% yield. Compound **8** was a colourless oil that was characterized by mass and ^1H NMR spectroscopy. The presence of a thiol group in **8** was confirmed by the appearance of a triplet at 2.07 ppm in the proton NMR spectrum, which was assigned to the SH proton. Upon addition of D_2O, this triplet disappeared and the splitting in the signal at 3.31 ppm, which was assigned to the CH_2 protons next to the SH group, was removed.

The reaction of the deprotected ligand **8** with $ReOCl_3(P(Ph)_3)_2$ led to the isolation of an unexpected rhenium complex **9**. This complex contained neither an N2S3 pentadentate ligand nor did it contain a thiazolidine ring-containing ligand. Instead, the X-ray structure showed that a 2-methyl-2-mercaptopropyl fragment had been lost from the ligand in the course of the reaction. The resultant rhenium complex contained the unusual asymmetric monoamine–monoamide–dithiol (MAMA) N2S2 ligand. The synthesis of asymmetric N2S2 ligands (9) and their reactions with technetium (10) have been reported previously, but the complex described here

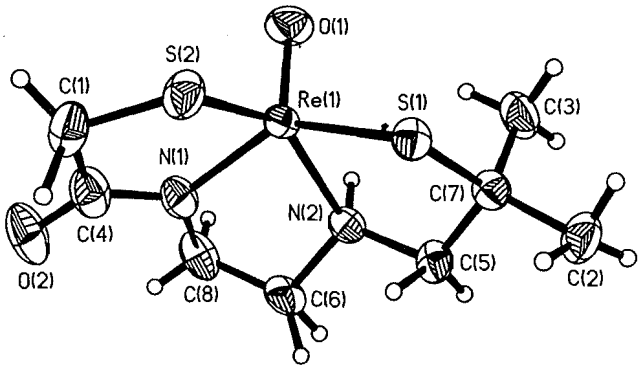
Fig. 2. The structure of the rhenium complex oxo(1,1-dimethyl-1,8-dimercapto-3,6-diazaoctan-7-onato-N^3,N^6,S^1,S^8)rhenium(V), **9**, showing the atom numbering.



represents the first example of a rhenium asymmetric N2S2 complex that has been examined by X-ray crystallography. In addition to the X-ray structure determination, complex **9** was characterized by vibrational spectroscopy. The Re≡O stretching frequency dominated the Raman spectrum and occurred at 972 cm^{-1}. The IR spectrum showed a strong absorption ($\nu_{Re\equiv O}$) at 973 cm^{-1}. It also showed the amide C=O absorption at 1606. The Re≡O stretch was well within the range of several well-characterized Re(V) complexes that contain the $(Re\equiv O)^{3+}$ core (11).

The structure of **7** is shown in Fig. 1 and selected bond lengths and angles are given in Table 4. The molecule was bicyclic, comprising 5-membered and 7-membered rings fused together. All the bond distances and bond angles were within the expected range. The S(3)—S(4) disulphide bond was 2.006(4) Å, which is slightly shorter than the disulphide bond in 2,2,5,5-tetramethyl-3,4,13-trithia-7,10-diazabicyclo[8.3.0]tridecane 2.020(2) Å) (1). The C(2)-S(3)-S(4)-C(5) torsional angle was 84.3(2)°. The amido nitrogen atom, N(10), had a shorter bond to C(11), 1.355(9) Å, than those to C(1) and C(9), which were 1.484(8) and 1.476(6) Å, respectively. This was expected because of the considerable π character of the N(10)—C(11) bond. S(13)—C(14) was significantly longer than C(12)—S(13) (1.865(6) vs. 1.824(7) Å). For thiazolidine compounds, we noted previously that a C—S bond adjacent to a bulky group is longer than normal and the other C—S bond is shorter than normal. The same effect appears to be present here even though the sulphur atom is not part of a ring system.

The structure of **9** is shown in Fig. 2 and selected bond distances and bond angles are given in Table 5. The ligand atoms bound to the rhenium atom formed a rough square pyramid such that the rhenium atom lay 0.747(5) Å above the best S(1), N(1), N(2), S(2) plane. The Re=O bond (1.681 (5) Å) was longer than most distances observed for these five coordinate complexes. This was probably caused by the presence of multiple bond character in the bond from the rhenium atom to the deprotonated nitrogen atom. We have noted this effect before (13). Although Re—O_{oxo} bonds are typically written as double bonds, they are really triple bonds. The extra bonding is provided by donation of electron density from an oxygen atom *p* orbital to an empty *d* orbital on the rhenium atom. Chatt and Rowe noted that the resultant Re—O bond is essentially nonpolar (14), with the result that the

oxygen atom cannot be protonated and is susceptible to nucleophilic attack (15). In **9** the multiple bonding from the rhenium atom to the deprotonated nitrogen atom weakens the Re—O bond and makes it longer and more polar. The result is that the oxo atom can act as a hydrogen bond acceptor (e.g., oxo(1,1,8,8-tetraethyl-3,6-diazaoctane-1,8-dithiolato)-rhenium, N(H)...O_{oxo} distance, 2.877(4) Å, Re—O distance, 1.709(2) Å (16); oxo(1,9-dimercapto-1,1,9,9-tetramethyl-3,7-diazanonato-*S,S,N,N'*)rhenium(V), N(H)...O_{oxo} distance, 2.967(6) Å, Re—O distance 1.685(3) Å (13)). Compound **9** also showed hydrogen bonding, but in this case, the oxo ligand was not involved. The competitive hydrogen bonding between the amino nitrogen atom and the amido oxygen atom on the ligand backbone was, apparently, favoured. The two Re—N distances were significantly different. The Re(1)—N(2) distance was 1.997(6) Å compared to 2.151(4) Å for the Re(1)—N(1) distance. This was in accordance with the observation that N(2), the amido nitrogen atom, became deprotonated upon chelation to Re(1), whereas N(1), the amino nitrogen atom, couples to the rhenium atom only through its lone-pair electrons. All other bond lengths and angles were in the expected range.

For **7** all intermolecular interactions were van der Waals. Pairs of phenyl rings, related by inversion centres, were parallel but the overlap of the rings was minimal. Pairs of adjacent molecules of **7**, related by inversion centres, were connected by an extensive hydrogen bonding network that involved the methanol and water molecules and O(1). These interactions were isolated, however: there was no evidence of any hydrogen-bonded chain or network formation. For **9** all the intermolecular interactions were van der Waals except for the N(1)—H(1)...O(1)′ hydrogen bond between molecules related by the 2_1 axis. This resulted in hydrogen-bonded chains of molecules up and down the *b* direction.

Estimation of the fines content of Athabasca oil sands using instrumental neutron activation analysis

Kingsley K. Donkor, Byron Kratochvil, and M. John M. Duke

Abstract: Knowledge of the "fines" or clay-rich mineral fraction is necessary for the efficient extraction of bitumen from bulk oil sands, and has environmental implications in tailings disposal. Current methods for estimating the fines in oil sand are laborious and of questionable accuracy. We propose here their estimation directly in bulk oil sand by instrumental neutron activation analysis (INAA) of the trace and major elements determinable. Correlations between fines content and individual elements fall in the range of 0.80 to 0.81 for dysprosium, samarium, and europium, and 0.75 to 0.77 for sodium, potassium, aluminum, and titanium. These results follow the expected geochemical relationships between major and trace elements and the mineral fraction of the oil sands. Principal component analysis (PCA) using a combination of elements gave correlations with fines content no better than those obtained from individual elements. However, the PCA approach can be considered more robust. Advantages of INAA over conventional methods to estimate the fines content of unprocessed oil sand include minimal sample preparation (including elimination of the use of organic solvents), rapid turnaround time, and the potential for automation.

Key words: instrumental neutron activation analysis, oil sand, elemental correlations, fines.

Résumé : Si l'on veut faire une extraction efficace du bitume à partir des sables bruts contenant de l'huile, il est important d'avoir une bonne connaissance des «fines» ou fraction minérale riche en argile; de plus, ces connaissances ont des implications dans la façon dont on dispose des résidus. Les méthodes courantes pour évaluer les fines sont très laborieuses et on peut se poser des questions sur leur précision. Dans ce travail, on propose de les évaluer directement dans les sables bruts contentant de l'huile en faisant appel à une analyse instrumentale par activation de neutrons (AIAN) des éléments que l'on peut déterminer comme éléments principaux ou à l'état de trace. Des corrélations entre les contenus des fines et les éléments individuels se situent entre 0,80 et 0,81 pour le dysprosium, le samarium et l'europium et 0,75 et 0,77 pour le sodium, le potassium, l'aluminium et le titane. Ces résultats sont en accord avec les relations géochimiques attendues entre les éléments principaux et ceux à l'état de trace et la fraction minérale des sables contenant de l'huile. L'analyse des composants principaux (ACP), utilisant une combinaison d'éléments, conduit à des corrélations entre le contenu des fines qui ne sont pas meilleures que celles obtenues pour des éléments individuels. Toutefois, l'approche ACP peut etre considérée comme plus sûre. Les avantages de l'AIAN par rapport aux méthodes conventionnelles pour l'évaluation des contenus en fines pour un sable non traité contenant de l'huile incluent la préparation minimale de l'échantillion (y compris l'élimination de l'utilisation de solvant organiques), le rapide temps de retour et le potentiel pour l'automation.

Mots clés : analyse instrumentale par activation de neutrons, sables contenant de l'huile, corrélations élémentaires, fines.

Introduction

The oil sands of Alberta represent one of the world's largest known oil reserves. Total oil reserves are estimated to be over 800 billion barrels of crude oil of which approximately 80% occurs in the Athabasca region (1). The Athabasca oil sands are a mixture of solids, bitumen, and water. The bulk of the solids is composed of sand-sized particles (mostly quartz), variable amounts of fines, and traces of heavy minerals. Fines are defined as mineral matter passing through a 325 U.S. (<44 μm) mesh sieve, and may be further subdivided into silt-sized (<44 μm >2 μm) and clay-sized (<2 μm) particles. Mineralogically the silt-sized fines of the Athabasca oil sands consist primarily of quartz and minor feldspar. The clay-sized fraction comprises minerals including illite and kaolinite (1).

Fines are detrimental to the hot-water processing of the oil sand, and to the disposal of the tailings stream, in that they stay suspended in the water phase. In the hot-water process these suspensions can form a barrier that prevents separation of bitumen. Breaking this barrier requires additional water and greater agitation.[3] With prior knowledge of the bitumen and fines levels of the incoming feed, plant processes can be opti-

mized and bitumen yields optimized. To determine processing requirements, oil sand companies carry out extensive coring programs in which cores are collected, sampled, and subsequently analyzed for bitumen and solids content. The analytical method most used for estimating the fines content has been particle size analysis with a Microtrac analyzer (2). This method involves prior removal of bitumen with organic solvents, is applicable over only a limited particle-size range, and cannot accurately measure nonspherical particles. The latter drawback may lead to a bias in the estimation of fines content.

Since the fines in the Alberta oil sands are predominantly clay minerals and silt-sized quartz we decided to investigate the possibility of developing an elemental "fingerprint" for their estimation. Quartz usually contains few impurities, therefore elements not present in the bitumen, pore water, or trace heavy minerals are likely to be associated with the clays. Of particular interest in this regard are the rare earth elements (REE). Numerous studies on the distribution and abundances of the REE in sedimentary rocks have been carried out and the salient conclusions summarized (3). Findings relevant to this study include the following: (*a*) the bulk of the REE in clastic sedimentary rocks are found in the clay (< 2 μm) and silt-sized fractions; (*b*) the silt-sized fraction of clastic sedimentary rocks tends to have lower total REE contents than the clay-sized fraction though the relative abundances between the two are similar; (*c*) the sand-sized fraction of clastic sedimentary rocks tends to have a lower total REE content than either the silt- or clay-sized fractions (on account of the extremely low REE levels in quartz, and fairly low REE levels in feldspars); (*d*) there is no correlation between REE content and clay mineralogy. These findings suggest that elemental analysis (especially one including the REE) might be developed as an indicator of the fines content of bulk oil sand.

For the elemental analyses, instrumental neutron activation analysis (INAA) (4–6) was chosen on account of its multielemental capability, speed, and ease of sample preparation. Using INAA, the concentrations of 11 elements could be readily determined following irradiation in a SLOWPOKE reactor via their short-lived radionuclides in samples of bulk oil sand.

Reported here is a study of the distribution of these elements over a 20 m length of oil sand core, along with an evaluation of the degree of correlation between their concentrations and the levels of fines present in the bulk oil sand.

Experimental

Samples and sample preparation

The oil sand core used in this study was provided by Syncrude Canada Ltd. from a region of the Athabasca oil sand deposit mined by Syncrude near Fort McMurray, Alberta. The core was approximately 20 m long and 7 cm in diameter, and was encased in 4 mm thick polyvinyl chloride. The section of the oil sands deposit transected by the core varied in grade from 1% to 15% bitumen by weight.

To obtain samples across a range of bitumen concentrations the core was visually stratified into regions defined as lean, medium, or rich in bitumen content. Eight test portions of oil sand, each weighing approximately 0.5 g, were selected from random locations in each of the three regions. The samples were placed directly into clean, 1.5 mL polyethylene irradiation vials that had been previously soaked in 10% nitric acid for several days, and rinsed thoroughly with deionized water and then with nanopure water to remove surface impurities. Each 1.5 mL vial was heat-sealed and inserted into a clean 7 mL polyethylene vial together with an additional empty 1.5 mL vial that served as a spacer. The 7 mL polyethylene vials were then heat-sealed and capped.

An additional 24 test portions, each weighing 2–3 g, were taken from locations immediately adjacent to the regions of the core from which the 0.5 g samples were obtained. These larger samples were subjected to Soxhlet extraction with 15–20 mL of toluene to separate the bitumen from the solids (7). The toluene extracts were centrifuged using a small bench-top centrifuge to remove most of the particulate material that passed through the filter thimble, then were quantitatively transferred to weighing dishes, and the toluene was evaporated overnight in a fumehood at room temperature. The dishes were reweighed and the amount of bitumen in the original samples calculated from the difference in the weights of the dishes before and after evaporation. Data processing was carried out on 23 samples, one from the bitumen-rich strata having been lost during the extraction process.

The solids remaining in the Soxhlet extraction thimbles were removed, weighed, and dry-sieved through a 325 mesh (44 μm) stainless steel sieve to separate the fines. Test portions of fines from each of the 23 sieved fractions were weighed into 1.5 mL nitric acid-washed polyethylene vials and prepared for analysis in the same manner as the 0.5 g bulk oil sand test portions.

Given that adjacent samples were collected for INAA and Soxhlet extraction, it became necessary to determine the local elemental variability of the oil sand. For this purpose nine transverse sections of core, representing a range of bitumen levels, were selected. Four subsamples of approximately 10 g each were collected with a scoop from each transverse section, weighed into acid-washed 7 mL irradiation vials, and sealed as described earlier for INAA. Following INAA, the portions were left for a week to decay, at which time they posed no radiation hazard. The decayed samples were then analyzed for their bitumen and solids content by Soxhlet extraction using 2.5–5.0 g portions as described earlier. Because of possible concerns about the representativeness of 0.5 g or even 10 g test portions, an additional experiment was done in which a 30 g test portion of oil sand was collected from a site adjacent to each of the nine locations sampled previously and also analyzed as above.

Three soil reference materials, SO-1, SO-2, and SO-3 (CANMET, Ottawa, Canada), were used as standards for quantification of all elements studied except chlorine. A fourth, SO-4, was run as a quality control sample. Three sediment reference materials, BCSS-1, MESS-1, and PACS-1 (National Research Council of Canada, Ottawa, Canada), were also analyzed, the former as a chlorine standard and the latter two for quality control purposes. Three sets of these standards were prepared, one weighed and sealed in 1.5 mL vials as for the 0.5 g samples, the second prepared in 7 mL irradiation vials as for the 10 g samples, and the third in 27 mL vials as for the 30 g samples.

INAA of elements that produce short-lived radionuclides

All irradiation and counting operations were performed at the

Table 1. Concentrations of elements (microgram per gram, unless otherwise stated) measured by INAA for 23 approximately 0.5 g portions of bulk oil sand.

University of Alberta SLOWPOKE-II Nuclear Reactor Facility. For the 0.5 g analyses, standards and unknowns were individually irradiated for 5 min at a thermal neutron flux of 1×10^{12} n cm^{-2} s^{-1}. Following a variable but timed decay period (ca. 20 min) each test portion was counted for 5 min (live-time) at a sample-to-detector distance of 6 cm. The 10 g test portions used in the lateral heterogeneity study were irradiated for 3 min at a thermal neutron flux of 1×10^{10} n cm^{-2} s^{-1}, allowed to decay for 15 min, then counted for 5 min (live-time) at a sample-to-detector distance of 6 cm to obtain data for Mn, K, Na, Dy, Eu, V, Al, Ti, Sm, Cl, and Br. The 30 g samples were irradiated in the outer site of the reactor for 5 min at a reduced thermal neutron flux of 5×10^9 n cm^{-2} s^{-1}, allowed to decay for 15 min, then counted for 5 min (live-time) at a sample-to-detector distance of 10 cm to obtain data for V, Al, and Ti. All samples were recounted for 10 min (live-time) at a sample-to-detector distance of 6 cm after a total of 120 min to obtain data for the elements listed above, with the exceptions of Sm and Cl. For Sm the amounts were below detection for several samples and near the limit of detection for the others: for Cl a 30 g standard was not run because earlier measurements on smaller samples had shown that concentrations did not vary with the fines content.

The γ-spectroscopy counting system included an automatic sample-changer mechanism modified from a Nuclear Chicago γ-ray counter interfaced to a PC with an Aptec MCA card for data acquisition. A vertical, closed-end, hyperpure (p-type) coaxial Ge detector (model 18180, EG & G Ortec, Oak Ridge, Tennessee, U.S.A.) operated at +2500 V was utilized for all γ spectroscopy. Detector specifications included a relative efficiency of 19.7%, a measured full width half maximum of 1.91 keV, and a peak-to-Compton ratio of 58:1 for the 1332 keV full energy peak of ^{60}Co. Signals from the Ge detector were amplified using an Aptec 6300 spectroscopy amplifier and the signals digitized by a Nuclear Data (ND) 575 ADC.

Spectral peak searching was accomplished using the software program SPAN (8). Spectrometer dead times were maintained at less than 10% for each sample. Decay corrections, dead-time corrections (9), and quantification of elements were performed using in-house programs along with two spreadsheet programs: Quattro Pro (V4.0; Borland Inc., U.S.A.) and Excel (V4.0; Microsoft Corp., U.S.A.). Concentrations of all elements were determined via an adaptation of the comparator (semi-absolute) method of INAA (10). Reference standards SO-1, SO-2, SO-3, and BCSS-I were used to determine specific activities (counts/microgram) for each element. The accuracy of the procedure was checked by analyzing the reference materials SO-4, MESS-1, and PACS-1. Measured and certified values were in good agreement for all three reference materials (11).

Results and discussion

Correlations of elemental data in oil sand and fines content

Eleven elements (Al, K, Na, Ti, Mn, Cl, Dy, Sm, Eu, Ba, and V) were determined with reasonable precision in the 23 0.5 g oil sand test portions using the analysis scheme described above. Table 1 lists the results of the INAA determinations of these elements, along with the values found for bitumen and fines by Soxhlet extraction and sieving. Correlation coeffi-

Table 2. Correlation coefficients of elemental concentrations versus weight percent *fines* in oil sand for 23 0.5 g test portions ranging from 5 to 50 wt.% fines.

Element	*r*-Value (fines)
Dysprosium (Dy)	0.81
Europium (Eu)	0.80
Samarium (Sm)	0.80
Aluminium (Al)	0.77
Sodium (Na)	0.77
Potassium (K)	0.76
Titanium (Ti)	0.75
Vanadium (V)	0.72
Barium (Ba)	0.69
Manganese (Mn)	0.44
Chlorine (Cl)	0.00

cients between the elemental concentrations and the fines content in the oil sand are listed in Table 2. With the exception of chlorine, all elements correlate positively with fines content, yielding *r*-values ranging from 0.69 to 0.81. Chlorine concentrations showed little or no correlation with fines content. This random distribution may be due (at least in part) to the occurrence of variable amounts of dissolved chloride salts in pockets of water trapped within the interstices of the sand particles.[3] Also, the Cl concentrations in bitumen average about 200 μg/g (11) compared with about 300 μg/g in the bulk solids. The correlation scatter plots for four elements (Dy, Sm, Eu, and Cl) are shown in Fig. 1. The scatter plots for dysprosium, europium, and samarium yield good correlations (*r*-value = 0.80) and can be used as models for measuring the fines content in oil sand. Using the uncertainty in the slopes of the plots and propagation of errors, the relative uncertainty for fines estimation is of the order of 10%.

A major reason why correlation between the REE and the fines is not even greater is likely to be due to passage of small clay particles through the Soxhlet extraction thimbles into the bitumen and to losses during dry sieving of the solids. In addition, the fraction of the fines composed of clays varies from sample to sample. The remainder of the fines is composed largely of quartz, which will tend to dilute the elemental signature from the clay-sized fraction. Furthermore, the Athabasca oil sands contain variable trace amounts of over 20 heavy minerals (12), the majority of which are iron-rich and REE-poor. However, some of them, such as zircon, apatite, and epidote, may contain fairly high levels of REE that could introduce additional variability in correlation. INAA of the bitumen extracts also showed dysprosium, samarium, europium, aluminium, sodium, and potassium contents to be very low and in some cases below detection limits (11).

Principal Component Analysis (PCA) (VM SAS V.120.1091 statistical package) was used to calculate correlations involving combinations of the elements determined in the 0.5 g oil sand samples with the fines content for the various test portions. Figure 2 shows correlation plots of fines content against combinations of (*a*) all the elements analyzed, (*b*) dysprosium, samarium, and europium. The PCA combination of Dy, Sm, Eu, Al, K, and Na, elements commonly associated with clay minerals, gave an *r*-value of 0.80. The correlations obtained were comparable to those of the individual elements. A possible advantage of using the PCA method for combining elements is that it tends to be more robust than correlation based on a single element in the event of analytical error in the determination of a single element.

Cross correlation of element concentrations in the 0.5 g oil sand samples showed strong positive correlations among the lanthanides (Dy, Sm, and Eu) and between Na and K. This is illustrated in Fig. 3 for Dy vs. Eu and Na vs. K. The correlations seen here among the lanthanides are similar to those found in other geological materials such as shales (4, 13–15). Since these elements correlate strongly among themselves in a variety of sedimentary materials, it is not surprising that multiple correlations by PCA do not give improved fits.

Oil sand regions with high bitumen content tend to contain less of those elements commonly associated with clay minerals, as shown in the inverse correlation of the fines with bitumen content in Fig. 4. An inverse relationship between bitumen content and clays is expected because increased clay content would reduce sediment permeability, thereby impeding bitumen infiltration. The correlation of vanadium with bitumen content differs from the other elements in that it levels off above 8% bitumen (Fig. 5). INAA of extracted bitumen shows a vanadium content of about 200 μg/g, while the fines contain about 30 μg/g (11). Vanadium in bitumen, like nickel, has been shown to be chemically bound in heterocyclic ring structures (16).

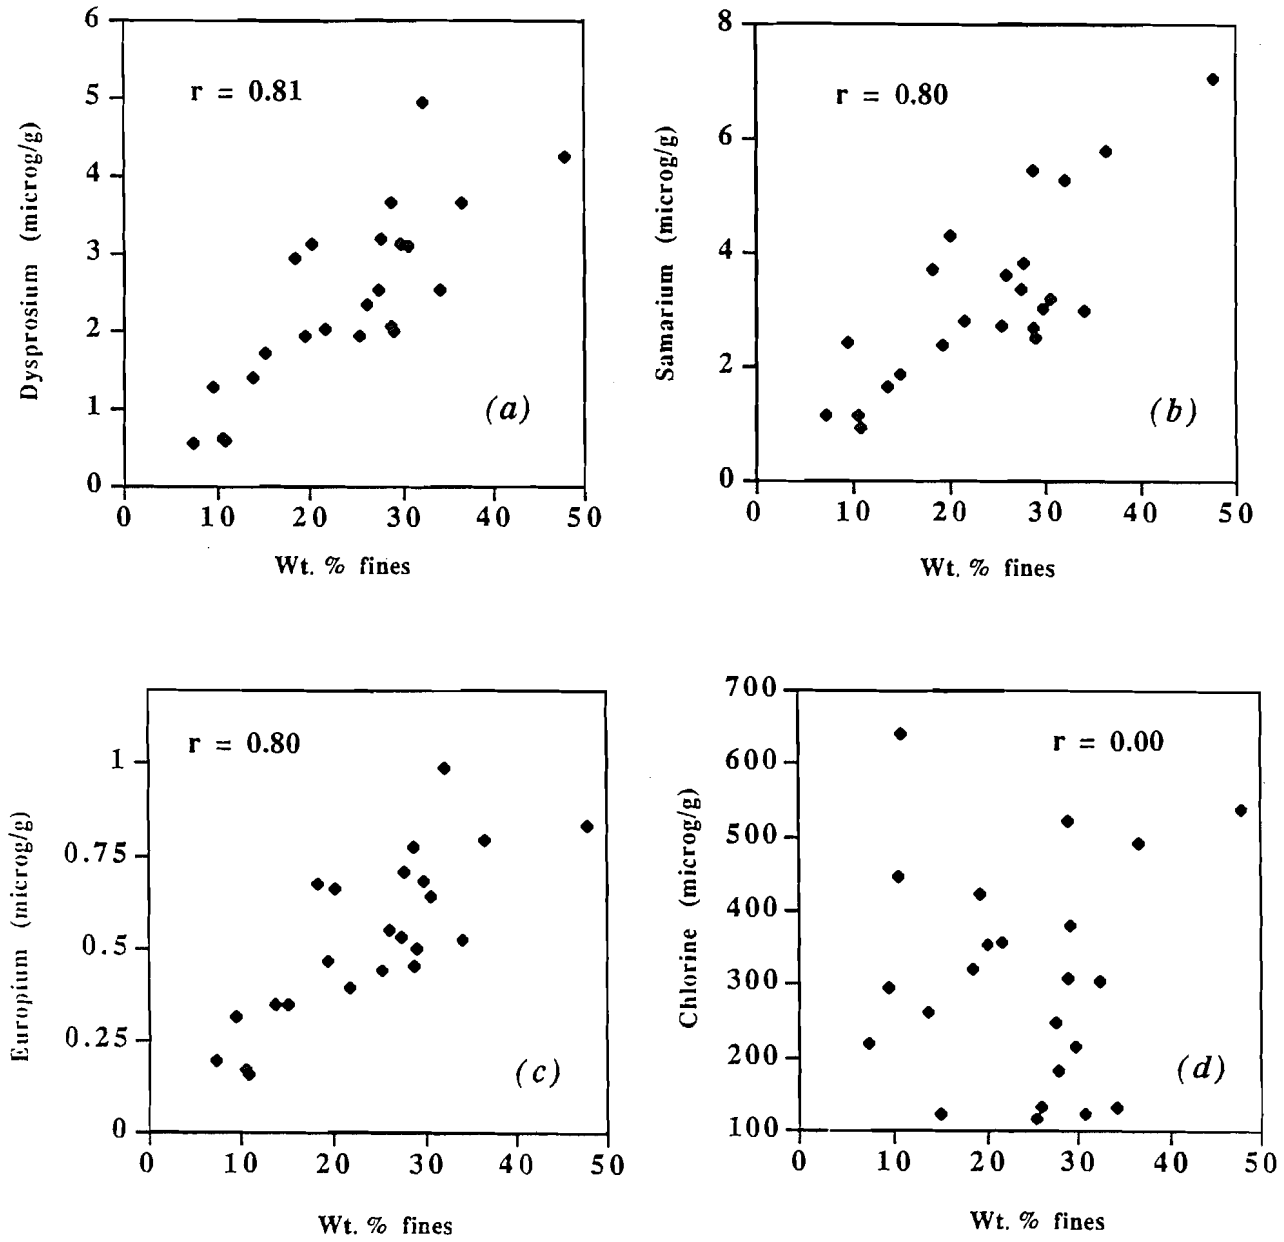
Evaluation of lateral heterogeneity in the oil sand core

Figure 6 shows the relative standard deviations of the selected elements determined for a set of four subsamples within each of the nine transverse sections studied. It can be seen that for all test portions from the nine regions, the relative standard deviations (RSDs) of the values for vanadium are less than 10%, those for dysprosium, barium, titanium, and aluminum are less than 17%, and for potassium, samarium, and europium are less than 20%. Also, except for one value for manganese of 26% and one for sodium of 27%, the RSDs for these two elements are less than 20%. On the other hand, chlorine shows significant scatter, with RSDs ranging from 10% to 60%. Since the majority of the elements studied had RSDs less than 20%, the core section was considered sufficiently homogenous in terms of the measured elements for the purpose of this study.

Results of the Soxhlet extraction analyses for bitumen and solids yielded RSD values ranging from 1% to 6% for bitumen, and less than 2% for solids (Table 3). These values also showed little lateral variability across the core for the nine zones studied, and indicate that a single 5 g sample adequately represents the transverse section of the core in terms of bitumen and solids content.

Correlations between element concentrations and fines content for the 30 g samples were also calculated for eight elements. The results of the correlations were compared with similar calculations for the 0.5 and 10 g samples. The results, Table 4, show no significant differences among the correlations for the eight elements listed. Test portion size does not appear, therefore, to affect the correlation results over this sample size range, and the results indicate that 0.5 g test portions were adequately representative for this study.

Fig. 1. Correlation plots for (*a*) dysprosium, (*b*) samarium, (*c*) europium, (*d*) chlorine concentrations versus fines content for 0.5 g portions of bulk oil sand.



In summary, correlations between fines content, defined as oil sand solids passing a 44 μm sieve, and the concentrations of several elements in the solids are sufficiently strong to warrant further study of elemental analysis as a way of measuring fines in bulk oil sand. Such studies, including comparisons with alternative methods, are currently underway. INAA appears to provide a straightforward way of determining a number of elements for this purpose.

Conclusions

Several elements, determined via their short-lived radionuclides by INAA, correlate well with the fines content of Athabasca oil sand as determined by toluene extraction and sieving of the resulting solids. Multielement correlations by principal component analysis gave about the same values as those obtained for individual elements, but may be more robust. Elemental and bitumen analyses of test portions collected across a test core in sizes ranging from 0.5 to 30 g showed little lateral heterogeneity over the 7 cm width of the core. INAA was chosen as the analytical method because analyses could be done nondestructively on samples without pretreatment and with rapid turnaround times. Manpower requirements are small and could be reduced even further by automation of the counting and reporting operations. Correlation between fines content and elemental concentrations will likely be improved as better methods of fines measurements are developed.

Structure and wavelength modification in retinylidene iminium salts

George R. Elia, Ronald F. Childs, James F. Britten, Daniel S.C. Yang, and Bernard D. Santarsiero

Abstract: The spectroscopic and structural properties of the perchlorate and triflate salts of *N*-*n*-butyl-retinylidene imine, **2** and **3**, have been examined in solution and solid phases. In solution these salts were found to exhibit very similar UV and NMR spectroscopic properties. However, in the solid state marked differences in their absorption spectra (**2**, λ_{max} = 504 nm; **3**, λ_{max} = 445 nm) and ^{13}C NMR spectra were found. The structures of the two salts were determined by X-ray crystallography. The cations in each of the salts were shown to have very similar conformations, detailed structures, and packing in their crystal lattices. The differences in the spectroscopic properties of the salts in the solid state could not be accounted for on the basis of any structural differences in the cations themselves. In terms of cation–anion interactions, a strong hydrogen bonding interaction was found in each case between the N-H proton and an oxygen atom of the counterion. However, there were significant differences between the two salts in terms of the N—H···O internuclear distances (**2**, N—H···O = 2.939(7) Å and in **3**, 2.85(1) Å). The results are strongly suggestive that the wavelength and positive charge delocalization in retinylidene iminium salts are controlled by variation of the distance between the anion and the proton bonded to the Schiff base nitrogen atom. The work reported here represents the first examples of secondary retinylidene iminium salts containing an N-alkyl substituent to be successfully analyzed by X-ray crystallography. The relationship of these observations in the solid state to the spectroscopic properties of the natural visual pigments is explored.

Key words: retinylidene iminium salts, iminium salts, cation–anion interactions.

Résumé : On a étudié les propriétés spectroscopiques et structurales des perchlorate et triflate de la *N*-*n*-butyl-rétinylidène imine, **2** et **3**, tant en solution qu'en phase solide. En solution, on a trouvé que ces sels présentent des propriétés spectroscopiques UV et RMN qui sont très semblables. Toutefois, à l'état solide, on a observé des différences marquées dans leurs spectres d'absorption (**2**, λ_{max} = 504 nm; **3**, λ_{max} = 445 nm) et dans leurs spectres RMN du ^{13}C. On a déterminé les structures des deux sels par diffraction des rayons X. Dans chacun de ces sels, les cations ont des conformations, des structures détaillées et des empilements très semblables. On ne peut pas expliquer les différences observées dans les propriétés spectroscopiques des sels à l'état solide sur la base de différences de structures dans les cations eux-mêmes. En termes d'interactions cation–anion, on a observé une forte interaction de liaison hydrogène entre le proton N-H et l'atome d'oxygène du contre-ion. Toutefois, il existe des différences importantes entre les deux sels en termes de distances internucléaires (**2**, N—H···O = 2,939(7) Å et dans **3**, 2,85(1) Å. Les résultats suggèrent fortement que la longueur d'onde et la délocalisation de la charge positive dans les sels rétinylidène iminium est contrôlée par une variation de la distance entre l'anion et le proton relié à l'atome d'azote de la base de Schiff. Le présent travail représente les premiers exemples des sels rétinylidène iminium secondaires contenant un substituant N-alkyle à avoir été examinés par diffraction des rayons X. On examine la relation de ces observations à l'état solide avec les propriétés spectroscopiques des pigments visuels naturels.

Mots clés : sels rétinylidène iminium, sels d'iminium, interactions cation–anion.

[Traduit par la rédaction]

Introduction

Over the past two decades there has been considerable interest in the natural pigments rhodopsin (1) and bacteriorhodopsin (2). The protein rhodopsin (R) consists of the 11-*cis* isomer of retinal covalently linked via a protonated Schiff base linkage to an apoprotein opsin consisting of 348 amino acids. In contrast, bacteriorhodopsin (bR) comprises all-*trans* retinal connected via a similar linkage to a lysine residue of a protein consisting of 248 amino acids (3).

Much attention has been given to seeking an understanding of the origin of the absorption spectra of these two pigments. A simple retinylidene Schiff base absorbs at 370 nm while its protonated counterpart exhibits a red-shifted absorption band at 440 nm (methanol) (4). In comparison, the natural pigments have absorption maxima at 506 nm for bovine rhodopsin and 570 nm for bacteriorhodopsin (5, 6). Thus, while protonation accounts for some of the bathochromic shift there are additional factors at play in the natural pigments.

There have been a number of studies addressing the mech-

anism by which the apoprotein can regulate the electronic properties of the chromophore. Cation–anion interactions have been suggested to be an important determinant in wavelength regulation. Blatz et al. showed that there was a linear relationship between the reciprocal of the square of the anion radius and the energy difference between the ground and the first excited states of a retinylidene salt (4). This correlation was then used to calculate the position of the absorption maximum as a function of the internuclear distance between the protonated Schiff base nitrogen atom and the counterion. However, the center to center distances calculated by Blatz have been criticized as being far too large to be present in a stable pigment (7).

On the basis of theoretical calculations performed on a protonated Schiff base of 11-*cis* retinal, Honig et al. suggested that a favourable chromophore–protein interaction is not only one in which the protonated Schiff base nitrogen atom is closely associated with a counterion but where an additional negative charge or polar group is positioned at the cyclohexenyl end of retinal (7). In principle, a charge located near the β-ionone ring could stabilize the excited state, resulting in a spectroscopic red shift. Studies on the dihydroretinals reported by Nakanishi, Honig, and co-workers were used to show that a negative charge could be located in the vicinity of the C5,C6 bond (8–10) and a positive charge near C7 (11). Solid state ^{13}C NMR experiments by Harbison et al. confirmed these results (12).

The conformation adopted by the C6,C7 bond of the retinal chromophore is also an important factor in wavelength regulation of retinylidene iminium salts (13). Solid state ^{13}C NMR studies of bR have been used to suggest that bR has a 6-s-*trans* conformation (12,13). Previous work in this group using a combination of solid state UV and ^{13}C NMR spectroscopic techniques suggested that the 6-s-*trans* conformation about the C6,C7 bond in a retinylidene iminium salt is associated with a large red shift in its corresponding absorption maximum (14).

Recent solution work by Sheves and co-workers has shown that a red shift in the absorbance spectrum of retinylidene iminium salts is accompanied by downfield ^{13}C NMR chemical shifts of the odd-numbered polyene carbons of the unsaturated chain (15). It was suggested that weakening of the Schiff base – counterion interaction causes a significant enhancement in π-electron delocalization along the polyene chain, leading to the observed spectroscopic properties.

Despite the considerable amount of attention focused on the spectral properties of retinylidene iminium salts, considerable uncertainty still exists with respect to the structure of these chromophores, the relative placement of other charged groups, and the relationship of their structure with their charge delocalization and electronic properties. In this study, a series of retinylidene iminium salts **1–4** were synthesized and characterized both in solution and the solid state. A unique combination of X-ray crystallography, solid state ^{13}C NMR, FTIR, and UV spectroscopic techniques have been used in an integrated manner to address the mechanisms by which the electronic properties of the retinal chromophore can be modified by its environment and, particularly, by the placement of counterions.

Results

The iminium salts **1–3** were synthesized using a modified procedure of Blatz et al. (4) while salt **4** was prepared by the method of Pankratz and Childs (16). Mixtures of the different isomers of **1–4** were obtained in these preparations, Table 1. The salts **1–3** were also found to be thermally unstable in CD_2Cl_2 solution, undergoing relatively slow isomerizations about various C=C bonds. In contrast, the isomerization of **4** was found to be fairly rapid at room temperature in CD_2Cl_2.

The ^1H NMR spectral data for **1–4** are summarized in Table 2. Assignments were based on first-order coupling constant information and comparison to previous work (14, 17, 18). In iminium salts **1–3** the aldiminium proton appears as a doublet of doublets. The largest of the coupling constants results from coupling across the C=N bond to the proton on the nitrogen (ca. 16 Hz). The presence and magnitude of these coupling constants are indicative of protonation on nitrogen and an *anti* C=N configuration (19).

Solution ^{13}C NMR data for **1–4** are given in Table 3. Assignment of the carbon atoms was accomplished by ^1H–^{13}C hetero shift correlations, J-modulated spin echo experiments, and comparison with literature data (14, 20). All spectra were acquired at ambient temperatures except for **4**, which was obtained at −60°C in order to minimize thermal isomerization. Comparison of the spectra with those of the corresponding imines shows that protonation of the imines produces a general downfield shift of the odd-numbered olefinic carbons and a slight upfield shift of the even-numbered carbons (20).

Solid state ^{13}C NMR spectra of the salts were obtained using cross polarization magic angle spinning (CPMAS) methods. The ^{13}C NMR chemical shifts of these compounds are listed in Table 3. Identification of the quaternary and methyl carbons was facilitated using a delay without coupling sequence that suppresses CH and CH_2 resonances (21). The remainder of the resonances were assigned by comparison with solution spectra and literature data (13,14).

are given in Table 4. Solid state samples were prepared by smearing micro-crystalline fragments onto a glass or quartz slide. The resulting absorption peaks were typically broader than those obtained from solution but still Gaussian in shape.

Single crystals of **2** and **3** suitable for X-ray crystallographic studies were generated by slow diffusion of diethyl ether into acetonitrile solutions of each compound. Crystals large enough for crystallographic analysis were exceedingly difficult to grow although, once obtained, the crystals were found to be stable to light and moisture at room temperature. The structures of **2** and **3** were determined by X-ray crystallography. Two different projections of the cation–anion pairs of **2** and **3** are shown in Figs. 1 and 2 and views of the unit cell packing are shown in Figs. 3 and 4, respectively.

Discussion

The two salts **2** and **3** have identical cations and only differ in their respective anions. Ideally, for the type of analyis undertaken here they should also have the same anion and only differ in the relative placement of the anion with respect to the cation. The alternative approach, used here, is to vary the anion. However, in doing this it is important to keep the changes as small as possible and to use a closely related series of anions. Unfortunately, retinylidene salts are difficult to obtain as single crystals. As such, the ideal has to be balanced by the realities of obtaining materials that not only are suitable for structure determination using single crystal X-ray techniques but that also differ in terms of their solid state spectroscopic properties. In this work salts **2** and **3** were found to both crystallize as well as exhibit different absorption spectra in the solid state. The two anions are different; however, they are similar in that they are each the salt of a strong acid and possess a single negative charge formally located on oxygen atoms bonded to the central atom (Cl or S).

In solution the properties of **2** and **3** are very similar. Thus the long-wavelength absorption maxima of CH_2Cl_2 solutions of **2** (472 nm) and **3** (465 nm) (Table 4) are essentially the same. Similarly, the ^{13}C NMR spectra of these two salts in solution are virtually identical, Table 3, Fig. 5. It is clear that in CH_2Cl_2 solution variation in the anion of the two salts has little effect on the conformation or charge distribution of the iminium cation.

Despite their similarity in solution it is also clear that there are major differences in these two salts when they are in the solid state. Thus the absorption maxima of **2** (504 nm) and **3** (445 nm) as crystalline solids differ by 59 nm, Table 4. Not only is there a substantial difference in the absorption spectra of the two salts in the solid state but **2** shows an uncharacteristic red shift in its absorption maximum in the solid as compared to the solution phase. In contrast, the chromophore of **3** (as well as those of **1** and **4**) exhibits the typical blue shift generally found with iminium salts (14,18). These results clearly suggest that the chromophores of **2** and **3** are different when in the solid state.

The dramatic differences in the solid state absorption spectra of **2** and **3** are accompanied by major and systematic differences in their solid state ^{13}C NMR spectra, Fig. 5. Examination of Fig. 5 reveals three significant differences. First, the solid state ^{13}C NMR spectra for these compounds differ significantly in the chemical shifts of the odd-numbered carbons, particularly C15, C13, C11, and C9. Second, the resonance positions of these carbons are further downfield in **2** than in **3**. Lastly, the magnitude of the differences between **2** and **3** tends to decrease with increasing distance from the nitrogen atom. The odd-numbered carbons of an iminium salt are particularly sensitive to π-electron distribution along the polyene chain. The systematic pattern in the differences in chemical shift for the odd-numbered carbons in the solid state spectra of **2** and **3** would indicate that less positive charge is delocalized over the polyene carbon atoms in **3** than in **2**.

The differences observed in the properties of **2** and **3** in the solid state stand in marked contrast to their similarity in solution. It is clear that the origin of these different properties of the chromophore in **2** and **3** in the solid state must be due to some specific interaction or conformational difference present

only in the crystal lattices of these two salts. For this reason it is of interest to examine carefully the solid state structures of these two salts.

Comparison of the structures of the two salts

As is evident from an examination of Figs. 1 and 2, the two salts have remarkably similar structures and packing arrangements within the crystal lattice. As was found in our earlier work with an N-phenyl substituted retinylidene iminium salt (22), the cations in **2** and **3** are bowed in the plane defined by atoms N, C14, C15, and C21 and bent normal to this plane, Figs. 1 and 2. The angle of intersection of the plane defined by C1, C4, C5, C6 and N, C14, C15, C21 is 20° for both **2** and **3**. The C6-C7-C8 bond angles of 130.1(5)° for **2** and 132(1)° for **3** are similar in size, with both being large as a result of the steric interactions between the methyl groups at C1 and the hydrogen atom at C8. Other relatively large bond angles are found at C7-C8-C9, C9-C10-C11, C11-C12-C13, and C13-C14-C15.

In terms of conformation, as can readily be seen in Figs. 1 and 2, both cations have a *trans* configuration about each of the C—C single and double bonds of their unsaturated chains. In particular, it should also be stressed that **2** and **3** both have an s-*trans* configuration about the C6—C7 bond. The C5-C6-C7-C8 torsion angles (173.3(5)° and 174(1)°, respectively), are the same within the experimental error.

Table 4. Absorption spectral data (nm) for retinylidene iminium salts.[a]

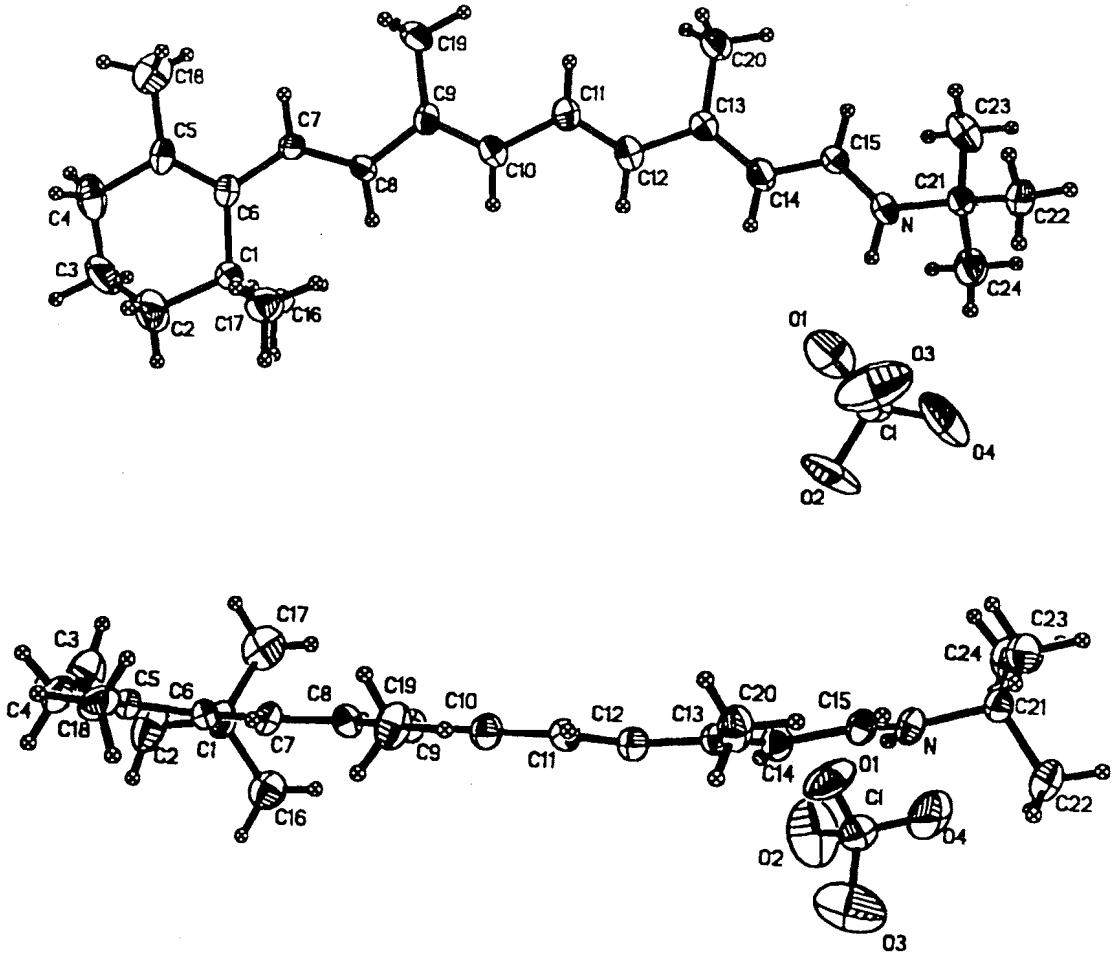
4	564[b]	4.25	505

[a]In CH_2Cl_2 at 22°C.
[b]At −70°C.

With the exception of the C20—C13 bond lengths, all bond lengths of the cations are the same within experimental error. The significance of this difference in the C20—C13 internuclear distance will be discussed later.

In summary, from the examination of the cations themselves there are no obvious differences in their conformations or structures that could account for their different solid state

Fig. 1. The conformation of **2**.



spectroscopic properties. The origin of the spectroscopic differences of the two salts must lie in the way the cations interact with other ions present within the crystal lattice.

Crystal packing and cation–anion interactions

The salts **2** and **3** were found to have different space groups and this impacts on the packing within the crystalline lattices. However, as can be seen from an examination of Figs. 3 and 4, in each case the cation–anion pairs are spatially arranged in a very similar manner with respect to each other. In each case the retinylidene cations lie on top of one another in a comparable π–π stacking fashion. The polar ends of the cations in **2** and **3** are all directed toward one another while the relatively nonpolar β-ionone rings are grouped together.

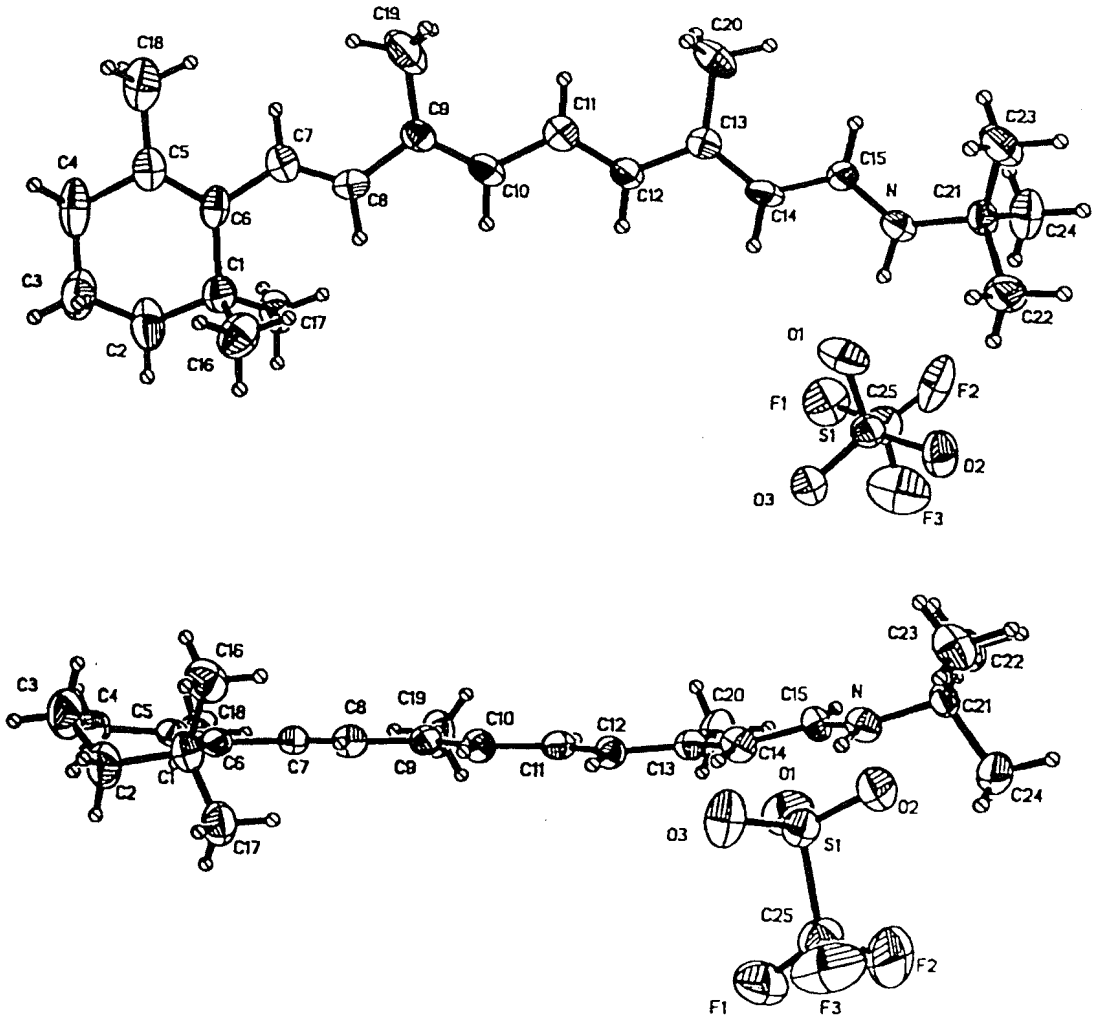
The closest cation–anion interactions in **2** and **3** are the hydrogen bonding interactions between the iminium proton of a cation and an oxygen atom of the perchlorate or triflate counterions. In general, it has been found from previous X-ray crystallographic determinations of salts that for organic cations with an OH or NH group bonded to a positively charged system there is always an anion located nearby such that a linear hydrogen bond exists between the anion and the hetero-atom bearing the proton. This has been found to be the case, for example, in every reported structure of protonated ketones (23). Similarly, in crystal structures of ammonium salts the anion is found to form a linear hydrogen bond with the acidic proton on the nitrogen (24).

Linear or near-linear hydrogen bonds exist between the proton on the nitrogen and an oxygen atom on the anion of both **2** and **3**. The N—H and H—O internuclear distances are imprecise owing to the uncertainty associated with crystallographically determined hydrogen atom positions. However, the corresponding N---O internuclear distances are determined with good precision. Examination of these cation–anion distances in the lattices of **2** and **3** shows that there is a very important difference. The shortest N---O distance in **2** (2.939(7) Å) is significantly longer than that in **3** (2.85(1) Å) (difference 7σ where $\sigma = (\sigma_1^2 + \sigma_2^2)^{1/2}$). The N---O contact in **3** is shorter than the sum of the van der Waals radii of the respective neutral atoms (2.90 Å).

The shorter N---O distance in **3** as compared to **2** would suggest a stronger hydrogen bonding interaction is present in the former salt. This is corroborated by the observation that the ^{1}H NMR chemical shift of the N(H) proton in **3** is 0.8 ppm further downfield from the analogous proton in **2**.

The observation of an abnormally short C13—C20 bond length of 1.47(1) Å in **3** versus 1.519(8) Å in **2** led to a detailed investigation of possible other significant cation–anion secondary interactions. Significant differences exist between the contacts observed in the two salts in terms of interactions involving C20—H---O and C20—H---F hydrogen bonds. In **3** two of the protons on C20 were found to be participating in hydrogen bonding with a fluorine or oxygen atom, respectively, of different anions, Fig. 6. The observed internuclear

Fig. 2. The conformation of **3**.



distances in **3** were F3---C20 (3.22(2) Å) and O3---C20 (3.34(1) Å). Although these distances are outside the sum of the van der Waals radii for fluorine and carbon (3.05 Å) and oxygen and carbon (3.10 Å), they are shorter by ca. 0.5 Å than the comparable interactions in **2**. (The closest C—H---O interaction in **2** is O2---C20 (3.800(8) Å).

Taylor and Kennard have shown in an extensive study of C—H hydrogen bonding interactions that C—H---O contacts are electrostatic and that they occur within certain distances (C---O, 3.0–4.0 Å) and angles (ϕ, ~90°–180°) (25). There are numerous examples of C–H---O bonds in the literature and it has been suggested that these interactions contribute significantly to the stability and tertiary structures of biomolecules such as nucleosides and amino acids (25–27). An activated C—H bond is polarized C(δ^-)—H(δ^+). As such, interaction of an anion with the C20 protons in combination with the partial positive charge on C13 would be expected to induce a shortening of the C13—C20 single bond.

The role of the anion in the ^{13}C NMR spectra

As was mentioned above, while the ^{13}C NMR spectra obtained for compounds **2** and **3** in solution are virtually identical there are significant differences in their chemical shifts in the solid state, Fig. 5. The resonance positions of the odd-numbered carbons of the polyenic chain of **3** are at higher field than the corresponding resonances of **2**, indicating that there is less positive charge induced on the carbon framework in **3**. As was established above, the only significant differences in the two structures in the solid state is in their hydrogen bonding interactions between the cations and anions. It must be concluded that the origin of the differences in the solid state ^{13}C NMR spectra are directly attributable to these hydrogen bonding interactions.

The regularity of the differences in chemical shifts of the unsaturated carbons in the solid state ^{13}C NMR spectra of the two salts suggests that the primary effect is due to the large variation in the N—H---O internuclear distances. The different N—H---O distances in **2** and **3** will result in a difference in the relative strengths of the hydrogen bonding interaction involving the nitrogen atom on the cations with an oxygen atom on the anion. The triflate counterion in **3** interacts more strongly with the N(H) proton than does perchlorate in **2**. As a result the N—H bond in **3** will be weaker through the stronger hydrogen bonding interaction with the triflate counterion. This will lead to a reduction in the fraction of positive charge induced on the carbon framework and the ^{13}C NMR chemical shifts of C15, C13, C11, and C9 in **3** will resonate at higher fields than those found in **2**. In the case of **2**, where the

Fig. 3. Unit cell packing in **2** with view along *y*-axis.

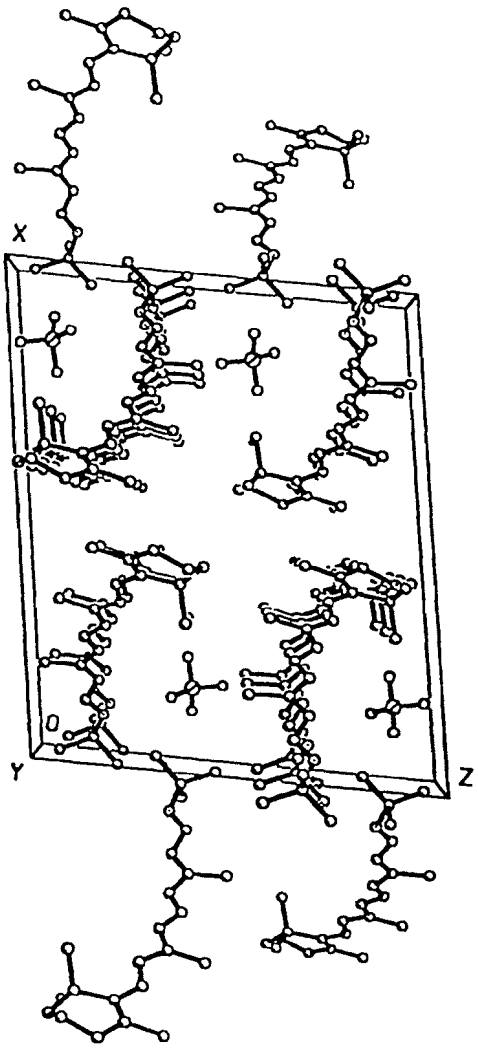


Fig. 4. Unit cell packing in **3** with view along *y*-axis.

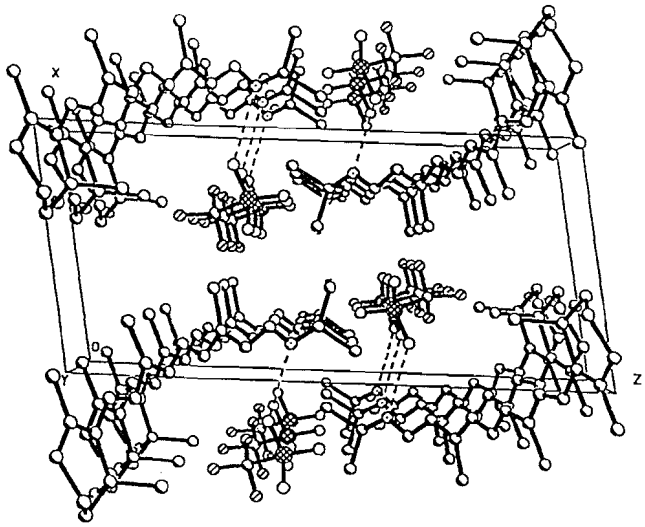

N—H---O1 interaction is much weaker than in **3**, more positive charge is borne by the odd-numbered carbons in the polyene chain. The secondary hydrogen-bonded interactions involving C20 in **3** could serve to assist delocalization of the positive charge through electron release to C13 along the polyenyl chain. However, we note that Bader has shown through theoretical calculations that if a hyperconjugative mechanism is operational at C20, then the C13—C20 bond should possess some π-character and, consequently, a downfield shift of the C20 resonance might be expected (28). No downfield shift was seen for C20 in **3** as compared to **2**.

One way of viewing the importance of these interactions of different anions with the N—H proton is to remember that a hydrogen atom in a molecule formally can only have a bond valence of 1. In the absence of any hydrogen bonding interaction, a full positive charge will formally reside on the nitrogen atom and carbon framework of a protonated imine. Hydrogen bonding of the N—H proton to a Lewis base will reduce the N—H bond valence in proportion to the bond valence associated with the hydrogen bond. This will result in a reduction of the fraction of positive charge induced on the nitrogen/carbon framework of the molecule. The importance of this hydrogen bonding on the degree of charge induction on a protonated imine can be seen by comparison of the properties of **2/3** with **4**. As can be seen from the data in Table 3, the solid state ^{13}C NMR chemical shifts of C13 and C11 in **4** are shifted further downfield by 3.5 and 1.5 ppm, respectively, relative to **2**. In compound **4** where the nitrogen atom is doubly substituted, the perchlorate counterion cannot participate in hydrogen bonding and so attenuates the fraction of positive charge to be delocalized on to the polyene carbons.

The solid state ^{13}C NMR chemical shifts for C15, C13, C11, and C9 in bR were reported by Harbison et al. to be 163.2, 169.0, 139.1, and 146.4 ppm, respectively (12). The ^{13}C NMR chemical shift differences between bR and **2/3** are illustrated in Fig. 7. The chemical shift values for C15 and C13 in bR are each shifted downfield by approximately 2 ppm compared to **2**, and by 5 ppm and 7 ppm compared to **3**, indicating that bR contains slightly more positive charge at C15 and C13 than do the comparable atoms in **2**.

The FTIR results corroborate the solid state ^{13}C NMR work described above in that the C=C stretching frequencies for bR, **2**, and **3** are 1530, 1539, and 1553 cm^{-1}, respectively (29). The lower stretching frequency exhibited by bR is suggestive of a decreased C=C bond strength caused by more extensive positive charge delocalization in its polyene chain.

Examination of the chemical shift differences of carbons C6–C8 in **2**, **3**, and bR (Fig. 7) reveals that these carbon atoms are substantially shifted to lower field in **2/3** than the corresponding carbon atoms in bR. This would indicate that there is a different type of specific interaction at the ring end of the retinylidene chromophore in bR than is observed in **2** and **3**. Harbison et al. (12) and Sheves and co-workers (15) have suggested that there is a nonconjugated positive charge present in the vicinity of C7–C9 in bR. However, in the recently reported structure of bR there are no obvious positive charges near these carbon atoms (30). The effect of the protein on ^{13}C NMR chemical shifts in bR may be due to the interaction of the polyene chain with four tryptophan residues (Trp86, Trp138, Trp182, and Trp189) that line the retinal pocket. It is possible that such an interaction with aromatic ring currents may be responsible for the observed effects.

Effect of cation/anion placement on absorption spectra

The absorption maxima of retinylidene iminium salts **2** (472

Fig. 5. Differences in ^{13}C chemical shift between **2** and **3**. Positive difference means that **3** is at higher field than **2**.

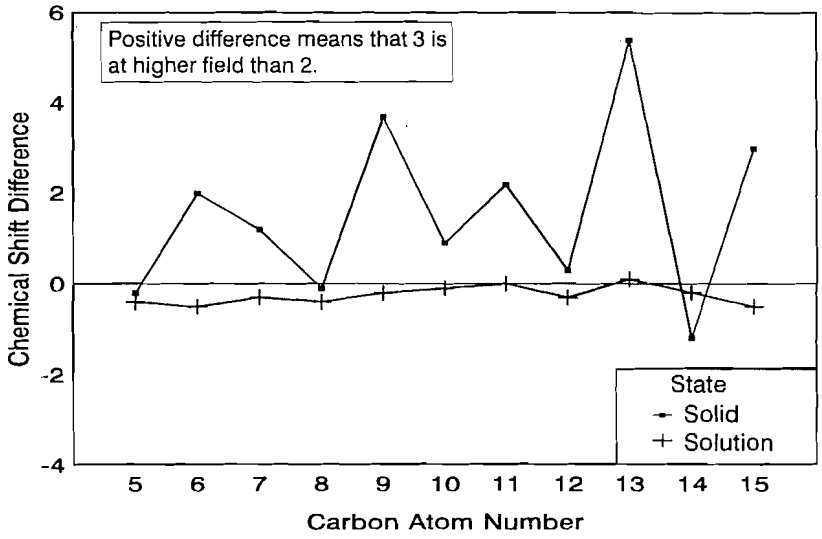

Fig. 6. Bottom view of hydrogen bonding interactions in **3**.

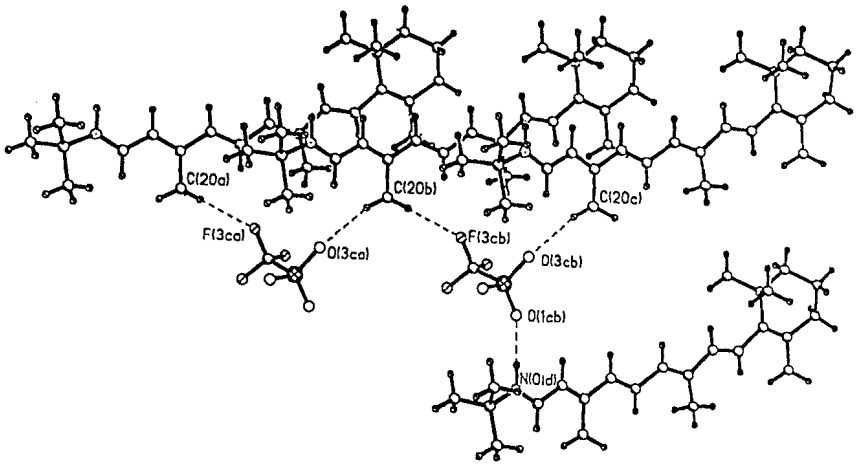


nm) and **3** (465 nm) are very similar in CH_2Cl_2 solution, Table 4. In contrast, their solid state absorption maxima differ by 59 nm (2631 cm^{-1}). As has been suggested earlier, this difference is consistent with a conformational change about the C6—C7 single bond (14) and indeed, Honig, Ebrey, and co-workers have indicated that twisting about the C6—C7 bond could alter the absorption maximum by about 50 nm (7).

The crystal structures of **2** and **3** show that both cations have 6-s-*trans* conformations in the solid state and, as such, the difference in their absorption spectra cannot be accounted for on the basis of conformational effects. Rather, the 2631 cm^{-1} (7.5 kcal/mol) difference in the absorption maxima of **2** and **3** in the solid state must primarily be the result of the variation in the differences in internuclear distance between N and O1. As was demonstrated above, the longer hydrogen-bonded interaction between O1 in ClO_4^- with the N-H proton in **2** results in more charge being induced on the carbon framework of this salt as compared to **3**. This will have the effect of destabilizing (raising) the ground state energy of **2** as compared to **3** and so causing a red shift in its absorption spectrum. *This result strongly supports the suggestion of Sheves (15) that the position of the absorption maximum of a retinylidene iminium salt can be simply regulated by change in the strength of the hydrogen bonding interaction between the N-H proton and the counterion.*

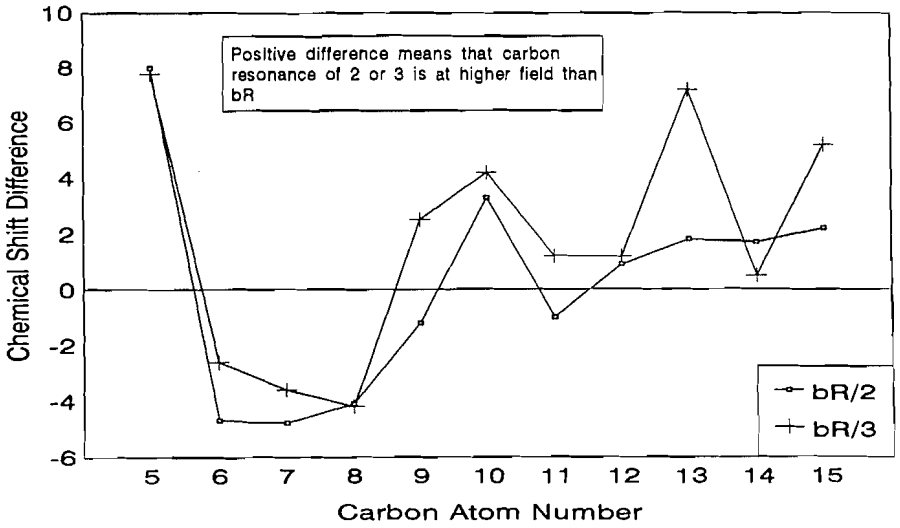
Conclusion

This work demonstrates the power of combining detailed structural and solid state packing information with solid state spectroscopic techniques to unravel the impact of cation–anion interactions in determining the properties of a system. Similar approaches could be used with other organic salts and lead to a better understanding of the importance of the placement of the counterion in determining the charge distribution, etc. of an organic ion.

Experimental section

CH_2Cl_2 was refluxed over P_2O_5 and distilled under a dry N_2 atmosphere prior to use. Similarly, diethyl ether was distilled from $LiAlH_4$, CH_3CN from P_2O_5 and then CaH_2. Dry solvents were stored over 4 Å molecular sieves in a glove bag that was

Fig. 7. Differences in ^{13}C chemical shift between bR and **2/3**. Positive difference means that carbon resonance of **2** or **3** is at higher field than bR.



continuously purged with N_2 in the presence of solid P_2O_5. Tertiary butylamine, *n*-butylamine, and *N*-methyl aniline were distilled and kept over 4 Å molecular sieves. CD_2Cl_2 (purchased in sealed 1 g ampules) and $CDCl_3$ were used without further purification. All-*trans* retinal (Aldrich) was used without further purification. All work was carried out under a nitrogen atmosphere and in dim red light. Solution ^1H NMR spectra were acquired at 500 MHz on a Bruker AM500 spectrometer. Solution ^{13}C NMR spectra were acquired on either a Bruker AC200 (50 MHz) spectrometer or a Bruker AM500 (125.8 MHz) spectrometer.

Solid state ^{13}C NMR spectra

Room temperature solid state ^{13}C NMR spectra of crystalline samples were obtained by CPMAS techniques with the use of a Bruker MSL100 (25 MHz) spectrometer. Spinning rates were approximately 4000 Hz. Methyl and quaternary carbon resonances were assigned using a delay without decoupling pulse sequence (21). Samples (0.1 g) were mixed with NaCl, finely ground, and densely packed into alumina rotors under a dry N_2 atmosphere. Adamantane was used as an external reference, and displayed resonances at 29.5 ppm (CH) and 38.6 ppm (CH_2) relative to tetramethylsilane.

UV spectra

Absorption spectra were recorded on a Hewlett Packard 8451A spectrophotometer. Solutions of the various compounds (about 10^{-5} M) were placed in 1 cm quartz cells to record their absorption spectra. Solid state absorption spectra were obtained from crystalline samples smeared onto a glass or quartz slide. A similar slide was used as a reference.

Infrared spectra

Infrared spectra were recorded on a Biorad-Digilab FTS-40 FTIR spectrometer. The samples were prepared as thin KBr discs.

Synthesis

All imines were synthesized using a modified procedure of Blatz et al. (14). The corresponding iminium salts were prepared by addition of an ethereal solution of the desired acid to the imine dissolved in ether at room temperature under a N_2 atmosphere.

Preparation of salts 1–3

Tertiary butylamine or *n*-butylamine (10 mmol) was added to a solution of retinal (1 mmol) in dry ether under a N_2 atmosphere and in the absence of light. The reaction mixture was stirred for 24 h over 4 Å molecular sieves. The mixture was filtered and ether and excess amine were removed under vacuum. The imine was rinsed three times with dry ether (5 mL) and the flask evacuated to ensure complete removal of amine (excess amine would interfere in the subsequent protonation). The imine was not characterized and was used immediately in the following step. Protonation was accomplished at room temperature by slow dropwise addition of an ethereal solution of either CF_3SO_3H or ClO_4H to an ethereal solution of imine. The resulting salt was filtered, recrystallized from CH_3CN–ether mixtures at −20°C, and dried under vacuum.

Preparation of 4

Freshly distilled *N*-methyl aniline (75 mg, 0.7 mmol) in dry ether (5 mL) was cooled in an ice bath. A slight excess of perchloric acid (110 mg of 70% $HClO_4$, 0.8 mmol) was added dropwise. A solution of all-*trans* retinal (200 mg, 0.7 mmol) in dry ether (2 mL) was added and the mixture stirred and allowed to stand until the salt precipitated from solution within about 10 min. The product was filtered, washed with dry ether, recrystallized from CH_3CN–ether, and dried under vacuum (yield 250 mg, 75%).

Single crystal X-ray crystallography. Collection of data

Single crystals (flat red needles) of iminium salts **2** (0.01 × 0.10 × 0.30 mm) and **3** (0.10 × 0.001 × 1.00 mm) suitable for X-ray diffraction studies were obtained from distillation of diethyl ether into an acetonitrile solution of each salt at −20°C.

[a]O1, O2, O3, O4: occupancy 0.70.
[b]O5, O6, O7, O8: occupancy 0.30.

16.556(7)Å, β = 99.12(2)°, V = 2502(2)Å^3, Z = 4, ρ_c = 1.168 g/cm^3, μ = 15.68 cm^{-1} (23°C, CuKα, λ = 1.54178) Å.

Compound **3**: $C_{25}H_{38}F_3NO_3S$ fw = 489.64

Monoclinic, $P2_1$, a = 9.068(3), b = 7.919(3), c = 19.243(9)Å, β = 99.87(3)°, V = 1361.5(9)Å^3, Z = 2, ρ_c = 1.194 g/cm^3, μ = 14.11 cm^{-1} (23°C, CuKα, λ = 1.54178 Å).

Cell constants were obtained from least-squares refinements using the setting angles of 24 carefully centered reflections in the range 47.04° < 2θ < 81.43° for **2** and 17 centered reflections in the range 21.19° < 2θ < 26.07° for **3**. Reflection intensities were measured using θ/2θ scans on a Rigaku AFC5R diffractometer for **2** ($2\theta_{max}$ = 100° (+h, +k, ±l), 5609 measured, 3242 unique, R_{int} = 0.053) and a Rigaku AFC6R diffractometer for **3** ($2\theta_{max}$ = 120° (+h, +k, ±l), 2229 measured, 2078 unique, R_{int} = 0.065). Both instruments used a 12 kW rotating anode generator. The data for both compounds were corrected for Lorentz and polarization effects and absorption. For **2**, an empirical absorption correction, based on azimuthal scans or several reflections, was applied, which resulted in transmission factors ranging from 0.84 to 1.00. In the case of **3** an empirical absorption correction using the program DIFABS (31) was applied, resulting in a transmission factor range from 0.53 to 1.00, which appears to be an *under*estimate for such a thin needle.

Solution and refinement of structures

Both structures were solved by direct methods (32), and the space group of **3** was verified to be noncentrosymmetric. The oxygen atoms of the perchlorate ion in **2** were found to be disordered in a 0.7:0.3 ratio. All non-hydrogen atoms were, with the exception of two of the disordered oxygen atoms O5 and O7 in **2**, refined anisotropically. Neutral atom scattering factors were taken from Cromer and Waber (33). Anomalous dispersion corrections (34) were applied to all non-hydrogen atoms. Full-matrix least-squares refinements, minimizing $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2/\sigma^2(F_o^2)$, were used in both cases. Hydrogen atoms were fixed in calculated positions. All calculations were performed using the TEXSAN crystallographic software package of Molecular Structure Corporation (35).

The final refinement cycle for **2**, using 1854 reflections with $I > 2.0\sigma(I)$, resulted in R = 0.059, S = 2.20, and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2)^{1/2}$ = 0.072, and gave a clean Fourier difference map (−0.20 to 0.30 e/Å^3). The final refinement cycle for **3**,

using 1330 reflections with $I > 3.0\sigma(I)$, resulted in $R = 0.057$, $S = 2.16$, and $R_w = 0.039$, and gave a clean Fourier difference map (-0.17 to 0.19 e/Å^3). Positional parameters and equivalent isotropic temperature factors for the non-hydrogen atoms of both structures are found in Tables 5 and 6, respectively.[2]

[2] Tables of hydrogen atom positional parameters and isotropic temperature factors, anisotropic temperature factors for all non-hydrogen atoms, interatomic bonds and bond angles, torsion angles, least-squares planes, intermolecular contacts, and F_o F_c reflection intensities have been deposited. They may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2. Tables of hydrogen atom parameters, bond lengths and angles for the anions, and packing diagrams for the cells have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, U.K.

The photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction. Part 11: Involving (*R*)-(+)-α-terpineol and (*R*)-(+)-limonene, substituting on 1,4-dicyanobenzene[1]

Donald R. Arnold, Dennis A. Connor, Kimberly A. McManus, Pradip K. Bakshi, and T. Stanley Cameron

Abstract: Irradiation of an acetonitrile–methanol (3:1) solution of 1,4-dicyanobenzene (**1**), biphenyl (**5**), and (*R*)-(+)-limonene (**21**) leads to formation of the 1:1:1 (methanol: **21**: **1**) photo-NOCAS adducts: 4-[(1*R*,2*S*,4*R*)-4-isopropenyl-2-methoxy-1-methylcyclohexyl]benzonitrile (**23**, 30%), 4-[(1*S*,2*R*,4*R*)-4-isopropenyl-2-methoxy-1-methylcyclohexyl]benzonitrile (**24**, 2%), 4-[(1*R*,2*R*,5*R*)-5-isopropenyl-2-methoxy-2-methylcyclohexyl]benzonitrile (**25**, 3%), and 4-[(1*S*,2*S*,5*R*)-5-isopropenyl-2-methoxy-2-methylcyclohexyl]benzonitrile (**26**, 1%). When an acetonitrile solution (no added methanol) of 1,4-dicyanobenzene (**1**), biphenyl (**5**), and (*R*)-(+)-α-terpineol (**22**) was irradiated under these conditions, the products were the cyclized 1:1 (**22**: **1**) photo-NOCAS adducts: (1*R*,2*S*,5*R*)-2-(4-cyanophenyl)-2,6,6-trimethyl-7-oxabicyclo[3.2.1]octane (**27**, 21%) and (1*S*,4*R*,6*R*)-6-(4-cyanophenyl)-1,3,3-trimethyl-2-oxabicyclo[2.2.2]octane (**28**, 2%). Structural assignments were based primarily upon detailed analysis of ^{1}H and ^{13}C nmr spectra and, for four of the products (**24**, **26**, **27**, and **28**), structures were firmly established by X-ray crystallography. The mechanism for the formation of these products is discussed, with emphasis on the intramolecular reactions of the intermediate alkene radical cations. Molecular mechanics (MM3) calculations gave information regarding the structure and energy of the conformers of **21** and **22** that was useful for predicting/explaining the observed reactivity on the basis of approach vector analysis; the transition state for cyclization incorporates the nucleophile and the alkene radical cation carbon atoms at the vertices of an obtuse triangle orthogonal to the plane of the π-system.

Key words: photoinduced electron transfer, radical cations, cyclization, terpenes.

Résumé : L'irradiation d'une solution de 1,4-dicyanobenzène (**1**), de biphényle (**5**) et de (*R*)-(+)-limonène (**21**) dans un mélange acétonitrile–méthanol (3 : 1) conduit à la formation d'adduits photo-NOCAS (substitution aromatique par combinaison photochimique de nucléophile et d'oléfine) 1 : 1 : 1 (méthanol : **21** : **1**) : 4-[(1*R*,2*S*,4*R*)-4-isopropényl-2-méthoxy-1-méthylcyclohexyl]benzonitrile (**23**, 40%, 4-[(1*S*,2*R*,4*R*)-4-isopropényl-2-méthoxy-1-méthylcyclohexyl]benzonitrile (**24**, 2%), 4-[(1*R*,2*R*,5*R*)-5-isopropényl-2-méthoxy-1-méthylcyclohexyl]benzonitrile (**25**, 3%) et 4-[(1*S*,2*S*,5*R*)-5-isopropényl-2-méthoxy-2-méthylcyclohexyl]benzonitrile (**26**, 1%). Quand on irradie dans les mêmes conditions un mélange de 1,4-dicyanobenzène (**1**), de biphényle (**5**) et de (*R*)-(+)-α-terpinéol (**22**) en solution dans de l'acétonitrile (sans y avoir ajouté de méthanol), les produits formés sont les adduits de photo-NOCAS cyclisés 1 : 1 (**22 : 1**) suivants : (1*R*,2*S*,5*R*)-2-(4-cyanophényl)-2,6,6-triméthyl-7-oxabicyclo[3.2.1]octane (**27**, 21%) et (1*S*,4*R*,6*R*)-6-(4-cyanophényl)-1,3,3-triméthyl-2-oxabicyclo[2.2.2]octane (**28**, 2%). Les attributions de structures ont été principalement faites sur la base d'études détaillées des spectres RMN du ^{1}H et du ^{13}C; de plus, pour quatre des produits (**24**, **26**, **27** et **28**), les structures ont été établies d'une façon ferme par diffraction des rayons X. On discute du mécanisme de formation de ces produits en insistant sur les réactions intramoléculaires des cations radicaux d'alcènes intermédiaires. Des calculs de mécanique moléculaire (MM3) fournissent de l'information relative à la structure et à l'énergie des conformères des composés **21** et **22** qui est utile pour prédire/expliquer la réactivité observée en se basant sur une approche d'analyse vectorielle; l'état de transition de la cyclisation incorpore le nucléophile et les atomes de carbones du cation radical de l'alcène aux sommets d'un triangle obtus orthogonal par rapport au plan du système π.

Mots clés : transferts photoinduits d'électrons, cations radicaux, cyclisation, terpènes.

Introduction

The first examples of the photochemical nucleophile–olefin combination aromatic substitution (photo-NOCAS) reaction involved methanol, serving as the nucleophile, simple olefins, e.g., 2-methylpropene (**2**), and 1,4-dicyanobenzene (**1**) (reaction [1]) (3*a*,*b*). The major product results from the nucleophile (methanol) combining with the olefin radical cation ($\mathbf{2}^{+\bullet}$), at the less substituted carbon, followed by substitution of the resulting β-alkoxyalkyl radical at the *ipso* position of the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\bullet}$) to give the *anti*-Markovnikov adduct (**3**). Subsequent studies have confirmed that the *anti*-Markovnikov mode of addition is preferred, and a mechanism, consistent with all of the observations, has been proposed (1, 3).

The scope of this reaction has recently been extended to include conjugated dienes (1*b*), nonconjugated dienes (1*d*,*e*), and alkenols (1*a*). The reactions of the nonconjugated dienes and alkenols (reactions [2], [3], [4], and [5]) are particularly relevant to this work. The intermediates involved in these reactions, alkene radical cations and alkyl radicals, can (and do) undergo intramolecular cyclization. This additional bond-forming reaction, proceeding to a more complex difunctional product, greatly extends the synthetic utility of the photo-NOCAS reaction. Of course, before this process is even considered for inclusion in a retrosynthetic strategy, the scope and limitations of the reaction will have to be understood. Rules, analogous to Baldwin's rules (4), for the cyclization of ionic intermediates, and Beckwith's rules (5), for the cyclization of radical intermediates, will have to be defined for radical ions.

The nonconjugated dienes previously studied were 2,5-dimethyl-1,5-hexadiene (**6**) and 2,6-dimethyl-1,6-heptadiene (**9**). Both of these dienes lead to 1:1:1 adducts indicative of intramolecular cyclization, at the radical cation stage, forming the 1,4-distonic radical cations, followed by attack of the nucleophile (methanol) and coupling of the resulting alkyl radical at the *ipso* position of the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\bullet}$). The products include six- and seven-membered saturated ring systems, resulting from 1,6-*endo*, *endo* and 1,7-*endo*, *endo* cyclization of the radical cations (reactions [2] and [3]) (1*d*,*e*).

Additional examples of intramolecular cyclization were observed with the alk-4-enols: 6-methyl-5-hepten-2-ol (**13**) and 5-methyl-5-hexen-2-ol (**16**). Initial formation of the alkene radical cation was followed by intramolecular nucleophilic attack by the hydroxyl group; 1,5-*exo* and 1,6-*endo* cyclized products were formed (reactions [4] and [5]) (1*a*).

We have now extended this study to two interesting related alkenes: a 1,5-diene, (*R*)-(+)-limonene ((4*R*)-1-methyl-4-(1-isopropenyl)cyclohexene) (**21**), and a 1,4-alkenol, (*R*)-(+)-α-terpineol ((4*R*)-4-(1-hydroxy-1-methylethyl)-1-methyl-1-cyclohexene) (**22**). We recognized, at the outset, that there were additional steric constraints associated with these cyclic systems, relative to the acyclic analogues, that might hinder/inhibit cyclization of the radical cations. Furthermore, the original stereogenic carbon will not be epimerized under these mild reaction conditions and, if the radical cations and (or), in the case of limonene (**21**), the intermediate β-alkoxyalkyl radical do cyclize, this process would lead to interesting chiral bicyclic structures.

Results

The acetonitrile–methanol (3:1) solution of 1,4-dicyanobenzene (**1**), biphenyl (**5**), and the alkene was irradiated, using our typical reaction conditions, with a medium-pressure mercury vapour lamp through Pyrex. Progress of the reaction was monitored by capillary column gas chromatography with a flame ionization detector (gc/fid). The first indication of the structure of the products was obtained from a gas chromatograph equipped with a mass selective detector (gc/ms). The products were isolated by medium-pressure liquid chromatography (mplc). The yields generally were based upon the quantity of pure isolated products with 1,4-dicyanobenzene (**1**) as the limiting reagent. The alkene was present in excess. When the photo-NOCAS products were difficult to separate, the total weight of the mixture was obtained and the ratio(s) of the isomers was determined by gc/fid (integrated peak intensity). These ratios were similar to those observed on the crude reaction mixture. The ratio of products was not dependent on the extent of conversion: these ratios remained constant during the irradiation.

The products from (*R*)-(+)-limonene (**21**) (reaction [6]) were the 1:1:1 (methanol: **21**: **1**) photo-NOCAS adducts: 4-[(1*R*,2*S*,4*R*)-4-isopropenyl-2-methoxy-1-methylcyclohexyl]-benzonitrile (**23**, 30%), 4-[(1*S*,2*R*,4*R*)-4-isopropenyl-2-methoxy-1-methylcyclohexyl]benzonitrile (**24**, 2%), 4-[(1*R*,2*R*,5*R*)-5-isopropenyl-2-methoxy-2-methylcyclohexyl]benzonitrile (**25**, 3%), and 4-[(1*S*,2*S*,5*R*)-5-isopropenyl-2-methoxy-2-methylcyclohexyl]benzonitrile (**26**, 1%). Isomers **23** and **24** result from *anti*-Markovnikov addition to the cyclic alkene; their combined yields make this the major mode of addition. Isomers **25** and **26** result from Markovnikov addition to the cyclic alkene. Under these conditions (methanol, 6 M) we found no evidence for cyclization of either the initially formed alkene radical cation ($\mathbf{21}^{+\bullet}$) or the intermediate β-alkoxyalkyl radical. Lowering the concentration of methanol (1 M) led to

Reaction [6]

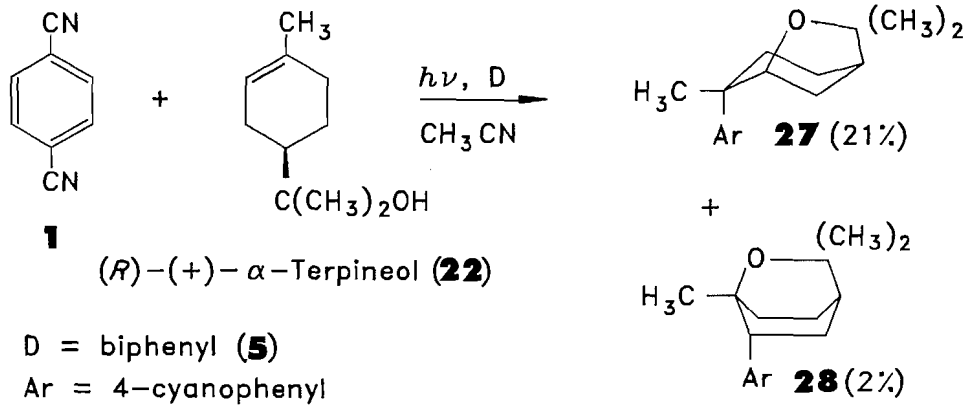
Ar = 4-cyanophenyl

Reaction [7]



D = biphenyl (**5**)

Ar = 4-cyanophenyl

decreased yields of the 1:1:1 adducts, but no cyclized products were detected (gc/ms).

When an acetonitrile solution (no added methanol) of 1,4-dicyanobenzene (**1**), biphenyl (**5**), and (*R*)-(+)-α-terpineol (**22**) was irradiated under these conditions, the products were the cyclized 1:1 (**22** : **1**) photo-NOCAS adducts: (1*R*,2*S*,5*R*)-2-(4-cyanophenyl)-2,6,6-trimethyl-7-oxabicyclo[3.2.1]octane (**27**, 21%) and (1*S*,4*R*,6*R*)-6-(4-cyanophenyl)-1,3,3-trimethyl-2-oxabicyclo[2.2.2]octane (**28**, 2%) (reaction [7]). Compound **27**, the major product, results from intramolecular 1,5-*exo* cyclization of the radical cation **22**$^{+\bullet}$. The minor product (**28**) results from 1,6-*endo* cyclization. When this irradiation was carried out in the usual mixed solvent, acetonitrile–methanol (3:1), the yield of cyclized products was greatly reduced and 1:1:1 (methanol : **22** : **1**) adducts became major products. These 1:1:1 adducts were detected (gc/ms) but were not isolated.

Structural assignments

Structural assignments for the products were based primarily upon detailed analysis of ^{1}H and ^{13}C nmr spectra and, for four of the products (**24**, **26**, **27**, and **28**), structures were firmly established by X-ray crystallography.[3] All of the products resulting from (*R*)-(+)-limonene (**21**) exhibit ^{1}H nmr spectra having an AA′XX′ pattern at 7–8 ppm, clearly indicating the presence of a 1,4-disubstituted aryl group. Also observed was a singlet at 3.1–3.4 ppm, which is consistent with a methoxy methyl group. The evidence of the signals of two protons in the vinyl region of the ^{1}H nmr spectrum of these products suggests the addition has taken place across the endocyclic alkene. These common features support the assumption that these products are 1:1:1 adducts involving the more heavily substituted cyclic alkene, without intramolecular cyclization into the double bond of the isopropenyl side chain.

The ^{13}C nmr spectra show a pair of doublets and three sin-

[3] Data for **24**, **26**, **27**, and **28** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Details of data collection, structural analysis and refinement, and tables of interatomic distances and bond angles have also been deposited with the Cambridge Crystallographic Data Centre and may be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

glets in the aromatic region, a singlet–triplet combination at low field, a mid-field quartet, and two high-field quartets, confirming the presence of the 4-cyanophenyl, the olefin, the methoxy methyl group, and two additional methyl groups, respectively.

The regiochemistry of the products from (*R*)-(+)-limonene (**21**) was determined from the shifts of the ^{13}C and ^{1}H nmr signals. In the ^{13}C nmr spectra, the signals of a carbon adjacent to an oxygen generally occur at lower field (72–94 ppm), relative to those adjacent to the 4-cyanophenyl group (37–55 ppm) (1, 3). The *anti*-Markovnikov adducts would have a quaternary carbon bearing methyl and aryl groups (37–55 ppm) and a methine carbon substituted by a methoxy group (72–94 ppm) (1, 3). Isomers **23** and **24** each have an off-resonance doublet at 81.56 and 84.42 ppm, respectively, and a singlet at 43.27 and 43.11 ppm, respectively; therefore, these are the *anti*-Markovnikov adducts. The Markovnikov adducts would have a quaternary carbon bearing methyl and methoxy groups (72–94 ppm) and a methine carbon substituted by an aryl group (37–55 ppm). Isomers **25** and **26** each show a singlet at 76.04 and 73.67 ppm, respectively, and an off-resonance doublet between 38 and 55 ppm.

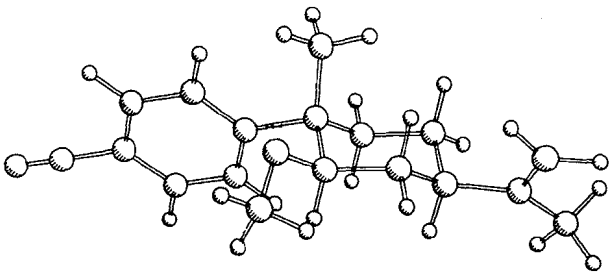
In the ^{1}H nmr, the signals of a proton on a carbon adjacent to an oxygen generally occur at lower field (3.2–3.7 ppm) than those adjacent to the 4-cyanophenyl group (2.4–3.0 ppm) (1, 3). The ^{1}H nmr spectra of isomers **23** and **24** show a single proton signal at 3.84 and 3.45 ppm, respectively. These are assigned to protons geminal to the methoxy group and thus confirms that these are *anti*-Markovnikov adducts. Isomers **25** and **26** have single proton signals at 3.09 and 2.56 ppm, respectively. These are assigned to protons geminal to the 4-cyanophenyl group. No single proton signals were observed in the region 3.2–3.7 ppm. This evidence confirms that these isomers, **25** and **26**, are Markovnikov adducts.

The stereochemical assignments for these isomers were more difficult to establish. Each of these isomers has three stereogenic centres, including one that was the original juncture of the ring and the isopropenyl substituent. This centre is not expected to epimerize under these (mild) reaction conditions; thus, once the relative configuration of the substituents is established, the absolute configuration will also be known. The structures of isomers **24** and **26** were firmly established by X-ray crystallography. These results confirm the validity of the interpretation based upon the nmr spectra. The assignment of stereochemistry for the other isomers, **23** and **25**, rests entirely upon the interpretation of the nmr, aided by comparison of the nmr spectra with those of the isomers **24** and **26**.

Compound **24**, 4-[(1*S*,2*R*,4*R*)-4-isopropenyl-2-methoxy-1-methylcyclohexyl]benzonitrile, shows a doublet of doublets at 3.45 ppm in the ^{1}H nmr spectrum. The coupling constants are 11.2 Hz and 4.2 Hz. These must be the axial–axial and axial–equatorial couplings of an axial proton geminal to the methoxy group. This is consistent with the X-ray determined structure for this compound, which shows the methoxy group in the equatorial position (Fig. 1).

The overlap of the other signals in the ^{1}H nmr spectrum made a complete assignment of the ring protons difficult. However, with the aid of proton–proton decoupling experiments, a "quartet" was found in the three-proton multiplet at 1.38–1.57 ppm which collapsed to a "triplet" upon irradiation of the proton geminal to the methoxy group. This "quartet" has

Fig. 1. X-ray structure of 4-[(1*S*,2*R*,4*R*)-4-isopropenyl-2-methoxy-1-methylcyclohexyl]benzonitrile (**24**).



a coupling of ca. 12 Hz, as does the "triplet" resulting from decoupling. As the methoxy group has vicinal protons on only one side, this "quartet" (1.38–1.57 ppm) must be partially due to an axial proton on C-3, vicinal to both the methoxy and isopropenyl groups. The three observed coupling constants of ca. 12 Hz each indicate that there must be two axial–axial couplings and a geminal coupling, evidence that the isopropenyl group must be in the equatorial position, in agreement with the X-ray structure.

The ^{13}C nmr spectral support for the axial position of the cyclohexyl methyl was provided by the coupling between the methyl carbon and the vicinal protons. This coupling ($^{3}J_{C-H}$) follows a Karplus relationship similar to that pertaining to vicinal proton–proton coupling ($^{3}J_{H-H}$), dependent on the dihedral angle of the coupled nuclei (6). In general, the magnitude of $^{3}J_{C-H}$ is ca. 0.6 that of analogous $^{3}J_{H-H}$. In the ^{13}C nmr spectrum of **24**, the quartet at 16.69 ppm was assigned to the cyclohexyl methyl group (evidence for this is provided in the structural proof of compound **23**). This quartet has a 16 Hz width at half-height. This broad a peak indicates the methyl group is axial, producing two axial–axial and one axial–equatorial vicinal proton–carbon interactions. Assignment of an axial methyl group is consistent with the X-ray results.

The assignment of the two methyl quartets in the ^{13}C nmr was done rigorously for the major product (**23**; 4-[(1*R*,2*S*,4*R*)-4-isopropenyl-2-methoxy-1-methylcyclohexyl]benzonitrile) and by comparison with others. A two-dimensional heterocorrelation spectrum of **23** showed correlation of the lower field quartet (29.14 ppm) in the ^{13}C nmr spectrum with the higher field singlet (1.19 ppm) in the ^{1}H nmr spectrum, as well as the higher field quartet (21.03 ppm) in the ^{13}C nmr spectrum with the lower field singlet (1.61 ppm) in the ^{1}H nmr spectrum. (The assignment of the methyl signals in the proton spectra had been done by double irradiation of the vinyl protons.) The quartets in the ^{13}C nmr spectra of the other products were assigned on the basis of shifts. Each ^{13}C nmr spectrum had a quartet near 21 ppm with half-height width about 25 Hz. The other quartet was found either lower or higher (16–29 ppm) and with half-height widths ranging from 10 to 16 Hz. The quartet (near 21 ppm) with the more consistent shift from isomer to isomer and a wider half-height was assigned to the methyl on the vinyl side chain since it is in a more consistent environment from isomer to isomer and because coupling through a double bond is expected to be greater. The other quartet in each spectrum is the cyclohexyl methyl group. This was consistent with the assignment done by heterocorrelation for **23**.

The major product, **23**, is the *anti*-Markovnikov stereoiso-

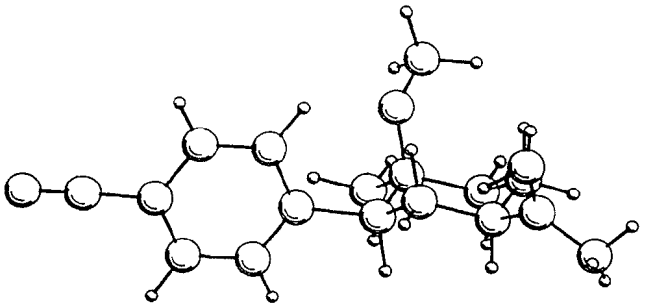

Fig. 3. X-ray structure of (1*R*,2*S*,5*R*)-2-(4-cyanophenyl)-2,6,6-trimethyl-7-oxabicyclo[3.2.1]octane (**27**).

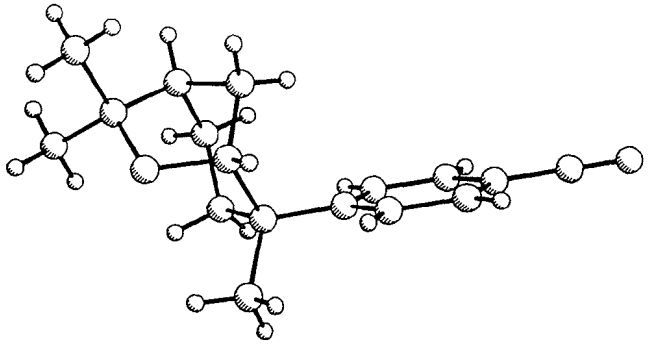

Fig. 4. X-ray structure of (1*S*,4*R*,6*R*)-6-(4-cyanophenyl)-1,3,3-trimethyl-2-oxabicyclo[2.2.2]octane (**28**).

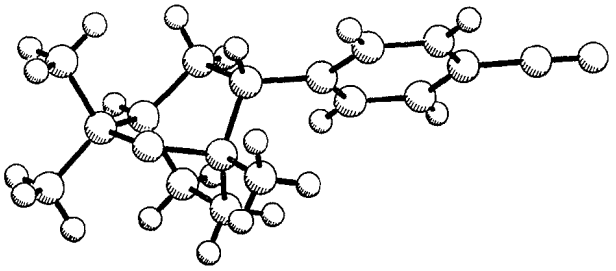

mer of the product, **24**, whose structure was determined by X-ray analysis. The ring protons of **23**, assigned using double irradiation experiments and COSY data, confirm the coupling relationships. There is a single proton resonance at 3.84 ppm which is the proton geminal to the methoxy group. The resonance exhibits a doublet of doublets having couplings of 4.0 Hz and 1.9 Hz . By comparison to the corresponding signal (3.45 ppm; 11.2 Hz and 4.2 Hz) in the other *anti*-Markovnikov product, **24**, the geminal proton must be equatorial and the methoxy group axial. The resonance at 2.32 ppm, a multiplet consisting of two 12.0 Hz couplings, was assigned as the proton geminal to the isopropenyl group. It must be coupled to both vicinal axial protons by 12.0 Hz. This indicates that the isopropenyl group must be in the equatorial position and the geminal proton is in the axial position.

The configuration at C-1, bearing a methyl and aryl ring, could not be simply determined by the carbon–proton coupling constant because the quartet at 29.14 ppm in the ^{13}C nmr spectrum showed no discernable fine structure and a half-height width of 15 Hz. Consequently, a two-dimensional NOESY spectrum was obtained as well. A nuclear Overhauser effect was observed between the cyclohexyl methyl group (1.19 ppm) and the vicinal axial methoxy proton (3.43 ppm) and the vicinal axial ring proton (1.95 ppm). Another nuclear Overhauser effect was observed between the aryl group protons (7.49 ppm) and the 1,3-diaxial protons (1.16 and 1.27 ppm). These results indicated that the methyl group was equatorial and the aryl group was axial.

The stereochemistry of product **26**, 4-[(1*S*,2*S*,5*R*)-5-isopropenyl-2-methoxy-2-methylcyclohexyl]benzonitrile, has been established by X-ray diffraction (Fig. 2) and the nmr data are in agreement. The single proton resonance at 2.56 ppm is the lowest field signal after the aromatic, vinyl, and methoxy proton signals and was assigned as the benzylic proton; a proton on a carbon adjacent to the 4-cyanophenyl group is in the range of 2.4–3.0 ppm (1, 3). The resonance at 2.56 ppm is a doublet of doublets having couplings of 12.1 Hz and 3.2 Hz. The benzylic proton was thus assigned to the axial position, putting the aryl ring in the equatorial position. This is in agreement with the structure and conformation established by X-ray diffraction. The cyclohexyl methyl group, geminal to the methoxy group, exhibits a quartet in its coupled ^{13}C nmr spectrum with a half-height width of 10 Hz. This supports the assignment that the methyl group is in the equatorial position.

The ^1H nmr spectrum of product **25**, 4-[(1*R*,2*R*,5*R*)-5-isopropenyl-2-methoxy-2-methylcyclohexyl]benzonitrile, includes a doublet of doublets (8.7 and 4.5 Hz) at 3.09 ppm. This signal was assigned to the benzylic proton. The couplings indicate that the benzylic proton is axial and the aryl group is in the equatorial position. Decoupling experiments indicate that the resonance at 2.41 ppm is due to the proton geminal to the isopropenyl group. A 500 MHz spectrum shows that the signal at 2.41 ppm is a quintet. If the proton is axial, it should not couple equally to the four vicinal protons as the experimental quintet indicates must be the case. The isopropenyl group is therefore axial. A NOESY correlation between one of the vinyl protons and the benzylic proton is further evidence of the 1,3-diaxial placement of the isopropenyl group and the benzylic proton. The cyclohexyl methyl group is assigned the equatorial position because the coupled ^{13}C nmr spectrum shows the width of the quartet (19.25 ppm) at half-height is ca. 10 Hz. This is too narrow for an axial methyl, which would have two axial–axial and one axial–equatorial proton couplings. This is consistent with the quartet (23.01 ppm) in product **26**, which is known to represent an equatorial methyl group as well.

The products resulting from (*R*)-(+)-α-terpineol (**22**) were identified as (1*R*,2*S*,5*R*)-2-(4-cyanophenyl)-2,6,6-trimethyl-7-oxabicyclo[3.2.1]octane (**27**) and (1*S*,4*R*,6*R*)-6-(4-cyanophenyl)-1,3,3-trimethyl-2-oxabicyclo[2.2.2]octane (**28**). The overall structures of **27** and **28** were firmly established by X-ray analysis of a single crystal (Figs. 3 and 4, respectively). The ^1H and ^{13}C nmr spectra are consistent with these structures. For **27**: the ^1H nmr spectrum exhibits three singlets in the aliphatic region, indicative of the three methyl groups: a benzylic methyl group and two methyl groups bonded to the same carbon, which is adjacent to a chiral centre; these two methyl groups are therefore nonequivalent. A broad doublet at low field (4.25 ppm) indicates a methine group at the bridgehead adjacent to an oxygen. An AA′XX′ pattern in the aromatic region of the ^1H nmr spectrum is indic-

ative of the 4-cyanophenyl group. The ^{13}C nmr spectrum of **27** indicates three methyl groups, two of which have very similar shifts (29.70 and 30.12 ppm). A singlet at 44.94 ppm indicates a benzylic quaternary carbon, and a singlet and doublet at 83.00 and 83.07 ppm, respectively, support the bridgehead methine group and quaternary carbon, both adjacent to oxygen. The signal of a carbon adjacent to an oxygen generally occurs at lower field (72–94 ppm) than those adjacent to the 4-cyanophenyl group (1, 3).

The ^1H and ^{13}C nmr spectra of **28** are also consistent with the structure determined by X-ray analysis of a single crystal (Fig. 4). The ^1H nmr spectrum exhibits three singlets in the aliphatic region, indicative of three methyl groups. The proposed structure has a methyl group at a bridgehead, as well as two methyl groups bonded to the same carbon, which is adjacent to a stereogenic centre; these two methyl groups are therefore nonequivalent. A triplet of triplets at lower field (2.50 ppm) indicates a methine group at the bridgehead not adjacent to an oxygen, unlike compound **27**, which indicates a much lower field signal (4.25 ppm) for the methine group at the bridgehead, thus supporting that the methine group is adjacent to an oxygen. An AA′XX′ pattern in the aromatic region of the ^1H nmr spectrum is indicative of the 4-cyanophenyl group. The ^{13}C nmr spectrum of **28** indicates three methyl groups, two of which have the same shift (28.94 ppm). A doublet at 49.39 ppm indicates a benzylic methine carbon, and two singlets at 72.90 and 73.78 ppm support the bridgehead quaternary carbon and the quaternary carbon, both adjacent to oxygen. The signal of a carbon adjacent to an oxygen generally occurs at lower field (72-94 ppm), than those adjacent to the 4-cyanophenyl group (1, 3). Another doublet at 33.59 ppm indicates the bridgehead methine group not adjacent to oxygen.

Discussion

The first steps of the photo-NOCAS reaction involve electron transfer from the donor (olefin) to the first excited singlet state of the acceptor (1,4-dicyanobenzene (**1**)) . The free energy for this process can be calculated using the Weller equation (eq. [8] (7)); electron transfer to the first excited singlet state of **1** from either (*R*)-(+)-limonene (**21**) or (*R*)-(+)-α-terpineol (**22**) is exergonic by at least 45 kJ mol^{-1} (Table 1). This process can be expected to occur at the diffusion-controlled rate (7).

[8] (7) $\Delta G_{et} = F\,(E_{1/2}{}^{ox}\,(D) - E_{1/2}{}^{red}\,(A) - e/\varepsilon\alpha) - E_{0,0}\,(A)$

Previous results have shown that the efficiency of the photo-NOCAS reaction can be increased by the addition of biphenyl (**5**), serving as a codonor. The explanation for this enhancement is based upon the relative efficiency of escape from the solvent cage of the initially formed alternative geminate radical ion pairs (1, 3). These reactions, [6] and [7], were also made more efficient upon the addition of the codonor, biphenyl (**5**).

Single electron transfer from (*R*)-(+)-limonene (**21**) can be expected to occur predominantly from the more substituted cyclic alkene, site of the more stable radical cation (**21**$^{+\bullet}$). The analogous acyclic diene radical cations, **6**$^{+\bullet}$ and **9**$^{+\bullet}$, cyclize 1,6-*endo*, *endo* and 1,7-*endo*, *endo* (reactions [2] and [3]) (1*d*,*e*). There is also evidence (esr spectroscopy) for the cyclization, and subsequent rearrangement, of the radical cation of 4-vinylcyclohexene (9). However, neither 4-vinylcyclohexene nor limonene (**21**) gave cyclized products upon anodic oxidation in methanol (10). Evidently, cyclization of the vinylcyclohexene and limonene (**21**$^{+\bullet}$) radical cations is slow in methanol solution relative to competing processes (nucleophilic attack, deprotonation, further anodic oxidation).

These results can be explained in terms of the alternative conformations available to limonene (**21**) and to the corresponding radical cation (**21**$^{+\bullet}$); there is good evidence that the structure of the alkene radical cation is similar to that of the neutral molecule (11). Molecular mechanics (MM3) calculations were used to determine the structure and relative energies of the conformers (Table 2*a*). Four conformers were identified; as expected, the global minimum conformer has the half-chair structure with the isopropenyl side chain equatorial.

Table 1. The oxidation potentials of (*R*)-(+)-limonene (**21**) and (*R*)-(+)-α-terpineol (**22**) and the calculated free energy change (ΔG_{et}) for the electron transfer process from the alkene to the electronic excited singlet state of the acceptor, 1,4-dicyanobenzene (**1**).

Alkene	$E_{1/2}{}^{ox}$(V)[a]	ΔG_{et}(kJ mol^{-1})[b]
(*R*)-(+)-Limonene (**21**)	2.15	−46.2
(*R*)-(+)-Terpineol (**22**)	1.97	−63.6

[a]Oxidation potentials were measured at a platinum electrode relative to the saturated calomel electrode (SCE), using tetraethylammonium perchlorate (0.1 m TEAP) as the electrolyte in acetonitrile. The anodic waves were irreversible; the half-wave potentials were estimated by subtracting 0.028 V from the peak potentials (8).

[b]Based upon the Weller equation (eq. [8]) (7); $E_{0,0}$ (**1**) 408.4 kJ mol^{-1}, $E_{1/2}{}^{red}$ (**1**) −1.66 V, the Coulombic attraction term was taken to be 5.4 kJ mol^{-1} (3*a*).

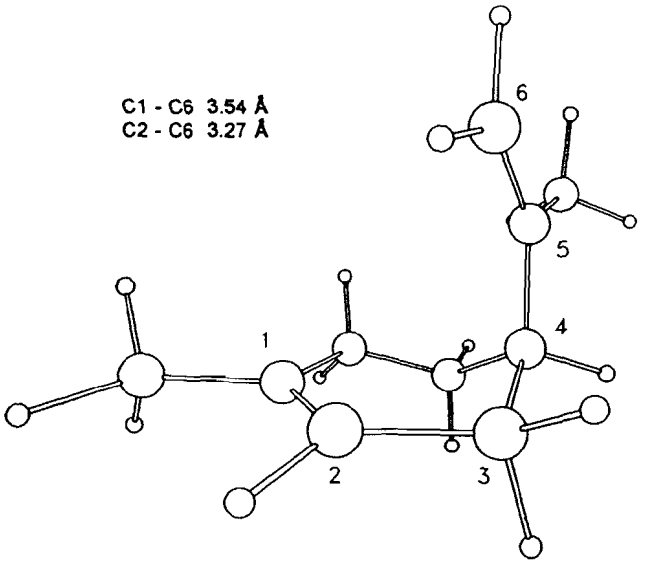
[b]Heat of formation.

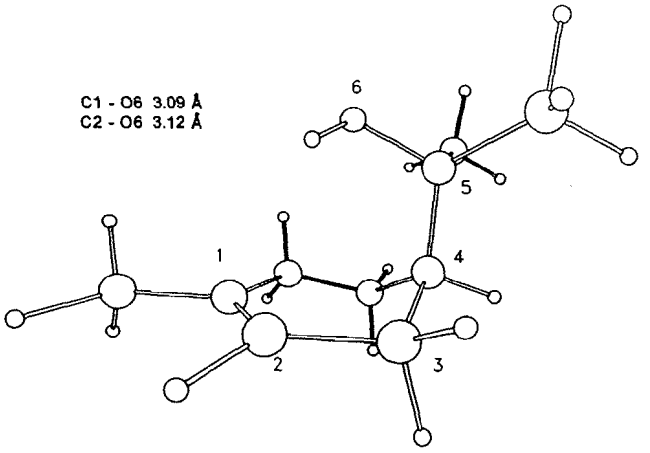
Fig. 5. (*R*)-(+)-Limonene, **21** (*axial-syn*). C1—C6, 3.54 Å. C2—C6, 3.27 Å.



The conformer required for cyclization, axial-*syn* (Fig. 5), is 7.3 kJ mol^{-1} less stable than this global minimum and is a minor (2.4% at 10°C) component of the equilibrium mixture. Furthermore, the structure of this axial-*syn* conformer is not favourably orientated for cyclization; the C1—C6 (3.54 Å) and C2—C6 (3.27 Å) distances are long. In addition, the isopropenyl π-molecular orbital (C5—C6), which must serve as the nucleophile, is not directed toward the half-filled π-bond of the radical cation (C1—C2). In view of these structural considerations, formation of 1:1:1 photo-NOCAS adducts, resulting from intermolecular nucleophilic (methanol) attack at the more heavily substituted (easier to oxidize) endocyclic double bond, without prior cyclization, is reasonable (reaction [6]).

It is interesting to compare the regio- and stereochemistry of these 1:1:1 photo-NOCAS adducts with those obtained from 1-methylcyclohexene (**29**) under analogous conditions (reaction [9]); the products from these reactions are similar. The *anti*-Markovnikov mode of addition dominates (86 and 89%) in both reactions. Coupling of the resulting β-alkoxyalkyl radical, with the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\bullet}$), occurs preferentially from the pseudo-axial position *trans* to the methoxy group; **23** and **30** are the major products. Pseudo-axial attack generally dominates during radical additions to substituted cyclohexenes (12). The initial attack of methanol on the limonene radical cation ($\mathbf{21}^{+\bullet}$) also occurs preferentially

Fig. 6. (*R*)-(+)-α-Terpineol, **22** (*axial-syn*). C1—O6, 3.09 Å. C2—O6, 3.12 Å.

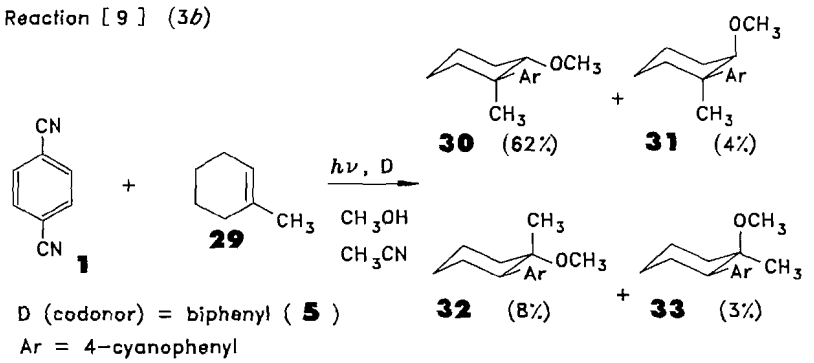


from the pseudo-axial position, of the half-chair conformer, *trans* to the equatorial isopropenyl side chain.

The radical cations of the acyclic analogues of terpineol (**22**), 6-methyl-5-hepten-2-ol ($\mathbf{13}^{+\bullet}$) and 5-methyl-5-hexen-2-ol ($\mathbf{16}^{+\bullet}$), undergo 1,5-*exo* and 1,6-*endo* cyclization under photo-NOCAS conditions (reactions [4] and [5]). The radical cation of terpineol ($\mathbf{22}^{+\bullet}$) also cyclizes both 1,5-*exo* and 1,6-*endo* (reaction [7]). Six conformers of terpineol (**22**) were identified by molecular mechanics (MM3). The conformer required for cyclization, axial-*syn* (Fig. 6), is 5.3 kJ mol^{-1} less stable than the global minimum and is a minor participant (4.9%, 10°C) at equilibrium. This conformer is nicely oriented for cyclization; the C1—O6 (3.09 Å) and C2—O6 (3.12 Å) distances are relatively short and a nonbonding pair of electrons on the oxygen (O6) is directed toward the radical cation (C1—C2). The thermal barrier for inverting the half-chair conformation of cyclohexenes is small; equilibration may occur during the lifetime of the radical cation. The preference for C2—O6 bonding, 1,5-*exo* cyclization, may be attributed to the relative stability of the intermediates. The major product (**27**) results from the *anti*-Markovnikov mode of addition, followed by coupling of the β-alkoxyalkyl radical, from the pseudo-axial position *trans* to the alkoxy group, with the dicyanobenzene radical anion ($\mathbf{1}^{-\bullet}$).

Conclusions

Knowledge of the scope and limitations of the photo-NOCAS reaction, involving methanol as the nucleophile, and of the



behaviour of alkene radical cations, continues to grow. The intramolecular reactivity of alkene radical cations, 1,5-*exo* and 1,6-*endo* cyclization, can be predicted using approach vector analysis; the favoured transition state incorporates the nucleophile and the alkene radical cation carbon atoms at the vertices of an obtuse triangle orthogonal to the plane of the π-system (4). The occurrence of cyclization can be explained/predicted on the basis of structural information obtained from molecular mechanics (MM3) calculations. These reactions have significant synthetic utility.

Experimental

General information

The ^1H and ^{13}C nmr spectra were obtained from a Bruker 250 MSL spectrometer or from a Nicolet 360 NB nmr spectrometer. Spectra were recorded in parts per million (ppm) and frequencies are reported relative to tetramethylsilane. Infrared spectra (ir) were recorded on a Nicolet 205 FTIR or on an air-purged Perkin–Elmer 180 grating spectrometer and are reported in wave numbers (cm^{-1}). Elemental analyses were performed by Canadian Microanalytical Service Ltd., B.C. Exact Mass determinations were obtained using a ZAB-E spectrometer. Measurements of optical rotation were carried out in ethanol solution on a Perkin–Elmer 141 polarimeter. Melting points were determined using a Cybron Corporation Thermolyne apparatus with a digital thermocouple and are corrected. Product yields and progress of the reactions were determined using a Hewlett–Packard (HP) 5890 gas chromatograph with a DB-1701 fused silica WCOT column (30 m × 0.25 mm, 0.25 μm film thickness) and a calibrated flame ionization detector (gc/fid) and are based upon 1,4-dicyanobenzene (**1**) as the limiting reagent. An HP 3392A integrator was interfaced with the gc/fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33 μm film thickness) interfaced with an HP 5970 mass selective detector (gc/ms) was also used for product analyses. Mass spectra are reported as *m/z* (relative intensity). Separation of product mixtures was generally carried out using preparative medium-pressure liquid chromatography (mplc) (*3b*). The mplc consists of a 2.5 cm × 1 m column packed with thin-layer chromatography (tlc) grade silica gel (without binder) (cat. no. 7747 Merck) at a pressure of 15 psi using helium (1psi = 6.9 kPa). Connected to the mplc was a uv spectrophotometer – fraction collector that collects ca. 10 mL fractions. Dry column flash chromatography (dc/fc) was also used (13). This column was also packed with thin-layer chromatography grade silica gel (without binder) (cat. no. 7747 Merck). Fraction sizes were ca. 5 mL.

Materials

Acetonitrile (Fisher ACS grade) was distilled twice, first from sodium hydride and then from phosphorus pentoxide. It was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), fractionally distilled (under nitrogen), and stored over molecular sieves (3 Å) (14). Methanol was distilled and then stored over molecular sieves (4 Å). Dicyanobenzene-1,4 (**1**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized three times from water and then dried in a vacuum oven for 15 h, 70°C, 0.25 Torr (1 Torr = 133.3 Pa). The (*R*)-(+)-limonene (**21**) (97%) was obtained from the Aldrich Chemical Co. The rotation was measured to be $[\alpha]_D^{21.5}$ +97.0 (*c* 1.26, 95% ethanol). Aldrich reports the rotation to be $[\alpha]_D^{20}$ +123 (neat). The (*R*)-(+)-α-terpineol (**22**) (99%) was obtained from the Fluka Chemika-BioChemika Co. The rotation was measured to be $[\alpha]_D^{21}$ +87.9 (*c* 2.02, absolute ethanol). Fluka reports the rotation to be $[\alpha]_D^{20}$ +85 ± 2 (neat).

Irradiations

Irradiations involving (*R*)-(+)-limonene (**21**) were carried out on solutions of 1,4-dicyanobenzene (**1**), the diene, and biphenyl (**5**) in acetonitrile–methanol (3:1). Irradiations involving (*R*)-(+)-α-terpineol (**22**) were carried out on solutions of acetonitrile with 1,4-dicyanobenzene, the alk-4-enol, and biphenyl. Solutions were irradiated in either 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, which were degassed by nitrogen ebullition. These samples were irradiated at 10°C using a CGE 1 kW medium-pressure mercury vapour lamp contained in a water-cooled Pyrex immersion well.

Cyclic voltammetric measurements

Cyclic voltammetry was used to obtain the oxidation potential of the alkenes. The apparatus has been described (15). The working electrode was a platinum sphere (1 mm diameter) and the counter electrode was a platinum wire. The reference electrode was a saturated calomel electrode (sce), which was connected to the solution (TEAP 0.1 M, acetonitrile) through a Luggin capillary. The alkene concentration was ca. 0.005 M. Since the anodic wave was irreversible, the half-wave potential was taken as 0.028 V before the anodic peak potential (8).

Formation of the methanol, (*R*)-(+)-limonene (21), 1,4-dicyanobenzene (1) photo-NOCAS adducts 23, 24, 25 and 26: reaction [6]

A solution of (*R*)-(+)-limonene (**21**) (7.8 mL, 6.6 g, 0.048 mol), 1,4-dicyanobenzene (**1**) (3.1 g, 0.024 mol), and biphenyl (**5**) (3.7 g, 0.024 mol) in acetonitrile–methanol (3:1, 240 mL) was degassed by nitrogen ebullition and irradiated for 8–10 days using a 1 kW lamp at 10°C. The solvent was removed on a rotary evaporator and the crude photolysate was separated by chromatography (mplc) using a linear solvent gradient (hexanes–dichloromethane). Further purification was achieved via additional chromatography using mplc and dc/fc. Four 1:1:1 adducts were isolated: **23**, **24**, **25**, and **26**.

Solvent effect on preferred protonation sites in nicotinate and isonicotinate anions

Jean-Claude Hallé, Jacques Lelievre, and François Terrier

Abstract: Potentiometric determinations of the two successive acidities of nicotinic and isonicotinic acids (AH_2^+) have been carried out in aqueous dimethyl sulfoxide mixtures containing up to 95% Me_2SO by volume. In both systems, the results reveal that the addition of Me_2SO induces a proton transfer from the pyridinium ring to the carboxylate group, the tautomeric equilibrium between the neutral forms of the two acids being displaced toward the zwitterionic form ($AH^{\pm}$) in aqueous solution, but toward the molecular form (AH°) in Me_2SO. An analysis of the data by means of Hammett relationships previously established for benzoïc acids over the whole range of H_2O/Me_2SO mixtures allowed the four microscopic acidity constants as well as the tautomeric equilibrium constant K_T pertaining to the complete ionization scheme of the two acids to be determined. At 20°C, there are equal populations of the tautomeric AH° and $AH^{\pm}$ species in the mixtures containing 38 and 47% Me_2SO for the nicotinic and isonicotinic systems, respectively. Hammett relationships describing the ionization behaviour of a number of substituted pyridinium cations in H_2O/Me_2SO mixtures are also discussed. Possible reasons accounting for the peculiar effects exerted by the NH_2, $CONH_2$, and COOH substituents on the process are suggested.

Key words: nicotinic and isonicotinic acids, substituted pyridines, acidities, tautomeric equilibrium, protonation sites, water – dimethyl sulfoxide mixtures.

Résumé : Les deux acidités successives des acides nicotinique et isonicotinique (AH_2^+) ont été déterminées par potentiométrie dans des milieux eau–diméthylsulfoxyde contenant jusqu'à 95% de Me_2SO en volume. L'addition de Me_2SO provoque le transfert protonique du cycle pyridinium vers le groupement carboxylate, de sorte que la forme zwittérionique $AH^{\pm}$, très majoritaire dans l'eau, cède progressivement la place à la forme moléculaire AH° qui devient unique dans le diméthylsulfoxyde. Le traitement des résultats, à l'aide des relations de Hammett d'énergie libre préalablement établies pour les acides benzoïques dans les mélanges H_2O/Me_2SO, permet les déterminations des quatre constantes microscopiques et de la constante de tautomérie K_T décrivant le schéma des ionisations successives de ces deux diacides. À 20°C, on a égalité entre les populations des formes zwittérionique ($AH^{\pm}$) et moléculaire (AH°) dans les milieux contenant respectivement 38% (acide nicotinique) et 47% (acide isonicotinique) de Me_2SO en masse. Les relations de Hammett d'énergie libre, décrivant l'ionisation d'un grand nombre de pyridines substituées dans les mélanges H_2O/Me_2SO, sont discutées. Les effets particuliers observés pour les substituants NH_2, $CONH_2$ et COOH sont analysés.

Mots clés : acides nicotinique et isonicotinique, pyridines substituées, acidités, equilibre tautomère, sites de protonation, milieux eau–diméthylsulfoxyde.

Introduction

A previous ^1H and ^{13}C nmr study has revealed that the tautomeric equilibrium between the neutral forms $AH^{\pm}$ and AH° of nicotinic acid, i.e., pyridine-3-carboxylic acid, is strongly solvent dependent (1), being largely displaced toward the zwitterionic form ($AH^{\pm}$) in aqueous solution (2–5) but almost completely biased toward the molecular form (AH°) in a 20:80 (v/v) water/dimethyl sulfoxide (Me_2SO) mixture (1). (Scheme 1). Obviously, such a structural change is expected to affect the reactivity of nicotinic acid, especially with respect to its potential ambident reactivity toward alkylating agents (6) or its behaviour as a general acid–base catalyst. This makes it of interest to know how the populations of the two tautomers $AH^{\pm}$ and AH° are progressively reversed on adding increasing amounts of Me_2SO to aqueous solutions of nicotinic acid. Also of interest are the medical uses of Me_2SO (7–11).

Scheme 1.

For other aqueous values previously reported see, for example: ref. 3 (T = 22°C; nicotinic acid: pK_{a_1} = 2.07, pK_{a_2} = 4.81, pK_A = 2.11, pK_B = 3.13, pK_C = 4.77, pK_D = 3.75, τ = 9%; isonicotinic acid: pK_{a_1} = 1.84, pK_{a_2} = 4.86, pK_A = 1.86, pK_B = 3.26, pK_C = 4.84, pK_D = 3.44, τ = 4%), and ref. 4 (t = 25°C; nicotinic acid: pK_{a_1} = 1.98, pK_{a_2} = 4.82, pK_A = 2.07, pK_B = 2.72, pK_C = 4.76, pK_D = 4.08, τ = 18%); isonicotinic acid: pK_{a_1} = 1.68, pK_{a_2} = 4.91, pK_A = 1.70, pK_B = 2.94, pK_C = 4.89, pK_D = 3.65, τ = 5%).

[b]Identical to pK_{a_2}.

[c]Identical to pK_{a_1}.

In this paper, we report a complete potentiometric analysis of the two acidities of the nicotinic acid cation AH_2^+ and of the related isomeric species derived from isonicotinic acid, i.e., pyridine 4-carboxylic acid, over the whole range of H_2O/Me_2SO mixtures. The apparent acidity constants K_{a_1} and K_{a_2} associated with the two successive deprotonation steps of AH_2^+ (eq. [1]) were determined and compared with the acidity constants associated with deprotonation of a few related monoacids, i.e., pyridinium cations and benzoic acids. On this basis we were able to estimate the various individual equilibrium constants K_A, K_B, K_C, K_D and therefore the tautomeric equilibrium constant K_T associated with Scheme 1. Our study provides a comprehensive understanding of the solvent effect on the equilibrium $AH^{\pm} \rightleftarrows AH°$ for the two isomers.

$$[1] \quad AH_2^+ \overset{K_{a_1}}{\rightleftharpoons} \underbrace{AH^{\pm} + AH°}_{AH} \overset{K_{a_2}}{\rightleftharpoons} A^-$$

Results and discussion

Table 1 summarizes the pK_{a_1} and pK_{a_2} values potentiometrically determined (see experimental section) for the two acidities of nicotinic acid and isonicotinic acid in aqueous solution as well as in a large number of aqueous Me_2SO mixtures containing up to 95.5% Me_2SO by weight (95% by volume). Table 2 gives the pK_a values measured for the ionization of a large number of substituted pyridinium and related pyrimidinium and quinolinium cations in the same media. As can be seen, the acidity of these cations is enhanced on addition of Me_2SO to the aqueous solutions, the effect being maximum for a Me_2SO content of ca. 80–85% by volume. This situation is consistent both with the few data previously reported in the literature for pyridinium cations (25) and the behaviour observed for similar NH^+/N equilibria in the anilinium (26–28) and imidazolium (29) series. Measurements of solvent transfer activity coefficients for various NR_4^+-type ions have been made (30) that have emphasized a somewhat better solvation of these cations by Me_2SO than by water, accounting for the observed decrease in the pK_a values. In contrast, it is well known that the acidity of carboxylic acids markedly decreases on transfer from aqueous to Me_2SO solutions (30, 31) as a result of the inability of Me_2SO to stabilize carboxylate anions by hydrogen-bonding solvation (30, 32). On these grounds, the influence of the Me_2SO content on the two successive deprotonations of the two nicotinic acids may be readily understood, at least qualitatively, by looking at Figs. 1. These compare the variations in the corresponding pK_{a_1} and pK_{a_2} values to those in the pK_a values for the reference acid compounds, i.e., pyridinium cation and benzoic acid.

As can be seen, changes in pK_{a_1} and pK_{a_2} of the AH_2^+ species in water-rich media ($\leq$20% Me_2SO) parallel those observed in the pK_a values of benzoic acid and pyridinium cation, respectively. Obviously this behaviour is in accord with deprotonation of AH_2^+ occurring according to path 1 of Scheme 1 and therefore with formation of the zwitterion $AH^{\pm}$ as the major species resulting from the first deprotonation process in these very aqueous media. However, it is also clear that it is the reverse situation that prevails in Me_2SO-rich mixtures

[q]Calculated (van't Hoff equation) from pK_a at 25°C (3.45) and standard enthalpy of ionization (ΔH_i^0 = 27.7 kJ mol^{-1}): reference 24.

(≥50% for nicotinic acid and ≥60% for isonicotinic acid). Then, the variations in pK_{a_1} and pK_{a_2} become closely similar to those in the pK_a values of pyridinium ion and benzoic acid, respectively. These results indicate that deprotonation of AH_2^+ now occurs according to path 2 of Scheme 1, thus confirming previous nmr observations that AH° is the predominant neutral form of nicotinic and isonicotinic acids in media of high Me_2SO content (1).

In the intermediate mixtures with a Me_2SO concentration in the range 20–60% the first deprotonation of AH_2^+ occurs concomitantly via paths 1 and 2 to yield a mixture of both tautomers $AH^{\pm}$ and AH° whose relative concentrations are governed by the equilibrium constant K_T. In such media, the measured acidity constants K_{a_1} and K_{a_2} become apparent acidity constants which are related to the four individual equilibrium constants of Scheme 1 by the following three independent equations [2]–[4].

$$[2] \quad K_A + K_B = K_{a_1}$$

$$[3] \quad \frac{1}{K_C} + \frac{1}{K_D} = \frac{1}{K_{a_2}}$$

$$[4] \quad \frac{K_B}{K_A} = \frac{K_C}{K_D} = K_T$$

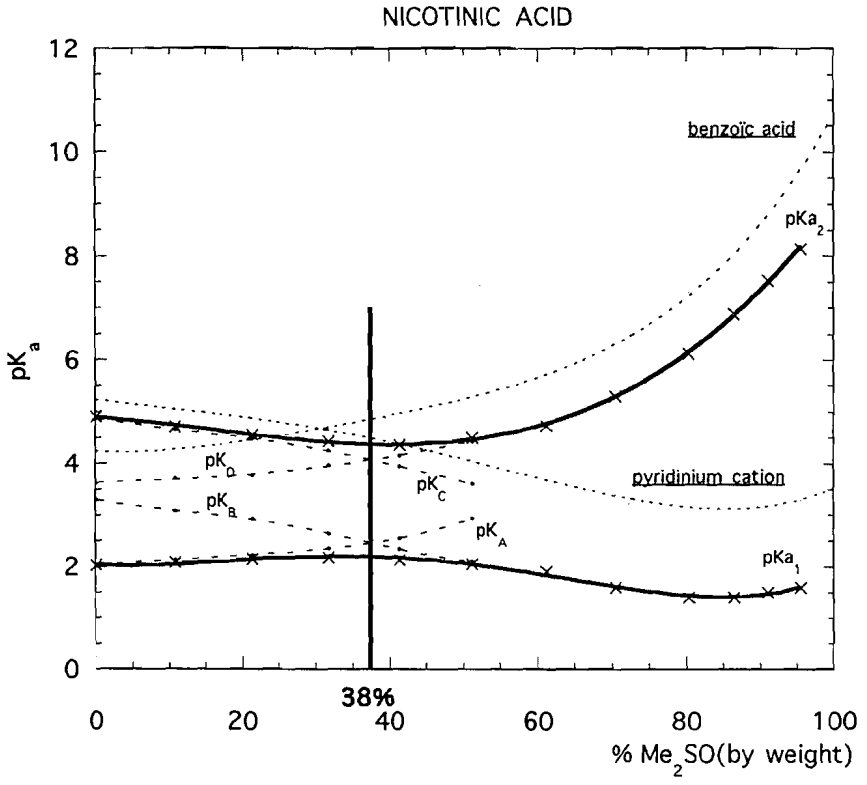
To analyze such a system, an additional relationship is needed that is usually provided by use of extrathermodynamic assumptions (33–35). However, another method has been shown to be applicable, when the acidity measurements are carried out in various aquo-organic mixtures (28, 29, 36). It is based on the experimental observation that the pK_a values determined in a given solvent S_1 for a series of structurally similar X-substituted acids (pK_X^{S1}) obeying the Hammett relationships [5] (37) are linearly related to the pK_a values measured for these acids in another solvent S_2 (pK_X^{S2}). Using eq. [5], where the influence of the solvent is included in

$$[5] \quad pK_H^S - pK_X^S = \rho^S \sigma^X$$

$$[6] \quad pK_X^{S_2} = \frac{\rho^{S_2}}{\rho^{S_1}} pK_X^{S_1} + pK_H^{S_2} - \frac{\rho^{S_2}}{\rho^{S_1}} pK_H^{S_1}$$

the reaction constant ρ^S, and eliminating the substituent constant σ_X between two solvents S_1 and S_2 affords eq. [6], which shows that plots of $pK_X^{S_2}$ vs. $pK_X^{S_1}$ must be linear with slopes

Fig. 1. Influence of solvent composition (H_2O/Me_2SO) on the measured acidity constants K_{a_1} and K_{a_2} (X—X) of the cationic forms of nicotinic and isonicotinic acids and on the microscopic constants K_A, K_B, K_C and K_D (● - - - - - ●); $t = 20°C$.



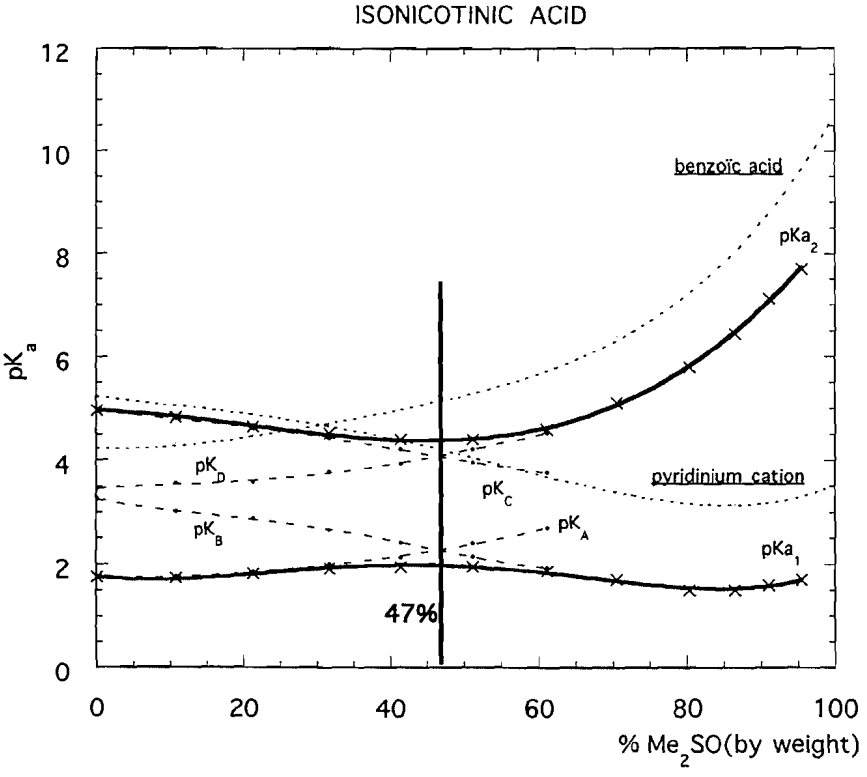


Table 3. Influence of solvent composition (H_2O/Me_2SO) on the slope and intercept values of the graph $pK_X^{H_2O/Me_2SO}$ versus $pK_X^{H_2O}$ (eq. [6]) for *meta* and *para* benzoic acids.[a]

	Percentage of Me_2SO (by weight)

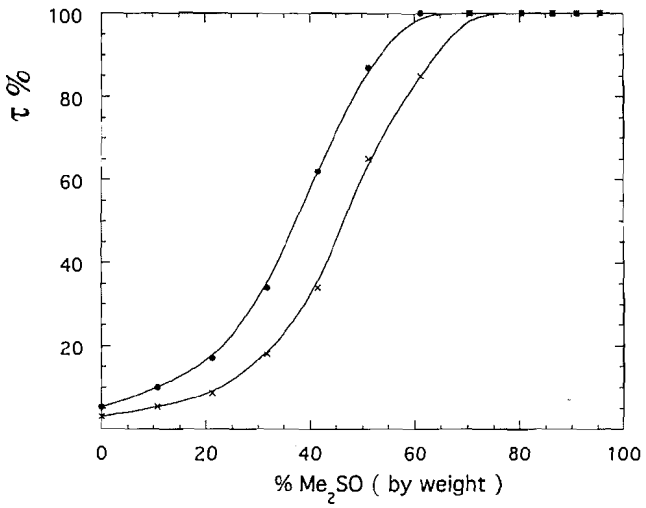
Intercepts	0.132	−0.170	−0.217	−0.426	−0.391	−0.514	−0.477	−0.590	−0.232	−0.120	+0.116
Calculated $pK_D^{H_2O}$ values for nicotinic acid	4.64	4.35	4.03	3.80	3.67	3.59	3.57	3.62	3.65	3.68	3.66
					$pK_D^{H_2O} = 3.63 \pm 0.06$						
Calculated $pK_D^{H_2O}$ values for isonicotinic acid	4.75	4.43	4.10	3.82	3.60	3.50	3.45	3.45	3.42	3.48	3.46
					$pK_D^{H_2O} = 3.46 \pm 0.04$						

[a]The slope and intercept values were calculated by linear regression analysis from previously published data (28, 29). The mean-square deviation analysis is always slower than 0.04 pK unit.

Fig. 2. Influence of solvent composition (H_2O/Me_2SO) on the percentage amount τ of molecular form AH° for nicotinic (●) and isonicotinic (X) acids; $t = 20°C$.



and intercepts being characteristic of the class of acids studied and depending only upon the solvents (28, 29, 36, 38, 39). In agreement with this expectation, the acid–base behaviour of oxygen acids like carboxylic acids and phenols (28, 38) and of nitrogen acids like anilinium (28) and imidazolium (29) cations was found to conform nicely to eq. [6] in H_2O/Me_2SO and H_2O/N-methylacetamide mixtures (39).

The similarity observed in the solvent dependence of the pK_{a_2} values for each of the two nicotinic acids studied and the pK_a value of benzoic acid at Me_2SO contents ≥50–60% suggests that the COOH functionality of AH° forms behaves, not only qualitatively but quantitatively, as that of other benzoic acids. Should this be true, the various relationships (eq. [6]) previously determined for *meta*- and *para*-substituted benzoic acids (28, 29) should hold nicely for pyridine carboxylic acids, allowing the pK_D values for ionization of the COOH groups of AH° to be calculated in water as well as in water-rich mixtures where they are not directly accessible. Such $pK_a^{H_2O} = pK_D^{H_2O}$ values estimated from eq. [6] with $pK_X^{S_2} = pK_a^{H_2O/Me_2SO}$, $pK_X^{S_1} = pK_a^{H_2O}$, are summarized in Table 3 for the two nicotinic acids (see Table 3 also for slopes and intercept values). As can be seen, the $pK_D^{H_2O}$ values obtained show remarkable consistency, affording the following average values: $pK_D^{H_2O} = 3.63 \pm 0.06$ for nicotinic acid and $pK_D^{H_2O} = 3.46 \pm 0.04$ for isonicotinic acid. Similar calculations of pK_D in all mixtures with ≤50 or 60% Me_2SO content also afforded satisfactory pK_a values for ionization of the COOH group of the AH° forms. The knowledge of pK_D in these systems is important since it makes possible to calculate the corresponding pK_A, pK_B, and pK_C values from eqs. [2]–[4]. The results are given in Table 1 and illustrated by the broken-line plots of Fig. 1. Plots of pK_A and pK_B, as well as those of pK_C and pK_D, versus the Me_2SO content, intersect in the mixtures containing 38 and 47% Me_2SO for nicotinic acid and isonicotinic acid, respectively. In these two mixtures, the tautomeric equilibrium constant, K_T, is equal to 1, with the differences between pK_{a_2} and pK_C as well as those between pK_A and pK_{a_1} fitting eq. [7] satisfactorily:

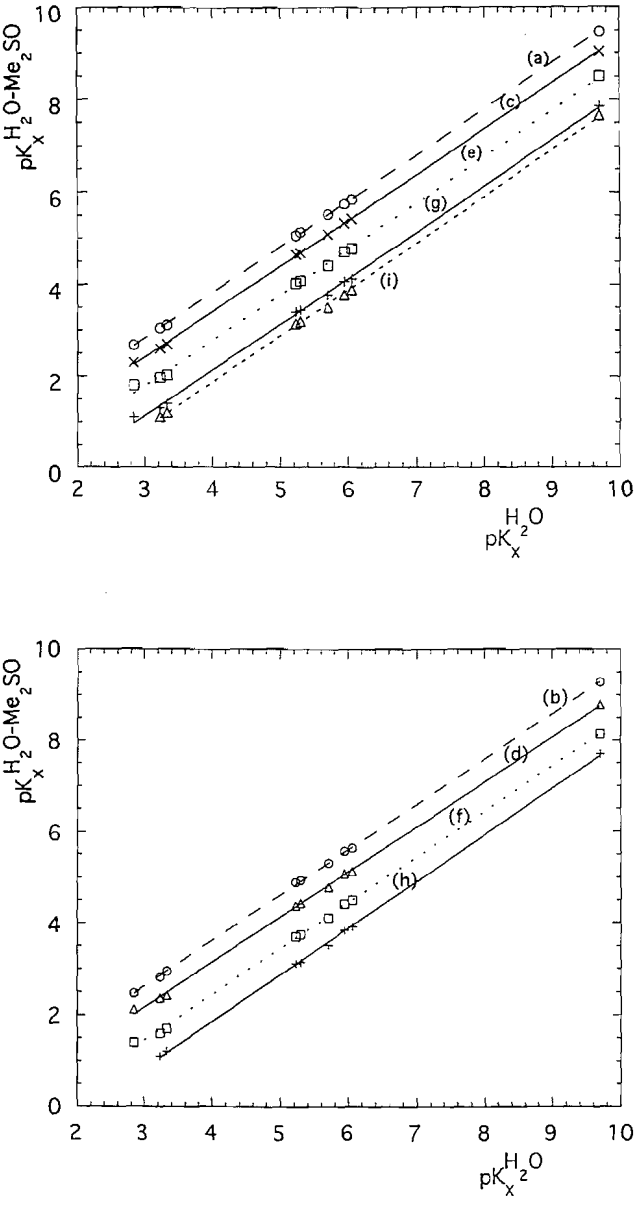
$$[7] \quad pK_{a_2} - pK_C = pK_A - pK_{a_1} = \log_{10} 2$$

$$[8] \quad \tau = \frac{100\,K_T}{1 + K_T}$$

From eq. [8], the percentages τ in the molecular forms AH° of nicotinic and isonicotinic acids have been calculated and are included in Table 1. The τ values calculated for aqueous solutions are equal to 5.3 and 3.1, respectively, at 20°C, in good agreement with those previously determined by Green and Tong at 22°C ($\tau = 9$ and 4, respectively) from a comparison of the acid–base behaviour of the two nicotinic acids with that of the related methyl esters (3). Figure 2 shows the rapid increase in the population of the molecular form with increasing Me_2SO content of the solutions. In mixtures with ≥80% Me_2SO, AH° becomes essentially the only neutral form of the two acids in the solutions, thus confirming our previous nmr observations.[1]

In principle, the determination of the various microscopic equilibrium constants K_A, K_B, K_C, and K_D in the intermediate range of Me_2SO concentrations could also derive from an estimation of the K_B values for the NH^+/N ionization of the pyri-

Fig. 3. Correlations $pK_X^{H_2O/Me_2SO}$ versus $pK_X^{H_2O}$ for substituted pyridines (see Table 2). Composition of H_2O/Me_2SO mixtures: (*a*) 10.8%, (*b*) 21.3%, (*c*) 31.7%, (*d*) 41.4%, (*e*) 51.2%, (*f*) 61.2%, (g) 70.5%, (*h*) 80.4%, (*i*) 86.4% Me_2SO (w/w). The slopes and intercepts values of the lines are available as supplementary material (Table 4); see footnote 2.



dinium ring of AH_2^+ through the use of appropriate Hammett relationships. We found, however, that a treatment of the data based on the correlation established for anilinium cations did not afford consistent results (28). This failure called for the construction of Hammett relationships pertaining directly to the behaviour of a homogeneous set of pyridinium cations and related heterocyclic cations in H_2O/Me_2SO mixtures (Table 2).

Prior to discussing the Hammett behaviour of these cations, some general features regarding the results summarized in Table 2 are worth mentioning. In a general way, our measured $pK_a^{H_2O}$ values are in excellent agreement with previous reports. Also, the pK_a values measured for the 2-aminopyridinium cation in H_2O/Me_2SO mixtures are fully consistent with previous determinations by Pawlak and Bates in these media (25). In contrast, our $pK_a^{H_2O/Me_2SO}$ values for the unsubstituted pyridinium cation differ notably from those reported by Gowland and Schmid in mixtures with $\leq$50% Me_2SO (40). Extrapolation of the pK_a values that we measured over the range 0–95% Me_2SO to pure Me_2SO (see Fig. 1) leads, however, to a $pK_a^{Me_2SO}$ value in good agreement with that directly determined by Benoit et al. in this solvent (24).

Another noteworthy result is that the acidity of all heterocyclic cations studied in this work increases continuously upon addition of Me_2SO up to 80–85% by weight, i.e., a mole fraction of $\approx$ 0.5. This behaviour is the same as that previously found for other NH^+/N acids such as anilinium (28) and imidazolium (29) cations. As shown by Fig. 3, the various $pK_X^{H_2O/Me_2SO}$ vs. $pK_X^{H_2O}$ plots are essentially parallel, with slopes being equal or very close to unity (see Table 4 in supplementary material[2]). Such a solvent independence of the reaction constant ρ^S is not surprising in itself – similar behaviour was previously observed for imidazolium cations (29) — but it implies that the difference in the acidity of two given compounds in the series remains the same over the whole range of Me_2SO concentrations. In this respect, it is interesting to note that the difference in the pK_a values for the NH^+/N ionization of nicotinium cation (pK_B, Table 1) and the related ethyl ester (Table 2) does not follow this behaviour well: the ΔpK value increases from $\leq$0.1 in water-rich media to $\approx$0.3 in Me_2SO-rich media. Obviously, the variation is not large and one might argue that it is the result of experimental error rather than of a specific behaviour of the COOH group. It turns out, however, that eq. [6] was never found to apply correctly when NH^+/N equilibria activated by a COOH group are involved in the correlations. The failure of 3-amino benzoïc acid (28) and urocanic acid (29) to enter the general relationships established for anilinium and imidazolium cations, respectively, is very illustrative for this situation. This suggests that the solvation of the COOH substituent is affected by the addition of Me_2SO to such an extent that it modifies the pK_a variations brought about by the solvent effect on the NH^+/N equilibria. This would explain why our data for nicotinic and isonicotinic acids cannot be satisfactorily analysed on the basis of the NH^+/N acidity behaviour of the common pyridinium cation. Interestingly, the log value of the solvent activity coefficients γ_t for the transfer of acetic acid from water to 90% Me_2SO has been measured: $\log \gamma_t = -1{,}5$ (41). Such a value supports the idea that the solvent change must affect the role of the COOH group. The abnormal behaviour of the 3-$CONH_2$ pyridinium cation may be explained along similar lines.

Other pyridinium compounds whose ionization does not fit the Hammett relations of eq. [6] are the 2-amino and 4-amino pyridinium cations.

Interestingly, an unexpected ionization behaviour of these compounds was previously observed in nonaqueous (42) and aqueous (43) solutions as well as in the gas phase (44). This was explained in terms of a strong contribution of the iminium structures **1** and **2** to the stabilization of the parent cations (42–44).

1 2

It turns out, however, that this explanation is not consistent with our finding that the 4-*N*,*N*-dimethylaminopyridinium cation obeys nicely the correlations of eq. [6]. On the other hand, it has been shown that 4-aminopyridine essentially exists in the amino form **3** in aqueous (ref. 33, pp. 152–154; refs. 45, 46) as well as in Me_2SO (47, 48) solution. Hence, an explanation of the peculiar ionization behaviour of the 4-amino (and 2-amino) pyridinium cation on the basis of a strong dependence of the tautomeric equilibrium of eq. [9] upon the Me_2SO concentration does not appear very attractive.

[9] 
3 4

In contrast, it is well known that the solvation of a primary ammonium group is very important and strongly affected by a transfer from a protic to a dipolar aprotic solvent. Thus, the log value of the solvent activity coefficient γ_t for the transfer of the *n*-butylammonium cation from water to 90% Me_2SO is -2.8 (41), indicating a much stronger stabilization of this species in Me_2SO rich mixtures. This suggests that the contribution of the NH_3^+ substituent must counteract to some extent the increase in acidity observed for other pyridinium cations. This behaviour is actually observed in Table 2 since the decrease in the pK_a values is $\cong$2.0 for pyridinium cations obeying eq. [6] but only $\cong$1.19 and 1.36 for the 4-amino and 2-amino pyridinium cations.

Our feeling is therefore that the abnormal behaviour of the two cations is for the most part the reflection of these solvation effects.

Experimental

Materials

Pyridine and pyrimidine derivatives were commercially available products that were purified according to standard recrystallization or distillation procedures.

Water and dimethyl sulfoxide (Chimiphar) were purified and their mixtures prepared as described earlier (49, 50).

Acidity constant measurements

Thermodynamic pK_a values were determined by potentiometry at 20°C, using an electronic pH meter (Tacussel Isis 20 000) equipped with a Tacussel TB/HA glass electrode and a Tacussel C8 saturated calomel electrode. The experimental procedure was previously described in detail (28, 29, 39, 49, 50).

Asymmetric synthesis of taxol and taxotère side chains by enolate hydroxylation

Stephen Hanessian and Jean-Yves Sancéau

Abstract: We report an asymmetric synthesis of the taxol and taxotère side chains by hydroxylation of enolates derived from N-substitued methyl 3-amino-3-phenyl propionate with the oxodiperoxymolybdenum (pyridine) (hexamethyl phosphoric triamide) complex (MoOPH).

Key words: taxol and taxotère side chains, hydroxylation.

Résumé : Nous décrivons une synthèse asymétrique des chaînes latérales du taxol et du taxotère par hydroxylation des énolates dérivés d'esters de l'acide 3-amino-3-phénylpropionique L-homo-phénylglycine au moyen du complexe oxodiperoxopyridino (hexaméthylphosphoramido) molybdène (MoOPH).

Mots clés : chaines latérales du taxol et du taxotère, hydroxylation.

Introduction

Taxol **1**, a complex diterpene isolated from the bark of *Taxus brefivolia* (1), and taxotère **2** a semi-synthetic analog (2), are currently considered to be among the most promising anticancer agents (3) (Fig. 1). Their clinically demonstrated effectiveness has stimulated considerable effort in total and analog synthesis (3), as well as in the development of efficient syntheses of the (2*S*,3*R*)-3-phenyl isoserine ester moiety at C-13 that is crucial for bioactivity. The synthetic approaches to this amino acid are centered around the use of chiral glycidate esters (4), opening of β-lactam rings derived from cycloaddition reactions (5), aldol condensations (6), and homologation of *(S)*-phenylglycine (7), intermediates derived from asymmetric dihydroxylation (8), or enzymes (9). With a few exceptions (4*a*, 4*d*), the methods involving glycidic esters and dihydroxycinnamic esters have relied principally on azide ion as a source of nitrogen. To the best of our knowledge only two methods are based on the introduction of the 2-hydroxyl group by hydroxylation of an enolate (10*a*,*b*). Our recent studies on stereocontrolled oxidation of enolates (11) derived from L-aspartic and glutamic acid derivatives (12) prompted us to extend our methodology to the synthesis of the taxol and taxotère side chains. In this paper we describe a stereocontrolled synthesis of methyl esters **6***a* and **6***b* by direct oxidation of β-aminoesters **5***a* and **5***b* using MoOPH as an electrophilic source of oxygen (Scheme 1).

Results

Methyl 3-amino-3-phenyl propionate **4** of high enantiomeric purity (>95%) was obtained from the corresponding acid **3** by resolution with D-tartaric acid following a literature procedure (13*a*). Benzoylation of **4** with benzoyl chloride, or treatment with di-*tert*-butyl dicarbonate in the presence of sodium bicarbonate furnished the N-protected derivatives **5***a* and **5***b* in 75% yield in each case.

Initially, we investigated the hydroxylation of the enolate dianions of **5***a* and **5***b* using racemic 2-phenylsulfonyl-3-phenyloxaziridine (14). Davis et al (10*b*) recently reported that reaction of the lithium dianion of **5***a* generated in the presence of LDA and LiCl with (+)-(camphorsulfonyl)oxaziridine at −100°C to −78°C afforded a preponderance of the desired *syn* isomer **6***a* (*syn/anti* 86:14). In an independent study, we had observed that treatment of the potassium enolate (KHMDS, −78°C to −25°C) of **5***a* with 2-phenylsulfonyl-3-phenyloxaziridine at −60°C led to a 86:14 *syn/anti* mixture in 65% yield. However, similar treatment of the potassium enolate of **5***b* proceeded with only moderate diastereoselectivity in favor of the *anti* isomer (*syn/anti* 40:60) in 62% yield. To clarify this intriguing reversal of selectivity, other metals were examined as counterions. Although the sodium enolate generated with NaHMDS gave a similar ratio (*syn/anti* 35:65), the use of LiHMDS furnished the highest *anti* selectivity (*syn/anti* 10:90). The sense of chiral induction with **5***a* can be rationalized according to Davis et al. (10*b*) where the potassium enolate, which may exist as an eight-membered ring **I** (Scheme 2), is preferentially attacked from the less hindered face of the

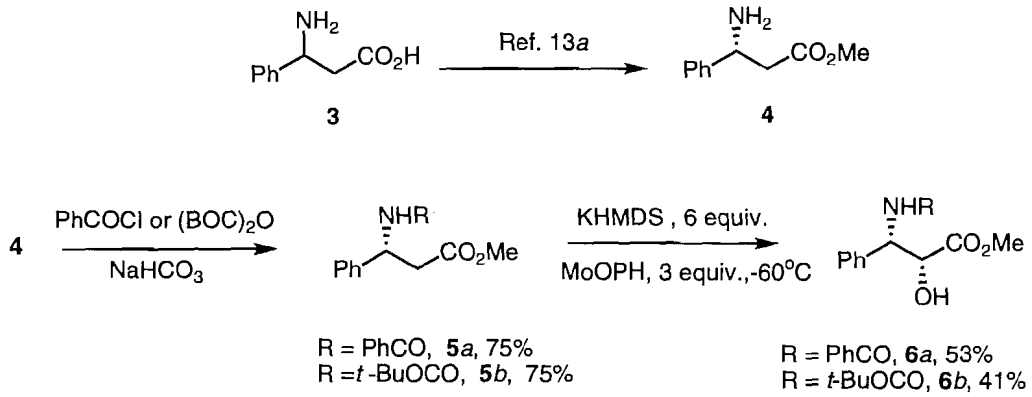
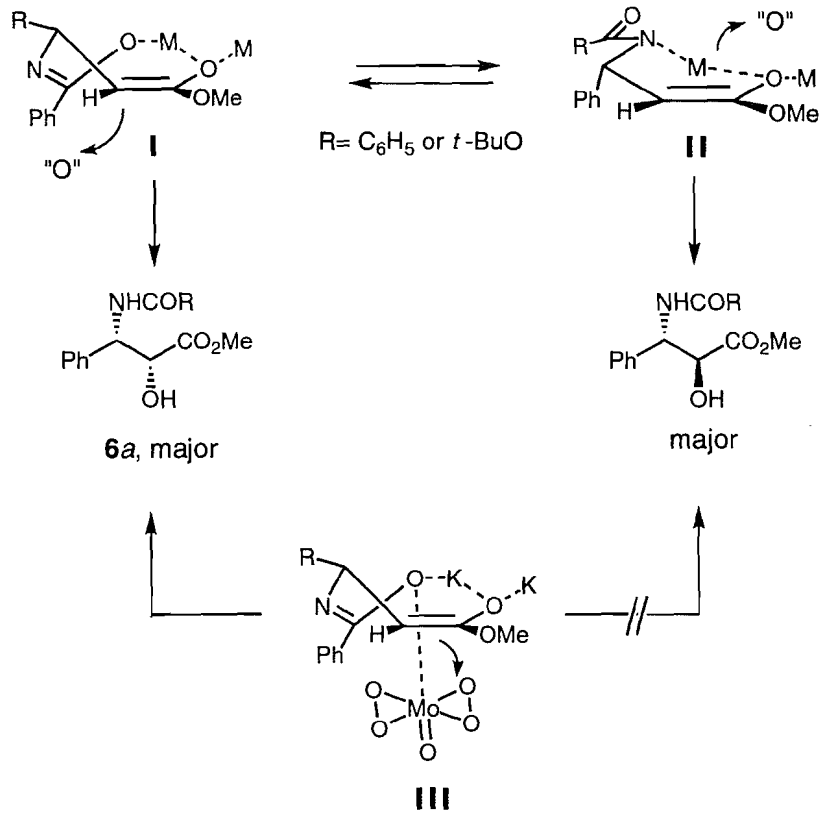


Scheme 2.



enolate, resulting in the formation of the *syn* hydroxylated product **6***a*. On the other hand, it is possible that the enolates of the carbamate derivative **5***b* preferentially adopt a six-membered ring chelate **II** resulting in a reversal of selectivity.

