As with the racemic dimer, coordinates for a conformer of the *meso* dimer (**2**) from pcmodel[4] were used as initial input for MM3(94) (21) and then minima on the MM3 potential energy surface were found by driving C(2)-C(1)-C(1′)-C(2′), C(1)-C(2)-C(3)-C(4), and C(1′)-C(2′)-C(3′)-C(4′) torsional angles. Again, all conformational minima had the five-membered rings in envelope conformations, with one atom, C(2) or C(2′), out of the plane. In numbering the molecule on which calculations were performed, C(1) and C(1′) are (*S*) and (*R*) stereogenic centres, respectively. Three unique families of conformations were found that can be defined by the sign of the C(1)-C(2)-C(3)-C(4) and C(1′)-C(2′)-C(3′)-C(4′) torsional angles. In one type of family, termed family **d**, these angles were both positive, which results in the flap of one envelope being directed towards the other half of the dimer, while the flap of the other envelope is directed away from the other half of the dimer. Thus, family **d** will be called the "in,out" family. There is also a fourth family of conformations, termed the **d′** or "out,in" family, that is enantiomeric to the "in,out" family (**d**). In the second unique family (**e**), the angle in the ring containing the (*S*) stereogenic centre was positive and the angle in the other ring negative, which results in both envelopes being flapped away from the other half of the dimer. This family is the "out, out" family. The third family (**f**) has "in,in" conformations for the five-membered rings. Saddlepoints on the surface were found by taking the approximate maxima on dihedral angle drives between minima and minimizing those points using full-matrix Newton–Rapson minimization in MM3. Confirmation that these points were indeed saddlepoints was provided by the presence of single imaginary frequencies in the calculated vibrational spectra. In some cases, it was necessary to use dihedral angle intervals as small as 1° in order to find the saddlepoints. Additional grid points for the potential energy surface were generated by first driving C(2)-C(1)-C(1′)-C(2′) from saddlepoints between the **d** and **e** families and between the **d** and **f** families from 0° to 360°, then taking points every 20° along these cuts and driving C(1)-C(2)-C(3)-C(4) and C(1′)-C(2′)-C(3′)-C(4′) slightly beyond the values found in the **d**, **e**, and **f** families. The four-dimensional energy surface was approximated as a three-dimensional surface by representing the changes in the two five-membered rings by means of the average of the difference between the C(1)-C(2)-C(3)-C(4) and C(1′)-C(2′)-C(3′)-C(4′) torsional angles. Using this approximation, conformations in the **d** family have differences close to 0°, those in the **e** family have average differences between 30° and 40°, similar to the actual sizes of the torsional angles, while those in the **f** family have average differences between −30° and −40°. The **d′** family would also have average differences close to 0°, in this case arising from differences between negative values whereas these angles both are positive in the **d** family. The 3D interpolation function in the program Sigmaplot was used to provide data at regular intervals. A contour representation is shown in Fig. 6. Cuts across the 3D potential energy surface are shown in Fig. 7.

There are three unique minima in the **d** family, termed **d1**, **d2**, and **d3**, in order of increasing C(2)-C(1)-C(1′)-C(2′) torsional angle, and two pairs of two unique minima related by centres of symmetry in each of the **e** family and **f** families, termed **e1**, **e2**, **e2′**, and **e1′**, and **f1**, **f2**, **f2′**, and **f1′**, respectively,

in order of increasing C(2)-C(1)-C(1′)-C(2′) torsional angle. Selected information about these minima are given in Table 4. Similar information about the saddlepoints has been deposited.[3]

Two minima, **d2** and **e1**, with C(2)-C(1)-C(1′)-C(2′) torsional angles of 155.1° and 81.7° and H-C(1)-C(1′)-H torsional angles of 158.5° and 72.2°, respectively, are calculated by MM3 to have about the same stability, and to be considerably more stable than the other five minima. The broadening in the NMR spectra arises from slow interconversions of conformers that exchange nonequivalent positions for identical atoms in the two halves of the dimer. In theory, this can occur by interconversion of conformers related by a centre of symmetry, for instance, **e1** and **e1′** or **f2** and **f2′** or by interconversion of conformers from enantiomeric families, for instance, **d1** and **d1′**, or **d2** and **d2′**. Saddlepoints are named by using letters to indicate conformational family, numbers to indicate the order of increasing torsional angle, and with an **s** added to indicate a saddlepoint. For instance, **ds2** is the saddlepoint in the **d** conformational family between **d1** and **d2** and **des1** is the saddlepoint between **d1** and **e1**. The lowest energy pathway on the surface that interconverts **e1** and **e1′** involves passing from **e1** (0.0 kJ mol^{-1}) over a barrier (**es2**) of 17.9 kJ mol^{-1} to reach **e2** (8.9 kJ mol^{-1}), then over another barrier (**es3**), the centre of this conformational family, 11.5 kJ mol^{-1} higher in energy than **e1** to reach **e2′** then over the enantiomer of the first barrier (**es2′**) to **e1′**. To interconvert **d2** and **d2′**, one route proceeds from **d2** (0.10 kJ mol^{-1}) over a barrier (**des2**) of 54.5 kJ mol^{-1}, to **e2** (8.9 kJ mol^{-1}), then to **e2′** as before, and over the **des2′** barrier to **d2′**. An alternative pathway proceeds from **d2** over a barrier (**ds2**) of 28.1 kJ mol^{-1} to **d1** (7.0 kJ mol^{-1}), then over a barrier (**des1**) of 34.2 kJ mol^{-1} to **e1**, then over a barrier (**des3′**) of 32.2 kJ mol^{-1} to **d3′**, and finally over a barrier (**ds3′**) of 57.6 kJ mol^{-1}, to **d2′**.

The seven minima from the MM3 calculations were used as input for AM1 calculations and geometry optimizations were performed. Data on energy minima are listed in Table 4. Three MM3 minima, **d1**, **e2**, and **f1**, were not AM1 minima, all minimizing to **e1**. The global minimum, **e1**, is the same by both methods; however, AM1 suggests that the five-membered rings are virtually planar, which is unlikely. By MM3, the second lowest minimum, **d2**, is almost equal in stability to the lowest; AM1 calculates that this conformation is 24.7 kJ mol^{-1} less stable and makes **d3** the second most stable conformation. Experimental evidence to be discussed following indicates that **d2** is not populated significantly, in contrast to the results of the MM3 calculations.

STO-3G calculations were performed on the lowest energy MM3 conformers and the results are given in Table 4. Again, the STO-3G results were closer to the AM1 results in energy but to the MM3 results in geometry. Conformer **e1** was the global minima.

Discussion for the *meso* dimer (2)

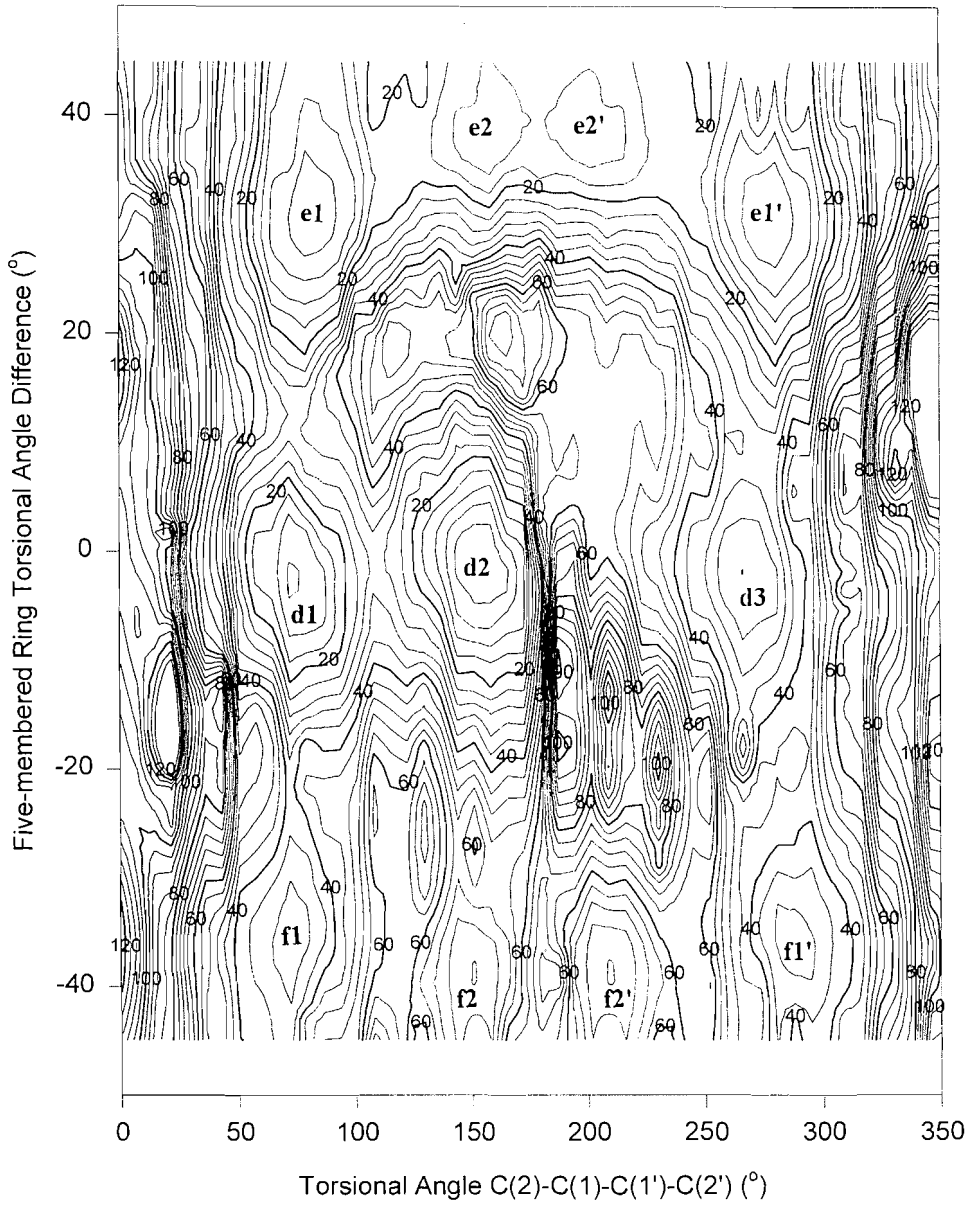
The low-temperature NMR spectra indicate that conformers with smaller C(2)-C(1)-C(1′)-C(2′) dihedral angles, that is, **e1** and (or) **d1**, are significantly more populated than the others. A 2.0 Hz coupling constant was measured between the protons on C(1) and C(1′) that corresponds to an H-C(1)-C(1′)-H angle of 65° or 111° using the Altona version (25) of the Karplus equation with electronegativities of 2.3 for $C(Me)_2CH_2$ and 2.41 for phenyl.[5] Differences between the bond angles and bond lengths along the coupling pathway in this molecule in comparison with those in the unstrained saturated model compounds used to develop the equation causes some uncertainty in the values of the calculated angles. However, the calculated value for the H-C(1)-C(1′)-H torsional angle of 158.5° present in **d2** is 10.7 Hz. The small observed magnitude of $^3J_{H,H}$ is only consistent with populated minima with H-C(1)-C(1′)-H torsional angles close to 65°. On the MM3 potential energy surface, **d1** and **e1**, with H-C(1)-C(1′)-H torsional angles of 68.3° and 72.2°, respectively, are consistent with this observation. The major difference between these two is in the direction of puckering of the five-membered rings; **d1** is an "in,out" structure while **e1** is an "out,out" structure. In these two conformers, which have C(2)-C(1)-C(1′)-C(2′) torsional angles of 74 and 82°, one *ortho* hydrogen lies over the other aromatic ring in its shielding cone. This geometric relationship explains the observation of a very large Δδ value of −1.10 ppm for one *ortho* aromatic proton. This value is much larger than those observed for stacking in the adenine dinucleotide ApA (26) or for adenine-naphthalene stacks (1). Moreover, in these conformers, the benzene ring containing the shielded hydrogen has the correct orientation to shield one methyl group (0.36 ppm shielding observed) and a methylene group (0.43 ppm shielding observed).

Because the *meso* compound shows temperature-dependent NMR spectra, S_{axis}-related conformers must have two substantial barriers separating them on the potential energy surface. The S_{axis}-related conformers have C(2)-C(1)-C(1′)-C(2′) torsional angles that deviate from 180° by equal amounts in opposite directions. Two substantial barriers are necessary to observe rate effects because the conformers can be interconverted by rotation about the central bond through either 180° or 0° and both directions of rotation must be slowed. $\Delta H^{\ddagger}$ is 42.8 kJ mol^{-1} for the smaller of these two barriers as determined by variable temperature NMR experiments. The MM3-calculated potential energy surface is shown in Figs. 6 and 7. Barriers calculated for passing through the C(2)-C(1)-C(1′)-C(2′) torsional angle of 0° were much larger than the observed barrier and it can be assumed that the interconversion process does not follow this route. The MM3-calculated potential energy surface does not contain a barrier for rotation around the C(1)-C(1′) bond through C(2)-C(1)-C(1′)-C(2′) torsional angles of 180° that is nearly as large as the observed barrier. In particular, as outlined in the results section, the largest barrier (**es2**) for interconverting the global minima, **e1** to **e1′**, is 17.9 kJ mol^{-1}. Therefore, the barrier calculated by the MM3(94) program is about 25 kJ mol^{-1} too small. Part of this difference must lie in the fact that MM3 does not account for aryl–aryl interactions. Stabilizing those conformations that have offset π–π stacking will increase the barrier by the amount of the stabilization, which has been calculated to be about 9 kJ mol^{-1} (3).

The NMR results suggest that the barrier to conformational interconversion includes a contribution from a substantial negative value of the entropy of activation ($\Delta S^{\ddagger} = -61.6 \pm 6.5$ J K^{-1} mol^{-1}). Conformer entropies are evaluated by MM3

[5] We thank Dr. J.S. Grossert for a basic computer program that calculates $^3J_{H,H}$ values based on Altona's equation (25).

Fig. 6. A contour diagram of the MM3(94) potential energy surface for the *meso* dimer (**2**). The *Y*-axis is the difference between the C(1)-C(2)-C(3)-C(4) and C(1)′-C(2)′-C(3)′-C(4)′ torsional angles divided by two. The locations of individual conformers on this surface are indicated with the letters used to describe them in the text.



and the saddlepoints for interconversion were found to have substantially less positive entropies than the minima. The $\Delta S^{\ddagger}$ values for the equilibria of the global minima with the two saddlepoints most likely to be barriers are, **e1** ⇄ **es2**, −19.0 J K^{-1} mol^{-1}, and **e1** ⇄ **es3**, −32.2 J K^{-1} mol^{-1}. While these values are considerably less than the value obtained from the NMR data, calculation of these values does indicate that a negative entropy of activation does make a significant contribution to the barrier.

On the AM1 potential energy surface, the global minimum, **e1**, is considerably more stable than the other two minima, consistent with the NMR observations that the most populated conformations have C(2)-C(1)-C(1′)-C(2′) torsional angles that are in the 60°–80° region. The AM1 surface curve shows two significant barriers to interconversion between the +86.0° and −86.0° conformers. There is a very large barrier to rotation through 0° and a smaller barrier of 54.6 kJ mol^{-1} for rotation about 180°. The size of the barrier to rotation through 180° is in reasonable agreement with that obtained by NMR measurements of 42.8 kJ mol^{-1}.

Additional compounds

During the photochemical studies, analogous diastereomeric dimers **3** and **4** were isolated where the aromatic ring was substituted with a methoxy group in the 5-position, and dimers **5** and **6** when a methoxy group was in the 6-position. In each

case, one of the dimers was crystalline and gave sharp signals in the NMR at room temperature. The other was an oil and gave broadened NMR signals at room temperature. Low-temperature NMR spectra of the methoxy *meso* dimers **4** and **6** were very similar to those of the unsubstituted *meso* dimer.

Compounds very similar to dimers **1** and **2** have been reported in the literature. Orliac-Le Moing et al. (27) have obtained both the racemic and *meso* forms of bis-1,1′-(2,2-dimethyl-1-indanol) (**7** and **8**, respectively) from the coupling of the radical anions produced by electrochemical reduction of the monomeric ketone. Both dimers were crystalline. The structure of the racemic compound was established by X-ray

crystallography. Although no numerical details were reported, the structure shown has the two OH groups approximately *anti* across the central C—C bond, with the two phenyl rings *gauche* and also the two $C(CH_3)_2$ groups *gauche*. The structure presented suggests that the torsional angle involving the phenyl rings is considerably less than 60° while that involving the $C(CH_3)_2$ groups is considerably more than 60°. This structure is probably similar to conformer **c1**, with a C(2)-C(1)-C(1′)-C(2′) torsional angle of 101.4° (MM3) or 97.6° (AM1).

The authors of this work did not observe broadened lines in the ^1H NMR spectrum of the *meso* dimer (**8**), which contained singlets at 1.04 ppm ($2 \times CH_3$) and 1.38 ppm ($2 \times CH_3$), and at 2.47 ppm ($2 \times CH_2$). This absence of broadening in a spectrum that is consistent with S_1 or S_2 symmetry indicates that the barriers to interconversion of the S_{axis}-related conformers in this compound are reduced in comparison to that in **2**. Two different barriers lie on the potential energy surface shown in Fig. 5, either of which could have been responsible for the broadening observed in the spectra of **2**. The strain energy of the tran-

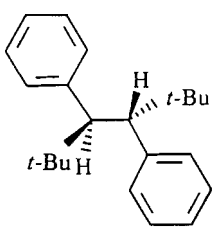
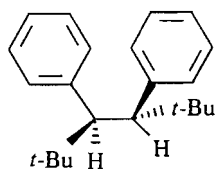
sition state (TS) for rotation with a C(2)-C(1)-C(1′)-C(2′) angle of 180° would not be increased as much as that of the minima or the other TS by introduction of additional substituents because in this 180° TS the new substituents are perfectly staggered. Thus, the barrier for going over the 180° TS should become smaller because the strain energies of the minima on the potential energy surface for rotation are greater. This argument suggests that the 180° TS is the barrier that slows rotation in **2**.

The conformational properties of **9** and **10**, the noncyclized analogues of **1** and **2**, have been investigated by means of molecular mechanics calculations, X-ray crystallography, and NMR measurements (15). In contrast to the current observations, in the solid state and solution, the *meso* compound **9** was present in the *anti* conformation, whereas the racemic compound **10** had the phenyl groups *gauche* in the solid state and in solution. For these compounds, the most stable conformations have the *tert*-butyl groups are far apart as possible. In the X-ray structure of **10**, the two phenyl rings adopt the offset π-stacked arrangement with the planes of the phenyl rings close to parallel.

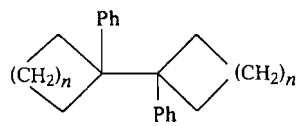


9



10

Crystallographic studies have been reported for a series of 1,1′-diphenyl-1,1′-bicycloalkyl systems **11** (n = 2–5), which



11

included 1,1′-diphenyl-1,1′-bicyclopentyl (17, 28). The major focus of this work was studying bond lengths as a function of steric interactions. The bicyclopentyl compound has a central C—C bond length of 1.575 Å. The energy as a function of the C(2)-C(1)-C(1)′-C(2)′ torsional angle was determined by MM2 (28) and by AM1 calculations (17). The MM2 method correctly predicted that the *gauche* conformation would be more stable than the *trans* conformation for the bicyclopentyl derivative, and the reverse would be true for the other three but the AM1 method gave an incorrect answer for the bicyclohe-

ptyl derivative. The central C—C bond lengths in **9** and **10** were 1.573–1.589 Å (15), considerably longer than those in **1**. Thus, compounds **1** and **2** are probably considerably less strained than their noncyclic analogues.

Conclusions

MM3(94) and STO-3G calculations indicate that the conformational potential energy surface for racemic-2,2,2′,2-tetramethyl-1,1′-biindanyl (**1**) contains seven minima, one of which is present in the solid state and this conformer probably is also the major contributor in solution. These conformers arise from restriction to rotation about the bond joining the two indanyl units and also from restriction to motion in the two hindered five-membered rings.

The potential energy surface for the *meso* diastereomer (**2**) is more complex, containing 14 minima in pairs related by centres or planes of symmetry. Variable temperature NMR spectra show that the S_{axis}-related conformers are undergoing interconversion at a rate that is slow on the NMR time scale at room temperature. NMR arguments based on the Karplus equation and the observation of the signal of a proton that has a large deshielding suggest that a single pair of S_2-related conformers are the major species present in solution.

The STO-3G results reproduce accurately the geometries and energies of the minima for these two compounds. MM3(94) results are in good agreement with the X-ray geometries but the relative stabilities of the conformers are far from those observed experimentally. Apparently, MM3 does not handle this type of mixed aromatic–aliphatic compound well. The AM1 results are in good agreement with observed conformer energies but the geometries are so poor in the saturated portion of the conformers that the energy agreement must be regarded as fortuitous. The global minima for both **1** and **2** have the benzene rings from the two halves of the molecules stacked in an offset manner. This effect may have been a factor in the poor performance by MM3(94).

Experimental

Proton (^{1}H) and carbon (^{13}C) NMR spectra at 250 and 62.8 MHz were obtained in $CDCl_3$ on an Bruker AC 250 F NMR spectrometer in automation mode; proton NMR spectra at 400 MHz were obtained on a Bruker AMX-400. Chemical shifts are reported in parts per million (δ) relative to tetramethylsilane (0.00) as an internal standard. The ^{13}C NMR spectrum of the solid sample was measured on a Bruker AMX-400 NMR spectrometer with magic angle spinning at 5 kHz.

Line shape analysis for the exchange of the H(1) and H(1)′ signals of the *meso* dimer (**2**) was done by means of the program Quabex (24) modified to run on a PC and compiled with Microsoft Fortran Powerstation. The output of this program was a two-dimensional matrix containing chemical shifts and intensities that were plotted using Sigmaplot. Chemical shift differences in the exchange region were obtained by an extrapolation of the very linear ($r = 0.9998$) plot of chemical shift difference against temperature using points every 5°C from −35 to −60°C. $T2$ values in the exchange region were initially obtained by fitting the signals at −35°C, assuming that the rate of exchange was negligible. However, the $T2$ value obtained was too great to fit the peaks from −15 to −26°C. It was found that the peak at −15°C was not very sensitive to the value of the exchange rate but was very dependent on the value of $T2$. Therefore, this peak was fit by adjusting the $T2$ value using an approximately correct k value. Then, this value of $T2$, 0.18 s, was used to fit the other spectra.

Materials

The preparation and characterization of compounds **1–6**, except for the low-temperature data for compound **2** given below, have been described previously (6).

X-ray structure determination

Racemic compound **1** forms white, air-stable needles with approximately square cross sections. The X-ray data were collected with a Rigaku AFC5R four-circle diffractometer attached to a 2.4 kW X-ray generator. *Crystal data:* $C_{22}H_{26}$, fw = 290.45, F(000) = 632, crystal size 0.20 × 0.20 × 0.40 mm; $a = 11.190(7)$, $b = 11.679(7)$, $c = 13.19(1)$ Å, $V = 1724(3)$ Å^3, space group *Pbcn* (no. 60), $Z = 4$, $\rho_C = 1.119$ g cm^{-3}; Mo Kα (graphite monochrometer) $\lambda = 0.71069$ Å, $\mu = 0.582$ cm^{-1}, 1416 unique measured reflections to 22 (max) of 46° with 643 observed ($I > 3\sigma(I)$). The cell dimensions were determined from 20 well-centered reflections with 2θ range 12–26°. The data were corrected for Lorentz and polarization effects but three azimuthal scans each showed less than 2% variation in intensity and no absorption corrections were applied.

The structure was solved by direct methods, which revealed the positions of all non-hydrogen atoms. The non-hydrogen atoms were refined anisotropically. All of the hydrogen atoms were placed in geometrically calculated positions with a C—H distance of 0.95 Å, their positions were not refined, and they were assigned fixed isotropic temperature factors with a value of $1.2 \times B_{eq}$ of the atom to which each was bonded. The final cycle of full-matrix least-squares refinement[6] (29) was based on 634 observed reflections ($I > 3\sigma(I)$) and 101 variable parameters, and converged (largest parameter shift was 0.0002 times its esd) with unweighted and weighted agreement factors of: $R = \Sigma||F_o| - |F_c|| / \Sigma|F_o| = 0.0357$, $R_w = [(\Sigma w(|F_o| - |F_c|)^2 / \Sigma wF_o^2)]^{1/2} = 0.0362$. The standard deviation of an observation of unit weight[7] was 1.731. The weighting scheme was based on counting statistics and included a factor ($p = 0.01$) to downweight the intense reflections. Plots of $w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, $\sin\theta/\lambda$, and various classes of indices showed no unusual trends. A correction for secondary extinction was applied (coefficient = 6.95×10^{-7}). The maximum and minimum peaks in the final difference Fourier map corresponded to 0.10 and −0.11 e Å^{-3}, respectively.

Neutral atom scattering factors for non-hydrogen atoms were taken from Cromer and Waber (30) and the scattering factors for hydrogen atoms were taken from Stewart, Davidson, and Simpson (31). Anomalous dispersion effects were

[6] Function minimized: $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2/s^2(F_o^2) \equiv [\sigma^2(F_o) + (pF_o/2)^2]^{-1}$, $F_o^2 = S(C - RB)/\text{Lp}$ and $\sigma^2(F_o^2) = [S^2(C + R^2B) + (pF_o^2)^2]/\text{Lp}^2$, S = scan rate, C = total integrated peak count, R = ratio of scan time to background counting time, B = total background count, Lp = Lorentz-polarization factor, p = p-factor.

[7] Standard deviation of an observation of unit weight: $[\Sigma w(|F_o| - |F_c|)^2/(N_o - N_v)]^{1/2}$, where N_o = number of observations, N_v = number of variables.

included in F_{calc} (32); the values for $\Delta f'$ and $\Delta f''$ were those of Cromer and Ibers (33). All calculations were performed using the TEXSAN (34) crystallographic software package of Molecular Structure Corporation.

Reflection in the ^{1}H NMR spectrum of $^{37}Cl/^{35}Cl$ isotope effects on the ^{19}F NMR chemical shifts of 1-chloro-2,4-difluorobenzene. An isotope effect over five bonds

Ted Schaefer, Guy M. Bernard, and Frank E. Hruska

Abstract: In an ABX high-resolution NMR spectrum the detection of combination peaks in the X region yields only the chemical shift of X, $J_{AX} + J_{BX}$, and the positive quantities $\{[(\nu_A - \nu_B) \pm \frac{1}{2}(J_{AX} - J_{BX})]^2 + J_{AB}{}^2\}^{1/2} = 2C_{\pm}$. However, the presence of an additional isotopic perturbation on $\nu_A - \nu_B$, the difference between the resonance frequencies of A and B, yields two X spectra; therefore four quantities, C. Hence all quantities in the surd become available from the composite X spectrum. A generalization to ABMRX spin systems, applicable to the ^{1}H and ^{19}F NMR spectra of the two isotopic molecules of 1-chloro-2,4-difluorobenzene, is possible. It turns out that, from the H-5(X) spectrum alone, the following spectral quantities are extractable: the two values of $\nu_A - \nu_B$ where A and B are the ^{19}F nuclei; J_{AB}; J_{AX} and J_{BX} with their relative signs; J_{MX} and J_{RX} where M and R are H-3 and H-6. No $^{37}Cl/^{35}Cl$ isotope effect is detectable on the ^{1}H shielding nor on any coupling constants. F-2 undergoes an isotope shift of $-1.64(3)$ ppb. The isotope shift, over five formal bonds, of F-4 is $-0.54(3)$ ppb (larger shielding in the presence of ^{37}Cl). This magnitude is three times larger than that over four formal bonds in another molecule, 2,6-dichloro-4-fluorophenol.

Key words: ^{1}H NMR, of 1-chloro-2,4-difluorobenzene, isotope effects in NMR, reflection of $^{37}Cl/^{35}Cl$ isotope effects on ^{19}F shielding in the ^{1}H NMR spectrum of 1-chloro-2,4-difluorobenzene; isotope effects in NMR, over three and five bonds by $^{37}Cl/^{35}Cl$ on ^{19}F shielding in 1-chloro-2,4-difluorobenzene; ^{19}F NMR, $^{37}Cl/^{35}Cl$ isotope effects over three and five bonds in 1-chloro-2,4-difluorobenzene.

Résumé : Dans un spectre RMN ABX à haute résolution, la détection des raies de combinaison dans la région de X ne fournit que le déplacement chimique de X, $J_{AX} + J_{BX}$ et les quantités positives $\{[\nu_A - \nu_B) \pm \frac{1}{2}(J_{AX} - J_{BX})]^2 + J_{AB}{}^2\}^{1/2} = 2C_{\pm}$. Toutefois, en présence d'une perturbation isotopique additionnelle sur $\nu_A - \nu_B$, la différence entre les fréquences de résonance de A et de B, il est possible d'obtenir deux spectres de X et donc quatre quantités C. Toutes les quantités deviennent donc disponibles à partir du spectre composé de X. Il est possible de faire une généralisation aux systèmes de spin ABMRX et de l'appliquer aux spectres RMN du ^{1}H et du ^{19}F de deux molécules isotopiques du 1-chloro-2,4-difluorobenzène. En fait, sur la base du spectre de seulement H-5(X), il est possible d'extraire les valeurs spectrales suivantes : les deux valeurs de $\nu_A - \nu_B$ dans lesquelles A et B sont les noyaux ^{19}F; J_{AB}; J_{AX} et J_{BX} et leurs signes relatifs; J_{MX} et J_{RX} pour lesquelles M et R sont H-3 et H-6. Il n'est pas possible de détecter l'effet isotopique $^{37}Cl/^{35}Cl$ sur le blindage du ^{1}H ou sur l'une quelconque des constantes de couplage. Le F-2 subit un déplacement isotopique de $-1,64(3)$ ppb. Le déplacement isotopique, sur cinq liaisons formelles, du F-4 est de $-0,54(3)$ ppb (un blindage plus important en présence de ^{37}Cl). Cette valeur est trois fois plus importante que celle sur quatre liaisons formelles dans une autre molécule, le 2,6-dichloro-4-fluorophénol.

Mots clés : RMN du ^{1}H, 1-chloro-2,4-difluorobenzène; effets isotopiques en RMN, réflexion des effets isotopiques $^{37}Cl/^{35}Cl$ sur le blindage du ^{19}F dans les spectres RMN du 1-chloro-2,4-difluorobenzène; effets isotopiques en RMN, à travers trois et cinq liaisons par $^{37}Cl/^{35}Cl$ sur le blindage du ^{19}F dans le 1-chloro-2,4-difluorobenzène; RMN du ^{19}F, effets isotopiques $^{37}Cl/^{35}Cl$ à travers trois et cinq liaisons dans le 1-chloro-2,4-difluorobenzène.

[Traduit par la rédaction]

Introduction

One aim of this report is to establish the existence of an unprecedented $^{37}Cl/^{35}Cl$ isotope effect, $^{5}\Delta F(^{37/35}Cl)$ over five formal bonds on an ^{19}F nmr chemical shift in a benzene derivative. Examples of $^{4,3}\Delta F(^{37/35}Cl)$ have recently been given from this laboratory (1). A second aim concerns a discussion of the structure of high-resolution nmr spectra arising from a class of spin systems described (2) as ABMRX···. The simplest member of this class, ABX, illustrates most of the basic principles of spectral analysis (2–5). It is true that computer analysis of nmr spectra is now a universal practice; yet an understanding of the fundamental properties of the spectrum, as consequences of the high-resolution Hamiltonian, can even today provide a more rapid or, indeed, correct (7), convergence in the machine analysis of a given spectrum.

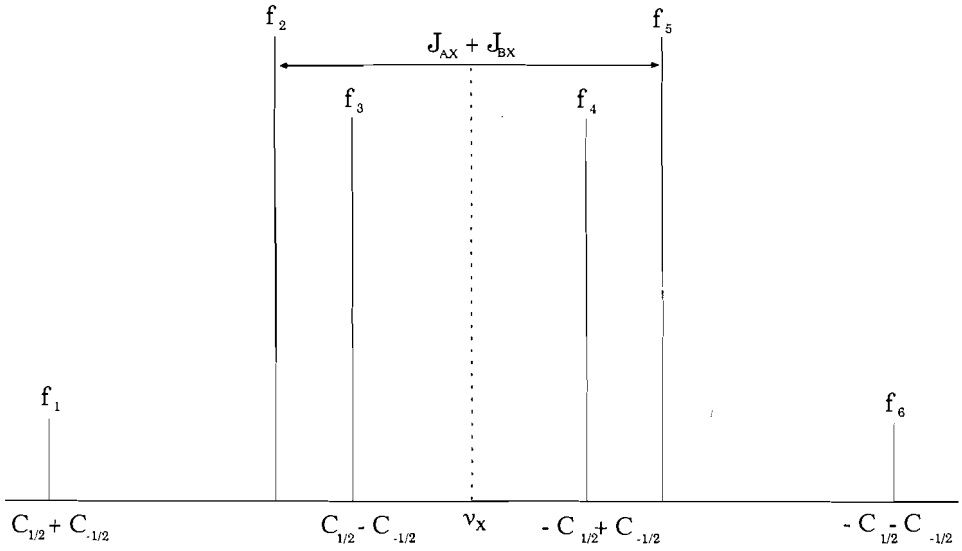
Scheme 1.



For example, it turns out that the $^{37}Cl/^{35}Cl$ isotope effect on the ^{19}F nmr spectrum of the title molecule can be determined from the ^{1}H nmr spectrum alone. In fact, for an ABX spectrum, in which the chemical shifts, but not the coupling constants, of nuclei A and (or) B undergo a secondary isotope effect, the latter can be determined from the X spectrum under certain circumstances, as discussed further below.

Some properties of ABMRX ··· spectra

(a) The ABX spectrum (refs. 2–6)

Concentrating on the X region, there occur two transitions of equal intensity, separated by $J_{AX} + J_{BX}$, as shown in Scheme 1. These transitions carry half the total intensity of the X spectrum. Four additional transitions can occur. They are also centered on ν_X, the resonance frequency of nucleus X. Their intensities can be deduced from eqs. [1]–[5], where $C > 0$, $0 \leq \theta \leq 180$.

$$[1] \quad 2C(\pm\tfrac{1}{2}) \cos 2\theta(\pm\tfrac{1}{2}) = [(\nu_A - \nu_B) \pm \tfrac{1}{2}(J_{AX} - J_{BX})]$$

$$[2] \quad 2C(\pm\tfrac{1}{2}) \sin 2\theta(\pm\tfrac{1}{2}) = J_{AB}$$

$$[3] \quad 2C(\pm\tfrac{1}{2}) = \{[(\nu_A - \nu_B) \pm \tfrac{1}{2}(J_{AX} - J_{BX})]^2 + J_{AB}{}^2\}^{1/2}$$

$$[4] \quad P(f_1) = P(f_6) = \sin^2 [\theta(\tfrac{1}{2}) - \theta(-\tfrac{1}{2})]$$

$$[5] \quad P(f_3) = P(f_4) = \cos^2 [\theta(\tfrac{1}{2}) - \theta(-\tfrac{1}{2})]$$

In these equations, $\nu_A - \nu_B$ is the positive difference in the resonance frequencies of nuclei A and B and P is a probability of transition. The intensities of peaks f_1 and f_6, the so-called combination lines, depend on the relative magnitudes of J_{AB} and C.

It follows that the X spectrum yields ν_X and $J_{AX} + J_{BX}$. Suppose now that ν_A and (or) ν_B undergo a small secondary isotope shift due, for example, to the presence of chlorine isotopes in the molecules. If the coupling constants do not display a detectable isotope effect (all known isotope effects on coupling constants arise from $^{1}H/^{2}H$ or $^{1}H/^{3}H$ substitution, none being found to date due to "heavier" substitutions (8)), then the sample of these molecules will display an X spectrum for each of the chlorine isotopes. Hence four quantities C are available and are related to four spectral quantities, namely, J_{AB}, $J_{AX} - J_{BX}$, and the two differences in chemical shift. The C values follow from differences in the peak frequencies shown in Scheme 1. The X spectrum now yields most spectral parameters of interest, with the exception, of course, of the individual values, ν_A and ν_B.

(b) The ABMRX ··· spectrum

By an obvious extension of eqs. [1]–[5], one has, for instance, eq. [6], where $m, r, x\cdots$ can each be $\pm\frac{1}{2}$. Suppose, as above, that the X region displays combination lines. The spectrum of nucleus X consists of a superposition of the patterns in Scheme 1, the centres of which are displaced from ν_X by $mJ_{MX} + rJ_{RX}$. The number of positive constants $C(m, r, x\cdots)$ is 2^n, where n is the number of M, R, and X nuclei. The spectral quantities in the surd of eq. [6] increase in number only as $(n + 2)$. Consequently, for an ABMX spectrum, as an example, there exist four C values in the X region. These values yield $\nu_A - \nu_B$ and the coupling constants J_{AB}, J_{AX}, and J_{BX}, together with the relative signs of the latter two.[2]

$$[6] \quad 2C(m, r, x\cdots) = \{[(\nu_A - \nu_B) + m(J_{AM} - J_{BM}) + r(J_{AR} - J_{BR}) + x(J_{AX} - J_{BX}) + \cdots]^2 + J_{AB}{}^2\}^{1/2}$$

If an isotope effect on $\nu_A - \nu_B$ exists, then its magnitude is also available from the X spectrum or from any of the other spectral regions M, R··· displaying combination peaks. This statement follows because now the number of C parameters becomes 2^{n+1}, and the number of quantities within the surd is $(n + 3)$.

[2] Similar generalizations can be made for $ABM_nR_oX_p$ ··· and, indeed, for $AB_2M_nR_oX_p$ ··· spin systems (9).

Table 1. The ^1H and ^{19}F nmr spectral parameters of 1-chloro-2,4-difluorobenzene in acetone-d_6 at 300 K.

[c]This column refers to the molecules containing ^{37}Cl atoms.
[d]In Hz to high frequency of internal C_6F_6 at 282.362 64 MHz.
[e]In Hz to high frequency of internal TMS at 300.134 93 MHz.
[f]Numbers in parentheses are the standard deviations in millihertz.
[g]As determined from the many repeated spacings in the ^{19}F spectral region.

Recognition of patterns of the kind discussed here has three advantages. First, if A and B represent, say, ^{19}F nuclei (see below), then only, say, ^1H spectra are needed for a fairly complete analysis: by no means do all laboratories carry ^{19}F probes. Second, excellent initial magnitudes of spectral parameters for an iterative computer analysis are then available, even when MRX··· are not quite "first-order" spins. Third, this approach has a significant pedagogical value.

Experimental

A dilute solution of 1-chloro-2,4-difluorobenzene (Aldrich) in acetone-d_6 (see Table 1 for details) was filtered into a 5 mm o.d. nmr sample tube. The tube was degassed by five freeze–pump–thaw cycles and was then flame-sealed to yield a reasonably symmetric top. The ^1H and ^{19}F nmr spectra were obtained with a Bruker AM 300 spectrometer at a probe temperature of 300 K. As many as 64 free induction decays were coadded, using 16–32 K data points and acquisition times of 40 s for spectral regions of 200 Hz. Zero-filling and resolution enhancement procedures gave linewidths at half-height of as little as 0.04 Hz.

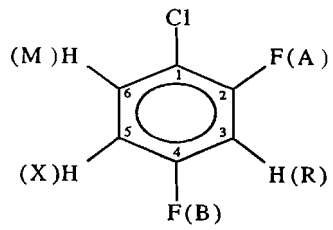
Results and discussion

Spectral analysis

Spectral analytical procedures employed the program NUMARIT (10) as extensively reworked by R. Sebastian and K. Marat (11). During these procedures it was found that slight inconsistencies existed between ^1H and ^{19}F transitions, originating in very small changes in the chemical shift differences between the ^{19}F nuclei, that is, the difference in chemical shift changed a little between the time of recording the ^1H nmr spectrum and that of acquiring the ^{19}F nmr data. We believe this change was caused by very small temperature variations, with the consequence that the fluorine shielding altered slightly and differentially: slight alteration of solvent effects. However, the spectral parameters in Table 1 are fairly reliable even though their standard deviations are somewhat larger than normal. It may also be noted that, probably because of the complexity introduced by the chlorine isotope effects, a satisfactory iterative fit, using the partially self-assigning computer program, was not easily forthcoming until the underlying spectral structure was ascertained as described below.

The ^{19}F parameters reflected in the spectrum of H-5

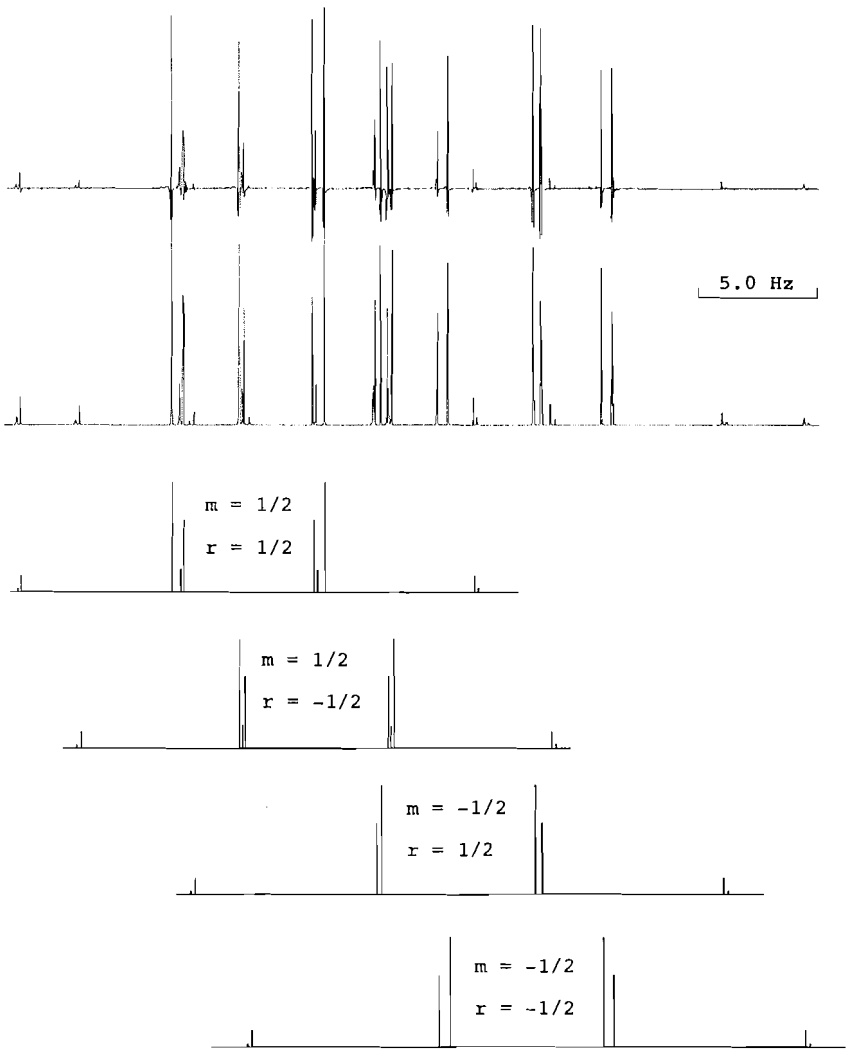
If the composite ^1H and ^{19}F nmr spectrum is treated as arising from an ABMRX system, then it is clear from eq. [6] that in the, say, X spectrum for a given chlorine isotope, eight quantities $C(m, r, x)$ are available (compare with the discussion of the ABX system) because m, r, and x can each be $\pm\frac{1}{2}$. This statement assumes that the so-called combination peaks (the weak peaks in Scheme 1, for example, for an ABX system) are detectable. The differences in the surd of eq. [6] can now be found in terms of the quantities C in a number of ways. One direct procedure (one has eight equations with which to work) involves elimination of all but one of these differences and so forth. This straightforward, if tedious, algebra was performed for the X spectrum (H-5) of **1**.



1

The subspectra of H-5 are indicated in Fig. 1. They are easily picked out, as is also illustrated in Fig. 1. Finally, the frequency differences between the centres of the subspectra yield sums and differences of coupling constants of H-5(X) with H-3(R) and H-6(M). Of course, $J_{AX} + J_{BX}$ is repeated four times if no isotopic perturbation of this sum is present, as is strongly

Fig. 1. The nmr spectrum at 300 MHz and 300 K of H-5 of 1-chloro-2,4-difluorobenzene, as a 5 mol% solution in acetone-d_6, is displayed at the top. Beneath it is shown the simulated spectrum using the spectral parameters in Table 1. The subspectra corresponding to various spin states of H-3, nucleus R, and H-6, nucleus M, are indicated by stick spectra. Each subspectrum contains a more intense set, corresponding to ^{35}Cl, of six peaks and a less intense set, corresponding to ^{37}Cl, of *four* peaks. Because no detectable isotope effect on the coupling constants exists, the peaks separated by $J_{AX} + J_{BX}$ (X = H-5) coincide for the molecule containing ^{35}Cl or ^{37}Cl (see Scheme 1). The combined ^1H and ^{19}F nmr spectra do not correspond exactly to a spin system, ABRMX, for a given isotope of chlorine in the sense that the internal proton chemical shifts are not all exceedingly large compared to $^nJ(^1H, ^1H)$; that is, $^nJ(^1H, ^1H)$ on the off-diagonals of the Hamiltonian matrix do somewhat affect the spectrum, the intensities more than the frequencies, as expected from perturbation theory. However, treatment as an ABMRX situation leads to a clear decomposition of the spectrum of H-5 and a set of reasonably accurate constants, C (see text), from which the internal fluorine chemical shifts of the isotopic molecules can be derived, as can all the spin–spin coupling constants involving H-5; also J_{AB}. Note that, in each subspectrum, the C values are $C(r, m, \pm\frac{1}{2})$.



indicated by the spectrum (at a linewidth of about 0.04 Hz no evidence of a doubling of the peaks separated by $J_{AX} + J_{BX}$ was observable). From the H-5 spectrum in Fig. 1, therefore, the following spectral parameters are obtained: J_{AX}, J_{BX} and their relative signs, $J_{AR} - J_{BR}$, $J_{AM} - J_{BM}$, J_{AB}, the two values of $\nu_A - \nu_B$ corresponding to the two kinds of isotopically labelled molecules (16 C values in total), as well as J_{MX} and J_{MR}. From the M and R regions individual values of J_{AM}, J_{BM},

J_{AR}, and J_{BR} follow, together with relative signs. The separations between these peaks and their intensities are determined by the same eight C values extracted from the X region, but by different combinations of them, so that the peak intensities may be undetectable. In fact, the combination peaks vanish in the M(H-6) and R(H-3) spectral regions of the present molecule.

Returning to the X(H-5) spectrum, the spectral parameters extracted from the C values differed by no more than 0.01 Hz from those obtained in the iterative analysis presented in Table 1. The internal chemical shifts of the fluorine nuclei, obtained from the H-5 spectrum, differed by 0.31(2) Hz or 1.1(1) ppb, being larger in the presence of ^{37}Cl. These numbers[3] represent $|^3\Delta F(^{37/35}\text{Cl}) - {}^5\Delta F(^{37/35}\text{Cl})|$. The known range of $^3\Delta F$ in fluorobenzene derivatives is 1.58–1.61 ppb (1) and therefore implies the existence of a finite $^5\Delta F$, about 0.5 ppb, in the molecule under discussion. Of course, the actual shifts of the ^{19}F nuclei are required to establish this number and are obtainable only from the ^{19}F nmr spectrum.

The isotope shifts

The chemical shifts in Table 1 give $^3\Delta F$ as $-1.64(3)$ ppb and $^5\Delta F$ as $-0.54(3)$ ppb, the negative sign meaning, conventionally, that the heavier isotope causes increased shielding. The $^5\Delta F$ is as large as $^4\Delta F$ in 2-chloro-6-fluorocyanobenzene and *three* times larger than $^4\Delta F$ in 2,6-dichloro-4-fluorophenol (1). A variety of fluorobenzene derivatives are to be synthesized in an attempt to establish patterns of $^{4,5}\Delta F$; $^3\Delta F$ appears to be constant within about 0.02 ppb. That $^5\Delta F(^{37/35}\text{Cl})$ can be larger than $^4\Delta F(^{37/35}\text{Cl})$ is reminiscent of an early measurement, yielding $^5\Delta F(^2\text{H}/^1\text{H})$ as -11 ppb in fluorobenzene-4-*d* and $^4\Delta F(^2\text{H}/^1\text{H})$ as -8 ppb in fluorobenzene-3-*d* (12).

[3] Some authors prefer to write the isotope shift for F-2 as $^3\Delta F + {}^7\Delta F$ and that for F-4 as $2(^5\Delta F)$.

DISQUAC characterization of the carbonyl–oxygen interactions in binary liquid organic mixtures containing linear molecules: ketones and a monoether, diether, or triether

J.A. González, J.M. Fernández Martínez, I. García de la Fuente, and J.C. Cobos

Abstract: The available data in the literature on vapor–liquid equilibria, excess Gibbs energies, and excess enthalpies for linear ketones + linear mono- or poly-ether mixtures are examined in terms of the DISQUAC group contribution model. Interaction parameters are reported. The quasichemical interchange coefficients are independent of the compounds in the systems; the dispersive interchange coefficients depend on the intramolecular environment of the carbonyl and (or) oxygen groups. Proximity effects, which seem to lead to an important increase of the interaction parameters, are briefly considered in treating systems including 1-methoxy-2-propanone or dimethyl carbonate molecules. DISQUAC consistently describes the experimental data of the mixtures investigated. The rather good representation obtained for vapor–liquid equilibria at high temperatures is noteworthy. A discussion in terms of effective and reduced dipole moments of binary mixtures containing carbonyl and oxygen groups in the same or different molecules is also presented.

Key words: liquids, mixtures, thermodynamics, dipole moments, group contributions.

Résumé : Faisant appel au modèle de contribution de groupe «DISQUAC», on a examiné les données disponibles dans la littérature relatives aux équilibres vapeur–liquide, aux énergies de Gibbs en excès et aux enthalpies en excès pour des cétones linéaires + des mélanges de mono- ou poly-éthers linéaires. On a déterminé les paramètres d'interaction. Les coefficients d'échange quasichimiques sont indépendants de la nature des composés dans les systèmes; les coefficients d'échange dispersifs dépendent de l'environnement intramoléculaire du groupe carbonyle et (ou) des oxygènes. Dans le traitement des systèmes comportant des molécules de 1-méthoxypropan-2-one ou du carbonate de diméthyle, on a brièvement considéré des effets de proximité qui semblent conduire à une augmentation importante des paramètres d'interaction. La méthode DISQUAC décrit d'une façon consistante les données expérimentales des mélanges étudiés. La représentation relativement bonne obtenue pour les équilibres vapeur–liquide à température élevée mérite d'être notée. On présente aussi une discussion en terme de moments dipolaires effectifs et réduits des mélanges binaires contenant des groupes carbonyles et des oxygènes dans les mêmes molécules ou dans des molécules différentes.

Mots clés : liquides, mélanges, thermodynamique, moments dipolaires, contributions de groupes.

[Traduit par la rédaction]

1. Introduction

DISQUAC (1, 2) is a group contribution method widely and successfully applied to many classes of mixtures using interaction parameters that are assumed to be structure dependent. This assumption improves predictions, mainly in the case of branched and cyclic molecules, and for the first members of homologous series. Moreover, it is remarkable that, for a given system, the same set of interchange coefficients can be used to represent rather accurately the thermodynamic properties: low-pressure fluid phase equilibria; vapor–liquid (VLE), liquid–liquid (LLE), or solid–liquid (SLE), equilibria; excess functions, such as Gibbs energies, G^E, enthalpies, H^E, or heat capacities at constant pressure, C_p^E; as well as the related partial molar excess quantities at infinite dilution.

On the other hand, systems are investigated in order of increasing complexity of molecular structure and intermolecular interactions. Attention is paid to the electronic structure and configuration of the organic molecules. Proximity and other intramolecular effects: steric hindrance, polarity, polarizability, and induction, are more carefully examined than usual.

An example of the philosophy of application of the model is the so-called CO/O project, in which mixtures containing the carbonyl (CO) and (or) the oxygen (O) groups are investigated in order to characterize intra- and inter-molecular effects related to the presence of the CO and O groups in the same or in different molecules. Up to now, the following classes of systems have been treated:

Polyethers and cyclic molecules, ethers or ketones, have been also studied in the framework of DISQUAC (3, 4).

Figure 1 is an example of the ability of DISQUAC to represent the recent data on excess functions at very high temperatures by Haan et al. (11) using our interchange coefficients published five years ago (10) (see also Fig. 2). It is noteworthy that the acetic anhydride + *n*-octane mixture shows a miscibility gap at room temperature, and that the same interaction parameters give an excellent description of the LLE coexistence curve of the acetic anhydride + *n*-heptane system (10).

The aim of this work was to develop the DISQUAC treatment of binary liquid organic mixtures containing linear ketones and linear mono- or poly-ethers. Previously, linear ketones + 2,5-dioxahexane systems were treated by assuming structure-dependent interchange coefficients for those contacts involving the carbonyl group (12–14). The zeroth approximation of DISQUAC was used for the carbonyl–oxygen (12) and oxygen–aliphatic contacts (15). The carbonyl–aliphatic contacts were represented by quasichemical interchange coefficients only with coordination number, *z*, equal to 10 (13, 14). DISQUAC interchange coefficients now being available for the interactions between the aliphatic group and the CO or O groups (3, 4), we report in this paper those for the CO–O contacts.

2. The DISQUAC model

2.1 Theory

In the framework of DISQUAC, mixtures of linear ketones with linear ethers are regarded as possessing three types of surface: (*i*) type a, aliphatic (CH_3, CH_2 in ketones and ethers); (*ii*) type e, oxygen (O in ethers); and (*iii*) type k, carbonyl (CO in ketones).

The equations used to calculate G^E and H^E are the same as in other applications (16). The reference value was chosen as coordination number, that is, $z = 4$.

The temperature dependence of the interaction parameters is expressed in terms of the dispersive (DIS) and (or) quasichemical (QUAC) interchange coefficients $C_{st,l}^{DIS}$ and $C_{st,l}^{QUAC}$, where s, t = a, e, or k, and l = 1 (Gibbs energy) or l = 2 (enthalpy). Heat capacity coefficients, l = 3, have not been considered.

2.2 Assessment of geometrical parameters

When DISQUAC is applied, the total relative molecular volumes, r_i, surfaces, q_i, and the molecular surface fractions, α_{si}, of the compounds present in the mixture are usually calculated

Table 2. Interchange coefficients, dispersive $C^{DIS}_{ae,l}$ and quasichemical $C^{QUAC}_{ae,l}$ (l = 1, Gibbs energy; l = 2, enthalpy) for contacts (a, e) (Type a, CH_3, CH_2 in n-alkanes; Type e, O in linear mono- or polyethers) for the ethers considered in this work (3). The coordination number used for the QUAC part is z = 4.

Ether	$C^{DIS}_{ae,1}$	$C^{DIS}_{ae,2}$	$C^{QUAC}_{ae,1}$	$C^{QUAC}_{ae,2}$
Methyl butyl ether	10.60	18.20	3.40	5.60
Diethyl ether	10.60	18.20	3.30	5.00
Dipropyl ether	10.60	18.20	2.80	2.90
Dibutyl ether	10.60	18.20	2.60	1.50
2,5-Dioxahexane	10.60	18.20	3.50	5.90
3,6,9-Trioxaundecane	10.60	18.20	2.90	3.70

Table 3. Interchange coefficients, dispersive $C^{DIS}_{ak,l}$ and quasichemical $C^{QUAC}_{ak,l}$ (l = 1, Gibbs energy; l = 2, enthalpy) for contacts (a, k) (4) (Type a, CH_3, CH_2 in n-alkanes; Type k, CO in linear ketones); n and m represent the number of C atoms of the n-alkyl group attached to the ketone under consideration. The coordination number used for the QUAC part is z = 4.

(n, m)	$C^{DIS}_{ak,1}$	$C^{DIS}_{ak,2}$	$C^{QUAC}_{ak,1}$	$C^{QUAC}_{ak,2}$
(1, 1)	2.90	5.05	6.08	8.25
(1, 2)	3.25	6.16	5.35	6.35
(1, ≥3)	3.31	6.92	5.29	5.94
(2, 2)	3.60	7.27	4.62	4.46
(2, ≥3)	3.65	8.03	4.56	4.04
(≥3, ≥3)	3.71	8.79	4.50	3.63

additively on the basis of the group volumes V_G and surfaces A_G, as recommended by Bondi (1968) (17). As volume and surface units, the volume V_{CH_4} and surface A_{CH_4} of methane are taken arbitrarily (15). The geometrical parameters for the groups referred to in this work are collected in Table 1.

2.3 Estimation of the interaction parameters

The three types of surface generate three pairs of contacts: (a, e); (a, k), and (e, k).

The (a, e) contact has been described in the past using DIS coefficients only, i.e., on the basis of the random mixing approximation ($C^{DIS}_{ae,1}$ = 15.73, $C^{DIS}_{ae,2}$ = 29.04) (15). DISQUAC improves the representation of the experimental data, especially that of H^E. The differences between random mixing and DISQUAC calculations increase with the oxygen surface fraction (3). The DIS and QUAC parameters needed in this work are listed in Table 2.

The (a, k) contacts have been described previously in terms of the quasichemical approximation with z = 10, assuming that the interaction parameters change regularly with the structure of the ketones (13, 14). Application of DIS and QUAC coefficients (Table 3; (4)) improves mainly the coexistence curves of liquid–liquid equilibria for the 2-propanone + n-alkane systems (González et al., unpublished results).

Hence, because the (a, e) and (a, k) parameters are known, only the DIS and QUAC interchange coefficients for the (e, k) contacts need to be fitted.

The general procedure used by us in the fitting of any set of interaction parameters has been described in detail elsewhere (18–20). However, in the present case the adjustment of the interchange coefficients is more complicated due to the lack of experimental data on G^E, as the QUAC enthalpic parameters depend on the first QUAC interchange coefficients. For this reason, we kept constant the $C^{QUAC}_{ek,1}$ coefficients for all the systems investigated. Moreover, in order to keep a lower number of interaction parameters, we also made the $C^{QUAC}_{ek,2}$ coefficients independent of the compounds in the mixture. After several calculations developed to study the change in the symmetry of the G^E and H^E curves with the interaction parameters, we finally took $C^{QUAC}_{ek,l}$ (l = 1, 2) = 0.50 together with the corresponding $C^{DIS}_{ek,l}$ (l = 1, 2) coefficients (Table 4).

For systems containing the longer symmetrical linear monoethers, say from dipropyl ether, calculations show that the main contributions to the excess functions are due to the aliphatic–CO and aliphatic–O contacts. Thus, the $C^{DIS/QUAC}_{ek,l}$ interchange coefficients obtained on the basis of the available data for alkanones + dibutyl ether mixtures can be used. In the case of shorter symmetrical monoethers, dimethyl or diethyl ether, such contributions decrease rather quickly with the size of the alkanone, when, moreover, size effects become very important. So different interaction parameters are needed. The $C^{DIS}_{ek,2}$ coefficients were estimated using the H^E data by Hirobe for the 2-propanone + diethyl ether mixture (21)[2] and taking into account, for such parameters, a variation with the size of the alkanone similar to that encountered previously. On the other hand, for nonsymmetrical linear monoethers (n-O-m) + n-alkane mixtures the interchange coefficients are mainly determined by the shortest group n (n, m are the numbers of aliphatic groups attached to the oxygen atom) (3). For the actual mixtures, this is still valid. So, we consider two groups of different DIS enthalpic parameters depending on the n, m values: $n \leq 2$ and $n, m \geq 3$ (Table 4). In exchange, the $C^{DIS}_{ek,1}$ coefficients can be considered as independent of the monoether. This is possible due to the smooth variation observed for such parameters from the 2-propanone + diethyl ether mixture to the 2-heptanone + dibutyl ether system (the only mixtures under consideration characterized by a set of VLE data (22, 23)). This variation agrees fairly well with the inductive effect observed in the $C^{DIS}_{ek,2}$ coefficients in a

[2] Cf. ref. 34.

Table 4. Interchange coefficients, dispersive $C^{DIS}_{ek,l}$ (l = 1, Gibbs energy; l = 2, enthalpy) for contacts (e, k) (this work) (Type e, O in linear mono- or poly-ethers; Type k, CO in linear ketones). The coordination number used for the QUAC part is z = 4; and $C^{QUAC}_{ek,1} = C^{QUAC}_{ek,2} = 0.50$.

series with a given monoether (Table 4). It is noteworthy that while these parameters depend on the position of the CO group in the ketone molecule (values can be obtained by interpolation of those for the 2-ketone and for the corresponding symmetrical molecule), this does not occur for the $C^{DIS}_{ek,1}$ coefficients.

Finally, we remark that polyethers were treated as monoethers; i.e., we made no distinction between the different oxygen atoms present in the polyether. In the case of mixtures of noncyclic monoethers with *n*-alkanes, the interchange coefficients are obtained by ignoring O atoms when ascertaining the n and m values of the *n*-O-*m* groups in polyethers, or as an average of the various types of *n*-O-*m* groups present. For example, both O atoms in 2,5-dioxahexane are of the 1-O-3 type, and the parameters used are those for methyl propyl ether (3). However, such rules cannot be kept for the mixtures under study.

Table 6. Molar excess enthalpies H^E for linear ketones (1) + oxaalkanes (2) systems at 298.15 K and equimolar composition. Comparison of experimental results (exp) (28) with DISQUAC calculations (calcd.) using the coefficients from Tables 2–4. Also listed is a comparison between experimental standard deviations (exp) for H^E, $\sigma(H^E)$, (eq. [2], obtained when data are correlated using a Redlich–Kister equation type) with DISQUAC results (N is the number of data points of each system).

3. Comparison with experiment

A detailed comparison between experimental data and calculated values from the DISQUAC model for the thermodynamic properties VLE, G^E, and H^E is presented in Tables 5 and 6 and in Figs. 2–7.

We note that for the sake of major clarity, Table 5 lists the relative standard deviations in pressure, $\sigma_r(P)$ defined by:

$$[1] \quad \sigma_r(P) = \{1/N[\Sigma (P_{exp} - P_{calc})^2/P_{exp}]^{1/2}\}$$

where N stands for the number of data points for each system. Similarly, Table 6 also lists the standard deviation for H^E, $\sigma(H^E)$ defined by:

$$[2] \quad \sigma(H^E)/\text{J mol}^{-1} = [1/N \Sigma (H^E_{exp} - H^E_{calc})^2]^{1/2}$$

We note the rather good description obtained for the VLE data at very high temperatures. For G^E at equimolar composition, differences between experimental and calculated values do not exceed 10% (Table 5). We also note, as mentioned above, that no distinction is made for homomorphic ketones when calculating G^E for a given ether.

Larger discrepancies are found for H^E of mixtures of ketones with 2,5-dioxahexane. Much better results can be obtained using different QUAC and DIS enthalpic parameters for each system of this type. In this case, the interchange coefficients vary in a rather erratic way, indicating inaccuracies in the experimental data, which may explain some of the observed discrepancies.

Predictions for G^E and H^E at equimolar composition and T = 298.15 K for several alkanones + linear monoethers are shown in Figs. 8 and 9.

4. Discussion

The linear ketones + dibutyl ether systems behave similarly to mixtures of these ketones with a common *n*-alkane: H^E is rather large and positive, lower than for the latter systems, and falls in the order 2-propanone > 2-butanone > 2-pentanone (Tables 6 and 7). This effect is primarily due to the fact that, although the actual dipole moments of the ketones listed above are approximately constant (Table 8), the effective dipole moment decreases as the length of the aliphatic chain increases (Table 8) and this weakens the ketoxy interactions in the condensed phase. In fact, the effective polarity of a molecule is reasonably well correlated by the dimensionless ratio (24)

$$[3] \quad \bar{\mu} = [\mu^2/4\pi\varepsilon_0\sigma^3 k_B T]^{1/2}$$

or equivalently, by virtue of the corresponding states principle, with

$$[4] \quad \bar{\mu} = [\mu^2 N_A/4\pi\varepsilon_0 V_c k_B T]^{1/2}$$

where $\bar{\mu}$ is the effective dipole moment and μ the permanent electric dipole moment, ε_0 is the permittivity of vacuum, σ is an appropriate molecular size parameter (say, the effective hard sphere diameter), N_A is the Avogadro constant, k_B is the Boltzmann constant, T is the thermodynamic temperature, and V_c the critical molar volume. To characterize the effective

polarity of a molecule with μ, it is also possible to define a reduced dipole moment (25) according to:

$$[5] \quad \mu^* = [\mu^2/4\pi\varepsilon_0\sigma^3\varepsilon]^{1/2}$$

where ε is the interaction potential. This expression may advantageously be transformed, by virtue of the corresponding states principle, to:

$$[6] \quad \mu^* = [\mu^2 N_A/4\pi\varepsilon_0 V_c k_B T_c]^{1/2}$$

where T_c is the critical temperature. Since critical molar volume data are much scarcer than critical pressure data P_c, one may use alternatively:

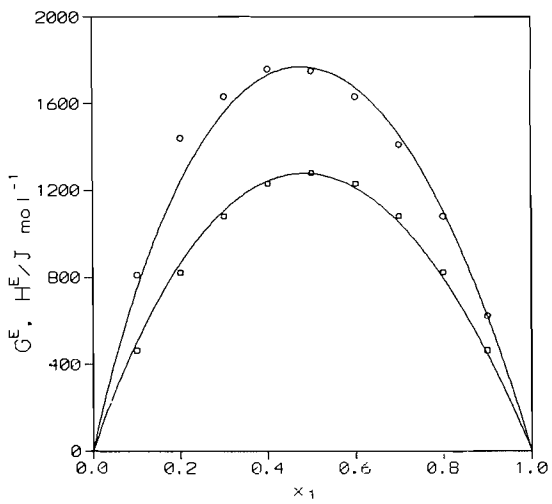
Fig. 10. Excess functions at temperature T for 1-methoxy-2-propanone (1) + solvents (2) systems. Points, experimental results (□, G^E of the 1-methoxy-2-propanone (1) + methylcyclohexane (2) mixture at 318 K (27); ○, H^E of the 1-methoxy-2-propanone (1) + n-hexane (2) mixture at 303.15 K (26)); solid lines, DISQUAC calculations.



tures containing 2,5-dioxahexane or 3,6,9-trioxaundecane, H^E is eventually negative for the shorter ketones, indicating the presence of strong forces between dissimilar molecules. For a common ketone, we note that the forces are stronger in the case of the diether because H^E (2,5-dioxahexane) < H^E (3,6,9-trioxaundecane) (Table 6). This may be because the effective dipole moment of the diether is larger than that of the triether (Table 8).

On the other hand, comparing H^E of systems containing n-heptane and homomorphic polar molecules (i.e., dimethyl carbonate (-O-CO-O- group), ethyl acetate (-CO-O- group), or 3-pentanone (-CO- group)) (Table 7), we note that each atom attached to the carbonyl group, while decreasing the overall dielectric dipole moment, increases the dissimilarity between the force fields of the polar compounds and the alkane, and hence also H^E.

It is also possible to compare mixtures containing esters or organic carbonates and n-alkanes with those of linear ketones and dibutyl ether (-O- group), or 2,5-dioxahexane (two -O- groups), respectively. In this case, we observe that when the two oxygen atoms and the -CO- group belong to the same molecule (the former directly attached to the latter, or separated by a number of aliphatic groups as in the 1-methoxy-2-propanone + n-hexane mixture (26)), H^E is larger than when the -CO- and -O- groups belong to different molecules (Tables 6, 7).

However, comparison of the interchange coefficients is rather difficult because mixtures containing carbonates or esters with n-alkanes are characterized, in terms of DISQUAC, by only one contact, while those of ketones + oxaalkanes have three contacts.

The natural continuation of the CO/O project is to investigate proximity effects, analyzing systems including two functional groups in the same molecule, namely -CO- and -O- groups (ketoethers), or the -CO- and -CO-O- groups (ketoesters). We expect that the proximity effects may lead to an important increase of the interchange coefficients. In fact, in a previous step we examined the 1-methoxy-2-propanone + n-hexane mixture (26) (Fig. 10) and the limiting case of the dimethyl carbonate + n-alkane systems (8, 9), assuming that the carbonate molecule is composed of two aliphatic groups, two oxygen atoms, and the -CO- group. For the 1-methoxy-2-propanone + n-hexane mixture, we obtained $C^{DIS}_{ek,l}$ = 5.0;

$C^{QUAC}_{ek,1}$ = 2.0 and $C^{DIS}_{ek,2}$ = 12.0; $C^{QUAC}_{ek,2}$ = 10.0 (the Gibbs energy parameters calculated using VLE data for the 1-methoxy-2-propanone + methylcyclohexane system (27) and assuming this molecule as an *n*-alkane (8)). This increase in the interchange coefficients may be due to stronger dipole–dipole interactions in the 1-methoxy-2-propanone molecule than those in the mixtures treated above. For dimethyl carbonate + *n*-alkanes mixtures, the behaviour is similar. The interchange coefficients are $C^{DIS}_{ek,1}$ = 14.2; $C^{QUAC}_{ek,1}$ = 28.2 and $C^{DIS}_{ek,2}$ = 28.5; $C^{QUAC}_{ek,2}$ = 36.5.

On the dissociation energy of $Ti(OH_2)^+$. An MCSCF, CCSD(T), and DFT study

A. Irigoras, J.M. Ugalde, X. Lopez, and C. Sarasola

Abstract: The dissociation energy of the $Ti(OH_2)^+$ ion–molecule complex was calculated by the multiconfigurational self-consistent field theory, coupled cluster theory, and two density functional theory based methods, using both all-electron basis sets and effective core potentials. The calculations show that approximate density functional theory gives results in better agreement with experiment than either the multiconfigurational self-consistent field theory or the coupled cluster theory, with both all-electron basis sets and effective core potentials. Nevertheless, the optimized geometries and harmonic vibration frequencies are very similar, irrespective of the level of theory used. The interconfigurational energy ordering of the two valence electronic configurations $d^{n-1}s$ and $d^{n-2}s^2$ of the ^4F electronic state of the titanium cation were also calculated and are discussed.

Key words: ab initio, dissociation energy, ion–molecule complex, effective core potentials, transition metals.

Résumé : On a calculé l'énergie de dissociation du complexe ion–molécule, $Ti(OH_2)^+$, à l'aide de la théorie de champ autocohérent multiconfigurationnel, de la théorie de l'agrégat couplé et de deux méthodes basées sur la théorie de la densité fonctionnelle, utilisant des ensembles de base de tous les électrons ainsi que tous les potentiels effectifs des noyaux. Les calculs montrent que la théorie approximative de la densité fonctionnelle conduit à des résultats qui sont en meilleur accord avec les données expérimentales que ceux obtenus à l'aide tant de la théorie du champ autocohérent multiconfigurationnel que de la théorie de l'agrégat couplé incorporant les ensembles de base de tous les électrons ainsi que tous les potentiels effectifs des noyaux. Néanmoins, les géométries optimisées et les fréquences de vibration harmonique sont très semblables, quel que soit le niveau de la théorie utilisé. On a aussi calculé l'ordre des énergies interconfigurationnelles des deux configurations électroniques de valence $d^{n-1}s$ et $d^{n-2}s^2$ de l'état électronique ^4F des cations du titane et on en discute.

Mots clés : ab initio, énergie de dissociation, complexe ion–molécule, potentiels effectifs des noyaux, métaux de transition.

[Traduit par la rédaction]

1 Introduction

Solvation of first-row transition metal ions by water has been the subject of much recent research work. Both experimental and theoretical methods have been used to gain insight into the bonding energies of water molecules to transition-metal positive ions. The $Ti(OH_2)^+$ cluster, in particular, was studied earlier by both experimentalists and theoreticians. Thus, the bond dissociation energy of the $Ti(OH_2)^+$ complex was first reported by Magnera et al., obtained by the use of collision-induced dissociation in a triple-quadrupole mass spectrometer (1). They gave a value of 38.0 ± 3 kcal/mol. Later, Dalleska et al. (2) reported the bond dissociation energies of water molecules from first-row transition-metal positive ions as determined by collision-induced dissociation in a guided ion beam mass spectrometer. The threshold energy for the collision-induced reactions is equivalent to the 0 K bond dissociation energy;[2] therefore, their value for the dissociation energy of the $Ti(OH_2)^+$ ion–molecule complex at 0 K is 36.9 ± 1.4 kcal/mol.[3] Simultaneously, ab initio molecular orbital theory was also used to estimate the dissociation of $Ti(OH_2)^+$. Rossi and Bauschlicher (3) reported calculations with the modified coupled pair functional (MCPF) method and a fairly large basis set. They obtained a value of 38.3 kcal/mol, using for the zero-point vibrational energy (ZPVE) correction the corresponding energy correction of the $Cu(OH_2)^+$ system. Magnusson and Moriarty (4) used both Möller–Plesset (MP) perturbation theory and truncated configuration interaction (CI) methods with a variety of basis sets. Their results show, as indeed do those of Rossi and Bauschlicher, that in every case the dissociation energy of the $Ti(OH_2)^+$ is overestimated with respect to the experimental value of Dalleska et al.

During recent years, however, there has been increasing interest in the use of gradient-corrected approximate density functionals (5, 6). In particular, there is growing evidence that approximate functionals yield accurate bonding energies for both the first- (7, 8) and second-row (9) transition metal complexes. Thus, in this work we consider the bonding energy of $Ti(OH_2)^+$. Our goal is to determine the reliability of the approximate density functionals BLYP and B3LYP used in conjunction with effective core potentials and valence basis sets of double- and triple-zeta quality. Comparison of available experimental data, with respect to both BLYP and B3LYP and multiconfigurational self-consistent field

(MCSCF) and coupled cluster (CCSD(T)) calculations with all-electron double-zeta and triple-zeta basis sets and effective core potentials, will be made. Inclusion of corrections due to the zero-point vibrational energy and to the basis set superposition energy, estimated with the counterpoise method (10) will also be explicitly considered.

2 Methods

All calculations reported in this paper have been carried out with the GAMESS (11) and the GAUSSIAN94/DFT (12) suites of programs.

2.1 Level of theory

Both ab initio molecular orbital MCSCF and CCSD(T) methods and BLYP and B3LPY approximate density functional theory (DFT) methods have been used in the present study. For the MCSCF calculations, a full optimization at the Hartree–Fock level of theory was initially carried out to properly select the active space window. In particular, we chose six orbitals, corresponding to the five 3*d* and the one 4*s* valence orbitals of titanium, to allocate three electrons. This active space will be denoted, as usual, (3/6). Both Ti^+ and $Ti(OH_2)^+$ have been fully optimized at this level of theory, while for the H_2O only the Hartree–Fock level was used. These structures were confirmed to be true minima by inspection of the force constants matrix, evaluated at the corresponding level of theory.

The singles and doubles, with a noniterative estimate for the triples, coupled cluster (CCSD(T)) calculations were carried out at the CCD optimized structures. Also, at this level of theory the zero-point vibrational energy corrections (ΔZPVE) were taken from a frequency calculation at the CCD level of theory.

The approximate DFT methods that were used are associated with the well-known Becke (5) and Lee, Yang, and Parr (6*d*) (BLYP) approximate functionals and the three-parameter hybrid approximate functional of Becke (13):

$$[1]\quad (1-a_0)E_x^{\mathrm{LSD}} + a_0E_x^{\mathrm{HF}} + a_xE_x^{\mathrm{B88}} + a_cE_c^{\mathrm{LYP}} + (1-a_c)E_c^{\mathrm{VWN}}$$

where $a_0 = 0.20$, $a_x = 0.72$, and $a_c = 0.81$, and LSD stands for the Slater exchange (14), B88 is the Becke 1988 exchange functional correction (5), LYP stands for the gradient-corrected correlation functional of Lee, Yang, and Parr (6*d*), and VWN for the local correlation functional of Vosko, Wilk, and Nusair (15). The choice of these two approximate DFT methods was largely motivated by their satisfactory performance as reported recently (8, 16) for transition-metal-containing systems.

2.2 Basis sets

2.2.1 All-electron basis sets

As indicated by Hay and co-workers (17), good uncontracted basis sets are normally too large for application to molecules and, so, need to be appropriately contracted. In the present paper three different contracted basis sets (18), two of double-zeta plus polarization quality, namely the DZVP and DZVP2 given by Salahub and co-workers (19), and one of triple-zeta plus polarization quality were used for the calculations. The triple-zeta-quality basis set, TZVP, used in the present paper is, for the titanium, that given by Schäfer, Hubert and Ahlrichs (20), supplemented by the two 4*p* polarization functions optimized by Wachters (21) for the excited states and augmented with a diffuse *s* function (with an exponent 0.30 times that of the most diffuse *s* function on the original set) and one diffuse *d* function (optimized by Hay (22)). For both the oxygen and hydrogen we have taken the standard 6-311++G(d,p) basis set of Pople and co-workers (23).

2.2.2 Effective core potentials (ECP)

The use of atomic effective core potentials (ECP) and model potentials (MP) to eliminate chemically inactive atomic core electrons from quantum mechanical calculations has become routine during the past decade (24). Because of the economic advantage associated with reduced size of the basis sets that can be achieved with the ECP method and corresponding nodeless pseudo-orbitals, the SKBJ relativistic compact effective potentials (24) were used. These consider the first 10 electrons of the titanium and the first 2 electrons of the oxygen to be part of the core, and the rest are described by the SKBJC valence basis set. Three different sets have been built from the standard SKBJC set. The smallest one has one extra heavy atom polarization function on the oxygen (SKBJC(d)); the intermediate one has one extra *d* polarization function on the oxygen and one *p*-type polarization function on the hydrogens (SKBJC(d,p)); finally, the largest one has a *d* polarization function on the oxygen plus two *p* polarization functions on the hydrogens (SKBJC(d,2p)). The contractions for these three sets are as follows:

SKBJC(d)→[4*sp*3*d*/2*sp*1*d*/2*s*]

SKBJC(d,p)→[4*sp*3*d*/2*sp*1*d*/2*s*1*p*]

SKBJC(d,2p)→[4*sp*3*d*/2*sp*1*d*/2*s*2*p*]

Since the importance of relativistic effects decreases steadily from the third-row transition-metal series to the first, it is customarily (3, 4) assumed that these are sufficiently small for titanium not to be considered explicitly in the all-electron basis sets. Therefore, the dissociation energies reported in this paper for all-electron basis sets were calculated as the difference between the energy of the isolated monomers and the complex, without considering relativistic effects, but including both BSSE and ZPVE corrections. All the structures shown in this paper have been confirmed to be true minima by a frequency calculation at the corresponding computational level. Further, these calculations have provided us with the zero-point vibrational energy (ZPVE) corrections.

3 Results

Discussion here is directed at finding out which of the methods used can be selected as a computational strategy that is economical and, at the same time, reliable. Multiconfigurational methods are adequate to describe properly the different configurations that arise from the nonequivalence of *d* orbitals in $d^{n-2}s^2$, $d^{n-1}s$, and d^n states (25). On the other hand, DFT, a monoconfigurational method that includes correlation and that seems to work properly for these kinds of systems (7–9,

Table 1. Total (E) (in au) and relative energy (Δ_{sd}). (in eV) and expectation value of the $\hat{S}^2$ operator for the sd^2 and d^3 electronic configurations of $Ti^+(^4F)$ calculated with the B3LYP and various basis sets and ECPs.

16), is computationally a less demanding method than the correlated ab initio MCSCF and CCSD(T) methods.

3.1 Ti^+

It was pointed out earlier (26) that the correct prediction of the interconfigurational energy ordering of the two valence electronic configurations, $d^{n-1}s$ and $d^{n-2}s^2$, of transition-metal atoms is crucial for the accurate description of the dissociation energies of the clusters. In particular, the ground state of the Ti^+ cation is the ^4F state, which corresponds to the $3d^24s^1$ electronic configuration, and the first excited state, the $^4F(3d^3)$, lies 0.10 eV above (27). However, it has been demonstrated (28) that subtraction of the relativistic corrections from the energies of both states switches the stability order, rendering a $^4F(3d^3)$ ground state with the $^4F(3d^24s^1)$ being the first excited state, 0.07 eV above.

Inspection of Table 1 reveals that the B3LYP method describes correctly the above-mentioned energy ordering. Thus, for the all-electron basis function sets used in the present research, of which neither accounts for the relativistic effects, the $^4F(3d^3)$ state should be found to be the ground state, as is the case, and $^4F(3d^24s^1)$ the first excited state. But, for the SKBJ(d) effective core potential, which does account for the relativistic effects, the $^4F(3d^24s^1)$ is predicted to be the ground state. Nevertheless, it is particularly worth noting that, for the all-electron basis functions, the relative energy difference is overestimated with respect to the experimental energy corrected for relativistic effects. The best relative energy is obtained at the B3LYP/TZVP level of theory, Δ_{sd} = 0.19 eV, which is to be compared with the relativistic corrected experimental energy of 0.07 eV. However, for the ECP the relative energy difference is only slightly underestimated. Indeed we predict a difference of 0.06 eV, while the experimental value is 0.1 eV. This again raises the question of the legitimacy of employing effective core potentials derived from atomic HF calculations in approximate DFT methods, a question that was addressed recently, and has been given an empirical justification (9, 29).

Results obtained with the MCSCF and CCSD(T) methods, collected in Tables 2 and 3, respectively, also deserve a short comment. It is observed that both, irrespective of whether effective core potentials or all-electron basis sets are used, predict a $^4F(3d^24s^1)$ ground state, with the $^4F(3d^3)$ state lying more than 0.2 eV above. While this energy ordering is qualitatively correct for the ECPs, it should be regarded as incorrect for the all-electron basis, for which the $^4F(3d^3)$ should be the lowest energy state, as stated above. Notice, also, that the qualitatively correct energy level ordering prediction obtained with the ECPs is unsatisfactory from a quantitative point of view, since the experimental energy difference is 0.1 eV while the MCSCF theory predicts 0.24 eV and the CCSD(T) theory 0.72 eV.

$Ti(OH_2)^+$ ion–molecule complex at various levels of theory. Data are given only for the $^4B_2$ state; however, it is worth noting that a $^4B^1$ state, nearly degenerate in energy and with a nearly coincident optimum geometry, has also been found in every case. Inspection of the data of Tables 4–6 reveals that both the approximate density functionals BLYP and the hybrid procedure B3LYP yield a shorter Ti—O bond length than the MCSCF(3/6) method, for the basis set investigated. This is a tendency reported recently for hydrogen-bonded complexes (30) and for charge-transfer complexes (31). However, for our ion–molecule complex the discrepancies between the approximate density functional and molecular orbital theories are not as severe as those found for the above-mentioned systems. On the other hand, for the coupled cluster (CCD) theory Ti—O and O—H optimized distances lie in between MCSCF and DFT values, as shown in Table 6. The largest discrepancy with the ECPs is found for the SKBJC(d), for which the B3LYP method predicts a Ti—O bond length 0.091 Å shorter than that of the MCSCF(3/6) method. Nevertheless, it should be pointed out that the O—H bond is predicted to be ~0.035 Å larger by both of the DFT-based methods used in the present paper. The agreement found for the TiOH bond angle for all the methods is also remarkable, see column 4 of Tables 4 and 6 and columns 4 and 7 of Table 5.

In summary, the MCSCF(3/6) method predicts a bond length close to 2.2 Å for the $Ti(OH_2)^+$ ion–molecule complex, the CCD theory prediction lies in the range between 2.18 and 2.15 Å, depending on the basis set used, and both of the DFT-based methods used predict it to be around 2.1 Å, irrespective of whether an all-electron basis function set or an effective core potential is used.

3.3 Dissociation energies

Table 7 shows the electronic energies, zero-point vibrational energy corrections, basis set superposition error energy corrections, and the dissociation energies of the $Ti(OH_2)^+$, calculated at various levels of theory. In every case, the dissociation energy has been calculated as the energy difference between the $^4B_2$ state of the $Ti(OH_2)^+$ and the most stable electronic configuration of the ^4F state of the Ti^+ plus the energy of one water molecule. In addition, both the zero-point vibrational energy correction and the basis set superposition error energy correction have been taken into account.

Inspection of Table 7 reveals that both approximate density functional based methods, BLYP and B3LYP, overestimate slightly the dissociation energy of the $^4B_2$ state of $Ti(OH_2)^+$, with respect to the best experimental value of 36.9 kcal/mol. The best value obtained using DFT with ECPs was obtained using the B3LYP/SKBJC(d,2p) method, i.e., 37.9 kcal/mol, only 1 kcal/mol higher than experiment. However, it should be mentioned that provision of the basis set superposition energy error must be taken into account, in order to arrive at such a good estimate, for it can be as large as 2.3 kcal/mol. When all-electron basis sets are used with our approximate DFT methods, the BSSE error appears to be smaller than for ECPs, and the dissociation energies are even closer to the experimental value. Remarkably, at the B3LYP/TZVP level of theory we obtain D_0 = 36.7 kcal/mol, only 0.2 kcal/mol below the experimental result. Notice that for the all-electron basis set, both the BLYP and B3LYP lead to estimates of D_0 within the error bars of the experimental value, namely 36.9 ± 1.4 kcal/mol. In addition, the B3LYP method also fits the estimate for D_0, using the SKBJC(d,2p), within the error bars. These data contribute to the mounting evidence that B3LYP also performs reliably for open-shell transition-metal-containing compounds (8, 9, 16).

On the other hand both molecular orbital theory methods, MCSCF(3/6) and CCSD(T), with ECPs severely underestimate the dissociation energy of the title compound by 7.7 and 6.7 kcal/mol, at the MCSCF(3/6)/SKBJC(d,2p) and CCSD(T)/SKBJC(d,2p) levels of theory, respectively. Using all-electron basis sets instead of ECPs does not remedy the apparent weakness of the method, although it improves the

Table 7. Total energies E (in hartree/particle), zero-point vibrational energy corrections ΔZPVE (in kcal/mol), basis set superposition error corrections BSSE (in kcal/mol), and dissociation energies D_0 (in kcal/mol), for the $Ti(OH_2)^+$ ion–molecule complex.

	DZVP2	−924.328 23	1.5	2.1	31.2
	TZVP	−924.495 05	1.5	1.0	32.9

estimate. Notice that at the MCSCF(3/6)/TZVP level of theory the dissociation energy is still underestimated by 7.2 kcal/mol, and by 4.0 kcal/mol at the CCSD(T)/TZVP level of theory. This is suggestive of the slower convergence of the CCSD(T) method with the basis set, with respect to the B3LYP. Hence, in the small basis sets used in this work, it yields poorer agreement with experiment. However, this might not be so in the complete basis set. It is worth pointing out that both the MCSCF and CCSD(T) calculations are affected by a noticeably large BSSE error of 3.6 kcal/mol, when ECPs are used (3).

Finally, our calculations highlight one more interesting point. Namely, the approximate ΔZPVE value of 1.7 kcal/mol, used by Rossi and Bauschlicher (3) for the first-row transition-metal positive water clusters is well justified, even for approximate density functional based methods.

4 Conclusions

Our calculations show that the approximate DFT functionals BLYP and B3LYP, with both double-zeta-quality all-electron basis sets and effective core potentials, correctly predict the energy ordering of the two electronic configurations associated with the ground ^4F state of Ti^+. However, the calculated relative energies are overestimated with respect to their corresponding experimental values for every all-electron basis set used in the present study. On the other hand, for the SKBJC(d) effective core potentials of Stevens et al. (24), a good estimate, only 0.04 eV smaller, of the true experimental interconfigurational energy is obtained. Both the MCSCF and CCSD(T) method perform more poorly than the B3LYP procedure, yielding only a qualitative correct estimate for Δ_{sd} with the SKBJC(d) effective core potential. All-electron basis sets are not successful even in predicting the expected energy level ordering.

Optimum molecular geometries of the $^4B_2$ state of the $Ti(OH_2)^+$ ion–molecule complex do not depend appreciably on the basis sets used, but they do depend on the method. Thus, the MCSCF method leads to the largest Ti—O optimum bond distances, namely 2.2 Å, DFT yields the shortest, around 2.1 Å, and CCSD(T) predicts an in-between value, close to 2.15 Å.

Finally, the dissociation energy of the $Ti(OH_2)^+$ ($^4B_2$), is best reproduced at the B3LYP/TZVP level of theory, and reasonable estimates are obtained at both the BLYP/SKBJC(d,2p) and B3LYP/SKBJC(d,2p) levels of theory. On the other hand, both molecular orbital theory methods, MCSCF and CCSD(T), severely underestimate the dissociation energy.

Therefore, it is concluded that the B3LYP method used in conjunction with either the SKBJC effective core potentials or triple-zeta-quality basis sets represents a feasible computa-

tional strategy to deal with the molecular and electronic structures of the first-row transition-metal ligand complexes. In particular, it should be an efficient and accurate method to aid in understanding recent experiments (32) on primary reactions of Ti^+ with small molecules in the gas phase. Such work is in progress in our laboratory.

Aqueous nonelectrolyte solutions. Part XIV. D-ice and D-hydrate freezing points of deuterium oxide – ethylene oxide solutions and the formula of congruent ethylene oxide D-hydrate

David N. Glew and Norman S. Rath

Abstract: D-ice freezing temperatures and D-hydrate formation temperatures have been measured by the dynamic cooling method for deuterium oxide – ethylene oxide (EO) solutions containing from 0 to 95.5 mol% EO. The D-ice and the congruent EO D-hydrate freezing temperatures exhibited standard errors (SEs) on a single measurement of 0.004°C and 0.017°C, respectively. The D-ice–D-hydrate eutectic temperature was observed at 1.500°C with standard error (SE) 0.002°C and at composition 2.207 mol% EO with SE 0.010 mol% EO. The congruent EO D-hydrate was found to freeze at 13.242°C with SE 0.007°C and at composition 12.60 mol% EO with SE 0.07 mol% EO. The formula of the congruent EO D-hydrate was EO·6.93D_2O with SE 0.045 mol D_2O/mol EO. Only one type of D-hydrate was found over the whole composition range down to –23°C: the shoulder of the D-hydrate freezing curve above 40 mol% EO resulted from the high activity coefficients of dilute deuterium oxide in concentrated EO solutions. Equations and best values for the D-ice freezing temperatures and the D-hydrate formation temperatures together with their SEs were evaluated by the method of least squares. Properties of EO D-hydrate are compared with those of EO hydrate.

Key words: clathrate D-hydrate of ethylene oxide, freezing of deuterium oxide – ethylene oxide, ethylene oxide D-hydrate, formula of ethylene oxide D-hydrate.

Résumé : Faisant appel à la méthode de refroidissement dynamique, on a mesuré les températures de congélation de la glace-D et de formation d'hydrate-D de solutions d'oxyde d'éthylène (OE), contenant de 0 à 95,5 mol% d'OE, dans l'oxyde de deutérium. Les erreurs standards (ES) sur une mesure unique des températures de congélation de la glace-D et des hydrates-D d'OE apparentés sont respectivement de 0,004°C et de 0,017°C. On a observé la température eutectique de la glace-D–hydrate-D à 1,500°C, avec une erreur standard (ES) de 0,002°C, et à une composition de 2,207 mol% d'OE, avec une erreur standard de 0,010 mol% sur l'OE. On a trouvé que l'hydrate-D de l'OE apparenté gèle à 13,242°C, avec une ES de 0,007°C, et à une composition de 12,60 mol% d'OE, avec une ES de 0,07 mol% sur l'OE. La formule de l'hydrate-D de l'OE apparenté est OE·6,932D_2O, avec une ES de 0,045 mol D_2O/mol OE. En abaissant la température jusqu'à –23°C, on n'a observé qu'un seul type d'hydrate-D sur l'ensemble de la plage de compositions : l'épaulement de la courbe de congélation de l'hydrate-D au-dessus de 40 mol% d'OE résulte de coefficients d'activité élevés de l'oxyde de deutérium dilué dans les solutions concentrées d'OE. On a fait appel à la méthode des moindres carrés pour déterminer les équations et les meilleures valeurs pour les températures de congélation de l'eau-D, les températures de formation de l'hydrate-D ainsi que leurs ES. On a comparé les propriétés de l'hydrate-D de l'OE avec celles de l'hydrate de l'OE.

Mots clés : clathrate hydrate-D d'oxyde d'éthylène, congélation d'oxyde de deuterium – oxyde d'éthylène, formule de l'hydrate-D de l'oxyde d'éthylène.

[Traduit par la rédaction]

Introduction

This work was part of earlier studies on aqueous nonelectrolyte solutions and the gas hydrates (1) and was a direct extension of work on EO hydrate reported recently (2). Deuterium oxide and EO liquids were miscible in all proportions, as in the water–EO system, and the enthalpies of mixing of deuterium oxide or water with EO were quantitatively similar (3). Solid EO D-hydrate was formed on cooling EO – deuterium oxide solutions over a very wide composition range. This study of the freezing behavior of EO – deuterium oxide solutions was made to define the stability of EO D-hydrate relative to that of EO hydrate.

In an earlier comparison of D-hydrates of krypton and xenon (4) with their hydrates (5, 6), the solid gas hydrates were formed only from dilute solutions of the gases in highly aqueous-rich phases. By contrast, in this work the formation

of EO D-hydrate from its solutions was directly comparable with that of EO hydrate over a wide range of liquid composition, extending from highly aqueous-rich phases to highly EO-rich phases.

A recent study (7) of the similar completely miscible aqueous tetrahydrofuran (THF) system has compared the melting temperatures of THF D-hydrate with THF hydrate over a more limited range of liquid composition.

A valuable review of the clathrate hydrates, including work on both EO hydrate and EO D-hydrate up to 1973, has been given by Davidson (8).

Extending our work on the water–EO system (1, 2), we now report measurements of D-ice freezing points and of D-hydrate formation temperatures from deuterium oxide solutions of EO. Just as the EO hydrate data were presented (2) in Tables 1–3 and Fig. 1, similar EO D-hydrate data are presented here in Tables 1D–3D and Fig. 1D; Fig. 2D is the difference of Fig. 1D minus Fig. 1.

Experimental

Materials

All materials were as described earlier (1, 2). EO was selected from the production of Dow Chemical Canada, Limited, and had impurities <80 ppm by wt. Deuterium oxide was obtained from Atomic Energy of Canada, Limited; analysis 99.72 mol% D_2O, 0.28 mol% H_2O; complete isotopic analyses have been given earlier (1).

Apparatus and procedure

The method of use of the freezing point cell has already been described (2). Some D-ice freezing points of EO solutions were earlier reported and analysed in a different manner (1).

Calibration of thermocouple of freezing point cell

The freezing point cell thermocouple was calibrated against a standardized (IPTS-48) platinum resistance thermometer between +15 and –25°C (1, 2). Calibrations were made prior to and at the end of the runs using deuterium oxide solutions. The SE on a single temperature determination, due only to electrical instrumental effects, (*i*) was 0.0035°C between –6.5 and +6.5°C, (*ii*) was 0.0070°C between –13 and –6.5 and between 6.5 and 13.0°C, and (*iii*) was 0.014°C between –26 and –13 and between 13 and 15°C. These estimates are minimum values for the SE for the three recorder ranges.

The original experimental temperatures, measured on the International Practical Temperature Scale of 1948 (IPTS-48), have been converted to the International Temperature Scale of 1990 (ITS-90), using the differences in Table 4 by Goldberg and Weir (9). This conversion has a root-mean-squared bias of less than 0.0004°C over the range –25 to +15°C, about an order of magnitude smaller than our most precise measurements. Temperatures and equations are reported in units of degree Celsius (ITS-90).

Measurement of temperature for freezing of D-ice

As for freezing ice (2), the freezing of D-ice from dilute EO solutions of deuterium oxide generally exhibited larger supercoolings (~0.3–0.6°C) than those shown for the formation of D-hydrate (~0.005–0.15°C) from the same solutions. Table 1D lists the D-ice freezing temperatures corrected for bias, assuming the same bias, –0.0126°C, found for freezing ice from water under the same conditions (2).

Measurement of temperature for formation of eutectic

The eutectic temperature was measured directly on solutions initially freezing D-ice and initially forming D-hydrate, using

Table 2D. (ITS-90). Variation of temperature for formation of D-hydrate with composition.

Table 2D (*concluded*).

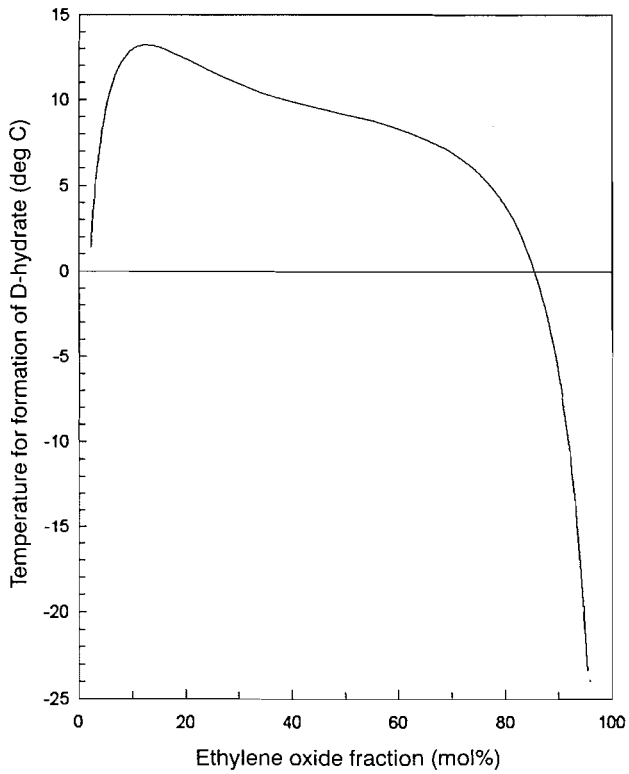
a final small cooling differential of ~0.1°C. The six observed eutectic temperatures are listed in Table 1D.

Measurement of temperature for formation of D-hydrate

With the developed cooling technique of the freezing point cell, the preselected temperature differential applied for the first formation of D-hydrate was ~0.4°C, and for subsequent formations was reduced to ~0.1°C. EO D-hydrate formation temperatures listed in Table 2D were extrapolated to zero supercooling (2).

In contrast to work on EO hydrate, many fewer runs were made on the formation of EO D-hydrate and very few measurements were repeated. In the congruent region, temperatures for D-hydrate formation were measured on the least sensitive

Fig. 1D. Freezing point curve of EO D-hydrate.



recorder range with largest SE. As a result random errors of measurement for EO D-hydrate are somewhat larger than those for EO hydrate.

Results and Discussion

Measurement of freezing of D-ice

Table 1D lists corrected temperatures for freezing of D-ice from deuterium oxide solutions containing between zero and 2.1876 mol% EO. The first column shows the run RD-number, the second column the solution composition, and the third the corrected temperature for freezing D-ice from the solution. The 36 measurements for freezing D-ice from EO solutions are best represented by the three-parameter equation,

$$[1] \quad T_{FDI} = 3.8000 - 1.0168\,C - 0.01518\,C^2$$
$$(0.0010) \quad (0.0031) \quad (0.00148)$$

where the freezing temperature T_{FDI} is in degree Celsius and C is the solution concentration of EO in mol% EO. Least-squares estimates of the SE on the parameters are shown in parentheses and the estimated SE on a single D-ice freezing point determination is 0.0037°C with 30 degrees of freedom.

The nine freezing points of 99.72 mol% deuterium oxide without EO give a mean temperature of 3.800°C with SE 0.0007°C and with SE on a single measurement 0.0020°C. The perfect agreement between the mean of the replicates and the regression is fortuitous, recognising that the minimum SE estimate from thermocouple calibration was 0.0035°C (1, 2).

Measurement of formation of eutectic

The eutectic temperature 1.500°C, with estimated SE 0.0020°C, is the mean of the six measurements listed in Table 1D, with initial solution compositions between 2.0758 and 2.7502 mol% EO. The SE for a single eutectic temperature measurement is 0.0049°C.

The eutectic composition 2.207 mol% EO, with SE 0.010 mol% EO, is estimated from the directly observed mean eutectic temperature together with the intersections of the curves for freezing of D-ice and for formation of D-hydrate. The D-ice–D-hydrate intersection estimate for the eutectic temperature is 1.477°C, with bias –0.023°C below the best observed mean value: this negative bias arises from the two biases for D-ice freezing and for D-hydrate formation.

Bias of the temperature for formation of D-hydrate at 2.207 mol% EO is at least –0.023°C, identical with that at the EO–water eutectic (2).

Measurement of formation of D-hydrate

Table 2D lists measurements of the formation temperature for EO D-hydrate from deuterium oxide solutions containing between 2.1876 and 95.5000 mol% EO. The first three columns show the RD-number, the solution composition, and the temperature for D-hydrate formation. Measurement precision justifies four decimal places for solution mol% EO, and three places for D-hydrate formation temperature °C. Figure 1D is a plot of these measurements showing the EO D-hydrate "freezing point" curve.

The measurements in Table 2D, shown in Fig. 1D, exhibit a continuous envelope at all compositions, without discontinuities of value or of slope: this confirms EO D-hydrate has a structure I type lattice (2) over the whole range of solution composition.

Regression analysis of data in Table 2D involves taking 13–16 adjacent measurements around a predefined solution composition and making a local analysis of D-hydrate formation temperature as a polynomial function of solution composition. The best-fit residuals are random and reconfirm the continuity of the measurements. Since the number of runs forming D-hydrate are many fewer than those forming hydrate, the number of D-hydrate measurements used in each regression is made to extend over about the same composition range as that used for the hydrate (2).

Estimates of temperature for formation of D-hydrate

Eutectic point data are listed in the first row of Table 3D. Estimates of the EO D-hydrate formation temperature with composition are listed in Table 3D and are defined by the 33 best-fit regression analyses at the compositions shown in column one. Estimates of the temperature for formation of D-hydrate, T_{FDH}; its SE, SE T_{FDH}; the SE on a single D-hydrate measurement, SE T_{obs}; the slope of the T_{FDH} envelope, and its SE are listed in columns two to six, respectively. In column seven the numbers separated by a dash indicate the number of measurements and of parameters used in the best model.

Errors of D-hydrate measurement are greatest at lowest temperatures for the most EO-rich (Deuterium oxide-dilute) solutions, as seen in the final row of Table 3D. Column four shows the progressive change of SE T_{obs} with increase both of D-hydrate formation temperature and of deuterium oxide content of the solution. The lower SE T_{obs} from 40 to 25 mol% EO and below 8 mol% EO derives from the use of more sensitive and accurate recorder ranges. In contrast, the higher SE T_{obs} in the congruent region between 9 and 22 mol% EO mainly

reflects use of the least sensitive recorder range. Over the very wide solution composition range 9–90 mol% EO, the SE on a single D-hydrate temperature determination is 0.018°C, and is sensibly constant.

The congruent temperature 13.242°C, with SE estimate 0.0065°C, is determined at the maximum of the D-hydrate formation curve representing 14 measurements with solution compositions between 7.7480 and 20.9993 mol% EO. The temperature for formation of EO D-hydrate, T_{FDH}, is best represented by the five-parameter equation,

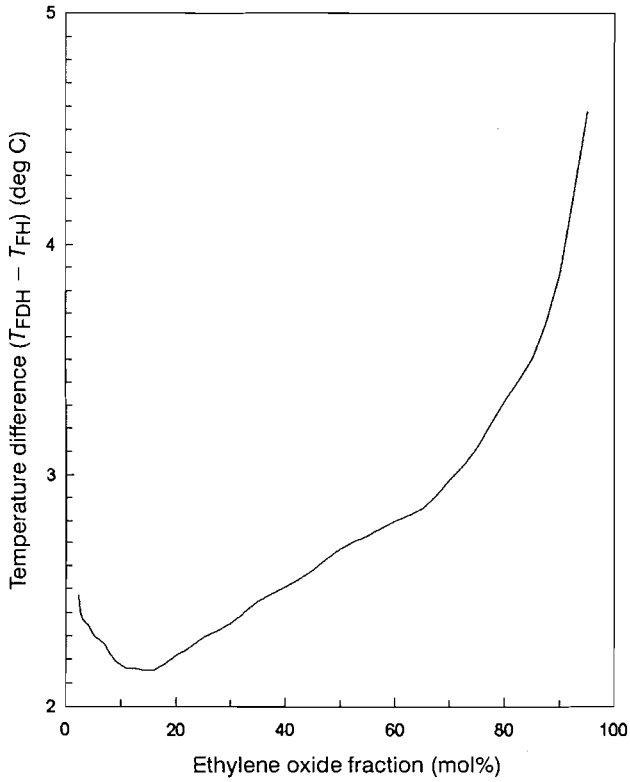
$$[2]\quad T_{FDH} = \underset{(0.0065)}{13.242} + \underset{(0.0042)}{0.0000D} - \underset{(0.00088)}{0.02940D^2} + \underset{(0.000203)}{0.002681D^3} - \underset{(0.000027)}{0.000098D^4}$$

where T_{FDH} is in °C and D = (mol% EO–12.604) = (C–12.604) mol% EO. Least-squares estimates of the SE on the parameters are shown in parentheses and the SE on a single hydrate temperature measurement is 0.017°C with 9 degrees of freedom, in good agreement with estimates from adjacent regressions.

The congruent composition 12.604 mol% EO, with SE 0.071 mol% EO, is determined as the composition for zero slope of eq. [2], and the SE from the error on that slope. Formula for the congruent EO D-hydrate is EO·6.93D_2O with SE 0.045 mol D_2O/mol EO.

Congruent EO D-hydrate comprises 6.63EO·46D_2O per unit cell, with EO molecules occupying mainly the six tetrakaidecahedral sites and filling about one third of the two dodecahedral sites. These estimates for the formula of EO D-hydrate are insignificantly different from those for the EO hydrate (2).

Fig. 2D. Stability difference of EO D-hydrate and EO hydrate.



The slope of the D-hydrate formation curve in the EO-rich region is negative and passes through a narrow minimum at 20–22 mol% EO and through a wide maximum at about 50 mol% EO. The small absolute values of the negative slopes between 14 and 65 mol% EO reflect (*i*) a high enthalpy change for crystallization of EO D-hydrate from solution (10), together with (*ii*) positive and high Raoult-law activity coefficients for deuterium oxide in these EO-rich solutions (2).

Comparison of EO D-hydrate with EO hydrate

The congruent solution for EO D-hydrate contains 12.605 mol% EO with SE 0.071 mol% EO, while that for EO hydrate contains 12.644 mol% EO with SE 0.021 mol% EO. The congruent composition difference of –0.039 mol% EO with the combined SE of 0.074 mol% EO shows that the difference is not statistically significant and could arise by pure chance at a probability level of greater than 50%. This clearly shows that the formula EO·6.93D_2O for EO D-hydrate is not significantly different from the better determined formula EO·6.91H_2O for EO hydrate (2).

At any given solution composition the formation temperature of EO D-hydrate is always higher than that of EO hydrate, indicating a greater stability of the D-hydrate relative to its solutions than that of the hydrate relative to its solutions. The temperature difference for formation of D-hydrate minus that for formation of hydrate provides a quantitative measure of the greater stability of the D-hydrate compared with the hydrate.

Figure 2D shows a plot of this temperature difference ($T_{FDH} - T_{FH}$) against solution composition evaluated at 48 EO fractions. The stability difference is 2.47°C at 2.207 mol% EO in the most EO-dilute region, the minimum stability difference is 2.16°C at the congruent point, and the greatest stability difference is 4.58°C at 95.00 mol% EO in the extreme EO-rich region.

We note that the composition dependence of the negative temperature difference curve, $-(T_{FDH} - T_{FH})$, has a geometrically similar shape to that of its constituent formation curves Fig. 1D for D-hydrate and Fig. 1 for hydrate (2). This requires that the envelope of the EO D-hydrate formation curve have a numerically smaller slope than that of the EO hydrate formation curve at all equal EO fractions.

Comparison of Table 3D with Table 3 (2) confirms that the absolute values of the slope for the EO D-hydrate formation curve are invariably slightly smaller than those for the EO hydrate at the same composition: this requires that the enthalpy change for formation of the EO D-hydrate from deuterium oxide solutions of EO be numerically larger than that for formation of the EO hydrate from water solutions of EO (10).

Comparison with THF D-hydrate and THF hydrate

In the study of the aqueous THF system (7) the difference of the melting temperature of THF D-hydrate minus that of THF hydrate is about 2.5°C with SE 0.5°C over the composition range 2.0–37.3 mol% THF. This temperature difference is similar to the values found here for the EO hydrates. The measurements (7) are not of sufficient accuracy to confirm or deny a minimum difference of temperature at the congruent composition, although this would be expected from enthalpy change considerations (10).

Chiral synthesis of (+)-8′-demethyl abscisic acid[1]

Patricia A. Rose, Bo Lei, Angela C. Shaw, M. K. Walker-Simmons, Scott Napper, J. Wilson Quail, and Suzanne R. Abrams

Abstract: An enantioselective synthesis of (+)-8′-demethyl ABA (**2**) is described. The chiral intermediate **7** was prepared by yeast reduction of a substituted monoprotected cyclohexa-2,5-dien-1,4-dione (**9**) synthesized through a phenol oxidation. The scope and limitations of the phenol oxidation is described. 8′-Demethyl ABA shows ABA-like activity in wheat embryo germination inhibition, showing that the 8′-methyl group is not essential for biological activity.

Key words: abscisic acid, phenol oxidation, yeast reduction.

Résumé : On décrit une synthèse énantiosélective de l'acide (+)-8′-déméthyl-abscisique (AAB) (**2**). On a préparé l'intermédiaire chiral **7** par réduction, à l'aide de levures, d'une cyclohexa-2,5-diène-1,4-dione substituée monoprotégée (**9**) obtenue par oxydation d'un phénol. On décrit la généralité et les limitations de l'oxydation des phénols. L'acide 8′-déméthyl-abscisique présente une activité semblable à celle de l'AAB comme inhibiteur de la germination des embryons de blé; ce résultat démontre que le groupe 8′-méthyle n'est pas essentiel à l'activité biologique.

Mots clés : acide abscisique (AAB), oxydation des phénols, réduction par des levures.

[Traduit par la rédaction]

Introduction

The plant hormone (+)-(S)-abscisic acid (ABA, **1**) regulates a wide range of processes in plants, including transpiration through controlling stomatal aperture and responses to environmental stress. In developing seeds, ABA affects accumulation of proteins, acquisition of desiccation tolerance, maintenance of dormancy, and inhibition of germination (for reviews on ABA action in plants, see ref. 1). We have used optically active analogs of the hormone to probe the mechanisms by which ABA triggers different physiological effects such as germination inhibition and induction of genes in plants (2, 3). Enantiomerically pure molecules are required for these investigations, as previous studies have shown that the enantiomers of ABA can have different effects in the same tissue, and optically pure analogs can be either ABA agonists or antagonists depending upon the enantiomer tested (4).

In this phase of our research we undertook to synthesize and test the optically pure ABA analog **2**, which lacks one of the geminal methyl groups of ABA, the 8′-carbon atom (following the conventional ABA numbering system). The aim was to provide analogs that could be used for differential screening to relate physiological and molecular effects in plant tissues. Methyl groups on the six-membered ring are important for activity. Racemic 8′-demethyl ABA had earlier been prepared and, in an assay looking at the growth inhibition of rice seedlings, was found to have moderate activity (5). Both enantiomers of the analog missing the 7′-methyl group are completely inactive in germination inhibition of excised wheat embryos, while the optically active analogs missing both of the geminal methyls have some activity (3).

In addition, the analog **2** is a probe for differentiating between the activity conferred by ABA and its oxidized metabolites. The major pathway of ABA metabolism is through oxidation of the 8′-methyl group, transiently affording 8′-hydroxy ABA, **3**, which then cyclizes through an internal Michael addition to phaseic acid (**4**). While **4** is generally considered to be inactive (6), a method for trapping the open form **3** has recently been developed, and it was found to be as active as ABA in increasing very long chain fatty acid production in Brassica embryos (7).

We had previously developed the synthesis of (+)-2′,3′-dihydroABA (**5**) (8), which is oxidized in a plant cell culture at the 8′-carbon to give 8′-hydroxy-2′,3′-dihydroABA, **6**. This metabolite cannot cyclize to form phaseic acid. Analog **5** was found to be as active as ABA in germination inhibition of wheat embryos (2) and in inducing freezing tolerance in plant cells; however, its metabolic product **6** was inactive (9). Compound **6** appeared to exist in equilibrium with the hemi-ketal formed through the 4′-carbonyl. The lack of activity of the metabolite may arise from inactivity of the predominant ring-

closed form. Compound **5** did not conclusively answer the question of whether ABA or 8′-hydroxy ABA was the active plant hormone in the wheat embryo assay. 8′-Demethyl ABA **2** cannot be oxidized to an 8′-hydroxy ABA intermediate, as it is missing the 8′-methyl group, making it a useful tool for differentiating between the activity of ABA and its metabolites.

We report here an enantioselective synthesis of (+)-8′-demethyl ABA, **2**, its activity in inhibiting wheat embryo germination, and its effect in reducing transpiration in wheat seedlings.

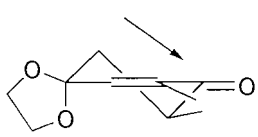
Results and discussion

Abscisic acid type compounds are readily synthesized by reaction of the appropriate cyclohexenone derivatives with side chains containing lithium acetylides. The dienoic side chain is generated by reduction of the propargylic alcohol with RedAl. Standard functional group manipulations afford a wide variety of analogs (10).

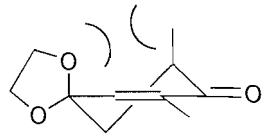
For the synthesis of 8′-demethyl ABA **2**, we decided to prepare chiral ring synthon **7** with the intention that the new chiral centre, generated through lithium acetylide addition to the carbonyl, would be formed stereoselectively. The preferred conformation for **7** presumably has the methyl group equatorial, to avoid 1,3-diaxial interactions between an axial methyl group and the ketal (Fig. 1). In the preferred conformation, the less hindered side of attack should be from the same face as the methyl group.

We synthesized the key intermediate **7** from 2,6-dimethylphenol in two steps: the first a phenol oxidation and the second a stereoselective yeast reduction. We had previously modified a phenol oxidation procedure for the synthesis of an achiral cyclohexadienone analog of ABA, **8** (11). The key intermediate for this synthesis, **9**, was prepared directly through an oxidation of 2,6-dimethyl phenol. The oxidation

Fig. 1. Conformations of enone **7**.



7, equatorial methyl



7, axial methyl

was a modification of Pelter's iodobenzene diacetate oxidation of phenols in methanolic solution (12), which affords quinone mono-dimethyl ketals. Replacing methanol with ethylene glycol and adding hexane to form a biphasic reaction mixture directly gave the more stable ethylene ketal in good yield.

As an aside, because the ethylene ketal is more convenient for synthetic purposes, we explored the scope of this reaction. This procedure worked for a number of phenols (entries 1–5, 7, Table I) in moderate yield. Unsubstituted phenol underwent oxidation to give the desired product (as determined by GC–MS), but the product was not stable to the work-up conditions (entry 5). Oxidation of *meta*-substituted phenols showed the steric limitations of this reaction. The introduction of one *meta* substitutent lowered the yield of ketalized product significantly (entry 8), whereas 3,5-dimethyl phenol (entry 9) produced only the quinone. Presumably, steric hinderance of the *meta* substituents hinders the formation of the 1,3-dioxolane ring. Phenols substituted with electron-withdrawing groups at either the *ortho* (difluoromethyl group) or *meta* (trifluoromethyl group) positions were unreactive, with only starting materials being recovered. The introduction of manipulable functional groups to the ring system can be accomplished, however, through an allyl group (entry 4) or a protected hydroxy methyl group (entry 7). Although 2-hydroxymethyl-6-methylphenol decomposed under the reaction conditions (entry 6), oxidation of its *tert*-butyldimethylsilyl ether gave the ketalized product in 67% yield (entry 7). This is a facile reaction that provides highly functionalized molecules in one step, and should prove to be useful in the synthesis of natural products and their analogs.

The second step in the synthesis of 8′-demethyl ABA was an enantioselective yeast reduction of the quinone monoketal **9** to introduce the chiral centre. Yeast reductions have previously been carried out under non-deketalizing conditions, and have been shown to reduce electron-deficient double bonds in reasonable yields and with good stereoselectivity (13). We were able to reduce quinone monoketal **9** in 50% yield (92% ee) to enone **7**, with little epimerization of the newly formed chiral centre, hydrolysis of the ketal, or overreduction of the second double bond.

The remaining steps in the synthesis of 8′-demethyl ABA closely follow those previously reported for the synthesis of ABA (14), with the exception of combining the alkyne addition and subsequent reduction of the triple bond into one step (see Fig. 2). Enone **7** was reacted with the lithium anion of *cis*-(5-*tert*-butyldimethylsiloxy-3-methylpent-3-enyne) (8), **10**, to give one diastereomer and after the alkyne addition was complete, Redal® was added directly to the reaction mixture, reducing the triple bond to a *trans* double bond, as well as cleaving the silyl protecting group, to give dienol **11** in a one-

[a]Yield based on GC analysis.

pot reaction in 38% yield. Yields for the Redal® reduction of the isolated alkyne were very low when the reaction was carried out independently. The bulky protecting group on the alcohol of the pentenyne chain was found to be necessary for obtaining high diastereoselectivity when reacted with chiral enone **7**. Addition of the lithium dianion of the unprotected alcohol gave a mixture of both *cis* and *trans* addition products. Assuming addition is only occurring at the less hindered face of the ketone (Fig. 1), either the remote bulky protecting group is contributing to the increased diastereoselectivity, or possibly the lithium anion of the unprotected alcohol is chelating with the oxygens on the ketal to facilitate addition from either face.

Dienol **11** was deketalized in 83% yield under standard conditions to give enone **12**, which was then oxidized to the aldehyde with MnO_2, and then to the ester (15) to give the methyl ester of 8′-demethyl ABA, **13**, in 35% yield over the two steps. Other oxidants gave unwanted isomerization of the *cis* double bond. Methyl ester **13** could be analyzed on a Chiralcel OD HPLC column, showing that no racemization of the 6′-methyl group of ketone **7** had occurred during addition of the side chain, and, using preparative HPLC, the compound was purified to greater than 99% ee. The methyl ester was cleaved using porcine liver esterase (to avoid possible aromatization of the ring under alkaline hydrolysis conditions) to give the desired (+)-8′-demethyl abscisic acid, **2**.

The stereoselectivity of the yeast reduction and diastereoselectivity of alkynylation were proven through an X-ray crystal structure of Mosher's ester **14**, made from an intermediate of which we had made quantities while trying to improve reduction of the triple bond. Compound **14** was prepared by reacting enone **7** with the lithium anion of **10** to give one diastereomer, **15**, in 83% yield (see Fig. 3). Alkyne **15** was deprotected in succession with Bu_4NF, to remove the silyl group, and then with pTsOH to remove the ketal, to form acetylenic alcohol **16**. The C1-hydroxy group of **16** was then coupled with *R*-(+)-α-methoxy-α-(trifluoromethyl)phenyl acetic acid using DCC to form the crystalline Mosher's ester. The X-ray structure is displayed in the PLUTON92 (16) drawing in Fig. 4 and shows the chiral center of enone **7** (generated by the yeast reduction) to be *R*, and relationship of the side-chain and 9′-methyl group of **2** to be *cis*, as shown.

Biological results

The effectiveness of compound **2** compared to (+)-ABA (**1**) as a germination inhibitor was determined with isolated wheat (cultivar Brevor) embryos. The compounds were tested over a range of concentrations and the concentrations required to inhibit embryo germination by 50% were 0.05 μM for (+)-ABA and 0.5 μM for (+)-8′-demethyl ABA. In a wheat seedling transpiration assay, 8 h after applying 100 μM (+)-ABA as a root drench, the transpiration rate of the seedlings was reduced by 80%. 8′-Demethyl ABA applied at 100 μM concentration reduced transpiration by 45% under the same conditions. This strong activity of an analog that has no 8′-methyl group available for oxidation suggests that ABA itself is the active hormone in germination inhibition, and transpiration reduction. These results do not preclude 8′-hydroxy ABA from also being biologically active, and investigations are ongoing to determine the biological activity of 8′-hydroxy ABA in wheat.

Experimental

apparatus and are uncorrected. ^{1}H NMR spectra were recorded on a Bruker AMX-500 spectrometer, employing $CDCl_3$ as solvent with $CHCl_3$ as reference, unless otherwise specified. For clarity, the conventional ABA numbering system is employed in assignments of peaks in the ^{1}H NMR spectra. IR spectra were obtained with a Perkin Elmer 237B instrument or a Perkin-Elmer Paragon 1000 FTIR. Optical rotations were obtained from a Perkin–Elmer 141 polarimeter. Flash column chromatography was performed using E. Merck silica gel 60 (230 – 400 mesh). High-resolution electron impact (HREIMS) mass spectra were recorded with a VG 70-250SEQ double-focusing hybrid spectrometer. Elemental analyses were carried out by the Microanalytical Laboratory of the University of Saskatchewan. Commercially available compounds were used in this work without further purification. Tetrahydrofuran was distilled over sodium and benzophenone (indicator). Fleischmann's brand bakers' yeast was used in the yeast reduction reaction. The wheat embryo germination assay was carried out as previously reported (8). The transpiration assay was carried out as previously reported (17).

X-ray analysis of 14

Crystal data: $C_{24}F_3O_5H_{25}$, M_r=450.45, monoclinic, $P2_1$, a = 11.91(2), b = 7.612(3), c = 12.50(1) Å, β=105.71(1)°, V = 1091(2) Å^3, Z = 2, $F(000)$ = 472, D_x = 1.372 Mg m^{-3}, μ = 0.11 mm^{-1}, crystal dimensions 0.68 × 0.12 × 0.09 (mm). Intensity data were measured at 123(2) K on an Enraf–Nonius CAD-4 diffractometer, using graphite monochromatized MoK_α (λ = 0.71073 Å) radiation. Intensity data were collected with ω scans to a maximum 2Θ angle of 49.7°. The unit-cell dimensions were obtained by a least-squares fit of 25 centered reflections in the range 17 ≤ 2Θ ≤ 29°. The scan width, Δω, for each reflection was (1.20 + 0.35 tan Θ)° with a scan speed of 0.40–2.74° min^{-1}. Three standard reflections were monitored every two hours for intensity and two standard reflections were monitored every 200 reflections for orientation. A total of 2130 reflections were measured, of which 2022 were unique (R_{merge} = 0.046) with index range h −14/+13, k 0/+8, l 0/+14, and 1328 were observed (I)2σ(I)). Intensities were corrected for Lorentz and polarization factors, but no correction was made for absorption.

The structure was solved by direct methods and refined using full-matrix least-squares techniques, minimizing the function to R = 0.112 and R_w = 0.103, S = 3.40. Final $(\Delta/\sigma)_{max}$ was 0.000. In the final difference map $\Delta\rho_{max}$ = 0.79 e Å^{-3} and $\Delta\rho_{min}$ = −0.92 e Å^{-3}. The function minimized was Σwith w = 1.0/(σ^2(F) + 0.0001 F^2). Because the crystal was weakly diffracting and the number of observed reflections was too small for anisotropic refinement, isotropic temperature factors were used for all non-hydrogen atoms. Once the non-hydrogen atoms were refined, H-atoms were placed in calculated positions on the corresponding C and O atoms (d(C—H) = 1.00, d(O—H) = 0.80 Å) and not refined. The U_{iso} of each hydrogen atom was assigned as equal to the U_{iso} of the attached atom plus 0.01. The configuration of the molecule was determined from the known configuration of Mosher's acid. All calcula-

Fig. 3. Synthesis of Mosher's ester **14**.

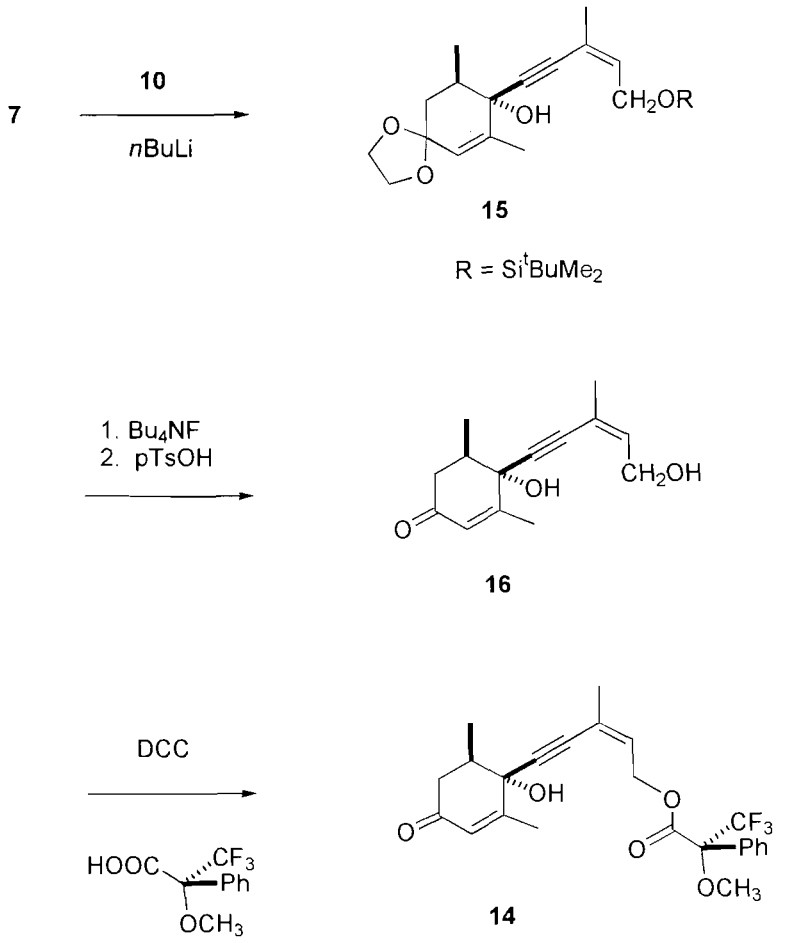

Fig. 4. PLUTON92 drawing of Mosher's ester **14**.

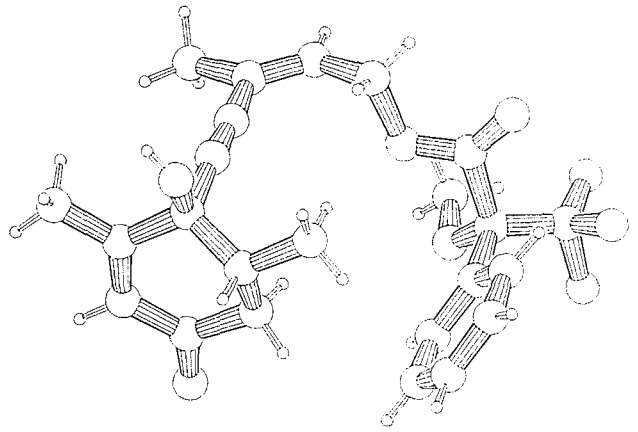

tions were performed with the NRCVAX crystallographic program package (18). The atomic scattering factors were taken from the International Tables for X-ray Crystallography (1974) (19).

Detailed atomic coordinates, bond distances and angles have been deposited at the Cambridge Crystallographic Data Center. These data can be obtained, on request, from the Director, Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, U.K.

General procedure for the preparation of quinone monoketals

2,6-Dimethyl-4,4-ethylenedioxycyclohexa-2,5-dienone (9) Iodobenzene diacetate (20.29 g, 0.063 mol) was suspended in hexane (250 ml), mechanically stirred, and cooled with an external ice bath. To the suspension was added 2,6-dimethyl phenol (3.66 g, 0.030 mol) in anhydrous ethylene glycol (20 mL). The ice bath was removed and the mixture stirred for 2 h before being quenched with H_2O (200 mL). The two phases were separated and the aqueous layer was extracted with ether (200 mL). The organic layers were combined and washed with 5% $NaHCO_3$ and saturated NaCl solution, dried over $MgSO_4$, and concentrated. Distillation under vacuum removed most of the iodobenzene by-product and the residue was purified by flash chromatography (5% EtOAc – hexane) to give 3.38 g (63%) of product as a solid. Recrystallization from ether–hexane gave a white crystal, mp 47–49°C. IR ($CHCl_3$) ν_{max} cm^{-1}: 1715 (C=O), 1630 (C=C). ^1H NMR, δ: 6.39 (s, 2H, H-3, H-5), 4.18 (s, 4H, OCH_2CH_2O), 1.86 (s, 6H, Me). ^{13}C NMR, δ: 186.4, 138.3 (2C), 135.5 (2C), 98.8, 65.3 (2C), 15.4 (2C). Synthesis of 8′-demethylABA

*(6*R*)-2,6-Dimethyl-4,4-ethylenedioxycyclohexa-2-enone (**7**)*
Sucrose (25 g) was dissolved in 1.0 L of 0.1 M HEPES buffer (pH 6.5) and warmed to 45°C. Yeast (50 g) was added and the mixture was shaken for 30 min. 2,6-Dimethyl-4,4-ethylenedioxycyclohexa-2,5-dienone (2.13 g) in ethanol (10 mL) was added dropwise. The fermentation mixture was shaken at room temperature and the reduction monitored by GC. After the reaction was completed (typically 3–4 h), 200 mL ether was added and the mixture was filtered through a pad of Celite®. Alternatively, centrifugation for 20 min at 10 000 rpm effectively removed the yeast cells. The filtrate was extracted with large quantities of ether (3 × 400 mL) to avoid emulsions. The combined ether extracts were dried over $MgSO_4$ and concentrated. Column chromatography (5% EtOAc – hexane) gave 1.08 g (50% yield) product as a colorless liquid. $[\alpha]_D^{20}$ +31.8 ($CHCl_3$, *c* 2.0). IR ($CHCl_3$) ν_{max} cm^{-1}: 1682 (C=O). ^1H NMR, δ: 6.32 (m, 1H, H-3), 3.87–4. 08 (m, 4H, OCH_2CH_2O), 2.73 (m, 1H, H-6), 2.15 (ddd, 1H, J = 2.1, 4.8, 13.3 Hz, H-5ax), 1.98 (t, 1H, J = 13.0 Hz, H-5eq), 1.77 (d, 3H, J = 1.5 Hz, $=CCH_3$), 1.14 (d, 3H, J = 7 Hz, CH_3). ^{13}C NMR, δ: 201.37 (C=O), 140.63 (C=), 137.20 (C=), 104.59, 65.06, 64.73, 41.56, 39.50, 15.77, 15.01. (+)-(1E,3Z)-(4R,5R)-4-Hydroxy-4-(4-carbomethoxy-3-methylbutyl-1,3-dienyl)-3,5-dimethylcyclohex-2-enone, ***13***

A mixture of MnO_2 (15 equiv. 4.1 mmol, 352 mg) and diene **12** (64 mg, 0.27 mmol) in 15 mL of acetone was stirred at room temperature for 1.5 h. The suspension was filtered and the cake of MnO_2 washed with excess ether. After concentration, 50 mg of aldehyde was recovered and directly reacted in the following manner. To the aldehyde (50 mg, 0.21 mmol) in MeOH (10 mL) was added sequentially MnO_2 (3.2 mmol, 274 mg), NaCN (0.65 mmol, 25 mg), and AcOH (0.21 mmol, 12 mL). The reaction was stirred at room temperature for 1.5 h. The suspension was filtered and washed with MeOH. After concentration, the residue was partitioned between Et_2O and H_2O and the organic layer washed with saturated NaCl solution, dried over Na_2SO_4, and concentrated. The crude product was purified on a Chromatotron eluting with ether, giving 25 mg (35% yield over the two steps) of the desired ester. Analysis on chiral HPLC (semiprep Chiralcel OD column, 10% IPA in hexane, flow rate of 4 mL/min) showed the product to be a 87:13 mixture of enantiomers. Preparative separation of the major enantiomer gave ester **13** with greater than 99% ee. $[\alpha]_D^{20}$ +359.4 (MeOH, *c* 1.38). A solid state NMR and X-ray crystallographic investigation of dynamic disorder in solid tetrahydronaphthalene derivatives

Glenn A. Facey, Terrence J. Connolly, Corinne Bensimon, and Tony Durst

Abstract: The solid state disorder of two tetrahydronaphthalene derivatives, *N*-methyl-*N*-methoxy-5,6,7,8-tetrahydro-1-naphthamide and 5,6,7,8-tetrahydro-1-naphthoic acid, was studied by solid state NMR and single crystal X-ray diffraction. The X-ray crystal structure of *N*-methyl-*N*-methoxy-5,6,7,8-tetrahydro-1-naphthamide was obtained at 123 K. It indicated the presence of two distinct molecular conformations. Solid state ^{13}C CP/MAS NMR data using the dipolar dephasing technique revealed that the two conformations of the molecule are dynamically disordered, while solid state ^{2}H NMR data, collected on a specifically deuterated analog, were used to determine the populations of each conformation as well as an apparent activation energy. Solid state NMR experiments were also used to show that 5,6,7,8-tetrahydro-1-naphthoic acid possesses the same type of dynamic disorder.

Key words: deuterium NMR, solid state NMR, dynamic disorder, X-ray, tetrahydronaphthalene derivatives

Résumé : Faisant appel à la RMN à l'état solide et à la diffraction des rayons X sur un cristal unique, on a étudié le désordre à l'état solide de deux dérivés du tétrahydronaphthalène, le *N*-méthyl-*N*-méthoxy-5,6,7,8-tétrahydro-1-naphthamide et de l'acide 5,6,7,8-tétrahydro-1-naphthoïque. On a déterminé la structure cristalline du *N*-méthyl-*N*-méthoxy-5,6,7,8-tétrahydro-1-naphthamide à 123 K. Elle indique la présence de deux conformations moléculaires distinctes. Les données de la RMN CP/MAS du ^{13}C à l'état solide, obtenues en utilisant la technique du déphasage dipolaire, ont révélé que les deux conformations de la molécule sont dynamiquement désordonnées; on a utilisé les données de la RMN du ^{2}H à l'état solide, obtenues à l'aide d'un analogue spécifiquement deutéré, pour déterminer les populations de chacun des conformères ainsi qu'une énergie d'activation apparente. On a aussi utilisé les expériences de RMN à l'état solide pour montrer que l'acide 5,6,7,8-tétrahydro-1-naphtoïque présente le même type de désordre dynamique.

Mots clés : RMN du deutérium, RMN à l'état solide, désordre dynamique, rayons X, dérivés tétrahydronaphtalènes.

Introduction

The structural characterization of molecules is typically tackled with a broad arsenal of techniques including all forms of spectroscopy, mass spectrometry, and diffraction. Often chemists will put a great deal of effort into the growth of single crystals suitable for X-ray diffraction analysis, as this technique is often the one that will prove, beyond doubt, the structure of the material in question. In this contribution, we would like to illustrate that although often essential, single crystal X-ray diffraction data can be open to interpretation and that in such instances solid state NMR spectroscopy is an essential complementary technique needed to fully characterize the solid state structure. Single crystal X-ray diffraction is a technique sensitive to long-range order. The collection of data takes hours or days. These two facts render the technique unable to distinguish between static disorder and dynamic disorder.

Unlike single crystal diffraction techniques, solid state NMR spectroscopy is a technique sensitive to short-range order. Typical data collection times for a single transient are on the hundreds of microseconds to tens of milliseconds time scale. These two facts make this technique sensitive to molecular motions and, as a result, the distinction between static and dynamic disorder is possible. Also, it has the advantage that polycrystalline powders rather than single crystals can be used. This study involves the structural characterization of the two tetrahydronaphthalene derivatives **5a** and **6a** (Scheme 1). It demonstrates the complementary nature of single crystal X-ray diffraction and solid state NMR spectroscopy.

Background

^{2}H is a spin $I = 1$ nucleus having three Zeeman states. The pure Zeeman states are perturbed by the electric quadrupolar interaction, producing two resonance frequencies for each crystallographically unique deuteron. The difference in frequency between the two resonances is determined by the quadrupolar coupling constant, $\chi = (e^2Qq//h)$, and the orientation of the electric field gradient tensor at the nuclear site with respect to the static magnetic field. For deuterons

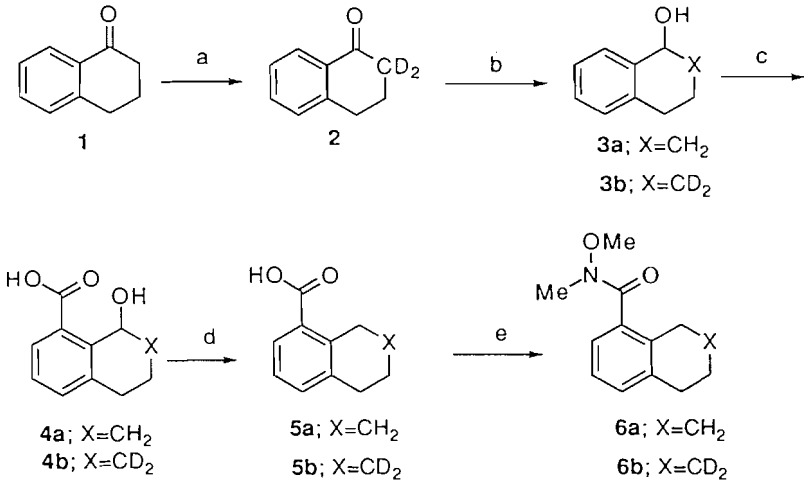
Scheme 1. Reagents: (a) K_2CO_3, THF:D_2O, Δ; (b) $LiAlH_4$, THF; (c) (*i*) *n*BuLi, TMEDA, Pentane, Δ, (*ii*) CO_2(s), (*iii*) HCl; (d) H_2, Pd/C, HOAc; (e) (*i*) $SOCl_2$, CH_2Cl_2, Δ, (*ii*) $(MeO(Me)NH_2^+Cl^-$, Et_3N, CH_2Cl_2.



attached to carbon atoms the electric field gradient tensor, V_{ij}, is very often axially symmetric with its largest component, $V_{zz} = eq$, parallel to the C—D bond and, since V_{ij} has a trace of zero, $V_{zz} = (V_{yy} + V_{xx})$ with $V_{yy} = V_{xx}$. In the cases where axial symmetry is not present, it is conventional to assign $V_{zz} > V_{yy} > V_{xx}$. It is useful to define an asymmetry parameter, η, where $\eta = (V_{yy} - V_{xx})/V_{zz}$ where $0 \leq \eta \leq 1$.

The ^2H NMR spectrum of a single crystal consists of a sharp doublet for every crystallographically distinct deuteron whose splitting depends on the orientation of the crystal with respect to the magnetic field. For polycrystalline powders, where all orientations of the crystals are represented equally, the result is an envelope or powder spectrum from the sum of all possible doublets. The lineshape for such spectra can be readily calculated (1). In general, the spectra are symmetric about the centre with three pairs of singularities separated by frequencies, $\Delta\nu_{zz}$, $\Delta\nu_{yy}$, and $\Delta\nu_{xx}$, where $\Delta\nu_{zz} > \Delta\nu_{yy} > \Delta\nu_{xx}$. The frequency separations are proportional to the principal components of V_{ij} and are given by:

$$[1] \qquad -\Delta\nu_{XX} = \frac{-3\chi}{4}(1-\eta)$$

$$[2] \qquad -\Delta\nu_{YY} = \frac{-3\chi}{4}(1+\eta)$$

$$[3] \qquad \Delta\nu_{ZZ} = \frac{3\chi}{2}$$

The negative signs are added to the frequency differences to maintain a trace of zero.

The electric quadrupolar interaction, dominating the lineshapes of solid state ^2H NMR spectra, is exceedingly sensitive to molecular motions (2). The motions give rise to an averaged electric field gradient tensor and modify the shape of the powder spectrum. The effects can be grouped into three categories based on the rates of the molecular motion:

(a) Slow motions: These are motions occurring on a time scale much longer than the reciprocal line width of the static spectrum ($\sim 10^4$ s^{-1}). The effects are negligible on the NMR spectrum as there is essentially no change in the electric field gradient tensor during the course of the quadrupolar echo measurement.

(b) Intermediate rate motions: These are motions that occur on a time scale of the same order as the reciprocal line width of the static spectrum ($\sim 10^4$–10^7 s^{-1}). These motions have a profound effect on the observed lineshape (3–6). The lineshapes are very sensitive to the spacing between the pulses in the quadrupolar echo experiment (7) as well as to the rate and mechanism of the molecular motion. Although reduced significantly in amplitude compared to the rigid spectrum, the intermediate rate spectra can be simulated (8–10) in order to confirm a particular mechanism of a molecular motion or to determine its rate at the temperature of the measurement.

(c) Fast molecular motions: These motions occur on a time scale much shorter than the reciprocal line width of the static spectrum ($>10^7$ s^{-1}). The motion gives rise to an averaged electric field gradient tensor and spectra take on the same type of lineshape as those for rigid systems with the frequency differences between pairs of spectral singularities reduced. Such spectra are insensitive to the rate of the motion but may often be used to confirm the mechanism for the molecular motion. Fast motion limit spectra may be temperature dependent in cases where the population ratio for the sites occupied during the motion changes with temperature (11).

Experimental

All solid state NMR spectra were acquired on a Bruker ASX-200 solid state NMR spectrometer. Solid state ^{13}C CP/MAS spectra were acquired using a Bruker MAS probe with 7 mm o.d. zirconia rotors. The ^1H π/2 pulses were 3.6 μs, and 1 ms contact times were used. The spinning rate was set at 4000 Hz and was stable to within 2 Hz. In some cases the spinning side bands were suppressed (12). The solid state ^2H NMR spectra were acquired using a Bruker wideline probe accepting 5 mm o.d. glass tubes. The quadrupolar echo tech-

nique (13) was used with 3.2 μs $\pi/2$ pulses and an interpulse delay of 35 μs. The receiver was gated on 33 μs after the second pulse and the data were left shifted to the top of the echo before Fourier transformation. Although the temperature was regulated with the variable temperature control unit of the spectrometer, it was measured directly by placing a thermocouple on the rf coil containing the sample immediately after data collection. The reported temperatures are accurate and precise to within 1 degree. ^2H T_1 measurements were made using the inversion–recovery technique with magnetization being sampled with a quadrupolar echo. In all measurements at least 10 recovery times were used and the T_1's were calculated using the three-parameter nonlinear fit provided by the software of the spectrometer.

The single crystal X-ray data for **6a** were collected at 123 K on a Rigaku diffractometer with Cu Kα radiation using the ω–2θ scan technique to a maximum 2θ value of 100°. The cell constants and an orientation matrix for data collection were obtained from least-squares refinement using the setting angles of 25 reflections in the range $80° < 2\theta < 100°$. A total of 1297 reflections was collected. The unique set contained only 1195 reflections. The standards were measured after every 150 reflections. No crystal decay was noticed. The data were corrected for Lorentz and polarization effects, no correction being made for absorption. The structure was solved by direct methods. All non-hydrogen atoms were refined anisotropically. The maximum and minimum peaks in the final difference Fourier map corresponded to 0.460 and −0.440 e/Å^3, respectively.

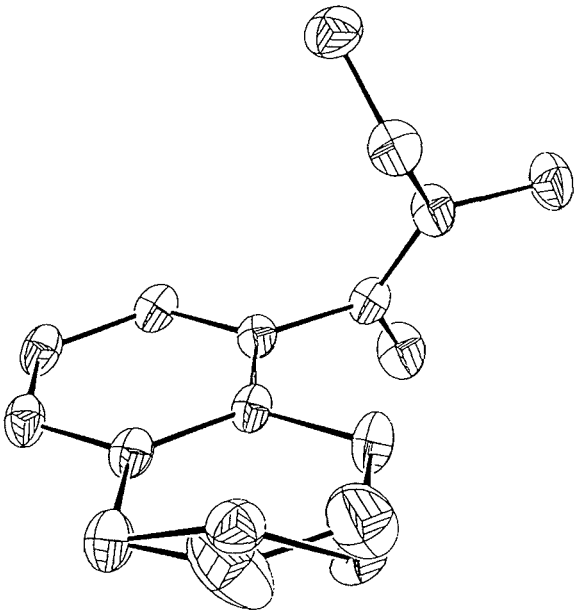
All materials used for this study were prepared according to Scheme 1 (14) and the details dealing with the synthesis will be published elsewhere.

Results and discussion

The single crystal X-ray diffraction data (deposited as supplementary material)[2] for **6a** taken at 123 K show that the compound crystallizes in the space group $P2_1/a$ with four molecules in the unit cell. The cell constants are as follows: a = 8.6171 Å; b = 12.2350 Å; c = 11.2223 Å, and β = 102.937°. An ORTEP plot of the structure is given in Fig. 1. The structure shows a molecular confirmation where the carbonyl bond is almost normal to the plane of the aromatic ring, thus leaving a great deal of void space around the methylene carbons in the 6 and 7 positions. Another very obvious feature of the crystal structure is that there are two sets of coordinates found for each of the carbons in the 6 and 7 positions of the cyclohexene moiety. This indicates that there are two conformations of the cyclohexene ring present in the crystal. The disorder was refined using fixed thermal parameters and letting the occupancies for the four sites occupied by carbons 6 and 7 refine. The results gave occupancies close to 0.75:0.25. The occupancies were then fixed to these values

[2] Supplementary material can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. These data have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

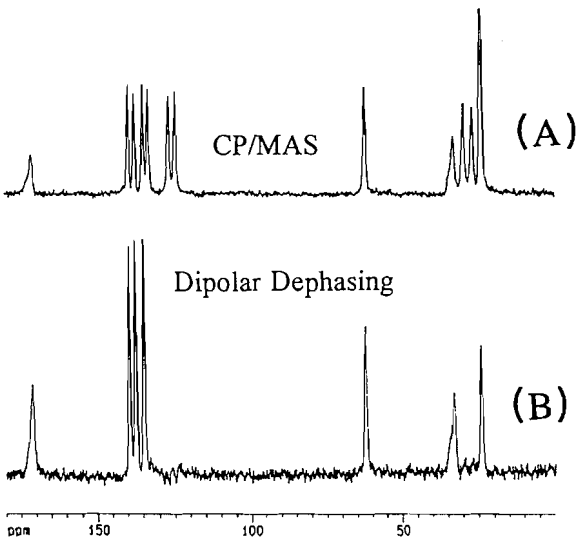
Fig. 1. ORTEP plot of the crystal structure of **6a** at 123 K refined under the assumption that the population ratio is 0.75:0.25.



and the thermal parameters refined. It is interesting to note that the thermal parameters are not equal for each of the two conformations, the major conformation having much larger thermal parameters than the minor one. One possible explanation of this may be that the local intermolecular forces for each of the sites may be different, allowing one of the conformations to have slightly more mobility than the other. The X-ray data are unable to confirm whether the structure is rigid with both conformations present (static disorder) or whether the two conformations are exchanging dynamically with one another (dynamic disorder).

The solid state ^{13}C CP/MAS NMR spectrum of **6a** taken at room temperature is shown in Fig. 2*A*. The spectrum is highly resolved, each nonequivalent carbon giving rise to a resonance. The only coincidental overlap occurs for the resonances of the carbons in the 6 and 7 positions on the cyclohexene ring. The carbonyl carbon and the *N*-methyl carbon are broadened from partially unaveraged dipolar interactions between ^{13}C and ^{14}N (15). If there was a static disorder in the structure at room temperature, one might expect to observe two resonances for each carbon atom in the molecule, one set for each of the two nonequivalent conformations (16). Furthermore, the intensities of the lines would approximately represent the population ratio of the conformers present. This does not seem to be the case. The ^{13}C CP/MAS spectrum acquired with dipolar dephasing is given in Fig. 2*B*. In dipolar dephasing experiments (17) a short delay (40 μs in this case) is inserted between the contact pulse and the beginning of the acquisition. During this delay the $^{13}C - {}^1H$ dipolar interactions are only partially averaged by the magic angle spinning. Also, the magnetization due to carbon nuclei having large $^{13}C - {}^1H$ dipolar interactions dephases and the corresponding resonances are absent from the frequency domain spectrum. This is true for fairly rigid carbon atoms directly bound to protons. Carbon atoms not bearing protons or methyl car-

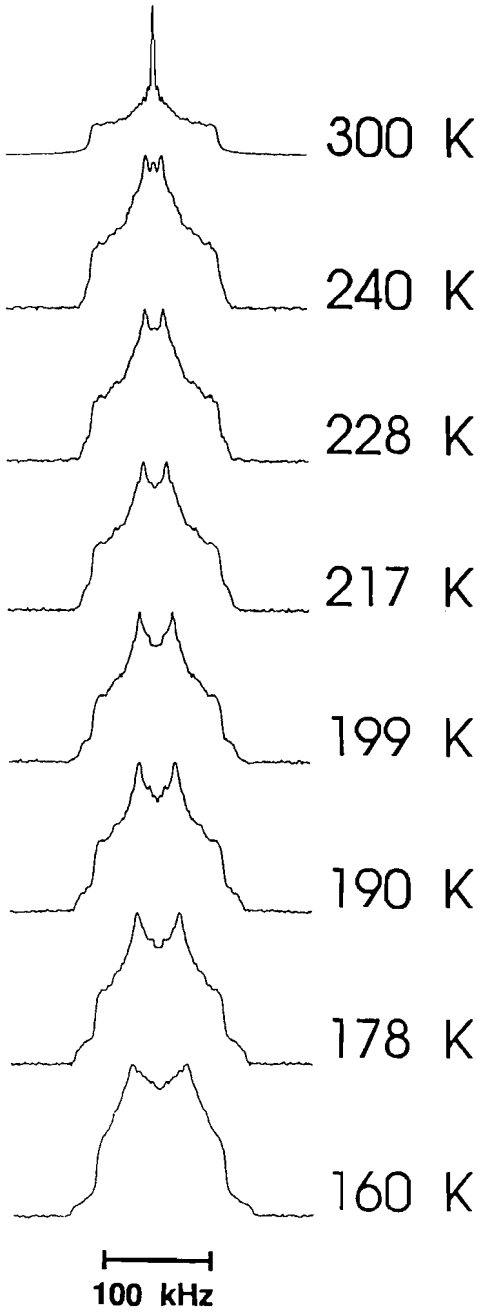
Fig. 2. (*A*) ^{13}C CP/MAS NMR spectrum of **6a** at room temperature. (*B*) Same as *A* with a 40 μs dipolar dephasing delay. In both traces the first-order spinning side bands were suppressed (12).



bons whose dipolar interactions with protons are averaged as a result of fast methyl group rotation, will show up in the spectrum, albeit slightly attenuated. The data in Fig. 2*B* show that not only do the carbonyl, methyl, and quaternary aromatic resonances survive the dephasing delay, but the 6 and 7 methylene carbons of the cyclohexene ring do as well. This can be the case only if the ^{13}C – ^{1}H dipolar interactions for these methylene carbons are averaged by some sort of molecular motion. Therefore, we can conclude that the nature of the disorder present in the structure at room temperature is dynamic rather than static. This, however, does not prove whether or not the disorder observed at 123 K in the X-ray data is static or dynamic in nature.

The analogue to **6a** labelled with deuterium on the 7 position, **6b**, was prepared to address the dynamic nature of the structural problem. The wideline solid state ^{2}H NMR spectra of **6b** are given in Fig. 3 as a function of temperature. At all temperatures the width of the powder spectrum is narrower than one would expect for a completely rigid system (18). Furthermore, at all temperatures above 178 K, the ^{2}H NMR spectra are in the fast motion limit. That is, the molecular motion is occurring at a rate much greater than the reciprocal width of the rigid powder spectrum (expected to be ~260 kHz) (18). Spectra collected below 178 K are in the intermediate motion regime. The separation between the spectral singularities at the top, middle, and base of the powder spectra are plotted against temperature in Fig. 4. One can see that one splitting (the separation of the middle shoulders) remains essentially constant throughout the entire temperature range. This indicates that the axis of the molecular motion must lie parallel to one of the two principal components of the electric field gradient tensor perpendicular to the C—D bond. Furthermore, the lineshape observed at 300 K is characteristic of a two-site exchange between equally populated sites with the C—D bond subtending the tetrahedral angle over the course of the motion. (18) These observations

Fig. 3. Broadline solid state ^{2}H NMR spectra of **6b** recorded as a function of temperature. The relaxation delay was greater than the T_1 by at least a factor of 5.



are consistent with the model depicted in figure 5. In this model, the cyclohexene moiety undergoes a transformation akin to the chair to chair inversion of cyclohexane. The sites however must not be equally populated over the entire temperature range as this would leave the spectra invariant with temperature. As the temperature is lowered one site becomes more populated than the other. The frequency differences between the singularities of the fast motion lineshape are determined by the eigenvalues of the averaged electric field gradient tensor. These are calculated by taking the weighted average of the electric field gradient tensors for each of the

Fig. 4. Plot of the frequency differences, $\Delta\nu'_{XX}$, $\Delta\nu'_{YY}$, and $\Delta\nu'_{ZZ}$, between the features of the solid state ^2H spectra of **6b** as a function of temperature.

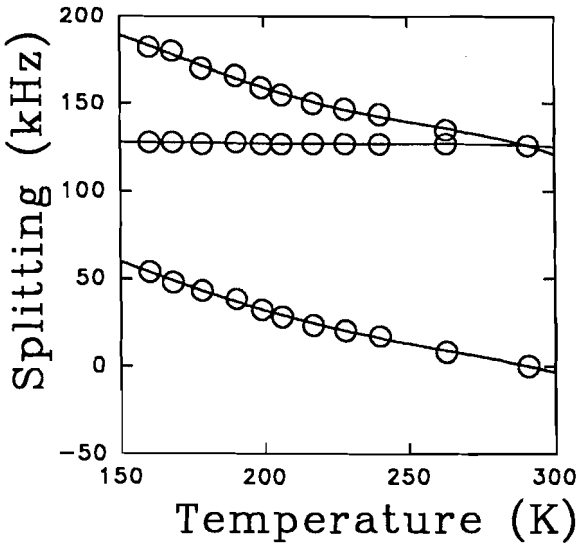


Fig. 5. Model depicting the inversion of the cyclohexene moiety.

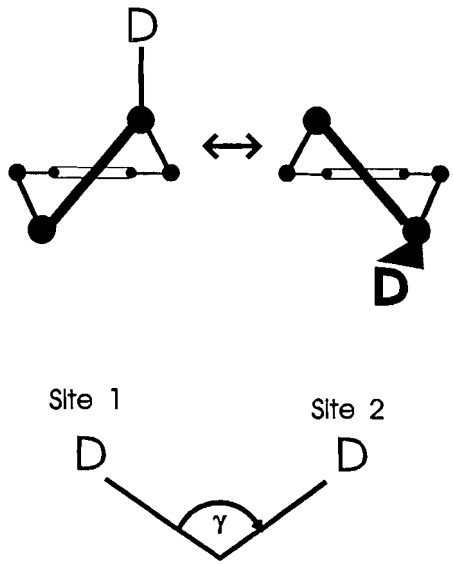


sites occupied over the course of the molecular motion, then diagonalizing the averaged tensor if necessary. To do this calculation we must define all of the electric field gradient tensors in a common axis system. This is most conveniently accomplished by choosing an axis defined by the motion and then redefining each of the tensors with respect to this new axis system in terms of the Euler angles, α, β, and γ (19). The electric field gradient for each of these sites is defined as follows:

$$[4]\qquad V(\alpha,\beta,\gamma)=\begin{bmatrix} a_{11} & a_{12} & a_{13} \\ a_{21} & a_{22} & a_{23} \\ a_{31} & a_{32} & a_{33} \end{bmatrix}$$

where $a_{ij} = a_{ji}$. Each of the matrix elements are defined as follows:

$$[5]\quad a_{11} = (\cos^2\alpha\cos^2\beta\cos^2\gamma+\sin^2\alpha\sin^2\gamma-2\sin\alpha\cos\alpha\cos\beta\sin\gamma\cos\gamma)V_{XX}+(\sin^2\alpha\cos^2\beta\cos^2\gamma+\cos^2\alpha\sin^2\gamma+2\sin\alpha\cos\alpha\cos\beta\sin\gamma\cos\gamma)V_{YY}+(\sin^2\beta\cos^2\gamma)V_{ZZ}$$

$$[6]\quad a_{22} = (\cos^2\alpha\cos^2\beta\sin^2\gamma+\sin^2\alpha\cos^2\gamma+2\sin\alpha\cos\alpha\cos\beta\sin\gamma\cos\gamma)V_{XX}+(\sin^2\alpha\cos^2\beta\sin^2\gamma+\cos^2\alpha\cos^2\gamma-2\sin\alpha\cos\alpha\cos\beta\sin\gamma\cos\gamma)V_{YY}+(\sin^2\beta\sin^2\gamma)V_{ZZ}$$

$$[7]\quad a_{33} = (\cos^2\alpha\sin^2\beta)V_{XX}+(\sin^2\alpha\sin^2\beta)V_{YY}+(\cos^2\beta)V_{ZZ}$$

$$[8]\quad a_{12} = (-\cos^2\alpha\cos^2\beta\sin\gamma\cos\gamma+\sin^2\alpha\sin\gamma\cos\gamma+\sin\alpha\cos\alpha\cos\beta(\sin^2\gamma-\cos^2\gamma))V_{XX}+(-\sin^2\alpha\cos^2\beta\sin\gamma\cos\gamma+\cos^2\alpha\sin\gamma\cos\gamma+\sin\alpha\cos\alpha\cos\beta(\cos^2\gamma-\sin^2\gamma))V_{YY}+(-\sin^2\beta\cos\gamma\sin\gamma)V_{ZZ}$$

$$[9]\quad a_{13} = (\cos^2\alpha\cos\beta\sin\beta\cos\gamma-\sin\alpha\cos\alpha\sin\beta\sin\gamma)V_{XX}+(\sin^2\alpha\sin\beta\cos\beta\cos\gamma+\cos\alpha\sin\alpha\sin\beta\sin\gamma)V_{YY}+(-\sin\beta\cos\beta\cos\gamma)V_{ZZ}$$

$$[10]\quad a_{23} = (-\cos^2\alpha\cos\beta\sin\beta\sin\gamma-\sin\alpha\cos\alpha\sin\beta\cos\gamma)V_{XX}+(-\sin^2\alpha\sin\beta\cos\beta\sin\gamma+\sin\alpha\cos\alpha\sin\beta\cos\gamma)V_{YY}+(\sin\beta\cos\beta\sin\gamma)V_{ZZ}$$

For the two-site model described in Fig. 5, we can define an axis normal to the plane defined by the two-site exchange with the origin on the carbon atom and then define the Euler angles with respect to this axis. We have $\alpha_1 = 0°$, $\beta_1 = 90°$, and $\gamma_1 = -54.75°$ for one site and $\alpha_2 = 0°$, $\beta_2 = 90°$, and $\gamma_2 = 54.75°$ for the second site. Substituting the values of α and β into

eqs. [5]–[10], we get:

$$[11] \quad V_i(\gamma_i) = \begin{bmatrix} \sin^2\gamma_i V_{YY} + \cos^2\gamma_i V_{ZZ} & \sin\gamma_i \cos\gamma_i (V_{YY} - V_{ZZ}) & 0 \\ \sin\gamma_i \cos\gamma_i (V_{YY} - V_{ZZ}) & \cos^2\gamma_i V_{YY} + \sin^2\gamma_i V_{ZZ} & 0 \\ 0 & 0 & V_{XX} \end{bmatrix}$$

Let the populations of the two sites equal P_1 and P_2. The weighted average of $V_i(\gamma_i)$ is given by:

$$[12] \quad \overline{V(\gamma)} = \begin{bmatrix} \sin^2\gamma V_{YY} + \cos^2\gamma V_{ZZ} & \sin\gamma\cos\gamma (V_{YY} - V_{ZZ})(P_2 - P_1) & 0 \\ \sin\gamma\cos\gamma (V_{YY} - V_{ZZ})(P_2 - P_1) & \cos^2\gamma V_{YY} + \sin^2\gamma V_{ZZ} & 0 \\ 0 & 0 & V_{XX} \end{bmatrix}$$

The eigenvalues, λ_i can be obtained by diagonalization.

$$\lambda_1 = \frac{(V_{YY} + V_{ZZ}) + (V_{YY} - V_{ZZ})\sqrt{1 - 4\sin^2\gamma\cos^2\gamma(1 - (P_2 - P_1)^2)}}{2}$$

$$[13] \quad \lambda_2 = \frac{(V_{YY} + V_{ZZ}) + (V_{YY} - V_{ZZ})\sqrt{1 - 4\sin^2\gamma\cos^2\gamma(1 - (P_2 - P_1)^2)}}{2}$$

$$\lambda_3 = V_{XX}$$

We can express the components of the unaveraged electric field gradient tensor, V_{ii}, in terms of χ and η then set γ to one half of the tetrahedral angle. The frequency splittings, $\Delta\nu'_{XX}$, $\Delta\nu'_{YY}$, and $\Delta\nu'_{ZZ}$ in the averaged spectrum can then be expressed as follows:

$$[14] \quad -\Delta\nu'_{XX} = \frac{\chi}{8}(3(1-\eta) - (3+\eta)\sqrt{1 + 8(P_2 - P_1)^2})$$

$$[15] \quad -\Delta\nu'_{YY} = -\frac{3}{4}\chi(1-\eta)$$

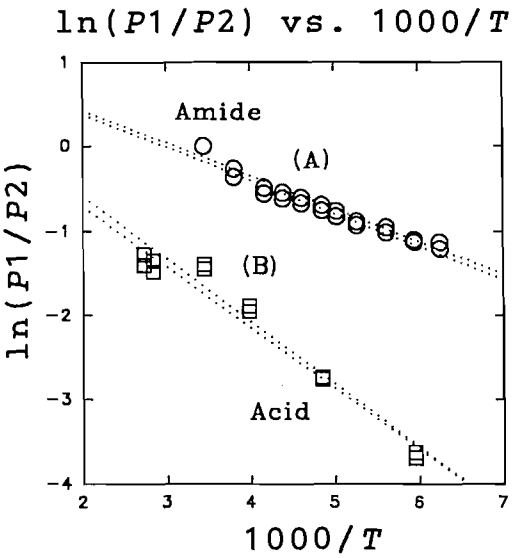
$$[16] \quad \Delta\nu'_{ZZ} = \frac{\chi}{8}(3(1-\eta) + (3+\eta)\sqrt{1 + 8(P_2 - P_1)^2})$$

If we know the quadrupolar coupling constant and asymmetry parameter for the rigid spectrum and have measured the splittings in an averaged spectrum, we can directly evaluate the populations of the sites at a given temperature. Unfortunately, χ and η are not available in the literature and our equipment did not allow the measurement of spectra at sufficiently low temperatures for their experimental determination. However, these data have been reported for cyclohexane (20) ($\chi = 173.7 \pm 1.7$ kHz and $\eta \leq 0.01$). If we assume that these parameters are not significantly different for our case, we can take $\chi = 174$ kHz and $\eta = 0$ and obtain the populations from eqs. [14] and [16]. The ratio of populations is expected to follow the Boltzman distribution, hence a plot of $\ln(P_1/P_2)$ vs. $1/T$ should be linear with slope $-\Delta E/R$, where ΔE is the energy difference between the two conformations and R is the gas constant. These data are plotted in Fig. 6*A* and the energy difference obtained is 3.2 ± 0.3 kJ/mol.

^{2}H T_1 relaxation times were measured as a function of temperature. When dominated by the quadrupolar interaction, in the case of a two-site exchange, the rate of relaxation can be described by (21):

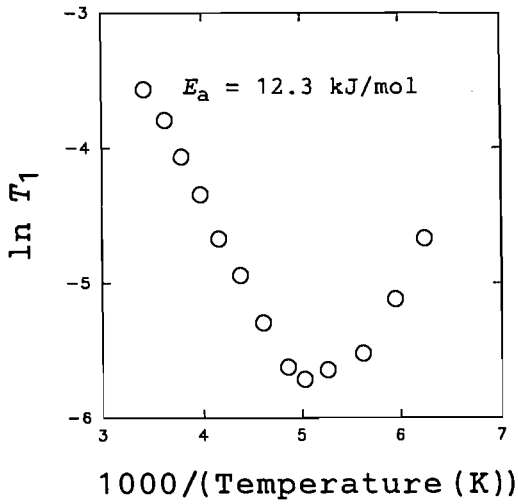
$$[17] \quad \frac{1}{T_1} = \frac{3}{16}\chi^2\left(\frac{\tau_c}{1 + (\omega_0\tau_c)^2} + \frac{4\tau_c}{1 + (2\omega_0\tau_c)^2}\right)$$

Fig. 6. (*A*) Plot of the population ratios calculated from eqs. [14] and [16] for **6b** as a function of temperature. (*B*) Same as *A* for **5b**.



where ω_0 is the angular Larmor frequency and τ_c is the correlation time. The T_1's were calculated from the inner singularities of the powder spectra. A plot of log T_1 vs. reciprocal temperature is presented in Fig. 7. A T_1 minimum is observed at ~196 K. This minimum occurs when $\omega_0\tau_c = 0.6158$ and can be used to determine the correlation time at the temperature of the minimum. The correlation time at 196 K is 3.19 ns. The slope of the line in the high-temperature regime can be used to evaluate an activation barrier from the Arrhenius relation. The activation barrier was evaluated at 12.3 ± 0.2 kJ/mol. We can compare this to that measured for cyclohexene in solution (22.2 kJ/mol) (22). Strictly speaking, activation energies and correlation times evaluated in this way assume that the populations remain equal throughout the entire temperature range, therefore the activation barrier

Fig. 7. Plot of $\ln(T_1)$ vs. $(1000/T)$ for the ^2H data collected for **6b**.



and correlation time presented here are best referred to as "apparent." The relatively low "apparent" activation energy evaluated here may be due to the large amount of void space in the vicinity of the cyclohexene moiety of **6b** in the crystal lattice.

If we make the reasonable assumption that **6b** is structurally identical to **6a**, we can conclude that the disorder observed in the X-ray diffraction data is dynamic in nature. By extrapolation of the data in Fig. 6*B* we can estimate the populations of the two conformations to be approximately 86:14. Based on this information, the initial 0.75:0.25 population ratio used in the X-ray diffraction data was replaced by 86:14 and a further refinement carried out. This modification, however, made very little difference to the atomic coordinates or thermal parameters.

The solid state ^{13}C CP/MAS NMR spectrum of **5a** taken at room temperature is shown in Fig. 8*A* with the corresponding dipolar dephased spectrum in Fig. 8*B*. Unlike the ^{13}C CP/MAS dipolar dephased spectrum of **6a**, the spectrum of **5a** does not show any significant intensity for the methylene carbons in the 6 and 7 positions. This observation can mean one of two things. Either the system is rigid with one or more conformations or there is a similar conformational exchange as observed for **6a** except that the population difference is very close to unity. In either case the net $^{13}C - {}^1H$ dipolar interaction would still be large and the ^{13}C signal for the methylenes would be expected to decay significantly during the 40 μs dipolar dephasing delay.

The wideline solid state ^2H NMR spectra of **5b** are given in Fig. 9 as a function of temperature. As with **6b**, the spectra are narrower than expected for a completely rigid system. Also similar to the ^2H spectra of **6b**, the spectra are temperature dependent and in the fast-motion limit. This eliminates the hypothesis that the system is completely rigid. A plot of the spectral frequency separations as a function of temperature are given in Fig. 10. The data are very similar to those in Fig. 4, indicating that the motion is of the same type as that observed for **6b**. If we assume the same model for dynamic disorder as in **6b** and that the quadrupolar coupling constant for the rigid system is 174 kHz with $\eta = 0$, then the

Fig. 8. (*A*) ^{13}C CP/MAS NMR spectrum of **5a** at room temperature. (*B*) Same as *A* with a 40 μs dipolar dephasing delay. The peaks marked with an asterisk are spinning side bands.

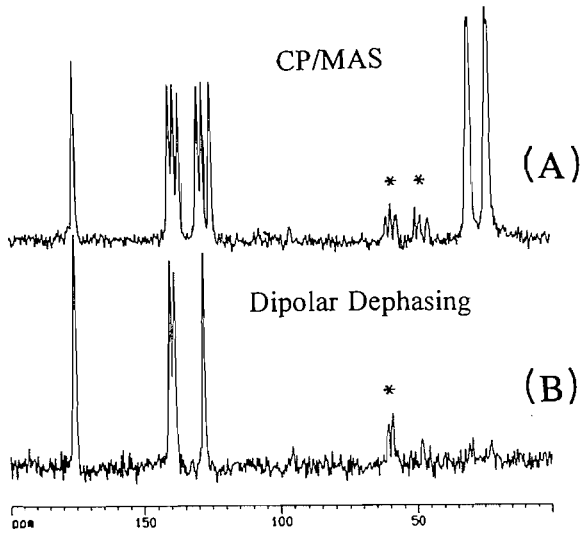


Fig. 9. Broadline solid state ^2H NMR spectra of **5b** recorded as a function of temperature. The relaxation delay was 10 s.

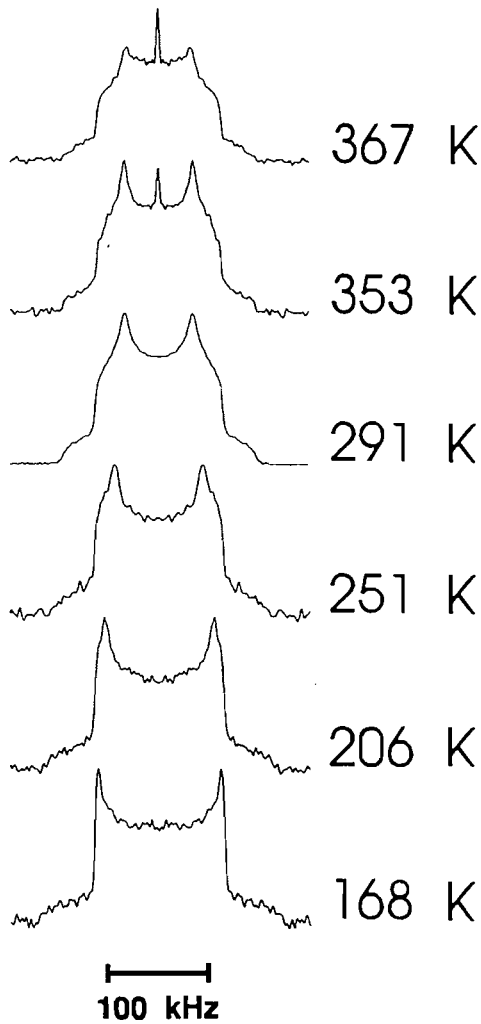

Fig. 10. Plot of the frequency differences, $\Delta\nu'_{XX}$, $\Delta\nu'_{YY}$, and $\Delta\nu'_{ZZ}$, between the features of the solid state ^2H spectra of **5b** as a function of temperature.

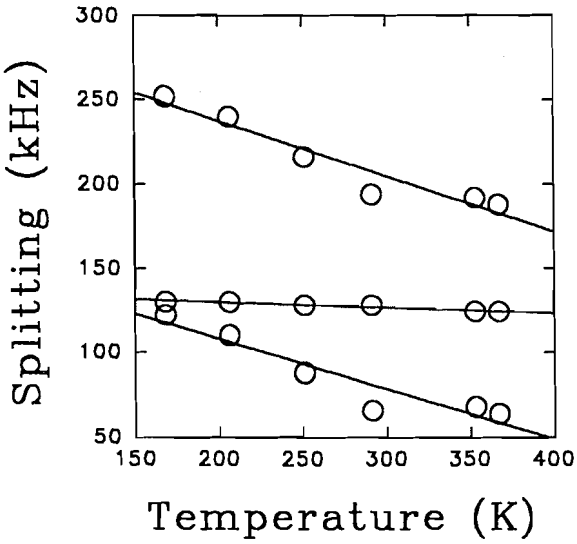

populations can be calculated as before and the energy difference between the two conformations evaluated. The data are plotted in Fig. 6*B* and give $\Delta E = 6.1 \pm 0.2$ kJ/mol. From both the ^{13}C and ^2H solid state NMR data it is apparent that **5b** undergoes an exchange akin to a chair-to-chair inversion of the cyclohexene ring in the solid state where one of the conformations is highly favoured with respect to the other. The fact that the population difference for **5b** is larger than that for **6b** may suggest that for the case of the acid there is less void space around the cyclohexene ring in the crystal lattice.

Conclusion

The X-ray crystal structure obtained for **6a** shows a molecular conformation where the carbonyl bond is almost normal to the plane of the aromatic ring. This conformation leaves a great deal of void space around the cyclohexene moiety, giving it the freedom to undergo molecular motions. The crystal structure shows that there are two distinct conformations present but is unable to confirm whether they are disordered statically or dynamically. Solid state ^{13}C CP/MAS data taken at room temperature reveal that the disorder is dynamic at room temperature, and the ^2H NMR data are able to evaluate the population ratios as a function of temperature as well as determine an apparent activation barrier based on a simple two-site ring inversion. The ^2H NMR data for **5b** support the notion that the same sort of ring inversion occurs in this compound; however, the population differences are much larger. The large population difference is consistent with the absence of methylene signals in the ^{13}C CP/MAS spectrum with dipolar dephasing.

Fonctionnalisation du δ-pyronène, un nouveau synthon terpénique

Marie Jeanne Quirin, Martine Taran et Bernard Delmond

Résumé : Le δ-pyronène, un synthon terpénique nouvellement accessible à partir du myrcène, composé développé industriellement, a été diversement fonctionnalisé. Il constitue une matière première intéressante pour accéder à des intermédiaires actuellement utilisés dans la synthèse de parfums et de rétinoïdes. De plus, de nouveaux composés terpéniques possédant un squelette cyclogéranyle particulier ont été préparés.

Mots clés : terpènes, pyronènes, dérivés cyclogéranyles, parfums.

Abstract: δ-Pyronene, a terpenic synthon recently made industrially available from myrcene, has been characterized. It is an excellent raw material for the preparation of numerous intermediates used in the synthesis of perfumes and retinoids. Furthermore, new terpenic compounds including the cyclogeranyl skeleton have been prepared.

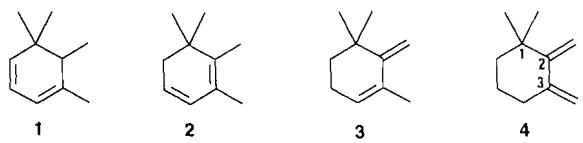
Key words: terpenes, pyronenes, cyclogeranyl derivatives, perfumes.

[Journal translation]

Introduction

Les pyronènes (Schéma 1) sont des hydrocarbures diéniques, possédant le squelette 1,1,2,3-tétraméthylcyclohexane, obtenus — essentiellement les isomères α **1** et β **2** — lors de la pyrolyse de l'α-pinène (1). Ils résultent alors d'une isomérisation thermique des alloocimènes formés intermédiairement (2).

Schéma 1.

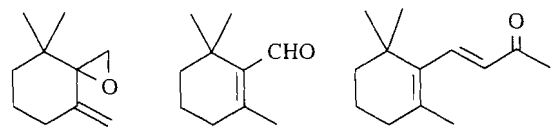


Le γ-pyronène **3** a été préparé (3) avec un bon degré de pureté lors de la dégradation d'Hoffman des sels d'ammonium de l'α-cyclogéranyle amine; cependant ce type de réaction réalisée sur le chlorhydrate de la diméthyl β-cyclogéranyle amine (4) conduit à un mélange de γ-pyronène **3** et de δ-pyronène **4**. Le δ-pyronène **4** (1,1-diméthyl-2,3-diméthylène cyclohexane) peut être cependant obtenu de manière plus spécifique et avec une excellente pureté à partir du mycène (5), matière première préparée industriellement à partir du β-pinène.

Aussi compte tenu de cette disponibilité récente et du peu de travaux (6) réalisés à ce jour concernant la chimie du δ-pyronène **4** nous avons entrepris d'analyser la réactivité de ce composé.

Lors d'un travail précédent (7) nous avons étudié son époxydation et montré que l'époxy-pyronène **5** (Schéma 2) était un synthon (8) permettant d'accéder à des intermédiaires importants (β-cyclocitral **6**, β-ionone **7**) utilisés par les industries des parfums et des cosmétiques.

Schéma 2.

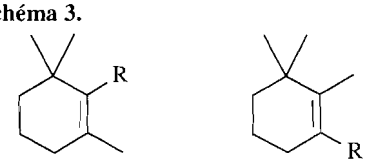


5 **6** **7**

Nous présentons dans ce mémoire différents aspects de la réactivité du δ-pyronène **4**, mettant en jeu le système diénique et conduisant, selon les réactifs, à des produits issus d'une addition-1,2 ou d'une addition-1,4.

Nous montrerons en particulier, que de nouveaux composés terpéniques appartenant à la série "iso" (Schéma 3) et dont le squelette cyclogéranyle diffère de la série normale par une localisation différente de la chaîne latérale fonctionnelle (R), peuvent être préparés à partir de ce composé.

Schéma 3.



série normale série "iso"

Résultats

Dihydroxylation du δ-pyronène 4

Nous avons réalisé la dihydroxylation du δ-pyronène **4** par le permanganate de potassium en milieu basique aqueux (9).

Reçu le 28 mars 1996.

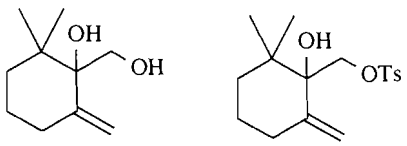
Après 15 h d'agitation à température ambiante, on observe la formation exclusive du diol **8** que l'on isole par flash-chromatographie, avec un rendement de 60% (Schéma 4).

Schéma 4.



8 **9**

La localisation du système dihydroxylé sur le squelette a pu être déduite d'une expérience de RMN 2D (10) mettant en jeu les corrélations $^{1}H/^{13}C$ à travers des couplages à longue distance (^{2}J et ^{3}J). Nous observons en particulier des corrélations de type ^{3}J entre d'une part le carbone quaternaire hydroxylé à 80,1 ppm et les protons du groupement *gem*-diméthyle à 0,89 ppm et d'autre part le carbone sp^2 de type méthylène à 110,7 ppm avec les protons allyliques appartenant au cycle et résonnant à 2,31 ppm.

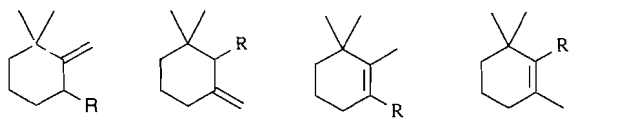
Comme lors de l'époxydation par les peracides (7), cette réaction n'est pas stéréosélective, cependant on note une addition sélective sur le méthylène en -2, que l'on peut interpréter par un effet électronique (+I) prépondérant du groupement *gem*-diméthyle sur cette double liaison.

Compte tenu de la haute régiosélectivité de cette réaction, le diol **8**, sans purification ultérieure, a été transformé, via son hydroxy-tosylate **9**, puis traitement de celui-ci à l'alumine en époxy-pyronène **5**, avec un rendement global de 52%. Cela constitue une voie d'accès nouvelle et sélective à l'époxy-pyronène **5** précurseur (6) du β-cyclocitral **6** et de la β-ionone **7**.

Hydroboration du δ-pyronène 4

Kane et Von Genk (11) avaient précédemment réalisé l'hydroboration du δ-pyronène par la diborane généré in situ dans le diglyme. Ils obtiennent avec un rendement médiocre les alcools correspondants à l'hydroboration respectivement des deux doubles liaisons. Nous avons, en ce qui nous concerne, réalisé cette réaction dans le tétrahydrofuranne en utilisant du diborane généré hors du réacteur. Dans ces conditions et après oxydation en milieu basique (H_2O_2/OH^-) on isole avec un rendement de 47% un mélange (24/76) constitué par du cyclohexane méthanol-3,3-diméthyl-2-méthylène **10** ("iso"-γ-cyclogéraniol) et du γ-cyclogéraniol **11** (Schéma 5).

Schéma 5.



10 R=CH_2OH **11** R=CH_2OH **14** R=CHO **15** R=CHO
12 R=CHO **13** R=CHO **16** R=CH_2Br **17** R=CH_2Br
18 R=CH_2OH

Par contre, lorsque l'on utilise un agent d'hydroboration hautement régiosélectif, le 9-BBN (bora-9-bicyclo[3,3,1]nonane) qui est très sensible à l'encombrement stérique de la double liaison, nous inversons la régiochimie de cette réaction et obtenons les alcools **10** et **11** dans un rapport 67/33 avec un rendement de 42%. L'alcool minoritaire **11** résulte de l'addition sur le méthylène en -2, plus encombré stériquement par le voisinage du groupement *gem*-diméthyle.

Les composés hydroxylés **10** et **11** aisément séparés par chromatographie sur alumine (6% H_2O) sont oxydés par le chlorochromate de pyridinium respectivement en "iso"-γ-cyclocitral **12** (Rdt 81%) et γ-cyclocitral **13** (Rdt 87%). Ces aldéhydes traités en présence d'alumine s'isomérisent quantitativement en "iso"-β-cyclocitral **14** et β-cyclocitral **15**.

L'alcool **10** ainsi que les aldéhydes **12** et **14** sont des composés inédits possédant un squelette cyclogéranyle avec une position différente de la chaîne fonctionnelle ("iso" cyclogéranyle).

Hydrobromation du δ-pyronène 4

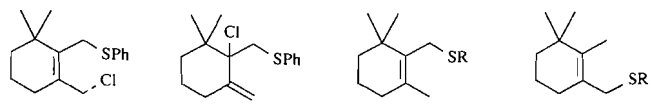
Par analogie avec les réactions réalisées sur le myrcène, le δ-pyronène **4** a été traité par une solution d'acide bromhydrique à 48% en présence de bromure cuivreux (12). La réaction est complète au bout de 2 h et nous mettons en évidence sur le brut réactionnel un mélange (70/30) des deux dérivés bromés **16** et **17**; l'addition d'acide bromhydrique sur le complexe δ-pyronène–Cu_2Br_2 a lieu préférentiellement sur la double liaison la plus réactive pour ce type de réaction.

Cependant si on prolonge le temps de réaction nous constatons l'évolution du dérivé bromé **17** qui subit une réaction de débromhydratation en γ-pyronène **3**. Sa disparition est totale au bout de 20 h; seul subsiste le bromure d'"iso"-β-cyclogéranyle **16**, qui sans être isolé est traité successivement par de l'acétate de potassium puis $LiAlH_4$ pour conduire à l'"iso"-β-cyclogéraniol **18** avec un rendement de 33% par rapport au δ-pyronène. Ceci constitue une nouvelle voie d'accès plus spécifique pour cet alcool également inédit.

Addition du chlorure de benzène sulfényle au δ-pyronène 4

La réaction du chlorure de benzène sulfényle (13) à −70°C sur le δ-pyronène **4** en solution dans du dichlorométhane conduit quantitativement à un mélange (56/44) des chlorosulfures **19** (adduit −1,4) et **20** (adduit −1,2) que nous ne pouvons séparer efficacement en raison de leur très faible stabilité (Schéma 6). Lors de cette réaction mettant en jeu un mécanisme ionique via un ion épisulfonium, on note de nouveau l'addition exclusive sur le méthylène -2 plus riche en électrons.

Schéma 6.



19 **20** **21** R=Ph **22** R=Ph
23 R=Et **24** R=Et

Cependant par un chauffage de 3 h au reflux du dichlorométhane, nous initions une isomérisation totale de l'adduit -1,2 en adduit -1,4 que l'on peut alors isoler par flash-chromatographie. Sa réduction par $AlLiH_4$ à 0°C dans l'éther anhydre conduit avec un rendement de 80% au phénylcyclogéranylsulfure **21**, intermédiaire particulièrement important (14) pour accéder via la sulfone correspondante à la vitamine A et à divers rétinoïdes.

Addition de thiols au δ-pyronène 4

Le δ-pyronène **4** a été traité dans un premier temps par le

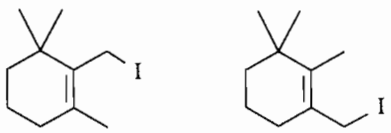
thiophénol (4 h à 90°C) en présence d'AIBN. Après purification du brut réactionnel sur colonne d'alumine désactivée, on isole avec un rendement de 90% un mélange (70/30) des sulfures **22** et **21** que l'on ne peut séparer que difficilement par chromatographie sur gel de silice imprégnée de 5% de nitrate d'argent. Une réaction analogue, réalisée sous rayonnement ultra-violet, avait été décrite par Takabe et al. (6).

L'addition de l'éthanediol sur le δ-pyronène **4** réalisée dans des conditions semblables (5 h à 50°C) nous a permis d'obtenir avec un rendement de 95% un mélange (60/40) des sulfures **24** et **23**, dont la séparation sur colonne de gel de silice est beaucoup plus aisée.

Ces réactions réalisées dans des conditions radicalaires on conduit à des mélanges de régioisomères. Cependant on observe pour chacun d'entre eux la formation exclusive de l'adduit -1,4 l'étape de transfert intervenant préférentiellement à partir du radical allylique le moins substitué.

Les deux sulfures **23** et **24** sont ensuite traités par un mélange d'iodure de méthyle et d'iodure de sodium dans l'acétonitrile (15). À partir du sulfure **24** on isole avec un rendement de 80% l'iodure d'"iso"β-cyclogéranyle **26**. Par contre, avec le sulfure **23** il n'est pas possible d'isoler l'iodure de cyclogéranyle **25** correspondant; il subit rapidement une réaction de déhydroiodation pour conduire au γ-pyronène **3** (Rdt 97%) (Schéma 7).

Schéma 7.



25 **26**

Cette observation nous a permis d'optimiser un procédé d'obtention du dérivé iodé **26**, en traitant directement le mélange des sulfures **23** et **24** par CH_3I–NaI. Après élimination sous pression réduite, de l'hydrocarbure **3**, nous isolons avec un rendement de 51% l'iodure d'"iso"β-cyclogéranyle **26**.

Conclusions

Les réactions d'addition réalisées selon des processus ioniques mettent en évidence une différence de réactivité significative pour les deux insaturations du δ-pyronène.

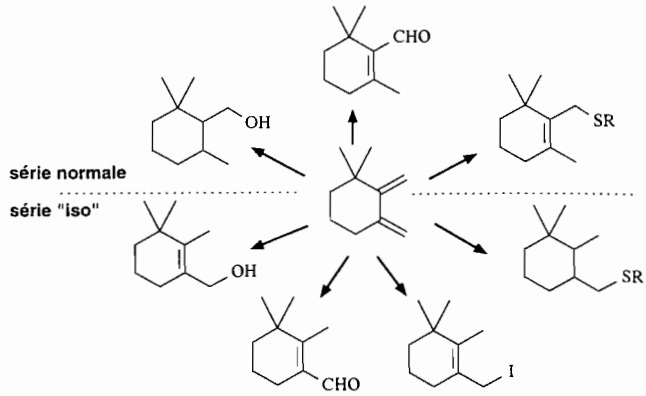
Ceci peut s'expliquer par la présence du groupement *gem*-diméthyle en -1 qui a un double rôle (électronique et stérique).

La double liaison la plus proche, semble plus réactive vis-à-vis de réactifs électrophiles, en raison de l'effet électronique inductif (+I) de ce groupe, dans la limite des contraintes stériques liées à l'approche du réactif.

Le δ-pyronène **4** constitue donc un synthon terpénique particulièrement efficace (Schéma 8) permettant l'accès direct à des composés de la série cyclogéranyle normale tels que le cyclogéraniol, le cyclocitral ou le cyclogéranylsulfure utilisés pour la synthèse de composés odorants ou de rétinoïdes.

D'autre part il est également le précurseur de terpénoïdes inédits possédant le squelette cyclogéranyle avec une position différente de la chaîne latérale fonctionnelle (série "iso").

Schéma 8.



Partie expérimentale

Les analyses de chromatographie en phase gazeuse (CPG) sont effectuées avec un appareil Intersmat IGC 121 FL (colonne capillaire 52 CB, 25 m).

Les spectres infra-rouge ont été enregistrés au moyen d'un spectrographe Unicam SP 200, soit en film, soit en solution dans le tétrachlorure de carbone. Les spectres de RMN ^1H et ^{13}C sont enregistrés en solution dans $CDCl_3$ avec le TMS comme référence interne sur un appareil Bruker AC 250 MHz. Les études par spectrométrie de masse ont été réalisées en basse résolution au moyen d'un appareil VG Micromass 16F.

Dihydroxylation du δ-pyronène 4

À une solution de 696 mg (4,4 mmol) de permanganate de potassium dans 1 L d'eau glacée sont ajoutés 25 mL d'une solution aqueuse de soude à 40%, puis 300 mg (2,2 mmol) de δ-pyronène **4**. Après 15 h d'agitation à température ambiante on ajoute une solution de $NaHSO_3$, puis on acidifie avec H_2SO_4 10%. Après extraction à l'éther, lavage avec une solution saturée de NaCl, puis séchage ($MgSO_4$), on isole après un flash-chromatographie 225 mg (Rdt 60%) du diol **8** pur (liquide incolore).

8 : RMN ^1H (δ) : 0,86 (3H, s), 0,89 (3H, s), 3,58 et 3,85 (AB; J_{AB} = 11 Hz), 4,97 (CH_2=); RMN ^{13}C (δ) : 22,5 (CH_2), 22,7 (CH_3), 24,1 (CH_3), 33,5 (CH_2), 37,9 (CH_2), 38,2 (*C*), 63,4 (CH_2OH), 80,1 (*C*-OH), 110,7 (CH_2=), 148,9 (*C*=). Anal. calc. pour $C_{10}H_{18}O_2$: C 70,59, H 10,59; trouvée : C 70,81, H 10,47.

Obtention de l'époxy-pyronène 5

À une solution de 1,22 g (7,2 mmol) de diol **8** dans 7 mL de pyridine refroidie à 0°C on ajoute 1,78 g (9,3 mmol) de chlorure de tosyle. L'agitation est maintenue pendant 3 h à 0°C, puis le milieu réactionnel est hydrolysé à cette température avec HCl 10%. Après extraction à l'éther le produit brut **9** est dissout dans 45 mL d'éther de pétrole puis agité, pendant 7 h à température ambiante en présence de 45 g d'alumine.

Après filtration et évaporation du solvant on isole 565 mg (Rdt 52%) d'époxy-pyronène (6) pur **5**.

Hydroboration du δ-pyronène 4

Avec le diborane

Le diborane préparé à partir de 1,1 mL (9 mmol) de $BF_3 : OEt_2$ et 172 mg (4,5 mmol) de $NaBH_4$ dans 10 mL de diglyme est envoyé à l'aide d'une canule dans 1,36 g (10 mmol) de δ-pyronène **4** en solution dans 10 mL de THF.

Après 1 h d'agitation à température ambiante la solution est traitée pendant 1 h avec 2 mL d'une solution de NaOH 3 N et 1,4 mL d'H_2O_2 30%.

Après extraction à l'éther, lavage (NaCl saturé) et séchage ($MgSO_4$), les solvants sont évaporés. Le produit brut est purifié par chromatographie sur colonne d'alumine désactivée (6% d'H_2O). On obtient 725 mg (Rdt 47%) d'un mélange (24/76; CPG) constitué par les alcools **10** et **11**.

Avec le 9-BBN

À une solution de 1,36 g (10 mmol) de δ-pyronène **4** dans 3 mL de THF on ajoute 22,7 mL (11,1 mmol) d'une solution 0,5 M de 9-BBN dans du THF, puis on porte au reflux pendant 6 h. Après refroidissement on ajoute 6 mL d'éthanol et 2 mL d'une solution de soude 6 N, puis goutte à goutte 4 mL (35,3 mmol) d'H_2O_2 à 30% et on agite pendant 1 h à 50°C.

Après concentration et extraction au pentane, les phases organiques sont lavées (NaCl saturé), séchées ($Mg SO_4$), puis évaporées sous pression réduite.

On isole 647 mg (Rdt 42%) d'un produit brut constitué par un mélange (67/33; CPG) des alcools **10** et **11** que l'on sépare par chromatographie sur alumine (6% H_2O) en éluant avec le mélange ether de pétrole/éther (8/2 à 6/4).

10 : RMN ^{1}H (δ) : 1,07 (3H, s), 1,10 (3H, s), 3,59 et 3,66 (CH_2OH), 4,59 et 4,81 (CH_2=); RMN ^{13}C (δ) : 21,5 (CH_2), 26,6 (CH_3), 29,5 (CH_3), 31,8 (CH_2), 37,0 (C), 41,6 (CH), 41,9 (CH_2), 65,7 (CH_2OH), 103,1 (CH_2=), 157,0 (C=). Anal. calc. pour $C_{10}H_{18}O$: C 77,92, H 11,69; trouvée : C 78,10, H 11,58.

11 : RMN ^{1}H (δ) : 0,86 (3H, s), 0,95 (3H, s), 3,55 et 3,86 (CH_2OH), 4,75 et 4,94 (CH_2=C); RMN ^{13}C (δ) : 23,1 (CH_2), 26,4 (CH_3), 28,5 (CH_3), 31,9 (CH_2), 33,9 (C), 36,4 (CH_2), 56,3 (CH), 59,5 (CH_2OH), 111,5 (CH_2=), 147,5 (C=).

Oxydation de l'alcool 10

À une solution de 690 mg (3,2 mmol) de chlorochromate de pyridinium dissous dans 6,6 mL de CH_2Cl_2 on ajoute 322 mg (2,1 mmol), d'alcool **10**, puis on agite pendant 45 min à température ambiante.

Le mélange est ensuite "flash" chromatographié sur alumine désactivée. On isole 260 mg (Rdt 81%) d'"iso"-γ-cyclocitral **12** qui s'isomérise quantitativement en "iso"-β-cyclocitral **14** au contact prolongé (1 nuit) avec de l'alumine en suspension dans de l'éther de pétrole.

12 (liquide incolore) : RMN ^{1}H (δ) : 0,92 (3H, s), 1,04 (3H, s), 4,65 et 4,93 (CH_2=), 9,60 (1H, d); RMN ^{13}C (δ) : 20,2 (CH_2), 26,8 (CH_2), 28,0 (CH_3), 28,2 (CH_3), 37,8 (C), 40,9 (CH_2), 54,6 (CH), 109,1 (CH_2=), 152,3 (C=), 203,7 (CHO). Anal. calc. pour $C_{10}H_{16}O$: C 78,94, H 10,53; trouvée : C 78,84, H 10,61.

14 (liquide jaune clair) : RMN ^{1}H (δ) : 1,05 (6H, s), 2,06 (3H, s), 10,09 (1H, s); RMN ^{13}C (δ) : 12,3 (CH_3), 18,0 (CH_2), 23,2 (CH_2), 27,2 (2 × CH_3), 36,4 (C), 38,5 (CH_2), 132,8 (C=), 161,7 (C=), 192,0 (CHO). Anal. calc. pour $C_{10}H_{16}O$: C, 78,94, H 10,53; trouvée : C 79,11, H 10,45.

Oxydation de l'alcool 11

À une solution de 965 mg (4,5 mmol) de chlorochromate de pyridinium dissous dans 10 mL de CH_2Cl_2 on ajoute 440 mg (2,9 mmol) d'alcool **11**, puis on agite pendant 45 min à température ambiante.

Le mélange est ensuite "flash" chromatographié sur alumine désactivée. On isole 377 mg (Rdt 87%) de γ-cyclocitral **13** qui par contact prolongé (1 nuit) avec de l'alumine en suspension dans l'éther de pétrole s'isomérise quantitativement en β-cyclocitral **15**.

13 : RMN ^{1}H (δ) : 0,87 (3H, s), 0,99 (3H, s), 2,60 (1H, m), 4,62 et 4,82 (CH_2=), 9,75 (1H, d); RMN ^{13}C (δ) : 22,7 (CH_2), 25,9 (CH_3), 28,0 (CH_3), 34,8 (C), 33,3 (CH_2), 37,3 (CH_2), 66,4 (CH), 112,3 (CH_2=), 143,3 (C=), 202,7 (CHO).

15 : RMN ^{1}H (δ) : 1,15 (6H, s), 2,04 (3H, s), 2,14 (2H, t), 10,08 (1H, s); RMN ^{13}C (δ) : 18,1 (CH_2), 18,6 (CH_3), 27,2 (2 × CH_3), 32,4 (C), 35,1 (CH_2), 40,1 (CH_2), 139,9 (C=), 155,5 (C=), 191,1 (CHO).

Hydrobromation du δ-pyronène 4

À une solution de 250 mg de CuBr dissout dans 12,5 mL d'HBr 48% sont ajoutés 900 mg (6,6 mmol) de δ-pyronène-**4**. Après 20 h d'agitation, la phase organique est extraite à l'éther. Après évaporation des solvants le mélange dissout dans 10 mL d'acétone est traité avec 2 g d'acétate de potassium pendant 24 h. Après addition d'éther, la solution organique est filtrée, concentrée et additionnée à une suspension de 610 mg d'$AlLiH_4$ dans 50 mL d'éther anhydre à 0°C. Après 3 h d'agitation, le milieu est versé sur de la glace, acidifié et extrait à l'éther. Après évaporation des solvants, on isole 335 mg (Rdt 33%) d'"iso"-β-cyclogéraniol **18** (liquide incolore).

18 : RMN ^{1}H (δ) : 0,93 (6H, s), 1,59 (3H, s), 3,99 (2H, s); RMN ^{13}C (δ) : 12,9 (CH_3), 19,3 (CH_2), 27,8 (2× CH_3), 28,7 (CH_2), 34,6 (C), 39,3 (CH_2), 63,7 (CH_2), 129,6 (C), 137,8 (C). Anal. calc. pour $C_{10}H_{18}O$: C 77,92, H 11,69; trouvée : 77,04, H 12,00.

Addition du chlorure de benzène sulfényle au δ-pyronène 4

δ-pyronène **4** (1,632 mg; 12 mmol) est ajouté à −70°C à une solution de 10 mL de dichlorométhane contenant 10 mmol de chlorure de benzène sulfényle, préparé à partir de thiophénol et de *N*-chlorosuccinimide, puis le mélange est laissé revenir à température ambiante. Après évaporation du solvant, le résidu est repris par CCl_4 puis filtré. Après concentration on obtient 2,8 g (Rdt ~ 100%) d'un mélange (56/44; RMN ^{1}H) constitué par les chlorosulfures **19** et **20**.

Isomérisation de 20 en 19

Le mélange brut des chlorosulfures est repris dans 10 mL de dichlorométhane, puis chauffé au reflux pendant 3 h. Après évaporation du solvant, on obtient 2,6 g (93%) du composé **19** (huile).

19 : RMN ^{1}H (δ) : 1,19 (6H, s), 3,72 (2H, s), 4,23 (2H, s), 7,26–7,36 (5H, Ph); RMN^{13} C (δ) : 19,0 (CH_2), 28,4 (2 × CH_3), 28,8 (CH_2), 31,7 (CH_2), 35,3 (C), 39,1 (CH_2), 45,7 (CH_2), 126,0 (CH, Ph), 128,6 (2 × CH, Ph), 129,0 (2 × CH, Ph), 133,6 (C), 137,9 (C), 138,9 (C).

Réduction du chlorosulfure 19

Chlorosulfure **19** (670 mg; 2,38 mmol) est ensuite ajouté à 0°C à une suspension de 280 mg de $LiAlH_4$ dans 15 mL d'éther anhydre. Après 6 h d'agitation, le milieu est versé sur de la glace, acidifié et extrait à l'éther.

Après évaporation des solvants, on récupère 470 mg (Rdt 80%) de phénylcyclogéranyl sulfure **21**.

21 : RMN ^{1}H (δ) : 1,09 (6H, s), 1,74 (3H, s), 3,61 (CH_2SPh), 7,10–7,33 (5H, Ph); RMN ^{13}C (δ) : 19,3 (CH_2), 20,3 (CH_3),

28,7 (2 × CH_3), 32,6 (CH_2), 33,0 (CH_2SPh), 34,6 (*C*), 39,4 (CH_2), 125,3 (*C*H, Ph), 128,2 (2 × *C*H, Ph), 128,7 (2 × *C*H, Ph), 131,9 (*C*), 133,6 (*C*), 139,0 (*C*).

Addition de thiophénol au δ-pyronène 4

À 4,033 g (29,6 mmol) de δ-pyronène **4** sont ajoutés 500 mg d'AIBN, puis 5 mL (48,7 mmol) de thiophénol. Le mélange réactionnel est ensuite porté à 90°C pendant 4 h, puis dilué à l'éther et lavé successivement avec une solution de NaOH / N et une solution saturée de NaCl. La phase organique après séchage ($MgSO_4$) est concentrée. On récupère 6,6 g (Rdt 90%) d'un mélange (70/30; RMN) des sulfures **22** et **21**.

Leur séparation peut être réalisée par chromatographie sur gel de silice imprégnée de 5% d'$AgNO_3$.

22 (liquide incolore) : RMN ^{1}H (δ) : 0,94 (6H, s), 1,44 (3H, s), 3,47 (CH_2SPh), 7,12–7,36 (5H, Ph); RMN ^{13}C (δ) : 13,3 (CH_3), 19,5 (CH_2), 28,0 (2 × CH_3), 30,0 (CH_2), 35,0 (*C*), 38,7 (CH_2), 39,5 (CH_2), 125,1 (*C*), 126,4 (*C*H, Ph), 128,7 (2 × *C*H, Ph), 131,1 (2 × *C*H, Ph), 136,9 (*C*), 138,9 (*C*). Anal. calc. pour $C_{16}H_{22}S$: C 78,05, H 8,94; trouvée : C 78,20, H 8,57.

Addition de l'éthanethiol au δ-pyronène 4

À 4,040 g (30 mmol) de δ-pyronène **4** sont ajoutés 500 mg d'AIBN, puis 4,4 mL (60 mmol) d'éthanethiol. Ce mélange réactionnel est agité à 50°C pendant 5 h, puis dilué à l'éther et lavé successivement avec une solution de NaOH / N et une solution saturée de NaCl. La phase organique est séchée sur $MgSO_4$, puis concentrée. On récupère 5,65 g (Rdt 95%) d'un mélange (60/40; RMN) des sulfures **24** et **23** que l'on sépare par chromatographie sur colonne de gel de silice.

24 (liquide incolore) : RMN ^{1}H (δ) : 1,00 (6H, s), 1,25 (3H, t), 1,65 (3H, s), 2,47 (2H, q), 3,14 (2H, s); RMN ^{13}C (δ) : 13,4 (CH_3), 15,0 (CH_3), 19,4 (CH_2), 25,6 (CH_2), 28,0 (2× CH_3), 29,7 (CH_2), 34,9 (*C*), 35,1 (CH_2), 39,5 (CH_2), 126,3 (*C*), 137,2 (*C*). Anal. calc. pour $C_{12}H_{22}S$: C 72,73, H 11,11; trouvée : C 72,81, H 11,07.

23 : RMN ^{1}H (δ) : 1,06 (6H, s), 1,28 (3H, t), 1,73 (3H, s), 2,55 (2H, q), 3,20 (2H, s); RMN ^{13}C (δ) : 14,8 (CH_3), 19,0 (CH_2), 20,2 (CH_3), 27,7 (CH_2), 28,7 (2× CH_3), 30,6 (CH_2), 32,8 (CH_2), 34,6 (*C*), 39,5 (*C*), 131.9 (*C*), 133,3 (*C*).

Obtention du dérivé iodé 26

À 530 mg (3,5 mmol) d'iodure de sodium, 4 mL (6,4 mmol) d'iodure de méthyle en solution dans 3 mL d'acétonitrile on ajoute 523 mg (2,6 mmol) de sulfure **24**. Le milieu est agité pendant 15 h à température ambiante et on obtient après chromatographie sur gel de silice (éluant éther de pétrole), 550 mg (Rdt 80%) d'iodure d'"iso"-β-cyclogéranyle **26**.

26 (huile colorée) : RMN ^{1}H (δ) : 1,06 (6H, s), 1,75 (3H, s), 3,50 (2H, s); RMN ^{13}C (δ) : 15,2 (CH_2), 19,6 (CH_2), 28,3 (2× CH_3), 32,5 (CH_2), 35,5 (*C*), 39,5 (CH_2), 58,7 (CH_2), 124,6 (*C*), 142,7 (*C*). Anal. calc. pour $C_{10}H_{17}I$: C 45,45, H 6,44; trouvée : C 46,30, H 7,10.

Remerciements

Nous remercions la Société Rhône Poulenc Nutrition Animale pour la fourniture de matières premières, M. Petraud et B. Barbe pour la réalisation des spectres de RMN et G. Bourgeois pour les spectres de masse (Centre d'Études Structurales et d'Analyse des Molécules Organiques, Université Bordeaux 1).

Stereoselectivity of directed epoxidations of 22-hydroxy-Δ^{23}-sterol side chains

Thomas G. Back and Denise L. Baron

Abstract: A series of 22-hydroxy-Δ^{23}-sterols comprising (3β,5α,6β,22*S*)-6-methoxy-3,5-cyclo-25,26,27-trinorcholest-23-en-22-ol (**6**), (3β,5α,6β,22*S*,23*E*)-6-methoxy-3,5-cyclo-26,27-dinorcholest-23-en-22-ol (**7**), 3β,5α,6β,22*R*)-6-methoxy-23-methyl-3,5-cyclo-25,26,27-trinorcholest-23-en-22-ol (**10**), 3β,5α,6β,22*S*,23*Z*)-6-methoxy-3,5-cyclo-26,27-dinorcholest-23-en-22-ol (**11**), and 3β,5α,6β,22*R*)-6-methoxy-3,5-cyclo-26,27-dinorergost-23-en-22-ol (**12**) were subjected to epoxidation with *m*-chloroperbenzoic acid and *tert*-butyl hydroperoxide in the presence of either vanadyl acetoacetonate or molybdenum hexacarbonyl, and the *threo*:*erythro* ratios of the products were determined. The results are of relevance for the synthesis of sterols with oxygenated side chains, such as brassinolide (**1**). The oxidations of **6** and **7** were *erythro* selective with all three oxidants, especially with the vanadium-catalyzed system. Peracid oxidation of the 22-*tert*-butyldimethylsilyl ether (**8**) and 22-pivaloate (**9**) of alcohol **7** showed similar *erythro* selectivity to that of the parent compound **7**. Allylic alcohol **10** gave exclusively the *erythro* epoxide with all three oxidants, while **11** and **12** were *threo*-selective under all three conditions. Molecular modeling indicated that *erythro* selectivity in the vanadium-catalyzed epoxidation of **10** was consistent with a destabilizing interaction ($A^{(1,2)}$ strain) between the *gem*-methyl and C(21) methyl groups in the conformation required for formation of the *threo*-isomer. The *threo*-selective peracid oxidations of **11** and **12** were attributed to $A^{(1,3)}$ strain between the *cis*-methyl groups and C(20) in the conformation required for formation of the *erythro*-epoxide. The differences in the calculated energies of conformations leading to the *threo*- and *erythro* epoxide diastereomers of substrates containing no *gem* or *cis* substituents proved too small to permit reliable prediction of diastereoselectivity.

Key words: 22-hydroxy-Δ^{23}-sterols, brassinosteroids, allylic alcohols, epoxidation, diastereoselectivity

Résumé : On a soumis une série de 22-hydroxy-Δ^{23}-stérols, comportant les (3β,5α,6β,22*S*)-6-méthoxy-3,5-cyclo-25,26,27-trinorcholèst-23-én-22-ol (**6**), (3β,5α,6β,22*S*,23*E*)-6-méthoxy-3,5-cyclo-26,27-dinorcholèst-23-en-22-ol (**7**), 3β,5α,6β,22*R*)-6-méthoxy-23-méthyl-3,5-cyclo-25,26,27-trinorcholést-23-én-22-ol (**10**), 3β,5α,6β,22*S*,23*Z*)-6-méthoxy-3,5-cyclo-26,27-dinorcholèst-23-en-22-ol (**11**), et 3β,5α,6β,22*R*)-6-méthoxy-3,5-cyclo-26,27-dinorergost-23-én-22-ol (**12**), à une époxydation par l'acide *m*-chloroperbenzoïque et l'hydroperoxyde de *tert*-butyle, en présence soit d'actoacétonate de vanadyle soit d'hexacarbonyle de molybdène; on a déterminé les rapport *thréo/érythro* des produits obtenus. Les résultats présentent de l'importance pour la synthèse de stérols portant des chaînes latérales oxygénées, comme le brassinolide (**1**). Les oxydations des composés **6** et **7** sont *érythro*-sélectives avec chacun des trois oxydants, particulièrement avec le système catalysé par le vanadium. Les oxydations du 22-*tert*-butyldiméthylsilyloxyde (**8**) et du 22-pivaloate (**9**) de l'alcool **7** par le peracide donnent des *érythro*-sélectivités semblables à celle du composé parent (**7**). L'alcool allylique **10** conduit exclusivement à l'époxyde *érythro* avec chacun des trois oxydants alors que les composés **11** et **12** sont *thréo*-sélectifs dans les trois conditions expérimentales. La modélisation moléculaire indique que l'*érythro*-sélectivité observée lors de l'époxydation du produit **10** catalysée par le vanadium pourrait être le résultat d'une interaction déstabilisante (tension $A^{(1,2)}$) entre le *gem*-diméthyle et les groupes méthyles en C(21) dans la conformation requise pour la formation de l'isomère *thréo*. Les oxydations *thréo*-sélectives des composés **11** et **12** obtenues avec le peracide sont attribuées à une tension $A^{(1,3)}$ entre les groupes *cis*-méthyles et le C(20) dans la conformation requise pour la formation de l'époxyde *érythro*. Les différences des énergies calculées des conformations conduisant aux époxydes *thréo* et *érythro* diastéréomères des substrats ne contenant pas de substituants *gem* ou *cis* sont trop faibles pour permettre de faire des prédictions satisfaisantes de la diastéréosélectivité.

Mots clés : 22-hydroxy-Δ^{23}-stérols, brassinostéroïds, alcools allyliques, époxydation, diastéréosélectivité.

Introduction

The discovery of numerous biologically active sterols containing oxygenated side chains has prompted interest in the development of new methods for their preparation (1). Among such compounds, brassinolide (**1**) (2) and related brassinosteroids are of particular interest because of their powerful plant growth promoting activity (3). The four contiguous stereocenters at C(20), C(22), C(23), and C(24) and the vicinal diol moiety at C(22) and C(23) in the side chains of these compounds provide the principal challenge in their synthesis. A number of strategies for this purpose have been reported (4), some of which exploit stereoselective epoxidations of appropriate unsaturated substrates (5), usually followed by reduction or reaction with carbanion nucleophiles. The hydroxyl-

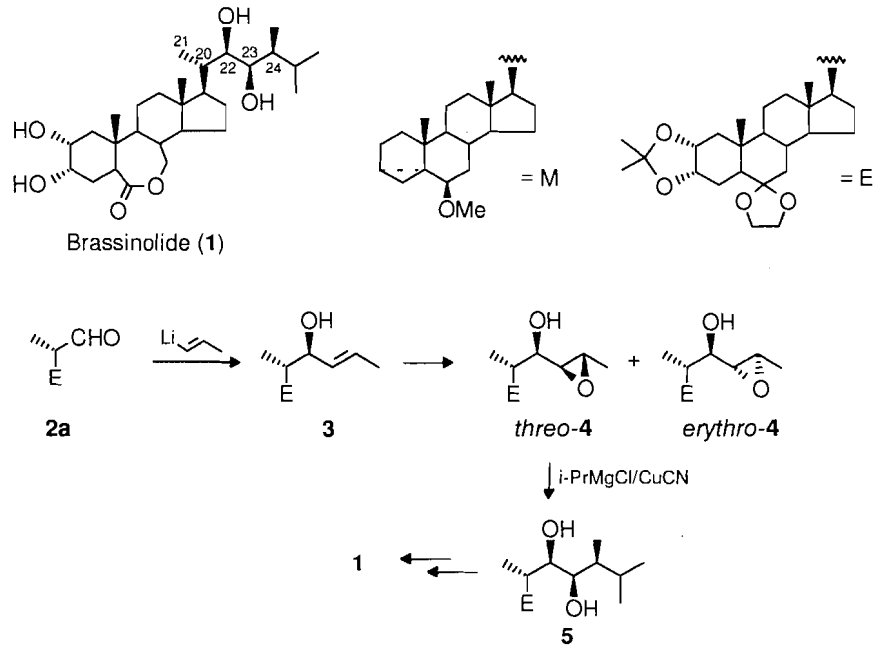
Scheme 1.



directed epoxidation of allylic alcohol **3**, followed by epoxide opening of **4** with an isopropyl nucleophile (Scheme 1), provides an exceptionally concise synthesis of the brassinolide side chain (6), but results in unfavourable diastereoselectivity in the epoxidation step unless a chiral oxidant is employed. Since this and other epoxide-based methods offer potential access to new brassinolide analogues and to stereoisomers that are of interest in structure–activity studies, as well as to other sterols possessing oxygenated side chains, a more detailed investigation of the stereoselectivity of the key epoxidation step was undertaken. Thus, allylic alcohols **6–12**, prepared as shown in Scheme 2, were subjected to three different epoxidizing conditions, in order to systematically observe the effects of substituents at the *t* (*trans*), *g* (*gem*), and *c* (*cis*) positions, as well as the effect of blocking the alcohol functionality through silyl ether or ester formation.

The directing effect of the hydroxyl group in the epoxidation of allylic alcohols with peracids was first noted by Henbest and Wilson (7). Subsequently, hydroxyl-directed vanadium-catalyzed epoxidations with *tert*-butyl hydroperoxide were reported, as well as those using other transition metal catalysts such as molybdenum and titanium, thereby providing improved diastereoselectivity in many instances (8). The inclusion of chiral, tartrate-based ligands with titanium catalysts gave rise to the widely employed Sharpless method for the enantioselective epoxidation of allylic alcohols (9).

The diastereoselectivity of peracid- and vanadium-catalyzed epoxidations has been studied with both cyclic and acyclic substrates. Several early models for the peracid epoxidation of allylic alcohols were proposed by Sassiver and English (10), Whitham and co-workers (11), and Chautemps and Pierre (12). In most cases, secondary acyclic allylic alcohols afford *threo*-epoxides preferentially, and the stereoselectivity is enhanced by the presence of a *cis* substituent. However, *erythro* selectivity is often observed when a substituent is present in the *gem* position. More recently, Sharpless and co-workers (8*d*, 13) proposed a revised model for peracid

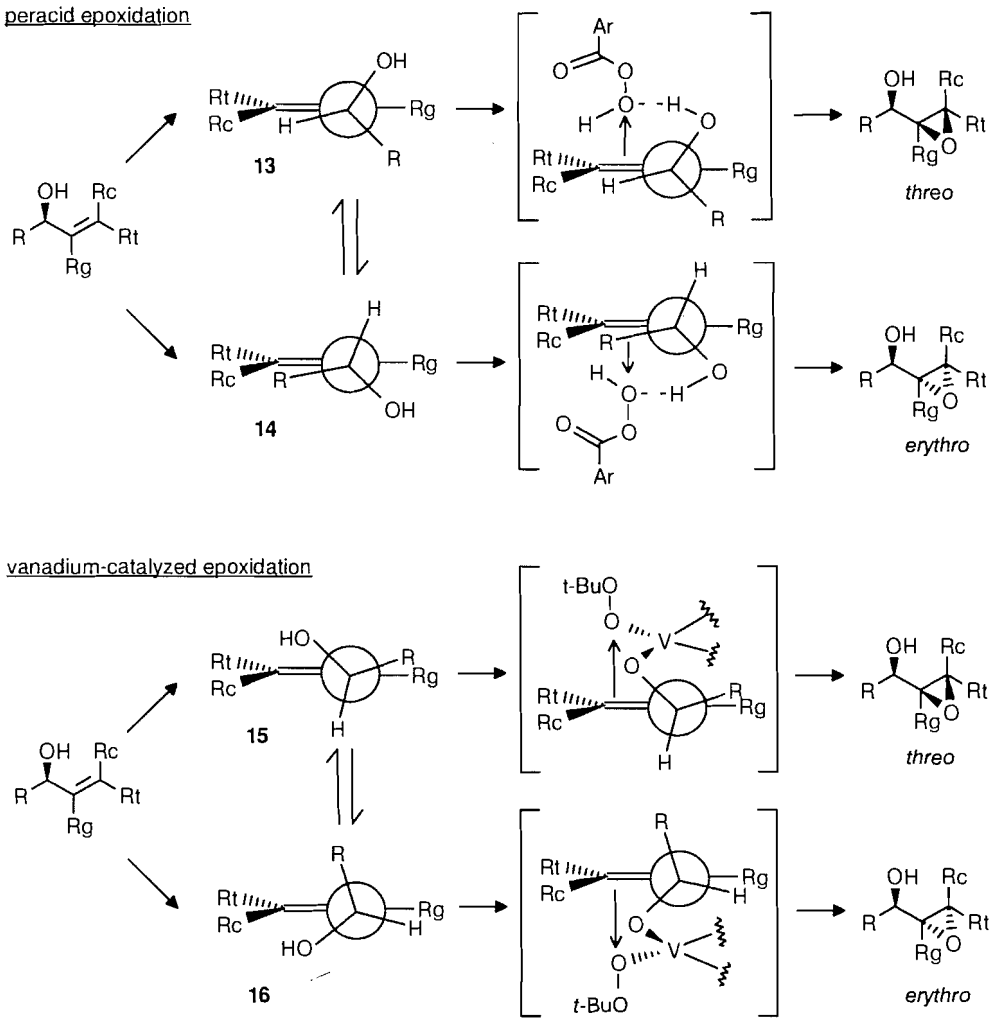
epoxidations with a preferred dihedral angle (O-C-C-C=) of 120° that accommodates the stereoelectronic requirement for back-side attack by the olefinic π-bond upon the peroxide moiety of the peracid. Thus, the two conformations **13** and **14** lead to *threo* and *erythro* epoxides, respectively, as shown in Scheme 3.

On the other hand, vanadium-catalyzed epoxidations with *tert*-butyl hydroperoxide are generally *erythro* selective, with enhancement or reversal of this stereoselectivity observed with bulky *gem* or *cis* substituents, respectively (8d, 13, 14). A preferred dihedral angle (O-C-C-C=) of 50° has been suggested for these types of oxidations (8d, 13), leading to *threo* and *erythro* epoxides via conformations **15** and **16**, respectively (Scheme 3). Molybdenum-catalyzed epoxidations resemble those of peracids when *trans* alkyl groups are present, and are intermediate in stereoselectivity between per-

Scheme 3.



acid- and vanadium-catalyzed epoxidations with many other types of allylic alcohols. The observed stereoselectivity has been rationalized by consideration of allylic strain (A-strain) and other interactions in the transition states derived from conformations corresponding to **13–16** (8d, 13, 14, 15).

Results and discussion

The Cram addition products **6**, **7**, and **10–12**, along with smaller amounts of their anti-Cram epimers, were obtained by the addition of the appropriate Grignard reagent or organolithium compound to aldehyde **2b** (Scheme 2). The silyl ether **8** and pivaloate **9** were prepared by silylation and esterification of **7**. Products **6**, **7**, and **10–12** were then subjected to epoxidation with *m*-chloroperbenzoic acid (MCPBA), and with *tert*-butyl hydroperoxide in the presence of catalytic amounts of either vanadyl acetoacetonate, or molybdenum hexacarbonyl. Compounds **8** and **9** were oxidized only with MCPBA. The results are shown in Table 1.

The configurations of the epoxide products in Table 1 were determined by spectroscopic methods and (or) by their stereospecific conversion to more easily identified products. Thus, *erythro*-**17** was treated with isopropylmagnesium chloride and cuprous cyanide (16) to give diol **24**, which underwent a stereospecific Corey–Winter deoxygenation (17) to the known (*Z*)-olefin **25** (18). The *erythro* epoxide **18** has been reported previously (6), and both it and *erythro*-**22** afforded the same *erythro* diol **26** when reduced with lithium borohydride in the presence of titanium tetraisopropoxide (19), thereby confirming the assignment of stereochemistry to *erythro*-**22**. Similar treatment of *threo*-**22** produced the diastereomeric *threo*-diol **27**. Epoxides **19** and **20**, obtained from epoxidation of silyl ether **8** and pivaloate **9**, respectively, were identified by comparison with the products of silylation and pivaloylation of the known *erythro* epoxide **18** (6). *Erythro*-**21** was subjected to regioselective ring-opening with mesitylene-selenolate (20), followed by Corey–Winter reaction of the resulting diol **28** to afford the olefin **29**, which was shown to be the (*Z*) isomer by NOE experiments. Finally, the *threo*-epoxide **23** was reduced with lithium borohydride – titanium tetraisopropoxide to diol **30**, which was in turn converted into the known sterol **31** (21). These transformations are shown in Scheme 4.

The following results are evident from Table 1. The unsubstituted allylic alcohol **6** and the *trans*-allylic alcohol **7** afforded the corresponding *erythro* epoxides with modest diastereoselectivity using MCPBA or Mo-catalysis, and with very high selectivity with V-catalysis. While *erythro* selectiv-

ity is expected in the V-catalyzed system because of the destabilizing $A^{(1,2)}$ strain between R and R_g in conformation **15** (Scheme 3) that leads to the *threo* epoxide, the effect is usually small when R_g = H. Moreover, the *threo* selectivity that is generally observed in the peracid epoxidations of other allylic alcohols can be attributed to $A^{(1,3)}$ strain between R and R_c in conformation **14**, although it is again small when R_c = H. Thus, the observation of *erythro* selectivity in the peracid oxidations of **6** and **7**, and its magnitude in the V-catalyzed cases, are somewhat atypical.

Furthermore, the alcohol group of the substrate is believed to act as an H-bond donor to the hydroxylic peracid oxygen atom (8*d*), and is thus responsible for the directing effect observed in the peracid epoxidation of allylic alcohols. Protection of the allylic alcohol moiety might therefore be expected to change the diastereoselectivity by disrupting its H-bonding

Table 2. Molecular modeling of allylic alcohol derivatives **6–12.**

[a]Dihedral angles (D.A.) refer to O-C(22)-C(23)-C= and are given in degrees; the D.A. is positive when C(23) moves clockwise relative to C(22) while sighting from C(22) to C(23).

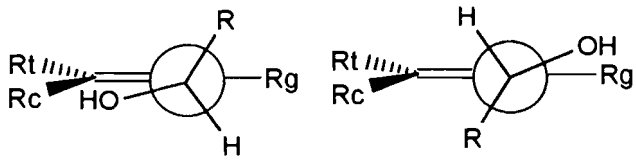
[b]Energies (E) are given in kJ mol^{-1}.

ability and freeing it from the constraints of the models in Scheme 3. Bulky O-protecting groups could further affect the stereochemistry by altering the preferred conformation through increased steric interactions. Surprisingly, however, neither silylation nor esterification of the hydroxyl group of **7** (i.e., to give **8** and **9**, respectively) had a significant effect upon the stereochemical outcome of the peracid epoxidation. Blocking the hydroxyl group is therefore not a useful strategy for changing the *erythro*:*threo* ratio and does not provide a means for realizing *threo* diastereoselectivity in this reaction.

The *gem*-substituted allylic alcohol **10** afforded the *erythro*-epoxide as essentially a single stereoisomer with all three oxidation methods. The predominant formation of this product is consistent with literature precedents, although the very high diastereoselectivity observed is unusual in the peracid oxidation.

Compounds **11** and **12**, the two substrates investigated that possess *cis* substituents, afforded the corresponding *threo*-epoxides as the major products with all three oxidation methods. This is attributed to destabilization of the *erythro* conformation **14** in the peracid oxidation by $A^{(1,3)}$ strain between R and R_c, but the cause is less obvious in the case of the less stereoselective V-catalyzed process.

In an attempt to gain further understanding of the stereoselectivity of the above oxidations, we subjected compounds **6–12** to molecular modeling with MacroModel (Version 4.5). Energy minimizations in the MM2 mode followed by Monte Carlo searches to determine the conformations corresponding to the global energy minima were performed for each compound. The results are shown in Table 2. It is noteworthy that the dihedral angle O-C(22)-C(23)-C(24) is relatively small for **6–10** (8.2°–24.3°), where R_c = H, indicating a roughly *syn*-coplanar geometry as shown in conformation **32**. In contrast, the dihedral angle in the *cis*-substituted compounds **11** and **12** is −158.1° and −158.5°, respectively, indicating an essentially *anti*-coplanar conformation **33**. Evidently, substantial A-strain between the hydroxyl group and the *cis* substituent results from replacement of H by Me in the *cis* position. This destabilizes the *syn* conformation **32** relative to **33** and leads to rotation about the C(22)—C(23) bond. On the other hand, A-strain is not significantly increased by silylation or esterification of the alcohol moiety in **8** and **9**, where the *syn* conformation **32** persists despite the relatively bulky O-substituents.



32(*syn*) **33**(*anti*)

We next investigated conformations **13–16** for each of the allylic alcohols **6**, **7**, and **10–12**, in order to identify any A-strain or other strongly destabilizing interactions. We envisaged that appropriately rotationally restricted conformations of the free alcohols could serve as models for their complexes with peracids or vanadium catalysts, and for the ensuing transition states, since the O-C(22)-C(23)-C(24) dihedral angles shown in **13–16** are required for stereoelectronic reasons, as explained earlier. The dihedral angles of compounds **6**, **7**, and **10–12** were therefore constrained to −120°, 120°, −50° and 50°, corresponding to the ideal conformations for *threo* and *erythro* epoxidations with peracids (**13** and **14**, respectively) and V-catalyzed *tert*-butyl hydroperoxide (**15** and **16**, respectively). The resulting energies are shown in Table 2. Compounds **8** and **9** were omitted from consideration because they lack a free hydroxyl group to direct the epoxidation.

The most striking differences in the calculated energies (ΔE) of the *erythro*- and *threo*-forming conformations were observed in the V-catalyzed epoxidation of **10** (−7.3 kJ/mol) and in the peracid oxidations of **11** and **12** (20.4 and 23.3 kJ/mol, respectively). The predicted and observed *erythro* selectivity in the former case is attributed to $A^{(1,2)}$ strain and the associated unfavourable steric interaction between the *gem*-methyl and C(21) methyl groups in the *threo* conformation **15**, where the nearest contact is only 2.242 Å. The strong *threo* selectivity of **11** and **12** is consistent with substantial $A^{(1,3)}$-strain in the *erythro* conformations **14**, where the closest contacts of 2.036 and 2.009 Å, respectively, are between the *cis*-methyl groups and the C(20) hydrogen atoms.

In contrast to the above cases, the differences in energies between the *threo*- and *erythro*-forming conformations in the

other examples in Table 2 are relatively small (ΔE is less than 5 kJ/mol). This suggests that more subtle secondary steric and stereoelectronic effects, as well as factors such as solvation and the possibility of reactions proceeding via higher energy conformations (Curtin–Hammett principle), can play a determining role in deciding the stereochemical outcome. The fact that the other examples in Table 2 predict modest *threo* selectivity, which it will be recalled is generally observed in the peracid oxidations of other allylic alcohols, while the corresponding *erythro* diastereomers were actually favoured with substrates **6–10**, demonstrates that caution must be used in attempts to predict the stereochemistry of these processes in the absence of strongly directing *cis* or *gem* substituents.

In summary, of the steroidal allylic alcohols that were studied, those lacking both *cis* and *gem* substituents (**6** and **7**) displayed strong *erythro* selectivity in vanadium-catalyzed epoxidation and modest *erythro* selectivity with the other oxidants investigated. Silylation or esterification of the hydroxyl group of **7** (to give **8** and **9**) did not significantly alter the course of the peracid epoxidation. The presence of a *gem* substituent in **10** resulted in the essentially exclusive formation of the *erythro* diastereomer with all three oxidants, while *cis*-substituted substrates **11** and **12** provided the only cases of *threo* selective epoxidations. Molecular modeling indicated $A^{(1,3)}$ strain in **14** as the cause of *threo* selectivity in the peracid oxidations of **11** and **12**, and $A^{(1,2)}$ strain between the *gem*-methyl and C(21) methyl groups in **15** as the reason for *erythro* selectivity in the V-catalyzed oxidation of **10**. However, modeling results proved inconclusive in attempts to rationalize the stereoselectivity of the other examples investigated.

Experimental section

Melting points were obtained on an A.H. Thomas hot-stage apparatus and are uncorrected. FT-IR spectra were recorded on a Mattson 4030 spectrometer. Proton (200 MHz) and ^{13}C NMR (50 MHz) spectra were acquired on a Bruker ACE 200 spectrometer, with deuteriochloroform as the solvent and residual chloroform as the internal standard. Other NMR spectra were obtained on a Bruker AM 400 instrument and are so indicated. Only selected signals are reported in ^1H NMR spectra. Low- and high-resolution mass spectra were obtained on a Kratos MS80 or a VG 7070 mass spectrometer. Elemental analyses were carried out by Ms. D. Fox of the Chemical Instrumentation Laboratory. Analytical TLC was carried out with Merck aluminum sheets coated with silica gel 60 F-254, and the spots were visualized with UV light, or by spraying with a 9% ammonium molybdate (VI) tetrahydrate solution in 16% aqueous sulfuric acid followed by heating for a few minutes. Preparative TLC was performed on Analtech 20 × 20 cm glass plates coated with 1 mm of silica gel GF. Flash chromatography was carried out according to the method of Still et al. (22). Radial chromatography was done on a model 7924T Chromatron using glass plates coated with 2 mm of Merck silica gel 60 PF-254.

2-Propenyllithium (23), (*E*)-1-propenylmagnesium bromide (24), and 2-methyl-1-propenyllithium (25) were prepared according to literature methods. Vinylmagnesium bromide was purchased from the Aldrich Chemical Co. 2-Propenyllithium and 2-methyl-1-propenyllithium were titrated with diphenylacetic acid (26), (*E*)-1-propenylmagnesium bromide was titrated using 1,10 phenanthroline and *sec*-butyl alcohol (27), and *n*-butyllithium was titrated with 2,5-dimethoxybenzyl alcohol (28). Aldehyde **2b** (29), allylic alcohol **7** (6), and di-(2,4,6-trimethylphenyl) diselenide (30) were synthesized according to literature methods. All other reagents were obtained from commercial sources and used without further purification. Anhydrous THF was obtained by distillation from lithium aluminum hydride. Anhydrous benzene, pyridine, DMF, and ether were obtained by distillation from calcium hydride.

(3β,5α,6β,22*S*)-6-Methoxy-3,5-cyclo-25,26,27-trinorcholest-23-en-22-ol (6) and its (22*R*) isomer

Vinylmagnesium bromide in THF (10.5 mmol) was added dropwise to a solution of aldehyde **2b** (3.00 g, 8.73 mmol) in 120 mL of dry THF at −78°C. The mixture was stirred for 1 h and then was quenched with aqueous NH_4Cl and diluted with ether. The aqueous layer was extracted with ether and the combined ether extracts were washed with aqueous $NaHCO_3$ and NaCl solutions, dried ($MgSO_4$), and evaporated in vacuo. The products were separated by flash chromatography (elution with 5% ethyl acetate – hexanes) to afford 2.02 g (62%) of **6**; mp 102–103°C (from hexanes) (lit. (31) mp 107–108°C) and 0.46 g (14%) of the 22*R* epimer; mp 122–123°C (from hexanes) (lit. (31) mp 124–125.5°C).