To improve the *syn* selectivity, we examined hydroxylations of **5***a* and **5***b* with MoOPH (15) in anticipation of an "internal" delivery of oxygen (12). Reaction of the potassium enolate derivative of **5***a* (KHMDS, −78°C to −25°C) with MoOPH (3 equiv.) was carried out at −60°C to give **6***a* as a 86:14 *syn/anti* mixture in 83% after column chromatography. The minor *anti* isomer can be removed almost quantitatively by one recrystallization from $CHCl_3$, yielding the expected amino acid **6***a* in 53% yield. The enantiomeric purity of this material was determined to be >97% by ^1H NMR and ^{19}F NMR analysis of its Mosher ester (16). Interestingly, treatment of the potassium enolate of **5***b* with MoOPH also proceeded with *syn* selectivity (*syn/anti* 86:14) in 65% yield. The taxotère side chain **6***b* could be isolated as a single diastereoisomer after two chromatographic purifications in 41% yield (ee >95% determined by analysis of ^1H NMR and ^{19}F NMR of Mosher ester derivative). The preponderance of the *syn* product in hydroxylations of **5**a and **5***b* with MoOPH can be rationalized by an initial coordination of the MoOPH reagent with the amide or carbamate groups (N or O) followed by an intramolecular delivery of oxygen as depicted in Scheme 2, expression **III** (12).

Previous examples of related enolate hydroxylations have utilized chiral non-racemic oxaziridine reagents derived from camphor (10*a*,*b*). As mentioned above, the Davis method (10*b*) generates the lithium enolate in the presence of lithium chloride (−42°C), and temperatures of −100°C to −78°C are needed for the stereoselective hydroxylation. Davies and co-

workers (10*a*), on the other hand, produce the *anti* isomer as a result of a mismatched reagent combination, which has to be inverted by a Mitsunobu protocol to give the desired *syn* product.

In summary, we have demonstrated that MoOPH can be an alternative reagent to provide the side-chain amino acids in taxol and taxotère in enantiomerically pure form. In both examples of hydroxylation, it was necessary to use more than stoechiometric amounts of base in order to achieve the yields quoted above.

Experimental

Tetrahydrofuran was distilled over benzophenone and potassium prior to use. Analytical thin-layer chromatography (TLC) was carried out on Merck Kieselgel silica gel 60 F_{254} glass plates. ^{1}H nuclear magnetic resonance spectra at 400 MHz were obtained on a Bruker WH-400 spectrometer. ^{1}H multiplicities are recorded by use of the following abbreviations: s, singlet; d, doublet; m, multiplet; br, broad; *J*, coupling constant (Hz). High-resolution FAB mass spectra were obtained by means of Kratos MS5OTCTA and AEI-MS 902 spectrometers at the Université de Montréal. Optical rotations were measured on a Perkin–Elmer 241 polarimeter at 25°C.

Melting points were measured on Büchi apparatus and are uncorrected. Column chromatography was done using the flash technique (17).

(3*R*)-Methyl-3-amino-3-phenylpropionate (4)

The procedure described by Wasserman and Berger (13*a*) for the preparation of (3*S*)-**4** was followed. A solution of (±)-**4** (3.8 g, 21.2 mmol) in MeOH was added in one portion to a refluxing solution of D-tartaric acid in MeOH (20 mL). After cooling overnight at −5°C, the white crystals were filtered off, mp 168–169°C; $[\alpha]_D$ −16.9 (*c* 3, H_2O). Recrystallization of this material from MeOH (20 mL) gave the D-tartrate salt (35–40% yield), which was recrystallized to constant physical properties; mp 169–170°C; $[\alpha]_D$ 19.3 (*c* 3, H_2O) (lit. (13*b*) mp 169–171°C; $[\alpha]_D$ −20.2 (*c* 7, H_2O)); ^{1}H NMR (D_2O) δ: 3.15 (dd, 2H), 3.67 (s, 3H), 4.49 (s, 2H), 7.47 (s, 5H). A solution of the above salt (3.72 g, 11.3 mmol) was treated with 1 N NaOH, affording **4** (1.7 g, 84%) as a colorless oil; bp 175–180°C (5 Torr (1 Torr = 133.3 Pa), Kugelrohr); $[\alpha]_D$ +11.6 (neat); (lit. (13*b*) $[\alpha]_D$ +12.1 (neat); lit. (13*c*) $[\alpha]_D$, +22.3 (*c* 1.99, $CHCl_3$)). ^{1}H NMR ($CDCl_3$) δ: 1.77 (s, 2H), 2.6 (d, 2H), 3.67 (s, 3H), 4.4 (m, 1H), 7.33–7.34 (m, 5H). The enantiomeric purity was detemined to be >95% by ^{1}H and ^{19}F NMR analysis of the corresponding Mosher ester derivative.

(3*R*)-*N*-Benzoyl-methyl-3-amino-3-phenylpropionate (5*a*)

To a stirred emulsion of **4** (204 mg, 1.14 mmol) and $NaHCO_3$ (163 mg) in CH_2Cl_2–H_2O (2:2 mL) was added freshly distilled benzoyl chloride (192 mg, 1.36 mmol). After vigorous stirring overnight, the aqueous phase was extracted three times with CH_2Cl_2 (20 mL). The combined organic layers were washed with brine, dried ($MgSO_4$), and evaporated. The resulting white solid was recrystallized from CH_2Cl_2–Et_2O (1:3), giving white needles of **5***a*, (244 mg, 75%); mp 120–121°C; $[\alpha]_D$ −20.2 (*c* 1.17, $CHCl_3$). ^{1}H NMR ($CDCl_3$) δ: 3 (dd, *J* = 5.6 Hz, *J* = 15.7 Hz, 2H), 3.65 (s, 3H), 5.64 (dd, *J* = 5.6 Hz, *J* = 8.4 Hz, 1H), 7.34–7.35 (m, 8H), 7.83–7.86 (d, 2H). MS (EI) *m/z*: 105 (100), 178 (15), 210; HRMS calcd. for $C_{17}H_{17}NO_3$: 283.3268; found: 283.2103.

(3*R*)-*N*-(*tert*-Butoxycarbonyl)-methyl-3-amino-3-phenylpropionate (5*b*)

To a stirred emulsion of **4** (767 mg, 4.3 mmol) and $NaHCO_3$ (363 mg) in CH_2Cl_2–H_2O (2:2 mL) was added di-*tert*-butyl dicarbonate (938 mg, 4.3 mmol). After vigorous stirring overnight, the aqueous phase was extracted three times with CH_2Cl_2 (20 mL). The combined organic layers were washed with brine, dried ($MgSO_4$), and evaporated. The resulting white solid was purified by column chromatography with 30% EtOAc – hexanes to provide **5***b* (905 mg, 75%) as white needles, mp 92–94°C; $[\alpha]_D$ +28 (*c* 1.1, $CHCl_3$); ^{1}H NMR ($CDCl_3$) δ: 1.4 (s, 9H), 2.82 (m, 2H), 3.6 (s, 3H), 5.1 (br s, 1H), 5.45 (br s, 1H), 7.2–7.4 (m, 5H); MS (EI) *m/z*: 83, 106, 150, 163, 223; HRMS calcd. for $C_{11}H_{13}NO_4$ (M – isobutylene)$^+$: 223.1332; found: 223.0845.

(2*R*,3*S*)-*N*-Benzoyl-3-phenylisoserine methyl ester (6*a*)

To a solution of KHMDS (0.5 M in toluene, 40 mL, 20 mmol, 6 equiv.) in dry THF (10 mL) was added dropwise at −78°C a solution of **5***a* (1g, 3.5 mmol) in THF (30 mL). The reaction mixture was warmed up to −25°C, stirred at this temperature, and then cooled back to −78°C. Freshly prepared MoOPH (15) (2.9 g, 5.25 mmol) was added in one portion. The resulting green solution was stirred at −60°C for 3 h, then quenched with saturated Na_2SO_3 (10 mL) followed by saturated NH_4Cl. The mixture was warmed up to room temperature and stirred until dissolution of the solids. The aqueous layer was extracted with THF (25 mL). The combined organic layers were washed successively with a mixture of 10% HCl – brine (1:1, 10 mL), 2% Na_2CO_3, brine, and dried over Na_2SO_4. After removal of the solvent, flash chromatography with 5% ether in CH_2Cl_2 gave unreacted ester **5***a* (50 mg), then **6***a* (86:14 *syn/anti* mixture by ^{1}H NMR, 833 mg, 84% yield based on consumed ester **5***a*). Recrystallization of this mixture from $CHCl_3$ yielded white needles of taxol side chain methyl ester **6***a* (560 mg, 53%), mp 180–181°C; $[\alpha]_D$ −47.5 (*c* 0.99, MeOH) (lit.(1) mp 184–185°C; $[\alpha]_D$ −49.6; lit.(4*g*) mp 184–185°C; $[\alpha]_D$ −48.1). ^{1}H NMR ($CDCl_3$) δ: 3.25 (br s, 1H), 3.86 (s, 3H), 4.65 (d, *J* = 1.83 Hz,1H), 5.76 (dd, *J* = 9.15 Hz, *J* = 1.83 Hz, 1H), 6.98 (d, *J* = 9.2 Hz, 1H); 7.3–7.6 (m, 8H), 7.7–7.8 (d, 2H). ^{1}H NMR and ^{19}F NMR analysis of this material showed the presence of small amounts of the *anti* diastereoisomer (<5%) and confirmed the enantiomeric purity (>97%).

(2*R*,3*S*)-*N*-(*tert*-Butoxycarbonyl)-3-phenylisoserine methyl ester (6*b*)

To a solution of KHMDS (0.5 M in toluene, 24 mL, 12 mmol, 6 equiv.) in dry THF (10 mL) was added dropwise at −78°C a solution of **5***b* (558 mg, 2 mmol) in THF (30 mL). The reaction mixture was warmed up to −25°C, stirred at this temperature, and then cooled back to −78°C. Freshly prepared MoOPH (1.3 g, 6 mmol, 3 equiv.) was added in one portion. The resulting green solution was stirred at −60°C for 3 h, then quenched with saturated Na_2SO_3 (10 mL) followed by saturated NH_4Cl. The mixture was warmed up to room temperature and stirred until dissolution of the solids. The aqueous layer was extracted with THF (25 mL). The combined organic layers were washed successively with a mixture of 10% HCl – brine (1:1, 10 mL),

2% Na_2CO_3, and brine, and dried over Na_2SO_4. After removal of the solvent, flash chromatography with 1% ether in CH_2Cl_2 gave **6***b* (86:14 *syn/anti* mixture by ^1H NMR) (383 mg, 65% yield based on consumed ester **5***b*). Two chromatographic purifications of this mixture with 20% EtOAc – hexanes provided the taxotère side–chain methyl ester **6***b* (240 mg, 41%) as white needles, mp 128–129°C; $[\alpha]_D$ −6.6 (*c* 1.1, $CHCl_3$) (lit. (4*g*) mp 130.5–131.5°C; $[\alpha]_D$ −7 (*c* 1.2, $CHCl_3$)). ^1H NMR ($CDCl_3$) δ: 1.4 (br s, 9H), 3.12 (br s, 1H), 3.84 (s, 3H), 4.47 (br s, 1H), 5.21 (d, 1H), 5.4 (d, 1H), 7.3–7.6 (m, 8H), 7.25–7.4 (m, 5H). ^1H NMR and ^{19}F NMR analysis of this material showed the presence of only one diastereisomer and confirmed the enantiomeric purity (>95%).

Correlation analysis of reactivity in the addition of substituted benzylamines to β-nitrostyrene

Neeta Jalani, Seema Kothari, and Kalyan K. Banerji

Abstract: The kinetics of addition of a number of *ortho*-, *meta*-, and *para*-substituted benzylamines to β-nitrostyrene (NS) in acetonitrile have been studied. The reaction is first order with respect to NS. The order with respect to the amine is higher than one. It has been shown that the reaction follows two mechanistic pathways, uncatalyzed and catalyzed by the amine. The Arrhenius activation energy for the catalyzed path is negative, indicating the presence of a pre-equilibrium (k_1, k_{-1}) leading to the formation of a zwitterion. The values of the rate constant, k_1, for the nucleophilic attack have been determined for 28 benzylamines. The rate constant k_1 was subjected to correlation analysis using Charton's LDR and LDRS equations. The polar regression coefficients are negative, indicating the formation of a cationic species in the transition state. The reaction is subject to steric hindrance by *ortho* substituents.

Key words: nucleophilic addition, benzylamines, correlation analysis, kinetics, alkene.

Résumé : On a étudié la cinétique de l'addition d'un certain nombre de benzylamines *ortho*-, *méta*- et *para*-substituées sur le β-nitrostyrène (NS) en solution dans l'acétonitrile. La réaction est du premier ordre en NS. L'ordre par rapport à l'amine est supérieur à un. On a montré que la réaction suit deux voies mécanistiques, l'une qui n'est pas catalysée et l'autre qui est catalysée par l'amine. L'énergie d'activation d'Arrhénius pour la voie catalysée est négative; ceci indique la présence d'un pré-équilibre (k_1, k_{-1}) conduisant à la formation d'un zwitterion. On a déterminé les valeurs pour les constantes de vitesse, k_1, pour l'attaque nucléophile par 28 benzylamines. Les constantes de vitesses, k_1, ont été soumises à une analyse de corrélation à l'aide des équations LDR et LDRS de Charton. Les coefficients de régression polaire sont négatifs, ce qui indique qu'il y a formation d'une espèce cationique dans l'état de transition. La réaction est sujette à l'empêchement stérique des substituants en *ortho*.

Mots clés : addition nucléophile, benzylamines, analyse de corrélation, cinétique, alcène.

[Traduit par la rédaction]

Introduction

Synthetic and mechanistic studies of additions to an activated carbon–carbon double bond are of immense importance. A number of reports about the addition of charged nucleophiles to activated systems have been published (1–4). However, not many reports are available about the addition of neutral nucleophiles to activated double bonds (5–10). In this paper, we report the addition of a number of monosubstituted benzylamines to β-nitrostyrene (NS). Attempts have been made to correlate rate and structure in this reaction. Mechanistic aspects are discussed.

Experimental

Materials

NS was prepared by the reported method (11). Its purity was checked by melting point. The preparation, purification, and specification of the substituted benzylamines have already been described (12). Acetonitrile was purified by the usual methods (13).

Received November 7, 1995.

Product analysis

Benzylamine (5.85 g, 0.05 mol) and NS (1.49 g, 0.01 mol) were made up to 100 mL in acetonitrile and kept for ca. 12 h to ensure completion of the reaction. The solvent was removed by distillation under reduced pressure. The product was characterized as 1-benzylamino-1-phenyl-2-nitroethane [PhCH($PhCH_2NH$)CH_2NO_2] on the basis of its ^1H NMR spectrum. The ^1H NMR spectrum (in $CDCl_3$) of the product exhibited signals for the CH and CH_2 groups at δ 3.25 [PhCH($PhCH_2NH$)-] and 4.0 (-CH_2NO_2), respectively.

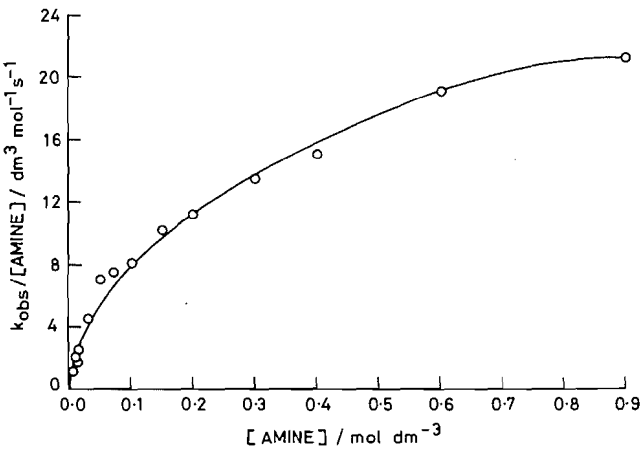
Kinetic measurements

The reaction was studied under pseudo-first-order conditions by keeping a large excess (×10 or greater) of benzylamine over NS. The solvent was acetonitrile. The reaction was followed spectrophotometrically by monitoring the decrease in NS concentration at 311 nm for ca. 80% reaction. The pseudo-first-order rate constant, k_{obs}, was evaluated from the linear ($r > 0.990$) plot of log [NS] versus time. Duplicate kinetic runs showed that the rate constants were reproducible to within ±3%.

Results and discussion

Rate laws and other data were obtained for all the compounds investigated. Since the results are similar, only representative data are reproduced here.

Fig. 1. Plot of k_{obs}/[amine] versus [amine] for the reaction of β-nitrostyrene with benzylamine.



The overall reaction may be represented as eq. [1].

[1] $ArCH_2NH_2 + Ph—CH=CH(NO_2) \rightarrow Ph—CH(NHCH_2Ar)—CH_2(NO_2)$

The reaction is first order with respect to NS. Further, the pseudo-first-order rate constant, k_{obs}, does not vary with the initial concentration of NS. Values of k_{obs} increase with an increase in the concentration of amine and the apparent order in [amine] is higher than one. Results are given in Tables 1 and 2, respectively.

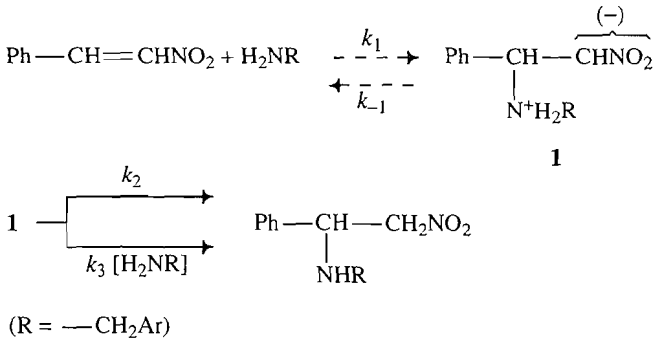
A plot of k_{obs}/[amine] versus [amine] is curvilinear (Fig. 1) with a decrease in slope with increase in amine concentration. However, at low [amine] (≤0.05 mol dm^{-3}), the dependence of k_{obs} on the amine concentration has the following form:

[2] $k_{obs}/[amine] = k + k_c\,[amine]$

This indicates that the addition of benzylamine to NS is catalyzed by a second molecule of the amine and k and k_c are the rate constants of the uncatalyzed and catalyzed reactions, respectively. The values of k and k_c were determined at different temperatures and the activation parameters evaluated are recorded in Table 3. It is observed that while the rate for the uncatalyzed path (k) increases with a rise in temperature, the rate for the catalyzed path (k_c) decreases. Thus the enthalpy of activation of the catalytic route is negative. This may be explained by assuming the presence of a pre-equilibrium in the reaction so that k and k_c are not the rate constants of elementary processes but are composite values.

It is seen that eq. [2] describes the dependence of k_{obs} on amine concentration only for low amine concentration. When the amine concentration is increased, the slope of the curve showing the dependence of the ratio k_{obs}/[amine] on [amine] decreases regularly (downward curvature). Thus a mechanism involving formation of a zwitterionic intermediate in the pre-equilibrium with its subsequent decomposition into the product, via a proton transfer, by two parallel routes, i.e., catalyzed and uncatalyzed, is proposed (Scheme 1). This assumption is also supported by observed large negative values of the entropy of activation. As the formation of the zwitterionic intermediate involves a high degree of charge distribution, solvation of two charged sites must result in large entropy losses.

Scheme 1.



The application of the steady-state treatment to this mechanism gives eq. [3].

[3] $$k_{obs}/[amine] = \frac{k_1\,(k_2 + k_3[amine])}{k_{-1} + k_2 + k_3[amine]}$$

Calculation of rate constants

The linear dependence of k_{obs}/[amine] on amine concentration suggests that $k_{-1} \gg k_3$[amine]. Further, $k_2 \leq k_{-1}$ because, if $k_2 \gg k_{-1}$, no catalysis will be observed as the nucleophilic attack is the rate-determining step, i.e., $k_{obs}/[amine] = k_1$. In the analysis of a kinetic equation of type [3] the condition $k_{-1} \gg k_2 + k_3$[amine] has generally been observed (14) and the observed second-order rate constant can be described by eq. [4], which is similar to eq. [2].

[4] $k_{obs}/[amine] = (k_1/k_{-1})(k_2 + k_3[amine])$

Thus, the constants k and k_c are expressed by eqs. [5] and [6], respectively.

[5] $$k = \frac{k_1 k_2}{k_{-1}}$$

[6] $$k_c = \frac{k_1 k_3}{k_{-1}}$$

At $k_{-1} \approx k_3$[amine] a curvilinear dependence of the second-order rate constant on the amine concentration (≥0.07 mol dm^{-3}) occurs according to eq. [3].

For reactions of the amines in which the difference between the constants k_1 and k is not less than one order of magnitude, the approximation [7] is quite acceptable (8).

[7] $$\frac{1}{(k_{obs}/[amine] - k)} \approx \frac{1}{k_1} + \frac{1}{k_c[amine]}$$

A plot of $(k_{obs}/[amine] - k)^{-1}$ against $[amine]^{-1}$ is a straight

line. The inverse of the intercept gives the rate constant, k_1, of the nucleophilic attack by amine on NS.

Correlation analysis of reactivity

The kinetics of the addition of benzylamine and 27 mono-substituted benzylamines to NS were studied. The kinetics were similar in all cases. The rate constants, k_1, at different temperatures were evaluated. The activation parameters were also calculated. The results are reported in Table 4.

The values of log k_1 at 288 K and at 318 K of the 28 amines are linearly related (r^2 0.9983, slope 0.8275 ± 0.0069). The value of the isokinetic temperature, obtained from the slope of this plot (15), is 636 ± 3 K. The linear correlation implies that all the amines react with the same mechanism (15). Further, a linear isokinetic relationship is a necessary condition for the validity of linear free energy relationships.

In the 1980s, Charton and Charton (16) introduced a triparametric LDR equation for the quantitative description of structural effects on chemical reactivities. It has the advantage of not requiring a choice of parameters, as the same three substituent constants are reported to cover the entire range of electrical effects of substituents. In this work we have applied the LDR equation, eq. [8], to the rate constant, k_1.

$$[8] \quad \log k_1 = L\sigma_1 + D\sigma_d + R\sigma_e + h$$

Here, σ_1 is a localized (field and (or) inductive) effect parameter, σ_d is the intrinsic delocalized (resonance) electrical effect parameter when active site electronic demand is minimal, and σ_e represents the sensitivity of the substituent to change in electronic demand by the active site. The latter two substituent parameters are related by eq. [9].

$$[9] \quad \sigma_D = \eta\sigma_e + \sigma_d$$

where η represents the electronic demand of the reaction site, which is given by $\eta = R/D$, and σ_D represents the delocalized electrical parameter of the diparametric LD equation.

For *ortho*-substituted compounds, it is necessary to account for the possibility of steric effects and Charton (16), therefore, modified the LDR equation to the LDRS equation, eq. [10], where υ is the well-known Charton's steric parameter based on van der Waals radii (17).

$$[10] \quad \log k_1 = L\sigma_1 + D\sigma_d + R\sigma_e + S\upsilon + h$$

The rates of addition of the *ortho*-, *meta*-, and *para*-substituted benzylamines showed excellent correlations with the LDR/LDRS equations (Table 5). All three series of substituted benzylamines meet the requirement of minimum number of substituents for analysis by the LDR and LDRS equations (16). We have used the standard deviation (sd), the coefficient of multiple determination (R^2), and Exner's (18) parameter ψ as measures of the goodness of fit.

Comparison of the L and D values for the substituted benzylamines shows that the addition of *para*-substituted benzyl-

amines is more susceptible to the delocalization effect than to the localized effect. However, the addition of *ortho*- and *meta*-substituted compounds exhibited a greater dependence on the field effect. In all cases, the magnitude of the reaction constants decreases with an increase in the temperature, pointing to a decrease in selectivity with increase in temperature.

All three regression coefficients, L, D, and R, are negative, indicating an electron-deficient reaction center in the transition state of the reaction. The positive value of η adds a negative increment to σ_d (eq. [9]), increasing the donor effect of the substituent where σ_d is negative and decreasing the acceptor effect where σ_d is positive. The substituent is, therefore, better able to stabilize a cationic reaction site. This also supports the presence of an electron-deficient center in the transition state of the rate-determining step. The negative value of S indicates that the reaction is subjected to steric hindrance by the *ortho* substituent. This may be due to steric hindrance of the *ortho* substituent to the approach of amines to NS.

We evaluated the significance level for all the three/four independent variables by determining the Student's t function for each coefficient (19). The significance level was found to be >99.99%. Thus all the parameters are required to explain the effect of structure on the reactivity of amines towards NS. There is no significant collinearity between the various substituent constants in all three series.

The percent contribution (17) of the delocalized effect, P_D, is given by eq. [11].

$$[11] \quad P_D = \frac{(|D| \times 100)}{(|L| + |D|)}$$

Similarly, the percent contribution of the steric parameter (17) to the total effect of the substituent, P_S, was determined by using eq. [12].

$$[12] \quad P_S = \frac{(|S| \times 100)}{(|L| + |D| + |S|)}$$

The values of P_D and P_S are also recorded in Table 5. The value of P_D for the addition of *para*-substituted benzylamines is ca. 44.1% whereas its values for the *meta*- and *ortho*-substituted amines are ca. 41.7 and 42.4%, respectively. It is seen that the P_D values for the *ortho* and *para* series are in the normal range (17) but that for the *meta*-series is somewhat more than the usual range (28 ± 5). This shows that from the *meta* position the delocalized effects are felt more strongly than expected. Presently,. no explanation of this observation is available. The value of P_S shows that there is considerable steric effect on the reaction. This is indicative of a high degree of C—N bond formation in the transition state of the first step of the reaction.

In many studies of nucleophilic additions to alkenes, the reactivity of substituted alkenes has been studied. We could not find any report on the reactivity of substituted benzylamines. The addition of primary and secondary amines to *trans*-(2-furyl)nitroethylene, in acetonitrile, exhibits (8) kinetics similar to those observed in the present case and is reported to follow similar mechanistic pathways. However, Kada et al. (7) observed a first-order dependence on amine concentration in the addition of secondary amines to 5-substituted *trans*-(2-furyl)nitroethylene.

Reflections on the outer-sphere mechanism of electron transfer[1]

Thomas W. Swaddle

Abstract: The quantitative efficacy of the Stranks–Marcus–Hush theory of volumes of activation $\Delta V^{\ddagger}$ for outer-sphere electron transfer between metal complexes in solution is assessed. The theory predicts $\Delta V^{\ddagger}$ accurately for several couples in aqueous solution, but is satisfactory for polar nonaqueous solvents only at pressures of ca. 100 MPa and above, and accuracy is not improved when the molecular nature of the solvent is allowed for through the Mean Spherical Approximation approach. At low pressures, the calculations become numerically unstable when the isothermal compressibility of the solvent is high and its relative permittivity is low, particularly for the more highly charged couples. For aqueous systems, departures from the predicted $\Delta V^{\ddagger}$ afford insights into the role of the counterions, the incursion of inner-sphere pathways, the enhanced reactivity of $Co^{III/II}$ cage complexes relative to conventional chelates, and the question of "spin forbiddenness" of electron transfer processes that involve a large change in spin multiplicity.

Key words: redox kinetics, inorganic reaction mechanisms, pressure effects, Marcus–Hush theory, activation volumes.

Résumé : On a évalué l'efficacité quantitative de la théorie de Stranks–Marcus–Hush des volumes d'activation, $\Delta V^{\ddagger}$, pour le transfert d'électrons de la couche extérieure entre des complexes métalliques en solution. La théorie prédit d'une façon précise les $\Delta V^{\ddagger}$ pour plusieurs couples en solutions aqueuses, mais pour les solvants non aqueux elle n'est satisfaisante qu'à des pressions d'environ 100 MPa et plus et sa précision n'est pas améliorée lorsqu'on tient compte de la nature moléculaire du solvant par le biais de l'approche d'une approximation sphérique moyenne. À de faibles pressions, les calculs deviennent numériquement instables lorsque la compressibilité isotherme du solvant est élevée et que sa permittivité relative est faible, particulièrement pour les couples les plus chargés. Pour les systèmes aqueux, les déviations par rapport aux valeurs de $\Delta V^{\ddagger}$ prédites fournissent des renseignements sur le rôle des contre-ions, sur les incursions de voies impliquant les sphères internes, l'augmentation de la réactivité des complexes de cage du $Co^{III/II}$ par rapport aux chélates conventionnels et la question de l'«empêchement par les spins» de processus de transferts d'électrons qui impliquent un grand changement dans la multiplicité des spins.

Mots clés : cinétique rédox, mécanismes de réactions inorganiques, effets de pression, théorie de Marcus–Hush, volumes d'activation.

[Traduit par la rédaction]

Introduction

For almost 30 years, my research group at The University of Calgary has maintained an interest in pressure effects in solution chemistry in a variety of contexts, including the elucidation of reaction mechanisms. The following short review will consider how high-pressure kinetics impinge upon an area in which Henry Taube has made seminal contributions, viz., the mechanisms of electron transfer processes in solution. Taube, with his student Russell Hunt (1), was also the first to use the effect of pressure P on reaction rate constants k as a mechanistic criterion in coordination chemistry, showing that the volume of activation $\Delta V^{\ddagger}$ ($= -RT(\partial \ln k/\partial P)_T$) for solvent water exchange on $Co(NH_3)_5OH_2^{3+}$ is +1.2 $cm^3\ mol^{-1}$, consistent with an S_N1 or $\mathbf{I_d}$ mechanism for this process. The pressure effect, however, is disappointingly small in this particular case, and this may explain why Taube did not pursue high-pressure kinetics further after leaving The University of Chicago. Nevertheless, during a visit to The University of Calgary in 1966, Taube responded most encouragingly to my question as to whether further high-pressure studies in inorganic solution chemistry would be worthwhile, and this has been a major theme in my research group ever since.

Probably the best known of Taube's scientific contributions is his elegant demonstration (2, 3) of the existence of a dichotomy between *inner-sphere* (ligand bridged) and *outer-sphere* mechanisms of electron transfer between transition metal complexes in solution, a possibility mooted as early as 1940 but not actually established until Taube's unequivocal study appeared in 1953 (4). Taube's approach depended upon the reduction of a substitution-inert oxidant to a labile product, concomitantly with oxidation of a labile reductant to an inert product; then, if electron transfer occurs via a bridging ligand X^{n-} (e.g., $X^{n-} = Cl^-$), that ligand becomes trapped in the first coordination sphere of the oxidized species:

Received October 30, 1995.

T.W. Swaddle.[2] Department of Chemistry, The University of Calgary, Calgary, AB T2N 1N4, Canada.

[1] This article is based upon a lecture presented at The University of Saskatchewan's *Taube Fest* on October 7, 1995, and is dedicated to Professor Henry Taube in gratitude for his friendship, encouragement, and scientific leadership.

[2] Telephone: (403) 220-5358. Fax: (403) 289-9488. E-mail: swaddle@acs.ucalgary.ca

[1] $$\underset{\text{inert}}{Co^{III}(NH_3)_5X^{(3-n)+}} + \underset{\text{labile}}{Cr(H_2O)_6^{2+}} \longrightarrow \{(NH_3)_5Co\cdots X\cdots Cr(OH_2)_5\}^{(5-n)+} + H_2O$$

$$\xrightarrow{H^+} \underset{\text{labile}}{Co(aq)^{2+}} + 5NH_4^+ + \underset{\text{inert}}{Cr^{III}(H_2O)_5X^{(3-n)+}}$$

Where X^{n-} is incapable of bridging (e.g., X = NH_3), a relatively slow outer-sphere electron transfer process occurs instead, and X does not appear in the oxidized product. If, however, both the reductant and its oxidized product are labile on the time scale of the redox experiment, this distinction is inapplicable. Furthermore, an outer-sphere mechanism can be unequivocally assigned only if ligand substitution rates on *both* reactants are much slower than the redox process. Candlin and Halpern (5), searching for alternative mechanistic criteria, recognized that the inner- and outer-sphere mechanisms differ in that the former requires expulsion of a first coordination sphere ligand (water, in eq. [1]) in the activation process, and so should be characterized by a more positive $\Delta V^{\ddagger}$ than would be expected for a corresponding outer-sphere path. Using pressure equipment left by Taube in Chicago, they found $\Delta V^{\ddagger}$ values ranging from +8 to +14 $cm^3\ mol^{-1}$ for the reduction of various $Co^{III}(NH_3)_5X^{(3-n)+}$ by $Fe(aq)^{2+}$, suggesting an inner-sphere mechanism.

This begs the question, however, of just what $\Delta V^{\ddagger}$ values would be expected for a genuine outer-sphere process. Donald R. Stranks, with whom I collaborated from 1970 until his untimely death in 1986, attacked this question (6) using the Marcus–Hush theory of outer-sphere electron transfer rates (7, 8). Some refinements of Stranks' treatment have subsequently been proposed (9), and in this article we assess the quantitative success of this approach.

Adaptation of the Marcus–Hush theory of electron transfer kinetics

In its simplest form, Marcus–Hush theory relates k for outer-sphere electron transfer to a free energy of activation $\Delta G^{\ddagger}$, which may be expressed in terms of a reorganizational energy λ and the free energy change ΔG^0 for the redox reaction, and a collision frequency Z appropriate for a bimolecular reaction in solution:

[2] $$k = Z \exp(-\Delta G^{\ddagger}/RT)$$

[3] $$\Delta G^{\ddagger} = (\lambda/4)[1 + (\Delta G^0/\lambda)]^2 = (\lambda/4) + \tfrac{1}{2}\Delta G^0 + \{(\Delta G^0)^2/4\lambda\} \approx (\lambda/4) + \tfrac{1}{2}\Delta G^0, \text{ if } \Delta G^0 << \lambda$$

The reorganizational energy comprises an internal contribution λ_{IR}, arising from the readjustment of the geometries (usually taken to mean the metal–ligand bond distances, which usually shorten on oxidation of the metal center and lengthen on its reduction) of the two reactants necessary for electron transfer to be possible, and a contribution λ_{SR} from the reorganization of the solvent. The Coulombic work of bringing the reactants together and medium (Debye–Hückel) effects should also be included in $\Delta G^{\ddagger}$ and Z. In current practice (10–12) Z is replaced by $K_{PREC}\kappa_{el}\nu_n$, where K_{PREC} is the formation constant for the assembly of a precursor complex of the reactants, κ_{el} is the electronic transmission coefficient (= 1 for adiabatic electron transfer), and ν_n is the nuclear frequency.

For *self-exchange* reactions, i.e., those involving no net chemical change ($\Delta G^0 = 0$), the pressure derivative of $-\ln k$ so calculated then gives a theoretical volume of activation $\Delta V_{CALC}^{\ddagger}$ (9):

[4] $$\Delta V_{CALC}^{\ddagger} = \Delta V_{IR}^{\ddagger} + \Delta V_{SR}^{\ddagger} + \Delta V_{DH}^{\ddagger} + \Delta V_{COUL}^{\ddagger} + \Delta V_{PREC}^{\ddagger}$$

where $\Delta V_{IR}^{\ddagger}$, $\Delta V_{SR}^{\ddagger}$, $\Delta V_{DH}^{\ddagger}$, $\Delta V_{COUL}^{\ddagger}$, and $\Delta V_{PREC}^{\ddagger}$ are, respectively, the contributions of internal reorganization, solvent reorganization, medium (Debye–Hückel) effects, the Coulombic work terms (i.e., the free energy component of the precursor formation constant K_{PREC}), and the pre-exponential part of K_{PREC} to the overall volume of activation.

Internal reorganization is often the major contributor to $\Delta G^{\ddagger}$ and hence the most significant influence upon k, since the atomic nuclei of both the oxidant and the reductant in self-exchange must be displaced away from their equilibrium positions towards a common geometry — usually implying bond lengthening and shortening, respectively — before electron transfer can occur. Exceptions occur when the oxidized and reduced species have similar bond lengths to their precursors (e.g., in the $Fe(phen)_3^{3+/2+}$ self-exchange)[3], when electron transfer is expected to be very fast. In contrast, *internal reorganization should make only a very small contribution* $\Delta V_{IR}^{\ddagger}$ *to* $\Delta V_{CALC}^{\ddagger}$, because expansion of the oxidant and the contraction of the reductant as they go to the transition state will effectively cancel. Stranks (6) used Hush's potential function to estimate $\Delta V_{IR}^{\ddagger} \approx +0.6\ cm^3\ mol^{-1}$ for most $ML_n^{(z+1)+/z+}$, this small contribution (barely outside experimental error) reflecting compressibility differences between the initial and transition states. As we shall see below, however, the possibility remains that pressure may hinder or favor the attainment of a special configuration of one of the reactants that provides a particularly efficient channel for electron transfer, in which case $\Delta V_{IR}^{\ddagger}$ would no longer be negligible.

The solvent reorganization contribution to $\Delta V_{CALC}^{\ddagger}$

[5] $$\Delta V_{SR}^{\ddagger} = (N_A e^2/16\pi\varepsilon_0)[\{(2r_1)^{-1} + (2r_2)^{-1} - \sigma^{-1}\} \times \{\partial(n^{-2} - D^{-1})/\partial P\}_T - (n^{-2} - D^{-1})\beta/3\sigma]$$

depends upon the effective radii r_1 and r_2 of the reactants (conveniently assumed to be pressure independent and roughly the same, r), the separation σ of the reactants at the maximum probability of electron transfer (usually assumed to be $r_1 + r_2$), the isothermal compressibility β of the solvent, its static dielectric constant or relative permittivity D, and its high-frequency dielectric constant, which is taken to be the square of the refractive index n; the other symbols have their usual SI meanings. It can be seen that eq. [5] will be dominated by n^{-2} for strongly polar solvents, i.e., those with high D, but the Pekar factor ($n^{-2} - D^{-1}$) and its pressure derivative may become numerically poorly defined for solvents of low polar-

[a] $[ML_n^{2+}] = [ML_n^{3+}] = 0.001$ mol kg^{-1} ($I = 0.009$ mol kg^{-1}), $r = 500$ pm, $\sigma = 1.0$ nm, $a = 800$ pm, $T = 25°C$, $\Delta V_{IR}^{\ddagger} = 0.6$ cm^3 mol^{-1}.

ity. Since the pressure dependences of both n and D are related to β (9), it follows that $\Delta V_{SR}^{\ddagger}$ is determined largely by β and will also, like β, be pressure dependent.

The consequences of these points are illustrated by Table 1, which shows that the calculation of $\Delta V_{SR}^{\ddagger}$ for water is numerically stable because D is high and, like β for this solvent, not markedly dependent on pressure over the customary experimental range (0–200 MPa). On the other hand, $\Delta V_{SR}^{\ddagger}$ for the less polar solvents methanol and acetone assumes large, numerically unstable values at low pressure that quickly fall with rising pressure because β is large and strongly pressure dependent, and this calculated behavior is typical of organic solvents in general.

The contributions to $\Delta V_{CALC}^{\ddagger}$ from ionic strength (I) and Coulombic effects

$$[6]\quad \Delta V_{DH}^{\ddagger} = \{RTz_1z_2CI^{1/2}/(1 + BaI^{1/2})^2\} \times [(\partial \ln D/\partial P)_T(3 + 2BaI^{1/2}) - \beta)]$$

$$[7]\quad \Delta V_{COUL}^{\ddagger} = (N_A z_1 z_2 e^2/4\pi\varepsilon_0\sigma)(\partial D^{-1}/\partial P)_T$$

are significant when neither of the reactant charge numbers z_1 and z_2 is zero, but are numerically of opposite sign (involving derivatives of ln D and D^{-1}, respectively) and tend to cancel.[4] This cancellation is fortuitously almost exact for a variety of solvents at the typical working ionic strength of $I \approx 0.1$ mol L^{-1} (14), but the values of $\Delta V_{DH}^{\ddagger}$ and $\Delta V_{COUL}^{\ddagger}$, for example, for acetone at ambient pressure and 25°C are numerically very large at this ionic strength (+49.7 and −47.6 cm^3 mol^{-1}, respectively) so that their cancellation and the calculation of $\Delta V_{CALC}^{\ddagger}$ are numerically unstable, i.e., highly sensitive to inadequacies of either the theory or the data used in the computation. This computational instability is clearly seen for solvents of low D and high β in Table 1, in which we consider minimal practical concentrations of reactants without supporting electrolyte.

[4] In Stranks' original presentation of the theory (6), the sign of $\Delta V_{DH}^{\ddagger}$ was reversed (13), giving an apparent agreement of $\Delta V_{CALC}^{\ddagger}$ with experiment for the few studies then available, including the aqueous $Co(en)_3^{3+/2+}$ exchange,[3] which, as we shall see below, is actually an anomalous case. This early apparent success of theory diverted attention from the problem of pressure effects on electron transfer kinetics for some years.

$\Delta V_{PREC}^{\ddagger}$ contributes only about +1 to +3 cm^3 mol^{-1} to the total $\Delta V_{CALC}^{\ddagger}$ listed in Table 1.

A further complication is that, in any one-electron transfer, at least one partner must be charged, so that, in solvents of low D in particular, ion pairing with counterions is to be expected at elevated ion concentrations. The extent of ion pairing can, in principle, be calculated from the Fuoss equation (9), but the consequences of such pairing are not obvious. Wherland (15) notes that ion pairs formed by cationic reactants in nonaqueous solvents are generally less reactive in electron transfer than the free ions, so that the experimental $\Delta V^{\ddagger}$ can be expected to be more negative than $\Delta V_{CALC}^{\ddagger}$ (since pressure breaks up ion pairs by favoring solvation of the separated ions), but the *extent* to which the ion pairs are less reactive is not calculable — the approximation made in some of our published work (9, 16), that ion pairs are inactive, is likely too extreme, although in those specific instances this makes little difference. On the other hand, electron transfer in *anionic* couples such as $MnO_4^{-/2-}$ (17) and $Fe(CN)_6^{3-/4-}$ (18) in aqueous solution shows strong catalysis by cations, and gives experimental $\Delta V^{\ddagger}$ values that are much more positive than $\Delta V_{CALC}^{\ddagger}$ even after allowing for the anticipated electrostatic effect of pairing on $\Delta V_{COUL}^{\ddagger}$.

Self-exchange reactions in nonaqueous solutions

The upshot of these considerations is that the foregoing adaptation of Marcus–Hush theory is unlikely to be satisfactory for nonaqueous systems. $\Delta V_{CALC}^{\ddagger}$ is numerically unstable for typical organic solvents at low pressures, does not allow for the unpredictable effects of possible ion pairing at practical ionic strengths, and furthermore has a very strong pressure dependence, i.e., a substantial compressibility coefficient of activation $\Delta\beta^{\ddagger} = -(\partial\Delta V^{\ddagger}/\partial P)_T$ (Table 1), that is not observed in practice. For example, Fig. 1 compares the theoretical and experimental pressure dependences of ln k in methanol for the $Ru(hfac)_3^{0/-}$ exchange[3] (19), which should be particularly amenable to theoretical treatment since z_1 and, therefore, $\Delta V_{DH}^{\ddagger}$ and $\Delta V_{COUL}^{\ddagger}$ are all zero and ion pairing effects should be minimal. The theoretical plot, however, is markedly curved and unrepresentative of the experimental ln k values, which are linearly dependent upon P within the error limits. The data

Fig. 1. Pressure effect on the logarithm of the rate constant for the $Ru(hfac)_3^{0/-}$ exchange in methanol-d_4 at 25.3°C. Total Ru concentrations (kg mol^{-1}): 0.060 (open circles), 0.026 (filled circles). Solid curve: calculated pressure effect. Broken line: linear least-squares fit of the data (19).

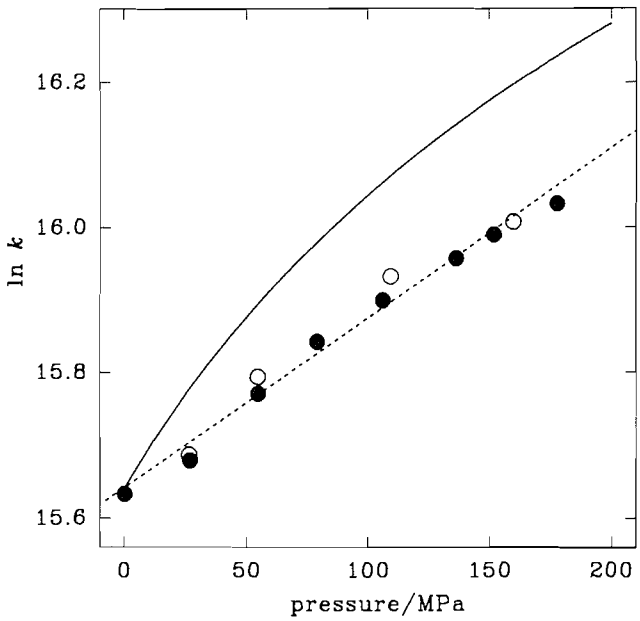

Fig. 2. Pressure effect on the logarithm of the rate constant for the $Fe(\eta^5\text{-}C_5H_5)_2^{+/0}$ self-exchange in acetonitrile at 0°C. Solid curve: calculated pressure effect. Broken line: linear least-squares fit of the data of Hunt and co-workers (20).

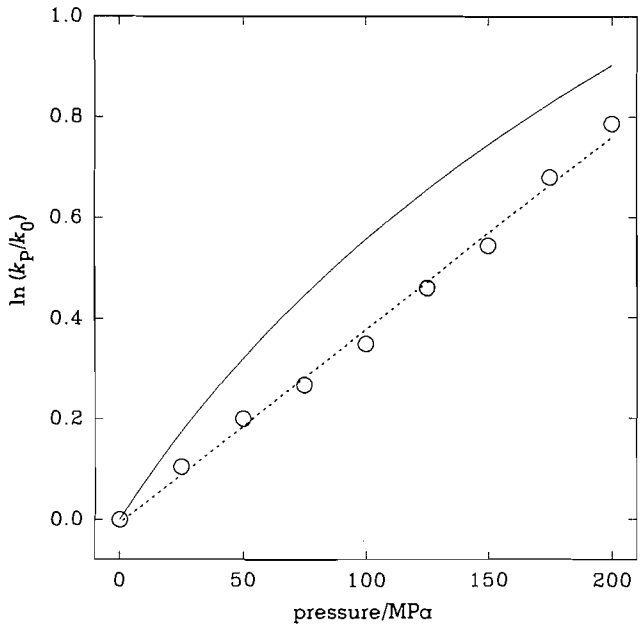

of Hunt et al. (ref. 20 and personal communication) for the ferrocene–ferricenium exchange in acetonitrile present a similar picture (Fig. 2). As Table 1 shows, however, $\Delta\beta^{\ddagger}$ is even more strongly dependent on pressure than is $\Delta V_{CALC}^{\ddagger}$. Thus, the intuitive expectation, that by taking further derivatives of a quantity with respect to pressure we should arrive at one which is sensibly pressure independent, is entirely wrong; the problem of finding a "good" parameter to summarize pressure effects simply gets worse. The situation is analogous to the sharp temperature dependences found for the experimental heat capacities of activation (the temperature derivative of the enthalpy of activation) for aquation of $Co(NH_3)_5X^{(3-n)+}$ (X^{n-} = Br^- and SO_4^{2-}) (21).

Table 1 and Figs. 1 and 2 do suggest, however, that the theory could be applied satisfactorily to organic solvents of moderate dielectric constant (i.e., those for which ion pairing is not expected to be dominant) *if attention were confined to the upper part of the pressure range.* The various parameters of Table 1 appear to be converging towards common values at high pressures for both aqueous and nonaqueous media. Furthermore, in the upper pressure range, the calculated ln k vs. P plots in Figs. 1 and 2 are roughly linear and parallel to the linear least-squares fit of the experimental data, i.e., the observed and calculated $\Delta V^{\ddagger}$ are actually in good agreement at elevated pressures. This can be explained by noting that solvents that are highly compressible in the bulk (i.e., that have much free volume) lose some of this high compressibility locally when solvating solute molecules or ions, which may be regarded as fillers of interstitial space in a quasi-lattice of solvent. As Hupp and co-workers (22) have shown, it is the *local* solvent environment of the reactants that determines $\Delta V_{SR}^{\ddagger}$, the most important contributor to $\Delta V_{CALC}^{\ddagger}$.

Unfortunately, development of this concept requires a full molecular dynamics computational treatment, and this is probably not feasible at present.[5] Besides, the traditional approach, in which phenomena are related to particular bulk properties of the various media, affords some conceptual satisfaction. As a compromise, the molecular nature of the solvent can be introduced into the dielectric-continuum Marcus–Hush theory through the Mean Spherical Approximation (MSA) approach (24–26). We find (27), however, that $\Delta V_{CALC}^{\ddagger}$ values so calculated are not sufficiently different from those computed as above to warrant the added mathematical complexity, except with solvents of very low D such as chloroform (but in those cases complications from ion pairing are expected to undermine the usefulness of the theory).

Wherland's recent review (15) deals with the general problem of electron transfer dynamics in nonaqueous systems, and also documents the extensive high-pressure kinetic studies made by him and his co-workers by NMR line-broadening on $Mn(CNR)_6^{2+/+}$ (R = various alkyl or aryl groups), ferrocene-ferricenium, cobalt(III/II) clathrochelate, and other self-exchange reactions in a variety of organic solvents. The problems noted above are again manifest to varying degrees in the quantitative interpretation of the $\Delta V^{\ddagger}$ measurements.

[5] M. Hilczer and M. Tachiya (23) report a molecular dynamics computer simulation of electron transfer in acetonitrile that predicts rate constants some 10^4-fold slower than does simple Marcus–Hush theory for small driving forces $-\Delta G^0$, and moves the Marcus "inverted" region (where $-\Delta G^0$ exceeds the reorganizational energy barriers, and further increases in $-\Delta G^0$ should result in *reduced* rates) beyond the experimentally accessible range. No computation of $\Delta V^{\ddagger}$ has yet been reported.

Table 2. Volumes of activation at 100 MPa for self-exchange in "well-behaved" $ML_n^{(z+1)+/z+}$ couples in aqueous media.[a]

Couple	I (mol kg^{-1})	T (°C)	$\Delta V^{\ddagger}$ (cm^3 mol^{-1})	$\Delta V_{CALC}^{\ddagger}$ (cm^3 mol^{-1})	Ref.

[d] $\Delta V_{IR}^{\ddagger}$ taken as zero.
[e] By high-pressure stopped-flow circular dichroism change.

Self-exchange reactions in aqueous solution: "well-behaved" couples

Table 1 does give confidence in the quantitative applicability of eqs. [4]–[7] to *aqueous* systems, for which β is small and shows relatively little pressure dependence, and for which D is large enough to minimize ion pairing and generate realistic values for $\Delta V_{SR}^{\ddagger}$, $\Delta V_{DH}^{\ddagger}$, and $\Delta V_{COUL}^{\ddagger}$. A small pressure dependence of $\Delta V_{CALC}^{\ddagger}$ is still predicted, but in most cases is unlikely to emerge beyond the experimental uncertainty over the usual 0–200 MPa range, so we may treat the experimental $\Delta V^{\ddagger}$ from an apparently linear ln k vs. P relationship as an *average* over this pressure range and compare it with $\Delta V_{CALC}^{\ddagger}$ for the mid-range pressure, 100 MPa.

Table 2 lists those aqueous self-exchange reactions[3] for which, to date, $\Delta V^{\ddagger}$ has been found to agree well with the predictions of eqs. [4]–[7] at 100 MPa (agreement is only fair in the $Co(diamsar)^{3+/2+}$ case). These "well-behaved" couples include not only $Co([9]aneS_3)_2^{3+/2+}$, in which both the Co^{II} and the Co^{III} are in the low-spin state, but also the cage complexes $Co(sep)^{3+/2+}$, $Co(diamsar)^{3+/2+}$, and $Co(diamsarH_2)^{5+/4+}$, in all of which the Co^{II} partner is in the high-spin state, i.e., in which the electron transfer process involves a large change in spin multiplicity, quartet→singlet and vice-versa. We return to this point below. Other salient points are the conformity to predictions of both 5+/4+ and 3+/2+ charge types, and also of the couple $Fe(H_2O)_6^{3+/2+}$, which has been thought to behave anomalously (32, 33) and for which an inner-sphere (aqua bridged) self-exchange mechanism has been proposed (32, 34), a possibility that the pressure result rules out. Finally, since the theory assumes adiabatic electron transfer, the self-exchange reactions listed in Table 2 are evidently fully adiabatic or close to it; non-adiabatic behavior should be revealed in $\Delta V^{\ddagger}$ values that are significantly more negative than predicted (9).

Self-exchange reactions in aqueous solution: "anomalous" couples

In contrast, Table 3 lists aqueous self-exchange reactions for which $\Delta V^{\ddagger}$ differs sharply from the theoretical value for an adiabatic outer-sphere process. In most cases, however, a reason for the discrepancy can be identified; in other words, $\Delta V^{\ddagger}$ serves as a criterion of a mechanistic anomaly in these instances. For the $Fe_{aq}^{3+/2+}$ exchange via the conjugate base $Fe(H_2O)_5OH^{2+}$, the measured $\Delta V^{\ddagger}$ is inconsistent with an outer-sphere process, but is precisely that calculated for an inner-sphere pathway in which a water ligand is expelled from the labile $Fe(H_2O)_6^{2+}$ and the OH^- ligand acts as a bridge between the Fe centers (cf. eq. [1]) (28). This interpretation receives support from Stranks' fragmentary report of $\Delta V^{\ddagger}$ for the analogous $Cr_{aq}^{3+/2+}$ exchange, in which the measurable exchange rate is carried by the conjugate base pathway and ligand bridging by OH^- has been demonstrated by oxygen isotope transfer (6).[6] Thus, Candlin and Halpern's contention (5), that $\Delta V^{\ddagger}$ can be used to distinguish between inner- and outer-sphere mechanisms of electron transfer, is vindicated.

The gross failure of theory to predict $\Delta V^{\ddagger}$ for the aqueous $Co(en)_3^{3+/2+}$ and $Co(phen)_3^{3+/2+}$ exchanges (Table 3) stands in contrast to the successes for $Co([9]aneS_3)_2^{3+/2+}$ and the $Co^{3+/2+}$ cage complexes (Table 2). It has long been argued that $Co^{III/II}$ exchanges in which the Co^{II} partner is high-spin ($^4T_{1g}$ ground state in O_h symmetry) and the Co^{II} low-spin ($^1A_{1g}$) are slow because of the large change in spin multiplicity accompanying electron transfer. Either the electron transfer occurs non-adiabatically (10–12) from ground state to ground state with a large multiplicity change, or there is a fast (39) but unfavorable high-spin to low-spin Co^{II} pre-equilibrium with adiabatic electron transfer between the low-spin Co^{II} and Co^{III} species. We have, in the past (16, 35, 36), favored the first explanation of the anomalously negative $\Delta V^{\ddagger}$ values for the $Co(en)_3^{3+/2+}$, $Co(phen)_3^{3+/2+}$, and "Co(edta)$^{2-/-}$" exchanges,[7] as nonadiabaticity would make a calculable negative volume contribution

[6] The exact conditions of Stranks' experiments were never reported. Neither is it clear whether the measured $\Delta V^{\ddagger}$ value given in ref. 6 refers to the pressure dependence of an experimental rate constant (first order in Cr^{III} (total) and Cr^{II}, inversely first order in $[H^+]$), or to exchange between the actual conjugate species $Cr(H_2O)_5OH^{2+}$ and Cr^{2+}; in the former case, 3.8 ± 0.7 cm^3 mol^{-1} should be subtracted from $\Delta V^{\ddagger}$ to allow for the volume change accompanying conjugate base formation (38), bringing $\Delta V^{\ddagger}$ into excellent agreement with the value calculated for an inner-sphere process, as in the $Fe^{III/II}$ case (28).

[7] Under the experimental conditions, the Co^{II} partner exists as $Co(Hedta)OH_2^-$, but the volume changes associated with deprotonation of pendant arm and the aqua ligand can be allowed for in $\Delta V_{CALC}^{\ddagger}$ (36).

Table 3. Some "anomalous" volumes of activation at 100 MPa for self-exchange in $ML_n^{(z+1)+/z+}$ couples in aqueous media.

[a]This work; $\Delta V_{IR}^{\ddagger}$ taken as +0.6 cm^3 mol^{-1} except as indicated.
[b]By radioisotope sampling at high pressure.
[c]$\Delta V^{\ddagger}$ shows some pressure dependence.
[d]By high-pressure stopped-flow circular dichroism change.
[e]Includes deaquation and deprotonation of $Co(Hedta)OH_2^-$, the form of the Co^{II} complex under the reaction conditions.
[f]By high-pressure NMR.
[g]$\Delta V_{IR}^{\ddagger}$ taken as zero.
[h]Includes an estimate of the Coulombic effect of ion association.
[i]Limiting value at zero pressure.
[j]$\Delta V_{IR}^{\ddagger}$ taken as +3.3 cm^3 mol^{-1} (6); assumes rate-controlling step is a one-electron transfer giving $2Tl(H_2O)_6^{2+}$.

of the right magnitude with reasonable values of the distance scaling factor (9). However, the recent recognition (31) that the cage complexes $Co(sep)^{3+/2+}$ and $Co(diamsar)^{3+/2+}$ conform to our adaptation of Marcus–Hush theory and yet behave very differently from the smaller complexes $Co(en)_3^{3+/2+}$, from which they are derived, forces the conclusion that all these couples undergo self-exchange adiabatically. The Co^{II} spin pre-equilibrium explanation is therefore now preferred, but suffers from the lack of any experimental information on the thermodynamics of the relevant pre-equilibria, although less than 1% low-spin Co^{II} would account for the observed rates (31). Binstead and Beattie found a volume of reaction of −10 cm^3 mol^{-1} for the high-spin to low-spin magnetic isomerism of $Co(terpy)_2^{2+}$ (40),[3] and, although this result may be complicated to a minor extent by dechelation equilibria (31), it is of the order required to account for the anomalies in $\Delta V^{\ddagger}$ for $Co(en)_3^{3+/2+}$ and $Co(phen)_3^{3+/2+}$.

It might be argued that the main difference in general properties between the "anomalous" $Co^{III/II}$ couples of Table 3 and the "well-behaved" $Co^{III/II}$ couples of Table 2 is that the Co^{II} species of the former category are all labile on the time scale of electron transfer, and therefore may offer an inner-sphere alternative to the outer-sphere path that is the only one available to the cage complexes. Such an inner-sphere alternative, however, would lead to the $Co(en)_3^{3+/2+}$ exchange being markedly *faster* than its $Co(sep)^{3+/2+}$ analogue, whereas it is *slower* by a factor of 10^5. Furthermore, as we have seen, $\Delta V^{\ddagger}$ for an inner-sphere process will be markedly more *positive* than for an analogous outer-sphere mechanism, whereas the anomalous Co couples of Table 3 all show $\Delta V^{\ddagger}$ values much more *negative* than are found for the obligate outer-sphere $Co^{III/II}$ exchanges of Table 2.

It remains for us to explain why the low-spin/high-spin $Co^{III/II}$ cage couples of Table 2 should undergo self-exchange relatively rapidly, and why the $\Delta V^{\ddagger}$ values conform so well to theoretical expectations for adiabatic outer-sphere processes. It should first be noted that the Co—N bond length differences between the Co^{III} and Co^{II} members of a couple are much the same (19–21 pm) for all the CoN_6-type complexes of Tables 2 and 3 (31), so that the explanations must be found elsewhere. Geue and Sargeson (ref. 41, and personal communication) answer the first question by pointing out that molecular mechanics calculations show that the cage complexes are strained, and hence destabilized, in their ground states, so that the transition states for electron transfer are more energetically accessible. An alternative explanation (probably equivalent, in the last analysis) is that geometrical (e.g., Jahn–Teller) distortions accompany the spin multiplicity change as bidentate chelate Co^{II} complexes approach the transition state, thereby contributing to the Franck–Condon energy barrier to electron transfer, but are suppressed in the rigid cage complexes (31). This latter explanation also gives an easy rationalization of the $\Delta V^{\ddagger}$ values — if the tendency of the complexes to distort while changing spin state is suppressed, there will be little associated volume change, and eqs. [4]–[7] are applicable without modification. It should also be remembered that Marcus–Hush theory treats the reactants as hard spheres, and this is likely a poor representation of the Co complexes of Table 3 but a good one for the cage complexes of Table 2. In any event, an important inference arises from all of this: *large spin multiplicity changes do not in themselves inhibit electron transfer appreciably*; rather, it is the associated geometrical distortions, where these can occur freely, that retard the reaction.

The ability of cations to catalyze anion–anion electron transfer is well established, and leads to anomalously *positive* values of $\Delta V^{\ddagger}$ (as for $MnO_4^{2-/-}$ and $Fe(CN)_6^{3-/4-}$, Table 3). The effect of cations on $\Delta V^{\ddagger}$ and k is much greater than can be accounted for by their calculated influence on the Coulombic and Debye–Hückel terms, so an actual electronic involvement of the counterion is implied. Curiously, for the cation-independent $MnO_4^{-/2-}$ pathway, $\Delta V^{\ddagger}$ is more negative than predicted, probably because of the unusually small size of the reactants. The molecular nature of the solvent may be asserting itself here, although the MSA approach actually gives a somewhat poorer prediction of $\Delta V^{\ddagger}$ than eqs. [4]–[7] (27). Treatment of the environment of the small precursor complex as an ellipsoidal cavity, rather than two spherical cavities, in the solvent can rationalize the surprisingly negative $\Delta V^{\ddagger}$ (17), but there is a distasteful arbitrariness in this procedure.

The final entry in Table 3 is enigmatic. The $Tl(H_2O)_6^{3+/+}$ exchange may involve either a one-electron endergonic process forming $2Tl(H_2O)_6^{2+}$, with scrambling on reconversion to thallium(I) and -(III), or a simultaneous two-electron exchange. For the one-electron process, Stranks (6) pointed out that, as for any electron transfer reaction involving net chemical change, a term involving the thermodynamic reaction volume ΔV^0 for the formation of $2Tl^{2+}$ must be added to eq. [4]:

$$[8]\quad \Delta V_{CALC}^{\ddagger} = \Delta V_{IR}^{\ddagger} + \Delta V_{SR}^{\ddagger} + \Delta V_{DH}^{\ddagger} + \Delta V_{COUL}^{\ddagger} + \Delta V_{PREC}^{\ddagger} + \lambda^{\ddagger}\Delta V^0$$

where $\lambda^{\ddagger} = 0.5 + \Delta G^0/8(\Delta G_{SR}^{\ddagger} + \Delta G_{IR}^{\ddagger}) = 0.72$ in this case. Stranks' calculations (6) appeared to give $\Delta V_{CALC}^{\ddagger}$ for a single-electron mechanism in excellent agreement with the observed value, whereas $\Delta V_{CALC}^{\ddagger}$ for a two-electron step was 12 $cm^3\ mol^{-1}$ more negative. These numbers, however, incorporate $\Delta V_{DH}^{\ddagger}$ with the sign reversed, and an estimated ΔV^0 of $-9.3\ cm^3\ mol^{-1}$ for the hypothetical formation of $2Tl^{2+}$ as compared with $-2.4\ cm^3\ mol^{-1}$ from a model now available (42), so that the experimental $\Delta V^{\ddagger}$ falls between the theoretical values for the one- and two-electron paths. At least, $\Delta V^{\ddagger}$ rules out an inner-sphere mechanism.

Outer-sphere reactions involving net chemical change

If $\Delta V_{11}^{\ddagger}$ and $\Delta V_{22}^{\ddagger}$ for the self-exchange reactions

$$[9]\quad A + A^+ \rightarrow A^+ + A \qquad (k_{11}, \Delta V_{11}^{\ddagger})$$

$$[10]\quad B + B^+ \rightarrow B^+ + B \qquad (k_{22}, \Delta V_{22}^{\ddagger})$$

can be calculated as above, then it becomes possible to calculate $\Delta V_{12}^{\ddagger}$ for the cross reaction

$$[11]\quad A + B^+ \rightarrow A^+ + B \qquad (k_{12}, K_{12}, \Delta V_{12}^{\ddagger}, \Delta V_{12}^0)$$

from an adaptation (43, 44) of Marcus' "cross relation" (eqs. [12]–[14]) (10), if K_{12} (the equilibrium constant for reaction [11], obtainable from its standard electrode potential change ΔE) and ΔV_{12}^0 (its volume of reaction, obtainable from the pressure dependence of ΔE (45–47)) are known:

$$[12]\quad k_{12} = (k_{11}k_{22}K_{12}f)^{1/2}W$$

$$[13]\quad \ln f = [\ln K_{12} + (w_{12} - w_{21})/RT]^2/4[\ln(k_{11}k_{22}/Z_{11}Z_{22}) + (w_{11} + w_{22})/RT]$$

$$[14]\quad \ln W = (w_{11} + w_{22} - w_{12} - w_{21})/2RT$$

$$[15]\quad \Delta V_{12}^{\ddagger} = [(\Delta V_{11}^{\ddagger} + \Delta V_{22}^{\ddagger} + \Delta V_{12}^0)/2] + C$$

$$[16]\quad C = [X\Delta V_{12}^0 \ln K_{12} - 2(\ln K_{12})^2(\Delta V_{11}^{\ddagger} + \Delta V_{22}^{\ddagger} - \Delta V_{11}^{w} - \Delta V_{22}^{w})]/X^2$$

$$[17]\quad X = 4[\ln(k_{11}k_{22}/Z_{11}Z_{22}) + (w_{11} + w_{22})/RT]$$

where w_{ij} are work terms with associated volume effects ΔV_{ij}^{w}. If ΔE is small, eqs. [12]–[14] and [15]–[17] are much simplified:

$$[18]\quad k_{12} = (k_{11}k_{22}K_{12})^{1/2}$$

$$[19]\quad \Delta V_{12}^{\ddagger} = (\Delta V_{11}^{\ddagger} + \Delta V_{22}^{\ddagger} + \Delta V_{12}^0)/2$$

Tests of eqs. [15]–[17] or [19] are elusive, as one must choose a system for which $\Delta V_{11}^{\ddagger}$ and $\Delta V_{22}^{\ddagger}$ are known and accountable for theoretically (Table 2), and for which k_{12} and ΔV_{12}^0 are measurable. The problem is usually that the high-pressure techniques (48, 49) available for the measurement of k_{12}, notably stopped-flow spectrophotometry, cannot produce reliable rate constants $>10^5\ L\ mol^{-1}\ s^{-1}$, so that eq. [18] limits the choice of participating couples to ones with fairly slow self-exchange rates and a rather small ΔE. The stability of the reactants and products over the relatively long duration of high-pressure experiments is another common source of difficulties. To date, a convincing test of eq. [15] has been possible with only one reaction: the reduction of $Fe(H_2O)_6^{3+}$ by $Co([9]aneS_3)_2^{2+}$, for which $\Delta V_{12}^{\ddagger}$ was predicted to be $-14.7\ cm^3\ mol^{-1}$ at 100 MPa, and values of -13.7 (ClO_4^- medium) and $-15.9\ cm^3\ mol^{-1}$ ($CF_3SO_3^-$) were found (43). With $Co(sep)^{2+}$ as reductant, the driving force was excessive (1.03 V) and eq. [15] failed, but so did the cross relation (eqs. [12]–[14]) — indeed, it is surprising that this reaction is just slow enough to be followed by stopped-flow spectrophotometry. Murguia and Wherland (44) have used equations similar to [15]–[17] to estimate $\Delta V^{\ddagger}$ for self-exchange of some Co clathrochelates from $\Delta V_{12}^{\ddagger}$ data.

An alternative approach involves the calculation of all the components of eq. [8] as outlined above, and van Eldik and coworkers (50) have successfully accounted for $\Delta V_{12}^{\ddagger}$ for the reduction of aqueous $Co(terpy)_2^{3+}$ by $V(H_2O)_6^{2+}$ ($\Delta V_{12}^{\ddagger} = -1.8\ cm^3\ mol^{-1}$) in this way.

Conclusions

For simple outer-sphere electron transfer reactions in aqueous media, $\Delta V^{\ddagger}$ can be satisfactorily calculated from the appropriate equations [4]–[8] and [15]–[17]. Where these fail, one can infer that some special mechanistic feature is operative, or that the reaction is inner-sphere. $\Delta V^{\ddagger}$ data help explain the enhanced redox reactivity of Co(III/II) cage complexes vis-à-vis the analogous "open" chelates, and show that large

changes in spin multiplicity in outer-sphere electron transfer do not *in themselves* limit redox rates — such reactions are not "spin forbidden". For polar nonaqueous media, eqs. [4]–[7] reproduce $\Delta V^{\ddagger}$ adequately at 100 MPa or more, but tend to overestimate it at low pressures, particularly when the solvent has a high isothermal compressibility. When the relative permittivity of the solvent is low, the calculations become numerically unstable, especially where the reactants carry high charges, but in such cases ion pairing becomes important, with unpredictable consequences.

Standard state heat capacities of aqueous electrolytes and some related undissociated species[1]

Loren G. Hepler and Jamey K. Hovey

Abstract: Uses of heat capacities of solutions of electrolytes are reviewed, with a particular emphasis on the standard state partial molar heat capacities and their applications to calculations of the effects of temperature on equilibrium constants, electrode potentials, enthalpies, and entropies. Methods of obtaining these standard partial molar heat capacities are summarized, followed by comparisons of values obtained in different ways. Many of the "best" such heat capacities are collected and then used as the basis for establishing single-ion heat capacities based on the convention that $C_p^{\circ}(H^+) = 0$, followed by illustrations of the convenient use of these quantities. Finally, there is brief discussion of theoretical analysis of these standard partial molar heat capacities in relation to ion–solvent interactions.

Key words: heat capacities, electrolytes; aqueous solutions, heat capacities; thermodynamics, electrolytes.

Résumé : On présente une revue de l'utilisation des capacités calorifiques de solutions d'électrolytes en insistant d'une façon particulière sur les capacités calorifiques molaires partielles dans l'état standard et leurs applications aux calculs des effets de la température sur les constantes d'équilibre, les potentiels d'électrode, les enthalpies et les entropies. On résume les méthodes d'obtenir ces capacités calorifiques molaires partielles standard et on présente ensuite un comparaison des diverses valeurs obtenues d'après les diverses manières. Plusieurs des «meilleures» propriétés, comme les capacités calorifiques, ont été rassemblées et ont ensuite été utilisées comme base pour l'établissement des capacités calorifiques d'un seul ion en se basant sur la convention que $C_p^{\circ}(H^+) = 0$; elles sont suivies par des illustrations sur l'utilisation commode de ces quantités. Enfin, on présente une brève discussion de l'analyse théorique de ces capacités calorifiques molaires partielles standard en relation avec les interactions ion–solvant.

Mots clés : capacités calorifiques, électrolytes, solutions aqueuses; thermodynamique.

[Traduit par la rédaction]

Introduction

Knowledge of heat capacities of pure substances is useful because such heat capacities can be used in a wide variety of thermodynamic calculations, many of which involve the effects of changing temperature on other thermodynamic properties such as Gibbs energies and related equilibrium constants, enthalpies, and entropies. The principle of these calculations and methods of carrying them out have been reviewed in many texts dealing with chemical thermodynamics.

Although it has been known for a long time that similar calculations for aqueous solutions of electrolytes could be useful, the general paucity of required experimental results severely limited these kinds of applications. In recent years, however, advances in calorimetry have made it practical to obtain reliable and accurate heat capacities of dilute aqueous solutions, thereby leading to the partial molar heat capacities needed for the kinds of calculations mentioned above.

In the remainder of this Introduction, we will provide words and equations (to be used later) to call attention to some of the uses of partial molar heat capacities: (*i*) We provide a review of experimental methods and illustrate methods of calculating the standard state partial molar heat capacities that will form the principal part of the rest of this paper. (*ii*) We provide a critical review of standard state partial molar heat capacities of aqueous inorganic electrolytes (also acetate ion, Ac^-) and a few non-ions such as HAc(aq), NH_3(aq), CO_2(aq), SO_2(aq), H_2S(aq), and H_3PO_4(aq, undissociated). (*iii*) We select "best" values of standard state partial molar heat capacities and provide specific illustrations of some of their uses. (*iv*) We refer briefly to uses of heat capacities in connection with theoretical attempts to improve or extend knowledge of ion–solvent interactions.

To introduce the need for the heat capacities that are the focus of this paper, we begin with the van't Hoff equation:

[1] $(\partial \ln K/\partial T)_p = \Delta_r H^\circ/RT^2$

Making the approximation that the standard state enthalpy of reaction, $\Delta_r H^\circ$, is a constant (independent of temperature), integration of eq. [1] leads to

[2] $\ln K = -(\Delta_r H^\circ/RT) + I$

in which I is a constant of integration.

Equation [2] is often useful over small ranges of temperature, but is generally inadequate for wide or even moderate ranges of temperature. One illustration of the inadequacy of this equation is provided by the observation that ln K is (for temperature-independent $\Delta_r H^\circ$) predicted to be a linear function of $1/T$, increasing or decreasing forever as the temperature increases or decreases, which is contrary to the reality that values of K and thence ln K for many reactions involving aqueous electrolytes pass through a minimum or maximum with changing temperature. The explanation for this kind of failure of eq. [2] is that $\Delta_r H^\circ$ is not generally a constant (independent of temperature), but depends on temperature as shown below.

Effects of temperature on $\Delta_r H^\circ$ and also on $\Delta_r S^\circ$ are described by the following equations:

[3] $(\partial \Delta_r H^\circ/\partial T)_p = \Delta_r C_p^\circ$

[4] $(\partial \Delta_r S^\circ/\partial T)_p = \Delta_r C_p^\circ/T$

Here we have used $\Delta_r C_p^\circ$ to represent the change in heat capacity for a chemical reaction, which is related to the heat capacities of the reactants and products of reaction by

[5] $\Delta_r C_p^\circ = \Sigma C_p^\circ(\text{products}) - \Sigma C_p^\circ(\text{reactants})$

For aqueous solutes, the relevant heat capacity denoted by C_p° is the standard state partial molar heat capacity.

Equations [3] and [4] shows that $\Delta_r H^\circ$ and $\Delta_r S^\circ$ are independent of temperature only in the special (unusual!) case in which $\Delta_r C_p - 0$. Because heat capacities generally depend on temperature, consider various approaches to making use of eq. [3] in combination with eq. [1]. One approach (others are discussed later) is to express the heat capacity of each substance or ion in terms of an empirical power series, such as

[6] $C_p^\circ = a + bT + cT^2 + \ldots$

Combination of equations [5] and [6] leads to

[7] $\Delta_r C_p^\circ = \Delta a + (\Delta b)T + (\Delta c)T^2 + \ldots$

We now illustrate the principle of making use of heat capacities by cutting off eq. [7] after the Δa term, which means that we are (for now) considering $\Delta_r C_p^\circ$ to be independent of temperature. In this case, integration of eq. [3] leads to

[8] $\Delta_r H^\circ = \Delta H_i + (\Delta a)T$

in which ΔH_i is a constant of integration. Insertion of eq. [8] in eq. [1] and integration leads to

[9] $\ln K = -(\Delta H_i/RT) + [(\Delta a)(\ln T)/R] + I$

in which I is another constant of integration.

Equation [9] corresponds to a nonlinear dependence of ln K on $1/T$. Further, it can be shown by differentiating eq. [9] with respect to temperature and setting the resulting derivative equal to zero that there is some temperature at which ln K is either a minimum or a maximum, which is a very substantial improvement over eq. [2]. It will be shown later that using a constant (independent of temperature) value of $\Delta_r C_p^\circ$ leads to remarkably accurate calculations of equilibrium constants over wide ranges of temperature, which justifies part of our focus on heat capacities at just one temperature (298.15 K). It will also be shown that such calculations can be extended to much wider ranges of temperature by making use of heat capacities that have been measured over relatively small ranges of temperature.

Rather than carry out the differentiation of eq. [9] as mentioned above to obtain the temperature at which the value of K passes through a maximum or minimum, we proceed in another way. Integrating eq. [3] between limits of $T = 298$ K and some T_m at which the value of K goes through a maximum or minimum, we obtain

[10] $\Delta_r H^\circ(\text{at } T_m) - \Delta_r H^\circ(\text{at } T = 298 \text{ K}) = \Delta_r C_p^\circ(T_m - 298)$

Setting $\Delta_r H^\circ(\text{at } T_m) = 0$ (because this corresponds to a maximum or minimum in ln K vs. $1/T$), we obtain the following simple equation that relates the temperature at which the value of K passes through a maximum or minimum to the values of $\Delta_r H^\circ$ and $\Delta_r C_p^\circ$ at just one temperature (298 K):

[11] $T_m = -[\Delta_r H^\circ(\text{at } T = 298 \text{ K})/\Delta_r C_p^\circ] + 298 \text{ K}$

Much of the rest of this paper is devoted to collection of C_p° values for $T = 298.15$ K, with a few illustrations of their uses; we will also cite measurements leading to C_p° values at other temperatures and their uses.

Although the focus in this paper is on the standard state partial molar heat capacities represented here by C_p°, non-standard state (for $m > 0$) partial molar heat capacities are also useful. Here we only mention that these non-standard state partial molar heat capacities are related to the temperature dependence of enthalpies of dilution and thence to the temperature dependence of activity coefficients and osmotic coefficients, as reviewed by Millero (1).

Experimental and calculation methods

One approach to obtaining standard state partial molar heat capacities is to solve eq. [1] for $\Delta_r H^\circ$, differentiate with respect to temperature, and combine with eq. [2] to obtain

[12] $\Delta_r C_p^\circ = R[2T(\partial \ln K/\partial T)_p + T^2(\partial^2 \ln K/\partial T^2)_p]$

Because of the magnification of uncertainties and errors associated with two differentiations, this approach is useful only when there are very accurate values for the equilibrium constant over a wide range of temperature. Our focus here is on other methods of obtaining standard state partial molar heat capacities of solutes.

Most of the standard state partial molar heat capacities that we will be considering have been derived from calorimetric

results expressed in terms of apparent molar heat capacities, $C_{p,\phi}$, which are defined in terms of measured quantities as

[13] $C_{p,\phi} = [C_p(\text{soln}) - n_1 C_{p,1}^*]/n_2$

In this defining equation, $C_p(\text{soln})$ represents the heat capacity of a solution containing n_1 moles of water and n_2 moles of solute and $C_{p,1}^*$ represents the molar heat capacity of water. The apparent molar heat capacity is related to the partial molar heat capacity of solute (C_p) by

[14] $C_p = C_{p,\phi} + n_2(\partial C_{p,\phi}/\partial n_2)$

At infinite dilution we have $n_2 = 0$ and thence the important relationship

[15] $C_p^\circ = C_{p,\phi}^\circ$

in which C_p° represents the standard state partial molar heat capacity of solute and $C_{p,\phi}^\circ$ represents the value of the apparent molar heat capacity that is obtained on extrapolation to $n_2 = 0$, corresponding to extrapolation to a composition of zero molality.

Apparent molar heat capacities of dilute solutions of strong electrolytes are represented accurately by equations of the form

[16] $C_{p,\phi} = C_p^\circ + (\omega)^{3/2} A_C(\rho_1^\circ)^{1/2}(m)^{1/2} + B_C\omega m$

in which C_p° represents the value of $C_{p,\phi}$ at $m = 0$ (see eq. [15]), A_C is derived from the Debye–Hückel theory and the dielectric constant of water, ρ_1° represents the density of water, m represents the molality, B_C is an adjustable parameter, and ω is defined by

[17] $\omega = 0.5\Sigma\nu_1(z_i)^2$

in which the ν_i are the subscripts in the chemical formula $A_{\nu+}B_{\nu-}$ and the z_i are the formal charges of the ions.

The experimental problems associated with obtaining accurate values of $C_{p,\phi}$ for dilute solutions are formidable because the difference between $C_p(\text{soln})$ and $n_1 C_{p,1}^*$ is very small compared with either $C_p(\text{soln})$ or $n_1 C_{p,1}^*$. It follows that accurate values of $C_{p,\phi}$ for dilute solutions can be obtained only from the results of extremely accurate measurements or from results of accurate measurements that lead reasonably directly to values of the difference represented by $[C_p(\text{soln}) - n_1 C_{p,1}^*]$ in the numerator of eq. [13]. The twin calorimeters designed, built, and used by Randall, Rossini, Gucker, and a few others, as reviewed by Parker (2), provided data of this kind and permitted the evaluation of the first reasonably accurate values of $C_{p,\phi}^\circ$ for aqueous electrolytes.

More recently, however, the Picker flow calorimeter (3) has permitted more accurate measurements to be made more rapidly, leading to most of the $C_{p,\phi}$ and derived C_p° values to be considered here. The clever principle of the original Picker calorimeter that was designed and built for measurements at or near 25°C has been adapted by Picker for measurements up to about 150°C and by Smith-Magowan and Wood (4) and others to permit measurements to much higher temperatures (and pressures).

Several publications (5–8) have reported consideration of and remedies for small systematic errors that may be present in flow calorimeters. In one of these papers Desnoyers et al. (5) also provide a useful summary of C_p° values that were obtained during the first few years of use of the Picker calorimeter in Desnoyers' laboratory.

Use of eq. [16] for evaluation of C_p° from measured values of $C_{p,\phi}$ at several molalities requires that we know the value of A_C from the Debye–Hückel theory. Because A_C depends on the second derivative of the dielectric constant of water with respect to temperature, there have been some uncertainties in choosing a "best" value. We therefore review briefly the results of several recent calculations.

Before going on to consider specific results, it is well to point out that some previous authors have written another version of eq. [16] in terms of $A_C(c)^{1/2}$ in which c represents concentration (molarity) rather than in terms of molality and $A_C(\rho_1^\circ)^{1/2}(m)^{1/2}$ as in our eq. [16]. Further, some authors have derived Debye–Hückel parameters that are appropriate to partial molar properties, while others have derived these parameters to be appropriate to apparent molar properties as in our eq. [16]. It is necessary to consider these complications and also lack of uniformity in symbols used to represent various quantities in making use of results of different authors. Because our eq. [16] contains the product $A_C(\rho_1^\circ)^{1/2}$, we will express results of various calculations in terms of this product.

Leduc et al. (9) have used published dielectric constants and densities of water to obtain values of $A_C(\rho_1^\circ)^{1/2}$ for several temperatures, including the value 28.95 J K^{-1} $mol^{-3/2}$ $kg^{1/2}$ for 25°C. Similar calculations have been reported by Perron et al. (10) for several temperatures; they have reported nearly the same value as above for 25°C. More recently, Pitzer and coworkers (11), Ananthaswamy and Atkinson (12), Archer and Wang (13), and Spitzer et al. (14) have reconsidered the temperature dependence of the dielectric constant of water and have carried out calculations of the various parameters to be used in Debye–Hückel equations for heat capacities and also other thermodynamic properties for wide ranges of temperatures. Results of all of these later calculations (11–14) are consistent with a "best" value of $A_C(\rho_1^\circ)^{1/2}$ from about 12–23% larger than the value from Desnoyers and colleagues (9, 10) that is given above.

In the favourable cases of electrolytes of 1:1 charge type for which we have accurate values of $C_{p,\phi}$ for sufficiently dilute solutions, choosing different reasonable (in the range cited above) values of $A_C(\rho_1^\circ)^{1/2}$ leads to very small differences in calculated values of C_p°, but for higher charge type electrolytes (14) or when results of accurate measurements are not available for sufficiently dilute electrolytes, choice of value for the Debye–Hückel parameter can have a significant effect on the value of the derived C_p°.

As will be seen later, most of the C_p° values that are selected as "best" for $T = 298.15$ K are based on measurements with Picker-type calorimeters and data analysis based on eq. [16] or similar equations. A simple and commonly adopted procedure for using eq. [16] is based on rearranging to obtain

[18] $C_{p,\phi} - (\omega^{3/2} A_C(\rho_1^\circ)^{1/2}(m^{1/2}) = C_p^\circ + B_C\omega m$

A graph of the quantity represented by the left side of eq. [18]

against m leads to a straight line, with the intercept at $m = 0$ being the value of C_p°.

Another approach that has proven useful is based on eq. [3] and enthalpies of reaction that have been measured at several temperatures. Early applications (15, 16) of this method involved calorimetric measurements leading to the standard enthalpies of ionization of aqueous benzoic acid at several temperatures (10–40°C). More recently and of more importance for our present purpose, Cobble, Criss, and others have used a method based on eq. [3] to obtain useful values of C_p° for several electrolytes over wide ranges of temperature, as first reported by Criss and Cobble (17). Their calorimetric measurements led to values of the standard state enthalpy of solution, $\Delta_S H^\circ$, of sodium chloride in water as represented by

[19] $\quad NaCl(cr) = Na^+(aq) + Cl^-(aq)$

at 13 temperatures ranging from 0.02°C to 95.18°C. The values of $\Delta_S C_p^\circ$ obtained as the derivative of $\Delta_S H^\circ$ with respect to temperature (see eq. [3]) can be expressed as

[20] $\quad \Delta_S C_p^\circ = C_p^\circ(Na^+,Cl^-) = C_p^\circ(NaCl)$

in which $C_p^\circ(Na^+,Cl^-)$ and $C_p^\circ(NaCl)$ represent the standard state partial molar heat capacity of aqueous sodium chloride and the molar heat capacity of NaCl(cr) at the temperature of interest. Because values of C_p° for NaCl(cr) were already known, Criss and Cobble (17) were able to obtain values of $C_p^\circ(Na^+,Cl^-)$ that were reported over the temperature range from 0 to 100°C. Gardner et al. (18) have carried out similar measurements at 114.25, 149.90, and 199.50°C and have combined these results with those from Criss and Cobble (17) to obtain values of $C_p^\circ(Na^+,Cl^-)$ that are reported over the 0–200°C range of temperatures. The method used in these two investigations (17, 180 and also others to be cited later has been called the "integral heat" method.

Bernarducci et al. (19) used still another method of obtaining a value for C_p°, based on combining a value of $C_{p,\phi}$ for a concentrated solution (relatively easy to measure) with the temperature dependence of the enthalpy of dilution to $m = 0$ for this same concentrated solution. They have applied this method to $FeCl_2(aq)$. Although their reported uncertainty (± 30 J K^{-1} mol^{-1}) in C_p° for 25°C is considerably larger than uncertainties attributed to values of C_p° for many electrolytes based on results of measurements with the Picker calorimeter or as derived from several applications of the "integral heat" method, it is likely that the method used by Bernaducci et al. (19) can also be applied usefully to some systems.

Analysis of heat capacity data for systems in which there is an identifiable chemical equilibrium requires consideration of what is now often called the "relaxation" contribution to the total heat capacity. An early example was provided by McCollum (20), who measured heat capacities of the system in which the equilibrium represented by $N_2O_4(g) = 2\ NO_2(g)$ contributes to the total measured heat capacity. Later, Randall and Taylor (21) wrote "If a reaction — for example, the dissociation of bisulfate ion into hydrogen and sulfate ions — is more complete at a higher temperature than at a lower, then the heat corresponding to the additional fraction of bisulfate dissociated at the higher temperature will be measured as though it were a part of the heat capacity of the solution." They (21) had recognized an important problem, but did not continue with any detailed thermodynamic calculations.

The first specific considerations and applications (22, 23) of relaxation contributions to the measured heat capacities of aqueous solutions were followed by many more, which will be cited later in connection with specific electrolytes. Here we call attention to general treatments by Mains et al. (24) and Blandamer et al. (25).

The principle of a relaxation contribution to a measured heat capacity can be illustrated by consideration of a simple imaginary system in which there is a temperature-dependent equilibrium between two isomeric forms of the same "substance," with these two isomeric forms mixing to form an ideal solution so that we need not be concerned here with such complications as activity coefficients, enthalpies of dilution, or the difference between $\Delta_r H$ and $\Delta_r H^\circ$. The chemical equilibrium in this imaginary system is represented by

[21] $\quad A = B \qquad K = f(1 - f)$

in which f represents the fraction of total substance that is in the B isomer form. The measured heat capacity of a system containing one mole is

[22] $\quad C_{p,meas} = (Q/\Delta T) = (1 - f)C_{p,A}^* + fC_{p,B}^* + (\Delta f/\Delta T)\Delta_r H$

in which $C_{p,A}^*$ and $C_{p,B}^*$ represent the heat capacities of the pure isomeric forms A and B, respectively. Because the changes in temperature in most measurements of heat capacities of solutions are small, it is common to replace $(\Delta f/\Delta T)$ with the differential equivalent, (df/dT), and thence obtain an analytical (rather than an equally useful and correct numerical) representation of the relaxation contribution to the total heat capacity. There is also the intangible matter of scientific beauty, which some of us see in an analytical representation. To evaluate the relaxation contribution, which is the last term on the right side of eq. [22], we begin by solving eq. [21] for f and then differentiating with respect to temperature to obtain

[23] $\quad df/dT = (dK/dT)/(1 + K)^2 = (K/K)(dK/dT)/(1 + K)^2$
$= K(d \ln K/dT)/(1 + K)^2 = K\Delta_r H^\circ/RT^2(1 + K)^2$

Using this last expression with the last term in eq. [22] and recognizing that $\Delta_r H^\circ = \Delta_r H$ for this ideal solution system, we obtain

[24] $\quad C_p^{rel} = K(\Delta_r H^\circ)^2/RT^2(1 + K)^2$

for the (always positive) relaxation contribution to the heat capacity.

Evaluation of C_p^{rel} for systems of nonideal electrolytes must include considerations of activity coefficients and their dependence on temperature (related to enthalpies of dilution) and to the distinction between $\Delta_r H$ and $\Delta_r H^\circ$ (also related to enthalpies of dilution), but the general principle is the same as outlined here for our simple imaginary ideal system. After values of C_p^{rel} have been calculated for an electrolyte system, these values are then subtracted from the experimental values of $C_{p,\phi}$ to obtain the $C_{p,\phi}$(species) values that are then combined with some version of the Debye–Hückel theory (such as eq. [16]) to obtain the standard state partial molar heat capacities

represented by C_p° to be used in various thermodynamic calculations of equilibrium constants, etc.

Because the details of calculation of C_p^{rel} are different for nearly every system that has been investigated, we do not try to illustrate any "typical" calculation. Instead, each reference cited here that involves any specific calculation of C_p^{rel} is followed by the symbol (C_p^{rel}) in the list of references.

Values of standard state partial molar heat capacities of aqueous solutes for T = 298.15 K and some of their uses

As background for our selection of "best" values for C_p° of aqueous solutes for 298.15 K, we begin by considering probable accuracies and uncertainties in values obtained in different ways.

It is now clear from experimental results and analysis reported in several publications already cited, in a recent analysis by Criss and Millero (26), and in other publications to be cited later that nearly all of the C_p° values derived from results of measurements with the Picker calorimeter have smaller uncertainties than do C_p° values derived from earlier measurements cited by Parker (2). Although we are not making use of the heat capacities for dilute solutions that have been cited by Parker (2), it is worth emphasizing that many of the results she has cited for more concentrated solution are still quite useful for other purposes.

Our considerations of the differences between C_p° values for the same solute reported by different users of Picker calorimeters and for a few solutes by the same users at different times provide one basis for estimating the experimental uncertainties to be associated with these values. Another contribution to the total uncertainty of C_p° values comes from the method of extrapolation to m = 0. As stated earlier in this paper, one common method for doing this extrapolation is based on eqs. [16] and [18]. But it should be recognized that other extrapolations that are consistent with the Debye–Hückel limiting law can also be justified; one such method of extrapolation, based on equations developed by Pitzer, has been used by Criss and Millero (26) because that formulation is well suited to combination with other thermodynamic quantities for calculation of the effect of temperature on activity coefficients. The difference in values of C_p° obtained by way of different extrapolation procedures is very small when there are values of $C_{p,\phi}$ for sufficiently dilute solutions, but becomes larger when such values are unavailable and extrapolations must be based on experimental results for less dilute solutions. All of these considerations lead us to suggest that total uncertainties in a few values of C_p° based on measurements with the Picker calorimeter may be as small as ± 1 J K^{-1} mol^{-1}, but most of these total uncertainties are in the range ± 2 to ± 4 J K^{-1} mol^{-1} for temperatures close to 25°C. For those systems for which it is necessary to make measurements on solutions of mixed electrolytes or for which C_p^{rel} is large, total uncertainties may be larger than ± 4 J K^{-1} mol^{-1}.

An illustration that provides partial justification for the uncertainty estimates above and that also leads to an estimate of uncertainties to be associated with values of C_p° obtained by application of the "integral heat" method can be based on consideration of values of C_p° for NaCl(aq) at 25°C.

The enthalpies of solution at several temperatures measured by Criss and Cobble (17) led them to $C_p^\circ = -79.1$ J K^{-1} mol^{-1} for NaCl(aq) at 25°C. The compilation by Desnoyers et al. (5), based only on measurements in their laboratory, lists $C_p^\circ = -84.4$ J K^{-1} mol^{-1} for NaCl(aq); their tabulated conventional single ion heat capacities lead to a calculated $C_p^\circ = -84$ J K^{-1} mol^{-1}. Criss and Millero (26) have analyzed several sets of reported values of $C_{p,\phi}$ and have obtained $C_p^\circ = -82.85$ J K^{-1} mol^{-1}; their tabulated single ion heat capacities lead to a calculated $C_p^\circ = -83.31$ J K^{-1} mol^{-1}. Hovey (27) has cited five values of C_p° ranging from -83.7 to -85.5 J K^{-1} mol^{-1}, with an average $C_p^\circ = -84.3$ J K^{-1} mol^{-1}; his tabulated single ion heat capacities lead to a calculated $C_p^\circ = -84.4$ J K^{-1} mol^{-1}. Clarke and Glew (28) have reviewed heat capacities and also other thermodynamic properties of NaCl(aq) over a range of temperatures and have selected $C_p^\circ = -83.94$ J K^{-1} mol^{-1} for NaCl(aq) at 298.15 K as the best value for overall consistency. Altogether, it now seems reasonable to select $C_p^\circ = -84$ J K^{-1} mol^{-1} as a "best" value for NaCl(aq) at 25°C, with a total uncertainty ± 1 J K^{-1} mol^{-1}. It therefore follows that the total uncertainty in the $C_p^\circ = -79.1$ J K^{-1} mol^{-1} reported by Criss and Cobble (17) is at least ± 4 J K^{-1} mol^{-1}. Further consideration of the calculations reported by Clarke and Glew (28) lead to the more specific estimate that the C_p° values from Criss and Cobble (17) for NaCl(aq) at temperatures up to about 100°C have probable uncertainties larger than ± 5 J K^{-1} mol^{-1} but smaller than ± 10 J K^{-1} mol^{-1}. Although these estimated uncertainties for C_p° values obtained by the integral heat method are larger than estimated uncertainties in C_p° values based on results of modern flow calorimetry, it is clear that C_p° values based on the integral heat method are accurate enough to be very useful.

Further support for the estimated uncertainty range for values of C_p° based on the integral heat method is provided by comparison of C_p° values for CsI(aq), for which we have -153.1 J K^{-1} mol^{-1} from Mitchell and Cobble's (29) application of the integral heat method and the probably more accurate -145.0 J K^{-1} mol^{-1} from flow calorimetry (5).

The comparisons of values of C_p° from the integral heat method with values of C_p° from modern flow calorimetry that we have cited have been chosen partly because of the importance of NaCl(aq) and partly to provide illustrations to support our estimates of uncertainties; it should not be assumed that these reasonable estimates of uncertainties represent established or even probable errors in the values of C_p° based on the integral heat method. For example, Mastroianni and Criss (30) have applied the integral heat method to obtain values of C_p° for $NaClO_4$(aq) over the range 0–95°C, including $C_p^\circ = 17.6$ J K^{-1} mol^{-1} for 25°C, which is in good agreement with C_p° = 15.2 and 16.6 J K^{-1} mol^{-1} from two sets of measurements (31, 32) with Picker flow calorimeters.

Jekel et al. (33) measured enthalpies of solution of $GdCl_3$(cr) at several temperatures and used these results to calculate $C_p^\circ = -435$ J K^{-1} mol^{-1} for $GdCl_3$(aq) at 25°C. Xiao and Tremaine (34) have made measurements with a flow calorimeter, leading to C_p° values for $Gd(ClO_4)_3$(aq), $La(ClO_4)_3$(aq), and $LaCl_3$(aq), which in turn lead to a calculated $C_p^\circ = -452$ J K^{-1} mol^{-1} for $GdCl_3$(aq) at 25°C. The difference (17 J K^{-1} mol^{-1}) between these two values of C_p° for $GdCl_3$(aq) that have been obtained in different ways is consistent with estimates of uncertainties already given here for 1:1

electrolytes because of the larger uncertainties in extrapolating to $m = 0$ for 3:1 electrolytes than for 1:1 electrolytes.

One use of standard state partial molar heat capacities is illustrated by beginning with calculation of $\Delta_r C_p^\circ$ for ionization of water as in

[25] $H_2O(liq) = H^+(aq) + OH^-(aq)$

For this calculation we use

[26] $\Delta_r C_p^\circ = C_p^\circ(H^+,X^-) + C_p^\circ(M^+,OH^-) - C_p^\circ(Na^+,X^-) - C_p^*(H_2O)$

Singh et al. (35) have applied eq. [26] by using their C_p° values for the electrolytes (HCl, NaCl, NaOH), (HBr, NaBr, NaOH), (HCl, KCl, KOH), and (HBr, KBr, KOH) to obtain $\Delta_r C_p^\circ = -214.1$, -215.7, -215.4, and -215.8 J K^{-1} mol^{-1}. Later C_p° values from Singh et al. (31) for aqueous $HClO_4$ and $NaClO_4$ led to $\Delta_r C_p^\circ = -213.8$ J K^{-1} mol^{-1}. Also, C_p° values from Enea et al. (36) for aqueous HNO_3, $NaNO_3$, and KNO_3 led to $\Delta_r C_p^\circ = -214.7$ and -214.6 J K^{-1} mol^{-1}. The average of all seven of these values is $\Delta_r C_p^\circ = -214.9$ J K^{-1} mol^{-1}. Because all of the heat capacities used in these calculations were obtained in the same laboratory, using the same flow calorimeter and the same experimental procedures, followed by the same kind of extrapolations to $m = 0$, some of whatever systematic errors were present have been cancelled in the subtraction of C_p° values shown in eq. [26].

It should also be mentioned that Allred and Woolley (7) have made flow calorimetric measurements in another laboratory, leading to values of C_p° for HCl(aq), NaCl(aq), and NaOH(aq) at 25°C (also two other temperatures). Their values of C_p° lead to $\Delta_r C_p^\circ = -216.8$ J K^{-1} mol^{-1} for ionization of water at 25°C, in satisfactory agreement with the values listed in the preceding paragraph.

On the basis of the eight value for $\Delta_r C_p^\circ$ of ionization of water cited (7, 31, 35, 36) in the two preceding paragraphs, we choose $\Delta_r C_p^\circ = -215$ J K^{-1} mol^{-1} as the best available value for ionization of water at 298 K. Because conventional single-ion heat capacities are based on $C_p^\circ(H^+) = 0$ and the molar heat capacity of pure water is known with excellent accuracy, this chosen best value for $\Delta_r C_p^\circ$ leads directly to a "best" conventional value for $C_p^\circ(OH^-)$ and is therefore a helpful start on compiling a useful collection of these single-ion heat capacities, to which we turn after one illustration of a use of heat capacities.

Earlier, we derived eq. [9] for the dependence of the equilibrium constant on temperature when $\Delta_r C_p^\circ$ is taken to be a constant, independent of temperature. Using the known value of $\Delta_r H^\circ$ at 298.15 K in eq. [8] permits evaluation of the constant of integration ΔH_i. Using the chosen value of $\Delta_r C_p^\circ = \Delta a$ with the known value of the equilibrium constant K at T = 298.15 K permits evaluation of the other constant of integration (I) and thence yields an equation that permits calculation of a value for the equilibrium constant at any temperature T. We carried out these calculations for several temperatures in the range 273–573 K (0–300°C) and found that the values of pK(calculated) differ by less than 0.02 from the best experimental values previously selected (37) for this temperature range. We also use our selected value of $\Delta_r C_p^\circ = -215$ J K^{-1} mol^{-1} and $\Delta_r H^\circ = 55\,815$ J mol^{-1} (37, 38) in eq. [11] to calculate $T_m = 557$ K (250°C) as the temperature where the equilibrium constant for ionization of water passes through a maximum. This calculated temperature is about 35° higher than the actual temperature (37) at which K passes through a maximum. Here we are not concerned with the small effect of the difference between $p = 1$ atm (or 1 bar) and the saturation pressure for $t > 100$°C, which has been discussed elsewhere (37).

It is possible to improve on the calculations summarized above by recognizing that C_p° values for electrolytes do depend on temperature and that $\Delta_r C_p^\circ$ also depends on temperature. Using $\Delta_r C_p^\circ = f(T)$ in eq. [3] leads to a more complicated version of eq. [8], which is then substituted in eq. [1] to obtain a more complicated version of eq. [9]. Later in this paper we cite some examples of such calculations, but it is worth emphasizing now that the simpler calculations described here, which are based on a constant (independent of temperature) $\Delta_r C_p^\circ$, are accurate enough over wide ranges of temperature to be useful for many purposes.

Tables 1–4 contain our selections of what we regard as "best" values for standard state partial molar heat capacities (C_p°) for $T = 298.15$ K for a large number of inorganic electrolytes and for a few "neutrals" (undissociated H_3PO_4, CO_2, SO_2, H_2S, NH_3) and one organic (acetic acid) that are related to electrolytes under consideration in this paper. All of the heat capacities listed in these tables are based on heat capacities of solutions that have been measured relative to the heat capacity of pure water, using modern flow calorimeters of the type developed by Picker et al. (3). Although we believe there are good reasons for basing our selections of best standard state partial molar heat capacities on heat capacities measured with flow calorimeters, we emphasize that heat capacities obtained in other ways are also useful. Some illustrations of such alternative heat capacities are provided in the following paragraphs.

Allred and Woolley (44) have used flow calorimetry to obtain standard state partial molar heat capacities of $NH_4^+Cl^-(aq)$ and $NH_3(aq)$; their results have been heavily weighted in selecting the values for these solutes that are listed in Tables 1 and 4, respectively. Allred and Woolley (44) have used their heat capacities in obtaining $\Delta_r C_p^\circ$ for

[27] $NH_4^+(aq) = H^+(aq) + NH_3(aq)$

at three temperatures. We select $\Delta_r C_p^\circ = 9$ J K^{-1} mol^{-1} as the best value (independent of temperature near 298 K) that can be derived from their results. We also note that Oloffson (65) has made calorimetric measurements leading to $\Delta_r H^\circ$ for reaction [27] at seven temperatures in the range 278–418 K and has derived (using eq. [3]) a temperature-independent $\Delta_r C_p^\circ = 11$ J K^{-1} P. Although it is likely that the uncertainty in the $\Delta_r C_p^\circ$ from measured heat capacities is slightly smaller than the uncertainty in the value derived by application of eq. [3] to enthalpies of reaction at several temperatures, the comparison cited here provides convincing evidence that the "integral heat" method based on eq. [3] can provide first-rate results.

Allred and Woolley (44) also used flow calorimetry to obtain standard state partial molar heat capacities of $Na^+,Ac^-(aq)$ and HAc(aq). On the basis of their results, we have selected (Table 4) $C_p(HAc) = 170$ J K^{-1} mol^{-1} as the best available value for 298.15 K. Two earlier calorimetric investi-

Table 1. Standard state partial molar heat capacities ($C_p°$)[a] of 1:1 aqueous electrolytes at 298.15 K.

[a]Units for $C_p°$ are J K^{-1} mol^{-1}.

gations (66, 67) led to $C_p°(HAc) = 165$ and 167 J K^{-1} mol^{-1}, each with larger uncertainty than the value we have selected, but in satisfactory agreement with the selected value. Allred and Woolley (44) used their heat capacities in calculating $\Delta_r C_p° = (-143 \pm 3)$ J K^{-1} mol^{-1} for the reaction represented by

[28] $HAc(aq) = H^+(aq) + Ac^-(aq)$

Olofsson (68) made calorimetric measurements leading to values of $\Delta_r H°$ at five temperatures in the range 274–373 K and used eq. [3] to derive $\Delta_r C_p° = (-143 \pm 5)$ J K^{-1} mol^{-1} for reaction [28]. Once again a comparison shows that calorimetrically measured heat capacities and calorimetrically measured enthalpies at several temperatures can lead to results that are in excellent agreement with each other, it being probable that the uncertainties are smaller for directly measured heat capacities than for heat capacities derived by way of eq. [3].

Table 5 contains our selections of "best" standard state partial molar heat capacities for single ions, all based on the common convention that sets $C_p°(H^+) = 0$. Using our previously selected $\Delta_r C_p° = -215$ J K^{-1} mol^{-1} for ionization of water with this convention and the accurately known molar heat capacity of water leads to $C_p°(OH^-) = -140$ J K^{-1} mol^{-1}. Then the value for $C_p°(Na^+,OH^-)$ listed in Table 1 leads to a value for $C_p°(Na^+)$. A further step is to use this value for $C_p°(Na^+)$ with the $C_p°(Na^+,Cl^-)$ listed in Table 1 to calculate a value for $C_p(Cl^-)$. There are, however, other routes to obtain these $C_p°$(ion) values. For example, the value for $C_p°(H^+,Cl^-)$ leads directly to a value for $C_p°(Cl^-)$, which can then be used with $C_p°(Na^+,Cl^-)$ to obtain a value for $C_p°(Na^+)$. We have considered a large number of these alternative routes to values for various $C_p°$(ion) and have selected those values that give the best overall fits to the $C_p°$ values listed in Tables 1–3, with allowance made for estimated uncertainties in the $C_p°$ values.

We have already illustrated how $C_p°$ values (only for T = 298.15 K) can be used in calculating the equilibrium constant for ionization of water over a wide range of temperatures. Similar calculations, using only $C_p°$ values for T = 298.15 K, have been carried out for other equilibria in several of the references (for examples see refs. 43, 50, 54, and 56) already cited.

Although we have chosen here to carry out calculations of equilibrium constants over a wide range of temperature by combining eqs. [1], [3], and [8] to obtain eq. [9], this same calculation can be done by combining eq. [8] with

[29] $\Delta_r S° = \Delta S_i + \Delta_r C_p° \ln T$

that is based on integration of eq. [4], to obtain $\Delta_r G° = \Delta_r H° - T\Delta_r S°$. Further use of this $\Delta_r G°$ in $\Delta_r G° = -RT \ln K$ permits

calculation of $K = f(T)$ as already done in another way. Similarly, combination of $\Delta_r G^\circ = \Delta_r H^\circ - T\Delta_r S^\circ$ for a cell reaction with $\Delta_r G^\circ = -nFE^\circ$ permits convenient calculations of standard state cell potentials (E°) over wide ranges of temperatures.

Heat capacities of aqueous solutions at temperatures other than T = 298.15 K

Heat capacities of solutions of several electrolytes have been measured over temperature ranges from 10 to 55°C. Results of such measurements permit evaluation of the parameters in various equations for $C_p^\circ = f(T)$, which then permit extrapolation to much higher temperatures. The Helgeson–Kirkham–Flowers (69) and Holmes–Mesmer (70) equations have been used many times for this purpose. An example of this kind of calculation using C_p° values for the temperature range 10–55°C for calculations that extend to 350°C is provided by Hovey et al. (55) for the second dissociation constant of sulfuric acid.

A clear illustration of the predictive power of the Helgeson–Kirkham–Flowers (HKF) and Holmes–Mesmer (HM) equations mentioned above is provided by consideration of values of $C_p^\circ[Na^+,Al(OH)_4^-]$. Hovey et al. (49) measured these heat capacities at four temperatures in the range 10–55°C and used the HKF equation to estimate heat capacities at much higher temperatures. Then Caiani et al. (71) measured these heat capacities at five temperatures in the range 53–245°C. Still

[a]Based on $C_p^\circ(H^+) = 0$.
[b]Units for C_p° are J K^{-1} mol^{-1}.

more recently, Chen et al. (72) have measured $\Delta_r H^\circ$ at five temperatures in the range 100–150°C for the reaction represented by

[30] $Al(OH)_3(cr) + OH^-(aq) = Al(OH)_4^-(aq)$

and applied eq. [3] to obtain values of $\Delta_r C_p^\circ$ and thence values of $C_p^\circ[Na^+,Al(OH)_4^-)]$. Although the complete collection of C_p° values based on these three sets of calorimetric measurements leads to the most accurate representation of the thermodynamic properties of this system, it is important to note that the high-temperature heat capacities predicted (49) on the basis of measurements over the relatively narrow range 10–55°C are in good agreement with the heat capacities that were measured or calculated via eq. [3] later.

As previously mentioned, we have not tabulated C_p° values from Criss, Cobble, and colleagues obtained by way of the integral heat method in selecting the "best" values for T = 298.15 K because we believe that values based on modern flow calorimetry are more accurate. But it should be recognized that their values for C_p° for several electrolytes are the best values available for $T > 298$ K and can be used for various calculations of the sort already described here and that have been described by Criss, Cobble, and colleagues.

Wood and colleagues at the University of Delaware have used a flow calorimeter of the type described in 1981 (4) for measurement of many heat capacities at high temperatures and also at various pressures, including measurements at temperatures above the critical temperature of water. Many of their results have been cited by Wood et al. (73). Other measurements have been reported for (H^+, Cl^-) to 140°C by Tremaine et al. (39), for [Na^+, OH^-] to 250°C by Simonson et al. (74), and for hydrolyzed and unhydrolyzed solutions of aluminum chloride by Conti et al. (75). We also mention that researchers at Brigham Young University have made calorimetric measurements leading to values of $\Delta_r H^\circ$ for several reactions at high temperatures and thence to useful values of $\Delta_r C_p^\circ$ for these high temperatures. All of these (and other) heat capacities for high temperatures are now sufficient in number and quality to justify a detailed review that cannot be included here.

Theoretical considerations of heat capacities of aqueous electrolytes

Theoretical analysis of C_p° values for aqueous electrolytes can contribute to our knowledge of ion–water interactions. Early efforts in this direction were reported by Zwicky (76) and by Everett and Coulson (77). More recent reports by Leyendekkers (78) and by Sen (79) illustrate two other approaches. Wood et al. (new work and a review are included in ref. 73) have worked on both theory and measurements to obtain information about partial molar heat capacities (also other thermodynamic properties) for aqueous electrolytes over a range of temperatures and pressures, including near and above the critical conditions for water. One theoretical prediction and experimental verification (80) is that the partial molar heat capacities of electrolytes approach $-\infty$ as T_c is approached from lower temperatures and approach $+\infty$ as T_c is approached from higher temperatures. We also mention that Oelkers et al. (81) have reviewed and extended earlier work by Helgeson and colleagues, such as that leading to the HKF equation (69).

Jolicoeur and Mercier (82), Conway (83) Tremaine et al. (84), French and Criss (85), and Abraham and Marcus (86) have reported methods of estimating "absolute" (rather than conventional) values of single ion heat capacities. It has been pointed out clearly and correctly in several of these papers that it may be appropriate to consider conventional ionic heat capacities when only ions of these same charge are being compared with each other (for example, to learn about the effects of ionic size on heat capacity), but it is necessary to consider "absolute" ionic heat capacities when comparing ions having different charges or when one is concerned with any quantitative theoretical analysis of heat capacities of hydration.

We also mention that Abraham and Marcus (86) and Criss and Millero (26) have provided useful reviews of standard state partial molar heat capacities of aqueous electrolytes. The first of these reviews (86) that was published in 1986 was concerned with both inorganic and organic electrolytes. Although parts of this review are now out of date because of research done in the past decade, the part that is devoted to organic electrolytes is still the best available review. In addition, there is a detailed discussion of the effects of ion–water interactions (hydration) on heat capacities. The more recent report by Criss and Millero (26) was concerned only with 1:1 electrolytes and is focussed on using heat capacities over a range of compositions as part of the evaluation of activity coefficients and osmotic coefficients as a function of both temperature and composition.

Acknowledgements

Effect of ligand structure, solvent, and temperature on the electrochemical behavior of polyarene–iron complexes

Alaa S. Abd-El-Aziz, Christine R. de Denus, Karen M. Epp, Simone Smith, Richard J. Jaeger, and David T. Pierce

Abstract: The electrochemical investigation of a number of polyarene–iron complexes ($[\mathbf{3}]^{2+}$–$[\mathbf{9}]^{5+}$) containing etheric, sulphide, and sulphone bridges indicated that there were various degrees of interaction based on the nature of the bridging heteroatoms. While the electrochemical investigation of all etheric complexes showed that the metallic moieties behaved as isolated redox centers, it was found that there was electronic communication (ca. 70–80 mV) for the isomeric sulphide complexes $[\mathbf{4}]^{2+}$ and $[\mathbf{6}]^{2+}$. The rate constant of the following chemical reaction (k_f) was calculated for some of these complexes and it was found that these rates were affected by the nature of the solvent, the bridging ligand, and the temperature. At various temperatures, k_f indicated a higher degree of stability for complexes containing sulphide bridges than for those containing etheric bridges, especially at room temperature. The effect of a strong coordinating solvent, such as acetonitrile, on the k_f of complex $[\mathbf{3}]^{2+}$ indicated that the substitution of the arene ligand with acetonitrile molecules proceeded as a dissociative mechanism. Controlled potential coulometry was also used to verify the transfer of two electrons in the first reduction process of the di-iron complexes.

Key words: cyclopentadienyliron, cyclic voltammetry, arene complexes, isolated and interacting redox centers.

Résumé : L'étude électrochimique d'un certain nombre de complexes polyarène–fer ($[\mathbf{3}]^{2+}$–$[\mathbf{9}]^{5+}$) contenant des ponts éthérés, sulfures et sulfones indique qu'il existe divers degrés d'interactions selon la nature des hétéroatomes créant les ponts. Même si l'étude électrochimique de tous les complexes éthérés ont montré que les portions métalliques se comporte comme des centres rédox isolés, il a été observé qu'il y a de la communication électronique (environ 70–80 mV) pour les complexes sulfurés isomères $[\mathbf{4}]^{2+}$ et $[\mathbf{6}]^{2+}$. On a calculé la constante de vitesse de la réaction chimque suivante (k_f) pour quelques-uns de ces complexes et on a trouvé qu'elles sont affectées par la nature du solvant, du coordinat servant de pont et par la température. À diverses températures, les valeurs de k_f indique que les complexes contenant des ponts sulfures sont plus stables que ceux contenant des ponts éthérés, particulièrement à la température ambiante. L'effet d'un solvant pouvant effectuer une forte coordination, tel que l'acétonitrile, sur la valeur k_f du complexe $[\mathbf{3}]^{2+}$ indique que la substitution du coordinat arène par de l'acétonitrile se produit par un mécanisme dissociatif. On a aussi utilisé de la coulométrie à potentiel contrôlé pour vérifier le transfert de deux électrons dans le premier processus de réduction des complexes di-fer.

Mots clés : cyclopentadiénylfer, voltampérométrie cyclique, complexes arènes, centres rédox isolés interagissants.

Introduction

Over the past few decades, the electrochemical behavior of organometallic materials has been the focus of interest of many chemists (1–6). Recent development in this field is due to the wide range of applications of these redox systems with specific interest being given to the arene complexes in light of their promising electrochemistry (7–14). The oxidation/reduction properties of oligomeric and polymeric materials have led to a thorough investigation of the electron transfer reactions in these complexes (15–23). This interest stems from the ability of these systems to exhibit mixed valency (3, 4, 24–27) and conductivity (28), as well as to sometimes act as electron reservoirs that initiate electron-transfer chain catalysis (1, 29–36).

Since the development of η^6-arene-η^5-cyclopentadienyliron complexes, numerous electrochemical studies have shown that these complexes undergo two successive one-electron reductions (1, 7–9, 37–41). The first reduction is chemically reversible and produces the neutral 19 e^- complex where the second reduction step leads to an anionic 20 e^- complex. It has been reported that the reversibility of the second reduction step is dependent on the nature of the arene or cyclopentadienyl rings (1, 8, 9, 41). Although Solodovnikov et al. have reported the formation of an extremely unstable 21 e^- dia-

nionic complex for the (naphthalene)FeCp system (42), it is the neutral arene systems that are the most important electron reservoirs and could be useful as catalysts in the reduction of other species existing in the solution via homogeneous charge transfer (43, 44). Electrolysis of this class of arene complexes led to the decoordination of the arenes and the formation of ferrocene as well as zerovalent iron (45–50).

There has been a tremendous effort to study the electrochemistry of bi- and polymetallic complexes because of the possible communication of the metallic species via the backbone of the coordinating ligands (7, 17, 20–25). The type of metal present as well as the bridging ligands often dictates whether the metal centers are interacting with, or isolated from, one another. The electrochemical studies of polyferrocenyl complexes demonstrate communication for the silicon-bridged species that is not evident in the case of the methylene-bridged analogues (20–23). In addition, Bard and coworkers have shown that, for the dicyclopentadienyliron phenanthroline complex, the planar polycyclic ligand allows for electrochemical communication to occur between the metal centers (7). The degree of communication is often determined by the separation of formal potentials (ΔE^0) measured by cyclic voltammetry (CV) (51). In an analogous manner, for a molecule with one redox center the CV would be the same as that for one containing multiple isolated redox centers (52). For such large systems with isolated redox centers, the electrochemical technique of controlled potential coulometry is often employed to determine the number of electrons involved in the electron transfer process (53–55).

Recently, we reported on the electrochemical behavior of a variety of cyclopentadienyliron-substituted benzenes and polycyclic and heterocyclic complexes (8, 9). It was found that the first reduction was chemically reversible in all the complexes while the second was dependent on the experimental conditions. We now wish to report on the effect of solvent, temperature, and bridging ligand for a series of isomeric bi- and poly-(cyclopentadienyliron) complexes with etheric, sulphide, and sulphone bridges. For some of these complexes, the rate constants of the following chemical reaction have also been determined.

Experimental

Chemicals

Organic solvents acetone (AC), acetonitrile (AN), and dimethyl sulfoxide (DMSO), were dried over calcium hydride for 2 days and were purified by distillation prior to their use. High-quality *N,N'*-dimethylformamide (DMF, Aldrich; Burdick and Jackson Brand, Baxter Scientific) was purged with purified dinitrogen and stored over Linde molecular sieves 4 Å (Strem Chemicals). Tetra-*N*-butylammonium perchlorate (TBAP) was received from Fluka and was used as the supporting electrolyte. Tetra-*N*-butylammonium hexafluorophosphate ($TBAPF_6$) was used as the supporting electrolyte for all coulometry and voltammetry associated with bulk-scale electrolysis, and was prepared by metathesis of tetra-*N*-butylammonium iodide (Aldrich) and ammonium hexafluorophosphate (Ozark–Mahoning) in acetone followed by recrystallization from ethanol. The η^6-arene-η^5-cyclopentadienyliron complexes used in this study were prepared according to previously described methods (56–58).

Electrochemical measurements

Cyclic voltammetric experiments were performed using a conventional three-electrode cell. The working electrode was either a platinum disk electrode (ca. 2 mm diam.) or a glassy carbon disk electrode (ca. 3 mm diam.). A quasi-reference electrode (Ag/AgCl) was utilized. However, ferrocene was added at the end of each experiment and served as the reference redox couple. The auxiliary electrode in these studies was a Pt wire. Temperatures from 293 to 233 K were obtained by means of a Dry Ice – acetone slush bath in a Dewar flask. The concentration of the complex was 2.0 mM, while that of the supporting electrolyte was 0.1 M. Before measurements, solutions were deaerated by passing high-purity nitrogen through them and the experiment was run under a blanket of purified nitrogen. An EG&G Princeton Applied Research model 263A potentiostat, interfaced with a microcomputer, was used in all experiments. CV simulations were run using the Digisim simulation program, version 2.0, from Bioanalytical Systems Incorporated.

All coulometry and voltammetry measurements associated with bulk-scale electrolysis experiments (conducted at the Chemistry Department, University of North Dakota) were performed with a three-electrode cell that was controlled by an EG&G Princeton Applied Research model 273 potentiostat. Electrolysis currents were recorded for a user-specified applied potential and were acquired over more than 300 s with a time interval of less than 0.5 s. The current–time set for each electrolysis was digitally integrated to yield total charge passed to within less than $\pm 1.0\%$ of comparable, electronically integrated currents. Stirred solution voltammograms were recorded before and after electrolysis to analyze for solution composition and were performed with a potential sweep rate of 0.02 V/s.

Bulk-scale electrolysis experiments were performed with the analyte at 3 mM concentration in 50 mL of DMF/0.1M $TBAPF_6$. Solutions were contained within a sealed electrochemical cell that was constantly purged with purified nitrogen and was cooled by partial immersion in a Dry Ice – acetone slush bath. Rapid stirring during electrolysis and voltammetry immediately before and after electrolysis was performed with a magnetic stir bar that was rotated at a constant rate at the cell bottom. The working electrodes used for controlled-potential coulometry were high surface area cylinders and were composed of either platinum mesh or reticulated vitreous carbon. A small platinum disk electrode (ca. 2 mm diam.) or larger glassy carbon disk electrode (ca. 3 mm diam.) was used as the working electrode for all voltammetry. The counter electrode in all cases was a platinum-mesh cylinder that was contained within a large, separate compartment containing DMF/0.1M $TBAPF_6$ in ionic contact with the analyte solution through a medium porosity glass frit. A silver wire coated with silver chloride acted as a quasi-reference electrode in DMF/0.1M $TBAPF_6$ and was separated from solution within a smaller fritted compartment. At the conclusion of each experiment, the quasi-reference potential was correlated to the potential of the ferrocene/ferrocinium couple (Fc/Fc^+) by addition of ferrocene to the solution.

Results and discussion

Our previous studies of monoiron arene complexes have shown two successive reduction steps for this class of cyclo-

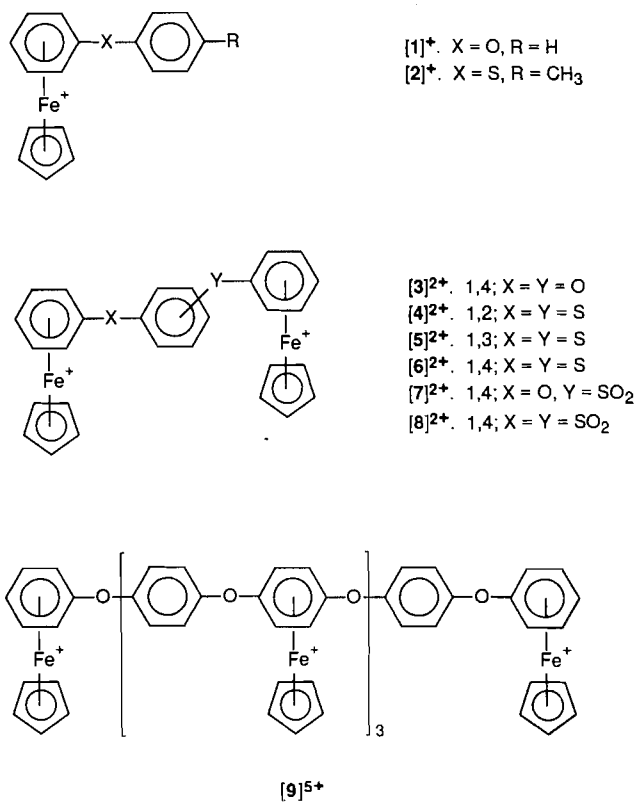
pentadienyliron arene complex (8, 9). The first reduction appeared to be chemically reversible at various temperatures when a HMDE was employed as the working electrode. In the present study, we have examined the electrochemistry of a number of arene complexes in DMF medium (Fig. 1) using platinum and (or) glassy carbon working electrodes. It was found that for the monometallic complexes ($[1]^+$, $[2]^+$) the chemical reversibility of the 18 e^-/19 e^- couple was dependent on the temperature and the nature of the substituent on the complexed arene. The first reduction at a platinum working electrode for these systems was chemically reversible at 253 K for both $[1]^+$ and $[2]^+$, leading to the formation of the stable 19 e^- complexes as outlined in Table 1. In contrast, studies at room temperature (293 K) indicated that although complex $[2]^0$ remained chemically stable, complex $[1]^0$ decomposed rapidly. A second wave for the reduction of the neutral 19 e^- complexes to the anionic 20 e^- complexes was also observed when a glassy carbon working electrode was used. This 19 e^-/20 e^- couple for complex $[2]^{0/-}$ was found to be chemically reversible ($E_{1/2}$ = −2.48 vs. Fc/Fc^+) at room temperature. These results are consistent with measurements reported previously (9).

Polyether complexes

Polyether complexes ($[3]^{2+}$–$[9]^{5+}$) also show two separate reduction steps, with the CV response being dependent on the nature of the complex, working electrode material, temperature, and solvent. It was found that for the oxygen-bridged arene complex $[3]^{2+}$, the chemical reversibility of both reduction steps was greatly dependent on the temperature and the solvent. At 293 K the first reduction (36 e^-/38 e^-) was partially chemically reversible while the second (38 e^-/40 e^-) was chemically irreversible. As the temperature was decreased to 233 K, the first process became chemically reversible as

Fig. 1. Complexes studied by cyclic voltammetry and controlled potential electrolysis.



shown in Fig. 2 and was recorded as a single wave at $E_{1/2}$ = −1.75 V vs. Fc/Fc^+. This suggested that the stability of the 38 e^- species formed by the first reduction increased with a decrease in temperature. In contrast to this behavior, the 40 e^- product from the second reduction remained unstable at all temperatures (293–233 K) and time frames (0.05–1.0 V/s) investigated. As indicated in Scheme 1, we are proposing that the bimetallic $[3]^{2+}$ complex reduces in two distinct steps and that in each step the complex adds two electrons. Since CV's of $[3]^{2+}$ are very similar in shape to those of the monoiron analogue ($[1]^+$), we are further proposing that the complex possesses electronically isolated iron centers on the time scale of our CV measurements. By this mechanism, each two-electron reduction is actually composed of separate one-electron reductions that occur in rapid succession at each iron site.

Such a mechanism is in agreement with previous findings for other complexes with noninteracting metal centers (52, 59, 60). However, conclusive evidence for two electrons being transferred in the first reduction process was obtained for $[3]^{2+}$ by controlled potential coulometry of a solution containing

Scheme 1.

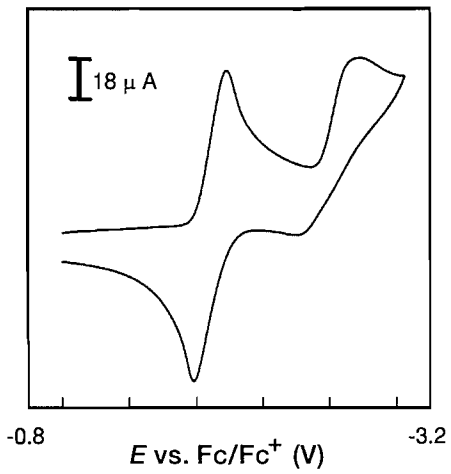

Fig. 3. Stirred solution voltammograms of 3.0 mM complex $[\mathbf{3}]^{2+}$ at 243 K in DMF/0.1 M $TBAPF_6$ recorded (*a*) before and (*b*) after partial electrolysis ($Q = 5.05$ C) at an applied potential of -1.93 V vs. Fc/Fc^+. Voltammograms were recorded with the same platinum disk working electrode and stirring rate.

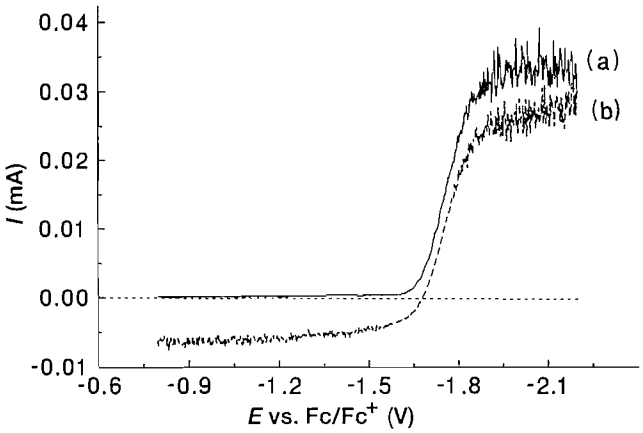
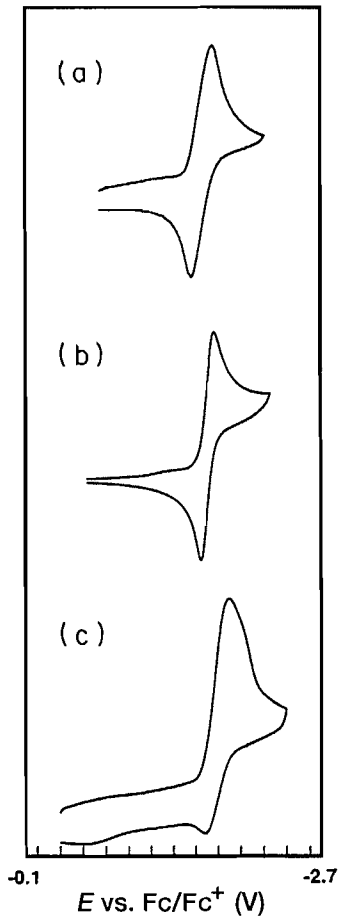


0.149 mmol of the complex at a large platinum mesh electrode. Plateau currents measured from stirred solution voltammograms (Fig. 3) recorded before and after a partial electrolysis at an applied voltage of -1.93 V vs. Fc/Fc^+ demonstrated that 18.1% of the complex was reduced without noticeable decomposition. From the 5.05 C of charge passed during electrolysis, an apparent *n*-value of 1.94 equiv./mol was determined. Electrolysis experiments that were extended to greater conversions demonstrated noticeable decomposition of the reduced complex, even at the lowest temperature of 228 K. Accurate coulometry was not possible with higher conversions because one or more of the decomposition products irreversibly adsorbed and passivated all electrode surfaces. Adsorption of these product(s) was especially severe at carbon electrode surfaces.

Solvent studies

The solubility of the dicationic complex $[\mathbf{3}]^{2+}$ in a number of solvents other than DMF (e.g., DMSO, AN, and AC) allowed for the examination of the electrochemical behavior of this sample complex and its reduced forms under a variety of conditions. It was observed that at 293 K the first reduction step was chemically irreversible in both AN and DMSO, while it was partially chemically reversible in the other two solvents at various CV scan rates (0.05–1.0 V/s). As the temperature was lowered to 253 K, the chemical reversibility of the 36 e^-/38 e^- couple increased in DMF, AN, and AC as indicated in Fig. 4. While it has been found that $[\mathbf{3}]^0$ may either undergo a second reduction or react with the solvent, the rate constants for the decomposition of the 38 e^- complex in a variety of solvents were analyzed in this work using the method described by Nicholson and Shain (61). By this method, the pseudo-first-order rate constant of the following chemical reaction was calculated at a variety of scan rates (0.05–1.0 V/s) with the average rate being reported with a standard deviation between 10 and 30%. It was found that the rate constant at 253 K was small for both AC ($k_f = 0.024$ s^{-1}) and DMF ($k_f = 0.037$ s^{-1}) while it was much greater for AN ($k_f = 0.577$ s^{-1}). This behavior may be attributed to the fact that AN is a stronger coordinating solvent to this class of arene cyclopentadienyliron complexes and that ligand substitution with the 38 e^- $[\mathbf{3}]^0$ complex is enhanced.

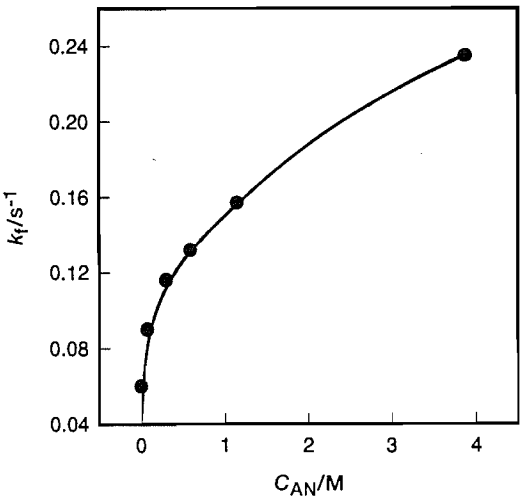
Fig. 4. Cyclic voltammogram at Pt of 2.0 mM complex $[\mathbf{3}]^{2+}$; $v = 0.2$ V/s at 253 K in (*a*) DMF containing 0.1 M TBAP; (*b*) AC containing 0.1 M TBAP; (*c*) AN containing 0.1 M TBAP.



Decoordination studies

To further investigate the effect of solvent on the kinetics of the following chemical reaction, complex $[\mathbf{3}]^{2+}$ was dissolved

Fig. 5. The rate constant of following chemical reaction k_f vs. concentration of AN, 2.0 mM complex $[\mathbf{3}]^{2+}$ in DMF containing 0.1 M TBAP.



in DMF and CVs were recorded after consecutive additions of AN to the electrochemical cell. The experiment was performed at 243 K due to the high chemical reversibility demonstrated by the 36 e^-/38 e^- couple in DMF at this temperature. Under these conditions, the couple showed a marked decrease in chemical reversibility as the solution concentration of AN was increased. This result clearly indicated that the neutral complex reacts with AN in some form of rate-limiting, ligand-substitution reaction. Such reactions were noted previously by Darchen, who showed that decoordination of monoiron complexes may result in the presence of a strong donor ligand such as $P(OMe)_3$, $CN(C_4H_9)$, or AN (45, 47).

Evidence for this type of substitution reaction was obtained by plotting the pseudo-first-order decomposition rate constant measured for the $[\mathbf{3}]^{2+/0}$ couple (61) against the concentration of AN (Fig. 5). The nonlinearity of the plot indicates a deviation from second-order behavior at high AN concentrations and thus the decomposition reaction was certainly not an associative process in which AN formed a transient coordinate intermediate with the neutral complex. A more chemically reasonable mechanism, and one which qualitatively fits the kinetic data in Fig. 5, was a dissociative interchange mechanism whereby $[\mathbf{3}]^0$ at least partially dissociates the arene ligand, and simultaneously adds one or more AN molecules (62). It should be noted, however, that distinguishing this mechanism from a completely dissociative process is not possible without activation parameters and that participation of a low-coordinate, fully dissociated intermediate during the decomposition reaction cannot be entirely ruled out (63). Because the ultimate fate of the AN-substituted product has been shown by CV in this work and by analysis in previous bulk electrolysis experiments (8, 9) to be neutral ferrocene and a decomplexed iron species, the reaction scheme given in Mechanism I has been proposed to explain the overall decomposition process associated with the $[\mathbf{3}]^{2+/0}$ couple. We have also been able to isolate and characterize these products using ^1H and ^{13}C NMR.

Although most of the experimental work reported herein centers on bimetallic systems ($[\mathbf{3}]^{2+}$–$[\mathbf{8}]^{2+}$), we have explored the electrochemical behavior of the pentairon polyether com-

Mechanism 1.

$$[\{(C_6H_5O)Fe^{II}Cp)\}_2C_6H_4]^{2+} + 2e^- \rightleftharpoons [\{(C_6H_5O)Fe^{I}Cp)\}_2C_6H_4]$$

$$[\{(C_6H_5O)Fe^{I}Cp)\}_2C_6H_4] + nS \xrightarrow{k} 2\,[S_n(Fe^{I}Cp)] + [(C_6H_5O)_2C_6H_4]$$

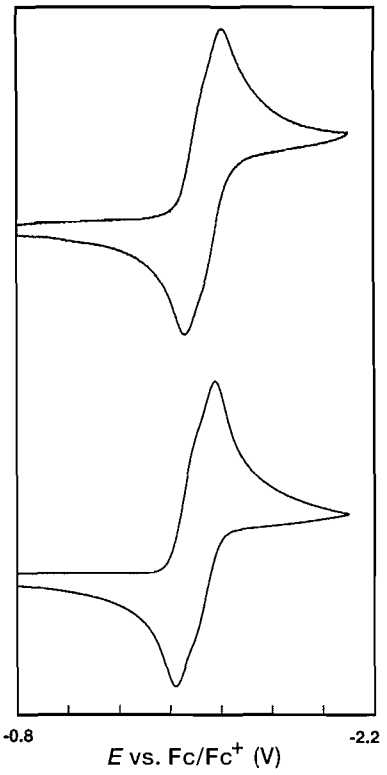
$$2\,[S_n(Fe^{I}Cp)]_2 \xrightarrow{\text{fast}} Fe^{II}(Cp)_2 + Fe^0 + 2nS$$

plex $[\mathbf{9}]^{5+}$. Our initial findings have shown that this complex exhibits voltammetry that is similar to the mono- and di-iron aryl ether complexes $[\mathbf{1}]^{2+}$ and $[\mathbf{3}]^{2+}$, namely, two distinct reduction processes centered at ca. −1.8 and −2.8 V vs. Fc/Fc^+. However, stability of the pentairon complex following the first reduction process appears to be much lower than that for either the mono- or di-iron analogues. Although this lower stability has made characterization of this redox process difficult, we are presently working towards characterizing the nature of the decomposition reaction and determining if indeed a total of five electrons are transferred to the complex during the first reduction step. Certainly, single reductive processes with such large multiplicity are decidedly rare. However, proof of such a system would indicate that these materials have a great deal of promise to behave as electron reservoirs.

Disulphide complexes

CV studies of bimetallic $CpFe^+$ complexes have been extended further to include sulphur-bridged aromatic compounds ($[\mathbf{4}]^{2+}$–$[\mathbf{6}]^{2+}$). Unlike the oxygen-bridged complex $[\mathbf{3}]^{2+}$, the sulphur-bridged complexes appear to show some measurable electronic communication between the iron centers on the CV time scale. In the case of the *o*- and *p*-substituted disulphide complexes ($[\mathbf{4}]^{2+}$ and $[\mathbf{6}]^{2+}$), two closely spaced processes are observed for the 36 e^-/38 e^- reduction waves corresponding to the reduction processes, which may be distinguished. Based on previous work by Bard and coworkers, it has been postulated that, for similar complexes, one metal moiety undergoes a reduction, which is closely followed by the reduction of the second metal moiety at a more negative potential (7). The presence of the sulphur bridge allows the increase in the electron density of the first iron moiety to be dispersed across to the second metal moiety, making it slightly more difficult to be reduced. Clearly, the behavior observed in the cyclic voltammetric results for $[\mathbf{4}]^{2+}$ and $[\mathbf{6}]^{2+}$ suggests that there is a small degree of electronic interaction between the two metals due to the presence of the sulphur bridge (64). The actual degree of communication can be gauged from the measured difference in formal potentials of the two one-electron reductions (ΔE^0). However, because waves for the distinct 36 e^-/37 e^- and 37 e^-/38 e^- reductions were severely overlapped for both $[\mathbf{4}]^{2+}$ and $[\mathbf{6}]^{2+}$, digital simulation of the CV wave shapes was used to extract the ΔE^0

Fig. 6. Cyclic voltammograms at Pt of 2 mM complex $[6]^{2+}$ in DMF containing 0.1 M TBAP; v = 0.1 V/s at 253 K. Simulated (bottom) and experimental (top).



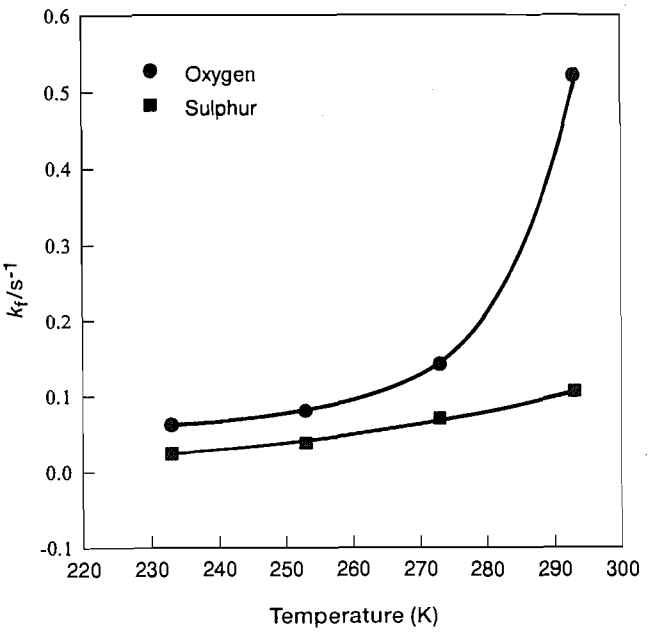
values. Simulation for complex $[6]^{2+}$ is shown in Fig. 6 along with the corresponding experimental voltammogram. Although small, the formal potential separations of ca. 70–80 mV measured for both complexes indicated a limited degree of electronic communication through the sulphur–arene bridge that was approximately the same for *para* and *ortho* substitution. Contrastingly, CV of the *meta* analogue $[5]^{2+}$ showed no measurable difference between formal potentials of its 36 e^-/37 e^- and 37 e^-/38 e^- couples, probably due to some electronic effects, and therefore behaved as if the iron centers were electronically isolated on the CV time scale.

As with the ether-bridged complex $[3]^{2+}$, the sulphide-bridged systems ($[4]^{2+}$–$[6]^{2+}$) also demonstrated instability of their 38 e^- species that caused solvent substitution and arene loss. However, the instability appeared to be much less pronounced for the sulphur analogues. Figure 7 compares the stability of the reduced complexes $[3]^0$ and $[5]^0$ in DMF. Although both 38 e^- species are unstable at room temperature, the sulphur-bridged analogue survives approximately five times longer than the ether-bridged species.

Sulphone complexes

The final group of bimetallic systems to be investigated in this work were complexes containing sulphone bridges ($[7]^{2+}$ and $[8]^{2+}$). Previous studies have shown that reduction of monoiron sulphones occurs at positive potentials of analogous aryl ether bridged complexes (9). Figure 8 compares voltammograms for the bimetallic sulphone $[8]^{2+}$, bimetallic ether $[3]^{2+}$, and the mixed bimetallic complex $[7]^{2+}$ recorded separately but in the same medium at 233 K. As found with the sulphide–arene bridged complexes $[4]^{2+}$ and $[6]^{2+}$, the bimetallic sulphone shows a small but finite potential separation between the 36 e^-/37 e^- and 37 e^-/38 e^- couples, suggesting some electronic communication between the iron centers of the molecule on the time scale of the CV measurement. A greater discrimination of the couples is observed for $[7]^{2+}$. However, this large formal potential separation of nearly 200 mV between the 36 e^-/37 e^- and 37 e^-/38 e^- couples was primarily due to the thermodynamically different iron environments and not to significantly enhanced electronic communication between the two centers. This clear observation of two one-electron reductions in the mixed complex lends further support to our claim that the initial reduction processes for all of our bimetallic complexes involve overall two-elecron reductions to 38 e^- species.

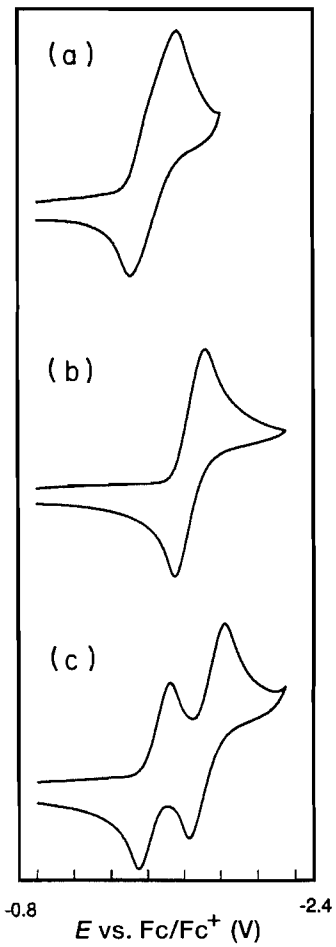
Fig. 7. Plot of temperature vs. the rate constant of the following chemical reaction for bimetallic complexes $[3]^{2+}$ and $[5]^{2+}$ in DMF.



Conclusion

These electrochemical studies have clearly shown the effect of the bridging ligand on the communication between the two metallic centers in bis(cyclopentadienyliron) arene systems. For the etheric complexes ($[3]^{2+}$ and $[9]^{5+}$) it was found that the iron centers were isolated in all cases, and that the rate of the following chemical reaction increased with both an increase in temperature and the number of iron centers present. A series of isomeric di-iron sulphide complexes ($[4]^{2+}$–$[6]^{2+}$) were also studied and it was determined that electrochemical recognition was apparent for complexes $[4]^{2+}$ and $[6]^{2+}$, with a ΔE^0 of 70–80 mV, while complex $[5]^{2+}$ did not show this behavior. Comparison of the rate constants of the following chemical reaction between complexes $[3]^{2+}$ and $[5]^{2+}$ indicated that this rate was dependent on the temperature, and it was accelerated for the etheric system. This suggested that the stability of the neutral species was approximately five times greater in the complexes with a sulphide bridge. It was also found that the electrochemical behav-

Fig. 8. Cyclic voltammogram at Pt; $\upsilon = 0.2$ V/s; 233 K: (*a*) complex $[8]^{2+}$ in DMF containing 0.1 M TBAP; (*b*) complex $[3]^{2+}$ in DMF containing 0.1 M TBAP; (*c*) complex $[7]^{2+}$ in DMF containing 0.1 M TBAP.



ior of complex $[3]^{2+}$ was greatly influenced by the solvent present. The effect of solvent on the kinetics was investigated using AN as the coordinating ligand, and it was found that there was a dependence of the following chemical reaction on the concentration of AN present. Controlled potential coulometry was used to determine that there were two electrons being transferred in the initial reduction step to produce the neutral radical species. Further evidence for a two-electron transfer was given by the investigation of complex $[7]^{2+}$, which contained a mixed oxygen–sulphone bridge. This complex indicated that two electrons were being transferred with a large ΔE^0 (200 mV) between the two reduction waves present, which led to a 38 e^- complex.

Electron transfer kinetics of cobaloxime complexes[1]

Kefei Wang and R.B. Jordan

Abstract: The rates of oxidation of $Co^{II}(dmgBF_2)_2(OH_2)_2$ by $Co^{III}(NH_3)_5X^{2+}$ (X = Br^-, Cl^-, and N_3^-) have been studied at 25°C in 0.10 M $LiClO_4$. The rate constants are 50 ± 9, 2.6 ± 0.2, and 5.9 ± 1.0 M^{-1} s^{-1} for X = Br^-, Cl^-, and N_3^-, respectively, in 0.01 M acetate buffer at pH 4.7. The relative rates are consistent with the inner-sphere bridging mechanism established earlier by Adin and Espenson for the analogous reactions of $Co^{II}(dmgH)_2(OH_2)_2$. The rate constants with $Co^{II}(dmgBF_2)_2(OH_2)_2$ typically are $\sim 10^3$ times smaller and this is attributed largely to the smaller driving force for the $Co^{II}(dmgBF_2)_2(OH_2)_2$ complex. The outer-sphere oxidations of cobalt(II) sepulchrate by $Co^{III}(dmgH)_2(OH_2)_2^+$ (pH 4.76–7.35, acetate, MES, and PIPES buffers) and $Co^{III}(dmgBF_2)_2(OH_2)_2^+$ (pH 3.3–7.42, chloroacetate, acetate, MES, and PIPES buffers) have been studied. The pH dependence gives the following rate constants (M^{-1} s^{-1}) for the species indicated: (1.55 ± 0.09) × 10^5 ($Co^{III}(dmgBF_2)_2(OH_2)_2^+$); (5.5 ± 0.3) × 10^3 ($Co^{III}(dmgH)_2(OH_2)_2^+$); (3.1 ± 0.5) × 10^2 ($Co^{III}(dmgH)_2(OH_2)(OH)$); (2.5 ± 0.3) × 10^2 ($Co^{III}(dmgBF_2)_2(OH_2)(OH)$). The known reduction potentials for cobalt(III) sepulchrate and the diaqua complexes, and the self-exchange rate for cobalt(II/III) sepulchrate, are used to estimate the self-exchange rate constants for the dioximate complexes. Comparisons to other reactions with cobalt sepulchrate indicates best estimates of the self-exchange rate constants are $\sim 2.4 \times 10^{-2}$ M^{-1} s^{-1} for $Co^{II/III}(dmgH)_2(OH_2)_2$ and $\sim 5.7 \times 10^{-3}$ M^{-1} s^{-1} for $Co^{II/III}(dmgBF_2)_2(OH_2)_2$.

Key words: electron transfer, cobaloxime, inner sphere, outer sphere, self-exchange.

Résumé : Opérant à 25°C, en solutions à 0,10 M de $LiClO_4$, on a étudié les vitesses d'oxydation du $Co^{II}(dmgBF_2)_2(OH_2)_2$ par du $Co^{III}(NH_3)_5X^{2+}$ (X = Br^-, Cl^- et N_3^-). Les constantes de vitesse sont de 50 ± 9, 2,6 ± 2 et 5,9 ± 1,0 respectivement pour X = Br^-, Cl^- et N_3^- dans un tampon acétate à 0,01 M, à un pH de 4,7. Les constantes de vitesse sont en accord avec un mécanisme de formation de pont dans la couche interne démontrée antérieurement par Adin et Espenson pour les réactions analogues du $Co^{II}(dmgH)_2(OH_2)_2$. Les constantes de vitesse pour le $Co^{II}(dmgBF_2)_2(OH_2)_2$ sont en général 1000 moins rapides et on attribue ce résultat principalement à une force motrice plus faible pour le complexe du $Co^{II}(dmgBF_2)_2(OH_2)_2$. On a aussi étudié es oxydations dans la couche externe du sépulcrate de cobalt(II) par le $Co^{III}(dmgH)_2(OH_2)_2^+$ (pH de 4,76 à 7.35, tampons acétate, MES et PIPES) et par le $Co^{III}(dmgBF_2)_2(OH_2)_2^+$ (pH de 3,3 à 7,42, tampons chloroacétate, acétate, MES et PIPES). Les relations avec le pH conduisent aux constantes de vitesse suivantes (M^{-1} s^{-1}) pour les espèces indiquées : (1,55 ± 0,09) × 10^5 ($Co^{III}(dmgBF_2)_2(OH_2)_2^+$); (5,5 ± 0,3) × 10^3 ($Co^{III}(dmgH)_2(OH_2)_2^+$); (3,1 ± 0,5) × 10^2 ($Co^{III}(dmgH)_2(OH_2)(OH)$); (2,5 ± 0,3) × 10^2 ($Co^{III}(dmgBF_2)_2(OH_2)(OH)$). On a utilisé les potentiels connus de réduction du sépulcrate de cobalt(III) et des complexes diaqua ainsi que la vitesse d'autoéchange pour le sépulcrate de cobalt(II/III) pour évaluer les constantes de vitesse d'autoéchange pour les complexes dioximates. Des comparaisons avec d'autres réactions du sépulcrate de cobalt indiquent que les meilleures évaluations des constantes de vitesse d'autoéchange sont d'environ 2,4 × 10^{-2} M^{-1} s^{-1} pour le $Co^{II/III}(dmgH)_2(OH_2)_2$ et d'environ 5,7 × 10^{-3} M^{-1} s^{-1} pour le $Co^{II/III}(dmgBF_2)_2(OH_2)_2$.

Mots clés : transfert d'électrons, cobaloxime, sphère interne, sphère externe, autoéchange.

[Traduit par la rédaction]

Introduction

The bis(dimethylglyoximato)cobalt(II) complexes ($Co^{II}(dmgH)_2$) are models for the B_{12r} state of coenzyme B_{12} (1). They are mild reducing agents, and the electron transfer can be either by an inner-sphere or an outer-sphere mechanism,

Scheme 1.

$$(H_3N)_5Co^{III}X + (H_2O)_2Co^{II}L \xrightleftharpoons{fast} (H_3N)_5Co^{III}\text{-}X\text{-}Co^{II}(OH_2)L + H_2O$$

$$(H_3N)_5Co^{III}\text{-}X\text{-}Co^{II}(OH_2)L \xrightarrow{k_{et}} (H_3N)_5Co^{II}\text{-}X\text{-}Co^{III}(OH_2)L$$

$$(H_3N)_5Co^{II}\text{-}X\text{-}Co^{III}(OH_2)L \xrightarrow{fast} Co^{II} + 5NH_3 + XCo^{III}(OH_2)L$$

depending on the nature of the oxidant. It has been shown (2) that the oxidation of $Co^{II}(dmgH)_2(OH_2)_2$ by $Co^{III}(NH_3)_5X^{2+}$ (X = halide and pseudohalide) proceeds by the classical X-bridged inner-sphere pathway (3) shown in Scheme 1 (L = $(dmgH)_2$, charges are omitted) by identifying the bridge-transferred product $Co^{III}(dmgH)_2(X)(OH_2)$.

Part of the present study concerns the rates of oxidation of $Co^{II}(dmgBF_2)_2(OH_2)_2$ by $Co^{III}(NH_3)_5X^{2+}$ (X = Br^-, Cl^-, and N_3^-). A comparison of these results with those of Adin and

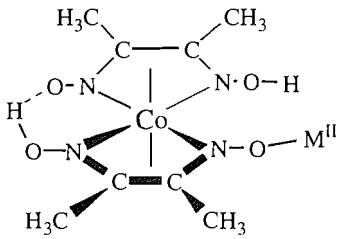
[1] 
1 2

Espenson (2) on $Co^{II}(dmgH)_2(OH_2)_2$ provides some measure of the effect of the -BF_2 substituents on the inner-sphere reactivity of these systems.

Studies of the reduction of the cobalt(III) derivatives have yielded less definitive mechanistic results. Prince and Segal (4), Balasubramanian et al. (5), and Dayalan and Vijayaraghavan (6) have studied the reduction of various $Co^{III}(dmgH)_2(L)_2^+$ and $Co^{III}(dmgH)_2(X)(L)$ (X = halide or pseudohalide, L = amine or pyridine) complexes by aqueous V^{2+}, Fe^{2+}, and Cr^{2+}. These studies were done in acidic media (pH < 3), and the $[H^+]$ dependence of the reaction rate was used as an important criterion to assign the mechanism. The $[H^+]$ dependence is attributed to protonation equilibrium of the $dmgH^-$ ligand, possibly as shown in eq. [1]. If eq. [1] is a rapidly maintained pre-equilibrium, then the apparent second-order rate constant is given by eq. [2],

$$[2] \qquad k_2 = \frac{k_0 K_a + k_H[H^+]}{K_a + [H^+]}$$

where k_H and k_0 are specific rate constants for reduction of the protonated (**1**) and unprotonated (**2**) complexes, respectively. In general, reductions by V^{2+} are either independent or first order in $[H^+]$ and may be controlled by substitution on $V(OH_2)_6^{2+}$ in some cases. The reactions with $Fe(OH_2)_6^{2+}$ show independent and inverse $[H^+]$ dependencies and the rate order is $I^- > Br^- > Cl^-$ for the reduction of $Co^{III}(dmgH)_2(py)(X)$ (6). This order is opposite to that for reduction of the $Co^{III}(NH_3)_5X^{2+}$ complexes, and was suggested as evidence for bridging through the oximate rather than the halide ligand. The $[H^+]^{-1}$ dependence of the Fe^{2+} reduction of $Co^{III}(dmgH)_2(py)(X)$ (6) also was taken to support such an oximate ligand bridged pathway. The bridged intermediate may be pictured as in **3**, which has some precedent from the complexation of $Co^{III}(dmgH)_2(OH_2)_2^+$ by aqueous iron(III) (7).



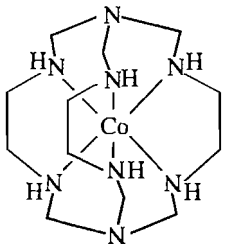
3

The most definitive criterion for establishing an inner-sphere mechanism is to identify the bridging ligand transferred product (3, 8). This is best done with Cr^{2+} as the reducing agent because the Cr^{III} product is substitution inert and can be separated and identified by standard methods. Unfortunately, only rather limited studies of this type have been done. Segal and Prince studied the $Cr^{2+} + Co^{III}(dmgH)_2(NH_3)_2^+$ reaction ($k_2 = 40 + 780 \times [H^+]$ M^{-1} s^{-1}, 25°C) and initially reported no bridge-transferred product, but later (4*c*) separated, by ion-exchange chromatography, a fraction containing $dmgH^-$ and Cr^{3+}. Balasubramanian and Vijayaraghavan (5*b*) did a product study for the Cr^{2+} reductions of $Co^{III}(dmgH)_2(N_3)(NH_3)$ and $Co^{III}(dmgH)_2(N_3)_2^-$ and reported the product ratios $Cr(dmgH)^+/CrN_3^{2+}$ of 2:1 and 1:2, respectively. These results indicate competitive bridging by the azide and oximate ligands, with the latter being more important for the neutral complex. However, it remains possible that the $Cr(dmgH)^+$ was produced by oxidation of a Cr^{2+}–dmgH complex during product analysis.

The main inconsistency between these studies is in the magnitude of K_a (eq. [1]). Prince and Segal (4) determined an approximate value of 0.25 M for $Co^{III}(dmgH)_2(NH_3)_2^+$; Balasubramanian et al. (5) and Dayalan and Vijayaraghavan (6) find values of $(1–7) \times 10^{-3}$ M for various $Co^{III}(dmgH)_2(X)(L)$ species. This difference might be ascribed to the charge on the complexes, but Adin and Espenson (9) had found earlier that $K_a \approx$ Å 0.3 M for various neutral alkyl species, $Co^{III}(dmgH)_2(R)(OH_2)$.

There are no reports of definite outer-sphere reductions of the cobaloxime(III). However, outer-sphere reductions of structurally similar Co(III) tetraaza macrocyclic complexes have been studied extensively by Endicott and co-workers (10–14). In these complexes, the tetraaza ligands form a square-planar chelating ring binding to the Co cation, with the two axial positions of Co occupied by water ligands. The cross reactions between these $Co^{III}(N_4)(OH_2)_2^{3+}$ and $Co^{II}(N'_4)(OH_2)_2^{2+}$ (N_4 and N'_4 represent different tetraaza macrocyclic ligands) are supposed to be outer sphere, and the cross-reaction rates have been determined and used with Marcus theory to calculate the rates for the electron self-exchange. The self-exchange rates were discussed in terms of the Franck–Condon barrier, which is the inner-sphere reorganization energy resulting from the bond length changes accompanying the electron-transfer process. In addition to being structurally analogous to the tetraaza complexes, the cobalt(II)–dioximes are also low spin, and provide further examples to test the effect of this feature on Co(III)/Co(II) self-exchange rates. Most Co(III)/Co(II) exchanges involve high-spin cobalt(II) and there has been some disagreement (15–22) on the influence of the spin state change on the electron exchange rate.