(3β,5α,6β,22*S*,23*E*)-6-Methoxy-3,5-cyclo-26,27-dinorcholest-23-ene 22-*tert*-butyldimethylsilyl ether (8)

Allylic alcohol **7** (6) (152 mg, 0.392 mmol), *tert*-butyldimethylsilyl chloride (154 mg, 1.02 mmol) and imidazole (107 mg, 1.57 mmol), were stirred in 3 mL of dry DMF at 65°C for 5 h. The mixture was diluted with ether, washed several times with water, dried ($MgSO_4$), and purified by flash chromatography (elution with 5% ethyl acetate – hexanes) to give 173 mg (88%) of silyl ether **8**: R_f 0.75 (7% ethyl acetate – hexanes); mp 150–153°C (from ether); IR (Nujol): 1250, 1124, 1096, 1027, 1004, 965, 773 cm^{-1}; ^1H NMR (200 MHz) δ: 5.51 −5.46 (m, 2 H), 4.10–4.08 (m, 1 H), 3.33 (s, 3 H), 2.78 (t, J = 2.8 Hz, 1 H), 1.67 (d, J = 4.2 Hz, 3 H), 1.03 (s, 3 H), 0.90 (s, 9 H), 0.88 (d, J = 5.8 Hz, 3 H), 0.72 (s, 3 H), 0.02 (s, 3 H), −0.02 (s, 3 H); mass spectrum, *m/z* (relative intensity): 500 (0.3, M^+), 499 (0.3), 485 (2), 443 (14), 185 (100). Anal. calcd. for $C_{32}H_{56}O_2Si$: C 76.73, H 11.27; found: C 76.77, H 10.96.

(3β,5α,6β,22*S*,23*E*)-6-Methoxy-3,5-cyclo-26,27-dinorcholest-23-enyl 22-pivaloate (9)

Allylic alcohol **7** (6) (134 mg, 0.347 mmol), trimethylacetyl chloride (213 μL, 1.73 mmol), and 4-dimethylaminopyridine (8.7 mg, 0.071 mmol) were stirred in 4 mL of dry pyridine at room temperature for 2.5 h. The mixture was then diluted with ether and water, washed with 10% HCl and $NaHCO_3$ solution, dried ($MgSO_4$), and purified by flash chromatography (elution with 10% ethyl acetate – hexanes) to afford 87 mg (53%) of ester **9**: R_f 0.50 (7% ethyl acetate – hexanes); mp 159.5–162°C (from ether); IR (KBr): 1726, 1281, 1165, 1097 cm^{-1}; ^1H NMR (200 MHz) δ: 5.64–5.30 (m, 3 H), 3.32 (s, 3 H), 2.77 (t, J = 2.7 Hz, 1 H), 1.69 (d, J = 5.9 Hz, 3 H), 1.23 (s, 9 H), 1.02 (s, 3 H), 0.99 (d, J = 6.8 Hz, 3 H), 0.75 (s, 3 H); mass spectrum, *m/z* (relative intensity): 470 (44, M^+), 455 (12), 438 (17), 415 (23), 283 (63), 57 (100). Anal. calcd. for $C_{31}H_{50}O_3$: C 79.10; H 10.71; found: C 78.86, H 10.63.

3β,5α,6β,22*R*)-6-Methoxy-23-methyl-3,5-cyclo-25,26,27-trinorcholest-23-en-22-ol (10) and its (22*S*) isomer

Aldehyde **2b** (1.5 g, 4.4 mmol) in 15 mL of dry THF was added over 45 min to a solution of 2-propenyllithium (6.5 mL of a 0.87 M solution in ether, 5.6 mmol) at −78°C. The reaction was quenched after 2 h and 15 min with aqueous NH_4Cl. The mixture was diluted with ether and the aqueous layer was extracted once with ether. The combined ether extracts were washed with aqueous $NaHCO_3$, dried (Na_2SO_4), and evaporated under vacuum. The products were separated by flash chromatography (elution with 0–10% ethyl acetate – hexanes) to afford 1.15 g (68%) of the less polar 22*R* allylic alcohol **10** and 486 mg (29%) of the more polar 22*S* epimer. The 22*R* isomer had R_f 0.59 (20% ethyl acetate – hexanes); mp 100–102.5°C (from hexanes); IR (KBr): 3468, 1650, 1642, 1077, 968, 896 cm^{-1}; ^1H NMR (200 MHz) δ: 4.99 (m, 1 H), 4.93 (m, 1 H), 4.11 (m, 1 H), 3.34 (s, 3 H), 2.78 (m, 1 H), 1.67 (s, 3 H), 1.03 (s, 3 H), 0.81 (d, J = 6.2 Hz, 3 H), 0.75 (s, 3 H); mass spectrum, *m/z* (relative intensity): 386 (13, M^+), 371 (10), 354 (12), 331 (22), 283 (100). Anal. calcd. for $C_{26}H_{42}O_2$: C 80.77, H 10.95; found: C 80.93, H 10.90.

The 22*S* isomer had R_f 0.41 (20% ethyl acetate – hexanes); mp 105–107°C (from hexanes); IR (KBr): 3474, 1643, 1098, 1016, 970, 897, 756 cm^{-1}; ^1H NMR (200 MHz) δ: 4.93 (m, 1 H), 4.91 (m, 1 H), 4.13 (d, J = 3.9 Hz, 1 H), 3.33 (s, 3 H), 2.78 (t, J = 2.7 Hz, 1 H), 1.78 (s, 3 H), 1.03 (s, 3 H), 0.96 (d, J = 6.9 Hz, 3 H), 0.77 (s, 3 H); mass spectrum, *m/z* (relative intensity): 386 (14, M^+), 371 (13), 354 (10), 331 (26), 283 (100). Anal. calcd. for $C_{26}H_{42}O_2$: C 80.77, H 10.95; found: C 80.58, H 11.08.

3β,5α,6β,22*S*,23*Z*)-6-Methoxy-3,5-cyclo-26,27-dinorcholest-23-en-22-ol (11) and its (22*R*) isomer

Aldehyde **2b** (200 mg, 0.581 mmol) in 1 mL of dry THF was added to a solution of (*E*)-1-propenylmagnesium bromide (2.0 mL of a 1.2 M solution in THF, 2.3 mmol) at −78°C. The reaction was worked up after 2 h and the product was purified as in the preparation of **6**, to afford 176 mg (78%) of the 22*S* isomer **11** and 36 mg (16%) of the 22*R* isomer. The 22*S* isomer **11** had R_f 0.53 (20% ethyl acetate – hexanes); mp 135–137°C (from acetone-methanol) (lit. (32) mp 136.5–137.5°C). The 22*R* isomer was a solid foam that had: R_f 0.17 (20% ethyl acetate – hexanes). The spectra of both epimers were in good agreement with those reported in the literature (32).

3β,5α,6β,22*R*)-6-Methoxy-3,5-cyclo-26,27-dinorergost-23-en-22-ol (12) and its (22*S*) isomer

Aldehyde **2b** (205 mg, 0.60 mmol) in 3 mL of dry THF was added to a solution of 2-methyl-1-propenyllithium (4.4 mL of a 0.26 M solution in ether, 1.2 mmol) at −78°C over 5 min. The mixture was stirred for 8 h and then was worked up and purified as in the preparation of **6**, providing 46 mg (23%) of starting material **2b**, 136 mg (57%) of the 22*R* isomer **12** and 45 mg (19%) of the 22*S* isomer. The 22*R* isomer **12** was a solid foam that had R_f 0.51 (20% ethyl acetate – hexanes); IR (KBr): 3461, 1098, 968 cm^{-1}; ^1H NMR (200 MHz) δ: 5.33 (br d, J = 8.1 Hz, 1 H), 4.45 (d, J = 8.1 Hz, 1 H), 3.33 (s, 3 H), 2.78 (t, J = 2.5 Hz, 1 H), 1.72 (s, 3 H), 1.66 (d, J = 0.8 Hz, 3 H), 1.02 (s, 3 H), 0.96 (d, J = 6.0 Hz, 3 H), 0.72 (s, 3 H); ^{13}C NMR (50.3 MHz) δ: 133.6 (C), 127.3 (CH), 82.4 (CH), 70.6 (CH), 56.5 (CH), 56.4 (CH_3), 52.7 (CH), 48.0 (CH), 43.4 (C), 42.8 (C), 41.9 (CH), 40.2 (CH_2), 35.3 (C), 35.1 (CH_2), 33.4 (CH_2), 30.6 (CH), 27.9 (CH_2), 25.9 (CH_3), 25.0 (CH_2), 24.2 (CH_2), 22.8 (CH_2), 21.5 (CH), 19.3 (CH_3), 18.2 (CH_3), 13.1 (CH_2), 12.3 (CH_3), 12.1 (CH_3); mass spectrum, *m/z* (relative intensity): 400 (2, M^+), 385 (3), 368 (3), 350 (7), 284 (55), 253 (56), 85 (100). Exact Mass calcd. for $C_{27}H_{44}O_2$: 400.3341; found: 400.3336. The ^1H NMR spectrum was in agreement with a literature spectrum of the 22*R* isomer prepared by a different method (33).

The 22*S* isomer had R_f 0.35 (20% ethyl acetate – hexanes); mp 138–142°C (from hexanes); IR (KBr): 3347, 1673, 1098, 1015, 986, 970 cm^{-1}; ^1H NMR (200 MHz) δ: 5.27 (br d, J = 9.6 Hz, 1 H), 4.41 (dd, J = 9.6, 3.7 Hz, 1 H), 3.33 (s, 3 H), 2.77 (t, J = 2.6 Hz, 1 H), 1.76 (d, J = 1.1 Hz, 3 H), 1.74 (d, J = 1.2 Hz, 3 H), 1.03 (s, 3 H), 1.01 (d, J = 6.3 Hz, 3 H), 0.75 (s, 3 H); mass spectrum, *m/z* (relative intensity): 400 (1, M^+), 382 (11), 367 (8), 350 (24), 335 (14), 327 (15), 253 (100). Anal. calcd. for $C_{27}H_{44}O_2$: C 80.94, H 11.07; found: C 80.71, H 11.11.

Epoxidation of allylic alcohol 6 with MCPBA — typical procedure

Allylic alcohol **6** (61 mg, 0.16 mmol) was treated with MCPBA (169 mg of 50%, 0.49 mmol) in 1 mL of dichloromethane for 2 h. After dilution with dichloromethane, the mixture was washed several times with K_2CO_3 solution and dried ($MgSO_4$). The volatile material was removed in vacuo and the residue was purified by flash chromatography (elution with 10% ether – hexanes) to afford 63 mg (100%) of an unseparated mixture of *threo-* and *erythro* epoxides **17** in the ratio of 36:64 as determined by ^1H NMR integration of their H-22 signals at δ 3.62 and 3.92, respectively. The signal from the *erythro* epoxide **17** was assigned by comparing the spectrum of the above mixture with the spectrum of the pure *erythro* diastereomer prepared by the vanadium-catalyzed procedure (see below). The diastereomers were separated by means of preparative TLC (50% ether – hexanes) of their corresponding benzoates.

The *erythro* benzoate had R_f 0.51 (50% ether – hexanes); mp 80–82°C (from ethyl acetate – methanol); IR (Nujol): 1719, 1268, 1098, 710 cm^{-1}; ^1H NMR (400 MHz) δ: 8.04 (dd, J = 8.3, 1.1 Hz, 2 H), 7.58 (t, J = 7.5 Hz, 1 H), 7.48 (dd, J = 7.7, 7.7 Hz, 2 H), 5.04 (dd, J = 5.7, 1.4 Hz, 1 H), 3.31 (s, 3 H), 3.11 (m, 1 H), 2.87 (dd, J = 5.3, 2.6 Hz, 1 H), 2.83 (dd, J = 5.3, 3.8 Hz, 1 H), 2.75 (t, J = 2.7 Hz, 1 H), 1.26 (d, J = 6.8 Hz, 3 H), 1.02 (s, 3 H), 0.79 (s, 3 H); ^{13}C NMR (50.3 MHz) δ: 165.7 (C═O), 133.1 (CH), 130.1 (C), 129.6 (CH), 128.4 (CH), 82.3 (CH), 75.2 (CH), 56.5 (CH), 56.3 (CH_3), 52.4 (CH), 51.0 (CH), 47.9 (CH), 46.7 (CH_2), 43.3 (C), 42.7 (C), 40.2 (CH_2), 38.1 (CH), 35.3 (C), 34.8 (CH_2), 33.3 (CH_2), 30.5 (CH), 28.0 (CH_2), 24.9 (CH_2), 24.0 (CH_2), 22.8 (CH_2), 21.5 (CH), 19.3 (CH_3), 13.6 (CH_3), 13.0 (CH_2), 12.1 (CH_3); mass spectrum, *m/z* (relative intensity): 492 (12, M^+), 477 (11), 460 (15), 437 (19), 105 (100). Exact Mass calcd. for $C_{32}H_{44}O_4$: 492.3240; found: 492.3226.

The *threo* benzoate had R_f 0.43 (50% ether – hexanes); mp 132–133°C (from hexanes–methanol); IR (Nujol): 1723, 1602, 1584, 1267, 1098, 757, 709 cm^{-1}; ^1H NMR (400 MHz) δ: 8.08 (dd, J = 8.2, 1.1 Hz, 2 H), 7.58 (t, J = 7.5 Hz, 1 H), 7.47 (dd, J = 7.8, 7.6 Hz, 2 H), 5.07 (m, 1 H), 3.32 (s, 3 H), 3.24 (m, 1 H), 2.82 (dd, J = 4.5, 4.5 Hz, 1 H), 2.75 (t, J = 2.6 Hz, 1 H), 2.61 (dd, J = 4.8, 2.7 Hz, 1 H), 1.27 (d, J = 6.8 Hz, 3 H), 1.02

(s, 3 H), 0.78 (s, 3 H); mass spectrum, *m/z* (relative intensity): 492 (6, M^+), 477 (7), 460 (7), 437 (12), 205 (53), 105 (100). Anal. calcd. for $C_{32}H_{44}O_4$: C 78.01, H 9.00; found: C 77.63, H 8.76.

Epoxidation of allylic alcohol 6 with vanadyl acetylacetonate and *tert*-butyl hydroperoxide — typical procedure

Allylic alcohol **6** (48 mg, 0.13 mmol) and $VO(acac)_2$ (0.4 mg, 0.001 mmol) were dissolved in 5 mL of toluene followed by the addition of *tert*-butyl hydroperoxide (0.50 mL of a 90% solution). After 12 h at room temperature the mixture was filtered through Celite and evaporated in vacuo. Flash chromatography (elution with 10% ether – hexanes) of the crude material afforded 47 mg (93%) of **17** with a *threo*:*erythro* ratio of <5:95 as determined by ^{1}H NMR integration. Epoxide **17** was isolated as a pure diastereomer after recrystallization from ether, mp 128–130°C; R_f 0.52 (50% ether-hexanes); IR (KBr): 3474, 1093, 1085 cm^{-1}; ^{1}H NMR (200 MHz) δ: 3.92 (br s, 1 H, 22-H), 3.33 (s, 3 H,), 2.97–2.88 (m, 2 H), 2.83–2.76 (m, 2 H), 1.03 (s, 3 H), 0.98 (d, J = 6.5 Hz, 3 H), 0.75 (s, 3 H); mass spectrum, *m/z* (relative intensity): 388 (44, M^+), 373 (60), 356 (73), 333 (100). Anal. calcd for $C_{25}H_{40}O_3$: C 77.27, H 10.37; found: C 76.87, H 10.34.

Epoxidation of allylic alcohol 6 with molybdenum hexacarbonyl and *tert*-butyl hydroperoxide — typical procedure

tert-Butyl hydroperoxide (0.5 mL of 90%) was added to a mixture of **6** (47.7 mg, 0.13 mmol) and $Mo(CO)_6$ (0.4 mg, 0.001 mmol) in benzene at 60°C. The reaction mixture was filtered through Celite after 8 h and the solvent was removed in vacuo. Purification of the crude product by flash chromatography (elution with 10% ether – hexanes) afforded 29 mg (58%) of the mixture of *threo*- and *erythro* epoxides **17** in the ratio of 26:74, as determined by ^{1}H NMR integration.

Epoxidation of compounds 7–12

These epoxidations were performed by the same procedures as described above for **6**. The yields and ratios of diastereomers are shown in Table 1, and the properties of the products are given below.

Threo *and* erythro *epoxides* ***18***

These compounds were reported previously (6).

Threo *and* erythro *epoxides* ***19***

The mixture of diastereomers had R_f 0.50 (7% ethyl acetate – hexanes); ^{1}H NMR (200 MHz) δ: (*threo* isomer): 3.33 (s, 3 H), 3.14 (br d, J = 6.9 Hz, 1 H), 2.79–2.73 (m, 3 H), 1.32 (d, J = 5.2 Hz, 3 H), 1.03 (s, 3 H), 0.98 (d, J = 6.5 Hz, 3 H), 0.92 (s, 9 H), 0.73 (s, 3 H), 0.051 (s, 3 H), 0.046 (s, 3 H). Signals from the major *erythro* isomer were identified by comparison with those of an authentic sample prepared by silylation of pure *erythro*-**18**. *Erythro*-**19**: R_f 0.50 (7% ethyl acetate – hexanes); mp 175–179°C (from ether–ethanol); IR (KBr): 1248, 1132, 1099, 1084, 836, 773 cm^{-1}; ^{1}H NMR (200 MHz) δ: 3.48 (m, 1 H), 3.33 (s, 3 H), 2.90 (dq, J = 5.2, 2.2 Hz, 1 H), 2.78 (t, J = 2.7 Hz, 1 H), 2.61 (dd, J = 5.4, 2.1 Hz, 1 H), 1.32 (d, J = 5.2 Hz, 3 H), 1.03 (s, 3 H), 0.98 (d, J = 6.5 Hz, 3 H), 0.90 (s, 9 H) 0.75 (s, 3 H), 0.055 (s, 3 H), 0.049 (s, 3 H); mass spectrum, *m/z* (relative intensity): 459 (4, M^+ – *t*-Bu), 427 (11), 335 (12), 283 (25), 253 (60), 73 (100). Anal. calcd. for $C_{32}H_{56}O_3Si$: C 74.36, H 10.92; found: C 74.17, H 11.03.

Threo *and* erythro *epoxides* ***20***

The mixture of diastereomers had R_f 0.43 (50% ether – hexanes); ^{1}H NMR (200 MHz) δ: (*threo* isomer) 4.81–4.78 (m, 1 H), 3.33 (s, 3 H), 2.85–2.79 (m, 3 H), 1.32 (d, J = 4.8 Hz, 3 H), 1.25 (s, 9 H), 1.13 (d, J = 6.9 Hz, 3 H), 1.03 (s, 3 H), 0.75 (s, 3 H). Signals from the major *erythro* isomer in the mixture were identified by comparison with those of an authentic sample prepared by treatment of pure *erythro*-**18** with pivaloyl chloride in refluxing pyridine in the presence of 4-dimethylaminopyridine. *Erythro* epoxide **20**: R_f 0.43 (50% ether – hexanes); mp 166–168°C (from ether); IR (KBr): 1731, 1162, 1154, 1096, 1081 cm^{-1}; ^{1}H NMR (200 MHz) δ: 4.79 (dd, J = 5.3, 1.3 Hz, 1 H), 3.32 (s, 3 H), 3.02 (dq, J = 5.2, 2.1 Hz, 1 H), 2.77 (t, J = 2.6 Hz, 1 H), 2.67 (dd, J = 5.3, 2.1 Hz, 1 H), 1.30 (d, J = 5.2 Hz, 3 H), 1.22 (s, 9 H), 1.10 (d, J = 6.8 Hz, 3 H), 1.03 (s, 3 H), 0.75 (s, 3 H); ^{13}C NMR (100.6 MHz) δ: 177.6 (C=O), 82.3 (CH), 73.8 (CH), 58.2 (CH), 56.5 (CH), 56.5 (CH_3), 53.7 (CH), 52.4 (CH), 47.9 (CH), 43.3 (C), 42.6 (C), 40.3 (CH_2), 39.1 (C), 37.8 (CH), 35.3 (C), 34.8 (CH_2), 33.3 (CH_2), 30.5 (CH), 28.0 (CH_2), 27.2 (CH_3), 24.9 (CH_2), 24.0 (CH_2), 22.7 (CH_2), 21.5 (CH), 19.2 (CH_3), 17.2 (CH_3), 13.4 (CH_3), 13.0 (CH_2), 12.0 (CH_3); mass spectrum, *m/z* (relative intensity): 486 (26, M^+), 471 (35), 454 (33), 431 (100). (3β,5α,6β,22*R*,23*S*)-6-Methoxy-3,5-cyclocholestane-22,23-diol (24)

Isopropylmagnesium chloride (10.2 mmol) in ether was added to a suspension of cuprous cyanide (92 mg, 1.0 mmol) in 10 mL of dry ether at −78°C. After 1 h, the *erythro*-epoxide **17** (794 mg, 2.04 mmol) in 15 mL of dry ether was added dropwise. The mixture was stirred for 15 min at −78°C and 1 h at room temperature. Aqueous NH_4Cl and ether were added and the aqueous layer was extracted once with ether. The combined ether extracts were washed with $NaHCO_3$ and NaCl solutions, dried ($MgSO_4$), and evaporated to dryness under vacuum. The crude product was purified by flash chromatography (elution with 10% ethyl acetate – hexanes) to afford 706 mg (80%) of diol **24**: R_f 0.27 (20% ethyl acetate – hexanes); mp 95–97°C (from hexanes); IR (KBr): 3423, 1099, 966, 759 cm^{-1}; ^1H NMR (200 MHz) δ: 3.72–3.60 (m, 1 H), 3.44–3.38 (m, 1 H), 3.33 (s, 3 H), 2.78 (t, J = 2.7 Hz, 1 H), 1.02 (d, J = 6.7 Hz, 6 H), 0.97 (s, 3 H), 0.94 (d, J = 7.1 Hz, 3 H), 0.77 (s, 3 H); mass spectrum, *m/z* (relative intensity): 432 (18, M^+) 417 (17), 400 (20), 377 (33), 313 (46), 283 (37), 43 (100). Anal. calcd. for $C_{28}H_{48}O_3$: C 77.73, H 11.18; found: C 77.34, H 10.76.

3β,5α,6β,22*Z*)-6-Methoxy-3,5-cyclocholest-22-ene (25)

Diol **24** (154 mg, 0.36 mmol) and 1,1′-thiocarbonyldiimidazole (71 mg, 0.39 mmol) were refluxed in 10 mL of dry toluene for 48 h. The mixture was diluted with ether, washed several times with water, and dried ($MgSO_4$). After removal of the volatile material under vacuum, the residue was flash chromatographed on neutral alumina (elution with 5% ethyl acetate – hexanes) to afford 122 mg (72%) of (3β,5α,6β,22*R*, 23*S*)-6-methoxy-3,5-cyclocholestane-22,23-thionocarbonate as a solid foam: R_f 0.55 (50% ether-hexanes); IR (KBr): 1287, 1098, 947, 933 cm^{-1}; ^1H NMR (400 MHz) δ: 4.92–4.89 (m, 2 H), 3.33 (s, 3 H), 2.79 (t, J = 2.7 Hz, 1 H); 1.07 (d, J = 6.4 Hz, 3 H), 1.03 (s, 3 H), 1.02 (d, J = 7.5 Hz, 3 H), 0.98 (d, J = 6.5 Hz, 3 H), 0.74 (s, 3 H); ^{13}C NMR (100.6 MHz) δ: 192.4 (C═O), 86.7 (CH), 83.6 (CH), 82.3 (CH), 56.6 (CH_3), 56.2 (CH), 52.1 (CH), 47.8 (CH), 43.3 (C), 42.8 (C), 39.9 (CH_2), 37.3 (CH), 36.2 (CH_2), 35.1 (C), 35.0 (CH_2), 33.3 (CH_2), 30.6 (CH), 28.4 (CH_2), 25.6 (CH), 24.9 (CH_2), 24.1 (CH_2), 23.2 (CH_3), 22.7 (CH_2), 21.7 (CH_3), 21.4 (CH), 19.2 (CH_3), 13.8 (CH_3), 13.1 (CH_2), 12.0 (CH_3); mass spectrum, *m/z* (relative intensity): 474 (58, M^+), 459 (53), 442 (74), 419 (96), 253 (81), 55 (100). Exact Mass calcd. for $C_{29}H_{46}O_3S$: 474.3168; found: 474.3149. The thionocarbonate was refluxed in 1.5 mL of trimethylphosphite for 96 h. It was then extracted several times with chloroform and the chloroform extracts were washed several times with 4% NaOCl solution. The remaining volatile material was removed in vacuo and the residue was purified by flash chromatography (elution with 10% benzene – hexanes) to afford 15 mg (54%) of olefin **25**, which furnished an ^1H NMR spectrum in close agreement with that reported in the literature (18).

3β,5α,6β,22*R*,23*S*)-6-Methoxy-3,5-cyclo-26,27-dinorcholestane-22,23-diol (26)

Erythro-epoxide **18** (108 mg, 0.268 mmol) and titanium(IV) isopropoxide (136 μL, 0.457 mmol) were dissolved in 5 mL of dry benzene and after 5 min lithium borohydride (23 mg 1.1 mmol) was added. The mixture stirred for 18 h at 50°C and then 5% H_2SO_4 solution and ether were added. After 20 min, the layers were separated and the aqueous layer was extracted once with ether. The combined ether extracts were washed with aqueous $NaHCO_3$, dried (Na_2SO_4), concentrated in vacuo, and purified by flash chromatography (elution with 5–10% ethyl acetate – hexanes) to give 60 mg (55%) of diol **26**: R_f 0.17 (20% ethyl acetate – hexanes); mp 156.5–161°C (from acetonitrile); IR (KBr): 3417, 1261, 1098, 1082, 969 cm^{-1}; ^1H NMR (400 MHz) δ: 3.52–3.44 (m, 2 H), 3.33 (s, 3 H), 2.78 (t, J = 2.7 Hz, 1 H), 1.03 (s, 3 H), 1.02 (t, J = 5.7 Hz, 3 H), 0.97 (d, J = 6.7 Hz, 3 H), 0.77 (s, 3 H); ^{13}C NMR (100.6 MHz) δ: 82.4 (CH), 75.7 (CH), 73.4 (CH), 56.6 (CH_3), 56.5 (CH), 52.7 (CH), 48.0 (CH), 43.4 (C), 42.8 (C), 40.3 (CH_2), 36.2 (CH), 35.3 (C), 35.0 (CH_2), 33.4 (CH_2), 30.6 (CH), 27.9 (CH_2), 27.0 (CH_2), 25.0 (CH_2), 24.1 (CH_2), 22.8 (CH_2), 21.5 (CH), 19.3 (CH_3), 13.1 (CH_2), 12.2 (CH_3), 12.0 (CH_3), 9.9 (CH_3); mass spectrum, *m/z* (relative intensity): 404 (29, M^+), 389 (34), 372 (32), 349 (62), 312 (66), 289 (100). Exact Mass calcd. for $C_{26}H_{44}O_3$: 404.3290; found: 404.3327.

The same diol **26** was obtained in 84% yield by the similar treatment of *erythro* epoxide **22**.

3β,5α,6β,22*R*,23*R*)-6-Methoxy-3,5-cyclo-26,27-dinorcholestane-22,23-diol (27)

threo Epoxide **22** (101 mg, 0.251 mmol) was treated with titanium(IV) isopropoxide (120 μL, 0.40 mmol) and lithium borohyride (23 mg, 1.1 mmol) as in the preceding procedure, except that the reaction was performed at room temperature for 24 h, to afford 25 mg (25%) of starting material **22** and 51 mg (50%) of diol **27** as a solid foam: R_f 0.12 (20% ethyl acetate – hexanes); IR (KBr): 3392, 1268, 1203, 1099, 1083, 969, 804, 756 cm^{-1}; ^1H NMR (200 MHz) δ: 3.49 (dt, J = 8.0, 2.9 Hz, 1 H), 3.44 (d, J = 8.3 Hz, 1 H), 3.33 (s, 3 H), 2.78 (t, J = 2.7 Hz, 1 H), 1.03 (s, 3 H), 1.00 (t, J = 7.5 Hz, 3 H), 0.91 (d, J = 6.1

Hz, 3 H), 0.73 (s, 3 H); ^{13}C NMR (50.3 MHz) δ: 82.4 (CH), 76.5 (CH), 74.3 (CH), 56.6 (CH_3), 56.4 (CH), 52.5 (CH), 48.0 (CH), 43.3 (C), 42.6 (C), 40.3 (CH_2), 37.3 (CH), 35.2 (C), 35.1 (CH_2), 33.3 (CH_2), 30.6 (CH), 27.9 (CH_2), 25.7 (CH_2), 24.9 (CH_2), 24.0 (CH_2), 22.8 (CH_2), 21.4 (CH), 19.3 (CH_3), 13.1 (CH_2), 12.1 (2 X CH_3), 9.6 (CH_3); mass spectrum *m/z* (relative intensity): 404 (45, M^+), 389 (55), 372 (48), 349 (100). Exact Mass calcd. for $C_{26}H_{44}O_3$: 404.3290; found: 404.3252.

3β,5α,6β,22*R*,23*S*)-6-Methoxy-3,5-cyclo-23-methyl-24-(2,4,6-trimethylphenylseleno)-25,26,27-trinorcholestane-22,23-diol (28)

Sodium borohydride (25 mg, 0.66 mmol) was slowly added to a solution of *erythro* epoxide **21** (88 mg, 0.22 mmol) and di-(2,4,6-trimethylphenyl) diselenide (47 mg, 0.12 mmol) in 8 mL of ethanol. After 6 h, the mixture was diluted with water, extracted several times with ether, and dried (K_2CO_3). The volatile material was removed in vacuo and the residue was purified by flash chromatography (elution with 10% ether – hexanes) to afford 105 mg (80%) of diol **28**: R_f 0.38 (20% ethyl acetate – hexanes); mp 153–155°C (from acetonitrile); IR (KBr): 3575, 3484, 1205, 1095, 1080, 850, 792 cm^{-1}; ^{1}H NMR (400 MHz) δ: 6.94 (s, 2 H), 3.59 (d, *J* = 6.2 Hz, 1 H), 3.34 (s, 3 H), 3.04 (d, *J* = 11.5 Hz, 1 H), 2.85 (d, *J* = 11.5 Hz, 1 H), 2.78 (t, *J* = 2.7 Hz, 1 H), 2.60 (s, 1 H, exchanged with D_2O), 2.56 (s, 6 H), 2.27 (s, 3 H), 2.08 (d, *J* = 6.2 Hz, 1 H), 1.30 (s, 3 H), 1.03 (s, 3 H), 0.99 (d, *J* = 6.7 Hz, 3 H), 0.75 (s, 3 H); mass spectrum, *m/z* (relative intensity): 602 (6, M^+, ^{80}Se), 584 (4), 384 (10), 352 (16), 329 (43), 289 (49), 200 (78), 119 (100). Anal. calcd. for $C_{35}H_{54}O_3Se$: C 69.86, H 9.04; found: C 69.78, H 8.91.

3β,5α,6β,22*E*)-6-Methoxy-3,5-cyclo-23-methyl-24-(2,4,6-trimethylphenylseleno)-25,26,27-trinorcholest-22-ene (29)

n-Butyllithium in hexanes (0.25 mmol) was added dropwise to a solution of **28** (83 mg, 0.14 mmol) in 6 mL of dry THF. After 5 min, 1,1′-thiocarbonyldiimidazole (43 mg, 0.24 mmol) was added and the mixture was refluxed for 4 h. It was quenched with aqueous NH_4Cl and extracted several times with ether. The ether layers were washed with water, dried (Na_2SO_4), concentrated in vacuo, and purified by flash chromatography (elution with 10% ether – hexanes) to give 70 mg (80%) of 3β,5α,6β,22*R*,23*R*)-6-methoxy-3,5-cyclo-23-methyl-24-(2,4,6-trimethylphenylseleno)-25,26,27-trinorcholestane-22,23-thionocarbonate: R_f 0.63 (50% ether – hexanes); mp 164.5–165.5°C (from ethanol); IR (KBr): 1597, 1313, 1272, 1156, 1098, 1086 cm^{-1}; ^{1}H NMR (200 MHz) δ: 6.95 (s, 2 H), 4.64 (s, 1 H), 3.34 (s, 3 H), 3.06 (br s, 2 H), 2.79 (m, 1 H), 2.56 (s, 6 H), 2.28 (s, 3 H), 1.62 (s, 3 H), 1.04 (d, *J* = 7.4 Hz, 3 H), 1.03 (s, 3 H), 0.70 (s, 3 H); ^{13}C-NMR (100.6 MHz) δ: 191.1 (C=O), 142.4 (C), 139.0 (C), 129.0 (CH), 127.2 (C), 91.23 (C), 91.15 (CH), 82.3 (CH), 56.6 (CH_3), 56.3 (CH), 52.5 (CH), 47.7 (CH), 43.3 (C), 42.8 (C), 39.9 (CH_2), 37.9 (CH), 35.1 (CH_2), 35.0 (C), 33.3 (CH_2), 30.5 (CH), 29.4 (CH_2), 28.3 (CH_2), 26.2 (CH_3), 24.9 (CH_2), 24.3 (2 × CH_3), 24.1 (CH_2), 22.7 (CH_2), 21.4 (CH), 20.9 (CH_3), 19.2 (CH_3), 13.5 (CH_3), 13.1 (CH_2), 11.9 (CH_3); mass spectrum, *m/z* (relative intensity): 644 (1, M^+, ^{80}Se), 628 (3), 596 (4), 369 (15), 337 (16), 283 (28), 197 (52), 119 (100). The thionocarbonate (30 mg, 0.046 mmol) was refluxed in 5 mL of trimethylphosphite for 72 h. The mixture was diluted with chloroform and washed several times with water. The chloroform layer was left under a stream of nitrogen for 14 h to remove traces of trimethylphosphite. After evaporation of the remaining solvent in vacuo the residue was purified by flash chromatography (elution with 5% ethyl acetate – hexanes) to afford 16 mg (61%) of olefin **29** as an oil: R_f 0.49 (7% ethyl acetate – hexanes); IR (KBr): 1098, 1016, 849 cm^{-1}; ^{1}H NMR (200 MHz) δ: 6.93 (s, 2 H), 4.97 (d, *J* = 9.8 Hz, 1 H), 3.40 (d, *J* = 10.7 Hz, 1 H), 3.34 (s, 3 H), 3.27 (d, *J* = 10.7 Hz, 1 H), 2.77 (m, 1 H), 2.58 (s, 6 H), 2.26 (s, 3 H) superimposed on 2.26–2.15 (m, 1 H), 1.82 (d, *J* = 1.2 Hz, 3 H), 1.03 (s, 3 H), 0.79 (d, *J* = 6.5 Hz, 3 H), 0.69 (s, 3 H); irradiation of the peak at δ: 4.97 (H-22) produced a 3.3% enhancement of the signal at δ: 1.82 (olefinic CH_3) and vice versa (3.4% enhancement); ^{13}C NMR (100.6 MHz) δ: 143.3 (C), 138.1 (C), 135.5 (CH), 128.5 (C), 128.41 (C), 128.36 (CH), 82.4 (CH), 56.6 (CH_3), 56.5 (CH), 56.4 (CH), 48.1 (CH), 43.4 (C), 42.7 (C), 40.2 (CH_2), 35.4 (C), 35.2 (CH), 34.9 (CH_2), 33.4 (CH_2), 30.5 (CH), 29.8 (CH_2), 28.0 (CH_2), 25.0 (CH_2), 24.5 (CH_3), 24.2 (CH_2), 23.2 (CH_3), 22.8 (CH_2), 21.6 (CH), 20.9 (CH_3), 20.6 (CH_3), 19.3 CH_3), 13.0 (CH_2), 12.5 (CH_3); mass spectrum, *m/z* (relative intensity): 568 (5, M^+, ^{80}Se), 536 (9), 337 (94), 253 (57), 119 (100). Exact Mass calcd. for $C_{35}H_{52}OSe$: 568.3190; found: 568.3228.

3β,5α,6β,22*R*,23*R*)-6-Methoxy-3,5-cyclo-26,27-dinorergostane-22,23-diol (30)

The *threo* epoxide **23** (119 mg, 0.29 mmol) was treated with titanium(IV) isopropoxide (145 μL, 0.486 mmol) and lithium borohydride (25 mg 1.1 mmol) according to the procedure for the conversion of *erythro*-**18** or *erythro*-**22** into diol **26**, except that the crude product was purified using radial chromatography (elution with 30% ether – hexanes) to give 91 mg (76%) of diol **30**: R_f 0.46 (20% ethyl acetate – hexanes); IR (KBr): 3417, 1099, 998, 757 cm^{-1}; ^{1}H NMR (200 MHz) δ: 3.56 (d, *J* = 8.0 Hz, 1 H), 3.49 (s, 1 H, exchanged with D_2O), 3.42 (dd, *J* = 7.8, 2.6 Hz, 1 H), 3.33 (s, 3 H), 2.78 (t, *J* = 2.8 Hz, 1 H), 2.04 (br s, 1 H, exchanged with D_2O), 1.03 (s, 3 H), 1.02 (d, *J* = 5.3 Hz, 3 H), 0.92 (d, *J* = 6.2 Hz, 3 H), 0.87 (d, *J* = 6.8 Hz, 3 H), 0.74 (s, 3 H); ^{13}C NMR (100.6 MHz) δ: 82.4 (CH), 77.0 (CH), 74.3 (CH), 56.6 (CH_3), 56.4 (CH), 52.6 (CH), 48.0 (CH), 43.4 (C), 42.6 (C), 40.3 (CH_2), 37.6 (CH), 35.2 (C), 35.1 (CH_2), 33.4 (CH_2), 30.6 (CH), 29.2 (CH), 27.9 (CH_2), 24.9 (CH_2), 24.1 (CH_2), 22.8 (CH_2), 21.5 (CH), 20.3 (CH_3), 19.3 (CH_3), 14.7 (CH_3), 13.1 (CH_2), 12.2 (2 × CH_3); mass spectrum, *m/z* (relative intensity): 418 (30, M^+), 403 (31), 386 (24), 363 (59), 289 (75), 41 (100). Exact Mass calcd. for $C_{27}H_{46}O_3$: 418.3447; found: 418.3419.

(3β,22*R*,23*R*)-26,27-dinorergost-5-ene-3,22,23-triol (31)

Diol **30** (7.4 mg, 0.018 mmol) and *p*-toluenesulfonic acid (0.283 mL of a 0.0125 M solution in 1,4 dioxane, 0.0354 mmol) were heated in 1 mL of 1,4-dioxane:water (5:1) for 4 h at 70°C. The 1,4 dioxane was removed in vacuo and the residue was diluted with ether, washed several times with water, dried ($MgSO_4$), and evaporated under vacuum. The crude material was purified by flash chromatography (elution with 0–10% methanol – chloroform) to give 5 mg (69%) of **31**, which was recrystallized from methanol – ethyl acetate: R_f 0.10 (25% ethyl acetate – benzene); mp 215–217°C (lit. (21) mp 219–221°C); ^{1}H NMR (200 MHz) δ: 5.36 (m, 1 H), 3.59–3.42 (m, 3 H), 2.30–2.23 (m, 2 H), 1.02 (d, *J* = 6.9 Hz, 3 H),

1.02 (s, 3 H) 0.93 (d, $J = 6.2$ Hz, 3 H), 0.87 (d, $J = 6.8$ Hz, 3 H), 0.71 (s, 3 H).

5-Perfluoroalkyldipyrromethanes and porphyrins derived therefrom

Tilak P. Wijesekera

Abstract: Acid-catalyzed condensation of pyrrole and perfluoroalkyl aldehydes produced, in a single step, α,β-unsubstituted 5-perfluoroalkyldipyrromethanes, which were isolated and characterized for the first time. These dipyrromethanes were used as the key intermediates in the synthesis of *trans*-perfluroalkylporphyrins as well as *meso*-tetrakis(perfluoroalkyl)porphyrins. The two-step procedure described here provides access to a wide variety of porphyrins with *trans* perfluoroalkyl groups.

Key words: 5-perfluoroalkyldipyrromethanes, perfluoroalkylporphyrins, electron-deficient porphyrins.

Résumé : La condensation acido-catalysée du pyrrole et des aldéhydes perfluoroalkylés produit en une seule étape les 5-perfluoroalkyldipyrrométhanes non substitués en positions α,β que l'on a isolés et caractérisés pour la première fois. Ces dipyrrométhanes sont utilisés comme intermédiaires clés dans la synthèse des *trans* perfluoroalkylporphyrines et des *méso*-tétrakis(perfluoroalkyl)porphyrines. Le procédé en deux étapes que l'on décrit dans cette publication donne accès à une grande variété de porphyrines avec le groupe perfluoroalkyle en position *trans*.

Mots clés : 5-perfluoroalkyldipyrrométhanes, perfluoroalkylporphyrines, porphyrines pauvres en électrons.

[Traduit par la rédaction]

Introduction

Electron deficiency created at the metal center has been shown to increase the catalytic activity of porphyrinatoiron(III) complexes towards hydroxylation of alkanes by oxygen and other oxidants (1). The electron-withdrawing groups most commonly employed at the *meso* positions are the perhalophenyls, because of the ease of accessibility of *meso*-tetraphenylporphyrins by the direct condensation of pyrrole and the corresponding aldehyde (2), and the ease of functionalization of the β positions of a preformed *meso*-tetraphenylporphyrin (3). However, due to the practical implications of the high cost (and the high mass per iron center) of catalysts carrying perfluorophenyl groups, our attention was directed towards the synthesis of metalloporphyrin systems having perfluoroalkyl groups at the *meso* positions. We report here a general synthetic route to *trans*-perhaloalkylporphyrins (**5**), using the key intermediates, 5-perfluoroalkyldipyrromethanes (**3**), which were prepared and isolated for the first time (4) by the direct condensation of pyrrole and the appropriate perfluoroalkyl aldehyde.

Results and discussion

Although acid-catalyzed co-condensation of pyrrole and an aldehyde produces *meso*-aryl or *meso*-alkyl porphyrins in good yields (5, 6), attempts to prepare *meso*-tetrakis(trifluoromethyl)porphyrin, even under harsher reaction conditions, lead only to very small quantities of porphyrin. However, the reaction of 2 equivalents of pyrrole (**1**) and one equivalent of trifluoroacetaldehyde (**2**, $R^1 = CF_3$; as the methyl or ethyl hemiacetal) in refluxing THF and concentrated HCl (50:1) produced the 5-trifluoromethyldipyrromethane **3***a* in yields up to 70% (see Scheme 1). Reaction times greater than 2–3 h and (or) stronger acid conditions generally led to increased quantities of oxidized and (or) polymerized by-products, but no porphyrin could be detected. Substitution of heptafluorobutyraldehyde (**2**, $R^1 = C_3F_7$; as the hydrate) for trifluoroacetaldehyde in the above condensation reaction gave the corresponding 5-heptafluoropropyldipyrromethane **3***b* in up to 50% yield. The purified dipyrromethanes were found to be stable in the refrigerator for several months.

5-Perfluoroalkyldipyrromethanes **3***a* and **3***b* were co-condensed separately with trifluoroacetaldehyde, heptafluorobutyraldehyde, and pentafluorobenzaldehyde, in $CHCl_3$ under acid conditions, to give, after oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ), the electron-deficient porphyrins **5***a–d*. Of the several acid catalysts that were previously employed for such condensations (7), montmorillonite K10 clay (8) not only gave the best isolated yields of the porphyrins, but also facilitated the purification procedure, since most of the polypyrrolic impurities were adsorbed on the clay. Condensation of the dipyrromethanes with perfluoroalkyl aldehydes **4***b* and **4***c* required longer reaction times (15–20 h) at reflux temperature, and the yields of the porphyrins were lower (5–10%), compared with the condensations with pentafluorobenzaldehyde **4***a*.

The two-step procedure described here provides, for the first time, a general method for the synthesis of porphyrins that carry perfluoroalkyl groups at opposite *meso* positions while the other two *meso* positions may have the same or different perhalocarbyl groups. As such, it differs from the recently published syntheses (9) of *meso*-tetrakis(perfluoroalkyl)porphyrins, where 2-(hydroxymethyl)pyrroles are subjected to tetramerization followed by cyclization. This allows

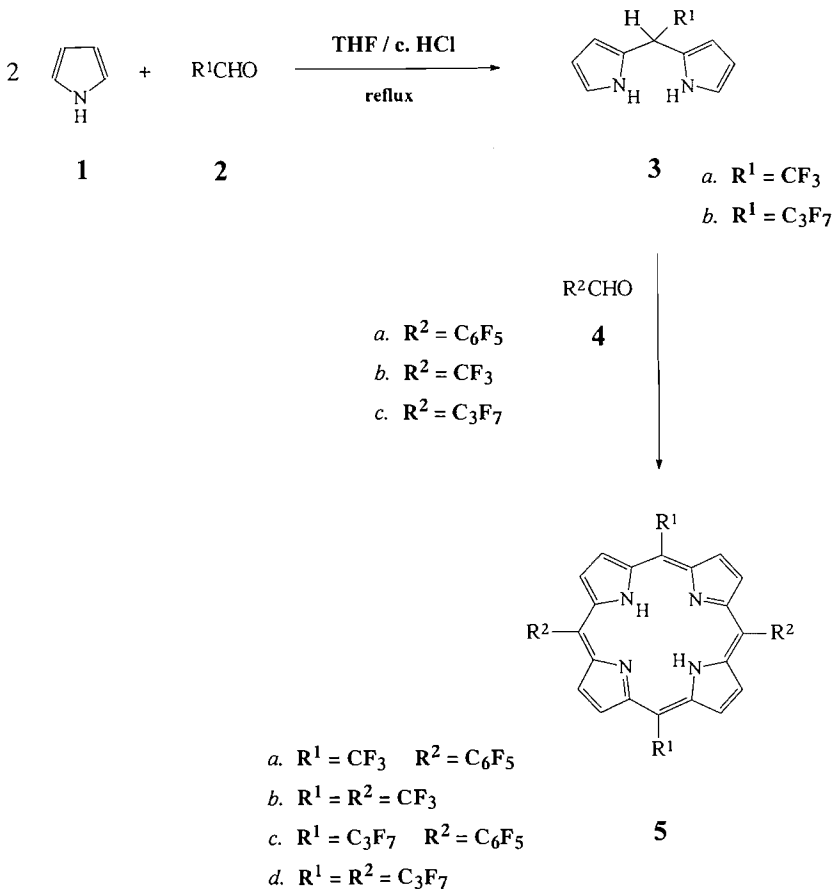
Scheme 1.



us to compare the effect of perhaloalkyl groups on the catalytic activity of porphyrinatoiron(III) systems with that of other electron-withdrawing groups. Iron insertion and β-halogenation of the *meso*-perfluorocarbylporphyrins **5***a–d* were carried out using modifications of literature procedures (2) and the catalytic studies using such complexes have been reported elsewhere (10).

Experimental

Methods and materials

Tetrahydrofuran chloroform and pyrrole were dried and distilled under argon just prior to use. Trifluoroacetaldehyde, methyl hemiacetal, and heptafluorobutyraldehyde hydrate (both technical grade) were purchased from Lancaster Synthesis Inc. and pentafluorobenzaldehyde was purchased from Aldrich Chemical Co. and used without further purification. Column chromatography was carried out on neutral alumina (Fisher A950/60–325 mesh) using the solvents indicated. Absorption spectra of the porphyrins were obtained using a Hewlett–Packard model 8452A diode array spectrophotometer. ^{1}H and ^{19}F NMR spectra were recorded on a Bruker MSL-300 instrument. Fast Atom Bombardment (FAB) high-resolution mass spectral analyses were carried out at the analytical laboratories of M-SCAN Inc. of West Chester, Pennsylvania, using a VG Analytical ZAB 2SE high-field mass spectrometer. Microanalyses were performed at Oneida Research Services Inc. of Whitesboro, New York. Melting points of the new compounds were obtained using a Fisher–Johns hot-stage melting point apparatus, and are uncorrected.

5-Trifluoromethyldipyrromethane (*3a*)

Pyrrole (3.35 g, 50 mmol), trifluoroacetaldehyde methyl hemiacetal (3.58 g, 27.5 mmol), and concentrated hydrochloric acid (2 mL) were refluxed in degassed tetrahydrofuran (100 mL) in an argon atmosphere for 2 h. The reaction mixture was cooled, then neutralized with $NaHCO_3$; the organic layer was diluted with $CHCl_3$ and washed with saturated $NaHCO_3$ and water. The dark orange-colored oil remaining after removal of the solvent was repeatedly extracted with low-boiling petroleum ether to separate the desired dipyrromethane product from the colored impurities. Petroleum ether was removed and the resulting oil was chromatographed on neutral alumina using CH_2Cl_2–hexane (1:1) for elution. The eluate was evaporated to dryness when the pure dipyrromethane solidified. The isolated yields varied between 50 and 70% depending on the purity of the commercially available technical grade trifluoroacetaldehyde methyl hemiacetal, anaerobic conditions of the reaction, and the method and extent of neutralization of the acid catalyst prior to isolation; mp 63–65°C; ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 7.96 (bs, 2H), 6.73 (s, 2H), 6.24 (m, 4H), 4.80 (q, 1H); ^{19}F NMR ($CDCl_3$, 282 MHz) δ (ppm): −68.05 (d). Accurate Mass calcd. for $C_{10}H_9N_2F_3$: 214.0718; found by HRMS (FAB): 214.0712 (ΔM = −2.7 ppm). Anal. calcd. for $C_{10}H_9N_2F_3$: C 56.08, H 4.24, N 13.08; found: C 55.88, H 4.20, N 12.95.

5-Heptafluoropropyldipyrromethane (*3b*)
This was prepared in 35–50% yields by reacting pyrrole and heptafluorobutyraldehyde, hydrate under conditions similar to those described above. Due to the high solubility of colored impurities in petroleum ether, prepurification prior to chromatography was avoided. This resulted in product purities of ~95% (GC) after one filtration through neutral alumina (CH_2Cl_2–hexane 1:1 as the eluent) and was used for the porphyrin syntheses without further purification. Analytical samples were prepared by the slow chromatography of the above material on neutral alumina using CH_2Cl_2–hexane 1:2 as the eluent; mp 64–66°C; ^{1}H NMR ($CDCl_3$, 300 MHz), δ (ppm): 8.12 (bs, 2H), 6.75 (s, 2H), 6.23 (s, 2H), 6.19 (q, 2H), 4.92 (t, 1H); ^{19}F NMR ($CDCl_3$, 282 MHz) δ (ppm): −82.86 (m, 3F), −115.21 (m, 2F), −127.11 (t, 2F). Accurate Mass calcd. for $C_{12}H_9N_2F_7$: 314.0654; found by HRMS (FAB): 314.0651 (ΔM = −0.9 ppm). Anal. calcd. for $C_{12}H_9N_2F_7$: C 45.87, H 2.89, N 8.92; found: C 46.10, H 3.02, N 8.70.

5,15-Bis(pentafluorophenyl)-10,20-bis(trifluoromethyl)porphyrin (*5a*)
Trifluoromethyldipyrromethane (**3***a*; 1.07 g, 5 mmol, in 10 mL $CHCl_3$) and pentafluorobenzaldehyde (**4***a*; 989 mg, 5 mmol, in 10 mL $CHCl_3$) were added to degassed $CHCl_3$ (200 mL) containing activated montmorillonite K-10 (7.5 g) and stirred at room temperature under argon for 24 h. A solution of DDQ (1 g) in benzene (60 mL) was added while gently heating the solution, and heating in air was continued for a further 1 h. The clay was removed by filtration (directly into a solution of DDQ (600 mg) in benzene (20 mL)), and was washed thoroughly with hot $CHCl_3$. The filtrate was refluxed for 90 min, solvent removed, and the residue was redissolved in $CHCl_3$ and chromatographed on neutral alumina using $CHCl_3$ as the eluent. The solution was evaporated to dryness, the residue redissolved in CH_2Cl_2, and the porphyrin crystallized from CH_3OH; yield: 478 mg; 24.1%. UV–VIS, λ_{max} nm (log ε): 406 (5.21), 506 (4.12), 538 (3.95), 586 (3.76), 638 (3.83); ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 9.71 (d, 4H), 8.91 (d, 4H), −2.73 (bs, 2H), ^{19}F NMR ($CDCl_3$, 282 MHz) δ (ppm): −36.12 (s, 6F), −136.17 (dd, 4F), −150.37 (t, 2F), −160.58 (t, 4F). Accurate Mass calcd. for $C_{34}H_{10}N_4F_{16}$: 778.0650; found by HRMS (FAB): 778.0630 (ΔM = −2.6 ppm). Anal. calcd. for $C_{34}H_{10}N_4F_{16}$: C 52.46, H 1.30, N 7.20; found: C 52.23, H 1.43, N 7.12.

5,10,15,20-Tetrakis(trifluoromethyl)porphyrin (*5b*)
Trifluoromethyldipyrromethane (**3***a*; 2.14 g, 10 mmol), trifluoroacetaldehyde methyl hemiacetal (technical grade, 2.2 g, 16.9 mmol), and activated montmorillonite K-10 clay (10 g) were placed in dry degassed $CHCl_3$ (500 mL) and heated at reflux under argon for 20 h. The reaction mixture was allowed to cool, a solution of DDQ (2 g) in benzene (60 mL) was added, and heating at reflux was continued for a further 1 h. The hot solution was filtered to remove the clay, then washed with hot CH_3OH, and more DDQ (1 g in 60 mL benzene) was added and refluxed for a further 12–15 h. The solvents were removed under reduced pressure, the solid was redissolved in a minimum amount of hot $CHCl_3$, and the solution was passed through neutral alumina. The forerunning porphyrin was eluted with $CHCl_3$, the solvent evaporated under reduced pressure, and the product crystallized from CH_2Cl_2–CH_3OH to isolate 165 mg (5.7%). UV–VIS, λ_{max} nm (log ε): 404 (5.08), 510 (3.94), 544 (3.94), 594 (3.63), 648 (3.92); ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 9.61 (s, 8H), −2.09 (bs, 2H); ^{19}F NMR ($CDCl_3$, 282 MHz)) δ (ppm): −40.86 (s; 12F). Accurate Mass calcd. for $C_{24}H_{10}N_4F_{12}$: 582.0714; found by HRMS (FAB): 582.0735 (ΔM = 3.6 ppm). Anal. calcd. for $C_{24}H_{10}N_4F_{12}$: C 49.50, H 1.73, N 9.62; found: C49.47, H 1.79, N 9.64.

5,15-Bis(heptafluoropropyl)-10,20-bis(pentafluorophenyl)porphyrin (*5c*)
This porphyrin was prepared by reacting 5-heptafluoropropyldipyrromethane (**3***b*; 3.14 g, 10 mmol) and pentafluorobenzaldehyde (1.96 g, 10 mmol) in refluxing $CHCl_3$ (400 mL) using activated montmorillonite K10 clay (10 g) as the catalyst. Reaction times of 8–10 h were sufficient and the yields varied between 10 and 15%. UV–VIS, λ_{max} nm (log ε): 406 (5.26), 506 (4.09), 540 (3.98), 584 (3.73), 638 (3.92); ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 9.58 (d, 4H), 8.92 (d, 4H), −2.58 (bs, 2H); ^{19}F NMR ($CDCl_3$, 282 MHz) δ (ppm): −81.22 (br t, 6F), −84.27 (m, 4F), −121.97 (br t, 4F), −138.73 (t, 4F), −153.10 (t, 2F), −163.37 (t, 4F). Accurate Mass calcd. for $C_{38}H_{10}N_4F_{24}$: 978.0522; found by HRMS (FAB): 978.0535 (ΔM = 1.3 ppm). Anal. calcd. for $C_{38}H_{10}N_4F_{24}$: C 46.65, H 1.03, N 5.73; found: C 46.40, H 1.20, N 5.89.

5,10,15,20-Tetrakis(heptafluoropropyl)porphyrin (*5d*)
This porphyrin was prepared by reacting 5-heptafluoropropyldipyrromethane (**3***b*; 1.57 g, 5 mmol) and heptafluorobutyraldehyde, hydrate (technical grade, 1.3 g) in refluxing $CHCl_3$ (200 mL) using activated montmorillonite K10 clay (5 g) as the catalyst, under the conditions described for **5***b*. Purification by chromatography on neutral alumina using CH_2Cl_2–hexane (1:2) as the eluent gave 230 mg (9.3%). UV–VIS, λ_{max} nm (log ε): 404 (5.01), 510 (3.98), 544 (3.91), 592 (3.70), 646 (3.89); ^{1}H NMR ($CDCl_3$, 300 MHz) δ (ppm): 9.50 (s, 8H), −2.30 (bs, 2H); ^{19}F NMR ($CDCl_3$, 282 MHz) δ (ppm): −80.4 (t, 12F), −81.3 (br s, 8F); −119.6 (br s, 8F). Accurate Mass calcd. for $C_{32}H_{11}N_4F_{28}$ (M + H): 983.0537; found by HRMS (FAB): 983.0548 (ΔM = 1.2 ppm). Anal. calcd. for $C_{32}H_{10}N_4F_{28}$: C 39.12, H 1.03, N 5.70; found: C 39.40, H 1.18, N 5.53.

Selection of new Fe(III)/Fe(II) chelating agents as catalysts for the oxidation of hydrogen sulfide to sulfur by air

Arthur E. Martell, Ramunas J. Motekaitis, Dian Chen, Robert D. Hancock, and Derek McManus

Abstract: The removal and oxidation to sulfur of H_2S, contained in a broad range of sour gas streams including natural gas, by a Fe(III)/Fe(II) chelate system imposes several requirements on the iron chelate that is employed as the redox catalyst. The solution of the catalyst must be neutral or mildly alkaline to efficiently absorb H_2S from the gas passed through the solution. The stability of the iron(III) chelate must be high enough that solid $Fe(OH)_3$ not precipitate at the pH employed. Also the stability of the iron(II) chelate must be high enough to prevent the precipitation of FeS from the reaction mixture. The difference in stabilities of the Fe(III) and Fe(II) chelates must be low enough so that the Fe(III) form can be reduced by HS^- and that the Fe(III) chelate can be regenerated by aeration of the solution at alkaline pH. An unexpected result of this study is that chelating agents designed for high stability of iron(III) chelates do not form satisfactory redox catalysts. Ligands that form suitable iron complexes as catalysts have both oxygen and nitrogen donors. All complexes investigated are readily reoxidized from the ferrous to the ferric chelate by air.

Key words: iron chelates, stability constants, redox potentials, hydrogen sulfide, redox catalysts.

Résumé : L'utilisation d'un système de chélate Fe(III)/Fe(II) pour l'enlèvement et l'oxydation du H_2S (en S) contenu dans une grande variété de sources de gaz aigres impose plusieurs limitations sur la nature du chélate de fer à utiliser comme catalyseur rédox. Pour que le H_2S soit absorbé efficacement à partir du gaz qui barbote dans la solution de catalyseur, il faut que celle-ci soit neutre ou légèrement alcaline. La stabilité du chélate de fer(III) doit être suffisamment élevée pour que le $Fe(OH)_3$ ne précipite pas au pH utilisé. Il faut aussi que la stabilité du chélate de fer(II) soit suffisamment élevée pour prévenir la précipitation du FeS à partir du mélange réactionnel. La différence dans les stabilités des chélates Fe(III) et Fe(II) doit être suffisamment basse pour que la forme Fe(III) puisse être réduite par HS^- et que le chélate Fe(III) puisse être régénéré par aération de la solution à un pH alcalin. Cette étude a conduit à un résultat inattendu; les agents chélatants développés pour donner des chélates de Fe(II) de grand stabilité ne donnent pas de catalyseurs rédox satisfaisants. Les coordinats qui forment des complexes de fer appropriés comme catalyseurs comportent à la fois des oxygènes et des azotes comme donneurs. Tous les complexes examinés peuvent facilement être réoxydés en chélate ferrique sous l'action de l'air.

Mots clés : chélates de fer, constantes de stabilité, potentiels rédox, sulfure d'hydrogène, catalyseurs rédox.

Introduction

Iron(III) chelate systems are used as catalysts for the removal of H_2S from various gas streams including natural gas and for the oxidation of H_2S to S_8 by air. The reaction is usually carried out in two steps. In the absorber, H_2S is absorbed from the gas by a neutral or mildly alkaline solution of the catalyst and is oxidized by the ferric chelate to sulfur, S_8, which is eventually removed by filtration or other means, while the catalyst is converted to the ferrous form of the complex. The reduced catalyst is then oxidized by air in a separate part of the apparatus, called the oxidizer. In most cases the catalyst used commercially is an iron(III)/iron(II) chelate, and the chelating agent is an aminopolycarboxylic acid, such as NTA (nitrilotriacetic acid), EDTA (ethylenediaminetetraacetic acid), or HEDTA (*N*-hydroxyethylethylenediamine-*N*,*N*′,*N*″-triacetic acid), but such information is for the most part proprietary. The use of iron chelates of aminopolycarboxylic acids as catalysts in this process is covered by a number of patents, only a few of which are cited here (1–3).

Significant operating costs are incurred in the process due to the oxidation and eventual loss of the chelating ligand, which then has to be continuously replenished. The oxidation is probably a radical reaction, and two papers describing this problem in detail have been published (4, 5). This paper describes the chelating agents that form iron(III)/iron(II) chelate systems that promise to be effective catalysts for hydrogen sulfide oxidation. The choice of chelating agent is controlled by the conditions required for carrying out an efficient industrial process. The questions involved in the possible oxidative degradation of the chelating agent are not addressed. Such studies would require a separate, in-depth, study of the oxidation of the iron chelates involved.

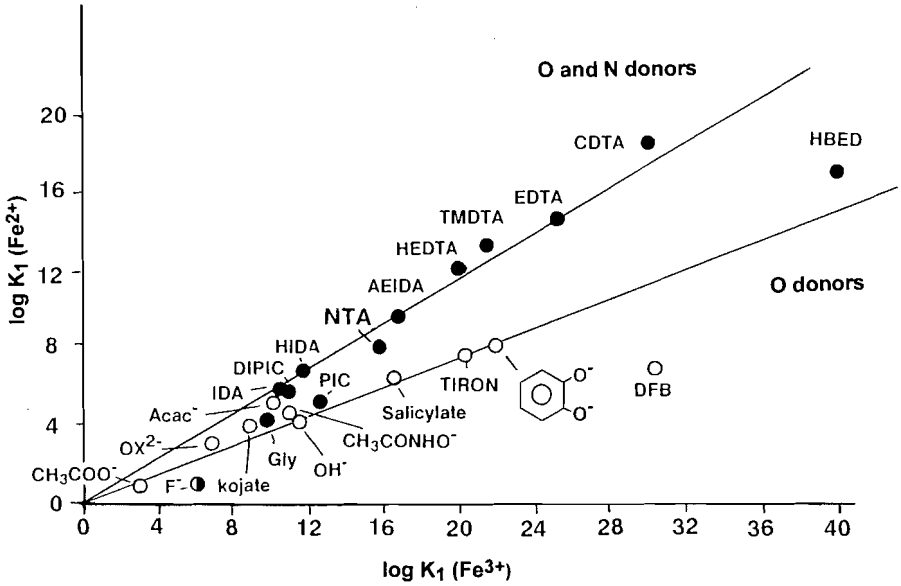
Fig. 1. Plot of log K_1 for complexes of Fe^{2+} against log K_1 for the corresponding complexes of Fe^{3+}. This type of diagram shows the relative preference of Fe^{+3} for the harder ligands containing negative oxygen donors (○) compared to the softer ligands containing a mixture of nitrogen and oxygen donors (●).

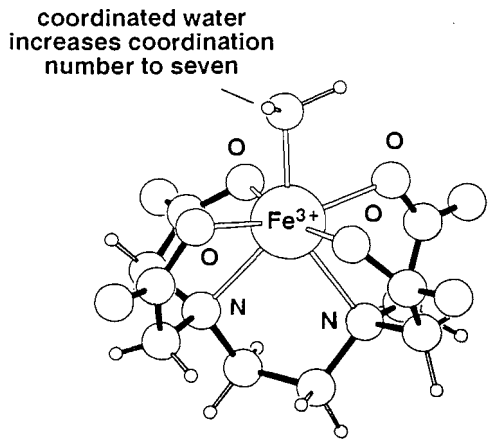


Iron chelating ligands

In Fig. 1 are plotted the log equilibrium constants (formation constants) of 24 ligands with ferric and ferrous ions. The equilibrium constants used are for one mole of ligand per mole of ferric ion or ferrous ion. Since the scales of the ordinate and abscissa are the same, it is seen that a change in the nature and number of donor groups increases the stabilities of the ferric complexes much more than the ferrous complexes. Also, since the Fe^{3+} is a small hard acid (on the HSAB scale) (6, 7) it prefers to coordinate to an oxygen donor ligand with negative oxygen donor groups such as hydroxamate, phenolate, and catecholate donor oxygens. Where the ligand has some of the softer nitrogen donors, the stability of the ferrous chelate increases with basicity, but not as much as that of the ferric chelate. Thus the data in Fig. 1 seem to divide into two groups: those with ligands having only oxygen donors, with a high ratio of Fe(III)/Fe(II) stabilities, and those with both oxygen and nitrogen donors, with a lower ratio of Fe(III)/Fe(II) stability constants. The factors governing the stabilities of metal chelates have been described in detail (8, 9).

An important consideration is the coordination number of the metal ion, since the most stable complexes will be formed when the number of donor atoms of a ligand matches the requirement of the metal ion, provided of course that the donor atoms are sterically available to combine with the metal ion. Most of the complexes of Fe(II) and Fe(III) are octahedral, with a coordination number of six for a metal ion, matched by the coordinating donor groups supplied by a hexadentate ligand. Some complexes of the Fe^{3+} ion, however, are seven-coordinate, probably due in part to steric problems associated with the ligand. To appreciate such steric effects, MM calculations were carried out using the MM program SYBYL (10). The Fe(III) was modeled using the TAFF force field (10), with ideal Fe—O and Fe—N bond lengths of 2.00 and 2.38 Å, respectively, and Fe—O and Fe—N force constants of 100 kcal, mol^{-1} $Å^{-1}$. The angle bending force constants around the Fe, which are the N-Fe-N, N-Fe-O, and O-Fe-O angle bending force constants, were set to zero, and the geometry was generated by van der Waals repulsion between the donor atoms. Trial coordinates for the MM calculations were either taken from crystal structures, or were generated with the model-building facility of SYBYL. The resulting coordinates were plotted with PLUTON (11). Figure 2 shows the results of this molecular mechanics simulation of the Fe(III) chelate of EDTA in aqueous solution. The seven-coordinate structure

Fig. 2. Structure of Fe(II) complex of EDTA generated by Molecular Mechanics calculation and the program SYBYL.



agrees well with the crystal structure described earlier for the Fe(III)–EDTA chelate (12).

Because the absorber solution must be neutral or mildly alkaline, the possible precipitation of FeS and of $Fe(OH)_3$ are important considerations. Since the solubility product of FeS is $10^{-18.1}$ (13), it seems that FeS would precipitate if the concentration of $[Fe^{2+}]$ exceeds $10^{-9.2}$ (assuming $[HS^-]$ to be 10^{-3} M and taking log K_2^a of H_2S as 14.3; the solubility product of FeS is obtained from the displacement equilibrium constant log $[M][H_2S]/[H^+]^2 = 3.0$). This places a lower limit on the stability constant of the ferrous chelate of the chelating agent selected. Similarly, if the solubility product of $Fe(OH)_3$ is $10^{-38.6}$ (14), it can be shown that $Fe(OH)_3$ would precipitate at pH 8.5 if the concentration of ferric ion is greater than $10^{-22.9}$ M. Thus the stability of the Fe(III) chelate must be higher than that which would allow the precipitation of Fe(III) as $Fe(OH)_3$ (in other words the pM ($-\log [M]$) must be higher than 22.9).

In this paper the pM ($-\log [M]$) of a metal ion is calculated for a metal buffer system in which there is an equal amount of the free chelating agent and metal chelate. Most metal chelates described below have 1:1 stoichiometry of metal ion M to chelating agent L; thus the stability constant $K = [ML]/[M][L]$. When $[L] = [ML]$, log $K = -\log [M]$ and the analogy to a hydrogen ion buffer is complete. When the ligand:metal stoichiometry is 2:1 or 3:1, the excess free ligand necessary to form a metal buffer solution is proportionally higher. The excess free ligand used in this paper is an equivalent amount (100%) of that needed to form the metal complex.

The standard reduction potential E_0 of ferric to ferrous ion under standard conditions is +0.770 V (15). Since pM is $-\log [M]$, the half cell for the reduction of iron at pH 8.5 in the presence of 100% excess ligand is

$$[1] \quad \begin{aligned} E &= 0.770 + 0.059\ (\text{pM (Fe(II))} - \text{pM (Fe(III))}) \\ E &= 0.770 - 0.059\ \Delta\ \text{pM} \end{aligned}$$

For the reduction of sulfur, the reaction is

$$S(s) + 2H^+ + 2e^- \rightleftharpoons H_2S$$

and the standard reduction potential is +0.141 V (15).

The above equation is written in terms of HS^- since the latter is virtually the only form at pH 8.5. Since the first dissociation constant of H_2S is $10^{-6.82}$ (14)

$$E = E_0 - 0.0295 \log [H_2S]/[H^+]^2$$

$$[H_2S] = 10^{6.82}[H^+][HS^-]$$

$$E = 0.141 - 0.0295 \log 10^{6.82}\ [HS^-]/10^{-8.5}$$

Assume that $[HS^-]$ is approximately 10^{-3} M, a reasonable concentration.

$$E = 0.141 - 0.0295\ (6.82 - 3 + 8.5)$$

$$E = -0.223$$

For the overall reaction the reduction potential of the iron chelate and the oxidation potential of HS^- are employed:

$$[2] \quad \begin{aligned} E &= 0.770 - 0.059\ \Delta\ \text{pM} + 0.223 \\ E &= 0.993 - 0.059\ \Delta\ \text{pM} \end{aligned}$$

For the two-electron redox reaction at pH 8.5 the conditional equilibrium constant may now be calculated.

$$[3] \quad \log K_c = (0.993 - 0.059\ \Delta\ \text{pM})/0.0295$$

Thus the values of the conditional constants K_c for the equilibrium

$$2Fe^{III}L + HS^- \rightleftharpoons 2Fe^{II}L + H^+ + S(s)$$

were calculated for Tables 1 and 2, for pH 8.5, 100% excess ligand, and assuming the concentration of HS^- to be 10^{-3} M.

The conditions used for Tables 1 and 2, and which apply to the conditional equilibrium constant K_c, specify pH 8.5, which corresponds to the pH used in the Wheelabrator "Low-Cat" process. The use of a much lower pH, such as 7.0, used in the Dow "Sulferox" system, would result in much lower S^{2-} and OH^- concentrations, and therefore the precipitation of FeS and $Fe(OH)_3$ would occur less readily. Thus, chelating agents labeled in Table 1 with (S) and (OH) and in Table 2 as (borderline), would be satisfactory. The rate of absorption of H_2S, however, would be slower, and a larger absorber vessel would be needed.

Another condition that may be employed for this process is the use of a lesser amount of excess ligand. The reduction of 100% excess ligand to 10% excess would reduce the pM value of the catalyst system by an order of magnitude. This change could be tolerated better in the low pH process, where the demands on the chelating agent to keep the iron in solution are not so stringent.

Because certain aminopolycarboxylate chelates are now in use commercially to form the iron chelate catalysts for this process, it seems appropriate to compare these systems with other aminopolycarboxylates. Table 1 compares 10 aminopolycarboxylates for which the stabilities meet the requirements for the oxidation of H_2S to S_8 at pH 8.5 and 10^{-3} M $[HS^-]$. The structures and names of the ligands are indicated in Plate 1. It is seen that the reaction is favorable for all ligands listed in Table 1 with conditional constants that vary between 10^8 and 10^{24}. It is seen that TMDTA and EGTA are unsatisfactory ligands because they do not prevent the precipitation of $Fe(OH)_3$ at pH 8.5. Also, NTA calculates out as a marginal ligand with respect to both FeS and $Fe(OH)_3$ precipitation. The fact that it is being successfully used in industrial applications indicates that the operating conditions are at least a little different from those used in the calculations. In some cases an additive is used to increase the complexation of iron(III).

A larger variety of chelating agents are listed in Table 2, including ligands with very basic oxygen donors designed to form very stable Fe(III) chelates. The structures and names of these ligands are given in Plate 2. It is noted that the stabilities of the Fe(II) complexes of four of these ligands have not been measured. Their values are estimated (extrapolated) from the stability constants of other transition divalent metal complexes with the same ligands. The accuracy of this approximation is considered adequate. It is seen in Table 2 that the stabilities of the Fe(III) chelates of TETA and ACAC are not high enough to prevent precipitation of $Fe(OH)_3$. The most

remarkable feature of the data in Table 2 is that the chelating agents that form very stable Fe(III) chelates are not suitable for the oxidation of H_2S to S_8. Any ligand that produces a conditional constant lower than 10^4 is considered too weak an oxidizing agent. This behavior may be rationalized on the basis of the fact that the Fe(III) chelate is very stable, compared to the Fe(II) chelate, and the metal ion therefore prefers to remain in the ferric form. A successful ligand is one that stabilizes the Fe(II) form sufficiently so that it is only moderately less stable than the Fe(III) chelate. The best measure of the relative effects of the ligand on these metal ions is the difference in pM values, since pM takes into account environmental considerations such as pH and concentration.

The reoxidation of the ferrous to the ferric chelate by air, which takes place in the oxidizer vessel, involves the following reaction:

$$4Fe^{II}L + O_2 + 4H^+ \rightleftharpoons 4Fe^{III}L + 2H_2O$$

and the equilibrium constant, in the form of a concentration constant, is

$$[4] \quad K' = \frac{[Fe^{III}L]^4}{[Fe^{II}L]^4[H^+]^4 P_{O_2}}$$

where all solution species are expressed as molar concentration, except the concentration of O_2 which is expressed as partial pressure.

If one takes pH 8.5 as the operating pH and employs 0.20 as the partial pressure of oxygen in air, and substitutes these values in eq. [4], one obtains an equation for the corresponding conditional constant.

$$K'([H^+]^4)0.2 = \frac{[Fe^{III}L]}{[Fe^{II}L]}$$

$$K'_c = K'(10^{-34})(0.2) = \frac{[Fe^{III}L]}{[Fe^{II}L]}$$

$$\log K'_c = \log K' - 34.7 = \log \frac{[Fe^{III}L]}{[Fe^{II}L]}$$

The emf corresponding to the overall reaction can be considered as the sum of the emf's of the half reactions for the oxidation of the iron chelate and the reduction of O_2. For the latter,

$$O_2 + 4H^+ + 4e \rightarrow 2H_2O$$

E is +1.229 V for unit molality of H^+ and unit partial pressure of O_2 (15).

$$E = 1.229 - 0.01479 \log 1/(0.2) - 0.059\ (8.5) = 0.727$$

For the whole reaction, E'_c is therefore:

$$[5] \quad E'_c = E(Fe^{II}L \rightarrow Fe^{III}L) + 0.727 \text{ V}$$

Therefore, K'_c can be expressed by the following:

$$[6] \quad \log K'_c = E'_c/0.01479$$

The values of log K'_c are given in Table 3 for oxidation of the ferrous chelates of the 21 systems described in Tables 1 and 2. It seems that, for all the chelate systems considered, whether or not they are satisfactory for the oxidation of H_2S in the absorber, the equilibrium constants for the oxidation reactions are very positive, and the oxidation of all the ferrous chelates to the ferric form is highly favored. The authors have checked the use of several iron chelates as catalysts in the oxidation of H_2S to S by air and have not encountered any difficulties due to slow kinetics. Although all phases of the reaction were adequately rapid, the reoxidation of the ferrous to the ferric chelate seemed to be the slower part of the process. The slowest part of the reoxidation is the dissolution of oxygen from air to the aqueous phase. This part of the process may be maximized by the use of an appropriate gas–liquid contacting device.

Although all the constants listed in Table 3 are highly positive, they do not provide information on the kinetics of reaction, except that the oxidation step is highly favored.

[a]Equilibrium constant for the reaction: $4Fe^{2+} + O_2 + 4H^+ \rightarrow 4Fe^{3+}L + 2H_2O$ at pH 8.5 and P_{O_2} of 0.20 (air) in the presence of 100% excess ligand.

[b]Oxidation potential of the Fe(II)/Fe(III) chelate couple in the presence of 100% excess ligand.

[c]Calculated from the equation $E_c = 0.059/n \log K_c$.

Conclusions

To form Fe(II)/Fe(III) chelates that are useful as catalysts for the oxidation of H_2S to S, a chelating agent must:

1. Function in the neutral or mildly alkaline pH range to rapidly absorb H_2S gas.
2. Form sufficiently stable Fe(III) chelates that are not converted to $Fe(OH)_3$ at alkaline pH.
3. Form sufficiently stable Fe(II) chelates to prevent precipitation of FeS from alkaline solution.
4. The Fe(III) chelates are generally more stable than the Fe(II) chelates, the ΔpM values varying between 5 and 13 for the amino carboxylic acids and up to 21 for the other ligands. If the Fe(III) chelate is too stable relative to the Fe(II) chelate (ΔpM > 16), the catalyst is ineffective. (The chelate prefers to remain in the Fe(III) state.)
5. Favorable redox reactions are associated with conditional constants that vary over a wide range of numerical values. At pH 8.5 and $[HS^-]$ of 10^{-3} M, the conditional constant may vary between 10^4 and 10^{24}.
6. Because all the ligands listed in Tables 1 and 2, and in Fig. 1, have Fe(III) stability constants that are higher than those of Fe(II), oxidation of the Fe(II) chelate to the Fe(III) chelate by air is a highly favored reaction. While there are ligands that stabilize the ferrous form more than the ferric chelates, such ligands are not useful in this process and are not discussed here.

Total synthesis of isodeoxypodophyllotoxin using the Me_3Sn radical initiated carbocyclization

Stephen Hanessian and Sacha Ninkovic

Abstract: The lactone portion of the podophylotoxin framework was assembled from a free-radical carbocyclization reaction, and the target structure was constructed based on intramolecular Friedel–Crafts reaction. In addition to isodeoxypodophyllotoxin, there were formed unusual tri- and tetracyclic compounds.

Key words: free-radical carbocyclization, C—Sn bond cleavage, podophyllotoxin analog.

Résumé : La partie lactone de la structure de la podophyllotoxine a été synthétisée en utilisant une carbocyclisation radicalaire. La structure entière a été construite en applicant une réaction de Friedel et Crafts intramoléculaire. En plus de l'isodéoxypodophyllotoxine, on isole des produits tri- et tétracycliques.

Mots clés : carbocyclisation radicalaire, scission de la liaison C—Sn, analoque de la podophyllotoxine.

Introduction

Over the years, the lignans (1) have been recognized as challenging targets for organic synthesis, particularly because of their unusual structures and interesting biological properties (2) (Fig. 1). A number of methods have been devised for the construction of this class of molecules (1), and several efforts have culminated in the total synthesis of podophyllotoxin **1** (3), steganacin **2** (4), their derivatives (5), and related compounds (6). These efforts have led to the development of the antitumor drugs (7) etoposide and teniposide which are glucosides of epipodophyllotoxin **4**. These semi-synthetic molecules are currently in use for treatment of a variety of tumors, including small cell lung carcinoma (8), testicular cancer (9), and malignant lymphoma (10).

Ward (3*a*) has recently reviewed the synthesis of molecules having the podophyllotoxin skeleton. To the best of our knowledge only 2,3-dibenzylbutyrolactones (11)[2] have been synthesized using a radical cyclization approach. More recently, a tributyltin hydride mediated carbocyclization provided the aryltetralin unit present in the isopicropodophyllotoxin skeleton (5*a*).

We recently reported that the trimethylstannyl radical adds to terminal olefins of a variety of dienes and trienes, leading to a number of interesting carbocyclic and heterocyclic systems of the tetrahydrofuran and pyrrolidine types (12). We have also reported a novel oxidative cleavage of the C—Sn bond with ceric ammonium nitrate (CAN) resulting in an aldehyde or acetal depending upon the conditions used (temperature, time, solvent, etc). This approach to the construction of 3,4-disubstituted tetrahydrofurans was applied to the total synthesis of the lignan antibiotic burseran (13) and to the kainoids (14).

We describe herein a total synthesis of racemic isodeoxypodophyllotoxin **3** using trimethylstannyl radical addition to a dienic system for the construction of the dibenzylbutyrolactone motif as well as the aryltetralin unit.

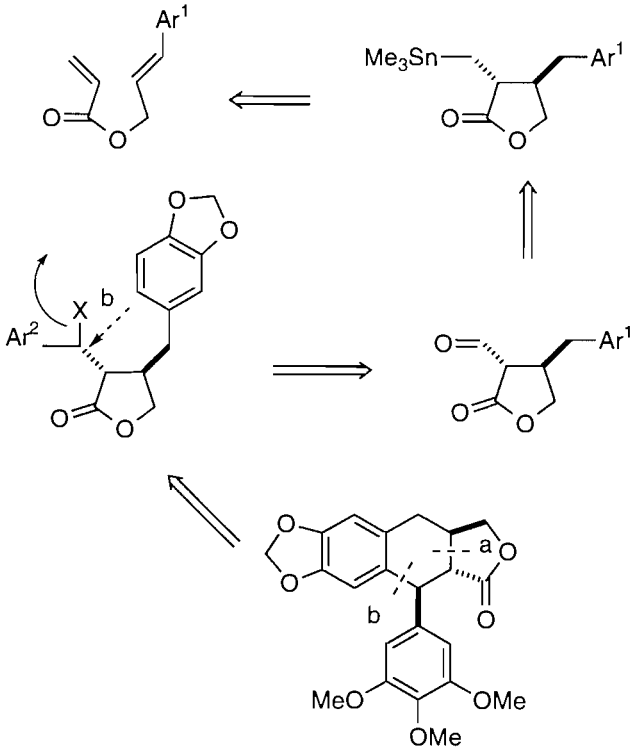
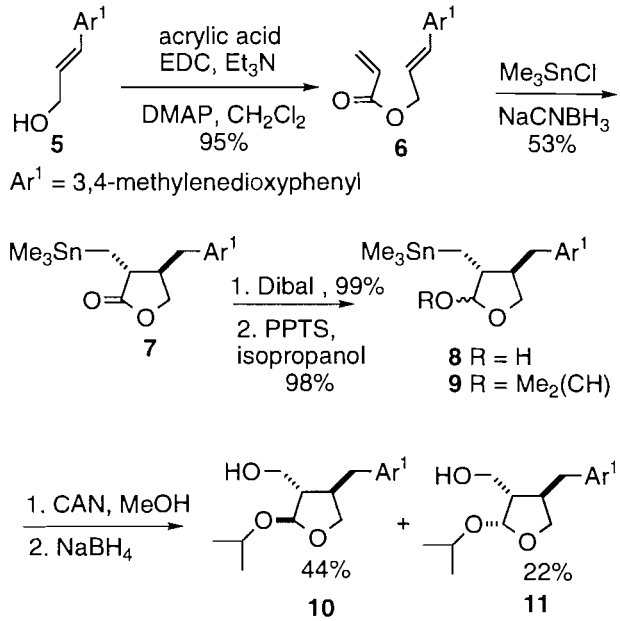
Fig. 2. Disconnective analysis.



Scheme 1.



construction of the tetracyclic system involves a reaction of the Friedel–Crafts type as a second step (bond b) where an important stereochemical issue must be addressed.

Our synthesis started with the treatment of diene **6**, obtained from alcohol **5** and acrylic acid, with trimethyltin radical generated according to Stork and Sher (15) (Scheme 1). This gave lactone **7** in 46% yield in a 4:1 *trans/cis* ratio, with the uncyclized reduced compound as a side-product. Although attempts to significantly increase the yield failed, a modest level of improvement resulted when it was found that the proportion of uncyclized by-product could be minimized by a slow addition of sodium cyanoborohydride to a refluxing solution of diene **6** over a period of 9 h. Thus, lactone **7** and its *cis* isomer were formed in an optimized yield of 53%. Separation by recrystallization afforded the major *trans*-lactone **7** in a ratio greater than 50:1. The structure of **7** was unambiguously proved by single crystal X-ray analysis and by nOe experiments. The remaining *cis*-lactone could be epimerized to the *trans*-lactone **7** (>9:1) under basic conditions.

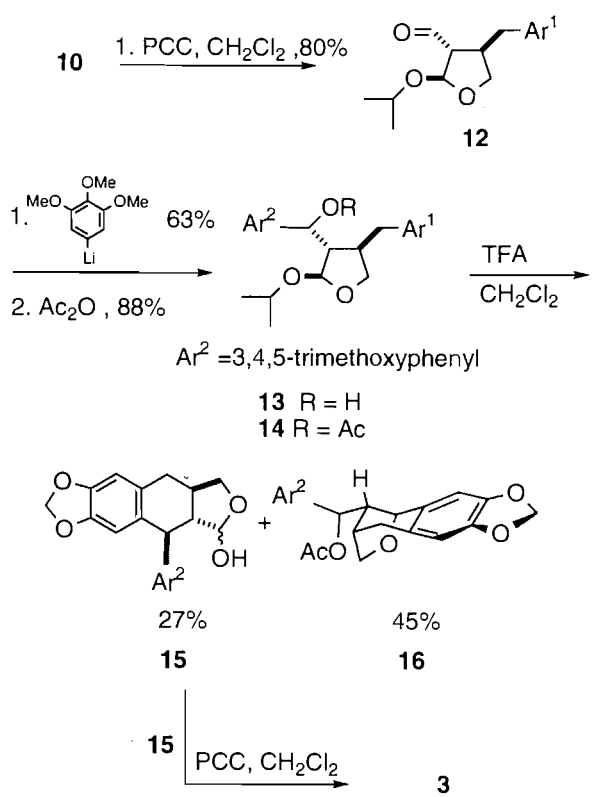
Although the radical carbocyclization proceeds exclusively in a 5-*exo*-trig mode (16), the observed selectivity favoring the *trans* isomer differs from the Me_3Sn-mediated carbocyclization of dienes leading to tetrahydrofurans and pyrrolidines, which give the *cis/trans* products in ratios of 2:1 (12, 13). The classical chairlike and boatlike transition states may probably not apply in the radical carbocyclizations of lactones since they would involve a rather rigid ester moiety.

At this stage of the synthesis, we had to address the problem of selective cleavage of the C—Sn bond with CAN, being cognizant of the fact that aryloxymethyl ethers are oxidized to the corresponding quinones under the same general oxidative conditions at low temperature and in a relatively short time (17). In addition, the problem of oxidative coupling (17*a*) loomed as a major obstacle to the intended sequence. We were encouraged, however, by our previous results (12), since chemoselective oxidative cleavage of the trimethylstannyl group was possible in the presence of an electron-rich aryl group as in our previously published total synthesis of burseran (13).

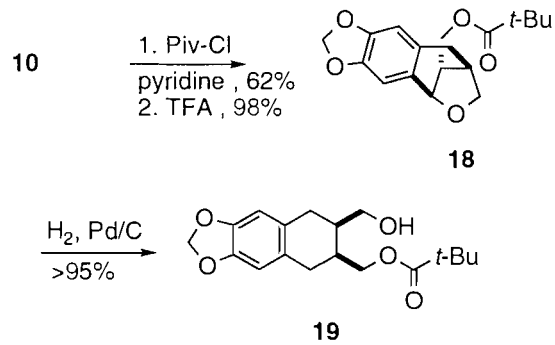
Attempts to selectively cleave the C—Sn bond in **7** under the CAN conditions led to decomposition. The main difference in comparison to the precursor to burseran (13) is that the γ position to the stannyl group bears a carbonyl group in **7**. Thus, the selective CAN oxidative destannylation of γ-stannyl lactones presented a case that warranted further study. To verify this hypothesis, the lactone was reduced to the hemiacetal **8** and protected as acetal **9** (1.5:1 favoring the β anomer vs. the α anomer) under acidic conditions. To our satisfaction, chemoselective cleavage of the trimethylstannyl group was achieved by slow addition of CAN at 0°C, giving the aldehyde derivative directly and without affecting the aromatic moiety. The alcohols **10** and **11** were obtained in 44 and 22% yield, respectively, after reduction with sodium borohydride. The stereochemical relationships in **10** and **11**, respectively, were confirmed by nOe experiments. It is possible that the presence of the electron-withdrawing carbonyl group reduces the reactivity at the C—Sn center, thus leading to undesired reactions in the attempted oxidative cleavage of **7**. Another possibility could involve the formation of a highly reactive β-dicarbonyl, which under the CAN conditions could further react giving dimerization and oligomerization products (18).

The trimethoxybenzyl group was introduced by treatment of aldehyde **12**, obtained from PCC oxidation of alcohol **10** with 3,4,5-trimethoxyphenyl lithium (19), producing an epimeric mixture of adducts **13** that was acetylated to afford the epimeric benzylic acetates **14** (Scheme 2). Our hope was that under acidic conditions, the Friedel–Crafts cyclization

Scheme 2.



Scheme 3.

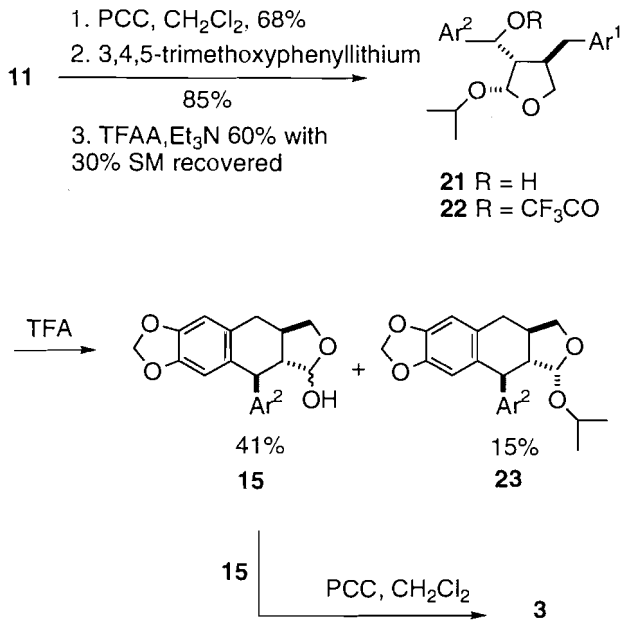


would be directed by the β-isopropoxy group, thus leading to the 1,2-*cis*/2,3-*trans* stereochemistry found in the podophyllotoxin type skeleton (Fig. 1). Treatment of **14** with trifluoroacetic acid gave the hemiacetal **15** in only 27% yield accompanied by a tetracyclic by-product **16** (45%). Extensive NMR studies corroborated the isodeoxypodophyllotoxin-type structure for **15**. Oxidation of **15** with PCC gave isodeoxypodophyllotoxin **3**. The by-product **16** arising in the Friedel–Crafts reaction had been formed as a result of an attack of the aromatic ring on the anomeric carbon, most probably via the intermediate oxocarbenium ion.

To clarify the nature of this cyclization, we attempted the same reaction with a similar substrate (Scheme 3). When alcohol **10** was protected as a pivaloyl ester and treated with TFA, the only result observed was aromatic substitution at the anomeric position leading to the tricyclic compound **18** in quantitative yield. This structure now has an oxygen atom of the tetrahydrofuran directly connected to a benzylic carbon. It was thus possible to cleave this C—O bond by hydrogenolysis to give compound **19** with a *cis* configuration at C3/C4 in which one of the two alcohol functions is protected. Since we were in possession of both anomers **10** and **11**, we decided to verify if the orientation of the isopropoxy group had an influence on the stereochemical outcome of the Friedel–Crafts reaction. Thus, following the identical sequences as for **10**, oxidation of alcohol **11** and subsequent treatment with 3,4,5-trimethoxyphenyl lithium produced one epimer of adduct **21** (Scheme 4). Protection of the alcohol was accomplished with trifluoroacetic anhydride to give **22**. When treated with TFA, adduct **22** underwent Friedel–Crafts ring closure to afford hemiacetal **15** in 41% yield, accompanied by the acetal **23** (15%). It is interesting that in the case of **22** the major products arise from the expected Friedel–Crafts cyclization of the methylenedioxyaryl moiety onto the benzylic cation generated on the other trimethoxyaryl moiety. In the case of **14**, however, the analogous Friedel–Crafts cyclization occurred to the extent of only 27%, the major product being the bridged compound **16** (>8:1 of isomeric acetals). This product may form in part in a competing Friedel–Crafts condensation on an incipient oxocarbenium ion, which may result from the facile trifluoroacetolysis of the 1,2-*trans* glycoside in the medium compared to **22**. It is also possible that one of the epimers of the benzylic acetates (2:1 ratio) in **14** is kinetically more prone to solvolysis to generate a benzylic cation intermediate to give **15**. Compound **16** was found to be a mixture of a major and a minor acetate in a ratio of >8:1, unlike the 2:1 ratio of the original **14**, which corroborates the above-stated hypothesis. The formation of the hemiacetal **15** may be the result of the aqueous work-up wherein the corresponding anomeric isopropoxy (or trifluoroacetate group) is cleaved. Finally, the possibility of neighboring group participation by the *anti*-oriented benzylic acetate in **14** may also play an important role in the predominance of kinetically labile intermediates. Thus, the anomeric configuration in **14** and **22** and the nature of the benzylic ester may have an important kinetic influence in these Friedel–Crafts condensations with regard to their rates of solvolysis and aqueous hydrolysis upon work-up.

The preferential oxidative cleavage of the C—Sn bond in the presence of the electron-rich aromatic ring in compound **9** is intriguing. In an effort to study the influence of the disposition of the aromatic ring vis-a-vis the trimethylstannyl group, we prepared model compounds in which the distance between the aryl group and the site of oxidative cleavage was varied (Scheme 5 and Table 1). There are several interesting observations emerging from this study. First, normal conditions (12, 13) (10 equiv. CAN, RT) cannot be utilized for the destannylation of compounds containing an electron-rich aromatic moiety due to competing reactions. When the substituted aromatic ring is replaced by a phenyl group, cleavage of the C—Sn bond under the above-mentioned conditions is achieved effectively leading, to dimethyl acetals as major products (entries 1 and 5). However, when a slow addition of 2 equivalents of CAN (condition b) over a period of 1.5 h at 0°C was carried out, destannylation occurred without affecting the

Scheme 4.



sensitive methylendioxyphenyl group (entries 3 and 4), while starting materials were completely recovered when Ar = Ph using the same conditions (entries 2 and 6). This suggests a probable involvement of a complexation between Ce(IV) of CAN and the electron-rich aromatic moiety in dilute solutions, thus permitting a faster destannylation. When on the other hand, $n > 3$ (entries 7 and 8), the methylenedioxyphenyl ring is preferentially attacked, leading to side reactions. In these cases the Ce(IV) is not effective in selectively cleaving the C—Sn group due to the longer distance separating it from the Me_3Sn function.

We believe that the mechanism of the chemoselective destannylation begins with a homolytic fragmentation of the stannyl radical cation generated by the electron transfer from CAN, producing an alkyl radical and Me_3Sn^+. A cerium (IV)-coordinated nitrate ester intermediate would then be formed after attack of a second molecule of CAN; this intermediate could then fragment in two different ways. The first could lead to the aldehyde and involve an intramolecular β-elimination while the second could produce nitrate esters by a ligand transfer from CAN. The intermediacy of an organocerium intermediate in which a C—Ce bond is involved cannot be ruled out. Nitrate esters and methyl ethers can be isolated in some instances, depending on the nature of the trimethylstannyl compound (12).

We have described a novel route to the podophyllotoxin skeleton that results in the *epi*-isomer as the major product. Friedel–Crafts cyclization in some oxonium ion intermediates leads to intriguing, di-, tri-, and tetracyclic structures.

Experimental section[3]

Acrylic acid 3-benzo[1,3]dioxol-5-yl-allyl ester 6

Method A

To a solution of methylenedioxy cinnamyl alcohol (2.0 g) and acrylic acid (6 mL, 6 equiv.) in dichloromethane (70 mL) was added, at 0°C, triethylamine (10 mL, 3 equiv.), EDC (7.0 g, 3 equiv.), and DMAP (cat). The reaction mixture was stirred at room temperature for 10 h and then poured into a separatory funnel containing 200 mL of ether and 20 mL of a 10% solution of HCl. The organic phase was washed twice with 20 mL of 10% HCl, four times with 20 mL of saturated sodium bicarbonate, and once with 30 mL of brine. The organic phase was dried ($MgSO_4$) and concentrated. Flash chromatography (10–20% ethyl acetate – hexane) gave 2.63 g (97%) of diene **6**.

Method B

To a solution of methylenedioxy cinnamyl alcohol (2.14 g) in dichloromethane (200 mL) was added at −15°C over a period of 10 min a solution of acryloyl chloride (5 mL, 5 equiv.) in dichloromethane (50 mL). The reaction mixture was brought to 0°C over 1 h and poured into a separatory funnel containing 350 mL of ether and 75 mL of a 10% solution of HCl. The organic phase was washed with 10% HCl, then with saturated sodium bicarbonate (40 mL), and finally with brine (50 mL). The organic phase was dried ($MgSO_4$) and concentrated. Flash

chromatography (10–20% ethyl acetate – hexane) gave 2.29 g (82%) of diene **6**. ^{1}H NMR ($CDCl_3$) δ: 6.94 (d, 1H, J = 1.6 Hz, *H* arom), 6.83 (dd, 1H, J = 7.9 and 1.6 Hz, *H* arom), 6.76 (d, 1H, J = 7.9 Hz, *H* arom), 6.59 (d, 1H, J = 15.9 Hz, *H* benzyl), 6.45 (dd, 1H, J = 17.3 and 1.6 Hz, $O_2CCH{=}CH_2$), 6.2–6.1 (m, 2H, OCH_2CH and $H_2C{=}CH$), 5.96 (s, 2H, O-CH_2-O), 5.85 (dd, 1H, J = 9.8 and 1.5 Hz, $O_2CCH{=}CH_2$), 4.79 (dd, 2H, J = 6.6 and 1.3 Hz, OCH_2). The compound was used immediately due to its instability.

(3,4-trans)-4-Benzo[1,3]dioxol-5-ylmethyl-3-(trimethylstannylmethyl)-dihydrofuran-2-one (7)

To a refluxing solution of diene **6** (51 mg) and trimethyltin chloride (64 mg, 1.5 equiv.), in *tert*-butanol (25 mL) was added a solution of sodium cyanoborohydride (75 mg) and AIBN (cat. 10%) in a 4:1 methanol/*tert*-butanol (5 mL) solution over a period of 9 h. After completing the addition, the reaction mixture was heated under reflux for 30 min more and then cooled to room temperature. Ammonium hydroxide (10% solution) was added until the solution became clear. The reaction mixture was then poured into a separatory funnel containing 40 mL of ether. The organic phase was next washed with brine (10 mL), dried ($MgSO_4$), and concentrated. Flash chromatography (10–20% ethyl acetate – hexane) gave 46 mg (53%) of compound **7** as a 1:4 *cis/trans* mixture. The isomers were separated by recrystallization in methanol to give compound **7**. The structure of **7** was substantiated by x-ray crystallography. ^{1}H NMR ($CDCl_3$) δ: 6.75 (d, 1H, J = 7.8 Hz, *H* arom), 6.62–6.57 (m, 2H, *H* arom), 5.95 (s, 2H, O-CH_2-O), 4.22 (dd, 1H, J = 9.1 and 7.0 Hz, H_1), 3.83 (dd, 1H, J = 1.6 Hz, H_1'), 2.92 (dd, 1H, J = 13.8 and 4.9 Hz, *H* benzylic), 2.55 (dd, 1H, J = 13.8 and 9.0 Hz, *H* benzylic), 2.45–2.30 (m, 2H, H_1 and H_3), 1.07 (dd, 1H, J = 13.1 and 5.2 Hz, CH_2Sn), 0.87 (dd, 1H, J = 13.1 and 9.5 Hz, CH_2Sn), 0.13 (s, 9H, $(CH_3)_3Sn$); ^{13}C NMR ($CDCl_3$) δ: 180.0 (*C*=O), 147.8, 146.3 (2 *C*-O arom), 131.7 (*C* quat. arom), 121.4, 108.7, 108.3 (*C*-H arom), 100.9 (O-CH_2-O), 70.6 (CH_2O), 47.4, 43.6 (*C*-3 and *C*-4), 37.6 (CH_2 benzylic), 10.9 (CH_2-Sn), −9.0 (CH_3Sn); MS (FAB+) for $C_{16}H_{22}O_4Sn$: 383 (M − Me). Anal. calcd. for $C_{16}H_{22}O_4Sn$: C 48.40, H 5.57; found: C, 48.55, H, 5.63.

Epimerization of 7

A solution of lactone **7** (170 mg, 1:2 *trans/cis*) and DBU (7 equiv., 0.45 mL) in toluene (13 mL) was refluxed for 30 h. After cooling to room temperature, the reaction mixture was poured into a separatory funnel containing 35 mL of ether and 7 mL of a 10% solution of HCl. The organic phase was washed with 6 mL of HCl (10%), then with saturated sodium bicarbonate, and finally with brine, and was dried ($MgSO_4$) and concentrated. Flash chromatography afforded 145 mg (85%) of a 9:1 *trans/cis* mixture of compound **7**, which could be further recrystallized in methanol to afford a white crystalline solid (>50:1 *trans/cis*).

*(3,4-*trans*)-4-Benzo[1,3]dioxol-5-ylmethyl-3-(trimethylstannylmethyl)-tetrahydrofuran-2-ol (8)*

Lactone **7** (2.3 g) was dissolved in toluene (125 mL, 0.04 M) and the solution was cooled to −78°C before adding slowly a solution of DIBAL in toluene (1.0 M solution, 1.2 equiv., 7 mL). The reaction was followed by TLC and, after 15 min, ice cubes were added until gas evolution stopped. A few drops of water were added, after which the reaction mixture was brought to 0°C and stirred for 30 min at the same temperature. After adding ether (150 mL) and stirring for another 90 min at room temperature, magnesium sulfate was added and the mixture was filtered. Flash chromatography (40% ethyl acetate – hexane) afforded 2.3 g (99%) of lactol **8**. ^{1}H NMR ($CDCl_3$) δ: 6.73–6.57 (m, 3H, C*H* arom), 5.92 (s, 2H, OCH_2O), 5.26 and 5.03 (2 d, 1H, J = 4.6 and 3.3 Hz, C*H* anom. α and β), 4.07–3.47 (m, 2H, CH_2O), 2.95–1.86 (m, 5H, $CHCH_2SnMe_3$, $CHCH_2CO_2Me$, CH_2CO_2Me), 0.99–0.72 (m, 2H, CH_2SnMe_3), 0.19–0.01 ($CH_2Sn(CH_3)_3$); MS (FAB+) for $C_{16}H_{24}O_4Sn$: 385 (M−Me).

*(3,4-*trans*)-5-[5-Isopropoxy-4-(trimethylstannylmethyl)-tetrahydrofuran-3-ylmethyl]-benzo[1,3]dioxole (9)*

Hemiacetal **8** (400 mg) and PPTS (30 mg) were dissolved in dry 2-propanol (10 mL, 0.1 M) and the solution was stirred vigorously for 24 h. The solvent was removed under reduced pressure untill 1 mL of 2-propanol was left. Ether (20 mL) was added and the organic phase was washed with saturated sodium bicarbonate and then with brine. The organic phase was dried ($MgSO_4$), filtered, and concentrated. Flash chromatography (20% ethyl acetate – hexane) gave 435 mg (98%) of acetal **9** as an inseparable 1:1.5 α,β mixture of anomers. ^{1}H NMR ($CDCl_3$) δ: 6.72 (d, 1H, J = 7.7 Hz, *H* arom), 6.64–6.58 (m, 2H, *H* arom), 5.92 (s, 2H, O-CH_2-O), 4.98 (d, 1H, J = 4.5 Hz, O-C*H*-O *cis*), 4.77 (d, 1H, J = 2.5 Hz, O-C*H*-O *trans*), 3.96–3.81 (m, 2H, Me_2CHO and CH_2O *cis/trans*), 3.62 (dd, 1H, J = 8.3 and 8.3 Hz, CH_2O *trans*), 3.50 (dd, 1H, J = 8.1 and 8.0 Hz, CH_2O *cis*), 2.86–2.80 (m, 1H, *H* benzyl *cis/trans*), 2.57 (dd, 1H, J = 13.7 and 9.2 Hz, *H* benzyl *trans*), 2.36 (dd, 1H, J = 13.9 and 10.1 Hz, *H* benzyl *cis*), 2.30–1.90 (m, 2H, H_2 and H_3 *cis/trans*), 1.22 and 1.15 (d, 6H, $(CH_3)_2CHO$ *trans*), 1.14–1.1 (m, 6H, $(CH_3)_2CHO$ *cis*), 0.94-0.80 (m, 2H, CH_2Sn *cis/trans*), 0.09 (s, 9H, Me_3Sn *cis/trans*); ^{13}C NMR ($CDCl_3$) δ: 147.5, 145.7, 134.5 and 134.4 (*C* quater. arom *cis/trans*), 121.3, 121.2 (*C* arom *cis/trans*), 109.6, 108.9, 108.2, 108.1 (OCHO *trans*, C arom *cis/trans*, OCH_2O *cis*), 103.2 (OCHO *cis*), 100.7 (OCH_2O *trans*), 71.8, 71.6 (*C*-4 *cis/trans*), 68.9, 68.3 (Me_2CHO *cis/trans*), 50.9, 49.8 (*C*-2, *C*-3 *trans*), 48.3, 47.2 (*C*-2, *C*-3 *cis*), 38.8, 38.5 (*C*-benzyl *cis/trans*), 23.8, 23.8, 21.7 ($(CH_3)_2CHO$ *cis/trans*), 14.8, 8.9 (CH_2Sn *trans/cis*), −9.0, −9.5 ($(CH_3)_3Sn$ *cis/trans*); MS (FAB+) for $C_{19}H_{30}O_4Sn$: 427 (M − Me), 368 (M+H−Me−2-propanol).

*(2,3-*trans*-3,4-*trans*)-4-Benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-carbaldehyde **12** and (2,3-*cis*-3,4-*trans*)-4-benzo[1,3]dioxol-5-ylmethyl-2-isopropoxy-tetrahydrofuran-3-carbaldehyde (**20**)*

Acetal **9** (90 mg) was dissolved in 4 mL (0.05 M) of methanol and cooled to 0°C. Slow addition of CAN (cerium ammonium nitrate, 2 equiv., 230 mg in 5 mL of methanol) was done with a syringe pump over a period of 1 h. After the addition was completed, saturated ammonium chloride (2 mL) was added and the mixture was poured into a separatory funnel with 10 mL of ether. Work-up was done by washing with water and then with brine (5 mL). The organic phase was dried ($MgSO_4$) and concentrated. Flash chromatography (20–40% ethyl acetate – hexane) gave 35 mg (59%) of an inseparable mixture of aldehydes **12** and **20** (2:1), 4 mg of alcohol **11** (6%), and 8 mg of alcohol **10** (12%).

*(2,3-*trans*-3,4-*trans*)-(4-Benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-yl)-methanol* ***10*** *and (2,3-*cis*-3,4-*trans*)-(4-benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-yl)-methanol (**11**)*

The aldehyde (35 mg) was dissolved in methanol (1.2 mL, 0.1 M), the reaction mixture was cooled to 0°C, and sodium borohydride (3 equiv., 14 mg) was added. After 1 h a saturated ammonium chloride solution was added followed by the usual work-up. Flash chromatography (30–40% ethyl acetate – hexane) gave 19 mg of alcohol **10** (53% yield) and 10 mg of alcohol **11** (29% yield).

*For alcohol **10**:* ^{1}H NMR ($CDCl_3$) δ: 6.71 (d, 1H, J = 7.9 Hz, *H* arom), 6.65 (d, 1H, J = 1.6 Hz, *H* arom), 6.71 (dd, 1H, J = 7.9 and 1.6 Hz, *H* arom), 5.91 (s, 2H, OCH_2O), 5.09 (d, 1H, J = 2.2 Hz, OC*H*O), 3.94–3.84 (m, 2H, Me_2CHO and H_4), 3.64 (dd, 1H, J = 8.6 and 8.4 Hz, H_4), 3.53–3.40 (m, 2H, CH_2OH), 2.80–2.64 (m, 2H, *H* benzyl), 2.17–2.10 (m, 1H, H_3), 2.03–1.99 (m, 1H, H_2), 1.21 and1.15 (2 d, 6H, J = 6.1 Hz, $(CH_3)_2CHO$); ^{13}C NMR ($CDCl_3$) δ: 147.6, 145.8 (2 *C*-O arom), 134.1 (*C tert.* arom), 121.3, 108.9, 108.1, and 105.0 (3*C*H arom and O*C*HO), 100.7 (O-*C*H_2-O), 71.5, 69.0, 63.4, 53.8, 42.6, 38.7, 23.6, 21.6 (Me_2CHO, *C*-3, *C*-4, CH_2OH, *C* benzyl, *C*-5 , $(CH_3)_2CHO$); HRMS for $C_{16}H_{22}O_5$ −1, calcd.: 293.1389; found: 293.1398; MS (FAB+) for $C_{16}H_{22}O_5$: 293 (M−1), 233 (M-1−2-propanol).

*for alcohol **11**:* ^{1}H NMR ($CDCl_3$) δ: 6.72 (d, 1H, J = 7.9 Hz, *H* arom), 6.68 (d, 1H, J = 1.6 Hz, *H* arom), 6.62 (dd, 1H, J = 7.8 and 1.6 Hz, *H* arom), 5.92 (s, 2H, OCH_2O), 5.26 (d, 1H, J = 5.2 Hz, OC*H*O), 4.01 (dd, 1H, J = 8.2 and 8.1 Hz, H_4), 3.91 (qq, 1H, J = 6.2 and 6.1 Hz, Me_2CHO), 3.78 (dd, 1H, J = 11.8 and 2.6 Hz, CH_2OH), 3.59–3.52 (m, 2H, CH_2OH and H_4), 2.81–2.69 (m, 2H, *H* benzyl), 2.54–2.45 (m, 1H, H_3), 1.97–1.93 (m, 1H, H_2), 1.18 and 1.15 (2 d, 6H, J = 6.2 Hz, $(CH_3)_2CHO$); ^{13}C NMR ($CDCl_3$) δ: 147.6, 145.9 (2 *C*-O arom), 133.7 (*C tert.* arom), 121.4, 108.9, 108.1, and 104.2 (3 *C*H arom and O*C*HO), 100.7 (O-*C*H_2-O), 69.4, 50.7, and 38.7 (Me_2CHO, *C*-3, and *C*-4), 71.8, 59.6, 39.2 (CH_2OH, *C* benzyl, and *C*-5), 23.5 and 21.7 ($(CH_3)_2CHO$); HRMS (FAB+) for $C_{16}H_{22}O_5$ −H, calcd.: 293.1389; found: 293.1379; MS (FAB+) for $C_{16}H_{22}O_5$: 293 (M − 1).

*(2,3-*trans*-3,4-*trans*)-4-Benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-carbaldehyde (**12**)*

Into a solution of alcohol **10** (121 mg) and molecular sieves in dichloromethane (0.1 M, 4.2 mL) was added PCC (2 equiv., 180 mg) at 0°C. The reaction mixture was brought to room temperature, stirred for 2 h, filtered over Celite–silica gel, and concentrated. Flash chromatography (30% ethyl acetate – hexane) gave 96 mg (80%) of aldehyde **12**. ν_{max} : 2960, 2925, 1720, 1495, 1485, 1435, 1370, 1360, 1240, 1090, 1030, 920, 800 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 9.46 (d, 1H, J = 1.4 Hz, C*H*O), 6.79–6.59 (m, 3H, *H* arom), 5.93 (s, 2H, OCH_2O), 5.42 (d, 1H, J = 2.1 Hz, OC*H*O), 4.01–3.87 and 3.71 (m and dd, 3H, J = 8.3 and 8.2 Hz, CH_2O, Me_2CHO), 2.81–2.71 (m, 4H, 2 *H* benzyl, C*H*CH_2 benzyl, and C*H*CHO), 1.22 and 1.16 (2 d, 6H, J = 6.2 Hz and 6.1 Hz, $(CH_3)_2CHO$); ^{13}C NMR ($CDCl_3$) δ: 199.2 (*C*HO), 147.8, 146.1, (2 *C*-O arom), 133.4 (*C tert.* arom), 121.5, 109.0, 108.3, and 101.8 (3 *C*H arom and O*C*HO), 100.9 (O-*C*H_2-O), 69.7, 64.1, and 41.9 (Me_2CHO, *C*HCHO, and *C*HCH_2 benzyl), 71.6, 38.3 (CH_2O and CH_2 benzyl), 23.6 and 21.7 ($(CH_3)_2CHO$).

*(2,3-*trans*-3,4-*trans*)-[(4-Benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-yl)]-(3,4,5-trimethoxyphenyl)-methanol (**13**)*

BuLi (2.4 M in hexane, 3.9 equiv., 0.45 mL) was added at −78°C to a solution of 3,4,5-trimethoxy-1-bromobenzene (18) (0.27g, 4 equiv.) in THF (6 mL). After stirring for 1 h at the same temperature, a solution of aldehyde **12** (80 mg) in THF (5 mL) was added to the reaction mixture over a period of 5 min. Stirring was continued for another hour at −78°C and the reaction was quenched by the addition of ice cubes. The mixture was then poured in ether (30 mL), washed with water and then with brine, dried over magnesium sulfate, and filtered. Evaporation of the solvent and flash chromatography of the residue afforded 80 mg (63%) of compound **13** as a 1:1 mixture of benzylic alcohols. ν_{max} : 3440, 2930, 1585, 1490, 1450, 1325, 1230, 1180, 1120, 1030, 1000, 920, 800, 730 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 6.63–6.27 (m, 5H, *H*arom), 5.91–5.86 (m, 2H, OCH_2O), 5.32, 4.98, 4.69, and 4.27 (4 d, 1H+1H, J = 1.5, 1.7, 6.1, and 8.8 Hz, OC*H*O and C*H*OH benzyl), 4.10–3.60 (m, 12H, 3 $(CH_3)O$, Me_2CHO and CH_2O), 2.72–2.05 (m, 4H, 2 *H* benzyl, C*H*CH_2 benzyl and C*H*CH benzyl) 1.25–0.98 (m, 6H, $(CH_3)_2CHO$); ^{13}C NMR ($CDCl_3$) δ: 153.2, 153.1, 147.5, 145.7, 138.2, 138.1, 137.6, 137.2, 134.4, 134.2 (7 *C* quat. arom), 121.2, 108.7, 108.6, 107.9, 105.0, 104.6, 103.6, 103.1, 92.9 (5 *C*H arom and O*C*HO), 100.8 (O-*C*H_2-O), 75.8, 74.9, 68.9, 68.7 (Me_2CHO, *C*HOH benzyl), 72.3, 71.6 (CH_2O), 60.8, 58.3, 57.9, 56.0, 55.9, 43.1, 41.7 (*C*HCH_2 benzyl, *C*HCHOH benzyl, 3 CH_3O), 39.7 and 38.9 (CH_2 benzyl), 23.7, 23.6, 21.6 and 21.4 ($(CH_3)_2CHO$); MS (FAB+) for $C_{25}H_{32}O_8$: 460 (M).

*(2,3-*trans*-3,4-*trans*)-Acetic acid-[(4-benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-yl)-]-(3,4,5-trimethoxyphenyl)-methyl ester (**14**)*

Into a solution of alcohol **13** (80 mg) in dichloromethane (3.5 mL) was added acetic anhydride (2 equiv.), triethylamine (3.5 equiv.), and DMAP (cat) at 0°C. The reaction mixture was brought to room temperature over 1 h and poured into a separatory funnel containing 30 mL of ether. The organic phase was then washed three times with HCl (10%), twice with 7 mL of saturated sodium bicarbonate, and once with 8 mL of brine. The organic phase was dried ($MgSO_4$), filtered, and concentrated. Flash chromatography (20–30% ethyl acetate – hexane) gave 77 mg (88%) of compound **14** as an isomeric mixture of benzylic acetates. ^{1}H NMR ($CDCl_3$) δ: 6.72–6.50, 6.32–6.23 (m, 5H, *H* arom), 5.94–5.90 (m 2H, OCH_2O), 5.73, 5.41, 5.10, and 4.81 (4 d, 2H, J = 8.3, 10.1, 1.5, and 1.7 Hz, OC*H*O and C*H*OAc), 3.94–3.62 (m, 12H, 3 $(CH_3)O$, Me_2CHO, CH_2O), 2.82–1.94 (m, 7H, C*H*CH_2 benzyl, C*H*CHOAc, CH_2 benzyl, and O_2CCH_3), 1.39, 1.22, 1.15, and 0.87 (4 d, 6H, J = 6.1 Hz, $(CH_3)_2CHO$); MS (FAB+) for $C_{27}H_{34}O_9$; 502 (M), 443 (M−2-propanol), 383 (M−2-propanol − O_2CCH_3).

*(trans-trans)-5-(3,4,5-Trimethoxyphenyl)-5,5a,6,8,8a,9-hexahydrofuro[3'-4'-6,7]naphtho[2,3-*d*][1,3]dioxol-6-9l (**15** and **16**)*

Trifluoroacetic acid (50 equiv.) was added to a solution of **14** (65 mg) in dichloromethane (12 mL) at 0°C. The reaction mixture was stirred for 30 min at the same temperature, poured into ether (25 mL), and washed with 5 mL of saturated sodium

bicarbonate and then with 6 mL of brine. The organic phase was dried ($MgSO_4$), filtered, and concentrated. Flash chromatography (30–40% ethyl acetate – hexane) gave 14 mg (27%) of compound **15** and 25 mg of compound **16** (45%) in an isomeric ratio of >8 to 1.

*For compound **15**:* ^{1}H NMR ($CDCl_3$) δ: 6.61 (s, 1H, C*H* arom), 6.41 (s, 2H, C*H* arom), 6.35 (s, 1H, C*H* arom), 5.89 (d, 1H, J = 1.3 Hz, OCH_2O), 5.87 (d, 1H, J = 1.4 Hz, OCH_2O), 5.14 (d, 1H, J = 4.2 Hz, HOC*H*O), 4.35 (dd, 1H, J = 7.8 and 7.7 Hz, CH_2O), 4.06 (d, 1H, J = 11.6 Hz, C*H* benzyl), 3.90 (s, 3H, CH_3O), 3.80 (m, 2H, 2 CH_3O), 3.59 (dd, 1H, J = 9.8 and 8.1 Hz, CH_2O), 3.00 (dd, 1H, J = 15.2 and 4.6 Hz, CH_2 benzyl), 2.73–2.57 (m, 2H, CH_2 benzyl, C*H*CH_2 benzyl), 1.99 (dd, 1H, J = 11.9, 4.2 Hz, C*H*CH benzyl); HRMS for $C_{22}H_{24}O_7$, calcd.: 400.1522; found 400.1525.

*For compound **16**:* ^{1}H NMR ($CDCl_3$) δ: 6.61 and 6.47 (2 s, 4H, C*H* arom), 6.70 and 6.58 (2 s, C*H* arom minor), 5.93–5.90 (m, OCH_2O minor), 5.88 (s, 2H, OCH_2O), 5.64 (d, 1H, J = 10.6 Hz, C*H*OAc), 5.50 (d, 1H, J = 10.7 Hz, C*H*OAc minor), 4.25–4.19 and 3.88–3.62 (m, 12H, 3 (CH_3)O, PhC*H*O, CH_2O), 3.15 (d, 1H, J = 16.9 Hz, CH_2 benzyl), 2.84 (dd, 1H, J = 16.9 and 2.3 Hz, CH_2 benzyl), 2.72 (s, 1H, C*H*CH_2 benzyl), 2.50 (d, 1H, J = 10.6 Hz, C*H*CHOAc), 2.12 (s, 3H, O_2CCH_3); HRMS for $C_{24}H_{26}O_8$, calcd.: 442.1628; found: 442.1602; MS (EI/HR) for $C_{24}H_{26}O_8$; 442 (M), 382 (M+H−OAc).

*Isodeoxypodophyllotoxin (**3**)*

PCC oxidation of the hemiacetal **15** (15 mg) was done following the same procedure as for compound **10**. Isodeoxypodophyllotoxin **3** (12 mg) was purified by chromatography with 30% ethyl acetate – hexane to give an amorphous solid. ^{1}H NMR ($CDCl_3$) δ: 6.60 (s, 1H, C*H* arom), 6.41 (s, 2H, C*H* arom), 6.35 (s, 1H, C*H* arom), 5.90 (d, 1H, J = 1.3 Hz, OCH_2O), 5.89 (d, 1H, J = 1.4 Hz, OCH_2O), 4.52 (dd, 1H, J = 8.6 and 6.2 Hz, CH_2O), 4.06 (d, 1H, J = 10.4, C*H* benzyl), 3.99 (dd, 1H, J = 10.0 and 8.7, CH_2O), 3.85 (s, 3H, CH_3O), 3.82 (s, 6H, 2 CH_3O), 3.01–2.91 and 2.68–2.47 (m, 4H, CH_2 benzyl, C*H*CH_2 benzyl, C*H*CH benzyl); HRMS for $C_{22}H_{22}O_7$, calcd.: 398.1366; found: 398.1378.

*Compound **18***

To a solution of alcohol **10** (15 mg) in pyridine (0.05 M, 1 mL) at 0°C, was added pivaloyl chloride (3 equiv.) and the reaction mixture was stirred overnight at room temperature. Ice cubes were added at 0°C and the reaction mixture was stirred 20 min at the same temperature and 15 min at room temperature before the solvent was removed under reduced presure. Flash chromatography (10% ethyl acetate – hexane) afforded 12 mg (62%) of **17**. ^{1}H NMR ($CDCl_3$) δ: 6.78–6.58 (m, 3H, *H* arom), 5.92, 5.91 (2 s, 2H, OCH_2O), 5.02 (d, 1H, J = 2 Hz, OC*H*O), 4.01–3.83, 3.65 (m, dd, 5H, CH_2O-Piv, 2 H_4, Me_2CHO), 2.84 (dd, 1H, J = 13.8, 6.3 Hz, *H* benzyl), 2.64 (dd, 1H, J = 13.8 and 8.3 Hz, *H* benzyl), 2.19–2.09 (m, 2H, H_2 and H_3), 1.26–1.13 (m, 6H, $(CH_3)_2CHO$), 1.19 (s, 9H, *t*-Bu).

Ester **17** (12 mg) was dissolved in dichloromethane (1 mL) and the trifluoroacetic acid (20 equiv.) was added at room temperature. The reaction mixture was stirred for 10 min, then poured into ether (50 mL), and the organic phase was washed with a saturated sodium bicarbonate solution and then with brine, dried over magnesium sulfate and filtered. The solvent was evaporated and the residue was purified by flash chromatography (20% ethyl acetate – hexane) to give 10 mg (>98%) of compound **18**. ^{1}H NMR ($CDCl_3$) δ: 6.63 (s, 1H, *H* arom), 6.60 (s, 1H, *H* arom), 5.90, 5.89 (2 d, 2H, OCH_2O), 4.61 (s, 1H, OC*H*Ph), 4.16–4.01, 3.65 (m, d, 4H, J = 8.7 Hz, CH_2O-Piv, 2 H_4), 3.13–3.06, (m, 1H, *H* benzyl), 2.78 (dd, 1H, J = 13.9 and 2.3 Hz, *H* benzyl), 2.56–2.51, 2.43 (m, dd, 2H, J = 8.5 and 7.0 Hz, H_2, H_3), 1.22 (s, 9H, *t*-Bu); ^{13}C NMR ($CDCl_3$) δ:178.4 (C=O), 147.6, 145.7 (2 *C*-O*tert.* arom), 132.5, 127.5 (2 *Ctert.* arom), 109.2, 107.8, (2 *C*H arom), 100.9 (O-CH_2-O), 78.1 (PhCHO), 71.1, 63.7 (2 CH_2O), 45.9, 36.1 (2 *C*H aliph.), 38.8 (*Ctert* of *t*-Bu), 37.8 (CH_2 benzyl), 27.2 (*t*-Bu).

*[1,3] (*trans*)-2,2-Dimethylpropionic acid 7-hydroxymethyl-5,6,7,8-tetrahydro-naphtho[2,3-*d*]dioxol-6-ylester (**19**)*

Compound **18** (3.5 mg) was dissolved in ethyl acetate (1 mL), Pd/C (10%) was added, and the mixture was hydrogenated under 45 psi (1 psi = 6.9 kPa) for 3 days. The reaction mixture was filtered over Celite and the filtrate was concentrated to afford compound **19** (98%); ^{1}H NMR ($CDCl_3$) δ: 6.55 (s, 2H, H arom), 5.88 (s, 2H, OCH_2O), 4.26, 3.93, 3.76, 3.64 (dd, dd, dd, dd, 4H, J = 11.0 and 5.8, 11.0 and 7.8, 10.9 and 7.3, 10.9 and 7.2 Hz, CH_2O), 2.80–2.58 (m, 4H, H benzyl), 2.48–2.37, 2.29–2.18 (m, 2H, CH aliph.), 1.21 (s, 9H, *t*-Bu); ^{13}C NMR ($CDCl_3$) δ:178.4 (C=O), 145.8, 127.4, 127.2 (2 C-Otert. arom, 2 Ctert. arom), 108.8, 108.7 (2 CH arom), 100.5 (O-CH_2-O), 64.5, 63.5 (2 CH_2O), 38.7, 37.9, 33.9, 31.3, 29.9 (2 CH aliph., Ctert of t-Bu, 2 CH_2 benzyl), 27.1 (*t*-Bu); HRMS for $C_{18}H_{24}O_5$, calcd.: 319.1545; found: 319.1566; MS (FAB+) for $C_{18}H_{24}O_5$; 319 (M−1).

*(2,3-*cis*-3,4-*trans*)-4-Benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-carbaldehyde (**20**)*

To a solution of alcohol **11** (130 mg) in dichloromethane (8 mL, 0.06 M) and molecular sieves, was added PCC (3 equiv., 290 mg). The reaction mixture was stirred for 2 h at room temperature then filtered over Celite and concentrated. Flash chromatography (20% ethyl acetate – hexane) gave 88 mg of aldehyde **20** (68% yield). ν_{max} : 2960, 1715, 1485, 1435, 1240, 1100, 1030, 920 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 9.46 (d, 1H, J = 2.7 Hz, C*H*O), 6.70 (d, 1H, J = 7.9 Hz, *H* arom), 6.64–6.59 (m, 2H, 2 *H* arom), 5.90 (s, 2H, OCH_2O), 5.42 (d, 1H, J = 5.3 Hz, OC*H*O), 4.09 (dd, 1H, J = 8.3 and 8.3 Hz, H_4), 3.83 (m, 1H, Me_2CHO), 3.63 (dd, 1H, J = 8.5 and 6.2 Hz, H_4), 3.19–3.06 and 2.81–2.52 (2 m, 4H, 2 *H* benzyl, H_2 and H_3), 1.13 and 1.07 (2 d, 6H, J = 6.2 Hz, $(CH_3)_2CHO$); ^{13}C NMR ($CDCl_3$): 199.3 (*C*HO), 147.7, 146.1, (2 *C*-O arom), 133.0 (*C tert.* arom), 121.6, 109.0, 108.2, and 102.2 (3 *C*H arom and OCHO), 100.8 (O-CH_2-O), 69.8, 61.2, and 39.5 (Me_2*C*HO, *C*-3, and *C*-4), 71.5, 39.5 (*C* benzyl and *C*-5), 23.4 and 21.7 ($(CH_3)_2$CHO).

*[(2,3-*cis*-3,4-*trans*)-(4-Benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-yl)-]-(3,4,5-trimethoxyphenyl)-methanol (**21**)*

BuLi (2.4 M in hexane, 3.9 equiv., 0.5 mL) was added at −78°C to a solution of 3,4,5-trimethoxy-1-bromobenzene (18) (0.300 g) in THF (10 mL). After stirring for 1 h at the same temperature, a solution of aldehyde **20** (87 mg) in THF (5 mL) was added to the reaction mixture over a period of 5 min. It was then stirred for another hour at -78°C and the reaction was quenched by the addition of ice cubes. The mixture is then poured into ether (30 mL), washed with water and then

with brine, dried over magnesium sulfate, and filtered. The solvent was evaporated and the residue was purified by flash chromatography to afford 90 mg (70%) of **21**. ν_{max} : 3490, 2945, 1595, 1505, 1495, 1450, 1420, 1360, 1240, 1130, 1040, 930 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 6.63–6.59 and 6.40–6.35 (m, 5H, *H* arom), 5.89 (m, 2H, OCH_2O), 5.35 and 5.06 (2 d, 1H+1H, *J* = 6.1 and 1.8 Hz, OC*H*O and C*H*OH benzyl), 4.09–3.81 (m, 11H, 3 CH_3O, Me_2CHO, and H_4), 3.62 (dd, 1H, *J* = 10.3 and 5.2 Hz, H_4), 2.82–2.70 (m, 1H, H_3), 2.25–2.13 (m, 3H, 2 *H* benzyl and H_2) 1.25 and1.18 (2 d, 6H, *J* = 6.2 Hz, $(CH_3)_2CHO$). ^{13}C NMR ($CDCl_3$) δ:153.1, 147.5, 145.7, 138.3, 136.8, 134.2 (7 *C* quat. arom), 121.3, 108.8, 107.8, 104.6, 103.8, and 102.5 (5 *C*H arom and OCHO), 100.8 (O-CH_2-O), 71.5 (*C*-5), 70.8, 69.6 (Me_2CHO, *C*HOH benzyl), 60.8, 56.1, 56.0, 40.9, 37.9 (*C* benzyl, *C*-2, *C*-3, 3 CH_3O), 23.7 and 21.8 ($(CH_3)_2CHO$); MS (NBA) for $C_{25}H_{32}O_8$; 461 (M + 1).

*(2,3-*cis*-3,4-*trans*)-Trifluoroacetic acid [(4-benzo[1,3]dioxol-5-ylmethyl-2-isopropoxytetrahydrofuran-3-yl)-]-(3,4,5-trimethoxyphenyl)-methyl ester (22)*

Into a solution of alcohol **21** (57 mg) in dichloromethane (0.05 M, 2.5 mL) was added trifluoroacetic anhydride (1.5 equiv., 0.027 mL) and triethylamine (3.5 equiv., 0.061 mL) at 0°C. The reaction mixture was warmed to room temperature over 1 h and poured into a separatory funnel containing 30 mL of ether. The organic phase was washed with HCl (10%), saturated sodium bicarbonate, and then with brine. The organic phase was dried ($MgSO_4$), filtered, and concentrated. Flash chromatography (20–30% ethyl acetate – hexane) gave 43 mg (60%) of compound **22** as well as 17 mg (30%) of starting material. ^1H NMR ($CDCl_3$) δ: 6.72–6.55 (m, 5H, *H* arom), 6.03 (d, 1H, *J* = 9.2 Hz, PhC*H*O), 5.93 and 5.92 (2 s, 2H, OCH_2O), 4.80 (d, 1H, *J* = 4.6 Hz, OC*H*O), 3.99 (dd, 1H, *J* = 8.2 and 8.2 Hz, H_4), 3.87 (s, 6H, 2 (CH_3)O *meta*), 3.85 (s, 3H, MeO *para*) 3.72-3.60 (m, 2H, Me_2CHO, H_4), 3.01 (dd, 1H, *J* = 13.3, 3.7 Hz, *H* benzyl), 2.68–2.46 (m, 3H, *H* benzyl H_3 and H_2) 1.11 and 0.91 (2 d, 6H, *J* = 6.2 Hz, $(CH_3)_2CHO$); ^{13}C NMR ($CDCl_3$) δ: 153.1, 147.7, 146.0, 138.5, 133.6, 132.8 (7 *C*quat. arom, C=O), 121.5, 108.9, 108.1, 104.5, 101.6 (5 *C*H arom and OCHO), 100.8 (OCH_2O), 81.0 (*C*H benzyl), 71.2 (CH_2O), 68.8, 60.8, 56.1, 53.8 (3 CH_3O, Me_2CHO, *C*-2, *C*-3), 40.5 (CH_2 benzyl), 23.5 and 21.4 ($(CH_3)_2CHO$).

*Compound **15** and (*trans-trans*)-6-isopropoxy-5-(3,4,5-trimethoxyphenyl)-5,5a,6,8,8a,9-hexahydrofuro[3′,4′:6,7]naphtho[2,3-*d*][1,3]dioxole (23)*

After dissolving compound **22** (40 mg) in dichloromethane (0.03 M, 2.5 mL), trifluoroacetic acid (6 equiv., 0.033 mL) was added at −15°C. The reaction mixture was stirred overnight at room temperature, poured into ether (25 mL), and washed with saturated sodium bicarbonate, then with brine. The organic phase was dried ($MgSO_4$), filtered, and concentrated. Flash chromatography with 20–40% ethyl acetate – hexane gave 12 mg of compound **15** (41%) and 5 mg of compound **23** (15%). PCC oxidation of **15** gave isodeoxypodophyllotoxin.

For compound 23: ^1H NMR ($CDCl_3$) δ: 6.59 (s, 1H, C*H* arom), 6.37 (s, 2H, C*H* arom), 6.31 (s, 1H, C*H* arom), 5.87 (d, 1H, *J* = 1.3 Hz, OCH_2O), 5.86 (d, 1H, *J* = 1.4 Hz, OCH_2O), 4.81 (d, 1H, *J* = 4.3 Hz, OC*H*O), 4.25 (dd, 1H, *J* = 7.7 and 7.7 Hz, CH_2O), 4.06 (d, 1H, *J* = 11.9, C*H* benzyl), 3.85 (s, 3H, CH_3O), 3.80 (m, 7H, 2 CH_3O, Me_2CHO), 3.57 (dd, 1H, *J* = 9.5 and 8.1 Hz, CH_2O), 2.97 (dd, 1H, *J* = 14.9 and 4.6 Hz, CH_2 benzyl), 2.69 (dd, 1H, *J* = 14.9 and 14.3 Hz, CH_2 benzyl), 2.59–2.50 (m, 1H, C*H*CH_2 benzyl), 1.97 (ddd, 1H, *J* = 16.1, 11.7, 4.2 Hz, C*H*CH benzyl), 1.18 and 1.09 (2 d, 6H, *J* = 6.1 and 6.2 Hz, $(CH_3)_2CHO$); ^{13}C NMR ($CDCl_3$) δ: 153.1, 146.0, 145.9, 140.7, 137, 133.4, 129.2 (8 *C*quat. arom), 109.6, 108.5, 106.1, 101.1 (4 *C*H arom and OCHO), 100.8 (OCH_2O), 72.4 (CH_2O), 77.2, 69.1, 60.9, 56.1, 54.3, 46.5, 37.7 (3 CH_3O, Me_2CHO, *C*HCH_2 benzyl, *C*HCH benzyl, *C*H benzyl), 34.1 (CH_2 benzyl), 23.7 and 22.3 ($(CH_3)_2CHO$); HRMS for $C_{25}H_{30}O_7$, calcd.: 442.1992; found: 442.2002; MS (EI/HR) for $C_{25}H_{30}O_7$: 442 (M), 382 (M−2-propanol), 351 (M−2-propanol − MeO).

Studies on the interaction of selenite and selenium with sulphur donors. Part 5. Thiocyanate[1]

Christopher Milne and John Milne

Abstract: The oxidation of thiocyanic acid by selenous acid has been shown to take place in an analogous way to that found for selenous acid oxidation of most thiols and thiolates to give the corresponding selenotrisulfide and disulfide products.

$$H_2SeO_3 + 4\ HSCN = Se(SCN)_2 + NCSSCN + 2\ H_2O$$

The products of this reaction have been studied by IR, Raman, and Se-77, C-13, and N-15 NMR spectroscopy. The vibrational spectra of the solid $Se(SCN)_2$ have been assigned based on S-bonded thiocyanate ligands and, through NMR and vibrational spectroscopy, both this linkage isomer and the isomer with N- and S-bonded thiocyanate have been identified and characterized in solutions of $Se(SCN)_2$. A complex combination of scalar relaxation processes, involving chemical exchange and quadrupolar effects, accounts for the line broadening observed in the carbon-13 NMR spectra.

Key words: selenite, thiocyanate, selenium dithiocyanate, Se-77, N-15, and C-13 NMR; Raman spectroscopy; linkage isomerism.

Résumé : On montre que l'oxydation de l'acide thiocyanique par l'acide sélénieux suit une voie analogue à celle trouvée pour l'oxydation de la plupart des thiols et des thiolates par l'acide sélénieux pour donner les sélénotrisulfures correspondants et des produits disulfurés.

$$H_2SeO_3 + 4\ HSCN = Se(SCN)_2 + NCSSCN + 2\ H_2O$$

On a étudié les produits de cette réaction par la spectroscopie IR, Raman et par la RMN du Se-77, du C-13 et du N-15. On a attribué les spectres de vibration du $Se(SCN)_2$ solide en se basant sur les ligands thiocyantes liés par le soufre, et au moyen de la RMN et de la spectroscopie vibrationnelle dans des solutions de $Se(SCN)_2$, on a identifié et caractérisé cet isomère de liaison et l'isomère où le thiocyanate est lié par l'azote et le soufre. Une combinaison complexe du processus de relaxation scalaire, impliquant un échange chimique et des effets quadrupolaires, est reponsable de l'élargissement de la raie observé dans les spectres de RMN du C-13.

Mots clés : sélénite; thiocyanate; dithiocyanate de sélénium; RMN du Se-77, du N-15 et du C-13; spectroscopie Raman; isomérie de liaison.

[Traduit par la rédaction]

Introduction

Selenium dithiocyanate was first prepared by Ohlberg and van der Meulen (1) from selenous acid and thiocyanic acid. They proposed that the main reaction was represented by

[1] $3\ H_2SeO_3 + 7\ HSCN = 3\ Se(SCN)_2 + 5\ H_2O + HCN + H_2SO_4$

as supported by chemical analysis of the products. Selenous acid usually reacts cleanly with thiolic compounds to give selenotrisulfide and disulfide products (2).

[2] $H_2SeO_3 + 4\ RSH = RSSeSR + RSSR + 2\ H_2O$

although some exceptions are known (3). Selenium dithiocyanate, as the solid and in solution, and the course of reaction [1] have not been studied by vibrational and NMR spectroscopic methods and this was of interest in relation to other thiol oxidations by selenous acid studied in this series (2*d*, 3*a*). Oxygen- and sulphur-bonded selenium (II) species have been observed in the course of the oxidation of sulfite and thiosulfate ions by selenous acid. Such linkage isomerism may arise in selenium dithiocyanate with both N and S bonding to selenium(II) possible, in addition to stereoisomerism arising from the *cis* or *trans* arrangement of the CN groups with respect to the SSeS plane. Stereoisomerism has been observed in solid selenopentathionates (4) but no evidence for it has been found

Received June 4, 1996.

C. Milne and J. Milne.[2] Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, ON K1N 6N5, Canada.

in solution phase (2*d*). Solid selenium dithiocyanate contains isolated $Se(SCN)_2$ molecules with S-bonding to Se(II) and a cis arrangement of the CN groups (5). No spectroscopic characterization of $Se(SCN)_2$ has been done and the reported stoichiometry (1) of the SeO_2/SCN^- reaction is exceptional compared to that of other reactions of SeO_2 with thiolates. This work was undertaken to explore the parallel with other work on SeO_2 oxidation of thiolates and extend our understanding of Se(II) chemistry.

Experimental section.

Materials

Freshly ground vitreous selenium (BDH), selenium dioxide (Aldrich), analyzed by titration (3*a*), trifluoroacetic acid (3 M), ammonium thiocyanate (Mallincrodt), and ^{13}C and ^{15}N enriched potassium thiocyanate (Cambridge Isotope Laboratories) were used directly. Dioxane and THF were treated with cuprous chloride to remove peroxide. These solvents as well as acetonitrile were distilled from phosphorus pentoxide to remove traces of water. Acetic acid was treated with acetic anhydride, then distilled. Dimethyl formamide was distilled from fresh Drierite. All boiling temperatures were within accepted ranges.

Preparations

Selenium dithiocyanate was prepared from solutions of selenium dioxide in dilute hydrochloric acid and aqueous thiocyanate (1), mixed at 0°C. The yellow crystals, which were thoroughly washed with glacial acetic acid and ether, were stable over a period of months at −5°C. The X-ray powder pattern confirmed that the product was identical with that characterized by Ohlberg and Vaughan (5). All solutions decomposed, producing red selenium, over a period of hours. Decomposition was accelerated by the presence of water.

Thiocyanogen, 0.2 M in a 1:20:13 mole ratio acetic anhydride/acetic acid/carbon tetrachloride solution was prepared by a standard method (6).

Methods

Raman spectra were measured as described previously (3). The mass spectrum was measured with a VG 7070E spectrometer. Selenium-77, carbon-13, and nitrogen-15 NMR spectra of solutions were measured on a Bruker AMX 500 spectrometer operating at 95.47, 125.77, and 50.69 MHz respectively. Carbon-13 spectra were also measured on Varian FT300 (75.46 MHz) and Gemini 200 (50.31 MHz) spectrometers. Sample concentrations were generally of the order of tenth molar. Selenium-77 spectra were taken using conditions described previously (2*d*). Normally at least 500 transients were taken, giving a signal-to-noise ratio (S/N) of 10. Nitrogen-15 spectra were measured using a 26 μs pulse width and a 15 s pulse delay. Spectra were made up from 120 transients, giving S/N of 8. At the end of an experiment no decomposition of the sample was observed. Spectral resolution was between 0.4 and 1.2 Hz/data point. The chemical shifts were measured from $CH_3{}^{15}NO_2$. Carbon-13 spectra were taken with a 16 μs pulse width and a 10 s pulse delay. A S/N of 20 was achieved with 32 transients. Spectral resolution was 0.5–1.2 Hz/data point. The MAS Se-77 NMR spectra were measured at 38.16 MHz on a Bruker ASX200 spectrometer using a 120 s pulse delay with a 4 μs pulse width. The spectral resolution was 44 Hz/data point. At 5 kHz spin rate S/N was 6 for 12 transients while at 2 kHz, S/N was 6 for the strongest signal with 57 transients. Although no CP enhancement of the signal was possible via protons, the spectrum was obtained easily.

Results and discussion

Selenothiocyanate, $SeSCN^-$, formation constant

Elemental selenium dissolves to a small extent in solutions of thiocyanate (29 ± 4 mg Se in 100 mL 0.20M NH_4SCN). Gravimetric analysis gives $K = 4 \times 10^{-3}$ for the equilibrium,

[3] $SCN^- + Se = SeSCN^-$

This is comparable to the formation constant for the selenothiosulfate (3.6×10^{-3} (2*d*)) but is much smaller than that observed for 2-hydroxyethanethiolate (0.382 (7)) and sulfite (0.515 (3)). There is an inverse relationship between the seleno-anion formation constant and the proton dissociation constant of parent sulphur acid. Thiocyanic acid (8) and the hydrogen thiosulfate[3] anion are moderately strong acids while 2-mercaptoethanol and the hydrogen sulfite ion, especially the HSO_3^- tautomer, which is the principal species in solution (9), are weak acids.

The reaction of selenous acid with thiocyanic acid

When selenous acid is added to aqueous thiocyanic acid in the molar ratio of 1:4 (1), a yellow coloured solution is formed from which slowly precipitate golden needles of selenium dithiocyanate (1). When this reaction is monitored by Se-77 NMR at 3°C, only the selenous acid signal at 1292 ppm is observed and this decreases in intensity with time. The solubility of $Se(SCN)_2$ in water is insufficient to permit observation of the signal for this product. The C-13 NMR spectrum of the solution exhibits initially a strong broad resonance with a half-height line width ($w_{1/2}$) of 45 Hz at 130.5 ppm that lies close to the chemical shift for aqueous SCN^- at 134 ppm (10), for which we found $w_{1/2}$= 13 Hz. The breadth and shift of this signal shows that thiocyanate is undergoing exchange with species such as the SeO_2SCN^- ion and $SeO(SCN)_2$, which are likely intermediates on the way to $Se(SCN)_2$, judging from the mechanism for reaction of thiols with H_2SeO_3[4]. A very weak signal is also observed at 104.4 ppm ($w_{1/2}$ = 2 Hz), which grows in intensity with time as the broad signal weakens and shifts down field to 132.7 ppm and $Se(SCN)_2$ precipitates. A solution of dithiocyanogen 0.20 M in 1/20/13 acetic anhydride/acetic acid/carbon tetrachloride (6) gave a narrow chemical shift ($w_{1/2}$= 2.2 Hz) at 108.9 ppm and the narrow signal in the aqueous H_2SeO_3–thiocyanate solution is due to this species. The 5.5 ppm difference in chemical shift results from solvent effects. No other signals were observed. The reaction of H_2SeO_3 with thiocyanic acid in 1:4 molar ratio leads to the typical products of H_2SeO_3/thiol reactions (2).

[4] $H_2SeO_3 + 4\ HSCN = NCSSeSCN + NCSSCN + 3\ H_2O$

In as much as no signal at 167.9 ppm, which would indicate the presence of CN^- ion, was observed even after a day of

[3] J. Milne, unpublished.

standing, dithiocyanogen appears to be stable in water under these conditions and no decomposition to cyanide and sulfate ion as reported by Ohlberg and Van der Meulen (1) was observed.

Crystalline selenium dithiocyanate

X-ray powder diffractometry confirms the orthorhombic unit cell found in earlier photographic work (5) with more precise unit cell dimensions (a = 9.908(1) Å; b = 13.047(2) Å; c = 4.417(3) Å). Refinement of the powder intensities under *Pnma* symmetry (Z = 4) gives atomic positions consistent with those reported and shows that the molecule has C_s symmetry, that the CN groups are *cis* with respect to the SSeS plane, and that the SCN groups are linear.[4]

The Raman spectrum of solid $Se(SCN)_2$ is shown in Fig. 1 and the IR and Raman spectra are listed in Table 1 along with a partial assignment of the bands. The crystal structure shows a central Se with S-bonded thiocyanate ligands and C_s symmetry for which 15 vibrational modes are expected (8A′ + 7A″). The three A′ stretching modes, ν(SeS), ν(SC), and ν(CN), are readily assigned by comparison with comparable modes for other selenotrithionate species (2*d*, 3*a*, 7) and for thiocyanate ion (11) and by their ease of observation by Raman spectroscopy where symmetric modes are usually strong, at 359, 678, and 2141 cm^{-1}, respectively. The band at 340 cm^{-1} is assigned to the *A″* SeS stretching mode, which lies below the *A″* stretching mode in bis(2-hydroxyethanethiol)selenium ($\nu(A')$ = 396 cm^{-1}; $\nu(A'')$ = 372 cm^{-1}(7)). Both the *A′* and *A″* SeX_2 stretching frequencies for the related SeX_2 molecules (X = Cl, F) (12) and the relative Raman intensities of these two SeS_2 stretching modes in Fig. 1 support this assignment. The weak IR band at 2068 cm^{-1} is the *A″* CN stretching mode. The in- and out-of-plane symmetric and asymmetric SCN deformation modes are assigned to the four peaks at 409,440,457, and 480 cm^{-1}, which are close to this mode in the SCN^- spectrum (11). The SeSC deformation modes are probably masked by the SeS stretching bands. The strong band at 168 cm^{-1} is assigned to the SSeS deformation mode, which is found in the spectra of the $Se(S_2O_3)_2^{2-}$ ion (2*d*) and $SeCl_2$ (12) at 162 and 165 cm^{-1}, respectively. The peaks at 110 and 131 cm^{-1} are assigned to the *A′* and *A″* torsional modes and the remaining low-frequency bands at 59, 74, and 104 cm^{-1} probably arise from lattice modes.

The electron impact mass spectrum of $Se(SCN)_2$ shows the characteristic isotopic intensity profile of Se (49/24/9/9/8 for isotopes 80/78/82/76/77; respectively) for the parent molecular ion (centred at 196), SeSCN (mass:138), SeS (mass:112), Se (mass:80). Species like SeN, SeN_2, SeNC, and $Se(NC)_2$ are not observed, indicating that N-bonded Se is either of low stability or not present. In addition, fragments such as CN, S, SCN are present in addition to HNCS, resulting from traces of water in the spectrometer itself.

The Se-77 NMR spectrum of crystalline $Se(SCN)_2$ at a MAS spin rate of 5 kHz consists of a single line at 997 ppm, which is the isotropic chemical shift. The single line at this spin rate indicates that only one site exists for the Se atoms in the unit cell, consistent with the reported crystal structure (5), and that the site is highly isotopic. At 2 kHz MAS spin rate, five lines are observed. The line intensities of the side bands

relative to the isotropic line intensity were used to calculate the chemical shift tensors by the Herzfeld–Berger method (13) giving $\sigma_{11} = -124 \pm 4$, $\sigma_{22} = -12 \pm 2$ and $\sigma_{33} = 136 \pm 6$ ppm. These chemical shift tensors are among the smallest observed (14) and are unusual in a compound of such low symmetry. This may be a reflection of the ionic character of the Se(II)—SCN bond. The electronegativity of the thiocyanate group has been reported to be comparable with that of chlorine (15).

Solutions of selenium dithiocyanate

Selenium dithiocyanate exhibits generally low solubility (1) and solutions precipitate red selenium within an hour at laboratory temperatures, especially in the presence of water. Saturation solubilities at 25°C, estimated to be 0.15 ± 0.3 M, are found for acetone, acetonitrile, dioxane, and tetrahydrofuran, which are among the best solvents for the compound. Decomposition was more rapid in acetone. The concentrations were sufficient for the measurement of IR, Raman, and NMR spectra provided that solutions were made up cold and run immediately.

NMR spectroscopy

The Se-77 NMR chemical shifts and intensities of $Se(SCN)_2$ in acetonitrile, acetic acid(HOAc), trifluoroacetic acid, (HOTFA), dimethyl formamide(DMF), dioxane, and tetrahydrofuran(THF) are listed in Table 2. In all cases except for HOTFA, two signals are observed with the least shielded the most intense. The chemical shifts are consistent with those of Se(II) compounds where the ligand has electronegativity

above 3.0 (16, 17). Comparison of the Raman spectra of these solutions (vide infra) with that of crystalline $Se(SCN)_2$ show that S-bonded $Se(SCN)_2$ is present. Two types of isomerism, rotational (4) and linkage (2*d*, 3), are expected for thiocyanate bound to Se(II). Rotational isomers with CN groups *cis* or *trans* to the SeS_2 plane have only been observed in solids (4) and are unlikely in solution due to the expected low barrier to rotation about the SeS bond. For the SS bond, this barrier, which is probably higher than or comparable to that for the SeS bond, is estimated to be 25–38 kJ mol^{-1} (18) and restricted rotation about the SS bond in 1,2-dithiane is rapid on the proton NMR time scale at ambient temperatures (19). In solution both the selenotrithionates and selenopentathionates exhibit O- and S-bonded linkage isomerism (2d,3) and selenium dithiocyanate apparently forms N- and S-bonded isomers in a similar fashion. Three isomers are possible, NCSSeSCN(SS), NCSSeNCS(NS), and SCNSeNCS(NN), and in analogous cases (3*a*, 20) all are observed. The observa-

tion of just two signals is probably due to the presence of just the SS and NS isomers. It is not possible to assign either signal unequivocally to the SS isomer on the basis of the chemical shift for the solid, which is known to contain the SS isomer, because of the uncertainty in the solid to solution shift, which is usually of the order of 10 ppm (14). The chemical shift for the solid, 997 ppm, lies between the two signals observed in the solution spectra. Since the shift range for Se(II) bonded to nitrogens (1128–1394 ppm (21)) is in general higher than that of Se(II) bonded to sulphurs (430–687 ppm (21)), as expected on the basis of the electronegativity difference between N and S, the more deshielded signal above 1000 ppm is assigned to the NS isomer and the more shielded signal, to the SS isomer. The signal intensities show that more of the NS isomer than the SS isomer is present in all solutions.

The N-15 NMR spectra of $Se(SCN)_2$ in THF and dioxane solutions show two peaks (THF: −100.3, −117.6 ppm; dioxane: −94.7, −106.1 ppm) with a distinct shoulder or skewing to the less screened side of the stronger peak. The spectrum of a 0.2 M solution of $Se(SCN)_2$ in THF is shown in Fig. 2. Curve resolution of the spectral envelope, assuming Lorentzian line shapes, shows three signals. The chemical shifts, half-height line widths, and relative peak areas for the curve-resolved peaks are given in Table 3. The SS isomer will exhibit a single N-15 resonance while the NS isomer is expected to give two N-15 signals, one for terminal N and the other for N bonded to Se. The nitrogen bonded to C and Se is expected to be less shielded than the terminal nitrogen and the signal to low field is therefore assigned to N-15 in the N-bonded thiocyanate moiety of the NS isomer, while the nearly overlapped signals to high field arise from the S-bonded thiocyanates in both the SS and NS isomers. The signal areas of the peaks for the NS and SS isomers are consistent with the areas determined from Se-77 NMR spectra and show that the NS isomer is present in higher concentration than the SS isomer. Upon cooling the THF sample to 223 K, the less shielded signal disappears, the signal at −117.6 ppm shifts to −119.6 ppm, and the half-height line width decreases to 220 Hz. The SS isomer is apparently favoured at lower temperatures.

The C-13 NMR spectrum of $Se(SCN)_2$ (natural abundance nitrogen) in THF consists of a single broad resonance at 115.9 ppm ($w_{1/2}$ = 131 Hz at 11.74 T). The most likely origin of the signal breadth is scalar relaxation due to chemical exchange and spin coupling to the quadrupole of nitrogen-14, with other relaxation processes playing a minor role. Both scalar relaxation processes are important. Spectra taken at lower field strengths give narrower signals ($w_{1/2}$ = 70 Hz at 7.044 T; $w_{1/2}$ = 40 Hz at 4.696 T). This behaviour is characteristic of broadening due to chemical exchange and not coupling to a quadrupolar relaxed nucleus (22). On the other hand, decrease in temperature results in narrowing of the C-13 signal down to T = 207.5 K, as shown in Table 4 and Fig. 3, which is typical of relaxation by coupling to a quadrupolar nucleus (22). Assuming that the half-height line width is inversely related to the correlation time and directly related to the rate of the correlation process, a plot of $\ln(w_{1/2})$ vs. $10^3/T$ should yield a straight line giving the activation energy for the process. The plot in Fig. 3 shows that the line width is governed by several processes and that as the temperature is lowered chemical exchange begins to play a more important role with the line eventually broadening with decrease in temperature. The limiting slope at the highest temperatures measured (decomposition occurred rapidly at elevated temperatures) gives an activation energy of 15 kJ/mol, which is low and consistent

Fig. 2. Nitrogen-15 NMR spectrum of $Se(SCN)_2$ dissolved in THF. Vertical lines indicate the position and maximum intensity of the N-15 bands in the SS and NS isomers. The Lorentzian lineshapes are indicated by dashed lines.

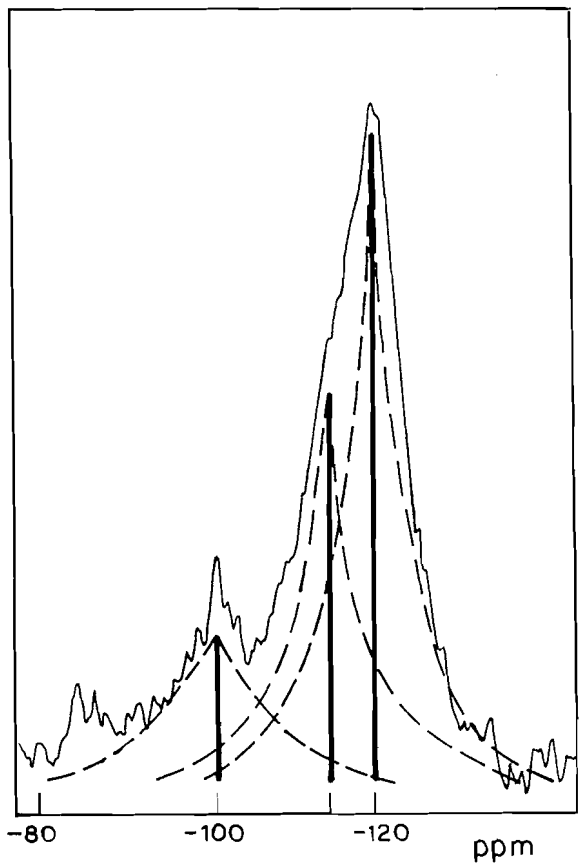

Fig. 3. A plot of the logarithm of the half-height line width vs. temperature (K) showing the transition from the quadrupole relaxation broadening to chemical exchange broadening.

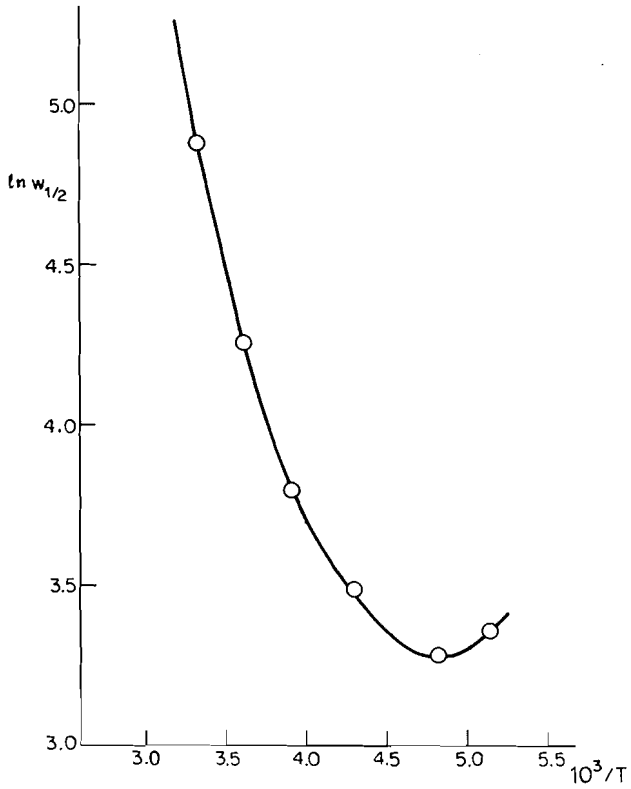

with a facile process such as tumbling of the solute in a weakly solvating solvent. The halfheight line widths for thiocyanogen (see above) and thiocyanate ion (0.2 M $KS^{13}CN$ in H_2O) are 2.2 and 13 Hz, respectively, and, since, in media of comparable viscosity, $Se(SCN)_2$ with its larger size would be expected to tumble more slowly and exhibit an even narrower signal due to quadrupolar relaxation, it is apparent that chemical exchange must contribute significantly to the signal broadening. Thiocyanogen and the thiocyanate ion are not expected to undergo chemical exchange but $Se(SCN)_2$ may undergo intermolecular and intramolecular thiocyanate exchange. No evidence for separate signals due to the SS and NS linkage isomers is observed in the ^{13}C spectrum and, in spite of quadrupole broadening effects, some indication of these isomers would be expected in view of their observation in the ^{15}N NMR spectrum. This indicates that the C-13 signals for the various carbon environments in the isomers of $Se(SCN)_2$ must differ by less than 2 ppm. Reported carbon-13 chemical shifts for ethylthiocyanate and isothiocyanate and the N- and S-bonded thiocyanate ligand in Co(III) complexes differ by 16.7 and 18.2 ppm, respectively (10).

Table 2 shows that the half-height line widths of the Se-77 signals are greater in acetic acid than those measured in THF and dioxane. Addition of trifluoroacetic acid to a dioxane solution of $Se(SCN)_2$ in dioxane leads also to signal broadening. A single narrow signal is observed for $Se(SCN)_2$ dissolved in 100% trifluoroacetic acid, indicating that rapid exchange between linkage isomers is occurring. The exchange is promoted by acid and no doubt occurs via the formation of thiocyanic and isothiocyanic acids, both of which are known (8) and may be readily formed by the protonation of the N-bonded and S-bonded $Se(SCN)_2$ isomers and cleavage of the bond to Se.

195.0	28.5
207.5	26.5
233.0	32.5
255.4	44.2
276.0	70.0
300.0	131.0

[3] $NCSSeSCN + H^+ = NCSSe^+ + HNCS$

[4] $HNCS = HSCN$

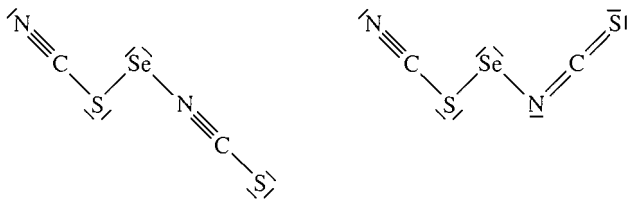
[5] $NCSSe^+ + HSCN = NCSSeNCS + H^+$

While the N-15 NMR spectra for $Se(SCN)_2$ in THF measured at low temperature show an increase in SS isomer concentration, the Se-77 spectra for DMF solutions at −33°C indicate a decrease in SS isomer concentration. A consideration of the relative intensities of the SS and NS isomer Se-77 NMR peaks in Table 2 shows that, in general, the SS isomer concentration falls with decreasing acidity of the solvent. This is consistent with the expected Brønsted and Lewis acidity of $Se(SCN)_2$. The SS isomer with two terminal nitrogens is expected to exhibit stronger basicity towards the proton than the NS isomer with a single terminal nitrogen and a more weakly basic terminal sulphur. Therefore the SS isomer would be favoured in acidic media. In more basic media it might be expected that the Se atom would act as a Lewis acid centre and that the NS isomer would be a stronger Lewis acid than the SS isomer on the basis of the greater electronegativity of nitrogen compared to sulphur. This would result in a higher relative concentration of the NS isomer in DMF due to coordination by the basic solvent at Se(II).

Vibrational spectroscopy

The Raman spectra of $Se(SCN)_2$ in acetonitrile, dioxane and THF, each of which provides a particular vibrational spectral window to observe the isomers present in solution, are listed in Table 1. The IR spectrum of the solution in THF is also given, as well as the spectra for solid $Se(SCN)_2$, the thiocyanate ion, and thiocyanogen. The Raman spectra of the $Se(SCN)_2$ solutions exhibit a strong parallel with that of the solid compound, indicating the presence of the SS isomer. Few additional bands are observed, which might be attributed to the NS isomer, or more correctly the N-bonded NCS group in the NS isomer, since the bands arising from the S-bonded group are probably very similar to related bands in the SS isomer. Additional bands in the Raman spectrum of the solution

compared to that of the solid are observed at 270, 570, and 938 cm^{-1} and the low-frequency member of the SeS stretching bands at 350 cm^{-1} increases in relative intensity when the $Se(SCN)_2$ is in solution. The IR spectrum of the THF solution provides more substantial evidence of the presence of the NS isomer. The strongest band in this spectrum is observed at 1778 cm^{-1}, which is readily attributed to the N-bonded thiocyanate, and a weak peak at 994 cm^{-1}, which may be due to an overtone. Judging from the frequency of the CN stretching mode in the N-bonded isomer, the CN bond adopts considerable double bond character when thiocyanate is N-bonded, consistent with a resonant form having a non-linear SeNC bond angle and doubly bonded terminal sulphur.



A B

The additional bands in the Raman spectrum are readily assigned on the basis of structure **B**. The band at 270 cm^{-1} is assigned to δ(N=Se-S). The increase in intensity of the peak at 350 cm^{-1}, which coincides with the asymmetric SeS stretching mode, is attributed to δ(Se-N=C). The comparable mode in BrCN, which is the closest isoelectronic species with which comparison can be made, lies at 342 cm^{-1} (23). The weak Raman bands near 570 cm^{-1} are assigned to δ(S=C=N) and that at 938 cm^{-1} to terminal C=S stretching. These latter modes may be compared with those of carbonyl sulfide (OCS), which has a related electronic structure with double bonds to sulphur and oxygen for which the δ(S=C=O) and (C=S) are at 520 and 859 cm^{-1}, respectively.

Conclusion

It is remarkable that, in spite of the complex mechanism involved (2*c*, footnote 4), SeO_2 reacts with thiols and thiolate-derived inorganic species like $S_2O_3^{2-}$ (2*d*) and SO_3^{2-} (3*a*) to give, in apparently 100% yield, the selenotrithionate derivative. and, with few exceptions (3), a disulfide oxidation product. Thiocyanate has now been shown to behave in an entirely analogous way, giving selenium dithiocyanate and thiocyanogen. Like the seleno-pentathionate and -trithionate species, $Se(SCN)_2$, which is S-bonded in the solid state (5), forms NS-bonded and SS bonded linkage isomers in solution. Thiocyanate is well known as an ambidentate ligand in metal coordination chemistry (10) and several covalent thiocyanates and isothiocyanates are known. Se(II) may also bind to the SCN group over sulphur or nitrogen. Unfortunately $Se(SCN)_2$ decomposes slowly in solution and further studies on the chemistry of this interesting Se(II) species will be difficult.

Electrochemical study of the reaction between progressively alkylated thiazine leucodyes and Fe(III) on a glassy carbon electrode

S. Ahmed and S.K. Saha

Abstract:An electrochemical investigation on five progressively alkylated thiazine dyes in the presence of Fe(III) ions is reported. The theory of the catalytic regeneration mechanism involving an electrode reaction followed by a coupled chemical reaction is applied to derive kinetic parameters of homogeneous reaction. The second-order rate constant for the reaction of thiazine leucodyes with Fe(III) ions was found to increase from 0.25×10^4 to 1.6×10^4 dm^3 mol^{-1} s^{-1} upon monomethylation and to vary from 0.7×10^4 for the dimethyl derivative to 1.4×10^4 dm^3 mol^{-1} s^{-1} for the tetramethyl one. The electron-donating nature as well as the hydrophobic characteristics of the methyl group influence the kinetics of the homogeneous reaction.

Key words: cyclic voltammetry, thiazine dyes, ferric ion, catalytic regeneration, kinetics.

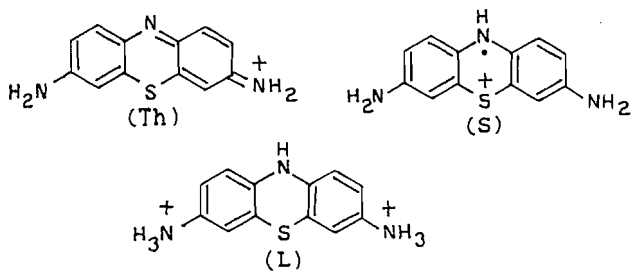
Résumé : Opérant en présence d'ions Fe(III), on a effectué une étude électrochimique de cinq colorants de la thiazine de plus en plus alklyés. Afin de déterminer les paramètres cinétiques de la réaction homogène, on a appliqué la théorie du mécanisme de la régénération catalytique impliquant une réaction à l'électrode suivie par une réaction chimique couplée. On a trouvé que la constante de vitesse du deuxième ordre des leucocolorants de la thiazine avec les ions Fe(III) passe de $0{,}25 \times 10^4$ à $1{,}6 \times 10$ dm^3 mol^{-1} s^{-1} par monométhylation et qu'elle passe de $0{,}7 \times 10^4$ pour le dérivé diméthylé à $1{,}4 \times 10$ dm^3 mol^{-1} s^{-1} pour le dérivé tétraméthylé. Le caractère électrodonneur ainsi que les caractéristiques hydrophobiques du groupe méthyle influencent tous les deux la cinétique de la réaction homogène.

Mots clés : voltampérométrie cyclique, colorants de la thiazine, ion ferrique, régénération catalytique, cinétique.

[Traduit par la rédaction]

1. Introduction

The most successful photogalvanic (PG) cell for solar energy conversion is the ferrous/thionine cell, yet this too is far from having ideal conversion efficiency (1, 2). In this PG cell the photoreduction of thionine (Th) by Fe(II) ions produces semithionine (S) and Fe(III) ions. Semithionine rapidly disproportionates to Th and leucothionine (L). The advantage of the



above system lies in achieving partial selectivity of charge carriers for appropriate electrodes. However, greatest efficiency would be obtained with a PG cell in which each electrode is perfectly selective for a different couple. Unfortunately, in homogeneous solution, thermal back reaction of electron transfer also takes place. This dissipation of free energy constitutes a considerable problem in the use of the ferrous/thionine PG cell for any practical purposes (3). The following reaction scheme adequately summarizes the whole process, including the relevant recombination reactions (pH 3) (4):

[1] $\mathrm{Th + Fe(II) + H^+} \xrightarrow{h\nu} \mathrm{S + Fe(III)}$

[2] $\mathrm{2S + H^+} \rightleftharpoons \mathrm{Th + L}$

Back reaction

[3] $\mathrm{S + Fe(III)} \longrightarrow \mathrm{Th + Fe(II) + H^+}$

[4] $\mathrm{L + Fe(III)} \longrightarrow \mathrm{S + Fe(II) + 2H^+}$

However, the homogeneous reaction scheme is very complicated and must be properly characterized. Solubility as well as aggregation characteristics of dyes are important criteria that control PG output. Alkyl substitution in dyes affects both these characteristics, and this prompted us to utilize some progressively alkylated thiazine dyes for a detailed study on homogeneous reactions with Fe(III) ions. In view of this, an electrochemical technique was adopted with the aid of dc voltammetry. An electrode reaction coupled with a chemical reaction is an interesting subject of investigation for electrochemists (5). The electrochemical reduction of progressively alkylated thiazine dyes to the corresponding leucodyes at the stationary electrode in the presence of Fe(III) ions may be described as a so-called "catalytic regeneration mechanism,"

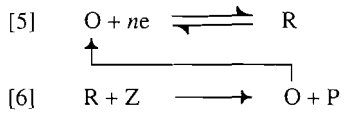
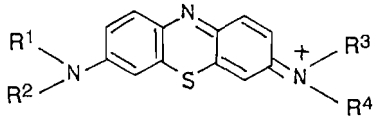
according to which an initial electroactive species is regenerated by the homogeneous chemical reaction. This mechanism can be represented by the following scheme (5):



If applied judiciously, this technique yields kinetic parameters of the chemical reaction from a simple electrochemical experiment. Although thermal back reactions have been studied in considerable detail by a flash photolysis technique (4, 6–8), the former technique has been applied only recently for the homogeneous reaction relevant to the ferrous/thionine PG cell. Kinetic parameters were also determined using an indium-doped SnO_2 electrode, assuming a pseudo-first-order reaction condition to prevail even though the experimental result did not always conform with theory (9). The present study was undertaken in view of the pivotal importance of the nature of the electrode surface in such a study and also to examine the role of hydrophobic interaction, if any, on the reaction kinetics. In this paper, we summarize the results of such an electrochemical study on the reaction between various alkyl derivatives of thiazine leucodyes with Fe(III) on a glassy carbon electrode that has been found to behave well in the present set of systems.

2. Experimental

Five progressively alkylated thiazine dyes, viz., thionine, azure C, azure A, azure B, and methylene blue, that are used for the present study were supplied by Aldrich Chemical Co., U.K. All other chemicals were of analytical grade (Aldrich/B.D.H.) and used as received. The structures of the dyes are given below:



Thionine(Th): $R^1 = R^2 = R^3 = R^4 = H$
Azure C(AzC):$R^1 = R^2 = R^3 = H$; $R^4 = CH_3$
Azure A(AzA):$R^1 = R^2 = H$; $R^3 = R^4 = CH_3$
Azure B(AzB):$R^1 = H$; $R^2 = R^3 = R^4 = CH_3$
Methylene blue (MB):$R^1 = R^2 = R^3 = R^4 = CH_3$

All the dyes were found to contain coloured impurities and were purified over a chromatographic column of silica gel using a chloroform–methanol mixture as eluent. Azure C was extracted efficiently with an 8:2 chloroform–methanol mixture whereas azure A was extracted with a 7:3 solvent mixture. All other dyes were eluted by less polar solvent mixtures than that used for azure A. Finally, the dyes were recrystallized and dried at 50°C under vacuum. Final purities of dye samples were checked by TLC using an 8:2 water – acetic acid mixture as the mobile phase, and the purities of all the dyes except AzC were found to be excellent. The commercial sample of AzC contained a high percentage of insoluble materials in addition to other coloured impurities. Even after repeated chromatographic treatment, the sample gave a faint additional spot on the TLC plate, indicating the presence of a small amount of impurity. Although this dye could not be purified up to the level of other four dyes, various analyses (spectral and analytical) showed that the final purity of the dye was satisfactory.

For electrochemical experiments, the supporting electrolyte was sulphuric acid. All solutions were purged with pure nitrogen before the experiment. Cyclic voltammetric experiments were carried out employing a BAS cyclic voltammograph (CV-27, U.S.A.). The working electrode was a glassy carbon microelectrode (MF-2012, BAS, diam. 3.2 mm) with a platinum wire as auxiliary electrode. Potentials were measured with respect to the saturated calomel electrode. All measurements were done at a constant pH of 2.0 and at room temperature (25 ± 1°C).

3. Results and discussion

A cyclic voltammogram of azure C (5.0×10^{-5} mol dm^{-3} in 0.1 mol dm^{-3} H_2SO_4) is shown in Fig. 1A. Voltammograms of all other dyes are similar and consistent with reversible two-electron transfer systems within the range of potential scan (v) of 5–100 mV s^{-1}. Data pertaining to the position of peak potentials and current ratios, i_{pc}/i_{pa}, for the five thiazine dyes are shown in Table 1. Current vs. (scan rate)$^{1/2}$ plots deviate from linearity above scan rates of 100 mV s^{-1} (plots not shown, see Table 1).

The peak potentials (E_{pa} and E_{pc}) are not sensitive to scan rates and ΔE_p's do not vary up to a scan rate of 300 mV s^{-1} except for AzC. This shows that the electrode processes are very fast and the quasi-reversibility is apparent only in AzC. Previous reports available for Th and MB were, however, consistent with the present observation (9–12). Diffusion coefficient (D_0) values are determined from cyclic voltammetry measurements as 3.05×10^{-6}, 2.66×10^{-6}, 4.40×10^{-6}, 4.90×10^{-6}, and 5.7×10^{-6} cm^2 s^{-1} for Th, AzC, AzA, AzB, and MB, respectively (determined from the slopes of i_{pc} vs. $v^{1/2}$ plots at slow scan rates, employing the Randles–Seveik equation (5)).

Interestingly, the D_0 value increases regularly upon progressive alkylation of the dye molecule, with the only exception being AzC. On the other hand, the Fe(II)/Fe(III) system exhibits irreversible electron transfer at the GC electrode in the potential range of 0.3–0.6 V (Fig. 2). But the couple is no longer electrochemically active in the presence of thiazine dyes, which of course have much higher heterogeneous kinetics (k_s(Th) = 5×10^{-3} cm s^{-1}, k_s (Fe) = 3.1×10^{-5} cm s^{-1} on a gold foil electrode (4)).

On the other hand, voltammograms of thionine and its derivatives in the presence of varying amounts of Fe(III) ions (5.0×10^{-5} – 1.0×10^{-3} mol dm^{-3}) show striking changes from those obtained in the absence of Fe(III) ions. The observed catalytic current results from the regeneration of dyes from the reduced leucodyes by reaction with Fe(III) ions. Representative voltammograms of AzC are shown in Fig. 1*b*,*c*. Along with the catalyltic regeneration of thiazine dyes in the presence of Fe(III) ions, which of course is believed to be the major process occurring in the system, a certain amount of semithiazines may also be present via a dismutation equilibrium (8). These semithiazines were oxidized at the GC electrode to give the small anodic peak current at higher positive potential on the reversed scan (Fig. 1*b*). Although the Fe(II)/Fe(III) couple is electrochemically inactive at the GC elec-

trode in the presence of thiazine dyes, its adverse effect on the voltammograms of the latter by increasing the background current cannot be ignored. To confirm that the experimental results conform to the theory of catalytically coupled reactions (EC′) of the type shown in eqs. [5] and [6] as a major process, it is necessary to draw a diagnostic plot of the current function against the potential scan rates.

This correlation can be seen by simply plotting $i_{pc}/v^{1/2}$ as a function of log v (13). A representative diagnostic plot for AzB is shown in Fig. 3. In the absence of any Fe(III) ions, the plots for all the dyes are linear and parallel to the potential scan rate axis up to 100 mV s^{-1} (Fig. 3*a*). This is expected for a diffusion-controlled reversible electrode process. However, at higher scan rates the observed upward shift of the plot is indeed the manifestation of positive deviation from the linear relationship of i_{pc} with $v^{1/2}$ (Table 1) for almost all the dyes. On the other hand, in the presence of Fe(III) ions (5.0×10^{-5} – 1.0×10^{-3} mol dm^{-3}), the diagnostic, the diagnostic plots are similar for all dyes and are indicative of an EC′ type of coupled catalytic chemical reaction. The catalytic regeneration of dyes as a major process is particularly apparent at lower scan rates as the reaction gets sufficient time for generation of dyes

Fig. 1. Cyclic voltammograms of AzC (5×10^{-5} mol dm^{-3}) in the presence of various concentrations of Fe^{3+}: (*a*) 0, (*b*) 8×10^{-4}, (*c*) 1.5×10^{-3} mol dm^{-3}. Supporting electrolyte: 0.1 mol dm^{-3} H_2SO_4.

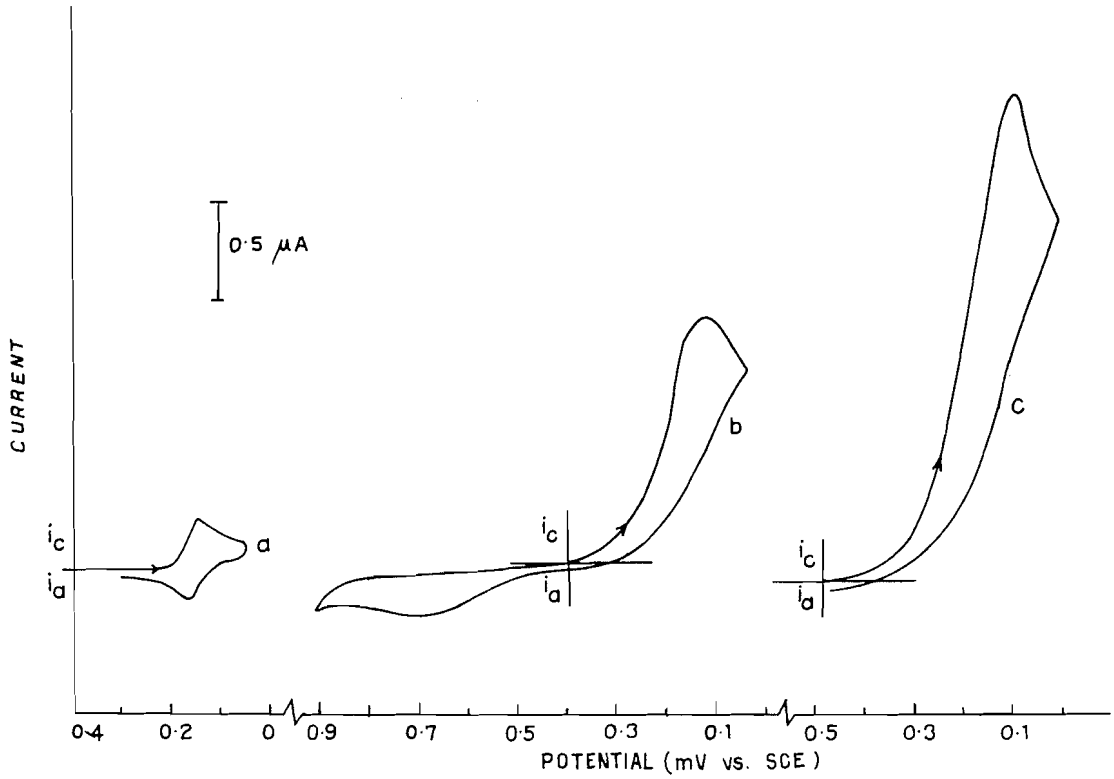

Fig. 2. Cyclic voltammograms of $FeCl_3$ (in the presence of 0.1 mol dm^{-3} H_2SO_4) at a GC electrode. Concentration of Fe(III): (1) 2×10^{-4}, (2) 4×10^{-4}, (3) 6×10^{-4}, (4) 8×10^{-4} mol dm^{-3}. Scan rate: 5 mV s^{-1}.

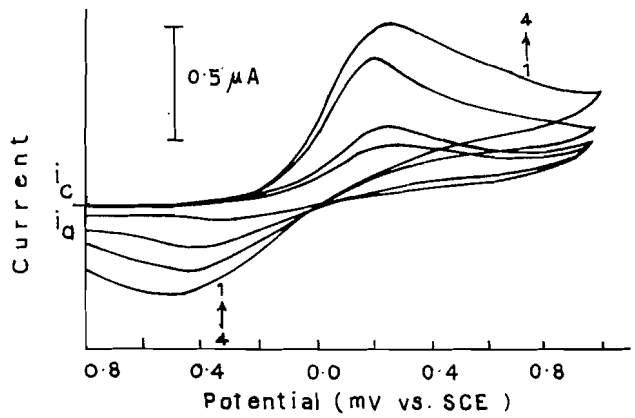


from the reduced leucoforms by reaction with Fe(III) ions, consistent with the theoretical model (14, 15). However, when the scan rate increases, the ratio of kinetic current in the presence of Fe(III) to the cathodic peak current in the absence of Fe(III), i_d/i_{pc}, should tend towards unity. But this situation was not attained in the present study even at a sweep rate of 300 mV s^{-1} (Fig. 3). Similar results were also observed by previous workers for the intermolecular electron transfer of Cytochrome C in presence of *pseudomonas* Cytochrome C551 (13) and for the homogeneous reaction of leucothionine with Fe(III) (9). Whereas we failed to identify any other mechanisms of coupled chemical reactions than EC′ to be operative in the present systems, the exact reason for the above remains uncertain.

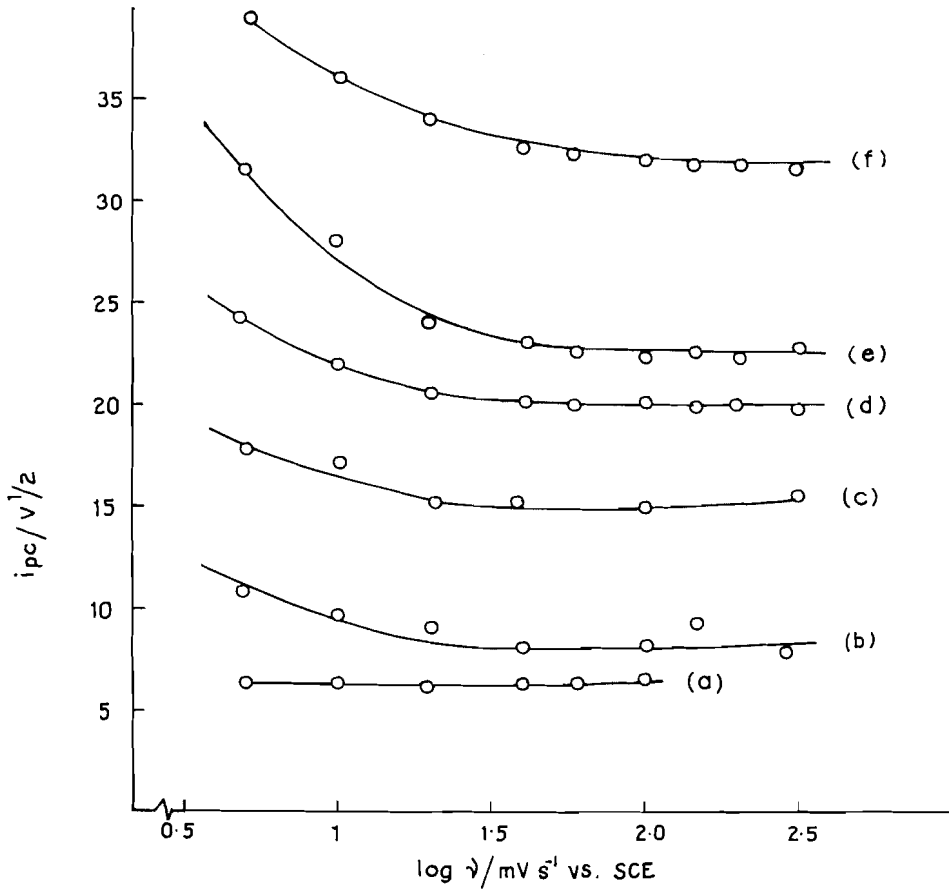
Despite the simplified approach in view of the above and the complicated back reaction in the present systems, attempts have been made to derive kinetic information form the observed data. Using a working curve (Fig. 14 of ref. 14) of i_k/i_d vs. the kinetic parameter, $(k_f/a)^{1/2}$, we plotted the data of k_f/a (where $a = nF/RT$) against $1/v$, which should be linear under first-order conditions (Fig. 4). The result shows marked deviation from the predicted linearity at slower scan rates, which is consistent with loss of first-order conditions. The reactant dye is not in sufficiently large excess and so is consumed to a considerable extent in the diffusion layer during the time period of a slower scan rate. Second-order kinetics is probably followed and the situation is identical to one that occurred in the intermolecular electron transfer of cytochrome C(13). Moreover, the initial slope of each curve (Fig. 4) at infinite scan rates is proportional to the true pseudo-first-order rate constant k_f^0,

$$k_f^0 = (nF/RT) \text{ (initial slope)}$$

Drawing tangents to the above curves at $1/v \rightarrow 0$ yields values of k_f^0 for each experiment. An alternative method of finding k_f^0 is to calculate the effective pseudo-first-order rate constant k_f', from each k_f/a value at a given scan rate where,

$$k_f' = (F/RT)\, v\, (k_f/a) \qquad \text{(ref. 13)}$$

Fig. 3. Diagnostic plots of current functions $i_{pc}/v^{1/2}$ vs. log v for AzB (5×10^{-5} mol dm^{-3} in 0.1 mol dm^{-3} H_2SO_4) at various concentrations of Fe^{3+}: (*a*) 0, (*b*) 2×10^{-4}, (*c*) 4×10^{-4}, (*d*) 6×10^{-4}, (*e*) 8×10^{-4}, (*f*) 1×10^{-3} mol dm^{-3}.



Plotting k_f' as a function of $1/v$ and extrapolating to $1/v \rightarrow 0$, one can evaluate the pseudo-first-order rate constant, k_f^0, at infinite scan rate. This latter method seems to be more convenient, and data for thionine are plotted in Fig. 5. (Similar plots for all other dyes are submitted as supplementary material.)[2] The nature of the plots is again similar for all five dyes and also similar to those observed by Hill and Walton for intermolecular electron transfer in cytochrome C(13). Finally, k_f^0 values at infinite scan rates and for varying concentrations of Fe(III) are plotted against the concentrations of Fe(III) ions in order to examine the second-order rate constants, k_2, for the homogeneous reaction of Fe(III) with various leucodyes. These plots are linear, indicating that the homogeneous reaction is first order with respect to Fe(III) ions and, indeed, the overall reaction is of second order (inset of Fig. 5). However, a striking feature is that, unlike Th, slopes of the plots for all other dyes decrease drastically at low Fe(III) concentrations (at $C_{Fe(III)} < 2.0 \times 10^{-4}$ mol dm^{-3} for AzC, AzA and at $C_{Fe(III)} < 4.0 \times 10^{-4}$ mol dm^{-3} for AzB, MB), resulting in the deviation of the plots from linearity. This result suggests that at low Fe(III) concentrations the actual scheme of reaction should be more complex than the one shown in eqs. [5] and [6] and supports the hypothesis that the return of leucodyes to the corresponding thiazine dyes by Fe(III) ions occurs by a two-step process via the formation of semithiazine as an intermediate species. Conversion of semithiazines to the corresponding thiazine dyes may occur either by Fe(III) or through the dismutation equilibrium (as mentioned before), forming leuco dyes and the original dyes. The latter process is, however, more significant at low Fe(III) concentrations (8). Nevertheless, observed gradients of the straight lines are significant and the second-order rate constants, k_2, derived from these data are depicted in Table 2.

Table 2. Second-order rate constants of the homogeneous reaction between thiazine dyes and Fe^{3+} ions.

Leucodyes	$k_2 \times 10^{-4}$ (dm^3 mol^{-1} s^{-1})
Th	0.25
AzC	1.60
AzA	0.70
AzB	1.00
MB	1.40

The table shows that the k_2 value for thionine is 0.25×10^4 dm^3 mol^{-1} s^{-1}, which is the lowest among all the dyes used.

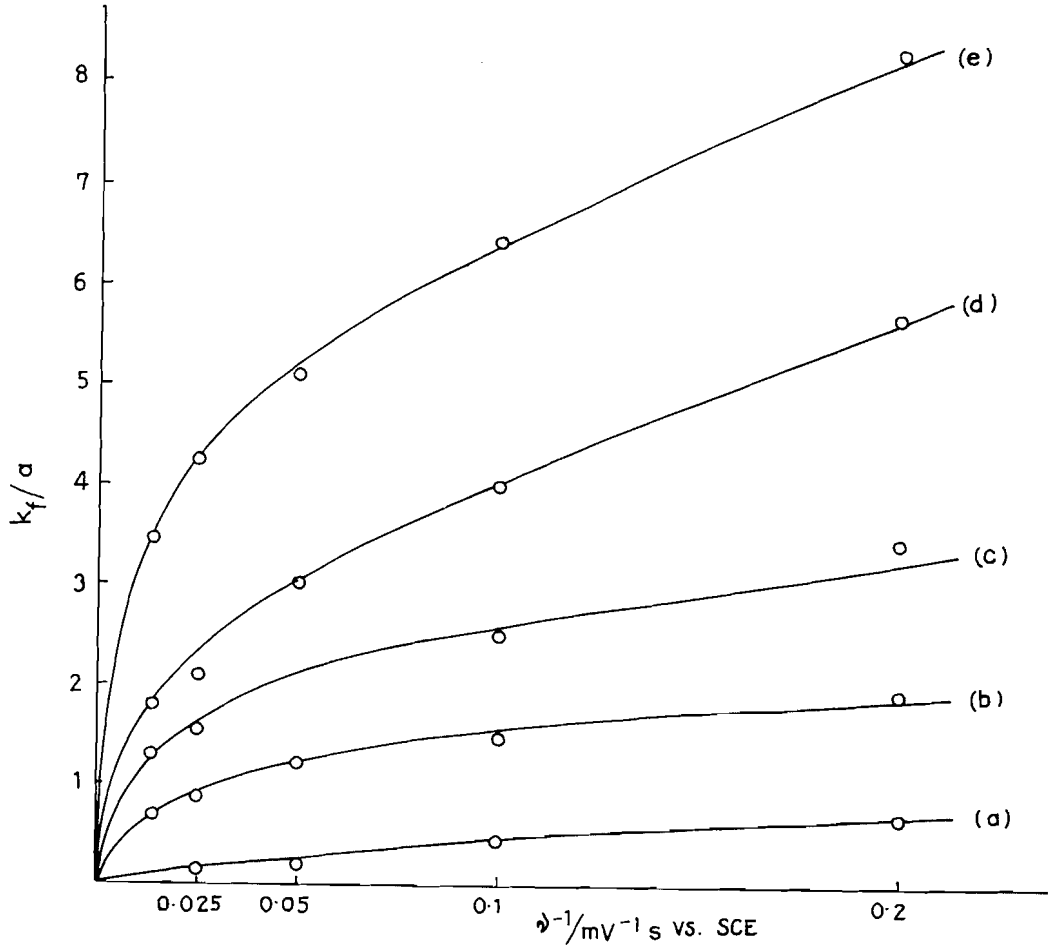
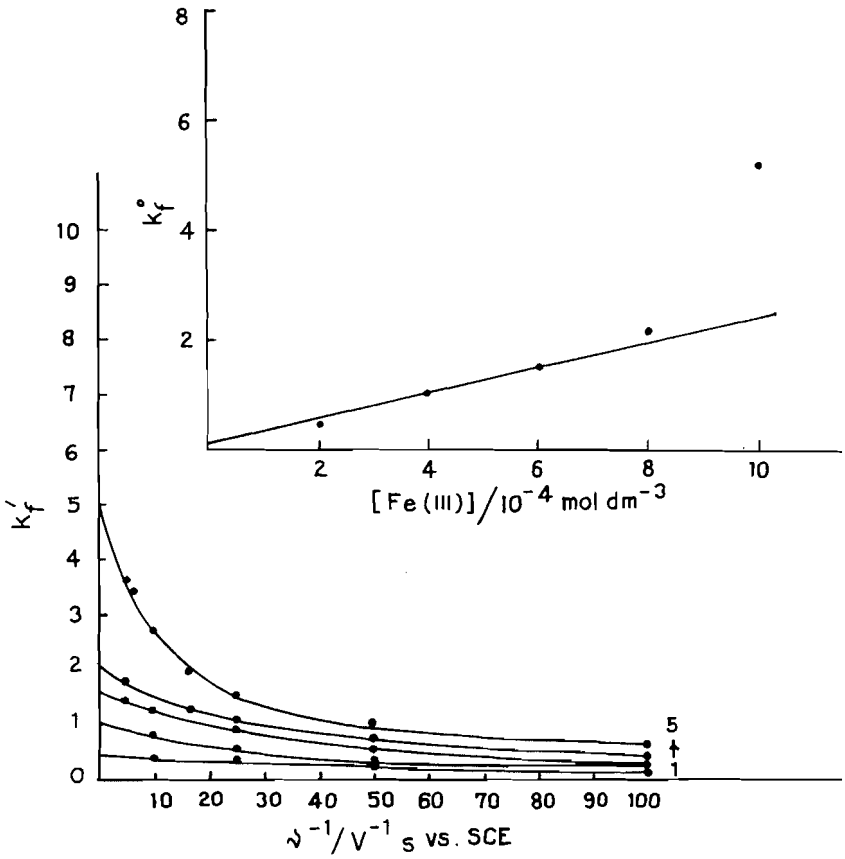
Fig. 4. Plots of kinetic parameter, k_f/a, against $1/v$ for the AzB–Fe(III) system at various concentrations of Fe^{3+}: (*a*) 2×10^{-4}, (*b*) 4×10^{-4}, (*c*) 6×10^{-4}, (*d*) 8×10^{-4}, (*e*) 1×10^{-3} mol dm^{-3} (in presence of 0.1 mol dm^{-3} H_2SO_4).



Upon progressive alkylation of the dyes this value increases regularly with an exception only for AzC, which gives the highest value of 1.6×10^4 dm^3 mol^{-1} s^{-1}. Regular increase of k_2 with progressive alkylation of the dye molecule would indeed be expected from the electron-donating nature of a methyl group. However, in the present systems, while the first methyl group brings about a sixfold increase of the rate, the second one causes a twofold decrease, and adding the third and the fourth has only a small effect (1.4-fold increase with each methyl). In fact, the leucodye with four methyl groups is oxidized more slowly than the dye with only one methyl group. It seems apparent that factors other than the electron-donating effect of the methyl group are involved. Substitution of hydrogens on the nitrogen of a dye molecule by methyl groups introduces hydrophobicity in the molecule as well. It has also been shown that a hydrophobic environment in the presence of certain micelles delays back electron transfer in solution (4, 16) while substitution with ionic or polar groups, for example disulfonated thionine, shows faster back electron transfer in PG cells (17, 18). Thus, increased hydrophobicity due to alkylation of the present dyes may in turn slow down the electron transfer reaction with Fe(III) ions in aqueous solution to some extent. These two mutually opposite effects of the methyl group may thus be responsible for the observed variation of rates. It is also important to note in this context that the formal potential values ($E^{0\prime}$) for progressively methylated dyes are 0.205, 0.175, 0.207, 0.281, and 0.196 V (average values for v between 5 and 100 mV s^{-1}, Table 1), respectively, and the observed lowest value of $E^{0\prime}$ for AzC is consistent with the above results. However, one can infer from the foregoing result that, with the exception of AzC, the PG output will decrease continuously with alkyl substitution in the dye molecule. All previous reports showed that PG output for the Fe(II)–MB cell is always less than that for the Fe(II)–thionine cell. An earlier report of second-order rate constants (measured by flash photolysis) ranged from values of 0.47×10^3 to 1.0×10^3 dm^3 mol^{-1} s^{-1} for various modified thiazine dyes (7). Ferreira and Harriman report a value of 9.0×10^4 dm^3 mol^{-1} s^{-1} for the Fe(III)–thionine system by a similar flash photolysis technique (8). On the other hand, with the help of an electrochemical method similar to one applied in the present study, Murthy and Srivastava estimated the value as 4.0×10^5 dm^3 mol^{-1} s^{-1} for the reaction between Fe(III) ions and leucothionine (9). While a close comparison between data reported

Fig. 5. Effective pseudo-first-order rate constant, k_f', as a function of reciprocal scan rate extrapolated to $1/v \rightarrow 0$, for experiments with the Th–Fe(III) system: (1) 2×10^{-4}, (2) 4×10^{-4}, (3) 6×10^{-4}, (4) 8×10^{-4}, (5) 1×10^{-3} mol dm^{-3} Fe^{3+} (in the presence of 0.1 mol dm^{-3} H_2SO_4) (lower figure). Pseudo-first-order rate constant, k_f^0, as a function of the concentrations of Fe^{3+} with the same system (upper figure).



by different methods and under different conditions is not always valid, the general trend of the present result is satisfactory and, especially, the observed variation of k_2 due to progressive alkylation of the dye molecule demonstrates the usefulness of the comparatively simpler electrochemical technique adopted in the present investigation.

COMMUNICATION

A study of the vacuum pyrolysis of 11-oxatricyclo[6.2.1.$0^{2,7}$]undeca-2,9-diene. The HeI ultraviolet photoelectron spectrum of 1,2-cyclohexadiene

Nick Henry Werstiuk, Chandra Deo Roy, and Jiangong Ma

Abstract: A newly developed ultraviolet photoelectron spectrometer – CO_2 laser apparatus that utilizes a 50-watt CW CO_2 laser as a directed heat source is used to study the vacuum pyrolysis of 11-oxatricyclo[6.2.1.$0^{2,7}$]undeca-2,9-diene (**4**). We report the HeI photoelectron spectrum of the strained cyclic allene 1,2-cyclohexadiene (**1**) that correlates with the HAM/3 ionization energies calculated with the optimized C_2 equilibrium structure obtained with AM1 and the molecular orbital energies of the optimized C_2 equilibrium structure calculated at the ab initio HF/6-31G** level of theory.

Key words: 11-oxatricyclo[6.2.1.$0^{2,7}$]undeca-2,9-diene, vacuum pyrolysis, HeI ultraviolet photoelectron spectrum, 1,2-cyclohexadiene.

Résumé : On a utilisé un spectromètre photoélectronique ultraviolet à laser au CO_2 de 50 watt CW développé récemment comme source de chaleur dirigée pour d'étudier la pyrolyse sous vide du 11-oxatricyclo[6.2.1.$0^{2,7}$]undéca-2,9-diène (**4**). On a déterminé le spectre photoélectronique HeI du cyclohexa-1,2-diène (**1**), un allène cyclique tendu; il existe une bonne corrélation entre ce spectre expérimental et les énergies d'ionisation HAM/3 calculées en utilisant une structure en équilibre C_2 optimisée obtenue avec AM1 ainsi que les énergies d'orbitales moléculaires de la structure en équilibre C_2 optimisée calculée au niveau ab initio HF/6-31G** de la théorie.

Mots clés : 11-oxatricyclo[6.2.1.$0^{2,7}$]undéca-2,9-diène, pyrolyse sous vide, spectre photoélectronique ultraviolet HeI, cyclohexa-1,2-diène.

Studies that combine ultraviolet photoelectron spectroscopy (pes) and calculations of molecular orbital (MO) energies and orbital coefficients at the semi-empirical or ab initio levels of theory provide fundamental information about the structures and bonding of stable compounds and transient species that is obtained by no other technique. In the past, transient species studied with pes generally were prepared by vacuum pyrolysis of compounds using electrically heated furnaces centimetres in length (1, 2). To facilitate the study of highly reactive transients in the gas phase, we developed a CW CO_2 laser – pes apparatus (the laser is used as a directed heat source to produce a hot zone that is 1–2 mm in length) and used it successfully to study the vacuum pyrolysis of a number of substrates (3–5).

Because of its unique structure and kinetic reactivity, the highly strained cyclic allene, 1,2-cyclohexadiene (**1**), has been the focus of studies by experimentalists and theoreticians for some time (6). When generated from a wide range of precursors in solution it is trapped with reactive dienes and hydroxylic solvents or it dimerizes and tetramerizes. And, there have been two reports of attempts to prepare and study **1** with the matrix isolation technique. Wentrup et al. pyrolyzed bicyclo[3.10]hexane-6-carbonyl chloride (**2**) at 1073 K and obtained infrared spectroscopic data that indicated the successful trapping of **1** in an Ar martix at 11 K (7). Runge and Sander subsequently challenged the conclusions reached in this paper on the basis of the results they obtained by pyrolyzing 6-bromo-6-(trimethylstannyl)bicyclo[3.10]hexane (**3**) at 873 K and trapping the pyrolysate at 10 K (8). Given these findings and the fact that (*a*) there have been no reports of the pe spectrum of **1** and (*b*) we wished to establish the scope and limitations of studying transient species with our newly devel-

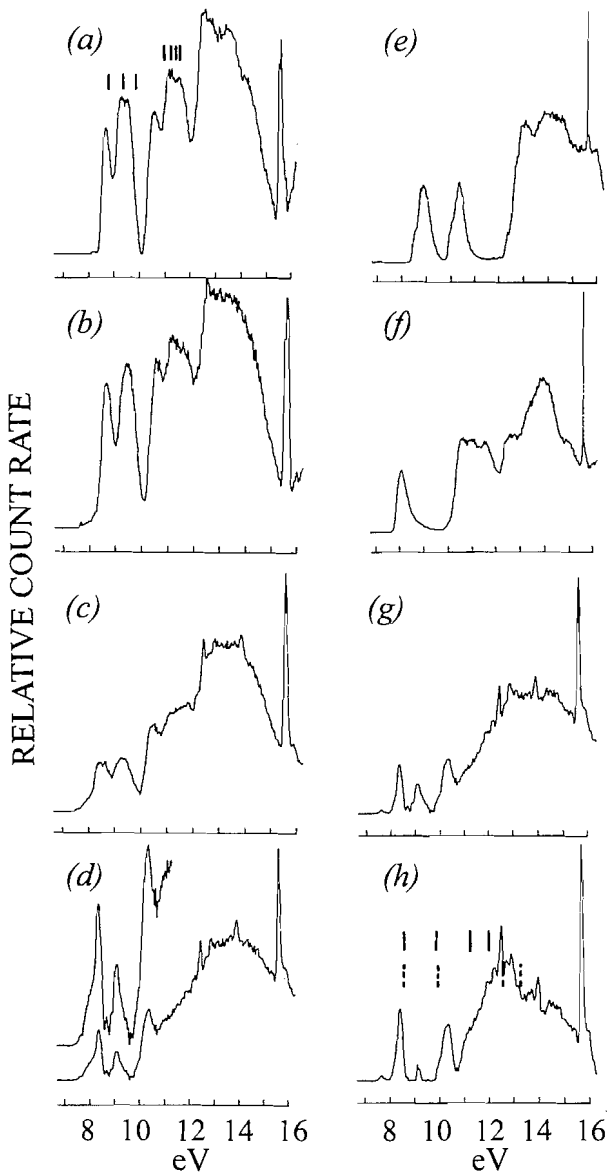
Fig. 1. (*a*) HeI photoelectron spectrum of **4** obtained at ambient temperature (the vertical lines mark the HAM/3 IEs calculated with the AM1 optimized equilibrium structure); (*b*) HeI photoelectron spectrum of **4** obtained at a laser power level of 26 W; (*c*) HeI photoelectron spectrum of the pyrolysate of **4** obtained at a laser power level of 46 W; (*d*) spectrum obtained by subtracting (*b*) from (*c*); (*e*) HeI photoelectron spectrum of furan obtained at a laser power level of 47 W; (*f*) HeI photoelectron spectrum of 1,3-cyclohexadiene obtained at a laser power level of 47 W; (*g*) spectrum obtained by subtracting (*f*) from (*d*); (*h*) spectrum obtained by subtracting (*e*) from (*g*) (the solid vertical lines mark the HAM/3 IEs calculated with the AM1 optimized equilibrium structure; the broken lines correspond to the negative of the MO energies calculated for the HF/6-31G** optimized equilibrium structure).

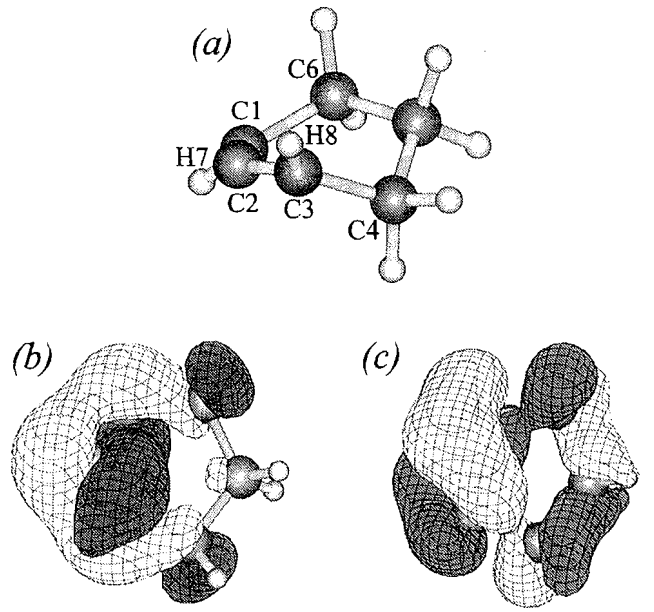


oped pes – CW CO_2 laser apparatus, we undertook to prepare **1** in the gas phase and obtain its pe spectrum. In this communication, we report the results of a study on the pyrolysis of 11-oxatricyclo[6.2.1.$0^{2,7}$]undeca-2,9-diene (**4**).

We chose to prepare and study **4** (9) with the expectation that its pyrolysis in a 1–2 mm hot zone of a quartz nozzle (3–5) would yield **1** and furan, a stable product that would be easily identified by photoelectron spectroscopy. The photoelectron spectra of **4** along with its pyrolysate obtained at two laser power levels are displayed in Fig. 1. Figure 1 (*a*) is the pe spectrum of **4** obtained at ambient temperature. The seven lowest ionization energies (IEs) (8.98, −9.54, 10.02, 11.06, 11.26, 11.53, and 11.69 eV) calculated with HAM/3 (10) — the equilibrium optimized structure of **4** obtained with AM1 (11) was used in this case — are marked on the spectrum as solid lines, indicating that this combination of computational methods yields the IEs with good accuracy and allowing the molecular orbitals of **4** to be characterized. Spectra (*b*) and (*c*) were obtained at laser power levels of 26 W (the tip of the nozzle is 550 ± 50°C) and 47 W(850 ± 50°C), respectively. It is seen that the latter one differs significantly from spectrum (*a*). Spectrum (*b*) (scaled by 0.7), not (*a*), was subtracted from (*c*) to obtain the difference spectrum (*d*)[2]. In this way, the effect of potential changes in the spectrum of **4** induced by the high temperature would be minimized although the signals due to **1** and furan would be reduced to some extent as well. Spectra of authentic samples of furan and 1,3-cyclohexadiene — the latter compound is formed from **1** via a 1,3-hydrogen shift (8) — were also obtained at 47 W and are displayed as spectra (*e*) and (*f*), respectively. Spectrum (*g*) is obtained by subtracting (*f*) (scaled by 0.28) from spectrum (*d*). This operation reduces the shoulder at 8 eV of the lowest IE peak found in (*d*) and brings out the lowest IE bands of furan at 9.00 and 10.38 eV, respectively. Spectrum (*h*) is obtained by subtracting the spectrum of furan (*e*), scaled by 0.4) from (*g*). There are no sharp bands centered at 9.60 eV in spectra (*g*) and (*h*) that are characteristic of the pe spectrum of 1-buten-3-yne (12), indicating that the retro Diels–Alder reaction of **1** observed by Runge and Sander (8) does not occur to a significant extent under the experimental conditions employed in this study. That **1** does not dimerize is indicated by the fact that spectra (*g*) and (*h*) do not exhibit a band at 9.6 eV, a peak seen in the spectrum (not shown; obtained at 47 W) of an authentic sample of **5** (13) that exhibits two low-IE bands of equal intensity at 8.40 and 9.60 eV. That the experimental pe spectrum (the vertical IEs of the two low-lying bands are 8.4 and 10.4 eV) obtained in this study correlates with the HAM/3 IEs (the four lowest ones at 8.60, 9.89, 11.40, and 12.00 eV calculated with the AM1 optimized C_2 structure are indicated with solid lines) and the negative of the energies of the four highest occupied MOs (8.64, 9.96, 12.61, and 13.12 eV, shown as broken lines) of the optimized C_2 structure obtained at the HF/6-31G** level of theory (*a*) indicates that **1** is obtained from **4** and (*b*) provides support

[2] We recognize that care should be exercised when difference spectra are obtained, especially when fairly featureless spectra are involved. Because the spectra acquired in this study differed in intensity, scaling was required to obtain the difference spectra. When spectrum (*d*) was obtained by subtracting (*b*) from (*c*), special attention was paid to the region at 10 eV to ensure that the subtraction did not yield a negative baseline. This criterion was also used in the other cases. That the low-IE band of furan is cleanly recovered in the difference spectrum (*d*) and the two low-IE bands of spectrum (*h*) are roughly equal in area, in our view, validates the process.

Fig. 2. (*a*) Optimized equilibrium structure of **1** obtained at the HF/6-31G** level of theory; (*b*) a display of the HOMO of **1**; (*c*) a display of the HOMO-1 of **1**.



that **1** is a chiral allenic singlet species (6). The optimized equilibrium C_2 structure calculated at the ab initio HF/6-31G** level of theory using Gaussian 94 (14) is displayed as Fig. 2(*a*). As seen from a comparison of several selected geometrical parameters, the ab inito and AM1 optimized C_2 structures of **1** are similar (HF/6-31G**: C1—C2 1.306 Å, C3—C4 1.526 Å, C4—C5 1.572 Å, ∠C1-C2-C3 133.9°, ∠H7-C1-C2-C3 141.4°, ∠C6-C1-C2-C3 −26.0°; *AM1*: C1-C2 *1.320* Å, C1—C6 *1.504* Å, C4—C5 *1.542* Å, ∠C1-C2-C3 *134.8*°, ∠H7-C1-C2-C3 *151.3*°, ∠C6-C1-C2-C3 *−23.4*°) with the largest difference seen in the H7-C1-C2-C3 dihedral angles. The C6-C1-C3-C4 dihedral angles of the structures obtained at the HF/6-31G** and AM1 levels of theory are −47.8° and −43.7°, respectively, approximately half the angle expected for an allene. Thus, the twist angles for the double bonds of the HF/6-31G** and AM1 structures are 20.7° and 22.8°, well within the value required to maintain effective overlap of adjacent *p* orbitals. The HOMO and HOMO-1 of **1** calculated with AM1 and visualized with HyperChem[3] are displayed as Figs. 2(*b*) and 2(*c*), respectively. The HOMO/HOMO-1 gap of **1** is surprisingly large (calculated 1.3 eV, experimental 2 eV) given that 2,3-pentadiene optimized with the C2-C3-C4 angle fixed at 134° exhibits a HOMO/HOMO-1 gap of 0.15 eV. This study also indicates that **4** may be useful for generating **1** in matrix isolation experiments.

New intermediates in the homolytic and heterolytic splitting of dihydrogen[1]

Robert H. Morris

Abstract: Some of the research of the author and his research group into the structure and reactions of dihydrogen complexes of transition metals is reviewed. The characterization of osmium complexes that can be regarded as having intermediate structures on the way to the homolytic splitting and to the heterolytic splitting of dihydrogen is described. The properties of an iridium complex with novel short proton–hydride contacts is also reviewed.

Key words: transition metal, dihydrogen, hydride, complexes, NMR, neutron diffraction, osmium, iridium.

Résumé : On présente une revue des travaux de recherche effectués dans les laboratoires de l'auteur sur la structure et les réactions des complexes dihydrogénés des métaux de transition. On décrit la caractérisation des complexes de l'osmium qui peuvent être considérés comme possédant des structures intermédiaires entre celles conduisant aux ruptures de la liaison H—H du dihydrogène soit homolytiques soit hétérolytiques. On passe aussi en revue les propriétés d'un complexe d'iridium qui comporte de nouveaux contacts courts hydrons–hydrure.

Mots clés : métal de transition, dihydrogène, hydrure, complexes, RMN, diffraction des neutrons, osmium, iridium.

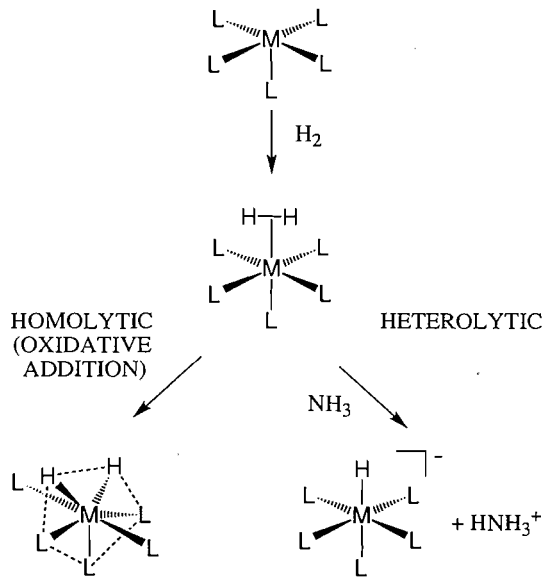
[Traduit par la rédaction]

Introduction

The reaction of dihydrogen gas with soluble transition metal complexes is an important step in many catalytic hydrogenation steps (1). The product of the reaction with H_2 is one of at least three complexes (Scheme 1).

The initial product, intermediate, or transition state contains a dihydrogen ligand coordinated side-on with a short H—H distance (2) (referred to as an η^2-H_2 ligand (3)). This complex might then undergo an oxidative addition reaction where the H—H bond is split homolytically to give, when starting with a six-coordinate dihydrogen complex, a seven-coordinate dihydride product (4).[3] Alternatively, if there is a suitable base present, the dihydrogen bond is split heterolytically to give a six-coordinate metal hydride product and a protonated base. This last reaction is an important feature of dihydrogen chemistry since H_2(g) is not an acid ($pK_a \approx 35$) while dihydrogen complexes can be very acidic with pK_a values of less than 0 (4). This lecture explores the structures and reactions of dihydrogen complexes and intermediates on the way to the dihydride or monohydride products.

Scheme 1. Homolytic splitting (oxidative addition) and heterolytic splitting of the H—H bond in dihydrogen complexes.



Types of dihydrogen complexes

Several hundred stable dihydrogen complexes have been prepared since the discovery of the first complex $W(H_2)(CO)_3(P^iPr_3)_2$ by Kubas et al. at Los Alamos National Laboratory in 1984 (2). Most have the metal in the d^6 electron configuration, i.e., Cr(0), Mo(0), W(0), Mn(I), Tc(I), Re(I),

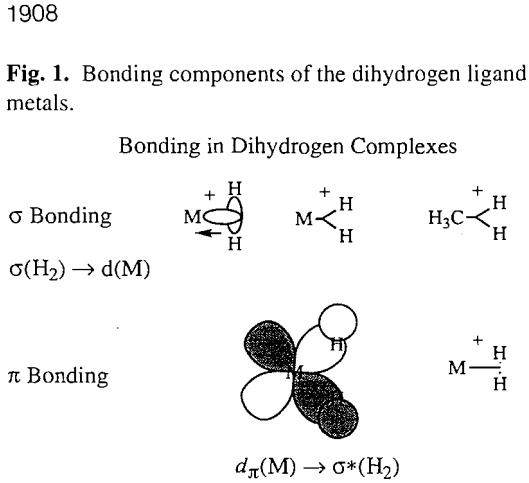
Fig. 1. Bonding components of the dihydrogen ligand to transition metals.



Fe(II), Ru(II), Os(II), Co(III), Rh(III), Ir(III). We reported the determination of the structure of the Fe(II) complex *trans*-$[Fe(H_2)(H)(dppe)_2]BF_4$, dppe = $PPh_2CH_2CH_2PPh_2$, by single crystal X-ray diffraction in 1985 (3). In the same year Crabtree and co-workers reported the existence of iridium dihydrogen complexes including an Ir(III) complex $[Ir(H_2)_2(H)_2(PCy_3)_2]^+$, which is proposed to have two dihydrogen ligands (5). Some unstable dihydrogen complexes with the metal in the d^6 configuration were also reported that year (6–8). A few stable complexes are known with the metal ion in other *d* configurations including the d^4 Re(III) complex $[Re(H_2)(H)_2(CO)(PMe_2Ph)_3]^+$, also reported by Crabtree's group (9).

Bonding

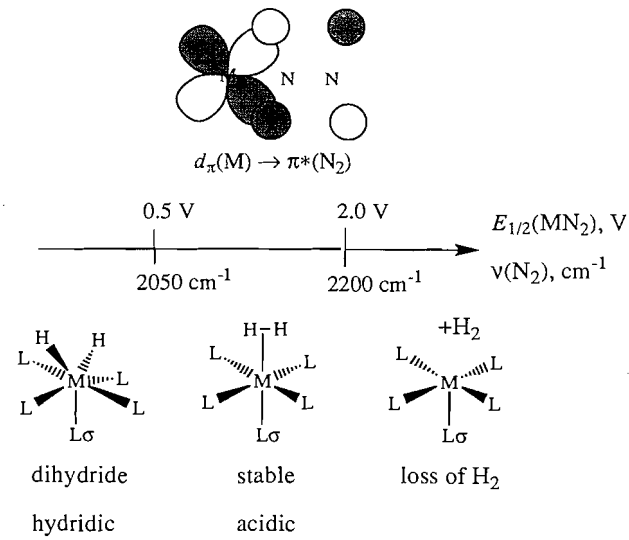
There are two important components to the bonding in dihydrogen complexes (Fig. 1). The first is the donation of σ electrons from H_2 into an empty metal orbital. If this were the only interaction it would be written as a three-centre, two-electron bond as in boron hydride chemistry. However strong main-group Lewis acids do not form stable H_2 complexes; for example the CH_5^+ ion has only transient existence at low temperature. The second crucial component is π-back-donation from a filled *d* orbital into the empty σ* orbital of H_2. The energy of these *d* electrons is an important determinant in the reactivity of the dihydrogen ligand. For example, the higher the energy of these *d* electrons, the more likely it is that the H_2 ligand will undergo homolytic cleavage.

Two methods that we have found to be useful for estimating the energies of the π-bonding *d* orbitals are to determine the infrared spectrum and the redox potentials of the corresponding *dinitrogen* complexes (10, 11). Since the σ and π components in $M(H_2)$ and $M(N_2)$ bonds are similar, the N_2 complexes are indicators of the properties of the H_2 complexes (Fig. 2).

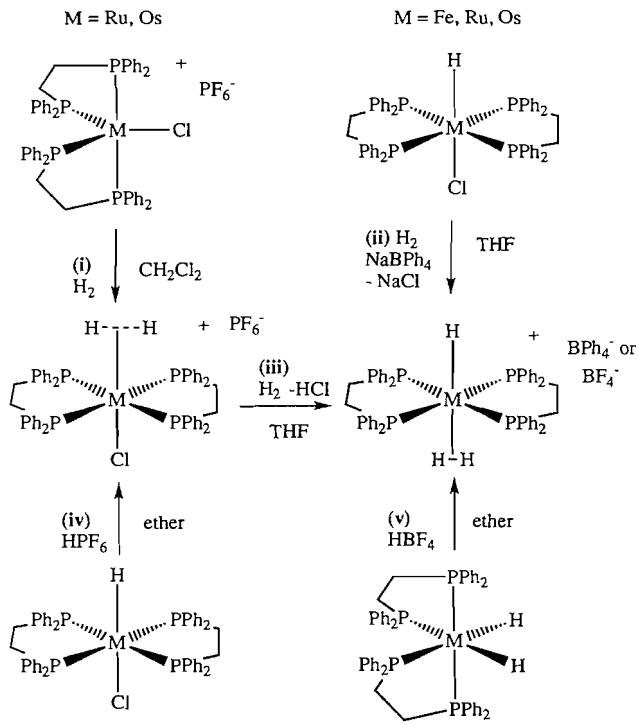
Electrochemical potentials $E_{1/2}(M(N_2)^+)$ of less than 0.5 V (versus NHE) and $\nu(N_2)$ values of less than 2050 cm^{-1} suggest that the complexes are too reducing to make stable H_2 complexes; instead, homolytic splitting occurs to give a dihydride. Redox potentials greater than 2 V and $\nu(N_2)$ greater than 2200 cm^{-1} indicate that there is not enough back-bonding to stabilize the η^2-H_2 ligand with respect to loss of H_2.[4] Therefore we choose metal ions and ligands (guided by Lever's additive electrochemical parameters for ligands as mentioned below) that give properties in the intermediate region. In an attempt to make very acidic dihydrogen complexes we try to work at the 2 V limit.

[4] These guidelines for the stability of dihydrogen complexes do not take into account the relative stabilities of products of dihydrogen loss or oxidative addition of the H—H bond. In certain cases the formation of products is particularly favorable for reasons other than the electronic considerations given here. Then these simple guidelines break down.

Fig. 2. N_2 stretching wave numbers and electrochemical potentials of dinitrogen complexes are indicators of the properties of corresponding dihydrogen complexes.



Scheme 2. Synthesis of dihydrogen complexes from H_2 gas (routes i, ii, and iii) or by adding a proton to a hydride complex (routes iv and v).



Synthesis of dihydrogen complexes

Scheme 2 illustrates two general methods for generating dihy-

drogen complexes. The first involves the reaction of metal complexes with dihydrogen gas (reactions i, ii, and iii). In the second (routes iv and v) a proton is added to a metal hydride complex to produce the H_2 ligand in the reverse of the heterolytic splitting reaction. The reactant in step i is a coordinatively unsaturated complex $[MCl(dppe)_2]PF_6$, where M is either Ru or Os, with interesting distorted trigonal bipyramidal structures. These react rapidly with 1 atm (101.3 kPa) H_2 to give complexes with dihydrogen *trans* to the chloride ligand in *trans*-$[M(H_2)Cl(dppe)_2]PF_6$, M = Ru, Os (12). The complexes with dihydrogen *trans* to hydride in *trans*-$[M(H_2)H(dppe)_2]^+$ are prepared by reacting *trans*-$MCl(H)(dppe)_2$ with Na^+ under 1 atm H_2, reaction (ii). A third reaction with H_2(g) (reaction iii) converts the chloride complex to the hydride complex in the presence of $NaBPh_4$. This reaction is not well understood.

The reactions of acid with the appropriate metal hydrides (steps iv, v) result in the formation of the same dihydrogen complexes as produced above with H_2. Reaction v involves a rearrangement after the protonation step. In this lecture I will concentrate on the chemistry with M being Os and the chelating phosphine ligand, dppe.

Homolytic splitting of dihydrogen

First I will look at intermediate structures on the way to the homolytic splitting of dihydrogen, reaction [1]. This reaction is favoured by metal ions with high *d*-electron energies and ligands that push electrons onto the metal ion. Both of these effects increase back-donation into the σ^* orbital of the H_2 ligand. Metals that form strong M—H bonds and ligands with the correct bite angles will favour the oxidative addition product while ligands with 90° angles will favour the reactant.

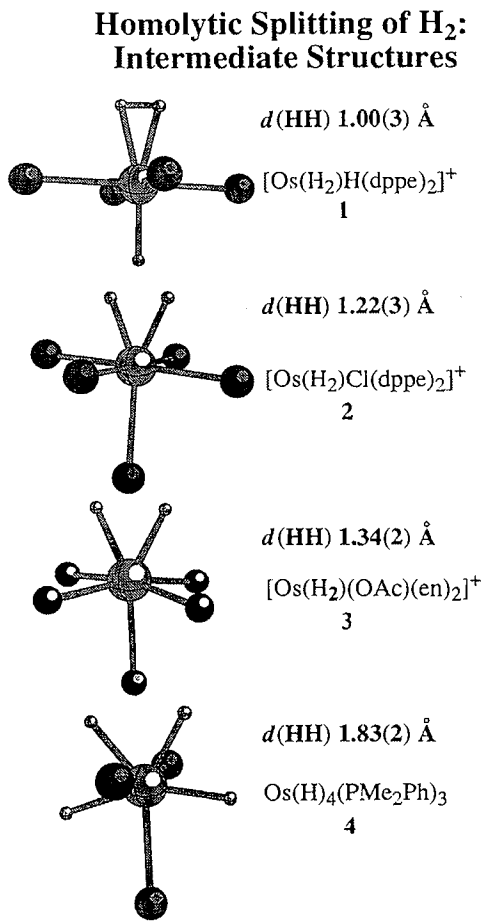
$$[1] \quad M(H_2)L_5 \rightleftarrows M(H)_2L_5$$

It is important to understand these factors since such reactions are found in several industrial catalytic processes. Related chemical reactions such as the homolytic splitting of carbon–hydrogen and silicon–hydrogen bonds follow similar principles. In addition, several fluxional rearrangements of metal hydride complexes involve the reverse of this reaction (4).

Determination of H—H distances in the solid state

How does one know when there is a short H—H distance? The question can be answered most precisely for solid samples. If large crystals are available, a neutron diffraction structure determination is done by the group of T.F. Koetzle at the Brookhaven National Laboratory. Hydrogens are located accurately by use of this method because ^1H nuclei diffract neutrons as well as any other nucleus. Such structure determinations over the last 8 years have revealed that a continuum of H—H distances is possible from short distances of 0.85 Å to long ones of 1.8 Å found in dihydride complexes. The 0.85 Å bond lengths are 0.11 Å longer than that of free H_2 gas. Occasionally the H atoms are located in X-ray diffraction studies of smaller crystals but the H—H distances so obtained are not as accurate due to the difficulty in detecting the two electrons of H_2 buried in the cloud of electrons of the transition metal. Solid state NMR has been applied by Zilm and Millar (13) to

Fig. 3. Structures of four osmium complexes whose structures trace out the oxidative addition of H_2.

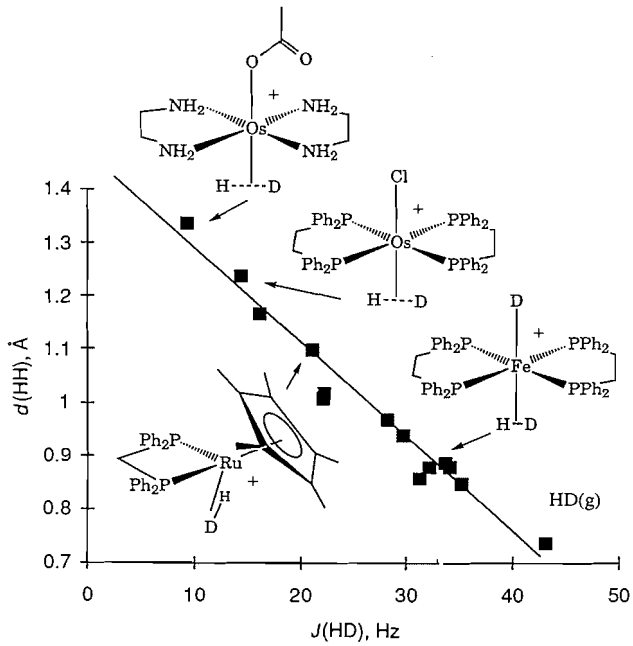


complexes containing H—H distances of less than 1.1 Å. Infrared spectroscopy will occasionally reveal the weak H—H mode found between 3000 and 2400 cm^{-1} in η^2-H_2 complexes (14). However, often ligand vibration overtones obscure these bands. Usually dihydride complexes can be identified by an M–H stretching mode with wave number between 2200 and 1500 cm^{-1}. The method of inelastic neutron scattering provides definitive proof for the existence of a short H—H distance when peaks due to quantum mechanical tunneling of nuclei through H–H librational barriers are observed (15).

Recently structures have become available for osmium complexes that illustrate the continuum of H—H distances possible (Fig. 3). The structures trace out a possible trajectory for the homolytic splitting reaction. All of these complexes have seven atoms coordinated to the central osmium. Complex *trans*-$[Os(H_2)H(dppe)_2]^+$ (**1**) at the top of the figure is octahedral with the dihydrogen ligand occupying one site on Os(II).[5] At the bottom of the figure is an example of an Os(IV) polyhydride complex $Os(H)_4(PMe_2Ph)_3$ (**4**) with no H—H bonding (16). The other two complexes have intermediate structures where the H–H splitting has been arrested. When the *trans* hydride ligand in **1** is replaced by chloride in $[Os(H_2)Cl(dppe)_2]^+$ (**2**) the H—H distance lengthens from 1.0

[5] P.A. Maltby, R.H. Morris, W. Klooster, T.F. Koetzle, J.S. Ricci, and A. Albinati. In progress.

Fig. 4. Plot of d(HH) determined in the solid state versus the J(H,D) coupling constant measured on the corresponding HD complex in solution.



to 1.22(3) Å (17). The origin of this effect is a combination of an increase in σ-Lewis acidity of the osmium and an increase in d–π electron energy. When the dppe ligands are replaced by ethylenediamine (en) ligands in *trans*-$[Os(H_2)(OAc)(en)_2]^+$ (**3**), while retaining a similar π-base ($O_2CCH_3^-$ versus Cl^-) *trans* to the H_2 ligand, the H—H distance lengthens to 1.34 Å (18). As discussed later, the en ligands make the Os centre considerably more reducing than the one containing the dppe ligands.

Determining H–H distances in solution

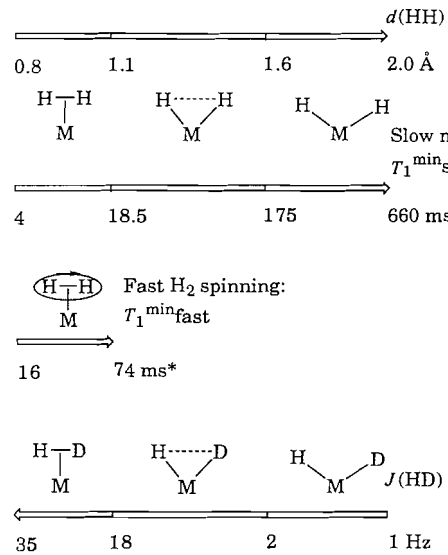
It is a more challenging problem to estimate H—H distances in solution. Yet this is important if we are to correlate structure with reactivity — for example, acidity, as expressed by the pK_a of the H_2 complex. We have found that the J(H,D) coupling of the HD ligand as observed in the ^1H NMR spectrum of the complex $M(HD)L_n$ correlates smoothly with the H—H distance determined by neutron diffraction studies (Fig. 4). We have good evidence that these complexes maintain the same structure in solution as in the solid state although there might be a small effect in replacing H by D. As indicated on the scale, a short H—H distance of 0.80 Å corresponds to a large J(H,D) of 32 Hz while dihydrides have couplings of less than 5 Hz. A relationship that holds for a large number of complexes is

$$[2] \quad d(\mathrm{HH}) = -0.0167\,(J(\mathrm{H,D})) + 1.42$$

In principle, the minimum T_1 value, T_1^{min}, of the H nuclei of the H_2 ligand should provide an accurate H—H distance in solution since in many cases dipolar relaxation of one H by its close neighbour dominates so that T_1 is proportional to $d(HH)^6$

[6] T_1^{min} must be corrected to account for the contributions to the relaxation rate from other dipolar nuclei.

Fig. 5. Scales relating J(H,D) and T_1(min) NMR parameters with H—H distance.



* At 400 MHz, corrected for dipolar contributions from other nuclei

(19). The T_1^{min} value is found by varying the temperature. If the H nuclei of the H_2 ligand have slow motion relative to the correlation frequency of tumbling of the complex in solution (approximately the spectrometer frequency), then the scale in Fig. 5 can be used to relate T_1^{min}(slow) at 400 MHz to d(HH).[6] Note how sensitive T_1^{min}(slow) is to the H—H distance. As the distance elongates from 0.8 to 1.6 Å the T_1^{min} value changes from 4 to 175 ms. Equation [3] is applied if the motion is known to be slow:

$$[3] \quad d(\mathrm{HH}) = 5.81 \sqrt[6]{\frac{T_1^{min}(\mathrm{slow})}{\nu}}$$

where ν is the spectrometer frequency in MHz and T_1^{min} (slow) is in seconds (20).