The present study reports the first outer-sphere reduction of $Co^{III}(dmgH)_2^+$ and $Co^{III}(dmgBF_2)_2^+$ by using the cobalt(II) sepulchrate ion ($Co(sep)^{2+}$) as the reducing agent. In $Co(sep)^{2+}$ (**4**), the cobalt(II) ion is encapsulated within a macrocyclic ligand cage.



4

The cage ligand prevents substitution on the cobalt(II) ion, so that the electron-transfer from $Co(sep)^{2+}$ to the cobaloximes(III) must be via an outer-sphere mechanism. The observed reaction rates are used to estimate the cobaloxime(III)/(II) electron self-exchange rates by the Marcus cross relationship and the results are compared to those of various $Co(N_4)(OH_2)_2^{3+/2+}$ complexes.

Experimental section

Materials

$Co(dmgBF_2)_2{\cdot}2H_2O$ was prepared according to Bakac et al. (23) $[Co^{III}(dmgH)_2(OH_2)_2]ClO_4$ was prepared by the method of Ablov et al. (24–26) through a series of cobaloxime(III) intermediates as described below.

$[Co^{III}(dmgH_2)(dmgH)Cl_2]{\cdot}2H_2O$, trans-*dichlorobis(dimethylglyoximato)cobalt(III) (ref. 24)*

A finely ground mixture of 2.38 g (0.01 mol) of $CoCl_2{\cdot}6H_2O$ (Fisher) and 2.32 g (0.01 mol) of dimethylglyoxime ($dmgH_2$, Fisher), was treated with ~15 mL of water and the slurry was stirred on a hot plate at 70–80°C for 15 min. The heating was turned off and 3–4 mL of H_2O_2 (30%, Fisher) were added slowly with stirring . The excess H_2O_2 was removed by boiling the solution for about 10 min, and ~30 mL of concentrated HCl (36%, BDH) was added to yield a dark-green precipitate. The mixture was cooled to room temperature, and then in an ice bath. The solid product was collected on a sintered glass filter and washed twice with dilute HCl (5% v/v), ethanol, and diethyl ether. Yield: 80%. The product was formulated as $[Co^{III}(dmg_2H_3)Cl_2]{\cdot}2H_2O$ according to the elemental analysis. Anal. calcd. for $[Co(C_4H_6O_2N_2)_2H_3Cl_2]{\cdot}2H_2O$: C 24.2, H 4.78, N 14.1, Cl 17.9; found: C 24.4, H 4.88, N 13.9, Cl 18.2. The NMR spectrum of this complex in d_6-DMSO shows methyl protons at 2.35 ppm and water as a broad peak at 7.5 ppm. The methyl proton resonance is shifted 0.44 ppm downfield from that in $dmgH_2$ (1.91 ppm). The shift upon coordination of $dmgH^-$ to cobalt(III) is consistent with the reported value of ~0.4 ppm for other cobaloxime(III) complexes (27).

$[Co^{III}(dmgH)_2Cl(H_2O)]$, trans-*chloroaquabis(dimethylglyoximato)cobalt(III)*

This product was prepared by aquation of $[Co^{III}(dmg_2H_3)Cl_2]{\cdot}2H_2O$ (22). The dichloro salt (1.8 g) was covered with 6–8 mL of boiling water and the mixture was stirred for 20 min on a steam bath, and then cooled in ice. The greenish yellow solid obtained by filtration was washed twice with ice-cold water, ethanol, and diethyl ether. Yield: 75–85%.

$[Co^{III}(dmgH)_2(OH)(OH_2)]$, trans-*hydroxoaquabis(dimethylglyoximato)cobalt(III) (ref. 23)*

$[Co^{III}(dmgH)_2Cl(OH_2)]$ (1.4 g) was covered with ~4 mL of a cold aqueous saturated Na_2CO_3 solution, and the mixture was stirred until the color changed from a yellowish green to gray-yellow. The precipitate was collected by filtration, washed twice with small amounts of cold water and cold ethanol, and finally with diethyl ether. Yield: 55%.

$[Co^{III}(dmgH)_2(OH_2)_2]ClO_4{\cdot}H_2O$, trans-*diaquobis(dimethylglyoximato)cobalt(III) perchlorate (ref. 26)*

When 0.7 g of $[Co(dmgH)_2(OH)(OH_2)]$ was dissolved in 4 mL of 2 M $HClO_4$, a yellowish brown solid precipitated, and more was formed when a few drops of concentrated $HClO_4$ were added. The product was collected by filtration, and washed twice with small amounts of ice-cold water and methanol, and finally with diethyl ether. Yield: 35%. The product was formulated based on the elemental analysis. Anal. calcd. for $[Co(C_4H_7O_2N_2)_2(OH_2)_2]ClO_4{\cdot}H_2O$: C 21.7, H 4.55, N 12.7; found: C 21.6, H 4.62, N 12.4. The NMR spectrum in d_6-DMSO shows the methyl protons at 2.54 ppm, and the water protons as a broad peak at 7.4 ppm. The electronic spectrum has a maximum at 240 nm with a molar absorptivity coefficient of 2.2×10^4 M^{-1} cm^{-1}, consistent with the values of 2.1×10^4 M^{-1} cm^{-1} (240 nm) and 1.95×10^4 M^{-1} cm^{-1} (238 nm) reported by Heckman and Espenson (28) and Kita and Jordan (29), respectively. Reduction of this complex in aqueous solution with amalgamated zinc under an argon atmosphere produces a bright yellow solution of $Co^{II}(dmgH)_2(OH_2)_2$. This species has a distinctive absorption maximum at 462 nm, with a molar absorptivity coefficient of 3.42×10^3 M^{-1} cm^{-1}, in agreement with a reported value of 3.40×10^3 M^{-1} cm^{-1} (28).

Solutions of $Co^{III}(dmgBF_2)_2(OH_2)_2^+$ were prepared by electrolysis of $Co^{II}(dmgBF_2)_2(OH_2)_2$ immediately before use. The electrolysis was done in an H-shaped electrolysis cell, with a sintered glass filter (10–20 μm) separating the anode and cathode compartments. The cathode was $Cu^{2+}(aq)/Cu$, and the anode was Pt in the $Co^{II}(dmgBF_2)_2$ solution. $LiClO_4$ (Amend) was added as the supporting electrolyte at a concentration of 0.09 M in both compartments. To avoid diffusion of Cu^{2+} ion into the anode compartment, the small amount of $Cu(NO_3)_2$ solution was carefully placed with a dropper at the bottom of the cathode compartment, and only the anode tube was stirred during the electrolysis. The electrolysis was carried out at ~1 V and 0.4–0.6 mA for 0.5–1 h, during which time most of the yellow color of the $Co^{II}(dmgBF_2)_2$ solution faded. If acetate buffer was required for the kinetic studies, the buffer was added to the solution of $Co^{II}(dmgBF_2)_2$ at pH ~ 4.7. The pH was adjusted with NaOH to the desired values for kinetic studies after the electrolysis.

The two halopentaamminecobalt(III) complexes, $[(H_3N)_5CoCl](ClO_4)_2$ (30) and $[(H_3N)_5CoBr](ClO_4)_2$ (30), and the azidopentaamminecobalt(III) complex $[(H_3N)_5CoN_3]Cl_2$ (31) were prepared according to the published methods.

1,3,6,8,10,13,16,19-Octaazabicyclo[6.6.6]eicosanecobalt-(III) trichloride (cobalt(III) sepulchrate trichloride, or $Co(sep)Cl_3$) was obtained from Aldrich, and the solution of $Co(sep)^{2+}$ was prepared by reduction of the cobalt(III) sepulchrate solution over amalgamated zinc under argon.

Redistilled water was used in all preparations and kinetic studies. Other chemicals used in the preparations are of reagent or analytical grade. For buffer preparations, sodium acetate was from Fisher, chloroacetic acid from BDH, and MES hydrate and PIPES from Aldrich.

Kinetic measurements

All kinetic runs were carried out at 25 ± 0.2°C. The ionic strength was maintained at 0.100 M with $LiClO_4$, and the total buffer concentration is 0.01 M. Acetate buffer was used in the studies of $Co^{II}(dmgBF_2)_2(OH_2)_2$ with $(H_3N)_5CoX^{2+}$, and the pH was kept at 4.72 ± 0.02 for all runs. Other buffers, MES, PIPES, and chloroacetic acid, were used in appropriate pH ranges in the studies of the cobaloxime(III)–$Co(sep)^{2+}$ system. The pH of each solution was measured with a Corning 125 pH meter.

The absorbance decrease due to the oxidation of $Co^{II}(dmgBF_2)_2(OH_2)_2$ by $(H_3N)_5CoCl^{2+}$ and $(H_3N)_5CoN_3^{2+}$ was followed on a Hewlett Packard 8451 diode array spectrophotometer at 454 nm, with the oxidant in excess. A 5.0 cm cylindrical spectrophotometer cell was used, and the reactant solutions were degassed with argon before measurement. The absorbance–time data (80 points over 3–4 half-lives) were analyzed by least squares to obtain the first-order rate constants. The reported second-order rate constants are the average of three measurements at different $(H_3N)_5CoX^{2+}$ concentrations.

The reaction between $(H_3N)_5CoBr^{2+}$ and $Co^{II}(dmgBF_2)_2(OH_2)_2$ was observed on a stopped-flow spectrophotometer (Cantech Scientific Ltd) at 454 nm. The data (256 points/trace) were collected to an MS-DOS 486 computer and at least 150 points for each trace were analyzed by least squares to give the first-order rate constants. The reported rate constants are the averages of at least six runs at each of three oxidant concentrations.

The kinetics of reduction of $Co^{III}(dmgH)_2(OH_2)_2^+$ and $Co^{III}(dmgBF_2)_2(OH_2)_2^+$ by $Co(sep)^{2+}$ were followed by stopped-flow spectrophotometry at 460 nm and 452 nm, respectively, with the $Co(sep)^{2+}$ in excess. The kinetic measurements were performed under anaerobic conditions, since the $Co(sep)^{2+}$ can reduce O_2 in the acidic media to produce H_2O_2, and $Co^{II}(dmgH)_2(OH_2)_2$ is extremely sensitive to O_2 and H_2O_2. The $Co(sep)^{2+}$ solution was transferred to the stopped-flow storage syringe through a serum cap under argon and the cobaloxime(III) solution in the other syringe was capped with a serum cap and degassed with argon for at least 20 min. The reduction of $Co^{III}(dmgH)_2(OH_2)_2^+$ shows biphasic behavior due to the formation and then decomposition of $Co^{II}(dmgH)_2(OH_2)_2$. The absorbance–time profiles were fitted to a biphasic model to obtain the first-order rate constants for the reduction and decomposition.

Results and discussion

Oxidation of $Co^{II}(dmgBF_2)_2(OH_2)_2$ by $(H_3N)_5CoX^{2+}$

For each system, the rate was studied at three cobalt(III) complex concentrations in at least 10-fold excess over the $Co^{II}(dmgBF_2)_2(OH_2)_2$ concentration in 0.01 M acetate buffer at pH 4.72. The observations indicate that the rate is first order in each reactant, and the second-order rate constants k_2 are collected in Table 1 along with the results reported by Adin and Espenson (2) on the oxidation of $Co^{II}(dmgH)_2(OH_2)_2$.

Adin and Espenson established a bridged inner-sphere mechanism for oxidation of $Co^{II}(dmgH)_2(OH_2)_2$ by $(NH_3)_5CoX^{2+}$ ($Br^- > Cl^- \gg F^-$) by the identification of $Co^{III}(dmgH)_2(X)(OH_2)$ as the exclusive product. They interpreted the variation of k_2 with bridging ligands as the order of stability of the X-bridged precursor complexes following the analysis suggested by Haim (32). The order of k_2 values suggests soft-acid character for the $Co^{II}(dmgH)_2(OH_2)_2$ complex.

A common inner-sphere mechanism for the $Co^{II}(dmgBF_2)_2(OH_2)_2$ and $Co^{II}(dmgH)_2(OH_2)_2$ reductants is consistent with the rate constant ratio $k_{2Br}/k_{2Cl} \approx 20$ for both cobaloxime(II) complexes. For $X = Cl^-$ and N_3^-, the reactivity difference is smaller for both $Co^{II}(dmgBF_2)_2(OH_2)_2$ and $Co^{II}(dmgH)_2(H_2O)_2$, with k_{2Cl}/k_{2N_3} ratio of ~0.4 in the former and ~2 for the latter. The different order may be due to some differences in affinity of Cl^- and N_3^- toward the two cobaloxime(II) complexes. For the outer-sphere reduction of $(H_3N)_5CoX^{2+}$ by $Ru(NH_3)_6^{2+}$ (33), the ratios k_{2Br}/k_{2Cl} and k_{2Cl}/k_{2N_3} of 6 and ~140, respectively, also indicate an inner-sphere mechanism of the cobalt(II) oximes.

The values of k_2 for $Co^{II}(dmgBF_2)_2(OH_2)_2$ oxidations are (1–6) × 10^3 times smaller than those of the $Co^{II}(dmgH)_2(OH_2)_2$ complex. Since the substitution lability for these two cobaloxime(II) complexes is not expected to differ substantially, based on our observed comparable solvent exchange rates for the two complexes (34), the large difference in the k_2 values indicate that the bridge-mediated electron-transfer process is rate controlling in the inner-sphere mechanism. The slower oxidation of $Co^{II}(dmgBF_2)_2(OH_2)_2$ may be due to its less favorable reduction potential of 0.65 V (NHE) compared to 0.36 V (NHE) for $Co^{II}(dmgH)_2(OH_2)_2$. If the Marcus theory (35) prediction of a square-root dependence of the rate on the equilibrium constant is also applicable to these inner-sphere electron transfers, then $Co^{II}(dmgH)_2(OH_2)_2$ is predicted to be ca. 2.8 × 10^2 more reactive. This factor would account in large part for the reactivity difference of the

[a]At 25°C with $\mu = 0.10$ M. Errors quoted are one standard deviation.
[b]Estimated as described in text vs. NHE by assuming a $pK_a' = 9$ for $Co^{II}L(OH_2)_2$ (L = $(dmgH)_2$ and $(dmgBF_2)_2$).

Fig. 1. pH dependence of the second-order rate constants for reduction of $Co^{III}(dmgH)_2$ by $Co(sep)^{2+}$ (25°C, $\mu = 0.10$ M, the calculated curve is generated by using parameters in Table 2).

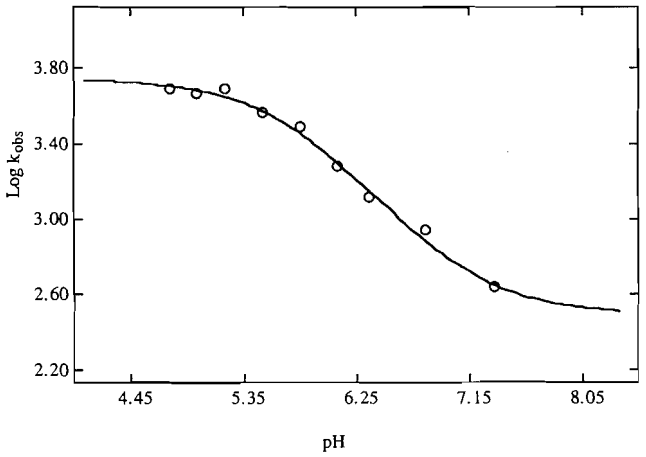

Fig. 2. pH dependence of the second-order rate constants for reduction of $Co^{III}(dmgBF_2)_2$ by $Co(sep)^{2+}$ (25°C, $\mu = 0.10$ M, the calculated curve is generated by using parameters in Table 2).

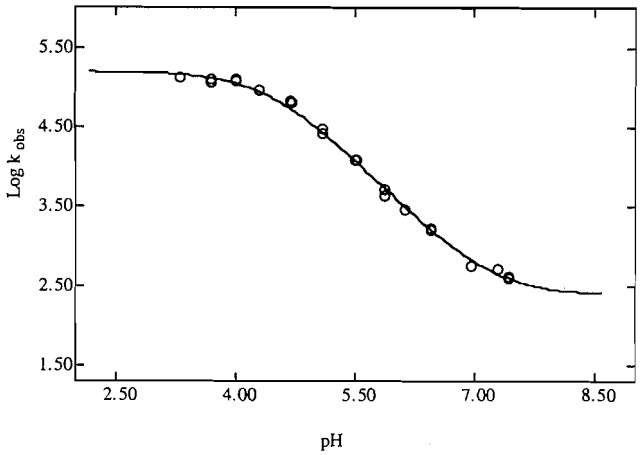


cobaloximes, and the remaining factor of ~10 could be attributed to less favorable precursor complex formation with $Co^{II}(dmgBF_2)_2(OH_2)_2$.

Reduction of cobaloximes(III) by $Co(sep)^{2+}$

The second-order rate constants for reduction of $Co^{III}(dmgH)_2(OH_2)_2^+$ and $Co^{III}(dmgBF_2)_2(OH_2)_2^+$ by cobalt(II) sepulchrate decrease with the acidity, as shown in Figs. 1 and 2, respectively. This dependence suggests an equilibrium involving the dissociation of the proton from the axial coordinated water, as shown in Scheme 2, with the diaqua form more reactive than the hydroxoaqua form.

Scheme 2.

$$(H_2O)_2Co^{III}L^+ \underset{}{\overset{K_a}{\rightleftharpoons}} (HO)(H_2O)Co^{III}L + H^+$$

$$(H_2O)_2Co^{III}L + Co(sep)^{2+} \xrightarrow{k_a} (H_2O)_2Co^{II}L + Co(sep)^{3+}$$

$$(HO)(H_2O)Co^{III}L + Co(sep)^{2+} \xrightarrow{k_b} (HO)(H_2O)Co^{II}L^- + Co(sep)^{3+}$$

L = $(dmgH)_2$ or $(dmgBF_2)_2$

From Scheme 2, the observed second-order rate constant k_{obs} is given by eq. [3]:

$$[3] \qquad k_{obs} = \frac{k_a[H^+] + k_bK_a}{K_a + [H^+]}$$

The values of pK_a, k_a, and k_b, obtained by least-squares analysis of the observed k_{obs} vs. $[H^+]$ data, are given in Table 2, and are used to obtain the calculated curves shown in Figs. 1 and 2.

The pK_a of 5.78 for $Co(dmgH)_2(OH_2)_2^+$ is in reasonable agreement with the value of 5.14 ± 0.02 (at 25°C, in 0.1 M $NaClO_4$) obtained from potentiometric titration by Ablov et al. (36). For $Co(dmgBF_2)_2(OH_2)_2^+$, the pK_a is lower by 1.4 units, as might be expected from the electron-withdrawing effect of the $-BF_2$ substituents in the modified macrocycle. In the pH ranges of our kinetic studies (4.8–7.4 for $Co^{III}(dmgH)_2^+$ and 3.3–7.4 for $Co^{III}(dmgBF_2)_2^+$), neither the ionization of the second proton ($pK_{a2} = 8.38 \pm 0.03$ for $Co^{III}(dmgH)_2(OH_2)_2^+$ (34)) nor the protonation of the dmgH ligand (eq. [1], $pK_a \sim 0.5$ (2) or ~2.5 (3, 4)) seems to have an influence on the k_{obs} measurement.

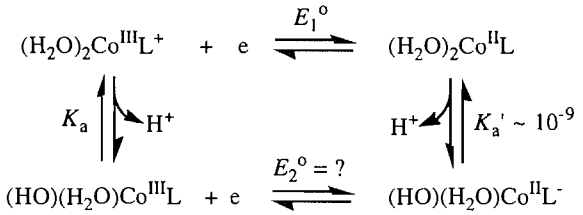
To analyse the reduction rate constants in terms of Marcus theory, one requires the reduction potentials of the reactants. These are known for $Co(sep)^{3+}$ and for the diaqua complexes, $Co(dmgH)_2(OH_2)_2^+$ and $Co(dmgBF_2)_2(OH_2)_2^+$, but not for the corresponding hydroxo complexes. The latter values have been estimated from the reaction cycle in Scheme 3.

From Scheme 3, the E_2^0 values are given by eq. [4]:

$$[4] \qquad E_2^0 = E_1^0 - 0.059\,(pK_a' - pK_a)$$

where the pK_a values are known from the kinetic results in

Scheme 3.



L = $(dmgH)_2$ or $(dmgBF_2)_2$

Table 2, but the pK_a' for diaqua cobaloxime(II) complexes are unknown. A value of $pK_a' = 9$ has been assumed since this is typical for bivalent first-row transition metal ions (37). The E^0 values are given in Table 2.

The self-exchange rate constants for the cobaloxime(III)/(II) couples have been estimated from the Marcus cross relationship (38), eq. [5],

$$[5] \quad k_{12} = (k_{11}k_{22}K_{12}f_{12})^{1/2}W_{12}$$

where k_{12} is the cross-reaction rate constant ($= k_{obs}$), k_{11} and k_{22} are the self-exchange rates for oxidant and reductant, and K_{12} is the equilibrium constant of the cross reaction. The f_{12} and work term corrections (W_{12} and w_{ij}) have been calculated from the following equations (39):

$$[6] \quad \ln f_{12} = \frac{[\ln K_{12} + (w_{12} - w_{21})/RT]^2}{4\ln(k_{11}k_{22}/Z^2) + (w_{11} + w_{22})/RT}$$

$$[7] \quad W_{12} = \exp[-(w_{12} + w_{21} - w_{11} - w_{22})/2RT]$$

$$[8] \quad w_{ij} = \frac{(4.225 \times 10^3)z_iz_j}{r(1 + 0.3285r\sqrt{\mu})}$$

where Z is the collision frequency, taken to be 1×10^{11}

M^{-1} s^{-1}, r is the sum of the radii of the reactants in Å, μ is the ionic strength, z_i is the charge on the ion, the numerical constants are for water at 25°C, and w_{ij} values are in cal mol^{-1}.

There has been a good deal of discussion (15–22) about the application of eq. [5] to cobalt(III)/(II) reactions because of the spin state changes involved and the possibility that the reactions are nonadiabatic. If the latter is the case, then a nonadiabatic factor κ of uncertain magnitude may be included on the right-hand side of eq. [5], and calculations of self-exchange rate constants become proportionately uncertain. Most recently, Shalders and Swaddle (22) have concluded that these reactions are essentially adiabatic.

For the specific case of reactions of $Co(sep)^{3+/2+}$, the justification and confidence in calculations based on eq. [5] can be tested by comparing observed and calculated values of k_{11} and k_{12} for systems in which these are known. Such results for 13 systems are summarized in Table 3, where the known k_{11} and k_{22} are used to give a calculated k_{12}, and k_{22} and k_{12} give a calculated k_{11}. For the vast majority of these systems, the observed and calculated values of k_{12} agree within a factor of ≤ 10, although the calculated values are always larger. Since k_{11} depends on $(k_{12})^2$, the calculated k_{11} are ≤ 100 times smaller than the experimental values. The two exceptions are $Co(bipy)_3^{3+}$ and $Co(phen)_3^{3+}$ where the calculated k_{12} is 20 and 50 times, respectively, larger than the experimental value, and the calculated k_{11} are proportionately much smaller. These exceptions might be ascribed to conjugation in the ligand, making self-exchange more favorable than when a reaction partner has no such conjugation. However, this effect does not appear in the terpy system. It should be noted that the first eight cobalt complexes listed in Table 3 have cobalt(II) in the high-spin state, but cobalt(II) is low spin for the remaining entries. There does not appear to be any systematic difference between these two types of systems.

To estimate k_{11} for the cobalt–oxime complexes, one could simply use the k_{11}(calcd.) in Table 3. However, for the other systems, k_{11}(calcd.) is typically 5–10 times smaller than k_{11}(obsd.), so that one might expect as an upper limit for the oximes that the true k_{11}(obsd.) $\approx 10 \times k_{11}$(calcd.) and this estimate has been entered in Table 3.

Endicott et al. (12) studied the variation of self-exchange rates with structure changes for a series of homologous *trans*-$Co(N_4)(OH_2)_2^{3+/2+}$ couples in which both Co(II) and Co(III) are low spin. The self-exchange rates were evaluated from the cross-reaction rates among these complexes. Structural studies have shown that the Co—N bond length changes very little between the Co(III) and Co(II) forms of these complexes, but the axial Co—OH_2 bond lengths are 0.38–0.57 Å longer for Co(II) because the unpaired electron occupies the antibonding d_{z^2} orbital. Endicott et al. attributed the variation of the self-exchange electron-transfer rates to the reorganization energies that result from changes in Co–OH_2 bond length Δd.

The cobaloxime systems are structurally similar to the $CoN_4(OH_2)_2$ complexes in that the equatorial Co—N bond lengths are 1.87–1.89 Å, and are very similar for the Co(III) and Co(II) forms (39). The lengthening of the axial Co—OH_2 bonds (Δd) for Co(II) compared to Co(III) is estimated as 0.31 Å for the $(dmgH)_2$ complex, from the Co—N(py) bond lengths in $Co^{II}(dmgH)_2(py)_2$ (40) and $Co^{III}(dmgH)_2(py)_2^+$ (41). For the $(dmgBF_2)_2$ complex, Co(II)—OH_2 and Co(III)—OH_2 bond lengths can be estimated as 2.28 and 1.97 Å from the Co—O bond lengths in $Co^{II}(dmgBF_2)_2(CH_3OH)_2$ (23) and $Co^{III}(dmgH)_2(X)(OH_2)$ (X = halide ions) (42). Therefore, Δd for both diaqua cobaloxime(II) complexes is estimated to be ~0.31 Å.

For these and other low-spin Co(II)/Co(III) systems, the self-exchange rates and structural change information are collected in Table 4. Our estimates for the cobaloxime complexes seem to conform reasonably with the suggestion of Endicott et al. (12) that larger structural change causes a smaller self-exchange rate constant for $CoN_4(OH_2)_2$ complexes. It is rather more surprising that the structurally quite different $Co([9]aneS_3)_2^{3+}$ and $Co(azacapten)^{3+}$ complexes also seem to follow this trend.

The chemistry of thujone. XVIII.[1] Homothujone and its derivatives

James P. Kutney, Yong-Huang Chen, and Steven J. Rettig

Abstract: The monoterpene thujone (**1**) is ring expanded regioselectively to provide homothujone (**4**) in order to explore its potential as a chiral starting material. Stereoselective Robinson annulation of homothujone provides an enone intermediate (**5**), further derivatization of which was undertaken to furnish functionalized naphthalenones useful for synthesis of the antifeedant (−)-polygodial and the ambergris fragrance (−)-Ambrox®.

Key words: thujone, homothujone, synthesis, naphthalenones, polygodial, Ambrox.

Résumé : On a effectué une expansion régiosélective de la thujone (**1**) en homothujone (**4**) afin d'explorer ses potentiels comme produit de départ chiral. L'annellation stéréosélective de Robinson réalisée au départ de l'homothujone conduit à une énone intermédiaire, **5**, qui a été transformée en dérivé pour fournir des naphtalénones fonctionnalisées utiles dans la synthèse de l'antiappétant (−)-polygodial et de la fragrance d'ambregris, (−)-Ambrox®.

Mots clés : thujone, homothujone, synthèse, naphtalénones, polygodial, Ambrox.

[Traduit par la rédaction]

Introduction

The logging practice of Western red cedar (*Thuja plicata* Donn) in British Columbia generates a waste material consisting of branches and leaves. This material, also called "slash," can be steam distilled to provide an essential oil containing the monoterpene thujone (**1**) in concentrations of 85–90%, Although this readily available oil can be of use in the perfumery and household chemical industry, higher grade chemical products originating from thujone are of interest in terms of economic benefit and environmental concern. For example, recent synthetic studies from our laboratories have established that thujone is a versatile chiral building block for enantioselective syntheses of biologically active natural products and their analogues including insect juvenile hormone analogues, insecticidal pyrethroids and aryl terpenoids, sesquiterpenes, and steroids (1).

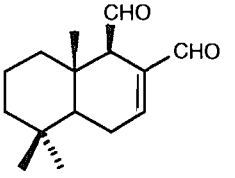
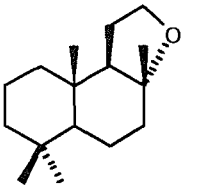
These diverse studies have revealed that **1**, via its rigid bicyclo[3.1.0]hexane system, affords regio- and stereo-selective reactions such as Robinson annulation to generate chiral synthons for terpene and steroid syntheses, and specific cyclopropyl ring-opening reactions of thujone analogues for a variety of interesting routes to chiral natural products and related compounds, etc.

To further elaborate upon the versatility of this readily available and inexpensive chiral synthon, it was of interest to consider ring expansion of **1** to "homothujone" (**4**) to ascertain whether the latter compound could increase the overall versatility and potential use of thujone in synthetic chemistry.



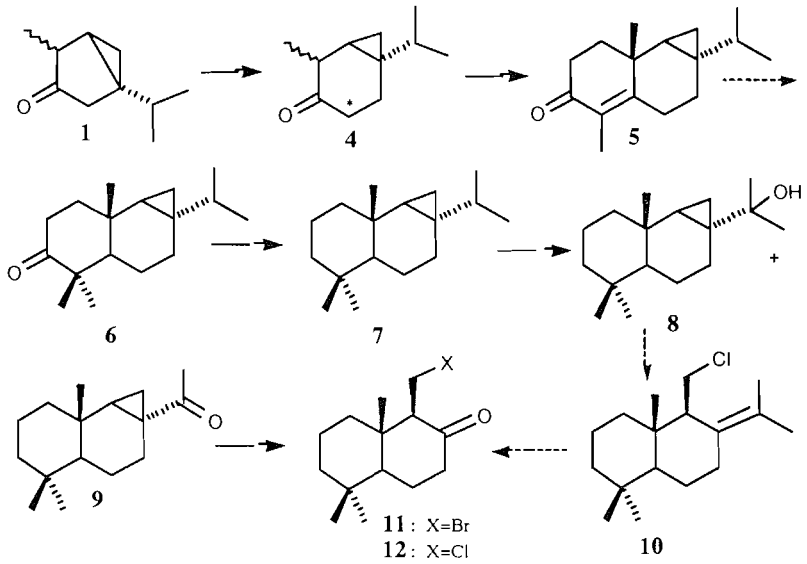
2



3

Scheme 1 shows the overall plan in which the concept is incorporated to afford functionalized *trans*-fused naphthalenones useful for further elaboration into (−)-polygodial (**2**) and (−)-Ambrox® (**3**). Homothujone (**4**) could be converted to enone **5** by Robinson annulation. Birch reduction of **5** followed by enolate trapping should produce a *trans* ketone **6** and, after reduction, the hydrocarbon **7**. Via a previously established ozonation reaction, **7** would afford **8** and **9**. Finally, acid-catalyzed cyclopropyl ring-opening reactions already developed in our laboratories (2) are expected to convert **8** and **9** to **10** and **11**, respectively. Functional groups in both **11** and **12** would then allow the final elaboration to either (−)-polygodial (**2**) or (−)-Ambrox® (**3**).

Scheme 1. The overall plan to develop the homothujone strategy.

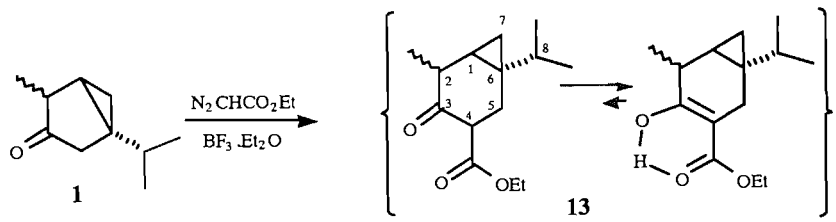


The apparent advantage of the homothujone strategy over previous routes to functionalized naphthalenones is that the *trans* A/B ring fusion could possibly be generated by the Birch reduction directly, rather than through a tedious stereochemical correction sequence from the A/B *cis*-fused systems obtained in earlier studies (1). The homothujone strategy might incorporate 7 of the original 10 carbon atoms present in thujone into potential target molecules in a novel way. In this publication, we would like to report our initial studies on this new strategy.

Results and discussion

Regioselective ring expansion of thujone

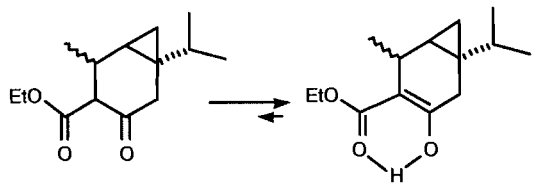
The desired regioselective ring expansion of thujone was



accomplished by treating thujone with ethyl diazoacetate and boron trifluoride etherate under nitrogen at room temperature (3). The β-ketoester 13,[3] which existed mainly in its enol form, was isolated in 70% yield. The mass spectrum of **13** showed a molecular ion at *m/z* 238. The UV spectrum indicated an absorption band at 258 nm (log ε = 3.980) while the IR spectrum displayed a broad hydroxyl absorption at 3370 cm^{-1}, an intense conjugated ester carbonyl stretching absorption at 1655 cm^{-1}, and a weak carbon–carbon double bond stretching absorption at 1615 cm^{-1}. The ^1H NMR spectrum revealed three separate one-proton signals at high field, δ 0.30 (dd, J = 4.4 and 8.8 Hz), 0.39 (t, J = 4.4 Hz), and 0.68 (dd, J = 4.4 and 8.8 Hz), corresponding to the three protons in the cyclopropane ring. Two methyl doublets (J = 5.6 and 4.4 Hz), corresponding to the two methyl groups at the isopropyl side chain, overlapped at δ 0.98 ppm. There were a one-proton multiplet at δ 1.03 ppm corresponding to the methine proton at C8, a methyl doublet (J = 7.2 Hz) at δ 1.24 ppm corresponding to the methyl at C2, and a methyl triplet (J = 6.8 Hz) at δ 1.31 ppm corresponding to the methyl of the ethyl ester group. A two-proton signal of AB type at δ 2.25–2.57 ppm (J = 16 Hz) was assigned to the methylene at C5 while a quartet (J = 7.2 Hz) at δ 2.64 ppm was due to the methine at C2. The J coupling constant between the methine protons at C1 and C2 was zero! A two-proton multiplet at δ 4.21 ppm corresponded to the methylene in the ethyl ester group and a very low-field singlet signal at δ 12.24 ppm was due to the hydroxyl proton in the enol form of **13**.

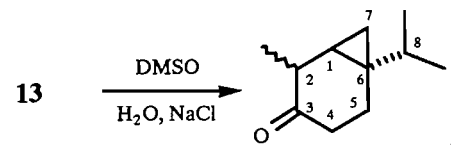
The spectroscopic data presented above could not differentiate the enol form of **13** from that of **14**, which would be the product of carbon insertion from the more substituted side of the carbonyl function in thujone. Crucial evidence was obtained, however, from the next step, i.e., the decarboxylation of the β-keto ester (**13**).

[3] Because thujone in use was a mixture of α-thujone and β-thujone (10:1), the product **13** was a mixture of two diastereomers in a similar ratio, as revealed by GC. No attempt was made to separate these two diastereomers. The ^1H NMR spectral data presented here represent the characterization of the major α diastereomer while other spectroscopic data are the gross properties of the diastereomeric mixture. This situation remains the same for homothujone **4**.

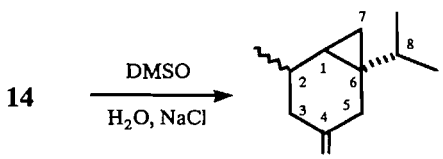


14

Treatment of **13** in moist DMSO with sodium chloride at 140°C for a few hours produced **4**[4] in 95% yield (4). The mass spectrum of **4** showed its molecular ion at *m/z* 166 while the IR spectrum indicated a carbonyl absorption at 1700 cm^{-1}. It is expected that **4** would have the three α protons (to the carbonyl group), that is, C2 and C4, in the region between δ 2.00 ppm and δ 3.00 ppm in the ^1H NMR spectrum whereas **15** available from **14** would reveal four protons in this region. To our surprise, **4** contained four protons in this region: two at δ 2.10 ppm (m), one at δ 2.35 ppm (m), and one at δ 2.47 (dt, J = 3.0 and 8.0 Hz) ppm. A series of decoupling experiments were performed to clarify the situation. Irradiation of the one-proton signal at high field (δ 0.72 ppm), which was assigned to one of the three cyclopropane protons, caused the multiplet at δ 2.47 ppm to collapse into a quartet (J = 8.0 Hz) in addition to the simplification of the complex two-proton signal at high field (δ 0.50 ppm), which was assigned to the two remaining cyclopropane protons. Irradiation of the signal at δ 0.50 ppm resulted only in the collapse of the signal at δ 0.72 ppm. Thus, the signal at δ 0.72 ppm was clearly due to the C1 proton while the signal at δ 2.47 ppm was assigned to the methine proton at C2. Irradiation of the methyl doublet resonance (J = 8.0 Hz) at δ 1.22 ppm led to the collapse of the C2 proton signal into a doublet (J = 3.0 Hz) and irradiation at δ 2.47 ppm transformed the methyl doublet signal at δ 1.22 ppm into a singlet and the C1 proton signal at δ 0.72 ppm into a doublet of doublets (J = 4.8 and 8.8 Hz), further confirming the assignment. The fact that the C2 proton was coupled only to the C1 proton and the methyl protons at δ 1.22 ppm suggested the correct structural assignment to **4** and thus **13**.



4: a/b

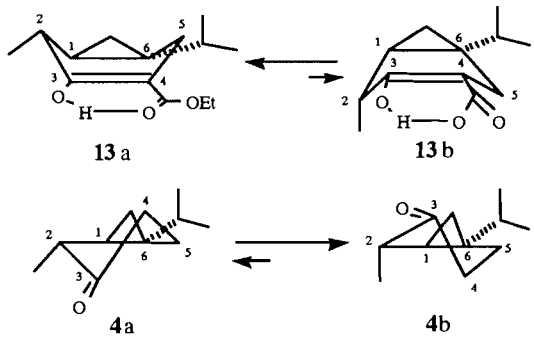


15: a/b

It is noteworthy that the coupling between the C1 proton and the C2 proton in compound **4** (J = 3.0 Hz) was rather different

[4] The product **4** was a mixture of α and β diastereomers (10:1) as indicated by GC. The ^1H NMR data described here represent the characterization of the major α diastereomer while other spectroscopic data are the gross properties of the diastereomeric mixture.

Fig. 1. Conformational analysis of **13**a and **4**a.



13 a **13** b

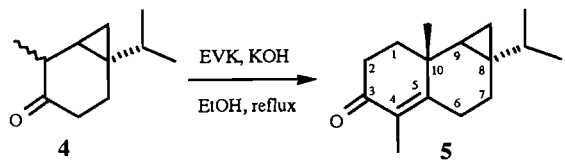
4a **4**b

from that in **13** (J = 0 Hz). This can be explained when one considers the possible conformations of these two compounds (Fig. 1). The enol form of compound **13**α[5] can have two boat-like conformers **13**a and **13**b. Conformer **13**b is less stable because of the repulsion between the axial methyl at C2 and the axial hydrogen at C5. Inspection of models reveals a dihedral angle H1–C1–C2–H2 close to 90° in conformer **13**a, which possesses an equatorial methyl group at C2. Therefore, the coupling constant between H1 and H2 is expected to be small. Among the two half-chair conformers of **4**a,[6] **4**b with an axial methyl group is considered more stable because it is devoid of the C2–methyl bond and the C1—H1 bond eclipsing interaction present in **4**a, and the flat nature of the plane involving C2–C1–C6–C5 also greatly reduces the repulsion between the axial methyl at C2 and the axial proton at C4 in **4**b. The dihedral angle H1–C1–C2–H2 is approximately 30° and therefore a larger coupling constant between H1 and H2 is expected.

The insertion reaction of a ketone by ethyl diazoacetate usually takes place from the less substituted or less bulky side. The formation of the reactive conformer shown in Fig. 2 is presumably faster than other possible conformers due to minimal *gauche* steric repulsions (5).

Stereoselective Robinson annulation of homothujone (4)

The Robinson annulation of homothujone (**4**) was carried out by refluxing the starting material with potassium hydroxide, the salt of 1–diethylamino-3–pentanone (ethyl vinyl ketone, EVK equivalent), and one equivalent of iodomethane in ethanol. Enone **5**, as shown, was isolated in 70% yield.



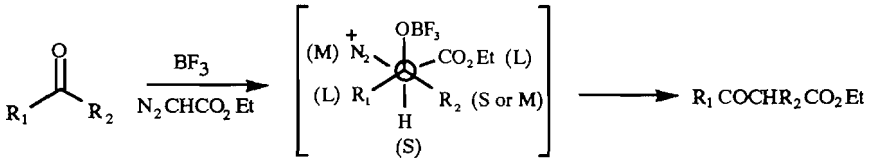
4 **5**

The structure of **5** was further confirmed by a series of NMR experiments. The structure **17**, which might possibly be formed by the ethyl vinyl ketone (EVK) Robinson annulation from the less substituted side of the carbonyl group, is inconsistent with the fact that only two methyl doublets were observed in the spectrum of the isolated product **5**. However,

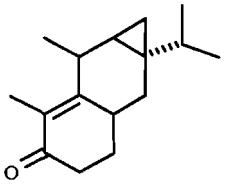
[5] As indicated in the previous footnotes, the ^1H NMR data thus far described for **13** and **4** represent their α diastereomers only.

[6] See footnote 5.

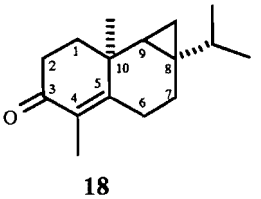
Fig. 2. Explanation for regioselectivity of the carbon insertion reaction.



the structure **18**, which was possibly generated from the β-face attack of the more substituted side, could accommodate all the spectroscopic data so far obtained. More evidence was needed to differentiate **5** and **18**.

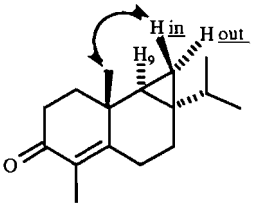


17

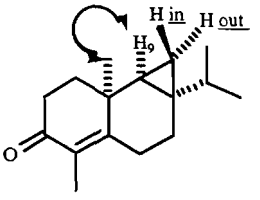


18

Inspection of molecular models reveals that the angular methyl group at C10 has different spatial relationships with the three cyclopropane protons in the diastereomers of **5** and **18**. In the case of **5**, the angular methyl is relatively close to the cyclopropane methylene proton directed into the concave face of the bicyclo[4.1.0]heptane moiety (i.e., H_{in}) but distant from the cyclopropane methine proton (i.e., H9) and the other methylene proton, which is directed away from the concave face of the bicyclo[4.1.0]heptane moiety (i.e., H_{out}). For **18**, the angular methyl is relatively close to H9 but distant from both methylene protons H_{in} and H_{out}. Thus, if the angular methyl is irradiated, a positive NOE enhancement for H_{in} will indicate the presence of **5** while a positive enhancement for H9 will suggest the existence of **18**. Fortunately, the ^{1}H NMR spectrum was fairly well resolved. The methyl singlet signal at δ 1.22 ppm, previously assigned to the angular methyl, was well separated from nearby signals and the three cyclopropane proton signals at high field were also well separated from each other. From a large number of recorded spectra of substituted cyclopropanes, it is generally observed that, in any designated cyclopropane, the magnitude of the vicinal coupling constant for *cis* protons (protons on the same side of a cyclyopropane plane, e.g., H9 and H_{out}) is always larger than that for *trans* protons (e.g., H9 and H_{in}) (6). Since each of the three coupling



5



18

constants in the AMX system, for the three cyclopropane protons of **5** or **18**, had to be either 4.8 Hz or 9.6 Hz , the coupling constant between H9 and H_{out} [J (H9,H_{out})] and the coupling constant between H9 and H_{in} [J (H9,H_{in})] should have values 9.6 Hz and 4.8 Hz, respectively, in order to satisfy the relationship: J (H9,H_{out}) > J (H9,H_{in}). J (H_{out},H_{in}) had to be 4.8 Hz to produce a triplet of J = 4.8 Hz observed in the spectrum and this triplet signal was due to H_{in}. Otherwise, if J (H_{out}, H_{in}) were 9.6 Hz, a triplet of J = 9.6 Hz would have been observed and this triplet would have been due to H_{out}. Thus, the consideration of magnitude for coupling constants enabled us to assign the triplet (J = 4.8 Hz) at δ 0.66 ppm to H_{in} but the two doublet of doublets signals at δ 0.30 and 0.50 ppm cannot be assigned further.

A two-dimensional ^{1}H–^{13}C heteronuclear correlation spectrum (2D-HETCOR) further confirmed the assignment. The proton (doublet of doublets) at δ 0.50 ppm correlated intensely with a tertiary carbon at δ 33.00 ppm but weakly with a secondary carbon at δ 12.60 ppm. Both the proton (triplet) at δ 0.66 pm and the proton (doublet of doublets) at δ 0.30 ppm correlated intensely with the secondary carbon at δ 12.60 ppm but not with the tertiary carbon at δ 33.00 ppm. This suggested that the proton (doublet of doublets) at δ 0.50 ppm was due to H9 and the quartet proton at δ 0.30 ppm was due to H_{out}.

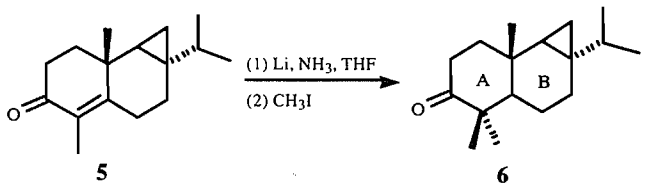
The determination of substitution of the above-mentioned carbons was facilitated by an APT (Attached Proton Test) (7) experiment. The carbon at δ 12.60 ppm was assigned as secondary since it was very intense in the off-resonance spectrum and did not invert its phase in the APT spectrum. Among the six carbons of inverse phase (which can be either primary or tertiary carbons) in the APT spectrum, four were sorted out as primary carbons since they had low chemical shifts in the ^{13}C spectrum (δ: 10.35, 18.55, and 19.20 ppm). As shown from the HETCOR spectrum, these four carbons also correlated well with four methyl singlets in the ^{1}H NMR spectrum. Thus, the other two carbons at δ 33.00 and 36.65 ppm must be tertiary carbons.

NOE experiments were then carried out on compound **5.** Irradiation at the angular methyl signal at δ 1.22 ppm resulted in a 4.0% enhancement of H_{in} at δ 0.66 ppm but no enhancement of either H9 or H_{out}. Therefore, the stereochemistry of **5** was finally confirmed. Irradiation of H_{in} at δ 0.66 ppm did not give a clear enhancement of the angular methyl signal but did cause a 10% enhancement of H_{out} and a negative enhancement of H9.

Generation of the *trans*-fused hydrocarbon 7

Having obtained the desired intermediate **5** in good overall yield from thujone, it was appropriate to evaluate some chemistry with this compound. Birch reduction of **5**, followed by iodomethane addition to trap the generated enolate (8), gave the *gem*-dimethylated ketone **6** in low yield (15%). Attempts to improve this reaction by addition of proton donors (i.e., water and *tert*-butanol) during the Birch reduction step, quenching of excess lithium with isoprene, and removal of ammonia prior to iodomethane addition did not prove fruitful. The by-products were relatively nonpolar and difficult to separate from each other.

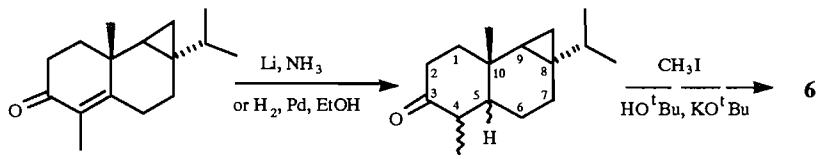
The mass spectrum of **6** revealed the molecular ion peak at



5 6

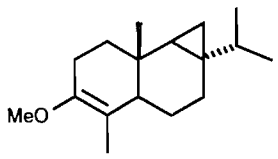
m/z 248 while the IR spectrum indicated a saturated carbonyl absorption at 1703 cm−1. The A/B ring junction was assigned to be *trans*, in accord with the known stereochemistry of the Birch reduction of 4,5-dehydrodecal-3-ones (9), although insufficient spectroscopic evidence was available for an unambiguous assignment.

To improve the yield of **6** from **5**, an alternative route to **6** was pursued. Reduction of **5** by lithium and ammonia produced a mixture of two compounds **20** and **21** in a ratio of 4:1. Because these two compounds were not convertible by treatment with potassium hydroxide in methanol (monitored by GC), they were judged to be two diastereomers of opposite A/B ring fusion with the major isomer **20** possessing the *trans* ring fusion as that of compound **6**, since both were major products obtained by trapping enolates derived from the Birch reduction of **5**. Compounds **20** and **21** were difficult to separate by column chromatography. The mass spectrum of the mixture (**20** and **21**) indicated a molecular ion at *m/z* 236, while the IR spectrum showed a carbonyl absorption at 1700 cm^{-1}. Catalytic hydrogenation of **5** with 5% Pd-C at room temperature in ethanol generated **20** and **21** at a ratio of 6:1.



5 20/21

Refluxing the reduction mixture containing **20** and **21** with iodomethane and potassium *tert*-butoxide in anhydrous *tert*-butanol under nitrogen resulted in a complex mixture that did not contain **6**, as indicated by GC. No further attempt was made to elucidate this mixture. The reaction carried out at room temperature gave only recovered starting material.



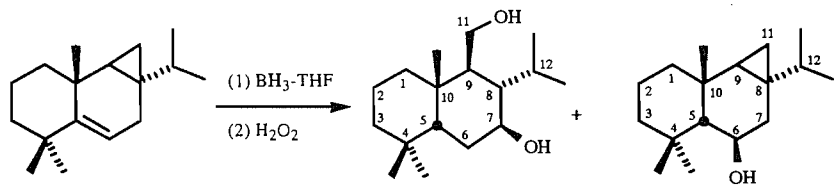
22

Treatment of the mixture of **20** and **21** (6:1) with sodium methoxide and iodomethane produced the enol ether **22** in 54% yield. This compound was characterized by a molecular ion peak at *m/z* 248 in its mass spectrum, and two methyl singlets at δ 1.57 and 3.50 ppm, corresponding to the vinylic methyl and the methoxyl methyl in the ^1H NMR spectrum. The A/B ring junction of **21** was *trans*, the same as that of **6.**

At this point, an alternative sequence to the A/B *trans*-fused hydrocarbon **7**, shown initially via the strategy in Scheme 1, was considered (Scheme 2).

Enone **5** was first methylated to **23** in 60% yield using sodium methoxide in DMSO (10). Decarbonylation of **23** utilizing the Wolf–Kishner–Huang Minlon conditions proceeded smoothly to give **24** in 67% yield.

Treatment of carbon–carbon double bonds by borane to form organoboranes, which are then decomposed with acetic acid to produce saturated C—C bonds, is a useful indirect method of carbon–carbon double bond reduction (11). However, such a treatment of **24** generated a complex mixture that was composed of several compounds, as detected by GC and the ^1H NMR spectrum. When an oxidative treatment of the intermediate organoboranes by basic hydrogen peroxide was carried out, diol **25** and alcohol **26** were isolated in 39% and 29% yield, respectively. The mass spectrum of **25**



24 25 26

had its molecular ion peak at *m/z* 268 while the IR spectrum indicated an intense hydroxyl absorption near 3500 cm^{-1}. The ^1H NMR spectrum showed three methyl singlets at δ 0.96, 0.98, 1.00 ppm and two methyl doublets at δ 1.01 ppm (J = 7.0 Hz) and 1.15 ppm (J = 7.0 Hz). Two multiplets appearing at δ 3.72 ppm (2H) and 4.04 ppm (1H) corresponded to the the methylene and methine protons attached to C11 and C7. An X-ray structure of **25** (crystallized from methylene chloride) is shown in Fig. 3. The *cis* A/B ring fusion is clearly revealed. Details of the X-ray studies will be published elsewhere.

Alcohol **26** had its molecular ion peak at *m/z* 250 in the mass spectrum and an hydroxyl absorption at 3450 cm^{-1} in the IR spectrum. The ^1H NMR spectrum indicated three multiplets at δ 0.14, 0.45, and 0.64 ppm, corresponding to the three cyclopropane protons. Two methyl doublets appeared at δ 0.85 ppm

Scheme 2. An alternative sequence to hydrocarbon **7**.

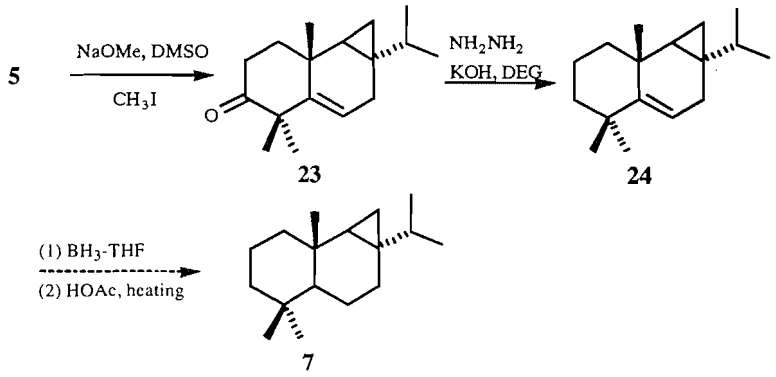


Fig. 3. Single crystal X-ray structure of **25** (PLUTO drawing).

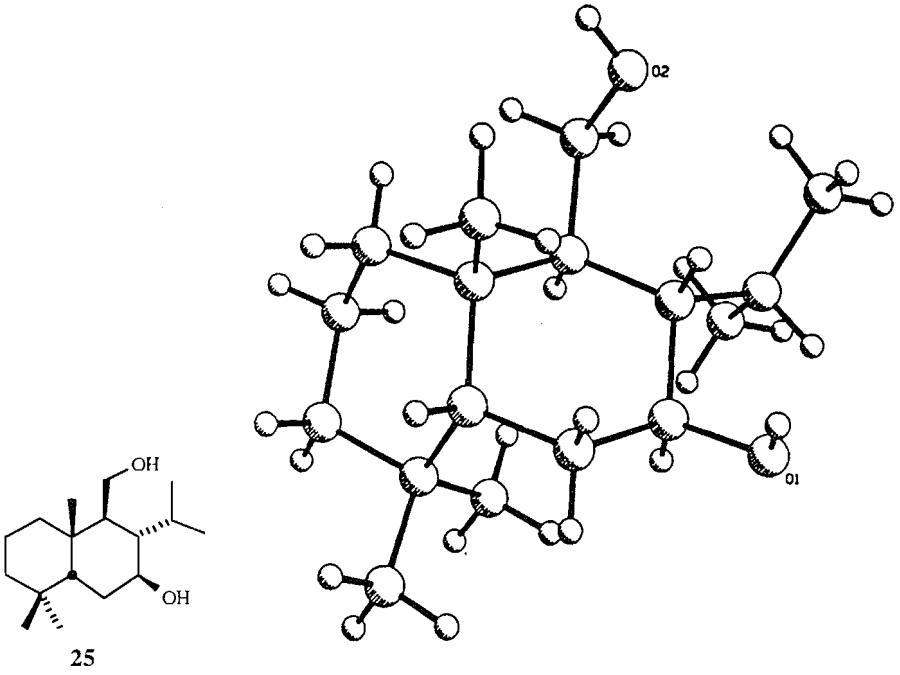
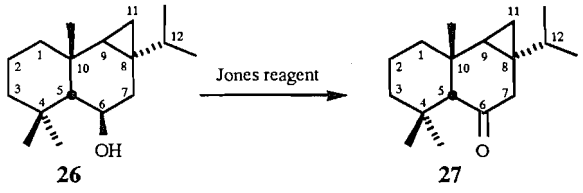


(J = 6.0 Hz) and 0.90 ppm (J = 6.0 Hz) while three methyl singlets were observed at δ 0.98, 1.10, and 1.16 ppm. A doublet of doublets at δ 2.14 ppm (1H, J = 5.2 and 7.4 Hz) was probably due to one of the methylene protons at C7 that was neighboring to the cyclopropane ring). A one-proton complex multiplet at δ 3.87 ppm was assigned to the proton at C6. By analogy to structure **25** and the following mechanistic explanation, the ring fusion of **26** was presumed to be *cis* and the hydroxyl should have β orientation.

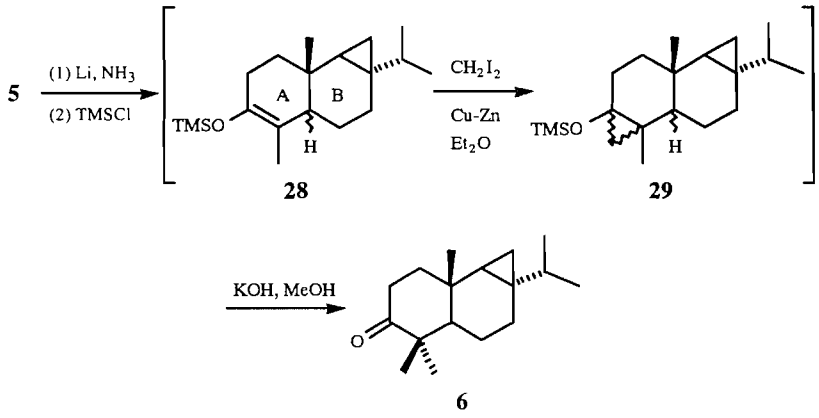
The oxidation of **26** by Jones reagent produced ketone **27** in 80% yield.

The mechanism associated with the formation of **25** and **26** is unknown but some specu-lative comments can be put forth. The presence of hydroxyl functions at C7 and C11 in **25** suggest an initial migration of the double bond in **24** to the C6–C7 position and the resultant vinyl cyclopropane function could undergo ring opening and functionalization. The ring opening of vinylcyclopropanes by borane has been previously observed (12) but usually a much more drastic condition is required. It is remarkable that the cleavage reaction of **24** took place at room temperature.

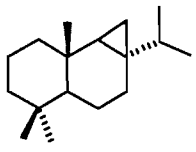


In a final attempt to improve the yield of **6**, the sequence in Scheme 3 was considered and put to an experimental test. Trimethylsilyl enol ether **28** was prepared by trapping the enolate generated in the Birch reduction of **5** with trimethylsilyl chloride (13). The crude product, containing two diastereomers as revealed from the previous enolate trapping with water, was then converted into a mixture of trimethylsilyl cyclopropyl ethers (**29**) using the Simmons–Smith reaction (14, 15). This mixture contained two diastereomers (**29**α and **29**β) that had the newly created cyclopropyl ring α and β oriented. The

Scheme 3. An alternative route to ketone **6.**



crude product from the Simmons–Smith reaction was hydrolyzed in warm potassium hydroxide – methanol solution without purification (15). A major compound isolated was identified as **6**, previously obtained in the Stork enolate trapping reaction, by comparing their MS, IR, NMR data. The overall yield of **6** from **5** was 45%.

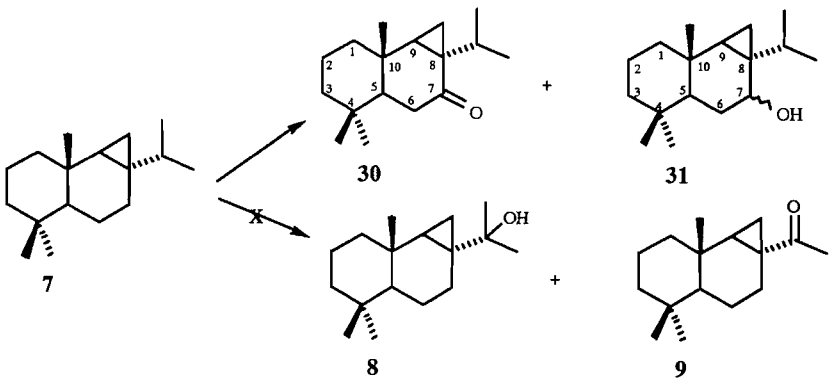


The reduction of **6** by the Wolf–Kishner–Huang Minlon method gave hydrocarbon **7** in 70% yield.

Ozonation of hydrocarbon 7

Ozonation of hydrocarbon **7** in ethyl acetate under conditions similar to those used previously (1) provided an unexpected complex mixture from which ketone **30** (35%) and alcohol **31** (5%) were isolated. The expected functionalization of the isopropyl side chain, as observed in ozonation of other thujone-derived intermediates (1), was not obtained and therefore the compounds **8** and **9** were not isolated.

Ketone **30** in its mass spectrum revealed a molecular ion at



m/z 248 and its IR spectrum displayed a conjugated carbonyl absorption at 1665 cm^{-1}. Its ^1H NMR spectrum indicated two methyl doublets at δ 0.84 ppm (J = 6.6 Hz) and 0.94 ppm (J = 6.6 Hz), corresponding to the two methyl groups of the isopropyl side chain, and three methyl singlets at δ 0.78, 1.11, and 1.30 ppm. A one-proton septet (J = 6.6 Hz) corresponding to the methine proton in the isopropyl side chain appeared at δ 1.84 ppm. A multiplet containing two protons at δ 2.00–2.30 ppm corresponded to the two methylene protons at C6. The corresponding alcohol **31** revealed spectroscopic data consistent with this structural assignment (see Experimental).

It is surprising that the previously observed selective ozonation of thujone derivatives could not be applied to the homothujone derivative **7**. The reasons for this reactivity change are unknown. Generally, a cyclohexane ring is more puckered than a cyclopentane ring. This may allow one of carbon–hydrogen bonds at C7 to be properly oriented towards the cyclopropane ring in **7**. This orientation may then facilitate the participation of the cyclopropyl group in the ozone insertion into this particular carbon–hydrogen bond and the initially formed secondary hydrotrioxide can then be decomposed into either the corresponding ketone or alcohol (16). It is noted here that oxidation of cyclopropyl methylene to cyclopropyl ketone can be effectively accomplished by other oxidizing reagents (17). The regioselective oxidation of homothujone derivatives at the methylene group by other reagents may find applications in a way complementary to the ozonation of thujone derivatives.

Conclusion

In summary, we have initiated studies on a new strategy to develop thujone as a chiral building block, in the context of synthesizing cyclohexane-containing natural products. Regio-

selective ring expansion of thujone was accomplished efficiently to furnish homothujone and the latter was further elaborated stereoselectively into more complex derivatives. Some novel chemistry of homothujone derivatives such as the organoborane-mediated cyclopropane ring opening and the unusual mode of ozonation is starting to demonstrate a departure from that of thujone derivatives retaining the bicyclo[3.1.0]hexane moiety. Such chemical novelty also presents new opportunities to explore efficiently the utility of thujone as a chiral building block and merits further research in the future.

Experimental

Homothujone experimental

Commercially available solvents were used for chromatography without further purification. Petroleum ether refers to the fraction boiling in the range of 30–60°C. Anhydrous diethyl ether and tetrahydrofuran were prepared by distillation from a mixture containing sodium and benzophenone. Anhydrous *n*-pentane was prepared by distillation from phosphorus pentoxide. Anhydrous ethanol was distilled from magnesium. Thujone was distilled from Western red cedar leaf oil, which was generously donated by Intrinsic Research and Development Incorporated.

Unless stated otherwise, all reactions were carried out under a positive pressure of anhydrous nitrogen. Unless otherwise stated, all reaction products were purified by "flash chromatography" using silica gel (230–400 mesh) supplied by E. Merck Co. with air pressure to obtain a suitable flow.

Melting points were measured using a Kofler block melting point apparatus and are uncorrected. Optical rotations were recorded on a Perkin–Elmer 141 automatic polarimeter in chloroform solution using a quartz cell of 10 cm path length with the concentration (in g/100 mL) given in parentheses. The ultraviolet spectra were recorded on Cary 15 or Perkin–Elmer Lambda 4B UV/VIS spectrometers using quartz cells of 1 cm path length. The infrared spectra were recorded on Perkin–Elmer 710, 710B, and 1710 spectrometers in chloroform solution using NaCl cells of 0.1 mm path length or as thin film using NaCl plates. The ^{1}H NMR spectra were obtained from Bruker WH-400 or Varian XL-300 spectrometers with deuteriochloroform as solvent and the chemical shifts are reported in the delta (δ) scale in ppm relative to tetramethylsilane. 13C spectra were taken on Varian XL-300 spectrometers and chemical shifts are reported in the delta (δ) scale in ppm relative to tetramethylsilane. The low- and high-resolution mass spectra were recorded on AEI-MS-9 and KRATOS-MS-50 spectrometers, respectively, using the electron impact ionization method, while the chemical ionization mass spectra were recorded on a Delsi Nermag R10-1 OC spectrometer using ammonia as carrier gas. Elemental analyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia.

*[1R-(1α,2α/β,6α)]-4-Ethoxycarbonyl-2-methyl-6-(1-methylethyl)bicyclo[4.1.0]heptan-3-one (**13**, the ketoester form) and [1R-(1α,2α/β,6α)]-4-ethoxycarbonyl-2-methyl-6-(1-methylethyl)bicyclo[4.1.0]hept-3-ene-3-ol (**13**, the enolester form)*

To a cooled solution (0°C) of thujone (**1**) (3.04 g, 20.0 mmol) and boron trifluoride etherate (4.26 g, 30.0 mmol) in anhydrous diethyl ether (25.0 mL), ethyl diazoacetate (3.42 g, 30.0 mmol) in anhydrous diethyl ether (5.0 mL) was added dropwise over a period of 30 min. The resulting solution was stirred under nitrogen at room temperature overnight, made basic with saturated aqueous sodium carbonate solution, and extracted with diethyl ether. The diethyl ether solution was washed with brine, dried over magnesium sulfate, and concentrated *in vacuo*. Column chromatography of the crude product with ethyl acetate:hexanes (1:30, v/v) produced β-ketoester **13** in 70% yield (3.34 g). The physical properties of **13** are as follows: UV (MeOH, c = 20.4 mg/L) $\lambda_{max.}$: 258 nm (log ε = 3.980); IR (film) $\nu_{max.}$: 3370 (O-H stretching), 1655 (C=O stretching), 1615 (C=C stretching) cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.30 (1H, dd, J = 4.4 and 8.8 Hz), 0.39 (1H, t, J = 4.4 Hz), 0.68 (1H, dd, J = 4.4 and 8.8 Hz), 0.98 (6H, two overlapped doublets, J = 5.6 and 4.4 Hz), 1.03 (1H, m), 1.24 (3H, d, J = 7.2 Hz), 1.31 (3H, t, J = 6.8 Hz), 2.25–2.57 (2H, AB type, J = 16 Hz), 2.64 (1H, q, J = 7.2 Hz), 4.21 (2H, m), 12.24 (1H, s); MS *m/z* (relative intensity): 238 (M^+, 35.0%), 192 (79.7%), 177 (66.4%), 149 (100.0%); high-resolution EIMS calcd. for $C_{14}H_{22}O_3$: 238.1569; found: 238.1570.

*[1R-(1α,2α/β,6α)]-2-Methyl-6-(1-methylethyl)bicyclo-[4.1.0]heptan-3-one (**4**)*

To ketoester **13** (2.70 g, 11.3 mmol) in DMSO (20.0 ml) was added sodium chloride (1.20 g, 20.9 mmol) and water (1.0 mL). The resulting mixture was refluxed at 140°C for 4 h, cooled down, diluted with water (40 mL), and extracted with diethyl ether (3 × 25 mL). The ether solution was dried over magnesium sulfate and concentrated in vacuo to give a crude product that was chromatographed with ethyl acetate:hexanes (1:8, v/v). Homothujone **4** was obtained in 96% yield (1.80 g). The physical properties of **4** are as follows: IR(film) $\nu_{max.}$: 3060, 1700 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.50 (2H, m), 0.72 (1H, m), 0.95 (3H, d, J = 6.4 Hz), 0.98 (3H, d, J = 6.4 Hz), 1.06 (1H, m), 1.22 (3H, d, J = 8.0 Hz), 1.84 (1H, m), 2.10 (2H, m), 2.35 (1H, m), 2.47 (1H, m); EIMS *m/z* (relative intensity): 166 (M^+, 18.3%), 123 (29.7%), 109 (58.0%), 96 (91.2%), 41 (100.0%); high-resolution EIMS, calcd. for $C_{11}H_{18}O$: 166.1358; found: 166.1360.

*[1aR-(1aα,7aβ,7bα)]-1,1a,2,3,6,7,7a,7b-Octahydro-4,7a-dimethyl-1a-(1-methylethyl)-5H-cyclopropa[a]-naphthalen-5-one (**5**)*

Homothujone **4** (341 mg, 2.05 mmol) was mixed with 1–diethylamino-3-pentanone-iodomethane salt (675 mg, 2.26 mmol) in anhydrous ethanol (20.0 mL) under an atmosphere of nitrogen. After the addition of potassium hydroxide (184 mg, ~80% pure, 2.57 mmol), the reaction mixture was heated to reflux for 1 h, cooled down, and diluted with water (30 mL). Petroleum ether (2 × 20 mL) was used to extract the above aqueous mixture. Concentration of the combined petroleum ether solution in vacuo furnished an oil, which was chromatographed to provide **5** in 70% yield (332 mg). The physical properties of **5** are as follows: $[\alpha]_D^{25} = 1.94 \times 10^2$ (c 1.00, $CHCl_3$); UV (MeOH, c 20.0 mg/L) $\lambda_{max.}$: 250 nm ((log ε = 4.133); IR (film) $\nu_{max.}$: 3060, 1660, 1620 cm^{-1}; ^{1}H NMR (400 MHz, $CDCl_3$) d: 0.30 (1H, dd, J = 4.8 and 9.6 Hz), 0.50 (1H, dd, J = 4.8 and 9.6 Hz), 0.66 (1H, t, J = 4.8 Hz), 0.90 (3H, d, J = 7.2 Hz), 0.93 (3H, d, J = 7.2 Hz), 1.01 (1H, m), 1.16 (3H,

s), 1.58 (2H, m), 1.74 (3H, s), 1.82 (1H, m), 1.93 (1H, m), 2.12 (1H, dt, J = 5.2 and 14.0 Hz), 2.35–2.70 (3H, m); EIMS *m/z* (relative intensity): 232 (M+, 57.2%), 217 (18.3%), 189 (60.1%), 161 (100.0%); high-resolution EIMS, calcd. for $C_{16}H_{24}O$: 232.1827; found: 232.2819. Anal. calcd. for $C_{16}H_{24}O$: C 82.70, H 10.41; found: 82.58, H 10.44.

*[1a*R*-(1*α*,7a*β*,7b*α*)]-Decahydro-4,4,7a-trimethyl-1a-(1-methylethyl)-5*H*-cyclopropa[a]naphthalen-5-one (**6**)*

Method A: Ammonia was distilled from sodium to a flask charged with enone **5** (419 mg, 1.81 mmol) under nitrogen. Pieces of lithium metal (13.8 mg, 1.99 mmol, 1.1 equiv.) were added and the resulting dark purple solution was stirred at −33°C for 1 h before iodomethane (1.3 mL) and anhydrous diethyl ether (5.0 mL) were introduced. The Dry Ice – acetone condenser was removed to allow ammonia to evaporate. The reaction mixture was stirred overnight and transferred to a separatory funnel containing water (15 mL) and ether (20 mL). The ether layer was separated, washed with brine (10 mL), and dried over magnesium sulfate. Evaporation of diethyl ether in vacuo resulted in a yellowish oil, which was chromatographed first with ethyl acetate:hexanes (1:15, v/v) and then benzene to furnish ketone **6** in 15% yield (63 mg).

Method B: Ammonia (~20 mL) was distilled from sodium to a solution of enone **5** (1.10 g, 4.74 mmol) in anhydrous ether (10 mL) under nitrogen. Lithium (35 mg, 4.98 mmol, 1.05 equiv.) was added. The dark purple mixture was stirred for 1.5 h at −33°C before freshly distilled trimethylsilyl chloride (1.20 mL, 2.0 equiv.) was injected. The resulting yellowish solution was warmed to room temperature and stirred for 1 h. Evaporation of ammonia and ether gave a yellowish crude oil. Anhydrous ether (10.0 mL) was introduced to the above crude product. Half of the solution (~5.0 mL) thus prepared was transferred to a new dry flask. Zinc–copper couple (powder, 314 mg) and distilled diiodomethane (0.80 mL) were added and the greyish mixture was refluxed overnight. Filtration through a layer of Celite afforded an ether solution, which was condensed to a colorless oil. This oil was then dissolved in methanol (10 mL). After introduction of potassium hydroxide (100 mg, ~80% pure, 1.78 mmol), the solution was refluxed 1 h and cooled down. Evaporation of solvent in vacuo and repeated column chromatography with ethyl acetate:hexanes (1:8, v/v) yielded **6** in 45% (262 mg).

The physical properties of **6** are as follows: $[\alpha]_D^{25}$ −8.3 (*c* 0.42, $CHCl_3$); IR (film) $\nu_{max.}$: 1703 (C=O stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.08 (1H, m), 0.35 (2H, m), 0.70–1.55 {20H, including 0.85 (6H, t, J = 2.4 Hz), 1.04 (3H, s), 1.21 (3H, s), 1.22 (3H, s)}, 1.70 (1H, m), 1.85 (1H, m), 2.30 (2H, m), 2.62 (1H, m); EIMS *m/z* (relative intensity): 248 (M^+, 18.6%), 230 (12.0%), 205 (27.2%), 41 (100.0%); high-resolution EIMS, calcd. for $C_{19}H_{28}O$: 248.2140; found: 248.2135.

*[1a*R*-(1*α*,7a*β*,7b*α*)]-Decahydro-4,7a-dimethyl-1a-(1-methylethyl)-5*H*-cyclopropa[a]naphthalen-5-one (**20**)*

Method A: Ammonia (5 mL) was distilled from sodium to a flask containing **5** (151 mg, 0.500 mmol) in anhydrous ether (3.0 mL) under an atmosphere of nitrogen. While the flask was kept at −33°C, small pieces of lithium were added slowly for about 1 h until a blue color persisted. After further stirring for 30 min, ammonium chloride was added to destroy excess lithium and ammonia was evaporated during warming up to room temperature. Concentration of the reaction mixture gave an oil which was chromatographed with ethyl acetate:hexanes (1:8, v/v) to give a mixture of **20** and **21** (124 mg, 82%) at a ratio of 4.3:1 as indicated by gas chromatography.

Method B: The solution of enone **5** (368 mg, 1.59 mmol) in ethanol (15.9 mL) was mixed with 10% palladium – charcoal catalyst (85 mg). The mixture was charged with 1 atm (101.3 kPa) hydrogen at room temperature and stirred for 2 h. Filtration through a layer of Celite gave a colorless solution, which was then concentrated in vacuo. A mixture of **20** and **21** at a ratio 6:1 as shown from GC was thus obtained (350 mg, 95% yield).

The physical properties of **20** are as follows: IR (film) $\nu_{max.}$: 1705 (C=O stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.09 (1H, t, J = 5.2 Hz), 0.40 (2H, m), 0.85 (3H, d, J = 6.0 Hz), 0.88 (3H, d, J = 6.0 Hz), 0.93 (3H, J = 8.0 Hz), 1.45 (3H, s), 1.73 (1H, m), 1.87 (1H, m), 2.24 (2H, m), 2.50 (1H, m) 2.89 (1H, m); EIMS *m/z* (relative intensity): 234 (M^+, 30.6%), 219 (16.3%), 191 (20.2%), 41 (100.0%); high-resolution EIMS, calcd. for $C_{16}H_{26}O$: 234.1984; found: 234.1980.

*[1a*S*-(1*α*,7a*β*,7b*α*)]-1,1a,2,4,6,7,7a,7b-Octahydro-4,4,7a-trimethyl-1a-(1-methylethyl)-5*H*-cyclopropa[a]-naphthalen-5-one (**23**)*

To the solution of enone **5** (109 mg, 0.470 mmol) in anhydrous DMSO (5.0 mL) was added sodium methoxide (55 mg, 1.0 mmol, 2.1 equiv.) under nitrogen. After the mixture was stirred for 5 h, iodomethane (100 mL, 1.61 mmol, 4.0 equiv.) was injected. Stirring continued for another 3 h. The reaction mixture was poured into a funnel containing 20 mL water. The aqueous mixture was extracted with hexanes (2 × 15 mL). After drying over magnesium sulfate, evaporation of solvent in vacuo, and chromatography with ethyl acetate:hexanes (1:8, v/v), ketone **23** was obtained (62 mg, 60% yield based on 10% recovery of starting material). The physical properties of **23** are as follows: IR (film) $\nu_{max.}$: 1700 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.20 (1H, t, J = 4.0 Hz), 0.39 (1H, dd, J = 4.0 and 10.0 Hz), 0.58 (1H, dd, J = 4.0 and 10.0 Hz), 0.80–1.40 {16 H, m, including 0.94 (6H, d, J = 6.0 Hz), 1.01 (3H, s), 1.18 (3H, s), 1.20 (3H, s)}, 1.84 (1H, m), 1.98 (1H, m), 2.14–2.35 (2H, m), 2.38–2.65 (2H, m), 5.41 (1H, t, J = 4.0 Hz); EIMS *m/z* (relative intensity): 246 (M^+, 36.4%), 231 (42.1%), 218 (5.9%), 203 (50.2%), 105 (100.0%); high-resolution EIMS, calcd. for $C_{17}H_{26}O$: 246.1984; found: 246.1988.

*[1a*S*-(1*α*,7a*β*,7b*α*)]-1a,2,4,5,6,7,7a,7b-Octahydro-4,4,7a-trimethyl-1a-(1-methylethyl)-1*H*-cyclopropa[a]-naphthalene (**24**)*

To the mixture of ketone **23** (500 mg, 2.03 mmol) in diethylene glycol (10 mL) was added potassium hydroxide (422 mg, ~80% pure, 6.02 mmol) and hydrazine hydrate (300 mL, 6.18 mmol) under nitrogen. After refluxing at 100–150°C for 1 h, water and excess hydrazine hydrate were distilled away through a Dean–Stark trap until the temperature reached 250°C. Further refluxing at 200°C continued for 4 h. The reaction mixture was then cooled to room temperature and and diluted with water (20 mL). The aqueous mixture was

extracted with petroleum ether (3 × 10 mL). Evaporation of solvent in vacuo and column chromatograghy with petroleum ether afforded **24** (316 mg, 67%). The physical properties of **24** are as follows: IR (film) $\nu_{max.}$: 3050 (C-H stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.15 (1H, m), 0.40 (2H, m), 0.87 (6H, d, J = 6.0 Hz), 1.05 (3H, s), 1.09 (3H, s), 1.16 (3H, S), 5.30 (1H, t, *J* = 4.0 H); EIMS *m/z* (relative intensity): 232 (M^+, 53.4%), 217 (39.3%), 204 (6.7%), 189 (62.1%), 105 (100.0%); high-resolution EIMS, calcd. for $C_{17}H_{28}$: 232.2191; found: 232.2196.

*[1S-(1α,2β,3α,4aα,8aα)]-Decahydro-3-hydroxy-5,5,8a-trimethyl-2-(1-methylethyl)naphthalenemethanol (**25**) and [1aS-(1α,3β,3aβ,7aβ,7bα)]-decahydro-4,4,7a-trimethyl-1a-(1-methylethyl)-3H-cyclopropa[a]naphthalen-3-ol (**26**)*

To the solution of **24** (100 mg, 0.43 mmol) in THF (5.0 mL) at 0°C under nitrogen was added borane (0.35 M in THF, 1.0 mL) in a dropwise manner. The resulting mixture was stirred for 5 h at room temperature and cooled to 0°C again. Aqueous sodium hydroxide solution (3.0 M, 1.0 mL) and hydrogen peroxide solution (aq., 30%, 1.0 mL) were added slowly. The resulting two-phase mixture was warmed to room temperature, stirred for 2 h, and saturated with sodium chloride. The THF layer was separated and the aqueous layer was extracted with ether (5 mL). The organic layers were combined and concentrated in vacuo. Column chromatography of the crude product with ethyl acetate:hexanes (first 1:8 and then 3:7, v/v) generated **25** (45 mg, 39%) and **26** (31 mg, 29%). The physical properties of **25** are as follows: mp = 136–138°C; $[\alpha]_D^{25}$ +23 (*c* 0.84, $CHCl_3$); IR (film) $\nu_{max.}$: 3500 (O-H stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.90–1.80 {26H, 0.96806 (3H, s), 0.98 (3H, s), 1.00 (3H, s), 1.01 (3H, d, *J* = 7.0), 1.15 (3H, d, *J* = 7.0)}, 1.97 (2H, m), 2.18 (1H, m), 3.72 (2H, m), 4.04 (1H, m); EIMS *m/z* (relative intensity): 250 ($M^+ - H_2O$, 1.2%), 235 (3.1%), 232 (1.7%), 123 (100%). Anal. calcd. for $C_{17}H_{32}O_2$: C 76.06, H 12.02; found: C 76.26, H 12.02. The physical properties of **26** are as follows: $[\alpha]_D^{25}$ + 13 (*c* 0.50, $CHCl_3$); IR (film) $\nu_{max.}$: 3400 (O-H stretching), 3060 (cyclopropane C-H stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.14 (1H, dd, *J* = 4.4 and 8.8 Hz), 0.45 (1H, dd, *J* = 4.4 and 8.8 Hz), 0.64 (1H, t, *J* = 4.4 Hz), 0.85 (3H, d, *J* = 6.0 Hz), 0.90 (3H, d, *J* = 6.0 Hz), 0.98 (3H, s), 1.10 (3H, s), 1.16 (3H, s), 2.14 (1H, dd, *J* = 7.5 and 15.0), 3.87 (1H, m); EIMS *m/z* (relative intensity): 250 (M^+, 2.1%), 232 (10.5%), 217 (12.8%), 207 (10.6%), 109 (100.0%); high-resolution EIMS, calcd. for $C_{17}H_{30}O$: 250.2297; found: 250.2307.

*[1aS-(1α,3aβ,7aβ,7bα)]-Decahydro-4,4,7a-trimethyl-1a-(1-methylethyl)-3H-cyclopropa[a]naphthalen-3-one (**27**)*

To the solution of alcohol **26** (20 mg, 0.080 mmol) in acetone (2.5 mL) was added Jones reagent (12 M CrO_3 in concentrated sulfuric acid) in a dropwise manner until the mixture changed to a steady orange color. Water (10 mL) was added and the aqueous mixture was extracted with hexanes (2 × 5 mL). Evaporation of solvent in vacuo and column chromatography with ethyl acetate:hexanes (1:8, v/v) afforded **27** (16 mg, 80%). The physical properties of **27** are as follows: IR (film) $\nu_{max.}$: 1700 cm^{-1}; ^1H NMR (400 MHz, C_6D_6) δ: 0.18 (2H, m), 0.53 (1H, m), 0.65 (3H, d, *J* = 7.2 Hz), 0.90 (3H, d, *J* = 7.2 Hz), 0.97 (3H, s), 1.01 (3H, s), 1.19 (3H, s), 2.29 (2H, AB type, *J* = 16.0 Hz). EIMS *m/z* (relative intensity): 248 (M^+, 10.6 %), 233 (2.8%), 205 (5.2%), 177 (9.6%), 109 (100.0%); high-resolution EIMS, calcd. for $C_{17}H_{28}O$: 248.2140; found: 248.2138.

*[1aR-(1α,7aβ,7bα)]-1a,2,3,3a,6,7,7a,7b-Octahydro-4,7a-dimethyl-1a-(1-methylethyl)-5-methoxyl-1H-cyclopropra[a]naphthalene (**22**)*

Ketone **20/21** (6:1, 200 mg, 0.855 mmol), obtained from palladium–charcoal catalyzed hydrogenation of **5**, was treated with sodium hydride (70 mg, 2.0 equiv., 60% in mineral oil) in anhydrous DMSO (5.0 mL) under nitrogen at room temperature for 1 h. Freshly distilled iodomethane (106 mL, 1.71 mmol, 2.0 equiv.) was added rapidly and the resulting mixture was stirred for another hour. The reaction mixture was then poured into water (20 mL) and the aqueous mixture was extracted with hexanes (2 × 15 mL). Evaporation of hexanes in vacuo and column chromatography with ethyl acetate:hexanes (1:8, v/v) gave **22** (91 mg, 54% based on recovery of starting material) and starting material **20/21** (42 mg). The physical properties of **22** are as follows: IR (film) $\nu_{max.}$: 3050, 1680 (C=C stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.08 (1H, m), 0.30 (2H, m), 0.70–1.70 {(22H, m,680 including 0.87 (6H, t, *J* = 6.0 Hz), 0.95 (3H, s), 1.60 (3H, s)}, 3.47 (3H, s); EIMS *m/z* (relative intensity): 248 (M^+, 40.2%), 233 (8.4%), 216 (2.9%), 137 (90.2%), 41 (100.0%); high-resolution EIMS, calcd. for $C_{17}H_{28}O$: 248.2140; found: 248.2137.

[1aR-(1α,7aβ,7bα)]-Decadydro-4,4,7a-trimethyl-1a-(1-methylethyl)-1H-cyclopropa[a]naphthalene (7)

Ketone **6** (250 mg, 1.01 mmol) in diethylene glycol (20 mL) was treated with potassium hydroxide (370 mg, 5.28 mmol) and hydrazine monohydrate (270 mL, 5.56 mmol). The mixture was heated at 100–150°C for 1.5 h under nitrogen. The temperature was then gradually raised to 220°C to distill off water and excess hydrazine over a period of 1.5 h. Refluxing continued at 210°C for 4 h. The mixture was cooled down, diluted with water, and extracted with petroleum ether (3 × 20 mL). Evaporation of the solvent in vacuo gave a brown oil, which was chromatographed with petroleum ether through a short column to yield **7** as a colorless oil (175 mg, 75%). The physical properties of **7** are as follows: IR (film) $\nu_{max.}$: 3050 (cyclopropane C-H stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) d: 0.07 (1H, m), 0.40 (2H, m), 0.84 (6H, t, *J* = 3.0 Hz), 1.10 (3H, s), 1.20 (3H, s), 1.22 (3H, s); EIMS *m/z* (relative intensity): 234 (M^+, 2.7%), 219 (4.5%), 191 (11.0%), 43 (100.0%); high-resolution EIMS, calcd. for $C_{17}H_{30}$: 234.2348; found: 234.2358.

*[1aS-(1α,7aβ,7bα)]-1,1a,3,3a,4,5,6,7,7a,7b-Decahydro-4,4,7a-trimethyl-1a-(1-methylethyl)-2H-cyclopropra[a]-naphthalen-2-one (**30**) and [1aS-(1α,7aβ,7bα)]-1,1a,3,3a,4,5,6,7,7a,7b-decahydro-4,4,7a-trimethyl-1a-(1-methylethyl)-2H-cyclopropra[a]naphthalen-2-ol (**31**)*

A stream of ozone–oxygen gas was passed through the solution of **7** (200 mg, 0.855 mmol) in ethyl acetate (10.0 mL) at −40°C for 7 h. Oxygen was passed through the solution for 15 min to remove the residual ozone in the solution. The reaction mixture was then treated with dimethyl sulfide (0.5 mL), and extracted with water (10 mL), and with 10% aqueous sodium

bicarbonate solution (10 mL). Removal of solvent in vacuo and chromatography of the crude product with ethyl acetate:hexanes (2:8, v/v) provided ketone **30** (74 mg, 35%) and alcohol **31** (10 mg, 5%). The physical properties of **30** are as follows: IR (film) $\nu_{max.}$: 1665 (C=O stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.75–1.35 {23H, m, including 0.78 (3H, s), 0.84 (3H, d, J = 6.6 Hz), 0.97 (3H, d, J = 6.6 Hz), 1.11 (3H, s), 1.30 (3H, s)}, 1.47 (1H, m), 1.63 (1H, m), 1.84 (1H, septet, J = 6.6 Hz), 2.00–2.30 (2H, m); MS *m/z* (relative intensity): 248 (M^+, 18.4%), 233 (15.2%), 205 (23.2%), 177 (42.3%), 41 (100.0%); high-resolution EIMS, calcd. for $C_{17}H_{28}O$: 248.2140; found: 248.2135. The physical properties of **31** are as follows: IR (film) $\nu_{max.}$: 3405 (O-H stretching) cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.13 (1H, m), 0.45 (2H, m), 0.86 (3H, s), 0.89 (3H, d, J = 6.0 Hz), 0.98 (3H, d, J = 6.0 Hz), 1.10 (3H, s), 1.20 (3H, s), 4.16 (1H, m); EIMS *m/z* (relative intensity): 250 (M^+, 0.8%), 232 (5.3%), 217 (4.5%), 43 (100.0%); high-resolution EIMS, calcd. for $C_{17}H_{30}O$: 250.2297; found: 250.2301.

Acknowledgments

We would like to express our gratitude to the Natural Sciences and Engineering Research Council of Canada for financial support and to Intrinsic Research and Development Inc. for generous samples of Western red cedar leaf oil.

Self-assembly of short and long-chain *n*-alkyl thiols onto gold surfaces: A real-time study using surface plasmon resonance techniques

Reno F. DeBono, Glenn D. Loucks, Deborah Della Manna, and Ulrich J. Krull

Abstract: Gold surfaces coated with monolayers of alkyl thiols are significant in the field of biosensors and chromatography. There is a general concern about the quality of coatings in terms of surface density and voids. The self-assembly of the short-chain hexane (C_6) thiol and long-chain dodecane (C_{12}) and hexadecane (C_{16}) thiols to polycrystalline gold surfaces has been investigated in situ and in real time using surface plasmon resonance (SPR) spectroscopy and surface plasmon microscopy (SPM). The self-assembly was followed based on observed changes in reflectivity at a fixed angle of incidence as a function of time. Our results indicate that the data for hexane, dodecane, and hexadecane thiol adsorption to gold surfaces were best fit by a two-step process rather than a one-step process. The mechanism may involve fast adsorption to the surface to give 80% (C_{12}, C_{16}) or 50% (C_6) coverage followed by a slow (100-fold slower) "rearrangement" of the adsorbed thiol. SPM shows these surfaces to be smooth and homogenous at a 4 μm scale. An understanding of the process of rearrangement could lead to control of the quality of coatings for analytical applications.

Key words: surface plasmon, alkyl thiols, gold, monolayer, kinetics, ellipsometry, microscopy.

Résumé : Les surfaces d'or enduites de monocouches d'alkylthiols présentent de l'intérêt dans le domaine des biosenseurs et de la chromatographie. Il existe une crainte généralisée au sujet de la qualité des enduits en termes de densité et de manques à la surface. Faisant appel à la spectroscopie de résonance des plasmons de surface (RPS) et de la microscopie des plasmons de surface (MPS), on a étudié in situ et en temps réel l'autoassemblage de chaînes courtes (hexane, C_6) et longues (dodécane, C_{12}, et hexadécane, C_{16}) de thiols à des surfaces d'or. On a suivi l'autoassemblage en se basant sur les changements observés dans la réflectivité, à un angle d'incidence fixe, en fonction du temps. Nos résultats indiquent que le meilleur ajustement des données pour les hexane-, dodécane- et hexadécane-thiols correspond à un processus en deux étapes plutôt qu'un processus en une étape. Il est possible que le mécanisme implique une adsorption rapide à la surface, conduisant à une couverture de 80% (C_{12} ou C_{16}) ou de 50% (C_6), qui serait suivie par un «réarrangement» lent (au moins 100 fois plus lent) du thiol adsorbé. La MPS montre que, à une échelle de 4 μm, ces surfaces sont lisses et homogènes. Une compréhension du processus de réarrangement pourrait conduire à une possibilité de contrôle de la qualité des enduits pour des applications analytiques.

Mots clés : plasmons de surface, alkylthiols, or, monocouches, cinétique, ellipsométrie, microscopie.

Introduction

The development of thin films that provide selective partitioning regions for chemical and biochemical sensors and for chromatographic purposes has led to a significant amount of work into adsorption, chemisorption, and covalent deposition of small molecules, proteins, polymers, and inorganic layers onto solid surfaces (1–6). The organization of organic molecules into monolayer films through self-assembly provides a facile method of preparing surfaces with a well-defined composition, structure, and thickness, and permits the control of chemical and physical properties of the surface. One type of film that exhibits these properties is obtained from the adsorption of *n*-alkyl organosulfur compounds to gold surfaces (7). The self-assembly process is driven through the formation of chemisorptive bonds between the thiol and the gold surface, increased van der Waals interaction between the alkyl chains, and increased entropy of the system as a result of removal of the solvation layer around the thiol molecules (40–45 kcal/mol). When a gold surface is exposed to alkyl thiol solutions an ordered alkyl thiol monolayer forms at the gold surface (8–11). Properties of the deposited film can be modified by varying the length of the hydrocarbon chain and by attachment of different functional groups at the opposite end of the alkyl thiol. Incorporation of functional groups allows the control of the chemical and physical properties at the external surface of the self-assembled membrane. Alkyl thiols with over 10 carbons in the alkyl chain form a densely packed crystalline-like monolayer assembly with an extended all-*trans* alkyl chain tilted 20–30° to the surface normal (12).

Investigations of the kinetics of formation of alkyl thiol monolayers on gold have been reported in the literature (7–10) based on analysis by ellipsometry, contact angle measurements, infrared spectroscopy, X-ray photoelectron spectros-

copy, and near-edge X-ray absorption fine structure (NEXAFS). These techniques provide an indication of adsorption kinetics based on the analysis of a series of different samples at different times during the adsorption process. Little information about real-time in situ adsorption has appeared. One approach has been to use a quartz crystal microbalance (QCM). For example, a QCM has been used to directly observe the adsorption/desorption from MeCN and DMF of several long-chain alkyl thiols on gold electrodes (11).

The optical techniques of surface plasmon resonance (SPR) spectroscopy and microscopy (SPM) can be used for the physical characterization and real-time observation of dynamic events in situ at an organic film located in close proximity to a metal surface. An understanding of the self-assembly process will lead to an improved capability for the design of chemically selective surfaces. This work reports a study of self-assembly of hexane, dodecane, and hexadecane thiols from 95% ethanol onto gold surfaces in situ, under static and dynamic solution flow conditions, using SPR and SPM.

Surface plasmon spectroscopy and microscopy

Figure 1*a* shows a prism of refractive index n_1 coated with a thin metal layer with a complex refractive index n_m in contact with a medium of refractive index $n_o < n_1$. Parallel polarized light of wavelength λ passes through the prism at an angle of incidence greater than the critical angle (which is defined by the prism and the outer medium) and reflects at the metal–prism boundary. A reflectivity curve (SPR curve) is produced (Fig. 1*b*) when the angle of incidence is varied while monitoring the reflected intensity. If the metal layer is sufficiently thin (<100 nm) then the reflectivity curve will exhibit a minimum at an angle Θ_{min}. This minimum arises as a result of resonant excitation involving the collective motion of conduction band electrons (surface plasmons), with a coherence length of L_c on the order of 10 μm for gold. Associated with this oscillating charge density wave is a strong evanescent wave with a penetration depth (d_p) into the outer contacting medium (n_o) of approximately 300 nm for λ = 632.8 nm. If an organic film of refractive index n_f is placed between the metal and the outer medium the reflectivity curve will be modified owing to its strong dependence on the environment near the metal surface. If $n_f > n_o$, then Maxwell's equations indicate that the SPR curve will shift to a larger angle of incidence as the thickness of the film (T_f) increases, and the angle of incidence becomes constant when $T_f > d_p$.

The surface plasmon resonance condition is determined by the spatial average of the thickness and refractive index of the organic film as sampled over the coherence length (L_c) near the metal surface. Differences in the profile of the film over distances greater than L_c will be detected as spatially resolved differences in reflected intensity at a fixed angle of incidence and these form the basis of surface plasmon microscopy (13, 14). These differences in intensity provide optical contrast to image regions of different optical mass (refractive index, thickness). Further details concerning the theory of surface plasmon resonance can be found in reviews by Raether (15, 16).

Experimental

Chemicals

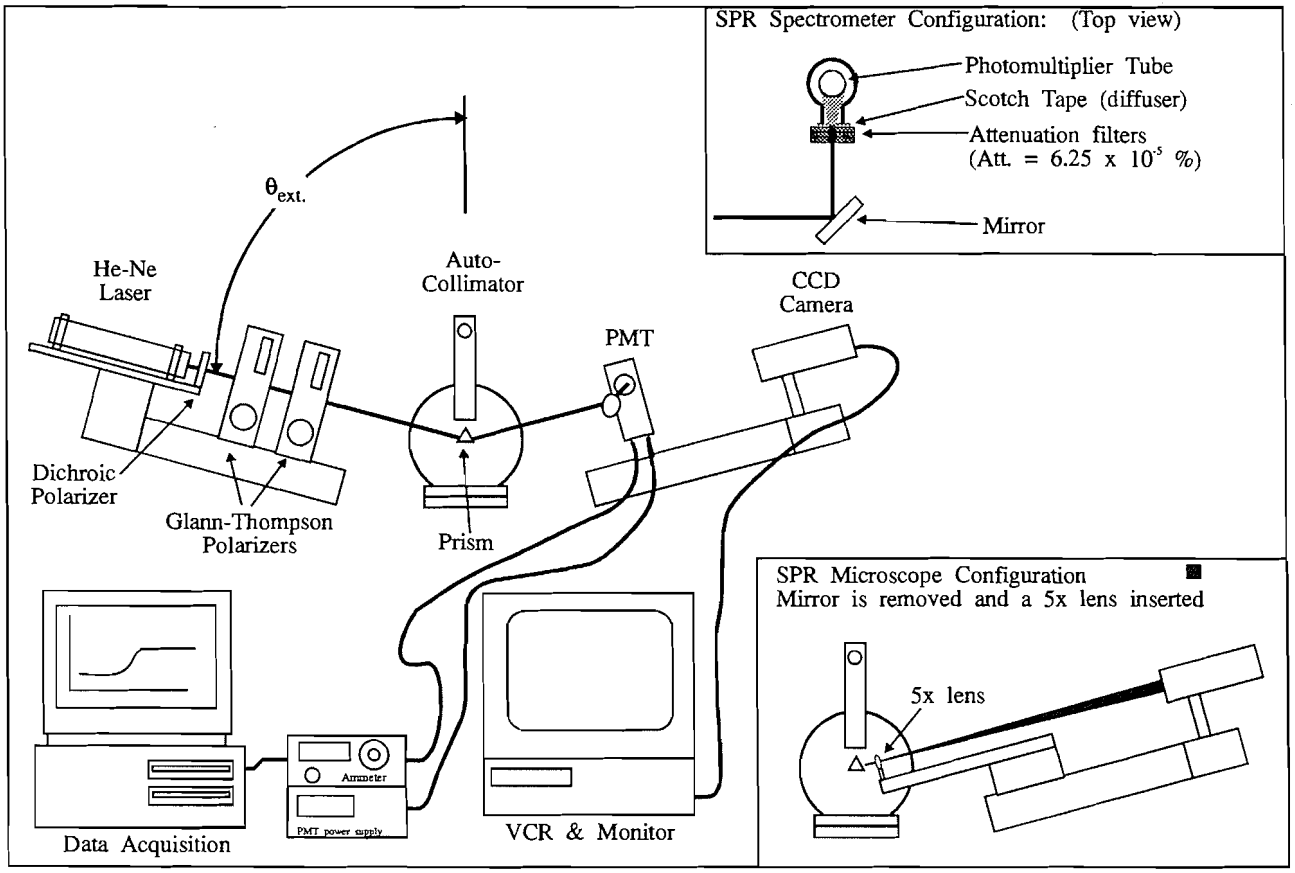
Absolute alcohol of pharmaceutical grade was obtained from Consolidated Alcohols (Toronto, Ont.). 95% (v/v) Ethanol was prepared by adding distilled water. All distilled water was obtained using a Milli-Q five-stage cartridge purification system (Millipore, Mississauga, Ont.) and was degassed before use. Diethyl disulfide, 1-hexane thiol, 1-dodecane thiol, and 1-hexadecane thiol were obtained from Aldrich Chemicals (Milwaukee, Wis.) and used as obtained. Stock solutions of 500 μM hexane, hexadecane, and dodecane thiols were prepared with 95% ethanol. Gold metal (99.99% purity) was obtained from DEAK International. Chromium rods were obtained from R.D. Mathis Co., Long Beach, Calif. Premium Quality glass wafers were supplied by Fisher Scientific (Pittsburgh, Pa.).

Equipment

Absorption measurements were done using an HP 8452A diode array spectrophotometer (Hewlett–Packard Company, Palo Alto, Calif.). Ellipsometry was done with an Auto-EL II nulling ellipsometer (Rudolph Research Corporation, Flanders, N.J.) with a 1 mW continuous wave helium–neon laser (632.8 nm) at a fixed angle of incidence of 70.00°. Ellipsometric data were analysed using a "Film 85" software package based on the McCrackin program (17) version 3.0, program 70 to determine the refractive index of the substrate and program 13 to determine the thickness of the alkyl thiol films.

Preparation of silver and gold-coated wafers was done using a Key High Vacuum Products model KV-301 metal vapour deposition instrument (Nesconset, N.Y.) operating at a maximum pressure of 8 μTorr (1 Torr = 133.3 Pa). Substrates

Fig. 2. Surface plasmon spectrometer and microscope.



to be coated were positioned 25 cm from a resistively heated molybdenum boat. Thickness and rate of deposition were monitored using a 5 MHz piezoelectric crystal mass balance. Refractive index measurements were done using an Abbé refractometer that was maintained at constant temperature using a water bath. Static contact angle (wettability) estimates were done by imaging a 10 μL drop of distilled water with a monocular microscope that contained a reticule protractor.

Surface plasmon spectrophotometer and microscope

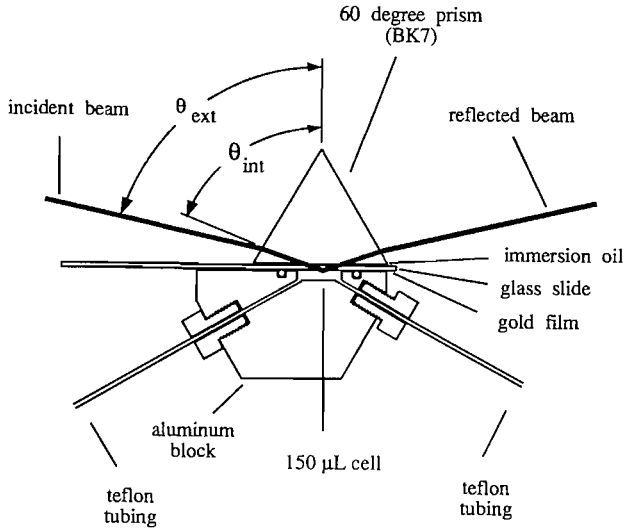
The experimental apparatus used for SPR is shown in Fig. 2. Angular control was achieved by the use of a goniometer from a Rudolph Research ellipsometer. This permitted the angle of incidence to be varied with a precision of 0.005°. The optical source was a 2 mW linearly polarized helium–neon (He-Ne) laser (Spectra Physics, Hughes), which emitted at 632.8 nm with a beam diameter of 2 mm, a divergence of 0.01 mradians, and a stability better than 0.8%. The He–Ne laser was positioned with the plane of polarization at approximately 45°. The optical train consisted of a He–Ne laser, a dichroic polarizer (Melles Griot) set at 45°, and two Glann–Thompson polarizers (referred to as Pol 1 and Pol 2). The optical beam passed though the dichroic polarizer and the Glann–Thompson polarizer, was refracted at the first prism face, and underwent total internal reflection at the prism base. The beam was then refracted again upon exiting the prism and was directed by a mirror (as shown in Fig. 2) through a series of attenuation filters and a diffuser (transparent Scotch™ tape) onto a Hamamatsu R-928 photomultiplier tube (PMT). The PMT current was measured with a Keithley electrometer, and the recorder output of this electrometer was passed to a Metra-Byte 12 bit analog-to-digital board or acquisition of data with an IBM-XT clone. For SPR work, Pol 1 was set at 45.00° while Pol 2 was set at either 0.00° (parallel) or 90.00° (perpendicular). Surface plasmon microscopy required the mirror to be removed and a 5× microscope lens positioned so that the focal point was at the base of the prism as shown in Fig. 2. The scattered light was collected by the lens to produce an image that was captured by a Hitachi KP-111 CCD solid state camera (Nedco, Mississauga, Ont.). The automatic gain control of the CCD camera was disabled. SPM work required careful control of the intensity of the source, which could be achieved by changing the orientation of the Glann–Thompson polarizer (Pol 1).

Procedures

Preparation of glass wafers

Glass slides were cleaned by soaking in a detergent solution in an ultrasonic bath for 1 h at 60°C followed by extensive rinsing in water and drying in an oven (100°C) for several hours. Wafers were then transferred to the vacuum deposition system where a thin layer of chromium (15–30 Å) was deposited at 0.5 Å/s at 5 μTorr. The bell jar was then back-filled with

Fig. 3. Flow cell design.



prepurified argon and the chromium rod was exchanged for a molybdenum boat containing gold. During this step, the chromium layer was exposed for a few minutes to atmospheric conditions, resulting in the formation of a thin chromium oxide layer. The system was then evacuated to 5 μTorr and approximately 430 Å of gold was deposited at a rate of 10 Å/s. The percent transmittance for a 10 Å chromium film at 632 nm was 96 ± 3% and for a 430 Å gold film was 6 ± 1%. Wafers were used within 30 min of gold deposition for thiol self-assembly experiments.

Prism and flow-through cell assembly

A 60.00° BK-7 prism (30.00 × 30.00 × 30.00 mm) was optically connected to the gold-coated glass wafer using a matching immersion oil (type B, Cargille Laboratories Inc., n = 1.515). The prism – glass slide assembly was then clamped to an aluminum flow-through cell (150 μL) and with a Viton O-ring pressed against the glass slide (Fig. 3). The Teflon tubing used was refluxed in methanol for 1 month in order to remove leachable contaminants. A Microperspex perisaltic pump (LKB Bromma) was used to pull solution through the cell at 0.30 mL/min for dynamic studies while a 10 mL syringe was used to pull 2 mL of solution for stop-flow studies. The entire assembly was transferred to the sample stage of the SPR apparatus and the autocollimator was used on the portion of the wafer extending past the prism to ensure that the plane of incidence was normal to the glass slide.

SPR reflectivity curves and fixed angle reflectivity measurements

A manual reflectivity scan was obtained by recording the reflected intensity from 70.00° to 90.00° in 0.50° steps for both parallel (I_p) and perpendicular (I_s) polarization modes. The minimum angle of incidence was determined from the parallel polarized scan. From the reflectivity scan a fixed angle of incidence was chosen for the time-dependent measurements. The angle was chosen to be approximately 1° less than the minimum angle, where a compromise between sensitivity and signal-to-noise ratio was achieved. The intensity of the source was recorded at the beginning and end of any time-dependent measurements to verify that drift in laser intensity had not occurred. At the end of the experiment, a second SPR curve was obtained to ensure that the system was working reproducibly. SPM imaging was then done. External angles (θ_{ext}) of incidence were converted to internal angles (θ_{int}) of incidence using the equation:

$$[1] \quad \theta_{int} = \theta_b - \arcsin\left(\frac{\sin(\theta_b - \theta_{ext})}{n_p}\right)$$

where θ_b is the base angle of the prism and n_p is the refractive index of the prism. All angles of incidence reported in the results section are internal angles of incidence.

Determination of normalization factor

All intensity measurements were converted to R_p/R_s reflectivity measurements by multiplying the ratio of I_p/I_s (parallel intensity/perpendicular intensity) by a normalizing factor (NF). The NF corrected for reflectivity losses at the prism faces, mirror, and attenuation filter, and for differential response of the PMT due to movement of the optical beam across the PMT surface as the angle of incidence was varied. The NF was obtained from a reflectivity scan using a blank wafer that was optically connected to the prism. The normalization factor was obtained by dividing the perpendicularly polarized scan (I'_s) by the parallel polarized scan (I'_p):

$$[2] \quad \text{Normalization factor} = I'_s\, I'_p$$

The uncertainty associated with R_p/R_s for each point in the reflectivity curve is 1.5% for $R_p/R_s > 0.10$. R_p/R_s below 0.01 had an absolute error of ±0.0015. This error encompassed the uncertainty associated with the internal angle of incidence of ±0.006° and electrometer noise.

Modelling and fitting program

SPR data were modelled and analyzed using a program developed in Quick Basic 4.5 (SPMOD7). A model based on application of the exact Fresnel equations was used to calculate R_p/R_s for an n-layered system where n could be varied (18). The reflectivity of this system can be described using the Fresnel equations, which can be written as a 2 × 2 matrix for each layer. Combining the two boundaries of one layer then yields a matrix describing the layer. Repeating the process for all the layers results in a product of matrices. An iterative fitting program varied the initial specified parameters by carrying out a one-dimensional minimization along favourable directions in n-dimensional space using Powell's method (19). The best fit was established by use of a chi squared (χ^2) parameter. Error estimates in the fitted values were obtained by varying the specified value until the χ^2 doubled. The final fitting parameter was reported as a normalized $\bar{\chi}^2$, dividing χ^2 by the number of points used in the fitting procedure.

Results and discussion

Surface plasmon resonance spectroscopy and microscopy were used to investigate the self-assembly of alkyl thiols at gold surfaces. The reflectivity curve (Fig. 4) for a 441 Å thick gold film in contact with 95% ethanol has a moderately sharp and well-defined minimum. Hence, a gold surface in contact

Fig. 4. Surface plasmon resonance curves for a bare gold wafer in contact with 95% ethanol and after exposure to 10 μM dodecane thiol. (-----) 95% ethanol; (——) after exposure to 10 μM dodecane thiol.

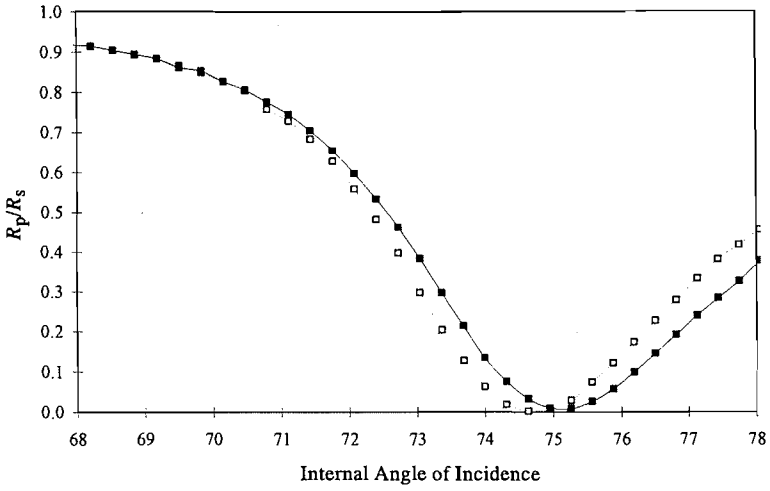


Fig. 5. Reflectivity response (θ = 74.000°) for exposure of the gold surface to 10 μM dodecane thiol in 95% ethanol from $t = 0$ to 1000 s. Delta R_p/R_s obtained by subtracting 0.0812 from R_p/R.

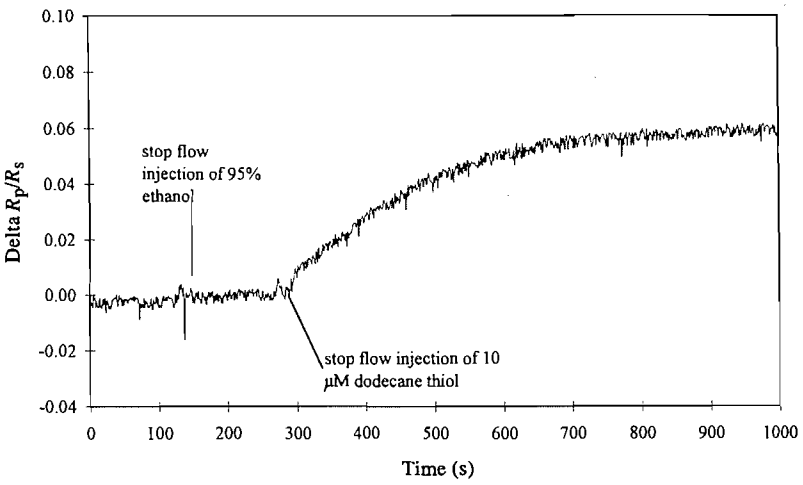


with 95% ethanol is capable of supporting surface plasmons and is expected to show sensitivity to optical mass changes occurring at the metal surface. The full width at half-height of the curve corresponds to a coherence length of 4 μm for the surface plasmon, defining the lateral resolution of this surface for SPM. Freshly prepared gold surfaces had a wettability angle of 48 ± 5°, indicating a partially hydrophobic surface. X-ray photoelectron spectroscopy indicated a thick gold film with no chromium present at the surface.

The UV absorption spectra of a disulfide exhibit two distinct bands at 210 nm and 255 nm while the thiol has one band at 205 nm. Absorption spectra of 500 μM hexane, hexadecane, and dodecane thiol solutions indicate that disulfide contamination did not exist above levels of 0.4% of the parent thiol. Attempts to generate the disulfide from the thiol by bubbling air through a 500 μM hexane thiol solution for 24 h did not generate any observable disulfide. This indicates that these solutions were not susceptible to air oxidation. The presence of disulfides at levels up to 0.4% is not expected to interfere with the adsorption of thiols, since thiol adsorption is favoured over disulfide adsorption onto gold surfaces by a factor of 75 (20). The critical micelle concentration of a lipid such as didodecanyl phosphatidyl choline in water is 400 μM (21). Hexane, dodecane, and hexadecane thiols were used at concentrations between 1 and 100 μM in 95% ethanol. Ethanol exhibits a much higher solvating power than water, hence the presence of micelles at these concentrations is not a consideration.

The reflectivity curves for a bare gold wafer in contact with 95% ethanol after exposure to 10 μM dodecane thiol for 8 h and to 95% ethanol for 15 h under stop-flow conditions are shown in Fig. 4. The change in reflectivity at a fixed angle of incidence of 74.000° upon exposure of the gold surface to 10 μM dodecane thiol is shown in Fig. 5. Exposure of the gold

Table 1. Exposure of gold wafer to 10 μM dodecane thiol.

	Bare gold surface	After exposure to 10 μM dodecane thiol
Contact angle (deg)	47 ± 5	100 ± 5
Ellipsometric measurements: δ	109.14 ± 0.005	107.35 ± 0.03
ψ	42.14 ± 0.07	42.12 ± 0.03
Minimum internal SPR angle	74.726 ± 0.006	75.210 ± 0.006
Reflectivity at 74.000	0.081 ± 0.001	0.160 ± 0.002

Table 2. Relative thickness (Å) of dodecane thiol monolayer.

Basis of relative thickness measurement	After exposure of dodecane thiol for 8 h	After subsequent exposure to 95% ethanol for 15 h
Minimum angle shift		22.2 ± 0.6
Reflectivity shift	16.5 ± 0.3	17.2 ± 0.3
Ellipsometry		16.4 ± 0.5
Theoretical all-*trans* length		17.1

surface to 10 μM dodecane thiol resulted in a rapid increase in reflectivity during the first 300 s, followed by a slow increase over the next 8 h. Exchanging the dodecane thiol solution with a fresh dodecane thiol solution after 8 h resulted in only a very slight increase with time, and replacement of the thiol solution with 95% ethanol resulted in a slight increase of reflectivity. This suggests that the adsorption process is irreversible. The wafer was then removed from the cell and was dried under argon. Subsequent ellipsometric and wettability measurements are summarized in Table 1. The shifts in θ_{min} to a larger angle of incidence, and the increase in reflectivity, are indicative of the formation of an organic layer with a refractive index larger than that of the contacting medium (95% ethanol, n = 1.3606).

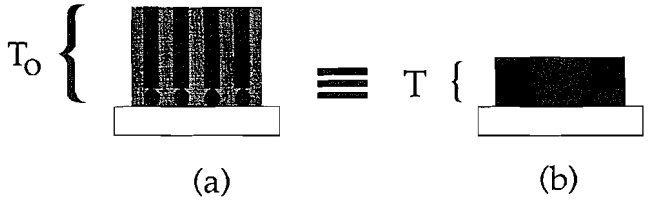
Fresnel equations can be used to convert from reflectivity to average thickness based on a multilayer model, where each layer is characterized by its dielectric constant and thickness. The multilayer model consists of Prism/Cr Au organic film/outer medium. The refractive index of the BK-7 prism is 1.515. The chromium layer was treated as a thin absorbing layer with a fixed dielectric constant of 6.26 + i 5.0 and variable thickness. The refractive index of the outer medium, which was 95% ethanol at 20°C, was 1.3606. Fitting of the reflectivity curve of the uncoated gold system using the Fresnel equations permitted accurate determination of chromium layer thickness and the dielectric constant and thickness of the gold layer in situ. Literature values for the dielectric constant of the gold layer can not be used since the dielectric constant of the gold film will show variations depending on preparation conditions. Based on the model for the uncoated gold system, the thickness of the chromium layer was determined to be 21 ± 8 Å and the dielectric constant and thickness of the gold film were $-13.29_{\pm 0.02}$ + i $1.29_{\pm 0.04}$ and 441 ± 3 Å, respectively, with a normalized χ^2 of 1.6. The real part of the dielectric constant of the gold film, which was determined from the SPR experiment, exhibited an absolute magnitude that was 13% larger than the literature value obtained by Johnson and Christy (22) for vacuum-evaporated gold films of −11.7 ± 0.2. The imaginary part of the dielectric constant of gold as determined by SPR agrees within experimental error with the literature value of 1.2 ± 0.1.

Once the dielectric constant of the gold layer had been established, the optical response of this system to the formation of an organic layer on the thin gold film could be determined. It is not possible to simultaneously determine both the refractive index and thickness of the organic layer on the gold surface. However, if the refractive index of the layer is known then the average relative thickness of the layer can be determined. The refractive index of liquid dodecane thiol is 1.46 and of crystalline polyethylene is 1.48. A refractive index of 1.5 was used to determine the relative thickness of the organic monolayers. Table 2 summarizes the relative average thickness values obtained from SPR and ellipsometric measurements for fully formed monolayers.

Good agreement exists between the experimental reflectivity and ellipsometric results, and theoretical all-*trans* length values, while the thickness based on the minimum angle shift is 5 Å larger than expected. The agreement between the theoretical all-*trans* length and the ellipsometrically determined thickness suggests that surface contamination is minimal. Wettability measurements of gold surfaces exposed to the atmosphere for 8 h are typically between 60° and 80°, compared to 47° within 30 min after thiol deposition as observed in these experiments.

During the adsorption process, intermediate surface coverage ($0 < \Phi < 1$) of the adsorbed molecules produced a partially formed monolayer as shown in Fig. 6*a*. The effective refractive index varies from that of the solvent (n = 1.3606) to that of a fully formed monolayer (approximately 1.5). To convert from reflectivity to relative thickness, an assumption must be

Fig. 6. A partially formed monolayer of surface coverage Θ is optically equivalent to a fully formed monolayer of refractive index 1.5000 and relative thickness (T) such that $T = \Theta T_f$. (*a*) A partially formed monolayer of surface coverage Θ and effective refractive index N_{eff} and thickness T_f. (*b*) Fully formed



made that a partially formed monolayer is optically equivalent to a fully formed monolayer of refractive index 1.5 and relative average thickness (T) as shown in Fig. 6*b*, such that T is given by:

$$[3] \quad T = \Phi T_f$$

where T_f is the final thickness of the fully formed monolayer. To test the validity of this assumption, the optical response of these two cases for the same surface coverage should be identical. Maxwell–Garnet theory (23) can be used to calculate the effective refractive index (n_{eff}) of the partially formed monolayer. It models this film as a random distribution of small spherical particles embedded in a solvent layer and equates the volume fraction of the film occupied by the particles with surface coverage. This allows the effective refractive index to be given as:

$$[4] \quad n_{eff}^2 = n_{sol}^2 \frac{(1 + 2\Phi B)}{(1 - \Phi B)}$$

where

$$B = \frac{(n_f^2 - n_{sol}^2)}{(n_f^2 + 2n_{sol}^2)}$$

where n_{sol} is the refractive index of the solvent. The reflectivity response of these two cases as a function of surface coverage at a fixed angle of incidence of 73.683° (which is within 1° of the minimum reflectivity for a bare gold surface in contact with 95% ethanol) is shown in Fig. 7. The optical response curves are similar with a maximum difference of 2% occurring at 50% surface coverage. This is well within experimental error and indicates that the assumption associated with eq. [3] is valid, and permits the experimentally determined reflectivity to be converted to average thickness values (Fig. 8).

Kinetics of adsorption

A study of the kinetics and process of alkyl thiol adsorption from ethanolic solutions onto gold has previously been reported. This work made use of NEXAFS (10) to study samples at various reaction times. The results indicated that adsorption occurred in two steps. The first step was rapid (about 10 min for 80% monolayer coverage), and resulted in a monolayer where the alkyl chains were highly entangled. A second slow step (time constant approx. 2 orders of magnitude larger than first step) was suggested to be related to the straightening of alkyl chains. Our work has been directed to an investigation of these processes in real time.

The adsorption process consists of a thiol molecule adsorbing to the surface and forming a chemisorptive bond with the gold surface:

$$[5] \quad RSH + Au \rightarrow RSAu^*$$

Desorption of the adsorbed thiol is assumed to be negligible since the strength of the chemisorptive bond (40–45 kcal/mol) is large. Hence, we will assume that the rate of change of the adsorbed thiol concentration is described by:

$$[6] \quad \frac{d\{RSAu^*\}}{dt} = k[RSH]\{Au\}$$

where $\{RSAu^*\}$ is the surface concentration of the adsorbed thiol and [RSH] is the bulk solution concentration of thiol (i.e., no time-dependent concentration gradient) and $\{Au\}$ is the surface concentration of available sites for thiol adsorption. The parameter $\{Au\}$ can be written as:

$$[7] \quad \{Au\} = \{Au\}_0 - \{RSAu^*\}$$

assuming the mobile precursor model, and that dissociative chemisorption does not apply, where $\{Au\}_0$ is the total concentration of gold sites available for binding with the thiol. Hence, surface coverage (Φ) is represented by the following ratio:

$$[8] \quad \Phi = \{RSAu^*\}/\{Au\}_0$$

Substituting this into eq. [6] gives the rate of change as a function of surface coverage:

$$[9] \quad \frac{d\Phi}{dt} = k[RSH](1-\Phi)$$

Assuming that [RSH] does not change significantly during the course of the adsorption process and combining k[RSH] to give a single rate constant, k_1, integration gives:

$$[10] \quad \Phi = 1 - \exp(-k_1 t)$$

Restating this equation in terms of relative thickness where T is relative thickness at time t and T_1 is the limiting thickness such that:

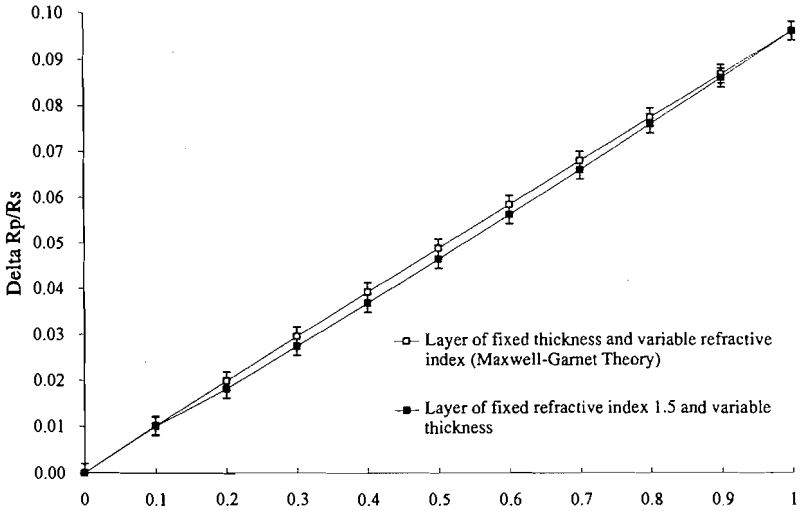
$$[11] \quad \Phi = T/T_1$$

substitution into eq. [10] and rearranging gives:

$$[12] \quad T = T_1[1-\exp(-k_1 t)]$$

The adsorption kinetics for the dodecane thiol follows a simple model for the first 1000 s with $T_1 = 14.4 \pm 0.8$ Å and $k_1 = (450 \pm 100) \times 10^{-5}$ s^{-1} but breaks down over the next 29 000 s (overall $\bar{\chi}^2 = 2.7$) where a further increase is observed as can be seen in Fig. 8 (note: statistics represent standard deviation of 3 to 6 experiments). Initially, when the thiol adsorbs to the surface, available adjacent gold sites will be blocked from incoming thiol molecules based on simple steric consider-

Fig. 7. The change in reflectivity (Delta R_p/R_s, $(R_p/R_s)_0 = 0.1176$) at a fixed internal angle of incidence 73.683° as a function of increasing surface coverage for two cases. Case I: a (⊟) layer of fixed thickness of 20 Å and variable effective refractive index. Increasing surface coverage results in an increase in the effective refractive index (1.3606 to 1.5000) of the layer based on Maxwell–Garnett theory. Case II: a (■) layer of fixed refractive index (n = 1.5000) and variable thickness. Increasing surface coverage results in an increase in thickness (0 to 20 Å) of the layer $T = \Theta T_0$. Modelling parameters used for bare gold system are prism (n = 1.5000), Cr ($\varepsilon' = 6.25$, $\varepsilon'' = 5$, t = 17 Å), Au($\varepsilon' = -13.23$, $\varepsilon'' = 1.41$, t = 440 Å), and 95% ethanol (n = 1.3606). Error bars correspond to experimental errors arising from reflectivity measurements.



ations. Enthalpy and entropic energy considerations will drive the individually adsorbed thiols to associate into a more ordered assembly with the alkyl chains pointing away from the surface. If association of the individually adsorbed thiols was slow, then the limiting thickness would have broken down much before the first 1000 s.

The gradual increase in average thickness over the next 8 h suggests that a new population of thiol binding sites on the gold surface slowly becomes available, permitting further adsorption, possibly as a result of rearrangement of the adsorbed monolayer on the gold surface. The rate constant of this step, k_2, is experimentally slow and is expected to be independent of solution concentration of the thiol. The integrated rate law of this step is given below.

$$[13] \quad T = T_2\,[1-\exp(-k_2 t)]$$

where T_2 is the limiting average relative thickness increase in Å as a result of the second process. The two rate laws can be directly combined assuming independence of process to give:

$$[14] \quad T = T_1[1 - \exp(-k_1 t)] + T_2[1 - \exp(-k_2 t)]$$

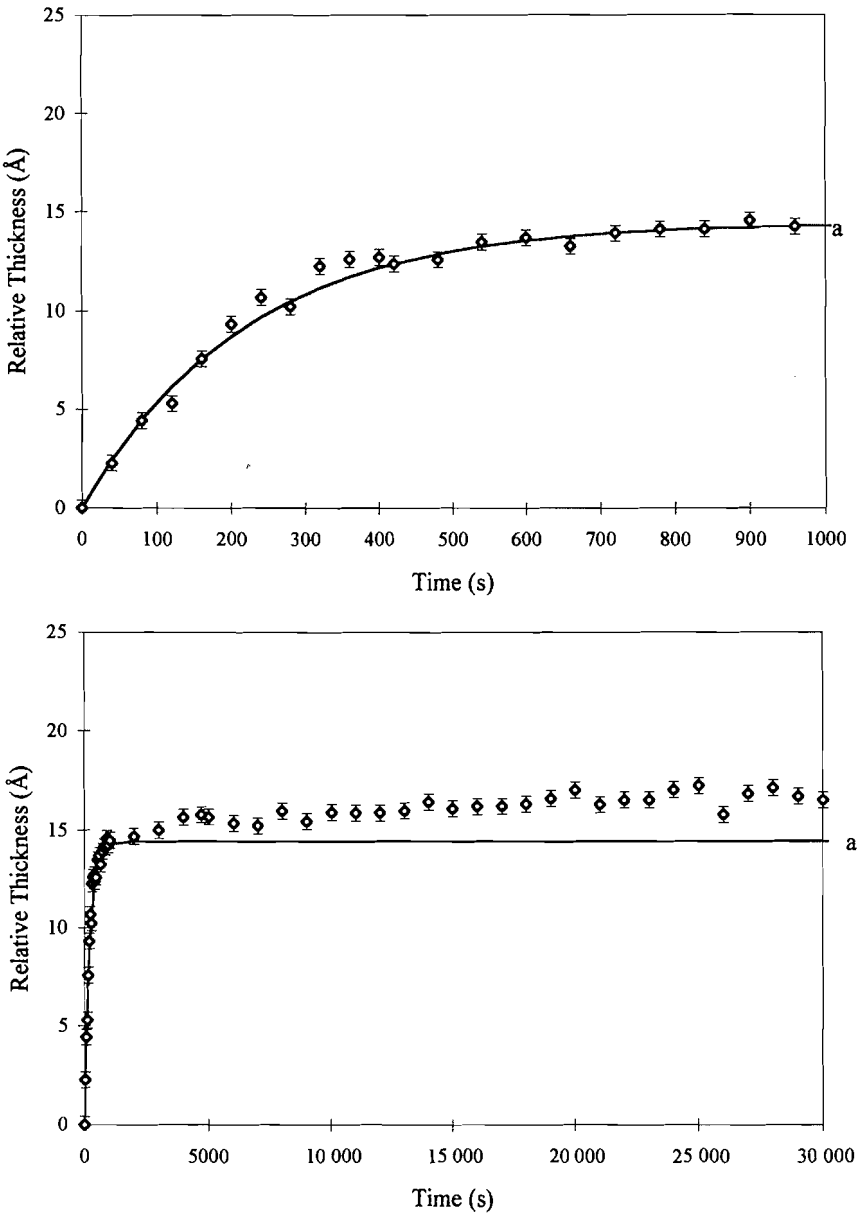
where T_2 is the average thickness (in Å) at time t (in s). Incorporating this second step with $T_2 = 3.5 \pm 0.9$ Å and $k_2 = (4 \pm 2) \times 10^{-5}$ s^{-1} into the model improves the overall fit (overall $\bar{\chi}^2$ = 0.7) between the experimental and theoretical curves between 1000 and 30 000 s as shown in Fig. 9.

The rate of adsorption of thiol to the surface is a function of the concentration and the surface binding as based on the number of available sites and interaction energies. The rate constants k_1 and k_2 were examined by alteration of the reaction conditions. The concentration gradient of dodecane thiol was increased by increasing the solution concentration 10-fold from 10 to 100 μM, and by increasing the rate of thiol delivery to the gold surface through the use of convective delivery by using dynamic flow (0.30 mL/min) conditions. Results are summarized in Table 3.

Increasing the concentration 10-fold increases the rate constant k_1 by a factor of 15 ± 6, suggesting that k_1 is under concentration control. Under dynamic flow conditions of 0.30 mL/min the rate constant k_1 may increase somewhat as a result of convective delivery of thiol to the surface, but this is not definitive given the precision of the results. Increasing the concentration 10-fold only increased k_2 by a factor of 4 ± 2, while using flow conditions did not increase this rate constant any further.

Table 4 summarizes the limiting thickness and rate constants that were measured for dodecane, hexane, and hexadecane thiols under static and dynamic conditions (0.30 mL/min) at 10 μM concentrations. Under static conditions and 10 μM concentration there is no definite correlation between chain length and k_1 and k_2. This is consistent with the assumption that no substantial concentration gradient exists at the interface, and that k_1 is dominated by bulk solution concentration of alkyl thiol. That k_2 is not related to chain length suggests the limiting step to reorganization is not based on van der Waals interactions between the alkyl chains but rather results

Fig. 8. Relative thickness change for exposure of gold surface to 10 μM dodecane thiol in 95% ethanol. "a" Single step adsorption model, $T_1 = 14.4 \pm 0.8$ Å, $k_1 = 450 \pm 100\ s^{-1}$; normalized $\bar{\chi}^2 = 2.7$.



from alterations of the sulfur–gold interaction at the metal surface.

The existence of a two-step mechanism suggests that between 20% (C_{12}, C_{16}) and 50% (C_6) of the surface could be differentially functionalized by removing a wafer after approximately 15 min of exposure to a 10 μM thiol solution (plateau at first adsorption step) and then reimmersing the wafer in a 10 μM thiol solution with a different terminal functional group for 8 h. Alternatively, a higher degree of control could be obtained by exposing the gold surface to a sequential series of thiol solutions via a stop-flow system while using SPR to monitor changes in surface coverage. This approach could prove useful in the functionalization and blocking of surfaces for chemically modified electrochemical detectors in order to enhance selectivity and film stability. It can also serve as a simple method of introducing electroactive mediators.

Ellipsometry and wettability results are summarized in Table 5 for a series of samples prepared concurrently, and allowed to stand for 24 h. The relative thickness of the fully formed hexane thiol layer according to in situ SPR measurements is 2 Å greater than the value obtained from ellipsometric measurements in air (Table 5). For the longer chain alkyl thiols C_{12} and C_{16}, in situ SPR measurements indicate that the films are 7 Å thicker than corresponding ellipsometric measurements. Removal of the alkyl thiol monolayers from a 95% ethanol environment to an air environment results in a decrease in thickness that is larger for the longer chain alkyl thiols and cor-

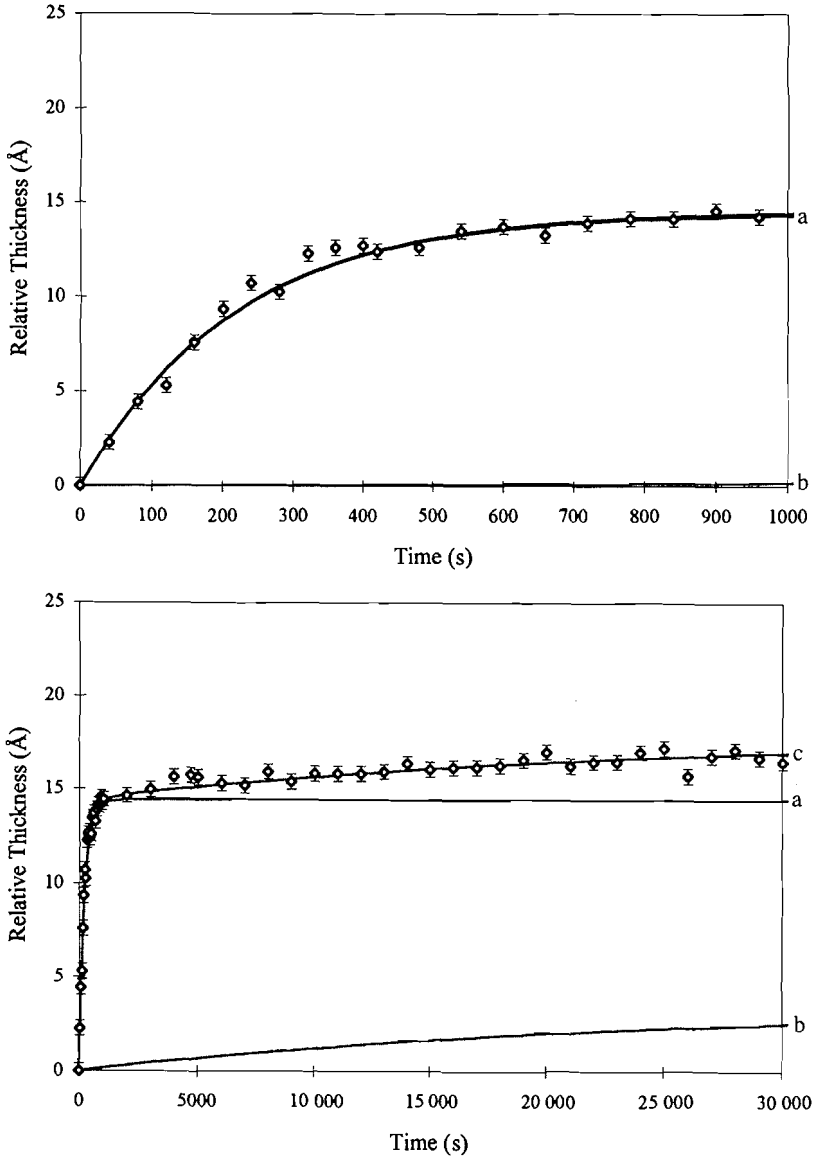
and "c", the combined two-step model, normalized $\bar{\chi}^2 = 0.7$.



relates with a 15° larger wettability measurement. This may suggest that an ordered layer of solvent may exist between the alkyl chain termini and the bulk solution, which is removed when the wafer is transferred to an air environment. Wettability angles for dodecane thiol and hexadecane thiol are 15° larger than the wettability angle observed for hexane thiol. For long-chain thiols ($n > 10$) the monolayer becomes more structurally homogeneous and densely packed as a result of greater van der Waals interaction between the alkyl chains. This leads to a higher density of methyl groups at the surface and increased hydrophobicity. Ideally, maximization of the van der Waals interaction (a $1/r^6$ distance dependence) between the alkyl chains is expected to result in a 30° tilt in the hydrocarbon chains in order to minimize the interaction distance.

Surface plasmon microscopy was used to search for microscopic structure within the formed alkyl thiol monolayers. No structure was observed for any of the monolayers at the 4 μm resolution level. This suggests that nucleation and growth of these organic layers occurred at the sub-microscopic level and that these films are optically homogenous. These results confirm that application of the Fresnel equations for solving the optical equations is appropriate.

Table 3. Rate constants and limiting thickness from SPR measurements as determined using static and dynamic conditions for adsorption of 10 and 100 μM dodecane thiol from 95% ethanol.

System	Conc. (μM)	T_1 (Å)	T_2 (Å)	$k_1 \times 10^{-5}$ (s^{-1})	$k_2 \times 10^{-5}$ (s^{-1})	$\bar{\chi}^2$

Table 5. Wettability angle and ellipsometric measurements of surface after exposure to alkyl thiol solutions.

Polycrystalline gold	Wettability angle ±5°	Relative thickness (Å) (ellipsometry) ±10%	Thickness (Å) based on reflectivity ±10%	Theoretical all-*trans* length (Å)
Freshly deposited	48	0		
Hexane thiol	90	11	13	9.6
Dodecane thiol	105	16	23	17.1
Hexadecane thiol	105	23	30	22.1

Conclusions

SPR experiments indicate that hexane, dodecane, and hexadecane thiol adsorption to gold surfaces occurred by a two-step process, with the first step being two orders of magnitude faster than the second step. Fast adsorption to the surface gave 80% (C_{12}, C_{16}) or 50% (C_6) coverage followed by a slow rearrangement of the adsorbed thiol. Growth and formation of domains of thiols were not observed at the microscopic level and the results suggest a relatively homogeneous thiol monolayer.

Formal transfers of hydride from carbon–hydrogen bonds. Attempted generation of H_2 by intramolecular protonolyses of the activated carbon–hydrogen bonds of dihydrobenzimidazoles

Philippe Brunet and James D. Wuest

Abstract: Protonolyses of carbon–hydrogen bonds can occur under suitable conditions to produce carbocations and H_2. In an effort to accelerate these fundamental reactions, we have attempted to make them intramolecular by devising compounds in which carbon–hydrogen bonds designed to be particularly good formal donors of hydride are held in close proximity to acidic sites. Dihydrobenzimidazoles **4** and **11** are compounds of this type, since the carbon–hydrogen bonds at C2 are activated as formal donors of hydride by adjacent lone pairs in a dihydroaromatic ring, and acidic anilinium and carboxylic acid groups are held nearby. Unfortunately, this proximity does not lead to the formation of H_2 by protonolysis; instead, other reactions intervene when compounds **4** and **11** are subjected to pyrolysis.

Key words: intramolecular protonolysis of carbon–hydrogen bonds, formal donors of hydride, generation of H_2, dihydrobenzimidazoles.

Résumé : La protonolyse des liaisons carbone–hydrogène peuvent se produire dans des conditions appropriées pour conduire à des carbocations et du H_2. Dans le but d'accélérer les vitesses de ces réactions fondamentales, on a essayé de faire des réactions intramoléculaires en construisant des composés dans lesquels des liaisons carbone–hydrogène comportant des donneurs formels d'hydrures particulièrement bons seront maintenues à faible distance des sites acides. Les dihydrobenzimidazoles **4** et **11** sont des composés de ce type puisque les liaisons carbone–hydrogène en C(2) sont activées comme donneurs formels d'hydrure par les paires non partagées adjacentes du noyau dihydroaromatique alors que les groupes acides anilinium et acide carboxylique sont maintenus à proximité. Malgré cette proximité, la protonolyse ne conduit malheureusement pas à la formation de H_2; quand les composés **4** et **11** sont soumis à une pyrolyse, il y a plutôt intervention d'autres réactions.

Mots clés : protonolyse intramoléculaire de liaisons carbone–hydrogène, donneurs formels d'hydrure, génération de H_2, dihydrobenzimidazoles.

Introduction

Carbon–hydrogen bonds serve as formal donors of hydride in a variety of well-known redox reactions (1). Of particular practical importance are the formal transfers of hydride from carbon–hydrogen bonds that occur during catalytic cracking and reforming, as well as closely related reactions in which protonolyses of the carbon–hydrogen bonds of simple alkanes by strong acids produce carbocations and H_2 (2). To learn more about these fundamental processes, we have prepared compounds designed to be especially good formal donors of hydride, and we have studied their reactions with acids (3, 4). This work has shown that orthoformamide **1** and related compounds are remarkably reactive substrates for protonolyses, and their activated central carbon–hydrogen bonds react with acids to liberate H_2 and give the corresponding guanidinium ions under surprisingly mild conditions.[3] To further accelerate protonolyses of carbon–hydrogen bonds, we have attempted to make them intramolecular by devising a series of compounds in which similarly activated carbon–hydrogen bonds are held in close proximity to acidic groups (6). In this article, we describe the synthesis and reactions of two dihydrobenz-

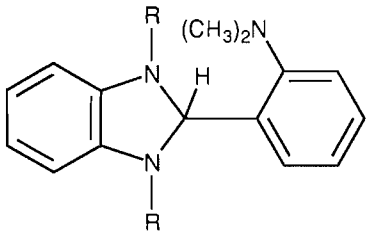
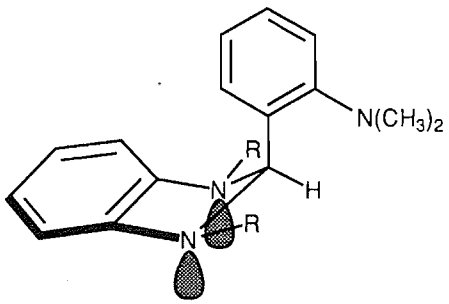
imidazoles that have been designed in this way to undergo intramolecular protonolyses of carbon–hydrogen bonds.

Results and discussion

Acid-catalyzed condensation of *N,N'*-dimethyl-1,2-benzenediamine (7) with 2-(dimethylamino)benzaldehyde (8) produced 2-[2-(dimethylamino)phenyl]-1,3-dimethyl-2,3-dihydro-1*H*-benzimidazole (**2**) in 75% yield. Dihydrobenzimidazole **2** incorporates a carbon–hydrogen bond at C2 able to serve as a



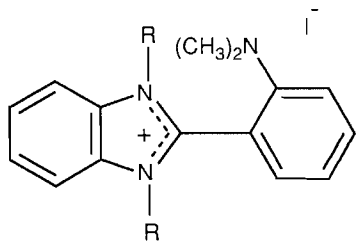
2 (R = CH_3)



2a (R = CH_3)

particularly effective formal donor of hydride for the following reasons : It is adjacent to two lone pairs in a dihydroaromatic ring, and loss of hydride would generate a stable benzimidazolium ion.[4] The conjugate acid of *N,N*-dimethylaniline is weaker (pK_a 5.1) than that of 1,2-benzenediamine (pK_a 4.5) (9), so protonation of compound **2** should produce a salt in which the hydridic carbon–hydrogen bond of the dihydrobenzimidazole unit is held in close proximity to an acidic dimethylanilinium group. We hoped that this juxtaposition would promote the formation of H_2 by intramolecular protonolysis.

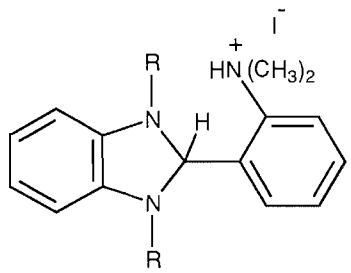
Examination of the IR spectrum of compound **2** in $CHCl_3$ revealed no Bohlmann bands in the region between 2750 and 2400 cm^{-1}, suggesting that the preferred conformation is structure **2a**, in which no lone pairs are antiperiplanar to the carbon–hydrogen bond at C2 (10).[5] Although this observation indicates that the carbon–hydrogen bond at C2 is not notably weakened and polarized by mixing of σ^*_{CH} with adjacent lone-pair orbitals, dihydrobenzimidazole **2** is nevertheless an effective reducing agent.[6] For example, treatment of com-



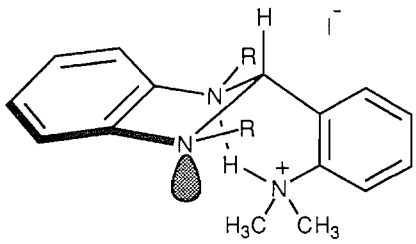
3 (R = CH_3)

pound **2** with methanolic I_2 at 25°C in the presence of K_2CO_3 rapidly produced benzimidazolium iodide **3** in 85% yield.

As expected, addition of aqueous HI to dihydrobenzimidazole **2** in deoxygenated ether provided salt **4** in high yield. Comparison of the ^1H NMR spectra of compounds **2** and **4** confirmed that the principal site of protonation is the nitrogen atom of the dimethylaniline group, since the hydrogens of this



4 (R = CH_3)



4a (R = CH_3)

group showed important downfield shifts while those of the benzenediamine unit experienced only moderate shifts. Curiously, the hydrogen at C2 appears at δ 5.86 ($CDCl_3$) in dihydrobenzimidazole **2** but is shifted *upfield* to δ 4.83 ($CDCl_3$) in salt **4**. This unexpected shielding presumably arises in part because intramolecular hydrogen bonding now favors conformation **4a**, in which the carbon–hydrogen bond at C2 becomes antiperiplanar to two lone pairs. This conclusion is supported by the presence of a Bohlmann band at 2698 cm^{-1} in the IR spectrum ($CHCl_3$) of salt **4**. Closely similar conformations are known to be preferred by other 2-substituted dihydrobenzimidazoles capable of participating in intramolecular hydrogen bonding (6). Direct evidence for the presence of an intramolecular hydrogen bond was provided by the concentration-independence of the chemical shift of the anilinium hydrogen.

Unfortunately, conformation **4a** is not suitable for the gen-

[4] The estimated hydride affinity of benzimidazolium is 200 kcal/mol (6*d*).

[5] The nitrogen atoms in dihydrobenzimidazoles are known to be distinctly pyramidal (6).

[6] Other dihydrobenzimidazoles are known to be effective reducing agents (11).

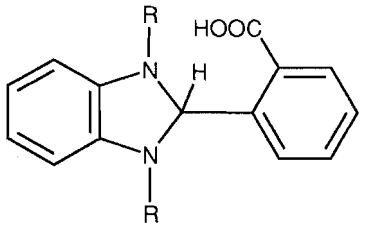
eration of H_2 by intramolecular protonolysis of the carbon–hydrogen bond at C2. The carbon–hydrogen bond is activated as a formal source of hydride by two antiperiplanar lone pairs, but the acidic hydrogen of the dimethylanilinium group is not nearby. Although more reactive conformers are presumably accessible, thermal decomposition of salt **4** led only to complex mixtures, and neither H_2 nor benzimidazolium salt **3** could be detected among the products.

A similar molecule designed to be able to undergo intramolecular protonolysis of a carbon–hydrogen bond is dihydrobenzimidazole **5**, which juxtaposes a carboxylic acid and a carbon–hydrogen bond that can serve as a good formal donor of hydride. We attempted to prepare this compound from the corresponding methyl ester **6**, which was obtained in 43% yield by acid-catalyzed condensation of *N,N'*-dimethyl-1,2-benzenediamine (7) with methyl 8-formyl-1-naphthalenecarboxylate (**7**). Ester **7** was made by adding CH_2N_2 to 1,8-naphthaldehydic acid (12), which was synthesized from acenaphthenequinone by a modification of the standard method (13). Unfortunately, basic hydrolysis of ester **6** and subsequent acidification did not provide the expected acid **5**, but gave instead the isomeric aminolactone **8** in 60% yield. Alternatively, compound **8** could be prepared more directly in 80% yield by treating *N,N'*-dimethyl-1,2-benzenediamine (7) in CH_2Cl_2 at 0°C with chlorolactone **9** (14), which was synthesized from 1,8-naphthaldehydic acid by a modification of the standard method (15).

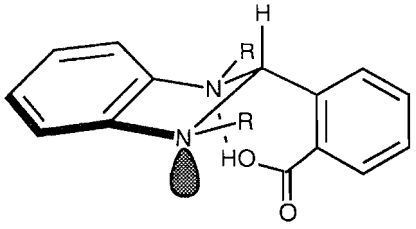
Although aminolactone **8** is not a dihydrobenzimidazole, it nevertheless incorporates a carbon–hydrogen bond activated as a formal donor of hydride by adjacent lone pairs on nitrogen and oxygen. As a result, it is readily oxidized. For example, treatment with methanolic I_2 in the presence of K_2CO_3 provided a 73% yield of internal salt **10**, which is the product expected as a result of intramolecular protonolysis in hypothetical dihydrobenzimidazole **5**. We suspected that compound **8** might be in equilibrium with the desired isomeric dihydrobenzimidazole **5**, so we subjected it to pyrolysis. Unfortunately, thermal decomposition generated only a complex mixture, and neither H_2 nor internal salt **10** was detected among the products.

We reasoned that the closely related dihydrobenzimidazole **11** would be less likely than compound **5** to isomerize to the corresponding isomeric aminolactone. In fact, direct condensation of *N,N'*-dimethylbenzene-1,2-diamine (7) with phthalaldehydic acid gave dihydrobenzimidazole **11** in 87% yield. The presence of a carbonyl band at 1719 cm^{-1} and Bohlmann bands at 2692 and 2637 cm^{-1} in the IR spectrum of compound **11** ($CHCl_3$) provided evidence that the product incorporates a carboxylic acid group and a carbon–hydrogen bond antiperiplanar to two lone pairs on nitrogen. This indicates that the product is in fact compound **11** and not the isomeric aminolactone **12**, and it suggests that intramolecularly hydrogen-bonded structure **11a** is the preferred conformation (6).

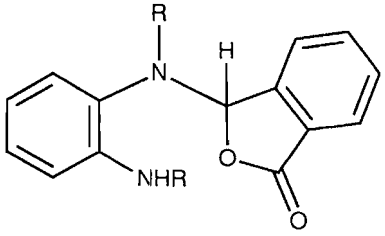
Dihydrobenzimidazole **11** is particularly susceptible to oxidation, and it even reacts with atmospheric oxygen at 25°C to produce internal salt **13** (16) in quantitative yield. However, despite the juxtaposition of a hydridic carbon–hydrogen bond and a carboxylic acid in dihydrobenzimidazole **11**, and despite its demonstrated ability to participate in redox reactions, it does not undergo intramolecular protonolysis to form H_2.



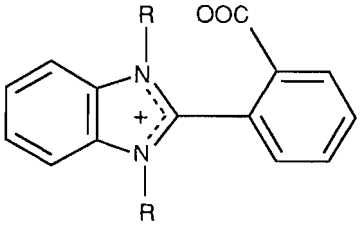
11 (R = CH_3)



11a (R = CH_3)



12 (R = CH_3)



13 (R = CH_3)

Instead, a complex mixture containing three principal components was formed when compound **11** was heated without solvent at 180°C. One of these products, isolated in 32% yield, is internal salt **13**, which is the expected result of intramolecular protonolysis; however, no H_2 could be detected. The other principal products are phthalide (**14**), which was recovered in 19% yield, and bis(benzimidazole) **15**, which was obtained in 14% yield.

We believe that these products result from rearrangement of dihydrobenzimidazole **11** to its less stable aminolactone isomer **12** by a process closely related to the one that intervened in the attempted synthesis of dihydrobenzimidazole **5**. Subsequent protonation then causes cleavage to *N,N'*-dimethyl-1,2-benzenediamine and cation **16**, which is reduced to phthalide by a formal intermolecular transfer of hydride from dihydrobenzimidazole **11**. This transfer yields an equivalent amount of internal salt **13**. Compound **13** and related dimethybenzimidazolium salts are capable of effecting intermolecular methylations (16), ultimately leading to the formation of bis(benzimidazole) **15**, as well as to *N,N,N'*-trimethyl-1,2-benzenediamine and *N,N,N',N'*-tetramethyl-1,2-benzenediamine (17), which are both detected in low yields among the products of pyrolysis. Support for this hypothesis is provided by the observation that a similar pyrolysis of internal salt **13** in the presence of two molar equivalents of *N,N'*-dimethyl-1,2-benzenediamine yielded bis(benzimidazole) **15** and *N,N,N'*-trimethyl-1,2-benzenediamine as major products.

Conclusions

By providing structures in which carbon–hydrogen bonds are activated as formal donors of hydride by adjacent lone pairs and are simultaneously held close to acidic sites, dihydrobenzimidazoles **4** and **11** and related compounds are designed to favor the generation of H_2 by intramolecular protonolyses of carbon–hydrogen bonds. Both compounds **4** and **11** are effective reducing agents and react readily in intermolecular redox processes with active oxidants such as I_2 and O_2. Nevertheless, neither undergoes protonolysis of the activated carbon–hydrogen bond, and pyrolysis does not produce detectible quantities of H_2. To be faster than alternative reactions, protonolysis therefore appears to require carbon–hydrogen bonds that are even more highly activated as formal donors of hydride than those in dihydrobenzimidazoles **4** and **11**, or nearby sites that are even more acidic. In pyrolyses of compounds **4** and **11**, other reactions intervene before protonolysis of the activated carbon–hydrogen bonds can take place.

Experimental section

General procedures

Infrared (IR) spectra were recorded on Perkin-Elmer model 783 or 1600 spectrometers. Varian VXR-300, Bruker AMX-300, or Bruker ARX-400 spectrometers were used to obtain ^1H and ^{13}C nuclear magnetic resonance (NMR) spectra. Chemical shifts are reported in parts per million downfield from internal tetramethylsilane (δ). Mass spectra were recording on a Kratos MS-50 TATC instrument or a VG Autospec instrument using chemical ionization (CI), electron impact (EI), or fast atom bombardment (FAB). Melting points were recorded on a Thomas–Hoover capillary apparatus. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn. Flash chromatography was performed in the normal way (18).

Toluene was dried by distillation from sodium, CH_3OH by distillation from magnesium, CH_2Cl_2 by distillation from CaH_2, and ether by distillation from the sodium ketyl of benzophenone. Other commercial reagents were used without further purification.

2-[2-(Dimethylamino)phenyl]-1,3-dimethyl-2,3-dihydro-1*H*-benzimidazole (2)

A solution of *N,N*-dimethyl-1,2-benzenediamine (0.921 g, 6.76 mmol) (7), 2-(dimethylamino)benzaldehyde (1.01 g, 6.77 mmol) (8), and (1*S*)-10-camphorsulfonic acid (0.081 g, 0.35 mmol) in benzene (15 mL) was heated at reflux for 16 h under N_2 in an apparatus fitted with a Dean–Stark trap. The mixture was then washed with 5% aqueous NaOH and water, the organic phase was dried with anhydrous $MgSO_4$, and volatiles were removed by evaporation under reduced pressure. Crystallization of the residue from 95% aqueous C_2H_5OH provided 2-[2-(dimethylamino)phenyl]-1,3-dimethyl-2,3-dihydro-1*H*-benzimidazole (**2**; 1.35 g, 5.05 mmol, 75%) as an analytically pure colorless solid: mp 105–106°C; IR ($CHCl_3$): 2862, 2826, 2790 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 2.63 (s, 6H), 2.75 (s, 6H), 5.86 (s, 1H), 6.43–6.47 (m, 2H), 6.72–6.77 (m, 2H), 7.23 (ddd, ^3J = 7.8 Hz, ^3J = 7.2 Hz, ^4J = 1.3 Hz, 1H), 7.29 (dd, ^3J = 8.1 Hz, ^4J = 1.3 Hz, 1H), 7.39 (ddd, ^3J = 8.1 Hz, ^3J = 7.2 Hz, ^4J = 1.7 Hz, 1H), 7.94 (dd, ^3J = 7.8 Hz, ^4J = 1.7 Hz, 1H); ^{13}C NMR (75 MHz, $CDCl_3$) δ: 33.0, 46.1, 86.1, 105.3, 119.0, 120.1, 124.8, 129.4, 129.4, 134.5, 142.5, 154.9; MS (CI) *m/e*: 268, 267, 252, 147; HRMS (EI) calcd. for $C_{17}H_{22}N_3$: 268.1814; found: 268.1802. Anal. calcd. for $C_{17}H_{21}N_3$: C 76.35, H 7.92, N 15.72; found: C 76.43, H 7.92, N 15.65.

2-[2-(Dimethylamino)phenyl]-1,3-dimethylbenzimidazolium iodide (3)

A stirred mixture of 2-[2-(dimethylamino)phenyl]-1,3-dimethyl-2,3-dihydro-1*H*-benzimidazole (**2**; 73 mg, 0.27 mmol) and K_2CO_3 (54 mg, 0.39 mmol) in CH_3OH (2 mL) was treated dropwise at 25°C with a solution of I_2 (73 mg, 0.29 mmol) in CH_3OH (8 mL). After 1 h, volatiles were removed by evaporation under reduced pressure, the residue was extracted with $CHCl_3$, and the extracts were decolorized with activated carbon. Removal of solvent from the extracts by evaporation under reduced pressure yielded 2-[2-(dimethylamino)phenyl]-1,3-dimethylbenzimidazolium iodide (**3**; 89 mg, 0.23 mmol, 85%) as a yellow solid, which was purified by recrystallization from CH_2Cl_2–benzene: mp 224-226°C; ^1H NMR (400 MHz, $CDCl_3$) δ: 2.59 (s, 6H), 4.01 (s, 6H), 7.18–7.22 (m, 2H), 7.63 (ddd, ^3J = 8.5 Hz, ^3J = 7.3 Hz, ^4J = 1.6 Hz, 1H), 7.63–7.67 (m, 2H), 7.76 (dd, ^3J = 7.7 Hz, ^4J = 1.6 Hz, 1H), 7.95–8.00 (m, 2H); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 33.8, 43.3, 110.4, 113.5, 118.6, 121.7, 127.4, 131.7, 133.0, 134.6, 150.5, 153.3; MS (FAB) *m/e*: 266; HRMS (EI) calcd. for $C_{17}H_{20}N_3 - CH_3$: 251.1422; found: 251.1410.

Hydriodide of 2-[2-(dimethylamino)phenyl]-1,3-dimethyl-2,3-dihydro-1*H*-benzimidazole (4)

A solution of 2-[2-(dimethylamino)phenyl]-1,3-dimethyl-2,3-dihydro-1*H*-benzimidazole (**2**; 113 mg, 0.423 mmol) in deoxygenated ether (1 mL) was stirred at 0°C under N_2 and treated with 57% aqueous HI (90 μL, 0.40 mmol). The precipitated solid was separated by centrifugation, washed with cold absolute C_2H_5OH and ether, and dried in vacuo to give the hydriodide of 2-[2-(dimethylamino)phenyl]-1,3-dimethyl-2,3-dihydro-1*H*-benzimidazole (**4**; 138 mg, 0.349 mmol, 87%) as a beige solid. Recrystallization from CH_2Cl_2–ether under N_2 provided an analytically pure sample: mp 156–157°C (dec.); IR ($CHCl_3$): 2803, 2698 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 2.72 (s, 6H), 3.61 (s, 6H), 4.83 (s, 1H), 6.76–6.80 (m, 2H), 6.93–6.97 (m, 2H), 7.44 (dd, ^3J = 7.6 Hz, ^4J = 1.3 Hz, 1H), 7.61 (dd, ^3J = 7.7 Hz, ^3J = 7.6 Hz, 1H), 7.80 (ddd, ^3J = 8.1 Hz, ^3J = 7.7 Hz, ^4J = 1.3 Hz, 1H), 8.64 (d, ^3J = 8.1 Hz, 1H), 12.16 (bs, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 34.6, 48.0, 94.5, 110.1, 122.5, 124.3, 126.6, 130.6, 132.3, 133.0, 140.3, 142.9; MS (EI) *m/e*: 267, 252, 147; HRMS (EI) calcd. for $C_{17}H_{22}IN_3 - HI$: 267.1736; found: 267.1726. Anal. calcd. for $C_{17}H_{22}IN_3$: C 51.63, H 5.61; found: C 51.59, H 5.68.

1,8-Naphthaldehydic acid

1,8-Naphthaldehydic acid was prepared by a modification of the standard method (13). A mixture of acenaphthenequinone (10.0 g, 54.9 mmol) and 30% aqueous KOH (70 mL) was heated at 140°C for 20 min in a poly(ethylene) bottle. The resulting blue solution was cooled, diluted with H_2O (180 mL), and acidified with concentrated aqueous HCl. This gave a precipitate that was separated by filtration, washed with H_2O, and dissolved in hot 95% aqueous C_2H_5OH. The resulting solution was decolorized with activated carbon, solvent was removed by evaporation under reduced pressure, and the residue was recrystallized from CH_3CN to give 1,8-naphthaldehydic acid (7.43 g, 37.1 mmol, 68%) as cream-colored needles: mp 166°C (lit. (13) mp 169–171°C); IR (KBr): 3300, 1690 cm^{-1}; ^1H NMR (400 MHz, CD_3CN) δ: 5.79 (s, 1H), 6.81 (s, 1H), 7.64–7.72 (m, 3H), 8.03 (dd, ^3J = 7.6 Hz, ^4J = 1.9 Hz, 1H), 8.24 (dd, ^3J = 8.3 Hz, ^4J = 1.1 Hz, 1H), 8.34 (dd, ^3J = 7.3 Hz, ^4J = 1.1 Hz, 1H); ^{13}C NMR (100 MHz, CD_3CN) δ: 97.0, 121.0, 126.4, 127.5, 127.9, 128.1, 129.4, 130.2, 130.4, 133.0, 134.8, 164.2; MS (CI) *m/e*: 201, 183.

3-Chloro-1*H*,3*H*-naphtho[1,8-*cd*]pyran-1-one (9)

Chloro-1*H*,3*H*-naphtho[1,8-*cd*]pyran-1-one (**9**) was prepared by a modification of the standard method (15). A stirred suspension of 1,8-naphthaldehydic acid (1.08 g, 5.39 mmol) in H_2O (10 mL) was treated dropwise with 1 N aqueous KOH until the solid dissolved. The resulting solution was diluted with H_2O (20 mL) and extracted with CH_2Cl_2, solvent was removed from the aqueous phase by evaporation under

reduced pressure, and the residue was dried at 80°C in vacuo. A suspension of the dried solid in dry toluene (7 mL) was treated with oxalyl chloride (1.75 g, 13.8 mmol). The mixture was stirred at 25°C for 24 h under dry air and then was heated at reflux for 1 h. Volatiles were removed by evaporation under reduced pressure to give a residue of 3-chloro-1*H*,3*H*-naphtho[1,8-*cd*]pyran-1-one (**9**), which was used without purification in subsequent procedures.

Methyl 8-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)-1-naphthoate (6)

A solution of *N,N'*-dimethyl-1,2-benzenediamine (1.10 g, 8.08 mmol) (7), methyl 8-formyl-1-naphthoate (**7**; 1.50 g, 7.00 mmol) (12), and (1*S*)-10-camphorsulfonic acid (0.152 g, 0.654 mmol) in deoxygenated benzene (50 mL) was heated at reflux for 17 h under N_2 in an apparatus fitted with a Dean–Stark trap. The mixture was then diluted with benzene and washed with 5% aqueous NaOH, H_2O, and saturated aqueous $CuSO_4$. The organic phase was dried with anhydrous $MgSO_4$, and solvent was removed by evaporation under reduced pressure. Recrystallization of the residue from CH_3CN gave methyl 8-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)-1-naphthoate (**6**; 1.00 g, 3.01 mmol, 43%) as a yellow solid: mp 160–161°C; IR ($CHCl_3$); 2867, 2804, 1717 cm^{-1}; ^1H NMR (400 MHz, CD_3CN) δ: 2.54 (s, 6H), 3.89 (s, 3H), 5.84 (s, 1H), 6.37–6.42 (m, 2H), 6.70–6.74 (m, 2H), 7.49 (dd, ^3J = 7.4 Hz, ^3J = 7.1 Hz, 1H), 7.63–7.68 (m, 2H), 7.95 (d, ^3J = 8.0 Hz, 1H), 8.05 (d, ^3J = 8.2 Hz, 1H), 8.41 (d, ^3J = 7.2 Hz, 1H); ^{13}C NMR (100 MHz, CD_3CN) δ: 32.5, 52.8, 87.6, 105.1, 119.0, 124.0, 126.5, 128.5, 128.9, 129.0, 130.0, 130.4, 132.3, 134.1, 135.9, 141.8, 171.7; HRMS (EI) calcd. for $C_{21}H_{20}N_2O_2$ − H: 331.1447; found: 331.1433.

3-[Methyl[(2-methylamino)phenyl]amino]-1*H*, 3*H*-naphtho[1,8-*cd*]pyran-1-one (8)

*Method A. By hydrolysis of methyl 8-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)-1-naphthoate (6)*

A solution of methyl 8-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)-1-naphthoate (**6**; 358 mg, 1.08 mmol) in THF (4 mL) was treated with 1.1 N aqueous LiOH (10 mL, 11 mmol). The resulting mixture was heated at reflux for 2 h, and then the volatiles were removed by evaporation in vacuo. The dried residue was extracted with $CHCl_3$ (50 mL), and solvent was removed from the extract by evaporation under reduced pressure. The residue was redissolved in deoxygenated H_2O (13 mL) and acidified at 0°C with deoxygenated 1 N aqueous HCl (1.05 mL, 1.05 mmol). The precipitated solid was separated by centrifugation, washed with H_2O, and dried in vacuo to give 3-[methyl[(2-methylamino)phenyl]amino]-1*H*, 3*H*-naphtho[1,8-*cd*]pyran-1-one (**8**; 208 mg, 0.653 mmol, 60%) as a white solid: IR ($CHCl_3$): 3418, 2815, 1711 cm^{-1}; ^1H NMR (400 MHz, CD_3CN) δ: 2.64 (s, 3H), 2.90 (d, ^3J = 3.2 Hz, 3H), 4.63 (bs, 1H), 6.64 (d, ^3J = 7.9 Hz, 1H), 6.72 (m, 1H), 6.78 (s, 1H), 7.13 (m, 1H), 7.60–7.72 (m, 4H), 7.95 (d, ^3J = 8.0 Hz, 1H), 8.14 (dd, ^3J = 8.3 Hz, ^4J = 1.1 Hz, 1H), 8.49 (dd, ^3J = 7.2 Hz, ^4J = 1.1 Hz, 1H); ^{13}C NMR (100 MHz, CD_3CN) δ: 30.5, 34.8, 95.5, 110.0, 116.9, 120.1, 124.9, 125.6, 126.3, 126.5, 127.0, 128.2, 128.3, 128.7, 129.5, 131.9, 133.5, 134.9, 144.6, 164.7; MS (CI) *m/e*: 319, 183; HRMS (FAB) calcd. for $C_{20}H_{18}N_2O_2$ − H: 317.1290; found: 317.1276.

Method B. By the direct reaction of N,N'*-dimethyl-1,2-benzenediamine with 3-chloro-1*H*, 3*H*-naphtho-[1,8-cd]pyran-1-one (9)*

A solution of *N,N'*-dimethyl-1,2-benzenediamine (1.72 g, 12.6 mmol) (7) in dry CH_2Cl_2 (6 mL) was stirred at 0°C under dry N_2 and treated dropwise with a solution of 3-chloro-1*H*, 3*H*-naphtho[1,8-*cd*]pyran-1-one (**9**) in CH_2Cl_2 (10 mL), which was prepared by the procedure described above. The mixture was kept at 25°C for 40 min, diluted with CH_2Cl_2, and washed successively with deoxygenated 5% aqueous NaOH, H_2O, and saturated aqueous $CuSO_4$. The organic phase was dried with anhydrous $MgSO_4$, and volatiles were removed by evaporation under reduced pressure. This yielded a sample of 3-[methyl[(2-methylamino)phenyl]amino]-1*H*, 3*H*-naphtho-[1,8-*cd*]pyran-1-one (**8**; 1.37 g, 4.30 mmol, 80%) identical to the product of method A.

8-(1,3-Dimethylbenzimidazolium-2-yl)-1-naphthoate (10)

A stirred mixture of 3-[methyl[(2-methylamino)phenyl]amino]-1*H*, 3*H*-naphtho[1,8-*cd*]pyran-1-one (**8**; 202 mg, 0.634 mmol) and K_2CO_3 (158 mg, 1.14 mmol) in CH_3OH (5 mL) was treated dropwise at 25°C with a solution of I_2 (169 mg, 0.666 mmol) in CH_3OH (10 mL). After 2 h, volatiles were removed by evaporation under reduced pressure, the residue was extracted with $CHCl_3$, and solvent was removed from the extracts by evaporation under reduced pressure. The residue was redissolved in CH_3OH and decolorized with activated carbon. Evaporation of solvent under reduced pressure left a residue of 8-(1,3-dimethylbenzimidazolium-2-yl)-1-naphthoate (**10**; 146 mg, 0.461 mmol, 73%) as a beige solid, which was purified by recrystallization from CH_3OH–ether: mp 305°C (dec.); IR (KBr): 1597 cm^{-1}; ^1H NMR (300 MHz, D_2O) δ: 3.77 (s, 6H), 7.68–7.76 (m, 2H), 7.76–7.81 (m, 2H), 7.83–7.86 (m, 2H), 7.88–7.94 (m, 2H), 8.16 (dd, ^3J = 7.8 Hz, ^4J = 1.8 Hz, 1H), 8.36–8.42 (m, 1H); ^{13}C NMR (75.4 MHz, D_2O) δ: 32.8, 113.5, 117.6, 126.0, 127.4, 127.5, 127.9, 129.0, 131.0, 132.3, 133.0, 134.8, 135.1, 136.9, 152.1, 176.3; MS (FAB) *m/e*: 317; HRMS (FAB) calcd. for $C_{20}H_{16}N_2O_2$ + H: 317.1290; found: 317.1276.

2-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)benzoic acid (11)

In a sealable tube, a solution of *N,N'*-dimethyl-1,2-benzenediamine (0.770 g, 5.65 mmol) (7) in deoxygenated ether (3 mL) was added to a stirred solution of phthalaldehydic acid (0.819 g, 5.46 mmol) in deoxygenated ether (1 mL). This caused the rapid precipitation of a yellow solid. The mixture was kept at 25°C for 15 min, and then volatiles were removed by evaporation in vacuo. Deoxygenated CH_3OH (12 mL) was added to the residue, the mixture was degassed, and the tube was sealed in vacuo. The tube was then heated in an oil bath at 140–150°C until the yellow solid had dissolved. Crystallization occurred when the solution was cooled. The tube was opened under Ar in a glove box, the mother liquors were removed, and the crystals were washed with CH_3OH and dried in vacuo. This provided 2-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)benzoic acid (**11**; 1.27 g, 4.73 mmol, 87%) as air-sensitive yellow needles: mp 198–199°C; IR ($CHCl_3$): 2804, 2692, 2637, 1719 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 2.61 (s, 6H), 4.90 (s, 1H), 6.62–6.67 (m, 2H), 6.87–6.91 (m, 2H), 7.45–7.49 (m, 1H), 7.54–7.60 (m, 2H), 8.05–8.10 (m, 1H),

12.4–13.5 (bs, 1H); ^{13}C NMR (100 MHz, $CDCl_3$) δ: 33.9, 95.1, 109.1, 121.8, 130.5, 131.4, 131.9, 133.4, 133.6, 134.7, 140.9, 169.5; MS (CI) *m/e* 269, 267, 253; HRMS (EI) calcd. for $C_{16}H_{16}N_2O_2$: 268.1212; found: 268.1202. Anal. calcd. for $C_{16}H_{16}N_2O_2$: C 71.61, H 6.01, N 10.45; found: C 71.26, H 6.12, N 10.62.

2-(1,3-dimethylbenzimidazolium-2-yl)benzoate (13) (ref. 16)

A solution of 2-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)benzoic acid (**11**; 200 mg, 0.745 mmol) in CH_3OH (10 mL) was stirred at 25°C for 1 h under O_2. Volatiles were then removed by evaporation under reduced pressure, and the residue was dried in vacuo. This yielded 2-(1,3-dimethylbenzimidazolium-2-yl)benzoate (**13**; 198 mg, 0.743 mmol, 100%) (16) as a beige solid, which was purified by recrystallization from CH_2Cl_2–ether: mp 275-277°C (lit. (16) mp 294–295°C); IR ($CHCl_3$): 1622 cm^{-1}; ^1H NMR (300 MHz, $CDCl_3$) δ: 3.73 (s, 6H), 7.23 (dd, ^3J = 7.6 Hz, ^4J = 0.7 Hz, 1H), 7.57–7.68 (m, 5H), 7.77 (ddd, ^3J = 7.6 Hz, ^3J = 7.6 Hz, ^4J = 1.3 Hz, 1H), 8.51 (dd, ^3J = 7.8 Hz, ^4J = 0.7 Hz, 1H); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 32.0, 112.2, 120.9, 126.2, 127.8, 129.5, 131.6, 131.9, 132.8, 142.6, 156.1, 167.2; MS (CI) *m/e*: 267; HRMS (EI) calcd. for $C_{16}H_{14}N_2O_2$: 266.1055; found: 266.1026.

Pyrolysis of 2-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)benzoic acid (11)

One arm of an H-tube was charged with a mixture of *trans*-stilbene (100 mg, 0.55 mmol) and 10% Pd on activated carbon (50 mg) in deoxygenated 95% aqueous C_2H_5OH (2 mL), and the other arm was charged with 2-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)benzoic acid (**11**; 47 mg, 0.18 mmol). The tube was sealed, the ethanolic suspension was stirred at 25°C in one arm, and the solid was heated in the other at 185°C for 8 days. The tube was then opened, the suspension was filtered, and solvent was removed from the filtrate by evaporation under reduced pressure. Examination of the residue by ^1H NMR spectroscopy showed that no 1,2-diphenylethane had been formed from *trans*-stilbene and therefore that no H_2 had been generated by the pyrolysis.

In a similar experiment, 2-(1,3-dimethyl-2,3-dihydro-1*H*-benzimidazol-2-yl)benzoic acid (**11**; 250 mg, 0.93 mmol) was pyrolyzed in a sealed tube at 180°C for 150 h. The pyrolysate was taken up in CH_3OH (1.3 mL), and the solution was diluted with H_2O. The aqueous mixture was then extracted with ether and with $CHCl_3$. Volatiles were removed from the aqueous phase by evaporation in vacuo to give a residue of 2-(1,3-dimethylbenzimidazolium-2-yl)benzoate (**13**; 79 mg, 0.30 mmol, 32%). The combined ether extracts were washed with 5% aqueous HCl and dried with anhydrous Na_2SO_4, and volatiles were removed from the dried solution by evaporation under reduced pressure. Flash chromatography (silica, hexane (75%) – ethyl acetate (25%)) of the residue yielded phthalide (**14**; 24 mg, 0.18 mmol, 19%), which was shown by ^1H NMR spectroscopy to be identical with an authentic sample.

The combined acidic washings were made basic by the addition of 50% aqueous NaOH, and the basic mixture was then extracted with CH_2Cl_2. The combined organic extracts were dried with Na_2SO_4, and volatiles were removed from the dried solution by evaporation under reduced pressure. Gradient chromatography (neutral alumina, hexane (80%)/ethyl acetate (20%) – hexane (65%)/ethyl acetate (35%)) of the residue gave 1-methyl-2-[2-(1-methylbenzimidazol-2-yl)phenyl]benzimidazole (**15**; 45 mg, 0.13 mmol, 14%) as a colorless solid. Recrystallization from C_2H_5OH/H_2O (7:3) provided an analytically pure sample: mp 239–240°C; ^1H NMR (300 MHz, $CDCl_3$) δ: 3.27 (s, 6H), 7.13–7.17 (m, 2H), 7.21–7.31 (m, 4H), 7.70–7.74 (m, 2H), 7.77–7.81 (m, 2H), 7.83–7.87 (m, 2H); MS (EI) *m/e*: 338, 323; HRMS (EI) calcd. for $C_{22}H_{18}N_4$: 338.1531; found: 338.1533. Anal. calcd. for $C_{22}H_{18}N_4$: C 78.07, H 5.36, N 16.56; found: C 77.79, H 5.39, N 16.42.

Ground- and excited-state properties of some naphthoflavyliums

Mourad Elhabiri, Paulo Figueiredo, Florian George, Jean-Paul Cornard, André Fougerousse, Jean-Claude Merlin, and Raymond Brouillard

Abstract: A series of five, structurally related, substituted 2-phenyl-benzopyrylium (flavylium) salts were synthesized and characterized by NMR, absorption, and fluorescence techniques. Their hydration and deprotonation constants were obtained through thermodynamic and relaxation kinetic methods. Metallic complexation with the two compounds possessing a catechol group and its effect on the fluorescence intensity was also studied. The ground state properties of the five pigments are correlated with the theoretical data collected through AM1 molecular orbital calculations.

Key words: naphthoflavylium synthesis, hydration and deprotonation constants, fluorescence, metallic complexation, molecular orbital calculations.

Résumé : Cinq sels de 2-phényl-benzopyrylium (flavylium) ont été synthétisés et caractérisés par leurs spectres de RMN, d'absorption et de fluorescence. Les constantes d'hydratation et de déprotonation ont été déterminées par des méthodes thermodynamiques et cinétiques. La complexation de certains métaux avec les deux composés possédant un groupe catéchol et l'effet de ce type de complexe sur l'intensité de fluorescence ont également été étudiés. Les propriétés de l'état électronique fondamental des cinq pigments sont en bon accord avec les données théoriques obtenues par les calculs d'orbitales moléculaires selon la méthode AM1.

Mots clés : synthèse de cations naphthoflavylium, constantes d'hydratation et de déprotonation, fluorescence, complexation métallique, calcul d'orbitales moléculaires.

Introduction

Diversely substituted 2-phenyl-benzopyrylium salts (henceforth referred to as flavylium salts) are frequently found in nature as the yellow to blue coloured pigments of most flowers and fruits (1, 2). They are the aglycone forms of a family of natural colourants, commonly known as anthocyanins (3), which have been consumed by humanity without any apparent unhealthy effects and have thus attracted the attention of numerous scientists for their use as an alternative to the hazardous synthetic dyes (4, 5). Unfortunately, the colourant properties of anthocyanins are somewhat unreliable under the physico-chemical conditions required for their possible use as food additives, namely mildly acidic pH values and interactions with an essentially aqueous environment (6–8). Indeed, in these conditions the flavylium form, which is usually stable at pH lower than 2, undergoes a hydration reaction (Scheme 1) leading to the formation of colourless forms. Moreover, both the coloured and colourless forms are susceptible to thermal and photochemical degradation (9, 10). Several recent studies have, for these reasons, addressed the problem of the stabilization of such colourants in aqueous solution through the formation of molecular complexes with a wide array of natural compounds (1, 2, 11–23).

An alternative path for the obtention of stable coloured pigments is through laboratory synthesis of anthocyanin analogues possessing simple substituent groups, such as OH, CH_3O, phenyl, etc., in key positions of the molecule (24–31) in order to provide not only the widest possible range of colours but also to protect the flavylium cation against nucleophilic attack in the pH domain referred to above (~3 to 5). Some of these synthetic flavylium compounds have revealed very interesting excited-state characteristics, namely fluorescence and photochromic properties (10, 25, 32–34).

With the objective of evaluating the influence on stability brought about by the introduction of different substituents in key positions of the flavylium skeleton, five compounds were synthesized: 2-benzo-naphtho[2,1-*b*]pyrylium chloride (**1**), 2-((3′,4′-dihydroxy)-benzo)-naphtho[2,1-*b*]pyrylium chloride (**2**), 2-((3′,4′-dihydroxy)-benzo)-3-*O*-methyl-naphtho[2,1-*b*]-pyrylium chloride (**3**), 2-naphtho-naphtho[2,1-*b*]pyrylium chloride (**4**), and 2-benzo-naphtho[1,2-*b*]pyrylium chloride (**5**), Scheme 2. The extended conjugated π-systems of these molecules prompted us also to study their emissive properties and to correlate them with the degree of rigidity predicted by semi-empirical molecular orbital calculations for their molecular structures.

Results

Thermodynamic and kinetic measurements in aqueous media

The electronic absorption spectra of flavylium cations present,

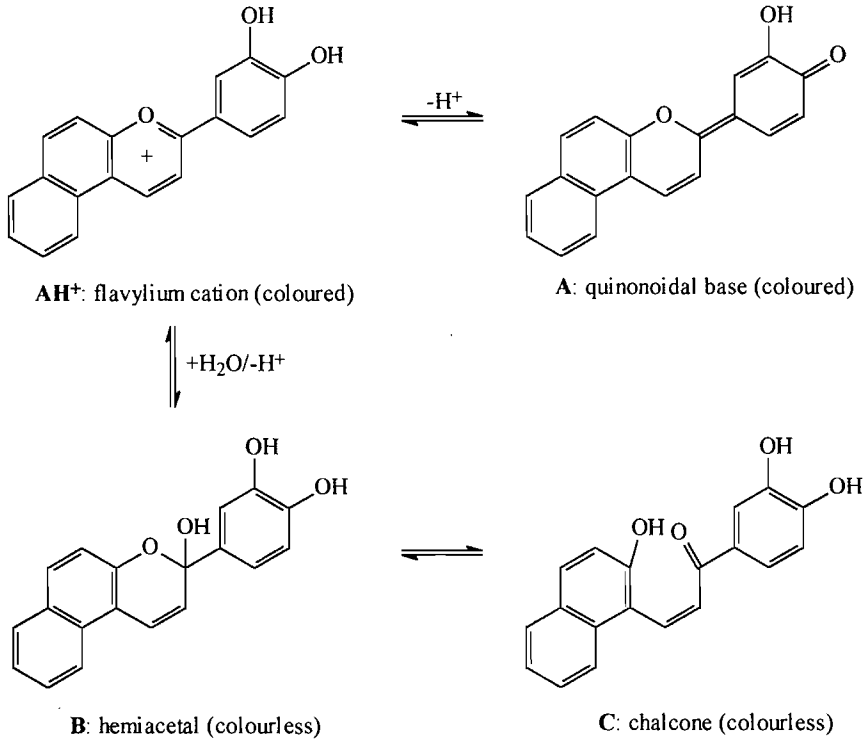
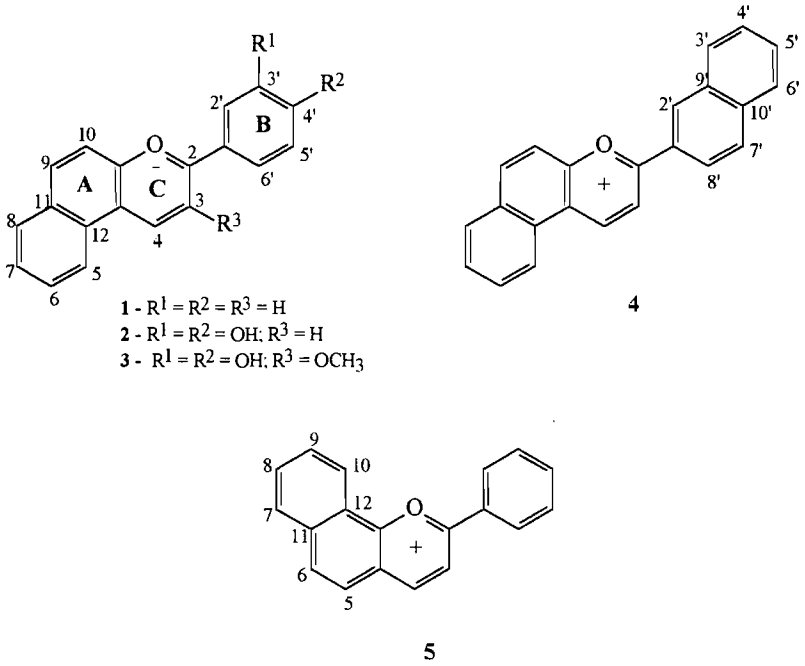


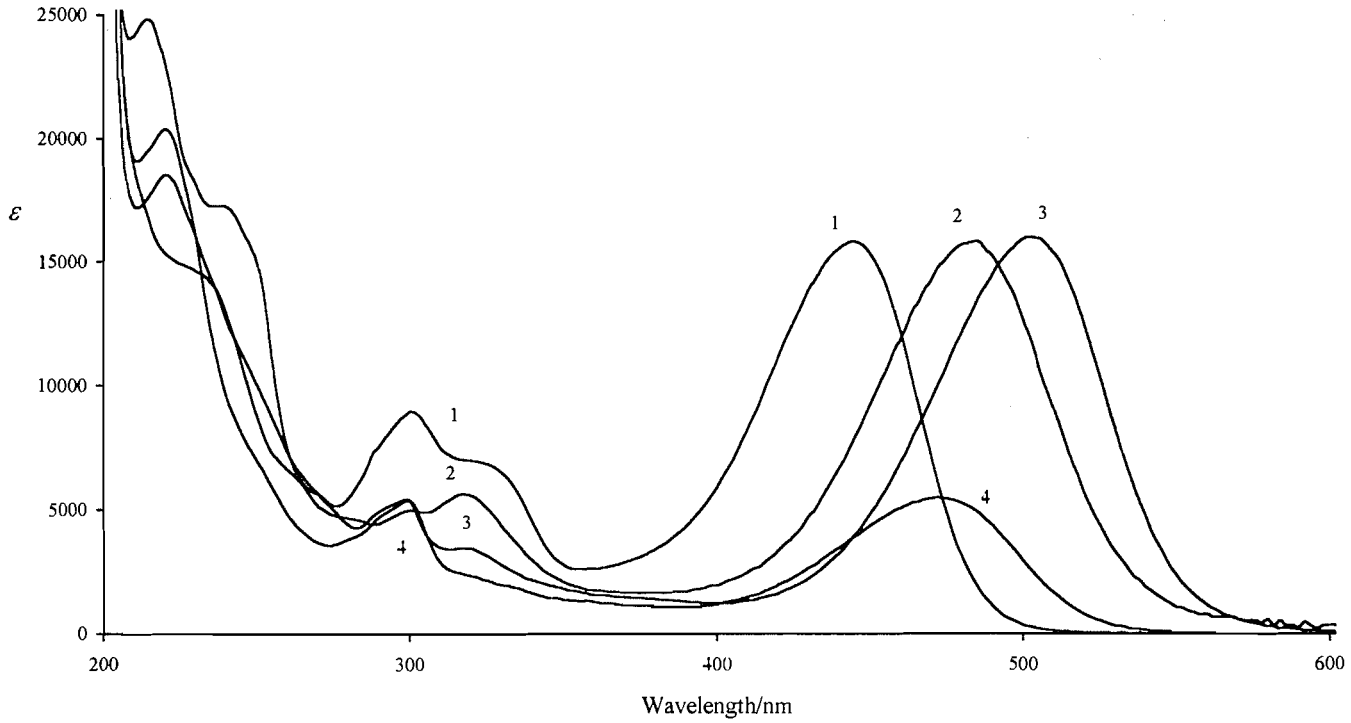
Scheme 2.



as a characteristic feature, a band in the visible spectral range, whose shape, maximum wavelength, and intensity are functions of the substitution pattern of the chromophoric system (26, 28, 31). Figure 1 reflects the spectral changes brought about by the introduction of different substituents in the same basic structure (β-naphthoflavylium, **1**). Going from **1** to **3**, it can be seen that the presence of the two hydroxyl groups in 3′ and 4′ produces a bathochromic shift from 444 nm to 484 nm and that further addition of the 3-*O*-methyl produces an even larger shift to 502 nm. The shape and intensity of the absorbance bands are also affected by the presence of different types of substituents even when they are linked to the same positions in the basic flavylium molecule (cf. compounds **2** and **4**).

The transformations undergone by these compounds in mildly acidic aqueous solution can be summarized by the equilibria

Fig. 1. Electronic absorption spectra of compounds **1–4**. pH = 1.0. Aqueous solutions with 4% MeOH.



[1] $AH^+ \underset{}{\overset{K_a}{\rightleftharpoons}} A + H^+$

[2] $AH^+ + H_2O \underset{}{\overset{K_h}{\rightleftharpoons}} (B + C) + H^+$

For the sake of simplicity, in eq. [2] the equilibria of hemiacetal (B) formation and subsequent ring opening to form the chalcone C are written as a whole since the second process occurs in a very fast step (35, 36). The increase in pH in aqueous solutions of these compounds with the subsequent attainment of the equilibrium described in eq. [2] produces significant modifications on the electronic spectra of the pigments (Fig. 2), notably a decrease in intensity of the visible band. This fact allows the obtention of a global value of $K' = K_a + K_h$, through a plot of $D_0/(D_0 - D)$ as a function of $[H^+]$, according to eq. [3] (20, 21, 23). Such a plot will give a straight line with an intercept/slope ratio equal to $K_h + K_a$.

$$[3] \quad \frac{D_0}{D_0 - D} = \frac{K_h + K_a}{K_h + K_a(1 - r_A)} + \frac{[H^+]}{K_h + K_a(1 - r_A)}$$

In eq. [3] D_0 represents the absorption of a strongly acidic (pH <1) pigment solution, D the absorption of a solution at a given, less acidic, pH, and r_A stands for the ratio of the molar absorption coefficients $\varepsilon_A/\varepsilon_{AH}{}^+$.

An alternative and complementary method to obtain the values of the equilibrium constants is by performing pH jumps, from very acidic to less acidic pH values, in aqueous solutions of the pigments, and measuring the resulting exponential decay of the visible absorption, which essentially reflects the relaxation of the pH-dependent equilibrium [2] according to an apparent first-order kinetics. The first-order rate constant k for [B] variation (defined by $d\Delta[B]/dt = -k\Delta[B]$) is directly delivered by the spectrophotometer software and can be represented by

$$[4] \quad k = k_2[H^+] + \frac{k_1}{1 + K_a/[H^+]}$$

where $k_1/k_2 = K_h$, i.e., k_1 is the hydration rate constant and k_2 the constant for the reverse process. Rearranging eq. [4] into eq. [5] allows the obtention of a $(K_a + K_h + [H^+])/k$ vs. $1/[H^+]$ straight-line plot with a slope equal to K_a/k_2 and an intercept of $1/k_2$. This leads directly to the values for k_2 and K_a, and through a combination with the results obtained from eq. [3], K_h and k_1 immediately follow. The theoretical treatment that permits the obtention of equilibrium rate constants is given in full detail in ref. 21.

$$[5] \quad \frac{K_a + K_h + [H^+]}{k} = \frac{1}{k_2} + \frac{K_a}{k_2}\frac{1}{[H^+]}$$

Table 1 reports the calculated hydration and deprotonation constants for pigments **1–4**.

Fluorescence properties

Most anthocyanins and some synthetic flavylium salts are known to exhibit fluorescence from all forms existing in mildly acidic aqueous solutions and even in some organic solvents (10, 25, 37, 38). However, all natural anthocyanins possess only very weak fluorescence intensities and poor fluorescence quantum yields, the same being true for the sim-

ple synthetic analogues studied so far. The extended conjugated systems of all pigments reported in this work and their planar molecular structures, especially in the cases of **1**, **2**, and **4** (Table 2), seemed to forecast a possible increase in emission intensity when compared to the above-mentioned pigments. Figure 3 compares the emission spectra of the flavylium forms of compounds **1–3** and **5**, where an influence of the substituents on emission intensity and wavelength is visible. Indeed, compounds **1**, **2**, and **3**, although absorbing at different wavelengths, emit at the same wavelength but the emission intensity of **2** is 500 times lower than that of **1**, and **3** is still less emissive. When compared to **1**, compound **5**, which can be considered as its isomer, is characterized by a strong Stokes shift in acidic methanolic solution, from 534 to 642 nm. Compound **4** also exhibits an emission band at 534 nm, its relative intensity being intermediate between those of **1** and **2**, in spite of being a more conjugated system.

Solvent effect

It is well known that flavylium forms of anthocyanic pigments present a negative solvatochromic behaviour, i.e., a displacement of the visible absorption band towards longer wavelengths with a reduction in medium polarity (39). Absorption and fluorescence emission spectra of pigments **1**, **4**, and **5** were thus performed in several solvents, ranging in polarity from chloroform to water, to assess the solvent influence on absorption and emission wavelengths and intensities of this particular type of flavylium salts. The solvents used were, in order of increasing polarity, chloroform, dichloromethane, formic acid, methanol, and water/HCl. The changes in absorption spectra caused by variation in medium polarity in **4** are presented in Fig. 4. Considerable changes in band shape can be observed, first the disappearance of the typical flavylium absorption and the clear vibrational structure at lower wavelength in methanol, which is also slightly perceptible both in chloroform and dichloromethane. In the cases of chloroform and dichloromethane, the typical bathochromic shift due to medium polarity on the flavylium absorption band is accompanied by the formation of a shoulder at ca. 420 nm. The two other pigments (**1** and **5**) show similar behaviour, notably a bathochromic shift with decreasing medium polarity and the appearance of structured absorbance bands in methanolic solution.

In what concerns fluorescence emission, a hypsochromic shift is observed when decreasing the medium polarity. Furthermore, strong differences of behaviour can be observed between the two isomers **1** and **5**, when comparing their fluo-

Fig. 3. Fluorescence emission spectra of **1**, λ_{EX} = 445 nm; **2**, λ_{EX} = 485 nm; **3**, λ_{EX} = 500 nm; and **5**, λ_{EX} = 600 nm. Acidic methanolic solutions.

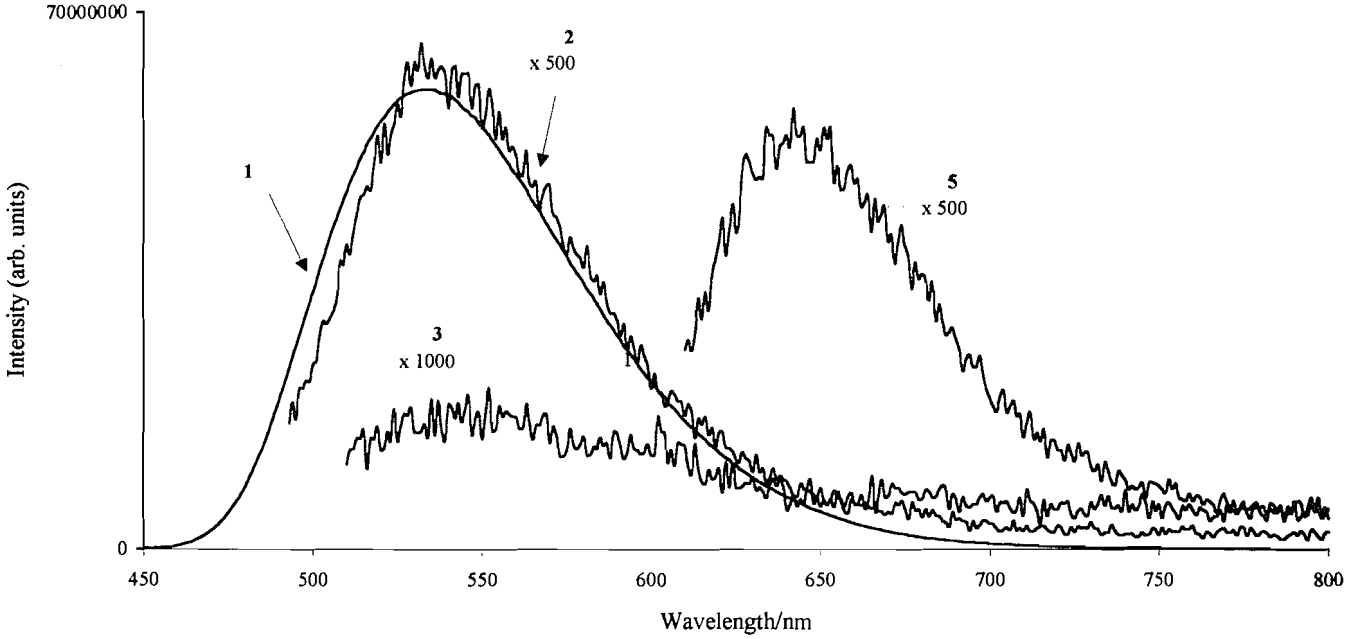

Fig. 4. Absorption spectra of **4** in H_2O, pH = 1.0 (*a*), CH_3OH (*b*), HCOOH (*c*), CH_2Cl_2 (*d*), and $CHCl_3$ (*e*). 3.25 × 10^{-4} M, T = 25°C. Inset: variation of λ_{max} as a function of medium polarity.

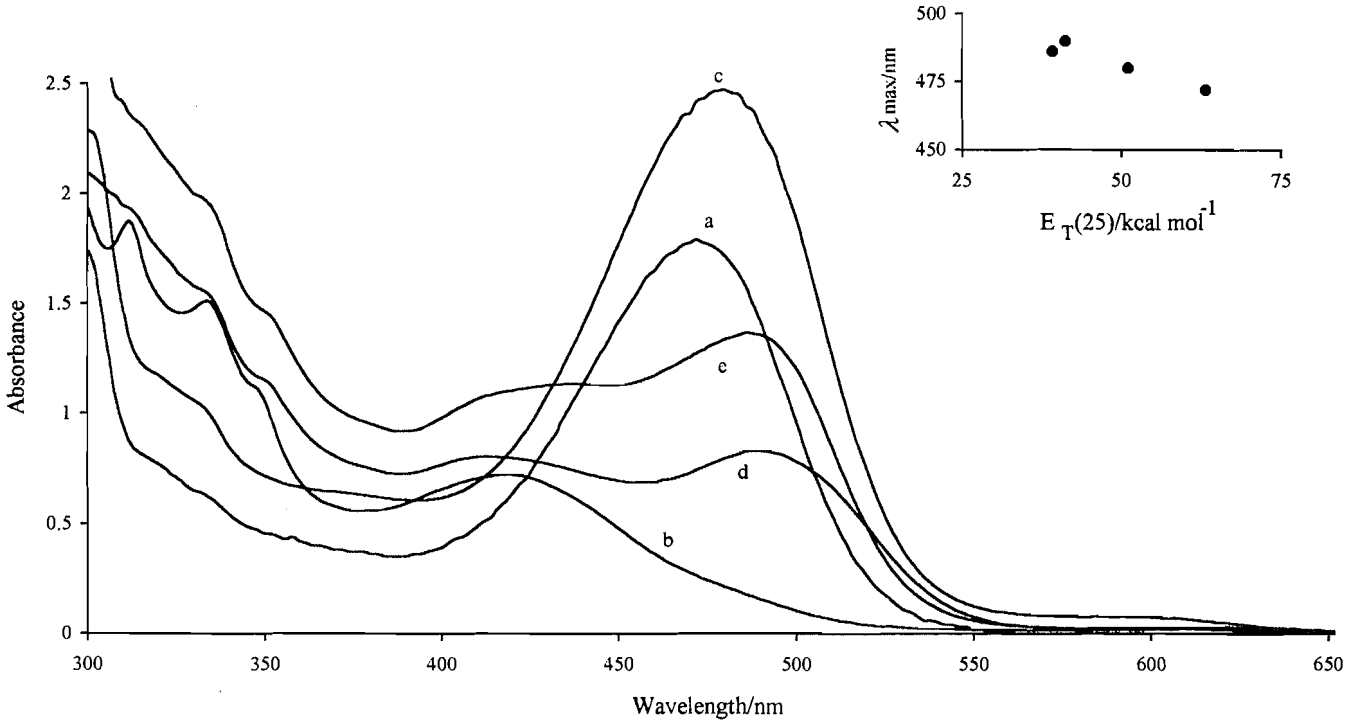
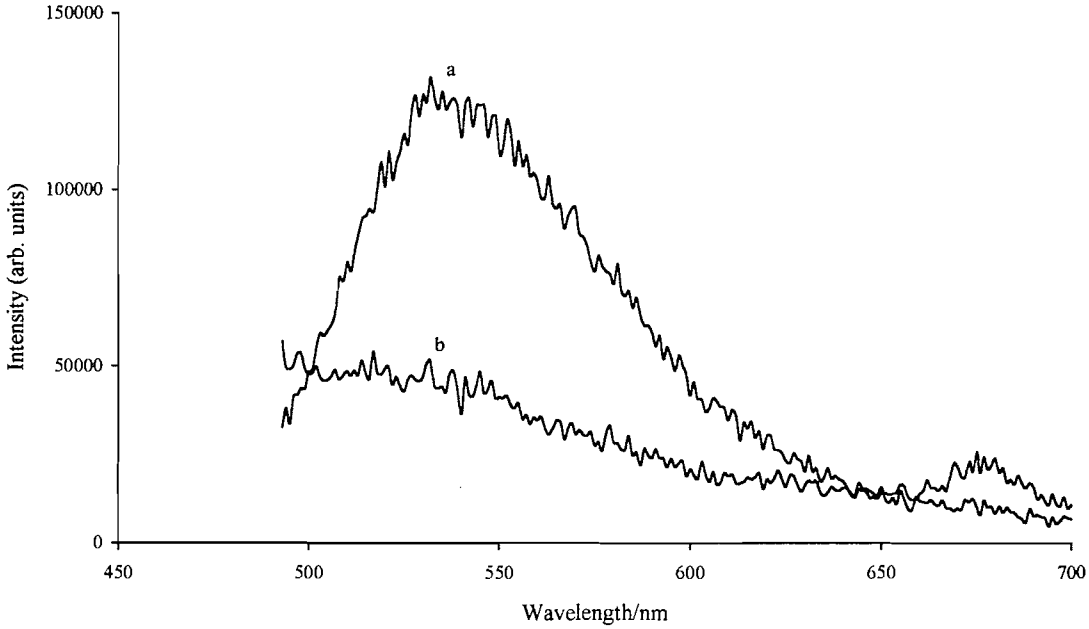


rescence properties in solvents of different polarity. In methanol both **1** and **5** show low-intensity emission bands, when excited at the maximum visible wavelength of their respective flavylium forms, this intensity strongly increasing when a few drops of concentrated formic acid are added to the solution. But in dichloromethane solutions, while **1** produces emission bands more intense than those found in acidic methanol, **5** displays only very weak fluorescence bands.

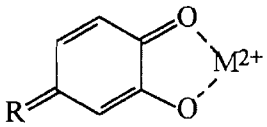
Photochromic behaviour

Certain synthetic flavylium salts, in mildly acidic aqueous media (3 < pH < 4), have shown interesting photochromic

Fig. 5. Fluorescence emission spectra of **2** in H_2O, pH ≈ 4.0, (*a*) without Al^{3+}, and (*b*) with Al^{3+}.



Scheme 3.



properties with either gain or loss of colour under light irradiation and the inverse behaviour in the dark (10, 32, 34). This prompted us to investigate the photochromic behaviour of the five naphthoflavyliums here reported. Yet, only pigment **3** revealed a manifest photochromic effect with loss of colour when submitted to irradiation, and a partial colour recovery in the dark. Colour recovery was not complete since side reactions of thermal and photo degradation occur.

Metallic complexation

Chelation between some small di- and trivalent metals and anthocyanins possessing a catechol group in ring B has been reported (1, 22, 40, 41) and discussed on the basis of phenolic proton(s) loss to form a quinonoidal structure (Scheme 3), which will be responsible for the bathochromic shift always observed. To our knowledge, no work has been done on the fluorescence properties of these metal complexes. This prompted us to investigate the fluorescence emission changes when europium(III) or aluminium(III) salts are added to stabilized solutions of compounds **2** and **3**.

For both compounds, the addition of a solution of $AlCl_3$ in large excess produces a bathochromic shift of 60 nm in the visible absorption band and a strong decrease of the fluorescence intensity at 534 nm characteristic of the flavylium cation, which is in accordance with the deprotonation model proposed above. Moreover, a faint emission band appears at 675 nm (Fig. 5) and 690 nm, respectively, for **2** and **3**, which becomes more intense when the solution is excited at the new maximum wavelength of the complex.

Discussion

Thermodynamic and kinetic measurements in aqueous media

The spectral changes shown in Fig. 1, namely, the bathochromic shifts observed between pigments **1**, **2**, and **3**, can be attributed to the increase in electron donor strength of the substituting OH and OCH_3 groups. A similar phenomenon is known to occur with natural, largely substituted, anthocyanins, which tend to absorb at longer wavelengths than the parent aglycones (2).

The equilibrium constants obtained through application of eqs. [3] and [5] are presented in Table 1. No values are displayed for pigment **5**, due to its insolubility in aqueous solution. In the cases of molecules **1** and **4**, which possess no OH group and thus cannot permit deprotonation (eq. [1]), K_h is directly obtained from eq. [3] and is equal to K'.

From the analysis of Table 1, it can be inferred that compound **4** is the most susceptible to hydration (lower pK_h), while **2** seems to suffer only a negligible water attack. This is evidenced by the fact that we can obtain the value for only a single equilibrium constant and is further stressed by the subtraction of the flavylium contribution (37) from the absorption spectra as a function of the pH. This results only on the rise of a new band with a maximum wavelength at ca. 555 nm, which is the same maximum wavelength obtained for a fresh solution of **2** at pH 7, where the quinonoidal base is the dominant species. Moreover, an isosbestic point at ca. 530 nm is observed, supporting the existence of only two forms in equilibrium. Since no other absorptions, attributable to the hemiacetal and (or) the chalcone forms, appear as a result of the subtraction, the value found for the equilibrium constant is assigned to K_a.

The greater or lower reactivity towards nucleophilic water attack can be correlated with the charge density in C-2 (given

by the parameter S_2^N), obtained through molecular orbital calculations. Examination of Table 2 allows the conclusion that an increase in S_2^N is accompanied by a diminution in pK_h. This confirms that, for these naphtho derivatives, the hydration reaction occurs in the same manner as that reported for common flavylium salts (2, 28). There is, however, an exception represented by compound **4**, which presents only a small increase in S_2^N relative to **1**, but has a considerably lower pK_h. A tentative explanation for this behaviour is given by taking into account the large absolute hardness value (η) that was computed, through molecular orbital calculations, for pigment **1** (3.31 eV) as compared to the value obtained for compound **4** (3.05 eV). This parameter is defined as $\eta = (E_{LUMO} - E_{HOMO})/2$ and is usually a reliable criterion for predicting reactivity, i.e., the larger the LUMO–HOMO gap the lower the reactivity of the molecule (31). The greater reactivity of **4** may therefore reflect a less aromatic character of this compound relative to **1** in spite of the presence of an additional benzene fragment in **4** (see below the discussion of the fluorescence properties).

Fluorescence properties

The spectra depicted in Fig. 3 demonstrate the influence that is brought about by different substituents on emission intensity and wavelength. The difference in emission intensity among pigments **1–3** may be due to the formation of a twisted intramolecular charge transfer state (TICT) in the excited state, caused by the presence of the OH groups in the case of **2** and further enhanced by the loss of coplanarity in **3** (Table 2). Some authors have already verified that, for similar molecules, the rigidity and consequent coplanarity of the moiety connected to C-2 of the benzopyrylium fragment has a marked influence on their fluorescence properties (25, 42–44). The formation of this TICT state can be viewed as a deactivation channel for the fluorescence emission.

The observed Stokes shift between **1** and **5** (Fig. 3) is attributable to the strong electron-donating properties of the benzyl moiety on position 11 of the latter (25). A strong bathochromic shift from 444 nm to 600 nm is also observed on the absorption spectra of these two compounds.

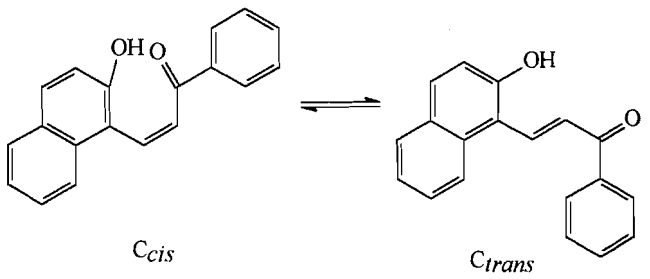
The structure of compound **4** (Scheme 2) leads us to anticipate a strong fluorescence emission. However, this is not observed. As stated before, it exhibits an emission intensity lower than **1**. This molecule is a good example that it is not simply by combining a great number of benzene fragments that a molecule becomes more aromatic, as demonstrated by the smaller $E_{LUMO} - E_{HOMO}$ gap (28) obtained from molecular orbital calculations applied to **4**. This gap, which is a good measure of the aromaticity of a molecule, was computed as 3.05 eV, compared to 3.31 eV for **1**.

Solvent effect

The insert of Fig. 4 depicts the existing correlation between E_T at 25°C (45) and the maximum wavelength of compound **4** in several solvents, the same relation holding for the two other compounds tested (**1** and **5**). This relation reflects the negative solvatochromic behaviour of these three naphthoflavyliums.

The existence of vibrational bands in the UV region of the absorption spectra, observed for compounds **1**, **4** (Fig. 4), and **5** in methanolic solution, should have their origin in the formation of a methoxy adduct to position 2 (see Scheme 2) of the chromophore, since when such a solution is quickly acidified to pH 1 a spectrum similar to the one observed in aqueous acidic solution is obtained. This methoxy adduct will thus be a methanolic analogous to the hemiacetal formed upon hydration of the flavylium cation, in aqueous medium.

Scheme 4.



The appearance of a shoulder next to the typical visible absorption band, in chloroform and dichloromethane solutions (Fig. 4), may be caused by a rigidization of the molecular structure in these less polar solvents.

The hypsochromic shift observed in fluorescence emission spectroscopy when the medium polarity is lowered, which appears to be in contradiction with the bathochromic shift observed in absorption spectra, can be explained by a greater delocalization of the positive charge in the excited state than in the ground state. This leads to a smaller stabilization of S_1 relative to S_0 by solvents of high polarity. Since the polarizability of S_1 is greater than that of S_0, less polar solvents stabilize the latter and result in a hypsochromic shift of the emission wavelength.

Finally, it may be the presence of a substituent in position 11, in pigment **5**, responsible for the creation of a deactivation channel, more effective in less polar solvents, that would account for the low intensity of emission displayed by this compound in dichloromethane solution, when compared to its isomer **1**.

Photochromic behaviour

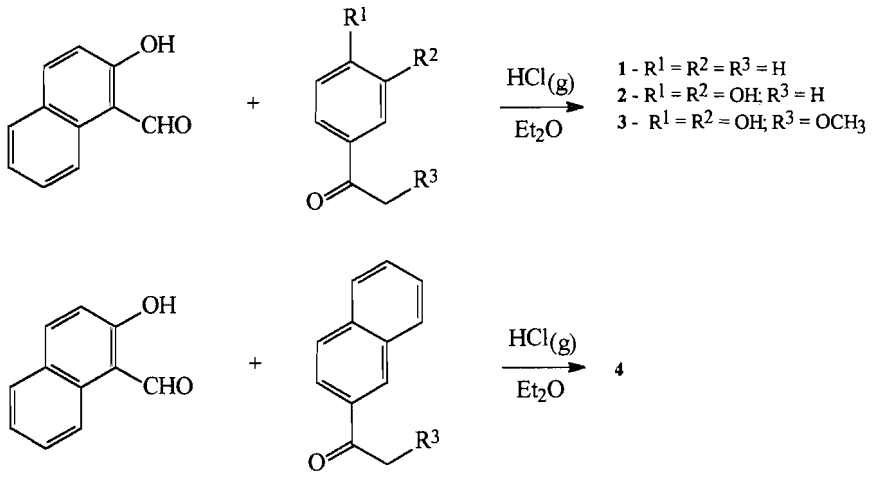
The photochromic properties here reported for compound **3**, in mildly acidic aqueous solutions, seem to be typical of some 3-substituted flavylium based pigments that form the colourless *cis*-chalcone (cf. Scheme 4) as the more stable isomer in the ground state (32, 46). Light irradiation allows us to overcome the energy barrier necessary to displace the equilibrium towards the *trans* isomer (also colourless). The *trans*-chalcone, thus formed in the excited state as the more stable isomer, does not possess the ability to cyclize and reform the flavylium cation according to the set of equilibria depicted in Scheme 1. The displacement of these equilibria towards *trans*-chalcone accumulation results therefore in a loss of colour. This reaction is thermally reversed in the dark.

The inverse process does also occur with some, 3-unsubstituted, flavylium compounds (34), i.e., stabilization of the *trans*-chalcone in the ground state with the irradiation producing a *trans*→*cis* photoisomerization with consequent recyclization of the *cis*-chalcone to reform the flavylium cation. This reaction is also reversed in the dark.

Metallic complexation

The new emission bands observed at 675 and 690 nm (Fig. 5) upon excitation of aqueous solutions of, respectively, compounds **2** and **3** in the presence of Al(III), although having the

Scheme 5.



same maximum wavelength as those of a fresh solution of the pigments at neutral pH (where the quinonoidal base is the predominant form in solution), are less intense. This fact may be explained by a quenching process as a consequence of aluminium complexation. Such quenching effect is increased when europium(III) replaces aluminium, since in this case no new emission band accompanies the decrease in the flavylium cation emission.

Conclusion

Ground-state properties of a series of structurally related pigments are shown to be strongly dependent on the substitution pattern and on the greater or lesser coplanarity and aromaticity of the molecule. Commonly, the stronger the electron donor character of the substituent(s), the greater the observed bathochromic shift. The twisting of the B ring relative to the rest of the molecule seems to act in the same direction. Concerning excited-state properties, it is the substitution pattern that seems to play the most significant role. Notably, substitution in position 11 seems to have a profound impact, namely, producing a significant Stokes shift. The other substitution patterns studied do not affect the emission wavelength, but the fluorescence intensity strongly decreases with the presence of donor substituents, through the possible formation of a nonfluorescent TICT state, indicating that nonsubstituted and planar compounds, like **1**, are good candidates for highly aromatic and fluorescent molecules.

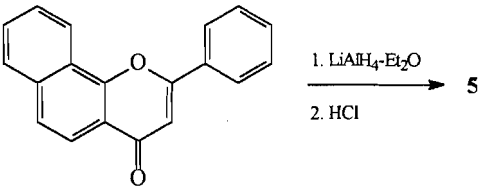
Computational

Molecular orbital calculations, using AM1 parametrization (47) were performed on a Escom P100 PC, using the HyperChem program (version 4, Hypercube, Inc., Ont. Canada).

Experimental

Fast atom bombardment (FAB) mass spectrometry was carried out either on a LBK 9000S or on a Thomson THN 208 instrument. Electron-spray ionization (ESI) mass spectrometry was carried out with a Bio-Q quadripole instrument. NMR spectra were recorded at 27°C on a Bruker AM-400 spectrometer operating at 400.14 MHz for ^{1}H and on a Bruker WP-200SY operating at 50 MHz for ^{13}C. Standard pulse frequences and

Scheme 6.



phase cycling scheme (48) were used to record ^{1}H–^{1}H COSY (49, 50). Samples (4–8 mg/mL) were prepared in $(CD_3)_2SO$–CF_3COOD (98:2), CD_3CN–CF_3COOD (98:2). Residual signals of the solvent were used as internal chemical shift reference. Electronic absorption spectra were acquired using a Hewlett–Packard diode-array spectrometer fitted with a quartz cell (d = 1 cm) equipped with a stirring magnet. A constant temperature in the cell was obtained by use of a Lauda water-thermostated bath. The temperature was measured in the spectrometer cell with a Cormak thermocouple and was kept at 25 ± 0.1°C throughout this work. Fluorescence emission spectra were recorded on a SPEX F111 Fluorolog and on a molecular microprobe operating in a way that favours observation of the flavylium emission bands (51). Solutions used in fluorescence measurements always had an absorbance of 0.2 at the excitation wavelength. The pH was measured with a Metrohm 654 pH-meter equipped with a micro-electrode. Milli-Q water was used in all aqueous sample preparations. All other solvents were of analytical grade except for fluorescence measurements where spectroscopic grade solvents were used. 2′-*O*-Methyl-3,4-dihydroxyacetophenone and 3,4-dihydroxyacetophenone were prepared from 2′-chloro-3,4-dihydroxyacetophenone, according to ref. 22. All other reagents used throughout the synthesis were of synthetic or analytical grade and used as received.

This particular class of benzopyrylium salts was prepared by two different methods. The first consists of acidic condensation of an appropriate aldehyde with a ketone (52) (Scheme 5). In the second, the synthesis proceeds through the reduction of the carbonyl group of a flavone by $LiAlH_4$ followed by a treatment with hydrochloric acid (Scheme 6).

General procedure for compounds 1–4

An equimolar solution of the suitable ketone and aldehyde

precursors was vigorously stirred in distilled diethyl ether oxide. Gaseous hydrogen chloride was gently bubbled (3 h) into the mixture to favour solubilization when the initial products presented weak solubilities. Precipitation of coloured crystals occurred after some minutes and was completed by keeping the reaction mixture at −20°C overnight. Crystals were washed several times with distilled diethyl ether oxide and dryed under vacuum.

*2-Benzonaphtho[2,1-*b*]pyrylium chloride (**1**)*
Total yield is 55%. UV–VIS ($CHCl_3$) λ_{max} (nm): 244, 301, 330, 456. ^{1}H NMR (CD_3CN/TFA) δ (ppm): 10.74 (1H, d, J = 9.2 Hz, H4), 9.51 (1H, d, J = 9.2 Hz, H3), 9.12 (2H, d, J = 2.2/7.5 Hz, H2′, H6′), 8.63–8.32 (5H, complex signals, H3′, H4′, H5′, H6, H7), 9.49 (1H, d, J = 9.0 Hz, H5), 8.84 (1H, d, J = 9.3 Hz, H8), 8,82 (1H, d, J = 9.2 Hz, H9), 9.37 (1H, d, J = 9.3 Hz, H10). ESI-MS *m/z*: 257.1 for $C_{19}H_{13}O$.

*2-((3′,4′-Dihydroxy)benzo)naphtho[2,1-*b*]pyrylium chloride (**2**)*
Total yield is 55%. UV–VIS (HCl 0.1 M) λ_{max} (nm): 240, 300, 320, 486. ^{1}H NMR (DMSO/TFA signals assigned by ^{1}H–^{1}H COSY) δ (ppm): 10.07 (1H, d, J = 9.2 Hz, H4), 8.98 (1H, d, J = 9.2 Hz, H3), 8.17 (1H, dd, J = 2.3/8.5 Hz, H6′), 8.02 (1H, d, J = 2.2 Hz, H2′), 7.13 (1H, d, J = 8.6 Hz, H5′), 8.85 (1H, d, J = 9.3 Hz, H5), 7.97 (1H, t, J = 8.0 Hz, H6), 7.87 (1H, t, J = 8.2 Hz, H7), 8.24 (1H, d, J = 9.4 Hz, H8), 8.26 (1H, d, J = 9.3 Hz, H9), 8.71 (1H, d, J = 9.3 Hz, H10). FAB-MS *m/z*: 289.3 for $C_{19}H_{13}O_3$ (100 M^+), 579.2 (observation of a dimer, which can also be noticed by a deviation to the law of Beer–Lambert, when concentrations superior to 2×10^{-5} M were used).

*2-((3′,4′-Dihydroxy)benzo)-3-*O*-methylnaphtho[2,1-*b*]-pyrylium chloride (**3**)*
Total yield is 75%. UV–VIS (HCl 0.1 M) λ_{max} (nm): 240, 300, 320, 504. ^{1}H NMR (DMSO/TFA signals assigned by ^{1}H–^{1}H COSY) δ (ppm): 9.45 (1H, s, H4), 8.27 (1H, dd, J = 2.3/8.8 Hz, H6′), 8.10 (1H, d, J = 2.3 Hz, H2′), 7.07 (1H, d, J = 8.7 Hz, H5′), 4.34 (3H, s), 7.04 (1H, d, J = 7.9 Hz, H5), 7.81 (1H, t, J = 8.1 Hz, H6), 7.90 (1H, t, J = 8.1 Hz, H7), 8.16 (1H, d, J = 9.0 Hz, H8), 8.14 (1H, d, J = 9.0 Hz, H9), 8.43 (1H, d, J = 9.0 Hz, H10). ESI-MS *m/z*: 319.34 for $C_{20}H_{15}O_4$.

*2-Naphthonaphtho[2,1-*b*]pyrylium chloride (**4**)*
Total yield is 60%. UV–VIS (CH_3COOH) λ_{max} (nm): 252, 300, 476. ^{1}H NMR (CD_3CN/TFA) δ (ppm): 10.74 (1H, d, J = 9.2 Hz, H4), 9.51 (1H, d, J = 9.2 Hz, H3), 9.12 (2H, d, J = 2.2/7.5 Hz, H2′, H6′), 8.63–8.32 (5H, complex signals, H3′, H4′, H5′, H6, H7), 9.49 (1H, d, J = 9.0 Hz, H5), 8.84 (1H, d, J = 9.3 Hz, H8), 8.82 (1H, d, J = 9.2 Hz, H9), 9.37 (1H, d, J = 9.3 Hz, H10). FAB-MS *m/z*: 307.1 for $C_{23}H_{15}O$ (100 M^+), 615.2 (once again observation of a dimer).

*2-Benzonaphtho[1,2-*b*]pyrylium chloride (**5**)*
α-Naphthoflavone (200 mg, 0.73 mmol) was dissolved in 10 mL of a mixture of diethyl ether oxide and toluene and 1.1 equivalent of $LiAlH_4$ (20 mg) was added. The solution was kept under reflux for 2 h, diluted with ethyl acetate, and washed with two portions (each 50 mL) of water. The organic phase was then acidified with hydrochloric acid. The solution turned green and was concentrated under vacuum. The pyrylium salt was purified on a silica column, first with $CHCl_3$ as eluent and after with $CHCl_3$–CH_3COOH (95.5). Total yield is 35%. UV–VIS (CH_3COOH–$CHCl_3$, 1:1) λ_{max} (nm): 244, 297, 383, 425, 604. ^{1}H NMR (CD_3CN/TFA) δ (ppm): 10.54 (1H, d, J = 9.2 Hz, H4), 8.84 (1H, d, J = 9.2 Hz, H3), 8.32–7.71 (10H, complex signals, H2′, H3′, H4′, H5′, H6′, H6, H7, H8, H9, H10), 8.79 (1H, d, J = 9.0 Hz, H5). FAB-MS *m/z*: 257.1 (100 M^+) for $C_{19}H_{13}O$.

Acknowledgments

The authors would like to thank Prof. F. Pina, from Universidade Nova de Lisboa, for some preliminary fluorescence measurements. P. Figueiredo wishes also to thank the European Union for a post-doc grant ERBCHBICT9441610.

Detection of Newcastle disease virus using an evanescent wave immuno-based biosensor

William E. Lee and H. Gail Thompson

Abstract: A fibre-optic-based evanescent wave biosensor has been used for the detection of virus. Polyclonal antibody directed against the model analyte, Newcastle disease virus, was covalently immobilized on aminosilane-coated quartz fibres, which served as the capture and concentration element of the sensor system. Radiolabelling studies demonstrated a high degree of antibody attachment to the quartz solid support. Maximal coverage could be attained with antibody solution as low as 10 μg/mL and carbonyldiimidazole as the cross-linking agent. Fluorescein-labelled anti-NDV served as the detector antibody in a sandwich format. Assay times were approximately 15 min with a limit of detection of about 2 ng of purified virus in 0.2 mL sample volume. The biosensor detection system possesses several desirable characteristics such as a limited number of mechanical components, a multiple use active surface, and low baseline variation, which indicate that it has the potential to serve as an on-line continuous monitoring device of an automated or semi-automated detection system.

Key words: fibre optic, biosensor, fluorescence, evanescence, immunoassay, antibody, Newcastle disease virus.

Résumé : On a utilisé un biosenseur d'onde évanescence basé sur une fibre optique pour la détection de virus. L'anticorps polyclonal dirigé contre l'analyte modèle, le virus de la maladie de Newcastle, a été immobilisé d'une façon covalente sur des fibres de quartz recouvertes d'aminosilane qui servent d'élément de capture et de concentration pour le système de senseur. Des études de radiomarquages ont démontré un degré élevé d'attachement des anticorps sur le support solide de quartz. Une couverture maximale peut être obtenue avec une solution contenant de l'anticorps à une concentration aussi faible que 10 μg/mL et du carbonyldiimidazole comme agent de réticulation. Les temps de dosage sont d'environ 15 min, avec une limite de détection d'environ 2 ng de virus purifié dans un volume de 0,2 mL d'échantillon. Le système de détection du biosenseur possède plusieurs caractéristiques souhaitables, telles qu'un nombre limité des composants mécaniques, une surface active qui peut être réutilisée et une faible variation de la ligne de base; ceci indique qu'il a le potentiel pour servir comme appareil permettant de faire une évaluation continue, en circuit, dans un système de détection automatisé ou semi-automatisé.

Mots clés : fibre optique, biosenseur, fluorescence, évanescence, immunodosage, anticorps, virus de la maladie de Newcastle.

Introduction

In the present paper we describe an immunoassay utilizing a fibre optic wave guide sensor and evanescent wave spectroscopy (1) for the detection and quantitation of virus in liquid samples. The phenomenon of evanescence is associated with total internal reflection and occurs when light is reflected at an interface where the refractive index decreases by a step value (1.46 to 1.33 for the quartz–water interface (2)). At the reflection point the confined or guided light generates a localized electromagnetic field (evanescent wave) in the adjacent medium that decreases in magnitude exponentially with distance from the interface. Thus the exterior surface of the optical fibre is electromagnetically coupled to the core and can act as an active sensor. The effective depth of penetration at the quartz–water interface is about one wavelength, i.e., less than 1 μm for visible light (2), and so fluorescently labelled molecules at or near the surface can be selectively excited. The evanescence effect allows for a high level of discrimination between fluorescent probe molecules immobilized on the surface and unbound probes in the bulk solution that do not interact significantly with the evanescent wave.

We have used Newcastle disease virus (NDV), an avian paramyxovirus, as the model analyte. In this assay system, quartz fibres are coated with aminosilane to which the capture element, polyclonal anti-NDV, is covalently immobilized. Sandwich immunoassays are carried out in a stepwise manner: target analyte is introduced to the capture surface, followed by fluorescein-labelled anti-NDV. The output signals are measured by monitoring the rise in fluorescence emitted from the fibre core. For comparison purposes, in order to determine the effectiveness of the antibody immobilization procedures, the same quartz fibres were used as a solid support for ELISA (enzyme-linked immunosorbent assay (3)) of NDV. It was found that the treated quartz fibres, when installed in the reaction cell of the fibre optic sensor, provide analyte recognition and sample concentration. Assays can be carried out in a flow-through manner by alternately pumping analyte and detector antibody through the cell. Individual assays required about 15 min to complete. The limits of detection were approximately 2 ng of purified virus.

Materials and methods

Equipment

The fibre-optic wave guide (FOWG) was manufactured by

ORD Inc. (North Salem, N.H.) and has been described previously (4). The fibres were made of optical grade quartz, 1 mm diameter, 6 cm length, and were purchased from ORD Inc. The light source in the FOWG was a 4 W quartz halogen lamp, and the photodetector was a Hamamatsu S1087-01 photodiode. Excitation and emission wavelengths were 485 and 530 nm, respectively. The liquids were driven through the flow cell by means of a Cole Parmer peristaltic pump, model 7553-30, with two pump heads, 7013 and 7014. The output of the photodetector was connected to a Hewlett Packard model 7015B XY recorder for data collection. A Beckman model 4000 γ-radiation counter was used to measure the radioactivity of ^{125}I. The same optical grade quartz fibres, as described above, were used as solid support for the enzyme immunoassays.

Reagents

Reagent grade acetone, methanol, chloroform, toluene, and 3-aminopropyltriethoxysilane (APTES) were obtained from Aldrich Chemical Co. (Milwaukee, Wis.). Phosphate-buffered saline (PBS) tablets, bovine serum albumin (fat free), fluorescein-labelled anti-guinea pig IgG from rabbit, anti-human IgG from goat, dimethyl sulfoxide, carbonyldiimidazole, and fluorescein isothiocyanate were obtained from Sigma Chemical Co. (St Louis, Mo.). Polystyrene Immulon-1 flat-bottom microtiter plates were purchased from Dynatek Laboratories (Chantily, Va). Purified La Sota NJ strain of NDV was grown from seed stock obtained from the American Type Culture Collection (Rockville, Md.) in embryonated hen eggs (5), purified by density gradient centrifugation (6), and suspended in PBS pH 7.0. Polyclonal antibody was purified from guinea pig serum using ammonium sulfate precipitation, followed by ion exchange chromatography. Anti-NDV was custom conjugated with horseradish peroxidase by Jackson ImmunoResearch Laboratories (West Grove, Pa.). The substrate reagents for the horseradish peroxidase, H_2O_2 and 2,2-azino-di(3-ethylbenzthiaoline) sulfonate (ABTS), were obtained from Kirkegaard and Perry (Gaithersburg, Md.). ^{125}I-labelled anti-human IgG from goat was obtained from Dupont. Protein concentrations were determined using a Coomassie blue assay kit (BioRad, Mississauga, Ont.) and IgG protein standards (Bio-Rad).

Silanization of quartz fibres

Quartz optical fibres (1 mm × 6 cm, 40 in total) were placed in a 15 × 90 mm glass receiver. The fibres were washed three times with acetone, three times with water, and twice with nitric acid (15%, v/v). The fibres were covered with nitric acid (15%), a condenser was installed, and the apparatus was placed in a Reacti-Therm heating module (Pierce Chemical Co., Rockford, Ill.) with the upper portion of the receiver wrapped in cotton batting. The fibres were heated for 2 h at reflux temperature. Afterwards, the fibres were rinsed thoroughly with water, then methanol, and dried in a convection oven for 2 h at 100°C. Two boiling chips were added to the glass receiver and the fibres were refluxed for 1 h in dry chloroform.

The fibres were rinsed three times with dry toluene. A 20% (v/v) solution of APTES in dry toluene was added in sufficient amount to cover the fibres. The receiver tube was closed with a glass stopper and secured with metal springs. The vial was placed on a Nutator shaker (Clay Adams, Parsippany, N.J.) and rotated gently overnight at room temperature. The fibres were rinsed repeatedly with dry toluene, then dried in the Reacti-Therm block under a stream of dry nitrogen. The coated fibres were stored in screw-cap polystyrene test tubes inside a desiccator. Elemental analysis of the silanized quartz surfaces by X-ray photoelectron spectroscopy indicated that the coverages were approximately 45–50% of the surface area (K. Kallury, personal communication). Ellipsometry data gave a thickness of approximately 11 Å, indicating that the coating was primarily monolayer silane (K. Kallury, personal communication).

Covalent attachment of antibodies to quartz fibres

Quartz fibres that had been previously treated with APTES were placed in glass test tubes (12 × 75 mm), about 10–15 fibres per tube, then 2 mL of 0.5 M carbonyldiimidazole in dimethyl sulfoxide was added to each tube. The test tubes were covered with Parafilm and incubated for 2 h at room temperature; gentle agitation was provided by a Nutator shaker. The supernatant solution was then decanted. The activated fibres were first washed three times with dimethyl sulfoxide, then three times with acetone, and finally dried at room temperature under a stream of dry nitrogen for 15 min. Once activated, quartz fibres were never stored, they were always immediately coupled with antibody by the following procedure.

If the antibody had been stored in sodium azide or some other stabilizer, preservative, or buffer that would react with the activated fibre, it was necessary first to purify the antibody solution by dialysis prior to the linking reaction. The antibody to be linked was then diluted to the working concentration (up to 100 μg/mL) in PBS pH 7.4. The activated fibres were placed in polystyrene 12 × 75 mm snap-cap test tubes (no more than 20 fibres per tube). Sufficient antibody solution to cover the fibres (0.5 mL) was added and the tubes were incubated at 4°C overnight with agitation provided by a Nutator shaker. After the coupling reaction was completed, the antibody solution was decanted. The fibres were washed three times with 0.1 M ethanolamine pH 8.5 and then were incubated with gentle shaking for 2 h at room temperature in the same solution. Finally, the antibody-linked fibres were washed three times with PBS. The fibres could be stored in buffer at 4°C for several days, or longer if the storage medium contained 0.02% sodium azide or merthiolate.

Conjugation of antibodies with fluorescein isothiocyanate

The procedure used to conjugate anti-NDV IgG with fluorescein isothiocyanate was similar to methods previously described (7). An aliquot of anti-NDV IgG (guinea pig) solution, 0.5 mL at 12 mg/mL, was diluted to 6 mL with 0.15 M sodium phosphate buffer, pH 9.0, to give a concentration of 1 mg/mL. A stock solution of fluorescein isothiocyanate (FITC), 1 mg/mL in 0.15 M sodium phosphate buffer, pH 9.0, was prepared. A volume of 10 μL FITC solution per mg of protein, in this case 60 μL, was added to the antibody solution. The pH was adjusted to 9.5 by the addition of 0.1 M sodium phosphate solution, pH 12.0. The reaction mixture was stirred for 1 h at room temperature while maintaining the pH at 9.5. The reaction mixture, about 10 mL total volume, was transferred to dialysis tubing and stirred overnight in a large flask containing 3.5 L of PBS. The PBS solution was changed and stirring continued for an additional 3 h. After dialysis, a uv–vis absorbance spectrum was recorded and a

Coomassie blue protein assay carried out. The A_{280} and A_{495} readings indicated a mole ratio of fluorescein to protein (F/P) of 2.3. The recovery of protein was about 85%. The FITC-conjugated antibody solution was stored frozen at −20°C in 1 mL aliquots.

Enzyme immunoassay on quartz solid support

Quartz fibres previously treated with APTES were cut using a small-bore tube cutter (Scientific Systems Inc., State College, Pa.) and sorted to 3 (±0.3) mm in length. Rubber gloves were used when handling the coated fibres. Capture antibody was covalently linked to the fibre segments according to the above-described procedures. The concentration of the capture antibody solution was 50 μg/mL. Blocking of the fibres was achieved by three successive 1 h incubations and washing with BSA-containing diluent buffer at 37°C. The fibres were placed in the wells of microtitre plates (one fibre per well). The antigen, NDV, was reconstituted in diluent buffer. Aliquots (200 μL) were incubated in the microtitre wells with the capture antibody-coated fibres for 1 h at 37°C. After incubation with NDV, the fibres were washed three times with PBS. Detector antibody (peroxidase-conjugated anti-NDV) was diluted 1/500 in diluent solution. Aliquots (200 μL) of diluted detector antibody were added to the wells containing the quartz fibres and the fibres were incubated for 1 h at 37°C. The fibres were washed several times with wash solution. Freshly prepared substrate, a mixture of ABTS and H_2O_2 solutions, was added, 200 μL per well, and the plate was placed on a Nutator shaker and allowed to develop at room temperature for 30 min. The absorbance of the reacted substrate in the wells was measured in a microtiter plate reader (Molecular Devices, Sunnyvale, Calif.) at 405 nm. The presence of the fibres in the wells did not affect the absorbance readings if the fibres were positioned away from the centres of the wells.

Fluorescence assays of NDV on the fibre-optic wave guide

Assays on the FOWG employed two methods to introduce antigen to the detector system. In one method, fibres coated with capture antibody were set into polystyrene test tubes, one fibre per tube, 0.5 mL of diluted NDV solution was added to each tube, and the tubes were sealed with polystyrene caps. The tubes were placed on their sides on the platform of a Nutator shaker and incubated at room temperature for 5 min. After incubation the fibres were rinsed three times with wash solution. A single fibre was installed in the flow cell of the FOWG. The cell was flushed with wash solution for 1 min and a baseline output signal was obtained during the flushing procedure. After the baseline had been recorded, detector antibody (FITC-labelled anti-NDV) solution was pumped through the flow cell and the resulting fluorescence signal was obtained by monitoring the voltage output of the photodetector with respect to time using the XY recorder. In the second method, the quartz fibres were incubated with NDV in the flow cell of the FOWG. That is, an antibody-coated fibre was installed in the flow cell and a 0.2 mL aliquot of diluted NDV solution was injected into the cell. After 5 min incubation, the flow cell was flushed with wash solution for 1 min. A baseline was obtained while wash solution was flowing through the system, then the detector antibody was introduced by means of the pump and the signal was recorded with respect to time by the XY recorder.

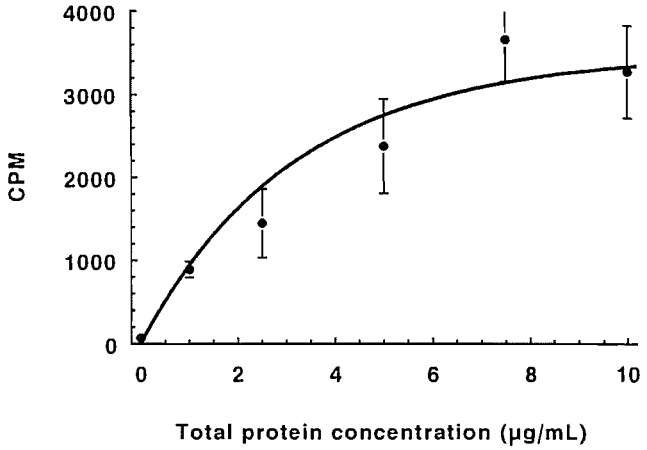

Fig. 2. Standard curve of radioactivity (cpm) versus spiked samples of ^{125}I-labelled goat IgG. Aliquots (1 mL) of labelled antibody were delivered to vials and counted.

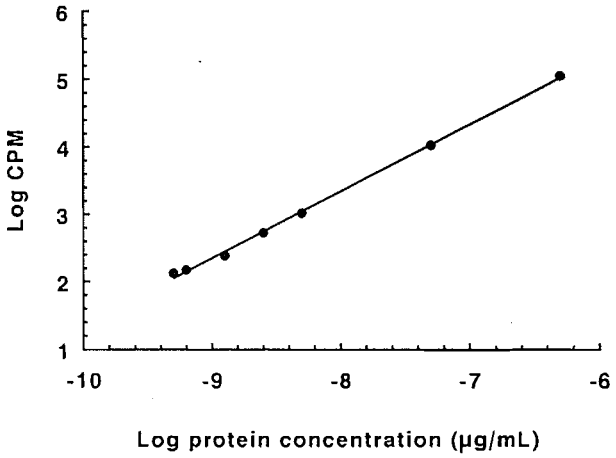

Results

Immobilization of antibodies on silanized quartz fibres

To measure the amount of antibody covalently immobilized by carbonyldiimidazole reaction on the quartz surface, activated silane-coated fibres were reacted with a mixture of ^{125}I-labelled goat anti-human IgG and native goat anti-human IgG. The radioactivity levels of the antibody-coated fibres were determined and the data are shown in Fig. 1. The relative amount of protein immobilized, taken as the γ irradiation emanating from the fibres, initially increased with increasing protein concentration and reached a plateau in the range of 7–10 μg/mL. The experiment was carried out using a ratio of 20/1 (w/w), native to ^{125}I-labelled anti-human IgG. Immobilization experiments with ratios ranging from 10/1 to 1000/1 produced similar results, i.e., a plateau in counts between 5 and 10 μg/mL.

It was possible to calculate the extent of protein coverage from the initial radioactivity of the stock radio-labelled antibody, the radioactivity of the protein coated fibre, and the ratio of native to labelled antibody. We have taken the molecular weight of IgG as 160 000 Da (8) and the specific volume of globular protein as 0.73 (9). By comparison of the radioactiv-

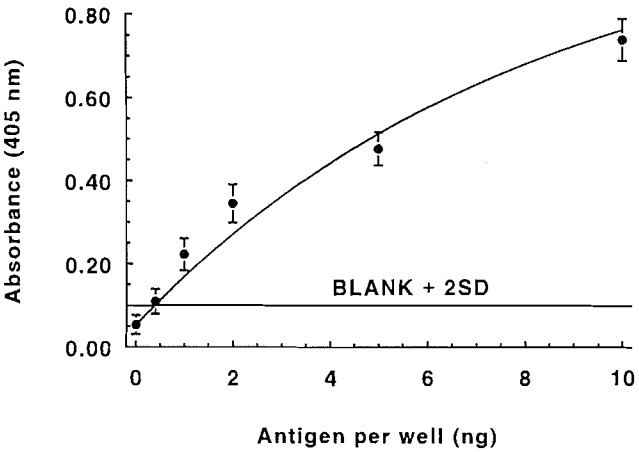
Fig. 3. Immunoassay of NDV using quartz as the solid support. Capture antibody was covalently attached to the solid phase. The LOD was taken to be the sample that produced a signal in excess of the background plus two standard deviations. For this assay the LOD was about 0.5–1.0 ng NDV in a total sample volume of 0.1 mL.



ity (cpm) of the protein-coated fibres (Table 1) with that of a standard curve of ^{125}I-labelled antibody (Fig. 2), the total amount of protein immobilized was calculated to be about 1 ng/mm^2. This latter value represents protein coverage of the fibres of about 20% of the surface area.

Enzyme immunoassay on quartz solid support: response of antibody-coated quartz fibres

Polyclonal antibody directed against NDV was covalently immobilized on quartz fibres (1 mm diam., cut to 3 mm length) according to the above-described methods. The fibres were placed in the wells (one per well) of microtitre plates. Consecutive incubations (30 min in duration) of antigen (NDV) and detector antibody (anti-NDV horse radish peroxidase conjugate) were carried out, substrate solution was added, and the absorbance was determined at 405 nm. The results of an assay are shown in Fig. 3. The lower limit of detection (LOD), taken to be the intersection of the background plus two standard deviations with the dose response curve, was about 0.5 ng (5 ng/mL for 0.1 mL sample). The detection limits were comparable to a colorometric microplate ELISA of NDV (10). These results suggest that the antibody-coating methods produce fibres suitable as capture elements that can be subsequently employed in a fibre-optic sensor. A similar enzyme immunoassay for NDV employing capture antibody noncovalently adhered (physiosorbed) to quartz fibres was less sensitive, having an LOD of about 20–50 ng (W. Lee, unpublished results).

Response of the fibre-optic wave guide

An experiment to determine the active area of the quartz fibre contained in the FOWG flowcell was carried out. Guinea pig immunoglobulin (anti-NDV) was covalently immobilized on quartz fibres and solutions of fluorescein-labelled second antibody (anti-guinea pig IgG from rabbit) were incubated with the fibres in test tubes. Sections of the fibre of increasing lengths were treated with the second antibody solution. The output of the FOWG increased in an approximately linear fashion with the length of fibre treated with the fluorescein-labelled second antibody. The data indicated that the active portion of the optical fibre extended essentially along its whole length (Fig. 4).

The immunosensor capability of the FOWG is shown in Fig. 5. Fibres coated with anti-NDV were treated with increasing amounts of NDV analyte. Detector antibody (fluorescein-labelled anti-NDV) was then pumped through the flow cell. For the blank sample (no NDV), there was a small increase in signal that corresponded to the fluorescein-labelled antibody in the flow cell passing through the evanescent zone of the fibre (Fig. 5). When the flow of detector antibody was interrupted and buffer solution passed through the system, the output signal decreased to approximately its initial value. For the second sample, a fibre incubated with NDV solution (17 ng/mL) was inserted into the flow cell. When detector antibody was pumped through the flow cell, there was a substantial increase in output signal. After the flow of detector antibody was interrupted and wash solution introduced, a small decrease in signal was observed. For fibres incubated in NDV solutions of 100 and 1000 ng/mL, the output signals increased

Fig. 4. Determination of the active area of the quartz fibre in the FOWG. Fibres were covalently coated with guinea pig IgG and then incubated with fluorescein-labelled anti-guinea pig IgG (0.005 μg/mL) with varying lengths of the fibre exposed to the second antibody.

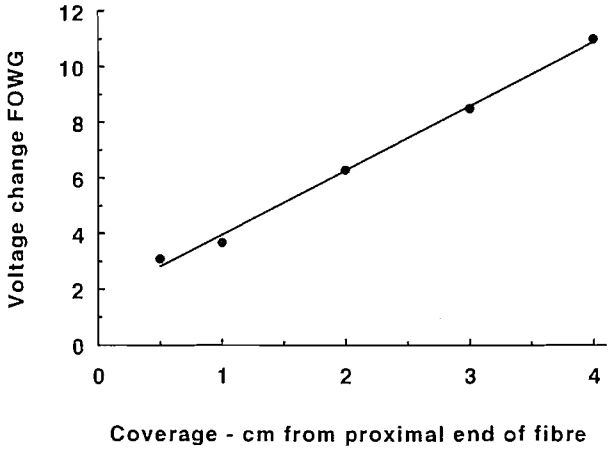


Fig. 5. Response of FOWG to NDV. The quartz fibre was incubated with NDV solution (0.5 mL) at room temperature. After incubation the fibre was washed with PBS. A baseline was recorded while flowing PBS through the flow cell. Detector antibody solution (fluorescein-labelled gp anti-NDV, 1 μg/mL) was pumped through the flow cell at a rate of 1.2 mL/min. A separate fibre was used for each run.

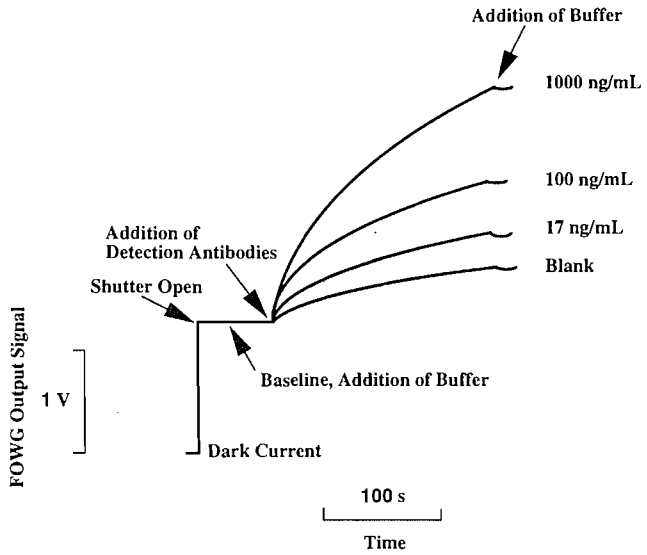

accordingly upon introduction of detector antibody. Higher concentrations of NDV yielded larger output signals (i.e., voltage changes).

Biosensor assay of NDV

Plots of the slopes (dv/dt) versus added NDV are more revealing. The slopes of the individual xy recording (e.g., data in Fig. 5), 1 min after introduction of detector antibody, were plotted against added NDV. A dose response is shown in Fig. 6. Signals were recorded over a range of about 2–250 ng. The limit of detection, taken to be the lowest amount of NDV that produces a signal two standard deviations above the background

Fig. 6. FOWG standard curve on NDV. The slopes of the output traces (e.g., Fig. 5) were determined 1 min after addition of detector antibody (0.5 μg/mL). The data points and error bars represent the mean standard deviation of three samples. A separate fibre was used for each determination. The background (blank) was taken to be the signal output produced by the detector antibody alone, with no analyte present.

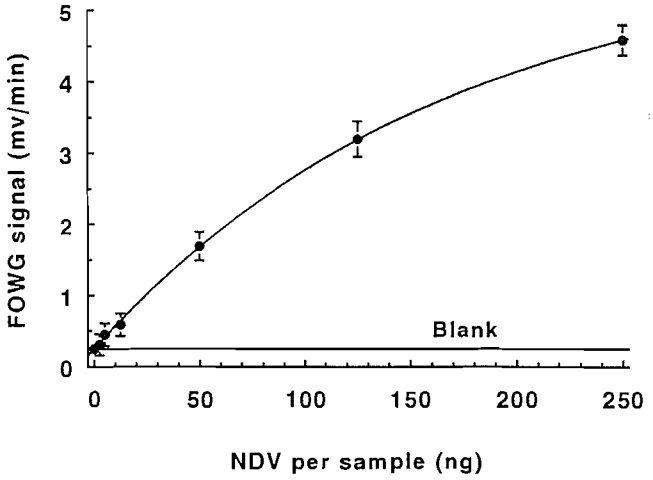

Fig. 7. FOWG assay of NDV carried out on a single fibre. The data points and error bars represent the mean standard deviation of three samples. The analyte sample was incubated for 5 min, detector antibody concentration was 2 μg/mL. The LOD was about 1 ng (volume 0.2 mL). The background (blank) was taken to be the signal output produced by the detector antibody alone, with no analyte present.

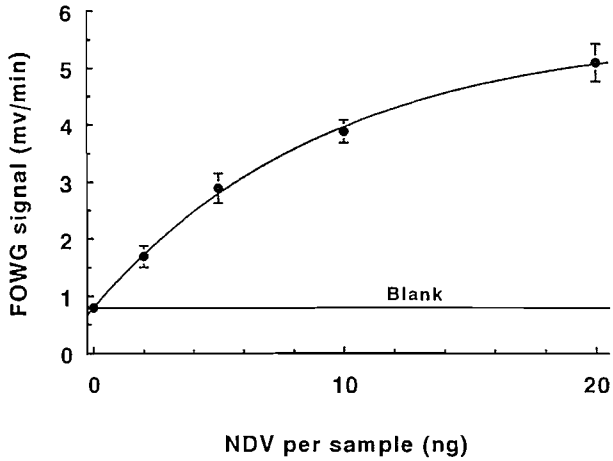

(blank sample), was about 2–3 ng. For the data shown in Fig. 6, each individual run (i.e., addition of NDV, followed by fluorescein-labelled anti-NDV) was carried out on a separate fibre. The reproducibility from fibre to fibre as indicated by the coefficient of variation (sd/mean) was about 0.15–0.20.

After a single run, only a fraction of the binding sites for antigen were occupied; the major portion of the available binding sites on the fibre remained vacant. It was possible to use a single fibre for repetitive assays of the same antigen provided the binding capacity was not overloaded. Between runs, the flow cell was flushed first with wash buffer solution for about 3 min, followed by a solution of 2 μg/mL guinea pig

anti-NDV for 5 min. The latter was the same antibody used for detection but without the fluorescein label and its effect was to block any free epitope sites on the NDV antigen captured during the previous run. Successive 200 μL aliquots of NDV solution were introduced to the flow cell and incubated for 5 min. After incubation the flow cell was flushed with wash solution for 1 min to establish a new baseline and then with fluorescein-labelled antibody to produce a signal. The results of a repetitive assay on a single fibre are shown in Fig. 7. The LOD for the assay was about 1.5 ng and the coefficient variations were about 0.10. For comparison, an immunofiltration assay of NDV that used a silicon sensor gave LODs in the order of 0.5–1.0 ng per 100 μL sample (11).

Discussion

This work describes a fibre-optic-based biosensor for a model virus. Detection of nanogram quantities of NDV was achieved using anti-NDV antibodies immobilized on aminosilane-coated fibres and fluorescein-labelled anti-NDV. Quartz, being composed primarily of silicon dioxide, is relatively chemically inert, save for extreme conditions. Such conditions are too harsh to maintain protein in an active state and so direct reaction of antibodies to quartz is not practical. To overcome this problem, 3-aminopropyltriethoxysilane was reacted with the quartz fibres at high temperature under anhydrous conditions. This procedure results in a covalently attached monolayer covering of silane. Proteins can be readily bonded to the modified fibre through the carboxyl function. In this work carbonyldiimidazole was used as the linking agent, although other protein fixative compounds are commercially available (12, 13). Radiolabelling studies indicated that maximal amounts of antibody, covering up to 20% of the fibre surface, could be covalently immobilized using antibody solution as low as 5–10 μg/mL.

One of the principle advantages of a fibre-optic biosensor is the flow-through design that can provide continuous on-line monitoring of liquid samples. Thus, the sensor has the potential to be incorporated into an automated or semiautomated system. Flow-through systems can include such features as a limited number of mechanical components, reusable solid support, low variations of background or negative control signals, and the potential for multi-recognition elements on a single fibre. Miniaturization and durability are achievable through the use of solid state electro-optic components. Immuno-based fibre-optic biosensors have been successfully employed in detection of proteins (14, 15, 16) and whole cells (17). Other applications of fibre-optic sensors include molecular recognition by receptors (18, 19), enzymes (20), and gene probes (21).

In conclusion, the feasibility of performing immunoassay for intact virus on a fibre-optic wave biosensor has been demonstrated. The limits of detection were about 2 ng for a 10 min assay at room temperature. The assays were further characterized by high reproducibility and low background.

Acknowledgements

We would like to thank Professor Michael Thompson and Dr. Krishna Kallury of the University of Toronto for carrying out the X-ray photoelectron spectroscopy and elipsometry experiments on the quartz surfaces and for many helpful discussions. In addition, we thank the molecular biology group at Defence Research Establishment Suffield for assistance with the antibody and virus preparations. This work has been carried out with the support of the Department of National Defence.

Excess partial molar enthalpies of alkane-mono-ols in aqueous solutions

Steven Hiroshi Tanaka, Hikari Infinity Yoshihara, Alice Wen-Chi Ho, Frankie W. Lau, Peter Westh, and Yoshikata Koga

Abstract: Excess partial molar enthalpies, H_A^E, of methanol, ethanol, and 1- and 2-propanols in aqueous solutions were measured directly, accurately, and in small increments in mole fraction at 25°C. From these data, the solute–solute enthalpic interactions, $H_{AA}^E \equiv N(\partial H_A^E/\partial n_A)$, were evaluated for each alcohol. These data indicate that three distinctively different mixing schemes, I, II, and III exist, as was the case for aqueous 2-butoxyethanol previously studied in our laboratory. The transition from mixing scheme I to II appears to take place gradually within a small composition range. As the hydrophobic moiety becomes smaller from 2-butoxyethanol to methanol, the locus of the transition moves to a higher value in mole fraction of the alcohol. At the same time, the range of transition becomes wider and the solute–solute enthalpic interaction weaker.

Key words: excess partial molar enthalpies in aqueous solutions, methanol, ethanol, 1-propanol, 2-propanol, enthalpic interaction, transition of mixing scheme.

Résumé : Opérant à 25°C et procédant par de faibles augmentations dans les fractions molaires, on a mesuré directement et d'une façon précise les enthalpies molaires partielles en excès, H_A^E, pour des solutions aqueuses de méthanol, d'éthanol et des 1- et 2-propanols. Utilisant ces données, on a évalué pour chaque alcool les interactions enthalpiques soluté–soluté, $H_{AA}^E \equiv N(\partial H_A^E/\partial n_A)$. Ces données suggèrent l'existence de trois schémas différents de mélanges, I, II et III, comme ce fût le cas pour le 2-butoxyéthanol étudié antérieurement dans notre laboratoire. Il semble que la transition du schéma de mélange I vers II se produit graduellement, à l'intérieur d'une faible plage de composition. Quand les portions hydrophobes deviennent plus petites en allant du 2-butoxyéthanol vers le méthanol, le foyer de la transition se déplace vers des valeurs plus élevés de la fraction molaire de l'alcool. En même temps, l'intervalle de transition devient plus grand et l'interaction enthalpique soluté–soluté devient plus faible.

Mots clés : enthalpies molaires partielles en excès en solutions aqueuses, méthanol, éthanol, propan-1-ol, propan-2-ol, interaction enthalpique, schéma de transition de mélange.

Introduction

Extensive thermodynamic studies have been carried out in this laboratory on aqueous solutions of *tert*-butyl alcohol (hereafter abbreviated as TBA) (1–5, 16) and 2-butoxyethanol (BE) (6–16). In particular, the excess partial molar enthalpies of the alcohol (A), H_A^E (A = TBA or BE), were measured directly, accurately, and in small increments in the mole fraction of A, x_A. They are replotted in Fig. 1. As a result, the excess enthalpic solute–solute interaction, H_{AA}^E,

$$[1] \quad H_{AA}^E \equiv N(\partial H_A^E/\partial n_A) = (1 - x_A)(\partial H_A^E/\partial x_A)$$

can be evaluated with a reasonable accuracy. H_{AA}^E signifies the effect of an additional molecule of A on the excess partial molar enthalpy of the existing A. Hence, if H_{AA}^E is negative, an additional A makes the enthalpic situation of A more favorable. Thus, one may state that the A–A interaction is attractive in terms of enthalpy. The value of H_{AA}^E then indicates the degree of such an interaction. Conversely, if $H_{AA}^E > 0$, the enthalpic A–A interaction is repulsive. Note that H_A^E is a sec-

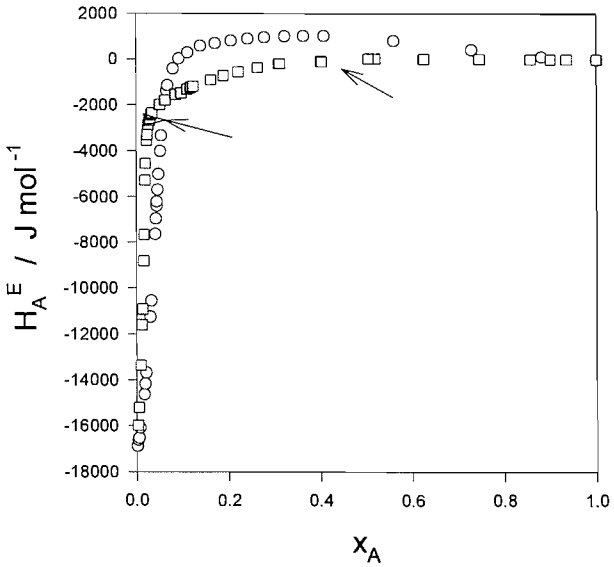

Fig. 2. The enthalpic solute–solute interaction, H_{AA}^{E}. ○: *tert*-butyl alcohol (TBA) at 26.9°C, ref. 1. □: 2-Butoxyethanol (BE) at 25°C, ref. 6. The lines are drawn as a guide. The thick straight line in the range $0.065 < x_{TBA} < 0.12$ in Fig. 2*a* shows the existence of mixing scheme II in TBA–H_2O.

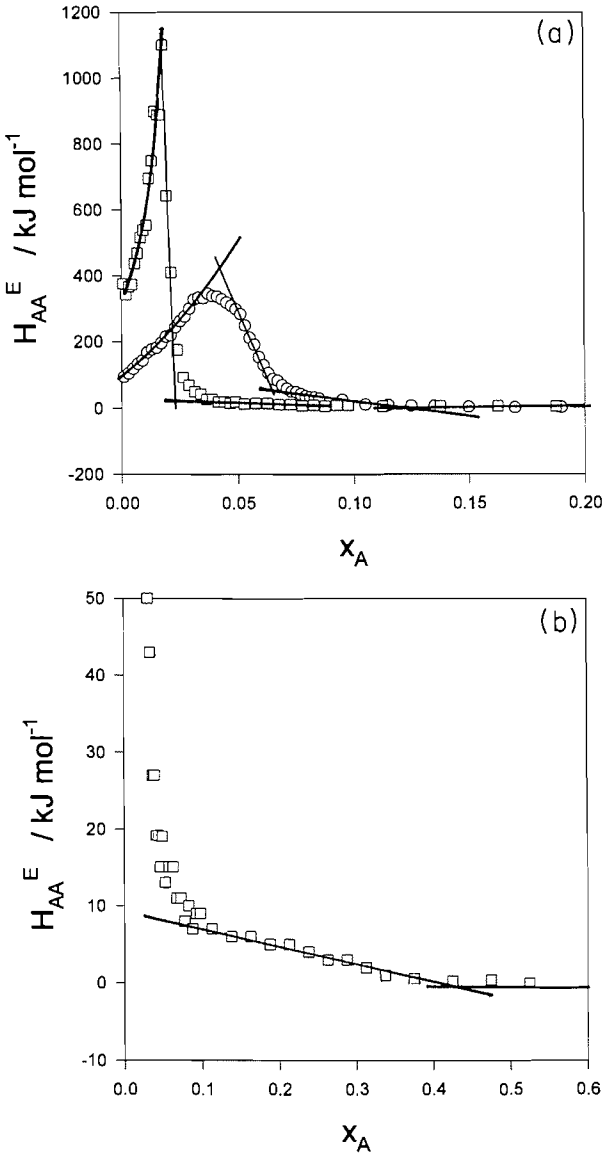


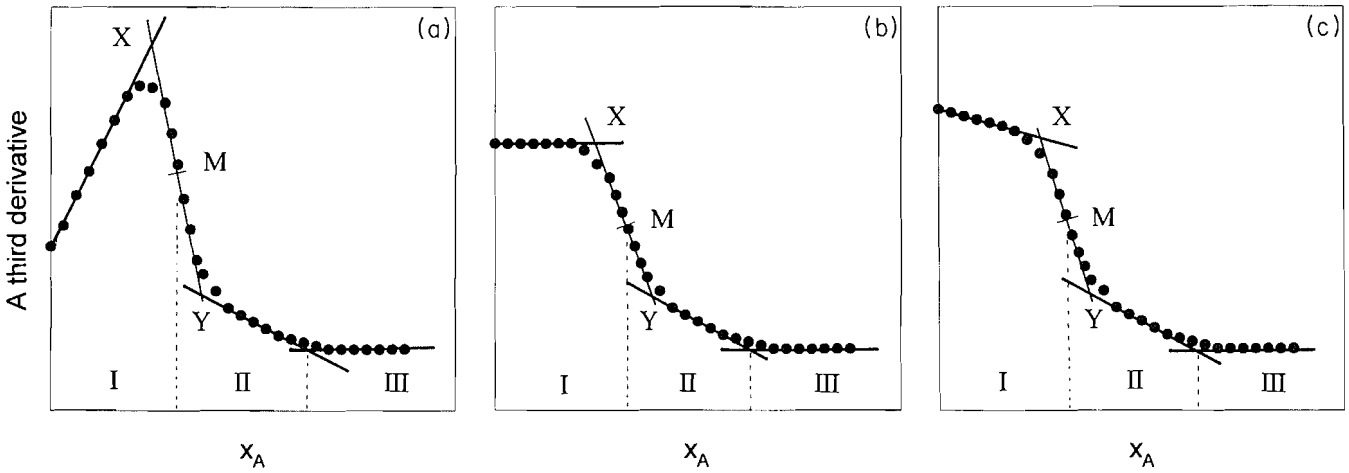
ond derivative of the Gibbs energy, hence H_{AA}^{E} is a third derivative.

Using various derivatives including those mentioned above, it was found (1–16) that the mixing scheme, the way in which the solute A and the solvent H_2O mix with each other, changes qualitatively at $x_{TBA} \approx 0.045$ for TBA–H_2O and at $x_{BE} \approx 0.0175$ for BE, both at 25°C. The threshold is characterized by anomalies in all the third derivatives of the Gibbs energy that have been investigated so far, including peaks in H_{AA}^{E} as shown in Fig. 2. For TBA–H_2O, the value of H_{AA}^{E} at the maximum reached 350 kJ mol^{-1}, while that of BE–H_2O was 1100 kJ mol^{-1}. For both cases, the mixing scheme operating in region I ($0 < x_{TBA} < 0.045$, $0 < x_{BE} < 0.0175$) is not inconsistent with the classical picture of "iceberg formation." Namely, it was concluded (16) that the solute enhances the hydrogen bond network of H_2O in the immediate vicinity, but diminishes the hydrogen bond probability in the bulk away from the solute. However, percolation of the hydrogen bond network (17) is still retained. That is, the hydrogen bond network is connected throughout the entire bulk at any instance. Region II is characterized by small and linearly decreasing values of H_{AA}^{E} up to about $x_{BE} \approx 0.46$, as shown in Fig. 2*b*. Mixing scheme II operative in this region was interpreted as consisting of two kinds of clusters, rich in each component. Hence, the hydrogen bond network is no longer percolated. Region III ($0.46 < x_{BE}$) is characterized by zero H_{BE}^{E} (Fig. 1) and almost zero excess partial molar entropy, S_{BE}^{E}. It was therefore concluded that the solute molecules cluster together, perhaps in a micellar form (6–16). The occurrence of three distinct regions in BE–H_2O is apparent even in the behavior of H_{BE}^{E} without calculating H_{AA}^{E}, as shown by the arrows in Fig. 1. For TBA–H_2O, on the other hand, there is no clear indication of the existence of region II (hence mixing scheme II) in the x_A dependence of H_A^{E}. The behavior of H_{AA}^{E}, however, shows the existence of mixing scheme II as shown by a thick straight line between $0.065 < x_{TBA} < 0.12$ in Fig. 2a. The clearer indication of region II for BE–H_2O may reflect the fact that there is the phase separation with LCST ($x_{BE} = 0.06$ and 50°C) close to the temperature of investigation. In fact, it was argued that mixing scheme II is such that the solution is "preparing" for the phase separation when the temperature becomes high enough (6–16). For TBA–H_2O, a phase separation is not apparent under normal pressures. It is known, however, that liquid–liquid phase separation with LCST occurs, when salt is added to TBA–H_2O (18).

Similar studies on aqueous solutions of dimethyl sulfoxide (DMSO) (19), 2-butanone (BUT) (20), and isobutyric acid (IBA) (21) also showed the existence of mixing schemes I, II, and III. In these cases, the transitions from I to II were found to be accompanied by a step anomaly in H_{AA}^{E} as depicted in Fig. 3*b* for BUT–H_2O, and IBA–H_2O, and in Fig. 3*c* for DMSO. Figure 3*a* represents a peak anomaly, as was the case for BE–H_2O mentioned above. For BE–H_2O, most third derivatives showed peak anomalies (Fig. 3*a*) (6–10, 13–16), while $(\partial C_p/\partial T)$, another third derivative, showed a step anomaly (Fig. 3*b*), at the same threshold (11, 12). It was thus argued (16) that whether an anomaly takes the form of a peak or a step is not intrinsically important. Rather, it is the dependence of H_{AA}^{E} on x_A in region I that dictates the type of anomaly when the transition from mixing scheme I to II occurs. Namely, whether H_{AA}^{E} or any third derivative increases (case a), stays constant (case b), or decreases (case c) as a function of x_A, within region I, decides the shape of the anomaly. Furthermore, we suggest that the width from point X to Y in Fig. 3 signifies the region in which the transition takes place. The narrower this width, the sharper the transition. In the limit of the zero width, the transition point will be mathematically singular. Thus, it may be more appropriate to define the nominal transition threshold as the middle point M, shown in Fig. 3. For BE–H_2O, the peak, point X, has been taken as the threshold for most of the third derivatives (6–10, 13–16), except for $(\partial C_p/\partial T)$ mentioned above, in which case point M was taken (11, 12, 16). Since peaks are very sharp for BE–H_2O, the difference in the threshold value is negligible whether point X or M is chosen.

The differences in terms of H_A^{E} and H_{AA}^{E} between BE and

Fig. 3. A sketch of the dependence of a third derivative on the mole fraction of alcohol, x_A, for mixing schemes I, II, and III, and the transitions thereof. The transition from mixing scheme I to II starts at point X and ends at Y. The mid point M is the nominal transition point. See text.



TBA are due to the properties of the individual solute. An obvious difference between the two is the size of the hydrophobic moiety, both being mono-ols. Hence, in the present work, we study aqueous solutions of methanol (ME), ethanol (ET), and 1- and 2-propanols (1P and 2P), in order to further elucidate the effects of hydrophobic moiety on the mixing scheme. While a more complete picture should await the data of other second and third derivatives, we report here the excess partial molar enthalpies, H_A^E, and the enthalpic A–A interactions, H_{AA}^E, and what can be deduced from such data.

Experimental

H_2O used was triply distilled immediately before use. Methanol (99.9+%, GLC), 1-propanol (99.5+%, HPLC), and 2-propanol (99.5+%, HPLC) were supplied by Aldrich. Ethanol was refluxed over Na metal, distilled, and stored over 3A molecular sieve. H_2O content in ethanol was found to be less than 0.7 mol% by Karl–Fischer titration. For determination of the excess partial molar enthalpies, two titration calorimeters were used: an LKB Bromma 8700, and a similar equipment constructed in this laboratory. Details of the latter are described elsewhere (18). The accuracy was estimated to be ±0.05 kJ mol^{-1} at worst.

Results and discussion

The values of H_A^E for A = ME, ET, 1P, or 2P are listed in Table 1 and plotted in Figs. 4–7, as a function of the mole fraction of solute, x_A. Existing data, H_A^E, although scarce, are also shown. As is evident from the figures, the general agreement between our data and the existing data is reasonable. For 1P–H_2O, the excess (integral) molar enthalpies, H_m^E, were determined in small increments in x_{1P} (~0.001) (26). Using these data, graphical differentiation was performed to obtain H_A^E, A = 1P. Namely, a smooth curve was drawn through the measured data points, the values of H_m^E on the curve were read off at the intervals $\delta x_A = 0.002$, the values of $(\partial H_m^E/\partial x_A)$ were approximated by those of $(\delta H_m^E/\delta x_A)$, and the values of H_A^E were calculated by

$$[2] \quad H_A^E = H_m^E + (1 - x_A)(\partial H_m^E/\partial x_A), \text{ (A = 1P)}$$

Fig. 4. The excess partial molar enthalpies of methanol, H_{ME}^E, at 25°C. ○: This work, □: ref. 22; △: ref. 23; ▽: refs. 24 and 27.

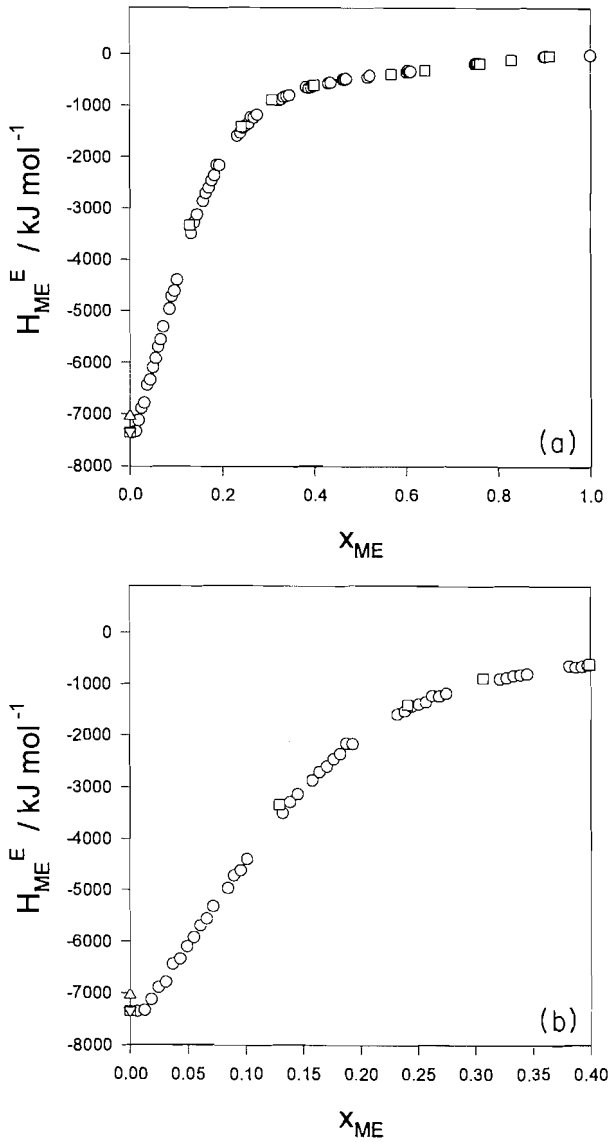


Table 1. The excess partial molar enthalpies of alkane-mono-ols in aqueous solutions, H_A^E, at 25°C. x_A is the mole fraction of alcohol, A = methanol (ME), ethanol (ET), 1- and 2-propanol (1P and 2P). H_A^E, with A = ME, ET, 1P, and 2P, are in the units of kJ mol^{-1}. The uncertainty in H_A^E is less than 0.05 kJ mol^{-1}.

[a]kJ mol^{-1}, ±0.05 kJ mol^{-1}.

The results are shown in Fig. 6. As is evident from Fig. 6*b*, the values of H_A^E thus calculated were in reasonable agreement with the measured values except at the low concentration end of the mole fraction scale, which is expected for any set of H_m^E data of high quality. For ET–H_2O, Ott et al. (25) fitted the following function to the data of H_m^E:

$$[3]\quad H_m^E = x_{ET}(1 - x_{ET})[\exp(-\alpha x_{ET})\Sigma b_j(1 - 2x_{ET})^j + \{1 - \exp(-\alpha x_{ET})\}\Sigma c_k(1 - 2x_{ET})^k]$$

with j = 0–2 and k = 0–4. We note that eq. [3] contains an exponential term, which is normally avoided as a fitting function. Using eq. [3], the excess partial molar enthalpy of ET, H_{ET}^E, was calculated by eq. [2] with A = ET. The results are shown in Fig. 5. The agreement with our data is good, including the low x_A region. Therefore, eq. [3] turned out to be a good choice as a fitting function. We note that an exponential term can be differentiated repeatedly. This property may have some bearing on the success of eq. [3] in leading to good values of H_{ET}^E.

The values of H_A^E extrapolated to $x_A = 0$ are listed in Table 2. These values signify the change in the enthalpic situation for the first molecule of A from its pure environment to the aqueous medium, i.e., the solute–solvent interaction at infinite dilution. If, aside from the direct interaction of the hydroxyl group of alcohol with H_2O, the mode of dissolution is dictated by the nonpolar moiety, the general trend in H_A^E from methanol to 2-butoxyethanol may be understandable, although the increments do not scale proportionally with the changes in size. These values of H_A^E at $x_A = 0$ may be interpreted with respect to various imaginary processes: cavity formation in H_2O, removal of alcohol from the pure liquid, insertion into the cavity, and subsequent modification of the hydrogen bond network of H_2O. The absolute value of the enthalpy involved in each step can be an order of magnitude larger than the combined result. It is quite feasible that the resulting value of H_A^E at $x_A = 0$ can be rather insensitive to the size of the hydrophobic moiety, while the enthalpy change involved in each process may depend sharply on it. This indicates the limitation of discussing details of the mixing scheme by using H_A^E data alone.

Table 2. H_A^E at infinite dilution.

The enthalpic A–A interactions, H_{AA}^E, were calculated graphically from the smoothed curves drawn through the measured data points using eq. [1]. They are plotted in Figs. 8, 9, and 10. The peak loci and their maximum values are listed in Table 3. The size difference in the nonpolar moiety is amplified in the values of H_{AA}^E at the peak. If these peaks represent approximately the point at which mixing scheme I starts to break down, as has been established for BE–H_2O (6–16), the maximum values of H_{AA}^E signify the A–A interaction between the two "hydrated" A molecules at their closest possible distance. Such an interaction is no doubt operational via the H_2O layers modified by the solute A. Hence the maximum values of H_{AA}^E listed in Table 3 represent the influence of A on the hydrogen bond network of H_2O in its immediate vicinity, which is probed by bringing another "hydrated" A to its closest possible vicinity.

When x_A is very small, the peculiar nature of H_2O associated with the hydrogen bond network must be retained. As x_A increases, however, such peculiar nature will eventually be lost and H_2O behaves as an ordinary polar solvent, giving rise to mixing scheme II. For BE–H_2O, it has been well established

Fig. 5. The excess partial molar enthalpies of ethanol, H_{ET}^{E}, at 25°C. ○: This work; □: ref. 22, ▽: refs. 23 and 27; ◇: ref. 24; △: calculated using the fitting function, eq. [3] for H_m^E in ref. 25. Equation [3] turned out to be a good choice, leading to good values of H_{ET}^{E}.

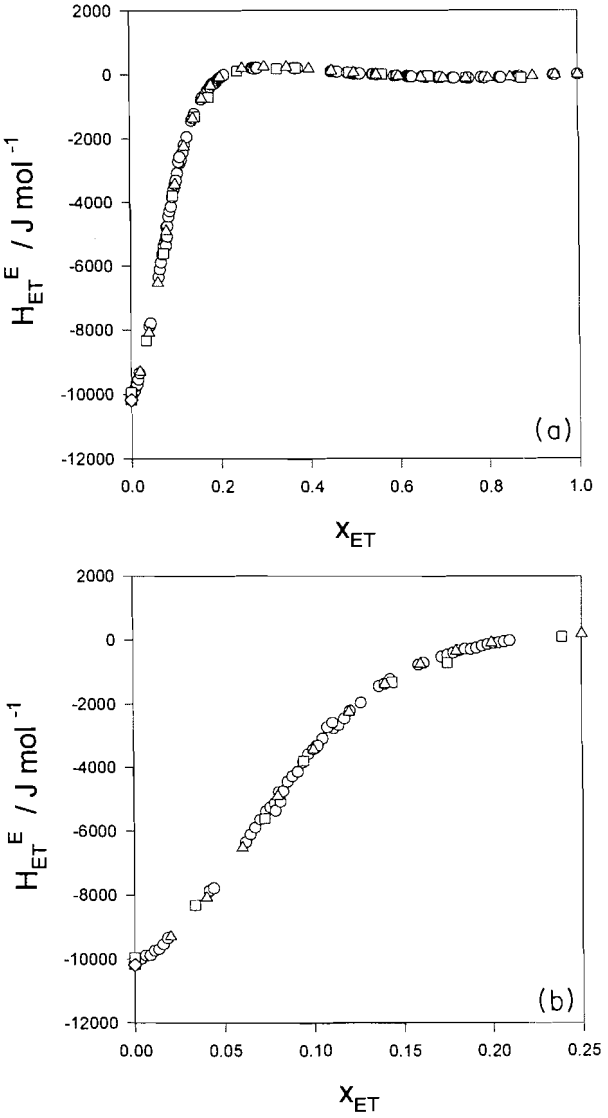

Fig. 6. The excess partial molar enthalpies of 1-propanol, H_{1P}^{E}, at 25°C. ○: This work; □: refs. 24 and 27; △: Graphically calculated using the data of H_m^E in ref. 26. See text.

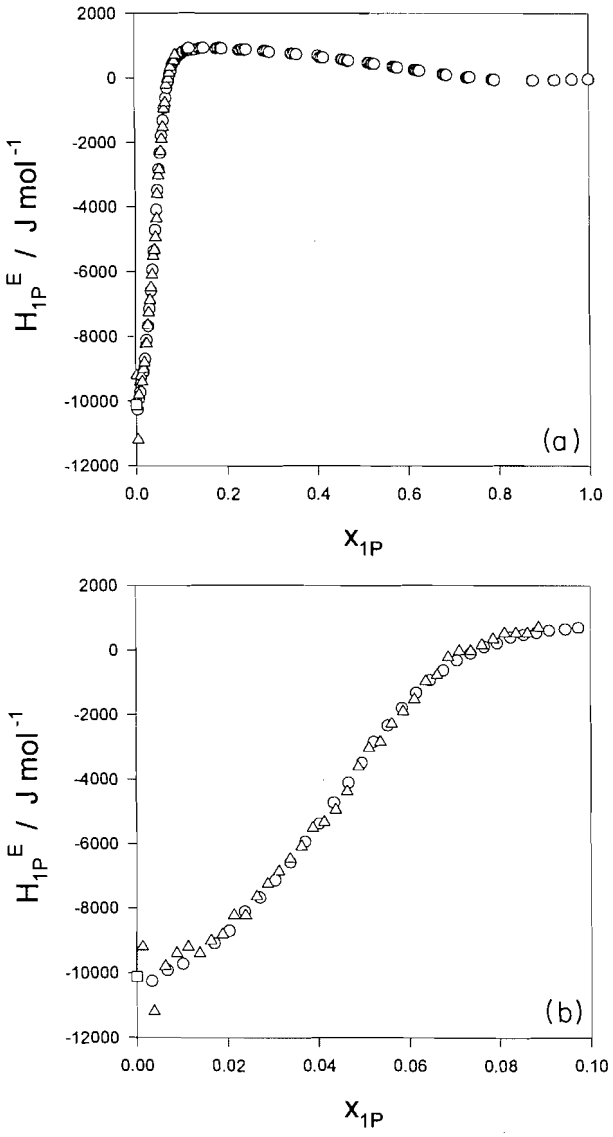

that mixing scheme II does indeed exist and the transition from I to II is rather abrupt. For TBA–H_2O, the transition seems gradual, as seen in Fig. 2. For other alcohols, we tentatively drew the lines representing mixing scheme II as shown in Figs. 8, 9, and 10, and determined points X, Y, and M accordingly. They are listed in Table 3. Since the values of H_A^E are smaller by tenfold in this region than those at $x_A = 0$, an accurate evaluation for H_{AA}^{E} is problematic. Hence, at least a tenfold improvement in sensitivity is required for calorimetry for an unequivocal conclusion on the subtle dependence of H_{AA}^{E} in this region. Nevertheless, we suggest tentatively that mixing scheme II is present in all cases studied, and that the transition from I to II takes place rather gradually, more so, the smaller the hydrophobic moiety. The observation that the transition from I to II takes place over a small composition interval (Table 3) may reflect nonuniformity in hydrogen bond strength in H_2O. If the transition is indeed associated with the loss of percolation in the hydrogen bond network (16), the percolation threshold is reached for the strongest hydrogen bond at point X in Fig. 3, and at point Y for the weakest ones.

The mixing scheme boundary between I and II for BE–H_2O was found to coincide with the incongruent melting point of the addition compound, $BE(H_2O)_{38}$, which was suggested to be a clathrate (28), thus hinting that mixing scheme I may be regarded as "preparing" for the formation of a clathrate solid when the temperature becomes low enough. The trend in the nominal transition point, point M in Table 3, as the hydrophobic moiety becomes larger from ME to BE, can be understood in terms of the number of H_2O participating in the formation of a clathrate. The smaller the hydrophobic moiety, the fewer H_2O molecules are required, hence the larger the threshold value in x_A.

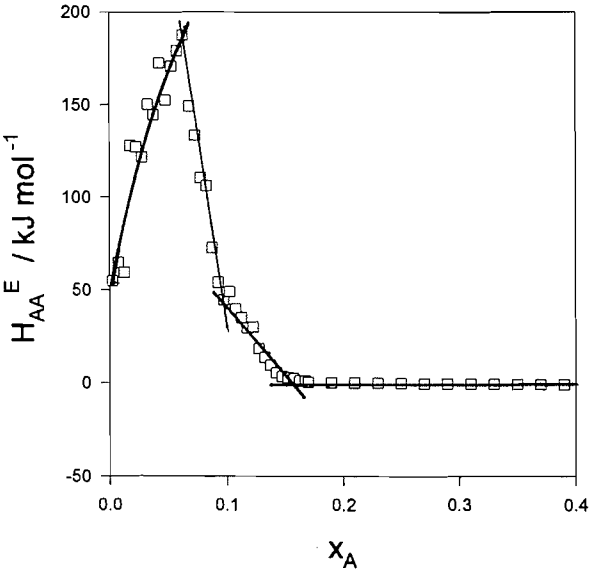

Fig. 10. The enthalpic solute–solute interaction, H_{AA}^{E}, at 25°C, for methanol.

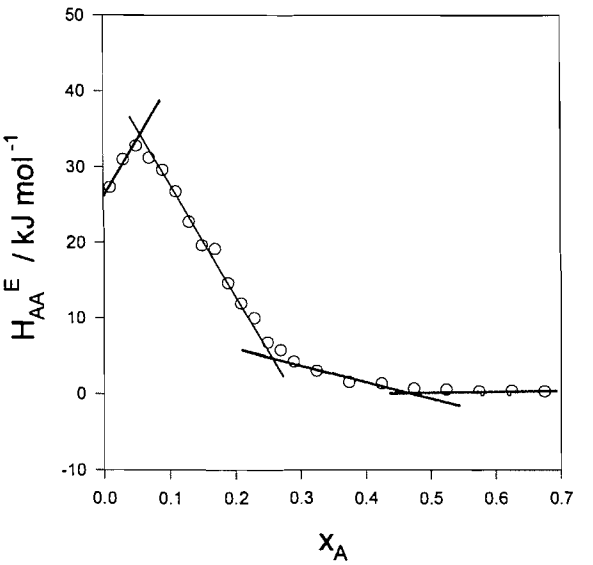

Other third derivatives, including the entropic interaction function S_{AA}^{E}, must be collected before more unequivocal conclusions can be drawn. Another very useful datum is the excess partial molar enthalpy of the solvent water, H_{W}^{E}, and its interaction, H_{WW}^{E}, or equivalently in a binary system, H_{WA}^{E}. The Gibbs–Duhem relation dictates that

$$[4] \quad x_A H_{AA}^{E} + (1 - x_A) H_{WA}^{E} = 0$$

Thus, a peak in H_{AA}^{E}, i.e., $(\partial H_{AA}^{E}/\partial x_A) = 0$, if H_{AA}^{E} is *differentiable at this point*, does not necessarily match with a peak in H_{WA}^{E}. But if the peak is indeed a singular point and hence H_{AA}^{E} is not differentiable, then H_{WA}^{E} also must be singular, although H_{WA}^{E} does not always take the form of a peak. Preliminary data of H_{W}^{E} obtained using a highly sensitive titration calorimeter, MicroCal OMEGA, indicated that H_{WA}^{E} for ET–H_2O showed a peak at about $x_A = 0.1$, near the midpoint M (see Table 3), rather than at the peak in H_{AA}^{E}. For 1P–H_2O, on the other hand, the peak in H_{WA}^{E} is at about $x_A = 0.06$, close to the peak of H_{AA}^{E}, reflecting the narrowness of the transition region. A series of careful measurements of H_{W}^{E}, among other data, are necessary for establishing whether mixing scheme II does indeed exist, exactly at which composition the transition from I to II occurs, and how wide the transition region is.

Rhenium complexes of *P,P,P′,P′*-tetrakis-(*o*-hydroxyphenyl)diphosphinoethane

Hongyan Luo and Chris Orvig

Abstract: Preparation of the hydrochloride salt of a new potentially hexadentate ligand precursor *P,P,P′,P′*-tetrakis(*o*-hydroxyphenyl)diphosphinoethane dihydrochloride (abbreviated $H_4P_2O_4{\cdot}2HCl$) is described. From $H_4P_2O_4{\cdot}2HCl$, neutral $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ and dianionic $[Re_2O_2Br_4(\mu\text{-}P_2O_4)]^{2-}$ dinuclear rhenium(V) complexes were synthesized. The complexes have been characterized by elemental analysis, infrared spectroscopy, mass spectrometry, and $^1H/^{31}P\{^1H\}$ NMR spectra. $^{31}P\{^1H\}$ NMR revealed that only one isomer, presumably the *anti*, was present for $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$, and that two isomers, both *anti* and *syn* isomers, were observed for $[Re_2O_2Br_4(\mu\text{-}P_2O_4)]^{2-}$. The coligands ($PPh_3$ for the former, Br^- for the latter) of both complexes underwent ligand exchange with pyridine.

Key words: rhenium, *P,P,P′,P′*-tetrakis(*o*-hydroxyphenyl)diphosphinoethane, dimer, isomers.

Résumé : On décrit la préparation de sels d'un nouveau précurseur d'un coordinat potentiellement hexadentate, les dichlorhydrates de *P,P,P′,P′*-tétrakis(*o*-hydroxyphényl)diphosphinoéthane ($H_4P_2O_4{\cdot}2HCl$). À partir du $H_4P_2O_4{\cdot}2HCl$, on a synthétisé les complexes dinucléaires du rhénium neutre $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ et dianionique $[Re_2O_2Br_4(\mu\text{-}P_2O_4)]^{2-}$. On a caractérisé les complexes par analyse élémentaire, spectroscopie infrarouge, spectrométrie de masse et spectroscopie RMN du $^1H/^{31}P\{^1H\}$. Les spectres RMN du $^{31}P\{^1H\}$ ont révélé qu'un seul isomère, probablement l'isomère *anti*, est présent dans le $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ alors que deux isomères, les deux isomères *anti* et *syn*, sont présents dans le $[Re_2O_2Br_4(\mu\text{-}P_2O_4)]^{2-}$. Les co-coordinats ($PPh_3$ du premier et Br^- du dernier) des deux complexes subissent des échanges de coordinats avec la pyridine.

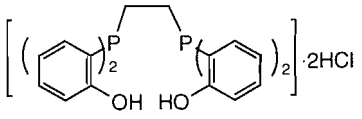
Mots clés : rhénium, *P,P,P′,P′*-tétrakis(*o*-hydroxyphényl)diphosphinoéthane, dimère, isomères.

[Traduit par la rédaction]

Introduction

The easy preparation of mixed (PO_2/HPO_2) complexes, $[MO(PO_2)(HPO_2)]$ (M = Re or Tc), from the direct interaction of a salt of bis(*o*-hydroxyphenyl)phenylphosphine ($H_2PO_2{\cdot}HCl$) with MO_4^-, suggests that this dihydroxylated phosphine is effective both as a reducing and a ligating agent, and that the combination of anchoring phenolate oxygen atoms and the softer phosphine P atoms stabilizes Re and Tc metal(V) centers (1). The ligand can both coordinate and reduce the metal center, a distinct advantage when considering potential ^{99m}Tc-radiopharmaceuticals where the only convenient source of ^{99m}Tc is $^{99m}TcO_4^-$ from a $^{99}Mo/^{99m}$Tc generator.

Deutsch and co-workers, working on Tc complexes with bidentate phosphine ligands such as DMPE, DEPE, DPPE (2, 3), showed that stable complexes of Tc in oxidation states from one to five can be formed with these ligands and auxiliary oxo or halo donor ligands. In our extended studies of functionalized phosphines, a novel, potentially hexadentate tetraprotic ligand, the dihydrochloride salt of *P,P,P′,P′*-tetrakis(*o*-hydroxyphenyl)diphosphinoethane ($H_4P_2O_4{\cdot}2HCl$) that contains two soft phosphine phosphorus donors and four hard phenolate oxygen anchors, has been synthesized. The classic hexadentate tetraprotic ligand, H_4edta, an N_2O_4 ligand, is known to form Tc complexes with such stoichiometries as $[TcO(edta)]^-$ (4) and $[Tc(\mu\text{-}O)(edta)]_2$ (5).



$H_4P_2O_4 \cdot 2HCl$

It was of interest to investigate the coordination chemistry of Tc/Re with this P_2O_4 donor set diphosphine ligand before pursuing the labeling of this ligand with ^{99m}Tc and evaluating its potential as an imaging agent. The results of the studies with Re are presented in this paper. Work with Tc is in progress and the results will be published elsewhere.

Experimental

Materials and methods

All chemicals were reagent grade and were used as received: phenol, PPh_3, dimethoxymethane, *n*-butyllithium, TMEDA (*N,N,N′N′*-tetramethylethylenediamine) (all above from Aldrich), $Cl_2PCH_2CH_2PCl_2$ (6), and NH_4ReO_4 (a gift from Johnson–Matthey, Inc.), $HCl_{(g)}$ (Matheson). $C_6H_5OCH_2OCH_3$ (mom-protected phenol) was prepared according to a published procedure (7), as was $[(n\text{-}Bu)_4N][ReOBr_4]$ (8).

Mass spectra were obtained with either a Kratos MS 50

Received December 5, 1995.

(electron impact ionization, EIMS) or a Kratos Concept II H32Q instrument (Cs^+-LSIMS with positive or negative ion detection). Only the most intense peaks are given where consistent isotopic patterns were observed. Infrared spectra were recorded as KBr pellets in the range 4000–400 cm^{-1} on a Perkin–Elmer PE 783 spectrophotometer and were referenced to polystyrene. Microanalyses were performed by Mr. P. Borda in this department. ^1H NMR spectra (300 MHz, 400 MHz, or 500 MHz) were recorded on Varian XL 300, Bruker WH-400 (^1H–^1H COSY), or Bruker AMX-500 ($^1H\{^{31}P\}$) spectrometers, respectively, with δ referenced to external TMS. $^{31}P\{^1H\}$ NMR spectra (81 MHz or 121 MHz) were recorded on Bruker AC-200E or Varian XL 300 spectrometers, respectively, with δ referenced to external H_3PO_4. The assignments were based on those for the unbound ligand and by comparison between analogous complexes.

(o-$C_6H_4OCH_2OCH_3$)$_2$$PCH_2CH_2P$($o$-$C_6H_4OCH_2OCH_3$)$_2$·0.5 H_2O ($(mom)_4P_2O_4$·0.5H_2O, mom = CH_2OCH_3)

This was prepared from $C_6H_5OCH_2OCH_3$ by modifying the procedure for $Ph_2P(o\text{-}C_6H_4\text{-}OCH_2OCH_3)$ ((mom)PO) (9). To an ice-cooled solution of methoxymethyl phenyl ether (21.8 g, 0.16 mol) in ca. 200 mL petroleum ether (bp 35–65°C, dried with anhydrous Na_2SO_4 overnight) was added a solution of 100 mL of 1.6 M n-BuLi in hexanes and 18.05 g TMEDA in 50 mL petroleum ether under N_2. The mixture was stirred for 4 h at room temperature. A yellow precipitate formed from the orange solution. This mixture was heated to ca. 40°C with stirring, and subsequently cooled to 0°C, at which point $Cl_2PCH_2CH_2PCl_2$ (9.30 g, 0.40 mol) in 20 mL petroleum ether was then added via a syringe. The mixture was stirred overnight, during which time it warmed to room temperature. The solvents were removed by rotary evaporation and to the residue was added Na_2HPO_4 (0.5 M, 200 mL). The reaction mixture was then extracted with Et_2O (2 × 200 mL) followed by $CHCl_3$ (2 × 100 mL). All the organic layers were combined, concentrated to a reddish oil under low pressure, diluted with MeOH (ca. 25 mL), and stored at −4°C overnight. A yellowish crude product was filtered off, washed with cold methanol (2 × 10 mL), and dried in vacuo. The yield of the off-white product was 11.5 g (45% based on $C_6H_5OCH_2OCH_3$). IR (cm^{-1}, KBr disk): 3060 (m, aromatic $\nu_{C\text{-}H}$); 3000–2800 (m, $\nu_{C\text{-}H}$, methyl and methylene of mom group); 1590, 1577, 1475, 1452, 1445, 1407 (all s). ^1H NMR ($CDCl_3$, 300 MHz): 7.24 (t, 4H, p-H), 7.14 (dd, 4H, o'-H), 7.03 (d, 4H, m-H), 6.91 (t, 4H, m'-H), 5.04 (s, 8H, OCH_2O), 3.17 (s, 12H, OCH_3), 2.28 (dd, 4H, backbone-CH_2). $^{31}P\{^1H\}$ NMR ($CDCl_3$, 121 MHz): −31.7 (s). Mass spectrum (EI), m/z: 638 ($[(mom)_4P_2O_4]^+$), 623 ($[(mom)_4P_2O_4 - CH_3]^+$). Anal. calcd. (found) for $C_{34}H_{41}O_{8.5}P_2$: C 63.06 (63.19), H 6.38 (6.24).

P,P,P',P'-Tetrakis(o-hydroxyphenyl)diphosphinoethane dihydrochloride salt ($H_4P_2O_4$·2HCl)

This was prepared from $(mom)_4P_2O_4$ by modifying the procedure for $Ph_2P(o\text{-}C_6H_4OH)$ or HPO (9). Anhydrous HCl gas was bubbled overnight, via a dispersion tube, into a stirred solution of $(mom)_4P_2O_4$ (7.36 g, 11.5 mmol) in 350 mL anhydrous methanol. (The white suspension dissolved to give a clear solution after 1 h, but became cloudy again overnight.) A fine white solid was removed by filtration, washed with ethanol (2 × 20 mL), and dried in vacuo. The yield was 3.95 g (74% based on $(mom)_4P_2O_4$). No recrystallization was necessary to obtain an analytically pure sample. IR (cm^{-1}, KBr disk): 3300–2500 (vs, b, $\nu_{O\text{-}H}$ and $\nu_{C\text{-}H}$); 1590, 1495, 1450 (all vs). ^1H NMR (DMSO-d_6, 300 MHz): 10.8 (br s, 4H, OH), 7.6–7.3 (overlapped multiplets, 8H), 7.0–6.8 (multiplet, 8H), 2.6 (br s, 4H, backbone-CH_2). $^{31}P\{^1H\}$ NMR (121 MHz): 43.5 (s, DMSO-d_6): −36.4 (s, py-d_5). EIMS, m/z: 462 ($[H_4P_2O_4]^+$), 368 ($[H_4P_2O_4 - C_6H_6O]^+$). Anal. calcd. (found) for $C_{26}H_{26}Cl_2O_4P_2$: C 58.33 (58.21), H 4.90 (4.84), Cl 13.24 (13.07).

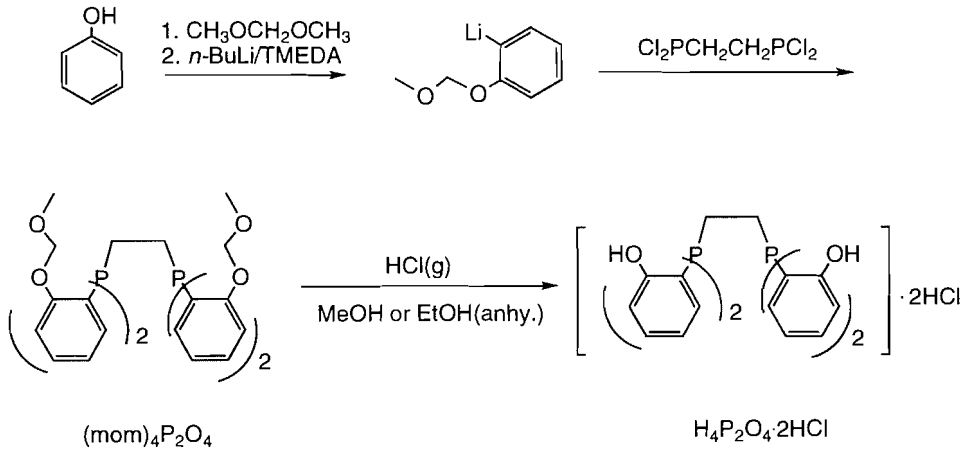
[$Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)$]

A mixture of $ReCl_4(PPh_3)_2$ (168 mg, 0.20 mmol), $H_4P_2O_4$·2HCl (109 mg, 0.20 mmol), and 8 drops of Et_3N in 15 mL ethanol was brought to reflux overnight. After the mixture was cooled to room temperature, a greenish yellow precipitate was isolated by centrifugation, washed with Et_2O, and dried in vacuo for 4 h. The yield was 40 mg (67%). The product was soluble in pyridine and DMSO (decomposes), slightly soluble in chloroform, but insoluble in diethyl ether. IR (cm^{-1}, KBr disk): 3060 (m, $\nu_{C\text{-}H}$); 1590, 1440 (both vs); 965 (s, $\nu_{Re=O}$). ^1H NMR (300 MHz, py-d_5): 7.70 (dd, 12H, o-H on PPh_3), 7.50 (dd, 2H), 7.40–7.20 (overlapped multiplets, 18H, m and p-H on PPh_3), 7.20 (d, 2H), 7.10 (d, 2H), 6.75 (m, 2H), 6.65 (t, 2H), 6.40 (t, 2H), 6.30 (t, 2H), 5.80 (dd, 2H), 2.85 (m, 2H, ethylene-H_A and -$H_{A'}$), 2.00 (d, 2H, ethylene-H_B and -$H_{B'}$). $^{31}P\{^1H\}$ NMR (81 MHz, py-d_5): 15.7, −11.3. LSIMS: m/z: 1459 ($[M + 1]^+$), 1423 ($[M - Cl]^+$), 1196 ($[M - PPh_3)]^+$), 1161 ($[M - Cl - PPh_3]^+$), 1124 ($[M - 2Cl - PPh_3]^+$), 645 ($[Re(P_2O_4)]^+$), 263 ($PPh_3 + 1$). Anal. calcd. (found) for $C_{62}H_{50}Cl_2O_6P_4Re_2$: C 51.07 (50.76), H 3.46 (3.59), Cl 4.86 (4.65).

[(n-Bu)$_4$N]$_2$[$Re_2O_2Br_4(\mu\text{-}P_2O_4)$]·$Me_2CO$

To a mixture of [(n-Bu)$_4$N][$ReOBr_4$] (77.6 mg, 0.10 mmol), [(n-Bu)$_4$N]Br (151 mg, 0.45 mmol), and $H_4P_2O_4$·2HCl (55.5 mg, 0.10 mmol) was added 20 mL toluene, and the mixture was refluxed for 2 h. From the resulting green oil, a green solid was precipitated with i-PrOH. Recrystallization from acetone gave emerald green crystals of the acetone solvate that were filtered, washed with cyclohexane, and dried in vacuo overnight. The yield was 31 mg (35%). The product was soluble in ethanol, acetone, chloroform, and dichloromethane, but insoluble in diethyl ether or cyclohexane. IR (cm^{-1}, KBr disk): 3060 (m, $\nu_{C\text{-}H}$); 2980, 2780 (s, $\nu_{C\text{-}H}$ of the n-Bu group), 960 (s, $\nu_{Re=O}$). ^1H NMR (500 MHz, acetone-d_6): 7.9–7.6 (overlapped m, 4H), 7.22 (t, ^1H), 7.16 (t, ^1H), 7.1–6.9 (overlapped m, 4H), 6.78 (t, 1H), 6.7–6.6 (overlapped m, 2H), 6.55 (t, ^1H), 6.2 (overlapped m, 2H), 4.14 (m, 2H, ethlyne-H_A and -$H_{A'}$), 3.45 (t, 16H, α-H of the n-Bu group), 2.65 (d, 2H, ethylene-H_B and -$H_{B'}$), 1.70 (quintet, 16H, β-H of the n-Bu group), 3.45 (sextet, 16H, γ-H of the n-Bu group), 0.95 (t, 24H, Me-H of the n-Bu group). $^{31}P\{^1H\}$ NMR (81 MHz, acetone-d_6): 18.0 (major); 17.0 (minor). LSIMS (+), m/z: 242 ($[(n\text{-}Bu)_4N]^+$), 645 ($[Re(P_2O_4)]^+$), 662 ($[ReO(HP_2O_4)]^+$); LSIMS (−), m/z: 645 ($[Re(P_2O_4)]^-$), 661 ($[ReO(P_2O_4)]^-$), 769 ($[ReO(P_2O_4) + 108]^-$). Anal. calcd. (found) for $C_{61}H_{98}Br_4N_2O_7P_2Re_2$: C 42.46 (42.62), H 5.72 (5.47), N 1.62 (1.71).

Scheme 1.



Results and discussion

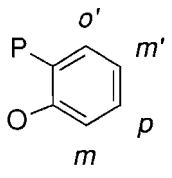
$H_4P_2O_4 \cdot 2HCl$

The new potentially hexadentate ligand $H_4P_2O_4 \cdot 2HCl$ was synthesized in a manner similar to that used to obtain the potentially tridentate $H_2PO_2 \cdot HCl$ (1). After protecting the phenol hydroxy group as a methoxymethyl (mom) ether (9), the mom-protected phenol was *ortho*-lithiated at low temperature under N_2, and 4 equivalents of it were then reacted with $Cl_2PCH_2CH_2PCl_2$ to give the mom-protected intermediate, $(mom)_4P_2O_4$. Upon treatment with anhydrous HCl gas in methanol or ethanol, the expected functionalized diphosphine was obtained as the dihydrochloride salt (Scheme 1).

For the intermediate, $(mom)_4P_2O_4$, the EIMS shows the expected parent ion peak (*m/z*: 638, $[(mom)_4P_2O_4]^+$), along with fragments formed from the parent ion by the loss of $-CH_3$, $-OCH_3$, $-CH_2OCH_3$, and $-OCH_2OCH_3$ groups. In the $^{31}P\{^1H\}$ NMR spectrum ($CDCl_3$), a singlet at -31.7 ppm, typical for a phosphine P, is present (10). The ^1H NMR spectrum shows four hydrogen resonances at 7.24, 7.14, 7.03, and 6.91 ppm in the aromatic range, corresponding to *p*-, *o'*-, *m*-, and *m'*-*H* of the phenyl ring[3] (assigned from a ^1H–^1H COSY spectrum). The resonances corresponding to methyl and methylene H atoms of the mom protecting group, appear as singlets at 5.04 and 3.17, respectively. The two methylene H nuclei in each mom group of $(mom)_2PO_2$ gave an AB quartet (1), indicating nonequivalence of the two methylene hydrogens because of prochirality. This was not the case with $(mom)_4P_2O_4$, however; the four chemically equivalent backbone H atoms give a doublet of doublets due to unequal coupling to the two P nuclei.

As was seen in $H_2PO_2 \cdot HCl$ (1), the formulation of a hydrochloride salt for its hexadentate analogue $H_4P_2O_4 \cdot 2HCl$ is supported by the elemental analysis and by the ^{31}P chemical shift, characteristic of a phosphonium P (10) at +43.5 ppm in DMSO-d_6. This salt dissociated in its ligand-exchange reactions (vide infra) and in basic solution, as is indicated by the chemical shift of -36.4 ppm in the $^{31}P\{^1H\}$ NMR spectrum in py-d_5. EIMS shows the presence of $[H_4P_2O_4]^+$. The ^1H NMR spectrum in DMSO-d_6 shows four overlapped H resonances in the aromatic region and a broad backbone H resonance at 2.6 ppm with the expected integral ratio.

[3] This is designated as in the following diagram:



Synthesis of complexes

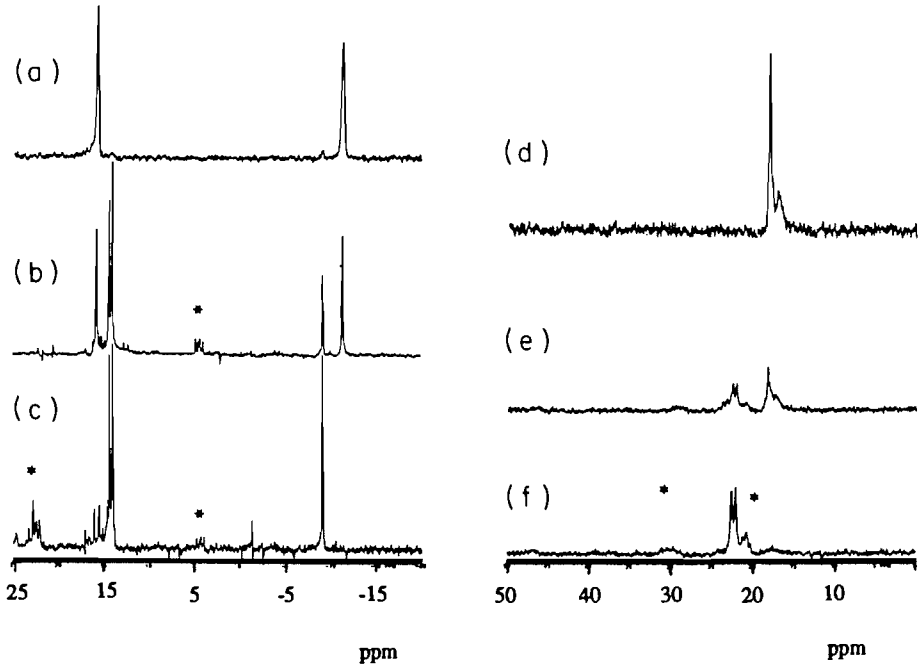
The phosphine hydrochloride salt $H_4P_2O_4 \cdot 2HCl$, when deprotonated by a base, reacted with $[ReCl_4(PPh_3)_2]$ forming a dinuclear complex $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$. Aerial oxidation was responsible for oxidizing Re(IV) to Re(V). In another trial without added base, the ligand did not react with the Re precursor; red crystals obtained from this trial were identified by X-ray crystallography as a partially oxidized mixture of *trans*-$[ReCl_4(PPh_3)_2]$ and *trans*-$[ReOCl_3(PPh_3)_2]$ (11, 12). A dinuclear dianionic complex $[Re_2O_2Br_4(\mu\text{-}P_2O_4)]^{2-}$ (as a $[(n\text{-}Bu)_4N]^+$ salt) was formed from the reaction of $[(n\text{-}Bu)_4N][ReOBr_4]$ with the ligand and added $[(n\text{-}Bu)_4N]Br$ in the absence of added base. These observations, taken together, suggest that an extra driving force is necessary to push forward the substitution reaction of $H_4P_2O_4$ with a precursor that contains PPh_3, consistent with observations reported for H_2PO_2 (1). In addition, chelation of the $P_2O_4^{4-}$ ligand to a single Re center is clearly not favored.

Both the dimetallic Re complexes are air stable in the solid state, and were characterized by elemental analysis, infrared spectroscopy, mass spectrometry, and $^1H/^{31}P\{^1H\}$ NMR spectroscopy. IR measurements confirmed the presence of Re=O multiple bonds and ensured that the multidentate ligands were coordinated as evidenced by the absorptions shifted in comparison with the free ligands. Both ^1H NMR and $^{31}P\{^1H\}$ spectra were very useful in verifying the diastereomeric structures of $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ and $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$ (vide infra).

Dinuclear (P_2O_4) Re complexes

Mass spectrometric data confirmed formation of dinuclear complexes when the expected parent ions and (or) their fragments were found, while microanalysis established the formulation of both compounds. The parent ion

Fig. 1. $^{31}P\{^1H\}$ NMR spectra (81 MHz) showing reactivity of the dinuclear complexes to pyridine (* decomposition products). (*a*) $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ in py-d_5; (*b*) *a* after standing for 6 months; (*c*) *b* after being heated to 100°C then cooled to room temperature; (*d*) $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$ in acetone-d_6; (*e*) *d* after 3 drops of py-d_5 were added; (*f*) *e* after being heated to 60°C then cooled to room temperature.



$[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4) + 1]^+$ (*m/z* = 1459) was present in the +LSIMS spectrum of $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$; however, the stronger peaks were *m/z* = 263 (PPh_3), 645 ($[Re(P_2O_4)]^+$), and 1161 ($[M - Cl - PPh_3]^+$ or $[Re_2O_2Cl(PPh_3)(\mu\text{-}P_2O_4)]^+$), indicating that the monodentate Cl^- or PPh_3 ligands were subject to dissociation from the complex under the ionization conditions. For the positive ion detection mode LSIMS spectrum of $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4]$, *m/z* = 242 ($[(n\text{-}Bu)_4N]^+$) was intense, and a much weaker peak for $[Re(P_2O_4)]^+$ was also found; in the negative ion detection mode, *m/z* = 79 (Br^-) was the most intense peak, with fragments found at *m/z* = 661 ($[ReO(P_2O_4)]^-$) and 769 ($[ReO(P_2O_4) + 108]^-$). The mass of 108 is that of the matrix, thioglycerol ($C_3H_8O_2S$). The dianionic parent ion $[Re_2O_2Br_4(\mu\text{-}P_2O_4)]^{2-}$ did not show in the negative ion mode, presumably due to a very strong interaction with the very polar matrix, thioglycerol, preventing the volatilization of the dianion.

There were similarities in the IR spectra of the two dinuclear complexes. Strong C–H stretching vibrations at 2960 and 2880 cm^{-1}, diagnostic for $[(n\text{-}Bu)_4N]^+$, were observed for $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$. Below 2000 cm^{-1}, almost all the absorptions in the spectrum of $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$ were observed in the spectrum of $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ as well. The Re=O stretches for $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$) and $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$) were found at 960 and 965 cm^{-1}, respectively, in the normal range for six-coordinate $Re^V{=}O$ complexes (13). The additional bands in $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ originated from PPh_3 bound to the Re(V) center.

A seven-coordinate complex, as formed from Tc(V) and $edta^{4-}$ (4), did not seem feasible for Re(V) with $P_2O_4^{4-}$. In $[TcO(edta)]^-$, the two neutral tertiary amine N atoms are approximately opposite the oxo ligand, the Tc—N bonds being somewhat lengthened by the *trans* influence (14). Thus, one consideration for $P_2O_4^{4-}$ is that the phosphine P atom, which is much softer than the amine N atom, will be found in *cis* positions relative to the oxo group to avoid the *trans* influence (as soft, neutral donors usually do). The phenolate rings of $P_2O_4^{4-}$ are also considerably less flexible than the carboxylate arms of $edta^{4-}$.

The $^{31}P\{^1H\}$ NMR spectrum of $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ showed two peaks of equal intensity, diagnostic for two nonequivalent phosphorus centers (Fig. 1*a*). This suggested that the two $\mu\text{-}P_2O_4^{4-}$ P nuclei were equivalent, as were the two PPh_3 P nuclei. Consistent with this, in the ^1H NMR spectrum (Fig. 2) there were eight types of aromatic hydrogen nuclei for the PO-phenyl rings of the complex, indicating that the four phenolate rings of the $\mu\text{-}P_2O_4^{4-}$ ligand were in two different environments, each including two equivalent rings. In this aromatic region, a doublet of doublets (7.70 ppm, *o*-H) and overlapped multiplets (~7.3 ppm, *m*-H and *p*-H) were also present, corresponding to the phenyl H nuclei of PPh_3 (Fig. 2). The four H and two P nuclei on the ethylene backbone form an AA′BB′XX′ spin system (one per diastereomer) because of chirality at the metal centre (Fig. 3, *anti*). The *syn* diastereomer was not present for this neutral dinuclear complex (vide infra). The appearance of two resonances (one triplet-like, the other doublet-like) corresponding to the H_A and H_B nuclei was complicated because of multiple couplings.

For $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$, two peaks were observed in the $^31P\{^1H\}$ spectrum, one major and one minor, at 18.0 and 17.0 ppm, respectively (Fig. 1*d*). In the ^1H NMR spectrum, there were more than eight signals for the PO-phe-

Fig. 2. ^{1}H NMR spectra of $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ (top, in py-d_5, 300 MHz) and $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$ (bottom, in acetone-d_6, 400 MHz), (# solvent or HOD; * impurity).

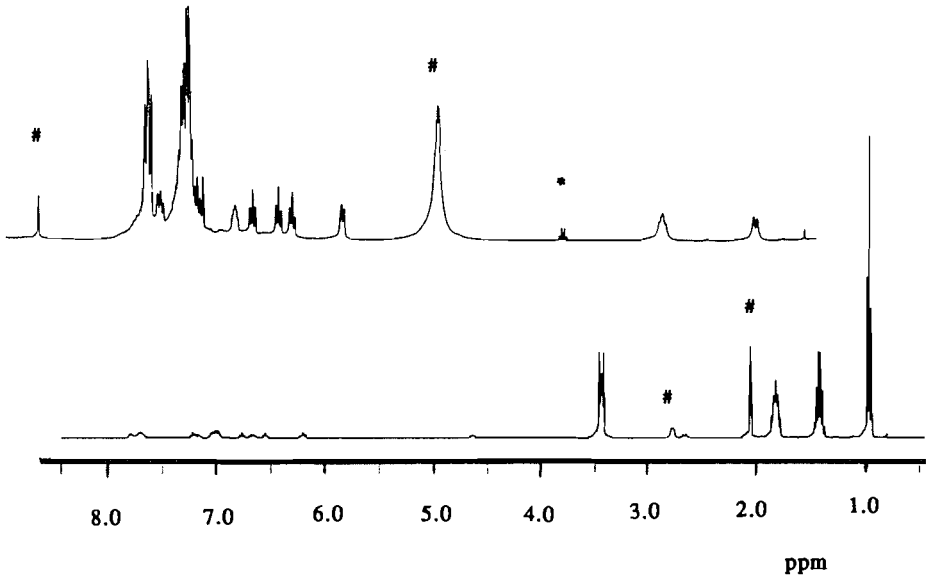


Fig. 3. Diastereomers of the dinuclear complexes showing the AA'BB'XX' system of the backbone (4H, 2P) in each.