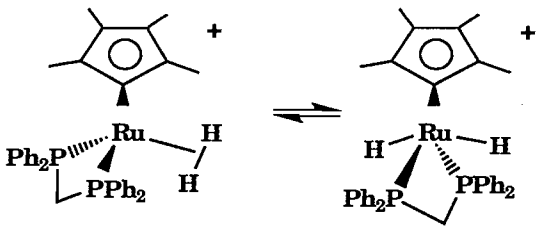
Unfortunately the dihydrogen ligand often has fast motion relative to 400 MHz and this makes the interpretation of T_1^{min} difficult. If the H_2 is rapidly spinning like a propeller then the scale for T_1^{min}(fast) applies (21). For a given H—H distance, the T_1 values measured are 4 times longer when there is fast spinning and a different equation is used to determine d(HH).

$$[4] \quad d(\mathrm{HH}) = 5.81 \sqrt[6]{\frac{T_1^{min}(\mathrm{fast})}{4\nu}} = 4.61 \sqrt[6]{\frac{T_1^{min}(\mathrm{fast})}{\nu}}$$

If the type of motion is not known, then a measured T_1^{min} value of 16 ms, for example, could correspond to either a 1.08 Å H_2 ligand with no extra motion or a 0.85 Å H_2 ligand with fast spinning relative to 400 MHz. Other types of motion such as hopping between sites could result in the calculation of distances between these two values. Therefore other spectroscopic methods need to be developed to elucidate the nature of the H_2 motion.

I will now illustrate examples of complexes in the fast-spin-

Fig. 6. Dihydride and dihydrogen tautomers of $[Ru(H_2)(C_5Me_5)(dppm)]BF_4$ in equilibrium.



ning and slow-motion regimes. The single crystal neutron diffraction structure of *trans*-$[Fe(H_2)H(dppe)_2]BPh_4$ was reported in 1989 (22). The H—H distance was 0.82(1) Å. Later it was discovered that the librational motion of the H_2 ligand even at 15 K in the solid state results in an underestimation of the H—H distance. This was traced to the crystallographic computer program fitting an ellipsoid to nuclear density smeared out, because of the librational motion, into the shape of a banana. If a "banana correction" is applied the H—H distance lengthens to about 0.85 Å. This value is then in better agreement with the distance of 0.90(1) Å determined by Zilm's group (13) using solid state NMR methods. In solution the large J(H,D) value of 32 Hz in *trans*-$[Fe(HD)(D)(dppe)_2]BF_4$ in acetone-d_6 is consistent with a short H—H distance. When the observed T_1^{min} value of 0.017 s at 400 MHz is substituted, only eq. [4] for fast spinning gives a distance of 0.88 Å, which agrees with the neutron and solid state NMR studies.

The complex $[Ru(H_2)(C_5Me_5)(dppm)]BF_4$ has an elongated H_2 ligand with a high barrier to spinning (23). The neutron structure shows that the dihydrogen ligand has an unusual elongation with a d(HH) of 1.10(1) Å. The H—H vector lies parallel to the C_5Me_5 ligand. In this orientation the H_2 ligand benefits from overlap of its σ^* orbital with the filled $d\pi$-bonding orbital of Ru(II) in the three-legged piano stool. Since there is no similar concentration of π-bonding electrons if the H_2 rotates 90°, a barrier results. In this respect the H_2 ligand is acting as a compass needle (24) to indicate the orientation of π electron density.

The J(H,D) value of 21 Hz for $[Ru(HD)(C_5Me_5)(dppm)]BF_4$ also indicates the presence of an elongated H_2 ligand with d(HH) = 1.05 Å (see eq. [2]). Of the two possible distances (1.10 and 0.90 Å, for slow and fast spinning, respectively) calculated from the T_1^{min} value (18 ms at 400 MHz), the longer distance is the logical one. In fact it was chosen 2 years before (25) the neutron structure was reported (23).

This system provides an interesting example of homolytic H_2 splitting. A dihydride tautomer and dihydrogen tautomer are in equilibrium (Fig. 6). Such tautomers become important when comparing the kinetics of proton transfer (see below).

The heterolytic splitting of dihydrogen

The existence of dihydrogen complexes allows a systematic study of the factors that determine the kinetics and thermodynamics of proton transfer in hydrogenation reactions.

As indicated earlier, acidic dihydrogen complexes have positive electrochemical potentials arising from combinations of electron-withdrawing ligands and a positive charge. Very acidic but stable dihydrogen complexes have $E_{1/2}(MN_2)$ near to 2 V vs. NHE. However, such positive $E_{1/2}$ values mean that there is little $d\pi \rightarrow \sigma^*$ back-bonding to the H_2 ligand and therefore a strong H—H bond. This can lead to a complex that is not as acidic as might be expected on the basis of $E_{1/2}$ values alone (see below).

A better knowledge of the heterolytic splitting of H_2 will serve us in many ways. There are industrial processes that rely on this reaction, including the recovery of nickel from nickel ores and the formation of methanol from synthesis gas. Nature's hydrogenase enzymes allow bacteria to utilize hydrogen as their fuel source. The action of this enzyme relies on a complex of nickel and probably iron and could involve the deprotonation of a dihydrogen complex at nickel (26) or iron. Understanding the heterolytic splitting of the H—H bond helps to unravel the factors involved in the more complex electrophilic cleavage of carbon–hydrogen bonds, a very promising way to functionalize methane gas (27, 28).

To my knowledge I am the "third generation" of chemists working in this area in Canada. The first was Jack Halpern when he was at the University of British Columbia. The second is Brian James, my Ph.D supervisor, also at U.B.C.

Kinetic and thermodynamic aspects of the acidity of dihydrogen complexes

An important kinetic feature of this chemistry is that a dihydrogen complex transfers a proton to a base more rapidly than a related dihydride complex. This is demonstrated by cooling an interconverting mixture of dihydrogen and dihydride forms of $[Ru(C_5H_5)H_2(dppe)]^+$ in CD_2Cl_2 until the rate of exchange is nil (at approx. 240 K). When a strong base, NaOEt, is added to this mixture, only the dihydrogen tautomer is deprotonated (eq. [5]) (25).

$$[5] \quad [Ru(C_5H_5)(\eta^2\text{-}H_2)(dppe)]BF_4 + [Ru(C_5H_5)(H)_2(dppe)]BF_4 + NaOEt \rightarrow Ru(C_5H_5)(H)(dppe) + [Ru(C_5H_5)(H)_2(dppe)]BF_4 + HOEt + NaBF_4$$

There is a small kinetic barrier to deprotonation of the η^2-H_2 tautomer because there is little rearrangement of the complex on going to the monohydride product $Ru(C_5H_5)(H)(dppe)$; both complexes are formally six-coordinate Ru(II), of the class RuX_2L_4 (29). There is a larger barrier to rearrange the dihydride tautomer, formally a seven-coordinate Ru(IV) complex (RuX_4L_3), into the monohydride RuX_2L_4 product.

Heinekey's group and my own have attempted to estimate the pK_a values of dihydrogen complexes in order to gain a semi-quantitative understanding of the heterolytic splitting reaction. In this lecture I will illustrate this approach by a study of the acidity of the complexes *trans*-$[Os(H_2)L(dppe)_2]^{2+}$, where the pK_a varies dramatically as a function of the *trans* ligand, L = Cl^- (**2**) and H^- (**1**) (17). These acidic dihydrogen complexes are titrated with bases PMe_2Ph and $Ru(C_5Me_5)(H)(PPh_3)_2$, respectively. The pK_a of the conjugate acid forms on the extrapolated aqueous scale are known: 6.5 for $HPMe_2Ph^+$ and 11.1 for $[Ru(C_5Me_5)(H)_2(PPh_3)_2]^+$. These are chosen because they do not displace the H_2 ligand and their relative concentrations are

readily determined by NMR spectroscopy. Bulky phosphines are particularly useful in the titration of dihydrogen complex acids (eq. [6]):

[6] *trans*-$[Os(H_2)Cl(dppe)_2]^+ + PMe_2Ph \rightleftarrows$

trans-$Os(H)(Cl)(dppe)_2 + HPMe_2Ph^+$

The equilibrium constant for eq. [6] can be obtained by use of ^1H and ^{31}P NMR spectroscopy. The pK_a of **2** with dihydrogen *trans* to chloride is determined to be 7.4.

There is a large increase in pK_a when H_2 is *trans* to hydride in **1** compared to when it is *trans* to chloride in **2**. Even the most basic phosphine P^{t}Bu$_3$ is not sufficiently basic to deprotonate **1**.[7] Therefore the complex $Ru(C_5Me_5)(H)(PPh_3)_2$ was used as the base (eq. [7]).

[7] *trans*-$[Os(H_2)H(dppe)_2]^+ + Ru(C_5Me_5)(H)(PPh_3)_2 \rightleftarrows$

cis and *trans*-$Os(H)_2(dppe)_2 + [Ru(C_5Me_5)(H)_2(PPh_3)_2]^+$

The pK_a of **1** is thus determined to be approximately 13.6.

An important factor that makes **1** much less acidic than **2** is the stronger H—H bonding in the former complex. We have evidence that the H—H distance is significantly shorter in **1** in solution. The H–D coupling constant of $[Os(HD)(D)(dppe)_2]^+$ (**1**-d_2) is 25.5 Hz and by use of eq. [2] this corresponds to an H—H distance of 1.00 Å. This is in agreement with the 1.00 Å distance from the T_1 method by use of eq. [4] for a fast-spinning H_2 ligand. It is also consistent with the distance in the solid state as measured by neutron diffraction (1.00 Å) when this distance has been corrected for librational motion. The J(H,D) value of **2**-d_1 is 13.9 Hz, which corresponds to a d(HH) in solution of 1.20 Å. This almost coincides with the H—H distance of 1.22(3) Å determined by neutron diffraction. The T_1(min) value gives a distance of 1.35 or 1.08 Å when eqs. [3] and [4] are applied, respectively. Since the other methods give d(HH) values between these limiting values, this suggests that the H_2 ligand has a motional frequency near to 400 MHz. In this case there is independent evidence that the frequency of the motion of the H_2 ligand is similar to that of the tumbling of the molecule from plots of ln T_1 versus $1/T$. These curves do not have the usual "V" shape and so eqs. [3] or [4] do not apply. A spectral density function needs to be determined to describe the as yet undefined motion of the H_2 ligand in the molecule so that the H—H distance can be calculated from the T_1 data. In summary, the best estimates of the H—H distances for **1** and **2** are 1.00 and 1.20 Å, respectively. The shorter H—H distance for **1** results in a less acidic complex.

Very acidic, stable dihydrogen complex

When L is changed to CH_3CN in *trans*-$[Os(H_2)(L)(dppe)_2]^{2+}$ then a very acidic complex *trans*-$[Os(H_2)(CH_3CN)(dppe)_2](BF_4)_2$, **5**, is obtained (30). The complex was found by low-temperature X-ray diffraction to have an H—H distance of 0.9(1) Å. When the isolated dihydrogen complex is dissolved in dry CH_2Cl_2 and treated with dry diethyl ether, it is partially converted into the monohydride complex *trans*-$[Os(H)(CH_3CN)(dppe)_2](BF_4)$ according to eq. [8].

[7] HP^{t}Bu$_3^+$ has a pK_a of 12.1.

Table 1. The properties of three osmium dihydrogen complex with H—H distances increasing from **1** to **5** to **2**.

Complex	**1**	**5**	**2**
Ligand	H^-	CH_3CN	Cl^-
J(H,D), Hz	25.5	21.4	13.9
d(HH), Å	1.0	1.1	1.2
pK_a	13.6	−2	7.4
$E_{1/2}$, V, vs. Fc^+/Fc	−0.20	+0.58	−0.13
$\Delta H_{BDE}\{M(H_2)\}$, kcal mol^{-1}	80	77	73

[8] $[Os(H_2)(CH_3CN)(dppe)_2](BF_4)_2 + Et_2O \rightleftarrows$

$[Os(H)(CH_3CN)(dppe)_2](BF_4) + HOEt_2(BF_4)$

Complex **5** is completely deprotonated by water. Therefore the pK_a of **5** is near to that of protonated ether, which has been estimated to be −2.3 on the aqueous scale.

To determine whether the acidity of dihydrogen complexes depends on the H—H bond length it is necessary to estimate the latter for the complexes in solution. As described above, the coupling constant J(H,D) is the best indicator. The H—H distances increase with L in *trans*-$[Os(H_2)L(dppe)_2]^{2+}$ as: $H^- < CH_3CN < Cl^-$ (Table 1).

The H-atom abstraction energy, $\Delta H_{BDE}\{M(H_2)\}$ as an indicator of H—H bonding

Tilset and Parker have described how metal–hydride bond dissociation energies, ΔH_{BDE}(MH), of complexes MHL_5 can be determined by measuring the pK_a of the hydride complex, p$K_a(MHL_5)$ and the electrochemical potential of the conjugate base hydride, $E_{1/2}(ML_5/ML_5^-)$ (31, 32). We made use of an identical thermochemical cycle to determine the bond dissociation energies (BDE) for dihydrogen complexes, MH_2L_5 (eqs. [9]–[13]) (11, 33).

[9] $M(HH)L_5 \rightarrow [MHL_5]^- + H^+$, $\Delta G = 1.37\ pK_a\{M(H_2)\}$

[10] $[MHL_5]^- \rightarrow MHL_5 + e^-$, $\Delta G = 23.1E_{1/2}(MH/MH^-)$

[11] $H^+ + e^- \rightarrow H^\cdot$, ΔG = constant

[12] $M(HH)L_5 \rightarrow MHL_5 + H^\cdot$, $\Delta G_{BDE} = 1.37\ pK_a\{M(H_2)\} + 23.1E_{1/2}(MH/MH^-) +$ constant

Thus the free energies of deprotonation of the dihydrogen complex (eq. [9]), the oxidation of the deprotonated complex (eq. 10), and the reduction of the proton (eq. [11]) combine to produce the free energy of the H-atom abstraction reaction (eq. [12]). The constant in the corresponding enthalpy expression, $\Delta H_{BDE}\{M(H_2)\}$, has been determined from the $\Delta H_{BDE}\{MH\}$ of known metal hydrides to be 66 as in eq. [13].

[13] $\Delta H_{BDE}\{M(H_2)\} = 1.37\ pK_a\{M(H_2)\} + 23.1\ E_{1/2}(MH/MH^-) + 66$

kcal/mol (pseudo aqueous) V vs. $Cp_2Fe^{+/0}$ in THF

The calculation of $\Delta H_{BDE}\{M(H_2)\}$ values that are larger than those expected for metal hydride bonds (55–75 kcal mol^{-1}) should signal the presence of H—H bonding since not only do M—H but also H—H bonds have to be broken when the H atom is abstracted from the dihydrogen complex (11).

The values required to calculate this energy for the complexes *trans*-$[Os(H_2)L(dppe)_2]^{2+}$ are listed in Table 1. The electrochemical potentials of the complexes *trans*-$[OsH(L)(dppe)_2]^+$ increase with L in the order $H^- < Cl^- < CH_3CN$. The ΔH_{BDE} values decrease as d(HH) increases. The ΔH_{BDE} values for **1** and **5** are large enough to suggest the presence of H—H bonding while that for **2** is of the magnitude typical of an osmium hydride BDE. Therefore there appears to be little H—H bonding in **2**, which has a stretched H—H distance of 1.2 Å. This work and the work on the corresponding ruthenium complexes (12) is the first to illustrate the importance of the *trans* ligand on the acidity of a dihydrogen complex. The general conclusion from this work is that there is little H—H bonding in dihydrogen complexes that have d(HH) $\geq$ 1.1 Å.

The effect on the acidity of changing the *cis* ligand from dppe in **5** to en in *trans*-$[Os(H_2)(CH_3CN)(en)_2]^{2+}$, **6**, en = $NH_2CH_2CH_2NH_2$ (18), can be predicted by use of eq. [13] and Lever's additive electrochemical method (34). The d(HH) in **6** is calculated by use of eq. [2] and J(H,D) of 17.7 Hz to be 1.2 Å. The $E_{1/2}$ value for the conjugate base hydride form of **6** can be predicted to be -0.8 ± 0.2 V vs. Fc^+/Fc. Therefore the pK_a of **6** is estimated to be 17 ± 3. Thus a dramatic decrease in acidity is predicted with the replacement of two dppe ligands with two electron-donating en ligands.

Intermediate structures in proton transfer from dihydrogen complexes

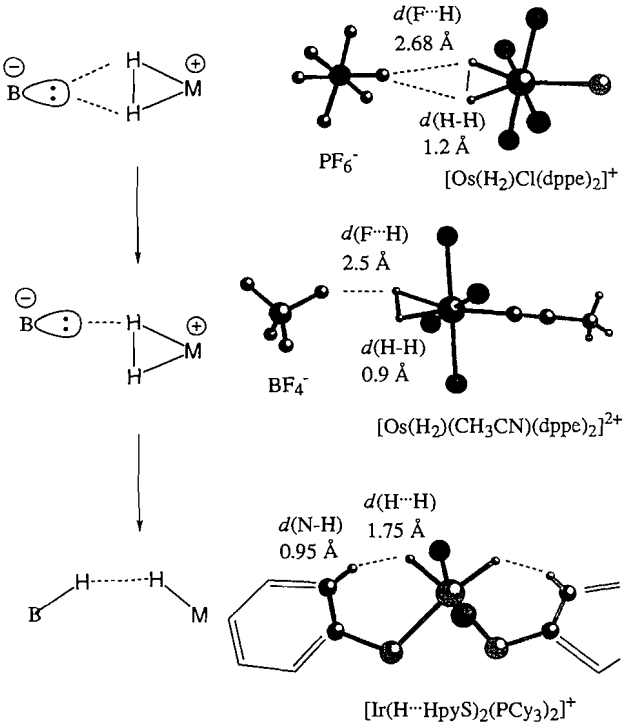
Figure 7 is arranged to show three structures that appear to trace out the trajectory of proton transfer from the dihydrogen ligand to a base. The top two structures show the positions of the anions in the solid state structures of **2** and **5**. These have a fluoride of the anion in proximity to the H_2 ligand, with the more acidic complex, **5**, having the shorter d(HF) of 2.5 Å. The anion is poised, as a stronger base might be, to receive a proton from the dihydrogen ligand in the heterolytic splitting reaction. The complex **1**, with a less acidic H_2 ligand, does not have a close H_2–F interaction.

The third structure of Fig. 7 can be viewed as being produced by transfer of a proton from an unstable iridium dihydrogen complex to the nitrogen of a coordinated mercaptopyridine ligand (35). The novel feature of this structure is that the proton and hydride remain in close proximity (d(HH) 1.75 Å), even in solution.

The complex $[Ir(H\cdots HNC_5H_4S)_2(PCy_3)_2]BF_4$, **7**, is prepared by reacting $Ir(H)_5(PCy_3)_2$ with $[HNC_5H_4SH]BF_4$ in CH_2Cl_2 (35). In a ^1H NMR experiment, irradiation of the hydride resonance of **7** in CD_2Cl_2 produces a large nuclear Overhauser enhancement of 11% in the NH signal. Therefore the proton on nitrogen and the hydride on iridium are in close proximity (Fig. 8). A distance of 1.75 ± 0.05 Å is calculated by use of eq. [3] and the minimum T_1 value of the hydrogens on N and Ir.

When complex **7** in CD_2Cl_2 is treated with D_2 gas at 1 atm, both the NH and IrH positions are rapidly deuterated (eq. [14]).

Fig. 7. Structures that appear to trace out the trajectory of heterolytic splitting of dihydrogen.



[14] $7 + 2D_2 \rightarrow [Ir(D\cdots DNC_5H_4S)_2(PCy_3)_2]BF_4 + 2H_2$

We propose that this reaction proceeds via the formation of an unobserved tautomeric complex containing a dihydrogen ligand. Such a complex might readily exchange H_2 with D_2. Heterolytic splitting of the D_2 complex produces the deuterated product (Scheme 3).

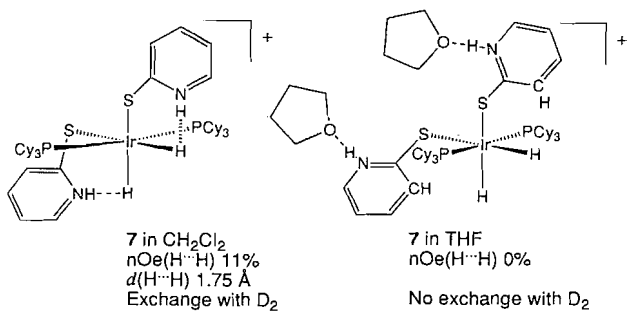
It appears that the proton–hydride interaction is crucial for fast H_2/D_2 exchange. When complex **7** is dissolved in THF-d_8 under D_2 gas, no exchange is observed under the conditions where exchange is complete with **7** in CD_2Cl_2. Since THF is a better hydrogen-bond acceptor than the iridium hydride, the complex adopts a new conformation where the pyridinium groups have rotated in order to hydrogen bond to the THF (Fig. 8). Now when the hydride resonances are irradiated, there is no nuclear Overhauser enhancement of the NH resonances and instead there is a weak enhancement of the peaks of the C-H groups *ortho* to the sulfur in the mercaptopyridinium ligands.

Both Crabtree's group (36) and our group discovered, independently, this type of proton–hydride interaction. It is turning out to be a common phenomenon in chemistry. We recently described the synthesis of iridium complexes with short proton···hydride···proton contacts. The search is now on for examples of short *intermolecular* proton···hydride interactions.

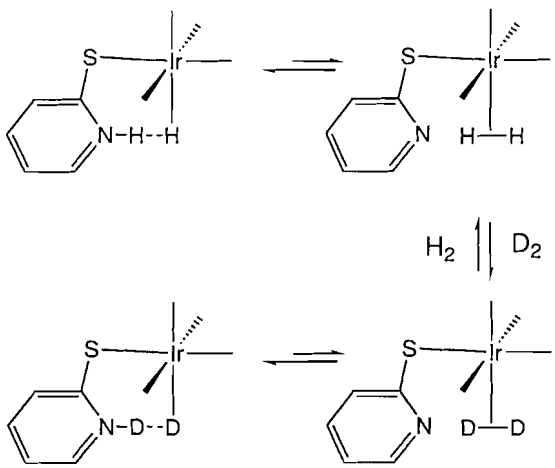
Conclusions

In the homolytic splitting of dihydrogen, there is a continuum of structures possible, with H—H distances ranging from 0.8

Fig. 8. Structure of **7** in CD_2Cl_2 and THF.



Scheme 3. A mechanism to explain H_2/D_2 exchange in complex **7**.



Å (dihydrogen complexes) to 1.1 Å (elongated dihydrogen complexes) to 1.3 Å (compressed dihydrides) to >1.6 Å (dihydrides). The energy of the *d* electrons is an important factor in determining the degree of activation of the H—H bond. The energy barrier to homolytic splitting can be high or low or the splitting can be arrested at structures M(H···H) anywhere between those of dihydrogen and dihydride complexes. The coupling constant *J*(H,D) and eq. [2] appear to be the best way of determining H—H distances in solution. The T_1 method should in principle give accurate H—H distances but the analysis is complicated by the undefined motion of the H_2 ligand. In certain cases the H_2 ligand has been shown to be spinning rapidly like a propeller so that eq. [4] with T_1^{min}(fast spinning) is appropriate for calculating *d*(HH), while in other cases the motion of the ligand is slow relative to the tumbling of the molecule. Other methods are needed to probe the motion of the H_2 ligand in solution.

For the heterolytic splitting of dihydrogen, a wide range of $pK_a\{M(H_2)\}$ values is possible: from −2 to greater than 17. The *trans* ligand has a large effect on the acidity of the H_2 ligand. Stable but very acidic complexes can be prepared and these will be tested as catalysts for new reactions. Hydrogen-atom abstraction enthalpies, $\Delta H_{BDE}\{M(H_2)\}$, which are calculated from $E_{1/2}$ and pK_a, reflect the amount of H—H bonding in dihydrogen complexes. Energies greater than or equal to 80 kcal mol^{-1}, which are observed for dihydrogen complexes with *d*(HH)<1.1 Å, suggest the presence of significant H—H bonding while values of less than 75 kcal mol^{-1}, which are observed for complexes with *d*(HH) greater than 1.1 Å, are more consistent with M—H bonding alone in a "compressed dihydride." If ΔH_{BDE} values can be predicted, then the acidity of dihydrogen complexes can be predicted by use of Lever's parameters.

New principles have been uncovered in the kinetics and mechanisms of proton transfer. Dihydrogen complexes have higher kinetic acidity than dihydrides. Stages of proton transfer from dihydrogen to a base are modeled in crystal structures. The proton transfer can be arrested in new IrH···HN interactions.

It is amazing how such simple complexes can have such a rich chemistry. There is the promise of more to come.

Acknowledgments

I acknowledge the excellent contributions of my current graduate students, Marcel Schlaf, Cameron Forde, Tina Fong, Sunghan Park, and Tanya Bartucz and those of students who have graduated from my lab including Dr Caroline Schweitzer, Dr Patricia Maltby, Dr Tim Burrow, Ms Samantha Drouin, Mr Paul Cappellani, Dr Maria Bautista, Ms Kelly Earl-Luck, Dr Andrea Sella, Dr Natalie Lazarowych, and Dr Rudy Luck. Many postdoctoral fellows have contributed to this work including Dr Wei Xu, Dr Ravi Ramachandran, Dr Bronwyn Greaves, Dr Philip Jessop, Dr Gouchen Jia, Dr Jeff Zubkowski, Dr Joel Ressner, and Dr Hormoz Azizian. Excellent undergraduate students who have contributed to this work include Amanda Chan, Thomas Schleis, Nada Ricciuto, Bain Chin, Adina Petroff, Cinzia D'Agostino, Martin Steinbeck, Suzanne Brinkmann, and Theresa Hoffstede. Crystallographers Dr Alan Lough and Dr Jeffrey Sawyer did key structure determinations by X-ray diffraction and Dr Wim Klooster and Dr Tom Koetzle of Brookhaven National Laboratory and Dr John Ricci of the University of Maine did the crucial neutron structure determinations. I thank Nick Plavac for obtaining NMR spectra and training students in NMR techniques. The work was funded by the Natural Sciences and Engineering Research Council of Canada, the Petroleum Research Fund as administered by the American Chemical Society, and Johnson Matthey, which provided loans of platinum metals.

1996 Noranda Award Lecture Thermal properties of solids: Étude in three-part anharmony[1]

Mary Anne White

Abstract: The harmonic oscillator is a useful starting point for understanding many intermolecular interactions, and it successfully predicts many properties. However, anharmonic terms in the interaction potential are responsible for several observed phenomena. This review summarizes our recent experimental investigations of three thermal properties of molecular solids that result from anharmonic intermolecular interactions, viz. thermal expansion, Grüneisen parameters, and thermal conductivity.

Key words: anharmonicity, thermal expansion, Grüneisen parameter, thermal conductivity.

Résumé : L'oscillateur harmonique est un point de départ utile pour la compréhension de plusieurs interactions moléculaires et elle permet de prédire avec succès plusieurs propriétés. Toutefois les termes anharmoniques dans le potentiel d'interaction sont responsables de plusieurs phénomènes observés. Cette revue résume nos récentes recherches expérimentales sur les trois propriétés des solides moléculaires qui résultent des interactions moléculaires anharmoniques à savoir l'expansion thermique, les paramètres de Grüneisen et la conductivité thermique.

Mots clés : anharmonicité, expansion thermique, paramètre de Grüneisen, conductivité thermique.

Introduction

Advancing understanding of forces is one of the common themes binding physical scientists. In principle, if we knew all intermolecular forces exactly, including their orientational dependence and how to handle many-body interactions, we could calculate virtually all properties of matter. However, we do not know all intermolecular potentials and, even for simple cases like the rare gases, mathematically exact potentials may not be achievable.

All is not lost, however, as we can understand many physical properties with very simple potentials. For example, even a square-well potential explains condensation of gases. However, a square-well has no sensitivity to intermolecular distance at the bottom of the well, and there are much better simple potentials.

One example is the Lennard–Jones "6-12" potential,

$$[1] \quad \phi(r) = -\frac{C_6}{r^6} + \frac{C_{12}}{r^{12}}$$

where the intermolecular potential, ϕ, is expressed in terms of the intermolecular separation, r. A Lennard–Jones potential can satisfactorily fit experimental observables such as sublimation energy, and it has the further advantage of being differentiable.

As useful as the Lennard–Jones potential is, many properties of matter can be considered using an even simpler potential, that of a harmonic oscillator as shown in Fig. 1 for Ar–Ar interactions, in comparison with a more accurate Ar–Ar potential derived from properties of solid and gaseous argon (1). The harmonic potential stems from Hooke's law considerations of intermolecular forces, viz.

$$[2] \quad F(r') = -kr'$$

where $F(r')$ is the restoring force and r' is the deviation from equilibrium intermolecular separation. As can be seen in Fig. 1, the harmonic potential is a good approximation near the minimum in the potential. Since atoms (and molecules) in solids far below their melting points are quite close to their lattice sites, i.e., near their minimum-energy positions, the harmonic approximation can be very useful in the solid state. For example, many of the features of lattice dynamics, including temperature dependence of heat capacity, can be well approximated starting from the harmonic potential.

Despite the great utility of the harmonic oscillator, many important properties arise from anharmonicity. Even rare gas solids are highly anharmonic, due to the presence of hard short-range interactions, as shown in Fig. 1.

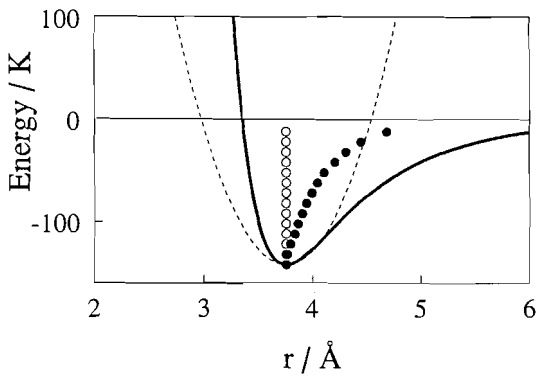
Fig. 1. Intermolecular potentials and thermal expansion for Ar. The solid line represents the Barker–Fisher–Watts potential for Ar–Ar interactions, using parameters from fits to solid and gaseous properties (1), and the broken line is a harmonic potential fit to the bottom of the Barker–Fisher–Watts well. (○) The average intermolecular separation for the harmonic potential, where different positions correspond to different thermal energies for the system. (●) The average intermolecular separation for the anharmonic Barker–Fisher–Watts potential, showing thermal expansion.



One of several observable consequences of anharmonicity is thermal expansion. As shown schematically in Fig. 1, a harmonic solid maintains the same lattice spacing as the temperature is increased, whereas an anharmonic solid generally shows an increase in lattice spacing with increasing temperature. Thermal expansion, α_j, is defined as

$$[3] \quad \alpha_j = \frac{1}{j}\frac{\mathrm{d}j}{\mathrm{d}T}$$

where j is a dimension in a given direction, a lattice parameter, or the volume, and deviation of α_j from the harmonic value of zero can be a direct measure of anharmonicity in the interaction potential.

Phonon–phonon interactions also result from anharmonicity. As a phonon of wave vector $\boldsymbol{q}$ moves through a lattice, some atoms are closer to each other than at their equilibrium distance while others are farther apart. If another phonon of wave vector $\boldsymbol{q}$ tries to pass through this part of the lattice, it will experience different elasticity and concomitant variation in the refractive index in the compressed region due to anharmonic terms in the intermolecular potential; the phonon $\boldsymbol{q}$ can be reflected from this, as if from a diffraction grating. If the wave vector is conserved, the reflected phonon has wave vector $\boldsymbol{q}''$:

$$[4] \quad \boldsymbol{q}'' = \boldsymbol{q} + \boldsymbol{q}'$$

and this is referred to as an N-process (N stands for "Normal"). If $\boldsymbol{q}$ and $\boldsymbol{q}'$ are so large that the resultant wave vector $\boldsymbol{q}''$ would lie outside the first Brillouin zone, then

$$[5] \quad \boldsymbol{q}'' + \boldsymbol{G} = \boldsymbol{q} + \boldsymbol{q}'$$

where $\boldsymbol{G}$ is a reciprocal lattice vector and this is called a U-process (U stands for Umklapp, indicating that the phonons turn back in this process (3)), which can lead to thermal resistance.

Phonon–phonon interactions lead to several important consequences: phonons have finite lifetimes; phonon energies are not sharply defined; phonon energies can be altered. Furthermore, the phonon–phonon collision probability depends on the number of phonons so the lifetimes of phonons will depend on the temperature. An observable consequence is that thermal conductivity, κ, of a real solid is finite ($\kappa = \infty$ for a harmonic solid) and temperature dependent. Furthermore, phonon–phonon interactions destroy the harmonic solid's dynamical independence of different lattice modes, and this could further affect thermal conductivity.

A useful parameter to consider when discussing anharmonicity is the Grüneisen (4) "constant," γ, which can be defined for mode j in terms of the frequency ω_j and the volume, V:

$$[6] \quad \gamma_j = -\frac{1}{2}\frac{\partial \ln \bar{\omega}^2}{\partial \ln V}$$

For a harmonic solid ω_j is independent of volume and therefore $\gamma = 0$; thus deviations of γ from zero can indicate anharmonic interactions.

Further manifestations of anharmonicity are that elastic constants of real solids depend on temperature and pressure (i.e., adiabatic and isothermal elastic constants are not the same); the heat capacity of a real solid rises above the Dulong–Petit value at high temperatures (5); spin-lattice interactions in a solid depend on anharmonicity (6). A recent review (7) shows the importance of anharmonicity in atomic displacement parameters (Debye–Waller factors) determined by X-ray diffraction.

Complete understanding of anharmonicity is not sufficient to understand all properties of solids; for example, anharmonicity alone is insufficient to explain behaviour near a displacive phase transition. Nevertheless, quantification of anharmonicity can lead to better understanding of many properties of materials, particularly with respect to interactions between phonons. It has been pointed out that molecular dynamics is superior to analytical methods that treat anharmonicity as a perturbation (8). Other methods also can be used: for example, a density functional approach has recently been used to study phononic properties of monatomic solids near the melting point (9).

Several aspects of anharmonicity have been summarized already (10), and the purpose of the present report is to review our experimental studies of properties associated with anharmonic effects in molecular solids.

Although the majority of the more than 14 000 000 chemical substances catalogued to date by Chemical Abstracts contain molecular units, our understanding of structural and dynamical properties of molecular solids is less complete than that of simpler atomic and metallic materials. The major difference between atomic and molecular solids lies in the degrees of freedom. Whereas atomic systems have only translational or lattice vibrational degrees of freedom, molecular systems also can have orientational and internal degrees of freedom. The former can in certain circumstances lead to orientationally disordered phases, and the latter can be associated with optical phonons that can play an important role in several physical properties. One of the purposes of our research has been to study the interplay between physical properties, especially those associated with thermally activated processes, and intermolecular potentials.

Experimental methods

In the work to be described, several physical properties have been determined experimentally. Thermal expansion, α, was determined from variable-temperature X-ray or neutron powder diffraction with Rietveld fitting procedures (11,12). Thermal conductivity, κ, was determined by steady-state determinations of the temperature gradient (dT/dx) of single crystals of cross-sectional area A with a quantified heat flux ($\dot{q}$), according to the definition of κ:

$$[7] \quad \kappa = \frac{\dot{q}}{A}\frac{dx}{dT}$$

Although the Grüneisen parameter, γ, can be determined through eq. [6], it was calculated here from the thermodynamic definition, which for the volume Grüneisen parameter is

$$[8] \quad \gamma_V = \frac{\alpha_V V_m}{\chi_T C_V}$$

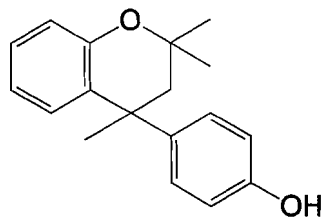
where α_V is thermal expansion, V_m is the molar volume, χ_T is the isothermal compressibility ($= -V^{-1}(\partial V/\partial P)_T$), and C_V is the molar heat capacity at constant volume. An expression analogous to eq. [8] gives γ_j, where j is one of the unit cell directions.

Inclusion compounds

Inclusion compounds are materials that are composed of more than one chemical component, with one species forming a host lattice in which one or more other species can reside as guests. For the situation of guest species trapped in the host lattice, Powell (14) coined the term clathrate. Examples include clathrate hydrates (H_2O as the host lattice; see ref. 15 for a review of structures) and several hydrogen-bonded organics. Through slight changes in the structure of the host and (or) guest species, inclusion compounds offer an opportunity to examine the role of guest–host interactions in determining properties associated with anharmonicity, such as thermal conductivity, thermal expansion, and the Grüneisen parameter.

A mystery concerning the thermal conductivity of a clathrate hydrate became apparent in 1981 (16): the thermal conductivity of tetrahydrofuran clathrate hydrate was found to be considerably less than that of ice, but even more puzzling was the temperature dependence, $d\kappa/dT > 0$ for $100\ K < T < 250\ K$. For a simple crystalline solid this temperature range should correspond to phonon–phonon interactions determining the mean phonon free path λ (i.e., phonon–phonon collisions limit the phonon lifetimes and the thermal conductivity), and thermal activation of phonons would be expected to lead to lower thermal conductivity at higher temperatures, i.e., $d\kappa/dT < 0$. Our measurement of the thermal conductivity of tetrahydrofuran (THF) clathrate hydrate down to 15 K showed (13) continuous decrease in thermal conductivity with decrease in temperature, more like what is observed in aperiodic systems such as glasses (17) than what had been the observed behaviour for crystalline solids. The low thermal conductivity of THF clathrate hydrate is consistent with Tse's observations (18) of increased thermal expansion and low-temperature Grüneisen parameter for THF clathrate hydrate relative to ice Ih, both indications of enhanced anharmonicity in the crystal potential. Our understanding of the temperature dependence of the thermal conductivity of clathrate hydrates is that the heat-carrying acoustic phonons have their mean free paths shortened by motions of the guest species (19). The cages within a clathrate hydrate are rather isotropic, such that even polar guests such as THF do not succumb to positional ordering forces except at low temperatures, as shown by dielectric measurements (20) and analysis of the heat capacity of the guests (21). On the basis of a resonance interaction between the acoustic phonons of the host lattice and the optic modes associated with the guest molecules, we have successfully fit the temperature dependence of the thermal conductivity of THF clathrate hydrate (19).

An ideal test of this model would be to remove the guest species from the clathrate hydrate and determine the thermal conductivity of the "empty" clathrate. However, although there are many different phases of "ice" under different conditions, the clathrand (empty clathrate) is not a stable structure. There are only a few inclusion compounds that are known to exist in the same structure both with and without guests. One of these, Dianin's compound (4-(3,4-dihydro-2,2,4-trimethyl-2H-1-benzopyran-4-yl)phenol, **1**), met both this criterion and



1

our additional requirement, viz. it is possible to grow rather large (mm dimensions in every direction) crystals both with and without guests. A further advantage of Dianin's host lattice became known as we studied various structural and dynamic properties: Dianin's compound can include either mobile guests (ethanol molecules reside two per cage and explore the cages of the host with liquidlike degrees of freedom as evidenced by heat capacity analysis (22) and solid state NMR (23)) or guests that are more rigidly trapped (one carbon tetrachloride molecule can be included per cage, and apparently the fit is rather tight so the CCl_4 molecule just librates at an average frequency of about 35 cm^{-1} (24)). Many of the results of our structural, thermal, and dynamical investigations of Dianin's compound and its clathrates have been summarized previously (25). In light of the present emphasis, we draw attention to the slight increase in thermal expansion with mobile ethanol guests, relative to the clathrand and the clathrate with the less mobile CCl_4 molecules as guests (see Fig. 2) (24, 26). However, the effect of the guest on the volume Grüneisen parameter is that γ_V is enhanced almost equally for ethanol and CCl_4 guests (27); see Fig. 3. (Of course α and γ are both anisotropic, and we have studied their directional dependences (24, 26, 27) but it does not resolve this apparent contradiction.)

Most striking is the effect of the guest on thermal conductivity: there is more thermal resistance (lower κ) when the

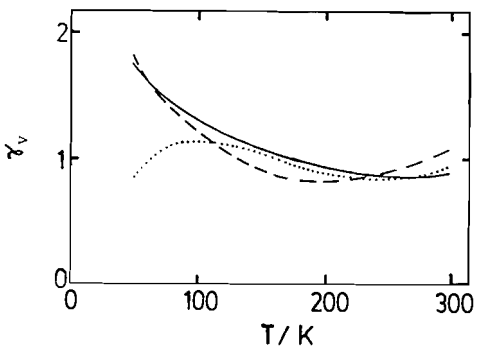

Fig. 4. The temperature dependence of the thermal conductivity, κ, for: (○) Dianin's compound; (▲) CCl_4 clathrate of Dianin's compound; (●) ethanol clathrate of Dianin's compound, with data from refs. 28 and 29; uncertainty in κ is ±10%.

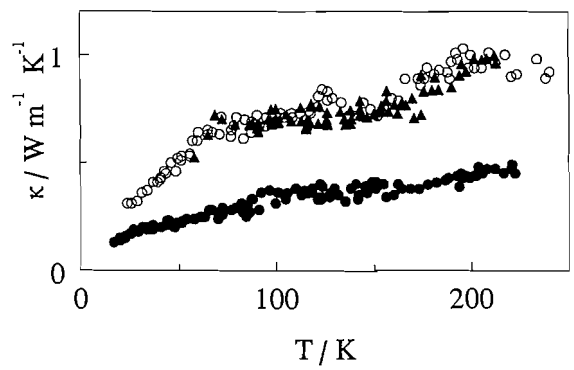
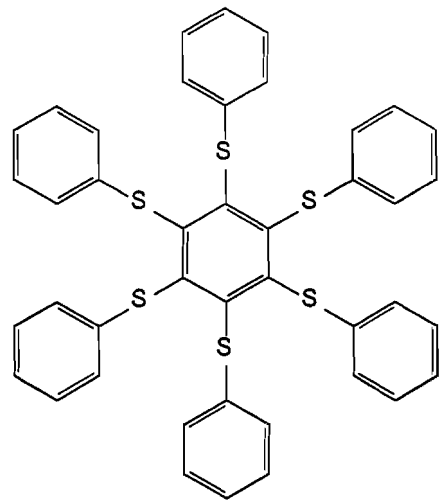


more mobile ethanol guests are present, but the presence of CCl_4 guests leaves κ virtually the same as for the clathrand (28, 29); see Fig. 4. We have interpreted this in terms of shortened lifetimes for the acoustic phonons when a mobile guest is present in the clathrate, i.e., showing that guest mobility enhances the anharmonic interactions in the system (29). Perhaps even more surprising is our finding that the thermal conductivity of the clathrand is low, with a positive temperature coefficient. Given the flexibility of the Dianin molecule, **1**, we interpret this as the effect of the parent molecule's optic phonons in attenuating the transmission of heat-carrying acoustic phonons (28).

We have recently extended our investigations to the more symmetrical host molecule, hexakis(phenylthio)benzene, **2**



2

(abbreviated HPTB) and its CBr_4 clathrate. In this case the host molecule and clathrate are not isomorphous (space groups $P\bar{1}$ and $R\bar{3}$, respectively (12)), so direct comparisons are more difficult. For example, the higher thermal expansion and Grüneisen parameter of HPTB relative to HPTB·$2CBr_4$ are not necessarily indicative of enhanced anharmonicity, as packing interactions will play an important role here (30). Nevertheless, our recent investigations of the thermal conductivity of HPTB·$2CBr_4$ show it to be similar to THF clathrate hydrate and Dianin's compound, viz. κ small and $(d\kappa/dT) > 0$.[3]

To summarize our conclusions concerning properties of inclusion compounds: we find rather large values of thermal expansion (which is evidence of the softness of the potential at large intermolecular distances), Grüneisen parameters that are considerably greater than zero, and low thermal conductivities with positive temperature coefficients, all indications that the crystal potential in these systems is rather anharmonic. We interpret $d\kappa/dT > 0$ as an indication of coupling between heat-carrying acoustic phonons and optic modes associated with the guests and (or) the host lattice. Although we do not know the physical origins of the coupling, if the lattice was perfectly harmonic such interactions could not take place. There is other evidence showing that this interaction can be "tuned" to some extent: in the urea–hexadecane inclusion compound, Ross has found $(d\kappa/dT) \approx 0$ in the high-temperature phase in which the guests are more disordered, and $(d\kappa/dT) < 0$ in the low-temperature (presumably ordered) phase (31).

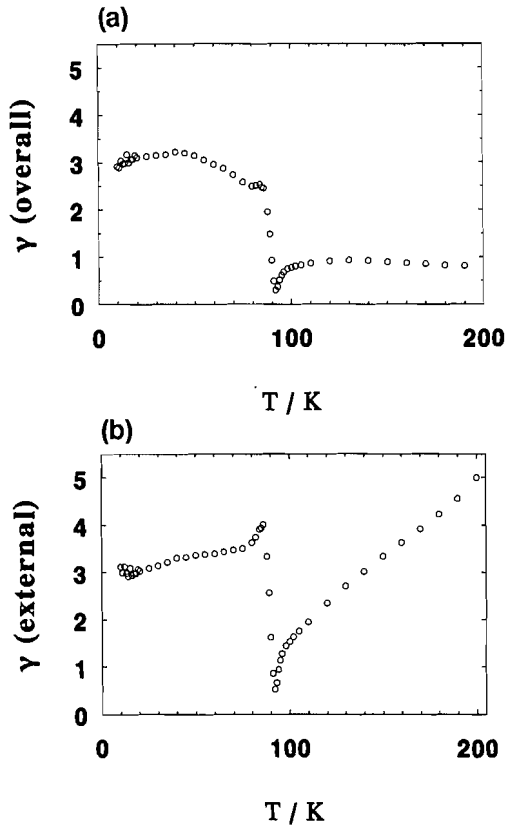
Single-component molecular systems

Although inclusion compounds can be useful in the context of delineating intermolecular interactions, there are a great many single-component molecular systems that also have interesting properties. Brief mention is made here of two systems that we have investigated recently, CBr_4 and C_{60}.

Solid state properties of tetrahedral molecules or molecular ions, especially methane and ammonium salts and their deuterated isotopomers, have been investigated extensively (32), largely because of the possibility of orientational disorder associated with only weak anisotropy in the intermolecular potential. CBr_4 is an interesting system to study because, unlike CH_4 and NH_4^+, it can be treated classically. As part of our analysis of the thermal conductivity of the inclusion compound HPTB·2CBr_4, we required data for the subambient heat capacity of CBr_4. Finding none in the literature, we measured this; details are published elsewhere (33). With that data, we were able to determine the volume Grüneisen parameter, γ_V, for CBr_4, as shown in Fig. 5. The important feature here is the increase in γ_V as $T \rightarrow 0$, in contrast with what one might predict (i.e., $\gamma_V \rightarrow 0$ as $T \rightarrow 0$ due to increased harmonicity). In solid carbon dioxide a similar low-temperature elevation of the Grüneisen parameter has been associated with the presence of low-frequency librational modes (34), and our heat capacity analysis also shows the presence of low-frequency librational modes in CBr_4, corresponding to an Einstein oscillator of characteristic temperature $\leq$60 K (33).

For C_{60} we have a rather different situation with respect to lattice dynamics. Whereas the internal modes and external modes are close in frequency range in CBr_4, the rather rigid C_{60} molecule leads to internal modes that are at much higher frequencies than the external (whole-molecule) modes. C_{60} has other interesting features, namely, a transition at about 260 K from a high-temperature orientationally disordered phase to a low-temperature phase in which there is still appreciable dynamical orientational disorder; the kinetic barrier to orientational order in this phase leads to a glassy phase transition ($T_g \approx 90$ K), and concomitant anomalous behaviour in a number of physical properties, including thermal conductivity (35), heat capacity (36), and thermal expansion (37). Our recent determinations (38) of the Grüneisen parameters of C_{60} are shown in Fig. 6. This figure includes both γ(overall), i.e., as determined from eq. [8] using the total heat capacity, and γ(external), determined from eq. [8] using only the external mode contributions to the heat capacity. γ(external) is small

Fig. 6. The temperature dependence of: (*a*) the overall Grüneisen parameter, γ(overall) and (*b*) the external Grüneisen parameter, γ(external) for C_{60}. Reprinted from ref. (38), Solid State Communications, **94**, M.A. White, C. Meingast, W.I.F. David, and T. Matsuo, "Anharmonic Interactions in C_{60}, as Determined by the Grüneisen Parameter", 481–484, Copyright 1995, with kind permission from Elsevier Science Ltd, The Boulevard, Langford Lane, Kidlington OX5 1GB, U.K.



for $T > T_g$, reflecting the anomalously small thermal expansion in this temperature range due to the temperature dependence of the degree of orientational disorder. Below T_g, γ(overall) $\approx$ γ(external) $\approx$ 3, showing C_{60} to be exceptionally anharmonic, especially given the low relative temperature (as low as $\Theta_D/5$, where Θ_D is the Debye characteristic temperature). We attribute this to low compressibility of C_{60} due to its hard core, compared with, for example, a rare gas solid (38). Indeed, γ(overall) for C_{60} is very similar to γ_c for graphite (39), which shows that low-temperature interactions in C_{60} are dominated by the (isotropic) intermolecular potential. Furthermore, intramolecular Grüneisen parameters, determined by IR and Raman spectroscopy through the method of eq. [6], range from -0.04 to 0.09 (40, 41), showing that internal modes do not contribute significantly to anharmonicity in C_{60}.

Conclusions

Our experimental investigations of thermal expansion, Grüneisen parameters, and thermal conductivity show molecular solids to be rather anharmonic in their intermolecular potentials. This is especially the case when there are low-frequency modes, for example, associated with orientational disorder or

libration of molecular units. Of the properties investigated, the most important is thermal conductivity, especially as it changes greatly in both magnitude and temperature dependence from one material to another. On the basis of our experiments, we suspect that coupling between heat-carrying acoustic phonons and low-frequency optic phonons may be responsible for the low thermal conductivities and positive temperature coefficients observed in several molecular systems. Anharmonicity likely plays a role in this coupling; direct investigations of phonon–phonon interactions in molecular systems would be very useful in delineating the mechanism.

Acknowledgements

This work would not have been possible without the contributions of many excellent co-workers. Those involved directly in the work described are W. Abriel, W.I.F. David, T. Matsuo, C. Meingast, D. Michalski, J. Ripmeester, R.G. Ross, I. Swainson, J. Tse, and M. Zakrzewski. P. Bessonette, D. Michalski, and V. Murashov provided helpful comments on this manuscript. A facile synthesis of metalla-octafluorocyclopentane complexes of ruthenium and nickel

Waltraud Gasafi-Martin, Gabriele Oberendfellner, and Konrad von Werner

Abstract: Reduction of the dihalogeno complexes $RuCl_2(PPh_3)_4$ and $NiBr_2L_2$ (L = tertiary phosphine) with sodium hydride in MeCN in the presence of tetrafluoroethylene gives complexes containing five-membered MC_4F_8 rings. 1,2-Dihydrotetrafluoroethane is a by-product of these syntheses, especially when hydrogen is added. The M—C bonds of the metalla-perfluorocyclopentane complexes are remarkably stable against hydrogenolysis.

Key words: metalla-octafluorocyclopentanes of ruthenium(II) and nickel(II).

Résumé : La réduction des complexes dihalogénés $RuCl_2(PPh_3)_4$ et $NiBr_2L_2$ (L = phosphine tertiaire) avec de l'hydrure de sodium dans MeCN, en présence de tétrafluoroéthène, conduit à des complexes contenant des cycles MC_4F_8 à cinq chaînons. Le 1,1,2,2-tétrafluoroéthane est un sous-produit de ces synthèses, particulièrement lorsqu'on ajoute de l'hydrogène. Les liaisons M—C des complexes du métalla-perfluorocyclopentane sont particulièrement stables vis-à-vis de l'hydrogénolyse.

Mots clés : métalla-octafluorocyclopentanes du ruthénium(II) et du nickel(II).

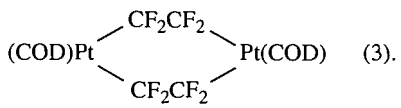
[Traduit par la rédaction]

Metal(O) complexes of group VIII metals are known to react with tetrafluoroethylene (TFE) to give a variety of different products by means of oxidative additions to the metal center. Typical reactions and products are listed below:

(*i*) Formation of a side-on bonded complex: $(Ph_3P)_2$ Pt(η_2-C_2F_4) (1).

(*ii*) Insertion of TFE into a metal-metal bond: $(OC)_4$ Co-CF_2CF_2-Co $(CO)_4$ (2).

(*iii*) Bridging of two metal centers by two molecules of TFE:



(3).

(*iv*) Coupling of two TFE units at the metal center, resulting in the formation of MC_4F_8 rings: $Fe(C_4F_8)(CO_4)$ (4), $Ru(C_4F_8)(CO)_2(PPh_3)_2$ (5), and $Ni(C_4F_8)$(1.5-COD) (6).

We have shown that sodium hydride in acetonitrile is a very efficient reagent for the reduction of dihalide complexes of group VIII metals, affording metal(O)–carbonylphosphine complexes of nickel, palladium, and ruthenium in high yield when the reaction is performed under CO (7). We now have extended the reduction with NaH to the preparation of metallaoctafluorocyclopentane derivatives of nickel(II) and ruthenium(II) (see Table 1). Starting materials were $RuCl_2(PPh_3)_4$ and $NiBr_2L_2$ (L = tertiary phosphine or diphosphine) and tetrafluoroethylene. In contrast, similar reactions of $PdCl_2(PPh_3)_2$ or $FeBr_2(PPh_3)_2$, with two equivalents of PPh_3 added to the iron compound, did not result in the formation of MC_4F_8 complexes in the presence of TFE. The method also failed to work with the nickel complexes L_2NiBr_2 (L_2: N,N′-chelating ligand). However, NiC_4F_8 (bipy) could be obtained from $NiC_4F_8(PPh_3)_2$ by means of ligand exchange in MeCN in good yield.

We believe that the formation of the metallaoctafluorocyclopentane complexes occurs through the following reaction sequence: (*a*) displacement of halide ions by hydride to give dihydridocomplexes, (*b*) reductive elimination of hydrogen resulting in the formation of metal(O) complexes, (*c*) sequential coupling of two molecules of TFE at the metal(O)center.

It is interesting to note that all of the crude reaction mixtures obtained from the NaH reactions contained some 1,2-dihydrotetrafluoroethane, the hydrogenation product of TFE. A further point of interest concerns the fact that $(Ph_3P)_2NiC_4F_8$ is formed even in the presence of carbon dioxide, acetaldehyde, or hydrogen. When the reaction was run under simultaneous application of TFE and hydrogen (10 bar each; 1 bar = 100 kPa), the yield of the complex rose to 30%.

The observation that 1,2-dihydrotetrafluoroethane is always found can be explained by assuming the following reaction sequence:

Table 2. Elemental analyses.

		Calculated				Found			
Compound	Formula	C	H	F	M	C	H	F	M
1	$C_{76}H_{60}F_8P_4Ru$	67.60	4.48	11.36	7.49	67.4	4.4	11.3	7.6
2	$C_{40}H_{30}F_8P_2Ni$	61.33	3.86	19.40	7.49	61.2	3.8	19.5	7.5
3	$C_{30}H_{24}F_8P_2Ni$	54.83	3.68	23.13	8.93	55.0	3.7	23.2	8.9
4	$C_{14}H_8F_8N_2Ni$	40.53	1.94	36.63	14.15	40.7	1.9	36.5	14.0

The unsaturated species L_n[M] is required for metallacycle formation. A high excess of tetrafluoroethylene will favour the formation of the metallacycle, whereas an addition of hydrogen should be expected to favour the formation 1,2-dihydrotetrafluoroethane.

The metal–carbon bonds of the complexes **1–4** are very stable against hydrogenolysis. Complex **1** did not react with hydrogen (20 bar) in toluene solution even in the presence of a very active hydrogenation catalyst (2% palladium on Al_2O_3) up to 60°C. Hydrogenation of **2** with the same catalyst in MeCN gave a surprising result: hydrogenation of the triphenylphosphine ligands set in at ca. 100°C; however, the NiC_4F_8 group was still intact.

Experimental part

All reactions and work-up procedures were carried out under dry nitrogen or argon, using carefully dried solvents. MeCN was distilled from P_4O_{10} through a column, and the main run was stored over molecular sieve (3 Å).

Typical procedure for the synthesis of 1–4

A stainless steel autoclave (150 mL), equipped with manometer, gas inlet, a thermocouple for temperature control, and a PTFE-coated stirring bar, was charged with a solution of $(Ph_3P)_4RuCl_2$ (or of a nickel complex L_2NiBr_2) in anhydrous MeCN (3.0 mmol of the complex in 50 mL solvent). Sodium hydride (6.6 mmol), as a 20% suspension of NaH in DAB9 mineral oil (obtained from Merck), was added with a syringe. The autoclave was closed, cooled to 0°C, and pressurized with TFE (10 bar), and the reaction was carried out with stirring under the conditions given in Table 1. After cooling to room temperature and releasing the pressure, the contents of the autoclave were transferred to a flask and the solvent was removed in vacuo. The residue was stirred with toluene (50 mL) at 40°C and filtered through a frit that contained 2 g of Celite. In the case of **3** and **4**, a mixture of toluene (40 mL) and CH_2Cl_2 (10 mL) was used. The filtrate was concentrated under vacuum and crystallization was induced by adding ether and (or) *n*-hexane and cooling. The product was collected on a frit, washed with cold *n*-hexane, and dried in vacuo. Recrystallization from CH_2Cl_2 and *n*-hexane and drying at 50°C at 10^{-3} mbar finally gave the pure products.

We did not attempt to fully optimize the yields.

Synthesis of 2,2′-bipyridine-nickelaoctafluorocyclopentane, 5

2,2′-Bipyridine (85.9 mg, 0.55 mmol) was added to a stirred solution of complex **2** (392 mg, 0.5 mmol) in 5 mL of MeCN. The solution soon became cloudy. After 1 h, *n*-hexane (2 mL) was added and the crystalline product was filtered off, washed with 5 mL of cold *n*-hexane, and dried at 10^{-3} mbar (yield: 253 mg). The element analyses of the complexes **1–5** are shown in Table 2.

Spectra

The IR spectra of all products in Nujol were measured with a Perkin Elmer 882 spectrophotometer. The bands observed for

the compounds **2**, **3**, and **5** in the region of 1300–750 cm^{-1} are in good agreement with the data reported in ref. 6 (maximum deviation: 15 cm^{-1}), although the methods of preparation were different. The spectra of **3** and **4** are very similar. The ruthenium complex **1** showed the following bands in the above region: 1306 w, 1261 m, 1210 w, 997 w, 916 w, 852 w, 799 s.

^{19}F NMR spectra were measured with a Bruker AC 300 instrument at 30°C. The couplings reported in Table 1 are based on the following assumptions:

1: $(AMX_2)_2$ spin system, where A is ^{31}P *cis* to α-CF_2, M is ^{31}P *trans* to α-CF_2 and X is ^{19}F of α-CF_2.

2, **3**, and **4**: $(AX_2)_2$ spin system, where A is ^{31}P and X is ^{19}F of α-CF_2.

Direct syntheses of pentakis(trifluoromethyl)cyclopentadienide salts and related systems[1]

Richard D. Chambers, Alex J. Roche, and Julian F.S. Vaughan

Abstract: The well-established synthesis of heptafluorobut-2-ene **2** from hexachlorobutadiene **1** and potassium fluoride has been further investigated, and novel dienes **3** and a triene **4** have been observed. Remarkably, the potassium salt of pentakis(trifluoromethyl)cyclopentadienide **7** has been isolated from this system. Salt **7** has also been obtained directly from **2**. Cyclopentadiene **6** has been isolated from salt **7** by distillation from sulphuric acid. Bi- and tri-cyclic analogues of **7** have also been obtained, i.e., **9** and **10**, by reaction of **2** with perfluorocyclopentene.

Key words: heptafluorobut-2-ene, pentakis(trifluoromethyl)cyclopentadienide, 5*H*-pentakis(trifluoromethyl)cyclopentadiene.

Résumé : On a étudié à nouveau la synthèse bien connue de l'heptafluorobut-2-ène **2** à partir de l'hexachlorobutadiène **1** et du fluorure de potassium; on a observé la formation de nouveaux dienes **3** et d'un triène **4**. D'une façon remarquable, on a isolé de ce système le pentakis(trifluorométhyl)cyclopentadiénure de potassium **7**. Par distillation du sel **7** en présence d'acide sulfurique, on a isolé le cyclopentadiène **6** à partir du sel **7**. La réaction du composé **2** avec le perfluorocyclopentène a permis aussi d'obtenir les analogues bi- **9** et tricycliques **10** du composé **7**.

Mots clés : heptafluorobut-2-ene, pentakis(trifluorométhyl)cyclopentadiénure, 5*H*-pentakis(trifluorométhyl)cyclopentadiène.

[Traduit par la rédaction]

There is a wide interest in methodology for the introduction of trifluoromethyl and other perfluoroalkyl groups into organic compounds (2), and we are concerned with the alkene (*Z*)-2*H*-heptafluorobut-2-ene **2** as a potential "building block" for this purpose. This F-alkene is especially significant because it can be obtained directly from hexachloro-1,3-butadiene **1**, by simple displacement using potassium fluoride in an aprotic solvent. This synthesis was described in 1963 by Maynard (3), from the du Pont Co., and has subsequently been used by other workers, including this laboratory (4). However, in recent further investigation of this reaction, we have discovered some remarkable new products.

The overall procedure involves heating hexachloro-1,3-butadiene **1** with anhydrous potassium fluoride in an aprotic solvent; Maynard (3) described *N*-methyl-2-pyrrolidinone and we have found that sulpholan is very satisfactory (4). The products vary significantly with reaction conditions, and we have now identified and separated from **2** two interesting new fluorinated dienes **3a** and **3b**, and even a triene **4**. These compounds were separated by fractional distillation and the stereochemistry of the major diene isomer **3a** follows from ^{19}F NMR coupling constant data, since it is known that ^{5}J(*cis*-CF_3,CF_3) values are greater than 10 Hz, ^{5}J(*trans*-CF_3,CF_3) values are typically less than 2 Hz, and ^{4}J(*trans*-CF_3,F) coupling constants are less than for ^{4}J(*cis*-CF_3,F) (5), as shown in Fig. 1. In contrast, we were unable to deduce the structure of the minor isomer **3b** (see experimental section) because the splitting in the ^{19}F NMR spectrum was insufficiently resolved.

The mechanism of formation of the dienes **3a** and **3b**, and the triene **4** is outlined in Scheme 1, arising from fluoride ion initiated oligomerization of **2**, and other evidence for this process stems from the fact that these compounds may also be obtained directly from **2** by heating with fluoride ion in a sealed system.

We have also examined the filtered sulpholan residue from the preparation of **2**, and, remarkably, the ^{19}F NMR spectrum showed only one sharp resonance at $\delta_F = -50$ ppm! It is unlikely that we would have been able to identify this component from this unusual signal, except for the fact that we had already synthesized various salts of the pentakis(trifluoromethyl)cyclopentadienide (6), and these had given similar ^{19}F NMR signals. FAB mass spectroscopy confirmed the presence of potassium (*m/z* 39 (100%), in the positive ion spectrum), and showed only a *m/z* 405 (100%) peak in the negative ion spectrum, which is consistent with **7**. Thus we had obtained potassium pentakis(trifluoromethyl)cyclopentadienide **7** in one step from hexachloro-1,3-butadiene and potassium fluoride! This is amusing to those of us who were seeking syntheses of **7** because, in our own laboratory, it is clear that we have been disposing of samples of **7** with the residue, following the synthesis of **2**!

5*H*-Pentakis(trifluoromethyl)cyclopentadiene (**6**) has been

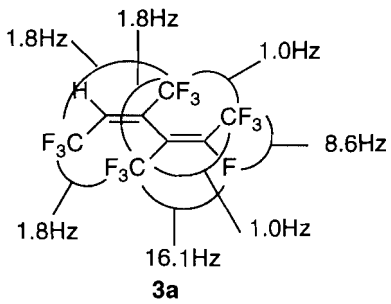
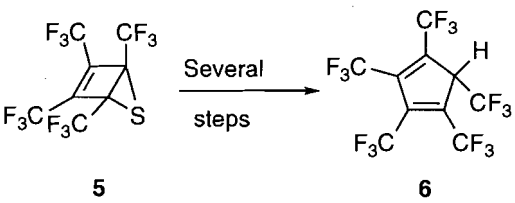


Scheme 2.



described by Laganis and Lemal (7) in several steps, starting with a valence isomer of tetrakis(trifluoromethyl)thiophene (**5**) (Scheme 2), and they also showed that **6** is a very strong acid ($pK_a \leq -2$). However, we have now been able to isolate and characterize the acidic diene **6** by distillation from the sulpholan residue, after the addition of concentrated sulphuric acid.

The mechanism of formation of **7** is probably that outlined in Scheme 3, essentially derived from **2**. The cyclization step to give **6** is extremely interesting because, as a *5-endo-trig* process, it is formally "disallowed" by the Baldwin rules (8). It seems more appropriate, therefore, to regard the process as an initial electrocyclic ring closure, to give **6**, followed by elimination of the acidic proton by fluoride ion, now acting as a base. In confirmation of this mechanism, we have also shown that **7** can be obtained by reaction of **2** with caesium fluoride in sulpholan in a sealed tube. Again this is a direct route to **7** from easily accessible starting materials.

Furthermore, a variety of salts may be obtained by reaction of an aqueous solution of the appropriate halide with the acidic diene **6** (Scheme 4). Single crystal X-ray structural analyses of tetraalkylammonium salts of **7** confirmed the product structure. However, rotation within the crystal, even at low temperatures, prevents a precise determination of bond lengths and angles.

The results described above pointed the way to a synthesis of a variety of more complex fluorocarbon salts. For example, we have shown that reaction of fluoride ion with **2** in the presence of perfluorocyclopentene **8** gave a mixture of two novel salts **9** and **10**, while the diene **3** in the presence of **8** with fluoride ion gave only **9**. These compounds were characterized by ^{19}F NMR and FAB mass spectrometry, which is a particularly valuable tool with these and related systems. However, attempts to obtain the corresponding dienes from **9** and **10**, by distillation from concentrated sulphuric acid, has, so far, led to products too complex to separate, although GLCMS revealed the presence of the desired dienes, but accompanied by other unidentified products.

Experimental

^1H NMR spectra were recorded on a Bruker AC250 spectrometer operating at 250.13 MHz, a Varian Gemini VXR200 spectrometer operating at 199.98 MHz, or a Varian VXR400S spectrometer operating at 399.96 MHz. ^{19}F NMR spectra were recorded on the Bruker AC250 spectrometer operating at 235.34 MHz or on the Varian VXR400S spectrometer operating at 376.29 MHz. ^{13}C spectra were recorded on the Varian VXR400S spectrometer operating at 100.58 MHz, or the Varian Gemini VXR200 spectrometer operating at 50.29 MHz. All spectra were recorded with TMS and fluorotrichloromethane as internal references. The *J* values are given in Hz. GLCMS mass spectra were recorded on a Fisons Trio 1000 spectrometer linked to a Hewlett Packard 5890 series II gas chromatograph fitted with a 20 m cross-linked methyl silicone capillary column. All GLCMS mass spectra were generated by electron impact. FAB mass spectra were recorded using a VG7070E spectrometer, and glycerol as a solvent. FTIR spectra were recorded on a Perkin Elmer 1600 series FTIR spectrometer. Solid samples were run as KBr discs, liquid samples were run as thin films between KBr plates, and volatile samples were run in a gas cell fitted with KBr plates.

Reaction of 1 with potassium fluoride

The method used was essentially that used by Maynard (3), using hexachlorobuta-1,3-diene **1** (334 g, 1.3 mol), potassium fluoride (600 g, 10.2 mol), and sulpholan (2 L). The volatile products were collected at liquid air temperatures, and fractional distillation gave (Z)-2H-*heptafluorobut-2-ene* **2** (105.1 g, 45%); bp 7–8°C (lit. (3) bp, 7–10°C); ν_{max}/cm^{-1}: 1220, 1310; δ_H(250 MHz; $CDCl_3$): 5.45 (dq, *J* 28.3 and 5.3, C*H*); δ_F(235 MHz; $CDCl_3$): −61.6 (3 F, s, CF_3CH), −76.2 (3 F, s, CF_3CF), −119.9 (1 F, s, C*F*); δ_C(100 MHz; $CDCl_3$):

101.3 (q, *J* 39.1, *C*H), 116.2 (qd, *J* 272.5 and 38.3, CF_3CF), 119.5 (q, *J* 269.5, CF_3CH), 150.8 (dqq, *J* 283.3, 41.2 and 5.9, $CFCF_3$); *m/z* 182 (M^+, 23%), 163 (54), 113 (90), 69 (100).

A higher boiling fraction (bp 78–80°C) was shown by GLCMS to contain three components, and preparative scale GLC (SE30/40°C) produced a 4:1 mixture of two isomers of *5H-perfluoro-3,4-bis(trifluoromethyl)hexa-2,4-diene* ***3a*** and ***b*** (13.2 g, 6%). For the diene mixture (Anal. calcd. for C_8HF_{13}: C 28.0, H 0.3%; found: C 28.0, H 0.2%); $\lambda_{max}(CH_3CN)$/nm: 295; ε/dm^3 mol^{-1} nm^{-1}: 1148; ν_{max}/cm^{-1}: 1400, 1300–1200. The major isomer was confirmed as the (*Z, E*) isomer (**3a**). δ_H(250 MHz; $CDCl_3$): 6.68 (q, *J* 6.3, C*H*); δ_F(235 MHz; $CDCl_3$): −60.8 (3 F, dqq, *J* 16.1, 1.8, 1.0, CF_3C-3), −62.3 (3 F, sept, *J* 1.8, CF_3C-4), −68.7 (3 F, m, *J* 1.8, 6-CF_3), −70.4 (3 F, dsept, *J* 8.6 and 1.0, 1-CF_3), −105.0 (1 F, qq, *J* 16.1 and 8.6, C*F*); *m/z*: 343 (M^+ − 1, 21%), 293 (100), 243 (98), 69 (50). The stereochemistry of the minor isomer **3b** has not been confirmed as yet; δ_H(250 MHz; $CDCl_3$): 6.41 (q, *J* 6.7, C*H*); δ_F(235 MHz; $CDCl_3$): −56.7 (3 F, s, CF_3C-3), −62.1 (3 F, s, CF_3C-4), −64.6 (3 F, s, 1-CF_3), −68.3 (3 F, s, 6-CF_3), −101.8 (1 F, s, C*F*); *m/z*: 343 (M^+ − 1, 20%), 293 (50), 69 (100). In the original diene distillate there was a component (1% by GLCMS) identified as *7H-perfluoro-3,4,5,6-tetra(trifluoromethyl)octa-2,4,6-triene* ***4***; *m/z*: 505 (M^+ − 1, 2%), 467 (33), 321 (66), 69 (100). The residual sulpholan solution was shown to contain *potassium pentakis(trifluoromethyl)cyclopentadienide* (***7***) (12.9 mmol, 3%) (by ^{19}F NMR integrated against an internal standard of 1,1,1-trifluorotoluene); δ_F(235 MHz; $CDCl_3$): −49.8 (s, CF_3); FAB+ *m/z*: 39 (M^+, 100%), FAB− *m/z*: 405 (M^+, 100%).

The residual sulpholan solution was filtered and 98% sulphuric acid (750 mL, 14.1 mol) was added dropwise under reduced pressure. Volatile products were collected at liquid air temperatures, and were shown by GLCMS to contain one compound identified as *5H-pentakis(trifluoromethyl)cyclopentadiene* (***6***) (4.5 g, 86%); ν_{max}/cm^{-1}: 2977, 1664, 1450–1000; δ_H(250 MHz; $CDCl_3$): 4.80 (q, *J* 5.6, C*H*); δ_F(235 MHz; $CDCl_3$): −57.1 (6 F, s, 2-CCF_3), −60.2 (3 F, s, 5-CCF_3), −60.9 (6 F, s, 1-CCF_3); δ_C(100 MHz; $CDCl_3$): 58.4 (q, *J* 32.1, C-5), 119.2 (q, *J* 275.1, CF_3C-5), 120.2 (q, *J* 272.4, CF_3C-1), 122.6 (q, *J* 284.1, CF_3C-1) 139.7 (q, *J* 40.4, C-1), 139.8 (q, *J* 40.3, C-2); *m/z*: 406 (M^+, 2%), 69 (100).

H_2O (100 mL) was added to **6**, producing *hydronium pentakis(trifluoromethyl)cyclopentadienide* (11.1 mmol, quant.); δ_F(235 MHz; D_2O): −51.4 (s, CF_3). On addition of aqueous tetraethylammonium iodide (15.9 g, 64.4 mmol), a precipitate formed, which was recrystallized (diethyl ether – hexane), giving colourless crystals identified as *tetraethylammonium pentakis(trifluoromethyl)cyclopentadienide* (5.7 g, 83% from

General procedure for salt formation

As above, an aqueous solution of the desired halide salt (typically 500% excess) was added to the aqueous hydronium pentakis(trifluoromethyl)cyclopentadienide solution. This mixture was stirred for 1 h, before extraction (dichloromethane) and recrystallization (ether–hexane).

Tetrapropylammonium pentakis(trifluoromethyl)cyclopentadienide: mp 141–142°C; ν_{max}/cm^{-1}: 3100, 1350, 1225; δ_H(250 MHz; $CDCl_3$): 0.96 (3 H, t, *J* 7.2, CH_3), 1.70 (2 H, sext, *J* 7.2, CH_3CH_2), 3.01 (2 H, m, NCH_2); δ_C(100 MHz; $CDCl_3$): 15.3 (s, CH_3), 31.0 (s, CH_3CH_2), 55.2 (s, NCH_2), 110.1 (q, *J* 19.0, CCF_3), 123.3 (q, *J* 270.5, CF_3); δ_F(235 MHz; $CDCl_3$): −50.9 (s, CF_3); FAB+ *m/z*: 186 (M^+, 100%); FAB− *m/z*: 405 (M^+, 75%), 91 (solvent, 100). Anal. calcd. for $C_{22}H_{28}F_{15}N$: C 44.7, H 4.7, N 2.4%; found: C 44.8, H 4.6, N 2.4%.

Tetrabutylammonium pentakis(trifluoromethyl)cyclopentadienide: mp 118–119°C; ν_{max}/cm^{-1}: 3050, 1500, 1225, 1150; δ_H(250 MHz; $CDCl_3$): 0.95 (3 H, t, *J* 7.2, CH_3), 1.33 (2 H, sext, *J* 7.2, CH_3CH_2), 1.60 (2 H, pent, *J* 7.2, NCH_2CH_2), 3.11 (2 H, m, NCH_2); δ_C(100 MHz; $CDCl_3$): 13.1 (s, CH_3), 19.2 (s, CH_3CH_2), 23.4 (s, NCH_2CH_2), 58.5 (s, NCH_2), 109.6 (q, *J* 18.5, CCF_3), 123.7 (q, *J* 269.9, CF_3); δ_F(235 MHz; $CDCl_3$): −50.1 (s, CF_3); FAB+ *m/z*: 242 (M^+, 100%); FAB− *m/z*: 405 (M^+, 100%). Anal. calcd. for $C_{26}H_{36}F_{15}N$: C 48.2, H 5.6, N 2.2%; found: C 48.2, H 5.7, N 2.0%.

Potassium pentakis(trifluoromethyl)cyclopentadienide: mp >330°C; ν_{max}/cm^{-1}: 1500, 1200, 1050; δ_F(235 MHz; $CDCl_3$): −49.8 (s, CF_3); FAB+ *m/z*: 39 (M^+, 100%); FAB− *m/z*: 405 (M^+, 100%). Anal. calcd. for $KC_{10}F_{15}$: C 27.0%; found: C 27.1%.

Caesium pentakis(trifluoromethyl)cyclopentadienide: mp >330°C; ν_{max}/cm^{-1}: 1500, 1250, 1100; δ_F(235 MHz; $CDCl_3$): −49.9 (s, CF_3); FAB+ *m/z*: 133 (M^+, 100%); FAB− *m/z*: 405 (M^+, 100%). Anal. calcd. for $CsC_{10}F_{15}$: C 22.3%; found: C 22.3%.

Thallium pentakis(trifluoromethyl)cyclopentadienide: mp >330°C; ν_{max}/cm^{-1}: 1450, 1200, 1100; δ_F(235 MHz; $CDCl_3$): −49.8(s, CF_3); FAB+ *m/z*: 93 (solvent, 100%), 205 (M^+, 41%); FAB− *m/z*: 405 (M^+, 100%). Anal. calcd. for $TlC_{10}F_{15}$: C 19.7%; found: C 19.6%.

CsF and ***2*** *in a sealed system*

A Carius tube containing **2** (1.18 g, 4.68 mmol), caesium fluoride (6.00 g, 39.47 mmol), and sulpholan (10 mL) was heated and rotated at 190°C for 3 days. Volatiles were removed under reduced pressure, and the sulpholan residue was shown by ^{19}F NMR (integrated against an internal standard of 1,1,1-trifluorotoluene) and FAB mass spectrometry to contain *caesium pentakis(trifluoromethyl)cyclopentadienide* (0.28 mmol, 13%), as above.

Monomeric and dimeric V(III) complexes supported by organic amides

Pietro Berno, Mark Moore, Ravinder Minhas, and Sandro Gambarotta

Abstract: Reaction of $VCl_3(THF)_3$ with two equivalents of R_2NLi (R = Cy, Me_3Si) yielded the two corresponding complexes $(Cy_2N)_2V(\mu\text{-}Cl)_2Li(THF)_2$ (**1**) and $[(Me_3Si)_2N]_2VCl(THF)$ (**2**). Both complexes decomposed in hot toluene. In the case of complex **1** the reaction led to dimerization and formation of the dimeric $[(Cy_2N)_2V(\mu\text{-}Cl)]_2$ (**3**). Reaction of **2** with $NaBH_4$ yielded the unprecedented borohydride derivative $[(Me_3Si)_2N]_2V(BH_4)(THF)$ (**4**). The structures of all the complexes were elucidated by X-ray analysis.

Key words: vanadium, trivalent, amide, borohydride, dinuclear.

Résumé : La réaction du $VCl_3(THF)_3$ avec deux équivalents de R_2NLi (R = Cy, Me_3Si) conduit aux deux complexes correspondants $(Cy_2N)_2V(\mu\text{-}Cl)_2Li(THF)_2$ (**1**) et $[(Me_3Si)_2N]_2VCl(THF)$ (**2**). Les deux complexes se décomposent dans le toluène bouillant. Dans le cas du complexe **1**, la réaction conduit à une dimérisation et à la formation du dimère $[(Cy_2N)_2V(\mu\text{-}Cl)]_2$, **3**. La réaction du composé **2** avec le $NaBH_4$ conduit au dérivé borohydrure inconnu $[(Me_3Si)_2N]_2V(BH_4)(THF)$, **4**. Les structures de tous les complexes ont été élucidées par diffraction des rayons X.

Mots clés : vanadium, trivalent, amide, borohydrure, dinucléaire.

[Traduit par la rédaction]

Introduction

There has been a steady growth of interest in the recent literature (1) in the chemistry of medium-valent vanadium complexes and, in particular, those containing the metal in the oxidation state +3. This is probably due to the rich and diversified chemical reactivity displayed by these derivatives which includes dinitrogen fixation (2), possible relevance for desulfurization processes (3), and formation of precursors for hydrogenation (4) and of reactive moieties such as nitrides (5), carbenes (6), alkyls (7), and hydrides (5*c*, 8). In fact, this particular oxidation state of vanadium combines a medium Lewis acidity with the presence of available *d* electrons, which together contribute to its fairly high reactivity. Last but not least, trivalent vanadium seems to play an important role in some naturally occurring systems such as vanadium nitrogenase (9) and others (see for example ref. 10), where remarkable transformations are carried out in a catalytic manner and under mild reaction conditions.

Anionic organic amides seem to be particularly versatile supporting ligands with which to study the chemistry of trivalent vanadium. There are several characteristics that make them unique. First of all, there is a virtually unlimited possibility of fine tuning the steric hindrance via the appropriate selection of the substituents attached to the nitrogen atom. Their rather strong reducing power (11) and electronic flexibility allow the stabilization of a rather wide range of oxidation states and, in particular, of the lower states. Finally, these ligands are readily available via simple deprotonation of commercially available primary or secondary amines.

We recently reported the preparation of several V(III) complexes supported by nitrogen-donor-based ligands and described their involvement in dinitrogen activation (2, 12) and hydrogen transfer processes (4, 5*c*). These findings encouraged us to extend further the chemistry of these derivatives toward further functionalization and in particular to attempt the preparation of hydrides and alkyls. In this perspective, complexes such as $(R_2N)_2VCl$, containing a chlorine atom that should be easy to replace, will be the most promising starting materials.

In this paper we describe the convenient and straightforward preparation of monomeric and dimeric V(III) halide complexes supported by organic amides and the transformation of one of them into an unusual borohydride derivative.

Experimental

All operations were performed under the inert atmosphere of a nitrogen-filled dry-box (Vacuum Atmosphere) or by using standard Schlenk techniques. Cy_2NLi (13) and $VCl_3(THF)_3$ (14) were prepared according to published procedures. $NaBH_4$ (Aldrich) was used as received. $(Me_3Si)_2NLi$ (Aldrich) was recrystallized from hexane. Infrared spectra were recorded on a Mattson 9000 FTIR instrument from Nujol mulls prepared in the dry-box. Samples for magnetic susceptibility measurements were weighed inside the dry-box equipped with an analytical balance, and sealed into calibrated tubes. Magnetic measurements were carried out with a Gouy balance (Johnson

Matthey) at room temperature. The magnetic moment was calculated following standard methods (15), and corrections for underlying diamagnetism were applied to the data (16). Elemental analyses were carried out with a Perkin Elmer PE 2400 CHN analyzer. Ratios between heavy atoms were determined by X-ray fluorescence by using a Philips XRF 2400 instrument.

Preparation of $(Cy_2N)_2V(\mu\text{-}Cl)_2Li(THF)_2$ (1)

Freshly prepared Cy_2NLi (6.96 g, 37.1 mmol) was added to a red suspension of $VCl_3(THF)_3$ (6.94 g, 18.6 mmol) in THF (100 mL) at −30°C. The color immediately turned green and the resulting suspension was stirred overnight at room temperature. After evaporation to dryness, toluene (120 mL) was added to the solid residue. The resulting suspension was filtered and the solution was concentrated to small volume. The addition of diethyl ether (150 mL) caused the precipitation of a dark microcrystalline solid (3.7 g, 5.8 mmol, 31%). Crystals suitable for X-ray analysis were obtained upon addition of hexane to a concentrated THF solution of **1** and storage at −25°C. IR (Nujol mull, cm^{-1}): 2671(br), 1449(vs), 1365(sh), 1343(m), 1248(br), 1162(s), 1145(s), 1121(br), 1034(vs), 980(w), 955(vs), 890(vs), 842(s), 804(m), 779(m), 728(w), 698(vs), 587(s), 513(s), 451(w). Anal. calcd. (found) for $C_{32}H_{60}O_2N_2Cl_2LiV$: C 60.66(60.11), H 9.54(8.99), N 4.41(4.21). $\mu_{eff} = 2.68\mu_B$.

Preparation of $\{[(CH_3)_3Si]_2N\}_2VCl(THF)$ (2)

A suspension of $VCl_3(THF)_3$ (7.06 g, 18.9 mmol) in THF (80 mL) was treated at room temperature with $(Me_3Si)_2NLi$ (6.3 g, 38 mmol). The color rapidly turned deep blue-green. After stirring for 3 h at room temperature, the solvent was evaporated in vacuo. The residual solid was redissolved in hexane (70 mL) and the resulting solution was filtered and allowed to stand overnight at −30°C. Dark blue-green crystals of **2** separated (7.9 g, 16.4 mmol, 87%). IR (Nujol mull, cm^{-1}): 1462(vs), 1376(m), 1249(s), 1001(w), 906(s), 890(s), 846(s), 784(m), 759(w), 690(m), 665(s). Anal. calcd. (found) for $C_{16}H_{44}N_2ClSi_4OV$: C 40.10(39.91), H 9.25(9.17), N 5.85(5.72). $\mu_{eff} = 2.79\mu_B$.

Preparation of $[(Cy_2N)_2V(\mu\text{-}Cl)]_2$ (3)

Solid Cy_2NLi (24.98 g, 133.4 mmol) was added to a red suspension of $VCl_3(THF)_3$ (24.92 g, 66.7 mmol) in THF (200 mL) at −30°C. The resulting dark green suspension was stirred overnight at room temperature. After evaporation of the solvent in vacuo, the dark brown solid residue was suspended in toluene (250 mL) and the resulting solution was boiled and filtered while hot. Dark brown crystals of **3** (14.98 g, 17 mmol, 51%) separated after allowing the resulting brown solution to stand at −25°C for 2 days. IR (Nujol mull, cm^{-1}): 2667(br), 1449(vs), 1364(sp), 1343(m), 1296(w), 1285(w), 1250(s), 1160(s), 1146(s), 1119(vs), 1067(w), 1037(vs), 980(w), 956(vs), 890(s), 841(s), 803(w), 778(m), 697(s), 612(w), 585(m), 514(s), 495(w), 484(w), 449(w), 424(w). Anal. calcd. (found) for $C_{24}H_{44}N_2ClV$: C 64.48(64.31), H 9.92(9.77), N 6.27(6.22). $\mu_{eff} = 1.79\mu_B$.

Preparation of $\{[(CH_3)_3Si]_2N\}_2V(BH_4)(THF)$ (4)

A solution of **2** (3.0 g, 6.3 mmol) in THF (100 mL) was stirred with $NaBH_4$ (1.9 g, 50.2 mmol) for 24 h at room temperature. The resulting deep blue mixture was filtered and the solvent evaporated in vacuo. The oily residue was dried overnight in vacuo at room temperature and the resulting solid was redissolved in hexane. The mixture was filtered to remove the small amount of insoluble material, concentrated, and allowed to stand at −30°C. Dark blue crystals of **4** (0.160 g, 0.3 mmol, 6%) were obtained. IR (Nujol mull, cm^{-1}): 2434(s), 2396(s), 2240(m), 2134(s), 1463(s), 1373(s), 1351(w), 1243(vs), 1167(w), 1129(m), 1020(w), 999(s), 881(v br), 663(s), 441(s). The extreme air sensitivity prevented elemental analysis determination. $\mu_{eff} = 2.91\mu_B$.

X-ray crystallography

Data were collected in the temperature range −144 to −161°C. The ω–2θ scan technique was used for suitable air-sensitive crystals mounted on glass fibers. Cell constants and orientation matrices were obtained from the least-squares refinement of 25 centered reflections. The intensities of three standard reflections, measured after every 150 reflections, showed no statistically significant decay over the duration of the data collections. Data were corrected for Lorentz and polarization effects, but no absorption corrections were applied to the data except for complex **4**. In this case, absorption corrections (DIFABS) significantly improved the agreement factors. The structures of **1**, **2**, and **3** were solved by direct methods by locating all the non-hydrogen atoms. Their positions were refined anisotropically. Hydrogen atom positions were introduced at their calculated positions except for complex **4** where the positions of the hydrogens connected to the boron atom were located from difference Fourier maps. The data were processed using the TEXSAN software package on a Digital VAX workstation. Refinements were carried out by using full-matrix least-squares techniques on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o2/\sigma2(F_o^2)$ and F_o and F_c are the observed and calculated structure factors. Atomic scattering factors and anomalous dispersion terms were taken from the usual sources (Cromer and Waber) (17). Details on the data collections and structure refinements are listed in Table 1. The final atomic coordinates are given as supplementary material.[2] Selected bond distances and angles are given in Table 2.

Results

According to Scheme 1, the reaction of $VCl_3(THF)_3$ with two equivalents of R_2NLi (R = Cy, $(CH_3)_3Si$) led to the formation of the corresponding derivatives $(Cy_2N)_2V(\mu\text{-}Cl)_2Li(THF)_2$ (**1**) and $\{[(CH_3)_3Si]_2N\}_2VCl(THF)$ (**2**). In both cases, the reactions were instantaneous and were accompanied by a rapid color change to dark green or blue-green. The two complexes were isolated in crystalline form. The formulation of the two species was indicated by the values of the combustion analy-

ses. The X-ray fluorescence spectrum confirmed the presence of chlorine in the expected ratio with the metal centers. Both complexes are paramagnetic at room temperature with magnetic moments as expected for the d^2 electronic formulation of V(III) metal centers.

The chemical connectivity of both complexes was elucidated by X-ray analysis. Complex **1** features a vanadium atom residing in the center of a distorted tetrahedron (N1-V1-N2 = 120.9(1)°, N1-V1-Cl1 = 106.0(1)°, Cl1-V1-Cl2 = 94.89(4)°) defined by the two nitrogen atoms of the two amide groups (V1—N1 = 1.902(3) Å, V1—N2 = 1.864(3) Å) and two chlorides (V1—Cl1 = 2.375(1) Å, V1—Cl2 = 2.355(1) Å). Similar to the case of the closely related titanium derivative $[(Cy_2N)_2Ti(\mu\text{-}Cl)_2(Li(TMEDA)]$ (18), the distortion of the coordination geometry is probably due to the large steric bulk of the amide groups since the angle subtended at vanadium by the two amide groups is significantly wider than expected for a normal tetrahedral angle. The two chloride atoms bridge to one lithium cation (Cl1—Li1 = 2.344(6) Å, Cl2—Li1 = 2.400(7) Å) forming an almost planar VCl_2Li core (torsion angle V1-Cl1-Li1-Cl2 = 3.7(2)°). Two molecules of THF complete the tetrahedral coordination geometry of the alkali

Scheme 1.

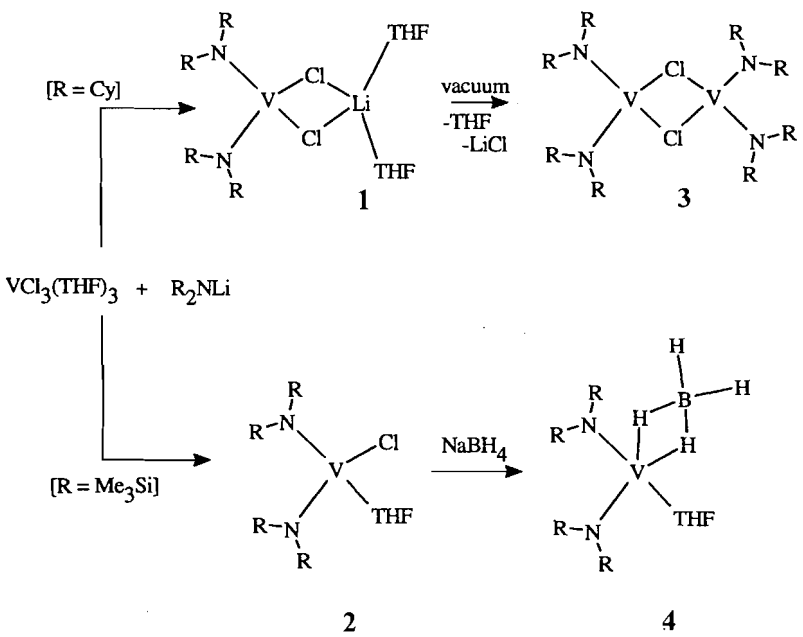

Fig. 1. ORTEP plot of **1**. Thermal ellipsoids are drawn at the 50% probability level.

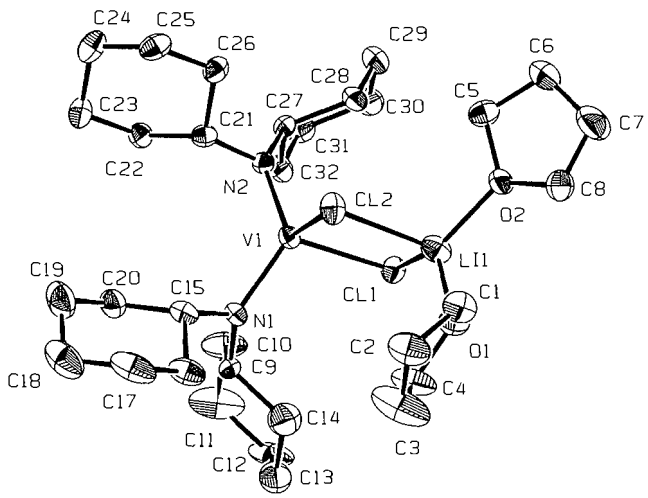

Fig. 2. ORTEP plot of **2**. Thermal ellipsoids are drawn at the 50% probability level.

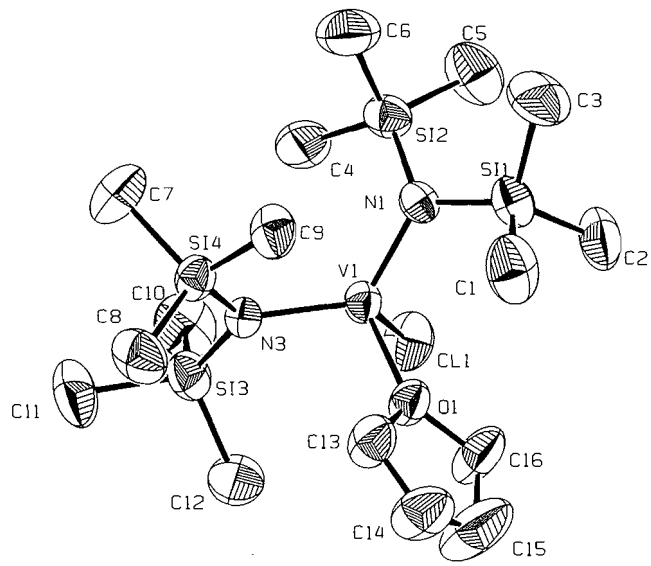

cation (Li1—O1 = 1.920(7) Å, Li1—O2 = 1.916(6) Å). The coordination geometry around each amide nitrogen atom is trigonal planar (C9-N1-C15 = 114.2(3)°, C9-N1-V1 = 131.1(2)°, C15-N1-V1 = 113.6(2)°), possibly suggesting some extent of π-interaction of the amide groups with the metal center.

The structure of complex **2** was more straightforward and predictable, consisting of a tetrahedral vanadium atom also placed in the center of a distorted tetrahedron (N1-V1-N3 = 122.7(1)°, N1-V1-Cl1 = 106.9(1)°, N1-V1-O1 = 113.2(1)°, Cl1-V1-O1 = 95.2(1)°) defined by two nitrogen atoms of two amide ligands (V1—N1 = 1.918(4) Å, V1—N3 = 1.953(3) Å), one chlorine (V1—Cl1 = 2.276(2) Å), and one oxygen atom of one molecule of THF (V1—O1 = 2.034(3) Å). Even in this case the distortion of the coordination geometry around vanadium is probably due to the large steric bulk of the two amide groups. The V—Cl and V—O distances are in the expected range for such bonds. The coordination geometry around each nitrogen atom is trigonal planar, again suggesting the possibility of some extent of π-interaction with the metal center (Si1-N1-V1 = 122.2(2)°, Si2-N1-V1 = 114.9(2)°, Si1-N1-Si2 = 102.5(2)°).

Both complexes were extremely air sensitive but stable at room temperature in both the solid state and solution under inert atmosphere. Nevertheless, a rather rapid color change to

Fig. 3. ORTEP plot of **3**. Thermal ellipsoids are drawn at the 50% probability level.

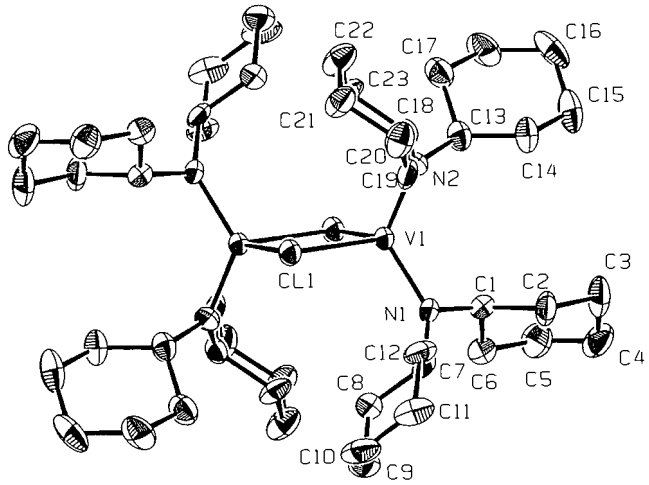

Fig. 4. ORTEP plot of **4**. Thermal ellipsoids are drawn at the 50% probability level.

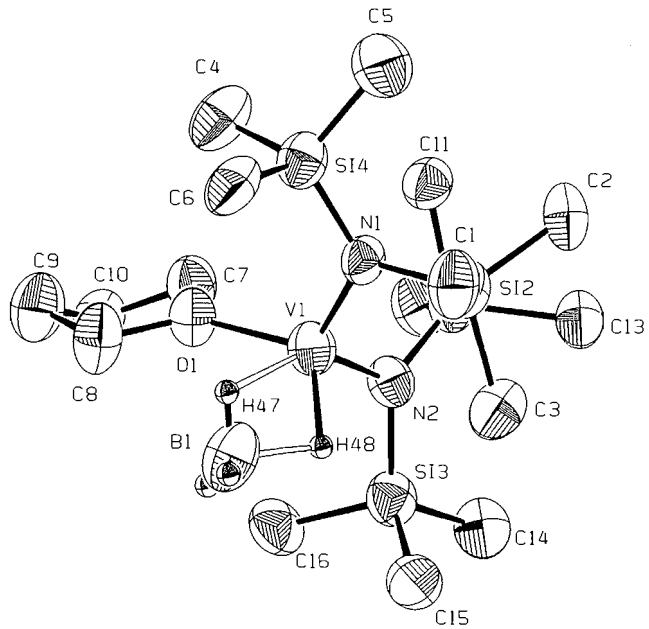

brown was observed upon heating toluene solutions of both complexes. While in the case of complex **2** this behavior may be attributed to the dissociation of THF from the coordination sphere of the metal center, in the case of complex **1** the thermal instability was unexpected since the heating should lead only to desolvation of the lithium cation. Nevertheless, the color change indicated that a reaction involving the vanadium center probably occurred. After suitable work-up, a new brown crystalline material **3** was isolated. Conversely, in the case of complex **2** the thermolysis led only to intractable solutions. The combustion analysis and X-ray fluorescence of **3** clearly indicated the loss of one chlorine atom per vanadium atom with respect to **1**. These data were in agreement with the formulation $[(Cy_2N)_2VCl]_2$. Further, the magnetic moment calculated on the basis of the proposed formula was found to be considerably reduced with respect to the value expected for a d^2 electronic configuration of the V(III) metal center, possibly indicating the presence of a magnetic coupling between the metal centers. To unambiguously characterize the complex, the molecular structure was elucidated by an X-ray analysis.

Complex **3** is dimeric and consists of two distorted tetrahedral vanadium centers linked together by two bridging chlorides, forming a planar V_2Cl_2 core (torsion angle V1-Cl1-V1a-Cl1a = 0.0°). The coordination geometry around each vanadium center is distorted tetrahedral (N1-V1-N2 = 120.8(2)°, N1-V1-Cl1 = 105.7(1)°, Cl1-V1-Cl1a = 92.85(5)°, N2-V1-Cl1 = 113.3(1)°) and is defined by two nitrogens of two amide groups (V1—N1 = 1.856(4) Å, V1—N2 = 1.875(4) Å) and two bridging chlorides. The V—Cl distances (V1—Cl1 = 2.391(2) Å, V1—Cl1a = 2.347(2) Å) are normal although slightly longer than in complexes **1** and **2**. As in the cases of complexes **1** and **2**, the distortion of the tetrahedral geometry around the metal centers can be ascribed to the large steric bulk of the amides. The coordination geometry around each nitrogen atom is also trigonal planar (V1-N1-C1 = 107.0(3)°, V1-N1-C7 = 137.0(3)°, C1-N1-C7 = 116.0(4)°), again suggesting some extent of π-interaction between the nitrogen atoms and the metal center. The intermetallic distance (V1—V1a = 3.266(2) Å) is rather long and excludes the presence of a direct bonding interaction.

Chlorine replacement reactions were attempted with $NaBH_4$. While in the case of **1** and **3** the work-up afforded only intractable materials, a clean reaction was observed with **2**. The reaction proceeded smoothly, resulting in the formation of a deep blue solution from which a new complex $\{[(CH_3)_3Si]_2N\}_2V(BH_4)(THF)$ (**4**) was isolated in low yield as a homogeneous crystalline mass. Unfortunately, the extreme air sensitivity prevented the obtaining of reproducible and meaningful values of the combusion analysis data. The magnetic moment, calculated on the basis of the formula where the chlorine atom of **2** has been replaced by a BH_4^- group, was as expected for the d^2 electronic configuration of a V(III) metal center. The IR spectrum of these species shows a rather unusual pattern with three intense absorptions at 2434, 2396, and 2134 cm^{-1} and a medium-intensity band at 2240 cm^{-1}. This spectrum is not in agreement with any of those commonly observed for the η^1-, η^2-, and η^3-bonded BH_4 groups (19). Since we were unable to understand the spectroscopic data and to obtain meaningful analytical data we have undertaken a crystallographic analysis.

The molecular structure of **4** was elucidated by X-ray analysis. The complex is virtually isostructural with complex **2**, with comparable bond distances (V1—N1 = 1.876(8) Å, V1—N2 = 1.940(8) Å, V1—O1 = 2.057(7) Å) and angles (N1-V1-N2 = 113.9(4)°, N1-V1-O1 = 119.0(4)°, N2-V1-O1 = 99.3(3)°). Even in this case the tetrahedral coordination geometry around the vanadium center is distorted. The V—B distance is rather long (V1—B1 = 2.38(2) Å) and falls in the expected range for a η^2-bonded BH_4 group. The hydrogen atom positions for the BH_4 group were obtained from difference Fourier maps. Although the crystal structure was not of sufficient accuracy to permit drawing definite conclusions about the positions of the hydrogen atoms, it indicates, as an interesting possibility, that the bonding mode of the BH_4^-

group may be regarded as somewhat intermediate between η^2-BH_4 and the limiting case of an aggregation of a V—H complex with BH_3. In fact, the two bridging hydrogens were found to possess significantly different bond distances with the vanadium and boron centers. In particular, one of the two bridging hydrogens was found in the normal bonding range with the boron atom (B1—H47 = 0.943 Å) while the second was significantly closer to the vanadium center (V1—H48 = 1.711(7) Å) and significantly further from the boron atom (B1—H48 = 1.43(7) Å).

Complex **4** represents one of the rare examples of a vanadium borohydride derivative (20) and we are actively investigating its chemical reactivity.

Supplementary information available

A full list of atomic coordinates, anisotropic thermal parameters, bond distances and angles for **1**, **2**, **3**, and **4** has been deposited.[2]

Observation of buttressing effect and hindered rotation about C(sp^2)—C(sp^2) single bond in styrenes coordinated to a ruthenium cation, Cp(diphosphine)Ru$^+$

Kenzo Ohkita, Hideo Asano, Hideo Kurosawa, Toshikazu Hirao, Yohko Miyaji, and Isao Ikeda

Abstract: Complexes of (η^5-cyclopentadienyl)(bis(di-*p*-tolylphosphino)ethane)ruthenium(II) cation with some styrenes containing *meta* or *para* substituents were prepared and their NMR spectra examined in detail. Variable-temperature NMR studies on the unsubstituted and *para*-substituted styrene analogues demonstrated occurrence of a restricted rotation about the C(sp^2)—C(sp^2) single bond of the styrenes where one of the *ortho* hydrogens of the styrene phenyl group receives a very large diamagnetic shielding effect by one of the phosphine tolyl groups. Similar studies on the *meta*-substituted styrene complexes showed existence of two unequally populated conformational isomers arising from the similar restricted rotation where the *meta* substituent in the dominant isomer was placed further away from the C=C group. The origin of such conformational isomerism was deduced to be the buttressing effect of the *meta* substituent transmitted via the *ortho*-hydrogen atom.

Key words: buttressing effect, hindered rotation, Ru–styrene complex.

Résumé : On a préparé un certain nombre de complexes du cation (η^5-cyclopentadiényl)(bis(di-*p*-tolylphosphino)éthane)-ruthénium(II) avec quelques styrènes contenant des substituants en *méta* et en *para* et on a examiné leurs spectres RMN en détail. Les études de RMN à température variable des analogues *para*-substitués et non substitués ont démontré, dans les cas où les hydrogènes en *ortho* du groupe phényle du styrène subissent un important blindage diamagnétique de la part de l'un des groupes tolyles de la phosphine, il existe une rotation restreinte autour de la liaison C(sp^2)—C(sp^2) des styrènes. Des études semblables avec les complexes de styrènes substitués en *méta* mettent en évidence l'existence de deux isomères conformationnels dont les populations sont semblables; cette situation découle de l'existence d'une rotation restreinte qui, dans l'isomère dominant, éloigne le substituant *méta* du groupe C=C. On a déduit que l'origine de cette isomérie conformationnelle est liée à l'effet de compression du substituant en *méta* qui est transmis par le biais de l'atome d'hydrogène en *ortho*.

Mots clés : effet de compression, rotation empêchée, complexe Ru–styrène.

[Traduit par la rédaction]

Introduction

Complexation of organic molecules to a metal center often brings about a unique opportunity to study new conformational and stereodynamic aspects of these molecules (1). Detailed examinations of solution dynamics of such metal complexes by means of NMR spectroscopy are of particular relevance to development of stereoselective, metal-mediated organic transformations (2*a*–*d*) and dynamic supramolecular devices (2*e*). We describe here a clear observation of hindered rotation about the C(sp^2)—C(sp^2) single bond of unsubstituted as well as substituted styrenes that was made possible by their complexation to a (η^5-cyclopentadienyl)(bis(di-*p*-tolylphosphino)ethane)ruthenium(II) cation. The hindered rotation about a C(sp^2)—C(sp^2) single bond has been a subject of some variable-temperature NMR studies on metal-free organic compounds (3), but its extension to metal-coordinated analogues is still limited.

Received January 17, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

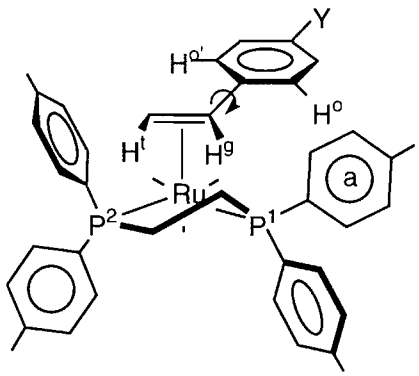
Results and discussion

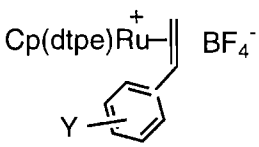
We previously reported (4) generation and stability estimation of a series of substituted styrene complexes [Ru(η^5-C_5H_5)(dtpe)(CH_2=CHC_6H_4Y)]BF_4 (dtpe = bis(di-*p*-tolylphosphino)ethane). In the present work we have examined variable-temperature ^{1}H NMR aspects of complexes **1**–**5**. The bis(di-*p*-tolylphosphino)ethane ligand was employed for the sake of ^{1}H NMR simplicity. Thus, the ^{1}H NMR resonances at room temperature of the unsubstituted and substituted styrene analogues can readily be interpreted as those having four nonequivalent phosphine-tolyl groups as well as four nonequivalent CH_2CH_2 protons arising from the chiral nature of the molecule; for typical room temperature spectra of **1**, **2**, and **3**, see

Scheme 1.



Figs. 1, 2*a*, and 3*a*; detailed assignments are described in the experimental section.

A particularly interesting feature in these spectra at room temperature is that the *ortho*-hydrogen resonance of the styrene ligand occurred at considerably higher field (e.g., δ 6.37 and 6.33 for **1** and **2**, respectively; marked H° in Figs. 1 and 2*a*) than those of the free styrene (upfield shift, Δδ = ca. 1 ppm). The large upfield shift suggests proximity of the *ortho*-hydrogen(s) to some face(s) of the phosphine-tolyl ring. This was confirmed by an analysis of variable-temperature ^{1}H NMR spectra described later. The solid state structure of **4** shown in Fig. 4, albeit with large *R* values (R = 0.102, R_w = 0.143) due to disorders about the BF_4 group, also indicates proximity of one *ortho*-hydrogen atom of the styrene to one phosphine-tolyl. The distance from the *ortho* hydrogen of the *m*-C_6H_4Cl group to the nearest tolyl ring is roughly estimated to be 2.6 Å. Next we show that the coordination geometry of the styrene in Fig. 4 is most likely maintained in **1**–**5** also *in solution*.



1 Y= H; **2** Y= *p*-OMe;
3 Y= *m*-F; **4** Y= *m*-Cl; **5** Y= *m*-Br
(dtpe= bis(di-*p*-tolylphosphino)ethane)

The first step of the structural determination in solution is unambiguous assignment of the *ortho*-hydrogen resonances of the phosphine-tolyls (δ 6.51, 7.22, 7.46, 7.72) made by a 2D ^{31}P–^{1}H COSY spectrum of **1** (Fig. 1), where it is only these resonances among the aromatic proton signals that show appreciable spin–spin couplings with ^{31}P nuclei. Figure 1 shows that the P^1 nucleus (δ −68.9) correlates with the *ortho* hydrogens at δ 7.22 and 7.46 and the P^2 nucleus (δ −62.6) with those at δ 6.51 and 7.72. Moreover, the ^{31}P–^{1}H COSY spectrum indicates that the vinyl hydrogen H^g (Scheme 1; the Cp ring omitted) at δ 3.45 shows spin–spin coupling with the P^1 nucleus, whereas the vinyl hydrogen H^t at δ 1.54 does so with the other phosphorus nucleus P^2, suggesting spatial proximity between H^g and P^1, and H^t and P^2.

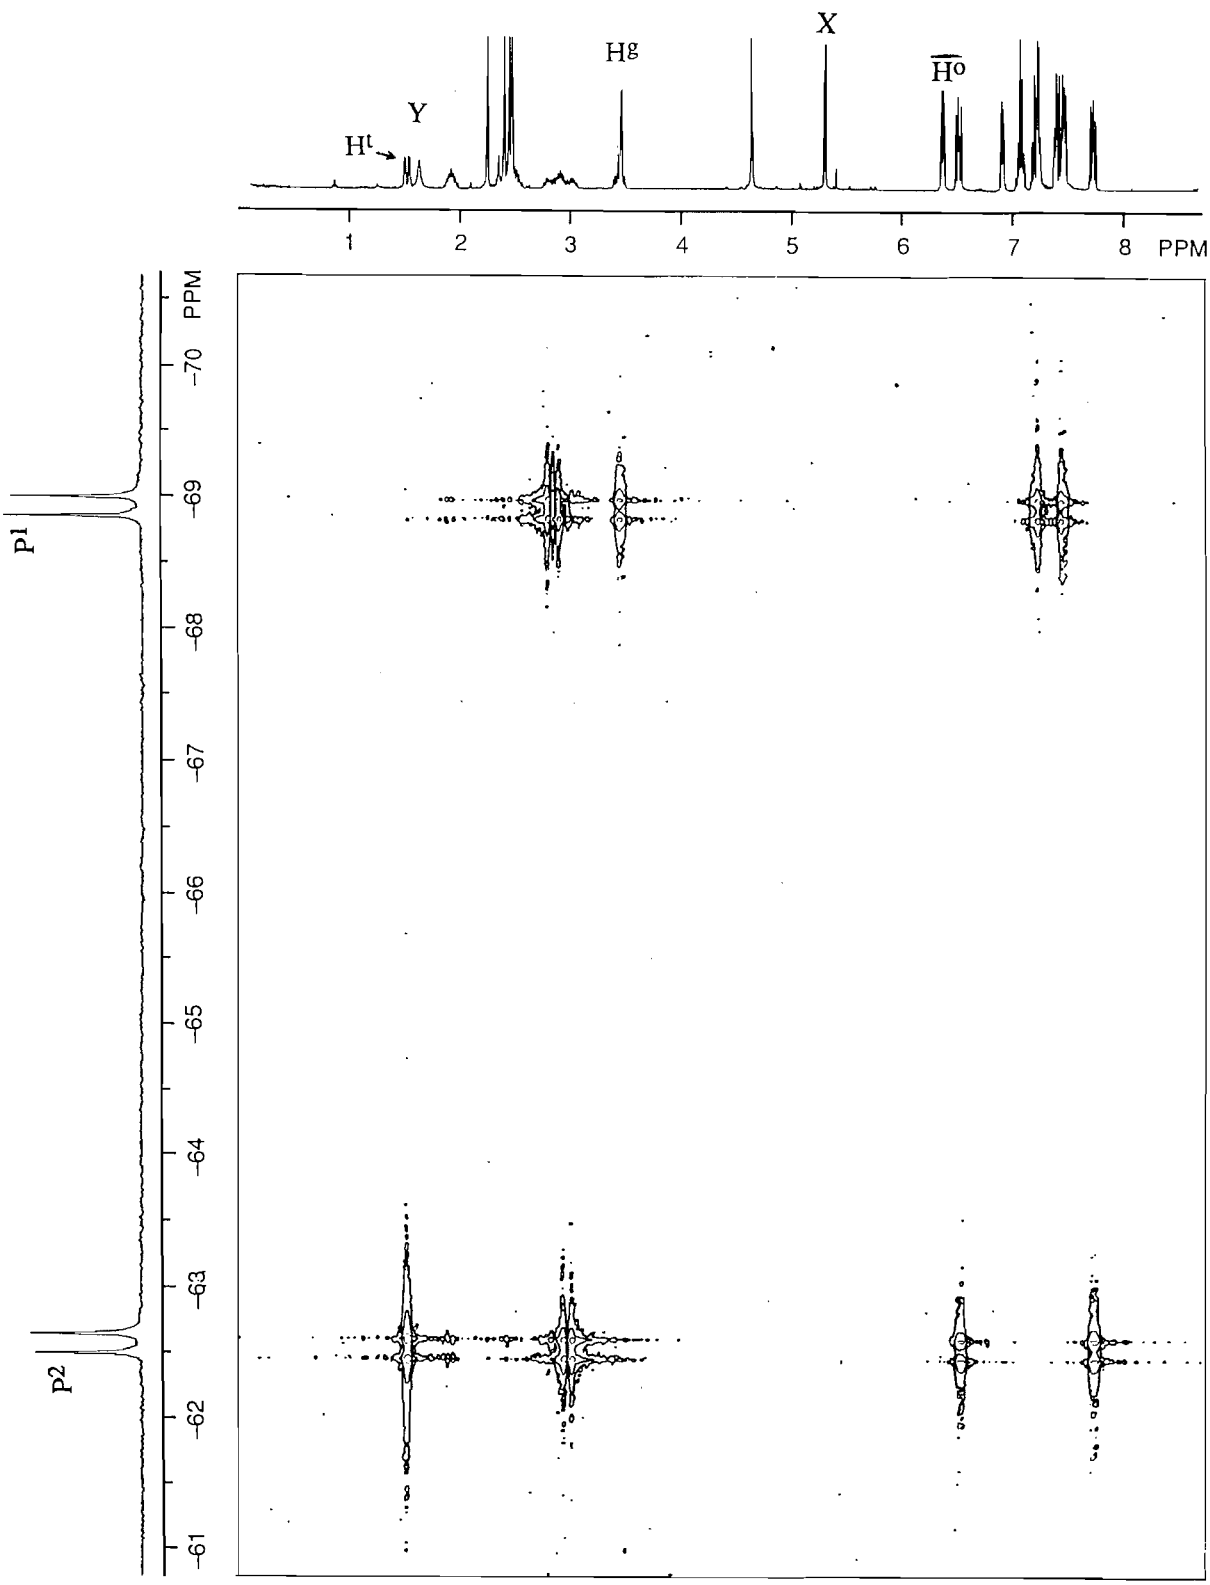
Next we carried out NOE experiments. Thus, selective irradiation of the peak at δ 7.46 due to the *ortho* hydrogens of one particular phosphine-tolyl group (a in Scheme 1) led to 1% increase of the *ortho*-hydrogen peak (δ 6.37) of styrene. The *ortho*-hydrogen resonance of this particular tolyl group (a) also had an NOE correlation (1%) with the resonance due to H^g. We thus presume that the C=C bond is oriented nearly parallel to the P–P vector also in solution, in accordance with the orientation of the C=C bond in analogous series of complexes (5).

All the ^{1}H NMR spectra showed remarkable temperature dependency. Typical variable-temperature spectra of the methoxy analog **2** are shown in Fig. 2. With decrease of the temperature, both the *ortho* (δ 6.33 at 25°C) and the *meta* (δ 6.62 at 25°C; marked H^m) hydrogen resonances of *p*-methoxystyrene became broader with some chemical shift change. Most significantly, the *ortho*-hydrogen resonance disappeared at ca. −45°C (with a 400 MHz instrument) and remained unobservable down to ca. −70°C below which it reappeared as two broad signals with equal intensity (1H each) at quite distant chemical shifts from one another (δ 5.1 and 6.8; Fig. 2*d*, marked H^o and $H^{o'}$). These became two doublets at δ 5.06 and 6.86 at −95°C (Fig. 2*e*). Similarly, the *meta*-hydrogen resonance split into two doublets, albeit with smaller separation (δ 6.32 and 6.67; marked H^m and $H^{m'}$), at −95°C. This smaller separation is in agreement with the coalescence of these *meta*-hydrogen resonances at lower temperature (−66°C) than that of the *ortho*-hydrogen resonances.

These observations can be best attributed to a restricted rotation about the C(sp^2)—C(sp^2) single bond of the styrene ligand (Scheme 1, Y = OMe) at the lower temperature.[2] As shown in Fig. 2, other proton resonances of **2** such as those of the vinylic and the tolyl ring protons also changed their chemical shifts to a smaller extent with decrease of the temperature. A few phosphine-tolyl proton resonances also began to broaden or disappear from ca. −80°C. The observation of small temperature dependency of the chemical shifts of most of the resonances may be attributed to a change of the degree of ion pair contacts and (or) a small change of internal ligand geometries (e.g., twisting about the P—C(tolyl) bond). Disappearance of the phosphine-tolyl proton resonances suggests commencement of a restricted rotation about the P—C bond at the very low temperature. At any rate, the appearance of one *ortho*-hydrogen resonance of the styrene at an extraordinarily high field (δ 5.06) clearly indicates fixation of the *ortho* hydrogen (H^o) in front of the phosphine-tolyl ring a (Scheme 1). Further NOE experiments to confirm this assumption at the low temperatures gave no satisfactory results. Assuming the

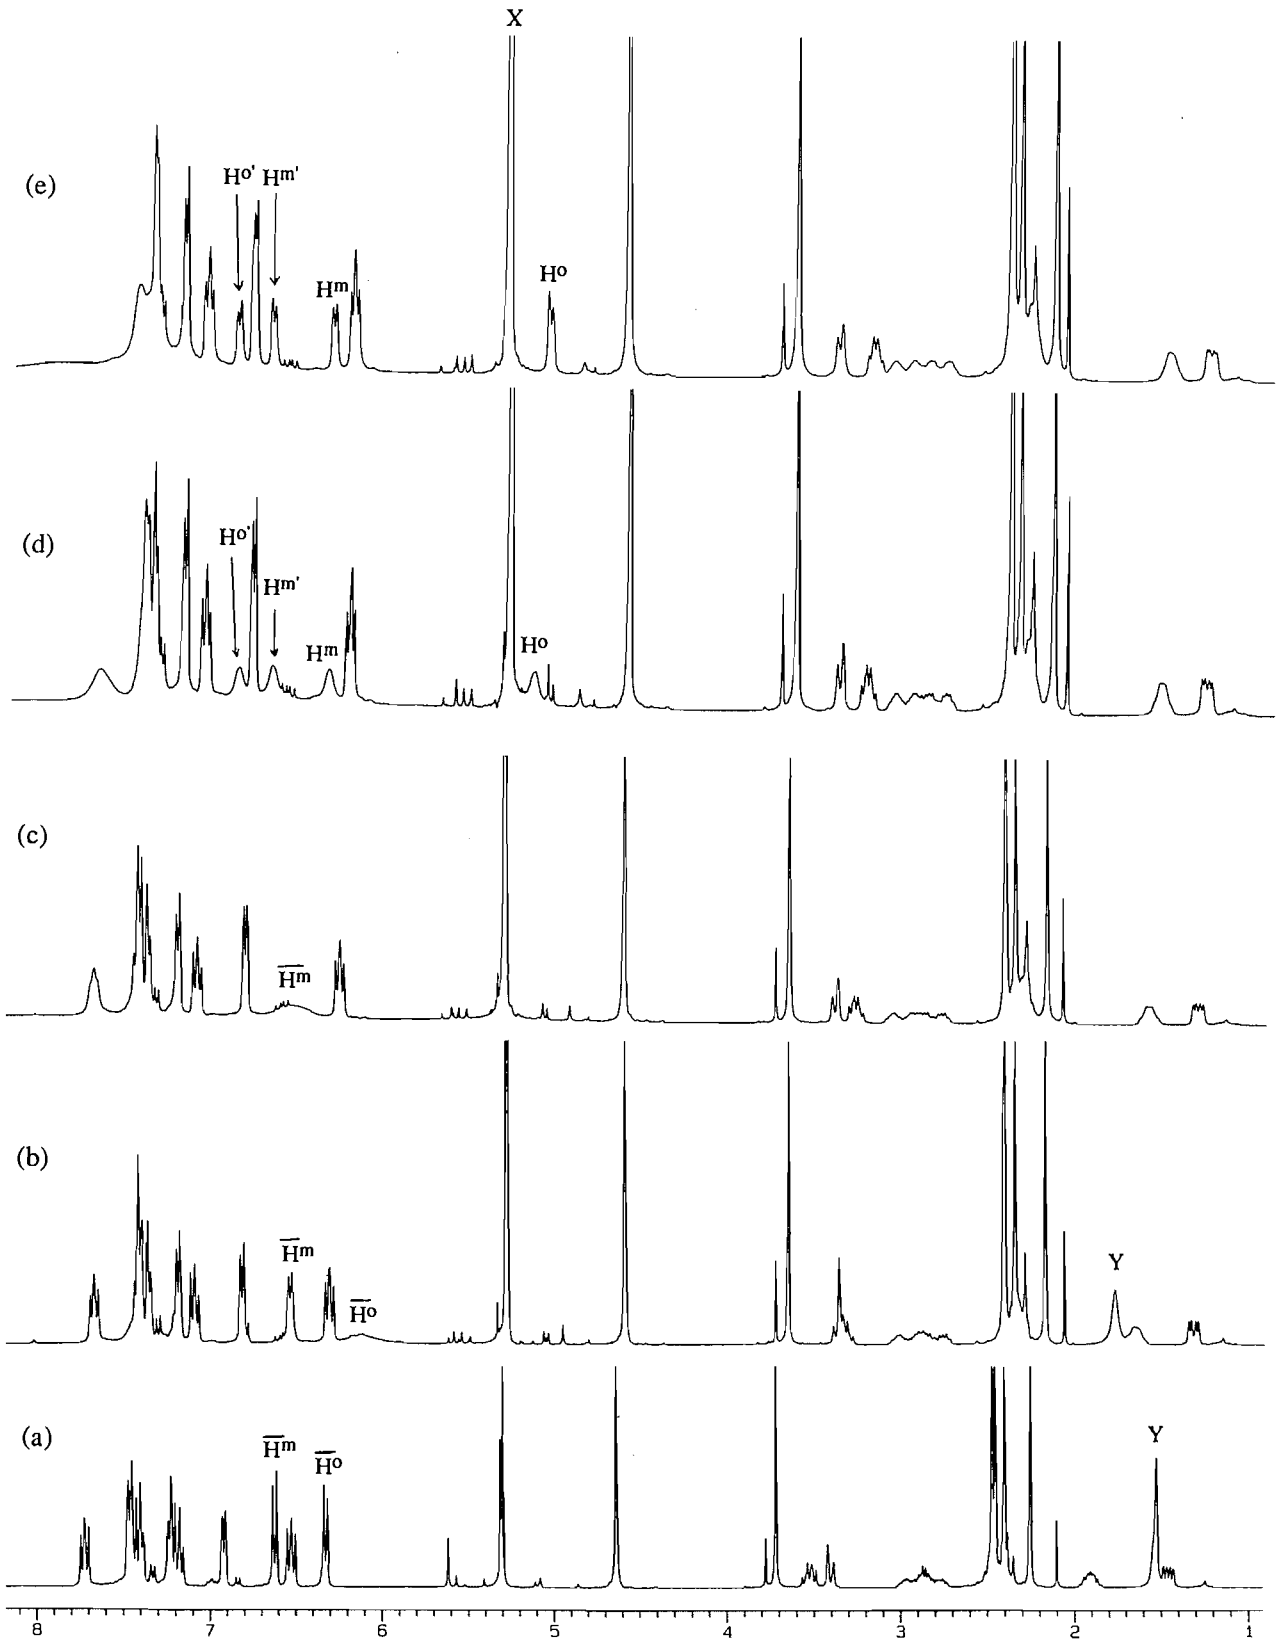
[2] One reviewer raised the possibility that the temperature-dependent ^{1}H NMR aspects are attributed to rotation of the olefin molecule about the Ru–Cc axis (Cc is center of C=C bond). This is assumed to be an unlikely path since molecular models suggest extremely severe steric strains during this rotation. Moreover, it is only the styrene *ortho* and *meta* proton resonances that had split into two resonances upon lowering of the temperature. The chemical shifts of the other protons should also have been affected by this rotation and therefore would have undergone splitting. Unfortunately, experiments to confirm spin–spin coupling connectivity between H^o and $H^{o'}$ or H^m and $H^{m'}$ at the low temperature, which is consistent with the path shown in Scheme 1, were unsuccessful owing to extreme broadness of these proton resonances ($^4J_{HH}$ is usually less than 3 Hz).

Fig. 1. $^{31}P-^{1}H$ COSY spectrum of **1** at 25°C in CD_2Cl_2. X denotes solvent signal, and Y H_2O signal. Note that the magnetic field becomes higher to the left of the ^{1}H chemical shift axis.

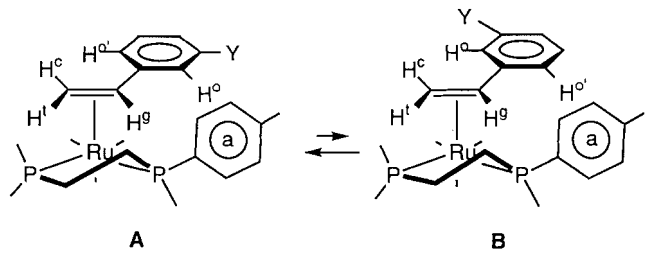


chemical shift difference of the *ortho* and *meta* hydrogens of **2** observed at −95°C to be those corresponding to the frozen state and ignoring chemical shift change with temperature, approximate $\Delta G^{\ddagger}$ values for the rotation at the coalescence temperature (−50°C and −66°C) were calculated (6) as 40.4 and 40.2 kJ/mol, respectively.

Fig. 2. ^{1}H NMR spectra (400 MHz) of **2** in CD_2Cl_2 at 25°C (*a*), −40°C (*b*), −66°C (*c*), −80°C (*d*), and −95°C (*e*). X denotes solvent signal, and Y H_2O signal.



Scheme 2.



The low-temperature NMR spectra of the unsubstituted styrene analog **1** likewise showed separate resonances at δ 5.09 and 6.92 for the *ortho* hydrogens of styrene, although observation of a consistent variable-temperature behavior of the *meta*-hydrogen resonances was hampered by their overlapping with other aromatic proton resonances. Thus, the hindered rotation about the C—C single bond is also apparent in the unsubstituted styrene.

The *meta*-fluoro- and *meta*-bromostyrene complexes also showed temperature-dependent NMR spectra (see Fig. 3), which are similar to those of the unsubstituted and *para*-substituted styrene complexes in one sense, but different from the latter in the other. The difference arises from occurrence of two rotational isomers with unequal population (Scheme 2).

In the ^{19}F NMR spectra of **3**, a single signal for *meta*-fluorine atom observed at room temperature at δ −50.2 (relative to $PhCF_3$, ddd, J_H = 6.2, 8.3, 10.5 Hz) split into two broad signals at δ −50.6 and −49.5 in a 64:36 ratio at −95°C. In the ^1H NMR spectra, with decrease of the temperature, a doublet for the *ortho* hydrogen vicinal to F (δ 5.74, J_F = 10.5 Hz, Δδ = 1.38, at room temperature; marked $\overline{H^o}$ in Fig. 3*a*) became broader, disappeared (Fig. 3*c*), and then reappeared at δ 4.5 at ca. −70°C (600 MHz instrument; Fig. 3*d*). Significantly, the intensity of the doublet (J = 10 Hz) at δ 4.44 at −95°C (Fig. 3*e*) corresponded to only ca. 0.6 atom H. In addition, a doublet for the other *ortho* hydrogen at δ 6.27 (J_H = 7 Hz; Δδ = 0.91) at room temperature (marked $\overline{H^{o'}}$) reappeared at −95°C as a broad doublet at δ 4.96 (Fig. 3*e*; marked $H^{o'}$) having an integration corresponding to ca. 0.4 atom H. Thus, these results suggest the isomer ratio **A**/**B** = 64/36 where the doublet at δ 4.44 in Figure 3*e* corresponds to H^o in **A** and the doublet at δ 4.96 to $H^{o'}$ in **B**. Unfortunately, it was unable to detect a lower field component of each *ortho*-hydrogen resonance pair, namely H^o in **B** and $H^{o'}$ in **A**, which should possess an integration value of 0.36 H and 0.64 H, respectively, possibly because of overlapping with aromatic signals at normal chemical shifts.

The ^1H NMR spectral aspect of *meta*-bromostyrene complex **5** at −95°C (Fig. 3*f*) was different from that of the *meta*-fluoro analog in that the resonances due to almost only one isomer were discernible. Thus, a singlet at δ 5.88 (Δδ = 1.68) at room temperature due to the *ortho* hydrogen vicinal to Br disappeared on lowering the temperature (from ca. −40°C), and reappeared at ca. −65°C as a very broad signal at ca. δ 4.7. Finally at −95°C this became a singlet at δ 4.48 (H^o in Fig. 3*f*) possessing an integration value corresponding to more than 0.9 atom H. In Fig. 3*f* we were unable to unambiguously define any doublet signal, in the range δ 4.0–6.5, assignable to the other *ortho* hydrogen ($H^{o'}$) that would have received a higher field shift by the phosphine-tolyl ring a relative to the δ 6.59 resonance (25°C). It might have been hidden in other stronger resonances. The ^1H NMR spectrum at −95°C of the *meta*-chlorostyrene analog **4** also showed the existence of almost only one isomer (δ 4.30 for the *ortho*-hydrogen vicinal to Cl; at room temperature, δ 5.73, Δδ = 1.67). Thus, the almost exclusive isomer in **4** and **5** at −95°C is the rotamer **A** in which the halogen atom is placed further away from the C=C bond.[3] This also corresponds to the solid state structure of **4** (Fig. 4). The degree of predominance of this isomer might have been enhanced particularly at the lower temperature judging from the considerable upfield shift of the *ortho*-hydrogen singlet for H^o on lowering the temperature. The cause of the observed isomer distribution in the *meta*-halogen-substituted styrene complexes may be steric in origin. Molecular models based on the structure of **4** suggested that the steric hindrance to the substituent Y by Cp in **B** is less significant than that by the phosphine-tolyl group in **A**. Thus, inter-ligand repulsions would play little significant role, if any, in determining the conformational preference. We explain the trend in the rotamer preference of the complexes in terms of internal steric strain in the styrenes, as follows.

Of two vinylic hydrogens (H^c, H^g) of styrene, H^c is closer to the *ortho* position than is H^g. Therefore, in both **A** and **B** one *ortho* hydrogen close to H^c is thought to receive greater steric constraints than the other *ortho* hydrogen close to H^g. Since in the *meta*-substituted styrenes the *ortho* hydrogen next to the substituent Y (H^o) is expected to be pushed away from Y, this particular *ortho* hydrogen would exert a larger steric hindrance to the vinylic hydrogens than does the other one ($H^{o'}$), resulting in the conformer involved in **A** being more stable than that in **B**. It is then understandable that the complex having the larger substituent (Y = Cl, Br) showed a larger **A**:**B** ratio than that having the smaller substituent (Y = F).

Concluding remarks

The present observation of the hindered rotation about the C—C single bond in styrenes was made possible by the large chemical shift difference of the *ortho*-hydrogen resonances undergoing coalescence, which in turn was brought about by the complexation of styrenes to the arylphosphine-ruthenium center. The close disposition of the styrene-aryl group to the phosphine-tolyl group proposed here may also have its origin, to some extent, in an aromatic edge–face interaction (8).

We also found that the distribution of the two rotamers arising from the *meta*-substituted styrenes depends on the steric bulk of the *meta* substituent. An indirect steric effect of a substituent group on a remote position transmitted over sp^2-carbon frameworks has attracted attention as a buttressing effect, particularly in studies of barriers to racemization of axially dissymmetric aromatic molecules (9). However, transmission of this effect via an intermediary hydrogen atom, which has clearly been confirmed in the present study, has rarely been detected (9*b*), particularly in a ground state event (10).

[3] An X-ray structure determination of a styrene derivative containing two alkoxy substituents at the *meta* and *para* positions (7) revealed the existence of a conformer analogous to **A**.

Fig. 3. ^{1}H NMR spectra in CD_2Cl_2 of **3** at 25°C (*a*), −15°C (*b*), −40°C (*c*), −70°C (*d*), and −95°C (*e*) and of **5** at −95°C (*f*). The spectra (*a*)–(*d*) were taken with a 600 MHz instrument, and (*e*) and (*f*) with a 400 MHz one. X denotes solvent signal, and Y H_2O signal.

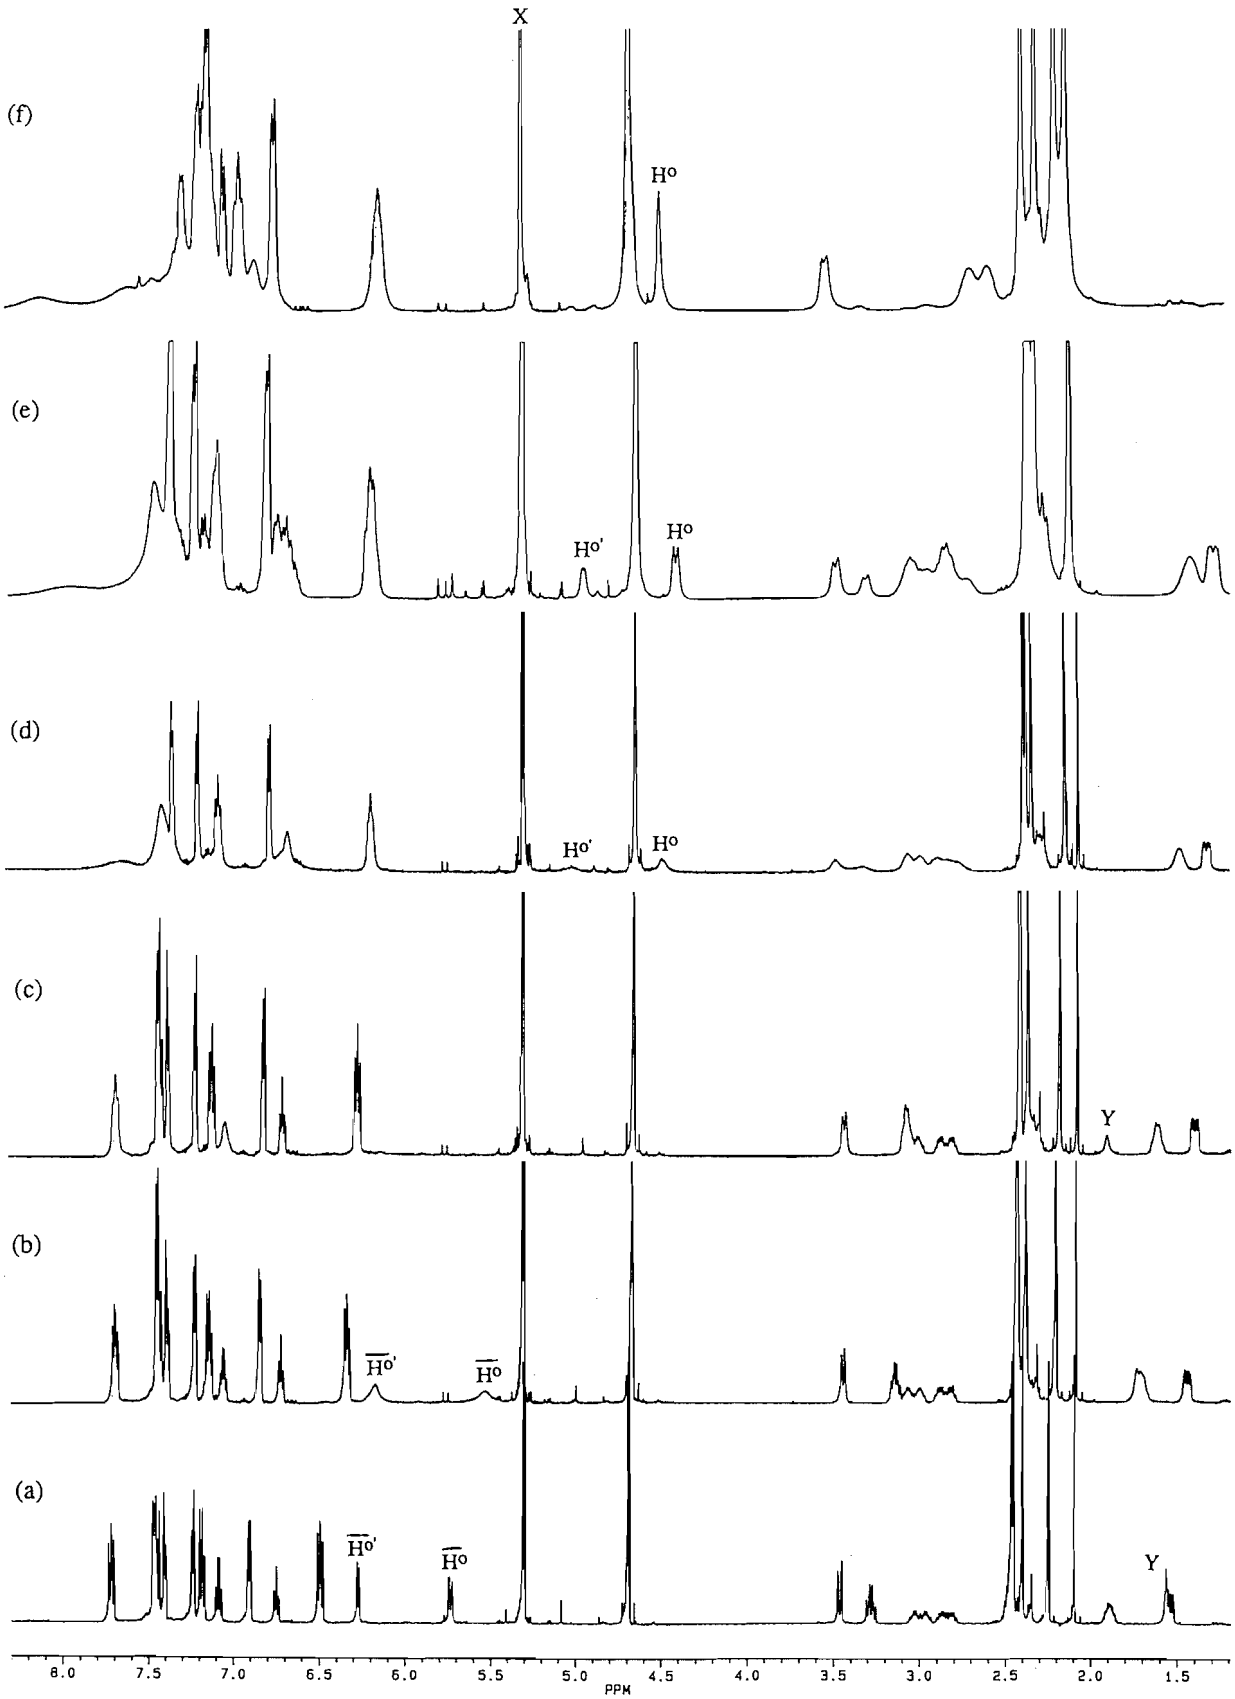


Fig. 4. Molecular structure of [Ru(η^5-C_5H_5)(dtpe)(CH_2=CHC_6H_4Cl-*m*)] BF_4 with thermal ellipsoids at 50% probability levels for non-hydrogen atoms. Relevant hydrogens are shown only for convenience at the idealized positions. The anion and CH_2Cl_2 of crystallization are omitted.

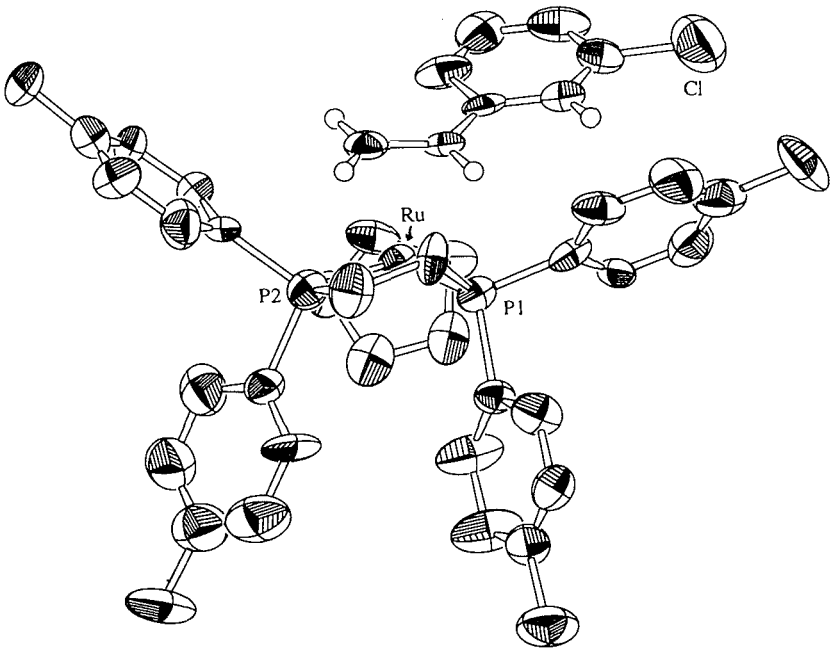

Experimental

Most of commercially available reagents were used without further purification. Silver tetrafluoroborate (purity 90%) was used after drying under vacuum. 1,2-Bis(di-*p*-tolylphosphino)ethane (dtpe) was prepared from tri-*p*-tolylphosphine and sodium metal in liquid ammonia followed by treatment with 1,2-dichloroethane (11). Preparation of Ru(η^5-C_5H_5)(dtpe)Cl was carried out according to the literature (12). ^{1}H NMR spectra were obtained on JEOL GSX-400 and Bruker AM600 spectrometers. Chemical shifts were referenced to $CHCl_3$ (δ 7.27) in $CDCl_3$ and $CHDCl_2$ (δ 5.30) in CD_2Cl_2. ^{31}P NMR spectra were obtained on a GSX-400 spectrometer operating at 162 MHz and chemical shifts were referenced to external $P(OMe)_3$ (δ 0.00). ^{19}F NMR spectra were obtained on a GSX-400 spectrometer operating at 376 MHz and chemical shifts were referenced to $PhCF_3$ (δ 0.00).

Preparation of [(η^5-C_5H_5)Ru(dtpe)(CH_2=CHC_6H_5)]BF_4 (1)

To a solution of 150 mg (0.229 mmol) of Ru(η^5-C_5H_5)(dtpe)Cl and 80 mg (0.77 mmol) of styrene in 5 mL of acetone, 70 mg (0.32 mmol) of silver tetrafluoroborate in 5 mL of acetone was added under inert atmosphere. The resulting dark red solution was stirred until the color turned yellow (ca. 1 h) and filtered. The filtrate was evaporated under reduced pressure. The residue was extracted with 3 mL of CH_2Cl_2 and purified through a short Florisil column. To the eluent was added *n*-hexane to give 160 mg (86%) of pale yellow fine needles. These were washed with ether and *n*-hexane; mp 145°C (dec.). ^{1}H NMR (CD_2Cl_2, 25°C) δ: 1.54 (dd, J_H = 5 Hz, J_P = 16 Hz, 1H, =CH*H* *trans* to Ph), 1.92 (m, 1H, PCH*H*-), 2.25 (s, 3H), 2.41 (s, 3H), 2.55 (s, 3H) and 2.57 (s, 3H) (each CH_3), 2.48 (m, 1H), 2.86 (dm, J_P = 39 Hz, 1H) and 2.95 (dm, J_P = 42 Hz, 1H) (each PCH*HC*H_2P), 3.45 (m, 2H, PhC*H*= and =CH*H* *cis* to Ph), 4.63 (s, 5H, C_p), 6.37 (d, J_H = 7 Hz, 2H, *ortho-H* of Ph), 6.51 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl), 6.91 (d, J_H = 7 Hz, 2H, *meta-H* of tolyl), 7.1–7.5 (m, 13H), 7.72 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl). The following *ortho-H* resonances of the other tolyl groups were defined by the ^{31}P–^{1}H COSY spectrum δ: 7.22 and 7.46. ^{31}P NMR (CD_2Cl_2, 25°C) δ: −62.6 (d, J_{PP} = 25 Hz), −68.9 (d). Anal. calcd. for $C_{43}H_{45}P_2BF_4Ru$: C 63.63, H 5.59; found: C 63.11; H 6.00.

[(η^5-C_5H_5)Ru(dtpe)(CH_2=CHC_6H_4OMe-*p*)]BF_4 (2)

This compound was prepared similarly as pale yellow fine needles of **2**·CH_2Cl_2 (59%); mp 150–155°C (dec.). ^{1}H NMR (CD_2Cl_2, 25°C) δ: 1.45 (ddd, J_H = 2.5, 8.0 Hz, J_P = 15 Hz, 1H, =CH*H* *trans* to Ar (Ar = C_6H_4OMe)), 1.91 (m, 1H, PCH*H*-), 2.25 (s, 3H), 2.40 (s, 3H), 2.47 (s, 3H) and 2.49 (s, 3H) (each CH_3), 2.45 (m, 1H), 2.81 (dm, J_P = 37 Hz, 1H) and 2.93 (dm, J_P = 40 Hz, 1H) (each PCH*HC*H_2P), 3.40 (dd, J_H = 2.5, 13 Hz, 1H, =CH*H* *cis* to Ar), 3.53 (ddd, J_H = 8.0, 13 Hz, J_P = 11 Hz, 1H, ArC*H*=), 3.73 (s, 3H, OCH_3), 4.63 (s, 5H, C_p), 6.33 (d, J_H = 8 Hz, 2H, *ortho-H* of Ar), 6.52 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl), 6.62 (d, J_H = 8 Hz, 2H, *meta-H* of Ar), 6.93 (d, J_H = 7 Hz, 2H, *meta-H* of tolyl), 7.1–7.5 (m, 10H), 7.72 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl). ^{31}P NMR (CD_2Cl_2, 25°C) δ: −62.5 (d, J_{PP} = 23 Hz), −68.6 (d). Anal. calcd. for $C_{45}H_{49}OP_2BF_4Cl_2Ru$: C 58.33, H, 5.33; found: C, 58.61, H 5.53. The presence of CH_2Cl_2 of crystallization was confirmed by the ^{1}H NMR spectrum in $CDCl_3$.

[(η^5-C_5H_5)Ru(dtpe)(CH_2=CHC_6H_4F-*m*)]BF_4 (3)

3 was prepared similarly as pale yellow fine needles of **3**·1/2

CH_2Cl_2 (78%); mp 133°C (dec.). ^{1}H NMR (CD_2Cl_2, 25°C) δ: 1.54 (ddd, J_H = 3.0, 8.1 Hz, J_P = 17 Hz, 1H, =CH*H trans* to Ar (Ar = C_6H_4F)), 1.89 (m, 1H, PCH*H*-), 2.26 (s, 3H), 2.41(s, 3H), 2.46 (s, 3H) and 2.48 (s, 3H) (each CH_3), 2.48 (m, 1H), 2.85 (dm, J_P = 34 Hz, 1H) and 2.97 (dm, J_P = 38 Hz, 1H) (each PCH*HCH*$_2$P), 3.29 (dt, J_H = 8, 12 Hz, J_P = 12 Hz, 1H, ArC*H*=), 3.46 (dd, J_H = 3, 12 Hz, 1H, =CH*H cis* to Ar), 4.70 (s, 5H, C_p), 5.74 (d, J_F = 10.5 Hz, 1H, *ortho-H* of Ar), 6.26 (d, J_H = 7 Hz, 1H, *ortho-H′* of Ar), 6.50 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl), 6.76 (dd, J_H = 7 Hz, J_F = 8 Hz, 1H, *para-H* of Ar), 6.91 (d, J_H = 7 Hz, 2H, *meta-H* of tolyl), 7.09 (dt, J_H = 7 Hz, J_F = 6 Hz, 1H, *meta-H* of Ar), 7.18 (dd, J_H = 7 Hz, J_P = 10 Hz, 2H, *ortho-H* of tolyl), 7.4–7.5 (m, 8H), 7.71 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl). ^{31}P NMR (CD_2Cl_2, 25°C) δ: −62.7 (d, J_{PP} = 23 Hz), −68.9 (d). ^{19}F NMR (CD_2Cl_2, 25°C) δ: −50.22 (ddd, J_H = 6, 8, 11 Hz, 1F, C*F*), −89.78 (q, J_{BF} = 9.5 Hz, 4F, BF_4). Anal. calcd. for $C_{43.5}H_{45}P_2BF_5ClRu$: C 59.91, H 5.20; found: C 60.09, H 5.21. The presence of 1/2 mol of CH_2Cl_2 of crystallization was confirmed by the ^{1}H NMR spectrum in $CDCl_3$.

[(η^5-C_5H_5)Ru(dtpe)(CH_2=CHC_6H_4Cl-*m*)]BF_4 (4)

Compound **4** was prepared similarly as pale yellow fine needles (75%); mp 137–139°C (dec.). ^{1}H NMR (CD_2Cl_2, 25°C) δ: 1.52 (ddd, J_H = 3, 8.1 Hz, J_P = 16 Hz, 1H, =CH*H trans* to Ar (Ar = C_6H_4Cl)), 1.82 (m, 1H, PCH*H*-), 2.25 (s, 3H), 2.40 (s, 3H), 2.46 (s, 3H) and 2.47 (s, 3H) (each CH_3), 2.45 (m, 1H), 2.83 (dm, J_P = 35 Hz, 1H) and 3.01 (dm, J_P = 39 Hz, 1H) (each PCH*HCH*$_2$P), 3.18 (ddd, J_H = 8.3, 13 Hz, J_P = 12 Hz, 1H, ArC*H*=), 3.52 (dd, J_H = 3, 13 Hz, 1H, =CH*H cis* to Ar), 4.71 (s, 5H, C_p), 5.73 (s, 1H, *ortho-H* of Ar), 6.48 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl), 6.52 (d, J_H = 7 Hz, 1H, *ortho-H′* of Ar), 6.92 (d, J_H = 7 Hz, 2H, *meta-H* of tolyl), 7.0-7.5 (m, 12H), 7.72 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl). ^{31}P NMR (CD_2Cl_2, 25°C) δ: −62.7 (d, J_{PP} = 23 Hz), −68.6 (d). Anal. calcd. for $C_{43}H_{44}P_2BF_4ClRu$: C 61.04, H 5.24; Found: C 60.57, H 5.31.

[(η^5-C_5H_5)Ru(dtpe)(CH_2=CHC_6H_4Br-*m*)]BF_4 (5)

This compound was prepared similarly as pale yellow fine needles (85%); mp 137°C (dec.). ^{1}H NMR (CD_2Cl_2, 25°C) δ: 1.50 (ddd, J_H = 3, 8.3 Hz, J_P = 17 Hz, 1H, =CH*H trans* to Ar (Ar = C_6H_4Br)), 1.79 (m, 1H, PCH*H*-), 2.25 (s, 3H), 2.40 (s, 3H), 2.48 (s, 3H) and 2.49 (s, 3H) (each CH_3), 2.48 (m, 1H), 2.85 (dm, J_P = 36 Hz, 1H) and 3.01 (dm, J_P = 38 Hz, 1H) (each PCH*HCH*$_2$P), 3.18 (ddd, J_H = 8.3, 13 Hz, J_P = 12 Hz, 1H, ArC*H*=), 3.52 (dd, J_H = 3, 13 Hz, 1H, =CH*H cis* to Ar), 4.72 (s, 5H, C_p), 5.88 (s, 1H, *ortho-H* of Ar), 6.48 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl), 6.59 (d, J_H = 7 Hz, 1H, *ortho-H′* of Ar), 6.90 (d, J_H = 7 Hz, 2H, *meta-H* of tolyl), 7.03 (t, J_H = 7 Hz, 1H, *meta-H* of Ar), 7.16 (m, 3H), 7.23 (d, J_H = 7 Hz, 2H, *meta-H* of tolyl), 7.4–7.5 (m, 6H), 7.72 (dd, J_H = 7 Hz, J_P = 11 Hz, 2H, *ortho-H* of tolyl). ^{31}P NMR (CD_2Cl_2, 25°C) δ: −62.7 (d, J_{PP} = 24 Hz), −68.7 (d). Anal. calcd. for $C_{43}H_{44}P_2BF_4BrRu$: C 58.00, H 4.98, found: C 57.77, H 5.24.

X-ray structure determination of 4·CH_2Cl_2

A yellow prismatic crystal with approximate dimensions of 0.40 × 0.30 × 0.20 mm was mounted in a glass capillary. All measurements were made on a Rigaku AFC 5R diffractometer with graphite monochromated Mo Kα radiation and a 12 kW rotating anode generator. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 24 centered reflections. Omega (ω) scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.30° with a take-off angle of 6.0°. Scans of (1.21° + 0.35 tan θ)° were made at a speed of 24.0°/min (in ω). Corrections for Lorentz and polarization effects were applied to the intensity data.

R_w	0.143

All calculations were made with the TEXSAN crystallographic software package of the Molecular Structure Corporation, Woodlands, Tex. The structure was solved by heavy-atom methods and refined by the full-matrix least-squares procedure, the function minimized being $\Sigma w(|F_o|-|F_c|)^2$. Only the non-σ-weighted least-squares procedure was performed, because σ-weighted calculations yielded larger *R* values and more distorted BF_4 geometries. These results may have arisen both from disorder about the BF_4 ion and the low quality of the crystal, as is evident in the fact that only 1/4 of the independent reflections were observed as significant. Experimental data for the X-ray diffraction analysis are shown in Table 1.[4]

Micelle-induced change of mechanism in the reaction of muonium with acetone

John M. Stadlbauer, Krishnan Venkateswaran, Hugh A. Gillis, Gerald B. Porter, and David C. Walker

Abstract: Muonium atoms add to the O atom of the carbonyl group of acetone to give the muonated free radical $(CH_3)_2\dot{C}$-O-Mu when the reaction takes place in water or hydrocarbons, but not when the acetone is localized in micelles. Micelles have no effect on the formation of muonated cyclohexadienyl radicals when muonium reacts with benzene under similar conditions. The addition reaction with acetone appears to have been subsumed by a faster alternative reaction in the micellar environment. Evidence is presented for this interpretation rather than for an inhibition of the radical or for a shift in the muon level-crossing resonance spectrum with hydrogen (muonium) bonding, though major shifts are seen for the spectrum of this radical in pure solvents of widely different dielectric constant. It is suggested that muonium's "abstraction" reaction takes over in micelles because significant micelle-induced enhancement effects were previously observed in that type of reaction. The data are consistent with a rate constant for the abstraction reaction of muonium with acetone in micelles of $>6 \times 10^8$ M^{-1} s^{-1}.

Key words: muonium, kinetic isotope effects, micelle enhancement, H/Mu-addition, H/Mu abstraction.

Résumé : Lorsqu'on opère en solution dans l'eau ou dans les hydrocarbures, les atomes de muonium s'ajoutent à l'atome d'oxygène du groupe carbonyle de l'acétone pour conduire à un radical muoné $(CH_3)_2\dot{C}$-O-Mu; ce n'est toutefois pas le cas lorsque l'acétone est localisée dans des micelles. Les micelles n'ont aucun effet sur la formation de radicaux cyclohexadiényles muonés lorsqu'on fait réagir des atomes de muonium avec le benzène, dans des conditions semblables. Il semble que, dans un environnement micellaire, la réaction d'addition sur l'acétone est dépassé par une autre réaction plus rapide. On présente des résultats confortant cette interprétation plutôt que celle faisant appel à une inhibition du radical ou à un déplacement du spectre de résonance de croisement au niveau du muon avec une liaison hydrogène (muonium); toutefois, on observe des déplacements pour les spectres de ce radical dans des solvants purs de constantes diélectriques fort différentes. On suggère que la réaction d'«enlèvement» des muonium se produit dans des micelles en raison des effets de rehaussement induit par les micelles qui ont été observés antérieurement dans ce type de réaction. Les données sont en accord avec une constante de vitesse, pour la réaction d'enlèvement du muonium avec l'acétone dans les micelles, qui serait supérieure à 6×10^8 M^{-1} s^{-1}.

Mots clés : muonium, effets isotopiques cinétiques, rehaussement par les micelles, addition H/muonium, enlèvement H/muonium.

[Traduit par la rédaction]

Introduction

Muonium (Mu) is the hydrogen isotope with a short-lived positive muon of one-ninth the mass of a proton as its nucleus. In aqueous solution it reacts like H, undergoing a variety of reaction types including reduction, substitution, combination, addition, and abstraction. In the case of ^1H reacting with acetone as a solute in acidified water, both "addition" and "abstraction' reactions occur, the former with $k_H = 0.9 \times 10^6$ M^{-1} s^{-1} and the latter with $k_H = 1.7 \times 10^6$ M^{-1} s^{-1} (1(*a*)). A recent value puts the total k_H some 40% lower, in strongly acid solution (1(*b*)).

The Mu analogues are given by eqs. [1] and [2],

[1] $$Mu + (CH_3)_2CO \longrightarrow (CH_3)_2\dot{C} - O - Mu$$

[2] $$Mu + (CH_3)_2CO \longrightarrow MuH + CH_3CO\dot{C}H_2$$

but with reaction [1] evidently dominant (2–4). Its reaction rate ($k_M = 8.7 \times 10^7$ M^{-1} s^{-1} at pH = 1 (5), and 1.1×10^8 M^{-1} s^{-1} at pH = 7 (6)) corresponds to a kinetic isotope effect (k_M/k_H) of ~45 for the overall rate and ~125 for the addition reaction.

The $(CH_3)_2\dot{C}$-O-Mu radical produced in reaction [1] has been thoroughly characterized by high-field muon spin-

rotation (μSR) studies of pure liquid acetone (2) and concentrated aqueous solutions (3). It has also been well characterized by level-crossing resonance spectroscopy (μLCR) in the neat liquid state (7) and in dilute solutions in hexane and in water (4). It has an isotropic muon hyperfine coupling constant (A_μ) of 26.1 MHz in neat acetone. This is 9 times larger than that of the analogous H-atom adduct (A_p), even after compensation for the 3.18-fold higher nuclear moment of μ^+ compared to p^+ [8]. This is by far the largest hyperfine-coupling isotope effect yet encountered. It has been variously attributed to the much smaller moment of inertia of Mu compared to ^1H in the rotation of O-Mu about the C—O bond axis (2), and to the greater hyperconjugation of the Mu isotope resulting from its higher librational frequency (3).

Another unique trait of the muonated free radicals formed when Mu adds to acetone is the fact that A_μ changes markedly with the molecular dipole of the solvent involved. A_μ is largest in water (3), intermediate in neat liquid acetone (2), and smallest in hydrocarbons (4). The increase from neat acetone to water has been ascribed to "muonium bonding," isotopomeric hydrogen bonding (3). In effect, the electrostatic bonding of $Mu^{\delta+}$ in C-O-Mu to an $O^{\delta-}$ of water reduces the moment of inertia (and the librational frequency) more than in neat acetone. There is also more muonium bonding to the O of acetone in neat liquid acetone than in a hydrocarbon solvent, hence the further decrease in A_μ.[5] This observed solvent effect on the hyperfine coupling of Mu requires that a full range of μLCR fields be covered in the present study, because the $(CH_3)_2\dot{C}$-O-Mu free radical in the micellar phase could have an A_μ intermediate between that in a pure hydrocarbon and that in water.

Surfactants are amphiphilic molecules that aggregate into roughly spherical micelles as their concentration passes through a critical micelle concentration. Organic solutes are invariably solubilized within these micelles, but Mu is not preferentially localized there (9, 10). Thus rate enhancements have been shown not to arise simply from "concentration amplifications." Instead, Mu diffuses indiscriminately in and out of the micellar phase, reacting with solutes according to non confined competitive kinetics.

In a Letter published a few years ago (4) we noted that the μLCR signal at 1840 MHz, corresponding to the Mu radical of eq. [1] from acetone in water, was missing when a large excess of micelles was added to the solution. In the present study we analyse the reason for this by exploring the effect of added surfactants as a function of their concentration up through the critical micelle concentration. We also look to see if, in those earlier experiments, there was merely a shift in the position of the level-crossing resonance due to a change in the polarity of the microenvironment.

Experimental

Muonium atoms form at the end of some muon tracks when water is bombarded by high-energy positive muons. They react as free thermalized Mu atoms with solutes present, but not with the water itself. The muons decay with mean lifetimes of 2.2 μs, so if the chemical lifetime of Mu is of the order of a microsecond, then the μSR technique can be used to watch reactions of Mu and to evaluate its reaction rate constant k_M. The μLCR technique, on the other hand, is used to directly observe only those muons that are already incorporated into free Mu radicals on the μs time scale of muon decay.

The present studies use only μLCR, conducted on the M20B surface muon channel at the TRIUMF cyclotron using the Helios superconducting magnet in longitudinal-field mode. The technique was fully described previously (11). At certain fields (B_R in eq. [3]) a muon–proton spin flip-flop occurs

$$[3] \quad B_R \simeq |\, 0.5(A_\mu - A_H)/(\gamma_\mu - \gamma_p)\,|$$

that results in loss of muon spin polarization due to resonance between the proton (A_H) and muon (A_μ) hyperfine couplings in a free radical, where the γs are the magnetogyric ratios of the muon and the proton. μLCR allows the determination of both the identity (11, 12) and yield (13) of free radicals that contain the muon as a Mu atom bonded in the α, β, or γ positions of a free radical. The μLCR spectrum is determined by measuring the muon's "asymmetry" as a function of applied longitudinal magnetic field. The ordinate ($A^+ - A^-$) is the difference in observed asymmetry when a small flip-field is added or subtracted to the main longitudinal field. This gives the plots a differential appearance with a resonance centered where the difference count rates cross the baseline. A computer fitting program then draws the lines and calculates the best resonance field (B_R), amplitude (Amp), and linewidth (ΔB) (see Fig. 1).

All solutions for these experiments were composed of reagent-grade chemicals (acetone, benzene, hexane, heptane, and decyltrimethylammonium bromide, hereafter DTAB) and triply distilled water. They were thoroughly deoxygenated by bubbling with pure nitrogen immediately before being pumped under nitrogen into the reaction cell. For the major series of experiments, samples of stock solutions of acetone in water at 100, 27, 10 mM were used with various amounts of the micelle-forming surfactant (DTAB) added. The actual concentration of micelles present was calculated, approximately, from the relationship, [micelle] = ([surfactant] – CMC)/A, where A is the aggregation number of the surfactant (48 for DTAB) and CMC the critical micelle concentration (65 mM for DTAB). DTAB was chosen because its solubility is relatively high and it forms large micelles to accommodate many acetone molecules. The concentration of DTAB was increased from 10 to 500 mM, corresponding to micelle concentrations of zero to 9.1 mM.

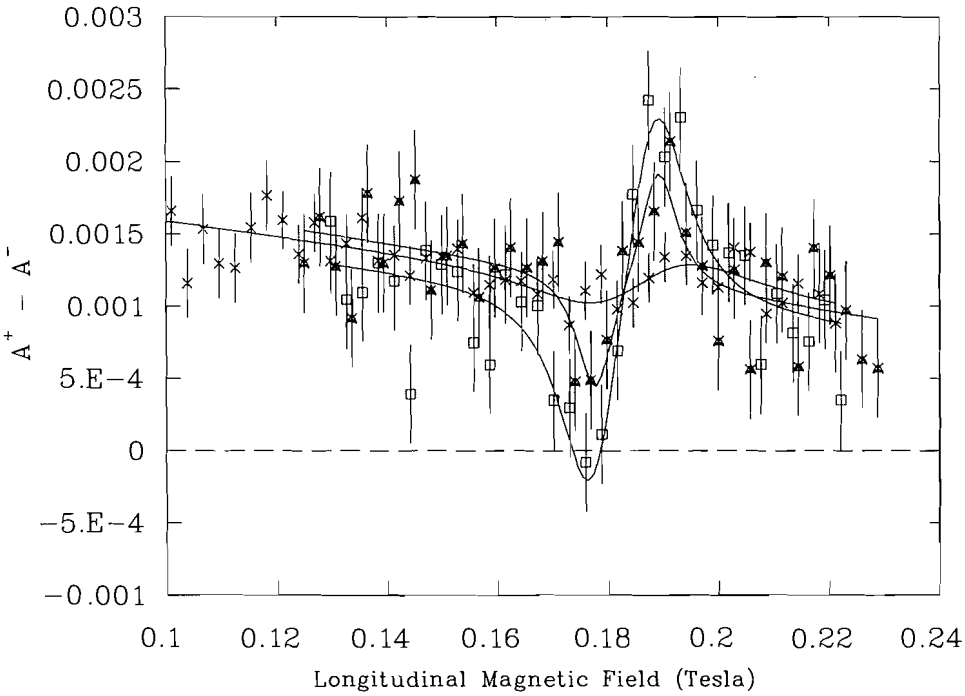
Results

1. μLCR spectra of Mu-acetone radicals

Figure 1 shows the μLCR spectra obtained for 27 mM solutions of acetone in water, and in solutions of DTAB below and above its CMC. The signal clearly decreases with increasing micelle concentration. These spectra correspond to resonances involving the six equivalent H_β atoms as reported previously for the $(CH_3)_2\dot{C}$-O-Mu radical (4, 7).

[5] A_p also increases (8), actually more than does A_μ, on moving from neat acetone to its solutions in water, so that A_μ/A_p falls from 9.0 to 4.5. Perhaps this suggests Mu bonding is somewhat weaker than H bonding.

Fig. 1. μLCR spectra of 27 mM acetone in: (*i*) water alone (□), (*ii*) with 25 mM DTAB added (△), and (*iii*) with 50 mM DTAB added (×).



The μLCR spectrum of this Mu radical shifts considerably as a result of changes to its microenvironment. Spectra were obtained for the radical in neat acetone (1540 G) and in various concentrations of water (~1820 G) and hexane (~1425 G). Figure 2(*a*) shows this variation of B_R, displayed as a function of the dielectric constant of the solvent. The latter is not the ideal parameter to use as a measure of the actual degree of hydrogen bonding (muonium bonding here), but the plot shows the strong dependence of hyperfine splittings on solvent polarity. The magnitude of B_R is proportional to the difference between A_μ and A_H, as in eq. [3], but it can, presumably, be almost totally attributed to changes in A_μ, with A_H = 56 MHz (4, 7), as shown in Fig. 2(*b*), because the H-atoms are attached to C and can exhibit no hydrogen bonding. (It should be noted that because Mu is attached to a C atom in Mu radicals from acrylamide, styrene, and most others studied so far, none of them show μLCRs that shift with the nature of the solvent or change when the solute is solubilized by micelles.)

Our data show no evidence for replacement of the Mu radical in water (at ~1820 G) by a buildup at a lower field (corresponding to B_R in a hydrocarbon) as the majority of acetone molecules get localized at micellar phases as surfactant is progressively added to an aqueous solution of acetone. The only resonances found were centered at 1820 G, with nothing at lower fields. Most experiments were scanned from 1200 to 2200 G, and occasionally from 600 to 2200 G.

2. Yields of Mu radical (P_R) from aqueous solutions of acetone as surfactant was added

Radical yields were determined using eq. [4] (13),

$$[4] \quad P_R = \frac{\mathrm{Amp}(\Delta B)^2(\gamma_\mu - \gamma_p)^2}{\mathrm{As}\cdot v_r^2}$$

Fig. 2. Plots of (*a*) B_R and (*b*) A_μ against the dielectric constant of the solvent, for the Mu radical from acetone in water and hexane solutions, and as neat acetone. (A_μ is calculated using eq. [3] with A_{H_β} = 56 MHz.)

[a] P_R is the radical yield (fraction of incident muons seen as radicals) calculated from Amp$(\Delta B)^2$ of the μLCR spectra at 1820 G using eq. [4].

where As is the intrinsic asymmetry of the apparatus, and v_r is the LCR frequency, proportional to $A_\mu A_p/B_R$. For a given resonance, $P_R \propto$ Amp$(\Delta B)^2$, and all yields for a given resonance can be normalized by comparison with neat acetone using the published yield of 0.41 (4).

Table 1 shows the Mu-radical yields obtained at three concentrations of acetone (100, 27, and 10 mM) for surfactant additions up through the CMC to micelle concentrations of 9 mM. These data are plotted as P_R against the surfactant concentration in Fig. 3.

Errors in P_R range from about 10% when the yields are high, to ~50% as they merge into the background. However, a clear trend is seen for all three acetone concentrations — the yield decreasing markedly as micelles form and solubilize the acetone molecules. At a concentration of 100 mM not all of the acetone is encapsulated in the micelles, even at the highest DTAB concentrations. This can explain why the radical yield drops to only ~25%, because there remains a high concentration of acetone in the water able to react with some Mu to form the observed radical product still in the aqueous phase. At 10 mM, on the other hand, the acetone concentration was so low that many of the muons in Mu decay before Mu reacts chemically, which results in P_R dropping off prematurely. Only at 27 mM is a complete scavenging curve seen.

3. Yields of Mu-benzene radicals (P_{R_b}) obtained in micelle solutions of benzene

μLCR studies of neat liquid benzene have established that the muonated cyclohexadienyl radical, resulting from Mu addition into the benzene ring, has its H_β resonance at $B_R \simeq$ 20 780 G [12]. This can be used to calibrate the asymmetry characteristics of the apparatus, as in the last line of Table 2. Virtually the same μLCR spectrum was obtained here for benzene solubilized in aqueous micelles, as in Fig. 4. This figure also shows the effect of adding 50 mM acetone to the 50 mM benzene in the 9 mM micelle. (All concentrations are moles per litre of total solution.) Only a small decrease in

Fig. 4. μLCR spectra of 50 mM benzene in 0.5 M DTAB solution: (*i*) with no added acetone (□), and (*ii*) with 50 mM acetone added (△).

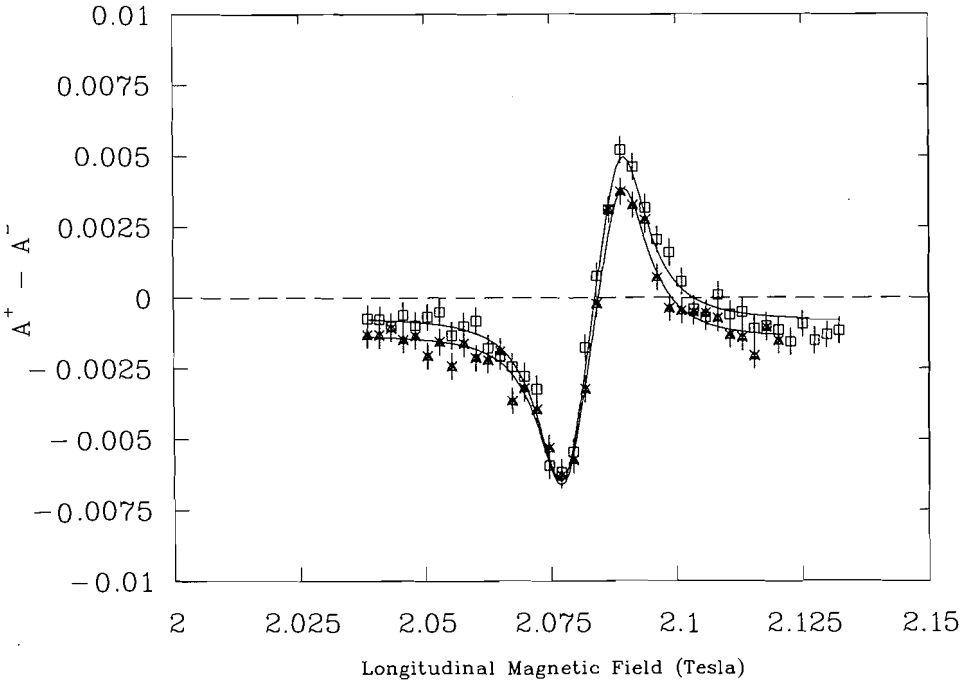

Table 2. Yields of Mu radicals in benzene solutions to which micelles and acetone were added. P_{R_b} is the Mu-cyclohexadienyl radical observed at $B_R \approx 20\,780$ G, whereas B_R (as in Table 1) would correspond to the Mu radical from acetone at 1820 G.

[Ac]/mM	[Bz]/mM	[DTAB]/mM	[mic]/mM	P_{R_b}
0	50	500	9.1	0.161
50	50	500	9.1	0.146
150	50	500	9.1	0.144
0	pure	0	0	[0.82][a]

[a]The value of 0.82 has already been established for the radical yield in neat liquid benzene (14). It was used here to put all P_R values on an absolute basis — as a normalizing factor for the actual asymmetry of the apparatus (As, in eq. [4]).

amplitude is evident. When this latter solution was scanned in the 1200–2200 G range, no resonance was observed corresponding to the $(CH_3)_2\dot{C}$-O-Mu radical.

Table 2 gives the actual yields of the Mu-benzene radicals in solution taking $P_{R_b} = 0.82$ in neat benzene (14). The yield of $P_{R_b} = \sim 0.16$ in the micelles is in reasonable accord with the yield of Mu in water previously established for a solute present at more than three solutes per micelle, on average, when the micelle concentration was ~9 mM (9). It is similar to the Mu-radical yield found for 10 mM acetone in water (Table 1). Evidently there is no significant loss of Mu-benzene radicals by encapsulating the benzene in micelles. This is in sharp contrast to acetone. Furthermore, acetone competes with the benzene for Mu when both solutes are localized in the micelles, but only weakly. (In the case of the 150 mM acetone experiment there was far too much acetone for it to be significantly accommodated by 9 mM micelles, which may account for a negligible further decrease.)

4. Related Mu-radical searches

To check the possibility that localization of acetone in micelles may greatly enhance the fraction of acetone molecules in the "enol" form, μLCR scans were run from 11 000 to 13 000 G, where H_β resonances typically occur when Mu adds to a vinyl group. None was found. The region around 19 000–20 000 G was also studied in the event Mu added to the C of acetone's carbonyl to form an oxyl radical, but, again, no resonances were detected.

μLCR's scans were performed on acetophenone in the 1200–2200 G range looking for carbonyl addition, and around 20 000 G for benzene ring-addition. Resonances were found only for the latter, showing that addition occurs at the benzene ring at least an order of magnitude faster than to a ketone carbonyl group. (These findings removed the possibility of checking whether the carbonyl radical of acetophenone would be curtailed like that of acetone when solubilized by micelles, so at the present time there are no data on other carbonyl compounds to compare with acetone.)

Discussion

The gross suppression by micelles noted earlier (4) is confirmed here by the observation of a gradual decrease of the Mu radical by progressive addition of surfactants to aqueous solutions of acetone. It is also now shown that the radical was not missed previously due to a shift in the μLCR spectrum of this Mu radical as the microenvironment of the acetone changes from water to micelle.

There is, nevertheless, a strong shift in A_μ on switching from water to pure hexane as solvent (as in Fig. 2). But,

even if the acetone radical moves between the aqueous and micellar phases as rapidly as photo-excited acetone seems to do (15), the fluctuation in coupling constant should not wipe out the signals here. This is because, in the μLCR technique, there is involved only the particular state, and thus its coupling constant, of the species that exists at the very moment when the muon decays.

Under almost identical conditions the Mu radical formed by reaction of Mu with benzene as solute was not suppressed by addition of micelles (Table 2), so the inhibition of the radical spectrum of acetone was not caused by spurious effects such as exclusion of Mu from the hydrophobic phase of the micelle, nor from interference by impurities in the surfactants. Also, micelles were found to enhance, not reduce, the overall rate of reaction of muonium with acetone — by a factor of about 250, in fact (4). Consequently, the radicals are not "missing" because of subsequent reactions of Mu radicals with the surfactants or their impurities.

It seems to be a case of an alternative faster reaction taking over when the interaction of Mu with acetone takes place within a micelle (or at its Stern-layer interface). Two other Mu-addition radicals are possible to envisage, though they seem unlikely, under the strained orientated localization of acetone in the Stern layer: first, a greatly enhanced occurrence of the enol tautomer of acetone, $CH_2{=}C(OH)CH_3$, giving the $CH_2(Mu)\text{-}\dot{C}(CH_3)OH$ radical; and second, preferred addition to the C of C=O rather than the O, giving the oxyl radical $(CH_3)_2C(Mu)\dot{O}$. The former might be expected to have a μLCR in the range 11 000–13 000 G, which is where vinyl adducts of Mu generally occur (12, 13, 15), but none was found here. Possible occurrence of the Mu-oxyl radical was also searched for (at ~20 000 G where Mu-thiyl radicals have resonances (16)) but, again, none was detected. μLCR can readily observe oxyl and thiyl radicals where ESR cannot due to rapid electron spin relaxations.

The most likely explanation for the present results seems to be for the abstraction reaction (eq. [2]) to supersede the normal addition reaction (eq. [1]) when the reaction occurs in micelles. This cannot be checked directly because the diamagnetic product of eq. [2] is not observable by μSR techniques (17); but there are good reasons for speculating along these lines — it is specifically abstraction reactions that have previously been seen to show large micelle-induced enhancements (9), and Mu is expected to react to some extent by this mechanism because this is the predominant reaction of its heavy isotope H, even in water (1).

A micelle-controlled mechanism would be given by reactions [5]–[7],

$$[5]\quad Mu_{(aq)} + Ac_{(aq)} \longrightarrow R$$

$$[6]\quad Mu_{(aq)} + mic \rightleftharpoons Mu_{(mic)}$$

$$[7]\quad Mu_{(mic)} + Ac_{(mic)} \longrightarrow D$$

where R represents the observed radicals at 1820 G (eq. [1]), and D the diamagnetic abstraction product (MuH) of eq. [2]. (Ac is acetone and mic the micelles.)

A steady-state treatment for short-lived Mu within the micelles, as in eq. [8],

$$[8]\quad \frac{-dMu_{(mic)}}{dt} = k_6[Mu_{(aq)}][mic] - [Mu_{(mic)}](k_{-6} + k_7[Ac_{(mic)}]) \simeq 0$$

leads to eq. [9] for the ratio R/D of product yields,

$$[9]\quad \frac{R}{D} = \frac{k_5[Ac_{(aq)}](k_7[Ac_{(mic)}] + k_{-6})}{k_6[mic].k_7[Ac_{(mic)}]}$$

and thus to eq. [10],

$$[10]\quad \frac{R_0}{R} = 1 + \frac{k_7[Ac_{(mic)}]k_6[mic]}{(k_5[Ac_{(aq)}](k_{-6} + k_7[Ac_{(mic)}])}$$

as the inverse of the fraction of Mu atoms leading to radicals (R_0 being the value of R with no surfactant added).

A major problem in trying to extract k_7 by "fitting" the data to eq. [10] is the fact that the fraction of acetone in the aqueous phase relative to the micellar phase is a nonlinear function of [mic] because micelles undoubtedly become saturated with acetone (perhaps after 10 or 20 molecules). Some indication of the magnitude of k_7 that is required to explain these data can, nevertheless, be gleaned from the observation that for 100 mM acetone (and 27 mM) the yield of radicals is halved by some 2.5 ± 0.5 mM of micelles (150–250 mM DTAB, as in Fig. 3). Leigh and Scaiano have determined an equilibrium constant of 52 for photochemically excited triplet acetone molecules at low concentrations in sodium dodecyl sulphate micelles, based on an escape rate of 10^8 s^{-1} (in ref. 15). If we take this 52 as an upper limit (because of the saturation effect) for our ground-state acetone in DTAB (similar in size, just of opposite charge), and the 10^8 s^{-1} as a lower limit for k_{-6} for muonium (estimated previously as ~5×10^8 in CTAB [9]), then we can proceed with an "order-of-magnitude" estimation in the following way. We take $[Ac_{(mic)}]/[Ac_{(aq)}][mic] < 52$ and put $k_{-6} > 10^8$ s^{-1}, and use $k_5 = 1 \times 10^8$ M^{-1} s^{-1} (6) and $k_6 \simeq 5 \times 10^{10}$ M^{-1} s^{-1} (9, 10) as published. For the limiting lower case, we also neglect $k_7[Ac_{(mic)}]$ relative to k_{-6} in the denominator of eq. [10], as if Mu generally does not react on encountering an acetone, even within a micelle. This gives a lower limit for k_7 of 6×10^8 M^{-1} s^{-1}.

Despite the obvious uncertainties in this estimate of k_7, all of its assumptions work in the same sense — a lower limit. It implies that Mu and acetone react very much faster within the micelle, consistent with observed micelle-induced rate enhancement of abstraction reactions (4). Also, the value $k_7 > 6 \times 10^8$ M^{-1} s^{-1} is not unreasonably high considering the fact that the abstraction reaction of Mu with 2-propanol undergoes a micelle-induced enhancement to $k > 10^{10}$ M^{-1} s^{-1} (9).

Our basic conclusion is that the "addition" reaction of Mu is subsumed by a faster competitive reaction for acetone in micelles, with "abstraction" a realistic alternative.

Homoleptic carbonyl cations of palladium(I), palladium(II), platinum(II), and gold(I) — simplified synthetic routes to their fluoroantimonate(V) salts

Changqing Wang, Sun Chau Siu, Germaine Hwang, Christian Bach, Bianca Bley, Matthias Bodenbinder, Helge Willner, and Friedhelm Aubke

Abstract: The original synthetic routes to the new noble metal carbonyl cations $[Au(CO)_2]^+$ and $[M(CO)_4]^{2+}$, M = Pd or Pt, as $[Sb_2F_{11}]^-$ salts are multi-step procedures that involve corrosive reagents and require commercially unavailable starting materials. We report here two general simplifications: (*i*) the sole use of liquid antimony(V) fluoride as reaction medium in a single-step carbonylation process, and (*ii*) the use of the commercially available chlorides $AuCl_3$ and MCl_2, M = Pd or Pt, as starting materials, in addition to the binary fluorosulfates $Au(SO_3F)_3$, $Pd[Pd(SO_3F)_6]$, and $Pt(SO_3F)_4$. The simplified routes developed here for $[Au(CO)_2][Sb_2F_{11}]$ and $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, should make these new reagents more easily available for wider use in synthesis. In addition, these routes are found suitable for the generation of new carbonyl cations of electron-rich metals.

Key words: metal carbonyl cations of Au(I), Pd(I), Pd(II), and Pt(II); solvolysis reactions in liquid SbF_5, reductive carbonylation in liquid SbF_5; carbonylations in strong acidic media.

Résumé : La première voie de synthèse des nouveaux cations carbonyles de métal $[Au(CO)_2]^+$ et de $[M(CO)_4]^{2+}$, M = Pd ou Pt, sous forme de sels de $[Sb_2F_{11}]^-$ est une synthèse en plusieurs étapes impliquant des agents corrosifs et qui requiert des produits de départ non disponibles commercialement. Nous rapportons deux simplifications générales : (*i*) l'emploi uniquement du fluorure d'antimoine(V) liquide comme milieu réactionnel dans une réaction de carbonylation en une étape et (*ii*) l'utilisation de $AuCl_3$, et de MCl_2, M = Pd ou Pt, comme produits de départ disponibles commercialement en plus des fluorosulfates binaires $Au(SO_3F)_3$, $Pd[Pd(SO_3F)_6]$, et $Pt(SO_3F)_4$. La méthode simplifiée développée ici pour la synthèse du $[Au(CO)_2][Sb_2F_{11}]$ et du $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd ou Pt, devrait rendre ces nouveaux réactifs plus facilement accessibles pour des synthèses de plus grande envergure. De plus on a trouvé que ces nouvelles méthodes sont plus appropriées pour générer les nouveaux cations carbonyles de métaux riches en électrons.

Mots clés : cations de métal carbonyle de Au(I), Pd(I), Pd(II), et Pt(II); réactions de solvolyse dans du SbF_5 liquide; carbonylation réductive dans du SbF_5 liquide; carbonylations dans des milieux fortement acides.

[Traduit par la rédaction]

Introduction

While three carbonyl chlorides of platinum(II), among them *cis*-$Pt(CO)_2Cl_2$, are the very first transition metal carbonyl compounds to be reported (1), thermally stable, uncharged binary (homoleptic) carbonyls of platinum (2, 3) as well as of palladium (2, 4) and gold (5) are still unknown (6). Transient fragments of all three metals containing carbon monoxide have been obtained by co-condensation of CO and the corresponding metal atom vapors (7) and studied by matrix isolation techniques only.

Recently, evidence has been obtained by us for the existence of the thermally stable homoleptic carbonyl cations $[Au(CO)_2]^+$ (8, 9) and $[M(CO)_4]^{2+}$, M = Pd or Pt (10, 11). The cations are generated either in solution of superacids (8, 10) or obtained in the solid state as $[Sb_2F_{11}]^-$ salts, $[Au(CO)_2][Sb_2F_{11}]$ (9) and $[M(CO)_4][Sb_2F_{11}]_2$ (11), M = Pd or Pt. As surprising as are the existence and the relatively high thermal stability of these ennea fluoro diantimonate(V) salts (usually well beyond 100°C), are the structural, spectroscopic, and bonding features of the metal carbonyl cations. Their molecular geometries, linear ($D_{\infty h}$) for $[Au(CO)_2]^+$ (9) and square planar for $[M(CO)_4]^{2+}$, M = Pd or Pt (11), are unprecedented among thermally stable transition metal carbonyls. Their average CO stretching vibrations occur at significantly higher wave numbers, between 2235.5 and 2260 cm^{-1} (8–10), than are found for free CO (2143 cm^{-1}) (12, 13). Likewise, ^{13}C chemical shifts are found at lower frequencies than CO (184

ppm) (14) while high-frequency shifts are usually observed for transition metal carbonyls relative to CO (15).

Homoleptic mononuclear carbonyl cations in thermally stable salts are uncommon and prior to our work were limited to the hexacarbonyl cations in group 7 of the type $[M(CO)_6]^+$, M = Mn, Tc, or Re, with $[AlCl_4]^-$ or $[FeCl_4]^-$ as anion (16). The noble gas formalism or the effective atomic number rule, which holds for the above-mentioned cations of the type $[M(CO)_6]^+$, M = Mn, Tc, or Re, is usually valid for binary metal carbonyls (6). However, in $[Au(CO)_2]^+$ there are 14 and in $[M(CO)_4]^{2+}$, M = Pd or Pt, 16 electrons associated with the central metal ion. This departure from the 18 electron count does not seem to cause unusual reactivity, a tendency towards metal–metal bonding resulting in cluster formation, or strong reducing power, as are commonly associated with such low electron counts in organo transition metal compounds (6).

There are, however, strong similarities in structural and spectroscopic features between the carbonyl cations and the isoelectronic cyanide anions $[Au(CN)_2]^-$ and $[M(CN)_4]^{2-}$, M = Pd or Pt (17, 18), which in turn suggest that CO in the homoleptic carbonyl cations acts predominantly as a σ-donor ligand. π-Back donation, the second component of a synergetic M—CO bonding (6), appears to be reduced to insignificance (19), judging by the various criteria cited above.

A consequence of the predominant σ-bonding and the concomitant reduction in π-back-bonding in metal carbonyl cations is the presence of positive partial charges on the carbon atom of the carbonyl group (electrophilic carbon) and the juxtaposition of positive partial charges on both the metal and the adjacent C-atoms (19).

Hence it is expected that homoleptic carbonyl cations will display different reactivities than do neutral carbonyls or the carbonylate anions, including the highly reduced carbonylates (20). Nucleophilic attack either on the metal center, resulting in a displacement of CO by the nucleophile, or on the adjacent C-atom is now possible, which in the latter case should lead to a chemical modification of the coordinated CO ligand.

So far very little is known about the reactivity of metal carbonyl cations. No systematic study has been undertaken. The only reported reaction is the substitution of CO by acetonitrile (9) according to:

[1] $[Au(CO)_2][Sb_2F_{11}] + 3\ CH_3CN \xrightarrow{CH_3CN} [Au(NC_2H_3)_2][SbF_6] + CH_3CNSbF_5$

which leads to the structurally characterized product $[Au(NC_2H_3)_2][SbF_6]$ (9).

A contributing reason for the lack of such systematic reactivity studies are the multi-step synthetic procedures used (8–11) in their synthesis. The highly reactive and corrosive reagents employed, among them SO_3, HSO_3F, and elemental fluorine, as well as the unavailability of many reagents and starting materials from commercial sources, severely limit synthetic work, frequently on account of safety concerns.

The purpose of this publication is to report on simplified procedures for syntheses of salts of the carbonyl cations of Au(I), Pd(I), Pd(II), and Pt(II) with $[Sb_2F_{11}]^-$ as the anion in all instances. The reaction medium chosen is liquid antimony pentafluoride, SbF_5, which is commercially available. The general synthetic procedure, solvolysis in liquid SbF_5 at slightly elevated temperatures (60–80°C) in the presence of gaseous CO at 0.5–2.0 atmospheres of pressure (1 atm = 101.3 kPa), has recently been reviewed by us (21). Two types of metal derivatives are used as starting materials: (*i*) binary metal fluorosulfates, whose syntheses are well known (22), and (*ii*) binary metal chlorides, which are all commercially available. Hence the syntheses of all known carbonyl-cation-containing salts of gold, palladium, and platinum from commercially available starting materials should be possible.

Experimental

(a) Chemicals

Palladium(II) chloride and platinum(II) chloride were donated to us by Prof. B.R. James, University of B.C. Gold(III) chloride was obtained from Johnson and Mathey. All three metal chlorides were manipulated and stored inside a dry box. They were used without further purification. Antimony pentafluoride, SbF_5, was obtained from Atochem North America and purified by distillation methods as described (9, 11). The binary fluorosulfates $Pd[Pd(SO_3F)_6]$ (23), $Pt(SO_3F)_4$ (24), $Au(SO_3F)_3$ (25), and $[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ (26) were synthesized by oxidation of the metal powders (all obtained from the Ventron Corporation) with bis(fluorosulfuryl)peroxide, $S_2O_6F_2$, in fluorosulfuric acid as reported (23–26). $S_2O_6F_2$ was obtained by the catalytic (AgF_2) fluorination of SO_3 (27) and HSO_3F technical grade (Orange County Chemicals) was purified by distillation as described before (28). Carbon monoxide was obtained from Medi Gas Inc.

(b) Instrumentation

Infrared spectra were recorded with a Bomem M.B–102 F.T.I.R instrument. Raman spectra were recorded with Bruker FRA–106 FT Raman accessory mounted on an optical bench of a Bruker IFS-66v instrument.

Gaseous and volatile reagents and products were manipulated and measured in a vacuum line of known volume. Pressure measurements were made with a Setra capacity manometer type 280E (Setra Instruments, Acton, Mass.). Synthetic reactions were carried out in various glass reactors (10–50 mL volume) fitted with Teflon stem valves (Young, London, U.K.) and Teflon-coated stirring bars. Solid materials were manipulated inside a Vacuum Atmosphere Corp. Drilab filled with dry N_2. Microanalyses were performed by Mr. P. Borda, Department of Chemistry, U.B.C.

(c) Synthetic reactions

The synthetic procedures and the methods of product isolation were adopted from the previously reported solvolytic conversions of $Au(CO)SO_3F$ and *cis*-$M(CO)_2(SO_3F)_2$, M = Pd or Pt (10), to $[Au(CO)_2][Sb_2F_{11}]$ (9) and $[M(CO)_4][Sb_2F_{11}]_2$ (11) in liquid antimony(V) fluoride in a CO atmosphere. The identification of known products was accomplished by the mass balance of the reaction, volumetric CO-uptake measurements, microanalysis for carbon only, the determination of melting or decomposition points, a comparison of the vibrational spectra with the published precedents (9, 11), and the characterization of by-products by their vibrational spectra.

To illustrate the synthetic procedure, the synthesis of $[Au(CO)_2][Sb_2F_{11}]_2$ (9) starting either from $Au(SO_3F)_3$ or from $AuCl_3$ is described below in detail. The solvolytic conversion of $[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ to the previously unknown $[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$ is also described below. The remaining reactions leading to $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, are carried out in an identical manner and on a comparable small scale.

(i) The synthesis of $[Au(CO)_2][Sb_2F_{11}]$ from $Au(SO_3F)_3$

About 3 mL SbF_5 was distilled onto 224 mg (0.494 mmol) of $Au(SO_3F)_3$ in vacuo. The 50 mL round-bottom flask was warmed to room temperature. No reaction between the orange $Au(SO_3F)_3$ and clear, colorless SbF_5 was observed. Carbon monoxide (4.85 mmol) was admitted to the reaction vessel. The mixture was warmed to 65°C to facilitate stirring. The solid present changed color from orange to brown after 10 min. White particles were visible in the mixture after 30 min. After 45 min, the solution turned dark yellow. The solid was gradually consumed at this stage. The solution was clear and colorless after 2 h and no solid appeared to be present. Heating was stopped and the solution was left stirring for 20 h.

At ambient temperature the solution separated into a white, cloudy, viscous upper layer and a light brown, oily lower layer. Warming the mixture to 80°C caused the two layers to combine to form a clear, colorless solution, but the brown oil returned upon cooling the reactor to room temperature. Infrared spectra of the volatile materials in the reactor were obtained at −196°C, −78°C, and 20.5°C. The volatiles were found to be CO, CO_2, $S_2O_5F_2$, and possibly $Sb_2F_9SO_3F$, respectively. The excess SbF_5 was removed in vacuo, leaving a white solid. CO (3.18 mmol) was removed from the reactor.

In total, 1.67 mmol CO appeared to react with 0.494 mmol $Au(SO_3F)_3$. The white solid was identified as $[Au(CO)_2][Sb_2F_{11}]$ by comparison of its vibrational spectra to published data (9). The conversion reaction proceeds quantitatively.

(ii) The synthesis of $[Au(CO)_2][Sb_2F_{11}]$ from $AuCl_3$

To 100.3 mg (0.33 mmol) of finely ground, yellow-orange, crystalline $AuCl_3$, contained in a reaction vial of an approximate volume of 100 mL, an excess of about 3 mL of purified SbF_5 was added in vacuo. The CO pressure was adjusted to about 0.6 atm. Upon warming the reaction mixture, first to room temperature and then to 60–70°C, in order to reduce the viscosity of SbF_5, the crystals turned black immediately and then slowly became white in color. After heating for 5 days no further change in color and CO-uptake was noted, and the reaction was judged to be complete. The excess of SbF_5 was removed in vacuo overnight, with the reactor at 55°C. In the highly volatile gaseous fraction only CO and COF_2 could be detected by IR spectroscopy. The white solid residue was identified as $[Au(CO)_2][Sb_2F_{11}]$, which had formed in quantitative yield.

(iii) The synthesis of $[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$

An amount of 27.2 mg (0.058 mmol) of orange-colored crystalline $[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$, used previously to obtain samples for the crystal structure determination by X-ray diffraction (26), was finely ground inside the dry box and transferred to a one-part reactor of an approximate volume of 50 mL. After weighing, approximately 2 mL of SbF_5 were added in vacuo. The reactor was kept at room temperature without stirring but with occasional shaking by hand, resulting in a swirling of the mixture. As time went by, the color of the suspension turned lighter, and became uniformly yellow after 6 months. After removal of all volatiles, 67.3 mg (expected were 68.4 mg) of a yellow powder was left behind. On heating in a melting point capillary the compound started to decompose at 115°C and gray spots appeared. At 145°C the material had turned uniformly dark. Carbon analysis: calcd. for $COF_{11}Sb_2Pd$: 2.05%; found: 2.05%. Vibrational spectra: (*a*) IR, $\bar{\nu}$ in cm^{-1}: 2032 vw, 2006 vs, 1970 w, 1349 vw, 1186 vw, 1045 vw, 884 vw, 721 vs, 708 s, 682 vs, 648 s, 569 vs, 492 ms, 390 m. (*b*) Raman, $\Delta\bar{\nu}$ in cm^{-1}: 2048 vs, 734 vw, ~710 vw, sh, 696 vs, 681 s, 643 vs, 571 ms, 409 m, 296 w, b, 248 w, 228 w, 135 vw, 82 w. Abbreviations: $\bar{\nu}$ = wave number, $\Delta\bar{\nu}$ = Raman shift, s = strong, m = medium, w = weak, v = very, b = broad and sh = shoulder.

Results and discussion

There are two general alternative routes of great simplicity found for all three fluoroantimonate(V) salts $[Au(CO)_2][Sb_2F_{11}]$ and $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt as described below.

As best illustrated by the original synthesis of $[Au(CO)_2][Sb_2F_{11}]$ (8, 9), the original approach is cumbersome and experimentally demanding. Starting with the synthesis of gold(III) fluorosulfate (24) according to:

$$[2] \quad 2\,Au + 3\,S_2O_6F_2 \xrightarrow[60°C]{HSO_3F} 2\,Au(SO_3F)_3$$

both the purification of the solvent, HSO_3F (28), and the synthesis of bis(fluorosulfuryl)peroxide, $S_2O_6F_2$ (27), by the catalytic fluorination of sulfur trioxide with elemental fluorine, are demanding procedures that require specially developed equipment (26, 27). Furthermore, by-products of the catalytic fluorination may be extremely hazardous (27*b*); however, their formation can be avoided according to a recent study (27*c*). The subsequent reductive carbonylation of $Au(SO_3F)_3$ according to:

$$[3] \quad Au(SO_3F)_3 + 3\,CO \xrightarrow[25°C]{HSO_3F} [Au(CO)_2]^+_{(solv)} + SO_3F^- + CO_2 + S_2O_5F_2$$

is straightforward, facile, and completed within a few hours, but nucleophilic displacement of one mole of CO by SO_3F^- on heating or on solvent removal according to:

$$[4] \quad [Au(CO)_2]^+_{(solv)} + SO_3F^- \longrightarrow Au(CO)SO_3F + CO_{(g)}$$

will produce $Au(CO)SO_3F$ in quantitative yield (8) that will, after isolation by sublimation, convert in liquid SbF_5 to the final product $[Au(CO)_2][Sb_2F_{11}]$ in a CO atmosphere of 580 mbar (1 bar = 100 kPa) according to:

$$[5] \quad Au(CO)SO_3F + CO + 4\,SbF_5 \xrightarrow[80°C,\ 10\ h]{SbF_5} [Au(CO)_2][Sb_2F_{11}] + 2\,Sb_2F_9SO_3F$$

Two additional complications are encountered in the reductive carbonylation of $Pt(SO_3F)_4$ (24) and the mixed valency compound $Pd[Pd(SO_3F)_6]$ (23). The rather slow reduction of $Pt(SO_3F)_4$ in HSO_3F by CO produces a solid, yellow intermediate of the composition $[Pt(CO)_4][Pt(SO_3F)_6]$, which has been isolated and characterized (29). This intermediate will convert completely under slightly more forcing conditions to white *cis*-$Pt(CO)_2(SO_3F)_2$. The reductive carbonylation of $Pd[Pd(SO_3F)_6]$ in HSO_3F produces, in addition to *cis*-$Pd(CO)_2(SO_3F)_2$ a second isomer with bridging CO groups according to the IR spectrum (10) which has so far not been isolated in pure form. Both forms of $Pd(CO)_2(SO_3F)_2$ are, however, easily converted in liquid SbF_5 and in the presence of CO to $[Pd(CO)_4][Sb_2F_{11}]_2$ (11).

These complications, the use of HSO_3F as solvent and the necessity to isolate the metal carbonyl fluorosulfates as intermediates, are all avoided when liquid SbF_5 is used as reaction medium. The reductive carbonylation of the binary fluorosulfates of palladium, platinum, and gold proceeds in a straight foward manner as, for example, .

[6] $Au(SO_3F)_3 + 3\ CO + 4\ SbF_5$

$$\xrightarrow[65°C,\ 1\ d]{SbF_5} [Au(CO)_2][Sb_2F_{11}] + CO_2 + S_2O_5F_2 + Sb_2F_9(SO_3F)$$

The rather low volatility of SbF_5 requires prolonged heating of the product mixture to ~65°C in vacuo during the product isolation. This causes no problems, because $[Au(CO)_2][Sb_2F_{11}]$, as well as $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, shows sufficient thermal stability well beyond 100°C.

The simplified synthetic procedure, initially developed for the preparation of $[Au(CO)_2][Sb_2F_{11}]$ and $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, has found two recent applications, which have significantly expanded the field of homoleptic metal carbonyl cations: (*i*) The solvolysis of $Hg(SO_3F)_2$ (30) in liquid SbF_5 in a CO atmosphere resulted in the isolation (31) and subsequent structural characterization (32) of $[Hg(CO)_2][Sb_2F_{11}]_2$, the first thermally stable carbonyl derivative of a post-transition metal. (*ii*) Reductive carbonylation of $M(SO_3F)_3$, M = Ru (33) or Os (34), in liquid SbF_5 allowed for the first time the isolation of $[M(CO)_6][Sb_2F_{11}]_2$ (35), M = Ru or Os. In the first case, carbonylation of $Hg(SO_3F)_2$ in HSO_3F was unsuccessful while, in the case of ruthenium and osmium, carbonyl fluorosulfates of the divalent metals were obtained as intermediates but they have so far not been isolated and completely characterized (35).

These synthetic reactions (31, 32, 35) as well as the syntheses of $[Au(CO)_2][Sb_2F_{11}]$ and $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, described here, still require binary fluorosulfates as starting materials. Their preparation is best accomplished by metal oxidation with $S_2O_6F_2$ in HSO_3F as reaction medium (23–25, 30, 33, 34). Hence neither the use of HSO_3F nor the difficulties involved in the synthesis of $S_2O_6F_2$ are completely avoided. Therefore a further simplification of the synthetic methodology is desirable.

Such a simplification is achieved when the metal chlorides $AuCl_3$ and MCl_2, M = Pd or Pt, are employed instead of the corresponding fluorosulfates. A precedent is seen in the reported solvolytic conversion of ICl_3 into $[ICl_2]$ $[SbF_6]$ (37). The conversion reaction of $AuCl_3$, formulated as:

[7] $AuCl_3 + SbF_5 + 3\ CO$

$$\xrightarrow[65°C]{SbF_5} [Au(CO)_2][Sb_2F_{11}] + COCl_2 + SbF_4Cl$$

is expected and solid $[Au(CO)_2][Sb_2F_{11}]$ is indeed formed and identified by comparison with an authentic sample (9). The mixed fluoride–chloride by-product formulated as SbF_4Cl is, unlike $Sb_2F_9(SO_3F)$ (38), not fully characterized and corresponds in its composition to materials encountered by Ruff and Plato (39) during the original synthesis of SbF_5 from $SbCl_5$ and HF and later described in more detail by Ruff (40).

Somewhat surprising is the observation, by gas phase IR, of COF_2 instead of $COCl_2$, which is usually obtained in the reductive carbonylation of $AuCl_3$ to give Au(CO)Cl (41–43). Since COF_2 can be prepared from $COCl_2$, phosgene, and a mixture of Sb(III) and Sb(V) fluorides (44), it is assumed that initially formed phosgene is quantitatively converted to carbonyl fluoride by reaction with an excess of SbF_5. Alternatively, the initial conversion of the starting material $AuCl_3$ to AuF_3 by SbF_5 may be considered. The synthesis of $[Au(CO)_2][Sb_2F_{11}]$ from AuF_3, CO, and SbF_5 as reaction medium is known (9) and will produce COF_2 as by-product. As in the solvolysis of $AuCl_3$, a black-brown color also develops here (9) immediately after combining the reagents. The nature of this black intermediate is unclear at the moment, but the disappearance of the black color as the reaction progresses provides an indication of when the conversion has gone to completion. Finally, a white solid product, suspended in SbF_5, is formed.

Black-brown intermediates that are similar in appearance are observed in the solvolysis reactions of $PdCl_2$ and $PtCl_2$, which proceed according to:

[8] $MCl_2 + 4\ CO + 6\ SbF_5$

$$\xrightarrow[80°C,\ 10–14\ d]{SbF_5} [M(CO)_4][Sb_2F_{11}]_2 + 2\ SbF_4Cl, \qquad M = Pd\ or\ Pt$$

In this case, the black-brown particles form as soon as the metal halide powders come in contact with SbF_5 even before CO is added, and it will take several days before sizable quantities of the white final products form.

Attempts to characterize the black intermediates by vibrational spectroscopy have been unsuccessful. The opaque powders do not scatter Raman light very well and give very poorly resolved FT-IR. As is in case of the solvolyses of $AuCl_3$ and AuF_3 (9), the slow disappearance of the black intermediates, allows monitoring the course of the reaction. Since all carbonylation reactions of metal halides in liquid SbF_5, appear to be heterogeneous processes, starting materials, intermediates, and final products are suspended rather than completely dissolved in liquid SbF_5. It is advisable to react small amounts at a time, to use a large excess of SbF_5,

and to grind the solid metal chlorides very finely inside a dry box before use. In case of solvolysis reactions in SbF_5 that involve fluorosulfates, it is advisable to reuse SbF_5 after product separation. The by-product formed, $Sb_2F_9(SO_3F)$ (38), is found to reduce the viscosity of antimony(V) fluoride (45) and hence facilitate the reaction. A potential dilutant, $C_4F_9SO_2F$, has so far found use only in the isolation of $[Hg(CO)_2][Sb_2F_{11}]$, where it is used to dissolve some of the excess of SbF_5 in a decanting procedure (32).

It is noticeable that solvolysis reactions in SbF_5 and in a CO atmosphere proceed very slowly, where the oxidation state of the metal does not change as in the conversion of MCl_2, M = Pd or Pt, into $[M(CO)_4]^{2+}$ salts. Since in MCl_2 the divalent metal ion is in a square-planar environment in both the α and β- forms (6), the conversion involves square-planar substitution, seemingly on solids. Hence the long reaction times are not surprising.

The remaining four synthetic reactions discussed here involve reductive carbonylation and solvolysis. All are considerably faster and are suggested to proceed via initially formed "naked" metal ions as intermediates (21). The "naked" metal cations are strong Lewis acids that are stabilized by coordination to CO to produce $[Au(CO)_2][Sb_2F_{11}]$, from either $AuCl_3$ or $Au(SO_3F)_3$ (25), or $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, from either $Pd[Pd(SO_3F)_6]$ (23) or from $Pt(SO_3F)_4$ (24). Hence the obvious advantage to produce the $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, from commercial reagents is in part offset by rather long reaction times and the necessity to react small quantities at a time as discussed above.

While all reactions discussed so far lead to previously known compounds in a simpler, more direct way, this is not the case in the solvolysis of *c*-$[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ (26) with an excess of SbF_5, which results in the formation of a new compound *c*-$[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$ according to:

[9] *c*-$[Pd_2(\mu\text{-}CO)_2](SO_3F)_2 + SbF_5$ → (25°C, 6 min; SbF_5) *c*-$[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2 + 2\ Sb_2F_9SO_3F$

To avoid oxidation of palladium, which is in the formal oxidation state +1, by SbF_5, the reaction is allowed to proceed at room temperature and requires reaction times of several months. Only very small quantities are reacted, because only small amounts of *c*-$[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ had been available and the objective was to obtain IR and Raman spectra of $[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$.

We previously reported the molecular structure of $[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ (26). During attempts to provide a complete vibrational analysis for the cyclic $[Pd_2(\mu\text{-}CO)_2]^{2+}$ cation, which has D_{2h} symmetry, two Raman active fundamentals, ν_5 and ν_6, remained undetected. They are expected to be weak, to occur at ≈600 cm^{-1}, and may perhaps be accidentally degenerate. For $[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$ all bands (listed in the experimental section) between 500 and 700 cm^{-1} are best attributed to Sb–F stretching vibrations according to precedents (9, 11, 32).

A clearer picture is found in the CO stretching region where the mutual exclusion principle is followed. In the IR spectrum the asymmetric CO stretch ν_7 (B_{1u}) is shifted from 1977 cm^{-1} with a ^{13}C satellite at ≈1940 cm^{-1} for the fluorosulfate to 2006 cm^{-1} with a ^{13}C satellite band at ≈1970 for the $[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]$. The Raman active ν_1 (A_g) stretch shifts from 2027 to 2048 cm^{-1} for the pair of compounds. Hence $\bar{\nu}_{av}(CO)$ has increased from 2002 cm^{-1} for $[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ to 2027 cm^{-1} for $[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$. Both values are well outside the range of $\bar{\nu}$ (CO) between 1700 and 1850 cm^{-1} commonly (6, 13*b*, 46) quoted for bidentate, symmetrically bridging CO groups in neutral molecules.

The noncoincidence of IR and Raman active modes is consistent with the retention of D_{2h} symmetry for the $[Pd_2(\mu\text{-}CO)_2]$-metallo cycle in both compounds. As in $[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ (26) where, according to the molecular structure, bidentate, weakly bridging fluorosulfate groups are present, no vibrational coupling between individual cations is apparent for $[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$ in the $\bar{\nu}$(CO) region. This is in contrast to observations for previously reported acetate derivatives determination (47, 48) where two $[Pd_2(\mu\text{-}CO)_2]^{2+}$ cations are linked by bidentate bridging acetate groups into tetranuclear clusters of the type $[Pd_4(\mu\text{-}CO)_4(\mu\text{-}CH_3CO_2)_4] \cdot 2\ CH_3CO_2H$ according to a crystal structure determination (47, 48). Extensive anion bridging, alternating with CO bridging, is also suggested for the halides of the type $[Pd(\mu\text{-}CO)(\mu\text{-}X)]_n$, X = Cl or Br (49, 50), even though the molecular structures are so far unknown.

In contrast to the clean synthesis of $[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$ from the fluorosulfate precursor reported here, the solvolysis in SbF_5 in the presence of CO and at 70°C produces $[Pd(CO)_4][Sb_2F_{11}]_2$ rather easily. But since the starting material $[Pd_2(\mu\text{-}CO)_2](SO_3F)_2$ is difficult to obtain, this is not a recommended synthetic route.

To conclude this report, a few exploratory reactions in liquid antimony(V) fluoride are briefly summarized. While *cis*-$M(CO)_2(SO_3F)_2$, M = Pd or Pt, are converted cleanly in SbF_5 to $[M(CO)_4][Sb_2F_{11}]_2$, M = Pd or Pt, in a CO atmosphere as discussed above, in the absence of CO different reactions occur. *cis*-$Pt(CO)_2(SO_3F)_2$ is solvolyzed cleanly in SbF_5 to give a white, crystalline solid of the composition $Pt(CO)_2(Sb_2F_{11})_2$. Attempts to determine its molecular structure failed, because the crystals did not diffract. Both $\bar{\nu}$ CO stretches are shifted by ~+20 cm^{-1} relative to *cis*-$Pt(CO)_2(SO_3F)_2$ but both remain Raman and IR active, which would be consistent with a bent $Pt(CO)_2$ moiety.

In contrast, *cis*-$Pd(CO)_2(SO_3F)_2$ converts in SbF_5 to a mixture of $[Pd(CO)_4][Sb_2F_{11}]_2$ and c-$[Pd_2(\mu\text{-}CO)_2][Sb_2F_{11}]_2$, according to the vibrational spectra. No attempt is made to separate the mixture because both components are known compounds.

When $Au(CO)(SO_3F)$ (8) is dissolved in SbF_5 in the absence of additional CO, a pale yellow oil results after the removal of the excess of SbF_5 in vacuo (9). The composition of this oil varies from one preparation to the next and the solvated cation $[Au(CO)]^+$ is so far only identified in solution of HSO_3F or of magic acid, HSO_3F–SbF_5 (9), but not in the solid state.

The solvolytic conversion of a halide into a fluoroantimonate salt in the presence of CO allows the generation of the well-known (16*a*, 51) cations $[M(CO)_6]^+$, M = Mn or Re, and their stabilization as $[Sb_2F_{11}]^-$ salts according to:

[10] $M(CO)_5Cl + CO + 3\ SbF_5$

$$\xrightarrow[0.5\text{–}0.8\ \text{atm CO}]{25\text{–}80^\circ C,\ SbF_5} [M(CO)_6][Sb_2F_{11}] + SbF_4Cl, \qquad M = Mn \text{ or } Re$$

The reactions proceed in a more facile manner than in the original syntheses, which employ $AlCl_3$ as Lewis acid and $AlCl_4^-$ as counteranoin at CO pressures of 200 atm, necessitating the use of an autoclave (51).

While the reaction of $Re(CO)_5Cl$ in SbF_5–CO is very straightforward, in the case of $Mn(CO)_5Cl$, a large excess of CO must be admitted to the reactor before slowly warming the reaction mixture from −196°C to 25°C, in order to avoid side reactions and the formation of colored materials. The vibrational spectra obtained for the two $[M(CO)_6][Sb_2F_{11}]$ salts, M = Mn or Re, do not differ significantly in the CO stretching region from previous reports (12, 52).

It is illustrated by the synthesis of $[Ir(CO)_6][Sb_2F_{11}]_3$ that reductive carbonylation of a binary halide in SbF_5 can lead to salts with new homoleptic carbonyl cations according to:

[11] $2\ IrF_6 + 15\ CO + 12\ SbF_5$

$$\xrightarrow[50^\circ C]{SbF_5} 2\ [Ir(CO)_6][Sb_2F_{11}]_3 + 3\ COF_2$$

Details on this reaction and the spectroscopic identification of the $[Ir(CO)_6]^{3+}$ cation will be published shortly (53).

Summary

The simplified synthetic approaches to the noble metal carbonyl salts $[Au(CO)_2][Sb_2F_{11}]$ (9) and $[M(CO)_4][Sb_2F_{11}]_2$ (11), M = Pd or Pt, reported here should facilitate wider use of these salts in synthesis. Their chemistry, which has so far remained largely unexplored, promises to be interesting. It remains to be seen how many more metal carbonyl cations can be generated in liquid SbF_5 in addition to $[Hg(CO)_2]^{2+}$ (31, 32) and $[M(CO)_6]^{2+}$, M = Ru or Os.

The energetics of the oxidative addition of trisubstituted silanes to photochemically generated $(\eta^5\text{-}C_5R_5)Mn(CO)_2$

Bentley J. Palmer and Ross H. Hill

Abstract: The rates for the oxidative addition reaction of trisubstituted silanes (Et_3SiH, Et_2MeSiH, $EtMe_2SiH$, Et_2SiH_2) to photochemically generated $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ ($R_5 = H_5$, Me_5, H_4Me) species have been measured for the temperature range 70 – 125 K. The reactions were carried out in either neat silane or a 50/50, by volume, mixture of methylcyclohexane and silane. The activation energies, determined using Arrhenius law, varied from 2 to 35 kJ/mol. The kinetic data fit an isokinetic relationship with an isokinetic temperature of 102 ± 6 K. The results are interpreted in terms of a variation in the loss of solvation prior to the oxidative addition. When the solvating molecule is methylcyclohexane, then loss of the solvent molecule precedes oxidative addition. In cases where solvation is by the silane, the incomplete loss of this silane precedes the oxidative addition.

Key words : mechanism, oxidative addition, solvation.

Résumé : Opérant à des températures allant de 70 à 125 K, on a mesuré les vitesses de la réaction d'addition oxydante de silanes trisubstitués (Et_3SiH, Et_2MeSiH, $EtMe_2SiH$ et Et_2SiH_2) à des espèces générées photochimiquement $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ ($R_5 = H_5$, Me_5, H_4Me). Les réactions ont été effectuées soit en présence de silane pur, soit dans un mélange 50/50 par volume de méthylcyclohexane et de silane. Les énergies d'activation, déterminées à l'aide de la loi d'Arrhenius, varient de 2 à 35 kJ mol^{-1}. Les données cinétiques s'ajustent à une relation isocinétique avec une température isocinétique de 102 ± 6 K. On interprète les résultats en termes d'une variation dans la perte de solvatation avant l'addition oxydante. Lorsque la molécule effectuant la solvatation est le méthylcyclohexane, la perte de la molécule de solvant précède alors l'addition oxydante. Dans les cas où la solvatation se fait par le silane, la perte incomplète de ce silane précède l'addition oxydante.

Mots clés : mécanisme, addition oxydante, solvatation.

[Traduit par la rédaction]

Introduction

Oxidative addition by d^6 systems is very important in catalytic (1) and stoichiometric processes including, for example, C-H activation by $(\eta^5\text{-}C_5H_5)Re(CO)PMe_3$ (2). In solution, the oxidative addition of trisubstituted silane to $(\eta^5\text{-}C_5H_5)Mn(CO)_2$ and $(\eta^5\text{-}C_5Me_5)Mn(CO)_2$ has been shown to result from irradiation of the corresponding tricarbonyl (3, 4).

In this paper we report the results of an experimental study of the oxidative addition of trialkyl silanes to d^6, $16e^-$ unsaturated species. The organometallic reagents were generated at low temperature by the irradiation of $(\eta^5\text{-}C_5R_5)Mn(CO)_3$ ($R_5 = H_5$, Me_5, H_4Me) species. The photochemical and thermal reactions are summarized in eqs. [1] and [2], respectively. It is also possible that the $16e^-$ intermediate may react with the photogenerated CO (eq. [3]). The reaction eqs. [1]–[3] neglect the possible involvement of solvation by the glass. In a low-temperature glass it is possible to cause the photochemical reaction, CO dissociation, to occur at a rate substantially faster than the subsequent thermal oxidative addition of the trialkylsilane. Consequently, at low temperatures, reaction [1] can be made to occur faster than reaction [2] thereby accumulating $(\eta^5\text{-}C_5R_5)Mn(CO)_2$. This was demonstrated previously by Wrighton and co-workers (5–7). As long as the back reaction with free CO is too slow to compete for the dicarbonyl, the rate of eq. [2] is directly measurable.

$$[1]\quad (\eta^5\text{-}C_5R_5)Mn(CO)_3 \xrightarrow{h\nu} (\eta^5\text{-}C_5R_5)Mn(CO)_2 + CO$$

$$[2]\quad (\eta^5\text{-}C_5R_5)Mn(CO)_2 + R'_3SiH \xrightarrow{\Delta} (\eta^5\text{-}C_5R_5)MnH(SiR'_3)(CO)_2$$

$$[3]\quad (\eta^5\text{-}C_5R_5)Mn(CO)_2 + CO \xrightarrow{\Delta} (\eta^5\text{-}C_5R_5)Mn(CO)_3$$

Since the above studies were released several significant contributions to our understanding of the oxidative addition reaction have appeared (8–11). Of particular interest have been the contributions to understanding the role of the solvation of the coordinatively unsaturated intermediate in these studies. These studies do prompt one to question the effect of the low-temperature glass in the previous studies. In this study we provide some evidence concerning the effect of solvation in the low-temperature glass environment.

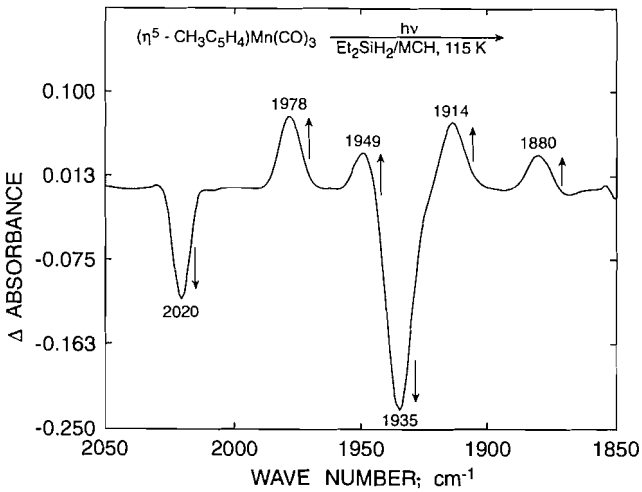
Fig. 1. FTIR spectral changes associated with the photolysis of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ in a 50/50 (v/v) mixture of $SiEt_2H_2$ and methylcyclohexane at 115 K. Spectrum prior to photolysis subtracted from spectrum after photolysis. Bands associated with $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ at 2020 and 1935 cm^{-1} appear negative while bands associated with $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ at 1949 and 1880 cm^{-1} and $(\eta^5\text{-}C_5H_4Me)\text{-}MnH(SiEt_2H)(CO)_2$ at 1978 and 1914 cm^{-1} appear positive.

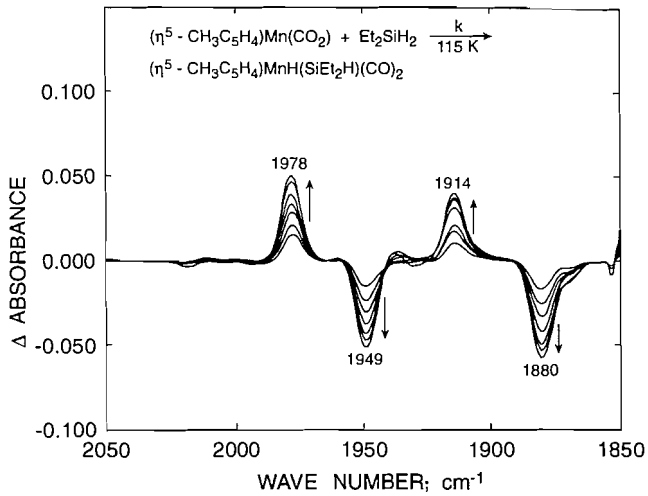


The kinetics of the oxidative addition of R'_3SiH ($R'_3 = Et_3$, Et_2Me, $EtMe_2$, Et_2H) to photogenerated $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ ($R_5 = H_5$, Me_5, H_4Me) have been studied in the temperature range 70–125 K. The results of this study are used to provide insight into the intimate details of the mechanism of the oxidative addition with emphasis on the effect of solvation on the energetics..

Results

A sample consisting of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ in Et_2SiH_2–methylcyclohexane was cooled to 115 K and photolyzed (Fig. 1). Upon photolysis there was a decrease in absorption bands at 2020 and 1935 cm^{-1} due to $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ and the appearance of absorption bands due to $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ at 1949 and 1880 cm^{-1} and due to $(\eta^5\text{-}C_5H_4Me)\text{-}MnH(SiEt_2H)(CO)_2$ at 1978 and 1914 cm^{-1}. The intermediate was previously identified in a 77 K glass (12). The product was assigned by comparison with similar species (3, 5–7). Subsequently, spectra were obtained as a function of time following the consumption of the $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ species and the formation of the oxidative addition product, $(\eta^5\text{-}C_5H_4Me)MnH(SiEt_2H)(CO)_2$. Figure 2 illustrates a typical result obtained for the reaction of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ with Et_2SiH_2 in a Et_2SiH_2–methylcyclohexane glass. In Fig. 2 are the absorbance difference spectra (spectrum after photolysis subtracted from subsequent spectra) showing the consumption of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ (negative peaks) and the formation of $(\eta^5\text{-}C_5H_4Me)MnH(SiEt_2H)(CO)_2$ (positive peaks). A plot of $\ln\{[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2]_{t=0}/[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2]_t\}$ against time (Fig. 3) is linear, and the slope yields the rate constant, k (3.78×10^{-4} s^{-1}), according to eq. [4]. For each of the systems studied, the decrease in absorbance due to $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ species (or increase in absorbance due to $(\eta^5\text{-}C_5R_5)Mn\ H(SiR'_3)(CO)_2$ species) was found to be first order in $(\eta^5\text{-}C_5R_5)Mn(CO)_2$. In both cases the kinetic results were interpreted in terms of the first-order rate law given in eq. [4].

Fig. 2. Changes in absorbance following the monitoring of the sample generated above showing the selected spectral changes following 8, 16, 27, 40, 56, 80, and 107 min.



$$[4]\quad \frac{-d\,[(\eta^5\text{-}C_5R_5)Mn(CO)_2]}{dt} = k\,[(\eta^5\text{-}C_5R_5)Mn(CO)_2]$$

The photolysis of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ in a $EtMe_2SiH$ glass at 90 K gave rise to absorption bands in the FTIR due to the $16e^-$ species, $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$, at 1942 and 1870 cm^{-1}, and an unassigned band at 1845 cm^{-1}. Two bands assigned to the oxidative addition product, $(\eta^5\text{-}C_5H_4Me)MnH(CO)_2(SiEtMe_2)$, appeared at 1968 and 1900 cm^{-1}. In a dilute trialkylsilane glass at 110 K (1:1 methylcyclohexane/$EtMe_2SiH$ mixture by volume at room temperature) photolysis resulted in bands due to $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$, at 1946 and 1876 cm^{-1}, and an unassigned band at 1847 cm^{-1}. The two CO bands assigned to the oxidative addition product appeared at 1972 and 1905 cm^{-1}.

The photolysis of $(\eta^5\text{-}C_5H_5)Mn(CO)_3$ in a methylcyclohexane–Et_2MeSiH glass at 125 K showed bands due to the $16e^-$ species, $(\eta^5\text{-}C_5H_5)Mn(CO)_2$, at 1954 and 1885 cm^{-1}, and two unassigned bands at 1868 and 1834 cm^{-1}. The origin of the unexplained bands was unclear; however, their intensity did not vary on the time scale of the kinetic run. Therefore, it was concluded that eq. [2] represented the net thermal chemistry of all the $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ ($R_5 = H_5$, Me_5, H_4Me) species studied. Relevant band positions for the compounds studied are summarized in Table 1.

For each of the systems studied, the photolysis of $(\eta^5\text{-}C_5R_5)Mn(CO)_3$ species in a dilute (50/50 v/v (289 K)) trialkylsilane–methylcyclohexane mixture or neat trialkylsilane (R'_3SiH) glass led to the loss of IR absorptions due to the starting complexes and the growth of new bands associated with the $16e^-$ species $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ and the oxidative addition product $(\eta^5\text{-}C_5R_5)Mn\ H(SiR'_3)(CO)_2$. It was not possible

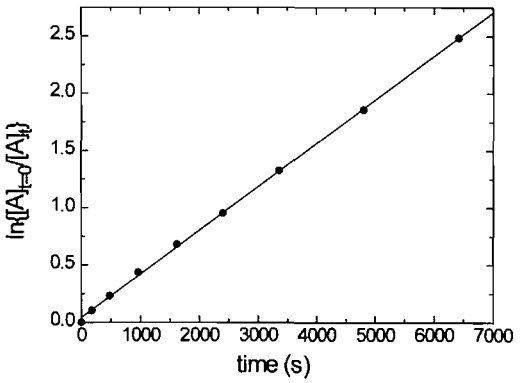
to see free CO (2132 cm^{-1}) in trialkylsilane (or a 1:1 trialkylsilane/methylcyclohexane mixture) glasses due to the overwhelming Si-H absorption. However, the stoichiometry of the photochemical loss of CO for the manganese complexes studied has been shown to be one mole of CO produced per mole of $(\eta^5\text{-}C_5R_5)Mn(CO)_3$ consumed (5). Although the direct monitoring of the increase or decrease in the CO absorption was not possible, it should be noted that photoproducts other than $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ were not, in general, detected. The two exceptions were in the monitoring of the $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$–$EtMe_2SiH$ and the $(\eta^5\text{-}C_5H_5)Mn(CO)_3$–$Et_2MeSiH$ systems. In these cases the intensity of the unassigned bands did not vary during the thermal reaction. It is interesting to note that previous workers (12) assigned bands in similar positions as due to a photogenerated monocarbonyl although it is unlikely that such a species would be stable under the conditions of this reaction. The calculated rate constants for reaction of trialkylsilanes with the $(\eta^5\text{-}C_5R_5)\text{-}Mn(CO)_2$ complexes are presented in Table 2.

Discussion

The photochemical loss of CO from $(\eta^5\text{-}C_5R_5)Mn(CO)_3$ to give coordinatively unsaturated species (eq. [1]) in low-temperature trialkylsilane and methylcyclohexane–trialkylsilane glasses is consistent with previous work (5–7). Unfortunately, the Mn-H stretch was not observed in the IR, consistent with it being much weaker than bands associated with the CO stretching (4). However, the formation of a two-band pattern in the IR (at higher frequency, relative to the unsaturated $16e^-$ species) concurrent with the disappearance of the two bands due to the intermediate was consistent with the oxidative addition of the trialkylsilane. The room temperature photolysis of each tricarbonyl–silane system resulted in the appearance of ^1H NMR peaks in the −14.0 to −12.0 ppm region consistent with the formation of metal hydrides (13). IR absorption spectra of all the oxidative addition products possess two, approximately equal intensity, CO absorption bands indicative of 90° OC-Mn-CO angles (based on arguments similar to those in ref. 14). Therefore, in agreement with earlier studies, each $(\eta^5\text{-}C_5R_5)Mn\ H(SiR'_3)(CO)_2$ complex is formulated as the *cis* isomer. This is consistent with the crystallographically determined structure of $(\eta^5\text{-}C_5H_4Me)MnH(SiMePhNp)(CO)_2$ (Np ≈ 1-$C_{10}H_7$), which has a 91.4° OC-Mn-CO angle, and $(\eta^5\text{-}C_5H_5)MnH(SiPh_3)(CO)_2$ with an 88.7° OC-Mn-CO angle (in the solid state), both prepared by photolysis of the appropriate tricarbonyl in the presence of trialkylsilane (15, 16). It should be noted that the oxidative addition of an Si—H bond to a transition metal center does not always result in complete Si—H bond breakage. The incomplete oxidative addition of an Si—H bond may be viewed as a two-electron three-center (M, Si, H) bond. Such an interaction has been observed, by neutron diffraction, in the complex $(\eta^5\text{-}C_5H_4Me)MnH(SiFPh_2)(CO)_2$ (17). Recent X-ray and neutron diffraction results, and ^{29}Si NMR studies to obtain the coupling constants J(SiMH), show that the extent to which the oxidative addition is complete is greater when there are electron-releasing ligands on M and (or) highly electron-withdrawing substituents (R′) on Si (15).

Fig. 3. A plot of $\ln\{[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2]_{t=0}/[(\eta^5\text{-}C_5H_4Me)Mn(CO)_2]_t\}$ against time for the experiment of Fig. 2.



The order of the reaction

The trialkylsilane concentration, for experiments conducted in a neat trialkylsilane glass, was not incorporated into the rate equation. The rate of a bimolecular reaction can be thought of as being dependent on two main factors; (*i*) the frequency of

[c]Insufficient data for statistical analysis.

collision between reacting molecules, and (*ii*) the collision energy (and geometry of the two species) being appropriate to surmount the activation barrier. Generally, for the case of gas phase reactions, the incorporation of reactant concentration is crucial. In gas phase reactions (assuming relatively low concentrations and pressure) there are a limited number of reactants and a great deal of empty space. Therefore, including the concentration of the reactive species is important in determining the rate of the reaction. Analogously, in solution, the inclusion of concentrations is important as a result of diffusional processes. However, in a neat trialkylsilane glass, clearly each $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ species is entirely surrounded by silane molecules. Therefore, the probability of each $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ molecule being surrounded by a sphere of silane molecules is unity. Hence, each collision that a $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ molecule undergoes is with a trialkylsilane molecule.

For kinetic experiments done in a 50/50 mixture of trialkylsilane/methylcyclohexane one cannot simply neglect the trialkylsilane concentration. The probability of a $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ species colliding with a trialkylsilane molecule, in a solvent mixture, cannot be assumed to be unity. In a neat trialkylsilane glass there is no doubt that the probability of the unsaturated species colliding with a trialkylsilane molecule is one. However, in a glass containing a mixture of two solvents the reduced probability of a $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ species colliding with a trialkylsilane molecule must be taken into consideration. In a 50/50 silane/methylcyclohexane mixture it is possible that, during the process of forming a glass, methylcyclohexane preferentially forms a coordination sphere around the $(\eta^5\text{-}C_5R_5)Mn(CO)_3$ molecules. However, this possibility does seem remote. The other extreme, which seems just as unlikely, is that in a 50/50 mixture the trialkylsilane preferentially forms a sphere around the tricarbonyl complex. The only workable assumption, and the one that was made, was that the $(\eta^5\text{-}C_5R_5)Mn(CO)_3$ molecules have a statistical ratio of trialkylsilane and methylcyclohexane surrounding them. The probability of $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ colliding with a trialkylsilane molecule would now be dependent on the concentration of trialkylsilane molecules surrounding the fragment.

Each of the rate constants was determined according to eq. [4]. Each of the rate constants in Table 2 is the result of dividing the observed rate by the silane concentration. The use of the silane concentration in cases where neat silane is utilized is expected to be a source of error. In spite of this limitation the relative correction provided by this procedure is perhaps the most appropriate procedure possible.

Analysis of the reaction energetics

For each $(\eta^5\text{-}C_5R_5)Mn(CO)_3$–$R'_3SiH$ system summarized in Table 2, the activation energy was determined using Arrhenius law. The activation parameters were determined from the slope and intercept of plots of $\ln(k)$ vs. $1/T$. For cases where rate constants were obtained in both neat silane glass and dilute silane–methylcyclohexane glass three sets of activation parameters were obtained. The first set of parameters was obtained from a plot of all the rate data for each silane. The second and third sets of activation parameters were obtained separately from plots of the data collected in neat silane and the dilute silane glass. All of these data are summarized in Table 3.

In a similar fashion, plots of $\ln(k/T)$ vs. $1/T$ were used to obtain the activation enthalpy and entropy from activated complex theory. The parameters obtained from the data collected in both neat and dilute silane, analyzed as above, are presented in Table 3.

The activation energies in Table 3, which include some literature data, cover a range of 44 kJ/mol. In cases where rate constants were determined in both neat and dilute glasses, two general cases were found. In the reaction of Et_2MeSiH with $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ no significant variation in the activation parameters was identified between the analysis of the individual data and the combined data. For the remainder of the data a significant variation was found between the activation energy in neat silane glass and in a mixed silane–methylcyclohexane glass. In each case the variation resulted in a lower activation barrier in the neat silane and a smaller preexponential factor. In terms of activated complex theory we have a lower activation enthalpy and a more negative entropy of activation in the neat silane glass.

In Fig. 4 a plot of the enthalpy of activation versus the entropy of activation is presented. When the measurements were made in different glasses the data for silane glass and for the silane–methylcyclohexane glass are given separately. All data points except for the data associated with the strongly electron-withdrawing $(\eta^5\text{-}C_5Cl_5)Mn(CO)_2$ fragment clearly define a free energy relationship. Such a correlation is indicative of an isokinetic relationship (IKR) (18,19). From the slope of the plot the isokinetic temperature is determined to be ca. 102 ± 6 K.

The presence of the free energy relationship is usually taken to indicate that all the reactions follow a similar mechanism, at least to the point of the rate-determining step. Perhaps of most significance within the data presented is that the reactions all fall along the same line. For example, the activation energy for reaction of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ with Et_2SiH_2 increased from 2 to 23 kJ/mol upon changing the media from neat silane to the silane–methylcyclohexane mixture. In spite of this change in glass both these points are in keeping with the free energy relationship. This indicates that a similar step is controlling the energetics of the reaction of these species in the different glasses.

Discussion of the oxidative addition reaction

The initial unsaturated complex formed upon CO extrusion is quickly solvated by the glassy medium. In neat silane, the solvent may coordinate through a C—H bond (eq. [5]). However, in dilute trialkylsilane the coordinating species could be methylcyclohexane (eq. [6]) or the trialkylsilane.

[5] $(\eta^5\text{-}C_5R_5)Mn(CO)_2 + HSiR_3 \longleftrightarrow (\eta^5\text{-}C_5R_5)Mn(CO)_2(HSiR_3)$

[6] $(\eta^5\text{-}C_5R_5)Mn(CO)_2 + MeC_6H_{11} \longleftrightarrow (\eta^5\text{-}C_5R_5)Mn(CO)_2(MeC_6H_{11})$

The reaction that was studied in this paper is the reaction of this solvated species with the silane to yield the oxidative addition product. According to the possible discrete solvated

[b]The solvent in these cases was methylcyclohexane (MCH).
[c]Insufficient data was obtained to provide a statistical estimate of the error.

systems described in eqs. [5] and [6], the oxidative addition reaction should be described according to eqs. [7] and [8].

[7] $(\eta^5\text{-}C_5R_5)Mn(CO)_2(HSiR_3) + HSiR_3 \longrightarrow (\eta^5\text{-}C_5R_5)MnH(SiR_3)(CO)_2 + HSiR_3$

[8] $(\eta^5\text{-}C_5R_5)Mn(CO)_2(MeC_6H_{11}) + HSiR_3 \longrightarrow (\eta^5\text{-}C_5R_5)MnH(SiR_3)(CO)_2 + MeC_6H_{11}$

The reaction energetics suggest that in methylcyclohexane-diluted glasses reaction [8] describes the dominant reaction observed kinetically. For example, the reaction with trialkylsilanes occurred with a ca. 9 kJ mol^{-1} higher barrier when the reaction was carried out in a hydrocarbon solvent. This suggests that the difference between the activation energies of eqs. [7] and [8] is associated with this different solvation (i.e., eqs. [5] and [6]). This allows one to surmise that the difference in solvation energies is on the order of 9 kJ mol^{-1} stronger for the methylcyclohexane than for the silane itself. Further evidence about the chemistry in the dilute glass is found from examination of the rate constants for reaction in the dilute glass. In Fig. 5 a plot of ln(k/T) vs. $1/T$ for the reactions of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ with various silanes in dilute glasses is given. The data fit a single line reasonably well with an activation enthalpy of 30 ± 2 kJ/mol and an activation entropy of −58 ± 2 J mol^{-1} K^{-1}). These activation parameters presumably apply primarily to the dissociation of the methylcyclohexane solvent according to the reverse of eq. [6].

While this simple explanation appears to account for the observations, we believe that it does not explain the data. This result is apparently inconsistent with the report based on photoacoustic calorimetry that indicates that solvation of $(\eta^5\text{-}C_5H_5)Mn(CO)_2$ with hydrocarbon is less stable than the solvation by silane (9).

Following the result of Burkey and co-workers (9), the solvation with hydrocarbon is less stable than the solvation with the silane. The differences in the apparent activation energetics must then be a result of the extent to which solvation must be lost prior to reaction. In the case of methylcyclohexane the limiting case is complete loss of the methylcyclohexane solvation prior to the oxidative addition reaction. This results in the barrier of ca. 30 kJ mol^{-1}. In the case of the silane adducts, while solvation is stronger, as demonstrated by Burkey and co-workers, only incomplete loss of the silane is required for the oxidative addition of the already coordinated silane to occur. In simple terms, eq. [5] is never reversed in the operation of eq. [7]. This indicates that eq. [7] does not require an additional silane and is best written as eq. [9].

[9] $(\eta^5\text{-}C_5R_5)Mn(CO)_2(HSiR_3) \longrightarrow (\eta^5\text{-}C_5R_5)MnH(SiR_3)(CO)_2$

The observation of the IKR is then due to the loss of solvation occurring to different extents in the different systems. In the case of systems with a low activation enthalpy and large negative activation entropy, such as Et_2SiH_2–$(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$, the reaction is an isomerism with a low barrier and a transition state that is highly ordered. This is consistent with an intermolecular isomerism. At the other extreme is the Et_3SiH–$(C_4H_4)Fe(CO)_2$ system, which apparently requires near complete loss of the silane from the coordination sphere.

Fig. 4. A plot of the enthalpy of activation versus the entropy of activation is presented for the reactions of silane with unsaturated metal fragments (data from Table 3).

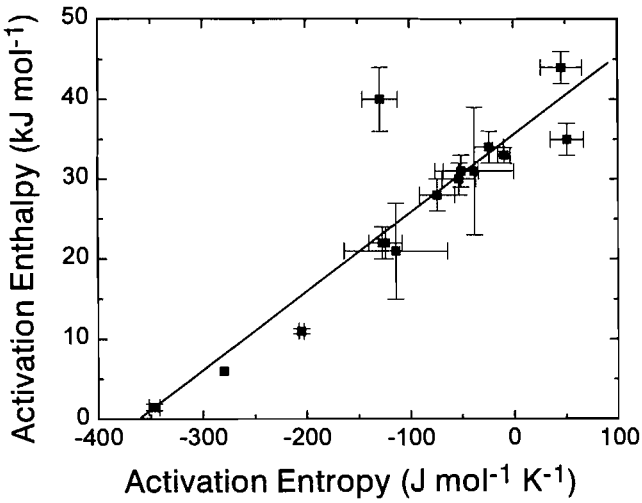

Fig. 5. A plot of $\ln(k/T)$ vs. $1/T$ for reaction of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ with various silanes in dilute glasses.

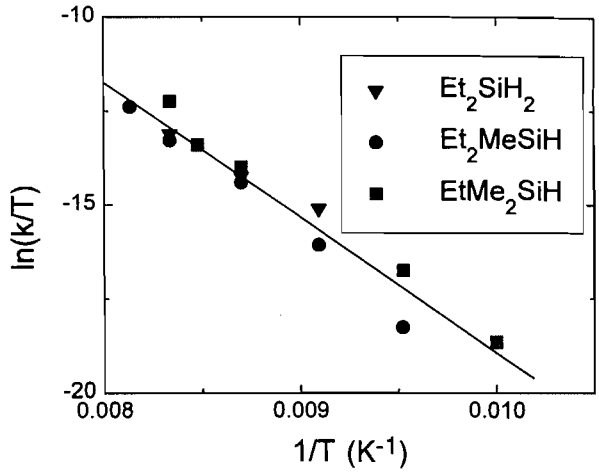

If solvent dissociation is the rate-limiting step, it is not surprising that the $(\eta^5\text{-}C_5Cl_5)Mn(CO)_2$–$Et_3SiH$ results could not be included in the full statistical analysis. The ability of the $(\eta^5\text{-}C_5Cl_5)Mn(CO)_2$ fragments to coordinate a solvent molecule should be much greater as a result of the electron-withdrawing nature of the $(\eta^5\text{-}C_5Cl_5)$ ligand. The $(\eta^5\text{-}C_5Cl_5)$ ligand should also affect the oxidative addition step. The calculated E_a value of 45 kJ mol^{-1} for the $(\eta^5\text{-}C_5Cl_5)Mn(CO)_3$–$Et_3SiH$ system is consistent with the enhanced ability of the $(\eta^5\text{-}C_5Cl_5)Mn(CO)_2$ fragments to strongly coordinate the silane molecule.

This interpretation of the data is also consistent with the general scheme presented by Yang and co-workers (11). The only modification required, and previously suggested by Burkey, is the inclusion of a silane-solvated dicarbonyl as a local minimum on the reaction coordinate. In the case of the $(\eta^5\text{-}C_5H_5)Mn(CO)_2$–$Et_3SiH$ discussed in that paper the difference between the local minimum in silane and in the hydrocarbon is not sufficiently different to be detectable.

Based on the above interpretation two points should be made. The first is that the intermediate dicarbonyl species for which spectroscopic data are presented are most likely solvated. The solvation does not provide a sufficient perturbation to allow us to spectroscopically assign silane or hydrocarbon solvation. The second point that must be considered is the use of a bimolecular rate constant for the interpretation of the reactions that occur according to eq. [9]. Equation [9] is unimolecular and k_{obs} would seem the appropriate rate constant to use for further work. However, to the extent that eq. [7] occurs, a bimolecular rate constant is required. The errors involved in the activation energy determinations are such that the differences imposed by the interpretation from k or k_{obs} are not significant.

Conclusions

The results of this study indicate that the oxidative addition of silane to photogenerated $(\eta^5\text{-}C_5R_5)Mn(CO)_2$ occurs through discrete processes dependent upon the nature of the reaction medium. In the absence of a solvent $(\eta^5\text{-}C_5R_5)Mn(CO)_2(HSiR_3)$ is the first intermediate formed following CO loss. This species undergoes an intramolecular rearrangement with incomplete loss of the silane. Where the reaction medium includes methylcyclohexane, $(\eta^5\text{-}C_5R_5)Mn(CO)_2(MeC_6H_{11})$ is formed. This species must undergo complete loss of the methylcyclohexane molecule in the oxidative addition step, resulting in a higher activation energy being observed for this process.

Experimental section

Instruments

Infrared spectral data were recorded by using a Bruker IFS 85 Fourier transform infrared spectrometer operating at 1 cm^{-1} resolution. ^{1}H NMR spectra were run on room temperature solutions using a Bruker SY100 NMR spectrometer. Chemical shifts are referenced to TMS. Irradiations were carried out by using the H_2O-filtered output (10 cm path length/Pyrex optics) from an Osram 100-W high-pressure Hg lamp. Low-temperature spectra were possible by means of a CTI Cryogenics model 22 cryocooler and a 350R compressor system equipped with a Lake Shore Cryotronics DRC 80C temperature controller. The temperature of the cell was monitored with a Lake Shore Cryotronics silicon diode sensor (DT500 DRC). The IR cell was constructed of high-conductivity copper and contained CaF_2 windows. The sample path length was 0.127 mm.

The trialkylsilane concentrations were corrected for solvent contraction associated with the lowering of the temperature. As a result of the experiments being conducted in the temperature range 70 –125 K, the volume of solvent was reduced considerably. In an effort to correct for the volume change, the percentage contraction was measured at 77 K. Both the neat trialkylsilane and the trialkylsilane–methylcyclohexane mixtures were measured for contraction. Neat trialkylsilane was placed in an NMR tube and the height of the meniscus was

Table 4. Percentage contraction of solvents at 77 K.

Solvent	% Contraction[a]

Compound	δ(Mn-H[a])
$(\eta^5\text{-}C_5H_4Me)MnH(SiEt_3)(CO)_2$	−13.50
$(\eta^5\text{-}C_5H_4Me)MnH(SiMeEt_2)(CO)_2$	−13.27
$(\eta^5\text{-}C_5H_4Me)MnH(SiMe_2Et)(CO)_2$	−13.09
$(\eta^5\text{-}C_5H_4Me)MnH(SiEt_2H)(CO)_2$	−12.63
$(\eta^5\text{-}C_5H_5)MnH(SiMeEt_2)(CO)_2$	−13.50
$(\eta^5\text{-}C_5Me_5)MnH(SiMeEt_2)(CO)_2$	−13.33
$(\eta^5\text{-}C_5Me_5)MnH(SiMe_2Et)(CO)_2$	−13.01

[a]Chemical shifts quoted, in ppm, relative to TMS.

measured. The NMR tube was then placed in a liquid nitrogen bath and allowed to equilibrate. Once the sample had equilibrated, at 77 K, the height of the meniscus was measured again and the percentage contraction calculated. The percentage contraction of the trialkylsilane–methylcyclohexane equal volume mixtures was measured in the same manner. Even though this method is not the most accurate method of measuring the solvent contraction, it is better than neglecting the volume contraction entirely. The percentage contraction for each solvent is summarized in Table 4, and the estimated error in the values is 10%.

Chemicals

The trialkylsilanes Et_3SiH, Et_2MeSiH, $EtMe_2SiH$, and Et_2SiH_2 were obtained from Petrarch Systems Inc. and used without further purification. The $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ was obtained from Alfa Products and used without further purification. The $(\eta^5\text{-}C_5H_5)Mn(CO)_3$ and $(\eta^5\text{-}C_5Me_5)Mn(CO)_3$ were purchased from Strem Chemicals and were recrystallized prior to their use.

Kinetic measurements

All the kinetic measurements were conducted similarly and a typical one will be described in detail. A 50/50 Et_2SiH_2/methylcyclohexane solution containing $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ was purged with N_2, and placed in a copper cell. The sample was then loaded into the cold head of the cryocooler, cooled to the appropriate temperature, and allowed to equilibrate. The solutions of $(\eta^5\text{-}C_5R_5)Mn(CO)_3$ (where $R_5 = H_5$, MeH_4, Me_5) were prepared so that the most intense absorption due to the CO ligands was between 0.2 and 1.0 (1×10^{-4} M). Subsequently, the sample was removed from the IR bench and photolyzed, using the Pyrex/water-filtered output (bandpass $\lambda > 313$ nm) of a high-pressure Hg lamp, so that approximately 15–20% of the $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$ was consumed and $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ was detected by FTIR. After photolysis the IR spectrum typically showed a mixture of $(\eta^5\text{-}C_5H_4Me)\text{-}Mn(CO)_3$, $(CH_3C_5H_4)$, and $(\eta^5\text{-}C_5H_4Me)Mn\,H(SiEt_2H)(CO)_2$. It should be pointed out that the relative amounts of these species depended on temperature and photolysis time. Generally, photolysis was conducted in 10 s intervals until the absorbance due to the intermediate was 0.1. After generating the $16e^-$ intermediate, FTIR spectra were then obtained as a function of time, in the dark, to monitor the disappearance of the $(\eta^5\text{-}C_5H_4Me)Mn(CO)_2$ and the formation of the oxidative addition product, $(\eta^5\text{-}C_5H_4Me)Mn\,H(SiEt_2H)(CO)_2$. Care was taken to ensure that the IR beam of the spectrometer did not accelerate the "dark" reactions between the $16e^-$ species and the trialkylsilane. For some of the experiments, the sample was left in the IR beam continuously. Duplicate experiments were conducted, in which the sample was placed in the IR beam only when spectra were collected. No beam-induced chemistry on the time scale of data acquisition was observed.

NMR analysis

A NMR characterization of the starting materials and their photo-generated oxidative addition products was conducted using a Bruker SY100 spectrometer. The typical procedure was as follows: To a 5 mm NMR tube containing approximately 0.5 mL of C_6D_6 was added 0.025 mL of Et_2SiH_2 and 0.003 mL of $(\eta^5\text{-}C_5H_4Me)Mn(CO)_3$. The NMR spectrum of the light yellow solution was obtained. The sample was then photolyzed for 1 min using the water-filtered (10 cm path length, Pyrex optics) output of a 100-W high-pressure Hg lamp. Another NMR spectrum was obtained and the sample was then photolyzed for an additional 5 min, whereupon a final NMR spectrum was obtained. Relevant chemical shifts are quoted in Table 5.

Synthesis, spectroscopic and structural studies of *O*-methyl and *O*-isopropyl monothiocarbonate (monoxanthate) derivatives of dimethyl- and diphenyltellurium(IV). Crystal structures of $Me_2Te[SCO_2(i\text{-}Pr)]_2$, $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, $Me_2TeCl[SCO_2Me]$, and $Me_2TeBr[SCO_2(i\text{-}Pr)]$

John E. Drake, Robert J. Drake, Layla N. Khasrou, Anil G. Mislankar, Raju Ratnani, and Jincai Yang

Abstract: Monothiocarbonate derivatives of diorganotellurium(IV), $R_2Te[SCO_2R']_2$, and $R_2TeX[SCO_2R']$, where R = Me, Ph; R′ = Me, i-Pr; X = Cl, Br, and I, have been prepared and characterized by vibrational and ^1H, ^{13}C, and ^{125}Te NMR spectroscopy. $Me_2Te[SCO_2(i\text{-}Pr)]_2$ (**2**): $P2_1/n$ (No. 14) with cell parameters a = 6.942(6) Å, b = 25.599(3) Å, c = 9.404(6) Å, β = 94.48(6)°, V = 1666(1) Å^3, Z = 4, R = 0.0648, R_w = 0.0624; $Ph_2Te[SCO_2(i\text{-}Pr)]_2$ (**4**): $P2_1/n$ (No. 14) with a = 12.360(4) Å, b = 12.277(3) Å, c = 15.066(3) Å, β = 102.82(2)°, V = 2229.1(9) Å^3, Z = 4, R = 0.0368, R_w = 0.0312; $Me_2TeCl[SCO_2Me]$ (**5**); $P2_1/c$ (No. 14) with a = 5.193(2) Å, b = 18.118(4) Å, c = 9.613(5) Å, β = 91.31(6)°, V = 904.2(6) Å^3, Z = 4, R = 0.0396, R_w = 0.0361; and $Me_2TeBr[SCO_2(i\text{-}Pr)]$ (**8**): $P2_1/n$ (No. 14) with a = 11.701(2) Å, b = 6.250(2) Å, c = 16.152(2) Å, β = 98.43(1)°, V = 1168.4(4) Å^3, Z = 4, R = 0.0369, R_w = 0.0325. In all molecules, the immediate environment about tellurium is that of the saw-horse structure in which the lone pair is assumed to be stereochemically active and occupying an equatorial position in a distorted trigonal bipyramid. In **2** and **5**, the terminal oxygen atoms are oriented toward tellurium, whereas in **4**, one O(i-Pr) group is oriented toward tellurium, as it is in **8**. In the latter cases, the terminal oxygen atoms act as weak bridges to form a pseudo dimeric species in **4** and a pseudo polymer in **8**. Supramolecular interactions in **2** and **5** lead to a sulfur-bridged dimer in the former and a chlorine-bridged polymer in the latter.

Key words: structure, tellurium, dimethyl, diphenyl, monothiocarbonates.

Résumé : On a préparé les dérivés monothiocarbonates des diorganotellure(IV), $R_2Te[SCO_2R']_2$ et $R_2TeX[SCO_2R']$ dans lesquels R = Me, Ph; R′ = Me, i-Pr; X = Cl, Br et I, et on les a caractérisés par les spectroscopies de vibration et de RMN du ^1H, du ^{13}C et du ^{125}Te. $Me_2Te[SCO_2(i\text{-}Pr)]_2$ (**2**) : $P2_1/n$ (No. 14) avec a = 6,942(6), b = 25,599(3) et c = 9,404(6) Å, β = 94,48(6)°, V = 1666(1) Å^3, Z = 4, R = 0,0648 et R_w = 0,0624; $Ph_2Te[SCO_2(i\text{-}Pr)]_2$ (**4**) : $P2_1/n$ (No. 14) avec a = 12,360(4), b = 12,277(3) et c = 15,066(3) Å, β = 102,82(2)°, V = 2229,1(9) Å^3, Z = 4, R = 0,0368 et R_w = 0,0312; $Me_2TeCl[SCO_2Me]$ (**5**) : $P2_1/c$ (No. 14) avec a = 5,193(2), b = 18,118(4) et c = 9,613(5) Å, β = 91,31(6)°, V = 904,2(6) Å^3, Z = 4, R = 0,0396 et R_w = 0,0361; $Me_2TeBr[SCO_2(i\text{-}Pr)]$ (**8**) : $P2_1/n$ (No. 14) avec a = 11,701(2), b = 6,250(2) et c = 16,152(2) Å, β = 98,43(1)°, V = 1168,4(4) Å^3, Z = 4, R = 0,0369 et R_w = 0,0325. Dans toutes les molécules, l'environnement immédiat du tellure correspond à une structure cavalière dans laquelle on suppose que la paire libre est stéréochimiquement active et qu'elle occupe une position équatoriale dans une bipyramide trigonale déformée. Dans les composés **2** et **5**, les atomes d'oxygène terminaux sont orientés vers le tellure, alors que dans le composé **4**, un groupe O(i-Pr) est orienté vers le tellure, comme c'est le cas dans le composé **8**. Dans ces derniers cas, les atomes d'oxygène terminaux agissent comme de faibles ponts conduisant à la formation d'espèces pseudo-dimériques dans le composé **4** et d'un pseudo-polymère dans le composé **8**. Des interactions supramoléculaires dans les

[Traduit par la rédaction]

Introduction

There have been a number of reports on the reactions of organotellurium(IV) compounds with a variety of 1,1-dithio ligands, such as *O*-alkyl dithiocarbonates (1–6), *N,N*-dialkyl dithiocarbamates (5–14), and *O,O*-dialkyl(alkylene) dithiophosphates (4–6, 14–21), as well as a recent extensive review of supramolecular associations in tellurium complexes with sulfur ligands (22). In general, the chemistry of monothio ligands has received much less attention but a few reports have appeared relating to main group element derivatives including those on monothiocarbamate compounds of thallium (23), tin (24, 25), and, most recently, tellurium (26) as well as on monothiophosphate compounds of tin (27, 28). No reports are evident on derivatives of monothiocarbonates (monoxanthates).

We report on the synthesis and characterization of a variety of diorganotellurium(IV) monothiocarbonates, $R_2Te[SCO_2R']_2$ and $R_2TeX[SCO_2R']$, where R = Me, Ph; R′ = Me, i-Pr; and X = Cl, Br, and I, and present the molecular structures of $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**, $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**, $Me_2TeCl[SCO_2Me]$, **5**, and $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**.

Experimental

Materials

$TeCl_4$, Me_4Sn, and COS gas were obtained from Aldrich. $TeBr_4$ and Me_2TeI_2 were obtained from Alfa and Organometallics, Inc., respectively. Ph_2TeCl_2 was prepared by the literature method (29) and Me_2TeCl_2 and Me_2TeBr_2 were prepared by an adaption of this method utilizing the reaction of $TeCl_4$ or $TeBr_4$ with Me_4Sn in toluene at 60°C under reflux for 4 h. The reactions were carried out under anhydrous conditions. All solvents were dried and distilled prior to use.

Preparation of the sodium salts of the *O*-alkyl monothiocarbonic acids

$NaSCO_2Me$ and $NaSCO_2(i\text{-}Pr)$

Sodium metal (approximately 1.0 g) was dissolved in dry methanol (20 mL) or isopropanol (25 mL) under nitrogen followed by the addition of dried benzene or toluene (5 mL). Sodium methoxide or isopropoxide was formed as a white slurry in the mixture accompanied by the evolution of hydrogen gas. Dry COS gas was then bubbled through the mixture for 15–20 min to give a white solid. The solvent and any unreacted alcohol were pumped off and the product washed with dichloromethane and left in the refrigerator for 1 day. The white solid formed was then washed with diethyl ether and dried under vacuum to give $NaSCO_2Me$: yield 81%. IR (cm^{-1}) distinctive features: 1592 vs, vbr, 1428 m, 1188 m, 1120 vs,br, 1040 m, 965 mw, 695 mw; Raman (cm^{-1}): 825 (100); or $NaSCO_2(i\text{-}Pr)$: yield 83%. IR (cm^{-1}): 1550 s, br, 1384 mw, 1371 m, 1186 s, 1086 s, br 973 m , 688 m; Raman (cm^{-1}): 830 (100). Both salts hydrolyse on exposure to the atmosphere.

Preparation of dimethylbis(*O*-methyl and *O*-isopropyl monothiocarbonato)tellurium(IV)

*$Me_2Te[SCO_2Me]_2$, **1**, and $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2***

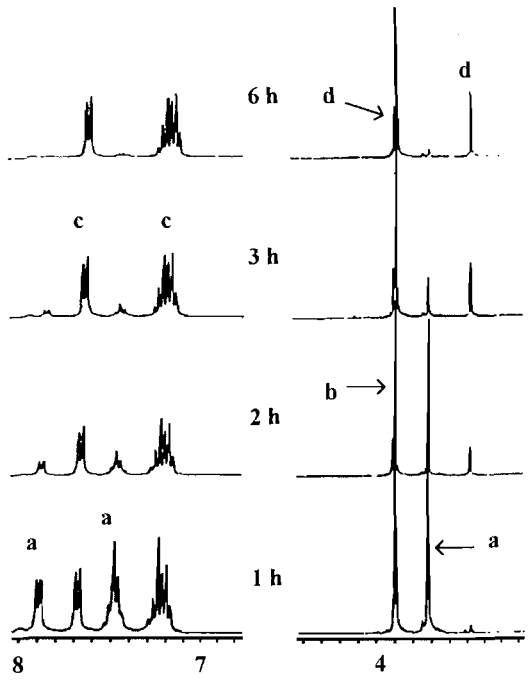
Typically, a slight excess of the dried sodium salt of *O*-isopropyl monothiocarbonic acid (0.278 g, 1.96 mmol) was added to a solution of dimethyltellurium dichloride (0.216 g, 0.94 mmol) in dried toluene (20 mL) and the mixture stirred for 2 h. The reaction mixture was filtered to remove NaCl and unreacted materials. The solvent was reduced to 5 mL under vacuum, *n*-hexane (approximately 5 mL) was added, and the solution was left overnight in the refrigerator at −6°C. The resulting precipitate was washed with *n*-hexane and dried under vacuum to give $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**: white crystals, mp 72–73°C, yield 87%. IR (cm^{-1}) main features: 1638 vs, 1150 vvs, 1091 vs, 843 s, 683 m; Raman (cm^{-1}): 547 [55], 537 [100], 315 [85]. Anal. calcd. for $C_{10}H_{20}O_4S_2Te$: C 30.33, H 3.56; found: C 30.69, H 3.42. Similarly, using $NaSCO_2Me$, $Me_2Te[SCO_2Me]_2$, **1** was formed: colorless crystals, yield 88.5%. IR (cm^{-1}) main features: 1648 s, 1262 s, 1126 vs, 1022 sh, 842 m, 638 s; Raman (cm^{-1}): 547 [45], 538 [75], 313 [100].

Preparation of diphenylbis(*O*-methyl and *O*-isopropyl monothiocarbonato)tellurium(IV)

*$Ph_2Te[SCO_2Me]_2$, **3**, and $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4***

Typically, a slight excess of the sodium salt of *O*-isopropyl monothiocarbonic acid (0.220 g, 1.55 mmol) was added to a solution of diphenyltellurium dichloride (0.262 g, 0.74 mmol) in dried toluene (20 mL). The color of the reaction mixture changed from colorless to yellow in a few minutes, but stirring was continued for 2 h to ensure complete reaction. The mixture was then filtered to remove NaCl and unreacted materials, before the volume of the solvent was reduced to approximately 5 mL under vacuum. Then *n*-hexane (approximately 5 mL) was added and the solution was left overnight in the refrigerator at −6°C. The crystals that formed were washed with *n*-hexane and dried under vacuum to give $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**: pale-yellow crystals, mp 99°C, yield 89%. IR (cm^{-1}) main features: 1653 s, 1149 vs, 1088 vs, 843 ms, 734 ms, 683 ms, 660 sh; Raman (cm^{-1}): 998 [55], 314 [100]. Anal. calcd. for $C_{20}H_{24}O_4S_2Te$: C 46.18, H 4.65; found: C 45.45, H 4.47. Attempts to isolate $Ph_2Te[SCO_2Me]_2$ in pure form using $NaSCO_2Me$, under similar conditions as described above, failed. Thus, an excess of $NaSCO_2Me$ (0.85 mmol) and Ph_2TeCl_2 (0.34 mmol) were added under nitrogen to dichloromethane or toluene (15 mL) and held for 10 min at −78°C. The unreacted materials and NaCl were filtered off and the ^1H NMR spectrum of the solution recorded immediately. Peaks assignable to $Ph_2Te[SCO_2Me]_2$, **3**, were predominant but peaks assignable to the diligand (Table 8) and Ph_2Te were also present even though the solution had been held at −78°C. The first-order rate constants at 295 K, $k_{295} = 3.45 \times 10^{-5}$ s^{-1}, apparent activation energy, $E_a = 41$ kJ mol^{-1}, and Arrhenius

Fig. 1. ^{1}H NMR spectrum of the decomposition of $Ph_2Te[SCO_2Me]_2$ taken after 1, 2, 3, and 6 h. Peaks due to $Ph_2Te[SCO_2Me]_2$, $[SCO_2Me]_2$, Ph_2Te, and $MeOSCO_2Me$ are labelled a, b, c, and d, respectively.



preexponential factor, $A = 6.0 \times 10^2$ s^{-1}. An example of a typical run is given in Fig. 1, which illustrates that additional decomposition occurs with two peaks of equal intensity appearing at 3.92 and 3.48 ppm, possibly attributable to $MeOSCO_2Me$. This requires the elimination of COS, and the infrared spectrum of the gas above the solution showed the strong parallel band centered at 2079 cm^{-1}, as well as weaker features at 859 and 527 cm^{-1}, attributable to COS.

Preparation of halodimethyl(*O*-methyl and *O*-isopropyl monothiocarbonato)tellurium(IV)

*$Me_2TeCl[SCO_2Me]$, **5**, $Me_2TeI[SCO_2Me]$, **6**, $Me_2TeCl[SCO_2(i\text{-}Pr)]$, **7**, $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**, and $Me_2TeI[SCO_2(i\text{-}Pr)]$, **9***

Typically, an equimolar amount of dried $NaSCO_2Me$ (0.078 g, 0.68 mmol) was added to a solution of Me_2TeCl_2 (0.158 g, 0.68 mmol) in dichloromethane (20 mL). The mixture was stirred for 2 h before being filtered to remove NaCl and unreacted materials. The solvent was removed under reduced pressure to yield the crude product, which was then recrystallized from a dichloromethane–*n*-hexane mixture to give $Me_2TeCl[SCO_2Me]$, **5**: white crystals, mp 78°C, 84% yield. IR (cm^{-1}) main features: 1655 ms, 1261 s, 1098 vs,br, 1024 sh, 864 mw, 634 vs; Raman (cm^{-1}): 543 [100 br], 319 [25]. Similarly, using $NaSCO_2(i\text{-}Pr)$ (0.160 g, 1.12 mmol) added to a solution of Me_2TeCl_2 (0.257 g, 1.12 mmol) in dichloromethane (20 mL), $Me_2TeCl[SCO_2(i\text{-}Pr)]$, **7** was formed: white crystals, mp 56–57°C, 84% yield. IR (cm^{-1}) main features: 1673 vs,br, 1150 vs, 1090 vs,br, 844 m, 673 m; Raman (cm^{-1}): 544 [60], 535 [100], 325 [90]. Anal. calcd. for $C_6H_{13}O_2SClTe$: C 23.08, H 4.20; found: C 22.72, H 4.32; In a similar fashion as just described for **5** and **7**, the reaction of equimolar amounts of $NaSCO_2Me$ or $NaSCO_2(i\text{-}Pr)$ with Me_2TeBr_2 or Me_2TeI_2 in dichloromethane gave $Me_2TeI[SCO_2Me]$, **6**: yellow viscous oil, 78% yield. IR (cm^{-1}) main features: 1655 s, 1264 vs, 1127 vs, 864 m, 647 ms; Raman (cm^{-1}): 521 [100 br], 315 [55]. $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**: pale-yellow crystals, mp 68–69°C, 86% yield. IR (cm^{-1}) main features: 1673 vs, 1153 vs, 1091 vs,br, 845 ms, 677 m; Raman (cm^{-1}): 539 [45], 527 [60], 325 [100]. Anal. calcd. for $C_6H_{13}O_2SBrTe$: C 20.20, H 3.67; found: C 20.52, H 3.77; and $Me_2TeI[SCO_2(i\text{-}Pr)]$, **9**: yellow crystals, 81% yield. IR (cm^{-1}) main features: 1674 s, 1155 s, 1091 s, 1020 sh, 843 ms, 677 w; Raman (cm^{-1}): 539 [45], 527 [60], 325 [100]. Attempts to obtain crystals of $Me_2TeI[SCO_2Me]$, **6**, failed. After 24 h at room temperature, the ^{1}H NMR spectrum of a solution of **6** showed peaks attributable to Me_2TeI_2, and the diligand, $[SCO_2Me]_2$, in approximately equimolar amounts and, after 36 h, these peaks dominated the spectra while two of equal intensity at 3.92 and 3.48 ppm had started to grow in. COS was also identified in the infrared spectrum of the vapour above the solution, as described above.

Preparation of chlorodiphenyl(*O*-methyl and *O*-isopropylmonothiocarbonato)tellurium(IV)

*$Ph_2TeCl[SCO_2Me]$, **10**, and $Ph_2TeCl[SCO_2(i\text{-}Pr)]$, **11***

Typically, an equimolar amount of dried $NaSCO_2Me$ (0.063 g, 0.55 mmol) was added to a solution of Ph_2TeCl_2 (0.195 g, 0.55 mmol) in dichloromethane (20 mL) held at 0°C and the mixture stirred for 1.5 h before being filtered to remove NaCl and unreacted materials. The solvent was removed under reduced pressure to yield $Ph_2TeCl[SCO_2Me]$, **10**: white solid, 82% yield. IR (cm^{-1}) main features: 1656 s,br 1266 m, 1189 sh, 1131 vs,vbr 1059 sh, 843 mw, 736 s, 683 s, 650 sh; Raman (cm^{-1}): 997 [100], 658 [35], 317 [15]. Similarly, using $NaSCO_2(i\text{-}Pr)$ (0.0620 g, 0.44 mmol) added to a solution of Ph_2TeCl_2 (0.154 g, 0.44 mmol) in dichloromethane (20 mL), $Ph_2TeCl[SCO_2(i\text{-}Pr)]$, **11** was formed: white solid, 87% yield. IR (cm^{-1}) main features: 1653 s, 1146 s, 1092 s, 843 ms, 737 ms, 686 ms, 678 ms; Raman (cm^{-1}): 998 [100], 657 [55], 320 [15]. Attempts at work-up to obtain X-ray quality crystals failed. The ^{1}H NMR spectrum of the solutions being used for recrystallization showed peaks attributable to Ph_2TeCl_2, Ph_2Te, and diligand in addition to those attributable to **10** and **11**.

Physical measurements

The elemental analyses were performed at Guelph Chemical Laboratories. Density measurements were performed by the flotation method. The infrared spectra were recorded on a Nicolet 5DX FT spectrometer as CsI pellets and the Raman spectra were recorded on a Ramanor U-1000 spectrometer using the 5145 Å exciting line of an argon ion laser with samples sealed in capillary tubes. The ^{1}H and ^{13}C NMR spectra were recorded on a Bruker 300 FT/NMR spectrometer in $CDCl_3$ using Me_4Si as internal standard. The ^{125}Te NMR spectra were recorded on a Bruker 200 FT/NMR spectrometer in $CDCl_3$ using Me_2Te as external standards as appropriate. The melting points were determined on a Fisher–Johns apparatus.

Table 1. Summary of crystallographic data, intensity collection, and structural refinement for $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**, $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**, $Me_2TeCl[SCO_2Me]$, **5**, and $Me_2TeBr[SCO_2(i\text{-}Pr)]_2$, **8**.

X-ray crystallographic analysis

White needle-like crystals of $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**, white block crystals of $Me_2TeCl[SCO_2Me]$, **5**, and yellow block crystals of $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**, and $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**, were sealed in thin-walled glass capillaries and mounted on a Rigaku AFC6S diffractometer, with graphite-monochromated Mo Kα radiation.

Cell constants and an orientation matrix for data collection, obtained from a least-squares refinement using the setting angles of 20 carefully centered reflections in the range $12.61 < 2\theta < 19.68°$ (for **2**), $12.70 < 2\theta < 15.67°$ (for **4**), $7.85 < 2\theta < 15.73°$ (for **5**), and $13.00 < 2\theta < 18.21°$ (for **8**) corresponded to monoclinic cells whose dimensions are given in Table 1. For **2**, **4**, and **8**, the systematic absences ($h0l$, $h+l \neq 2n$; $0k0$, $k \neq 2n$) are observed and for **5** they are ($h0l$, $l \neq 2n$; $0k0$, $k \neq 2n$). Based on statistical analyses of intensity distributions and the successful solution and refinement of the structures, the space groups were determined to be $P2_1/n$ (No. 14) for **2**, **4**, and **8**, and $P2_1/c$ (No. 14) for **5**.

The data were collected at a temperature of 23 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 50.0°. The ω scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.23° for **2** and **5**, 0.30° for **4**, and 0.29° for **8** with a takeoff angle of 6.0°. Scans of $(0.58 + 0.30 \tan\theta)°$ for **2**, $(1.05 + \tan\theta)°$ for **4**, and $(1.63 + 0.30 \tan\theta)°$ for **5** and **8** were made at a speed of 8.0 (**2** and **4**) and 32.0°/min (in ω) for **5** and **8**. The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of two rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. The diameter of the incident beam collimator was 0.5 mm, and the crystal to detector distance was 400.0 mm.

Of the 3401 (**2**), 4340 (**4**), 1844 (**5**), or 2395 (**8**) reflections that were collected, 3029 (**2**), 4141 (**4**), 1654 (**5**), or 2277 (**8**) were unique (R_{int} = 0.169 (**2**), 0.031 (**4**), 0.183 (**5**), or 0.031 (**8**)). The intensities of three representative reflections, which were measured after every 150 reflections, remained constant throughout data collection, indicating crystal and electronic stability (no decay correction was applied).

The linear absorption coefficient for Mo Kα is 20.36 cm^{-1} (**2**), 15.43 cm^{-1} (**4**), 37.57 cm^{-1} (**5**), and 60.73 cm^{-1} (**8**). An empirical absorption correction, based on azimuthal scans of several reflections, was applied, which resulted in transmission factors ranging from 0.38 to 1.00 (**2**), 0.90 to 1.00 (**4**), 0.554 to 1.00 (**5**) and 0.35 to 1.00 (**8**). The data were corrected for Lorentz and polarization effects.

The structures were solved by direct methods.[4] With the exception of the phenyl rings in compound **2**, which were constrained to a regular hexagon with C—C distances set at 1.40 Å and C-C-C angles at 120°, the non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in their idealized positions with C—H set at 0.95 Å and with isotropic thermal parameters set at 1.2 times that of the carbon

[4] G.M. Sheldrick. Crystallographic computing 3. *Edited by* G.M. Sheldrick, C. Kruger, and R. Goddard. Oxford University Press, Oxford, England. 1985. p. 175.

atom to which they were attached. The final cycle of full-matrix least-squares refinement[5] (30) was based on 921 (**2**), 2301 (**4**), 1001 (**5**), and 1170 (**8**) observed reflections ($I > 3.00\sigma(I)$) and 104 (**2**), 160 (**4**), 82 (**5**), and 100 (**8**) variable parameters, and converged (largest parameter shift was 0.003 times its esd) with unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.0648$ (**2**), 0.0368 (**4**), 0.0396 (**5**), and 0.0369 (**8**) and $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2)]^{1/2} = 0.0624$ (**2**), 0.0312 (**4**), 0.0461 (**5**), and 0.0325 (**8**).

The standard deviation of an observation of unit weight[6] was 2.00 (**2**), 1.39 (**4**), 1.69 (**5**), and 1.50 (**8**). The weighting scheme was based on counting statistics and included a factor ($p = 0.007$ (**2** and **5**), 0.008 (**4**), and 0.006 (**8**)) to downweight the intense reflections. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, $\sin\theta/\lambda$, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.87 and −0.88 e/Å^3, respectively, for **2**, 0.67 and −0.50 e/Å^3, respectively, for **4**, 0.61 and −0.86 e/Å^3, respectively, for **5**, and 0.61 and −0.65 e/Å^3, respectively, for **8**. Neutral-atom scattering factors were taken from Cromer and Waber (30). Anomalous dispersion effects were included in F_c (31); the values for $\Delta f'$ and $\Delta f''$ were those of Cromer (32). All calculations were performed using the TEXSAN (33) crystallographic software package of Molecular Structure Corp. Although the best data sets collected for **2** and **8** were less than ideal, satisfactory solutions of the structures were achieved.

The final atomic coordinates and equivalent isotropic thermal parameters (Tables 2, 3, 4 and 5) are given, respectively, for **2**, **4**, **5**, and **8** for the non-hydrogen atoms, and important distances and bond angles in Tables 6 and 7. The molecular structures of the four compounds are displayed as ORTEP diagrams. Tables of final fractional coordinates and thermal parameters of hydrogen atoms and anisotropic thermal parameters have been deposited.[7]

Calculation of Pauling bond order

The formula proposed by Pauling (34) for calculating the bond orders of partial bonds is given by $d_n - d = -0.60 \log n$, where d_n is the bond length for bond number n, and d is the length of the single bond of the same type. Based on the C—C single bond of 1.54 Å, Pauling's formula gives a bond length of 1.36 Å for $n = 2$; 1.72 Å for $n = 0.5$; and 1.90 Å for $n = 0.25$. These give percentage increases in bond length for the partial bonds of approximately 12 and 23%, respectively, for $n = 0.5$ and 0.25. It is reasonable to assume that similar relationships relating bond order to interatomic distances for the much longer secondary interactions or partial bonds involving Te and S should utilize percentage differences "normalized" to 1.54 as follows rather than absolute differences. Pauling's relationship, which can written as $n = 10^X$, where $X = (d - d_n)/0.6$, can be modified to allow for percentage differences "normalized" to 1.54 to give $X = [1.54(d - d_n)/d]/0.6$ or $X = 2.57(d - d_n)/d$. Based on a Te—S single bond length of 2.63 Å, typical calculated values of the lengths of Te--S partial bonds for various values of n are as follows: 2.63 Å ($n = 1.0$), 2.75 (0.75), 2.94 (0.50) 3.25 (0.25), and 3.66 Å ($n = 0.10$). Based on the assumption that the appropriate Te—Cl and Te—Br single bond lengths are those found in the corresponding Me_2TeX_2 compounds of 2.51 and 2.68 Å, respectively, for X = Cl, Br, then typical values of the lengths of Te--X partial bonds for various values of n are as follows: for Te--Cl, 2.51 Å ($n = 1.0$), 2.63 (0.75), 2.81 (0.50) 3.11 (0.25), and 3.51 Å ($n = 0.10$) and for Te--Br, 2.68 Å ($n = 1.0$), 2.80 (0.75), 3.00 (0.50) 3.32 (0.25), and 3.75 Å ($n = 0.10$). On the basis that a Te—O single bond length is 2.11 Å, then typical calculated values of Te--O partial bonds for various values of n are 2.11 Å ($n = 1.0$), 2.21 (0.75), 2.35 (0.50) 2.60 (0.25), and 2.92 Å ($n = 0.10$). These calculated values appear to be compatible with the sum of the van der Waals radii of Te and S (35).

Results and discussion

A cross section of dimethyl- and diphenyltellurium(IV) monothiocarbonate (monoxanthate) derivatives, $Me_2Te[SCO_2Me]_2$, **1**, $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**, $Ph_2Te[SCO_2Me]_2$, **3**, $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**, $Me_2TeCl[SCO_2Me]$, **5**, $Me_2TeI[SCO_2Me]$, **6**, $Me_2TeCl[SCO_2(i\text{-}Pr)]$, **7**, $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**, $Me_2TeI[SCO_2(i\text{-}Pr)]$, **9**, $Ph_2TeCl[SCO_2Me]$, **10**, and $Ph_2TeCl[SCO_2(i\text{-}Pr)]$, **11**, are prepared in 80–90% yields by the reaction of the appropriate dimethyl- or diphenyltellurium dihalide with the sodium salt of *O*-methyl or *O*-isopropyl monothiocarbonic acid in appropriate molar ratios in accord with the reactions

[1] $R'_2TeCl_2 + 2NaSCO_2R \rightarrow R'_2Te[SCO_2R]_2 + 2NaCl$
(R′ = Me, Ph; R = Me, i-Pr)

[2] $R'_2TeX_2 + NaSCO_2R \rightarrow R'_2TeX[SCO_2R] + NaX$
(X = Cl, Br, I)

All of the compounds are more susceptible to exposure to the atmosphere than is the case for their dithiocarbonate analogues (1, 36). The halogen derivatives are less soluble than the bis compounds in common organic solvents such as C_6H_6, CS_2, CCl_4, and $CHCl_3$. Only compounds **2**, **4**, **5**, and **8** could be recrystallized as X-ray quality crystals, **2** and **5** being white, and **4** and **8** pale yellow. In general, the Me_2Te derivatives are more stable in solution than the Ph_2Te analogues. Thus, the NMR spectra of the Me_2Te species **1**, **2**, **5**, **7–9**, and even **6**, which is the only derivative that is obtained as a viscous oil, show no signs of decomposition when run immediately after the solutions are formed. By contrast, for the Ph_2Te species **3**, **4**, **10**, and **11**, even the initial spectra of the solutions being used for recrystallization show additional peaks that can be

---

[5] Least-squares: Function minimized: $\Sigma w(|F_o| - |F_c|)^2$, where $w = 4F_o^2(F_o^2)$, $\sigma^2(F_o^2) = [S^2(C + R^2B) + (pF_o^2)^2]/(Lp)^2$, S = scan rate, C = total integrated peak count, R = ratio of scan time to background counting time, Lp = Lorentz-polarization factor, and $p = p$ factor.

[6] Standard deviation of an observation of unit weight: $[\Sigma w(|F_o| - |F_c|)^2/(N_o - N_v)^{1/2}$, where N_o = number of observations and N_v = number of variables.

attributed to the presence of diphenyltellurium and the diligand.

Thus by way of illustration, for $Ph_2Te[SCO_2Me]_2$, **3**, the reductive elimination to Ph_2Te and $[SCO_2Me]_2$ is already underway (*approximately* 40% decomposed) when the first spectrum is run after dissolution (see Fig. 1). The dissociation obeys first-order kinetics reasonably well with a half-life of only 5.5 h at room temperature and an apparent activation energy of 41 kJ mol^{-1}. By comparison, $Ph_2Te[S_2COEt]_2$ had a half-life of 22.9 h and an apparent activation energy of 57 kJ mol^{-1}. The reductive elimination is a general phenomenon for related compounds of this type but in additon, with these monothiocarbonates, COS is eliminated apparently from the diligand to give a species in solution whose NMR is consistent with the formulation $MeOSCO_2Me$.

The NMR spectra of the mixed halide derivatives indicate that their decomposition initially involves disproportionation to the dihalide and bis derivative, with the latter then immediately undergoing reductive elimination.

The crystal structures of $Me_2Te[SCO_2(i\text{-}Pr)]_2$, 2, $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, 4, $Me_2TeCl[SCO_2Me]$, 5, and $Me_2TeBr[SCO_2(i\text{-}Pr)]$, 8

Dimethylbis(*O*-isopropyl monothiocarbonato)tellurium(IV), **2**, and diphenylbis(*O*-isopropyl monothiocarbonato)tellurium(IV), **4**, both crystallize in the space group $P2_1/n$. The ORTEP diagrams (Figs. 2 and 3) illustrate that for both molecules the immediate environment about tellurium can be described as the saw-horse structure typical of tellurium(IV) compounds in which the lone pair is apparently stereochemically active and occupying an equatorial position in a distorted trigonal bipyramid, approximately in the position of the Te1 label. The two carbon atoms of the methyl or phenyl groups occupy the other two equatorial positions with the axial positions being occupied by the sulfur atoms of the monothiocarbonate (monoxanthate) groups. As can be seen from Table 6, the Te—C bond lengths are essentially the same in **2** and **4** (avg. 2.10(3) and 2.115(7) Å, respectively), which is a common feature in diorgano-tellurium(IV) compounds with sulfur ligands (1–21) but is in contrast to Te—C bonds in general where the mean Te—C(aromatic) bond length, 2.116 Å, is shorter than that of Te—C(alkyl), 2.158 Å (37). In the corresponding xanthate derivatives, $Me_2Te[S_2COEt]_2$ and $Ph_2Te[S_2COEt]_2$, the Te—C bond lengths are also similar, 2.12(5) and 2.1339(9) Å, respectively (1).

The S-Te-S angles of 169.9(6)° and 168.10(6)° in **2** and **4**, respectively, are very similar to those reported for $Me_2Te[S_2COEt]_2$, $Ph_2Te[S_2COEt]_2$, $Me_2Te[S_2CNMe_2]_2$, and $Me_2Te[SCONMe_2]_2$ (1, 12, 26) so the slight distortion from linear appears to be independent of whether the organic sub-

[a]Symmetry equivalent position (x, 1/2 − y, z − 1/2) is denoted by a prime and (3/2 − x, y − 1/2, 3/2 − z) by double prime.

stituent on tellurium is methyl or phenyl, or whether a monothio or dithio group is axial. In $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**, the Te(1)—S(1) bond is distinctly longer, 2.662(8) Å, than the Te(1)—S(2) bond, 2.569(8) Å. The sulfur atom associated with the longer bond is 3.663(7) Å from the tellurium atom of an adjacent molecule and this is the only intermolecular contact that is less than the sum of the van der Waals radii of 3.86 Å. The same phenomenon was found in the related dithiocarbonate, $Me_2Te[S_2COEt]_2$, where the Te—S bonds were 2.667(2) and 2.590(2) Å, and a Te--S intermolecular contact of 3.814(2) Å was associated with the longer Te—S bond. Although a distance of 3.633(7) Å corresponds to a Pauling partial bond order of only 0.10, it may be of significance because in $Ph_2Te(SCO_2(i\text{-}Pr)]_2$, **4**, where there are no secondary interactions, the two Te—S bond lengths are similar, with an average value of 2.624(8) Å, which is close to the value of 2.62(2) Å found in $Ph_2Te[S_2COEt]_2$, which also has no secondary Te--S intermolecular interactions (1). In both of the dithiocarbonates, $Me_2Te[S_2COEt]_2$ and $Ph_2Te[S_2COEt]_2$, the second S atom was oriented toward the Te atom at distances ranging from 3.265(2) to 3.336(2) Å, which correspond to Pauling partial bond orders of approximately 0.23. When these sulfur atoms are included in the coordination sphere, the orientation of the atoms about tellurium in $Me_2Te[S_2COEt]_2$ can be described as a pseudo pentagonal bipyramid. In similar fashion, the terminal oxygen atoms of the monoxanthate groups in $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**, are oriented toward tellurium at an average Te--O distance of 3.05(8) Å, and the alkoxy groups are oriented away from tellurium at an average Te--O(i-Pr) distance of 4.50(7) Å. Te--O distances of 3.05 Å, which were also observed for the terminal oxygen atoms in the related monothiocarbamate derivative, $Me_2Te[SCONEt_2]_2$

Fig. 2. ORTEP plot of the molecule $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms are omitted for clarity.

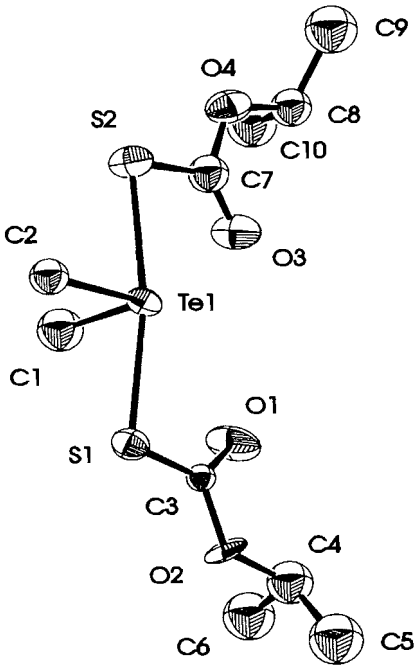

Fig. 3. ORTEP plot of the molecule $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms are omitted for clarity.

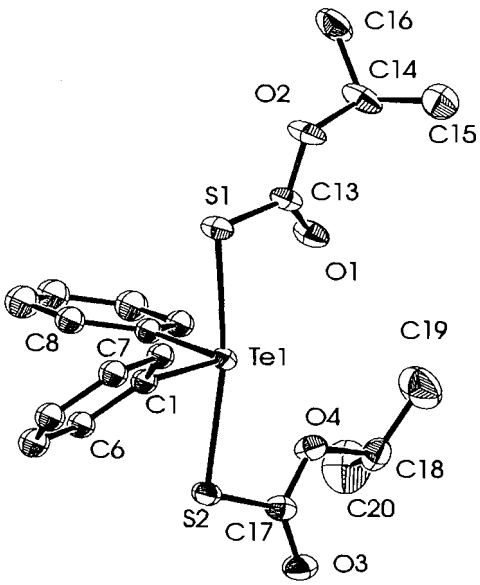
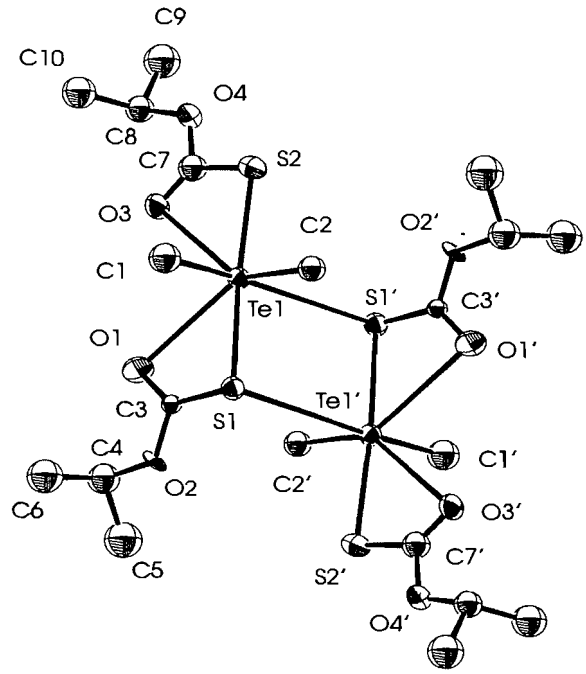


(26), correspond to a Pauling partial bond order of only 0.07, which is closer to the bond order of weak Te--S *inter*molecular interactions rather than Te--S *intra*molecular interactions. Nevertheless, if the weak interactions are included in the coordination sphere, then S(1), S(2), C(2), O(1), and O(3) form a pentagonal plane (mean deviation from plane is 0.032) with Te(1) just below the plane (0.109 Å). The second methyl group

Fig. 4. ORTEP plot of molecules of $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**, with both intra- and intermolecular associations shown leading to a dimeric species. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms are omitted for clarity.



takes up one axial position with C(1) at 1.943 Å above the plane. The intermolecular Te--S bond occupies the other axial position to give a C(1)-Te(1)--S(1)′ angle of 172.0(9)°, which is less distorted from linear than the S(1)-Te(1)-S(2) angle. The resulting approximately rectangular bridge system, with Te(1)-S(1)--Te(1)′ and S(1)-Te(1)--S(1)′ angles of 94.2(2)° and 85.8(2)°, respectively, is seen in Fig. 4 and results in a Te--Te′ distance within the pseudo dimer of 4.659(4) Å. This is essentially the same as was observed in $Me_2Te[SCONEt_2]_2$, where the Te--Te′ distance was 4.575(1) Å. Thus the environment about tellurium in the dimer can be described as that of a distorted pentagonal bipyramid.

By contrast, in $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**, there is no Te--S secondary interaction and both monothiocarbonate groups are not oriented in the same fashion. One group is oriented as in **2**, with a similar Te--O(terminal) distance of 3.051(5) Å, but the second group is turned around so that the oxygen atom of the O(i-Pr) group is now pointed toward tellurium at a similar distance of 3.150(5) Å, and in such a manner that S(1), S(2), C(1)phenyl, O(1), and O(4)alkoxy form a pentagonal plane (mean deviation from plane is 0.057) with Te(1) just below the plane (0.045 Å) and C(7) of the second phenyl group directly above it (2.043 Å). The two planar SCO_2 cores of the monoxanthate groups have a dihedral angle of 21.2(2)°, which is virtually the same as the 20.4(2)° angle found for the SCON planar cores in $Me_2Te[SCONEt_2]_2$ and similar to the 13.5(2)° found in **2**. However, the terminal oxygen atom, which is oriented away from tellurium, is involved in a Te--O intermolecular interaction of a similar distance, 3.260(6) Å, to give a virtual dimer (Fig. 5) in which the Te--Te″ distance of 6.021(1) Å is considerably larger than in **2** or $Me_2Te[SCONEt_2]_2$. When the Te--O intermolecular interac-

Fig. 5. ORTEP plot of molecules of $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**, with both intra- and intermolecular associations shown leading to a dimeric species. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms are omitted for clarity.

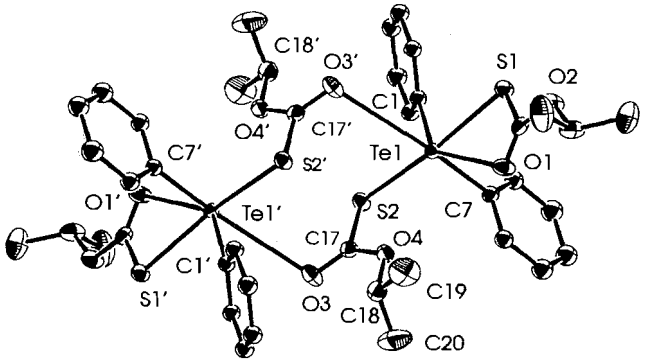


Fig. 6. ORTEP plot of the molecule $Me_2TeCl[SCO_2Me]$, **5**. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms are omitted for clarity.

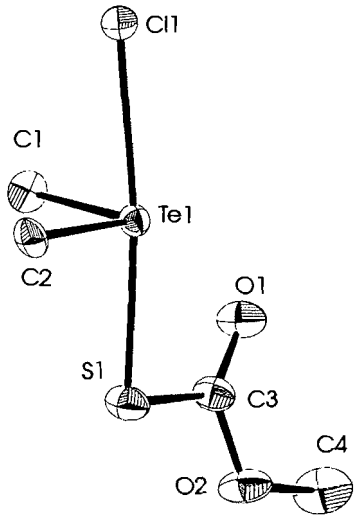
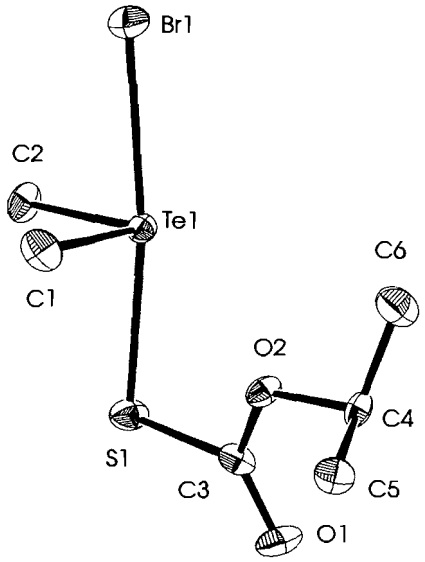


tion is included in the coordination sphere, the environment around Te in **4** becomes that of a distorted pentagonal bipyramid with the axial positions occupied by a phenyl group and the intermolecular terminal oxygen atom to give a C(7)-Te(1)--O(3)″ angle of 169.5(2)° that is no more distorted from linear than the S(1)-Te(1)-S(2) angle.

Chlorodimethyl(*O*-methyl monothiocarbonato)tellurium-(IV), **5**, and bromodimethyl(*O*-isopropyl monothiocarbonato)tellurium(IV), **8**, crystallize in the space groups $P2_1/c$ and $P2_1/n$, respectively. The ORTEP diagrams (Figs. 6 and 7) illustrate that the immediate environment about tellurium can yet again be described as the saw-horse structure typical of tellurium(IV) compounds in which the lone pair is apparently stereochemically active and occupying an equatorial position in a distorted trigonal bipyramid, approximately in the position of the Te1 label. The two methyl groups occupy the other two equatorial positions with the axial positions being occupied by the halogen atom and the sulfur atom of the monothiocarbonate group. It is also clear from the two ORTEP diagrams that the terminal oxygen atom is oriented toward tellurium in $Me_2TeCl[SCO_2Me]$, **5**, with a Te(1)—O(1) distance of 2.984(8) Å (Fig. 7), whereas in $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**, the oxygen atom of the alkoxy group is the one oriented toward tellurium (Fig. 8) with the Te(1)—O(2) distance of 2.930(6) Å being similar. As can be seen from Table 7, the Te—C bond lengths in **5** are slightly shorter than in **8**, and are closer to the value in **2** where both terminal oxygen atoms are oriented toward tellurium. However, the differences are close to the error limits and the C-Te-C bond angles show no particular trends for all four molecules.

Fig. 7. ORTEP plot of the molecule $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**. The atoms are drawn with 30% probability ellipsoids. Hydrogen atoms are omitted for clarity.



The X-Te-S angles of 173.1(1)° and 172.68(8)° in **5** and **8**, respectively, are similar to those reported for the analogous monothiocarbamates, $Me_2TeCl[SCONEt_2]$ and $Me_2TeBr[SCONEt_2]$ (26). The Te—S bond lengths in **5** and **8** are shorter than even the shorter of the two Te—S bonds in the bis analogues, **2** and **4**, and correspond to bond orders of 1.37 and 1.22, if the average Te—S bond length in the bis species is taken as corresponding to a bond order of 1.0. Correspondingly, the Te—Cl and Te—Br bonds, 2.703(3) and 2.796(2) Å, respectively, are distinctly longer than in α-Me_2TeCl_2, 2.51(3) Å (38), Me_2TeBr_2, 2.67(4) Å, or Ph_2TeBr_2, 2.682(3) Å (39), to give bond orders of 0.63 and 0.78, respectively, which are slightly higher than found for the corresponding monothiocarbamates, $Me_2TeX[SCONEt_2]$. In the latter compounds, the halogen atoms have an intermolecular association with an adjacent tellurium atom to form unsymmetrical Te-X--Te′ bridges in which the X-Te--X′ and Te-X--Te′ angles are close to 90°. The resulting dimeric species with four-center rectangular bridges have Te--Te′ distances of 4.381(1) and 4.556(2) Å, respectively, for $Me_2TeX[SCONEt_2]$, where X = Cl and Br, respectively. Surprisingly, the closest Te--Te distances in **5** and **8** are 5.7974(8) and 6.2496(2) Å, respectively, indicating that similar four-center bridges are not formed with these monothiocarbonates.

Fig. 8. ORTEP plot of a sequence involving the molecule $Me_2TeCl[SCO_2Me]$, **5**, with both intra- and intermolecular associations shown leading to a polymeric chain. The atoms are drawn with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity.

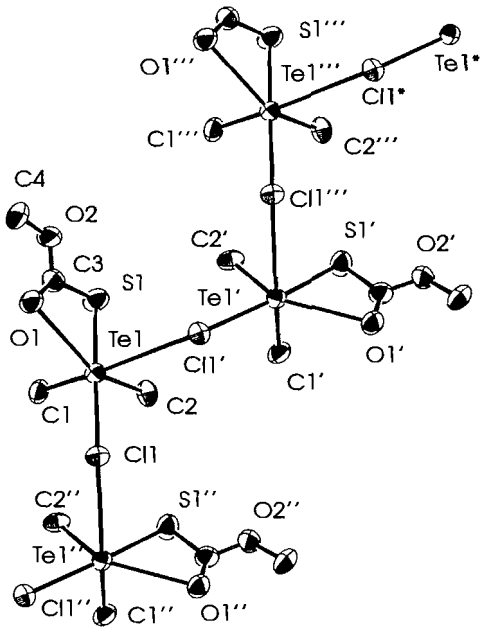


Fig. 9. ORTEP plot of a sequence involving the molecule $Ph_2TeBr[SCO_2(i\text{-}Pr)]$, **8**, with both intra- and intermolecular associations shown leading to a polymeric species. The atoms are drawn with 50% probability ellipsoids. Hydrogen atoms are omitted for clarity.

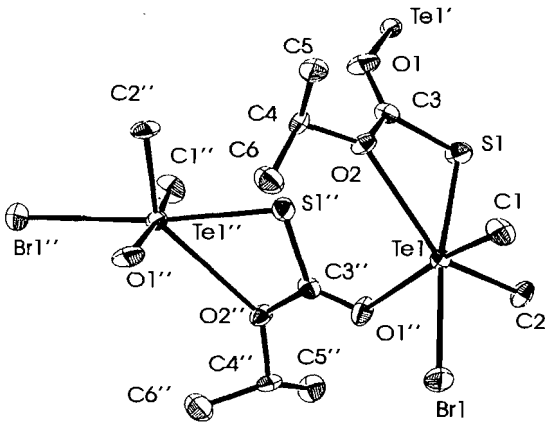

In $Me_2TeCl[SCO_2Me]$, **5**, there is a Te--Cl intermolecular interaction of 3.494(3) Å, which corresponds to a bond order of 0.10 and which is similar to the corresponding interaction in $Me_2TeCl[SCONEt_2]$. However, rather than a Te-Cl--Te′ angle of 89.22(5)° as found in the latter, the angle is 138.3(3)° in **5**, which results in the formation of a zigzag chain rather than a dimer, as can be seen in Fig. 8. The Te--Cl′ interaction is *trans* to a Te–methyl bond at a C(1)-Te(1)--Cl(1)′ angle of 166.3(3)° in a distorted octahedral environment about tellurium. There are no comparable intermolecular interactions involving the bromine atom in $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**. However, as in **4**, the terminal oxygen atom, which is oriented away from the tellurium center, is only 3.097(3) Å away from an adjacent tellurium atom and this Te--O intermolecular interaction appears to fulfil the function of the chlorine atom in **5** because it is now *trans* to a Te–methyl bond at a C(1)-Te(1)--O(1)″ angle of 174.8(3)° in a distorted octahedral environment about tellurium, as can be seen in Fig. 9. The lack of Te--Br interactions is surprising because in Me_2TeBr_2 there are two intermolecular interactions with Te--Br distances of 3.560 (4) and 3.661 (4) Å, which are associated with the longer of the two Te—Br bonds, and in Ph_2TeBr_2 the closest such interaction reported is 3.93 Å (39), yet the shortest secondary Te--Br contact in **8** of 4.833(2) Å is considerably longer than the sum of the van der Waals radii. Te--X associations are extensive and in, for example, a series of R_2TeCl_2 compounds with different R groups (36, 38, 40–42), Te--Cl interactions are consistently found (43), with the exception of $(p\text{-}BrC_6H_4)_2TeCl_2$ where Te--Br interactions of 3.71 and 3.80 Å replace those expected for Te--Cl (43). Thus the absence of Te--Br associations in **8** supports the conclusion that even the weak Te--O interactions found in these monoxanthate derivatives are important in establishing the molecular arrangements in the solid state.

Within the four structures described, there are changes involving the orientations of the monoxanthate groups, the intermolecular interactions, the nature of the R groups on tellurium or in the monoxanthate, and different halogen atoms substituting for one of the monoxanthate groups. Despite these variations, the bite angle S—Te--O remains essentially constant regardless of whether the oxygen is terminal or alkoxy, at an average of 54.9(14)° with a S--O bite distance averaging 2.62(3) Å. Further, the bond lengths and angles within the planar SCO_2 core remain relatively unchanged. The SCO(R) angles are consistently distinctly smaller, 112(3)° on average, than the OCO and SCO(terminal) angles, 123(4)° and 125(2)° on average, respectively. The angles are consistent with π-bond character being less significant in the C—OR bonds than in the corresponding C—NR_2 bonds in the monothiocarbamates where the average $SCN(R_2)$ angle was closer to 120°, at 116.8(8)° (26). The C=O(terminal) bonds are, as expected, considerably shorter, 1.21(4) Å on average for all four molecules, than the C—O(alkoxy) bonds at an average of 1.338(8) Å. They are also slightly shorter than those in the monothiocarbamates, yet within values for other C=O bonds involved in secondary interactions (44).

Infrared and Raman spectra

In many respects, given that we have crystal structures of bis and halo derivatives, the vibrational spectra are disappointingly uninformative. In general, these monothiocarbonates appear to be relatively poor scatterers and the quality of the Raman spectra is very variable so that no attempt has been made at extensive assignments. However, certain characteristic features are clearly evident and these are provided in linear form for each compound in the experimental section.

As was to be expected from the vibrational spectra of the related dithiocarbonate (1), dithiocarbamate (7, 8, 12), and monothiocarbamate derivatives (26), three peaks arising primarily from the stretching vibrations of the monothiocarbonate core dominate the infrared spectra of compounds **1–11** in the 1700–1000 cm^{-1} region. These are similar, though not

[a]The spectra were recorded in $CDCl_3$ and reported in ppm from Me_4Si.
[b]Number of protons and multiplicities are in parentheses (s = singlet; d = doublet; sept = septet, m = multiplet).
[c]Coupling constants in Hz shown in square brackets [ ].
[d]Peaks attributable to the corresponding diligands are seen at 3.91 (s) for $[SCO_2Me]_2$ and at 5.14 (1 H, sept) and 1.31 (6 H, d) for $[SCO_2(i\text{-}Pr)]_2$.

identical, in appearance to corresponding peaks in the starting salts and are generally much stronger and broader than any peaks in the region associated with vibrations attributable to methyl, isopropyl, or phenyl groups. The positions of the peaks indicate that the major contributions involve stretching of the three C—O bonds. Thus, for example, in all of the species containing the SCO_2(i-Pr) moiety, **2**, **4**, **7–9**, **11**, the three peaks are seen at 1638–1674 (mainly C=O stretching), 1146–1155 (mainly C–O stretching), and 1088–1092 cm^{-1} (mainly O–$CH(CH_3)_2$ stretching). In the species containing the SCO_2Me moiety, **1**, **3**, **5**, **6**, **10**, the corresponding peaks are seen at 1638–1656, 1261–1266, and 1098–1131 cm^{-1} (mainly O–CH_3 stretching). The differences probably arise in that mixing with the OCH_3 rocking modes is significant in the latter case as was noted for the $Me_2TeX[S_2COMe]$ derivatives (45). The positions of these three modes may also be compared with those in methylacetate where the assignments are 1768 (C=O stretching), 1268 (C–O stretching), and 1049 cm^{-1} (O–CH_3 stretching). Thus, the proposed assignments are consistent with the assumption that these modes primarily involve the stretching of the C—O bonds but the modes are probably mixed and no doubt involve contributions from S–C stretching as well as from OCH and, in particular, OCH_3 rocking. The fourth stretch of the SCO_2C core is seen between 634 and 683 cm^{-1}, which is the region typical of a single-bonded C–S stretching vibration, and is at lower frequency than in the salts where the C—S bond would have more partial π-bond character. In the Ph_2Te compounds, **3**, **4**, **10**, **11**, the characteristic *f*-phenyl and *v*-phenyl modes, which are both of similar intensity, are observed at ca. 735 and 685 cm^{-1}. As a result, the fourth stretching vibration is normally only observed as a shoulder on the *v*-phenyl mode at 650–660 cm^{-1}. The Raman spectra of the Me_2Te compounds, **1**, **2**, **5**, **6**, **7**, **8**, and **9**, all show peaks of high relative intensity that correspond to the asymmetric and symmetric Te–CH_3 stretching vibrations in similar, though not identical, relative intensities and positions as have been reported for the dihalides, Me_2TeX_2, where X = Cl, Br, and I (46). This is consistent with the C-Te-C bond angles and distances being similar in all species. Unfortunately, as indicated above, the Raman spectra are of such variable quality that, in contrast to the situation with the corresponding halomonothiocarbamates (26) and halodithiocarbonates (45), specific assignments below 400 cm^{-1} to Te–S stretching vibrations and, in particular, to the Te–X stretching vibrations, which are expected in the region below 250 cm^{-1}, cannot be made with confidence.

Nuclear magnetic resonance spectra

The ^{1}H NMR spectral data for compounds **1–11** are presented in Table 8. The methyl group directly attached to tellurium is seen as a sharp singlet at 2.58 and 2.56 ppm, respectively, for $Me_2Te[SCO_2Me]_2$, **1**, and $Me_2Te[SCO_2(i\text{-}Pr)]_2$, **2**. These values for the TeCH_3 chemical shifts are essentially the same as the corresponding bis dithiocarbonate derivatives (1) and slightly larger than those of the bis monothiocarbamates (26). A small, but essentially stepwise, increase is seen in TeCH_3 for $Me_2TeCl[SCO_2Me]$, **5**, compared to $Me_2TeI[SCO_2Me]$, **6**, 2.85 and 2.93 ppm, respectively, and along the series

Table 9. ^{13}C and ^{125}Te NMR chemical shifts for the dimethyl-, diphenyl-, halodimethyl-, and halodiphenyltellurium monothiocarbonates **1–11**.[a]

Compounds	Te-*C*	O-*C*	OC-*C*	SO*C*O	^{125}Te

[a]The spectra were recorded in $CDCl_3$ and reported in ppm from Me_4Si for ^{13}C and from Me_2Te for ^{125}Te.

$Me_2TeCl[SCO_2(i\text{-}Pr)]$, **7**, $Me_2TeBr[SCO_2(i\text{-}Pr)]$, **8**, and $Me_2TeI[SCO_2(i\text{-}Pr)]$, **9**, 2.82, 2.86, and 2.92 ppm, respectively, as one of the monothiocarbonate groups is replaced by Cl, Br, or I. This was also observed in the Me_2TeXL series, where X = $SCONEt_2$ and $SCON(CH_2)_3CH_2$ (26). Changes in the chemical shifts of methyl groups have been related to changes in the electronegativity of the groups attached to the central atom, and the slightly larger shift towards the values observed for Me_2TeCl_2, Me_2TeBr_2, and Me_2TeI_2, of 3.13, 3.26, and 3.27 ppm, respectively, is consistent with the effective electronegativity of the monothiocarbonate being slightly greater than the monothiocarbamate. In the spectra of the bis-substituted diphenyltellurium derivatives $Ph_2Te[SCO_2Me]_2$, **3**, and $Ph_2Te[SCO_2(i\text{-}Pr)]_2$, **4**, the phenyl protons are seen as a pair of multiplets in the regions 7.91–7.87 and 7.50–7.40 ppm with intensities corresponding to 4H and 6H, respectively, as is to be expected for the *meta* and *ortho/para* protons. There is a typical small upfield shift in the corresponding chloro-substituted derivatives, $Ph_2TeCl[SCO_2Me]$, **10**, and $Ph_2TeCl[SCO_2(i\text{-}Pr)]$, **11**.

The relative intensities of the peaks associated with the monothiocarbonate groups are as expected for the formulation of the compounds. The values of the chemical shifts within the monothiocarbonate groups of all of the compounds are found to be similar, though not identical, to each other and to those of the appropriate salts, $NaSCO_2Me$ and $NaSCO_2(i\text{-}Pr)$, from which they were prepared. Thus, there are no significant trends as a result of being linked to tellurium, let alone as a result of changing the organo group or halogen attached to tellurium as illustrated by the fact that in all of the compounds, **2**, **4**, **7**, **8**, **9**, and **11**, the C*H* signal is seen as a septet in the range 5.04–5.00 ppm and the CH_3 signal as a doublet of six times the intensity in the range 1.25–1.21 ppm.

The ^{13}C NMR spectral data for compounds **1–11** are displayed in Table 9. The peaks attributable to the organo groups in the monothiocarbonates again are seen at positions close to those found in the starting salts. However, although the SCO_2R chemical shifts are similar for all 11 compounds, covering the range 170.67–174.68 ppm, they are considerably shifted relative to the values in the starting salts of 186.89 and 185.8 ppm for $NaSCO_2Me$ and $NaSCO_2(i\text{-}Pr)$, respectively. This is consistent with the planar carbon atom of the monothiocarbonate group having essentially the same environment, as is suggested by the X-ray structures of **2**, **4**, **5**, and **8**, in solution in all 11 compounds, which differs from that of the starting salts. Similarly, in the corresponding $R_2Te[S_2COR]_2$ compounds, the S_2COR chemical shifts were all close to 220 ppm compared with values of ca. 232 ppm for the dithiocarbonate salts, and in the monothiocarbamates, $R_2Te[SCONEt_2]_2$ and $R_2TeX[SCONEt_2]$, the S*C*ON chemical shifts were in the range 167–172 ppm with the chemical shift of the salt again close to 12 ppm higher with a value of 183.31 ppm for $NaSCONEt_2$. The chemical shifts of the methyl groups attached to tellurium are essentially the same regardless of the organic group in the monothiocarbonate. The value close to 15.1 ppm for Te*C*H_3 in **1** and **2** is only slightly higher than that found for the monothiocarbamate derivatives, $Me_2Te[SCONR_2]_2$, ca. 14.8 ppm (25) but lower than those reported for related derivatives containing ligands with two sulfur atoms such as $Me_2Te[S_2COR]_2$ (1), $Me_2Te[S_2CNR_2]2$ (8, 12), and $Me_2Te[S_2POGO]_2$ (21) of ca. 15.5, 16.6, and 19.2 ppm, respectively. The halo derivatives, **5–9**, show a slight trend with values of ca. 20, 19, and 18 ppm for $Me_2TeX[SCO_2R]$ where X = Cl, Br, and I, respectively, which places the Te*C*H_3 chemical shifts approximately between those of the bis compounds and those of the dihalides, Me_2TeCl_2, 26.9, Me_2TeBr_2, 25.1, and Me_2TeI_2, 22.0 ppm. The chemical shifts of the phenyl carbon atoms are similar in the bis compounds **3** and **4** as are those in the two chloro derivatives **10** and **11**.

The ^{125}Te NMR chemical shifts for compounds **1–11** are also displayed in Table 9. The peaks attributable to **1** and **2**, of 466.4 and 459.3, respectively, lie between the values of 445–448 ppm found for the bis monothiocarbamate derivatives,

$Me_2Te[SCONR_2]_2$ and those of 475–482 ppm for the bis dithiocarbonates, $Me_2Te[S_2COR]_2$. As with the monothiocarbamates, the substitution of a monothiocarbonate group by a halogen results in an upfield shift toward the chemical shifts of the dihalides to give values of ca. 565 for **5** and **7**, 544.4 for **8**, and 510 ppm for **6** and **9**. The corresponding values for the Me_2TeX_2 species are 733.8, 649.2, and 519.6 ppm for X = Cl, Br, and I, respectively. The values of the chemical shifts for the $Ph_2TeCl[SCO_2R]$ derivatives, **10** and **11**, of 806.5 and 803.5 ppm, respectively, are similarly between those of the corresponding $Ph_2Te[SCO_2R]_2$ derivatives, **3** and **4**, of 734.2 and 730.0 ppm, respectively, and that of Ph_2TeCl_2, 910 ppm. Even the initial ^{125}Te NMR spectra of **3** and **4** show a peak at 690 ppm attributable to the formation of Ph_2Te, which arises from the reductive-elimination of $Ph_2Te[SCO_2R]_2$. This peak increases in intensity as those due to **3** or **4** disappear. Similarly, the spectra of **10** and **11** eventually show a peak at 910 ppm attributable to Ph_2TeCl_2, which arises from the disproportionation of $Ph_2TeCl[SCO_2R]$.

Organoplatinum(IV) derivatized vinyl monomers and polymers prepared by oxidative addition

Sudhir Achar, Richard J. Puddephatt, and John D. Scott

Abstract: Organoplatinum(IV) complexes of general formula [$PtXMe_2R(NN)$], containing vinyl substituents, have been prepared by oxidative addition of RX, (RX = methyl 2-(bromomethyl)acrylate, 2-(bromomethyl)acrylic acid, 2-bromoethyl methacrylate, acryloyl chloride, and chloromethylstyrene), to [$PtMe_2(NN)$], NN = 2,2′-bipyridine or 4,4′-di-*tert*-butyl-2,2′-bipyridine. Polymers with organoplatinum(IV) substituents have been prepared either by free radical polymerization of the organoplatinum(IV) derivatized monomers or by free radical polymerization of the organic monomers, followed by the oxidative addition of the C-X substituents of these polymers to [$PtMe_2(NN)$]. In the latter method, it is generally not possible to metallate all the C—X bonds, but a high degree of platinum incorporation can be achieved.

Key words: organoplatinum, polymer, oxidative addition, vinyl.

Résumé : On a préparé des complexes organoplatine(IV) de la formule générale [$PtXMe_2R(NN)$], contenant des substituants vinyliques, en faisant appel à une addition oxydante de RX (RX = 2-(bromométhyl)acrylate de méthyle, acide 2-(bromométhyl)acrylique, méthacrylate de 2-bromo-éthyle, chlorure d'acryloyle et chlorométhylstyrène) sur le [$PtMe_2(NN)$], NN = 2,2′-bipyridine ou 4,4′-di-*tert*-butyl-2,2′-bipyridine. On a préparé les polymères contenant des substituants organoplatine(IV) par polymérisation radicalaire des monomères organoplatine(IV) dérivatisés ou par polymérisation radicalaire des monomères organiques, suivie d'une addition oxydante des substituants C-X de ces polymères sur le [$PtMe_2(NN)$]. Dans cette dernière méthode, il n'est généralement pas possible de faire la métallation de toutes les liaisons C—X, mais le degré d'incorporation du platine est élevé.

Mots clés : organoplatine, polymère, addition oxydante, vinyle.

[Traduit par la rédaction]

Introduction

Polymers containing transition metals are of interest as potential catalysts or materials (1); they are often classified based on structure, according to whether the metals are incorporated in the backbone polymer chains (2–4) or are pendant to them (6–8). The metal may be present as an organometallic (contains M—C bonds) or coordination complex (no M—C bonds). Organometallic polymers are often synthesized by polymerizing organometallic monomers or by derivatizing a preformed organic polymer (1–11). We have been interested in using the oxidative addition reaction to introduce organoplatinum functionality into polymerizable monomers or into polymers, with the platinum groups either appended to or incorporated into the polymer backbone (12–15). Routes to both chain and dendrimeric oligomers and polymers have been developed using variants of this methodology. This paper reports details of the application of oxidative addition reactions to the synthesis of monomers and polymers in which organoplatinum groups are appended to a derivatized vinyl functionality. A preliminary account of parts of this work has been published (16). In most other polymers with pendant organotransition metal centres, the metal is bound to the polymer by coordination to η-cyclopentadienyl or η-arene groups or the organometallic group may be bound to the polymer by a group V or VI donor such as a phosphine or a nitrogen or oxygen donor ligand (1–11, 17–23). The methodology described below yields relatively rare examples of vinyl monomers and polymers in which the metals are directly bonded to the monomer or polymer via metal–carbon σ-bonds (22, 23).

The approach used is based on the easy oxidative addition of organic halides to platinum(II), a reaction that occurs in very high yield for alkyl halides containing a wide range of functional groups (24, 25). In particular, addition of alkyl or acyl halides, R-X, to [$PtMe_2$(bipy)], **1a**, bipy = 2,2′-bipyridine, is essentially quantitative and yields [$PtXMe_2R$(bipy)] (26–29). In the present work the group R contains a polymerizable vinyl group and the oxidative addition may be carried out before or after polymerization of the vinyl monomer.

Results and discussion

Synthesis of mononuclear complexes

The complex $[PtMe_2(bipy)]$, **1**, is very reactive in oxidative addition but the products often have limited solubility. To overcome the solubility problem, the new complex $[PtMe_2(bu_2bipy)]$, **2**, bu_2bipy = 4,4′-di-*tert*-butyl-2,2′-bipyridine, was used (15, 30). Both **1** and **2** are red solids, the color arising from the presence of a metal-to-ligand charge transfer (MLCT) band in the visible region of the spectrum (31, 32), and the oxidative addition of alkyl or acyl halides, RX, occurs with bleaching of the colour on formation of the platinum(IV) products $[PtXRMe_2(bipy)]$ and $[PtXRMe_2(bu_2bipy)]$. The reactions can also be monitored by ^1H NMR since the methylplatinum coupling constant, $^2J(PtCH_3)$ decreases from 84–86 Hz in **1** or **2** to 69–72 Hz in the platinum(IV) products (26–29).

The reactions used to prepare potential vinyl monomers with organoplatinum(IV) substituents are shown in Scheme 1. In most cases, the oxidative additions occurred essentially quantitatively but gave the products as a mixture of *trans* and *cis* isomers **3** and **4**. Selected ^1H NMR data and the *trans*/*cis* product ratios are given in Table 1 and complete data are listed in the experimental section. The *trans* isomers **3** have a plane of symmetry perpendicular to the $PtMe_2N_2$ plane and so give a single methylplatinum resonance and, in complexes that contain a CH_2Pt group, a single CH_2Pt resonance. The *cis* isomers **4** have lower symmetry and give two methylplatinum resonances and an "AB" multiplet for the CH^aH^bPt protons (when present). The isomers were readily identified by these characteristic features and the isomer ratios were determined by integration of the ^1H NMR spectra. Attempts to separate the isomers by fractional crystallization or column chromatography were unsuccessful, and they were used in subsequent studies as the mixture of isomers.

Successful reactions were carried out with methyl 2-(bromomethyl)acrylate, 2-(bromomethyl)acrylic acid, 2-bromoethyl methacrylate, acryloyl chloride, and chloromethylstyrene (Scheme 1), thus giving a variety of vinyl monomers containing platinum(IV). All products were isolated as air-stable, pale yellow solids that gave satisfactory analytical data.

The formation of **3b** and **4b** by oxidative addition of 2-(bromomethyl)acrylic acid to **1** is noteworthy because it indicates that the oxidative addition occurs at a much faster rate than methyl–platinum bond cleavage by the carboxylic acid group (33). The reaction of **2** with acryloyl chloride is noteworthy since it was the only case in which the product of *cis* oxidative addition was the major product (Table 1). The sample of chloromethylstyrene used for reaction with **1** and **2** was a mixture of the *meta* and *para* isomers in a 70:30 ratio (the mixture is not readily separable). Fortunately, the oxidative additions occurred selectively to give the *trans* isomers **3** only. Hence the product from **1** was formed a mixture of **3g** and **3h**, and from **2** a mixture of **3i** and **3j**, respectively. In each case, the product ratio corresponded closely to the 30:70 ratio present in the reagent.

Polymeric complexes

Polymeric complexes containing platinum(IV) could be prepared in two ways, as illustrated in Scheme 2 for the case of 2-bromoethyl methacrylate. The free radical polymerization of the mixture of monomers **3c** and **4c** in chlorobenzene, employing azobisisobutyronitrile, AIBN, as initiator, gave the polymer **5** (Scheme 2; note that, for simplicity, the scheme shows only the *trans* isomer **3c** and its product but it is, of course, expected that the polymer will contain platinum(IV) centres with both *cis* and *trans* stereochemistry). The polymer **5** precipitated from solution as it formed and it was not sufficiently soluble to give an NMR spectrum or to allow molecular weight determination.

A similar polymer **6** was prepared by polymerization of the organic monomer 2-bromoethyl methacrylate to its polymer **7** (M_n = 9800, M_w = 16 000, polydispersity 1.6) followed by oxidative addition of the polymer to **1**. However, even using excess **1**, only about 75% of the bromoethyl groups were found to be metallated in the final polymer **6**, which precipitated as it formed (Scheme 2, again only the *trans* oxidative addition product is shown; a more random arrangement of the metallated units than shown is also likely). Hence, the fully metallated polymer can only be obtained from the metallated monomer **3c**,**4c**. The platinum-containing polymers have low solubility in all common organic solvents and it is possible that the precipitation of the partially metallated polymer prevents complete platination. To overcome the solubility problem, additional reactions were carried out with $[PtMe_2(bu_2bipy)]$, **2**. The reactants **2** and the organic polymer **7** were reacted in the molar ratios (based on monomer) of 1:10, 1:4, 1:2, 1:1.33, and 1:1 in acetone to yield the platinated polymers **8a–e**, respectively. Elemental analyses gave a direct measure of the proportion of bromoethyl groups platinated and the results are given in the experimental section. The analytical data indicate a correlation between the amount of platinum used and the amount incorporated, but again it was not possible to metallate all the bromoethyl groups present in the polymer. The solubility of the organoplatinum polymers **8a–e** in THF decreased with increasing platinum content, and samples **8d** and **8e** were not soluble enough for molecular weight determination by gel permeation chromatography. The GPC molecular weight data (experimental section) are similar to that for the organic polymer. It might be expected that the hydrodynamic radius of the platinated polymers would be less than for the organic polymer due to reduced solvation, thus

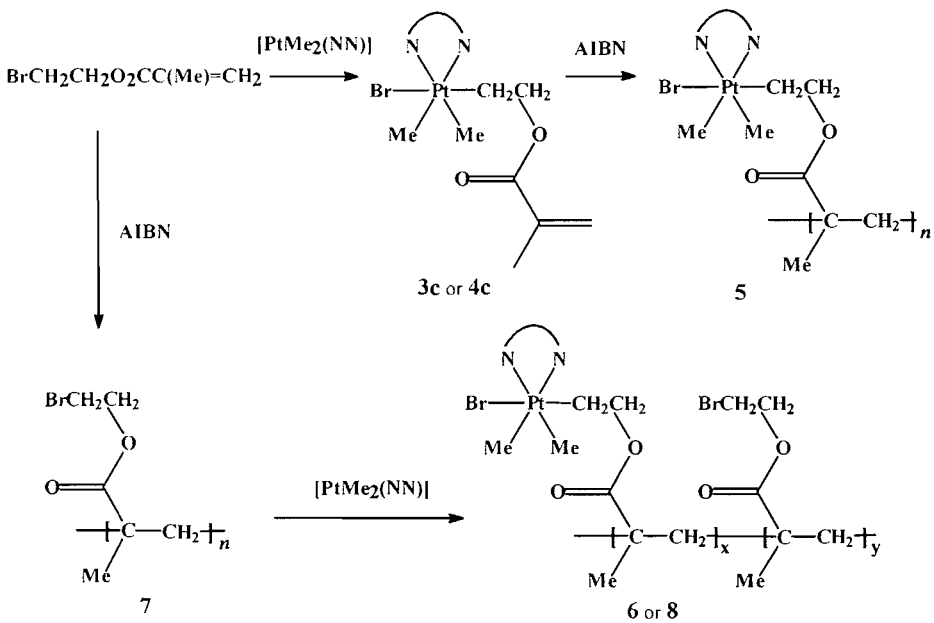
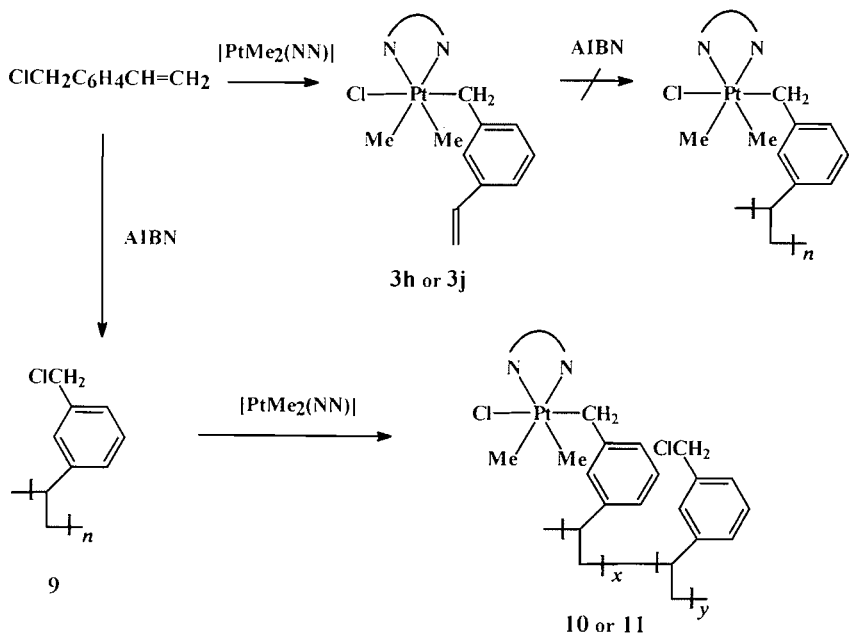
Scheme 2.



leading to lower GPC molecular weights. Either this is not so or perhaps there is some association between the platinated polymer chains that compensates for this effect. It is reasonable to assume that the chain length is not affected by the metallation step. In the ^{1}H NMR spectra of the polymers **8a–e** in acetone, the peaks due to PtMe, *tert*-butyl, and other aliphatic groups were broad and not completely resolved. To prove the presence of PtMe groups, the polymer **8**–d^6 was synthesized by the oxidative addition of poly(2-bromoethyl methacrylate) to [Pt(CD_3)$_2$(bu_2bipy)] in a ratio of 4:1 and the presence of CD_3Pt groups was then proved by ^{2}H NMR. Two broad resonances were observed in the ^{2}H NMR. The more intense peak at δ = 1.3 was assigned to the CD_3 groups *trans* to nitrogen (present for both *trans* and *cis* oxidative addition), while the less intense resonance at δ = 0.5 was assigned to the CD_3 group *trans* to bromide (present for *cis* oxidative addition only) and integration therefore gave the ratio *trans*:*cis* = 55±5:45±5, essentially the same as for oxidative addition of the monomer to **2** (Table 1). The observation of the CD_3 peaks in the ^{2}H NMR clearly proves the presence of the MePt groups in the polymer **8**.

The platinum(IV) monomers **3g,3h** derived from chloromethylstyrene were sparingly soluble in common organic solvents and hence their solution polymerization could not be carried out. The analogous monomers with bu_2bipy ligands, **3i,3j**, were more soluble but still did not undergo free radical polymerization in the presence of azobis(isobutyronitrile) initiator. The platinated polymer of chloromethylstyrene could only be prepared by polymerization of the organic monomer to give the polymer **9** (M_n = 6800, M_w = 15 000, M_w/M_n = 2.2) followed by reaction with **1** or **2** to give **10** or **11** (Scheme 3; note that only the *meta*-chloromethylstyrene isomer is illus-

Scheme 3.



trated for simplicity and that the structure shown is an idealized one and a more random arrangement is likely). The polymers precipitated as pale yellow powders and were sparingly soluble in common organic solvents. Again, complete platination of all chloromethyl groups did not occur on reaction with excess **1** or **2**. It is noteworthy that **11** is more soluble in acetone than **10** and that **11** contains a higher incorporation of platinum (77% of chloromethyl groups platinated) than **10** (62%). This suggests that the precipitation of the partially metallated polymer, with some of the chloromethyl groups coiled back away from the reaction surface, prevents further platination. To check if insolubility alone would prevent further reaction of chloromethyl groups with platinum(II) reagent, Merrifield's resin (which is an insoluble, cross-linked chloromethylated styrene – divinyl benzene copolymer with all chloromethyl groups at the polymer surface) was reacted, as a suspension in acetone, with excess **1** to give the platinated resin, **12**, in which essentially all of the chloromethyl groups were platinated. This clearly shows that the oxidative addition of chloromethyl groups to **1** can occur under heterogeneous conditions provided the chloromethyl groups are located on the polymer surface. Other groups have also successfully derivatized Merrifield's resin to introduce metal substituents, although not by oxidative addition (34–36).

The chemistry of compounds derived from chloromethylstyrene and acryloyl chloride was similar. Thus, the monomers **3e**,**4e** and **3f**,**4f** derived from acryloyl chloride did not undergo free radical polymerization but the organic monomer could be polymerized to give **13** and then platinated to give **14** or **15** (Scheme 4, again simplified for clarity).

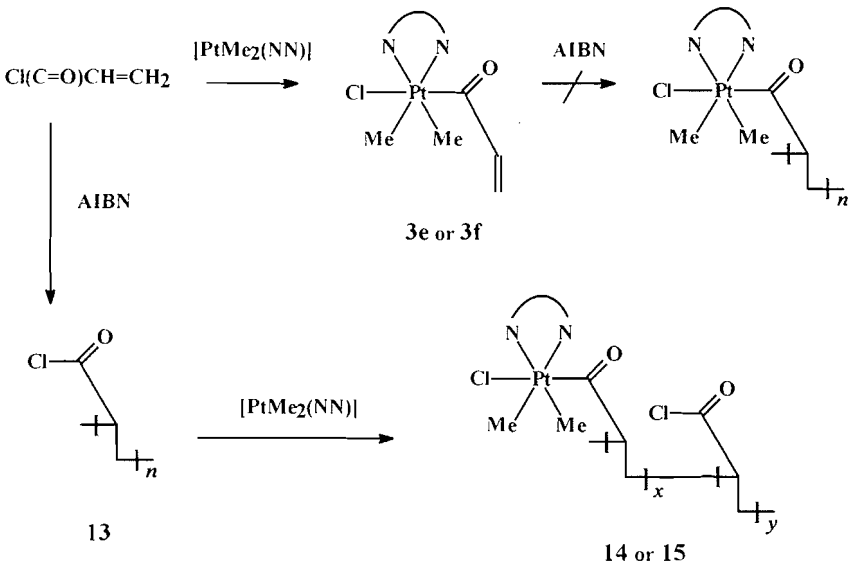
As expected, the metallated polymers differ significantly in their physical properties from either the organic polymers or the organometallic monomers. For example, the organoplatinum monomer **3c**,**4c** melts with decomposition at 166°C and the organic polymer **7** exhibits a glass transition in the range 65–79°C, as determined by differential scanning calorimetry (DSC) but is not crystalline and gives no distinct melting endotherm. However, the polymers **5** and **6** each exhibit a very broad endothermic transition over the range 60–160°C, with the peak at 115°C, and there is a melting endotherm that begins at 210°C and peaks at 243°C. When samples of the polymers **5** and **6** were heated to 150°C for 30 min and then cooled and reheated, the broad endotherm in the region 60–160°C was not observed while the melting endotherm was unchanged. Thus, it appears that the polymers **5** and **6** precipitate in a strained conformation that relaxes on heating above 60°C.

TGA studies indicated that the organic polymer, **7**, undergoes complete weight loss over the temperature range 335–395°C, while the organoplatinum polymers decompose over a much wider range. The organoplatinum polymers **5**, **6** and **8a–e** exhibit similar patterns for the TGA thermograms, all decomposing over a wide range of temperature from 240 to 600°C. The decomposition onset temperatures gradually increased with the increase in the platinum content for the series **8a–e**, which clearly reveals the effect of metallation on decomposition characteristics; details for these and other polymers are given in the experimental section.

Experimental

^{1}H NMR spectra were recorded using Varian XL 200 or Gemini 300 MHz spectrometers. FTIR spectra were recorded as KBr disks by using a Bruker IR/32 spectrometer. Thermal analyses were carried out using a Perkin Elmer DSC7 and TAC7/DX differential scanning calorimeter and thermogravimetric analyzer, respectively. The heating rate was 20°C/min and a sample mass of 5–10 mg was used. Nitrogen was used as the purge gas. The molecular weight measurements were carried out using a Waters 600 GPC with Waters 410 differential

Scheme 4.



refractometer as the detector. Two ultrastyragel columns were used in series (10^3 Å and 10^2 Å) and THF was used as the solvent. The system was calibrated with linear polystyrene standards. In the NMR listings, a vinyl group is defined as $-CH^a{=}CH^bH^c$, with H^a *trans* to H^b.

[$PtBrMe_2\{CH_2C(COOMe){=}CH_2\}$(bipy)], 3a,4a

To a solution of [$PtMe_2$(bipy)] (0.05 g) in acetone (10 mL) was added methyl 2-(bromomethyl)acrylate (0.02 mL) and the mixture was stirred for 2 h. The solution color changed from red-orange to pale yellow and the product precipitated as a white powder. The product was separated, washed with ether, and dried under vacuum. Yield 86%. IR: ν(CO) = 1714 cm^{-1}, ν(C=C) = 1601 cm^{-1}. ^1H NMR in CD_2Cl_2: **3a**: δ: 1.39 (s, 6H, ^2J(PtH) = 70 Hz, Me_2Pt), 2.50 (s, 2H, ^2J(PtH) = 97 Hz, CH_2Pt), 3.08 (s, 3H, CH_3-O), 4.98 (m, 1H, ^4J(PtH) = 26 Hz, $CH_2{=}$), 5.52 (m, 1H, ^4J(PtH) = 29 Hz, $CH_2{=}$), 7.63 (t, 2H, H^5 of (bipy)), 8.07 (t, 2H, H^4 of (bipy)), 8.21 (d, 2H, H^3 of (bipy)), 8.78 (d, 2H, H^6 of (bipy)); **4a**: δ: 0.48 (s, 3H, ^2J(PtH) = 71 Hz, MePtBr), 1.30 (s, 3H, ^2J(PtH) = 70 Hz, MePtN), 2.46 (s, 2H, ^2J(PtH) = 97 Hz, CH_2Pt), 3.63 (s, 3H, CH_3-O). Anal. calcd. for $C_{17}H_{21}BrN_2O_2Pt$: C 36.4, H 3.8, N 5.0; found: C 36.5, H 3.5, N 4.8.

The following complexes were prepared similarly.

[$PtBrMe_2\{CH_2C(COOH){=}CH_2\}$(bipy)], 3b,4b

Yield 90%. [$PtBrMe_2\{CH_2CH_2OCOC(CH_3){=}CH_2\}$($bu_2$bipy)], 3d,4d

Yield 85%. ^1H NMR in CD_2Cl_2: **3d**: δ: 1.36 (s, 6H, ^2J(PtH) = 70 Hz, Me_2Pt), 1.46 (b, 18H, *tert*-butyl protons), 1.71 (m, 3H, Me-C=), 3.41 (t, 2H, ^3J(PtH) = 45 Hz, CH_2-O), 5.37 and 5.7 (m, 1H each, $CH_2{=}$), 7.65, 8.18, 8.78 (2H each, H^5, H^3, and H^6 of (bu_2bipy), respectively); **4d**: δ: 0.53 (s, 3H, ^2J(PtH) = 74 Hz, MePtBr), 1.38 (s, 3H, ^2J(PtH) = 70 Hz, MePtN), 1.98 (m, 3H, Me-C=), 2.2 (m, 1H, CH_2Pt, other H signal is obscured), 4.28 and 4.66 (m, 1H each, CH_2-O), 5.53 and 6.1 (m, 1H each, $CH_2{=}$), 7.75 and 9.06 (2H each, H^5 and H^6 of (bu_2bipy), respectively, H^3 peak obscured).

[$PtClMe_2$(CO-CH=CH_2)(bipy)], 3e,4e

Yield 90%. IR: ν(C=O) = 1653 cm^{-1}. ^1H NMR in CD_3COCD_3: **3e**: δ: 1.46 (s, 6H, ^2J(PtH) = 72 Hz, Me_2Pt), 4.77 (d, 1H, $J(H^cH^a)$ = 11 Hz, H^c), 5.38 (d, 1H, $J(H^bH^a)$ = 17 Hz, H^b) and 6.57 (dd, 1H, $J(H^aH^b)$ = 17 Hz, $J(H^aH^c)$ = 11 Hz, H^a), 7.85 (dt, 2H, H^5 of (bipy)), 8.32 (dt, 2H, H^4 of (bipy)), 8.7 (dd, 2H, H^3 of (bipy)), 9.1 (dd, 2H, H^6 of (bipy)). **4e**: δ: 0.71 (s, 3H, ^2J(PtH) = 74 Hz, MePtCl), 1.39 (s, 3H, ^2J(PtH) = 72 Hz,

MePtN), 4.80 (d, 1H, $J(H^cH^a)$ = 11 Hz, H^c), 5.73 (d, 1H, $J(H^bH^a)$ = 17 Hz, H^b), 7.35 (dd, 1H, $J(H^aH^b)$ = 17 Hz, $J(H^aH^c)$ = 11 Hz, H^a). Anal. calcd. for $C_{15}H_{17}ClN_2OPt$: C 38.2, H 3.6, N 5.9; found: C 37.8, H 3.4, N 6.1.

[$PtClMe_2(CO\text{-}CH{=}CH_2)(bu_2bipy)$], 3f,4f

Yield 80%. ^1H NMR in CD_3COCD_3: **3f**: δ: 1.41 (s, 6H, $^2J(PtH)$ = 72 Hz, Me_2Pt), 4.78 (d, 1H, $J(H^cH^a)$ = 10 Hz, $J(H^cH^b)$ = 2 Hz, H^c), 5.4 (d, 1H, $J(H^bH^a)$ = 17 Hz, $J(H^bH^c)$ = 2 Hz, H^b) and 6.55 (dd, 1H, $J(H^aH^b)$ = 17 Hz, $J(H^aH^c)$ = 10 Hz, H^a). **4f**: δ: 0.69 (s, 3H, $^2J(PtH)$ = 75 Hz, MePtCl), 1.35 (s, 3H, $^2J(PtH)$ = 72 Hz, MePtN), 1.46 (b, 18H, *tert*-butyl), 4.85 (d, 1H, $J(H^cH^a)$ = 10 Hz, $J(H^cH^b)$ = 2 Hz, H^c), 5.72 (d, 1H, $J(H^bH^a)$ = 17 Hz, $J(H^bH^c)$ = 2 Hz, H^b), 7.38 (dd, 1H, $J(H^aH^b)$ = 17 Hz, $J(H^aH^c)$ = 10 Hz, H^a), 7.85, 8.7, and 8.93 (m, 2H each, H^5, H^3, and H^6 of (bu_2bipy)). Anal. calcd. for $C_{23}H_{33}ClN_2OPt$: C 47.3, H 5.7, N 4.8; found: C 47.4, H 5.8, N 4.9.

[$PtClMe_2(CH_2\text{-}C_6H_4\text{-}CH{=}CH_2)$(bipy)], 3g,3h

Yield 88%. ^1H NMR, 300 MHz, $CDCl_3$: **3h**: δ: 1.46 (s, 6H, $^2J(PtH)$ = 69 Hz, Me_2Pt), 2.77 (s, 2H, $^2J(PtH)$ = 93 Hz, CH_2Pt), 4.98 (d, 1H, $J(H^cH^a)$ = 11 Hz, H^c), 5.22 (d, 1H, $J(H^bH^a)$ = 17 Hz, H^b) and 6.2 (dd, 1H, $J(H^aH^b)$ = 17 Hz, $J(H^aH^c)$ = 11 Hz, H^a), 6.1–6.6 (m, 8H, C_6H_4 ring protons of the two isomers), 7.45 (m, 2H, H^5 of (bipy)), 7.9 (m, 4H, H^4 and H^3 of (bipy)), 8.68 (m, 2H, H^6 of (bipy)). Resolved peaks of **3g**: δ: 1.45 (s, 6H, $^2J(PtH)$ = 69 Hz, Me_2Pt), 2.79 (s, 2H, $^2J(PtH)$ = 95 Hz, CH_2Pt), 5.0 (d, 1H, $J(H^cH^a)$ = 11 Hz, H^c), 5.41 (d, 1H, $J(H^bH^a)$ = 17 Hz, H^b) and 6.34 (dd, 1H, $J(H^aH^b)$ = 17 Hz, $J(H^aH^c)$ = 11 Hz, H^a). Anal. calcd. for $C_{21}H_{23}ClN_2Pt$: C 47.2, H 4.3, N 5.2; found: C 46.8, H 4.2, N 5.3.

[$PtClMe_2(CH_2\text{-}C_6H_4\text{-}CH{=}CH_2)(bu_2bipy)$], 3i,3j

Yield 93%. ^1H NMR, 300 MHz, $CDCl_3$: **3j**: δ: 1.36 (b, 36H, *tert*-butyl protons), 1.42 (s, 6H, $^2J(PtH)$ = 69 Hz, Me_2Pt), 2.76 (s, 2H, $^2J(PtH)$ = 94 Hz, CH_2Pt), 4.96 (d, 1H, $J(H^cH^a)$ = 11 Hz, H^c), 5.18 (d, 1H, $J(H^bH^a)$ = 17 Hz, H^b) and 6.17 (dd, 1H, $J(H^aH^b)$ = 17 Hz, $J(H^aH^c)$ = 11 Hz, H^a), 6.0–6.7 (m, 8H, C_6H_4 ring protons of the two isomers), 7.4 (m, 2H, H^5 of (bu_2bipy)), 7.81 (s, 2H, H^3 of (bu_2bipy)), 8.57 (d, 2H, $^3J(PtH)$ = 12 Hz, H^6 of (bu_2bipy)). Resolved peaks of **3i**: δ: 1.40 (s, 6H, $^2J(PtH)$ = 69 Hz, Me_2Pt), 2.78 (s, 2H, $^2J(PtH)$ = 96 Hz, CH_2Pt), 5.01 (d, 1H, $J(H^cH^a)$ = 11 Hz, H^c), 5.42 (d, 1H, $J(H^bH^a)$ = 17 Hz, H^b), 6.32 (dd, 1H, $J(H^aH^b)$ = 17 Hz, $J(H^aH^c)$ = 11 Hz, H^a), 7.42 (m, 2H, H^5 of (bu_2bipy)), 7.86 (s, 2H, H^3 of (bu_2bipy)), 8.52 (d, 2H, $^3J(PtH)$ = 12 Hz, H^6 of (bu_2bipy)). Anal. calcd. for $C_{29}H_{39}ClN_2Pt$: C 53.9, H 6.1, N 4.3; found: C 53.6, H 6.4, N 4.2.

Polymerization of [$PtBrMe_2\{CH_2CH_2OCOC(CH_3){=}CH_2\}$(bipy)] to give 5

A solution of [$PtBrMe_2\{CH_2CH_2OCOC(CH_3){=}CH_2\}$(bipy)] (0.12 g) and azobisisobutyronitrile (0.015 g) in freshly distilled chlorobenzene (5 mL) was degassed by three freeze–pump–thaw cycles at 10^{-5} Torr (1 Torr = 1.33 Pa), then sealed under vacuum and heated to 60°C. After 8 h the product had precipitated, heating was stopped, the solvent was rotoevaporated, and the product was washed with ether and dried. Yield 50%. IR: ν(CO) = 1722 cm^{-1}. Anal. calcd. for $C_{18}H_{23}BrN_2O_2Pt$: C 37.6, H 4.0, N 4.9; found: C 37.1, H 3.9, N 4.6.

Poly(2-bromoethyl methacrylate), 7

A solution of freshly distilled 2-bromoethyl methacrylate (3.5 g) and azobisisobutyronitrile (0.02 g) in dry chlorobenzene (3 mL) was degassed by freeze–pump–thaw cycles at 10^{-5} Torr, then sealed under vacuum and heated to 60°C for 1 day. The solution became more viscous. The polymer was precipitated with methanol and dried. Yield 80%. IR: ν(CO) = 1728 cm^{-1}. ^1H NMR in acetone: δ: 0.9–1.8 (b, Me and C-CH_2), 3.73 (b, CH_2CH_2Br), 4.35 (b, CH_2CH_2Br). GPC (THF): M_n = 9800; M_w = 16 000; polydispersity = 1.63.

[$PtMe_2$(bipy)] with poly(2-bromoethyl methacrylate) to give 6

Solutions of poly 2-bromoethyl methacrylate (0.05 g) in acetone (10 mL) and [$PtMe_2$(bipy)] (0.15 g) in acetone (10 mL) were mixed and stirred at room temperature for 1 day. The precipitated product was separated and washed with ether and dried. Yield 60%. Anal. calcd. for $C_{18}H_{23}BrN_2O_2Pt$-$(C_6H_9BrO_2)_{0.35}$: C 37.6, H 4.1, N 4.4; found: C 37.1, H 4.1, N 4.3. TGA: decomp. onset, 290°C; weight loss: 39% at 630°C. Similarly the organoplatinum polymers **8a–8e** were prepared by the reaction of [$PtMe_2(bu_2bipy)$] and poly 2-bromoethyl methacrylate. The platinum complex **2**, and the preformed polymer **7**, were reacted in ratios corresponding to 1:10, 1:4, 1:2, 1:1.33, and 1:1 to yield the organoplatinum polymers **8a–8e**, respectively. **8a**: Anal. calcd. for $C_{18}H_{23}BrN_2O_2Pt$-$(C_6H_9BrO_2)_{13}$: C 39.1, H 4.9, N 0.8; found: C 39.1, H 4.8, N 0.9. GPC: M_n = 10 000, M_w = 15 500, polydispersity 1.55. TGA: decomp. onset, 240°C; residue: 20% at 580°C. **8b**: Anal. calcd. for $C_{18}H_{23}BrN_2O_2Pt(C_6H_9BrO_2)_{3.57}$: C 41.4, H 5.2, N 2.0; found: C 41.3, H 5.3, N 2.0. GPC: M_n = 9700, M_w = 14 700, polydispersity 1.51. TGA: decomp. onset, 256°C; residue: 26% at 580°C. **8c**: Anal. calcd. for $C_{18}H_{23}BrN_2O_2Pt$-$(C_6H_9BrO_2)_{1.96}$: C 42.6, H 5.4, N 2.6; found: C 43.1, H 5.5, N 2.7. GPC: M_n = 10 300, M_w = 15 000, polydispersity 1.45. TGA: decomp. onset, 260°C; residue: 29% at 580°C. **8d**: Anal. calcd. for $C_{18}H_{23}BrN_2O_2Pt(C_6H_9BrO_2)_{0.92}$: C 43.8, H 5.5, N 3.2; found: C 43.3, H 5.4, N 3.2. GPC: insufficiently soluble. TGA: decomp. onset, 274°C; residue: 34% at 580°C. **8e**: Anal. calcd. for $C_{18}H_{23}BrN_2O_2Pt(C_6H_9BrO_2)_{0.5}$: C 44.5, H 5.6, N 3.6; found: C 43.9, H 5.3, N 3.5. TGA: decomp. onset, 278°C; residue: 35% at 580°C.

Poly(acryloyl chloride), 13

Azobisisobutyronitrile (0.02 g) was added to freshly distilled acryloyl chloride (5 mL) and the mixture was degassed. The sealed ampoule was heated to 70°C for 1 day. Only partial polymerization was observed. The monomer was separated from the polymer by evaporation under vacuum. GPC: M_n = 4300; M_w = 5000; M_w/M_n = 1.16. ^1H NMR in CD_3COCD_3, 200 MHz; δ: 2.3, 2.56 and 3.24 (broad peaks).

The organoplatinum polymers **14** and **15** were prepared as above.

Polymer 14: ^1H NMR, 200 MHz, dmso-d^6; δ: 0.3–2.2 (b, 9H, PtMe, -CH-CH_2-), 7.4–9.8 (b, 6H, (bipy)). Anal. calcd. for $C_{15}H_{17}ClN_2OPt$: C 38.2, H 3.6, N 5.9; found: C 38.0, H 4.2, N 6.0. TGA: decomp. range 200–790°C, weight loss 58%.

Polymer 15: ^1H NMR, 200 MHz, $CDCl_3$; δ: 1.1–2.3 (b, *tert*-butyl, PtMe and -CH-CH_2-), 7.3–9.7 (b, (bipy)). Anal. calcd.

for $C_{23}H_{33}ClN_2OPt(C_3H_3OCl)_{0.9}$: C 46.3, H 5.4, N 4.2; found: C 45.6, H 5.6, N 4.1.

Poly(chloromethylstyrene), 9

To the mixture of the *meta* and *para* isomers of chloromethylstyrene (6 mL) (distilled under reduced pressure) was added azobisisobutyronitrile (0.025 g) and the mixture was then degassed by several freeze–pump–thaw cycles at 10^{-4} Torr and sealed under vacuum. The sealed ampoule was heated to 60°C for 8 h. The polymer was purified by repeated precipitation into methanol from acetone. The polymer was isolated as a white, amorphous material. ^{1}H NMR, 200 MHz, CD_3COCD_3, δ: 1.6 and 1.82 (b, 3H, -CH-CH_2-), 4.56 (b, 2H, CH_2Cl), 6.64, 7.15 (b, 4H, benzene ring protons). GPC: M_n = 6800; M_w = 15 000; M_w/M_n = 2.2. TGA: decomp. 323–600°C, weight loss 63%.

[$PtMe_2$(bipy)] with poly(chloromethylstyrene) to give 10

Solutions of the polymer **9** (0.05 g) in acetone (10 mL) and [$PtMe_2$(bipy)] (0.20 g) in acetone (15 mL) were mixed and stirred at room temperature. The product polymer precipitated from the solution. It was separated, washed with ether, and dried. Yield 70%. ^{1}H NMR, 200 MHz, dmso-d^6, δ: 1.22 (b, 9H, PtMe and -CH-CH_2-), 5.9 (b, 4H, benzene ring protons), 7.36, 7.9 and 8.4 (b, 8H, bipyridine protons). Anal. calcd. for $C_{21}H_{23}ClN_2Pt(C_9H_9Cl)_{0.62}$: C 50.8, H 4.6, N 4.4; found: C 48.9, H 4.7, N 4.3. TGA: decomp. 270–580°C, weight loss 69%. Similarly the polymer **11** was prepared from the polymer **9** and **2**: Yield 78%. ^{1}H NMR, 200 MHz, $CDCl_3$, δ: 1.45 (b, 27H, PtMe, *tert*-butyl and -CH-CH_2-), 4.35 (trace, broad, unreacted chloromethyl groups), broad peaks in the region from δ = 5–9, with peaks at 6.2, 7.15, and 8.05 (10H, benzene ring and bipyridine protons). Anal. calcd. for $C_{29}H_{39}ClN_2Pt(C_9H_9Cl)_{0.32}$: C 55.0, H 6.1, N 4.0; found: C 55.6, H 6.5, N 3.8. TGA: decomp. 300–480°C, weight loss 47%.

[$PtMe_2$(bipy)] with Merrifield's resin

To a suspension of Merrifield's resin (0.05 g) in acetone (10 mL) was added an excess amount of [$PtMe_2$(bipy)] (0.05 g) in acetone (5 mL). The mixture was stirred for 1 day. The resin was separated, washed thoroughly with ether, and dried. Anal. calcd. for $C_9H_8(C_{21}H_{23}ClN_2Pt)_{0.15}$: C 74.4, H 5.9, N 2.1; found: C 72.9, H 6.6, N 2.1.

Synthesis of the complexes [PdClR(cod)] (R = benzyl, ethyl; cod = 1,5-cyclooctadiene). β-Elimination from [PdClEt(cod)] to give the η^1,η^2, and η^3 isomers of $[Pd_2(\mu\text{-}Cl)_2(C_8H_{13})_2]$

Robert A. Stockland, Jr., Gordon K. Anderson, Nigam P. Rath, Janet Braddock-Wilking, and J. Christopher Ellegood

Abstract: Treatment of $[PdCl_2(cod)]$ with tetrabenzyltin gives the benzylpalladium complex $[PdCl(CH_2Ph)(cod)]$ (cod = 1,5-cyclooctadiene), **1a**, whose structure has been determined by X-ray crystallography. It adopts approximate square-planar geometry, with the double bonds perpendicular to the square plane. The corresponding ethylpalladium derivative **1b** has been prepared by a similar method, but it is considerably less stable. It decomposes by β-elimination to produce ethene and a transient hydride complex, which either undergoes migratory insertion to give $[Pd_2(\mu\text{-}Cl)_2(\eta^1,\eta^2\text{-}C_8H_{13})_2]$, **2a**, or dinuclear reductive elimination with a second molecule of **1b** to produce ethane, $[PdCl_2(cod)]$, free cyclooctadiene, and palladium metal. Complex **2a** has also been prepared by reaction of $[PdCl_2(cod)]$ with $NaBH_4$. At higher temperatures **2a** converts to an equilibrium mixture with its η^3-allyl isomer, **2b**. Reactions of $[PdCl_2(cod)]$ or K_2PdCl_4 in the presence of cyclooctadiene in aqueous solution to produce **2a** or **2b** have also been investigated.

Key words: palladium, diene complexes, allyl complexes, isomerization, β-elimination.

Résumé : Le traitement du $[PdCl_2(cod)]$ avec le tétrabenzylétain conduit au complexe benzylpalladium $[PdCl(CH_2Ph)(cod)]$ (cod = cycloocta-1,5-diène), **1a**, dont on a déterminé la structure par diffraction des rayons X. Il adopte une géométrie plan carré dans laquelle les doubles liaisons sont perpendiculaires au plan carré. On a préparé le dérivé éthylpalladium correspondant, **1b**, par une méthode semblable; il est toutefois beaucoup moins stable. Il se décompose par une élimination β pour former de l'éthène et un hydrure complexe transitoire qui peut donner lieu soit à une insertion migratoire conduisant au $[Pd_2(\mu\text{-}Cl)_2(\eta^1,\eta^2\text{-}C_8H_{13})_2]$, **2a**, soit à une élimination réductrice dinucléaire avec une deuxième molécule de **1b** qui fournit de l'éthane, du $[PdCl_2(cod)]$, du cyclooctadiène libre et du palladium métallique. On a aussi préparé le complexe **2a** par réaction du $[PdCl_2(cod)]$ avec le $NaBH_4$. À des températures plus élevées, le composé **2a** se transforme en un mélange à l'équilibre avec l'isomère η^3-allyle **2b**. On a aussi étudié les réactions du $[PdCl_2(cod)]$ ou du K_2PdCl_4 en solution aqueuse, en présence de cyclooctadiène, qui conduisent aux produits **2a** ou **2b**.

Mots clés : palladium, complexes diéniques, complexes allyliques, isomérisation, élimination β.

[Traduit par la rédaction]

Introduction

Since the first platinum complexes of the type [PtClR(cod)] (cod = 1,5-cyclooctadiene) were reported by Clark and Manzer (1), they have served as excellent precursors to a range of organoplatinum species, including bis(phosphine) (2) or diphosphine (3) compounds, or dppm-bridged A-frames (4).

Received March 1, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

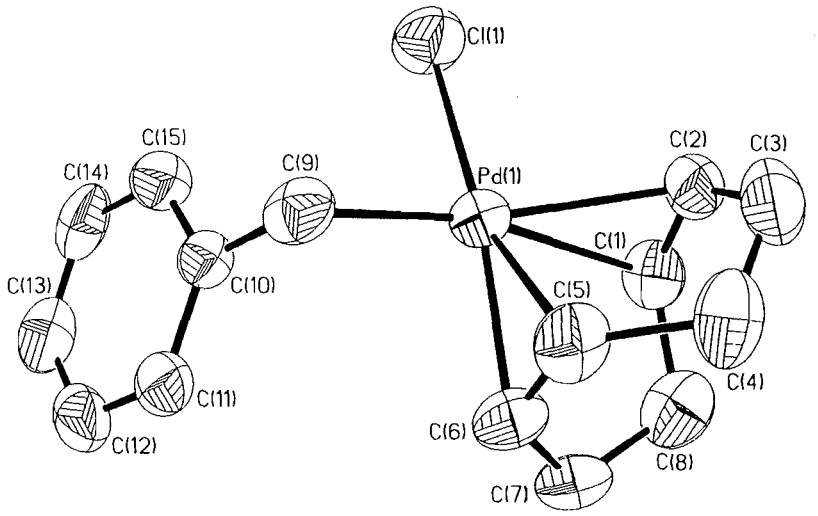
The corresponding palladium complexes have proved more elusive. The preparation of [PdClMe(cod)] was first reported in 1977, from the reaction of the dimethyl species with chlorinated solvents or with $[PdCl_2(cod)]$, but it was found to be unstable (5). More recently, a superior synthesis from $[PdCl_2(cod)]$ and tetramethyltin has been reported (6), and we have shown that [PdClMe(cod)] is a suitable precursor to a number of chloride-bridged methylpalladium complexes (7). The pentafluorophenyl complex $[PdCl(C_6F_5)(cod)]$ has been prepared and structurally characterized, and it has been shown to undergo rearrangements that involve migration of the aryl group on to the cyclooctadiene ring (8). In this paper, we report the preparation and structure of $[PdCl(CH_2Ph)(cod)]$, **1a**, and the difficult isolation and facile rearrangement of its ethyl analogue.

Results and discussion

The synthesis of $[PdCl(CH_2Ph)(cod)]$, **1a**, is similar to that of its methyl analogue (6, 7), except that a longer reaction time is required. Thus, refluxing a dichloromethane solution of

Fig. 1. Projection view of the molecular structure of [PdCl(CH_2Ph)(cod)], **1a**, showing the atom-labeling scheme.



[$PdCl_2$(cod)] with a slight excess of tetrabenzyltin for 7.5 h, followed by purification, gave the product as a yellow solid in good yield. Its ^{1}H and ^{13}C{^{1}H} NMR spectra exhibit the expected resonances. The ^{1}H NMR spectrum displays a singlet at 3.59 ppm due to the benzyl CH_2 hydrogens, and two multiplets at 4.87 and 5.89 ppm due to the coordinated alkene hydrogens *trans* to Cl and CH_2Ph, respectively, in addition to multiplets due to the cyclooctadiene CH_2 groups and the aromatic hydrogens. The significant difference between the two =CH chemical shifts is due to the difference in *trans* influence between the Cl and CH_2Ph groups, the benzyl group weakening the Pd–alkene interaction *trans* to itself and making it more like a free alkene. Consistently, the ^{13}C{^{1}H} NMR spectrum contains two signals due to the nonequivalent alkene moieties, two signals assigned to the aliphatic carbons of cyclooctadiene, a benzylic carbon resonance at 35.8 ppm, and four aromatic signals.

The crystal structure of **1a** belongs to the space group $P2_12_12_1$, and its molecular structure is shown in Fig. 1. Bond distances and angles are given in Table 1. The structure exhibits approximate square planar geometry about palladium, the metal center being coordinated by the two alkene groups of the diene, the benzyl CH_2 group and Cl. The double bonds lie approximately perpendicular to the square plane. The C—C distance for the alkene lying *trans* to the benzyl group is 1.334(10) Å, close to that expected for the free diene, whereas the other C—C bond is lengthened slightly (1.379(10) Å), indicating a stronger alkene–metal interaction *trans* to Cl. The Pd—C and Pd—Cl distances are 2.051(7) and 2.336(2) Å, respectively.

When compared with the few related organopalladium complexes that have been reported previously, namely, [PdClR(cod)] (R = C_6F_5 (8), CH_2SO_2Ph (9)) and the [PdCl{CH($SiMe_3$)PMe_2Ph}(cod)]$^+$ cation (10), the present complex displays the longest Pd—C(alkene) bonds *trans* to the organic fragment and the longest Pd—Cl distance. These features suggest that the benzyl group exhibits the greatest

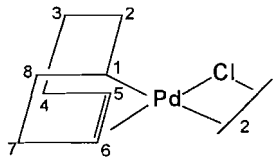
trans influence among these organic groups. Within the diene ligand a weaker Pd—C(alkene) interaction *trans* to the benzyl group may induce a stronger Pd—C(alkene) interaction *trans* to Cl which, in turn, results in weakening of the Pd—Cl bond.

Whereas [PdClMe(cod)] reacted with carbon monoxide to produce the corresponding acetyl complex (7), we found that treatment of the benzyl complex with CO (1 atm (101.3 kPa)) at ambient temperature resulted in rapid decomposition.

The reaction of [$PdCl_2$(cod)] with tetraethyltin proved to be more complicated. When the reaction was performed at temperatures above 20°C extensive decomposition took place in addition to formation of dimeric species (vide infra), and long reaction times at ambient temperature also led to decomposition and the formation of palladium mirrors. On the other hand, at 0°C or below the reaction was extremely slow. Excess Et_4Sn also promoted decomposition. We have found that by use of a deficiency of Et_4Sn (ca. 0.6 mol-equiv. per Pd) and relatively short reaction times (ca. 4 h) at 20°C we can isolate [PdClEt(cod)], **1b**, in pure form, albeit in low yield. Since much of the [$PdCl_2$(cod)] is recovered unchanged (and able to be used again), however, the yield of the ethylpalladium complex is 78% based on the amount of [$PdCl_2$(cod)] actually consumed. Longer reaction times result in further reaction of [PdClEt(cod)] and lower isolated yields. The ^1H and $^{13}C\{^1H\}$ NMR spectra of [PdClEt(cod)] are unsurprising, resonances due to the ethyl group being observed in addition to the signals for coordinated cyclooctadiene.

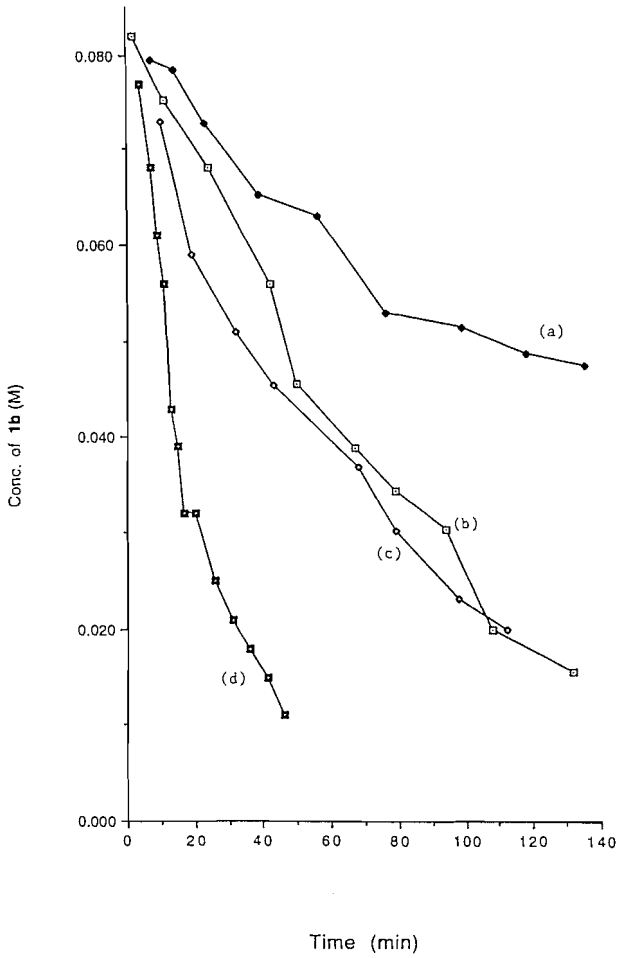
When a C_6D_6 solution of [PdClEt(cod)], **1b**, was allowed to stand at ambient temperature a precipitate formed, along with some palladium metal. Analysis of the remaining solution by ^1H NMR spectroscopy revealed the presence of the dimeric complex [$Pd_2(\mu\ Cl)_2(\eta^1,\eta^2\text{-}C_8H_{13})_2$], **2a**. Signals due to ethene (5.19 ppm) and ethane (0.80 ppm), as well as free 1,5-cyclooctadiene, were also observed. The precipitate was identified as [$PdCl_2$(cod)], which is sparingly soluble in benzene, by its ^1H NMR spectrum in $CDCl_3$ solution. The structure of **2a** was determined from its ^1H and $^{13}C\{^1H\}$ NMR spectra (see Experimental), peak assignments being made from ^1H–^1H and ^{13}C–^1H correlation spectra. The ^1H NMR spectrum shows the expected two olefinic resonances, and the signal due to H1 appears as a multiplet at 3.90 ppm. The resonances for one hydrogen on each of the carbons adjacent to the site of metalation, i.e., C2 and C8, appear at an unusually low frequency (0.40 and 0.60 ppm, respectively), whereas the remaining hydrogens resonate between 1.1 and 2.1 ppm.



2a

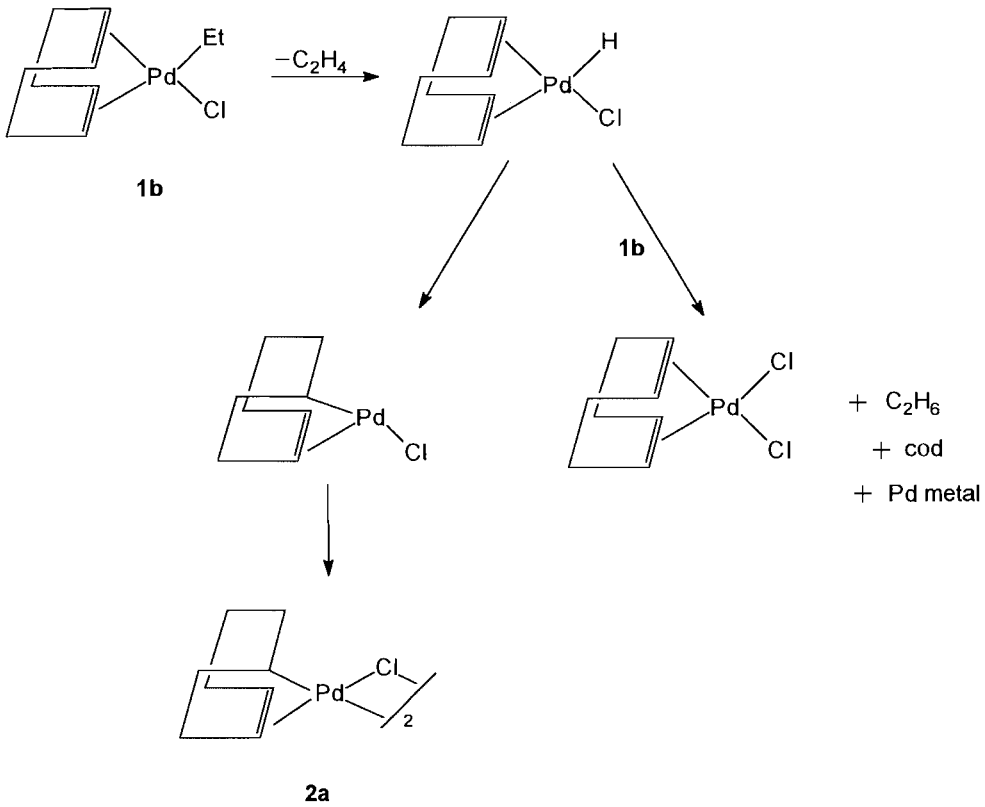
The disappearance of [PdClEt(cod)], **1b**, in benzene solution may be accounted for by the sequence of reactions shown in Scheme 1. β-Hydride elimination from **1b** produces ethene and [PdClH(cod)] (although the latter has not been detected). The hydride complex may follow either of two competing pathways, namely, rearrangement and dimerization to give **2a**, or dinuclear reductive elimination with a molecule of **1b** to produce ethane, [$PdCl_2$(cod)], cyclooctadiene, and palladium metal. It might be anticipated that in the early stages of the reaction, when **1b** is present in relatively high concentration, reaction of [PdClH(cod)] with **1b** would be favored, but this is difficult to ascertain because [$PdCl_2$(cod)] precipitates from solution.

Fig. 2. Plot of the disappearance of **1b** with time (*a*) in dichloromethane, (*b*) in benzene, (*c*) in benzene in the presence of 0.1 mol-equiv. of Et_4Sn, (*d*) in benzene in the presence of 1.0 mol-equiv. of Et_4Sn.



When monitored in C_6D_6 solution, the disappearance of **1b** (which initially contained 10% **2a**) displayed a half-life of 70 min. The reaction occurred more slowly in CD_2Cl_2 solution (Fig. 2), with a half-life of 150 min. Reaction in dichloromethane also resulted in greater conversion to **2a** (ca. 60%). In contrast, when dissolved in CD_3CN **1b** reacted completely within 25 min to produce [$PdCl_2$(cod)] and palladium metal, as well as free cyclooctadiene, ethene, and ethane, with no dimer being detected at all. Integration of the olefinic signals due to [$PdCl_2$(cod)] and cyclooctadiene in the ^1H NMR spectrum indicated that they were formed in equal amounts. When 1 mol-equiv. of Et_4Sn was added to **1b** in C_6D_6 solution decomposition took place much more rapidly (Fig. 2) to give [$PdCl_2$(cod)] and palladium metal, as well as C_2H_4 and C_2H_6, but **2a** was not formed. With 0.1 mol. equiv. of Et_4Sn the disappearance of **1b** was rapid initially (presumably until the

Scheme 1.



Et_4Sn was exhausted), then the rate of decomposition decreased to that of **1b** alone in benzene solution.

The origin of the observed rate difference in benzene and dichloromethane is uncertain. Acetonitrile may be a sufficiently good nucleophile for palladium to displace cyclooctadiene, and the resulting $[PdClEt(CD_3CN)_2]$ may decompose rapidly to give C_2H_4 and $[PdClH(CD_3CN)_2]$. Further reaction with **1b** would produce C_2H_6 and $[PdCl_2(cod)]$ and Pd metal, thereby accounting for the observed products. Rapid decomposition in the presence of Et_4Sn is consistent with our observations regarding the synthesis of **1b**. Excess Et_4Sn is likely to result in formation of $[PdEt_2(cod)]$, which would decompose by β-hydride elimination followed by reductive elimination of ethane. The dimethyl analogue was also reported to be unstable (5), although it would be susceptible only to Pd—C bond cleavage or reductive elimination. When the reaction of $[PdCl_2(cod)]$ with Et_4Sn was monitored by ^{119}Sn NMR, spectroscopy signals due to Et_4Sn and Et_3SnCl only were observed, indicating that only one ethyl group is transferred to palladium. Even with only 1 mol-equiv. of Et_4Sn, however, it is likely that some $[PdEt_2(cod)]$ is formed (leaving some $[PdCl_2(cod)]$ unreacted), which would decompose readily.

Complex **2a** underwent no further reaction in benzene or dichloromethane solution at ambient temperature, but when a C_6D_6 solution of **2a** was heated to 70°C rearrangement to its allyl isomer $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}C_8H_{13})_2]$, **2b**, occurred. The conversion was 60% complete after 5 h, but then the reaction appeared to reach equilibrium, and further heating caused decomposition. Complex **2b** was identified by its ^1H and $^{13}C\{^1H\}$ NMR spectra. It exhibits triplet and quartet resonances for the allyl functionality in its ^1H NMR spectrum, and the expected five resonances in its $^{13}C\{^1H\}$ NMR spectrum (see Experimental). That an equilibrium between **2a** and **2b** was indeed established was demonstrated by heating a toluene-d_8 solution of **2b** to 100°C for 30 min. Analysis of the solution revealed the presence of **2a** and **2b** in a 1:2 ratio, consistent with that found starting from **2a**.

Espinet and co-workers have shown (8) that $[PdCl(C_6F_5)(cod)]$ undergoes a slow rearrangement in solution at ambient temperature to give a mixture of $[Pd_2(\mu\text{-}Cl)_2(\eta^1,\eta^2\text{-}C_8H_{12}\cdot C_6F_5)_2]$ and $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}C_8H_{12}\cdot C_6F_5)_2]$, the ratio of which was found to depend on the solvent employed. Interconversion of the two isomers was not detected at ambient temperature, and only 20% of $[Pd_2(\mu\text{-}Cl)_2(\eta^1,\eta^2\text{-}C_8H_{12}\cdot C_6F_5)_2]$ was converted to its η^3-allyl isomer after refluxing in chloroform for 80 h. They interpreted this to indicate that $[Pd_2(\mu\text{-}Cl)_2(\eta^1,\eta^2\text{-}C_8H_{12}\cdot C_6F_5)_2]$ is not an intermediate in the formation of the allyl complex, but that both are formed from a common intermediate $[Pd_2(\mu\text{-}Cl)_2(\eta^1\text{-}C_8H_{12}\cdot C_6F_5)_2]$, in which the remaining double bond is uncoordinated (8). In our work **2b** is not formed at 25°C so **2a** could be an intermediate in its formation, but a common intermediate of the type $[Pd_2(\mu\text{-}Cl)_2(\eta^1\text{-}C_8H_{13})_2]$ is also possible with coordination of the free double bond being much faster than rearrangement to the allyl form at ambient temperature. Equilibration of **2a** and **2b** occurs relatively easily at higher temper-

atures, suggesting that there is a lower activation barrier than in the pentafluorophenyl-substituted system. Espinet and coworkers pointed out the significance of slow isomerization of η^1,η^2- to η^3-allyl species and its relevance to organic synthesis via allylmetal complexes (11, 12). Related slow η^1,η^2- to η^3-allyl rearrangements have been observed previously (13, 14).

Although **2a** alone does not convert to **2b** at ambient temperature, we found that addition of free chloride ion (in the form of bis(triphenylphosphine)iminium chloride) to a CD_2Cl_2 solution of **2a** resulted in complete conversion to **2b** within 12 h. In contrast, addition of sodium acetate had no such effect. Addition of chloride to **2a** may result in bridge opening to form a species of the type $[PdCl_2(\eta^1,\eta^2\text{-}C_8H_{13})]^-$, in which rearrangement to the η^3 form occurs more readily. The rearrangement is likely to occur by a series of reversible β-eliminations, and this should be enhanced by the increased electron density on the palladium center in an anionic species. Since acetate is a weaker nucleophile for palladium, the addition of NaOAc resulted in no rate enhancement.

The formation of **2a** from [PtClEt(cod)], and its rearrangement to **2b**, prompted us to investigate alternative methods for the preparation of these dimeric complexes. It had been reported (15) that treatment of $PdCl_2$ with 2.3 equivalents of 1,5-cyclooctadiene in aqueous acetone for 20 h at ambient temperature produced **2a** in high yield. This was shown to occur by Wacker oxidation of one equivalent of cyclooctadiene to cycloocten-5-one, and addition of the HPdCl moiety thus formed to a second cyclooctadiene was proposed to account for the formation of **2a** (15). We have also obtained **2a** by this method. In addition, we found that **2a** can be prepared by treatment of $[PdCl_2(cod)]$ with 1.2 mol-equiv. of $NaBH_4$ in CH_2Cl_2–MeOH solution. When the reaction is carried out at ambient temperature extensive decomposition occurs, but if the reaction is performed at −60°C **2a** is formed cleanly and, although some decomposition to palladium metal occurs during the isolation procedure, the complex can be obtained in good yield. Complex **2b** has been prepared previously, by reaction of $[Pd(\eta^3\text{-}C_8H_{13})(cod)]ClO_4$ with excess LiCl (16). The corresponding bromide-bridged complex was also produced by passing CO through an ethanol solution of $PdCl_2$ and NaCl in the presence of excess 3-bromocyclooctene (17).

Since $[PdCl_2(cod)]$ is formed rapidly from cyclooctadiene and palladium(II) chloride or a tetrachloropalladate(II) salt, it seemed likely that it would be an intermediate in the formation of **2a** from $PdCl_2$ and 1,5-cyclooctadiene (15). Thus, we studied the reactions of $[PdCl_2(cod)]$ with free cyclooctadiene under a variety of conditions. When $[PdCl_2(cod)]$ alone was heated to 70°C for 5 min in water or in aqueous acetone a complex mixture of products was obtained, but when heated with 1 equivalent of cyclooctadiene in water conversion to **2a** occurred within 5 min, although considerable decomposition also took place. Decomposition was inhibited by addition of acetic acid. Thus, heating an aqueous acetic acid solution of $[PdCl_2(cod)]$ with free cyclooctadiene to 70°C for 5 min resulted in very little decomposition to palladium metal, and a mixture of **2a** and **2b** was obtained (eq. [1]). Heating to 100°C gave **2b** only. Whereas the presence of acetic acid appeared to stabilize the system (and promote allyl formation), reaction of $[PdCl_2(cod)]$ was inhibited by addition of hydrochloric acid. Heating a solution of the complex with 1 or 10 equivalents of cyclooctadiene in 6 M HCl resulted in quantitative recovery of $[PdCl_2(cod)]$. Similarly, heating an aqueous solution of $[PdCl_2(cod)]$ with free cyclooctadiene in the presence of 100 equivalents of sodium chloride produced no reaction.

[1] $[PdCl_2(cod)] + cod \xrightarrow[70°C,\ 5\ min]{H_2O/HOAc}$  +

2a **2b**

Reactions involving K_2PdCl_4 gave similar results. When an aqueous solution of the salt containing 2 equivalents of cyclooctadiene was heated to 70°C for 5 min a mixture of $[PdCl_2(cod)]$ and **2a** was obtained, but considerable decomposition occurred. Addition of acetic acid again stabilized the system against decomposition. Prolonged heating to 70°C of an aqueous acetic acid solution of K_2PdCl_4 with cyclooctadiene produced a mixture of **2a** and **2b**, whereas heating of the mixture to 100°C gave the allyl complex **2b** as the sole product. Reaction of K_2PdCl_4 with cyclooctadiene was inhibited by excess HCl, only a small amount of $[PdCl_2(cod)]$ being formed after 35 min at 70°C, and neither of the dimeric complexes **2a** or **2b** was observed.

A number of points emerge from these studies. When $[PdCl_2(cod)]$ or K_2PdCl_4 was heated to 70°C in aqueous solution in the presence of excess cyclooctadiene a mixture of **2a** and **2b** was obtained within a few minutes. Thus, **2b** was formed much more rapidly than when **2a** was heated to the same temperature in benzene. At 100°C **2b** was formed as the exclusive product, suggesting that the equilibrium position between the two isomers considerably favors the η^3-allyl form at this temperature in aqueous solution. The role of acetic acid in preventing decomposition is unclear. On the other hand, the presence of excess HCl inhibited reaction of $[PdCl_2(cod)]$ to form **2a** and **2b**. If, as suggested by Stille and James (15), oxidation of cyclooctadiene proceeds by initial attack of water on the coordinated diene of $[PdCl_2(cod)]$ followed by loss of HCl, it would be expected that this process should be suppressed by the presence of HCl.

The observation that excess HCl also inhibits the formation of $[PdCl_2(cod)]$ from K_2PdCl_4 and cyclooctadiene is interesting. The reason for this may simply be that in the presence of a

high concentration of free chloride, dissociation of Cl^- from $PdCl_4^{2-}$ is suppressed, thereby preventing coordination of the diene. This is significant in that reported procedures for the preparation of [$PdCl_2$(cod)] often involve the use of HCl. Whereas the initial report of the synthesis of the complex involved reaction of Na_2PdCl_4 with cyclooctadiene in methanol or acetone solution (18), more recent methods involve the use of a dilute solution of HCl in ethanol (19, 20). The concentration of HCl employed in these cases is considerably lower than that used here, but it should be pointed out that the presence of a high concentration of HCl could have a detrimental effect on the yield of [$PdCl_2$(cod)] prepared by this method.

Experimental

All reactions were carried out under an atmosphere of argon. Solvents were dried and distilled immediately prior to use. Tetraethyltin was obtained from Aldrich. Tetraphenyltin and tetrabenzyltin were prepared from $SnCl_4$ and the appropriate Grignard reagent. [$PdCl_2$(cod)] was prepared according to the method of Chatt et al. (18). NMR spectra were recorded on a Varian XL-300, Varian Unity plus 300, or Bruker ARX-500 spectrometer. ^{1}H and ^{13}C chemical shifts are relative to the residual solvent resonance. Microanalyses were performed by Atlantic Microlab, Inc, Norcross, Ga.

Preparation of [PdCl(CH_2Ph)(cod)], 1a

To a dichloromethane solution of [$PdCl_2$(cod)] (0.50 g, 1.8 mmol) was added $Sn(CH_2Ph)_4$ (1.2 g, 2.4 mmol). The yellow solution was refluxed for 7 h. The resulting black mixture was passed through a Hyflo Supercel column to remove palladium metal, then the solvent was evaporated. The residue was dissolved in a 80:20 mixture of CH_2Cl_2/hexane, and the solution was passed through a 14 × 1 cm silica column. The column was eluted with a total of 1 L of solvent, and the yellow fraction was collected. The solvents were evaporated, leaving the product as a yellow powder that was dried in vacuo (0.39 g, 66%). ^{1}H NMR ($CDCl_3$), δ(H): 2.39 m (CH_2), 3.59 s (CH_2Ph), 4.87 m, 5.89 m (=C*H*), 7.14 m, 7.43 m (C_6H_5). ^{13}C{^{1}H} NMR ($CDCl_3$); δ(C): 27.5, 30.9 (CH_2), 35.8 (CH_2Ph), 104.5, 123.7 (=*C*H), 125.7, 128.6, 129.5, 143.9 (C_6H_5). Anal. calcd for $C_{15}H_{19}ClPd$: C 52.81, H 5.61; found: C 52.81, H 5.66.

Preparation of [PdClEt(cod)], 1b

Tetraethyltin (0.307 mL, 1.55 mmol) was added by syringe to a CH_2Cl_2 (40 mL) solution of [$PdCl_2$(cod)] (0.772 g, 2.71 mmol). The system was protected from light, and stirred for 4 h at 20°C, then cooled in an ice bath. The solvent was evaporated at 0°C. The residue was washed with hexane to remove the tin compounds, then extracted with three 15 mL portions of benzene. The benzene extract was frozen in an ice bath, and the benzene was removed in vacuo, leaving the product as a yellow solid (0.156 g, 36% yield based on Et_4Sn used). ^{1}H NMR (CD_2Cl_2), δ(H): 1.26 t (CH_3), 1.57 m, 1.75 m (CH_2), 2.24 q (CH_2CH_3), 4.98 m, 5.72 m (=C*H*). ^{13}C{^{1}H} NMR (CD_2Cl_2), δ(C): 17.7 (CH_3), 27.3 (CH_2), 30.2 (CH_2CH_3), 30.7 (CH_2), 101.0, 123.6 (=*C*H). The benzene-insoluble material was identified as unreacted [$PdCl_2$(cod)] (0.567 g).

Preparation of $[Pd_2(\mu\text{-}Cl)_2(\eta^1,\eta^2\text{-}C_8H_{13})_2]$, 2a

(a) From $[PdCl_2(cod)]$ and Et_4Sn

To a CH_2Cl_2 solution of $[PdCl_2(cod)]$ (0.30 g, 1.05 mmol) was added tetraethyltin (0.30 mL, 1.5 mmol) by syringe. The solution was stirred at ambient temperature for 15 h, during which time a mirror was deposited on the inside of the flask. The resulting solution was passed through a Hyflo Supercel column, and the solvent was evaporated. The yellow residue was washed with hexane, then extracted with benzene. The benzene solution was filtered to remove unreacted $[PdCl_2(cod)]$, then evaporated to dryness to leave the product as a yellow powder (0.12 g, 46%). ^1H NMR (C_6D_6), δ(H): 0.40 (m) H2; 0.60 (dd, 6.2 and 14.4 Hz) H8; 1.45 (dt, 10.8 and 4.4 Hz) H3, H3′; 1.55 (m) H7, H7′; 1.70 (m) H2′, H4; 1.92 (m) H4′; 2.13 (m) H8′; 3.90 (m) H1; 5.60 (m) H5; 5.88 (dt, 6.7 and 8.3 Hz) H6. $^{13}C\{^1H\}$ NMR (C_6D_6), δ(C): 26.3 (C7), 27.0 (C3), 28.7 (C4), 35.7 (C2), 40.2 (C8), 56.0 (C1), 100.7 (C5), 105.2 (C6). Anal. calcd. for $C_{16}H_{26}Cl_2Pd_2$: C 38.27, H 5.22; found: C 38.31, H 5.16.

(b) From $[PdCl_2(cod)]$ and $NaBH_4$

$[PdCl_2(cod)]$ (0.20 g, 0.70 mmol) was dissolved in CH_2Cl_2 (60 mL), and $NaBH_4$ (0.032 g, 0.85 mmol) was added. The mixture was cooled to −60°C and methanol (1 mL), previously cooled to −78°C, was added. After 24 h the solvents were removed in vacuo and the residue was extracted with CH_2Cl_2. After passing through a Hyflo Supercel column, the CH_2Cl_2 was evaporated to leave the product as a light yellow powder, which was washed with hexane and dried (0.134 g, 76%).

Preparation of $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}C_8H_{13})_2]$, 2b

K_2PdCl_4 (0.10 g, 0.31 mmol) was dissolved in a mixture of water (25 mL) and acetic acid (25 mL). The solution was heated to 100°C, then 1,5-cyclooctadiene (0.37 mL, 3.0 mmol) was introduced. The solution changed immediately from red to yellow, then to black. The mixture was maintained at this temperature for 20 min, then cooled in an ice bath, and extracted with CH_2Cl_2 (50 mL). The CH_2Cl_2 solution was washed with water (200 mL), then the solvent was evaporated to leave the product as a light yellow powder (0.043 g, 49%). ^1H NMR ($CDCl_3$), δ(H): 1.45 m, 6H (CH_2), 1.85 m, 2H (CH_2), 2.35 m, 2H (CH_2), 4.75 q, 2H (CH), 5.30 t, 1H (CH). δ(C): 23.2 (1C), 25.1 (2C), 31.1 (2C), 78.6 (2C), 105.0 (1C). Anal. calcd for $C_{16}H_{26}Cl_2Pd_2$: C 38.27, H 5.22; found: C 38.57, H 5.13.

Decomposition of 1b

The conversion of [PdClEt(cod)], **1b**, to $[Pd_2(\mu\text{-}Cl)_2(\eta^1,\eta^2\text{-}C_8H_{13})_2]$, **2a**, under various conditions was monitored by ^1H NMR spectroscopy using a Varian Unity plus 300 spectrometer. A 0.08 M solution of **1b**, containing about 10% **2a**, to which 0.01 M anisole was added as a standard, was prepared. A spectrum was recorded (using either a 1 s or 15 s delay between pulses) at ambient temperature approximately every 15 min. The olefinic signals due to the reactant and product were integrated relative to the anisole signal (3H) at 6.8 ppm.

X-ray structure determination

Light yellow colored rectangular plates were obtained by slow evaporation of a benzene/toluene (1:1) solution of $[PdCl(CH_2Ph)(cod)]$ at 0°C. A crystal of dimensions 0.4 × 0.1 × 0.06 mm was mounted on a glass fiber in random orientation and was coated with Superglue. Preliminary examination and data collection were performed using a Siemens P4RA automated single crystal X-ray diffractometer using monochromated Mo Kα radiation (λ = 0.71073 Å) at 22°C. Autoindexing of 10 centered reflections from the rotation photograph indicated an orthorhombic lattice. Equivalent reflections were checked to confirm the Laue symmetry and a fractional index search was conducted to confirm the cell lengths. Final cell constants and orientation matrix for data collection were calculated by least-squares refinement of the setting angles for 35 reflections ($12° < 2\theta < 25°$). Intensity data were collected using $\overline{\omega}$ scans with fixed scan speed. Friedel pairs were collected to confirm the absolute structure. Three representative reflections measured every 97 reflections showed 13.2% variation during data collection. Crystal data and intensity data collection parameters are listed in Table 2.

Data reduction was carried out using XSCANS and structure solution and refinement were carried out using the SHELXTL-PLUS (5.03) software (21). An absorption correction was applied to the data using equivalent reflections and $\overline{\psi}$ scan reflections. The structure was solved by the Patterson method and refined successfully in the space group $P2_12_12_1$. Full-matrix least-squares refinement was carried out by minimizing $\Sigma\omega(F_o^2 - F_c^2)^2$. The non-hydrogen atoms were refined using the appropriate riding model AFIX = m3. The final residual values were $R(F) = 5.18\%$ for 2042 observed reflections ($I > 2\sigma(I)$) and $wR(F^2) = 9.18\%$; $s = 1.0$ for all data. The absolute structure was confirmed by the Flack method ($x = -0.09(8)$). Structure refinement parameters are listed in Table 2. The atomic coordinates for the non-hydrogen atom are listed in Table 3. A projection view of the molecule, showing the atom labeling, is presented in Fig. 1 (non-hydrogen atoms are represented by 50% probability ellipsoids).

Complete listings of anisotropic displacements for the non-hydrogen atoms, and of positional and isotropic displacement

coefficients for the hydrogen atoms, have been submitted as supplementary material.[2]

Acknowledgments

Thanks are expressed to the donors of the Petroleum Research Fund, administered by the American Chemical Society, and the National Science Foundation (grant numbers CHE-9101834 and CHE-9508228) for support of this work, and to Johnson Matthey Aesar/Alfa for a generous loan of palladium salts. R.A.S. and J.C.E. were supported during summer 1993 and 1994, respectively, as NSF-REU fellows under grant number CHE-9200156. The support of the NSF (grant number CHE-9318696), the U.S. Department of Energy (DE-FG02-92CH10499), and the University of Missouri Research Board for the purchase of the Unity plus and ARX spectrometers is gratefully acknowledged.

High-pressure methods as a tool in organometallic syntheses: facilitation of oxidative addition to platinum(II)

Andrew R.L. Skauge, Richard D. Shalders, and Thomas W. Swaddle

Abstract: High-pressure (2 GPa) batch reactors now commercially available may offer substantial accelerations of organometallic syntheses, without resort to heating, when the activation process is multicentered or involves the generation and solvation of ions. As an example of the latter class of reactions, the kinetics of the oxidative additions of methyl and ethyl iodides (RI) to dimethyl(2,2′-bipyridine)platinum(II) in acetone have been studied over the pressure range 0–200 MPa. The volumes of activation $\Delta V_I^{\ddagger}$, if assumed to be constant over this range, are -11.7 ± 0.3 and -9.7 ± 0.7 cm^3 mol^{-1}, respectively, implying an acceleration of ca. 3000-fold for a batch synthesis of this sort at 2 GPa. However, a possible slight pressure dependence of $\Delta V_I^{\ddagger}$ may reduce this acceleration to ca. 1 000-fold. The $\Delta V_I^{\ddagger}$ data and the 500-fold retardation on going from R = Me to R = Et are consistent with an S_N2 attack of Pt^{II} on the α-carbon in the alkyl iodides, forming I^- and $[RMe_2Pt(bpy)]^+$.

Key words: volumes of activation, high pressure, oxidative addition, platinum(II), organometallic syntheses.

Résumé : Lorsque le processus d'activation est multicentrique ou qu'il implique la génération ou la solvatation d'ions, les réacteurs discontinus à haute pression (2 GPa) qui sont maintenant disponibles commercialement peuvent s'avérer utiles pour accélérer de façon convaincante les synthèses d'organométalliques, sans chauffage. À titre d'exemple de réaction impliquant une solvatation d'ions, on a étudié la cinétique des additions oxydantes des iodures de méthyle et d'éthyle (RI) sur le diméthyl(2,2′-bipyridine)platine(II), dans l'acétone, à des pressions allant de 0 à 200 MPa. Si l'on fait l'hypothèse qu'ils sont constants sur l'ensemble de ces pressions, les volumes d'activation, $\Delta V_I^{\ddagger}$, de ces deux réactions sont respectivement de $-11,7 \pm 0,3$ et $-9,7 \pm 0,7$ cm^3 mol^{-1} et, pour une synthèse discontinue de cette sorte à 2 GPa, ceci implique une accélération par un facteur de 3000. Toutefois, il est possible qu'une faible dépendance du $\Delta V_I^{\ddagger}$ sur la pression puisse réduire cette accélération à un facteur d'environ 1000. Les données de $\Delta V_I^{\ddagger}$ et un ralentissement par un facteur de 500 en passant de R = Me à R = Et sont en accord avec un mécanisme d'attaque S_N2 du Pt(II) sur le carbone en α des iodures d'alkyles conduisant à la formation de I^- et de $[RMe_2Pt(bpy)]^+$.

Mots clés : volumes d'activation, pression élevée, addition oxydante, platine(II), synthèses d'organométalliques.

[Traduit par la rédaction]

The routine use of pressures on the order of 1 GPa (10 kbar) as a synthetic tool has gained acceptance among organic chemists (1–9), but to date has not found significant application in organometallic chemistry. Apart from the obvious advantage of producing enhanced activities of gaseous reactants, pressure P can influence the maximum attainable *yield* of a reaction through the equilibrium constant K if the reaction volume ΔV (the molar volume of the products minus that of the reactants) is nonzero:

$$[1] \quad \Delta V = -RT(\partial \ln K/\partial P)_T$$

Received January 24, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

A.R.L. Skauge, R.D. Shalders, and T.W. Swaddle.[1]

Similarly, pressure influences the *rate* constant k of the reaction through the volume of activation $\Delta V^{\ddagger}$ (the molar volume of the transition state minus that of the reactants):

$$[2] \quad \Delta V^{\ddagger} = -RT(\partial \ln k/\partial P)_T$$

It is commonly assumed that ΔV and $\Delta V^{\ddagger}$ are independent of pressure, in which case $\ln K$ and $\ln k$ would be linearly dependent upon P. In principle, one can use the quite precise measurements of ΔV or $\Delta V^{\ddagger}$ that can be made at 0.1–200 MPa to predict the outcome of batch syntheses run in autoclaves at 1–2 GPa (pressures now routinely accessible with commercial pressure equipment). In practice, however, $|\Delta V|$ and $|\Delta V^{\ddagger}|$ often become smaller as the pressure is increased beyond 100 MPa. Linear extrapolations of $\ln K$ or $\ln k$ values from low-pressure measurements will therefore tend to overestimate the pressure effect, but at least they place upper limits on what can be achieved for a given reaction with high-pressure techniques.

In this article, we consider only the kinetic aspect — specifically, the potential of high pressures to accelerate syntheses that would otherwise be too slow, without resort to heating that might bring about thermal decomposition. Theoretical expectations for such accelerations, based on typical negative $\Delta V^{\ddagger}$ values (assumed to be independent of P), are given in

Table 1. Rate constants k_P at high pressures relative to atmospheric pressure for some typical volumes of activation.[a]

	k_P/k_0 [b] at 25°C for $\Delta V^{\ddagger}$ =		
P/MPa	−10	−20	−30 cm³/mol⁻¹
0	1	1	1
100	1.50	2.24	3.35
200	2.24	5.02	11.25
400	5.02	25.2	126.6
1000	56.5	3.19×10^3	1.80×10^5
2000	3.19×10^3	1.02×10^7	3.24×10^{10}

[a]Assumed independent of pressure.
[b]Acceleration factors, or retardation factors for the corresponding positive values of $\Delta V^{\ddagger}$.

Table 1. For positive $\Delta V^{\ddagger}$ values, these would be retardation factors; pressure-induced retardation could be useful synthetically in suppressing unwanted side reactions if these have a positive $\Delta V^{\ddagger}$ while that of the reaction of interest is negative or near zero.

An armchair experimentalist might identify at least three types of organometallic reaction as being likely candidates for high-pressure synthetic procedures.

1. **Slow reactions that involve the formation of several bonds between initially separate molecules** (cf. Diels–Alder reactions in conventional organic chemistry). These can be expected to have strongly negative $\Delta V^{\ddagger}$ values, and so to be accelerated by hydrostatic pressure. Ryabov (10) points out that organometallic reactions requiring such multicentered activation tend to have high $\Delta H^{\ddagger}$ and strongly negative $\Delta S^{\ddagger}$, and hence are often too slow for conventional synthetic operations. In general, however, trends in $\Delta V^{\ddagger}$ values tend to parallel those in $\Delta S^{\ddagger}$, so we may anticipate very favorable pressure-induced accelerations for this class of reactions.
2. **Syntheses with unwanted homolytic side reactions.** Homolytic bond fission is generally associated with positive $\Delta V^{\ddagger}$. Indeed, this has been demonstrated for some organometallic cases, viz., Cr—C homolysis pathways in the decompositions of aqueous $(H_2O)_5CrCH(CH_3)_2^{2+}$, $(H_2O)_5CrC(CH_3)_2OH^{2+}$, and $(H_2O)_5CrCH_2C_5H_4NH^{3+}$, for which $\Delta V^{\ddagger} = +26$ (low-pressure limit), +15, and +19 cm³ mol⁻¹, respectively. In these reactions, the homolytic pathway is progressively "squeezed out" and the heterolytic alternative, where significant, emerges as the pressure is increased (11, 12).
3. **Slow reactions involving a substantial increase in solvation.** Any development of electric charge en route to the transition state demands an increase in solvation and hence a negative contribution to the volume of the system. This may overwhelm any positive contributions from bond breaking, so that the overall $\Delta V^{\ddagger}$ can be strongly negative even for a dissociatively activated process (13). Organometallic *oxidative addition* reactions can be of this type; for example, the slow addition of methyl iodide to β-diketonatobis(triphenylphosphite)rhodium(I) complexes evidently involves a rate-determining step that produces iodide and methylrhodium(III) ions, and $\Delta V^{\ddagger}$ values of −9, −18, −19, and −23 cm³ mol⁻¹ were found for the trifluorobenzoylacetone complex in 1,2-dichloroethane, dichloromethane, acetone, and chloroform, respectively (14).

It therefore would seem that pressure acceleration could be used to advantage to force to useful degrees of completion those oxidative addition reactions that are thermodynamically feasible but normally too slow for practical purposes. To evaluate the likely usefulness of this approach in platinum chemistry and to gain mechanistic insights, we have used high-pressure stopped-flow spectrophotometry to study the addition of methyl and ethyl iodides (RI) to dimethyl(2,2′-bipyridine)platinum(II):

$$[3]\quad RI + Me_2Pt(bpy) \xrightarrow{k_1} [RMe_2Pt(bpy)]^+ + I^- \xrightarrow{k_2} RMe_2Pt(bpy)I$$

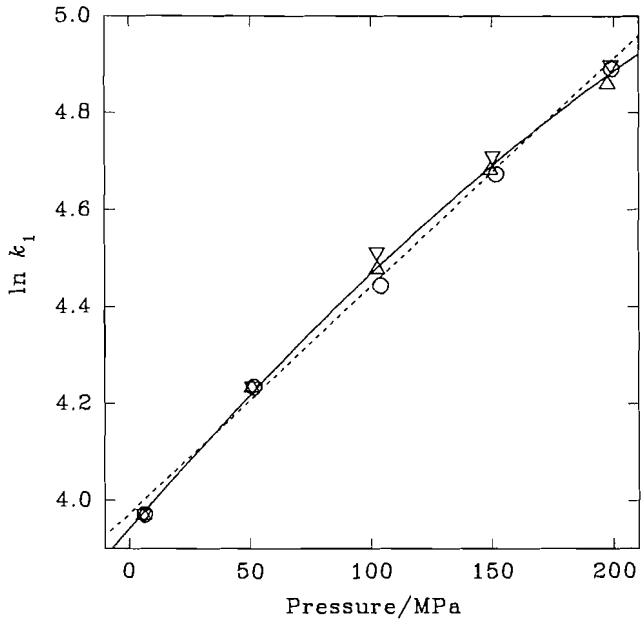
Reactions of this type are of special interest in that they afford routes to organometallic polymers (15, 16), and in any event they provide informative models of the process of oxidative addition at d^8 square-planar centers, which is of industrial importance (e.g., in the Monsanto process for acetic acid). Thus, for reaction [3] with R = Me in acetonitrile solvent, Crespo and Puddephatt (17) were able, using ^{1}H NMR at −40°C, to detect the actual Pt^{IV} intermediate $[Me_3Pt(bpy)]^+$ and demonstrate that it contained a molecule of coordinated solvent; as the solution warmed to 0°C, iodide ion replaced the coordinated CH_3CN, *trans* to the added methyl group. Detection of major concentrations of the intermediate implied that the rate constant k_1 was greater than k_2 at these temperatures in CH_3CN, but for O-donor solvents such as acetone and methanol (which have less affinity for Pt than does CH_3CN), this was possible only at −80°C. Over the range −7.5 to 20°C in acetone, addition of MeI to $Me_2Pt(bpy)$ proceeded to form $Me_3Pt(bpy)I$ with monophasic second-order kinetics, corresponding to a rate-controlling initial step characterized by k_1 with $\Delta H_1^{\ddagger} = 24.9$ kJ mol⁻¹ and $\Delta S_1^{\ddagger} = -129$ J K⁻¹ mol⁻¹ (18).[2] These kinetic data are consistent with the addition of the solvent molecule to Pt synchronously with the attack of Pt^{II} on the methyl iodide (an S_N2 mechanism, as opposed to radical or radical-chain alternatives (17, 18)) together with the augmented solvation associated with the development of ions in this initial step.

This strongly negative $\Delta S_1^{\ddagger}$ for RI = MeI for reaction [3] in acetone led us to anticipate a correspondingly strongly negative $\Delta V_1^{\ddagger}$, and hence good prospects for synthetically useful pressure-induced accelerations of other, slower, oxidative additions at Pt^{II} centers (e.g., reaction [3] with methyl acetate in place of MeI). The S_N2 mechanism implies slower substitution with more sterically hindered nucleophiles, and we therefore studied reaction [3] with both EtI and MeI to ascertain whether $\Delta V_1^{\ddagger}$ is significantly affected by steric factors.

After this work was completed, we learned of the high-pressure kinetic study by Dücker-Benfer, van Eldik and Canty (19) of the *palladium* analogue of reaction [3] (R = MeI, solvent = acetone), which differs in that both the oxidative addition ($\Delta V^{\ddagger} = -11.9 \pm 0.6$ cm³ mol⁻¹) and subsequent reductive

[2] The activation energy cited in ref. 18 is in fact the enthalpy of activation.

Fig. 1. Pressure dependence of k_1 for addition of MeI to Pt(bpy)Me_2 in acetone at 25°C. Circles: [MeI] = 4.02 mmol L^{-1}. Down triangles: [MeI] = 3.01 mmol L^{-1}. Up triangles: [MeI] = 2.01 mmol L^{-1}. Each data point is the mean of three k_1 values. Broken line: linear regression (eq. [4]). Solid curve: quadratic regression (eq. [5]).



elimination of ethane ($\Delta V^{\ddagger} = -17 \pm 1$ cm^3 mol^{-1}) could be observed — reductive elimination in the Pt^{IV} complex is negligible because of its high activation energy, even though addition of MeI to the Pt^{II} complex is faster than to the Pd^{II} (18). Comparison of our results with $\Delta V^{\ddagger}$ for the latter pathway is instructive.

Experimental

Preparation of dimethyl(2,2′-bipyridine)platinum(II)

In our hands, Pt(bpy)Me_2 was best prepared via Pt(COD)Cl_2 (COD = 1,5-cyclooctadiene), by variations of the methods of Clark and Manzer (20) and Puddephatt et al. (16, 21). Pt(COD)Cl2 was made in 88% yield by heating K_2PtCl_4 (1.7 mmol) in aqueous 1-propanol with COD (1.46 mL) at 60°C for 1.5 h. Addition of NaI to a suspension of Pt(COD)Cl_2 in acetone gave Pt(COD)I_2 quantitatively. Treatment of this solid with methyllithium in diethyl ether under N_2 at 0°C for 2 h, followed by hydrolysis with ice-cold saturated aqueous NH_4Cl, ether extraction, and evaporation of the ether layer gave Pt(COD)Me_2. Reaction of this solid with bpy in acetonitrile gave a 75% yield of moisture-sensitive Pt(bpy)Me_2, which was recrystallized from acetone to give red needles, the authenticity of which was confirmed by CHN analyses and NMR spectroscopy (22).

High-pressure kinetics

Freshly prepared solutions of Pt(bpy)Me_2 and a 20-fold excess of MeI (or 5000-fold excess of EtI) in redistilled anhydrous acetone were loaded into an HPSF-56 high-pressure stopped-flow spectrophotometer (Hi-Tech Scientific Ltd., Salisbury, U.K.) thermostated at 25.0 ± 0.1°C. Pressures were measured with an Autoclave Engineers digital gauge, calibrated (±0.2 MPa) against a Pressurements T3800/4 deadweight gauge. After each pressurization, the system was allowed to re-equilibrate thermally for 30–45 min before firing reagent mixing shots. At least three shots were fired for each pressure and set of concentrations, and the progress of the reaction after mixing was monitored spectrophotometrically through the decay of the absorbance maximum of Pt(bpy)Me_2 at 475 nm (molar absorbance $\varepsilon = 1828 \pm 6$ L mol^{-1} cm^{-1}). The absorbance data were collected and analyzed in terms of a pseudo-first-order rate equation on a dedicated Apple IIe computer. The reaction with EtI at atmospheric pressure was actually slow enough to follow by conventional spectrophotometry with lower [EtI], but the high-pressure experiments required the stopped-flow approach because of the long thermal equilibration times.

Results

It was confirmed by NMR spectroscopy that the products of the reactions of Pt(bpy)Me_2 with MeI and EtI in acetone were indeed Me_3Pt(bpy)I and Me_2EtPt(bpy)I, respectively. The stopped-flow data gave excellent fits to the pseudo-first-order rate equation — better than ±0.1% in the calculated rate constant k_{obsd} — and values of k_{obsd} were accurately proportional to [MeI] or [EtI] (supplementary material, Table S1[3]). There was no evidence for the formation of a long-lived intermediate $[Me_3Pt(bpy)(Me_2CO)]^+$ in the reaction with MeI; furthermore, the reaction of 0.19 mmol L^{-1} Pt(bpy)Me_2 with 4.0 mmol L^{-1} EtI, which was slow enough to follow in a conventional spectrophotometer, showed a strictly maintained isosbestic region at 378–385 nm. Therefore, since the spectra obtained immediately after mixing corresponded to Pt(bpy)Me_2 and the final spectra to RMe_2Pt(bpy)I, k_{obsd}/[RI] values represent k_1 for reaction [3].

Figures 1 and 2 show the pressure dependences of ln k_1 for reaction [3] in acetone with R = Me and Et, respectively. Linear least-squares regression (eq. [4]) represents the data adequately for both MeI and EtI addition, giving $k_1^0 = 53 \pm 1$ L mol^{-1} s^{-1} with $\Delta V_1^{\ddagger} = -11.7 \pm 0.3$ cm^3 mol^{-1} for the combined data for MeI, and $k_1^0 = 0.104 \pm 0.004$ L mol^{-1} s^{-1} with $\Delta V_1^{\ddagger} = -9.7 \pm 0.7$ cm^3 mol^{-1} for EtI, at 25.0°C. The zero (≈ atmospheric) pressure rate constant k_1^0 for MeI agrees satisfactorily with 49 L mol^{-1} s^{-1} extrapolated from the data of Puddephatt et al. (18).

$$[4] \quad \ln k_1 = \ln k_1^0 - (\Delta V_1^{\ddagger}/RT)P$$

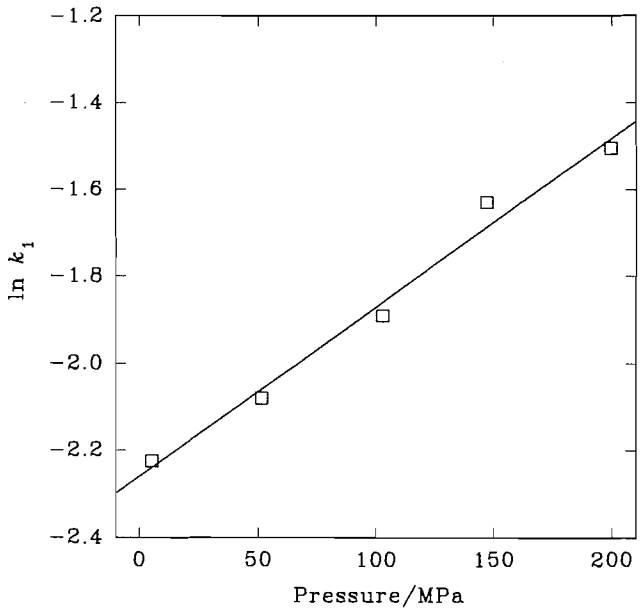
For MeI addition, however, a possible slight nonlinearity of the ln k_1 vs. P plot is discernible for the combined data. For simplicity, the data may be fitted to the quadratic expression

$$[5] \quad \ln k_1 = \ln k_1^0 - (\Delta V_1^{0\ddagger}/RT)P + (\Delta\beta^{\ddagger}/2RT)P^2$$

giving $k_1^0 = 51 \pm 1$ L mol^{-1} s^{-1} (in still better agreement with Puddephatt et al. (18)), the limiting zero-pressure volume of activation $\Delta V_1^{0\ddagger} = -14.4 \pm 0.7$ cm^3 mol^{-1}, and the compress-

[3] Table S1, showing pressure dependences of rate constants for the reactions of MeI and EtI with Pt(bpy)Me_2 in acetone at 25°C (1 page) has been deposited as supplementary material and can be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Fig. 2. Pressure dependence of k_1 for addition of EtI to Pt(bpy)Me_2 in acetone at 25°C. Each data point is the mean of three k_1 values. Solid line: linear regression (eq. [4]).



ibility coefficient of activation $\Delta\beta^{\ddagger} = -(\partial\Delta V_1^{\ddagger}/\partial P)_T = -0.027 \pm 0.007$ cm^3 mol^{-1} MPa^{-1} (all uncertainty limits are standard deviations σ). Thus, for reaction [3] with RI = MeI, the curvature of the ln k_1 vs. P plot is significant, though barely so, at the 95% confidence level ($\approx 2\sigma$). If eq. [5] is adopted, then the $\Delta V_1^{\ddagger}$ values from the linear regressions represent the mean or mid-range (100 MPa) value of this parameter. For RI = EtI, use of eq. [5] rather than eq. [4] is clearly unwarranted (Fig. 2).

Discussion

The $\Delta V_1^{\ddagger}$ values from the linear fits are not very different for R = Me and Et, and imply that, if a 2 GPa press for batch samples is available, the greatest pressure accelerations of reactions of the type [3] that might be anticipated would be about 3000-fold at ambient temperature (cf. Table 1). This is probably an overestimate, since the data for MeI suggest that $\Delta\beta^{\ddagger}$ is non-zero, but $|\Delta\beta^{\ddagger}|$ itself can be expected to decrease with pressure — there is no general agreement on equations for extrapolation of the pressure dependences of rate or equilibrium constants far beyond the data base (23), and certainly eq. [5], the simplest nonlinear regression equation, is acceptable only for *interpolation* of data at best. Taking these results together with those for the Pd analogue of reaction [3] (19) and oxidative addition at Rh^I centres (14), we conclude that a synthetic organometallic chemist may expect pressure accelerations of oxidative addition reactions of some three orders of magnitude if a 2 GPa press is used.

The large (500-fold) retardation in reaction [3] in acetone on going from MeI to EtI, together with the similar moderately strongly negative values of $\Delta V_1^{\ddagger}$ for the two reactants, supports Puddephatt's view of the mechanism as an S_N2 process (17, 18). Nucleophilic attack of Pt^{II} on the α-carbon of RI along the axis perpendicular to the plane of the square-planar complex would clearly be very susceptible to steric hindrance from substituent groups on that carbon atom. Volume decreases due to R—Pt bond formation, plus solvation of the incipient ions together with any coordination of solvent in the sixth site of the Pt^{IV} intermediate, will overwhelm the positive contribution to $\Delta V_1^{\ddagger}$ from C—I bond breaking. The striking similarity of our $\Delta V_1^{\ddagger}$ value for reaction [3] with RI = MeI to that reported by van Eldik's group (19) for the ca. 10-fold slower but otherwise analogous Pd^{II} reaction ($\Delta V_1^{\ddagger} = -11.9 \pm 0.6$ cm^3 mol^{-1}) supports this interpretation.

Oxidative fluorination in the Ph_2SO–XeF_2–Cl^- system and fluorine exchange in the $Ph_2S(O)F_2$–$Ph_2S(O)F^+$ system

Xiaobo Ou and Alexander F. Janzen

Abstract: Oxidative fluorination of diphenyl sulfoxide with xenon difluoride occurs under mild conditions in the presence of chloride ion to give $Ph_2S(O)F_2$ in quantitative yield. Chloride ion appears to react with xenon difluoride to generate fluoride ion, and a mechanism of oxidative fluorination is proposed that involves anionic $Ph_2S(O)F^-$ and radical $Ph_2S(O)F^\cdot$ intermediates. Addition of cationic $Ph_2S(O)F^+$ to $Ph_2S(O)F_2$ initiates rapid fluorine exchange, presumably via a symmetrical fluorine-bridged intermediate, and this exchange process was monitored by ^{13}C and ^{19}F NMR spectroscopy. In the presence of chloride ion, $Ph_2S(O)Cl_2$ is formed and can be identified by ^{13}C NMR and by its hydrolysis to Ph_2SO_2. Mechanisms are proposed for these reactions, and ab initio molecular orbital calculations (GAUSSIAN92) were carried out of the postulated intermediates.

Key words: preparation of $Ph_2S(O)F_2$, $Ph_2S(O)F^+$, and $Ph_2S(O)Cl_2$; oxidative fluorination in the Ph_2SO–XeF_2–Cl^- system; fluorine exchange in the $Ph_2S(O)F_2$–$Ph_2S(O)F^+$ system.

Résumé : La fluoration oxydante du diphénylsulfoxyde par le difluorure de xénon s'effectue dans des conditions douces, en présence d'ion chlorure, pour donner le $Ph_2S(O)F_2$, avec un rendement quantitatif. Il semble que l'ion chlorure réagit avec le difluorure de xénon pour générer l'ion fluorure; on propose un mécanisme pour la fluoration oxydante qui implique le $Ph_2S(O)F^-$ anionique et le $Ph_2S(O)F^\cdot$ radicalaire comme intermédiaires. L'addition du $Ph_2S(O)F^+$ cationique sur le $Ph_2S(O)F_2$ initie un échange rapide des ions fluorures, probablement par le biais d'un intermédiaire symétrique à pont fluor; on a suivi ce processus par spectroscopie RMN du ^{13}C et du ^{19}F. En présence d'ion chlorure, il se forme du $Ph_2S(O)Cl_2$ qui a été identifié par RMN du ^{13}C et par son produit d'hydrolyse, le Ph_2SO_2. On propose des mécanismes pour ces réactions et on a effectué des calculs d'orbitales moléculaires ab initio (GAUSSIAN92) sur les intermédiaires postulés.

Mots clés : préparation de $Ph_2S(O)F_2$, $Ph_2S(O)F^+$ et $Ph_2S(O)Cl_2$, fluoration oxydante dans le système Ph_2SO–XeF_2–Cl^-; échange d'ions fluorures dans le système $Ph_2S(O)F_2$–$Ph_2S(O)F^+$.

Results and discussion

Oxidative fluorination in the Ph_2SO–XeF_2–Cl^- system

The oxidative fluorination of S(IV) to S(VI) derivatives, as well as of Se(IV) and Te(IV), has been carried out with a variety of oxidizing agents such as F_2 (1), ClF (2), BrF_3 (3), XeF_2 (4), CF_3OF (5), CF_3OCl (6), OF_2, SF_5OF (7), AgF_2 (8), and electrochemically (9). Occasionally, CsF or KF is added as a catalyst (10). Zupan and Zajc carried out the oxidation of Ph_2SO by XeF_2, and postulated that $Ph_2S(O)F_2$ was formed as an intermediate that hydrolysed rapidly to the sulfone Ph_2SO_2 (11). Using elemental fluorine, Ruppert prepared $Ar_2S(O)F_2$ and $ArS(O)F_3$, and also characterized the cations $Ar_2S(O)F^+$ and $ArS(O)F_2^+$ (12). Wilson carried out the oxidation of SO_2 with XeF_2 in the presence of fluoride and chloride ions (13). We have studied the oxidation of organo-phosphorus, -sulfur, -tellurium, and -iodine compounds using XeF_2 as the oxidizing agent (14), and noted the catalytic effect of halide ion on the oxidative fluorination of phenyltellurium(IV) compounds (15).

The synthesis of $Ph_2S(O)F_2$ was carried out by adding XeF_2 and ~1% Et_4NCl to Ph_2SO in dichloromethane in a polytetrafluoroethylene (ptfe) bottle at room temperature, eq. [1]. The reaction was complete within 5 min and $Ph_2S(O)F_2$ was formed in essentially quantitative yield. Its ^{13}C NMR spectrum (Table 1 and Fig. 1) is in agreement with that reported by Ruppert (12).

$$[1] \quad Ph_2SO + XeF_2 \xrightarrow[CH_2Cl_2]{Et_4NCl\ (\sim 1\%)} Ph_2S(O)F_2 + Xe$$

During the reaction, the pale green colour of Cl_2 was visible, and traces of the hydrolysis product, Ph_2SO_2, were sometimes detected by ^{13}C NMR, but hydrolysis could be completely eliminated by further drying of solvents and reagents.

In the absence of chloride ion, reaction [1] proceeds sluggishly over a period of 2–6 days. Evidently, chloride ion is an

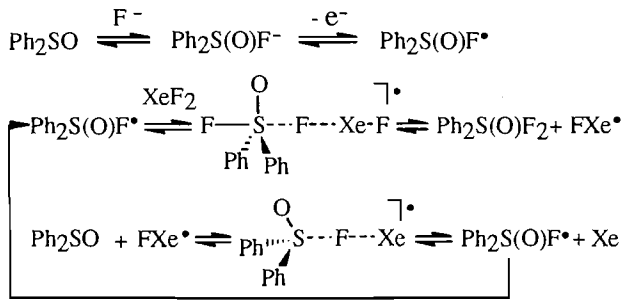
Scheme 1. Proposed mechanism of oxidative fluorination of Ph_2SO by XeF_2 in the presence of fluoride ion.



effective catalyst, and we propose that chloride ion is a convenient source of anhydrous and HF-free fluoride ion, as a result of its oxidation by XeF_2, according to eq. [2].

$$[2] \quad 2\,Cl^- + XeF_2 \xrightarrow{CH_2Cl_2} 2\,F^- + Cl_2 + Xe$$

The appearance of the pale green colour of Cl_2 during the synthesis of $Ph_2S(O)F_2$ is in agreement with eq. [2], and previous studies have shown that XeF_2 oxidizes HCl to Cl_2 (16). Anhydrous and HF-free fluoride ion is a powerful base (17) and, as discussed below, molecular orbital calculations point to a reason why F^-, but not Cl^-, catalyzes the oxidation of S(IV).

We propose that oxidative fluorination of Ph_2SO in the presence of fluoride ion proceeds according to the mechanism of Scheme 1, in which the fluoroanion $Ph_2S(O)F^-$ is oxidized to the radical $Ph_2S(O)F^{\cdot}$, followed by cleavage of weak [S--F--Xe]$^{\cdot}$ bridging bonds.

There is support in the literature for the mechanism of Scheme 1. For instance, the addition of fluoride ion to sulfur(IV) compounds produces stable anions, e.g., SO_2F^-, SF_5^-, $CF_3SF_4^-$, etc. (18), and related sulfur(V) radicals are known, e.g., $SOF_3^{\cdot}$, $SF_5^{\cdot}$, $ROSF_4^{\cdot}$, etc. (19). Anion-to-radical oxidation, as proposed in Scheme 1, is known for other fluorinated species, e.g., oxidation of $PhSiF_5^{2-}$ to $PhSiF_5^{\cdot -}$ (20). Our experiments do not allow us to identify the oxidizing agent that converts $Ph_2S(O)F^-$ to $Ph_2S(O)F^{\cdot}$, although Cl_2 or XeF_2 are possibilities. In the case of oxidation of $PhSiF_5^{2-}$ to $PhSiF_5^{\cdot -}$, numerous one-electron acceptors can be used, including metal ions, halogen compounds, tetracyanoethylene, etc. (20). The intermediacy of $FXe^{\cdot}$ has been proposed before (21), and its spectrum is known (22).

The mechanism of Scheme 1 explains why some oxidations, but not others, are carried out in the presence of fluoride ion. A fluoride ion allows the formation of anions, which are then oxidized to radicals. But radicals can be formed without the intermediacy of anions because many oxidizing agents are themselves sources of free radicals, e.g., $SO_3F^{\cdot}$ from $S_2O_6F_2$ (23), or $CF_3O^{\cdot}$ from CF_3OF (24). More vigorous reaction conditions of heating or irradiation may, however, be required if radicals are generated directly from oxidizing agents because bonds of moderate strength must be broken, e.g., RO—OR, Cl—Cl, F—XeF, whereas only very weak bridging bonds, i.e., [S--F--Xe]$^{\cdot}$, are cleaved if oxidation occurs in the presence of fluoride ion.

Such a mechanistic analysis can be extended to other well-known oxidations. For example, the Reed reaction, i.e., the chlorosulfonation of organic compounds with chlorine and SO_2, generally includes the following steps (25):

$$[3] \quad R^{\cdot} \xrightarrow{SO_2} R\text{-}SO_2^{\cdot} \xrightarrow{Cl_2} R\text{-}SO_2Cl + Cl^{\cdot}$$

By analogy with the cleavage of [S--F--Xe]$^{\cdot}$ bonds in Scheme 1, oxidation of sulfur(IV) compounds in the Reed reaction may involve cleavage of the [S--Cl--Cl]$^{\cdot}$ bridged bond, as proposed in eq. [4].

$$[4] \quad R\text{-}SO_2^{\cdot} \xrightleftharpoons{Cl_2} [R(O)_2S\text{--}Cl\text{--}Cl]^{\cdot} \searrow\!\!\nearrow R\text{-}SO_2Cl + Cl^{\cdot}$$

The mechanism of Scheme 1 postulates that F^-, rather than Cl^-, forms an anionic $Ph_2S(O)X^-$ intermediate. In an attempt to uncover any differences between the reactivity of F^- and Cl^- ions, or $F^{\cdot}$ and $Cl^{\cdot}$ radicals, we carried out ab initio calculations of several anionic and radical species **1**–**4** using the GAUSSIAN92 program (26). Phenyl substituents in **1** and **2** have been replaced with fluoro substituents in **3** and **4** in order to simplify the calculation. Experimental structural data are available for compounds such as **5**–**7**, and our analysis is based on a simple comparison between calculated and experimental structures. S—X bond lengths are also known for related compounds such as SOF_2 (158.5 pm), SO_2F_2 (157.0 pm), $SOCl_2$ (207.0 pm), and SO_2Cl_2 (199.0 pm) (27).

The calculated structures of fluoroanion **1** and chloroanion **3** reveal a significant difference in S—X bond length. The S—F bond length in **1** is 162.9 pm, which may be compared with experimental S—F bond lengths of 153.9–159.6 pm in **5**–**7**, for an average lengthening of 3.9%. On the other hand, the chloroanion **3** has a calculated S--Cl bond length of 230.5 pm, which is 12.6% longer than the experimental S—Cl bond length of 204.7 pm in **7**. The lengthened/weakened S--Cl bond

$Ph_2S(O)Cl_2$	—	145.9	124.4	129.4	131.1

Scheme 2. Proposed mechanism of fluorine exchange in the $Ph_2S(O)F_2$–$Ph_2S(O)F^+$ system.

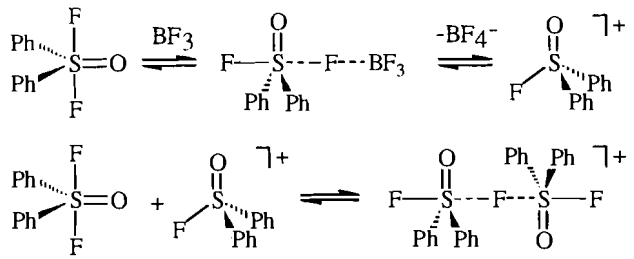

Fig. 1. Distribution of ^{13}C NMR chemical shifts. The 45:55 mixture of $Ph_2S(O)F^+$ and $Ph_2S(O)F_2$ was prepared by adding BF_3 to a solution of $Ph_2S(O)F_2$ in CD_2Cl_2.

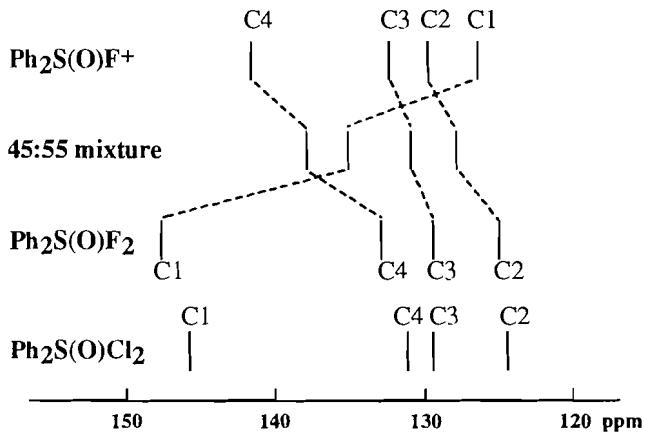


in **3** implies a short-lived intermediate of low concentration, which makes further oxidation to a chloro radical less likely. The relatively short/strong S—F bond in fluoroanion **1**, $Ph_2S(O)F^-$, however, implies a more stable intermediate of greater concentration, which favours subsequent oxidation to the fluoro radical **2**, $Ph_2S(O)F^{\cdot}$. Such an interpretation can explain the unique role of fluoride ion in Scheme 1, and is consistent with catalysis of oxidation reactions by CsF and KF (10).

Quite a different conclusion is reached on the basis of the calculated structures of radical species **2** and **4**. Both S—F and S—Cl bond lengths are shorter/stronger in the radicals than in the anions and, most significantly, both S—F and S—Cl bonds in the radicals are comparable in length to those in the stable compounds **5**–**7**. These results suggest that both fluoro and chloro radicals are reasonable intermediates. According to this interpretation, fluorosulfur(V) radical $Ph_2S(O)F^{\cdot}$ may be formed from sources of $F^{\cdot}$, or by oxidation of fluoroanion $Ph_2S(O)F^-$, whereas chlorosulfur(V) radical $Ph_2S(O)Cl^{\cdot}$ can only be formed from sources of $Cl^{\cdot}$. It is interesting to speculate whether the behaviour of the F^-–$F^{\cdot}$ system in oxidation reactions, as discussed above, is shared by the closely related OH^-–$HO^{\cdot}$ system.

Fluorine exchange in the $Ph_2S(O)F_2$–$Ph_2S(O)F^+$ system

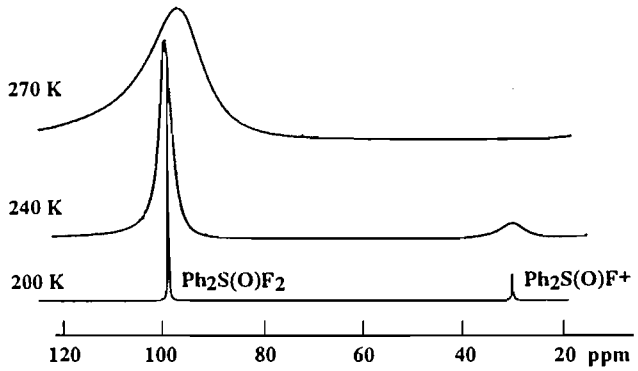
Reaction pathways change abruptly in the presence of a Lewis acid. Addition of BF_3 to $Ph_2S(O)F_2$ gives the cation $Ph_2S(O)F^+$ in essentially quantitative yield. This cation is stable indefinitely in ptfe equipment and can be characterized by ^{19}F and ^{13}C NMR (Table 1 and Fig. 1). Since C1–F and C2–F coupling is clearly visible, there cannot be any fluorine exchange in the cation that is rapid on the NMR time scale. Rapid fluorine exchange does occur on mixing $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$, and such exchange presumably involves the cleavage of a symmetrical intermediate with a weak $[S\text{--}F\text{--}S]^+$ bridging bond, as proposed in Scheme 2.

In support of the mechanism of Scheme 2, it may be noted that related cations of S(VI) are known, e.g., OSF_3^+, OSF_2Cl^+, RSF_4^+ (31), and rapid fluorine exchange between cationic and neutral species via fluorine-bridged intermediates has been studied in related tellurium(VI) fluorides, e.g., the Ph_3TeF_2X–Ph_3TeFX^+ system (X = F, Cl, OH) (32, 33).

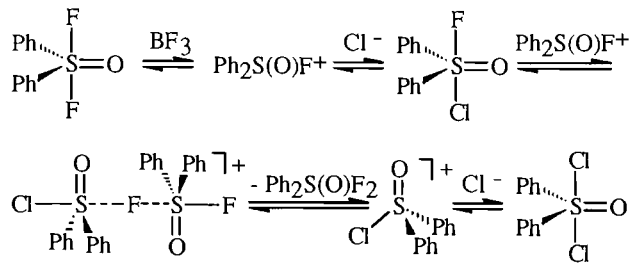
Mixtures of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$ were prepared in two ways, either by mixing samples of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+BF_4^-$, or by adding less than an equivalent of BF_3 to $Ph_2S(O)F_2$. The latter method is generally more convenient because it reduces the handling of moisture-sensitive compounds. Rapid fluorine exchange in the $Ph_2S(O)F_2$–$Ph_2S(O)F^+$ system can be monitored by either ^{13}C or ^{19}F NMR. The ^{13}C NMR chemical shift of C1 moves upfield by 21.6 ppm, as $Ph_2S(O)F_2$ is converted to $Ph_2S(O)F^+$, in agreement with the trend established for a variety of main group fluorides in which C1 shifts upfield by 16 to 26 ppm as F^- is removed (34). In mixtures of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$, only the weighted average ^{13}C chemical shifts can be observed at ambient temperature because of rapid fluorine exchange, as illustrated in Fig. 1 for a 45:55 mixture.

Typical variable-temperature ^{19}F NMR spectra of the $Ph_2S(O)F_2$–$Ph_2S(O)F^+$ system are shown in Fig. 2. Rapid fluorine exchange is slowed down at −73°C, and integration of

Fig. 2. Variable-temperature ^{19}F NMR spectrum of a 3:1 molar mixture of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+BF_4^-$ in CD_2Cl_2.

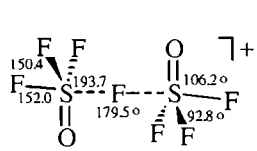


Scheme 3. Proposed mechanism of formation of $Ph_2S(O)Cl_2$.

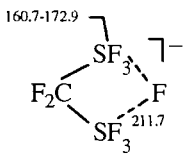


the low-temperature spectrum gives a direct measure of the ratio of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$. This ratio can also be obtained from the room temperature ^{13}C NMR spectrum and the weighted average of the C1–C4 chemical shifts.

That bridged S--F--S bonds are indeed longer/weaker than terminal S—F bonds in typical sulfur fluorides, as required by the mechanism of Scheme 2, is apparent from the calculated S--F bridge bond of 193.7 pm in **8**. An experimental value of 211.7 pm has been found for the S--F bridge bond in **9** (35). Calculated and experimental terminal S—F bond lengths in **8** and **9** are considerably shorter, in the range 150–173 pm.



8 (3-21G*)



9 (exp)(35)

The mechanism of fluorine exchange in the $Ph_2S(O)F_2$–$Ph_2S(O)F^+$ system can be generalized and applied to the synthesis of $Ph_2S(O)Cl_2$, as proposed in Scheme 3. Both mechanisms of Scheme 2 and Scheme 3 involve cleavage of [S--F--B]$^+$ and [S--F--S]$^+$ bridging bonds.

$Ph_2S(O)Cl_2$ was prepared by adding an excess of Et_4NCl to a solution containing the cation $Ph_2S(O)F^+$, and was identified by ^{13}C NMR and by its hydrolysis to Ph_2SO_2. The C1–C4 chemical shifts of $Ph_2S(O)Cl_2$ are very similar to those of $Ph_2S(O)F_2$, as seen in Table 1 and Fig. 1, and the absence of C1–F and C2–F coupling confirms that no S—F bonds are present. The possibility that an exchange process is responsible for lack of C1–F or C2–F coupling was eliminated by preparing a sample containing a mixture of $Ph_2S(O)Cl_2$ and $Ph_2S(O)F_2$. This mixture showed eight ^{13}C NMR peaks, as expected for a mixture of "rigid" $Ph_2S(O)Cl_2$ and $Ph_2S(O)F_2$. Hydrolysis of this mixture gave only Ph_2SO_2, eq. [5], as confirmed by ^{13}C NMR.

$$[5] \quad Ph_2S(O)Cl_2 + Ph_2S(O)F_2 \xrightarrow{H_2O} Ph_2SO_2 + HX$$

Some evidence for the stoichiometry and mechanism of Scheme 3 was obtained by adding varying amounts of Cl^- to a solution containing $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$. If the amount of Cl^- is less than that of $Ph_2S(O)F^+$, the ^{13}C NMR spectrum shows only four broadened and averaged C1–C4 peaks, as all species in solution undergo rapid halogen exchange in the presence of excess cation $Ph_2S(O)F^+$. If the amount of Cl^- exceeds that of cation $Ph_2S(O)F^+$, then halogen exchange is stopped and the ^{13}C NMR spectrum shows eight carbon peaks expected for a mixture of "rigid" $Ph_2S(O)Cl_2$ and $Ph_2S(O)F_2$. Integration of the ^{13}C NMR spectrum shows that each mole of cation $Ph_2S(O)F^+$ produced half a mole of $Ph_2S(O)Cl_2$ and half a mole of $Ph_2S(O)F_2$, consistent with the stoichiometry of Scheme 3.

Brief investigation by ^{13}C NMR showed that no fluorine exchange occurs in a mixture of $Ph_2S(O)F_2$ and Ph_2SO_2, nor in a mixture of Ph_2SO_2 and $Ph_2S(O)F^+$.

In conclusion, the coordination model of reaction mechanisms (33) denotes the four elementary steps of chemical reactions as +C, −C, $+C^c$, $-C^c$. If cyclic steps, $+C^c$ or $-C^c$, are absent, and if bond formation, +C, is a diffusion-controlled process, then it follows that any mechanistic analysis must focus on the elementary steps of bond cleavage, −C. The mechanism of Scheme 1 identifies the [S--F--Xe]$^\cdot$ bridged bond as the bond that is cleaved during oxidative fluorination in the Ph_2SO-XeF_2-Cl^- system under mild thermal conditions. The mechanisms of Schemes 2 and 3 identify the [S--F--B]$^+$ and [S--F--S]$^+$ bridged bonds as the bonds that are cleaved during fluorine exchange in the $Ph_2S(O)F_2$–$Ph_2S(O)F^+$ system, and during the synthesis of $Ph_2S(O)Cl_2$.

Experimental

NMR spectra were recorded on a Bruker AM300 spectrometer at 282.4 (^{19}F) and 75.47 (^{13}C) MHz, and chemical shifts were measured relative to internal C_6F_6 (−162.9 ppm with respect to $CFCl_3$) and $SiMe_4$, respectively.

XeF_2 (Air Products), Ph_2SO (Matheson, Coleman & Bell), and CD_2Cl_2 (Aldrich) were used without further purification. Et_4NCl and Et_4NBr (Eastman) were recrystallized from dry CH_3CN and stored in a desiccator over P_2O_5. All solvents were dried by distillation and stored over 5 Å molecular sieve, and ptfe equipment was dried at 100°C for several days.

Preparation of $Ph_2S(O)F_2$ with catalyst

Solid Ph_2SO (61 mg, 0.30 mmol) was added to a solution of XeF_2 (54 mg, 0.32 mmol) in CD_2Cl_2 (0.3 mL) at 25°C in an NMR tube with a ptfe insert. Ph_2SO dissolves completely in CD_2Cl_2, but a negligible reaction occurred within 30 min, as judged by exceedingly slow xenon gas evolution. Et_4NCl (2.0 mg, 0.012 mmol) was then added to this mixture, and a rapid

reaction occurred with vigorous evolution of xenon gas. The reaction was complete within 5 min. The ^{13}C NMR spectrum of the solution confirmed that $Ph_2S(O)F_2$ was formed in essentially quantitative yield. ^{13}C NMR of $Ph_2S(O)F_2$: δC1 147.8, J(C1, F) = 17.1 Hz, δC2 124.9, J(C2, F) = 6.1 Hz, δC3 129.2, δC4 132.9. ^{19}F NMR: δF 99.0.

For similar amounts of Ph_2SO and XeF_2, the amount of Et_4NCl catalyst could be reduced to 0.5 mg, without reducing the yield of $Ph_2S(O)F_2$.

In one experiment, 4 mg of Et_4NBr was added to similar amounts of Ph_2SO and XeF_2, and the product $Ph_2S(O)F_2$ was formed in greater than 95% yield.

The use of Ph_3CCl as a catalyst was investigated. Ph_3CCl (20 mg, 0.072 mmol) was added to a mixture of Ph_2SO (60 mg, 0.30 mmol) and XeF_2 (54 mg, 0.32 mmol) in CD_2Cl_2 (0.3 mL) at 25°C in a NMR tube with a ptfe insert. No product, $Ph_2S(O)F_2$, was found after 12 h.

Preparation of $Ph_2S(O)F_2$ without catalyst

Solid XeF_2 (44 mg, 0.26 mmol) and Ph_2SO (50 mg, 0.25 mmol) were dissolved in CD_2Cl_2 (0.3 mL) in a ptfe-lined NMR tube. There was no immediate reaction, as judged by the absence of xenon gas evolution. After 2 days, a 1:2 molar mixture of Ph_2SO and $Ph_2S(O)F_2$ was found. After 6 days, all Ph_2SO was converted to $Ph_2S(O)F_2$, but the C1 peak was exchange broadened and C1–F coupling was not observed in this sample.

Preparation of $Ph_2S(O)F^+$ BF_4^-

Excess BF_3 was bubbled into a solution of $Ph_2S(O)F_2$ (72 mg, 0.30 mmol) in CD_2Cl_2 (0.5 mL) at 25°C to give $Ph_2S(O)F^+$ BF_4^- in essentially quantitative yield. Excess BF_3 was pumped off. ^{13}C NMR of $Ph_2S(O)F^+$ BF_4^-: δC1 126.3, J(C1, F) = 10.9 Hz, δC2 129.8, J(C2, F) = 1.3 Hz, δC3 132.2, δC4 141.5. ^{19}F NMR: δF 29.5.

Preparation of mixtures of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$

Various amounts of BF_3 were bubbled into a solution of $Ph_2S(O)F_2$ in CD_2Cl_2 at 25°C to generate a mixture of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$. The ratio of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$ was determined by ^{13}C or ^{19}F NMR, as described in the text.

Preparation of $Ph_2S(O)Cl_2$

To a 45.55 molar mixture of $Ph_2S(O)F_2$ and $Ph_2S(O)F^+$, prepared from $Ph_2S(O)F_2$ (60 mg, 0.25 mmol) and BF_3 as described above, was added Et_4NCl (18 mg, 0.12 mmol), and the ^{13}C NMR spectrum recorded. An excess of Et_4NCl (50 mg, 0.32 mmol) was then added, and the ^{13}C NMR spectrum recorded and integrated. ^{13}C NMR of $Ph_2S(O)Cl_2$: δC1 145.9, δC2 124.4, δC3 129.4, δC4 131.1.

This mixture of $Ph_2S(O)F_2$ and $Ph_2S(O)Cl_2$ was hydrolyzed by addition of H_2O (25 μL, 1.4 mmol) to give only sulfone Ph_2SO_2.

The $Ph_2S(O)F_2$ and Ph_2SO system

Ph_2SO (30 mg, 0.15 mmol) was added to freshly prepared $Ph_2S(O)F_2$ (75 mg, 0.31 mmol) in CD_2Cl_2 at 25°C. Eight separate ^{13}C NMR signals were observed for $Ph_2S(O)F_2$ and Ph_2SO, however, C1–F and C2–F coupling was not observed in $Ph_2S(O)F_2$ in this sample.

The $Ph_2S(O)F^+$ and Ph_2SO system

Ph_2SO (15 mg, 0.074 mmol) was added to a solution of $Ph_2S(O)F^+$ BF_4^- (72 mg, 0.23 mmol) in CD_2Cl_2 at 25°C. Separate ^{13}C NMR signals were observed for $Ph_2S(O)F^+$ and Ph_2SO, and C1–F coupling was retained in $Ph_2S(O)F^+$.

Molecular orbital calculations

Ab initio molecular orbital calculations were performed with the GAUSSIAN92 system of programs (26) at the 3-21G* level with full optimization, except for the phenyl substituent where a fixed standard geometry was chosen. Calculated structures were compared with related experimental structures.

Acknowledgements

We thank the University of Manitoba for a graduate fellowship award (to X.O.). Dr. R.G. Syvret (Air Products, Allentown, Pa.) is thanked for a sample of XeF_2.

Synthesis of dimethylplatinum(IV) compounds, $[\{PtMe_2X_2\}_n]$, $[\{PtMe_2XY\}_n]$, and, in solution, *fac*-$[PtMe_2X(H_2O)_3]^+$, where X and Y are anionic ligands

Trevor G. Appleton, Campbell J. D'Alton, John R. Hall, Michael T. Mathieson, and Mark A. Williams

Abstract: Oxidative addition of X_2 (X = Cl, Br, I) to *cis*-$[PtMe_2L_2]$ (L = pyridine, py, or L_2 = *N,N,N′,N′*-tetramethylethylenediamine (tmen) gave $[PtMe_2X_2L_2]$. For X = Br, I, treatment with aqueous $HClO_4$ gave insoluble $[\{PtMe_2X_2\}_n]$, but for X = Cl, $[PtMe_2Cl_2(H_2O)_2]$ remained in solution, with $[\{PtMe_2Cl_2\}_n]$ depositing only from concentrated solution. $[PtMe_2L_2]$ (L = py, 1/2(tmen)) with water gave $[PtMe_2(OH)_2L_2]$, which, on treatment with $HClO_4$ gave *cis*-$[PtMe_2(H_2O)_4](ClO_4)_2$ in solution. Water also reacted with $[PtMe_2(nbd)]$ (nbd = norbornadiene) to give $[\{PtMe_2\}(OH)_2\}_n]\cdot mH_2O$. Alcohols ROH (R = Me, Et) with *cis*-$[PtMe_2py_2]$ gave $[PtMe_2(OR)(OH)py_2]$, which reacted with aqueous $HClO_4$ solution to give *fac*-$[PtMe_2(OR)(H_2O)_3]ClO_4$ in solution. Addition of chloride to this solution caused precipitation of $[\{PtMe_2(OR)Cl\}_n]$. Reaction of $[\{PtMe_2XY\}_n]$ with $AgNO_3$ in water gave *fac*-$[PtMe_2X(H_2O)_3](NO_3)$ in solution (X = Y = Cl, Br, I or Y = Cl, X = OR); for X = I added acid was necessary to prevent precipitation of $[\{PtMe_2I(OH)\}_n]$. Reaction of a solution of *fac*-$[PtMe_2Br(H_2O)_3](NO_3)$ with $AgNO_2$ gave *fac*-$[PtMe_2(NO_2)(H_2O)_3](NO_3)$ in solution, but an analogous reaction with AgSCN gave a complex in solution formulated as *fac*-$[PtMe_2(SCN)(H_2O)_3](NO_3)$ only in low yield.

Key words: platinum, methyl, pyridine, aqua, alkoxide, oxidative addition, NMR.

Résumé : L'addition oxydante de X_2 (X = Cl, Br, I) sur le *cis*-$[PtMe_2L_2]$ (L = pyridine, py, ou L_2 = *N,N,N′,N′*-tétraméthyléthylènediamine (tmen)) conduit à $[PtMe_2X_2L_2]$. Pour X = Br, I, le traitement de ces derniers produits avec des solutions aqueuse de $HClO_4$ conduit aux complexes insolubles $[\{PtMe_2X_2\}_n]$, mais, avec le produit dans lequel X = Cl, le $[PtMe_2Cl_2(H_2O)_2]$ demeure en solution alors que le $[\{PtMe_2X_2\}_n]$ ne se dépose qu'en solutions concentrées. Le $[PtMe_2L_2]$ (L = py, 1/2(tmen)) réagit avec l'eau pour fournir du $[PtMe_2(OH)_2]$ qui, par traitement avec du $HClO_4$, fournit du *cis*-$[PtMe_2(H_2O)_4](ClO_4)_2$ qui reste en solution. L'eau réagit aussi avec le $[PtMe_2(ndb)]$ (nbd = norbornadiène) pour donner du $[\{PtMe_2\}(OH)_2\}_n]\cdot mH_2O$. Les alcools ROH (R = Me, Et) réagissent avec le *cis*-$[PtMe_2py_2]$ pour conduire au $[PtMe_2(OR)(OH)py_2]$ qui réagissent avec des solutions aqueuses de $HClO_4$ pour fournir du *fac*-$[PtMe_2(OR)(H_2O)_3]ClO_4$ qui reste en solution. L'addition de chlore à cette solution provoque une précipitation de $[\{PtMe_2(OR)Cl\}_n]$. La réaction des produits $[\{PtMe_2XY\}_n]$ avec du $AgNO_3$ dans l'eau fournit les *fac*-$[PtMe_2X(H_2O)_3](NO_3)$ qui restent en solution (X = Y = Cl, Br, I ou Y = Cl, X = OR); pour X = I, il est nécessaire d'ajouter de l'acide pour empêcher la précipitation de $[\{PtMe_2I(OH)\}_n]$. La réaction d'une solution de *fac*-$[PtMe_2Br(H_2O)_3](NO_3)$ avec du $AgNO_2$ fournit du *fac*-$[PtMe_2(NO_2)(H_2O)_3](NO_3)$ qui reste en solution; toutefois, une réaction analogue avec du AgSCN conduit, avec un faible rendement, à un complexe en solution auquel on a attribué la formule *fac*-$[PtMe_2(SCN)(H_2O)_3](NO_3)$.

Mots clés : méthylplatine, pyridine, aqua, alcoolate, addition oxydante, RMN.

[2] The authors express their appreciation of the contributions of Professor Howard C. Clark to the fields of inorganic and organometallic chemistry.

Introduction

An important aspect of the chemistry of methylplatinum(IV) compounds is the remarkable robustness of the mixed alkyl–aqua cations *fac*-$[PtMe_3(H_2O)_3]^+$ (**1**) (1), *fac*-$[PtMe_2Br(H_2O)_3]^+$ (**2**) (2), and *cis*-$[PtMe_2(H_2O)_4]^{2+}$ (**3**) (3). In **1**, all three coordinated water ligands are labilized by the high *trans* effect of the methyl groups (4, 5). In **2** and **3** only the water ligands *trans* to the methyl groups are labile (2, 3, 6). Displacement of water molecules coordinated *cis* to the methyl ligands requires heating or long standing. Exploitation of the differential lability of the aqua ligands in dimethylplatinum(IV) complexes, combined with the photolabilization of coordination sites *trans* to bromide in dimethylbromo compounds (7), has allowed the synthesis of a wide range of derivatives — for example, with amino acids and related ligands (6, 8–14). These compounds were all prepared using **2** or **3** as starting material. The chemistry of dimethylplatinum(IV) compounds containing anionic ligands other than bromide or hydroxide has been much less developed. The possibility exists, with appropriate choice of X^- in *fac*-$[PtMe_2X(H_2O)_3]^+$, of fine-tuning the lability of water bound *trans* to X^- through the *trans* effect of X^-.

In this paper, synthetic routes are described to substances that may be used as starting materials for synthesis of a wide range of dimethylplatinum(IV) compounds, including $[\{PtMe_2X_2\}_n]$, $[\{PtMe_2XY\}_n]$, and *fac*-$[PtMe_2X(H_2O)_3]^+$ for a range of anionic ligands X^- and Y^-. Compounds where X^- is an alkyl or aryl group will be described in a subsequent paper. A preliminary account of some of these results has been published (15).

Results and discussion

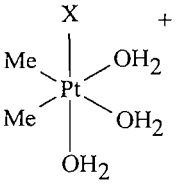
General methods for synthesis of $[\{PtMe_2X_2\}_n]$ and $[\{PtMe_2XY\}_n]$

Many dimethylplatinum(IV) complexes $[PtMe_2X_2L_2]$ and $[PtMe_2XYL_2]$ have been prepared by oxidative addition of X_2 or XY to dimethylplatinum(II) compounds *cis*-$[PtMe_2L_2]$ or of MeX to *trans*-$[PtMeYL_2]$, where, for example, L is a tertiary phosphine or arsine (16–19) or L_2 is 2,2′-dipyridyl (bpy) (20, 21). However, ligands of these types bind strongly to the metal, and cannot easily be removed from $[PtMe_2XYL_2]$ to yield $[\{PtMe_2XY\}_n]$.

Clark and Manzer (22) showed that $PtMe_2$(cod) (cod = 1,5-cyclooctadiene) will react with many oxidative addition reagents X_2 or XY to give dimethylplatinum(IV) products. For example, reaction with Br_2 yields $[\{PtMe_2Br_2\}_n]$ (**4**), and reaction with MeI gives $[\{PtMe_3(\mu_3\text{-}I)\}_4]$. These reactions were postulated to proceed through an unstable platinum(IV) intermediate, $[PtMe_2XY(cod)]$, from which the diolefin dissociated. Such a synthesis represents the most direct route to $[\{PtMe_2XY\}_n]$, but is subject to two limitations. The first is that the platinum(II) diolefin compound may not be sufficiently reactive to react with the reagent XY at all. The second is that there is an alternative decomposition route for the intermediate platinum(IV) diolefin compound, reductive elimination of MeY to yield a platinum(II) product. Thus, reaction of $[PtMe_2$(diolefin)] (diolefin = cod or norbornadiene, nbd) with CF_3I produces first $[PtMe(CF_3)$(diolefin)] (23), then $[Pt(CF_3)_2$(diolefin)] (22, 23). We have used $[PtMe_2$(nbd)] (**5**) in reactions with potential oxidants XY, as nbd is more easily displaced from the metal than cod (24).

A second general route is by removal of the pyridine ligands from $[PtMe_2X_2py_2]$ or $[PtMe_2XYpy_2]$ (py = pyridine). Pyridine ligands *trans* to methyl are relatively labile, and may often be removed by treatment with acid under relatively mild conditions. Thus, when $[\{PtMe_2Br_2\}_2]$ (**4**) was first prepared by refluxing $[\{PtMe_3(\mu_3\text{-}I)\}_4]$ with bromine, the crude product was purified by reaction with pyridine to give $[PtMe_2Br_2py_2]$ (**6**), followed by treatment with aqueous $HClO_4$ to regenerate **4** (25). In some cases the desired dimethylbis(pyridine)platinum(IV) complex may be prepared from platinum(IV) precursors, (e.g., $[PtMe_2Cl_2py_2]$ (**7**) (25)), but they are usually prepared by oxidative addition of X_2 or XY to *cis*-$[PtMe_2py_2]$ (**8**). A comparison of the reactions of *cis*-$PtMe_2L_2$ with MeI showed that the compounds where L = py (**8**), L_2 = bpy (**9**), and L_2 = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine, tmen (**10**), were all very reactive, and that acid removed the N-donor ligands from $[PtMe_3Ipy_2]$ and $[PtMe_3I$(tmen)] under conditions where $[PtMe_3I$(bpy)] was unreactive (24). We have included some reactions of **10** in this paper for comparison with those of **8**. We also describe in the experimental section a revised procedure for synthesis of **8**.

The most direct route to the preparation of an ion *fac*-$[PtMe_2X(H_2O)_3]^+$ is by reflux of sparingly soluble



$[\{PtMe_2XY.mH_2O\}n]$

$[\{PtMe_2XY\}_n]$ (Y^- = halide) with an aqueous solution of silver ion. In a few cases, the most convenient route to $[\{PtMe_2XY\}_n]$ or *fac*-$[PtMe_2X(H_2O)_3]^+$ was by substitution reactions commencing with one of the available dimethylplatinum(IV) cations, **2** or **3**.

Characterization of products

The most useful information was obtained from ^1H NMR spectra. The protons of each methyl group bound to platinum show a sharp singlet with "satellites" due to coupling with ^{195}Pt (I = $^1/_2$, 34% abundance). It is unlikely that both δ(H) and $^2J_{Pt-CH_3}$ will be coincident for non-equivalent methyl groups. The value of $^2J_{Pt-CH_3}$ is dependent primarily on the ligand *trans* to methyl (26–28), with, for example, typical ranges of 67–74 Hz *trans* to pyridine, and 77–82 Hz *trans* to water. ^{13}C NMR spectra can also provide useful information, although $^1J_{Pt-C}$ tends to be influenced more, relatively, by ligands *cis* to methyl than $^2J_{Pt-CH_3}$ (7, 29). The shielding of the methyl ^{13}C nucleus also depends on the *trans* ligand, with higher nuclear shielding *trans* to water than *trans* to halide (cf., ^1H (28) or ^{15}N (30) bound to platinum). Other resonances in ^{13}C and ^1H NMR can also provide useful confirmation of structure. For example, for complexes $[PtMe_2XYpy_2]$, the number of distinct resonances from pyridine ligands and the values of coupling constants to ^{195}Pt (expected to be small *trans* to methyl) help to confirm the structures assigned.

The dependence of δ(Pt) on the ligand set (especially the donor atoms), including the well-known shielding of the metal nucleus when bound to heavy donor atoms (e.g., I^-, S-donors) (30–32), provided confirmation of the ligands bound to platinum.

NMR data are given in Table 1, and microanalyses in Table 2.

X = Br

As mentioned above, $[\{PtMe_2Br_2\}_n]$ (**4**) was previously prepared by reaction of $[\{PtMe_3(\mu_3\text{-}I)\}_4]$ with bromine (25), or by reaction of $[PtMe_2(cod)]$ with bromine (22). We found that $[PtMe_2(nbd)]$ reacts with bromine in a similar way to give **4** in good yield. IR spectroscopy has shown that there are both terminal and bridging bromide ligands in **4**, and, from comparison of the spectrum with that of $[\{PtMe_3(\mu_3\text{-}Br)\}_4]$, a "cubane" structure with triply bridging bromide, has been proposed (33), analogous to that in $[\{PtBr(\text{-}CH_2CH_2CH_2)(\mu_3\text{-}Br)\}_4]$ (34). **4** is insoluble in non-coordinating solvents and in water, but dissolves in methanol to yield $[PtMe_2Br_2(MeOH)_2]$ (**11**) (29).

$[PtMe_2Br_2py_2]$ (**6**) was previously prepared by reaction of **4** with pyridine (25). This isomer, with pyridine *trans* to the methyl groups, is expected because the high *trans* effect of the methyl groups will direct the incoming pyridine ligands to the *trans* coordination sites. This *trans* effect also facilitates removal of pyridine by acid, to re-form **4**. We have also prepared **6** by reaction of *cis*-$[PtMe_2py_2]$ (**8**) with bromine in choroform. $[PtMe_2(tmen)]$ with bromine in chloroform yielded $[PtMe_2Br_2(tmen)]$ (**12**), which gave **4** when a suspension in dilute aqueous perchloric acid was refluxed for 3 h.

An aqueous solution of *fac*-$[PtMe_2Br(H_2O)_3](NO_3)$ (**3**) was prepared by reaction of a suspension of **4** in water with one mol equivalent of silver nitrate (2).

X = Cl

As noted above, $[PtMe_2Cl_2py_2]$ (**7**) was prepared by reaction of $[PtMe_2Br_2py_2]$ (**6**) with chlorine in refluxing chloroform (25). This preparation worked well provided that sufficient chlorine was passed through the solution. When the supply of chlorine was limited, an additional product was present, which, from NMR data (Table 1), was identified as $[PtMe_2ClBrpy_2]$ (**13**). The ^{195}Pt chemical shift was close to midway between δ_{Pt} for **6** and **7**. There was only one singlet with satellites for the methyl groups, and only one set of pyridine peaks in ^1H and ^{13}C NMR spectra. The Pt–CH_3 coupling constant was consistent with pyridine as the ligand *trans* to methyl (26–28). The ^1H-coupled ^{195}Pt NMR spectrum for each of the compounds **6**, **7**, and **13** showed a septet, as expected from coupling with the protons of two equivalent methyl groups. We have also prepared **7** by reaction of chlorine with *cis*-$[PtMe_2py_2]$ (**8**) in chloroform.

$[\{PtMe_2Cl_2\}_n]$ (**14**) by refluxing a suspension of $[PtMe_2Cl_2py_2]$ (**7**) in aqueous perchloric acid, followed by concentration of the resultant solution. This preparation differs from that of the dibromo analogue, **4**, in that **4** is always present as a solid suspended in the reaction mixture once the pyridine has been removed from **6**, while reaction of **7** under similar conditions yields a clear solution. The desired product, **14**, does indeed precipitate when the solution is concentrated, but care needs to be taken as contamination with $[Hpy]^+(ClO_4)^-$ can occur if too much solvent is removed. The product obtained by following the procedure given in the Experimental Section gave an IR spectrum similar to that described by Hall and Swile (33), who interpreted the spectrum in terms of a tetrameric structure, $[\{PtMe_2Cl(\mu_3\text{-}Cl)\}_4]$. There were no peaks attributable to $[Hpy](ClO_4)$, and no peaks assignable to coordinated water, in the IR spectrum.

The solid **14** was insoluble in chloroform and dichloromethane. Like the dibromo analogue, **4**, it dissolved readily in methanol. NMR data (Table 1) were all consistent with the presence of $[PtMe_2Cl_2(MeOH)_2]$ (**15**) in solution. The ^1H and ^{13}C spectra in CD_3OD each showed a singlet with satellites from the methyl groups. The Pt–CH_3 coupling constant was consistent with methanol as the ligand *trans* to methyl (26–29). The ^1H-decoupled ^{195}Pt NMR spectrum in methanol showed a single peak, at significantly higher frequency than that for $[PtMe_2Br_2(MeOH)_2]$ (**11**), as expected with replacement of bromo by chloro ligands (30–32). The ^1H-coupled ^{195}Pt spectrum showed a septet.

Unlike **4**, the solid **14** dissolved slowly in water. Prolonged standing was required, although the process was accelerated by ultrasonication, but the material was ultimately quite soluble. NMR data were quite similar to those for the methanol complex **15**, including the observation of a septet in the ^1H-coupled ^{195}Pt NMR spectrum. The complex in solution was therefore formulated as $[PtMe_2Cl_2(H_2O)_2]$ (**16**). The ^1H and ^{13}C NMR spectra in D_2O showed no detectable pyridine peaks. The aqua complex **16** is formed when $[PtMe_2Cl_2py_2]$ (**7**) reacts with aqueous perchloric acid, and does not precipitate from dilute solution.

If a small amount of $[PtMe_2BrClpy_2]$ (**13**) was present as an impurity with $[PtMe_2Cl_2py_2]$ (**7**) in the solid that was treated with perchloric acid, and the solid isolated after concentration of the solution was dissolved in methanol, peaks assignable to $[PtMe_2BrCl(MeOH)_2]$ (**17**) were observed in the ^1H, ^{13}C, and ^{195}Pt NMR spectra. A solution of the same solid in D_2O showed peaks from $[PtMe_2BrCl(D_2O)_2]$ (**18**) in the ^1H and ^{13}C NMR spectra.

It was also possible to obtain $[\{PtMe_2Cl_2\}_n]$ (**14**) by reaction of $[PtMe_2(nbd)]$ (**5**) with chlorine, but it was not always easy to separate the product from compounds formed by chlorination of nbd.

Refluxing an aqueous solution of $[PtMe_2Cl_2(H_2O)_2]$ (**16**) with one mol equivalent of silver perchlorate gave a solution of *fac*-$[PtMe_2Cl(H_2O)_3](ClO_4)$ (**19**).

X = I

$[\{PtMe_2I_2\}_n]$ (**20**) was prepared by Clark and Manzer (22) by reaction of $[PtMe_2(cod)]$ with iodine. We prepared **20** by a similar reaction, starting with $[PtMe_2(nbd)]$ (**5**). Hall and Swile (25) reported that $[\{PtMe_2I\cdot PtMe_2I_2\}_n]$ is sometimes formed as a by-product in the preparation of $[\{PtMe_3(\mu_3\text{-}I)\}_4]$ from $K_2[PtCl_6]$ and methyl Grignard reagent. They prepared $[PtMe_2I_2py_2]$ (**21**) and $[PtMe_2I_2(en)]$ (**22**) (en = 1,2-diaminoethane) from reaction of this solid with pyridine and en, respectively, and isolated **20** by reaction of **22** with aqueous $HClO_4$.

We prepared $[PtMe_2I_2py_2]$ (**21**) by reaction of *cis*-$[PtMe_2py_2]$ (**8**) with iodine in chloroform. Reaction of an aqueous suspension of **21** with perchloric acid gave **20**, which, like the dibromo analogue, **4**, was insoluble in nondonor solvents and in water. Reaction of a suspension of **20** in dilute aqueous perchloric acid with one mol equivalent of silver perchlorate gave a solution of *fac*-$[PtMe_2I(H_2O)_3](ClO_4)$ (**23**). Solid $[\{PtMe_2I(OH)\}_n]$ began to precipitate from a solution of **23** if the pH of the solution was increased above 2, so the dilute perchloric acid was necessary to keep **23** in solution. A minor set of methyl peaks (up to 10% of total intensity) was also present in NMR spectra of a D_2O solution (δ(H) 1.22, $^2J_{Pt-CH_3}$ 81.6 Hz; δ(C) −13.2, $^1J_{Pt-C}$ 679.7 Hz) that did not correspond to any previously reported compound. The NMR parameters correspond to a platinum(IV) complex with methyl *trans* to aqua, and the species present has been tentatively formulated as $[PtMe(D_2O)_5]^{3+}$ (**24**).

X = CN

We previously reported (7) the preparation of some dimethylcyano complexes, including $[PtMe_2(CN)Ipy_2]$ (**25**) (by reaction of *cis*-$[PtMe_2py_2]$ (**8**) with ICN), $[\{PtMe_2(CN)I\}_n]$ (**26**) (by reaction of **25** with $HClO_4$), $[\{PtMe_2(CN)Br\}_n]$ (by acidification of a solution of $[PtMe_2Br(CN)_2(H_2O)]^-$), and $[\{PtMe_2(CN)_2\}_n]$ (**27**) (by acidification of a solution of $[PtMe_2(CN)_3(H_2O)]^-$). A solution of *fac*-$[PtMe_2(CN)(MeOH)_3](ClO_4)$ in methanol was prepared by reaction of **25** successively with $AgClO_4$ and $HClO_4$ in methanol, but attempts to obtain a solution of *fac*-$[PtMe_2(CN)(H_2O)_3]^+$ (e.g., by addition of dilute aqueous $HClO_4$ to the methanol solution of *fac*-$[PtMe_2(CN)(MeOH)_3](ClO_4)$) caused precipitation of $[\{PtMe_2(CN)(OH)\cdot 3H_2O\}_n]$ (7).