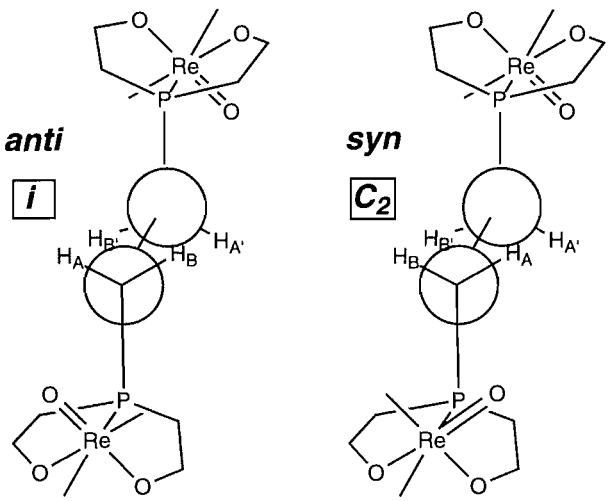
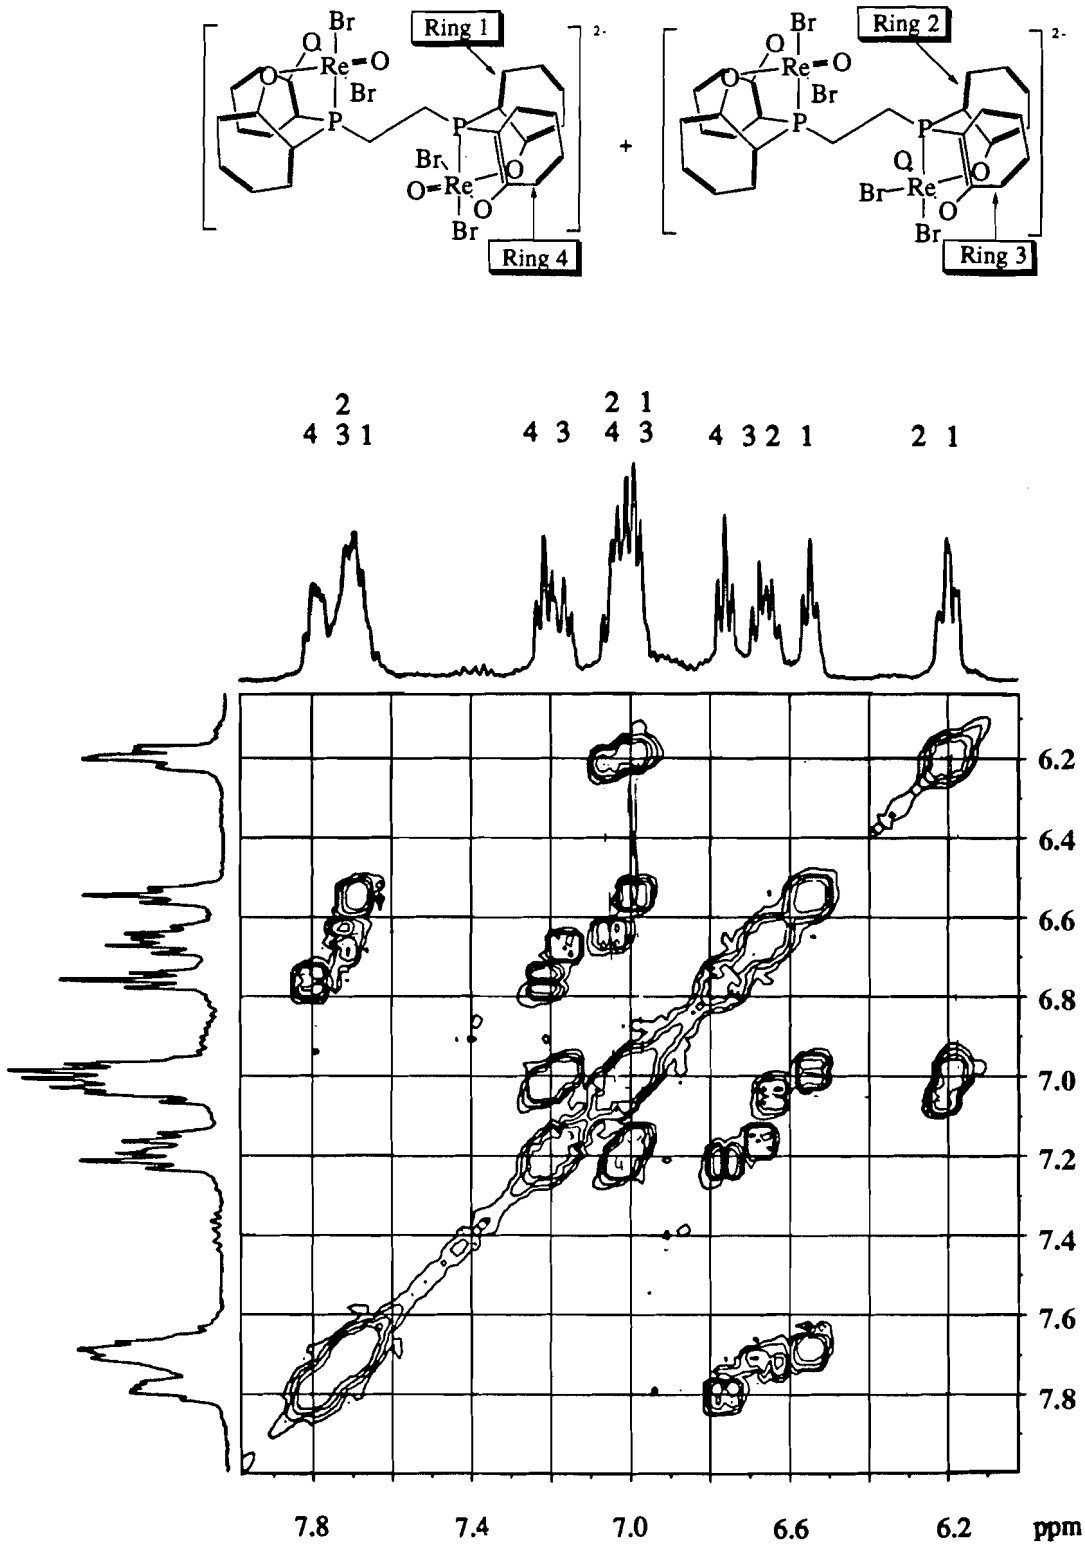


nyl rings in the complex (Fig. 2). In fact, 16 H signals (some of them overlapped) in the aromatic region (6.0–8.0 ppm) were correlated into four groups by a ^{1}H-^{1}H COSY experiment (Fig. 4), indicating that there were four PO-phenyl ring environments (numbered ring 1 to ring 4 as shown in Fig. 4). The H resonances corresponding to the *o'*-H of the four PO-phenyl rings were identified in the ^{1}H{^{31}P} NMR spectrum (each simplified from a multiplet to a doublet upon decoupling as shown in Fig. 5). The ^{1}H NMR signals corresponding to rings 1 and 4 were stronger in intensity than those of rings 2 and 3, and the ^{31}P NMR signal at 18.0 ppm was more intense than that at 17.0 ppm. Taken together, these data indicate that there are one major and one minor isomer present in the $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$ sample. In the ^{13}C{^{1}H} NMR spectrum, only eight signals were observed in the aromatic region, tentatively assigned to the major isomer eight PO-phenyl ring carbon atoms that had hydrogen atoms attached; those of the minor isomer, and quaternary carbons in both isomers, were not observed because the sample was too dilute. For the ethylene H nuclei, a similar AA'BB'XX' spin system was observed for $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$, and H_A and H_B were found to be coupled strongly to each other. The chemical shifts for the C_2H_4 ethylene H nuclei of the backbone of each isomer coincide since only two resonances are present. Upon phosphorus decoupling, both H_A and H_B signals appeared as doublets.

Two models, *anti* (*i*) and *syn* (C_2), proposed for the dinuclear complexes are shown in Fig. 3. Assumptions with adequate precedent have been used to formulate these models: neutral P donor(s) are *cis* to the Re=O, and the PO_2 donor set of each end of $P_2O_4^{4-}$ is facially coordinated. Both assumptions are based on the coordination of PO_2^{2-} in *fac*-$[ReZCl(PPh_3)(PO_2)]$ (Z = O or NPh) (1). In fact, P *trans* to M=O, M≡N, or M=NR has not been observed for complexes of this type (M = Re or Tc) incorporating phosphine (11, 15–22) or functionalized phosphine (1, 23, 24) ligands; the P donors are always *cis*.

The two models can be described as *syn* and *anti* with respect to the two Re=O groups, and they have C_2 and *i* symmetry, respectively (Fig. 3). With aid of a 3-D model, it is easy to reason why there is only one isomer for $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$, while there are two isomers for $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$, as shown in the ^{31}P NMR spectra (Figs. 1*a* and 1*d*, respectively). $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ exists presumably as the *anti* isomer (*i* symmetry); the *syn* isomer is not feasible because of the two bulky PPh_3 groups. For this complex, a proposal with the two P donors *trans* to each other can also be rejected because the mutual P–P coupling is quite small. Either arrangement with the two P donors *trans* or *cis* to each other is possible based on modeling and has actually been observed for the complexes *fac*-$[ReZCl(PPh_3)(PO_2)]$ (Z = O or NPh) (1). In modeling $[Re_2O_2Br_4(\mu\text{-}P_2O_4)]^{2-}$, both *syn* and *anti* isomers are found to

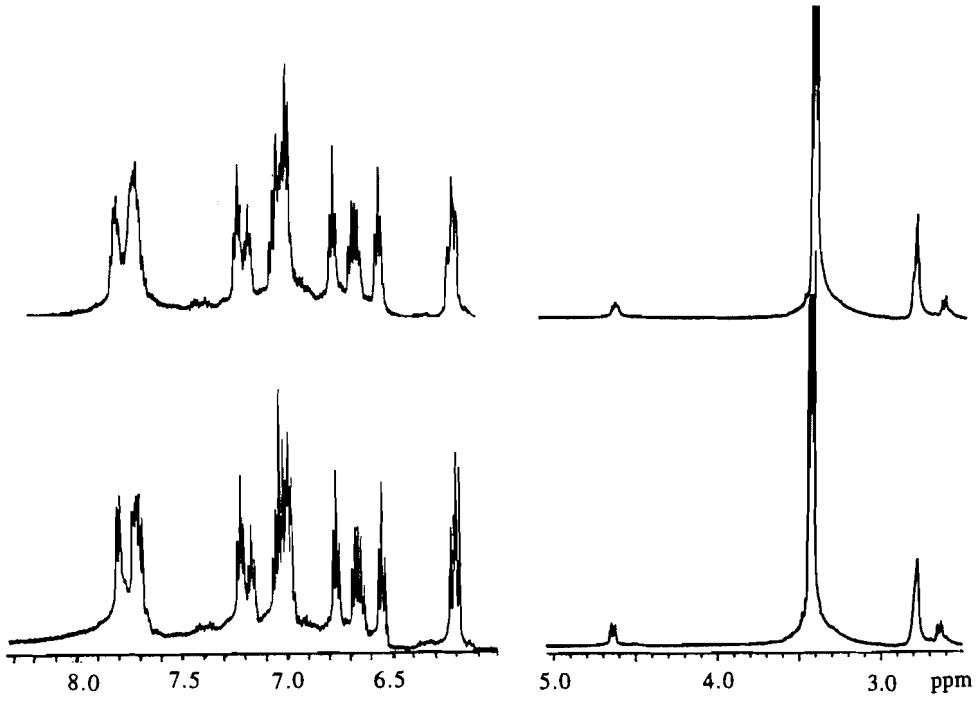
Fig. 4. The proposed isomers and the ^1H–^1H COSY spectrum (400 MHz) of $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$ (aromatic region); the correlated H resonances are designated by the same number as the respective PO phenyl ring.



be feasible as Br^- is much less bulky, and this might be the case as indicated by the NMR results.

The two P signals at 15.7 and −11.3 ppm in the $^{31}P\{^1H\}$ NMR spectrum (Fig. 1*a*) for $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ are assigned to the P nuclei of the $\mu\text{-}P_2O_4^{4-}$ and PPh_3 ligands, respectively. Phenolato-anchored phosphine P nuclei experience a greater deshielding effect than the PPh_3 ligand in such complexes as $[ReZCl(PO_2)(PPh_3)]$ (Z = O or NPh) (1), due to

Fig. 5. ^1H (top) and $^1H\{^{31}P\}$ (bottom) NMR spectra (500 MHz) of $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$ (aromatic and ethylene regions).



stronger donation (25). This $\mu\text{-}P_2O_4^{4-}$ P chemical shift was found to be quite close to that of $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$, at 18.0 (major) and 17.0 (minor) ppm (Fig. 1*d*). Further support for this assignment is depicted by Fig. 1*c*, where the PPh_3 P signal is identified by its replacement with py-d_5.

Reactivity with pyridine

The replacement of PPh_3 in $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ with pyridine (py-d_5) was monitored in the $^{31}P\{^1H\}$ NMR spectrum by the appearance of a free PPh_3 singlet at −9.1 ppm, and by the decrease in intensity of the upfield P signal (−11.3 ppm, bound PPh_3) in the original spectrum (Fig. 1*c*). The substitution is very slow (Fig. 1*b*); however, after the solution was heated to 100°C and then cooled to room temperature, the substitution was complete, at which time the bound PPh_3 P signal (−11.3 ppm) disappeared completely, and the downfield P signal (15.7 ppm) was replaced by two singlets (14.3 and 14.0 ppm). Clearly, the PPh_3 ligands in the complex are labile and the assignment of the bound PPh_3 in the original $^{31}P\{^1H\}$ NMR spectrum is verified. No attempt was made to fully characterize the new complex formed with pyridine; however, *syn* and *anti* isomers would be consistent with the appearance of the two singlets at 14.3 and 14.0 ppm.

Pyridine (py-d_5, 3 drops) was added to $[(n\text{-}Bu)_4N]_2[Re_2O_2Br_4(\mu\text{-}P_2O_4)]$ in acetone-d_6. Changes in the ^{31}P resonances were also observed in the $^{31}P\{^1H\}$ NMR spectrum: the original peaks were reduced in intensity, while two new singlets appeared (Fig. 1*e*). After heating to 60°C for 10 min and then cooling to room temperature (the solution changed to yellowish green from the original emerald green), these spectral changes were complete, whereupon the original P signals (18.0 and 17.0 ppm) disappeared completely, giving rise to two singlets at 22.1 and 22.6 ppm (Fig. 1*f*). The dianionic complex is also labile to substitution. Again, similar *syn* and *anti* isomers would be consistent with the substituted products.

Conclusion

The hydrochloride salt of a new ligand, the potentially hexadentate and tetraprotic $H_4P_2O_4{\cdot}2HCl$, was synthesized and characterized. With this salt, neutral $[Re_2O_2Cl_2(PPh_3)_2(\mu\text{-}P_2O_4)]$ and dianionic $[Re_2O_2Br_4(\mu\text{-}P_2O_4)]^{2-}$ dinuclear rhenium(V) complexes were synthesized and characterized. The rigidity of the ligand frame and (or) *trans* influence make it impossible for all the donor atoms to bind a single $Re^V{=}O$ centre. However, this ligand can bridge two Re(V) centers, incorporating monodentate oxo, chloro, and PPh_3 ligands to complete the coordination sphere of each Re(V). These complexes are important since they provide useful information about the coordination preference of the $P_2O_4^{4-}$ ligand. Work on the $^{99}Tc/^{99m}Tc$ complex of this ligand and its radiopharmaceutical chemistry is in progress.

Acknowledgments

We wish to thank the Natural Sciences and Engineering Research Council of Canada, the British Columbia Health Research Foundation, and the Du Pont Merck Pharmaceutical Company for operating grants, Johnson Matthey, Inc. for NH_4ReO_4, and Mr. G. Clentsmith and Professor M. D. Fryzuk for a sample of $Cl_2PCH_2CH_2PCl_2$.

An unusual fatty acid and its glyceride from the marine fungus *Microsphaeropis olivacea*[1]

Chao-Mei Yu, Jonathan M. Curtis, Jeffrey L.C. Wright, Stephen W. Ayer, and Ziba R. Fathi-Afshar

Abstract: Two new metabolites (**1** and **2**) were isolated from the marine fungus *Microsphaeropsis olivacea*. The structures were elucidated, through analysis of the spectroscopic data, as an unusual methyl-branched unsaturated fatty acid, 10-methyl-9*Z*-octadecenoic acid (**1**), and the glyceride (**2**). The locations of the double bond and the methyl branching were determined from the electron impact (EI) mass spectrum of the picolinyl derivative of **1** and from MS/MS data on the hydrogenation products of **1** and **2**.

Key words: *Microsphaeropsis olivacea*, marine fungus, methyl-branched unsaturated fatty acid, picolinyl ester.

Résumé : On a isolé deux nouveaux métabolites (**1** et **2**) à partir du champignon marin *Microsphaeropsis olivacea*. Faisant appel à des données spectroscopiques, on a établi que les structures sont associées à un acide gras insaturé portant un méthyle comme chaîne latérale, l'acide 10-méthyloctadéc-9*Z*-ènoïque (**1**) et de son glycéride (**2**). Les positions des doubles liaisons et de la ramification méthyle ont été déterminées par spectrométrie de masse par impact électronique sur le dérivé pinacolyle du composé **1** et par des données de SM/SM sur les produits d'hydrogénation des composés **1** et **2**.

Mots clés : *Microsphaeropsis olivacea*, champignons marins, acide gras insaturé portant une ramification méthyle.

[Traduit par la rédaction]

Introduction

Terrestrial microorganisms have long been a traditional source of biologically active metabolites but, after extensive studies, it is increasingly difficult to discover new bioactive agents from this source. In contrast, marine microorganisms are attracting more attention as sources of novel bioactive compounds. These ocean-life forms likely evolved different physiological and biosynthetic capabilities to survive in the unique marine environment at increased salinity and pressure, variable temperatures, and different nutrient compositions. Such capabilities may result in the production of metabolites not found previously in terrestrial microorganisms (1).

Our search for new pharmaceutical-lead compounds from marine microbes led us to investigate the metabolites of the marine fungus *Microsphaeropsis olivacea* (strain SF-10), isolated from a Florida sponge, and to the discovery of a new methyl-branched and unsaturated fatty acid (**1**) and its monoglyceride (**2**) (Fig. 1). In this paper, we describe the production, isolation and structure elucidation of **1** and **2** through their chemical and spectroscopic analyses.

Results and discussion

Metabolite **1**, a colorless oily compound, was isolated from the EtOAc extract of the culture filtrate of *M. olivacea*. The molecular formula of $C_{19}H_{36}O_2$ was determined from the high-resolution EI mass spectrum. The ^{1}H NMR spectrum indicated that this compound is an unsaturated linear fatty acid, but the unusual structural feature of an olefinic methyl branch (δ_H 1.65, d, 1.2 Hz) encouraged us to complete the structural elucidation. The multiplicity of the individual carbons was obtained by ^{13}C NMR data (Table 1) and DEPT experiments, indicating 1 terminal methyl group, 1 olefinic methyl group, a trisubstituted double bond (thereby implying the branching position of the olefinic methyl group), 14 methylene groups, and a carboxyl carbon (δ_C 178.11) that was supported by a characteristic infrared absorption at 1733 cm^{-1}. The HMQC experiment showed connectivities between the carbons and protons with the exception of C-4–C-7 and C-13–C-17. This is due to the extensive overlaps of the methylene proton resonances in the range δ 1.29–1.31, which correspond to 18 protons.

In the ^{1}H–^{1}H COSY spectrum, the resonance at δ 2.26 was assigned to the methylene protons H_2-2 adjacent to the carboxyl group, based on chemical shift considerations and supported by the long-range C/H correlation with C-1 in the HMBC experiment. This methylene group was also coupled with H_2-3 (δ 1.59), which in turn was coupled with other methylene groups (δ 1.29–1.31) indicating the connectivity of CH_2-2/CH_2-3/other CH_2 groups. In the HMBC experiment the methylene protons at H_2-2 and H_2-3 were observed to have $^3J_{CH}$ correlation with two methylene carbons C-4 (δ 30.29) and C-5 (δ 30.37), respectively, which established the partial

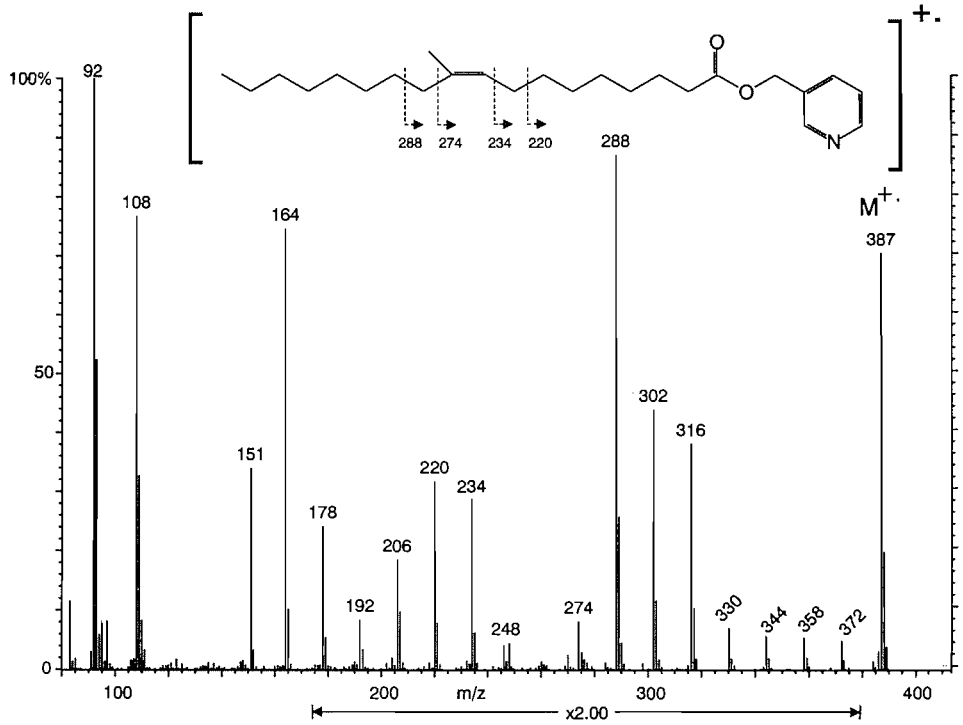
[a]Assigned from the HMBC spectrum.

structure -$CH_2CH_2CH_2CH_2COOH$ and the assignments of C-4 and C-5.

From further interpretation of the ^1H–^1H COSY data, it was found that an olefinic methine proton H-9 (δ 5.11) showed adjacent coupling with H_2-8 (δ 1.97) and allylic couplings with the olefinic methyl group H_3-19 (δ 1.65) as well as H_2-11 (δ 2.01). Each of H_2-8 and H_2-11 was further coupled with other methylene groups of the long hydrocarbon chain at δ 1.29–1.31. The HMBC between C-7/H_2-8, C-10/H_2-8, C-9/H_2-11, C-9/H_3-19, C-10/H_2-11, C19/H_2-11, and C-12/H_2-11 helped in the assignment of C-7, and provided further support for the observed ^1H–^1H COSY correlations and determined the partial structure -$CH_2CH_2C(CH_3)$=$CHCH_2CH_2$-.

The final partial structure of $CH_3CH_2CH_2$- was identified from the HMBC from both C-16 (δ 33.08) and C-17 (δ 23.75) to the terminal methyl group H_3-18 (δ 0.89). Therefore, the combined NMR data led to a structural formula of **1** as $CH_3CH_2CH_2(CH_2)_nCH_2CH_2(CH_3)C$=$CHCH_2CH_2(CH_2)_mC$ $H_2CH_2CH_2CH_2COOH$ where n and m could not be determined from the NMR data alone.

Fig. 2. The low-resolution EI mass spectrum of **3** from GC/MS analysis.

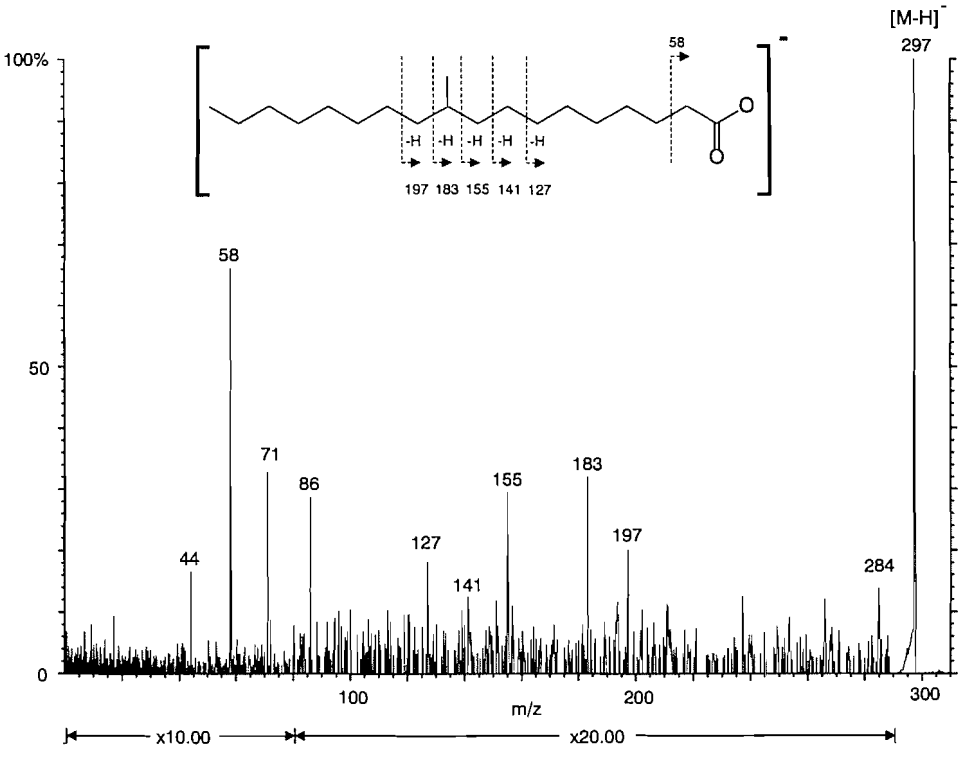


The major difficulties usually encountered in the structure elucidation of long-chain fatty acids by NMR involve the determination of the positions of methyl branching and double bonds. However, location of the double bonds and methyl branching in long-chain fatty acids can be achieved via EIMS analysis of derivatives that strongly localize the charge, for example, on a pyridine ring (2). In this case, the 3-picolinyl ester (**3**) of **1** was prepared (3), and GC/MS analysis of **3** showed the expected molecular ion at *m/z* 387 (Fig. 2). It was anticipated that a diagnostic difference of 40 mass units, corresponding to the trisubstituted double bond -(CH_3)C=CH-, would be found between adjacent ions in the series of charge-remote fragmentations (2). In general, the fragment ions corresponding to vinylic cleavages are of relatively low intensity whereas those due to cleavage at the allylic positions are more intense (2). Furthermore, an enhancement in fragment ion intensity for cleavage at the allylic position on the distal side of the double bond is expected (4). This behavior is clearly seen for **3** in Fig. 2 where the difference of 40 mass units between *m/z* 234 and 274 establishes the location of the double bond. In addition, the enhanced intensity of the peak at *m/z* 288, due to fragmentation at the allylic position, confirms that the weaker peak at *m/z* 274 is indeed due to fragmentation adjacent to the double bond.

Thus, the GC/MS analysis of the 3-picolinyl ester of **1** unambiguously assigned the position of the double bond as Δ^9. However, the data cannot distinguish between a branching position for the methyl group at either C-9 or C-10. To establish this, it was necessary to reduce **1** to the methyl-branched saturated derivative **4**. As previously reported (5), under appropriate conditions for collision-induced decomposition, molecular carboxylate anions of such saturated fatty acids undergo charge-site-remote fragmentations (in an analogous manner to picolinyl ester derivatives of fatty acids in the positive ion mode), resulting in a series of fragment ions characteristic of the alkyl chain. Thus, from the electrospray MS/MS spectrum (Fig. 3) of the $[M - H]^-$ ion of **4** at *m/z* 297, the position of methyl branching was determined by a mass difference of 28 (-$CH(CH_3)$-) rather than 14 (-CH_2-) between the adjacent fragment ions *m/z* 183 and *m/z* 155, proving that the methyl branch is at C-10.

Metabolite **2** was isolated from the CH_2Cl_2 extract from mycelium of *M. olivacea* as a colorless oily compound. The ^1H and ^{13}C NMR data (Table 1) showed signals almost identical with those of **1** except for the additional characteristic signals of a glycerol moiety (H_2-1′: 4.05 (dd), 4.13 (dd); H-2′: 3.80 (m) and H_2-3′: 3.54 (dd), 3.55 (dd)). This suggested that **2** was the glyceride ester of **1**. Further support for this hypothesis was provided by the high-resolution EI mass spectrum, which indicated the expected molecular formula of $C_{22}H_{42}O_4$ plus accurate mass measurement for the fragment ion at *m/z* 278 measured as the formula $C_{19}H_{34}O$ corresponding to the loss of a glycerol molecule. Analysis of **2** by electrospray mass spectrometry in the positive ion mode gave major peaks at *m/z* 371 (MH^+), 393 ($[M + Na]^+$), and 353 ($[MH - H_2O]^+$). The MS/MS spectrum of the MH^+ ion (Fig. 4*a*) shows a major fragment ion at *m/z* 279, once again due to loss of a glycerol moiety, plus a minor fragment at *m/z* 297, which is the protonated fatty acid. The position of the substituted double bond is recognized as Δ^9, the same as that of **1**, from the MS/MS spectrum of the $[M + Na]^+$ ion (Fig. 4*b*). The observed series of charge-remote fragment ions from *m/z* 378 down to *m/z* 294 are due to losses of increasingly large neutral fragments incorporating varying numbers of methylene groups, and the 68 mass unit difference between *m/z* 294 and 226 indicated cleavage at the allylic positions. Interestingly, there is a change in

Fig. 3. The negative ion electrospray MS/MS spectrum of the $[M - H]^-$ ion of **4**.



the dominant fragmentation mode, from simple radical cleavage giving rise to the series from *m/z* 294 to 378 to one involving loss of a hydrogen to give the fragment ions at *m/z* 225, 197, 183, and 169. The position of the methyl branch in **2** was verified by the preparation of the hydrogenation product (**5**) (Fig. 1) and subsequent MS analysis. This gave an $[M - H]^-$ ion at *m/z* 371 in the negative ion electrospray mass spectrum. The MS/MS fragmentation of this ion exhibited only one fragment ion at *m/z* 297, which is the stable carboxylate anion formed by loss of the glyceride moiety. The MS/MS spectrum of this fragment ion at *m/z* 297 (which was present in the electrospray mass spectrum of **5**) shows fragmentation identical to that of **4** (Fig. 3), confirming that the methyl group is located at C-10.

The stereochemistry of the double bond in **1** and **2** was established as *Z* configuration from the NOESY spectrum, which showed the through-space correlations between H_3-19 and H-9, H_3-19 and H_2-12, and between H-9 and H_2-7. Based on these combined data, the structures of 10-methyl-9*Z*-octadecenoic acid and 2,3-dihydroxypropyl-10-methyl-9*Z*-octadecenate were assigned to **1** and **2** respectively (Fig. 1).

Different fatty acids possessing an olefinic methyl branch, such as 7-methyl-7-hexadecenoic acid and 7-methyl-6*E*-hexadecenoic acid, have been reported from whale oil (6) and sponge (7), respectively. To our knowledge, **1** and **2** are the first examples of fungal fatty acids having a methyl branch on a *cis*- double bond. Branched methyls can be introduced in fatty acids through the addition of C_1 units, such as *S*-adenosyl methionine, or by introduction of an isoprenoid unit. This fatty acid probably arose through the former biosynthetic pathway.

Experimental

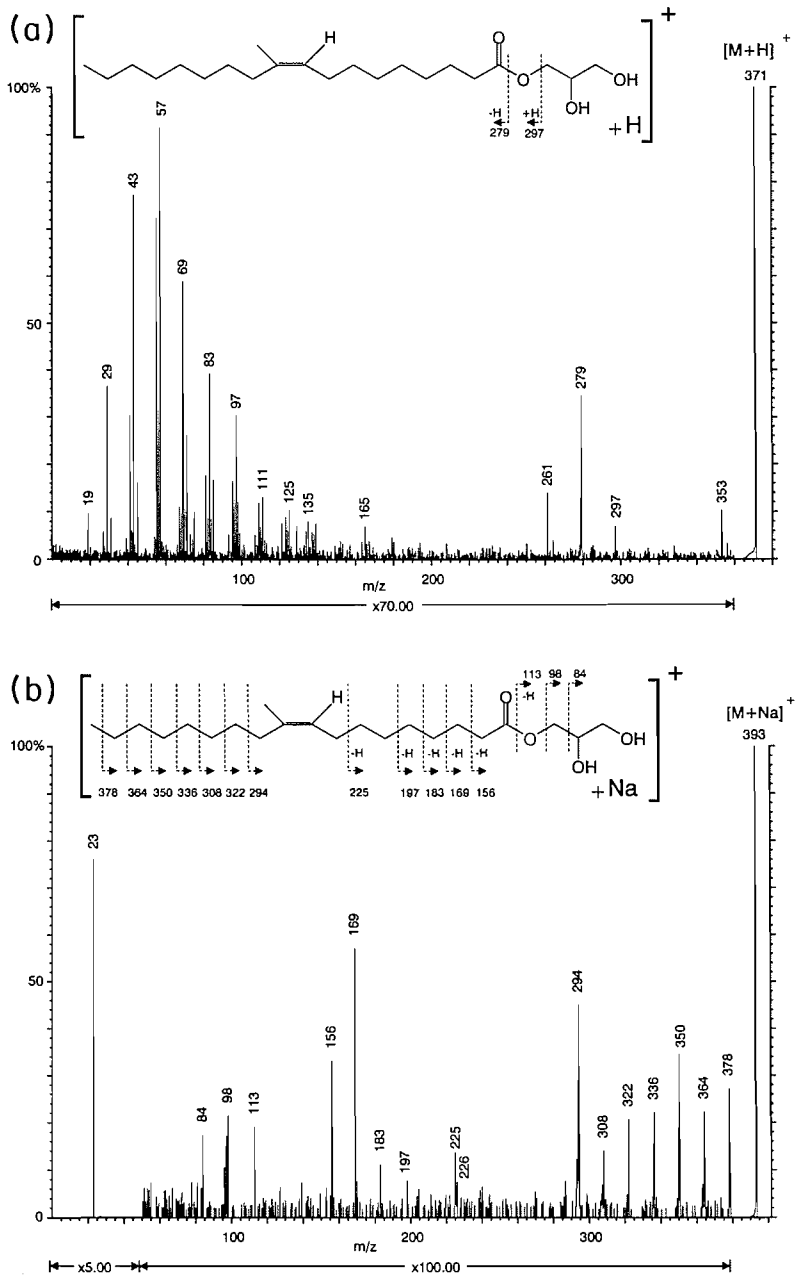
General experimental procedures

NMR spectra were recorded in CD_3OD using a Bruker AMX 500 spectrometer equipped with a Bruker X-32 computer using UXNMR software. Chemical shifts are expressed relative to internal standard (CD_3OD: δ_H 3.30 ppm, δ_C 49.00 ppm). The IR spectrum was measured using a Bomem FT-IR spectrometer (model DA3.02) using a solid film of sample deposited on an AgCl window, and the UV spectrum was obtained using a Hewlett–Packard 1090 HPLC equipped with diode array detector. All EIMS experiments (GC/MS and high-resolution EI) were performed using a VG Organic ZAB-EQ mass spectrometer. GC/MS analysis was carried out on a Hewlett–Packard 5890 Series II GC with a J & W DB225 GC column (30 m × 0.25 mm i.d., 0.25 mm phase thickness). All electrospray and MS/MS experiments were performed using a VG Organic AutoSpec-oaTOF hybrid double-focusing orthogonal acceleration time-of-flight mass spectrometer. MS/MS experiments used a collision energy of 400 eV and Xe collision gas. 3-Pyridylcarbinol was purchased from Aldrich Chemical Company, Milwaukee, Wis.

Fermentation

The producing microorganism identified as *Microsphaeropsis olivacea* was isolated from a marine sponge, *Agelus sp.*, collected off Sombrero Key East, Florida. One loopful of a culture of *M. olivacea* (strain F-10) from an agar slant was used to inoculate five 500-mL Erlenmeyer flasks, each containing media (100 mL) composed of 2.5% glucose and 2.5% pharma-

Fig. 4. The positive ion electrospray MS/MS spectra of **2**: (*a*) $[M + H]^+$, (*b*) $[M + Na]^+$.



media, and incubated on a rotary shaker (210 rpm) for 3 days at 25°C. The broth (5 mL) of this seed culture was inoculated into each of 60 500-mL Erlenmeyer flasks containing production medium (100 mL) composed of 2% molasses, 3% dextrin, 1.5% fish meal, and 1.5% pharmamedia. The fermentation was carried out under the same conditions for 7 days. The culture broth was filtered, respectively, through a cloth filter and a Millipore filter with pore size of 0.8–8.0 μm. The mycelium was lyophilized for the extraction.

Extraction and isolation

*Isolation of **1** from the EtOAc extract of the culture filtrate*
The crude extract (650 mg) was subjected to reversed phase flash column chromatography on Bakerbond® C-18 eluting with an increasing step gradient of methanol in H_2O (60–100%). The fraction eluted with 95% MeOH was rechromatographed on Bakerbond® C-18 eluting with 85% acetonitrile in H_2O. Final purification of **1** was achieved using normal phase flash column chromatography (Merck silica gel 60) and elution with CH_2Cl_2/MeOH (9.3:0.7) to yield 7 mg of **1**.

*Isolation of **2** from the CH_2Cl_2 extract of the mycelia*
This extract (6 g) was obtained through partition of the MeOH extract of the mycelia between H_2O and CH_2Cl_2. It was subjected to flash column chromatography on Merck LiChroprep® RP-18 with gradient elution of MeOH in H_2O (25–100%), and then with MeOH and CH_2Cl_2 (1:1). The fraction

eluted by MeOH was fractionated by a flash column on Bakerbond® C-18 using acetonitrile/H_2O gradient (50–100%). The fraction eluted with 80% acetonitrile was further purified through a flash column on Merck silica gel 60 using hexane and EtOAc (2:3). The fraction containing mainly **2** was finally purified by a flash column on Bakerbond® C-18 eluting with 95% MeOH, to obtain 7.4 mg of the pure metabolite **2**.

Metabolite 1: A colorless oil; R_f value 0.16, TLC on Merck silica gel precoated plate in CH_2Cl_2–MeOH (9.5:0.5); UV (MeOH) λ_{max}: 210 nm; IR (film) cm^{-1}: 3448, 2930, 2858, 1733, 1458. HREIMS, $C_{19}H_{36}O_2$ ($M^{+\bullet}$) *m/z*: 296.2703 (+ΔM 1.2 mmu). ^1H and ^{13}C NMR spectral data are given in Table 1.

Picolinyl derivatization of 1: A small quantity of **1** (0.33 mg) in a 1.0 mL Reacti-Vial™ was treated with 175 μL of thionyl chloride at 100°C for 10 min. The reaction solution was blown down to dryness with a N_2 stream, and then treated with 165 μL of 20% 3-pyridylcarbinol in acetonitrile. The mixture was reacted for 1 min at 100°C. The reaction product (**3**) was identified by GC/MS analysis, *m/z* 387 ($M^{+\bullet}$) and fragment ions shown in Fig. 2.

Hydrogenation of 1: 0.25 mg of **1** was hydrogenated in MeOH over a catalytic amount of PtO_2. The hydrogenation product (**4**) was directly analysed by negative ion electrospray MS: *m/z*: 297 ($[M - H]^-$) and fragment ions shown in Fig. 3.

Metabolite 2: A colorless oil; R_f value 0.23, TLC on Merck silica gel precoated plate in CH_2Cl_2–MeOH (9.5:0.5); UV (MeOH) λ_{max}: 210 nm; IR (film) cm^{-1}: 3400, 2925, 2855, 1740, 1458. HREIMS, $C_{22}H_{42}O_4$ ($M^{+\bullet}$) *m/z*: 370.3085 (ΔM –0.2 mmu), $C_{19}H_{34}O$ $[(M - C_3H_8O_3)^{+\bullet}]$ *m/z* 278.2612 (ΔM –0.3 mmu). Positive ion electrospray MS gave *m/z* 371 (MH^+), 393 ($[M + Na]^+$), and 353 ($[MH - H_2O]^+$). The MS/MS spectra of *m/z* 371 and 393 are shown in Fig. 4. ^1H and ^{13}C NMR spectral data are given in Table 1.

Hydrogenation of 2: 0.50 mg of **2** was hydrogenated in MeOH over a catalytic amount of PtO_2. The hydrogenation product (**5**) was directly analysed by negative ion electrospray, MS *m/z* (%): 371 ($[M - H]^-$, 100), 297 (23). The MS/MS spectrum of the fragment ion *m/z* 297 is virtually identical to that given as Fig. 3 for M^- of **4**.

Dissociation constants of host–guest complexes of alkyl-bearing compounds with β-cyclodextrin and "hydroxypropyl-β-cyclodextrin"

Oswald S. Tee, Timothy A. Gadosy, and Javier B. Giorgi

Abstract: Dissociation constants (K_d) of host–guest complexes formed from β-cyclodextrin or "hydroxypropyl-β-cyclodextrin" (β-CD and Hp-β-CD) and several types of aliphatic guests (alcohols, alkanesulfonate ions, alkylamines, and α-amino acids), with up to eight carbons in a chain, are reported. These constants were determined by inhibition kinetics and by a spectrofluorometric displacement method based on competition with 1-anilino-8-naphthalenesulfonate ion as a fluorescent probe. The value of K_d for a particular amine is close to that for the corresponding alcohol. For linear alkyl derivatives, there are strong correlations between pK_d ($= -\log K_d$) and the chain length of the guest, with slopes around 0.5, complementing trends that were noted earlier. Furthermore, the strengths of binding of various aliphatic derivatives to β-CD and to Hp-β-CD are close, with K_d values for the two CDs usually being within a factor of 2 of each other. Overall, for the binding of over 50 alkyl-bearing derivatives, there is a good correlation of pK_d for Hp-β-CD with that for β-CD, with unit slope. These observations imply that the binding of simple aliphatic guests to Hp-β-CD is not greatly influenced by the modification of the hydroxyl groups on the primary side of the β-CD cavity but this may not be true for longer aliphatic derivatives ($>C_8$) or for aromatics that penetrate farther into the CD cavity.

Key words: cyclodextrins, host–guest complexes, dissociation constants.

Résumé : On a mesuré les constantes de dissociation (K_d) de complexes hôte–invité formés à partir de β-cyclodextrines ou d'«hydroxypropyl-β-cyclodextrine» (β-CD et Hp-β-CD) et plusieurs types d'invités aliphatiques (alcools, ions alcanesulfonates, alkylamines et acides α-aminés) comportant jusqu'à huit atomes de carbone. On a déterminé ces constantes par l'inhibition de la cinétique et par une méthode de déplacement spectrofluorométrique qui est basée sur une compétition avec l'ion 1-anilino-8-naphtalènesulfonate comme sonde fluorescente. La valeur du K_d pour une amine donnée est très proche de la valeur pour l'alcool correspondant. Pour les dérivés alkyles linéaires, il existe une forte corrélation entre le pK_d ($= -\log K_d$) et la longueur de la chaîne de l'invité; les pentes de 0,5 sont un complément aux tendances notées antérieurement. De plus, les forces de liaison de divers dérivés aliphatiques à la β-CD et à la Hp-β-CD sont très semblables; les valeurs de K_d pour les deux CD sont généralement à l'intérieur d'un facteur de deux l'une par rapport à l'autre. Dans l'ensemble, pour la liaison de plus de 50 dérivés portant des groupes alkyles, il existe une bonne corrélation entre le pK_d de la Hp-β-CD et celui de la β-CD et la pente est égale à l'unité. Ces observations impliquent que la liaison d'invités aliphatiques simples à la Hp-β-CD n'est pas beaucoup influencée par la modification des groupes hydroxyles sur le côté primaire de la cavité de la β-CD; ceci n'est toutefois pas vrai avec les dérivés comportant des chaînes aliphatiques plus longues ($>C_8$) ou pour les dérivés aromatiques qui pénètrent plus dans la cavité de la CD.

Mots clés : cyclodextrines, complexes hôte–invité, constantes de dissociation.

[Traduit par la rédaction]

Introduction

A key feature of Supramolecular Chemistry is non-covalent binding between the constituents of supermolecules (1, 2). Moreover, non-covalent assembly of carefully chosen precursors is easier and faster than conventional synthesis as a means of developing novel catalytic systems and new materials (3). Better understanding of the interactions responsible for non-covalent binding, and their relative importance to molecular recognition, requires knowledge of complexation constants and how they vary with host–guest structure and the medium (2, 4). The present paper reports dissociation constants of complexes formed between two cyclodextrins (CDs) (5) and some aliphatic derivatives in water. Most of the values were specifically required for ongoing studies of the effects of cyclodextrins on reactivity (6–8), while others were obtained for comparative purposes or for future use.

[1] $A + B \underset{K_d}{\overset{K_f}{\rightleftharpoons}} A{\cdot}B$

There are many ways of estimating dissocation constants (K_d) or formation constants ($K_f = 1/K_d$), based on the alteration of some chemical or physical property that is brought about by complexation (eq. [1]) (9). However, for any particular equilibrium the choice between different methods may not be easy since each one has its own specific requirements and limitations. For example, direct spectrophotometric methods require that either A or B or the complex A·B has a suitable absorption, and that there is a well-behaved, measureable spectral change that accompanies complexation. Likewise, the use of inhibition kinetics (10) requires a probe reaction that is not interfered with by the "inhibitor," except by competitive inhibition (11). A further requirement is that the site on the host occupied by the inhibitor/guest is basically the same as that involved in the probe reaction; otherwise the inhibition is not truly "competitive" and misleading results will be obtained (8, 11).

A different type of limitation, one that is common to many analytical methods, is due to the requirement or assumption of very unequal host and guest concentrations ($[A]_0 \gg [B]_0$ or $[B]_0 \gg [A]_0$). This inequality allows for a mathematical simplification inherent to various "graphical" treatments (e.g., Benesi–Hildebrand, Eadie, and Scatchard plots (9)) but often it is a condition that is difficult or even impossible to fulfil. One improvement in the present work results from removal of this constraint. The other main improvement results from nonlinear fitting of saturation data to an appropriate hyperbolic function, rather than the traditional use of a double-reciprocal plots, with their statistical deficiencies (12), or of other methods based on linearization of the data (9).

Methods and results

Using inhibition kinetics, we have determined dissociation constants for complexes of various aliphatic alcohols with β-cyclodextrin (β-CD) and "hydroxypropyl-β-cyclodextrin" (Hp-β-CD) (5). The method is based on the retarding effect of a CD-binding species on the rate of basic cleavage of *m*-nitrophenyl acetate (mNPA) by a CD (8*c*, 10).

Given that there is hydrolysis of the ester (S) in the basic medium, eq. [2], and cleavage through an ester·CD complex, eq. [3], the dependence of the rate constant for ester cleavage on [CD] is as given by eq. [4]. From experiments over a range of CD concentration, [CD], one finds values of k_u, k_c, and K_S, preferably by nonlinear fitting of eq. [4] (6).[5]

[2] $S \xrightarrow{k_u}$ products

[3] $S + CD \underset{K_S}{\rightleftharpoons} S{\cdot}CD \xrightarrow{k_c}$ products

[4] $$k_{obs} = \frac{(k_u K_S + k_c[CD])}{(K_S + [CD])}$$

[5] $[CD] = (k_{obs} - k_u)K_S/(k_c - k_{obs})$

Rearrangement of eq. [4] leads to an expression for [CD] in terms of k_{obs} (eq. [5]), from which one can estimate [CD], as long as k_{obs} is determined under the same conditions as k_u and k_c. In the presence of an inhibitor (I) that also binds to the CD (eq. [6]) the concentration of unbound CD is reduced and k_{obs} is decreased in accord with eq. [4], if $k_c > k_u$, as in the present case. Traditionally (9, 10), experiments are carried out with high $[I]_0 \gg [CD]_0$ so that the approximation $[CD] = [CD]_0 K_d/(K_d + [I]_0)$ is reasonably valid. Between this expression and eq. [5], [CD] can be eliminated to give an equation relating k_{obs} and $[I]_0$ that is suitable for the graphical estimation of K_d.

[6] $CD + I \underset{K_d}{\rightleftharpoons} CD{\cdot}I$

A major problem with the above approach is that it is not always convenient or even possible to maintain the condition that $[I]_0 \gg [CD]_0$, particularly when the inhibitor has a low solubility in water, which is usually the case with species that bind strongly to CDs. Our approach removes requirement of the inequality by calculating K_d values at various $[I]_0$, directly. Using eq. [5], we estimate [CD] for a given $[I]_0$, and then calculate $[CD{\cdot}I] = [CD]_0 - [CD]$, and $[I] = [I]_0 - [CD{\cdot}I] = [I]_0 - ([CD]_0 - [CD])$, taking account of mass balance. Substitution of these concentrations into $K_d = [CD][I]/[CD{\cdot}I]$ leads to an estimate of the desired dissociation constant (eq. [7]). This procedure is carried out for several different $[I]_0$ and the estimates are averaged. The calculations are conveniently carried out using commercial spreadsheet software (see Experimental).

[7] $K_d = [CD]([I]_0 - [CD]_0 + [CD])/([CD]_0 - [CD])$

Table 1 contains K_d values for 18 alcohols and 5 alkanesulfonate ions binding to β-CD and Hp-β-CD, most of which were determined by the inhibition method just outlined. It also contains values taken from the literature, particularly those for β-CD, that were obtained in other ways (13–15).

The inhibition of mNPA cleavage also works well for the binding of aliphatic ketones,[6] but we did not use it for complexes formed by CDs and alkylamines because amines react with esters in basic solution.[7] To circumvent this problem, we developed a methodology based on competition for the CD between a guest and a fluorescent probe, which in the present case is the 1-anilino-8-naphthalenesulfonate anion (ANS). Mathematically, it is similar to the inhibition method, but with specific particularities.

In aqueous solution, the fluorescence of ANS is very weak but in nonpolar media it is much stronger. Likewise, when ANS is bound to CDs (eq. [8]) its fluorescence intensity is enhanced (16) and for 1:1 binding[8] the relative fluorescence F_{rel} (= I_{obs}/I_0) varies with [CD] in accord with eq. [9] (9).

[5] Note that a usual condition of the experiments to characterize the saturation kinetics is that $[S]_0 > [SCD] \ll [CD]$, so that one can set [CD] equal to $[CD]_0$ in eq. [4]. Likewise, for the inhibition experiments, $[S]_0$ is kept low, so that it does not significantly affect [CD] compared to the effect of the added inhibitor. See last paragraph of the Experimental.

[7] In fact, it was studies of the effects of CDs on ester aminolysis (cf. 7*g*, 7*h*) that required us to determine K_d values for {amine·CD} complexes.

[8] Since we were primarily concerned with the quantitation of 1:1 binding, we have avoided conditions (long alkyl chains, very high [CD]) that tend to give rise to 2:1 (CD:guest) binding.

[a]At 25°C, in aqueous solution. All of the values for Hp-β-CD were determined, in this work, in a phosphate buffer of pH 11.6.

[b]Most of the values for alcohols and β-CD were determined by Matsui et al., using a spectral displacement method (13). The remaining values (those given with errors) were determined earlier in this laboratory, by the inhibition method (8*c*).

[c]All but one of the values for RSO_3^- and β-CD are taken from Satake et al. who used a conductimetric method (14*a*,*b*). Very similar results were obtained by Park and Song, using an ANS fluorescence probe method (14c). Earlier experiments in this laboratory on the binding of these ions to α-CD, using the inhibition method (8*c*), gave results in reasonable agreement with those from conductimetry (14*a*,*b*).

[d]Reinsborough and co-workers (15) found similar values of K_d for RSO_3^- binding to Hp-β-CD, using fluorescent probe displacement and conductimetry.

$$[8]\quad ANS + CD \underset{K_{ANS}}{\rightleftharpoons} ANS{\cdot}CD$$

$$[9]\quad F_{rel} = \frac{(F_0 K_{ANS} + F_c[CD])}{(K_{ANS} + [CD])}$$

Figure 1 shows observed data and calculated curves for the effects of β-CD, γ-CD, and Hp-β-CD on the relative fluorescence of ANS in aqueous solution and Table 2 contains the appropriate constants derived from nonlinear fitting of eq. [9] to the data. As seen in Fig. 1, binding ANS to β-CD and γ-CD causes substantial increases in its fluorescence and these may be used as the basis of competition experiments (14*c*, 17–23).

Fig. 1. Effects of added cyclodextrins on the fluorescence of ANS in aqueous solution at pH 11.60: β-CD, ▼; Hp-β-CD, ■; γ-CD, □. Note that the vertical scale on the left is for Hp-β-CD and that it is 16 times greater than that on the right for the others two CDs. The actual data for Hp-β-CD extend to [Hp-β-CD] = 20 mM.

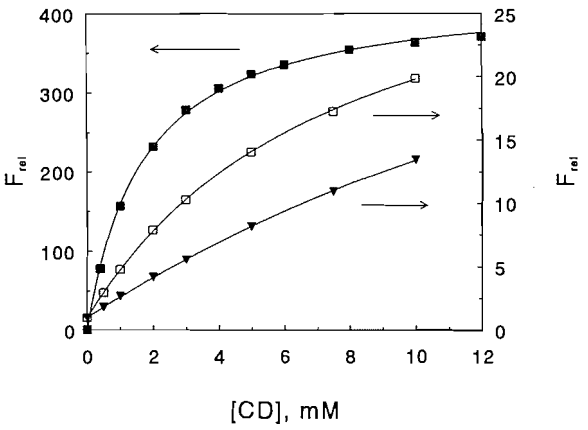

Table 2. Effects of cyclodextrins on the fluorescence of the 1-anilino-8-naphthalenesulfonate ion (ANS) due to complexation.[a]

CD	F_c	K_{ANS}, mM	
		This work	Literature values (ref.)
β-CD	46.7 ± 1.7	26.8 ± 1.3	9.1–90[b]
Hp-β-CD	430 ± 2	1.71 ± 0.04	
γ-CD	34.5 ± 0.4	7.81 ± 0.17	0.79(22), 3.6(19)

[a]At 25°C, in an aqueous phosphate buffer (0.2 M) of pH 11.6. Values of F_c and K_{ANS} were obtained from nonlinear fitting of eq. [9] to relative fluorescence data ($F_{rel} = I_{obs}/I_0$), with $F_0 = 1$ (see Fig. 1).

[b]Literature values of K_{ANS} (in mM) are: 9.1 (21), 11 (20, 23), 12 (14*c*), 13 (17*b*), 15 (22), 16 (18), 17 (17*a*), 90 (19).

On the other hand, ANS binding to α-CD is much weaker and the resulting fluorescence increase is small (16), making it less suitable as a probe, in our experience.[6] By contrast, the binding of ANS to Hp-β-CD is stronger than that to β-CD and it brings about a very large enhancement in fluorescence (Fig. 1).

The literature contains several values of K_{ANS} for the complexation by β-CD (Table 2, footnote *b*), ranging from 9 to 90 mM, but most fall within 13±4 mM. We have settled on a value of 27 mM as being appropriate for our conditions (pH 11.6, 0.2 M phosphate buffer), whereas colleagues have obtained more "normal" values of 10.5±1.3 and 16.4±1.5 mM at lower pH and lower ionic strength.[9] ANS binding under our conditions is discussed further in the experimental section.

When another guest is added to a solution of ANS and a CD, the amount of free CD is reduced, so that some of the CD-bound ANS dissociates, and the ANS fluorescence diminishes, as shown in the examples in Fig. 2. From such decreases, the free [CD] can be estimated from eq. [10], obtained by rearrangement of eq. [9]. Substitution of these CD

[a]At 25°C, in aqueous solution at pH 11.60. Individual K_d values were obtained from eq. [7] (with $[I]_0$ = $[guest]_0$), using [CD] values estimated from eq. [10] and F_{rel} in column 3. See the Experimental for more details.
[b]Less than $[CD]_0$ = 10.00 mM due to depletion of CD by binding to ANS. For [CD] = 9.98 mM, a reference fluorescence F_{ref} (= 13.40) was calculated from eq. [9] and the observed intensities were scaled to this, giving F_{rel} in column 3.

concentrations into eq. [7], for each of several $[guest]_0$, leads to estimates of K_d for the guest and these estimates are averaged. Again, the calculations can be most easily carried out in a spreadsheet, an example of which is given in Table 3.

$$[10] \quad [CD] = (F_{rel} - F_0)K_{ANS}/(F_c - F_{rel})$$

As a test of the above fluorescent probe method under our conditions, we looked first at the effects of some alcohols on ANS fluorescence in the presence of β-CD and Hp-β-CD and found values of K_d that are in reasonable to good agreement with those determined in other ways (Table 4 (*a*)). We then applied the method to the binding of several alkylamines and related derivatives, and obtained the K_d values presented in Table 4 (*b*). For the purposes of comparison, Table 4 also contains values that were found in the literature (13, 17, 23–25).

We have also used the fluorescence method to find K_d values for the binding of α-amino acids to β-CD, for the purposes of studies of the reaction of these nucleophiles with esters in the presence of CDs (cf. ref. 26). Our attempts were only partially successful in that smaller derivatives appear to bind weakly, if at all. However, derivatives with larger alkyl or aryl substitutents at the α-carbon of the amino acid bind strongly enough to cause significant decreases in ANS·CD fluorescence, analysis of which afforded the dissociation constants given in Table 4 (*c*).

We have had only limited success using the fluorescent probe method for the binding of ketones to CDs.[6] In general, we have found inhibition kinetics easier to use and to give more reproducible results, perhaps because it is less susceptible to trace impurities (which may quench fluorescence) and to instrumental fluctuations.

Discussion

In earlier work (6, 7*c*, 14*c*) it was noted that the strength of binding of several *n*-alkyl derivatives to CDs, expressed by $pK_d = -\log K_d$, increases monotonically with alkyl chain length, for up to about eight carbons.[10] Similar correlations are found in the present results for both β-CD and Hp-β-CD, and these are summarized in Table 5, along with some others for comparison. The data for β-CD are plotted in Fig. 3.

For reasons given earlier (7*c*), correlations of pK_d with chain length (N) may be treated as linear free energy relationships (LFERs) whose slopes are measures of the sensitivity of binding to structural change in the guests. In the present case, the slopes are in the range 0.4–0.6 (Table 5, Fig. 3), corresponding to free energy increments of 0.55–0.82 kcal/mol for each CH_2 group that is sequestered by the CD. These increments are close to those (0.7–0.9 kcal/mol) found for the transfer of simple aliphatics from water to organic solvents (27). Given this observation, one might infer that hydrophobic interactions (27) largely determine the binding of aliphatics to CDs in aqueous solution but one must recognize that the size and surface area of alkyl chains also increase linearly with *N*, so that van der Waals interactions (4) may contribute to the chain length dependence, as well. Consistent with this latter view, we have found that the binding of nitrophenyl alkanoate esters to both α-CD and β-CD shows a significant, but reduced, dependence on chain length in 60% aqueous DMSO, even though hydrophobic effects are largely absent in this medium (28).

We now compare the binding of aliphatics to Hp-β-CD and β-CD, to see the effects of hydroxypropylation of the primary hydroxy groups of β-CD. For a given *n*-alkylamine, the strength of binding to the two CDs is very similar, being marginally greater for β-CD (Table 4). Both CDs show good linear correlations of pK_d with the chain length of the alkylamines, with similar slopes of ~0.5 (Table 5), and so the pK_d values for binding to β-CD and to Hp-β-CD are strongly correlated (r = 0.997), with near unit slope (0.95 ± 0.05). In

[10] At greater chain lengths, complications set in. First, the chain length dependence of pK_d levels off (6, 7*c*, 7*f*, 14, 15), presumably because of the finite depths of the CD cavities. Second, the intrusion of 2:1 (CD:guest) binding becomes increasingly significant, even at fairly low [CD] (e.g., 7*b*, 7*d*, 7*e*, 14*c*).

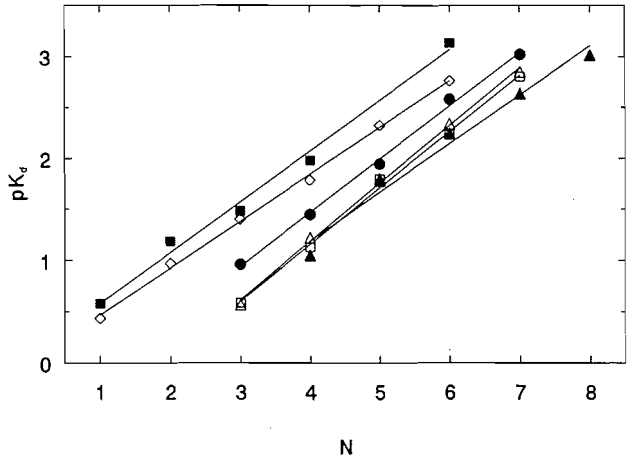
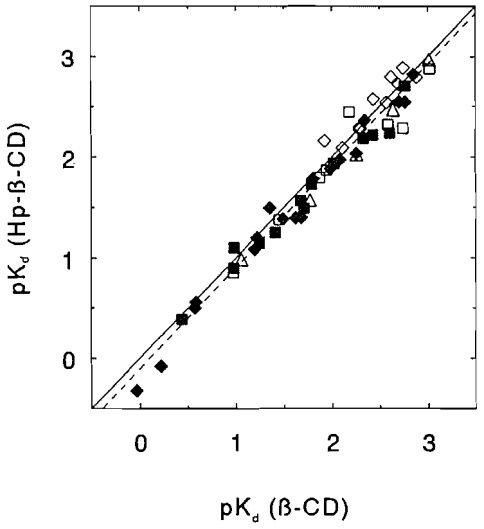
[a]In aqueous solution at 25°C. The slope, standard deviation (s.d.), and correlation coefficient (r) are taken from linear least-squares analysis of pK_d against N.
[b]Based on results given by Matsui et al. (13). For the 1-alkanols, the points for methanol and ethanol were not included because we suspect that their K_d values are distorted due to the binding of more than one guest molecule, since this is evident at high [guest].[9]
[c]From K_d values determined in this work (Table 1 or Table 4).
[d]From K_d values determined in earlier studies in this laboratory (8).
[e]Based on data given in Table 1, taken largely from Satake et al. (14).
[f]Results submitted for publication.[6]

Fig. 3. Correlations of the binding of linear aliphatics to β-CD with alkyl chain length, N. The points are R-OH, Δ; RCH(OH)Me, ■; R-CO_2^-, □; RSO_3^-, ▲; R-NH_2, ●; R-COMe, ◇. There are similar correlations for Hp-β-CD (see Table 5).



fact, similar correlations are found for other alkyl derivatives, and in a communication (29) we noted a strong correlation between the pK_d values for a collection of 28 aliphatics binding to β-CD and Hp-β-CD, with unit slope. With the addition of new results, this correlation can now be extended to 54 derivatives, comprising 18 alcohols, 10 aryl alkanoates, 5 alkanesulfonate ions, 8 amines, and 13 ketones,[6] for which the slope = 1.01 ± 0.03, intercept = −0.11 ± 0.14, and r = 0.983 (Fig. 4). The collection of guests includes some branched and cyclic compounds (e.g., Tables 1 and 4) and without these the

Fig. 4. Correlation between the binding of aliphatics to Hp-β-CD and to β-CD. The solid diagonal line is for pK_d (Hp-β-CD) = pK_d (β-CD); the adjacent broken line is the actual correlation line (see text). The points are as follows: nitrophenyl alkanoates, ◇; alcohols, ◆; RSO_3^-, Δ; amines, ■; ketones, □.



correlation is decidedly better (r = 0.991, 42 points), but the slope is essentially unchanged (1.04 ± 0.02). Thus, to a very good approximation, the strength of binding of simple aliphatics to β-CD and Hp-β-CD is the same, and the closeness of the K_d values for the two CDs implies that the guests enter from the wider opening of the CD cavity that is rimmed by secondary hydroxy groups (5), and that the guests do not penetrate far enough into the cavity to interact strongly with the groups on the other side.

Apparently, a similar situation exists for other types of guests binding to Hp-β-CD. For example, 4-(2-pyridylazo)-*N*,*N*-dimethylaniline binds equally well to Hp-β-CD and β-CD (30), as do the tetraphenylborate ion and BF_4^- (15). For two naphthalene derivatives, 1- and 2-naphthyl acetate, binding to Hp-β-CD is about twice as strong as that to β-CD (31). By contrast, we note that ANS binds to Hp-β-CD 16 times more strongly than to β-CD (Table 2) but for a related fluorescent probe, 2-*p*-toluidino-6-naphthlenesulfonate ion, binding by Hp-β-CD is only slightly (about 15%) stronger (15*b*).

Recently, Hamasaki et al. (32) prepared substituted CDs that are functionalized with a *p*-dimethylaminobenzamido group in place of one of the primary hydroxyls. These derivatives exhibit TICT fluorescence, which can be altered by the binding of guests in the CD cavities. Of relevance to the present discussion, we note their β-CD derivative binds aliphatic alcohols 1.4 to 4 times stronger than unfunctionalized β-CD. So, as with Hp-β-CD, the modification on the primary side of β-CD does not cause a large positive or negative effect on the inclusion of guests, even though it is envisaged that inclusion of the guest forces the fluorophoric group out of the cavity and into the bulk medium (32). The effects of "capping" of the primary side of the β-CD cavity are more variable, depending on the nature of the "cap" and the type of guest that is included, but in many cases the effects on the strength of binding are relatively small (33).

In addition to the correlations discussed above, other fea-

Table 6. Example of estimation of a dissociation constant by inhibition kinetics. Inhibitor = *n*-BuOH; $[Hp\text{-}\beta\text{-}CD]_0$ = 2.00 mM; ester = mNPA; k_u = 0.0502 s^{-1}; k_c = 0.956 s^{-1}; K_S = 6.98 mM.[a]

$[I]_0$, mM	k_{obs}, s^{-1}	k_{scal}, s^{-1}	[CD], mM	[PI], mM	K_d, mM

				Standard deviation	±1.0

[a]At 25°C, in 0.2 M aqueous phosphate buffer of pH 11.6. For this $[CD]_0$, the expected k_{calc} = 0.252 s^{-1} and so k_{obs} is scaled to this, as follows: $k_{scal} = k_{obs}(0.252)/(0.237)$. It should be understood that the actual spreadsheet carried more significant figures.

[b]For this set of data the graphical method also works very well, giving K_d = 64.7 ± 0.8 mM.

tures of the present results are noteworthy. For example, K_d for *n*-HexNMe$_2$ binding to Hp-β-CD is virtually the same as that for *n*-HexNH$_2$ and Hp-β-CD. In fact, this type of situation is common since the K_d values for alcohols (ROH), alkanoate ions (RCO_2^-), and alkanesulfonate ions (RSO_3^-) having the same alkyl groups are comparable (Fig. 3), and the binding of the analogous amines (RNH_2) is only slightly stronger (Tables 1 and 4, Fig. 3). Also, all the alkyl derivatives show very similar sensitivities to changes in chain length (Table 5). Taken together, these similarities must mean that the binding of such aliphatic guests is almost solely due to inclusion of their alkyl groups and that the hydrophilic end groups of the bound guests are sufficiently outside the CD cavity that they do not interact strongly with its rim. These are useful observations that may be utilized to estimate K_d values prior to their determination.

Conclusions

In this work, and in earlier studies (6, 7*c*–*f*), we have noted various correlations of pK_d with alkyl chain length, as well as the strong correlation between the pK_d values for the binding of alkyl-bearing compounds to Hp-β-CD and β-CD, with unit slope (Fig. 4). Such correlations have great predictive value for the purposes of planning experiments and for estimating K_d values that may be difficult to determine. At the same time, in combination with other types of studies (4), they may provide information about modes of binding and contribute to our understanding of the factors involved in host–guest complexation in aqueous solution.

Experimental

The cyclodextrins were purchased from Aldrich and from Wacker Chemie, and were used as received. The "hydroxypropyl-β-cyclodextrin" had an average molecular weight of 1500, corresponding to alkylation of six of the seven primary OH groups of β-CD by 2-hydroxypropyl groups. We found no appreciable difference in the behaviour of Hp-β-CD from the two suppliers. Most of the other reagents were purchased from Aldrich and used as supplied.

For the inhibition method of determining K_d, the kinetics of the cleavage of mNPA in the presence of several concentrations of inhibitor ([inhibitor]) were followed by monitoring the first-order appearance of the nitrophenolate ion at 390 nm, in a stopped-flow spectrophotometer with the temperature of the cell kept at 25.0±0.1°C, as previously (8*c*). The rate constants for various $[inhibitor]_0$ were analyzed as outlined in the main text, using a spreadsheet to do the calculations, as shown by the example given in Table 6.

To determine dissociation constants of amine·CD complexes we used competition between the amines and the fluorescent probe ANS for the CD (17–23). First, dissociation constants (K_{ANS}) for the CD·ANS complexes were determined in a basic solution, the same as that to be used with the amines. A solution containing a CD (0–20 mM for β-CD or γ-CD; 0–40 mM for Hp-β-CD) in a 0.4 M sodium phosphate – NaOH buffer of pH 11.60, and a solution containing 200 μM ANS were mixed (1:1) in a stopped-flow apparatus, yielding final concentrations half of the foregoing. The observation cell was irradiated at 383 nm, and the fluorescence was measured at either 474 nm (β-CD), 468 nm (Hp-β-CD), or 473 nm (γ-CD). These wavelengths may not correspond to the actual fluorescence maxima of the CD·ANS complexes, but they were found to be the best for our apparatus, an Applied Photophysics SX17MV spectrofluorimeter. Uncorrected fluorescence values, obtained as the averages of several scans, were then converted into relative fluorescence, using $F_{rel} = I_{obs}/I_0$, where I_0 is the fluorescence intensity at zero [CD]. Analysis of the F_{rel} values at several [CD] (Fig. 1) were carried out by nonlinear regression of eq. [9] (34), giving the fitted constants F_c and K_{ANS} in Table 2.

Several experiments were carried out on the binding of ANS to β-CD, with variable results. Depending on the range of [β-CD] used, we obtained K_{ANS} values ranging from 12 to 50 mM, but most were between 20 and 35 mM, with the highest values coming from experiments where [β-CD] was taken up to 30 mM.[11] In general, we found that eq. [9] gave good fits to the fluorescence data only when [β-CD] <15 mM, probably because of the intrusion of 2:1 binding at high [CD]. Accordingly, we have used the value of 26.8 ± 1.3 mM, obtained from the data with [CD] in the range 0–10 mM, as shown in Fig. 1, and we restricted all further experiments to the same [β-CD] range. By contrast, ANS with Hp-β-CD gave well-behaved fluoresecence data for [CD] up to 20 mM (Fig. 1).

Dissociation constants for the amines complexing with β-CD or Hp-β-CD were obtained as follows. Solution 1 contained the amine and, where necessary, 10 mM β-CD. For most of the amines, this solution was prepared in a 0.4 M phosphate buffer, and adjusted to pH 11.60. In the case of *n*-propylamine, *n*-butylamine, *n*-pentylamine, cyclopentylamine, and cyclohexylamine, the solutions were prepared in water and set to pH 11.60, using the amine as the buffering species. Solution 2 contained CD (β-CD, 10 mM or Hp-β-CD, 5.0 mM) and ANS in water. Both solutions were then mixed to

[11] The normal solubility of β-CD in water is about 16 mM (5), but higher concentrations are attainable in a strong phosphate buffer of pH 11.6.

give final concentrations of 10 mM β-CD + 50–100 μM ANS or 2.5 mM Hp-β-CD + 25 μM ANS. Amine concentrations, which were governed primarily by solubility, varied between 0 and 250 mM (3-amino-1-propanol) and 0 and 5.2 mM (*n*-octylamine). The mixed solution in the observation cell of the spectrofluorimeter, maintained at 25.0 ± 0.1°C, was irradiated at 383 nm, and the fluorescence intensity (I_{obs}) was taken as the average of several scans at 474 nm (β-CD) or 468 nm (Hp-β-CD) for each $[amine]_0$.

For estimation of K_d values (e.g., Table 3), the observed fluorescence intensities, I_{obs} (column 2, Table 3), must first be scaled to bring them into line with the previous ANS/CD "calibration" curves described by eq. [9] with the parameters in Table 2. From the initial $[ANS]_0$ and $[CD]_0$, the actual [ANS] was calculated by solving the quadratic that is obtained by expansion of:

$$K_{ANS} = [ANS][CD]/[CD \cdot ANS]$$
$$= [ANS]([CD]_0 - ([ANS]_0 - [ANS]))/([ANS]_0 - [ANS])$$

Using this [ANS], [CD] was then found from $[CD]_0 - ([ANS]_0 - [ANS])$ and a reference fluorescence (F_{ref}) was evaluated from eq. [9]. This F_{ref} was set equivalent to the observed fluorescence intensity with no guest present (I_{ng}), and the other I_{obs} were converted to relative fluorescence values using $F_{rel} = I_{obs}.F_{ref}/I_{ng}$ (column 3, Table 3). These values of F_{rel} were then used to calculate values of [CD] from eq. [10] for the various $[guest]_0$ (column 4, Table 3), from which estimates of K_d were obtained using eq. [7] (column 7, Table 3). All of these manipulations were carried out in a spreadsheet designed for the purpose.

Dissociation constants for complexation of the amino acids by β-CD were also determined as above, with minor differences. The solutions were set to pH 9.88, to correspond to other experiments (26), using the amino acid as the buffering species. The concentration ranges of the α-amino acids varied between 0 and 200 mM (L-valine, L-cysteine, and DL-norvaline) and 0 and 5.0 mM (L-tyrosine).

Prompted by a referee's comment, we have referred to a paper by Selvidge and Eftink (*9a*) in which they point out some of the same problems that we do and they present an analysis of the use of various concentrations, $[guest]_0$ and $[probe]_0$, in relation to the strengths of guest and probe binding. When they estimate guest binding constants, using their equations [10]–[12], they correct for [probe·CD]. So do we in the fluorescence method, but it only makes a difference of 1% *at most*, for the lowest $[guest]_0$ of the strongest binding guest that was studied. When using the inhibition method, developed earlier (*8a,b*), we did not make this correction, but even there it would only make a difference of 2% in the worst case. The major difference between our approach and that of Selvidge and Eftink (*9a*) is that they used double-reciprocal plots to find the binding constants of their spectroscopic probes, whereas we prefer to use nonlinear fitting.

Acknowledgement

We thank the Natural Sciences and Engineering Research Council of Canada for an operating grant, a post-graduate scholarship, summer student awards, and an equipment grant. We also thank Professor Susan Mikkelsen for several helpful discussions.

Spectator catalysis in the cleavage of *p*-nitrophenyl acetate and *p*-nitrophenyl hexanoate by "hydroxypropyl-β-cyclodextrin"

Timothy A. Gadosy and Oswald S. Tee

Abstract: Aliphatic alcohols that form host–guest complexes with "hydroxypropyl-β-cyclodextrin" retard the cleavage of *m*-nitrophenyl acetate by hydroxypropyl-β-cyclodextrin in basic aqueous solution, due to competitive inhibition. By contrast, these same species do not inhibit the reaction of *p*-nitrophenyl acetate and *p*-nitrophenyl hexanoate to the same extent and, in some cases, the addition of alcohols serves to increase the rate of reaction. The observed reaction kinetics require the presence of a process that has *one* molecule of the "potential inhibitor" in the transition state for ester cleavage. Rate constants, k_a, for the reaction of the {ester·hydroxypropyl-β-cyclodextrin} complexes with a series of potential inhibitors show a strong dependence on the ability of the potential inhibitor to bind to the cyclodextrin. On the other hand, rate constants for the kinetically equivalent reaction of the ester with the {cyclodextrin·potential inhibitor} complex show little dependence on the alcohol structure and they vary over a very limited range. The negative logarithms of the apparent dissociation constant of the potential inhibitor from the transition state show a strong dependence on the ability of the potential inhibitor to bind to hydroxypropyl-β-cyclodextrin, indicating that the binding of the potential inhibitor in the initial state and the transition state is similar. It is concluded that the cleavage of *p*-nitrophenyl acetate and *p*-nitrophenyl hexanoate by hydroxypropyl-β-cyclodextrin in the presence of 14 potential inhibitors can occur with the ester largely outside of the hydroxypropyl-β-cyclodextrin cavity during the transition state, allowing the cavity to be occupied by a molecule of potential inhibitor.

Key words: cyclodextrin, spectator catalysis, esterolysis.

Résumé : À cause d'une inhibition compétitive, les alcools aliphatiques qui forment des complexes hôtes–invités avec l'«hydroxypropyl-β-cyclodextrine» retardent le clivage de l'acétate de *m*-nitrophényle par l'hydroxypropyl-β-cyclodextrine en solution basique aqueuse. Par opposition, ces mêmes espèces n'inhibent pas la réaction de l'acétate de *p*-nitrophényle et de l'hexanoate de *p*-nitrophényle de la même façon et, dans certains cas, l'addition d'alcools sert même à augmenter la vitesse de la réaction. Les résultats cinétiques observés suggèrent l'existence d'un processus qui comporte *une* molécule d'«inhibiteur potentiel» dans l'état de transition du clivage de l'ester. Les constantes de vitesse, k_a pour les réactions des complexes {ester·hydroxypropyl-β-cyclodextrine} avec une série d'inhibiteurs potentiels montre une forte dépendance sur l'habilité de l'inhibiteur potentiel à se lier à la cyclodextrine. Par ailleurs, les constantes de vitesse pour la réaction cinétiquement équivalente de l'ester avec le complexe {cyclodextrine·inhibiteur potentiel} ne présente qu'une faible dépendance sur la structure de l'alcool et leurs variations ne sont que très faibles. Les logarithmes négatifs des constantes de dissociations apparentes des inhibiteurs potentiels à partir de l'état de transition montrent une forte dépendance sur l'habilité de l'inhibiteur potentiel à se lier à l'hydroxypropyl-β-cyclodextrine; ceci indique que la fixation de l'inhibiteur potentiel dans l'état initial est semblable à l'état de transition. On en conclut que le clivage de l'acétate de *p*-nitrophényle et de l'hexanoate de *p*-nitrophényle par l'hydroxypropyl-β-cyclodextrine en présence de 14 inhibiteurs potentiels peut se produire alors que l'ester est nettement à l'extérieur de la cavité de l'hydroxypropyl-β-cyclodextrine durant l'état de transition; ceci permet à la cavité d'être occupée par une molécule d'inhibiteur potentiel.

Mots clés : cyclodextrine, catalyse en spectateur, estérolyse.

Introduction

The cleavage of phenyl esters by cyclodextrins (CDs) in basic aqueous media has been studied extensively over the last several years (1–11). Of particular interest to us is the cleavage of nitrophenyl alkanoates (8, 10, 11) since these compounds provide a convenient series of substrates differing in acyl chain length or position of the nitro substituent, which allows one to probe both initial state and transition state binding as a function of structural or hydrophobic differences. We have shown previously that the *m*-nitrophenyl esters are more reactive than their *para* isomers towards α-CD, β-CD, and "hydroxypropyl-β-cyclodextrin" Hp-β-CD[3] (8, 10). These results support a mechanism whereby the carbonyl group of the *meta* ester (**1**)

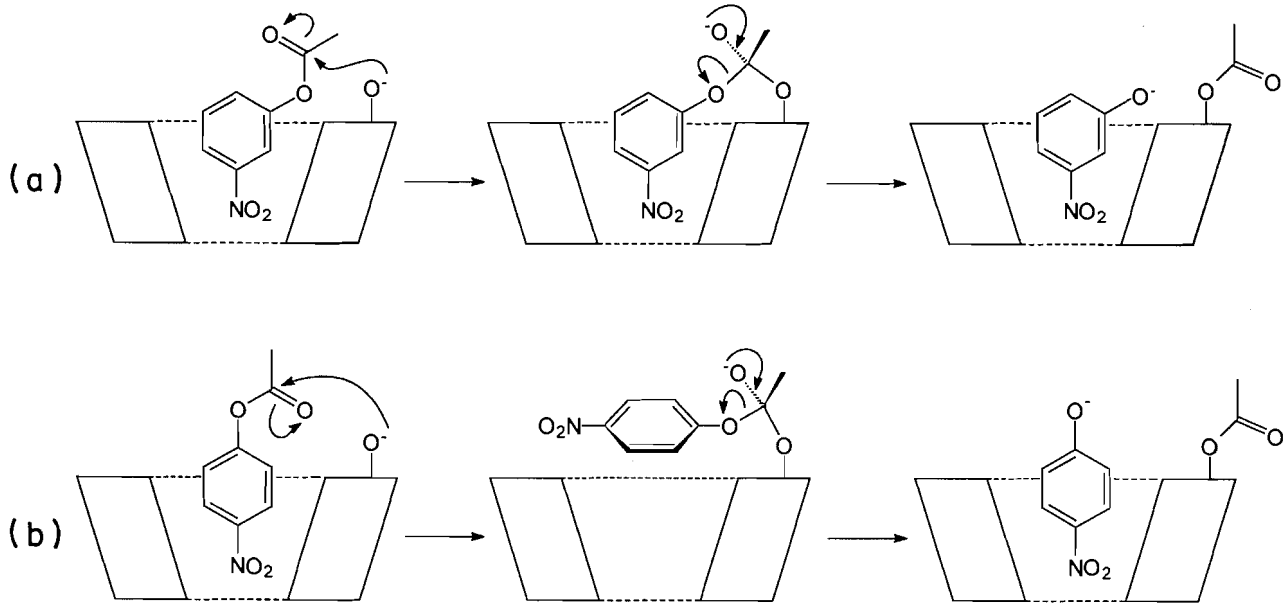
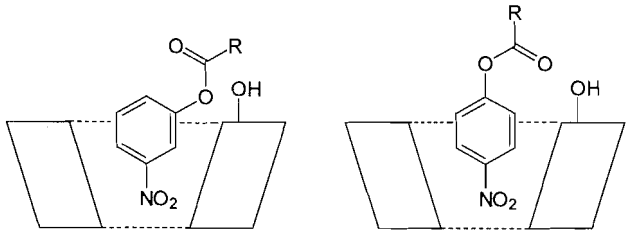
[3] We note that for the nitrophenyl esters reacting with Hp-β-CD the difference in reactivity between the *meta* and *para* isomers decreases with increasing alkyl chain length, and that *p*-nitrophenyl decanoate is more reactive than its *meta* isomer (10).

Scheme 1.



is closer to an ionized hydroxy group than in the case of the *para* esters (**2**). This conclusion is also supported by NMR data, which indicate that the O=C···OH distance is greater in the {*p*-ester·CD} complex than in the {*m*-ester·CD} complex (12). Likewise, the rate enhancement afforded to the cleavage reaction is inversely dependent on the carbonyl–hydroxy group separation (13).

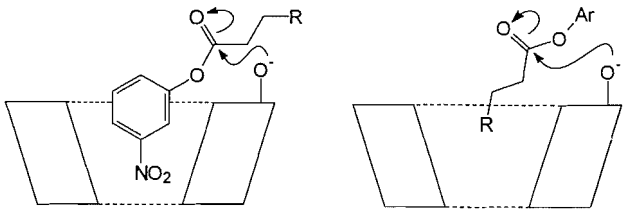


1 **2**

Saturation kinetics and NMR data (12) have shown that the *p*- and *m*-nitrophenyl acetates are bound initially via aryl group inclusion. The *meta* ester is bound to the CD in such a way that the carbonyl group is better oriented for the rate-limiting nucleophilic attack of an ionized CD hydroxy group on the carbonyl carbon of the ester (Scheme 1*a*). However, for the *para* ester to undergo nucleophilic attack, the ester must first lift out of the CD cavity, to bring the carbonyl group closer to the ionized hydroxy group (Scheme 1*b*) (14). This means that the CD cavity is virtually empty[4] during the transition state for ester cleavage. It is conceivable, therefore, that a species with the correct geometry and size might be able to occupy the cavity during the transition state of the cleavage reaction.

It has been shown that the cleavage of *m*-nitrophenyl acetate (mNPA) by α-CD and β-CD is inhibited by molecules such as simple aliphatic alcohols, alkanoate ions, and alkanesulphonate anions. On the other hand, the analogous cleavage of *p*-nitrophenyl acetate (pNPA) in the presence of such "potential inhibitors" (PIs) is retarded to a much lesser degree, and it is even *accelerated* in some instances. This finding is consistent with a situation where the binding of a PI does not allow the normal transition state geometry of the cleavage of mNPA (Scheme 1*a*), but the binding of the PI has little or no effect on the cleavage of pNPA, since the ester is outside the CD cavity during the transition state (Scheme 1*b*) (14).

Both *m*- and *p*-nitrophenyl alkanoates, longer than the acetate and propionate, bind to α-, β-, and Hp-β-CD by inclusion of their acyl chains. The stability of the {ester·CD} complexes shows a strong dependence on the ester chain, with the negative logarithm of the binding constant increasing linearly with the acyl chain length (8, 10). For cleavage of these esters by CDs the mode of transition state binding is not as simple. The *meta* esters show very little dependence of transition state binding on acyl chain length, consistent with a situation in which aryl inclusion is important in the transition state (**3**). The *para* esters, on the other hand, show very little dependence of transition state binding on chain length up to about the hexanoate, after which the transition state binding shows a strong dependence on ester chain length. This behaviour is evidence of a switch in mode of transition state binding from aryl group inclusion (**3**) to acyl group inclusion (**4**) (8, 10) as the acyl chain is lengthened beyond C_5.



3 **4**

It has also been demonstrated that the cleavage of *p*-nitrophenyl hexanoate (pNPH) by β-CD is not inhibited by the presence of various PIs (15), although the ester is bound by its acyl chain in both the initial state and the transition state. Not only is the reaction not inhibited, it is *catalyzed* by many alco-

[4] In this case we use the term "empty" to mean a lack of any species, other than water, in the cavity.

hols acting as the PI, which means that in the transition state the ester is oriented in such a way that the binding of the PI does not interfere with formation of the transition state and that it can actually lead to a more reactive geometry. The involvement of a molecule of PI is supported by the observation of saturation kinetics that indicate the formation of a 1:1:1 {pNPH·β-CD·PI} complex (15).

The strengths of binding of small molecules containing simple alkyl groups (e.g., alcohols, alkanoate esters, alkanesulphonate ions) to Hp-β-CD are essentially identical to those for binding to β-CD (16, 17) but larger compounds may bind to Hp-β-CD much more tightly than to β-CD (18). For example, 1,8-anilinonaphthalenesulphonate ion (1,8-ANS) is bound more tightly to Hp-β-CD than to β-CD by more than an order of magnitude (17). However, the size of the guest alone cannot account for the difference in binding strengths to these two CDs, since 4-(2-pyridylazo)-*N*,*N*-dimethylaniline complexes with β-CD and Hp-β-CD with dissociation constants of 2.9 and 3.3 mM, respectively (19). Because of the similarity in binding behaviours of alcohols and of alkanoate esters to β-CD and Hp-β-CD (16), we were interested in seeing whether transition state binding in the cleavage of pNPA and pNPH by Hp-β-CD in the presence of PIs is also similar to that for the parent CD or if there is a substantial difference. Some difference was anticipated since the cleavage of nitrophenyl esters by Hp-β-CD is less efficient than that by β-CD (10).

The aim of this paper is to demonstrate how alcohols mediate the cleavage of pNPA and pNPH by Hp-β-CD, and to compare these results with those obtained previously for α-CD and β-CD.

Results

We have examined the effect of various alcohols, containing three to six carbons, on the rates of cleavage of pNPA and pNPH in basic aqueous solution containing Hp-β-CD. The reactions were carried out in a 0.20 M phosphate buffer at pH 11.60. Before discussing the results, we review the pertinent kinetic models used to understand them.

The esters (S) undergo cleavage in the basic medium, eq. [1], and through an ester·CD complex (S·CD), eq. [2], or its kinetic equivalent, so that the dependence of k_{obs} on CD concentration ([CD]) is given by eq. [3], where K_s is a dissociation constant.

$$[1]\quad S \xrightarrow{k_u} \text{Products}$$

$$[2a]\quad S + CD \underset{K_s}{\rightleftharpoons} S{\cdot}CD$$

$$[2b]\quad S{\cdot}CD \xrightarrow{k_c} \text{Products}$$

$$[3]\quad k_{obs} = \frac{k_u K_s + k_c[CD]}{K_s + [CD]}$$

The addition of an inert PI, capable of binding to CD, eq. [4], reduces the concentration of free CD, and k_{obs} is reduced in accord with eq. [3], assuming $k_c > k_u$.

$$[4]\quad CD + PI \underset{K_I}{\rightleftharpoons} CD{\cdot}PI$$

In the CD-mediated cleavage of *m*-nitrophenyl acetate (mNPA) the addition of a PI causes a reduction in the k_{obs}, which obeys the model for competitive inhibition just presented. Analysis of the dependence of k_{obs} on PI concentration by a method described in detail elsewhere (14, 17) allows for the determination of the dissociation constant (K_I) of the CD·PI complex. Values of K_I obtained in this way for PIs binding with α-CD and β-CD (14) generally agree well with results in the literature obtained by other methods (14, 16, 17, 20). The K_I values for alcohols (Table 1) and alkanesulphonate anions binding to Hp-β-CD were also determined by this method and they are reported elsewhere (16, 17).

[b]Not determined because 2-HexOH inhibited the reaction, see text.

For the present study only aliphatic alcohols of three to six carbons were examined as PIs. They span a wide structural variety, including straight and branched chain (primary, secondary, and tertiary), as well as cyclic alcohols. Overall, the 14 alcohols studied span two orders of magnitude in K_I, providing a range of ability to bind to Hp-β-CD. The addition of these alcohols to the reaction medium of the cleavage of pNPA and pNPH by Hp-β-CD did not inhibit the reaction in the manner required for competitive inhibition, with 2-hexanol (2-HexOH) and the cleavage of pNPA being the sole exception (vide infra). In some cases the addition of PI caused a slight depression in k_{obs} , while in others there was a distinct *acceleration* (Figs. 1 and 2).

As stated above, 2-HexOH did inhibit the reaction of pNPA in the presence of Hp-β-CD. Analyzing the dependence of k_{obs} on [PI] affords a K_I for the {2–HexOH·Hp-β-CD} complex of 14.0 ± 0.9 mM, which is indistinguishable from the value obtained from the inhibition of the cleavage of mNPA (13.2 ± 1.4 mM). It is interesting to note that 2-HexOH did not inhibit the cleavage of pNPA in the presence of β-CD, although it binds to β-CD with similar strength, K_I = 11 mM (14, 20).

In analyzing our data for PI-mediated cleavage, we have taken as our working hypothesis that a reaction occurs between the PI and the ester·CD complex, eq. [5]. Combining

Fig. 1. The effect of alcohols on the cleavage of pNPA by Hp-β-CD. The symbols are ■, i-PrOH; ●, 2-PenOH; ▼, neo-PenOH. The solid lines were calculated using eq. [6] and the appropriate constants found in Tables 1 and 3. The broken lines are those expected for competitive inhibition, calculated using eq. [3] and [CD], corrected for {CD·PI} formation. Likewise, [PI] on the horizontal axis is corrected.

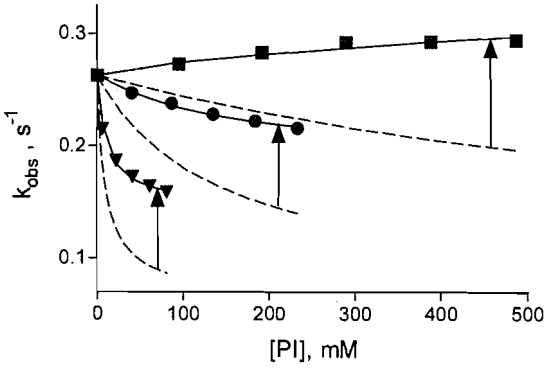

Fig. 2. The effect of alcohols on the cleavage of pNPH by Hp-β-CD. The symbols are ■, i-PrOH; ●, 2-PenOH; ▼, neo-PenOH. The solid lines were calculated using eq. [6] and the appropriate constants found in Tables 1 and 3. The broken lines are those expected for competitive inhibition, calculated using eq. [3] and [CD], corrected for {CD·PI} formation. Likewise, [PI] on the horizontal axis is corrected.

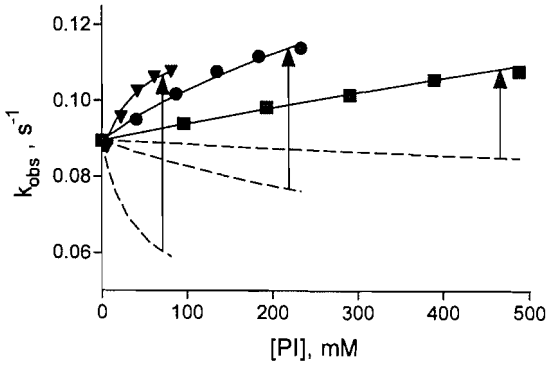

eq. [5] with the two for the reaction in the absence of PI (eqs. [1] and [2]) the expression for k_{obs} is now as described by eq. [6].

$$[5]\quad S\cdot CD + PI \xrightarrow{k_a} \text{Products} + PI$$

$$[6]\quad k_{obs} = \frac{k_u K_s + (k_c + k_a[PI])[CD]}{K_s + [CD]}$$

Equation [6] is not particularly convenient since it is both nonlinear and bivariate but it is made more tractable by linearization, which also brings about a separation of variables, as in eq. [7]. This manipulation amounts to correcting the observed rate constant for the background reaction and the binding of the substrate to the CD, leaving only the terms due to reactions with the CD. Proper use of either eqs. [6] or [7] requires that the amounts of free CD and free PI are employed. These can be calculated from the initial concentration of both species, knowing K_I (7, 14, 21).

[a]As in Table 1.
[b]Values of K_I for the alcohols are given in Table 1.

$$[7]\quad k_{corr} = \frac{k_{obs}(K_s + [CD]) - k_u K_s}{[CD]} = k_c + k_a[PI]$$

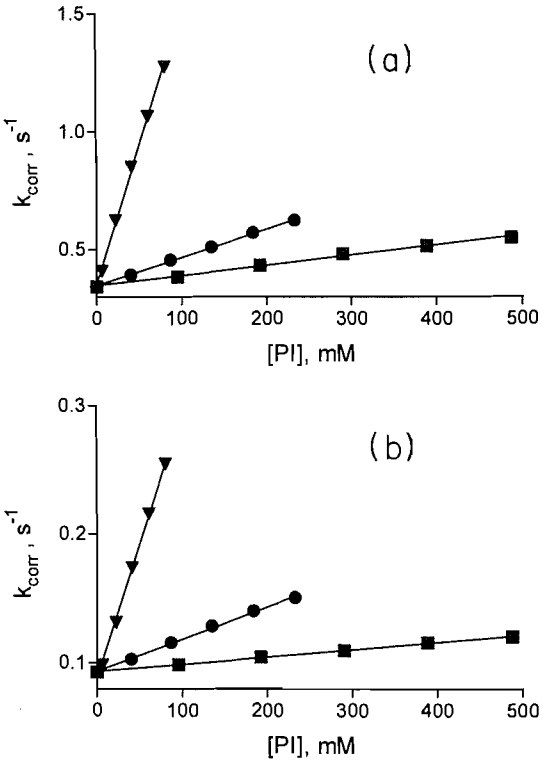
According to eq. [7], variations in k_{corr} with [PI] should be linear and the slope equals the rate constant k_a. Several examples of this analysis are shown in Fig. 3 and the linearity of the plots indicates that the assumption of only one molecule of the PI being involved in the transition state is valid. Tables 1 and 2 summarize the k_a values obtained for pNPA and pNPH reacting with Hp-β-CD in the presence of 13 and 14 alcohols, respectively.

The k_a values increase markedly with the ability of the alcohol to bind to Hp-β-CD. For the cleavage of pNPA by Hp-β-CD they range from 0.35 to 17 M^{-1} s^{-1}, an increase of almost 50-fold. These values are decidedly lower than those observed in the case of β-CD, which ranged from 2.8 to 83 M^{-1} s^{-1} (14). For the cleavage of pNPH by Hp-β-CD the k_a values range from 0.10 to 1.1 M^{-1} s^{-1}, an increase of only a factor of 11, whereas for reaction with β-CD, the k_a values varied from 1.4 to 61 M^{-1} s^{-1}, a 44-fold range (21). This difference may be associated with the fact that β-CD forms reactive {S·CD·PI} complexes, whereas there was no evidence for ternary complex formation with Hp-β-CD (vide infra).

Discussion

The results reported above support a cleavage pathway involving the ester (pNPA or pNPH), Hp-β-CD, and *one* molecule of PI. Since the alcohols span a variety of structural types it is unlikely that they interact in a covalent manner; it is more likely that they act as inert space fillers, or "spectators," simply occupying the CD cavity during the transition state for ester cleavage. This same conclusion was drawn for the analogous processes involving α- and β-CD (14, 21) and in the case of pNPA it is consistent with a mechanism for ester cleavage that has the ester largely outside the CD cavity during the

Fig. 3. Examples of the linear dependence of k_{corr} on [PI] (eq. [7]) for the cleavage of pNPA (*A*) and pNPH (*B*) by Hp-β-CD, for the same data as presented in Figs. 1 and 2, respectively. For such plots, [PI] must be corrected for the formation of {CD·PI}. The symbols are the same as in Figs. 1 and 2.



transition state (Scheme 1*b*). For the cleavage of pNPH, we must consider a situation where the acyl portion of the ester is either completely outside of the cavity, or intrudes only slightly, which is different from what seems to happen in the absence of PI (**4**). As detailed below, our analysis of the data with the various PIs supports this interpretation.

The rate constants for the reaction of the PI with the S·CD complex (k_a) increase regularly for pNPA and pNPH as the ability of the PI to bind to the CD increases (Tables 1 and 2). For each ester, there is a good linear free energy relationship[5] (LFER) between the rate constants and the dissociation constants for the CD·PI complexes (eqs. [8] and [9], where $pK_I = -\log K_I$):

[8] pNPA, $\log k_a = 0.77pK_I - 0.87$ ($N = 13$, $r = 0.992$)

[9] pNPH, $\log k_a = 0.74pK_I - 1.52$ ($N = 14$, $r = 0.979$)

These LFERs support the hypothesis that the PI is bound inside the CD cavity during the transition state and the slopes of ~0.75 indicate that its mode of binding is similar to that in the CD·PI complex. The fact that the slopes of the two relationships are almost the same strongly suggests that the involvement of the PI in the two cases is very similar, although the two esters themselves may interact differently in the transition state. Most probably the transition state for the cleavage of both esters is one where the ester resides largely *outside* the CD cavity.

The slope of eq. [9] for the reaction of pNPH with Hp-β-CD is the same as that of the analogous reaction with β-CD (0.75), and lower than that observed with α-CD (1.02) (21). These slopes indicate that the 2-hydroxypropyl groups on the primary side of the CD do not influence the dependence of k_a on the ability of the PI to bind to the CD, whereas altering the width of the CD cavity appears to play a more significant role. This difference can be ascribed to the wider cavities of β-CD and Hp-β-CD allowing the PI to "move around" in the transition state, which decreases the sensitivity of the transition state binding to the nature of the PI because the CDs can more easily accommodate the ester.

The results in the case of pNPA are somewhat different. The slope of the LFER in eq. [8] (0.77) falls in between those observed for β-CD (0.67) and α-CD (1.02) (14). The larger slope for Hp-β-CD means that the cleavage of pNPA is more sensitive to the ability of the PI to bind to Hp-β-CD than to β-CD. This is consistent with a mechanism whereby the pNPA sits outside of the cavity in order for the nucleophilic attack to occur, orienting the phenyl ring directly above the CD cavity (Scheme 1*b*), thereby forcing the PI further down into the CD cavity, where it would come into contact with the 2-hydroxypropyl groups to a greater extent, thus giving a stronger dependence of log k_a on pK_I. The absence of this "extra sensitivity" in the cleavage of pNPH is in agreement with a transition state similar to **4** where the acyl group is oriented towards the CD cavity but largely or completely outside of it. Therefore, the PI would not be forced down further into the CD cavity to bring it into contact with the 2-hydroxypropyl groups, and the behaviour with Hp-β-CD would be similar to that observed with β-CD, as is the case.

Since the PI seems to be bound to the CD in more or less the same way in the initial and transition states, it may be more appropriate to consider the reaction as taking place between the ester and the CD·PI complex (eq. [10]), which is kinetically indistinguishable from that in eq. [5]:

[10] $S + CD{\cdot}PI \xrightarrow{k_b} \text{Products} + PI$

The rate constant for this process can be determined from that for the third-order reaction of S + CD + PI → products ($k_3 = k_a/K_s = k_b/K_I$), using $k_b = k_aK_I/K_s$, and values calculated in this manner are given in Tables 1 and 2.

The values of k_b do not show as much variation with the alcohol as k_a, and they fall within much narrower ranges, 4.0–15 M^{-1} s^{-1} for pNPA and 3.7–21 M^{-1} s^{-1} for pNPH, with most of them being within the ranges of 4–9 M^{-1} s^{-1} and 4–10 M^{-1} s^{-1}, respectively. These values are lower than those for the analogous reactions with β-CD (14, 21), and lower than the second-order rate constant for the reaction of Hp-β-CD with the esters, $k_2 = k_c/K_s$ (Table 3), but they are consistent with the reaction as described in eq. [10], as long as the ester is mainly outside of the cavity during the transition state, so that the PI may be accommodated (transition states **5** for pNPA; **6** for pNPH).

To examine further the transition state binding we have used a method developed by Kurz (23), which allows one to

[5] Although we are aware that the reliability of LFERs has been recently brought into question (22), we feel that they are valid tools for the analysis of physical organic data and continue to use them.

Table 3. Parameters for the cleavage of pNPA and pNPH by CDs.[a]

estimate the stabilization imparted to the transition state by the catalyst in a catalyzed reaction. This method affords an *apparent* dissociation constant of the transition state containing the catalyst into the transition state for the uncatalyzed reaction and the catalyst. It has been widely used by enzymologists (24) and by us for the analysis of CD-mediated processes (8–11, 14, 21, 25 and references therein).

Applying transition state theory to the reaction in eq. [2*b*], we obtain an expression for the rate of reaction given by eq. [11]:

$$[11] \quad \text{rate} = k_c[\text{S}\cdot\text{CD}] = \nu[\text{TS}]$$

and likewise we obtain eq. [12] for the PI-mediated reaction in eq. [5]:

$$[12] \quad \text{rate} = k_a[\text{S}\cdot\text{CD}][\text{PI}] = \nu[\text{TS}\cdot\text{PI}]$$

Dividing eq. [11] by eq. [12] yields an expression for the apparent dissociation of the PI from the PI-containing transition state (eq. [13]), in terms of the known constants k_c and k_a (or k_2 and k_3) [14]:

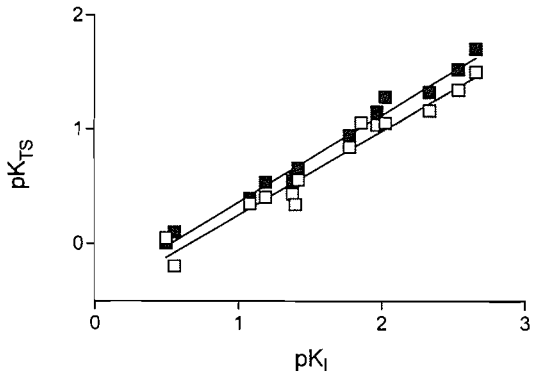
$$[13] \quad \text{TS} + \text{PI} \underset{K_{TS}}{\rightleftharpoons} \text{TS}\cdot\text{PI}$$

$$[14] \quad K_{TS} = \frac{[\text{TS}][\text{PI}]}{[\text{TS}\cdot\text{PI}]} = \frac{k_c}{k_a} = \frac{k_2}{k_3}$$

The values of K_{TS} for the cleavage of pNPA and pNPH by Hp-β-CD in the presence of PIs are shown in Tables 1 and 2. Using either formalism in eq. [14] for the calculation of K_{TS} is acceptable since $k_2 = k_c/K_s$ and $k_3 = k_a/K_s$.

As discussed in detail elsewhere (25), variations in the values of pK_{TS} (= $-\log K_{TS}$) can be used as a probe of transition state binding. In this study we look at LFERs between pK_{TS} for

Fig. 4. Correlation of transition-state binding (pK_{TS}) of alcohols with pK_I for the binding of the alcohols to Hp-β-CD. Solid squares are for the cleavage of pNPA and open squares are for pNPH cleavage.



the transition state binding in {TS·PI} and pK_I for the initial state binding in the CD·PI complex. For the cleavage of pNPA and pNPH by Hp-β-CD in the presence of a large number of alcohols we found:

$$[15] \quad \text{pNPA}, \quad pK_{TS} = 0.77pK_I - 0.41 \quad (N = 13, r = 0.992)$$

$$[16] \quad \text{pNPH}, \quad pK_{TS} = 0.74pK_I - 0.49 \quad (N = 14, r = 0.979)$$

These two correlations are shown in Fig. 4. Except for the intercept terms, the equations are identical to those in eqs. [8] and [9] since $K_{TS} = k_c/k_a$ and k_c is a constant for a particular ester reacting with Hp-β-CD (Table 3).

We interpret the similarity between the slope and intercept term of eqs. [15] and [16] to indicate that the binding of the PI in the initial state and the transition state is similar for the alcohol-mediated cleavage of both esters. Although both sets of data in Fig. 4 are almost coincident, this does not necessarily imply that the esters are included in the CD cavity to the same extent during the transition state. Since the intercepts of both eqs. [15] and [16] are so similar it is possible that the PIs are in identical environments during the alcohol-mediated cleavage, which would necessitate the placement of the ester completely outside of the CD cavity; on the other hand, it is possible that the similarity is fortuitous and the result of interactions involving both the ester and the distal 2-hydroxypropyl groups. With β-CD there is a definite difference between the two corresponding correlations: pNPA, $pK_{TS} = 0.67pK_I + 0.19$ (14); pNPH, $pK_{TS} = 0.75\ pK_I + 0.53$ (21). Not only are the slope and intercept terms different for β-CD than for Hp-β-CD, but the PI is bound more tightly in the cleavage of pNPH than pNPA, which is opposite to that observed with Hp-β-CD, and pK_{TS} has a different dependence on pK_I in the cleavage of the two esters.

One of the major contributing factors to the difference observed between β- and Hp-β-CD for the cleavage of pNPH may be the formation of ternary {S·CD·PI} complexes. Such complexes were apparent in the PI-mediated cleavage of pNPH by β-CD (21), but no evidence of ternary complex formation was observed with any of the alcohols and pNPH + Hp-β-CD. Tee et al. found that in the transition state the alcohol is bound in a manner very similar to the ternary complex, although the binding in the transition state is weaker (21). The

dependences of pK_{TS} on pK_I for the PI-mediated cleavage of pNPH by both β- and Hp-β-CD are the same, but the transition state binding for β-CD is stronger. This observation substantiates the claim that the ester is included in the transition state for the cleavage of pNPH by β-CD, but not in the cleavage by Hp-β-CD. The exact origin of these differences is unclear but they are most probably due to the 2-hydroxypropyl groups on the primary side of the Hp-β-CD cavity preventing the formation of the ternary complex involving pNPH.

The differences between the cleavage of pNPA by β-CD and Hp-β-CD in the presence of PIs are not so easy to explain. We know that pNPA and the alcohols studied bind to β-CD and Hp-β-CD with equal strengths (16) and so it has been concluded that the binding occurs to the wider side of the CD cavity (16, 17). Presumably the alcohols approach the CD cavity from the wider secondary face of the cavity, since the hydroxypropyl groups on the primary face do not appear to affect the binding. For a molecule of alcohol to be included in the CD cavity, one or more molecules of water must be excluded. If, during the rate-limiting step, water molecules are required to move in or out of the cavity via the narrow side of the cavity, then the 2-hydroxypropyl groups may retard this process and lead to a less stable transition state. Such an effect in the case of pNPH would mean that both water transport and lack of ternary complex formation play significant roles in the transition state destabilization of the cleavage pNPH by the Hp-β-CD, relative to β-CD.

Conclusions

This paper presents data that show that the cleavage of pNPA and pNPH by Hp-β-CD can occur with a molecule of a PI in the CD cavity. Although both esters bind to Hp-β-CD, as evidenced by saturation kinetics (10), and pNPH is included in the CD cavity during the transition state for the cleavage reaction in the absence of PI (10), it does not necessarily follow that the esters are in the CD cavity during the transition state for the PI-mediated cleavage. The PI may allow for the formation of a transition state of different geometry, which may be more or less reactive. It is clear from the present and earlier results that the inclusion of a PI in the transition state for the cleavage of pNPA and pNPH does not necessarily inhibit the reaction, and that the effect of the PI depends on the size and shape of both the ester, the PI, and the CD.

We conclude that the esters are largely outside of the CD cavity during the transition state for the PI-mediated cleavage of pNPA and pNPH by Hp-β-CD. We note that there are differences between the cleavage of these esters by β-CD and Hp-β-CD, while the only structural differences between the two CDs are the 2-hydroxypropyl groups on the Hp-β-CD, which are by all accounts located away from the centre of activity. Although the exact nature of the effect due to the 2-hydroxypropyl groups is unclear, they may act to restrict the movement of species in and out of the CD via the narrow side of the cavity, which may be necessary to allow for the inclusion of the PI during the transition state.

Experimental

We used Hp-β-CD that has an average molecular weight of 1500, from the Aldrich Chemical Company, without further purification. This material corresponds to a β-CD where about six of the seven hydrogens on the primary hydroxy groups have been replaced by 2-hydroxypropyl groups. The *p*-nitrophenyl acetate and hexanoate were purchased from Sigma and used as received.

The alcohols used as PIs were purchased from Aldrich and were of the highest grade available. After prolonged storage, some secondary alcohols formed peroxides; this was tested for by mixing several millilitres of the alcohol with a saturated solution of KI. If peroxides are present I_2 and I_3^- are formed, giving the solution a yellow colour. Solutions found to contain peroxides were either distilled prior to use or replaced with a fresh supply. **Warning:** the distillation of alcohols containing peroxides must be watched *very* carefully, so as to prevent the distillation flask from boiling dry, which may lead to an explosion.

All reactions were carried out in a 0.20 M phosphate buffer at pH 11.60 and 25.0 ± 0.1°C. The reactions were initiated by mixing equal volumes of phosphate buffer (0.40 M) containing the PI with a solution containing Hp-β-CD (40 or 4.0 mM) and ester ($[pNPA]_o$ = 100 μM; $[pNPH]_o$ = 50 μM). The final concentrations of all species were half of these, after mixing.

The kinetics of ester cleavage were followed by monitoring the first-order appearance of *p*-nitrophenolate ion at 405 nm, using an Applied Photophysics SX17MV stopped-flow spectrophotometer, as described previously (11, 26). The pseudo first-order rate constants, k_{obs}, were determined by fitting a single exponential equation to the absorbance data, using software provided by the instrument manufacturer. The determination of k_{obs} was repeated 5 to 10 times and the values were averaged.

Our analysis based on eq. [7] requires the use of known values of k_u, k_c, and K_s, which were available from previous work (Table 3).

Studies on the interaction of selenite and selenium with sulphur donors. Part 4. Thiosulfate[1]

Shermin Rahim and John Milne

Abstract: Raman and Se-77 NMR spectroscopy confirm that when selenous acid is reduced by thiosulfate in water selenopentathionate and tetrathionate are formed.

$$H_2SeO_3 + 4S_2O_3^{2-} + 4H^+ = Se(S_2O_3)_2^{2-} + S_4O_6^{2-} + 3H_2O$$

Depending upon the stoichiometry and pH, two isomers of the selenopentathionate ion, O- and S-bonded, are formed. Insufficiently acid solutions cause decomposition to selenium and tetrathionate ion.

$$Se(S_2O_3)_2^{2-} = Se + S_4O_6^{2-}$$

Fresh solutions prepared from crystalline sodium selenopentathionate and water undergo slow decompositon. NMR and Raman spectra show the presence of both the O-bonded and S-bonded linkage isomers. The O-bonded isomer facilitates the formation of tetrathionate. Addition of thiosulfate to selenotrithionate solution or sulfite to selenopentathionate solution yields trithionate with no indication of dithionate or tetrathionate formation. This suggests that simple S—S bond formation at selenium does not occur but that there may be direct attack of the incoming ligand on the attached ligand.

Key words: selenite, thiosulfate, selenopentathionate, Se-77 NMR, Raman spectroscopy, linkage isomerism.

Résumé : Les spectroscopie Raman et RMN du ^{77}Se confirment que, lorsque l'acide séléneux est réduit par le thiosulfate dans l'eau, il se forme des séléno-pentathionate et tétrathionate.

$$H_2SeO_3 + 4S_2O_3^{2-} + 4H^+ = Se(S_2O_3)_2^{2-} + S_4O_6^{2-} + 3H_2O$$

Suivant la stoechiométrie et le pH, les deux isomères de l'ion sélénopentathionate, liés par O et par S, se forment. Des solutions insuffisamment acides provoquent une décomposition en sélénium et en ion tétrathionate.

$$Se(S_2O_3)_2^{2-} = Se + S_4O_6^{2-}$$

Des solutions fraîchement préparées à partir de sélénopentathionate de sodium et de l'eau se décomposent lentement. Les spectres Raman et de RMN indiquent la présence des deux isomères liés par O et par S. L'isomère lié par O facilite la formation de tétrathionate. L'addition de thiosulfate à une solution de sélénotrithionate ou de sulfite à une solution de sélénopentathionate conduit à la formation de trithionate et il n'y a aucune indication de formation de dithionate ou de tétrathionate. Ces résultats suggèrent qu'il ne se produit pas de formation d'une liaison S—S simple au niveau du sélénium, mais qu'il peut se produire une attaque du coordinat qui arrive sur le coordinat qui est attaché.

Mots clés : sélénite, thiosulfate, sélénopentathionate, RMN du ^{77}Se, spectroscopie Raman, isomérie de liaison.

Introduction

The formation of the selenopentathionate ion, $Se(S_2O_3)_2^{2-}$, was first reported by Norris and Fay (1, 2). The anion was produced by the reduction of selenous acid with thiosulfate in acid solution and the reaction was used as the basis of an iodimetric method of analysis for selenites.

[1] $H_2SeO_3 + 4S_2O_3^{2-} + 4H^+ = Se(S_2O_3)_2^{2-} + S_4O_6^{2-} + 3H_2O$

Crystalline selenopentathionates were prepared by Foss (3, 4), using this reaction, and the X-ray structure determination of barium selenopentathionate dihydrate showed that the selenium is S-bonded and occupies the central position in the anion (5). Reaction [1] parallels that of selenous acid with thiols (6) and with thiocyanic acid (7),[3]

[2] $H_2SeO_3 + 4RSH = RSSeSR + RSSR + 3H_2O$

and their mechanisms (8, 9) are no doubt closely related. Reactions of selenous acid with sterically hindered thiols (8) and with sulfite ion (10) both produce -SSeS- analogues but the oxidation products are exceptional. Hindered thiols produce significant amounts of thiosulfonate, RSO_2SR, in addition to disulfide, and sulfite yields sulfate instead of dithionate ion. Although the formation of the selenopentathionate anion and the reaction stoichiometry have been established for reaction [1], spectroscopic methods have not been used and the precise nature of the sulphur oxoanion is not known. Moreover, the possibility of linkage isomerism, like that observed for selenotrithionate ion (10) and for thiosulfato–metal coordination complexes (11), has not been explored for the selenopentathionate ion. For these reasons, we undertook an investigation of reaction [1] by Raman and Se-77 NMR spectroscopy.

Experimental section

Materials

Freshly ground vitreous selenium (BDH; >99.5%), sodium thiosulfate (BDH), and sodium sulfite (BDH), were all used directly. Selenium dioxide (Aldrich) was analyzed before use by titration against standard NaOH. Distilled water, purged of oxygen by passage of nitrogen, was used thoughout.

Preparations

Sodium selenopentathionate 3-hydrate and sodium pentathionate 1.5-hydrate were prepared by the standard literature methods (3, 12). The 0.375 M tetrathionate solution was made up from a sodium thiosulfate solution and the stoichiometrically required amount of potassium triiodide solution, which were mixed dropwise at ambient temperature. The mixtures of selenous acid, sodium thiosulfate, and sulfite were made up at 0°C from deoxygenated aqueous solutions of the sodium salt and SeO_2.

Methods

The Se-77 NMR spectra were measured with a Bruker AMX 500 spectrometer operating at 95.47 MHz. A 30° tip angle was used with a 0.3 s acquisition time and no pulse delay. Between 1000 and 4000 transients were collected for each spectrum with a resolution of 3 Hz/data point. A line broadening of 5 Hz was applied and the signal-to-noise ratio was between 5 and 100, depending upon the signal. All signal line widths were estimated to lie between 3 and 20 Hz. The samples were contained in 10 mm diameter precision NMR tubes and the probe temperature was held at 5°C. All chemical shifts were measured by sample replacement with respect to saturated selenous acid in water at 22°C (13). The chemical shifts are all listed relative to $\delta(Me_2Se) = 0.0$ ppm ($\delta(Me_2Se) = \delta(H_2SeO_3) + 1300$ ppm (13)).

Raman spectra were measured with a Jobin–Yvon Ramanor HG.2S monochromator in conjunction with a PAR/Hamamatsu photon-counting system. The spectra were excited with the krypton ion line at 647.1 nm and the slits were fixed at 1600 μm, giving a resolution of better than 7 cm^{-1} at 1000 cm^{-1}. Quantitative spectra were measured at ambient temperature (23°C) and normalized against 1.0 M perchloric acid for which the 930 cm^{-1} band was taken to have an intensity of 6.45 cm^2 L mol^{-1} (14).

Results and discussion

Selenothiosulfate, $SeS_2O_3^{2-}$, formation constant

Elemental selenium dissolves to a very small extent in thiosulfate solutions (56 mg in 100 mL 2.0 M sodium thiosulfate) to produce a colourless solution. The formation constant for the reaction,

[3] $S_2O_3^{2-} + Se = SeS_2O_3^{2-}$

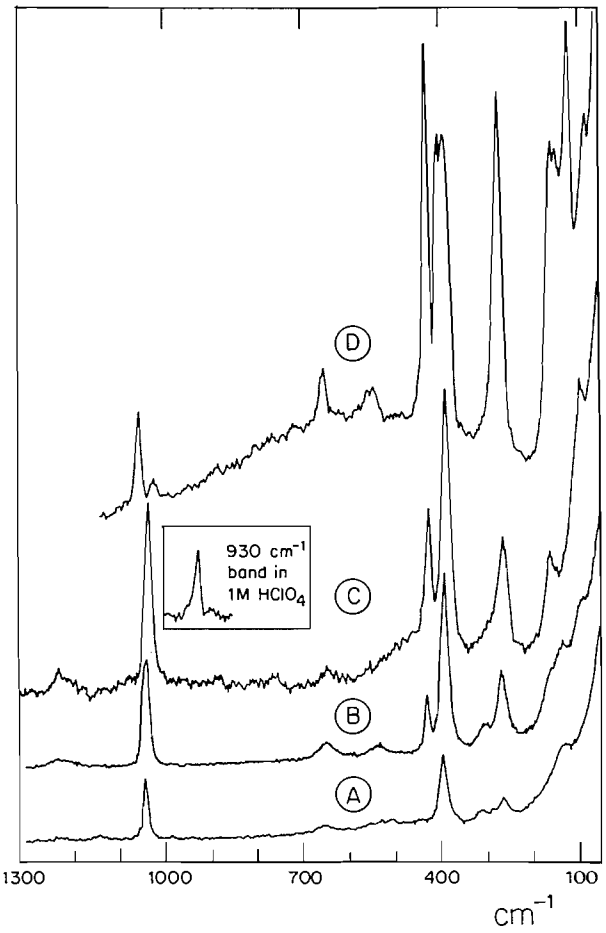
was determined by gravimetry and found to be 3.6×10^{-3} at 23°C. Selenothiosulfate formation is much less extensive than formation of the selenothiolate anion formed with 2-hydroxyethanethiolate, $HOCH_2CH_2S^-$ ($K = 0.47$ at 23°C), reflecting the decreased basicity of the terminal sulphur attached to an $[SO_3^{2-}]$ moiety relative to that of sulphur attached to $[CH_2CH_2OH^-]$. The concentration of the selenothiosulfate ion was too small for observation of an NMR signal by routine Se-77 NMR or Raman spectroscopy.

Reaction of selenite and thiosulfate

The Se-77 NMR spectrum of a 1:4:4 molar ratio solution of $SeO_2/Na_2S_2O_3/HCl$ ($c(SeO_2) = 0.5$ M), prepared by dropwise addition of a $Na_2S_2O_3$ solution to SeO_2 in HCl at 0°C, exhibits a single chemical shift at 774.3 ppm, which lies in the range of chemical shifts for Se(II) bound to two sulphur neighbours (10). The Raman spectrum of a solution prepared in the same way but with $c(SeO_2) = 0.43$ M is shown in Fig. 1 (trace B). This spectrum shows no peaks due to thiosulfate or sulfate ion. The Raman spectrum of a 0.38 M solution of sodium tetrathionate prepared by iodine oxidation of thiosulfate ion is shown in Fig. 1 (trace A). The appearance of the characteristic $S_4O_6^{2-}$ peak at 1045 cm^{-1}, to the high-frequency side of the selenopentathionate peak at 1031 cm^{-1}, and the peaks at 310 and 135 cm^{-1} in trace B is consistent with complete reaction of selenous acid and thiosulfate in acid solution as shown in eq. [1]. The other $S_4O_6^{2-}$ peaks are masked by selenopentathionate peaks at 263, 397, 520, 652, and 1237 cm^{-1}. The Raman spectrum of a 1.0 M solution of selenopentathionate, made up from the sodium salt and taken immediately after preparation,

[3] C.J. Milne and J. Milne. Manuscript in preparation.

Fig. 1. Raman spectra. Trace A: 0.375 M $S_4O_6^{2-}$; trace B: 1:4:4 $SeO_2/S_2O_3^{2-}$/HCl molar ratio ($c(SeO_2)$ = 0.43 M); trace C: 1.00 M $Na_2Se(S_2O_3)_2$ (spectrum taken immediately after makeup); trace D: crystalline $Na_2Se(S_2O_3)_2 \cdot 3H_2O$.



is given in trace C of Fig. 1 and that of crystalline $Na_2Se(S_2O_3)_2$ is given in trace D. The spectrum in trace B parallels that of the $Se(S_2O_3)_2^{2-}$ ion in traces C and D when allowance is made for the presence of the $S_4O_6^{2-}$.

The Raman spectral bands for the selenopentathionate ion in solution and in the sodium salt are listed in Table 1, along with a tentative assignment of the modes, according to the principal atomic motion that is taking place. The spectra of the pentathionate ion in solution and solid are also listed. The symmetric and asymmetric stretching and deformation modes for the [SO_3] units (1031–1053 cm^{-1}, 1210–1235 cm^{-1}, 632–652 cm^{-1}, 520–545 cm^{-1}) and the δ(SSO) mode (304–310 cm^{-1}) are assigned by comparison with similar modes in the thiosulfate ion (1004 cm^{-1} ($\nu_s(SO_3)$), 1106 cm^{-1} ($\nu_a(SO_3)$), 670 cm^{-1} ($\delta_s(SO_3)$), 538 cm^{-1} ($\delta_a(SO_3)$), 339 cm^{-1} (δ(SSO)) (15)). No attempt has been made to distinguish between in-phase and out-of-phase members of these modes, which lie relatively close together for each spectrum within each vibrational mode description, nor has the effect of local symmetry lowering on the doubly degenerate modes been considered. The symmetric stretching mode of the SSeS chain (263–269 cm^{-1}) is readily identified in the spectra by its intensity and by comparison with the related mode in the selenotrithionate ion (285 cm^{-1} (10)). The slightly lower frequency in the spectrum of $Se(S_2O_3)_2^{2-}$ may be attributed to the greater mass of the groups attached to the selenium in $Se(S_2O_3)_2^{2-}$ compared to $Se(SO_3)_2^{2-}$. The most intense observed bands in the spectra of both anions (385–431 cm^{-1}) are assigned to the symmetric and asymmetric, or in- and out-of-phase SS stretching modes (distal SS bonds in the spectrum of the $S_5O_6^{2-}$ ion). The frequencies of these bands are to be compared to the SS stretching frequency in the $S_2O_3^{2-}$ ion (447 cm^{-1} (15)). For the pentathionate, the sharp peaks in the range 480–500 cm^{-1} are assigned to the proximal SS stretching modes ($\nu(SS)_{prox}$). These modes are expected to lie to higher frequency than the distal SS stretching modes based upon the relative SS bond distances (16) as determined in crystalline $BaS_5O_6 \cdot 2H_2O$ (5) (d(SS)(distal) = 2.14 Å; d(SS)(proximal) = 2.04 Å). The predicted frequencies for these distances are 360 (distal) and 470 (proximal) cm^{-1} (16). The bands at 143–162 cm^{-1} in the spectrum of the selenopentathionate and 196–288 cm^{-1} in the pentathionate probably arise from $\delta(SChS)_s$, judging from their strength. The remaining low-frequency bands are assigned to torsional and lattice modes.

The Se-77 NMR spectrum of sodium selenopentathionate dissolved in 1:1 H_2O/HOAc by volume gives a single resonance at 775.8 ppm comparable with the chemical shift observed for the solution with 1:4:4 $SeO_2/Na_2S_2O_3$/HCl molar ratio (774.3 ppm). The signal in acidic solutions lies 107 ppm below the signal for selenotrithionate ion (881 ppm (10)), consistent with greater shielding as a result of binding to sulphur of lower oxidation state in the selenopentathionate compared to the sulphur in selenotrithionate. These acidic solutions are stable over a period of hours but neutral or basic solutions are less stable and precipitate elemental Se, usually within minutes. The variable stability of these solutions is not understood at present but preparation at 0°C improves their stability. A solution of 1:1 $SeO_2/Na_2S_2O_3$ molar ratio ($c(SeO_2)$ = 0.10 M) gives an NMR spectrum consisting of three signals at 770.2, 826.5, and 1310.5 with peak area ratio of 5.0/1.1/18. The deshielded signal arises from selenite ion (13) and the two signals with lower shifts belong to Se(II) species. The ratio of the intensities of the Se(IV) and Se(II) peaks is observed to be 3.0 to 1.0, which corresponds to the stoichiometry required by the reaction

$$[4]\quad H_2SeO_3 + S_2O_3^{2-} = 1/4S_4O_6^{2-} + 1/4Se(S_2O_3)_2^{2-} + 1/2HSeO_3^- + 1/4SeO_3^{2-} + 3/4H_2O$$

Apparently reaction [1] goes to completion but is limited by the amount of thiosulfate present. Two Se(II) species are formed in this solution. The Se-77 NMR spectrum of a 1.0 M solution of selenopentathionate ion, made up in water from crystalline sodium selenopentathionate at room temperature, shows only two signals at 775.0 and 832.5 ppm with intensity ratio 12.6/1.2, respectively, indicating the presence of the same species as in the 1:1 $SeO_2/S_2O_3^{2-}$ mixture. No selenium precipitation occurred in this solution during the period of time necessary for both Se-77 and Raman (vide infra) spectra to be recorded.

Two kinds of isomerism might be expected to occur in pentathionates, (*i*) rotational isomerism, which has been reported in crystalline solids for a variety of trichalcogen chains, where the terminal attached groups, [SO_3] groups in this case, may lie *cis* or *trans* with respect to the three-chalcogen plane (17,

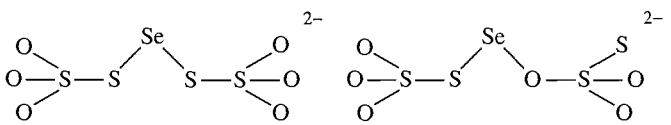
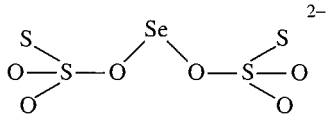
18) and (*ii*) S- and O-bonded linkage isomerism, where the $[S_2O_3]$ moiety may be bound to the central chalcogen by sulfur or oxygen. This latter type of isomerism has been observed for the selenotrithionate ion (10) in solution and S- and O-bonded isomers have been reported in Co(III) complexes (11*a*) although there is some controversy in this latter case (11*d*). The barrier to rotation about an SS bond has been estimated to be 21 kJ mol^{-1} (19). Moreover, rotation about the SS bond in 1,2-dithiane is rapid on the proton NMR time scale at ambient temperatures (20). Rotation about SeS bonds is expected to be less hindered than that about SS bonds and the observation of two Se-77 NMR peaks in the spectrum of the selenopentathionate ion is unlikely to arise from this type of isomerism. The NMR spectra are best accounted for by the formation of S- and O-bonded linkage isomers, of which three are possible.





The signal at 775 ppm is due to the [SS] isomer and that at 832.5 ppm, to either the [OS] or [OO] isomer. In the selenotrithionate isomers the signal for the [OO] isomer is 310 ppm less shielded than that of the [SS] isomer and that of the [OS] isomer is only 78 ppm less shielded. On this basis, since the second signal in the spectrum of the sodium selenopentathionate solution is only 58 ppm less shielded, it probably arises from the [OS] isomer. Further support for this interpretation comes from work by Kice, Wilson, and Espinola (21), who report the chemical shift for *t*-BuSOSeSBu-*t* at 854 ppm. The presence of S- and O-bonded isomers is supported by the Raman spectrum shown in Fig. 2 of the same 1.0 M sodium selenopentathionate solution used for the NMR experiment. This spectrum shows two strong bands, at 882 and 1089 cm^{-1}, in addition to those shown for the [SS] isomer in Fig. 1 (trace C). These bands correspond, respectively, to the single bond SO and the symmetric SO_2 stretching modes of the O-bonded thiosulfate moiety and may be compared with the related modes for the H_2SO_4 molecule (ν(S-O) = 910, $\nu_s(SO_2)$ = 1137 cm^{-1} (15)). Furthermore, comparison of the intensities of the remaining strong bands at 318, 391, 430, and 1033 cm^{-1}, relative to that of the 1 M $HClO_4$ normalization band in the spectra in both figures, shows that the bands assigned to the [SS] isomer have decreased in intensity as would be expected with the formation of the isomer. The spectrum of the O-bonded isomer should also exhibit characteristic bands corresponding to ν(SeO) and ν(SS(terminal)). These are probably overlapped with the $\delta(SO_3)$ modes in the spectrum in Fig. 2. Selenium oxygen single bond stretching lies in the region of 650 cm^{-1} in the selenotrithionate ion (10) but SS(terminal) stretching vibrations are much more variable, appearing near 450 cm^{-1} in thiosulfate ion (15) and at 758 cm^{-1} in SSF2 (22). The weak band at 1280 cm^{-1} arises from $\nu_a(SO_2)$ of the O-bonded thiosulfate group in the [OS] isomer.

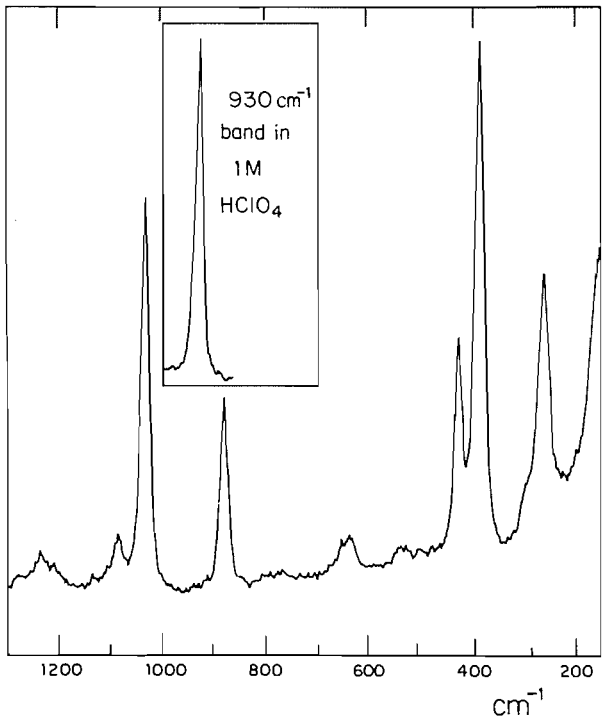

Fig. 3. Raman spectra of 0.48 M $K_2S_3O_6$ (trace A), a mixture of 0.50 M $Na_2Se(S_2O_3)_2$ and Na_2SO_3 (trace B), and a mixture of 0.29 M $Na_2Se(SO_3)_2$ and SO_4^{2-} (see text) and 0.87 M $Na_2S_2O_3$ (trace C).

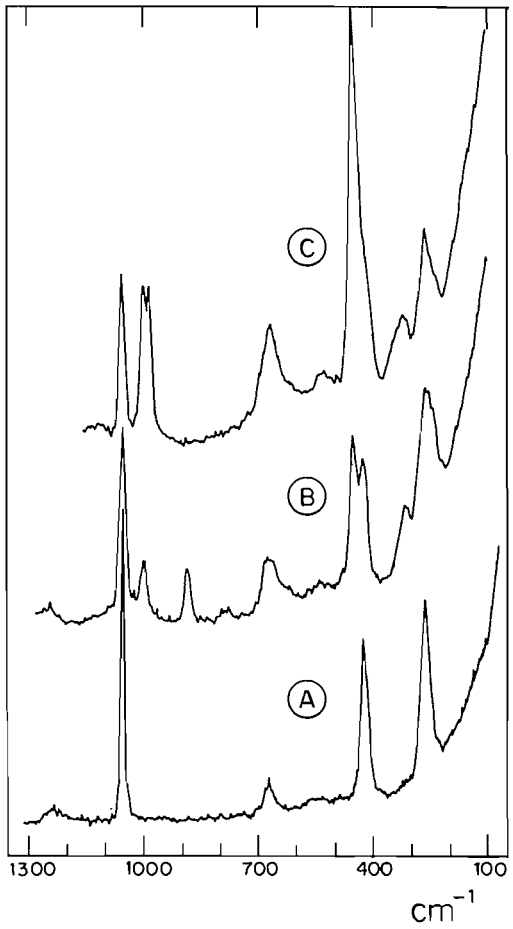

Reactions of excess sulphur donor anions with selenopenta- and selenotri-thionates

It is well known that the addition of excess sulphur donor to -SSeS- species causes decomposition to elemental selenium and the corresponding -SS- species (9). Kinetic studies have shown that nucleophilic attack on the three-chalcogen chain for bis(alkylthio)selenides (23) may occur at Se or S. The addition of thiosulfate in excess of that required for reaction [1] produces, over a period of days, copious amounts of elemental selenium. The Raman spectrum of the filtrate from the solution shows the characteristic bands of the tetrathionate anion at 395 and 1040 cm^{-1} with reduced intensity of the selenopentathionate spectrum. No evidence of other polythionates was found. To find out more about the mechanism of attack of excess sulphur donor on selenopolythionate anions, the reactions of selenopentathionate with sulfite and selenotrithionate with thiosulfate were studied. The Raman spectrum of a solution 0.50 molar in sodium selenopentathionate and sodium sulfite, which was mixed and left to stand for 24 h then filtered, is given in Fig. 3, trace B. The characteristic peaks of the [SS] isomer of the selenopentathionate anion at 389 and 1035 cm^{-1} are missing but some of the [OS] isomer is present, judging from the presence of peaks at 882 and 1089 cm^{-1}. It would be of great interest to locate the frequency of the SS stretching band in this isomer. This mode would be expected to be strong but we can only conclude that it is hidden by the envelope at 400–490 cm^{-1}. The remaining bands are readily assigned to thiosulfate (335, 450, 535, 673, and 1000 cm^{-1}) and trithionate (263, 427, 672, and 1053 cm^{-1}, trace A in Fig. 3). The broad band near 675 cm^{-1} consists of $[SO_2]$ deformation modes, and the envelope around 440 cm^{-1} contains SS stretching modes, from the [OS] isomer of selenopentathionate, thiosulfate, and trithionate ions. The breadth of the band at 1052 cm^{-1}, compared to that in the spectrum of the trithionate ion (trace A), shows that there is some contribution to this peak also from selenopentathionate. No band at 397 cm^{-1}, which would be resolved from the peak at 430 cm^{-1} under the conditions used, is observed, indicating the absence of significant concentrations of tetrathionate ion. The spectrum indicates that decomposition is occurring by the reaction

[5] $Se(S_2O_3)_2^{2-} + SO_3^{2-} = S_3O_6^{2-} + S_2O_3^{2-} + Se$

This result appears to support a mechanism in which electrophilic attack by sulfite takes place at the sulphur attached to Se, similar to the nucleophilic attack of thiolate proposed for bis(alkylthio) selenides (23). In another possible mechanism, which has been proposed (9), SS links between the ligands (SO_3^{2-} and $S_2O_3^{2-}$) would be formed by rearrangement of the three-coordinate intermediate, $Se(SO_3)(S_2O_3)_2^{4-}$, resulting in the formation of elemental selenium and either $S_4O_6^{2-}$ and SO_3^{2-} or $S_3O_6^{2-}$ and $S_2O_3^{2-}$. Such a mechanism would be facilitated by the near proximity of the ligands in the three-

coordinate complex. Given equivalent opportunity for SS bond formation, the ratio of $S_4O_6^{2-}$ to $S_3O_6^{2-}$ from such a three coordinate complex would be 1:2. However, if the attack occurred at one of the sulphurs of the SSeS chain, trithionate would be produced exclusively, as observed. Electrophilic attack may occur on the chain sulphur of the [SS] isomer or on the terminal sulphur of the [OS] isomer to form trithionate. In view of the low formation constant for $SeS_2O_3^{2-}$, the species left after trithionate formation, elemental selenium would be precipitated, releasing thiosulfate.

$$[6]\quad O_3SSSeSSO_3^{2-} \xrightarrow{SO_3^{2-}} O_3SSSO_3^{2-} + SeSSO_3^{2-}$$

$$[7]\quad SeSSO_3^{2-} = Se + SSO_3^{2-}$$

A third mechanism, which involves nucleophilic attack by the chain sulphur of the selenopentathionate ion on S(IV) in the O-bonded sulfite ligand of the complex, is discussed below.

Addition of excess sodium thiosulfate to a solution of sodium selenotrithionate, made by the reaction (10)

$$[8]\quad H_2SeO_3 + 2HSO_3^- + SO_3^{2-} \longrightarrow Se(SO_3)_2^{2-} + SO_4^{2-} + 2H_2O$$

also produced large amounts of elemental Se. The Raman spectrum of the solution ($c(Se(SO_3)_2^{2-}$ = 0.29 M; $c(S_2O_3^{2-})$ = 0.87 M), filtered after a day of standing, is given in Fig. 3, trace C. No characteristic strong peaks for the selenotrithionate ion at 236, 285, and 1030 cm^{-1} (10) appear in the spectrum, showing that reaction is complete. Judging from the absence of any peaks at 387, 882, and 1032 cm^{-1}, selenopentathionates are not present in significant amounts. Foss (4) has reported that thiosulfate ion displaces sulfite from selenotrithionate to give selenopentathionate,

$$[9]\quad Se(SO_3)_2^{2-} + 2S_2O_3^{2-} = Se(S_2O_3)_2^{2-} + 2SO_3^{2-}$$

but this is not supported by the Raman spectra. The spectrum is readily accounted for by the presence of sulfate (980 cm^{-1}, reaction [8]), trithionate (263, 427, 1053 cm^{-1}, trace A, Fig. 3), thiosulfate (339, 447, 538, 1004 cm^{-1} (15)), which was present in stoichiometric excess, and selenosulfate (310 cm^{-1} (10)).

$$[10]\quad Se(SO_3)_2^{2-} + S_2O_3^{2-} \rightarrow S_3O_6^{2-} + SeSO_3^{2-}$$

$$[11]\quad SeSO_3^{2-} = Se + SO_3^{2-}$$

The small amount of sulfite present as a result of equilibrium [11] (K = 2 (10)) is not detected because of the low intensity of sulfite modes (I(970 cm^{-1}) = 3.5 cm^2 L mol^{-1} and I(480 cm^{-1}) = 1.5 cm^2 L mol^{-1}) and overlap with strong bands of other anions present. The broad peak at 670 cm^{-1} has contributions from [SO_3] deformations for all sulphur-containing ions present. The presence of $SeSO_3^{2-}$ ion is only detected because of the very great intensity of the SeS stretching mode at 310 cm^{-1} (10), which appears on the side of the SSO deformation mode of the $S_2O_3^{2-}$ ion at 340 cm^{-1}. It is unlikely that the products of reaction [10] are produced by direct nucleophilic attack of thiosulfate ion on the sulfite sulphur of the S-bonded selenotrithionate ion for steric reasons. However, if some of the $Se(SO_3)_2^{2-}$ ion was present as the O-bonded isomer, then direct attack could occur.

Conclusions

The reaction of selenous acid with thiosulfate ion parallels that of other sulphur donors such as thiols and thiocyanic acid. The selenopentathionate ion in solution exhibits linkage isomerism like that of the selenotrithionate ion but it appears that only SSeS and OSeS linkages are formed for the selenopentathionate, compared to all three possible linkages to selenium in the case of selenotrithionate (10). The compounds isolated from these solutions show only SSeS linkages. No evidence for such linkage isomerism is observed in the case of the analogous pentathionate and trithionate ions in solution.[4] Solutions of selenopentathionate undergo slow decomposition to produce elemental selenium and tetrathionate ion and this process probably proceeds via the O-bonded isomer, which only appears in solutions of selenopentathionate upon standing and before decomposition to give elemental selenium. This isomerization step would provide a plausible intermediate for the process, with a terminal sulphur atom that could attack the proximal sulphur of the neighbouring thiosulfate group, producing tetrathionate. A similar mechanism accounts for the formation of trithionate in solutions of thiosulfate and selenotrithionate, where the sulfite sulphur is exposed to nucleophilic attack by thiosulfate via the O-bonded selenotrithionate isomer. A similar mechanism would be possible for the selenopentathionate/sulfite reaction and this is particularly attractive inasmuch as the sulfite coordination to Se(II) in the SeO_2/sulfite reaction takes place initially over oxygen (10). The importance of Se in these mechanisms, i.e., the initial coordination of sulfite or thiosulfate to selenium in the three-chalcogen chain of the selenopolythionate ions, seems likely in view of the relative inertness of the central sulphur in trithionate to attack by thiosulfate to form tetrathionate in these studies. It might be expected that, if the reaction proceeded by direct attack on sulphur as proposed in other studies (23), the susceptibility of the proximal sulphur in selenopentathionate and pentathionate ions would be comparable. This aspect should be checked and, obviously, further Raman studies and rate studies will be needed to reveal the details of these reactions.

Mixed alkali effect in sodium thiocyanate – potassium thiocyanate – acetamide melt systems

Sekh Mahiuddin

Abstract: Electrical conductivity and molar volume of the $0.25[x\text{NaSCN} + (1-x)\text{KSCN}] + 0.75\text{CH}_3\text{CONH}_2$ systems were measured as functions of temperature (≈293.15–358.15 K) and composition ($x = 0.0 - 1.0$ mol fraction). Temperature dependence of the electrical conductivity was non-Arrhenius in nature and has been analysed by using the Vogel–Tammann–Fulcher (VTF) equation. Molar volume data were fitted to an equation similar to the VTF equation based on the free volume model. Molar volumes and intrinsic volumes were found to be additive in nature. Electrical conductivity isotherms deviate from linearity in different fashion for different temperature regions. The onset of the mixed alkali effect is governed by the anion polarization effect, by a contribution of the auto-dissociated molten acetamide, and by polymeric-type solvated ions.

Key words: electrical conductivity, sodium thiocyanate, potassium thiocyanate, acetamide, mixed alkali effect.

Résumé : On a mesuré les conductivités électriques et les volumes molaires des systèmes $0{,}25[x\text{NaSCN} + (1-x)\text{KSCN}] + 0{,}75\text{CH}_3\text{CONH}_2$ en fonction de la température (d'environ 293,15 à 358, 15 K) et de la composition. La relation entre la température et la conductivité électrique n'est pas du type Arrhénius et on l'a analysée en utilisant l'équation de Vogel–Tammann–Fulcher (VTF). Les données de volumes molaires ont été ajustées à une équation semblable à celle de VTF basée sur le modèle des volumes libres. On a trouvé que les volumes molaires et les volumes intrinsèques sont de nature additive. La déviation des isothermes de conductivité électrique par rapport à la linéarité varient de manières différentes suivant les diverses régions de température. Le début de l'effet des alcalins mixtes est gouverné par l'effet de polarisation de l'anion, par une contribution de l'acétamide fondu autodissocié et par le type d'ions solvatés polymériques.

Mots clés : conductivité électrique, thiocyanate de sodium, thiocyanate de potassium, acétamide, effet d'alcalins mixtes.

Introduction

A pronounced deviation from additivity in the form of minima or maxima is generally observed in ionic and mass transport properties as the concentration of one of the alkali ions is progressively changed in a glass or melt medium (1–6) while the total alkali ion concentration is kept constant. This phenomenon is usually referred to as the mixed alkali effect (MAE). Physical properties that have been used to detect the MAE are conductivity, dielectric loss, viscosity, chemical durability, and internal friction (1, 2). A similar phenomenon has also been observed for metal cation pairs (7) with a large difference in ionic radii between the two ions. The mixed alkali effect, a particular example of the general phenomenon of the mixed cation effect, is well documented (1–3). Although there are many theories to explain the MAE, no theory explains all the data.

A significant MAE has been observed in electrical conductivity and (or) viscosity isotherms for oxide glass systems (1, 2) having an inherent rigid network structure. On the other hand, in systems containing hydrate melt as medium (5, 6) the MAE in conductivity and (or) viscosity isotherms has been detected but to a lesser extent (ca. 4%). Recently, interest has arisen in looking for the MAE in molecular liquid media (8–11) where no rigid network structure exists and deviations (minima or maxima) in electrical conductivity have been observed. Moynihan (4) suggested that the MAE may only be observed in systems with high viscosity and conductivity. On the other hand, Easteal and Emson (12) suggested, based on their studies, that the MAE becomes significant when the total alkali metal ion concentration in the system is high.

Molten acetamide is a good nonaqueous solvent for many inorganic salts due to its dipolar nature (13), and molten acetamide–electrolyte binary systems have a tendency to form supercooled liquid (14). It has been reported that Na^+ ion forms a polymeric type of solvated ion of low ionic mobility with acetamide (15). It would be interesting to study the behaviour of the electrical conductivity of Na/KSCN–acetamide systems with respect to composition and temperature and to determine whether significant MAEs can be observed in the electrical conductivity isotherms, in comparison to Na/KSCN in hydrate melts (5, 6) and aqueous (10) media. In the present communication, the purpose is to investigate the MAE in $0.25[x\text{NaSCN} + (1-x)\text{KSCN}] + 0.75\text{CH}_3\text{CONH}_2$ by measuring density and electrical conductivity as functions of composition and temperature. This system possesses high conductivity and supercooling properties, which are the criteria (4) for detecting the MAE.

Experimental section

Both NaSCN (LOBA, extra pure) and KSCN (BDH, LR grade) were recrystallized twice from distilled water and dried over P_2O_5 in a vacuum desiccator. Acetamide (SD, LR grade) was recrystallized twice from hot methanol. Final drying was done in a vacuum desiccator over fused calcium chloride. To avoid exceeding the solubility of both NaSCN (≃30 mol%) and KSCN (≃28 mol%) in molten acetamide, total alkali ion concentration was kept at 0.25 mol fraction. Six samples were prepared.

Densities (ρ) of all solutions were measured accurate to 0.01% by using a precalibrated single-stem pyknometer (≃9.5 cm^3). Electrical conductivity (κ) measurements were made by using a Precision Component Analyser-6425 (Wayne Kerr) operating in the 2.5×10^{-9} to 10 S range with a sensitivity ±0.01 nS, and platinized platinum electrodes (cell constant = 113.2 m^{-1}) with a field frequency of 1.5 kHz. The sample was put in a glass tube with ground joint and the measuring cell was well fitted to prevent diffusion of moisture. The sample tube was purged with dry nitrogen and the test sample was introduced under nitrogen atmosphere. All the measurements were made as functions of composition ($x = 0.0 - 1.0$ mol fraction) and temperature (≃293.15–358.15 K). A Schott-Geräte thermostat type CT-1450 was used to maintain the temperature of the measurements to ±0.02 K.

Results and discussion

Measured density values of 0.25 [xNaSCN + (1 − x)KSCN] + 0.75CH_3CONH_2 are linear functions of temperature and are presented in Table 1. The electrical conductivity (κ) and molar volume (V) of the present systems as functions of temperature and composition are presented in Table 2.

The measured conductivity values were found to exhibit non-Arrhenius variation with temperature, with ≃17–28% deviation within the temperature range of the study. The following equation of the Vogel–Tammann–Fulcher (VTF) type has often been used successfully to fit conductivity data, and this is again the case with the present systems.

$$[1] \quad \kappa = A \exp[-B/(T - T_0)]$$

Here A and B are constant parameters and T_0 is the ideal glass transition temperature. The best-fit values of A, B, and T_0 obtained by least squares are listed in Table 3.

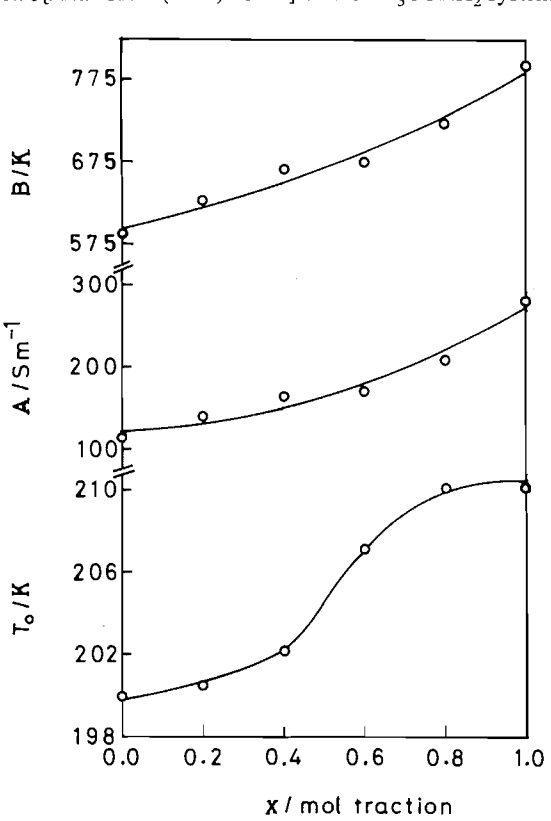
The onset of the MAE in the present systems has been examined by plotting T_0, A, and B versus x in Fig. 1. It is interesting to observe the nature of the variation of T_0 as a function of composition with both positive (in the Na^+-ion-rich region) and negative (in the K^+-ion-rich region) deviations. In general, either negative or positive deviations in T_g or T_0 with alkali ion concentration have been reported for mixed alkali systems in hydrate melts (4–6) or molecular liquids (8–11) but a system with both positive and negative deviations in T_0 has not yet been reported. For x = 1.0, the system represents the binary system 0.25NaSCN + 0.75CH_3CONH_2 with T_0 = 210.1 K, which is in reasonable agreement with T_g = 234 K (14) reported for the system 0.225NaSCN + 0.775CH_3CONH_2. The observed variation of T_0, A, and B with x (Fig. 1) reveals that the systems exhibit MAE. A probable mechanism for the peculiar variation of T_0 with x will be examined below.

Table 1. Least-squares fitted values of the density equation, $\rho = a - b(T - 273.15)$ for the 0.25[xNaSCN + (1 − x)KSCN] + 0.75CH_3CONH_2 systems.

x	a/kg m^{-3}	b/kg m^{-3} K^{-1}	σ^a
0.0	1227.5 ± 0.1	0.7258 ± 0.0024	0.09
0.2	1222.4 ± 0.1	0.7539 ± 0.0031	0.07
0.4	1218.6 ± 0.2	0.7684 ± 0.0041	0.11
0.6	1213.2 ± 0.2	0.7875 ± 0.0040	0.11
0.8	1212.3 ± 0.1	0.7847 ± 0.0031	0.09
1.0	1206.3 ± 0.2	0.7889 ± 0.0036	0.10

[a]Root-mean-square deviation.

Fig. 1. Variation of T_0, A, and B with composition, x, for the 0.25[xNaSCN + (1 − x)KSCN] + 0.75CH_3CONH_2 systems.



The conductivities of the present systems also vary nonlinearly with the molar volume. Molar volume dependence of the conductivity is explained by using the following equation, similar to eq. [1], derived based on the free volume model:

$$[2] \quad \kappa = A' \exp[-B'/(V - V_0)]$$

where A' and B' are constant parameters and V_0 is the intrinsic volume. The best-fit values of A', B', and V_0 are illustrated and presented in Fig. 2 and Table 4, respectively. From Fig. 2 it is apparent that V_0 decreases linearly with x. However, A' and B' vary nonlinearly with x. The composition dependence of A' and B' can be represented with reasonable accuracy by empirical equations of a polynomial type $A' = 80.03 + 6.53x +$

1.0	210.1 ± 1.1	283.6 ± 18.3	793.3 ± 15.1	0.006

$75.92x^2$ and $B' \times 10^5 = 1.759 + 0.560x + 0.192x^2$ with standard deviations 4.87 and 0.025, respectively. In Fig. 2 the variation of molar volume with composition is also shown for different temperatures.

In $K^+ - Na^+$ mixed alkali systems the K^+ ion has a smaller ionic potential than the Na^+ ion. In the K^+-ion-rich region, the K^+ ion behaves like an inert solute in the medium. As the K^+ ions are progressively replaced by Na^+ ions, Na^+ ions interact with acetamide and result in a polymeric-type solvated ion (15). The variation of V with x (Fig. 2) reveals that the polymeric solvated ion does not seem to cause detectable deviation in the molar volume of the present systems.

On the other hand, the molar volumes of the present systems are linear functions of temperature of the form

$$[3]\quad V = V' + b'T$$

where V' and b' are constant parameters at a particular composition and are presented in Table 5. As the system has an inherent tendency to supercool (14), the temperature dependence of the molar volume may also be represented as

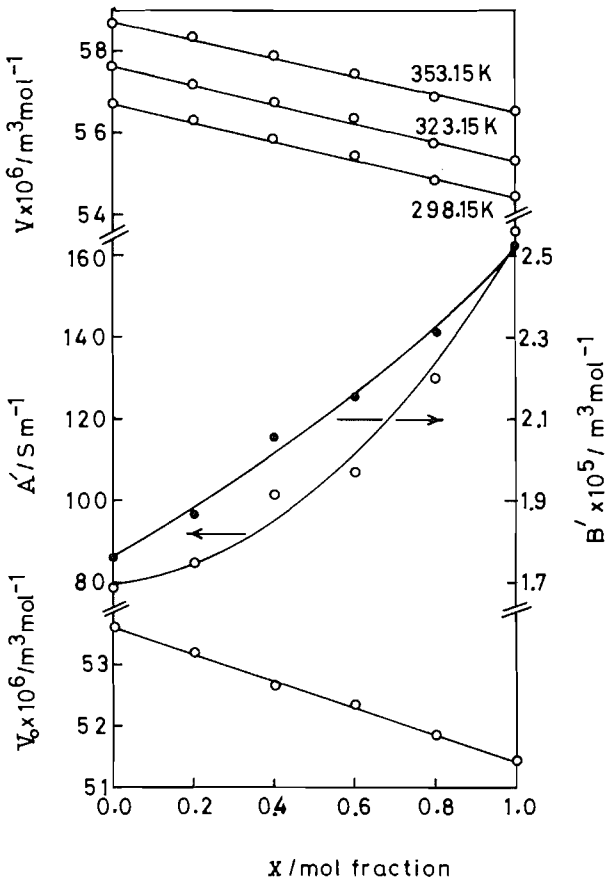
$$[4]\quad V = V_0 + b'(T - T_0)$$

Comparison of eqs. [3] and [4] gives

$$[5]\quad V' = V_0 - b'T_0$$

The values of the intrinsic volume, V_0, calculated from eq. [5]

Fig. 2. Plots of V_0, A', B', and V vs. x for the 0.25 [xNaSCN + (1 − x)KSCN] + 0.75CH_3CONH_2 systems (open and closed circles are observed and solid lines represent calculated values, respectively).



at different compositions using the values of T_0 (eq. [1] and Table 3) and the values of V' and b' (eq. [3] and Table 5) are also presented in Table 4. It is apparent from Table 4 that the V_0 calculated from eq. [5] are reasonably comparable (within 0.8%) with those from eq. [2]. Equilibrium properties such as molar volume and intrinsic volume are additive in nature and vary linearly with composition in spite of the fact that the nature of the composition dependence of T_0 for the present system is not the same throughout.

To examine the MAE in the present system, the composition dependence of the conductivity isotherms is depicted in Fig. 3. An equation of the following type (8) has been used for the concentration dependence of the electrical conductivity:

$$[6] \quad \kappa = a_1 \exp(b_1 x + c_1 x^2)$$

where a_1, b_1, and c_1 are constant parameters. Computed values of the parameters are presented in Table 6. A reasonably good fit has been obtained (Table 6 and Fig. 3).

It is very interesting to note the nature of the variation of conductivity with x above and below ≃323.15 K. The deviation of the κ isotherm from additivity in the temperature range 358.15–353.15 K is positive (≃4.6%, which is more than the uncertainties involved in the experimental data) and is pronounced in the K^+-ion-rich region. Such positive deviation

[a]Root-mean-square deviation.

decreases progressively with decrease in temperature and becomes negative (≃27% in the Na^+-ion-rich region). The deviations (positive and negative) from additivity as observed in the electrical conductivity (Fig. 3) may be attributed to the onset of the MAE in the present system.

From Fig. 3 it is apparent that the nature of the variation of κ with x varies with temperature. There is no clear transition, such as that reported in the Arrhenius plot of viscosity for the 0.225NaSCN + 0.775CH_3CONH_2 binary system (14). On the contrary, the κ vs. x isotherms of the 0.3[xKSCN + (1 − x)NaSCN] + $Ca(NO_3)$ 2·4.06H_2O (5), 0.3[xNaSCN + (1 − x)KSCN] + 0.7 $Na_2S_2O_3$·5.1H_2O (6), and [xNaSCN + (1 − x) KSCN] + RH_2O (10) systems are reported to exhibit a negative deviation from additivity. Similarly $NaNO_3$ – hydrate melt (16), –water (9), and –glycerol (8) systems also exhibit negative deviation in κ vs. x isotherms, and the anion polarization model (APM) (17, 18) has been used to explain the MAE on the electrical conductivity. Berchiesi et al. (14) suggested that the transition at ca. 293 K in the Arrhenius plot of the viscosity may be due to a change in liquid structure. Since our temperature range for the study is above and around 293 K, the nature of the deviation in conductivity isotherms above and below ≃323.15 K (Fig. 3) may be of different origin.

Fig. 3. Plots of conductivity isotherms versus composition for the $0.25[x\text{NaSCN} + (1 - x)\text{KSCN}] + 0.75\text{CH}_3\text{CONH}_2$ systems (circles and solid curves represent observed and calculated values (from eq. [6]), respectively, and broken lines represent the additive property).

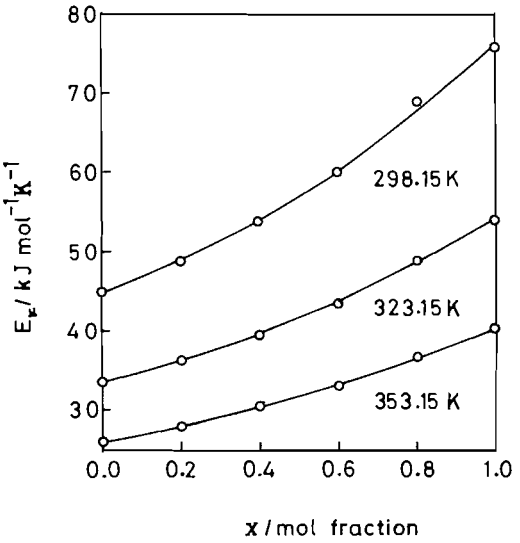
Fig. 4. Variation of activation energy, E_κ, with composition for the $0.25[x\text{NaSCN} + (1 - x\text{KSCN}] + 0.75\text{CH}_3\text{CONH}_2$ systems (circles and solid curves represent observed and calculated values (from the polynomial equation up to the second degree), respectively).