An attempt was made to prepare **26** directly by reaction of $[PtMe_2(nbd)]$ (**5**) with ICN in chloroform. A white solid precipitated that appeared to be a mixture of **26** and [PtMe(CN)(nbd)].

An alternative method was also used to prepare $[\{PtMe_2(CN)_2\}_n]$ (**27**). A methanol solution of $[PtMe_2(CN)Ipy_2]$ (**25**) was refluxed with one mol equivalent of $AgClO_4$. After removal of precipitated AgI, the solution would then contain $[PtMe_2(CN)py_2(MeOH)](ClO_4)$. One mol equivalent of KCN was added, and the solution was heated. The solution would now contain $[PtMe_2(CN)_2py_2]$. Perchloric acid was added and the solution again refluxed. Solid $[\{PtMe_2(CN)_2\}_n]$ (**27**) precipitated (ν(C≡N) 2201 cm^{-1}). It has been suggested (7) that **27** is a network polymer, with Pt-C≡N-Pt bridging.

X = OH

The amphoteric solid $[\{PtMe_2(OH)_2\}_n]\cdot mH_2O$ (**28**) was previously prepared by reaction of $[\{PtMe_2Br_2\}_n]$ (**4**) with NaOH solution, followed by neutralization with $HClO_4$ solution (3). Monaghan and Puddephatt (21) reported that a complex formulated as $[PtMe_2(OH)(H_2O)(bpy)](OH)$ or as $[PtMe_2(OH)_2(bpy)]\cdot H_2O$ (**29**) was obtained by prolonged stirring of a suspension of $[PtMe_2(bpy)]$ (**9**) in water. We have repeated this preparation with similar results. Addition of $HClO_4$ solution to this compound did not cause displacement of the bpy ligand.

cis-$[PtMe_2py_2]$ (**8**) was sparingly soluble in water, slowly dissolving with prolonged stirring or gentle heating. ^1H and ^{13}C NMR spectra of a D_2O solution showed peaks corresponding to methyl groups bound to platinum(IV) *trans* to pyridine, as well as peaks from coordinated pyridine. The species in solution was formulated as $[PtMe_2(OD)_2py_2]$ (**30**). Removal of solvent water yielded $[PtMe_2(OH)_2py_2]\cdot 6H_2O$ as a white hygroscopic solid. The reaction of water with **8** presumably gives an initial hydrido product, $[PtMe_2(OH)(H)py_2]$, which then reacts with water to give **30** and H_2 (21, 35). When $HClO_4$ solution was added to a solution of **30**, pyridine was displaced to give *cis*-$[PtMe_2(H_2O)_4]^{2+}$ (**3**) in solution, with Hpy^+.

$[PtMe_2(tmen)]$ (**10**) was insoluble in water, and no change occurred when an aqueous suspension was allowed to stand. When the suspension was heated under reflux, the solid dissolved, with some deposition of platinum metal. ^1H and ^{13}C NMR spectra of a D_2O solution were consistent with the presence of $[PtMe_2(OD)_2(tmen)]$ (**31**). Removal of solvent water gave $[PtMe_2(OH)_2(tmen)]\cdot 7H_2O$ as a white hygroscopic solid. Heating a solution of **31** with aqueous $HClO_4$ gave **3** in solution, with $(H_2tmen)^{2+}$.

$[PtMe_2(nbd)]$ (**5**) was insoluble in water, and no change occurred when an aqueous suspension was allowed to stand. When the suspension was heated under reflux for 30 min, the color of the suspended solid changed from cream to white. This solid dissolved in both acid and alkali, and the solution in D_2SO_4–D_2O gave a ^1H NMR spectrum corresponding to *cis*-$[PtMe_2(H_2O)_4]^{2+}$ (**3**). The solid was therefore formulated as $[\{PtMe_2(OH)_2\}_n]\cdot mH_2O$ (**28**), presumably formed by loss of nbd from a platinum(IV) intermediate $[PtMe_2(OH)_2(nbd)]$.

X = OMe

Monaghan and Puddephatt (21) reported that $[PtMe_2(bpy)]$ (**9**) reacts with methanol to give $[PtMe_2(OMe)(H_2O)(bpy)]\cdot OH$. An alternative formulation of this product is $[PtMe_2(OMe)(OH)(bpy)]\cdot H_2O$ (**32**), although the ionic formulation was preferred by Monaghan and Puddephatt because conductivity of an aqueous solution corresponded to a 1:1 electrolyte (21). We have reproduced this synthesis. The bpy ligand was not displaced when a solution in dilute aqueous $HClO_4$ was heated under reflux.

cis-$[PtMe_2py_2]$ (**8**) dissolved in methanol to produce a yellow solution that faded to colorless over 2 h. After 6 h, solvent was removed to give a solid whose ^1H and ^{13}C NMR spectra in D_2O each showed one singlet with satellites from methyl-platinum groups *trans* to pyridine, one set of peaks from coordinated pyridine, and a singlet with satellites assigned to methoxide bound to platinum(IV). No peaks from Pt-H were observed in the ^1H NMR spectrum. The solid analysed for $[PtMe_2(OMe)(OH)py_2]\cdot 4H_2O$, and was nonconducting in aqueous solution. The compound present in solution was therefore formulated as $[PtMe_2(OMe)(OH)py_2]$ (**33**). Heating a solution of **33** in methanol with sodium chloride gave $[PtMe_2(OMe)Clpy_2]$ (**34**).

Heating **33** with aqueous perchloric acid caused removal of the pyridine ligands to give *fac*-$[PtMe_2(OMe)(H_2O)_3](ClO_4)$ (**35**) in solution (with $[Hpy](ClO_4)$). The methoxide ligand remained bound to platinum, as evidenced by the observation of coupling to ^{195}Pt in ^1H and ^{13}C NMR spectra in D_2O. Even several days' standing in 0.5 M $HClO_4$ solution did not cause detectable reaction. Addition of NaOH solution to increase the pH to 4 caused precipitation of a white solid, which, after drying, analysed for $[\{PtMe_2(OMe)(OH)\cdot 3H_2O\}_n]$ (**36**). This

solid slowly redissolved in dilute aqueous $HClO_4$ solution to give a solution of **35**.

Addition of one mol equivalent of NaCl to an aqueous solution of **35** caused slow precipitation of a white solid, which analysed for $[\{PtMe_2(OMe)Cl.H_2O\}_n]$ (**37**). The same product was obtained by reaction of a methanol solution of $[PtMe_2(OMe)Clpy_2]$ (**34**) with $HClO_4$. Refluxing an aqueous suspension of **37** with one mol equivalent of $AgClO_4$ gave AgCl and **35** in solution.

$[PtMe_2(tmen)]$ (**10**) was not soluble in methanol. With standing it did dissolve, but appeared to give a mixture of products. $[PtMe_2(nbd)]$ (**5**) was not soluble in methanol, and did not react, even under reflux.

The chemical stability of these methoxide complexes is remarkable compared with the reactivity of most transition metal alkoxides toward hydrolysis and β-hydride elimination. Monaghan and Puddephatt (21) noted the robustness of **32** and its phenanthroline analogue, and Abbott and co-workers (36) found that non-organometallic platinum(IV) alkoxides such as *trans*-[Pt(malonato)$_2$(OR)(OH)] hydrolysed very slowly in acidic solution. It is noteworthy that in these compounds the robust platinum–alkoxide bonds are all *trans* to ligands with weak to moderate *trans* effects. The trimethylplatinum(IV) alkoxide, $[\{PtMe_2(OMe)\}_n]$, is presumably tetrameric with triply bridging methoxide *trans* to methyl groups, which have high *trans* effect. It is very sensitive to hydrolysis, and has not been completely characterized (37).

X = OEt

Monaghan and Puddephatt (21) found that ethanol reacted with $[PtMe_2(bpy)]$ (**9**) in a manner similar to methanol. We prepared ethoxide complexes by procedures similar to those used for analogous methoxide compounds: $[PtMe_2(OEt)(OH)py_2]\cdot 3H_2O$ (**38**), *fac*-$[PtMe_2(OEt)(H_2O)_3]^+$ (**39**) (in solution), $[\{PtMe_2(OEt)(OH)\cdot 0.5H_2O\}_n]$ (**40**), and $[\{PtMe_2(OEt)Cl\cdot 2H_2O\}_n]$ (**41**). Both $[PtMe_2(tmen)]$ (**10**) and $[PtMe_2(nbd)]$ (**5**) were insoluble in ethanol, and no reaction was observed when these substances were heated with ethanol.

X = SCN

Reaction of an aqueous solution of *cis*-$[PtMe_2(D_2O)_4]^{2+}$ (**3**) with two mol equivalents of NaNCS in D_2O gave a species in solution whose ^1H NMR spectrum showed one singlet with satellites from the methyl groups. The Pt–CH_3 coupling constant, 65.6 Hz, was relatively low, as would be expected if the methyl groups were *trans* to S-bound thiocyanate. The complex present was therefore formulated as $[PtMe_2(SCN)_2(D_2O)_2]$ (**42**) in which thiocyanate ligands have replaced the water molecules initially coordinated *trans* to methyl. Heating a solution of **42** with more NaNCS ultimately gave *cis*-$[PtMe_2(SCN)_4]^{2-}$ (**43**) in solution, with low concentrations of *fac*-$[PtMe_2(SCN)_3(D_2O)]^-$ (**44**) detected as an intermediate when the reaction was monitored by ^1H NMR. **43** was previously obtained by reaction of *fac*-$[PtMe_2Br(H_2O)_3]^+$ (**2**) with excess KNCS (2). When a solution of **42** was allowed to stand, $[\{PtMe_2(NCS)_2\}_n]$ (**45**) slowly precipitated. This solid, which is probably polymeric with Pt-N≡C-S-Pt bridging, was previously obtained when a solution of *fac*-$[PtMe_2Br(SCN)_3]^{2-}$ was allowed to stand (2).

Heating a D_2O suspension of **45** with one mol equivalent of $AgClO_4$ gave *cis*-$[PtMe_2(D_2O)_4]^{2+}$ (**3**) as the only methyl-platinum compound detectable by ^1H NMR (30% yield after 3 h). When a solution of *fac*-$[PtMe_2Br(D_2O)_3](NO_3)$ (**2**) in D_2O was refluxed with excess AgSCN for 3 h, then filtered, three methyl-platinum(IV) species were detected by ^1H and ^{13}C NMR in the filtrate: starting complex **2**, **3**, and a third species that was probably *fac*-$[PtMe_2(SCN)(D_2O)_3]^+$ (**46**). It was present in only 20% yield at this stage of the reaction, and, with further heating, these peaks decreased in intensity. No ^{195}Pt peak was observed in the region corresponding to the anticipated chemical shift of **46** (between −1000 and −2000 ppm). A peak was observed at −318 ppm, which could correspond to a platinum(II) species such as $[Pt(SCN)(D_2O)_3]^+$ (30, 38, 39), which could be formed by reductive elimination of ethane from **46**.

X = NO_2

Reaction of $NaNO_2$ with a D_2O solution of *cis*-$[PtMe_2(D_2O)_4]^{2+}$ (**3**) gave $[PtMe_2(NO_2)_2(D_2O)_2]$ (**47**) in solution, but no solid precipitated from this solution. Heating with excess $NaNO_2$ gave *cis*-$[PtMe_2(NO_2)_4]^{2-}$ (**48**) in solution, previously obtained by heating *fac*-$[PtMe_2Br(H_2O)_3](NO_3)$ (**2**) with excess $NaNO_2$ (2). The Pt–CH_3 coupling constants in these compounds corresponded to methyl groups *trans* to N-bound nitrite.

A solution of *fac*-$[PtMe_2Br(D_2O)_3](NO_3)$ (**2**) in D_2O was refluxed with $Ag(^{15}NO_2)$. A new set of peaks was observed in each of the ^1H and ^{13}C NMR spectra, corresponding to methyl groups *trans* to water. The ^{195}Pt NMR spectrum showed a doublet from coupling with ^{195}Pt, indicating that one nitrite ligand was bound to platinum through nitrogen. The ^{195}Pt–^{15}N coupling constant, 664.1 Hz, was as expected for nitrite bound to platinum(IV) *trans* to a ligand of low *trans* influence (40, 41). The species in solution was therefore formulated as *fac*-$[PtMe_2(^{15}NO_2)(D_2O)_3]^+$ (**49**).

Experimental section

Literature methods were used to prepare the starting materials $[PtMe_2(nbd)]$ (**5**) (24), $[PtMe_2(tmen)]$ (**8**) (24), $[\{PtMe_2Br_2\}_n]$ (**4**) (42), $[\{PtMe_2(OH)_2\}_n]\cdot mH_2O$ (**28**) (42), and *fac*-$[PtMe_2Br(H_2O)_3]^+$ (**2**) in solution (2). Microanalyses were provided by the microanalytical service in this department.

100 MHz ^1H, 25.1 MHz ^{13}C, and 21.4 MHz ^{195}Pt NMR spectra were run on a JEOL FX-100 spectrometer, 200 MHz ^1H and 50.2 MHz ^{13}C NMR spectra on a Bruker ACF 200 spectrometer, and 400 MHz ^1H spectra on a JEOL GX-400 spectrometer. Details of acquisition were as previously described (12, 24). All shifts are positive to higher frequency. Unless otherwise stated, ^{13}C and ^{195}Pt spectra were ^1H-decoupled. For ^1H and ^{13}C spectra in organic solvents, the reference was tetramethylsilane (TMS). For ^{13}C NMR spectra in D_2O, dioxane was used as an internal reference with δ(C) taken as 67.73. For ^1H NMR spectra in D_2O, the reference was the methyl signal of $Na(Me_3Si(CH_2)_3SO_3)$ (TSS). For ^{195}Pt spectra the reference was a separate sample containing 0.5 g $Na_2[PtCl_6]$ per cm^3 (δ(Pt) = 0).

Preparation of *cis*-$[PtMe_2py_2]$ (8)

This procedure described below is a modification of that previously described (24). *cis*-$[PtMe_2(nbd)]$ (**5**) (3.2 g, 10.1 mmol) was dissolved in 25 cm^3 freshly distilled dry diethyl

ether. Dry distilled pyridine (2.45 cm^3, 30.3 mmol) was slowly added while the solution was stirred under nitrogen, and with the flask shielded from light with aluminum foil. Stirring was continued for 30 min, during which time the product deposited from solution. It was filtered off, and washed with small volumes of ether, then with hexane, then dried in the dark under reduced pressure. Yield was 3.1 g (80%). A second crop was obtained if the filtrate was stirred for several hours more in the dark.

Oxidative additions to [$PtMe_2$(nbd)] (5)

The general method is similar to that described by Clark and Manzer for reactions of [$PtMe_2$(cod)] (22), and is illustrated by the reaction of **5** with bromine.

Reaction of 5 with bromine

[$PtMe_2$(nbd)] (**5**) (0.30 g, 0.95 mmol) was dissolved in dichloromethane (10 cm^3), and bromine (0.15 g, 0.94 mmol) was added dropwise. The solution was stirred for 30 min. The yellow product, [{$PtMe_2Br_2$}$_n$] (**4**), precipitated during this time. It was filtered off, washed with dichloromethane, then with ether, and air-dried. Yield was 0.36 g (97%).

Analogous reactions were carried out with other reagents, with variations as noted below.

Reaction of 5 with iodine

Yield of [{$PtMe_2I_2$}$_n$] (**20**) (dark brown solid) was 0.40 g (89%).

Reaction of 5 with water

[$PtMe_2$(nbd)] (**5**) (0.30 g) was suspended in water (20 cm^3) and the suspension was heated under reflux for 1 h. The mixture was cooled, the white solid was filtered off, washed with water, then with acetone, and dried in a vacuum desiccator over phosphorus(V) oxide. Yield of [{$PtMe_2(OH)_2 \cdot 1.5H_2O$}$_n$] (**28**) was 0.12 g (46%).

Oxidative additions to *cis*-[$PtMe_2py_2$] (8)

The general procedure is similar to that previously described (24) for reaction of **8** with MeI, and is illustrated by the reaction with bromine.

Reaction of 8 with bromine

cis-[$PtMe_2py_2$] (**8**) (0.50 g, 1.30 mmol) was dissolved in chloroform (10 cm^3) and bromine (0.20 g, 1.30 mmol) was slowly added, with stirring. The solution was evaporated to dryness under reduced pressure, and the resultant yellow solid, [$PtMe_2Br_2py_2$] (**6**), was washed with ether and dried in air. Yield was 0.70 g (99%).

Variations for analogous reactions with other reagents are noted below.

Reaction of 8 with chlorine

Chlorine gas was bubbled through a chloroform solution (10 cm^3) containing **8** (1.30 mmol) for 10 min, then the solution was taken to dryness. The pale yellow product, [$PtMe_2Cl_2py_2$] (**7**), was obtained in 97% yield.

Reaction of 8 with iodine

The brown solid, [$PtMe_2I_2py_2$] (**21**) was obtained in 56% yield.

Reaction of 8 with cyanogen iodide

The reaction with ICN was carried out in benzene. The white product, [$PtMe_2$(CN)Ipy_2] (**25**), was obtained in 96% yield.

Reaction of 8 with water

cis-[$PtMe_2py_2$] (**8**) (0.20 g, 0.52 mmol) was suspended in water (20 cm^3) and the suspension was stirred for 12 h, during which time the solid dissolved. Solvent water was removed under reduced pressure, and the resultant white solid was dried in a vacuum desiccator over phosphorus(V) oxide. Yield of [$PtMe_2(OH)_2py_2] \cdot 6H_2O$ (**30**) was 0.26 g (95%).

Reaction of 8 with methanol

cis-[$PtMe_2py_2$] (**8**) (0.30 g, 0.78 mmol) was dissolved in dry methanol (20 cm^3). The solution was allowed to stand for 6 h, then taken to dryness under reduced pressure. The oily material was washed with a small volume of water, then with acetone, and dried in air. Yield of the white solid, [$PtMe_2$(OMe)(OH)$py_2] \cdot 4H_2O$ (**33**), was 0.38 g (95%).

Reaction of 8 with ethanol

The reaction was carried out in a similar way to that with methanol, except that the ethanol solution was allowed to stand for 9 h. Yield of the white solid [$PtMe_2$(OEt)-(OH)$py_2] \cdot 3H_2O$ (**38**) was 85%.

Oxidative additions to [$PtMe_2$(tmen)] (10)

Reaction of 10 with bromine

The reaction was carried out in a similar way to that of *cis*-[$PtMe_2py_2$] (**8**) with bromine. Yield of the yellow solid [$PtMe_2Br_2$(tmen)] (**12**) was 94%.

Reaction of 10 with water

[$PtMe_2$(tmen)] (**10**) (0.30 g) was suspended in water (20 cm^3) and the suspension was heated under reflux 20 min. During this time the solid dissolved. The solution was filtered, and water was then removed under reduced pressure. The resultant white solid was washed with a small volume of water, then dried in a vacuum desiccator over phosphorus(V) oxide. Yield of [$PtMe_2(OH)_2$(tmen)] $\cdot 7H_2O$ (**31**) was 0.13 g (72%).

Preparation of [$PtMe_2$(OMe)Clpy_2] (34)

[$PtMe_2$(OMe)(OH)$py_2] \cdot 4H_2O$ (0.30 g, 0.60 mmol) was dissolved in methanol (20 cm^3) and solid sodium chloride (0.035 g, 60 mmol) was added. The mixture was heated at 50°C for 2 h. The solution was then filtered, and taken to dryness. The resultant white solid was washed with ether and air-dried. Yield of **34** was 0.23 g (86%).

Reaction of [$PtMe_2Br_2py_2$] (6) with chlorine

A sample of **6** was prepared, either from *cis*-[$PtMe_2py_2$] (**8**) and bromine as detailed above, or by reaction of [{$PtMe_2Br_2$}$_n$] (**4**) with pyridine (25). To convert **8** completely to [$PtMe_2Cl_2py_2$] (**7**), the following procedure, based on that of Hall and Swile (25) was used. A solution of **6** (3.0 g) in chloroform (50 cm^3) was brought to reflux. Chlorine gas, generated by reaction of MnO_2 with concentrated HCl, was bubbled through the refluxing solution, which turned orange due to the release of Br_2. A pale yellow solid precipitated. Heating and passage of Cl_2 was continued for 30 min. The solid was

filtered off and washed with cold chloroform. To ensure that none of the pyridine ligands were lost in the chlorination treatment, the solid was dissolved in pyridine at ambient temperature, and recovered by removal of pyridine under reduced pressure. It was then redissolved in the minimum volume of hot chloroform, and crystallized by addition of ethanol. Yield of $[PtMe_2Cl_2py_2]$ (**7**) was 2.1 g (85%).

To obtain a product that contained approximately equimolar quantities of **7** and $[PtMe_2BrClpy_2]$ (**13**), a similar procedure was used, except that passage of chlorine was stopped as soon as a solid precipitated.

Removal of coordinated pyridine from $[PtMe_2X_2py_2]$ and $[PtMe_2XYpy_2]$

The general procedure is illustrated by the removal of pyridine from $[PtMe_2Br_2py_2]$ (**6**), based on the procedure of Hall and Swile (25). Variations in particular cases are noted.

Preparation of $[\{PtMe_2Br_2\}_n]$ (4) from $[PtMe_2Br_2py_2]$ (6)

To a suspension of **6** (0.30 g) in water (10 cm^3) was added 0.5 cm^3 70% perchloric acid. The mixture was heated under reflux 3 h. The yellow solid was filtered off, washed with water, then with acetone, and air-dried. Yield of $[\{PtMe_2Br_2\}_n]$ (**4**) was 0.21 g (98%).

Preparation of $[\{PtMe_2I_2\}_n]$ (20) from $[PtMe_2I_2py_2]$ (21)

Yield of the dark brown solid, **20**, was 76%.

Preparation of $[\{PtMe_2Cl_2\}_n]$ (14) from $[PtMe_2Cl_2py_2]$ (7)

To a suspension of **7** (0.40 g) in water (30 cm^3) was added 1 cm^3 70% $HClO_4$. The mixture was heated under reflux 1 h, to give a clear pale yellow solution, which was filtered. Water was removed under high vacuum while the flask was immersed in a water bath at 50°C (higher temperatures could lead to decomposition) until a solid began to precipitate. The flask was stored overnight in a refrigerator. The pale yellow solid was filtered off, washed quickly several times with small volumes of ice-cold water, dried in air, then in a vacuum desiccator over $CaCl_2$. Yield of **14** was 0.17 g (65%).

Preparation of $[\{PtMe_2(CN)_2\}_n]$ (27)

A sample of $[PtMe_2(CN)Ipy_2]$ (**25**) was prepared (7), and 0.4 g (0.75 mmol) was dissolved in methanol (30 cm^3). $AgClO_4$ (0.155 g, 0.75 mmol) was added, and the mixture was heated under reflux for 15 min. Precipitated AgI was filtered off, and KCN (0.49 g, 0.75 mmol) was added to the filtrate, which was then heated under reflux for 15 min. Perchloric acid (0.5 cm^3 70% solution) was added (**CAUTION — HOOD**) and the solution was heated under reflux 1 h. The solution was filtered, then reduced in volume under reduced pressure to 1 cm^3. Water (5 cm^3) was added. A colorless solid formed, which was filtered off, washed with water, then with acetone, and air-dried. Yield of **27** was 0.18 g (77%).

Reaction of $[PtMe_2(OH)_2py_2]\cdot 6H_2O$ (30) with $HClO_4$

30 (0.30 g) was suspended in water (10 cm^3) and 0.5 cm^3 70% $HClO_4$ solution was added. The solid dissolved. The solution was heated at 80°C 30 min, then filtered and concentrated under reduced pressure to 3 cm^3. ^{13}C and ^{195}Pt NMR spectra showed that the solution contained *cis*-$[PtMe_2(H_2O)_4]^{2+}$ (**3**). The solution also contained $[Hpy](ClO_4)$.

Addition of 1 M NaOH solution to increase the pH to 7 caused precipitation of a white solid, which was filtered off, washed with water, then with acetone, and dried in a vacuum desiccator over phosphorus(V) oxide. Yield of $[\{PtMe_2(OH)_2\cdot H_2O\}_n]$ (**28**) was 0.15 g, 91% based on **30**. Dissolution of the solid in the minimum volume of 1M $HClO_4$ solution gave a solution of *cis*-$[PtMe_2(H_2O)_4](ClO_4)_2$ free from pyridinium salts.

Reaction of $[PtMe_2(OMe)(OH)py_2]\cdot 4H_2O$ (33) with $HClO_4$

A sample of **33** was treated in a similar way to that described above for **30**, except that the solution was heated for only 15 min. NMR spectra of the resultant solution were consistent with the presence in solution of *fac*-$[PtMe_2(OMe)(H_2O)_3]^+$ (**35**) as well as Hpy^+.

Addition of 1 M NaOH solution to increase the pH to 4.0 caused precipitation of a white solid that was filtered off, washed with water, and dried in a vacuum desiccator over phosphorus(V) oxide. Yield of $[\{PtMe_2(OMe)(OH)\cdot 3H_2O\}_n]$ (**36**) was 65% based on **33**.

NaCl (0.032 g, 0.54 mmol) was added to 3 cm^3 0.180 M $[PtMe_2(OMe)(H_2O)_3]^+$ solution (containing 0.54 mmol **35**). The mixture was stirred to dissolve the solid, then allowed to stand for 12 h. The white solid that precipitated was filtered off, washed with water, and dried in a vacuum desiccator over phosphorus(V) oxide. Yield of $[\{PtMe_2(OMe)Cl.H_2O\}_n]$ (**37**) was 0.15 g (91%), based on the quantity of **35** initially in solution.

Reaction of $[PtMe_2(OEt)(OH)py_2]\cdot 3H_2O$ (38) with $HClO_4$

Similar procedures to those used for the methoxide complexes gave *fac*-$[PtMe_2(OEt)(H_2O)_3]^+$ (**39**) in solution, and the white solids $[\{PtMe_2(OEt)(OH)\cdot 0.5H_2O\}_n]$ (**40**) (59% yield based on **38**) and $[\{PtMe_2(OEt)Cl\cdot 2H_2O\}_n]$ (**41**) (89% based on the quantity of **39** initially in solution).

Removal of coordinated tmen from $[PtMe_2X_2(tmen)]$

$[\{PtMe_2Br_2\}_n]$ (**4**) was prepared from $[PtMe_2Br_2(tmen)]$ (**12**) in 95% yield by a similar procedure to that described above, starting with the bis(pyridine) analogue, **6**.

A solution of *cis*-$[PtMe_2(H_2O)_4]^{2+}$ (**3**), with H_2tmen^{2+}, was prepared from $[PtMe_2(OH)_2(tmen)]\cdot 7H_2O$ (**31**) by a procedure similar to that described above for the pyridine analogue, **30**.

Preparation of $[\{PtMe_2(SCN)_2\}_n]$ (45)

Solid $[\{PtMe_2(OH)_2\cdot 1.5H_2O\}_n]$ (**28**) (0.20 g, 0.70 mmol) was dissolved, with warming and stirring, in the minimum volume of 1 M $HClO_4$ solution. NaNCS (0.12 g, 1.48 mmol) was added, and the solution stirred to dissolve the solid. The solution was allowed to stand 24 h, during which time a pale yellow solid formed. The solid was filtered off, washed with water, then with acetone, and dried in a vacuum desiccator over silica gel. Yield of **45** was 0.13 g (54%).

Preparation of *fac*-$[PtMe_2X(H_2O)_3]^+$ by halide abstraction from $[\{PtMe_2XY\}_n]$

The general procedure is illustrated by the preparation of *fac*-$[PtMe_2Br(H_2O)_3]NO_3$ (**2**) in solution, based on the procedure of Hall and Swile (2).

*Preparation of **3** in solution*

$[\{PtMe_2Br_2\}_n]$ (**4**) (0.30 g, 0.78 mmol) was suspended in

water (10 cm^3) containing $AgNO_3$ (0.13 g, 0.78 mmol), and the mixture was stirred while heated under reflux 2 h, with protection from light. The mixture was cooled, and precipitated AgBr was filtered off, leaving $[PtMe_2Br(H_2O)_3]^+$ as the only methyl-platinum complex detectable by NMR in the yellow solution. The solution could be concentrated under reduced pressure, and the reaction could be carried out in D_2O, if desired.

Complexes *fac*-$[PtMe_2X(H_2O)_3](NO_3)$ (X = Cl (**19**), OMe (**35**)) were similarly prepared. For X = I (**23**), 0.20 cm^3 70% $HClO_4$ solution was added before the mixture was refluxed, to prevent precipitation of $[\{PtMe_2I(OH)\}_n]$.

Preparation of *fac*-$[PtMe_2(^{15}NO_2)(D_2O)_3](NO_3)$ (49) in solution

$Na(^{15}NO_2)$ (0.182 g, 2.6 mmol) was added to a solution of $AgNO_3$ (0.439 g, 2.6 mmol) in 5 cm^3 water. Solid $Ag(^{15}NO_2)$ precipitated, and was filtered off, washed with ice-cold water, and dried in a vacuum desiccator over silica gel. Yield was 0.272 g (68%).

To 5 cm^3 0.26 M $[PtMe_2Br(D_2O)_3](NO_3)$ (**2**) solution in D_2O (1.3 mmol) was added $Ag(^{15}NO_2)$ (0.20 g, 1.3 mmol), and the mixture was heated under reflux for 1 h while protected from light. The mixture was cooled, and solid was filtered off. From NMR measurements, the yield of **49** in solution was 70%.

An analogous reaction of a solution of **2** with Ag(SCN) gave only 20% yield in solution of a complex formulated as *fac*-$[PtMe_2(SCN)(D_2O)_3]^+$ (**46**).

Synthesis and characterization of mono- and bi-nuclear palladium(II) and platinum(II) complexes containing acetamidine ligands

Anshu Singhal and Vimal K. Jain

Abstract: The reactions of $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ with acetamidines in 1:2 stoichiometry afforded mononuclear complexes, $[MCl_2\{ArNHC(Me)NAr\}(PR_3)]$ (**I**) (M = Pd or Pt; $R_3 = Et_3$, Bu_3, Me_2Ph, $MePh_2$; Ar = Ph or 4-MeC_6H_4 (tol)). Treatment of $[M_2Cl_4(PR_3)_2]$ with Li[ArNC(Me)NAr] under anerobic conditions gave acetamidino-bridged binuclear complexes, $[M_2Cl_2(\mu\text{-}ArNC(Me)NAr)_2(PR_3)_2]$ (**II**). The reaction of $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}allyl)_2]$ with Ag[ArNC(Me)NAr] gave acetamidino-bridged allyl complexes $[Pd_2(\mu\text{-}ArNC(Me)NAr)_2(\eta^3\text{-}allyl)_2]$ (**III**). All the complexes were characterized by elemental analyses and NMR (^1H, ^{31}P, ^{195}Pt) spectroscopy. The mononuclear complexes (**I**) exist in two isomeric forms differing in the coordination of monodentate acetamidine ligand. The ^{31}P and ^{195}Pt NMR data on binuclear complexes (**II**) indicate that there is no significant Pt–Pt interaction. The allyl complexes (**III**) (allyl = C_3H_5) exhibit formation of all three possible isomers, whereas methallyl (allyl = C_4H_7) derivatives exist only in one configuration.

Key words: palladium, platinum, acetamidine, NMR (^1H, ^{31}P, ^{195}Pt), mononuclear complexes, binuclear complexes.

Résumé : Les réactions du composé $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ avec les acétamidines dans un rapport de 1 : 2 conduisent aux complexes mononucléaires $[MCl_2\{ArNHC(Me)NAr\}(PR_3)]$ (**I**) (M = Pd ou Pt; $R_3 = Et_3$, Bu_3, Me_2Ph, $MePh_2$; Ar = Ph ou 4-MeC_6H_4(tol). En traitant le composé $[M_2Cl_4(PR_3)_2]$ avec le Li[ArNC(Me)NAr], dans des conditions anaérobiques, on obtient les complexes binucléaires avec le groupe acétamidino ponté, $[M_2Cl_2(\mu\text{-}ArNC(Me)NAr)_2(PR_3)_2]$ (**II**). La réaction du $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}allyl)_2]$ avec Ag[ArNC(Me)NAr] donne les complexes allyliques avec le groupe acétamidino ponté : $[Pd_2(\mu\text{-}ArNC(Me)NAr)_2(\eta^3\text{-}allyl)_2]$ (**III**). On a caractérisé tous les complexes par analyse élémentaire et par la spectroscopie de RMN du ^1H, ^{31}P, et ^{195}Pt. Le complexe mononucléaire (**I**) existe sous deux formes isomères qui diffèrent par la coordination du ligand acétamide monodentate. Les données de la RMN du ^{31}P et du ^{195}Pt indiquent qu'il n'y a pas d'interaction Pt–Pt significative dans les complexes binucléaires (**II**). Les complexes allyliques (**III**) (allyle = C_3H_5) montrent la formation de tous les trois isomères possibles, tandis que les dérivés méthallyliques (allyl = C_4H_7) existent seulement dans une seule configuration.

Mots clés : palladium, platine, acétamidine, RMN du ^1H, ^{31}P, ^{195}Pt, complexes mononucléaires, complexes binucléaires.

[Traduit par la rédaction]

Introduction

Recently we isolated a series of binuclear palladium(II) and platinum(II) complexes containing one-, two-, and three-atom donor bridging ligands (1–3). The complexes with three-atom donor bridging ligands, e.g., carboxylate (2) and triazenido (3), show unusually strong metal–metal interactions in the d^8 configuration of the metal ion. To assess whether a metal–metal interaction in a d^8 configuration is a general feature of a three-atom bridging ligand, we have chosen amidines that are isoelectronic to carboxylate and triazenes as ligands.

A wide variety of platinum group metal complexes of amidines as well as their anions are now known. The anion acts in a monodentate (4, 5), bidentate chelating (6, 7), or bridging (8–10) fashion and also assists in stabilizing metal–metal bonds (11) in a manner similar to isoelectronic 1,3-disubstituted triazenido, carboxylato groups, etc. The amidino complexes are usually obtained either by the reaction of $[RNCR'NR]^-$ with metal salts or by deprotonation of coordinated neutral amidine in a precursor "M(NRCR'NHR)." Neutral amidines have two possible bonding sites, namely, via the amine-N or the imine-N atom; coordination through the latter is usually observed (4, 5, 12) rather than through more the basic amine-N atom.

In view of the above and in pursuance of our interest in platinum group metal complexes we have synthesized a series of mono- and bi-nuclear palladium(II) and platinum(II) complexes with acetamidines.

Results and discussion

The reaction of the chloro-bridged dimers $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ with acetamidines in 1:2 stoichiometry readily afforded mononuclear complexes of the type

Received December 15, 1995.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

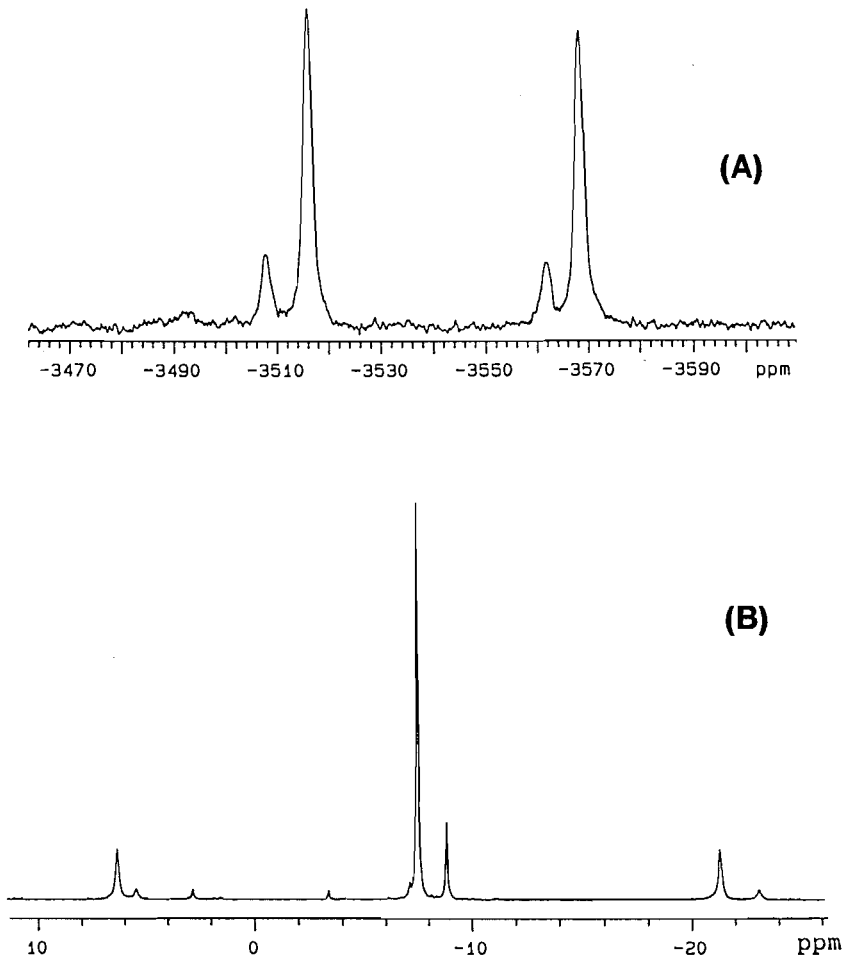
Fig. 1. $^{195}Pt\{^1H\}$ (*A*) and $^{31}P\{^1H\}$ NMR spectra (*B*) of the complex $[PtCl_2(PBu_3)\{PhNC(Me)NHPh\}]$ in $CDCl_3$.

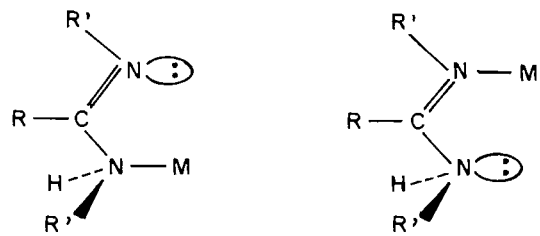


$[MCl_2(PR_3)\{ArNC(Me)NHAr\}]$ (**I**) (M = Pd or Pt; $R_3 = Et_3$, Bu_3, Me_2Ph, $MePh_2$; Ar = Ph or 4-$CH_3C_6H_4$ (tol)). The palladium complexes are yellow while the analogous platinum complexes are pale yellow.

The ^{31}P spectra of most of these complexes showed two resonances, except for a few platinum complexes where one resonance with platinum satellites was observed. Similarly, the ^{195}Pt NMR spectrum of $[PtCl_2(PBu_3)\{PhNC(Me)NHPh\}]$ displayed two doublets (δ −3542.2 ppm (d), ^1J(Pt–P) 3361 Hz (major isomer); δ −3534.8 ppm (d), ^1J(Pt–P) 3474 Hz (minor isomer)) (Fig. 1). The ^1J(Pt–P) coupling constants (Table 1) indicate that in every case nitrogen is *trans* to the phosphine ligand (13). One would expect a magnitude of ^1J(Pt–P) ~3600 Hz for *cis* configuration (phosphine *trans* to chloride). The palladium complexes appear to have a *trans* configuration since the IR spectra in the region 500–200 cm^{-1} for both series of complexes are comparable.

There are two different N donor atoms in amidines. Accordingly, two signals in the ^{31}P NMR spectra can be attributed to the molecules containing amino-N and imino-N coordinated ligand (Fig. 2). No isomerization was noticed on keeping the solution for few hours. We recently reported ligation via different nitrogen atoms in a triazene complex

Fig. 2. Amine–N and imine–N coordination for amidine ligand.



$[PtCl_2(PBu_3)(PhNNNHPh)]$ (3). Interestingly, the X-ray analysis of $[Pt\{C_6H_3)(CH_2NMe_2)_2$-2,6$\}\{tolNC(H)NHtol\}]$-$[CF_3SO_3]$ revealed coordination through imino nitrogen, and this configuration is retained in solution (5). Coordination through imino nitrogen has been suggested for the allyl complexes (5), $[PdCl(\eta^3\text{-}C_3H_5)\{ArNC(H)NHAr\}]$; however, for these complexes Toniolo and co-workers (14) reported ligation via the more basic amine N atom.

In the ^1H NMR spectra the CMe and NH signals for the imine-coordinated isomer appeared at δ ~1.8 and 8.50–9.06 ppm, respectively. The assignment was made by comparison

Table 1. ^{1}H and $^{31}P\{^{1}H\}$ NMR data for palladium and platinum complexes containing acetamidine ligands.

[a]Due to major isomer.

[b]s = singlet, d = doublet, t = triplet, m = multiplet, dt = doublet of triplet; br = broad.

[c]Chemical shift degeneracy; two isomers are present in a 1:1 ratio as evident from the ^{1}H NMR spectrum.

[d]Only one isomer is formed.

[e]NMR data for the complex prepared from the acetato-bridged platinum complex $^{31}P\{^{1}H\}$ in $CDCl_3$: –8.4 (^{1}J = 3629 Hz, major); –10.3 (minor) ppm. ^{1}H NMR spectrum is similar to the spectrum for the complex prepared from the chloro-bridged platinum derivative.

[f]NMR data for the complex prepared from the acetato-bridged platinum complex $^{31}P\{^{1}H\}$ in C_6D_6: δ –24.3 (^{1}J = 3747 Hz, minor isomer); –25.4 (^{1}J = 3690 Hz, major isomer); ^{1}H in C_6D_6: 1.14 (d, 11.3 Hz, PMe_2, major); 1.19 (d, 11.1 Hz, minor); 1.37 (s, CMe, minor); 1.40 (s, CMe, major); 6.55–7.63 (m, Ph).

[g]Another doublet due to the *anti* protons is merged to tol-Me signal.

with the spectra (5) of $[PdCl(\eta^3\text{-}C_3H_5)(ArNC(H)NHAr)]$ and $[Pt\{C_6H_3(CH_2NMe_2)_2\text{-}2,6\}\{tolNC(H)NHtol\}][CF_3SO_3]$. The resonances for the amine-coordinated isomer were assigned at δ 6.2–6.5 ppm (NH) and ~2.7 ppm (CMe). In general, the imine-coordinated isomer predominated and for a few platinum complexes was formed exclusively. The magnitude of ^1J(Pt–P) for the imine-coordinated isomer is smaller (~110 Hz) than that of the corresponding amine-coordinated complex. This is in agreement with the fact that ^1J(Pt–P) for the complexes containing sp^3 hybridized nitrogen is greater than for those complexes with sp^2 hybridized N donor atom (3).

Acetamidinato-bridged binuclear complexes

The binuclear acetamidinato-bridged palladium(II) and platinum(II) complexes can readily be obtained by the following reaction routes (eqs. [1] and [2])

[1] $[M_2Cl_2(\mu\text{-}X)_2(PR_3)_2] + 2LiAm \longrightarrow [M_2Cl_2(\mu\text{-}Am)_2(PR_3)_2] + 2LiX$

[2] $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-allyl})_2] + AgAm \longrightarrow [Pd_2(\mu\text{-}Am)_2(\eta^3\text{-allyl})_2] + 2AgCl$

(M = Pd or Pt; X = Cl or OAc; Am^- = PhNC(Me)NPh or tolNC(Me)Ntol; $R_3 = Et_3$, Bu_3, Me_2Ph, $MePh_2$; allyl = C_3H_5 or C_4H_7).

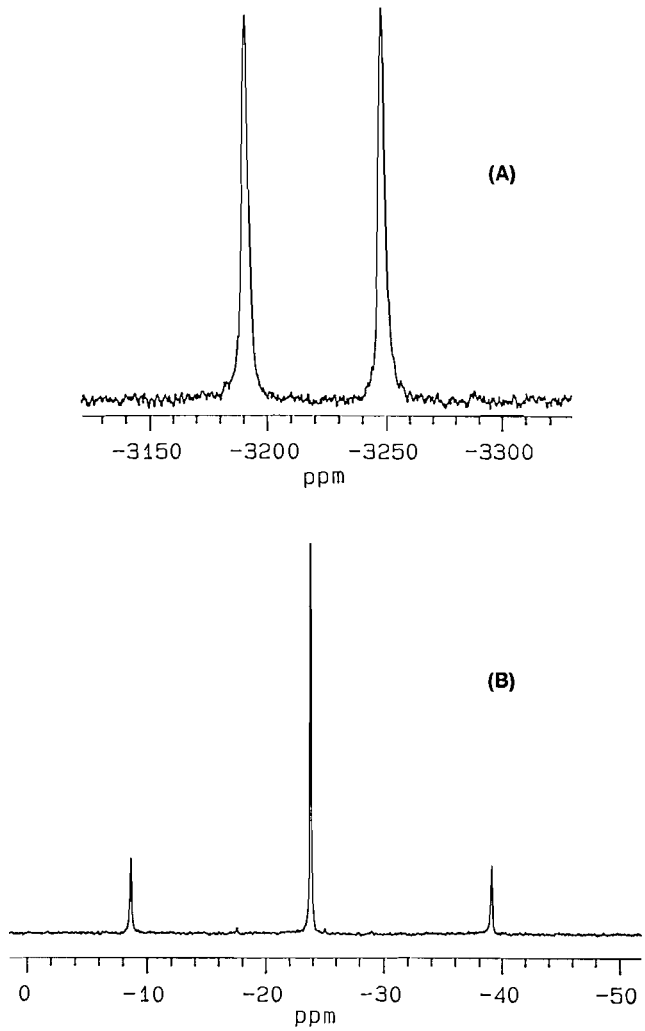
The palladium complexes are orange while the analogous platinum complexes are lemon-yellow crystalline solids, soluble in common organic solvents. The mass spectrum of $[Pd_2Cl_2(\mu\text{-tolNC(Me)Ntol})_2(PBu_3)_2]$ showed a molecular ion peak at 1163, suggesting binuclear composition of these complexes. Besides a number of other peaks, peaks at *m/e* 581 and 546 can be assigned to mononuclear ions $[PdCl(PBu_3)(tolNC(Me)Ntol)]^+$ and $[Pd(PBu_3)(tolNC(Me)Ntol)]^+$, respectively.

NMR Spectra of II

The ^1H NMR spectra showed the expected integration and peak multiplicities (Table 1). The ^{31}P NMR spectra displayed a single resonance for tertiary phosphines. The ^1J(Pt–P) couplings for these complexes are comparable to those of the corresponding triazenido-bridged complexes (3). The platinum NMR spectra of $[Pt_2Cl_2(\mu\text{-PhNC(Me)NPh})_2(PR_3)_2]$ showed a single doublet ($R_3 = Bu_3$: $\delta^{195}Pt\{^1H\}$ −3244 (d) ppm, ^1J(Pt–P) = 3635 Hz; $R_3 = Me_2Ph$: δ −3220 (d) ppm, ^1J(Pt–P) = 3692 Hz) (Fig. 3). Interestingly, when the complexes were prepared from the acetato-bridged platinum complexes (X = OAc, eq. [1]), two isomeric forms, sym *cis* and sym *trans*, were revealed by the ^{31}P NMR data. One of the peaks had chemical shifts and coupling constant consistent with the spectra of the complexes prepared by the chloro-bridged route (X = Cl, eq. [1]). The second peak showed a slightly higher coupling constant (~57 Hz) than the other, and has been assigned to the sym *cis* isomer based on our earlier data on binuclear complexes. The palladium complexes existed exclusively in one isomeric form irrespective of the method of preparation (X = Cl or OAc; eq. [1]).

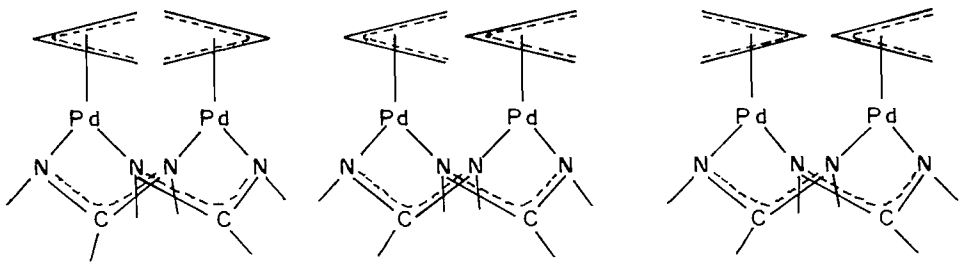
The complexes with isoelectronic bridging carboxylate (2) and triazene (3) ligands, $[Pt_2Cl_2(\mu\text{-}Y)_2(PR_3)_2]$ (Y = $RCOO^-$ or

Fig. 3. $^{195}Pt\{^1H\}$ (*A*) and $^{31}P\{^1H\}$ NMR (*B*) spectra of the complex $[Pt_2Cl_2(\mu\text{-PhNC(Me)NPh})_2(PMe_2Ph)_2]$ in $CDCl_3$.



ArNNNAr⁻), show platinum–platinum interaction with formal bond order zero as revealed by presence of ^nJ(Pt–P) and ^nJ(Pt–Pt) couplings in the ^{31}P and ^{195}Pt NMR spectra (2, 3). Accordingly, one would expect similar behaviour for acetamidino-bridged complexes. However, such couplings were not present in the ^{31}P and ^{195}Pt NMR spectra (Fig. 3). This suggests that metal–metal interactions in these complexes are vanishingly small. The observed trend of M—M separation is evident from the X-ray structures of $[Pd_2(\mu\text{-tolNNNtol})_2(\eta^3\text{-allyl})_2]$ (Pd—Pd = 2.856(1) Å) (15), $[Pd_2(\mu\text{-OAc})_2(\eta^3\text{-allyl})_2]$ (Pd—Pd = 2.94 Å) (16), and $[Pd_2(\mu\text{-NHC(Ph)NH})_2(\eta^3\text{-allyl})_2]$ (Pd—Pd = 3.128(1) Å (17). The Pd—Pd separation in the latter can be compared with the pyrazolato-bridged complexes, $[M_2Cl_2(\mu\text{-}Me_2pz)_2(PR_3)_2]$ (M = Pd, 3.115(1) Å; M = Pt, 3.170(1) Å) (18, 19). For bis-pyrazolato-bridged binuclear platinum complexes ^nJ(Pt–P) and ^nJ(Pt–Pt) are not observed. The bite distances of bridging triazenido, carboxylato, and amidino groups in Ni(II), Pd(II), and Pt(II) lantern-type complexes are of the order of ~2.23, ~2.25, and ~2.34 Å, respectively (20). This trend of ligand bite is reflected in the

Fig. 4. Different isomers for the $[Pd_2(\mu\text{-amidino})_2(\eta^3\text{-allyl})_2$ complex.



^nJ(Pt–Pt) and ^nJ(Pt–P) couplings for $[Pt_2Cl_2(\mu\text{-}Y)_2(PR_3)_2]$ complexes where Y = $ArNNNAr^-$, $RCOO^-$, $ArNC(Me)NAr^-$. Seemingly, the ligand-induced metal–metal interactions in binuclear d^8 metal complexes stabilized with isoelectronic bridging ligand (e.g., three-atom bridging ligands) are influenced by the ligand bite angle.

NMR spectra of allyl complexes, III

The methallyl palladium complexes showed only one set of resonances in the ^1H NMR spectra, indicating the existence of only one isomer. However, the allyl complexes exhibited three sets of resonances. This indicates that there are all three possible isomers (Fig. 4) in solution. It may be noted that earlier workers have reported one (17), two (21), and three (22) isomers for $[Pd_2(\mu\text{-amidino})_2(\eta^3\text{-allyl})_2]$ complexes.

Experimental

The complexes $[M_2Cl_2(\mu\text{-}Cl)_2(PR_3)_2]$ (M = Pd or Pt; $R_3 = Et_3$, Bu_3, Me_2Ph, $MePh_2$) (23), $[M_2Cl_2(\mu\text{-}OAc)_2(PR_3)_2]$ (2), $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-allyl})_2]$ (24, 25), acetamidines (22, 26), ArN=C(Me)-NHAr (Ar = Ph, 4-MeC_6H_4 (tol), and silver amidinate (22) were prepared by literature methods. All reactions were carried out in dried and distilled analytical grade solvents under a nitrogen atmosphere. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Varian XLR-300 or Bruker AMX-500 spectrometer in freshly prepared $CDCl_3$ or C_6D_6 solutions. Chemical shifts are referred to internal solvent peak ($CHCl_3$ δ 7.26 ppm) for ^1H and 85% H_3PO_4 for ^{31}P. $^{195}Pt\{^1H\}$ NMR spectra were recorded on a Varian XLR-300 instrument operating at 64.49 MHz and the spectra were referenced with external Na_2PtCl_6 in D_2O. Elemental analyses were carried out by the Analytical Chemistry Division of this research centre. Melting points were determined in capillary tubes in the open and were uncorrected. Representative examples of the synthetic routes to the various compounds are reported below. Analytical data for the complexes are given in Table 2.

Preparation of $[PtCl_2\{PhN{=}C(Me)\text{-}NHPh\}(PMe_2Ph)]$

To a dichloromethane solution (15 cm^3) of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ (111 mg, 0.137 mmol), a solution of *N,N*-diphenylacetamidine (58.6 mg, 0.279 mmol) in dichloromethane (5 cm^3) was added with stirring at room temperature. After an hour of stirring, the solvent was stripped off and the residue was recrystallized from dichloromethane–hexane mixture (1:2, v/v) in 78% (131 mg) yield as a pale yellow crystalline solid.

Preparation of $[Pd_2Cl_2(\mu\text{-}PhNC(Me)NPh\}_2(PMe_2Ph)_2]$

To a THF solution (20 cm^3) of Li[PhNC(Me)NPh], prepared in situ by neutralizing *N,N'*-diphenylacetamidine (70.5 mg, 0.336 mmol) with a hexane solution (0.69 M, 0.5 cm^3) of *n*-BuLi, was added solid $[Pd_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ (105 mg, 0.166 mmol) with vigorous stirring. The reactants were stirred at room temperature for 2 days. The solvents were stripped off in vacuo. The residue was extracted with benzene and filtered. The filtrate was concentrated in vacuo and the residue was recrystallized from benzene–hexane solution in 59% (95.9 mg) yield.

Preparation of $[Pd_2Cl_2(\mu\text{-}tolNC(Me)Ntol\}_2(PBu_3)_2]$

To a THF solution (20 cm^3) of Li[tolNC(Me)Ntol], prepared as in earlier preparation from *N,N'*-di-*p*-tolylacetamidine (94 mg, 0.395 mmol) and *n*-BuLi solution in hexane (0.8 cm^3, 0.53 M), solid $[Pd_2Cl_2(\mu\text{-}OAc)_2(PBu_3)_2]$ (146 mg, 0.181 mmol) was added. The reaction mixture was stirred at room temperature for 30 h. The solvents were removed in vacuo and the residue was extracted with benzene and filtered. The filtrate was evaporated in vacuo and the residue was recrystallized from hexane (yield, 128 mg, 61%).

Preparation of $[Pt_2Cl_2(\mu\text{-}PhNC(Me)NPh\}_2(PMe_2Ph)_2]$

To a THF solution (10 cm^3) of Li[PhNC(Me)NPh], prepared from *N,N'*-diphenylacetamidine (83 mg, 0.393 mmol) and *n*-BuLi solution (0.8 cm^3, 0.5 M), a benzene solution (10 cm^3) of $[Pt_2Cl_2(\mu\text{-}Cl)_2(PMe_2Ph)_2]$ (154 mg, 0.191 mmol) was added with vigorous stirring. The reaction mixture was stirred at room temperature for 60 h. The solvents were stripped off in vacuo and the residue was extracted with benzene and filtered. The filtrate as concentrated to 2 cm^3 and layered with hexane (5 cm^3), whereupon crystals of the title complex were obtained (yield 133 mg, 60%).

Preparation of $[Pd_2(\mu\text{-}PhNC(Me)NPh\}_2(\eta^3\text{-}C_4H_7)_2]$

To a dichloromethane solution (15 cm^3) of $[Pd_2(\mu\text{-}Cl)_2(\eta^3\text{-}C_4H_7)_2]$ (80 mg, 0.203 mmol) was added silver diphenylacetamidinate (147 mg, 0.42 mmol). The reaction mixture was stirred for 3 h at room temperature. The solvent was removed under reduced pressure and the residue was extracted with dichloromethane and filtered. The filtrate was concentrated in vacuo to 2 cm^3 and layered with hexane (5 cm^3), which on cooling in a freezer gave the crystals of the title complex (yield 49 mg, 33%).

Table 2. Physical and analytical data for the palladium and platinum complexes containing acetamidine ligands.

Complex	Recrystallization solvent (% yield)	Melting point (°C)	% Analysis found (calcd.) C	H	N

Oxidative addition of a B—B bond by an iridium(I) complex: molecular structure of *mer-cis*-[Ir(PMe$_3$)$_3$Cl(Bcat)$_2$]

Chaoyang Dai, Graham Stringer, Todd B. Marder, R. Thomas Baker, Andrew J. Scott, William Clegg, and Nicholas C. Norman

Abstract: The B—B bond in B_2cat_2 (cat = 1,2-$O_2C_6H_4$) is readily activated by [Ir(PMe$_3$)$_3$Cl(COE)] (COE = η^2-cyclooctene) (**1**) to yield a novel iridium(III) bis(boryl) complex *mer-cis*-[Ir(PMe$_3$)$_3$Cl(Bcat)$_2$] (**2**). This complex is the first structurally characterized iridium bis(boryl) compound, and is the first metal bis(boryl) complex for which two distinct boryl group environments are observed in solution. Colourless crystals of **2** are monoclinic, $P2_1/n$, with unit cell dimensions a = 8.9638(7) Å, b = 32.197(2) Å, c = 9.3980(7) Å, and β = 90.385(2)°.

Key words: iridium, boron, diboron, boryl, oxidative addition, X-ray structure, trimethylphosphine.

Résumé : La liaison B—B du B_2cat_2 (cat = 1,2-$O_2C_6H_4$) est facilement activée par [Ir(PMe$_3$)$_3$Cl(COE)] (COE = η^2-cyclooctène) (**1**) pour conduire à un nouveau complexe bis(boryl)iridium(III), *mer-cis*-[Ir(PMe$_3$)$_3$Cl(Bcat)$_2$] (**2**). Ce complexe est le premier bis(boryl)iridium dont la structure a été caractérisée, et c'est le premier complexe bis(boryl)métal pour lequel on a observé, en solution, deux environnements distincts pour les groupes boryles. Les cristaux de **2** sont incolores, monocliniques, groupe d'espace $P2_1/n$ avec a = 8,9638(7), b = 32,197(2), c = 9,3980(7) Å et β = 90,385(2)°.

Mots clés : iridium, bore, dibore, boryle, addition oxydante, diffraction des rayons X, structure, triméthylphosphine.

[Traduit par la rédaction]

Introduction

Attention has recently been paid to the transition metal catalyzed addition of B—B bonds in $(RO)_2B$—$B(OR)_2$ compounds to alkenes (1) and alkynes (2) and a key step of this process is believed to be the oxidative addition of the B—B bond to the transition metal centre. We have recently reported B—B oxidative addition by the Co(0) complex [Co(PMe$_3$)$_4$] (3*a*), and the Rh(I) complex [Rh(PPh$_3$)$_3$Cl] (3*b*), we (2*c,f,g*) and others (2*a,b,e,h*) have reported this reaction with Pt(0) phosphine complexes such as [Pt(PPh$_3$)$_2$(η^2-C_2H_4)], and He and Hartwig recently observed oxidative addition of B_2cat_2 (cat = 1,2-$O_2C_6H_4$) or its 4-^{t}Bu derivative by [Fe(CO)$_4$] (4*a*) and [Cp$_2$W] (4*b*) fragments. The current work examines the reactivity of B_2cat_2 toward the Ir(I) complex [Ir(PMe$_3$)$_3$Cl(COE)] (COE = η^2-cyclooctene) (**1**) and we report herein the synthesis and molecular structure of a new iridium bis(boryl) complex *mer-cis*-[Ir(PMe$_3$)$_3$Cl(Bcat)$_2$] (**2**)

There were several early reports on the synthesis of metal bis(boryl) complexes by Schmid and Nöth, although none were prepared via B—B oxidative addition, and none were well characterized. Thus, these authors reported (5*a,b,c*) that the reaction of Y_2BX with [Co(dppe)$_2$(H)] (dppe = $Ph_2PCH_2CH_2PPh_2$) gave the 19-electron Co(II) bis(boryl) complexes *trans*-[Co(dppe)$_2$(BY_2)$_2$] (eq. [1]).

[1] $$2Y_2BX + 2\,[Co(dppe)_2(H)] \rightarrow \textit{trans}\text{-}[Co(dppe)_2(BY_2)_2] + [Co(dppe)_2X_2] + H_2$$

(X = Cl, Br, I; Y = Br, I, Ph; Y_2B = Ph_2B, PhClB; Y_2B = $C_{12}H_8B$)

Utilizing these cobalt "boryl transfer reagents" they claimed to have prepared two Ni(II) bis(boryl) compounds [Ni(dppe)$_n$(BPh_2)$_2$] (n = 1, 2) (eq. [2])

[2] $[Co(dppe)_2(BPh_2)_2] + [Ni(dppe)_nBr_2] \rightarrow [Co(dppe)_2Br_2] + [Ni(dppe)_n(BPh_2)_2]$ ($n = 1, 2$)

In addition, the reaction of $[Pt(PPh_3)_4]$ with Me_2BBr in 1:2 ratio gave a compound that was proposed to be a six-coordinate Pt(IV) bis(boryl) complex $[Pt(PPh_3)_2Br_2(BMe_2)_2]$ (*5d*). However, none of the compounds in these early reports were structurally characterized, and their true nature remains unknown.

Among the few recently structurally characterized metal bis(boryl) complexes, $[Co(PMe_3)_3(Bcat)_2]$ is a paramagnetic compound with a distorted square pyramidal structure with an unusually small B-M-B angle of 67.9(4)°. The geometry of this novel cobalt complex can be viewed alternatively as a distorted tetrahedron with the two boryl ligands occupying a single coordination site (*3a*). All reported (*2b,c,e*) Pt(II) bis(boryl) compounds are of the form *cis*-$[Pt(PR_3)_2(Bcat)_2]$ and exhibit the expected four-coordinate square planar geometry and relatively small B-M-B angles of ca. 76°–81°. The

[3] 
Rh(III) bis(boryl) complex $[Rh(PPh_3)_2Cl(Bcat)_2]$ has a five-coordinate distorted square pyramidal configuration with one boryl group *trans* to Cl, the other *trans* to the vacant site (6). In the solid state, the B-Rh-B angle is 79.0(3)°, and in solution the complex is fluxional, giving only one broad signal in the $^{11}B\{^1H\}$ NMR spectrum. When the 4-^{t}Bu-catB analogue was examined, only one ^{13}C resonance for the ^{t}Bu groups was observed even at −80°C, indicating fast exchange of boryl group environments as might be expected for a five-coordinate complex. The octahedral complex *cis*-$[Fe(CO)_4\{B(1,2\text{-}O_2\text{-}4\text{-}^tBuC_6H_3)\}_2]$ (*4a*) has a B-Fe-B angle of 82.8(4)°. There has been only one Ir bis(boryl) complex reported to date, namely $[IrH(Bcat)_2(CO)(dppe)]$ (7), which was only observed by NMR spectroscopy in the reaction of *fac*-$[IrH_3(CO)(dppe)]$ with excess HBcat (eq. [3]).

It was proposed to have a C_s structure with both boryl groups *trans* to the bidentate chelating phosphines. Compound **2**, *mer-cis*-$[Ir(PMe_3)_3Cl(Bcat)_2]$, reported here is thus the first structurally characterized Ir bis(boryl) compound, and the first metal bis(boryl) complex in which two distinct boryl group environments are observed in solution.

Results and discussion

Addition of B_2cat_2 to a THF solution of **1** at room temperature results in complete conversion (90% isolated yield, see experimental section) to the iridium bis(boryl) complex **2** (eq. [4]). The solution structure of **2** was established by ^1H, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$, and $^{11}B\{^1H\}$ NMR spectroscopy, and its solid state structure was confirmed by a single-crystal X-ray diffraction study on crystals grown by layering hexane over a CH_2Cl_2 solution.

[4] 
1 2

The $^{31}P\{^1H\}$ NMR spectrum of **2** displays a doublet at −40.9 ppm ($^2J_{P-P}$ = 27.5 Hz) and a broad peak at −50.8 ppm in 2:1 ratio. The latter broad signal clearly indicates that one phosphine ligand is *trans* to a boryl group and the resonance is influenced by the boron nucleus (^{11}B, spin 3/2, 80.4% natural abundance; ^{10}B, spin 3, 19.6% natural abundance) as the resonance of the spin 1/2 nucleus in the *trans* position will display significant broadening due to quadrupolar coupling (8). The $^{11}B\{^1H\}$ NMR spectrum clearly displays two well-separated resonances at 32.6 and 41.7 ppm, respectively, in which the first signal is consistent with a Bcat group *trans* to chloride as shown in the Ir boryl complexes $[Ir(PMe_3)_3(Cl)(H)(Bcat)]$ (9) (δ 32.8 ppm) and $[Ir(PEt_3)_3(Cl)(H)(Bcat)]$ (10) (δ 33.5 ppm), while the other resonance at 41.7 ppm is quite close to the value of δ 44.7 ppm in an iridium tris(boryl) complex *fac*-$[Ir(PEt_3)_3(Bcat)_3]$ (11) in which the boryl groups are all *trans* to the phosphine ligands. Also in the ^1H NMR spectrum, four sets of catecholate proton resonances are observed at (7.07 and 6.76) and (7.12 and 6.83) ppm, and six carbon resonances are observed at (110.53, 120.71, and 149.84) and (115.58, 120.76, and 150.03) ppm in the $^{13}C\{^1H\}$ NMR spectrum in $CDCl_3$. From these results, the structure of **2** can be assigned unambiguously as *mer-cis*-$[Ir(PMe_3)_3Cl(Bcat)_2]$, with one boryl group *trans* to chloride and the other *trans* to the unique trimethylphosphine ligand.

The structure of **2** is further confirmed by single crystal X-ray diffraction. A summary of the crystallographic data and parameters for data collection and refinement is presented in Table 1, selected bond distances and bond angles are given in Table 2, and final atomic coordinates are given in Table 3. The molecular structure of **2** consists of an octahedral arrangement with *mer* phosphine ligands. The two catecholatoboryl groups are mutually *cis* with an unusually large B-Ir-B angle of 91.6 (2)°, vide supra. The two BO_2 planes of these boryl moieties are essentially perpendicular to one another, the angle between the two boryl planes being 107.2°. The boron *trans* to chloride has an iridium–boron distance of 2.024(6) Å, which is the same within statistical error as that in the compound *mer*-$[Ir(PMe_3)_3Cl(H)(Bcat)]$ (**3**) (2.023(10) Å), which was produced through the oxidative addition of the H—B bond in HBcat to **1** (9). The other iridium–boron bond distance is 2.080(6) Å, which is very close to the value of 2.093(7) Å in *fac*-$[Ir(PMe_3)_3H_2(BC_8H_{14})]$, prepared from the reaction of $[Ir(PMe_3)_4H]$ with 9-BBN dimer and in which the BC_8H_{14} boryl group is *trans* to PMe_3 (12). These two Ir—B bond distance values are in accordance with the fact that PMe_3 has a larger *trans* influence than Cl. For further comparison, the Ir—B bond in *trans*-$[Ir(PPh_3)_2Cl(CO)(H)(Bcat)]$ is 2.045(5) Å where boron is *trans* to chloride (10). Crabtree and co-workers reported (13) a novel Ir(IV) boryl complex $[Ir(PMe_3)_3(biphBF)Cl]BPh_4$ prepared by the reaction of $[Ir(PMe_3)_3Cl(biph)]$ (biph = biphenyl-2,2-diyl) with $NOBF_4$. The molecular structure of $[Ir(PMe_3)_3(biphBF)Cl]^+$ was determined and the Ir—B bond distance was found to be 2.00(1) Å with the boryl group *trans* to a phosphine ligand, but, unfortunately, the structure is not very accurate.

Among the Ir—P bond distances in complex **2**, the two mutually *trans* phosphine groups have Ir—P distances of 2.3286(14) and 2.3224(13) Å, respectively, which are very similar to the two *trans* Ir—P distances in compound **3** (2.307(2) and 2.304(2) Å). However, the PMe_3 group *trans* to

[b] $R = \Sigma||F_o| - |F_c|| / \Sigma|F_o|$; $wR = [\Sigma w(F_o^2 - F_c^2)^2 / \Sigma w(F_o^2)^2]^{1/2}$.

Bcat in **2** has a significantly longer Ir—P distance of 2.3989(13) Å while the PMe_3 group *trans* to hydride in complex **3** displays an Ir—P bond distance of only 2.351(2) Å. This suggests that the Bcat boryl group has a larger *trans* influence than PMe_3 and even hydride ligands, at least in this octahedral system.

Conclusion

Oxidative addition of the B—B bond in B_2cat_2 to [Ir(PMe_3)$_3$Cl(COE)] readily generates a new iridium bis(boryl) complex *mer-cis*-[Ir(PMe_3)$_3$Cl(Bcat)$_2$], the molecular structure of which demonstrates that there are two distinct boryl groups. NMR studies show that these remain distinct in solution. The boryl group shows a larger *trans* influence than hydride. The reactivity of this novel metal bis(boryl) complex with alkenes and alkynes is currently being investigated, as are the reactions of diborane (4) compounds with other Ir(I) complexes.[4]

Experimental section

General procedures

Reactions and NMR sample preparations were performed under a dry nitrogen atmosphere using glove box techniques. THF was freshly distilled from sodium benzophenone ketyl, hexane from sodium metal, and CH_2Cl_2 from CaH_2 under an N_2 atmosphere. NMR solvents were distilled from CaH_2 ($CDCl_3$) or Na metal (C_6D_6) following three freeze–pump–thaw cycles. [Ir(PMe_3)$_3$Cl(COE)] (**14**) and B_2cat_2 (**15**) were

prepared by established methods. NMR spectra were recorded on Bruker AC 200 (^{1}H at 200 MHz, ^{13}C at 50 MHz, ^{31}P at 81 MHz) or AMX 500 (^{1}H at 500 MHz, ^{11}B at 160 MHz) spectrometers. The ^{1}H chemical shifts were referenced to the internal standard tetramethylsilane (TMS) and ^{13}C chemical shifts were referenced to the solvent resonances as an internal standard. The ^{31}P and ^{11}B chemical shifts were referenced to the external standards 85% H_3PO_4 and $F_3B{\cdot}OEt_2$, respectively. The ^{11}B NMR spectrum was obtained using a background subtraction routine to remove resonances due to borosilicate glass in the NMR probe and NMR tube. This was accomplished by recording the spectrum of an NMR tube containing the same volume of pure solvent and with identical acquisition parameters to those of the sample and by subtracting this background FID from that of the sample. Coupling constants are reported in Hz. Multiplicities are reported as (br) broad, (s) singlet, (d) doublet, (vt) virtual triplet, and (m) multiplet. Elemental analysis was obtained from M-H-W Laboratories, Phoenix, Arizona, U. S. A.

Preparation of *mer-cis*-[Ir(PMe_3)$_3$Cl(Bcat)$_2$] (2)

A solution of B_2cat_2 (84 mg, 0.35 mmol) in 2 mL THF was added to a solution of [Ir(PMe_3)$_3$Cl(COE)] (200 mg, 0.35 mmol) in 10 mL THF. The solution turned almost colourless immediately. After stirring for 1 h, the solvent was removed under reduced pressure and the colourless residue was washed with hexane and dried in vacuo to yield 220 mg (90%) of complex **2**. ^{31}P{^{1}H} NMR (81 MHz, 25°C in C_6D_6), δ: −40.9 (d, $^2J_{P-P}$ = 27.5 Hz, 2P, *trans* PMe_3), −50.8 (br, PMe_3). ^{11}B{^{1}H} NMR (160 MHz, 25°C in C_6D_6), δ: 41.7 (br, Bcat), 32.6 (br, Bcat). ^{1}H NMR (500 MHz, 25°C in $CDCl_3$), δ: 1.15 (d, $^2J_{P-H}$ = 7.5 Hz, 9H, PMe_3), 1.48 (vt, $^2J_{P-H}$ = 3.7 Hz, 18H, PMe_3), 7.12, 6.83 (AA′BB′, 4H, Bcat), 7.07, 6.76 (AA′BB′, 4H, Bcat). ^{13}C{^{1}H} NMR (50 MHz, 25°C in C_6D_6), δ: 17.73 (d, J_{P-C} = 26 Hz, PMe_3), 19.52 (dvt, J_{P-C} = 19 Hz, $^3J_{P-C}$ = 4.5 Hz, PMe_3), 110.86 (s), 121.24 (s), 150.65 (s, Bcat), 111.86(s), 121.45 (s, Bcat). In C_6D_6, two resonances due to the inequivalent *C*-O groups of the two Bcat ligands are coincident. ^{13}C{^{1}H} NMR (50 MHz, 25°C in $CDCl_3$), δ: 18.06 (dm, J_{P-C} = 26 Hz, PMe_3), 19.57 (dvt, J_{P-C} = 19.5 Hz, $^3J_{P-C}$ = 4.2 Hz, PMe_3), 110.53(s),

Molecular structure determination

Crystals of **2** suitable for X-ray diffraction studies were obtained by diffusion of a layer of hexane into a CH_2Cl_2 solution of **2**. Data were collected at low temperature on a Siemens SMART CCD area-detector diffractometer using graphite-monochromated MoK_α radiation (λ = 0.71073 Å) and narrow-frame ω scan methods. The single crystal was mounted on a glass fiber with a coating of perfluoropolyether oil, cell parameters were refined from the observed setting angles for selected reflections, and intensities were measured from a series of frames each covering a 0.3° oscillation in ω. An absorption correction was carried out using a semi-empirical method, based on sets of equivalent reflections measured at different positions.

The structure was solved by direct methods, and refined by full-matrix least-squares techniques (16). The refinement was on F^2 of all independent reflections, to minimize $\Sigma w(F_o^2 - F_c^2)^2$, with weighting $w^{-1} = \sigma^2(F_o^2) + (0.0407P)^2 + 10.1457P$, where $P = (F_o^2 + 2F_c^2)/3$; the refined isotropic extinction parameter χ is defined such that F_c is multiplied by $(1 + 0.001\chi F_c^2\lambda^3/\sin 2\theta)^{-1/4}$. Anisotropic displacement parameters were refined for all non-hydrogen atoms, and isotropic hydrogen atoms were constrained to ride on their parent carbon atoms with fixed bond lengths and idealized bond angles. Programs were standard Siemens control and integration software, version 5 of SHELXTL (16), and local programs.

Details of the crystal determination including complete tables of coordinates, bond distances and angles, and anisotropic displacement parameters have been deposited.[5]

[5] A complete set of data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Tables of bond lengths and angles and atomic coordinates have also been deposited with the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, U.K. Structure factor amplitudes are no longer being deposited and may be obtained directly from the authors (either T.B.M. or W.C.).

Alkylaluminum complexes containing pyridyl amido ligands. Syntheses and characterization of $AlMe_2[N(CH_2\text{-}2\text{-}Py)_2]$, $Al_2Me_5[N(CH_2\text{-}2\text{-}Py)_2]$, and Al_2Me_4[2,3,5,6-tetra(2-pyridyl)piperazyl], an unusual carbon–carbon bond coupling product

Steven J. Trepanier and Suning Wang

Abstract: The reactions of $AlMe_3$ with di(2-pyridylmethyl)amine have been investigated. Two new complexes, $AlMe_2[N(CH_2\text{-}2\text{-}Py)_2]$ (**1**) and Al_2Me_4[2,3,5,6-tetra(2-pyridyl)piperazyl] (**3**), were obtained as the major and the minor product, respectively, from the reaction of $AlMe_3$ with di(2-pyridylmethyl)amine in a 1:1 ratio in toluene at 23°C. The reaction of $AlMe_3$ with di(2-pyridylmethyl)amine in a 2:1 ratio yielded a dinuclear complex $Al_2Me_5[N(CH_2\text{-}2\text{-}Py)_2]$ (**2**). These complexes were fully characterized by NMR, and elemental and single-crystal X-ray diffraction analyses. Crystal data: **1**, $C_{14}H_{18}N_3Al$, monoclinic, $P2_1/m$, $a = 7.568(2)$, $b = 7.340(1)$, $c = 13.120(8)$ Å, $\beta = 104.17(3)°$, $V = 706.6(4)$ Å^3, $Z = 2$; **2**, $C_{17}H_{27}N_3Al_2$, triclinic, $P\bar{1}$, $a = 8.422(1)$, $b = 16.711(6)$, $c = 7.659(1)$ Å, $\alpha = 91.94(2)°$, $\beta = 113.08(1)°$, $\gamma = 85.17(2)°$, $V = 988.2(4)$ Å^3, $Z = 2$; **3**, $C_{28}H_{32}N_6Al_2$, monoclinic, $P2_1/c$, $a = 7.522(8)$, $b = 15.841(8)$, $c = 11.584(4)$ Å, $\beta = 98.53(5)°$, $V = 1365(1)$ Å^3, $Z = 2$. Compound **1** is a mononuclear complex with the aluminum atom in an approximately trigonal bipyramidal geometry and the amido nitrogen atom in a trigonal planar geometry. Compound **2** contains two aluminum centers bridged by an amido nitrogen atom where one of the aluminum atoms has a tetrahedral geometry while the other has a trigonal bipyramidal geometry. The dinuclear compound **3** can be described as the result of two unusual C—C bonds coupling between the methylene carbon atoms of two molecules of **1**. The aluminum coordination environment in **3** is similar to that of **1**.

Key words: aluminum, amide, pyridyl, 2,3,5,6-tetra(2-pyridyl)piperazine, structure.

Résumé : On a étudié les réactions du $AlMe_3$ avec la di(2-pyridylméthyl)amine. On a obtenu deux nouveaux complexes, le $AlMe_2[N(CH_2\text{-}2\text{-}Py)_2]$ (**1**) (produit majoritaire) et le Al_2Me_4[2,3,5,6-tétra(2-pyridyl)pipérazyl] (**3**) (produit minoritaire), à partir de la réaction de $AlMe_3$ avec la di(2-pyridylméthyl)amine dans un rapport de 1 : 1 dans le toluène à 23°C. La réaction de $AlMe_3$ avec la di(2-pyridylméthyl)amine dans un rapport de 2 : 1 conduit à un complexe dinucléaire $Al_2Me_5[N(CH_2\text{-}2\text{-}Py)_2]$ (**2**). On a caractérisé complètement ces complexes par : la RMN, l'analyse élémentaire et la diffraction de rayons X sur un monocristal. Le composé **1**, $C_{14}H_{18}N_3Al$, appartient au groupe d'espace monoclinique $P2_1/m$, avec $a = 7{,}568(2)$, $b = 7{,}340(1)$, $c = 13{,}120(8)$ Å, $\beta = 104{,}17(3)°$, $V = 706{,}6(4)$ Å^3, $Z = 2$; le composé **2**, $C_{17}H_{27}N_3Al_2$, appartient au groupe d'espace triclinique $P\bar{1}$, avec $a = 8{,}422(1)$, $b = 16{,}711(6)$, $c = 7{,}659(1)$ Å, $\alpha = 91{,}94(2)°$, $\beta = 113{,}08(1)°$, $\gamma = 85{,}17(2)°$, $V = 988{,}2(4)$ Å^3, $Z = 2$; le composé **3**, $C_{28}H_{32}N_6Al_2$, appartient au groupe d'espace monoclinique $P2_1/c$, avec $a = 7{,}522(8)$, $b = 15{,}841(8)$, $c = 11{,}584(4)$ Å, $\beta = 98{,}53(5)°$, $V = 1365(1)$ Å^3, $Z = 2$. Le composé **1** est un complexe mononucléaire avec l'atome d'aluminium dans une géométrie bipyramidale trigonale approximativement et l'atome d'azote du groupe amido dans une géométrie plane trigonale. Le composé **2** contient deux centres aluminium pontés par un atome d'azote du groupe amido; un des atomes d'aluminium a une géométrie tétraédrique tandis que l'autre à une géométrie bipyramidale trigonale. Le composé dinucléaire **3** peut être décrit comme étant le résultat de deux couplages inhabituels des liaisons C—C entre les atomes de carbone méthyléniques de deux molécules du composé **1**. L'environnement de la coordination de l'aluminium du composé **3** est similaire à celui du composé **1**.

Mots clés : aluminium, amide, pyridyl, 2,3,5,6-tétra(2-pyridyl)pipérazine, structure.

Introduction

The chemistry of organoaluminum complexes containing amido or imido ligands has been an area of considerable interest due to the versatile structural and bonding features of the complexes and their potential applications in materials and catalysis (1). Most of the earlier work in this area focuses on the monodentate and bidentate aliphatic amido and imido ligands (1, 2). Our group has been interested in building polynuclear alkylaluminum complexes containing polydentate aromatic amido or imido ligands because the electronic properties and structural features displayed by these complexes are drastically different from those of aliphatic amido or imido complexes (3), but have hardly been explored previously. For example, we observed recently that by coordination, the alkylaluminum moiety can induce or enhance the luminescence of amido ligands containing an aromatic functional group such as pyridyl, which provides a possible new avenue for the development of new chemiluminescent materials. The synthesis and structural elucidation of these organoaluminum complexes are the indispensable steps towards the understanding of their electronic structures, and hence the design of useful luminescent materials. In this report, the syntheses and structures of two novel alkylaluminum complexes with the tridentate ligand, di(2-pyridylmethyl)amido, and a dinuclear complex with a hexadentate diamido ligand, 2,3,5,6-tetra(2-pyridyl)piperazyl, formed through an unusual carbon–carbon bond coupling are described. The luminescence and electronic properties of these compounds are currently under investigation and will be presented in a subsequent report.

Experimental section

The reactions were conducted under an atmosphere of dry and oxygen-free nitrogen or argon, employing either a Vacuum Atmosphere inert atmosphere glove box or standard Schlenk-line techniques. Solvents were distilled from the appropriate drying agents under nitrogen. ^{1}H NMR and ^{13}C NMR spectra were recorded at 300 and 75.4 MHz, respectively, on a Brüker AC-300 spectrometer. Elemental analyses were performed by Desert Analytics, Arizona, or Canadian Microanalytical Service, Delta, British Columbia. Trimethylaluminum was purchased from Aldrich Chemical Co. Di(2-pyridylmethyl)amine was prepared by a modified procedure reported in the literature (4).

Synthesis of $AlMe_2[N(CH_2\text{-}2\text{-}Py)_2]$ (1)

A 2.0 M solution of $Al(CH_3)_3$ (2.0 mL, 4.0 mmol) in toluene was added to di(2-pyridylmethyl)amine (0.80 g, 4.0 mmol) dissolved in 5.0 mL of toluene at 23°C. The solution immediately became pink and was stirred for 0.5 h. Concentration of the solution afforded pink crystals of compound **1**. Yield 80%. ^{1}H NMR (C_6D_6, 298 K, δ, ppm): −0.11 (s, 6H, CH_3), 4.38 (s, 4H, CH_2), 6.62 (m, 2H, Py), 6.86 (m, 2H, Py), 7.13 (m, 2H, Py), 8.48 (m, 2H, Py). ^{13}C NMR (C_6D_6, 298 K, δ, ppm): 55.63 (CH_2), 121.23, 121.57, 136.45, 145.09, 161.23 (py). Anal. calcd. for $C_{14}H_{18}AlN_3$: C 65.89, H 7.06, N 16.47; found: C 64.12 (63.53), H 6.91 (6.76), N 16.15 (15.99). The pure crystals of compound **1** are colorless. However, the surfaces of these crystals are always coated with pink luminescent substances upon crystallization. ^{1}H NMR of the solution obtained by dissolving the single crystals of **1** also indicated the presence of an unknown impurity that could be accountable for the low carbon content of the CHN analysis.

Synthesis of $Al_2Me_5[N(CH_2\text{-}2\text{-}Py)_2]$ (2)

A 2.0 M solution of $Al(CH_3)_3$ (0.5 mL, 1.0 mmol) in toluene was added to di(2-pyridylmethyl)amine (0.10 g, 0.5 mmol) dissolved in 6.0 mL of toluene at 23°C. A colorless solution was obtained. After being stirred for 1.5 h, the solution was evaporated to dryness in vacuo, affording colorless crystalline solids. The ^{1}H NMR spectrum of this solid indicated that it is the pure compound **2**. Yield >90%. Compound **2** can be recrystallized readily from toluene and hexane. ^{1}H NMR (C_6D_6, 298 K, δ, ppm): −0.90 (s, 9H, CH_3), −0.78 (s, 3H, CH_3), 0.12 (s, 3H, CH_3), 3.45 (d, 2H, CH_2, $^2J_{H-H}$ = 16 Hz), 4.44 (d, 2H, CH_2, $^2J_{H-H}$ = 16 Hz), 6.42 (m, 4H, Py), 6.83 (m, 2H, Py), 8.18 (d, 2H, Py). ^{13}C NMR (C_6D_6, 298 K, δ, ppm): 56.04 (CH_2), 121.25, 122.89, 138.49, 144.46, 162.27 (Py). Anal. calcd. for $C_{17}H_{27}Al_2N_3$: C 62.39, H 8.26, N 12.85; found: C 61.46, H 8.02, N 12.86.

Synthesis of Al_2Me_4[2,3,5,6-tetrakis(2-pyridyl)piperazyl] (3)

Compound **3** was isolated as a minor dark-brown product from the reaction of $Al(CH_3)_3$ with di(2-pyridylmethyl)amine as described for the synthesis of compound **1**. Independent syntheses for this compound have not been successful. ^{1}H NMR (C_6D_6, 298 K, δ, ppm): 0.28 (s, 12H, CH_3), 4.78 (d, 2H, CH, $^3J_{H-H}$ = 2.7 Hz), 4.81 (d, 2H, CH, $^3J_{H-H}$ = 2.7 Hz), 6.47 (m, 4H, Py), 6.57 (d, 4H, Py), 6.73 (m, 4H, Py), 8.43 (d, 4H, Py). ^{13}C NMR (C_6D_6, 298 K, δ, ppm): 66.39 (CH), 121.56, 123.49, 135.16, 149.30, 160.91 (Py). Anal. calcd. for $C_{28}H_{32}Al_2N_6$: C 66.40, H 6.32, N 16.60; found: C 66.32, H 6.38, N 16.76.

2,3,5,6-Tetra(2-pyridyl)piperazine

The addition of H_2O to the toluene solution of **3** yielded the free ligand 2,3,5,6-tetra(2-pyridyl)piperazine quantitatively. The free ligand is a light yellow solid. ^{1}H NMR ($CDCl_3$, 298 K, δ, ppm): 4.42 (s, 4H, CH), 6.68 (d, 4H, Py), 7.04 (m, 4H, Py), 7.31 (m, 4H, Py), 8.59 (d, 4H, Py). MS (EI), *m/e*: 395 (M^+, calcd. 394.5).

X-ray crystallographic analysis

All crystals for single-crystal X-ray diffraction were obtained from concentrated toluene/hexane solutions, mounted, and flame sealed in glass capillaries under nitrogen. Data were collected on a Rigaku AFC6S diffractometer with graphite-monochromated Mo-Kα radiation, operated at 50 kV and 35 mA. Three standard reflections were measured every 147 reflections. At the end of data collection, the intensity of the standards of compound **1** and compound **2** decreased by 3% and 5%, respectively, while no decay was observed for **3**. Data were processed on a Silicon Graphics computer using the TEXSAN crystallographic package (5) and corrected for decay and Lorentz-polarization effects. Neutral scattering factors (6) were taken from Cromer and Waber. The systematic absences ($0k0$, $k = 2n + 1$) of **1** agree with the monoclinic space groups $P2_1$ and $P2_1/m$. The space group of **1** was determined to be $P2_1/m$, based on the statistical analysis and the successful solution and refinement of the structure. The crystal of **2** belongs to the triclinic space group $P\bar{1}$. The crystals of **3**

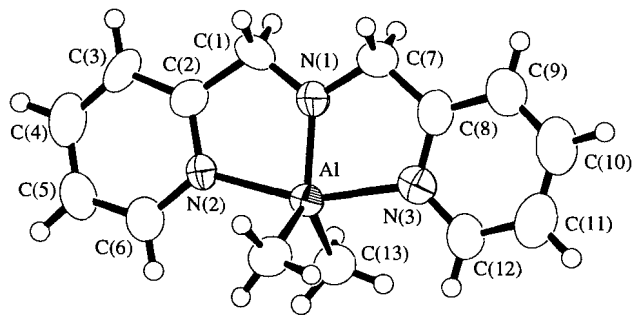
belong to the monoclinic space group $P2_1/c$, uniquely determined by the systematic absences ($0k0$, $k = 2n + 1$, $h0l$, $l = 2n + 1$). All structures were solved by direct methods. Full-matrix least-squares refinements minimizing the functions $\Sigma w (|F_o| - |F_c|)^2$ were applied. All non-hydrogen atoms were refined anisotropically. The positions of hydrogen atoms were either calculated or located directly from the difference Fourier maps and not refined. Their contributions in structural factor calculations were included. Crystallographic data are given in Table 1. Tables of hydrogen atom coordinates, anisotropic thermal parameters, and complete lists of bond lengths and angles have been deposited.[2]

Results and discussion

Synthesis and structure of $AlMe_2[N(CH_2\text{-}2\text{-}Py)_2]$ (1)

Compound 1 was isolated as the major product from the reaction of $Al(CH_3)_3$ with di(2-pyridylmethyl)amine in a 1:1 ratio in toluene at 23°C. The structure of **1** was determined by X-ray diffraction analysis. The positional and isotropic thermal parameters of non-hydrogen atoms are listed in Table 2 (*a*). Important bond lengths and angles are given in Table 3 (*a*). An ORTEP diagram showing the molecular structure of **1** is given in Fig. 1.

Fig. 1. An ORTEP diagram showing the molecular structure of **1** with labelling scheme and 50% thermal ellipsoids.



Compound **1** is a mononuclear complex with a C_{2v} symmetry. The molecular plane coincides with the crystallographically imposed reflection plane. The aluminum center in **1** is coordinated by one amido nitrogen atom, two methyl groups, and two pyridyl groups in a distorted trigonal bipyramidal environment as evidenced by the N(2)-Al-N(3) bond angle of 158.5(2)° and the sum of bond angles around the Al atom on the basal plane, 360.0°. The deviation of the N(2)-Al-N(3) angle from linearity is believed to be caused by the geometric

[2] Copies of material on deposit may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Tables of hydrogen atom parameters and complete lists of bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

constraint of the ligand. Five-coordinate aluminum amido complexes are not very common, but an increasing number of examples are being reported, including $AlMe_2$-$(Et_2NCH_2CH_2NCH_2CH_2NEt_2)$, $Al_2Me_4(2\text{-}NCH_2Py)_2$, and $Al_4(8\text{-quinolylimido})_2(CH_3)_7(OCH_3)$ reported recently by our group (3, 7) and $Al_5H_7(NPr^i)_2(HNPr^i)_2(NCH(CH_3)CH_2N$-$(CH_3)_2)$ reported by Perego and Dozzi (2*d*). The amido N(1)—Al bond length (1.826(4) Å) is significantly shorter than the pyridyl N(2)—Al (2.103(4) Å) and N(3)—Al bond lengths (2.137(5) Å), reflecting the relatively high affinity of the amido atom to the aluminum center. The amido N(1) atom has a trigonal planar geometry. Some contribution of the lone pair to the Al—N(1) bond order is therefore conceivable. The N(1)—Al bond length is indeed significantly shorter than the known amido–aluminum bond lengths (>1.95 Å) where the amido nitrogen atom has a tetrahedral geometry (2, 3, 8), indicative of the participation of the nitrogen lone pair in the Al—N(1) bond. The structure of compound **1** resembles that of $AlMe_2(Et_2NCH_2CH_2NCH_2CH_2NEt_2)$, reported earlier by our group, where the amido ligand has a trigonal planar geometry (7). However, in contrast to the highly fluxional behavior of $AlMe_2(Et_2NCH_2CH_2NCH_2CH_2NEt_2)$ in solution (7), compound **1** retains its solid state structure in solution, as established by NMR spectroscopic studies. The relatively structural rigidity of compound **1** in solution can be attributed to the relatively rigid structure of the di(2-pyridylmethyl)amido ligand (dpa), in comparison with the *N*,*N*,*N*′,*N*′-tetraethyldiethylenediamine amido (tda) ligand (Fig. 2). The corresponding bidentate ligand, 2-(pyridylmethyl)amido, is known to function as a bridging ligand via the amido atom producing the dinuclear compound (3*c*), $Al_2Me_4[N(CH_2\text{-}2\text{-}Py)]_2$. The mononuclear structure of **1** is apparently stabilized by the chelating effect of the tridentate dpa ligand and the coordination saturation of the aluminum center.

As shown in Fig. 3, the molecules of **1** are packed parallel to each other in the crystal lattice, resulting in extensive π interactions between the aromatic rings. The shortest atomic contact distance between the rings is 3.698(1) Å between the C(3) and C(5′) atoms.

Synthesis and structure of $Al_2Me_5[N(CH_2\text{-}2\text{-}Py)_2]$ (2)

The amido atom in the dpa ligand has two lone pairs of electrons. One can therefore predict that it is possible for the amido atom in **1** to bind to the second aluminum center, forming a dinuclear complex. In fact, it is more common for secondary amido ligands to coordinate to two metal centers as a bridging ligand than to coordinate to one metal center only (1, 3, 7, 8). We therefore performed the reaction of di(2-pyridylmethyl)amine with 2 equivalents of $AlMe_3$, which indeed yielded a new colorless dinuclear complex $Al_2Me_5[N(CH_2\text{-}2\text{-}Py)_2]$ (**2**) in quantitative yield. Compound **2** was fully characterized by NMR and elemental and X-ray diffraction analyses. The posi-

tional and isotropic thermal parameters of nonhydrogen atoms are given in Table 2 (*b*). Selected bond lengths and angles are listed in Table 3 (*b*). An ORTEP diagram showing the molecular structure of compound **2** is given in Fig. 4.

As observed in **1**, the $AlMe_2$ unit is chelated by three nitrogen atoms. The geometry around the Al(2) atom is similar to that in **1**, a distorted trigonal bipyramid. The amido Al(2)—N(1) distance (2.002(4) Å) is, however, significantly longer than that in **1**, consistent with the tetrahedral geometry of the amido N(1) atom. The $AlMe_3$ unit is attached to the N(1) atom with a typical amido nitrogen (tetrahedral) – aluminum bond length (2.020(4) Å). Compound **2** can be considered as the result of the addition of one $AlMe_3$ unit to compound **1**, which removes the C_2 rotational symmetry axis in **1**, resulting in an approximate C_s symmetry. As the consequence of the C_s symmetry, the two methyl groups of the Al(2) atom and the two protons of the methylene groups are inequivalent. In solution, compound **2** retains its solid state structure, as confirmed by the presence of three distinct methyl resonances in a 1:1:3 ratio (two from the Al(2) unit and one from the Al(1) unit) and a well-resolved AB coupling pattern of the CH_2 groups with a typical $^2J_{H-H}$ coupling constant (9) (16 Hz) in the ^1H NMR spectrum of **2**.

In the crystal lattice, the most significant $\pi - \pi$ interactions are between the N(3) and the N(3′) pyridyl rings with the shortest atomic distance being 3.454(7) Å between C(8) and C(10′) (Fig. 5).

Fig. 6. An ORTEP diagram showing the molecular structure of **3** with labelling scheme and 50% thermal ellipsoids.

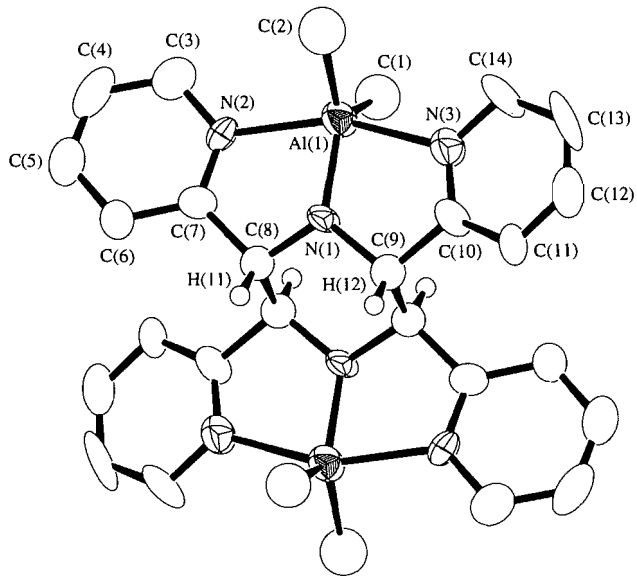

Fig. 7.

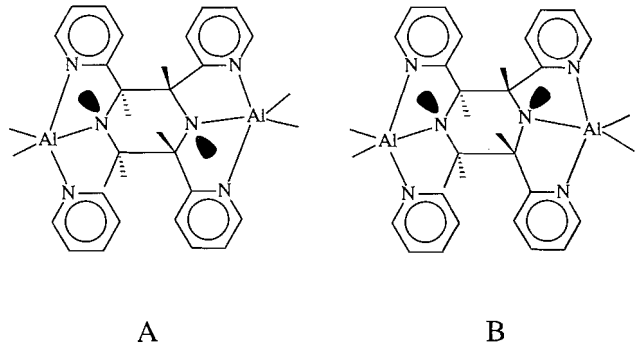

Fig. 8. A unit cell packing diagram showing the intermolecular interactions of compound **3** in the crystal lattice.

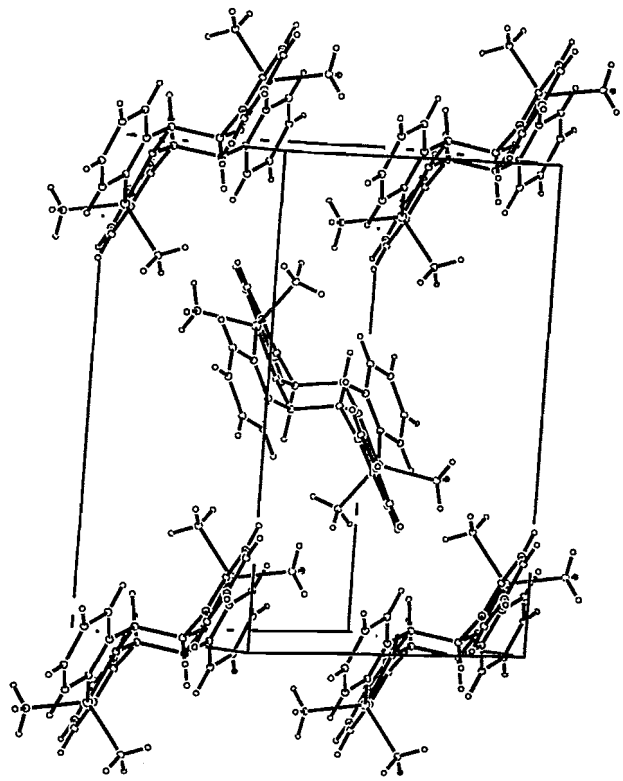

Synthesis and structure of $Al_2(CH_3)_4$[2,3,5,6-tetra(2-pyridyl)piperazyl] (3)

Compound **3** was isolated as a minor dark-brown crystalline product from the reaction of $Al(CH_3)_3$ with di(2-pyridylmethyl)amine in a 1:1 ratio as described for compound **1**. Compound **3** was characterized by elemental, NMR, and X-ray diffraction analyses. Positional and isotropic thermal parameters of non-hydrogen atoms are given in Table 2 (*c*). Selected bond lengths and angles are listed in Table 3 (*c*).

As shown in Fig. 6, compound **3** has two aluminum ions and a crystallographically imposed inversion center symmetry. The coordination environment and bond lengths and angles around each aluminum center resemble that in **1**. There are, however, substantial changes of bond lengths and angles around the amido N(1) atom. The geometry of the N(1) atom is about 5° from planarity (the sum of angles around N(1) is 354.9°). The N(1)—C(8) and N(1)—C(9) distances (1.457(7) Å, 1.483(8) Å) are considerably longer than the corresponding ones in **1**. Each mononuclear unit also deviates significantly from planarity. In comparison with compound **1**, the most interesting feature of **3** is the formation of two carbon–carbon bonds between the two methylene carbon atoms C(8) and C(9′), C(9) and C(8′), leading to the formation of an unprecedented ligand, the deprotonated 2,3,5,6-tetra(2-pyridyl)piperazine (tppz). The C(8)—C(9′) and C(9)—C(8′) distances (1.569(9) Å) are a typical C—C single bond distance. The bond angles around C(8) and C(9) are typical for a tetrahedral geometry (105.0(5)–113.0(6)°). The hydrogen atoms bonded to C(8) and C(9), located directly from the difference Fourier map, are *trans* to the hydrogen atoms on C(8′) and C(9′). The unusual 2,3,5,6-tetra(2-pyridyl)piperazyl ligand could be considered as the consequence of two C—C bond couplings and the elimination of two H_2 molecules between two di(2-pyridylmethyl)amido ligands. Such a C—C coupling reaction is rare. It is conceivable that compound **1** is the direct precursor of compound **3** and converted to **3** through the elimination of two hydrogen molecules. Unfortunately, we have not been able to establish the link between compound **3** and compound **1**. The details of the formation mechanism of **3** have not yet been understood. The free tppz ligand was obtained by hydrolyzing compound **3**.

The presence of the inversion center in the crystal structure of **3** gives the molecule of **3** an approximate C_{2h} symmetry. All the methine protons and the methine carbon atoms are therefore equivalent. Hence, only one proton or carbon resonance due to the methine groups should be observed in the ^1H NMR spectrum or the ^{13}C NMR spectrum of **3**. The ^{13}C NMR spectrum of **3** indeed showed that there is only one type of methine carbon atom. Interestingly, however, two doublet proton resonances of the methine groups with a 2.7 Hz coupling constant

were observed in the ^{1}H NMR spectrum of **3**, indicative of the presence of two different methine protons. Variable temperature ^{1}H NMR spectra recorded at 298–215 K did not reveal any dynamic behavior. One possible explanation for the NMR spectra of **3** is that instead of the trigonal planar geometry, the amido nitrogen atom has a pyramidal geometry in solution. The two lone pairs from the two amido atoms can be either *trans* or *cis* to each other (Fig. 7). In the case of a *trans* geometry, all methine protons are equivalent (**A**). In the case of a *cis* geometry, however, there are two different types of methine protons, one being *cis* to the lone pairs and the other being *trans* to the lone pairs (**B**). The ^{1}H NMR spectrum of **3** is consistent with the structure **B**. We therefore propose that compound **3** has the structure **B** in solution.

Some $\pi - \pi$ interactions appear to be evident as shown by the lattice packing diagram of **3**. The shortest atomic distance between the pyridyl rings is 3.58(1) Å between C(6) and C(7′) (Fig. 8).

The free ligand, di(2-pyridylmethyl)amine, is not luminescent. Compounds **1** and **2**, however, are luminescent at 23°C when irradiated by UV light. The complexation of the alkylaluminum to the ligand clearly plays an important role in promoting the luminescence of the ligand. Efforts are being taken by our group to investigate the luminescent properties of **1** and **2** and the formation mechanism of compound **3**.

The synthesis, and molecular and crystal structure of diphenyl(2-oxidonaphthylmethyliminoacetato)tin(IV)

Frank E. Smith, Lian Ee Khoo, Ngoh Khang Goh, Rosemary C. Hynes, and George Eng

Abstract: The new diorganotin complex ($(C_6H_5)_2Sn(OC_{10}H_6CH{=}NCH_2COO)$) was prepared and characterized by ^1H NMR, IR, elemental analysis, and a single crystal X-ray diffraction study. The crystals are monoclinic, space group $P2_1/a$ with a = 16.9167(9) Å, b = 19.1276(16) Å, c = 26.538(2) Å, β = 100.534(6)°, V = 8442.5(11) Å^3, Z = 16, and D_{calc} = 1.574 Mg m^{-3}. The final discrepancy factors are R_F = 0.030, and R_W = 0.021 for 6524 significant reflections. The tin atom has a distorted trigonal bipyramidal coordination, with no short intermolecular contacts. The two axial Sn—O bonds of 2.12 Å and 2.09 Å and the equatorial Sn—N bond of 2.14 Å are among the shortest found in related complexes.

Key words: diorganotin(IV), bicycloazastannoxide, trigonal bipyramidal, antitumour.

Résumé : On a préparé le nouveau complexe diorganoétain ($(C_6H_5)_2Sn(OC_{10}H_6CH{=}NCH_2COO)$) et l'on l'a caractérisé par IR, RMN du ^1H, analyse élémentaire et diffraction des rayons X sur un cristal unique. Les cristaux sont monocliniques, groupe d'espace $P2_1/a$ avec a = 16,9167(9), b = 19,1276(16) et c = 26,538(2) Å, β = 100,534(6)°, V = 8442,5(11) Å^3, Z = 16. D_{calc} = 1,574 Mg m^{-3}, R_F = 0,030 et R_W = 0,021 pour 6524 réflexions significatives. L'atome d'étain adopte une coordination bipyramidale trigonale déformée et ne comporte pas de contacts intermoléculaires courts. Les longueurs des deux liaisons Sn—O (2,12 et 2,09 Å) et de la liaison équatoriale (2,14 Å) sont parmi les plus courtes observées dans des complexes apparantés.

Mots clés : diorganoétain(IV), bicycloazastannoxyde, bipyramidal trigonal, antitumoral.

Introduction

The chemotherapeutic properties, especially antitumour activities, of organotins continue to be the focus of many reports (1–5). A variety of organotin complexes structurally related to cis-platin and its derivatives (6, 7) have been investigated for anti-tumour properties (3–5, 8–10). In an encouraging number of instances, the results show the organotins to be more effective than cis-platin or carboplatin (3). Studies of structure–activity relationships have shown that the factors influencing activity may be very subtle differences in bond lengths or bond angles, reinforcing the value of structural investigations in this field (10–13). Recent reports of the activity of certain diorganotin derivatives of pyridine 2,6-dicarboxylic acid and some related compounds (14, 15) against the P388 lymphocytic leukemia tumour, both in vitro and in vivo, led us to report the synthesis and characterization of a series of diorganotin iminodiacetates (16) and diorganotin(IV)-N-arylidene-α-amino acid complexes (17). In line with these developments, we now report the synthesis and characterization of diphenyl(2-oxidonaphthylmethyliminoacetato)tin(IV), including the results of a full X-ray structural analysis. The structure of the ligand (*N*-2-hydroxynaphthalideneglycine) before deprotonation is shown in Fig. 1.

A full X-ray structural analysis of the diphenyltin complex of the deprotonated ligand has been carried out and the results are reported along with a variety of spectroscopic data.

other chemicals were purchased from the Aldrich Chemical Company. All were used without further purification.

Microanalyses

The carbon, hydrogen, and nitrogen microanalyses were carried out on a Control Equipment Corporation 240XA elemental analyser at the School of Chemical Sciences, Universiti Sains Malaysia, Penang, Malaysia.

NMR spectra

The ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ on a Bruker AC-P 300MHz spectrometer. ^1H NMR data, δ (ppm): 9.18 (^3J(Sn-N=CH) = 64.93 c/s, -CH=N-); 4.49 (^3J(Sn-N-CH_2) = 24.23 c/s, -N-CH_2-), 7.0–8.1 (Ar protons). ^{13}C NMR data, δ (ppm): 166.62 (-CH=N-), 57.80, 172.74 (-N-CH_2-); 171.03, 140.32, 137.36, 136.77, 136.39, 136.02, 133.70, 130.70, 129.64, 129.08, 129.05, 127.28, 124.58, 124.11, 110.40, 108.47 (aromatic C).

IR spectra

The IR spectra were obtained on a Perkin Elmer FTIR 1725 instrument with the samples as KBr discs. ν(O=C-O)$_{asym}$, 1680 cm^{-1}; ν(C=N), 1600 cm^{-1}; ν(O=C-O)$_{sym}$, 1325 cm^{-1}.

Preparation of ligand

A mixture of free (*dl*) glycine (0.1 mol) and 2-hydroxy-1-naphthaldehyde (0.15 mol) in 300 mL of absolute ethanol and 30 mL of methanol was stirred overnight before refluxing for 3–4 h. After cooling in the refrigerator, a crystalline precipitate formed, which was filtered, washed with petroleum ether (60–80°C), dried, and recrystallized from methanol to give the pure product in 50–60% yield.

Analytical data for *N*-2-hydroxynaphthalideneglycine mp 206–208°C (dec.). Anal. calcd. for $C_{13}H_{11}NO_3$: C 68.10, H 4.85, N 6.11; found: C 68.34, H 4.87, N 6.24.

Preparation of diphenyl(2-oxidonaphthylmethyliminoacetato)tin(IV)

Triethylamine (2 cm^3) was added to a stirred solution of *N*-2-hydroxynaphthalideneglycine (10 mmol) in absolute ethanol (25 cm^3). After the dropwise addition of a solution of diphenyltin dichloride (10 mmol) in absolute ethanol (10 cm^3), the mixture was stirred and heated for 2 h on a water bath. Once the resulting mixture was left to stand, the product crystallized, was filtered, dried, and then recrystallized from ethanol. Yield 75%, mp 198–200°C. Anal. calcd. for $C_{25}H_{19}NO_3Sn$: C 60.03, H 3.85, N 2.80; found: C 59.83, H 3.85, N 2.08.

X-ray data collection, structure solution and refinement

The crystallographic data are summarized in Table 1. The intensity data were collected at 295 K on a Nonius diffractometer run by the NRCCAD diffractometer control program (18), using the θ/2θ scan mode and profile analysis (19); 9115 reflections were measured, of which 8640 were unique. Of these, 6524 had $I_{net} > 2.5\sigma(I_{net})$. The h, k, and l ranges were −16 to 16, 0 to 18, and 0 to 26, respectively. The minimum and maximum transmission factors were 0.487 and 0.692. Absorption corrections were made from 4 ψ scans. The structure was solved by direct methods, followed by difference Fouriers. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions. Secondary extinction was refined as in Larson (20) as 0.8564(31). The refined parameter is the average length of a mosaic block in μm. The final least-squares cycle was calculated with 196 atoms, 1082 parameters, and 6524 out of 8640 reflections. Weights based on counting statistics were used. Final residuals are $R_F = 0.030$, $R_W = 0.021$ for data with $I_{net} > 2.5\sigma(I_{net})$, $R_F = 0.055$, $R_W = 0.025$ for all data. The goodness of fit was 1.88. Maximum shift/error was 0.023. In the last difference Fourier map, the top peak was 0.36 e/Å^3, and the deepest hole was −0.32 e/Å^3. Scattering factors were taken from the literature (21). All computation was performed using the NRCVAX system of crystal structure solving programs (22).

Results and discussion

In the presence of triethylamine, diphenyltin dichloride reacts with the tridentate ligand *N*-2-hydroxynaphthalideneglycine to give a bicycloazastannoxide. Although organotin carboxylates frequently have di- or polymeric structures resulting from intermolecular bridging by carbonyl oxygen atoms (16, 23), the results of a previous study on similar bicycloazastannoxides, including the crystal and molecular structure of $Bu_2Sn(OC_6H_4CH{=}NCH(i\text{-}Pr)COO)$, shows that these compounds have five-coordinate monomeric structures (17). The title compound shows strong carboxylate absorption bands at 1680 and 1325 cm^{-1}. The separation of 325 cm^{-1} between ν(O=C-O)$_{asym}$ and ν(O=C-O)$_{sym}$ is indicative of a unidentate bonding mode for the carboxylate moiety (24). Further evidence for the fact that the free carbonyl group on the ligand is not involved in coordination with another tin atom can

Fig. 2. Molecular structure and atom numbering scheme.

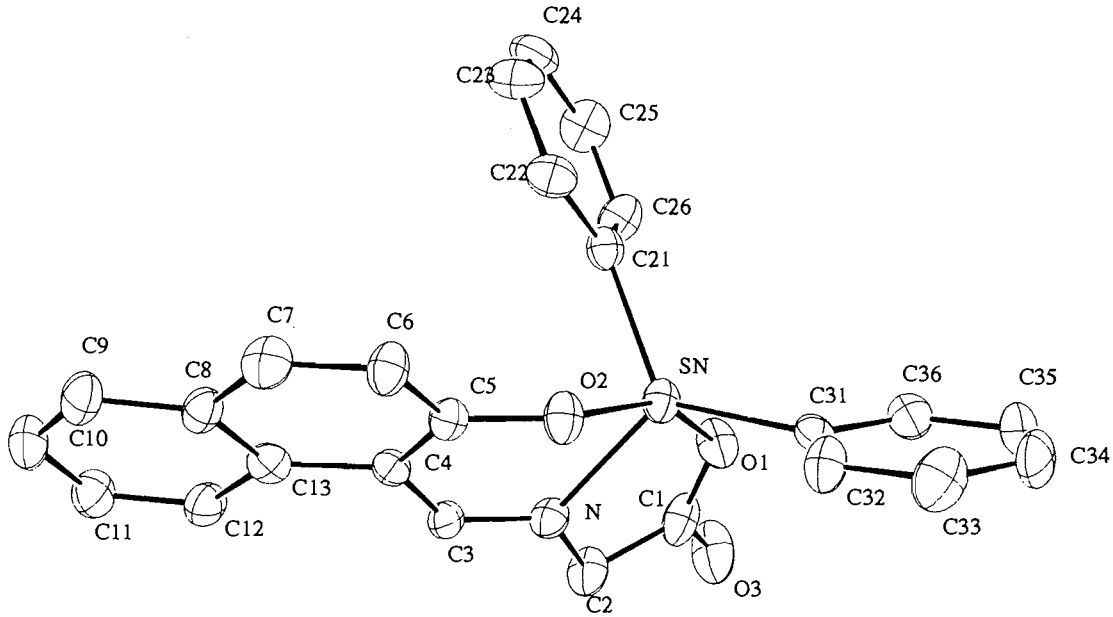

Fig. 3. Packing in the unit cell.

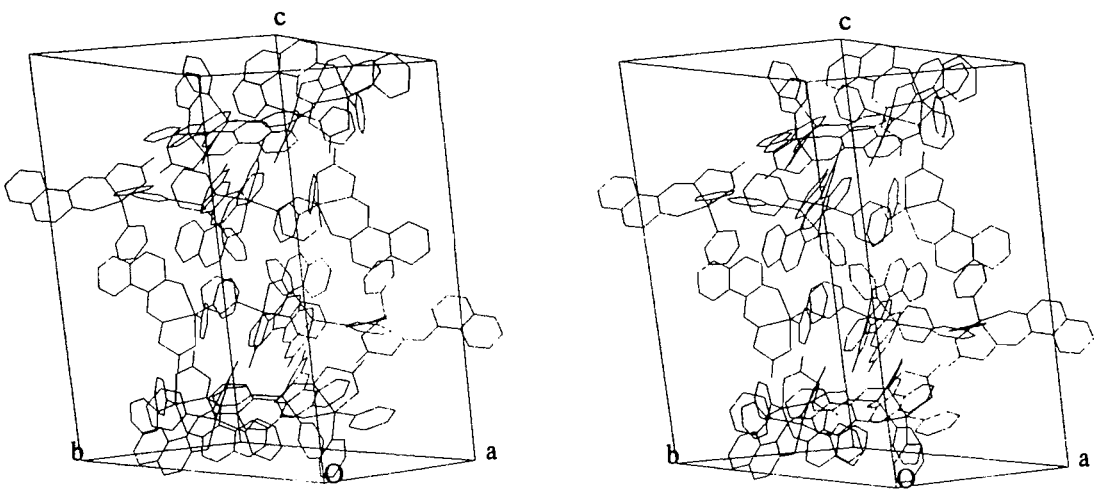

be deduced from the short C—O distance of 1.216(8) Å (mean value). Similar C—O bond lengths of 1.179(13) and 1.213(16) Å have been reported for the corresponding nonbridging carbonyl groups in the compounds $Ph_3SnCl{:}2HOC_6H_4CH{=}NCH_2CO_2Et$ (25) and $Bu_2Sn(OC_6H_4CH{=}NCH(i\text{-}Pr)COO)$, respectively (17). The determination of ^3J(Sn-N=CH) and ^3J(Sn-N-CH_2) coupling constants in the proton NMR spectrum of the complex at 64.93 and 24.23 c/s, respectively, is strongly suggestive of the presence of an intramolecular Sn—N bond (17, 26, 27). An ORTEP (28) plot of the organotin complex, including the atom-numbering scheme, is given in Fig. 2. The unit cell was found to be very large, containing 16 molecules, with 4 molecules in the asymmetric unit. In view of the unusually large size of the unit cell, the structure was checked for missing symmetry using the program MISSYM (29). No additional symmetry was identified. By doubling the tolerances to 0.5 Å displacement for axes and planes and 0.9 Å for inversion centres and translational symmetry, a "pseudo" glide plane (1/2, 0.528, 0), for the tin atoms only, could be located, but even this failed once oxygen and nitrogen atoms were included. The presence of four crystallographically unique molecules per asymmetric unit was therefore verified. A stereo pair showing the packing arrangement of the molecules in the unit cell is shown in Fig. 3. The final fractional coordinates of non-hydrogen atoms with equivalent isotropic thermal parameters are listed in Table 2, while selected bond lengths and bond angles are in Table 3. The bond lengths and angles for the title complex are reported as mean values taken over the four molecules in the asymmetric unit. A complete listing of the bond lengths and angles for each of the molecules in the asymmetric unit, calculated hydrogen atom parameters, and

[a]The means are taken from the values found in the four molecules in the asymmetric unit.

anisotropic thermal parameters have been deposited as Tables T-1, T-2, S-2, and S-3, respectively.[2]

The ligand behaves as a tridentate chelating agent via the phenolic oxygen, the imino nitrogen, and a carboxylate oxygen. The two phenyl groups and the imino nitrogen take up the equatorial positions and the two oxygens the axial sites in a distorted trigonal bipyramidal arrangement around the tin. The tin atom lies in the ligand plane and forms a five-membered and a six-membered chelate ring with the ligand. The closest Sn—O distance between the complexes is 5.3982(8) Å between Sn(b) and O3(d), thus there are no close contacts between the complex entities, and no intermolecular tin–oxygen bridging.

The structure of the title complex is very similar to that reported for $Bu_2Sn(OC_6H_4CH{=}NCH(i\text{-}Pr)COO)$ (17). Lists of the corresponding bond lengths and angles for the two complexes are given in Table 3. The two axial Sn—O bonds of 2.124(4) and 2.092(4) Å and the equatorial Sn—N bond of 2.142(5) Å appear to be the shortest ever reported in complexes of this type. This compound, and a range of similar ones, will be tested for their activities against human tumour cell lines — MCF-7 (a mammary tumour) and WiDr (a colon carcinoma). The results of these tests, along with the structural data reported above, will enable comparison with the active compounds reported previously (3, 4, 5, 13).

[2] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of bond lengths and angles, and of hydrogen atom parameters have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

Pd(0)-catalyzed addition of $Me_3SnSnMe_3$ to α,β-alkynic aldehydes and ketones. Synthesis of (*Z*)-β-trimethylstannyl α,β-alkenic aldehydes and ketones. Preparation and synthetic uses of substituted (*Z*)-4-trimethylstannyl-1,3-butadienes

Edward Piers and Richard D. Tillyer

Abstract: Treatment (dry tetrahydrofuran, reflux) of the α,β-alkynic aldehydes **26**–**28** and ketones **29**–**36** with $Me_3SnSnMe_3$ in the presence of a catalytic amount of $(Ph_3P)_4Pd$ provides fair to excellent yields of the corresponding (*Z*)-β-trimethylstannyl α,β-alkenic aldehydes **41**–**43** and ketones **44**–**51**. The carbonyl compounds **41**–**51**, upon reaction with methylenetriphenylphosphorane under suitable conditions, are smoothly converted into the (*Z*)-4-trimethylstannyl-1,3-butadienes **61**–**71**, respectively. Treatment of the aldehyde **41** with the anion of trimethyl phosphonoacetate and the aldehyde **42** with the anion of the phosphonoacetate **73** produces excellent yields of the 5-trimethylstannyl-2,4-heptadienoates **72** and **74**, respectively. The synthetic potential of (*Z*)-4-trimethylstannyl-1,3-butadienes is illustrated by the conversion of **62** into the functionalized, stereodefined conjugated dienes **76** and **78** and by transformation of **87** into the structurally novel diene **84**. Diels–Alder reactions of **84** with tetracyanoethylene and dimethyl acetylenedicarboxylate provide the spiro[3.5]nonane derivatives **88** and **89**, respectively.

Key words: Diels–Alder cycloaddition, organocopper(I), transmetallation, alkylidenecyclobutane, (*E*)-4-lithio-1,3-butadienes, spiro[3.5]nonane.

Résumé : Le traitement des aldéhydes **26**–**28** et des cétones **29**–**36** α,β-alcyniques avec du $Me_3SnSnMe_3$ (tétrahydrofurane sec, reflux), en présence d'une quantité catalytique de $Pd(PPh_3)_4$, conduit aux aldéhydes **41**–**43** et aux cétones **44**–**51** (*Z*)-β-triméthylstannyl-α,β-alcéniques correspondantes avec des rendements allant de corrects à excellents. Par réaction avec le méthylènetriphénylphosphorane, les composés carbonylés **41**–**51** se transforment facilement en (*Z*)-4-triméthylstannylbuta-1,3-diènes, **61**–**71**, respectivement. Le traitement de l'aldéhyde **41** avec l'anion phosphonoacétate de triméthyle et de l'aldéhyde **42** avec l'anion du phosphonoacétate **73** conduit respectivement à d'excellents rendements aux 5-triméthylstannylhepta-2,4-diénoates **72** et **74**. Le potentiel de synthèse des (*Z*)-4-triméthylstannylbuta-1,3-diènes a été illustré par la conversion du composé **62** en diènes conjugués fonctionnalisé stéréodéfinis **76** et **78** et par la transformation du composé **87** en diène **84** de structure nouvelle. Les réactions de Diels–Alder du composé **84** avec le tétracyanoéthène et l'acétylènedicarboxylate de diméthyle conduisent respectivement aux dérivés spiro[3.5]nonanes **88** et **89**.

Mots clés : cycloaddition de Diels–Alder, organocuivre(I), transmétallation, alkylidènecyclobutane, (*E*)-4-lithiobuta-1,3-diènes, spiro[3.5]nonane.

Introduction

A recent report (1) from this laboratory disclosed, inter alia, that alkyl 2-alkynoates (general structure **1**), upon treatment with hexamethylditin in the presence of a catalytic amount of tetrakis(triphenylphosphine)palladium(0), are converted into the corresponding alkyl (*Z*)-2,3-bis(trimethylstannyl)-2-alkenoates **2** (eq. [1]). This process, which is generally clean and efficient, is compatible with the presence of a variety of functional groups in R[1]. It was also shown (1) that the *Z* isomers **2** are thermally unstable and, when heated to 75–95°C, rearrange smoothly to the *E* isomers **3** (eq. [2]). We report in this paper that the $(Ph_3P)_4Pd$-catalyzed addition of $Me_3SnSnMe_3$ to α,β-alkynic aldehydes and ketones of general structure **4** does not lead to the formation of the corresponding α,β-bis(trimethylstannyl) α,β-alkenic carbonyl compounds, but instead provides, directly and highly stereoselectively, (*Z*)-β-

[4]).

Results and discussion

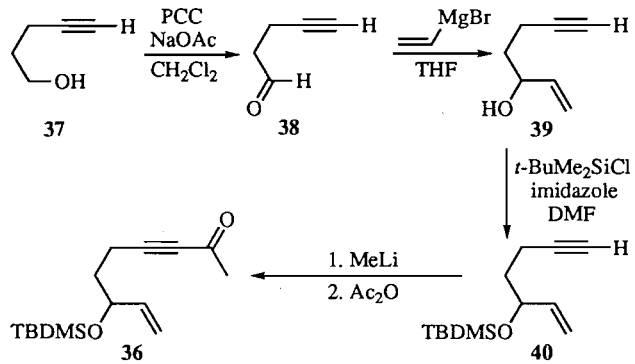
Preparation of α,β-alkynic aldehydes and ketones

Of the 11 α,β-alkynic aldehydes and ketones employed in this study, substrates **26**–**35** were prepared as summarized in Table 1. Two straightforward synthetic steps were employed in each case. For example, sequential treatment of a solution of 4-*tert*-butyldimethylsilyloxy-1-butyne (**9**) in dry tetrahydrofuran (THF) with methyllithium (1 equiv.) and paraformaldehyde (4 equiv.) gave the primary alcohol **16**, which, upon oxidation with pyridinium chlorochromate in the presence of sodium acetate (3), provided 5-*tert*-butyldimethylsilyloxy-2-pentynal (**26**) (Table 1, entry 1). In a similar fashion, the 1-alkynes **10** and **11** were transformed, via the alcohols **17** and **18**, into the α,β-alkynic aldehydes **27** and **28**, respectively (entries 2 and 3). Analogous chemical processes, using appropriate 1-alkynes as starting materials and ethanal (entries 4–8), 2-methylpropanal (entry 9), and heptanal (entry 10) as electrophilic reagents, afforded the α,β-alkynic ketones **29**–**35**.

All the products listed in Table 1 were distilled, except for the alcohol **23** (entry 8). This substance is quite volatile and, therefore, in order to avoid excessive loss of material, crude **23** was not purified but was oxidized directly to the required ketone **33**. It should also be noted that conversion of 1,6-heptadiyne (**13**) into the secondary alcohol **22** (entry 7) was accompanied by a small amount of a polar, uncharacterized side product that was assumed to be the diol resulting from reaction at both terminal alkyne functions of the starting material.

The final ketonic substrate **36** employed in this study was prepared as shown in Scheme 1. Thus, oxidation of 4-pentyn-1-ol (**37**), followed by reaction of the resultant aldehyde **38** with vinyl magnesium bromide, provided the enynol **39**. Treatment of **39** with *tert*-butyldimethylsilyl chloride under

Scheme 1.



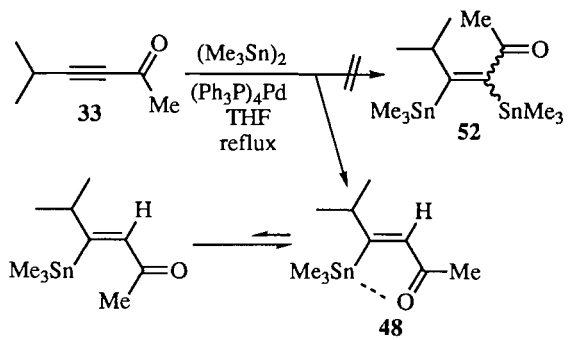
"standard" conditions (4) produced **40**, which, upon sequential treatment with methyllithium and acetic anhydride, afforded the functionalized α,β-alkynic ketone **36**.

Collectively, the substrates **26–36** contain a range of functional groups in addition to the α,β-alkynic aldehyde and ketone moieties. These include primary silyl ether, secondary allylic silyl ether, primary chloride, terminal alkyne, and terminal alkene functions. Based on the results of our earlier studies (1), it seemed highly likely that each of these functional groups would be compatible with the reaction of the substrates with hexamethylditin in the presence of a palladium(0) catalyst.

Pd(0)-catalyzed reaction of the α,β-alkynic aldehydes and ketones 26–36 with hexamethylditin

Initial experiments were carried out using the structurally simple substrate **33**. Thus, employing a procedure similar to that reported previously in connection with the Pd(0)-catalyzed reaction of hexamethylditin with α,β-alkynic esters (1), tetrakis(triphenylphosphine)palladium(0) (5 mol%) was added to a stirred solution of **33** (1 equiv.) and $Me_3SnSnMe_3$ (1 equiv.) in dry THF (argon atmosphere) and the resulting mixture was refluxed (eq. [5]). The progress of the reaction was monitored

[5]



by thin-layer chromatography (tlc), which showed that all of the starting material had been consumed after a reaction period of ~5 h. Removal of most of the solvent and purification of the crude material by flash chromatography on silica gel (5) provided a single product. Inspection of the ^1H nuclear magnetic resonance (nmr) spectrum of this material showed clearly that the product was not the initially expected (*Z*)- (or (*E*))-α,β-bis(trimethylstannyl) α,β-alkenic ketone **52** (1), but was, in fact, (*Z*)-5-methyl-4-trimethylstannyl-3-hexen-2-one (**48**) (eq. [5]). Of particular note in the ^1H nmr spectrum of **48** is the presence of only one 9-proton signal (δ 0.09, $^2J_{Sn-H}$ = 54 Hz) due to the Me_3Sn group and the appearance of a 1-proton doublet (δ 6.77, J = 1.5 Hz, $^3J_{Sn-H}$ = 127 Hz[2]) derived from the alkenic proton at C-3. The magnitude of $^3J_{Sn-H}$ associated with the C-3 proton is characteristic of coupling between tin and a proton that are *trans* to one another on a carbon–carbon double bond (6). This *trans* relationship in product **48** was confirmed by a nuclear Overhauser enhancement (nOe) difference experiment in which irradiation at δ 6.77 caused an increase in the intensity of each of the signals at δ 2.75 (-C*H*Me_2), 1.03 (-CH*Me_2*), and 2.20 (C(O)Me). The enhancement of the methyl resonance of the acetyl group indicates that this substance exists largely in the conformation shown in formula **48**. Presumably, this arrangement is stabilized by coordination of the carbonyl oxygen with the tin atom (see ref. 7 and citations therein). On the other hand, the alternative (planar) conformation (see eq. [5]) would be notably destabilized by steric repulsion between the acetyl methyl group and the Me_3Sn function.

The conversion of **33** into **48** (eq. [5]) was clean and efficient (80% yield of purified product). Examination (tlc, ^1H nmr spectroscopy) of the crude material prior to purification showed that this dark oil did not contain the bis(trimethylstannane) **52**. Furthermore, the geometric isomer of the isolated product **48** could not be detected either. To demonstrate the generality of this process, each member of the structurally diverse set of α,β-alkynic aldehydes and ketones (**26–32**; **34–36**) (vide supra) was subjected to the Pd(0)-catalyzed reaction with hexamethylditin. The results of this study, including the transformation of **33** into **48**, are summarized in Table 2.

The conversion of α,β-alkynic aldehydes and ketones into the corresponding (*Z*)-β-trimethylstannyl α,β-alkenic carbonyl compounds does indeed turn out to be a general reaction. As shown by the data given in Table 2, the starting materials **26-36** are transformed into the products in fair to excellent yields. In each of the summarized conversions, the product was obtained as a single geometric isomer. In the ^1H nmr spectrum of each of the products, the resonance due to the olefinic proton exhibited a $^3J_{Sn-H}$ value consistent with that expected for the *Z* isomer (trans relationship between the trimethylstannyl group and the olefinic hydrogen) (6).

The reactions summarized in Table 2 were carried out in refluxing dry THF, with an initial substrate concentration between 0.3 and 0.6 molar. In each case, 0.05 equiv. of the palladium(0) catalyst ($(Ph_3P)_4Pd$) was employed. Under these conditions, the reactions were generally complete within reasonable reaction times. The products were conveniently purified by flash chromatography (silica gel) (5) of the crude oils derived by removal of most of the solvent (reduced pressure) from the reaction mixtures.

The reactions summarized in entries 7 and 10 of Table 2 require special mention. Reaction of the keto diyne **32** with $Me_3SnSnMe_3$ in the presence of $(Ph_3P)_4Pd$ provided in good yield (69%) (*Z*)-4-trimethylstannyl-3-nonen-8-yn-2-one (**47**) (eq. [6]). The fact that the terminal alkyne function of **32** does not interfere with the "normal" reaction of the alkynic ketone moiety is particularly noteworthy, since it is known (8) that the elements of $Me_3SnSnMe_3$ can be added to 1-alkynes

[2] This value represents the average of the (very similar) $^{117}Sn-H$ and $^{119}Sn-H$ coupling constants.

Table 2. Conversion of α,β-alkynic aldehydes and ketones **26–36** into (*Z*)-β-trimethylstannyl α,β-alkenic aldehydes and ketones **41–51**.

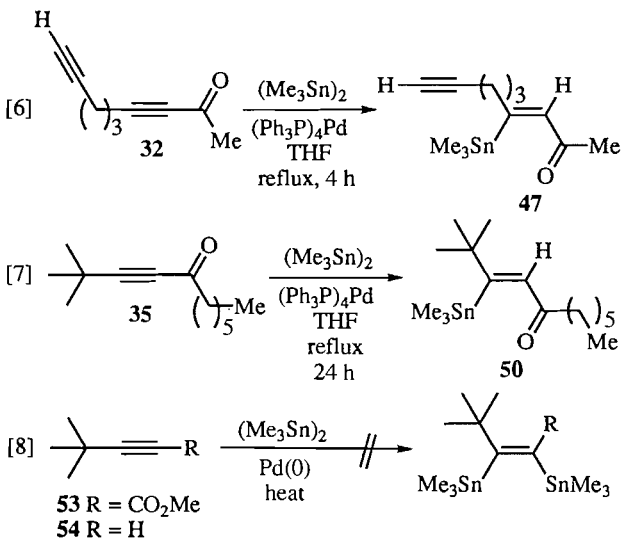
under conditions similar to those employed for the conversion of **32** into **47** (eq. [6]). The chemoselectivity displayed in the **32** → **47** transformation shows clearly that Pd(0)-catalyzed reactions of terminal alkynes with $Me_3SnSnMe_3$ are appreciably slower than those involving α,β-alkynic aldehydes and ketones.

The reaction involving substrate **35** was found to be sluggish (Table 2, entry 10, eq. [7]). Thus, even after a reaction



time of 24 h, analyses (tlc, gas–liquid chromatography (glc)) of aliquots of the reaction mixture showed the presence of the starting material **35**, along with $Me_3SnSnMe_3$. Furthermore, monitoring of the reaction mixture by tlc indicated that, as reaction times were increased, a number of minor side products were produced. Work-up and product isolation after a reaction time of 24 h produced product **50** in 48% yield (eq. [7]). The fact that the transformation of **35** into **50** occurred at all is noteworthy, since it has been shown that neither the alkynic ester **53**[3] nor the 1-alkyne **54** (8) react with $Me_3SnSnMe_3$ in the presence of a Pd(0) catalyst, even after prolonged heating of the reaction mixtures (eq. [8]).

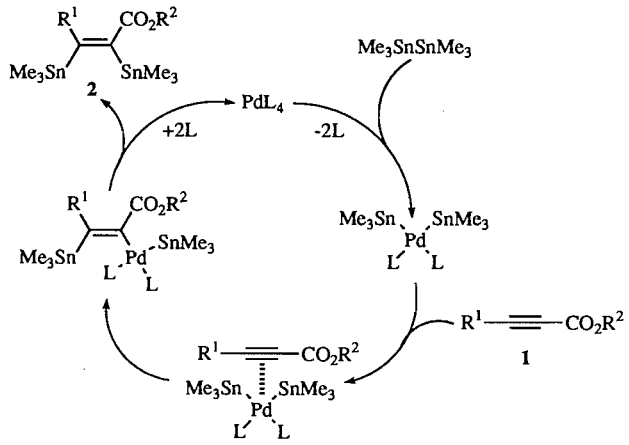
Mechanistic considerations

The Pd(0)-catalyzed addition of $Me_3SnSnMe_3$ to α,β-alkynic esters, as summarized in eq. [1], has been proposed to proceed via the catalytic cycle shown in Scheme 2 (1). Furthermore, the thermal rearrangement of the resultant products **2** into the corresponding geometric isomers **3** (eq. [2]) has been rationalized as shown in eq. [9] (1). Thus, according to this proposal, thermolysis of **2** results in (reversible) migration of the α-Me_3Sn group from carbon to the ester carbonyl oxygen to produce the trimethylstannyl allenoate intermediate **55**. A second migration of the Me_3Sn group back to the α carbon, but to the side of the intermediate opposite the β-Me_3Sn function, would provide the *E* isomer **3**. Of the three compounds shown in eq. [9], it is apparent that both **2** and **3** are more stable than the allenoate **55**. However, presumably due primarily to steric repulsion between the two Me_3Sn groups in the *Z* isomer **2**, the equilibrium between **2** and **3** overwhelmingly favors the latter isomer.

Presumably, the Pd(0)-catalyzed reaction of α,β-alkynic

[3] Unpublished work carried out in these laboratories by R.T. Skerlj.

Scheme 2.



aldehydes and ketones (general formula **4**) with $Me_3SnSnMe_3$ proceeds via a catalytic cycle analogous to that shown in Scheme 2 (see eq. [10]). It seems reasonable to conclude that

[9] 
[10] 
the initial products produced from these processes are the (*Z*)-2,3-bis(trimethylstannyl) α,β-alkenic carbonyl compounds of general structure **56**. To account for the fact that the isolated products are the mono(trimethylstannyl) substances **5**, we propose that **56** and the geometric isomers **58** are unstable with respect to the allenoates **57** (eq. [10]). Thus, in contrast to the ester series, it appears that the first-formed products **56** readily isomerize to the allenoates **57** and that, upon work-up, the latter species are protonated from the side opposite the β-Me_3Sn group to provide the observed products of general structure **5**.

The rationale presented above is supported to some degree by work published by Tsuda et al. (9). These workers reported that the structures of intermediates derived from the reaction of diisobutylaluminum hydride with α,β-alkynic carbonyl compounds are dependent on the nature of the carbonyl group in the substrate. Thus, for example, treatment of methyl propynoate with i-Bu_2AlH in hexamethylphosphoramide (HMPA) produces the alkenylalane **59** (eq. [11]), while an identical reaction involving 1-hexyn-3-one as the substrate affords the diisobutylalanyl allenoate **60** (eq. [12]). The similarities between these results and those derived from our studies (vide supra) are striking.

[11] 
[12] 
Conversion of the (*Z*)-β-trimethylstannyl α,β-alkenic aldehydes 41–43 and ketones 44–51 into the substituted (*Z*)-4-trimethylstannyl-1,3-butadienes and related compounds

Substituted (*Z*)-4-trimethylstannyl-1,3-butadienes of general structure **6**, along with reagents and synthetic intermediates derived therefrom, are, potentially, valuable substances for organic synthesis. However, prior to the work described herein, a convenient method for preparing **6** had not been reported in the chemical literature and, consequently, the synthetic utility of these materials has not been investigated systematically. The work described above had resulted in the development of a concise, efficient, and experimentally straightforward method for preparing substituted (*Z*)-β-trimethylstannyl α,β-alkenic aldehydes and ketones of general structure **5** (Tables 1 and 2). Obviously, these substances should serve as suitable substrates for the synthesis of the corresponding dienes **6**.

Reaction of the aldehyde **41** with methylenetriphenylphosphorane (prepared from BuLi and $[Ph_3PMe]Br$) in dry THF at room temperature provided, cleanly and efficiently, the trimethylstannyl diene **61** (Table 3, entry 1). In a similar fashion, the aldehydes **42** and **43** were transformed into the dienes **62** and **63**, respectively, in excellent yields (entries 2 and 3).

The (*Z*)-β-trimethylstannyl α,β-alkenic ketones of general structure **5** (R^2 = alkyl) could also be converted into the corresponding dienes **6** using the procedure described above, but, in these cases, complete conversion of the starting materials into products was not complete even after reaction times of several hours at room temperature. Furthermore, long reaction times created "dirty" reaction mixtures and the isolated yields of the desired trimethylstannyl dienes were generally unsatisfactory. In fact, of the ketones subjected to these conditions, only **48** was converted efficiently into the corresponding diene **68** (entry 8), although the reaction time was 10 times that required for the aldehydes **41–43**.

It seems likely that the sluggish nature of the conversion of the ketones **5** into the dienes **6** using $Ph_3P{=}CH_2$ in THF is due to a competition between the required Wittig process and an enolate-forming reaction resulting from the reagent acting as a base rather than a nucleophile. It has been reported (10) that reaction of enolizable ketones with $Ph_3P{=}CH_2$ (prepared from $[Ph_3PMe]Br$ and $NaOC(Et)Me_2$) in benzene provides the corresponding alkenes in good yields. Use of this protocol in

Table 3. Preparation of substituted (*Z*)-4-trimethylstannyl-1,3-butadienes **61–71**.

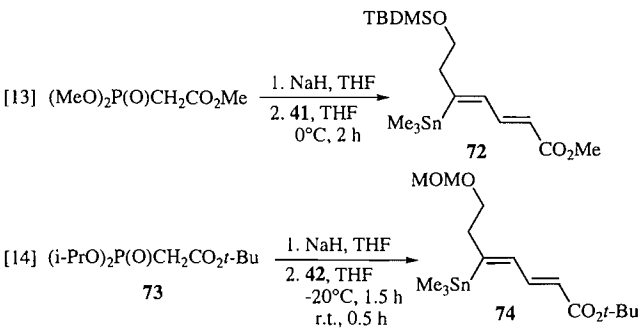
[c]TBDMS = *tert*-butyldimethylsilyl.
[d]MOM = methoxymethyl.

the present work proved to be satisfactory. As can be seen from a perusal of Table 3, subjection of the ketones **44–47** and **49–51** to these reaction conditions provided good to excellent yields of the corresponding dienes (entries 4–7, 9–11).

The aldehydes **41** and **42** also react smoothly with Wittig–Horner reagents. For example, treatment of **41** with the anion of trimethyl phosphonoacetate in dry THF at 0°C afforded the 5-trimethylstannyl-2,4-heptadienoate **72** in 92% yield (eq. [13]). Similarly, reaction of **42** with the reagent derived from treatment of the phosphonate **73** with NaH in dry THF gave the *tert*-butyl ester **74** (91%, eq. [14]).

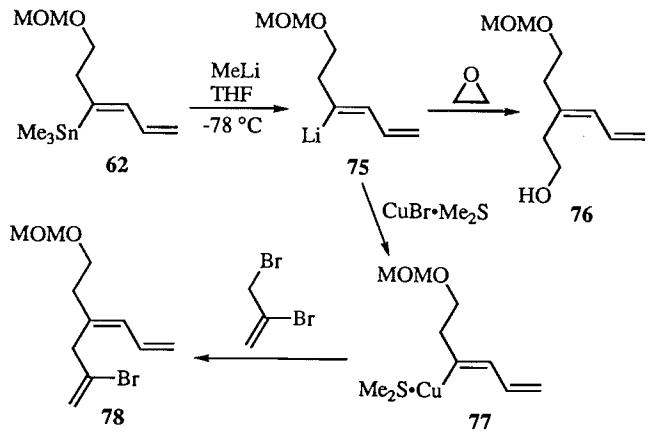


All of the Wittig (**61–71**) and Wittig–Horner (**72**, **74**) products prepared as described above exhibited spectral properties in full accord with the assigned structures. Details are given in the experimental section.

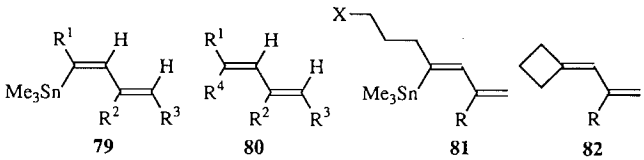
Synthetic uses of (*Z*)-4-trimethylstannyl-1,3-butadienes

We end this discussion with a description of a brief preliminary study on the synthetic utility of the substituted (*Z*)-4-trimethylstannyl-1,3-butadienes. It is evident that these substances should be excellent precursors of organometallic reagents derived by initial transmetallation of the alkenyl Me_3Sn function. Indeed, treatment of (*Z*)-6-methoxymethoxy-4-trimethylstannyl-1,3-hexadiene (**62**) with MeLi (1.1 equiv.) in dry THF at −78°C, followed by addition of ethylene oxide to the resultant solution of the lithio diene reagent **75**, afforded the functionalized diene **76** in 71% yield (Scheme 3). On the other hand, treatment of the lithio diene **75** with 1 equiv. of copper(I) bromide – dimethyl sulfide complex (11) provided the organocopper(I) reagent **77**, which, upon reaction with 2,3-dibromopropene, gave the substituted (*Z*)-1,3,6-hep-

Scheme 3.



tatriene **78** (83%). Clearly, **62** and related substances of general structure **79** (Table 3 and eqs. [13] and [14]) should serve as suitable precursors for the synthesis of a wide variety of stereochemically defined dienes of general structure **80**.



79 **80** **81** **82**

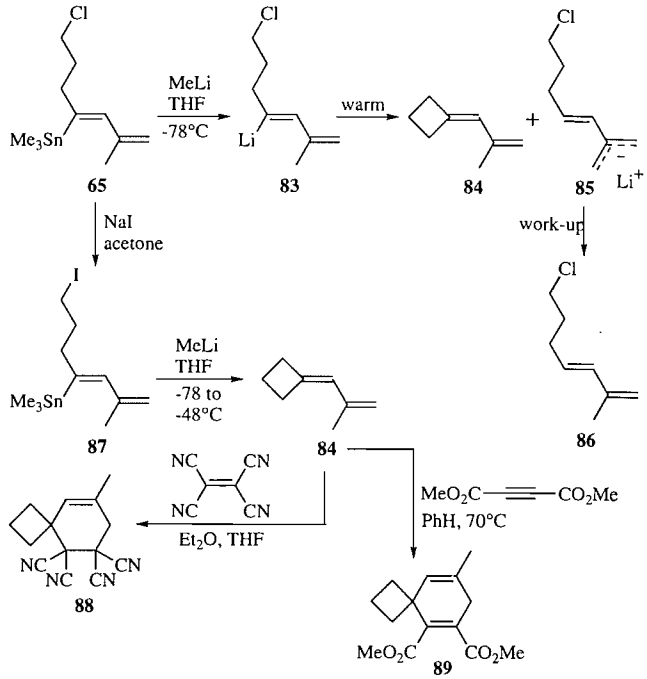
The possibility of employing functionalized (*Z*)-4-trimethylstannyl-1,3-butadienes of general structure **81** (X = leaving group) as synthetic precursors of substituted dienes possessing the novel general structure **82** was also investigated briefly (see Scheme 4). Treatment of (*Z*)-7-chloro-2-methyl-4-trimethylstannyl-1,3-heptadiene (**65**) with MeLi in dry THF at −78°C, followed by warming of the reaction mixture to −48°C, did not lead to a clean reaction. Analyses (glc) of aliquots of the reaction mixture showed the presence of two major products that, on the basis of ^{1}H nmr spectroscopy, appeared to be the desired diene **84** and the noncyclized material **86** (Scheme 4). The ratio of these two products varied somewhat, depending on the reaction conditions, but the most favorable result produced **84** and **86** in a ratio of about 6:1.

It seems reasonable to propose that the mixture of **84** and **86** is produced via a competition between two processes, one involving ring closure of the intermediate **83** (displacement of chloride ion to provide **84**) and the other involving internal proton transfer from the vinyl methyl group to the lithium-bearing carbon (five-membered cyclic transition state) to give the substituted allyllithium **85**. Protonation of the latter species during work-up would produce **86**. If this proposal is correct, increasing the rate of the ring closure reaction without appreciably affecting the rate of the proton transfer process would resolve the difficulty. To that end, treatment of the chloride **65** with NaI in acetone gave the corresponding iodide **87** (Scheme 4). Reaction of the latter compound with MeLi in dry THF (−78 to −48°C), followed by a suitable work-up procedure, gave cleanly a solution of the diene **84** in Et_2O–THF. No other product could be detected by gas–liquid chromatographic analyses.

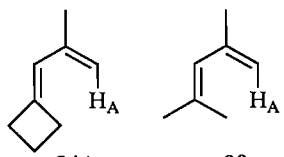
Due to the volatile nature of the diene **84**, attempts to isolate it free from solvent were not carried out. Instead, the solution of **84** derived from the work-up procedure was placed under an atmosphere of argon and was treated with tetracyanoethylene, which was added in small batches. Upon complete disappearance of the starting material (analyses by glc), the mixture was concentrated and the crude product was purified by flash chromatography. Recrystallization (petroleum ether) of the acquired solid provided, in 69% yield, the functionalized spiro[3.5]nonene **88**. In a similar fashion, when a solution of the diene **84** in benzene was treated with dimethyl acetylenedicarboxylate and the resultant mixture was heated at 70°C for 36 h (argon atmosphere, sealed tube), the substituted spiro[3.5]nonadiene **89** was obtained in 70% yield (Scheme 4).

The Diels–Alder reactivity of the diene **84** is noteworthy and can probably be attributed primarily to two factors. In the conformation required for the cycloaddition reaction (see **84A**), the steric repulsion between H_A and the cyclobutyl methylene group would be less severe than that present

Scheme 4.



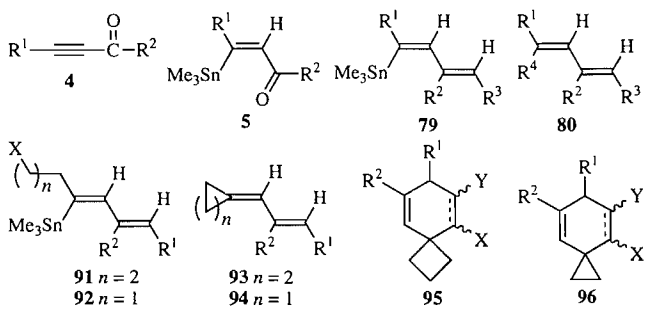
between H_A and a methyl group in, for example, an acyclic diene such as **90**. Therefore, Diels–Alder reactions of **84** would be expected to be more facile than those of acyclic analogs (e.g., **90**). Furthermore, conversion of **84** into a Diels–Alder product is accompanied by a decrease in the angle strain associated with the four-membered ring, since the conversion involves translation of one of the cyclobutyl carbons from an sp^2 to an sp^3 center. This release of strain would be "felt" by the transition state for the cycloaddition process.



84A **90**

Conclusion

The research results summarized above show that readily prepared α,β-alkynic aldehydes and ketones (general structure **4**) serve as excellent synthetic precursors of the corresponding (*Z*)-β-trimethylstannyl α,β-alkenic aldehydes and ketones (structure **5**) and that the latter substances are readily trans-



4 **5** **79** **80**

91 $n = 2$
92 $n = 1$

93 $n = 2$
94 $n = 1$

95 **96**

formed into substituted, stereochemically defined dienes of general structure **79**. The possibility of using the alkenyltrimethylstannyl function in **79** as a "handle" for introducing functionalized alkyl substituents was successfully demonstrated and, thus, dienes of general structure **80** are also available via the developed methodology.

It was also shown, by the conversion of **87** into **84** (Scheme 4), that substances of general structure **91** (X = I) should serve as effective precursors for the preparation of alkyldienecyclobutanes (see **93**). Successful Diels–Alder reactions of **93** with suitable dienophiles (see the conversions of **84** into **88** and **89**, Scheme 4) would provide spiro compounds of general structure **95**. It seems likely that similar processes involving conversions of **92** (X = Cl, Br, or I) into functionalized spiro[2.5]octanes **96**, via dienes of general structure **94**, should also be possible. Studies related to these possibilities, along with investigations into further synthetic uses of (*Z*)-β-trimethylstannyl α,β-alkenic carbonyl compounds and dienes derived therefrom, are currently underway in our laboratories.

Experimental

General information

Melting points and distillation temperatures (short-path Kugelrohr distillations) are uncorrected. Infrared (ir) spectra were recorded using potassium bromide pellets or liquid films on sodium chloride discs. Proton (^{1}H) and carbon (^{13}C) nuclear magnetic resonance (nmr) spectra were recorded using $CDCl_3$ solutions. Signal positions in ^{1}H nmr spectra were measured relative to the signals for Me_4Si (δ 0) (internal standard) or $CHCl_3$ (δ 7.25), while resonances in ^{13}C nmr spectra were measured relative to the signal for $CDCl_3$ (δ 77.0). Tin-hydrogen coupling constants (J_{Sn-H}) are given as the average of the ^{117}Sn and ^{119}Sn values. Molecular mass determination (high-resolution mass spectrometry) for substances containing Me_3Sn are based on ^{120}Sn. Flash chromatography (5) and conventional column chromatography were carried out with 230–400 and 70–230 mesh silica gel (E. Merck), respectively. Thin-layer chromatography (tlc) was accomplished with commercial aluminum-backed plates (E. Merck, Type 5554). Gas–liquid chromatography (glc) was performed on instruments equipped with flame ionization detectors and 25 m × 0.21 mm fused silica columns coated with cross-linked SE-54. Commercial $(Me_3Sn)_2$ (Organometallics Inc.) was stored under an inert atmosphere (glove box) and was generally distilled (water aspirator pressure) just prior to use, while commercial $(Ph_3P)_4Pd$ was used without further purification. Aqueous NH_4Cl–NH_4OH (pH 8) was prepared by the addition of ~50 mL of aqueous ammonia (58%) to ~950 mL of saturated aqueous NH_4Cl.

Note: Unless otherwise stated, all reactions were carried out under an atmosphere of dry argon in flamed-dried glassware.

Note: All compounds for which high-resolution mass measurements are given exhibited clean ^{1}H nmr spectra and showed essentially one spot on tlc analyses.

General procedure 1. Preparation of the propargylic alcohols 16–25

To a cold (−78°C), stirred solution of the terminal alkyne (1 equiv.) in dry THF (~3–6 mL per mmol of substrate) was added a solution of MeLi (1 equiv.) in Et_2O. The mixture was stirred at −78°C for 10 min and at −20°C for 1 h. For the preparation of the primary alcohols **16–18**, solid paraformaldehyde (4 equiv.) was added and the mixture was allowed to warm to room temperature. On the other hand, for the synthesis of each of the secondary alcohols **19–25**, the solution of the lithium acetylide was recooled to −78°C prior to addition of the appropriate aldehyde and, after the mixture had been stirred at −78°C for 10 min, it was allowed to warm to room temperature. After each reaction mixture had been stirred for 30 min at room temperature, saturated aqueous $NaHCO_3$ and Et_2O were added. The phases were separated and the aqueous phase was extracted with Et_2O. The combined organic extracts were dried ($MgSO_4$) and concentrated. Each of the crude products, except substance **23** (see Table 1), was purified by flash chromatography, followed by distillation.

The following compounds were prepared via this general procedure.

5-tert-*Butyldimethylsilyloxy-2-pentyn-1-ol (**16**)*

Flash chromatography (130 g of silica gel, 7:3 petroleum ether – Et_2O) of the crude product derived from the terminal alkyne **9** (12) (2.8 g, 15 mmol) and paraformaldehyde (1.8 g, 4 equiv.), followed by distillation (75–80°C/0.5 Torr; 1 Torr = 133.3 Pa) of the acquired material, gave 2.4 g (74%) of the alcohol **16**, a colorless oil that displayed ir (neat): 3394, 2227, 1473, 1109 cm^{-1}; ^{1}H nmr (300 MHz) δ: 0.06 (s, 6H), 0.89 (s, 9H), 1.80–1.95 (br m, 1H), 2.43 (tt, 2H, *J* = 7, 2 Hz), 3.72 (t, 2H, *J* = 7 Hz), 4.24 (br signal, 2H); on addition of D_2O, the signal at δ 1.80–1.95 disappeared and the signal at δ 4.24 sharpened to a t (*J* = 2 Hz). Exact Mass calcd. for $C_7H_{13}O_2Si$ (M^+ − *t*-Bu): 157.0685; found: 157.0679.

*5-Methoxymethoxy-2-pentyn-1-ol (**17**)*

Purification (flash chromatography, 280 g of silica gel, 35:65 petroleum ether – Et_2O; distillation, 110–120°C/0.5 Torr) of the crude product obtained from the 1-alkyne **10** (8.5 g, 74 mmol) and paraformaldehyde (8.9 g, 4 equiv.) provided 8.6 g (80%) of the alcohol **17**, a colorless oil that exhibited ir (neat): 3424, 2227, 1151, 1111, 1029 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.75–0.90 (br m, 1H), 1.52 (tt, 2H, *J* = 6.5, 2 Hz), 3.38 (s, 3H), 3.65 (t, 2H, *J* = 6.5 Hz), 4.24 (dt, 2H, *J* = 6, 2 Hz), 4.64 (s, 2H); on addition of D_2O, the signal at δ 0.75–0.90 disappeared, and the signal at δ 4.24 collapsed to a br s. Exact Mass calcd. for $C_5H_7O_2$ (M^+ − C_2H_5O): 99.0446; found: 99.0446.

7-tert-*Butyldimethylsilyloxy-2-heptyn-1-ol (**18**)*

This compound was prepared from the terminal alkyne **11** (13) (2.0 g, 9.4 mmol) and paraformaldehyde (1.2 g, 4 equiv.). Flash chromatography of the crude product on silica gel (85 g, 7:3 petroleum ether – Et_2O) and distillation (100–110°C/0.5 Torr) of the derived oil gave 1.9 g (81%) of the alcohol **18**, a colorless oil that showed ir (neat): 3362, 2230, 1256, 1107, 838 cm^{-1}; ^{1}H nmr (300 MHz) δ: 0.04 (s, 6H), 0.86 (s, 9H), 1.57 (m, 4H), 1.78 (br s, 1H), 2.23 (m, 2H), 3.61 (t, 2H, *J* = 7 Hz), 4.24 (br t, 2H, *J* = 2 Hz); on addition of D_2O, the signal at δ 1.78 disappeared. Exact Mass calcd. for $C_9H_{27}O_2Si$ (M^+ − *t*-Bu): 185.0998; found: 185.0997.

6-tert-*Butyldimethylsilyloxy-3-hexyn-2-ol (**19**)*

Purification (flash chromatography, 80 g of silica gel, 7:3

petroleum ether – Et_2O; distillation, 80–90°C/0.5 Torr) of the crude product obtained from the 1-alkyne **9** (1.5 g, 8.2 mmol) and acetaldehyde (0.7 g, 2 equiv.) provided 1.7 g (92%) of the alcohol **19**, a colorless oil that displayed ir (neat): 3368, 2250, 1256, 818 cm^{-1}; ^1H nmr (300 MHz) δ: 0.04 (s, 6H), 0.86 (s, 9H), 1.39 (d, 3H, J = 8 Hz), 2.25 (br s, 1H), 2.38 (dt, 2H, J = 7, 2 Hz), 3.68 (t, 2H, J = 7 Hz), 4.49 (m, 1H); on addition of D_2O, the signal at δ 2.25 disappeared, and the signal at δ 4.49 simplified to a br q (J = 8 Hz). Exact Mass calcd. for $C_8H_{15}O_2Si$ (M^+ − t-Bu): 171.0842; found: 171.0834.

*7-Chloro-3-heptyn-2-ol (**20**)*
This substance was prepared from 5-chloro-1-pentyne (**12**) (4.0 g, 39 mmol) and acetaldehyde (3.4 g, 2 equiv.). Flash chromatography of the crude product on silca gel (150 g, 7:3 petroleum ether – Et_2O) and distillation (65–70°C/0.5 Torr) of the derived oil gave 4.9 g (85%) of the alcohol **20**, a colorless oil that showed ir (neat): 3372, 1089, 1050, 881 cm^{-1}; ^1H nmr (300 MHz) δ: 1.36 (d, 3H, J = 8 Hz), 1.80 (quintet, 2H, J = 8 Hz), 2.33 (td, 2H, J = 8, 2 Hz), 2.75 (br s, 1H), 3.59 (t, 2H, J = 8 Hz), 4.46 (m, 1H); on addition of D_2O, the signal at δ 2.75 disappeared, and the signal at δ 4.46 simplified to a br q (J = 8 Hz). Exact Mass calcd. for $C_7H_{11}{}^{35}ClO$: 146.0499; found: 146.0504.

*8-tert-Butyldimethylsilyloxy-3-octyn-2-ol (**21**)*
Flash chromatography (80 g of silica gel, 7:3 petroleum ether – Et_2O) of the crude product derived from the terminal alkyne **11** (13) (2.0 g, 9.4 mmol) and acetaldehyde (0.8 g, 2 equiv.), followed by distillation (110–120°C/0.5 Torr) of the acquired material, gave 2.2 g (90%) of the alcohol **21**, a colorless oil that displayed ir (neat): 3353, 2248, 1256 cm^{-1}; ^1H nmr (300 MHz) δ: 0.33 (s, 6H), 0.87 (s, 9H), 1.40 (d, 3H, J = 8 Hz), 1.56 (m, 4H), 1.74–1.80 (br m, 1H), 2.22 (m, 2H), 3.60 (t, 2H, J = 6 Hz), 4.50 (m, 1H); on addition of D_2O the signal at δ 1.74–1.80 disappeared and the signal at δ 4.50 simplified to a br q (J = 8 Hz). Exact Mass calcd. for $C_{10}H_{19}O_2Si$ (M^+ − t-Bu): 199.1155; found: 199.1156.

*3,8-Nonadiyn-2-ol (**22**)*
This compound was derived from 1,6-heptadiyne (**13**) (1.0 g, 11 mmol) and acetaldehyde (2.4 g, 5 equiv.). Flash chromatography of the crude product on silica gel (65 g, 65:35 petroleum ether – Et_2O) and distillation (80–85°C/0.5 Torr) of the derived material afforded 0.88 g (60%) of the alcohol **22**, a colorless oil that exhibited ir (neat): 3301, 2247, 2118, 1154, 1013, 882 cm^{-1}; ^1H nmr (400 MHz) δ: 1.41 (d, 3H, J = 6.5 Hz), 1.65–1.75 (m, 3H), 1.95 (t, 1H, J = 2.5 Hz), 2.25–2.40 (m, 4H), 4.49 (m, 1H); on addition of D_2O, the signal at δ 1.65–1.75 collapsed to a quintet (2H, J = 7 Hz), and the signal at δ 4.49 simplified to a br q (J = 6.5 Hz). Exact Mass calcd. for $C_9H_{11}O$ (M^+ − H): 135.0810; found: 135.0815.

*5-Methyl-3-hexyn-2-ol (**23**)*
This substance was derived from 3-methyl-1-butyne (**14**) (3.0 g, 44 mmol) and acetaldehyde (3.9 g, 2 equiv.). After work-up of the reaction mixture, the solution containing the product was concentrated by distillation (atmospheric pressure) through a Vigreaux column (50 × 2 cm). Distillation (80–90°C/10 Torr) of the residual material gave a crude oil (4.6 g) that consisted mainly of the alcohol **23**. This material was used immediately for the next (oxidation) reaction (vide infra).

*7-tert-Butyldimethylsilyloxy-2-methyl-4-heptyn-3-ol (**24**)*
Flash chromatography (300 g of silica gel, 7:3 petroleum ether – Et_2O) of the crude product derived from the terminal alkyne **9** (12) (8.2 g, 45 mmol) and 2-methylpropanal (4.8 g, 1.5 equiv.), followed by distillation (110–120°C/0.5 Torr) of the acquired material, gave 9.7 g (85%) of the alcohol **24**, a colorless oil that displayed ir (neat): 3368, 2218, 1256, 1113, 836, 777 cm^{-1}; ^1H nmr (400 MHz) δ: 0.06 (s, 6H), 0.89 (s, 9H), 0.96, 0.98 (d, d, 3H each, J = 6 Hz in each case), 1.70 (br d, 1H, J = 4 Hz), 1.82 (m, 1H), 2.42 (td, 2H, J = 8, 2 Hz), 3.70 (t, 2H, J = 8 Hz), 4.13 (br m, 1H); on addition of D_2O, the signal at δ 1.70 disappeared, and the signal at δ 4.13 simplified to a br d (J = 6 Hz). Exact Mass calcd. for $C_{11}H_{21}O_2Si$ (M^+ − i-Pr): 213.1311; found: 213.1318.

*2,2-Dimethyl-3-undecyn-5-ol (**25**)*
This material was synthesized from 3,3-dimethyl-1-butyne (**15**) (3.5 g, 43 mmol) and heptanal (7.3 g, 1.5 equiv.). Flash chromatography of the crude product on silica gel (250 g, 7:3 petroleum ether – Et_2O), followed by distillation (80–85°C/0.5 Torr) of the acquired liquid, gave 8.1 g (96%) of the alcohol **25**, a colorless oil that exhibited ir (neat): 3342, 2238, 1460, 1265 cm^{-1}; ^1H nmr (300 MHz) δ: 0.87 (m, 3H), 1.20 (s, 9H), 1.25–1.70 (m, 10H), 2.85 (br s, 1H), 4.33 (br t, 1H, J = 8 Hz); on addition of D_2O, the signal at δ 2.85 disappeared. Exact Mass calcd. for $C_{13}H_{24}O$: 196.1828; found: 196.1819.

General procedure 2. Oxidation of the alcohols 16–25 to the α,β-alkynic aldehydes 26–28 and ketones 29–35
A mixture of the alcohol (1 equiv.), NaOAc (0.3 equiv.), and pyridinium chlorochromate (1.5 equiv. for the alcohols **16–18**, 2.5 equiv. for the alcohols **19–25**) in dry CH_2Cl_2 (~5-10 mL per mmol of alcohol substrate) was stirred (2 h for the alcohols **16–18**, 2.5 h for the alcohols **19–25**) at room temperature. Dry Et_2O (the same volume as that used for the reaction mixture) was added and the mixture was filtered through a column of Florisil® (~30 g per g of propargylic alcohol), using Et_2O as eluant. The material remaining in the reaction vessel was rinsed (and sonicated) thoroughly with Et_2O, and the washings were also passed through the Florisil® column. The combined eluate was dried ($MgSO_4$) and concentrated. The crude product was purified by flash chromatography and (or) distillation.

The following carbonyl compounds were prepared via this general procedure.

*5-tert-Butyldimethylsilyloxy-2-pentynal (**26**)*
Flash chromatography (80 g of silica gel, 5:1 petroleum ether – Et_2O) of the crude product derived from oxidation of the alcohol **16** (2.4 g, 11 mmol), followed by distillation (75–85°C/0.5 Torr) of the acquired liquid, gave 1.7 g (72%) of the aldehyde **26**, a colorless oil that exhibited ir (neat): 2740, 2207, 1673, 1275 cm^{-1}; ^1H nmr (300 MHz) δ: 0.05 (s, 6H), 0.87 (s, 9H), 2.60 (t, 2H, J = 8 Hz), 3.77 (t, 2H, J = 8 Hz), 9.15 (s, 1H). Exact Mass calcd. for $C_7H_{11}O_2Si$ (M^+ − t-Bu): 155.0528; found: 155.0532.

*5-Methoxymethoxy-2-pentynal (**27**)*
This compound was obtained by oxidation of the alcohol **17** (3.6 g, 25 mmol). Flash chromatography of the crude product on silica gel (120 g, 4:6 petroleum ether – Et_2O), followed by distillation (90–95°C/0.5 Torr) of the derived oil, gave 1.9 g

(57%) of the aldehyde **27**, a colorless oil that displayed ir (neat): 2827, 2207, 1669, 1115, 1111, 963 cm^{-1}; ^1H nmr (400 MHz) δ: 2.72 (t, 2H, J = 7 Hz), 3.38 (s, 3H), 3.72 (t, 2H, J = 7 Hz), 4.64 (s, 2H), 9.18 (s, 1H). Exact Mass calcd. for $C_7H_9O_3$ ($M^+ - H$): 141.0551; found: 141.0546.

*7-*tert*-Butyldimethylsilyloxy-2-heptynal (**28**)*
Oxidation of the alcohol **18** (0.9 g, 3.7 mmol), followed by purification (flash chromatography, 40 g of silica gel, 5:1 petroleum ether – Et_2O; distillation, 95–100°C/0.5 Torr) of the crude product gave 0.7 g (74%) of the aldehyde **28**, a colorless oil that showed ir (neat): 2742, 2202, 1673, 838 cm^{-1}; ^1H nmr (300 MHz) δ: 0.05 (s, 6H), 0.90 (s, 9H), 1.65 (m, 4H), 2.46 (t, 2H, J = 8 Hz), 3.63 (t, 2H, J = 6 Hz), 9.18 (s, 1H). Exact Mass calcd. for $C_9H_{15}O_2Si$ ($M^+ - t$-Bu): 183.0842; found: 183.0834.

*6-*tert*-Butyldimethylsilyloxy-3-hexyn-2-one (**29**)*
This substance was derived from oxidation of the alcohol **19** (0.2 g, 0.9 mmol). Flash chromatography of the crude product on silica gel (45 g, 9:1 petroleum ether – Et_2O), followed by distillation (70–80°C/0.5 Torr) of the acquired oil furnished 0.15 g (74%) of the ketone **29**, a colorless oil that displayed ir (neat): 2214, 1680, 1113, 839 cm^{-1}; ^1H nmr (300 MHz) δ: 0.08 (s, 6H), 0.89 (s, 9H), 2.30 (s, 3H), 2.56 (t, 2H, J = 8 Hz), 3.76 (t, 2H, J = 8 Hz). Exact Mass calcd. for $C_8H_{13}O_2Si$ ($M^+ - t$-Bu): 169.0685; found: 169.0684.

*7-Chloro-3-heptyn-2-one (**30**)*
Flash chromatography (80 g of silica gel, 9:1 petroleum ether – Et_2O) of the crude product derived from the alcohol **20** (1.5 g, 10 mmol), followed by distillation (60–65°C/0.5 Torr) of the acquired liquid, gave 1.1 g (74%) of the ketone **30**, a colorless oil that showed ir (neat): 2215, 1677, 1232, 734 cm^{-1}; ^1H nmr (300 MHz) δ: 2.0 (quintet, 2H, J = 7 Hz), 2.30 (s, 3H), 2.54 (t, 2H, J = 7 Hz), 3.51 (t, 2H, J = 7 Hz). Exact Mass calcd. for $C_7H_9{}^{35}ClO$: 144.0343; found: 144.0343.

*8-*tert*-Butyldimethylsilyloxy-3-octyn-2-one (**31**)*
The crude product obtained from oxidation of the alcohol **21** (1.0 g, 3.9 mmol) was purified by flash chromatography (75 g of silica gel, 9:1 petroleum ether – Et_2O) and distillation (95–100°C/0.5 Torr). The resultant product **31** (0.76 g, 76%), a colorless oil, displayed ir (neat): 2212, 1680, 1360, 1104 cm^{-1}; ^1H nmr (300 MHz) δ: 0.04 (s, 6H), 0.88 (s, 9H), 1.62 (m, 4H), 2.30 (s, 3H), 2.38 (t, 2H, J = 7 Hz), 3.62 (t, 2H, J = 6 Hz). Exact Mass calcd. for $C_{10}H_{17}O_2Si$ ($M^+ - t$-Bu): 197.0998; found: 197.1006.

*3,8-Nonadiyn-2-one (**32**)*
This material was obtained by oxidation of the alcohol **22** (0.13 g, 1.0 mmol). Flash chromatography of the crude product on silica gel (35 g, 9:1 petroleum ether – Et_2O), followed by distillation (120–130°C/6.0 Torr) of the derived liquid, gave 0.07 g (55%) of the ketone **32**, a colorless oil that showed ir (neat): 2215, 1680, 1231 cm^{-1}; ^1H nmr (400 MHz) δ: 1.79 (quintet, 2H, J = 7 Hz), 1.98 (t, 1H, J = 2.5 Hz), 2.31 (s, 3H), 2.32 (td, 2H, J = 7, 2.5 Hz), 2.50 (t, 2H, J = 7 Hz). Exact Mass calcd. for C_9H_9O ($M^+ - H$): 133.0653; found: 133.0651.

*5-Methyl-3-hexyn-2-one (**33**)*
Oxidation of the previously prepared, crude 5-methyl-3-hexyn-2-ol (**23**) (vide supra), followed by work-up of the reaction mixture, gave a solution of the ketone **33**. Concentration of this solution by distillation (atmospheric pressure) of the solvent through a Vigreaux column (50 × 2 cm) gave an oil that, upon distillation (80–90°C/10 Torr), provided 2.7 g (57% from 3-methyl-1-butyne (**14**)) of the ketone **33**, a colorless oil that displayed ir (neat): 2208, 1679, 1228 cm^{-1}; ^1H nmr (300 MHz) δ: 1.20 (d, 6H, J = 8 Hz), 2.29 (s, 3H), 2.68 (septet, 1H, J = 8 Hz). Exact Mass calcd. for $C_7H_{10}O$: 110.0732; found: 110.0726.

*7-*tert*-Butyldimethylsilyloxy-2-methyl-4-heptyn-3-one (**34**)*
Flash chromatography (150 g of silica gel, 9:1 petroleum ether – Et_2O) of the crude product derived from the alcohol **24** (2.9 g, 11 mmol), followed by distillation (95–105°C/0.5 Torr) of the acquired liquid, gave 2.4 g (81%) of the ketone **34**, a colorless oil that showed ir (neat): 2214, 1676, 1118, 779 cm^{-1}; ^1H nmr (400 MHz) δ: 0.08 (s, 6H), 0.90 (s, 9H), 1.18 (d, 6H, J = 8 Hz), 2.58–2.68 (m, 3H), 3.80 (t, 2H, J = 6 Hz). Exact Mass calcd. for $C_{10}H_{17}O_2Si$ ($M^+ - t$-Bu): 197.0998; found: 197.1003.

*2,2-Dimethyl-3-undecyn-5-one (**35**)*
This compound was derived from oxidation of the alcohol **25** (4.0 g, 20 mmol). Flash chromatography of the crude product on silica gel (150 g, 9:1 petroleum ether – Et_2O) and distillation (75–80°C/0.5 Torr) of the acquired liquid provided 2.9 g (72%) of the ketone **35**, a colorless oil that exhibited ir (neat): 2213, 1675, 1263, 1142 cm^{-1}; ^1H nmr (300 MHz) δ: 0.87 (m, 3H), 1.28 (br s, 15H), 1.63 (m, 2H), 2.50 (t, 2H, J = 7 Hz). Exact Mass calcd. for $C_{13}H_{22}O$: 194.1672; found: 194.1680.

3-*tert*-Butyldimethylsilyloxy-1-hepten-6-yne (40)
To a stirred solution of 4-pentyn-1-ol (**37**) (3.0 g, 36 mmol) in dry CH_2Cl_2 (100 mL) was added NaOAc (0.9 g, 0.3 equiv.) and PCC (12 g, 1.5 equiv.). After the mixture had been stirred for 2 h at room temperature, dry Et_2O (~100 mL) was added and the mixture was filtered through a column of Florisil® (~100 g, elution with Et_2O). The material remaining in the reaction vessel was rinsed (and sonicated) thoroughly with Et_2O, and the washings were also passed through the Florisil® column. The combined eluate was dried ($MgSO_4$) and most of the solvent was removed by distillation (atmospheric pressure) using a Vigreaux column (50 × 2 cm). The remaining crude product **38** was dissolved in dry THF (100 mL) and the solution was cooled to −78°C. A solution of vinyl magnesium bromide (2 equiv.) in THF was added and the mixture was allowed to warm to room temperature. Saturated aqueous NH_4Cl (~50 mL) and Et_2O (50 mL) were added and the phases were separated. The aqueous phase was extracted with Et_2O and the combined organic extracts were dried ($MgSO_4$) and concentrated by distillation (atmospheric pressure) using a Vigreaux column (50 × 2 cm).

To a stirred solution of the crude oil **39** thus obtained in dry DMF (80 mL) was added imidazole (6.1 g, 2.5 equiv.) and *tert*-butyldimethylsilyl chloride (8.1 g, 1.5 equiv.). The mixture was stirred at room temperature overnight. Saturated aqueous $NaHCO_3$ (~50 mL) and Et_2O (~50 mL) were added and the aqueous phase was extracted with Et_2O. The combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. Flash chromatography of the crude product on

silica gel (180 g, 98:2 petroleum ether – Et_2O), followed by distillation (80–90°C/0.5 Torr) of the derived oil gave 2.5 g (31%) of the alkyne **40**, a colorless oil that showed ir (neat): 3314, 3081, 2121, 1254, 838 cm^{-1}; ^1H nmr (400 MHz) δ: 0.02 (s, 3H), 0.06 (s, 3H), 0.89 (s, 9H), 1.68 (m, 2H), 1.92 (t, 1H, J = 4 Hz), 2.22 (m, 2H), 4.22 (m, 1H), 5.05 (ddd, 1H, J = 10, 2, 2 Hz), 5.17 (ddd, 1H, J = 16, 2, 2 Hz), 5.88 (ddd, 1H, J = 16, 10, 6 Hz). Exact Mass calcd. for $C_{13}H_{24}OSi$: 224.1597; found: 224.1593.

7-*tert*-Butyldimethylsilyloxy-8-nonen-3-yn-2-one (36)

To a cold (−78°C), stirred solution of the 1-alkyne **40** (0.44 g, 2.0 mmol) in dry Et_2O (10 mL) was added MeLi (1 equiv.) in Et_2O. After the reaction mixture had been stirred at −78°C for 10 min and at −20°C for 1 h, it was recooled to −78°C and then was transferred slowly (over ~10 min, via cannula) into a cold (−78°C), stirred solution of Ac_2O (2 equiv.) in dry Et_2O (8 mL). After the resultant mixture had been stirred for 10 min at −78°C and 30 min at −48°C, saturated NH_4Cl–NH_4OH (pH 8, 15 mL) was added and the vigorously stirred mixture was allowed to warm to room temperature. The phases were separated and the aqueous phase was extracted with Et_2O. The combined organic extracts were washed with saturated aqueous NH_4Cl, dried ($MgSO_4$), and concentrated. Flash chromatography of the crude product on silica gel (50 g, 9:1 petroleum ether – Et_2O), followed by distillation (90–100°C/0.5 Torr) of the acquired liquid, gave 0.33 g (63%) of the ketone **36**, a colorless oil that displayed ir (neat): 3082, 2211, 1681, 1228, 838 cm^{-1}; ^1H nmr (400 MHz) δ: 0.03 (s, 3H), 0.06 (s, 3H), 0.89 (s, 9H), 1.74 (m, 2H), 2.31 (s, 3H), 2.41 (m, 2H), 4.22 (m, 1H), 5.08 (ddd, 1H, J = 10, 2, 2 Hz), 5.19 (ddd, 1H, J = 17, 2, 2 Hz), 5.77 (ddd, 1H, J = 17, 10, 6 Hz). Exact Mass calcd. for $C_{11}H_{17}O_2Si$ (M^+ − *t*-Bu): 209.0998; found: 209.0995.

General procedure 3. Pd(0)-catalyzed reaction of α,β-alkynic aldehydes 26–28 and ketones 29–36 with hexamethylditin. Preparation of compounds 41–51

To a stirred solution of the α,β-alkynic aldehyde or ketone (1 equiv.) in dry THF (for **26**, **28**, **30**, and **33–35**, ~2 mL per mmol of substrate; for **27**, **29**, **31**, **32**, and **36**, ~3 mL per mmol of substrate) (argon atmosphere) was added $(Me_3Sn)_2$ (1 equiv.) and $Pd(Ph_3)_4$ (5 mol%). The mixture was allowed to reflux for the time indicated in Table 2. In each case, the progress of the reaction was monitored by tlc. When the reaction was complete, the solvent was removed and the viscous residual oil was purified by chromatography and distillation.

The following (*Z*)-β-trimethylstannyl α,β-alkenic aldehydes and ketones were prepared via this general procedure.

*(Z)-5-*tert*-Butyldimethylsilyloxy-3-trimethylstannyl-2-pentenal (41)*

Flash chromatography (100 g of silica gel, 95:5 petroleum ether – Et_2O) of the crude product derived from the aldehyde **26** (1.5 g, 7.1 mmol), followed by distillation (110–120°C/0.5 Torr) of the acquired oil, provided 2.4 g (87%) of the aldehyde **41**, a colorless oil that displayed ir (neat): 2743, 1685, 1563, 1099, 776 cm^{-1}; ^1H nmr (300 MHz) δ: 0.04 (s, 6H), 0.26 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.86 (s, 9H), 2.69 (td, 2H, J = 6.5, 1.3 Hz, $^3J_{Sn-H}$ = 46 Hz), 3.69 (t, 2H, J = 6.5 Hz), 6.68 (dt, 1H, J = 5.5, 1.3 Hz, $^3J_{Sn-H}$ = 114 Hz), 9.56 (d, 1H, J = 5.5 Hz, $^4J_{Sn-H}$ = 5.5 Hz); in nOe difference experiments, irradiation at δ 6.68 caused enhancement of the signals at δ 2.69 and 9.59, irradiation at δ 9.59 caused enhancement of the resonance at δ 6.68, and irradiation at δ 2.69 increased the intensities of the signals at δ 6.68 and 3.69; ^{13}C nmr (75.4 MHz) δ: −7.2, −5.2, 18.4, 26.0, 43.7, 62.2, 140.3, 178.2, 192.4. Exact Mass calcd. for $C_{13}H_{27}O_2SnSi$ (M^+ − Me): 363.0802; found: 363.0806.

(Z)-5-Methoxymethoxy-3-trimethylstannyl-2-pentenal (42)

Flash chromatography (120 g of silica gel, 65:35 petroleum ether – Et_2O) and distillation (100–105°C/0.5 Torr) of the crude product obtained from the aldehyde **27** (1.9 g, 13 mmol) provided 3.1 g (76%) of the product **42**, a colorless oil that showed ir (neat): 1683, 1562, 1151, 1043, 776 cm^{-1}; ^1H nmr (400 MHz) δ: 0.25 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 2.77 (td, 2H, J = 6.5, 1.3 Hz, $^3J_{Sn-H}$ = 44 Hz), 3.61 (t, 2H, J = 6.5 Hz), 4.58 (s, 2H), 6.72 (dt, 1H, J = 5.5, 1.3 Hz, $^3J_{Sn-H}$ = 113 Hz), 9.59 (d, 1H, J = 5.5 Hz, $^4J_{Sn-H}$ = 5.5 Hz). Exact Mass calcd. for $C_9H_{17}O_3Sn$ (M^+ − Me): 293.0199; found: 293.0201.

*(Z)-7-*tert*-Butyldimethylsilyloxy-3-trimethylstannyl-2-heptenal (43)*

Purification (flash chromatography, 30 g of silica gel, 95:5 petroleum ether – Et_2O; distillation, 120–130°C/0.5 Torr) of the crude product acquired from 0.3 g (1.2 mmol) of the aldehyde **28** furnished 0.45 g (88%) of the product **43**, a colorless oil that exhibited ir (neat): 2742, 1685, 1562, 1256, 1106, 775 cm^{-1}; ^1H nmr (300 MHz) δ: 0.02 (s, 6H), 0.25 (s, 9H, $^2J_{Sn-H}$ = 55 Hz), 0.87 (s, 9H), 1.48 (m, 4H), 2.49 (br t, 2H, J = 6.5 Hz, $^3J_{Sn-H}$ = 47 Hz), 3.59 (t, 2H, J = 6 Hz), 6.62 (dt, 1H, J = 6, 1.3 Hz, $^3J_{Sn-H}$ = 115 Hz), 9.55 (d, 1H, J = 6 Hz, $^4J_{Sn-H}$ = 5.5 Hz); in nOe difference experiments, irradiation at δ 6.62 caused enhancement of the signals at δ 9.55 and 2.49, while irradiations at δ 9.55 and 2.49 caused, in each case, enhancement of the resonance at δ 6.62; ^{13}C nmr (300 MHz) δ: −7.3, −5.2, 18.4, 25.3, 26.0, 32.4, 41.0, 62.7, 138.6, 181.9, 192.6. Exact Mass calcd. for $C_{15}H_{31}O_2SiSn$ (M^+ − Me): 391.1115; found: 391.1112.

*(Z)-6-*tert*-Butyldimethylsilyloxy-4-trimethylstannyl-3-hexen-2-one (44)*

The crude product obtained from the starting material **29** (0.13 g, 0.58 mmol) was purified by flash chromatography (30 g of silica gel, 96:4 petroleum ether – Et_2O) and distillation (110–120°C/0.5 Torr) to produce 0.21 g (90%) of the ketone **44**, a colorless oil,that exhibited ir (neat): 1682, 1573, 1192, 1095, 776 cm^{-1}; ^1H nmr (300 MHz) δ: 0.00 (s, 6H), 0.10 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.84 (s, 9H), 2.19 (s, 3H), 2.63 (td, 2H, J = 6.5, 1.3 Hz, $^3J_{Sn-H}$ = 49 Hz), 3.62 (t, 2H, J = 6.5 Hz), 6.82 (br s, 1H, $^3J_{Sn-H}$ = 121 Hz); in nOe difference experiments, irradiation at δ 6.82 caused enhancement of the signals at δ 2.63 and 2.19, irradiation at δ 2.63 increased the intensity of the resonances at δ 3.62 and 6.82, and irradiation at δ 2.19 caused enhancement of the signal at δ 6.82; ^{13}C nmr (75.4 MHz) δ: −7.4, −5.3, 18.2, 25.9, 30.0, 42.5, 62.0, 136.7, 172.4, 197.3. Exact Mass calcd. for $C_{14}H_{29}O_2SiSn$ (M^+ − Me): 377.0959; found: 377.0966.

(Z)-7-Chloro-4-trimethylstannyl-3-hepten-2-one (45)

Flash chromatography (75 g of silica gel, 95:5 petroleum ether – Et_2O) of the crude product derived from 0.80 g (5.5 mmol) of

the substrate **30**, followed by distillation (100–105°C/0.5 Torr) of the acquired oil produced 1.4 g (81%) of the ketone **45**, a colorless oil that showed ir (neat): 1682, 1572, 1202, 774 cm^{-1}; ^1H nmr (300 MHz) δ: 0.12 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.85 (br quintet, 2H, J = 7 Hz), 2.23 (s, 3H), 2.59 (br t, 2H, J = 7 Hz, $^3J_{Sn-H}$ = 48 Hz), 3.50 (t, 2H, J = 7 Hz), 6.82 (br s, 1H, $^3J_{Sn-H}$ = 120 Hz); in nOe difference experiments, irradiation at δ 6.82 caused enhancement of the resonances at δ 2.59 and 2.23, while irradiation at δ 2.59 increased the intensity of the signals at δ 1.85, 3.50, and 6.82; ^{13}C nmr (75.4 MHz) δ: −7.4, 30.2, 31.6, 36.6, 44.1, 135.6, 174.6, 197.5. Exact Mass calcd. for $C_9H_{16}{}^{35}ClOSn$ (M^+ − Me): 294.9912; found: 294.9912.

*(Z)-8-*tert*-Butyldimethylsilyloxy-4-trimethylstannyl-3-octen-2-one (**46**)*

Purification (flash chromatography, 35 g of silica gel, 96:4 petroleum ether – Et_2O; distillation, 120–130°C/0.5 Torr) of the crude product obtained from 0.16 g (0.63 mmol) of the starting material **31** yielded 0.27 g (83%) of the ketone **46**, a colorless oil that displayed ir (neat): 1682, 1572, 1103, 776 cm^{-1}; ^1H nmr (300 MHz) δ: 0.04 (s, 6H), 0.12 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.88 (s, 9H), 1.35–1.55 (m, 4H), 2.22 (s, 3H), 2.44 (br t, 2H, J = 6.5 Hz, $^3J_{Sn-H}$ = 49 Hz), 3.60 (t, 2H, J = 6.5 Hz), 6.79 (br s, 1H, $^3J_{Sn-H}$ = 122 Hz); in nOe difference experiments, irradiation at δ 6.79 caused enhancement of the signals at δ 2.44 and 2.22, while irradiations at δ 2.22 and 2.44 caused, in each case, enhancement of the resonance at δ 6.79; ^{13}C nmr (75.4 MHz) δ: −7.5, −5.3, 18.3, 25.6, 25.9, 30.1, 32.5, 39.7, 62.9, 134.7, 176.8, 197.6. Exact Mass calcd. for $C_{16}H_{33}O_2SiSn$ (M^+ − Me): 405.1272; found: 405.1266.

*(Z)-4-Trimethylstannyl-3-nonen-8-yn-2-one (**47**)*

Flash chromatography (35 g of silica gel, 95:5 petroleum ether – Et_2O) of the crude product derived from the substrate **32** (0.18 g, 1.3 mmol), followed by distillation (70–80°C/0.5 Torr) of the resultant liquid, gave 0.27 g (69%) of the ketone **47**, a colorless oil that showed ir (neat): 3308, 2119, 1681, 1571, 772 cm^{-1}; ^1H nmr (400 MHz) δ: 0.12 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.63 (quintet, 2H, J = 7.5 Hz), 1.97 (t, 1H, J = 2.5 Hz), 2.19 (td, 2H, J = 7.5, 2.5 Hz), 2.22 (s, 3H), 2.54 (td, 2H, J = 7.5, 1.3 Hz, $^3J_{Sn-H}$ = 48 Hz), 6.62 (br s, 1H, $^3J_{Sn-H}$ = 120 Hz); in nOe experiments, irradiation at δ 6.62 caused signal enhancement at δ 2.54 and 2.22, irradiation at δ 2.54 caused signal enhancement at δ 6.62 and 1.63, and irradiation at δ 2.22 enhanced the signal at δ 6.62. Exact Mass calcd. for $C_{11}H_{17}OSn$ (M^+ − Me): 285.0302; found: 285.0302.

(Z)-5-Methyl-4-trimethylstannyl-3-hexen-2-one (**48**)

The crude product obtained from the substrate **33** (0.20 g, 1.8 mmol), upon subjection to flash chromatography (45 g of silica gel, 98:2 petroleum ether – Et_2O) and distillation (70–75°C/0.5 Torr), furnished 0.40 g (80%) of the ketone **48**, a colorless oil that exhibited ir (neat): 1682, 1568, 1203, 770 cm^{-1}; ^1H nmr (300 MHz) δ: 0.09 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 1.03 (d, 6H, J = 6.5 Hz), 2.20 (s, 3H), 2.75 (septet of d, J = 6.5, 1.5 Hz, $^3J_{Sn-H}$ = 54 Hz), 6.77 (d, 1H, J = 1.5 Hz, $^3J_{Sn-H}$ = 127 Hz); in nOe difference experiments, irradiation at δ 6.77 produced signal enhancements at δ 1.03, 2.20, and 2.75, while irradiation at δ 2.75 caused enhancement of the resonances at δ 1.03 and 6.77; ^{13}C nmr (75.4 MHz) δ: −6.9, 21.7, 30.1, 36.2, 130.7, 183.0, 197.9. Exact Mass calcd. for $C_9H_{17}OSn$ (M^+ − Me): 261.0301; found: 261.0297.

*(Z)-7-*tert*-Butyldimethylsilyloxy-2-methyl-5-trimethylstannyl-4-hepten-3-one (**49**)*

Flash chromatography (140 g of silica gel, 95:5 petroleum ether – Et_2O) of the crude product obtained from the substrate **34** (2.3 g, 9.2 mmol), followed by distillation (130–135°C/0.5 Torr) of the acquired liquid, afforded 3.6 g (94%) of the ketone **49**, a colorless oil that showed ir (neat): 1678, 1572, 1256, 1098, 777 cm^{-1}; ^1H nmr (400 MHz) δ: 0.04 (s, 6H), 0.12 (s, 9H, $^2J_{Sn-H}$ = 55 Hz), 0.87 (s, 9H), 1.12 (d, 6H, J = 7 Hz), 2.66 (m, 3H), 3.66 (t, 2H, J = 6.5 Hz), 6.88 (br s, 1H, $^3J_{Sn-H}$ = 127 Hz); in nOe difference experiments, irradiations at δ 6.88 and 2.66 caused signal enhancements at δ 2.66 and 6.88, respectively. Exact Mass calcd. for $C_{16}H_{33}O_2SnSi$ (M^+ − Me): 405.1272; found: 405.1269.

*(Z)-2,2-Dimethyl-3-trimethylstannyl-3-undecen-4-one (**50**)*

Purification (flash chromatography, 75 g of silica gel, 97:3 petroleum ether – Et_2O; distillation, 120–130°C/0.5 Torr) of the crude product acquired from 1.0 g (5.2 mmol) of the starting material **35** furnished 0.90 g (48%) of the ketone **50**, a colorless oil that exhibited ir (neat): 1685, 1562, 779, 532 cm^{-1}; ^1H nmr (300 MHz) δ: 0.16 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.86 (m, 3H), 1.13 (s, 9H), 1.27 (br signal, 6H), 1.50–1.67 (m, 2H), 2.49 (t, 2H, J = 7.5 Hz), 6.75 (s, 1H, $^3J_{Sn-H}$ = 130 Hz); in nOe difference experiments, irradiation at δ 6.75 caused signal enhancements at δ 1.13 and 2.49, irradiation at δ 2.49 caused signal enhancements at δ 6.75 and 1.50–1.67, and irradiation at δ 1.13 increased the intensity of the resonance at δ 6.75; ^{13}C nmr (75.4 MHz) δ: −3.6, 14.1, 22.6, 24.3, 29.0, 29.7, 31.6, 40.0, 43.4, 130.3, 184.9, 201.0. Exact Mass calcd. for $C_{15}H_{29}OSn$ (M^+ − Me): 345.1241; found: 345.1237.

*(Z)-7-*tert*-Butyldimethylsilyloxy-4-trimethylstannyl-3,8-nonadien-2-one (**51**)*

Flash chromatography (75 g of silica gel, 95:5 petroleum ether – Et_2O) and distillation (130–135°C/0.5 Torr) of the crude product derived from the substrate **36** (0.84 g, 3.2 mmol) gave 1.3 g (95%) of the ketone **51**, a colorless oil that displayed ir (neat): 1682, 1571, 837, 776 cm^{-1}; ^1H nmr (400 MHz) δ: 0.02 (s, 3H), 0.05 (s, 3H), 0.12 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.89 (s, 9H), 1.45–1.65 (m, 2H), 2.21 (s, 3H), 2.35–2.60 (m, 2H), 4.10 (m, 1H), 5.05 (ddd, 1H, J = 10, 2, 2 Hz), 5.14 (ddd, 1H, J = 18, 2, 2 Hz), 5.80 (ddd, 1H, J = 18, 10, 6 Hz), 6.80 (br s, 1H, $^3J_{Sn-H}$ = 124 Hz). Exact Mass clacd. for $C_{17}H_{33}O_2SiSn$ (M^+ − Me): 417.1272; found: 417.1270.

General procedure 4. Preparation of the (Z)-4-(trimethylstannyl)-1,3-butadienes 61–63 and 68

To a cold (0°C), stirred suspension of methyltriphenylphosphonium bromide (for **61–63**, ~1.8 mmol per mmol of substrate; for **68**, ~2.0 mmol per mmol of substrate) in dry THF (~7 mL per mmol of substrate) was added a solution of *n*-BuLi in hexane (for **61–63**, ~1.3 mmol per mmol of substrate; for **68**, ~1.5 mmol per mmol of substrate). After the resulting yellow solution/suspension had been stirred for 10 min at 0°C and for 30 min at room temperature, a solution of the aldehyde (or ketone) in dry THF (~2 mL per mmol of substrate) was added. The reaction mixture was stirred at room temperature for the time indicated in Table 3. Water (~0.5 mL per mL of reaction solu-

tion) and Et_2O (~0.5 mL per mL of reaction solution) were added and the phases were separated. The aqueous phase was extracted with Et_2O and the combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. The crude product was purified by chromatography and distillation.

The following (*Z*)-4-trimethylstannyl-1,3-butadienes were prepared via this general procedure.

*(Z)-6-*tert*-Butyldimethylsilyloxy-4-trimethylstannyl-1,3-hexadiene (**61**)*

Flash chromatography (120 g of silica gel, 98:2 petroleum ether – Et_2O) of the crude product obtained from the aldehyde **41** (2.7 g, 7.2 mmol), followed by distillation (105–110°C/0.5 Torr) of the acquired liquid, gave 2.4 g (87%) of the diene **61**, a colorless oil that showed ir (neat): 3087, 3049, 1621, 1574, 1100, 774 cm^{-1}; ^1H nmr (300 MHz) δ: 0.04 (s, 6H), 0.21 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.88 (s, 9H), 2.49 (br t, 2H J = 7 Hz, $^3J_{Sn-H}$ = 55 Hz), 3.57 (t, 2H, J = 7 Hz), 5.10 (dd, 1H, J = 11, 1.5 Hz), 5.15 (dd, 1H, J = 16, 1.5 Hz), 6.30 (m, 1H), 6.64 (br d, 1H, J = 11 Hz, $^3J_{Sn-H}$ = 131 Hz); ^{13}C nmr (75.4 MHz) δ: −8.0, −5.1, 18.4, 26.0, 43.6, 63.6, 117.1, 137.7, 142.6, 147.3. Exact Mass calcd. for $C_{14}H_{29}OSiSn$ (M^+ − Me): 361.1010; found: 361.1018. Anal. calcd. for $C_{15}H_{32}OSiSn$: C 48.02, H 8.60; found: C 48.00, H 8.70.

*(Z)-6-Methoxymethoxy-4-trimethylstannyl-1,3-hexadiene (**62**)*

Purification (flash chromatography, 230 g of silica gel, 9:1 petroleum ether – Et_2O; distillation, 95–105°C/0.5 Torr) of the crude product derived from the aldehyde **42** (5.84 g, 19.0 mmol) provided 4.76 g (82%) of the diene **62**, a colorless oil that displayed ir (neat): 3086, 1623, 1149, 1045, 771 cm^{-1}; ^1H nmr (300 MHz) δ: 0.02 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 2.55 (br t, 2H, J = 6 Hz, $^3J_{Sn-H}$ = 53 Hz), 3.24 (s, 3H), 3.50 (t, 2H, J = 6 Hz), 4.60 (s, 2H), 5.10 (br d, 1H, J = 10 Hz), 5.15 (br d, 1H, J = 17 Hz), 6.30 (m, 1H), 6.66 (br d, 1H, J = 11 Hz, $^3J_{Sn-H}$ = 125 Hz); ^{13}C nmr (75.4 MHz) δ: −8.2, 40.3, 55.0, 67.8, 96.2, 117.3, 137.6, 142.4, 147.7. Exact Mass calcd. for $C_{10}H_{19}O_2Sn$ (M^+ − Me): 291.0407; found: 291.0406.

*(Z)-8-*tert*-Butyldimethylsilyloxy-4-trimethylstannyl-1,3-octadiene (**63**)*

The crude product obtained from the aldehyde **43** (0.10 g, 0.25 mmol) was purified by flash chromatography (30 g of silica gel, 98:2 petroleum ether – Et_2O) and distillation (110–115° C/0.5 Torr) to produce 0.08 g (81%) of the diene **63**, a colorless oil that exhibited ir (neat): 3086, 1622, 1574, 1255, 1105, 775 cm^{-1}; ^1H nmr (300 MHz) δ: 0.04 (s, 6H), 0.20 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.88 (s, 9H), 1.30–1.55 (m, 4H), 2.28 (br t, 2H, J = 7 Hz, $^3J_{Sn-H}$ = 56 Hz), 3.59 (t, 2H, J = 6 Hz), 5.06 (dd, 1H, J = 10, 1.5 Hz), 5.13 (dd, 1H, J = 16, 1.5 Hz), 6.13 (m, 1H), 6.59 (br d, 1H, J = 11 Hz, $^3J_{Sn-H}$ = 136 Hz); ^{13}C nmr (75.4 MHz) δ: −8.1, −5.2, 18.4, 26.1, 26.5, 32.5, 40.6, 62.1, 116.5, 137.8, 140.3, 152.1. Exact Mass calcd. for $C_{16}H_{33}OSnSi$ (M^+ − Me): 389.1323; found: 389.1329.

*(Z)-2,5-Dimethyl-4-trimethylstannyl-1,3-hexadiene (**68**)*

Flash chromatography (150 g of silica gel, petroleum ether) of the crude product derived from 3.6 g (13 mmol) of the ketone **48**, followed by distillation (90–105°C/0.5 Torr) of the acquired material, gave 3.1 g (87%) of the diene **68**, a colorless oil that displayed ir (neat): 3083, 1632, 1602, 1188, 769 cm^{-1}; ^1H nmr (300 MHz) δ: 0.14 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 1.03 (d, 6H, J = 7 Hz), 1.77 (s, 3H), 2.51 (septet of d, J = 7, 1.5 Hz, $^3J_{Sn-H}$ = 60 Hz), 4.74 (br s, 1H), 4.78 (br s, 1H), 6.45 (br s, 1H, $^3J_{Sn-H}$ = 144 Hz); ^{13}C nmr (75.4 MHz) δ: −6.3, 22.7, 23.1, 36.9, 112.6, 138.5, 147.2, 152.9. Exact Mass calcd. for $C_{10}H_{19}Sn$ (M^+ − Me): 259.0509; found: 259.0512.

General procedure 5. Preparation of the (*Z*)-4-(trimethylstannyl)-1,3-butadienes 64–67 and 69–71

To a stirred suspension of methyltriphenylphosphonium bromide (2.5 equiv.) in dry benzene (room temperature, ~9 mL per mmol of ketone substrate used) was added a solution of sodium 2-methyl-2-butoxide (2.5 equiv.) in dry benzene (1.75 M). After the mixture had been stirred for 20 min at room temperature, a solution of the ketone (1 equiv.) in dry benzene (~4 mL per mmol of the ketone) was added and stirring was continued for the time indicated in Table 3. Water (~0.5 mL per mL of reaction solution) and Et_2O (~1 mL per mL of reaction solution) were added and the phases were separated. The aqueous phase was extracted with Et_2O and the combined organic extracts were washed with brine, dried ($MgSO_4$), and concentrated. The crude product was purified by chromatography and distillation.

The following (*Z*)-4-trimethylstannyl-1,3-butadienes were prepared via this general procedure.

*(Z)-6-*tert*-Butyldimethylsilyloxy-2-methyl-4-trimethylstannyl-1,3-hexadiene (**64**)*

Flash chromatography (35 g of silica gel, 98:2 petroleum ether – Et_2O) of the crude product derived from 0.20 g (0.51 mmol) of the ketone **44**, followed by distillation (105–110°C/0.5 Torr) of the acquired liquid, gave 0.17 mg (86%) of the diene **64**, a colorless oil that exhibited ir (neat): 3083, 1633, 1604, 1572, 1255, 774 cm^{-1}; ^1H nmr (300 MHz) δ: 0.04 (s, 6H), 0.13 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.88 (s, 9H), 1.76 (s, 3H), 2.45 (td, 2H, J = 7, 1.3 Hz, $^3J_{Sn-H}$ = 55 Hz), 3.56 (t, 2H, J = 7 Hz), 4.57 (br s, 1H), 4.79 (br s, 1H), 6.53 (br s, 1H, $^3J_{Sn-H}$ = 137 Hz); ^{13}C nmr (75.4 MHz) δ: −7.2, −5.2, 18.4, 22.7, 26.0, 43.6, 63.7, 112.9, 141.8, 144.9, 146.6. Exact Mass calcd. for $C_{15}H_{31}OSiSn$ (M^+ − Me): 375.1166; found: 375.1161.

*(Z)-7-Chloro-2-methyl-4-trimethylstannyl-1,3-heptadiene (**65**)*

Purification (flash chromatography, 35 g of silica gel, 98:2 petroleum ether – Et_2O; distillation, 85–90°C/0.5 Torr) of the crude product obtained from the ketone **45** (0.29 g, 0.73 mmol) gave 0.13 g (57%) of the diene **65**, a colorless oil that displayed ir (neat): 3082, 1632, 1605, 897 cm^{-1}; ^1H nmr (300 MHz) δ: 0.14 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.77 (s, 3H), 1.81 (quintet, 2H, J = 7 Hz), 2.38 (td, 2H, J = 7, 1.3 Hz, $^3J_{Sn-H}$ = 54 Hz), 3.50 (t, 2H, J = 7 Hz), 4.76 (br s, 1H), 4.80 (br s, 1H), 6.52 (br s, 1H, $^3J_{Sn-H}$ = 136 Hz). Exact Mass calcd. for $C_{10}H_{18}{}^{35}ClSn$ (M^+ − Me): 293.0119; found: 293.0114.

*(Z)-8-*tert*-Butyldimethylsilyloxy-2-methyl-4-trimethylstannyl-1,3-octadiene (**66**)*

The crude product obtained from the ketone **46** (0.16 g, 0.37 mmol) was purified by flash chromatography (30 g of silica gel, 97:3 petroleum ether – Et_2O) and distillation (110–115°C/0.5 Torr) to afford 0.12 g (75%) of the diene **66**, a colorless oil that showed ir (neat): 3081, 1572, 1562, 1255, 1103, 775 cm^{-1};

^{1}H nmr (300 MHz) δ: 0.03 (s, 6H), 0.12 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.88 (s, 9H), 1.29–1.55 (m, 4H), 1.76 (s, 3H), 2.24 (br t, 2H, J = 7 Hz, $^3J_{Sn-H}$ = 55 Hz), 3.59 (t, 2H, J = 6 Hz), 4.74 (br s, 1H), 4.79 (br s, 1H), 6.47 (br s, 1H, $^3J_{Sn-H}$ = 139 Hz); ^{13}C nmr (75.4 MHz) δ: −7.4, −5.3, 18.3, 22.7, 26.0, 26.5, 32.4, 40.4, 60.1, 112.6, 142.5, 146.2, 146.6. Exact Mass calcd. for $C_{17}H_{35}OSn$ (M^+ − Me): 403.1479; found: 403.1472.

*(Z)-2-Methyl-4-trimethylstannyl-1,3-nonadien-8-yne (**67**)*

The ketone **47** (1.22 g, 4.07 mmol; in 8 mL of dry benzene) was converted into the diene **67** by treatment with the Wittig reagent (2.5 equiv.; in 15 mL of dry benzene) at room temperature for 30 min. Flash chromatography (65 g of silica gel, petroleum ether) of the crude product, followed by distillation (70–80°C/0.5 Torr) of the liquid obtained, provided 1.01 g (83%) of the diene **67**, a colorless oil that exhibited ir (neat): 3212, 1632, 3082, 2120, 897, 770 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.13 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 1.57 (quintet, 2H, J = 7 Hz), 1.76 (s, 3H), 1.94 (t, 1H, J = 2.6 Hz), 2.16 (td, 2H, J = 7, 2.6 Hz), 2.34 (td, 2H, J = 7, 1.3 Hz, $^3J_{Sn-H}$ = 55 Hz), 4.75 (br s, 1H), 4.79 (br s, 1H), 6.51 (br s, 1H, $^3J_{Sn-H}$ = 139 Hz); ^{13}C nmr (75.4 MHz) δ: −7.3, 17.8, 22.7, 28.8, 39.4, 68.4, 84.4, 112.9, 143.5, 144.9, 146.6. Exact Mass calcd. for $C_{12}H_{19}Sn$ (M^+ − Me): 283.0509; found: 283.0510.

*(Z)-6-*tert*-Butyldimethylsilyloxy-2-isopropyl-4-trimethylstannyl-1,3-hexadiene (**69**)*

Purification (flash chromatography, 35 g of silica gel, 97:3 petroleum ether – Et_2O; distillation, 110–115°C/0.5 Torr) of the crude product obtained from the ketone **49** (0.17 g, 0.41 mmol), furnished 0.11 g (64%) of the diene **69**, a colorless oil that showed ir (neat): 3090, 1625, 1461, 1255, 1007, 775 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.04 (s, 6H), 0.12 (s, 9H, $^2J_{Sn-H}$ = 53 Hz), 0.87 (s, 9H), 1.02 (d, 6H, J = 7 Hz), 2.27 (br septet, 1H, J = 7 Hz), 2.48 (br t, 2H, J = 7 Hz, $^3J_{Sn-H}$ = 53 Hz), 3.56 (t, 2H, J = 7 Hz), 4.71 (br s, 1H), 4.80 (br s, 1H), 6.60 (br s, 1H, $^3J_{Sn-H}$ = 140 Hz); ^{13}C nmr (75.4 MHz) δ: −7.1, −5.2, 18.4, 21.6, 26.0, 34.0, 43.7, 63.8, 108.9, 143.4, 156.4. Exact Mass calcd. for $C_{17}H_{35}OSiSn$ (M^+ − Me): 403.1479; found: 403.1474.

*(Z)-5,5-Dimethyl-2-*n*-hexyl-4-trimethylstannyl-1,3-hexadiene (**70**)*

Flash chromatography (35 g of silica gel, 98:2 petroleum ether – Et_2O) of the crude product obtained from the ketone **50** (0.11 g, 0.31 mmol), followed by distillation (105–110°C/0.5 Torr) of the acquired material, afforded 0.09 g (81%) of the diene **70**, a colorless oil that exhibited ir (neat): 3038, 1630, 899, 770 cm^{-1}; ^{1}H nmr (300 MHz) δ: 0.15 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.88 (m, 3H), 1.07 (s, 9H), 1.30 (br s, 6H), 1.42 (m, 2H), 2.01 (br t, 2H, J = 8 Hz), 4.72 (br s, 1H), 4.77 (br s, 1H), 6.49 (br s, 1H, $^3J_{Sn-H}$ = 151 Hz); ^{13}C nmr (75.4 MHz) δ: −3.6, 14.2, 22.8, 22.7, 29.4, 30.7, 31.8, 37.1, 38.9, 111.2, 137.3, 151.3, 156.6. Exact Mass calcd. for $C_{16}H_{31}Sn$ (M^+ − Me): 343.1448; found: 343.1453.

*(Z)-7-*tert*-Butyldimethylsilyloxy-2-methyl-4-trimethylstannyl-1,3,8-nonatriene (**71**)*

The crude product acquired from the ketone **51** (0.09 g, 0.21 mmol) was purified by flash chromatography (30 g of silica gel, 97:3 petroleum ether – Et_2O) and distillation (125–130°C/0.5 Torr) to afford 0.08 g (85%) of the diene **71**, a colorless oil that displayed ir (neat): 3081, 1632, 1253, 1084, 775 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.04 (s, 3H), 0.06 (s, 3H), 0.14 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 0.90 (s, 9H), 1.40–1.60 (m, 2H), 1.78 (s, 3H), 2.19–2.40 (m, 2H), 4.10 (br m, 1H), 4.76 (br s, 1H), 4.80 (br s, 1H), 5.03 (ddd, 1H, J = 10, 2, 2 Hz), 5.14 (ddd, 1H, J = 17, 2, 2 Hz), 5.81 (ddd, 1H, J = 17, 10, 6 Hz), 6.50 (br s, 1H, $^3J_{Sn-H}$ = 139 Hz); ^{13}C nmr (50 MHz) δ: −7.3, −4.8, −4.3, 18.2, 22.7, 25.9, 36.4, 38.9, 73.6, 112.7, 113.7, 141.8, 142.6, 145.9, 146.7. Exact Mass calcd. for $C_{18}H_{35}OSiSn$ (M^+ − Me): 415.1480; found: 415.1478.

Methyl *(2E,4Z)*-7-*tert*-butyldimethylsilyloxy-5-trimethylstannyl-1,4-heptadienoate (72)

To a cold (0°C), stirred suspension of NaH (1.02 g, 21.2 mmol) in 100 mL of dry THF was added dropwise, over a period of ~5 min, trimethyl phosphonoacetate (3.87 g, 21.2 mmol) and the resultant slurry was stirred at 0°C for 5 min and at room temperature for 20 min. The mixture was then recooled to 0°C and a solution of the aldehyde **41** (5.35 g, 14.2 mmol) in 25 mL of dry THF was added. The resulting suspension was stirred at 0°C for 2 h. Water (~50 mL) and Et_2O (~50 mL) were added and the phases were separated. The aqueous phase was extracted with Et_2O (2 × 40 mL) and the combined organic extracts were washed (brine, 40 mL), dried ($MgSO_4$), and concentrated. Flash chromatography (250 g of silica gel, 94:6 petroleum ether – Et_2O) of the crude product and distillation (140–150°C/0.5 Torr) of the acquired liquid provided 5.65 g (92%) of the diene **72**, a colorless oil that displayed ir (neat): 1723, 1626, 1268, 1100, 776 cm^{-1}; ^{1}H nmr (400 MHz) δ: 0.03 (s, 6H), 0.27 (s, 9H, $^2J_{Sn-H}$ = 54 Hz), 0.87 (s, 9H), 2.57 (br t, 2H, J = 7 Hz, $^3J_{Sn-H}$ = 50 Hz), 3.62 (t, 2H, J = 7 Hz), 3.73 (s, 3H), 5.80 (br d, 1H, J = 15 Hz), 6.73 (br d, 1H, J = 11 Hz, $^3J_{Sn-H}$ = 122 Hz), 7.30 (dd, 1H, J = 15, 11 Hz, $^4J_{Sn-H}$ = 7 Hz); in nOe difference experiments irradiation at δ 2.57 caused signal enhancement at δ 6.73 and 3.62, irradiation at δ 5.80 caused resonance enhancement at δ 6.73, and irradiation at δ 6.73 caused enhancement of the signals at δ 5.80 and 2.57. Exact Mass calcd. for $C_{16}H_{31}O_3SnSi$ (M^+ − Me): 419.1065; found: 419.1070.

Preparation of the phosphonate reagent 73

A stirred mixture of triisopropyl phosphite (3.2 g, 15 mmol) and *tert*-butyl bromoacetate (3.0 g, 15 mmol) was heated at 125°C for 1.5 h. Direct distillation (fraction collected between 110 and 115°C/0.5 Torr) of the oil thus obtained gave 3.5 g (81%) of the phosphonate **73**, a colorless oil that exhibited ir (neat): 1730, 1289, 1107, 991 cm^{-1}; ^{1}H nmr (400 MHz) δ: 1.27 (d, 6H, J = 7 Hz), 1.29 (d, 6H, J = 7 Hz), 1.42 (s, 9H), 2.77 (d, 2H, $^2J_{P-H}$ = 22 Hz), 4.68 (m, 2H); ^{13}C nmr (75.4 MHz) δ: 23.8 (d, $^3J_{P-C}$ = 5 Hz), 23.95 (d, $^3J_{P-C}$ = 4 Hz), 27.8, 36.6 (d, $^1J_{P-C}$ = 134 Hz), 70.9 (d, $^2J_{P-C}$ = 6 Hz), 81.6, 164.9 (d, $^2J_{P-C}$ = 6 Hz); ^{31}P nmr (122 MHz) δ: 16.2 (tt, J = 22, 8 Hz).

***tert*-Butyl *(2E,4Z)*-7-methoxymethoxy-5-trimethylstannyl-1,4-heptadienoate (74)**

To a cold (0°C), stirred suspension of NaH (0.26 g, 6.4 mmol) in 25 mL of dry THF was added slowly, over a period of ~5 min, a solution of the phosphonate reagent **73** (1.8 g, 6.4 mmol) in 10 mL of dry THF. After the mixture had been stirred at 0°C for 5 min and at room temperature for 20 min, it

was cooled to −20°C and a solution of the aldehyde **42** (1.17 g, 3.8 mmol) in 10 mL of dry THF was added. The mixture was stirred at −20°C for 1.5 h and was then allowed to warm to room temperature (30 min). Water (~20 mL) and Et_2O (~40 mL) were added and the phases were separated. The aqueous phase was extracted with Et_2O (2 × 20 mL) and the combined organic extracts were washed (brine, 20 mL), dried ($MgSO_4$), and concentrated. Flash chromatography of the crude product on silica gel (65 g, 4:1 petroleum ether – Et_2O), followed by distillation (190–210°C/0.5 Torr) of the acquired material, gave 1.4 g (91%) of the diene **74**, a colorless oil that showed ir (neat): 1703, 1626, 1368, 1045, 770 cm^{-1}; ^1H nmr (400 MHz) δ: 0.25 (s, 9H, $^2J_{Sn-H}$ = 52 Hz), 1.48 (s, 9H), 2.64 (br t, 2H, J = 7 Hz, $^3J_{Sn-H}$ = 49 Hz), 3.33 (s, 3H), 3.54 (t, 2H, J = 7 Hz), 4.58 (s, 2H), 5.72 (br d, 1H, J = 15 Hz), 6.74 (br d, 1H, J = 11 Hz, $^3J_{Sn-H}$ = 120 Hz), 7.21 (dd, 1H, J = 15, 11 Hz, $^4J_{Sn-H}$ = 7 Hz); in nOe difference experiments, irradiation at δ 6.74 caused enhancement of the resonances at δ 5.72 and 2.64, irradiation at δ 2.64 caused signal enhancement at δ 3.54 and 6.74, and irradiation at δ 5.72 increased the intensity of the signal at δ 6.74; ^{13}C nmr (75.4 MHz) δ: −7.8, 28.2, 41.0, 55.3, 67.5, 80.1, 96.4, 123.2, 139.5, 144.2, 160.5, 166.5. Exact Mass calcd. for $C_{15}H_{27}O_4Sn$ (M^+ − Me): 391.0931; found: 391.0938. Anal. calcd. for $C_{16}H_{30}O_4Sn$: C 47.42, H 7.47; found: C 47.59, H 7.39.

(*E*)-3-((2-Methoxymethoxy)ethyl)-3,5-hexadien-1-ol (76)

To a cold (−78°C), stirred solution of the trimethylstannyl diene **62** (0.87 g, 2.84 mmol) in dry THF (50 mL) was added a solution of MeLi (3.1 mmol) in Et_2O. After the mixture had been stirred for 45 min at −78°C, ethylene oxide (~2.5 g, ~57 mmol) was added via a syringe (the barrel of the syringe was cooled using a piece of Dry Ice, in order to facilitate the transfer of the volatile liquid). The resulting mixture was stirred at −78°C for 5 min and at −20°C for 20 min and was then allowed to warm to room temperature (30 min). Saturated aqueous $NaHCO_3$ (10 mL) and Et_2O (30 mL) were added, the phases were separated, and the aqueous phase was extracted with Et_2O (3 × 20 mL). The combined organic extracts were washed (brine, 20 mL), dried ($MgSO_4$), and concentrated. Flash chromatography of the crude product on silica gel (40 g, 2:3 petroleum ether – Et_2O) and distillation (110–120°C/0.5 Torr) of the derived liquid gave 0.38 g (71%) of the alcohol **76**, a colorless oil that exhibited ir (neat): 3401, 3085, 1647, 1150, 1109, 1039 cm^{-1}; ^1H nmr (400 MHz) δ: 1.74 (br s, 1H), 2.39 (br t, 2H, J = 6.5 Hz), 2.49 (t, 2H, J = 6.5 Hz), 3.34 (s, 3H), 3.67 (t, 2H, J = 6.5 Hz), 3.70 (br m, 2H), 4.61 (s, 2H), 5.05 (dd, 1H, J = 10, 1.5 Hz), 5.15 (dd, 1H, J = 17, 1.5 Hz), 6.06 (br d, 1H, J = 11 Hz), 6.60 (ddd, 1H, J = 17, 11, 10 Hz); on addition of D_2O the signal at δ 3.70 sharpened to a t (J = 6.5 Hz), and the signal at δ 1.74 disappeared; ^{13}C nmr (75.4 MHz) δ: 34.4, 37.1, 55.3, 61.2, 66.5, 96.4, 116.8, 129.9, 132.5, 136.3. Exact Mass calcd. for $C_{10}H_{16}O_2$ (M^+ − H_2O): 168.1151; found: 168.1152. Anal. calcd. for $C_{10}H_{18}O_3$: C 64.49, H 9.74; found: C 64.49, H 9.88.

(*Z*)-6-Bromo-4-((2-methoxymethoxy)ethyl)-1,3,6-heptatriene (78)

To a cold (−78°C), stirred solution of the trimethylstannyl diene **62** (0.35 mg, 1.13 mmol) in dry THF (5 mL) was added a solution of MeLi (1.24 mmol) in Et_2O. After the mixture had been stirred for 45 min at −78°C, CuBr·Me_2S (256 mg, 1.24 mmol) was added. The resulting bright pink solution/suspension was stirred at −78°C for 5 min and at −48°C for 15 min. To the resulting bright orange-red solution was added 2,3-dibromopropene (1.5 g, 7.6 mmol) and the resulting colorless solution was stirred at −48°C for 45 min. Aqueous NH_4Cl–NH_4OH (pH 8) (5 mL) and Et_2O (10 mL) were added and the vigorously stirred mixture was allowed to warm to room temperature. The phases were separated and the aqueous phase was extracted with Et_2O (3 × 10 mL). The combined organic extracts were washed (brine, 10 mL), dried ($MgSO_4$), and concentrated. Flash chromatography (40 g of silica gel, 9:1 petroleum ether – Et_2O), followed by distillation (100–110°C/0.5 Torr) of the acquired liquid, furnished 244 mg (83%) of the triene **78**, a colorless oil that showed ir (neat): 3086, 1626, 1150, 1072, 917 cm^{-1}; ^1H nmr (400 MHz) δ: 2.38 (br t, 2H, J = 6 Hz), 3.35 (br s, 5H), 3.62 (t, 2H, J = 6 Hz), 4.60 (s, 2H), 5.12 (dd, 1H, J = 11, 1.5 Hz), 5.20 (dd, 1H, J = 17, 1.5 Hz), 5.48 (br s, 1H), 5.62 (br s, 1H), 6.13 (br d, 1H, J = 11 Hz), 6.54 (ddd, 1H, J = 17, 11, 11 Hz); ^{13}C nmr (75.4 MHz) δ: 36.6, 42.8, 55.2, 66.1, 96.3, 117.5, 117.8, 130.4, 130.9, 132.4, 134.6. Exact Mass calcd. for $C_9H_{12}{}^{79}BrO_2$ (M^+ − C_2H_5O): 215.0072; found: 215.0064. Anal. calcd. for $C_{11}H_{17}BrO_2$: C 50.59, H 6.56; found: C 50.85, H 6.58.

(*Z*)-7-Iodo-2-methyl-4-trimethylstannyl-1,3-heptadiene (87)

A stirred solution of NaI (1.80 g, 11.8 mmol) and the trimethylstannyl diene **65** (0.36 g, 1.18 mmol) in dry acetone (10 mL) was allowed to reflux overnight. Most of the acetone was removed, Et_2O (20 mL) and water (10 mL) were added to the residue, the phases were separated, and the aqueous phase was extracted with Et_2O (3 × 10 mL). The combined organic extracts were washed (water, 10 mL), dried ($MgSO_4$), and concentrated. Flash chromatography of the crude product on silica gel (35 g, 95:5 petroleum ether – Et_2O) and distillation (100–110°C/0.5 Torr) of the derived liquid afforded 0.41 mg (86%) of the diene **87**, a colorless oil that exhibited ir (neat): 3080, 1632, 1215, 896, 769 cm^{-1}; ^1H nmr (400 MHz) δ: 0.16 (s, 9H, $^2J_{Sn-H}$ = 56 Hz), 1.78 (s, 3H), 1.87 (quintet, 2H, J = 7 Hz), 2.34 (br t, 2H, J = 7 Hz, $^3J_{Sn-H}$ = 54 Hz), 3.15 (t, 2H, J = 7 Hz), 4.76 (br s, 1H), 4.80 (br s, 1H), 6.54 (s, 1H, $^3J_{Sn-H}$ = 132 Hz); ^{13}C nmr (50 MHz) δ: −7.3, 6.2, 22.7, 33.6, 40.8, 113.0, 143.8, 144.0, 146.5. Exact Mass calcd. for $C_{10}H_{18}ISn$ (M^+ − Me): 384.9477; found: 384.9476.

5,5,6,6-Tetracyano-8-methylspiro[3.5]non-8-ene (88)

To a cold (−78°C), stirred solution of the trimethylstannyl diene **87** (0.19 g, 0.47 mmol) in dry THF (2 mL) was added a solution of MeLi (0.52 mmol) in Et_2O. After the solution had been stirred for 10 min at −78°C and 20 min at −48°C, water (0.5 mL) and Et_2O (2 mL) were added and the mixture was allowed to warm to room temperature. The phases were separated and the aqueous phase was extracted with Et_2O (2 × 2 mL). The combined organic extracts were dried ($MgSO_4$). The ethereal solution of the reaction product **84** exhibited essentially one non-solvent peak by glc analyses and was used immediately in the next step. To this solution (argon atmosphere) was added (in portions of 5 mg) tetracyanoethylene (~50 mg), until the reaction was shown to be complete (glc analyses). The solvent was removed and the white solid

obtained was dissolved in a minimum amount of Et_2O. Flash chromatography of this solution on silica gel (25 g, 1:1 petroleum ether – Et_2O) and recrystallization of the acquired solid from petroleum ether gave 0.08 mg (69%) of the spiro compound **88** as colorless crystals that displayed mp 166–167°C; ir (KBr disk): 2253, 1440, 883, 696 cm^{-1}; ^1H nmr (400 MHz) δ: 1.88 (br s, 3H), 2.08–2.10 (m, 1H), 2.17–2.24 (m, 3H), 2.73–2.75 (m, 2H), 2.95 (br s, 2H), 5.99 (br s, 1H). Exact Mass calcd. for $C_{14}H_{12}N_4$: 236.1062; found: 236.1056.

5,6-Bis(methoxycarbonyl)-8-methylspiro[3.5]nona-5,8-diene (89)

To a cold (−78°C), stirred solution of the trimethylstannyl diene **87** (0.17 g, 0.43 mmol) in dry THF (2 mL) was added a solution of MeLi (0.47 mmol) in Et_2O. After the solution had been stirred for 10 min at −78°C and 20 min at −48°C, water (0.5 mL) and benzene (2 mL) were added and the mixture was allowed to warm to room temperature. The phases were separated and the aqueous phase was extracted with benzene (3 × 1 mL). The combined organic extracts were dried ($MgSO_4$). To this solution of the crude product **84** was added dimethyl acetylenedicarboxylate (360 mg, 2.6 mmol) and the resultant solution (argon atmosphere) was heated (70°C) in a sealed tube for 36 h. The solvent was removed and the residual oil was purified by flash chromatography (30 g of silica gel, 1:1 petroleum ether – Et_2O) and distillation (100–110°C/0.5 Torr) to give 0.07 g (70%) of the spiro compound **89**, a colorless oil that crystallized on standing. Recrystallization of this material from pentane produced colorless crystals that exhibited mp 55−56°C; ir (KBr disk): 1724, 1635, 1440, 1267, 1051, 754 cm^{-1}; ^1H nmr (400 MHz) δ: 1.72 (br s, 3H), 1.72–1.80 (m, 1H), 1.92–1.96 (m, 3H), 2.58–2.59 (m, 2H), 2.82 (br s, 2H), 3.73 (s, 3H), 3.88 (s, 3H), 5.73 (br s, 1H). Exact Mass calcd. for $C_{14}H_{18}O_4$: 250.1205; found: 250.1203.

Synthesis, characterization, and reactivity of a ruthenium(II) *N,N′,N″*-tris(2-pyridyl)phosphine complex. X-ray analysis of $RuCl_2(PPh_3)(Ppy_3)$ (py = 2-pyridyl)

Richard P. Schutte, Steven J. Rettig, and Brian R. James

Abstract: Reaction of $RuCl_2(PPh_3)_3$ with Ppy_3 (py = 2-pyridyl) in benzene produced the *N,N′,N″*-Ppy_3 complex $RuCl_2(PPh_3)(Ppy_3)$ **1**. Crystals of $RuCl_2(PPh_3)(Ppy_3)\cdot 2CH_2Cl_2$ ($C_{35}H_{31}Cl_6N_3P_2Ru$) are monoclinic, $a = 17.269(2)$, $b = 10.797(1)$, $c = 20.604(1)$ Å, $\beta = 107.461(6)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by the Patterson method and was refined by full-matrix least-squares procedures to $R = 0.039$ and $R_w = 0.035$ for 4184 reflections with $I \geq 3\sigma(I)$. Complex **1** reacts in MeOH or benzene with two-electron donors (L) to give the chloride-substituted, $[RuCl(L)(PPh_3)(Ppy_3)]PF_6$, or the triphenylphosphine-substituted products, $RuCl_2(L)(Ppy_3)$, (L = CO, MeCN, PhCN), respectively. $[RuCl(MeOH)(PPh_3)(Ppy_3)]BPh_4$ was also isolated. The non-coordinated phosphorus atom in **1** was oxidized to form $RuCl_2(PPh_3)(OPpy_3)$.

Key words: ruthenium, pyridylphosphines, crystal structure

Résumé : La réaction du $RuCl_2(PPh_3)_3$ avec de la Ppy_3 (py = 2-pyridyle) dans le benzène conduit à la formation du complexe *N,N′,N″*-Ppy_3 du $RuCl_2(PPh_3)(Ppy_3)$ **1**. Les cristaux du $RuCl_2(PPh_3)(Ppy_3)\cdot 2CH_2Cl_2$ ($C_{35}H_{31}Cl_6N_3P_2Ru$) sont monocliniques, groupe d'espace $P2_1/c$, avec $a = 17,269(2)$, $b = 10,797(1)$, et $c = 20,604(1)$ Å, $\beta = 107,461(6)°$ $Z = 4$. On a résolu la structure par la méthode de Patterson et on l'a affinée par les méthodes des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0,039$ et $R_w = 0,035$ pour 4184 réflexions avec $I \geq 3\sigma(I)$. Dans du MeOH ou du benzène, le complexe **1** réagit avec des donneurs à deux électrons (L) pour fournir respectivement des produits substitués par le chlore, $[RuCl(L)(PPh_3)(Ppy_3)]PF_6$, ou des produits substitués par la triphénylphosphine, $RuCl_2(L)(Ppy_3)$, (L = CO, MeCN, PhCN). On a aussi isolé le $[RuCl(MeOH)(PPh_3)(Ppy_3)]BPh_4$. On a oxydé l'atome de phosphore non coordiné du produit **1** pour former du $RuCl_2(PPh_3)(OPpy_3)$.

Mots clés : ruthénium, pyridylphosphines, structure cristalline.

[Traduit par la rédaction]

Introduction

The *N,N′,N″*-coordination mode of tris(2-pyridyl)phosphine (Ppy_3, py = 2-pyridyl), where the ligand binds to the metal centre via the three pyridyl nitrogens, has been observed with a variety of transition metals. All, except one, are cationic sandwich complexes containing two *N,N′,N″*-Ppy_3 ligands and are of the general formula $[M(Ppy_3)_2]^{2+}$ (M = Mn, Co, Ni, Cu, Zn, Ru) (1–3). The X-ray crystal structures of the zinc (2) and the ruthenium (3) complexes have been determined and confirm the *N,N′,N″*-coordination mode. Rarer are the half-sandwich complexes containing only one *N,N′,N″*-Ppy_3 ligand, the only example (prior to this work) being $Zn(Ppy_3)(NO_3)_2$ (2). In this case, the complex is neutral and contains both a monodentate and a bidentate nitrate ligand. Thus, the *N,N′,N″*-coordination mode has generally been observed in sandwich complexes of the first-row transition metals.

This paper reports on the synthesis, characterization, and reactivity of the *N,N′,N″*-Ppy_3, half-sandwich complex $RuCl_2(PPh_3)(Ppy_3)$ **1**. In MeOH, one of the chloro ligands in **1** is labile, and this led to the investigation of some chloride-substitution reactions with neutral two-electron donors. Alternatively, the triphenylphosphine ligand in **1** can be replaced by carrying out the substitution reactions in benzene. This reactivity is similar to that of the well-known $RuCl(PPh_3)_2(Cp)$ complex (Cp = η^5-cyclopentadienyl), which also contains a facial six-electron donor ligand (4). Our interest in 2-pyridylphosphine complexes stems from their potential as homogeneous catalysts in aqueous media (5). This present paper focuses on complex **1**, which turned out to be water insoluble. Related complexes such as $[RuCl(PPh_3)(Ppy_3)_2]Cl$, which contains chelated *P,N*-coordinated Ppy_3 ligands, are water soluble and will be discussed elsewhere (6).

Experimental

All manipulations were carried out under Ar using standard Schlenk techniques. Solvents (Fisher or BDH) were dried and distilled under N_2 prior to use. MeCN and PhCN were dried

Received February 2, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

over CaH_2 for 24 h prior to fractional distillation, and stored under argon in the dark. NH_4PF_6 (Aldrich), $NaBPh_4$ (Aldrich), and *m*-$ClC_6H_4C(O)OOH$ (*m*-CPBA) (Aldrich, 80–85% Tech. grade) were used as supplied. $RuCl_2(PPh_3)_3$ (7) and Ppy_3 (8) were prepared according to published procedures.