It is reported that molten acetamide, like water, under goes auto-dissociation into $(CH_3CONH_3)^+$ and $(CH_3COHN)^-$ ions (13). The positive deviation (≈4.6%) in conductivity in the K^+-ion-rich region above 323.15 K is due to the contribution of $(CH_3CONH_3)^+$ and $(CH_3CONH)^-$ ions and the higher mobility of the K^+ ion. In the Na^+-ion-rich region, according to the anion polarization model (APM) (17, 18), the SCN^- ion becomes more polarized towards Na^+ than towards K^+ due to its smaller ionic size, resulting in a decrease in the ionic mobility and, in turn, the conductivity. A similar magnitude of the deviation (≈4%), either positive or negative, was observed for Na^+–K^+ mixed alkali systems in hydrate melts (5, 6) or molecular liquid (8) as solvent. The negative deviation in conductivity (≈27%) in the Na^+ -ion-rich region below ≈323.15 K may be governed by two factors: firstly, due to the greater polarization of SCN^- on the Na^+ ion causing a decrease in the ionic mobility, and secondly, interaction of Na^+ ion with acetamide resulting in a polymeric type of solvated ion (15) with further decrease in ionic mobility. As a result a rigid structure with very high relaxation time prevails in the Na^+-ion-rich region in the present system (15, 19). Therefore, the high relaxation time, which is also one of the criteria (4) for the onset of MAE, together with the polarization effect causes maximum negative deviation in the electrical conductivity in the Na^+-ion-rich region. At the intermediate temperature (≈323.15 K) the above effects are almost counterbalanced and the variation of conductivity with composition becomes nearly linear.

The overall nature of variation of electrical conductivity with composition over the entire temperature range of the study (Fig. 3) is also reflected in the variation of T_0 with x (Fig. 1). It has been suggested (6) that the positive or negative deviations in κ would cause negative or positive deviations in T_0. Similar trends in T_0 and κ with x (Figs. 1 and 3) prevail in the present systems and the above explanation may also be applicable for the nature of the variation of T_0 vs. x.

To detect MAE further in the present systems, the activation energy, E_κ, for ion conduction has been calculated from the following relation

$$[7] \quad E_\kappa = \text{BR}[T/(T - T_0)]^2$$

where R is the gas constant. Values of the B and T_0 parameters required to calculate E_κ have been taken from Table 3. The activation energy for ion conduction varies smoothly with x (Fig. 4) in spite of the fact that the variation of T_0 with x is not the same throughout. The activation energy for the system

with $x = 1.0$ at $T = 298.15$ K is reasonably comparable with the average activation energy for the $NaSCN–CH_3CONH_2$ system studied by Berchiesi et al. (14). Therefore, the composition dependence of the B parameter appears to dominate over the variation of T_0 with x to govern the composition dependence of the activation energy.

From the nature of the variation of T_0, B, κ, and E_κ with composition (Figs. 1, 3, and 4) it may be concluded that the MAE exists in the present systems even though the systems are volumetrically ideal in nature. In addition to the polarization effect of the SCN^- ion towards the Na^+ ion, the auto-dissociation of molten acetamide and the polymeric-type solvated Na^+ ion with less ionic mobility also contribute towards positive and negative deviations in the electrical conductivity.

Propargyl calix[4]arenes and their complexes with silver(I) and gold(I)

Wei Xu, Jagadese J. Vittal, and Richard J. Puddephatt

Abstract: A calix[4]arene **1***b* has been substituted at the lower rim by reaction with propargyl bromide to give either the 1,3- bis(propargyl) derivative **2***b*, which is formed regioselectively, or the tetrakis(*O*-propargyl)calix[4]arene **3** under different reaction conditions. The molecular structure of **2***b* has been characterized by X-ray analysis (monoclinic, space group $P2_1/c$, $Z = 4$, $a = 10.960(1)$, $b = 24.302(3)$, $c = 10.673(1)$ Å, $\beta = 112.99(8)°$, $R = 0.0516$). The molecules of **2***b* in the crystal are arranged in a "head-to-head, tail-to-tail" manner with a phenyl substituent of one molecule partly enclosed in the bowlic cavity of another. Since the two $OCH_2C{\equiv}CH$ groups are accessible, **2***b* can be polymerized by heating to 250°C and the polymerized propargyl calix[4]arene derivatives are stable up to 460°C. Compound **3** exists as a mixture of conformers, the ratio of partial cone to 1,3-alternate conformations being 4:1 or 2:1, dependent on the preparative conditions. These propargyl calix[4]arene derivatives can be further derivatized to form silver(I) or gold(I) alkynyl units by reaction with $AgNO_3$ or $[AuCl(SMe_2)]$, respectively, and base. Further reaction of these transition metal complexes with phosphines yields calixarene derivatives with two metal-phosphine units at the lower rim of the calix[4]arene bowl.

Key words: calix[4]arene, propargyl, gold, silver, polymer.

Résumé : On a substitué un calix[4]arène. **1***b*, sur sa portion inférieure en le soumettant à une réaction avec du bromure de propargyle qui conduit au dérivé 1,3-bis(propargyle), **2***b*, qui se forme régiosélectivement, ou au tétrakis(*O*-propargyl)calix[4]arène, **3**, sous des conditions réactionnelles différentes. La structure moléculaire du composé **2***b* a été caractérisée par diffraction des rayons X (monoclinique, groupe d'espace $P2_1/c$, $Z = 4$, $a = 10,960(1)$, $b = 24,302(3)$ et $c = 10,673(1)$ Å, $\beta = 112,99(8)°$ et $R = 0,0516$). Dans le cristal, les molécules de **2***b* sont arrangées de façon « tête à tête, queue à queue » avec un substituant phényle d'une molécule partiellement entouré dans la cavité d'une autre. Puisque les deux groupes $OCH_2C{\equiv}CH$ sont accessibles, le produit **2***b* peut être polymérisé par chauffage à 250°C et les dérivés polymérisés propargyl calix[4]arène sont stables jusqu'à 460°C. Le composé **3** existe sous la forme de conformères pour lesquels le rapport des conformations à cône partiel/alterné-1,3 est de 4 : 1 ou de 2 : 1 suivant les conditions de préparation. On peut préparer de nouveaux dérivés de ces dérivés propargyl calix[4]arènes de façon à former des unités argent(I) ou or(I) alcynyles par réactions respectivement avec du $AgNO_3$ ou du $[AuCl(SMe)_2]$ en présence de base. Des réactions ultérieures de ces complexes de métaux de transition avec des phosphines fournissent des dérivés de calixarène comportant deux unités métal-phosphine dans la partie inférieure du bol du calix[4]arène.

Mots clés : calix[4]arène, propargyle, or, argent, polymère.

Introduction

Calix[4]arenes are useful building blocks for more complicated molecules with unusual properties (1) and the hydroxyl substituents that are usually present are very useful for chemical modification. General procedures have been developed for regio- and stereoselective functionalization at the lower rim of calix[4]arenes such as *tert*-butylcalix[4]arene, **1***a* (2–6). However, it has proved to be more difficult to study the regio- and stereo-selectivity of reactions of the parent calix[4]arene, **1***b*. The derivative 1,3-bis(*O*-propargyl)-*tert*-butylcalix[4]arene, **2***a*, has been reported (6) and such compounds are of interest as potential encapsulating ligands for transition metal ions by coordination to the alkynyl substituents (7). This paper reports the regioselective synthesis of a new 1,3-dipropargyl calix[4]arene derivative **2***b* and a tetrapropargyl calix[4]arene derivative **3**, together with a study of their conformations, conformational mobility, thermal properties, and ability to form complexes with silver(I) and gold(I).

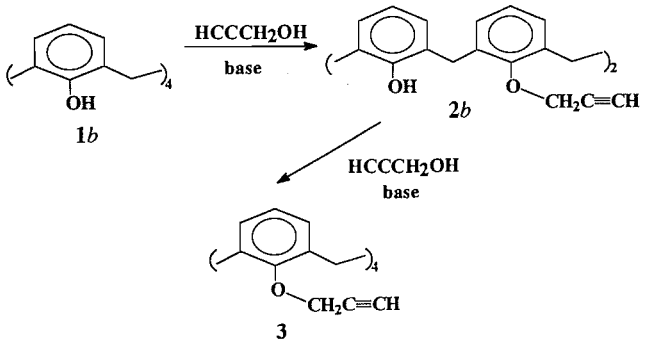
Results and discussion

Regioselective synthesis and structure of 1,3-bis(*O*-propargyl)calix[4]arene, 2*b*

Calix[4]arenes are readily converted into a wide variety of derivatives at the lower ring by alkylation of the phenolic groups (8). In this way, the 1,3-bis(*O*-propargyl)calix[4]arene **2***b* was prepared regioselectively in high yield (92%) from propargyl bromide and calix[4]arene **1***b* in a 1:2 ratio in acetone solution in the presence of potassium carbonate as shown in Scheme 1. The ^1H NMR spectrum of **2***b* exhibited an AB

Scheme 1.



pattern for the bridging methylene groups at δ 3.40 and 4.40 ppm ($^2J_{HH}$ = 14 Hz), a triplet for the acetylenic proton at 2.58 ppm ($^4J_{HH}$ = 4 Hz), a doublet for the methylene groups of the propargyl units at 4.25 ppm ($^4J_{HH}$ = 4 Hz), an A_2B system for the aromatic protons at 6.66–7.08 ppm, and a singlet for the phenolic protons at 7.05 ppm (confirmed by D_2O exchange). These data, together with the ^{13}C NMR evidence, show that **2***b* in solution exists in the cone conformation (1).

The conformation of **2***b* in the solid state was determined by an X-ray structure determination. The 1,3-bis(*O*-propargyl)calix[4]arene **2***b* adopts the cone conformation in a distorted form as shown in Fig. 1. The two benzene rings bearing propargyl groups are almost parallel to each other (interplanar angle 2.28(1)°), while the two phenolic rings have a relatively large interplanar angle (77.7(1)°) and are tilted to place the two hydroxy groups almost inside the cavity with a small O...O separation of 2.9 Å. This arrangement allows intramolecular hydrogen bond formation between proximal hydroxy and ether groups with OH..O distances of 2.0–2.3 Å. These hydrogen bonds are probably responsible for holding the molecule in the cone conformation (8*a*). There are a number of related dihydroxycalixarenes, which display similar hydrogen bonding, of which a bis(*O*-cyanomethyl) analog is particularly striking (6*a*). In addition to these intramolecular hydrogen bonds, there is structural evidence for weak intermolecular "tail-to-tail" hydrogen bonds between C≡C-H..OH groups of adjacent molecules, leading to chains of molecules (Fig. 2*b*). These are examples of so-called "soft" CH..O hydrogen bonds (8*b*). Finally, a phenyl group of each calixarene molecule is partially enclosed in the bowlic cavity of a neighboring molecule (Fig. 2*a*), thus creating "head-to-head" association that leads to blocking of the entrance to the cavity. Small molecule inclusion, which has often been observed in 1,3-dialkylated *tert*-butylcalix[4]arenes, is therefore not present in **2***b*. Bond lengths and angles are unexceptional and are summarized in Table 1.

Synthesis and conformations of the tetrakis(*O*-propargyl)calix[4]arene 3

The calixarene **2***b* did not react with excess propargyl bromide and base at room temperature (7), but either **1***b* or **2***b* did react with excess propargyl bromide in refluxing acetone in the presence of K_2CO_3 to give the new tetrapropargyl calix[4]arene derivative **3**. At short reaction times, a mixture of products representing various stages of alkylation were present but, after 1 day, complete conversion to the tetrakis(*O*-propargyl)calix[4]arene **3** occurred. After 24 and 48 h reflux,

the calix[4]arene **3** was present as a mixture of the partial cone and 1,3-alternate conformers in 2:1 and 4:1 ratios, respectively. Clearly, in the absence of hydroxyl groups to take part in hydrogen bonding, the cone conformation is no longer preferred and so there is a major difference from **2***b* in this respect.

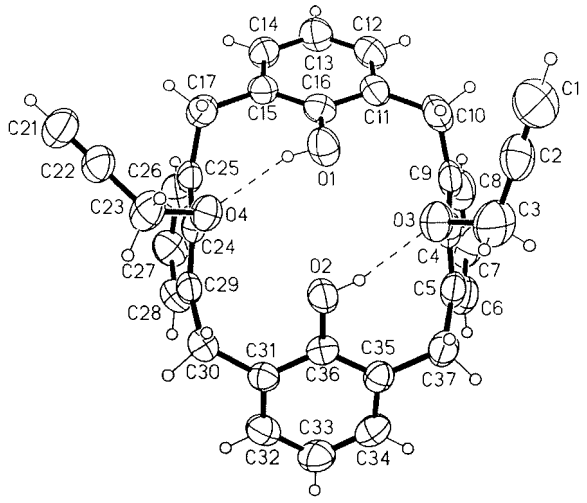
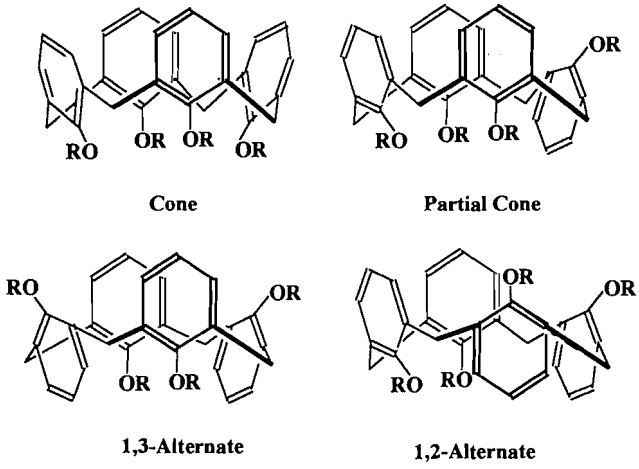
Fig. 1. A view of the molecular structure of **2***b*, showing the cone conformation and intramolecular OH..O hydrogen bonding.

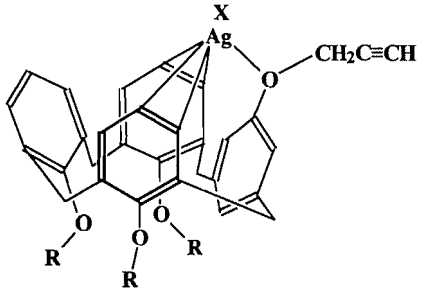


Scheme 2.



Many tetrakis(*O*-alkyl)calix[4]arene derivatives (though only if the alkyl group is smaller than propyl) are conformationally flexible at room temperature. A schematic representation of the four possible conformers of tetrakis(*O*-propargyl) calixarene with the different orientations of the phenyl rings of the cyclic tetramer is shown in Scheme 2. It has been established that the conformations of calix[4]arenes can be determined by the splitting pattern of the $ArCH_2Ar$ methylene protons in the ^1H NMR spectra and by the number of peaks in the ^{13}C NMR spectra (6, 8). The conformational isomerism of **3** is demonstrated from the observation that the ratio of 1,3-alternate to partial cone conformer is dependent on the conditions of formation, and this observation also shows that the interconversion between conformers is very slow at room temperature. In agreement with the latter conclusion, the ^1H NMR spectrum of **3** recorded at room temperature at 300 MHz showed sharp signals with no evidence of exchange broadening (Fig. 3). The ^1H NMR spectrum in the methylene region is particularly informative (Fig. 3). The minor 1,3-alternate conformer has higher symmetry and gives rise to single resonances of equal intensity due to the CH_2 groups of the propargyl (H^1, 4.08 ppm, d, J(HH) = 4 Hz) and CH_2Ar_2 (H^2, 3.76 ppm, s) groups. The major partial cone conformer has lower symmetry and its spectrum is correspondingly more complex. There are two nonequivalent CH_2Ar_2 groups and each has nonequivalent protons CH^aH^b, thus giving rise to four resonances labelled H^{3a}, H^{3b}, H^{4a}, H^{4b}. There are three nonequivalent propargyl groups in a 1:1:2 ratio, and the CH_2 protons of the last propargyl groups are also nonequivalent. Each CH_2 resonance appears as a doublet due to the coupling $^4J(CH_2CCH)$. Hence there are four resonances, two appearing as doublets (H^5, H^6) and two (H^{7a}, H^{7b}) as more complex multiplets due to the extra coupling $^2J(H^{7a}H^{7b})$. The ratio of partial cone to 1,3-alternate conformer was 4:1 as determined by integration of the spectra, and the spectral assignments are in agreement with those for similar compounds (8). The ^{13}C NMR spectra in both the $ArCH_2Ar$ and OCH_2CCH regions (Experimental section) provided a further diagnostic tool to confirm that the only conformations present are the partial cone and 1,3-alternate at room temperature (9).

It has previously been reported that the conformation of *O*-alkylated calixarenes can be frozen as a single conformation, the partial cone, by complexation with the silver cation, which binds to two arene groups and one ether group (10). In agreement, addition of silver(I) trifluoroacetate to a solution of **3** gave the tetrakis(*O*-propargyl)calix[4]arene–silver(I) complex **4**, which was shown by its ^1H NMR spectrum to exist only as the partial cone conformer. Hence weak binding of the silver cation probably occurs as shown in **4** and not by binding to the C≡C bonds of the propargyl substituents (11).

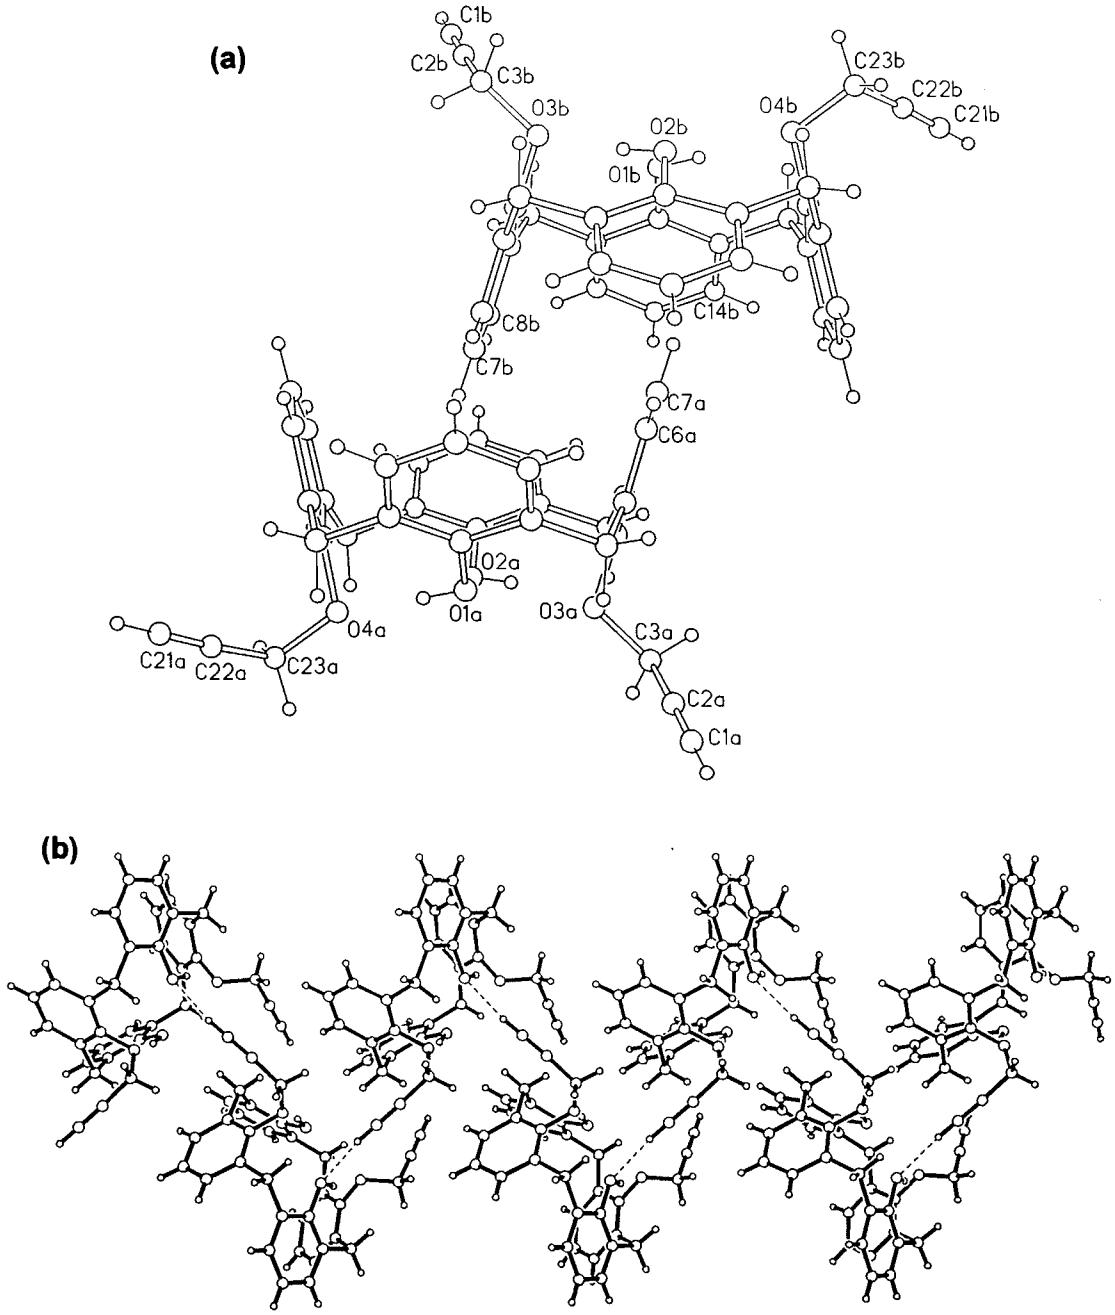


4: R= CH_2CCH; X = O_2CCF_3

Polymerization of the propargyl calix[4]arene derivatives

It is known that the dipropargyl derivatives of bisphenols are attractive building blocks for resins for use as advanced composites, adhesives, coatings, and electronics applications (12). Hence polymerization of the propargyl calix[4]arenes was studied (13). The polymerization of **2***a* or **2***b* was performed by heating in diphenyl ether for 6 h at 120°C and then for 2 h at 150–160°C without a catalyst (12, 13). The polymerization proceeded without evolution of any volatiles and produced a solid thermoset resin **5**. The polymer **5** is soluble in many organic solvents and is neither hygroscopic nor moisture sensitive. The molecular weight of **5***a*, as estimated by gel permeation chromatography (GPC) with THF as eluent and using polystyrene standards, was M_w = 56 000 with a polydispersity (M_w/M_n = 3.2). Differential scanning calorimetry (DSC) measurements of the poly(1,3-(*O*-propargyl)-*tert*-butylcalix[4]-arene), **5a**, shows an exceptionally high glass transition temperature, T_g, of the polymer at 250°C (14). TGA of the polymer **5***a* in air (Fig. 4) shows that decomposition with weight loss occurs above 460°C, which is slightly higher than for its

Fig. 2. Intermolecular interactions in **2***b*: (*a*) The head-to-head arrangement, showing mutual aryl group inclusion. (*b*) The tail-to-tail association involving C≡CH..O hydrogen bonding.



precursor **2***a* (440°C). Clearly, the propargyl calix[4]arene polymer has excellent thermal stability. The polymer is formed through opening of the triple bonds of the propargyl groups. Thus, **5***a* gave broad ^{1}H NMR resonances at δ = 1.0, 2.1 and 3.7, 6.3, and 7.0 which are assigned to the *t*-Bu, CH_2, =CH, and aromatic protons, respectively. In agreement, the FTIR showed the absence of alkyne groups, with no bands corresponding to the bands of **2***a* due to $\nu_{CC\text{-}H}$ = 3289 cm^{-1} (s) or $\nu_{C\equiv C}$ = 2120 cm^{-1} (w).

Complexes of 2 and 3 with transition metals

There is much current interest in the properties of calix[4]arenes as ligands (13, 15–18) and so the synthesis of alkynylmetal complexes from the propargylcalix[4]arenes was studied. Treatment of **2***a* with [AuCl(SMe_2)] in the presence of sodium acetate as base gave the digold(I) complex **6***a*. The ^{1}H NMR spectrum of **6***a* is broad but the observation of only two broad signals due to the methylene protons of the calixarene at 3.4 and 4.2 ppm, one broad resonance due to the methylene protons of the propargyl groups at 4.3 ppm, and one broad Bu^t resonance at 1.1 ppm indicates that **6***a* is primarily in the cone conformation. The FTIR spectrum showed the absence of a CC-H proton (disappearance of the band due to ν_{CCH} at 3275 cm^{-1}) and the presence of a new weak band due

Fig. 3. The ^{1}H NMR spectrum of compound **3** in the methylene region.

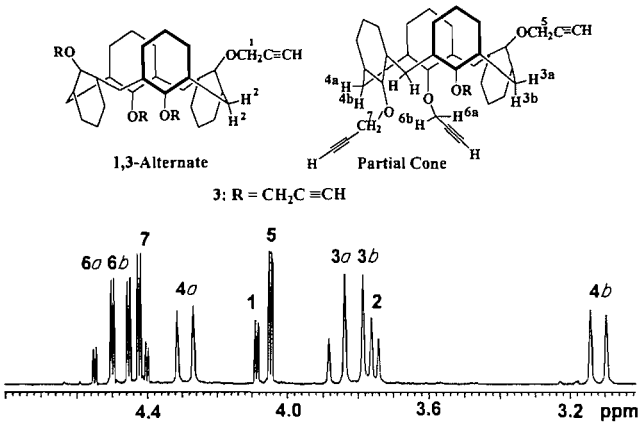


Fig. 4. (*a*) TGA of **2***a*; (*b*) TGA of polymeric **2***a*.

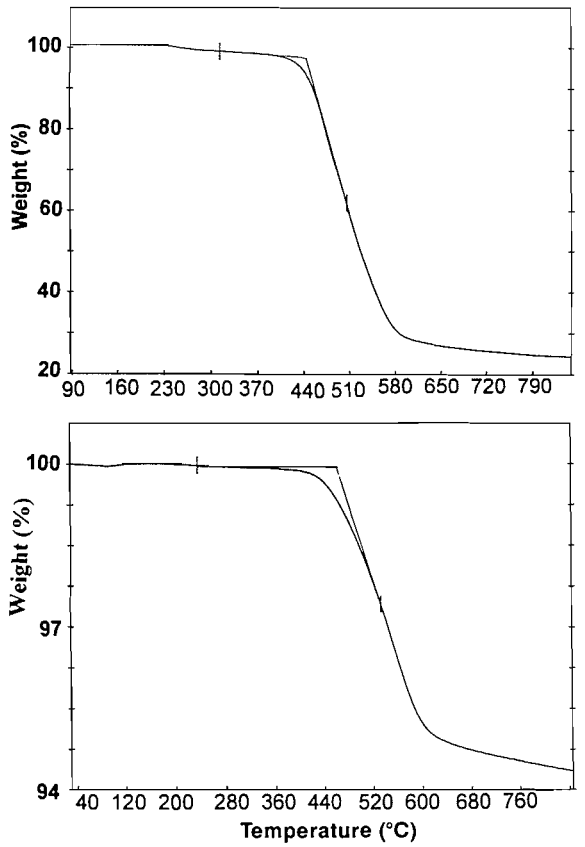


to $\nu_{C\equiv CAu}$ at 1988 cm^{-1}. Alkynylgold(I) complexes are usually oligomeric or polymeric $(RC\equiv CAu)_n$ to allow the gold(I) centres to be linear 2-coordinate. Complex **6***a* could be of this type or each gold(I) centre could be weakly ligated by oxygen donors present in the calixarene skeleton; since **6***a* is soluble in organic solvents it is probably not polymeric (19). In similar ways, **2***a* reacted with silver nitrate and ammonia to give **6***b*, and **3** reacted with $[AuCl(SMe_2)]$ and sodium acetate to give complex **7** as shown in Scheme 3.

Further reaction of these propargylmetal complexes **6** and **7** with either monodentate or bidentate phosphine ligands gave the corresponding complexes **8** and **9** as shown in Scheme 3. The complexes **8***a*–**8***d* are in the cone conformation and have C_2 symmetry, with the two metal-phosphine units at the lower rim of the calix[4]arene. The resonances in the ^{1}H NMR spectra due to the CH_2 groups serve as spectroscopic probes, and clearly indicate the cone conformation. The complexes **9***a* and **9***b* give similar ^{1}H NMR resonances as for their precursor **3**, indicating that the complexation of the propargyl groups does not change the conformation and that there is still a mixture of the partial cone and 1,3-alternate conformations, which do not easily interconvert. The complexes **8** and **9** do not exhibit the inclusion behaviour that is typical of other calixarenes (1), perhaps because the bulky metal-phosphine substituents at the lower rim cause the aryl rings to which they are bound to tilt in such a way as to close access to the top of the bowl (20).

Conclusion

This work has shown that the calixarene **1***b* can be functionalized with two or four propargyl groups at the lower rim and that the reaction to give the dipropargyl derivative is regioselective. Preliminary studies indicate that silver(I) can be incorporated into the propargylcalix[4]arenes either by weak π-bonding to the arene groups or, in the presence of base, by forming σ-bonded propargylsilver(I) groups. Gold(I) also forms propargyl derivatives containing two or four gold atoms. Clearly there is potential for further derivatization of these propargylcalix[4]arenes with metal substituents but it may prove difficult to develop useful inclusion chemistry. In this sense, the incorporation of propargyl groups at the upper rim is preferred and the synthesis and coordination chemistry of such compounds is planned.

Experimental section

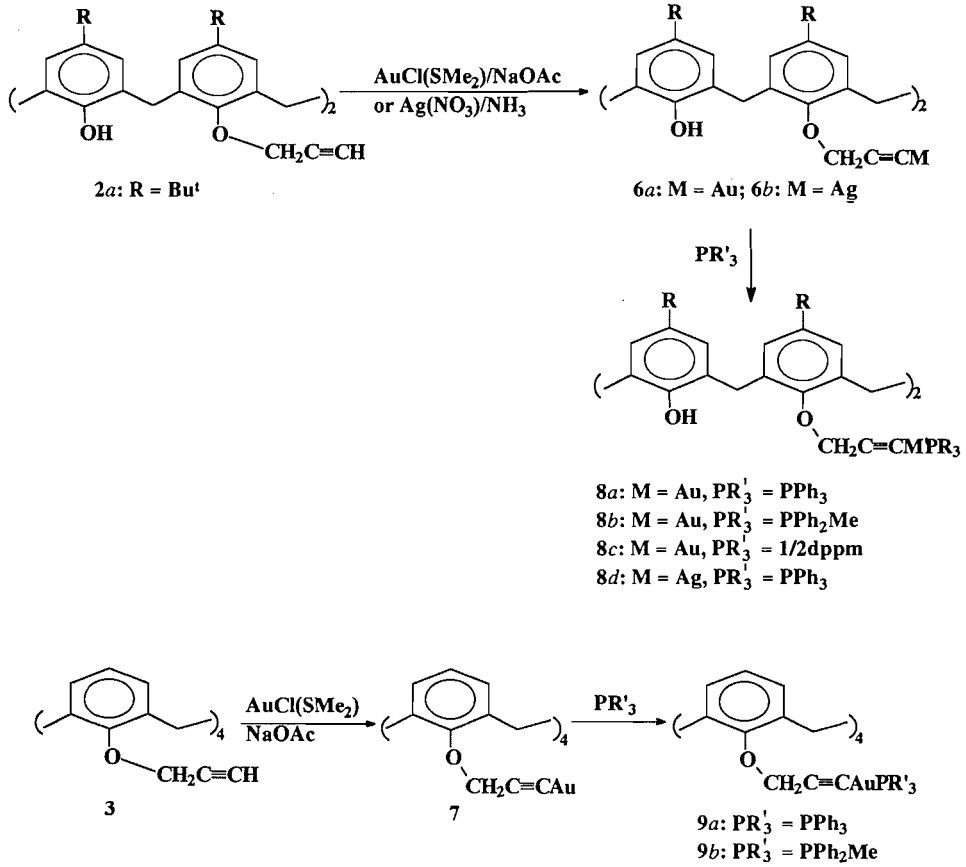
The precursor compounds 5,11,17,23-tetra-*tert*-butylcalix[4]arene, **1***a* (21), calix[4]arene **1***b* (22), 5,11,17,23-tetra-*tert*-butyl-25,27-bis(propargyl)calix[4]arene, **2***a* (7), and $[AuCl(SMe_2)]$ (19) were prepared by literature methods. Molecular modeling was carried out using PCMODEL.[2] NMR spectra were collected by using a Varian Gemini 300 spectrometer. ^{1}H and ^{13}C NMR chemical shifts were measured relative to partially deuterated solvent peaks, but are reported relative to tetramethylsilane. ^{31}P NMR chemical shifts were determined relative to 85% H_3PO_4 as external standard. IR spectra were recorded as Nujol mulls using a Bruker IFS32 FTIR spectrometer. The molecular weights of poly[1,3-(*O*-propargyl)-*tert*-butylcalix[4]arene] and of poly[1,3-(*O*-propargyl)calix[4]-arene] were measured by GPC using THF as solvent and polystyrene standards for calibration. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn. Mass spectra were recorded by using a Finnegan mat 8230 mass spectrometer.

1,3-Di-*O*-propargylcalix[4]arene, 2*b*

A solution of calix[4]arene **1***b* (0.5 g, 1.18 mmol) and $BrCH_2CCH$ (0.5 g, 4.2 mmol) in acetone (100 mL) and K_2CO_3 (1.2 g, 8.7 mmol) were stirred for 12 h at 20°C. The solvents

[2] PCMODEL Molecular Modeling Software, version 4.2, Serena Software, 1992.

Scheme 3.



were removed under vacuum and the residue was extracted using chloroform (20 mL). **2***b* can be further purified by crystallization, by slow diffusion of methanol into a chloroform solution. The light yellow crystals of **2***b* (0.54 g, 92%) were collected by filtration, washed with hexane (3 × 20 mL), and dried under vacuum, mp 182–184°C. Spectroscopic data for **2***b*: FTIR: ν_{OH} = 3423 cm^{-1} (s), ν_{CCH} = 3275 cm^{-1} (s), ν_{CC} = 2118 cm^{-1} (w). NMR in $CDCl_3$, δ(^{1}H): 2.58 (t, $^4J_{HH}$ = 4 Hz, 2H, CC*H*), 3.40, 4.40 (ABq, $^2J_{HH}$ = 13 Hz, 8H, ArCH_2Ar), 4.80 (d, $^4J_{HH}$ = 4Hz, 4H, OC*H*), 6.66–6.73 (m, 4H, Ar*H*), 6.85 and 6.82 (s, 4H, Ar*H*), 7.08 and 7.06 (s, 4H, Ar*H*), 7.05 (s, 2H, O*H*). δ(^{13}C): 63.46 (*C*H_2CCH), 31.85 (Ar*C*H_2Ar), 78.32 (CH$_2$*C*CH), 153.03, 151.37, 133.42, 129.01, 128.56, 128.26, 125.75, 119.25 (Ar). EI-MS, *m/e*: 500; calcd. for $C_{34}H_{28}O_4$: 500.

Single crystal X-ray analysis of 2*b*

Single crystals of complex **2***b* were obtained as described above. A suitable crystal with dimensions of 0.42 × 0.35 × 0.22 mm was selected, mounted at the end of a glass fibre, and used for the experiments. The diffraction experiments were carried out using a Siemens P4 diffractometer with the XSCANS software package[3] using graphite monochromated Mo K radiation at 23°C. The cell constants were obtained by centering 25 high-angle reflections (20.7 ≤ Θ ≤ 21.7°). The Laue symmetry 2/*m* was determined by merging symmetry equivalent reflections. A total of 5666 reflections were collected in the Θ range 2.0–25.0° (−13 ≤ h ≤ 1, −1 ≤ *k* ≤ 28, −12 ≤ *l* ≤ 12) in Θ–2Θ scan mode at variable scan speeds (2–10 deg/min). Background measurements were made at the ends of the scan range. Three standard reflections were monitored at the end of every 297 reflections collected. An empirical absorption correction was applied to the data. The maximum and minimum transmission factors are 0.956 and 0.939, respectively. The space group $P2_1/c$ was determined from the systematic absences (*h*0*l*, *l* = 2*n* + 1 and 0*k*0, *k* = 2*n* + 1). The data processing, solution, and the initial refinements were done using the SHELXTL-PC programs (23). The final refinements were performed using SHELXL-93 software programs (24). Anisotropic thermal parameters were refined for all the non-hydrogen atoms. The hydrogen atoms were not directly located but were included in the calculated positions for the purpose of structure factor calculations only. In the final least-squares refinement cycles on F^2 the model converged at R_1 = 0.0516, wR_2 = 0.1046, and GOf = 1.008 for 2659 observations with $F_o \geq 4\sigma(F_o)$, 366 parameters, and R_1 = 0.1101, wR_2 = 0.1288 for all 4612 data. In the final difference Fourier synthesis the electron density fluctuates in the range 0.17 to −0.17 e Å^{-3}, of which the top peak was associated with O(1) at a distance of 1.06 Å. There is no shift in the mean or the maximum shift/esd in the final cycles. A secondary extinction coefficient was refined to 0.0035(5). Experimental detail and crystal data are summarized in Table 2. The positional and thermal parameters, bond distances and angles, the anisotropic thermal parameters,

Tetrakis(*O*-propargyl)calix[4]arene-Ag(CF_3COO), 4

A mixture of **3** (0.2 g, 0.35 mmol) and Ag(CF_3COO) (0.08 g, 0.36 mmol) in acetone (100 mL) was stirred for 2 h at room temperature. The product **4** (0.26 g, 93%) was precipitated by adding methanol (10 mL). Spectroscopic data of **4:** FTIR: ν_{CCH} = 3289 cm^{-1} (s), ν_{CC} = 2120 cm^{-1} (w). ^{1}H NMR in $CDCl_3$: δ: 2.20 (t, 1H, $^4J_{HH}$ = 4 Hz, CC*H*), 2.50 (t, 2H, $^4J_{HH}$ = 4 Hz, CC*H*), 2.54 (t, 1H, $^4J_{HH}$ = 4 Hz, CC*H*); 4.29 and 3.12 (AB q, 4H, $^2J_{HH}$ = 21 Hz, ArCH_2Ar), 3.82 (AB q, 4H, $^2J_{H\text{-}H}$ = 21 Hz, ArCH_2Ar), 4.48 (AB q, 4H, $^4J_{HH}$ = 4 Hz, $^2J_{HH}$ = 24 Hz, OCH_2), 4.46 (d, $^4J_{HH}$ = 4 Hz, 2H, OCH_2), 4.04 (d, $^4J_{HH}$ = 4 Hz, 2H, OCH_2); 6.46–7.42 (m, 12H, Ar*H*). Anal. calcd. for $C_{42}H_{32}AgO_6F_3$: C 63.3, H 4.0; found: C 63.0, H 3.8%.

Poly[1,3-(*O*-propargyl)calix[4]arene), 5

A solution of **2** (0.5 g) in Ph_2O (10 mL) was heated to 120°C for 6 h and then heated to 150–160°C for another 2 h under nitrogen atmosphere, to give an orange-brown hard resin (0.5 g) after evaporation of the Ph_2O. The polymer was purified by dissolving the solid obtained above in THF (2 mL) and then precipitating with MeOH (20 mL). The precipitate **5** was a yellow solid, which was dried under vacuum. Spectroscopic data of *poly[1,3-(*O*-propargyl)-*tert*-butylcalix[4]arene*, **5***a*: FTIR: ν_{OH} = 3370 cm^{-1} (s). ^{1}H NMR in $CDCl_3$: δ: 1.1 (br, Bu^t), 2.1 (br, ArCH_2Ar), 3.2 (br, ArCH_2Ar) 3.4 (br, OCH_2), 6.3 (br, =C*H*), 7.0 (br, Ar and O*H*). Spectroscopic data of *poly(1,3-(*O*-propargyl)calix[4]arene)*, **5***b*: FTIR: ν_{OH} = 3370 cm^{-1} (s). ^{1}H NMR in $CDCl_3$; δ: 2.2 (br, ArCH_2Ar), 3.3 (br, 8H, ArCH_2Ar), 3.4 (br, 4H, OCH_2), 6.1 (br, =C*H*), 7.0 (br, 10H, Ar and O*H*).

1,3-Bis(*O*-propargylsilver)tetra-*tert*-butylcalix[4]arene, 6*b*

A solution of **2***a* (0.5 g, 0.69 mmol) in THF (5 mL) was mixed with a solution of $AgNO_3$ (0.235 g, 1.38 mmol) in ammonia (10 M, 5 mL) and the mixture was stirred for 3 h. The product precipitated as the volume of solvent was reduced, and was purified by dissolving in CH_2Cl_2 (5 mL) and then precipitating by addition of MeOH (20 mL). The yellow product was filtered, washed with MeOH, and dried under vacuum. FTIR: ν_{CC} = 2058 cm^{-1} (w). ^{1}H NMR in $CDCl_3$, δ: 1.1 (br, m, 36H, Bu^t), 3.4 (br, ArCH_2Ar), 4.2 (br, 4H, ArCH_2Ar), 4.2 (br, 4H, OCH_2), 7.0 (br, 10H, Ar and O*H*). Anal. calcd. for $C_{50}H_{58}Ag_2O_4$: C 64.0, H 6.2; found: C 63.7, H 5.9%. Complex **6***a* was prepared in a similar way but using [AuCl(SMe$_2$)] with NaOAc as base. Spectroscopic data for *1,3-bis(*O*-propargylgold)tetra-*tert*-butylcalix[4]arene*, **6***a*: FTIR: ν_{CC} = 2015 cm^{-1} (w). ^{1}H NMR in $CDCl_3$, δ: 1.1 (br, m, 36H, Bu^t), 3.4 (br, 4H, ArCH_2Ar), 4.2 (br, 8H, ArCH_2Ar and OCH_2), 7.0 (br, 10H, Ar and O*H*). Anal. calcd. for $C_{50}H_{58}Au_2O_4$: C 53.8, H 5.2; found: C 54.0, H 5.3%. Complex **7** was prepared in a similar way from the calixarene **3**. Spectroscopic data for

Kinetic energy analysis of atomic multiplets. II. $s^m d^n$ configurations

Toshikatsu Koga, Hidenori Aoki, and Ajit J. Thakkar

Abstract: A kinetic energy analysis of total energy differences in 822 atomic multiplets arising from $s^m d^n$ ($m = 0,1,2$; $n = 2$–8) electronic configurations is performed within the nonrelativistic, restricted Hartree–Fock framework. For the 444 multiplets arising from the d^n and $s^2 d^n$ configurations of 27 atoms in groups 2–10, a very good linear correlation between the total energy difference and the kinetic energy difference of the outermost d-electrons is demonstrated. For the 378 multiplets arising from the sd^n configuration, on the other hand, a good linear correlation is obtained provided that the multiplets are classified into groups based on spin multiplicity.

Key words: kinetic energy, atomic multiplets, $s^m d^n$ configurations, Hartree–Fock approximation.

Résumé : Une analyse de l'énergie cinétique des différences de l'énergie totale de 822 multiplets atomiques dérivant de configurations électroniques $s^m d^n$ ($m = 0,1$ ou 2; $n = 2$–8) a été réalisée dans le cadre restreint, non relativiste de Hartree–Fock. Pour les 444 multiplets dérivant des configurations d^n et $s^2 d^n$ des 27 atomes des groups 2–10, on a obtenu une très bonne corrélation linéaire entre la différence de l'énergie totale et la différence de l'énergie cinétique des électrons d des couches les plus extérieures. Par ailleurs, pour les 378 multiplets dérivant de la configuration sd^n, on a obtenu une bonne corrélation à la condition que les multiplets soient classifiés en groupes basés sur la multiplicité de leurs spins.

Mots clés : énergie cinétique, multiplets atomiques, configurations $s^m d^n$, approximation de Hartree–Fock.

[Traduit par la rédaction]

Introduction

Using numerical Hartree–Fock data, we recently examined (1) the correlation of the total energy E with the kinetic energy $T(nl)$ of electrons in a particular atomic orbital nl in 115 atomic multiplet states arising from the $s^m p^n$ ($m = 1,2$; $n = 2$–4) electronic configurations of 20 main group atoms. We found (1) that, despite non-negligible contributions from the core electrons, there *is* a reasonably accurate linear relationship between the kinetic energy difference ΔT of the electrons in open subshells and the total energy difference ΔE, though the proportionality constant depends on both the atom and electron configuration.

Our study (1) was motivated by an earlier one[2] that used electron momentum distributions for the interpretation of Hund's rules. Kinetic energies T are just one half of the second moments $\langle p^2 \rangle$ of the radial electron momentum density. The theoretical background of our kinetic energy analysis of atomic multiplets is the virial theorem (2), which holds exactly for both exact and Hartree–Fock wave functions:

$$[1a] \quad E = -T = V/2$$

where V is the potential energy. Application of eq. [1a] to two states gives

$$[1b] \quad \Delta E = -\Delta T = \Delta V/2$$

which relates the total energy difference to the differences in the two components. Equation [1] implies that the total energy E can be analyzed using either of its two components, T or V. There is no unique decomposition of the potential energy V into orbital contributions because the potential energy operator has a two-electron component. On the other hand, choosing the kinetic energy T has the advantage that it permits an unambiguous decomposition into orbital contributions since the kinetic energy operator is a one-electron operator. The kinetic energy analysis allows us to focus on the electrons in open subshells thus obtaining insight, albeit at the expense of exactness.

In this paper, we extend the kinetic energy analysis to atomic multiplets arising from $s^m d^n$ electronic configurations with $m = 0,1,2$, and $n = 2$–8. A total of 822 multiplet states are examined for 27 atoms from groups 2–10. For the multiplets arising from the d^n and $s^2 d^n$ configurations, we demonstrate an accurate linear correlation between the total energy difference ΔE and the kinetic energy difference $\Delta T(d)$ of electrons in unfilled d- subshells; thus $\Delta E = -a\Delta T(d)$ where a is a positive constant common to all the multiplets from a chosen configuration of an atom. The Pearson correlation coefficients are greater than 0.999 in most cases. In the case of multiplets from the sd^n configuration, we again obtain an accurate linear relationship in the form $\Delta E = -a\Delta T(d) + b$, where a is a positive

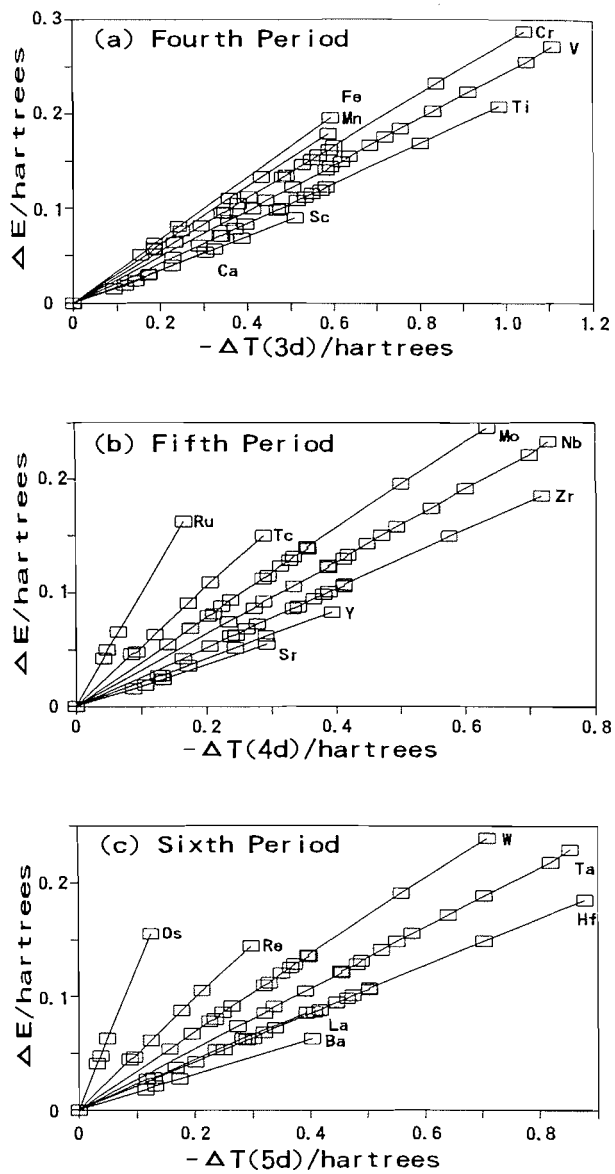
constant as before but b is an additional constant that depends not only on the chosen configuration and atom but also on the spin multiplicities of both the multiplets and their parent d^n multiplets. Hartree atomic units are used throughout this paper.

Computational details

All our numerical Hartree–Fock calculations were carried out with an enhanced version of the MCHF72 program (3). The required multiplet energy expressions were taken mainly from Slater (4) and Condon and Odabasi (5). Our total energies were converged to 10 significant figures and various orbital properties to 7 or more significant figures. Errors in the virial ratio V/T were less than 1×10^{-10}, which guarantees the applicability of our basic equations [1*a*] and [1*b*].

We chose 27 atoms from groups 2–10 in the fourth (Ca through Ni), fifth (Sr through Pd), and sixth (Ba through Pt excluding Ce–Lu) periods of the periodic table for our analysis of multiplet states arising from d^n, sd^n, and s^2d^n electronic configurations. The configurations with n = 1,9,10 were excluded since they lead to only one or two energy levels. The numbers of multiplets examined in this study are summarized in Table 1 for each atom and each configuration.

Fig. 1. Linear correlation between ΔE and $-\Delta T(d)$ for the multiplets arising from the d^n configuration.



3. Results and discussion

3.1 d^n Configuration

Configurations of this type lead to 222 multiplet states. For each atom, we examined the total energy difference ΔE and the kinetic energy difference $\Delta T(d)$ of electrons in the outermost unfilled d subshell relative to the corresponding quantities for the ground state of the same configuration. Figure 1 shows that the correlation between ΔE and $-\Delta T(d)$ is surprisingly good for all 21 atoms. We then performed least-squares fits of the data to the simple linear equation,

$$[2] \quad \Delta E = -a\Delta T(d)$$

The proportionality constants a and the correlation coefficients R are summarized in Table 2. All the correlation coefficients (except that for Ca) are larger than 0.999, showing that the linear fits are accurate. The proportionality constants increase

Table 2. Correlation between the total energy difference ΔE and the kinetic energy difference $\Delta T(d)$ of the outermost d electrons for the 222 multiplet states arising from the d^n configuration. The proportionality constant a in the equation $\Delta E = -a\Delta T(d)$ is given together with the correlation coefficient R.

with the number of d electrons in the same period, with a minor exception in the first three atoms of the sixth period. However, there seems to be no simple relationship between the value of a and the number of d electrons. Since the values of a are quite different from 1, it is clear that the kinetic energy differences of the core electrons are far from negligible (1). However, adding the kinetic energy contributions from inner electrons such as those in the np subshell does not improve the quality of the fits significantly. Equation [2] captures the essentials of the physics and leads to good fits.

3.2 s^2d^n Configuration

Similarly, we examined the correlation between ΔE and $-\Delta T(d)$ for the 222 multiplets arising from s^2d^n configurations. Figure 2 shows that there is a very accurate linear correlation. The quality of the correlation is similar to that found earlier (1) for the s^2p^n configuration although there are more multiplets in the s^2d^n configuration. Table 3 lists the results of a regression analysis of the data using the linear formula [2]. The correlation coefficients are larger than 0.999 in most cases; exceptions are found for Ti, Zr, Pt, and Hf. The Pt atom is a special exception in that its proportionality constant a is negative. This means that ΔE increases with increases in $\Delta T(d)$ rather than with decreases in $\Delta T(d)$ as anticipated from eq. [1b]. A finer analysis for Pt shows that $\Delta T(4d)$, from the 10 electrons in the filled $4d$ subshell, is larger than $\Delta T(5d)$, and $-\Delta T(4d)$ has the expected positive correlation with ΔE. Similarly, for the Rh, Pd, and Ir atoms, $\Delta T(d)$ for the inner d subshell closest to the outermost d subshell is larger than for the outermost d subshell, but the reason for this remains unclear.

3.3 sd^n Configuration

We examined the 378 multiplet states arising from the sd^n configurations of 21 atoms for a correlation between the total energy difference ΔE and the kinetic energy difference $\Delta T(d)$ of the outermost d subshell. However, we could not find any good correlation between ΔE and $-\Delta T(d)$ for any atom. The situation is illustrated in Fig.3 (a) for the Cr atom, which has the most multiplets.

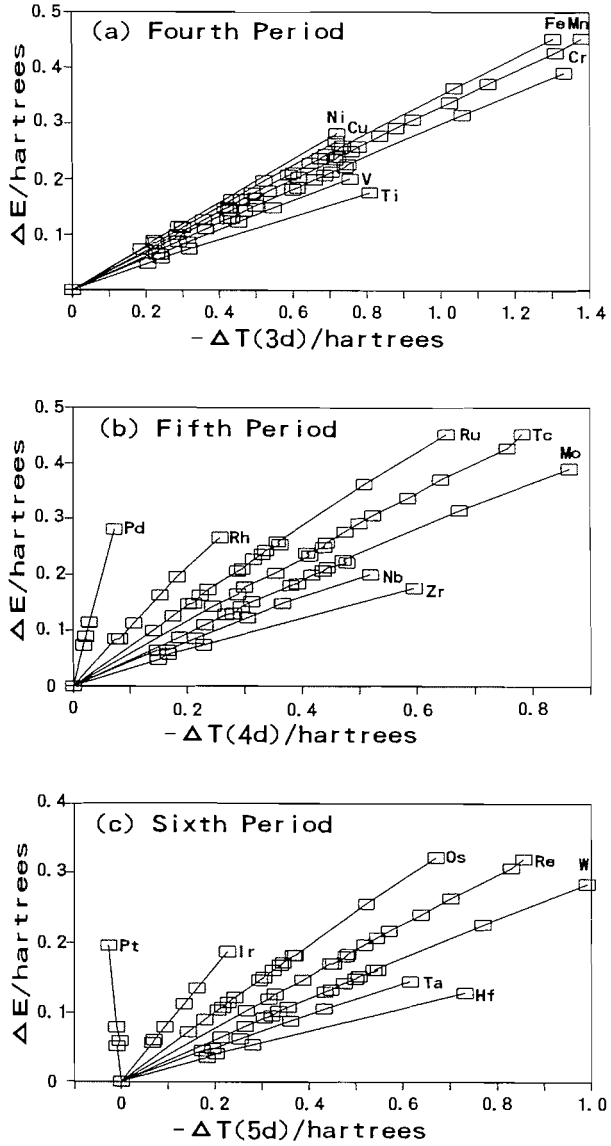
In multiplets arising from sp^n configurations, $\Delta T(sp) = \Delta T(s) + \Delta T(p)$ has a reasonably accurate linear correlation with ΔE, although $\Delta T(p)$ alone does not (1). Thus, we examined the correlation of $\Delta T(sd) = \Delta T(s) + \Delta T(d)$ with ΔE, where $\Delta T(s)$ is the kinetic energy difference for the singly occupied s orbital. However, since the magnitude of $\Delta T(s)$ is more than 10 times smaller than that of $\Delta T(d)$, this did not lead to any essential improvement in the correlation between ΔE and ΔT.

Finally, we made a careful analysis of the data and found that if all the multiplets from an sd^n configuration of an atom are grouped according to their spin multiplicity $2S + 1$ and the spin multiplicity $2S' + 1$ of their parent d^n multiplets, then a linear relationship,

$$[3] \quad \Delta E = -a\Delta T(d) + b$$

works very nicely. The constant a is common to all the mul-

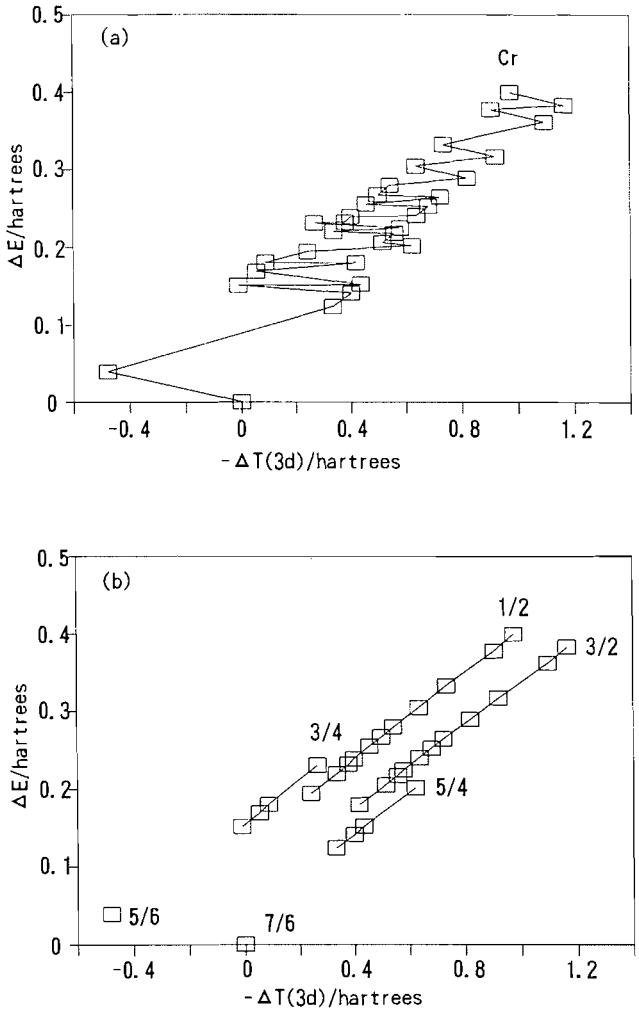
Fig. 2. Linear correlation between ΔE and $-\Delta T(d)$ for the multiplets arising from the s^2d^n configuration.



tiplets corresponding to a chosen configuration and atom, but the other constant b also depends on the spin multiplicities $2S + 1$ and $2S' + 1$, but not the orbital multiplicity $2L + 1$. Figure 3(*b*) illustrates some linear correlations between ΔE and $-\Delta T(d)$, obtained by the grouping of multiplets, for the Cr atom. Using the same procedure, we can obtain similar correlations for all the other atoms. Three more examples are given in Fig. 4 for the sd^2 multiplets of Sc, the sd^3 multiplets of Zr, and the sd^4 multiplets of Ta. Note that the sd^n and sd^{10-n} multiplets have a similar profile in the correlation between ΔE and $-\Delta T(d)$ due to the particle–hole relationship. Table 4 summarizes the constants a and b together with the correlation coefficient R for 21 atoms. All the correlation coefficients are larger than 0.999 and the linear relationship [3] is as accurate as eq. [2] for the d^n and s^2d^n multiplets.

An ad hoc explanation is possible for the success of the spin multiplicity grouping of sd^n multiplets. As we observed in Fig. 1 and Table 2, all the d^n multiplets are on a straight line. Addition of an electron to an s orbital causes a splitting of the original d^n multiplet into two new multiplets according to the spin quantum number ($m_s = +1/2$ or $-1/2$) of the s electron. Further more, the width of the splitting depends on the spin multiplicity of the parent d^n multiplet. Thus we need two spin multiplicities $2S + 1$ and $2S' + 1$ to characterize the correlation between ΔE and $-\Delta T(d)$ of sd^n multiplets. This splitting mechanism can be observed roughly in Fig. 3(*b*) by drawing lines that are $(2S + 1)$-weighted "averages" of two lines with the same $2S' + 1$. The two average lines corresponding to $2S' + 1 = 2$ and 4 and the average point from $2S' + 1 = 6$ all lie on a single line passing through the origin.

Fig. 3. Correlation between ΔE and $-\Delta T(d)$ for the multiplets arising from the sd^5 configuration of the Cr atom. (*a*) Without grouping. (*b*) With grouping based on the spin multiplicities $(2S + 1)/(2S' + 1)$.



4. Concluding remarks

Using numerical Hartree–Fock calculations, we have shown that there is a very accurate linear correlation between ΔE and $-\Delta T(d)$ of 822 atomic multiplets arising from the s^md^n electronic configurations of 27 atoms. For the d^n and s^2d^n multiplets, the correlation can be expressed by $\Delta E = -a\Delta T(d)$ using a single parameter a. For the sd^n multiplets, an additional parameter b is needed because of the interaction of two open

Table 4. Correlation between the total energy difference ΔE and the kinetic energy difference $\Delta T(d)$ of the outermost d electrons for the 378 multiplet states arising from the sd^n configuration. Parameters a and b in the equation $\Delta E = -a\Delta T(d) + b$ are given together with the correlation coefficient R. Multiplet states are classified based on their spin multiplicities $2S + 1$ and their parent d^n spin multiplicities $2S' + 1$.

shells, and the correlation is expressed by $\Delta E = -a\Delta T(d) + (b)$. These linear relationships are quite accurate, as indicated by correlation coefficients greater than 0.999 in most cases.

The reciprocal nature of momentum and position space suggests that ΔE may also be correlated with $\Delta\langle r\rangle_d$, the difference in the radii of the outermost d orbitals, instead of $\Delta T(d) = \Delta\langle p^2/2\rangle_d$. We have verified for several atoms that this is approximately true, although the correlation is less accurate with $\Delta\langle r\rangle_d$ than with $\Delta T(d)$. Moreover, the theoretical basis is less firm for the correlation of ΔE with $\Delta\langle r\rangle_d$. Of course, correlations involving other measures of change in orbital size such as $\Delta\langle r^2\rangle_d$ are also possible.

Finally, it would be interesting to examine whether the accurate linear relationship observed within a nonrelativistic framework persists in a relativistic one, particularly for atoms in the sixth period.

Dispersion formulas for real- and imaginary-frequency-dependent hyperpolarizabilities

David M. Bishop

Abstract: The dynamic second hyperpolarizability for real frequencies, $\gamma_{\|}(-\omega_\sigma;\omega_1,\omega_2,\omega_3)$ in the limit $\omega_i \rightarrow 0$ can be expressed as $\gamma_{\|}^{0} + A_{\|}^{0}\omega_L^2$, where $\omega_L^2 = \omega_\sigma^2 + \omega_1^2 + \omega_2^2 + \omega_3^2$ and $\gamma_{\|}^{0}$ is the frequency-independent (static) quantity; the parallel subscript (||) indicates that the polarization and electric fields all lie along the same axis. In this paper the coefficient $A_{\|}^{0}$ is evaluated exactly for the H atom and very accurately for H^-, He, and Li^+. A similar analysis is carried out for $\gamma_{\|}(-i\omega;i\omega,0,0)$ in the limit $\omega \rightarrow \infty$.

Key words: nonlinear optics, hyperpolarizabilities, dispersion formulas.

Résumé : On peut exprimer la deuxième hyperpolarisabilité dynamique de fréquences réelles, $\gamma_{\|}(-\omega_\sigma;\omega_1,\omega_2,\omega_3)$ dans la limite $\omega_i \rightarrow 0$, peut être exprimée sous la forme $\gamma_{\|}^{0} + A_{\|}^{0}\omega_L^2$, dans laquelle $\omega_L^2 = \omega_\sigma^2 + \omega_1^2 + \omega_2^2 + \omega_3^2$ et $\gamma_{\|}^{0}$ est la quantité (statique) indépendant de la fréquence; l'indice parallèle (||) indique que la polarisation et les champs électriques sont situés dans le même axe. Dans ce travail, on a fait une évaluation exacte de $A_{\|}^{0}$ pour l'atome d'hydrogène et d'une façon précise pour H^-, He et Li^+. On a effectué une analyse semble pour $\gamma_{\|}(-i\omega;i\omega,0,0)$, dans la limite $\omega \rightarrow \infty$.

Mots clés : optique non linéaire, hyperpolarisabilités, formules de dispersion.

Introduction

Hyperpolarizabilities govern nonlinear optical processes and as such are of much current interest, both theoretically and experimentally. They describe molecular behaviour in the presence of static or oscillating (optical) electric fields and for a detailed introduction the reader is referred to three recent special-issue publications (1–3). In this paper we are concerned with the relationships between the second hyperpolarizabilities and the frequencies of the defining electric fields, i.e., the dispersion. It is well known (4–6) that this property, for real frequencies, can be expressed as

$$[1] \qquad \gamma_{\|}(\omega) = \gamma_{zzzz}(-\omega_\sigma;\omega_1,\omega_2,\omega_3) = \gamma_{\|}^{0} + A_{\|}^{0}\omega_L^2 + O(\omega^4)$$

in the limit that $\omega_i \rightarrow 0$, where $\omega_L^2 = \omega_\sigma^2 + \omega_1^2 + \omega_2^2 + \omega_3^2$ and $\omega_\sigma = \omega_1 + \omega_2 + \omega_3$. Since we will only be considering atoms, the atomic axis z can double as the laboratory axis and $\gamma_{\|}(\omega)$ can also be interpreted as the isotropic or mean value of γ. There have, however, been no *direct* calculations of the coefficient $A_{\|}^{0}$, though values have been obtained by fitting $\gamma_{\|}(\omega)$ values. In this paper we show how $A_{\|}^{0}$ can be found analytically and exactly for the H atom, as well as obtaining accurate values for H^-, He, and Li^+.

In the limit $\omega \rightarrow \infty$, the standard second hyperpolarizability for imaginary frequencies can be written as:

$$[2] \qquad \gamma_{\|}(i\omega) = \gamma_{zzzz}(-\omega;i\omega,0,0) = A_{\|}^{\infty}\omega^{-2} + O(\omega^{-4})$$

At the other limit ($\omega \rightarrow 0$) the relationship in eq. [1] can still be applied. This particular, imaginary-frequency, second hyperpolarizability is of interest since it regulates the dispersion-polarizability coefficients that govern the nonclassical contribution to the change in electronic polarizability due to long-range interactions between colliding atoms (7).[2] The constant $A_{\|}^{\infty}$ turns out to be zero but its components, to be discussed later, are not and they are of some use as a check on calculations of $\gamma_{\|}(i\omega)$.

Both $\gamma_{\|}(\omega)$ and $\gamma_{\|}(i\omega)$ can be written in a sum-over-electronic-states (SOS) formulation and this leads to a positive and a negative contribution

$$[3] \qquad \gamma_{\|}(\omega) = \gamma_{\|}^{(+)}(\omega) - \gamma_{\|}^{(-)}(\omega)$$

$$[4] \qquad \gamma_{\|}(i\omega) = \gamma_{\|}^{(+)}(i\omega) - \gamma_{\|}^{(-)}(i\omega)$$

[2] There is a misprint in eq. (13) of this reference in the fourth line: replace "$-\omega_m\omega_\sigma(\omega_2+\omega_3)$" by "$-\omega_m\omega_3(\omega_2+\omega_3)$".

Coefficients $A_{\parallel}^{0(+)}$, $A_{\parallel}^{0(-)}$, $A_{\parallel}^{\infty(+)}$, and $A_{\parallel}^{\infty(-)}$ can be attached to these contributions. The SOS definitions of $\gamma_{\parallel}^{(+)}(\omega)$, $\gamma_{\parallel}^{(-)}(\omega)$, etc. are, in their most general form (7, 8):

[5] $$\gamma_{zzzz}^{(+)}(-\omega_\sigma;\ \omega_1,\ \omega_2,\ \omega_3) = \hbar^{-3}\Sigma_P\Sigma_m\Sigma_n{}'\Sigma_p\langle 0|z|m\rangle\langle m|z|n\rangle\langle n|z|p\rangle\langle p|z|0\rangle/(\omega_m-\omega_\sigma)(\omega_n-\omega_2-\omega_3)(\omega_p-\omega_3)$$

[6] $$\gamma_{zzzz}^{(-)}(-\omega_\sigma;\ \omega_1,\ \omega_2,\ \omega_3) = \hbar^{-3}\Sigma_P\Sigma_m\Sigma_n\langle 0|z|m\rangle\langle m|z|0\rangle\langle 0|z|n\rangle\langle n|z|0\rangle/(\omega_m-\omega_\sigma)(\omega_n-\omega_3)(\omega_n+\omega_2)$$

[7] $$\gamma_{zzzz}^{(+)}(-i\omega_\sigma;\ i\omega_1,\ i\omega_2,\ i\omega_3) = \hbar^{-3}\Sigma_P\Sigma_m\Sigma_n{}'\Sigma_p\langle 0|z|m\rangle\langle m|z|n\rangle\langle n|z|p\rangle\langle p|z|0\rangle \times [\omega_m\omega_n\omega_p-\omega_m(\omega_2+\omega_3)\omega_3-\omega_n\omega_\sigma\omega_3-\omega_p\omega_\sigma(\omega_2+\omega_3)]/(\omega_m{}^2+\omega_\sigma{}^2)(\omega_n{}^2+(\omega_2+\omega_3)^2)(\omega_p{}^2+\omega_3{}^2)$$

[8] $$\gamma_{zzzz}^{(-)}(-i\omega_\sigma;\ i\omega_1,\ i\omega_2,\ i\omega_3) = \hbar^{-3}\Sigma_P\Sigma_m\Sigma_n\langle 0|z|m\rangle\langle m|z|0\rangle\langle 0|z|n\rangle\langle n|z|0\rangle \times [\omega_m\omega_n{}^2+\omega_m\omega_2\omega_3+\omega_n\omega_\sigma\omega_2-\omega_n\omega_\sigma\omega_3]/(\omega_m{}^2+\omega_\sigma{}^2)(\omega_n{}^2+\omega_3{}^2)(\omega_n{}^2+\omega_2{}^2)$$

In these equations $\omega_\sigma = \omega_1 + \omega_2 + \omega_3$, z is the electric dipole moment operator, and Σ_P infers a summation over the 24 permutations of $-\omega_\sigma$, ω_1, ω_2, and ω_3 or their imaginary analogues. The prime on the sum over n in eqs. [5] and [7] indicates the exclusion of the electronic ground state (0); for m or $p = 0$, $\langle 0|z|0\rangle = 0$ for atoms, so inclusion or not of the ground state makes no difference. ω_m is the circular electronic transition frequency between the mth excited state, with wave function $|m\rangle$, and the ground state, with wave function $|0\rangle$.

Use of the binomial theorem allows expansion of the energy denominators in eqs. [5] and [6] and we can then collect the terms that are quadratic in the optical frequencies ω_σ, ω_1,.... This leads to the coefficients of $\omega_L{}^2(= \omega_\sigma{}^2 + \omega_1{}^2 + \omega_2{}^2 + \omega_3{}^2)$ being

[9] $$A_{\parallel}^{0(+)} = 12X(-2,\ 0,\ 0) + 8X(0,-2,\ 0) + 8X(-1,-1,\ 0) + 2X(-1,\ 0,-1)$$

and

[10] $$A_{\parallel}^{0(-)} = 6Y(-3)Y(-2) + 14Y(-1)Y(-4)$$

where

[11] $$X(i,\ j,\ k) = \Sigma_m\Sigma_n{}'\Sigma_p\langle 0|z|m\rangle\langle m|z|n\rangle\langle n|z|p\rangle \times \langle p|z|0\rangle E_m{}^{i-1}E_n{}^{j-1}E_p{}^{k-1}$$

and

[12] $$Y(k) = \Sigma_m\langle 0|z|m\rangle\rangle m|z|0\rangle E_m{}^k$$

In eqs. [11] and [12] $E_m = \hbar\omega_m$ is the energy of the mth excited state relative to the ground state energy ε_g. $Y(k)$ are half the usual sum rules, i.e., $S(k-1) = 2Y(k)$. In deriving eqs. [9] and [10], use has been made of the symmetry between the indices m and p.

For $\gamma_{\parallel}^{\infty(+)}$ and $\gamma_{\parallel}^{\infty(-)}$, we can extract from eqs. [7] and [8] those terms with a ω^{-2} dependence as $\omega \rightarrow \infty$. This gives

[13] $$A_{\parallel}^{\infty(+)} = 8X(2,\ 0,\ 0) + 4X(0,\ 2,\ 0) - 8X(1,\ 1,\ 0)$$

and

[14] $$A_{\parallel}^{\infty(-)} = 4Y(1)Y(-2) + 4Y(-1)Y(0)$$

The degree of dispersion in the limiting cases of $\omega \rightarrow 0$ for $\gamma_{\parallel}(-\omega_\sigma;\omega_1,\omega_2,\omega_3)$ and of $\omega \rightarrow \infty$ for $\gamma_{\parallel}(-i\omega;i\omega,0,0)$ is thus dictated by the values of $X(i,j,k)$ and $Y(k)$. In the next section we show how these may be found exactly for the H atom.

Hydrogen atom

The trick to obtaining exact values for $X(i,j,k)$ and $Y(k)$ is to be able to make the energy denominators or numerators disappear. This can be rigorously accomplished for the H atom. Then the next step is to use the closure rule, $\Sigma_m|m\rangle\langle m| = 1$, so the summations disappear, and finally to carry out the simple integration that remains.

The first step requires the following relations, where $\varepsilon_g = -1/2$ au, is the ground state energy of the H atom and $\psi_0 = e^{-r}/\sqrt{\pi}$ the corresponding wave function,

[15] $$(H_0-\varepsilon_g)z\psi_0 = r^{-1}z\psi_0$$

[16] $$(H_0-\varepsilon_g)f_1 = z\psi_0$$

[17] $$(H_0-\varepsilon_g)f_2 = f_1$$

[18] $$(H_0-\varepsilon_g)f_3 = f_2$$

[19] $$(H_0-\varepsilon_g)zf_1 = (z^2/4r)(-r^2+4r+2)\psi_0 - f_1/z + zf_1/2$$

[20] $$(H_0-\varepsilon_g)g_1 = zf_1 - \langle 0|z|f_1\rangle\psi_0 = zf_1 - (9/4)\psi_0$$

[21] $$(H_0-\varepsilon_g)g_2 = g_1 - \langle 0|z|g_1\rangle\psi_0 = g_1 - (81/16)\psi_0$$

[22] $$(H_0-\varepsilon_g)h_1 = zf_2 - \langle 0|z|f_2\rangle\psi_0 = zf_2 - (43/8)\psi_0$$

Equations [16]–[18] are definitions of the functions f_1, f_2, and f_3 and they may be obtained from these equations by using the method of Coulson (9); f_1 is also the negative of the first-order perturbation wave function for a perturbing operator z. Likewise, eqs. [20]–[22] define the functions g_1, g_2, and h_1 and g_1 is the second-order perturbation wave function for a perturbing operator z. Solution of eqs. [16]–[18] and [20]–[22] gives:

[23] $$f_1 = z(r+2)\psi_0/2$$

[24] $f_2 = z(2r^2 + 11r + 22)\psi_0/12$

[25] $f_3 = z(6r^3 + 62r^2 + 287r + 574)\psi_0/144$

[26] $g_1 = r^2[(r^2 + 6r + 18) + (2r^2 + 10r + 15)P_2]\psi_0/24$

[27] $g_2 = r^2[3(4r^3 + 45r^2 + 270r + 810) + (24r^3 + 222r^2 + 818r + 1227)P_2]\psi_0/1440$

[28] $h_1 = r^2[(8r^3 + 85r^2 + 430r + 1290) + (16r^3 + 158r^2 + 662r + 993)P_2]\psi_0/720$

where $P_2 = (3\cos^2\theta - 1)/2$. Equations [23]–[25] are in accord with those of Dalgarno and Kingston (10).

Let us now consider, as an example, the term $X(-2,0,0)$ where the energy denominator is $E_m{}^3E_nE_p$. By replacing $z\psi_0$ in $\langle p|z|0\rangle$ by $(H_0 - \varepsilon_g)f_1$, eq. [16], and then using the Hermitean properties of the operator, E_p will be cancelled. Doing the same thing for $\langle 0|z|m\rangle$, but three times in succession, will remove $E_m{}^3$. This leaves

[29] $X(-2, 0, 0) = \Sigma_m\Sigma_n{}'\Sigma_p\langle f_3|m\rangle\langle m|z|n\rangle\langle n|z|p\rangle\langle p|f_1\rangle/E_n$

Use of closure for the sums over m and p, which is now possible, gives

[30] $X(-2, 0, 0) = \Sigma_n{}'\langle f_3|z|n\rangle\langle n|z|f_1\rangle/E_n$

and, with eq. [20], we obtain

[31] $X(-2, 0, 0) = \Sigma_n{}'\langle f_3|z|n\rangle\langle n|g_1\rangle$
$= \langle f_3|z|g_1\rangle - \langle f_3|z|0\rangle\langle 0|g_1\rangle$

The second term in the last step takes care of the exclusion from the summation over n of the ground state. The integration is now trivial and for the H atom:

[32] $X(-2, 0, 0) = 119539/192 - (319/24)(81/16)$

In a similar fashion:

[33] $X(0, -2, 0) = \langle g_1|g_2\rangle - \langle g_1|0\rangle\langle 0|g_2\rangle$
$= 1640867/3840 - (81/16)(771/64)$

[34] $X(-1, -1, 0) = \langle f_2|z|g_2\rangle - \langle f_2|z|0\rangle\langle 0|g_2\rangle$
$= 2015191/384 - (43/8)(771/64)$

[35] $X(-1, 0, -1) = \langle h_1|z|f_2\rangle - \langle h_1|0\rangle\langle 0|z|f_2\rangle$
$= 1264709/1920 - (1285/96)(43/8)$

[36] $X(2, 0, 0) = \langle 0|z^2r^{-1}|g_1\rangle - \langle 0|z^2r^{-1}|0\rangle\langle 0|g_1\rangle$
$= 243/32 - (1/2)(81/16)$

[37] $X(0, 2, 0) = \langle zf_1|H_0 - \varepsilon_g|zf_1\rangle$
$= 241/16$

[38] $X(1, 1, 0) = \langle 0|z^3|f_1\rangle - \langle 0|z^2|0\rangle\langle 0|z|f_1\rangle$
$= 99/8 - (1)(9/4)$

The much simpler terms $Y(k)$ require closure only once (after the energies have been eliminated) and are given by:

[39] $Y(1) = \langle 0|z^2r^{-1}|0\rangle$

[40] $Y(0) = \langle 0|z^2|0\rangle$

[41] $Y(-1) = \langle f_1|z|0\rangle$

[42] $Y(-2) = \langle f_2|z|0\rangle$

[43] $Y(-3) = \langle f_3|z|0\rangle$

[44] $Y(-4) = \langle f_2|f_2\rangle$

These terms were evaluated previously in ref. 10; they can also be found from the recursion relation in ref. 11.

The exact values of all the required functions are collected in Table 1. Using eqs. [9] and [10], we then find, in atomic units,

$$A_{\parallel}{}^{0(+)} = 693509/48$$

and

$$A_{\parallel}{}^{0(-)} = 95145/64$$

With the value (12) of $\gamma_{\parallel}{}^0 = 10665/8$ this means that

[45] $\gamma_{\parallel}(\omega) = \gamma_{\parallel}{}^0[1 + (2488601/255960)\omega_L{}^2]$

in the limit $\omega_i \to 0$ for the H atom. The quotient in eq. [45] is approximately 9.722617, which is in complete agreement with the result in ref. 4 that was found by fitting known calculated $\gamma_{\parallel}(\omega)$ values to eq. [1].

For the limiting expression for $\gamma_{\parallel}(i\omega)$, we use eqs. [13] and [14] and find $A_{\parallel}{}^{\infty(+)} = A_{\parallel}{}^{\infty(-)} = 79/4$ and thus both the positive and negative parts of $\gamma_{\parallel}(i\omega)$ drop off with respect to ω^{-2} at the same rate and cancel.

It might be mentioned that all the calculations so far reported were performed on a TI-37 Galaxy Solar calculator.

Two-electron systems

To obtain the same properties for the two-electron systems H^-, He, and Li^+, we used accurate variational wave functions, since no analytic ones exist. The $X(i,j,k)$ and $Y(k)$ were found in the same fashion that we have previously used for the calculation of the static and dynamic second hyperpolarizabilities themselves: the sums-over-states were in each

Table 1. Values of $X(i,j,k)$, $Y(k)$, and $A_{\|}$ in atomic units.[a]

	H	H^-	He	Li^+
$X(-2,0,0)$	213239/384	3.075 11 (9)	4.024 540	0.282 712 (−2)

$A_{\|}^{\infty(-)}$	79/4	1.062 90 (4)	4.911 74	0.251 21

[a]The atomic unit of the second hyperpolarizability is $e^4a_0^4E_h^{-3}$ and it is equivalent to 6.23538 × 10^{-65} C^4 m^4 J^{-3}. Numbers in parentheses are the powers of 10 by which the entry is to be multiplied.

case replaced by sums over a pseudo-spectral series (8). The wave functions, which were explicitly electron correlated, were a generalization of those of Thakkar and Smith (13) and Thakkar (14):

$$[46]\quad \Psi^L(r_1, r_2, r_{12}, \theta_1, \theta_2, \phi_1, \phi_2) = \sum_{l_1,l_2}\sum_{k=1}^{N^{l_1l_2}} C_k^{l_1l_2}(1+P_{12})r_1^{l_1}r_2^{l_2}\mathcal{Y}_{Ll_1l_2}^{M_L}(\hat{r}_1, \hat{r}_2)\exp(-\alpha_k^{l_1l_2}r_1 - \beta_k^{l_1l_2}r_2 - \gamma_k^{l_1l_2}r_{12})$$

where, in vector-coupling notation:

$$[47]\quad \mathcal{Y}_{Ll_1l_2}^{M_L}(\hat{r}_1, \hat{r}_2) = \sum_{m_1,m_2}(l_1m_1l_2m_2|l_1l_2LM_L) \times Y_{l_1}^{m_1}(\hat{r}_1)\,Y_{l_2}^{m_2}(\hat{r}_2)$$

and r_1, θ_1, and ϕ_1 are the coordinates of electron 1; r_{12} is the interelectronic separation and Y_l^m are spherical harmonics. The nonlinear parameters were chosen in a pseudorandom fashion and, as before, 140, 140, and 190 functions were used to describe the ^1S, ^1P, and ^1D states, respectively, for He (15). For H^-, 200, 150, and 175 functions were used (16) and, for Li^+, 100, 100, and 150 functions (17).

The integral evaluations and sums lead to the results for $X(i,j,k)$ and $Y(k)$, which are given in Table 1. Combined, they produce the dispersion coefficients $A_{\|}^{0(+)}$, etc., which are also shown in this table. Once again, in all three cases, the positive and negative parts of $\gamma_{\|}(i\omega)$ tail off with respect to ω^{-2} in exactly the same way (within numerical accuracy). It is not immediately apparent from eqs. [13] and [14] why this should be so and it is not, in general, true for $\gamma_{\perp}(i\omega)$. In the Appendix a proof is given. The value of $A_{\|}^{0}/\gamma_{\|}^{0}$ for He was found before (15) by fitting $\gamma_{\|}(\omega)$ values; the result, 2.189, agrees perfectly with the result here. Since all measurements of $\gamma_{\|}(\omega)$ are reported as relative to the calculated value for He, there is no experimental value of $A_{\|}^{0}/\gamma_{\|}^{0}$ of He with which to compare.

To conclude, we have evaluated exactly for the H atom the limiting dispersion in the second hyperpolarizability for both real and imaginary frequencies. For H^-, He, Li^+ we have done the same thing but with resort to nonexact, though accurate, variational wave functions.

Acknowledgements

I thank Dr. Janusz Pipin for providing me with the two-electron results for $X(i,j,k)$ and $Y(k)$ and the Natural Sciences and Engineering Research Council of Canada for financial support.

Appendix

The proof that $A_{\|}^{\infty(+)} = A_{\|}^{\infty(-)}$ can be most easily shown for the H atom; the generalization for any other atom follows in a straightforward way. We will require the following identity:

[A1] $(H_0 - \varepsilon_g)z\psi = z(H_0 - \varepsilon_g)\psi - \partial\psi/\partial z$

and thus:

[A2] $(H_0 - \varepsilon_g)z\psi_0 = -\partial\psi_0/\partial z$

Also, from the odd integral derivatives, we have:

[A3] $\partial\langle 0|z|0\rangle/\partial z = 2\langle(\partial\psi_0/\partial z)|z|0\rangle + 1 = 0$

[A4] $\partial\langle f_1|z|f_1\rangle/\partial z = 2\langle(\partial f_1/\partial z)|z|f_1\rangle + \langle f_1 f_1\rangle = 0$

[A5] $\partial\langle 0|z|g_1\rangle/\partial z = \langle(\partial\psi_0/\partial z)|z|g_1\rangle + \langle 0|g_1\rangle + \langle 0|z|(\partial g_1/\partial z)\rangle = 0$

First we will show that $2X(2,0,0) = X(1,1,0)$. From eq. [36], using eqs. [A2] and [A3], we find

[A6] $X(2,0,0) = -\langle(\partial\psi_0/\partial z)|z|g_1\rangle - \langle 0|g_1\rangle/2$

or, alternatively, using the Hermitean properties, and eqs. [A1], [A5], and [20]:

[A7] $X(2,0,0) = \langle 0|z|(H_0 - \varepsilon_g)(zg_1)\rangle - \langle 0|g_1\rangle/2 = \langle 0|z^2|(H_0 - \varepsilon_g)g_1\rangle - \langle 0|z|(\partial g_1/\partial z)\rangle - \langle 0|g_1\rangle/2$

$$= \langle 0|z^3|f_1\rangle - (9/4)\langle 0|z^2|0\rangle + \langle(\partial\psi_0/\partial z)|z|g_1\rangle + \langle 0|g_1\rangle/2$$

Addition of eqs. [A6] and [A7] gives $X(1,1,0)$ as displayed in eq. [38], hence

[A8] $2X(2,0,0) = X(1,1,0)$

With this relationship, we now need to show that

$$A_{\|}^{\infty(+)}/4 = X(0,2,0) - X(1,1,0) = \langle zf_1|(H_0 - \varepsilon_g)(zf_1)\rangle - \langle 0|z^3|f_1\rangle + Y(-1)Y(0)$$

is equal to

$$A_{\|}^{\infty(-)}/4 = \langle f_1|f_1\rangle/2 + Y(-1)Y(0)$$

This is done by the following relations, using eqs. [16], [A1], and [A4]:

$$\langle zf_1|(H_0 - \varepsilon_g)(zf_1)\rangle - \langle 0|z^3|f_1\rangle = \langle zf_1|(H_0 - \varepsilon_g)(zf_1)\rangle - \langle(H_0 - \varepsilon_g)f_1|z^2|f_1\rangle = \langle zf_1|(H_0 - \varepsilon_g)(zf_1)\rangle - \langle f_1|z^2|(H_0 - \varepsilon_g)f_1\rangle$$

$$= \langle z^2 f_1|(H_0 - \varepsilon_g)f_1\rangle - \langle zf_1|\partial f_1/\partial z\rangle - \langle f_1|z^2|(H_0 - \varepsilon_g)f_1\rangle = -\langle zf_1|\partial f_1/\partial z\rangle = \langle f_1 f_1\rangle/2.$$

Topological properties of the electronic structures of the reactants, transition states, and products of the reactions of the hydroxyl radical with the series $C_2H_nF_{6-n}$, n = 1–6

Jaime M. Martell, James B. Tee, and Russell J. Boyd

Abstract: Properties of the bond critical points, including the electron density and its Laplacian, and distances to bonded nuclei, for all species (reactants, transition states, and products) in the reactions of the hydroxyl radical with the series $C_2H_nF_{6-n}$, n = 1–6 were calculated using Bader's atoms-in-molecules methodology. The electron density and its Laplacian at the bond critical points correlate with bond strength, as measured by bond dissociation energies. The positions of the bond critical points vary with the electronegativity of surrounding atoms. Charge development in the course of the reactions was monitored using Mulliken population analysis at the HF/6-31G(d), HF/6-311G(d,p)//HF/6-31G(d), MP2/6-311G(d,p)//HF/6-31G(d), and HF/6-311G(d,p)//MP2/6-31G(d,p) levels of theory, and natural population analysis and Bader population analysis at the highest common level of theory, MP2/6-311G(d,p)//HF/6-31G(d). In general, there is a buildup of charge in the transition states, concentrated near the reaction centre, which dissipates somewhat as the reaction proceeds to products. The description of charge transfer varies somewhat with the three methods.

Key words: topological properties, atomic charges, charge development, reactions of the hydroxyl radical with fluorinated ethanes.

Résumé : Faisant appel à la méthodologie des atomes dans les molécules de Bader, on a calculé les propriétés des points critiques des liaisons, y compris la densité électronique et son laplacien, ainsi que les distances entre les noyaux liés pour toutes les espèces (réactifs, états de transition et produits) des réactions du radical hydroxyle avec la série $C_2H_nF_{6-n}$ dans laquelle n = 1–6. La densité électronique et son laplacien aux points critiques de la liaison donnent une bonne corrélation avec la force de la liaison telle que mesurée par les énergies de dissociation. Les positions des points critiques des liaisons varient avec l'électronégativité des atomes avoisinants. Le développement de la charge au cours des réactions est déterminé en faisant appel à une analyse de population de Mulliken aux niveaux HF/6-31G(d), HF/6-311G(d,p)//HF/6-31G(d), MP2/6-311G(d,p)//HF/6-31G(d) et HF/6-311G(d,p)//MP2/6-31G(d,p), à une analyse naturelle de population et à une analyse de population de Bader au niveau les plus élevé de la théorie, MP2/6-311G(d,p)//HF/6-31G(d). En général, il se produit une accumulation de charge dans les états de transition; elle est concentrée près de la région centre et elle se dissipe un peu au fur et à mesure que la réaction progresse vers les produits. La description du transfert de charge varie un peu avec les trois méthodes.

Mots clés : propriétés topologiques, charges atomiques, développement de la charge, réactions du radical hydroxyle avec d'éthanes fluorés.

[Traduit par la rédaction]

1. Introduction

Charge development at the transition state (TS) is central to chemistry because most reactions involve electron transfer in the TS. This concept has been investigated theoretically for S_N2 reactions involving charged nucleophiles (1). Experimental studies must look at indirect evidence such as the effect of substituents on the reaction rate. One of the most extensively studied reaction classes is hydrogen abstractions, such as is being considered here. These show interesting effects, for example, the attack of substituted toluenes by bromine radicals correlates (2) with σ^+, and polar effects are even observed in abstractions by alkyl radicals (3). These results show that charged species need not be involved for charge to have a significant effect on the reaction. The reactions of hydroxyl radicals (OH) with hydrofluorinated ethanes (HFEs) are formally charge neutral, but significant charge development at the TS is expected due to the influence of the electronegative oxygen atom.

Bader et al. (4, 5) have developed a theory of "atoms in molecules," in which the gradient vector field and the scalar field of the electron density $\rho(\boldsymbol{r})$ are used to study the bonds, atomic interactions, reactivities, and stabilities of molecular systems. The essential topological properties of the electron density, $\rho(\boldsymbol{r})$, can be summarized by the complete specification of its critical points at which $\nabla\rho(\boldsymbol{r}) = 0$. A critical point, $\boldsymbol{r}_c$, is classified according to its rank and signature (4*a*). The rank λ of a

critical point equals the number of non-zero eigenvalues of the Hessian matrix of $\rho(\boldsymbol{r}_c)$, while the signature σ is the algebraic sum of the signs of the eigenvalues, and the classification is written as (λ,σ). If the eigenvalue is positive its associated eigenvector or gradient path (the path of steepest ascent) originates at, and is directed away from, the critical point. For negative eigenvalues the gradient path terminates at, and is directed toward, the critical point.

In the case of a nondegenerate critical point, four types of critical points are possible: (3,−3), which usually occurs only at a nucleus; (3,+3), a cage critical point; (3,+1), a ring critical point; and (3,−1), a bond critical point. Only bond critical points are considered in this study.

The Laplacian of the electron density,

$$[1] \quad \nabla^2\rho(\boldsymbol{r}) = \frac{\partial^2\rho}{\partial x^2} + \frac{\partial^2\rho}{\partial y^2} + \frac{\partial^2\rho}{\partial z^2}$$

identifies the regions of space wherein the electron density is locally concentrated or depleted. In three dimensions, when $\nabla^2\rho(\boldsymbol{r}) < 0$, then $\rho(\boldsymbol{r})$ is greater than its average value at neighbouring points, and when $\nabla^2\rho(\boldsymbol{r}) > 0$, $\rho(\boldsymbol{r})$ is less than its average value at neighbouring points. Thus a minimum in $\nabla^2\rho(\boldsymbol{r})$ with a negative value means that the electron density is locally concentrated in that region of space, even though the electron density itself exhibits no corresponding maximum. Studies of molecular systems using the properties of $\nabla^2\rho(\boldsymbol{r})$ show that a bond can be characterized in terms of the bond path and the electron density at the bond critical point, $\rho(\boldsymbol{r}_c)$ (6). Also, the magnitude of the electron density at the bond critical point provides a measure of the bond strength (7, 8).

Three methods are used in this study for calculating atomic charges. The Mulliken method (9) is computationally very inexpensive, but suffers at least conceptually because the overlap populations are divided equally between two bonded atoms, irrespective of their relative electronegativities. Thus, it tends to underestimate electron populations on electronegative atoms. Natural population analysis is carried out in terms of localized electron-pair "bonding" units. It is also relatively inexpensive, and has the advantage of being essentially basis-set independent. Bader and Nguyen-Dang (4*b*) devised an electron density partitioning method in which an atom in a molecule is defined as a real space surrounded by a zero-flux surface, and the space occupied by the atom is referred to as the atomic basin. The atomic charge of an atom is obtained by integrating $\rho(\boldsymbol{r})$ over the atomic basin to obtain its average electron population N, and then subtracting this from the nuclear charge Z, i.e., $Q = Z - N$. While this method is conceptually more rigorous, it requires much more human and computer effort, and has been criticized for overestimating the electron population on electronegative atoms (10). For Mulliken population analysis (MPA) four levels of theory were employed: HF/6-31G(d), HF/6-311G(d,p)//HF/6-31G(d), MP2/6-311G(d,p)//HF/6-31G(d), and HF/6-311G(d,p)//MP2/6-31G(d,p). This allowed the investigation of the effects of increased basis-set size, electron correlation, and use of electron correlation in geometry optimizations, respectively (starting from a base theory of HF/6-31G(d)). For natural population analysis (NPA) and Bader population analysis (BPA), only the highest common level of theory used on all the species (MP2/6-311G(d,p)//HF/6-31G(d)) was employed.

2. Computational methods

Ab initio MO calculations were carried out with the GAUSSIAN 90 (11) and GAUSSIAN 92/DFT (12) program packages, employing the optimized geometries of the reactants (13, 14), transition states (15, 16), and products (14, 17) as published previously. The NBO program[3] (included as link 607 of GAUSSIAN 92) was used to calculate the NPA charges.

The topological analysis calculations were performed using a vectorized version of the PROAIM (18) program package. Wave function files from the highest common level of theory employed in this study (MP2/6-311G(d,p)//HF/6-31G(d)) were used as input. For each bond a (3,−1) critical point was located. Integration of atomic charges was performed for each atom, using 96 ϕ and 64 θ planes outside of the β sphere, and the maximum values of 140 points per surface path and 80 basic gradient paths. Threshold values of 0.001 and 0.002 were used for the volume calculation, and the primitive cutoff algorithm was employed.

3. Results and discussion

A. Properties of bond critical points

Properties of bond critical points for reactants, transition states, and products, are given in Tables 1, 2, and 3, respectively. In general, the electron densities at the bond critical points, $\rho(\boldsymbol{r}_c)$ increase with increasing substitution of the species by fluorine atoms, as expected, since these atoms are electron rich and thus increase the overall electron density. This may also be due to a contraction of the molecule: if the C—C distance shortens, as it does with increasing fluorine substitution (13, 14), $\rho(\boldsymbol{r}_c)$ would likely increase. Given the same number of fluorines, values of $\rho(\boldsymbol{r}_c)$ are affected by substitution patterns.

For C—C bond critical points, $\rho(\boldsymbol{r})$ tends to be larger when the fluorine substituents are divided as evenly as possible between the two carbons; this trend applies to reactants, transition states, and products, although the trend is weak in the latter. For the product radicals, and the transition states, there is also a trend to higher values for higher substitution on the β-carbon.

In contrast to the C—C case, values of $\rho(\boldsymbol{r})$ at C—F bond critical points are larger for species where as many fluorines as possible are on one carbon. A second trend is for higher values at α-carbons for transition states and products, although the first trend will take precedence, e.g., in CF_3-CHF values are higher on the highly substituted β-carbon.

Trends in $\rho(\boldsymbol{r})$ at C—H bond critical points are varied. For reactants and products, there is the general trend to increasing values with increasing fluorine substitution and, within a molecule, to larger values on the more substituted carbon. For transition states, values are again higher on the more substituted carbon, but the correlation of higher values with increasing number of fluorines is weaker. Values at β-carbons are lower when there is a β-fluorine *gauche* to the reaction centre. For the special case of the critical bond at the bond being broken in the TS (C1—H1 in Table 2), values are much lower than for other C—H bonds. The predominant trend here is for values to increase with the number of α-fluorines, with a secondary trend for lower values as the number of β-fluorines

[a]Only bonds that are unique by symmetry are given. C_α denotes the most highly substituted carbon. An atom labelled with 0 is in the symmetry plane, 1 is not. See Fig. 1 of ref. 13 for individual geometries.
[b]In atomic units.
[c]For bond A—B, r_A and r_B are the distances, in Å, from the bond critical point to atoms A and B, respectively.
[d]The designations g and t indicate the atom is *gauche* or *trans*, respectively, to a fluorine.

[a]All species are asymmetrical, except where noted. For numbering scheme, see Fig. 2 of ref. 15 for C_2H_6 + OH, and Fig. 1 of ref. 16 for other species. The designations g and t refer to the hydrogen being abstracted as *gauche* or *trans*, respectively, to a β-F.

[b]In atomic units.

[c]For bond A—B, r_A and r_B are the distances, in Å, from the bond critical point to atoms A and B, respectively.

[d]C_s symmetry.

[e]Bond critical point not found.

increases. Values are also slightly lowered when there are β-fluorines *gauche* to H1.

For the bond critical point of the bond being formed (H1—O in Table 2), the magnitudes of $\rho(r)$ are again low. Higher values are seen when there are β-fluorines *gauche* to H1, and for increasing substitution on the β-carbon, except for CH_2F—CHF_2 + OH being higher than CHF_2—CH_2F + OH.

In contrast, $\rho(r_c)$ values in the hydroxyl group are much larger, and have very different trends. There is a weak trend to

[a]Only bonds that are unique by symmetry are given. The α-C is the radical centre. Atom numbering scheme is as in Fig. 1 of ref. 17. See Fig. 1 of ref. 14 for individual geometries.
[b]In atomic units.
[c]For bond A—B, r_A and r_B are the distances, in Å, from the bond critical point to atoms A and B, respectively.

decreasing values with increasing substitution, and lower values are seen when there are β-fluorines *gauche* to H1. It should be noted that the range of values is small, 0.3769−0.3796.

Most of the above trends are consistent with $\rho(r_c)$ providing a measure of bond strength (7). Thus, the forming and breaking bonds have particularly low values. Higher values are seen in C—X bonds for more highly substituted carbons. For transition states, the intramolecular hydrogen bond formed when there is a β-fluorine *gauche* to the reaction centre (16) leads to higher $\rho(r_c)$ values for C_β—H_β and H1—O bonds, the latter at the expense of the hydroxyl bond.

An exception is provided by C—C bonds. If bond dissociation energy (BDE) is used as a measure of bond strength, then C—C bonds are stronger when there is a greater electronegativity difference between the two groups (as observed in the reactant ethanes (13, 14)), but the same trend is not seen in the $\rho(r_c)$ values. As well, the $\rho(r_c)$ values do not correlate with the C—C bond lengths.

Many of the trends in the electron densities are seen again in the Laplacian of the electron density, $\nabla^2\rho(r)$. For most bonds in this study $\nabla^2\rho(r)$ is negative at the bond critical point, indicating a local concentration of charge. All C—F bonds have positive values, except for slightly negative values in the CF_3 group of the CF_3—CHF_2 + OH TS. The anomalous values of $\nabla^2\rho(r)$ for the C—F bonds derive from the unique behaviour of the Laplacian distributions for fluorine atoms, where the electron density is tightly bound and very localized in all of its compounds (ref. 5, p. 274).

For the C—C critical points, the trends are particularly similar to those for the electron density, with the following exceptions: in the products, the trend to larger magnitudes for more symmetrically substituted radicals, which was weak for the

electron densities, is now more effective (see for example the cases for $C_2H_2F_3$); for transition states, there is a strong dependence on the number of fluorines, but no consistent trends with substitution patterns.

The trends in $\nabla^2\rho(r)$ values for C—F bond critical points are at variance with their $\rho(r)$ trends, and also vary with category, i.e., reactants, products, or transition states. For reactants, within a molecule the higher values are on the less substituted carbon. Higher values are also seen in symmetrically substituted molecules, and there is a general trend to higher values with increasing number of fluorines. For transition states, values are usually higher on the α-carbon, with an exception for $CH_2F—CHF_2$ + OH. On both α- and β-carbons, $\nabla^2\rho(r_c)$ decreases with increasing number of fluorines on that carbon. For products, within a radical much larger values are seen at the α-carbon. For isomers with the same number of fluorines, $\nabla^2\rho(r_c)$ is higher in the case where fluorines are distributed as evenly as possible between the carbons; this trend is particularly pronounced for values at the β-centre.

Values of $\nabla^2\rho(r)$ at C—H bond critical points are almost always more negative on the more highly substituted carbon, and as fluorine substitution as a whole increases. For transition states, magnitudes on the β-carbon are lower for hydrogens *gauche* to the reaction centre. Magnitudes of $\nabla^2\rho(r_c)$ for C1—H1 are much lower than for other C—H bonds. They are higher when there are α-fluorines, but decrease when there are β-fluorines. There is no dependence on the total number of fluorines.

For H1—O, $\nabla^2\rho(r_c)$ is more negative when there are β-fluorines, especially if they are *gauche* to H1. There is a general increase in magnitude with increasing substitution. Magnitudes of $\nabla^2\rho(r_c)$ for O—H2 are by far the highest of any bond types in this study. Starting from the parent C_2H_6 + OH reaction, values increase for monosubstituted systems, then are fairly steady (between −2.7497 and −2.7641) when there are two or more fluorines, with more negative values when there are β-fluorines, particularly if they are *gauche* to H1.

A relatively large negative value of $\nabla^2\rho(r_c)$ together with a relatively large $\rho(r_c)$ value indicate a strong covalent bond (ref. 5, 290). Thus, it is again seen that the forming and breaking bonds are weak, and bonds are stronger when there is a high degree of substitution by electronegative fluorine atoms, and for cases of intramolecular hydrogen bonding. Particularly strong bonds are seen in the hydroxyl units.

On the other hand, the positive values of $\nabla^2\rho(r)$ seen at the C—F bond critical points do not indicate that these are weak bonds. Rather, as a result of charge transfer in these polar bonds, the bond critical point moves closer to the carbon nucleus (see below) and the associated bonded charge concentration now lies within the boundary of the fluorine atom (ref. 5, p. 278).

The sum of the distances (r_A and r_B) from the bond critical point to the associated nuclei is usually longer than the bond length, due to curvature in the bond path (the bond critical point will only lie on the internuclear axis if this axis coincides with an axis of symmetry (19)). These distances can be used as a one-dimensional indication of the size of the atom within the molecule and, assuming fairly constant bond (or bond path) lengths, trends in the absolute difference between r_A and r_B for a given bond type can be used as an indication of substituent effects on that bond type.

For C—C bonds, the larger atom is the more highly substituted one, and for transition states and products α-carbons are larger in case of equal substitution. For reactants, the $r_A - r_B$ difference is seen to increase with an increasing difference in the fluorine substitution at the two carbons, and with the total number of fluorines.

For C—F bonds, the $r_A - r_B$ difference decreases slightly with increasing number of fluorines. For transition states and products, the difference is larger at β-carbons.

For C—H bonds, the $r_A - r_B$ difference is larger at the more substituted carbon, at least for reactants and transition states, and for the latter larger differences are seen at the α-carbon when there is equal substitution at the two carbons. For products, the difference in a given radical is largest at the α-carbon, except when there are two β-fluorines. For reactants and products there is a general increase in $r_A - r_B$ differences with increasing substitution.

For the bond in the hydroxyl unit, whose length is remarkably constant through the series (16), the $r_A - r_B$ difference is also nearly constant, except for $CF_3—CHF_2$ + OH, where the bond critical point is closer to the oxygen atom than it is in other transition states.

There is a larger variance in lengths for the bonds being broken (C1—H1) and formed (H1—O) at the TS. Here a better measure of substituent effects on a bond type is the relative length from the critical point to the nearest atom. For H1—O this is fairly constant (28 ± 0.6%). More variance is seen for C1—H1 (31.1–33.4%), with a slight trend to lower values with increasing substitution. For a given number of fluorines, lower values are seen for the TS where they are distributed as evenly as possible between the two carbons.

The above results in the position of the bond critical point are consistent with those seen previously for binary hydrides (20). There it was noted that the position of r_c correlated, although not in a linear fashion, to the electronegativity of the non-hydrogen atom, i.e., as the electronegativity increased, r_c moved closer to the hydrogen (this correlation led to a method for calculating group electronegativities (21). Here, r_c is closer to the least electronegative atom, or to the atom which has less electronegative substituents. Thus, the carbon atom with the largest atomic basin is that which is more substituted with fluorines, or is closer to the incoming oxygen. The same factors lead to smaller hydrogen atoms.

B. Atomic charges

Atomic charges calculated by MPA at four levels of theory, and by NPA and BPA at the MP2/6-311G(d,p)//HF/6-31G(d) level, for all heavy atoms plus the hydrogen being abstracted, are given in Table 4. Starting from the base theory of HF/6-31G(d), the following trends can be seen as the level of theory is increased. Employing a larger basis set (6-311G(d,p)) has dramatic effects, usually reducing the magnitude of the charge. Including electron correlation at the MP2 level has varying effects depending on the atom, similar to previous results (22, 23). Carbon atoms become more negative or less positive. Hydrogens usually become more positive, with some exceptions for more highly substituted species, where the positive charge lessens slightly. Oxygens become less negative in OH and H_2O, and more negative in transition states, with the degree of difference increasing with the number of α-fluorines. Fluorines are less negative, by about 0.8. When electron correlation is employed in the geometry optimizations, varying effects are seen. In general, the change in charge is greater

[a]The α-C is always that written on the right. Atom labelling scheme is generally the same as in Table 3.
[b]A bond critical point was not found for the forming H–O bond, rendering the charge integrations for these atoms meaningless.

for greater geometry changes, and on the oxygen atoms.

The BPA charges are often much larger than the MPA values, and in cases of moderate magnitudes the signs are often different. While experiment cannot give us numbers with which to compare, given their opposing trends noted above with regard to electronegative atoms, the two methods should give results on either side of the expected "actual charges." Simple chemical intuition is not always reliable in judging the relative accuracy of the results. For example, in all the commonly used electronegativity scales carbon is slightly more electronegative than hydrogen, so it is reasonable to expect that in ethane the carbons should have a slight negative charge and the hydrogens should be slightly positive. This is the case for the MPA results, but the opposite situation is seen in the BPA results. However, the dipole moment derivatives for methane correspond to to a bond dipole in the sense C^+—H^- (24), and this conclusion is supported by an analysis (25) of NPA charges (which do not have the basis set quality dependence of MPA charges; on the other hand, NPA does predict a negative charge on the carbons in ethane, as seen in Table 4). A more general conclusion is that MPA leads to the wrong charge distribution in most C—H bonds (26). The high ionic character for C—F bonds as indicated by the BPA charges also seems surprising at first. However, carbon and hydrogen have roughly the same electronegativity, and it is generally recognized that hydrogen fluoride has a large ionic character.

The NPA charges for oxygens and hydrogens are intermediate between the other two methods, although charges on the latter tend to be close to those obtained by either one of MPA or BPA. Charges on fluorines tend to be close to one of the MPA values, usually either at the HF/6-31G(d) or HF/6-311G(d,p)//MP2/6-31G(d,p) level. The greatest variance is seen with the carbon charges, which tend to be more negative or less positive than with the other methods.

For individual atom types, the following trends are noted at the various levels of theory. With MPA and BPA, charges at α-carbons are more negative than at β-carbons, except when the number of α-fluorines is greater than the number of β-fluorines. With NPA, β-carbons are more negative, except if the number of β-fluorines is greater than the number of α-fluorines. With MPA, β-fluorines are usually more negative than α-fluorines, except when there are more fluorines on the β-carbon. Similar trends are observed with NPA, with fewer exceptions. With BPA, there is less variance, and the trends are sometimes opposite. For example, in CH_2F—CHF, MPA gives more negative results for the β-fluorine, but at BPA the more negative value is for the α-fluorine. Charges on hydrogens roughly correlate with the electronegativity of nearby atoms, i.e., as the number of nearby electronegative atoms increases, so does the positive charge on the hydrogen. Charges on oxygen atoms are smallest in the reactant (OH), largest in the product (H_2O), and vary little in the TS, at least with BPA and MPA, and for the latter, smaller magnitudes are seen when MP2 geometries are used. There is more variance in the NPA charges, with magnitudes tending to increase with the number of α-fluorines.

C. Charge development in the reactions

The changes in atomic charges from the reactant to the transition state, and from the transition state to the product, are given for each reaction by the MPA, NPA, and BPA methods, at the MP2/6-311G(d,p)//HF/6-31G(d) level of theory, in Table 5. In going from the reactant to the transition state, C_α always becomes more negative with the BPA method. MPA results are smaller by a factor of up to 10, and the change is often positive when there are no α-fluorines. With NPA, C_α always becomes more positive, and the magnitude is usually larger than with BPA. Less drastic changes are seen at C_β, which in most cases has a slight positive change, and there is better agreement between BPA and MPA. With NPA the change is negative, and the magnitude, while smaller than that for C_α, is still larger than for the other methods.

Table 5. Change in atomic charges from reactants to transition state, and from transition state to products, at MP2/6-311G(d,p)//HF/6-31G(d) level of theory.

[a]As written, the second carbon is attached to the reaction centre (α). The g and t designations refer to the abstracted H being *gauche* or *trans*, respectively, to a β-F.

[b]BPA numbers not available since the bond critical point for the forming H—O bond was not found.

Fluorines attached to the α-carbon become slightly more positive, by about 0.05 with MPA, about 0.03 with NPA, and <0.01 with BPA. For β-fluorines little change is seen, with relatively larger $\Delta Q_{r\rightarrow ts}$ values with MPA and NPA. The abstracted hydrogen becomes more positive, in relative order BPA > MPA ≈ NPA, and the oxygen more negative, with magnitudes in relative order NPA > BPA > MPA.

The above MPA and BPA results are consistent with the influence of the incoming, electronegative oxygen atom, which will draw electron density away from the hydrogen. The impending loss of a relatively electropositive substituent, and (or) an electrostatic effect from the oxygen atom, leaves more electrons at the α-carbon, and a concomitant slight decrease in charge at the remaining substituents. A slightly different picture emerges from the NPA results, where the α-carbon becomes more positive. The oxygen atom again plays a prime role, with the carbon atom losing electron density due to an inductive effect. However, since the positive change on the carbon is greater than the positive change on the hydrogen, it is likely that other forces are at play as well.

As the reaction proceeds to products, the oxygen atom moves away from the ethyl radical, so its influence is no longer felt, and many of the changes in atomic charges are reversed. In going from TS to product, C_α always becomes more positive with MPA (except in $CH_2F—CHF_2 + OH$), in some cases more than compensating for the buildup of charge at the TS. With NPA, C_α continues to become more positive. The BPA changes are smaller, with varying signs. If the change in charge from reactant to product is considered, BPA always predicts that C_α is more negative in the product (except in the case of $CF_3—CHF_2$ + OH), consistent with the increase in electronegativity in going from an sp^3- to sp^2-hybridized carbon.

The MPA results for C_β usually continue the trend to positive changes observed in going from reactant to TS, and with NPA it continues to become more negative. Signs for the BPA changes vary, and the magnitude is often smaller than for MPA, with $CF_3—CHF_2$ + OH again being a notable exception.

For α-fluorines, the trend of MPA results to more positive values, which was seen for the change from reactant to TS, continues but with slightly smaller values, and a few exceptions where the value is slightly negative. With BPA, and NPA in most cases, the values of $\Delta Q_{ts\rightarrow p}$ are slightly negative. All three methods give very small magnitudes for β-fluorine values.

For the reacting hydrogen atom, the BPA method continues the trend to more positive charge, although the effect is smaller than before. It also continues to become more positive with NPA, with the effect having about the same magnitude as for reactants to transition states. Much smaller magnitudes are seen in the MPA results, where the sign of the change varies. The oxygen atom undergoes similar trends as for reactants to transition states, with the effect again being much smaller with MPA.

A general trend seen in these results is that there is a buildup of charge in the TS, concentrated near the reaction centre. The charge buildup on α-carbon atoms dissipates somewhat as the reaction proceeds to products, with MPA and BPA. With NPA, the buildup of positive charge continues. For other atoms the buildup or depletion of charge continues, but the effect is smaller.

4. Conclusions

The magnitudes of the electron density and its Laplacian at the bond critical points are in most cases correlated with the bond strength, as measured by bond dissociation energies. The position of the bond critical point varies with the electronegativity of the surrounding atoms.

The three methods used to calculate atomic charges give somewhat different descriptions of electron transfer in the reactions. In general, there is a buildup of charge in the TS, concentrated near the reaction centre. As the reaction proceeds to products the charge buildup on the α-carbon dissipates somewhat, while for other atoms the buildup or depletion of charge continues, but at a lesser rate.

Of the three methods used to calculate atomic charges, BPA is the most sophisticated, but MPA appears to give more realistic results, at least when relative atomic electronegativities are considered. However, the BPA results are consistent with bond polarities determined in previous studies, and they give a reasonable picture of the charge development in the reactions. The NPA results are in many cases intermediate between the other two, but appear to overestimate charge transfer on carbon atoms.

Analysis of magnesium–carbon bonding in magnesium anthracene systems[1]

Ralf Stegmann and Gernot Frenking

Abstract: Ab initio calculations at the MP2/3-21G(*) level of theory have been carried out for the magnesium–anthracene complexes 9,10-magnesiumanthracene·$3H_2O$ (**1**) and the 9-methyl (**2**), dimethyl (**3**), and 9,10-bis(methylsilyl) (**4**) substituted derivatives. The theoretically predicted geometries of the anthracene ligands are also reported. The calculated geometries of **1–4** are in very good agreement with experimental values for the corresponding THF complexes. The Mg—$C_{9,10}$ bonds of the bridged structures are rather long and the anthracene ligands are folded by ~40° along the C_9–C_{10} line in the complexes. Analysis of the electronic structure shows clearly that the Mg—$C_{9,10}$ bonds should be considered as purely ionic. This is revealed by topological analysis of the electron density distribution and its associated Laplacian. The electron density at the Mg—$C_{9,10}$ bond critical points $\rho(\boldsymbol{r}_b)$ is very low and the Laplacian $\nabla^2\rho(\boldsymbol{r}_b)$ and the energy density H_b have positive values. The ionic nature of the Mg—$C_{9,10}$ bond is also indicated by the natural bond order (NBO) analysis, which gives a Lewis structure with two lone pairs at C_9 and C_{10} but no Mg—$C_{9,10}$ bonds. The NBO method gives a charge donation from Mg to the anthracene ligand of nearly two. The theoretically predicted NMR chemical shifts using the GIAO method give ^{13}C resonances for the complex **1** and for anthracene and anthracene dianion that are in good agreement with experimental values.

Key words: magnesium–anthracene complexes, ab initio calculations, analysis of magnesium–carbon bonding.

Résumé : On a effectué des calculs ab initio au niveau MP2/3-21(G*) de la théorie pour les complexes suivants du magnésium avec des anthracènes : 9,10-magnésiumanthracène·$3H_2O$ (**1**) et pour les dérivés substitués 9-méthyl- (**2**), 9,10-diméthyl- (**3**) et 9,10-bis(méthylsilyl)- (**4**). On rapporte aussi les géométries prédites par la théorie pour les coordinats anthracènes. Les géométries calculées des composés **1–4** sont en bon accord avec les valeurs expérimentales des complexes correspondants avec le THF. Les liaisons Mg—$C_{9,10}$ des structures pontées sont relativement fortes et les coordinats anthracènes sont repliés d'environ 40° le long de la droite reliant C_9 à C_{10} dans les complexes. L'analyse de la structure électronique montre clairement que les liaisons Mg—$C_{9,10}$ devraient être considérées comme purement ioniques. Cette conclusion est révélée par l'analyse topologique de la distribution de la densité électronique et du laplacien qui lui est associé. La densité électronique aux points critiques de la liaison Mg—$C_{9,10}$, $\rho(\boldsymbol{r}_b)$ est très faible et le laplacien, $\nabla^2\rho(\boldsymbol{r}_b)$ ainsi que la densité d'énergie, H_b, ont des valeurs positives. La nature ionique de la liaison Mg—$C_{9,10}$ est aussi indiquée par l'analyse NBO qui conduit à une structure de Lewis comportant deux paires non partagées en C_9 et en C_{10}, mais pas des liaisons Mg—$C_{9,10}$. La méthode NBO conduit à un don de charge du Mg au coordinat anthracène de pratiquement deux. Les déplacements chimiques en RMN prédits d'un point de vue théorique à l'aide de la méthode GIAO conduisent à des résonances en ^{13}C pour le complexe **1** et pour l'anthracène et le dianion de l'anthracène qui sont en bon accord avec les valeurs expérimentales.

Mots clés : complexes magnésium–anthracène, calculs ab initio, analyse des liaisons magnésium–carbone.

[Traduit par la rédaction]

Introduction

In 1965, Ramsden found that elementary magnesium reacts with anthracene in tetrahydrofuran (THF) to form an orange compound, which has the magnesium atom in a bridging position between the C_9 and C_{10} position (1). The discovery made by Ramsden remained in a dormant stage, until in 1980 Bogdanovic et al. found that magnesium anthracene systems can be used for the hydrogenation of magnesium under very mild conditions (2). This finding triggered numerous experimental studies about the properties and application of these synthetically and industrially interesting compounds (3–5). It was found that magnesium anthracene compounds are excellent reducing agents for transition metal salts, and that they can be used to prepare Grignard components in a very convenient way.

The key to the fascinating chemistry of the magnesium-anthracene system is the unusual Mg—C bond. X-ray structure analyses of the magnesiumanthracene·3THF complex and substituted derivatives show that the magnesium atom is usually pentacoordinate with three THF molecules surrounding the Mg atom (5). The Mg—$C_{9,10}$ bond distances are very long (2.2–2.35 Å) and the C_9-Mg-C_{10} bond angle is very sharp (71°–79°). The anthracene moiety of the complex is folded along the C_9–C_{10} line by 26°–45°. The complexes with bulky

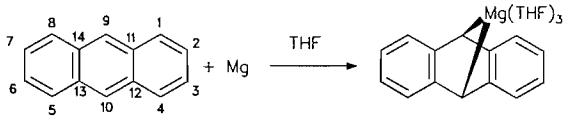
trimethylsilyl substituents at C_9 and C_{10} have only two THF molecules around the Mg atom (5).

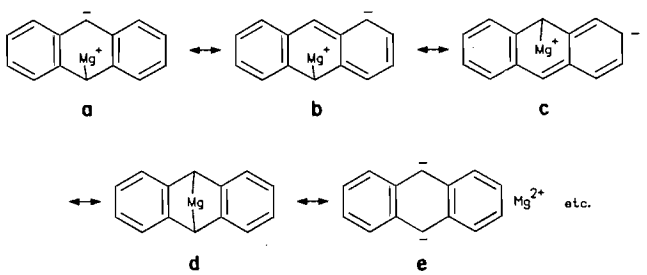
Scheme 1.



The Mg—C bonding in these complexes appears not to be very strong. The equilibrium between magnesium and anthracene and the adduct is temperature dependent and can be strongly influenced by substituents in the 9 and 10 positions (3). At 0°C, the equilibrium between magnesium and anthracene in THF and the complex is nearly 100% on the adduct side, while at 60°C the equilibrium is strongly shifted toward the starting materials (3*h*). An interesting observation is that at 60°C the equilibrium of the parent compound is only 23% on the complex side, and while one methyl group in the C_9 position enhances the product concentration to 51%, two methyl groups at C_9 and C_{10} reduce the complex concentration to only 5% (Scheme 1) (3*h*).

The nature of the Mg—C bonding in magnesium anthracene systems is not fully understood. The low thermal stability of magnesium anthracene systems speaks against a significant covalent contribution. Since the NMR data of the magnesium–anthracene complexes differ significantly from those of the dianion of Li_2[anthracene] (6), Bogdanovic concluded that an ionic structure can be ruled out (3*f*). The dominant feature of the NMR spectrum of Li_2[anthracene] is the strong shift of the ^{13}C resonances of $C_{9,10}$ towards higher field by 49.8 ppm relative to anthracene (6). The ^{13}C signals of $C_{9,10}$ of Mg-anthracene·3THF are shifted to even higher fields by 68.5 ppm (3*f*). A higher charge concentration at $C_{9,10}$ in the Mg complex than in the anthracene dianion was regarded by Bogdanovic as an unlikely reason for the larger high-field shift. This author interpreted the ^{13}C signals of $C_{9,10}$ as indicating a change in the hybridization of $C_{9,10}$ towards sp^3 (3*f*). Bogdanovic suggested ionic–covalent resonance forms for the description of the Mg—$C_{9,10}$ bonds (Scheme 2). It should be noted that resonance forms such as **b** and **c** should not be very important, because the anthracene moiety is strongly bent along the $C_{9,10}$ line.

Scheme 2.



There has been no theoretical investigation of the structure and bonding of these compounds. In this paper we report the theoretically predicted geometries of the parent compound 9,10-magnesiumanthracene·$3H_2O$ (**1**) using ab initio quantum mechanical methods at the Hartree–Fock and MP2 levels of theory. The water ligand has been taken to mimic THF. We also report theoretical results for the substituted derivatives 9-methyl- (**2**), 9,10-dimethyl- (**3**), and 9,10-(methyl)silyl-magnesiumanthracene·$3H_2O$ (**4**). The latter compound was taken as model for 9,10-(trimethyl)silyl-magnesiumanthracene·$3H_2O$), which could not be calculated for computational reasons. The focus of this study is the analysis of the Mg—C bonding interactions. To this end we employed topological analysis of the electron density distribution $\rho(r)$, its gradient field $\nabla\rho(r)$, and the associated Laplacian $\nabla^2\rho(r)$ developed by Bader (7). The electronic structure of the complexes has also been examined by using the natural bond orbital (NBO) method developed by Weinhold and co-workers (8).

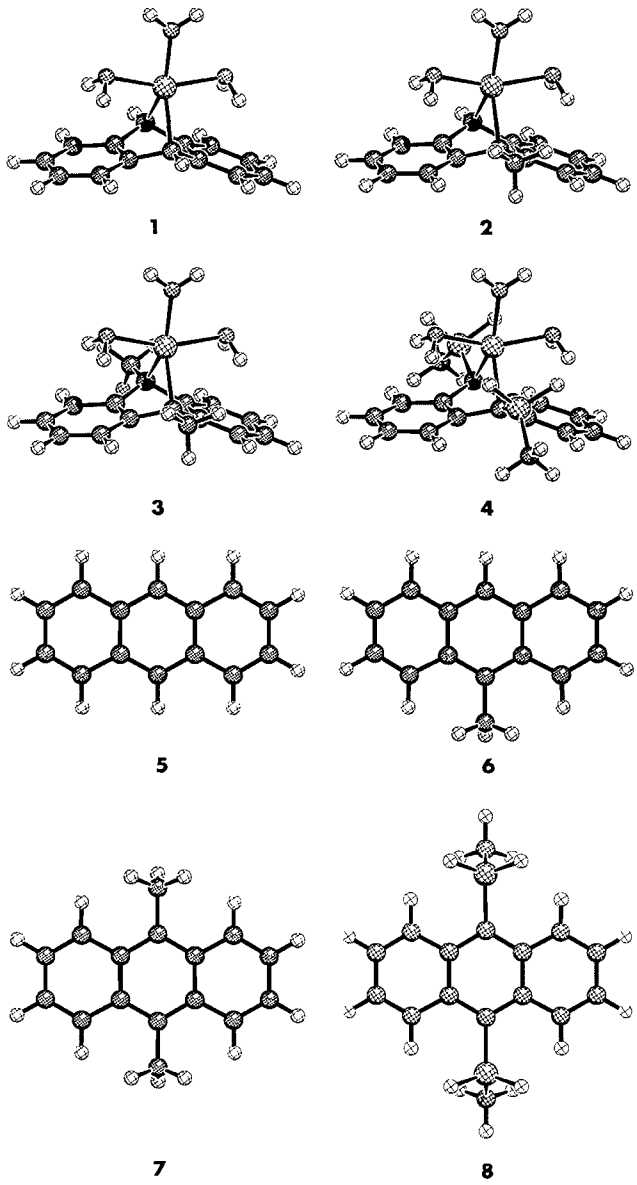
Method

The geometry of **1** has been optimized at the Hartree–Fock (HF) and MP2 (Møller–Plesset perturbation theory terminated at second order) (9) levels of theory using 3-21G(*) and 6-31G** basis sets (10). Geometry optimizations have also been carried out with the semiempirical method PM3 using the actual Mg parameters (11). The harmonic vibrational frequencies have been calculated at HF/3-21G(*) using analytical second derivatives. The geometries of **2**–**4** and the anthracene species **5**–**8** were optimized at MP2/3-21G(*). The calculated geometry of **1** was not very different when larger basis sets were employed. Because this study focusses on the structure and not the energy of the molecules, calculations at the MP2/3-21G(*) level of theory are sufficient. The program TURBOMOLE was used for the geometry and energy calculations (12). The NMR chemical shifts were calculated using the direct version of the GIAO method (13). The HF/GIAO calculations were carried out with a DZ + P basis set (14). For topological analysis of the electron density distribution the programs EXTREME, SCHUSS, GRIDV, and CONTOUR were employed (15). The NBO calculations (8) were carried out with the program Gaussian 92 (16).

Results and discussion

The optimized structures of the complexes **1**–**4** and anthracenes **5**–**8** are shown in Fig. 1. Table 1 shows the Mg—$C_{9,10}$ bond lengths of **1** calculated at PM3, HF/3-21G(*), HF/6-31G**, MP2/3-21G(*), and MP2/6-31G**. It is obvious that the Mg—$C_{9,10}$ bond distance using the semiempirical method PM3 is much too short, while the ab initio values are in good agreement with experiment. Table 2 gives the theoretical and experimental geometries of **1**–**8**. The ab initio calculations give geometries that are in good agreement with experimental values. It should be noted that the experimental

Fig. 1. Optimized geometries (MP2/3-21G(*)) of the magnesium–anthracene complexes **1–4** and the anthracene ligands **5–8**.



data deduced from X-ray structure analysis are subject to disorder and solid-state effects.

The anthracene moiety of complexes **1–4** is folded along the C_9–C_{10} line. The value of the folding angle depends upon the definition of the vectors forming the angle, τ. We took the midpoints of the lines connecting C_{13}–C_{14}, C_9–C_{10}, and C_{11}–C_{12} as one definition of the folding angle τ (τ_1), and the midpoints of C_5–C_8, C_9–C_{10}, and C_1–C_4 as another definition, which is denoted τ_2. The folding angle of **1** is then calculated to be $\tau_1 = 47.3°$ and $\tau_2 = 38.2°$ (Table 2). Experimentally, two different molecules in the disordered crystal structures were found, for which the angles between the two phenylene planes were reported as $\tau = 26.6°$ and 30.6° (*5a*). The folding angle of the 1,4-dimethyl derivative of **1** has experimentally been reported with a value of $\tau = 40.95°$ (*5b*), which is in good agreement with the calculated value. Similar values of $\tau = 41.2°$ (*5d*) and $\tau = 45°$ (*5c*) have been reported for the trimethylsilyl derivative of **1**. It should be noted that the phenylene rings in the two crystal forms of **1** are slightly bent (*5a*).

The calculated Mg—$C_{9,10}$ distances of **1–4** are in good agreement with the observed values. The experimental Mg—$C_{9,10}$ bond lengths of **1** show some scattering, due to the disorder of the crystal (*5a*). The calculations predict that the Mg—$C_{9,10}$ bond lengths of the 9,10-substituted complexes **2–4** have slightly *shorter* bond lengths than the parent compound **1**. The calculated C_9-Mg-C_{10} angle is not very different for the four complexes. The theoretical values are between 76.1° (**1**) and 77.5° (**3**). This is in good agreement with the experimental results, which show bond angles C_9-Mg-C_{10} between 70.9° and 78.2° (5). It should be kept in mind that the experimental results refer to THF complexes, while the calculated structures have water molecules as ligands.

The effect of substituents at the $C_{9,10}$ position upon the C—C bond lengths of anthracene is negligible (Table 2). It is interesting to compare the calculated C—C bond lengths of the anthracene moieties in the complexes **1–4** with those of anthracene (**5**) and anthracene dianion ($\mathbf{5}^{2-}$). The C_1–C_2 distance of **5** (1.379 Å) becomes longer in $\mathbf{5}^{2-}$ (1.428 Å). Slightly shorter C_1—C_2 distances than in $\mathbf{5}^{2-}$ are calculated for the complexes **1–4** (1.413–1.414 Å). The C_2–C_3 bond length of **5** (1.438 Å) becomes shorter in $\mathbf{5}^{2-}$ (1.401 Å) and it changes little in the complexes (1.403–1.407 Å). The C_1–C_{11} bond length of **5** (1.442 Å) becomes slightly shorter in $\mathbf{5}^{2-}$ (1.430 Å) and reduces even more in the complexes (1.412–1.415 Å). The largest change is found for the C_9—C_{11} bond, which becomes much longer, from 1.410 Å in **5** to 1.430 Å in $\mathbf{5}^{2-}$ and 1.497–1.499 Å in **1–4**. The C_{11}—C_{12} bond length of **5** (1.453 Å) becomes longer in $\mathbf{5}^{2-}$ (1.472 Å) but then it becomes shorter in the complexes **1–4** (1.443–1.449 Å). The changes in the C—C distances from **5** and $\mathbf{5}^{2-}$ to the complexes indicate an enhanced aromatic conjugation within the two outer phenylene rings, while C_9 and C_{10} change towards singly bonded carbon atoms. The bond length alternation in the outer phenyl rings is clearly reduced in **1–4** as compared to **5** and $\mathbf{5}^{2-}$ (Table 2).

We come to the analysis of the magnesium–carbon bonding in the complexes **1–4**. Figure 2 shows the contour line diagrams of the Laplacian distribution for the four compounds in the C_9-Mg-C_{10} plane. For comparison, we show also the Laplacian distribution for the anthracene dianion ($\mathbf{5}^{2-}$) using the geometry of the folded anthracene moiety of **1** (Fig. 2*e*). The areas of charge depletion ($\nabla^2\rho(r) > 0$) are indicated by broken lines, and the areas of charge concentration ($\nabla\rho(r) < 0$) are shown by solid lines. The magnesium atom is characterized by a large area of charge depletion. The shape of the Laplacian distribution around Mg indicates clearly that there is no charge concentration in the valence region. The metal atom has lost its valence electrons. There is an area of charge concentration at C_9 and C_{10} pointing toward the magnesium atom. This area of charge concentration is larger in the complex **1** than in the isolated anthracene dianion moiety (compare Figs. 2*a* and 2*e*). Visual inspection of the Laplacian distribution shows that the Mg—$C_{9,10}$ bonds are strongly polar. Also, the Mg—O bond is characterized by charge concentration at the oxygen end and charge depletion at the magnesium. Unlike C_9 and C_{10}, the charge concentration at the oxygen atom shows little deformation towards the Mg atom. This is reasonable, because oxygen

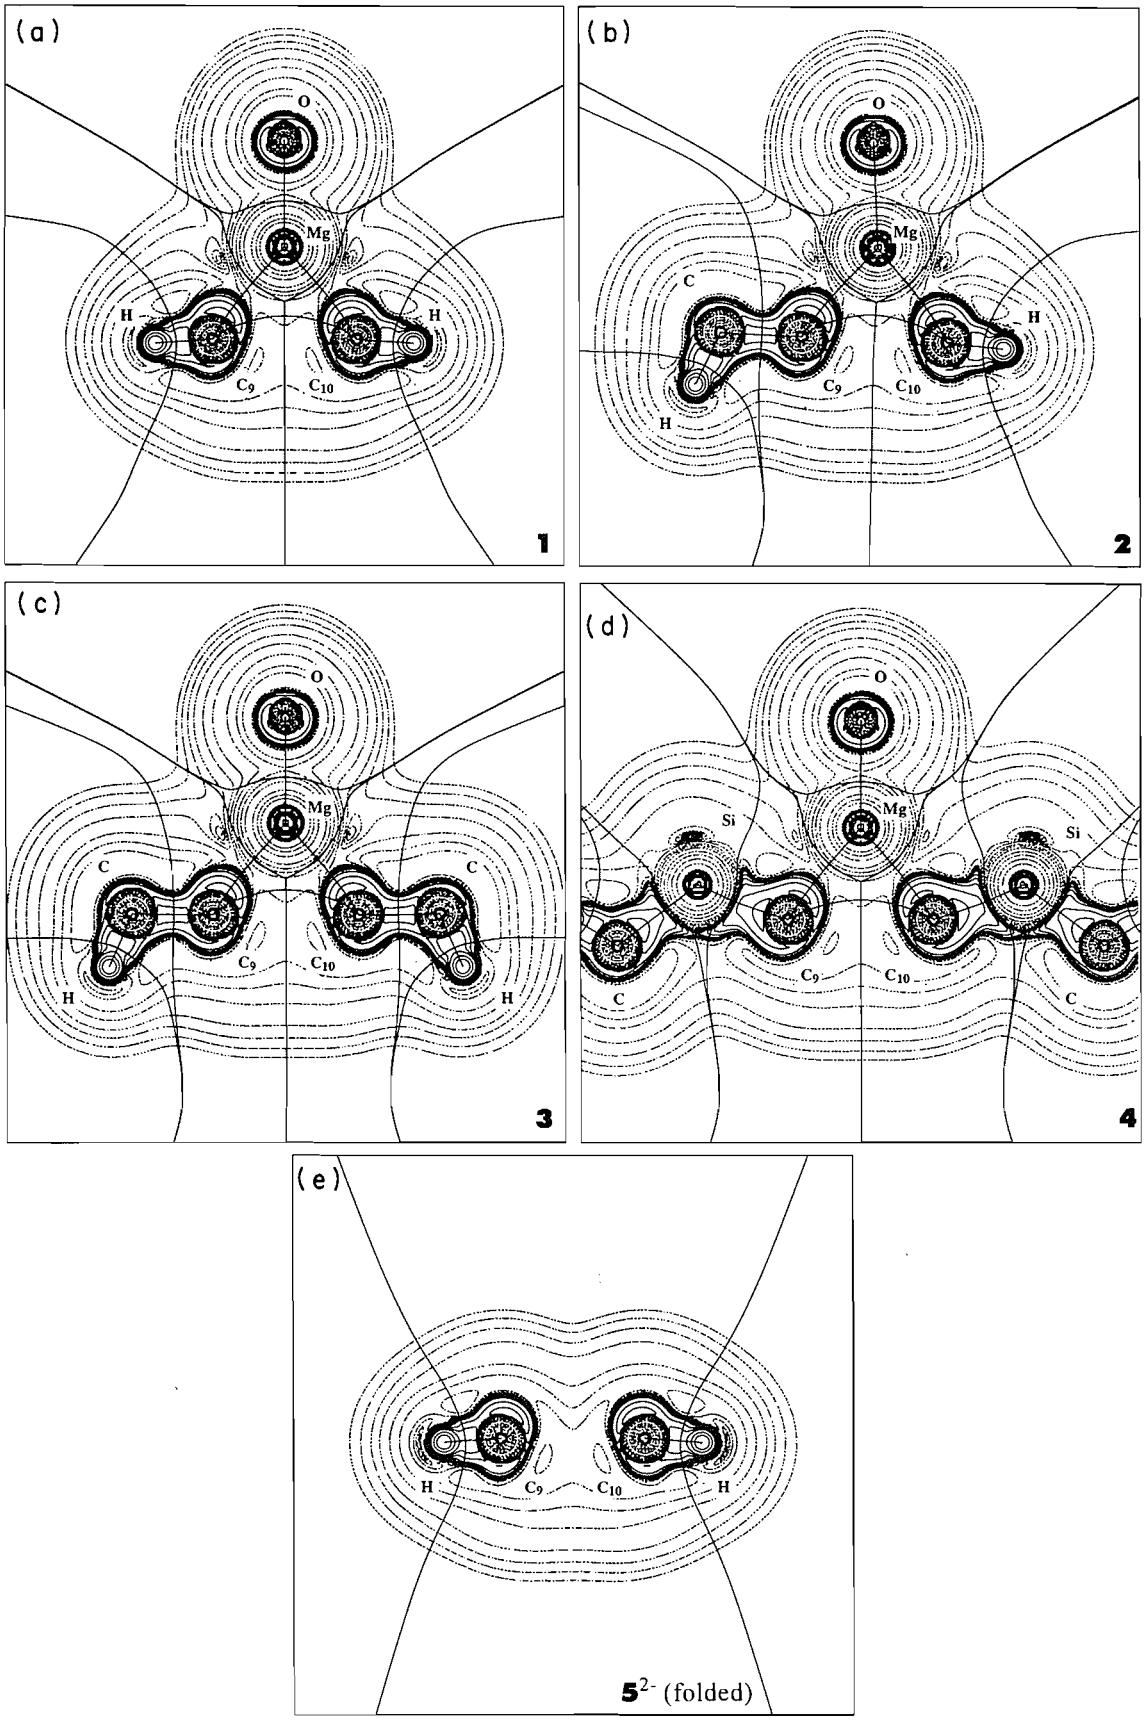


Fig. 2. Contour line diagrams of the Laplacian distribution $\nabla^2\rho(\boldsymbol{r})$ at MP2/3-21G(*). The diagrams are plotted in the C_9–Mg–C_{10} plane. The values $\nabla^2\rho(\boldsymbol{r})$ represented by the contour lines are (in hartrees) 0.001 for the outermost line, then 0.002, 0.004, 0.008, 0.02, 0.04, etc. Figures (*a*)–(*d*) show the complexes **1**–**4**. Figure (*e*) shows the anthracene dianion using the geometry of the anthracene ligand in **1**. Broken lines indicate charge depletion ($\nabla^2\rho(\boldsymbol{r}) > 0$), solid lines indicate charge concentration ($\nabla^2\rho(\boldsymbol{r}) < 0$). The solid lines connecting the atomic nuclei are the bond paths, the solid lines separating the atomic nuclei indicate the zero-flux surfaces in the plane. The crossing points of the bond paths and zero-flux surfaces are the bond critical points $\boldsymbol{r}_b$.

is more electronegative and less polarizable than carbon. The difference between the very polar Mg—$C_{9,10}$ and Mg—O bonds and the truly covalent C—H, C—C (**2** and **3**, Figs. 2*b* and 2*c*), and C—Si bonds (**4**, Fig. 2*d*) becomes obvious by comparing the Laplacian distribution in the interatomic region. The C—H, C—C, and C—Si bonds show continuous areas of charge concentration between the bonded atoms.

Figure 2 shows not only bond paths for the Mg—C_9 and Mg—C_{10} bonds in **1**–**4**, but there is also a bond path between the carbon atoms C_9 and C_{10}. In addition, there is a ring critical point for the C_9MgC_{10} moiety. It follows that topological analysis of the electron density distribution assigns a cyclic structure to the C_9MgC_{10} moiety of **1**–**4**. A closer examination of Fig. 2 shows that the C_9–C_{10} bond path is bent inward, and that the bond critical point is close to the ring critical point. Such a situation is typical for the opening of a three-membered ring. A merging of the C_9–C_{10} bond critical point $\boldsymbol{r}_b$ and the ring critical point $\boldsymbol{r}_c$ would yield a singularity in ρ, which is called a catastrophe point in the configuration space (ref. 7, p. 114).

The relationship between structure diagrams obtained from critical point bond paths and classical chemical bonds has been discussed in detail by Bader (7). Here it is sufficient to say that a bond path does not necessarily indicate a chemical bond. Two helium atoms, which are 100 Å away, are still connected by a bond path, and they have a bond critical point. It is possible, however, to distinguish within the atoms-in-molecules theory (7) between *shared interactions*, which are typical for covalent bonds, and *closed-shell interactions*, which are typical for ionic bonds and van der Waals interactions. It has been shown that for shared interactions (covalent bonding) between two atoms the Laplacian at the bond critical point $\nabla^2\rho(\boldsymbol{r}_b)$ is negative and large in magnitude, and that the electron density at the bond critical point $\rho(\boldsymbol{r}_b)$ is also large in magnitude (ref. 7, p. 290f). For closed-shell interactions it holds that $\nabla^2\rho(\boldsymbol{r}_b) > 0$ and $\rho(\boldsymbol{r}_b)$ is relatively small. It has also been shown that the energy density at the bond critical point H_b is negative for covalent bonds, while it is zero or slightly positive for closed-shell interactions (17).

Table 3 shows the calculated results of the topological analysis for **1**–**4**. For the C_1–C_2 and C_9–C_{11} ring bonds of **1** it is found that $\nabla^2\rho(\boldsymbol{r}_b) < 0$, $\rho(\boldsymbol{r}_b)$ is rather large, and $H_b < 0$. These values are typical for covalent bonds. The results of the topological analysis for the C_9–C_{10}, Mg–O, and Mg–$C_{9,10}$ interactions are clearly different. The values for $\nabla^2\rho(\boldsymbol{r}_b)$ are positive and the magnitude of $\nabla^2\rho(\boldsymbol{r}_b)$ and $\rho(\boldsymbol{r}_b)$ is much lower than for the C—C ring bonds. The H_b values for the Mg—O and Mg—$C_{9,10}$ bonds are positive, while the C_9–C_{10} interactions have slightly negative values (Table 3). It follows that *the topological analysis of the electron density distribution classifies the Mg—$C_{9,10}$ bonds as purely ionic*! We checked if the results of the topological analysis change significantly when a larger basis set is employed. To this end we repeated the calculations at the MP2 level using a 6-31G(*) basis set for $C_{9,10}$ and Mg at the MP2/6-31G(**) optimized geometry. For the other atoms a 3-21G basis set was employed. The energy density and the Laplacian at the Mg—$C_{9,10}$ bond critical points changed only slightly, and the values were still positive (H_b = 0.007 hartree/Å^3, $\nabla^2\rho(\boldsymbol{r}_b)$ = 4.398 e/Å^5).

There is additional theoretical evidence for a classification of the Mg—$C_{9,10}$ bonds of Mg-anthracene as purely ionic bonds. The NBO analysis (8) of the wave function gives the charge distribution and the most important Lewis structure of the molecule. We examined the wave functions of **1**–**4** at the MP2/3-21G(*) level. The most important result of the NBO analysis is that there is no Mg—C bond in the optimal Lewis structure! The NBO results give two lone pairs at C_9 and C_{10}. It follows that the resonance form **e** shown in Scheme 2 gives the best representation of the magnesium–anthracene complexes. The hybridization at $C_{9,10}$ is very interesting. The NBO analysis indicates that the lone pairs at $C_{9,10}$ in complexes **1**–**4** are nearly pure *p* AOs, while the bonds to the neighbouring carbon atoms are essentially sp^2 hydridized (Table 4). The hybridization at $C_{9,10}$ is nearly the same in the planar equilibrium form $\mathbf{5}^{2-}$, in the folded geometry, and finally in the complex ligand. The calculated charge distribution (Table 4) indicates that the partial charge of the Mg–anthracene complexes at $C_{9,10}$ is significantly larger than in anthracene^{2-}, which is in agreement with the Laplacian distribution shown in Figs. 2*a* and 2*e*. This is a reasonable result, because the charge is delocalized in the π-system of planar anthracene^{2-}, while it is more localized at the lone pairs of $C_{9,10}$ in the folded anthracene moiety of **1**–**4**. Table 4 shows that the partial charges at $C_{9,10}$ increase from planar $\mathbf{5}^{2-}$ (−0.40 e) to folded $\mathbf{5}^{2-}$ (−0.46 e). The electron transfer from $Mg(H_2O)_3$ to the anthracene ligand leads to a further increase of the negative partial charge at $C_{9,10}$ (Table 4). The NBO analysis indicates that the $Mg(H_2O)_3$ moiety donates 1.67–1.78 electrons to the anthracene part. The Mg—$C_{9,10}$ overlap-weighted bond order is very low. It follows that the NBO analysis supports the interpretation of the Mg—$C_{9,10}$ bonding in magnesium–anthracene complexes as ionic with negligible covalent contributions. The NBO analysis of the wave function using 6-31G(*) basis sets at $C_{9,10}$ and Mg gave very similar results. The most important Lewis structure had no Mg—$C_{9,10}$ bond. We enforced a Lewis structure with Mg—$C_{9,10}$ bonds. The polarization of the Mg—$C_{9,10}$ bonds was 6.8% at Mg and 93.2% at $C_{9,10}$. This result shows that covalent contributions to the Mg—$C_{9,10}$ bonds are indeed negligible.

We calculated the NMR chemical shifts of the complex **1**, anthracene (**5**), and anthracene dianion ($\mathbf{5}^{2-}$) at the optimized (planar) geometry and with the frozen geometry taken from **1**. The latter form is 15.3 kcal/mol (MP2/3-21G(*)) higher in energy than the planar form. The calculated and experimental ^{13}C chemical shifts of the THF complex are shown in Table 5.

Table 2. Geometry data of structures **1–8** at the MP2/3-21G(*) level of theory. Bond distances in angstrom, bond angles in degrees, folding angle τ in degrees. Experimental values for the THF complexes are given in parentheses.

[a]Electron density at the bond critical point $\rho(r_b)$ (e/Å^3), energy density at the bond critical point H_b (hartree/Å^3), Laplacian at the bond critical point $\nabla^2\rho(r_b)$ (e/Å^5), bond distance R_{ab} (Å), distance of the bond critical point for the bond A—B from atom A Δr_{ab} (Å).

The theoretically predicted ^{13}C resonance signals for **5** are in very good agreement with experiment. For the ^{13}C signals of $C_{9,10}$ of the dianion $\mathbf{5}^{2-}$ the calculations predict a shift towards higher field by 61.4 ppm, from 126.6 ppm to 65.2 ppm (Table 5). This is in reasonable agreement with the experimentally observed shift from 126.2 ppm for **5** to 75.1 ppm for Li_2[anthracene]. It should be noted that the latter compound is taken as reference for free $\mathbf{5}^{2-}$, although the structure of the compound is not known. The HF/GIAO calculation for $\mathbf{5}^{2-}$ using the folded geometry of the anthracene moiety of **1** gives a surprising result. The calculations predict that the ^{13}C signals of the planar and folded anthracene dianion are nearly the same (Table 5). A particularly surprising result is the calculated resonances for $C_{9,10}$. Although the charge distribution and the C—C bond lengths of $C_{9,10}$ are clearly different between the planar equilibrium geometry $\mathbf{5}^{2-}$ and in the complex **1**, the ^{13}C signals differ only by 1.1 ppm (Table 5). We want to point out that previous theoretical analyses of the correlation between the electronic structure and the NMR chemical shifts of numerous molecules suggest that *there is generally no correlation between partial charges and NMR resonances* (20). The chemical shift is very sensitive to the electronic structure of the molecule and there are many factors that can strongly influence the position of the NMR resonance. There seems to be a fortuitous cancellation of the diamagnetic and paramagnetic contributions to the ^{13}C resonances of $C_{9,10}$ that leads to nearly identical values for planar and folded $\mathbf{5}^{2-}$.

The HF/GIAO calculations for the ^{13}C signals of $C_{9,10}$ predict a further shift, by 24.5 ppm, towards higher field from planar $\mathbf{5}^{2-}$ to **1** (Table 5). This is in agreement with the experimentally observed high-field shift of 17.4 ppm from 75.1 ppm for $\mathbf{5}^{2-}$ to 57.7 ppm for **1**. Thus, the calculated ^{13}C signals for the compounds given in Table 5 reproduce the experimentally observed resonances quite well.

Summary

The ab initio calculations at the MP2/3-21G(*) level of theory predicted for the magnesium–anthracene complexes **1**–**4** are in very good agreement with X-ray structure analyses of the related THF complexes. Inspection of the electronic structure of the complexes using topological analysis of the electron density distribution and its associated Laplacian shows clearly that the Mg—$C_{9,10}$ bonds should be considered as purely ionic. This follows from the Laplacian distribution of the compounds and the calculated values for the charge density and energy density at the Mg—$C_{9,10}$ bond critical points. An ionic character of the Mg—$C_{9,10}$ bonds is also suggested by the NBO analysis, which gives a Lewis structure with two lone pairs at C_9 and C_{10} and no Mg—C bonds. The NBO calculations predict that the partial charge of the anthracene moiety is nearly −2. The HF/GIAO calculations give ^{13}C NMR signals for the magnesium–anthracene complex **1**, anthracene, and anthracene dianion that are in good agreement with experimental values.

Acknowledgments

It is a pleasure to acknowledge continuous support by the Bader group in providing the programs for the topological analysis of the electron density distribution. This work has been supported by the Deutsche Forschungsgemeinschaft (SFB 260-D19 and Graduiertenkolleg Metallorganische Chemie) and by the Fonds der Chemischen Industrie. Excellent services by the computer centers HRZ Marburg, HRZ Giessen, HHLRZ Darmstadt, and KFA Jülich are gratefully acknowledged.

The 1,2,3,5-ditelluradiazolyl [HCN_2Te_2] species. Theoretical characterizations of the cation, radical, and radical dimers

William M. Davis and John D. Goddard

Abstract: Dithia- and diselena-diazolyl radicals (HCN_2E_2 E = S, Se) and dimers are important building blocks in the design of low-dimensional molecular conductors. Research on the tellurium-based analogues is much rarer. This work reports the molecular and electronic structures of the cation, radical, and radical dimers of 1,2,3,5-ditelluradiazolyl using ab initio theory including electron correlation by Møller–Plesset perturbation theory up to partial fourth order (MP4SDQ). A face-to-face C_{2v} dimer is predicted to be bound with respect to two radicals by approximately 18 kcal/mol. A C_{2h} dimer also has been studied and is ca. 2 kcal/mol less stable than the C_{2v} conformer. Relaxing symmetry constraints on the dimers led to more energetically stable structures at the Hartree–Fock level but the C_{2v} structure remains the most stable at a level of theory including electron correlation effects. The results for the Te compounds along with our earlier research on the S and Se analogues provide predictions for the geometries, vibrational frequencies, and ionization potentials for the Te species to assist in future experiments.

Key words: tellurium, ab initio, ditelluradiazolyl, dimers, binding.

Résumé : Les radicaux dithia- et disélénadiazolyles (HCN_2E_2, E = S, Se) et leurs dimères sont des blocs de construction importants dans le développement de conducteurs moléculaires de faibles dimensions. Des recherches sur des analogues ayant le tellure comme base sont beaucoup plus rares. Dans ce travail, on a calculé les structures moléculaires et électroniques du cation, du radical et des radicaux dimères du 1,2,3,5-ditelluradiazolyle en utilisant la théorie ab initio, y compris la corrélation d'électrons par la théorie des perturbations de Møller–Plesser jusqu'au quatrième ordre partiel (MP4SDQ). Il est prévu qu'un dimère face à face C_{2v} sera lié par environ 18 kcal/mol par rapport aux deux radicaux. On a aussi étudié un dimère C_{2h} et il est moins stable que le conformère C_{2v} par environ 2 kcal/mol. Au niveau de Hartree–Fock, des contraintes de symétrie de relaxation appliquées aux dimères ont conduit à des structures énergétiquement plus stables, mais la structure C_{2v} demeure la plus stable à un niveau de la théorie qui inclut les effets de corrélation d'électrons. Les résultats pour les composés du Te en relation avec nos études antérieures sur les analogues du S et du Se conduisent à des prédictions au sujet des géométries, aux fréquences vibrationnelles et aux potentiels d'ionisation des espèces du Te qui pourront aider dans des expériences futures.

Mots clés : tellure, ab initio, ditelluradiazolyle, dimères, fixation.

[Traduit par la rédaction]

Introduction

Much research on molecular conductors is based on the use of charged π-radicals, either in the form of charge transfer salts such as TTF-TCNQ (tetrathiafulvalene-tetracyano *p*-diquinodimethane) or radical ion salts such as those based on the TMTSF (tetramethyltetraselenafulvalene) and TTF donors (1). An alternative approach involves the use of neutral rather than charged radicals. Interest in the development of molecular conductors based on these neutral π-radicals has driven recent experimental and theoretical studies of various heterocyclic thiazyl and selenazyl radicals. In particular, derivatives of 1,2,3,5-dithia- and 1,2,3,5-diselenadiazolyl [RCN_2E_2]·**1b** represent "building blocks" (2) that, in the solid state, adopt stacked structures with nearly equal monomer–monomer distances. As with any one-dimensional structure with a half-filled electronic band, these stacked radicals are prone to a Peierls instability, i.e., a tendency to dimerize (3).

This paper presents theoretical studies of the tellurium radicals, **1b**, their dimers, and the corresponding cations, **1a**. It represents a continuation of our theoretical examination of the dichalcogen diazolyl system HCN_2E_2 (E = S, Se, Te). Our earlier results on the S and Se analogues were in good agreement with available experimental data (4).

Our theoretical approach to these main group heterocycles concerns itself with the prediction of the geometries of the radical dimers to suggest possible solid state structures. In addition, the binding energy of the dimer with respect to the

Computational methods

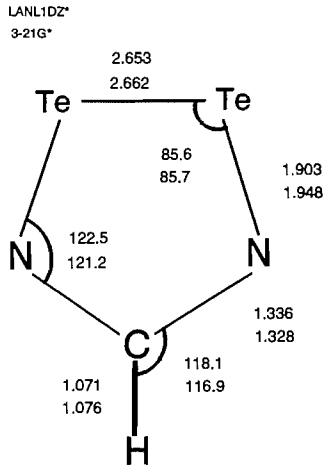
All-electron Hartree–Fock results were obtained using Gaussian 90 (5) or Gaussian 92 (6). The split valence 3-21G* basis set encoded into the program for carbon, nitrogen, and hydrogen was used. The 3-21G* basis set for tellurium was taken from Dobbs and Hehrey (7) and Huzinagay (8) and includes six *d*-type polarization functions.

The effective core potential Hartree–Fock predictions also were performed with Gaussian 90 (5) and Gaussian 92 (6). For tellurium, relativistic effective core potentials (RECPs) were chosen along with energy-optimized shared exponent valence Gaussian basis sets. The RECPs had been generated from relativistic Dirac–Fock atomic orbitals, rather than standard Hartree–Fock orbitals as is the case for the ECPs for the first and second row atoms. The Hay–Wadt LANL1DZ basis set (9) encoded within the Gaussian 90 and 92 programs was chosen. This basis set employs a full split-valence basis set for the first row elements (e.g., C, N) and a {core} plus six valence electron representation for tellurium. To augment this basis set, a set of six Cartesian *d*-type polarization functions was added to tellurium. In these core potential calculations, the exponents for the six *d* polarization functions for tellurium were taken from Jaisen and Stevens (10). This augmented basis set will be referred to as LANL1DZ*.

Stationary points at the SCF level were found using energy gradient methods and the geometry optimization algorithms of Schlegel (11) and Baker (12). The nature of these stationary points was confirmed by determining the SCF harmonic vibrational frequencies using analytical second-derivative methods for the all-electron approach and numerical differences of analytical first derivatives for the core potential based methods. The SCF harmonic vibrational frequencies were scaled (13) by 0.90 when used as predictions of the experimental anharmonic frequencies. This empirical reduction of double-zeta or larger basis set SCF vibrational frequencies by approximately 10% is well established (13).

Electron correlation effects on relative energies were included in the all-electron and effective core potential calculations using Møller–Plesset perturbation theory (14) to second (MP2), third (MP3), and partial fourth order (including single, double, and quadruple excitations (MP4SDQ)). Disk space limitations prohibited an extension to full fourth order, i.e., MP4SDTQ.

Fig. 1. Optimized geometries for the ditelluradiazolium cation from closed shell Hartree–Fock theory.



Results and discussion

This study predicts the properties and structures of the prototypal 1,2,3,5-ditellura radical **1b** and cation **1a** at levels comparable to our earlier study of the sulfur and selenium heterocycles (4). These earlier predictions were in good agreement with available experiments (4). Theoretical studies of the isolated dimers also provide a first step towards understanding the associated dimers in any solid state structure that might be adopted by the ditelluradiazolyl radical.

Geometries

Optimized geometries of the ditelluradiazolium cation

The optimized geometries of this closed shell cation in its $^1A_1$ ground electronic state are shown in Fig. 1. The effects of basis set were tested by comparing the all-electron 3-21G* geometry with the effective core potential LANL1DZ* structure. These differences are rather small, the largest being the Te—Te distance, which varies by about 3% from the all-electron result, changing from 2.662 Å (3-21G*) to 2.653 Å (LANL1DZ*). The Te—N distances change from 1.948 Å with the all-electron method to 1.903 Å with the core potential. These slight changes in geometry may be due to the relativistic parametrization of the effective core potential basis set for Te (9).

The structural changes that accompany ionization of the $^2A_2$ radical **1b** to the $^1A_1$ cation **1a** are of relevance to photoelectron spectroscopy. These geometry changes can all be related to the bonding/antibonding properties of the a_2 singly occupied molecular orbital (SOMO, **2**). This orbital is both Te—N and Te—Te antibonding within the five-membered ring. Accordingly, the Te—Te and Te—N bond distances of the radical are shortened significantly upon ionization. To a first approximation, the removal of an electron from the a_2 SOMO should not affect the C—N distances as the carbon atom lies in a nodal plane. Ionization of **1b** nonetheless produces a small increase in the C—N distance within the ring. There have been

Fig. 2. Optimized geometries for the ditelluradiazolyl radical with the unrestricted Hartree–Fock model.

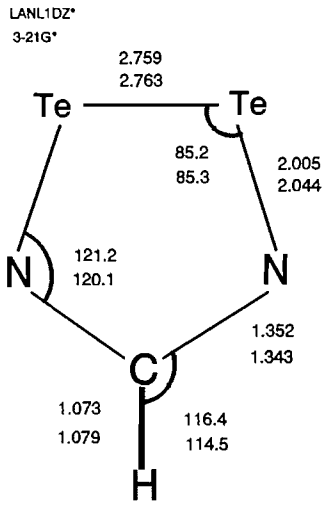


Fig. 3. Optimized geometries for the C_{2v} conformation of the ditelluradiazolyl dimer.

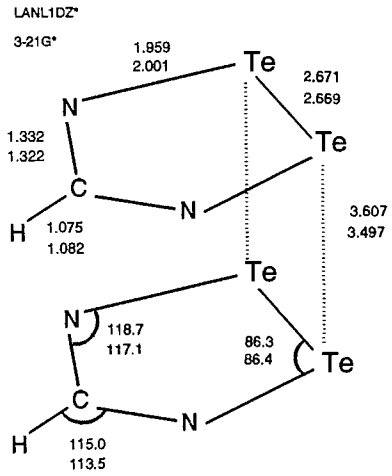


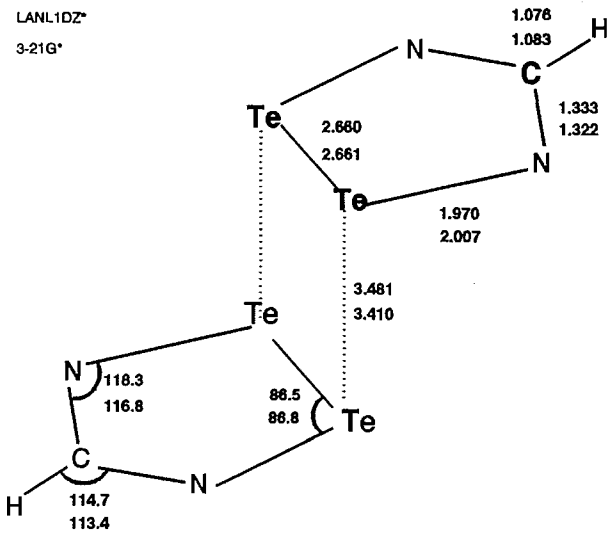
no experimental studies to date on the Te containing cation or on closely similar compounds. There clearly would be difficulties in obtaining sufficient vapor pressure of the tellurium compound to obtain a gas phase photoelectron spectrum.