NMR spectra were recorded at room temperature (r.t.) on a Varian XL-300 MHz (300 MHz for ^1H; 121.4 MHz for ^{31}P) spectrometer. ^1H chemical shifts were recorded using the residual proton of the solvent as internal standard. All ^{31}P chemical shifts were referenced to external 85% H_3PO_4, by setting the chemical shift for $P(OMe)_3$ (Aldrich) at 141.00 ppm (relative to 85% H_3PO_4) in the appropriate solvent (9). Infrared spectra were recorded on a Mattson Genesis Series FTIR spectrometer as Nujol mulls between KBr plates or as KBr pellets. UV–visible spectra were recorded on a Hewlett–Packard-8452A diode array spectrometer. Solid state visible spectra were recorded by dissolving a small amount of complex in either MeOH or CH_2Cl_2 and placing the solution on a glass plate (UV cutoff 300 nm) and allowing the solvent to evaporate so that a thin amorphous film was left behind. The thin film was then placed in the beam of the spectrometer and the spectrum recorded. Conductivity measurements were made at 25°C using a model RCM151B Serfass conductance bridge (A. H. Thomas Co. Ltd.) connected to a 3403 cell from the Yellow Springs Instrument Company. The cell constant was determined by measuring the resistance of an aqueous solution of KCl (0.0100 M, $\sigma = 0.001\,413$ ohm^{-1} cm^{-1} at 25°C) (10). Solutions of $\sim 1 \times 10^{-3}$ M in CH_3NO_2 or MeOH were made just prior to use. Elemental analyses were performed by Mr. P. Borda of this department.

Preparation of $RuCl_2(PPh_3)(Ppy_3)$, 1

Benzene (30 mL) was added to a mixture of $RuCl_2(PPh_3)_3$ (0.48 g, 0.50 mmol) and Ppy_3 (0.13 g, 0.50 mmol). The resulting red solution was refluxed for 7 h in which time a dark red precipitate formed. After the volume was reduced in half, hexanes (40 mL) were added to complete precipitation. The red precipitate was filtered, washed with hexanes (3 × 10 mL) to remove any residual PPh_3, and dried under vacuum (0.32 g, 92%). Anal. calcd. for $C_{33}H_{27}Cl_2N_3P_2Ru$: C 56.66, H 3.89, N 6.01; found: C 56.65, H 3.89, N 5.96%.

Single crystals for an X-ray diffraction study were grown by Et_2O diffusion into a CH_2Cl_2 solution of the complex. The crystals isolated contained two CH_2Cl_2 solvates.

Preparation of $[RuCl(MeOH)(PPh_3)(Ppy_3)]BPh_4$, 2

$NaBPh_4$ (0.022 g, 0.064 mmol) was added to a clear orange solution of **1** (0.042 g, 0.060 mmol) in MeOH (30 mL). After being stirred for 0.5 h, the solution volume was reduced (to ~10 mL) under vacuum during which time an orange precipitate formed. The mixture was stirred for a further 0.5 h and then the precipitate was filtered off and washed with MeOH (2 × 1 mL) and dried under vacuum (24 h), (0.033 g, 54%). Anal. calcd. for $C_{58}H_{51}BClN_3OP_2Ru$: C 68.61, H 5.06, N 4.14; found: C 67.85, H 4.94, N 4.21%.

Preparation of $[RuCl(CO)(PPh_3)(Ppy_3)]PF_6$, 3

To a degassed solution of **1** (0.13 g, 0.19 mmol) and NH_4PF_6 (0.032 g, 0.20 mmol) in MeOH (6 mL), CO gas (1 atm (101.3 kPa)) was added, and the mixture was heated at 65°C for 2 h. The initial red suspension formed a clear yellow solution, which was pumped to dryness and the residue dissolved in acetone (5 mL). The resulting turbid, orange solution was filtered through Celite 545® along with acetone washings (15 mL). The clear filtrate was pumped to dryness and MeOH added (1 mL) to form a yellow precipitate, which was filtered off and dried under vacuum (0.12 g, 75%). Anal. calcd. for $C_{34}H_{27}ClF_6N_3OP_3Ru$: C 48.79, H 3.48, N 5.02; found: C 48.65; H, 3.38; N, 4.96%.

Preparation of $[RuCl(MeCN)(PPh_3)(Ppy_3)]PF_6$, 4

To a suspension of **1** (0.085 g, 0.121 mmol) and NH_4PF_6 (0.020 g, 0.122 mmol) in MeOH (4 mL) was added a solution of MeCN in MeOH (1 mL, made by mixing 0.05 mL of MeCN in 5 mL of MeOH) and the resulting mixture refluxed for 10 min. The orange solution was pumped to dryness and the residue dissolved in acetone (5 mL) and filtered through Celite 545®. The volume was reduced (to ~3 mL) and ether (40 mL) added to form a yellow precipitate. The product was collected by filtration, washed with ether (3 × 5 mL), and dried under vacuum (0.084 g, 82%). Anal. calcd. for $C_{35}H_{30}ClF_6N_4P_3Ru$: C 49.45, H 3.56, N 6.59; found: C 49.58, H 3.64, N 6.73%.

Preparation of $[RuCl(PhCN)(PPh_3)(Ppy_3)]PF_6$, 5

To a red suspension of **1** (0.098 g, 0.14 mmol) and NH_4PF_6 (0.023 g, 0.14 mmol) in MeOH (10 mL) was added PhCN (0.05 mL) with a syringe. The resulting mixture was refluxed for 15 min during which time an orange solution formed. The MeOH was removed under vacuum and the residue dissolved in acetone (50 mL) and filtered through Celite 545®. The filtrate was concentrated (~5 mL) and Et_2O (30 mL) added. The yellow precipitate was filtered off and dried under vacuum (0.091 g, 71%). Anal. calcd. for $C_{40}H_{32}ClF_6N_4P_3Ru$: C 52.67, H 3.53, N 6.14; found: C 52.80, H 3.55, N 5.96%.

Preparation of $RuCl_2(CO)(Ppy_3)$, 6

To a red suspension of **1** (0.13 g, 0.19 mmol) in C_6H_6 (10 mL) was added CO gas (1 atm). The suspension was refluxed for 42 h in which time an orange-brown suspension developed. Hexanes (30 mL) were added to further precipitation and the precipitate collected by filtration. The product was reprecipitated from CH_2Cl_2 (15 mL) by Et_2O (20 mL), filtered, and dried in vacuo (0.05 g, 56%). Anal. calcd. for $C_{16}H_{12}Cl_2N_3OPRu$: C 41.31, H 2.60, N 9.03; found: C 41.05, H 2.64, N 8.91%.

Preparation of $RuCl_2(MeCN)(Ppy_3)$, 7

To a red suspension of **1** (0.13 g, 0.18 mmol) in C_6H_6 (10 mL) was added MeCN (1 mL, 19 mmol). The suspension was refluxed for 17 h. After the mixture was cooled to room temperature, the red precipitate was filtered off, washed with C_6H_6 (4 × 5 mL), and dried in vacuo (24 h), (0.06 g, 68%). Anal. calcd. for $C_{17}H_{15}Cl_2N_4PRu \cdot 1/6C_6H_6$: C 44.00, H 3.28, N 11.40; found: C 44.15, H 3.46, N 11.04%. The $1/6C_6H_6$ solvate was confirmed in the ^1H NMR ($CDCl_3$) spectrum at 7.36 ppm (s). Attempts to remove the solvate by heating (78°C, 24 h) under vacuum caused decomposition of the complex.

Preparation of $RuCl_2(PhCN)(Ppy_3)$, 8

To a red suspension of **1** (0.18 g, 0.25 mmol) in C_6H_6 (10 mL) was added PhCN (1 mL, 11 mmol). The suspension was refluxed for 4 h, then stirred for a further 16 h at room temperature. Hexanes (30 mL) were added and the red precipitate

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Mo K_α (λ = 0.71069 Å) radiation, graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1), $\sigma^2(F^2) = [S^2(C + 4B)]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m-n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

collected by filtration. This product was reprecipitated from CH_2Cl_2 (5 mL) with Et_2O (50 mL) and dried under vacuum (78°C, 16 h), (0.12 g, 88%). Anal. calcd. for $C_{22}H_{17}Cl_2N_4PRu$: C 48.90, H 3.17, N 10.37; found: C 48.87, H 3.50, N 10.09%.

Preparation of $RuCl_2(PPh_3)(OPpy_3)$, 9

A solution of **1** (0.21 g, 0.29 mmol) with excess *m*-CPBA (0.11 g, 0.51 mmol based on 80% purity) in $CHCl_3$ (25 mL) was stirred for 24 h. Hexanes (160 mL) were added and the resulting brown precipitate filtered. The brown precipitate was redissolved in $CHCl_3$ (5 mL), and hexanes (10 mL) added to form a light brown precipitate that was removed by filtration and discarded. Hexanes (150 mL) were added to the red filtrate causing formation of an orange-red precipitate that was collected and dried under vacuum (78°C, 48 h), (0.15 g, 52%). Anal. calcd. for $C_{33}H_{27}Cl_2N_3OP_2Ru$: C 55.39, H 3.80, N 5.87; found: C 55.14, H 3.80, N 6.06%.

X-ray crystallographic analysis of $RuCl_2(PPh_3)(Ppy_3)\cdot 2CH_2Cl_2$

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least squares on 2 sin θ/λ values for 25 reflections with 2θ = 20.1°–29.4°. The intensities of three standard reflections, measured every 200 reflections throughout the data collection, decayed linearly by 19%. The data were processed,[2] for Lorentz and polarization effects, decay, and absorption (semi-empirical, abased on azimuthal scans).

The structure was solved by the Patterson method. The asymmetric unit contains one molecule of the metal complex and two crystallographically independent dichloromethane molecules. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in calculated positions (C—H = 0.98 Å, B_H = 1.2 $B_{bonded\ atom}$). No correction for secondary extinction was necessary. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (11). The largest peak on the final difference map (0.72 e Å^{-3}) was located near the Ru atom. Final atomic coordinates and equivalent isotropic thermal parameters, selected bond lengths, and selected bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, complete tables of bond lengths and angles, torsion angles, non-bonded contacts, and least-squares planes have been deposited as supplementary material.[3]

Results and discussion

Synthesis and characterization of $RuCl_2(PPh_3)(Ppy_3)$ 1

The synthesis and reactivity of **1** are summarized in Fig. 1 and characterization data for **1–9** are reported in Tables 5–8.

Complex **1** is readily made by reaction of equimolar amounts of $RuCl_2(PPh_3)_3$ and Ppy_3, and its crystal structure is shown in Fig. 2. The Ppy_3 ligand binds facially via the three pyridyl nitrogens, forming three six-membered rings, and the coordination sphere is completed by *cis* chlorides and a PPh_3. The geometry at Ru is close to octahedral with the angles ranging from 84.9(1)° to 94.9(1)°. The Ru(1)—N(3) bond, *trans* to the PPh_3, is slightly longer than the Ru(1)—N(1 and 2) bonds *trans* to Cl, (2.117(4) Å versus 2.075(4) Å and 2.090(4) Å, respectively). These values are similar to those reported for $[Ru(Ppy_3)_2][C_7H_7SO_3]_2$ (2.06(1)–2.09(1) Å) (3), which has two Ppy_3 ligands coordinated facially through the pyridyl nitrogens and is the only other ruthenium structure reported for a Ppy_3 ligand bound in this manner. The Ru(1)—Cl(1 and 2) bond lengths are identical and the Ru(1)—P(2) bond length is typical for that of a Ru(II) phosphine complex (12).

Bond lengths in the Ppy_3 ligand do not change upon coordi-

[a] $B_{eq} = (8/3)\pi^2\Sigma\Sigma U_{ij}a^*_i a^*_j(\mathbf{a}_i \cdot \mathbf{a}_j)$.

nation when compared to data for the free ligand (13), but bond angles do change somewhat. The C(1)-P(1)-C(6) angle (between the two py groups *trans* to Cl) increases slightly to 104.2(2)°, while the C(1)-P(1)-C(11) and C(11)-P(1)-C(6) angles decrease to 98.8(2)°, as compared to an average of 101.9° in the free ligand (13). These angles in **1** are similar to those found in $[Ru(Ppy_3)_2][C_7H_7SO_3]_2$ (100.9(8)°, 99.6(8)°, and 99.6(7)°) (3).

The solution structure of **1** in $CDCl_3$ is consistent with the X-ray structure. The $^{31}P\{^1H\}$ NMR spectrum contains two singlets (Table 5), the result of two uncoupled phosphorus nuclei. The low-field signal is assigned to the PPh_3, while the high-field signal is assigned to the Ppy_3 ligand, the assignments being based on the coordination chemical shift Δ values of 47.7 and 5.56 ppm for the PPh_3 and the Ppy_3 ligands, respectively (14–16). The small Δ value for the Ppy_3 ligand is

consistent with its noncoordination. $^{31}P\{^1H\}$ NMR data for other *N,N',N''*-coordinated Ppy_3 complexes have not been reported. As well, the ^1H NMR ($CDCl_3$) spectrum (Table 6) shows multiple peaks in the phenyl region and is consistent with the complex containing two equivalent (*trans* to Cl) and one inequivalent (*trans* to PPh_3) pyridyl rings. For example, the H6 protons (H adjacent to N in the 2-pyridyl group) give rise to two signals with an integration ratio of 2:1. (That the H6 proton occurs at the most downfield position has been established by others (17, 18).) Thus, the solid state structure of **1** is maintained in $CDCl_3$. However, when **1** is dissolved in MeOH the complex dissociates a chloride (described below).

The synthesis and structure of **1** are similar to those of other Ru(II) complexes containing a facially coordinated six-electron donor ligand. Three examples are $RuCl_2(PPh_3)([9]aneS_3)$ (19), $RuCl(PPh_3)_2(Cp)$ (4), and $RuCl(PPh_3)_2(Tp)$ (20) (where $[9]aneS_3$ = 1,4,7-trithiacyclononane, and Tp = hydrotris(pyrazol-1-yl)borate). The remainder of the coordination spheres is completed by PPh_3 and Cl ligands, relative numbers of each

depending on the charge of the facial ligand. Finally, all of the complexes have been synthesized by PPh_3 ligand displacement from $RuCl_2(PPh_3)_3$, although this is not the most convenient method for $RuCl(PPh_3)_2(Cp)$ (4).

Dissociation of chloride from 1

The molar conductivity of **1** is reported in Table 7. In CH_3NO_2, complex **1** is essentially a nonconductor, while in MeOH the conductivity approaches that expected for a 1:1 conductor. The solvents have comparable dielectric constants (ε = 38.6 for CH_3NO_2, and 32.6 for MeOH (25)), but the higher donor number of MeOH (20.0 vs. 2.7 (25)) leads to the formation of an ionic complex containing a coordinated MeOH (Fig. 1). The complex was isolated as $[RuCl(MeOH)(PPh_3)(Ppy_3)]$-$BPh_4$, **2**, but no NMR data could be recorded because of low solubility. Unfortunately the C analysis for **2** is 0.76% low, but two bands in the IR spectrum can be assigned to a coordinated MeOH: ν_{OH} at 3207 cm^{-1} and ν_{OC} at 1001 cm^{-1}. For neat MeOH the corresponding bands appear at 3342 and 1033 cm^{-1}, respectively (26); the shifts are consistent with MeOH coordination.

The very similar UV–visible spectra of **1** in CH_2Cl_2 and in the solid state (Table 8) imply that the solution structure of **1** in CH_2Cl_2 is the same as that in the solid state (i.e., of the neutral $RuCl_2(PPh_3)(Ppy_3)$). The lower wavelength maxima observed in MeOH are partially attributed to the formation of the coordinated MeOH complex **2**. The spectrum of **2** in CH_2Cl_2, shows a λ_{max} at 414 nm, essentially the same as the 416 nm λ_{max} observed for **1** in MeOH, but the other λ_{max} for **2** (at 368 nm) corresponds to that seen for **1** in CH_2Cl_2. "Solvent effects" on the spectra are clearly important, and this is also evident when addition of a large excess of LiCl (even upto ~10 M) to an MeOH sample of **1** resulted in a change in the 416 nm maximum, to 422 nm, and not the 434 nm position seen for **1** in CH_2Cl_2.

Other ruthenium(II) phosphine complexes containing coordinated MeOH have been reported: the five-coordinate $RuCl_2(PMA)(PPh_3)$ (PMA = *o*-diphenylphosphino-*N,N*-dimethylaniline) reversibly binds MeOH in benzene, as determined by 1H NMR spectroscopy (27); the isolated $Ru(H)_2(CO)(PPh_3)_2(MeOH)$ has been characterized by IR and NMR spectroscopies (28); and $Ru(O_2CCF_3)_2(MeOH)(CO)(PPh_3)_2$ has been characterized by X-ray analysis (29). More closely related, the ionic behaviour observed for **1** parallels that of $RuCl(PPh_3)_2(Cp)$, which is a non-electrolyte in acetone but dissociates appreciably in MeOH (22). Haines and Du Preez isolated the complex $[Ru(MeOH)(PPh_3)_2(Cp)]BPh_4$, which they identified by NMR and IR spectroscopy, although no actual data were presented. As here, the product was not obtained analytically pure. Nevertheless, the ability of $RuCl(PPh_3)_2(Cp)$ to dissociate chloride in MeOH has led to a variety of chloride exchange reactions for the Cp complex (4), and similar reactivity is seen with **1**.

Chloride-substitution reactions

The chloride-substitution reactions are summarized in Fig. 1.

When **1** was heated in CD_3OD under 1 atm CO gas, the initially red suspension changed into a clear yellow solution; the in situ $^{31}P\{^1H\}$ NMR spectrum contained two singlets attributed to the species $[RuCl(CO)(PPh_3)(Ppy_3)]Cl$. However, on a synthetic scale, attempts to isolate this salt always resulted in the formation of an oil. A similar reaction carried out in the presence of NH_4PF_6, however, did allow for isolation of $[RuCl(CO)(PPh_3)(Ppy_3)]PF_6$ **3** as an analytically pure yellow salt.

The $^{31}P\{^1H\}$ NMR (CD_3OD) spectrum of **3** matched that of the in situ species and consisted of two singlets for two uncoupled phosphorus nuclei. The IR spectrum contained a single CO stretch and the compound was a 1:1 conductor in nitromethane. The H6 protons of the Ppy_3 ligand gave rise to three signals in the ^1H NMR spectrum indicating the inequivalence of the three pyridyl groups. These data are consistent with the structure given in Fig. 3, which shows the compound as a racemate.

There is a solvent dependence for the formation of **3**. In ace-

[c]In MeOH. Calculated using the molecular weight for $RuCl_2(PPh_3)(Ppy_3)$ (699.52 g mol^{-1}). If calculated with the molecular weight of $[RuCl(MeOH)(PPh_3)(Ppy_3)]Cl$ (731.56 g mol^{-1}) the molar conductivity is 64.4.

[d]Appropriate reference appears in parentheses for the Cp complexes.

tone, the reaction at room temperature was slow (11 d) and a mixture of mainly **3** and some $RuCl_2(CO)(Ppy_3)$ **6** (see below) was obtained. The minor product is formed via displacement of the PPh_3 of **1**. In MeOH, the formation of the cationic MeOH intermediate allows for a more efficient mechanism for the formation of **3**.

Use of a procedure similar to that described above for **3** allowed for isolation of the nitrile complexes

$[RuCl(L)(PPh_3)(Ppy_3)]PF_6$, where L = MeCN (**4**) or L = PhCN (**5**). The isolated complexes (Fig. 3) were characterized in the same manner as **3**. Only one equivalent of MeCN was used to make **4**. When excess or neat MeCN was used, the isolated product contained small amounts of impurities, as determined by $^{31}P\{^1H\}$ NMR. Similarly, when $RuCl_2(PPh_3)(Ppy_3)$ and one equivalent of NH_4PF_6 were refluxed in a mixture of PhCN and some acetone (needed to dissolve NH_4PF_6), the isolated product mixture contained **5** and a second product which showed a $^{31}P\{^1H\}$ singlet at δ 6.30 (in acetone-d_6) or 5.05 (in CD_2Cl_2). This second product, also formed from refluxing $RuCl_2(PhCN)(Ppy_3)$ **8** in MeOH with one equivalent of NH_4PF_6 and excess PhCN, is tentatively formulated as $[RuCl(PhCN)_2(Ppy_3)]PF_6$. The complex was not further characterized because of the presence of other minor impurities. Finally, when **1** is refluxed in neat PhCN without NH_4PF_6, $RuCl_2(PhCN)(Ppy_3)$ **8** is formed (see below).

In summary, the best route to chloride-substitution products of **1** is via reactions in MeOH, which allow for dissociation of chloride and disfavour substitution of PPh_3, which occurs in other solvents.

Triphenylphosphine-substitution reactions

By use of a nonpolar solvent such as benzene, the PPh_3 in **1** is readily displaced, the chemistry being similar to that of $RuCl(PPh_3)_2(Cp)$, where the PPh_3 has been replaced by other phosphines, CO, and isocyanides, to name a few (4).

The refluxing of **1** in C_6H_6 under 1 atm CO gas gives two precipitated products, based on the $^{31}P\{^1H\}$ NMR ($CDCl_3$) spectrum which contained two singlets at δ 2.36 (major) and 4.77 (minor). The complex $RuCl_2(CO)(Ppy_3)$ **6** giving rise to the singlet at 2.36 ppm was separated as an orange solid by precipitation from CH_2Cl_2 with Et_2O, while the minor product was not characterized. The ^1H NMR ($CDCl_3$) spectrum of **6** contained two H6 signals integrating in a 2:1 ratio, and the NMR data and the single νCO IR band are consistent with a structure analogous to that of $RuCl_2(PPh_3)(Ppy_3)$ (Fig.3).

Similar reactions of **1** with MeCN and PhCN (Fig. 1) allowed for isolation of $RuCl_2(MeCN)(Ppy_3)$ **7** and $RuCl_2(PhCN)(Ppy_3)$ **8**, respectively, with structures similar to that of the CO complex. These two complexes were isolated in slightly different manners. Complex **8** formed as a red precipitate during the reaction in benzene, the remainder of the product being precipitated by addition of hexanes. The product was then reprecipitated from CH_2Cl_2 with Et_2O to remove a C_6H_6 solvate that otherwise was not removed under vacuum. Finally, **8** was heated under vacuum to remove any remaining solvates, and an analytically pure product was produced. Complex **7** was isolated directly as a red precipitate from the C_6H_6 solution without the addition of hexanes and dried under vacuum for 24 h. The analysis of this complex was calculated including 1/6 mol of C_6H_6 solvate. The C_6H_6 solvate was confirmed by integration of the ^1H NMR ($CDCl_3$) spectrum. When **7** was heated in vacuum (78°C, 24 h) the complex partially decomposed, becoming red-brown in colour; the elemental analysis had a much lower nitrogen percentage, suggesting that MeCN was being lost.

A further factor perhaps assisting the substitution of the PPh_3 in **1** is that the complex is only slightly soluble in C_6H_6, and thus the concentration of the substituting ligand is high,

relative to that of **1**. The longer reaction time required for the CO complex in comparison to the nitrile complexes (42 versus 17–20 h) is probably the result of the relatively low concentration of CO versus that of the nitriles.

There is a striking similarity between the carbonyl and nitrile stretches of the *N,N',N''*-Ppy_3 complexes and those of the analogous Cp complexes (see Table 7; no data could be found for the Cp analogues of **7** and **8**). For example, the cationic carbonyl complexes produced by substitution of the chloride in **1**, or in $RuCl(PPh_3)_2(Cp)$, have essentially the same CO stretches, indicating that the electronic properties of the Ru centre, in terms of back-donation into the π orbital of the CO ligand, are the same. The implication is that the 14-electron fragments $RuCl(Ppy_3)$ and $Ru(PPh_3)(Cp)$ have similar electronic properties. Within either the Ppy_3 or Cp systems, the cationic complexes have the higher ν_{CO} or ν_{CN} values, consistent with the usual property of less π-back-donation from the Ru in the cationic systems.

Reaction of 1 with oxygen and *m*-CPBA

The in situ reaction of **1** with 1 atm O_2 gas in $CDCl_3$ was followed by $^{31}P\{^1H\}$ NMR spectroscopy and, after 3 d at room temperature, signals for **1** and a new species were present in the spectrum. The new signals are for the complex $RuCl_2(PPh_3)(OPpy_3)$ **9** (see Fig. 3), which was synthesized independently using *m*-CPBA as the O-atom donor. In the O_2-system, after 12 d, **9** is the only species present along with a small peak for $OPPh_3$ (δ_P 29.6). Thus, the free phosphorus of the Ppy_3 group in $RuCl_2(PPh_3)(Ppy_3)$ is oxidized to the phosphine oxide, indeed at a rate comparable to that of free Ppy_3. The presence of $OPPh_3$ in the spectrum of the in situ reaction suggests that a second ruthenium product is being formed; this could be a paramagnetic ruthenium-oxo or -peroxo-type species (30) but, because of the relatively small amount of $OPPh_3$ formed, no attempts were made to isolate this other product. In the system of **9** from **1** using *m*-CPBA, the benzoic acid by-product was removed by selective precipitation with hexanes. Reaction of $RuCl_2(PPh_3)_3$ with $OPpy_3$ gave a complex mixture of products including **9**.

Other complexes containing a coordinated $OPpy_3$ ligand have the general formula $[M(OPpy_3)_2][X]_2$ (M = Mn, Co, Ni, Cu, Zn, with $X = ClO_4$ (1); or M = Ru, with $X = PF_6$ (31)), and have been synthesized directly using $OPpy_3$. The $OPpy_3$ ligands coordinate via the three pyridyl nitrogens and form octahedral complexes. Infrared data are not reported for the Ru complex, but the ν_{PO} stretches for the first-row transition metal complexes range from 1231 to 1236 cm^{-1}; **9** gives a similar ν_{PO} stretch at 1235 cm^{-1}. These νPO values are higher than that of the free $OPpy_3$ ligand, 1215 cm^{-1} (1), the increase possibly resulting from the configuration imposed on the ligand upon coordination, or from an increase in $p\pi$–$d\pi$ bonding between the oxygen and phosphorus, caused by an increase in the electronegativity of the phosphorus, induced by the coordinating pyridyl groups (1). This is consistent with the general trend for phosphine oxides (OPR_3) which show an increase in the ν_{PO} wave numbers as R becomes more electronegative (ref. 25, p. 827).

A comparison of the UV–visible spectra of **9** with those of **1** (Table 8) shows that oxidation of the Ppy_3 ligand has only a small influence on the electronic environment at the metal centre, and imply that **9** also dissociates chloride in MeOH.

Nucleophilic addition to di- and poly-iron arene complex cations

Alaa S. Abd-El-Aziz, Debbie A. Armstrong, Shelly Bernardin, and Harold M. Hutton

Abstract: Hydride and cyanide addition to a series of di- and polycyclopentadienyliron arene complex cations with etheric bridges is described. Reaction of the di-iron complexes with sodium borohydride resulted in the formation of a number of adducts. *p*-Methyl- and *o,o*-dimethylphenoxybenzene cyclopentadienyliron complexes were used as models in this study to allow for the characterization of the analagous di-iron complexes. The use of HH COSY and CH COSY NMR techniques enabled us to identify the isomeric nature of these adducts. The hydride addition results indicated that the etheric substituent had the predominant effect over the methyl group, leading to a higher addition ratio to the *meta*-, followed by the *ortho*-, then the *para*-positions. It was also clear that in the di-iron system, the hydride addition to each complexed arene ring took place independently. The addition of the cyanide anion to di- and poly-iron arene systems was more selective than that of the hydride anion. Reaction of sodium cyanide with *p*-methyl- or *o*-methyl-substituted arene complexes led to the formation of one adduct, with the cyanide being added to the *meta* position to the etheric bridges. However, cyanide addition to the di-iron complex, with a methyl substituent attached at the *meta* position of each complexed arene, led to the formation of a mixture of adducts. Cyanide addition to the poly-iron system with *p*-substituted arenes proved to be very selective, allowing for the formation of one adduct. Oxidative demetallation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) produced the uncomplexed polyaromatic ethers with cyano groups in a very good yield.

Key words: cyclopentadienyliron, arene, nucleophilic addition, hydride, cyanide.

Résumé : On décrit l'addition des ions hydrure et cyanure à une série de complexes cationiques di- et polycyclopentadiénylfer–arène avec ponts éthers. La réaction des complexes bi-fer avec le borohydrure de sodium conduit à la formation d'un certain nombre d'adduits. Dans cette étude, on a utilisé les *p*-méthyl- et *o,o*-diméthylphénoxybenzène cyclopentadiénylfer comme modèles permettant de caractériser les complexes di-fer analogues. L'utilisation des techniques de RMN HH COSY et CH COSY ont permis d'identifier la nature des produits isomères de ces adduits. Les résultats obtenus pour l'addition d'hydrure ont indiqué que le substituant éther a un effet plus important que celle du méthyle; ceci conduit à un rapport d'addition plus élevé pour la position *méta*, suivie alors par les positions *ortho* et *para*. Il est également clair que, dans le système bi-fer, l'addition d'hydrure à chacun des noyaux arènes se fait d'une façon indépendante. L'addition de l'anion cyanure aux systèmes di- et poly-fer–arène est plus sélective que celle de l'anion hydrure. La réaction du cyanure de sodium avec les complexes arènes *p*-méthyl- ou *o*-méthyl-substitués conduit à la formation d'un adduit dans lequel le cyanure s'ajoute en position *méta* par rapport au pont éther. Toutefois, l'addition du cyanure au complexe di-fer portant un substituant méthyle en position *méta* de chaque arène complexé conduit à la formation d'un mélange d'adduits. L'addition de cyanure au système poly-fer avec des arènes *p*-substitués s'avère sélective et conduit à la formation d'un seul adduit. La démétallation oxydante de la 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) conduit, avec de très bons rendements, à des éthers polyaromatiques non complexés portant des groupes cyano.

Mots clés : cyclopentadiénylfer, arène, addition nucléophile, hydrure, cyanure.

Introduction

Addition of carbanions, hydrides, phosphorus and nitrogen anions to organometallic complexes has led to novel routes to the functionalization of aromatic compounds (1–15). It is well known that the complexation of a metal moiety, such as $(CO)_3Cr$, $(CO)_3Mn^+$, $(C_6H_6)Fe^{2+}$, or $CpFe^+$ to an aromatic system activates the arene ring towards nucleophilic addition reactions (4-26). In a review by Davies et al., a set of rules was presented to predict the site of nucleophilic addition to organo-transition metal cations containing unsaturated hydrocarbon ligands (1). Other reports have indicated that addition occurs on the *exo* face of the arene ligand, as confirmed by NMR and X-ray crystallographic studies (27, 28).

Due to the ease of complexation of the $(CO)_3Cr$ moiety with aromatic systems, the vast majority of research in this field has involved the use of these types of complexes (8). Addition of

nucleophiles to (arene)$Cr(CO)_3$ has led to the formation of anionic [$(CO)_3$Cr(cyclohexadienyl)] intermediates. These adducts are air sensitive and usually undergo oxidative demetallation without isolation, allowing for the functionalization of the arene compounds (2). A novel characteristic of the cyclohexadienyl intermediates is that they may react with electrophilic reagents, enhancing the flexibility of this methodology.

Tremendous effort has been directed toward the use of cationic metal moieties such as $(CO)_3Mn^+$, $CpFe^+$, or $(C_6H_6)Fe^{2+}$ for the activation of arenes, allowing for the formation of neutral functionalized cyclohexadienyl complexes. The use of $(CO)_3Mn^+$ species as an activating group has led to the synthesis of a number of potentially biologically active chiral compounds (16, 17), as well as the functionalization of heterocyclic and cyclohexadiene compounds (15, 18, 19). Addition reactions of a variety of nucleophiles (H^-, CN^-, $CH_3COCH_2^-$, CH_3^-, Cl_3C^-) to cyclopentadienyliron arene cations have also been investigated (27–43). Sutherland et al. examined the hydride addition reactions of various substituted $[(C_6H_5X)FeCp]^+$ systems (37). This study demonstrated that strongly electron-donating substitutents direct hydride addition to the *meta* and *para* positions of the substituent, while the strongly electron-withdrawing substituent directs to the *ortho* position. These results are consistent with those predicted from molecular orbital calculations (32–36). Steric effects from the methyl groups *ortho* to the electron-withdrawing substituent of arene complexes have been reported with hydride addition (41). When *ortho* positions were hindered, addition in the *meta* and *para* positions increased. However, cyanide addition did not display the same sensitivity to steric factors; addition in this case occurred in the *ortho* position only. It was proposed that steric, electronic, and free valency effects all play a role in nucleophilic addition reactions (32, 37).

We have developed an efficient synthetic route to di- and polycyclopentadienyliron arene cations (44–48). The need to devise simple methods for functionalization of these types of complexes led us to the study of nucleophilic substitution and addition reactions. Our recent investigation of the functionalization of polyaromatic arene complexes via nucleophilic substitution has been successful (44–46). In this article we report hydride and cyanide addition to a number of methyl-substituted mono-, di-, and polycyclopentadienyliron complexes.

Results and discussion

Hydride addition

Hydride addition to bis(cyclopentadienyliron) arene di-cations resulted in the formation of a number of isomers. Due to the complexity of the NMR spectra of these adducts, the mono-iron systems were used as models for this investigation. While hydride addition to $CpFe^+$ complexes of monosubstituted arenes has been carefully examined (37), hydride addition to disubstituted arene complexes has not been reported. Reactions of (η^6-isomeric phenoxytoluene-η^5-cyclopentadienyliron) cations with an excess of sodium borohydride gave rise to a mixture of adducts, as illustrated in Scheme 1. The ^1H and ^{13}C NMR spectra were complicated by the number of isomers present; thus it was necessary to characterize the products using HH COSY and CH COSY techniques. For proton assignment, the chemical shifts of the individual isomers were determined from the connectivities in the HH COSY spectrum. Once this information was obtained, ^{13}C chemical shifts were then assigned using CH COSY.

It has been established that a phenoxy substituent attached to the arene $CpFe^+$ complex directs the addition of the nucleophile to *meta* > *ortho* > *para*, whereas a methyl substituent directs *ortho* > *meta* > *para* (29–32, 37). In this study, it was very clear that the phenoxy substituent has a stronger influence on the site of addition than has the methyl substituent due to its greater strength as an electron-donating group. For clarity, we will refer to the site of addition with respect to the etheric bridge. As shown in Scheme 1, the major adduct for complex [**1**] was [**3b**] (66%), formed at the position *meta* to the phenoxy substituent. The second most abundant isomer [**3a**] (30%) displayed addition *ortho* to the phenoxy group. Trace amounts of the product *ipso* to the methyl substituent (*para* to the phenoxy substituent), [**3c**] (4%), were present; however, it was difficult to fully characterize this isomer. For complex [**2**], in which the positions *ortho* to the phenoxy substituent are hindered by methyl groups, the major addition was at the *meta* position with respect to the phenoxy group [**4b**] (60%), as illustrated in Scheme 1. Addition *para* to the phenoxy gave rise to the second most abundant isomer [**4c**] (28%). The minor isomer, [**4a**] (12%), resulted when addition *ipso* to the methyl group took place. Attempts to separate the various isomers by means of column chromatography were

unsuccessful due to the instability of these products. The ^1H and ^{13}C NMR data of the addition products [**3**] and [**4**] are listed in Tables 1 and 2. For the purpose of identification, the site of hydride addition has been designated position one, and numbering proceeds around the ring, so that the phenoxy group is the lowest possible number. As an example, Fig. 1 illustrates the 2D HH COSY for the hydride addition to complex [**1**] (adducts [**3a–c**]).

Reaction of 1.0 mmol of 1,4-bis[(η^6-4-methylphenoxy-η^5-cyclopentadienyl)iron]benzene cation [**5**] with 5.0 mmol of sodium borohydride produced a mixture of isomers, as shown in Scheme 2. Since the complexed arene rings are separated from one another by a (OC_6H_4O) group, as shown in Scheme 2, the addition to each of these rings should be independent. Thus a variety of symmetrical and asymmetrical adducts should be obtained. If the addition takes place at the same site on both rings, there will be no significant change in the chemical shifts between the protons or carbons of one cyclohexadienyl ring and the other. As an example, it was not possible to distinguish between the chemical shift for the *ortho-ortho* isomer [**6a**] and the asymmetric *ortho* addition of isomer [**6c**]. The relative percentage of the addition product calculated

from the NMR spectra for each isomer was based on the total amount of specific addition in each adduct. The *meta* isomer was calculated to be 59%, which was the total of the hydride addition in *meta-meta* [**6b**], *meta-ortho* [**6c**], and the trace *meta-para*. The total *ortho* addition was 35%, which represents the addition *ortho-ortho* [**6a**], *ortho-meta* [**6c**], and a trace of *ortho-para* adduct. Trace amounts of the *para* addition products were also observed (6%). It is also important to note that we did not observe diastereomers for these adducts. The ^{1}H and ^{13}C NMR chemical shifts are shown in Tables 3 and 4, where [**6a**] and [**6b**] represent the symmetrical *ortho* and *meta* isomers, respectively, as well as the *ortho* and *meta* addition of the asymmetrical structure [**6c**].

As part of this study, we blocked the two positions *ortho* to the etheric bridges by two methyl groups in order to enhance addition to the *meta* position. Hydride addition to 1,4-bis[(η^6-(2,6-dimethyl)phenoxy-η^5-cyclopentadienyl)iron]benzene hexafluorophosphate, [**7**], resulted in the formation of three major isomers, as well as traces of a few minor isomers, as shown in Scheme 3. Using the same strategy as described above, the predominant isomer was determined to be the *meta* adduct [**8a**] (51%); *para* [**8b**] (41%) and traces of *ortho* adducts (8%) were also present. The spectral analyses for these adducts are given in Tables 3 and 4. The position of hydride addition was found to be dependent on the substituents on the ring.

Cyanide addition

Nitrile groups are unique in their ease of transformation to other functional groups such as acids, esters, amines, and amides (49, 50). This versatility is valuable in the investigation of synthetic routes for the functionalization of organic and polymeric compounds. In the past few years, we have been involved in the synthesis and characterization of polyaromatic ethers with or without pendant metallic moieties (44–47). In this article, we report the addition of cyanide to a number of $CpFe^+$ polyaromatic ether complexes. Schemes 4 and 5 show the relative distribution of adducts obtained from cyanide addition to isomeric bis(η^6-methylphenoxy-η^5-cyclopentadienyl)ironbenzene hexafluorophosphate [**5**, **9**, and **12**] . In the case of complexes [**5**] and [**9**], single pure products [**10**] and [**11**] were obtained. Cyanide attack on [**5**] and [**9**] took place *meta* to the etheric bridge and *ortho* to the methyl group. In contrast, the *meta* isomer [**12**] gave rise to three possible adducts [**13a–c**]. These isomers displayed *ortho* addition with respect to both etheric and methyl substituents [**13a**] and addition *ortho* to the etheric bridge and *para* to the methyl group [**13b**]. As well, the asymmetrical isomer displayed addition *ortho* to one complexed arene ring with respect to both substituents and *ortho* to the etheric bridge, as well as *para* to the methyl substituent for the second complexed arene [**13c**]. The ^{1}H and ^{13}C NMR of the bimetallic adducts are listed in Tables 5 and 6.

The higher selectivity of the cyanide addition was intriguing and prompted us to examine the polyiron systems. Polyaromatic ether complexes with pendant cyclopentadienyliron moieties [**14**]–[**19**] were treated with an excess of NaCN, as described in Scheme 6. Selective addition *meta* to the etheric bridges was obtained in all of these complexes, leading to the formation of the neutral (cyclohexadienyl)FeCp systems [**20**]–[**25**] in yields of 72–81% (based on the recovered starting cationic complexes). Separation of these adducts from their starting cationic complexes was carried out simply by

extracting the adducts from the mixture with chloroform. These results are consistent with those obtained for the analogous diiron complexes. Figure 2 illustrates ^{1}H NMR of the hepta-iron adduct [**24**] as an example of cyanide addition to the poly-iron series. The detailed NMR data for adducts [**20–25**] are given in Tables 7 and 8. Overall, the *meta* position is influenced by both the etheric and methyl substituents. Infrared spectroscopy was used to confirm the presence of the cyano groups. The ν_{CN} for all cyano adducts were in the range of 2228–2229 cm^{-1}. Our findings are consistant with those of Watts and co-workers, who proposed that addition is influenced by both the inductive and resonance effects of the substituents (29–32).

The free functionalized organic product can be obtained through a simple oxidative demetallation step using 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ). As an example, a solution of di- or poly-iron cyclohexadienyl adducts [**10**] and [**24**] in acetonitrile was reacted with DDQ for 30 min, leading to the free organic compounds [**26**] and [**27**] in 75 and 78% yield, respectively (Scheme 6). Spectral and analytical data for these compounds are listed in the experimental section of the paper.

In conclusion, spectral data for the hydride reactions of mono- and di-iron arene complexes showed that the etheric substituent has a larger overall effect on the charge distribution on the ring in comparison to the methyl substituent(s). The proportions of the isomers for the bimetallic complexes were in agreement with their analogous monoiron species. In contrast, the reactions of the cyanide anion with di- and poly-iron arenes were selective, with addition at the *meta* position to the etheric bridges. The only isomer that gave a mixture of adducts was the bis[(η^6-3-methylphenoxy-η^5-cyclopentadienyl)iron]benzene hexafluorophosphate [**12**]. In this case, the addition was *ortho* and *para* to the methyl group and *ortho* to the etheric bridges. The oxidative demetallation proved to be successful, allowing for the liberation of the functionalized nitrile compounds from their corresponding iron moieties. The selectivity of the cyanide addition to the poly-iron system provides a unique route to the functionalization of polyaromatic ethers.

Experimental

Measurements

^{1}H and ^{13}C NMR spectra were recorded at 200 and 50 MHz (Gemini 200), respectively, while HH COSY and CH COSY were recorded on a Bruker 500 NMR spectrometer, with chemical shifts calculated from $CDCl_3$ (7.26 for proton and 77.00 for carbon). Coupling constants were measured in Hz. IR spectra were recorded with an FT-IR Bomem MB102 spectrometer.

Reagents

Starting complexes [**1**, **2**, **5**, **7**, **9**, **12**, **13–28**] were prepared by established procedures (45-47). Sodium borohydride (Alfa), DDQ (Aldrich), and sodium cyanide (Aldrich) are commercially available and were used without further purification. All solvents (reagent grade) were used without further purification, with the exception of THF, which was freshly distilled. Silica gel, 60–100 mesh, was used in the column chromatographic purification of the liberated arenes.

Hydride addition reactions

In a 25 mL flask, 0.5 mmol of arene complex and 1.25 mmol of $NaBH_4$ (monoiron complexes) or 2.5 mmol of $NaBH_4$ (diiron complexes) in 10 mL of THF and 1.0 mL of DMF were stirred for 3 h under nitrogen. The bright orange product was then filtered through sintered glass, washed with 10 mL of water, and extracted with $CHCl_3$ (3 × 20 mL). The bright orange extract was washed with water, dried over $MgSO_4$, and the solvent was removed by rotary evaporation, yielding a red or orange oil.

Cyanide addition reactions

An example of the cyanide addition reactions: In a 25 mL flask, 0.5 mmol of 1,4-bis[(η^6-4-methylphenoxy-η^5-cyclopentadienyl)iron]benzene hexafluorophosphate and 3.0 mmol of NaCN in 5 mL of DMF and 1 drop of water were stirred for 3 h under a nitrogen atmosphere. The red solution was extracted with $CHCl_3$ (2 × 20 mL), washed with water, and dried over $MgSO_4$. The solvent was evaporated off, yielding a red oily product.

Demetallation reactions

To a solution of the adduct (0.5 mmol) in 10 mL of acetonitrile, 0.5 mmol of DDQ (2,3-dichloro-5,6-dicyano-1,4-benzoquinone) was added, and the resulting mixture was left to stir for 30 min at room temperature. The black solution was then filtered through sintered glass and evaporated to dryness. The product was dissolved in CH_2Cl_2, placed on a short silica gel column and eluted with $CHCl_3$ and CH_2Cl_2; the resulting solutions were dried over $MgSO_4$ and evaporated to dryness to give the free functionalized polyaromatic ethers (**26** and **27**), which have been characterized:

26: ν_{CN}: 2236 cm^{-1}. ^{1}H NMR δ: 2.50 (s, 2CH_3), 6.90 (d, 8.6 Hz, 2H, Ar), 7.11 (d, 8.6 Hz, 2H, Ar), 7.54 (d, 7.8 Hz, 2H, Ar),

7.63 (s, 2H, Ar), 7.71 (d, 8.0 Hz, 2H, Ar); ^{13}C NMR δ: 21.66 (CH_3), 115.81 (CN), 117.74, 120.46, 130.04, 133.38, 133.88 (ArH), 112.90, 115.52, 144.70 (q). Anal. calcd. for $C_{22}H_{16}O_2N_2$: C 77.63, H 4.74, N 8.23; found: C 77.41, H 4.93, N 8.41.

27: ν_{CN}: 2234 cm^{-1}. ^{1}H NMR δ: 2.49 (s, 6H, CH_3), 7.64 (s, 2H, Ar), 7.76 (d, 8.1 Hz, 2H, Ar), 7.54 (d, 8.1 Hz, 2H, Ar), 7.63 (s, 5H, Ar), 7.57 (d, 8.1 Hz, 5H, Ar), 7.73 (d, 8.1 Hz, 5H, Ar), 6.77–7.34 (m, 24H, Ar). ^{13}C NMR δ: 21.70 (CH_3), 115.40, 115.23 (CN), 119.41, 119.82, 121.90 , 122.71, 130.53, 130.92, 134.36, 133.40 (ArH), 112.57, 115.22, 115.30, 144.31 (q). Anal. calcd. for $C_{87}H_{51}O_{12}N_7$: C 75.37, H 3.71, N 7.07; found: C 75.22, H 3.89, N 6.92.

Evidence for an intramolecular transition metal Arbuzov reaction

Zhao Chen, Chet Jablonski, and John Bridson

Abstract: Reaction of [CpCo(C_3F_7)(I)(L)], (L = PPh_2Me (**1***a*), $PPhMe_2$ (**1***b*), PMe_3 (**1***c*), and $PPh(OMe)_2$ (**2**)), with $PPh(OMe)_2$ affords diastereomeric Co- and P-chiral metallophosphinates CpCo(C_3F_7)(L)(P(O)Ph(OMe)), **4***a*,*b*,*c* and **6**, respectively. The solid state structure and relative configuration of the lower R_f diastereomeric phosphinate CpCo(C_3F_7)($PPh(OMe)_2$)(P(O)Ph(OMe)), **6**-2, was determined by X-ray diffraction. *RR*;*SS*-**6**-2 crystallizes in the triclinic system with space group $P\bar{1}$(no. 2), with a = 12.928(4) Å, b = 14.683(4) Å, c = 7.666(2) Å, α = 103.50(2)°, β = 101.31(3)°, γ = 109.50(2)°, V = 1272.8(7) Å^3, Z = 2, and R = 0.036 (R_w = 0.030) for 2867 reflections with $I > 3.00\sigma(I)$. CpCo(C_3F_7)(I)($PPh(OMe)_2$), **2**, reacts with PPh_2Me to yield the same Co- and P-chiral phosphinate products as obtained for the reaction of **1***a* with $PPh(OMe)_2$, albeit with different optical yields. The product stereochemistry is not accounted for by the established mechanism for transition metal Arbuzov-like dealkylations, which requires formation of a common, ionic intermediate [CpCo(C_3F_7)(PPh_2Me)($PPh(OMe)_2$)]$^+$, **3**, via iodide substitution and subsequent nucleophilic attack at carbon. A parallel intramolecular dealkylation pathway is proposed to account for the results.

Key words: stereochemistry, mechanism, Arbuzov, Co(III) complex, chiral metal, X-ray

Résumé : La réaction du [CpCo(C_3F_7)(I)(L)], (L = PPh_2Me (**1***a*), $PPhMe_2$ (**1***b*), PMe_3 (**1***c*) et $PPh(OMe)_2$ (**2**)) avec du $PPh(OMe)_2$ conduit aux métallophosphinates diastéréomériques Co- et P-chiraux CpCo(C_3F_7)(L)(P(O)Ph(OMe)) **4***a*,*b*,*c* et **6** respectivement. Faisant appel à la diffraction des rayons X, on a déterminé les structures solides et les configurations relatives du phosphinate diastéréomère de R_f le plus faible, CpCo(C_3F_7)($PPh(OMe)_2$)(P(O)Ph(OMe)), **6**-2. Le composé *RR*;*SS*-**6**-2 cristallise dans le système triclinique, groupe d'espace $P\bar{1}$ (n° 2) avec a = 12,928(4), b = 14,683(4) et c = 7,666(2) Å, α = 103,50(2)°, β = 101,31(3)° et γ = 109,50(2)°, V = 1272,8(7) Å^3, Z = 2 et R = 0,036 (R_w = 0,030) pour 2867 réflexions avec $I > 3{,}00\sigma(I)$. Le CpCo(C_3F_7)(I)($PPh(OMe)_2$), **2**, réagit avec du PPh_2Me pour conduire aux mêmes produits Co- et P-chiraux que ceux obtenus par réaction du composé **1***a* avec du $PPh(OMe)_2$; les rendements optiques sont toutefois différents. On ne peut pas expliquer la stéréochimie du produit en se basant sur le mécanisme établi pour les réactions de désalkylations de type Arbuzov des métaux de transition pour lesquels il est nécessaire de former un intermédiaire ionique commun, [CpCo(C_3F_7)(PPh_2Me)($PPh(OMe)_2$)]$^+$, **3**, par le biais d'une substitution de l'iodure et d'une attaque nucléophile subséquente au niveau du carbone. Pour expliquer les résultats, on propose une voie réactionnelle parallèle de désalkylation intramoléculaire.

Mots clés : stéréochimie, mécanisme, Arbuzov, complexe de Co(III), métal chiral, rayon X.

[Traduit par la rédaction]

Introduction

Phosphites and phosphonites react readily with transition metal iodides to give metallophosphonates and -phosphinates, respectively (1, 2). Mechanistic studies have identified the predominant mechanism as a two-step sequence (cf. eq. [1]) that parallels the classic organophosphorus Arbuzov rearrangement (3–9). Initial halide substitution at the metal centre gives a cationic phosphite or phosphonite intermediate that can, in favourable circumstance, be directly observed (1, 3–7, 9–12). Subsequent attack of halide ion at carbon occurs with C—O bond cleavage to displace the thermodynamically stable phosphoryl species. In the course of our studies of transition-metal-mediated Arbuzov chemistry as a platform for diastereoselective synthesis of P-chiral phosphinates from prochiral phosphonites, asymmetric Co(III) auxiliaries have been developed that afford P-chiral products with fair to good optical yields (2, 6, 13, 14). In this report we present evidence, derived from product distribution studies, which suggests that a novel, intramolecular dealkylation pathway competes with the accepted mechanism of eq. [1].

Received February 1, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

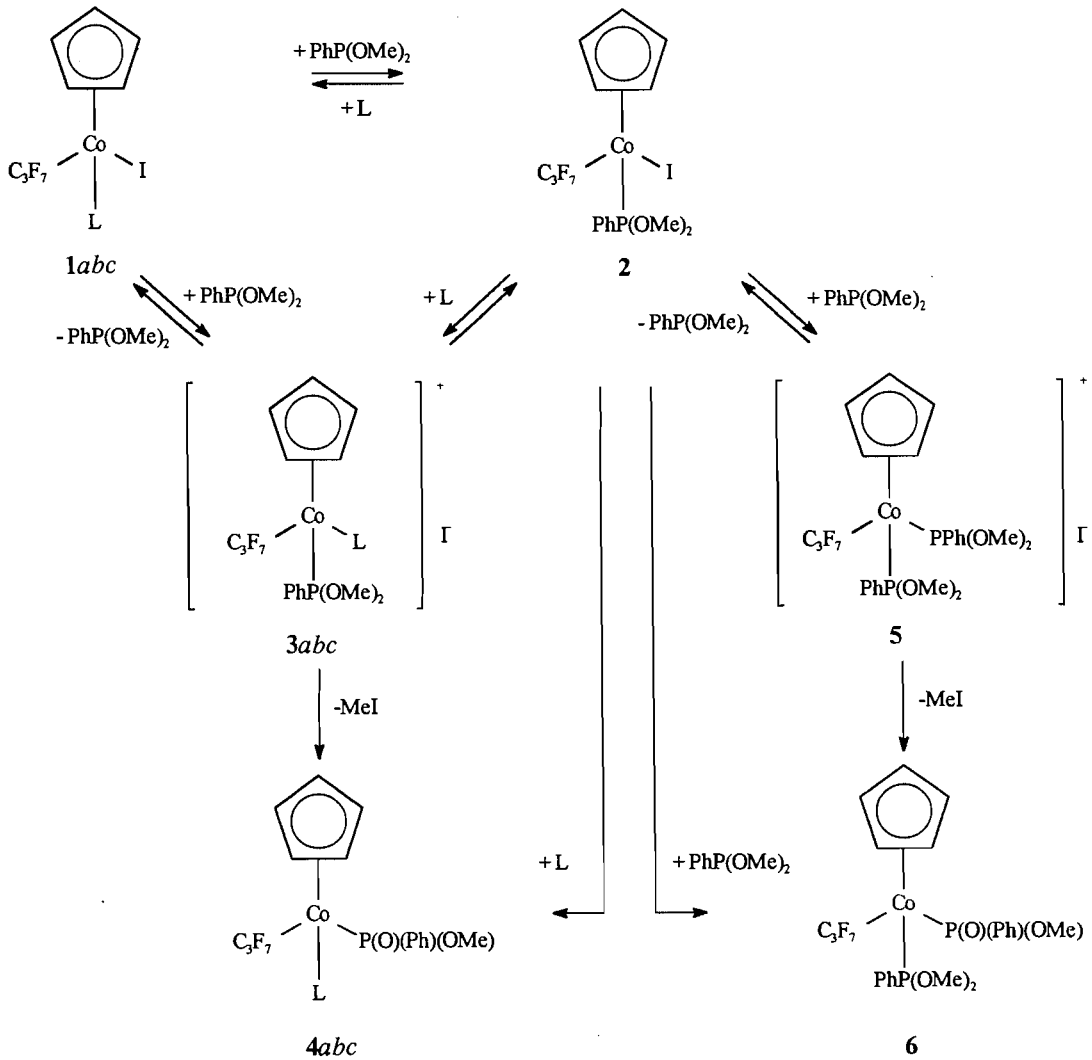
Results and discussion

Substitution and Arbuzov chemistry of 1 and 2

Treatment of the iodo phosphine complexes η^5-CpCo(C_3F_7)(L)(I) (**1***a*, L = PPh_2Me; **1***b*, L = $PPhMe_2$; **1***c*, L = PMe_3 (5); **2**, L = $PPh(OMe)_2$ (14)) with one equivalent of dimethyl phenylphosphonite in acetone at ambient temperature for 20 h affords a complex reaction mixture containing prod-

[1] $L_n\text{-[M]-X} + P(OR)_nR'_{3-n} \longrightarrow [\,L_n\text{-[M]-P(OR)}_nR'_{3-n}]^+X^- \xrightarrow{-RX} L_n\text{-[M]-P(O)(OR)}_{n-1}R'_{3-n}$

Scheme 1.



a, PPh_2Me; *b*, $PPhMe_2$; *c*, PMe_3

ucts derived from simple phosphine substitution, halide substitution – Arbuzov dealkylation, as well as combinations of both processes (cf. Scheme 1). Product structure was confirmed by comparison of NMR parameters with known compounds (**1***c* (5) and **2** (14)) and by full analytical and spectroscopic characterization in the case of **1***a* and **1***b* (cf. Tables 1–3). Two diastereomeric pairs of enantiomers with characteristically different ^1H NMR spectra were detected for all Co- and P-chiral metallophosphinates, η^5-$CpCo^*(C_3F_7)(L)(P^*(O)Ph(OMe))$ **4***a*,*b*,*c* and **6**.

Relative stereochemistry at chiral Co and P for the diastereomeric pairs of phosphine-substituted phosphinates **4***a* and **4***b* was empirically assigned by comparison of relative chromatographic R_f values with those of crystallographically determined *RR*;*SS* and *RS*;*SR*-**4***c* (5). We have found that *RR*;*SS* diastereomers of this type consistently elute before the *RS*;*SR* form on silica gel thin-layer chromatographic (TLC) plates. Thus the relative stereochemistry of the higher R_f diastereomers is assigned *RR*;*SS*-**4***a*-1 and *RR*;*SS*-**4***b*-1 and of the lower R_f diastereomers is *RS*;*SR*-**4***a*-2 and *RS*;*SR*-**4***b*-2.

The relative stereochemistry of the lower R_f phosphonite-substituted product **6**-2 was unambiguously established by single crystal X-ray diffraction study. The ORTEP representation of the molecular structure obtained (cf. Fig. 1) shows a

[a]^1H NMR (300.1 MHZ) chemical shifts in $CDCl_3$ relative to internal TMS; *J* values in Hz; m = multiplet, d = doublet.

typical pseudo-octahedral, three-legged piano-stool structure with average interligand bond angles (93.7°) approaching 90°. The phosphoryl P-atom is distorted from ideal tetrahedral geometry showing a moderate opening of the Co-P=O angle to 117.8° that is accommodated by a closing of the MeO-P-C(10) angle to 100.5°. A substantial multiple bond character (15) for the phosphoryl group is inferred from the P=O distance (1.487(3) Å), which is considerably shorter than the P(1)—O(1) single bond length measured for **6**-2 (1.625(3) Å) but comfortably in the normal range for free (15), P-coordinated (16, 17), or even P=O bridging (18) phosphoryl groups in a wide range of chemical environments (16, 17). The CIP ligand priority sequence Cp > $PPh(OMe)_2$ > P(O)(OMe)Ph > C_3F_7 for Co (19–21) and Co > OMe > O > Ph for P unambiguously fix the relative stereochemistry of **6**-2 as $R_{Co}R_P$. CIP priority differences for phosphonite and phosphine show that

Table 3. ^{13}C and ^{31}P NMR data for η^5-$CpCo^*(C_3F_7)(L)(X)$.[a]

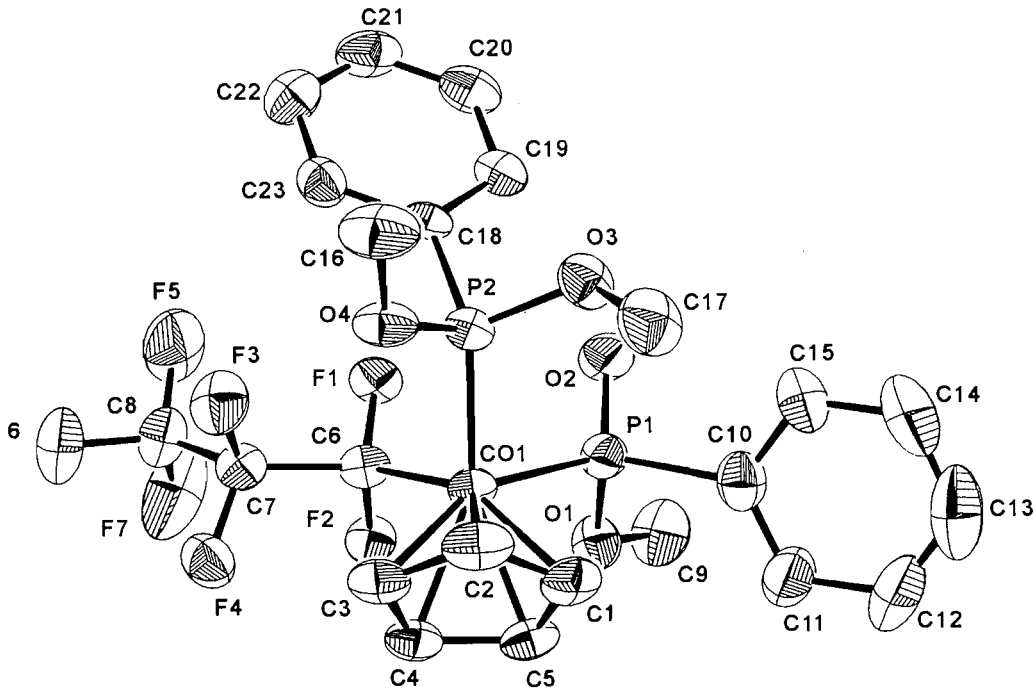
RR;*SS*-**6**-2 has the same relative stereochemistry as the lower R_f *RS*;*SR* diastereomers in the phosphine substituted series.

Product distribution was examined in detail for the case of reaction of **1***a* with $PPh(OMe)_2$. Careful preparative thick-layer chromatographic (PLC) isolation gives, in order of decreasing R_f values, unreacted **1***a*, dark-green phosphonite complex η^5-$CpCo^*(C_3F_7)(PPh(OMe)_2)$(I), **2**, two orange, phosphine-metallophosphonate diastereomers η^5-$CpCo^*(C_3F_7)(PPh_2Me)$-(P^*(O)Ph(OMe)), **4***a*-1,2, followed by two light-orange phosphonite-metallophosphinate diastereomers (14) η^5-$CpCo^*(C_3F_7)(PPh(OMe)_2)(P^*(O)Ph(OMe))$, **6**-1,2. The iodo-phosphonite complex **2** is stable for months in the solid state or in acetone solution; however, it reacts readily in the presence of methyldiphenylphosphine to afford the same sequence of products.

Product distribution was also monitored by ^1H NMR spectroscopy. We (14) as well as others (22) have observed that piano-stool Co(III) metallophosphonates such as **4** tend to be substitution inert, hence the phosphonite complexes **6**-1 and **6**-2 must derive from stepwise halide substitution and Arbuzov dealkylation of **2**. The observation that no phosphonite-containing products, **6**, were observed for the reaction of **1***a* with dimethyl phenylphosphonite in the presence of excess PPh_2Me (mole ratio **1***a*:$PPh(OMe)_2$:PPh_2Me = 1:1:10) suggests a facile phosphine substitution that establishes the equilibrium **1***a* + $PPh(OMe)_2$ ⇄ **2** + PPh_2Me. Pre-equilibrium phosphine exchange was confirmed from observation of concentration/time curves vs. starting material ratios in acetone-d_6 solution. A labile species with δ_{Cp} = 5.60 ppm was observed and tentatively assigned as the cationic intermediate **3***a*; how-

Fig. 1. ORTEP plot of η^5-CpCo*(C_3F_7)(PPh(OMe)$_2$)(P*(O)Ph(OMe)), **6**-2.



ever, we are unable to unequivocally distinguish whether formation of **4** proceeds by direct phosphine exchange (**2** → **4**) and (or) via the proposed cationic intermediate **3***a* (**1**,**2** → **3** → **4**). Nevertheless, all directly observed products follow directly from consideration of Scheme 1.

Stereochemistry and optical yields

If cationic $[\eta^5$-CpCo(C_3F_7)(PPh$_2$Me)(PPh(OMe)$_2$)$]^+I^-$, **3***a*, is the unique intermediate for transition metal Arbuzov dealkylation (Scheme 1), treatment of the iodo-phosphine complex η^5-CpCo(C_3F_7)(PPh$_2$Me)(I), **1***a*, with dimethyl phenylphosphonite or of the iodo-phosphonite complex η^5-CpCo*(C_3F_7)(PPh(OMe)$_2$)(I), **2**, with methyldiphenylphosphine is expected to produce identical optical yields of P-chiral metallophosphinate product, **4**. In that event %de is fully determined by $\Delta\Delta G^{\ddagger}$ for iodide attack at the diastereotopic methoxy groups of intermediate **3***a* as shown in Scheme 1. In contrast with this hypothesis, we find that the optical yield of phosphinate η^5-CpCo(C_3F_7)-(PPh$_2$Me)(P(O)-Ph(OMe)) (%de = 100 × ([**4***a*-1]−[**4***a*-2])/([**4***a*-1]+[**4***a*-2])) is sensitive to reactant composition in acetone (cf. Table 4). Table 4 shows the dependence of optical yield on reactant composition as determined by integration of ^{1}H NMR spectra in the Cp region. Relative stereochemistry for the Co- and P-chiral metallophosphinates **4***a* and **4***b* was assigned by comparison of TLC R_f values with that of crystallographically determined **4***c*. (5). Reaction of **1***a* with PPh(OMe)$_2$ resulted in increased optical yield for **4***a*-1, **4***a*-2 compared with reaction of **2** with PPh$_2$Me (cf. Table 4 entries 1 and 3). The product distribution studies are inconsistent with the formation of a common intermediate and therefore imply the presence of a parallel reaction channel with a different optical yield. We propose a competing, intramolecular pathway, which is possible only for the iodophosphonite **2**.

There is ample literature precedent that establishes that intramolecular alkyl migrations can lead to metallophosphonates (23–25). We therefore propose an intramolecular attack of iodide at carbon, concerted with associative nucleophilic attack at the metal by PPh$_2$Me. Expulsion of MeI from **2** gives the metallophosphinate **4***a*-1, **4***a*-2 in a single step as illustrated in Scheme 2. Optical yield for **4***a* formation via the intramolecular pathway is then a function of $\Delta\Delta G^{\ddagger}$(intramolecular) rather than $\Delta\Delta G^{\ddagger}$(intermolecular) for iodide attack at diastereotopic OMe (cf. Scheme 2). Optical yields will then reflect the position of the equilibrium connecting the starting materials **1** and **2**. In the presence of excess PPh$_2$Me the equilibrium **1***a* + PPh(OMe)$_2$ ⇄ **2** + PPh$_2$Me shifts to the left and effectively shuts off the intramolecular route. Under these conditions (cf. Table 4, entry 6) the intermolecular sequence **1***a*→**3***a*→**4***a* provides the dominant route to phosphinate product. If our interpretation is correct, higher %de in the presence of excess PPh$_2$Me can be interpreted as less efficient optical induction for the intramolecular vs. intermolecular pathway. Accordingly, the lowest optical yields were measured in methanol solvent (cf. Table 4, entry 8) since hydrogen bonding limits iodide nucleophilicity and the intramolecular pathway operates exclusively (cf. discussion below).

Attempts to further test for the proposed intramolecular Arbuzov reaction mechanism by reacting $[\eta^5$-CpCo(C_3F_7)-(PPh$_2$Me)(PPh(OMe)$_2$)$]^+SbF_6^-$, prepared by iodide abstraction of 2 followed by in situ treatment with PPh$_2$Me, with NaI in acetone failed. Reaction under these conditions resulted in nucleophilic attack of iodide on cobalt rather than carbon. The

2

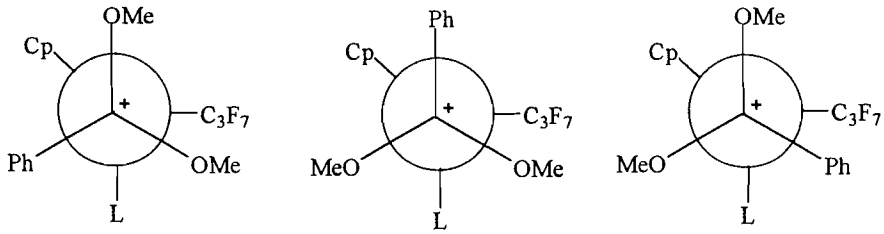
iodo complexes, resulting from phosphonite/phosphine substitution, were isolated in a 14.5:1 ratio in > 90% chemical yield.

Brunner's early studies (26) of coordinatively saturated, pseudo-tetrahedral, piano-stool complexes elegantly established dissociative substitution with dominant retention of configuration at chiral metal. Fewer examples of associative activation have been identified (27–30). The latter require an ancillary ligand capable of removing an electron pair in order to avoid formation of high-energy 20 e^- species. Established cases involve hapticity decreases ($\eta^5 \rightarrow \eta^3$ "ring slippage" (27)) of indenyl or cyclopentadienyl or linear→bent NO isomerization (31). In a relevant study Landon and Brill (3) reported second-order kinetics for the Arbuzov rearrangement of η^5-CpCo(dppe)I with $P(OMe)_3$ and steric inhibition for the increased bite-angle ligand dppp (1,3-bis(diphenylphosphino)propane), implying an associative reaction. The stereochemical consequences pursuant to the presence of a prochiral phosphonite in the present study allow detection of an otherwise masked reaction mechanism.

Solvent effects

Solvent effects also support the proposed intramolecular Arbuzov dealkylation. Free iodide ion is strongly solvated in protonic solvents and is considerably less nucleophilic (6), hence attack at carbon required for Arbuzov dealkylation is inhibited. Complex **1***a* reacts with $PPh(OMe)_2$ in the presence of excess PPh_2Me via initial displacement of iodide; however, the second step is effectively blocked in methanol and Arbuzov dealkylation does not proceed readily (cf. Table 4, entry

Fig. 2. GMMX determined conformational energies for **3**.



L	E_I (rel) kJ/mol	E_{II} (rel) kJ/mol	E_{III} (rel) kJ/mol
PMe_3	0	9.6	13.4
$PPhMe_2$	0	3.3	>12.5
PPh_2Me	3.8	0	6.3

7). If other reaction pathways were available under these conditions, **4***a*-1, and **4***a*-2 would still be formed.

Strikingly different results were obtained when the reaction was carried out starting with **2** in the methanol-d_4 (cf. Table 4, entry 8). Addition of one equivalent of PPh_2Me resulted in the formation of four Cp peaks in the ^1H NMR spectrum assigned to **1***a*, **2**, **4***a*-1, and **4***a*-2. Arbuzov dealkylation occurs readily from **2** even when the two-step pathway **2**→**3***a*→**4***a* is blocked in protonic media. Since iodide is non-nucleophilic under these conditions, iodide attack at OCH_3 cannot occur from outside the coordination sphere. In contrast, protonic solvent is expected to have little effect on a concerted mechanism involving **3** that avoids formation of free iodide. Optical yields in this experiment are determined exclusively by the intramolecular mechanism and decreased to %de = 28, consistent with a decreased optical induction in the intramolecular route.

It is reasonable to expect that low dielectric media will inhibit iodide substitution since the process involves substantial charge separation. Indeed (cf. Table 4, entry 4) we find that the optical yield for the reaction of **2** with PPh_2Me drops as the solvent changes from acetone (ϵ = 20, %de = 32) to benzene (ϵ = 4, %de = 15).

Ligand sphere effects on optical yield

$\Delta\Delta G^{\ddagger}$ for attack of iodide at the diastereotopic phosphonite methoxy groups will of course determine optical yield. Previous studies of Co→P chiral induction for **1**→**4** (L = $PPh_2NH(C^*H(Me)Ph)$) identified (2, 13, 14) intramolecular N—H···O═P hydrogen bonding as a pivotal parameter for Co→P chiral induction. We were therefore surprised to find that optical yields measured for **1**→**4** (L = phosphine, phosphonite), which cannot reduce the number of low-energy conformers by intramolecular hydrogen bonding, were in some cases superior. Measured optical yields for **1**→**4** decreased along the series L = PPh_2Me (40%) < $PPhMe_2$ (33%) < PMe_3 (18%). It was of interest to determine the effect of ligand steric requirements on the efficacy of Co→P optical induction.

Molecular mechanics global minimum conformational searches for the intermediates **3***a–c* were carried out using the GMMX algorithm (32) with the assumption that insight relevant to diastereoselection in the transition state for intermolecular dealkylation might be provided. Starting structures for the cations **3**, obtained from model compounds derived from crystallographic data, were minimized using the MMX (33) force field, which has been shown to be appropriate for related piano-stool molecules (34, 35). GMMX searches of conformational space used a combined Monte Carlo internal – Cartesian randomization protocol that examined rotations about all specified bonds with less than 3-fold symmetry. Conformations meeting energy criteria were then MMX minimized, checked for redundancy, and retained subsequent to a final energy assessment. Surviving conformations within a 12.5 kJ/mol band containing the lowest energy structure were retained. Further cycles removed/re-added hydrogen atoms in calculated positions and minimized in order to dislodge structures from saddle points. Finally, the surviving conformations were checked for redundancy and energy criteria. The process was continued until no further conformations were lost.

The GMMX conformational searches identified three staggered Co-$P(OMe)_2Ph$ rotamers for the intermediate **3***a,b,c*. Figure 2 shows Newman projections along with the calculated relative MMX energies. Literature evidence (36, 37) strongly suggests that the region between the almost 90° L-Co-C_3F_7 is the least sterically accessible for pseudo-octahedral piano stools. The GMMX calculations concur, and rotamers I and II, which place the least sterically demanding group (OMe) in that region, are always most stable. Face/edge Cp–Ph interactions (38–40) may also contribute to the relative stability of rotamers I and II. Differences are small; however, the relative increase in the energy of rotamer I with respect to II as phenyl groups accumulate on the phosphine donor L can be traced to increasing Ph–L steric interactions.

Curtin–Hammett restrictions (41) preclude a direct relation between conformer population and optical yield, however, based on the GMMX calculations described above, a case can be made for the direction of chiral induction and ligand sphere effects on the measured %de for **1**→**3**→**4**. It is clear that the critical step for chiral induction occurs on attack of iodide at the diastereotopic OMe groups of **3**, which displaces the phosphoryl product. We have previously established a preference for a dominant *anticlinal* Cp-Co-P═O conformation (2, 13, 14, 42, 43) in piano-stool metallophosphonate and metallophosphinate complexes. Assumption of significant product-like character in the transition state predicts a preference for

attack at the *anticlinal* Cp-Co-P-OMe, and conformer II (R_{Co} configuration shown in Fig. 2) is then correctly linked to the major product ($R_{Co}R_P$). Optical yields will then parallel the II/I ratio, which increases along the series PMe_3 (18%de) < $PPhMe_2$ (33%de) < PPh_2Me (40%de).

Experimental

General

All manipulations were performed under a dry nitrogen atmosphere using standard Schlenk techniques. Nitrogen was purified by passing though a series of columns containing granular phosphorus pentoxide, 3A molecular sieves, and BASF DEOX catalyst (100°C). Acetone, methanol, and methylene chloride were distilled from activated 4A molecular sieves. Reactions were monitored by analytical thin-layer chromatography (precoated TLC plates, silica gel F-254, Merck). NMR spectra were recorded on a General Electric GN300-NB spectrometer operating at a proton frequency of 300.1 MHz. Preparative thick-layer chromatographic (PLC) purification was carried out using a Chromatotron (Harrison Associates) with 1–2 mm thick silica $gel_{60}PF_{254}$(Merck) adsorbent. The compounds $CpCo(C_3F_7)(CO)$(I) (44), **1***c* (5), and **2** (14) were prepared using the established procedures. Commercial samples of dimethyl phenylphosphonite, diphenylmethylphosphine, dimethylphenylphosphine, trimethylphosphine, $AgSbF_6$, and perfluoropropyl iodide (Aldrich) were used as received. Melting points were measured in sealed, nitrogen-filled capillaries and are uncorrected. C, H analyses were provided by Canadian Microanalytical Service Inc., Delta, B.C.

Preparation of η^5-$CpCo^*(C_3F_7)(PPh_2Me)$(I) (**1***a*) and η^5-$CpCo^*(C_3F_7)(PPhMe_2)$(I) (**1***b*).

PPh_2Me (90.1 mg, 0.450 mmol) was added dropwise to a stirred 25 mL, black, CH_2Cl_2 solution of η^5-$CpCo^*(C_3F_7)$-(CO)(I) (197.4 mg, 0.4407 mmol) contained in a 100 mL Schlenk flask and stirred at ambient temperature (20°C) for 12 h. Removal of volatiles under water aspirator followed by oil pump vacuum overnight left a dark green solid, which was purified by thick-layer radial PLC on silica gel (CH_2Cl_2) to give **1***a* (245.9 mg, 0.3966 mmol, 90.0%). **1***b* was prepared in 86.6% yield from η^5-$CpCo^*(C_3F_7)$(CO)(I) and $PPhMe_2$ in an analogous manner. Physical, analytical, and spectroscopic data for **1***a,b* are presented in Tables 1–3.

Reaction of η^5-$CpCo^*(C_3F_7)(PPh_2Me)$(I) (**1***a*) with $PPh(OMe)_2$ in acetone

η^5-$CpCo^*(C_3F_7)(PPh_2Me)$(I) (134.0 mg, 0.2161 mmol), $PPh(OMe)_2$ (38.0 mg, 0.2188 mmol), and acetone (25 mL) were mixed in a 50 mL Schlenk flask and stirred at ambient temperature (20°C) for 24 h. Removal of volatiles under water aspirator followed by oil pump vacuum overnight left a dark-green solid, which was purified by PLC on silica gel. Elution with CH_2Cl_2 separated (in order of decreasing R_f values) a dark-green zone containing **1***a* (71.6 mg, 0.115 mmol) and **2** (20.9 mg, 0.0354 mmol). Continued elution with acetone separated two orange zones containing **4***a*-1, **4***a*-2 (**4***a*-1: 22.4 mg, 0.0346 mmol; **4***a*-2: 8.4 mg, 0.013 mmol), followed by two light-orange zones containing **6**-1, **6**-2 (**6**-1: 7.6 mg 0.012 mmo l; **6**-2: 3.1 mg 0.0050 mmol). Physical, analytical, and spectroscopic data for **4***a*-1,2 are presented in Tables 1–3.

[a]Estimated standard deviations in the least significant figure are given in parentheses.

Reaction of η^5-$CpCo^*(C_3F_7)(PPhMe_2)$(I) (**1***b*) with $PPh(OMe)_2$ in acetone

η^5-$CpCo^*(C_3F_7)(PPh_2Me)$(I) (41.3 mg, 0.0749 mmol), $PPh(OMe)_2$ (20.8 mg, 0.122 mmol), and acetone (25 mL) were mixed in a 50 mL Schlenk flask and stirred at 50°C for 12 h. Removal of volatiles under water aspirator followed by oil pump vacuum overnight left a dark-green solid, which was purified by PLC on silica gel. Elution with CH_2Cl_2 separated (in order of decreasing R_f values) a dark-green zone containing **1***b* and **2** (17.6 mg). Continued elution with acetone separated two orange zones containing **4***b*-1, **4***b*-2 (**4***b*-1: 10.9 mg, 0.0186 mmol; **4***b*-2: 5.3 mg, 0.0090 mmol). Physical, analytical, and spectroscopic data for **4***b*-1,2 are presented in Tables 1–3.

Table 6. Selected intramolecular distances[a] and angles for **6**-2.

[a]Estimated standard deviations in the least significant figure are given in Parenthesis.

Reaction of η^5-CpCo*(C_3F_7)(PPh(OMe)2)(I) 2 with PPh_2Me in acetone

η^5-CpCo*(C_3F_7)(PPh(OMe)$_2$)(I) (147.0 mg, 0.2491 mmol), PPh_2Me (51.0 mg, 0.255 mmol), and acetone (25 mL) were mixed in a 50 mL Schlenk flask and stirred at ambient temperature (20°C) for 24 h. Removal of volatiles under water aspirator followed by oil pump vacuum overnight left a dark-green solid, which was purified by PLC on silica gel. Elution with CH_2Cl_2 separated (in order of decreasing R_f values) a dark-green zone containing **1***a* (62.1 mg, 0.100 mmol) and **2** (6.6 mg, 0.011 mmol). Continued elution with acetone separated two orange zones containing **4***a*-1, **4***a*-2 (**4***a*-1: 45.1 mg, 0.0696 mmol; **4***a*-2: 21.0 mg, 0.0324 mmol), followed by two light-orange zones containing **6**-1, **6**-2 (**6**-1: 7.9 mg 0.013 mmol; **6**-2: 4.4 mg 0.0071 mmol).

Reaction of η^5-CpCo*(C_3F_7)(PPh(OMe)2)(I) 2 with $AgSbF_6$ following with PPh_2Me and then NaI in acetone

A 10 mL colourless, acetone solution of $AgSbF_6$ (29.1 mg, 0.0847 mmol) was added dropwise with stirring into a 20 mL dark-green acetone solution of η^5-CpCo*(C_3F_7)(PPh(OMe)$_2$)(I) (44.0 mg, 0.0755 mmol) contained in a 50 mL Schlenk flask at ambient temperature (20°C). A white precipitate of AgI formed. Dropwise addition of PPh_2Me (16.6 mg, 0.0829 mmol) resulted in the formation of a brown solution. Treatment of the solution with NaI (22.8 mg, 0.1521 mmol) gave an immediate colour change to deep green. Removal of volatiles under water aspirator pressure followed by oil pump vacuum overnight left a dark-green solid. ^{1}H NMR analysis ($CDCl_3$) of the residue in cyclopentadienyl region showed two resonances corresponding to **1***a* (δ = 5.09 ppm, 75.0%) and **2** (δ = 5.19 ppm, 17.2%). The phosphinate complexes **4***a*-1, **4***a*-2 were not detected.

NMR tube reaction of η^5-CpCo*(PPh(OMe)2)(I), 2, with PPh_2Me in acetone-d_6

A 5 mm NMR tube was charged with η^5-CpCo*(C_3F_7)(PPh(OMe)$_2$)(I) (13.44 mg, 0.02276 mmol), PPh_2Me (4.78 mg, 0.0239 mmol), and acetone-d_6 (0.86 mL) and capped with a septum. The sample was equilibrated at ambient temperature (20°C) for 24 h. The ^{1}H NMR spectrum showed **1***a* (δ = 5.25 ppm, 45.4%), **2** (δ = 5.37 ppm, 5.5%), **4***a*-1 (δ = 5.20 ppm, 23.5%), **4***a*-2 (δ = 4.95 ppm, 8.4%), **6**-1 (δ = 5.18 ppm, 7.1%), **6**-2 (δ = 4.98 ppm, 6.3%), respectively. A parallel reaction was carried out for CpCo*(C_3F_7)-(PPh(OMe)2)(I) with PPh_2Me, resulting in **1***a* (δ = 5.25 ppm, 30.1%), **2** (δ = 5.37 ppm, 4.2%), **4***a*-1 (δ = 5.20 ppm, 26.9%), **4***a*-2 (δ = 4.95 ppm, 13.3%), **6**-1 (δ = 5.18 ppm, 7.6%), **6**-2 (δ = 4.98 ppm, 8.0%), respectively.

Reaction of η^5-CpCo*(C_3F_7)(PPh_2Me)(I), 1*a*, with $PPh(OMe)_2$ in acetone in the presence of excess PPh_2Me

η^5-CpCo*(C_3F_7)(PPh_2Me)(I) (27.0 mg, 0.0435 mmol), $PPh(OMe)_2$ (7.6 mg, 0.045 mmol), and PPh_2Me (95.8 mg, 0.478 mmol) were mixed in 10 mL of acetone in a 50 mL Schlenk flask and stirred at ambient temperature (20°C) for 24

[a]cf. ref. 46.
[b]$R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[c]$R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)]^{1/2}$.
[d]GOF = $(\Sigma(|F_o| - |F_c|)/\sigma)/(n - m)$) where n = no. of reflections, m = no. of variables, and σ^2 = variance of ($|F_o| - |F_c|$).

h. Removal of volatiles under water aspirator followed by oil pump vacuum overnight left a dark-green solid. ^{1}H NMR analysis in $CDCl_3$ showed three cyclopentadienyl resonances corresponding to **1***a* (δ = 5.09 ppm, 51.4%), **4***a*-1 (δ = 5.06 ppm, 40.1%), and **4***a*-2 (δ = 4.87 ppm, 10.8%).

Reaction of η^5-CpCo*(C$_3$F$_7$)(PPh$_2$Me)(I), 1*a*, with PPh(OMe)$_2$ in acetone/methanol

η^5-CpCo*(C$_3$F$_7$)(PPh$_2$Me)(I) **1***a* (21.8 mg, 0.0352 mmol), PPh(OMe)$_2$ (6.0 mg, 0.035 mmol), and PPh$_2$Me (69.1 mg, 0.345 mmol) were combined in 3/2 (v/v) acetone/methanol (10 mL) in a 50 mL Schlenk flask at ambient temperature (20°C) and stirred for 24 h. The ^{1}H NMR spectrum of the crude product showed only one cyclopentadienyl resonance (δ = 5.09 ppm) assigned to the starting material **1***a* in $CDCl_3$. A similar reaction starting with η^5-CpCo(C$_3$F$_7$)(PPh(OMe)$_2$)(I) **2** (43.3 mg, 0.0734 mmol) and PPh$_2$Me (14.7 mg, 0.0735 mmol) in 3/2 (v/v) acetone/methanol gave **1***a* (δ = 5.09 ppm, 50.7%), **2** (δ = 5.19 ppm, 11.0%), **4***a*-1 (δ = 5.06 ppm, 11.25%), **4***a*-2 (δ = 4.87 ppm, 6.6%), respectively.

Reaction of η^5-CpCo*(C$_3$F$_7$)(PMe$_3$)(I) (1*c*) with PPh(OMe)$_2$ in acetone

PPh(OMe)$_2$ (258.6 mg, 1.520 mmol) was added dropwise to a stirred 40 mL dark green acetone solution of η^5-CpCo*(C$_3$F$_7$)(CO)(I) (334.7 mg, 0.7554 mmol) in a 100 mL Schlenk flask at 50°C until the solution became clear yellow in colour (around 5 h). Removal of volatiles under water aspira-

tor pressure followed by oil pump vacuum overnight left an orange solid, which was purified by PLC on silica gel. Elution with 9/1 acetone/methanol separated (in order of decreasing R_f value) a deep orange zone containing **4***c*-1 (236.7 mg, 0.4515 mmol), two yellow-green zones containing **6**-1 (15.6 mg, 0.0298 mmol) and **6**-2 (6.7 mg, 0.0128 mmol), respectively, and an orange zone containing **4***c*-2 (114.2 mg, 0.2178 mmol).

Crystal structure determination of η^5-$CpCo^*(C_3F_7)(PPh(OMe)_2)(P(O)(OMe)Ph)$, 6-2

A diastereomeric mixture of **6**-1 and **6**-2 was prepared as described previously (14). The lower R_f diastereomer was separated using preparative thick-layer radial chromatography and recrystallized by slow evaporation of a methylene chloride – hexane solvent mixture. An orange single crystal was selected and mounted on a glass fibre for X-ray analysis. Crystal data were collected at ambient temperature on a Rigaku AFC6S diffractometer with graphite monochromated Mo Kα radiation, λ = 0.71069 Å, and a 2 kW sealed tube generator using the ω scan technique to a maximum 2θ value of 50.0°. Positional parameters and selected bond distances and angles are given in Tables 5 and 6, respectively. Cell constants and an orientation matrix for data collection were determined from least-squares refinement using the setting angles of the 20 carefully centered reflections in the range $9.22 < 2\theta < 17.73°$ and are given in Table 7. The space group $P\bar{1}$ (no. 2) was assigned on the basis of systematic absences and on the successful solution and refinement of the structure. Omega (ω) scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.31° with a take-off angle of 6.0°. Scans of $(1.47 + 0.30 \tan \theta)°$ were made at a speed of 4.0°/min (in ω). Weak reflections ($I < 10.0\sigma(I)$) were rescanned (max 2) and the counts accumulated to assure good counting statistics. Stationary counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1.

The linear absorption coefficient for Mo Kα is 8.7 cm^{-1}. An empirical absorption correction, based on azimuthal scans of several reflections, was applied, resulting in transmission factors ranging from 0.95 to 1.00. The data were corrected for Lorentz and polarization effects. a correction for secondary extinction was applied with coefficient = 0.25290 $\mp 10^{-6}$. The structure was solved by direct methods (45) using the Molecular Structure Corporation TEXSAN software. Non-hydrogen atoms were refined anisotropically. Idealized hydrogen atoms were included at the calculated positions and were not refined.

Tables of atomic coordinates, bond distances and angles, and torsion angles for η^5-$CpCo^*(C_3F_7)(PPh(OMe)_2)(P^*(O)Ph(OMe))$, **6**-2, have been deposited as supplementary material.[2]

[2] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of atomic coordinates and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K. Structure factor tables are no longer being deposited, but may be obtained from the author.

Pyridine-2-selenolate and -2-tellurolate as ligands: a multinuclear (^{77}Se, ^{119}Sn, ^{125}Te) magnetic resonance study of some tin(IV) complexes, and X-ray structural analyses of $Sn(SPh)_2(2\text{-}Se\text{-}C_5H_4N\text{-}N,Se)_2$ and $Sn(SPh)_{1.85}(2\text{-}Se\text{-}C_5H_4N)_{2.15}$[1]

Naveen Chopra, Leslie C. Damude, Philip A.W. Dean, and Jagadese J. Vittal

Abstract: Reactions between $Sn(E'Ph)_n$ (E' = S or Se; n = 2 or 4) and the bis(pyridine) dichalcogenides 2,2'-$(C_5H_4NE)_2$ (E = Se or Te), abbreviated py_2E_2, have been studied using multinuclear (^{77}Se, ^{119}Sn, ^{125}Te) magnetic resonance. In this way the occurrence of the pyridine-2-chalcogenate complexes $Sn(E'Ph)_{4-x}(Epy)_x$ (E' = S or Se; E = Se, x = 1–4; E = Te, x = 1 or 2) has been demonstrated. The pattern of ^{119}Sn NMR chemical shifts for $Sn(E'Ph)_{4-x}(Sepy)_x$ (E' = S or Se, x = 0–4) is consistent with bidentate bonding for the $pySe^-$ ligand when x = 1 and 2. The $pyTe^-$ ligand is probably bidentate also in all four complexes containing this ligand. As part of the NMR analysis, ^{77}Se and (or) ^{125}Te NMR data were obtained for py_2Te_2 and for the new mixed dichalcogenides PhE'ER (E' = S, Se, or Te; E ≠ E' = Se or Te; R = 2-py or Ph), which were produced in the systems $Ph_2E'_2$:R_2E_2. The complex $Sn(SPh)_2(Sepy)_2$ (**1**) was isolated pure and its structure determined by the single crystal X-diffraction technique. The compound crystallizes in the monoclinic space group $P2_1/n$, with unit cell dimensions a = 9.7929(9) Å, b = 22.340(2) Å, c = 11.368(1) Å, β = 108.803(7) °, V = 2354.3(4) Å^3, d_{calc} = 1.837 g cm^{-3}, and Z = 4. Refinement by full-matrix least squares on F^2 gave agreement factors $R1$ = 0.0425 and $wR2$ = 0.0882 for 2823 independent reflections with $F_o \geq 4\sigma(F_o)$ and 258 variables. The structure confirms that the $PySe^-$ ligand behaves in a chelating manner. The molecule $Sn(SPh)_2(2\text{-}Se\text{-}C_5H_4N\text{-}N,Se)_2$ has a distorted octahedral structure with the PhS^- ligands in *cis* positions and the two Se donor atoms in *trans* positions. The Sn—Se, Sn—S, and Sn—N distances are 2.6291(8) and 2.6358(8) Å, 2.475(2) and 2.464(2) Å, and 2.325(5) and 2.333(5) Å. The bite angles N-Sn-Se of the chelating ligands are 65.9(1)° and 65.8(1)°. En route to **1**, the yellow crystalline compound $Sn(SPh)_{1.85}(2\text{-}Se\text{-}C_5H_4N)_{2.15}$ (**2**) was isolated. This was shown by ^{119}Sn NMR spectroscopy to contain both $Sn(2\text{-}Se\text{-}C_5H_4N)_2(SPh)_2$ and $Sn(2\text{-}Se\text{-}C_5H_4N)_3(SPh)$. The crystal and molecular structure of **2** was determined by single crystal X-ray diffraction techniques. Crystal data: monoclinic, space group $P2_1/n$, a = 9.795(2) Å, b = 22.355(4) Å, c = 11.362(2) Å, β = 108.87(3)°, V = 2354.2(8) Å^3, d_{calc} = 1.837 g cm^{-3}, d_{obs} = 1.87(5) g cm^{-3}, Z = 4, $R1$ = 0.0306, $wR2$ = 0.0651 for 2756 data ($F_o \geq 4\sigma(F_o)$) and 258 parameters. Crystallographic evidence for the presence of co-crystallized $Sn(2\text{-}Se\text{-}C_5H_4N)_3(SPh)$ occurs only in a minor lengthening of one of the two Sn—S bonds, Sn—S(1) (compared with expectation for **1**), and an excess of electron density at S(1) when the data are modelled as $Sn(2\text{-}Se\text{-}C_5H_4N)_2(SPh)_2$. These effects are attributed to a crystallographic disorder of SPh and η^1-{2-Se-C_5H_4N} at the S(1)Ph site, involving isostructural $Sn(\eta^2\text{-}\{2\text{-}Se\text{-}C_5H_4N\})_2(\{\eta^1\text{-}\{2\text{-}Se\text{-}C_5H_4N\})(SPh)$ and $Sn(\eta^2\text{-}\{2\text{-}Se\text{-}C_5H_4N\})_2(SPh)_2$.

Key words: pyridine-2-selenolate, pyridine-2-tellurolate, tin complexes.

Résumé : Utilisant la résonnance magnétique de noyaux multiples (^{77}Se, ^{119}Sn, ^{125}Te), on a étudié les réactions entre le $Sn(E'Ph)_n$ (E' = S ou Se; n = 2 ou 4) et les dichalcogénures de bis(pyridine) 2,2'-$(C_5H_4NE)_2$ (E = Se ou Te), représentés en abrégé par py_2E_2. On a pu ainsi démontrer la formation des complexes 2-chalcogénates de pyridine $Sn(E'Ph)_{4-x}(Epy)_x$ (E' = S ou Se; E = Se, x = 1–4; E = Te, x = 1 ou 2). L'allure des déplacements chimiques de la RMN du ^{119}Sn du composé $Sn(E'Ph)_{4-x}(Sepy)_x$ (E' = S ou Se, x = 0–4) est en accord avec une liaison bidentate pour le ligand $pySe^-$ lorsque x = 1 et 2. Le ligand $pyTe^-$ est probablement bidentate dans tous les quatre complexes où on le retrouve également. Dans le cadre de cette analyse par RMN, on obtenu les données relatives au complexe py_2Te_2 et aux nouveaux dichalcogénures mixtes PhE'ER (E' = S, Se, ou Te; E ≠ E' = Se ou Te; R = 2-py ou Ph), qui se forment dans les systèmes $Ph_2E'_2$: R_2E_2. On a isolé, à l'état pur, le complexe $Sn(SPh)_2(Sepy)_2$ (**1**) et

on a déterminé sa structure par la technique de diffraction des rayons X sur un monocristal. Le composé cristallise dans le groupe d'espace monoclinique $P2_1/n$, avec a = 9,7929(9) Å, b = 22,340(2) Å, c = 11,368(1) Å, β = 108,803(7)°, V = 2354,3(4) Å^3, d_{calc} = 1,837 g cm^{-3}, et Z = 4. L'affinage par la méthode des moindres carrés, matrice complète, sur F^2 conduit à des facteurs d'agrément $R1$ = 0,0425 et $wR2$ = 0,0882 pour 2823 réflexions indépendantes avec $F_o \geq 4\sigma(F_o)$ et 258 variables. La structure confirme que le ligand PySe$^-$ se comporte de manière chélatante. La molécule $Sn(SPh)_2(2\text{-}Se\text{-}C_5H_4NB\mathit{N,Se})_2$ a une structure octaédrique déformée avec les ligands PhS$^-$ en positions *cis* et les deux atomes donneurs Se en positions *trans*. Les distances Sn—Se, Sn—S et Sn—N sont respectivement de : 2,6291(8) et 2,6358(8) Å, 2,475(2) et 2,464(2) Å, et de 2,325(5) and 2,333(5) Å. Les angles d'attache N-Sn-Se des ligands chélatants sont de 65,9(1)° et de 65,8(1)°. Au cours de la synthèse du composé **1**, on a isolé le composé jaune cristallin $Sn(SPh)_{1,85}(2\text{-}Se\text{-}C_5H_4N)_{2,15}$ (**2**). La spectroscopie de RMN du ^{119}Sn a montré qu'il contient les deux complexes $Sn(2\text{-}Se\text{-}C_5H_4N)_2(SPh)_2$ et $Sn(2\text{-}Se\text{-}C_5H_4N)_3(SPh)$. On a déterminé la structure cristalline et moléculaire du composé **2** par la technique de diffraction des rayons X sur un monocristal. Le composé cristallise dans le groupe d'espace monoclinique $P2_1/n$, avec a = 9,795(2) Å, b = 22,355(4) Å, c = 11,362(2) Å, β = 108,87(3)°, V = 2354,2(8) Å^3, d_{calc} = 1,837 g cm^{-3}, d_{obs} = 1,87(5) g cm^{-3}, Z = 4, $R1$ = 0,0306, $wR2$ = 0,0651 pour 2756 données ($F_o \geq 4\sigma(F_o)$) et 258 paramètres. Les preuves cristallographiques de la présence du composé co-cristallisé $Sn(2\text{-}Se\text{-}C_5H_4N)_3(SPh)$ reposent uniquement sur une élongation mineure de l'une des deux liaisons Sn—S, Sn—S (1) (comparée à ce qui était attendu pour le composé **1**), et sur un excès de la densité électronique en S(1) lorsque les données sont modélisées sur le composé $Sn(2\text{-}Se\text{-}C_5H_4N)_2(SPh)_2$. On attribue ces effets à un désordre cristallographique de SPh et de η^1-{2-Se-C_5H_4N} au niveau du site S(1)Ph, impliquant les composés isostructuraux $Sn(\eta^2\text{-}\{2\text{-}Se\text{-}C_5H_4N\})_2(\{\eta^1\text{-}\{2\text{-}Se\text{-}C_5H_4N\})(SPh)$ et $Sn(\eta^2\text{-}\{2\text{-}Se\text{-}C_5H_4N\})_2(SPh)_2$.

[Traduit par la rédaction]

Introduction

The ligand chemistry of 2-O-$C_5H_4N^-$ and is well developed (1), as is that of 2-S-$C_5H_4N^-$, pyt$^-$ (2–4). In contrast, there appear to be only two published studies of the ligand behaviour of pyridine-2-selenolate, Sepy$^-$, both appearing during the course of the present work (5, 6*a*),[3] and none concerning pyridine-2-tellurolate, pyTe$^-$. As ligands, pySe$^-$ and pyTe$^-$ have several interesting features that make them worthy of study. They contain donor atoms of disparate "hardness"/"softness", the "soft" chalcogen and the "borderline" pyridinic nitrogen (7*a*). Thus an otherwise unstable bond between an acid and base of mismatched "hard"/"soft" character, or an unusual coordination number or geometry (6*a*), may be stabilized by *N,chalcogen*-chelation. As well, coordination of the N along with the chalcogen may help saturate the coordination sites of a metal and so reduce or prevent chalcogen bridging, leading to higher volatility than in the metal chalcogenates themselves (6*a*). Further, the presence of ^{77}Se or ^{125}Te nuclei at the chalcogen may allow use of chalcogen NMR to follow their reactions.

As a contribution to the study of the ligand behaviour of pySe$^-$ and pyTe$^-$, we present here our results for several of their tin(IV) complexes. These complexes were prepared in solution using methods described earlier for tin(IV) complexes of pyt$^-$ and its N-oxide (4). The tin complexes comprise a model system in which information from the ^{77}Se/^{125}Te NMR chemical shifts is bolstered by both ^{119}Sn NMR chemical shifts and one-bond coupling between $^{119/117}$Sn and ^{77}Se/^{125}Te. During the course of the study we were able to isolate $Sn(SPh)_2(Sepy)_2$ and $Sn(SPh)_{1.85}(Sepy)_{2.15}$, and their structures have been determined by X-ray analytical methods.

Experimental

Materials

Diphenyldiselenide (Aldrich) showed no impurities by ^{13}C or ^{77}Se NMR, and was used as received. Literature methods were used for diphenyldisulfide (8), 2,2′-dipyridyldiselenide, py_2Se_2 (9), $Sn(SPh)_4$ and $Sn(SePh)_4$ (10), and $Sn(SPh)_2$ and $Sn(SePh)_2$ (11).

A low yield of 2,2′-dipyridylditelluride, py_2Te_2, was obtained by the method of ref. 12. Exact Mass in mass spectrum, calcd. for $C_{10}H_8N_2{}^{126}Te^{130}Te$: 411.8786; found: 411.8777, 411.8773 (duplicate measurements). Proton and ^{13}C NMR data obtained for this compound are consistent with those reported (13) while our work was in progress.[4]

All solvents for use in NMR sample preparation or synthesis were dried over 3A molecular sieves and sparged with Ar(g) before use.

Syntheses of $Sn(SPh)_2(2\text{-}Se\text{-}C_5H_4N)_2$ (1) and $Sn(SPh)_{1.85}(Sepy)_{2.15}$ (2)

Under Ar, a solution of py_2Se_2 (0.290 g, 0.923 mmol) in CH_2Cl_2 was added to solid $Sn(SPh)_2$ (0.312 g, 0.926 mmol). The mixture was stirred for 2 h, then filtered through a medium sinter under Ar pressure, giving a yellow filtrate and a khaki residue. The volume of the filtrate was reduced to 2 mL in a flow of Ar, and then hexane (1 mL) was added. On standing, bright yellow crystals formed at room temperature, and crystallization was completed by overnight refrigeration at 5°C. The crystals were separated by fitration and washed with CH_2Cl_2:hexane = 1:10 (2 × 1.5 mL). The yield was 0.337 g, but ^{119}Sn NMR showed the presence of ca. 13 mol% $Sn(SPh)(Sepy)_3$, which was not removed by two further recrystallizations from 1:1 CH_2Cl_2:hexane. Anal. of recrystallized product. calcd. for $C_{21.85}H_{17.85}N_{2.15}S_{1.85}Se_{2.15}Sn_1$: C 39.86, H 2.73, N 4.57; found: C: 39.87, 39.74; H: 2.64, 2.59; N: 4.56, 4.51. Single crystal X-ray analysis of the product, **2**, confirmed that $Sn(SPh)_2(Sepy)_2$ and $Sn(SPh)(Sepy)_3$ co-crystallize (see Results and discussion).

An NMR sample of **2** (82 mg in 3 mL of CH_2Cl_2) was prepared in a 10 mm o.d. NMR tube. To this was added $Sn(SPh)_4$ (ca. 5 mg) until the ^{119}Sn NMR spectrum showed the presence

[3] An additional paper describing the synthesis of $Sn(Sepy)_x$ (x = 2,4), $Pb(Sepy)_2$, and $Pb(3\text{-}Me_3Si\text{-}2\text{-}SeC_5H_3N)_2$, and the strucutural analysis of $Sn(Sepy)_2$, appeared after the completion of our manuscript (6*b*).

[4] An incorrect value of δ_{Te} for 2,2′-py_2Te_2 is given in ref. 13 (S.J. Dunne and E.I. von Nagy-Felsobuki, private communication).

R indices (all data)	$R1$ = 0.0767, $wR2$ = 0.1012		$R1$ = 0.0706, $wR2$ = 0.0845

$R1 = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$; $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma wF_o^4]^{1/2}$; GoF = $[\Sigma w(F_o^2 - F_c^2)^2/(n - p)]^{1/2}$ where n is the number of reflections and p is the number of parameters refined.

of a small amount of $Sn(SPh)_3(Sepy)$. At this stage, the solvent volume was reduced to ca. 1.5 mL and 1.5 mL of hexane was layered on. Refrigeration overnight yielded 33 mg of bright yellow single crystals, which were isolated by decantation. Tin-119 NMR spectroscopy of a sample of this product, **1**, in CH_2Cl_2 showed the presence of only $Sn(SPh)_2(Sepy)_2$ ($Sn(SPh)(Sepy)_3$:$Sn(SPh)_2(Sepy)_2 < 0.02$). Elemental analysis confirmed the purity of **1**. Anal. calcd. for $C_{22}H_{18}N_2S_2Se_2Sn$: C 40.58, H 2.78, N 4.30; found: C 40.64, H 2.62, N 4.30. A smaller second crop of product was obtained from the decantate on more extended refrigeration.

X-ray structure determination

$Sn(SPh)_2(Sepy)_2$

Yellow crystals of **1** were obtained from a mixture of CH_2Cl_2 and C_6H_{14} as described above. A suitable crystal was selected (size 0.44 × 0.21 × 0.19 mm) and mounted, for diffraction experiments, at the end of a glass fibre using epoxy glue. The diffraction experiments were carried out on a Siemens P4 4-circle diffractometer with XSCANS software package (14*a*) using graphite monochromated Mo Kα radiation at 25°C. The cell constants and orientation matrices were determined (14*a*) by centering 26 high-angle reflections ($24.2° \leq 2\theta \leq 25.0°$). A total of 5170 reflections were collected in the θ range 1.8°–25.0° ($-1 \leq h \leq 11$, $-1 \leq k \leq 26$, $-13 \leq l \leq 13$) in ω–2θ scan mode at variable scan speeds (1–10 deg. min^{-1}). Background measurements were made at the ends of the scan range. Three standard reflections were monitored for every 297 data measured. A Gaussian absorption correction was applied to the data after indexing the faces of the data crystal (six faces and the face indices are {011}, ($\bar{1}$01) and (100)) and measuring the distances between them. SHELXTL (15) programs were used for data processing, solution, and refinements. The space group $P2_1/n$ was unambiguously determined from the systematic absences. All the non-hydrogen atoms in the neutral molecule were refined anisotropically. All the hydrogen atoms were placed in calculated ideal positions and included for the purpose of structure factors calculations only. In the final least-squares refinement cycles on F^2, the model converged at $R1$ = 0.0425, $wR2$ = 0.0882, and Gof = 1.013 for 2823 reflections with $F_o \geq 4\sigma(F_o)$ and 258 parameters, and $R1$ = 0.0767, $wR2$ = 0.1012 for all 4126 data. In the final difference Fourier synthesis the electron density fluctuates in the range 0.533 to −0.453 e Å^{-3}. There is no shift in the final cycles. An extinction correction was refined to 0.00160 (14a). The experimental details and crystal data are shown in Table 1, and the positional and thermal parameters in Table 2.

$Sn(SPh)_{1.85}(Sepy)_{2.15}$

Yellow crystals of **2** were obtained by recrystallization of the crude product from a mixture of CH_2Cl_2 and C_6H_{14} (1:1, v:v) at 5°C, as described above. A suitable crystal was selected (size 0.44 × 0.26 × 0.23 mm) and mounted, for diffraction experiments, at the end of a glass fibre using expoxy glue. Density measurements were made by the neutral buoyancy method using a mixture of CCl_4 and 1,2-$C_2H_4Br_2$. The diffraction experiments were carried out on an Enraf–Nonius CAD4F diffractometer using graphite monochromated Mo Kα radiation at 25°C. The cell constants and orientation matrices were determined (14*b*) by centering 22 high-angle reflections ($25.5° \leq 2\theta \leq 28.0°$). A total of 5194 reflections were

Table 2. Atomic coordinates ($\times 10^4$) and equivalent isotropic displacement parameters ($Å^2 \times 10^3$) for **1**. U(eq) is defined as one third of the trace of the orthogonalized U_{ij} tensor.

collected in the θ range 1.8°–25.0° ($-1 \leq h \leq 11$, $-1 \leq k \leq 26$, $-13 \leq l \leq 13$) in ω–2θ scan mode at variable scan speeds (0.97–4.1 deg min^{-1}) and with a scan width of 0.7 + 0.35 tan θ, with a maximum time per datum of 40 s. Background estimates were made by extending the scan by 25%. Three standard reflections were monitored every 120 min of data collection. A Gaussian absorption correction was applied to the data after indexing the faces of the data crystal (six faces and the face indices are {011}, (10$\bar{1}$) and ($\bar{5}4\bar{1}$)) and measuring the distances between them. SHELXTL (15) programs were used for data processing, solution, and the least-square refinements on F^2. The space group $P2_1/n$ was unambiguously determined from the systematic absences. The structure is isomorphous and isostructural with the pure form of the compound, [Sn(Sepy)$_2$(SPh)$_2$]. During the least-squares refinement cycles, it was found that one of the Sn—S bond lengths was longer than the other (Sn—S(1), 2.486(2) Å vs. Sn—S(2), 2.467(2) Å, $\Delta/\sigma = 7.1$). Chemical analysis and solution ^{119}Sn NMR data (see above, and following) show that the data crystal must contain both Sn(Sepy)$_2$(SPh)$_2$ and Sn(Sepy)$_3$(SPh). However, comparison with the structure of **1** (*pure* Sn(Sepy)$_2$(SPh)$_2$) suggests that only the S(1)Ph is contaminated (see below). Assuming that only the S(1)Ph is contaminated, comparison of the electron densities in the S(1) and S(2) positions gave the composition SPh/Sepy = 0.89/0.11, in fair agreement with an average composition (Sn(Sepy)$_{2.15}$(SPh)$_{1.85}$) calculated for **2** from the C, H, and N microanalyses and the average composition [Sn(SPh)$_{\sim 1.87}$(Sepy)$_{\sim 2.13}$] obtained by ^{119}Sn NMR, both for the same batch of crystals from which the data crystal was chosen. The site occupancies of S(1), C(12), C(16), H(12), and H(16) were fixed on the basis of the elemental analysis for the subsequent least-squares cycles (see footnote 5, re: deposited material). All the non-hydrogen atoms in the neutral molecule were refined anisotropically. All the hydrogen atoms were placed in calculated ideal positions and included for the purpose of structure factors calculations only. In the final least-squares refinement cycles on F^2, the model converged at $R1 = 0.0306$, $wR2 = 0.0651$, and Gof = 1.021 for 2756 reflections with $F_o \geq 4\sigma(F_o)$ and 258 parameters, and $R1 = 0.0706$, $wR2 = 0.0845$ for all 4136 data. In the final difference Fourier synthesis the electron density fluctuates in the range 0.41(9) to −0.58(9) e Å^{-3}. The four top peaks resided near the S(2), Se(1), and Sn at distances of 0.67–0.96 Å. There is no shift in the final cycles. An extinction correction was refined to 0.00185 (11). The experimental details and crystal data are shown in Table 1 and Table 3 contains the positional and thermal parameters.

The agreement factors obtained when the crystal was

Table 3. Atomic coordinates ($\times 10^4$) and equivalent isotropic displacement parameters ($Å^2 \times 10^3$) for **2**. U(eq) is defined as one third of the trace of the orthogonalized U_{ij} tensor.

[a]Occupancy factor 1.16875.
[b]Occupancy factor 1.01250.

assumed to be pure $Sn(Sepy)_2(SPh)_2$ were as follows: $R1$ = 0.0304 and $wR2$ = 0.0686, Gof = 0.993 for 2756 reflections and 258 parameters; $R1$ = 0.0705 and $wR2$ = 0.0906 for all data. In the final Fourier synthesis, the four top peaks, with electron density range 0.58–0.51, resided around S(1) at distances 0.55–0.80 Å. The changes in the interatomic distances, bond angles, thermal parameters, etc., produced by this assumption are otherwise insignificant.

Tables of anisotropic thermal parameters, hydrogen atom coordinates, selected weighted least-squares planes and selected dihedral angles for **1** and **2** have been deposited as the supplementary material.[5]

[5] Copies of tables of anisotropic thermal parameters, hydrogen atom coordinates, selected weighted least-square planes, selected dihedral angles, and selected closest non-bonded distances for **1** and **2** may be purchased from: the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. The tables of hydrogen atom coordinates have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge, CB2 1EZ, U.K.

NMR spectra

Proton and ^{13}C-{^1H} NMR spectra of samples in 5 mm o.d. NMR tubes were obtained using Varian Gemini-200 or Varian XL-300 NMR spectrometers. For ^{119}Sn-{^1H}, ^{77}Se-{^1H}, and ^{125}Te-{^1H} NMR, samples were prepared in 10 mm o.d. NMR tubes. These spectra were measured using either the XL-300 spectrometer or a Varian XL-200, depending on availability. Internal references for ^1H and ^{13}C NMR spectra were the solvent residuals. External references for ^{119}Sn, ^{77}Se, and ^{125}Te NMR spectra were neat $SnMe_4$, neat Me_2Se, and neat $SnMe_4$ (ν[^{125}Te for Ph_2Te_2 {0.5 M CH_2Cl_2}]/ν[^{119}Sn for neat $SnMe_4$]) = 0.846 409 ± 0.000 002 at 295 ± 2 K (16) and δ_{Te}(neat Me_2Te, external) = δ_{Te} (Ph_2Te_2 {0.5 M in CH_2Cl_2}) + 422 (17*a*), respectively.

Mass spectrum

The mass spectrum of 2,2′-py_2Te_2 was measured with a Finnigan MAT 8230 spectrometer at 70 eV using isobutane for chemical ionization.

Elemental microanalysis

Carbon, hydrogen, and nitrogen microanalyses were carried out by Guelph Chemical Laboratories Ltd.

Results and discussion

(*i*) PhE'Epy (E' = S or Se; E = Se or Te)

When $Sn(E'Ph)_4$ (E' = S or Se) reacts with py_2E_2 (E = Se or Te), PhE'Epy are possible products. So far as we are aware, no NMR data have been reported for these particular mixed dichalcogenides. Therefore, to facilitate analysis of the reaction mixtures described in the following sections, PhE'Epy were prepared separately from $Ph_2E'_2$ and py_2E_2 and their ^{77}Se and (or) ^{125}Te NMR spectra measured. The results are summarized in Table 4. For the sake of completeness, data for PhTeEpy (E = Se or Te) are included in Table 4 as well, and the table also contains data for the series PhE'EPh, for comparison. Again, all these species were prepared by mixing the symmetrical dichalcogenides. The system Ph_2Te_2:py_2Te_2 was used to confirm[4] δ_{Te} for py_2Te_2.

The rate at which redistribution occurs in $Ph_2E'_2$:py_2E_2 or $Ph_2E'_2$:Ph_2E_2 mixtures depends on the lightest chalcogen in the mixture. At the concentrations used in this study (ca. 0.05 mol/L of solvent) the redistributions are complete in minutes at room temperature (in the time of mixing and initial NMR spectroscopic measurement) when the lightest chalcogen is Te, hours when it is Se, and appear not to have reached equilibrium in weeks when it is S. These rates correlate with the energies of homolytic bond cleavage Te—Te < Se—Se < S—S (*7b*).

The assignments for PhE'ER (R = Ph or py) are straightforward except for the diselenide and ditelluride of formula PhE'Epy. We find that the line widths of R_2Se_2 and R_2Te_2 are reproducibly larger for R = py than for R = Ph, $\Delta\Delta\nu_{1/2(Se)} \approx 2$ Hz and $\Delta\Delta\nu_{1/2(Te)} \approx 16$ Hz, probably because of residual coupling to ^{14}N when R = py. In PhE'Epy (E = E' = Se or Te) the two ^{77}Se or ^{125}Te resonances are of similarly disparate line width and we assign the broader line to the -Epy group.

The ^{77}Se and ^{125}Te resonances of PhE'ER (R = py or Ph; E = Se or Te) show behaviour analogous to Normal Halogen Dependence (19): the shielding of ^{77}Se or ^{125}Te in the ER group depends on the chalcogen E' in the order S < Se < Te. In the ^{77}Se and ^{125}Te NMR spectra (E = ^{77}Se or ^{125}Te), the ratio $[\delta_E(PhSeER) - \delta_E(PhTeER)]/[\delta_E(PhSER) - \delta_E(PhTeER)] = 0.23$ for E = ^{77}Se, R = py or Ph, and 0.30 for ^{125}Te, R = py or Ph, providing the assignment for PhEE'py (E = E' = Se or Te) is made as described above. The invariance of the ratios with R lends support to the proposed assignments. The value of 0.30 for E = ^{125}Te is close to the average found for the analogous ratio in halogen-containing species of a variety of elements (20), while the value of 0.23 for E = ^{77}Se is at the lower end of such values.

(*ii*) $Sn(SPh)_{4-x}(Sepy)_x$

Tin-119 NMR spectra show that four new species, each giving one ^{119}Sn signal with ^{77}Se satellites, are formed sequentially when py_2Se_2 is added to $Sn(SPh)_4$ in gradually increasing amount. The ^{77}Se NMR spectra of the mixtures show a corresponding four signals for selenium attached to tin, which can be assigned from their order of appearance and their $^{117/119}Sn$ satellite splittings. The ^{77}Se NMR spectra also show a signal from pySeSPh (see above) and, in py_2Se_2-rich mixtures, a signal from unreacted diselenide. The formation of pySeSPh shows that PhS^- and $pySe^-$ ligands are interchanging in the $Sn(SPh)_4$:py_2Se_2 mixtures, although the existence of unreacted py_2Se_2 in the equilibrium mixtures, even at the lowest $Sn(SPh)_4$:py_2Se_2 ratio investigated (1:0.5), shows that the interchange is incomplete. Evidently $Sn(SPh)_{4-x}(Sepy)_x$ are being formed according to equilibrium [1], E' = S, E = Se. Table 5 contains ^{119}Sn and ^{77}Se NMR data for $Sn(SPh)_{4-x}(Sepy)_x$.

Table 4. Selenium-77 and ^{125}Te NMR data for PhE'ER (R = py or Ph) and the corresponding symmetrical species in CH_2Cl_2 at ambient probe temperature.

Compound	E',E	δ_{Se}[a]	δ_{Te}[b]
PhE'Epy	S,Se	538.7	
	S,Te		1000
	Se,Se	412.4,[c] 486.9[d]

	S,Te		1016
	Se,Te	257.9	836
	Se,Se	461.0[e]	
	Te,Te		417[f,g]
py_2E_2	—,Se	443.0[h]	
	—,Te		410[g]

[a]Reproducibility ±0.5 ppm.
[b]Reproducibility ±1 ppm or better, except as noted; uncertainty from referencing ±3 ppm.
[c]PhE'- (tentative assignment).
[d]-Epy (tentative assignment).
[e]Earlier ^{77}Se NMR data are available for this compound, e.g., ref 17*b*.
[f]Reproducibility approximately ±5 ppm.
[g]Earlier ^{125}Te NMR data are available for this compound, e.g., ref 17*a*.
[h]δ_{Se} = 439 ($CDCl_3$) (18).

[1] $Sn(E'Ph)_4 + n\ py_2E_2 \rightleftarrows Sn(E'Ph)_{4-x}(Epy)_x + m\ pyE_{2-y}E'Ph_y$ (equilibrium mixture)

The complexes $Sn(SPh)_{4-x}(Sepy)_x$ form more readily for x = 1 or 2 than for x = 3 or 4. The latter two species become major components of the mixtures only in the presence of a significant excess of py_2Se_2, e.g., when py_2Se_2:$Sn(SPh)_4$ = 5.5, the relative amounts of the three species present are $Sn(SPh)_2(Sepy)_2 > Sn(SPh)(Sepy)_3 > Sn(SePy)_4$. Redistribution (equilibrium [2])

[2] $2\ Sn(E'Ph)_{4-x}(Epy)_x \rightleftarrows Sn(E'Ph)_{4-x+1}(Epy)_{x-1} + Sn(E'Ph)_{4-x-1}(Epy)_{x+1}$

is significant for x = 1 and 3, but not for x = 2.

Structural information can be deduced from the *pattern* of ^{119}Sn NMR chemical shifts that is observed for $Sn(SPh)_{4-x}(Sepy)_x$. Defining $\Delta\delta_{Sn}$ (*4-x,4-x-1*) as $\delta_{Sn}[Sn(E'Ph)_{4-x}(ER)_x] - \delta_{Sn}[Sn(E'Ph)_{4-x-1}(ER)_{x+1}]$, the data (Table 5) for the series where E' = S, E' Se, R = py give $\Delta\delta_{Sn}(4,3) = 243$, $\Delta\delta_{Sn}(3,2) = 349$, $\Delta\delta_{Sn}(2,1) = 121$, $\Delta\delta_{Sn}(1,0) = 145$ ppm. Significantly, the values of $\Delta\delta_{Sn}$ (*4,3*) and $\Delta\delta_{Sn}$(*3,2*) are relatively large. A different pattern is observed for $Sn(SPh)_{4-x}(SePh)_4$, $\Delta\delta_{Sn}(4,3) = 41.7$, $\Delta\delta_{Sn}$ (*3,2*) = 44.2, $\Delta\delta_{Sn}$ (*2,1*) = 46.8, $\Delta\delta_{Sn}$ (*1,0*) = 49.5

[j]Could not be observed with certainty at ambient probe temperature; at 213 K, $^1J(^{117/119}Sn-^{77}Se)_{Avg}$ ≈1200 Hz.
[k]$^1J(^{117/119}Sn-^{125}Te)_{Avg}$; at 213 K, $^1J(^{117/119}Sn-^{125}Te)_{Avg}$ ≈1040 Hz.

ppm for E = S, E′ = Se, R = Ph (22). Using previous arguments (4), the difference between the two patterns is associated with initial replacement of SPh^- by *chelating* $Sepy^-$ in the series $Sn(SPh)_{4-x}(Sepy)_x$. A similar process cannot occur in $Sn(SPh)_{4-x}(SePh)_x$. For $Sn(SPh)_{4-x}(Sepy)_x$, bi- for mono-dentate replacement occurs until a coordination number of six is reached, after which SPh^- is replaced by *monodentate* $Sepy^-$. In the series $Sn(SPh)_{4-x}(pyt)_x$ (4), this argument was bolstered by a structure determination for $Sn(\eta^2\text{-pyt})_2(\eta^1\text{-pyt})_2\cdot$pytH. Since only one ^{77}Se NMR signal is observed for $Sn(SPh)_{4-x}(Sepy)_x$ (x = 3 or 4), but ^1J(Sn–Se) is maintained, there must be rapid intramolecular exchange of chelating and monodentate $Sepy^-$ in these complexes at ambient probe temperature. There is no dramatic decrease in the magnitude of the time-averaged ^1J when the monodentate $Sepy^-$ is incorporated, and therefore the monodentate $pySe^-$ must be *Se*-bonded. Thus $Sn(SPh)_{4-x}(Sepy)_x$ should be formulated $Sn(SPh)_3$(Sepy-*N,Se*), $Sn(SPh)_2$(Sepy-*N,Se*)$_2$, Sn(SPh)(Sepy-*N,Se*)$_2$(Sepy-*Se*), and Sn(Sepy-*N,Se*)$_2$(Sepy-*Se*)$_2$ for x = 1 through 4. The formulation of $Sn(SPh)_2$(Sepy-*N,Se*)$_2$ is confirmed by the X-ray structural analysis given below, and that of Sn(SPh)(Sepy-*N,Se*)$_2$(Sepy-*Se*) is given strong support by its co-crystallization with $Sn(SPh)_2$(Sepy-*N,Se*)$_2$ in **2** (see below). Pure $Sn(SPh)_2(Sepy)_2$ cannot be isolated in the presence of $Sn(SPh)(Sepy)_3$ (see Experimental), but it can be isolated in the presence of $Sn(SPh)_3$(Sepy-*N,Se*), presumably because co-crystallization is now prevented by the different shapes of the two complexes. The structure of pure $Sn(SPh)_2$(Sepy-*N,Se*)$_2$, **1**, is described below.

(*iii*) $Sn(SePh)_{4-x}(Sepy)_x$

These complexes are formed in the system $Sn(SePh)_4$:py_2Se_2, according to eq. [1], E′ = E = Se. For $Sn(SePh)_{4-x}(Sepy)_x$, 0 < x < 4, two different sets of ^{77}Se satellites are found around each ^{119}Sn NMR signal, and two ^{77}Se NMR signals are observed for each complex. Assignment can be made on the basis of the relative intensities of the two sets of satellites, together with a knowledge of the expected magnitude of $^1J(^{119}Sn-^{77}Sepy)$ from the series $Sn(SPh)_{4-x}(Sepy)_x$ (Table 5). Tin-119 and ^{77}Se NMR data for $Sn(SePh)_{4-x}(Sepy)_x$ are included in Table 5. It can be seen from the data that ^1J is significantly larger for *Sn–Se*Ph coupling than for *Sn–Se*py. Also, the values of $^1J(^{119}Sn-^{77}Sepy)$ vary irregularly with x. The pattern of $\Delta\delta_{Sn}$ is again $\Delta\delta_{Sn}(4,3)$,$\Delta\delta_{Sn}(3,2) > \Delta\delta_{Sn}(2,1)$, $\Delta\delta_{Sn}(1,0)$ and we conclude that the structures of $Sn(SePh)_{4-x}(Sepy)_x$ parallel those of $Sn(SPh)_{4-x}(Sepy)_x$ discussed above. Then the irregularity observed for $^1J(^{119}Sn-^{77}Sepy)$ must reflect changes in coordination number and ratio of bi- and monodenate $Sepy^-$ ligands.

Equilibrium [1] lies further to the right for E′ = E = Se than for E′ = S, E = Se, e.g., when $Sn(SePh)_4$:py_2Se_2 = 1:0.5, no detectable pySeSePh or py_2Se_2 is found at equilibrium, only Ph_2Se_2. Also, unlike $Sn(SPh)_2(Sepy)_2$, discussed above, $Sn(SePh)_2(Sepy)_2$ *does* undergo significant redistribution, eq. [2], x = 2, and we have been unable to isolate pure

[6] In contrast, distorted dodecahedral coordination has been reported for Sn(2-S-C_5H_3N-3-$SiMe_3$-*N,S*)$_4$ (24).

$Sn(SePh)_2(Sepy)_2$. These observations are consistent with the expectation that replacement of $SePh^-$ by another Se-donor ligand should be easier than replacement of PhS^- by the Se-donor ligand, reflecting the greater ease of oxidation of $SePh^-$.

(*iv*) $Sn(SPh)_{4-x}(Tepy)_x$ (x = 1 or 2)

Mixtures of $Sn(SPh)_4$ and py_2Te_2 or of $Sn(SPh)_2$ and py_2Te_2 are not particularly stable, and some decomposition was evident during the extended periods necessary to obtain both ^{119}Sn and ^{125}Te NMR spectra at either ambient probe temperature or at 213 K. However, we were able to fully characterize $Sn(SPh)_3(Tepy)$ and $Sn(SPh)_2(Tepy)_2$. This appears to be the first evidence for ligand behaviour by $Tepy^-$. The complex $Sn(SPh)_3(Tepy)$ was the major species at $Sn(SPh)_4$:py_2Te_2 = 1:1 or 1:5. Both these mixtures contain both unreacted py_2Te_2 and pyTeSPh, as evidenced by ^{125}Te NMR. Solutions in which $Sn(SPh)_2(Tepy)_2$ is the major species can be made by oxidative addition, eq. [3], E′ = S, but some decomposition is indicated by change of the mixture from pale orange to dark brown with the formation of a black insoluble species.

[3] $Sn(E'Ph)_2 + py_2Te_2 \rightarrow Sn(E'Ph)_{4-x}(Tepy)_x$

(with decomposition)

No evidence was found for $Sn(SPh)(Tepy)_3$ or $Sn(Tepy)_4$ when mixing, and NMR spectral measurements were carried out either at ambient probe temperature or at 213 K.

Sn-119 and ^{125}Te NMR data for $Sn(SPh)_{4-x}(Tepy)_x$ (x = 1 or 2) are included in Table 5. It is important to note that for these complexes the values of $\Delta\delta_{Sn}(4\text{-}x,4\text{-}x\text{-}1)$ ($\Delta\delta_{Sn}(4,3)$ = 318, $\Delta\delta_{Sn}(3,2)$ = 427 ppm) are much larger than the corresponding values found (22) for $Sn(SPh)_{4-x}(TePh)_x$ ($\Delta\delta_{Sn}(4,3)$ = 113, $\Delta\delta_{Sn}(3,2)$ = 139 ppm). This suggests that the first two $pyTe^-$ ligands introduced into $Sn(SPh)_{4-x}(Tepy)_x$ behave as *N,Te*-chelates, but data for the full series $Sn(SPh)_{4-x}(Tepy)_x$ are necessary to strengthen this conclusion. It is *possible* that chelation of $Tepy^-$ in $Sn(SPh)_{4-x}(Tepy)_x$ (x = 1 or 2) may be prevented by steric congestion, but then it is not obvious why $Sn(SPh)_{4-x}(pyTe\text{–}Te)_x$ (x = 3,4) should not be formed, since the analogous $TePh^-$-containing species have been prepared in solution by an oxidative addition (22).

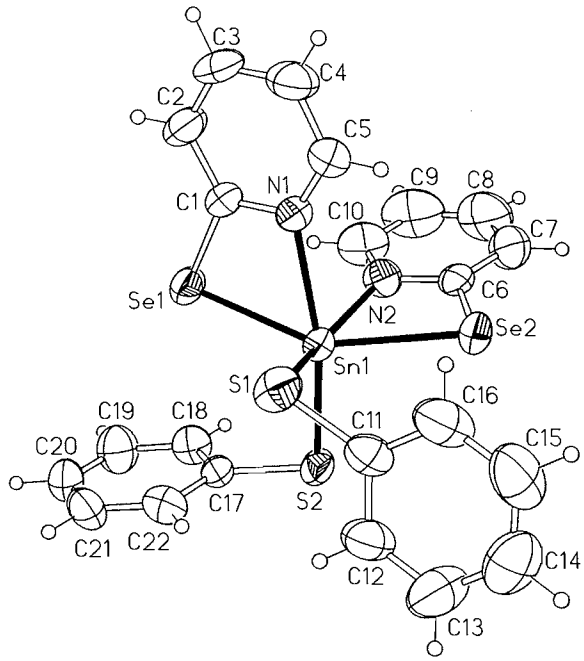
(*v*) $Sn(SePh)_{4-x}(Tepy)_x$

The behaviour of mixtures of $Sn(SePh)_4$ and py_2Te_2 (eq. [2]) or of $Sn(SePh)_2$ and py_2Te_2 (eq. [3]) is generally similar to that of the thiolate analogues, except that here both ^{125}Te and ^{77}Se couple to ^{119}Sn. The mixtures provide ^{119}Sn, ^{125}Te, and ^{77}Se NMR evidence for $Sn(SePh)_{4-x}(Tepy)_x$ (x = 1 or 2), along with unreacted py_2Te_2 and pyTeSePh. In no mixture examined was $Sn(SePh)_2(Tepy)_2$ the major tin-containing species.

Details of the NMR spectra are given in Table 5. The magnitudes of $^1J(^{119}Sn\text{–}^{77}Se)$ and $^1J(^{119}Sn\text{–}^{125}Te)$ are quite different for $Sn(SePh)_3(Tepy)$ and, together with the relative satellite intensities in the ^{119}Sn NMR spectrum, this makes assignment of the ^1J couplings straightforward for this species. Even at 213 K, the ^1J couplings of $Sn(SePh)_2(Tepy)_2$ are not completely resolved, but they are evidently of similar magnitude, and it is possible that the assignments should be reversed.

Again, a comparison of $\Delta\delta_{Sn}(4,3)$ and $\Delta\delta_{Sn}(3,2)$ for phenyl (22) and 2-pyridyl analogues shows that $pyTe^-$ is most probably behaving in a chelating manner: the values are 302 and 410 ppm for $Sn(SePh)_{4-x}(Tepy)_x$ and 89 and 102 ppm for $Sn(SePh)_{4-x}(TePh)_x$.

Fig. 1. Perspective view of the molecule $Sn(SPh)_2(2\text{-}Se\text{-}C_5H_4N\text{-}N,Se)_2$.



(vi) Structure of $Sn(SPh)_2(Sepy)_2$, 1

The crystal structure of **1** consists of discrete $Sn(SPh)_2(Sepy)_2$ molecules. The closest approach is 2.267 Å between H(16) and H(12) (x − 0.5, 1.5 − y, z − 0.5). Figure 1 shows a perspective view of the molecule and gives the numbering scheme. The bond distances and bond angles are given in Table 6.

Monomeric $Sn(SPh)_2(Sepy)_2$ has the structure $Sn(SPh)_2(C_5H_4NSe\text{-}N,Se)_2$, with bidentate chelating $pySe^-$ ligands. This confirms the conclusion reached from the ^{119}Sn NMR data. There is distorted octahedral coordination about the Sn, with the two S atoms mutually *cis*, the two Se atoms mutually *trans*, and the two N atoms mutually *cis*. The configuration is very similar to that found for $Sn(C_5H_4NS\text{-}N,S)_2Cl_2$, **3** (24), and for $Sn(C_5H_4NS\text{-}N,S)_2(C_5H_4NS\text{-}S)_2$, **4**, in $Sn(pyt)_4pytH$ (4), but quite different from the distorted dodecahedral structure of $Sn(2\text{-}S\text{-}C_5H_3N\text{-}3\text{-}SiMe_3\text{-}N,S)_4$ (25) or the *trans*-diorganyl grossly distorted octahedral (or distorted tetrahedral (26)) structures of various complexes $R_2Sn(pyt)_2$ (R = Me (27), *c*-C_6H_{11} (28), or Ph (29)) and $Bu^n{}_2Sn(2\text{-}S\text{-}5\text{-}NO_2\text{-}C_5H_3)_2$ (26).

The Sn—S distances of 2.464(2) and 2.475(2) Å are very similar to those of the monodentate pyt^- ligands in **4** (4), but slightly lower than those of $Sn(SPh)_4(bipy)$, which range from 2.497(1) to 2.502(1) Å (30) Similarly, the Sn—N distances of 2.325(5) and 2.333(5) Å are identical within experimental uncertainty to those of the chelating ligands in **4**. They are, however, slightly larger than those of **3** (2.271(9) and 2.256(9) Å), and much smaller than the values found (26–29)

for the diorganyltinbis(pyridine-2-thiolates) (2.636(4) −2.77(1) Å), consistent with the *semi*-chelating nature of the *N,S* ligand in the latter. The Sn—Se distances, 2.6291(8) and 2.6358(8) Å, are comparable to the values of 2.648(3)–2.669(3) Å observed in the octahedral anion of $(Ph_4As)_2[Sn\{Se_2C{=}C(CN)_2\}_3]$ (31), but longer than analogous distances observed in various tetrahedral species of the general type $Sn(SeR)_4$ (32, 33), as expected.

The geometry of the $Sepy^-$ ligands is unexceptional (5, 6). The bite of the ligands observed in **1**, 65.78(13)° and 65.93(12)° falls outside the range of 58.9(4)°–62.9(4)° found for polymeric $Cd(Sepy)_2$ (6*a*). The Sn-Se-C angles of **1**, 78.5(2)° and 79.5(2)°, are similar to the corresponding intrachelate angles in $Cd(Sepy)_2$, 77.5(5)° and 76.5(6)° (6*a*), but smaller than the corresponding angles found (33) in either form of $Sn(SePh)_4$ (96.0(3)° and 96.5(3)° in the orthorhombic form, 95.1(3)° and 95.7(3)° in the monoclinic form), consistent with the formation of a small chelate ring in **1**. The intrachelate Sn-N-C angles of **1**, 102.4(4)° and 102.9(4)°, are slightly larger than the corresponding angles found for the chelate rings of either **3** (98.1(7)° and 100.0(7)°) or **4** (99.6(4)° and 98.5(4)°). This is consistent with the presence of a longer Sn–chalcogen bond in the chelate rings of **1** than in those of **3** or **4**.

(*vii*) Structure of $Sn(SPh)_{1.85}(Sepy)_{2.15}$, 2

Overall, the structure of the neutral molecule that provides a solution in the X-ray analysis of **2** is remarkably similar to that

Table 7. Bond distances and angles for $Sn(SPh)_{1.85}$ $(2\text{-}Se\text{-}C_5H_4N)_{2.15}$, **2**.

observed for **1**. Selected bond distances and angles are given in Table 7, using the same numbering scheme as in Fig. 1. The agreement factors, estimated standard deviations, residual electron density, thermal parameters, etc. indicate that this is a very good X-ray analysis (34, 35). Indeed, if considered in isolation, the X-ray analysis could easily be mistaken for that of **1**; only the NMR and elemental analytical data (see experimental section) tell us that the compound is not **1**. There is, however, a discrepancy involving the Sn—S distances. In **2**, the Sn—S(1) distance exceeds the Sn—S(2) distance by more than in **1** ($\Delta/\sigma = 7.1$ vs. 3.9). As well, if the data measured here are interpreted as due to **1**, there is excess electron density in the vicinity of S(1) (see Experimental). The data are of sufficiently high quality that these admittedly minor discrepancies warrant further discussion.

We can account for the anomalies occurring in **2** as follows: since the Sn—S(2) distances of **1** and **2** are identical (2.466(2) vs. 2.464(2) Å), there is no disorder involving S(2)Ph; partial occupation of the SPh site by Sepy occurs only at S(1)SPh. In our refinement we allowed the pyridyl group of the contaminant to occupy its two possible orientations with equal probability. Since the Sn—Se bond length will exceed the Sn—S bond length, incorporation of 15% of Sepy extends Sn—S(1) in the (average) molecule, which provides a solution for the data. Incorporating the disorder also has the effect of removing the excess electron density in the vicinity of S(1) (see Experimental). It is noteworthy that substitution of Sepy for SPh occurs at only one of the two chemically identical, though crystallographically distinct (see above), SPh sites of $Sn(Sepy)_2(SPh)_2$. Selective substitution of this type has been

observed in other instances (for recent reviews, see ref. 36).

The proof of co-crystallization and resulting disorder in **2** provides another example in support of the crystallographers' maxim, formalized by Parkin (36), that extra caution must be exercised if there are any unusual measured bond lengths. When in doubt, evidence from spectroscopic and chemical analysis should be sought to correctly formulate compounds and to understand the crystallographic anomaly.

It is evident that in order for $Sn(Sepy)_2(SPh)_2$ and $Sn(Sepy)_3(SPh)$ to co-crystallize as **2** in the manner detected, the structure of $Sn(Sepy)_3(SPh)$ must be the same as that of $Sn(Sepy)_2(SPh)_2$ in **1**, i.e., it must be *cis*-$Sn(\eta^2\text{-Sepy})_2(\eta^1\text{-Sepy})(SPh)$. Thus the formulation $Sn(\eta^2\text{-Sepy})_2(\eta^1\text{-Sepy})(SPh)$ proposed from the pattern of ^{119}Sn NMR chemical shifts (see above) is confirmed.

Acknowledgments

This work was made possible by funding from the Natural Sciences and Engineering Research Council of Canada in the form of an Individual Research Grant to P.A.W.D. and an Equipment Grant to the Department of Chemistry for the purchase of the Siemens service X-ray diffractometer. We thank Professor N.C. Payne for access to the Enraf–Nonius X-ray diffractometer, and we are grateful to S. England and V.M. Richardson of this department for expert technical assistance in obtaining some of the NMR spectra.

Ionically conducting polyether composites

J.R. Stevens and W. Wieczorek

Abstract: Ionic conductivity in polymer–salt electrolytes occurs in the amorphous regions of the complex. Poly(ethylene oxide) (PEO) is the best polyether for complexing salts. Unfortunately, it is partially crystalline at ambient temperatures. With inorganic (i.e., alumina) or organic (i.e., poly(acrylamide) (PAAM)) fillers the crystallization of PEO is inhibited and the room temperature conductivity is enhanced in these mixed phase systems by over two orders of magnitude (to $\sim 10^{-4}$ S/cm) above the base PEO–salt system ($<10^{-6}$ S/cm). Even adding PAAM to an initially amorphous system (oxymethylene-linked PEO–$LiClO_4$) increases the room temperature conductivity by 2 to 3 times. Various alkali metal salts (Li, Na) and NH_4SCN are used with α-Al_2O_3, θ-Al_2O_3, PAAM′ and poly(*N,N*′-dimethyl acrylamide) as fillers. The aluminas stiffen the complex and increase T_g. The addition of the organic fillers lowers T_g, as is to be preferred. It is suggested that changes in the conductivity with changes in salt and filler concentration are due to changes in the ultrastructure and morphology and are the result of an equilibrium between various Lewis acid – Lewis base reactions. Qualified success has been achieved in modelling ionic conductivity in these composite electrolyte systems using an effective medium approach. In this approach it has been assumed that the main conductivity enhancement takes place in thin amorphous layers of the polyether that coat the dispersed polyacrylamide particles separated in a microphase. In the best complexes this layer is identified by a second T_g.

Key words: polyethers, composites, ionic conductivity, phase structure, Lewis acids and bases.

Résumé : La conductivité ionique des électrolytes de la forme sel de polymères se produit dans les régions amorphes du complexe. Le poly(oxyde d'éthylène) («PEO») est le meilleur éther pour la complexation des sels. En présence de garnitures inorganiques (par exemple, de l'alumine) ou organique (par exemple, le poly(acrylamide) (PAAM)), la cristallisation du «PEO» est inhibé; dans ces systèmes de phases mixtes, la conductivité à la température ambiante est de deux ordres de grandeur plus élevée (rehaussée à environ 10^{-4} S/cm) que celle du système de base «PEO»–sel ($<10^{-6}$ S/cm). Même l'addition de PAAM à un système initialement amorphe («PEO»–$LICIO_4$ lié par de l'oxyméthylène) provoque une augmentation (par des facteurs de deux à trois) de la conductivité à la température ambiante. Divers sels de métaux alcalins (Li, Na), de même que la NH_4SCN, peuvent être utilisés comme garnitures de concert avec de l'α-Al_2O_3, du θ-Al_2O_3, du PAAM et du poly (*N,N*′-diméthyl acrylamide). Les alumines solidifent le complexe et augmentent la valeur de T_g. Comme on peut l'espérer, l'addition de garnitures organiques diminue la valeur de T_g. Il a été suggéré que les changements dans la conductivité associés à des changements dans la concentration en sel et en garniture sont dus à des changements dans l'ultrastructure et la morphologie et qu'ils sont le résultat d'un équilibre entre diverses réactions d'acides et de bases de Lewis. Utilisant une approche faisant intervenir le milieu effectif, on a obtenu des résultats mitigés dans le modelage de la conductivité ionique dans ces systèmes électrolytes composites. Dans cette approche, on fait l'hypothèse que l'augmentation principale de la conductivité se produit dans des couches minces amorphes de polyéther qui recouvrent les particules dispersées de polyacrylamide séparées dans une microphase. Dans les meilleurs complexes, cette couche est identifiée par une deuxième valeur de T_g.

Mots clés : polyéthers, composite, conductivité ionique, structure de la phase, acides et bases de Lewis.

Introduction

Polymer electrolytes are complexes of electronodonor polymers with various inorganic or organic salts or acids (1). The entropic and enthalpic characteristics of the polymer–salt system should promote the dissociation of the dopant salt or acid. For cation solvation it is necessary for the polymer to contain series of heteroatoms each with lone electron pairs (usually O, N, S) that have inter or intramolecular spacings in the polymer matrix conducive to the coordination of the heteroatoms with the acceptor cations. The anions are only weakly coordinated, if at all; they usually simply "dig" into the polymer matrix.

In these systems ionic transport mainly occurs through a coupling of the ions with relaxing polymer segments in the amorphous regions of a highly viscoelastic material; high cationic transport numbers and fast structural and ion relaxation times are important. Another requirement is, then, that the amorphous regions of the material be as far above the liquid–glass transition as possible in the operating temperature and pressure range. The final requirement is structural and chemical stability; such characteristics as degradation, moisture absorption, phase separation, and crystallization over time would be detrimental to a useful polymer electrolyte.

The most intensely studied polymer electrolytes (2–5) are based on poly(oxa alkanes), poly(aza alkanes), or poly(thia alkanes). These studies are motivated by the possibility of a variety of applications among which are (*i*) solid state primary

and secondary microbatteries with a lithium or lithium alloy anode and a composite cathode containing intercalated materials, (*ii*) electrochemical sensors, and (*iii*) electrochromic devices (displays and "smart" windows). The range of conductivities depends on the kind of application and is $10^{-3} - 10^{-4}$ S/cm for batteries; conductivities can be lower for sensors and electrochromic applications.

This report deals with polymer electrolytes based on poly(oxa alkanes) or polyethers and particularly on poly(ethylene oxide) (PEO) based composites complexed with alkali metal salts (Li, Na) and NH_4SCN. These materials have a complicated phase structure consisting of an amorphous phase, a crystalline phase, and at least one in a range of crystalline complex phases formed between the incorporated polymers and the salt. The contribution of each particular phase to the conduction process changes with temperature, causing difficulties in the interpretation of experimental results; the mechanism for ionic conductivity in polymeric electrolytes has yet to be established. PEO is unfortunately about 70% crystalline at ambient temperatures with conductivities in the low range of $10^{-7} - 10^{-8}$ S/cm. The volume of flexible amorphous phase and the ionic conductivity increase dramatically as the polyether melts. For polymer–salt complexes the melting temperatures range between 65°C and 140°C depending on the salt concentration. However, at temperatures exceeding the melting point the mechanical and electrochemical stability of these electrolytes deteriorates.

Since chains containing ethylene oxide (EO) provide just the right spacing and solvation properties to coordinate and encapsulate suitable cations, considerable work has been done to synthesize EO configurations that limit or eliminate crystallization. This research has taken three main directions. The first is to limit the length of the chain segments containing EO monomeric units to between 4 and 15. Such lengths are long enough to effectively complex alkali metal cations but too short to effectively crystallize. Examples are polymer networks, random and block EO – propylene oxide (PO) copolymers, randomly variable length segments of PEO joined by methyleneoxide units, and comblike systems with short chain EO or EO–PO sequences as the comb "teeth" and backbones like poly(dimethyl siloxane) and poly(phosphazene) (5). The second is to use plasticizing salts that form complexes with low-temperature eutectics with the pristine PEO phase, and the third is to add fillers that reduce the crystallizing tendencies of the PEO polymer host.

From the point of view of ease of preparation as well as commercial application the third idea is the simplest. Generally two types of composite polymeric electrolytes are considered. The first is based on inhomogeneous mixtures of polymer and inorganic or organic additives that are not dissolved in a common low molecular weight volatile solvent. These are mixed phase systems and are the subject of this study. Examples of organic additives, and the ones used here, are poly(*N,N'*-dimethylacrylamide) (NNPAAM) and polyacrylamide (PAAM). Hydrogen bonding is possible in PAAM composites but not in NNPAAM composites since NNPAAM lacks an amidic hydrogen. Blend-based composite polymeric electrolytes are the second type (6, 7). Examples are systems obtained by the dissolution of two (usually high molecular weight) components in an appropriate solvent followed by the evaporation of the solvent; miscible or partially miscible blends of both components are formed. In the present work the application of solid inorganic and organic additives is explored in an attempt to prevent crystallization and to enhance the ionic conductivity over that for the basic PEO–salt system. The overall objective has been to understand the role of the filler additives (organic and inorganic powders and high molecular weight polymers with special properties) in ionic conduction in these composite PEO-based electrolytes. Various aspects of this work have been reported previously in different publications (8–12). This paper assembles all of the relevant results from these publications for the purpose of discussing and comparing physical and chemical properties. Gray has reported studies using low molecular weight additives with the objective of improving the mechanical properties of PEO-based electrolytes (3, 6).

Experimental

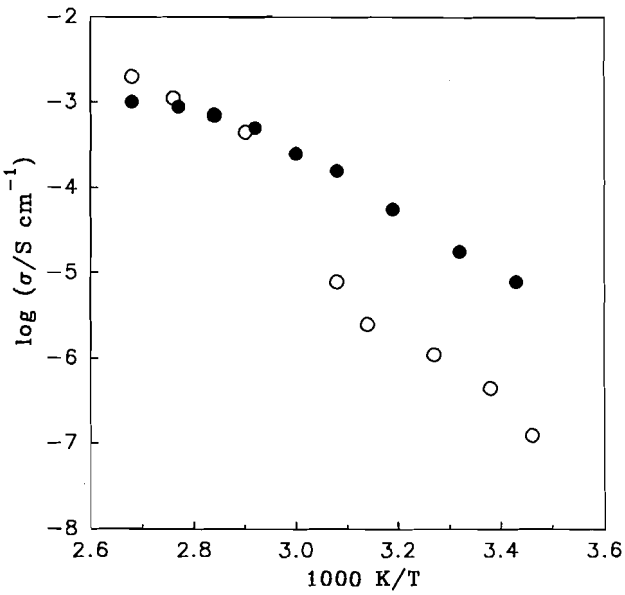
Sample preparation

NNPAAM ($M_w = 1.3 \times 10^5$, Polysciences, reagent grade) and PEO (Aldrich, reagent grade, $M_w = 5 \times 10^6$) were used without further purification and after drying under vacuum ($<10^{-4}$ Torr; 1 Torr = 133.3 Pa) at 50–70°C for 48 h. The synthesis of oxymethylene-linked PEO (OMPEO) followed that of Nicholas et al. (13). The resulting transparent elastomers were dried under vacuum for 48 h before synthesizing the polymer electrolyte. Polyacrylamide PAAM ($M_w = 1.6 \times 10^5$) was prepared by the free radical polymerization of acrylamide (Aldrich, reagent grade) using benzoyl peroxide (Aldrich reagent grade) as initiator. The product was dried under vacuum at 100°C for 48 h. Commercially available α-Al_2O_3(Aldrich reagent grade, fraction with grain sizes less than 5 μm) and θ-Al_2O_3 (with grain sizes less than 2 μm) were used as inorganic fillers. Amorphous aluminum oxide θ-Al_2O_3 was obtained by thermal dehydration of aluminum hydroxide performed at 1100°C. The details concerning the preparation of these inorganic fillers as well as the separation of these fillers into fraction of different grain sizes have been described elsewhere (14, 15). Acetonitrile (Aldrich, reagent grade) was doubly distilled and stored over type 4A molecular sieves. All of the steps in the preparation procedure were performed in an argon-filled drybox (moisture content lower than 20 ppm). $LiClO_4$ (Aldrich, reagent grade), $NaClO_4$ (Aldrich, reagent grade), NH_4SCN (Aldrich, reagent grade), and NaI (Aldrich, reagent grade) were dried under vacuum ($<10^{-4}$ Torr) at 120°C prior to incorporation. The concentration of salts was equal to 10 mol% with respect to the ether oxygen concentration. The solid components were mixed in appropriate amounts in a small glass reactor and then acetonitrile was added to form an approximately 5 mass% suspension with respect to all solid components. The mixture was magnetically stirred until a homogenous suspension was obtained. Excess acetonitrile was removed by vacuum distillation. The composite electrolytes obtained were dried under vacuum ($<10^{-4}$ Torr) for 48–72 h at 60°C. The concentration of fillers in the composite electrolytes varied between 5 and 50 vol%. All samples were equilibrated at ambient temperature for at least a month before undertaking any experiments.

DSC studies

DSC data were obtained between –110 and 150°C using a

Fig. 1. Comparison of the temperature dependence of ionic conductivity measured for [○] $(PEO)_{10}NaI$ electrolyte and [●] $(PEO)_{10}NaI$–θ-Al_2O_3 (10 mass%) composite electrolyte.



DuPont TA 2910 scanning calorimeter with a low-temperature measuring head and liquid nitrogen cooled heating element. Approximately 15 mg samples in aluminum pans were stabilized by slow cooling to –110°C and then heated at 10°C/min to 150°C. An empty aluminum pan was used as a reference.

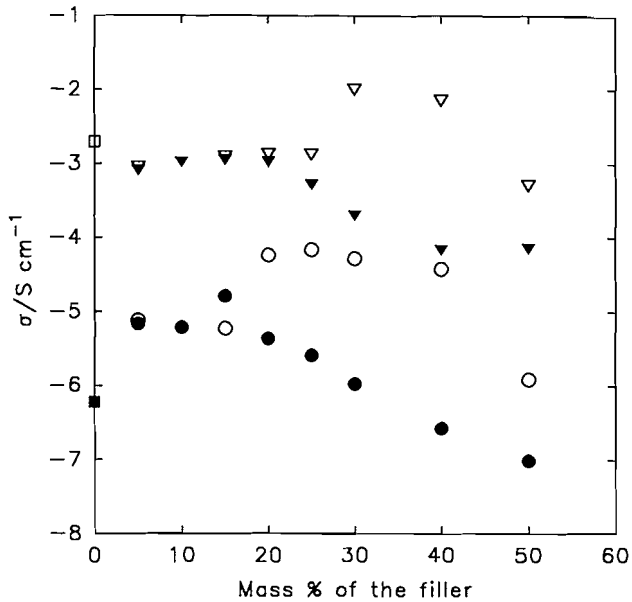
Conductivity measurements

Ionic conductivity was determined using the complex impedance method in the temperature range –20 to 100°C. The samples were sandwiched between stainless steel blocking electrodes and placed in a temperature-controlled furnace. The impedance measurements were carried out on a computer-interfaced HP 4192 impedance analyzer over the frequency range 5–13 MHz. The peak-to-peak voltage in impedance experiments was equal to 1 V.

Conductivity results

Figure 1 compares the temperature dependence of the conductivities for the $(PEO)_{10}NaI$ and $(PEO)_{10}NaI$–θ-Al_2O_3 (10 mass%) systems. The θ-Al_2O_3 grain sizes were less than 2 μm. At temperatures up to about 60°C, which roughly corresponds to the melting temperature of the crystalline PEO phase (T_m), conductivities measured for the composite system are higher; above this temperature the ionic conductivities of both systems are comparable. An abrupt change in the conductivity of the $(PEO)_{10}NaI$ electrolyte near T_m for the crystalline PEO phase is evident and is not observed for the composite electrolyte. As can be seen in Table 1, the addition of 10 mass% of θ-Al_2O_3 to the $(PEO)_{10}NaI$ electrolyte reduces the fraction of the crystalline PEO phase (X_c) by 34%, increasing the conductivity as shown for ambient temperatures in Fig. 1. Although lowering X_c improves the conductivity, the addition of stiff filler grains results in lowering the flexibility of the composite electrolyte; the higher glass transition temperature (T_g) measured for the $(PEO)_{10}NaI$–θ-Al_2O_3 system is evidence of this.

Fig. 2. Comparison of isotherms of ionic conductivity of PEO–PAAM–$LiClO_4$ composite electrolytes at [○] 25°C and [▽] 100°C with isotherms of ionic conductivity of PEO–NNPAAM–$LiClO_4$ composite electrolytes at [●] 25°C and [▼] 100°C. [■], [□]: Conductivities measured for the $(PEO)_{10}LiClO_4$ electrolyte at 25°C and 100°C, respectively.



As PAAM is added to the $(PEO)_{10}LiClO_4$ electrolytes, the ambient temperature conductivity increases to a plateau as is observed in Fig. 2. At 25°C the ionic conductivities of the majority of the PEO–PAAM–$LiClO_4$ composite electrolytes are higher than for the $(PEO)_{10}LiClO_4$ electrolyte. For the PEO–NNPAAM–$LiClO_4$ electrolytes, conductivity initially increases with the addition of the filler and then decreases for NNPAAM concentrations higher than 15 mass%. For NNPAAM concentrations higher than ~30 mass%, conductivities are lower than for the $(PEO)_{10}LiClO_4$ system.

At 100°C, conductivities of composite systems containing 20–40 mass% of PAAM are still higher than for the $(PEO)_{10}LiClO_4$ electrolyte. For NNPAAM electrolytes, conductivities are almost the same as for the $(PEO)_{10}LiClO_4$ electrolyte up to 20 mass% of NNPAAM and gradually decrease for higher NNPAAM concentrations. As can be seen from Table 1, PAAM is effective at reducing crystallization in the $(PEO)_{10}LiClO_4$ electrolyte series. The amount of the crystalline PEO phase in these composite electrolytes is lower than for the $(PEO)_{10}LiClO_4$ system. Two T_g's are observed for samples containing 15 and 25 mass% of PAAM. One is comparable to the T_g of the $(PEO)_{10}LiClO_4$ electrolyte, the other is roughly comparable to the T_g of the undoped PEO system. It can be concluded that the addition of PAAM plasticized the PEO–$LiClO_4$ electrolyte and separated out a flexible amorphous phase of low T_g. Similar trends are also observed for the PEO–$LiClO_4$ based composite electrolytes containing NNPAAM. Although the presence of two different T_g's is not observed, the T_g's of PEO–NNPAAM–$LiClO_4$ composite electrolytes are lower than for the $(PEO)_{10}LiClO_4$ system and decrease with an increase in the NNPAAM concentration. For concentrations of NNPAAM below ~25 mass% the addition of NNPAAM reduces the frac-

[c]X_c calculated on the basis of DSC data according to the procedure described in ref. 9.

tion of the crystalline PEO phase. For higher concentrations the X_c increases and approaches that for the $(PEO)_{10}LiClO_4$ electrolyte. These changes in X_c account for the decrease in conductivity observed at ambient temperatures for composite PEO–NNPAAM–$LiClO_4$ electrolytes with high concentrations of NNPAAM.

Figure 3 compares the temperature dependence of conductivity measured for the PEO–PAAM (40 mass%) blends (10 mol% of $LiClO_4$) with that for the same blends interchanging the $LiClO_4$ salt with NH_4SCN. As can be seen, conductivities measured for electrolytes containing NH_4SCN are slightly higher over the entire temperature range. This cannot be easily explained on the basis of the differential scanning calorimetry (DSC) results presented in Table 1 since there is no evidence of the presence of the low T_g flexible amorphous phase for the electrolytes doped with NH_4SCN. Also X_c for the electrolyte containing NH_4SCN is higher than for the composite electrolyte with $LiClO_4$. The NH_4^+ cations are less tightly bound to the polyether chains as was shown from FT-IR and Raman measurements (12, 16).

Assuming the facilitating effect of these polyacrylamides on the conductivity of the $(PEO)_{10}LiClO_4$ electrolyte, it is interesting to analyze the effect of the addition of polyacrylamides on the ambient temperature conductivities of the amorphous

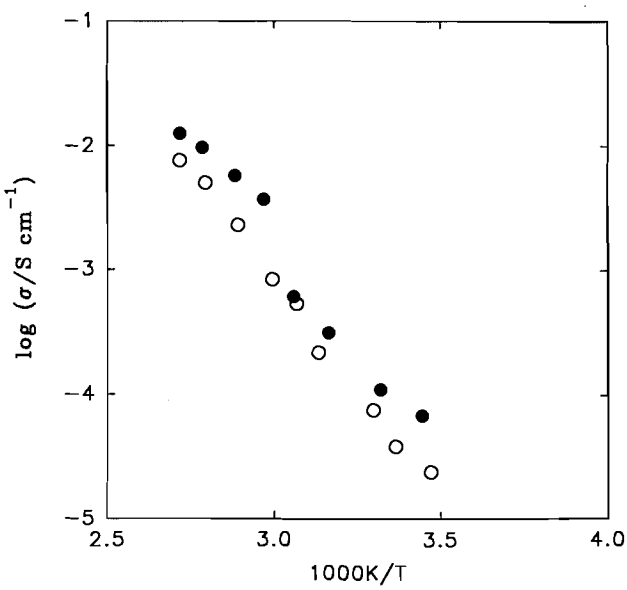

Fig. 4. Comparison of the isotherm of ionic conductivity of OMPEO–PAAM–$LiClO_4$ composite electrolytes at [○] 25°C with the isotherm of ionic conductivity of PEO–NNPAAM–$LiClO_4$ composite electrolytes at [●] 25°C. [□]: Conductivity measured for OMPEO–$LiClO_4$ electrolytes. All samples with 10 mol% of $LiClO_4$ with respect to ether oxygen concentration.

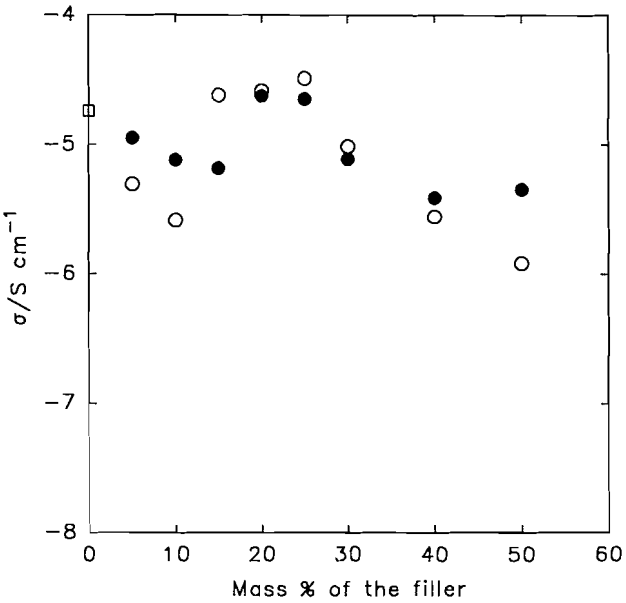

Fig. 5. Comparison of the isotherm of ionic conductivity of OMPEO–PAAM blend-based composite electrolytes doped with [○] $LiClO_4$ and [●] $NaClO_4$. T = 25°C.

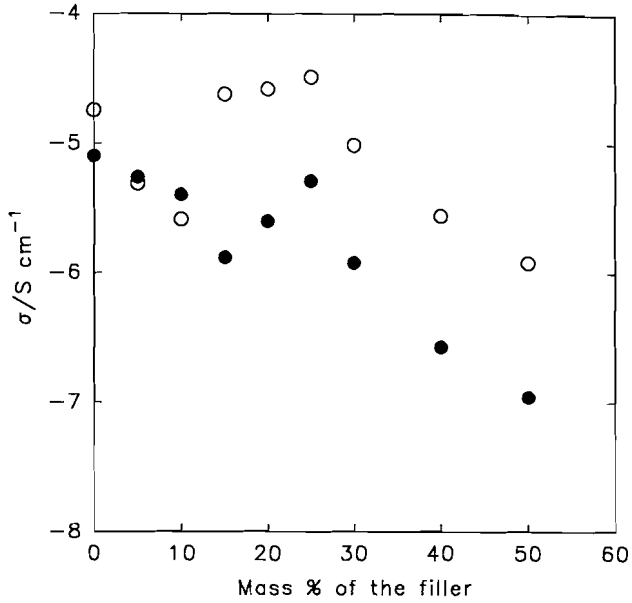


OMPEO–$LiClO_4$ electrolyte. This effect is shown in Fig. 4 in which conductivity isotherms at 25°C for the OMPEO–PAAM–$LiClO_4$ and OMPEO–NNPAAM–$LiClO_4$ systems are presented. As can be seen, the addition of polyacrylamides initially decreases the ionic conductivity for PAAM concentrations up to ~10 mass% and for NNPAAM concentrations ~15 mass%. This trend is reversed for samples containing 20–25 mass% of these polyacrylamides. In this filler concentration range conductivities of composite electrolytes are roughly 2–3 times higher than for the base OMPEO–$LiClO_4$ electrolyte. For concentrations of polyacrylamides exceeding 25 mass%, conductivity again decreases. As can be seen from Table 1, for polyacrylamide concentrations equal to 15 and 25 mass% two T_g's are observed, similar to the $(PEO)_{10}LiClO_4$–PAAM systems. The lower T_g is comparable to the T_g of the undoped OMPEO, the higher to the T_g of the $(OMPEO)_{10}LiClO_4$ electrolyte. Note that for systems containing NNPAAM, the higher T_g decreases with an increase in NNPAAM concentration and, for the sample with 50 mass% of NNPAAM, T_g is roughly the same as for the undoped OMPEO. This effect is similar to that previously described for the PEO–$LiClO_4$–NNPAAM composite electrolytes. The presence of a larger fraction of a flexible amorphous phase accounts for the higher conductivities measured for composite electrolytes in comparison with the base OMPEO–$LiClO_4$ system. As can be seen conductivities measured for most of the electrolytes containing NNPAAM are higher than for systems with PAAM (except in the 15–30 mass% range). The higher conductivities measured for electrolytes containing NNPAAM for concentrations higher than 30 mass% can be explained by the higher flexibility (lower T_g) of the amorphous phase of these electrolytes compared to the OMPEO–PAAM–$LiClO_4$ composite electrolytes.

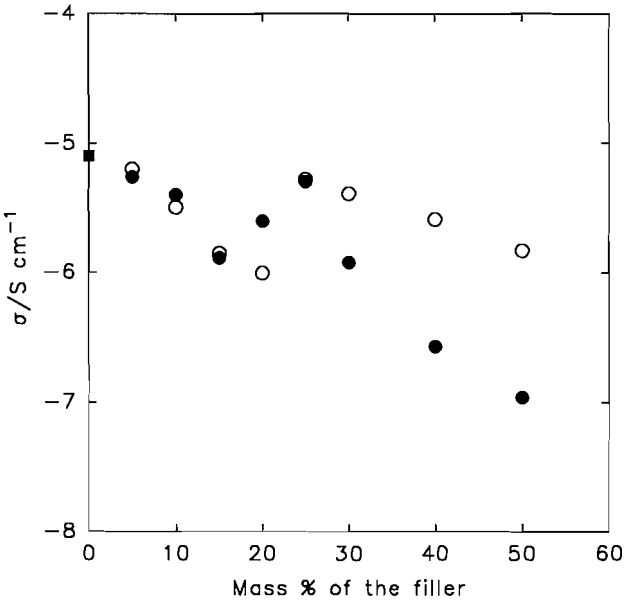
In Fig. 5 the effect of the addition of various alkali metal salts ($NaClO_4$, $LiClO_4$) on the ambient temperature conductivity of OMPEO–PAAM blends is shown. The shape of the conductivity isotherms measured for both systems is qualitatively the same. However, except for the concentrations of PAAM up to 10 mass%, conductivities measured for the electrolytes containing $LiClO_4$ are higher. This is consistent with the lower T_g values measured for these composite electrolytes as shown in Table 1.

In Fig. 6 the effects of the addition of inorganic (i.e., α-Al_2O_3) and organic (i.e., PAAM) fillers on the ambient temperature conductivity of OMPEO–$NaClO_4$ electrolyte are compared. Conductivity isotherms measured for both systems show the same trend: an initial drop in conductivity followed by an increase in conductivity with the conductivity maximum for samples containing ~25 mass% of the filler, followed by a decrease in conductivity for higher filler concentrations. Up to filler concentrations of ~25 mass%, conductivities measured for both composite systems are roughly the same. For higher filler concentrations conductivities measured for the electrolytes containing α-Al_2O_3 are higher. This is in agreement with the DSC data showing higher flexibility (lower T_g) for the OMPEO–$NaClO_4$–α-Al_2O_3 system in this filler concentration range.

Conductivity mechanism — discussion

The ion conduction behaviour of composite polyether-based electrolytes can be explained in terms of a classification of components as either Lewis acid or Lewis base or as, in the case of the aluminas, amphoteric. Examples of Lewis bases are the ether oxygens of PEO and OMPEO, anions such as ClO_4^-, I^-, SCN^-, the carbonyl oxygens of PAAM or NNPAAM, and the nitrogens of the NH_2 and $N(CH_3)_2$ groups of, respectively, PAAM and NNPAAM. Li^+, Na^+, and NH_4^+, cations can be classified as Lewis acids. Both θ- and α-Al_2O_3

Fig. 6. Comparison of the isotherm of ionic conductivity of OMPEO–PAAM–$NaClO_4$ composite electrolytes at [●] 25°C with the isotherm of ionic conductivity of OMPEO–α-Al_2O_3–$NaClO_4$ composite electrolytes at [○] 25°C. [■]: Conductivity measured for OMPEO–$NaClO_4$ electrolytes. All samples with 10 mol% of $NaClO_4$ with respect to ether oxygen concentration.



are of an amphoteric Lewis acid–base character, which is manifested through the coexistence of the surface Al (acid) and O (base) groups. In the case of aluminas there is also the possibility of the adsorption of water molecules on the surfaces resulting in the formation of surface OH groups. As discussed below, we believe that the changes in the ultrastructure and morphology of composite electrolytes and therefore the conductivity are the result of an equilibrium between various Lewis acid – Lewis base reactions.

After the addition of alkali metal salts and alumina to the crystalline PEO-based electrolytes there is a competition between alumina acidic surface groups and alkali metal cations for the ether oxygens. Surface Al groups can act as nucleation centres, in the crystallization of PEO from acetonitrile solutions. Since there are a large number of these centres the crystallization proceeds more rapidly and, as a result, more disorder is frozen into the new solid. This is manifested by a decrease in the fraction of the crystalline PEO phase and hence an increase in ambient temperature conductivity as shown in Fig. 1 for the $(PEO)_{10}NaI$–θ-Al_2O_3 composite electrolyte. However, an attachment of acidic θ-Al_2O_3 centres to PEO also results in an increase in T_g. θ-Al_2O_3 has smaller average grain sizes than the α-Al_2O_3 used as an additive to OMPEO-based electrolytes. Also the surface area of θ-Al_2O_3 is larger (approximately 900 m^2/g) in comparison to the surface area of α-Al_2O_3 (approximately 100–150 m^2/g). Therefore there are more active centres in the case of θ-Al_2O_3, which is a stronger acid than α-Al_2O_3. This results in stronger attachment of θ-Al_2O_3 to the PEO polymer host; a stiffening of the system results. For the OMPEO–$NaClO_4$–α-Al_2O_3 electrolytes some of Na^+ cations can be replaced by the acidic α-Al_2O_3 centres in the coordination spheres of ether oxygens. This results in a slight decrease in T_g that is, however, not high enough to enhance the conductivity of these OMPEO–$NaClO_4$ based composite electrolytes.

In the case of systems containing polyacrylamides there is a competition between the base centres of the polyethers and the polyacrylamides in the complexation of alkali metal cations. As has been already discussed in our previous papers (9, 10), there is a possibility of the formation of three different types of complexes.

Type I complexes: polyether–M^+–polyether complexes (M=Li, Na) involving Lewis base ether oxygens from the polyether chain. These complexes incorporate transient cross-links (intra or intermolecular) between the polyether chains via alkali metal cations, which stiffen the polyether host and reduce the electrolyte conductivity.

Type II complexes: mixed polyether–M^+–NNPAAM (PAAM) complexes involving Lewis base ether oxygens from the polyether chain and Lewis base carbonyl oxygens or (and) amide nitrogens from the NNPAAM (PAAM) chains.

Type III complexes: NNPAAM–M^+–NNPAAM complexes involving the Lewis base carbonyl oxygens or (and) amide nitrogens of NNPAAM (PAAM).

The formation of these complexes has been recently observed in FT-IR and FT-Raman studies (9–11). For concentrations of polyacrylamides up to 25 vol% the formation of type II complexes is more probable, thus leading to a reduction in X_c. For the higher polyacrylamide concentrations the probability of the formation of type III complexes increases.

The presence of type II and type III complexes reduces the number of transient cross-links in the polyether phase. This is manifested by a decrease in T_g and in some composite systems by the presence of flexible polyether phase with a T_g comparable to the T_g of undoped polyether (see Table 1). From the results in Table 1 it seems that the Li^+ cation, being a stronger Lewis acid than the Na^+ cation, forms complexes within the polyacrylamide phase more easily than Na^+ and at the expense of Type I complexes. Therefore more Li^+ than Na^+ transient crosslinks are present in the polyacrylamide-rich microphases of these composite electrolytes. As a result there is a lower T_g and therefore a higher conductivity for the lithium electrolytes than for the sodium electrolytes (see Fig. 5 and Table 1). In the case of PAAM the formation of hydrogen bonds between NH_2 groups and oxyanions such as ClO_4^- can occur. This will lower the mobility of ClO_4^- anions and therefore the conductivity is lower, as observed in Figs. 2, 4, and 5 for PAAM-based systems with PAAM concentrations higher than ~25–30 mass%. This might also be an explanation of the lower conductivities observed for OMPEO–PAAM–$NaClO_4$ systems in comparison with OMPEO–$NaClO_4$–α-Al_2O_3 electrolytes for filler concentrations higher than 25 mass%. Another explanation of this behaviour might involve the lower basicity of the surface α-Al_2O_3 groups compared to that of the PAAM Lewis acid groups.

For composite systems with NNPAAM, it was shown from FT-IR studies (11) that Li^+ cations are preferentially coupled to the carbonyl oxygens of NNPAAM. The depletion of Li^+ cations from the polyether phase results in a decrease in conductivity for composite electrolytes containing over ~25–30 mass% of NNPAAM.

Different types of interactions should probably be assumed in the case of the PEO–PAAM–NH_4SCN electrolytes. NH_4^+,

cations are the weakest Lewis acids amongst Li^+, Na^+, and NH_4^+. Drastic changes in the flexibility (T_g) and X_c of PEO–NH_4SCN electrolytes are not observed following the addition of PAAM. However, the conductivity of these systems was the highest among the composite polyether–PAAM electrolytes described. FT-IR experiments (12) showed the formation of $(SCN^-)_2$ dimers as well as the co-coordination of NH_4^+ by both PEO and PAAM. It is also evident from FT-IR experiments (12, 16) that NH_4^+ cations are more loosely bound to polyether oxygens than are Li^+ and Na^+, which is an explanation for the higher conductivities measured for NH_4SCN-doped composite systems. Despite intensive studies the exact mechanisms for ionic conduction in electrolytes containing NH_4SCN is still unknown.

FT-IR experiments performed on various composite systems containing polyacrylamides (9–12) confirm the possibility of the formation of various complexes involving polyether, alkali metal salt (or NH_4SCN), and polyacrylamide. Changes in the positions of the maximum of the C-O-C, C=O, and N-H stretching modes were observed. An analysis of the peak characteristic for the ClO_4^- anions shows that in composite electrolytes there is a reduction in the concentration of contact ion pairs compared to the pure polyether-based electrolytes (11). This also confirms an increase in conductivity in polyether-based composite electrolytes.

Conductivity models

Ion-conducting polymer systems, formed by the dissolution of salts in suitable ion-coordinating polymers, have a great potential for applications in numerous electrochemical devices. Although an understanding of the macroscopic properties associated with an efficient ionic transport in polymer electrolytes has advanced and the specific demands on salt and host structures that give high conductivity are rather well established (5, 17), a detailed microscopic picture of ionic conduction in these materials has not been achieved. Despite the ease of preparation of composite systems such as those discussed in this report, the problem of the mechanism of ionic conduction in such systems is even more acute. The best that we have been able to do is to use an "effective medium" theory (EMT) approach (7, 9–11, 18). This approach has had some success and has been applied assuming that the PEO–polyacrylamide (PAAM or NNPAAM) composites contain three components with different electrical properties. These are (*i*) a highly conductive uncomplexed polyether interface layer surrounding the polyacrylamide core, (*ii*) dispersed insulating polyacrylamide–salt complexes, and (*iii*) a matrix polyether–salt ionic conductor. It was further assumed that components (*i*) and (*ii*) could be combined in a composite unit that was spherically symmetric. Under these assumptions the components were considered to be embedded in a self-consistent effective medium with the same effective conductivity as the composite. The model connects an enhancement of ionic conductivity (see Figs. 2, 4, and 5) with the existence of a highly conductive amorphous layer on the surface of the polyacrylamide, i.e., component (*i*) in the composite unit: a layer within which there has been a depletion of transient cross-links due to the preference of cations for polyacrylamide. This layer has a lower T_g and therefore increased flexibility.

For some of the composite electrolytes the ionic conductivity has an Arrhenius temperature dependence over a certain temperature range (see Fig. 3). For these composites the order–disorder temperature (T_D) is the temperature at which a change in the conduction mechanism is expected. T_D can be calculated using a semiempirical approach (11, 19), which yields a linear relationship between the natural logarithm of the conductivity preexponential factor ($\ln \sigma_0$) and the Arrhenius activation energy for conduction (E_a), and which includes such parameters as T_D, the theoretical cation and anion concentrations, and the frequency of oscillation of the ions as they await the next activated step. For example, for the PEO–PAAM–NH_4SCN composite a linear relation between $\ln \sigma_0$ and E_a has been found for both the experimentally determined dc conductivity and the value of conductivity obtained from the EMT model. The characteristic temperatures T_D calculated from both data sets agree and are equal to 71°C. This temperature roughly corresponds to the melting temperature of the undoped PEO phase. Such behaviour was previously found for other composite polymeric electrolytes (18).

Conclusions

Ionic conductivity in mixed phase composite electrolytes based upon PEO and using inorganic (Al_2O_3) and organic (PAAM, NNPAAM) fillers to inhibit or prevent the crystallization of PEO has been discussed. Various alkali metal salts (Li, Na) and NH_4SCN were used. In general, the room temperature conductivity is enhanced by over two orders of magnitude above the base PEO–salt system. Even adding PAAM and NNPAAM to an initially amorphous system (OMPEO) increases the room temperature conductivity by 2 to 3 times. It is suggested that changes in the conductivity with changes in salt and filler concentration are due to changes in the ultrastructure and morphology and are the result of an equilibrium between various Lewis acid – Lewis base reactions. Qualified success has been achieved in modelling ionic conductivity in these composite electrolyte systems using an effective medium approach. In this approach it has been assumed that the main conductivity enhancement takes place in thin amorphous layers of the polyether that coat the dispersed polyacrylamide particles separated in a microphase. In the best complexes this layer is identified by a second T_g.

Novel (fulvalene)dichromium alkyl and acyl complexes of the types $FvCr_2(CO)_{6-n}L_nRR'$ and $Et_4N[FvCr_2(CO)_{6-n}L_nR]$ (R, R′ = Me, CH_2CN, COMe; L = CO, PMe_2Ph; *n* = 0, 1, 2)

István Kovács and Michael C. Baird

Abstract: The compound $FvCr_2(CO)_6Me_2$ (**1**) is obtained, via the intermediate formation of $Et_4N[FvCr_2(CO)_6Me]$ (**2**), by stepwise addition of 2 equivalents of methyl iodide to $(Et_4N)_2[FvCr_2(CO)_6]$; the analogous cyanomethyl compounds $FvCr_2(CO)_6(CH_2CN)_2$ (**3**) and $Et_4N[FvCr_2(CO)_6(CH_2CN)]$ (**4**) are formed similarly. Compound **1** readily undergoes CO insertion upon treatment with 2 equivalents of PMe_2Ph, giving rise to *trans,trans*-$FvCr_2(CO)_4(PMe_2Ph)_2(COMe)_2$ (**6**), also in two steps via *trans*-$FvCr_2(CO)_5(PMe_2Ph)(Me)(COMe)$ (**8**). The neutral methyl "half" of **2** reacts similarly with PMe_2Ph to form $Et_4N[$*trans*-$FvCr_2(CO)_5(PMe_2Ph)(COMe)]$ (**7**), while the anionic "half" of **2** is alkylated with $ClCH_2CN$ to give $FvCr_2(CO)_6(CH_2CN)Me$ (**5**). Treatment of **5** with PMe_2Ph also results in CO insertion into the Cr—Me bond to give *trans*-$FvCr_2(CO)_5(PMe_2Ph)(CH_2CN)(COMe)$ (**10**). Although **3** is inert to both substitution and insertion reactions with PMe_2Ph, the phosphine-substituted dialkyl (fulvalene)dichromium complex *trans,trans*-$FvCr_2(CO)_4(PMe_2Ph)_2(CH_2CN)_2$ (**9**) is prepared by reaction of $ClCH_2CN$ with $(Et_4N)_2[FvCr_2(CO)_4(PMe_2Ph)_2]$.

Key words: chromium, metal–metal bonds, fulvalene.

Résumé : On a obtenu le composé $FvCr_2(CO)_6Me_2$ (**1**), par le biais de la formation de $Et_4N[FvCr_2(CO)_6Me]$ (**2**), par une addition par étapes de deux équivalents d'iodure de méthyle à du $(Et_4N)_2[FvCr_2(CO)_6]$; les composés cyanométhylés analogues, $FvCr_2(CO)_6(CH_2CN)_2$ (**3**) et $Et_4N[FvCr_2(CO)_6(CH_2)]$ (**4**), se forment de la même manière. Par traitement avec deux équivalents de PMe_2Ph, le composé **1** subit facilement une insertion de CO qui conduit en deux étapes au *trans,trans*-$FvCr_2(CO)_4(PMe_2Ph)_2(COMe)_2$ (**6**) par le biais de l'intermédiaire *trans*-$FvCr_2(CO)_5(PMe_2Ph)(Me)(COMe)$ (**8**). De la même manière, la «moitié» méthylée neutre du composé **2** réagit avec le PMe_2Ph pour conduire à la formation de $Et_4N[$*trans*-$FvCr_2(CO)_5(PMePh)(COMe)]$ (**7**) alors que la «moitié» anionique du composé **2** est alkylée par le $ClCH_2CN$ et conduit au $FvCr_2(CO)_2(CH_2CN)Me$ (**5**). Le traitement du composé **5** à l'aide de PMe_2Ph provoque aussi une insertion de CO dans la liaison Cr—Me et fournit le *trans*-$FvCr_2(CO)_5(PMe_2Ph)(CH_2CN)(COMe)$ (**10**). Même si le composé **3** est inerte aux réactions tant de substitution que d'insertion avec le PMe_2Ph, il est possible de préparer le complexe dialkyl(fulvalène)chrome substitué par une phosphine, *trans,trans*-$FvCr_2(CO)_4(PMe_2Ph)_2(CH_2CN)_2$ (**9**), par réaction du $ClCH_2CN$ avec du $(Et_4N)_2[FvCr_2(CO)_4(PMe_2Ph)_2]$.

Mots clés : chrome, liaisons métal–métal, fulvalène.

[Traduit par la rédaction]

Introduction

In previous papers (1), we have explored the chemistry of fulvalenedichromium and -dimolybdenum complexes of the types $FvM_2(CO)_4L_2$, $FvM_2(CO)_4L_2HX$, $FvM_2(CO)_4L_2H_2$, and $FvM_2(CO)_4L_2X_2$ (M = Cr, Mo; X = Cl, Br, I; L = CO, tertiary phosphines). Following our earlier work on 17-electron, metal-centered radicals (2), the main impetus to this work was a desire, ultimately successful (1c,d), to find and study compounds of the type $FvM_2(CO)_4L_2$ that would undergo spontaneous, thermal metal-metal bond homolysis to give the novel biradical isomers $L(CO)_2M(\mu\text{-}Fv)M(CO)_2L$. In the course of our research, the above-mentioned examples of halo and hydrido classes of compounds were also perforce prepared as starting meterials and (or) products of reactions of the compounds $FvM_2(CO)_4L_2$. We (1a) and others (3) have also demonstrated that protonation of anionic complexes of the type $[FvM_2(CO)_4L_2]^{2-}$ results in the formation of the hydrides $FvM_2(CO)_4L_2H_2$, and we now extend our research on fulvalene complexes to examples of alkyl and acyl (fulvalene)dichromium carbonyl complexes, obtained by treating the anionic species $[FvCr_2(CO)_4L_2]^{2-}$ with various alkyl halides.

Received January 25, 1996.

This paper is dedicated to Professor Howard C. Clark in recognition of his distinguished contributions to chemistry in Canada.

Experimental section

General comments

All manipulations were carried out under purified nitrogen using standard Schlenk techniques and a Vacuum Atmospheres glovebox. All solvents were freshly distilled under nitrogen from sodium benzophenone ketyl. Deuterated solvents were purchased from CDN Isotopes and CIL, degassed, and stored in the glovebox. PMe_2Ph, methyl iodide, and chloroacetonitrile were products of Aldrich and were used as received. The compound $(Et_4N)_2[FvCr_2(CO)_6]$ was prepared as previously (*1d*). IR spectra were recorded on a Bruker IFS 25 FT-IR spectrometer using a 0.2-mm NaCl cell. NMR spectra were acquired on a Bruker AM-400 (400.1 MHz ^1H, 100.6 MHz $^{13}C\{^1H\}$, 162.0 MHz $^{31}P\{^1H\}$) NMR spectrometer; IR data are compiled in Table 1. FAB(+)-MS analyses were performed on a Fisons VG Quattro triple quadrupole mass spectrometer using 3-nitrobenzyl alcohol as the matrix. Elemental analyses were carried out by Canadian Microanalytical Services Ltd. (Delta, B.C.).

$FvCr_2(CO)_6Me_2$ (1)

A solution of 0.10 g (0.15 mmol) $(Et_4N)_2[FvCr_2(CO)_6]$ in 5 mL THF was treated with 20 μL (0.32 mmol) of chloroacetonitrile at room temperature. The color changed instantly from yellow to brown, and an IR spectrum indicated that formation of $FvCr_2(CO)_6Me_2$ was complete in ~3 h. Although no other products appeared according to both IR and ^1H NMR studies, evaporation of the solvent resulted in the formation of a yellow-brown oil, which could not be obtained free of THF; some decomposition also occurred, and thus microanalytical characterization of **1** was not successful although all spectroscopic data were consistent with the formulation. ^1H NMR (acetone-d_6), δ: 0.62 (s, 6H, Me), 5.10 ("t," 4H, Fv), 5.37 ("t", 4H, Fv). $^{13}C\{^1H\}$ NMR (acetone-d_6), δ: −5.0 (s, Me), 88.3 (s, Fv), 89.8 (s, Fv), 102.5 (s, C-1 Fv), 238.9 (s, CO *cis* to Me), 249.0 (s, CO *trans* to Me). IR spectroscopic data are shown in Table 1.

$Et_4N[FvCr_2(CO)_6Me]$ (2)

This compound was detected by IR spectroscopy in a reaction carried out as above but with only 0.10 mL of methyl iodide added (Table 1). In an NMR experiment, a solution of 15 mg $(Et_4N)_2[FvCr_2(CO)_6]$ in 0.6 mL acetone-d_6, was treated with methyl iodide dropwise until complete consumption of the starting material had occurred. Since some **1** was always present, no attempt was made to isolate the monomethyl compound, which was unambiguously characterized by IR and NMR spectroscopy. ^1H NMR (acetone-d_6), δ: 0.53 (s, 3H, CrMe), 1.36 (tt, $J_1 = 7$ Hz, $J_2 = 2$ Hz, 12H, CH_2*Me*), 3.42 (q, $J = 7$ Hz, 8H, CH_2N), 4.35, 4.71, 4.80, 4.93 ("t," each 2H, Fv). $^{13}C\{^1H\}$ NMR (acetone-d_6), δ: −2.4 (s, CrMe), 7.7 (s, CH_2*Me*), 52.9 (s, CH_2N), 82.0, 82.3, 86.3, 86.7 (s, all Fv), 90.4 (s, C-1 Fv), 112.9 (s, C-1 Fv), 240.3 (s, CO *cis* to Me), 245.8 (s, CO of anionic moiety), 252.7 (s, CO *trans* to Me).

$FvCr_2(CO)_6(CH_2CN)_2$ (3)

Compound **2** (0.10 g, 0.16 mmol) was dissolved in 5 mL of THF and 20 μL (0.32 mmol) of chloroacetonitrile were injected into the stirred solution at room temperature. The yellow reaction mixture instantly turned deep red and an IR analysis carried out ~1 h later indicated complete consumption of the dianion and formation of a single product, $FvCr_2(CO)_6(CH_2CN)_2$ (Table 1). Evaporation of the solvent resulted in the formation of a red-brown oil. Our attempts to purify this material did not meet with success, but spectroscopic characterization unambiguously established its identity. ^1H NMR (acetone-d_6), δ: 1.62 (s, 4H, CH_2), 5.34 ("t", 4H, Fv), 5.74 ("t", 4H, Fv). $^{13}C\{^1H\}$ NMR (acetone-d_6), δ: −15.4 (s, $CrCH_2$), 89.9 (s, Fv), 93.4 (s, Fv), 102.2 (s, C-1 Fv), 127.4 (s, CN), 238.8 (s, CO *cis* to CH_2CN, 248.2 (s, CO *trans* to CH_2CN).

$Et_4N[FvCr_2(CO)_6(CH_2CN)]$ (4)

A solution of 0.10 g (0.16 mmol) **1** in 5 mL of THF was treated with 10 μL (0.16 mmol) $ClCH_2CN$, added dropwise at room temperature (~10 min). The yellow reaction mixture instantly turned deep red and an IR analysis showed complete consumption of the dianion and formation of $Et_4N[FvCr_2(CO)_6(CH_2CN)]$ (Table 1). Addition of an extra 10 mL of $ClCH_2CN$ transformed this intermediate into **3** within ~2 h without color change. Evaporation of the solvent when only $Et_4N[FvCr_2(CO)_6(CH_2CN)]$ was present resulted in the formation of a red-brown oily residue containing THF, which could not be removed. Attempts to purify this compound led to extensive decomposition to unidentified materials, but it was characterized spectroscopically. ^1H NMR (acetone-d_6), δ: 1.30 (s, 2H, CH_2), 1.36 (tt, $J_1 = 7$ Hz, $J_2 = 2$ Hz, 12H, CH_2*Me*), 3.42 (q, $J = 7$ Hz, 8H, CH_2N), 4.42, 4.82, 5.02, 5.19 ("t," each

2H, Fv). $^{13}C\{^1H\}$ NMR (acetone-d_6), δ: −12.8 (s, $CrCH_2$), 7.7 (s, CH_2Me), 52.9 (s, CH_2N), 82.6, 83.0, 86.4 (s, all Fv), 87.9 (s, C-1 Fv), 88.7 (s, Fv), 116.3 (s, C-1 Fv), 128.1 (s, CN), 240.9 (s, CO *cis* to CH_2CN), 245.3 (s, CO of anion), 250.3 (s, CO *trans* to CH_2CN). See Table 1 for IR data.

$FvCr_2(CO)_6(CH_2CN)Me$ (5)

A solution of 0.10 g (0.16 mmol) $(Et_4N)_2[FvCr_2(CO)_6]$ was dissolved in 5 mL of THF and reacted with 10 μL (0.16 mmol) of $ClCH_2CN$, added dropwise at room temperature. The yellow reaction mixture instantly turned deep red and an IR analysis showed complete consumption of the dianion and formation of $Et_4N[FvCr_2(CO)_6(CH_2CN)]$. Addition of 10 μL (0.16 mmol) of methyl iodide transformed this intermediate into compound **5** in ~2 h (IR). Evaporation of the solvent resulted in the formation of a red-brown oil, but attempts to further purify the material were unsuccessful. Nevertheless, **5** was satisfactorily characterized spectroscopically in solution and its identity seems firmly established. ^1H NMR (acetone-d_6): δ: 0.64 (s, 3H, Me), 1.59 (s, 2H, CH_2), 5.11, 5.30, 5.48, 5.64 ("t", each 2H, Fv). $^{13}C\{^1H\}$ NMR (acetone-d_6), δ: −15.8 (s, CH_2), −5.2 (Me), 88.7, 89.1, 90.5, 92.6 (s, all Fv), 100.6 (s, C-1 Fv), 103.9 (s, C-1 Fv), 127.5 (s, CN), 238.6 (s, CO *cis* to Me), 239.2 (s, CO *cis* to CH_2CN), 248.5 (s, CO *trans* to CH_2CN), 248.6 (s, CO *trans* to Me). For IR data see Table 1.

***trans,trans*-$FvCr_2(CO)_4(PMe_2Ph)_2(COMe)_2$ (6)**

A solution of **1**, prepared as above, was evaporated to dryness and the resulting brown material was redissolved in a 2:1 toluene–hexane solvent mixture. Addition of 0.6 mL (4.2 mmol) of PMe_2Ph resulted in precipitation of a yellow solid. A second, smaller crop of precipitate was recovered from the decanted solvent by concentrating under reduced pressure. The combined yellow solids were washed with 5 × 20 mL of hexane and dried. Yield: 0.74 g (1.05 mmol, 86%). The product was recrystallized from THF–hexane at −20°C, but did not give analytically pure samples. However, spectroscopic and mass spectrum data were consistent with the proposed structure. ^1H NMR (acetone-d_6), δ: 1.87 (d, J_{PH} = 9 Hz, 12H, PMe), 2.35 (s, 6H, COMe), 4.26 (m, 4H, Fv), 4.53 (m, 4H, Fv), 7.45 (m, 6H, *m,p*-Ph), 7.69 (m, 4H, *o*-Ph). $^{13}C\{^1H\}$ NMR (acetone-d_6): δ: 18.8 (d, J_{PC} = 30 Hz, PMe), 49.4 (s, CO*Me*), 91.9 (s, Fv), 93.4 (s, Fv), 103.9 (s, C-1 Fv), 129.3 (d, J_{PC} = 9 Hz, *o*-Ph), 130.0 (d, J_{PC} = 8 Hz, *m*-Ph), 130.2 (s, *p*-Ph), 140.8 (d, J_{PC} = 38 Hz, *ipso*-Ph), 250.8 (d, J_{PC} = 45 Hz, CO), 272.4 (d, J_{PC} = 18 Hz, *C*OMe). $^{31}P\{^1H\}$ NMR (acetone-d_6), δ: 58.2. FAB(+)-MS, *m/z*(%): $[M + H]^+$ = 707(0.7), $[M - 3CO - Me]^+$ = 607(1), $[M - 4CO - Me]^+$ = 579(1), $[M - 4CO - 2Me]^+$ = 564(2.5), $[M - PMe_2Ph - 2CO]^+$ = 512(10), $[M - PMe_2Ph - 3CO]^+$ = 484(3), $[M - PMe_2Ph - 4CO]^+$ = 456(8), $[M - PMe_2Ph - 4CO - Me]^+$ = 441(4), $[M - 2PMe_2Ph - 4CO]^+$ = 318(41). IR data are listed in Table 1.

Reaction of freshly generated **3** (0.04 mmol) with 20 μL (0.14 mmol) of PMe_2Ph was attempted in 5 mL THF solution, both thermally and photochemically. In an experiment carried out at room temperature and ambient light over 3 days, the reaction mixture decomposed and a precipitate formed in a green solution; only very weak carbonyl bands were detected in the IR spectrum, at 1944 and 1869 cm^{-1}. Irradiation of a solution of **3** and PMe_2Ph with a 200-W Hanovia lamp led to the same result, but much more quickly (~3 h).

$Et_4N[$*trans*-$FvCr_2(CO)_5(PMe_2Ph)(COMe)]$ (7)

This compound was characterized spectroscopically in situ when an acetone-d_6 solution of $(Et_4N)_2[FvCr_2(CO)_6]$ (15 mg) was "titrated" consecutively with equimolar amounts of methyl iodide and PMe_2Ph at room temperature. ^1H NMR (acetone-d_6), δ: 1.36 (tt, J_1 = 7 Hz, J_2 = 2 Hz, 12H, CH_2Me), 1.89 (d, J_{PH} = 9 Hz, 6H, PMe), 2.37 (s, 3H, COMe), 3.42 (q, J = 7 Hz, 8H, CH_2N), 4.23 ("t", 2H, Fv), 4.40 (m, 2H, Fv), 4.46 (m, 2H, Fv), 4.54 ("t," 2H, Fv), 7.43 (m, 3H, *m,p*-Ph), 7.74 (m, 2H, *o*-Ph). $^{13}C\{^1H\}$ NMR (acetone-d_6), δ: 18.7 (d, J_{PC} = 30 Hz, PMe), 49.5 (s, CO*Me*), 81.6, 82.1, 90.9, 91.7 (s, all Fv), 92.0 (s, C-1 Fv), 111.7 (s, C-1 Fv), 129.1 (d, J_{PC} = 8 Hz, *o*-Ph), 130.0 (s, *p*-Ph), 130.1 (d, J_{PC} = 8 Hz, *m*-Ph), 141.2 (d, J_{PC} = 37 Hz, *ipso*-Ph), 246.2 (s, CO of anion), 251.3 (d, J_{PC} = 44 Hz, CO of CrCOMe). $^{31}P\{^1H\}$ NMR (acetone-d_6), δ: 59.0. For IR see Table 1.

***trans*-$FvCr_2(CO)_5(PMe_2Ph)Me(COMe)$ (8)**

This compound was observed in NMR scale reactions when PMe_2Ph was added slowly to **1** dissolved in 0.6 mL of acetone-d_6, or when methyl iodide was added to the in situ generated $Et_4N[$*trans*-$FvCr_2(CO)_5(PMe_2Ph)(COMe)]$. Both reactions resulted in various mixtures of this compound and **2**. ^1H NMR (acetone-d_6), δ: 0.50 (s, 3H, CrMe), 1.96 (d, J_{PH} = 9 Hz, 6H, PMe), 2.38 (s, 3H, COMe), 4.58 (m, 2H, Fv), 4.72 (m, 2H, Fv), 4.86 ("t," 2H, Fv), 4.93 ("t", 2H, Fv), 7.46 (m, 3H, *m, p*-Ph), 7.74 (m, 2H, *o*-Ph). $^{13}C\{^1H\}$ NMR (acetone-d_6), δ: −4.8 (s, CrMe), 18.8 (d, J_{PC} = 30 Hz, PMe), 49.4 (s, CO*Me*), 88.3, 88.9, 92.4, 93.6 (s, all Fv), 102.7 (s, C-1 Fv), 104.0 (s, C-1 Fv), 129.35 (d, J_{PC} = 9 Hz, *o*-Ph), 130.1 (d, J_{PC} = 8 Hz, *m*-Ph), 130.3 (s, *p*-Ph), 140.7 (d, J_{PC} = 39 Hz, *ipso*-Ph), 239.3 (s, CO cis to Me), 249.5 (CO *trans* to Me), 250.7 (d, J_{PC} = 44 Hz, CO cis to COMe). $^{31}P\{^1H\}$ NMR (acetone-d_6), δ: 57.9.

***trans,trans*-$FvCr_2(CO)_4(PMe_2Ph)_2(CH_2CN)_2$ (9)**

A solution of 0.30 g (0.34 mmol) $FvCr_2(CO)_4(PMe_2Ph)_2I_2$ (4d) was dissolved in 10 mL of THF and mixed with a large excess of sodium suspension (prepared from sodium dispersion in mineral oil (Aldrich) by washing with 3 × 10 mL of hexane) in 10 mL of THF. The reaction mixture immediately changed color from purple to yellow, but stirring was continued for 1 h. The reaction mixture, containing $Na_2[FvCr_2(CO)_4(PMe_2Ph)_2]$ (IR, ν_{CO}: 1778 and 1680 cm^{-1}) (4d), was filtered through Celite to give a clear, golden-yellow filtrate, which was reacted with 30 μL (0.47 mmol) of chloroacetonitrile. After 3 h, the NaCl precipitate was filtered off, the reaction mixture was concentrated to ~3 mL, and the alkyl complex was precipitated with 10 mL of hexane and collected and dried under reduced pressure. *trans,trans*-**9** was obtained as a poorly soluble, yellow powder in 0.22 g (0.31 mmol), 91 % yield. ^1H NMR (acetone-d_6), δ: 1.23 (d, J_{PH} = 2 Hz, 4H, CH_2), 1.91 (d, J_{PH} = 9 Hz, 12H, PMe), 4.55 (m, 4H, Fv), 4.58 (m, 4H, Fv), 7.50 (m, 6H, *m,p*-Ph), 7.74 (m, 4H, *o*-Ph). $^{13}C\{^1H\}$ NMR (DMSO-d_6): δ: −14.9 (d, J_{PC} = 15 Hz, CH_2), 19.2 (d, J_{PC} = 31 Hz, PMe), 88.1, 89.8 (s, both Fv), 100.5 (s, C-1 Fv), 128.5 (d, J_{PC} = 9 Hz, *o*-Ph), 129.3 (s, CN), 129.6 (d, J_{PC} = 7 Hz, *m*-Ph), 129.7 (s, *p*-Ph), 139.1 (d, J_{PC} = 39 Hz, *ipso*-Ph), 251.6 (d, J_{PC} = 46 Hz, CO). $^{31}P\{^1H\}$ NMR (acetone-d_6), δ: 61.2. FAB(+)-MS, m/z(%) $[M + Na]^+$ = 723(1), $[M - 2CO]^+$ = 644(1.5), $[M - 2CO - CH_2CN]^+$ = 604(2), $[M - 4CO - CH_2CN]^+$ = 548(4), $[M - PMe_2Ph - 4CO]^+$ = 450(13.5), [M

$- PMe_2Ph - 4CO - CH_2CN]^+ = 410(25)$, $[M - PMe_2Ph - 4CO - 2CH_2CN]^+ = 370(8)$, $[M - 2PMe_2Ph - 4CO]^+ = 312(31)$, $[M - 2PMe_2Ph - 4CO - CH_2CN]^+ = 272(22.5)$. IR data are listed in Table 1.

***trans*-$FvCr_2(CO)_5(PMe_2Ph)(CH_2CN)(COMe)$ (10)**

A solution of 0.27 g (0.41 mmol) $(Et_4N)_2[FvCr_2(CO)_6]$ in 45 mL of THF was reacted with 25 μL (0.41 mmol) of $ClCH_2CN$, added at room temperature. The mixture turned red instantly, and IR spectroscopic monitoring indicated completion of the formation of $Et_4N[FvCr_2(CO)_6CH_2CN]$ in ~1 h. At this point, 50 μL (0.80 mmol) of methyl iodide were added and complete formation of **3** was observed after ~1 h. The resulting brown solution was then stirred with 0.15 mL (1.05 mmol) of PMe_2Ph for 0.5 h, and an IR spectrum showed that compound **4** was the only carbonyl containing product. The solvent was removed under reduced pressure and 40 mL of a 1:1 THF-hexane mixture was used to extract **4** from the resulting solid. This solution was filtered and evaporated to dryness to give 0.15 g (0.25 mmol, 62%) of a yellow-brown solid. Although attempted recrystallizations did not result in analytically pure product, **4** was thoroughly characterized by spectroscopic means. ^1H NMR (acetone-d_6), δ: 1.43 (s, 2H, CH_2), 1.98 (d, J_{PH} = 9 Hz, PMe), 2.40 (s, 3H, COMe), 4.70 (m, 2H, Fv), 4.76 (m, 2H, Fv), 5.08 ("t," 2H, Fv), 5.22 ("t", 2H, Fv), 7.47 (m, 3H, *m,p*-Ph), 7.76 (m, 2H, *o*-Ph). $^{13}C\{^1H\}$ NMR (acetone-d_6), δ: −15.3 (s, $CrCH_2$), 18.9 (d, J_{PC} = 31 Hz, PMe), 49.4 (s, CO*Me*), 89.2, 91.7, 93.0, 94.0 (s, all Fv), 101.2 (s, C-1 Fv), 105.9 (s, C-1 Fv), 127.6 (s, CN), 129.5 (d, J_{PC} = 9 Hz, *o*-Ph), 130.2 (d, J_{PC} = 7 Hz, *m*-Ph), 130.5 (s, *p*-Ph), 140.7 (d, J_{PC} = 38 Hz, *ipso*-Ph), 239.8 (s, CO cis to CH_2CN), 249.2 (s, CO *trans* to CH_2CN), 250.6 (d, J_{PC} = 44 Hz, CO of CrCOMe), 271.9 (d, J_{PC} = 18 Hz, *C*OMe). $^{31}P\{^1H\}$ NMR (acetone-d_6), δ: 57.5. FAB(+)-MS, *m/z*(%): (No $[M]^+$ appeared) $[M - CO]^+ = 565(2)$, $[M - 2CO]^+ = 537(3)$, $[M - 6CO]^+ = 425(7.5)$, $[M - 6CO - Me]^+ = 410(17)$, $[M - PMe_2Ph - 2CO]^+ = 399(13)$, $[M - 6CO - Me - CH_2CN]^+ = 370(27)$, $[M - PMe_2Ph - 6CO]^+ = 287(15)$, $[M - PMe_2Ph - 6CO - Me]^+ = 272(27)$. IR data are listed in Table 1.

Results and discussion

Dianionic fulvalene complexes, $[FvM_2(CO)_6]^{2-}$ (M = Mo, W), have been shown to undergo nucleophilic reactions with various alkyl halides to give dialkyl derivatives of the types $FvM_2(CO)_6R_2$ (R = Me, CH_2Ph, CH_2OMe, etc.) (3*a*,*b*), Not reported to date, however, are analogous reactions of the anionic complex $[FvCr_2(CO)_6]^{2-}$, which is expected to react with alkyl halides as in eq. [1] to give alkylchromium species. We now report the results of an investigation of such reactions.

[1] $[FvCr_2(CO)_6]^{2-} + 2RX \rightarrow FvCr_2(CO)_6R_2 + 2X^-$

To our surprise, addition of $BrCH_2CN$ to a THF solution of $(Et_4N)_2[FvCr_2(CO)_6]$ did not result in the formation of the anticipated dialkyl product, but resulted instead in oxidation to $FvCr_2(CO)_6$ (1*c*, *d*). Similar reactions with XCH_2CO_2Et (X = Cl, Br, I) were also briefly investigated by IR and ^1H NMR spectroscopy, and all resulted in the formation of $FvCr_2(CO)_6$. ^1H NMR spectra of the reaction mixtures temporarily exhibited very broad fulvalene resonances before those of $FvCr_2(CO)_6$ began to emerge, and it would seem that electron-transfer-initiated radical reactions rather than nucleophilic substitutions take place, resulting in metal-metal bond formation. We obtained similar results for the reaction of $(Et_4N)_2[FvMo_2(CO)_6]$ with $BrCH_2CN$, and similar reactions have been reported for mononuclear metal carbonyl anions (4).

Hexacarbonyl Alkyl Compounds

Not all alkyl halides oxidize the $[FvCr_2(CO)_6]^{2-}$ anion, however. Treatment of $(Et_4N)_2[FvCr_2(CO)_6]$ with 2 equivalents or more of methyl iodide resulted in the formation of the rather unstable dimethyl compound $FvCr_2(CO)_6Me_2$ (**1**) (eq. [2], Scheme 1).

[2] $(Et_4N)_2[FvCr_2(CO)_6] + 2MeI \rightarrow FvCr_2(CO)_6Me_2$ **1**

Compound **1** was thoroughly characterized by spectroscopic methods and the data are fully consistent with the structure shown in Scheme 1. Thus the ^1H NMR spectrum exhibited a Cr-Me resonance at δ 0.62 and fulvalene multiplets at δ 5.10 and 5.37, while the $^{13}C\{^1H\}$ NMR spectrum exhibited a relatively shielded Cr-Me resonance at δ -5.0, fulvalene resonances at δ 88.3, 89.8, and 102.5, and two CO resonances at δ 238.9 (cis to Me) and 249.0 (trans to Me). Assignments of the ^{13}C resonances were made on the basis of data for $CpMo(CO)_3Me$ (5), and the results imply that the CO ligands do not interchange on the NMR time scale. While this work was in progress we learned that compound **1** has also been prepared by McGovern and Vollhardt.[3]

When only 1 equivalent of MeI was slowly added to a solution of dianion, the very sensitive, monoanionic intermediate $Et_4N[FvCr_2(CO)_6Me]$ (**2**) could be identified (Scheme 1). All spectroscopic data for this unstable species are consistent with the suggested structure, the ^1H NMR spectrum exhibiting a methyl resonance (δ: 0.53) and two sets of fulvalene hydrogens. Similarly the $^{13}C\{^1H\}$ NMR spectrum exhibited a Cr-Me resonance at δ −2.4, two sets of fulvalene resonances, and three CO resonances, two for the neutral and one for the anionic "half."

It is interesting to note that the IR spectrum exhibited one set of carbonyl bands of frequencies comparable with those of **1** (2000 and 1924 cm^{-1}) and a second set of considerably lower frequencies (1902, 1810, 1788 and 1727 cm^{-1}), comparable with those of $(Et_4N)_2[FvCr_2(CO)_6]$ (Table 1). Thus the chromium atoms of the two "halves" of **2** appear to be in very different electronic environments. Possibly a result of this dissimilarity is the large difference (22.5 ppm) between the two Fv C-1 carbon resonances, at δ 90.4 and 112.9.

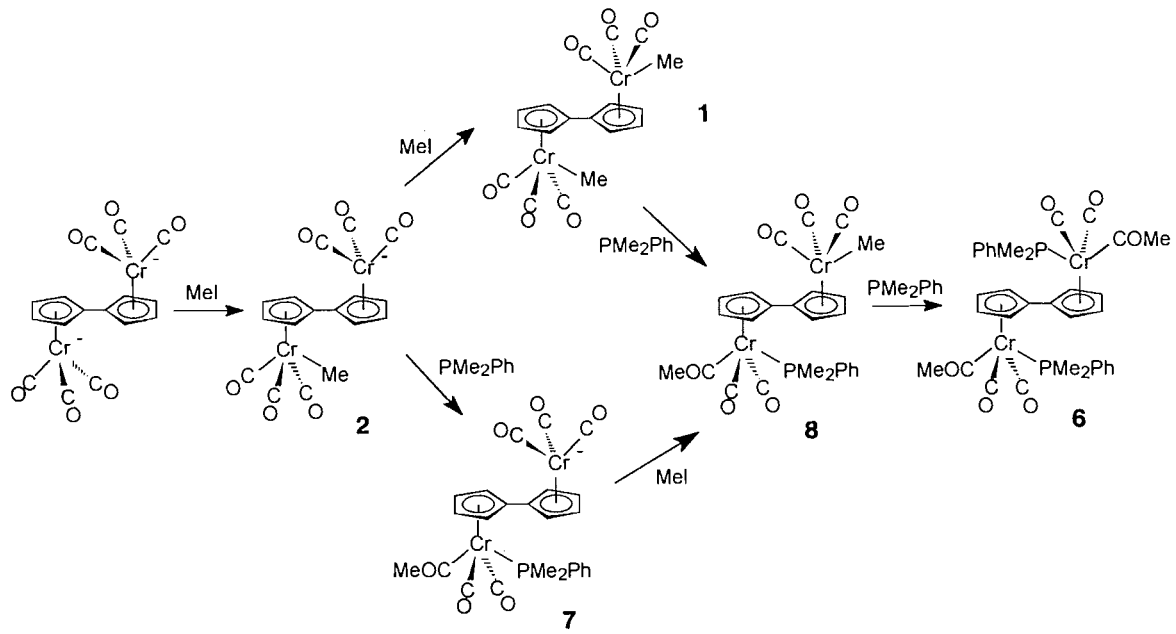
Surprisingly, when $(Et_4N)_2[FvCr_2(CO)_6]$ was treated with an excess not of $BrCH_2CN$ but of $ClCH_2CN$, complete formation of $FvCr_2(CO)_6(CH_2CN)_2$ (**3**) took place at room temperature (eq. [3]), no $FvCr_2(CO)_6$ being formed at all.

[3] $[FvCr_2(CO)_6]^{2-} + 2\ ClCH_2CN \rightarrow FvCr_2(CO)_6(CH_2CN)_2$ **3**

The product was characterized by IR and NMR spectroscopy, although it could not be isolated analytically pure. However,

[3] P.A. McGovern and K.P.C. Vollhardt, private communication.

Scheme 1.



the ^1H and $^{13}C\{^1H\}$ NMR spectra exhibit patterns of resonances similar to those of **1**, the $CrCH_2$ proton and carbon resonances appearing at δ 1.62 and −15.4, respectively. Two resonances were observed in the CO region at δ 238.8 (*cis* to CH_2) and 248.2 (*trans* to CH_2) in about 2:1 ratio, suggesting a lack of interchange of these ligands. The carbonyl stretching bands of **3** are observed at higher frequencies than those of **1**, consistent with the greater electron-withdrawing power of the cyanomethyl group. The reasons for the differences in products from reactions of $(Et_4N)_2[FvCr_2(CO)_6]$ with $BrCH_2CN$ and $ClCH_2CN$ are not at all clear; understanding must await a mechanistic study.

Interestingly, when only 1 equivalent of $ClCH_2CN$ was slowly added to a solution of $(Et_4N)_2[FvCr_2(CO)_6]$, sole formation of the anionic alkyl intermediate $Et_4N[FvCr_2(CO)_6(CH_2CN)]$ (**4**) was observed, confirming the intermediacy of this complex in eq.[3]. This anionic alkyl compound was also too labile to be obtained pure, but was characterized spectroscopically. As is the case with **2**, the IR spectrum of **4** suggests the presence of "neutral" (2011 and 1938 cm^{-1}) and "anionic" (1897, 1795, and 1727 cm^{-1}) "halves," and the ^1H and $^{13}C\{^1H\}$ NMR spectra exhibit two sets of resonances. Also, as with **2**, the $^{13}C\{^1H\}$ NMR spectrum of **4** exhibited an unusually large difference (~28 ppm) between the two fulvalene bridgehead carbon resonances, at δ 87.9 and 116.3. Reaction of **4** with a second equivalent of $ClCH_2CN$ to give **3** was, because of decreased nucleophilicity of the monoanion, rather slow (~1 h) relative to the very rapid reaction with the first equivalent.

Successful formation of the anionic alkyl compounds $(Et_4N)[FvCr_2(CO)_6Me]$ (**2**) and $(Et_4N)[FvCr_2(CO)_6(CH_2CN)]$ (**4**) offered opportunities to synthesize mixed dialkyl complexes, and the compound $FvCr_2(CO)_6(CH_2CN)Me$ (**5**) was prepared as outlined in eq. [4], via addition of MeI to $(Et_4N)[FvCr_2(CO)_6(CH_2CN)]$. The product was thoroughly characterized spectroscopically. As can be seen in Table 1, the IR spectrum clearly exhibited two pairs of carbonyl stretching bands, one pair at 2006 and 1931 cm^{-1} attributable to the methyl "half," and another at 2021 and 1959 cm^{-1} that is attributable to the cyanomethyl "half." (Compare with data for **1** and **3**.) Furthermore, the ^1H NMR spectrum exhibited Me and CH_2 resonances at δ 0.64 and 1.59, respectively, and two sets of fulvalene resonances, while the $^{13}C\{^1H\}$ NMR spectrum exhibited Me and CH_2 resonances at δ −5.2 and −15.8, respectively, a CN resonance, and two sets each of fulvalene and CO resonances.

[4] $(Et_4N)[FvCr_2(CO)_6(CH_2CN)] + MeI \rightarrow$

$FvCr_2(CO)_6(CH_2CN)Me$
5

Tertiary phosphine-substituted compounds

In an unsuccessful attempt to synthesize phosphine-substituted analogues of **1**, it was found that **1** readily *added* 2 equivalents of PMe_2Ph at room temperature. The consequence was a sequence of migratory CO insertion reactions into the Cr—Me bonds (eq. [5]), resulting in formation of the diacetyl compound $FvCr_2(CO)_4(PMe_2Ph)_2(COMe)_2$ (**6**) in good yield. Although **6** is also too unstable to be isolated analytically pure, the mass spectrum and ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra are all completely consistent with the *trans,trans* structure shown in Scheme 1. Thus the FAB mass spectrum exhibited a protonated molecular ion and several reasonable fragmentation peaks. In addition, the ^1H and $^{13}C\{^1H\}$ NMR spectra each exhibited only single acetyl Me and PMe resonances and single sets of fulvalene resonances, consistent with a symmetrical *trans,trans* structure (see experimental section), while the $^{31}P\{^1H\}$ NMR spectrum exhibited only one singlet. The $^{13}C\{^1H\}$ NMR spectrum exhibited only one doublet for two CO ligands, at δ 250.8 and with a relatively large (J_{PC} 45 Hz) coupling constant suggestive of a *cis*-P-Cr-CO and consequently a *trans*-P-Cr-COMe arrangement (5). The MeCO res-

onance appeared at δ 272.4 (J_{PC} 18 Hz), quite similar to that of $CpMo(CO)_2(PMe_2Ph)COMe$ (266.8 (12.5)) (5).

[5] $FvCr_2(CO)_6Me_2 + 2PMe_2Ph \rightarrow$
1

trans,trans-$FvCr_2(CO)_4(PMe_2Ph)_2(COMe)_2$
6

To our knowledge, **6** is the first well-characterized acylchromium complex of the type $CpCr(CO)_2L(COMe)$ (L = phosphorus donor) that has been prepared via a spontaneous, ligand-assisted CO insertion into a Cr–alkyl bond. Two other examples of compounds of the type $CpCr(CO)_2L(COMe)$ were prepared as minor products, either in photochemical substitution reactions of $CpCr(CO)_3Me$ with L (L = PPh_3, $P(OMe)_3$) (6*a*) or in an apparent Arbuzov reaction of [$CpCr(CO)_2${P(OMe) 63}] with $P(OMe)_3$ (6*b*); both exist as mixtures of *cis* and *trans* isomers. Indeed, although photochemical substitution reactions of complexes of the type $CpCr(CO)_3R$ (R = alkyl) with phosphorus donors have attracted a great deal of attention, reactions invariably resulted in the formation of mono- and bis-substituted alkyl complexes (7). An attempt to substitute **1** with PPh_3 under thermal conditions failed, and an experiment carried out under UV irradiation resulted in the formation of $FvCr_2(CO)_6$ instead of substitution.

When the reaction of **1** was performed with small aliquots of PMe_2Ph added slowly to the reaction mixture, intermediate formation of the methyl-acetyl complex $FvCr(CO)_5(PMe_2Ph)(Me)(COMe)$ (**8**, Scheme 1) could be detected by NMR spectroscopy. Although this compound could not be obtained selectively, it was characterized in situ by NMR spectroscopy. The ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra are completely compatible with the suggested formulation, with the acetyl group and PMe_2Ph ligands occupying mutually *trans* positions. Thus the ^1H NMR spectrum exhibited CrMe, CrCOMe, and PMe resonances at δ 0.50, 2.38, and 1.96, respectively, in addition to four two-hydrogen fulvalene resonances at δ 4.58, 4.72, 4.86, and 4.93. The $^{13}C\{^1H\}$ NMR spectrum exhibited CrMe, CrCOMe, and PMe resonances at δ −4.8, 49.4 and 18.8, respectively, six fulvalene resonances, three CO resonances, and one MeCO resonance. There is also only a single resonance in the $^{31}P\{^1H\}$ NMR spectrum, confirming the presence of a single geometric isomer.

As indicated in Scheme 1, **8** was also formed by reaction of $Et_4N[FvCr_2(CO)_6Me]$ with first PMe_2Ph, then MeI. As shown, direct addition of PMe_2Ph to the methyl "half" of $Et_4N[FvCr_2(CO)_6Me]$ resulted in the formation of the anionic acetyl compound $Et_4N[FvCr_2(CO)_5(PMe_2Ph)(COMe)]$ (**7**), the IR spectrum of which exhibited carbonyl bands at 1897, 1808, 1789, and 1725 cm^{-1}, similar to those of $(Et_4N)_2[FvCr_2(CO)_6]$, and at 1920, 1837.5, and 1636 (C═O) cm^{-1}, similar to those of **6;** thus **7** presumably assumes the structure shown in Scheme 1, with a *trans* acetyl "half." The ^1H NMR spectrum exhibited a PMe doublet resonance (δ 1.89), an acetyl resonance (δ 2.37), and four fulvalene multiplets (δ 4.23, 4.40, 4.46, and 4.54). The $^{13}C\{^1H\}$ NMR spectrum exhibited single PMe and CO*Me* resonances, as well as six fulvalene, two CO, and one *C*OMe resonance, while the presence of only one resonance in the $^{31}P\{^1H\}$ NMR spectrum confirmed the presence of only a single isomer. As with the other monoanionic complexes **2** and **4**, the $^{13}C\{^1H\}$ NMR spectrum exhibited a large difference (19.7 ppm) between the two bridgehead carbon resonances (δ 92.0 and 111.7).

Contrary to our expectations, addition of an excess of PMe_2Ph to **3** under thermal and photochemical conditions did not result in the formation of a substituted derivative **3**, but rather in decomposition to unidentified precipitates in both cases. The IR spectra indicated the possible formation of trace amounts of a substituted product (1944 and 1869 cm^{-1}), but this reaction was not investigated further.

Consequently, in accord with different substitution behaviours of the homodialkyl compounds **1** and **3**, the mixed alkyl compound **5** reacted with PMe_2Ph only the methyl "half", resulting in the formation in good yield of the mixed alkyl acyl compound $FvCr_2(CO)_5(PMe_2Ph)(CH_2CN)(COMe)$ (**10**) (eq. [6]).

[6] $FvCr_2(CO)_6(CH_2CN)Me + PMe_2Ph \rightarrow$
3

trans-$FvCr_2(CO)_4(PMe_2Ph)(CH_2CN)(COMe)$
10

Although the molecular ion of **10** could not be observed in the mass spectrum, the fragmentation pattern is quite consistent with the formulation suggested. The IR spectrum exhibited sets of carbonyl bands at 2019 and 1949 cm^{-1} and at 1922, 1844, and 1639 (C═O) cm^{-1}, similar to those of **4** and **6**, respectively, and suggesting that the acetyl "half" assumes the *trans* isomeric form. The ^1H NMR spectrum exhibited the expected $CrCH_2$ (δ 1.43), PMe (δ 1.98), and COMe (δ 2.40) resonances, as well as four fulvalene resonances (δ 4.70, 4.76, 5.08, 5.22). The $^{13}C\{^1H\}$ NMR spectrum exhibited single $CrCH_2$ (δ −15.3), PMe (δ 18.9), CO*Me* (δ 49.4), and CN (δ 127.6) resonances, as well as six fulvalene resonances (δ 89.2, 91.7, 93.0, 94.0, 101.2, 105.9). three CO resonances (δ 239.8, 249.2, 250.6), and a *C*OMe resonance (δ 271.9).

Earlier it was shown that reduction of *cis,cis*-$FvMo_2(CO)_4L_2Br_2$ (L = PPh_3, PCy_3, PXy_3) with sodium dispersion readily afforded the corresponding dianions (1*b*). Similar treatment of *cis,cis*-$FvCr_2(CO)_4(PMe_2Ph)_2I_2$ (1*d*) was carried out with an excess of sodium dispersion in THF, resulting in the formation of the very air-sensitive salt $Na_2[FvCr_2(CO)_4(PMe_2Ph)_2]$ (eq. [7]).

[7] *cis*,cis-$FvCr_2(CO)_4(PMe_2Ph)_2I_2$ + excess Na →

$Na_2[FvCr_2(CO)_4(PMe_2Ph)_2]$

This salt was then treated with $ClCH_2CN$ to give **9** in excellent yield (eq. [8]).

[8] $Na_2[FvCr_2(CO)_4(PMe_2Ph)_2] + 2\ ClCH_2CN \rightarrow$

$FvCr_2(CO)_4(PMe_2Ph)_2(CH_2CN)_2$
9

The FAB mass spectrum of **9** exhibited a peak at 723 amu, attributed to the molecular ion plus Na^+, as well as several reasonable fragmentation ions. Consistent with a *trans,trans* structure, the ^1H and $^{13}C\{^1H\}$ spectra are very simple. The

former exhibited single $CrCH_2$ (δ 1.23) and PMe (δ 1.91) resonances and only two fulvalene resonances (δ 4.55, 4.58), while the $^{13}C\{^1H\}$ NMR spectrum exhibited a $CrCH_2$ doublet at δ −14.9 (J_{PC} 15 Hz), confirming the presence of a Cr—C bond. In addition, only three fulvalene resonances (δ 88.1, 89.8, 100.5) and one CO carbon doublet (δ 251.6) were observed in the CO region, consistent with the symmetric structure anticipated for the *trans,trans* isomer. No sign of isomerization to *cis,trans* or *cis,cis* forms could be detected in solutions of **9**.

Multinuclear NMR spectra of $[Pt(L)Cl_3]^-$ (L = pyridine derivatives) complexes and crystal structure of *trans*-Pt(2,6-di(hydroxymethyl)pyridine)$_2Cl_2.2H_2O$

Fernande D. Rochon, André L. Beauchamp, and Corinne Bensimon

Abstract: Complexes of the type $[Pt(L)Cl_3]^-$ (L = pyridine derivative) were synthesized and studied by ^{13}C and ^{195}Pt NMR spectroscopies. The ^{195}Pt signals were observed between −1720 and −1897 ppm. No correlation between the δ(Pt) and the pK_a of the protonated pyridine derivatives was found. The chemical shifts vary with the substituents on the pyridine ligand. Compounds with substituents in *ortho* positions were observed at lower fields, except for complexes containing hydroxy or amine groups. The latter compounds were observed at higher fields, close to the signals of the Pt-unsubstituted pyridine compound. These results were explained in terms of the solvent effect. The chemical shifts δ(C) and the coupling constants $J(^{13}C–^{195}Pt)$ were measured and the results interpreted with a view of obtaining information on the nature of the Pt—N bond. The possibility of π-bonding between platinum and the pyridine ligand is examined. The conformation of the pyridine ring in relation to the platinum plane and the energies of the rotation barriers around the Pt—N bond in these types of platinum(II) complexes are briefly discussed. The crystal structure of *trans*-$Pt(2,6\text{-}(HOCH_2)_2py)_2Cl_2\cdot 2H_2O$ was determined by X-ray diffraction. The compound is monoclinic, *C2/m*, $a = 7.022(6)$, $b = 15.646(13)$, $c = 8.344(10)$ Å, ß = 93.35(8)°, $Z = 2$, $R = 0.037$. The platinum atom is located at the junction of the twofold axis and the mirror plane, the N atoms and the *para*-C atom of the pyridine ring are situated on the twofold axis, and the chloride ligands are on the mirror plane. The compound crystallizes with molecules of water, which are H-bonded to the hydroxy groups. The Pt—Cl bond distance is 2.306(2) Å, and that of the Pt—N bond is 2.041(6) Å. The dihedral angle between the platinum and the pyridine planes is 79.8°.

Key words: platinum, pyridine derivatives, NMR, crystal structure.

Résumé : Des complexes de type $[Pt(L)Cl_3]^-$ (L = dérivé de la pridine) ont été etudiés par spectroscopie RMN du ^{13}C et du ^{195}Pt. Les signaux ^{195}Pt ont été observés entre −1720 et −1897 ppm. Aucune correlation entre les δ(Pt) et les pK_a des dérivés protonés de la pyridine n'a été déduite. Les déplacements chimiques dépendent des substituants sur la pyridine. Les composés avec des substituants en positions *ortho* été observé à des champs plus faibles, à l'exception des complexes contenant des groupements hydroxy ou amine. Ces derniers ont été observés à champ plus élevé, proche de celui observé pour $[Pt(pyridine)Cl_3]^-$. Ces résultats ont été interprétés en fonction de l'effet de solvant. Les déplacements chimiques δ(C) et les constantes de couplage $J(^{13}C–^{195}Pt)$ ont été mesurés et les résultats interprétés en vue d'obtenir des informations sur la nature de la liaison Pt—N. La possibilité de liaison π dans ce type de complexes a été examinée. La conformation du noyau de la pyridine par rapport au plan du platine ainsi que les énergies des barrières de rotation autour du lien Pt—N dans ce type de complexes de platine(II), sont brièvement discutées. La structure cristalline du composé *trans*-$Pt(2,6\text{-}(HOCH_2)_2py)_2Cl_2]\cdot 2H_2O$ a été déterminée par diffraction des rayons -X. Le composé cristallise dans le groupe d'espace monoclinique *C2/m*, $a = 7,022(6)$, $b = 15,646(13)$, $c = 8,344(10)$ Å, β = 93,35(8)°, Z = 2 et R = 0,037. L'atome de platine est situé à la jonction de l'axe de rotation 2 et du miroir, les ligands Cl^- sont localisés sur le miroir et les atomes N et C (para) sont sur l'axe 2. Les liens Pt—Cl et Pt—N sont 2,306(2) et 2,041(6) Å. L'angle dièdre entre le plan de la pyridine et celui du platine est 79,8°. Le composé cristallise avec des molécules d'eau qui forment des ponts hydrogènes avec les groupements hydroxy des ligands.

Mots clés : platine, dérivés de la pyridine, résonance magnétique nucléaire, structure cristalline.

Introduction

Pyridine complexes of platinum(II) have been known for a long time, but studies of the nature of the metal–ligand bond are relatively scarce in the literature. Pyridine has six π molecular orbitals (1). The three bonding orbitals are filled, while the three higher energy antibonding orbitals are empty and could accept electron density from the metal. The orientation of the pyridine ring in the platinum complexes can give useful information on the type of orbitals involved in the Pt—L (L = pyridine derivatives) bonding. Bond lengths are usually sensitive to the presence of multiple bonding but, in this case, bond length values are generally not accurate enough to provide unambiguous conclusions. Multinuclear NMR spectroscopy can also give some indication of the strength of the Pt—L bond. The σ bond will cause a deshielding effect on the ligand and a shielding effect on the metal, while back-donation from the metal to the ligand should produce the opposite effect.

The ^{195}Pt NMR signals are particularly sensitive to the presence of substituents on the ligands, especially those in *ortho* positions of the pyridine ligands. These effects are not always predictable in NMR spectroscopy and the origins of the different observed chemical shifts are not well understood. A few authors have made systematic ^{195}Pt NMR studies of platinum(II)–pyridine complexes. Motschi, Sze, and Pregosin have characterized a series of compounds of the type trans-Pt(py-X)$(C_2H_4)Cl_2$ (2), while Marzilli et al. (3) have studied three types of complexes: *cis*- and *trans*-Pt(py-X)$(DMSO)Cl_2$ and *cis*-$[Pt(py\text{-}X)(DMSO)_2Cl]^+$. These authors tried to correlate the pK_a of the protonated py-X ligands to the ^{195}Pt chemical shifts of the complexes. They observed correlations for pyridine ligands containing substituents in *para* position only. For Pt(py-X)$(DMSO)Cl_2$, the authors found, for the *cis* isomer, a very small shielding on the platinum atom as the pK_a values increase, and the reverse for the *trans* isomer. But the differences in chemical shifts are very small and we believe that the observed correlations might not be highly significant. ^{13}C NMR spectroscopy can also give useful information on the nature of the metal–ligand bond. Unfortunately, it is not easy to interpret the overall effects.

Compounds of the type $[Pt(py)Cl_3]^-$ are simple (no isomers), easy to prepare with a good purity, and very soluble in water. We have now synthesized a long series of these complexes with pyridine ligands containing different substituents and we have measured their ^{13}C and ^{195}Pt NMR spectra. The results were interpreted with a view to obtaining information on the factors governing their chemical shifts and also on the nature of the Pt–pyridine bond and molecular conformation. A few disubstituted compounds of the type *trans*-Pt$(L)_2Cl_2$ were studied in order to evaluate approximately the rotation barriers in these complexes. In an attempt to crystallize the monosubstituted complex with 2,6-di(hydroxymethyl)pyridine, we obtained single crystals of the disubstituted compound. Disubstituted complexes are always obtained in these reactions as a by-product, and they are usually filtered out of the solution. The crystal was studied by X-ray diffraction and the results are described below.

Experimental

The ^{195}Pt NMR spectra were measured on a Bruker WH-400 (85.832 MHz) spectrometer, while the ^{13}C NMR spectra were obtained on a Bruker WP-80 operating at 20.15 MHz. The spectra of the platinum complexes were measured at concentrations near saturation in 10 mm tubes, while the ^{13}CNMR spectra of the ligands were measured in the normal 5 mm tubes. Most of the spectra were measured in D_2O (or chloroform). The external standard for the ^{195}Pt spectra was $[Pt(H_2O)_6]^{4+}$ (δ = 0 ppm). The decomposition points were measured on a Fisher–Johns instrument. The ligands were bought from Aldrich and K_2PtCl_4 from Johnson Matthey and Co. The latter was recrystallized from water before use.

Synthesis of K[Pt(L)Cl_3]

The complexes were synthesized according to the published method (4) with slight modifications. The reaction time varied between 3 and 48 h depending on the ligand. The compounds with pyridine (3 h at 75°C), 4-methylpyridine (3 h at 75°C), and 2,6-dimethylpyridine (12 h at 65°C) have already been reported (4). The complex with 3-methylpyridine was prepared by the same method (3 h. at 75°C). Yield: 30%. mp 180–195°C (dec.).

L = 2-methylpyridine, 2-(methylamino)pyridine, 2,3-dimethylpyridine, 2,4-dimethylpyridine, 2,5-dimethylpyridine, 3,4-dimethylpyridine, 3,5-dimethylpyridine, 4-cyanopyridine, 4-acetylpyridine, 4-tert-butylpyridine, and 4-(hydroxymethyl)pyridine

Two mmoles each of K_2PtCl_4 and of the ligand were dissolved in 50 mL of DMF and the solution was stirred during 3 h at 80°C. The mixture was filtered and the filtrate evaporated to dryness under reduced pressure. The residue was washed with ether and dried. It was then dissolved in acetone and the mixture was filtered to eliminate KCl and K_2PtCl_4. The filtrate was evaporated to dryness and the residue was washed with chloroform and finally dried. The ^{195}Pt and ^{13}C NMR spectra confirmed the purity of the compounds. 2-Methylpyridine, yield 81%, mp 160–170°C (dec.); 2-(methylamino)pyridine, yield 45%, mp 155–165°C (dec.); 2,3-dimethylpyridine, yield 79%, mp 205–220°C (dec.); 2,4-dimethylpyridine, yield 70%, mp 220–230°C (dec.); 2,5-dimethylpyridine, yield 46%, mp 210–220°C (dec.); 3,4-dimethylpyridine, yield 51%, mp 155–160°C (dec.); 3,5-dimethylpyridine, yield 40%, mp 160–165°C (dec.); 4-cyanopyridine, yield 45%, mp 185–200°C (dec.); 4-acetylpyridine, yield 48%, mp 195–205°C (dec.); 4-*tert*-butylpyridine, yield 45%, mp 200–205°C (dec.); 4-(hydroxymethyl)pyridine, yield 35%, mp 210–220°C (dec.).

L = 2,3,6-trimethylpyridine and 2,4,6-trimethylpyridine

Two mmoles each of K_2PtCl_4 and of the ligand were dissolved in 75 mL of DMF. The mixture was stirred for 48 h at 60°C and then filtered. The filtrate was then treated as described for 2-methylpyridine. Yields: 45% and 34%, mp 195–200°C (dec.) and 155–165°C (dec.), respectively.

L = 2-(aminomethyl)pyridine, 2-(hydroxymethyl)pyridine, 2-methoxypyridine, 2,6-dimethoxypyridine, and 2,6-di(hydroxymethyl)pyridine

Two mmoles each of K_2PtCl_4 and of the ligand were dissolved in 50 mL of water. The mixture was stirred overnight at room temperature and then filtered. The filtrate was then evaporated to dryness under reduced pressure and the residue was washed with ether and dried. The product was then dissolved in ace-

Synthesis of *trans*-Pt(py)$_2Cl_2$ complexes (L = 2-methylpyridine and 3-methylpyridine)

These complexes were synthesized according to the method described by Kauffman for the synthesis of the pyridine complex (5). Yields: 68%, 75%; mp 210–220°C (dec.) and 195–205°C (dec.), respectively.

Data collection and resolution of the crystal structure

The data collection (2θ/θ) was made at room temperature, on a Syntex $P\bar{1}$ diffractometer, with graphite-monochromatized MoKα radiation (0.71069 Å). The unit cell parameters were calculated from the least-squares refinement of the angles of 15 centered reflections. A rapid data collection suggested a *C* Bravais lattice. Therefore a slower collection was made assuming a *C* lattice. The crystal data are summarized in Table 1. The scan rate varied between 1 and 24° min^{-1}. The intensity data were corrected for absorption (Gaussian integration) and for the effects of Lorentz and polarization. The coordinates of the Pt atom were determined from a three-dimensional Patterson synthesis and the positions of all the other non-hydrogen atoms were obtained by structure factor and Fourier-map calculations. The positions of the H atoms (except those on O atoms, which could not be located) were fixed at their calculated positions with isotropic $U = 0.076$ Å^2. The refinement of the structure was done using full-matrix least-squares calculations minimizing $\Sigma w(F_o - F_c)^2$. Isotropic secondary-extinction corrections (6) were included in the calculations. Individual weights $w = 1/\sigma^2(F)$ were applied. The scattering curves of Cromer and Waber (7) were used for Pt, Cl, N, and C and that of Stewart, Davidson and Simpson (8) was used for H. The anomalous dispersion terms of Pt and Cl were included (9). The calculations were performed using the programs already described (10).[2]

Results and discussion

The complexes K[Pt(L)Cl_3] (L = pyridine derivative) were synthesized by modifying the reported method (4). For most of the complexes, the reaction of K_2PtCl_4 with the ligand was done in dimethyl formamide, in a Pt–ligand mole ratio close to 1:1. The time of reaction varied with the ligand, between 3 and 48 h. A longer time was required for ligands that have substituents in positions 2 and 6. The reactions were performed between 60 and 80°C, except for 2-(aminomethyl)pyridine, 2-(hydroxymethyl)pyridine, 2-methoxypyridine, 2,6-dimethoxypyridine, and 2,6-di(hydroxymethyl)pyridine, whose reactions were done at room temperature and in aqueous medium. These compounds were studied by multinuclear NMR spectroscopy.

^{195}Pt NMR

The variation of the electronic effects on the platinum atom, by the presence of different substituents on the pyridine ligands, can be studied by ^{195}Pt NMR spectroscopy. While the σ bond causes a shielding effect on the δ(Pt), back-donation from the metal to the ligand will produce the opposite effect. An increase of the intrinsic basicity of the ligand should lead to a stronger σ bond and a larger electron density on the platinum atom. As a result, the δ(Pt) should shift towards higher fields. The intrinsic basicity of the ligands can be evaluated from the gas phase protonic affinities or by the Hammett constants but these values are not easily accessible. The pK_a values of the protonated ligands are available for most pyridine derivatives and they should give useful information on the strength of the σ bond.

The ^{195}Pt NMR spectra of the platinum(II) complexes were measured in D_2O and the results are shown in Table 2. The signals were observed between −1720 and −1897 ppm. An attempt was made to find a correlation between the δ(Pt) of all the complexes and the pK_a of the protonated pyridine derivatives. No general relation was found. The chemical shifts of the complexes were found to vary with the substituents on the ligand, and the compounds can be classified into four groups. The signals of the first group of complexes, which contain ligands with no substituents in *ortho* positions, were observed between −1805 and −1818 ppm. The pK_a values for these protonated ligands vary between 1.77 and 6.46 (11). The second group of complexes contains pyridine derivatives with a methyl or methoxy substituent in position 2 (pK_a between 3.20 and 6.63) and the δ(Pt) were found at slightly lower field,

between −1763 and −1796 ppm. The compounds containing methyl or methoxy substituents in positions 2 and 6 (pK_a between 6.72 and 7.48), which form the third group, showed resonances at the lowest field, between −1720 and −1754 ppm. The fourth group, which is composed of platinum compounds containing pyridine derivatives with hydroxy or amine groups in positions 2 or (and) 6, were observed at the highest fields, between −1820 and −1897 ppm. The pK_a of these protonated ligands vary between 3.31 and 8.10. These observations do not show any relation between the δ(Pt) and the pK_a values. It seems that factors other than the basicity of the ligands influence the ^{195}Pt NMR signals of the complexes.

The data obtained from the three first groups of platinum(II) complexes are in agreement with the results observed by Pregosin (12), who reported a ^{195}Pt downfield shift when the ligand became more sterically demanding, close to the binding site. Therefore, the bulkiness around the binding N atom seems to be the first factor governing the ^{195}Pt chemical shifts. The compounds with two substituents in *ortho* positions (third group) are observed at the lowest field (≈−1740 ppm) while those with no substituent in *ortho* positions (first group) are observed at higher field (≈−1810 ppm).

The complexes of the fourth group, which contain ligands with hydroxy or amine groups in positions 2 and (or) 6, do not follow this rule. Compounds with -CH_2OH groups in positions 2 and (or) 6 were observed at higher fields (−1820 and −1839 ppm), close to those of complexes with no substituents in *ortho* positions. Two hypotheses were investigated in order to explain these data. The observed different chemical shifts might be attributed to different Pt–ligand π-bonding or (and) to the solvent effect around the platinum atom. In both explanations, the effects depend on the conformation of the complexes, namely, on the orientation of the pyridine ring with respect to the platinum coordination plane.

Orientation of the pyridine ligands in the Pt(II) complexes

A crystallographic review of pyridine–platinum(II) complexes was made in order to determine the conformation of the pyridine ring in these complexes. We have chosen only the compounds that have chloride ligands in *cis* positions to the pyridine ligand. The results have shown that for pyridine ligands without *ortho* substituents, the dihedral angles between the coordination plane of the platinum atom and the plane of the pyridine ring vary from 44° to 59° (13–19). For the 2-methylpyridine complex, the angle is 72° (20). For complexes containing ligands with substituents in positions 2 and 6, they vary from 82° to 89° (16, 21–25). Obviously, the pyridine ring is frozen in a nearly perpendicular orientation by the *ortho* substituents. For a dihedral angle of 72°, the Cl --- C_{methyl} distance (~3.2 Å) is substantially less than the sum of the van der Waals radii (~3.9 Å), and further reducing this angle would be energy costly. Thus, oscillation of the pyridine ligand is restricted to a narrow ±15° range about 90°, and 180° rotation to reach the other vertical orientation is probably obstructed by very high repulsion when the pyridine ligand tries to become coplanar with the coordination plane. For ligands without *ortho* substituents, at the lower limit of 45°, the H --- Cl distance (~2.77 Å) is also less than the sum of the van der Waals radii (~3.1 Å), but it increases rapidly as the pyridine is rotated towards the vertical orientation. Therefore, these ligands can freely oscillate over a large ±45° range about 90°.

Simple molecular mechanics calculations were run with the PC-MODEL package[3] to estimate the contribution of nonbonded contacts to the rotation barrier in these systems. Energy was calculated as the pyridine was rotated about the Pt—N bond with respect to the coordination plane, over the representative 0°–90° range of dihedral angles. Rigid idealized bond lengths and bond angles were used, but for each dihedral angle the methyl groups were allowed to adopt the orientation of lowest energy. The energy vs. dihedral angle curve showed a maximum for 0° (coplanar), as expected, with values (kJ/mol) of 150 for pyridine, 1280 for 2-methylpyridine, and 2700 for 2,6-dimethylpyridine. These values are certainly overestimated, since steric strain can be relieved by relatively energy-inexpensive variations of other geometrical parameters (e.g., small changes of bond angles or out-of-plane deformations). For instance, increasing the N—Pt—Cl angle to 93° reduces the above values to 90, 850, and 1580 kJ/mol, and for 97°, they become 40, 440, and 860 kJ/mol, respectively. It is noteworthy that even for the latter fairly large distortion, the rotation barrier remains very high for 2- and 2,6-substituted ligands. When the dihedral angle between the platinum and the pyridine planes is about 45°, the maximum energies (assuming *cis* bonds of 90°) are drastically reduced to approximately <10, 120, and 185 kJ/mol for the pyridine, 2-methylpyridine, and

[3] PCMODEL Program, Version 88.0, Serena Software.

2,6-dimethylpyridine complexes, respectively. Therefore, for pyridine complexes the angle can vary between 45 and 90° with almost no loss of energy due the repulsion of the *cis* ligands. For 2,6-dimethylpyridine, the most stable conformation is greater than 70° where the *cis* repulsions become negligible.

Variable-temperature NMR experiments were run to check this different behavior with respect to rotation. For this purpose, $[PtLCl_3]^-$ compounds are useless, since rotation about the Pt—N bond would not generate distinguishable rotamers. Instead, *trans*-PtL_2Cl_2 complexes were used, with the ligands 2-methyl- and 3-methylpyridine, which can form two unequivalent rotamers (methyl groups on the same or opposite sides of the PtN_2 plane, respectively). The ^1H spectrum of *trans*-Pt(2-methylpyridine)$_2Cl_2$ was measured in chloroform. The aromatic multiplets were too complicated to be analyzed, but the methyl signal at ~2.25 ppm appeared as two sharp peaks 11 Hz apart. The relative intensities (65:35) indicate that the two forms have comparable stabilities, as expected. These peaks remained unaffected as temperature was increased to the maximum possible temperature of 50°C. Therefore, the energy barrier can be calculated to be >71 kJ/mol. For *trans*-Pt(3-methylpyridine)$_2Cl_2$, the ^{13}C and ^1H NMR spectra were measured in a mixture of chloroform and Freon-21 between 25° and −100°C. A single sharp methyl resonance was observed over the whole temperature range covered. The other signals all showed single peaks also. This can be due to the presence of a single rotamer (unlikely), the resonances are too close to be resolved (possible), or fast exchange between the two rotamers because of a low rotation barrier (likely). Considering that no broadening was detected at the lowest temperature used (−100°C) and assuming that the separation of the methyl signals for the two rotamers would be the same as above, an upper limit of 29 kJ/mol can be calculated for the rotation barrier.

Although these results provide only rough estimates, they support the overall picture of a highly restricted perpendicular orientation for *ortho*-substituted pyridines and much greater orientation flexibility for ligands without *ortho* substituents.

^{195}Pt data and solvation effects

These observations on the conformation of the complexes suggest that the main factor influencing the δ(Pt) of the platinum complexes is the solvent effect. For the pyridine complex, the two H atoms in positions 2 and 6 are not large enough to prevent the approach of water molecules, especially when the angle is close to 45°. The molecules of solvent are attracted towards the platinum centre below and above the platinum plane, thus increasing the electron density in the close environment of the Pt atom. Therefore the δ(Pt) should be observed at higher field. With compounds containing two $-CH_3$ substituents in positions 2 and 6, the pyridine and platinum planes must be perpendicular to each other. The two hydrophobic methyl groups are then located directly above and below the platinum plane, preventing the approach of water molecules. Therefore the electron density on the platinum atom is reduced compared to the pyridine compound. The platinum chemical shift of the 2,6-dimethylpyridine complex is observed at lower field than those of the compounds without hydrophobic substituents in *ortho* positions.

To demonstrate this solvent effect, platinum compounds containing ligands with substituents in positions 2 and 6, which can recreate an environment similar to the solvent effect, were studied. One such example is $[Pt(2,6\text{-}(HOCH_2)_2py)Cl_3]^-$, whose platinum resonance was observed at much higher field (−1839 ppm) than the other 2,6-disubstituted complexes with hydrophobic groups (−1720 to −1754 ppm) . In fact, it was observed very close to the value measured for $[Pt(py)Cl_3]^-$ (−1816 ppm). Other platinum complexes containing hydroxy or amine groups in *ortho* positions (which form the fourth group) were also observed at similar higher fields. The hydrophilic groups in *ortho* positions are located above and below the platinum plane and create an environment similar to that observed in the pyridine complex. These observations confirm the hypothesis on the importance of the solvent effect on the chemical shifts in ^{195}Pt NMR spectroscopy.

Nevertheless, even if the solvent effect can explain the δ(Pt), the presence of Pt–pyridine π-bonding is not excluded. In Zeise's salt (26), the π bond is formed from the overlap of the filled d_{yz} orbital of platinum (the platinum plane is in the *xy* plane and ethylene is along the y axis) with the vacant π* of ethylene, since C_2H_4 is perpendicular to the platinum plane. Considering that all the π* orbitals of pyridine have a nodal plane through the six-membered ring, back-donation could take place via $d_{xy} \rightarrow \pi^*$, if the pyridine ring is perpendicular to the coordination plane, or via $d_{yz} \rightarrow \pi^*$, if it is coplanar. For pyridine, π_4^* (LUMO) has the right symmetry (1) for accepting back-donation from the metal, since it has no nodal plane on the N atom (contrary to π_5^*). In the conformation with a dihedral angle of ≈90°, which is accessible for all ligands, $d_{xy} \rightarrow \pi^*$ interaction could occur, but this type of back-donation is not believed to be appreciable. The fact that complexes with ligands, without *ortho* substituents, have dihedral angles around 50° has led a few authors to suggest that $d_{yz} \rightarrow \pi^*$ bonding would exist (16, 26). Therefore, the observed dihedral angle would result from two factors: the π bond ($d_{yz} \rightarrow \pi^*$), which would tend to bring the pyridine ring in the coordination plane, while the Cl ··· H(ortho) steric repulsions would tend to bring the two planes perpendicular to each other. Furthermore, the d_{xy} orbital was suggested to contribute in the bonding of the two *cis* Pt—Cl bonds, which would reduce its involvement in the Pt—L π bond (26).

Since ^{13}C NMR spectroscopy had provided information on similar π-bonding problems in Ru(II) and Rh(III) compounds (27), the spectra were recorded for our $[Pt(L)Cl_3]^-$ complexes.

^{13}C NMR

The ^{13}C NMR spectra of pyridine and its methyl derivatives and their Pt(II) complexes were measured in D_2O. The experimental data for the ligands are shown in Table 3, while those of the complexes, along with $\Delta\delta(\delta_{complex} - \delta_{ligand})$ are shown in Table 4.

For the free pyridine molecules, three factors will influence the electron density on the carbon atoms, and thus the chemical shifts of the ligands. There are three different mesomeric forms of pyridine produced by the delocalization of the π electrons, two of which have a δ^- charge on the N atom and a δ^+ charge on the *ortho* or *para* C atoms. These mesomeric forms decrease the electron density on the carbon atoms in positions 2, 4, and 6 (28). The second factor is the inductive effect of the nitrogen atom, which is more important for closer carbon

atoms. Therefore the carbon atoms in positions 3 and 5 are influenced only by the inductive effect and are observed at higher fields. Those located in position 4 are only slightly influenced by the inductive effect of the N atom, and appear at intermediate chemical shifts. The chemical shifts of the pyridine C atoms in D_2O were found at 149.43, 137. 84, and 125.00 ppm for atoms in positions 2, 4, and 3, respectively. The last factor that influences the C chemical shifts is a local effect due to the presence of substituents at different positions. The addition of a methyl group increases the ionic mesomeric forms of the pyridine derivative, and the electron density on the C atoms to which it is bonded decreases. When a -CH_3 substituent is in position 2, the δ(C) of C2 varies between 155.34 and 158.40 ppm, an increase of about 7.5 ppm when compared to pyridine. A substituent in position 3 or 5 increases the δ(C) of C3 or C5 by about 9.5 ppm, and a -CH_3 substituent in position 4 increases the δ(C) of C4 by about 12 ppm (Table 3). The presence of a -CH_3 group creates a greater deshielding on its ring C atom when it is far from the N atom. The chemical shifts of the methyl groups vary between 16.31 to 23.72 ppm and those located in positions 2 and 6 are the most deshielded.

Upon coordination of the pyridine ligand to the platinum atom, the formation of the σ bond will decrease the electron density on the ligand and especially on the atoms close to the binding site, namely, those in positions 2 and 6. Furthermore, the ionic mesomeric forms will be more favored, reducing the electron density in positions 2, 4, and 6. As a result, all the chemical shifts of the carbon atoms are shifted towards lower field upon coordination.

Since it was postulated that pyridine would form multible bonding with platinum, while the 2,6-disubstituted compounds would only form *a* σ bond, attempts were made to study this hypothesis by ^{13}C NMR spectroscopy. The chemical shifts of the complexes containing ligands with methyl groups in positions 2 and (or) 6, were compared with those of the complexes with pyridine ligands with no substituents in ortho positions. A comparison of $\Delta\delta$ ($\delta_{complex} - \delta_{ligand}$) for the different complexes should give useful information. The average $\Delta\delta$ for the pyridine complexes with no *ortho* substituents are 4.84 for C(2), 2.19 for C(3), 1.88 for C(4), 1.79 for C(5), and 5.03 ppm for C(6) (Table 4). For Pt compounds containing ligands with a methyl substituent in position 2, the corresponding $\Delta\delta$ values are 3.56, 2.71, 1.63, 2.16, and 5.58 ppm, while they are 4.40, 2.65, 1.77, 2.40, and 4.42 ppm for the 2,6-disubstitued compounds. If π-bonding is more important in complexes containing ligands with no *ortho* substituents, the electronic density on the ligand should be larger for these complexes, and the $\Delta\delta$ should be smaller. In our case, we have not observed smaller shifts for the compounds containing ligands with no substituents in *ortho* positions, compared to the *ortho*-disubstituted complexes. Therefore, our results do not support the hypothesis that π-bonding would be less important in the 2,6-disubstituted pyridine complex.

It could be argued that the aquation reactions of the different ligands are different. The extent of hydration for unsubstituted pyridine might be more important than the hydration reaction with 2,6-dimethylpyridine. To study this influence, a second comparison was done using the chemical shifts of three ligands measured in chloroform. The $\Delta\delta$ ($\delta_{complex\ in\ D_2O} - \delta_{ligand\ in\ CDCl_3}$) values are 4.57, 3.45, and 4.17 ppm for pyridine, 4.20, 4.47, 3.52, 3.67, and 5.70 ppm for 2-methylpyridine, and 4.46, 4.16, and 3.48 ppm for 2,6-dimethylpyridine. Again, the $\Delta\delta$ values are similar for the pyridine and the 2,6-dimethylpyridine complexes. Therefore, these results confirm that π-bonding, if present, is probably similar for all the platinum complexes.

Attempts were made to confirm the presence of Pt→L π-bonding from the ^{13}C NMR spectra of the complexes. We can compare our results with a Ru(II) compound known to form metallic multiple bonding with pyridine (27). According to the authors, C(4) is the most reliable probe to study this effect. The chemical shift of C(4) of the pyridine ligand in $[Ru(NH_3)_5(pyridine)]^{2+}$ is 134.6 ppm, for a $\Delta\delta$ value of −3.2 ppm (δ of pyridine measured in D_2O). Therefore, upon coordination of pyridine to ruthenium(II), the electron density on the ligand is increased. For the corresponding Rh(III) and Co(III) compounds $[M(NH_3)_5(pyridine)]^{3+}$ (Rh(III) and Co(III) are harder metals than Ru(II)), the π-bonding should be reduced and the chemical shifts of C(4) were observed at 141.9 ($\Delta\delta$ = 4.1 ppm) and 142.7 ppm ($\Delta\delta$ = 4.9 ppm), respectively. Our values vary from 1.17 to 2.04 ppm. This comparison seems to confirm the multiple nature of the Pt—N bond in pyridine–platinum(II) complexes. Nevertheless, its extent seems much less important than in Ru(II) pyridine complexes, but probably more than in Rh(III) and Co(III) compounds. Yet, the strength of the σ bond might vary with different metals and different oxidation states.

Table 5. $J(^{13}C-^{195}Pt)$ coupling constants (Hz) of the complexes $K[Pt(py)Cl_3]$.

Ligand	^3J 2-CH_3	^3J 6-CH_3	^3J C(3)	^4J C(4)	^3J C(5)

2,4,6-CH_3(py)	22.1	22.1	30.9		30.9

n.o., not observed.

The $J(^{13}C-^{195}Pt)$ coupling constants were also measured and are shown in Table 5. The ^3J couplings were observed on C3 and C5 and vary from 27.7 to 44.1 Hz. The ^4J (with C4) are much smaller (11.8–14.7 Hz) and they could be measured only on two complexes. For the ligands with methyl substituents in positions 2 and 6, the ^3J vary between 22.1 and 30.9 Hz. The smaller values for the methyl C atoms are caused by the different hydridizations (sp^3 vs. sp^2). No ^2J values could be measured. These values are usually too small to be observed, due to the inadequate orientation of the different orbitals. Grim, Keiter, and McFarlane (29) have made a ^{31}P NMR study of compounds of the type *cis*- and *trans*-$Pt(PR_3)_2Cl_2$. The authors have observed larger $J(^{31}P-^{195}Pt)$ coupling constants when the extent of π-bonding increased. In our work, we have not observed any differences between the coupling constants of the different platinum complexes.

Structure of *trans*-$Pt(2,6\text{-}(HOCH_2)_2py)_2Cl_2$

The crystal structure of a platinum complex containing ligands with substituents in positions 2 and 6 capable of recreating the solvent effect around the platinum atom was determined. The ligand chosen for this study was 2,6-di(hydroxymethyl)pyridine. The two hydroxy groups could be located close to the Pt atom above and below the plane, as suggested from ^{195}Pt NMR spectroscopy. The monosubstituted complex did not produce crystals suitable for X-ray diffraction. Therefore, the disubstituted compound was analyzed. The refined atomic parameters of the complex are listed in Table 6. A labelled diagram of the molecule is shown in Fig. 1. The platinum atom is located at the junction of a 2-fold axis and a mirror plane, the chloro ligands are on the mirror plane, while the N and C(4) atoms are on the 2-fold axis. The compound crystallized with molecules of water that are also situated on a 2-fold axis. As expected, the coordination around Pt(II) is square planar (perfect plane by symmetry). The six atoms of the pyridine ring are in a plane with deviations N, 0.000; C(2), −0.003(5); C(3),

N′: 0, −y, 0; Cl′: −x, 0, −z.

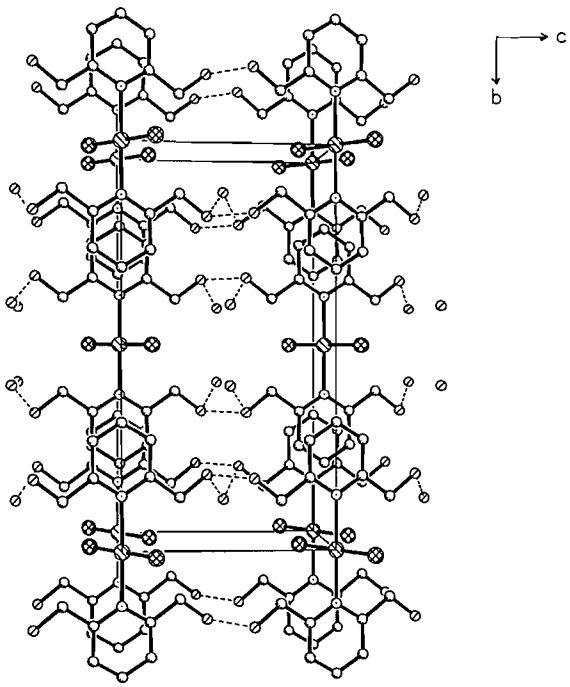
−0.003(6); C(4), 0.001; C(2′), 0.003(6); and C(3′), −0.003(6) Å. The C(5) and the hydroxyl−O atoms are also in the pyridine plane, with deviations of −0.037(6) and −0.012(5) Å, respectively. The dihedral angle between the platinum and the pyridine planes is 79.8°, close to the value of 81.6° observed in K[Pt(2,6-dimethylpyridine)Cl_3] (21).

The crystal Pt(2,6-$(HOCH_2)_2$py)$_2Cl_2$ is the *trans* isomer as expected for 2,6-disubstituted compounds. It has been shown that it is not possible to synthesize *cis* isomers containing two pyridine ligands with substituents in positions 2 and 6 (4, 25). The bond distances and angles are listed in Table 7. The Pt—Cl bond length is normal (2.306(2) Å), and the Pt—N bond distance is 2.041(6) Å. Pt—N bond distances for pyridine ligands usually seem slightly shorter than those observed for similar Pt – primary amine compounds, but it is difficult to compare since the *trans* ligand must be taken into consideration and few compounds of these types have been reported. The Pt—N bonds in *trans*-Pt(*tert*-butylamine)$_2Cl_2$ are 2.041(6) and 2.053(6) Å (30), while in a *trans* pyridine derivative compound, the Pt—N (pyridine) bonds are slightly shorter, 2.013(4) Å (31). In *trans*-Pt(pyridine)$_2Cl_2$, the bond distance is 1.98(1) Å (13) and it is 1.991(11) Å in *trans*-Pt(4-EtCOOpy)$_2Cl_2$ (15). The slightly shorter bond observed in Pt–pyridine compounds might indicate the presence of π bonds, but there are not enough data available at the moment in the literature to reach such a conclusion. The present structure does not show any evidence of bonds shorter than those observed in Pt – primary amine complexes. The presence of two bulky substituents in *ortho* positions might be an important factor in slightly increasing the Pt—N distances.

The O atoms in the hydroxy groups are located in the plane of the pyridine ring, but away from the platinum atom. The crystal *trans*-Pt(2,6-$(HOCH_2)_2$py)$_2Cl_2$ is stabilized by intermolecular hydrogen bonding between the hydroxy groups and the water molecules. The distance O ··· O is 2.754(6) Å with an angle C(5)—O ··· O of 103.1(3)° and the distance O ··· O(w) is 2.789(6) Å, with an angle C(5)—O ··· O(w) = 103.4(3)°. These results indicate that the conformations of the hydroxy groups in the crystal are different from those suggested by the ^{195}Pt NMR spectra. The presence of lattice molecules of water is probably a major factor responsible for the different conformation in the solid state, since hydrogen bonds provide an important contribution to crystal packing energy. This observation does not weaken the conclusion reached from ^{195}Pt NMR spectroscopy. Since the dihedral angle between the Pt plane and the pyridine plane is close to 90°, rotations around the -CH_2OH groups within the free species could easily bring the hydroxy groups in the close environment of the platinum atom on both sides of the Pt plane.

A packing diagram of the molecules is shown in Fig. 2. The Pt atoms are located at $z = 0$ and the lattice water molecules are all located at $z = {}^1/_2$. The pyridine rings are stacked in the crystal along the x direction, at approximately $y \approx {}^1/_4$ and ${}^3/_4$ and $z = 0$.

Fig. 2. Packing diagram in the crystal *trans*-Pt(2,6-$(HOCH_2)_2py)_2Cl_2 \cdot 2H_2O$.



Conclusion

The ^{13}C NMR spectra of the platinum(II) complexes do not rule out the multiple nature of the Pt—N bond, but the extent of π-bonding is small compared to ruthenium(II)–pyridine complexes. In this work, we have assumed that the extent of the σ bond remains the same when substituents are added on the pyridine ring. This hypothesis might not be acceptable, but it is not easy to separate the two types of bonding since only the overall effect can be observed. ^{15}N NMR spectroscopy might bring more information on the nature of the Pt—N bond than a ^{13}C NMR study. Nevertheless, except for pyridine, most of the ^{15}N enriched ligands are not easily available.

The ^{195}Pt NMR spectroscopic results have provided useful information in the study of this series of platinum(II) complexes. The solvent effect plays a major role in the determination of the platinum chemical shifts. Complexes containing ligands with no substituents in the *ortho* position would allow the molecules of solvent (water) to approach the platinum atom on both sides of the platinum plane, thus increasing the electron density in the close environment of the metallic center. On the other hand, compounds containing 2,6-dimethylpyridine with two hydrophobic methyl groups on each side of the platinum plane (since the Pt and pyridine planes are perpendicular to each other), do not allow the approach of the molecules of solvent in the close environment of the Pt atom, thus reducing the electronic density around the Pt atom. The latter compounds are observed at lower fields. The Pt compounds with ligands that can recreate the solvent effect, such as 2,6-di(hydroxymethyl)pyridine, are observed again at higher fields, like the pyridine complex.

The crystal structure determination of *trans*-Pt(2,6-$(HOCH_2)_2py)_2Cl_2$ has shown that all the hydroxy groups are in the same plane as the pyridine ring and point away from the platinum atom. In aqueous solution, the ^{195}Pt NMR spectra of $K[Pt(2,6\text{-}(HOCH_2)_2py)Cl_3]$ and related compounds have shown that the hydroxy groups seem to be close to the platinum atom. If we assume that the angle between the platinum plane and the pyridine plane is close to 90°, the hydroxy groups could be thought of as recreating, around the Pt atom, a hydrophilic environment similar to the solvent effect. The different orientation of the hydroxy groups observed in the solid state results from the formation of hydrogen bonds with the molecules of lattice water, which would stabilize this conformation. A rotation around the $-CH_2OH$ groups could bring the hydroxy groups into the close environment of the platinum atom on both sides of the Pt plane as suggested by the solution spectra.

This work confirms that π-bonding, if present, is not different for *ortho*-unsubstituted or *ortho*-substituted ligands in the Pt(II) complexes. But the presence of multiple bonding is not essential to explain the conformation of the ligands in the Pt(II) complexes. The energy difference for dihedral angles of 45° and 90° in $[Pt(pyridine)Cl_3]^-$ is very small (<10 kJ mol^{-1}) and could easily be overcome, for example, by very weak dipole–dipole attractions between the *ortho* H atoms and the *cis* chloro ligands. Some interesting results from the literature might strengthen this suggestion. The crystal structures of the compounds *trans*-Pt(DMSO)(3,5-dimethylpyridine)I_2 (32) and *trans*-Pt(pyridine)$_2I_2$ (33) have shown that the dihedral angles between the Pt and the pyridine ring are 79° and 75°, respectively. These angles are much larger than those observed for Pt-dichloro compounds containing ligands with no substituents in positions 2 and 6 (44°–59°). The larger angle might be caused by the absence of dipole–dipole attractions between the *ortho* H atoms of the pyridine derivative and the cis iodo ligands.

Bis- and tris(amidine)fluoroboron cations and mixed tetrahaloborate anions: NMR studies of mixed boron trihalide adduct redistribution reactions involving amidines as strong nitrogen bases[1]

J. Stephen Hartman, Zheng Yuan, Arnold Fox, and Anh Nguyen

Abstract: Amidines as strong Lewis bases react with amidine–mixed boron trihalide adduct systems $D{\cdot}BF_nCl_{3-n}$ ($n = 0$–3) in the presence of excess boron trihalide to give complex mixtures of products including the mixed tetrahaloborate anions $BF_nCl_{4-n}^-$ and the fluoroboron cations $D_2BF_2^+$ and D_3BF^{2+}, which coexist with the neutral adducts $D{\cdot}BF_nCl_{3-n}$. Excess amidine rapidly displaces chloride ion from the chlorofluoroborate anions and neutral mixed boron trihalide adducts to give high yields of the fluoroboron cations. The D_3BF^{2+} cations of the amidines 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU) and 1,5-diazabicyclo[4,3,0]non-5-ene (DBN) are inert and have been isolated as their hexafluorophosphate salts. $(DBN)_2BF_2^+$ is inert and has been isolated as its hexafluorophosphate salt, but $(DBU)_2BF_2^+$ is highly reactive.

Key words: amidines, fluoroboron cations, mixed boron trihalide adducts, redistribution reactions, fluorine-19 NMR, boron-11 NMR, 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU), 1,5-diazabicyclo[4,3,0]non-5-ene (DBN)

Résumé : Les amidines, comme de fortes bases de Lewis, réagissent avec les systèmes d'adduits amidine–trihalogénures de bore mixtes, $D{\cdot}BF_nCl_{3-n}$ ($n = 0$–3), en présence d'un excès de trihalogénure de bore, pour donner des mélanges complexes de produits contenant les anions mixtes tétrahalogénoborates, $BF_nCl_{4-n}^-$, ainsi que les cations fluorure de bore $D_2BF_2^+$ et D_3BF^{2+} qui coexistent avec les adduits neutres $D{\cdot}BF_nCl_{3-n}$. L'excès d'amidine déplace rapidement l'ion chlorure des anions chlorofluoroborate et des adduits trihalogénures de bore mixtes neutres pour conduire, avec des rendements élevés, aux cations fluorure de bore. Les cations D_3BF^{2+} des amidines 1,8-diazabicyclo[5.4.0]undéc-7-ène (DBU) et 1,5-diazabicyclo[4.3.0]non-5-ène (DBN) sont inertes et ont été isolés sous la forme de sels hexafluorophosphate. Le $(DBN)_2BF_2^+$ est inerte et a été isolé comme son sel hexafluorophosphate: toutefois, le $(DBU)_2BF_2^+$ est extrêmement réactif.

Mots clés : amidines, cations fluorure de bore, adduits mixtes de trihalogénures de bore, réactions de redistribution, RMN du fluor-19, RMN du bore-11, 1,8-diazabicyclo[5.4.0]undéc-7-ène (DBU), 1,5-diazabicyclo[4.3.0]non-5-ène (DBN).

[Traduit par la rédaction]

Introduction

Earlier work in this laboratory (1,2) has shown that low-steric-hindrance tertiary amines selectively displace heavy halide ion X^- (X = Cl, Br) from nitrogen-donor mixed boron trihalide adducts $D{\cdot}BF_2X$ to form bis(amine)difluoroboron cations (eq. [1]). With pyridines the adducts $D{\cdot}BFX_2$ also react, and form bis(pyridine)fluorohaloboron and tris(pyridine)fluoroboron cations as in eq. [2] (3). We now report the extension of our

[1] $$D{\cdot}BF_2X + D' \rightarrow DD'BF_2^+ + X^-$$

[2] $$D{\cdot}BFX_2 + D' \rightarrow DD'BFX^+ + X^- \xrightarrow{D'} DD'_2BF^{2+} + X^-$$

work to mixed boron trihalide adducts of amidines (4), which as strong nitrogen bases of low steric hindrance should be capable of driving the formation of fluoroboron cations even more effectively than is possible with pyridines as donors.

The basicity of the amidine functional group >N—CR=N— is enhanced by electron delocalization toward the imino nitrogen as in structure **1b**. The substituent on the imino nitrogen atom, the site of protonation and of complex formation, has the strongest influence on amidine basicity (5), although basicity is also affected by substitution at the central

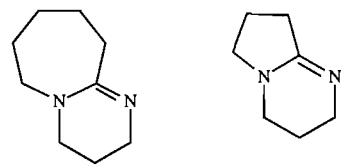
1a 1b

carbon atom and the amino nitrogen (6). Amidines with their strong basicity have interesting coordination chemistry (7). Monomeric, dimeric, and cluster metal amidine complexes have been studied. N-H containing acyclic amidines can lose a proton to form [R′—N═CR—N—R″]$^-$ species, which can act as bridging ligands (7, 8). To avoid problems of N-H proton transfer, we have limited our work to *N,N,N′*-trialkyl-substituted amidines. Following preliminary studies with *N,N,N′*-trimethylacetamidine (Me_2N-CMe═NMe) and *N,N,N′*-trimethylbenzamidine, which are not commercially available, our work on amidine interactions with mixed boron trihalide adducts has involved 1,8-diazabicyclo[5,4,0]undec-7-ene (DBU, **2**) and 1,5-diazabicyclo[4,3,0]non-5-ene (DBN, **3**). Both of these amidines are readily available and have become



2, DBU 3, DBN

well established as strongly basic yet non-nucleophilic reagents in organic synthesis (9, 10). DBN is one of the strongest amidine bases, with a pK_b of about 0.5 in 50% aqueous ethanol (11). DBU is almost as basic, with a pK_b of 1.1 in 1 M aqueous solution and 0.6 in 10% aqueous solution (Table I of ref. 10). This compares to pK_b values of 2.9–3.4 for simple aliphatic trialkylamines and 7.2–8.8 for simple pyridines (12).

Despite the reputation of DBU and DBN as strongly basic yet non-nucleophilic reagents (9, 10), a number of recent reports have shown that these bases can indeed act as nucleophiles (13), notably towards halogenated derivatives of main group elements (14), and a few DBU–metal complexes have recently been reported (15).

Experimental

Materials

Most compounds utilized in this work are moisture sensitive. They were handled with standard inert-atmosphere Schlenk line and glove bag techniques (16). Carefully dried solvents were used.

Boron trifluoride gas (Matheson) was passed through a glass tube packed with sodium fluoride in order to remove traces of HF. Boron trichloride gas (Matheson, bp 12.7°C) was condensed with a slush bath at −63°C on the Schlenk line, and a trap-to-trap distillation was carried out. The pure liquid BCl_3, which is clear and colorless, was diluted to 0.5 M in $CDCl_3$ and stored at −10°C in a closed Schlenk vessel.

Boron tribromide (Alfa Inorganics) was treated with mercury to remove bromine and was transferred into small ampoules by trap-to-trap distillation on a high-vacuum line. The sealed ampoules were stored in the dark to prevent photochemical formation of bromine and were opened as needed in the glove bag.

Commercial DBU (Abbott Laboratories; Air Products and Chemicals, Inc.) was distilled under reduced pressure and dry nitrogen (130–134°C at 20 Torr (1 Torr = 133.3 Pa)) using microdistillation apparatus sealed with Apiezon M grease and linked to a Schlenk line. The purified DBU (clear and almost colourless) and DBN (Aldrich, 95%) were stored over Lindé 5 Å molecular sieves prior to use.

N,N,N′-Trimethylacetamidine and *N,N,N′*-trimethylbenzamidine were synthesized according to the procedure of Wilson et al. (17), using $Ti(NMe_2)_4$ that had been synthesized by the procedure of Bradley and Thomas (18) and vacuum distilled. The amidine products were vacuum distilled and stored in tightly sealed 5 mL flasks over activated Lindé 3 Å molecular sieves before use.

Hexane was dried with sodium wire. Deuterated chloroform (Merck, minimum isotopic purity 99.8% D) was dried with Lindé 5 Å molecular sieves that were baked in advance in a muffle furnace at 400°C for more than 3 h and cooled over a period of 0.5 h in a vacuum desiccator. Sodium tetraphenylborate (Fisher, 99.6%), sodium hexafluorophosphate (Alfa, 98%), and ammonium hexafluorophosphate (Aldrich, 99.5%) were used as supplied.

C_6F_6 (Whittaker) was used as a secondary internal reference for ^{19}F chemical shifts (−162.7 ppm from $CFCl_3$). $Et_2O{\cdot}BF_3$, prepared by reaction of BF_3 with diethyl ether and fractionation of the liquid product, was used as the ^{11}B external reference. Nitromethane (Fisher), distilled at 101–102°C, was used as the external reference for ^{15}N.

Boron trihalide adducts

Boron trihalide adducts were synthesized as described previously (2, 19), with a bubbler added to control the flow rate of the gas. BF_3 or BCl_3 was slowly bubbled into an anhydrous hexane solution of the amidine (hexane:amidine = 5:1– 10:1 v/v) under a positive nitrogen atmosphere until no additional precipitation occurred. The reaction took place at 0°C in an ice bath, with stirring. DBU·BF_3 and DBN·BF_3 are very stable in water, and DBU·BF_3 did not change over a month on standing in air. The separation of boron trifluoride adducts from the solution was initially carried out by syringe/septum methods (2, 3), but in view of the stability of DBU·BF_3 and DBN·BF_3 to hydrolysis, in later work the adducts were filtered in air and washed with hexane and water to remove organic and inorganic impurities, followed by drying in air and under vacuum and storage in a Schlenk vessel.

Synthesis and isolation of fluoroboron cations

Difluoroboron cations $D_2BF_2^+$ and monofluoroboron cations D_3BF^{2+} were formed by similar methods. In most situations, a solution of 0.05–0.10 mL 1.0 M BCl_3 in $CDCl_3$ was added to a solution of 0.3–0.4 mL 0.3–0.5 M D·BF_3 in $CDCl_3$ in a 5 mm NMR tube. Both of these solutions were kept at −63°C in a slush bath. After 10–20 min, during which time D·BF_nCl_{3-n} formed (2, 3, 19), a solution of 0.2–0.4 mL of 1 M amidine in $CDCl_3$ was added. Syringes (1 mL and 50 μL) were used to

inject the various reagents. A very narrow glass rod with an enlargement at the bottom was especially useful for mixing reagents in the NMR tube. The whole process was carried out in a glove bag under a nitrogen atmosphere. Since redistribution reactions occur rapidly in these systems, only a few minutes were required for the fluoroboron cations to form.

Monitoring by ^{19}F NMR showed that the best ratio of Cl to F for the formation of the $D_2BF_2^+$ cations of DBU and DBN is 0.8:1. For the D_2BFCl^+ and D_3BF^{2+} cations the best ratio of Cl to F is (1.2–1.5):1. Both have the same precursor, $D{\cdot}BFCl_2$, and only half as much free amidine is needed for D_2BFCl^+ formation as for D_3BF^{2+}. Some D_2BFCl^+ was always formed along with D_3BF^{2+}.

Neither $D_2BF_2^+$ nor D_3BF^{2+} was isolated directly from the $CHCl_3$ mother solution by precipitating as $D_2BF_2^+Cl^-$ or $D_3BF^{2+}Cl_2^-$. A precipitate that did form in such a solution containing $(DBU)_2BF_2^+$ gave a fast atom bombardment mass spectrum (FAB spectrum (20)) with only one strong peak corresponding to $DBU{\cdot}H^+$, indicating that the precipitate is $[DBU{\cdot}H]^+Cl^-$.

Sodium tetraphenylborate was added in an attempt to precipitate fluoroboron cations as their tetraphenylborate salts, as in related systems (2, 3). However, FAB analysis indicated that only $[D{\cdot}H]^+BPh_4^-$ (D = DBU, DBN) were isolated in 1:1 $CHCl_3$–EtOH solution.

$(DBU)_3BF^{2+}$, $(DBN)_3BF^{2+}$, and $(DBN)_2BF_2^+$ were isolated by selective precipitation as their hexafluorophosphate salts. A white precipitate appeared immediately when a saturated $NaPF_6$ or NH_4PF_6 solution in ethanol was added to a cation-containing 1:1 $CHCl_3$–EtOH solution. Recrystallization was carried out from a 1:1 acetone–EtOH solution. The fluoroboron hexafluorophospates are soluble in acetone and insoluble in EtOH.

High-quality single crystals suitable for X-ray crystallography were grown by a solvent diffusion process. The key to growing these crystals is that absolute EtOH must be very gently added to fluoroboron cation-containing hexafluorophosphate-containing acetone solution along the glass wall of a 10 mm diameter tube to keep the surface in an undisturbed state. The acetone solution must be a little less than saturated. The slower the diffusion process, the higher the quality of the crystal. After 20 h of solvent diffusion, excellent crystals began to appear.

Since $(DBU)_2BF_2^+$ decomposes in water and alcohol, it could not be isolated by the general method. Other unsuccessful attempts included use of a large amount of hexane to precipitate it from the mother solution, and the direct addition of a saturated solution of $NaPF_6$ or NH_4PF_6 in $CHCl_3$ to the mother solution.

Tris(DBU)monofluoroboron hexafluorophosphate

In a −63°C slush bath, a solution of BCl_3 in $CHCl_3$ was added to a solution of $DBU{\cdot}BF_3$ in $CHCl_3$ in a 1:0.8 molar ratio. After stirring for 10 min, a fourfold excess (over BCl_3) of 1 M DBU in $CHCl_3$ was added and the solution was stirred for another 10 min. This solution was mixed with absolute ethanol in a 1:1 volume ratio. NH_4PF_6, as a saturated solution in ethanol, was slowly added with vigorous stirring until no additional precipitate formed. The white solid, very stable to hydrolysis, was washed with several portions of water and ethanol. ^{19}F NMR spectrum in acetone: δ −129.9 ppm, 1:1:1:1 quartet; δ −70.8 ppm, 1:1 doublet (quartet:doublet ~ 1:12); ^{11}B NMR spectrum: δ 4.7 ppm, 1:1 doublet; $J(^{11}B–^{19}F)$ = 50.7 Hz; $J(^{19}F–^{31}P)$ = 710.6 Hz; no ^{19}F or ^{11}B extraneous peaks. FAB spectrum (NBA matrix): peak at *m/z* 631 having an isotope pattern consistent with $\{[(DBU)_3BF^{2+}](PF_6^-)\}^+$. The elemental analysis is given in Table 1.

Table 1. Elemental analyses of (amidine)fluoroboron hexafluorophosphates.

Tris(DBN)monofluoroboron hexafluorophospate

Needle-like transparent crystals of tris(DBN)monofluoroboron hexafluorophosphate were obtained by using a procedure similar to that for the DBU analogue. Since $(DBN)_3BF^{2+}$ was always present with $(DBN)_2BF_2^+$ and both of them could be precipitated by PF_6^-, the amount of PF_6^- was controlled so that only the doubly charged cation was precipitated and the singly charged cation remained in solution. ^{19}F NMR spectrum in acetone: δ −141.1 ppm, 1:1:1:1 quartet; δ −70.8 ppm, 1:1 doublet; ^{11}B NMR spectrum in acetone: δ 3.6 ppm, 1:1 doublet; $J(^{11}B–^{19}F)$ = 47.8 Hz; no additional ^{19}F or ^{11}B NMR peaks. The elemental analysis is given in Table 1.

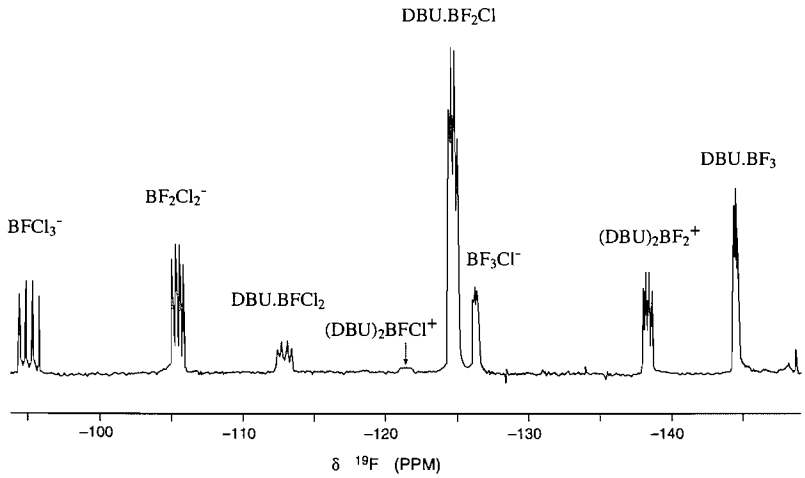
Bis(DBN)difluoroboron hexafluorophosphate

1M BCl_3 in $CHCl_3$ was added to a solution of $DBN{\cdot}BF_3$ in $CHCl_3$, in a 1:3 molar ratio in a −63°C slush bath. After stirring for 5 min, a twofold excess of 1 M DBN in $CHCl_3$ solution was added, and the solution was stirred for 5 min. A twofold excess (v/v) of water was added to the $CHCl_3$ solution and the mixture was shaken for 5 min in a separatory funnel. Addition of saturated $NaPF_6$ to the water phase with stirring gave a white precipitate that was filtered, washed with several portions of water and $CHCl_3$, and recrystallized from 1:1 acetone–EtOH. ^{19}F NMR spectrum in acetone: δ −146.5 ppm, 1:1:1:1 quartet; δ −70.8 ppm, 1:1 doublet (quartet:doublet ~ 1:6). ^{11}B NMR spectrum in acetone: $J(^{11}B–^{19}F)$ = 31.6 Hz; no ^{19}F or ^{11}B extraneous peaks. FAB spectrum: *m/z* at 297 $[(DBN)_2BF_2]^+$(100%) and 173 $[(DBN)BF_2]^+$. The elemental analysis is given in Table 1.

Instrumentation

Most spectra of the DBU and DBN systems were obtained on a Bruker AC-200 multinuclear Fourier Transform NMR spectrometer operating at 188.31 MHz (^{19}F), 64.20 MHz (^{11}B), and

Fig. 1. 188.2 MHz ^{19}F NMR spectrum of a DBU·BF_nCl_{3-n} solution in $CDCl_3$ with mole ratio DBU:BF_3:BCl_3 = 2:1:1.



20.29 MHz (^{15}N), with 8K FIDs and spectral windows varying from 6000 Hz (^{11}B) to 35 000 Hz (^{19}F). For ^{19}F, between 200 and 2000 30° pulses were usually accumulated, with a relaxation delay of 1.1 s. ^{19}F spin-lattice relaxation times were determined on the AC-200 instrument using the inversion–recovery (180°–τ–90°) pulse sequence. ^{15}N spectra of DBN and DBU were obtained by the INEPT technique (21), but low signal strength prevented ^{15}N NMR studies of the adducts.

Variable-temperature ^{19}F NMR studies of the trimethylacetamidine and trimethylbenzamidine systems were carried out on a Bruker WP-60 multinuclear Fourier Transform NMR spectrometer operating at 56.4 MHz. High-field ^{11}B spectra of the DBU and DBN systems were obtained on a Bruker AM-500 spectrometer at 160.64 MHz, with a spectral width of 20 000 Hz and 8K and 16K FIDs, and 1000–2000 30° pulses. High-field ^{11}B spectra of the trimethylacetamidine and trimethylbenzamidine systems were obtained on a Bruker WH-400 instrument operating at 128.51 MHz.

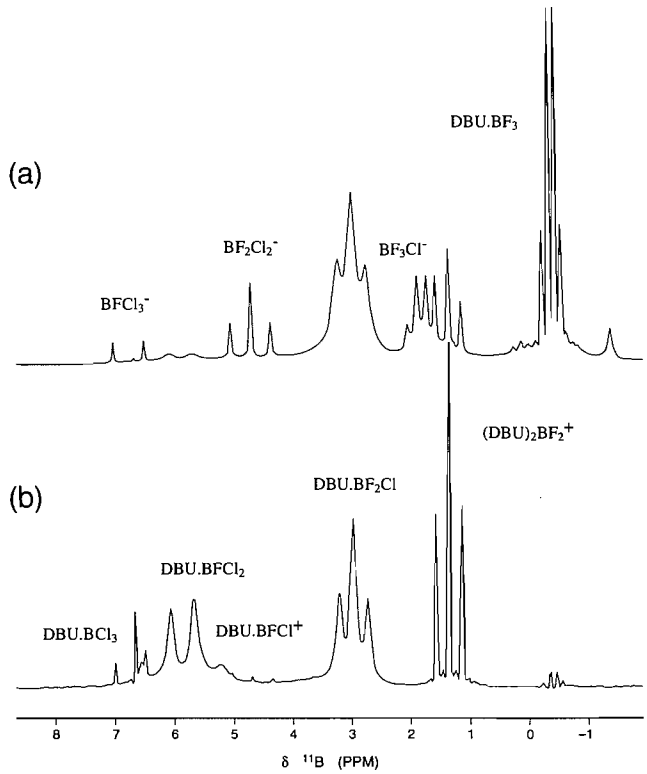
FAB spectra were obtained on an AEI MS-30 (Kratos Ltd, Manchester) double-beam mass spectrometer coupled to a saddle field atom gun (Ion Tech Ltd, Teddington, U.K.), retrofitted with a Kratos FAB source in beam 1. The accelerating voltage was 4 kV. 3-Nitrobenzyl alcohol (NBA) was used as a liquid matrix in most cases. Data were collected on a DS-55 Kratos data system. A Hewlett–Packard 2631G printer was used to plot the spectra and mass intensity data. Signals from the matrix were subtracted automatically in the computer system in most situations. The BMASROS program was utilized for interpretation of isotope patterns.

Results

The DBU·BF_nCl_{3-n} system

Figures 1 and 2 show ^{19}F and ^{11}B NMR spectra of solutions of DBU·BF_3 following (*i*) BCl_3 addition to induce F,Cl exchange and form the mixed boron trihalide adducts DBU·BF_nCl_{3-n}, and (*ii*) addition of sufficient DBU to complex the excess Lewis acid. Large amounts of the mixed chlorofluoroborate anions $BFCl_3^-$, $BF_2Cl_2^-$, and BF_3Cl^-, identified by their chemical shifts and coupling constants (22), are present in addition

Fig. 2. 160.4 MHz ^{11}B NMR spectra of DBU·BF_nCl_{3-n} solutions in $CDCl_3$. (*a*) Cl < F; (*b*) Cl > F.



to the neutral boron trihalide adducts DBU·BF_nCl_{3-n} (n = 0–3) and the $(DBU)_2BF_2^+$ cation. There are also small amounts of DBU·BCl_3 and $(DBU)_2BFCl^+$. In samples with higher Cl:F ratios a signal arising from $(DBU)_3BF^{2+}$ can also be detected, and the DBU·BCl_3 peak is large. Most ^{19}F signals are 1:1:1:1 quartets due to coupling to ^{11}B (I = 3/2), and most ^{11}B signals give first-order multiplets that confirm the number of fluorines attached. The ^{11}B–^{19}F coupling constants are consistent in both ^{11}B and ^{19}F spectra and confirm our peak assignments, except $(DBU)_3BF^{2+}$ and $(DBU)_2BFCl^+$, which give broad ^{19}F

signals because of more efficient quadrupole relaxation of boron (23). Better resolution is obtained from a solution of the hexafluorophosphate salt of $(DBU)_3BF^{2+}$ in acetone than from the $CDCl_3$ solutions described above. Table 2 gives the NMR parameters of the amidine–haloboron cations and amidine – boron trihalide adducts, and chlorofluoroborate anions. At −40°C most ^{11}B NMR signals become very broad due to increased efficiency of ^{11}B quadrupole relaxation, with only the DBU·BCl_3 peak remaining sharp, and several small peaks appear in the 6.3–6.9 ppm region of the spectrum that might arise from species such as $(DBU)_2BCl_2^+$ or $(DBU)_3BCl^{2+}$ (3).

Positive ion fast atom bombardment mass spectra (FAB spectra) (20) obtained directly from these solutions confirm the presence of the fluoroboron cations. Parent ion peaks were observed for $(DBU)_2BF_2^+$, *m/z* 353, and $(DBU)_2BFCl^+$, *m/z* 369 (isotope cluster). Our FAB results will be reported in more detail elsewhere.

Monitoring the DBU·BF_3 + BCl_3 system by ^{19}F NMR as DBU is added to the system is instructive. Before adding any DBU, all redistribution reactions are so rapid that separate ^{19}F signals could not be observed for any individual species. Chemical exchange was slowed sufficiently at the DBU:BF_3:BCl_3 ratio of 1.6:1:1 that some resonances were resolved, despite the excess of Lewis acid (Fig. 3*a*). The broad peaks at −144 ppm (DBU·BF_3) and −126 ppm indicate that rapid chemical exchange occurs among some species. However, the peaks assigned to $BFCl_3^-$, $BF_2Cl_2^-$, and DBU·BF_2Cl are sufficiently well resolved to show splittings due to $^{11}B–^{19}F$ coupling. Fluorine exchange occurs at very different rates in different species, as we observed previously in the mixed tetrahaloborate anions (22) where the BFX_3^- species underwent the slowest exchange, followed by successively faster exchange in $BF_2X_2^-$ and BF_3X^-. The same pattern occurs here, with exchange slow in $BFCl_3^-$ and $BF_2Cl_2^-$ but faster in BF_3Cl^-.

When no excess Lewis acid remains (DBU:BF_3:BCl_3 = 2:1:1), chemical exchange is slow on the NMR time scale and all of the peaks are well resolved (Fig. 3*b*). Further additions of DBU (Figs. 3*c* and 3*d*) led to diminution and eventual disappearance of all of the signals arising from chlorofluoroboron species, adducts and anions alike, so that only the $(DBU)_2BF_2^+$ and DBU·BF_3 ^{19}F signals remained as major signals, along with a very small $(DBU)_3BF^{2+}$ signal. As the titration proceeded, the DBU·BF_2Cl and DBU·$BFCl_2$ signals first increased and then decreased and disappeared. This is consistent with the following reactions:

[3] $$BF_nCl_{4-n}^- + DBU \rightarrow DBU·BF_nCl_{3-n} + Cl^-$$

[4] $$DBU·BF_2Cl + DBU \rightarrow (DBU)_2BF_2^+ + Cl^-$$

Figure 4 shows the changes in relative concentrations of the BF_2-containing species, and is consistent with stepwise formation of $(DBU)_2BF_2^+$ from $BF_2Cl_2^-$ by chloride ion displacement as the amount of DBU increases. Redistribution reactions among BF, BF_2, and BF_3-containing species must also be taking place since the mole percentage of BF_2-containing species as a whole, compared to total fluorine in the system, is increasing throughout the reaction.

Formation of $(DBU)_3BF^{2+}$ and $(DBU)_2BFCl^+$ (very minor species in the samples described above, with a 1:1 ratio of Cl to F) is favoured by higher ratios of Cl to F. This gives larger proportions of DBU·$BFCl_2$ and $BFCl_3^-$ in the initial solution, and these then undergo stepwise displacement of Cl^- by DBU as in eq. [5]. Figure 5 shows the ^{19}F and ^{11}B spectra of a sample

Fig. 3. ^{19}F NMR monitoring of the titration of a DBU·BF_3 + BCl_3 solution with DBU. The DBU:BF_3: BCl_3 ratios are: (*a*) 1.6:1:1; (*b*) 2:1:1; (*c*) 2.6:1:1; (*d*) 3.4:1:1.

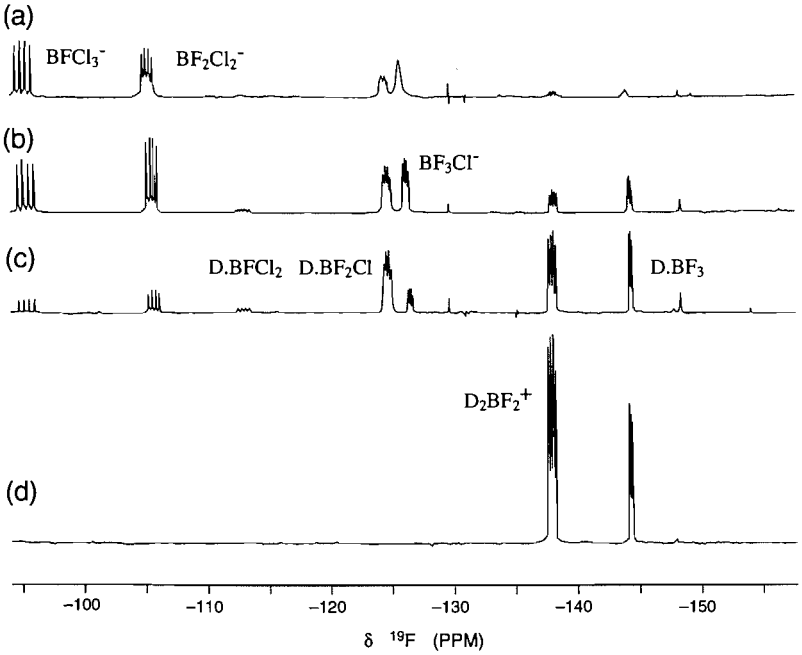

Fig. 4. Formation of $(DBU)_2BF_2^+$ from $BF_2Cl_2^-$ and DBU·BF_2Cl in a DBU·BF_nCl_{3-n} solution by successive additions of DBU, as monitored by ^{19}F NMR. ○, $BF_2Cl_2^-$; □, DBU·BF_2Cl; △, $(DBU)_2BF_2^+$; X, percent of total ^{19}F intensity arising from all three of the BF_2 species.

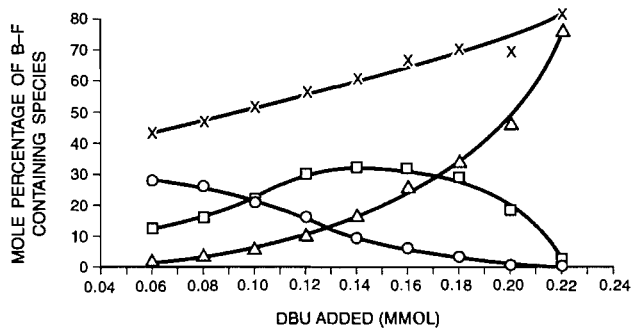

[5] $$BFCl_3^- \xrightarrow[-Cl^-]{DBU} DBU{\cdot}BFCl_2 \xrightarrow[-Cl^-]{DBU} (DBU)_2BFCl^+ \xrightarrow[-Cl^-]{DBU} (DBU)_3BF^{2+}$$

with a higher Cl:F ratio following the addition of two equivalents of DBU. There are strong $(DBU)_3BF^{2+}$ and $(DBU)_2BF_2^+$ ^{19}F signals and no other major peaks. The $(DBU)_3BF^{2+}$ ^{19}F signal has a partially collapsed ^{11}B–^{19}F coupling pattern (23). The ^{11}B spectrum has strong peaks from both of these cations and also a strong DBU·BCl_3 peak, but no other peaks. Note that DBU·BCl_3 is inert to Cl^- displacement by DBU under our conditions. $(DBU)_3BF^{2+}$ was isolated from such solutions as its PF_6^- salt, and is very stable to hydrolysis, as are the analogous ions D_3BH^{2+} (24) and D_3BBr^{2+} (25). $(DBU)_2BF_2^+$ is immediately decomposed by water, methanol, and ethanol, as determined by addition of these compounds to $CDCl_3$ solutions containing $(DBU)_2BF_2^+$. Its high reactivity contrasts with the inertness of most $D_2BF_2^+$ (2, 3) and $D_2BH_2^+$ (26) cations, including $(DBN)_2BF_2^+$, which is described below, and also with DBU·BF_3 and $(DBU)_3BF^{2+}$, which are very stable to hydrolysis. It is surprising that $(DBU)_2BF_2^+$, which is intermediate between the latter two compounds and has intermediate values of ^{19}F and ^{11}B NMR parameters, should be so different in its properties.

The reaction of DBU·BF_3, BCl_3, and a slight excess of DBU in $CDCl_3$ in a sealed thick-walled 5 mm NMR tube at 50°C was monitored by ^{19}F NMR. Initially the spectrum resembled Fig. 1, with peaks of the chlorofluoroborate anions, DBU – mixed boron trihalide adducts, and DBU–fluoroboron cations, but all of the ion peaks, cations and anions alike, diminished in intensity while the DBU·BF_2Cl and DBU·$BFCl_2$ peaks increased to become the major species. Table 3 gives the changes in relative ^{19}F peak intensities wth time of reaction. DBU·BF_3 diminished slightly and then stayed constant. $(DBU)_2BFCl^+$ first increased and then diminished. These results show conclusively that the initial mixture containing the chlorofluoroborate anions is far from equilibrium, at least in the presence of a small excess of DBU.

The resolution of the $BF_nCl_{4-n}^-$ ^{19}F NMR signals is always in the order $BFCl_3^- > BF_2Cl_2^- > BF_3Cl^-$. Some samples give an especially sharp $BFCl_3^-$ resonance, with the septet of equal-intensity peaks arising from ^{10}B–^{19}F coupling (^{10}B, 20% abundant, $I = 3$) being well resolved in addition to the 1:1:1:1 quartet arising from ^{11}B–^{19}F coupling (^{11}B, 80% abundant, $I = 3/2$)

Fig. 5. The ^{11}B and ^{19}F NMR spectra of $(DBU)_3BF^{2+}$ and $DBU)_2BF_2^+$, obtained from $CDCl_3$ solutions of $DBU{\cdot}BF_nCl_{3-n}$ to which an excess of DBU was added.

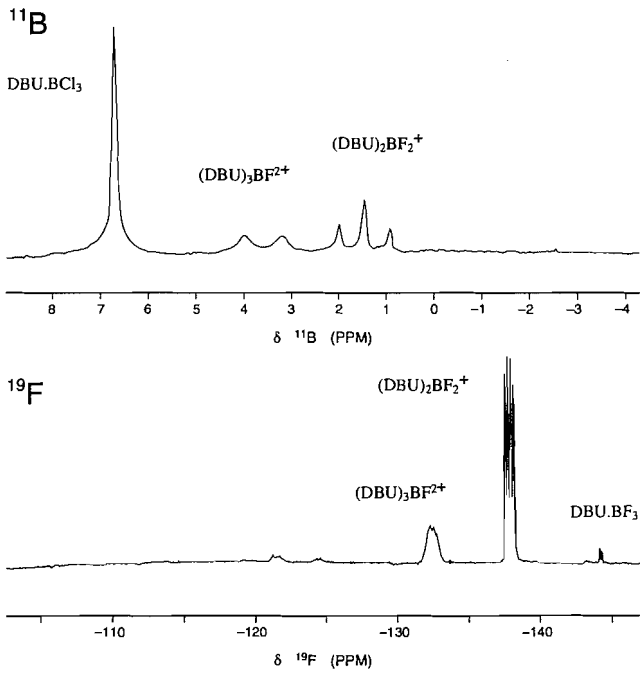

Table 3. Changes in relative ^{19}F peak intensities of a $DBU/BF_3/BCl_3$ sample[a] on reaction in a sealed tube at 50°C.

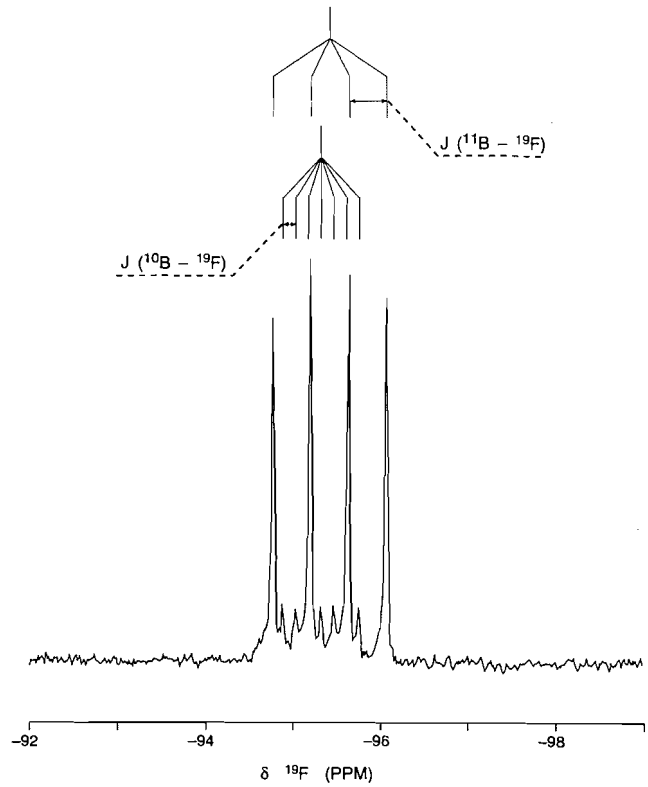
Time (h)	0	1	3	6	22	40
$BFCl_3^-$	5	8	5	4	2	2
$BF_2Cl_2^-$	4	4	4	2	2	2
BF_3Cl^-	2	1	1	1	0	0
$(DBU)\cdot BFCl_2$	7	10	15	18	27	29
$(DBU)\cdot BF_2Cl$	24	27	31	37	43	47
$(DBU)\cdot BF_3$	9	5	4	5	5	5
$(DBU)_2BFCl^+$	7	9	12	9	9	6
$(DBU)_2BF_2^+$	43	36	29	25	13	8

[a]0.15 mmol $DBU\cdot BF_3$, 0.15 mmol BCl_3, and 0.18 mmol DBU in $CDCl_3$.

(Fig. 6). Since the magnetogyric ratio of ^{10}B is only 1/3 that of ^{11}B, the magnitude of $J(^{10}B–^{19}F)$ is only 1/3 that of $J(^{11}B–^{19}F)$ (27). The ^{19}F isotope shift between $^{10}BFCl_3$ and $^{11}BFCl_3$ is 0.092 ppm, appreciably greater than the corresponding value for BF_4^-, 0.050 ppm (28), ketone$\cdot BF_3$ adducts, 0.066 ppm (29), or $(quinuclidine)_2BF_2^+$, 0.064 ppm, in accord with heavier nearby atoms increasing the effect (30).

^{19}F spin-lattice relaxation times in a typical $DBU{\cdot}BF_nCl_{3-n}$ solution in $CDCl_3$ were as follows: $DBU\cdot BF_3$, 0.93 s; $DBU\cdot BF_2Cl$, 0.60 s; $DBU\cdot BFCl_2$, 0.61 s; $(DBU)_2BF_2^+$, 0.23 s; $(DBU)_2BFCl^+$, 0.14 s. Because of the strong dependence of spin-lattice relaxation on solvent viscosity the relative times are more significant than the individual values. The more hindered the molecular tumbling about boron, the shorter is the spin-lattice relaxation time, as we observed in an analogous series of pyridine adducts and cations (3). The cations, with two large substituents on boron, are unable to tumble effectively about either donor–boron bond since the second donor interferes, and the cations have by far the shortest spin-lattice relaxation times.

Fig. 6. 188.2 MHz ^{19}F spectrum of $BFCl_3^-$ in $CDCl_3$, showing multiplets arising from spin–spin coupling to ^{10}B and ^{11}B.

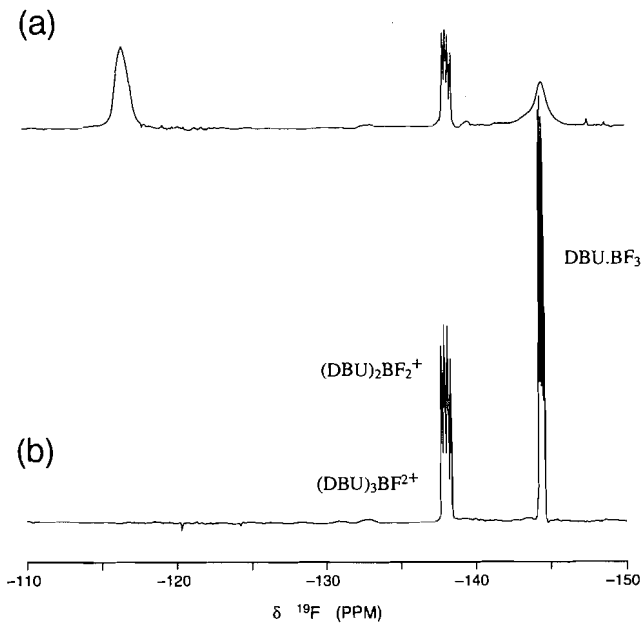


The $DBU{\cdot}BF_nBr_{3-n}$ system

Chemical exchange that is rapid on the NMR time scale restricts ^{19}F NMR monitoring of species containing B—Br bonds in the $DBU{\cdot}BF_nBr_{3-n}$ system. A moderate excess of DBU slows chemical exchange sufficiently to give a well-resolved ^{19}F 1:1:1:1 quartet for $(DBU)_2BF_2^+$, in addition to broad peaks at δ −117 ppm, −133 ppm ($(DBU)_3BF^{2+}$), and −144 ppm ($DBU\cdot BF_3$) (Fig. 7*a*), and in some solutions −114 ppm. The $(DBU)_3BF^{2+}$ peak remains broad due to ^{11}B quadrupole relaxation effects, but broadening of the other peaks must be caused by chemical exchange. On further addition of DBU, the $DBU\cdot BF_3$ peak becomes a well-resolved 1:1:1:1 quartet and the low-field absorption, apparently arising from rapidly exchanging bromofluoroboron species, disappears (Fig. 7*b*), consistent with complete displacement of Br^- from the bromofluoroboron species. Changing the proportions of Br to F changes the proportions of the $(DBU)_3BF^{2+}$ and $(DBU)_2BF_2^+$ cations as in the $DBU{\cdot}BF_nCl_{3-n}$ system.

The $DBU/BF_3/BCl_3/BBr_3$ system gives ^{19}F spectra similar to those of the $DBU{\cdot}BF_nCl_{3-n}$ system if $BCl_3 > BBr_3$, and similar to spectra of the $DBU{\cdot}BF_nBr_{3-n}$ system if $BBr_3 > BCl_3$. The DBU·BFClBr adduct resonance could not be detected.

Fig. 7. 188.2 MHz ^{19}F NMR spectra of the DBU·BF_nBr_{3-n} system. (*a*) DBU:BF_3:BBr_3 = 8:3:2; (*b*) excess DBU added.



The DBN·BF_nCl_{3-n} system

The DBN·BF_nCl_{3-n} system behaves similarly to the corresponding DBU adduct system. All of the DBN·BF_nCl_{3-n} adducts, the mixed chlorofluoroborate anions, and the DBN fluoroboron cations are readily formed and detected by NMR. The reactivity of DBN·BF_2Cl is similar to that DBU·BF_2Cl, with excess amidine displacing chloride very rapidly, but DBN·$BFCl_2$ reacts with DBN much faster than DBU·$BFCl_2$ reacts with DBU, consistent with the decreased steric hindrance of DBN compared to DBU. The chemical shifts of some adducts and cations differ by several ppm from those of the corresponding DBU species (Table 2). $(DBN)_3BF^{2+}$ formation is favoured by a high ratio of Cl to F, and its ^{19}F signal, like that of its DBU analogue, is poorly resolved in $CDCl_3$ due to ^{11}B quadrupole relaxation effects. $(DBN)_2BFCl^+$, which gives a broad ^{19}F NMR signal in $CDCl_3$, is an intermediate in the formation of $(DBN)_3BF^{2+}$ from DBN·$BFCl_2$, and its ^{19}F signal first increases and then decreases in intensity when excess DBN is added. $(DBN)_2BF_2^+$ and $(DBN)_3BF^{2+}$ are inert and both have been isolated as their hexafluorophosphate salts. $(DBN)_2BF_2^+$ is stable in water up to 85°C but decomposes at 100°C generating fluoride ion (^{19}F δ −119.9 ppm; confirmed by dissolving NaF) and boric acid (^{11}B δ ~19 ppm; broad band (31); also generated by decomposition of the chloroboron species by water extraction).

All cations were confirmed by FAB. For $(DBN)_2BF_2^+$, peaks at *m/z* 297, ($(DBN)_2BF_2^+$) and at *m/z* 173, ($(DBN)BF_2^+$) were observed both from solution and from the PF_6^- salt; for $(DBN)_2BFCl^+$, peaks at *m/z* 313, ($(DBN)_2BFCl^+$) and at *m/z* 189, ($(DBN)BFCl^+$) were observed from solution. The PF_6^- salt of $(DBN)_3BF^{2+}$ gave a peak at *m/z* 547 that was confirmed as $\{[(DBN)_3BF](PF_6)\}^+$ by its isotope pattern.

The DBN·BF_nBr_{3-n} system

Addition of excess DBN to a DBN·BF_3 + BBr_3 solution at −63°C in $CDCl_3$ gave a ^{19}F 1:1:1:1 quartet at δ −79.6 ppm, $J(^{11}B-^{19}F)$ = 113.3 Hz, assigned to $BFBr_3^-$ (lit. (22) δ: −78.6 ppm, $J(^{11}B-^{19}F)$ = 111.3 Hz in CH_2Cl_2), and a very broad band that moved to lower frequency (higher field) as the amount of DBN increased, consistent with (*i*) rapid chemical exchange among species containing both fluorine and bromine, and (*ii*) rapid displacement of bromide ion by DBN. Surprisingly, addition of excess DBN gave only a large DBN·BF_3 and a small BF_4^- ^{19}F resonance, without the expected large DBN–fluoroboron cation peaks. This system merits further study.

MeC(=NMe)NMe_2 and PhC(=NMe)NMe_2 mixed boron trihalide adduct systems

The *N,N,N'*-trimethylacetamidine and *N,N,N'*-trimethylbenzamidine BF_nCl_{3-n} and BF_nBr_{3-n} adduct systems in $CDCl_3$ and CD_2Cl_2 behave similarly to the corresponding DBU and DBN systems. Their low-temperature ^{19}F and ambient-temperature ^{11}B NMR parameters are included in Table 2. As with DBU and DBN, mixed tetrahaloborate anions were present. ^{19}F chemical shifts change appreciably (up to 2.5 ppm) between ambient temperature and −53°C. Low temperatures slow the exchange processes and allow ^{19}F NMR detection of signals that apparently arise from amidine·BF_nBr_{3-n} adducts and additional bromofluoroborate anions, whereas $BFBr_3^-$ is the only bromofluoroboron species that can be observed at ambient temperature. However, the low-temperature ^{19}F spectra were poorly resolved, with most $^{11}B-^{19}F$ spin–spin multiplets collapsed due to increased efficiency of ^{11}B quadrupole relaxation. (More efficient ^{11}B quadrupole relaxation also broadens the ^{11}B spectra of all of the amidine adduct systems at low temperatures.)

Discussion

General

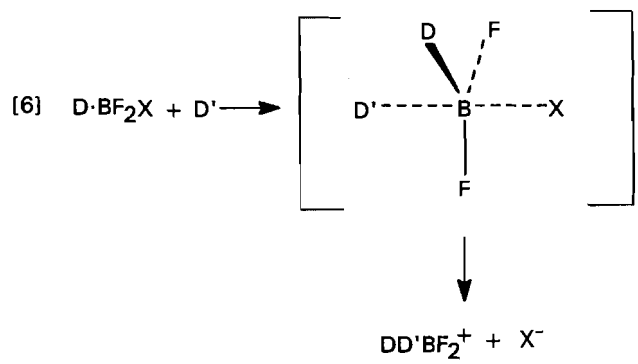
Of the various classes of organic Lewis bases that form mixed boron trihalide adducts (32), amidines are at one extreme in their high ability to form fluoroboron cations by heavy halide ion displacement (eqs. [1] and [2]). Weak donors such as dimethyl ether (33) amd methyl acetate (34) do not undergo these reactions at all, whereas benzoate esters (35) and tetramethylurea (36), like the lowest-steric-hindrance tertiary-amine mixed boron trihalide adducts (1, 2), form $D_2BF_2^+$ only. Pyridine adducts form $D_2BF_2^+$ very rapidly from D·BF_2X and, unlike the above bases, also form D_2BFCl^+, $D_2BFBr_2^+$, and D_3BF^{2+} from pyridine·BFX_2, but the reaction is slow (3). In the amidine – mixed boron trihalide adduct systems all of the above cation types form rapidly. The amidine·BF_2Cl and amidine·$BFCl_2$ adducts give fluoroboron cations within minutes, while redistribution reactions in the amidine·BF_nBr_{3-n} are rapid even on the NMR time scale so NMR signals of individual amidine–bromofluoroboron species cannot be detected at ambient temperature. The strong basicity of amidines (stronger than trialkylamines and far stronger than pyridines) and their low steric hindrance (only two substituents on the donor nitrogen) clearly favour fluoroboron cation formation. Except for those prepared from mixed boron trihalide adducts, the relatively few four-coordinate fluoroboron cations known are primarily formed with chelating donors (37).

While heavy halide ion displacement from mixed boron trihalide adducts by amidine occurs rapidly, other reactions are

much slower. For example, days at 50°C are required to attain equilibrium in the sealed-tube reaction of Table 3. A wide range of reaction rates is not surprising in complex exchanging systems, and has been noted in other $D{\cdot}BF_nX_{3-n}$ adduct systems (3, 32).

The ^{19}F and ^{11}B NMR parameters of the amidine – mixed boron trihalide adducts and fluoroboron cations follow the patterns seen in other adduct systems (2, 3, 19, 38), with the number and type of heavy halogen atoms having greater effects than the donor or the fluorines. ^{19}F chemical shifts are also affected by donor steric hindrance (3, 19). DBU has greater steric hindrance than DBN since the five-membered ring of DBN holds back the amidine substituents from the imino nitrogen donor site more effectively than the seven-membered ring of DBU. The approximately 5 ppm shift to high frequency (low field) of the ^{19}F chemical shifts of the $DBU{\cdot}BF_nCl_{3-n}$ adducts, compared to the corresponding DBN adducts (Table 2), reflects the greater steric hindrance. This effect doubles to 10–11 ppm in the $D_2BF_2^+$ and D_2BFCl^+ ions where the presence of two donor molecules should lead to greater steric interaction about boron. Interestingly, the chemical shift difference between the D_3BF^{2+} ions of DBU and DBN does not increase further but remains at 11 ppm.

We attempted ^{15}N NMR of these systems but low signal intensities, even with the INEPT sequence (21), prevented this. Our ^{15}N chemical shift values for the pure liquid amidines (DBU: −179 ppm (imino N); −289 ppm (amino N); DBN: −195 ppm (imino N); −288 ppm (amino N)) are consistent



with other amidine ^{15}N chemical shifts (39), although our DBU values differ appreciably from a published value (−172 ppm (imino N); −295 ppm (amino N) (15)). The 16 ppm difference between the imino nitrogen chemical shifts of DBU and DBN is consistent with somewhat greater steric inhibition of resonance, i.e., of planarity of the >N—C=N— system, in DBU: the imino nitrogen moves slightly closer to the chemical shift range for simple imines, −30 to −75 ppm (39*b*). Steric inhibition of resonance is also consistent with the decreased Bronsted basicity of DBU compared to DBN. The greater reactivity of $(DBU)_2BF_2^+$ compared to $(DBN)_2BF_2^+$ can be rationalized in terms of the greater steric hindrance introduced by DBU, but the extreme difference in stability between these cations, as well as between $(DBU)_2BF_2^+$ and $(DBU)_3BF^{2+}$, is surprising.

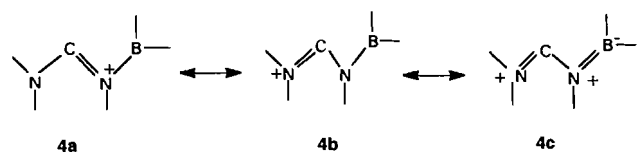
Chloride ion is readily displaced from $DBU{\cdot}BF_2Cl$ and $DBU{\cdot}BFCl_2$ by excess DBU but $DBU{\cdot}BCl_3$ is unaffected (Fig. 5). This is typical of the differences in reactivity of mixed vs. unmixed boron trihalide adducts: the mixed-halogen adducts are always far more susceptible to displacement of halide ion than the unmixed-halogen adducts of the same donor (1–3). However, we cannot completely exclude the possibility that the large low-field ^{11}B NMR peak of Fig. 5 arises from BCl_4^- rather than from $DBU{\cdot}BCl_3$, since BCl_4^- and $D{\cdot}BCl_3$ adducts give ^{11}B singlets of very similar chemical shift (3). Even if BCl_4^- were present in place of $DBU{\cdot}BCl_3$, the same argument would apply: it would be equally noteworthy that no Cl^- is displaced from BCl_4^- while all of the available Cl^- is displaced from the mixed chlorofluoroboron species, and our conclusion, that chloride displacement occurs much more easily from mixed- than from unmixed-halogen species, would remain valid.

A unique feature of the amidine adduct systems is the formation of large amounts of the mixed chlorofluoroborate anions along with the mixed boron trihalide adducts and fluoroboron cations. These anions cannot be detected in the pyridine or tertiary-amine mixed boron trihalide adduct systems that do give fluoroboron cations (1–3). Mixed chlorofluoroborate anions have, however, been formed in the tetramethylurea (TMU) BF_nCl_{3-n} adduct system, along with $(TMU)_2BF_2^+$, although preparation conditions were different (36), but there was no evidence for $(TMU)_2BFCl^+$ or $(TMU)_3BF^{2+}$ formation.

High-field ^{11}B NMR would be a useful supplement to ^{19}F NMR as a routine monitoring technique for detecting the non-fluorine-containing boron species. Because it was not routinely available, and because of the very small chemical shift dispersion of the various D_nBCl_{4-n} species including BCl_4^- (3), we know less about the behaviour of the non-fluorine-containing boron species in these systems than the fluorine-containing ones.

Mechanistic implications

Heavy halide ion displacement from mixed boron trihalide adducts is highly selective, in the order of $BF_2X \gg BFX_2 \gg BX_3$, and we have previously explained this in terms of fluorine-to-boron π-bonding stabilization of the transition state, the stabilization increasing with the number of fluorines. Evidence from our earlier studies (2, 3) supports an associative (S_N2) reaction mechanism (eq. [6]), although the same π-bonding considerations would lead to similar selectivity if there were a dissociative mechanism with a three-coordinate intermediate or transition state. π-Bonding in the transition state, from the donor molecule as well as from halogen, can also account for the far more rapid reaction in adduct systems in which the donor can π-bond to boron in the transition state, e.g., pyridines (3), than in cases where it cannot, e.g., aliphatic tertiary amines (2). Amidines resemble pyridines in that they can stabilize the transition state by π-bonding to boron (structure **4c**). Together with the high basicity and low steric hindrance of amidines, this can account for the very rapid formation of amidine–fluoroboron cations.



The large and varying amounts of mixed tetrahaloborate

anions that are present in freshly prepared amidine – mixed boron trihalide adduct solutions are a complicating factor. We (32, 36) and others (40) have discussed possible exchange reactions about boron, including donor-for-halogen exchange that would lead to both mixed tetrahaloborate anions and haloboron cations. The formation, and disappearance on standing, of mixed chlorofluoroborate anions in the tetramethylurea adduct system, from solutions containing both $TMU{\cdot}BF_3$ and $TMU{\cdot}BCl_3$ (36) seems consistent with this pattern. We proposed that redistribution of substituents about boron is caused by an initial dissociation of the weak $TMU{\cdot}BF_3$ donor–acceptor bond, followed by rapid fluorine exchange between the freed BF_3 with the four-coordinate boron species, giving a generalized redistribution reaction including donor-for-halogen as well as halogen-for-halogen exchange, generating the mixed chlorofluoroborate anions as well as $(TMU)_2BF_2^+$, a typical reaction being eq. [7], in which the chlorine bridge in the transition state or reactive intermediate is similar to the fluorine bridge of the $B_2F_7^-$ ion (41). Mechanisms of this type have been dealt with in detail by Janzen and co-workers (42).

[7] $D{\cdot}BCl_3 + BF_3 \longrightarrow$ 
$D{\cdot}BCl_2^+ + BF_3Cl^-$

A number of features are different in the amidine – mixed boron trihalide adduct systems. One is that the amidine–boron donor–acceptor bond should be much stronger than the oxygen–donor donor–acceptor bond of the TMU adducts, and at least as strong as the nitrogen–boron donor–acceptor bonds in tertiary amine – boron trihalide adducts (43) because of the greater base strength and lower steric hindrance of amidines compared to tertiary amines. The strength of the amidine–boron donor–acceptor bond would prevent an initial BF_3 dissociation step. However, our solutions are prepared using an excess of BCl_3, and the following reaction is plausible:

[8] $DBU{\cdot}BF_3 + BCl_3 \longrightarrow$ 
$DBU{\cdot}BF_2^+ + BFCl_3^-$

There is, however, experimental evidence suggesting that the formation of large amounts of the chlorofluoroborate ions is extraneous to the amidine$\cdot BF_nX_{3-n}$ adduct systems, and is an artifact of the preparation method. ^{19}F spectra of freshly prepared samples (e.g., Fig. 1) show a mismatch between high chlorofluoroborate anion concentrations and lower concentrations of the boron cations than would be required to balance the charge. The total negative charge of the boron-containing anions would have to equal the total positive charge of the boron-containing cations if the only source of ionic species were donor-for-halogen redistribution reactions about boron. A non-boron-containing cation must be present in these cases, and this has been confirmed by the precipitation from some solutions of solids that by FAB analysis are the amidine hydrochlorides, $[amidine{\cdot}H]^+{\cdot}Cl^-$. (An excess of haloboron cations over haloborate anions would not be a problem since since Cl^- and Br^- are well known to be counterions in related fluoroboron cation-forming mixed boron trihalide adduct systems (1–3).)

Furthermore, sealed-tube equilibration studies (Table 3) show that the initial mixtures, with chlorofluoroborate anions present in large and varying amounts, are not at equilibrium. The closest approach to equilibrium observed by us (Table 3, 40 h at 50°C) gives relative proportions that resemble other mixed boron trihalide adduct systems (2, 3, 32) far more closely than do the initial mixtures, with the neutral mixed boron trihalide adducts as the major species. Only two of the three mixed tetrahaloborate anions can still be detected, and the BF_3 adduct, $D_2BF_2^+$, and D_2BFCl^+ are present in similar low concentrations. Since the chlorofluoroborate ion concentrations diminish markedly, they cannot be major species at equilibrium.

Equation [8] cannot be the whole story because (*i*) the chlorofluoroborate ions are present initially, without sufficient fluoroboron cation counterion present to balance the charge; and (*ii*) amidinium hydrochloride salts instead of fluoroboron cation salts precipitate from solution, showing the presence of large amounts of protonated amidine in solution, despite preparation and handling of the amidines and solvent under rigorously dry conditions so that water is unlikely to be a source of $amidine{\cdot}H^+$. However, these observations are accounted for if the $amidine{\cdot}H^+$ cations and the chlorofluoroborate anions are both formed through reaction of amidine with the chloroform solvent. Strong bases can attack chloroform with the generation of carbenes (44):

[9] $D + CHCl_3 \rightarrow D{\cdot}H^+ + CCl_3^-$

$\downarrow$

$CCl_2 + Cl^-$

Since the chlorofluoroborate anions are formed initially when excess boron trihalide is present but not under excess-base conditions, a concerted mechanism is likely in which the boron trihalide assists by facilitating the removal of chloride ion from chloroform:

[10] $D + CHCl_3 + BF_nCl_{3-n} \longrightarrow$ 
$D{\cdot}H^+ + CCl_2 + BF_nCl_{4-n}^-$

Alternatively, reaction [9] might continue under excess amidine conditions, but the chlorofluoroborate anions would undergo chloride displacement by amidine (eq. [3]) so that their concentrations would not build up.

Thus the greater base strength of amidines, compared to trialkylamines or pyridines, leads to the formation of chlorofluoroborate ions in solution, but indirectly through attack on the chloroform solvent rather than directly through donor-for-halogen redistribution reactions about boron. A similar reaction in methylene chloride, the solvent in much of our work with *N,N,N'*-trimethylacetamidine and *N,N,N'*-trimethylbenzamidine, is possible as well, although CHCl is a less stable carbene than CCl_2 (44), and can account for the formation of mixed tetrahaloborate anions in this solvent as well.

Conclusions

The combination of high basicity, π-bonding stabilization of the transition state, and low steric hindrance makes the amidines the most effective Lewis bases studied to date for generating fluoroboron cations from mixed boron trihalide adducts. Only the amidine·BF_nCl_{3-n} adduct systems have been studied in detail because the amidine·BF_nBr_{3-n} systems undergo extremely rapid chemical exhange and displacement of all B—Br bonds by excess amidine. The presence of large and variable amounts of the mixed chlorofluoroborate anions $BF_nCl_{4-n}^-$ in our freshly prepared samples appears to be related to attack of amidine on the chloroform solvent, via a carbene mechanism, rather than an integral part of the redistribution equilibria in the amidine·BF_nCl_{3-n} systems. We cannot exclude the possibility that the chlorofluoroborate anions may also form by donor-for-halogen redistribution reactions in the amidine·BF_nCl_{3-n} adduct systems, as they apparently do in the TMU·BF_nCl_{3-n} adduct system.

Acknowledgements

We are indebted to the late Mel Farquharson for his assistance in the early stages of the DBU work. We also thank Abbott Laboratories, North Chicago, Illinois, U.S.A., for providing a sample of DBU, Tim Jones for technical assistance, Prof. Alex F. Janzen for helpful discussions, the Department of Chemistry, University of Manitoba, for its hospitality to J.S.H. while this paper was being written, the Departments of Chemistry at McMaster University and the University of Guelph for access to high-field ^{11}B nmr, and the Natural Sciences and Engineering Research Council of Canada for financial support.

Photochemical nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction, Part 12. Factors controlling the regiochemistry of the reaction with alcohol as the nucleophile[1]

Donald R. Arnold, Mary S.W. Chan, and Kimberly A. McManus

Abstract: The photo-NOCAS reaction that combines methanol, serving as the nucleophile, and the radical cation of 4-methyl-1,3-pentadiene (**14**$^{+\bullet}$), substituting on the 1,4-dicyanobenzene radical anion (**1**$^{-\bullet}$), yields (*E*)-1-(4-cyanophenyl)-4-methoxy-4-methyl-2-pentene (**15**) as the major product. This regioisomer arises from bonding of methanol to C-4, the more heavily alkyl-substituted carbon of the diene, giving the less alkyl-substituted allylic radical. All previous examples of the photo-NOCAS reaction have yielded major adduct(s) having regiochemistry consistent with the *anti*-Markovnikov rule; the more heavily substituted (more stable?) β-alkoxyalkyl radical was the predominant intermediate. Empirically derived heats of formation and high-level ab initio molecular orbital calculations (MP2/6-31G*//HF/6-31G*) provide convincing evidence that of the two alternative allylic radicals, generated upon addition of methanol to **14**$^{+\bullet}$, that which has the more alkyl substituted allylic radical moiety is, in fact, **not** the more stable. Of course, the total structure of the intermediate must be considered; the stabilizing effect of alkyl substitution on the carbon next to the oxygen of the ether moiety cannot be ignored. Ab initio molecular orbital calculations (MP2/6-31G*//HF/6-31G*) are reported for the radical cations of 2-methylpropene (**2**$^{+\bullet}$), 2-methyl-2-butene (**6**$^{+\bullet}$), 2-methyl-1,3-butadiene (**9**$^{+\bullet}$), 4-methyl-1,3-pentadiene (**14**$^{+\bullet}$), and 2,4-dimethyl-1,3-pentadiene (**18**$^{+\bullet}$). Calculations were also carried out on possible intermediates (bridged radical cations, distonic radical cations, and β-alkoxyalkyl radicals) involved upon reaction of these radical cations with methanol. Results of these calculations provide a basis for explaining/predicting the regiochemistry of the photo-NOCAS reaction involving methanol as the nucleophile: the major adduct(s) result(s) from attachment of methanol to that end of the alkene or diene which gives rise to the more stable intermediate radical. The more stable radical is **not** necessarily the more heavily alkyl substituted.

Key words: photoinduced electron transfer, radicals, radical cations, ab initio molecular orbital calculations.

Résumé : La réaction de photo-NOCAS permet de combiner le méthanol, qui agit comme nucléophile, et le cation radical du 4-méthylpenta-1,3-diène (**14**$^{+\bullet}$), qui se substitue sur l'anion radical du 1,4-dicyanobenzène (**1**$^{-\bullet}$), et fournit du (*E*)-1-(4-cyanophényl)-4-méthoxy-4-méthylpent-2-ène (**15**) comme produit principal. Le régioisomère résulte d'une liaison du méthanol au C-4, le carbone du diène le plus substitué par des groupes alkyles, qui conduit au radical allylique le moins substitué par des groupes alkyles. Tous les exemples de réactions photo-NOCAS rapportés antérieurement ont toujours fourni des produits majoritaires dont la régiochimie était en accord avec la règle *anti*-Markovnikov correspondant à un intermédiaire prédominant comportant le radical β-alkoxyalkyle le plus substitué (le plus stable?). Les chaleurs de formation que l'on peut obtenir empiriquement de même que des calculs d'orbitales moléculaires ab initio à des niveaux élevés (MP2/6-31G*//HF/6-31G*) fournissent des données qui permettent de conclure d'une façon convaincante que, des deux radicaux allyliques alternatifs générés par l'addition de méthanol sur **14**$^{+\bullet}$, le radical qui porte la moitié radicalaire allylique la plus substituée par des groupes alkyles n'est, en fait, pas le plus stable. Il est évident que l'on doit considérer la structure totale de l'intermédiaire; on ne peut pas faire abstraction de l'effet stabilisant de la substitution alkyle sur le carbone voisin de l'oxygène de la portion éther. Des calculs d'orbitales moléculaires ab initio (MP2/6-31G*//HF/6-31G*) ont été effectués sur les cations radicaux 2-méthylpropène (**2**$^{+\bullet}$), 2-méthylbut-2-ène (**6**$^{+\bullet}$), 2-méthylbuta-1,3-diène (**9**$^{+\bullet}$), 2-méthylpenta-1,3-diène (**14**$^{+\bullet}$) et 2,4-diméthylpenta-1,3-diène (**18**$^{+\bullet}$). On a aussi effectué des calculs sur des intermédiaires possibles, des cations radicaux pontés, des cations radicaux distoniques et des radicaux β-alkoxyalkyles impliqués lors des réactions de ces cations radicaux avec le méthanol. Les résultats de ces calculs fournissent une base pour expliquer/prédire la régiochimie de la réaction de photo-NOCAS impliquant le méthanol comme

[Traduit par la rédaction]

Introduction

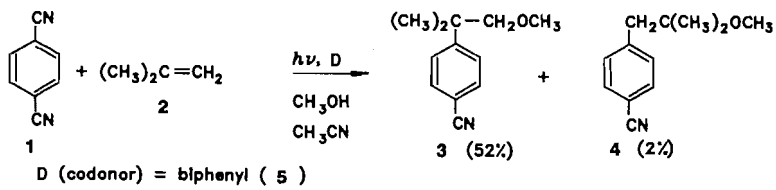
From the first examples of the photochemically induced nucleophile–olefin combination, aromatic substitution (photo-NOCAS) reaction, involving methanol, 2-methylpropene (**2**), and 1,4-dicyanobenzene (**1**) (reaction [1] (1*a*,*b*)) and of methanol, 2-methyl-2-butene (**6**), and 1,4-dicyanobenzene (**1**) (reaction [2] (1*f*)), the regiochemistry of the combination has been described as *anti*-Markovnikov (1*a*,*b*). That is, the nucleophile (methanol) bonds with the most hydrogenated of the ethenoid carbon atoms (3). Upon first consideration, since the combination of a nucleophile with an olefin radical cation leads ultimately to a radical intermediate (Scheme 1), the regiochemistry might be expected to be analogous to that of radicals adding to alkenes, which generally does follow the *anti*-Markovnikov rule (4). Originally, of course, Markovnikov's rule was developed for predicting the regiochemistry of electrophilic addition (hydrogen halide) to alkenes (3). While both of these rules are useful, they are hardly explanations for the observed reactivity.

The original electronic interpretation of Markovnikov's rule, *the electrophile adds to the alkene to produce the more stable carbocation intermediate*, is still accepted (3*b*, 5). Generally, the more heavily alkyl-substituted carbocation is also the more stable. This rule is followed even when the carbocation is bridged with the electrophile (6). On the other hand, the original mechanistic explanation for the *anti*-Markovnikov rule for radical addition to alkenes, *the radical adds to the alkene to produce the more stable radical intermediate,* has been shown to be incorrect (7). The regiochemistry of the radical addition to alkenes is generally controlled by polar and steric factors; the transition state is early along the reaction coordinate, and the regiochemistry is determined before differences in the stability of the alternative free-radical intermediates becomes important. The addition of radicals to alkenes may also be influenced by bridging within the radical intermediate (8). Clearly, to be able to predict the regiochemistry of product formation from the photo-NOCAS reaction, *all* of the factors that influence the regiochemistry must be understood.

The results that forced this study at this time involve a photo-NOCAS reaction that combines methanol and an unsymmetrically substituted diene, followed by substitution on 1,4-dicyanobenzene (**1**). One previous example of this type has been reported: the photo-NOCAS reaction that combines methanol, 2-methyl-1,3-butadiene (**9**), and 1,4-dicyanobenzene (**1**), behaves "normally." Four 1:1:1 adducts are obtained (reaction [3] (1*c*)). Accepting the fact that the regiochemistry is determined upon addition of methanol to the diene radical cation, step 3 of the proposed mechanism (Scheme 1), the major products (**10**, **11**, and **12**, 0.89) arise from attack of methanol at C-1 of the diene. Attack at C-1 gives the more heavily substituted, (presumably) more stable allylic radical, that is, *anti*-Markovnikov addition (1c). The need for additional thought on the matter arose with new results from the photo-NOCAS reaction combining methanol, 4-methyl-1,3-pentadiene (**14**), and 1,4-dicyanobenzene (**1**) (reaction [4]). This reaction is *not* regioselective; in fact, more than half of the products (**15**, 0.57) result from attack of methanol at C-4. Attack at C-4 leads to formation of a less alkyl-substituted, *less stable (?)*, allylic radical than does attack at C-1. Attack at C-4 is also significantly *more sterically hindered* than attack at C-1.

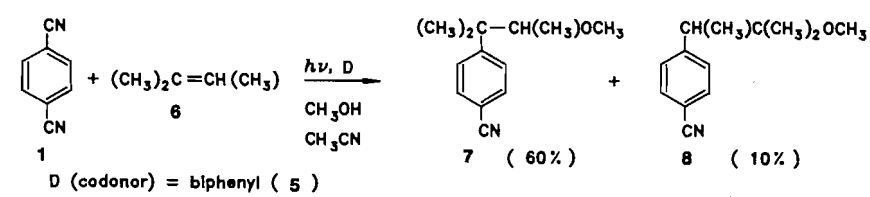
The regiochemistry returns to "normal" with the combination of methanol and the radical cation of 2,4-dimethyl-1,3-pentadiene (**18**$^{+\bullet}$) (reaction [5]). The isomeric photo-NOCAS adducts **19**, **20**, and **21** result from addition of methanol to the

Reaction [1] (1a,b)

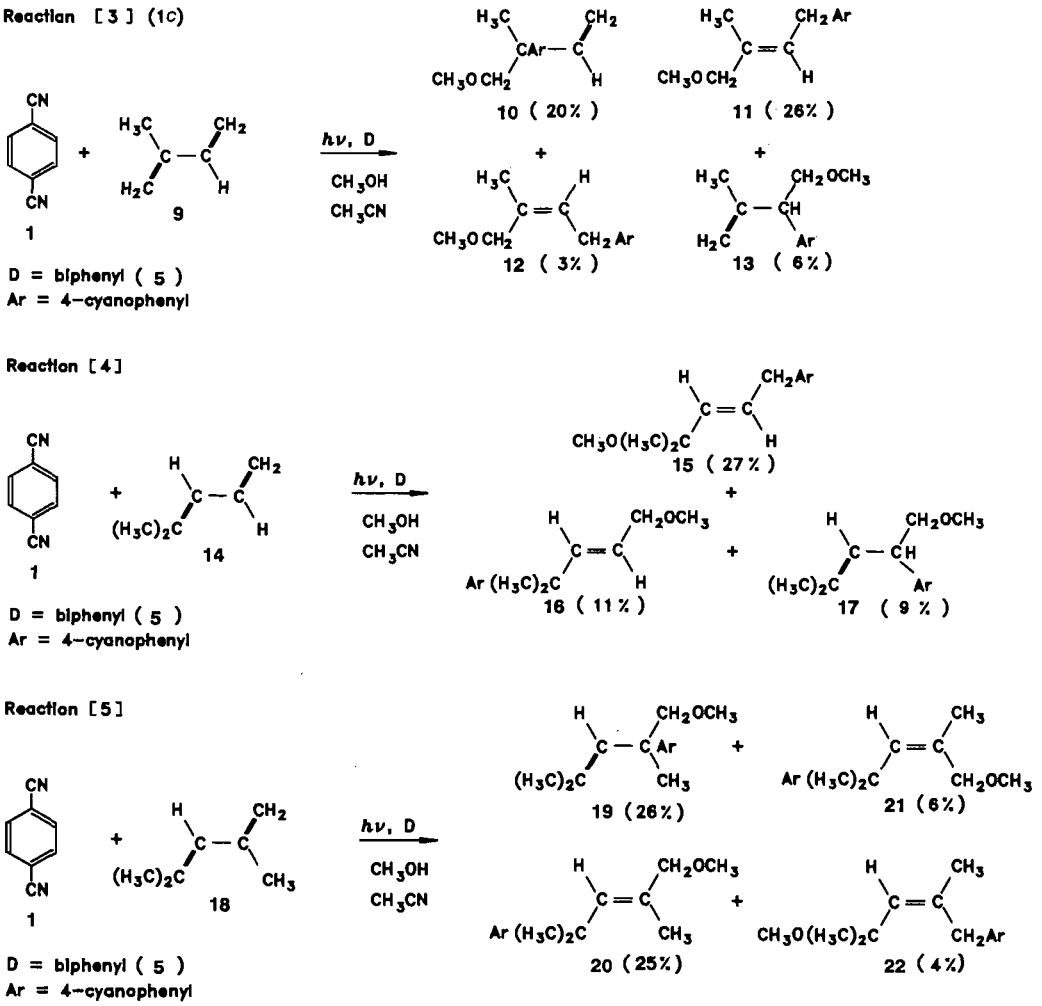


D (codonor) = biphenyl (5)

Reaction [2] (1f)



D (codonor) = biphenyl (5)



less alkyl-substituted position, giving the more heavily alkyl-substituted allylic radical. The combined yields of these adducts make this, *anti*-Markovnikov, the major (0.93) mode of addition.

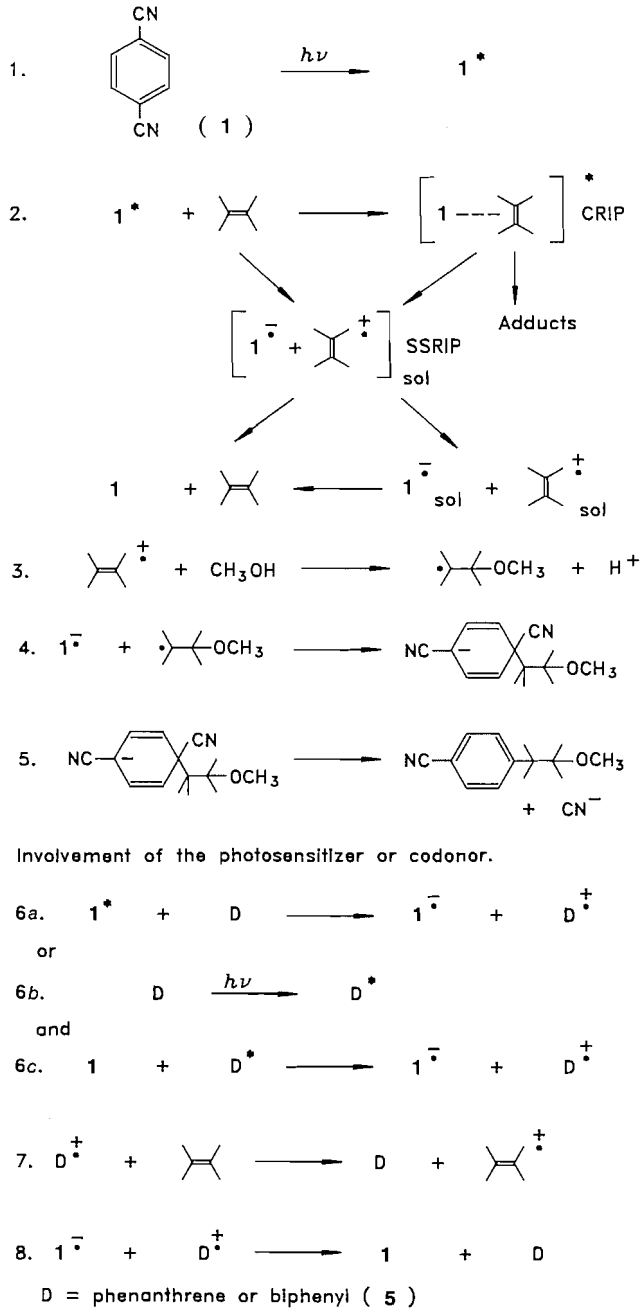
The main objective of this project was to establish criteria useful for explaining/predicting the regiochemistry of the photo-NOCAS reaction, involving the combination of an alcohol (methanol) and the radical cation of an alkene or diene, substituting on 1,4-dicyanobenzene (**1**).

Results

An acetonitrile–methanol (3:1) solution of 4-methyl-1,3-pentadiene (**14**), 1,4-dicyanobenzene (**1**), and biphenyl (**5**) was irradiated with a medium-pressure mercury vapour lamp through Pyrex (reaction [4]). Progress of the reaction was followed by capillary column gas chromatography with a flame ionization detector (gc/fid). The ratio of products was determined by integration of the peak areas in the gc/fid. The yields of isolated products, based upon the amount of **1** consumed, were consistent with this ratio. While the efficiency of the reaction was increased upon the addition of biphenyl (**5**), serving as a codonor (Scheme 1, steps *6a* and 7), the ratio of products was similar with and without biphenyl (**5**). The product ratio was also independent of the extent of conversion, irradiating in the presence of 5. The first indication of the structure of the major product, (*E*)-1-(4-cyanophenyl)-4-methoxy-4-methyl-2-pentene (**15**, 27%), was evident from the mass spectrum (gc/ms) where major peaks were 73 *m/z* for the methoxypropyl fragment (C_4H_9O) and 142 *m/z* ($C_{10}H_8N$) for the ion resulting upon loss of the methoxypropyl fragment. Another fragment is dominant in the other two adducts: both (*E*)-4-(4-cyanophenyl)-1-methoxy-4-methyl-2-pentene (**16**, 11%) and 4-(4-cyanophenyl)-5-methoxy-2-methyl-2-pentene (**17**, 9%) have a major peak at 170 *m/z* ($C_{12}H_{12}N$) due to loss of the methoxymethylene fragment.

Similar irradiation of an acetonitrile–methanol solution of 2,4-dimethyl-1,3-pentadiene (**18**), **1**, and **5** gave four photo-NOCAS adducts: 4-(4-cyanophenyl)-5-methoxy-2,4-dimethyl-2-pentene (**19**, 26%), (*E*)-4-(4-cyanophenyl)-1-methoxy-2,4-dimethyl-2-pentene (**20**, 25%), (*Z*)-4-(4-cyanophenyl)-1-methoxy-2,4-dimethyl-2-pentene (**21**, 6%), and (*Z*)-1-(4-cyanophenyl)-4-methoxy-2,4-dimethyl-2-pentene (**22**, 4%) (reaction [5]). Again, the regiochemistry of the adducts was readily established from the mass spectral fragmentation pattern. Adducts **19**, **20**, and **21** have a major fragment at 184 *m/z* ($C_{13}H_{14}N$) indicative of the loss of the methoxymethylene fragment. The base peak in the mass spectrum of **20** and **21** is 85 *m/z* (C_5H_9O) for the ion resulting from loss of the arylpropyl fragment. Major fragments from **22** had 116 *m/z* (C_8H_6N),

Scheme 1.



for the ion resulting from loss of the arylmethyl fragment, and 73 *m/z*, for the methoxypropyl fragment (C_4H_9O).

Structural assignments

Structural assignments of the products were based primarily upon detailed analysis of ^1H and ^{13}C nmr spectra. Mass and infrared spectra and elemental analyses were also useful. Adduct **15**, from reaction [4], was identified as (*E*)-1-(4-cyanophenyl)-4-methoxy-4-methyl-2-pentene. The ^1H nmr spectrum exhibits a singlet (3.11 ppm) indicative of a methoxy methyl group. A doublet at 3.40 ppm represents an aryl-substituted methylene group. A doublet and a doublet of triplets appear in the vinyl region of the ^1H nmr spectrum, representing a vinyl proton adjacent to a quaternary carbon and a vinyl proton adjacent to a methylene group, respectively. The coupling constant (16.2 Hz) between these vinyl protons is indicative of the *E* configuration. An AA′XX′ pattern in the aromatic region of the ^1H nmr spectrum is indicative of the 4-cyanophenyl group. In the ^{13}C nmr spectrum of **15**, there is a low-field quartet (50.31 ppm) that is consistent with the methyl of the methoxy group, and a singlet (74.65 ppm), which indicates a quaternary carbon bonded to the methoxy group. The aryl-substituted methylene gives a triplet at higher field (38.83 ppm). Two vinyl methine groups are also present (127.04 and 138.28 ppm).

Compound **16** was identified as (*E*)-4-(4-cyanophenyl)-1-methoxy-4-methyl-2-pentene. The ^1H nmr spectrum exhibits a singlet (3.33 ppm) indicative of a methoxy methyl group. A low-field doublet (3.93 ppm) represents a methylene group, methoxy substituted. A doublet and a doublet of triplets appear in the vinyl region of the ^1H nmr spectrum, representing a vinyl proton adjacent to a quaternary carbon and a vinyl proton adjacent to a methylene group, respectively. The coupling constant (15.9 Hz) between these vinyl protons is indicative of the *E* configuration. An AA′XX′ pattern in the aromatic region of the ^1H nmr spectrum is indicative of the 4-cyanophenyl group. There is a low-field quartet (58.09 ppm) in the ^{13}C nmr spectrum of **16** that is consistent with the methyl of the methoxy group. The methoxy-substituted methylene group shows up as a triplet at 73.09 ppm. A higher field singlet (40.88 ppm) indicates a quaternary carbon bonded to the aryl group. Two vinyl methine groups are also present (123.98 and 141.79 ppm).

Compound **17** was identified as the 1,2-addition product resulting from attack of methanol at the less substituted end of the diene: 4-(4-cyanophenyl)-5-methoxy-2-methyl-2-pentene. The low-field singlet in the ^1H nmr spectrum (3.32 ppm) is indicative of the methoxy methyl group. An ABX pattern (3.51, 3.55, and 3.84 ppm) was observed for the protons on the methylene group next to an oxygen and the benzylic/allylic methine group. The presence of a trisubstituted alkene is indicated by the protons of two methyl groups exhibiting two doublets at 1.64 and 1.74 ppm, resulting from long-range coupling to the vinyl proton. The signal for this vinyl proton appears at 5.27 ppm as a broad doublet due to long-range coupling to the methyl protons and typical vicinal coupling (8.8 Hz) to the benzylic/allylic methine proton. The AA′XX′ pattern in the aromatic region of the ^1H nmr spectrum is indicative of the 4-cyanophenyl group. In the ^{13}C nmr spectrum of **17**, there is a low-field quartet (58.98 ppm) that is consistent with the methyl of the methoxy group and a triplet at 76.54 ppm supports a methylene group substituted with a methoxy group. A higher field doublet (44.82 ppm) indicates a methine group, aryl substituted. A vinyl methine carbon and a vinyl quaternary carbon are also present (123.48 and 135.27 ppm, respectively).

Compound **19**, from reaction [5], was identified as the 1,2-addition product resulting from attack of methanol at the less substituted end of the diene: 4-(4-cyanophenyl)-5-methoxy-2,4-dimethyl-2-pentene. The ^1H and ^{13}C nmr spectra of **19** were similar to those of compound **17**. Unlike **17**, **19** has a benzylic/allylic methyl group, which eliminates the coupling of the vinyl proton with the benzylic/allylic proton observed in **17**. As a result, the vinyl proton in **19** appears as a multiplet

due to long-range couplings to the vinyl methyl protons. Also, the ABX pattern that was observed with compound **17** has now been simplified to an AB pattern (3.29 and 3.37 ppm, 8.8 Hz), indicating a methylene group adjacent to a quaternary stereogenic centre. In the ^{13}C nmr spectrum, an aryl-substituted quaternary carbon (44.68 ppm) and a lower field methoxy-substituted methylene (82.58 ppm) are observed. There is also a vinyl methine carbon and a vinyl quaternary carbon (129.71 and 134.99 ppm, respectively).

Compound **20** was identified as the 1,4-addition product resulting from attack of methanol at the less substituted end of the diene: (*E*)-4-(4-cyanophenyl)-1-methoxy-2,4-dimethyl-2-pentene. The ^1H and ^{13}C nmr spectra of **20** are similar to those of compound **16**. The differences can be attributed to the additional methyl group, which shows up as a doublet in the ^1H nmr spectrum, due to long-range coupling to the vinyl proton. A singlet at 3.76 ppm represents a methoxy-substituted methylene group. A multiplet appears in the vinyl region of the ^1H nmr spectrum, representing the vinyl proton adjacent to a quaternary carbon with long-range coupling (1.2 Hz) to the vinyl methyl protons. In the ^{13}C nmr spectrum of **20**, there is a low-field quartet (57.68 ppm) that is consistent with the methyl of the methoxy group The methoxy-substituted methylene shows up as a triplet at 78.94 ppm. A higher field singlet (39.95 ppm) indicates a quaternary carbon bonded to the aryl group. A vinyl methine group and a vinyl quaternary carbon are also evident (134.15 and 136.33 ppm). The decision in favour of the *E* configuration for **20** was based upon the results of a double-irradiation experiment leading to a nuclear Overhauser effect (nOe). When the vinyl proton was irradiated, an enhanced signal was observed for the protons on the methyl groups attached to the benzylic carbon, the protons on the methylene group (methoxy substituted), and for the *ortho*-aryl protons.

Compound **21**, (*Z*)-4-(4-cyanophenyl)-1-methoxy-2,4-dimethyl-2-pentene, was identified as the configurational isomer of **20**. The ^1H and ^{13}C nmr spectra show characteristic patterns similar to those of compound **20**. The *Z* configuration was assigned on the basis of the observed nOe. In this case, when the vinyl proton was irradiated, an enhancement was observed in the signals due to the protons on all three of the methyl groups and for the *ortho*-aryl protons. The configurations of **20** and **21** were further substantiated by use of the ACD/CNMR ^{13}C simulation program (Version 1.1, 1995); calculated and observed ^{13}C chemical shifts were in good agreement.[3]

Compound **22** was identified as the 1,4-addition product resulting from attack of methanol at the more substituted end of the diene: (*Z*)-1-(4-cyanophenyl)-4-methoxy-2,4-dimethyl-2-pentene. The ^1H and ^{13}C nmr spectra of **22** are similar to those of compound **15**. The differences can be attributed to the additional methyl group, which shows up as a doublet in the ^1H nmr spectrum, long-range coupled to the vinyl proton. A singlet at 3.78 ppm represents a methylene group, aryl substituted, which is further supported by a triplet at 37.75 ppm in the ^{13}C nmr spectrum. A multiplet appears in the vinyl region of the ^1H nmr spectrum, representing the vinyl proton adjacent to a quaternary carbon and having long-range coupling (1.2 Hz) to the vinyl methyl protons. In the ^{13}C nmr spectrum of **22**, there is a low-field quartet (50.16 ppm) that is consistent with the methyl of the methoxy group, and a singlet (75.09 ppm), which indicates a quaternary carbon bonded to the methoxy group. A vinyl methine group and a vinyl quaternary carbon are also present (132.24 and 135.25 ppm). The decision in favour of the *Z* configuration for **22** was based upon the results of a double-irradiation experiment leading to a nuclear Overhauser effect (nOe). When the vinyl proton was irradiated, enhancement was observed in the signals due to the protons on all three of the vicinal methyl groups.

Calculations

Ab initio molecular orbital calculations were carried out, using the GAUSSIAN 92 package of programs (9, 10), to obtain fully optimized structures (UHF/6-31G*) of the radical cations of 2-methylpropene (**2**), 2-methyl-2-butene (**6**), 2-methyl-1,3-butadiene (**9**), 4-methyl-1,3-pentadiene (**14**), and 2,4-dimethyl-1,3-pentadiene (**18**). The results of these calculations: optimized structures, and spin and charge density distribution obtained from Mulliken population analysis, are shown in Tables 1–5 and Figs. 1–5. The total energies, corrected for spin contamination, were obtained from single point calculations with Møller–Plesset perturbation theory (MP2) at the HF/6-31G* geometries. A thorough search was made for possible intermediates involved upon reaction of methanol with these alkene and diene radical cations.

Discussion

The proposed mechanism for the photo-NOCAS reaction is shown in Scheme 1, specifically for the combination of methanol adding to the radical cation of an alkene (1). The dominant issue here is the determination of those factors which influence the regiochemistry of the reaction, presumably established during step 3 of this scheme. The products obtained upon combination of methanol with the dienes provide strong support for this, step 3, as the initial bonding event. All of the photo-NOCAS adducts bear the methoxy group at a terminal carbon of the initial diene. Multiple products result from subsequent addition of the resulting intermediate allylic radical, at either of the ambident ends, to an *ipso* position of the 1,4-dicyanobenzene radical anion ($\mathbf{1}^{-\bullet}$) during step 4.

This deceptively simple representation of the initial bonding (Scheme 1, step 3) has been expanded (Scheme 2): step 3*a* represents the initial formation of a dipole-induced radical-ion complex; step 3*b* represents formation of a bridged radical cation; step 3*c* involves the formation of the new carbon–oxygen bond resulting in a distonic radical cation, and, finally, step 3*d* is the deprotonation from the oxygen of the distonic radical cation that yields the β-alkoxyalkyl radical. Similar species have been proposed to explain reactions of radical cations in the gas phase, observed by mass spectrometry (11). In principle, of course, not all of these steps may be necessary and some of them may be reversible. Our approach is now clear: we will consider the structure, energy, and the spin and charge distribution for all of these hypothetical intermediates and search for agreement between theory and the experimentally observed product ratios.

The results of the calculations relevant to the reaction of 2-methylpropene (**2**) (reaction [1]) are summarized in Tables 1, 6, 7, 8, and 9, and in Figs. 1, 6, 7, 8, and 9. The alkene radical

cation, **2**$^{+\bullet}$, remains planar, the dihedral angle C-1,C-2,C-3,C-4 is −180°. A significant proportion, almost half, of the positive charge density is borne by the methyl groups, leaving one-third on the terminal methylene carbon (C-1). The vertical ionization potential (9.39 eV), taken from the eigenvalue for the HOMO of the neutral molecule (**2**), and the adiabatic ionization potential (8.81 eV), taken as the difference in the calculated (MP2/6-31G*//HF/6-31G*) total energies of the fully optimized structures of the neutral molecule and the radical cation, are in good agreement with the experimental value (9.24 eV, vertical ionization potential) obtained from the photoelectron spectra (12).

A thorough search was made for the distonic radical cation,

Fig. 1. 2-Methylpropene radical cation ($2^{+\bullet}$).

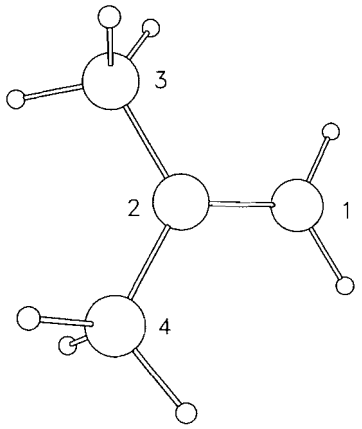

Fig. 2. 2-Methyl-2-butene radical cation ($6^{+\bullet}$).

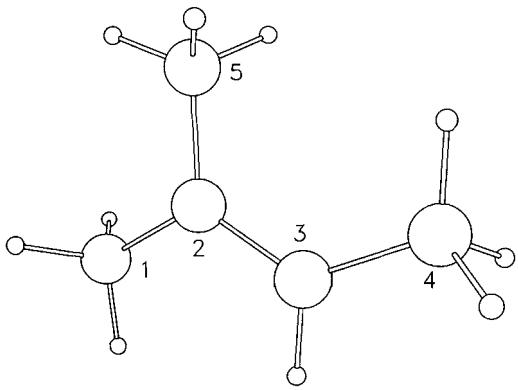

Fig. 3. 2-Methyl-1,3-butadiene radical cation ($9^{+\bullet}$).

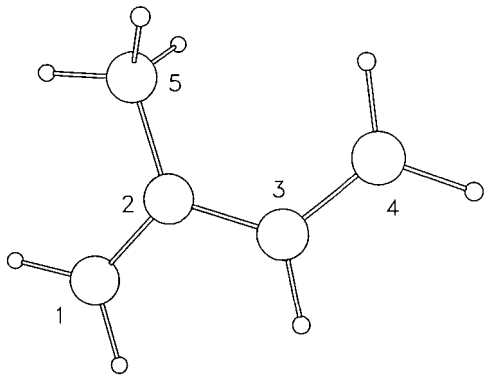

with methanol bonded to C-1; several conformers were found, the structure of the fully optimized global minimum (*anti*), $\mathbf{2a}^{+\bullet}$, is depicted in Table 6*a*,*b* and Fig. 6*a*. This structure is accurately described as **distonic** (11). The C-1,O-5 bond length is relatively long (1.57 Å), there is no evidence for bridging; the C-2,O-5 distance is 2.47 Å. The excess α-spin density resides largely (1.12) on C-2 while the positive charge density (0.79) is distributed over C-1, O-5, and C-6. This structure is significantly (92 kJ mol^{-1}) more stable than the components, i.e., the alkene radical cation, $\mathbf{2}^{+\bullet}$, and methanol.

An analogous fully optimized structure was found with

Fig. 4. 4-Methyl-1,3-pentadiene radical cation ($14^{+\bullet}$).

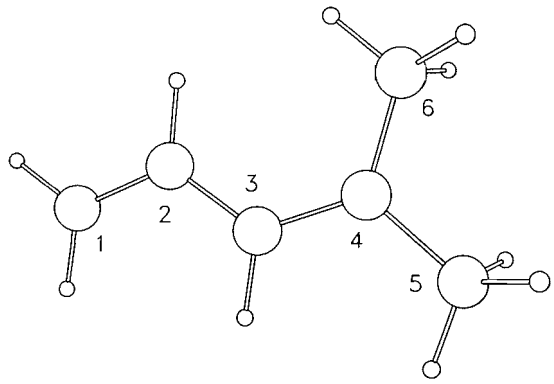

Fig. 5. 2,4-Dimethyl-1,3-pentadiene radical cation ($18^{+\bullet}$).

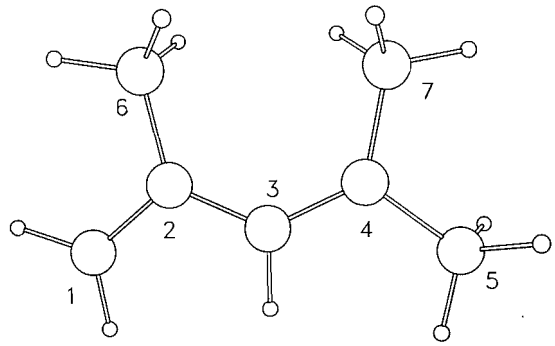
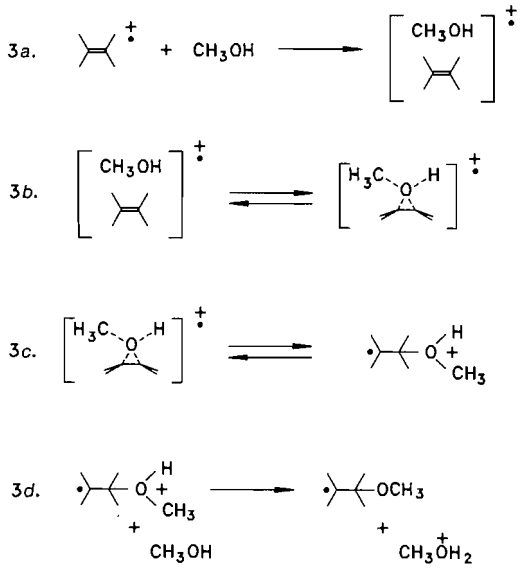


Scheme 2.



methanol bonded to C-2 ($\mathbf{2b}^{+\bullet}$, Table 6*c*,*d* and Fig. 6*b*). In fact, this distonic radical cation (*gauche*), $\mathbf{2b}^{+\bullet}$, is more stable (6.1 kJ mol^{-1}) than $\mathbf{2a}^{+\bullet}$. A factor contributing to the stability of $\mathbf{2b}^{+\bullet}$ is the additional charge delocalization; the methyl groups, C-3 and C-4, each bear significant (0.16) positive charge density.

Starting the calculation with a bridged structure, symmetrically constrained to have equal C-1,O-5 and C-2,O-5 bond

lengths, also converges to a minimum (no negative vibrational frequencies) **2c**$^{+\bullet}$ (Table 7 and Fig. 7). However, when this structure is fully optimized upon removing the symmetry constraint, the structure reverts to the distonic radical cation **2b**$^{+\bullet}$. This bridged structure may be an intermediate, preceding formation of the distonic radical cations, or may form during the equilibration of the distonic radical cations. The energy of this structure would then set a lower limit (24–30 kJ mol^{-1}), presumably only slightly below the activation energy for this equilibration.

and *anti* rotamers around the C-1,O-5 and C-2,O-5 bonds (Table 8 and Fig. 8). From $\mathbf{2a}^{+\bullet}$, the *anti* conformer, **2a•**, was the more stable, while from $\mathbf{2b}^{+\bullet}$, the *gauche* conformer, **2b•**, was preferred. Consistent with experimental results, there is no evidence for bridging in the β-alkoxyalkyl radical (8c). The calculations show the expected trend, the tertiary radical (**2a•**) is more stable (by only 1.3 kJ mol^{-1} !) than the primary radical (**2b•**).

The relative energies (MP2/6-31G*//HF/6-31G*) of these species are shown in Table 9 and Fig. 9. The values for the β-alkoxyalkyl radicals have been incorporated in this plot by

including a molecule of methanol to serve as a base in the deprotonation step (Scheme 2, step 3*d*). It must be emphasized that these calculations are relevant to the individual species in the gas phase. This, of course, is a gross oversimplification considering the charge separation and resulting large dipole of some of these species. In an attempt to assess the importance of solvent interaction, the Onsager reaction field model has been applied (SCRF/MP2/6-31G*//SCRF/HF/6-31G*) (13). The radius of the solute cavity was calculated using the volume key word in the GAUSSIAN program, and the dielectric constant was set at 35.0 (ca. acetonitrile). The most significant effect of including solvent interaction is a reversal of the rela-

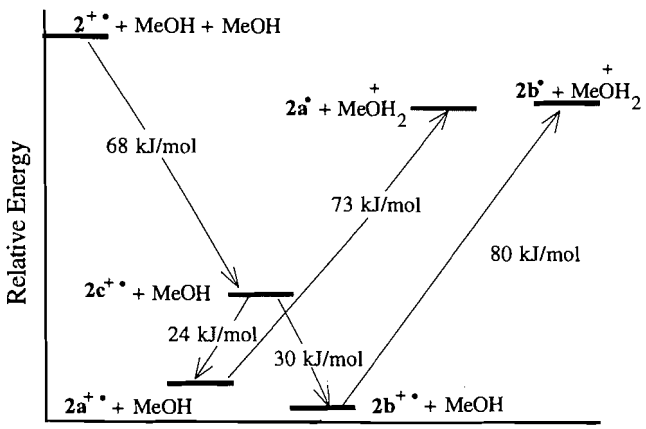
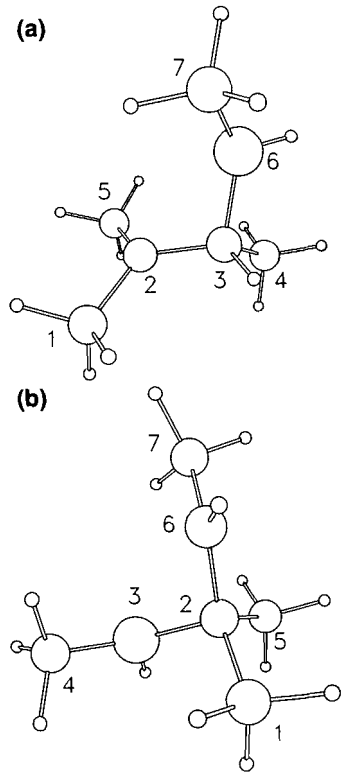
Fig. 9. Relative energies (MP2/6-31G*//HF/6-31G*) for 2-methylpropene intermediates.



tive order of stability of the two distonic radical cations. In the gas phase, $\mathbf{2b}^{+\bullet}$ is more stable than $\mathbf{2a}^{+\bullet}$ (6.1 kJ mol^{-1}); including the solvent dielectric renders $\mathbf{2a}^{+\bullet}$ more stable than $\mathbf{2b}^{+\bullet}$ (9.5 kJ mol^{-1}). As expected, there is essentially no solvent effect upon the difference in the relative stability of the radicals $\mathbf{2a}^{\bullet}$ and $\mathbf{2b}^{\bullet}$ ($\Delta\Delta$ = 0.34 kJ mol^{-1}).

The difference in the calculated total energy of the alternative β-alkoxyalkyl radicals, $\mathbf{2a}^{\bullet}$ and $\mathbf{2b}^{\bullet}$, is consistent with the observed product ratio (reaction [1]). The major product (**3**, 0.96) results from methanol bonding to C-1. **Hypothesis**: rapid equilibration of the distonic radical cations, through the bridged radical cation, is followed by irreversible deprotonation. The irreversibility of the deprotonation is a logical consequence of the low acidity of the media. The observed product regiochemistry therefore reflects the relative rates of formation of the alternative β-alkoxyalkyl radicals; formation of the more stable β-alkoxyalkyl radical is favoured.

Fig. 10. (*a*) 2-Methyl-2-butene–methanol distonic radical cation (C-3 bonded) ($\mathbf{6a}^{+\bullet}$); (*b*) 2-methyl-2-butene–methanol distonic radical cation (C-2 bonded, C2—O6 bond length constrained) ($\mathbf{6b}^{+\bullet}$).



For the photo-NOCAS reaction involving 2-methyl-2-butene (**6**), the products (reaction [2]), and the calculations (Tables 2, 10, 11, 12, 13 and Figs. 2, 10, 11, 12, 13) are consistent with this hypothesis. The vertical ionization potential (8.93 eV) and the adiabatic ionization potential (8.27 eV) are in good agreement with the experimental value (8.68 eV, vertical ionization potential) taken from the photoelectron spectra (12). The radical cation $\mathbf{6}^{+\bullet}$ is planar, the dihedral angle C-1,C-2,C-3,C-5 is −180°. The methyl groups bear a significant share of the positive charge density. The local charge density is, in fact, highest (0.25) on the less substituted alkene carbon (C-3).

The structure of the distonic radical cation with methanol bonded to C-3 ($\mathbf{6a}^{+\bullet}$) was fully optimized. The C-3,O-6 bond length is 1.58 Å, and there is no evidence for bridging; the C-2,O-6 distance is long, 2.46 Å. Calculations on the alternative structure, with methanol bonded to C-2 ($\mathbf{6b}^{+\bullet}$), converged only with a structural constraint; the C-2,O-6 bond length was held to 1.58 Å. Nevertheless, this distonic radical cation ($\mathbf{6b}^{+\bullet}$), with methanol bonded to C-2, is more stable (3.5 kJ mol^{-1}) than the alternative structure ($\mathbf{6a}^{+\bullet}$), with methanol bonded to C-3. Again, in this case, the methyl groups C-1 and C-5 of the distonic radical cation, $\mathbf{6b}^{+\bullet}$, each bear significant (0.14) positive charge density (Table 10*d*).

The structure of the bridged radical cation, **6c**$^{+\bullet}$ (Table 11 and Fig. 11), was fully optimized without structural constraints; in fact, removing the constraint from **6b**$^{+\bullet}$ gave **6c**$^{+\bullet}$. Both carbon–oxygen distances, C-2,O-6 and C-3,O-6, are long (2.81 and 2.95 Å). In this case, the differences in energy

between the alternative distonic radical cations and this bridged radical cation is small (±5 kJ mol^{-1}); it seems likely that equilibration among these intermediates would be rapid. Deprotonation of the distonic radical cation **6a**$^{+\bullet}$ leads to the tertiary β-alkoxyalkyl radical, **6a**$^{\bullet}$, which is more stable (6.4 kJ mol^{-1}) than the secondary β-alkoxyalkyl radical, **6b**$^{\bullet}$, resulting from deprotonation of **6b**$^{+\bullet}$ (Table 12 and Fig. 12).

The relative energies (MP2/6-31G*//HF/6-31G*) of these intermediates are shown in Table 13 and Fig. 13. Again, in this case, the major effect of including the solvent dielectric is to reverse the relative stabilities of the distonic radical cations: **6a**$^{+\bullet}$ becomes more stable than **6b**$^{+\bullet}$ (5.1 kJ mol^{-1}). The relative stability of the β-alkoxyalkyl radicals (**6a**$^{\bullet}$ and **6b**$^{\bullet}$) is unaffected.

The formation of **7** as the major (0.86) photo-NOCAS adduct in reaction [2] is consistent with the hypothesis: rapid equilibration of the initially formed intermediates, followed

by irreversible deprotonation from the distonic radical cations, with preferential formation of the more stable β-alkoxyalkyl radical, **6a**•.

For both of these reactions (reactions [1] and [2]), it is interesting to note the alternation in the order of relative stability (MP2/6-31G*//HF/6-31G*) between the distonic radical cations, **2b**$^{+\bullet}$ more stable than **2a**$^{+\bullet}$, and **6b**$^{+\bullet}$ more stable than **6a**$^{+\bullet}$, and the relative stability of the β-alkoxyalkyl radicals, **2a**• more stable than **2b**•, and **6a**• more stable than **6b**•. An indication of the cause of this effect is the significant positive charge density borne by the methyl group(s) on the carbon next to the protonated oxygen atom of the distonic radical cations. For the distonic radical cations, the increased stability resulting from additional positive charge delocalization is greater than the difference in stability between secondary (or even primary) versus tertiary alkyl radicals. Since results to be described later will further challenge the general statement, "The more heavily substituted radical is the more stable," additional consideration has been given to this generalization. For reaction [1], relevant isodesmic reactions are shown (reactions [1*a*] – [1*e*]).

The isodesmic reaction [1*b*] involves a dissection of the alternative intermediates **2a**• and **2b**•. The calculated heat of reaction [1*b*] agrees well with that for reaction [1*a*]. In addi-

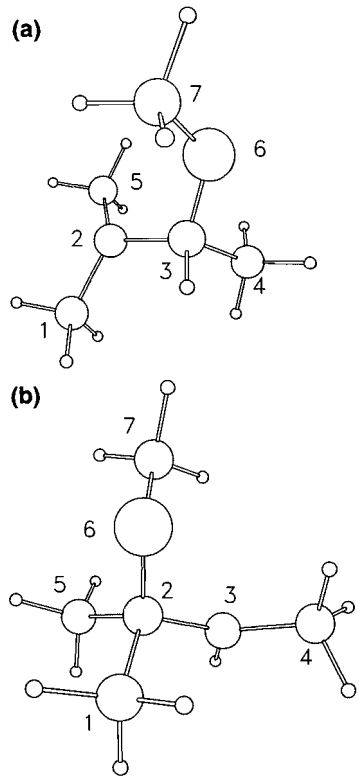
tion, in this case, experimentally determined heats of formation of the components are available (14); the agreement is encouraging.

The dissection illustrated in the isodesmic reaction [1*e*] is, in fact, the combination of two isodesmic reactions, [1*c*] and [1*d*]. The isodesmic reaction [1*c*] reveals the fact that alkyl substitution on the carbon bonded to oxygen of the ether leads

Fig. 12. (*a*) 2-Methyl-2-butene–methanol radical (C-3 bonded) (**6a**•); (*b*) 2-methyl-2-butene–methanol radical (C-2 bonded) (**6b**•).



to increased stability. The calculated (MP2/6-31G*//HF/6-31G*) total energies of the isomeric *tert*-butyl and isobutyl radicals show the expected trend; the tertiary radical is 24.0 kJ mol^{-1} more stable than the primary radical (reaction [1*d*]). Combining these two equations gives an indication of the relative importance of these two factors influencing the stability of the radicals **2a**• and **2b**•. This isodesmic reaction, [1*e*], is significantly less exothermic (−8.7 kJ mol^{-1}) than indicated upon consideration of "radical" stability alone (reaction [1*d*]).

Analogous isodesmic reactions, relevant to reaction [2], are shown (reactions [2*a*] – [2*e*]). Again, in this case, experimental data is available for reaction [2*b*]; the calculated value is in good agreement with the experimental results (14). The same trend is observed: the *tert*-radical is more stable than the *sec*-radical (reaction [2*d*]), but the difference is attenuated by the stabilizing influence of alkyl substitution on the carbon adjacent to the oxygen of the ether (reaction [2*c*]). The relevant isodesmic reaction (reaction [2*e*]) lies in favour of the *tert*-radical over the *sec*-radical by only 4.2 kJ mol^{-1}.

The optimized structure for the radical cation of 2-methyl-1,3-butadiene (**9**$^{+\bullet}$) has the expected planar structure with normal bond lengths and angles (Table 3 and Fig. 3). The vertical ionization potential (8.67 eV) and the adiabatic ionization potential (8.45 eV) are in good agreement with the experimental value (8.85 eV, vertical ionization potential) taken from the photoelectron spectra (12). The charge densities at the two termini, C-1 and C-4, are identical. The charge densities at C-2 and C-3 are also identical. These values provide no basis for

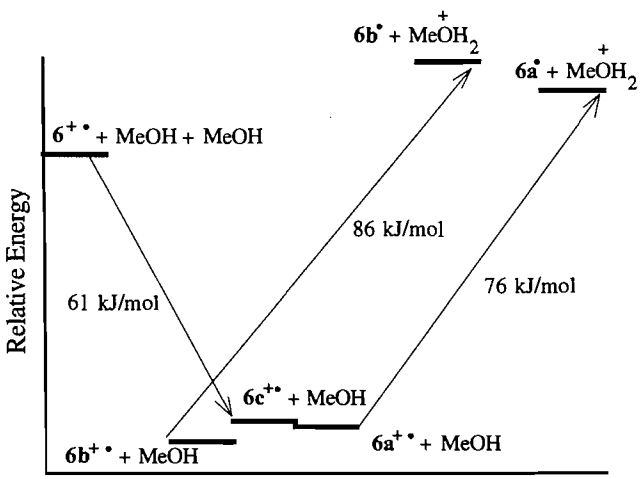
Fig. 13. Relative energies (MP2/6-31G*//HF/6-31G*) for 2-methyl-2-butene intermediates.



predicting the regiochemistry of the addition. There is, however, significant charge density on the methyl group (C-5). If this charge is summed in with the charge on C-1 and C-2, the argument could be made that more than half (0.58) of the positive charge is in this region; the major products (0.89) do arise from methanol attack at C-1 (reaction [3]).

Two fully optimized structures were obtained for the alternative distonic radical cations (Table 14 and Fig. 14), methanol bonded to C-1 (**9a**$^{+\bullet}$) or to C-4 (**9b**$^{+\bullet}$); **9a**$^{+\bullet}$ is 7.3 kJ mol^{-1} more stable than **9b**$^{+\bullet}$. These structures are accurately described as distonic; the charge and spin are separated. The positive charge is largely associated with the ether moiety, the ether-methyl, and methylene (C-1 or C-4) groups. For **9a**$^{+\bullet}$, the C-1,O-6 bond is 1.54 Å. There is no evidence for bridging; the C-2,O-6 distance is 2.44 Å, and the dihedral angle C-3,C-

Fig. 14. (*a*) 2-Methyl-1,3-butadiene–methanol distonic radical cation (C-1 bonded) (**9a**$^{+\bullet}$); (*b*) 2-methyl-1,3-butadiene–methanol distonic radical cation (C-4 bonded) (**9b**$^{+\bullet}$).

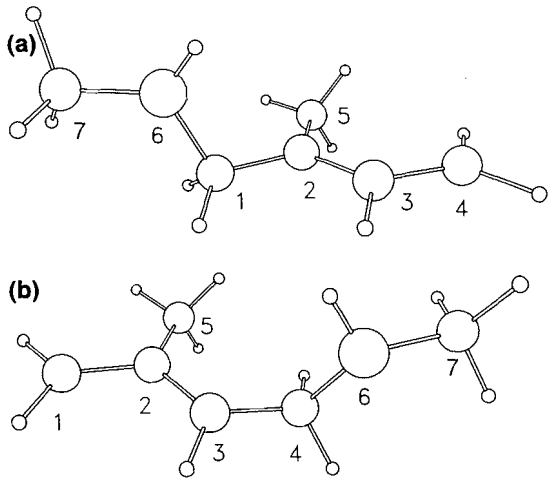

Fig. 15. (*a*) 2-Methyl-1,3-butadiene–methanol radical (C-1 bonded) (**9a**$^{\bullet}$); (*b*) 2-methyl-1,3-butadiene–methanol radical (C-4 bonded) (**9b**$^{\bullet}$).

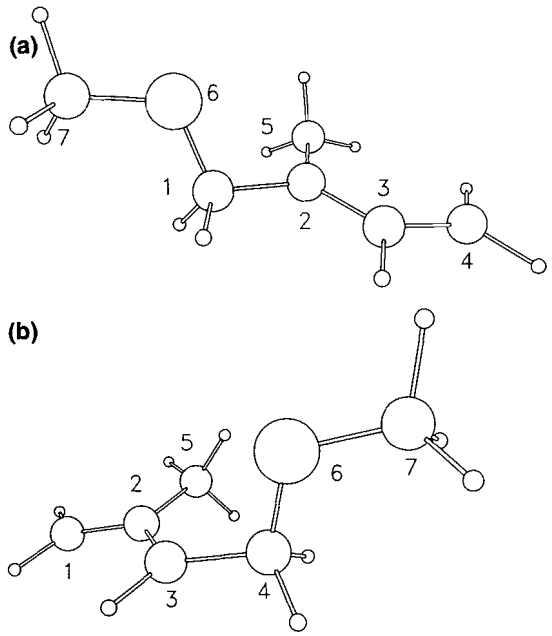

2,C-1,O-6 is 106°. The allylic radical moiety is essentially planar (dihedral angle C-1,C-2,C-3,C-4 is 178°). The structure of **9b**$^{+\bullet}$ is similar, with no evidence for bridging. A thorough search was made for a bridged radical cation(s) and none was found. Deprotonation from the oxygen of the distonic radical cations, **9a**$^{+\bullet}$ and **9b**$^{+\bullet}$, gave the radicals, **9a**$^{\bullet}$ and **9b**$^{\bullet}$ (Table 15 and Fig. 15). The radical with methanol bonded to C-1 (**9a**$^{\bullet}$) is the more stable (8.5 kJ mol^{-1}). In this case, the more stable radical cation (**9a**$^{+\bullet}$) and the more stable radical (**9a**$^{\bullet}$) both have the methanol bonded to C-1; the allylic radical moiety is the more heavily alkyl-substituted.

The relevant isodesmic reaction shows the calculated (MP2/6-31G*//HF/6-31G*) total energies of the isomeric 1,1-dimethyl- and 1,2-dimethyl-substituted allylic radicals follow the expected trend; the 1,1-disubstituted radical is 6.7 kJ mol^{-1} more stable than the 1,2-disubstituted radical (reaction [3*b*]). Calculations of the relative stability of the radicals (**9a**$^{\bullet}$ and **9b**$^{\bullet}$, reaction [3*a*]) and the isodesmic reaction [3*b*] are consistent with the observed product ratio (reaction [3]).

The radical cation of 4-methyl-1,3-pentadiene (**14**$^{+\bullet}$), in the s-*trans* conformation, is planar (dihedral angle C-1,C-2,C-

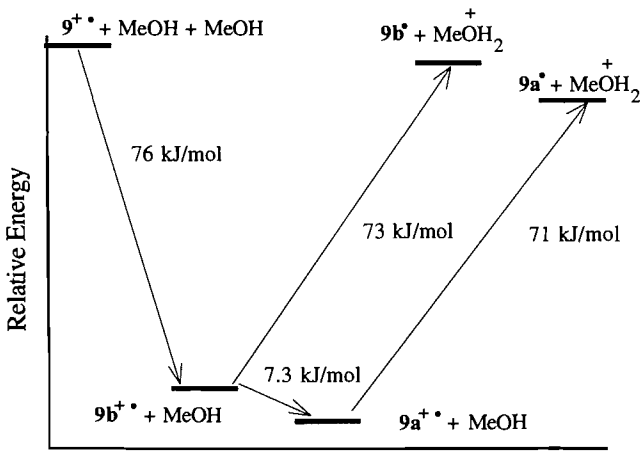
Fig. 16. Relative energies (MP2/6-31G*//HF/6-31G*) for 2-methyl-1,3-butadiene intermediates.



3,C-4 is −180°, C-2,C-3,C-4,C-5 is 180°, Table 4, Fig. 4). The calculated vertical ionization potential (8.23 eV) and the adiabatic ionization potential (7.90 eV) are in good agreement with the experimental value (8.28 eV, vertical ionization potential) taken from the photoelectron spectra (12). The charge density, at a single position, is greatest at C-1 (0.23); however, significant charge is borne by the methyl groups and if the positive charges on C-3,C-4,C-5, and C-6 are summed, this is the region of highest charge density (0.62).

A fully optimized structure for a distonic radical cation, with methanol bonded to C-4, was obtained (**14a**$^{+\bullet}$, Table 17*a*,*b* Fig. 17*a*). The C-4,O-7 bond length was relatively long (1.71 Å) and there was no evidence for bridging. An analogous structure with methanol bonded to C-1, **14b**$^{+\bullet}$, was obtained; with a C-1,O-7 bond length of 1.56 Å, and no evidence for

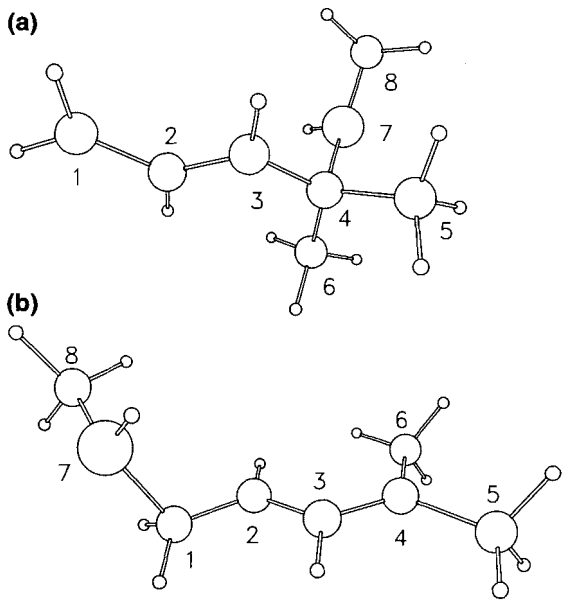
Fig. 17. (*a*) 4-Methyl-1,3-pentadiene–methanol distonic radical cation (C-4 bonded) (**14a**$^{+\bullet}$); (*b*) 4-methyl-1,3-pentadiene–methanol distonic radical cation (C-1 bonded) (**14b**$^{+\bullet}$).



bridging (Table 17*c*,*d*, Fig. 17*b*). The calculations reveal that **14b**$^{+\bullet}$ is of higher energy (9.2 kJ mol^{-1}) than **14a**$^{+\bullet}$. A major factor contributing to the relative stability of **14a**$^{+\bullet}$ must be the significant charge density borne by the methyl groups, C-5 and C-6. Deprotonation from the oxygen of the distonic radical cation **14a**$^{+\bullet}$ gives the radical **14a**$^{\bullet}$, which is more stable (5.1 kJ mol^{-1}) than the analogous radical, **14b**$^{\bullet}$, obtained from **14b**$^{+\bullet}$ (Tables 18, 19, and Figs. 18, 19). Including the solvent dielectric in these calculations has a large effect upon the relative energies of the distonic radical cations; **14b**$^{+\bullet}$ is now more stable (49.8 kJ mol^{-1}) than **14a**$^{+\bullet}$. As expected, there is little solvent effect on the relative energies of the radicals, **14a**$^{\bullet}$ and **14b**$^{\bullet}$.

The 1,4-adducts from **14** have the *E* configuration (**15** and **16**); the *Z* isomers were not detected. This stereochemistry is a reflection of the preferred configuration of the starting diene; the s-*trans* conformer of **14** is favoured. The calculated (MM3) difference in energy between **14** s-*cis* and **14** s-*trans* is 14 kJ mol^{-1}. The s-*trans* conformation is planar while the s-*cis* conformer is twisted with a calculated dihedral angle, C-1,C-2,C-3,C-4, of 43°. The configuration of the intermediate allylic radicals, **14a**$^{\bullet}$ and **14b**$^{\bullet}$, is a reflection of the conformation of the initial diene.

While the observed product ratio, preferential addition of methanol to C-4 (reaction [4]), and the calculated relative energies of the alternative radicals, **14a**$^{\bullet}$ more stable than **14b**$^{\bullet}$ (reaction [4*a*]), are consistent with the proposed hypothesis, this is the only reaction studied, so far, where the order of radical stability was not anticipated. The more stable radical, **14a**$^{\bullet}$, has the *mono*-substituted (C-3) allylic radical, compared to **14b**$^{\bullet}$, with a *tri*-substituted (C-2,C-4,C-4) allylic radical. Calculations based upon the isodesmic reaction (reaction [4*b*]) support the notion that the total structure of the intermediate radical, not just the allylic radical moiety, must be taken into account. Formation of the more heavily substituted ether, less substituted allylic radical, is favoured in this case.

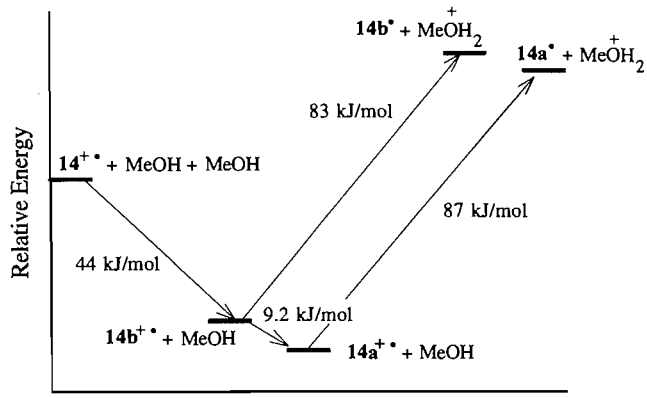
Fig. 19. Relative energies (MP2/6-31G*//HF/6-31G*) for 4-methyl-1,3-pentadiene intermediates.



radical cation, **18**$^{+\bullet}$, is on C-4,C-5, and C-6, with only 0.20 on C-1. The major mode of addition, forming **19**, **20**, and **21** (reaction [5]), results from initial bonding of methanol to C-1, giving the more heavily substituted allylic radical, which is, in this case, the more stable (reaction [5*a*]).

There is convincing experimental evidence that the neutral molecule, **18**, is significantly (ca. 50°) twisted from the s-*cis* conformer (15*a*). Published calculations (HF/6-31G) on the neutral molecule indicate a global minimum structure with a dihedral angle C-1,C-2,C-3,C-4 of 52°, i.e., twisted from s-*cis*, and another conformer C-1,C-2,C-3,C-4 of 180°, s-*trans*, 9.3 kJ mol^{-1} higher energy (15*b*). Higher level calculations (MP2/6-31G*//HF/6-31G*) reduce this energy difference to 7.9 kJ mol^{-1}. Earlier molecular mechanics calculations (MMP1) found two twisted conformers, dihedral angles C-1,C-2,C-3,C-4, of 52° and 163°, with a difference in energy of only 1.3 kJ mol^{-1} (15c). MM3 calculations also give two twisted conformers, C-1,C-2,C-3,C-4 of 49° and 149°; in this case, 0.5 kJ mol^{-1} in favour of the twisted s-*trans* conformer. In view of the twist in this neutral molecule, it is not surprising that both *Z* (**21** and **22**) and *E* (**20**) 1,4-adducts have been identified among the products.

The planarity (calculated) of the radical cation, **18**$^{+\bullet}$, is in marked contrast with the significant twist in the neutral molecule. A thorough search was made for conformational minima of **18**$^{+\bullet}$; two were found. The lowest energy conformer is essentially planar s-*trans* (dihedral angle, C-1,C-2,C-3,C-4 of −179°). A twisted s-*cis* (C-1,C-2,C-3,C-4 of −12°) shallow minimum was also found, 12.3 kJ mol^{-1} above the global minimum. These minima are separated by a rotational barrier estimated (MP2/6-31G*//HF/6-31G*) to be 73 kJ mol^{-1} above the global minimum, s-*trans* conformer. The total overlap between C-2 and C-3, obtained by Mulliken population analysis, is 0.48 for both conformers of **18**$^{+\bullet}$. These values can be compared with a barrier of only 11 kJ mol^{-1} for rotation around the C-2—C-3 bond of the neutral molecule, s-*cis* twisted **18**, and the total overlap between C-2 and C-3 of 0.37 (s-*trans*, 0.41). Clearly, the radical cation, **18**$^{+\bullet}$, is inherently more planar than the neutral molecule.

An important question generated by this discussion is: what is the best/easiest method for obtaining the relative heats of formation of these intermediate radicals? The ab initio calculations discussed so far utilized reasonably large basis sets and included electron correlation (MP2/6-31G*//HF/6-31G*, cor-

rected for spin contamination). These numbers are basis-set dependent. The results of the calculations for the isodesmic reactions, using various basis sets, and other methods (16, 17), have been listed (reactions [1*a*]–[5*b*] and Tables 20 and 21). For example, the difference in stability of the alternative intermediate radicals, **2a**• and **2b**•, is very basis-set/method dependent. Calculations on the isodesmic reaction (reaction [1*c*]) reveal that a major contribution can be attributed to variation in the calculated total energy for the ethers (*tert*-butyl methyl ether and isobutyl methyl ether) upon inclusion of electron correlation. The differences in the heats of formation of these two ethers, determined by various methods, are summarized in Table 21. It was, to some extent, reassuring to note that further increasing the basis set (MP2/6-311+G*//MP2/6-31G*) had little effect on the calculated total energies of these species. It was also interesting to note the general agreement between the energies calculated (MP2/6-31G*//HF/6-31G*) and those derived by Benson's empirical rules (16). In only two cases, reactions [1*b*] and [2*b*], were experimental data available (14); there is good agreement between the experimental and calculated values (±3 kJ mol^{-1}). In marked contrast, the agreement between both the values derived from the ab initio calculations and the experimental values with results obtained from a semi-empirical molecular orbital method (AM1 (17)) is generally poor.

An additional observation worthy of note deals with the relative abundance of 1,4- versus 1,2-adducts from the conjugated dienes. This regiochemistry is determined during the coupling of the allylic radical with the 1,4-dicyanobenzene radical anion (**1**$^{-\bullet}$), step 4, Scheme 1. Previous results have led to the hypothesis that preferential coupling occurs at that end of the ambident allylic radical with highest spin density, moderated by steric interactions. Two 1,2-adducts were observed, **17** from reaction [4] and **19** from reaction [5]. In both cases, these adducts are less sterically hindered than the alternative pair of isomers, which were not observed.

Conclusions

1. The regiochemistry of the photo-NOCAS reaction (step 3, Scheme 1) with methanol acting as the nucleophile, combining with the radical cation of an alkene or diene, can be predicted on the basis of the *anti*-Markovnikov rule. Addition occurs at that position which yields the most stable intermediate radical.

2. The regiochemistry is not controlled by steric factors. The nucleophile (methanol) does not always add preferentially to the least hindered site.

3. The nucleophile (methanol) does not always add preferentially to the carbon bearing the greatest positive charge density.

4. The more heavily alkyl-substituted radical is not (necessarily) the more stable.

5. Ab initio molecular orbital calculations (MP2/6-31G*// HF/6-31G*, corrected for spin contamination) lend support to the hypothesis that the addition proceeds by initial formation of bridged radical cation complexes, followed by formation of alternative distonic radical cations. Subsequent deprotonation from the oxygen of the distonic radical cations to give β-alkoxyalkyl radicals determines the regiochemistry.

6. Isodesmic reactions based upon empirically derived heats of formation (Benson's rules) are also useful for predicting relative free-radical stability.

7. Not surprisingly, in view of the small differences in the

stability of these radicals, the agreement between theory and experiment is not absolute.

8. The alternative 1,2- versus 1,4-addition is controlled by spin density and steric factors.

9. The stereochemistry of the photo-NOCAS 1,4-adducts involving dienes is a reflection of the relative stability of the alternative s-*cis* and s-*trans* conformers of the starting neutral diene. This ratio is accurately predicted, based upon relative energies of the conformers calculated by molecular mechanics (MM3).

10. The regiochemistry of the photo-NOCAS reaction is dependent upon the nucleophile. Preliminary results indicate that the regiochemistry of the reaction with cyanide anion is different from that reported here for the addition of methanol.

Experimental

General information

^1H and ^{13}C nmr spectra were obtained from a Bruker 250 or 400 MSL spectrometer. Spectra were recorded in parts per million and frequencies are relative to tetramethylsilane. Infrared spectra (ir) were recorded on a Nicolet 205 spectrometer and are reported in wave numbers (cm^{-1}). Elemental analyses were performed by Canadian Microanalytical Service Ltd., B.C. Exact Mass determinations were obtained using a CEC 21-110 mass spectrometer. Progress of the reaction was followed by gas chromatography using a Hewlett–Packard (HP) 5890 gas chromatograph fitted with a DB-1701 fused silica WCOT column (30 m × 0.25 mm, 0.25-μm film thickness) and a calibrated flame ionization detector (gc/fid). An HP 3392A integrator was interfaced with the gc/fid to obtain peak areas. An HP 5890 gas chromatograph with a 5% phenyl methyl silicone fused silica WCOT column (25 m × 0.20 mm, 0.33-μm film thickness) interfaced with an HP 5970 mass selective detector (gc/ms) was also used for product analyses. Mass spectra are reported as *m/z* (relative intensity). Separation of product mixtures was generally carried out using preparative medium-pressure liquid chromatography (mplc) (1*a*). The mplc consists of a 2.5 cm × 1 m column packed with thin-layer chromatography (tlc) grade silica gel (with binder) (cat. no. 81632, Rose Scientific Ltd.) at a pressure of 20 psi using helium (1psi = 6.9 kPa). Connected to the mplc was a UV spectrophotometer – fraction collector that collects ca. 10-mL fractions. Preparative gas chromatography (prep-gc) was carried out on a Varian Aerograph model 920 instrument using a 1/4 in. × 6 ft aluminum column packed with 20% SE-30 on Chromasorb W 60/80 NAM.

Materials

Acetonitrile (Fisher ACS grade) was distilled twice, first from sodium hydride and then from phosphorus pentoxide. It was then passed through a column of basic alumina, refluxed over calcium hydride for 24 h (under a nitrogen atmosphere), fractionally distilled (under nitrogen), and stored over molecular sieves (3 Å) (18). Methanol was distilled and then stored over molecular sieves (4 Å). 1,4-Dicyanobenzene (**1**) (Aldrich) was purified by treatment with Norite in methylene chloride, followed by recrystallization from 95% ethanol. Tetraethylammonium perchlorate (TEAP) (Aldrich) was recrystallized three times from water and then dried in a vacuum oven for 15 h, 70°C, 0.25 Torr (1 Torr = 133.3 Pa). Biphenyl (**5**) (Eastman Kodak Co.) was recrystallized from methanol. 4-Methyl-1,3-pentadiene (**14**) (≥98%) was obtained from Fluka Chemika-BioChemika. 2,4-Dimethyl-1,3-pentadiene (**18**) (≥98%) was obtained from Aldrich Chemical Co.

Irradiations

Irradiations were generally carried out on solutions of acetonitrile–methanol (3:1) with 1,4-dicyanobenzene (**1**), the diene, and biphenyl (**5**) serving as a codonor. Solutions were irradiated in either 2 cm i.d. Pyrex tubes or 5 mm Pyrex nmr tubes, which were degassed by nitrogen ebullition. These samples were irradiated at 10°C using a CGE 1-kW medium-pressure mercury vapour lamp contained in a water-cooled quartz immersion well.

Combination of methanol, 4-methyl-1,3-pentadiene (14), and 1,4-dicyanobenzene (1) to form photo-NOCAS adducts 15, 16, and 17: reaction [4]

A solution of 4-methyl-1,3-pentadiene (**14**) (0.40 g, 0.55 mL, 0.005 mol), 1,4-dicyanobenzene (**1**) (0.6 g, 0.005 mol), and biphenyl (**5**) (0.4 g, 0.003 mol) in acetonitrile–methanol (3:1, 40 mL) was degassed by nitrogen ebullition for 5 min and irradiated for 44 h. The solvent was removed to yield a crude photolysate. The crude photolysate was separated by mplc using a linear solvent gradient of hexanes – (5% diethyl ether, 95% hexanes). The products eluted in the order **17**, **16**, and **15**.

Combination of methanol, 2,4-dimethyl-1,3-pentadiene (18), and 1,4-dicyanobenzene (1) to form photo-NOCAS adducts 19, 20, 21, and 22: reaction [5]

A solution of 2,4-dimethyl-1,3-pentadiene (**18**) (3.0 g, 4.0 mL, 0.031 mol), 1,4-dicyanobenzene (**1**) (2.5 g, 0.020 mol), and biphenyl (**5**) (1.6 g, 0.010 mol) in acetonitrile–methanol (3:1, 160 mL) was degassed by nitrogen ebullition for 5 min and irradiated for 94 h. The solvent was removed to yield a crude photolysate. The crude photolysate was separated by mplc using a linear solvent gradient of hexanes – (5% diethyl ether, 95% hexanes). Further purification was achieved via additional chromatography using mplc. Four 1:1:1 adducts eluted in the order **19**, (**21** and **22**; together) and **20**. Some additional separation of **21** and **22** was achieved using prep-gc.

*4-(4-Cyanophenyl)-5-methoxy-2,4-dimethyl-2-pentene (**19**)*

The yield of **19** was 26%: infrared (Nicolet 205) *ν*: 2972(s), 2929(s), 2876(s), 2829(m), 2227(s), 1606(s), 1503(m), 1475(m), 1450(s), 1408(m), 1386(m), 1376(m), 1196(m), 1169(m), 1116(s), 1104(s), 1066(m), 1019(m), 985(m), 963(m), 841(s), 822(m); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.10 (d, 3H, $^4J_{1-3}$ = 1.2 Hz, vinyl CH_3 (1-H)), 1.46 (s, 3H, CH_3), 1.70 (d, 3H, $^4J_{1'-3}$ = 1.2 Hz, vinyl CH_3 (1′-H)), 3.26 (s, 3H, OCH_3), 3.29 (d, 1H, $2J_{5-5'}$ = 8.8 Hz, H of methylene group, methoxy substituted (5-H)), 3.37 (d, 1H, $^2J_{5-5'}$ = 8.8 Hz, H of methylene group, methoxy substituted (5′-H)), 5.48 (m, 1H, $^4J_{1-3}$ = 1.2 Hz, $^4J_{1'-3}$ = 1.2 Hz, vinyl H (3-H)), 7.47 (d, 2H, $^3J_{2'-3'}$ = 8.6 Hz, $^3J_{5'-6'}$ = 8.6 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.55 (d, 2H, $^3J_{2'-3'}$ = 8.6 Hz, $^3J_{5'-6'}$ = 8.6 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 19.73 (q), 23.92 (q), 26.83(q), 44.68 (s, quaternary carbon, aryl substituted), 59.33 (q, OCH_3), 82.58 (t, OCH_2), 109.37 (s, quaternary aryl carbon, cyano substituted), 119.25 (s, CN), 128.14 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 129.71 (d, vinyl CH), 131.71 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 134.99 (s, vinyl quaternary carbon), 153.21 (s, quaternary aryl carbon, alkyl-substituted); ms *m/z*: 51(5), 53(5), 77(7), 89(5), 103(5), 115(9), 116(12), 127(8), 128(6), 129(5), 130(11), 140(7), 142(100), 143(12), 153(7), 154(11), 156(8), 168(8), 184(59), 185(9), 229(9). Anal. calcd. for $C_{15}H_{19}NO$: C 78.56, H 8.35, N 6.11; found: C 78.73, H 8.29, N 6.04.

*(E)-4-(4-Cyanophenyl)-1-methoxy-2,4-dimethyl-2-pentene (**20**)*

The yield of **20** was 25%: infrared (Nicolet 205) *ν*: 2967(s), 2928(s), 2875(m), 2819(m), 2228(s), 1606(m), 1503(m), 1467(m), 1450(m), 1401(m), 1382(m), 1363(m), 1192(m), 1114(s), 1096(s), 1062(m), 1020(w), 839(s); ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.14 (d, 3H, $^4J_{2-3}$ = 1.2 Hz, vinyl CH_3 (2-H)), 1.44 (s, 6H, 2 CH_3's), 3.31 (s, 3H, OCH_3), 3.76 (s, 2H, methylene group, methoxy substituted), 5.77 (m, 1H, $^4J_{2-3}$ = 1.2 Hz, vinyl H (3-H)), 7.47 (d, 2H, $^3J_{2'-3'}$ = 8.5 Hz, $^3J_{5'-6'}$ = 8.5 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.58 (d, 2H, $^3J_{2'-3'}$ = 8.5 Hz, $^3J_{5'-6'}$ = 8.5 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); The nOe experiment: the vinyl proton was irradiated. An nOe was observed for the signals due to protons on the methyl groups (benzylic), protons on the methylene group (methoxy substituted), and the *ortho*-aryl protons; ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 15.10 (q), 30.96 (q, 2 CH_3's), 39.95 (s, quaternary carbon, aryl substituted), 57.68 (q, OCH_3), 78.94 (t, OCH_2), 109.23 (s, quaternary aryl carbon, cyano substituted), 119.15 (s, CN), 127.02 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.07 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 134.15 (s, vinyl quaternary carbon), 136.33 (d, vinyl CH), 156.16 (s, quaternary aryl carbon, alkyl-substituted); ms *m/z*: 55(19), 72(27), 73(15), 85(100), 115(11), 116(27), 140(13), 142(59), 154(20), 156(11), 167(21), 168(10), 182(32), 184(28). Exact Mass calcd. for $C_{15}H_{19}NO$: 229.1467; found: 229.1462.

*(Z)-4-(4-Cyanophenyl)-1-methoxy-2,4-dimethyl-2-pentene (**21**)*

The yield of **21** was 6%: ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.41 (s, 6H, 2 CH_3's), 1.75 (d, 3H, $^4J_{2-3}$ = 1.5 Hz, vinyl CH_3 (2-H)), 2.90 (s, 3H, OCH_3), 3.29 (s, 2H, methylene group, methoxy substituted), 5.71 (m, 1H, $^4J_{2-3}$ = 1.5 Hz, vinyl H (3-H)), 7.48 (d, 2H, $^3J_{2'-3'}$ = 8.8 Hz, $^3J_{5'-6'}$ = 8.8 Hz, H's adjacent

to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.58 (d, 2H, $^3J_{2'-3'}$ = 8.8 Hz, $^3J_{5'-6'}$ = 8.8 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); The nOe experiment: the vinyl proton was irradiated. An nOe was observed for the signals due to protons on the methyl groups (benzylic), protons on the vinyl methyl group, and the *ortho*-aryl protons; ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 21.79 (q), 31.84 (q, 2 CH_3's), 40.10 (s, quaternary carbon, aryl substituted), 57.94 (q, OCH_3), 71.06 (t, OCH_2), 109.28 (s, quaternary aryl carbon, cyano substituted), 119.16 (s, CN), 127.03 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 131.99 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 134.52 (s, vinyl quaternary carbon), 137.78 (d, vinyl CH), 156.56 (s, quaternary aryl carbon, alkyl-substituted); ms *m/z*: 51(7), 53(8), 55(22), 72(20), 73(35), 77(7), 85(100), 115(8), 116(19), 127(7), 140(8), 142(28), 154(11), 167(10), 182(13), 184(8). Exact Mass calcd. for $C_{15}H_{19}NO$ (50/50 mixture of **21** and **22**): 229.1467; found: 229.1455.

(Z)-1-(4-Cyanophenyl)-4-methoxy-2,4-dimethyl-2-pentene (22)

The yield of **22** was 4%: ^{1}H nmr (250.13 MHz, $CDCl_3$) δ_{TMS}: 1.34 (s, 6H, 2 CH_3's), 1.59 (d, 3H, $^4J_{2-3}$ = 1.2 Hz, vinyl CH_3 (2-H)), 3.20 (s, 3H, OCH_3), 3.78 (s, 2H, methylene group, aryl substituted), 5.34 (m, 1H, $^4J_{2-3}$ = 1.2 Hz, vinyl H (3-H)), 7.29 (d, 2H, $^3J_{2'-3'}$ = 7.9 Hz, $^3J_{5'-6'}$ = 7.9 Hz, H's adjacent to alkyl-substituted aryl carbon (2′-H, 6′-H)), 7.57 (d, 2H, $^3J_{2'-3'}$ = 7.9 Hz, $^3J_{5'-6'}$ = 7.9 Hz, H's adjacent to cyano-substituted aryl carbon (3′-H, 5′-H)); The nOe experiment: the vinyl proton was irradiated. An nOe was observed for the signals due to protons on the three methyl groups; ^{13}C nmr (62.90 MHz, $CDCl_3$) δ: 23.96 (q), 28.17 (q, 2 CH_3's), 37.77 (t, CH_2, aryl substituted), 50.16 (q, OCH_3), 75.09 (s, quaternary carbon adjacent to oxygen), 109.63 (s, quaternary aryl carbon, cyano substituted), 119.16 (s, CN), 129.57 (d, aromatic CH adjacent to alkyl-substituted aryl carbon), 132.14 (d, vinyl CH), 132.24 (d, aromatic CH adjacent to cyano-substituted aryl carbon), 135.25 (s, vinyl quaternary carbon), 146.13 (s, quaternary aryl carbon, alkyl substituted); ms *m/z*: 53(13), 55(12), 73(21), 89(18), 113(16), 116(29), 140(12), 142(13), 154(19), 155(11), 156(13), 167(25), 182(100), 183(15), 197(30), 214(22). Exact Mass calcd. for $C_{15}H_{19}NO$ (50/50 mixture of **21** and **22**): 229.1467; found: 229.1455.

Synthesis of some phosphino- and arsinobenzenechromium tricarbonyl derivatives and metal carbonyl clusters

William R. Cullen, Steven J. Rettig, and Hongli Zhang

Abstract: The synthesis of a number of new phosphino- and arsinobenzenechromium tricarbonyl ligands $ER_2C_6H_5Cr(CO)_3$ (ER_2 = PEt_2, PPr^i_2, PBu^t_2, PPh_2, $AsPh_2$ $AsMe_2$), $ER[C_6H_5Cr(CO)_3]_2$ (ER = PEt, PBu^t, PPh, AsPh) has been achieved by reacting lithium derivatives of benzenechromium tricarbonyl with appropriate chlorophosphines or iodoarsines. The spectroscopic properties of these ligands are described. The structure of $Pr^i_2PC_6H_5Cr(CO)_3$ was determined by an X-ray crystallographic study. This is the first solid state structure to be reported for a phosphinobenzenechromium tricarbonyl derivative. The structures of four metal carbonyl cluster complexes were also determined. Crystals of $Pr^i_2PC_6H_5Cr(CO)_3$ (**3**, $C_{15}H_{19}CrO_3P$) are monoclinic, space group $P2_1/c$, a = 8.150(2) Å, b = 13.490(2) Å, c = 15.125(1) Å, β = 100.19(1)°, Z = 4; those of $Ru_3(CO)_{11}[PPr^i_2C_6H_5Cr(CO)_3]$ (**15**, $C_{26}H_{19}CrO_{14}PRu_3$) are monoclinic, space group $P2_1/n$, a = 8.565(2) Å, b = 21.808(3) Å, c = 17.167(3) Å, β = 97.41(2)°, Z = 4; those of $Ru_3(CO)_{10}[PPh_2C_6H_5Cr(CO)_3]_2$ (**19**, $C_{32}H_{15}CrO_{14}PRu_3$) are orthorhombic, space group $Pbca$, a = 17.367(4) Å, b = 24.471(5) Å, c = 16.096(3) Å, Z = 8; those of $Ru_3(CO)_{10}[PPr^i_2C_6H_5Cr(CO)_3]_2 \cdot CH_2Cl_2$ (**16**, $C_{40}H_{38}Cr_2O_{16}P_2Ru_3 \cdot CH_2Cl_2$) are orthorhombic, space group $P2_12_12$, a = 13.832(3) Å, b = 17.558(2) Å, c = 10.144(1) Å, Z = 2; and those of $Os_3(CO)_9[PEt_2C_6H_5Cr(CO)_3]_3$ (**26**, $C_{48}H_{45}Cr_3O_{18}Os_3P_3$) are trigonal, space group $P\bar{3}$, a = 15.7558(4) Å, c = 12.662(1) Å, Z = 2. The structures were solved by the Patterson method and were refined by full-matrix least-squares procedures to R = 0.031, 0.027, 0.029, 0.025, and 0.029 (R_w = 0.027, 0.024, 0.024, 0.023, and 0.025) for 2326, 4110, 3878, 3046, and 4093 reflections with $I \geq 3\sigma(I)$, respectively.

Key words: metal carbonyl clusters, phosphinobenzenechromium tricarbonyl derivatives, arsinobenzenechromium tricarbonyl derivatives, crystal structures.

Résumé : On a synthétisé un certain nombre de nouveaux ligands, les phospino et arsinobenzène chrome tricarbonyle $ER_2C_6H_5Cr(CO)_3$ (ER_2 = PEt_2, PPr^i_2, PBu^t_2, PPh_2, $AsPh_2$, $AsMe_2$), $Er[C_6H_5Cr(CO)_3]_2$, (ER = PEt, PBu^t, PPh, AsPh) en faisant réagir des dérivés lithiés du benzène chrome tricarbonyle avec les chlorophosphines ou les iodoarsines appropriés. On décrit les propriétés spectroscopiques de ces ligands. On a déterminé, par cristallographie de rayons X, la structure du composé $Pr^i_2PC_6H_5Cr(CO)_3$. Cette publication représente la première étude d'un dérivé phosphinobenzène chrome tricarbonyle dans l'état solide. On a également déterminé la structure des complexes de quatre agrégats de métal tricarbonyle. Les cristaux de $Pr^i_2C_6H_5Cr(CO)_3$ (**3**, $C_{13}H_{19}CrO_3P$) appartiennent au groupe d'espace monoclinique $P2_1/c$, avec a = 8,150(2) Å, b = 13,490(2) Å, c = 15,125(1) Å, β = 100,19(1)°, Z = 4; les cristaux de $Ru_3(CO)_{11}$ $[PPr^i_2C_6H_5Cr(CO)_3]$ (**15**, $C_{26}H_{19}CrO_{14}PRu_3$) appartiennent au groupe d'espace monoclinique $P2_1/n$, avec a = 8,565(2) Å, b = 21,808(3) Å, c = 17,167(3) Å, β = 97,41(2)°, Z = 4; les cristaux de $Ru_3(CO)_{10}[PPh_2C_6H_5Cr(CO)_3]_2$ (**19**, $C_{32}H_{15}CrO_{14}PRu_3$) appartiennent au groupe d'espace orthorhombique $Pbca$, avec a = 17,367(4) Å, b = 24,471(5) Å, c = 16,096(3) Å, Z = 8; les cristaux de $Ru_3(CO)_{10}[PPr^i_2C_6H_5Cr(CO)_3]_2 \cdot C_2Cl_2$ (**16**, $C_{40}H_{38}Cr_2O_{16}P_2Ru_3 \cdot CH_2Cl_2$) appartiennent au groupe d'espace orthorhombique $P2_12_12$, avec a = 13,832(3) Å, b = 17,558(2) Å, c = 19,144(1) Å, Z = 2; et les cristaux de $Os_3(CO)_9[PEt_2C_6H_5Cr(CO)_3]_3$ (**26**, $C_{48}H_{45}Cr_3O_{18}Os_3P_3$) appartiennent au groupe d'espace trigonal $P\bar{3}$, avec a = 15,7558(4) Å, c = 12,662(1) Å, Z = 2. On a résolu les structures par la méthode de Patterson et on les a affinées par la méthode des moindres carrés, matrice complète, jusqu'à des valeurs de R = 0,031, 0,027, 0,029, 0,025 et 0,029 (R_w = 0,027, 0,024, 0,024, 0,023 et 0,025) pour respectivement 2326, 4110, 3878, 3046 et 4093 réflexions avec $I \geq 3\sigma(I)$.

Mots clés : agrégats de métal carbonyle, dérivés phosphinobenzène chrome tricarbonyle, dérivés arsinobenzène chrome tricarbonyle, structures des cristaux.

Introduction

The pyrolysis of metal cluster derivatives of arylphosphines and arsines has proved to be a fruitful procedure for the preparation of cluster-bound arynes such as benzyne, ferrocyne, and naphthyne (1–3). We have also described how similar reactions give rise to derivatives of benzynechromium tricarbonyl (4). The present paper is principally concerned with the preparation and characterization of some metal carbonyl derivatives of the type $M_3(CO)_{12-n}(ER_2Ar')_n$ (M = Ru, Os; E = As, P; R = alkyl, aryl; Ar' = $(\eta^6\text{-}C_6H_5)Cr(CO)_3$; n = 1, 2) that have been used as precursors in the synthesis of aryne derivatives. We also describe the preparation of seven new phosphines and arsines containing the $(\eta^6\text{-}C_6H_5)Cr(CO)_3$ moiety.

Experimental

Unless otherwise stated, all reactions and subsequent manipulations involving organometallic reagents were conducted under an argon atmosphere by using standard Schlenk and vacuum line techniques.

Phosphorus trichloride, chlorodiethylphosphine, dichloroethylphosphine, chlorodiphenylphosphine, and dichlorophenylphosphine were purchased from Strem Chemicals Inc. They were stored under argon after distillation under reduced pressure. The purity of all phosphines was ascertained by using $^{31}P\{^1H\}$ NMR spectroscopy. Ruthenium trichloride (kindly loaned by Johnson Matthey Ltd.), *n*-butyllithium (Aldrich), chromium hexacarbonyl (Strem), and osmium carbonyl (Steck) were used as received.

Column chromatography was carried out by using silica gel (230–400 mesh) or neutral alumina (80–200 mesh, Brockman Activity I) obtained from BDH Co.

^1H NMR spectra were recorded on Varian XL-300 (299.94 MHz), Bruker WH-400 or a WH-200FT (400.00 MHz, or 200.00 MHz) spectrometers, and are referenced to $CDCl_3$ or CD_2Cl_2 set at 7.25 ppm, and 5.32 ppm, respectively, at ambient temperature. $^{31}P\{^1H\}$ NMR spectra were recorded on Varian XL-300 (121.42 MHz) or Bruker WH-200 (80.96 MHz) spectrometers and are referenced to external PPh_3 ($CDCl_3$) set at −5.6 ppm relative to 85% H_3PO_4 (aq) unless otherwise indicated. All chemical shifts are reported in ppm and coupling constants in Hz.

Infrared spectra were recorded by using a Perkin–Elmer 598, 783 or 1710 FTIR spectrophotometer. The spectra were calibrated by using the 1601 cm^{-1} band of polystyrene.

Low-resolution electron impact (EI) mass spectra were obtained by using a Kratos/AEI MS902 mass spectrometer, which was operated in the direct insertion mode (70 eV, 120–150°C source temperature). Fast atom bombardment (FAB) mass spectra were measured using an updated MS-9 mass spectrometer equipped with a FAB source. The matrix was 3-nitrobenzyl alcohol.

The following reagents were prepared by literature methods: $C_6H_5Cr(CO)_3$ (5), $Ru_3(CO)_{12}$ (6), $Os_3(CO)_{11}(CH_3CN)$, $Os_3(CO)_{10}(CH_3CN)_2$ (7), $(CH_3)_2AsI$ (8), Bu^t_2PCl (9), $(CH_3CN)_3Cr(CO)_3$ (10), $Ru_3(CO)_{11}(CH_3CN)$ (11), $Na[(C_6H_5)_2CO]$ (~0.025 M in THF) (12).

Preparation of Bu^tPCl_2

A freshly prepared Grignard solution of Bu^tMgCl (2 M, 250 mL) was added dropwise with stirring to phosphorus trichloride (68.5 g, 44 mL, 0.5 mol) dissolved in diethyl ether (200 mL) at −20°C: the temperature of the reaction mixture was then allowed to rise to room temperature. The mixture was refluxed for 1 h and then filtered to remove the white solid. Distillation of the filtrate under reduced pressure gave Bu^tPCl_2 as a colorless liquid (35 g, 45%), which solidified on standing, bp 143–148°C (760 Torr; 1 Torr = 133.3 Pa). $^{31}P\{^1H\}$ NMR (121.4 MHz, C_6D_6) δ: 199.9 (s). ^1H NMR (300 MHz, C_6D_6) δ: 1.0 (d).

Preparation of Pr^iPCl_2

A Grignard solution of Pr^iMgCl in ether (1.25 M, 800 mL) was added dropwise to a stirred diethyl ether solution of PCl_3 (55.0 g, 26 mL, 0.4 mol). A white precipitate formed during the addition and the reaction mixture was refluxed for an additional 2 h. The solution was separated from the precipitate by filtration through a medium porosity Schlenk filter. The ether solvent was removed by distillation at atmospheric pressure and the oily residue was distilled under reduced pressure. The product was an air-sensitive, colorless liquid (30 g, 65%), bp 27°C (3 mmHg). $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 139.2 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 1.80–1.91 (m, 2H), 1.05 (q, 6H).

Preparation of $[C_6H_5Cr(CO)_3]PBu^t_2$, 2

A solution of $C_6H_6Cr(CO)_3$ (1.0 g, 4.7 mmol) in THF (20 mL) in a Schlenk tube was cooled to −78°C and treated dropwise with *n*-BuLi in hexane (3.0 mL, 1.6 M, 4.8 mmol). The resulting solution was stirred at −78°C for 50 min, when Bu^t_2PCl (1.0 mL, 5.2 mmol) was added. The reaction mixture was stirred at −78°C for 1 h, warmed to room temperature, and stirred continuously for an additional hour. After evaporating the solvent in vacuo, the residual oil was dissolved in CH_2Cl_2 (20 mL) and then filtered under nitrogen through a frit packed with Celite to remove LiCl. The solvent was removed in vacuo to afford a red oil. Hexane (5 mL) was added to the red oil, the resultant suspension was stirred vigorously, and a yellow pre-

cipitate was obtained. The solid was further purified by recrystallization from hexane–CH_2Cl_2 (2/1) to yield **2** as a yellow crystalline solid: yield 80%. IR (KBr) ν(CO): 1960 (vs), 1900 (vs), 1880 (s), 1870 (sh), 1865 (s) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.42 MHz, $CDCl_3$) δ: 42.8 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.7 (t, J(H-H) = 6Hz, 2H), 5.6 (t, *J*(H–H) = 6 Hz, 1H), 5.2 (t, *J*(H–H) = 6 Hz, 2H), 1.2 (d, *J*(P–H) = 10 Hz, 18H). MS (EI) *m/e*: 358 [P^+]. Anal. calcd. for $C_{17}H_{23}CrO_3P$: C 56.97, H, 6.47; found: C 56.80, H 6.52.

Preparation of $[C_6H_5Cr(CO)_3]PPr^i_2$, 3

Compound **3** was synthesized by the procedure described for the preparation of **2** except that Pr^i_2PCl (0.75 mL, 5.0 mmol) was used instead of Bu^t_2PCl. Yellow crystals of **3** were obtained after recrystallization from hexanes–CH_2Cl_2 (2:1) at −30°C (1.1 g, 70%). IR (KBr) ν(CO): 1970 (s), 1880 (s, br) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.42 MHz, $CDCl_3$) δ: 13.9 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.33 (t, *J*(H–H) = 5 Hz, 3H), 5.18 (t, *J*(H–H) = 5 Hz, 2H), 1.95 (q, 2H), 1.05 (dd, *J*(H–H) = 5.5 Hz, 12H). MS (EI) *m/e*: 330 [P^+]. Anal. calcd. for $C_{15}H_{19}CrO_3P$: C 54.55, H 5.76; found: C 54.72, H 5.87.

Preparation of $[C_6H_5Cr(CO)_3]PEt_2$, 4

Chlorodiethylphosphine (0.97 mL, 8.0 mmol) was similarly used to afford **4** as a red oil, which was ~90% pure according to its ^{31}P NMR spectrum. ν(CO): 1978 (s), 1885 (s) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.42 MHz, $CDCl_3$) δ: −13 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.4 (t, *J*(H–H) = 6 Hz, 3H), 5.2 (t, *J*(H–H) = 6 Hz, 2H), 1.8 (q, 4H), 1.2 (m, 6H). IR (CH_2Cl_2) MS (EI) *m/e*: 302 [P^+].

Preparation of $[C_6H_5Cr(CO)_3]AsMe_2$, 5

A similar procedure was used to prepare **5** from Me_2AsI as a yellow solid (70% yield). IR (KBr) ν(CO): 1960 (s), 1880 (s, br) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.4 (S, 6H), 5.5 (t, *J*(H–H) = 5.5 Hz, 3H), 5.3 (t, *J*(H–H) = 5.5 Hz, 2H). MS (EI) *m/e*: 318 [P^+]. Anal. calcd. for $C_{11}H_{11}AsCrO_3$: C 41.53, H 3.49; found: C 41.63, H 3.49.

Preparation of $[C_6H_5Cr(CO)_3]PPh_2$, 1

A similar procedure was used to prepare **1** from Ph_2PCl as a yellow crystalline solid (85% yield). IR (KBr) ν(CO): 1980 (s), 1900 (s, br) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.42 MHz, $CDCl_3$) δ: −5.2 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.4 (br s, 10H), 5.4 (t, 1H), 5.2 (m, 4H). MS (EI) *m/e*: 398 [P^+].

Preparation of $[C_6H_5Cr(CO)_3]_2AsPh_2$, 6

A similar procedure was used to synthesize **6** from Ph_2AsI as a yellow crystalline solid (80% yield). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.4 (br s, 10H), 5.3 (br s, 1H), 5.2 (br s, 4H). MS (EI) *m/e*: 358 [P^+]. Anal. calcd. for $C_{21}H_{15}O_3AsCr$: C 57.03, H 3.42. Found: C 56.74, H 3.21.

Preparation of $[C_6H_5Cr(CO)_3]_2PBu^t$, 8

Benzenechromium tricarbonyl (1.62 g, 7.55 mmol) was dissolved in THF (25 mL) at −78°C. A solution of *n*-butyllithium in hexane (4.8 mL, 1.6 M, 7.7 mmol) was added slowly with a syringe to the cold, stirred solution. The solution was then stirred at −78°C for 50 min. Cl_2PBu^t (0.65 g, 4 mmol) in THF (10 mL) was then added dropwise with a syringe to the solution. The reaction mixture was stirred at −78°C for an additional hour and allowed to warm to room temperature. The solvent was evaporated in vacuo. The residual red oil was dissolved in CH_2Cl_2 (20 mL) and then filtered through a short column of silica gel under nitrogen. Dark red impurities and LiCl were left on the top of the column. Evaporation of the eluate followed by crystallization of the solid residue from CH_2Cl_2–hexanes (1:2) afforded **8** (70% yield) as a yellow crystalline solid. IR (KBr) ν(CO): 1970 (s), 1890 (s, br) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.42 MHz, $CDCl_3$) δ: 20.7 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.7 (t, *J*(H–H) = 6 Hz, 2H), 5.4 (t, *J*(H–H) = 6 Hz, 4H), 5.2 (d, *J*(H–H) = 6 Hz, 4H). 1.2 (d, *J*(P–H) = 10 Hz, 9H). MS (EI) *m/e*: 514 [P^+]. Anal. calcd. for $C_{22}H_{21}Cr_2O_3P$: C 51.37, H 3.72; found: C 51.27, H 3.71.

Preparation of $[C_6H_5Cr(CO)_3]_2PEt$, 9

The same procedure used for the synthesis of **8** was followed for the preparation of **9** from $EtPCl_2$, as a yellow crystalline solid (65% yield). IR (KBr) ν(CO): 1962 (s), 1851 (s, br) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.42 MHz, $CDCl_3$) δ: −5.5 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.4 (t, *J*(H–H) = 6 Hz, 6H), 5.2 (t, *J*(H–H) = 6 Hz, 4H), 1.8 (q, *J*(H–H) = 6 Hz, 4H), 1.2 (m, 6H). MS (EI) *m/e*: 486 [P^+]. Anal. calcd. for $C_{20}H_{15}O_6Cr_2P$: C 49.39, H 3.12; found: C 49.75 H 3.34.

Preparation of $[C_6H_5Cr(CO)_3]PPh$, 7

The same procedure was followed for the preparation of **7** from $PhPCl_2$ as a yellow crystalline solid (70% yield). IR (Nujol) νCO): 1970 (s), 1900 (s, br), cm^{-1}. $^{31}P\{^1H\}$ NMR (121.42 MHz, $CDCl_3$) δ: −4.0 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.3–7.6 (m, 5H), 5.6 (t, *J*(H–H) = 6 Hz, 4H), 5.3 (t, *J*(H–H) = 6 Hz, 2H), 5.2 (d, *J*(H–H) = 6 Hz, 4H). MS (EI) *m/e*: 534 [P^+]. Anal. calcd. for $C_{24}H_{15}CrO_6P$: C 53.94, H 2.83; found: C, 53.60, H 2.85.

Preparation of $[C_6H_5(CO)_3]AsPh_2$, 10

The same procedure was followed for the preparation of **10** from $PhAsI_2$ as a yellow solid (70% yield). MS (EI) *m/e*: 578 [P^+]. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.4 (br s, 5H), 5.5 (t, 4H), 5.3 (t, 2H), 5.15 (s, 4H). Anal. calcd. for $C_{24}H_{15}CrO_6As$: C 49.84, H 2.62; found: C 49.50, H 2.43.

Procedure A. Preparation of $Ru_3(CO)_{11}][AsMe_2(C_6H_5Cr(CO)_3)]$, 11

A freshly prepared $Na(Ph_2CO)$ solution was added dropwise to a rapidly stirred solution of $Ru_3(CO)_{12}$ (200 mg, 0.31 mmol) and $(CH_3)_2As[C_6H_5Cr(CO)_3]$ (100 mg, 0.31 mmol) in THF (25 mL) until the solution darkened in color (typically 5–10 drops). When TLC examination of the reaction mixture showed that no starting material remained, the solvent was removed *in vacuo*. The resulting dark red oil was dissolved in CH_2Cl_2 (3 mL) and was chromatographed on a silica gel column with CH_2Cl_2–hexanes (1:1.4) as eluent to give three bands. Band 1 (yellow) was $Ru_3(CO)_{12}$ (trace amount) identified by IR spectroscopy and TLC. Band 3 was the disubstituted ruthenium cluster $Ru_3(CO)_{10}[AsMe_2(C_6H_5Cr(CO)_3)]_2$ **8** (trace amount). Band 2 gave red crystalline **11** (245 mg, 85% yield). IR (KBr) ν(CO): 2100 (m), 2040 (s), 2020 (s), 1890 (sh), 1900 (s) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$) δ: 1.9 (s, 6H), 5.3 (t, *J*(H–H) = 6.6 Hz, 2H), 5.4 (d, *J*(H–H) = 6 Hz, 2H), 5.6 (t, *J*(H–H) = 6.6 Hz, 1H). Mass spectrum (FAB): *m/e*: 931 [P^+]. Anal. calcd. for $C_{22}H_{11}AsCrO_{14}Ru_3$: C 28.43, H 1.20; found: C 28.14, H 1.23.

Procedure B. Preparation of $Ru_3(CO)_{10}[AsMe_2(C_6H_5Cr\text{-}(CO)_3)]_2$, 12

The title compound was prepared in a way similar to that used for the monosubstituted compound **11** except that a little over 2 equivalents of the arsine (210 mg, 0.62 mmol) was used. The product was purified by using column chromatography with CH_2Cl_2–hexanes (1:1) as eluent and was isolated in 70% yield. ^1H NMR (300 MHz, $CDCl_3$) δ: 5.5 (t, J(H–H) = 6 Hz, 2H), 5.4 (d, J(H–H) = 6.3 Hz, 4H), 5.2 (m, 4H), 1.8 (s, 12H). Mass spectrum (FAB): *m/e*: 1223 [P^+]. Anal. calcd. for $C_{32}H_{22}As_2Cr_2ORu_3$: C 31.51, H 1.82; found: C 31.29, H 1.93.

Procedure C. Preparation of $Os_3(CO)_{11}[AsMe_2(C_6H_5Cr(CO)_3)]$, 13

The compound $[Os_3(CO)_{11}(MeCN)]$ (200 mg, 0.22 mmol) was stirred in CH_2Cl_2 (30 mL) with $Me_2AsC_6H_5Cr(CO)_3$ (70 mg, 0.22 mmol) for 2 h at room temperature to afford a clear yellow solution. Silica gel (200–400 mesh, 5 mL) was then added to the crude solution and the solvent was removed *in vacuo*. The dried residual silica gel was added to the top of a silica gel column. By using CH_2Cl_2–hexanes (1:1:8) as eluent, the pure yellow **13** was obtained in 90% yield (235 mg) from the first band. ^1H NMR (300 MHz, $CDCl_3$) δ: 5.5 (t, 1H), 5.4 (d, 2H), 5.2 (t, 2H), 2.0 (s, 6H). Mass spectrum (FAB) *m/e*: 1198 [P^+]. Anal. calcd. for $C_{22}H_{11}AsCrO_{14}Os_3$: C 22.08, H 0.93; found: C 22.16, H 0.98. The second band that was eluted gave a small amount of the disubstituted cluster derivative identified by using mass spectrometry.

Procedure D. Preparation of $Os_3(CO)_{10}[AsMe_2C_6H_5Cr(CO)_3]_2$, 14

The procedure used for the preparation of **14** was identical to that used for **13** with the exception that $[Os_3(CO)_{10}(MeCN)_2]$ (100 mg, 0.1 mmol) was used. Pure **14** was thus obtained in 70% yield. ^1H NMR (300 MHz, $CDCl_3$) δ: 5.5 (t, 4H), 5.2 (t, 6H), 1.9 (s, 12H).Mass spectrum (FAB) *m/e*: 1487 [P^+]. Anal. calcd. for $C_{32}H_{22}As_2Cr_2O_{16}Os_3$: C 25.85, H 1.49; found: C 25.71, H 1.57.

Procedure E. Preparation of $Ru_3(CO)_{11}[PPr^i2C_6H_5Cr(CO)_3]$, 15

Addition of PPN^+Cl^- (10 mg) to a solution of $Ru_3(CO)_{12}$ (200 mg, 0.31 mmol) and $Pr^i{}_2PC_6H_5(CO)_3$ (103 mg, 0.31 mmol) in THF (40 mL) resulted in gas evolution. After stirring for 30 min, the solvent was removed from the red solution under reduced pressure. The residue was dissolved in CH_2Cl_2 (2 mL) and applied to a silica gel column, with CH_2Cl_2–hexanes (1:1.7) as eluent. The first band proved to contain $Ru_3(CO)_{12}$ and the third band was characterized as $Ru_3(CO)_{10}[PPr^i{}_2C_6H_5(CO)_3]_2$. The major second band afforded **15** as a red powder in 80% yield after solvent evaporation. Crystals of **15** were grown from CH_2Cl_2–hexanes (1:2.5) at −30°C. The crystals thus obtained were washed with hexanes and dried in vacuo for 1 min. IR (CH_2Cl_2) ν(CO): 2100 (s), 2049 (vs), 2017 (vs), 1978 (vs), 1907 (vs) cm^{-1}. 942 [P^+]. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 58.9 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.7 (t, J(H–H) = 6.2 Hz, 3H), 5.2 (t, J(H–H) = 6.3 Hz, 2H), 2.5 (m, 2H), 1.2–1.4 (m, 12H). Mass spectrum (FAB) *m/e*: Anal. calcd. for $C_{26}H_{19}CrO_{14}PRu_3$: C 33.16, H 2.03; found: C 32.84, H 1.90.

Procedure F. Preparation of $Ru_3(CO)_{10}[Pr^i{}_2PC_6H_5Cr(CO)_3]_2$, 16

The title complex was prepared in the same manner as described for the preparation of the monosubstituted cluster **15** except that a little over 2 molar equivalents of $Pr^i{}_2PC_6H_5Cr(CO)_3$ (215 mg, 0.65 mmol) was used. Following chromatography with CH_2Cl_2–hexanes (1:1.3) as eluent, pure **16** was obtained in 70% yield as a dark red powder. X-ray-quality crystals were grown from CH_2Cl_2–hexanes (1:2.5) at −4°C. IR (KBr) ν(CO): 2022 (s), 1973 (vs), 1903 (vs) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 54.6 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.75 (t, 6H), 5.2 (t, J(H–H) = 6.3 Hz, 4H), 2.5 (m, J(H–H) = 6.1 Hz, 4H), 1.2–1.4 (m, 24H). Mass spectrum (FAB) *m/e*: 1244 [P^+]. Anal. calcd. for $C_{41}H_{40}Cl_2Cr_2O_{16}P_2Ru_3$: C 37.06, H 3.04. found: C 37.03, H 2.97.

Preparation of $Os_3(CO)_{11}[Pr^i{}_2PC_6H_5Cr(CO)_3]$, 17

The yellow complex **17** was obtained in 80% yield by using procedure **C**. IR (KBr) ν(CO): 2100 (w), 2050 (s), 2030-2000 (vs, br), 1990-1960 (vs, br), 1940 (w), 1910 (s), 1890 (s) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 27.8 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.7 (t, 3H), 5.2 (t, 2H), 2.5 (m, 2H), 1.2-1.4 (m, 12H). Mass spectrum (FAB) *m/e*: 1209 [P^+]. Anal. calcd. for $C_{26}H_{19}CrO_{14}Os_3P$: C 25.83, H 1.59; found: C 25.89, H 1.59.

Preparation of $Os_3(CO)_{10}[Pr^i{}_2PC_6H_5Cr(CO_3]_2$, 18

The yellow complex **18** was isolated in 80% yield by using procedure **D**. IR (KBr) ν(CO): 2080 (m), 2010 (sh), 2000 (vs), 1970 (vs), 1900 (s, br) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 21.7 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.7 (t, 6H), 5.2 (t, 4H), 2.4 (m, 4H), 1.1–1.4 (m, 24H). Mass spectrum (FAB) *m/e*: 1513 [P^+]. Anal. calcd. for $C_{40}H_{38}Cr_2O_{16}Os_3P_2$: C 31.79, H 2.54; found: C 31.63, H 2.50.

Preparation of $Ru_3(CO)_{11}[Ph_2PC_6H_5Cr(CO)_3]$, 19

The complex **19** was isolated, by following procedure **A**, as a red powder (~70% yield). This powder was dissolved in CH_2Cl_2 (10 mL), layered with hexanes (20 mL), and stored in a freezer for a week to give red-orange prism-like crystals. IR (Nujol) ν(CO): 2100 (s), 2060 (sh), 2040 (s), 2020 (vs), 2000 (vs), 1970 (vs), 1960 (sh), 1900 (s) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 37.3 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.4–7.6 (br s, 10H), 5.6 (t, J(H–H) = 6 Hz, 3H), 5.1 (t, J(H–H) = 6 Hz, 2H). Mass spectrum (FAB) *m/e*: 1011 [P^+]. Anal. calcd. for $C_{32}H_{15}CrO_{14}PRu_3$: C 38.07, H 1.50; found: C 38.21, H 1.55.

$Ru_3(CO)_{10}[Ph_2PC_6H_5Cr(CO)_3]_2$, 20

Compound **20** was isolated in 60% yield by following procedure **B**. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 36.5 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.4–7.6 (br s, 5H), 5.5 (t, 6H), 5.1 (t, 4H). Mass spectrum (FAB) *m/e*: 1381 [P^+]. Anal. calcd. for $C_{52}H_{30}Cr_2O_{16}P_2Ru_3$: C 45.26, H 2.20; found: C 45.39, H 2.28.

Preparation of $Os_3(CO)_{11}[Ph_2PC_6H_5Cr(CO)_3]$, 21

Solid **21** was obtained in 80% yield by following procedure **C**. IR (KBr): ν(CO) 2150 (s), 2060 (vs), 2020 (vs), 2000 (vs), 1970 (vs), 1900 (vs) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, CD_2Cl_2) δ: 0.3 (s). ^1H NMR (300 MHz, CD_2Cl_2) δ: 7.5 (m, 10H), 5.8 (td, J(H–H) = 5.8 Hz, 1H), 5.6 (td, J(H–H) = 5.7 Hz,

2H), 5.2 (td, J(H–H) = 5.8 Hz, 2H). Mass spectrum (FAB) *m/e*: 1277 [P^+]. Anal. calcd. for $C_{32}H_{15}CrO_{14}Os_3P$: C 30.07, H 1.19; found: C 30.15, H 1.23.

Preparation of $Ru_3(CO)_{11}[Et_2PC_6H_5Cr(CO)_3]$, 22

Compound **22** was obtained in 85% yield by using procedure **A**. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 28.2 (s). IR (KBr): 2100 (s), 2040 (s), 2020 (s), 1980 (vs), 1970 (vs), 1950 (s), 1900 (s), 1870 (s) cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$) δ: 5.5 (td, J(H–H) = 7 Hz, 1H), 5.3 (td, J(H–H) = 7 Hz, 2H), 5.2 (2dd, J(H–H) = 7 Hz, 2H), 2.0–2.4 (m, 4H), 1.2–1.4 (2t, J(H–H) = 7 Hz, 6H). Mass spectrum (FAB) *m/e*: 915 [P^+]. Anal. calcd. for $C_{24}H_{15}CrO_{14}PRu_3$: C 31.55, H 1.66; found: C 31.47, H 1.66.

Preparation of $Ru_3(CO)_{10}[Et_2PC_6H_5Cr(CO)_3]_2$, 23

The dark red product **23** was isolated in 75% yield by using procedure **B**. IR (KBr) ν(CO): 2070 (w), 2020 (s), 2000–1910 (s, br), 1910–1880 (s, br), cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 28.4 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.6 (t, J(H–H) = 7 Hz, 1H), 5.4 (t, J(H–H) = 7 Hz, 2H), 5.2 (d, J(H–H) = 7 Hz, 2H), 2.0–2.4 (m, 8H), 1.2–1.5 (2t, J(H–H) = 7 Hz, 12H). Mass spectrum (FAB) *m/e*: 1189 [P^+]. Anal. calcd. for $C_{38}H_{32}Cl_2Cr_2O_{16}P_2Ru_3$: C 34.91, H 2.54; found: C 34.74, H 2.59.

Preparation of $Os_3(CO)_{11}[Et_2PC_6H_5Cr(CO)_3]$, 24

The yellow product **24** was obtained in 80% yield by following procedure **E**.IR (KBr) ν(CO): 2100 (m), 2060 (s), 2030 (s), 2000 (vs), 1980 (sh), 1970 (vs), 1910 (s), 1900 (sh), 1880 (s), 1870 (sh), cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: −9.1 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.5 (t, J(H–H) = 7 Hz, 1H), 5.4 (t, J(H–H) = 7 Hz, 2H), 5.2 (d, J(H–H) = 7 Hz, 2H), 2.2–2.4 (m, 4H), 1.2–1.4 (t, J(H–H) = 7 Hz, 6H). Mass spectrum (FAB) *m/e*: 1182 [P^+]. Anal. calcd. for $C_{24}H_{15}CrO_{14}Os_3P$: C 24.40, H, 1.28; found: C 24.56, H 1.31.

Preparation of $Os_3(CO)_{10}[Et_2PC_6H_5Cr(CO)_3]_2$, 25

The use of procedure **D** afforded **25** in 70% yield. IR (KBr) ν(CO): 2075 (m), 2010 (sh), 1980 (vs, br), 1890 (s, br) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: −9.8 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.5 (t, J(H–H) = 7 Hz, 1H), 5.3 (t, J(H–H) = 7 Hz, 2H), 5.2 (d, J(H–H) = 7 Hz, 2H), 2.2–2.6 (m, 4H), 1.2–1.5 (2t, J(H–H) = 7 Hz, 6H). Mass spectrum (FAB) *m/e*: 1456 [P^+]. Anal. calcd. for $C_{36}H_{30}Cr_2O_{16}Os_3P_2$: C 29.71, H 2.08. found: C 29.96, H 2.14.

Preparation of $Os_3(CO)_9[Et_2PC_6H_5Cr(CO)_3]_3$, 26

A solution of $Os_3(CO)_{11}[Et_2PC_6H_5Cr(CO)_3]$ (300 mg) was heated in refluxing n-octane under a nitrogen atmosphere for 15 h. After this time TLC showed that no starting material was present. The solvent was then removed under reduced pressure and the resulting brown oil was transferred to a silica gel column. Elution with hexane gave one yellow band, which was $Os_3(CO)_{12}$, as identified by IR spectroscopy. Subsequent elution with hexanes–CH_2Cl_2 (1:1.7) afforded three bands. Bands 1 and 3 contained trace amounts of unidentified products. The major band 2 contained the complex **26**. Orange crystals suitable for X-ray structure analysis were grown from hexanes–CH_2Cl_2 (3:1) at −30°C. IR (KBr) ν(CO): 1965 (vs, br), 1930 (s), 1890 (vs, Br) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: −15.9 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 5.6 (t, J(H–H) = 7 Hz, 3H), 5.4 (t, J(H–H) = 7 Hz, 6H), 5.2 (d, J(H–H) = 7 Hz, 6H), 2.0–2.5 (m, 12H), 1.2–1.4 (m, 18H). Mass spectrum (FAB) *m/e*: 1729 [P^+]. Anal. calcd. for $C_{48}H_{45}Cr_3Os_3P_3$: C 33.33, H 2.63; found: C 32.93, H 2.62.

Preparation of $Ru_3(CO)_{11}[PhP\{C_6H_5Cr(CO)_3\}_2]$, 27

The title compound was prepared by three different methods but always in low yield. Method **A** resulted in 25% yield and method **E** in 15% yield. An excess of $PhP[C_6H_5Cr(CO)_3]_2$ (200 mg) was added to a cool solution of $Ru_3(CO)_{11}(MeCN)$ (100 mg, 0.15 mmol, 20 mL of CH_2Cl_2) generated in situ. The resulting solution was stirred for 1 h and the solvent was removed *in vacuo*. The ^{31}P NMR spectrum of the crude product indicated the presence of **27** in low yield.

27: yellow solid. IR (CH_2Cl_2) ν(CO): 2100 (s), 2050 (s), 2040 (s), 1970 (s), 1900 (s) cm^{-1}. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 37.6 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.4–7.6 (m, 5H), 5.8 (m, 6H), 5.3 (m, 4H). Mass spectrum (FAB) *m/e*: 1147 [P^+]. Anal. calcd. for $C_{35}H_{15}Cr_2O_{17}PRu_3$: C 36.69, H 1.32; found: C 36.65, H 1.40.

Preparation of $Os_3(CO)_{11}[PhP\{C_6H_5Cr(CO)_3\}_2]$, 28

The yellow solid **28** was isolated in 50% yield by using procedure **C**. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 0.1 (s). ^1H NMR (300 MHz, $CDCl_3$) δ: 7.6 (m, 2H), 7.4 (m, 3H), 5. 7 (t, 6H), 5.4 (q, 4H). Mass spectrum (FAB) *m/e*: 1415 [P^+]. Anal. calcd. for $C_{35}H_{15}Cr_2O_{17}Os_3P$: C 29.75, H, 1.07; found: C 29.50, H 1.31.

Preparation of $Ru_3(CO)_{11}[Ph_2AsC_6H_5Cr(CO)_3]$, 29

The red product **29** was obtained in 10% yield by following procedure **A**. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$) δ: 7.3 (m, 10H), 5.3 (t, 2H), 5.1 (3H). Mass spectrum (FAB) *m/e*: 1054 [P^+]. Anal. calcd. for $C_{32}H_{15}AsCrO_{14}Ru_3$: C 36.48, H 1.44; found: C 36.64, H 1.56.

X-ray crystallographic analyses

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 27.8–33.1° for **3**, 35.7–40.1° for **15**, 20.1–30.7° for **19**, 30.1°–36.8° for **16**, and 40.1°–45.5° for **26**. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, decayed linearly by 7.8% for **15** and by 2.1% for **19** and showed only small random fluctuations for other complexes. The data were processed and corrected for Lorentz and polarization effects, decay (where appropriate), and absorption (empirical, based on azimuthal scans for three reflections).[2]

The structures were solved by the Patterson method. The structural analysis of **26** was initiated in the centrosymmetric space group $P\bar{3}$ on the basis of the E-statistics and the Patterson function. This choice was confirmed by subsequent calculations. Complex **16** has exact (crystallographic) C_2 symmetry and complex **26** has exact C_3 symmetry.

The dichloromethane solvent in **16** was modeled as 1:1 disordered over two sites, both carbon atoms lying on the twofold

[a]Temperature 294 K, Rigaku AFC6S diffractometr, MoK_α (λ = 0.71069 Å) radiation, graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1), $\sigma U2.(F^2) = [S^2(C + 4B)]/Lp^2$ (S = scan rate, C = scan rate, C = scan count, B = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

axis. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in calculated positions (C—H = 0.98 Å, $B_H = 1.2\ B_{bonded\ atom}$). Secondary extinction corrections were applied for **3** and **26**, the final values of the extinction coefficients being $1.13(3) \times 10^{-6}$ and $3.9(2) \times 10^{-7}$, respectively. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (13). A parallel refinement of the mirror image of **16** gave significantly higher residuals, the R and R_w ratios being 1.083 and 1.100, respectively. Final atomic coordinates and equivalent isotropic thermal parameters, selected bond lengths, and selected bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, bond lengths, bond angles, torsion angles, intermolecular contacts, and least-squares planes are included as supplementary material.[3]

Results and Discussion

Two different strategies were utilized previously to prepare

[3] Copies of material on deposit may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2. Tables of hydrogen atom coordinates and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallograhic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, 12 Union Road, Cambridge CB2 1EZ, UK.

[b] Occupancy 0.50.

phosphino- and arsinobenzenechromium tricarbonyl derivatives. The first was the thermal replacement of three carbonyls from $Cr(CO)_6$ by an aryl group attached to the phosphine. Thus, refluxing the arylphosphine and chromium hexacarbonyl in a decalin solution gives rise to two series of complexes: monomeric $R_2PC_6H_5Cr(CO)_3$ and dimeric $[R_2PC_6H_5Cr(CO)_2]_2$. This route gives low yields, requires considerable time, and is limited in scope (14). For some phosphines, such as Ph_3P and $(m\text{-tolyl})_3P$, only the dimers are isolated (14).

The second strategy employed for the formation of $R_2PC_6H_5Cr(CO)_3$ involves the reaction of a chlorophosphine with the lithium derivative of benzenechromium tricarbonyl $(\eta^6\text{-}LiC_6H_5)Cr(CO)_3$, in THF or Et_2O, at low temperature. Two indirect routes to the lithiated intermediate have been developed; one involves a *trans*-metallation reaction between bis(η^6-phenyltricarbonylchromium)mercury and *n*-butyllithium (15). The second, more efficient, route involves *trans*-metallation of $[\eta^6\text{-}(Bu^n{}_3Sn)C_6H_5]Cr(CO)_3$ with *n*-BuLi in THF at −78°C (16). The butyltin derivative can be synthesized by the reaction of $(MeCN)_3Cr(CO)_3$ with (tributylstannyl)benzene.

Semmelhack et al. (17) developed a high-yield direct lithiation method involving addition of *n*-BuLi to $C_6H_6Cr(CO)_3$ in THF at −78°C in the presence of TMEDA. Subsequent addition of halophosphine or arsine affords the desired phosphino- and arsinobenzenechromium tricarbonyl derivatives. This method was adopted for the present investigation; 10 complexes (**1–10**) were prepared in this work including the three known compounds $Ph_2PC_6H_5Cr(CO)_3$ **1**, $PhP[C_6H_5Cr(CO)_3]_2$ **7**, and $Ph_2AsC_6H_5Cr(CO)_3$ **6**, which were isolated in higher yields than previously reported (16*a*, 18). In our hands the yields of the $R_2P[C_6H_5Cr(CO)_3]$ phosphines are higher than those of $RP[C_6H_5Cr(CO)_3]_2$. Recrystallization is best employed as a purification method because of the possibility of decomposition of the compounds on silica gel or alumina. Compounds **1–10** are all yellow solids, except $Et_2PC_6H_5Cr(CO)_3$, **4**, which is a red oily liquid; all are soluble in a range of organic solvents. In the solid state, the compounds are stable for long periods of time under an inert atmosphere. In general, their spectroscopic properties are much as expected. The ^{31}P NMR shifts can be fitted reasonably well to the Grim and McFarlane equation (19): δ (w.r.t. 85% H_3PO_4) = $-62 + \Sigma\sigma^P$ if σ^P for the $C_6H_5Cr(CO)_3$ moiety is taken as +20.

The crystal structure of $Pr^i{}_2P(C_6H_5)Cr(CO)_3$ **3** is shown in Fig. 1 and selected bond lengths and bond angles appear in

Fig. 1. Molecular structure of $Pr^i_2PC_6H_5Cr(CO)_3$, **3**; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

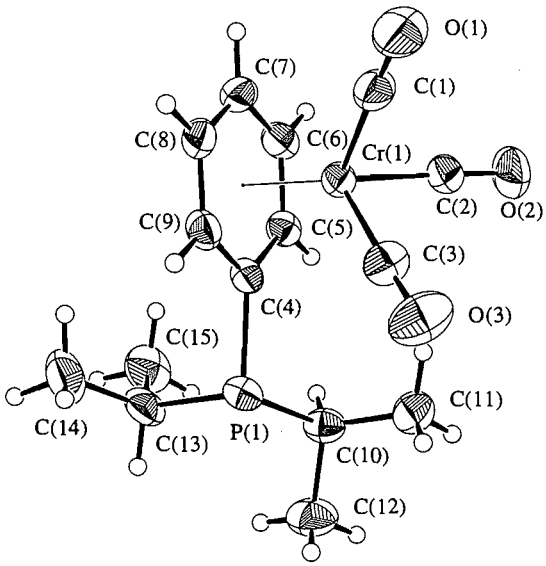

Table 3. The "three-legged piano-stool" geometry is typical of (η^6-arene)$Cr(CO)_3$ complexes. The CO-Cr-CO angles range from 87.6(1)° to 89.0(1)° and the $Cr(CO)_3$ moiety is partially eclipsed (i.e., midway between eclipsed and staggered relative to the η^6-phenyl ring). A staggered structure is rare for monosubstituted arenes (20).

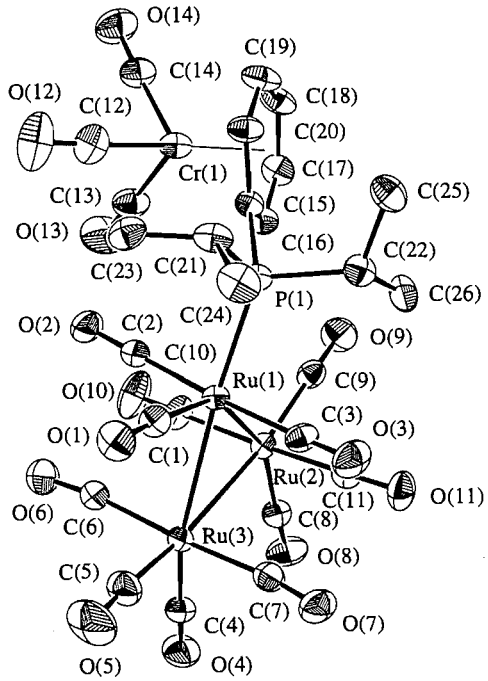
One of the isopropyl groups in the Pr^i_2 moiety is oriented almost perpendicular to the π-arene moiety. This conformation forces the remaining isopropyl group below the plane of the π-arene ring, with the $Cr(CO)_3$ moiety.

The structure of $Ph_2AsC_6H_5Cr(CO)_3$, **6** (21), is very similar to that of **3**. In fact the change from Ph_2As to Pr^i_2P is barely discernible in the $C_6H_5Cr(CO)_3$ moiety. The ring C—C bonds of **3** vary between 1.391(4) and 1.419(3) Å in an apparently random manner; however, in **6** there appears to be some tendency towards an alternation in the bond lengths.

With the advent of mild synthetic routes (22), many tertiary phosphine and arsine derivatives of $Ru_3(CO)_{12}$ and $Os_3(CO)_{12}$ have been prepared; however, only one contains a benzene chromium tricarbonyl moiety. To fill in this gap, 10 new derivatives of $Ru_3(CO)_{12}$, **11**, **12**, **15**, **16**, **19**, **20**, **22**, **23**, **27**, and **29** were synthesized and characterized. Most reactions employed sodium benzophenone ketyl (BPK) as catalyst. PPN salts were also used to assist the substitution reactions although this method is less satisfactory. The catalyzed reactions with the ligands $(R_2EC_6H_5)Cr(CO)_3$ (R_2E = Me_2As, Pr^i2P, Et_2P, Ph_2P) afford the expected mono- or di-substituted products in good yield with the yields of the monosubstituted derivatives being higher. However, under the same conditions $Ph_2AsC_6H_5Cr(CO)_3$ and $PhP[C_6H_5Cr(CO)_3]_2$ yield only the monosubstituted products **27** and **29**. $Bu^t_2PC_6H_5Cr(CO)_3$ appears to react only to a limited extent under these conditions and $PhAs[C_6H_5Cr(CO)_3]_2$ or $Bu^tP[C_6H_5Cr(CO)_3]_2$ not at all. The bulk of the ligands is probably the determining factor; however, it should be noted that the very bulky PFc_2Ph (Fc = ferrocenyl) forms $Ru_3(CO)_{10}(PFc_2Ph)_2$ in high yield (23).

Fig. 2. Molecular structure of $Ru_3(CO)_{11}[Pr^i_2PC_6H_5Cr(CO)_3]$, **15**; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.



Substitution reactions of $Os_3(CO)_{12}$ are facilitated by the use of the activated clusters, $Os_3(CO)_{11}(MeCN)$ and $Os_3(CO)_{10}(MeCN)_2$ (24), and the new complexes **13**, **14**, **17**, **18**, **21**, **24**, **25**, **28** were prepared by using this methodology. The bulky ligands $Bu^tP[C_6H_5Cr(CO)_3]_2$ and $Bu^t_2PC_6H_5Cr(CO)_3$ failed to react. The trisubstituted derivative $Os_3(CO)_9[(Et_2PC_6H_5)Cr(CO)_3]_3$, **26**, was obtained by refluxing $Os_3(CO)_{11}[Et_2PC_6H_5Cr(CO)_3]$ in *n*-octane: compound **26** was the major product in addition to $Os_3(CO)_{12}$. The spectroscopic properties of the cluster derivatives are much as expected.

The crystal structures of two monosubstituted complexes **15** and **19** have been determined. ORTEP plots are shown in Figs. 2 and 3. Metrical data are summarized in Tables 3 and 4. The phosphine ligands are equatorial and the longest of the Ru—Ru bonds is *cis* to the ligand. The average metal–metal distances in **15** and **19** are 2.8908 and 2.8729 Å, respectively, which is greater than the 2.854 Å found for $Ru_3(CO)_{12}$. This expansion has been attributed to the bulk of the ligands. The cone angles of the isopropyl-and phenyl- phosphines are estimated to be 164° and 154°, respectively, by using data from the structure of $Ru(CO)_3[Pr^i_2PC_6H_5Cr(CO)_3]_2$.[4]

The disubstituted ruthenium cluster $Ru_3(CO)_{10}[Pr^i_2P(C_6H_5Cr(CO)_3)]_2$ **16** also has been crystallographically characterized and the structure is shown in Fig. 4. Selected metrical data for the 1:1 dichloromethane solvate are listed in Tables 3 and 4.

The structure is that commonly found for $M_3(CO)_{10}L_2$ clusters where the two ligands occupy equatorial positions at opposite ends of one of the Ru—Ru bonds. The structure of

[4] W.R. Cullen, S.J. Rettig, and H. Zhang. Unpublished results.

[a]Here and elsewhere, A refers to the unweighted centroid of the η^6-coordinated aromatic ring.

[b]Symmetry operation: x, y, z.

[c]Symmetry operation: $1 - y, x - y, z$.

$Os_3(CO)_{10}(PFc_2Ph)_2$ provides a rare example of the alternative 1,2-*trans*,*cis* arrangement of the phosphine ligands (25). In **16** the three Ru—Ru bond distances (mean value 2.8923 Å) are the same within experimental error. This is in contrast to the monosubstituted complexes **15** and **19** in which there are significant differences in the three Ru—Ru separations with the Ru—Ru bond *cis* to the phosphine ligand being significantly elongated. In other disubstituted complexes, $Ru_3(CO)_{10}L_2$, the

Fig. 3. Molecular structure of $Ru_3(CO)_{11}[Ph_2PC_6H_5Cr(CO)_3]$, **19**; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

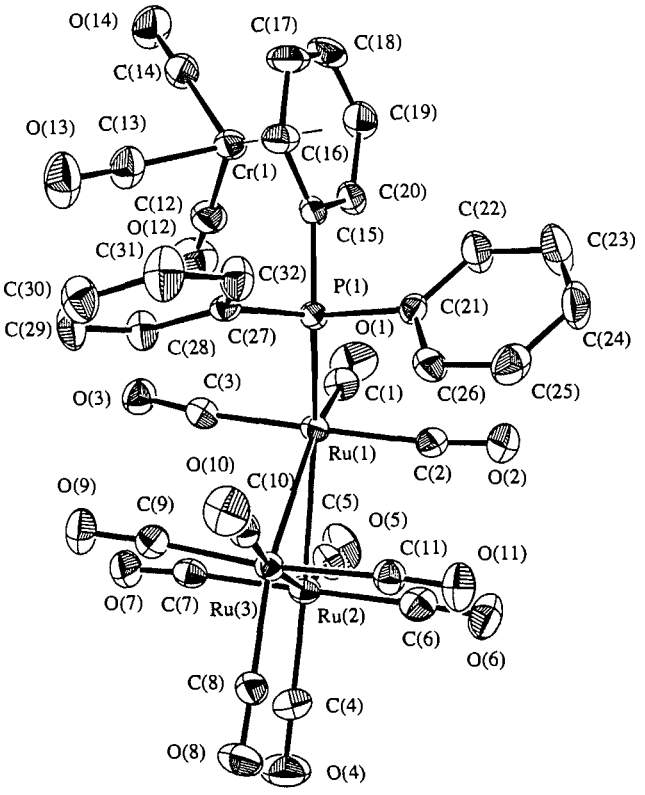

Fig. 4. Molecular structure of $Ru_3(CO)_{10}[Pr^i_2PC_6H_5Cr(CO)_3)]_2$, **16**; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

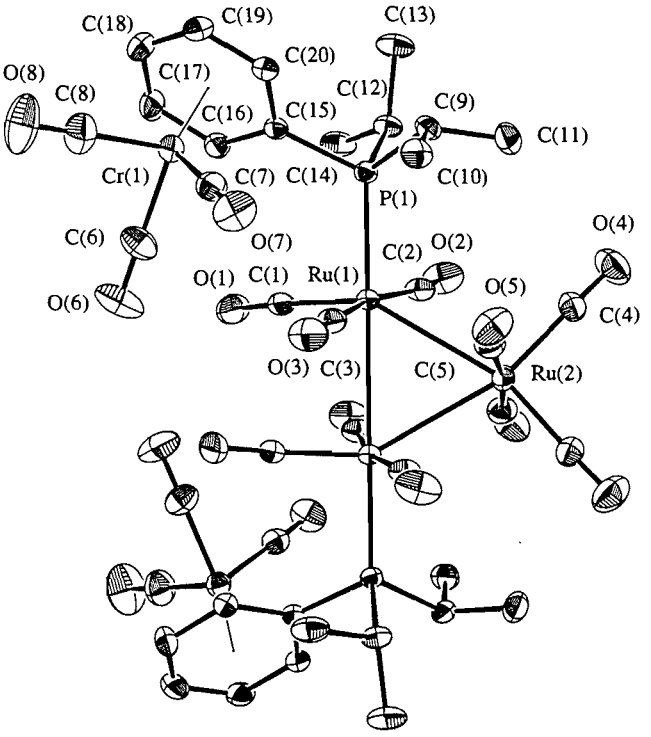

Fig. 5. Molecular structure of $Os_3(CO)_9[Et_2PC_6H_5Cr(CO)_3]_3$, **26**; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

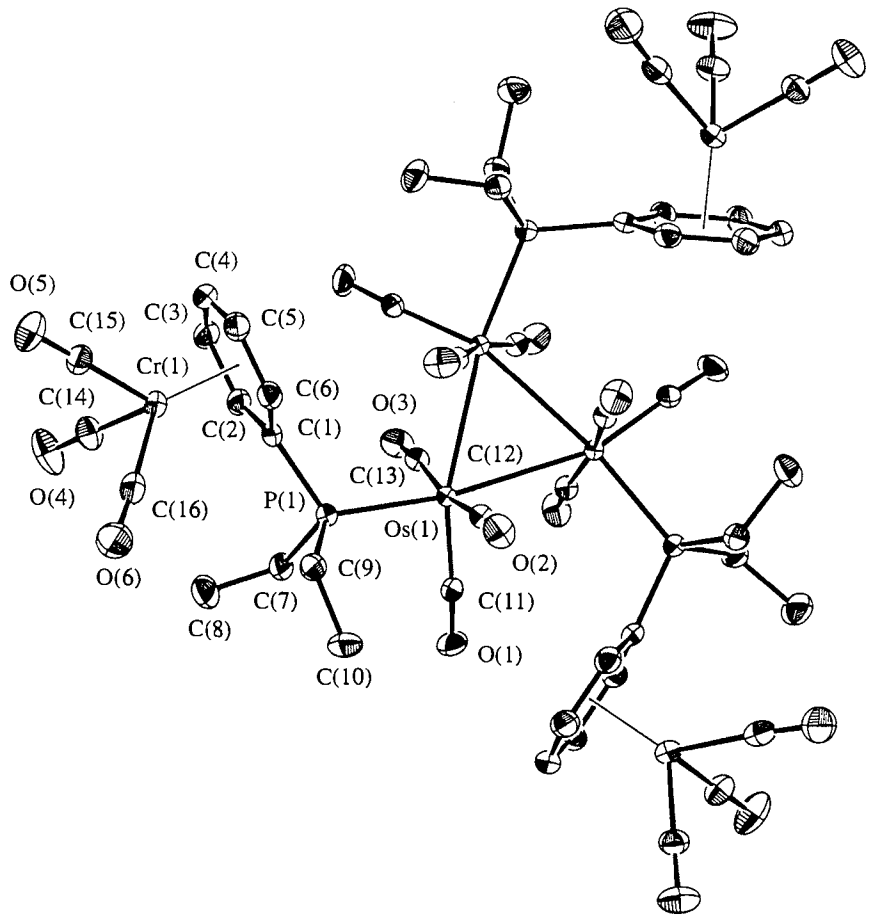

M_3 frame is essentially an isosceles triangle (26). The average Ru—Ru bond distance in **16** is longer than that in the parent carbonyl (mean 2.854 Å) by 0.04 Å and is not significantly different from that in the monosubstituted complex **15** (mean 2.8908 Å).

In **16** the introduction of two phosphine ligands results in considerable twisting of the RuL'_4 units about the Ru—Ru bonds. Unlike the monosubstituted complexes, none of the equatorial carbonyls are found on the Ru_3 plane; for example, CO(1) and CO(4) lie on opposite sides of the Ru_3 plane by 0.73 Å and 0.64 Å, respectively. As a result, all the axial carbonyls are also moved from their idealized positions. Consequently there are no pronounced differences in the bond distances between axial carbonyls and equatorial carbonyls (mean 1.911 Å); the pseudoequatorial Ru—CO(1) bond at the substituted ruthenium atom is the shortest (1.872(4) Å).