Optimized geometries of the ditelluradiazolyl radical and dimers

To assess the geometrical changes upon dimerization of the radicals, optimized structures of both the isolated radicals and their corresponding dimers were determined. The radicals were restricted to C_{2v} symmetry to reduce the computational burden. However, checks of this restriction were made by predicting the harmonic vibrational frequencies. Further discussion is given below and it is simply noted here that the C_{2v} monomer is a minimum energy structure at the UHF level. Two conformations were considered for the dimers, the "face-to-face" C_{2v} and "back-to-back" C_{2h} structures. For the dimers the C_{2v} and C_{2h} symmetry constraints were relaxed in order to assess the energetic stabilization that might occur with the removal of symmetry constraints. The monomer rings themselves were constrained to be overall planar in all the dimer calculations. The conformations of the dimers and any symmetry restrictions were chosen with reference to the experimentally observed X-ray crystallographic structures of the sulfur and selenium diazolyl dimers (4).

For the predicted structures, the agreement between the two basis sets at the Hartree–Fock level is very good. Figure 2 presents the UHF optimized geometries of the ditelluradiazolyl radical. The results for this radical (2.76 Å (Te—Te), 2.01–2.04 Å (Te—N), and 1.34–1.35 Å (N—C)) can be used as a prediction for future gas phase experiments on the structure of this compound. A rough comparison of the Te—N bond distance with some recently available experimental results (Te—N = 1.918 Å (15), Te—N = 1.966 Å (16)) can be made. These comparisons are only approximate as the available experimental results are for rather different compounds (15, 16). (Spin contamination in the UHF treatment of the radicals might have geometrical consequences. The value of S^2 for the Te radical with the 3-21G* basis was 1.044 while the proper value for a pure doublet is 0.75. However, the major effect as revealed by

Fig. 4. Optimized geometries for the C_{2h} conformation of the ditelluradiazolyl dimer.



restricted open shell studies on a structure constrained to have C_{2v} symmetry (of Fig. 7) is to shorten the distances in the rings slightly. The C—N distance decreases from 1.34 to 1.32 Å comparing the UHF and ROHF structures of the radical.) It is interesting to speculate how the inclusion of electron correlation by Møller–Plesset perturbation theory or in a density functional model would change the radical geometries. Preliminary results[2] with a core potential plus split valence polarized basis set and the B3LYP approach predicted r(Te–Te) = 2.725 Å, r(Te–N) = 1.986 Å, and r(C–N) = 1.351 Å within 1% agreement with the Hartree–Fock results shown in Fig. 2. Electron correlation does not appear to be affecting the geometry qualitatively.

The theoretical structures of the tellurium dimer are more complex and are summarized in Figs. 3–6. As the Te—N antibonding a_2 singly occupied molecular orbital (SOMO) **2** of the radical is involved in the dimerization, the individual rings have reduced antibonding character upon dimerization. Consequently, the Te—N distances shorten slightly, as do the intramolecular Te—Te bond lengths. For the C_{2v} and C_{2h} structures, the distance between the rings is predicted to be in the range 3.5–3.6 Å. With the B3LYP method and a core potential plus split valence polarized basis set, the interannular distance is predicted to be 3.525 Å, which is qualitatively similar to that found at the Hartree–Fock level. When symmetry constraints are relaxed, the dimer adopts a "short–long" structure with two rather different interannular distances as shown in Figs. 5 and 6. In all cases, the monomer retains its essential structure within the dimers as revealed by very limited changes in the bond lengths and bond angles upon dimerization. For tellurium, which has a van der Waals radius of ca. 2.06 Å (17), the monomer–monomer distance is significantly shorter than twice this van der Waals radius in both the C_{2v} and C_{2h} dimers. The lower symmetry dimers have one Te—Te distance that is approximately twice the van der Waals radii of tellurium. These lower symmetry dimers appear to have adopted a structure with only one significant interannular Te–Te interaction.

Restricted open shell Hartree–Fock (ROHF) results

ROHF studies on the radicals were carried out with this version of the Hartree–Fock method and showed that the C_{2v} structure was not a minimum. A distortion to C_s symmetry was energetically favourable (see Fig. 4). This situation is reminiscent of the doublet instability problem, the most

famous example being that of the allyl radical (18–21). This distortion at the ROHF level can be viewed as due to a second-order Jahn–Teller (SOJT) effect. The ROHF solution isolates two geometries that might be associated with the "resonance structures" but a C_{2v} minimum results when the spin restriction is released and UHF is employed. The energy difference between the C_s and C_{2v} structures is quite small (approximately 3 kcal/mol favoring the C_s forms) despite fairly significant changes in geometrical parameters such as the C—N bond lengths. These ROHF results suggest that the Te–N rings may distort easily.

Infrared and UV–photoelectron spectra

The theoretical infrared spectra of the cation and the radical are presented in Tables 1 and 2. As can be seen from the infrared intensities, only four bands of appreciable intensity are predicted at approximately $505(b_1)$, $605(b_2)$, $1110(b_2)$, and $1230(a_1)$ cm^{-1} for the cation. For the radical, three bands of appreciable intensity are predicted at approximately $405(b_1)$, $505(b_2)$, and $1100(a_1)$ cm^{-1}.

The theoretical spectra of the Te dimers are presented in

[a]Binding energies in kcal/mol, total energies in atomic units (au). A positive binding energy indicates that the dimer is bound with respect to two radicals.

[b]ZPVE = zero point vibrational energy.

zolyl radical is presented in Table 7. Koopmans' theorem indicates that the first ionization potential will be lower than for the S or Se radicals and should appear at ca. 7.08 eV. The remaining Koopmans' thoerem predictions for the ionization energies in the range of 7 to 17 eV are at 9.24, 9.72, 10.94, 11.28, 12.41, 13.82, 14.92, and 16.24 eV. All these ionization energies are shifted about 1 eV to higher energy than the corresponding peaks predicted for the Se compound (4).

Energetics

The energetics of dimerization of the radicals proved very sensitive to the theoretical method employed (Table 8). As a radical recombination reaction, the SCF approach will not be quantitatively accurate, therefore electron correlation effects must be included (22). At a low order of Møller–Plesset perturbation theory (MP2) our earlier work (4) showed the C_{2v} sulfur dimer to be bound by ca. 42 kcal/mol and the C_{2v} selenium dimer by a larger amount, ca. 58 kcal/mol. At the same level of theory, the C_{2v} tellurium dimer is predicted to be bound by ca. 61 kcal/mol. These binding energies include the changes in zero point vibrational energies between the two radicals and the dimer. However, upon extending the theory to higher levels, namely to third (MP3) and partial fourth (MP4SDQ) order, the binding energies using the LANL1DZ* and 3-21G* basis sets change to ca. 6.4 and 4.0 kcal/mol (with the ZPVE correction included) for the sulfur species (4). Similar changes are observed for the diselena- and ditellura-diazolyl radical dimers. For the tellurium compounds, computer resources were only sufficient to determine the MP3 and MP4SDQ energies using the LANL1DZ* basis set. The calculated binding energies for the ditelluradiazolyl radical dimer using this basis set were ca. 14.9 (MP3) and 18.1 kcal/mol (MP4SDQ). Comparing these results with the LANL1DZ* and 3-21G* results on the sulfur dimer, the binding energy of the tellurium species using the 3-21G* basis set is estimated to be in the neighbourhood of 15 kcal/mol. Thus, the tellurium dimer is predicted to be more strongly bound by approximately 10 kcal/mol relative to the sulfur dimer. The small binding energies for the tellurium compounds are consistent with the limited structural changes predicted between the monomer and the dimer (vide supra).

To ascertain if the C_{2v} dimer is indeed the most stable, the binding energies of three other dimers were predicted. At the Hartree–Fock level, the distorted C_{2h} dimer is the most stable of the four dimers studied. However, upon extending the theory to include electron correlation effects, MP4SDQ, the C_{2v} dimer is marginally more stable by ca. 0.3 kcal/mol.

Conclusions

This study extends our earlier theoretical research on the Group 16 elements S and Se to include Te. At the Hartree–Fock level, the agreement between the two basis sets, all-electron and ECP, for the structures is very good. Differences noted between the all-electron and effective core potential results probably can be attributed to the relativistic parametrization of the core potential for Te and the neglect of such effects in the 3-21G* basis set.

Vibrational frequency analyses of the cation and radical monomers showed that both are minima in C_{2v} symmetry.

The radical dimers all have at least one imaginary frequency. The common imaginary mode in all the dimers corresponds to a breaking of the imposed constraint of planarity of the rings.

Predictions of the binding energy of the two radicals to give the radical dimer indicate that the Te species will be more strongly bound than the corresponding S and Se species. The C_{2v} dimer is probably the most stable of the four possible dimers studied in this work. These predictions for the ditelluradiazolyl system can be used to guide further experiments.

Finally, we briefly compare our predictions for the tellurium compounds with our earlier results (4) on the sulfur and selenium analogues. Key results are summarized in Table 9 along with the available experimental data (4) for the sulfur and selenium compounds. Our predictions of the same properties for the tellurium species should be approximately as reliable as those for the sulfur and selenium compounds.

A unified approach to dynamic NMR based on a physical interpretation of the transition probability

Alex D. Bain and G.J. Duns

Abstract: A general theory of the effect of dynamics (relaxation and (or) exchange) on NMR spectra is presented. This theory is based on a reexamination of the transition probability. The classic expression for this is as the square of the transition moment, but we feel it is useful to separate the square into two separate terms. In the generalization presented here, we show that one of these terms corresponds to the share of the initial magnetization that each spin coherence receives at the start of the experiment. The second term is how much that coherence contributes to the total detected signal. The final intensity is the product of these two factors. For a static spectrum, these two terms are complex conjugates, so the product is real and we recover the standard transition probability. When there is dynamics, the product becomes complex, so the time evolution includes oscillatory and dispersive terms. This means that a dynamic spectrum is still a sum of individual transitions, but the lineshapes are distorted in phase, intensity, position, and linewidth by the dynamic process. In this paper we develop the general theory, and illustrate it with a calculation of the classic problem of mutual exchange in an AB spin system.

Key words: NMR spectroscopy, transition probability, chemical exchange, kinetics.

Résumé : On présente une théorie générale de l'effet des processus dynamiques (relaxation et (ou) échange) sur les spectres RMN. Cette théorie est basée sur un réexamen de la probabilité de transition. L'expression classique pour ceci implique le carré du moment de transition; toutefois, on croit qu'il est utile de séparer le carré en deux termes. Dans la généralisation présentée ici, on montre que l'un de ces termes correspond à la partie de la magnétisation initiale que chaque cohérence de spin reçoit au début de l'expérience. Le second terme est un reflet de la partie de cette cohérence qui contribue au signal qui est détecté. L'intensité finale est le produit de ces deux facteurs. Pour un spectre statique, ces deux termes sont des conjugués complexes et le produit est donc réel; on récupère donc la probabilité de transition standard. Quand le spectre est dynamique, le produit devient complexe et l'évolution avec le temps comprend des termes oscillatoires et de dispersion. Ceci signifie qu'un spectre dynamique est encore une somme de transitions individuelles, mais, à cause du processus dynamique, les formes des bandes sont déformées par la phase, l'intensité, la position et la largeur de la bande. Dans ce travail, on a développé la théorie générale et on l'a illustrée à l'aide d'un calcul du problème classique de l'échange mutuel dans un système de spins AB.

Mots clés : RMN spectroscopie, probabilité de transition, échange cinétique, cinétique.

Introduction

Dynamic Nuclear Magnetic Resonance (1–4) means NMR in which spin relaxation and (or) chemical exchange contribute to the spectra, in a nontrivial way. If the rates of these processes are quite different from frequency separations in the spectrum, dynamic effects can be easily calculated (or ignored). However, as more complex systems are studied, and more sophisticated experiments are developed, it is becoming clear that dynamics should be included from the start of any description of an NMR spectrum.

Received September 6, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

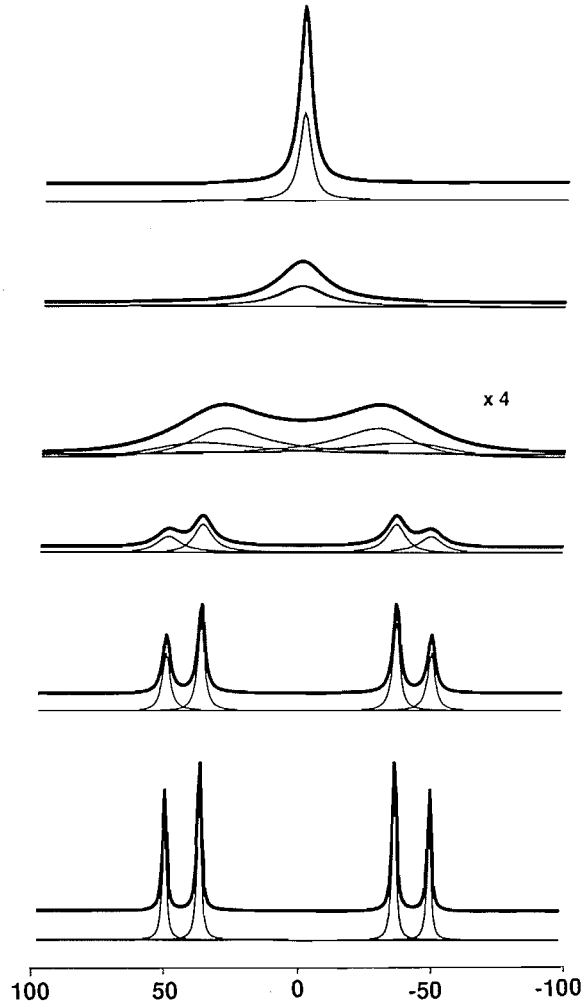
The title we have used here is a conscious reference to Binsch's classic work (5) on the subject. Indeed, many of the individual components of what we describe have been published elsewhere. We feel, however, that it is useful and important to bring together familiar concepts with those that may be novel to a given reader. This will produce a unified picture in which dynamic spectra are treated in the same way as other NMR spectra.

The foundation of this effort is a reexamination of the transition probability. In this part of the work, there is little that is exclusively nuclear or magnetic about the spectroscopy. The discussion could equally apply to any form of coherent spectroscopy, but we formulate it in terms of NMR. A familiar example is shown in Fig. 1, which shows the lineshape due to mutual exchange in an AB system. It is clear that the static spectrum of an AB spin system at equilibrium is made up of four transitions whose intensities are proportional to the transition probabilities. All the other spectra in Fig. 1 are of the same spin system, with different rates of mutual exchange. The traditional approach to exchange has been to treat these as single lineshapes — to calculate the total signal at any given

Fig. 1. NMR lineshapes of an AB spin system undergoing mutual exchange. The heavy, top line represents the total lineshape, and the lighter lines the four individual components. The parameters of the spin system are as follows: the chemical shift difference between the sites is 86 Hz, the coupling constant is 13 Hz, and T_2 for each site is 5 s. Starting from the bottom, the rates of exchange, in s^{-1}, are 0.1, 5, 25, 125, 625, 3125. Note that the vertical scale in the fourth spectrum from the bottom (rate = 125 s^{-1}) has been multiplied by 4 to show the lineshape more clearly. In the top two spectra, the two main components are almost coincident, and the two minor components are almost zero.



frequency. The dynamic spectra are then traced as a function of frequency (6–13). Johnston (14) has recently published a detailed discussion of these methods. They are, in some way, reminiscent of a continuous wave spectrometer, since they calculate the total signal. In contrast, we prefer (15) to regard all these spectra as the sum of four transitions (16). The signal at any given frequency is the sum of the contributions of the four lines. Furthermore, we deal with the four transitions in the time domain, as we would do with a pulse Fourier transform spectrum. The results are the same, of course, but the reformulation simplifies and clarifies the solution.

To define the transitions in Fig. 1, we need to go back and examine the transition probability. This is usually given by time-dependent perturbation theory (17), or Fermi's Golden Rule No. 2 (18). If ϕ_i is the initial state, ϕ_f the final state, and I_x the perturbation, then the transition probability is given in eq. [1]. Two factors make up the transition probability, and they are complex conjugates, so the intensity is real. In the generalization presented in this paper, these two factors have a physical interpretation: they are the projections of the individual transitions along the total magnetization. In a dynamic system, the two factors are not complex conjugates, so the lineshapes in Fig. 1 are more complex. In spite of this, we may still treat them as transitions, as in the static case.

$$[1] \quad \text{Transition probability} \propto |\langle\phi_f|I_x|\phi_i\rangle|^2 = \langle\phi_f|I_x|\phi_i\rangle^*\langle\phi_f|I_x|\phi_i\rangle$$

In a pulse NMR experiment, the z magnetization is flipped into the xy plane, and the individual transitions start to precess. During the detection, the total xy magnetization is measured as a function of time. We will show that one of the factors in eq. [1] comes from the fact that the total z magnetization (converted to xy magnetization by the first pulse) must be divided amongst the individual NMR coherences. Each line in the spectrum gets its share before it starts precessing. The other factor comes from how visible each transition is to the detector. In a static 1D spectrum, these factors may be different for each line in the spectrum, but they are complex conjugates so the intensity of each line is always real. If we have a pulse experiment, the spin manipulations fit "between" these two factors. The initial magnetization is divided into the individual coherences, these are manipulated by the pulse sequence, and then the signal is detected. In a dynamic system the two factors are no longer equal, and the transition probability has both real and imaginary parts. The real and imaginary terms give the intensity and phase distortions that are common in pulse experiments. All the spectra in Fig. 1 are made up of four transitions; the only difference is the character of the transition probability.

Basic theory

The fundamental equation for this work is the equation of motion for the density matrix (19), as in eq. [2].

$$[2] \quad i\frac{h}{2\pi}\frac{\partial}{\partial t}\rho = [H, \rho]$$

It is more convenient to reexpress this equation in Liouville space (19–21), in which the density matrix becomes a vector, and the commutator with the Hamiltonian becomes the Liouville superoperator. We will use bold-face upper-case italic letters to denote superoperators. Equation [2] becomes eq. [3].

$$[3] \quad i\frac{h}{2\pi}\frac{\partial}{\partial t}\rho = \boldsymbol{L}\rho$$

If we use frequency units ($h/2\pi = 1$), then the formal solution to eq. [3] is given in eq. [4], in which exp( ) denotes the exponential of a matrix.

$$[4] \quad \rho(t) = \exp(-i\boldsymbol{L}t)\rho(0)$$

Relaxation or chemical exchange can be easily added in Liouville space, by including a Redfield matrix, $\boldsymbol{R}$, for relaxation, or a kinetic matrix, $\boldsymbol{K}$, to describe exchange. This restricts this particular description to first-order kinetics in the reaction. The equation of motion becomes eq. [5].

$$[5] \quad \rho(t) = \exp(-i\boldsymbol{L} - \boldsymbol{R} - \boldsymbol{K})t\,\rho(0)$$

In NMR, we detect the magnetization in the xy plane, so we may say that we always measure the expectation value of the I_x operator. This is just the unweighted sum of all the I_{xi} operators for the individual spins i. It may be a function of several time variables, including the time during the acquisition, but it is always given by eq. [6].

$$[6] \quad \langle I_x(t)\rangle = \mathrm{trace}(I_x\rho(t))$$

In Liouville space, both the density matrix and the I_x operator become vectors. The scalar product of these Liouville space vectors is the trace of their product as operators. Therefore, the NMR signal, as a function of a single time variable, t, is given by eq. [7], in which the parentheses denote a Liouville space scalar product.

$$[7] \quad \text{NMR signal} = (I_x|\,\rho(t))$$

We start at equilibrium. In the high-temperature approximation, the equilibrium density operator is proportional to the sum of the I_z operators, which we will call F_z. If there are multiple exchanging sites with unequal populations, p_i, the sum is a weighted one, as in eq. [8].

$$[8] \quad F_x = \sum_{i=1}^{n} p_i I_{xi}$$

We assume that a simple, nonselective pulse has been used at the start of the experiment. This rotates the equilibrium z magnetization onto the x axis. Note that neither the equilibrium state nor the effect of the pulse depend on the dynamics or the details of the spin Hamiltonian (chemical shifts and coupling constants). The equilibrium density matrix is proportional to F_z. After the pulse the density matrix is therefore given by F_x, and it will evolve as in eq. [4] or [5]. If we substitute eq. [5] into eq. [7], we get the NMR signal as a function of time t, as given by eq. [9]. In this equation we distinguish the sum of the operators weighted by the equilibrium populations, F_x, from the unweighted sum, I_x. The detector sees each spin (but not each coherence!) equally well.

$$[9] \quad \text{NMR signal} = (I_x|\exp\{(-i\boldsymbol{L} - \boldsymbol{R} - \boldsymbol{K})t\}F_x)$$
$$= (I_x|\exp\{(-i\boldsymbol{L} - \boldsymbol{R} - \boldsymbol{K})t\}\,|F_x)$$

This equation can be solved several ways (22). One method involves diagonalizing the Liouville matrix, $i\boldsymbol{L} + \boldsymbol{R} + \boldsymbol{K}$. If $\boldsymbol{U}$ is the matrix with the eigenvectors as columns, and Λ is the diagonal matrix with the eigenvalues down the diagonal, then we can write eq. [9] as eq. [10]. This is similar to other eigenvalue problems in quantum mechanics, such as the transformation to normal coordinates in vibrational spectroscopy.

$$[10] \quad \text{NMR signal} = (I_x|U^{-1}\exp(-i\Lambda t)U|F_x)$$

Note that the Liouville matrix, $i\boldsymbol{L} + \boldsymbol{R} + \boldsymbol{K}$ may not be Hermitian, but it can still be diagonalized. Its eigenvalues and eigenvectors are not necessarily real, however, and the inverse of U may not be its complex-conjugate transpose. If we allow complex numbers in it, eq. [10] is a general result. Since Λ is a diagonal matrix we can expand in terms of the individual eigenvalues, λ_j. We can also apply $\boldsymbol{U}^{-1}$ ("backwards") to I_x, and obtain eq. [11]. This is the fundamental result on which this paper is based.

$$[11] \quad \text{NMR signal} = \sum_j (U^{-1}I_x)_j^*(UF_x)_j \exp(i\lambda_j t)$$

Practical considerations

For a single spin-1/2, the solution to eq. [11] is very easy. There are three coherences: the z magnetization and the two counter-rotating xy magnetizations. Both $\boldsymbol{L}$ and $\boldsymbol{R}$ are diagonal, so eq. [11] separates into three one-dimensional equations. For the z magnetization, the matrix element of $\boldsymbol{L}$ is zero, and that of $\boldsymbol{R}$ is $1/T_1$, so it behaves as $e^{-t/T1}$. For the xy magnetizations, the matrix elements of $\boldsymbol{L}$ are $+/-\omega$, and that of $\boldsymbol{R}$ is $1/T_2$. The xy magnetizations behave as $e^{i\omega t}e^{-t/T2}$.

For a general system, these sets of equations are huge, as written. For n spins-1/2, the density matrix has 2^{2n} elements, so the Liouville matrix has 2^{4n} elements. However, we can separate all the density matrix elements according to coherence level (23), that is, how many quanta are in the associated transition. In this case, the matrices block, and the largest single block is the one corresponding to the single-quantum transitions. This single-quantum block is precisely the matrix that Binsch deals with (11, 12). In general, there is an equation like [11] for each order of coherence. The amount of calculation needed in this approach is similar to standard density matrix methods.

The quantities $(\boldsymbol{U}^{-1}I_x)_j$ and $(\boldsymbol{U}F_x)_j$ in eq. [11] are projections of the eigenvector j along I_x. From the above equations, we can interpret these as follows. The term $(\boldsymbol{U}F_x)_j$ is the amount that the transition j received from the total x magnetization, created from the equilibrium state, and $(\boldsymbol{U}^{-1}I_x)_j$ is how much that transition contributes to the observed signal. These two terms may not be equal, as we will see in exchanging systems. An informal way of thinking about these terms is to consider the transition moment, $\langle\phi_f|I_x|\phi_i\rangle$. If we consider that the ket-bra operator $|\phi_f\rangle\langle\phi_i|$ represents the transition, then the transition moment is the projection of the transition operator along the I_x operator.

In the usual preparation–evolution–detection paradigm, neither the preparation nor the detection depend on the details of the Hamiltonian, except in special cases. Starting from equilibrium, a hard pulse gives a density matrix that is just proportional to F_z. The detector picks up only the unweighted sum of the spin operators, I_x. It is only during an evolution (perhaps between sampling points in an FID) that we must divide these totals amongst the various lines in the spectrum. Therefore, one of the factors in the transition probability represents the conversion from preparation to evolution; the other factor represents the conversion back from evolution to detection.

Equations [10] and [11] are the basic equations we will work with. For instance, they say that any time-domain NMR

signal is the sum of decaying oscillations (15). This is obvious from the fact that it is described by a first-order differential equation, but eq. [11] gives a way of calculating the values of these exponentials for any system, static or dynamic. The distinctions amongst different types of spectra lie in the eigenvalues and eigenvectors of the Liouville matrix $iL + R + K$. Equation [11] describes static spectra, spin relaxation, and spectra showing the effects of chemical exchange or T_2 relaxation, in a single, unified picture.

Static spectra

If we have no dynamics ($K = 0$, and R only a perturbation), then the Liouville matrix is Hermitian and all the eigenvalues are pure imaginary. We can restrict our attention to the block containing the single-quantum transitions, and diagonalize that matrix. The positions of the lines in the spectrum are given by the eigenvalues and the intensities are governed by how much the eigenvector overlaps with I_x. The amount that an individual transition receives and the amount it contributes are equal, and the transition probability is their product. This is exactly Banwell and Primas' "direct method," in which they solve for the transitions directly (24), rather than for the energy levels. Because of the size of the matrices, this is not an efficient way of simulating a static spectrum. However, the philosophy of dealing directly with the observables is very important.

For an example, the AB spin system has a Liouville matrix given in eq. [12]. The coupling constant is J, and we may assume that $\omega_B = -\omega_A = -\delta/2$, so that δ is the frequency difference between the two sites. We define the usual angle, θ, for the AB system by the equation $\tan(\theta) = J/2\delta$. The Liouville space basis used here is the superspin equivalent of the four product operators (I_x^A, $I_x^A I_z^B$, I_x^B, $I_x^B I_z^A$), and a set of rules for calculating these elements are given elsewhere.[2]

$$[12]\quad \begin{pmatrix} i\omega_A & iJ/2 & 0 & -iJ/2 \\ iJ/2 & i\omega_A & -iJ/2 & 0 \\ 0 & -iJ/2 & i\omega_B & iJ/2 \\ -iJ/2 & 0 & iJ/2 & i\omega_B \end{pmatrix}$$

The four eigenvalues, which give the positions of the lines, are $+/- J/2 +/- ((J/2)^2 + (\delta/2)^2)^{1/2}$, as you expect for an AB system. The matrix of eigenvectors as columns is given in eq. [13], in which $c = \cos(\theta)$, $s = \sin(\theta)$ and δ is defined above.

$$[13]\quad \text{Eigenvectors} = \begin{pmatrix} c & s & c & s \\ c & s & -c & -s \\ -s & c & s & -c \\ -s & c & -s & c \end{pmatrix}$$

In the basis used in eq. [12], the total x magnetization is proportional to the vector (1,0,1,0). Taking the dot product with the eigenvectors shows that the outer lines get ($\cos\theta - \sin\theta$) from the total, whereas the inner lines get ($\cos\theta + \sin\theta$). The squares of these terms give the familiar AB system intensities: ($1 - \sin 2\theta$) and ($1 + \sin 2\theta$).

T_1 relaxation and evolution in coupled spin systems

The approach described above has always been the standard approach for T_1 relaxation in coupled spin systems (25) relaxation matrix analysis for NOESY spectra (26, 27), and experiments on slow chemical exchange (28–31). We are dealing with the block of the density matrix corresponding to z magnetizations. The oscillation frequencies are all zero, so only the Redfield or kinetic matrix survives. This is symmetric, or at least can be made so (28). In a T_1-type experiment, we do not measure the z magnetizations directly, but their dynamics during the delay follows eq. [10]. We take linear combinations of the z magnetizations that decay exponentially, as in eq. [11], and let them decay (32, 33). Werbelow and Grant have used the analogy of normal modes (25), mentioned above. At the end of the delay, we transform the linear combinations back into the familiar z magnetizations that correspond to the lines in the spectrum.

In principle, the Redfield matrix could connect every density matrix element with every other one. However, we can usually ignore elements that connect two coherences with different frequencies. For the z magnetizations, which are all degenerate in frequency, the off-diagonal elements of R are crucial for explaining observed effects. For the other elements of the density matrix, L has non-zero diagonal and off-diagonal elements that, we often assume, dominate the elements of R. Therefore, we diagonalize L and then calculate the diagonal element of R, which we call $1/T_2$. This implies that the xy magnetization decays as a single exponential. However, if there are degenerate transitions, off-diagonal elements must be included, and multi-exponential decay will be observed. For instance, methyl groups pass through multiple-quantum filters easily (34) because of such relaxation effects.

Chemical exchange and scalar relaxation

If the elements of a relaxation or kinetic matrix become comparable with frequency differences in the spectrum, distortions appear in the spectrum. Chemical exchange is perhaps the most familiar example, but when relaxation becomes very efficient (as in viscous solutions), similar effects occur. In this case, the matrix $iL + R + K$ must be non-Hermitian, since its diagonal elements have both real and imaginary parts. Therefore, the eigenvalues and eigenvectors may have complex values, and the inverse of U is no longer its adjoint. Now the precession in eq. [11] has both a real and imaginary part: the real part gives the decay rate, and the imaginary part gives the frequency. The intensity and phase of each line are given by the transition probabilities calculated from the components of the eigenvectors along I_x, as in eq. [11].

In this case, the concept of a transition is generalized. The transition gets a certain amount of coherence from the initial x magnetization, but this is not equal to how much it contributes to the detected signal. Also, each coherence is not necessarily on the x axis at the start of the precession, at least formally. For a static spectrum they all start together, but not for a dynamic

[2] The SIMPLTN program is available from A.D.B. at e-mail address given in footnote 1.

spectrum. The overall spectrum is still in-phase, as we well know. The phase of the full spectrum is determined by the sum of the real and imaginary parts of each component of the FID at $t = 0$. This is the trace of $\boldsymbol{iL} + \boldsymbol{R} + \boldsymbol{K}$. We can add a constant to the diagonal without disturbing the eigenvectors, so we add an imaginary number to cancel out the imaginary part of the trace. In some sense, this is like zero-order phasing in a FT spectrum.

For example, two-site equally populated exchange is described by the matrix in eq. [14]. The two lines are at +/− δ/2, and k is the exchange rate.

$$[14] \quad \begin{pmatrix} i\delta/2 - k & k \\ k & -i\delta/2 - k \end{pmatrix}$$

Following Reeves and Shaw (16), we can define two parameters, α and β, as in eq. [15].

$$[15] \quad \alpha = \sqrt{k^2 - (\delta/2)^2} \qquad \beta_{\pm} = \frac{\alpha \pm i\delta/2}{k}$$

With these definitions, one possibility for the matrix with the eigenvectors as columns is given in eq. [16], and its inverse in eq. [17].

$$[16] \quad \boldsymbol{U} = \begin{pmatrix} 1 & 1 \\ -\beta_- & \beta_+ \end{pmatrix}$$

$$[17] \quad \boldsymbol{U}^{-1} = \frac{k}{2\alpha} \begin{pmatrix} \beta_+ & -1 \\ \beta_- & 1 \end{pmatrix}$$

These expressions, used in eq. [5] in our preliminary communication (15), give the Reeves and Shaw expressions, which give the familiar Gutowsky and Holm formula.

Another example of these phenomena is the mutual exchange in an AB spin system. This is a classic example, with an analytical solution. We can start with the Liouville matrix for the AB spin system in eq. [12], and then we include the terms that represent spins leaving site A and going to site B. The result is given in eq. [18]. If we set $\omega_B = -\omega_A = -\delta/2$, the symmetry of the matrix allows us to break it into two 2 × 2 complex matrices, which can be diagonalized analytically. The resulting lineshapes match the published solutions (35).

$$[18] \quad \begin{pmatrix} i\omega_A - k & iJ/2 & k & -iJ/2 \\ iJ/2 & i\omega_A - k & -iJ/2 & k \\ k & -iJ/2 & i\omega_B - k & iJ/2 \\ -iJ/2 & k & iJ/2 & i\omega_B - k \end{pmatrix}$$

For more complex systems, the matrices are larger and the calculation of the matrix elements may be more complex, but the formalism is the same. Binsch uses the same matrix as in eq. [18], and extracts the same eigenvalues and eigenvectors. The difference between this work and that of Binsch is that he calculates the total signal as a function of frequency (6), following Gordon's method (6). We believe it is better to leave the signal as a sum of absorption and dispersion lines.

One advantage of this approach is that it simplifies viewing the results. The position, linewidth, phase, and intensity of each line are strong functions of the exchange rate, but they are still determined by the real and imaginary magnetizations at time zero, and the frequency and decay rate. A simulated FID can be calculated from these parameters, in the format of a commercial NMR program. The powerful processing and display routines can be used to compare the simulation with real data, and to plot the comparisons. Furthermore, recent advances in fitting spectra in the time-domain (36) can be applied directly to exchanging systems.

General pulse experiments

Equation [11] provides the basis for a general description of pulse NMR experiments. For simple experiments with hard pulses, the evolution of the spin system during a delay is the only part that involves the static Hamiltonian. The equilibrium state, the effect of a pulse, and the detection all are independent of chemical shifts and couplings. We extract the spectrum by observing the time dependence of the total x magnetization as a function of time. For a single pulse experiment, this is simply the acquisition time. For higher dimensionality, there are more time variables, but no significant complication.

The description of the effect of a pulse is straightforward. Since it does not depend on the spin system, simple rules based on commutation relations or Wigner matrices will work. If the pulses are effectively instantaneous, the calculation is easy (37).

During a delay, the description of the evolution depends on the spin system. For a weakly coupled system, the way that the product operators evolve in time is familiar. For two weakly coupled spins, the single-quantum coherence oscillates back and forth between I_x and I_xI_z (37). For strongly coupled systems, the evolution is more complex (38), and it is worthwhile to consider another basis for Liouville space. The superspin formalism (21) takes this approach, and switches to what is called the Hamiltonian basis for the evolution. This is also the approach taken in the SIMPLTN program.[2] The evolution is then calculated using eq. [11].

Note that this is a completely general approach. The eigenvectors of $\boldsymbol{iL} + \boldsymbol{R} + \boldsymbol{K}$, in the matrix $\boldsymbol{U}$, provide a change of basis for the density matrix. The evolution then proceeds as in eq. [11], in which the eigenvalues are completely general. If they are pure imaginary, then we have the oscillations at the resonant frequencies. If they are pure real, we are dealing with a T_1-type experiment, and the eigenvalues are the relaxation rates. If the eigenvalues have a real and an imaginary part, then we have line broadening and dynamic frequency shifts that are characteristic of this regime.

This approach provides a rigorous description of the effect of dynamics on pulse experiments. Relaxation and other dynamic effects are often added *post facto* in many theories. Since eq. [11] is general, we can use it to explore the effect of exchange on pulse experiments, or the utility of pulse experiments applied to exchanging systems (39–42).

Conclusions

This reformulation of the transition probability provides a

general and concise picture of dynamic NMR. The fundamental equations are [10] and [11], and these are determined by the eigenvalues and the eigenvectors of the Liouville matrix. The eigenvalues give the position and widths of the lines in the spectrum. The eigenvectors determine the transition moments, which give us the intensities and the phases of the lines. Together, these determine all the dynamics of the system: evolution during a delay, relaxation of either the z or xy magnetizations or of the lineshapes in chemically exchanging systems. Of course, any other formalism must give the same answers as the one presented here. The choice of formalism is partly aesthetic, and we feel that this generalization of the superspin approach gives a particularly neat solution.

Much of this theory is implicit in the earlier work cited here. For the particular case of chemical exchange lineshapes, the method does not significantly change the calculation. Both the present work and the standard method involve the diagonalization of the same non-Hermitian matrix. However, the physical interpretation of the transition probability clarifies the picture considerably.

One practical advantage is in the analysis of dynamic spectra. The simulation can be presented in the format of the raw experimental FID, so comparisons are simplified. Much development has gone into the development of fitting procedures for spectra. These use a variety of methods to fit the frequency, width, and position of a series of lines to either the time-domain or frequency-domain data. If the phase is added to list of parameters, all these methods can be applied to exchange lineshapes as well. In general, we feel it is useful to bring all these different approaches to dynamic NMR together, to produce a single, unified 'theory'.

Acknowledgements

We would like to thank Dr. K.D. Sales and Dr. G.E. Hawkes at Queen Mary and Westfield College for their hospitality and their comments. Dr. Ruth Lynden-Bell provided some very helpful encouragement and criticisms. Dr. I. Najfeld and Dr. E.R. Johnston sent copies of their work prior to publication. The work was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC).

Non-additivity of intermolecular forces in helium and beryllium clusters

O. Novaro

Abstract: New results on nonadditive effects on small beryllium clusters are presented using the LCAO-MO-SCF method including variational and perturbational (MP-4) configuration effects. Three- and four-body contributions to the interaction energy of these clusters are dominant, and are used to explain the very different behaviour of bulk beryllium as compared to liquid helium. This is relevant because the atomic ground states of Be and He are strikingly similar ($1s^2 2s^2$: $^1S_0$ and $1s^2$: $^1S_0$) and also He_2 and Be_2 share the honour of being the two hardest-to-detect dimers in the whole periodic system. The similitude is lost for larger He_n and Be_n systems because the former, as was shown by R.F.W. Bader 25 years ago, have very small three-body energies (≤1%). Be_n clusters will be shown here to have three-body energies that actually outweigh the pairwise additive ones. The consequences of this are discussed.

Key words: intermolecular forces, non-additivity, He and Be clusters.

Résumé : Utilisant la méthode LCAO-MO-SCF, y compris des effets variationnels et perturbationnels (MP-4) de configuration, on a obtenu de nouveaux résultats sur les effets non additifs de petits agrégats de béryllium qui ont été obtenus. Les contributions de trois et quatre corps à l'énergie d'interaction de ces agrégats sont dominants. On utilise cette observation pour expliquer le comportement différent du béryllium em masse par rapport à celui de l'hélium liquide. Ceci présente de l'intérêt parce que les états atomiques fondamentaux du Be et du He sont remarquablement semblables ($1s^2 2s^2$:$^1S_2$ et $1s^2$:$^1S_0$) et aussi parce que le He_2 et le Be_2 se partagent l'honneur d'être les deux dimères les plus difficiles à détecter dans tout le système périodique. À cause du fait, démontré il y a près de 25 ans par R.F.W. Bader, que les premiers ont de très faibles énergies à trois corps (≤1%) la similitude est perdue pour les systèmes He_n et Be_n plus gros. On montrera ici que les agrégats de Be_n possèdent des énergies à trois corps qui l'emporte sur ceux qui sont additifs par paire. On discute des conséquences de ces conclusions.

Mots clés : forces intermoléculaires, non-additivité, agrégats de He et Be.

[Traduit par la rédaction]

Introduction

Certainly the hardest-to-detect elementary dimers are He_2 and Be_2. As recently as 1984 Bondybey (1) could correctly state that the properties of Be_2 remained virtually unknown. The first experimental observation of a He_2 bound state (a single bound state, in fact) is even more recent (2, 3). This makes the helium dimer the weakest molecular bond (4), incomparably more so than any other noble gas dimer. In fact, a recent study by a Canadian laboratory (5) proposes that He($1s^2$) and Be($2s^2$) should have the most similar bonding properties where their X_2 and XH molecules are concerned. On the other hand, the bulk properties of beryllium, a semi-metal, are completely different from those of the noble gases, with the case of helium (a liquid even at the lowest temperatures) having no conceivable similarity to solid Be. Here we look for the answer to the following question: why do the similarities found between noble gas and beryllium dimers completely disappear in large aggregates of these elements? The answer lies in the three-body effects of the Be_3 versus the He_3, Ne_3, etc. trimers, as we shall try to show here.

Received September 19, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of this 65th birthday.

[1] Member of El Colegio Nacional.

The first fully ab-initio study of three-body nonadditive effects was carried out by R.F.W. Bader et al. (6) (the definition of nonadditive contributions to the energy will be discussed in the following section). They reached the following conclusion: nonadditive contributions to the energy of He_3 calculated at the LCAO-MO-SCF level of approximation, were 10 times larger than estimated before by perturbation treatments (7). Still, their relative role in He_3 binding was at most a few percent of the pairwise additive contributions (6). KoČos and LeČ (8) confirmed these results to be valid at the Hartree–Fock limit. The convergence of the many-body expansion for He_n clusters was first tested by Novaro and Beltrán-López (9) at this same level of accuracy. Much more recently, high level ab-initio calculations 910) have again confirmed that many-body nonadditive interactions are a few percent of the pairwise additive contributions for small He_n clusters.

As concerns Be_3 and Be_4, they were studied by Novaro and KoČos (11), also at the LCAO-MO-SCF level, who found that nonadditive effects were quite large, large enough in fact to make the convergence of the many-body expansion (see following section) doubtful at best. We here present recent results (12) at the CI level for Be_n clusters that confirm that the main difference between bulk He and Be is based on their nonadditive energies.

Method

In the quantum mechanical study of the total energy of an *n*-

particle system, the interaction energy is computed as the total energy of the system minus the energy of its constituents:

$$[1] \quad E_{int}(n) = E(n) - \sum_{i=1}^{n} E_i$$

where E_i is the calculated energy (at the same level of precision as the calculation of $E(n)$) for the i^{th} particle of the system. The interaction energy $E_{int}(n)$ in turn can be divided in terms of different order interactions within the system. One can define the interactions between pairs, triplets, etc. up to interactions involving n particles simultaneously. By defining the sum of the calculated energies of the n individual particles as the one-body energy:

$$[2] \quad E_1(n) = \sum_{i=1}^{n} E_i$$

we can go on to define the two-body energy of the system as:

$$[3] \quad E_2(n) = \sum_{i<j}^{\{n\}} E_{ij}$$

the three-body energy as:

$$[4] \quad E_3(n) = \sum_{i<j<k}^{\{n\}} E_{ijk}$$

the four-body energy as:

$$[5] \quad E_4(n) = \sum_{i<j<k<l}^{\{n\}} E_{ijkl}$$

To obtain $E_2(n)$ we sum up the interaction energy of all pairs from which the individual particle energies are subtracted. To obtain $E_3(n)$ we similarly add the interactions of all triplets from which the component pair and individual particle energies are subtracted, and so on. Through these definitions the interaction energy of an n-particle system can be expressed as a finite sum

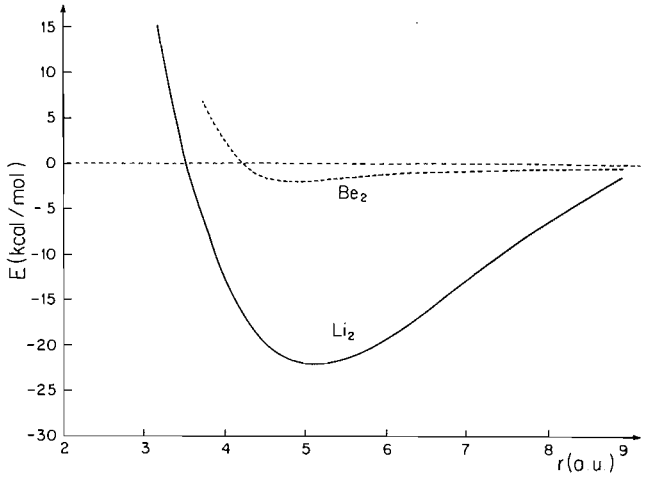
$$[6] \quad E_{int}(n) = E_2(n) + E_3(n) + E_4(n) + \ldots\ldots E_n(n)$$

This is the many-body expansion of the interaction energy and it will be considered to be convergent if the higher order terms are systematically smaller than the lower order terms. In fact, in many applications to study large aggregates, the hypothesis that E_3 (n) and higher terms are negligible with respect to E_2 (n) is postulated uncritically.

We here, on the contrary, want to calculate E_3 (n), etc. with the highest possible precision. We must stress that eq. [6] provides an exact representationof the interaction energy of an n-particle system. Only the level of approximation with which the different terms are calculated limits the precision within E_{int} (n) is given.

For the case of small Be and Li clusters, previous calculations at the SCF level already exist for the multibody expansion. To go beyond the SCF level we here use the Møller–Plesset perturbation theory approximation to the correlation energy corrections. We do these calculations utilizing the Gaussian-92 program (13) on UNAM's Cray-YMP4/468 computer. The basis set used is the Gaussian-92 internal 6-311+G(3df) having one diffuse p-function, three 5d-functions, and one 7f-function. The frozen-core approximation of the correlation energy is obtained at the fourth-order Møller–Plesset approximation.

Fig. 1. Potential energy curves for the beryllium and lithium dimers.



In reality the computational cost added to the calculation of the total energy of an n-particle system by calculating its different m-body contributions given in eq. [6] is not high because $m \leq n$ and $E_m(n)$ implies much less computer memory than $E(n)$ itself. On the other hand, the individual m-body terms contained in the sum:

$$E_m(n) = \sum_{i<j<\ldots<m}^{\{n\}} E_{ij\ldots m}$$

all have different geometries so several configurations for the triplets, quartets, etc. have to be calculated.

Results

Using the method described in the preceding section, we calculated the interaction energies of the Be_2, Be_3, Be_4, and Li_2, Li_3, Li_4 systems as well as their pairwise additive and many-body nonadditive contributions. These energies are given in Table 1. The first thing we notice is that the Be dimer is very slightly bound, especially compared to the Li dimer. This is also evident in Fig. 1, which shows for Li_2 a deep potential energy well with steep walls towards both the united-atom and the separated-atom limits. For Be_2, in contrast, a very shallow well, as well as a very flat potential energy curve, is evident. In fact, the Be_2 curve resembles noble gas dimer curves, very different from that of Li_2. But as we look at the other numbers in Table 1, the differences between beryllium and lithium seemingly diminish. As concerns the interaction energy, for Be_3 it already is quite similar to that for Li_3 and for Be_4, in fact, it is even more attractive than for Li_4.

Also notable is the very poor convergence of the many-body expansion for both lithium and beryllium. In Li_3 three-body repulsions already cancel over 50% of the pair attractions. Li_4 is even more extreme as $E_3(n)$ is larger in magnitude

Table 1. Many-body decomposition of the interaction energy $E_{int}(n)$ onto pairwise $E_2(n)$, three-body $E_3(n)$, and four-body $E_4(n)$ contributions, for the Be_2, Be_3, Be_4, Li_2, Li_3, and Li_4, clusters.

Cluster Be_n, Li_n	Total energy $E(n)$	$E_{int}(n)$	$E_2(n)$	$E_3(n)$	$E_4(n)$	Total non-additive contribution
Be_2	−29.229 29	−0.002 89	−0.002 89	—	—	—
Be_3	−43.881 26	−0.041 15	−0.000 75	−0.040 40	—	−0.040 40
Be_4	−58.600 40	−0.146 72	+0.031 50	−0.210 80	−0.032 58	−0.178 22
Li_2	−14.899 16	−0.035 09	−0.035 09	—	—	—
Li_3	−22.344 43	−0.048 32	−0.096 93	−0.048 61	—	+0.048 61
Li_4	−29.829 83	−0.101 66	−0.163 42	−0.178 82	−0.117 06	+0.061 76

and opposite in sign to the pair energy $E_2(n)$. This means that all of the attraction of Li_4 may be considered due to the four-body term $E_4(n)$. If we pause to consider that there is only one quartet inscribed in Li_4 versus four triplets and six pairs, it becomes evident that for larger clusters higher order nonadditive terms in the many-body expansion will always dominate the pairwise additive energies.

In the case of Be_n clusters the situation is even more striking. For Be_3 almost all of the interaction energy $E_{int}(n)$ comes from the three-body term. As would be expected from the noble-gas-like potential energy curve for Be_2, pairwise attractions are always very small; it is only the comparatively large three-body attractions that make Be_3 stable, with some 20 times larger binding energy than Be_2. In the case of Be_4 this is even more evident as all of the stabilization is due to three-body attractions. The pairwise term in fact is repulsive. This means simply that the equilibrium positions of the four beryllium nuclei are determined by the strong three-body attractions, making the inscribed dimers somewhat short, so short that each Be–Be distance falls on the repulsive part of the curve in Fig. 1. But even these pair repulsions are smaller than the repulsive four-body term. The main result, however, is that for Be_4 clusters the stabilization comes entirely from three-body interactions. We can safely generalize: Be_n cluster geometries and stabilities are mainly determined by nonadditive forces. This is in absolute contrast with He_n clusters for which nonadditive effects are very small. We shall see the consequences of this in the following section.

Discussion

We have seen that nonadditive contributions to the binding energy of the smallest Be_n clusters ($n \geq 3$) are decisive. For medium-size clusters ($n \geq 5$) one can observe the fact that three-body contributions to the total binding energy are larger than pairwise (two-body) contributions has become a rule, rather than an exception. Let us pause for a moment to consider the consequences of this fact. Two-body energies are directly associated with the chemical bond between two individual partners in a given cluster. Three-body energies are not localized on a particular bond. They really correspond to the change in the distance and the energy of any bond between two partners introduced by a third one. They are by their very definition delocalized. The fact that three-body terms are so large in beryllium has great consequences.

For helium, we have known since the work of Bader et al. (6) that three-body effects, while non-negligible, are a small correction of the total energy. Thus we may conclude that the "weakest and weirdest molecular bond (4): He_2" may only lead to the very weakly bound bulk behaviour of liquid helium even at temperatures near 0 K.

The second weakest elementary chemical bond, Be_2, does not prepare us for the bulk beryllium metal properties at room temperature. This is because Be_2 does not contain the main cause of the metal stability: the quite large three-body energy appears only for beryllium trimers and beyond. Dominant in size, delocalized in nature, it is in essence the image of a metallic bond-in-the-making even for the small Be_3, Be_4 molecules.

Although the language of nonadditivity is not too familiar, what we have concluded above is of course not a new concept. We have seen in the previous section, for instance, that the nonadditivity for Li_n clusters is also quite large. We could make a parallel discussion about H and Li, with apparently quite indistinguishable and ($1s^1$: and $1s^2 2s^1$:$2S_{1/2}$) ground states. Yet H_2 is tightly bound while H_3 is very unstable. In contrast, the change from Li_2 to Li_3 and beyond is only a straightforward tendency to the classical metal bond in lithium. The argument of the presence of the empty $2p^0$ subshell in Li in regard to this tendency is too well known to merit any further comment here. Naturally, for Be the $2p^0$ subshell should play a quite similar role.

In short, the answer to our original question: since He_2 and Be_2 have similar bonding properties, why are bulk beryllium and helium so utterly different? has an obvious answer. The many body effects are very different in both cases. By the expression "many-body effects" we are not speaking of 10^{24} particles interacting. We in fact are referring to much smaller system. Many-body effects are already dominant for the small "metallic" Be_3 and Li_3 clusters.

Acknowledgements

A quarter of a century has elapsed since I met Richard Bader during his first trip to Mexico, invited by our mutual friend Virgilio Beltrán. For a person with a fresh Ph.D. and new research responsibilities and projects, it was an invaluable and invigorating experience to collaborate with Richard, a brilliant and enthusiastic scientist with whom we established the first ab-initio study of three-body nonadditive effects. His irrepressible energy (even though he was particularly sensitive to the high altitude of Mexico City) and the pleasure of sharing quality moments with our families linger on in my memory. Even though I have since pursued other fields of research, my

curiosity about nonadditive effects has not waned and in fact it has given me the chance of collaborating with several friends in different countries, like John Murrell, Wlodek KoČos, Ludwig Bruch, Feng Wen-Lin, Enrico Clementi, Ilya Kaplan, and others. Curiously, with Richard Bader our opportunities for scientific and even personal contacts have been scarce. My loss. I always, however, have followed his many successes in research and his growing scientific stature and my admiration for him is ever increasing. I sincerely congratulate the authors of this initiative to honour Richard Bader and hope that this very modest contribution on my part to this special volume of the Canadian Journal of Chemistry serves to add my sincere homage to this exceptional scientist and friend.

I would also like to thank Ilya Kaplan and Jorge Hernández for the use of the beryllium results that will appear in more extended form in a joint paper. To Ilya I am further indebted for his reading of and comments on this manuscript and, in general, for his unselfish help. I also acknowledge financial support from Conacyt and DGAPA to this line of research.

On the differential geometry of interatomic surfaces

Paul L.A. Popelier

Abstract: Using differential geometry, we propose the total curvature of interatomic surfaces to characterize bonds. In this way visual interpretations of interatomic surfaces are now rigorously quantified. The analysis of the intrinsic geometry of an interatomic surface is implemented in the program MORPHY 2.0. It is shown that the total curvature depends on anionic polarizability, electronegativity differences, and steric effects determined by the total chemical environment of the bonded atoms in question. In general the proposed index measures the external chemical distortion of an atom in a molecule. It can be used in the context of uniform electric fields and in conformational studies.

Key words: interatomic surfaces, differential geometry, total curvature.

Résumé : Utilisant la géométrie différentielle, on propose la courbature totale des surfaces interatomiques pour caractériser les liaisons. De cette façon, des interprétations visuelles des surfaces interatomiques sont maintenant rigoureusement quantifiées. L'analyse de la géométrie intrinsèque d'une surface interatomique est introduite dans le programme MORPHY 2.0. Il a été démontré que la courbature totale dépend de la polarisabilité anionique, des différences d'électronégativité et des effets stériques déterminés par l'environnement chimique total des atomes en question qui sont liés. En général, l'indice proposé mesure la distorsion chimique externe d'un atome dans une molécule. On peut l'utiliser dans le contexte de champs électriques uniformes et dans des études conformationnelles.

Mots clés : surfaces interatomiques, géométrie différentielle, courbature totale.

[Traduit par la rédaction]

1. Introduction

The gradient vector field of the charge density ρ is the carrier of the topological information hidden in molecules, complexes, and crystals. It naturally partitions these systems into atomic basins, each of which adopts a particular shape governed by the *total* charge density. In the course of the last two decades many publications in the field of "Atoms in Molecules" (AIM) have shown pictures of gradient vector fields of ρ revealing a wealth of atomic shapes.

It emerges that some shapes recur repeatedly like the signature of an atom in a given chemical environment (1). On the other hand, it also appears that the geometry of the interatomic surfaces (IAS) that bound the atomic basin is very sensitive to the full chemical environment of the atom.

In view of these observations, the introduction of a measure to quantitatively characterize the shape of an IAS would be timely. For that purpose we propose to use concepts from a mathematical branch called differential geometry since it rigorously provides intrinsic properties of geometrical objects using calculus.

First, selected differential geometrical concepts are briefly reviewed and immediately illustrated with a simple (parametrized) model surface. In Sect. 3.1 we concisely expound on how the analytical expression for an interatomic surface is constructed. Some technical details on the computation of the total curvature C are given in Sect. 3.2. The last section (Sect. 4) presents various data sets of total curvatures for small molecules. The meaning of this measure is interpreted for a series of ionic lithium compounds and related to the behaviour of the IAS in a uniform electric field. Inspecting the hydride series AH_n, it is suggested that charge transfer influences the total curvature. It is demonstrated by means of a series of 10 methyl derivatives that C does not solely parallel charge transfer. Finally, it is shown that our index can be used in conformational studies (e.g., ethane).

2. Mathematical concepts

Differential geometry is the study of geometric figures using the methods of calculus. In particular, the introductory theory investigates curves and surfaces embedded in three-dimensional Euclidean space (2). It is a vast and rich area of mathematics (3–5) from which we will selectively sample and review the elements neccessary for the present investigation. Although most elegant and compact, we have chosen not to formulate the following equations along the lines of tensor analysis.

It can be proven that a curve in three-dimensional space is uniquely determined by two local invariant quantities, curvature and torsion, as functions of arc length. Similarly, a surface is uniquely determined by local invariant quantities called the first and second fundamental forms. In the following brief review, $\boldsymbol{x} = \boldsymbol{x}(u, v)$ denotes a coordinate patch on a sufficiently differentiable surface. For convenience we introduce the notation $\boldsymbol{x}_u \equiv \partial \boldsymbol{x}/\partial u$ and $\boldsymbol{x}_v \equiv \partial \boldsymbol{x}/\partial v$, such that

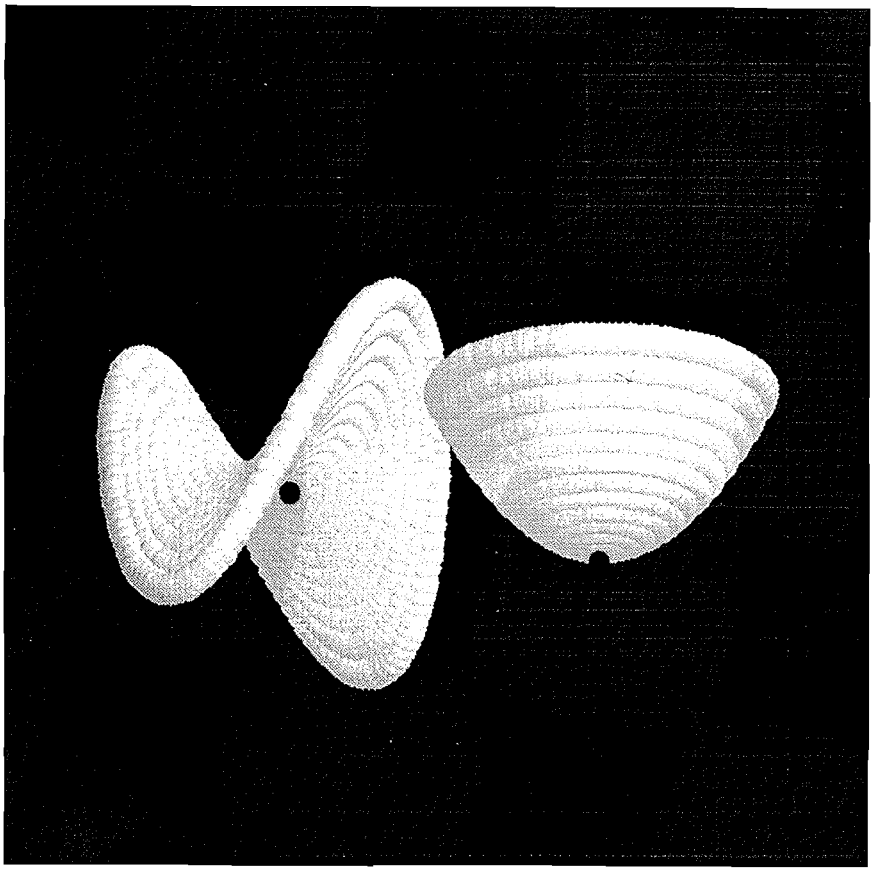
Fig. 1. Representation of two simple surfaces described by the model equation [2] (see text). The left surface corresponds to $\alpha = 1$ and $\beta = -1$ and is hyperbolic. The right surface is elliptic and has been generated with both parameters α and β set to 1. The origin of each surface is marked by a black dot.



$d\boldsymbol{x} = \boldsymbol{x}_u du + \boldsymbol{x}_v dv$. The function I_1 defined below is called the *first fundamental form* of $\boldsymbol{x}$.

$$[1] \qquad \begin{aligned} I_1 &= (\boldsymbol{x}_u \cdot \boldsymbol{x}_u)du^2 + 2(\boldsymbol{x}_u \cdot \boldsymbol{x}_v)du dv + (\boldsymbol{x}_v \cdot \boldsymbol{x}_v)dv^2 \\ &= E du^2 + 2F du dv + G dv^2 \end{aligned}$$

where $E = \boldsymbol{x}_u \cdot \boldsymbol{x}_v$, $F = \boldsymbol{x}_u \cdot \boldsymbol{x}_v$, and $G = \boldsymbol{x}_v \cdot \boldsymbol{x}_v$. The quantities E, F, and G are called the *first fundamental coefficients.*

As a direct illustration of the developed theory we will compute essential quantities defined by these and following equations for a simple model surface described by:

$$[2] \qquad \boldsymbol{x}(u, v) = u\boldsymbol{e}_1 + v\boldsymbol{e}_2 + (\alpha u^2 + \beta v^2)\boldsymbol{e}_3$$

where $\boldsymbol{e}_1$, $\boldsymbol{e}_2$, and $\boldsymbol{e}_3$ are the unit vectors of a global axis system, u, v are the independent variables, and α, β are parameters introducing the appropriate flexibility to illustrate certain surface characteristics semiquantitively. Figure 1 represents two examples of simple surfaces described by eq. [2]. The left surface corresponds to $\alpha = 1$, $\beta = -1$ and the right one to $\alpha = 1$, $\beta = 1$.

Clearly, using the first derivatives

$$[3] \qquad \begin{aligned} \boldsymbol{x}_u &= \boldsymbol{e}_1 + 2\alpha u \boldsymbol{e}_3 \\ \boldsymbol{x}_v &= \boldsymbol{e}_2 + 2\beta v \boldsymbol{e}_3 \end{aligned}$$

we obtain for the first fundamental coefficients:

$$[4] \qquad \begin{aligned} E &= \boldsymbol{x}_u \cdot \boldsymbol{x}_u = 1 + 4\alpha^2 u^2 \\ F &= \boldsymbol{x}_u \cdot \boldsymbol{x}_v = 4\alpha\beta uv \\ G &= \boldsymbol{x}_v \cdot \boldsymbol{x}_v = 1 + 4\beta^2 v^2 \end{aligned}$$

The first fundamental form I_1 is positive definite and depends only on the surface and not on the particular representation. The first fundamental coefficients themselves are not invariant under a parameter transformation. Denoting the dimensions of u and v by D_u and D_v, respectively, and knowing that components of $\boldsymbol{x}$ are expressed in units of length or L, it is clear that components of $\boldsymbol{x}_u$ have the dimension L/D_u. The dimensions of E, F, and G are L^2/D_u^2, L^2/D_uD_v, L^2/D_v^2, respectively.

An important intermediate quantity is $EG - F^2$ and it can be proven that

$$[5] \qquad EG - F^2 = |\boldsymbol{x}_u \times \boldsymbol{x}_v|^2$$

The area A of a surface patch is calculated with the aid of this quantity by the double integral:

$$[6] \qquad A = \int\int \sqrt{EG - F^2}\, du dv$$

In this work, areas of patches on interatomic surfaces approximating this integral are obtained by Gauss–Legendre quadrature. For the model surface this quantity amounts to:

$$[7] \qquad EG - F^2 = 4\alpha^2u^2 + 4\beta^2v^2 + 1$$

In an analogous manner we now proceed to define the *second fundamental form* denoted by I_2 by:

$$[8] \qquad \begin{aligned} I_2 &= -\mathrm{d}\boldsymbol{x}\cdot\mathrm{d}\boldsymbol{N} = -(\boldsymbol{x}_u\mathrm{d}u + \boldsymbol{x}_v\mathrm{d}v)\cdot(\boldsymbol{N}_u\mathrm{d}u + \boldsymbol{N}_v\mathrm{d}v) \\ &= L\mathrm{d}u^2 + 2M\mathrm{d}u\mathrm{d}v + N\mathrm{d}v^2 \end{aligned}$$

where $L = -\boldsymbol{x}_u\cdot\boldsymbol{N}_u$, $M = -\frac{1}{2}(\boldsymbol{x}_u\cdot\boldsymbol{N}_v + \boldsymbol{x}_v\cdot\boldsymbol{N}_u)$, $N = -\boldsymbol{x}_v\cdot\boldsymbol{N}_v$, and $\boldsymbol{N}$ is the unit normal defined by:

$$[9] \qquad \boldsymbol{N} = \frac{\boldsymbol{x}_u \times \boldsymbol{x}_v}{|\boldsymbol{x}_u \times \boldsymbol{x}_v|}$$

The functions L, M, and N are called the *second fundamental coefficients*.

As before, the function I_2 is invariant (in the same sense that I_1 is invariant) under a parameter transformation that preserves the direction of $\boldsymbol{N}$.

Alternative expressions for L, M, and N that we have implemented for this work are

$$[10] \qquad L = \boldsymbol{x}_{uu}\cdot\boldsymbol{N}, \qquad M = \boldsymbol{x}_{uv}\cdot\boldsymbol{N}, \qquad N = \boldsymbol{x}_{vv}\cdot\boldsymbol{N}$$

The results for these newly introduced quantities for the model surface are

$$[11] \qquad \boldsymbol{x}_{uu} = 2\alpha\boldsymbol{e}_3, \qquad \boldsymbol{x}_{uv} = 0, \qquad \boldsymbol{x}_{vv} = 2\beta\boldsymbol{e}_3$$

$$[12] \qquad \boldsymbol{x}_u \times \boldsymbol{x}_v = 2\alpha u\boldsymbol{e}_1 - 2\beta v\boldsymbol{e}_2 + \boldsymbol{e}_3$$

$$[13] \qquad |\boldsymbol{x}_u \times \boldsymbol{x}_v| = (4\alpha^2u^2 + 4\beta^2v^2 + 1)^{-1/2}$$

$$[14] \qquad L = \boldsymbol{x}_{uu}\cdot\boldsymbol{N} = 2\alpha(4\alpha^2u^2 + 4\beta^2v^2 + 1)^{-1/2}$$

$$M = \boldsymbol{x}_{uv}\cdot\boldsymbol{N} = 0$$

$$N = \boldsymbol{x}_{vv}\cdot\boldsymbol{N} = 2\beta(4\alpha^2u^2 + 4\beta^2v^2 + 1)^{-1/2}$$

Since $\boldsymbol{N}$ is dimensionless the dimension of L is L/D_u^2.

A discriminant D defined as $LN - M^2$ determines qualitatively the nature of the surface in the neighbourhood of a point. We can distinguish four cases: a point is elliptic, hyperbolic, parabolic, or planar when D is strictly positive, strictly negative, zero (without L, M, N all being zero), and when $L = M = N = 0$, respectively. It should be pointed out that ellipticity, etc. is a *local* property, i.e., it refers to the character of a single point on a surface, not to the global surface. This classification is again independent of the representation of the surface. The discriminant for our model surface is given by:

$$[15] \qquad LN - M^2 = 4\alpha\beta(4\alpha^2u^2 + 4\beta^2v^2 + 1)^{-1}$$

In the neighbourhood of an elliptic point the surface lies on the same side of the tangent plane at the point. On the other hand, the surface lies on both sides of the tangent plane in the neighbourhood of a hyperbolic point. Such a point is easy to visualize as the center of an ordinary saddle.

The central quantity for our present discussion is the *Gaussian curvature* K at a given point. A convenient definition is

$$[16] \qquad K = \frac{LN - M^2}{EG - F^2}$$

This is again an invariant property of the surface. Since $(EG - F^2) > 0$ the sign of K classifies a point as elliptic, hyperbolic, or parabolic (or planar). It is clear that on each point of a plane the Gaussian curvature K vanishes. Another useful special case is the spherical surface. For every point on a sphere with radius a we have $K = 1/a^2$. It follows from the previous dimensional analysis that the dimension of K for a point on a general surface is indeed $1/L^2$. The Gaussian curvature for the model surface is

$$[17] \qquad K = 4\alpha\beta(4\alpha^2u^2 + 4\alpha^2v^2 + 1)^{-2}$$

As an example we focus on the origin of each surface in Fig. 1. These points are marked by black dots and correspond to $u = v = 0$. Consequently, $K = 4\alpha\beta$ and the classification of the origin depends only on the signs of α and β and on whether they vanish. It then follows that the origin in the left surface is hyperbolic and in the right surface is elliptic. Since the denominator of K and $(4a^2u^2 + 4a^2v^2 + 1)^{-2}$ in eq. [17] is strictly positive, this statement is true for any point on the respective surface, not just the origin. Furthermore, increased values of α or β steepen the surface at the origin and increase the Gaussian curvature, which is in line with geometrical intuition.

When the Gaussian curvature is integrated over a surface S we obtain the *total curvature* C.

$$[18] \qquad C = \int\int_S K\mathrm{d}S$$

It is very important to note that C is dimensionless. It adopts the following analytical form for the model surface.

$$[19] \qquad \begin{aligned} C &= \int\int_R K\mathrm{d}S = \int\int_D K(\boldsymbol{x}(u, v))|\boldsymbol{x}_u \times \boldsymbol{x}_v|\mathrm{d}u\mathrm{d}v \\ &= 4\alpha\beta\int_0^u\int_0^v (4\alpha^2u^2 + 4\alpha^2v^2 + 1)^{-3/2}\mathrm{d}u\mathrm{d}v \end{aligned}$$

If interatomic surfaces were *compact*, characterizing them using the total curvature C would not quite lead to a useful classification. This statement is a corollary of two well-known theorems, as is explained below. According to the Heine–Borel theorem, a surface is compact if and only if it is bounded and closed. A sphere and a torus are examples of compact surfaces. On the other hand, the Gauss–Bonet theorem proves that for compact surfaces (which must be orientable and sufficiently differentiable) the total curvature is just a multiple of π and is a topological invariant. The total curvature of a sphere, for example, is 4π and for a torus is zero. Since interatomic surfaces are not bounded, they are not compact. Therefore the Gauss–Bonet theorem does not apply to them. As a result we do not *necessarily* recover trivial multiples of π when computing C for an IAS.

3. Implementation

3.1 Analytical expression of the surface

An IAS consists of a bundle of gradient paths that originate at infinity and terminate at the so-called *bond critical point* (6). This point is one of the four possible types of critical points (i.e., $\nabla\rho = \mathbf{0}$) and is denoted by $(3,-1)$. It can be regarded as the center of the IAS. Gradient paths are traced by solving the following system of ordinary differential equations given an initial point through which the path is passing:

$$[20] \qquad \frac{d\boldsymbol{r}}{dl} = \frac{\nabla\rho(\boldsymbol{r})}{\|\nabla\rho(\boldsymbol{r})\|}$$

It has been shown before that solving this system with analytical tools is possible but unsatisfactory (7). A more successful scheme solves the ordinary differential equations using a numerical integrator with adaptive step-size control like the Cash–Karp–Runge–Kutta method (8) and then fits Chebyshev polynomials and trigonometric functions to the points on the IAS. Each component $x_i(l,\theta)$ of a point on the surface is then given by the *explicit* parametric equation:

$$[21] \qquad x_i(l,\theta) = \sum_{m,n}^{M,N} (d_{inm}\cos(m\theta) + d'_{inm}\sin(m\theta))T_n(l)$$

where d_{inm}, d'_{inm} are fitted, T_n is the nth degree Chebyshev polynomial, l is the length of a gradient path on the IAS, and θ is an angular coordinate.

The IAS is constructed by following the gradient paths backwards, away from the bond critical point, starting from a set of *initial points*. These initial points form a circle with a small radius r_ε (typically 0.001 atomic units) in the *eigenplane* (7). The Chebyshev fit only extends over the interval $[-l_{max}, 0]$.

The analytical description of the IAS leaves a small puncture near the bond critical point that we have minimalized by setting r_ε to a really small value like 10^{-6}. So, practically, we assume that the IAS is only bounded for large negative l values and not for $l = 0$.

Excellent fits can be obtained with a moderate number of fitting basis functions (fewer than 50). The quality of the fit is measured by quasi-continuous error estimates such as a global root-mean-square value (7). A value of 10^{-4} atomic units (au) or less is quite typical for a surface up to the 10^{-9} au charge density contour surface. This basically means that the analytical expressions perfectly reproduce the numerical surface.

3.2 Calculation of total curvature

Since the availability of an analytical expression for the IAS (7) it has been possible to obtain fast and accurate surface-related derivatives for computing local and integrated surface curvatures. Derivatives of high-order Chebyshev polynomials do not pose problems and are evaluated rapidly.

It is crucial to test the stability of the total curvature C with respect to various parameters. All surfaces have been fitted with Chebyshev polynomials up to order 40 and with a set of 51 trigonometric functions.[2] The relative accuracy of the differential equation integrator was kept at 10^{-4} (for a precise definition see ref. 8, p. 711) and the minimum allowed step size was fixed at 10^{-7} au.

Secondly, the behaviour of C was monitored as a function of the size of the patch on the IAS. In general, interatomic surfaces extend to infinity and a well-behaved total curvature should converge with more negative l values. Tests for the N|H IAS in ammonia show rather slow convergence but stability is essentially reached for $l < -10$ au (the changes in C are of the order of 10^{-4}). The total curvature varies slightly more for the C|O surface in carbon monoxide. It is well known that Gaussian functions do not properly describe the outer regions of a molecule. We must therefore suspect that gradient paths are not very meaningul in zones where the charge density is as low as 10^{-12} au or less, especially at a moderate level of theory like HF/6-31G**. Consequently the local curvature of the IAS in the outer region is not trustworthy. Since the total curvature is a purely geometrical quantity, not weighted by (extremely low) charge densities or their gradient, the outer region will unduly affect C.

This phenomenon has prompted us to compute the total curvature only for a well-defined and reliable patch on the IAS. There is good evidence that the 0.001 au charge density envelope may be considered as the practical edge of the molecule and thus of its constituent atoms. We have fitted a very accurate continuous contour line to points on the IAS where $\rho = 0.001$ au. This smooth and analytical contour line then bounds the IAS everywhere. All total curvature values quoted below have been computed with a grid extending only to the 0.001 au charge density contour level. We believe that results drawn from these numbers genuinely reflect what happens well inside the molecule and should therefore relate to chemical insight.

Finally, the effect of stability of C on the quadrature grid size was explored. Throughout, we use a grid with 60 radial and 120 angular points, which is sufficient.

4. Applications

Before interpreting the data a general comment is worth inserting. The "outer" shape of an atomic basin is determined by the geometry of the interatomic surfaces bounding it. This is the shape we focus on in the following discussion. But an atom also has an "inner" shape, which is determined by the pattern of the gradient vector field inside the atom. One might say that gradient paths distort space. They establish non-Euclidean geodesics and exhibit a Riemannian curvature that characterizes the whole atomic subspace. This is of course the ultimate curvature to be investigated and is therefore the subject of future work.

All wave functions were generated using the program CADPAC (9) using the 6-31G** basis set (10), 6-31GE,[3] and a [13*s*5*p*/4*s*3*p*] set (4) for lithium.

Table 1 presents the total curvature for a set of four ionic closed-shell lithium compounds: LiF, LiH, $LiCH_3$, and LiO^-. Three quantities consistently indicate that these compounds are ionic. The charge density at the bond critical point or ρ_b

[2] The trigonometric basis set is $\{1, \cos(n\theta), \sin(n\theta)\}$, where $n = 1,2,\ldots,25$.

[3] The basis set is obtained from the 6-31G basis set by adding diffuse functions and polarization functions. More details are found in the CADPAC manual.

Table 1. The total curvature C and additional quantities[a] of some ionic lithium compounds computed using two different basis sets.

Molecule	d(Li–A)[b]	ρ_b	$\nabla^2\rho_b$	q(Li)	$L(\Omega)$	C
HF/6-31G**						
LiF	1.537	0.086	0.767	0.910	3×10^{-4}	1.27

LiO^-	1.678	0.062	0.472	0.831	3×10^{-5}	6.18

[a]All quantities are given in atomic units unless stated otherwise. Symbols are explained in the main text.
[b]The distance between the two nuclei is given in Å.

is about 10 times smaller than for a typical covalent bond. The Laplacian at the bond critical point or $\nabla^2\rho_b$ is positive and the net charge q(Li) is approaching the value of exactly one. This net charge is obtained by integrating the charge density over the atomic basin of lithium and substracting this population from the nuclear charge. The integration error is typically assessed by $L(\Omega)$, which should ideally vanish (12).

It is a good approximation to regard the charge transfer from lithium to the neighbouring atom as constant within the present series since the maximum discrepancy for q(Li) is only 0.085 e using the 6-31GE basis set. This fact is consistent with the earlier observation of Bader and Beddall (13) for wave functions close to the Hartree–Fock limit. As expected, the well-known AIM quantities are quite insensitive to the variation in basis set. This is also true for the total curvature, with the exception of LiO^- where the highly polarizable O^{2-} anion benefits from the better description provided by the extra diffuse functions.

The inclusion of correlation at the MP2 level does not alter the order $LiF < LiH < LiCH_3 < LiO^-$ as ranked by the total curvature C. It is well known that anions are the most affected by correlation, which is reflected by the pronounced changes for LiO^-. It can be seen from Table 1 that all properties d(Li—A), ρ_b, $\nabla^2\rho_b$, and q(Li) vary considerably for this molecule and only marginally for the other molecules in this set. Since the qualitative conclusions of the present study do not alter with electron correlation we will not systematically investigate its effect on the non-ionic compounds discussed below.

Since the present molecules are nearly completely ionic one may view them as a point charge perturbing a polarizable anion. Exact calculations for the polarizability of free anions yield 15.1 au for F^- (14), 206 au for H^- (15), and an infinite value for O^{2-} (16).[4] This is exactly the order reflected by the total curvature computed with the 6-31GE basis set, predicting that the CH_3^- group must be a very polarizable charge cloud. This conclusion is plausible since the basic methyl anion has a diffuse lone pair of strong sp^3 character and because carbon and hydrogen have a virtually identical electronegativity.

Table 2. The influence of a uniform electric field on the total curvature C of the interatomic surface in the hydrogen molecule and hydrogen fluoride.

Field[a]	$C(H_2)$	C(HF)
−0.050	0.146	1.067
−0.010	0.006	1.386
−0.005	0.001	1.425
−0.001	0.000	1.455
0.000	0.000	1.463
0.001	0.000	1.471
0.005	0.001	1.501
0.010	0.006	1.539
0.050	0.146	1.837

[a]The field strength is expressed in au.

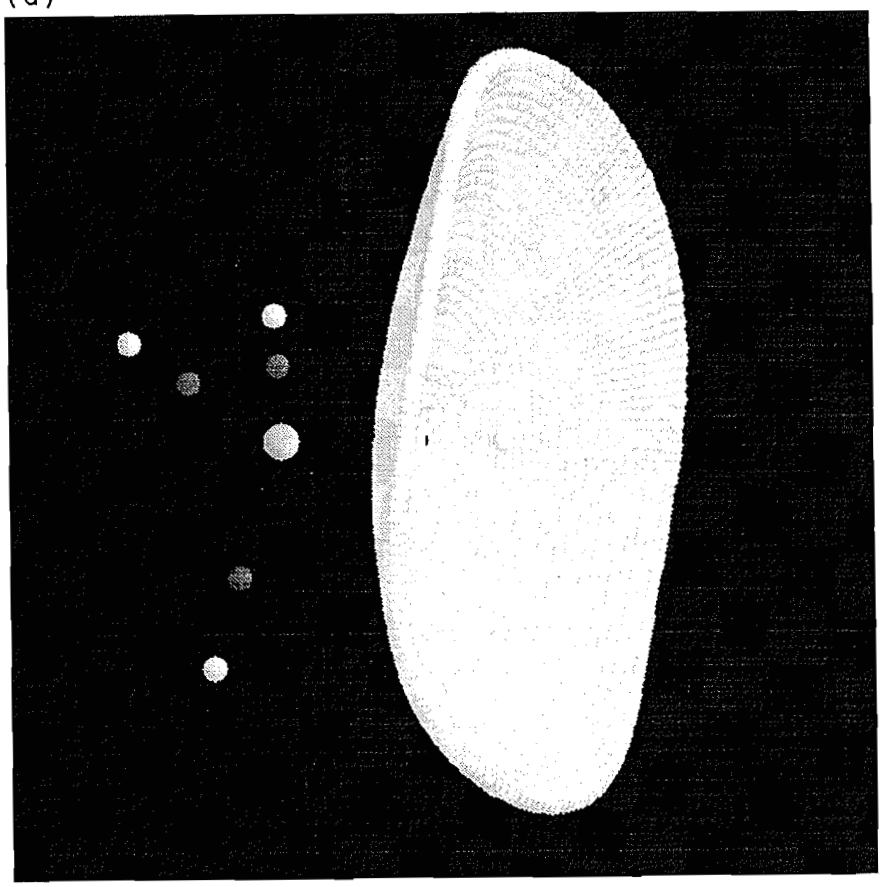
Further evidence that the total curvature C is indeed affected by the extent of polarization of an atom emerges from the behaviour of H_2 and HF in a uniform electric field. The results are shown in Table 2 for a field strength E_z along the molecular axis varying from −0.05 to +0.05 au. Hydrogen fluoride shows an excellent linear correlation ($\rho = 0.9997$) between C and E_z, yielding $C = 7.6973\,E_z + 1.4604$. The linear dependence for H_2 is weaker ($\rho = 0.9883$) and here $C = 3.0349\,E_z - 0.0094$. It is tempting to relate the slope of these equations with $\alpha_s(\Omega)$, which was previously introduced (18) as the associated contribution to the polarizability resulting from the shift in interatomic surface. Using the values quoted in ref. 18 for HF and H_2, the difference in response of the IAS to the applied field could be explained semi-quantitatively. The main point, however, of this small excursion is to indicate that C can be used in studying atoms in electric fields and that the polarization of a charge cloud within an atomic basin does change the intrinsic geometry of its bounding IAS.

The next series of molecules constitutes the classic set of hydrides AH_n where A = H, Li, Be, B, C, N, O, F and n varies, producing H_2, LiH, BeH_2, BH_3, methane, ammonia, water and hydrogen fluoride. Detailed three-dimensional pictures of the atoms encompassed by this set have recently been published for the first time (1). Figure 2 shows the C|H IAS in methane and the corresponding contour map for the Gaussian curvature K.

From Table 3 it is seen that the total curvature for the A|H IAS increases steadily as the charge transfer from H to A increases. Since it was shown before that the charge transfer defined by AIM recovers the basic idea underlying electronegativity, it seems plausible to surmise that the total curvature increases with increasing electronegativity.

[4] The species O^{2-} is unstable with respect to decomposition into a free O^- ion and a free electron; see ref. 17.

(a)



(b)

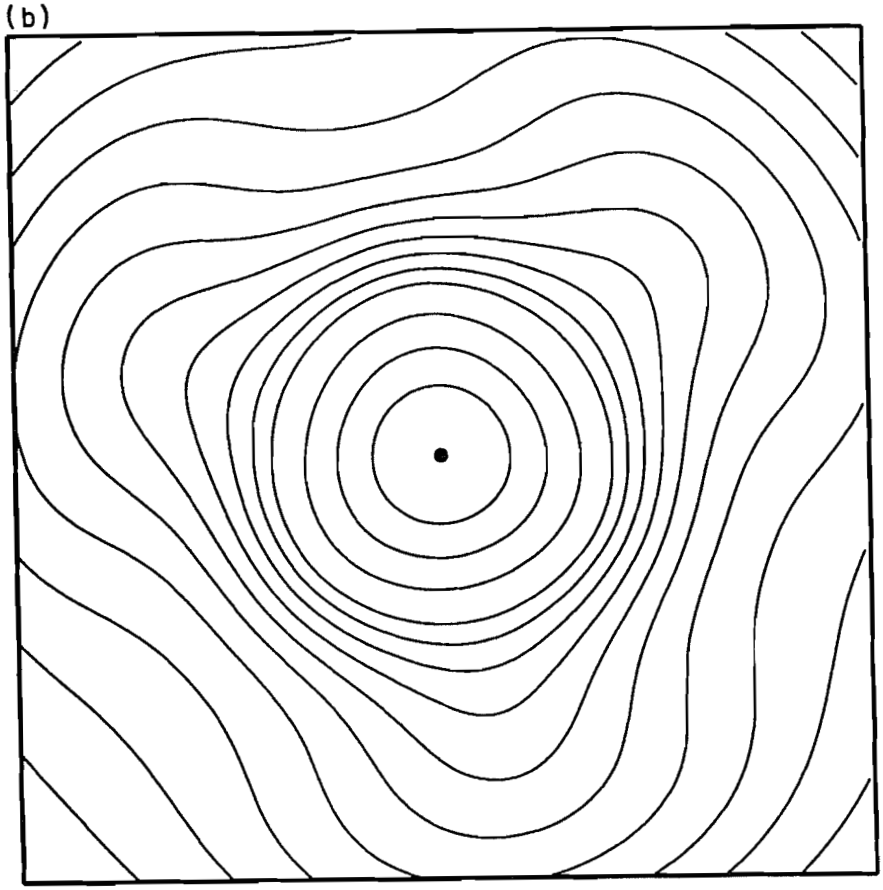


Fig. 2. (*a*) A three-dimensional representation of the C|H interatomic surface in methane. The bond critical points are marked by grey dots. This picture should be compared with the corresponding contour map of Fig. 2*b*. (*b*) A contour map of the Gaussian curvature K of the interatomic surface between C and H in methane. The outer contour line corresponds to a curvature of 0.001 and the contours increase as 0.005, 0.01, 0.015, 0.02, 0.025, 0.03, 0.035, 0.04, 0.045, 0.05, 0.06, 0.07, 0.08, and 0.09. The bond critical point is marked by a dot. Note that the expected threefold symmetry becomes more pronounced towards the outer regions of the interatomic surfaces, which correspond to an l value of about −3.

Table 3. The charge transfer q and the total curvature C and area[a] for the A|H interatomic surface in the second row hydrides AH_n.

Molecules	q(H)	C	Area
H_2	0.000	0.000	28.08
LiH	−0.893	2.741	28.90
BeH_2	−0.873	0.002	35.31
BH_3	−0.718	—[b]	—
CH_4	0.062	0.692	32.00
NH_3	+0.373	1.084	24.88
OH_2	+0.619	1.297	19.18
HF	+0.757	1.463	14.73

[a]The interatomic surface is bounded by a contour line of constant charge density (0.001 au). The area is given in $(au)^2$.
[b]Instabilities in the IAS prevent the computation of a reliable number at present.

Even if charge transfer does influence the total curvature,[5] it cannot be the only effect because the CH bond in methane shows virtually no charge transfer, yet the curvature amounts to 0.692. Similarly, in the $^2\Pi$ diatomic CH the total curvature is reasonable but charge transfer is essentially absent. The series of diatomics, CH, NH, OH, and HF, shows an increase in IAS total curvature resembling that of the present hydride series. These four diatomic molecules are examples of shared interactions characterized by a reasonably large value for ρ_b and a (strongly) negative $\nabla^2\rho_b$ value. In NH, OH, and HF there is an increasing polarization of the shared charge towards the non-hydrogen atom, but the "mechanism" by which this might change the curvature is not clear, the more so because the bond critical point shifts as well in this series.

Because of the symmetry in methane we cannot invoke the fairly large intra-atomic dipole moment of carbon. This measure is the first moment $\boldsymbol{M}(\Omega)$ and determines the displacement of the atom's centroid of negative charge from the position of its nucleus. These contributions will cancel each other in methane and can therefore not be the cause for the shape of the C|H surface.

To shed more light on this matter we have computed the total curvature for several other C—H bonds in saturated hydrocarbons, all of which show negligible charge transfer. In staggered ethane $C = 0.996$ for all six C—H bonds, whereas in the *anti–anti* conformation of propane three types of C—H are found: $C = 1.476$ for hydrogens attached to the central methylene carbon, $C = 1.365$ or $C = 1.022$ for hydrogens attached to a methyl carbon.

It emerges from these observations that the total curvature of C|H interatomic surfaces is very sensitive to the total chemical environment. This becomes intuitively obvious on inspecting Fig. 3. As a rule, a higher number of carbons attached to the carbon of the C|H IAS will increase the total curvature. This measure seems to probe how far atoms that are "pushed" together in a molecule distort each other. "Clashes" with third-party atoms can severely modify the curvature of the IAS between two atoms. This effect has been sufficiently documented in preliminary tests in more "crowded" systems like acetamide and urea. The total curvature for the C|O IAS takes the values −0.116, 0.000, 0.022, 0.174, and 0.242 in formaldehyde, carbon monoxide, formamide, urea, and acetamide, respectively. It can visually be verified that basins that are more distorted at their boundary yield higher total curvature values for their interatomic surface(s). There is no straightforward means of reducing this emerging phenomenon to known physical principles or quantities. The question why the C|H IAS in methane has a considerable curvature is equivalent to asking why this surface simply appears the way it does. One might explain its shape as a compromise between four equally distortable hydrogen atoms covalently bound to a carbon atom with a different distortability.

It is remarkable that the total curvature of the IAS in BeH_2 is almost zero. The shape of this surface is quite similar to the IAS in C≡O, which also has a vanishing total curvature. This is caused by an annihilation of negative contributions to the Gaussian curvature K by positive ones, as shown in Fig. 4.

This similarity can be explained by a common physical ground. Both bonds show a considerable charge transfer, the value for C≡O being 1.33 e. Given that in these molecules there is no "steric" phenomenon influencing the total curvature C and assuming that charge transfer enhances C, we are left with the question why C is nevertheless essentially zero. Carbon monoxide has a large and diffuse (weakly bound) charge distribution on carbon, which leads to a very pronounced polarization opposing the charge transfer moment. This explains the near-zero dipole moment of this molecule. Similarly, berylium has a diffuse valence density, again leading to large atomic polarization. One may hypothesize that the total curvature absorbs both the charge transfer and back-polarization effect.

The fact that the total curvature C is not just mirroring charge transfer is demonstrated by a set of methyl derivatives given in Table 4. In their work on substituent effects of methyl derivatives (19), Wiberg and Breneman have ordered 20 moieties with C_{3v} symmetry according to increasing pop-

[5] Ideally, one wishes to isolate the possible effect of charge transfer on the total curvature C. Constructing a molecule in which two of its atoms show only charge transfer without mutual polarization is virtually impossible unless one resorts to very artificial systems like $LiBe^{5+}$. This species is supposed to eliminate any polarization effect on the IAS and isolate the influence of charge transfer (if present at all) on the total curvature.

Fig. 3. A three-dimensional representation of three C|H interatomic surfaces in the *anti–anti* conformation of propane. The top surface has the highest total curvature (C = 1.476) followed by the bottom (right) one (C = 1.365). The left surface has a much lower total curvature (C = 0.996), identical to the value in the staggered conformation of ethane. This picture provides visual support for the observation that C is very sensitive to the total chemical environment of the atomic basin.

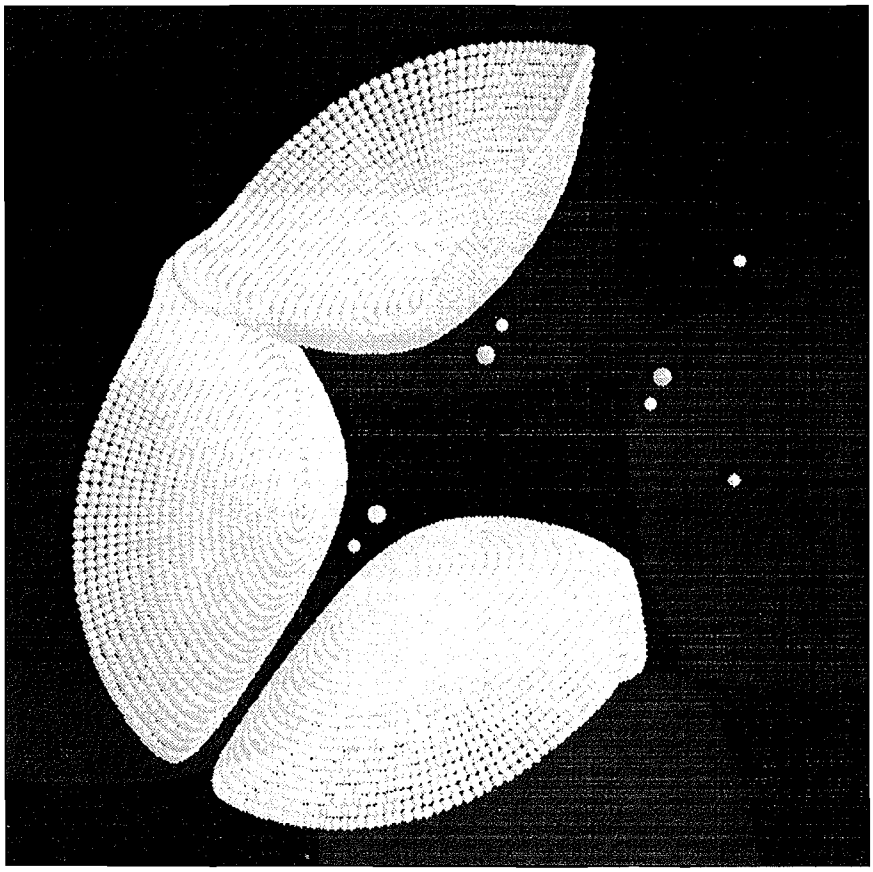

Fig. 4. A relief map of the Gaussian curvature K of the C|O interatomic surface in carbon monoxide. In the outer region of the IAS the curvature practically vanishes, which is the equivalent of near planarity.

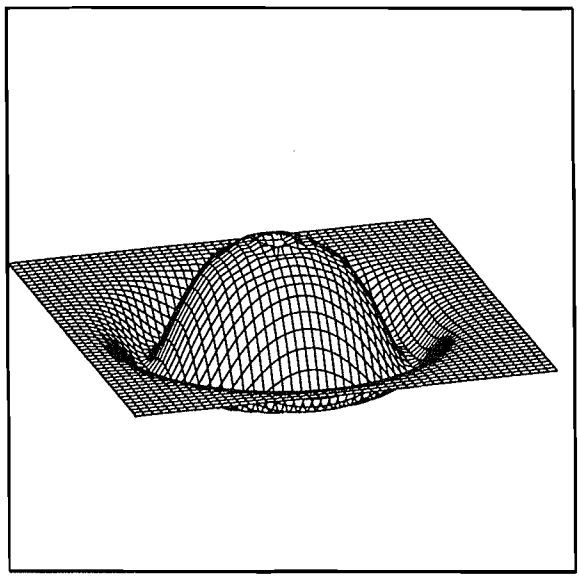

Table 4. The charge transfer q and the total curvature C and area[a] of the C|A[b] interatomic surface in methyl substituted derivatives.

Molecules	C	$q(CH_3)$[c]	Area
CH_3Cl	−0.08	+0.316	42.6
CH_3S^-	−0.08	−0.287	49.3
CH_3 C≡CH	−0.08	+0.362	40.5
CH_3BeH	0.00	−0.875	36.5
CH_3 C≡N	0.03	+0.362	39.4
$CH_3N_2^+$	0.03	+0.840	36.5
CH_3OLi	0.12	+0.618	38.9
CH_3O^-	0.19	+0.474	39.9
CH_4	0.69	+0.061	32.0
CH_3Li	3.05	−0.902	26.4

[a]The interatomic surface is bounded by a contour line of constant charge density (0.001 au). The area is given in $(au)^2$.
[b]The letter "A" represents the atom of the substituent group directly attached to the methyl carbon.
[c]The charge transfer is measured with respect to the population of the whole methyl group, which is 9.000 e. The present values are quoted from ref. 19.

Table 5. The total curvature C and area[a] for the C—C interatomic surface in various conformations of ethane.[b]

τ[c]	ΔE[d]	C	Area
0	12.6	0.000	42.3
15	10.8	−0.054	42.5
30	6.4	−0.168	42.9
45	1.9	−0.267	43.4
60	0.0	−0.304	43.6

[a]The interatomic surface is bounded by a contour line of constant charge density (0.001 au). The area is given in $(au)^2$.
[b]Ethane has been fully optimized at the 6-31G** level only fixing the torsion angles.
[c]This HCCH torsion angle is given in degrees: 0° and 60° correspond to the eclipsed and staggered conformations, respectively.
[d]This energy difference is given in kJ/mol.

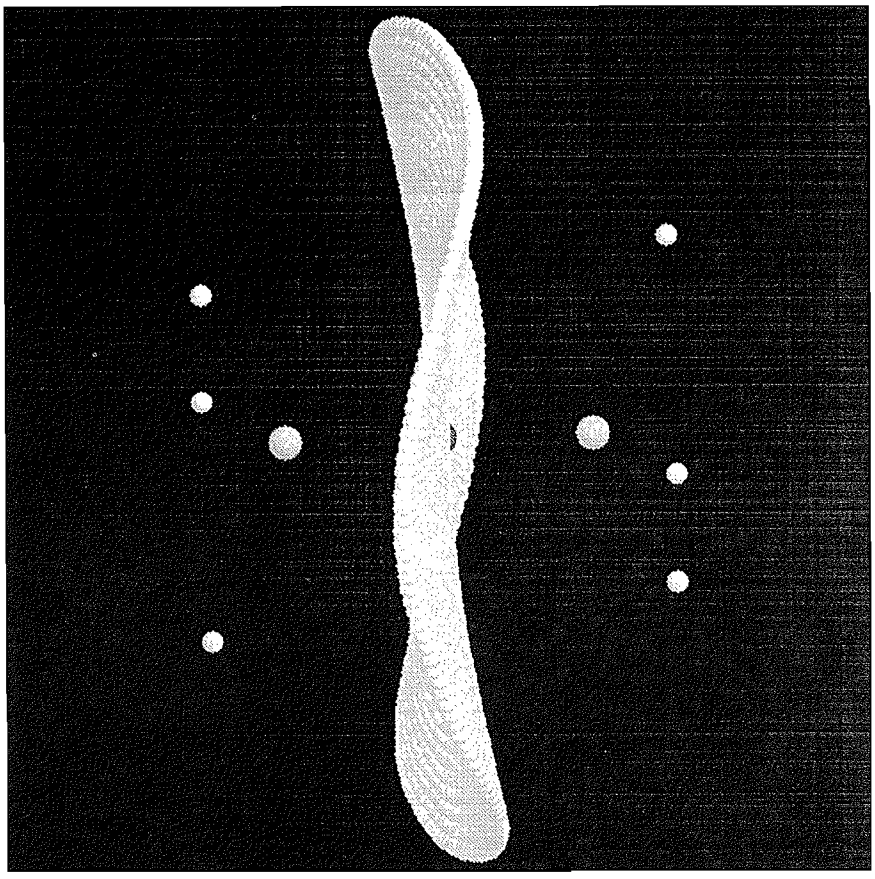
ulation of the methyl group. We focus on the IAS between the methyl carbon and the substituent atom attached to it. The 10 molecules we selected from this list fall, broadly speaking, in three categories according to C. The first group has a very small C value with the ionic compound CH_3BeH again showing a vanishing total curvature. Although the population of the methyl group varies considerably in this subset, C is not able to discriminate these systems very well. Under the hypothesis that the total curvature is influenced by charge transfer, polarization, and steric crowding one may speculate that these molecules have enough flexibility to allow these effects to cancel each other and reach an "atomic distortion equilibrium." The two other groups CH_4 and CH_3Li, which have been discussed before, contain only one member.

Finally, we simply point out that the total curvature index can also be applied in conformational analyses. A simple example is reported in Table 5 where the central torsion angle in ethane is varied from 0° to 60°. The total curvature of the C|C surface becomes more negative in a sinusoidal manner on going from the eclipsed to the staggered conformation. The latter IAS is represented in Fig. 5 as an example of a predominantly hyperbolic surface, because for the total curvature (which is an integral) to be negative there must be dominant contributions of surface points with a negative Gaussian curvature.

5. Conclusion

A purely geometrical index is proposed to characterize interatomic surfaces in molecules. This index is called the total curvature C and stems from a rigorous application of differential geometry. It is dimensionless and gauges the intrinsic geometry of a surface regardless of its representation or position in space.

Fig. 5. A three-dimensional representation of the C|C interatomic surface in the staggered conformation of ethane. This surface has a negative total curvature.



The total curvature measures the chemical distortion of an atom in a molecule, which is a combination of polarization deformation, charge transfer, and steric effects. Although it is a single-bond oriented quantity it is sensitive to the complete chemical environment of the bonded atoms.

For a series of ionic diatomics with a practically constant charge transfer, C measures the distortion of the anion by the positive neighbouring charge. It is conjectured that increasing electronegativity differences between two bonded atoms increases the total curvature of the IAS. Other simultaneous influences on C should be included since the charge transfer in methyl derivatives is not reflected on a one-to-one basis in the total curvature of the IAS between the methyl carbon and the substituent.

The proposed index can be used to probe the response of an IAS in uniform electric fields and can be employed in conformational studies.

It remains speculative whether a straightforward and interesting relationship exists between the HSAB principle (20) and the total curvature.

Theoretical examination of the Diels–Alder reaction of 1,3-butadiene with cyclopentadiene and 2*H*-phosphole

Steven M. Bachrach and Laureta M. Perriott

Abstract: All Diels–Alder reactions between 1,3-butadiene and cyclopentadiene or 2*H*-phosphole have been examined at the MP4SDQ/6-31G*//HF/6-31G* level. There is remarkable similarity between the two systems. The thermodynamic product is the bicyclo[4.2.0]nonadiene while the kinetic product is the norbornene product. There is a slight kinetic preference for the *endo* addition and for the butadiene to be in the *s-trans* conformation. Except for the case where butadiene is the diene component and addition is *endo*, the reactions are concerted and synchronous. In these other two cases, the reaction is stepwise with a diradical intermediate.

Key words: phosphole, Diels–Alder reaction, topological electron density analysis.

Résumé : On a étudié toutes les réactions de Diels–Alder entre le buta-1,3-diène et le cyclopentadiène ou le 2*H*-phosphole au niveau MP4SDQ/6-31G*//HF/6-31G*. Il existe une similarité remarquable entre les deux systèmes. Le produit thermodynamique est le bicyclo[4.2.0]nonadiène alors que le produit cinétique est le produit norbornène. Il y a une légère préférence cinétique en faveur de l'addition *endo* et pour que le butadiène soit dans la conformation *s-trans*. À l'exception du cas où le butadiène agit comme butadiène et que l'addition est *endo*, toutes les réactions sont concertées et synchrones. Dans ces deux autres cas, la réaction se fait par étape avec un intermédiaire diradicalaire.

Mots clés : phosphole, réaction de Diels–Alder, analyse topologique de la densité électronique.

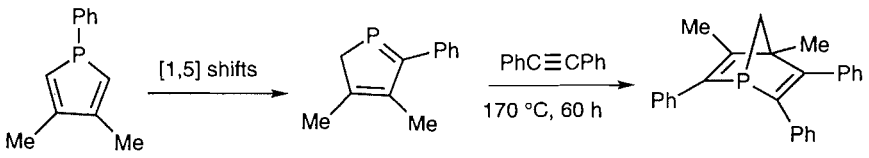
Introduction

The Diels–Alder reaction of phosphaalkenes has been a subject of intense study (1, 2). A wide variety of these reactions have been carried out; however, there are limited examples where the phosphaalkene acts as the dienophile. The propensity for phosphaalkenes to dimerize limits its use as a dienophile. One significant exception is the chemistry of 2*H*-phospholes (3).

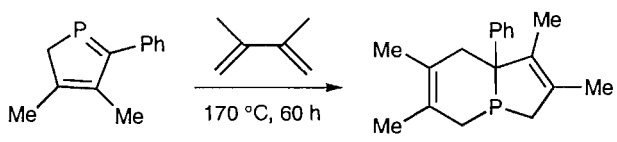
Mathey et al. first demonstrated the Diels–Alder chemistry of 2*H*-phosphole in the attempted reaction of a 1*H*-phosphole with diphenylacetylene (Scheme 1) (4). The actual recovered product appeared to arrive from the Diels–Alder reaction of a 2*H*-phosphole with the acetylene. Mathey suggested that a facile [1,5]-phenyl shift precedes the Diels–Alder reaction. We recently examined this reaction using theoretical methods and found a low barrier for the [1,5]-hydrogen shift for 1*H*-phosphole (5). Furthermore, the activation energy for the Diels–Alder reaction of 2*H*-phosphole with acetylene is less than the barrier for the hydrogen shift (6), supporting Mathey's mechanism.

Scheme 1.



As further proof of the intermediacy of 2*H*-phosphole, Mathey reports the reaction of the phosphole with 2,3-dimethyl-1,3-butadiene, recovering the Diels–Alder product where the phosphole acts as the dienophile, with addition across the P=C bond (Scheme 2) (4). Further experiments have shown this propensity for 2*H*-phosphole to act as the dienophile in reactions with conjugated systems (7, 8).

Scheme 2.



Received September 28, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

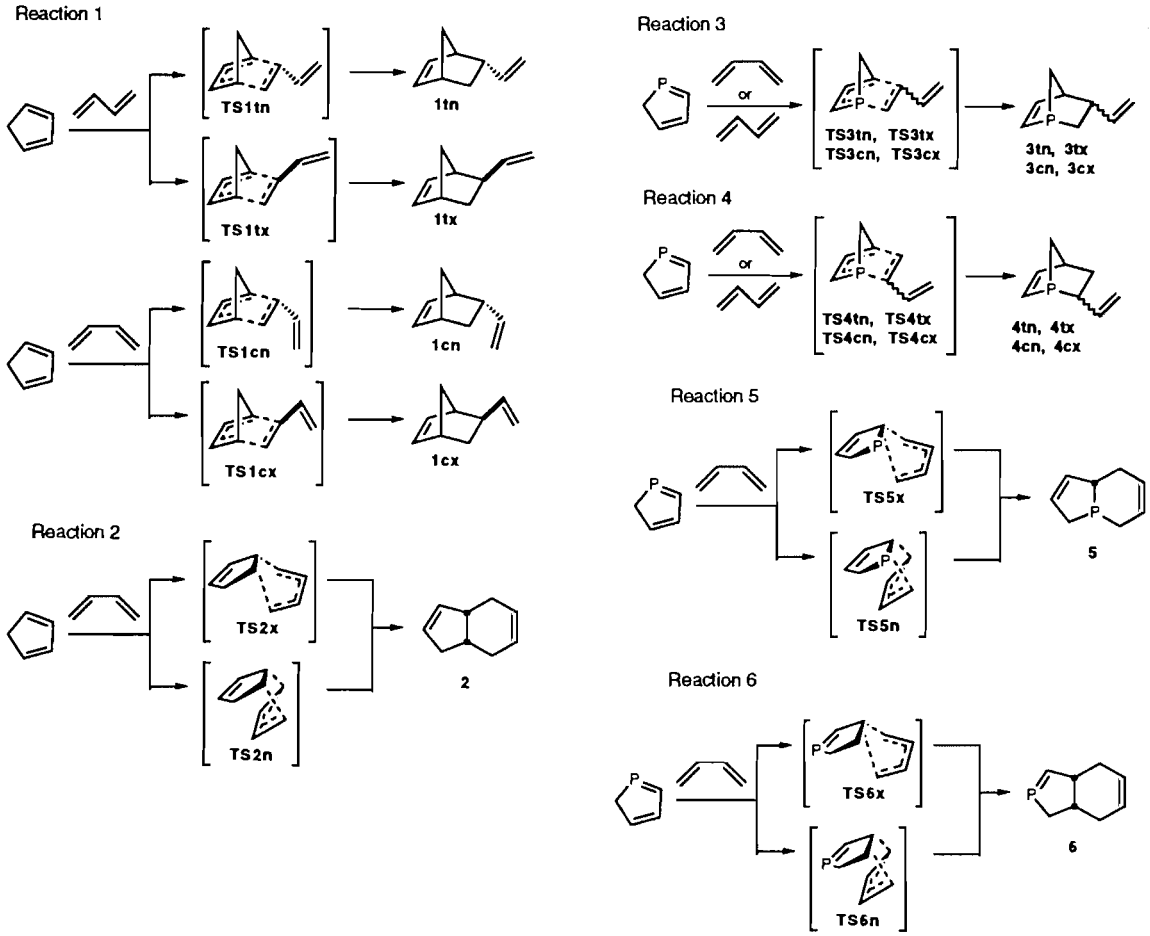
Scheme 3.



Continuing our theoretical examination of the pericyclic reactions of phosphaalkenes (6, 9–13), we report here ab initio calculations on the Diels–Alder reaction of 2*H*-phosphole with 1,3-butadiene (Scheme 3). We have examined all possible reactions: 2*H*-phosphole (diene) + 1,3-butadiene (dienophile), Reactions 3 and 4, which have differing regiochemistry; 2*H*-phosphole (dienophile) + 1,3-butadiene (diene) with addition across the C=P bond, Reaction 5; and 2*H*-phosphole (dienophile) + 1,3-butadiene (diene) with addition across the phosphole C=C bond, Reaction 6. As a comparison, we examined the hydrocarbon analogue: the Diels–Alder reaction of cyclopentadiene (diene) + 1,3-butadiene (dienophile), Reaction 1, and the reaction of cyclopentadiene (dienophile) + 1,3-butadiene (diene), Reaction 2. We have examined the *endo* vs. *exo* selectivity of product formation and the *cis* vs. *trans* selectivity of the 1,3-butadiene. Using the topological electron density method of Bader (14), we assess the degree of bond formation in the transition states and judge the synchronicity of these reactions.

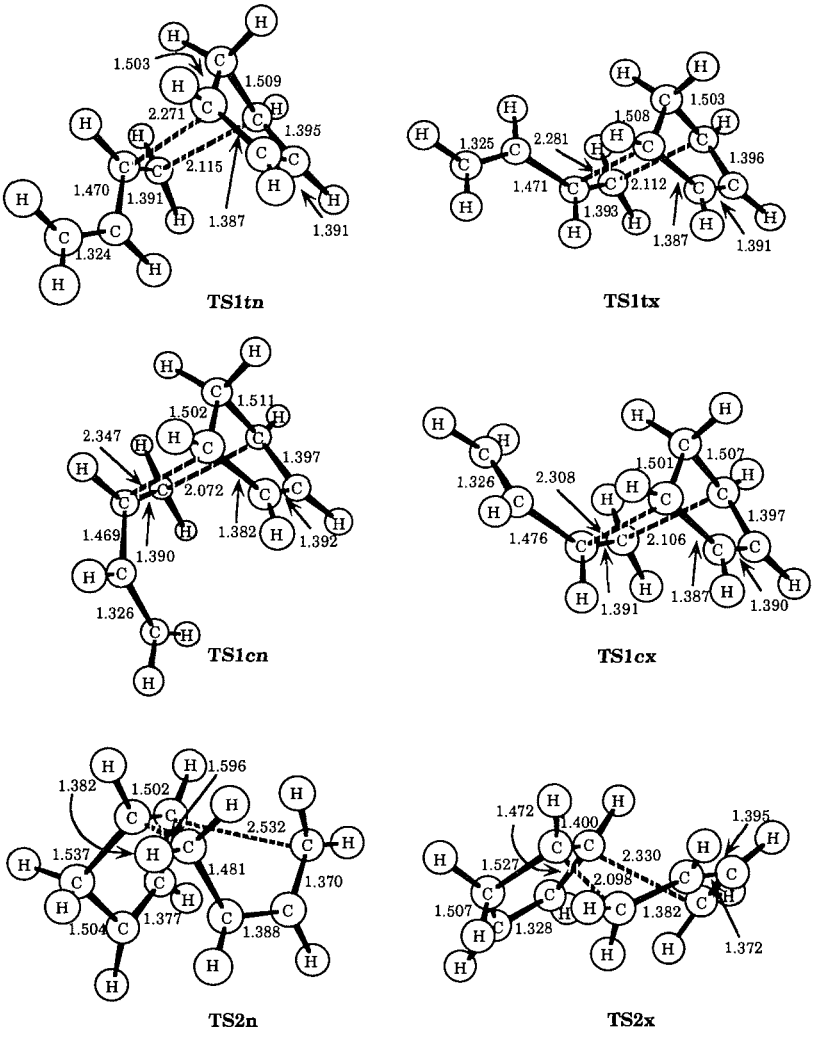
The only applicable experimental result (4) is the reaction shown in Scheme 2, which shows a clear preference for the phosphole to act as the dienophile with addition across its C=P bond. Mathey did report that another minor unidentified compound was produced.

There have been two important theoretical studies of related systems. Li and Houk (15) examined the dimerization of 1,3-butadiene at the RHF and CASSCF levels. The concerted reaction is found to be about 5 kcal mol^{-1} more favorable than the biradical pathway. In addition, the TS with the dienophilic butadiene in the *trans* conformation is 0.8 kcal mol^{-1} lower in energy than the *cis* conformation. (Houk's earlier study of the Diels–Alder reaction between butadiene and acrolein indicated a slight preference for the *cis* conformation of acrolein (16).) At the CASSCF(6,6) level, the *exo* TS is 0.2 kcal mol^{-1} below the *endo* TS, contrary to the experimental evidence, which indicates a slight preference for *endo* selectivity. Jorgensen, Lim, and Blake (17) examined the Diels–Alder reaction of cyclopentadiene with isoprene and cyclopentadiene. They find a distinct preference for the *cis* conformation of isoprene and *endo* selectivity. All studies have indicated that the concerted pathways show some degree of synchronicity, based on the distances of the forming σ-bonds. We will compare our results with these previous theoretical studies.

Computational methods

The structures of all species involved in Reactions 1–6 were completely optimized at the HF/6-31G* level. The nature of these geometries was confirmed with analytical frequencies; all ground states had all real frequencies and the transitions states had one and only one imaginary frequency. The geometries of the transitions states are drawn in Figs. 1 and 2, while those of the products are drawn in Figs. 3 and 4.

Fig. 1. HF/6-31G* optimized geometries of **TS1–TS2**. All distances are in Å.



The activation energy of Diels–Alder reactions is known to be sensitive to electron correlation (11, 17–19). Activation energies are dramatically overestimated at HF and underestimated at MP2. However, the HF and MP2 optimized geometries of TSs for Diels–Alder reactions do not differ substantially. Therefore, we have obtained single-point energies at MP4SDQ/6-31G*//HF/6-31G*. Previous studies have shown that computations at this level are adequate to describe the systems under study in this report. Reaction energies are listed in Table 1 and activation energies are given in Table 2.

As described below, the *endo* transition states of Reactions 2 and 6 appear to have biradical character. To better treat these states, Reactions 2 and 6 (through *endo* TSs) were reexamined at UHF/6-31G*. Both reactions were found to have an intermediate state (**INT2** and **INT6**) and transition states leading to and from the intermediate. **INT2** was optimized at UMP2/6-31G* since it could not be located on the UHF surface. Since the main focus of this paper is the concerted mechanism, we report only the UHF energies.

All energy calculations were performed using GAUSSIAN92 (20) or GAUSSIAN94 (21).

Results

Reaction 1

For the reaction of cyclopentadiene with butadiene where butadiene acts as the dienophile, four TS are possible, leading to four different products. The reaction of *trans*-1,3-butadiene with cyclopentadiene can proceed through an *endo* TS (**TS1tn**, where **t** indicates *trans*-1,3-butadiene and **n** indicates *endo* orientation) or an *exo* TS (**TS1tx**, where **x** indicates *exo*). The reaction of *cis*-1,3-butadiene can also proceed through an *endo* (**TS1cn**, where **c** indicates *cis*-1,3-butadiene) or *exo* (**TS1cx**) TS. The four products differ by having an *endo* or *exo* vinyl group that is either *s-cis* (**1cn** and **1cx**) or *s-trans* (**1tn** and **1tx**) to the saturated two-carbon bridge. These possibilities are shown in Scheme 3.

The geometries of these four products are very similar (Fig. 3). In fact, the variation in any C—C distance among the four isomers is less than 0.005 Å. All distances and angles are in expected ranges for typical C—C and C=C bonds and norbornene systems. The most stable isomer is **1tn**, which lies 1.42 kcal mol^{-1} below its rotational isomer **1cn** and 0.32 kcal mol^{-1} below its *exo* isomer. Presumably, poor steric interactions in both **1cn** and **1cx** reduce the energy difference between these two isomers to only 0.09 kcal mol^{-1}, compared to the difference of 0.32 kcal mol^{-1} between **1tn** and **1tx**. Formation of the most stable isomer (**1tn**) is exothermic, with reaction energy (using *trans*-1,3-butadiene) of −22.96 kcal mol^{-1} (Table 1).

Sum[a]	6.78	6.78	6.63	6.94

[a]Sum of bond orders of active bonds (rows 5–10).

We located four transition states, corresponding to the different paths shown in Scheme 3. Overall, the geometries of the four isomeric TSs of Reaction 1 are also very similar. The bond distances in the butadiene and cyclopentadiene fragments vary by less than 0.007 Å among the isomers. The forming bonds between the two fragments are of different lengths; the forming bond to the carbon bearing the vinyl group is longer than the other forming bond in all four TSs. This asymmetry is slightly greater in the *cis* isomers (difference in bond distances of about 0.20 Å) than in the *trans* isomers (difference of 0.16 Å).

There is remarkable synchronicity in these TSs. The bond distances of the partially broken/formed double bonds in the butadiene and cyclopentadiene fragments vary by less than 0.1 Å. This is even more apparent when examining the bond orders (Table 3). The bond orders for these bonds only vary from 1.56 to 1.62. The bond order of the forming σ-bonds is about 0.3. Summation of the bond orders of these active bonds is nearly 7 in all four TSs, suggesting a synchronous concerted reaction.

The most favorable TS for Reaction 1 is **TS1tn** with an activation energy of 26.10 kcal mol^{-1}. **TS1tx** lies only 0.24 kcal mol^{-1} higher, and **TS1cn** is only 0.38 kcal mol^{-1} higher still. The preference for *endo* over *exo* approach is 0.24 kcal mol^{-1} in the *trans* case and 0.76 kcal mol^{-1} in the *cis* case.

While there is no experimental data to which we can directly compare these results, we can compare our calculations with theoretical results of related systems. Jorgensen, Lim, and Blake (17) have examined the reaction of cyclopentadiene with isoprene at MP3/6-31G*//HF/6-31G*. The geometries of the TSs for the reaction of cyclopentadiene with isoprene are very similar to ours, particularly the distances of the forming σ-bonds. The larger differences in these bond lengths in the *cis* isomers relative to the *trans* isomers are found in the isoprene case. Energetic preference for the *endo* approach is indicated in both the isoprene and our butadiene studies. However, in the isoprene reaction, the lowest TS is the *endo-cis* isomer, favored by 0.53 kcal mol^{-1} over the *endo-trans* isomer. Houk and co-workers noted a preference of the *endo-cis* TS over the *endo-trans* of 0.6 kcal mol^{-1} in the reaction of butadiene with acrolein (16) (but at a much lower computational method). In the dimerization of cyclopentadiene, Jorgensen et al. found an *endo* preference of 2.71 kcal mol^{-1} (17). Clearly, the preference for *endo* over *exo* is confirmed, but the selection of *cis* over *trans* is not corroborated, though the energy differences in all cases is very small.

Reaction 2

The reaction of cyclopentadiene with butadiene, where cyclopentadiene acts as the dienophile, can proceed through two isomeric transition states, **TS2n** with an *endo*

approach or **TS2x** having an *exo* approach, as shown in Scheme 3.

We located four rotamers of the product **2**. **2a** and **2b** have the six-membered ring in the chair conformation and a staggered relationship across the fused bond. **2c** and **2d** have a boat conformation for the six-membered ring and a near eclipsed relationship across the fused bond. **2c** can be thought of as the direct product of an *endo* attack, while **2d** is the product from *exo* attack. The lowest energy rotamer is **2a**, and as expected, the boat conformers are somewhat higher in energy. The reaction energy is -35.40 kcal mol^{-1}. The experimental value for this reaction is not known. We can estimate the heat of formation of bicyclo[4.3.0]-3,7-nonadiene using Benson's group equivalents (25) (with the strain estimate of cyclopentene and cyclohexene) and with the experimental values for cyclopentadiene and 1,3-butadiene estimate the enthalpy of reaction to be -34 kcal mol^{-1}. Product **2a** is 12.44 kcal mol^{-1} more stable than **1tn**.

The bond lengths in the four rotamers of **2** differ only in the fused bond length. In the lower energy chair conformers this bond is 1.548 Å long, which increases to 1.564 Å in the higher energy boat conformers. This increase reduces the eclipsing interactions across this bond in **2c** and **2d** and accounts for the higher energy of the boat conformers.

The geometries of the two transition states **TS2n** and **TS2x** are drawn in Fig. 1. The bond distances in **TS2x** are similar to those found in **TS1** and related Diels–Alder TSs. There is little bond alternation in the butadiene fragment, and the dienophilic double bond has a similar distance. The other bonds of the cyclopentadiene fragment have begun to adjust to the loss of conjugation between the original double bonds. The forming C—C σ-bond distances are 2.330 and 2.098 Å, very similar to the forming distances in **TS1**. The shorter distance is to the carbon of the cyclopentadiene adjacent to the saturated carbon. The bond orders for **TS2x** indicate a synchronous TS. The forming/breaking double bonds have bond orders ranging from 1.55 to 1.68 and the sum of the active bond orders is 6.99. The activation energy through **TS2x** is 30.72 kcal mol^{-1}, or 4.62 kcal mol^{-1} greater than through **TS1tn**. In other words, **TS2** has a perfectly ordinary structure.

The same cannot be said for **TS2n**. The length of the dienophilic C—C bond of cyclopentadiene is 1.502 Å, compared to 1.400 Å in **TS2x**. The butadiene fragment has one long C—C bond (1.481 Å) and then two adjacent shorter bonds (1.388 and 1.370 Å), compared to the non-alternation in **TS2x**. Most striking are the distances for the forming two σ-bonds: 1.596 and 2.532 Å. These distances suggest one C—C bond is nearly formed in the TS and the second has barely begun to form. The geometry suggests a biradicaloid structure, where one new σ-bond has formed, creating two separated allylic systems. The bond orders support this notion. The shorter of the forming σ-bonds has a bond order of 0.80, and the "allylic" C—C bonds have bond orders from 1.60 to 1.69. The sum of the active bond orders is only 6.64, a significant loss of "bonds" in this TS. Since it is well known that biradical structures are poorly described at RHF, we will revisit this structure in a later section.

The activation energy for Reaction 2 through **TS2x** is 30.72 kcal mol^{-1}, 4.62 kcal mol^{-1} higher than the activation energy for Reaction 1.

Reaction 3

Analogous to Reaction 1, the Diels–Alder reaction of 2*H*-phosphole with butadiene as the dienophile proceeds through four stereoisomeric transition states. In addition there is also the regioselection of the vinyl group ending up adjacent to the carbon bridgehead (Reaction 3) or the phosphorus bridgehead (Reaction 4).

Of the four isomeric products of Reaction 3, the lowest energy is **3tn**, which is 0.50 kcal mol^{-1} more stable than the *exo* isomer. The *cis* isomer **3cn** lies 1.49 kcal mol^{-1} above the *trans* isomer, while **3cx** lies 0.23 kcal mol^{-1} higher still. This ordering (and the energy differences) are similar to the hydrocarbon case **1**. The geometries of **3** (shown in Fig. 4) are as expected, with little variation among the four isomers, and are similar to **1**, outside of the substitution of P for C at the bridgehead.

The four isomeric TSs are drawn in Fig. 2. The active C—C bonds that are either breaking or forming a π-bond vary from 1.385 to 1.390 Å, a remarkably small range, among the four isomers, while the active P—C distance varies only from 1.727 to 1.729 Å. The forming C—C σ-bond distance is 2.33 Å in the *trans* TSs and 2.38 Å in the *cis* TSs while the forming C—P σ-bond distance is shorter in the *cis* TSs than in the *trans* TSs. This reflects the steric interaction between the vinyl group and the cyclopentadiene fragment that lengthens the C—C distance in the *cis* isomer, which compensates by having a shorter C—P distance. These C—C distances are a bit longer than in **TS1** due to the longer C—P bond that is being formed in **TS3**, relative to the two C—C bonds being formed in **TS1**.

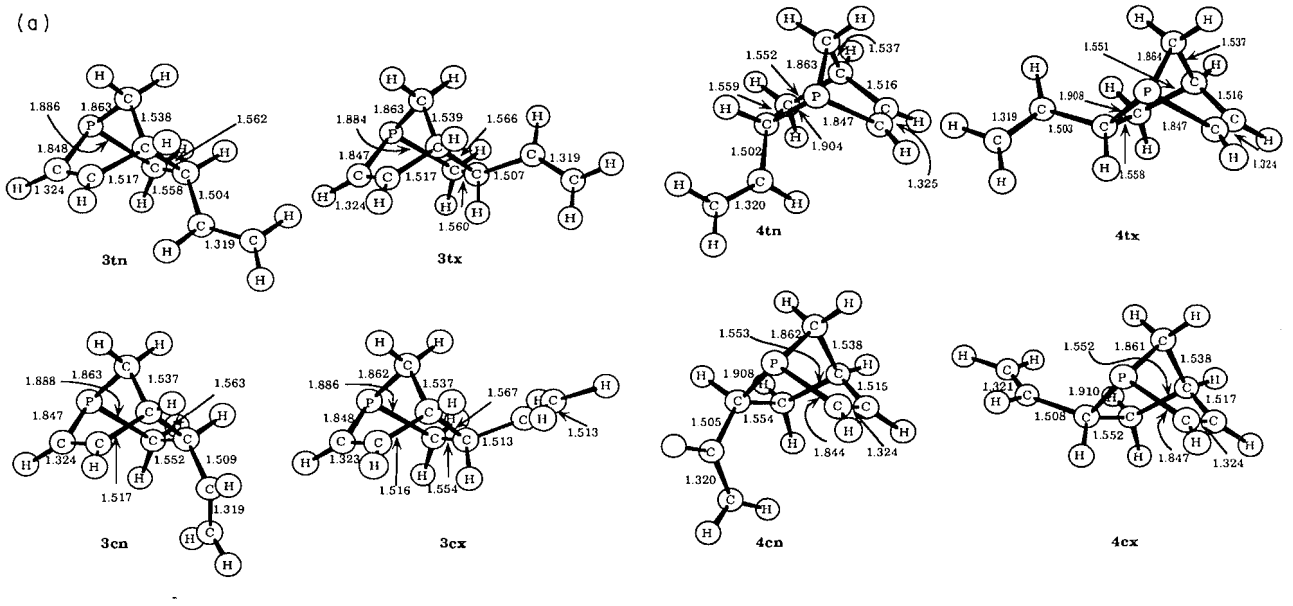
While it is clear from the active C—C distances that the TS appears synchronous, it is difficult to judge whether the C—P distances are also formed/broken to the same extent. The use of bond orders allows for direct comparison of different bond types, such as in this case. The bond orders for the active bonds involved in the π-bonds range from 1.56 to 1.67 only. The sum of the active bond orders is about 6.80. We have previously seen that the estimated bond order for partial C—P bonds is too low (6, 13), and an increased value would move the bond order sum to near 7. Just as for the hydrocarbon case, the TSs for Reaction 3 appear synchronous.

The smallest activation energy is through **TS3tn**, with a barrier of 16.71 kcal mol^{-1}. The barrier through **TS3tx** is only 0.18 kcal mol^{-1} higher, while the *cis* TSs are higher still. Again we see a preference for the *endo* over *exo* TS and for *trans* over *cis* conformation of the butadiene fragment. The relative order of the four TSs for Reactions 1 and 3 are identical, with nearly identical energy differences between the isomers. However, the barrier for the phosphorus case is nearly 10 kcal mol^{-1} lower than the hydrocarbon. This difference is in accord with our previous studies of phospha Diels–Alder reactions (6, 11, 12).

Reaction 4

The Diels–Alder reaction of 2*H*-phosphole with butadiene as the dienophile can proceed through four different TSs to give four isomeric products with the vinyl group adjacent to the phosphorus. The lowest energy product is **4tn**; the *exo* isomer is 0.33 kcal mol^{-1} higher in energy and the *cis* isomers are 0.90 kcal mol^{-1} higher still. **4tn** is 0.38 kcal mol^{-1} higher than **3tn**. The difference in energy between *endo* and *exo* isomers is

Fig. 4. HF/6-31G* optimized geometries of **3–6**. All distances are in Å and relative energies of **5** and **6** (MP4) are in kcal mol^{-1}.



reduced in **4** compared to **3**, especially in the *cis* case. In **4**, the vinyl group is adjacent to the phosphorus and therefore farther removed from the norbornene framework than in **3**, where it is adjacent to the carbon bridgehead. This increased separation diminishes the difference in steric interactions between the vinyl group and either the methylene or ethylene bridge. The geometries of the isomers of **4** are quite similar to each other and to the isomers of **3**.

Just as for the **TS3**, the geometries of **TS4** display a synchronous reaction. The active C—C double bonds have similar length in all four structures, which are also identical to the distances in **TS3**. Bond orders for the active bonds, including the P=C bond, range from 1.55 to 1.63 only, and the sum of the active bond orders is about 6.8.

The partially formed P—C bond distance is about 2.55 Å in the *trans* isomers and 2.6 Å in the *cis* isomers. These are longer than in **TS3**, reflecting the interaction of the vinyl group adjacent to the phosphorus in **TS4** vs. that adjacent to the carbon bridgehead in **TS3**.

TS4tn is the lowest energy TS for Reaction 4, with a barrier of 17.85 kcal mol^{-1}. As for Reactions 1 and 3, there is a slight preference for *trans* over *cis* and *endo* over *exo* TSs. **TS4tn** lies 1.14 kcal mol^{-1} above **TS3tn**.

Reaction 5

The Diels–Alder reaction of 1,3-butadiene with 2*H*-phosphole as the dienophile can occur via addition across the C=P (Reaction 5) or the C=C (Reaction 6) bond. We located three conformations of the product **5**, two boat conformers that correspond to direct *endo* **5a** and *exo* **5c** approach and a chair conformer **5b** (Fig. 4). The lowest energy conformer is **5a**. The reaction energy is −31.73 kcal mol^{-1}, nearly 6 kcal mol^{-1} more exothermic than Reaction 3.

The *endo* **TS5n** is 3.28 kcal mol^{-1} lower than **TS5x**, but it is 1.98 kcal mol^{-1} higher than **TS3tn**. The activation barrier for Reaction 5 is therefore about 10 kcal mol^{-1} lower than in Reaction 2, again showing the effect of replacing carbon with phosphorus in a Diels–Alder reaction.

The structure of **TS5x** is typical for phospha Diels–Alder reactions. There is little alternation in the butadiene fragment. The forming C—C and C—P distances fall in typical ranges. The bond orders of the active π-bonds range from 1.51 to 1.69, a little larger scatter than the other TSs examined here. The sum of the active bond orders is 6.78. With a slightly larger, more realistic, value for the forming C—P bond, this sum is close to the ideal value of 7.

The structure of **TS5n** is more unusual. While there is little alternation in the butadiene fragment, the bond orders for the active π-bonds range from 1.51 to 1.73, a wider range than usual. Further, the forming C—C distance is longer than the forming C—P distance, which is very short, only 2.337 Å. The active bond order sum is the same as for **TS5x**.

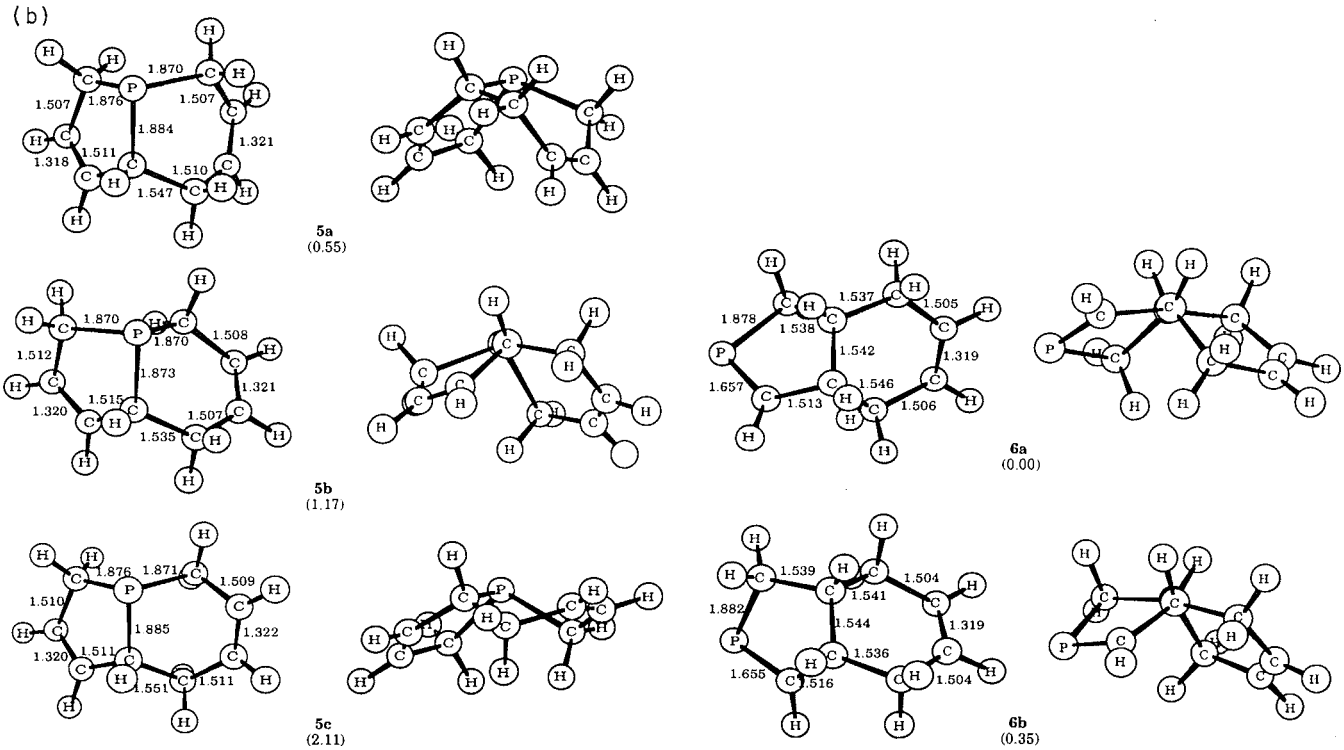
Reaction 6

Reaction 6 is the Diels–Alder reaction of 1,3-butadiene with 2*H*-phosphole as the dienophile, with addition across its C=C. The active bonds in this reaction are identical to Reaction 2; the difference is the "spectator" role of the C=P vs. the C=C bond. We located two chair conformations of the product **6**, but could not find any boat structures. The reaction energy is −32.90 kcal mol^{-1}, and is the most exothermic of the Diels–Alder reactions of 1,3-butadiene and 2*H*-phosphole.

The geometry of **TS6x** is as expected, except for the slightly short forming C—C distance of 1.976 Å. Otherwise, the structure shows only small alternation in butadiene and standard bond lengths. The bond orders in **TS6x** indicate the least synchronous of the concerted reactions examined here. The bond orders of the active π-bonds range from 1.48 to 1.71; nevertheless the sum of the bond orders is 6.94. Bond order is conserved, which is expected of a concerted reaction. The activation energy through **TS6x** is 29.67 kcal mol^{-1}, by far the largest value of any Diels–Alder reaction of 2*H*-phosphole with butadiene. However, this barrier is about 1 kcal mol^{-1} less than for the analogous reaction, Reaction 2.

Just as the geometry of **TS2n** indicated possible biradical character, the structure of **TS6n** also appears to have biradical

Fig. 4 (*concluded*).



character. Since the active bonds for these two TSs are identical, this similarity is not unexpected. The butadiene fragment has two C—C bonds of length 1.382 Å (an allylic system) and the C—C bond adjacent to the forming C—C σ-bond is 1.490 Å, just short of a standard single bond distance. The distance of the original C=C in phosphole is 1.519 Å. The two forming C—C single bonds have lengths 1.582 Å (nearly fully formed) and 2.331 Å. The bond orders reflect this biradical character as well. The new, short C—C bond has order 0.85. The allylic system in butadiene shows bond orders of 1.67 and 1.62, while the allylic system in phosphole, which includes the C—P bond, has bond orders of 1.57 and 1.62. This *endo* TS is best examined at the UHF level, which will be discussed below.

UHF analysis of reactions 2 and 6

The RHF calculations of Reactions 2 and 6 proceeding through the *endo* TSs strongly suggest biradical character. We therefore decided to reexamine these two reactions at the UHF level, which is more appropriate for treatment of biradical systems. Since the main focus of this work is the concerted Diels–Alder reaction, and given the enormous computational demands for examining all these reactions for biradical intermediates, etc., we have examined these two reactions at the UHF level only.

Before proceeding to the UHF results, we wish to note one additional unusual aspect of the RHF TSs for these two reactions. Tracing the intrinsic reaction coordinate (IRC) for the two TSs indicates that these TSs do not connect the presumed reactant with product. Rather, **TS2n** connects **1cn** with **2** and **TS6n** connects **4cn** with **6**. One should keep in mind that these results are for the RHF surface, which is likely to be totally inappropriate for describing these two reactions.

Reexamination of Reaction 2 at UHF/6-31G* led to the reaction sequence shown in Scheme 4. A stable intermediate **INT2** could not be located at UHF, but was optimized at UMP2/6-31G*. A TS leading from reactants to **INT2** was located (**TS2n′**) as was the TS connecting **INT2** with product (**TS2n″**). The optimized structures are drawn in Fig. 5. The critical geometric features of these structures are the distances of the forming bonds between the two fragments. In **TS2n′**, the distance between one terminal C of butadiene and the C adjacent to the saturated carbon of cyclopentadiene is 2.100 Å, while there is no interaction between the other end of the addends. In **INT2** the one new C—C bond has essentially formed (1.564 Å) while the other still has not begun to form. Finally, in **TS2n″**, the second new bond has begun, indicated by a distance of 2.286 Å.

The activation energy (UHF/6-31G*) to reach **TS2n′** is 21.6 kcal mol^{-1}. **INT2** lies 2.4 kcal mol^{-1} above reactants. **TS2n‴** is 10.3 kcal mol^{-1} above the intermediate, or 12.7 kcal mol^{-1} above reactants.

A similar situation arises for Reaction 6 at UHF/6-31G*, also shown in Scheme 4. Again, a stable intermediate was located (**INT6**) along with TSs leading to (**TS6n′**) and from (**TS6n″**) this intermediate. The progress of the reaction can be monitored via the forming bond distances. The first bond formed is between the terminal carbon of butadiene and the carbon of cyclopentadiene adjacent to the saturated center. This distance is 2.119 Å in **TS6n′** and the bond is formed in **INT6**, having a distance of 1.552 Å. The second bond is not formed at all by **INT6** but begins to form in **INT6n″**, with a separation of 2.207 Å. These structures are drawn in Fig. 5.

TS6n′ lies 19.4 kcal mol^{-1} above reactants, while **INT6** is actually more stable than reactants, lying 3.3 kcal mol^{-1} below

Scheme 4.

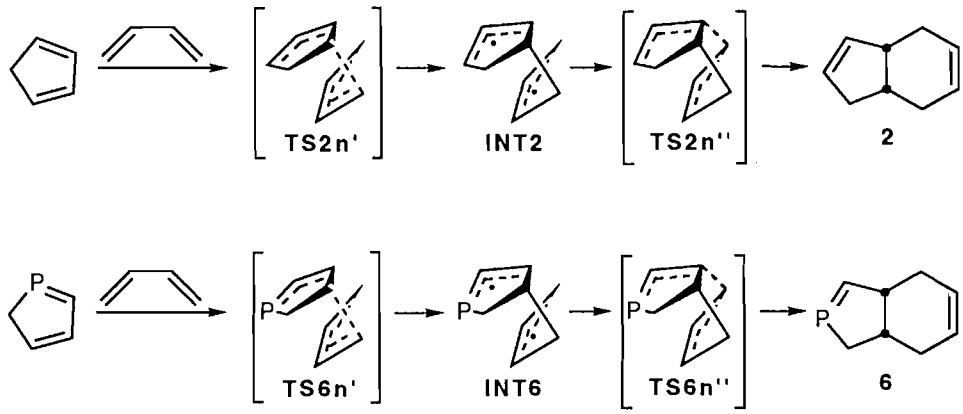


Fig. 5. UHF/6-31G* optimized geometries of transition states and intermediates from Scheme 5. All distances are in Å and relative energies are in kcal mol^{-1}.

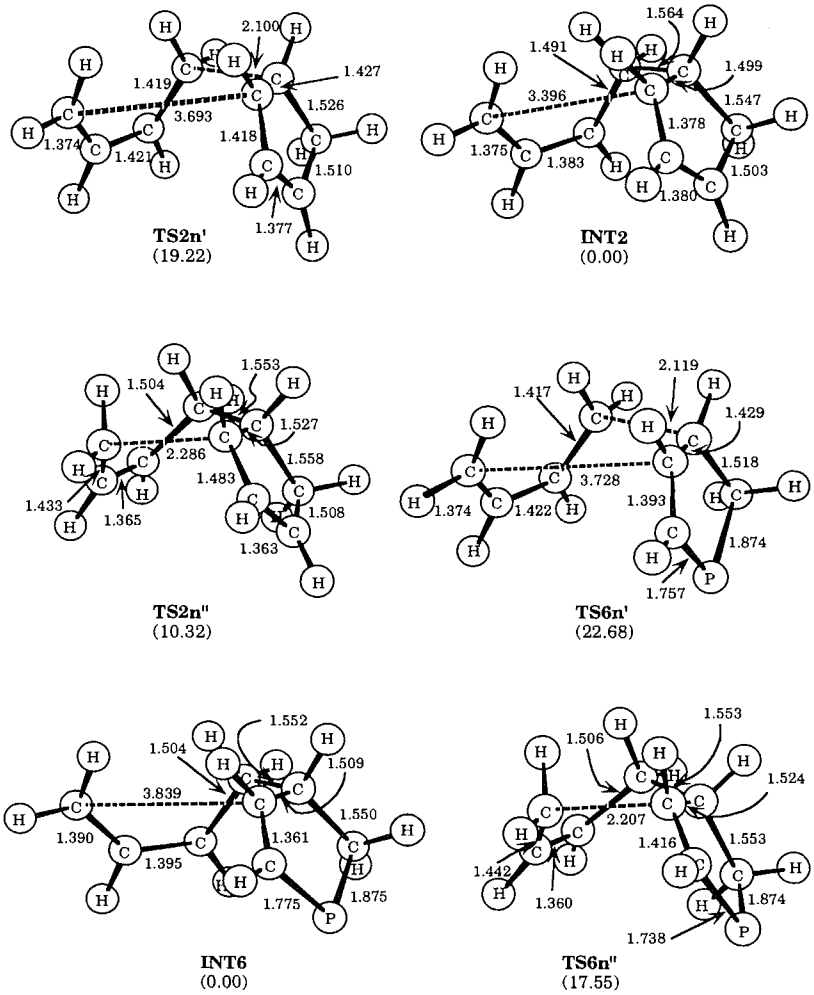

reactants. The barrier for the second step is 17.6 kcal mol^{-1}, or in other terms, **TS6n″** lies 14.3 kcal mol^{-1} above reactants.

At UHF/6-31G*, Reactions 2 and 6 forming the *endo* product proceed through a two-step process. In the first step, one new C—C single bond is formed, creating a stable biradical, which then forms the second new bond in the second step.

Discussion

We first examine the reactions for which we located concerted TS, i.e., excluding the reactions through **TS2n** and **TS6n**. The Diels–Alder reaction of cyclopentadiene with 1,3-butadiene can proceed in two ways, with either reagent acting as the

diene or dienophile. The reaction with butadiene as the dienophile (Reaction 2) is favored under thermodynamic control, which is understandable in terms of the greater ring strain in the norbornene product **1** than the bicyclic product **2**. The reaction where butadiene acts as the dienophile (Reaction 1) is kinetically favored. For normal, electron-demand, Diels–Alder reactions, the rate is dependent on the dienophile LUMO energy. The LUMO of butadiene is lower than in cyclopentadiene, making it the better dienophile. For Reaction 1 there is slight preference for *endo* selectivity and the *trans* conformation of the butadiene. This selectivity is consistent with previous calculations.

Products **5** and **6** are more stable than **3** and **4**, analogous to the hydrocarbon case. However, the energy difference is smaller in the former case. This is likely attributable to the decreased ring strain energy in **3** and **4** relative to **1** since phosphorus occupies the bridgehead position in the former compounds, and is better suited to accommodate the small ring angles than is carbon.

Products **3** and **4** are kinetically favored over **5** and **6**, again similar to the hydrocarbon case. The activation energy for Reactions 3, 4, and 5 (*exo* only) are about 10 kcal mol^{-1} less than for Reactions 1 and 2. A principle reason is the high HOMO and extremely low LUMO (0.0750 eV) of 2*H*-phosphole, making this reagent extremely reactive, particularly noticeable in the low activation energy of the reaction leading to **5n**. The activation energy for Reaction 6 is very similar to those of Reactions 1 and 2, where the active bonds all involve just carbon.

There is a distinct preference for *endo* selectivity in all of the phosphole reactions, though this selectivity is reduced in Reaction 4. The longer distance between the vinyl group and the five-membered ring in Reaction 4 compared to that in Reaction 3 dampens the discrimination. Reaction through the *trans* conformation of butadiene is also slightly favored in the reactions of phosphole. Again, this is consistent with the hydrocarbon results.

All of the concerted TSs are remarkably synchronous based on both bond distances (where appropriate comparisons can be drawn) and empirical bond orders. Perhaps most intriguing are the results of the reactions of phosphole. Even though the symmetry has been substantially broken by the phosphorus substitution, and the forming σ-bonds have very different lengths, the bond orders of the forming/breaking π-bonds are very close. The new σ-bonds have bond orders that match the degree of bond making/breaking at the other active bonds. This is best seen in the conservation of bond order between reactant, TS, and product.

The stepwise, biradical pathway for the Diels–Alder reactions has been shown to be about 10 kcal mol^{-1} less favorable than the concerted pathway for the reaction of 1,3-butadiene with ethylene and 5 kcal mol^{-1} less favorable in the dimerization of 1,3-butadiene (15). For the reactions examined in this study, the stepwise pathway will be further stabilized due to the possible formation of two allylic radicals. While detailed examination of the stepwise vs. concerted reactions is beyond the scope of this paper, two of the reactions examined here clearly proceed by the biradical pathway.

The reactions proceeding through **TS2n** and **TS6n** are distinctly different from the others. These transition states strongly suggest a biradical pathway. Our low-level investigation of the biradical pathway for both reactions confirms a biradical intermediate and therefore a two-step reaction mechanism. Our methods do not allow for direct energetic comparisons between the concerted (RHF) and biradical (UHF) energies, but it is clear that the biradical pathway is preferred for these two cases, since we were unable to locate a concerted TS.

Reactions 2 and 6, which proceed through the *exo* TSs, can proceed in a concerted fashion, providing some indication of the delicate balance between the competing mechanisms. In the *endo* TSs, there is sufficient steric interaction in the concerted approach to favor the stepwise mechanism, which diminishes the steric interactions and provides for stabilization of the two radical centers through allylic delocalization. The steric interactions are small enough in the *exo* TSs for the concerted TS to occur.

The most striking aspect of this study is how similar the results are for the phosphole and cyclopentadiene reactions. For both systems, kinetic control leads to the norbornene product and thermodynamic control leads to the bicyclo[4.3.0]nonadiene product. There is a slight preference for the *endo* TS and also for the butadiene (as dienophile) to react in the *trans* conformation. The TSs are concerted and synchronous, except for the case where butadiene is the diene and addition is *endo*. For this situation, both phosphole and cyclopentadiene react in a stepwise fashion. The only difference of note is the lower activation energies for the reactions of phosphole. The C=P double bond reacts analogously to the C=C double bond, except that its smaller bond energy leads to reduced activation barriers.

Finally, the calculated results are consistent with the experimental results. The reaction shown in Scheme 2 is conducted at high temperature (170°C) and for 5 days (4). The observed product corresponds with our thermodynamic product and, under these conditions, thermodynamic control is likely to prevail.

Conclusion

A major theme of our research program has been to explore the mechanistic changes brought on by replacing carbon with phosphorus in pericyclic reactions. In this paper, we explore the effects of replacing a carbon in cyclopentadiene with phosphorus. There is near-perfect similarity in the predications of the stereochemistry, energetics, and mechanistic path for these two systems. Thermodynamic preference is for formation of the bicyclo[4.3.0]nonadiene product, while kinetic preference is for the norbornene product. The *endo* TSs are lower in energy than *exo* TSs, with preference for the butadiene to be in the *trans* conformation. For the reaction of butadiene as the diene component and *endo* orientation, the reaction with both cyclopentadiene and 2*H*-phosphole proceeds through a stepwise, biradical mechanism; otherwise all reactions have concerted TSs, which show synchronous bond formation/cleavage. These results are in agreement with our previous studies, strongly indicating that the C=P double bond behaves identically to the C=C double bond in pericyclic reactions.

Inner-shell excitation spectroscopy of aniline, nitrobenzene, and nitroanilines

Cássia C. Turci, Stephen G. Urquhart, and Adam P. Hitchcock

Abstract: Oscillator strengths for C 1s, N 1s, and O 1s excitation spectra of aniline, nitrobenzene, and the isomeric nitroanilines have been derived from inner-shell electron energy loss spectroscopy recorded under low momentum transfer conditions (>2.5 keV impact energy and small scattering angle, $\theta \leq 2°$). Extended Hückel Molecular Orbital (EHMO) calculations carried out within the equivalent core analogy are used to aid spectral interpretation. These spectra are used to investigate the sensitivity of core excitation spectroscopy to charge transfer interactions in aromatic molecules that have both electron-donating and electron-withdrawing substituents. Strong multielectron excitation features were not found, although these had been anticipated from photoemission studies. The C 1s $\rightarrow \pi^*$ and N 1s $(NH_2) \rightarrow \pi^*$ spectral features of the nitroanilines are found to be strongly dependent on the substitution pattern (*ortho*, *meta*, or *para*).

Key words: electronic structure, inner-shell excitation, nitroanilines, EHMO calculations.

Résumé : En se basant sur la spectroscopie de la perte d'énergie des électrons des couches internes dans des conditions de faible transfert du moment (énergie d'impact >2,5 keV et faible angle de diffusion, $\theta \leq 2°$), on a dérivé les forces d'oscillateur des C 1s, N 1s et O 1s pour les spectres d'excitation de l'aniline, du nitrobenzène et des nitroanilines isomères. Comme aide à l'interprétation spectrale, on a utilisé des calculs d'orbitales moléculaires de Hückel étendues (OMHE) effectués à des conditions correspondantes à celle de l'analogie équivalente à celles des couches internes. On a utilisé ces spectres pour étudier la sensibilité de la spectroscopie d'excitation des couches intérieures aux interactions de transfert de charge dans des molécules qui portent à la fois des substituants électrodonneurs et électroattracteurs. On n'a pas observé de caractéristiques de fortes excitations multiélectroniques, même si on les avait anticipées sur la base des études de photoémission. On a observé que les caractéristiques spectrales des transitions C 1s $\rightarrow \pi^*$ et N 1s $(NH_2) \rightarrow \pi^*$ des nitroanilines dépendent fortement des positions (*ortho*, *méta* ou *para*) des substituants.

Mots clés : structure électronique, excitation des couches intérieures, nitroanilines, calculs d'OMHE.

I. Introduction

This study was motivated by observations in the early 1980s of intense satellite structures in the N 1s X-ray photoelectron spectra of gas phase and condensed *para*-nitroaniline and related compounds (1–11). The X-ray photoelectron spectrum (XPS) of solid *para*-nitroaniline exhibits a single sharp line attributed to N 1s(NH_2)[2] ionization and a 2 eV doublet with approximately equal intensity components initially attributed to N 1s(NO_2) ionization. Early interpretations (1) suggested that the lower binding energy component of the two peaks attributed to N 1s(NO_2) ionization was actually a multiconfigurational state in which N 1s(NO_2) ionization combined with a $\pi \rightarrow \pi^*$ excitation resulted in a state at *lower* energy than that of the one-electron N 1s(NO_2) ionization i.e., a *shake-down* satellite. This unusual situation was ascribed to a facile intramolecular charge transfer in this classic push–pull, donor–acceptor species. However, the N 1s XPS spectrum of gas phase *para*-nitroaniline was found to have a single broad N 1s(NO_2) peak (2) that, upon better resolution, was shown to consist of an asymmetric peak structure (6). Further work involving comparisons of vapour and solid state XPS spectra of *para*-nitroaniline (2, 6, 9, 11), and quantum calculations (4–6, 12) led to alternate spectral interpretations, including a more conventional *shake-up* picture in which the main line, one-electron N 1s(NO_2) ionization was attributed to the lower energy component of the doublet and the intense satellite at 2 eV higher energy was attributed to a $(NH_2) \rightarrow (NO_2)$ charge-transfer satellite of the N 1s(NH_2) line. Differences between the gas and solid state N 1s XPS were attributed to intermolecular charge transfer (9, 10, 12, 13) or hydrogen bonding effects in the solid (6).

The presence of the intense shake (charge transfer) satellites in the N 1s (and to a lesser extent, the O 1s) XPS led us to wonder whether the donor–acceptor character of disubstituted benzenes such as nitroaniline might give rise to analogous intense multielectron satellite structures in the core excitation spectra. Core excitation spectra might be expected to show satellite features closely related to those in core ionization

[2] The core level involved is indicated by this notation. The character of the upper level of a given transition is indicated by a subscript, e.g., π^*_{NO}.

when the same core hole is involved. However, the discrete core excited states are neutral and the excited electron can have strong shielding effects such that the electron reorganization (charge transfer) that leads to XPS satellite lines may be strongly suppressed. Thus, rather than dramatic shake-up features analogous to those seen in XPS, there might be threshold onsets at the energy of the XPS shake-up signal superimposed on other spectral features in the continuum region of the core excitation spectrum (similar to those identified in the core spectra of some simple molecules such as CO and N_2 (14)), but there may not be any strong, sharp-line, multi-electron excitations built upon the main 1s $\rightarrow \pi^*$ discrete transitions. The initial motivation of our study was then to determine which of these two scenarios the experimental spectrum most resembled.

Another interesting theme of the core excitation spectroscopy of these molecules is the dependence of the C 1s $\rightarrow \pi^*$ structure on the nature of the disubstitution pattern (*ortho* versus *meta* versus *para*). While the core excitation spectra of several homo disubstituted benzenes have been studied previously (15, 16), to our knowledge this is the first study of the core spectra of a hetero disubstituted benzene. The pattern of unoccupied π^* orbitals will be affected by π^* electronic interaction between the NH_2 and NO_2 substituents through the ring-π^* system which, in turn, will depend on the substitution pattern. This, along with changes in the C 1s chemical shifts, should be reflected in the C 1s $\rightarrow \pi^*$ signals. If a characteristic signature for *ortho*, *meta*, and *para* substitution patterns can be identified, this could be useful with regard to analytical applications of NEXAFS spectroscopy, such as polymer microanalysis (16, 17).

In this work, inner-shell electron energy loss spectroscopy (ISEELS) has been used to record the C 1s, N 1s, and O 1s spectra of the three isomeric nitroanilines. In addition, the core spectra of nitrobenzene and aniline have been measured, in order to use spectral comparisons to aid assignment. The experimental conditions (high impact energy and small scattering angle) are such that the ISEELS spectra are expected to exhibit the same spectral features with similar relative intensities as those of the corresponding photoabsorption spectra. To our knowledge, aniline is the only one of these species for which core excitation spectra have been reported earlier (18–20), namely, X-ray absorption (NEXAFS) studies of the condensed multilayer solid.

The experimental spectra are reported on absolute oscillator strength scales using a previously developed conversion scheme (21). Extended Hückel (EHMO) calculations and a simple semiempirical molecular orbital method (22–24), carried out within the equivalent ionic core virtual orbital model (EICVOM) (25, 26), have been used to assist spectral assignments and to explore aspects of the virtual molecular orbital electronic structure of these species.

II. Experiment

The gas phase ISEELS spectrometer employed in these experiments has been described in detail previously (27). Basically, it is a high-vacuum apparatus consisting of an electron gun, sets of electrostatic deflector plates for beam steering, beam current monitors, a gas cell, a post collision deceleration lens, a hemispherical electrostatic energy analyzer, and a single electron counting detection system. The detector pulses are processed by standard electronics (preamplifier, amplifier, discriminator) and are counted by a microcomputer that also scans the analyzer voltages and stores the acquired data. The spectrometer is operated under conditions of small momentum transfer where the electronic excitations are dominated by electric-dipole-allowed transitions. The impact energy is 2.5 keV plus the energy loss and the scattering angle is ~2°C. The overall spectral resolution was typically in the range of 0.6–0.8 eV full width at half maximum (fwhm), although the C 1s spectrum of aniline was recorded with a resolution of 0.45 eV.

All samples were obtained commercially; aniline from BDH, nitrobenzene from Baker, and nitroanilines (*ortho*, *meta*, *para*), from Eastern. All samples had a stated purity better than 98%. They were run without further purification, except aniline and nitrobenzene, which were submitted to multiple freeze–pump–thaw cycles to remove any dissolved impurity gases or highly volatile components prior to their use. The least volatile samples, *para*-nitroaniline (mp 149°C), *meta*-nitroaniline (mp 114°C), and *ortho*-nitroaniline (mp 75°C) were placed inside a small glass tube attached directly to the collision cell of the spectrometer. For the *para* and *meta* compounds, the tube was gently heated with an internally mounted quartz–halogen bulb, while the end plates of the gas cell were water cooled to trap the vaporized sample and avoid insulating deposits on sensitive parts of the spectrometer. The aniline and nitrobenzene samples were sufficiently volatile to be introduced into the gas cell through a leak valve from a flask at low vacuum. Multiple spectra were obtained to confirm reproducibility.

The energy-loss scale was calibrated by recording the spectrum of a mixture of the unknown and a suitable reference molecule. The C 1s and O 1s spectra were calibrated using the C 1s $\rightarrow \pi^*$ (290.74(4) eV) (28, 29) and the O 1s $\rightarrow \pi^*$ (535.4(2) eV) (30) transitions of CO_2. The N 1s spectra were calibrated using the N 1s $\rightarrow \pi^*$ (401.10(2) eV) transition of N_2 (28, 29). The signal associated with a particular core edge was isolated from the underlying valence-shell ionization continuum by subtracting a smooth curve determined from a curve fit of the function $a(E - b)^c$ to the pre-edge experimental signal. These background subtracted spectra were then converted to absolute oscillator strength scales using a method described and tested previously (21).