The molecular structure of the trisubstituted derivative $Os_3(CO)_9[Et_2PC_6H_5Cr(CO)_3]_3$ **26** has been determined. The relevant bond distances and angles are tabulated in Tables 3 and 4 and an ORTEP plot of the structure is shown in Fig. 5. The molecule **26** has a crystallographic threefold axis, and the structure contains an equilateral triangular Os_3 core with the three phosphine ligands bound one to each osmium atom in pseudo-equatorial sites. The Os-Os bond distances are identical at 2.9013(3) Å and are longer than those in the parent carbonyl (average 2.877 Å (27)), by 0.024 Å. In $Os_3(CO)_9(PPh_3)_3$ the average Os—Os bond distance is also increased to 2.91 Å, but in trisubstituted ruthenium clusters the average Ru—Ru separation is essentially the same as that found in $Ru_3(CO)_{12}$ (28).

In **26** the phosphorus atoms are coordinated at pseudo-equatorial sites and are all situated away from the Os_3 plane by 0.52 Å in the same direction. The Os—P bond at 2.344(1) Å is surprisingly shorter than the Ru—P bond found in **19** (2.372(1) Å) and **15** (2.384(1) Å). In some other trisubstituted complexes the phosphine ligands are arranged in such a way that one lies below the M_3 plane, while the other two lie above it (28).

The products of the thermal decomposition of some of these cluster complexes will be reported in a forthcoming publication (29).

Synthesis of *meso*-phenyl-4,6-dipyrrins, preparation of their Cu(II), Ni(II), and Zn(II) chelates, and structural characterization of bis[*meso*-phenyl-4,6-dipyrrinato]Ni(II)

Christian Brückner, Veranja Karunaratne, Steven J. Rettig, and David Dolphin

Abstract: *meso*-Phenyldipyrromethanes can be oxidized by 2,6-dicyano-3,5-dichloro-*para*-benzoquinone (DDQ) to the corresponding *meso*-phenyldipyrrins. As expected, these novel, stable bipyrrolic pigments readily form metal chelates with copper(II), nickel(II), and zinc(II). Their UV–VIS spectra are compared with a series of known alkyl-substituted dipyrrin chelates and, based on the UV–VIS spectral analysis, the dihedral angle between the two ligands in the bis[*meso*-phenyldipyrrinato]Ni(II) complex was calculated to be 42°. The molecular structure of this complex was determined by X-ray crystallography, essentially confirming the calculation. Crystals of $C_{30}H_{22}N_4Ni$ are orthorhombic, $a = 17.156(3)$, $b = 35.217(1)$, $c = 7.886(1)$ Å, $Z = 8$, space group *Fddd*. The structure was solved by direct methods and refined by full-matrix least-squares procedures to $R = 0.040$ and $R_w = 0.031$ for 1058 reflections with $I \geq 3\sigma(F^2)$. The central nickel is coordinated in a distorted square-planar fashion by four nitrogens. The pair of the planar dipyrrinato ligands enclose a dihedral angle of 38.5°. This is the lowest angle reported for nickel(II) complexes of this kind. As a result of this, and in sharp contrast to previously described nickel(II) dipyrrin chelates, the central metal is diamagnetic.

Key words: *meso*-phenyldipyrromethanes, *meso*-phenyldipyrrins, *meso*-phenyldipyrrinato transition metal chelates, X-ray crystallography.

Résumé : Sous l'influence de la 2,6-dicyano-3,5-dichloro-*para*-benzoquinone (DDQ), on peut oxyder les *méso*-phényldipyrrométhanes en *méso*-phényldipyrrines correspondantes. Comme on pouvait s'y attendre, ces nouveaux pigments bipyrroliques stables forment des chélates métalliques avec le cuivre(II), le nickel(II) et le zinc(II). On a comparé leurs spectres UV–VIS avec ceux d'une série de chélates connus de dipyrrines substitutées par des groupes alkyles et, sur la base d'une analyse des spectres UV–VIS, on a calculé que l'angle dièdre entre les deux coordinats du complexe bis[*méso*-phényldipyrrinato]Ni(II) est de 42°. La structure moléculaire de ce complexe, telle que déterminée par diffraction des rayons X, confirme essentiellement les conclusions obtenues par calculs. Les cristaux du $C_{30}H_{22}N_4Ni$ sont orthorhombiques, groupe d'espace *Fddd*, avec $a = 17,156(3)$, $b = 35,217(1)$ et $c = 7,886(1)$ Å et $Z = 8$. La structure a été résolue par des méthodes directes et affinée par la méthode des moindres carrés jusqu'à des valeurs de $R = 0,040$ et $R_w = 0,031$ pour 1058 réflexions avec $I \geq 3\sigma(F^2)$. Le nickel central est coordiné d'une façon plan carré déformée par les quatre azotes. La paire de coordinats dipyrrinato plans forme un angle dièdrdre de 38,5°. Cette valeur correspond à l'angle le plus faible rapporté pour des complexes de nickel(III) de cette espèce. Il en résulte que, par opposition à ce qui a été décrit antérieurement pour les chélates de nickel(II) dipyrrine, le métal central est diamagnétique.

Mots clés : *méso*-phényldipyrrométhanes, *méso*-phényldipyrrines, *méso*-phényldipyrrinato, chélates des métaux de transition, diffraction des rayons X.

Introduction

Dipyrrins (**1**), also known as dipyrromethenes, are basic, brightly colored, fully conjugated flat bipyrrolic molecules. Their propensity to strongly chelate transition metals has long been recognized (1, 2). Their structure, atom numbering scheme, and the formal nomenclature for dipyrrins is shown below. Positions 1 and 9 are also referred to as α positions, positions 2, 3, 7, and 8 as β positions, and position 5 as the *meso* position.

Received December 1, 1995.

This paper is dedicated to Professor Howard C. Clark in recognition of his contributions to Canadian chemistry.

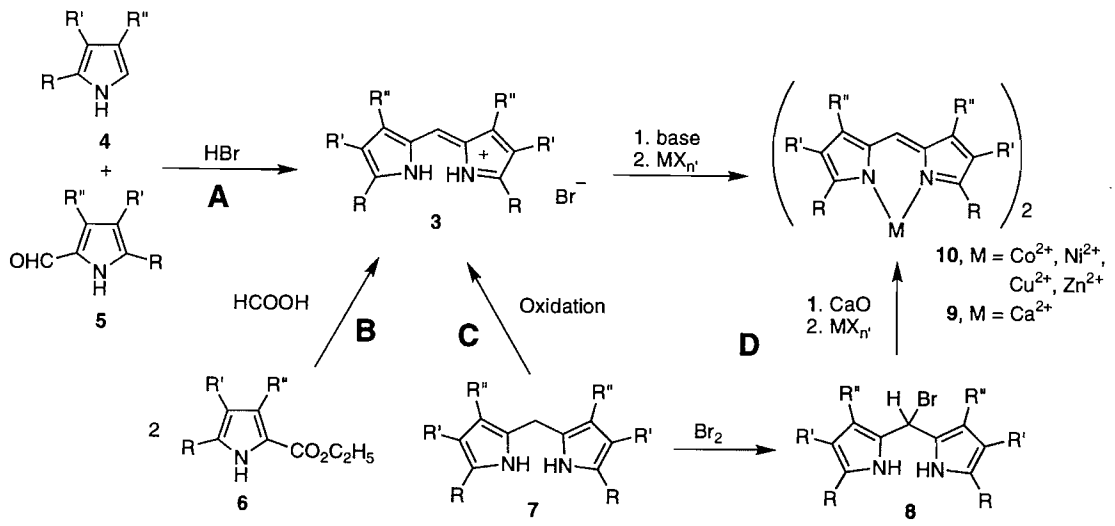
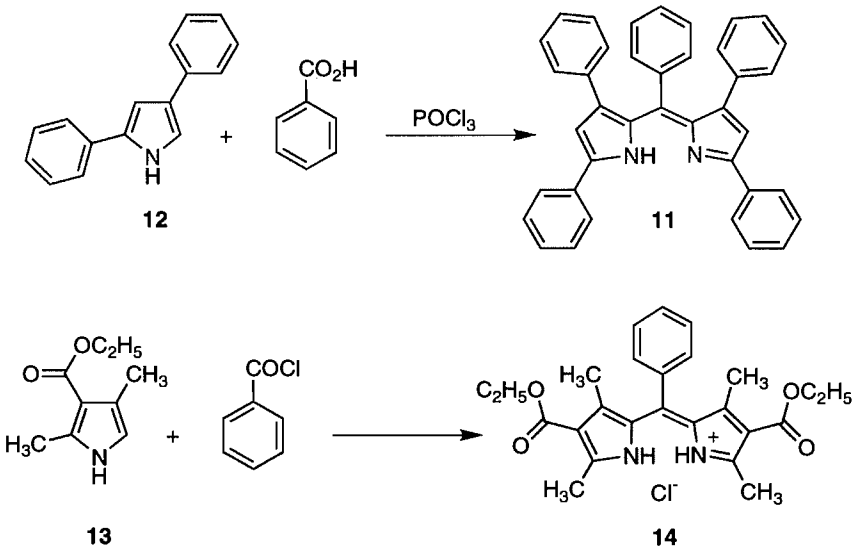
5-Phenyl-4,6-dipyrrin
2-(2-*H*-Pyrrol-2-ylidene-methyl-phenyl)pyrrole

Scheme 1.



Scheme 2.



Scheme 1 outlines the principal pathways for the synthesis of α- and β-alkyldipyrrins (3) and their chelate-type mode of metal complex formation. Four main synthetic pathways can be distinguished:

A: The "classic" acid-catalyzed reaction of an α,β-alkyl-α′-free pyrrole (**4**) with a trialkylpyrrole-α-aldehyde (**5**) (1, 4);

B: The reaction of an α,β-alkyl-α′-ethyloxycarbonylpyrrole (**6**) in concentrated formic acid (5).

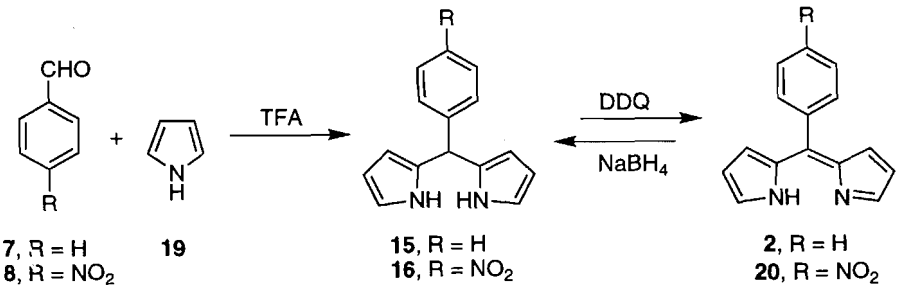
C: The oxidation of hexaalkyl-dipyrromethanes (**7**) by ferrous chloride (1) or 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) (6).

D: The *meso*-bromination of a dipyrromethane to yield the *meso*-bromo-dipyrromethane **8**, and subsequent reaction with calcium oxide to form the calcium chelate (**9**), yields directly a metal chelate. The calcium chelate can easily be transmetallated with a variety of transition metals (7–9).

In all other cases, reaction of dipyrrin (**3**) with a divalent transition metal salt yields the corresponding dipyrrinato complexes **10**. None of the methods A, B, or D has the potential to give access to *meso*-substituted, α,β-free dipyrrins (**2**). Only route C offers access to the title compounds by oxidation of a *meso*-phenyldipyrromethane (10). As will be outlined later in detail, this route was, indeed, successful in providing the title compounds.

meso-Alkyl-substituted dipyrrins are less common (1, 11–13) and the synthesis of *meso*-phenyl-substituted dipyrrins is even rarer, in fact, we are only aware of four previous syntheses, two of them shown in Scheme 2. Rogers (14, 15) confirmed in 1943 a finding of Gabriel from 1908 (16) that described the formation of **11** by reaction of 2,4-diphenylpyrrole (**12**) with in situ generated benzoyl chloride. In a similar approach, Treibs et al. reacted pyrrole **13** with benzoyl chloride to yield the hexasubstituted *meso*-phenyldipyrrin hydrochloride **14** (5). It is noteworthy that in both instances the pyrroles were substituted, particularly at one α and at least one β position. This prevents polymerization of the pyrroles during the harsh reaction conditions, consequently, these methods are not options to synthesize *meso*-phenyl, α-unsubstituted dipyrrins. A disadvantage of the protecting α-phenyl moieties is that they introduce severe steric interligand interactions

Scheme 3.



17, R = H
18, R = NO_2

19

15, R = H
16, R = NO_2

2, R = H
20, R = NO_2

upon metal complex formation. Moreover, *meso*-phenyl substitution concomitant with β-substituents also introduces intra-ligand steric interactions that can, for instance in the case of **14**, lead to deviations from planarity and even chemical instability (17). No reports were made on the metal complexation properties of either **11** or **14**. In 1985 the X-ray structure of bis[1-(2,6-dichlorobenzyl)-5-(2,6-dichlorophenyl)-dipyrrinato]zinc(II) was reported (18). This *meso*-phenyl and α-substituted dipyrrin complex was the kinetic product in the Rothemund-type condensation of the sterically hindered 2,6-dichlorobenzaldehyde with pyrrole, and its isolation was unexpected and fortuitous. Similarly unanticipated, Cavaleiro et al. isolated and crystallized *meso*-aryl-substituted dibenzofuranyldipyrrin in an attempted tetraarylporphyrin synthesis from *o*-acetoxybenzaldehyde and pyrrole (19). These synthetic pathways towards *meso*-phenyl dipyrrins and their metal complexes cannot be generalized. Recently two reports appeared in the literature in which *meso*-phenyl-substituted dipyrrin moieties were integral parts of larger molecules. The BF_2 complex of an α-methyl-*meso*-phenyldipyrrin unit was the input unit of a molecular photonic wire (20) and an α-thiophenyl and β-alkyl-substituted *meso*-phenyldipyrrin was synthesized in the course of research towards polyheterocyclic ligands; however, neither the complexing properties nor the conformation of this compound were reported (21).

The stereochemistry of pyrrin ligands around the metal is dependent on the bulkiness of the substituents in the α and α′ positions, and has found interest (22) since Porter (23) called attention to this phenomenon; however, only a limited number of structural data are available (18, 22, 24, 25). Few α-unsubstituted dipyrrinato complexes have been prepared (26, 27) and in no case has a crystal structure been described. Therefore, it was interesting to investigate the complex geometry of the α′-unsubstituted *meso*-phenyldipyrrin ligands of type **2** and to contrast these findings with published data. This and the general interest for novel ligand classes for use in transition metal catalysis (28), photometric metal detection (29), or biomedical purposes (30) prompted us to investigate the synthesis and the metal complexing properties of α,β-unsubstituted *meso*-phenyldipyrrins.

Results and discussion

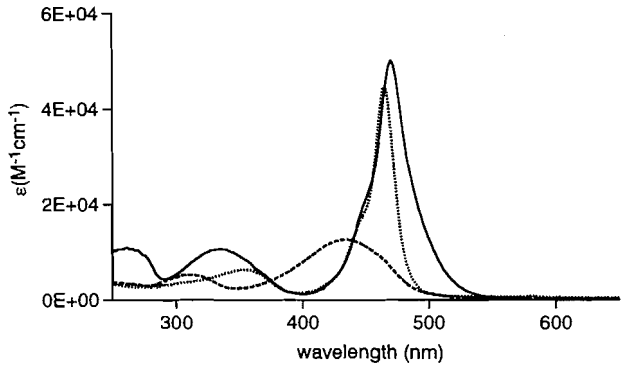
Synthesis of 5-phenyldipyrromethanes 15 and 16

The *meso*-phenyldipyrromethanes **15** and **16** were synthesized by the acid- catalyzed condensation of benzaldehyde (**17**) or *p*-nitrobenzaldehyde (**18**), with pyrrole (**19**). Pyrrole was also used as solvent according to a procedure of Lee and Lindsey (10) (see Scheme 3). The synthesis of **16** offers the great practical advantage over the synthesis of **15** or other dipyrromethanes described by Lee and Lindsey, in avoiding any chromatography during the work-up or purification of the compound; thus it is amenable to large-scale (≥10.0 g product per experiment) preparations. The higher electrophilicity of *p*-nitrobenzaldehyde compared to benzaldehyde likely results in a faster reaction rate and a stabilization of the resulting dipyrromethane towards acid-catalyzed decompositions. Both these aspects in combination with the simple work-up explain the high overall yield of 82% for **15** vs. the reported 49% (10) for **16**.

Preparation and characterization of *meso*-phenyldipyrrins 2 and 20

Dehydrogenations with DDQ have found wide application in the synthesis of pyrrolic pigments (31). In particular, DDQ is useful in the conversion of any type of reduced porphyrins (e.g., porphyrinogens or chlorins) to the corresponding fully unsaturated porphyrins (32). Porphyrinogens are intermediates (33) in the synthesis of *meso*-tetraarylporphyrins according to the methods of Adler et al. (34) or Lindsey and Wagner (35), i.e., the acid-catalyzed cyclization of pyrrole and benzaldehydes. Hence, it was not unexpected that the reaction of *meso*-phenyldipyrromethanes **15** or **16** with one equivalent of DDQ smoothly formed the desired dipyrrins **20** and **2** (Scheme 3). *p*- and *o*-Chloranil are equally well suited to perform the conversion. Reduction of **2** or **20** with $NaBH_4$ in MeOH regenerates the leuko form **16** or **15**. In dilute solution, the oxidation products are bright yellow in color. The optical spectrum of **2** under acidic and basic conditions is shown in Fig. 1. The two-band pattern of the protonated species is analogous to that of 1, 2, 3, 7, 8, 9-hexamethyldipyrrin hydrobromide (11), but ~14 nm hypsochromically shifted, with slightly lower extinction coefficients. The bands have been assigned to $\pi^* \leftarrow \pi$ transitions and are indicative of the marked planarity of these fully conjugated aromatic systems. Addition of acid protonates the basic imine-type nitrogen of the 2*H*-pyrrole unit and this removal of non-degeneracy of the linear resonator in combination with the presence of a positive charge induces a bathochromic shift of 42 nm and a tripling of the extinction coefficient (36). For steric reasons, it can be inferred that the phenyl moiety is approximately perpendicular to the plane of the dipyrrin. Consequently, the phenyl group is not in full conjugation with the pyrrolic system and substituents on the phenyl group minimally influence the π-cloud of the dipyrrin. This explains the close similarity of the optical spectrum of **2** and its *p*-nitro derivative **20**; a similar

Fig. 1. Optical spectra of **2** in CH_2Cl_2 – 0.5% MeOH – trace NH_4OH (broken line) and in CH_2Cl_2 – 0.5% MeOH – trace HCl (dotted line), and of **20** in CH_2Cl_2 – 0.5% MeOH – trace HCl (solid line).



situation is also found in variously phenyl-substituted *meso*-tetraphenylporphyrins (37). The nitro compound **20**, and its metal complexes, exhibit a band at ~260 nm that we attribute to the *p*-nitro moiety. The optical spectrum of **2** is closer to that of the hexamethyldipyrrin than to the spectrum of **11**, which is about 110 nm bathochromically shifted (17), possibly reflecting the extended conjugation (and distortion) of this system by the α-phenyl groups.

The signals in the ^1H and ^{13}C NMR of the *meso*-phenyldipyrrins indicate a plane of symmetry. This is consistent with formulating the dipyrrins as adopting a planar conformation and a rapid tautomeric exchange of the NH proton between the two nitrogens. The ^1H NMR shifts for the β-protons of **2** of 6.39 and 6.47 ppm and for the α-protons of 7.78 ppm attest to the aromatic character of these compounds.

Alkyldipyrrins of type **3** are, owing to their basicity, generally isolated and purified as their hydrobromide or hydrochloride salts (1). Although conditions for thin-layer and column chromatography of dipyrrin hydrobromides have been described (mixture of formic acid, methanol, and chloroform – silica gel (38)), it is not common practice. Their free bases are also reportedly less stable. We were surprised to find that in case of the *meso*-phenyldipyrrins, column chromatography (CH_2Cl_2 – silica gel) of their free bases posed no difficulty.

Formation and characterization of transition metal chelates of the *meso*-phenyldipyrrins

General data and synthesis

A concentrated MeOH solution of the *meso*-phenylpyrrins **2** or **20**, when mixed with a methanolic solution of the divalent metal ions Ni^{2+}, Cu^{2+}, and Zn^{2+}, as their acetates, yields the corresponding highly colored metal complexes (Scheme 4). The complexes are stable and do not require any special handling. Analyses confirmed the stoichiometry of the precipitates as $M(ligand)_2$. The metal complexes formed X-ray quality dichroic (metallic green–red) crystals.

The vibrational spectra of the metal complexes are similar to those of their ligands. This is not unexpected as conjugation is already attained in the planar ligand moiety before coordination to a metal. Thus, intraligand vibrations will undergo only minor shifts upon metal chelation. This has been rationalized before for the metal complexes of hexaalkylpyrrins (39).

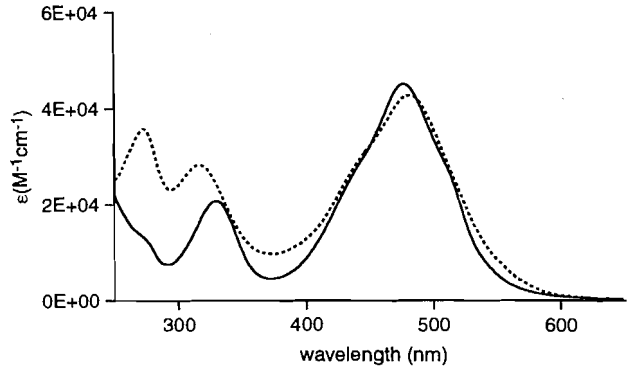
Fig. 2. Optical spectra of **21** in $CHCl_3$ (broken line) and **22** in $CHCl_3$ (solid line).

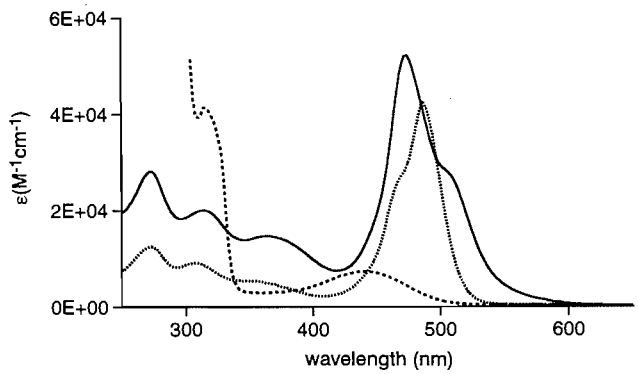


UV–VIS spectra

The optical properties of the metal compounds are strongly dependent on the central metal but the nickel chelates **21** and **22** are very similar (Fig. 2). This similarity, in particular with respect to λ_{max} and log ϵ, is indicative of a very similar stereochemistry of these two compounds. The UV–VIS spectrum of the zinc chelate **23** resembles that of the protonated ligand, suggesting the absence of any metal ← metal transitions (see Fig. 3). However, metal ← ligand charge transfer transitions are generally observed in this energy region and they cannot be excluded (27), though other authors have assigned this band exclusively to intraligand π* ← π transitions and the bands in the 320–350 nm region to charge transfer transitions (40). The electronic spectra of the nickel and the copper chelates **20**, **21**, and **24** follow the same general pattern as that of **23** (see Figs. 2 and 3). The UV–VIS spectra of the metal chelates are nearly indistinguishable in non- or weakly coordinating solvents such as benzene, methanol, methylene chloride, or chloroform but show changes in pyridine, most noticeable for the zinc chelate, as also shown in Fig. 3. Table 1 lists selected UV–VIS data of some known dipyrrinato-metal complexes (**25**–**40**) and of the novel compounds **21**, **23**, and **24**.

When comparing the longest wavelength absorption of the Zn-chelate **23** at 486 nm against the equivalent transitions of

Fig. 3. Optical spectra of **23** in CH_2Cl_2 (dotted line) and pyridine (dashed line), and **24** in $CHCl_3$ (solid line).



the alkyl-substituted analogues **25–32**, it is remarkable that the *meso*-phenylpyrrin chromophore is distinguished by the highest transition energy. An equivalent trend can be seen in the nickel (**22** vs. **33–36**) and copper (**24** vs. **37–40**) chelate series. Hyperconjugation effects have been suggested for the progressive bathochromic shift with increasing methyl substitution (27). Extended π-conjugation can be evoked for the bathochromically shifted optical spectrum in case of dipyrrins **28** and **32**. The absence of both effects in the zinc, nickel, and copper chelates **21–24** rationalize their relatively high transition energies. The introduction of a *meso*-methyl substituent in chelates **29** and **30** leads, when compared to their *meso*-unsubstituted analogues **27** and **28**, to a relatively small change in the energy of the longest wavelength transition; however, their extinction coefficients significantly decrease. This, based on theoretical considerations, may be taken as a sign of distortion from planarity (17). Based on the foregoing, the high extinction coefficients of the metal chelates of the *meso*-phenyldipyrrins seem to indicate that the ligands are flat. In the absence of any β-substituent and hence any intraligand steric crowding, and in analogy to the conformation of *meso*-tetraphenylporphyrins (42), this appears to be a reasonable assumption. As will be detailed later, the single crystal X-ray structure of **22** shows that the assumption of planarity is, in fact, valid.

The stereochemistry of the ligands around the central metal is strongly dependent on the metal type. The preference of zinc(II) for a tetrahedral, and of nickel(II) and, even more so, of copper(II) for a square-planar coordination sphere is well documented (43). Regardless of the α substituents present in the dipyrrin ligands, the realization of a tetrahedral coordination sphere poses no interligand steric interactions. Consequently, and in analogy to the stereochemistry of the zinc chelates of alkyldipyrrins, compound **23** can be assigned a tetrahedral structure (9, 22, 27, 40). The picture is more complex for the nickel and copper chelates. It has been found in previous studies that α substituents prevent square-planar coordination due to interligand crowding. This forces the complex into a distorted tetrahedral structure in which the two approximately planar α-methyldipyrrinato ligands are inclined (as determined by X-ray crystal structure analysis) at an angle (referred to as dihedral angle) of 76.3° for nickel chelate **33** (24) and 66° for copper chelate **39** (25). With hydrogen as the sole α substituents no a priori statement can be made about the stereochemistry around the metal. It has been suggested that some electronic interaction exists between the π-systems of the two dipyrrin units coordinated to the same metal ion in the "tetrahedral" Co(II) and Cu(II) complexes (44). Motekaitis and Martell presented an MO theory model and derived a relationship (eq. [1]) in which the intensity of the longest wavelength transition is assumed to change with the tetrahedral angle θ between the ligands:

$$[1] \quad \frac{\epsilon^{\theta}}{\epsilon^{90}} = \sin^2 \theta$$

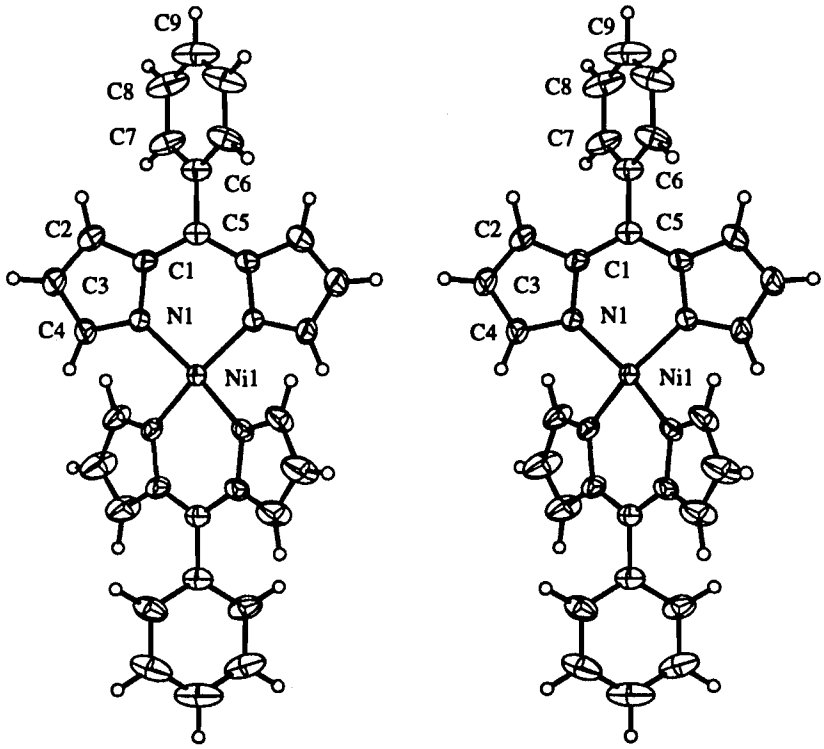
θ is the tetrahedral angle, ϵ^{θ} is the extinction coefficient of a reference compound known to be tetrahedral, i.e., θ = 90°, and ϵ^{θ} is the extinction coefficient of a similar compound whose geometry is to be determined. According to eq. [1], the calculated tetrahedral angle in the *meso*-phenyldipyrrin nickel complex **22** would be 42°, and in the copper complex **24**, 48°. There are, however, precautions to be taken when applying Martell's methodology for determination of the interligand dihedral angle. The prerequisite that the ligands are flat and coordinate in exactly the same MN_4 fashion to the complexes to be compared must be strictly fullfilled. Fergusson and coworkers (22), for instance, published the crystal structure analysis of the palladium chelate of 3,3′,5,5′-tetramethyl-4,4′-diethoxycarbonyldipyrrin in which the dipyrrin unit was *not* planar. The tendency for palladium to achieve square-planar coordination geometry is strong enough to distort the planar ligand and to enforce a stepped arrangement of the ligands around the metal centre. With little change in transition energy, the extinction coefficients were reduced compared to the analogous tetrahedral cadmium, mercury, or zinc complexes. However, the application of eq. [1] gives incorrect results when compared to the actual structures. A second example can be derived from examination of the literature. Based on the extinction coefficient of **31**, Martell determined the dihedral angle of the copper analogue to be 40° (9). However, considering the steric requirement of the ethoxycarbonyl moiety and setting it against the crystallographically determined dihedral angle of 66° for **39** or values determined for the complexes **37**–**40**, this value appears to be considerably too low. Murakami et al. investigated the IR spectrum and the ligand-field bands of this complex and proposed the involvement of the carbonyl oxygen in this copper chelate, giving a CuN_4O_2 coordination (41). In light of this it becomes apparent that the dihedral angle predicted by Martell's method had to be in error. In the present case, however, the prerequisites of similarly flat ligands forming in all cases a MN_4 coordination sphere are most likely fullfilled and, consequently, the theoretically determined values may be significant. Indeed, the X-ray crystal structure analysis for nickel complex **22** proved the value determined by Martell's method to be fairly accurate (3.5° deviation, Table 1). As for the copper chelate, a final experimental proof of the calculated value still awaits, but the value of 48° is in agreement with the calculated value of one other α-unsubstituted copper chelate **37** and, as expected, is significantly smaller than for the α-alkyl-substituted chelates. The calculated values for the copper chelates have to be taken with some reservation as shown by the discrepancies of the values determined by ligand field transition band analysis and by Martell's method.

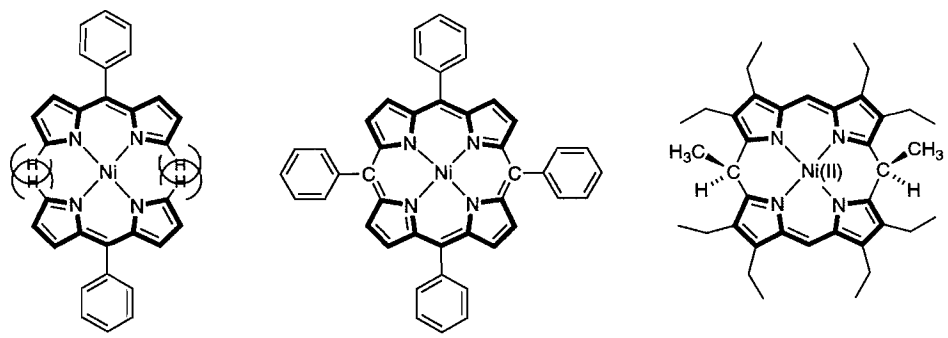
The change of the optical spectrum of **23** upon the addition of pyridine (Fig. 3) results from an expansion of the Zn-coordination sphere from tetrahedral ZnN_4 to a distorted tetragonal pyramid ZnN_5. This forces the dipyrrinato ligands to take up a smaller dihedral angle, which probably accounts for the observed spectrum. The nickel chelate UV–VIS spectrum shows only a slight change upon addition of pyridine. This is analogous to, for instance, the reluctance of the square- planar nickel(II) porphyrins to expand their coordination sphere and the small changes in their optical spectrum associated with any additional coordination (45). This effect is even more pronounced in the case of the Jahn–Teller ion copper(II).

Magnetic properties

The magnetic properties of nickel(II) complexes with N-donor ligands may permit conclusions regarding their coordination geometry. Square-planar complexes are typically diamagnetic, and tetrahedral complexes paramagnetic (43). All

Fig. 4. ORTEP plot (stereoview) of **22**; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.





22 41 42

nickel(II) chelates of dipyrrins have been described as paramagnetic and, therefore, their description as distorted tetrahedral rather than distorted square planar is plausible regardless of the actual dihedral angle between the ligands. To our surprise, the nickel chelates **21** and **22**, as judged by the sharp ^1H and ^{13}C NMR, proved to be diamagnetic. This suggests that they are (distorted) square planar. On the basis of a comparison of the steric interactions in the cyclic and planar [meso-tetraphenylporphyrinato]nickel(II) (**41**) or the cyclic and saddle-shaped [5,15-dimethyl-5,15-dihydrooctaethylporphyrinato]-nickel(II) (**42**) (46), it becomes clear that a planar coordination can be excluded since the two α-hydrogens of the opposing ligands would occupy the same space (given standard Ni—N bond lengths) in case of square- planar coordination. To unambiguously answer the question about the dihedral angles in the nickel chelate, an X-ray crystal structure analysis of a single crystal of **22** was undertaken.

Crystal structure analysis

An ORTEP representation of **22** as it exists in the crystal together with the numbering system employed in Tables 2 and 3 is shown in Fig. 4. Atom coordinates and B_{eq} are listed in Table 2. Selected bond parameters are listed in Table 3, and the crystallographic data are listed in Table 4.

The molecule has D_2 symmetry, which makes the two ligands equivalent and endows a C_2-axis passing through the *p*-hydrogens of the *meso* substituent, the methine carbons, and the central metal. The planes of the two essentially planar dipyrrin ligands enclose a dihedral angle of 38.5°, in close agreement with the calculated value of 42°. The equivalent angle in [3,3′,5,5′-tetramethylpyrrinato]nickel(II) (**33**) is, as mentioned above, 76.3° (24). The small angle results directly from the smaller size of the α-H as compared to the α-methyl group. The bite angle N–Ni–N_a of the ligand is 94.3°, which is, within the experimental uncertainty, equal to the bite angle

observed for **33**. The N–Ni–N$_b$ angle is 152.5°. Unlike in the latter structure, no distortion in the sense of a deviation of colinearity of the two local twofold axes of each Ni-ligand group can be detected. The four Ni—N distances are equal (1.879(2) Å), and unusually short for complexes of this kind. We regard this effect to be partially due to the reduced ionic radius of the d^8 low spin ion vs. the high-spin congener in **33** (47) and partially due to the reduced interligand steric interactions. The extent of the steric effect becomes perceptible if the bond length is compared to those in related nickel complexes **33**, nickel porphyrin (**41**), a ruffled nickel porphyrin (**42**), and a 5,10-dihydroporphyrin system (**43**) as listed in Table 5. The quasi-rigid porphyrin core (in complex **41**) resists undue radial expansions or contractions in the equatorial plane of the core. Therefore, the metal – porphyrin nitrogen bond lengths are

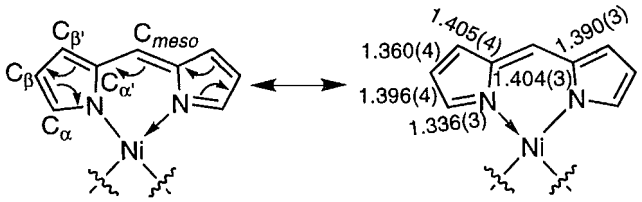
restricted relative to the normal range of values that are found in metal – monodentate nitrogen ligand bond lengths, which results in a "stretched" bond length of ~1.96 Å. Ruffled nickel porphyrins can reduce the bond length by about 0.03 Å; in the saddle-shaped **42**, which is essentially a strapped bisdipyrri-

Fig. 5. Intraligand bond lengths, and limiting resonance structures of the dipyrrinato ligand.



nato nickel(II) compound, the bond length is a further 0.025 Å shorter. The removal of the ligand strap concomitant with the introduction of α-methyl groups introduces severe steric interactions in **33** but allows for a large dihedral angle, nonetheless, a long Ni—N bond length is recorded for this class of complexes. Removal of a large portion of this interaction by the replacement of the methyl groups with hydrogens in **22** allows the two ligands to achieve "pseudo-planarity" and results in the shortest Ni—N bond length of its class.

Inspection of the intraligand bond lengths reveals that two types of C—N bonds exist, a short C_{α}—N bond and a long $C_{\alpha'}$—N bond. The differences can be accounted for in terms of a resonance description of the π-electrons in the ligand molecule. Figure 5 shows the two limiting resonance structures and the associated bond lengths. According to this simplified picture, the C_{α}—N bond would receive partial π-contribution, the $C_{\alpha'}$—N bond would not. The difference in double bond character of these bonds explains the observed bond length differences in a qualitative way. The deviation of the $C_{\alpha'}$–N bond length from the expected 1.42 Å for a C—N single bond reflects the aromatic character of the pyrrole unit itself, albeit the analogous bond length in pyrrole is about 0.04 Å shorter (50). The $C_{\alpha'}$—C_{meso} bond and the C_{α}—C_{β} bond have a formal bond order of 1.5, and hence their bond lengths are as expected. The mean plane of the *meso*-phenyl group is tilted 58.1° with respect to the mean plane of the dipyrrin unit. This deviation from the, perhaps, expected orthogonal finds its parallels in the structure of *meso*-tetraphenylporphyrins (38, 51).

NMR spectroscopy

The ^1H and ^{13}C NMR data of the diamagnetic metal chelates **21–23** are largely as expected, and similar to the spectra of the protonated ligands. One noticeable exception is a large low field shift of the α-protons in the nickel chelates **21** and **22**, i.e., a shift of +2.48 ppm for **22** as compared to the zinc analog **23**. This also is evidence of the small dihedral angle of the ligand mean planes in the nickel complex. The α-protons experience shielding effects of both the aromatic dipyrrinato systems and thus are more shielded than in the tetrahedral zinc complex, where such "double" shielding cannot occur.

Conclusion

The *meso*-phenyl-4,6-pyrrins can be conveniently prepared from the corresponding dipyrromethanes. They exhibit properties similar to previously described alkyl-substituted dipyrrins with the exception that they exhibit a significantly higher $\pi^* \leftarrow \pi$ transition energy as judged by their hypsochromically shifted UV–VIS spectra. The *meso*-phenyldipyrrins form metal complexes with nickel(II), copper(II), and zinc(II). Their spectroscopic data can be rationalized in the context of the previously described dipyrrinato complexes; however, the lack of a bulky α-substituent allows unique properties to this class of ligands. Based on optical and ^1H NMR data, the zinc complex can be assigned a tetrahedral structure. Both the nickel and the copper complex can be described as distorted square-planar complexes. The distortion from planarity of the nickel complex was predicted to be 42°, based on UV–VIS data analysis. An X-ray crystal structure analysis determined the angle to be 38.5° and the Ni—N distance to be 1.879(2) Å. This is the smallest angle and the shortest Ni—N bond length recorded for dipyrrinato complexes. As a consequence of this, and in contrast to previously described [dipyrrinato]nickel(II) complexes, the [*meso*-phenyldipyrrinato]nickel(II) complexes are diamagnetic. The stereochemistry of the copper complex is assumed to be similar to that of the nickel complex. Studies to utilize the unique steric requirement of the *meso*-phenyldipyrrin ligand, e.g., to form coordination polyhedra with no precedent in the dipyrrinato field, such as octahedral M(III)(ligand)$_3$ complexes, are currently under way in our laboratories.

Experimental section

Instrumentation and materials

Melting points were determined on a Thomas model 40 Micro Hot Stage and are uncorrected. The infrared spectra were measured with a Perkin–Elmer model 834 FT-IR instrument. The NMR spectra were measured with a Bruker AC 200 FT spectrometer and are expressed in parts per million (δ) relative to the external standard TMS. The low- and high-resolution mass spectra were obtained by Dr. G. Eigendorf and co-workers of this department using an AEI MS9 and a Kratos MS50 spectrometer, respectively. The electronic spectra were measured on a HP 8452A photodiode array spectrophotometer. Elemental analyses were performed by Mr. P. Borda of this department on a Fisons CHN/O Analyzer, model 1108.

meso-Phenyldipyrromethane **15** was synthesized according to the procedure of Lee and Lindsey (10). All other reagents and solvents were commercially available and of reagent grade or higher, and were, unless otherwise specified, used as recieved. The silica gel used in flash chromatographies was Merck Silica Gel 60, 230–400 mesh.

5-(4-Nitrophenyl)dipyrromethane (16)

Nitrobenzaldehyde (**18**) (3.0 g, 19.87 mmol) was dissolved in freshly distilled pyrrole (**19**) (44.0 g, 0.66 mol). The mixture was degassed by bubbling with N_2 for 10 min. TFA (0.15 mL, 0.1 equiv based on the benzaldehyde) was added and the mixture was stirred under N_2 until no starting aldehyde could be detected by TLC (ca. 15 min). The volume of the slightly yellow mixture was reduced under high vacuum at 50°C to a viscous oil. This oil was dissolved in CH_2Cl_2 (100 mL) and cyclohexane (50 mL) was added. Without heating, the mixture was reduced on the rotary evaporator until precipitation just began. Scratching with a glass rod caused rapid crystallization of an slightly greenish solid which, after drying at 50°C/0.2 Torr (1 Torr = 133.3 Pa) for 24 h gave 3.85 g (71.2%) of analytically pure compound **16**. A second crop of lesser purity was obtained from the mother liquor upon further evaporation

(0.55 g, 10.3%); mp 158°C; UV–VIS (MeOH) λ_{max} nm (rel. intensity): 222 (1.0), 266 (0.77); ^{1}H NMR (200 MHz) δ: 5.58 (s, 1H), 5.87 (m, 2H), 6.18 (dd, J = 11.8, 2.5 Hz, 2H), 6.74 (m, 2H), 7.37 (d, J = 11.8 Hz, 2H), 7.95 (br s, 2H), 8.14 (d, J = 11.8 Hz, 2H); ^{13}C NMR (50 MHz) δ: 43.8, 107.8, 108.8, 118.0, 123.8, 129.2, 130.8, 146.9, 149.7; LR-MS (EI) *m/e*: 267 (100.0, M^+), 220 (9.7, $MH^+ - NO_2$), 201 (16.3, $M^+ - C_4H_4N$), 154 (9.7), 145 (47.3, $MH^+ - Ph - NO_2$). Exact Mass calcd. for $C_{15}H_{13}N_3O_2$: 267.10078; found: 267.10080. Anal. calcd. for $C_{15}H_{13}N_3O_2$: C 67.41, H 4.9, N 15.72; found: C 67.23, H 4.98, N 15.62.

5-Phenyl-4,6-dipyrrin (2)

meso-Phenyldipyrromethane (15) (500 mg, 2.25 mmol) was dissolved with the help of a heat gun in benzene (25 mL). A solution of 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (537 mg, 2.35 mmol) dissolved in benzene (5 mL) was added and the mixture stirred until no starting material could be detected by tlc (1 h). The black precipitate was filtered off and air-dried to provide 440 mg (85 %) of crude 2, which was used for metal complex formation. An analytical sample was purified by column chromatography (silica gel, 25 g, 1% MeOH in $CHCl_3$). The bright yellow main fraction was collected and evaporated to dryness. The yellow film was dissolved in acetone (20 mL) and precipitated by diffusion of cyclohexane into this solution to yield a yellow-brown precipitate (55.0 % based on crude material); mp 184°C; IR (neat): 1555, 1450, 1435, 1340, 1055 cm^{-1}; UV–VIS (CH_2Cl_2 – 0.5% MeOH – trace NH_4OH) λ_{max} (log ε): 310 (3.75), 434 (4.10) nm; (CH_2Cl_2 – 0.5% MeOH – trace HCl) λ_{max} (log ε): 354 (4.02), 466 (4.65) ^{1}H NMR (200 MHz, acetone-d_6) δ: 6.39 (m, 2H), 6.47 (d, J = 3.5 Hz, 2H), 6.39–6.47 (m, 5H), 7.78 (s, 2H), ~12.5 (s, very broad, 1H); ^{13}C NMR (50 MHz, acetone-d_6) δ: 118.3, 128.5, 129.2, 129.7, 131.3, 135.0, 138.0, 144.6; nm; LR-MS (EI, 180°C) *m/e*: 220 (77, M^+), 219 (100, $M^+ - H$). Exact Mass calcd. for $C_{15}H_{12}N_2$: 220.10005; found: 220.10012. A consistent elemental analysis (deviation 3.0% from the calculated values) could not be achieved, possibly due to varying amounts of solvation and (or) salt formation.

5-(4-Nitrophenyl)-4,6-pyrrin (20)

This compound was prepared from **16** by a method analogous to that used for the preparation of compound **2**. Yield after chromatography: 59%; mp 189–191°C; IR (neat): 1555, 1520, 1515, 1510, 1450, 1340, 1050 cm^{-1}; UV–VIS (CH_2Cl_2 – 0.5% MeOH – trace NH_4OH) λ_{max} (log ε): 264 (3.99), 300 (4.08), 434 (4.38) nm; (CH_2Cl_2 – 0.5% MeOH – trace HCl) λ_{max} (log ε): 258 (4.16), 336 (4.17), 470 (4.74) nm; ^{1}H NMR (200 MHz, acetone-d_6) δ: 6.21 (m, 2H), 6.40 (m, 2H), 7.36 (d, J = 8 Hz, 2H), 7.55 (s, 2H), 7.96 (d, J = 8 Hz, 2H), ~12.0 (very broad, 1H); ^{13}C NMR (50 MHz, acetone-d_6) δ: 119.0, 123.7, 128.8, 128.9, 132.4, 139.5, 140.9, 144.6, 145.6; LR-MS (EI, 150°C) *m/e*: 265 (100, M^+), 234 (18.8, $MH^+ - 2O$), 228 (68.2), 218 (96.5, $M^+ - HNO_2$). Exact Mass calcd. for $C_{15}H_{11}O_2N_3$: 265.0851; found: 265.08501.

Bis[5-(4-nitrophenyl)-4,6-pyrrinato]Zn(II) (23)

To a solution of dipyrrin **20** (100 mg, 3.77×10^{-4} mol) in MeOH (10 mL) was added zinc acetate dihydrate (420 mg, 5 equiv.) in MeOH (10 mL) and the mixture was heated on a water bath for 4 h. The mixture was evaporated to dryness on the rotary evaporator and the remaining solids were tritrurated with $CHCl_3$. The resulting bright orange-yellow solution was filtered though a short plug of silica gel and allowed to slowly evaporate. Compound **23** was obtained as dark orange lumps with a bright green metallic lustre, which were, after drying (0.1 Torr/50°C), analytically pure (180 mg, 81%); mp > 300°C; IR (neat): 1590, 1541, 1515, 1405, 1372, 1335, 1243, 1190, 1025, 995 cm^{-1}; UV–VIS (CH_2Cl_2) λ_{max} (log ε): 486 (4.97), 352 (4.08), 308 (4.30), 272 (4.42) nm; (pyridine) λ_{max} (rel. intensity): 440 (0.2), 316 (1.0); ^{1}H NMR (200 MHz, $CDCl_3$) δ: 6.45 (dd, J = 0.8, 4.2, 1H), 6.59 (dd, J = 0.8, 4.2, 1H), 7.59 (s, 1H), 7.75 (d, 9.2 Hz, 1H), 8.35 (d, 9.2 Hz, 1H); LR-MS (EI) *m/e*: 592 (40.3, M^+), 295 (88.8), 280 (48.7), 265 (100, ligand$^+$). Anal. calcd. for $C_{30}H_{20}N_6O_4Zn$: C 60.63, H 3.39, N 14.1; found: C 60.71, H 3.3, N 14.00.

Bis[5-(4-nitrophenyl)-4,6-pyrrinato]Ni(II) (21)

Compound **20** was prepared using the procedure for the preparation of **23**. Slow evaporation of a $CHCl_3$ – 1% MeOH solution of **21** yielded a dark brown-orange microcrystalline material, which was, after drying (0.1 Torr/50°C) analytically pure; mp, 230°C; IR (neat): 1595, 1555, 1520, 1335, 1370, 1240, 1040, 1020, 995 cm^{-1}; UV–VIS (CH_2C_2) λ_{max} (log 274 (4.58), 318 (4.47), 484 (4.63) nm; (MeOH) λ_{max} (rel. intensity): 272 (0.47), 292, sh (0.45), 466, sh (0.96), 482 (1.0) nm; (pyridine) λ_{max} (rel. intensity): 316 (1.0), 456, br (0.43), 486 (0.48); ^{1}H NMR (200 MHz) δ: 6.66 (d, J = 4.1 Hz, 1H), 7.52 (d, J = 8.6 Hz, 1H), 8.26 (2 overlapping d, 2H), 10.83 (s, 1H); LR-MS (EI, 180°C) *m/e*: 586 (48.3, M^+), 539 (15.6, $M^+ - HNO_2$), 464 (15.3, $M^+ - Ph - NO_2$). Exact mass calcd. for $C_{30}H_{20}N_6NiO_4$: 586.08997; found: 586.08992. Anal. calcd. for $C_{30}H_{20}N_6NiO_4$: C 61.36, H 3.43, N 14.31; found: C 6.57, H 3.36, N 14.20.

Bis[5-(4-nitrophenyl)-4,6-pyrrinato]Cu(II) (24)

Dipyrrin (20) (100 mg, 3.77 mmol) was dissolved in minimal warm MeOH (~5 mL) and, with stirring, a solution of copper acetate monohydrate (380 mg, 5 equiv) in MeOH (5 mL) and concentrated ammonia (0.5 mL) was added. The metal complex precipitated from the dark orange solution almost instantaneously. The precipitate was filtered off after stirring for 12 h at room temperature, then dried and chromatographed on a short (10 × 2.5 cm, 1% MeOH – $CHCl_3$) column of silica gel. The first intensely orange band was collected and slow evaporation of the solvent furnished 160 mg (72%) of the metal complex 24 as black needles with a green metallic lustre. Alternatively, repeated recrystallization from $CHCl_3$–MeOH yields dark green, dichroic microcrystals with a metallic lustre. After drying (0.1 Torr/50°C) an analytically pure sample was obtained; mp > 300°C; UV–VIS ($CHCl_3$) λ_{max} (log ε): 274 (4.52), 314 (4.21), 368 (4.26), 474 (4.72) nm; (MeOH) λ_{max} (rel. intensity): 268 (0.72), 308 (0.47), 374 (0.39), 468 (1.0), 502, sh (0.53); LR-MS (EI) *m/e*: 591 (6.6, M^+), 295 (100), 280 (68.6), 264 (44.3), 248 (26.5), 234 (49.0). Exact Mass calcd. for $C_{30}H_{20}O_4N_6{}^{65}Cu$: 593.08240; found: 593.08305. Anal. calcd. for $C_{30}H_{20}CuN_6O_4$: C 60.63, H 3.39, N 14.15; found: C 60.70, H 3.54, N 14.03.

Bis[5-phenyl-4,6-pyrrinato]Ni(II) (22)

Prepared in 76% yield in an analogous fashion as described for **23**. Slow evaporation of an acetone solution gave **22** as dichroic crystals; mp (dec.) 240°C; IR (neat): 1575, 1535, 1505,

1410, 1380, 1345, 1245, 1035, 1030, 1000 cm^{-1}; UV–VIS ($CHCl_3$) λ_{max} (log ϵ): 324 (4.33), 472 (462) nm; (MeOH) λ_{max} (rel. intensity): 264 (0.18), 314 (0.23), 458 (0.83), 478 (1.0); ^1H NMR (300 MHz, $CDCl_3$) δ: 6.73 (d, J = 4.6 Hz, 4H), 7.38–7.46 (m, 10H), 7.60 (d, J = 4.5 Hz, 4H), 9.63 (s, 4H); ^{13}C NMR (50 MHz, $CDCl_3$) δ: 127.4, 129.1, 130.7, 134.5, 136.8, 139.4, 143.7, 147.7, 173.0; LR-MS (EI, 200°C) *m/e*: 496 (100, M^+), 430 (18.8), 419 (18.2), 219 (74.8). Exact Mass calcd. for $C_{30}H_{22}N_4Ni$: 496.11978; found: 496.12071. Anal. calcd. for $C_{30}H_{22}N_4Ni$: C 72.47, H 4.46, N 11.27; found: C 72.33, H 4.70, N 11.3.

X-ray crystallographic analysis of bis[5-phenyl-4,6-pyrrinato]Ni(II) (22)

Crystallographic data appear in Table 4. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 23.3°–33.6°. The intensities of three standard reflections, measured every 200 reflections throughout the data collection, decayed linearly by 2.3%. The data were processed, corrected for Lorentz and polarization effects, decay, and absorption (empirical, based on azimuthal scans for three reflections). The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an *E*-map or from subsequent difference Fourier syntheses (52). The molecule has exact D_2 (crystallographic 222) symmetry. Non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in calculated positions with C—H = 0.98 Å and $B_H = 1.2\ B_{bonded\ atom}$. No correction for secondary extinction was necessary. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International Tables for X-Ray Crystallography* (53). Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, scheme of the unit cell, symmetry operators, and least-squares planes are included as supplementary material.[2]

Absorption spectroscopy of (Ind)Ni(PPh_3)X (Ind = indenyl, 1-Me-indenyl; X = Cl, Br, Me) and M(Ind)$_2$ (M = Ni, Ru; Ind = indenyl)

Malken Bayrakdarian, Martin J. Davis, Christian Reber, and Davit Zargarian

Abstract: The electronic structures of two types of transition metal indenyl complexes have been studied. The first type, a series of (Ind)Ni(PPh_3)X compounds (Ind = indenyl, 1-Me-indenyl; X = Cl, Br, Me) was investigated by absorption spectroscopy and Extended Hückel Molecular Orbital calculations. The energy differences between calculated levels are in good agreement with experimental band positions. For example, the lowest energy singlet–singlet band maximum for (Ind)Ni(PPh_3)Cl is at 19 500 cm^{-1} and the calculated HOMO−LUMO difference is 19 817 cm^{-1}. For X = Me, the calculated energy difference increases to 21 930 cm^{-1} and the corresponding absorption band is at 22 500 cm^{-1}. The influence of the metal–ligand interactions on the molecular orbitals is discussed. The second category of indenyls, the bis(indenyl) compounds of Ni and Ru, show absorption spectra that are markedly different from those of nickelocene and ruthenocene. For example, in comparison to nickelocene, the first absorption band of Ni(Ind)$_2$ is 5700 cm^{-1} higher in energy and is more intense by two orders of magnitude; in contrast, the first absorption maximum of Ru(Ind)$_2$ is 6600 cm^{-1} lower in energy than observed for ruthenocene. The characteristics and relaxation dynamics of the lowest energy excited states are discussed.

Key words: absorption spectroscopy, indenyl, nickel, ruthenium, EHMO analysis.

Résumé : Nous avons étudié la spectroscopie électronique de deux types de composés dont l'élément de transition est lié à un ou deux ligands indényle. Les spectres d'absorption des composés (Ind)Ni(PPh_3)X (Ind = indényle, 1-méthylindényle; X = Cl, Br, méthyle) sont présentés. Les maxima des bandes sont comparés aux différences d'énergie entre orbitales moléculaires calculées avec la méthode «Extended Hückel». Un exemple illustratif en est la première bande singulet–singulet du (Ind)Ni(PPh3)Cl qui est mesurée à 19 100 cm^{-1}, très proche à la différence d'énergie HOMO − LUMO calculée de 19 817 cm^{-1}. Pour le composé (Ind)Ni(PPh3)Me la bande correspondante est décalée vers une énergie plus élevée dont le maximum est à 22 500 cm^{-1}. La différence HOMO−LUMO calculée est de 21 930 cm^{-1}. L'influence des différents ligands sur les caractéristiques des orbitales moléculaires est discutée. Les composés de la 2^e catégorie étudiée sont du type M(Ind)$_2$, avec M = Ni, Ru. Leurs spectres sont comparés à ceux du nickélocène et du ruthénocène. La première bande du Ni(Ind)$_2$ est à une énergie de 5700 cm^{-1} plus élevée que celle du nickelocène et son intensité est plus grande de deux ordres de grandeur. La première bande du Ru(Ind)$_2$ se trouve à une énergie de 6600 cm^{-1} plus basse que celle du ruthénocène. Les caractéristiques du premier état excité et les mécanismes de relaxation sont discutés.

Introduction

Metallocene and mono-Cp (Cp = cyclopentadienyl) complexes of transition metals have fascinated chemists over the past four decades for many reasons, including their unusual electronic structures, interesting patterns of reactivity, and the particular symmetry inherent in their molecular structures. The nature of the interaction between the orbitals of the Cp ligand and the metal centre (M) is of key importance to these properties and has been the subject of numerous theoretical and experimental investigations (1, 2). In contrast, the chemistry of complexes containing ligands analogous to Cp, such as the indenyl and the fluorenyl ligands, remains much less developed. The limited studies of this class of complexes have nevertheless demonstrated that the presence of benzo moieties in these ligands often leads to significant changes in the properties of their complexes. For instance, certain indenyl and fluorenyl complexes exhibit ligand substitution reaction rates that are orders of magnitude larger than those seen for their Cp analogues (3). Similarly, a number of stoichiometric and catalytic reactions are better promoted by some indenyl complexes relative to the Cp analogues (4–6). Such enhancement of reactivity is conventionally attributed to the flexible hapticity of the indenyl and fluorenyl ligands, which provides a means for stabilizing the reaction intermediates (3).

As part of an ongoing research program to develop the chemistry of late metal Ind complexes (Ind = indenyl and its substituted derivatives), we have begun a systematic investigation of the electronic spectra of a series of late metal mono- and bis-Ind complexes. This investigation has two main components: on the one hand, comparisons of structural and spectroscopic features of analogous Cp and Ind complexes are used to pinpoint the salient differences in the M–Cp and M–Ind interactions; on the other hand, Extended Hückel Molecular Orbital (EHMO) calculations are carried out where necessary in order to determine the relative energies of metal and ligand orbitals and their varying contributions to the overall bonding picture in these complexes. An attempt is then made to draw correlations between the emerging MO diagrams and the observed structural and spectral differences for the species considered. This approach has the potential to improve our understanding of some of the underlying reasons for the major differences between Cp and Ind complexes. The present paper reports the results of our studies on the indenyl complexes IndNi(PPh_3)X and M($Ind)_2$ (M = Ni and Ru).

Experimental

Materials

The preparative work was carried out using standard Schlenk techniques and an argon-filled dry box; the solvents were dried and distilled before use following established procedures. The complexes $NiCp_2$ and $RuCp_2$ were purchased from Aldrich and purified by vacuum sublimation prior to use. Ni($Ind)_2$ (7, 8) and Ru($Ind)_2$ (9) were prepared according to literature procedures. Reacting $(PPh_3)_2NiX_2$ (X = Cl and Br) with IndLi (Ind = indenyl and 1-Me-indenyl) furnished the complexes (Ind)Ni(PPh_3)X, which were, in turn, reacted with MeMgBr or MeLi to give the methyl derivatives (X = Me). A more detailed description of the preparation and characterization of the compounds (Ind)Ni(PPh_3)X, including their solid state structures, is given elsewhere (10).

Spectroscopy

The sample solutions were prepared in a glove box using dry solvents. Typical concentrations were on the order of 10^{-3} M. Absorption spectra were measured in 1 cm quartz cells capped with recessed Suba•Seal septa (Aldrich) on a Varian Cary 5E spectrometer.

Extended Hückel Molecular Orbital (EHMO) calculations

EHMO calculations were carried out using a program package based on the ICON code (11, 12). Atomic coordinates and unit cell parameters obtained from X-ray diffraction data (10) were transformed to a Cartesian coordinate system by the program package. Standard values were used for all parameters describing atomic orbitals. A maximum of 58 atoms and 156 valence orbitals were used. Atomic coordinates and summaries of the output for the EHMO calculations presented in Fig. 2 and Table 2 are provided as supplementary material.[2]

Results and discussion

(a) Indenyl hapticity in (Ind)Ni(PPh_3)X

In theory, an idealized pentahapto indenyl ligand is one in which all carbon atoms of the five-membered ring are symmetrically coordinated to the metal atom. In reality, however, most indenyl complexes display some deviation from this ideal η^5 mode whereby the metal atom is somewhat less strongly coordinated to the ring-junction carbons (C3a and C7a). A number of parameters are used to measure the extent of such deviations, or "slip-fold distortions," including the so-called slip value, which is defined as $\Delta M—C = M—C_{avg.}$ (for C3a and C7a) − $M—C_{avg.}$ (for C3 and C1) (8); thus, the smaller the slip value the less significant the distortion. The extent of "slippage" normally depends on the formal electron count of the complex such that most compounds with 18 or fewer electrons exhibit little distortion (e.g., Fe(η^5-$Ind)_2$ with $\Delta M—C = 0.04$ Å (8)), whereas significant distortions are usually found in compounds in which a pentahapto indenyl would place more than 18 electrons in the metal valence orbitals (e.g., (η^3-Ind)Ir($PMe_2Ph)_3$ with $\Delta M—C = 0.79$ Å (13)). In some cases, however, slip-fold distortions might be larger than expected even in formally 18-electron compounds. For instance, even though the complexes (Ind)Ni(PPh_3)Cl would be 18-electron species with pentahapto indenyls, their solid state structures show significantly slipped indenyls with $\Delta M—C \approx 0.25$ Å (10). The relatively large distortion observed here might be attributed to the tendency of Ni(II) complexes to prefer 16- vs. 18-electron configurations.

An even more unusual feature of the indenyl hapticity in the complexes (Ind)Ni(PPh_3)Cl is that the displacement of Ni away from C3a and C7a is not towards C-2, as expected, but rather towards C-3, as illustrated in Fig. 1. This "sideways slippage" leads to unequal distances between the nickel atom and the carbons of the five-membered ring such that Ni—C7a > Ni—C3a > Ni—C1 > Ni—C2 > Ni—C3 (10). Therefore, the hapticity of the indenyl ligand in these compounds appears to lie somewhere in the continuum defined by the η^5, η^3, and the (η^1,η^2) coordination modes. We have suggested that this sideways slippage is caused by the different *trans* influences of the PPh_3 and Cl ligands (10). Consistent with this reasoning, replacing Cl in the Ind complexes by the higher *trans* influence ligand Me results in a "symmetrically slipped" indenyl ligand, i.e., Ni—C1 = Ni—C3 and Ni—C3a = Ni—C7a (Fig. 1). A similar situation exists in the analogous Cp complexes: in the complex (Me-Cp)Ni(PPh_3)I the Ni—C distance for the carbon atom *trans* to PPh_3 is longer than that *trans* to iodide

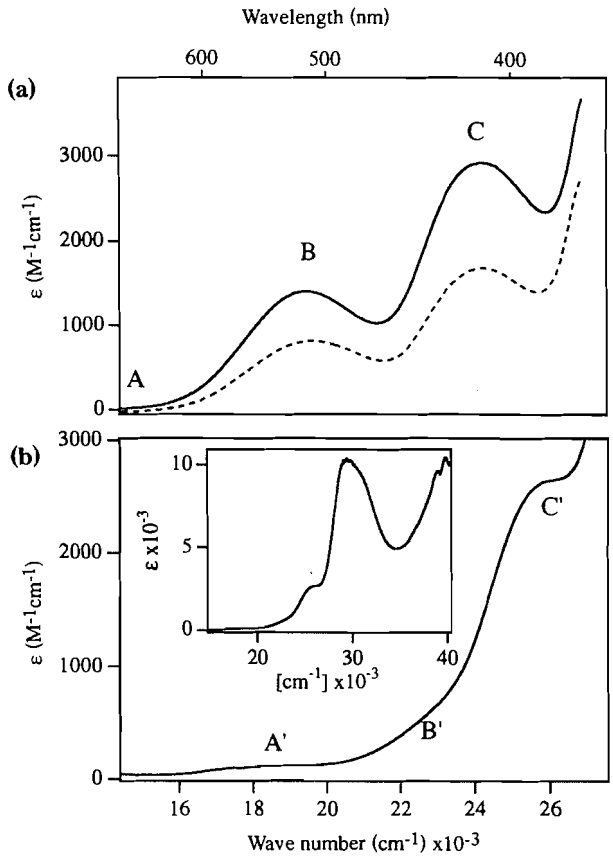
(14), whereas in the alkyl analogue CpNi(PPh_3)(CF_3) all Ni—C bonds are fairly equal (15).

To study the effect of the indenyl hapticity on the MO diagram and the electronic transitions of the complexes (Ind)Ni(PPh_3)X, we have recorded their absorption spectra and carried out EHMO calculations, as described below.

(b) Absorption spectra, band assignments, and EHMO calculations for (Ind)NiPPh$_3$X

The results of the absorption spectra for the complexes (Ind)NiPPh$_3$X are summarized in Table 1, and the spectra for three selected indenyl compounds are presented in Fig. 2. The halo derivatives show similar absorption spectra consisting of a broad band (B) at approximately 520 nm followed by a more intense band centered at 410 nm (C), as illustrated in Fig. 2*a*. Methyl substitution at the 1 position of the indenyl ligand has only a small effect on transition energies, but appears to change the band intensities, as shown by the comparison in Fig. 2a and Table 1. Based on their intensities, these transitions are spin-allowed bands from the singlet electronic ground state, which have typical molar absorptivities of 10^3–10^4 M^{-1} cm^{-1} (16). Weak, low-energy bands were observed for these complexes at ca. 700 nm (A), which most likely correspond to the spin-forbidden transition to the lowest energy triplet state. The weak intensity of this band is caused by the magnitude of the spin-orbit coupling, which for 3*d* metal ions normally leads to absorption bands ca. 100 times weaker than spin-allowed transitions (17).

Fig. 2. Absorption spectra of (Ind)Ni(PPh_3)X compounds. (*a*) X = Cl; Ind = indenyl (solid line), 1-Me-indenyl (dotted line); (*b*) X = Me; Ind = 1-Me-indenyl.



The methyl derivative (1-Me-indenyl)Ni(PPh_3)Me shows a different spectrum than the halo compounds, as illustrated in Fig. 2*b*. A weak, low-energy band is observed at 543 nm (A′), again most likely corresponding to the transition to the lowest energy triplet state. A band of comparable intensity to the first spin-allowed band for the halide compounds is observed as a shoulder at 445 nm (B′), higher in energy by approximately 3000 cm^{-1} than for the compounds in Fig. 2*a*. A second band (C′), comparable in intensity to the band C of the halide complexes, is observed at an energy higher by 2000 cm^{-1}. The inset to Fig. 2*b* shows the absorption spectrum of the methyl compound up to higher energy. An intense band is observed at 339 nm, most likely corresponding to an allowed electronic transition; similar intense bands at this energy were observed for dilute solutions of some of the halide compounds (Table 1).

The spectra for the Ind complexes show qualitative similarities to those reported for the analogous Cp complexes (18). The latter show only one absorption band between 600 nm and 400 nm with a molar absorptivity similar to those of the two bands observed for the Ind complexes in this region (Table 1). For example, the band maximum for CpNi(PPh_3)Cl is at 512 nm, the same wavelength as for the analogous Ind compound, and has a molar absorptivity of 900 M^{-1} cm^{-1} (18). At higher energy, an intense band is observed at 331 nm (ϵ = 8500 M^{-1} cm^{-1}), very similar to the bands of the (Ind)Ni(PPh_3)Cl com-

[a]The energy of the HOMO was set to 0 cm^{-1} to simplify comparison to the spectra. Atomic orbitals contributing less than 1% to the MO are not included in the sums for indenyl and phenyl fragments.

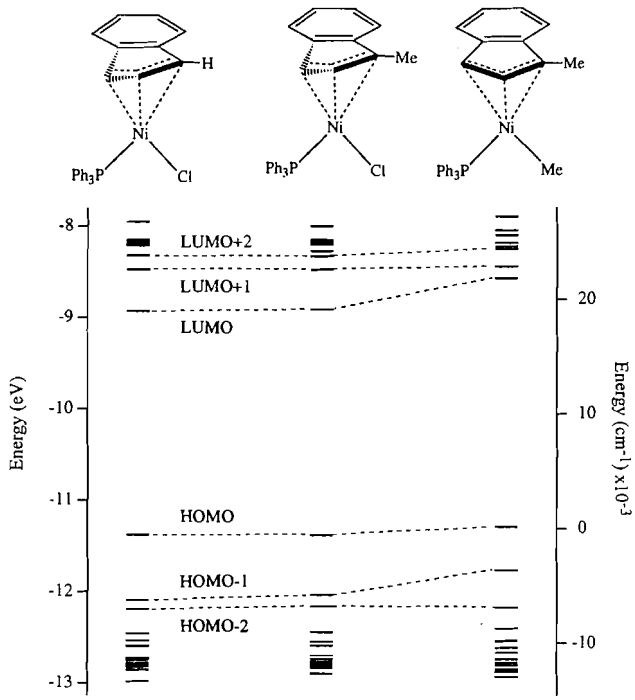
pounds in this region. Weak triplet transitions are reported between 600 and 800 nm. The maximum of the first spin-allowed band for CpNi(PPh_3)Me is observed at an energy higher by 5800 cm^{-1} than in the Cl analogue (18). A shift in the same direction, albeit smaller (3000 cm^{-1}), was observed in the Ind compounds.

The results of EHMO calculations carried out on the complexes (Ind)Ni(PPh_3)X (Ind = indenyl and X = Cl; Ind = 1-Me-indenyl and X = Cl and Me) allow a qualitative assignment of the bands observed in the absorption spectra and can be used to discuss some of the important spectroscopic differences between the Cl and the Me compounds. The energy levels and orbital characteristics for the HOMO–LUMO energy range, which is the region of interest for low-energy electronic transitions, are summarized in Fig. 3 and in Table 2. Very similar orbital energies were obtained for (indenyl)Ni(PPh_3)Cl and (1-Me-indenyl)Ni(PPh_3)Cl, in good qualitative agreement with their similar solid state structures and absorption spectra. The calculated HOMO–LUMO gaps of 19 817 cm^{-1} and 19 898 cm^{-1} for the indenyl and 1-Me-indenyl compounds, respectively, are in excellent agreement with the energy of the first spin-allowed transition in the absorption spectra observed at approximately 19 500 cm^{-1}. The energy of the second band in the spectra presented in Fig. 2*a* (ca. 24 000 cm^{-1}) corresponds to a number of energy gaps, so that in principle several transitions (e.g., HOMO-2→LUMO, HOMO-1→LUMO, HOMO→LUMO+1, and HOMO→LUMO+2) could contribute to this band.

In the case of (1-Me-indenyl)Ni(PPh_3)Me, we calculate a HOMO–LUMO gap of 21 930 cm^{-1}, again in good agreement with the experimental transition energy of 22 500 cm^{-1}. A number of orbital energy gaps correspond to the transition energy of the second, more intense band in the spectrum of this complex. Due to the absence of a center of inversion in our compounds, parity selection rules do not apply and even *d–d* bands have considerable intensities. The highest energy level included in Fig. 3 has mainly π^* character on both the Ind ligands and the phenyl groups of PPh_3, leading to an allowed transition from the HOMO. This transition corresponds to the intense band observed at approximately 29 500 cm^{-1} in dilute solutions and calculated at 27 360 cm^{-1}, showing once again good agreement between the calculated energies and the spectroscopic data.

In the chloro compounds, the HOMO and LUMO are primarily a combination of nickel 3*d* and indenyl π orbitals (Table 2). The main contribution to the higher energy orbitals LUMO+1 and LUMO+2 comes from the Ind ligand and the phenyl groups of PPh_3, respectively; this explains their fairly constant energy levels in all three compounds. The main difference between the EHMO energies for the compounds in Fig. 3 concerns the LUMO and HOMO-1 orbitals, both of which are higher in energy for (Ind)Ni(PPh_3)Me than for the

Fig. 3. EHMO energy levels for the three compounds whose spectra are presented in Fig. 2. The wave number scale applies to (1-Me-indenyl)Ni(PPh_3)Me, with the energy of the HOMO set to 0 cm^{-1} for comparison with the spectroscopic data.



two chloro derivatives. The higher LUMO energy leads to a shorter wavelength for the first spin-allowed transition in the Ni–Me compound, as observed in the spectra. The higher energy of the HOMO-1 level decreases the difference between the first and the following absorption transitions, a likely reason for the overlapping bands in Fig. 2*b*. The contributions from the Me ligand to the LUMO and HOMO-1 orbitals are 3–4 times larger than those of the Cl ligand, as summarized in Table 2.

The use of EHMO calculations to analyze the electronic spectra of our complexes seems justified in light of the general agreement between experimental transition energies and calculated energy gaps. The close correspondence between measured absorption bands and calculated orbital energies is remarkable, especially in view of the simplifications involved in the EHMO scheme and the neglected electron–electron repulsions (19). To be sure, the observed agreement might arise from a fortuitous cancellation of contributions from electron-pairing energies and Madelung-type ionic interactions (20), both of which are neglected in the EHMO methodology. Nevertheless, our comparison indicates that the spectroscopic signatures for the different electronic structures of the compounds (Ind)Ni(PPh_3)X are reflected in the EHMO calculations. The match between spectroscopic and calculated data for the indenyl complexes studied here is in contrast to the difficulties encountered in rationalizing the spectroscopic data for the analogous Cp compounds using semi-empirical MO calculations (18). We plan to undertake a broader study of a number of Ind and Cp complexes and to use more advanced semi-empirical MO techniques in order to investigate the origins of this discrepancy and the limitations of our approach.

(c) Indenyl hapticity in $Ni(Ind)_2$ and $Ru(Ind)_2$

Detailed descriptions of the solid state structures of $Ni(Ind)_2$ (8) and $Ru(Ind)_2$ (21) have been reported in the literature. It is instructive for our analysis to briefly compare these structures to the corresponding Cp analogues. For example, nickelocene adopts a centrosymmetric structure with parallel, staggered, and very nearly planar Cp rings (approximate D_{5d} symmetry), and the Ni atom is displaced by only 0.03 Å from the fivefold axes of the rings (22). In contrast, the two Ind ligands in $Ni(Ind)_2$ are highly distorted toward trihapto coordination, with an average slip value of ca. 0.42 Å. Thus, the flexible hapticity of the Ind ligands stabilizes $Ni(Ind)_2$ by avoiding an unfavorable 20 electron configuration obtained in the presence of two η^5-Ind ligands. A different situation exists in the two Ru compounds where the rings are planar, nearly parallel, and fully eclipsed and show no significant deviation from a pentahapto coordination. The similarity in the structures of $Ru(Ind)_2$ and ruthenocene reflects the formal electron count of these complexes (18 electrons), which does not necessitate any distortions in the Ind compounds.

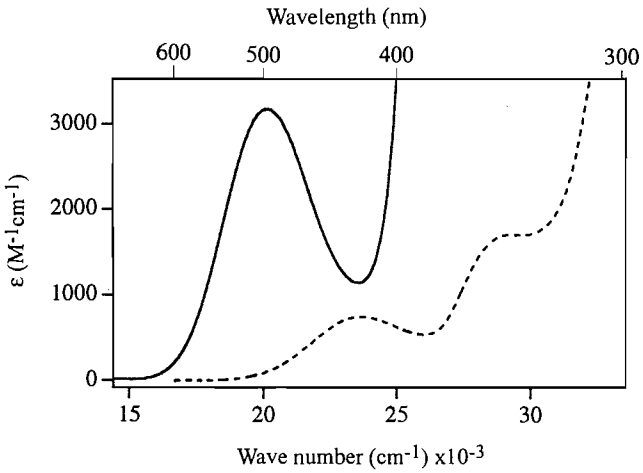
We set out to study the electronic spectra of these bis(indenyl) complexes and compare them to the corresponding spectra for the metallocenes in order to examine the electronic consequences of replacing Cp ligands by Ind. The results of this study are described in the following section.

(d) Absorption spectra and electronic structures of $Ni(Ind)_2$ and $Ru(Ind)_2$

The absorption spectra of the two bis-indenyl compounds are shown in Fig. 4 and their band energies and intensities are summarized in Table 1. The UV–visible spectrum of $Ni(Ind)_2$ shows an intense, broad absorption band in the green spectral region with its maximum at 20 200 cm^{-1} and a molar absorptivity of 3180 M^{-1} cm^{-1}, very different from nickelocene whose lowest-energy absorption band is in the red spectral region with a first maximum at 14 500 cm^{-1} and a much lower molar absorptivity of 60 M^{-1} cm^{-1} (23–25). The band maximum of $Ni(Ind)_2$ is higher in energy by 5700 cm^{-1} and more intense by almost two orders of magnitude than in nickelocene. This dramatic difference can not be explained by the lower symmetry alone since $Ni(Ind)_2$ retains its center of inversion in the solid state and hence parity selection rules apply. Even if the symmetry of $Ni(Ind)_2$ is somewhat relaxed in solution, we would still expect the molar absorptivities for formally Laporte-forbidden *d–d* bands to be significantly lower than those reported in Fig. 2 and Table 1 for indenyl compounds without a center of inversion. The intensity of this band indicates that the lowest excited state is no longer a ligand-field level but involves important contributions from ungerade parity molecular orbitals, leading to allowed electronic transitions.

The width of the first absorption band for both compounds is 5000 cm^{-1}, but nickelocene shows two maxima at low temperatures, due to at least two different overlapping *d–d* transitions (24, 26). In contrast, the first absorption band in $Ni(Ind)_2$ is symmetric, indicating that one electronic state determines the band shape. These observations imply that the character of the lowest energy excited state of $Ni(Ind)_2$ is not similar to that of nickelocene where all low-energy transitions are parity forbidden *d–d* bands (25). The large width for a single band is caused by large structural changes between the ground- and

Fig. 4. Absorption spectra of $Ni(Ind)_2$ (solid line) and $Ru(Ind)_2$ (dotted line).



excited states, as expected for bands with significant charge transfer character.

Further supporting this assignment is the absence of luminescence from $Ni(Ind)_2$ at temperatures higher than 5 K. We observed no luminescence from $Ni(Ind)_2$ doped into ruthenocene between 500 and 1800 nm with the same instrumentation used for detecting weak near-infrared and visible luminescence for nickelocene and cobaltocene doped into single crystals of ruthenocene (26, 27). Large structural changes between the ground- and lowest energy excited states are probably responsible for the efficient nonradiative relaxation processes, which quench luminescence from $Ni(Ind)_2$. All observations illustrate that the first excited state of $Ni(Ind)_2$ is dramatically different from nickelocene.

The spectroscopic comparison of ruthenocene and $Ru(Ind)_2$ also reveals significant differences in the nature of the lowest energy excited state. $Ru(Ind)_2$ shows a more intense first band than ruthenocene for which the lowest energy *d–d* transition occurs at 30 000 cm^{-1} with a molar absorptivity of 200 M^{-1} cm^{-1} (28). However, the increase in intensity for the Ru compounds is less dramatic than for the analogous nickel compounds, consistent with the similar solid state structures for $Ru(Ind)_2$ and ruthenocene. Although precise bandwidths are difficult to determine quantitatively for the overlapping bands of ruthenocene, widths larger than 3000 cm^{-1} are observed for both ruthenocene and $Ru(Ind)_2$, with the first band maximum of the latter being 6600 cm^{-1} lower in energy. A detailed EHMO study of $M(Ind)_2$ (M = Fe, Ru) has established that the first excited electronic state of these compounds has significant indenyl π character (9). The metal d orbitals and one of the indenyl π orbitals are at the same energy, leading to a large π contribution to the LUMO; this is in agreement with our observation of a large, intense band for the transition from HOMO, which is mainly metal *d* to LUMO, which is a combination of metal *d* and indenyl π.

As was found for $Ni(Ind)_2$, we did not observe any luminescence for $Ru(Ind)_2$. The absence of luminescence in these bis(Ind) complexes is in agreement with a detailed study on the photophysics and photochemistry of bis(arene)ruthenium compounds that showed that ring-tilting in the excited state favors nonradiative relaxation and quenches luminescence (29). Large excited state distortions of this type are quite probable in both the $Ru(Ind)_2$ and the $Ni(Ind)_2$ compounds, given the well-documented facility with which indenyl ligands undergo hapticity changes accompanied by folding (3), but they are much less likely for the metal-centered *d–d* transitions in metallocenes. Another possible source of luminescence quenching is the number of high-energy C—H oscillators that can act as potential acceptors for the electronic excitation energy. Although this is found to be a less important factor in bis(arene)ruthenium compounds (29), its importance in lowering the luminescence quantum yield for bis(indenyl) compounds cannot be ignored given that the latter compounds possess 14 C—H oscillators compared to 10 in the corresponding metallocenes.

Conclusion

The comparison of absorption spectra for indenyl compounds and their cyclopentadienyl analogues shows that this method offers a very sensitive probe into metal – aromatic ligand bonding and molecular symmetry. Our results indicate strong correlations between structural characteristics, spectroscopic parameters, and metal – aromatic ligand bonding. In addition, this combination of techniques provides some insight into the nature and properties of the low-energy excited electronic states, information not routinely available with other techniques. In this sense, the present approach, which focuses on the HOMO–LUMO energy differences, complements past work on the photoelectron spectroscopy of Ind complexes (9) where the focus is the relative energies of low-lying occupied MOs. Future work will involve preparing related derivatives and investigating them with structural, spectroscopic, and more sophisticated molecular orbital studies.

A pentaammineruthenium(III) dimer with the novel bridging ligand 4,4′-dicyanamidobiphenyl dianion

Manuel A.S. Aquino, Christopher A. White, Corinne Bensimon, J.E. Greedan, and Robert J. Crutchley

Abstract: The novel ligand 4,4′-dicyanamidobiphenyl dianion (bp^{2-}) has been synthesized and characterized by ^{13}C NMR spectroscopy, cyclic voltammetry, and crystallography. The crystal structure of $[Ph_4As]_2[bp]\cdot H_2O$ showed that bp^{2-} is approximately planar with a dihedral angle of 8.2° between phenyl ring planes and the cyanamide groups in an *anti* conformation. The water of crystallization is asymmetrically hydrogen bonded between cyanamide groups of adjacent bp^{2-} ions. The crystal data for $C_{62}H_{48}N_4As_2+H_2O$ are monoclinic crystal system and space group $P2_1/c$ with $a = 12.998(5)$ Å, $b = 13.465(4)$ Å, $c = 28.703(13)$ Å, $\beta = 98.94(3)°$, $V = 4963(3)$ Å^3, and $Z = 4$. The structure was refined by using 4555 reflections with $I > 2.5\sigma(I)$ to an R factor of 0.058. The complex, $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})][X]_4$, where X = tosylate or PF_6^- ions, was also synthesized and characterized by ^1H NMR spectroscopy, cyclic voltammetry, spectroelectrochemistry, and temperature-dependent magnetic susceptibility measurements. From cyclic voltammetry measurements, the comproportionation constants to form the mixed-valence complex $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})]^{3+}$ were estimated to be 4.1, 16, and 22 in water, acetonitrile, and nitromethane, respectively. The trend and magnitude of K_c suggests solvent valence trapping of a weakly coupled Class II ion. The MMCT band of the mixed-valence complex had to be deconvoluted from the low-energy LMCT band and had the following properties in acetonitrile, $\nu_{max} = 8400$ cm^{-1}, $\varepsilon_{max} = 3300$ M^{-1} cm^{-1}, and $\Delta\nu_{1/2} = 3300$ cm^{-1}. The weak superexchange mediating properties of bp^{2-} compared to 1,4-dicyanamidobenzene dianion were suggested to arise from the larger barrier to the formation of the radical anion bp^-.

Key words: cyanamido, mixed valence, superexchange, ruthenium.

Résumé : On a synthétisé le nouveau ligand dianionique, 4,4′-dicyanamidobiphényle (bp^{2-}) et on l'a caractérisé par la spectroscopie de RMN, la voltampérométrie cyclique et par cristallographie. La structure du cristal de $[Ph_4As]_2[bp]\cdot H_2O$ montre que l'anion bp^{2-} est approximativement plan avec un angle dièdre de 8,2° entre les cycles phényles plans, et les groupes cyanamides sont dans une conformation *anti*. L'eau de cristallisation est liée de façon asymétrique par des liaisons hydrogènes entre les groupes cyanamides adjacents aux ions bp^{2-}. Les cristaux de $C_{62}H_{48}N_4As_2 + H_2O$ appartiennent au groupe d'espace monoclinique $P2_1/c$ avec $a = 12,998(5)$ Å, $b = 13,465(4)$ Å, $c = 28,703(13)$ Å, $\beta = 98,94(3)°$, $V = 4963(3)$ Å^3 et $Z = 4$. On a affiné la structure en utilisant 4555 réflexions avec $I > 2,5\sigma(I)$ jusqu'à un facteur de R de 0,058. On a également synthétisé le complexe $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})][X]_4$, X = ion tosylate ou PF_6^-, et on l'a caractérisé par la spectroscopie de RMN, la voltampérométrie cyclique, la spectroélectrochimie et par les mesures de susceptibilité magnétique en fonction de la température. À partir des mesures de voltampérométrie cyclique, on a évalué la constante de compropornation à 4,1, 16 et 22 dans l'eau, dans l'acétonitrile et dans le nitrométhane respectivement. La tendance et l'importance de K_c suggèrent une capture de valence d'un ion de classe II faiblement couplé par le solvant. La bande de valence mixte du complexe MMCT doit être déconvolutée à partir de la bande LMCT de faible énergie et a les propriétés suivantes dans l'acétonitrile, $\nu_{max} = 8400$ cm^{-1}, $\varepsilon_{max} = 3300$ M^{-1} et $\Delta\nu_{1/2} = 3300$ cm^{-1}. On suggère que les propriétés de suréchange faible de l'ion bp^{2-} compares avec celles du dianion 1,4-dicyanobenzène, sont dues à la plus grande barrière à la formation de l'anion radicalaire bp^-.

Mots clés : cyanamido, valence-mixte, suréchange, ruthénium.

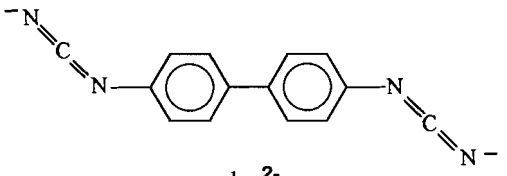
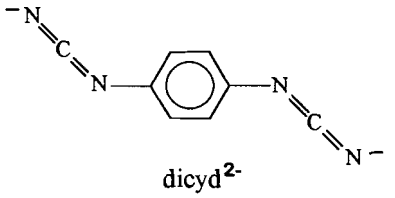
Introduction

Biphenyl spacers have played an important role in elucidating the effect of medium on electron transfer rates and spin interactions (1–4). For example, McLendon and co-workers (1) have examined the dependence of the rate of electron transfer between porphyrins on the dihedral angle between phenyl rings of a biphenyl spacer. The rate of electron transfer was shown not to follow the expected cos θ relationship but to qualitatively follow a cos 2θ function, with maxima at 0 and 90° and a minimum at 45°. This dependence was anticipated by a theory for bis-porphyrin systems developed by Cave, Marcus, and Siders (5). More recent studies have focussed on incorporating polyphenyl spacers into supramolecular assemblies (6) and, in this regard, the long-range (nm scale) transfer of electrons or energy will depend on the geometric and electronic properties of the bridge. The effect of these properties can be described by the intercomponent



bp^{2-}



$dicyd^{2-}$

interaction energy, H, whose distance dependence is expected (7) to follow

$$[1] \quad H = H_0 \exp(-\beta r)$$

where β is an attenuation factor and r is the separation between two metal ions. It has been suggested (6) that β for hole transfer superexchange through polyphenylene bridges is approximately equal to zero. These investigations have practical application to poly(*p*-phenylene), a polymer that has been studied extensively (8) for its possible electronic and photonic applications.

Because our research program is uniquely suited to the study of hole transfer superexchange through π-donor aromatic systems, we decided to synthesize dicyanamidobiphenyl dianion (bp^{2-}) in order to compare its abilities as a superexchange mediator with those of 1,4-dicyanamidobenzene dianion ($dicyd^{2-}$). The complexes, $[\{(NH_3)_5Ru\}_2(\mu\text{-dicyd})]^{4+}$ where $dicyd^{2-}$ can be unsubstituted, 2,5-dimethyl, 2,5-dichloro, or 2,3,5,6-tetrachloro-1,4-dicyanamidobenzene dianion, possess Ru(III) ions that are strongly antiferromagnetically coupled (9, 10). The mechanism for metal–metal exchange was suggested to be hole transfer superexhange via the highest occupied orbital (HOMO) of the bridging $dicyd^{2-}$ ligand. In addition, the mixed-valence complexes $[\{(NH)_5Ru\}_2(\mu\text{-dicyd})]^{3+}$ are also strongly coupled systems that show a remarkable solvent dependence of metal–metal coupling (11, 12).

The bp^{2-} ligand should be one in which the conditions for superexchange within a biphenyl moiety are considerably enhanced and a comparison with the $dicyd^{2-}$ ligand will lead to greater insight into those factors controlling hole transfer superexchange.

Experimental

Physical measurements

Ultraviolet–visible near-infrared absorption spectra were taken on a Cary 5 spectrophotometer. The IR spectra of the samples in KBr discs were obtained with a Perkin-Elmer 1600 series FTIR spectrophotometer. ^1H and ^{13}C NMR spectra were run on a Varian XL-200 NMR spectrometer or a Bruker AMX-400 NMR spectrometer at 300 K and referenced to TMS (0.00 ppm). C, H, and N elemental analyses were performed by Canadian Microanalytical Services Ltd. The experimental setup used to perform non-aqueous (13) and aqueous (14) cyclic voltammetry experiments has already been described. The ferricenium/ferrocene couple with E^0 = 665 mV vs. NHE (15) was used in nonaqueous solvents as an internal calibrant. Spectroelectrochemistry was performed with a Pyrex–quartz cell of published design (16). Tetrabutylammonium hexafluorophosphate (TBAH) was recrystallized twice from ethanol and vacuum dried at 110°C overnight. Temperature-dependent magnetic susceptibility measurements were performed on a Quantum Design S.Q.U.I.D. magnetometer from 5 to 300 K in a 1.0 T field.

Materials

All chemicals and solvents were reagent grade or better. Benzidine (Anachemia), tetraphenylarsonium chloride hydrate $[Ph_4As][Cl]\cdot H_2O$ (Aldrich), and anhydrous acetonitrile (99+%, Aldrich) were used as received. Nitromethane (99+%, Aldrich) had to be distilled to remove impurities that decomposed the Ru(III) dimer. $[(NH_3)_5Ru(OH_2)][PF_6]_2$ was prepared according to literature procedures (17).

Preparation of N,N′-dicyano-4,4′-diaminobiphenyl·H_2O, $bpH_2\cdot H_2O$

To a gently refluxing solution of ammonium thiocyanate (7.6 g) in 100 mL of acetone was added dropwise a solution of benzoyl chloride in 100 mL of acetone. Over the 15 min. addition, the stirred solution became yellow and ammonium chloride precipitated. An acetone solution of benzidine (9.2 g in 100 mL) was then added dropwise over a 30 min. period to the refluxing reaction mixture. After addition was complete, the reaction mixture was allowed to reflux for 1 h, and then added to 1.5 L of water to ensure complete precipitation of the yellow benzoyl thiourea intermediate, which was filtered off and washed with water. This intermediate was then transferred to a 1 L Erlenmeyer flask containing 350 mL of 2.5 M NaOH solution. The reaction mixture was brought to a boil and maintained at that temperature for 5 min and then allowed to cool to 65°C. A solution of $Pb(acetate)_2\cdot 3H_2O$ (24 g) in 120 mL water was added, causing the reaction mixture to turn brown and then slowly black with the formation of lead sulfide. The formation of lead sulfide should take no more than 10 min, after which the reaction mixture is filtered into an ice-cooled suction flask. Immediate addition of glacial acetic acid (55 mL) to

the filtrate precipitated the white product, which was filtered and washed copiously with water. Recrystallization from acetone–water yields fine white needles. Yield: 5.9 g (50%); mp: decomposes >200°C. IR: ν(NCN) = 2224 cm^{-1}. Dimer formation is indicated by a strong ν(C=N) band centered at 1680 cm^{-1} that is absent in the monomer (18). ^{13}C NMR: 5 peaks at 137.7, 133.8, 127.5, 115.4, and 112.0 ppm in DMSO-d_6. ^1H NMR: 7.62 (doublet, 4H), 7.05 (doublet, 4H), and 10.23 (broad singlet, 2H) ppm in DMSO-d_6. The presence of a water of recrystallization was confirmed by a water resonance at 3.44 ppm which integrated for two protons. Anal. calcd.for $C_{14}H_{12}N_4O$: C 66.65, H 4.79, N 22.21; found: C 66.69, H 4.63, N 22.34.

Preparation of bis(tetraphenyl arsonium) 4,4′-dicyanamidobiphenyl, $[Ph_4As]_2[bp]\cdot H_2O$

To a solution of bpH_2 (0.23 g) in 2 M NaOH (30 mL) was added a solution of $[Ph_4As][Cl]$ (0.82 g) in water (10 mL). A canary-yellow precipitate immediately formed. This was filtered and washed with water and vacuum dried. The crude product was dissolved in boiling acetonitrile (60 mL) and the solution gravity filtered. Ether was allowed to diffuse into the filtrate, which over 2 days gave golden crystals. Yield: 0.79 g (83%). IR: ν(NCN) = 2088 cm^{-1}. Anal. calcd. for $C_{62}H_{50}As_2N_4O$: C 73.23, H 4.96, N 5.51; found: C 72.77, H 5.13, N 5.69.

Preparation of $[\{(NH_3)_5Ru\}_2(\mu\text{-}bp)][PF_6]_4\cdot$acetone

Under argon, $[(NH_3)_5Ru(OH_2)][PF_6]_2$ (1.0 g) and bpH_2 (0.25 g) were dissolved in 75 mL acetone. The solution was allowed to stir for 16 h at room temperature, then filtered, and exposed to air. Upon stirring for 2 h, the complex oxidized, turning the solution from a light green to a dark blue-green colour. Tetrabutylammonium bromide (1.5 g) was added to the solution to precipitate the green bromide complex. This was filtered, washed with acetone and allowed to dry. The bromide salt was then dissolved in water (35 mL), filtered and the filtrate added to a solution of NH_4PF_6 (3.3 g) in water (10 mL). The resulting blue-green precipitate was filtered, washed with ice-cold water, and vacuum dried. Recrystallization was achieved by diffusing ether into an acetone solution of the complex. Yield: 1.02 g (82%). IR: ν(NCN) = 2110 cm^{-1}. Anal. calcd.for $C_{17}H_{44}F_{24}N_{14}OP_4Ru_2$: C 16.43, H 3.57, N 15.77; found: C 16.70, H 3.57, N 15.26.

Preparation of $[\{(NH_3)_5Ru\}_2(\mu\text{-}bp)][tosylate]_4\cdot 2H_2O$

Metathesis of the bromide complex (as prepared above) in aqueous solution with potassium tosylate yielded the tosylate complex in 80% yield. The complex was recrystallized by acetone diffusion into an acetone–water solution of the complex. IR: ν(NCN) = 2106 cm^{-1}. Anal. calcd.for $C_{42}H_{70}N_{14}O_{14}Ru_2S_4$: C 38.06, H 5.32, N 14.79; found: C 37.64, H 5.05, N 14.72.

Crystal structure determination of $[Ph_4As]_2[bp]\cdot H_2O$

A suitable cubic crystal was grown by allowing a saturated warm DMSO solution to slowly cool to room temperature. The crystal was mounted on a glass capillary and measurements made on a Picker diffractometer with Cu $K\alpha_1$ radiation. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement using the setting angles of 30 reflections in the range $80 < 2\theta < 100$ and corresponded to a monoclinic cell. Based on systematic absences, the space group was determined to be $P2_1/c$. For $Z = 4$ and fw = 1016.95 g, the calculated density is 1.361 g/cm^3.

The data were collected using the ω-2θ scan technique to a maximum 2θ value of 119.9°. A total of 8182 reflections were collected with a unique set of only 6270 reflections. The standards were measured after every 150 reflections and no crystal decay was noticed. The data were corrected for Lorentz and polarization effects (19). No absorption correction was made.

The structure was solved by direct methods. All the atoms were refined anisotropically except the hydrogen atoms, which were calculated. The final cycle of full-matrix least-squares refinement was based on 4555 observed reflections ($I > 2.5\sigma(I)$) and 623 variable parameters. Weights based on counting statistics were used. The maximum and minimum peaks on the final differences Fourier map corresponded to −0.490 and 1.250 e/A^3, respectively. All the calculations were performed using the NRC VAX crystallographic software package (20).

Full listings of positional and thermal parameters, bond angles and lengths, and dihedral angles have been deposited as supplementary material.[2]

Results and discussion

The bridging ligand

Crystals of the free dianion ligand $[Ph_4As]_2[bp]$ are air stable, unlike those of $[Ph_4As]_2[dicyd]$ that must be stored under argon. Crystal data and atomic parameters for $[Ph_4As]_2[bp]$ are compiled in Tables 1 and 2, respectively. The structure of bp^{2-} is shown in Fig. 1 and selected bond lengths and angles are given in Table 3. As shown in Fig. 1, bp^{2-} adopts an approximately planar geometry suggesting significant π interactions between the two phenyl rings and between the cyanamide groups and their respective phenyl rings. The π interaction between the phenyl rings favours a planar geometry but this is opposed by steric repulsion between *ortho* hydrogens, which results in a small but significant dihedral angle of 8.2° between the phenyl ring planes. There are many crystal structures of phenylcyanamide ligands (9, 10, 21–23) that show cyanamide groups coplanar with phenyl rings. Crystal structures of uncoordinated 1,4-dicyanamidobenzene dianion ($dicyd^{2-}$) and its substituted derivatives (10, 23) have all shown the cyanamide groups to adopt an *anti* conformation, as do those of bp^{2-}. The apparent stability of the *anti* conformation arises in part from its minimal repulsion between cyanamide anion groups. An additional feature in the crystal structure of bp^{2-} is the presence of a water of crystallization, hydrogen bonded between adjacent bp^{2-} ligands to form a chain of alternating bp^{2-} and water molecules within the crystal lattice. The nitrogen to oxygen separations (Table 3) are

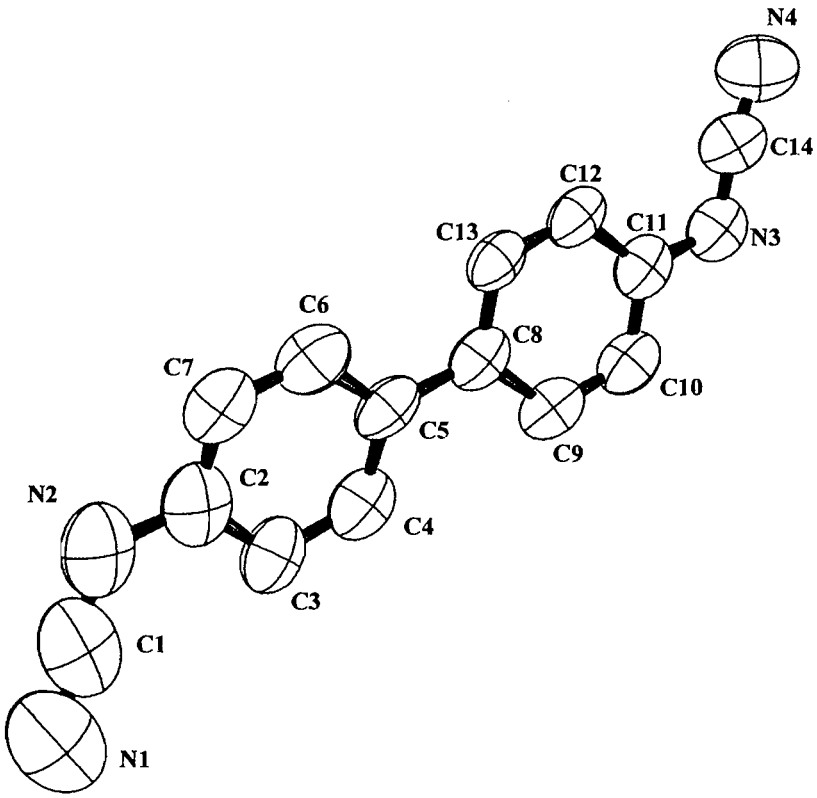
$$bp^{\cdot-} \underset{L_2}{\overset{-e^-}{\rightleftharpoons}} bp$$

consistent with one-electron redox processes and good reversibility is shown by equivalent anodic and cathodic currents at scan rates greater than or equal to 200 mV s^{-1}. In addition, the ratio of anodic peak current functions, $i_p/\nu^{1/2}$ found for the electrochemical responses of bp^{2-} with those of equimolar fer-

Fig. 1. ORTEP drawing of bp^{2-}. The tetraphenyl arsonium counterions and water molecule have been excluded for clarity.

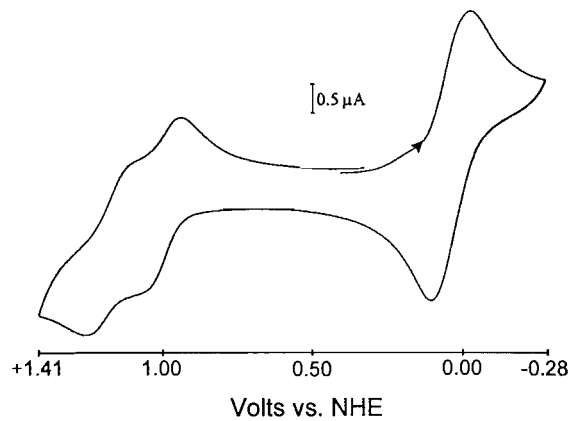


rocene gave for L_1 a value of 0.90 and for L_2 a value of 0.95. At slower scan rates, reversibility of the L_2 couple is significantly decreased as shown by the reduction of both anodic and cathodic currents relative to the L_1 couple and by the fouling of the working electrode. Drying the solvent did not appear to improve reversibility.

The complex

The cyclic voltammogram of $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})]^{4+}$ in acetonitrile (Fig. 2), and the electrochemical data in this solvent as well as water and nitromethane (Table 4), are indicative of a weakly coupled mixed-valence state for this complex. In Fig. 2, the overlap of Ru(III/II) couples results in only a single cathodic and anodic peak of twice the current intensity of the one-electron ligand couples at more positive potentials. Richardson and Taube (25) have given a graphical method of evaluating the separation between overlapping Ru(III/II) couples (ΔE in Table 4) from the separation of anodic and cathodic peaks in the cyclic voltammetry experiment. From the values of ΔE, the estimated comproportionation constants K_c for $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})]^{3+}$ in water, acetonitrile, and nitromethane are 4.1, 16, and 22, respectively. We have interpreted similar but much greater solvent dependence in K_c for $[\{(NH_3)_5Ru\}_2(\mu\text{-dicyd})]^{4+}$ complexes as due to solvent-induced valence trapping (11, 12) and this may play a role here as well. However, in the case of very weakly coupled mixed-valence complexes, a considerable contribution to K_c is derived from the electrostatic repulsion between metal ions. Ferrere and Elliott (26) have proposed the following expression for this electrostatic contribution,

Fig. 2. Cyclic voltammogram of $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})][PF_6]_4$, platinum disk working electrode (1.6 mm diameter), scan rate 200 mV/s, 0.1 M TBAH in acetonitrile.



[2] $\Delta E_e = 1/(4\pi\varepsilon\varepsilon_0 R)$

where ε is the dielectric constant of the solvent, ε_0 is the vacuum permittivity constant, and R is the separation between metal ions. For $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})]^{3+}$, the metal–metal separation is estimated at 15.6 Å, assuming the cyanamides retain an *anti* conformation upon coordination, and thus ΔE_e is esti-

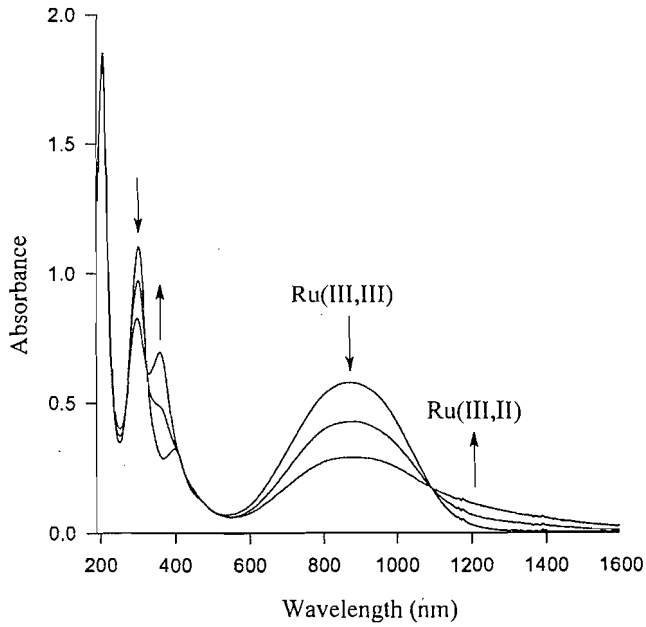
Fig. 3. Spectroelectrochemical reduction of $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})][PF_6]_4$ at fixed potential to form the mixed-valence complex; 0.1 M TBAH in acetonitrile. The initial spectrum is that of the Ru(III,III) complex with the other spectra taken at approximately 3 min intervals.



mated to be 12, 23, and 25 mV in water, acetonitrile and nitromethane, respectively. The over 35 mV separation in ΔE (see Table 4) between water and either acetonitrile or nitromethane can therefore not be entirely accounted for by differences in electrostatic repulsion and may indicate some degree of solvent trapping of the mixed-valence state in water. Indeed, the magnitude of K_c in aqueous solution is very close to that predicted on purely statistical grounds and suggests no metal–metal coupling (Class I behavior) (27). Further evidence of metal–metal coupling can be found in the spectroelectrochemical studies.

The solvent-dependent electronic absorption spectral data together with assignments for $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})]^{4+}$ are given in Table 5 and a representative spectrum of the complex in acetonitrile is shown in Fig. 3. A spectroscopic analysis of the Ru(III)–cyanamide chromophore (28) showed that two ligand-to-metal charge transfer (LMCT) transitions can be expected from the interaction of the two nonbonding π symmetry electron pairs of the cyanamide moiety with the Ru(III) ion. In Table 5, the energy and extinction coefficient of lowest energy LMCT band, $b_1^* \leftarrow b_1$, are clearly dependent on the solvent. Similar effects have been seen for both inner (22) and outer sphere (29) perturbations of the Ru(III)-cyanamide moiety and have been rationalized in terms of the Ru(III)–cyanamide π overlap integral.

Spectroelectrochemical reduction of $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})]^{4+}$ to the mostly mixed-valence complex in solution is shown in Fig. 3. The platinum mesh working electrode was held at fixed potential (−85 mV vs. NHE) and the spectra shown in Fig. 3 were taken at approximately 3 min intervals. Because the Ru(III/II) couples overlap, it was assumed that reduction to the mixed-valence complex was complete when the intensity of the $b_1^* \leftarrow b_1$ LMCT band of the Ru(III,III) complex was reduced by approximately one-half. It was possible to cycle between the extremes shown in Fig. 3 with no change in isosbestic points and the absorbance maxima of the Ru(III, III) complex spectrum. However, upon further reduction with loss of LMCT band intensity, the instability of the Ru(II, II) complex became apparent because oxidation of the solution did not regenerate the Ru(III, III) spectrum. The Ru(II, II) complex is not expected to absorb at all above 500 nm and will therefore not interfere with deconvolution of the metal-to-metal charge transfer (MMCT) band from the $b_1^* \leftarrow b_1$ LMCT band.[3] The MMCT band appears in Fig. 3 as the low-energy tail that grows in with the formation of the Ru(III, II) complex. The process to deconvolute the MMCT transition from the low energy band envelope has been described in detail (11) but the main assumptions are that the MMCT transition can be represented by a single Gaussian band and the energy and band shape of the LMCT transition does not change upon reduction of one of the Ru–cyanamide chromophores. The spectral data for the deconvoluted MMCT band are ν_{max} = 8400 cm^{-1}, ε_{max} = 2200 M^{-1} cm^{-1}, and $\Delta\nu_{1/2}$ = 3300 cm^{-1}. The high-energy tail of the the MMCT band does not significantly contribute (<1%) to the intensity of the LMCT band maximum. Nevertheless, the MMCT extinction coefficient needs to be corrected for the comproportionation equilibrium for which the actual proportion of mixed-valence species is defined (30) as

$$[3] \quad P = [\text{Ru(III, II)}]/([\text{Ru(III, II)} + [\text{Ru(III, III)} + [\text{Ru(II, II)}])$$

or in terms of the comproportionation constant

$$[4] \quad P = K_c^{1/2}/(2 + K_c^{1/2})$$

Because K_c = 16 in acetonitrile, P = 0.67, and the corrected intervalence absorption band has ε_{max} = 3300 M^{-1} cm^{-1}. The comproportionation constant and Hush theory resonance exchange integral (31, 32), estimated at H_{ad} = 400 cm^{-1}, are consistent with a weakly coupled Class II mixed-valence com-

[3] The Ru(II,II) dimer possesses no charge transfer chromophores that would absorb in the visible or NIR regions and ligand field transitions would be at wavelengths much lower than 500 nm.

plex (27). However, the value of $\Delta\nu_{1/2}$ derived by nonlinear curve fitting analysis is far narrower than that predicted by Hush theory, $\Delta\nu_{1/2}$(calc) = 4400 cm^{-1}, and may be an artifact in this instance.

Metal–metal coupling and the nature of the bridging ligand

Metal-metal coupling in the mixed-valence complex $[\{(NH_3)_5Ru\}_2(\mu\text{-dicyd})]^{3+}$ is substantially greater than that found for the bp^{2-} analogue. For $[\{(NH_3)_5Ru\}_2(\mu\text{-dicyd})]^{3+}$ in acetonitrile (10), $K_c = 6.8 \times 10^4$ and its MMCT band has ν_{max} = 6910 cm^{-1}, ε_{max} = 4090 M^{-1} cm^{-1}, and $\Delta\nu_{1/2}$ = 2640 cm^{-1}. The magnitude of its comproportionation constant and narrowness of the MMCT band (Hush theory $\Delta\nu_{1/2}$ = 4000 cm^{-1}) support a strongly coupled Class II assignment for the $[\{(NH_3)_5Ru\}_2(\mu\text{-dicyd})]^{3+}$ ion (27, 32, 33). In addition, previous studies have shown that intramolecular antiferromagnetic coupling of the Ru(III,III) complex $[\{(NH_3)_5Ru\}_2(\mu\text{-dicyd})]^{4+}$ is sufficiently strong to render the complex diamagnetic in the solid state (9) and, in poor donor solvents, an essentially diamagnetic ^1H NMR spectrum is observed (34), slightly perturbed by the trace Boltzmann population of the triplet excited state (e.g., in nitromethane-d_3: *trans* ammine, 18.24; *cis* ammine, 4.90; phenyl, 6.12 ppm). In contrast, temperature-dependent magnetic susceptibility studies of $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})][PF_6]_4$ showed no evidence of intramolecular antiferromagnetic coupling and a Curie–Weiss fit of the data between 60 to 300 K gave $\theta = -42$ K, indicating intermolecular antiferromagnetic exchange. The ^1H NMR spectrum of this complex in acetonitrile-d_3 is dramatically affected by its paramagnetism, with the *cis* ammine protons appearing as a broad singlet resonance contact shifted to 57.3 ppm and two singlet phenyl ring proton resonances pseudocontact shifted to −41.2 and 20.7 ppm. The *trans* ammine protons were not observed and are believed to be >250 ppm.

From the above, it is clear that $dicyd^{2-}$ is a superior mediator of superexchange metal–metal coupling compared to bp^{2-}. If it is assumed that the dominant mechanism for superexchange is hole transfer via the HOMO of the bridging ligand,[4] the differences in metal–metal coupling must be due to the nature of the HOMO, its energy, and continuity. A measure of the relative energies of free bp^{2-} and $dicyd^{2-}$ HOMOs is the difference in L_1 redox couples in Table 4. Because the L_1 of bp^{2-} is 780 mV more positive than that of the oxidized ligand, there must exist a larger energy barrier to the creation of the oxidized ligand virtual state from the bp^{2-} ligand, as is required by the hole transfer superexchange mechanism. The energy barrier to oxidation exists because the steric repulsion between *ortho* hydrogens of the phenyl rings forces the biphenyl moiety to be nonplanar and thereby weakens the π interactions between phenyl rings. If the energy of the π superexchange pathway could be raised, this would reduce the energy gap between metal orbitals and the superexchange pathway. The hypothetical biphenyl dianion bridging ligand, for which the protons at the 4 and 4′ ring positions have been removed, meets these requirements and would optimize hole transfer superexchange within the biphenyl moiety.

[4] This seems reasonable because both are π-donor aromatic dianion ligands.

An example of a bridging ligand that contains a biphenyl dianion spacer is 3,3′,5,5′-tetrapyridylbiphenyl dianion ($tpbp^{2-}$) (35). The mixed valence complex, $[\{(ttrpy)Ru\}_2(\mu\text{-tpbp})]^{3+}$ where ttrpy is 4′-*p*-tolyl-2,2′,6′,2″-terpyridine, possesses an extraordinarily intense MMCT band centered at 1820 nm with ε_{max} = 27 000 M^{-1} cm^{-1} in acetonitrile (35*a*). The comproportionation constant of the complex is approximately 600 and its Hush resonance exchange integral is estimated to be 1200 cm^{-1} These values are significantly greater than those found for $[\{(NH_3)_5Ru\}_2(\mu\text{-bp})]^{3+}$; however, the nature of the spectator ligands has changed and because this can have a dramatic effect on ruthenium 4d-orbital energies, the relative superexchange mediating properties of bp^{2-} and $tpbp^{2-}$ cannot be properly evaluated. In addition, superexchange via $tpbp^{2-}$, can occur by both electron transfer, owing to the presence of the pyridine moieties, and hole transfer, through σ and π pathways of the biphenyl moiety, whereas for the bp^{2-} ligand, effective superexchange is probably restricted to hole transfer via its π HOMO.

There are only a few other examples of multi-atom bridging ligands that are likely to mediate hole transfer superexchange coupling in mixed-valence complexes. These are: malonitrile anion derivatives (36), triazole anion derivatives (37), bibenzimidazolate dianion (38), and finally the azodicarbonyl dianion ligands (39). Importantly, the magnitude of coupling in $[\{Ru(bpy)_2)\}_2(\mu\text{-adc})]^{3+}$, where adc^{2-} is an azodicarbonyl dianion derivative and bpy is 2,2′-bipyridine, is so great that the authors have suggested that the Ru(II)-adc^{-}(radical)-Ru(II) resonance form may make an significant contribution to the mixed-valence state (39). While this magnitude of coupling may be possible through the $dicyd^{2-}$ ligand, the nonplanarity of bp^{2-} limits its superexchange mediating properties. Work to synthesize the 2,7-dicyanamidophenanthrene dianion ligand, which should contain a planar biphenyldicyanamido moiety, is in progress.

Preparation and structure of 2-chloro-1,3-dimethyldiaza-2-arsenane, 1,3-dimethyldiaza-2-arsenanium tetrachlorogallate, and butadiene cycloadducts of diazarsenium cations

Neil Burford, Charles L.B. Macdonald, Trenton M. Parks, Gang Wu, Borzena Borecka, Witold Kwiatkowski, and T. Stanley Cameron

Abstract: 1,3-Dimethyldiaza-2-arsenanium tetrachlorogallate (crystal data: $C_5H_{12}AsCl_4GaN_2$, $M = 386.61$, orthorhombic, space group $Pca2_1$, $a = 14.432(3)$ Å, $b = 6.7580(14)$ Å, $c = 13.905(3)$ Å, $V = 1356.2(5)$ Å^3) is synthesized by the routine chloride ion abstraction procedure from 2-chloro-1,3-dimethyldiaza-2-arsenane (crystal data: $C_5H_{12}AsClN_2$, $M = 210.54$, monoclinic, space group $P2_1/n$, $a = 7.206(1)$ Å, $b = 9.650(1)$ Å, $c = 13.021(2)$ Å, $\beta = 99.61(2)°$, $V = 892.8(2)$ Å^3). X-ray crystallographic studies of both compounds are described together with that for 2-chloro-1,3-dimethyldiaza-2-arsolidine (crystal data: $C_4H_{10}AsClN_2$, $M = 196.51$, monoclinic, space group $P2_1/n$, $a = 6.959(7)$ Å, $b = 9.23(2)$ Å, $c = 12.14(2)$ Å, $\beta = 95.4(1)°$, $V = 777(4)$ Å^3) providing useful structural comparisons. In contrast to the closely related arsolidinium salts, the diazarsenanium gallate exhibits a monomeric solid state structure. Rapid and quantitative cycloaddition reactions of the diazarsolidinium and diazarsenanium cations with 2,4-dimethylbutadiene give similar cycloadducts. The Diels–Alder type arsolidinium adduct is structurally characterized (crystal data: $C_{10}H_{20}AsCl_4GaN_2$, $M = 454.73$, orthorhombic, space group $Pca2_1$, $a = 18.471(2)$ Å, $b = 7.000(2)$ Å, $c = 13.738(1)$ Å, $V = 1776.2(8)$ Å^3), and the related structure of the arsenanium cycloadduct is confirmed by 2D NMR.

Key words: arsenium, cycloadditions, arsenanium, Diels–Alder, cyclochloroarsines.

Résumé : On peut synthétiser le tétragallate de 1,3-diméthyldiaza-2-arsénanium (données cristallographiques : $C_5H_{12}AsCl_4GaN_2$, $M = 386,61$, orthorhombique, groupe d'espace $Pca2_1$, $a = 14,432(3)$ Å, $b = 6,7580(14)$ et $c = 13,905(3)$ Å, $V = 1356,2(5)$ Å^3) par la méthode usuelle d'enlèvement de l'ion chlorure du 2-chloro-1,3-diméthyldiaza-2-arsénane (données cristallographiques : $C_5H_{12}AsClN_2$, $M = 210,54$, monoclinique, groupe d'espace $P2_1/n$, $a = 7,206(1)$, $b = 9,650(1)$ et $c = 13,021(2)$ Å, $\beta = 99,61(2)°$, $V = 892,8(2)$ Å^3). Afin de pouvoir faire des comparaisons de structures utiles, on décrit les études de diffraction des rayons X de ces deux composés en même temps que celle du 2-chloro-1,3-diméthyldiaza-2-arsolidine (données cristallographiques : $C_4H_{10}AsClN_2$, $M = 196,51$, monoclinique, groupe d'espace $P2_1/n$, $a = 6,959(7)$, $b = 9,23(2)$ et $c = 12,14(2)$ Å, $\beta = 95,4(1)°$, $V = 777(4)$ Å^3). Par opposition aux structures très apparentées des sels d'arsolidinium, le gallate de diazarsénanium présente une structure monomérique à l'état solide. Des réactions de cycloadditions rapides et quantitatives des cations diazarsolidinium et diazarsénanium avec le 2,4-diméthylbutadiène conduisent à des cycloadduits semblables. On a caractérisé la structure de l'adduit de type Diels–Alder du cation arsolidinium (données cristallographiques : $C_{10}H_{20}AsCl_4GaN_2$, $M = 454,73$, orthorhombique, groupe d'espace $Pca2_1$, $a = 18,471(2)$, $b = 7,000(2)$ et $c = 13,738(1)$ Å, $V = 1776,2(8)$ Å^3) et on a confirmé la structure apparentée du cycloadduit du cation arsénanium par RMN en 2D.

Mots clés : arsénium, cycloadditions, arsénanium, Diels–Alder, cyclochloroarsines.

[Traduit par la rédaction]

Introduction

The structural simplicity of systems containing coordinatively unsaturated (low coordinate) centres makes them attractive for reactivity studies. In this context, pnictogenium cations **1** have garnered attention due to their structure and bonding analogy with carbenes. Numerous phosphenium **1***a* derivatives have been reported (1, 2) since their initial discovery (3) and isola-

tion (4), establishing them as a principal focus in the development of phosphorus chemistry. Despite the identification of various arsenium cations **1***b* (5, 6), few examples have been comprehensively characterized (7), and the heavier congeneric systems **1***c* (8, 9) and **1***d* (9, 10) are rarely mentioned in the literature. The use of a Hückel framework **2** allowed for the isolation of the first arsenium derivative (11). However, in the absence of such charge delocalization, heterolytic As—Cl bond cleavage from the chloroarsolidines **3Cl** and **4Cl** provided dimeric structures **6** in the solid state (7), in contrast to the phospholidinium **7** analogue (2).

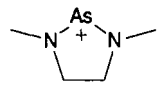
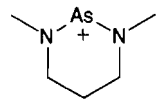
b: **X** = **NMe**

We present here the preparation and structures of the six-membered diazarsenane **5Cl** and the tetrachlorogallate salt of the corresponding diazarsenanium cation **5**, which is clearly

3

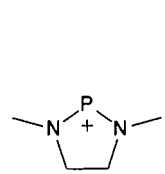


4

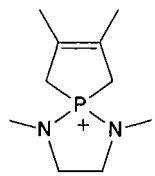


5

monomeric in the solid state. In addition, we describe the rapid and quantitative cycloaddition reactions of **4** (preliminary communication, see ref. 12) and **5** with 2,3-dimethylbutadiene, which contrast the spirocyclic formation **8** observed for **7** (13). The Diels–Alder type adduct **4BD**[$GaCl_4$] has been



7

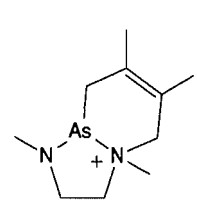


8

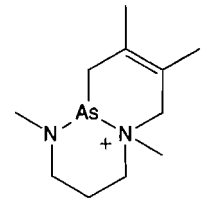
structurally characterized, and the related structure of the cycloadduct **5BD** is confirmed by 2D NMR.

Experimental procedures

Arsenic trichloride and triethylamine (BDH) were distilled under nitrogen before use. Gallium trichloride and 2,3-dimethyl-1,3-butadiene (Aldrich) were sublimed in vacuo before use. *N*,*N*′-dimethyl-1,3-propanediamine and *N*,*N*′-dimethylethylenediamine (Aldrich) were used as received.



4BD



5BD

Compounds **4Cl** and $\mathbf{4}_2[GaCl_4]_2$, were prepared as previously reported (7). Diethyl ether was dried over sodium with benzophenone, CCl_4 was dried over P_2O_5, CD_2Cl_2 and CH_2Cl_2 were dried over P_2O_5 and CaH_2, and all solvents were stored in evacuated bulbs. Solids were handled in VAC Vacuum/Atmospheres or MBraun nitrogen-filled glove box while liquids were manipulated in a nitrogen-filled glove bag. Unless otherwise indicated, all reactions were performed in sealed reactors (14), which were flame-dried before use. Melting points were recorded on a Fisher–Johns apparatus and are uncorrected. Elemental analyses were performed by Beller Laboratories, Göttingen, Germany. Infrared spectra were recorded as Nujol mulls on CsI plates using a Nicolet 510P FT-IR spectrometer. NMR spectra were recorded on either a Bruker AC-250 spectrometer with samples flame sealed in 5 mm Pyrex tubes or a Bruker AMX400 spectrometer with samples sealed in 5 mm commercial thin-walled NMR tubes. All chemical shifts are reported in ppm relative to an external standard (TMS for ^1H and ^{13}C). Variable temperature (VT) NMR studies involved equilibration times of 10 min at each temperature. NMR samples of reaction mixtures were prepared by decanting an aliquot of the reaction mixture into an NMR tube, removing the volatiles in vacuo, and introducing an appropriate amount of CD_2Cl_2 in vacuo. Unless otherwise indicated, crystalline samples were obtained by slow removal of solvent and were washed by cold spot back-distillation (14).

Preparation of 5Cl[2]

A solution of *N*,*N*′-dimethyl-1,3-propanediamine (4.96 g, 48.5 mmol) and triethylamine (25 mL) in diethyl ether (20 mL) was slowly added (45 min) dropwise to a solution of $AsCl_3$ (8.80 g, 48.5 mmol) in diethyl ether (125 mL) in a 3-neck flask, under a continuous stream of dry nitrogen gas. Immediate reaction produced a copious white precipitate; the mixture was stirred overnight then filtered under nitrogen and the solid was washed with two portions (25 mL) of fresh ether. The washings were added to the filtrate and the volume of the solution was reduced by removal of the solvent in vacuo and cooling to −18°C produced colourless crystals that were recrystallized from fresh ether and characterized as 2-chloro-1,3-dimethylcyclo-1,3-diaza-2-arsahexane (2-chloro-1,3-dimethyldiaza-2-arsenane), 5.81 g, 27.6 mmol, 57%; mp 47.0–48.5°C; IR (cm^{-1}): 2744(m), 2718(m), 2702(m), 2687(w), 1276(vs), 1227(vs), 1207(m), 1146(vs), 1133(vs), 1125(vs,sh), 1091(s), 1050(vs), 1037(vs), 941(vs), 925(s), 891(s), 837(vs), 570(vs), 540(m), 414(m), 361(vs), 342(m), 320(w), 285(s,sh), 263(vs), 239(vs), 233(vs); ^1H NMR (CD_2Cl_2): 2.88 (CH_2N, m, 4H), 2.63 (CH_3, s, 6H), 1.94 (CH_2, m, 2H); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 48.4 (CH_2N), 40.3 (CH_3), 27.8 (CH_2).

[2] First reported briefly in ref. 6.

Preparation of 5[$GaCl_4$]

A solution of **5Cl** (0.45 g, 2.1 mmol) in CH_2Cl_2 (20 mL) was slowly added to a solution of $GaCl_3$ (0.38 g, 2.1 mmol) in CH_2Cl_2 (40 mL) over a period of 15 min. Approximately 90% of the solvent was removed in vacuo and the solution was cooled to 5°C to produce yellow crystals characterized as 1,3-dimethyldiaza-2-arsenanium tetrachlorogallate, 0.39 g, 1.0 mmol, 48%; mp 52.0–54.5°C; IR (cm^{-1}): 1347(w), 1284(vs), 1242(vs), 1205(s), 1184(w), 1152(vs), 1118(vs), 1102(m), 1084(s), 1049(vs), 1040(vs), 955(vs), 913(w), 879(s), 862(m), 806(w), 752(w), 601(s), 588(s), 551(w), 493(w), 387(vs, sh), 378(vs), 362(vs), 339(vs), 301(w), 266(w), 255(w), 232(s); ^1H NMR (CD_2Cl_2): 3.49 (CH_2N, m, 4H), 3.34 (CH_3, s, 6H), 2.29 (CH_2, m, 2H); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 51.6 (CH_2N), 42.6 (CH_3), 26.2 (CH_2). Anal. (%) calcd.: C 15.53, H 3.13, N 7.25; Found C 15.97, H 3.29, N 7.35.

Preparation of 4BD[$GaCl_4$] (ref. 12)

2,3-Dimethylbutadiene (0.11 g, 1.3 mmol) in CH_2Cl_2 (7 mL) was added dropwise (8 min) to a stirred solution of **4**[$GaCl_4$] (0.32 g, 0.42 mmol) in CH_2Cl_2 (40 mL). Slow removal of the solvent in vacuo afforded air-sensitive colourless crystals, which were characterized as 1-azonia-1,3,4,7-tetramethyl-7-aza-6-arsabicyclo(4.3.0)non-3-ene tetrachlorogallate, **4BD**[$GaCl_4$], 0.21 g, 0.46 mmol, 55%; mp 139–140°C; IR (cm^{-1}): 1657(w), 1413(m), 1325(w), 1300(w), 1270(m), 1241(m), 1171(m), 1116(m), 1073(m), 1058(w), 1009(m), 984(m), 967(s), 940(w), 924(w), 885(w), 867(m), 798(w), 784(m), 737(w), 655(w), 597(w), 581(m), 569(m), 525(w), 453(w), 423(w), 383(vs), 366(s), 349(m), 313(w), 228(w); ^1H NMR (CD_2Cl_2): 3.90 (d of d of d, 1H), 3.85 (d, 1H), 3.69 (d of d, 1H), 3.55 (d, 1H), 3.49 (d of d, 1H), 3.22 (s, 3H), 3.15 (t of d), 1H), 3.10 (d, 1H), 2.97 (s, 3H), 2.67 (d, 1H), 1.95 (m, 6H); $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 130.4, 128.8, 62.8, 62.2, 59.1, 52.2, 41.8, 37.6, 20.7, 20.3; see discussion for COSY analysis. Anal.(%) calcd.: C 26.41, H 4.43; found: C 26.02, H 4.49. ^1H and ^{13}C NMR spectra of the reaction mixture show **4BD**[$GaCl_4$] as the only product.

Preparation of 5BD[$GaCl_4$]

2,3-Dimethyl-1,3-butadiene (0.24 g, 2.9 mmol) in CH_2Cl_2 (6 mL) was added over a period of 4 min to a solution of **5**[$GaCl_4$] (1.11 mmol) in CH_2Cl_2 (90 mL) prepared in situ. The mixture was allowed to stir for 20 min. The solvent was removed in vacuo to give a viscous yellow oil that solidified upon standing overnight and was characterized as 1-azonia-1,3,4,7-tetramethyl-7-aza-6-arsabicyclo(4.4.0)dec-3-ene tetrachlorogallate, **5BD**[$GaCl_4$], 0.849 g, 1.81 mmol, 82%; mp 83.5–87.5°C; IR (cm^{-1}): 1343(w), 1313(m), 1301(m), 1286(w), 1267(m), 1234(m), 1204(s), 1200(s), 1184(m), 1156(vs), 1135(s), 1123(m), 1097(w), 1074(m), 1051(m), 1042(s), 1029(m), 1003(s), 982(vs), 946(s), 913(s), 884(s), 847(vs), 806(w), 788(w), 770(vs), 738(w), 657(m), 611(m), 583(s), 548(w), 503(s), 405(m,sh), 381(vs,br), 365(vs), 343(s), 317(m), 288(w), 257(w); ^1H NMR (ppm, CD_2Cl_2): 3.71 (m, 3H), 3.69 (m, 3H), 3.39 (d, 1H), 3.36 (d, 1H), 3.14 (s, 3H), 3.05, (s, 3H), 3.01 (m, 2H), 2.47 (d, 1H), 2.39 (m, 1H), 1.90 (s, 3H), 1.74 (m, 1H); $^{13}C\{^1H\}$ NMR (ppm, CD_2Cl_2): 124.6, 122.8, 65.0, 57.4, 48.9, 45.6, 43.9, 33.1, 22.2, 19.5, 19.0; see discussion for COSY analysis. ^1H and ^{13}C NMR spectra of the reaction mixture show **5BD**[$GaCl_4$] as the only product.

Recrystallization of 4Cl

Evacuated samples of **4Cl** stored at 4°C for weeks sublimed onto the glass walls of the vessel or tube. The crystals (mp 19°C) were mounted in a nitrogen-filled glove bag under a stream of cold nitrogen (liquid nitrogen boil-off). The X-ray diffraction data were collected at −60°C.

X-ray crystallography

Crystals were selected and mounted in Pyrex capillaries in the drybox. Pertinent crystallographic data are summarized in Table 1. Unit-cell parameters were obtained from the setting angles of 18 accurately centered reflections with $6.13 < 2\theta < 50.04°$ for **5**[$GaCl_4$], 24 accurately centered reflections with $20 < 2\theta < 26°$ for **4Cl**, 20 accurately centered reflections with $35 < 2\theta < 40°$ for **5Cl**, and 22 accurately centered reflections with $30.31 < 2\theta < 45.55°$ for **4BD**[$GaCl_4$]. The choice of space groups was based on systematically absent reflections and was confirmed by the successful solution and refinement of the structures. The stability of the crystals was monitored using three standard reflections; significant decay was not observed. Data were corrected for Lorentz and polarization effects, and the absorption corrections were applied based on the program DIFABS (15). Scattering factors (16) were corrected for anomalous dispersion.

Structures were solved by direct methods to find the heavy atoms with the remaining atoms located from difference Fourier synthesis (18). The hydrogen atoms were placed in geometrically calculated positions with a C—H distance of 0.96 Å (**5**[$GaCl_4$]), 0.95 Å (**4Cl** and **5Cl**), or 1.08 Å (**4BD**[$GaCl_4$]); their positions were not refined, and they were assigned fixed isotropic temperature factors with a value of 1.2 B_{eq} of the atom to which each was bonded. The models were refined using full-matrix least-squares techniques based on F, minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where the weight is defined as $w = 4F_o^2/\sigma^2(F_o^2)$ $(\sigma^2(F_o) + (p\ F_o/2)^2)^{-1}$ and σ is derived from counting statistics (18). Supplementary material containing crystal data, atomic positional parameters, anisotropic thermal parameters, and bond lengths and angles for **5**[$GaCl_4$], **4Cl**, **5Cl**, and **4BD**[$GaCl_4$] has been deposited.[3]

Results and discussion

Chlorodiazarsenane and diazarsenanium tetrachlorogallate

The halide ion abstraction technique, now commonplace in the preparation of phosphenium salts (1), is also applicable for the formation and isolation of arsenium derivatives. The first examples, **3**[$GaCl_4$] and **4**[$GaCl_4$], were shown to adopt novel dimeric structures **6** in the solid state (7). We have now extrapolated the synthetic procedure to the six-membered (cyclohexane derivative) diazarsenane framework (6). 2-Chloro-1,3-

[a] $I > 2.00\ \sigma(I)$

dimethyldiaza-2-arsenane **5Cl** reacts with $GaCl_3$, in an essentially identical fashion to the arsolidine **4Cl** (7), to give chloro-1,3-dimethyldiaza-2-arsenanium **5** tetrachlorogallate. Compounds **5Cl** and **5**$[GaCl_4]$ have been comprehensively characterized and crystallographic views of the solid state structures are illustrated in Figs. 1 and 2, respectively. The structure of 2-chloro-1,3-dimethyldiaza-2-arsolidine **4Cl** (−60°C; Fig. 3) is also described for comparison. Selected bond lengths and angles for the three compounds are compared with those for **4**$_2[GaCl_4]_2$ (7) in Table 2.

Crystals of **5**$[GaCl_4]$ were of poor quality and provided only limited data. Nevertheless, the distinctly ionic structure shows no evidence of interaction between cations (shortest intercationic As–N 5.62(2) Å) (Fig. 4) in contrast to the dimeric **6** structure of **4**$[GaCl_4]$ (as well as **3**$[GaCl_4]$) (7). This implies that the association between monomers in **6** is weak, consistent with the relatively long intermonomer bonds observed in **6**, and ^{1}H NMR spectroscopic data for **4**$_2[GaCl_4]_2$, which indicate a monomer–dimer equilibrium in solution (7). Cation–anion contacts in **5**$[GaCl_4]$ (3.363(9) and 3.58(1) Å) (Fig. 4) are within the sum of the van der Waals' radii for As and Cl (As, 2.0 Å; Cl, 1.7 Å (19)), but are significantly longer than the As—Cl bonds in **4Cl** (2.390(5) Å) and **5Cl** (2.357(2) Å), and are comparable to the cation-anion contacts observed in the structure of **4**$_2[GaCl_4]_2$ (3.296(2) and 3.424(2) Å) (7). The resulting polymeric lattice of **5**$[GaCl_4]$ is reminiscent of the solid state structures observed for $(Me_2Si(N^tBu)_2E)[GaCl_4]$ (E = Sb, Bi) (9). The As—N bonds (1.68(3) and 1.67(2) Å) are significantly shorter than the shortest bond of **4**$_2[GaCl_4]_2$ (1.752(5) and 1.949(4) Å(7)), implicating a degree of π-bonding over the N-As-N moiety.

In spite of the monomeric structure observed for **5**$[GaCl_4]$, the neutral arsenane **5Cl** also adopts a dimeric arrangement involving a four-membered As_2N_2 intermonomer contact that is similar to that of the corresponding arsolidines **3Cl** and **4Cl** as well as the dications **6**. Such arrangements contrast that observed for related chloroarsines (11, 20), which involve four-membered As_2Cl_2 contacts. The intermonomer contact is significantly shorter in **4Cl** (As–N′ 2.84(1) Å) than in **5Cl** (As–N′ 3.250(5) Å), and both are substantially longer than observed for **4**$[GaCl_4]$ (2.103(8) Å) (7). These interactions are well within the sum of the van der Waals' radii for As and N (As, 2.0 Å; N, 1.5 Å (19)) and impose a pseudo-tetracoordinate environment on N(2). The shorter interaction in **4Cl** has a measurable impact on the structural features of the arsolidine heterocycle, which exhibits slight differences in the As–N bond lengths as well as the geometries at the nitrogen centres. N(1) is essentially planar (sum of the angles 359.3°), while N(2) is clearly pyramidalized (sum of the angles 339.4°). The geometrically indistinguishable nitrogen centres of **5Cl** have bond angle sums (N(1), 348°; N(2), 347°) that are substantially greater than expected for an sp^3 (328.5°) hybridized site. In this context, the relatively long (see for example refs. 20 and 21) As—Cl bonds (**4Cl**, 2.390(5) Å; **5Cl**, 2.357(2) Å) and relatively short endocyclic As—N bonds (**4Cl**, 1.77(1) Å, 1.870(8) Å; **5Cl**, 1.796(4) Å, 1.803(5) Å; typical range 1.82-1.88 Å (see for example ref. 22)) in both compounds implicate a degree of As—N π-bonding.

Fig. 1. ORTEP view (50% probability ellipsoids) of the dimeric unit of **5Cl** showing the closest intermolecular interactions, As(1)–N(2)′ 3.250(5) Å (hydrogen atoms omitted for clarity).

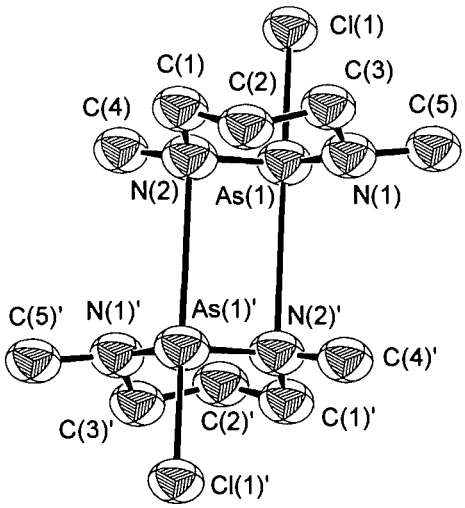

Fig. 2. PLUTO view of $5[GaCl_4]$.

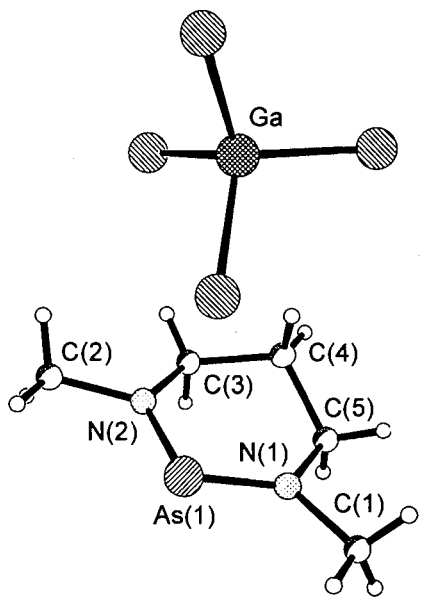

Fig. 3. ORTEP view (50% probability ellipsoids) of the dimeric unit of **4Cl** showing the closest intermolecular interactions, As(1)–N(2)′ 2.84(1) Å (Hydrogen atoms omitted for clarity).

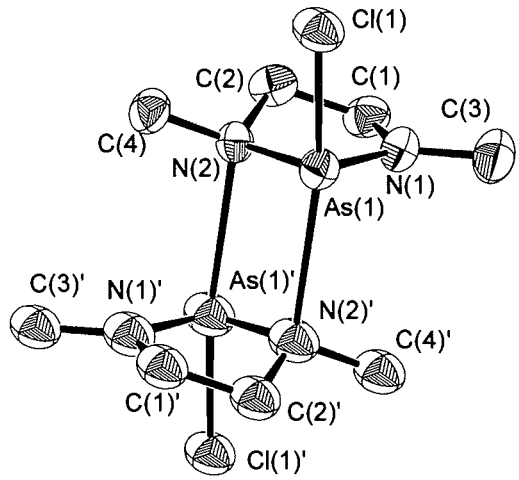

Fig. 4. The unit cell of $5[GaCl_4]$, showing the closest cation–anion contacts.

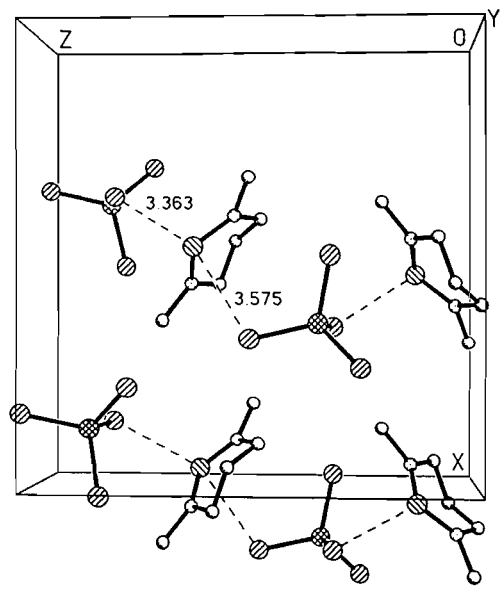

The ^1H NMR spectra for **5Cl** (δ: 2.88m, 2.63s, 1.94m) and $5[GaCl_4]$ (δ: 3.49m, 3.34s, 2.29m) are interpreted as very similar AA′BB′CD spin systems and differ only in chemical shift, with the salt exhibiting the expected deshielding. Consistent with integration values, the lower frequency multiplet is assigned to the azamethylene protons and the singlet to the methyl protons. Neither spectrum shows significant changes at −80°C.

Diazarsenium-butadiene cycloaddition

Compounds $4[GaCl_4]$ and $5[GaCl_4]$ react rapidly with 2,3-dimethylbutadiene in CH_2Cl_2 to give a single product, as shown by ^1H NMR spectra of the reaction mixtures. The isolated products are spectroscopically similar and an X-ray crystallographic study of the product from $4[GaCl_4]$ reveals a tetrachlorogallate salt of cycloadduct **4BD**, in which the diene is assymmetrically bound to the arsolidinium heterocycle (across one of the As—N bonds).

The bicyclic structure of the cation is shown in Fig. 5 and selected bond lengths and angles are given in Table 2. The cross-ring As(1)—N(2) bond is significantly longer (2.056(10) Å) than that of As(1)—N(1) (1.797(11) Å), and is comparable (within experimental error) to the corresponding bond observed in the dication **6b** (As – tetracoordinate N, 1.949(4) Å; As – tricoordinate N, 1.752(5) Å). The cross-ring bond in **4BD** is anomalously long in comparison to the As—N bonds in **4Cl**, **5Cl**, and $4[GaCl_4]$, and may be considered an intramolecular donation to an amino-alkyl-arsenium centre. Consistently, intermolecular donor interactions to the dithiarsolidinium cation are also long (7), as are those to phosphe-

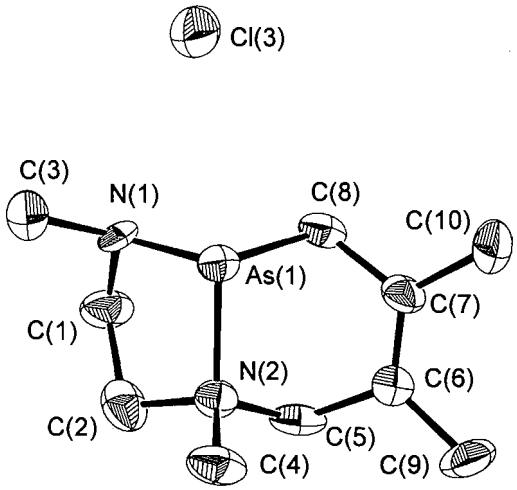
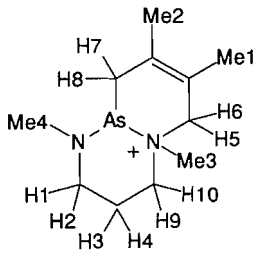
Fig. 5. ORTEP view (50% probability ellipsoids) of the cation in **4BD**[$GaCl_4$] and closest chlorine atom, As(1)–Cl(3) 3.382(6) Å, of the tetrachlorogallate anion (hydrogen atoms omitted for clarity).

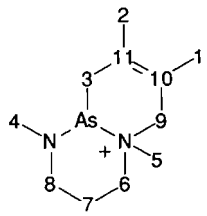


nium centres (23). In the other extreme, the bicyclic structure of **4BD** can be viewed as an ammonium-arsine.

The complex ^1H NMR spectra of **4BD**[$GaCl_4$] (previously reported (24)) and **5BD**[$GaCl_4$] (Fig. 6) in CD_2Cl_2 were resolved by COSY techniques at 400 MHz. Methyl groups 1, 2, 3, and 4 (illustrated in **9**) are observed as singlets at 1.90, 1.74, 3.05, and 3.14 ppm, respectively. The six methylene protons are observed in the usual region, with the signals for those closest to the nitrogen atoms farther downfield. While it has been possible to identify the signals produced by each of the protons in a vicinal pair, it has not been possible to identify which of the two protons is responsible for which of the signals. Protons 1 and 2 are observed as multiplet signals at 3.01 and 3.71 ppm. Likewise, protons 3 and 4 exhibit multiplets at 1.74 and 2.39 ppm. Protons 5 and 6 exhibit a doublet at 3.36 ppm and a multiplet at 3.69 ppm, while protons 7 and 8 each



9



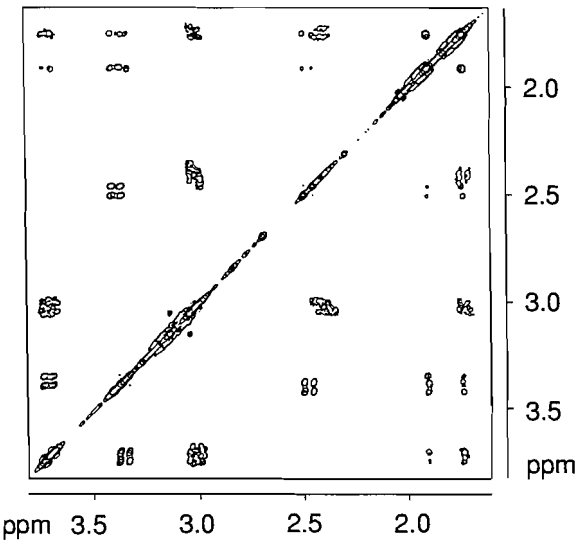
10

produce a doublet at 2.47 ppm and 3.39 ppm. Finally, protons 9 and 10 each produce multiplet signals at 3.01 ppm and 3.71 ppm.

A (^1H, ^{13}C) HETCOR spectrum has allowed for unambiguous assignment of the carbon signals for **5BD**[$GaCl_4$] (illustrated in **10**): 1, 22.2 ppm; 2, 19.0 ppm; 3, 33.1 ppm; 4, 43.9 ppm; 5, 48.9 ppm; 6, 57.4 ppm; 7, 19.5 ppm; 8, 45.6 ppm; and 9, 65.0 ppm. Two quaternary carbon signals were found at 122.8 and 124.6 ppm. The lower field signal is presumably due to carbon 10.

Formation of cations **4BD** and **5BD** are in contrast to the butadiene cycloaddition reaction observed for the diazaphospholidinium cation **7**, which results in the oxidative cycloaddition phosphonium product **8** (13). The arsenium cycloaddition reactions may be classified as Diels–Alder-type reactions with the As-N unit behaving as a "hetero-dienophile," and in the context of reactions observed for phosphaalkynes (25), phosphaalkenes (26) and phosphinines (27). Qualitative MO analysis reveals that the HOMO of the diene and the LUMO of the dienophile can be considered as the dominant interaction determining the structure of the transition state in a "normal electron-demand" process (see for example ref. 28). A comprehensive theoretical study of these reactions is in progress.

Fig. 6. Two-dimensional (^1H, ^1H) COSY NMR of **5BD**[$GaCl_4$].



Conclusions

The diazarsenanium tetrachlorogallate salt adopts a monomeric structure in the solid state, in contrast to the corresponding arsolidinium salt. Nevertheless, both salts undergo quantitative Diels–Alder-like cycloaddition reactions with 2,3-dimethylbutadiene, involving one As-N bond as the olefin, and contrasting the observations for the corresponding phospholidinium cation.

Secondary ion mass spectroscopy (SIMS) and kinetics of the catalysis of bisulphite oxidation by aqueous iron

R.R. Martin and Jinjiang Li

Abstract: The catalytic activity of Fe(II) and Fe(III) in the aqueous oxidation of bisulphite by molecular oxygen at bisulphite concentrations similar to those in cloud water has been studied. Secondary Ion Mass Spectroscopy (SIMS) of insoluble sulphates derived from bisulphite after oxidation by $^{18}O_2$ gives different $^{18}O/^{32}S$ ratios for Fe(II) and Fe(III), indicating that the oxidation mechanism is different in these two species.

Key words: oxidation, bisulphite, iron, secondary ion mass spectroscopy.

Résumé: On a étudié l'activité catalytique du Fe(II) et du Fe(III) sur l'oxydation aqueuse du bisulfite par l'oxygène moléculaire, à des concentrations de bisulfite semblables à celles que l'on rencontre dans l'eau de pluie. La spectroscopie de masse des ions secondaires (SMIS) des sulfates insolubles obtenus par oxydation du bisulfite par du $^{18}O_2$ conduit à des rapports différents de $^{18}O/^{32}S$ pour le Fe(II) et le Fe(III); ce résultat indique que le mécanisme de l'oxydation est différent avec ces deux espèces.

Mots clés : oxydation, bisulfite, fer, spectroscopie de masse des ions secondaires.

[Traduit par la rédaction]

Introduction

The rate of oxidation of S(IV) in solution has been the subject of considerable study (1). Transition metal ions in solution are known to act as catalysts, as is the case with Fe(III)(2). Recent work has shown synergistic interactions between Fe(III) and Cu(II) (3). The mechanism for the reaction has been the subject of debate, which is likely to continue since the reaction, complex in itself, has kinetics strongly dependent on both the pH and ionic strength of the solution (4).

The archetypical mechanism advanced by Backstrom (5) suggests that in the oxidation of bisulphite the metal ion is reduced, leading to formation of a bisulphite radical that reacts rapidly with molecular oxygen. Kraft and van Eldick (6) proposed a mechanism for the oxidation of aqueous HSO_3^- in which Fe(III) is reduced to Fe(II), followed by reaction of the Fe(II)–HSO_3^- complex to produce sulphate, peroxide, $S_2O_6^{2-}$, and Fe(III). More recently van Eldick et al. (7) have proposed that oxidative cycling of Fe(III) and Fe(II) in the presence of molecular oxygen occurs with the pseudo-zero-order oxidation of Fe(II) by SO_5 species. Other mechanisms have been suggested, see for instance Conklin and Hoffman (8). In this paper we examine the kinetics of the oxidation of dilute HSO_3^- by molecular oxygen in solution at pH 4.6 maintained by an acetate – acetic acid buffer with Fe(III) and Fe(II) as catalysts. Reaction has been attempted in the absence of oxygen and in solutions in equilibrium with air and pure oxygen. The effect of adding the complexing agent 1,10-phenanthroline was also studied. Secondary Ion Mass Spectroscopy (SIMS) can be used in conjunction with isotopically enriched reactants to study the oxidation reactions (9). In this work SIMS is used to estimate the $^{18}O/^{32}S$ ratio in $BaSO_4$ precipitated from solution after oxidation of bisulphite with $^{18}O_2$; differences in this ratio obtained with Fe(III) and Fe(II) as catalysts can give an indication of differences in the reaction mechanisms.

Experimental

The kinetics of the oxidation of bisulphite was measured using 100 ppb ferrous or ferric iron and 20 ppm bisulfite at 25°C in a solution buffered to a pH of 4.6 by a 0.01 M acetate – acetic acid buffer. The effect of oxygen was examined by excluding oxygen completely or by bubbling either air or pure oxygen through the system. The effects of varying both iron and buffer concentrations were also examined. An additional set of experiments was carried out using 20 ppm bisulphite and 100 ppb ferrous and (or) ferric iron at 25, 30, and 35°C to establish the activation energies for the reactions. In all cases the temperature was controlled to within 0.05°C.

Two further experiments were carried out using 20 ppm bisulphite and 100 ppb solutions of ferrous and ferric iron in 3.3×10^{-3} M 1,10-phenanthroline. The concentration of the Fe(II)–1,10-phenanthroline complex was measured using the absorption band centred at 508 nm with a Shimadzu 160 UV spectrometer. All solutions were prepared using reagent grade materials and distilled deionized water. Bisulphite solutions were prepared fresh daily. Analysis for ionic species was carried out using a Dionex DX-100 ion chromatograph.

Table 1. Specific rate constant for bisulfite oxidation as a function of temperature in the Fe(III) and Fe(II) systems.

Iron species	T/°C	k
Fe(III)	25 ± 0.05	0.019 ± 0.0005
Fe(III)	30 ± 0.05	0.035 ± 0.0009
Fe(III)	35 ± 0.05	0.50 ± 0.00125
Fe(II)	25 ± 0.05	0.015 ± 0.0004
Fe(II)	30 ± 0.05	0.025 ± 0.0006
Fe(II)	35 ± 0.05	0.038 ± 0.001

The SIMS experiment was carried out by preparing a solution 0.1 M in bisulphite and 0.1 M in either Fe(II) or Fe(III) buffered to a pH of 4.6 as before. Argon was bubbled through the solution for 3 h and the resulting solution was exposed to 20 kPa of $^{18}O_2$ for 48 h at 23°C. The resulting sulphate was precipitated from solution with $BaCl_2$, and the precipitate was dried and pressed into indium foil to reduce charging during SIMS analysis. The mass spectrum was obtained using a Cameca IMS 3f instrument with a 5 nA Cs^+ primary ion beam at 7.5 keV net energy rastered over a square 250 μm on edge, while secondary ions were collected from a central spot 150 μm in diameter to avoid edge effects from the ion crater created by the primary ion beam. A 100 V offset was applied to the sample holder to suppress molecular secondary ions.

Results and discussion

The reaction did not proceed in the absence of molecular oxygen, showing that it is the sole oxidizing agent in our system. The reaction was pseudo zero order in oxygen and first order for bisulphite in the presence of either Fe(II) or Fe(III), a result consistent with reports by other authors (10). The oxygen result is not surprising considering the large excess of oxygen used. The result confirmed that it was not necessary to use pure oxygen in our work.

No sulphur-containing ions other than HSO_3^- and SO_4^{2-} were detected during analysis using ion chromatography. Parenthetically, the kinetics were the same in unstirred solutions in contact with air. In addition, we noted that the oxidation rate is negatively correlated with buffer concentration. The latter observation is consistent with the series of iron complexes formed with the acetate buffer system (11).

The variation in specific rate constants with temperature between 25 and 35°C for both iron species is shown in Table 1. The activation energies determined from these data using the Arrhenius equation were 73.8 ± 2 and 70.9 ± 2 kJ mol^{-1} for the ferric and ferrous systems, respectively, in agreement with Hara and Okita (10). These activation energies fall within experimental error for both species, a result consistent with oxidative cycling between Fe(III) and Fe(II) as suggested elsewhere (6, 7).

Figure 1 shows a plot of the concentration of bisulphite vs. time in Fe(II) and Fe(III) solutions in the presence of 1,10-phenanthroline. Little reaction is observed in the complexed Fe(II) system while reaction ceases in the Fe(III) solution after 10–20 min. Such reaction as may be inferred during the initial few minutes in the Fe(II) solution may be attributed either to Fe(III) impurity in the standards used and (or) reaction prior to the relatively slow sequestration of Fe(II) by 1,10-phenanthroline. Cessation of reaction in the Fe(III) system corresponds to quantitative recovery of the Fe(III) as the Fe(II)–1,10-phenanthroline complex. Clearly the Fe(II)–1,10-phenanthroline complex suppresses the catalytic action of Fe(II). This result is consistent with observations by Lee et al. (12) who have shown the formation constant for the Fe(II) complex to be seven orders of magnitude greater than that for Fe(III); as well, Fe(II) will displace Fe(III) from 1,10-phenanthroline.

Fig. 1. Plot of concentration of bisulfite vs. time in the presence of either Fe(III) or Fe(II).

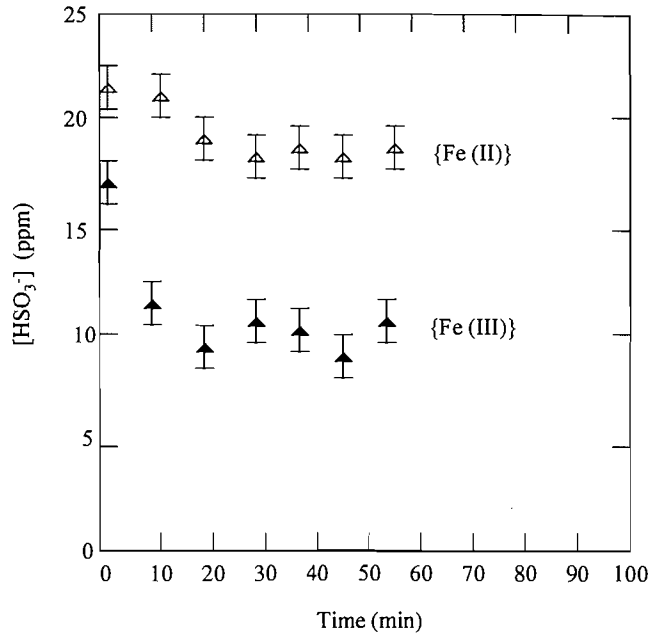

Fig. 2. Development of the 1,10-penanthroline/Fe(II) complex in the Fe(III)-catalyzed system.

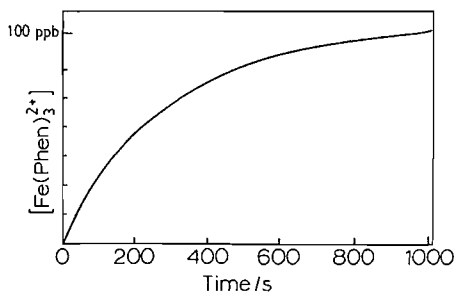

It should be noted that the Fe(II)–1,10-phenanthroline complex develops relatively slowly, taking about 10 min to develop fully under our experimental conditions. The growth in the absorbance attributed to the complex formation with time is shown in Fig. 2, which was obtained directly from the spectrometer.

Behra and Sigg (13) have reported that Fe(II) is the predominant oxidation state in fog water with a half-life for oxidation to Fe(III) at pH 5 and 5°C of 4.6 years. Our results support redox cycling of iron during oxidation since complexation of Fe(II) by 1,10-phenanthroline interrupts the cycle by sequestering Fe(II). It should be noted, however, that Fe(II) is a catalyst for bisulphite oxidation in its own right. Redox cycling is also consistent with our observation that the oxidation kinetics

Table 2. Ratio $^{18}O/^{32}S$ secondary ion yield in sulphate after oxidation with $^{18}O_2$ with Fe(III) and Fe(II) as catalysts.

Iron species	Ratio, secondary ion yield $^{18}O/^{32}S$
Fe(III)	0.34 ± 0.15
Fe(II)	1.20 ± 0.03

are essentially independent of the starting material, Fe(II) or Fe(III).

The SIMS experiment was undertaken to estimate the $^{18}O/^{32}S$ ratio obtained by oxidation of bisulphite by $^{18}O_2$ in systems dominated by either Fe(II) or Fe(III). Significant differences would be indicative of different reaction mechanisms. The results, shown in Table 2, give ratios of 1.2/1 and 0.34/1 for Fe(II) and Fe(III) systems, respectively. The SIMS data used in constructing Table 2 were based on analysis of three distinct sites on the surface of the barium sulfate precipitates mounted on indium foil. These results are subject to large relative errors due to differential charging, which arises because the particle distribution and size is non-uniform and varies from site to site. Changes in surface charging have a significant effect on secondary ion yield.

It is difficult to propose a unique reaction mechanism from our results, both because the system is complicated by the presence of a buffer that forms a series of complexes with the iron species and because more than one mechanism is consistent with the results. It is reasonable to suggest that the Fe(III) reacts in a manner similar to that proposed in the original Backstrom (5) mechanism:

$$Fe(III) + HSO_3^- \rightarrow Fe(II) + HSO_3^{\bullet}$$

$$HSO_3^{\bullet} + \tfrac{1}{2}O_2 + H_2O \rightarrow 2SO_4^{2-} + 4H^+$$

When the bisuphite is oxidized in $^{18}O_2$ this step yields an $^{18}O/^{32}S$ ratio of 0.5.

Benson (14) has suggested that peroxide complexes of Fe(II) and O_2 are formed during oxidative cycling of Fe:

$$Fe(II) + O_2 \rightarrow Fe(II)O_2$$

followed by slow oxidation of Fe(II) to Fe(III) by molecular oxygen. Reaction of the peroxide with bisulphite in $^{18}O_2$:

$$Fe(II)O_2 + 2HSO_3^- \rightarrow Fe(II) + 2SO_4^{2-} + 2H^+$$

yields an $^{18}O/^{32}S$ ratio of 1:1.

At any rate it appears that the ratio of $^{18}O/^{32}S$ will be lower in the Fe(III) system than that obtained with Fe(II). The preponderance of Fe(II) in cloud water suggests that this is the principle iron catalyst responsible for oxidation of bisulphite. The Fe(II) peroxide species may play an important role in the oxidation mechanism.

The behaviour of the system is consistent with that expected for the following simplified mechanism:

$$Fe(III) + HSO_3^- \rightarrow Fe(II) + HSO_3^{\bullet}$$

$$HSO_3^{\bullet} + \tfrac{1}{4}O_2 + \tfrac{1}{2}H_2O \rightarrow SO_4^{2-} + 2H^+$$

$$Fe(II) + O_2 \rightarrow Fe(II)O_2$$

$$Fe(II)O_2 + 2HSO_3^- \rightarrow Fe(II) + 2SO_4^{2-} + 2H^+$$

Net: $Fe(III) + 3HSO_3^- + \tfrac{5}{4}O_2 + \tfrac{1}{2}H_2O \rightarrow Fe(II) + 3SO_4^{2-} + 4H^+$

followed by slow oxidation of Fe(II) to Fe(III):

$$4Fe(II) + O_2 + 4H^+ \rightarrow 4Fe(III) + 2H_2O$$

As long as Fe(II) oxidation is slow, Fe(II) will become the dominant catalytic agent as the concentration of Fe(III) falls. While we do not suggest that this is a definitive mechanism, especially in a system such as the buffer used in our work, it does explain our observations. First, reaction with Fe(II) does not proceed when the system contains 1,10-phenanthroline, while reaction with Fe(III) is quenched after a 10 min induction period when 1,10-phenanthroline is added. Further, this induction period corresponds to quantitative recovery of the 1,10-phenanthroline–Fe(II) complex. Second, the activation energies for the two systems are within experimental error, reflecting the strong coupling between Fe(III) and Fe(II). Third, the ratio of $^{18}O/^{32}S$ for the Fe(II)-catalyzed oxidation is close to unity (1.2/1) while it is 0.34/1 for the Fe(III) system.

Conclusions

The kinetics of iron-catalyzed bisulphite oxidation are consistent with oxidative cycling of ferrous and ferric iron, as reported elsewhere.

SIMS analysis of sulfates precipitated after oxidation of bisulphite in systems dominated by each of the iron species yields significantly different $^{18}O/^{32}S$ ratios when oxidation is carried out in the presence of $^{18}O_2$. Fe(III) yields a ratio of $^{18}O/^{32}S$ less than unity, suggesting that H_2O is an oxygen source. The Fe(II) system yields a ratio close to unity; a species such as Fe(II) peroxide is thus implicated in the reaction mechanism. SIMS provides a powerful tool for probing the reaction mechanism.

These results, combined with those obtained by Behra and Sigg, imply that Fe(II) is the dominant iron catalyst in cloud water.

Study of formation and fragmentation of ionic complexes of polydentate ligands with Al(III) and glycerol by fast atom bombardment mass spectrometry. Part 1: Polydentate ligands

Mandapati Saraswathi and Jack M. Miller

Abstract: The complexation reactions of aluminum ions with polydentate ligands such as 12-crown-4, 15-crown-5, 18-crown-6, 1,10-dithia-18-crown-6, dicyclohexyl-18-crown-6, dibenzo-18-crown-6, and dibenzo-24-crown-8 and acyclic analogs mono-, di-, tri-, tetra-, penta-, and hexaethylene glycols were studied using FAB mass spectrometry. These cyclic ligands form $(M + 117)^+$, $(M + 157)^+$, $(M + 231)^+$, and $(M + 253)^+$ ions with different aluminum-containing species. Collisionally activated dissociations of these adduct ions gave fragment ions, initially due to the loss of ligands directly attached to aluminum, followed by insertion of aluminum into the remaining ligand skeleton. Further fragmentation of the metal-containing species gave ions corresponding to consecutive losses of C_2H_4O units. Fragmentations of deuterium-labelled ions were used to help in establishing fragmentation pathways. Selectivity towards metal chelation is observed in this order: 12-crown-4 < 15-crown-5 < 18-crown-6. The elemental compositions of adduct ions were confirmed by high-resolution measurements. The formation of $(M + Al - 2H)^+$ ion, obtained by the displacement of two hydroxy protons, is more favored for tetra- and pentaethylene glycols.

Key words: crown ethers, polyethylene glycols, aluminum(III)–glycerol, ionic complexes and ion dissociations.

Résumé : Utilisant la spectrométrie de masse BAR, on a étudié les réactions de complexation des ions aluminium avec des ligands polydentates suivants : 12-couronne-4, 15-couronne-5, 18-couronne-6, 1, 10-dithia-18-couronne-6, dicyclohexyl-18-couronne-6, dibenzo-18-couronne-6 et le dibenzo-24-couronne-8 et avec les analogues mono, di, tri, tétra, penta et hexaéthylène. Ces ligands cycliques forment des ions $(M + 117)^+$, $(M + 157)^+$, $(M + 231)^+$ et $(M + 253)^+$ avec différentes espèces contenant de l'aluminium. Les dissociations, activées par des collisions, de ces ions adduits donnent des ions fragments, initialement à cause de la perte du ligand attaché directement à l'aluminium suivie de l'insertion de l'aluminium dans le squelette du ligand restant. Une fragmentation plus poussée de l'espèce contenant le métal donne des ions correspondants à la perte consécutive d'unités C_2H_4O. On a utilisé les fragmentations d'ions marqués au deutérium dans le but de déterminer le processus de fragmentation. On observe une sélectivité dans la chélation du métal dans l'ordre suivant : 12-couronne-4 < 15-couronne-5 < 18-couronne-6. Des mesures à haute résolution ont permis de confirmer la composition élémentaire de ces ions adduits. La formation de l'ion $(M + Al - 2H)^+$, obtenu par le déplacement de deux protons hydroxyliques, est plus favorisée pour les tétra et pentaéthylène glycol.

Mots clés : éthers couronnes, polyéthylène glycol, aluminium(III)–glycérol, complexes ioniques et dissociation d'ions.

Introduction

The host–guest chemistry of crown ethers has been studied extensively because of the importance of these complexes in synthesis, in phase transfer catalysis, and as complexing agents for unwanted or dangerous ionic contaminants (1). The strength of metal–ligand complexes formed from crown ethers in solution depends on the size of the ring, on the metal ion, and on the solvent in which the reaction occurs (2). These multidentate systems have also been studied extensively by molecular mechanics methods (3). Mass spectrometry offers conditions useful for evaluating cation–ligand complexation in the absence of solvents. Recent studies on crown ether complexation reactions in the gas phase also show selectivity in binding with alkali metal ions and are useful in assessment of cation–ligand interaction (4). However, in some cases these cation complexation reactions are dependent on the matrix used in fast atom bombardment mass spectrometry (5).

Fast atom bombardment and electrospray ionization methods are useful techniques for the evaluation of both strong and weak interactions. Metal complexes arising from binding of cations with ligands such as cyclodextrins (6), bleomycin (7), bipyridyl amino acid (8), arylmethyl ethers (9), amines (10), nitriles (11), and nucleobase-substituted polyethers (12) were studied by these techniques. A recent study suggests the possibility of chiral recognition by using chiral crown ethers in the gas phase (13). Bowers and co-workers (14) predicted gas

phase conformations by accurate measurements of collision cross sections of alkali metal ion complexes of 18-crown-6 using ion chromatography techniques. Collisionally activated dissociation (CAD) of metal – crown ether complexes resulted in the formation of distonic radical cations by the homolytic cleavage of C—C bonds and elimination of neutral C_2H_4O units from the complex to yield abundant fragment ions (4*c*–*e*,15), which is analogous to the fragmentation of protonated crown ethers (16). During the CAD process, cations residing within the binding cavity of a ligand behave very differently from the cations binding from the outside of the ligand cavity. The dissociation of the larger metal ion – ligand complexes led to the formation of metal ions in greater abundance (4*c*, 12).

Crown ethers, which often serve to transport ionic species to specific sites (17), have not been studied with aluminum ions in the mass spectrometer. Therefore, we undertook the study of the interaction of aluminum ions with crown ethers and their open-chain counterparts. In the present study, the formation and fragmentation processes of cation–ligand complexes and the generation of cyclic ions between aluminum ions and polyethylene glycols are also discussed.

Experimental

All mass spectrometric experiments were conducted using a Kratos (Manchester, U.K.) Concept 1S double focusing (EB configuration) mass spectrometer, fitted with an Ion Tech. (Teddington, U.K.) fast atom gun. The gun was operated at 6–8 kV with the gun current 0.5–1 μA, using xenon as a bombarding gas. Source pressure was maintained at (1–2) × 10^{-5} Torr (1 Torr = 133.3 Pa). All data were recorded at 8 kV accelerating voltage at a scan rate of 8 s/decade, over a mass range of 11–950 u at 1100 resolution with an inter scan delay of 2 s. Samples were prepared by dissolution of the ether in a matrix mixture containing $AlCl_3$ (~0.5 mg) in glycerol (25–30 mg) water, (2 μL), and TFA (2 μL). One microlitre of solution was loaded on to the stainless steel FAB probe tip. The *m/z* measurements were calibrated with 2,4,6-tris(perfluoroheptyl)-1,3,5-triazine. For each run, 8–10 scans were averaged and the background was subtracted using the Kratos DART / MACH3 data system. Equimolar solution data were recorded by using equal volumes of sample solution and constant amounts of glycerol (25–30 mg), water (2 μL), and TFA (2 μL) and equal quantities of $AlCl_3$ (~0.5 mg). High-resolution mass measurements were made at a resolving power of 10 000. Linked scan spectra were recorded keeping the *B/E* or B^2/E constant for daughter and precursor ion analysis, respectively. The main beam intensity was reduced to 45–50% of its original value, using helium in the first field-free region collision cell, to obtain CAD spectra.

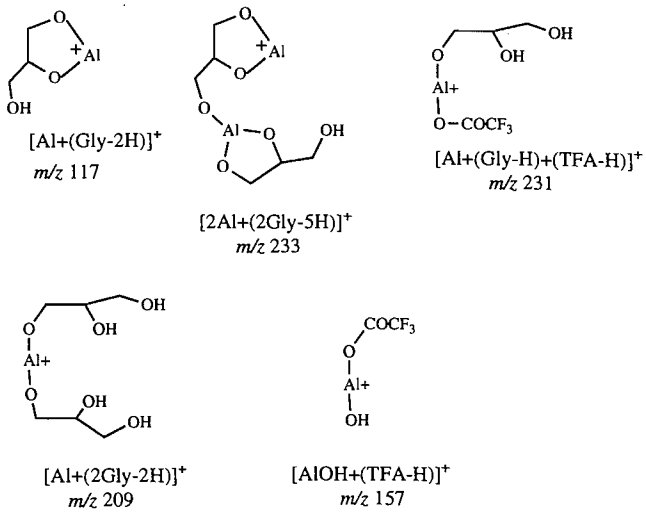
All samples were commercially available (Aldrich, Parish) and used without further purification. Glycerol-d_3 was prepared by exchange reactions with deuterium oxide.

Results and discussion

Crown ethers

To study the complexation of aluminum ions with crown ethers, aluminum chloride was first dissolved in glycerol. As for other metal chlorides used to make metal–ligand complexes, a few microlitres of water were added to make the solution homogeneous. This process led to partial hydrolysis of the aluminum chloride. Finally, crown ether was mixed with the metal ion – matrix solution and spectra were recorded. Some ions were observed above the molecular ion region but the spectrum is complicated by chemical noise. By increasing the concentration of the crown ether, a FAB spectrum of the crown ether is ultimately obtained.

Scheme 1. Ions produced from $AlCl_3$/glycerol/TFA/H_2O.



On analyzing the spectrum of the matrix mixture of $AlCl_3$ with glycerol and water, we found that the spectrum is dominated by glycerol ions and some ions containing aluminum and glycerol. The noise level, however, was not reduced. Addition of a few microlitres of trifluoroacetic acid (TFA) to the matrix reduced the noise and produced ions with predictable masses at *m/z* 27, $\{Al^+\}$, 93 $\{(Gly + H)^+\}$, 117 $\{[Al + (Gly - 2H)]^+\}$, 209 $\{[Al + (2Gly - 2H)]^+\}$, 231 $\{[Al + (Gly - H) + (TFA - H)]^+\}$, 233 $\{[Al_2 + (2Gly - 5H)]^+\}$. In addition, clusters of these ions with 116 [Al + (Gly − 3H)] and 114 (TFA) units are also observed. The spectrum recorded with the substitution of glycerol and water by glycerol-d_3 and D_2O showed increase in *m/z* according to the number of hydroxy groups present in an ion: *m/z* 117 shifted to 118, *m/z* 209 to 213, and *m/z* 231 and 233 to *m/z* 233 and 234, respectively. Structures proposed for these ions are given in Scheme 1. Replacement of TFA with acetic acid and the use of a solution of $AlCl_3$ do not produce good spectra.

Aluminum foil and anhydrous aluminum chloride were used by other workers to generate aluminum ions (Al^+) (18). Finally, we tried using the combination of $AlCl_3$ (instant mixing) in glycerol with 2 μL each of TFA and water. The spectrum obtained with crown ether produced ions with an addition of 117, 157, 231, and 253 units to the crown ether. Use of monothioglycerol in place of the glycerol matrix produced the $(M + 18)^+$ ion as the base peak due to trace amounts of ammonium salts present in the thioglycerol. The formation of the $(M + 133)^+$ ion further suggested that the *m/z* 117 ion formed in a glycerol matrix was a complex of aluminum and glycerol. Other ions were not significant enough to check the presence of the thioglycerol unit.

The mass spectra of the crown ethers 12-crown-4 (**1**), 15-

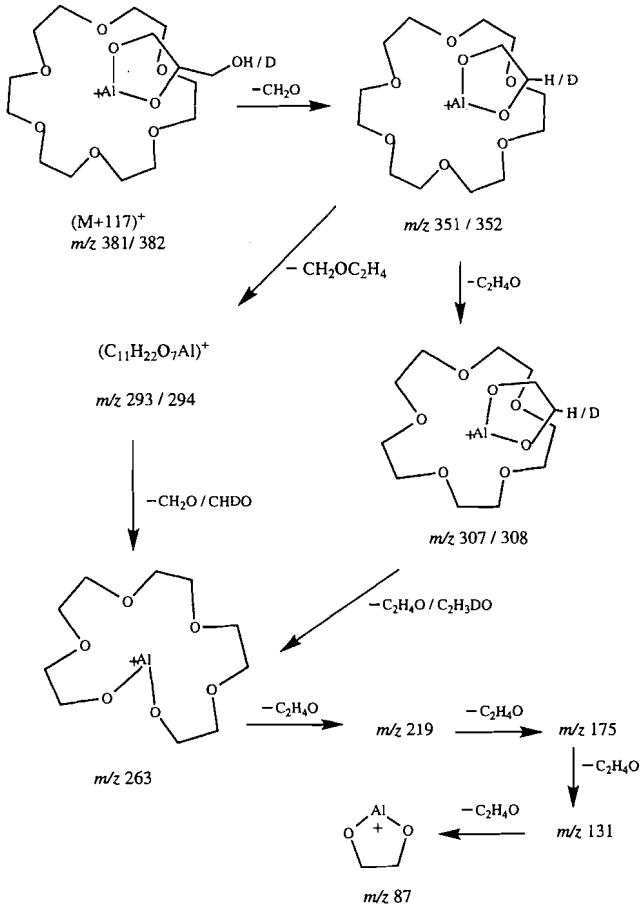
crown-5 (**2**), 18-crown-6 (**3**), 1,10-dithia-18-crown-6 (**4**), dicyclohexyl-18-crown-6 (**5**), dibenzo-18-crown-6 (**6**), and dibenzo-24-crown-8 (**7**) were analyzed in the aluminum–glycerol – TFA–water matrix. Relative abundances of ions obtained from these cyclic ligands are listed in Table 1. All compounds yield the *m/z* 45 $(C_2H_5O)^+$ ion as the most abundant ion, except for dibenzo-18-crown-6, which produced *m/z* 121 $\{(C_6H_4O_2CH)^+\}$as the base peak in the spectrum. Formation of the *m/z* 121 ion is a characteristic fragmentation of dibenzocrowns (19). Other abundant ions are $(M + H)^+$, $(M + 117)^+$, $(M + 157)^+$, $(M + 231)^+$, and $(M + 253)^+$. Less abundant ions due to the consecutive losses of C_2H_4O units from $(M + H)^+$ ions were also seen in the spectrum.

Spectra obtained with glycerol-d_3 and D_2O instead of glycerol and water show that the mass of $(M + H)^+$, $(M + 117)^+$, and $(M + 157)^+$ ions increased by one unit, and the mass of $(M + 231)^+$ ions by two units. There is no change in the mass of the $(M + 253)^+$ ion.

Experiments with 1,2-propanediol as the matrix in place of glycerol gave ions from 18-C-6 corresponding to $(M + H)^+$, $(M + 101)^+$, $(M + 157)^+$, $(M + 215)^+$, and $(M + 253)^+$ in addition to the other ions below the molecular ion region. Similarly, in ethylene glycol the spectrum of 18-C-6 also shows $(M + H)^+$, $(M + 157)^+$ and $(M + 253)^+$ ions in addition to the formation of $(M + 87)^+$ and $(M + 201)^+$ ions above the molecular region. Formation of $(M + 117)^+$, $(M + 101)^+$, and $(M + 87)^+$ from glycerol, 1,2-propanediol, and ethylene glycol, respectively, indicates that these complexes correspond to the adduct ions of the $\{Al + (matrix - 2H)\}^+$ complex. Similar changes with respect to the matrix are also observed in the mass of $(M + 231)^+$, $(M + 215)^+$, and $(M + 201)^+$ ions, which suggests the participation of the matrix in the formation of these ions. However, there is no change in the mass of $(M + 157)^+$ and $(M + 253)^+$ ions. The spectrum of 18-C-6 recorded in $AlCl_3$, glycerol, acetic acid, and water gave $(M + H)^+$, $(M + 117)^+$, $(M + 61)^+$, and $(M + 177)^+$ ions but no $(M + 157)^+$ ion. Therefore, we conclude that TFA participates in the formation of $(M + 157)^+$, $(M + 231)^+$, and $(M + 253)^+$ ions. The $(M + 231)^+$ ion is a complex of $\{Al + (Gly-H) + (TFA - H)\}^+$ with 18-C-6, which shows a mass increase of 2 u in D_2O experiments. The $(M + 253)^+$ ion is a complex of $\{[Al + (2TFA - 2H)] + M\}^+$, and remains unchanged during D_2O exchange. Finally, the composition of the $(M + 157)^+$ ion can be accounted for with one exchangable proton as the $\{M + [AlO,H + (TFA-H)]\}^+$ ion. High-resolution mass measurements of $(M + 117)^+$, $(M + 157)^+$, $(M + 231)^+$, and $(M + 253)^+$ ions fit with the proposed formula (Table 2). Despite the use of $AlCl_3$, no chloride-containing species are observed in the spectra. Thus the aluminum coordinates to the crown and matrix-derived anions to form a unipositive complex cation.

Experiments carried out with equimolar solutions of analytes **1**, **2**, and **3** under identical conditions can give metal-

Scheme 2. Collisionally activated dissociation of $(M + 117)^+$ ion from 18-crown-6.



complexed ions in relative complexation by aluminum ions. Relative abundances of $(M + 117)^+$, $(M + 157)^+$, $(M + 231)^+$, and $(M + 253)^+$ ions directly indicate the metal ion binding strengths with crown ethers. These are in the order of 18-C-6 > 15-C-5 > 12-C-4. Experiments with an equimolar solution of mixed ligands 12-C-4 / 15-C-5 and 15-C-5 / 18-C-6 showed the selectivity in the formation of metal-complexed ions. The abundances of the significant cluster ions $(M + 117)^+$, $(M + 157)^+$, $(M + 231)^+$, and $(M + 253)^+$ vary as 18-C-6 > 15-C-5 > 12-C-4. This analysis was not extended to other crown ethers that are less polar and have solubility problems on mixing with a polar matrix. Although, regular spectra of 1,10-dithia-18-crown-6, dicyclohexyl-18-crown-6, dibenzo-18-crown-6, and dibenzo-24-crown-8 have been collected using solutions of these compounds prepared from 1,2-dibromoethane and methanol, this process does not keep the sample in the matrix for sufficiently long to run the competitive analysis.

Ion dissociations

The dissociation of $(M + 117)^+$, $(M + 157)^+$, $(M + 231)^+$, and $(M + 253)^+$ ions from 12-C-4, 15-C-5, and 18-C-6 shows similar types of fragmentation. Hence, the fragmentation processes of ions from 18-C-6 only are discussed (Scheme 2). These metal chelated ions $(M + 117)^+$, $(M + 157)^+$, $(M + 231)^+$, and $(M + 253)^+$ show formation of precursor ions, which are cluster ions of crown with various ionic aluminum species surrounded by glycerol, TFA, and OH groups.

$\{M + (Al + Gly - 2H)\}^+$, m/z *381*

Unimolecular dissociation and collisionally activated dissociation differ in the removal of neutral fragments to produce *m/z* 293 and 307 ions from the most abundant ion at *m/z* 351, which is formed from the parent ion by the loss of CH_2O. Formation of *m/z* 293 is a facile process in unimolecular decomposition whereas formation of *m/z* 307 is favored under the CAD conditions. This suggests that formation of *m/z* 307 is a higher energy process. Further dissociation of ions at *m/z* 293 and 307 gives rise to *m/z* 263 by the loss of CH_2O and C_2H_4O units, respectively.

Fragmentation of *m/z* 263 by consecutive losses of C_2H_4O units led to the formation of ions at *m/z* 219, 175, 131, and 87. The normal FAB mass spectrum of 18-C-6 shows $(M + H)^+$ at *m/z* 265 and $(M + H - H_2)^+$ at *m/z* 263 ions in glycerol matrix. If the ion at *m/z* 263 obtained during CAD of the $(M + 117)^+$ ion corresponds to the $(MH - H_2)^+$ ion of 18-C-6, the further fragmentation of *m/z* 263 should produce ions at *m/z* 177, 133, and 89. They have significant abundances as observed in the CAD spectrum of the $(MH - H_2)^+$ ion from 18-C-6 in a glycerol matrix. The CAD spectrum of the $(M + H)^+$ ion of 18-C-6 also shows the formation of similar ions at *m/z* 177, 133, and 89 (16). However, formation of *m/z* 87 is a less significant process from *m/z* 263 and 265 of 18-C-6. Therefore, there probably is another structure accounting for some of *m/z* 263 that is different from that normally expected from the $(MH - H_2)^+$ ion. It might have been produced by the insertion of an AlO^+ ion into the crown. Crown ethers have been shown to undergo more facile bond insertion reactions than open-chain analogs with Fe^+ and Co^+ (20). Abundant ions at *m/z* 175, 131, and 87 arising from *m/z* 263 should have an aluminum ion in them (Scheme 2). The dissociation of $(M + 118)^+$ at the *m/z* 382 ion shows the retention of deuterium in the $(P - 30)^+$, $(P - 74)^+$, and $(P - 88)^+$ ions. This suggests that the formation of $(P - CH_2O)^+$ comes from a glycerol moiety. Further loss of C_2H_4O and $CH_2OC_2H_4$ is exclusively from the crown, since the loss of C_2H_4O and $CH_2OC_2H_4$ from glycerol would involve loss of D, to give an ion at *m/z* 308 and 294, respectively. The processes of formation of *m/z* 263 may be directly from the $(P - CH_2O)^+$ (*m/z* 352) ion and from the $(P - CH_2O,C_2H_4O)^+$ (*m/z* 308) ion and (or) by the elimination of CHDO from *m/z* 294 (Scheme 2).

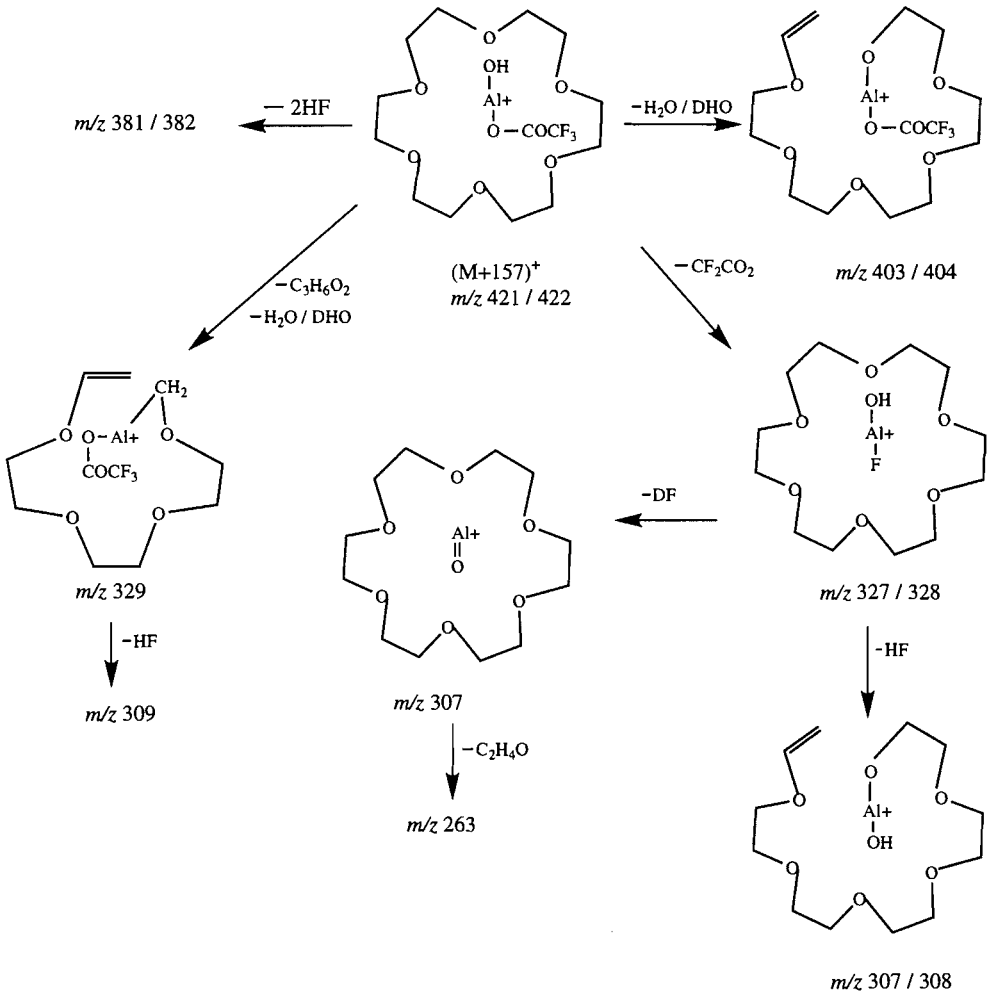
$\{M + [AlOH + (TFA - H)]\}^+$, m/z *421*

This ion, on fragmentation, produces major ions at *m/z* 328 and 327 from labelled and unlabelled parent ions, respectively. The ion at *m/z* 327/328 is due to a characteristic loss of CF_2CO_2 from the parent ion by the migration of F to the metal ion. Formation of another abundant ion at *m/z* 329 is explained by losses of ($C_2H_4OCH_2O$ and H_2O/DHO) groups from the parent ion (Scheme 3). This ion, on elimination of HF, forms *m/z* 309. Fragmentation of *m/z* 327/328 by the removal of HF/DF may produce *m/z* 307. Other fragment ions at *m/z* 263, 219, 175, 131, and 87 are also observed.

Fragmentation of the $(M + 231)^+$ ion (m/z *495)*

This ion contains two exchangeable protons with primary and secondary hydroxyl groups from glycerol. The decomposition

Scheme 3. Fragmentation of $(M + 157)^+$ ion under CAD from 18-crown-6.



of the ion at *m/z* 495/497 involves the loss of one of the deuteriums during the elimination of CF_3CO_2D to give the ion at *m/z* 381/382. The dissociation of a partially labelled ion $(M + 231)^+$ at *m/z* 496 shows mainly the loss of CF_3CO_2H. Elimination of unlabelled TFA as the major process can be explained in terms of the bond fission energies of O–D and O–H and the ease of exchange of protons on the glycerol moiety of this ion during the analysis. Further dissociation of *m/z* 381/382 is similar to the fragmentation of the $(M + 117)^+$ ion.

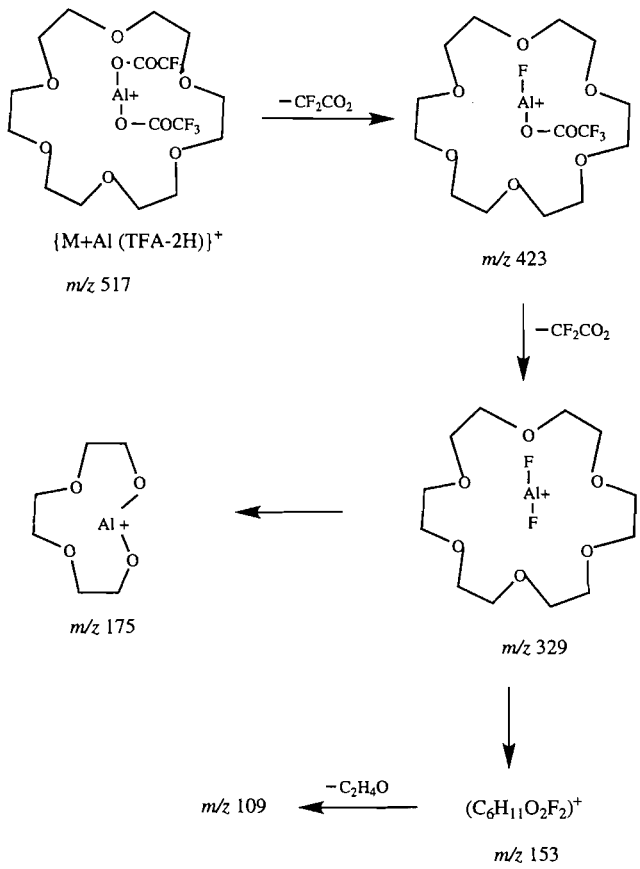
Fragmentation of $(M + 253)^+$ (m/z *517)*

Fragmentation of this ion produces an abundant ion at *m/z* 423 due to the loss of CF_2CO_2, by transfer of F to the metal (Scheme 4). Further fragmentation also involves the loss of another CF_2CO_2 moiety, which is a characteristic of the presence of another TFA group in the ion. The migration of an F to the aluminum yields an abundant ion at *m/z* 329. This ion is a complex of 18-C-6 and $(AlF_2)^+$. Interestingly AlF_2^+ ion interactions are detected while $AlCl_2^+$ ions are not seen. The elimination of HF is also observed from the *m/z* 423 and 329 ions. Other significant ions produced from *m/z* 329 are at *m/z* 175, 153, and 109. The fragmentation of *m/z* 329 into *m/z* 175 may involve the transfer of F from Al back to the ligand skeleton and binding of aluminum to oxygens of the ether is shown. Formation of *m/z* 153 involves transfer to the ether fragment instead of the Al-containing species. Formation of low-abundance ions due to consecutive losses of C_2H_4O units from *m/z* 423 and 329 is also observed.

Mass spectra of glycols obtained from $AlCl_3$–glycerol–TFA

The FAB mass spectra of mono- (**8**), di- (**9**), tri- (**10**), tetra- (**11**), penta- (**12**), and hexaethylene glycols (**13**) were run in the $AlCl_3$ – glycerol – water and TFA matrix mixture. Relative abundances of ions obtained from these compounds are listed in Table 3. Commonly observed ions from glycols are $(M + Al - 2H)^+$ and $(M + 117)^+$. In addition, ions due to consecutive losses of C_2H_4O units from these $(M + Al - 2H)^+$ and $(M + 117)^+$ ions are also observed. Ethylene glycol does not form an $(M + 117)^+$ ion and gives ions corresponding to $(C_2H_5O)^+$, $(HOAlOC_2H_4OH)^+$, and $\{(HOC_2H_4O)_2Al\}^+$ with significant abundances. D_2O experiments with tetraethylene glycol show no mass shift in the formation of the $(M + Al - 2H)^+$ ion. Therefore, the two hydroxyl protons of the glycol are substituted by Al^{3+} in producing the $(M + Al - 2H)^+$ ion, which forms a cyclic ether with aluminum ion. The $(M + 117)^+$ ion

Scheme 4. Collisionally activated dissociation of {M + Al (TFA − H)$_2$}$^+$ ion from 18-crown-6.

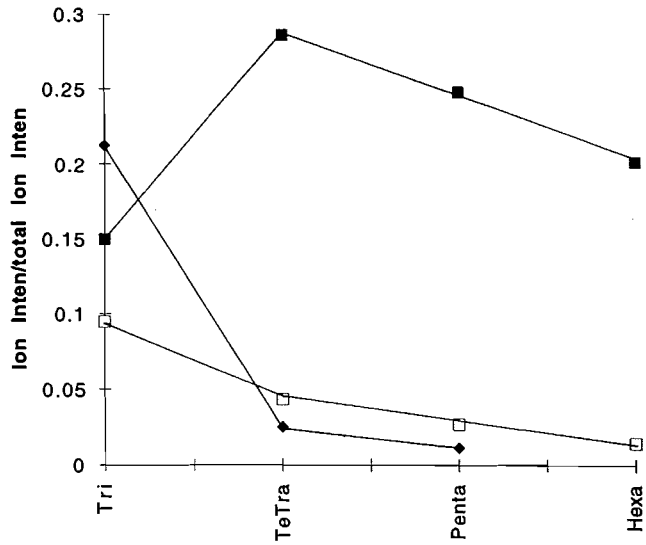


shows an increase in the mass by 1 u during D_2O exchange. Exact Mass measurements of the $(M + Al - 2H)^+$ ion from triethylene glycol at *m/z* 175 show a good fit for $(C_6H_{12}O_4Al)^+$ with an error of 3.4 ppm (observed 175.05449, theoretical 175.05509).

Formation of a cyclic $(M + Al - 2H)^+$ ion depends on the number of ethylene oxide (C_2H_4O) units and is observed from triethylene glycol to pentaethylene glycol as the base peak. Although in hexaethylene glycol the abundance of $(M + Al - 2H)^+$ ion is significant, the $(C_2H_5O)^+$ ion is the base peak. Formation of this ion from hexaethylene glycol is less favoured because of a lower probability of the two ends meeting for the intra-molecular substitution process to occur. Diethylene glycol does not give the $(M + Al - 2H)^+$ ion and formation of the $(M + 117)^+$ ion predominates. In 11-, 14-, 17-, and 20-membered rings derived from tri-, tetra-, penta-, and hexaethylene glycols, respectively, on formation of the $(M + Al - 2H)^+$ ion, the existence of donor–acceptor interactions between ethereal oxygens and aluminum results in highly stable metal–ligand complexes. In diethylene glycol this type of coordination may not be possible in the 8-membered ring to form $(M + Al - 2H)^+$ ion.

Ions $(M + H)^+$, $(M + Al - 2H)^+$, and $(M + 117)^+$ obtained from equimolar solutions of glycols under identical conditions can be compared to obtain the relative metal ion affinity of glycols. A ratio of the intensity of $(M + H)^+$, $(M + Al - 2H)^+$, and $(M + 117)^+$ ions individually and total ion intensity vs.

Fig. 1. A ratio of ion intensity of $(M + Al - 2H)^+$, $(M + H)^+$, and $(M + 117)^+$ ions and total ion intensity vs. glycols. $(M + Al\text{-}2H)^+$ -■-; $(M + H)^+$ -□-; $(M + 117)^+$ -◆-.



glycol chain length is presented as a graph (Fig. 1). The cyclic $(M + Al - 2H)^+$ ion formation is highly favored in tetraethylene glycol and formation of $(M + H)^+$ and $(M + 117)^+$ ions is gradually decreased as the chain length increases. Ethylene glycol and diethylene glycol are less effective at complexing in the presence of glycerol matrix and only reagent ions dominated the spectrum at constant molar concentrations. 1,3-Propanediol and 2-butene1,4-diol also yield abundant $(M + 117)^+$ ions (Table 3).

Ion dissociations

The CAD spectra of $(M + Al - 2H)^+$ ions from tri- and pentaethylene glycols show ions corresponding to the elimination of C_2H_4O units, which ultimately leads to the formation of *m/z* 87 [$(C_2H_4O_2Al)^+$]. The further decomposition of *m/z* 87 gives rise to *m/z* 43 [$(AlO)^+$]. $(M + 117)^+$ from triethylene glycol yields an ion at *m/z* 175, i.e., $(M + Al - 2H)^+$, by the elimination of glycerol. The further fragmentation of this ion is identical with the fragmentation of the $(M + Al - 2H)^+$ ion. Another adduct from the same glycol corresponding to the {(M − H) + [Al (TFA − H)]}$^+$ ion dissociates to produce ions at *m/z* 175 by the removal of CF_3CO_2H. Another abundant ion is at *m/z* 235. The $(M + 233)^+$ ion of pentaethylene glycol gives ions due to loss of C_2H_4O units from the parent ion in addition to the formation of the most abundant $(M + Al - 2H)^+$ ion at *m/z* 263. Further fragmentation of *m/z* 263 also involves the loss of ethylene oxide units. The fragmentation of the $(M + Al - 2H)^+$ ion (*m/z* 263) from pentaethylene glycol is similar to the fragmentation of *m/z* 263 produced from the decomposition of the $(M + 117)^+$ ion of 18-C-6 (Scheme 2).

The metastable ion analysis at constant B^2/E of the $(M + Al - 2H)^+$ ion at *m/z* 263 gives $(M + 117)^+$ and {M + (Al_2 + 2Gly − 5H)}$^+$ ions as precursors. However, the $(M + Al - 2H)^+$ ion from trigol has another abundant precursor ion at *m/z* 193 corresponding to {(M − H) + AlOH)}$^+$ in addition to the $(M + 117)^+$ ion.

Conclusions

These polydentate ligands formed abundant adduct ions with various ionic aluminum species. The complexation reactions of these crown ethers in the gas phase showed selectivity in binding with respect to ligand in the order 18-C-6 > 15-C-5 > 12-C-4. Dissociations of adduct ions initially give fragment ions due to loss of the non-crown species attached directly to aluminum. The insertion of aluminum ion into the crown ether chain was also observed. Formation of analogous $(M + Al - 2H)^+$ ions was observed in the FAB spectra of tri-, tetra-, penta-, and hexaethylene glycols. The stability of these ions depends on the distribution of charge through electrostatic interaction with ethereal oxygens. In mono- and diethylene glycols such types of charge distribution may not be possible. Since aluminum reagents are strong Lewis acids, strong binding of aluminum to donor molecules is observed. The complexation reactions of crown ethers with aluminum ions may fall into a distinct class of aluminum host–guest chemistry.

Structure and bonding of organosilicon compounds containing silicon–silicon and silicon–germanium bonds: an X-ray absorption fine structure study

Jian Z. Xiong, Detong Jiang, Craig E. Dixon, Kim M. Baines, and T.K. Sham

Abstract: Si K-edge X-ray Absorption Fine Structures (XAFS) spectroscopy has been used to study the structure and bonding of a series of highly symmetric organosilicon compounds, $Si(CH_3)_4$, $Ge[Si(CH_3)_3]_4$, $Si[Ge(CH_3)_3]_4$, and $Si[Si(CH_3)_3]_4$, in the gas phase. It was found that there is a significant difference in the absorption coefficient in the near-edge region between local Si–Si interactions in these compounds and long-range Si–Si interactions in crystalline solids and that the Si—Si bond length in the molecule $Si[Si(CH_3)_3]_4$ is 2.364(10) Å and the Si—Ge bond lengths in $Si[Ge(CH_3)_3]_4$ and $Ge[Si(CH_3)_3]_4$ are 2.38(3) Å and 2.396(15) Å, respectively. These results and their comparison to Si—Si and Si—Ge interatomic distances in crystalline solids are discussed.

Key words: XAFS, EXAFS, organosilicon, Si—Ge bond length.

Résumé : On a utilisé la spectroscopie d'absorption des structures fines de rayons X du Si («XAFS») pour étudier la structure et les modes de liaison d'une série de composés organosiliciés hautement symétriques, $Si(CH_3)_4$, $Ge[Si(CH_3)_3]_4$, $Si[Ge(CH_3)_3]_4$ et $Si[Si(CH_3)_3]_4$, en phase gazeuse. On a observé des différences importantes dans les coefficients d'absorption, dans la région près de la surface, entre les interactions locales Si–Si de ces composés et les interactions Si–Si à longue distance dans les solides cristallins; on a aussi trouvé que la longueur de la liaison Si—Si dans la molécule de $Si[Si(CH_3)_3]_4$ est de 2,364(10) Å alors que les longueurs des liaisons Si—Ge dans les composés $Si[Ge(CH_3)_3]_4$ et $Ge[Si(CH_3)_3]_4$ sont respectivement de 2,38(3) et 2,396(15) Å. On discute de ces résultats et de leur comparaison avec les distances interatomiques Si—Si et Si—Ge observées dans des solides cristallins.

Mots clés : «XAFS», «EXAFS», organosilicié, longueur de la liaison Si—Ge.

[Traduit par la rédaction]

1. Introduction

The structure and electronic properties of molecular systems containing group IV elements with Si—C, Si—Si, and Ge—Si bonds are of particular interest in connection with their implications for the structure and electronic properties of group IV based electronic materials. Si–Ge atomic layer superlattice materials (1), for example, play an important role in modern electronic devices.

The objective of this research is to use the X-ray absorption fine structure (XAFS) technique to investigate the structure and bonding properties of prototype molecules of high symmetry: $Si(CH_3)_4$ (TMS), $Ge[Si(CH_3)_3]_4$, $Si[Ge(CH_3)_3]_4$, and $Si[Si(CH_3)_3]_4$. These compounds are selected because the central metal atom (Si or Ge) is in a perfect tetrahedral site. For example, the central atom in $Si[Si(CH_3)_3]_4$ and $Si[Ge(CH_3)_3]_4$ is bonded to four Si or Ge atoms, respectively. The local geometry of Si and Ge in their pure crystalline state has the same local symmetry. It would be interesting to compare the local structure (first shell) of Si and Ge in these model compounds to those of crystalline Si, Ge, Si–Ge alloys, and Si–Ge superlattices and ask questions about the structure and bonding relationship in terms of the local metal–metal interaction in the $SiSi_4$ and $SiGe_4$ moieties versus the extended metal–metal interaction in the corresponding semiconductors.

X-ray Absorption Fine Structure (XAFS) spectroscopy deals with the measurement and interpretation of the photon energy-dependent X-ray absorption coefficient above a specific core level threshold (edge) of an element in a chemical environment (2). XAFS is essentially the modulation (due to the presence of surrounding atoms) of the otherwise smooth monotonic atomic absorption coefficient (in the free atom) and it extends to as much as 1000 eV above the threshold. For molecules in the gas phase, for example, the absorption coefficient increases abruptly as the photon energy approaches the ionization threshold of a core level (Si 1*s* in this study). These features arise from the excitation of a core electron into previ-

ously unoccupied atomic (Rydberg) and molecular orbitals that are bound, and into resonance states that are quasi-bound (potential barrier states, sometime known as shape resonance) (3). These processes often result in sharp absorption features at the edge followed by resonance characteristic of the local environment extending to ~50 eV above the threshold. This region has been traditionally called NEXAFS (Near Edge X-ray Absorption Fine Structures) or XANES (X-ray Absorption Near Edge Structures) (4). It contains information about the symmetry and bonding of the molecular system surrounding the absorbing atom. Beyond this region and up to as much as 1000 eV above, the absorption coefficient exhibits oscillations and this region is called EXAFS (Extended X-ray Absorption Fine Structures) (2). EXAFS arises from the interference of the outgoing photoelectron wave with the backscattering photoelectron wave. Thus, it contains information about the nature of the absorbing and backscattering atoms (usually the nearest neighbouring atoms), the interatomic distances (bond length), and the dynamic behaviour (vibrational motion of the neighbouring atoms relative to the absorbing atom that stretches and compresses the bond). EXAFS is now a reasonably established technique for the determination of local structures (5). It can be used to extract bond lengths, R; coordination numbers, N; and Debye–Waller factors, $\exp(-2\sigma^2k^2)$, where σ^2 is the mean-square relative displacement of the interatomic distance between the absorbing atom and the backscattering atom for a disordered system such as molecules in the gas phase or in solution. In this paper, we report the Si K-edge X-ray absorption measurements of the above-mentioned compounds with emphasis on the analysis of the EXAFS. The results are compared with other structure analysis methods such as electron diffraction and X-ray crystallography. It should be noted that the advantage of EXAFS over standard X-ray crystallography is that it does not require a single crystal. As it turns out, growing good quality single crystals for these high vapour pressure solids is quite challenging. The phase function and amplitude function of the Si–Ge pair obtained from the EXAFS analysis are also reported; they can be used as model functions for the analysis of Si K-edge EXAFS for semiconductor systems containing Si—Ge bonds.

The paper is organized as follows. In Sect. 2, the experimental procedures are briefly described, followed by a more detailed description of the EXAFS analysis procedures in Sect. 3. A discussion on the X-ray Absorption Near Edge Structure (XANES), followed by the EXAFS results and their comparison with literature values, is given in Sect. 4. A summary and conclusion can be found in Sect. 5.

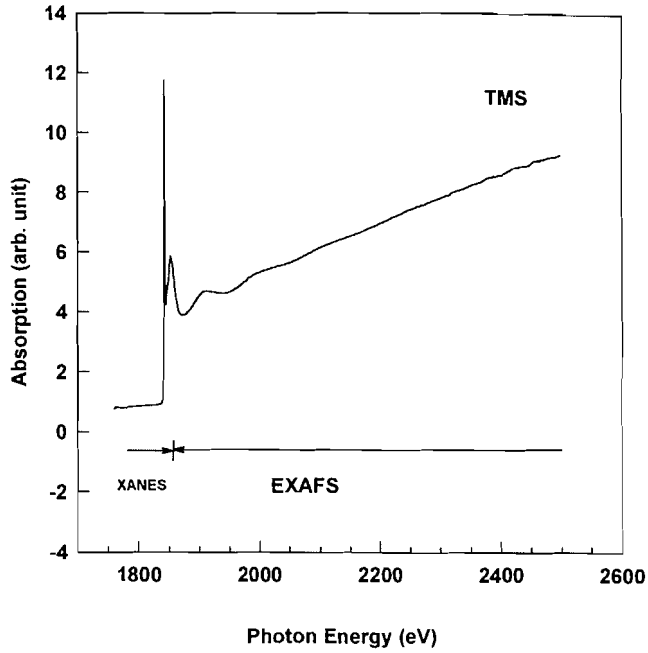
2. Experimental procedures

TMS was obtained commercially (from Petrarch System Inc.). $Si[Si(CH_3)_3]_4$ (6), $Ge[Si(CH_3)_3]_4$ (7), and $Si[Ge(CH_3)_3]_4$ (8) were synthesized according to literature procedures. Except for TMS, all the samples are white solids with vapour pressure sufficient (milliTorr to tens of milliTorr at room temperature) for gas phase measurements at room temperature.

The XAFS (both XANES and EXAFS) experiments were performed using the Ontario Centre for Materials Research–Canadian Synchrotron Radiation Facility (OCMR–CSRF), high-vacuum double-crystal (DCM) beamline at the Aladdin ring (SRC); which is operated by the University of Wisconsin–Madison. The monochromator was equipped with a pair of InSb (111) crystals for these measurements and has a resolution of 0.8 eV at the Si K-edge (9). All the spectra were recorded with a gas ionization chamber (with a cell length of 6.625 in.) in total ion yield mode. The ion yield signal is normalized to the incoming flux, which was at $\sim 10^9$ photons/s as monitored by an in-line ion chamber filled with N_2 gas to ~1.0 Torr (1 Torr = 133.3 Pa) (9). The photon energy was calibrated by setting the K-edge inflection point of the absorption spectrum of a clean Si (100) wafer at 1839.1 eV as determined by the first peak position in the first derivative of the Si K-edge XANES.

All the measurements were carried out at room temperature except for $Si[Ge(CH_3)_3]_4$. The gas pressure was maintained at about 100, 30, and 10 mTorr for TMS, $Si[Si(CH_3)_3]_4$, and $Ge[Si(CH_3)_3]_4$, respectively. The pressure fluctuation, which was quite small, was also simultaneously monitored during the measurement. For $Si[Ge(CH_3)_3]_4$, the temperature of the ionization chamber was maintained at 65°C in order to increase its vapour pressure to about 20 mTorr. Extreme care was taken to eliminate any cross-contamination of the samples: the ion chamber was rinsed with organic solvent and baked before another sample was introduced. A background spectrum was also recorded before the sample was introduced. All spectra reported here are the sum of as many as 10 scans (35 min/scan) to ensure a quality signal-to-noise ratio.

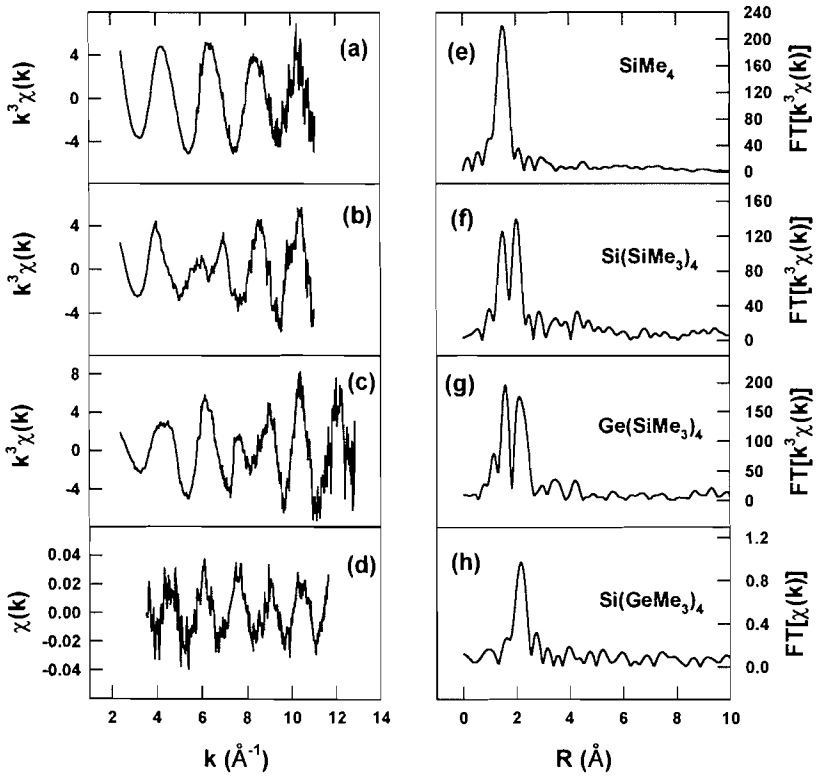
Fig. 1. A raw Si K-edge XAFS data set of TMS, where the XANES and EXAFS regions are noted.



3. EXAFS data analysis

Figure 1 shows a typical set of Si K-edge X-ray absorption data for TMS before data reduction, where the XANES and EXAFS regions are noted. The reproducibility of data from multiple scans for each sample was checked in both E (X-ray photon energy) space and k (photoelectron wave number) space to identify any suspicious features in the spectra due to experimental artifacts.

Fig. 2. $k^3\chi(k)$ of (*a*) $SiMe_4$ (Me = CH_3), (*b*) $Si(SiMe_3)_4$, and (*c*) $Ge(SiMe_3)_4$; $\chi(k)$ of (*d*) $Si(GeMe_3)_4$; and the magnitude of Fourier transform of (*e*) $SiMe_4$, (*f*) $Si(SiMe_3)_4$, (*g*) $Ge(SiMe_3)_4$, and (*h*) $Si(GeMe_3)_4$.



The EXAFS interference function is defined by $\chi(k) = [\mu(E) - \mu_0(E)]/\mu_0(E)$, where $\mu_0(E)$ is the atomic absorption coefficient. The experimental energy origin (E_0) is set at 1843 eV for all the compounds. The difference between the energy origin of the samples and the reference phase functions was used as a floating parameter in the later curve-fitting analysis. Following the usual data reduction procedure (2), in which the post-edge background was removed by a 3-section cubic spline fit and then normalized by the edge jump obtained by extrapolation of a straight line fit above the edge using the software package BAN (10), the k^3-weighted $\chi(k)$ for TMS, $Ge[Si(CH_3)_3]_4$, and $Si[Si(CH_3)_3]_4$ (Figs. 2(*a*)–(*c*)) and $\chi(k)$ for $Si[Ge(CH_3)_3]_4$ (Fig. 2(*d*)) were extracted from the respective raw data. Figures 2(*e*)–(*h*) show the magnitude of the Fourier transforms of the k-weighted $\chi(k)$ data. It can be seen that for a simple molecule such as TMS, there exists a single sinusoidal oscillation in its EXAFS, while in more complicated molecules, such as $Ge[Si(CH_3)_3]_4$ where Si has two different types of neighbouring atoms (Ge and C), the spectrum exhibits a beating of two sinusoidal waves in k space.

The data analysis in this work was conducted using the nonlinear least-squares curve-fitting program EXAFIT of K.R. Bauchspiess (11). The parameterized function used to fit the data is

$$\chi(k) = \sum_{j=1}^{n} \frac{N_j}{k_j R_j^2} S_0^2 S(k_j) f_j(k_j)\, e^{-2k_j^2\sigma_j^2} e^{-2R_j/\lambda} \sin[2k_j R_j + \phi_j(k_j)]$$

where the sum is over all the neighbouring atomic shells. The physical meaning of all the variables in this formula has been discussed extensively in the literature (2, 11, 12); it will not be repeated here. The effective backscattering amplitude

$$S_0^2 S(k_j)\, |f_j(k_j)|\, e^{-2k_j^2\sigma_j^2} e^{-2R_j/\lambda}$$

and the phase $\phi_j(k_j)$ used in the fitting were calculated using ab initio XAFS theory (FEFF, version 5.03) (13). The curve-fitting was performed in both R-space and k-space. In a typical curve-fitting for a single shell, four parameters, namely, ΔE_0, R, σ^2, and N, were varied simultaneously, where ΔE_0 is the difference between the energy origin calculated from FEFF and 1843 eV, σ^2 is the mean-square relative displacement of the interatomic distance R between the absorbing atom and the backscattering atom, and N is the coordination number.

The residual sum of squares used in this work is defined as (12)

$$\chi^2 = \frac{N_{pts}}{N_{pts} - n} \frac{1}{N} \sum_{j=1}^{N} (\text{Data}_j - \text{Model}_j)^2$$

where $N_{pts} = 2 + 2\Delta k \Delta R/\pi$ is the number of relevant independent points (14), n is the number of fitting parameters used, and N is the number of total data points. This is the quantity minimized in the nonlinear least-squares curve-fitting. The uncertainties of the results were estimated by finding the deviation of a parameter from its best-fit value (by fixing this parameter while leaving all others floating), which doubles the residual sum of squares between the fit and data. These uncer-

Fig. 3. Normalized Si K-edge XANES of TMS, $Ge(SiMe_3)_4$, $Si(SiMe_3)_4$, $Si(GeMe_3)_4$, and crystalline Si (100).

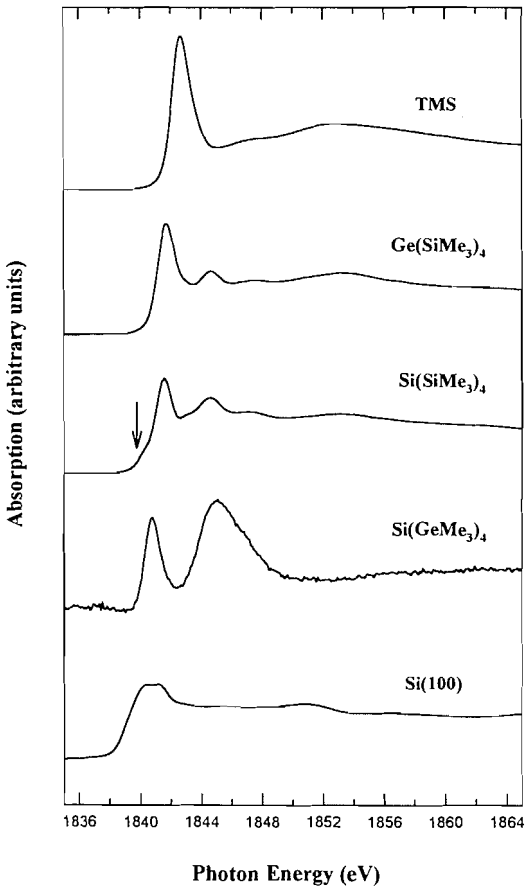


Fig. 4. Comparison of (*a*) experimental $Si(SiMe_3)_4$ XANES with (*b*) simulated $Si(SiMe_3)_4$ XANES (see text).

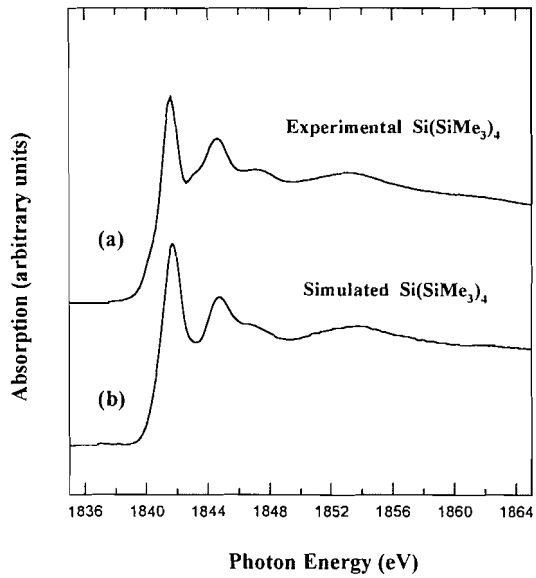

tainties include all the effects of correlations between all the parameters, and the error bars estimated in this way are found to be too conservative (15).

In the nonlinear least-squares minimization analysis, a major source of uncertainties on the EXAFS structural parameters is the parameter correlation (e.g., between R and ΔE_0 and between N and σ^2). It is then sometimes desirable to use the structural parameters obtained from model compounds that are structurally similar to the sample to limit the number and the physically meaningful range of the fitting parameters in the nonlinear least-squares fitting process. The structural results obtained for the well-defined molecules in this study could, to a certain extent, serve the purpose of providing EXAFS empirical references to disentangle more complicated structural problems, e.g., in a Si—Ge atomic layer superlattice.

4. Results and discussion

Figure 3 shows the Si K-edge absorption of TMS, $Si[Si(CH_3)_3]_4$, $Si[Ge(CH_3)_3]_4$, and $Ge[Si(CH_3)_3]_4$ as well as crystalline Si(100). In this section, the XANES features are first discussed briefly, followed by a detailed analysis of the EXAFS and their implications.

4.1. Si K-edge XANES: general observations

Figure 3 shows the Si K-edge XANES of all the four compounds together with that of a single crystal Si(100). Although the spectra for some of these compounds have been published before (16), the spectra in Fig. 3 are of higher quality in the signal-to-noise ratio and are free of contamination. These data agree generally with the previously published results (16) (except that the energy position for TMS is now recalibrated to 2 eV higher binding energy than in the previous report and the low-energy shoulder for $Si[Ge(CH_3)_3]_4$ reported earlier is no longer seen as the result of the precaution described in Sect. 2 to eliminate contamination[3]). In this paper, we will only summarize the qualitative observation of the XANES features and point out some important observations that have not been reported previously.

Several interesting features from Fig. 3 are noted. First, TMS exhibits a single intense resonance at the threshold followed by some weak ones, while the other molecules exhibit more intense multiple resonances. Second, the spectra of $Si[Si(CH_3)_3]_4$ and $Ge[Si(CH_3)_3]_4$ appear to be quite similar with the exception of the small low-energy shoulder in the former. Third, the first peak of the $Si[Ge(CH_3)_3]_4$ spectrum is located at about the same energy as the low-energy shoulder of the $Si[Si(CH_3)_3]_4$ spectrum. Based on comparison of the experimental spectra of $Si[Si(CH_3)_3]_4$, $Ge[Si(CH_3)_3]_4$, and $Si[Ge(CH_3)_3]_4$, the low-energy shoulder in $Si[Si(CH_3)_3]_4$ (see Fig. 3, noted by an arrow) is assigned to transitions from Si 1*s*, originating from the central Si (Si^a), to molecular orbitals of essentially Si–Si character. The remaining features are dominated by transitions originating from the surrounding

[3] $Si[Ge(CH_3)_3]_4$ is a very difficult sample to run in the gas phase because it has very low vapour pressure and low mass percentage of Si. Therefore, it is easily contaminated by $Si[Si(CH_3)_3]_4$ or $Ge[Si(CH_3)_3]_4$, which have higher vapour pressures and a higher edge jump. It is believed that the previously reported spectrum (16) was contaminated with $Si[Si(CH_3)_3]_4$. The spectrum reported in Fig. 3 was taken with extreme care. It was reproducible with heating and even after being sealed in the ion chamber for hours during the long EXAFS scans.

four silicon atoms (Si^b). The above assignment is derived from the following procedure: the spectra of $Si[Si(CH_3)_3]_4$, $Ge[Si(CH_3)_3]_4$, and $Si[Ge(CH_3)_3]_4$ were normalized to an edge jump of unity, and then the $Si[Ge(CH_3)_3]_4$ spectrum, which represents the contribution from the central atom Si^a, was added to the scaled spectrum of $Ge[Si(CH_3)_3]_4$ (by a factor of 4 in the vertical), which represents the contribution from the four surrounding atoms Si^b. The resultant spectrum was normalized to an edge jump of unity. The simulated $Si[Si(CH_3)_3]_4$ spectrum, shown in Fig. 4, is very similar to that of $Si[Si(CH_3)_3]_4$. This procedure assumes that the chemical and structural (symmetry) environment at the Si in $Si[Ge(CH_3)_3]_4$ is the same as that of Si^a in $Si[Si(CH_3)_3]_4$, that the environment of the surrounding silicon atoms in $Ge[Si(CH_3)_3]_4$ is similar to that in $Si[Si(CH_3)_3]_4$, and that the Si K-edge spectrum is the sum of contributions from all the Si atoms. In other words, the Si—Si and Si—Ge bonds are assumed to be chemically very similar (in valence electron distribution) and the nearest neighbouring atoms are primarily responsible for the general shape of the XANES. These assumptions are valid, as supported by Fig. 4, which shows nearly identical features implying that Si—Si and Si—Ge bonds are quite similar chemically. Since the absorption feature in the near edge region is sensitive to multiple scattering processes that involve primarily valence electrons, the absorbing atoms with similar electron distribution and local symmetry would yield similar XANES, as shown in Fig. 4. This point was not adequately addressed previously (16). The same cannot be said for the EXAFS (vide infra) because in the EXAFS region, the kinetic energy of the photoelectron increases considerably and the core electrons become more important in the single scattering process that is the dominant contribution to the EXAFS. This is why the Si K-edge EXAFS between the Si–Si and Si–Ge pairs look very different, although the nature of these two chemical bonds is generally considered similar (in valence electron distribution) in main group chemistry. It should also be noted that the more intense second resonance (1844.6 eV) in $Si[Ge(CH_3)_3]_4$ relative to the progressively weaker second resonance in the Si–Si and Si–C systems may indicate a more effective caging effect (potential barrier) in the $Si[Ge(CH_3)_3]_4$ system. More detailed MS-Xα analysis of these features will be presented elsewhere (17).

Another interesting point is that the first resonance in crystalline Si is split despite the fact that its local structure is identical to the central atom in $Si[Si(CH_3)_3]_4$ and $Si[Ge(CH_3)_3]_4$, which exhibit a single resonance peak in this region (Fig. 3). The splitting of the intense Si K-edge absorption peak in crystalline Si is the result of long-range order effects (band structure). It is interesting to note that this splitting is rounded off even in nano-structure Si such as porous silicon, which contains networks of crystalline Si of nm dimension (18), indicating that the long-range order has to go beyond nanometers to produce this effect.

4.2. EXAFS analysis

Figure 2 shows the k^n-weighted EXAFS data ($n = 0$ or 3) $\chi(k)$ for all the compounds and their corresponding Fourier Transform (FT) of ($k^n \chi(k)$). The FT technique is an established procedure that separates the phase and the amplitude of the EXAFS (2, 19). As expected, only one noticeable shell is observed for TMS (the Si–C shell) and $Si[Ge(CH_3)_3]_4$ (the Si–

Fig. 5. (*a*) Magnitude of the Fourier transform (solid line) and the fit (broken line) in *R*-space (transform range is 2.6–10.9 $Å^{-1}$); (*b*) $k^{2.5}$-weighted data (solid line) and the fit (broken line) in *k*-space; (*c*) Fourier filtered data (solid line) and the fit (broken line) (filtering window range is 0.6–2.4 C) for TMS. The vertical lines define the fitting range. The insertion in (*a*) shows the schematic structure of the molecule (hydrogen atoms were neglected).

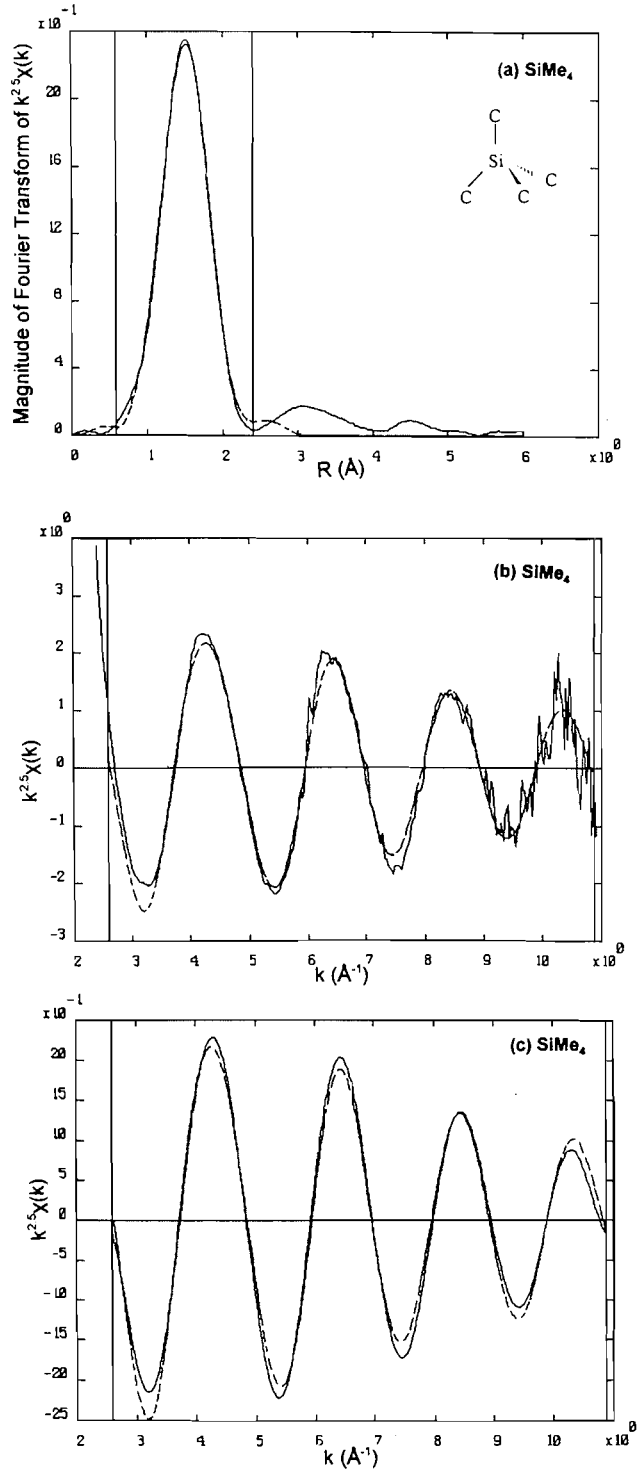

Table 1. EXAFS fitting range and results for $Si(CH_3)_4$ and $Ge(Si(CH_3)_3)_4$ in k-space (with Fourier filtering) and R-space.

Molecule		Parameter	k-space	R-space
$Si(CH_3)_4$	N_{pts} = 11	Data range	2.6–10.9 Å^{-1}	0.6–2.4 Å
	Si–C shell	ΔE_0 (eV)	8.5 ± 2	7 ± 3
		R (Å)	1.887 ± 0.015	1.879 ± 0.015
		σ^2 (Å^2)	0.003 ± 0.002	0.003 ± 0.002
		N	4.2 ± 0.8	4.5 ± 0.6
$Ge(Si(CH_3)_3)_4$	N_{pts} = 12	Data range	2.4–12.4 Å^{-1}	1.2–2.8 Å
	Si–C shell	ΔE_0 (eV)	6.2 ± 3	5.9 ± 3
		R (Å)	1.889 ± 0.020	1.888 ± 0.015
		σ^2 (Å^2)	0.003 (fixed)	0.003 (fixed)
		N	3.9 ± 1	3.9 ± 0.5
	Si–Ge shell	ΔE_0 (eV)	6.2[a]	5.9[a]
		R (Å)	2.394 ± 0.015	2.397 ± 0.015
		σ^2 (Å^2)	0.004 ± 0.003	0.004 ± 0.002
		N	1.2 ± 0.5	1.2 ± 0.4

[a]The difference between this value and that of the Si–C shell was fixed at zero in fitting.

Ge shell),[4] while two shells are seen for $Si[Si(CH_3)_3]_4$ (Si–C and Si–Si shells) and $Ge[Si(CH_3)_3]_4$ (Si–C and Si–Ge shells), in both k- and R-space. The detailed analyses for each of the four compounds are discussed below.

4.2.1. $Si(CH_3)_4$ (TMS)