III. EHMO calculations

Extended Hückel molecular orbital (EHMO) calculations were used to predict the core excitation spectra using the equivalent ion core virtual orbital model (EICVOM) (25, 26), as described previously (31–33). In the EICVOM method the localization and reorganization effects associated with core excitation are simulated by replacing the core excited atom with the element of one larger nuclear charge (the equivalent core approximation) and the valence electron count is corrected by adding a positive charge. The virtual orbital energies of the ground state of the cation are interpreted as the relative energies (approximate term values) of core $\rightarrow$ valence excited states while the intensities of each transition are assumed to be proportional to the sum of the square of the coefficients of the electric dipole coupled (2p) atomic orbitals on the 1s excited atom for each virtual MO (Σc^2_{N2p} for C 1s excitation, Σc^2_{O2p}

for N 1s excitation, and Σc^2_{F2p} for O 1s excitation). Extended Hückel calculations were performed with the CACAO molecular program (34) using the default EHMO parameters. The CACAO program provides pictures of the orbitals involved in the transitions that help to identify the spatial characteristics of the core excited electron density. The molecular geometries used in the calculation were ground-state experimental geometries taken from the literature (35).

To account for site-dependent core-hole localization effects on the virtual MOs (15) and the different chemical shifts in the 1s energies, the EHMO calculation of each spectrum is constructed from the results of calculations of the equivalent core analogy species with the core hole at all possible distinguishable sites (e.g., for *para*-nitroaniline, four distinct C 1s sites and two distinct N 1s sites). The core excitation spectrum for each site is constructed from the MO coefficients of all of the unoccupied MOs, with a peak at each eigenvalue assigned an area equal to the 2p density at the core excited atom (as given by twice the reduced charge matrix element (33)) and a width related to the eigenvalue. The experimentally observed line widths have been used as a guide to selecting fixed line widths in four ranges of eigenvalues, with gradually increasing line widths to account for the decreasing lifetime of higher energy continuum states.

Two procedures were explored for matching the EHMO to the absolute experimental energy scale. In the first one the zero of the eigenvalue scale for each component was set to the measured or estimated ionization potential (IP) (2, 36). The components were then added and the sum was shifted to match experiment at the prominent lowest energy π^* resonance. In the second procedure each site spectrum was placed on an absolute excitation energy scale by setting the strongest 1s $\rightarrow$ π^* feature in each site spectrum to the energy of the assigned experimental feature (table 8 provides details). The weighted sum of the individual site spectra (e.g., for C 1s in nitrobenzene, a 2:2:1:1 sum of C 1s(2,6), C 1s(3,5), C 1s(4), and C 1s(C-NO_2); see Fig. 2) was then the EHMO 1s spectrum for that species. The intensity of the EHMO spectrum was then scaled so that the integrated 1s $\rightarrow$ π^* intensity for experiment and EHMO was the same. To simulate the nonresonant part of the spectrum, an oscillator strength continuum component, generated from the tabulated values for the atom (37), was added. The second procedure, that in which the components are matched individually to experiment, gave more satisfactory agreement with experiment. This approach was used to calculate the spectra of each core level of all five molecules (a total of 14 predicted spectra).

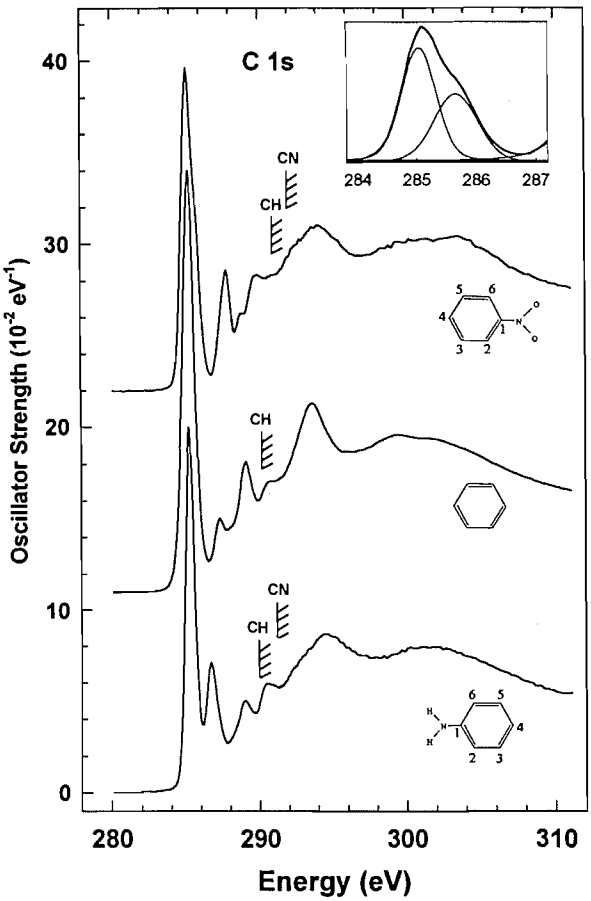
IV. Results

A. C 1*s* spectra

A.1 Aniline and nitrobenzene: monosubstituted models

The main features of the C 1s spectra of all five molecules of this study can be readily related to those of benzene (38). First we discuss the spectra of the two singly substituted benzenes, which act as models for the nitroanilines. Figure 1 compares the C 1s spectra of aniline and nitrobenzene with that of benzene. The energies, term values, and proposed assignments of the spectral features of aniline are presented in Table 1 along with results from the literature (19, 20), while the values for

Fig. 1. C 1s oscillator strength spectra of aniline and nitrobenzene, compared to that of benzene (38). All of the spectra were derived from energy loss spectra recorded under near-dipole scattering conditions (2800 eV impact energy, 2° scattering angle) with 0.7 eV fwhm resolution. The hatched lines indicate the measured IPs (36). The insert is an expansion and curve fitting of the first π^* peak in nitrobenzene.



nitrobenzene are presented in Table 2. (Note that the tables only list the spectral features that can be readily observed in the accompanying figures. A number of weaker shoulders, which can be detected on closer examination, have not been tabulated. Our orientation in this study is to explain the main features and their chemical trends. We believe an exhaustive interpretation of all core excitation features is best delayed until higher resolution data are acquired).

Since the orbitals of the amine group interact very little with those of the π manifold, the C 1s $\rightarrow$ π^* region of aniline should be relatively similar to that of benzene, modified mainly by the chemical shift of the C 1s(C-N) site and possibly by a splitting of the e_{2u} ($\equiv 1\pi^*$) orbital of benzene. The lowest energy peak in the C 1s spectrum of aniline is a relatively narrow symmetric line (0.8 eV fwhm) while there is a second band at 1.5 eV higher energy. Based on the similarity of the separation of these first two bands to the separation of the C 1s(C-H) and C 1s(C-N) IPs (1.0 eV (36)), we attribute the second component to the C 1s(C-N) $\rightarrow$ $1\pi^*$ transition. The third resolved peak, that at 289.0 eV, is attributed to the C 1s(C-H) $\rightarrow$ $2\pi^*$ transition (correlating with the b_{2g} ($\equiv 2\pi^*$)

orbital of benzene). There is debate concerning the assignment of the corresponding feature in benzene. Both experimental and theoretical studies provide evidence that the final state at 289 eV in benzene is one in which the one-electron ($C\ 1s^{-1}$, $\pi^*(b_{2g})$) configuration is heavily mixed with the ($C\ 1s^{-1}$, π^{-1}, π^{*2}) multi-electron excited configuration (39–41). By analogy to benzene, it is likely that the 289 eV feature in aniline may also contain contributions from multi-electron ($C\ 1s^{-1}$, π^{-1}, π^{*2}) excitations. We do not see any evidence in the aniline C 1s spectrum for the splitting of the $1\pi^*(e_{2u})$ into $2a_2$ and $4b_1$ levels, expected from the reduction of symmetry from that of benzene. According to the electron transmission spectrum of aniline (42) this splitting is of the order of 0.5 eV, which should be detectible. However, transitions to the $2a_2$ orbital are found from quantum calculations to have negligible intensity (see Sect. A.2).

The situation is rather different in nitrobenzene since the π and π^* orbitals of the nitro group interact with those of the ring. Essentially, four π^* orbitals must be considered in the spectral assignments of the C 1s spectrum of nitrobenzene (and also in the nitroanilines) — the three intrinsic π^* orbitals of the ring plus the π^*_{NO} — whereas only the three π^* orbitals of the ring are involved in aniline. While the nitrobenzene spectrum superficially resembles that of benzene, in fact there are marked differences. In particular, if the C 1s spectrum was analogous to that of aniline there should be a C 1s(C-N) → $1\pi^*$ peak around 286.1 eV, about 1 eV above the main C 1s(C-H) → π^* line at 285.1 eV since the C 1s(C-H)/C 1s(C-N) chemical shift is 1.0 eV (36). No such peak exists. However, there is a high-energy shoulder on the first peak, with a separation of 0.64 eV (see the insert to Fig. 1), which is effectively the C 1s(C-N) → $1\pi^*$ transition, but with a significant shift to lower energy because of mixing of the $1\pi^*_{C=C}$ and π^*_{NO} orbitals. In fact, the EHMO calculations (see next section) indicate that interaction of the $1\pi^*_{C=C}$ and π^*_{NO} orbitals has a major effect on all of the C 1s → π^* transitions, such that the second, fully resolved peak in the C 1s spectrum of nitrobenzene (287.8 eV) also arises from C 1s(C-H) → $1\pi^*/\pi^*_{NO}$ transitions. The C 1s → $2\pi^*$ transitions are relatively unchanged from those in benzene and aniline and are attributed to the peak at 288.8 eV and part of the broader signal at 289.7 eV.

At higher energy, the C 1s continua of aniline and nitrobenzene are relatively similar, each exhibiting a two-peaked pattern very similar to that of benzene (38). These features are attributed to C 1s → $\sigma^*_{C\text{-}C}$ transitions. According to the bond length correlation (43), which relates the position of 1s → σ^*_{XY} transitions referenced to the ionization threshold to the X—Y bond length, there should also be C 1s → σ^*_{CNH} (aniline) and C 1s → σ^*_{CNO} (nitrobenzene) features appearing around 291 eV. Broader structures in this region are so assigned in each species. The term value of the σ^*_{CN} feature in aniline is 1.6 eV smaller than that in nitrobenzene, consistent with the shorter C—N bond length in aniline (1.431 Å) than that in nitrobenzene (1.478 Å) (43).

[c]π^*_{mix} refers to a higher energy MO of π^* symmetry with both π^*_{NO} and $\pi^*_{C=C}$ character.

pares the experimental C 1s spectrum of nitrobenzene with that predicted from the EHMO-EICVOM calculations. In addition to illustrating the methodology used to align the individual site components with experimental data, this figure nicely reveals the important role of $\pi^*_{C=C}$ and π^*_{NO} orbital mixing in the C 1s spectrum. According to EHMO, the main π^* contribution for C_1 and $C_{3,5}$ excitations is from the $\pi^*(5b_1)$ orbital, which is an admixture of the π^*_{NO} and $\pi^*_{C=C}$ orbitals. However, at both the C_4 and $C_{2,6}$ sites, there is significant contribution from both the $4b_1$ and $5b_1$ orbitals, with each of these MOs having a combined $\pi^*_{C=C}$ and π^*_{NO} character. There is no significant contribution from the $3a_2$ component (derived from splitting of the e_{2u} orbital of benzene) at any C 1s site. At higher energy there is a small contribution from C 1s $\pi^*(6b_1)$ transitions at each site. Thus, EHMO suggests that the relatively simple experimental spectrum arises from the C 1s(C-H)/C 1s(C-N) chemical shift and a complex overlap of transitions to the $4b_1$ and $5b_1$ orbitals, which have a site-dependent mix of $\pi^*_{C=C}$ and π^*_{NO} character.

As illustrated in Fig. 2, the EHMO predictions for nitrobenzene are in reasonable agreement with experiment in the π^* region (284–288 eV). There is less satisfactory agreement in the region of the continuum onset (288–291 eV), in part because EHMO cannot reproduce spatially extended Rydberg states. There is also disagreement between calculation and experiment in the region of the continuum resonances (and this is true for all species of this study). These resonances are related to 1s excitations to high-lying σ^* MOs, which in some cases have a relatively localized character associated with specific structural aspects of the molecule (43). EHMO often predicts the correct pattern of high-energy σ^* features, but typically places the σ^* resonances at higher energies and with significantly distorted intensities. This could be related to inadequacies of EHMO and other semi-empirical quantum

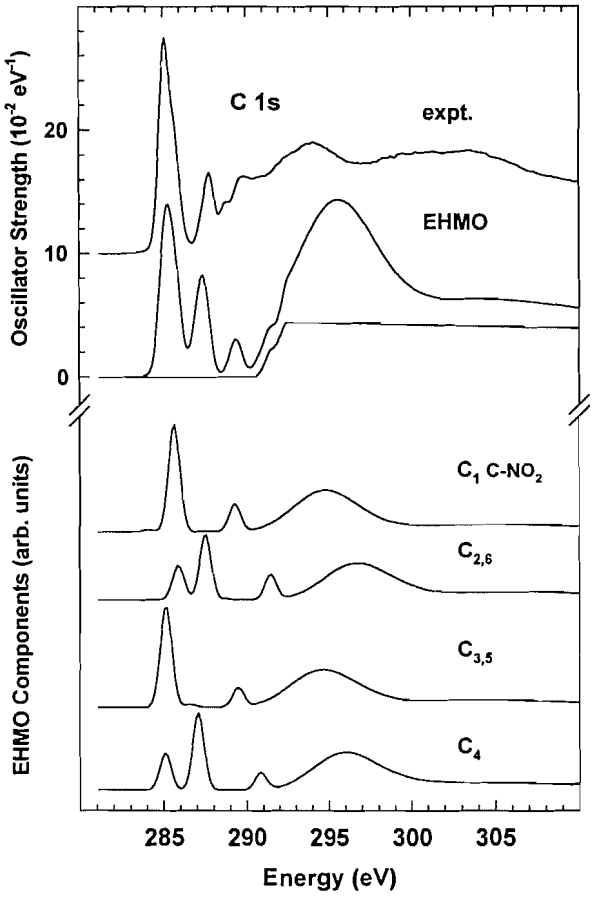
[a]{$\pi^*(2a_2)$, $\pi^*(4b_1)$} correlates with the e_{2u} orbital while $2\pi^*(5b_1)$ correlates with the b_{2g} orbital in benzene.
[b]The $4b_1$ and $5b_1$ orbitals are a site-dependent mix of the b_1 component derived from the $1\pi^*$ (e_{2u}) and the $1\pi^*_{NO}$ (b_1) orbital of the NO_2 group.

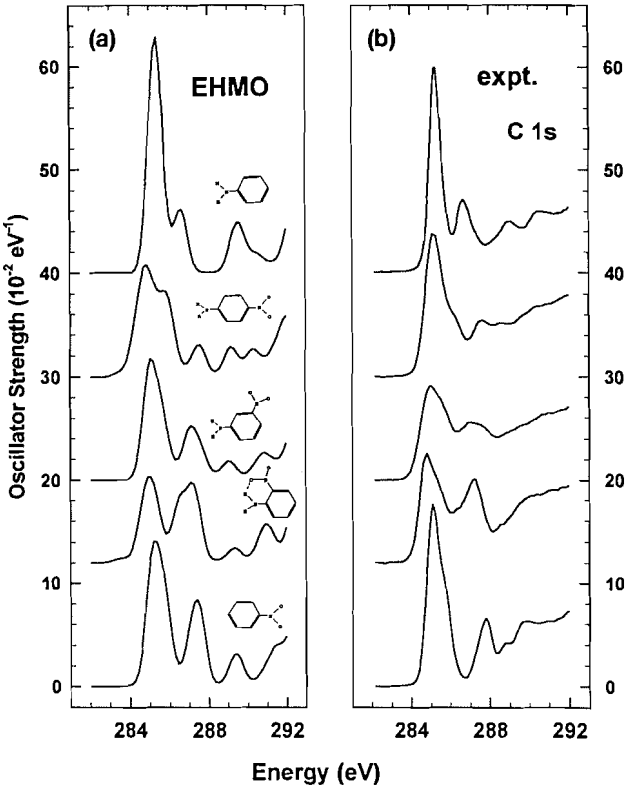
Fig. 2. EHMO predicted C 1s spectrum of nitrobenzene compared to experiment. The full C 1s EHMO spectrum is the sum of the indicated constituent components and a nonresonant ionization signal estimated from that tabulated for atomic carbon (37), aligned at the C 1s IPs. The EHMO component spectra were aligned with experiment at the approximate position of the main π^* resonance, with exact values chosen to obtain the best visual agreement with experiment (see Table 8).



calculations (44) at treating high-energy molecular orbitals. Interestingly, while EHMO overestimates the energy of high-lying σ^* levels, CNDO (44) appears to predict the corresponding levels at energies below those observed experimentally.

The EHMO results for aniline (Table 3, Fig. 3) are a close match to the qualitative spectral description given in the preceding section. The C 1s spectrum of gaseous aniline presented in this work is very similar to the C 1s NEXAFS spectrum of a multilayer of solid aniline on Ag(110) (19). The energies and assignments of the spectral features are generally in agreement with the present work. Solomon et al. (19) and Luo et al. (20) attributed the peaks at 286.9 and 288.7 eV in the NEXAFS spectrum of solid aniline to the presence of the NH_2 group, which, leads to chemical shifts in the C 1s levels and lifts the degeneracy of the $1\pi^*(e_{2u})$ molecular orbitals of benzene. The NEXAFS spectrum of solid aniline has been interpreted by Luo et al. (20) on the basis of high-level multiconfigurational self-consistent field (MCSCF) calculations, in which both relaxation and correlation effects are taken into account. One notable difference among these three studies of C 1s excited aniline is that we and Luo et al. (20) attribute the

Fig. 3. (*a*) C 1s spectra of aniline, the isomeric nitroanilines, and nitrobenzene in the region of the C 1s $\rightarrow \pi^*$ excitation, predicted from EHMO calculations. See the text and Table 8 for details of the line widths and shifts used to construct the predicted spectra. (*b*) Corresponding region of the experimental C 1s oscillator strength spectra.



lowest energy peak to C 1s (C-H) $\rightarrow \pi^*$ $(4b_1)$ transitions whereas Solomon et al. (19) have attributed it to combined C 1s $\rightarrow \pi^*(2a_2)$ and C 1s $\rightarrow \pi^*(4b_1)$ transitions. Although C 1s $\rightarrow \pi^*(a_2)$ transitions are allowed at the $C_{2,6}$ and $C_{3,5}$ sites in C_{2v} symmetry, both the EHMO and MCSCF calculations indicate that these have negligible intensity (see Table 3). Another interesting aspect of the EHMO results for aniline (and nitrobenzene) is that there is a reversal in ordering of the a_2/b_1 components associated with the $1\pi^*_{C=C}$ orbital between the ground and N 1s/ O1s states (where $a_2 < b_1$), and all of the C 1s excited states (where $b_1 < a_2$) . The reversal occurs because the C 1s core hole stabilizes the $\pi^*_{C=C}(b_1)$ orbital by 1.1–1.4 eV (see Table 3), but not the a_2 orbital. The "avoidance" of the core hole by the a_2 orbital is the reason there is no contribution from C 1s $\rightarrow \pi^*(a_2)$ transitions. Thus, on the basis of both energetics and intensities, EHMO indicates the main C 1s $\rightarrow \pi^*$ intensity is associated with the b_1 orbitals and not the a_2 orbital.

Table 4 compares our C 1s EHMO predictions of the lower energy π^* features of aniline with those from the MCSCF calculations reported by Luo et al. (20). The MCSCF calculations also indicate that transitions to the $\pi^*(a_2)$ orbital have negligible intensities. They show that the lowest core excited state is the $\{C\ 1s(3, 5)^{-1}, \pi^*(4b_1)\}$ state, which is almost degenerate (ΔE = 0.03 eV) with the $\{C\ 1s(2, 6)^{-1}, \pi^*(4b_1)\}$ state. The energy shift of the $\{C\ 1s(3, 5)^{-1}, \pi^*(4b_1)\}$, $\{C\ 1s(4)^{-1}, \pi^*(4b_1)\}$, and $\{C\ 1s(C\text{-}N)^{-1}, \pi^*(4b_1)\}$ states relative to the

Table 4. Relative spacings of C 1s → π* transitions for aniline from experiment and calculation.

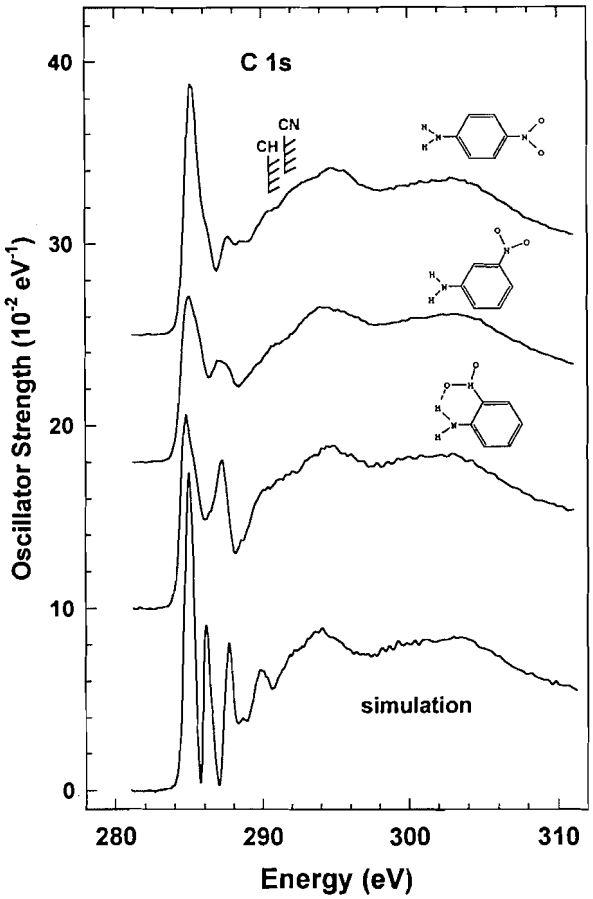
[a]From XPS (36).
[b]Assumes −ε from EHMO is equal to the term value. Typically this overestimates the transition energy by about 4 eV (see Table 8).
[c]E_{rel} is the energy relative to the C 1s(3, 5) → 1π*($4b_1$) transition.
[d]The splitting attributable to this separation is not detected. This value is an upper bound based on the 0.45 eV resolution of our ISEELS system and that of <0.2 eV in the NEXAFS study (20).

Fig. 4. C 1s oscillator strength spectra of the *ortho*-, *meta*-, and *para*-nitroaniline, compared to a simulation that is the sum of the C 1s spectra of nitrobenzene (shifted by −0.1 eV) and aniline (shifted +0.8 eV) minus that of benzene (shifted by +0.5 eV) (the shifts are the IP shifts). See Fig. 1 for experimental details.



lowest core excited state are also presented in Table 4. Overall the EHMO results agree very well with those from MCSCF calculations. Based on the energy differences between different core-excited states, Luo et al. (20) assigned the first resonance (285.4 eV) to $C_{2,3,4}$ → π*($4b_1$) transitions and the second resonance (286.8 eV) to C 1s(C-N) → π*($4b_1$) transitions, as in the present work. Our calculations indicate that the 290.5 eV feature, which lies above the C 1s(C-N) IP, is the C 1s(C-N) → π*($5b_1$) transition, as first proposed by Solomon et al. (19).

A.3 C 1s spectra of nitroanilines

The C 1s spectra of the isomeric nitroanilines are presented in Fig. 4, while the energies, term values, and proposed assignments are given in Tables 5, 6, and 7. The C 1s chemical shifts of nitroanilines have not been measured although an average C 1s IP of 291.1 eV for *para*-nitroaniline has been reported (2). Based on this value and the shifts between the C 1s(C-H) and the C 1s(C-N) IPs of 1.1 eV for aniline and 1.0 eV for nitrobenzene, we estimate the C 1s IPs of all three nitroanilines as 290.8 eV (C 1s(C-H)) and 291.8 eV (C 1s(C-N)).

If there was negligible interaction between the nitro and amine groups, one might expect the C 1s spectra of the nitroanilines to be similar to a weighted sum of the C 1s spectra of aniline and nitrobenzene as proposed by the "building block" approach (18). Figure 4 includes a comparison to a simulation of the spectrum generated in this manner. The substantial difference between the simulation and any of the nitroaniline spectra in the region of the π* structure indicates that the two substituents interact electronically to affect the unoccupied π* structure. Thus the details of the C 1s spectra provide insight into the donor–acceptor (push–pull) interactions between the NH_2 and NO_2 groups, through their influence on the carbon 2p contributions to the π* orbitals. Because the π^*_{NO} and $\pi^*_{C=C}$ levels of the three nitroanilines will interact in a manner similar to that in nitrobenzene, the spectral features are best explained using the nitrobenzene assignments as a model.

We attribute the first band (285–286 eV) in each of the nitroanilines to C 1s(C-H) → 1π* transitions and the second band (286.5–288.5 eV) to the superposition of C 1s(C-N) → 1π* and C 1s(C-H) → 2π* transitions. Both bands are structured in all three molecules, which is likely the effect of chemical shifts in the C 1s IPs, as well as shifts in state energies associated with the influence of the core-hole location on the energy of the π* orbitals. The C 1s continuum shape in all three nitroanilines is rather similar and can be readily interpreted as the doubly peaked structure of benzene with additional contribution from C 1s → σ^*_{CNO}, σ^*_{CNH} transitions around 290–292 eV. Further details of the ($C\ 1s^{-1}$, π*) spec-

tral assignments are provided by the EHMO results, which give insight into core-hole relaxation and delocalization effects.

Figure 3 plots an expansion of the experimental C 1s spectra for all five species in the π^* region between 284 and 290 eV, in comparison to the EHMO predictions. Table 8 lists the alignments that were used to generate each of the EHMO spectral predictions. If EHMO is a good tool for predicting core excitation on a relative energy scale, the "EHMO error" (SHIFT − IP) should be rather similar for all sites. Indeed the shifts are quite similar, with an average value of 4.1(1) eV, corresponding to a systematic overstabilization of the orbital energies, similar to that found for EHMO core excitation predictions in other systems (15, 32, 33). There are a few larger deviations, with the extrema of the EHMO errors being values of 2.2 and 5.5 eV for the C 1s(1) and C 1s(2) sites of *meta*-nitroaniline. It is possible these larger deviations are related to errors in the estimated IPs. Alternatively they may give insight into unusual, site-specific aspects of the electronic structure.

Figure 3 emphasizes that the C 1s → π^* signal varies con-

[d]See Fig. 8 for sketches of these orbitals.

[e]N 1s IPs estimated from those of *p*-nitroaniline (2). The solid state XPS data (48) suggest the ΔIP N 1s (NO_2 – NH_2) of *meta* is 0.7 eV higher than that in *para*, with identical NH_2 IPs. However, this gives an unreasonably large term value for the π^*_{NO} state. Thus we believe the reported *meta–para* difference (48) is specific to the solid state, as suggested in comparisons of gas and solid paranitroaniline (11–13). We assume that the N 1s IPs of all three isomers are the same in the gas phase.

siderably with the substitution pattern. Some of these changes can be attributed to variations in the C 1s energies as the position of the two electronegative substituents changes. However, additional effects, in particular changes in the electronic communication between the two substituents, are clearly important factors. Overall EHMO gives good agreement with the experimental spectra, giving confidence that the relative orbital energies and LCAO compositions predicted by EHMO are reasonable. The orbital characters of the component lines give insight into spectral assignments, in particular addressing the roles of (*i*) the C 1s chemical shifts; (*ii*) the contributions of the "$1\pi^*$" and "$2\pi^*$"; (*iii*) the site-dependent mixing of the $\pi^*_{C=C}(b_1)$ and $\pi^*_{NO}(b_1)$ components, in setting the detailed spectral shape of the C 1s → π^* signals. It is important to observe that, although the symmetry of the ground state and excited state conformations of *ortho*- and *meta*-nitroaniline is

[d]From XPS (2).

C_s, C_{2v}-based labels for the *para* isomer are used in the following discussion because of the similarity of the shapes of the C 1s MOs involved in the π^* transitions. As with nitrobenzene the EHMO component spectra indicate that the first four spectral features are a superposition of a number of 1s → $\pi^*(b_1)$ transitions at the distinct C 1s sites. In each case the $\pi^*(b_1)$ orbital has both $\pi^*_{C=C}$ and π^*_{NO} character. For C_1 (C-NO_2) and C_5 excitations in all three isomeric nitroanilines, C_3 excitation for *ortho*- and *para*-nitroaniline, and C-NH_2 excitation for the *meta* isomer, the C 1s → $\pi^*(6b_1)$ transition dominates. For the other sites (C_2 for *meta*- and *para*-nitroanilines, C_4 for *ortho*- and *meta*-nitroanilines, C-NH_2 for *ortho*- and *para*-nitroanilines, and the C_6 site for all nitroanilines) there is significant contribution from both the $6b_1$ and $5b_1$ orbitals. At higher energy there is a small contribution from C 1s → $7b_1$ ($2\pi^*$) transitions at all sites. In all three nitroanilines (as in nitrobenzene) the EHMO results suggest this $2\pi^*$ contribution comes about 0.5 eV higher in energy than in aniline or benzene. However these calculations do not take into account mixing with a doubly excited configuration ($C1s^{-1}$, π^{-1}, π^{*2}) that may shift the $2\pi^*$ transition to lower energy. The EHMO predicted spectra (Fig. 3) are consistent with our proposed

assignments of the experimental spectra, which are outlined in detail in Tables 5–7.

B. N 1*s* spectra

B.1 Aniline and nitrobenzene: monosubstituted models

Figure 5 plots the N 1s spectra of nitrobenzene and aniline. The N 1s spectrum of methyl amine (digitized from ref. 45) is also plotted in order to investigate possible effects of delocalization of the ring π^* orbitals onto the amine group. Energies, term values, and proposed assignments are given in Tables 1 and 2.

The dramatic difference between the N 1s spectra of aniline and nitrobenzene is associated with the essentially saturated character of the NH_2 group and the unsaturated character of the NO_2 group. Thus the N 1s spectrum of nitrobenzene is dominated by the strong N 1s $\rightarrow \pi^*_{NO}$ transition at 403.8 eV whereas the discrete structure in the N 1s spectrum of aniline is much weaker and can be interpreted as mainly Rydberg/σ^*_{NH} in character, as supported by the similarity of the discrete regions of the N 1s spectra of aniline and methyl amine. The N 1s continuum of aniline exhibits a broad feature centered at 407.6 eV, which is attributed to the N 1s $\rightarrow \sigma^*_{CN}$ resonance. It occurs at higher energy than the corresponding σ^*_{CN} resonance in methyl amine (404.6 eV), consistent with the shorter C—N bond length in aniline (1.431 Å) as compared to that in methyl amine (1.465 Å). Nitrobenzene has its main σ^*_{NO} resonance at 413.2 eV, with a weaker second resonance at 418.5 eV. According to the bond length correlation (43) there should only be a single N 1s $\rightarrow \sigma^*_{NO}$ resonance. However, this ignores delocalization effects, which, in molecules like CO_2 and NO_2, leads to a breakdown of the local bond picture of core excitation (46). Thus the higher energy band at ~418 eV is attributed to a second σ^*_{NO} resonance. The two σ^*_{NO} resonances are analogous to the σ_g^* and σ_u^* resonances in CO_2 (46), i.e., orbitals that can be described as positive and negative combinations of two localized σ^*_{NO} orbitals (see Sect. C for further discussion and a comparison to the corresponding O 1s $\rightarrow \sigma^*_{NO}$ features). The lower energy continuum band in nitrobenzene (413.2 eV) will also contain contributions from N 1s $\rightarrow \sigma^*_{CN}$ excitations. The positions predicted from the bond length correlation for the σ^*_{NO} and σ^*_{CN} resonances are 413 eV and 411 eV, respectively (R_{N-O} = 1.218 Å, R_{C-N} = 1.478 Å), in reasonable agreement with experiment.

B.2 N 1s spectra of nitroanilines

The N 1*s* spectra of the nitroanilines are presented in Fig. 6 while the energies, term values, and proposed assignments are summarized in Tables 5–7. Figure 6 also contains a simulated

spectrum, which is the sum of the N 1s spectra of aniline shifted up by 0.7 eV, and nitrobenzene shifted down by 0.3 eV, to account for differences in the IPs. As with the C 1s spectral simulation, if there was negligible interaction between the two substituents one would expect the measured N 1s spectra of the nitroanilines to be similar to this simulated spectrum. The poor agreement, particularly in the region below 403 eV, indicates there is significant electronic interaction between the NH_2 and NO_2 groups. The deviations from the simulated spectrum are thus a manifestation of the donor–acceptor character of nitroanilines.

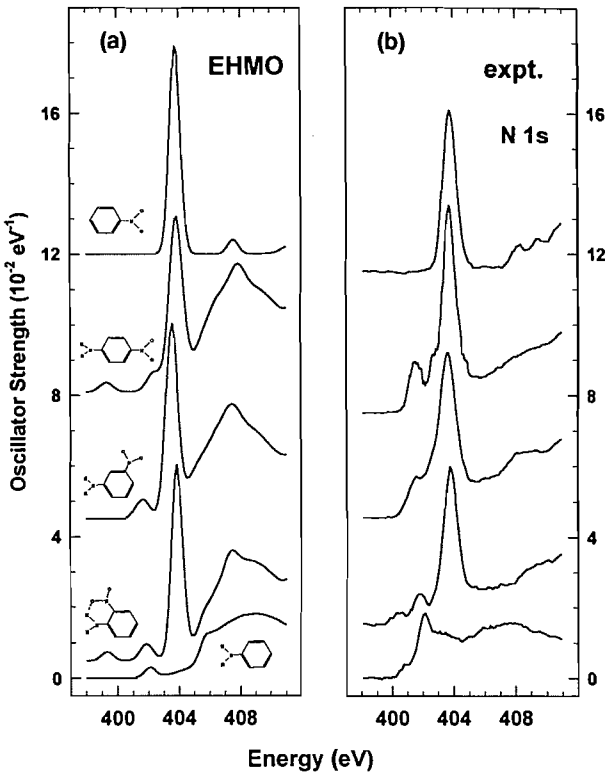
While the main features of the N 1s spectra of the three isomeric nitroanilines are similar (because of the dominance of the strong N 1s(NO_2) components) there are significant differences in the weak features between 400 and 403 eV that are associated with N 1s(NH_2) excitations. The main spectral feature around 404 eV is clearly the π^*_{NO} resonance. The N 1s continuum contains three broad resonances. The broad, lower energy feature, which is considered to extend from 406 to 410 eV, corresponds to the N 1s $\rightarrow \sigma^*_{CNH}$ transition in aniline and the σ^*_{CNO} resonance in nitrobenzene. The two higher energy features (~413, ~418 eV) correspond to the two continuum resonances in nitrobenzene. With regard to our initial motivation to search for evidence for strong shake-up effects analogous to those seen in XPS, if there was an abrupt threshold onset to the {N 1s$(NH_2)^{-1}$, (π^{-1}, π^*)} shake-up process this would appear as a continuum rise around 414 eV. While there are indications of a weak shoulder at this energy, particularly in the *ortho* and *para* species, these signals are quite weak. Clearly multi-electron excitations are much weaker than the corresponding $\pi \rightarrow \pi^*$ satellite signal in core ionization of nitroanilines (11, 12).

Although the main features of the N 1s spectra can be interpreted in terms of N 1s(NO_2) excitation as outlined above, there are notable differences among the N 1s(NH_2) signals in the nitroanilines. From XPS (1–11) the N 1s(NH_2) component is expected to be more sensitive than the N 1s(NO_2) component to charge transfer interactions between the amine and nitro groups. Of course, these interactions will depend on the substitution pattern. Clearly the lower energy part of the N 1s spectrum is strongly dependent on the pattern of substitution. Initially we were puzzled as to how to interpret this part of the N 1s spectra. If the peaks at 401.6–401.8 eV are correlated with the lowest energy N 1s $\rightarrow$ 3s peak in aniline (which is suggested by similarity in term value), then there is a large intensity enhancement. One then has difficulty in assigning the weak peak observed around 400 eV in *ortho*-nitroaniline. Alternatively one could correlate the 401.6 eV peak in the nitroanilines to the main discrete N 1s $\rightarrow$ 3p/π^* peak in aniline and the 400 eV peak to the lowest energy (3s) band in aniline. With this assignment the absence of the (3s) peak in the *meta* and *para* isomers is puzzling. Neither of these trial assignments are considered acceptable. A different and more satisfactory interpretation is provided by comparison with the EHMO calculations.

B.3 Comparison to N 1s EHMO predicted spectra

Figure 7 plots expanded presentations of the N 1s spectra of the five molecules, in comparison to the N 1s predictions from EHMO. As with the C 1s region, there is reasonable agreement between calculation and experiment. The N 1s spectra are

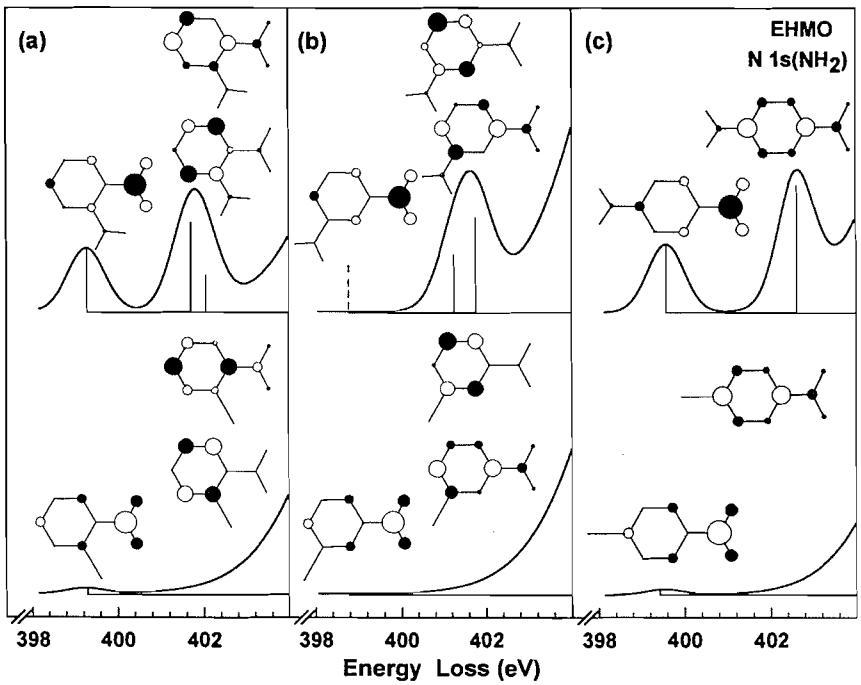
Fig. 7. (*a*) N 1s spectra of aniline, the isomeric nitroanilines, and nitrobenzene in the region below the N 1s IP, predicted from EHMO calculations. See the text and Table 8 for details of the line widths and shifts used to construct the predicted spectra. (*b*) Corresponding experimental N 1s oscillator strength spectra.



dominated by the strong π^*_{NO} and σ^*_{NO} resonances. EHMO predicts the N 1s(NO_2) component spectra contain a weak, higher energy π^* state of mixed $\pi^*_{NO}/\pi^*_{C=C}$ character that probably corresponds to the well-resolved band at 408.3 eV in nitrobenzene. The corresponding feature in the nitroanilines may exist in the 408–410 eV region but it would be masked by the N 1s(NH_2) $\rightarrow \sigma^*_{CNH}$ and N 1s(NO_2) $\rightarrow \sigma^*_{CNO}$ transitions. A similar, higher energy π^* feature is seen in the EHMO and experimental O 1s spectra (see Fig. 10 and Sect. C). While the N 1s(NO_2) $\rightarrow \pi^*_{NO}$ transition dominates the N 1s edge, there are features clearly attributable to N 1s(NH_2) excitation that EHMO reproduces quite well. In particular, the experimental pattern of the weaker features below 404 eV is also found in the calculated spectrum, with two low-lying N 1s(NH_2) peaks predicted by EHMO in *ortho*- and *para*-nitroaniline but only one in *meta*-nitroaniline. To better understand the origin of these signals it is useful to examine the MOs involved and their dependence both on substitution pattern and on the presence or absence of conjugation.

Figure 8 presents an expansion of the EHMO predictions of the N 1s(NH_2) component of the spectrum of *ortho*-, *meta*-, and *para*-nitroaniline calculated with the hydrogen atoms of the NH_2 group in the plane (the minimum energy conformation) and with the NH_2 group rotated by 90°. In addition Fig. 8 presents schematic MO diagrams of the low-energy π^* orbitals in these N 1s(NH_2) core excited species. In the planar geometry EHMO indicates there are two π^* bands with the

Fig. 8. Comparison of EHMO spectral predictions for N 1s(NH_2) → π* excitations of (*a*) *ortho*-, (*b*) *meta*-, and (*c*) *para*-nitroaniline. The upper trace in each panel is the predicted spectrum for the planar geometry while the lower trace is that calculated with the NH_2 rotated 90°, to place the H atoms out of the plane of the ring. Sketches for the lower energy π* orbitals are shown. These MO plots are projections of the 2pπ density with the diameter of the circles proportional to the 2pπ LCAO coefficient. The intensity of the peaks in the EHMO predicted spectrum is proportional to the 2pπ density on the core excited NH_2.



lower energy component being mainly π^*_{NO} while the higher energy component is mostly $\pi^*_{C=C}$ in character. In (planar) *meta*-nitroaniline there is only one N 1s(NH_2) → π* peak because the lower energy N 1s(NH_2) → π^*_{NO} excitation has zero intensity. When the NH_2 group is rotated by 90°, the π* delocalization is broken, the N 2p contribution to the π* orbital disappears, and the transitions are predicted to have essentially zero intensity. The EHMO results indicate that the intensity of N 1s(NH_2) → π* features in the nitroanilines and related molecules are sensitive to molecular geometry in a way that may be helpful in conformational analysis.

The agreement between EHMO and experiment for these N 1s(NH_2) excitations is surprisingly good, especially when one notes that the N 1s spectra of methylamine and aniline indicate there are significant contributions from N 1s(NH_2) → Rydberg transitions that EHMO cannot reproduce. The EHMO results for aniline (lowest curve in Fig. 7) indicate the $1\pi^*_{C=C}$ orbital has some density on the NH_2 group. This component increases considerably when the nitro group is added. The two low-lying N 1s(NH_2) excitations in *ortho*- and *para*-nitroaniline are reproduced by EHMO although the predicted separation of the two N 1s(NH_2) → π* components is larger than found experimentally. It is interesting to compare the N 1s spectra of nitroanilines with that of phenylurea (16). In both species a planar geometry leads to some $\pi^*_{C=C}$ density at the NH nitrogen atom. However the N 1s → $\pi^*_{C=C}$ transitions are much stronger in nitroaniline than in phenylurea, probably because of the strong charge-transfer coupling of the NO_2 and NH_2 groups through the ring π and π* orbitals.

It is also of interest to consider how the donor–acceptor character of these molecules is reflected in other aspects of the EHMO calculations of the core excitation spectra. Table 9 lists the total (valence electron) energy for planar and nonplanar geometries of the nitroanilines as well as a summary of the behaviour of the HOMO–LUMO gaps for different positions of the core hole in aniline, nitrobenzene and *ortho*-, *meta*-, and *para*-nitroanilines. In the neutral nitroaniline molecules the HOMO is localized on the carbons and the NH_2 (donor) substituent while the LUMO is localized on the ring and the NO_2 (acceptor) group. This expresses the donor–acceptor nature of the compound. The HOMO–LUMO gap is notably smaller in *meta*- relative to *ortho*- or *para*-nitroaniline, consistent with the less favourable situation with regard to "resonance stabilization" of the π-charge transfer (47).

The creation of a core hole changes the electron distribution in different ways. If an N 1s core hole is created on the NH_2 group, the levels with large NH_2 character are stabilized relative to those levels localized on the carbon ring or on the NO_2 group. In this situation, the charge distribution in the HOMO changes while that in the LUMO has practically the same shape as in the neutral molecules. At the same time, placing the core hole on the donor substituent increases the HOMO–LUMO gap. On the other hand, if the core hole is created on the N or O of the NO_2 group, the orbitals with NO_2 character

[a]In *ortho*-nitroaniline there is a 0.02 eV difference in $\Delta E_{H\text{-}L}$ when the O 1s hole is moved from the O atom closer to the NH_2 group to that farther from the NH_2 group. In all other cases, $\Delta E_{H\text{-}L}$ was the same for O 1s holes on each O atom.

are stabilized. In this situation the HOMO–LUMO gap decreases, facilitating the intramolecular donor → acceptor charge transfer with respect to the neutral state. In both types of core excitation the *meta* species follows a similar pattern but the HOMO–LUMO gap is smaller, reflecting less resonance stabilization. While the changing HOMO–LUMO gaps in calculations carried out on the "in-plane" geometry reflect the donor–acceptor aspect of these molecules, the situation is markedly different when the calculation is carried out with the NH_2 group rotated to remove $\pi_{C=C}/\pi_{NO}$ delocalization onto the NH_2. In the nonplanar geometry the changes with core-hole location parallel those seen in the in-plane geometry, but the HOMO–LUMO gap is similar in all three isomers. This is consistent with removing the π-delocalization component of the charge transfer.

C. O 1s spectra

Figure 9 plots the O 1s spectra of the nitroanilines and nitrobenzene, while the energies, term values, and proposed assignments of the spectral features are given in Tables 2, 5, 6 and 7. The O 1s spectra for all four species are very similar. They are dominated by the strong O 1s → π^*_{NO} transition at 531 eV. At 534 eV there is a weak feature that could be either a Rydberg state (3s, based on its term value) or a weak excitation to a higher energy π* orbital. On the basis of the EHMO results we assign the 534 eV feature to a second O 1s → π* transition. Figure 10 plots expanded regions of the O 1s spectra in comparison to the O 1s EHMO spectra. As with the C 1s and N 1s spectra, there is good agreement between the EHMO predictions and the experimental O 1s spectra. EHMO predicts a dominant O 1s → π^*_{NO} feature and a relatively strong second O 1s → π^*_{mix} transition (π^*_{mix} is an orbital of mixed π^*_{NO} and $\pi^*_{C=C}$ character). The predicted π^*_{mix} feature likely corresponds to the weak signal at 534 eV in the experimental spectrum. The O 1s EHMO spectra were also determined for the molecules with the NO_2 group rotated by 90°. In this case the π^*_{mix} feature disappears, confirming that the 534 eV feature involves π^*_{NO} delocalization onto the ring.

The O 1s continuum has two broad resonances at 538 and 541 eV, with the higher more intense than the lower energy peak. While EHMO calculations are relatively poor at predicting the *positions* of continuum features, the general shape is often reasonable and thus the calculations can provide some insight into spectral assignments. According to the EHMO calculations there are three main contributions to each of the N 1s and O 1s continua. Figure 11 plots the molecular orbitals for N 1s(NO_2) and O 1s excited *para*-nitroaniline (the EHMO results for the 1s continua are similar for the *ortho* and *meta*

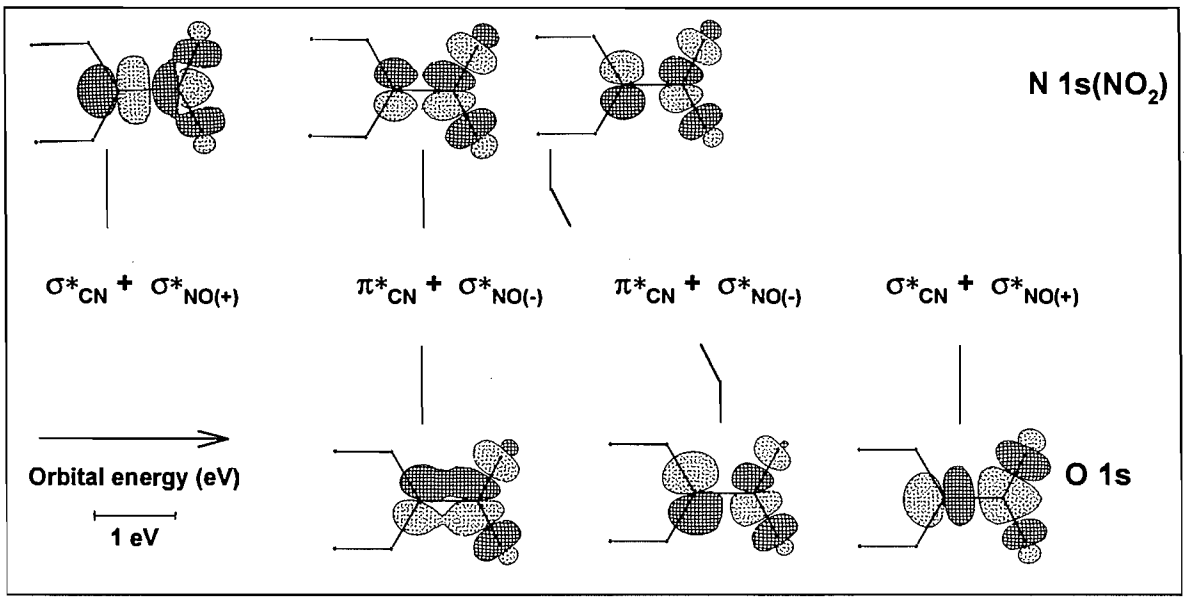
isomers). The figure shows only that portion of the MO which is critical to the core excitation under consideration. The two most intense contributions are mainly σ^*_{NO} in character, where $\sigma^*_{NO}(-)$ and $\sigma^*_{NO}(+)$ are (+/-) and (+/+) linear combinations of localized σ*(N-O) basis functions. These are analogous to the σ_u^* and σ_g^* resonances that are observed in the O 1s spectrum of CO_2 (46). In *para*-nitroaniline these continuum orbitals have a partial π^*_{CN} and σ^*_{CN} in addition to a σ^*_{NO} character according to the EHMO calculations. In the N 1s spectrum the σ^*_{NO} features are attributed to the peaks around 413 and 418 eV. Interestingly, relative to the situation in the O 1s spectrum, $\sigma^*_{NO}(+)$ is at much lower energy than $\sigma^*_{NO}(-)$ in the N 1s spectra and thus the $\sigma^*_{NO}(-)/\sigma^*_{NO}(+)$ ordering predicted by EHMO for the O 1s spectrum is reversed to a $\sigma^*_{NO}(+)/\sigma^*_{NO}(-)$ ordering in the N 1s continuum. This is because, in the presence of a N 1s core hole, there is strong mixing with the σ^*_{CN} orbital, which leads to a much lower energy of the $\sigma^*_{NO}(+)$ orbital in N 1s core-excited than O 1s core-excited nitroanilines. The reversal of $\sigma^*_{NO}(+)/\sigma^*_{NO}(-)$ orbital ordering predicted by EHMO is a plausible explanation of the change in the relative intensities of the continuum features between the N 1s and O 1s spectra.

V. Summary

The C 1s, N 1s, and O 1s electron energy loss spectra of aniline, nitrobenzene, and *ortho*-, *meta*-, and *para*-nitroaniline have been recorded under dipole conditions and converted to oscillator strengths. The spectra do not exhibit any unusual features attributable to exceptionally strong shake-down or shake-up processes, associated either with multi-electron excitations or with the threshold of the shake-up process observed in XPS. This is consistent with electronic shielding from the core-excited electron providing strong damping of the charge-transfer relaxation process believed to give rise to signal from shake-up ion states in the XPS (1–11). Assignments for all spectral features have been proposed through a combination of analysis of systematic trends and comparison to EHMO results. The EHMO results do not reproduce completely all characteristics of the experimental spectra, but they are very useful for providing a good understanding of the effect of the core hole and for giving important insight into the interpretation of the core excitation spectra. A minor revision has been suggested to a previous assignment of the C 1s NEXAFS spectrum of solid aniline (19). The low-energy N 1s(NH_2)→ π* features in the N 1s spectra of the nitroanilines were found to be remarkably sensitive to the substitution pattern and the extent of π-delocalization. While some aspects of the π* signals in the C 1s and N 1s spectra may be characteristic of ring substitution patterns it is difficult to generalize from this example because of effects specific to the nitro-

Fig. 11. Sketches of selected high-energy molecular orbitals of σ^*_{NO} character in the region of the C-NO_2 group derived from extended Hückel calculations of N 1s(NO_2) and O 1s excited *para*-nitroaniline. In each case these three orbitals are the only significant contributions to continuum resonance intensity. The vertical lines indicate the relative spacing of the orbital eigenvalues for each core excited species. A shift of 10 eV was applied between the N 1s(NO_2) and O 1s energy scales. Each orbital has large $\sigma^*_{C=C}$ components in addition to those plotted.



anilines, namely strong $\pi^*_{C=C}/\pi^*_{NO}$ mixing and electronic interaction through the ring π/π^* system between the donor and acceptor groups of the nitroanilines.

Cohesive properties of metals as determined from atomic charge densities

Yoram Tal

Abstract: A direct relation between the charge density of a free atom, $\rho_a(r)$, and the cohesive energy of the corresponding metal is proposed. This relation is based on an approximation for the metallic charge density, $\rho_m(r)$, that is constructed from $\rho_a(r)$ through $\rho_m(r) \cong \rho_a(r) + \bar{\rho}$ where $\bar{\rho} = \Omega_0^{-1} \int_{R_0}^{\infty} \rho_a(r) d^3r$, Ω_0 being the atomic volume of the metallic atom, and R_0 the corresponding Wigner–Seitz radius. The cohesive energy E_{coh} is then related to $\bar{\rho}$ through $E_{coh} \cong (3/10)(3\pi^2)^{2/3}\Omega_0\bar{\rho}^{5/3}$. A systematic study of 29 metallic elements including the 3*d* and 4*d* transition elements shows that the proposed relation is, in general, at least as accurate as recent ab initio results. In the same fashion, an expression for the metallic bulk modulus is derived. This expression requires, in addition to $\bar{\rho}$, the values of $\rho_a(R_0)$ and its first derivative $\rho'_a(R_0)$. The computed bulk moduli are, again, at least as good as the ab initio ones for the set of metallic elements studied.

Key words: cohesive energies, bulk moduli, charge density, transition elements.

Résumé : On propose une relation directe entre la densité de charge d'un atome libre $\rho_a(r)$ et l'énergie de cohésion du métal correspondant. Cette relation est basée sur une approximation pour la densité de charge métallique, $\rho_m(r)$, que l'on peut construire à partir de $\rho_a(r)$ par l'équation $\rho_m(r) \cong \rho_a(r) + \bar{\rho}$ dans laquelle $\bar{\rho} = \Omega_0^{-1} \int_{R_0}^{\infty} \rho_a(r) d^3r$, Ω_0 est le volume atomique de l'atome métallique et R_0 est le rayon correspondant de Wigner–Seitz. On peut alors relier l'énergie de cohésion, E_{coh}, à $\bar{\rho}$ par l'équation $E_{coh} \cong (3/10)(3\pi^2)^{2/3}\Omega_0\bar{\rho}^{5/3}$. Une étude systématique de 29 éléments métalliques, y compris les éléments de transition 3*d* et 4*d*, montre que la relation proposée est, en général, au moins aussi précise que les résultats ab initio récents. De la même manière, on a dérivé une expression pour le module du métal à l'état global. Pour cette expression, il faut les valeurs de $\rho_a(R_0)$ et de sa première dérivé $\rho'_a(R_0)$, en plus des valeurs de $\bar{\rho}$. Encore une fois, les valeurs calculées pour ce module, pour l'ensemble d'éléments métalliques étudiés, sont en un accord au moins aussi bon que celles obtenues par des calculs ab initio.

Mots clés : énergies de cohésion, module global, densité de charge, éléments de transition.

[Traduit par la rédaction]

Introduction

The idea of using free atom information to explain the cohesive properties of metals is perhaps as old as the theory of cohesion itself. The free electron theory of metals (1–3) is the first example of such an approach, where atomic valency considerations were used to distinguish between frozen ionic cores and the free electron gas formed by the valence electrons. Wigner and Seitz (4) later made a more detailed application of this idea by using a frozen core potential to calculate the energy band and cohesive properties of metallic sodium. This approach of Wigner and Seitz has subsequently evolved into a more formal pseudopotential theory (5).

A different application of atomic data is exemplified by the overlapping charge density (OCD) model (6), in which a model crystal potential is constructed from a superposition of atomic charge densities. In a recent review paper on self-consistent energy band calculations, Koelling (7) discusses the OCD model and points out that it is actually a prescription for a model charge density. It is a reasonably good prescription, one might add, since the difference between the exact metallic charge density and the superposition of the corresponding atomic charge densities is usually much smaller than either of these charge densities.

Closely related to the OCD model is the renormalized atom (RA) method (8). This method may similarly be considered a prescription for constructing a model charge density from atomic orbitals, although in practice the total charge density is never used in the calculation of cohesive properties. The success of the RA method in predicting cohesive energies may largely be attributed to a fortunate cancellation of energy terms that occurs because of the "frozen" potential condition (9). On the other hand, the method requires a careful choice of the various terms that enter the cohesive energy expression, in order to get an effective cancellation of terms.

A more direct approach to the calculation of cohesive energies has recently been taken by Chelikowsky (10), who has been able to accurately predict such quantities (for simple metals) solely from atomic kinetic energy terms.

The present paper combines, in a way, many of the ideas outlined above. First, an approximation to the charge density difference between the metallic and atomic charge densities is constructed solely from the free atom charge density and the radius of the metallic Wigner–Seitz cell. This charge density difference is then used to determine the cohesive properties of metals.

Theory

The Wigner–Seitz cell of a metallic atom is first approximated by a sphere whose radius is defined by $R = (3\Omega/4\pi)^{1/3}$, where

[1] Fax: 972-4-9906576

Ω is the atomic cell volume. The metallic charge density is, to first ap-proximation, a sum of atomic charge densities. Conservation of charge therefore implies that the net increase in electronic charge per Wigner–Seitz cell with respect to the unbounded state is

$$[1] \quad N_m = \int_R^\infty \rho_a(r) d^3r$$

where $\rho_a(r)$ is the charge density of the free atom. The total electronic charge within each cell must, of course, equal the nuclear charge in order to preserve the electroneutrality of the system.

A further simplifying assumption, concerning the nature of the charge distribution in the metal, can be made on the basis of previous experience. It turns out that the charge density difference $\delta\rho(r) = \rho_m(r) - \rho_a(r)$, $\rho_m(r)$, being the metallic charge density, is essentially constant. This statement is substantiated by both ab initio (11) and model (6) calculations. Accordingly, one can write

$$[2] \quad \delta\rho(r) \cong \bar{\rho} \equiv N_m/\Omega$$

which means that, to first order, the metallic charge density differs from the corresponding atomic density by a uniformly spread charge $\bar{\rho}$ whose magnitude is determined by the Wigner–Seitz radius, eqs. [1] and [2].

As in the overlapping charge density (OCD) model (6, 7), which uses a similar idea to construct the metallic potential, one still has to define the appropriate atomic configuration whose charge density is to be used in eq. [1]. This issue will be discussed in the next section.

Having established an approximation for $\delta\rho(r)$, one next wishes to calculate the energy difference associated with it, namely, the cohesive energy. Because of the virial theorem, which has the same form for both the free atom and the metallic atom in its equilibrium geometry, i.e., $E = -T$, one has

$$[3] \quad E_{coh} \equiv E_a - E_m{}^0 = T_m{}^0 - T_a \equiv E_k{}^0$$

(the superscript 0 denotes the equilibrium geometry of the metal). Only kinetic energy differences need be calculated. Note that eq. [2] implies $\rho_m(r) = \rho_a(r) + \bar{\rho} > \rho_a(r)$ which is consistent with $E_k > 0$. Finally, E_k may be estimated from a free electron model in which the additional N_m electrons per unit cell are considered to occupy an energy band above the bound atomic levels. The Fermi level of this band is given by

$$[4] \quad E_F = \frac{1}{2}(3\pi^2\bar{\rho})^{2/3}$$

and the corresponding kinetic energy difference is therefore

$$[5] \quad E_k = C_k N_m \bar{\rho}^{2/3}$$

where $C_k = (3/10)(3\pi^2)^{2/3}$. Atomic units are used here and throughout the manuscript unless otherwise specified.

Equations [1]–[3] yield an explicit expression for the cohesive energy of a monoatomic metal in terms of the free atom charge density and the Wigner–Seitz radius, namely,

$$[6] \quad E_{coh} = \frac{3}{10}(3\pi^2)^{2/3}\Omega_0^{-2/3}\left\{\int_{R_0}^\infty \rho_a(r) d^3r\right\}^{5/3}$$

where Ω_0 is the equilibrium atomic cell volume and R_0 is the corresponding Wigner–Seitz radius.

When Ω differs from Ω_0 the virial theorem no longer holds in its simple form, eq. [3], and one should write, instead

$$[7] \quad E \equiv E_m - E_a = E_k + E_v$$

where E_k is given by eq. [5] and E_v is the potential energy difference between the metallic and the free atom. The magnitude of E_v is irrelevant to the calculation of cohesive energies since $E_v^0 = -2E_k^0$ as previously discussed. It is necessary, however, to know its derivatives with respect to Ω in order to calculate bulk moduli. This point will be discussed towards the end of this section. We now turn to calculate the derivatives of E_k with respect to Ω.

Let $x \equiv \rho_a(R)/\bar{\rho}$ and $y \equiv -R\rho'_a(R)/\bar{\rho}$ where $\rho_a(R)$ is the value of ρ_a at $r = R$ and $\rho'_a(R)$ is the first derivative of ρ_a at R. With these definitions the following relations are easily derived

$$[8a] \quad \frac{dN_m}{dR} = -4\pi R^2 \rho_a(R)$$

$$[8b] \quad \frac{d\bar{\rho}}{dR} = -\frac{3}{R}\bar{\rho}[1 + x]$$

$$[8c] \quad \frac{dx}{dR} = \frac{1}{R}[3x(x + 1) - y]$$

The kinetic contributions to the pressure and to the bulk modulus are consequently given by

$$[9] \quad P_k = -\frac{dE_k}{d\Omega} = \frac{5}{3}C_k\bar{\rho}^{5/3}\left(x + \frac{2}{5}\right)$$

$$[10] \quad B_k = -\Omega\frac{dP_k}{d\Omega} = \frac{10}{9}C_k\bar{\rho}^{5/3}\left[(x + 1)^2 + \frac{1}{2}y\right]$$

One recognizes in eqs. [9] and [10] the well-known free electron gas expressions, slightly modified by the fact that the number of free electrons depends on Ω. If this dependence is ignored, then $x = y = 0$ and the free electron formulas are recovered. It turns out that as $R \to 0$ both x and y become negligibly small.

Equation [10] might be used as a rough approximation to the bulk modulus, but it usually gives too large values. To get better results one needs to consider the nature of E_v. In the spirit of the free electron assumption made earlier it seems reasonable to assume that E_v originates from an exchange–correlation interaction of the free electron gas. In doing so one implicitly assumes that all the additional Coulombic interactions, which result from the superposition of atomic charge densities, cancel each other. In other words, the net effect of such a superposition is, approximately, a constant shift in the potential. If this is the case one may calculate the exchange–correlation effect on the free electron bulk modulus by using

[a]All values, except for bulk moduli are in atomic units. Values of $\rho(R)$ are in milli atomic units. Values of bulk moduli are in Mbar. The values of Ω_0 were taken from ref. 11. Values of N_m were computed from eq. [1]. Values of E_{coh} were computed from eq. [6]. Values of λ, B_k, and B were computed from eqs. [12], [10], and [11], respectively.

the Hedin–Ludqvist relation.

$$[11] \quad B = B_k[1 - \alpha\xi\cdot\lambda(r_s)]$$

where $r_s = ((3/4)\pi\bar{\rho})^{1/3}$ and

$$[12] \quad \lambda(r_s) = 1 + \frac{b\xi}{1+\xi}$$

Here $\xi = r_s/a$, $\alpha = (4/9\pi)^{1/3}(a/\pi)$ where a and b are numerical constants whose values are $a = 21$ and $b = 0.7734$. A similar application of eq. [11] was successfuly made by Moruzzi et al. (11) in treating the muffin-tin interstitial charge as a free electron gas.

Results and discussion

Atomic charge densities of 29 metallic elements were computed using the relativistic self-consistent field program of Liberman et al. (12). The electronic configuration was, in most cases, the free atom experimental ground state configuration. This choice was made, in particular, for all the simple metals having only S and P valence electrons. In such cases the ground state is distinct both experimentally and computationally. The transition metal elements, however, possess at least two nearly degenerate configurations, namely, $d^{n-1}s^1$ and $d^{n-2}s^2$. Furthermore, it turns out that the ground state energy of the Kohn–Sham Hamiltonian is none of the above but, in general, a $d^{n-x}s^x$ configuration where x is a non-integral number. These difficulties were discussed in other papers and the conclusion seems to be that, in general, the $d^{n-1}s^1$ configuration is

a preferable choice for a model density calculation (8). This configuration was therfore used here with only few exceptions. Three of these exceptions occur at the beginning of the d series, namely, at Ti, Zr, and Nb. For these elements both $d^{n-1}s^1$ and $d^{n-2}s^2$ configurations were calculated. The other two exceptions are Cr and Mn for which the $d^n s^0$ configuration was included in addition to the $d^{n-1}s^1$ configuration.

Having obtained the appropriate free atom chrge densities it is a simple matter to apply eq. [6] in order to get cohesive energies. The results are displayed in Fig. 1 along with the experimental values and the theoretical results of Moruzzi et al. (11). The accuracy of the present results is comparable with, or even slightly better than, the best ab initio calculations.

In general, the largest relative errors are found when E_{coh} is small and second-order effects are expected to become important. Hence in both Na and K only ~50% of E_{coh} is recovered by the present model. On the other hand, for large values of E_{coh} the present model seems to be working surprisingly well. Note, in particular, the 3d series for which the present results are considerably better than the ab initio results.

A similar pattern is observed for the bulk moduli displayed in Fig. 2. The overall agreement of the present results with experimental data is striking, particularly in view of the relatively large errors in the ab initio results for the 3d transition metal series. It was found, however, that eq. [11] does not work well for small values of B_k. Hence, for values of $B_k < 0.3$ Mbar it is much better to use B_k itself as an approximation for B rather than to apply eq. [11].

Table 1 displays some numerical results of the present calculation. Consider, in particular, the values of N_m (eq. [1]), which in the present theory play the role of the number of valence electrons, N_v, in other theories. Yet the values of N_m hardly resemble the values usually assigned to N_v. A possible reason for this apparent discrepancy is that "valence electrons" is a rather loose term, which helps in singling out the significant contributions to cohesion within the framework of a single particle model, but is much less successful than N_m in predicting the *net* cohesive effect.

Certainly, one should not be too naive to think that the success of the present model is totally unrelated to some fortunate cancellation of errors. Yet, it may perhaps create some hope that within density functional theory one might be able to find a direct relation between charge density differences and cohesive properties.

Applications and evaluation of IGAIM ^{13}C and ^{1}H chemical shift calculations for unsaturated hydrocarbons and organolithium compounds

Nick Henry Werstiuk and Jiangong Ma

Abstract: Wave functions obtained at the RHF/6-31+G(d) level of theory were used with the new method IGAIM (individual gauges for atoms in molecules) developed by Keith and Bader to calculate the isotropic ^{13}C and ^{1}H NMR chemical shifts of a group of neutral molecules (bicyclo[3.2.1]octa-2,6-diene (**1**), bicyclo[3.2.1]oct-6-ene (**2**), bicyclo[2.2.1]hepta-2,5-diene (**3**), benzene (**4**)), carbanions (prop-2-en-1-yl (allyl) (**5**), bicyclo[3.2.1]octa-3,6-dien-2-yl (**8**)), and lithium complexes (prop-2-en-1-yllithium (**6**) and its dimer **7**, bicyclo[3.2.1]octa-3,6-dien-2-yllithium (**9**)). The theoretical isotropic ^{13}C NMR chemical shifts of the neutral molecules, relative to the calculated value for TMS(tetramethylsilane), are in excellent agreement with the experimental values, with differences between the sets of data ranging from +4.9 to −7.1 ppm. For the same group of compounds the theoretical ^{1}H shifts are lower than the experimental values by increments ranging between 0.4 and 1.29 ppm. For allyllithium, which exists as an unsymmetrical fluxional dimer, the theoretical averaged ^{13}C shifts are larger, 2.6 ppm for the terminal carbons and 16.7 ppm for the central carbon, than the experimental values. In the case of **8**, originally considered to be a bishomoaromatic species, the theoretical ^{13}C chemical shifts of its Li^{+} complex **9** differ from the experimental ones for THF-solvated **9** by values that range from +6.2 to −15.0 ppm. Yet, the relative theoretical chemical shifts — of special importance is the fact that the carbons of the vinylene bridge of this compound are unusually shielded relative to the parent diene **1** — correlate with the experimental data. The ^{1}H chemical shifts calculated for the hydrocarbons **1**, **2**, **3**, **4** and the lithium complexes **7** and **9** range from 0.08 to 1.38 ppm less than the experimental values. To gain information on whether variations in charge density play a significant role in determining the magnitudes of the chemical shifts, we used AIMPAC calculations to obtain the atom electron populations of diene **1**, **5**, **6**, dimer **7**, **8**, and **9**. We find no obvious correlation between the charges on the carbon atoms and the ^{13}C shifts for this set of compounds.

Key words: IGAIM, calculations, ^{13}C and ^{1}H chemical shifts, unsaturated hydrocarbons, organolithium compounds.

Résumé : On a utilisé les fonctions d'onde obtenues au niveau RHF/6-31+G(d) de la théorie en relation avec la nouvelle méthode JIADM (jauges individuelles pour les atomes dans les molécules) développée par Keith et Bader pour calculer les déplacements chimiques isotropes en RMN du ^{1}H et du ^{13}C d'un groupe de molécules neutres (bicyclo[3.2.1]octa-2,6-diène (**1**), bicyclo[3.2.1]oct-6-ène (**2**), bicyclo[2.2.1]hepta-2,5-diène (**3**), benzène (**4**)), de carbanions (prop-2-èn-1-yle (allyle) (**5**), bicyclo[3.2.1]octa-3,6-dièn-2-yle (**8**)) et de complexes du lithium (prop-2-èn-1-yllithium (**6**) et son dimère **7**, bicyclo[3.2.1]octa-3,6-dièn-2-yllithium (**9**)). Les déplacements chimiques théoriques isotropes en RMN du ^{13}C des molécules neutres, relatifs aux valeurs calculées pour le TMS (tétraméthylsilane), sont en bon accord avec les valeurs expérimentales; les différences entre les ensembles de données varient de +4,9 à −7,1 ppm. Pour le même groupe de composés, les déplacements théoriques des ^{1}H sont plus faibles que les valeurs expérimentales par des incréments variant de 0,4 à 1,29 ppm. Pour l'allyllithium qui existe sous la forme d'un dimère en fluxion asymétrique, les déplacements théoriques moyens du ^{13}C sont plus élevés (2,6 ppm pour les carbones terminaux et 16,7 ppm pour l'atome de carbone central) que les valeurs expérimentales. Dans le cas du produit **8**, qui avait originalement été considéré comme une espèce bishomoaromatique, les déplacements chimiques théoriques du ^{13}C de son complexe avec le lithium, **9**, diffèrent des valeurs expérimentales pour le composé **9** solvaté par du THF par des valeurs allant de +6,2 à −15,0 ppm. Malgré tout, les déplacements chimiques théoriques relatifs — ce qui présente le plus d'importance est le fait que les carbones du pont vinylène de ce composé sont inhabituellement blindés par rapport au diène parent, **1** — présentent une corrélation avec les données expérimentales. Les déplacements chimiques calculés du ^{1}H pour les hydrocarbures **1**, **2**, **3** et **4** et les complexes avec le lithium, **7** et **9**, se situent à des valeurs allant 0,08 à 1,38 ppm plus faibles que les valeurs expérimentales. Afin d'obtenir de l'information sur le rôle que jouent les variations dans la densité de charge dans la détermination des amplitudes des déplacements chimiques, on a fait appel à des calcul de AIMPAC pour déterminer les populations électroniques des

Introduction

The bicyclo[3.2.1]octa-3,6-dien-2-yl anion (**8**) has attracted the attention of chemists for over 30 years. Apart from the historical interest, this anion has been the object of a number of studies aimed at determining whether it is homoaromatic (1–3). The enhanced kinetic and thermodynamic acidities of the allylic hydrogens of bicyclo[3.2.1]octa-2,6-diene (**1**) and the unusual chemical shifts of the hydrogens and carbons of the vinylene bridge of its lithium complex **9** solvated with THF (the hydrogens are shielded by 1.98 and 2.51 ppm and the carbons by 39.7 and 49.6 ppm relative to the **1**) were taken as evidence that the anion is bishomoaromatic. It was estimated from the ^{1}H NMR data that **8** had 30–40% of the ring current of benzene. Anion **8** has also been the subject of a number of theoretical studies (4–7). While the results of one of the theoretical studies (6) were used to support the initial interpretation of the experimental data, Lindh et al. (7) concluded, as did two other groups of researchers (4, 5), that the interactions between unoccupied and occupied orbitals necessary to achieve bicycloaromaticity do not take place, in their view, because the distance between the interacting bridges is too large. They suggested that the dominant interaction at the equilibrium distance is electrostatic in nature and proposed that the unusual chemical shifts arise from a through-bond redistribution of charge and not from the bishomoaromaticty of **8**.

Our long-standing interest in the chemistry of carbanions, especially in the factors controlling their stability, coupled with the fact that there are a number of methods available — including IGAIM (individual gauges for atoms in molecules)

recently developed by Keith and Bader (8) — for calculating magnetic response properties such as shieldings and magnetic susceptibilities (9) led us to study of a group of the unsaturated hydrocarbons **1**, **2**, **3**, **4**, the carbanions **5** and **8**, and their lithium complexes **6**, **7** and **9** with a relatively small basis set (6-31+G(d)). We chose the IGAIM method because Keith and Bader showed that IGAIM yields absolute carbon shieldings that agree better with experimental values than those obtained by conventional CHF calculations using the same basis set (8). Our objectives were twofold. Firstly, we set out to establish whether the IGAIM method is useful for calculating ^{13}C and ^{1}H chemical shifts of relatively large molecules with a relatively small basis set — as pointed out by Jørgensen and co-workers recently (10), this information is not available — and, in the same instance begin to gain some understanding of the NMR spectroscopy exhibited by **9**. In this connection, we also obtained the atom charges of **1**, **5**, **6**, **7**, **8**, and **9** with the AIMPAC suite of programs developed by Bader and co-workers (11). In the event that we found IGAIM to be useful for calculating chemical shifts at the 6-31+G(d) level of theory, we planned to carry out a theoretical study of the magnetic susceptibilties of benzene, **1**, **8**, and **9** at the same level of theory, the goal being to analyze the atom susceptibilities on the basis of basin and surface components. Bader and Keith showed that this approach gives information on the flux in current through interatomic surfaces, namely ring currents, induced by a magnetic field (12). In this paper we report the theoretical isotropic ^{13}C and ^{1}H chemical shifts obtained with IGAIM along with the atom charges calculated with AIMPAC and correlate the results with available experimental NMR data.

Computational method

The derivation and detailed description of the IGAIM method are documented in a paper published by Keith and Bader (8). The optimized equilibrium geometries of the compounds were calculated at the RHF/6-31+G(d) level of theory with GAUSSIAN 92 (13). Perturbed wave functions were obtained for these geometries with CADPAC (14), and PROAIMV (11) was used to calculate the magnetic response properties. The atom electron populations were obtained with PROAIMV and PROMEGA (11). All calculations were carried out on IBM RS/6000 model 530, 350, and 320H workstations.

Results and discussion

Calculations on hydrocarbons

We carried out the calculations at the RHF/6-31+G(d) level of theory because (*a*) it is necessary to include diffuse functions on heavy atoms when carrying out calculations on carbanions, (*b*) we wished to establish whether IGAIM calculations on fairly large molecules with a relatively small basis set yield chemical shifts that correlate with experimental data, and (*c*) at the time this study was carried out the scratch disk space available for CADPAC calculations was limited to 2 GB for each temporary file. We studied **1** because it is necessary to track the changes in ^{13}C and ^{1}H chemical shifts in going from **1** to **8** and **9**. Bicyclooctene **2** was studied because it is the dihydro analogue of **1** and its experimental ^{13}C chemical shifts have been published. While norbornadiene (**3**) was studied because its olefinic carbons are unusually deshielded, benzene was studied because it is the archtypical aromatic system that exhibits a large ring current. The total energies of **1–9** obtained at the 6-31+G(d) level of theory are given in Table 1.

[a]In hartrees, calculated at the HF/6-31+G(d)//6-31+G(d) level of theory.

Keith and Bader showed that increasing the size of the basis set (the uncontracted Gaussian basis set [13s8p5d] and 6-311++G(2d,2p) were used) produced only small changes in the shieldings (8). Thus, we expected to find a good correlation between the theoretical chemical shifts and the experimental values for the compounds of interest to us. Because gas-phase absolute chemical shieldings (σ)[2] relative to the bare nucleus are obtained with IGAIM, the theoretical isotropic ^{13}C (Table 2) and ^{1}H chemical shifts (δ) (Table 3) of the unsaturated hydrocarbons including benzene are referenced to the calculated gas-phase ^{13}C and ^{1}H shieldings of tetramethylsilane(TMS) obtained at the same level of theory. The IGAIM isotropic chemical shifts calculated in this way were compared to the values obtained in solution. It is important to note here that the differences between the gas phase and solution chemical shifts of neutral compounds, in general, are small: for ^{13}C the differences usually are in the range of 1 to 2 ppm; for ^{1}H the differences usually fall in the region of 1 ppm unless hydrogen bonding is involved (17).

It is seen that the differences between the theoretical and the experimental solution ^{13}C shifts of the hydrocarbons **1**, **2**, **3**, and **4** range from +9.9 to −7.1 ppm (Table 2). Even so, the correlation between the theoretical and experimental ^{13}C chemical shifts of **1**, **2**, **3**, and **4** is remarkably good (Fig. 1) with the correlation coefficient being 0.999. Of significance is the fact that the relative theoretical chemical shifts of the vinylic carbons of **1**, **2**, and **3** — in this compound the carbons are unusually deshielded — follow the experimental values exactly. The IGAIM ^{13}C chemical shift of benzene, the archtypical aromatic system, is identical to the gas-phase experimental value (Table 2). This result indicates that IGAIM calculations at the 6-31+G(d) level of theory will be useful for studying the magnetic response properties of aro-

[2] The NMR chemical shift is a tensorial property. IGAIM calculations yield the three principle components, which are averaged to obtain the isotropic shifts. Ideally, the IGAIM principle components should be compared with the experimental values if they are available (15, 16).

matic systems. There is an excellent linear correlation (the correlation coefficient is 0.992) between the theoretical and experimental ^1H chemical shifts of **1**, **3**, and **4** (Table 3, Fig. 2) as well, although the calculated chemical shifts are systematically low by around 1 ppm. Except for the bridgehead hydrogens of **1** and **3**, the relative chemical shifts of the hydrogens correlate closely with the experimental values.

Calculations on the allyl and bicyclo[3.2.1]octa-3,6-dien-2-yl anions and their lithium salts

To establish whether IGAIM can be used to calculate chemical shifts of carbanions and their lithium complexes with the 6-31+G(d) basis, we studied the allyl and bicyclo[3.2.1]octa-3,6-dien-2-yl anions **5** and **8** and their lithium complexes **6**, **7**, and **9** without including solvent molecules such as H_2O or THF. Our first goal was to determine the degree to which Li^+ complexation, and dimer formation in the case of **5**, affects the ^{13}C shieldings of carbanions **5** and **8**, and to establish whether the theoretical chemical shifts correlate with the experimental data available for **7** and **9**. Figures 3(*a*), 3(*b*), and 3(*c*) display the optimized equilibrium geometrical structures of **6**, **7**, and **9**, respectively, labelled with selected geometrical parameters. In going from **5** to **6** there is a slight increase in the C1—C2 bond length (the value for **5** is given in parentheses) and C1 and C3 are pyramidalized as indicated by the H4,C3,C2,H6 and H5,C3,C2,H6 dihedral angles. The atom charges of **5**, **6**, **7**, **8**, and **9** calculated from the electron populations obtained with AIMPAC are summarized in Figs. 4(*a*), 4(*b*), and 4(*c*). The values given in parentheses in 4(*a*) and 4(*c*) are the charges for the uncomplexed anions **5** and **8**, respectively. From the data given in Table 4 is seen that in going from **5** to **6** the chemical shifts of the terminal carbons and the central carbon atom increase by 10.5 and 15.2 ppm, even though the electron populations of terminal carbons C1 and C3 and the center carbon C2 increase by 0.067 and 0.101, respectively (Fig. 4(*a*)). It is clear that there is no relationship between charge density and the ^{13}C chemical shifts of the allyl anion (18). Other factors play a more important role (19). As is seen from atom charges shown in Fig. 4(*a*), the electron populations of the carbons increase at the expense of the hydrogens. While the results of an earlier ^{13}C NMR study were interpreted on the basis that allyllithium is an ionic monomeric species (20), cryoscopic

measurements and variable temperature ^{13}C isotopic perturbation NMR studies established that allyllithium exists as a fluxional, unsymmetrical dimer in THF over a wide temperature range (21). Consequently, we studied **7** with IGAIM. Because of hardware limitations, we could not solvate the dimer with THF or even H_2O. The optimized geometrical structure of **7** along with selected parameters is displayed in Fig. 3(*b*). As was found in earlier ab initio studies at the 3-21G level of theory (22, 23) and confirmed by the isotopic perturbation NMR experiments, the dimer has C_i symmetry. The geometri-

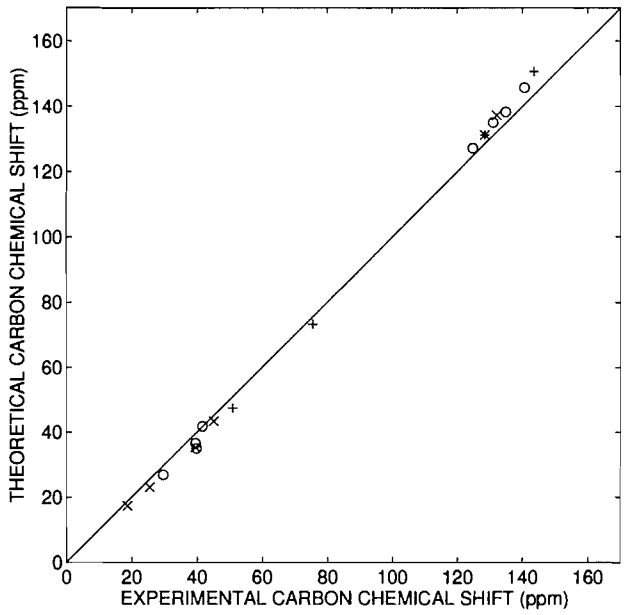

Fig. 2. Plot of theoretical versus experimental ^{1}H chemical shifts: **1** (○); **3** (+); **4** (*).

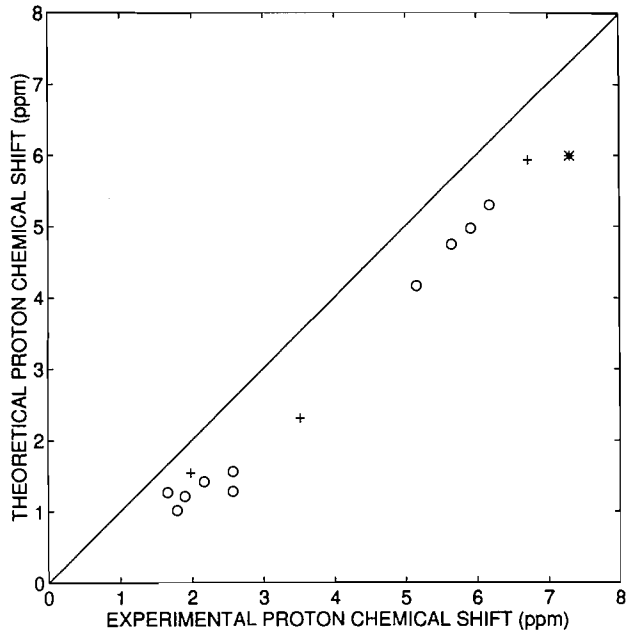

cal parameters and chemical shifts we obtained in this study correlate closely with those obtained in the earlier IGLO study of **7** (23). The atom charges calculated with AIMPAC (Fig. 4(*b*)) show that there is a substantial difference (0.242 and 0.247 au) in the charges of the methylene carbons. This is also the case for the hydrogens. Yet the average values, −0.350 and −0.352, are virtually identical to the carbon-atom charges calculated for the methylene carbons of **6**. The charges on C2 and C5 and on the lithiums are also close to the values obtained for **6**. The theoretical absolute shieldings and chemical shifts, which are referenced to the theoretical absolute ^{13}C shielding of the methyl group of TMS, are given in Table 4. While the terminal carbons (compare C1 and C4 with C3 and C6) of the allyl fragments of the static dimer **7** differ in chemical shift by 53.4 ppm, there is an excellent correlation between averaged ^{13}C chemical shifts and the experimental values obtained for **7** in THF solution. That the averages of the theoretical chemical shifts of C1, C3, C4, and C6, and C2 and C5 correlate with the nmr data even at 107 K, a temperature at which the "inside" (H8, H10, H12, and H16) and "outside" (H7, H9, H13, and H15) hydrogens do not equilbrate, is in keeping with the view that allyl groups of **7** undergo a helicopter-type rotation (20). The relationship between the theoretical and experimental ^{13}C chemical shifts is displayed graphically in Fig. 5. The theoretical ^{1}H chemical shifts of the **5**, its lithium complex **6**, and the unsymmetrical dimer **7** along with the experimental data for **7** are given in Table 5. It is seen that the average of the theoretical chemical shifts of the "outside" hydrogens (H7, H9, H13, and H15) and of **7** is smaller than the average of the "inside" (H8, H10, H12, and H16) ones. While these average values are 0.35 and 0.57 ppm less than the experimental values obtained at 37°C, the relative chemical shifts are in accord with assignments made on the basis of vicinal coupling constants by West et al. (24). The relationship beween the theoretical and experimental shifts is shown graphically in Fig. 6. It is interesting to note that the hydrogens of the C3 and C6 methylene groups of the static structure are considerably more shielded (2 ppm) than the hydrogens of the C1 and C4 methylenes. This is undoubtedly due to the fact that (*a*) there is a significant degree of pyramidalization at C3 and C6 of the dimer, and (*b*) the electron populations of C3 and C6 and the associated hydrogens are larger than the populations of the the C1 and C4 methylenes (Fig. 4(*b*)).

The optimized equilibrium geometrical structure of bicyclo[3.2.1]octa-3,6-dien-2-yllithium (**9**) labelled with selected geometrical parameters is displayed as Fig. 3(*c*). The lithium cation is located in the *endo* position in keeping with the X-ray diffraction structure of **9** solvated with one molecule of TMEDA (25). Hardware limitations precluded studies on **9** solvated with H_2O, THF, or TMEDA. Even so, there is good agreement between the geometrical parameters calculated for **9** and the X-ray diffraction data obtained for TMEDA-solvated **9**, which turns out to be an unsymmetrical species. The largest differences between the theoretical and experimental geometrical parameters are seen in the C5–C6 (**9**, 1.531 Å; TMEDA-solvated **9**, 1.508 Å), C1–C7 (**9**, 1.531; TMEDA-solvated **9**, 1.512), Li–C2 (**9**, 2.219; TMEDA-solvated **9**, 2.440), Li–C3 (**9**, 2.068; TMEDA-solvated **9**, 2.194), and Li–C4 (**9**, 2.219; TMEDA-solvated **9**, 2.515) internuclear distances. Selected geometrical parameters of the free anion **8** are given in parentheses in Fig. 4(*c*). There are only slight changes in the geometrical structure when **8** is converted into **9**. In keeping with the results obtained for conversion of **5** into **6**, the electron populations of the carbons (C2 (Δ0.150 au), C3(Δ0.119 au), and C4(Δ0.150 au)) of the allylic unit of **8** increase substantially when it is converted into **9** (Fig. 4(*c*)). As was found for the allyl anion, this occurs predominately at the expense of hydrogens attached to these carbons, although the other hydrogens and the bridgehead carbons C1 and C5 relinquish electrons as well. Noteworthy is the fact that the

carbons of the vinylene bridge, C6 and C7, also gain electrons (0.067 au) when **8** is converted into **9** (see Fig. 4(*c*)). These carbons also gain 0.046 and 0.038 electrons, respectively, when the parent diene **1** (the value for C7 of **1** is shown in square brackets) is converted into **8**. Overall, carbons C6 and C7 of **1** gain 0.113 and 0.105 electrons, respectively, when **1** is converted into **9**, predominately from the bridgehead carbons C1 and C5 and hydrogens H16 and H17 of the vinylene bridge. Also noteworthy is the fact that C2, C3, and C4 of the allylic unit of **9** bear virtually the same charges as the carbons

of the methylene carbons C2 and C4. The theoretical chemical shifts of the bridgehead carbons C1 and C5 change only marginally even though the electron populations of these carbons decrease in going from **1** to **9**. The 9.6 ppm decrease in chemical shift of C8 found experimentally in going from **1** to THF-solvated **9** is accurately reproduced by the IGAIM calculations. The greatest differences between the calculated values for **9** and experimental values for THF-solvated **9** are found for C6 and C7 of the vinylene bridge and C3 of the allylic unit (Table 6). The calculated chemical shifts of C6 and C7 — they are not sufficiently shielded — are too large by 15.0 and 14.6 ppm, respectively (Table 6). Even so, the calculated increases in the shieldings of C6 and C7 of **1** in going to **9** are 28.8 and 39.4 ppm, respectively, in reasonable agreement with the increases (37.9 and 49.6 ppm) found experimentally when **1** is converted into THF-solvated **9**. Given the fact that there is no clear correlation between the changes in electron populations of C1, C3, C5, and C8 and the variations in the ^{13}C chemical

shifts when **1** is converted into **9**, it is unlikely that the increases in electron populations of C6 and C7 are the major source of the increase in shielding experienced by these carbons.

The theoretical ^{1}H chemical shifts of **8** and **9** along with the experimental values for the THF-solvated **9** are given in Table 7 and displayed graphically in Fig. 6. The correlation coefficient of the data for **7** and **9** is 0.979. It is seen that the relative chemical shifts are in accord with the experimental values although the differences between the two sets of data range between 0.08 and 1.38 ppm. The shielding of H16 (1.07 ppm) and H17 (1.52 ppm) found calculationally in going from **1** (the atom charges of H16 and H17 are 0.022 and 0.027 au) to **9** (the atom charges of H16 and H17 are 0.018 au) is in keeping with the experimental findings that H16 and H17 are shielded by 1.98 and 2.51 ppm, respectively, when **1** is converted into THF-solvated **9**. It is also of interest to note that the relative chemical shifts of H9 and H10 only correlate with the experimental data when **8** is converted into its Li^+ complex **9**, showing that Li^+ exhibits a long-range effect when complexed with **8**.

Conclusions

IGAIM calculations at the 6-31+G(d) level of theory give ^{13}C and ^{1}H chemical shifts of unsaturated hydrocarbons — including benzene, the archtypical aromatic system — and unsaturated organolithium compounds that correlate well with experimental data. This result suggests that the IGAIM method will be generally useful for calculating magnetic response properties of these classes of compounds with the 6-31+G(d) basis. Changes in theoretical chemical shieldings do not correlate with variations in electron populations.

Some results on the electrostatic energy of ionic crystals

Hanno Essén and Arne Nordmark

Abstract: We define a class of ionic cyrstals, the alternating Bravais lattice ionic crystals, which has the NaCl and CsCl structures as members. We calculate the electrostatic energy of finite pieces and study the convergence to the macroscopic Madelung limit. For the one-parameter family of trigonal lattices we calculate the dependence of the electrostatic energy on the parameter. The NaCl and CsCl structures correspond to minima, the CsCl minimum being deeper. This is due to long-range effects; for small clusters the NaCl structure is favored. We also study the Madelung constant of simple cubic lattices as a function of spatial dimension, and discuss the results. We finally calculate the electrostatic repulsion of two constant unit charge distributions in the unit cube. This quantity, a six-dimensional integral, can be integrated analytically five times, leaving a simple one-dimensional integral to be done numerically.

Key words: ionic crystal, Madelung constant, ionic cluster, electrostatic energy.

Résumé : On définit une classe de cristaux ioniques, les cristaux ioniques de maille de Bravais alternante, dont font partie le NaCl et le CsCl. On a calculé l'énergie électrostatique de piéces finies et on a étudié la convergence vers la limite macroscopique de Madelung. Pour la famille à un paramétre des mailles trigonales, on a calculé la dépendance de l'énergie électrostatique sur le paramètre. Les structures du NaCl et du CsCl correspondent à des minima, celui du CsCl étant plus profond. Ceci est le résultat d'effets à longue distance; pour de petits agrégats, la structure du NaCl est celle qui est favorisée. On a aussi étudié la constante de Madelung de mailles cubiques simples en fonction de la dimension spatiale et on discute des résultats. On a finalement calculé la répulsion électrostatique des distributions unitaires de charge à deux constantes dans unité de cube. Cette quantité, une intégrale à six dimensions, peut être intégrée analytiquement cinq fois; on obtient une intégrale simple unidimensionnelle à être intégrée d'une façon numérique.

Mots clés : cristal ionique, constante de Madelung, agrégat ionique, énergie électrostatique.

[Traduit par la rédaction]

1. Introduction

The subject of the electrostatic energy of ionic crystals is an old one and much work has followed the pioneering efforts by Madelung (1). This paper is partly didactic and attempts to clarify known results, and partly presents results that we believe to be new.

Most of the work on these problems, including the present, uses the assumption that the ions can be treated as point charges. This is valid provided they are non-overlapping spherical charge distributions. It was not really until the pioneering work by Richard Bader that these assumptions were put on a sound theoretical basis (2). Bader's work shows that one can rigorously partition molecules and crystals into atoms and find the shape and charge of these.

We start by defining a class of ionic crystals, the alternating Bravais lattice (ABL) ionic crystals. It includes two of the most common types of such crystals, the NaCl and CsCl structures. For this class we are able to give some explicit formulas for the electrostatic energy, some of which we believe to be new. We study how the electrostatic energy (per molecule) of finite clusters converges to a macroscopic limit. We suggest an efficient numerical method to calculate the Madelung constants of this class. We then calculate this constant as a function of the parameter of the one-parameter family of orthorhombic (trigonal) lattices. This function throws some light on the interrelation between the NaCl and CsCl structures. We find that for small clusters the NaCl structure is energetically favored while CsCl has the largest Madelung constant and thus has lower energy in the macroscopic limit.

We also consider the dependence on the spatial dimension of the energy of small ionic clusters and of the Madelung constant. We find that, for the simple cubic case, these grow monotonically with dimension n, but eventually very slowly. Finally we calculate a related quantity of physical interest: the electrostatic interaction energy of constant charge distributions in a cube.

Received June 27, 1995.

This paper is dedicated to Professor Richard F.W. Bader on the occasion of his 65th birthday.

2. Alternating Bravais lattice ionic crystals

Consider a Bravais lattice with basis vectors $\boldsymbol{a}_1$, $\boldsymbol{a}_2$, $\boldsymbol{a}_3$. We call a crystal an *alternating Bravais lattice* (ABL) *ionic crystal* when there is an ion of charge

$$[1] \qquad q(i, j, k) = (-1)^{i+j+k}$$

at

$$\boldsymbol{r}(i, j, k) = i\boldsymbol{a}_1 + j\boldsymbol{a}_2 + k\boldsymbol{a}_3$$

The meaning of this definition is that as one goes along a line defined by a lattice basis vector the charges alternate in sign. That is, along the line $\boldsymbol{r}(\lambda) = \lambda\boldsymbol{a}_1 + j_0\boldsymbol{a}_2 + k_0\boldsymbol{a}_3$ there are charges $q(i) = q_0(-1)^i$ at integer values, $\lambda = i$, of the parameter.

It should be immediately clear that the NaCl crystal is an example of an ABL ionic crystal. With lattice basis vectors of the simple cubic (sc) lattice,

[2] $$\boldsymbol{a}_1 = \boldsymbol{e}_1 \equiv (1, 0, 0),\ \boldsymbol{a}_2 = \boldsymbol{e}_2 \equiv (0, 1, 0),$$

$$\boldsymbol{a}_3 = \boldsymbol{e}_3 \equiv (0, 0, 1)$$

the NaCl structure is obtained. It is only a little less obvious that the CsCl crystal also can be obtained. The lattice basis vectors of the body-centered cubic (bcc) lattice,

[3] $$\boldsymbol{a}_1 = \frac{1}{\sqrt{3}}(-1, 1, 1),\ \boldsymbol{a}_2 = \frac{1}{\sqrt{3}}(1, -1, 1),$$

$$\boldsymbol{a}_1 = \frac{1}{\sqrt{3}}(1, 1, -1)$$

are then the appropriate ones. Since there is a continuous transformation between these two sets of lattice basis vectors, and indeed between any two sets of lattice basis vectors, one may regard all ABL ionic crystals as, in a sense, topologically equivalent. In particular, one can take a unified view of the two standard structures (NaCl and CsCl) and study transformations between them. The zinc blende structure is not in the ABL class.

3. Electrostatic energy

The electrostatic (Coulomb) interaction energy of N^3 ions of charge $q(i,j,k)$ at positions $\boldsymbol{r}(i,j,k)$ is

[4] $$\Phi_N = \frac{1}{2}\sum_{ijk=1}^{N}{\sum_{lmn=1}^{N}}' \frac{q(i, j, k)q(l, m, n)}{|\boldsymbol{r}(i, j, k) - \boldsymbol{r}(l, m, n)|}$$

The prime on the sum means that the terms with zero denominator are excluded. If we have an ABL arrangement of the ions we can use eq. [1] and get

[5] $$\Phi_N(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3) = \frac{1}{2}\sum_{ijk=1}^{N}{\sum_{lmn=1}^{N}}' \times \frac{(-1)^{i+j+k+l+m+n}}{|(i-1)\boldsymbol{a}_1 + (j-m)\boldsymbol{a}_2 + (k-n)\boldsymbol{a}_3|}$$

for the total electrostatic energy. In the macroscopic limit when N becomes large this quantity will go to minus infinity. If we divide it by the number of (neutral) molecules, $N^3/2$, we get the electrostatic energy per molecule in the form

[6] $$\phi_N(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3) = \frac{2}{N^3}\Phi_N(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3)$$

and this should have a finite macroscopic limit

[7] $$\phi = \lim_{N\to\infty} \phi_N$$

Note that N should be even if the macroscopic piece is to be neutral; otherwise it has charge minus one, but this does not affect convergence.

The sum in eq. [5] is a six-dimensional sum. It is seen, however, to depend essentially only on differences between summation indices. If we put

[8] $$I = i - l,\ J = j - m,\ K = k - n$$

some calculation shows that the energy per molecule can be rewritten

[9] $$\phi_N = \frac{1}{N^3}\sum_{IJK=-(N-1)}^{(N-1)}{}' \times \frac{(-1)^{I+J+K}(N - |I|)(N - |J|)(N - |K|)}{|I\boldsymbol{a}_1 + J\boldsymbol{a}_2 + K\boldsymbol{a}_3|}$$

The full interaction energy can thus be written as this three-dimensional sum (over $(2N-1)^3 - 1$ terms). The total charge of the ions summed over, including the positive one in the middle, is -1 for even N and $+1$ for odd. The transformation of the summation indices done here is analogous to the transformation to center-of-mass and relative coordinates that is well known from the two-body problem (compare Sect. 9, especially formula [44]).

4. Relation to the Madelung constant

In ionic crystals one usually estimates the energy of an ion in the crystal by means of the Madelung (1) constant. This constant is thus the sum of all electrostatic interaction energies of the ion with all the other ions of the crystal. There is a large literature on the calculation of Madelung constants. For a review see Tosi (3). Johnson and Templeton (4) give the values of this constant for many structures. For modern methods of calculation see Christiansen et al. (5). For a careful investigation of the mathematics of lattice sums in general, see Glasser and Zucker (6).

The general conclusion is that calculation of Madelung constants is a difficult problem. Slow convergence and dependence on order of summation are a few of the problems (Borwein et al. (7)). It is of special importance to avoid summing in such a way that there is a dipole moment (Smith (8)) and to sum over neutral chunks. With ABL crystals these problems can be handled in a unified and natural way. The sum should simply be over a parallelepiped with edges parallel to the lattice basis vectors $(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3)$ placed symmetrically around the central ion. Such a sum can be written

[10] $$\alpha_M = -\sum_{ijk=-M}^{M}{}' \frac{(-1)^{i+j+k}}{|i\boldsymbol{a}_1 + j\boldsymbol{a}_2 + k\boldsymbol{a}_3|}$$

and the macroscopic limit of these sums,

[11] $$\alpha = \lim_{M\to\infty} \alpha_M$$

Table 1. This table illustrates the slow convergence of ϕ_N and α_N to the two traditional Madelung constants for the NaCl and CsCl structures.

N	$-\phi_N$(NaCl)	$-\phi_N$(CsCl)	α_{N-1}(CsCl)
2	1.456 029 925 6300	1.424 077 966 6800	2.263 010 770 3212
4	1.628 723 191 4176	1.603 719 655 2523	1.947 351 124 0847
8	1.693 917 644 6892	1.683 696 940 0257	1.848 352 785 3331
16	1.721 993 913 6163	1.722 980 563 5781	1.804 086 719 3739
32	1.735 064 935 0971	1.742 731 582 3887	1.783 047 012 0754
64	1.741 382 517 4569	1.752 673 339 8033	1.772 780 083 5976
128	1.744 490 021 4990	1.757 665 856 0027	1.767 707 540 3185
256	1.746 031 364 4517	1.760 168 170 9412	1.765 186 223 1587
512	1.746 798 986 0756	1.761 420 924 3686	1.763 929 269 4904
Extrapolated	1.747 564 60	1.762 674 78	1.762 674 78

is thus the Madelung constant α. Usually it is assumed that the nearest neighbor distance, R_n, is 1 and we will adopt this convention.

The sequence $\alpha_M (M = 2, 3, \ldots)$ converges monotonically to the appropriate Madelung constant. For the NaCl structure this sum is over cubic "shells" and for CsCl is it over the corresponding rhombohedral "shells." When Madelung constants are looked at from the conventional point of view these two crystals appear very different (8).

It is interesting to note that for $M = N - 1$ the two sums [9] and [10] go over the corresponding terms and that, in fact,

$$[12] \qquad \phi_N = -\alpha_{N-1} + \text{"surface terms"}$$

Here "surface terms" represent sums in which increased weight is given to terms near the surface of the parallelepiped. As N grows larger the relative importance of these decreases and the two sequences have the same limits (apart from sign):

$$[13] \qquad \phi = -\alpha$$

This is a natural result that normally has been taken for granted, but we have checked it numerically and it holds. For an example see Table 1. Since the sum [10] is simpler than [9], this result can be used to speed up calculation of ϕ. On the other hand, while the sequences ϕ_N give a measure of the energy of finite (parallelepipedal) clusters of $N^3/2$ molecules, the unconverged Madelung sums α_M are of no particular physical significance.

5. Numerical considerations

Nowadays it is easy to try plug formula [9] or [10] into a computer to find the relevant limit. The convergence is, however, quite slow. This has physical reasons. Convergence means that the surface terms of eq. [12] become negligible. But volume varies as N^3 and surface area like $8N^2$, so N must, of course, be quite large before $8N^2$, and corresponding physical surface effects, can be neglected in comparison with N^3.

Ewald (9) developed analytic methods for speeding up the convergence and many methods have been suggested since then. We have used a method for convergence improvement introduced by Shanks (10), as reported by Levin (11). This method extrapolates a sequence ϕ_N to the limit ϕ by making certain assumptions about the analytical behavior of the terms. We found that it gives values for Madelung constants, accurate to four digits, cheaply and with very little programming. A little extra effort is needed to find the following, nine-digit-accurate, values for the usual Madelung constants

$$[14] \qquad \alpha(\text{NaCl}) = 1.747\,564\,60$$

$$[15] \qquad \alpha(\text{CsCl}) = 1.762\,674\,78$$

Here there is an uncertainty of one in the last digit. The convergence can be studied in Table 1.

For the simple cubic NaCl structure one can find a much faster and more accurate path to the Madelung constant based on analytical formulae of Borwein et al. (7). This is discussed in Sect. 8. At present, however, these do not extend to non-cubic lattices.

The ϕ_N values of Table 1 show that, for small N (up to ~16, or 2048 molecules) the NaCl structure is energetically favored compared to the CsCl structure, while for higher N the opposite is true. This physically relevant fact cannot be obtained from the corresponding Madelung sequences; the α_N for CsCl are larger than those for NaCl for all N.

6. A one-parameter lattice family

To compare different lattices in a reliable way one should find a continuous path between them. We thus study the one-parameter family of trigonal (rhombohedral) lattices that have the lattices [2] and [3] as members. Hoppe (12) was the first to do this; we do it in a somewhat different way that follows naturally from the ABL concept.

We first put

$$[16] \qquad \boldsymbol{\varepsilon}_1 = \boldsymbol{e}_1,\ \boldsymbol{\varepsilon}_2 = \frac{1}{2}(-1, \sqrt{3}, 0),\ \boldsymbol{\varepsilon}_3 = \frac{1}{2}(-1, -\sqrt{3}, 0)$$

for three unit vectors 120° apart in the xy-plane, so that $\boldsymbol{\varepsilon}_i \cdot \boldsymbol{\varepsilon}_j = -1/2$, $(i \neq j)$. We can now define the family of lattice (unit length) basis vectors

$$[17] \qquad \boldsymbol{a}_1(\theta) = \sqrt{2/3}(\sqrt{1 - \cos\theta}\,\boldsymbol{\varepsilon}_i + \sqrt{1/2 + \cos\theta}\,\boldsymbol{e}_3), \qquad i = 1, 2, 3$$

Table 2. This table illustrates some properties of the one-parameter family of trigonal lattices for different values of the parameter θ.

θ(deg)	cos θ	$V(\theta)$	$R_n(\theta)$	$\alpha(\theta)$	Lattice type	Crystal
0	1	0	0	$-\infty$?	Half-line	—
15	0.966	0.058	0.261	−9.527	—	—
45	0.707	0.455	0.765	−0.0396	—	—
60	1/2	0.707	1	1.2357	fcc	—
75	0.259	0.913	1	1.6532	—	—
90	0	1	1	1.7476	sc	NaCl
104	−0.242	0.893	1	1.7182	—	—
109.47	−1/3	0.770	1	1.7627	bcc	CsCl
115	−0.423	0.559	0.681	1.4601	—	—
120	−1/2	0	0	1.3863	Plane	—

depending on the parameter θ. They are all of length one, $|\boldsymbol{a}_i(\theta)| = 1$, and all make the same angle θ

$$[18] \qquad \boldsymbol{a}_i(\theta)\cdot\boldsymbol{a}_j(\theta) = \cos\theta \quad (i \neq j)$$

with one another. The volume of the parallelepiped spanned by these vectors is given by

$$[19] \qquad V(\theta) = \boldsymbol{a}_1\cdot(\boldsymbol{a}_2 \times \boldsymbol{a}_3) = (1 - \cos\theta)\sqrt{1 + 2\cos\theta}$$

and the surface area is $A(\theta) = 8|\boldsymbol{a}_1 \times \boldsymbol{a}_2| = 8 \sin\theta$.

Since we are interested in the nearest neighbor normalized Madelung constants we also note that the nearest neighbor distance in this lattice family is given by

$$[20] \qquad R_n(\theta) = \begin{cases} \sqrt{2 - 2\cos\theta} & \text{for } 0 < \theta < 60° \\ 1 & \text{for } 60° \leq \theta \leq 109°.47 \\ \sqrt{3 + 6\cos\theta} & \text{for } 109°.47 < \theta < 120° \end{cases}$$

Thus $R_n = 1$ for all angles between 60° and 109°.47 (the "tetrahedral angle"), since for these values the nearest neighbor is along a lattice vector $\boldsymbol{a}_i$. The new nearest neighbor that appears below θ = 60° is one of the same charge. At θ = 109°.47, which corresponds to the CsCl structure, the new nearest neighbor is of opposite charge. Some relevant values of θ and the corresponding lattices are listed in Table 2.

7. Energy of orthorhombic ABL crystals

Let $\phi_N(\boldsymbol{a}_1, \boldsymbol{a}_2, \boldsymbol{a}_3)$ be defined by eq. [9]. By means of the lattice family of the previous section we now define

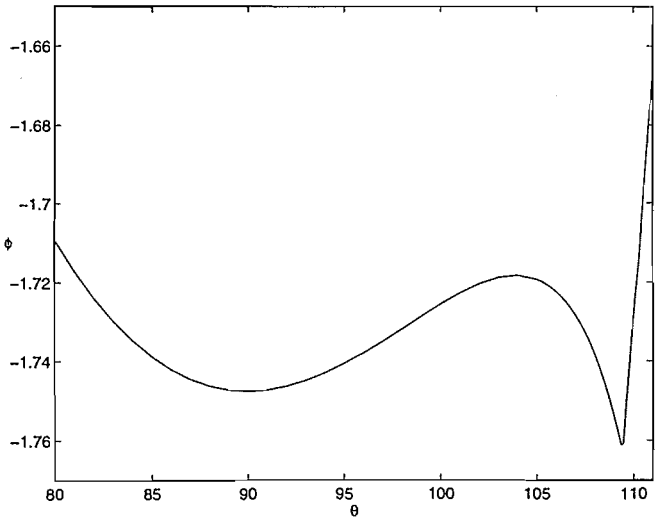
$$[21] \qquad \phi_N(\theta) \equiv R_n(\theta) \cdot \phi_N(\boldsymbol{a}_1(\theta), \boldsymbol{a}_2(\theta), \boldsymbol{a}_3(\theta))$$

Here we have introduced a nearest neighbor normalization so that

$$[22] \qquad \lim_{N\to\infty} \phi_N(\theta) = \phi(\theta) = -\alpha(\theta)$$

is the (negative) nearest neighbor normalized Madelung constant. The physical model underlying the nearest neighbor normalization is that of hard sphere (billiard ball) ions. For such a model system the electrostatic potential energy is the full potential energy.

Fig. 1. Plot of the function φ(θ). The two minima correspond to the NaCl structure (at θ = 90°) and the CsCl structure (at θ = 109°.47). These minima clearly have different characters.



The function $\phi_2(\theta)$, which represents the electrostatic energy of four molecules (8 ions), can be calculated explicitly and is given by

$$[23] \qquad \phi_2(\theta) = -R_n(\theta)\frac{3}{2}\left(2 - \frac{1}{\sqrt{2 + 2\cos\theta}} - \frac{1}{\sqrt{2 - 2\cos\theta}} + \frac{1}{2\sqrt{3 - 2\cos\theta}} + \frac{1}{6\sqrt{3 + 6\cos\theta}}\right)$$

This function has a global minimum at θ = 90° where its value is −1.456. It has a shallow local minimum at θ = 109°.47 where it is −1.424. Between these two minima there is a local maximum at θ = 109°.27; the value of the function at this point is only 2×10^{-5} higher than at θ = 109°.47 (the calculations were done using Maple (13)). In practice this means that the NaCl structure is the only stable structure for this system. As we saw in Table 1 the NaCl structure is predicted to be the electrostatically most stable up to $N \approx 16$.

In Fig. 1 we have plotted the function φ(θ) near its relevant minima. It shows a local minimum at θ = 90°, corresponding

to the NaCl structure. There is a local maximum at roughly $\theta = 104°$ which is 0.0455 higher than the global minimum at $\theta = 109°.47$, the CsCl structure. We see that the two minima are very different. The CsCl minimum is very narrow and sharp. Its shape is determined by the fact that a new nearest neighbor appears at this angle; if it were not for the nearest neighbor normalization the function would go down to minus infinity towards $\theta = 120°$. Our results agree with those of Hoppe (12) who calculated the same curve using a different, but equivalent, parameter.

It has been known for a long time that substances that have the NaCl structure can go into the CsCl structure when pressure is applied. Conversely, CsCl changes into the NaCl structure at high temperatures (see Tosi (3) or Pauling (14) and references therein). The curve in Fig. 1 gives some feeling for the electrostatics going on in these transitions.

8. The electrostatic energy of simple cubic ABL clusters and crystals as a function of dimension

It is of some interest to note that one can easily generalize the concept of ABL ionic crystals from spatial dimension three to any (integer) spatial dimension. Here, of course, only dimensions one and two of direct physical interest, but higher dimensions may be of interest to illustrate the general trend.

In this section we will limit ourselves to the simple cubic case, so formula [9] becomes

$$[24] \qquad \phi_N = \frac{1}{N^3} {\sum_{IJK=-(N-1)}^{(N-1)}}' \times \frac{(-1)^{I+J+K}(N-|I|)(N-|J|)(N-|K|)}{\sqrt{I^2+J^2+K^2}}$$

If now consider only the smallest, $N = 2$, cluster (or molecule), the generalization of this formula to arbitrary dimension n is

$$[25] \qquad \phi_2(n) = F(n,0) = \frac{1}{2^n} {\sum_{i_1=-1}^{1}} \cdots {\sum_{i_n=-1}^{1}}' \times \frac{(-1)^{\sum_{k=1}^n i_k} \prod_{k=1}^n (2-|i_k|)}{\sqrt{\sum_{k=1}^n i_k^2}}$$

The direct calculation of this quantity by means of nested summation loops rapidly becomes unwiedly as n increases. We shall calculate it by means of a recursion method.

We start by defining

$$[26] \qquad F(n,j) = \frac{1}{2^n} {\sum_{i_1=-1}^{1}} \cdots {\sum_{i_n=-1}^{1}} \times \frac{(-1)^{\sum_{k=1}^n i_k} \prod_{k=1}^n (2-|i_k|)}{\sqrt{\sum_{k=1}^n i_k^2 + j}}$$

for $n, j > 0$. We also define

$$[27] \qquad F(0,0) = 0 \quad \text{and} \quad F(0,j) = \frac{1}{\sqrt{j}}$$

Table 3. This table lists the electrostatic energies, $\phi_2(n)$, of neutral ionic hypercubic molecules of dimension n and the Madelung constants $\alpha(n)$ of simple cubic ABL crystals. The spatial dimensions n = 1–6, n = 10, 50, and 100 are given and the results are accurate to 14 digits.

n	$-\phi_2(n)$	$\alpha(n)$
1	1.000 000 000 000 00	1.381 971 451 866 13
2	1.292 893 218 813 45	1.615 542 626 712 83
3	1.456 029 925 629 98	1.747 564 594 633 18
4	1.566 760 389 639 21	1.839 399 084 045 05
5	1.649 648 475 530 74	1.909 337 815 618 77
6	1.715 436 948 530 18	1.965 557 039 009 08
⋮	⋮	⋮
10	1.890 851 969 665 06	2.118 310 501 384 82
50	2.371 200 612 411 97	2.553 231 760 698 21
100	2.551 846 198 763 93	2.721 232 274 628 21

and then find the recursive relation

$$[28] \qquad F(n,j) = F(n-1,j) - F(n-1,j+1), \; n > 0, \; j \geq 0$$

for these sums. The quantities of interest, $F(n,0)$, can then easily be generated. They will correspond to the electrostatic energy of neutral hypercubic ionic molecules of dimension n. Some results are given in Table 3.

The Madelung constant for a simple cubic ABL crystal of dimension n can be defined as

$$[29] \qquad \alpha(n) = (-1)^n \lim_{M\to\infty} {\sum_{i_1=-M}^{M}} \cdots {\sum_{i_n=-M}^{M}}' \frac{(-1)^{i_1+\ldots+i_n}}{\sqrt{\sum_{k=1}^n i_k^2}}$$

(compare eq. [10]). Here the prime indicates that the term with $i_1 = i_2 = \ldots = i_n = 0$ is to be excluded. In the case $n = 1$ one obtains (Kittel (15))

$$[30] \qquad \alpha(1) = (-1) {\sum_{k=-\infty}^{\infty}}' \frac{(1-)^k}{k} = 2\sum_{k=1}^{\infty}(-1)^{k+1}\frac{1}{k} = 2\log 2 \approx 1.38197$$

but for higher dimensions there is no obvious analytic result. In direct numerical calculations the number of terms would be roughly $(2M)^n$ so a calculation would rapidly become very cumbersome for large n. Borwein et al. (7) have, however, using theta functions and the Mellin transform, derived the analytical expression

$$[31] \qquad \alpha(n) = \frac{1}{\sqrt{\pi}} \int_0^\infty \left\{ \left[\sum_{k=-\infty}^{\infty} (-1)^k \exp(-k^2 t) \right]^n - 1 \right\} \frac{dt}{\sqrt{t}}$$

for the simple cubic Madelung constant as a function of n. (It follows from eq. (28) in ref. 7.) This formula is easily programmed and gives the numerical results of Table 3.

The number of nearest neighbors with opposite charge increases by two for each dimension. It is thus not surprising that the Madelung constants increase with n, as we find. The increase, however, becomes smaller with each new dimen-

sion and, formula [31] can be used to show that the asymptotic behavior is given by

$$[32] \qquad \alpha(n) \asymp \frac{2}{\sqrt{\pi}}\sqrt{\log n}$$

For large n the increase is thus very slow. Table 3 shows that the difference between the Madelung constant and $-\phi_2(n)$ decreases with increasing n. This means that the lattice summation converges more rapidly in higher dimensions. Physically this seems natural as the field produced by a neutral hypercube must correspond roughly to a multipole field one order higher for each new dimension.

9. The interaction energy of two constant charge distributions in a cube

Consider the electrostatic energy of a system of $\mathcal{N}$ (positive) charged particles of charge q at $\boldsymbol{r}_i$. This electrostatic energy is

$$[33] \qquad \Phi = \sum_{i<j}^{\mathcal{N}} \frac{q^2}{r_{ij}}$$

Assume that the number $\mathcal{N}$ is large and that the particles are evenly distributed (randomly or in some ordered way) in a cubic region of side L. We can then estimate this energy using the continuum approximation, i.e., we assume that we are dealing with the self-interaction of a charge density $\rho = (\mathcal{N}q)/L^3$ (constant inside the cube and zero outside). We can thus write

$$[34] \qquad \Phi \approx \frac{1}{2} C_c \frac{(\mathcal{N}q)^2}{L}$$

where C_c is a dimensionless number that we now proceed to calculate. This number is of interest in the theory of ionic crystals but is also of interest in other areas of solid state theory (16).

Consider two electrons of charge e in a cubic box of side length L. Assume that both electrons have constant charge density

$$[35] \qquad \rho = e/L^3$$

in this box. The Coulomb, electrostatic, interaction energy of these charge distributions is then:

$$[36] \qquad \left[\int_{r_1 \in \Omega_L^1} \left(\int_{r_2 \in \Omega_L^2} \frac{dV_2}{|\boldsymbol{r}_1 - \boldsymbol{r}_2|} \right) dV_1 \right] \left(\frac{e}{L^3}\right)^2 \equiv C_c \frac{e^2}{L}$$

Here Ω_L^a $(a = 1,2)$ denote the cubic regions over which the integration variables, $\boldsymbol{r}_a = (x_a, y_a, z_a)$, take their values. We now introduce units so that $e = L = 1$. These regions are then

$$[37] \qquad \Omega^a = \{(x_a, y_a, z_a);$$

$$0 < x_a < 1,\ 0 < y_a < 1,\ 0 < z_a < 1\}, \qquad a = 1, 2$$

and the energy can simply be expressed as

$$[38] \qquad C_c = \int_{\Omega^1} \int_{\Omega^2} \frac{dV_1 dV_2}{|\boldsymbol{r}_1 - \boldsymbol{r}_2|}$$

or, alternatively, in the form

$$[39] \qquad C_c = \int_0^1 \int_0^1 \int_0^1 \int_0^1 \int_0^1 \int_0^1 \times \frac{dx_1 dy_1 dz_1 dx_2 dy_2 dz_2}{\sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2}}$$

which shows explicitly that this is a six-dimensional integral.

To calculate this integral we first transform to center-of-mass and relative coordinates for the two "electrons":

$$[40] \qquad \boldsymbol{r} = \boldsymbol{r}_1 - \boldsymbol{r}_2$$

$$[41] \qquad \boldsymbol{R} = \frac{1}{2}(\boldsymbol{r}_1 + \boldsymbol{r}_2)$$

For the x-components we then have explicitly

$$[42] \qquad x = x_1 - x_2, \qquad x_1 = X + \frac{1}{2}x$$

$$\Longleftrightarrow$$

$$[43] \qquad X = \frac{1}{2}(x_1 + x_2), \qquad x_2 = X - \frac{1}{2}x$$

and similarly for the y- and z-components. This transformation makes the three integrations over $\boldsymbol{R} = (X, Y, Z)$ trivial and the result is the three-dimensional integral

$$[44] \qquad C_c = \int_{-1}^1 dx \int_{-1}^1 dy \int_{-1}^1 dz \frac{(1 - |x|)(1 - |y|)(1 - |z|)}{\sqrt{x^2 + y^2 + z^2}}$$

(compare formula [9]). Because of symmetry this gives

$$[45] \qquad C_c = 8 \int_0^1 dx \int_0^1 dy \int_0^1 dz \frac{(1 - x)(1 - y)(1 - z)}{\sqrt{x^2 + y^2 + z^2}}$$

We now transform first to cylindrical coordinates

$$[46] \qquad x = \rho \cos\varphi, \qquad y = \rho \sin\varphi$$

Because of a further symmetry the integral now becomes

$$[47] \qquad C_c = 16 \int_0^{\pi/4} d\varphi \int_0^{1/\cos\varphi} \rho d\rho \int_0^1 dz \times \frac{(1 - \rho\cos\varphi)(1 - \rho\sin\varphi)(1 - z)}{\sqrt{\rho^2 + z^2}}$$

Finally we transform to spherical coordinates by means of the transformation

$$[48] \qquad z = r\cos\theta, \qquad \rho = r\sin\theta$$

We must now split the integration over θ into two integrals because of the corner at $z = 1$, corresponding to $\theta = \arctan(1/\cos\varphi)$. We thus get

$$[49] \qquad C_c = 16 \int_0^{\pi/4} d\varphi \times \left\{ \left[\int_0^{\arctan(1/\cos\varphi)} \sin\theta\, d\theta \int_0^{1/\cos\theta} r^2 dr + \int_{\arctan(1/\cos\varphi)}^{\pi/2} \sin\theta\, d\theta \int_0^{1/(\cos\varphi \sin\theta)} r^2 dr \right] \times \frac{(1 - r\sin\theta\cos\varphi)(1 - r\sin\theta\sin\varphi)(1 - r\cos\theta)}{r} \right\}$$

Here the r-integrations are trivial. The θ-integrations can be done analytically and we have used Maple (13) to do them. The result is

$$[50] \qquad C_c = 16 \int_0^{\pi/4} \Phi_c(\varphi) d\varphi$$

where the integrand is the function

$$\begin{aligned}[51] \qquad \Phi_c(\varphi) = \frac{1}{120}[&5\cos(\varphi)^5 \ln(\sqrt{\cos(\varphi)^2+1}+1) \\ &- 5\cos(\varphi)^5 \ln(\cos(\varphi)) + 4\cos(\varphi)^5 \sin(\varphi) \\ &- 4\cos(\varphi)^4 \sin(\varphi)\sqrt{\cos(\varphi)^2+1} \\ &- 5\cos(\varphi)^4 \sin(\varphi)\ln(\cos(\varphi)) \\ &+ 5\cos(\varphi)^4 \sin(\varphi)\ln(\sqrt{\cos(\varphi)^2+1}+1) \\ &- 20\cos(\varphi)^4 + 15\cos(\varphi)^3\sqrt{\cos(\varphi)^2+1} \\ &- 3\sin(\varphi)\sqrt{\cos(\varphi)^2+1}\cos(\varphi)^2 - 6\sin(\varphi) \\ &+ 10\cos(\varphi) + 6\sin(\varphi)\sqrt{\cos(\varphi)^2+1} \\ &- 20\ln(\sqrt{\cos(\varphi)^2+1} - \cos(\varphi))\cos(\varphi)^2 \\ &+ 10\sin(\varphi)\ln(\sqrt{\cos(\varphi)^2+1} - \cos(\varphi))\cos(\varphi) \\ &- 10\sqrt{\cos(\varphi)^2+1}\cos(\varphi)]/\cos(\varphi)^4 \end{aligned}$$

This formula is taken (almost) directly from Maple output; to get it one must use *simplify* with "*assume* $\cos(\varphi) > 0$."

The final φ-integration can not be done analytically by Maple, but it turns out that the function Φ_c is nearly constant (it varies with roughly 10%) over the interval 0–$\pi/4$. It is thus easy to get very accurate numerical results. Maple, with the default ten-digit accuracy, gives

$$[52] \qquad C_c = 1.882\,312\,645$$

and this is the desired constant. We have checked the calculation by using other, more straightforward, numerical methods.

10. Conclusions

Electrostatic interactions are at the root of many subtle and long-range effects in crystals and molecules. They indicate that it is physically difficult to regard the energy of some three-dimensional region as arising locally within that region. This is also connected with the lack of transferability of the Bader atoms (ions), a problem that was discussed by Bader and Becker (17) from a different point of view.

In this paper we have discussed various aspects of the electrostatic interaction energy. In particular we have studied the (macroscopic) Madelung constants for a class of ionic crystals, and the electrostatic interaction energies for finite clusters. One unusual aspect of our treatment is that we have shown that the electrostatic energy can be reduced to a simple sum over the crystal which differs from the Madelung sums by the presence of "surface terms." We also believe that some of our other results are either new or, at least, represent a novel way of viewing these problems.

Acknowledgments

This research has come about in the tolerant and open-minded climate of Prof. Martin Lesser's research group at the Department of Mechanics at KTH. This group has many similarities to Prof. Richard Bader's group where one of us (H.E.) spent two years as a post doc in 1981–1982. We would also like to thank one of the referees of the Canadian Journal of Chemistry for useful comments and references. These led to the discovery of an error in an earlier version of this manuscript.

The role of hydrogens in stabilizing organic ions

Kenneth B. Wiberg, Paul von Rague Schleyer, and Andrew Streitwieser

Abstract: The changes in electron density that result from processes in which ions are formed were examined using both electron density difference maps and calculations of electron populations using Bader's theory of atoms in molecules. The processes include the loss of an electron from a neutral precursor forming a radical cation, the loss of an electron from a free radical forming a carbocation, the addition of a proton to ammonia, the addition of an electron to a free radical forming a carbanion, and the loss of a proton from a neutral precursor forming an anion. In the reactions forming cations, the new positive charge resides mainly at the hydrogens, and the heavy atoms generally gain electron density. The anion-forming reactions lead to negative charge being shared among atoms but, again, much of the charge appears at the hydrogens. $\sigma-\pi$ polarization is an important feature of the charge distribution in all of the ions. There is an advantage to placing the charge at the periphery of an ion since this will minimize its electrostatic energy.

Key words: electron density, anions, cations, radical cations, $\sigma-\pi$ polarization.

Résumé : Faisant appel à des cartes de différences de densité électronique ainsi qu'à des calculs de densités de population dans le cadre de la théorie des atomes dans des molécules, on a étudié les changements dans la densité électronique qui découlent de processus dans lesquels il se forme des ions. Les processus comprennent la perte d'un électron par un précurseur neutre conduisant à un cation radical, la perte d'un électron par un radical libre conduisant à la formation d'un carbocation, l'addition d'un proton à de l'ammoniac, l'addition d'un électron à un radical libre conduisant à la formation d'un carbanion et la perte d'un proton d'un précurseur neutre conduisant à la formation d'un anion. Dans les réactions conduisant à des cations, la nouvelle charge positive réside principalement au niveau des hydrogènes et généralement les atomes lourds subissent un gain de densité électronique. Lors des réactions conduisant à la formation d'anions la charge négative est partagée parmi les atomes, mais, encore une fois, la plus grande partie de la charge apparaît sur les hydrogènes. La polarisation $\sigma-\pi$ est une caractéristique importante de la distribution de charge dans tous ces ions. Il y a un avantage à placer la charge à la périphérie d'un ion puisque ceci a tendance à minimiser son énergie électrostatique.

Mots clés : densité électronique, anions, cations, radicaux cations, polarisation $\sigma-\pi$.

1. Introduction

It is well established that charged species are stabilized by spreading the charge over as large a surface area as possible (1). In organic ions, this suggests that a considerable part of the charge should be transferred to the hydrogens at the periphery of the ion. The hydrogens should be a good source for electron density since they have a small nuclear charge and cannot hold onto their electron density as well as other atoms with larger nuclear charges. They may also be able to accept some electron density in the formation of anions. This report will be concerned with the role hydrogens play in the stabilization of ions.

Several processes that form positively or negatively charged ions were examined using ab initio molecular orbital theory. The structural parameters for the compounds and ions were obtained via MP2 (2) or Becke3LYP (3) geometry optimizations. Both procedures correct for electron correlation, and generally give similar relative energies and charge distributions. The 6-31G* basis set was used for saturated compounds and carbocations, and 6-31+G* was used for compounds and ions having lone pairs. The analysis of the charge distribution was made either using Bader's theory of atoms in molecules (AIM) (4) to obtain electron populations, or using electron density difference plots between the ions and their neutral precursors.

2. Formation of radical cations via photoelectron spectroscopy

Photoelectron spectroscopy is a process in which a radical cation is formed via the loss of an electron from a neutral precursor (5). It is a vertical excitation, and so it is appropriate to use the same geometry for the precursor and the ion. The MP2/6-31G* wave functions for the two species were converted into three-

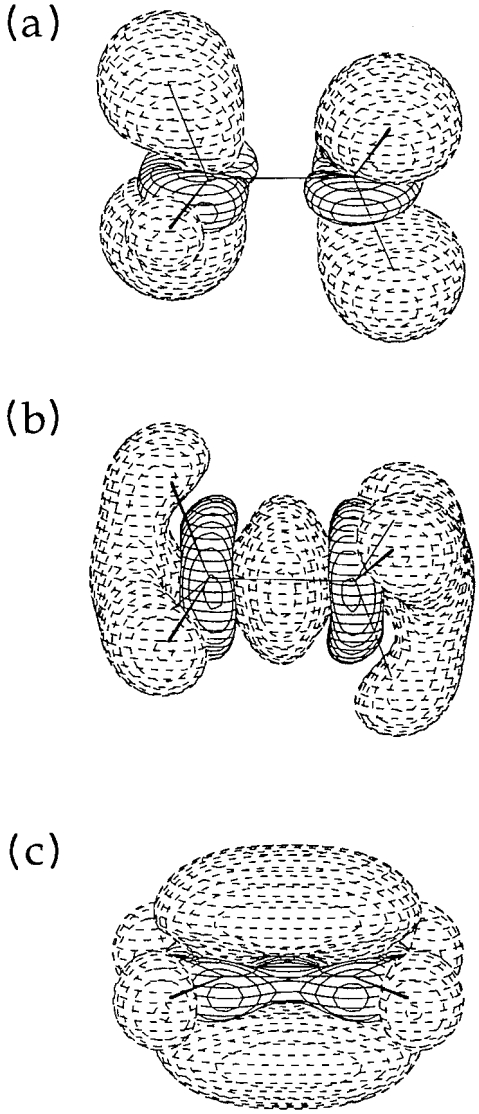
Fig. 1. Change in electron density distribution on going from (*a*) ethane using the highest CH bonding orbital, (*b*) ethane using the highest C—C bonding orbital, and (*c*) ethene using its π orbital to their radical cations calculated at the MP2/6-31G* level. The contour level is 0.005 e/au^3. Loss of electron density is indicated by broken contours.



dimensional arrays of electron density, and the distribution for the neutral compound was subtracted from that of the radical cation. The difference density was visualized as a 3-D plot.

Ethane provides a good example of this approach. The highest occupied MO's of ethane are a pair of degenerate CH bonding orbitals. The difference density between ethane and the radical cation formed by removal of an electron from one of these MO's is shown in Fig. 1*a* where the broken contours indicate regions that lose electron density on going to the radical cation, and solid contours show regions that gain density. As expected, electron density is lost from the hydrogens but, at the same time, the carbons gain some electron density. Separate integrations of the regions in the figure that have gained and lost electron density found a 0.122*e* gain by the carbons and a 1.122*e* loss by the hydrogens.

The electron populations may also be derived using Bader's theory of atoms in molecules (AIM) in which the electron density is integrated within atomic volume elements defined by zero-flux surfaces (4). Each hydrogen of ethane has 0.981*e*. With this radical cation, the hydrogen populations are not equal because of the loss of symmetry in taking an electron from one of a pair of degenerate orbitals. Two of the hydrogens have 0.847*e* and the other four have 0.739*e* for a net loss of 1.24*e* at the hydrogens. Thus, both methods agree that more than one electron is taken from the hydrogens in forming the radical cation.

The next ethane MO is associated with the C—C bond. The difference density between ethane and the radical cation formed by loss of an electron from this MO is shown in Fig. 1*b*. Loss is seen at the C—C bond and also at the hydrogens, but the carbons again gain charge density. Integration of the regions in Fig. 1*b* indicates a 0.12*e* gain at each carbon, a 0.32*e* loss at the C—C bond, and a 0.15*e* loss at each hydrogen. Thus, even for this MO, the hydrogens contribute 90% of the electron that is lost in the photoionization.

The AIM electron populations were calculated for this radical cation. Each hydrogen has 0.797*e*, for a loss of 0.18*e* on going to the radical cation. It can be seen that the two methods are in good agreement.

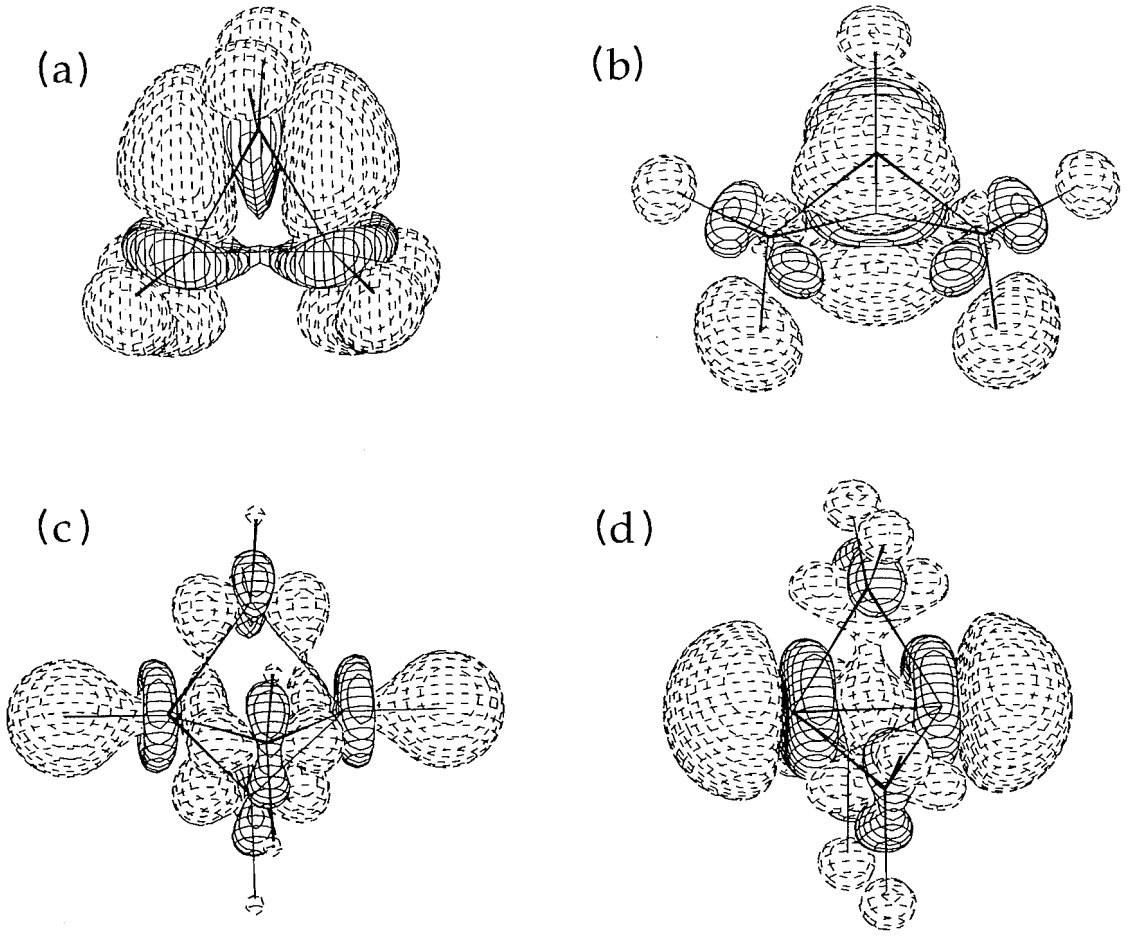
Ethene provides another interesting example. Here, the lowest energy radical cation is formally derived by the loss of one of the π electrons. Will charge be taken from the hydrogens in this case? Figure 1*c* shows that this is the case, and that the electron density near the carbons is again increased. Integration of the electron loss and gain regions in Fig. 1*c* showed that 0.180*e* is gained in the vicinity of the carbons, and that 1.180*e* is lost at the hydrogens and the carbon π orbital. The loss of electron density at the hydrogens is also seen in the AIM populations. Each hydrogen of ethene has 0.946*e*, and each hydrogen of the radical cation had 0.780*e*, for a loss of 0.166*e* on going to the radical cation. Thus, the hydrogens contribute about 66% of the electron that is lost on photoionization.

This procedure was also applied to several cyclic hydrocarbons: cyclopropane, bicyclo[1.1.0]butane, bicyclo[1.1.1.]pentane, and [1.1.1]propellane (Fig. 2) (6). Again, the broken contours indicate regions that lose electron density on going to the radical cation, and the solid contours indicate regions that have gained density.

In agreement with the ethane result, the electron density loss is found largely at the hydrogens and in the bonding regions, and the carbons again gain electron density in the process. With cyclopropane, the difference density is not symmetrical with respect to the three C—C bonds because in forming the radical cation the electron is taken from one of a pair of degenerate orbitals, leading to incipient Jahn–Teller distortion. Here, the electron is taken from two of the bent C—C bonds and from the hydrogens, and at shorter distances from the nuclei the carbons gain electron density. The changes for bicyclobutane are similar, except that the central C—C bond becomes a major source of the lost electron.

The difference density for bicyclo[1.1.1]pentane (Fig. 2*c*) shows that the bridgehead protons lose considerable electron density on going to the radical cation. Some density is lost from the C—C bonds, but at shorter distances from the nuclei the carbons gain electron density. With [1.1.1]propellane (Fig.

Fig. 2. Change in electron density distribution on going from cycloalkanes to their vertical radical cations calculated at the MP2/6-31G** level. The contour level is 0.005 e/au^3. The compounds are: (*a*) cyclopropane; (*b*) bicyclo[1.1.0]butane; (*c*) bicyclo[1.1.1]pentane; and (*d*) [1.1.1]propellane. The HOMO of cyclopropane is degenerate, and only one of the pair of possible radical cations is depicted, maintaining the cyclopropane geometry.



2*d*) much electron density is lost from the nonbonded density near the bridgehead carbons.

To make the changes more quantitative, the positive and negative regions in Fig. 2 were integrated, giving the results shown in Table 1. In each case, there is a sizable positive sum corresponding to the increases in electron density in the regions near the carbon atoms.

The atomic charges also were obtained using AIM, and the carbon and hydrogen charges were separately summed. These data also are given in Table 1. Again, it is seen that much of the decrease in electron density on going to the cation is seen at the hydrogens. In most cases, the carbons have a much smaller decrease in electron density, and in the case of bicyclo[1.1.1]pentane, C1 is calculated to have in increase in electron density. The small loss seen at most carbons is due to the volume element used in the AIM integrations that includes some of the volume near the carbons for which there is a loss of electron density.

Both methods of examining the changes in electron density agree that the hydrogens provide a large part of the loss in density on going to the cations.

3. Protonation of ammonia

A simple example of the conversion of a neutral molecule to a charged ion is found in the protonation of ammonia. The changes in electron density on protonation have been examined making use of the Mulliken population analysis, and it was concluded that most of the positive charge appears at the hydrogens (7). In view of the difficulties sometimes associated with the Mulliken populations (8), it seemed appropriate to examine this process using other methods of analysis.

There is relatively little change in structure in this process (Table 2), and so it is reasonable to use the ammonium ion geometry for both the ion and for the location of the nitrogen and three hydrogens of ammonia. The use of the same nuclear coordinates for both species is essential since otherwise large shifts in charge density resulting from the nuclear motions will confuse the interpretation of the electron density difference plots. Both the MP2 and B3LYP levels of theory were used, and there were no significant differences between them with regard to structure or relative energies. To be sure that the small change in geometry between the equilibrium structure of

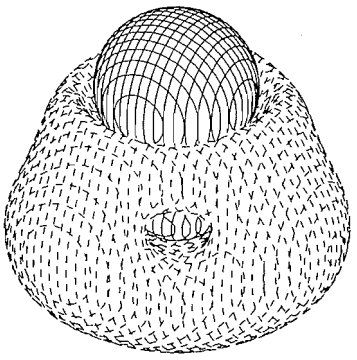
ammonia and the structure based on ammonium ion has no effect, the AIM atomic charges were calculated (Table 2). The changes in the hydrogen charges are only 0.002*e*, which is negligible.

The change in electron density in this process is shown in Fig. 3 where loss is shown by broken contours and gain is shown by solid contours. The MP2 and B3LYP wave functions gave essentially the same plot. It can be seen that the three hydrogens of ammonia lose electron density on protonation, and that both the added proton and the nitrogen nucleus gain density. Thus, the nitrogen, which has a significant negative charge in ammonia because of its higher electronegativity as compared to hydrogen, retains its negative charge in the ion, and in fact increases it slightly despite the overall positive charge in the ion. The increase in electron density at nitrogen on protonation is also seen in the AIM nitrogen atomic charges given in Table 2.

The changes in electron density shown in Fig. 3 may be made more quantitative by integrating the positive and negative regions. With the B3LYP wave functions, the region that gains electron density (the added proton and the nitrogen) corresponds to 0.56*e*, and the other region corresponds to a loss of 0.56*e*. This is in good accord with the populations given in Table 2. For the three hydrogens of ammonia there is a loss of 3 × (0.532 − 0.365) or 0.50*e*. With the MP2 wave functions, integration of the regions in Fig. 2 give 0.49*e* gain and loss, respectively. The AIM populations give a loss for the ammonia hydrogens of 3 × (0.537 − 0.374) or 0.50*e*. The increase in electron density at nitrogen on protonation is small (0.03*e*), but that is expected since it already has a considerable negative charge because of its electronegativity. The important conclusion is that all of the added positive charge (and a little more) appears at the hydrogens.

Fig. 3. Change in electron density distribution on going from ammonia to ammonium ion calculated at the MP2/6-31+G* level. The contour level is 0.001 e/au^3. Note the loss of electron density at the three original hydrogens and the gain in electron density at the nitrogen and the added hydrogen.



4. Formation of carbocations from free radicals

With carbon compounds, the largest charge transfer from the hydrogens would be expected in the formation of carbocations. This has been examined by Bader via a comparison of the AIM charges in the carbocation and the hydrocarbon precursors (9). He found that the hydrogens do receive much of the positive charge in the formation of the carbocations.

The shift in electron density on forming these ions is most readily studied by considering the loss of an electron from a radical. Since both species have three-coordinate carbons, it is reasonable to use the same geometry for both. The stabilization of cations is more dependent on the details of their structures than in the case of the radicals, and so the cation geometries will be used for both species. The loss of an electron from methyl radical, isopropyl radical, *tert*-butyl radical, and allyl radical has been studied, and the results are visualized in Fig. 4.

Again, it can be seen that the electron is taken from the hydrogens and the *p*-orbital that contained the odd electron, and that in other regions the carbons gain electron density on going to the cations. The magnitude of the changes in Fig. 4 were obtained by integrating separately the positive and negative regions, giving the results shown in Table 3.

The methyl cation is by far the least stable of the simple carbocations. Integration of the regions in Fig. 4 indicate that 1.2 electrons are taken from the hydrogens and the carbon *p*-orbital, and that the other carbon orbitals gain 0.2*e*. The AIM populations suggest that 0.89*e* is taken from the hydrogens and 0.11*e* is taken from the carbon. The difference between the two estimates of the charge shift is that the AIM procedure includes the carbon *p*-orbital along with the region shown with solid contours in Fig. 4. As a result, it includes part of the region in which charge density is lost.

Fig. 4. Change in electron density distribution on going from (*a*) methyl radical, (*b*) allyl radical, (*c*) isopropyl radical, and (*d*) *tert*-butyl radical to the corresponding carbocations via the loss of an electron. The calculations used the MP2/6-31G** level of theory, and the contour level is 0.005 e/au^3.

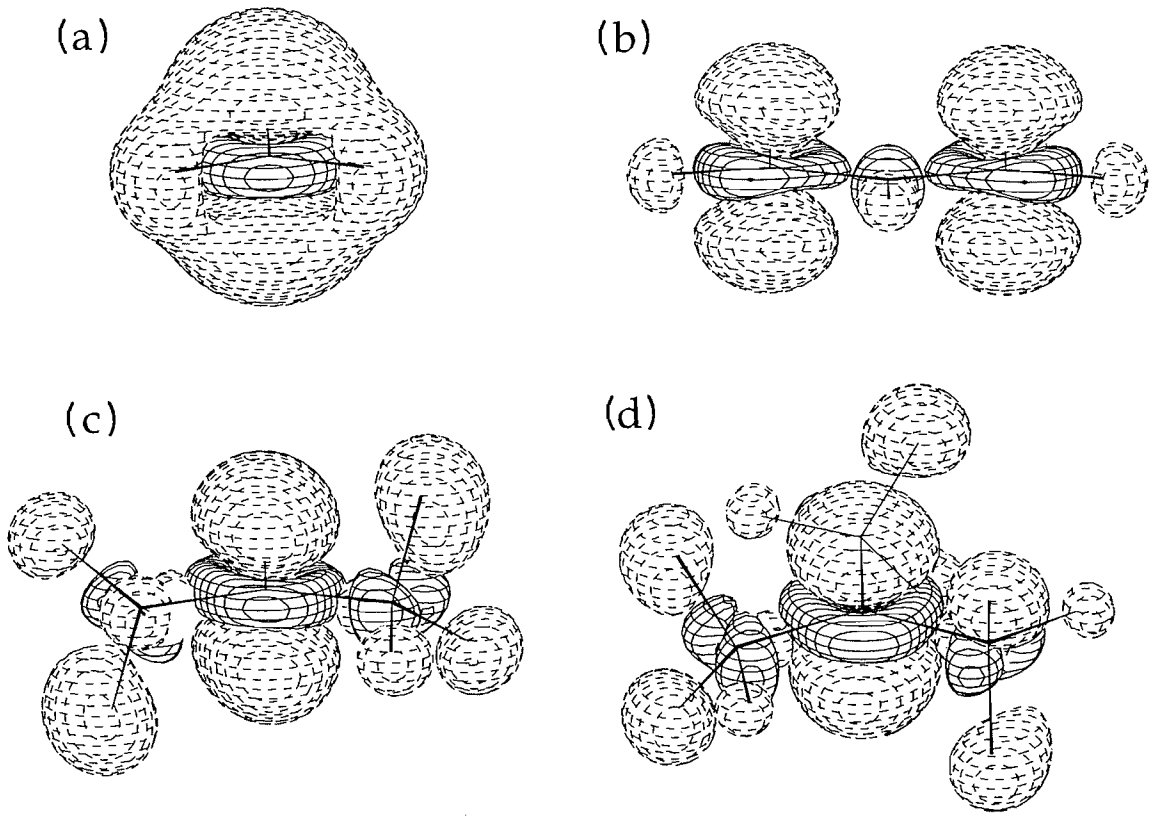


Table 2. Structures and energies of NH_3 and NH_4^+.[a]

Species	Level[b]	Energy	r(XH)	∠(HXH)	q_H	q_X
NH_4^+	B3LYP	−56.90612	1.028	109.5	0.532	−1.126
NH_3	B3LYP	−56.56698	1.016	108.2	0.365	−1.096

[a]Total energies are given in hartrees, bond lengths in Å, bond angles in degrees, and AIM charges (q) in electrons.
[b]All calculations used the 6-31+G** basis set.

Table 3. Changes in electron density on going from radicals to cations derived by integration of 3D difference density plots.

Compound	Electron loss	Electron gain
Methane	1.158	0.160
Isopropyl	1.194	0.195
tert-Butyl	1.228	0.230
Allyl	1.180	0.183
Cyclopropylcarbinyl	1.222	0.223
Cyclobutyl	1.205	0.206

The important conclusion is that much of the positive charge appears at the hydrogens that are in the nodal plane of the empty carbon p-orbital. When the electron is removed from the half-filled p-orbital of the radical, the increased electronegativity of the carbon leads to charge withdrawal from the hydrogens via the σ-bonds. Thus, the conversion of the radical to the cation involves considerable reorganization of charge density.

The isopropyl cation is the simplest secondary cation, and it is considerably more stable than the methyl cation Experimental nmr data are consistent with the theoretical structure (10), which has been found to have C_2 symmetry with a hydrogen on one methyl group aligned with one side of the empty car-

Table 4. Percent decreases in population at carbon and hydrogen on going from the radical to the cation based on AIM populations.

Compound	Position	% at H	% at C
Methyl[a]		65.3	34.7
Isopropyl[b]	C2	15.8	11.9
	C1	81.9	−9.6
tert-Butyl[b]	C2	6.3	
	C1	107.8	−14.1
Allyl[b]	C2	11.4	6.5
	C1	52.5	29.6

[a]The decreases with respect to methane are 76% from the hydrogens and 24% from the carbons.
[b]C2 is the cationic site.
[c]C2 is the central carbon.

bon *p*-orbital and a hydrogen of the second methyl aligned with the other side of the *p*-orbital.

An examination of Fig. 3 shows that the hydrogens that are aligned with the *p*-orbital suffer a greater loss of electron density than the other pairs of hydrogens, as would be expected from the usual hyperconjugation picture. However, all of the hydrogens, including the one attached to the cationic center, suffer loss of charge density. Integrations of the separate regions in Fig. 4 found 1.19*e* was taken from the set of hydrogens and the carbon *p*-orbital and 0.19*e* was gained by the other carbon orbitals.

The AIM analysis also found large changes in the charges for the hydrogens. The methyl carbons are calculated to gain electron population on going to the cation, whereas the cationic carbon loses electron population (Table 4).

The *tert*-butyl cation is quite similar to the isopropyl cation. The structure used in this study had C_{3h} symmetry for convenience in presentation. At the MP2/6-31G* level, it was calculated to be a transition state, but with a very low imaginary frequency (70*i* cm^{-1}). The minimum was slightly distorted from this symmetry, and has a negligibly lower energy (11). The charge integrations (Table 3) show the same pattern as found with the isopropyl cation. Here, 1.23*e* are taken from the hydrogens and the carbon *p*-orbital and 0.23*e* are gained by the other carbon orbitals. The AIM populations show that the central carbon gains electron population on going from the radical to the cation, and that the methyl carbons lose a small amount of electron population. The hydrogens are again a major source of the electron density that is lost on going to the cation.

With the allyl cation, the formation from the allyl radical leads to a net loss of 0.53*e* from the four hydrogens at the terminal methylene groups, and 0.30*e* from the methylene carbons. This is especially interesting in that these hydrogens are in the nodal plane of the π system, and thus the loss of electron density must involve σ–π polarization, as also found with the methyl cation. The loss of electron density from these hydrogens also is clear in Fig. 4.

5. Formation of carbanions from radicals

The conversion of a radical to an anion by the addition of an electron is the converse of the process used in studying the carbocations. Here, the radicals are not as pyramidal as the anions, but the change in charge density on going to the more strongly pyramidal structure should be small for the radicals. The application of this method to the simple carbanions is questionable since they are not bound species, and can decrease their energies by the loss of an electron (12). However, there are some carbanions that are stable species in the gas phase. This includes vinyl anion (13), cyclopropyl anion (14), bicyclo[1.1.0]butyl-1 anion (15), and allyl anion (16). The formation of these ions from the corresponding radicals, using the anion geometries for the latter, led to the electron density shifts shown in Fig. 5.

Table 5. Changes in electron density on going from radicals to anion derived by integration of 3D difference density plots.

Compound	Electron loss	Electron gain
Allyl anion	0.141	1.140
Bicyclobutyl-1 anion	0.206	1.204
Cyclopropyl anion	0.182	1.179
Vinyl anion	0.166	1.164

In each case, the largest change in electron density is found at the carbanion lone pairs. There are large charge shifts to the hydrogens in vinyl anion, but near the carbons there is a loss of density. This is the opposite of what was found in the formation of carbocations from radicals where the carbons gained electron density despite the overall loss of an electron. A gain of electron density at the hydrogens is found for all of the compounds in Fig. 5. The positive and negative regions in the figure were integrated giving the values shown in Table 5. It is interesting to compare the effects of removing an electron (Fig. 4*b*) and adding an electron to an allyl radical (Fig. 5*b*).

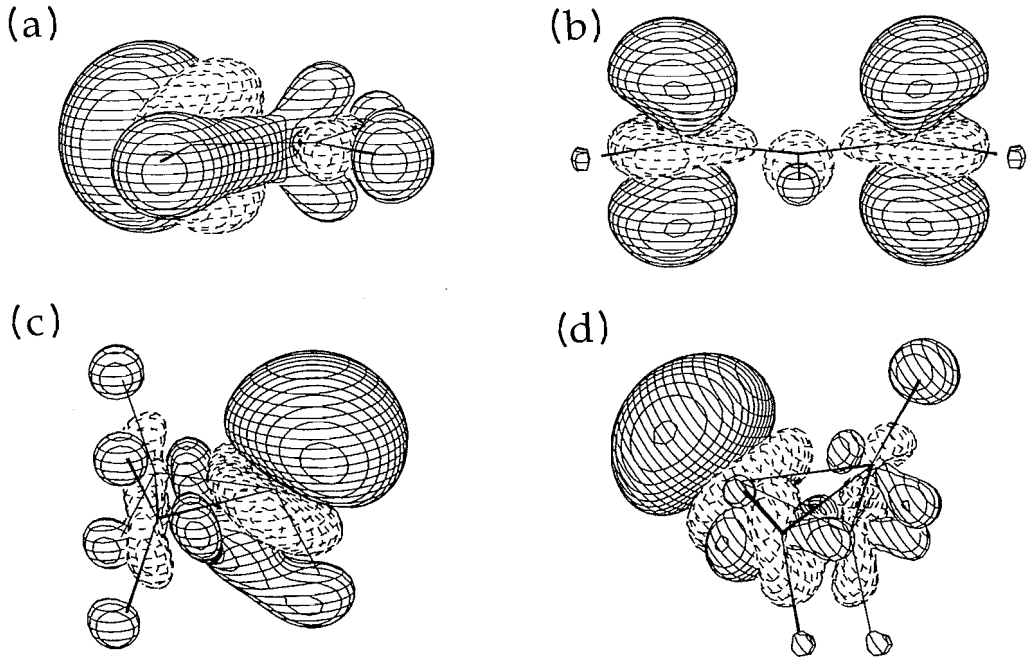
The AIM electron populations for the four anions and the corresponding radicals are given in Table 6. The large charge shifts for the carbons formally bearing the positive charge are due to the formation of the anionic lone pair. However, with the exception of allyl anion, only about one third of the charge is found at this carbon and the rest is distributed over the other carbons and the hydrogens.

6. Formation of anions by proton abstraction

The removal of a proton from methane to form methide ion is formally the reverse of the protonation of ammonia, and it also was examined (Table 7). An important difference from the ammonia case is that the carbon and hydrogen have similar electronegativities, and there is little charge separation in methane. In methide ion, the electron density released by the lost proton is found at both the hydrogens and the carbon, and the AIM populations show that 42% of the charge appears at the hydrogens and 58% at the carbon.

The abstraction of protons from ammonia or water are related processes (Table 8). Here, the central atoms have a higher electronegativity than the hydrogens and, as a result, they have a relatively large negative charge. As a further result, one might expect that it would be relatively difficult to

Fig. 5. Change in electron density on going from a (*a*) vinyl radical, (*b*) allyl radical, (*c*) cyclopropyl radical, and (*d*) bicyclo[1.1.0]butyl-1 radical to the corresponding anions by the addition of an electron, calculated at the MP2/6-31+G** level. The contour level is 0.001 e/au^3.



add additional electron density to them. The data in Table 8 support this expectation. In the abstraction of a proton from ammonia, 73% of the electron density from the proton appears at the remaining hydrogens, and only 27% appears at the nitrogen. Similarly, in the abstraction of a proton from water, 75% of the electron density from the proton appears at the hydrogen and 25 % appears at the oxygen.

The more interesting ions are those formed by the ionization of carboxylic acids and enols. A number of these compounds have been examined,[2] and we will examine formic acid and 5-hydroxypentadienal here.

The changes in electron distribution in the ionization of these compounds was examined using the average structures so that the effect of moving nuclear charges would not overwhelm the shifts in the distributions. The changes in charge are shown in Fig. 6. In the conversion of formic acid to formate ion, the electron density originally associated with the acid proton (~0.5*e*) is about equally distributed between the aldehydic proton and the two oxygens. The electron density difference plot for the conversion of hydroxypentadienal to its enolate ion shows that much of the negative charge appears at the carbon-bound protons even though they are in the nodal plane of the π system. This is also found in the changes in AIM and NPA electron populations on going from the hydroxyaldehyde to its anion (17).

7. Conclusions

In the conversion of neutral precursors to the corresponding cations or anions, hydrogens accept much of the charge, even when the charge is formally associated with a π system and the hydrogens are in the nodal plane of this system. This is espe-

[2] The details of this investigation will be presented elsewhere (17).

cially true in the formation of cations where the hydrogens bear much of the charge, and the heavier atoms generally gain electron density despite the development of an overall positive charge. The change in charge in the formation of anions is not as dramatic but, in many cases, the majority of the negative charge is found at the hydrogens.

In the conversion of a radical to a carbocation, an electron is taken from the carbon making it more electronegative. As a result, there is a tendency for the carbon to contract the electron density in its σ bonds, leading to an increase in electron density in these regions. The opposite is seen when an electron is added to a radical to form a carbanion. Here, the carbon becomes less electronegative and electron density in its σ bonds becomes dispersed, leading to a decrease in density in these regions. The origin of the shifts in electron density resulting from the addition or loss of a proton is not as obvious, but in each case the MO that is involved will have a significant component at the first-row element that is involved, and thus its electronegativity can be modified, leading to the effects described above.

Although there is formal σ–π separation in many cases, σ–π polarization is an important factor in determining electron distributions in ions. When π electrons move in one direction, the σ electrons tend to move in the opposite direction so as to minimize electron repulsion. The neglect of this polarization in the application of resonance concepts and FMO arguments will lead to incorrect conclusions about electron distributions.

Calculations

The ab initio calculations were carried out using Gaussian 95 (18). The AIM integrations were done using PROAIM (19). The 3D plots, along with their integration, were made using CASGEN (20).
